In order to obtain **2a** in some quantity, we initially tried to carry out the Ponzio reaction of aldoxime **1a** according to the original conditions given in the literature. However, to our disappointment, duplication proved to be quite unsatisfactory; the yields of **2a** were always lower, the major product being benzoic acid. We have therefore undertook a systematic study to find the optimum conditions to obtain **2a** in acceptable yields.

Bubbling of nitrogen dioxide gas into an ice-cooled solution of **1a** in ether, followed by quenching with water and extraction with aqueous sodium hydrogencarbonate led to little or no dinitromethyl compound. Dropwise addition of an ethereal solution of **1a** to a solution of 2 equiv of nitrogen dioxide in the same solvent gave the desired product only in a low yield. Increase in amount of nitrogen dioxide from 2 to 5 equiv improved the yield of **2a** appreciably, but the benzoic acid was the main product as yet. To our satisfaction, acceptable results were obtained with good reproducibility when the reaction of **1a** was allowed to proceed in the presence of 10 equiv of nitrogen dioxide and the solvent was removed under reduced pressure immediately after complete disappearance of **1a** on TLC plate. Aqueous work-up of the reaction mixture as described in the literature led to poor results.

Using the optimized conditions defined above, a series of substituted benzaldehyde oximes **1b—1h** and 1-naphthaldehyde oximes **1i—1j** were converted into the corresponding dinitromethylated arenes **2b—2j**, the yields and physical properties of which are presented in Table 1. No spectral data of these appear to have been reported previously in the literature. (Dinitromethyl)arenes are colorless crystals which can be stored indefinitely under the exclusion of light and moisture. They are readily soluble in dichloromethane, chloroform, carbon tetrachloride, benzene, ethanol, and ether; fairly soluble in hot hexane, and slightly soluble in cold hexane. They melt without decomposition.

In some cases trinitromethylated compounds were obtained as the minor product. These compounds are thermally unstable and on heating readily decompose under the evolution of nitrogen oxides to afford arenecarboxylic anhydride.[10)] In contrast to (dinitromethyl)-arenes which appear as a yellow spot on TLC and

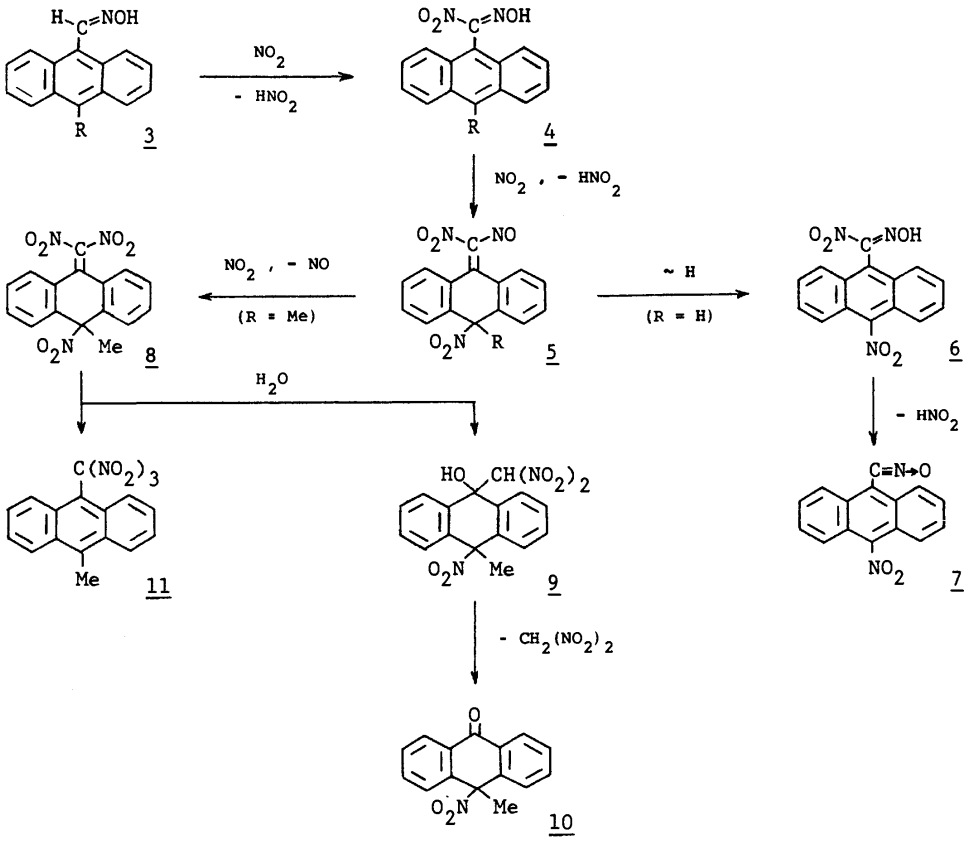
move slowly, (trinitromethyl)arenes are colorless on TLC, run fast, and could be examined only in ultraviolet light. Trinitromethyl group is characterized by its very intense antisymmetric vibration of the nitro groups, which appears as split infrared bands at around 1600 cm^{-1}.

Quite perplexing results were obtained when 9-anthracenecarbaldehyde oxime (**3**; R=H) and 10-methyl-9-anthracenecarbaldehyde oxime (**3**; R=Me) were subjected to the conditions of the Ponzio reaction. The former compound gave 10-nitro-9-anthracenecarbonitrile oxide (**7**) as the major product together with 9-anthracenecarboxylic acid as a by-product, whereas the latter compound produced mainly 10-methyl-10-



Scheme 1.

nitro-9-anthrone (**10**), 9-methyl-10-trinitromethylanthracene (**11**) being the minor product. Anomalous results observed in the anthracene system pose an interesting problem, a possible solution to which is outlined in Scheme 1.

Abstraction of the oxime hydrogen from **4** followed by attachment of nitrogen dioxide at the meso position leads to the triene intermediate **5**. When R in **5** is hydrogen atom, a facile aromatization would ensue to form the oxime **6**, which loses nitrous acid to give the nitrile oxide **7**.[11] When R in **5** is methyl group, oxidation of nitroso group to nitro group would occur in preference to aromatization to produce the triene **8**, which either undergoes hydration to form carbinol **9** or isomerizes to **11** possibly via homolytic fission of the carbon-nitrogen bond at the quaternary carbon atom. The carbinol **9** would suffer the retro nitro-aldol reaction to be cleaved into ketone **10** and dinitromethane.

When (dinitromethyl)benzene **2a** was treated with fuming nitric acid (d=1.5) or mixed acid at −20—−10 °C for a few hours, there was obtained *m*-nitrophenyldinitromethane (**2g**) as the sole product in accord with the literature report.[7] Neither the formation of trinitromethylated arenes nor the anomalous reaction similar to that observed during the nitration of (dicyanomethyl)arenes took place under the conditions employed.[12] However, when a mixture of **2a** and fuming nitric acid was allowed to stand for several days at room temperature, the initially formed **2g** slowly underwent further nitration on the alkyl side-chain to afford *m*-nitrophenyltrinitromethane (**12**) as the main product. *m*-Nitrobenzoic acid was a side product. In contrast to Titov's claim,[7] no para substitution products could be obtained.

Experimental

All melting points were determined on a hot stage apparatus and are uncorrected. Infrared spectra were run as KBr pellets on a Hitachi 260-10 spectrophotometer and only prominent peaks are recorded. ^{1}H and ^{13}C NMR spectra were obtained on Hitachi R-600 and JNM-FX-100 spectrometers using TMS as an internal standard. Unless otherwise stated, NMR data refer to deuteriochloroform solutions.

Aromatic aldoximes were prepared according to the conventional procedure.[13] Nitrogen dioxide was obtained from commercial source (Seitetsu Kagaku Co., Ltd., Osaka) and used without purification.

Preparation of (Dinitromethyl)arenes (2). To a solution of nitrogen dioxide (20 mmol) in ether (2 ml) chilled in ice was added a solution of aldoxime (2 mmol) in ether (10 ml). The blue reaction mixture immediately turned deep green and the liberation of gaseous product was observed. After standing for 30—60 min, when TLC monitoring showed completion of the reaction, the reaction mixture was evaporated under reduced pressure. The oily residue was taken up in ether, and the ethereal solution was extracted with 0.5 M aqueous potassium hydroxide (1 M = 1 mol dm^{-3}) until the initial yellow aqueous phase became almost colorless. The combined alkaline extracts were saturated with sodium chlo-

ride, made weakly acidic by the addition of hydrochloric acid, and extracted with ether. Evaporation of the former ethereal extract gave parent aldehyde and arenecarboxylic acid, while removal of the solvent from the latter ethereal extract afforded **2** and carboxylic acid. The product **2** was further purified by chromatography on silica gel using hexane–dichloromethane as the eluent.

Reaction of 9-Anthracenecarbaldehyde Oxime (3; R=H) with Nitrogen Dioxide. To a solution of nitrogen dioxide (2.6 mmol) in dry ether (1 ml) at 0 °C was added dropwise a solution of 9-anthracenecarbaldehyde oxime (0.058 g; 0.26 mmol) in the same solvent (15 ml). The resulting green mixture was stirred for 2 h, allowing gradually to attain room temperature. After this time TLC monitoring showed complete disappearance of aldoxime. The solvent was removed together with nitrogen dioxide under reduced pressure and a yellow residue was taken up in chloroform and chromatographed on a silica gel column. Elution with chloroform gave 10-nitro-9-anthracenecarbonitrile oxide (**7**) as yellow crystals, mp 212—215 °C. Yield, 0.038 g (55%). ^{1}H NMR: δ=7.6—8.0 (m, 6H) and 8.3—8.5 (m, 2H); IR: 2275, 1520, 1310, 1275, 1255, and 765 cm^{-1}. Found: C, 67.67; H, 3.21; N, 10.46%. Calcd for $C_{15}H_8N_2O_3$: C, 68.18; H, 3.05; N, 10.60%.

Further elution with methanol gave 9-anthracenecarboxylic acid as yellow crystals.[14] Yield, 0.020 g (35%).

Reaction of 10-Methyl-9-anthracenecarbaldehyde Oxime (3; R=Me) with Nitrogen Dioxide. A suspension of aldoxime (0.264 g; 1.12 mmol) in dry ether (20 ml) was stirred and a stream of nitrogen dioxide was slowly passed at 0—10 °C until the reaction mixture turned to a blue clean solution. After standing for 1 h at room temperature, the mixture was diluted with water (30 ml). Effervescence was followed by separation into two layers. The yellow organic phase was separated, dried with sodium sulfate, and evaporated under reduced pressure. A yellow oily residue was chromatographed on silica gel using hexane–dichloromethane (1 : 1) as the eluent to give 10-methyl-10-nitro-9-anthrone (**10**) as colorless crystals, mp 145—152 °C (decomposition under foaming).[15] Yield, 0.0753 g (27%). MS (70 eV) *m/z* (rel intensity) 253 (M^+, 1), 237 (13), and 207 (100); ^{1}H NMR: δ=2.33 (s, 3H) and 7.40—8.63 (m, 8H); ^{13}C NMR: δ=31.03 (q), 88.94 (s), 125.76 (s), 128.05 (d), 130.09 (d), 134.42 (d), and 139.68 (s); IR: 1680, 1600, 1550, 1340, 1300, and 940 cm^{-1}. Found: C, 70.83: H, 4.52; N, 5.14%. Calcd for $C_{15}H_{11}NO_3$: C, 71.14; H, 4.38; N, 5.53%.

The minor product was identified as 9-methyl-10-trinitromethylanthracene (**11**) by direct comparison with the authentic specimen obtained by the other route.[2]

Nitration of (Dinitromethyl)benzene (2a). The reaction was carried out under various conditions. The typical results are shown below:

a) Compound **2a** (0.614 g; 3.37 mmol) was dissolved into fuming nitric acid (10 ml, *d*=1.5) at −20 °C and the resulting mixture was left for 2 h at this temperature, then poured into brine (300 ml). The organic phase was extracted with ether and the extract was evaporated to leave a yellow solid, which was recrystallized from hexane–dichloromethane to give *m*-nitrophenyldinitromethane (**2g**) as nearly colorless plates, mp 122—124 °C (lit,[7] 127—129°C). Yield, 0.665 g (87%). Found: C, 37.20; H, 2.07; N, 18.47%. Calcd for $C_7H_5N_3O_6$: C, 37.02; H, 2.22; N, 18.50%.

Infrared and ^{1}H NMR spectral inspection of the crude product mixture showed the absence of other important products.

When the reaction mixture was allowed to stand for several days at room temperature, TLC monitoring revealed the gradual accumulation of the second nitration product, which was easily separated from **2g** by chromatography on silica gel and identified as *m*-nitrophenyltrinitromethane (**12**). Colorless prisms, mp 63—65 °C (lit,[7] 65 °C). ^{1}H NMR: δ=7.86—7.97 (m, 2H) and 8.58—8.72 (m, 2H); IR: 1610, 1575, 1530, 1350, 1290, 1225, 870, 840, 800, and 730 cm^{-1}. Found: C, 30.96; H, 1.51; N, 18.30%. Calcd for $C_7H_4N_4O_8$: C, 30.90; H, 1.48; N, 20.59%.

Attempted nitration of **2a** with fuming nitric acid in dichloromethane led to recovered substrate.

b) Compound **2a** (0.099 g, 0.054 mmol) was dissolved into concentrated sulfuric acid (5 ml) to yield a slightly yellow solution, to which fuming nitric acid (5 ml) was added and the resulting mixture was left to stand for 2 h at room temperature. Quenching with water followed by usual work-up gave the expected product **2g** in 78% yield. Mp 122—124 °C.

The authors thank Advanced Instrumentation Center for Chemical Analysis, Ehime University, for ^{13}C NMR determinations and elemental analyses.

Electron Spin Resonance Studies of Anion Radicals of Benzoylsilanes

Kunio MOCHIDA* and Keiji YAMAMOTO†
Department of Chemistry, Faculty of Science, Gakushuin University, 1-5-1 Mejiro, Tokyo 171
†Department of Chemical Engineering, Tokyo Institute of Technology, Meguro, Tokyo 152
(Received March 22, 1988)

ESR studies of anion radicals of seven substituted benzoylsilanes were investigated. ESR data of these anion radicals are discussed in comparison with those of aryl alkyl ketones. ESR spectra of secondary product derived from the anion radical of benzoylsilanes were also examined.

Metalloidal ketones have been of considerable interest as homologs of ketones; in this connection, their unusual chemical and spectroscopic properties have been compared with those of the common ketones.[1] The large bathochromic shifts observed in the electronic spectra of metalloidal ketones recently received attention.[2] Several quantitative theories have been presented to account for these shifts in lower energies.[3]

A variety of physical techniques have been employed in order to clarify the electronic spectra of metalloidal ketones. Electron spin resonance (ESR) is potentially useful to study this problem. An examination of the ESR spectra of anion radicals of benzoylsilanes gives quantitative information which is concerned with the unpaired electron occupying the π^* level.[3a]

Now we describe the ESR spectra of anion radicals of seven substituted benzoylsilanes. The ESR spectra of the secondary derived product derived from the anion radicals of benzoylsilanes are also reported.

Results and Discussion

ESR Spectra of Anion Radicals. Substituted benzoylsilanes (**1**) were reduced with potassium metal in 1,2-dimethoxyethane (DME) at −80 °C. These conditions were chosen so as to prevent any formation of secondary anion radicals derived from the anion radicals of **1**. The ESR spectra of the anion radicals of **1** are shown in Figs. 1—5. The g factors and hyperfine splitting constants (hfsc), determined by computer simulation, of anion radicals of **1** are summarized in Table 1 together with those of certain reported benzoylsilanes and two alkyl aryl ketones (**2**).

The ESR spectrum of an anion radical of benzoyltrimethylsilane (**1a**) obtained by potassium reduction in DME at −80 °C comprised about 15 lines, due to ring protons having g=2.0039. The experimental spectrum of the anion radical of **1a** was reproduced by computer simulation with the listed hfsc's. The ESR spectrum of the anion radical of **1a** observed in this study coincides exactly with that reported by Bock and co-workers.[4]

Each line splits further into a multiplet due to 9 equiv methyl protons (a_{SiMe}=0.14 G (1G=10^{-4} T)).

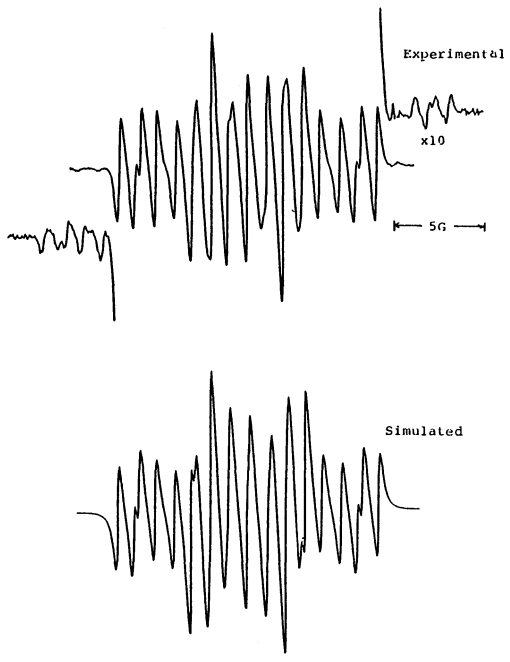

Fig. 1. ESR spectrum of anion radical of benzoylphenyldimethylsilane (**1b**) at −80 °C.

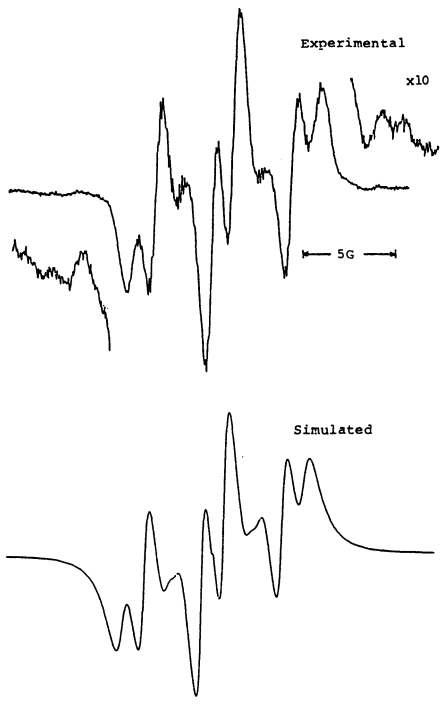

Fig. 2. ESR spectrum of anion radical of *p*-methoxylbenzoyltrimethylsilane (**1d**) at −80 °C.

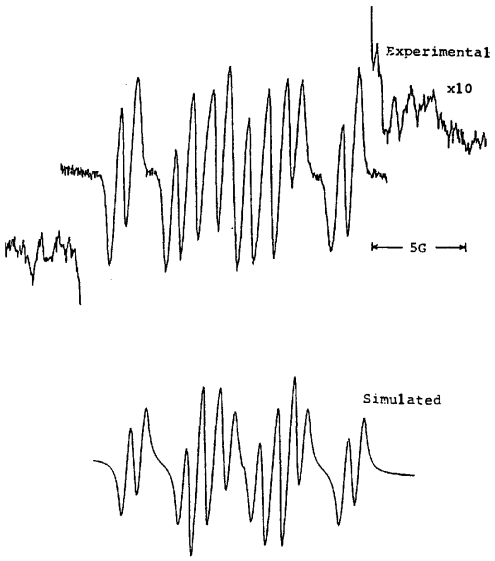

Fig. 3. ESR spectrum of anion radical of *m*-methoxylbenzoyltrimethylsilane (**1e**) at −80°C.

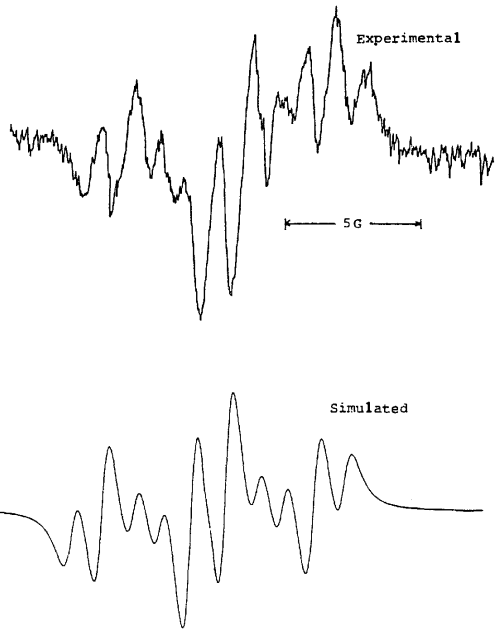

Fig. 4. ESR spectrum of anion radical of *p*-*t*-butylbenzoyltrimethylsilane (**1f**) at −80°C.

Under higher gain, the ^{29}Si splitting (natural abundance=4.7%, I=1/2) of the anion radical of **1a** (a_{Si}=8.86 G) was detected. The fact that the hyperfine coupling constants of two-protons are not equivalent indicates a restricted rotation of the phenyl group about the carbon-carbon bond.

The ESR spectrum of an anion radical of benzoyldimethylphenylsilane (**1b**), shown in Fig. 1, was interpreted in the same manner as described for **1a**. The ESR spectrum was reproduced by computer simulation with the hfsc's listed in Table 1. None of the hfsc's of both ortho- and meta-protons are equivalent.

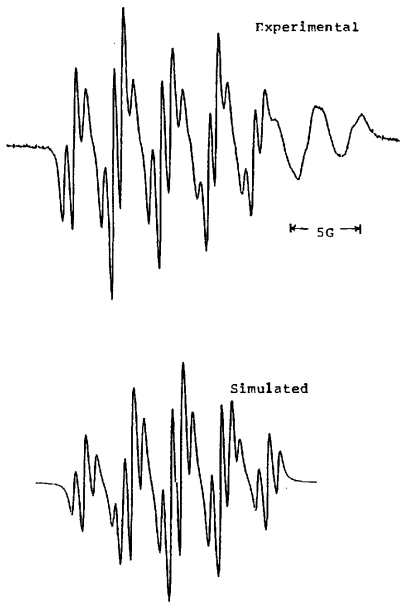

Fig. 5. ESR spectrum of anion radical of *p*-nitrobenzoyltrimethylsilane (**1g**) at −80°C.

This fact also indicates a restricted rotation of the phenyl ring. Attempts to determine the rotational barrier by studying the temperature dependence of the ESR spectrum of the anion radical of **1b** were unsuccesful, since the spectrum was essentially unchanged over a temperature range between 0 and −80 °C. Upon warming above 0 °C, the new spectra of certain species, derived from an anion radical of **1b**, gradually appeared. The secondary ESR spectrum will be discussed later.

The ESR spectrum of an anion radical of *p*-methoxylbenzoyltrimethylsilane (**1d**) in DME at −80 °C is shown in Fig. 2. About 8 lines due to ring protons, and g=2.0040, were observed. Under higher gain, ^{29}Si splitting of the anion radical of **1d** (a_{Si}=9.53 G) was detected. The coupling constants of two non-equivalent meta-protons could be determined by computer simulation.

The ESR spectra of anion radicals of *m*-methoxylbenzoyltrimethylsilane (**1e**) (g=2.0042) and *p*-*t*-butylbenzoyltrimethylsilane (**1f**) (g=2.0040) are shown in Figs. 3 and 4, respectively. The coupling constants of the anion radical of **1e**, shown in Table 1, were determined by computer simulation while taking the ESR data of the related silyl ketyls into consideration. The ESR spectrum of the anion radical of **1f** exhibits an essentially similar pattern to that of the anion radical of **1d**. The ESR spectra of **1e** and **1f** were also reproduced by computer simulation with the hfsc's listed in Table 1. Some of the line intensities of an anion radical of **1f** were not satisfactorily reproduced by computer simulation.

The ESR spectrum of an anion radical of *p*-nitrobenzoyltrimethylsilane (**1g**) (g=2.0051) and its computer simulation are shown in Fig. 5. At low field

various contaminant signals appeared as the result of another signals. The assignment of the coupling constants of ortho and meta-protons was determined while taking those of the anion radical of *p*-nitroacetophenone into consideration.[5]

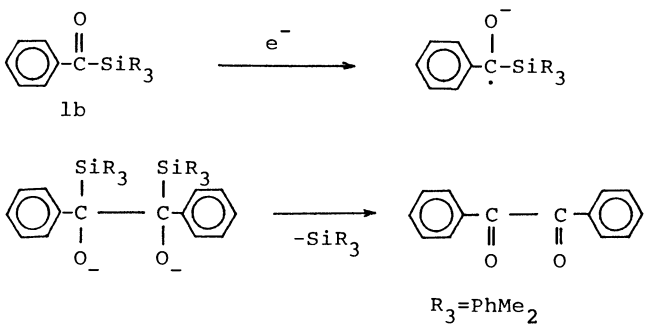
Three ESR spectra of anion radicals of benzoylgermanes, $PhCOGeR_3$ (R_3=Me_3, **3a**; R_3=$PhMe_2$, **3b**; R_3=Ph_3, **3c**) were also examined. These spectra all exhibit similar patterns (**3a**; g=2.0032, $a_{o\text{-}H}$=4.63, 3.45 G, $a_{m\text{-}H}$=1.32, 0.92 G, $a_{p\text{-}H}$=5.65 G. **3b**; g=2.0032, $a_{o\text{-}H}$=4.32, 3.38 G, $a_{m\text{-}H}$=1.22, 0.90 G, $a_{p\text{-}H}$=5.52 G. **3c**; g=2.0030, $a_{o\text{-}H}$=4.24, 3.34 G, $a_{m\text{-}H}$=1.24, 0.88 G, $a_{p\text{-}H}$=5.54 G). It may well be that the ESR spectra obtained can be assigned to the germyl radical adducts of benzoylgermanes, $[PhC(OGeR_3)GeR_3]$.[6]

As shown in Table 1, the g factors of the anion radicals of **1** are larger than those of the carbon analogs **2**. It has been pointed out that the larger g factors of anion radicals of silylketyls reflect the lower energy of the carbonyl π^* orbital in these radical anions.[3b,7] The interaction of silicon's d orbital with the π^* orbital leads to a lowering of the energy of this orbital. Electron delocalization of $Si\leftarrow C_\pi$ in the radical anions of **1** can be shown form the ^{29}Si coupling constants.

Secondary Anion Radicals. When the anion radical of **1b** was allowed to warm to above 0 °C, a new ESR spectra of the secondary anion radical arising from the original radical of **1b** gradually appeared. The new anion radical was found to be a 1,4-bis(phenyldimethylsilyl)benzene anion radical ($a_{o,\ m\text{-}H}$=2.54 G and a_{SiMe}=0.31 G). The ESR the spectrum of the 1,4-bis(phenyldimethylsilyl)benzene anion radical was confirmed by computer simulation and by a comparison with an authentic anion radical. Then, the 1,4-bis(phenyldimethylsilyl)benzene anion radical changed to an unidentified paramagnetic species with time. The formation of 1,4-bis(phenyldimethylsilyl)-benzene is not easy to explain. In general, the formation of a trace of benzene is known in reactions of phenyl-substituted silyl compounds with alkali metals.[8] Silyl anions have been reported to react with benzene to give 1,4-bis(phenyldimethylsilyl)benzene.[9]

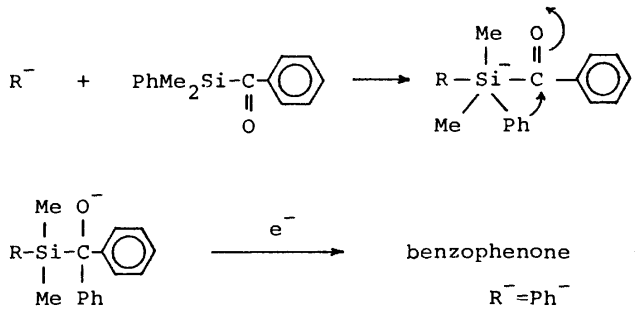
The radical anion of **1b** when warmed to 20 °C changed to either benzophenone ketyl ($a_{o\text{-}H}$=2.60 G, $a_{m\text{-}H}$=0.87 G, and $a_{p\text{-}H}$=3.45 G) or benzil anion radical ($a_{o\text{-}H}$=1.00 G, $a_{m\text{-}H}$=0.36 G, and $a_{p\text{-}H}$=1.10 G), the change being dependent upon the amounts of **1b** and potassium metal used. Benzophenone ketyl and benzil anion radical are stable under these conditions.

The formation of benzil from **1b** can be interpreted by a mechanism involving a coupling of the initially formed radical anion of **1b**, followed by an elimination of the phenyldimethylsilyl anion, as outlined below.



There may be an alternative mechanism which involves a dimerization of the benzoyl radical, first formed by an elimination of the silyl anion radical of **1b**.

The formation of benzophenone from **1b** might be explained by the work of Brook and co-workers.[10] Thus, an attack by a nucleophile must occur on the silicon atom of **1b**, followed by a 1,2-migration of a phenyl group to the adjacent carbonyl group, as shown below. The α-silyl alkoxide formed may



undergo homolysis of a silicon-carbon bond to give benzophenone. An analogous mechansim for the formation of benzil and benzophenone has been postulated by Arberti and co-workers.[6]

Experimental

ESR Measurements. All the ESR spectra were obtained using a Varian E-9 ESR spectrometer. The field sweep of the spectrometer was calibrated with an aqueous solution of Fremy's salt (a_N=13.07 G). The *g* factors were determined by reference to that of Fremy's salt (*g*=2.0055) using a dual cavity.

Materials. Benzoyltrimethylsilane,[3a] benzoylphenyldimethylsilane,[3a] *p*-methoxylbenzoyltrimethylsilane,[3a] *m*-methoxylbenzoyltrimethylsilane,[3a] *p*-nitrobenzoyltrimethylsilane,[3a] benzoyltrimethylgermane,[3a] benzoylphenyldimethylgermane,[11] and benzoyltriphenylgermane[12] were prepared according to the cited literatures. DME was dried over sodium-potassium alloy.

ESR Studies of Anion Radicals of Benzoylsilanes. The ESR samples were prepared in 3-mm Pyrex sample tubes which were sealed to an 8-mm tube having a side arm and an "O" ring fitting for attaching the sample preparation tube to the vacuum line. The desired potassium metal was placed in the side arm, a very small amount of the desired benzoylsilane was placed in the sample tube, and the entire apparatus was attached to a vacuum line. The sample was degassed and DME was transferred from the reservoir while filling the sample tube to a height of about 70—100 mm. The potassium was then distilled from the side arm into the upper portion of the Pyrex sample tube, and the tube was sealed off. The samples were kept frozen in liquid nitrogen until used. To develop the radical anion of benzoylsilane, the contents of the sample tube were allowed to warm to slightly above the melting point; the tube was then inverted in order to bring the sample into contact with the mirror, at which time the sample tube was immediately inserted into the variable-temperature probe of the spectrometer, which was cooled to about −80 °C.

The authors thank Prof. Tadashi Suehiro of Gakushuin University for making Varian E-9 ESR spectrometer available for our use. We also thank Toshiba Silicone Co. Ltd. for a gift of chlorosilane.

(Received December 11, 1987)

The effect of the wettability of an injection nozzle on the size of oil droplets in water has been studied. Dodecane as an oil was dispersed into a continuous water phase through various polymers attached to the top of each single nozzle. The polymer filters used were polyethylene (PE), poly(vinyl chloride) (PVC), poly(vinyl alcohol) (PVA), cellophane (CP), and cotton (CT). The hydrophilic cotton filter is found to be more effective as the injection nozzle than any other hydrophobic polymer filter tested to disperse smaller oil droplets of dodecane into the continuous water phase. The droplet size is reduced with an increase in the hydrogen-bonding force of the polymer-filter surfaces. This may be attributed to the strong adhesion tension between the water molecules and hydrophilic groups of the polymer surface.

The technique for the dispersion of one liquid into another immiscible liquid is of importance in various fields. Droplet formation in the dispersion (from single nozzles and/or orifices) of one liquid into another immiscible liquid will assure the homogeneous size of the droplets. Many studies have been carried out;[1-7] most have been concerned with the effect of flow conditions, nozzle shapes and diameters, and the physical properties of the dispersed phase and/or continuous phase on the droplet formation. The sizes of the droplets formed are fairly large. However, few studies have been made of the influence of the chemical properties of the polymer filters attached to the nozzle top on the droplet formation.

The wettability of a polymer surface is of importance in various fields and is also of great theoretical interest. The contact angle is very useful in the evaluation of wettability. The magnitude of the contact angle is determined by the balance of forces at the boundary line between a liquid, a solid, and a second fluid, which is normally air. This balance of forces is described by Young's equation:

$$\gamma_S = \gamma_{SL} + \gamma_L \cos\theta \quad (1)$$

where γ_{SL} is the interfacial tension between a solid and a liquid and where γ_S and γ_L are the surface tension of the solid and liquid phases.

Zisman[8,9] proposed the critical surface tension (γ_C) as a unifying concept, and it was found to be useful in correlating the wettability of many polymer surfaces. Since γ_L and θ are measured easily, we should then be able to obtain γ_L from Zisman plots.[8,9] Zisman and his co-workers observed that $\cos\theta$ is usually a monotonic function γ_C for a homogeneous series of liquids. Each line extrapolates to zero θ at a certain γ_L value, which Zisman[9] called the critical surface tension γ_C; since various series extrapolated to about the same value, he proposed that γ_C was a quantity characteristic of a given solid. The critical surface tension concept has provided a useful means of summarizing wetting behavior.

In recent years, many scientists, for example Fowkes,[10] Owens,[11] Kaeleble,[12] Wu,[13] and Kitazaki,[14] have developed equations for assuming the surface tension (γ_S) of a solid. Especially, Kitazaki et al.[14] reported that the surface free energy of an organic material was divided into three components: the dispersion force (non-polar γ^d), the interaction force of polar characters (γ^p), and the hydrogen-bonding force (γ^h). The surface tension of a solid and a liquid may, therefore, be described as follows:

$$\gamma_S = \gamma_S^d + \gamma_S^p + \gamma_S^h \quad (2)$$

$$\gamma_L = \gamma_L^d + \gamma_L^p + \gamma_L^h \quad (3)$$

The interfacial tension between solid and liquid phases (γ_{SL}) may be written by:

$$\gamma_{SL} = \gamma_S + \gamma_L - 2(\gamma_S^d \gamma_L^d)^{1/2} - 2(\gamma_S^p \gamma_L^p)^{1/2} - 2(\gamma_S^h \gamma_L^h)^{1/2} \quad (4)$$

One interesting variation is obtained by combining Eqs. 1 and 4:

$$\gamma_L(1+\cos\theta) = 2(\gamma_S^d \gamma_L^d)^{1/2} + 2(\gamma_S^p \gamma_L^p)^{1/2} + 2(\gamma_S^h \gamma_L^h)^{1/2} \quad (5)$$

When the critical surface tension can not be obtained from Zisman plots, the force components of a solid can be given from the contact angle measurements with Eq. 5.

In this study, we investigate the wetting behavior of polymers in terms of the force components. We discuss the effect of the wettability of the injection nozzle on the size of oil droplets in water.

Experimental

Material. Polymers: The polymer samples used are shown in Table 1. Films of PE and PVC were washed by the methods described by Tamai et al.,[15] while those of PVA and CP were washed by the method of Matsunaga et al.[16] Textile fibers of CT were purified by Soxhlet extraction with ethanol and diethyl ether; the fibers were dried by means of a through-flow of air and shaped into a sheet under pressure.

Dispersed and Continuous Phases: Dodecane as an oil was purchased from the Tokyo Kasei Co., Ltd. It was purified by conventional distillation and was chromatographi-

cally pure. The water employed for the continuous phase was twice-distilled water.

Standard Liquids: The series of standard liquids used here for measurements of the contact angle were chosen on the basis of the classification (three series of liquids; non-polar, polar, or hydrogen bonding liquids) proposed by Kitazaki et al.[14] The classification is as follows: **A** series (non-polar) liquids, $\gamma_L=\gamma_L^d$; **B** series(polar) liquids, $\gamma_L=\gamma_L^d+\gamma_L^p$;C series(hydrogen bonding) liquids, $\gamma_L=\gamma_L^d+\gamma_L^p+\gamma_L^h$. The standard liquids used here were obtained from the Tokyo Kasei Co., Ltd. Their purification by conventional distillation was found to be chromatographically satisfactory.

Apparatus and Procedure. Measurements of the Droplet Size: All the polymer filters were holed with glass rods of given diameters. The hole size of the polymer filters was changed by using glass rods with various diameters. The polymer filter was attached to the top of the single nozzle. The instrument, with each polymer filter, is depicted in Fig. 1. The single droplets were formed statically (velocity of the dispersed phase=0) through the polymer filter after the instrument has been immersed in water at 30 °C. Their diameters were determined from photographs.

Estimation of the Wettability of the Polymer Surface: The wettability of the polymer surface was estimated by measurements of the advancing contact angle (θ_a), using three series of liquids (**A**-series, **B**-series, and C-series liquids) as is shown in Table 2. The wettability was evaluated by means of the critical-surface tension and its components as obtained from a Zisman plot and Eq. 5. The advancing contact angles (θ_a) were measured by the sessile-drop (I) and inverted-bubble (II) methods, both shown in Fig. 2.[17] The measurements of the contact angles and the surface tension of standard liquids were performed with a Goniometer G-II (Erma Co., Ltd.) and a Wilhelmy-type Surface Tensiometer ST-1 (Shimadzu Co., Ltd.) at 30 °C.

Results and Discussion

Observation of Oil-Droplet Formation. Figure 3 shows the results of the observation of oil droplets formed through a polymer filter with a constant hole size at 30 °C. As can be seen in Fig. 3, the droplets formed with a polymer filter vary considerably in size.

In general, for a stationary continuous phase, drop-

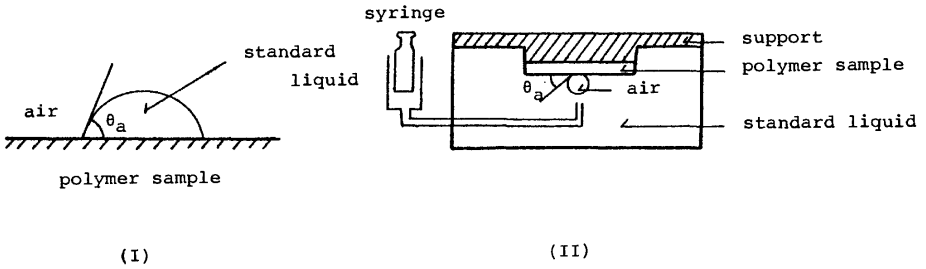

Fig. 2. Schematic diagram of an apparatus for measuring the contact angle by the sessile drop (I) and inverted bubble (II) methods.[17]

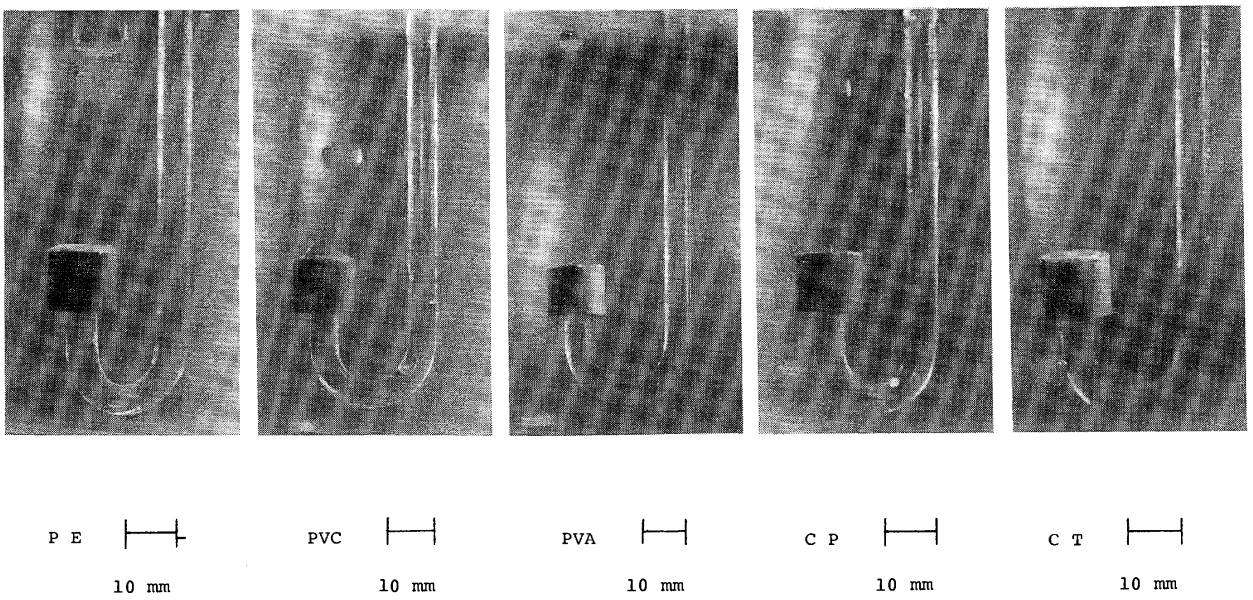

Fig. 3. Photographs of oil droplet formation.

let formation from a single nozzle is classified into several types in terms of the velocity (v) of the dispersed phase: (1) when the v is equal to zero, droplets are formed separately: (2) when the v is low, droplets are formed in a chainlike manner, and (3) when the v is high, droplets are sprayed out. If the velocity of the dispersed phase is markedly low (if, that is, the effect of the velocity is negligible), single droplets are formed "statically." Harkins and Brown[2] have reported that the droplet size is proportional to the interfacial tension between immiscible liquids, the radius of the nozzle, etc. At the same time the droplet size is inversely proportional to the local acceleration of gravity and the density difference between immiscible liquids. When the radii of nozzles with installed polymer filters are the same, droplets of the same size must be formed. It is, however, clear that the size of the oil droplets formed is greatly dependent on the chemical properties of the polymers (Fig. 3). The oil does not spread out over the filter surfaces of PVA, CP, and CT, while it does spread out over those of PE and PVC. It can, then, be postulated that the droplet size is closely related to the wettability of the polymer-filter surfaces.

The Size of Oil Droplets. Table 3 lists the size of the oil droplets obtained from a study of photographs (Fig. 3). By the replacement of one hydrogen atom of the ethylene group of polyethylene (PE) by a chlorine atom or a hydroxyl group, the size of the oil droplets formed is reduced (PE, 10.11 mm; PVC, 9.05 mm; PVA, 6.08 mm). It seems that a poor wettability of the polymer surface (the hydrophilic surface) by the oil would make the size of the droplet smaller. One should note that the size of the droplets formed through a cotton filter (1.34 mm) is the smallest, being about 1/8 of that of those formed through a PE filter.

Figure 4 exhibits the sizes of droplets against the change in the inner diameters of polymer filters (outer

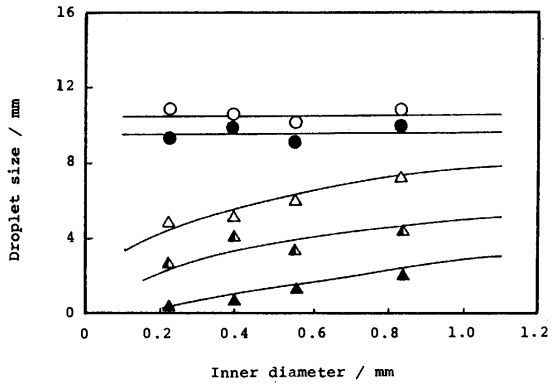

Fig. 4. The change of droplet size as a function of varying inner diameter of filter at 30 °C (outer diameter=constant). (○): PE, (●): PVC, (△): PVA, (△): CP, (▲): CT.

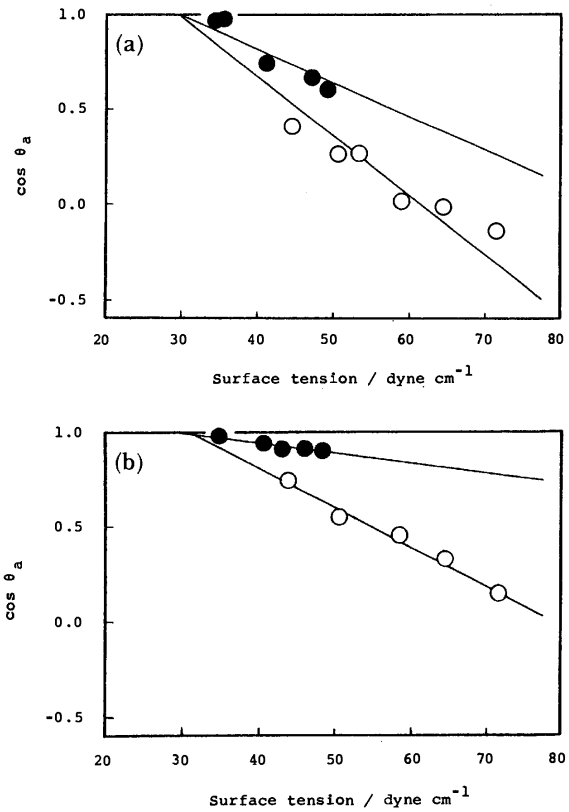
diameter=constant). The sizes of the oil droplets formed through PE and/or PVC filters do not change much with a decrease in the hole size of the filters. However, for the PVA, CP, and CT filters, the sizes of the oil droplets formed decrease with a decrease in the hole size of the polymers. Furthermore, for the CT filter, when a low pressure is exerted on the oil, the size of the oil droplets obtained is smaller than the hole size of the filters.

Effect of the Wettability of the Polymer Filter Surface on the Sizes of Oil Droplets. Let us now consider the effect of the surface-tension components on the sizes of the oil droplets.



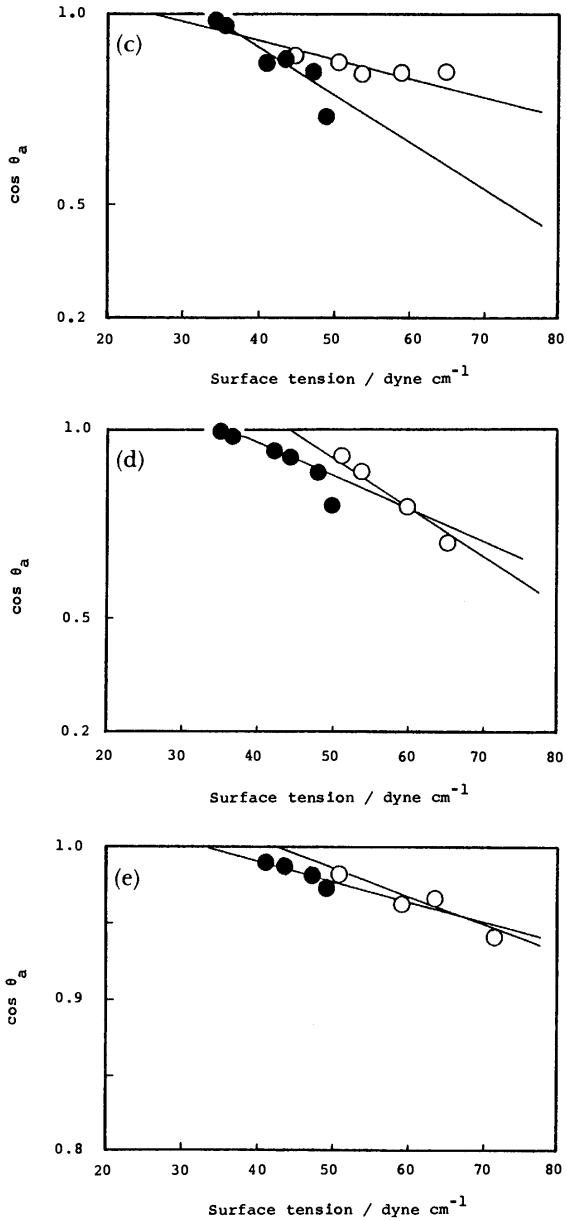


Fig. 5. Zisman plot for **B** series and C series liquids. (a) PE, (b) PVC, (c) PVA, (d) CP, (e) CT. (●): **B** series liquids, (○): C series liquids.

Figure 5(a—e) represent plots of cos θ_a versus γ_L for various series (**B** series and **C** series) on polymers. As can be seen in these figures, each cos θ_a is a monotonic function γ_L for **B**-series liquids and for **C**-series liquids. The value of γ_L, extrapolated to zero θ_a in these figures, corresponds to the γ_C obtained with **B**-series and **C**-series liquids, as has been mentioned above. The γ_S^h was obtained from the difference between the two values of γ_C. According to Kitazaki et al.,[14] the γ_S^d is the value of γ_L extrapolated to zero θ_a for **A**-series liquids, while the γ_S^p is the γ_C difference between **A**-series and **B**-series liquids. All **A**-series liquids, however, spread out over the polymer-filter surfaces used here, so the plots could not be measured. Therefore, the γ_S^d and γ_S^p were obtained from measurements of the con-

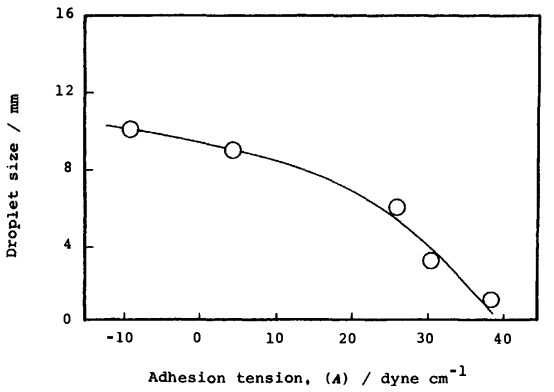

Fig. 7. Effect of adhesion tension on droplet size.

tact angles of two different liquids of the **B** series by using Eq. 5. The results of γ_s^d, γ_s^p, and γ_s^h are summarized in Table 4.

The dispersion force (γ_s^d) of the polymer surfaces, except for CT, are almost the same, while the non-dispersion forces (γ_s^p and γ_s^h) of polymer surfaces are dependent on the kind of polymer. Kitazaki et al.[19] have mentioned that γ_s^h correlates with the wettability of solids by liquids with hydrogen-bonding, like water, glycol, and formamide. The values of γ_s^h at 30 °C are plotted against the size of the oil droplets in Fig. 6. The size of the oil droplets is reduced with an increase in γ_s^h. This may indicate that the droplet size is reduced by using polymer filters, which are easily bonded to water molecules because of hydrogen bonding formation.

Interaction between Water Molecules and Polymer Surfaces. In general, the term "wetting" is taken to mean the phenomenon which occurs when a solid/air interface is replaced by a solid/liquid interface. In practice, we may distinguish three distinct types of wetting (adhesional, immersional, spreading) which are involved when a dry solid is placed into a liquid so that it is completely immersed within the liquid. Immersional wetting is the phenomenon whereby a unit area of surface is completely immersed in the liquid. In this phenomenon, a specific area of the solid/air interface is converted to a solid/liquid interface. The work involved, A, per unit area of the surface is given by:

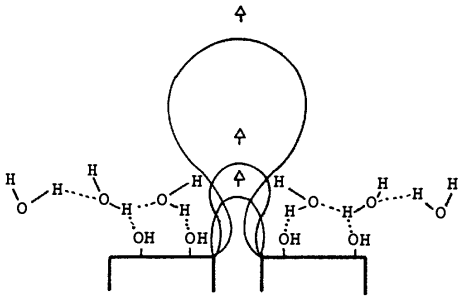
$$A = \gamma_S - \gamma_{SL} = -\Delta G \quad (6)$$

From Eqs. 4 and 6, we obtain:

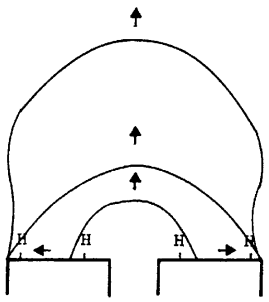
$$A = 2(\gamma_S^d \gamma_L^d)^{1/2} + 2(\gamma_S^p \gamma_L^p)^{1/2} + 2(\gamma_S^h + \gamma_L^h)^{1/2} - \gamma_L \quad (7)$$

The relationship between the adhesion tension and the size of the oil droplets obtained is shown in Fig. 7. The size of the oil droplets becomes smaller with an increase in the adhesion tension. As can be seen from Eq. 6, the adhesion tension also means a change in the surface free energy. If the free energy (negative) of a liquid/polymer interface is large, in other words, the interface is thermodynamically stable. This is reasonable if the wetting of the liquid is carried out spontaneously. Since a water/hydrophilic polymer such as a water/cotton interface is thermodynamically stabilized, a decrease in the droplet size results from the prevention of oil spreading. That is, the droplet size is dependent on the interaction between water molecules and polymer surfaces.

Formation Process of Oil Droplets. The above suggestion is illustrated by the schematic model of the formation process of oil droplets shown in Fig. 8. Figures 8(A) and (B) exhibit typical examples of a hydrophilic-surface polymer (PVA) and of a hydrophobic-surface polymer (PE). In the case of Fig. 8(B), as the γ_s^h of polymer surface and adhesion tension of polymer-water are small, the interaction between the water molecules and the polymer surface is weak (no water/polymer interface is stabilized); the oil which comes out from a hole is spread out over the surface of



(A)



(B)

Fig. 8. Schematic model for formation process of oil droplets. (A) hydrophilic polymer (PVA, CP, CT), (B) hydrophobic polymer (PE, PVC).

the polymer filter (the arrow →), and then the droplet grows along the outer edge of the filter. Necking occurs over the surface of the polymer filters and results in the increase in the size of the oil droplets. In the case of Fig. 8(A), on the other hand, the interaction between the water molecules and the polymers is stronger because of hydrogen bonding (the water/polymer interface is stabilized by the large reduction in the surface free energy). As a result, water molecules are adsorbed strongly on the polymer surfaces. Therefore, the oil droplets which come out from a hole do not spread out over the surface of the polymer filter by the adsorption of water molecules (a droplet grows toward the arrow —▷); as a result, the necking which occurs in the vicinity of a hole brings about the decrease in the size of the oil droplets.

Conclusion

We conclude that the size of an oil droplet formed through a hole is dependent on the chemical property (wettability) of the polymer-filter surface. A cotton filter is most suitable for the formation of small-sized oil droplets. This may be attributed to the fact that the interaction between the continuous phase (water) and the hydrophilic polymer-filter surface, which has a large hydrogen-bonding force (γ_s^h), becomes strong; in other words, the adhesion tension between water molecules as a continuous phase and the polymer-filter surface becomes large.

Permeability Control of Polyelectrolyte Complex Membrane Including Chitosan Derivative as a Component

Yasuo KIKUCHI† and Naoji KUBOTA*,††
Department of Environmental Chemistry and Engineering, Faculty of Engineering,
Oita University, Dannoharu, Oita 870-11
(Received February 4, 1988)

The properties of polyelectrolyte complexes (PEC) and PEC membranes were investigated in the systems of glycol chitosan (GC)-poly(vinyl sulfate) (PVSK) and methyl glycol chitosan (MGC)-(carboxymethyl)dextran (CMD). The degree of dissociation and the conformation of GC and CMD depend upon pH, because GC and CMD are weak polybase and weak polyacid, respectively. On the basis of this knowledge, a research into the pH dependence of dissociation and viscosity of GC and CMD was carried out. PEC including chitosan derivative as a constituent was synthesized at the adequate pH, pH 3.0 in the GC-PVSK system and pH 7.0 in the MGC-CMD system. PEC membranes were prepared, and the permeability of KCl, urea, and sucrose through the GC-PVSK membrane was determined under various pH. It was revealed that the permeability of KCl, urea, and sucrose varies with the solution pH. The permeability in the neutral region was 2—10 times as high as that in acidic region. The increase of permeability in neutral region was considered from IR spectra of membranes to be due to swelling caused by a conformational change.

Polyelectrolyte complexes (PEC) are expected to find a great many applications because of diversity of their structures and properties.[1-3] In particular, membrane application was widely developed, and there have been many studies on the permeability of ions and low-molecular-weight solutes through PEC membranes.[1-5] The investigation on PEC membrane, however, is confined mostly to synthetic polymers, and only a few works on PEC membranes made up of polysaccharide are available.[6,7]

On the other hand, a large amount of chitin is biosynthesized every year and chitin and chitosan derivatives have aroused great interest in recent years.[8] Many-sided applications of them have been proposed as to occupy a field of functional materials. We have already reported about the transport of alkali metal ions through PEC membranes which consist of chitosan derivatives and/or dextran derivatives, methyl glycol chitosan (MGC)-glycol chitosan (GC)-poly(vinyl sulfate) (PVSK),[9] MGC-(carboxymethyl)dextran (CMD)-PVSK,[10] and [2-(diethylamino)ethyl]-dextran (EA)-CMD-PVSK[11] systems.

The present article describes the characterization of GC and CMD and the preparation of PEC and PEC membranes in the GC-PVSK and MGC-CMD systems. Further, the permeability of KCl, urea, and sucrose was determined under various pH conditions in the GC-PVSK membrane, and it is exhibited that the permeation is controlled by pH change. This investigation will support the drug delivery system, the release control capsule, and so on.

Experimental

GC (D.P. 400; nitrogen content 5.51 wt%), PVSK (D.P. 1500; sulfur content 18.91 wt%), and MGC (D.P. 400; nitrogen content 3.33 wt%) were of reagent grade for the colloidal titration supplied by Wako Pure Chemical Industry, Ltd. CMD (mol wt 3×10^7; sodium content 7.38 wt%) was provided by Meito Sangyo Co., Ltd. Deionized water (0.3 $\mu S\,cm^{-1}$) which was degassed with boiling was used for all reagents.

Deionization of GC and CMD solution (0.02 base mol dm^{-3}) was performed by use of a mixture of cation and anion exchangers. After adding NaCl up to 0.1 mol dm^{-3}, 50 cm^3 of GC solution was neutralized by HCl, followed by the back titration with 0.5 mol dm^{-3} NaOH at 25 °C in nitrogen atmosphere. In the case of CMD, 50 cm^3 of CMD solution was directly titrated with 0.5 mol dm^{-3} NaOH after addition of NaCl. In order to estimate the degree of dissociation, hydrogen ion concentration was corrected by back titration of polyelectrolyte-free blank solution.[12] All titrations were carried out with a Hiranuma UCB-7 autoburet and a Horiba M-8 pH meter.

Intrinsic viscosity of GC, PVSK, MGC, and CMD was measured with an Ostwald viscometer in the presence of 1 mol dm^{-3} NaCl in a water bath controlled at 25±0.02 °C.

The preparation of PEC was achieved as described in the previous paper.[9] By the results of potentiometric titrations, GC solution was added dropwise to 100 cm^3 of PVSK solution at pH 3.0, and CMD solution was added dropwise to 100 cm^3 of MGC solution at pH 7.0. In the GC-PVSK system, the resulting precipitate of PEC was dried at 30 °C on a Petri dish. In the MGC-CMD system, the precipitate was interposed between silicone rubbers (50×50×0.5 mm), pressed with PMMA plates (50×50×5 mm) and dried at 30 °C. Thus the PEC membranes about 75 μm in thickness were obtained. The membranes were washed with methanol to remove micro ions prior to the permeation experiment. The measurement of permeability of KCl, urea, and sucrose was carried out with a diaphragm type cell which has 4.0 cm^2 of effective area. In the left-hand chamber of the cell 25 cm^3 of pH 3.0 solution was introduced, and 25 cm^3 of 0.05 mol dm^{-3} KCl, 0.01 mol dm^{-3} urea, or 0.02 mol dm^{-3} sucrose in the

right-hand chamber, of which pH value was adjusted as the same as that of the left-hand chamber. Similarly the measurement of permeability was performed under proper pH from 3.5 to 7.0. Each pH was adjusted by the citrate or 2-amino-2-hydroxymethyl-1,3-propanediol buffer solution. The cell was then placed in a thermostat controlled at 30 °C, and 0.1 cm^3 of samples were withdrawn from both sides of the membrane every 2 h. KCl was determined by measuring K^+ ion with a Shimadzu AA-640 atomic absorption spectrophotometer. Urea and sucrose were determined with a Hitachi 100-10 spectrophotometer by the biacetyl monoxime method and the phenol–sulfuric acid method, respectively. IR spectra of GC-PVSK membranes previously immersed for 4 h in the pH 3.0, 4.0, 5.0, 6.0, and 7.0 solutions were taken with a Hitachi 270-50 IR spectrophotometer.

Results and Discussion

The applications of chitin and chitosan derivatives have been energetically investigated recently, because they have been produced in a comparable amount to cellulose and have the specific structure of amino polysaccharide. GC is also a chitosan derivative which is hydroxyethylated at the 6-position. Water-insoluble chitosan results in a water-soluble chitosan derivative by this etherification to make GC a very useful reagent for the colloidal titration.[13] However, the degree of dissociation (protonation) varies with pH of the solution, because GC has a primary amino group at the 2-position.[14] The pH dependence of the degree of dissociation, α, of glycol chitosan hydrochloride (GCH) was examined by the potentiometric titration, and is shown in Fig. 1. Free primary amino group was dominant in the pH region above 6.63, and primary ammonium ion was dominant in the region below 6.63. Therefore, pH has to be kept below pH 6.63 in order to prepare the ion-bonded PEC which includes GC as a component.[15] Figure 1 also indicates the pH dependence of the degree of dissociation of CMD by the potentiometric titration. Free carboxyl group was preferential in the pH region below 3.64, and the carboxylate ion was preferential in the region above 3.64. Consequently, pH has to be kept above pH 3.64 for the purpose of preparing the ion-bonded PEC which contains CMD as a component.

Furthermore, $pK=pH-\log\{\alpha/(1-\alpha)\}$ vs. α plots are shown in Fig. 2. It is exhibited that intrinsic and apparent pK of GCH in 0.1 mol dm^{-3} NaCl solution are 6.35 and 6.63, respectively. It was already known that a break is observed in the pK-α curve when the conformational change of macromolecular chain occurs like a helix↔coil transition of poly(L-glutamic acid).[16] No conformational change seems to occur in the main chain of GC, as pK-α curve is linear. We could not observe the conformational change in GC by the potentiometric titration, while Rha et al. have reported that the conformational change occurs in chitosan by the measurement of intrinsic viscosity.[17] They have obtained the result that as the pH of solution was increased, the intrinsic viscosity or the hydrodynamic volume of chitosan was decreased. Our measurement of the intrinsic viscosity, $[\eta]$, of GC showed that the intrinsic viscosity at high pH is larger than that at low pH, on the contrary. These results are shown in Fig. 3. This effect seems to be due to the 2-hydroxyethyl group, but it is indefinite in detail. Further investigation should be performed on this point. Figure 2 also gives the pK-α plots of CMD. It is exhibited that intrinsic and apparent pK of

CMD in 0.1 mol dm^{-3} NaCl solution are 3.2 and 3.64, respectively. It appears that there is no conformational change in main chain of CMD similarly to GC, for the pK-α curve is continuous. These results of potentiometric titration of CMD were consistent with Gekko's results.[18] The pH dependence of [η] of CMD is shown in Fig. 3. The [η] of CMD changed at about pH 3, and this pH value was same as the inflection point in the α-pH curve in Fig. 1 which indicates the conditions of dissociation of CMD. The [η] of CMD is supposed to increase on account of a more bulky conformation caused by the inter- and intramolecular electrostatic repulsions between dissociable groups, -OCH_2COOH, in the pH region above 3.64.

In addition, Fig. 3 shows the relationship between [η] and pH of MGC and PVSK dealt in this paper, which are strong polybase and strong polyacid, respectively. Linear curves were obtained with respect to the [η]-pH plots of MGC and PVSK. It is apparent that [η] of these two polyelectrolytes is not influenced by pH, because the degree of dissociation of strong polyelectrolytes is constant over wide range of pH.

On the above conclusion, PEC was prepared. In the system of GC-PVSK, i.e., weak polybase-strong polyacid system, GC solution was added dropwise to PVSK solution at pH 3.0. In the system of MGC-CMD, i.e., strong polybase-weak polyacid system, CMD solution was added dropwise to MGC solution at pH 7.0. These synthetic conditions are summarized in Table 1 with the properties of membranes. It was thought that PEC has a ladder-like structure of ionic bond between ammonio groups in GC or MGC and -OSO_3^- group in PVSK or -OCH_2COO^- group in CMD, respectively. Further, inter- and intramolecular hydrogen bond seems to take place, because polysaccharides which are constituents of these PEC have many hydroxyl groups.

Transparent PEC membranes of 75 μm in thickness were obtained from both of the PEC. GC-PVSK membrane was very sturdy and similar to a cellophan membrane. MGC-CMD membrane was moisture-sensitive and extremely swollen in water. It has been reported that once PEC is prepared containing at least one strong polyelectrolyte component, ionic bond of PEC is maintained throughout wide pH range.[19] This concept, however, was not suitable for the MGC-CMD membrane. On the other hand, GC-PVSK membrane was stable over wide range of pH, and the stability of GC-PVSK seems to be due not only to the above reason but also to packing of GC. This fact manifests that PEC consisting of GC and PVSK is

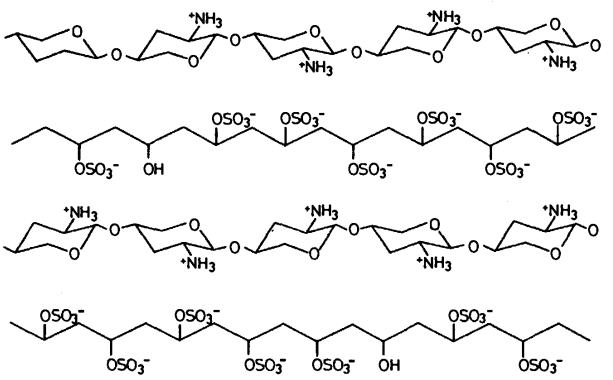

Fig. 5. Schematic model of polyelectrolyte complex in the system of glycol chitosan-poly(vinyl sulfate).

favorable for a membrane material.

Thus the permeability of KCl, urea, and sucrose through this membrane was investigated, and the results are shown in Fig. 4. Permeability, P, was evaluated by the following equation, which derived from the Fick's law of diffusion:[3]

$$Pt = -\frac{V}{2A} \ln \frac{\Delta C}{C_0},$$

where t is the time, V is the volume of each chamber of the cell, A is the area of membrane, C_0 is the initial concentration of solutes in the right-hand chamber, and ΔC is the difference of concentrations in the right- and left-hand chambers. Figure 4 shows that the permeability of KCl, urea, and sucrose depends on the molecular weight and pH. Each permeability decreased proportionally to the molecular weight in the order of KCl>urea>sucrose. GC-PVSK membrane has a cation-exchange ability, because GC is a rigid molecule and the density of cation site of GC is lower than that of anion site of PVSK, as described previously.[15] Schematic model of PEC consisting of GC and PVSK is represented in Fig. 5. Therefore, the electric potential on the left-hand chamber must be higher than that on the right-hand chamber when salt such as KCl was permeated. The electric potential difference between both sides of the membrane was actually 7—8 mV at pH 3.0 after 10 h. Furthermore, permeability increased at about pH 5 where the degree of dissociation and intrinsic viscosity change as shown in Figs. 1 and 3. IR spectra of the GC-PVSK membranes treated for 4 h with the buffer solutions of pH 3.0, 4.0, 5.0, 6.0, and 7.0 are shown in Fig. 6. The absorption band at 1530 cm^{-1} assigned to primary ammonium ion was present in all membranes, whereas 1600 cm^{-1} assigned to primary amino group of GC was absent. That is to say, the dissociation of GC in the membrane was not observed at pH from 3.0 to 7.0. It is clear that breaking of ionic bonds is not responsible for the increase in permeability. Considering that GC has a conformation swelling

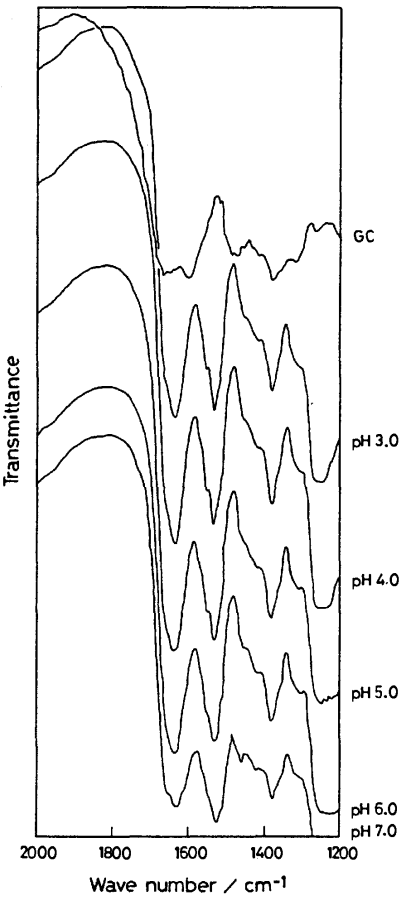

Fig. 6. IR spectra of glycol chitosan and treated polyelectrolyte complex membranes consisting of glycol chitosan and poly(vinyl sulfate).

as pH increases and PVSK has a flexible polymer chain, it is thought that GC-PVSK membrane becomes rather swollen to form a bulky conformation, and hence the permeability increases. Rha et al. have prepared micro capsule whose diffusion rate for γ-globulin and BSA was decreased by decrease in pH, where chitosan was gelified with alginate.[17] PEC membrane in the system of GC-PVSK has controllable permeability for KCl, urea, and sucrose to some extent, even though PEC is previously prepared at a constant pH value.

These investigations suggest a possibility of permeation control of PEC membrane consisting of GC, which is a amino polysaccharide, and PVSK, which has a flexible polymer chain, because it is possible to control the permeability by pH which controls the conformation and packing of PEC.

Partial Oxidation of Isobutene to Methacrylic Acid on V_2O_5-P_2O_5 Catalysts

Mamoru Ai
Research Laboratory of Resources Utilization, Tokyo Institute of Technology,
4259 Nagatsuta, Midori-ku, Yokohama 227
(Received February 13, 1988)

The vapor-phase air oxidation of isobutene was studied with V_2O_5, V_2O_5-TiO_2, V_2O_5-MoO_3, V_2O_5-P_2O_5, V_2O_5-P_2O_5-TeO_2, and heteropoly compound catalysts, such as $H_3PMo_{12}O_{40}$, $Cs_2HPMo_{12}O_{40}$, $H_5PMo_{10}V_2O_{40}$, and $Cs_{2.5}H_{2.5}PMo_{10}V_2O_{40}$, in the presence of water vapor. On pure V_2O_5, the oxidation products were acetic acid and carbon oxides, plus small amounts of acetone and methacrylaldehyde. With the addition of TiO_2 to V_2O_5, the selectivity to acetic acid increased a little, but the formation of methacrylaldehyde disappeared. The addition of MoO_3 to V_2O_5 enhanced the formations of acetone and methacrylaldehyde, to a certain extent, but methacrylic acid was not obtained. With the V_2O_5-P_2O_5 catalysts, the yield of methacrylic acid attained 21 mol%, the sum of the yields of methacrylaldehyde and methacrylic acid attained 30 mol%, and the yield of acetic acid attained also 30 mol%. The P/V atomic ratio=1.6 catalyst was better than the P/V=1.06 catalyst in the formation of methacrylic acid. Further, the performance of the P/V=1.6 catalyst was better than that of the heteropoly compound catalysts. The results were discussed in the light of the acid-base properties of the catalysts.

Methacrylic acid is an important chemical as a raw material of so-called organic glass. It is currently produced by a two-step partial oxidation of isobutene. The first step, oxidation of isobutene to methacrylaldehyde, is performed with multicomponent oxide catalysts which are similar to those used in the oxidation of propylene to acrylaldehyde. A number of studies have been made of this reaction, as summarized in several review articles.[1-4] The second step, oxidation of methacrylaldehyde to methacrylic acid, is performed mostly with heteropoly compound catalysts based on molybdovanadophosphoric acid, $H_{3+x}PMo_{12-x}V_xO_{40}$ (x=1—2), and its salts. Besides the patent information,[2-4] several scientific works have been done on this reaction.[5-10] It is recognized that the effective catalytic performance of heteropoly compounds is ascribed to their eminent acidic property as well as their redox property. However, it is also known that these compounds are decomposed at around 400 °C and lose their catalytic activity.

On the other hand, the V_2O_5-P_2O_5 (P/V=1.0 to 1.2) system is a unique catalyst possessing a surprisingly high selectivity in the oxidation of butane to maleic anhydride and, moreover, it is stable enough at around 400 °C. Recently, it was found that the V_2O_5-P_2O_5 system possesses an enhanced acidic property.[11,12]

In view of the acid-base property of the reactant and product, the enhanced-acid catalyst is expected to be effective for "acid-formation-type" partial oxidations.[13-16] Indeed, the V_2O_5-P_2O_5 catalysts are found to be effective for the oxidation of acrylaldehyde to acrylic acid[17] and that of isobutyric acid to methacrylic acid.[18] Further, it was recently found that propylene is oxidized directly to acrylic acid.[19]

From these findings, we can predict that the V_2O_5-P_2O_5 catalysts are effective for the oxidation of isobutene to methacrylic acid, also. Therefore, in this study, we focused our attention on the oxidation of isobutene to form methacrylic acid, since no detailed information about this reaction has yet been reported.

Experimental

Oxidation Procedures. The reaction was carried out with a continuous-flow system using tertiary butyl alcohol (TBA) as the starting material for isobutene. It was confirmed that almost all of the TBA is converted promptly into isobutene and water over every catalyst tested. The reactor and the experimental procedures were the same as those employed in the previous works.[17-19] Air was fed in from the top of the reactor with a fixed rate of 400 ml (at 20 °C)/min and a mixture of TBA and water with a TBA/H_2O volumetric ratio of 1/4 was introduced into the preheating section of the reactor by means of a micro liquid-feeder. The feed rate was TBA/H_2O/Air=0.014/0.22/1.00 mol h^{-1} and the amount of catalyst used was 10 to 30 g.

The yield (mol%) is defined as (except for carbon oxides); 100·(moles of product)/(moles of TBA fed in). On the assumption that the formation of carbon oxides is accompanied with those of acetone and acetic acid; that is, C_4H_8 →acetone+CO_x and C_4H_8→acetic acid+2 CO_x, the yield of carbon oxides is calculated as follows; 100·([moles of CO_x]−[moles of acetone] −2[moles of acetic acid])/4 (moles of TBA fed in).

Catalysts. The catalysts used in this study were the same as those used in the previous works.[15-19]

Results

Performance of the V_2O_5 Catalyst. The oxidation of isobutene was conducted with a 10 g-portion of pure V_2O_5 catalyst under the conditions described in the Experimental section. The products were acetic acid and carbon oxides, plus small amounts of acetone and methacrylaldehyde. The methacrylic acid was not detected. The change in the yields of the partial oxidation products with the elevation of the reaction temperature is shown in Fig. 1.

Performance of the V_2O_5-TiO_2 Catalyst. The

results obtained with a 10 g-portion of the V_2O_5-TiO_2 (Ti/V atomic ratio=6/4) catalyst are shown in Fig. 2. This catalyst was a little more active than the pure V_2O_5 catalyst. The yield of acetone attained 12 mol% at the isobutene conversion of 50 to 70% and selectivity to acetic acid also increased. However, the formation of methacrylaldehyde was not observed.

Performance of the V_2O_5-MoO_3 Catalysts. Figure 3 shows the results obtained with a 10 g-portion of the V_2O_5-MoO_3 (Mo/V=2/8) catalyst. This catalyst was much less active than the pure V_2O_5 catalyst for the consumption of isobutene. A small amount of methacrylaldehyde was obtained, but methacrylic acid was not obtained. The main partial oxidation product was acetic acid. Figure 4 shows the results obtained with a 10 g-portion of the Mo/V=8/2 catalyst. The perfor-

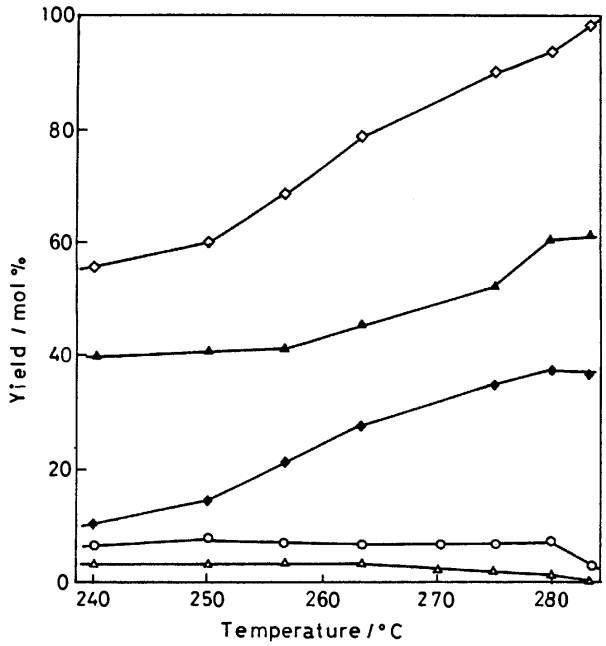

Fig. 1. Oxidation of isobutene with the pure V_2O_5 catalyst. (◇)=isobutene conversion. Yield: (●)=methacrylic acid, (○)=methacrylaldehyde, (▲)=acetic acid, (△)=acetone, (◆)=carbon oxides.

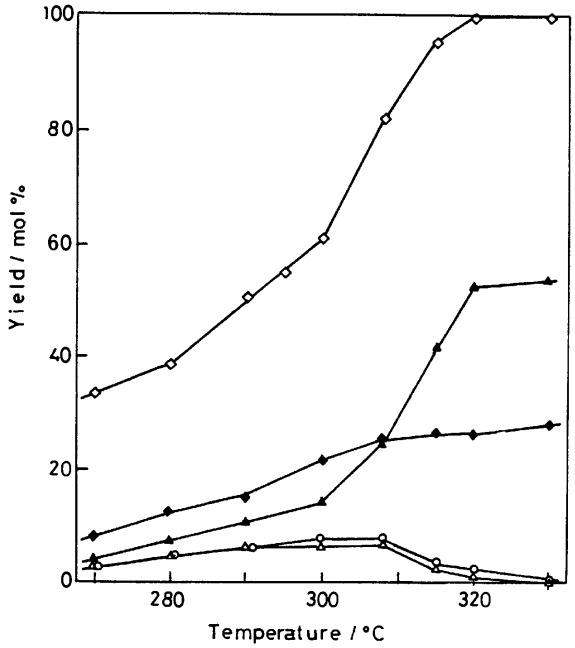

Fig. 4. Oxidation of isobutene with the V_2O_5-MoO_3 (Mo/V=8/2) catalyst. Symbols as in Fig. 1.

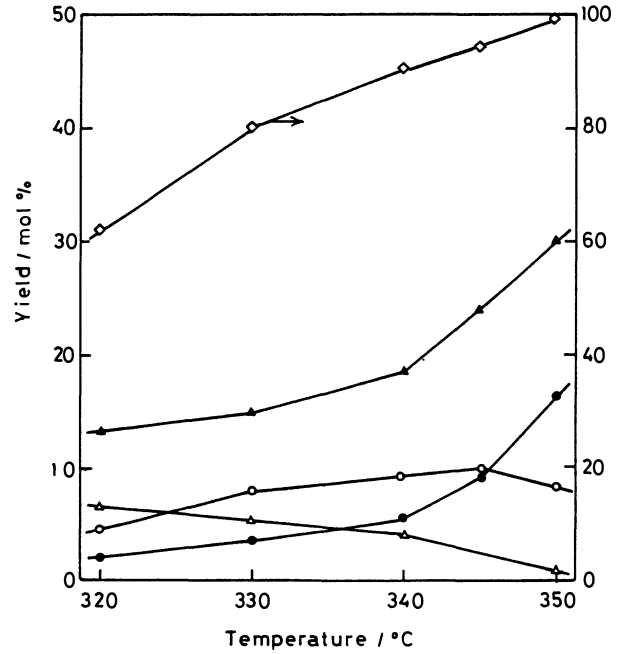

Fig. 5. Oxidation of isobutene with the V_2O_5-P_2O_5 (P/V=1.06) catalyst. Symbols as in Fig. 1.

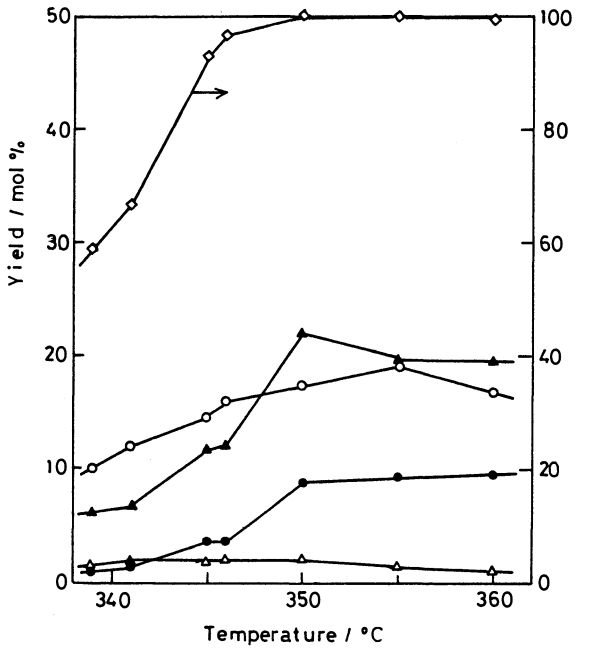

Fig. 7. Oxidation of isobutene with the $H_3PMo_{12}O_{40}$ catalyst. Symbols as in Fig. 1.

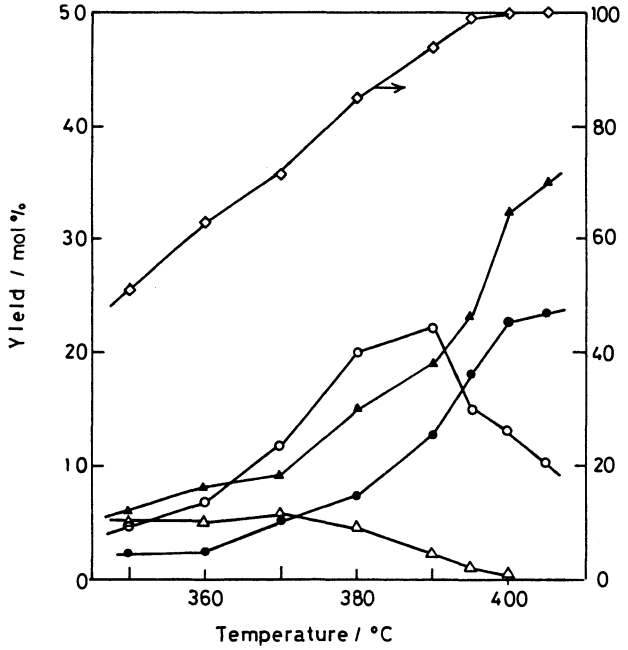

Fig. 6. Oxidation of isobutene with the V_2O_5-P_2O_5 (P/V=1.6) catalyst. Symbols as in Fig. 1.

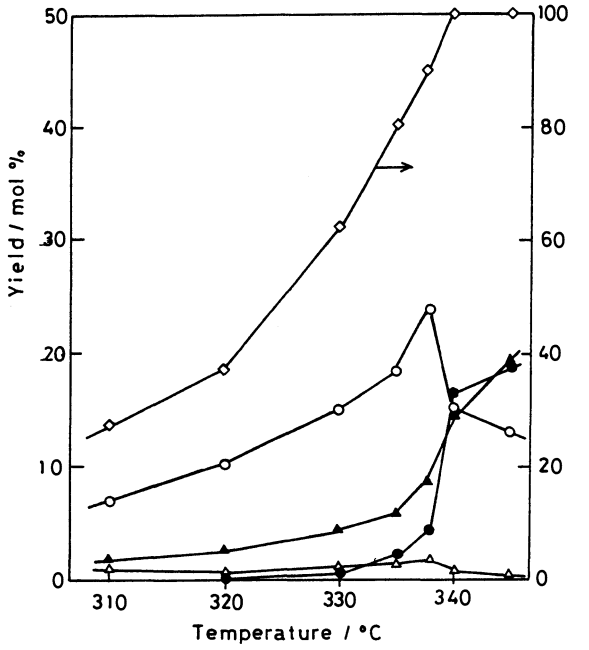

Fig. 8. Oxidation of isobutene with the $Cs_2HPMo_{12}O_{40}$ catalyst. Symbols as in Fig. 1.

mance of this catalyst was similar to that of the Mo/V=2/8 catalyst.

Performance of the V_2O_5-P_2O_5 Catalysts. Figure 5 shows the results obtained with a 20 g-portion of the V_2O_5-P_2O_5 (P/V=1.06) catalyst. The formation of methacrylic acid attained 15 mol% and that of methacrylaldehyde was much greater than in the reaction with the pure V_2O_5 catalyst.

Figure 6 shows the results obtained with a 20 g-portion of the V_2O_5-P_2O_5 (P/V=1.6) catalyst. This catalyst was markedly less active than the P/V=1.06 catalyst. However, the yields of methacrylic acid and methacrylaldehyde were greater. The yield of methacrylic acid attained 21 mol%, the sum of the yields of methacrylic acid and methacrylaldehyde attained about 30 mol%, and the yield of acetic acid attained also about 30 mol%.

Since it has been reported[19] that the V_2O_5-P_2O_5-

TeO_2 ternary system performs better than the V_2O_5-P_2O_5 binary system in the oxidation of propylene to acrylic acid, the Te/P/V=0.15/1.2/1 catalyst was tested in the oxidation of isobutene. It was found that the catalytic performance is not improved by the addition of TeO_2 to the V_2O_5-P_2O_5 system.

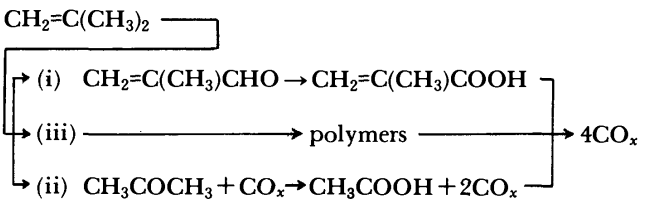
Performance of the Heteropoly Compound Catalysts. Since heteropoly compounds are known to be effective as catalysts for the oxidation of methacrylaldehyde to methacrylic acid, the performance of these catalysts was examined. The results obtained with a 30g-portion of $H_3PMo_{12}O_{40}$ and $Cs_2HPMo_{12}O_{40}$ catalysts are shown in Figs. 7 and 8, respectively. The sum of the yields of methacrylic acid and methacrylaldehyde attained about 30 mol% as in the reaction with the P/V=1.6 catalyst (Fig. 5), but the formation of acetic acid was lower.

The performance of the $H_5PMo_{10}V_2O_{40}$ and $Cs_{2.5}H_{2.5}PMo_{10}V_2O_{40}$ was also tested. It was found that the performances of these catalysts were comparable to that of the P/V=1.6 catalyst.

It should also be noted that the activity of these heteropoly compounds decreases gradually with the duration of the reaction time at temperatures above 350 °C.

Discussion

The character of the curves of methacrylic acid and methacrylaldehyde shown in Figs. 5 and 8 reveals that methacrylaldehyde is an intermediate in the oxidation of isobutene to methacrylic acid. Similarly, the shape of the curves of acetic acid and acetone shown in Figs. 1 to 8 also reveals that acetone is an intermediate in the oxidation of isobutene to acetic acid. Further, it appears that methacrylaldehyde, acetone, and a part of carbon oxides are formed by the following three parallel pathways.



Reaction i is an allylic oxidation, Reaction ii is an oxidative C-C fission, and Reaction iii is a deep oxidation and/or polymerization.

Methacrylaldehyde was not obtained with the V_2O_5-TiO_2 catalyst. This indicates that the catalyst is lacking in the function to promote Reaction i. However, it promotes Reaction ii with a high selectivity than the pure V_2O_5 catalyst. This can easily be understood from the fact that V_2O_5-TiO_2 is very effective as a catalyst for the oxidative C-C fission of butene to form acetic acid.[20,21]

In the case of the pure V_2O_5 and V_2O_5-MoO_3 catalysts, a small amount of methacrylaldehyde was obtained, but methacrylic acid was not obtained. This finding suggests that these catalysts possess a catalytic function to promote Reaction i, to a certain extent, but they are lacking in the function to convert the methacrylaldehyde to methacrylic acid.

Appreciable amounts of methacrylic acid and methacrylaldehyde were obtained with the V_2O_5-P_2O_5 and heteropoly compound catalysts, indicating these catalysts possess both the function to promote Reaction i and that to promote the oxidation of methacrylaldehyde to methacrylic acid. As may be seen in Fig. 5 to 8, the yield of methacrylaldehyde passes through a maximum at the isobutene conversion of about 90%, indicating that methacrylaldehyde is more stable than isobutene under the conditions used.[22]

It has been pointed out[16] that the basic sites of catalyst promote the oxidative C-C fission rather than the allylic oxidation. In line with this thought, the results can be explained as follows. On the pure V_2O_5, about 60 to 70% of isobutene is directed to Reaction ii. The addition of a more basic oxide such as TiO_2 to V_2O_5 enhances the basic property of catalyst.[23] Therefore, the selectivity to Reaction ii increases to about 70 to 90%, but the function to promote Reaction i disappears. On the other hand, the addition of an acidic oxide such as MoO_3 to V_2O_5 induces an increase in the selectivity to Reaction i at the expense of a decrease in the selectivity to Reaction ii. This may be caused by an enhancement of the acidic property and/or a suppression of the basic property.

The addition of P_2O_5 to V_2O_5 induces a marked increase in the acidic property and, at the same time, a marked decrease in the basic property.[11] This may be the reason why a markedly higher selectivity to Reaction i can be obtained with the V_2O_5-P_2O_5 catalysts.

On the other hand, the possession of an enhanced acidic property seems to be required to promote selectively the oxidation of methacrylaldehyde to methacrylic acid.[8] This may be one of the reason why the V_2O_5-P_2O_5 catalysts are effective for the oxidation of isobutene to methacrylic acid.

It has been proposed[15] that heteropoly compounds are similar to V_2O_5-P_2O_5 system in their balance between acidic and basic properties. This may be the reason why similar catalytic performances are obtained in the oxidation of isobutene with the V_2O_5-P_2O_5 and heteropoly compounds.

However, it should be noted that a great extent of Reaction ii is accompanied with Reaction i even with the V_2O_5-P_2O_5 and heteropoly compound catalysts, that is, the suppression of Reaction ii is difficult. This may be a main disadvantage of this process.

It is interesting to note that the P/V=1.6 catalyst exhibits a higher yield of methacrylic acid than the P/V=1.06 catalyst, unlike the case of the oxidation of butane to maleic anhydride, and that the $Cs_2HPMo_{12}O_{40}$ catalyst shows a higher yield of methacrylic acid than the $H_3PMo_{12}O_{40}$ catalyst. At present, it is hard to

describe clearly the reason. Further study on the oxidation of methacrylaldehyde is necessary. This will be studied in forthcoming paper.

Kinetic Studies of Fast Equilibrium by Means of High-Performance Liquid Chromatography. XVII. Separation of Tautomers of 1,3-Cyclohexanediones

Masataka MORIYASU,* Atsushi KATO, and Yohei HASHIMOTO
Kobe Women's College of Pharmacy, Motoyamakita-machi, Higashinada-ku, Kobe 658
(Received January 21, 1988)

Synopsis. Tautomers of 1,3-cyclohexanediones have been separated by means of low-temperature high-performance liquid chromatography (HPLC). The ratios of keto- and enol-forms have been found to be highly solvent dependent, which is explained in terms of solute-solvent and solute-solute hydrogen bonding.

We have already separated keto- and enol-forms of various β-dicarbonyl compounds[1-3] by means of low-temperature HPLC. However, the separation of tautomers of cyclic β-diketones has been unsuccessful, even though various column packings including narrow-pore silica gel, wide-pore silica gel, and narrow-pore diol-silica (chemically bonded silica-gel packings which contain alcoholic hydroxyl-groups) have been tried under various conditions. In the course of this study, we found that only wide-pore diol-silica achieved the separation. The nature of the keto-enol tautomerism of 1,3-cyclohexanediones was found to differ markedly from other β-dicarbonyl compounds, which is explained in terms of ring dimer formation of the enol-form in nonpolar media.

Experimental

1,3-Cyclohexanedione and 5,5-dimethyl-1,3-cyclohexanedione (dimedone) were obtained commercially. These were used without further purification because no peak attributable to the impurity appeared on the chromatograms.

The HPLC apparatus for low-temperature measurements have been detailed elsewhere.[1,2] In the present work it was necessary to cool the column to about −60 °C.

Wide-pore diol-silica (Nucleosil 4000-OH, 7 μm, from M. Nagel) was slurry packed into a stainless steel column (4.6 mm×10 cm). Various other column packings of different types were also tried, but no satisfactory results were obtained.

Results and Discussion

Among various column packings tested, only wide-pore diol-silica seems to separate tautomers. As shown in Fig. 1, the separation was attained on Nucleosil 4000-OH under the solvent system composed of hexane and ethyl acetate. For the complete separation in which the interconversion between tautomers during chromatography is negligible, a low column temperature (−60 °C) was necessary. The interconversion of 1,3-cyclohexanediones seems to be highly sensitive to the solvent. The solvent system composed of hexane and 1-propanol, which had given satisfactory separations of tautomers of various β-dicarbonyl compounds, did not give any separation even at −60 to −70 °C. Furthermore, addition of a minute amount of alcohols to the eluent (hexane-ethyl acetate) seriously depressed the separation. It seems that the interconversion was very fast in alcohols. The interconversion seems to be somewhat slower in less polar solvents, but still too fast to measure the rate constants at 0 °C or lower. The interconversion also seems to be activated on the surface of the adsorbent. On both narrow-pore and wide-pore silica gel, the interconversion seems to be fast, since no separation was attained. Acidic silanol group seems to drastically accelerate the interconversion. Although narrow-pore diol-silica did not, wide-pore diol-silica gave the separation, probably due to its low concentration of residual silanol group and less content of alcoholic -OH groups. In addition to 1,3-cyclohexanediones, separation of tautomers of 1,3-cycloheptanedione was also tried, but no separation was attained, even at −70 °C.

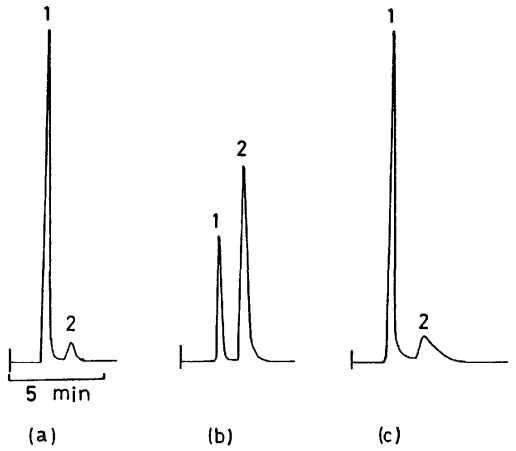

Fig. 1. HPLC separation of tautomers of 1,3-cyclohexanediones. Column: Nucleosil 4000-DIOL, 7 μm (4.6 mm×10 cm). Eluent: hexane:ethyl acetate=100:50. Flow rate: 2.5 $cm^3 min^{-1}$. Detector: UV 254 nm. Column temperature: −60 °C. Sample: (a) 10 mM dimedone in chloroform, (b) 10 mM dimedone in ethyl acetate, (c) 10 mM 1,3-cyclohexanedione in chloroform. 1: keto-form, 2: enol-form.

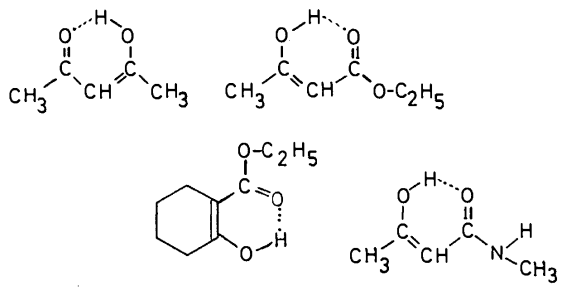
Table 1. Percentages of Enol-Form of 1,3-Cyclohexanedione and Dimedone in Different Solvents

Solvent	Enol-form/%	
	1,3-Cyclohexanedione	Dimedone
Carbon tetrachloride[a]	28	5
Chloroform	30	12
Dichloromethane	26	10
Diethyl ether	72	70
Ethyl acetate	78	69
Tetrahydrofuran	48	54
Acetonitrile	60	50
1-Propanol	92	95
Ethanol	93	97

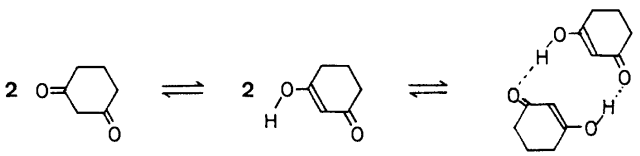
10 mM solution, 25 °C. a) 1 mM solution.

Peak identification in Fig. 1 was done by comparing the present HPLC data with other data obtained by UV or NMR.[4] It is established that 1,3-cyclohexanediones are highly ketonic in dilute nonpolar media such as chloroform and cyclohexane[4] or in the gaseous phase.[5] With increasing concentration, the ratios of keto-form decrease. Since in chloroform the peak area with shorter retention time in Fig. 1 decreases with increasing concentration, the peak should be attributed to the keto-form. The percentages of enol-form were determined from peak area measurements for 1,3-cyclohexanedione in chloroform as follows: 89% (750 mM, 1 M=1 mol dm^{-3}), 85% (500 mM), 77% (250 mM), 58% (100 mM), 53% (70 mH), 33% (20 mM), 24% (5 mM), and 20% (2 mM). The reported values by means of NMR and UV[4] are as follows: 89% (770 mM, NMR), 82% (510 mM, NMR), 71% (240 mM, NMR), 52% (103 mM, NMR), 46% (68 mM, NMR), 25% (19 mM, UV), and 15% (4.2 mM, UV). Both results agree rather well. With similar procedures the percentages of enol-form of dimedone in chloroform were also determined, the results being as follows: Our results; 33% (100 mM), 23% (60 mM), 21% (40 mM), 15% (20 mM), and 10% (6 mM). NMR or UV data;[4] 28% (94 mM, NMR), 18% (63 mM, NMR), 5% (42 mM, NMR), 14% (39 mM, UV), and 4% (6.2 mM, UV). The ratios of keto- and enol-forms in different solvents at dilute concentration (10 mM) at 25 °C were also measured, and the results are summarized in Table 1.

The chromatographic behavior and the nature of the tautomerism of 1,3-cyclohexanediones differ markedly from other various β-dicarbonyl compounds



we investigated previously.[1-3] (1) For the separation of tautomers of 1,3-cyclohexanediones, a lower column temperature than for other β-dicarbonyl compounds is necessary. This suggests a faster interconversion of 1,3-cyclohexanediones. (2) The keto form is eluted faster than the enol-form for 1,3-cyclohexanediones on adsorption chromatography, which is the reverse to other β-dicarbonyl compounds. (3) For 1,3-cyclohexanediones, the percentages of enol-form are higher in polar solvents such as alcohols, which is also opposite in the case of other β-dicarbonyl compounds. These characteristic features can be explained in terms of the difference of structure between enol-forms of 1,3-cyclohexanediones and others. As shown above, enol-forms of most β-dicarbonyl compounds such as β-diketones, β-keto esters including cyclic ones, and β-keto amides form chelated intramolecular hydrogen bonds. Consequently, enol-forms are less polar chemically than keto-forms.[6] Since adsorption on silica gel (or diol-silica) surface will occur by intermolecular hydrogen bonding between polar groups of substances and -OH group of the stationary phase, strongly chelated enol-forms may not be easily adsorbed. Thus, the enol-forms are eluted faster than the keto-forms, although alcohols are usually more polar than ketones. Strongly chelated enol-forms also might be somewhat resistant to hydrogen abstraction by a solute molecule which is one of the fast steps of keto-enol conversion. The situation differs for 1,3-cyclohexanediones. The equilibrium of 1,3-cyclohexanediones is explained in terms of the following three labile species, ketone monomer, enol monomer, and enol dimer.[4,7] Due to geometrical restrictions, intra-



molecular hydrogen bonds cannot be formed for enol-forms. Thus, enol-forms should be more polar and eluted later than keto-forms. As shown above, in non-polar solvents such as cyclohexane and chloroform or in gaseous phase, the ketone monomer is predominant. With increasing concentration, the intermolecular hydrogen-bonded enol dimer begins to be formed. In protic solvents such as alcohols, enol monomer may be predominant due to strong solute-solvent intermolecular hydrogen bonds. Thus, the ratios of keto- and enol-forms of 1,3-cyclohexanediones differ markedly from other β-dicarbonyl compounds. The behavior rather resembles the case for the separation of rotamers of formanilide[8] in which the (*E*)-rotamer forms an intramolecular hydrogen-bonded ring dimer.

Proton NMR Spectra of Methyl Alkanoates in Aromatic Solvents

Takashi HOSHINO* and Yoshio IMAMURA
Department of Chemistry, Faculty of Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162
(Received February 5, 1988)

Synopsis. The splitting of methylene peaks in ^{1}H NMR spectra was studied for long-chain methyl alkanoates in 1-chloronaphthalene as a function of the carbon number, n_c, of alkyls. With increase in n_c, the singlet peak of methylene is first split into a doublet and then into a triplet.

ASIS (Aromatic-Solvent-Induced Shift) phenomena in NMR have been widely accepted by organic chemists and applied successfully to conformational studies on organic molecules.

In 1967, a peculiar solvent effect by an aromatic solvent was reported by Liu.[1] He observed that methylene envelopes in ^{1}H NMR spectra of long-chain hydrocarbons (the number of carbons >16) were split into doublets in 1-chloronaphthalene. Similar observations have been reported for other solute molecules with long alkyl chains. For example, Gonzalez de la Campa et al. reported on a series of *N*-alkylmaleimides[2] and alkyl 11-maleimidoundecanoates in benzene solution,[3] and Winnik et al.[4] also reported on the octadecyl ester of benzophenone-4-carboxylic acid in 1-chloronaphthalene. In ^{1}H NMR spectra of these compounds, splittings of methylene signals were observed for shorter alkyl chains rather than for *n*-alkanes, and it was suggested that terminal substituted groups seemed to accentuate the splitting of methylene peaks of ^{1}H NMR spectra, observed in aromatic solvent.

The first theoretical investigation was carried out by Ando and Nishioka.[5] They concluded that the splitting of peaks in aromatic solvent arose from increase in the number of gauche forms for long chain hydrocarbons. On the other hand, Winnik et al. applied T_1 measurements[4] and used the heteronuclear (^{13}C-^{1}H) shift correlated two-dimensional NMR spectroscopy.[6] They concluded that the splitting was due to a solvent effect associated with the chain end, and conclusively ruled out the presence of slowly interconverting gauche and trans conformations for long alkyl chains. Furthermore, several papers have been published to discuss the origin of these phenomena, without setting the issue.

In this paper, we intend to present another example of similar phenomenon to add to information so as to facilitate insight into the reason for the splitting found for methylene peaks of substituted alkyl chains.

Experimental

Methyl alkanoate compounds with alkyl carbon (n_c=6 to 24) were used as solute substances. The compounds and solvents used were of the best available commercial grade. The samples were prepared in an about 0.5 M solution (1 M=1 mol dm^{-3}) of deuterated benzene or a mixed solvent of 90 vol% 1-chloronaphthalene/10 vol% deuterated benzene. NMR spectra were observed using a JEOL FX-100 NMR spectrometer operated at 100 MHz at ambient temperature, unless otherwise indicated.

Results and Discussion

100 MHz ^{1}H NMR spectra of a series of methyl alkanoates in 1-chloronaphthalene are shown in Fig. 1. The carbon number of alkyl chains, n_c, is in the range from 6 to 24. Triplet peaks at higher fields were assigned to their terminal methyl protons and the rest to methylene protons. The peaks which appeared in lower fields at about δ 3.4 and 2.2, were assigned to the methyl and methylene adjacent to the ester group, respectively, but they are not shown in Fig. 1. The small peaks at the lowest field were assigned to β methylene protons to the carbonyl. A singlet methylene peak was observed for the compounds with n_c ranging from 6 to 10. When n_c=12, one more partially resolved peak appeared in the spectrum as a shoulder. Then, there are two distinguishable peaks in the spec-

a) 1-Chloronaphthalene. b) Present investigation.

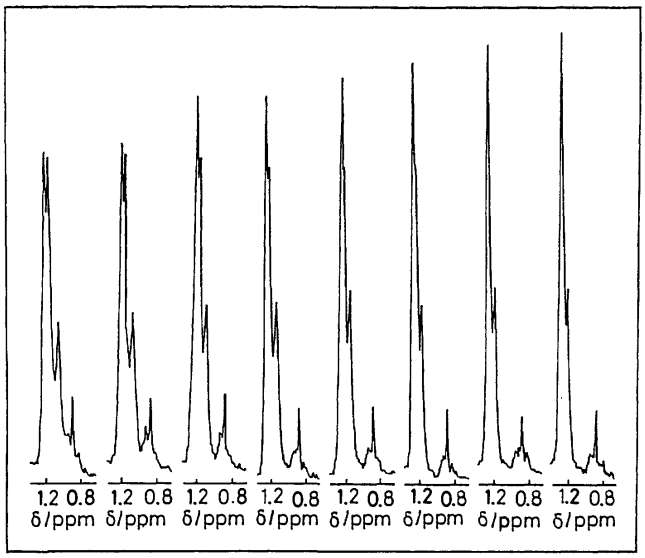

Fig. 2. The ^{1}H NMR spectra of methyl eicosanoate in 1-chloronaphthalene solution at various temperatures; 25, 38.8, 55.0, 70.3, 85.3, 99.7, 115.5, and 129.5 °C from left to right, respectively.

tra of the compounds for n_c=12 to 18. When $n_c \geqslant 20$, the lower field peak further split into a doublet, and a distinct triplet peak was recognized. A peak splitting at n_c=12 was also observed in benzene solutions but no splitting at n_c=20 in 1-chloronaphthalene was observed in benzene, as shown in Table 1, which shows a list of the splitting behavior for substituted alkanes in aromatic solvent. This splitting at n_c=12 has substantially the same character as observed in the case of a series of *N*-alkylmaleimides[2)] and alkyl 11-maleimidoundecanoates[3)] in benzene solutions. On the other hand, the second splitting of the lower field peak observed in 1-chloronaphthalene solutions for $n_c \geqslant 20$ was not observed in the case of benzene solutions. The splitting for $n_c \geqslant 20$ seems to be consistent with the results obtained by Liu[1,7)] for a series of alkanes. He reported that the splitting was observed only in 1-chloronaphthalene solutions[1)] but not in benzene solutions for alkanes.[7)] We considered that the nature of the origin of this splitting of the peak of the methylene envelope for $n_c \geqslant 12$ is different from that of the splitting effect in the case of alkanes.

The splitting for n_c=12 seems to be strongly dependent on the presence of the ester function. In the series of 1-chloroalkanes in 1-chloronaphthalene solutions, the splitting was not observed for n_c less than 18. This behavior is the same as in the case of alkanes.

^{1}H NMR spectra of methyl eicosanoate of n_c=20 in 1-chloronaphthalene solutions at various temperatures are shown in Fig. 2. The chemical shift differences among the three peaks in the methylene envelope decrease with temperature raise, and the two lower field peaks for the methylene coalesce at about 100 °C. This temperature is lower than that reported for *n*-alkanes. Winnik et al.[6)] calculated the energy barrier to be 120 kJ mol^{-1} for *n*-alkanes by assuming the two site exchange. They suggested that this value was too large for the constraint of the interconversion between gauche and trans conformers to account for the splitting phenomena.[5)] In this study, the energy barrier for methyl alkanoates was calculated to be about 80 kJ mol^{-1} using the coalesce temperature method.[8)] This value is less than the value reported for alkanes but still large for the ordinary interconversion energy. However, in order to make further discussion on the results of our observation, it may be desirable to establish a new molecular model for the solvent-solute interaction.

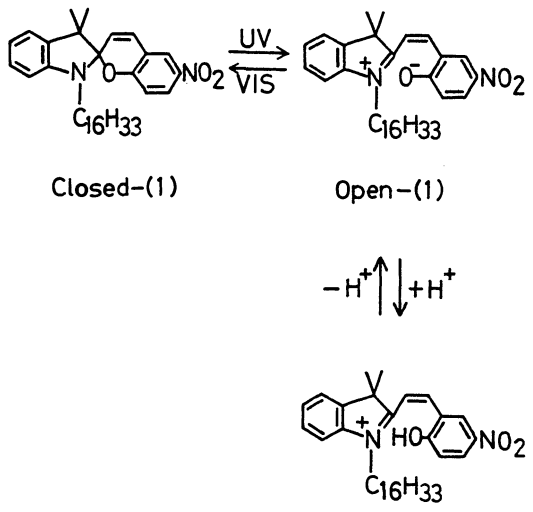
Photo-Excitable Membranes. Effects of pH of the Solution on the Photoresponse of Poly(vinyl chloride) Membrane Doped with a Spirobenzopyran Derivative

Jun-ichi ANZAI, Yasushi HASEBE, Akihiko UENO, and Tetsuo OSA*
Pharmaceutical Institute, Tohoku University, Aobayama, Sendai 980
(Received February 18, 1988)

Synopsis. The magnitude of the photoinduced membrane potential across a poly(vinyl chloride)/spirobenzopyran membrane depends considerably on the pH of the solution adjacent to the membrane surface which is exposed to light. The photoresponse is enhanced in the acidic region, while is depressed in the alkaline region. The results are explained in terms of the formation of the asymmetric membrane and of the charge density on the membrane surface.

Several reports have appeared on the photoinduced membrane potential across the polymer membranes modified with spirobenzopyran derivatives.[1-6] To improve the photoresponse of the membranes, we have employed a plasticized poly(vinyl chloride) membrane doped with spirobenzopyran derivative **1** and found followings; (1) UV irradiation induces membrane potential changes of more than 100 mV with a response time of 1—2 min, (2) the photoinduced potential changes arise from the change in charge density on the membrane surface (i.e., surface potential change), which stems from the photo-generated open form of **1**, and (3) the content of open form of **1** is higher on the UV-irradiated surface than that on the nonirradiated surface (i.e., formation of asymmetric membrane).[7-11]

The effects of pH of the solution on the photoresponse were also checked in the range of pH 5.3—8.0.[9] In this pH range, the photoresponse of the PVC/**1** membrane slightly depended on the pH of the solution. The present paper reports the pH-dependent photoresponse of the PVC/**1** membrane over the wide pH range of 3—12 under the condition that the pH values of both aqueous solutions separated with the membrane are not equal with each other. To our knowledge, such systematic study of the pH effect on the photoresponse of the spiropyran-doped membrane has not appeared.



Experimental

Materials. PVC (molecular weight of ca. 70000) was purchased from Wako Co., Ltd. and used without further purification. Diisodecyl phthalate (DIDP) and tetrahydrofuran (THF) are of extra pure reagent grade. The synthetic procedure and analytical data of **1** were described previously.[9]

Membrane Preparation. PVC/**1** membrane of ca. 0.15 mm thickness was prepared by pouring the mixture of 250 mg of PVC, 0.5 ml of DIDP, 30 mg of **1**, and 20 ml of THF onto a flat Petri dish (8.5 cm diameter), and allowing the solution to evaporate at room temperature. The membrane was conditioned by soaking it in 5 mM ($M=mol\cdot dm^{-3}$) Britton-Robinson buffer for ca. 15 h before use.

Membrane Potential Measurement. All measurements were conducted at 25 °C using a U-shaped glass cell (Fig. 1). The composition of the electrochemical cell for the membrane potential measurements was as follows; Ag/AgCl|0.1 M $(CH_3)_4NCl$|electrolyte solution (c_1)|PVC/**1** membrane|electrolyte solution (c_2)|0.1 M $(CH_3)_4NCl$|Ag/AgCl. The electrode in the c_1 compartment was earthed. The pH value of the solutions were regulated with 5 mM Britton-Robinson buffer. Photoirradiation was carried out from the c_2 side with a 500 W xenon lamp using cut-off filters to isolate UV ($320\ nm<\lambda<400\ nm$) and visible ($490\ nm<\lambda$) light. Noise level in the potential was within 1 mV under the present experimental conditions.

Results and Discussion

Figure 2 shows the magnitude of photoinduced membrane potential, $\Delta(\Delta\phi)$, as a function of pH of the c_2 side solution. The pH value of the c_1 side solution was maintained constant at 3 or 12, and the membrane surface facing the c_2 solution was exposed to light. In the range of pH 3—7, the $\Delta(\Delta\phi)$ value scarcely depended on the pH of the c_2 solution, while, above pH 8, the $\Delta(\Delta\phi)$ value decreased almost linearly with increasing the pH. Such tendency was observed for both cases when the pH of the c_1 solution was maintained at 3 and 12.

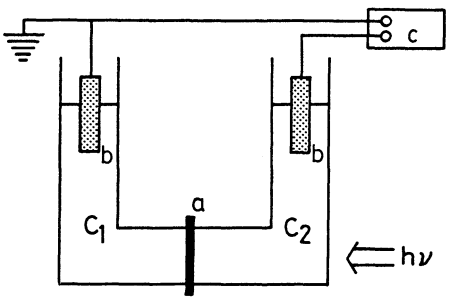


Fig. 1. Schematic representation of the cell for measuring membrane potential. a; Membrane, b; Ag/AgCl electrode, c; potentiometer.

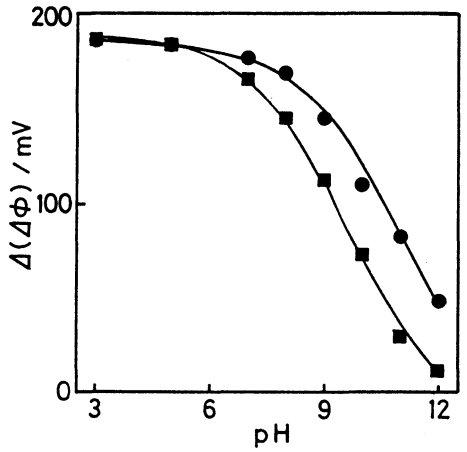

Fig. 2. Effects of pH of the c_2 solution on the photoresponse of the PVC/1 membrane. The pH value of the c_1 solution was constant at 3 (—■—) or 12 (—●—). The membrane surface facing the c_2 solution was exposed to light.

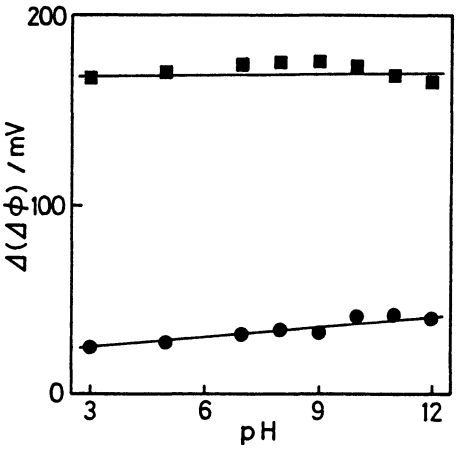

Fig. 3. Effects of pH of the c_1 solution on the photoresponse of the PVC/1 membrane. The pH value of the c_2 solution was constant at 3 (—■—) or 12 (—●—). The membrane surface facing the c_2 solution was exposed to light.

These results are compatible with our idea[7-11] that the photoinduced membrane potential stems from the change in charge density on the UV-irradiated surface of the membrane. In the case of the PVC/1 membrane, the charge density of the membrane surface is considered to depend on the amount of the protonated form of **1** which has an electrically positive net charge. It is envisaged that the pH of the c_2 side solution considerably affects the equilibrium of protonation to the open **1** on the irradiated surface.

Figure 3 shows the results obtained when the pH of the c_1 side solution was varied from 3 to 12 with keeping the pH of the opposite side solution constant at 3 or 12. The membrane surface facing c_2 solution was exposed to light. Contrary to the data shown in Fig. 2, the effects of pH of the c_1 solution was small. When the c_2 solution was maintained at pH 3, the photoinduced potential of 160—180 mV was observed irrespective of pH value of c_1 solution. This result consists with the fact that the photochemical reaction from the closed-**1** to the open form is severely depressed on the nonirradiated surface of the membrane (i.e., asymmetric membrane), as was previously shown spectrophotometrically.[11] On the other hand, the $\Delta(\Delta\phi)$ value decreased to 20—40 mV when the pH of the c_2 solution was 12. These observations also show that the photoresponse of the PVC/1 membrane depends on the change in charge density of the irradiated surface, not of the opposite surface, of the membrane. These findings should be important in relation to the mechanistic study on the pH-dependent photoresponse of the enzyme-modified PVC/1 membrane,[10] which can be used as a sensitive layer of a novel class of potentiometric enzyme sensors.[12]

Effect of the Aggregation Number on Gel Chromatographic Patterns of Micellar Systems

Noriaki FUNASAKI,* Sakae HADA, and Saburo NEYA
Kyoto Pharmaceutical University, Yamashina, Kyoto 607
(Received March 18, 1988)

Synopsis. Gel chromatographic patterns and their derivatives of micellar systems are predicted as a function of the total surfactant concentration and the aggregation number m by plate theory and asymptotic theory. These predicted patterns provide the basis for estimation of monomer concentration and m from experimental chromatographic data.

Gel chromatography has provided important information about aqueous surfactant solution; e.g., micellar size,[1,2] monomer concentration,[2-4] and mixed micelle formation.[5] This technique has been also used for investigations of self-association of proteins,[6,7] but a wealth of knowledge obtained from such studies has not well been utilized for surfactants.

For quantitative analysis of self-associating systems, a large amount of sample is usually charged into a gel column so that a plateau region may appear on the elution curve.[2-7] For a nonassociable solute, asymptotic theory presumes the elution curve of a rectangle possessing the same concentration and volume with those of the charged sample.[3,4,6] For a self-associable solute with the aggregation number m, this theory predicts the equation[4,6]

$$V_c = C_1V_1/C_0 + (C_0 - C_1)V_m/C_0 \quad (1)$$

Here V_c is the centroid of elution profile defined as

$$V_c = \int_0^{C_0} V dC/C_0 \quad (2)$$

C_0 and C_1 denote the total concentration and the monomer concentration, and V_1 and V_m denote the elution volumes of monomer and m-mer, respectively. For proteins, first derivative of the elution curve often provides more detailed information than the original curve,[6,7] but has not yet been reported for surfactants.

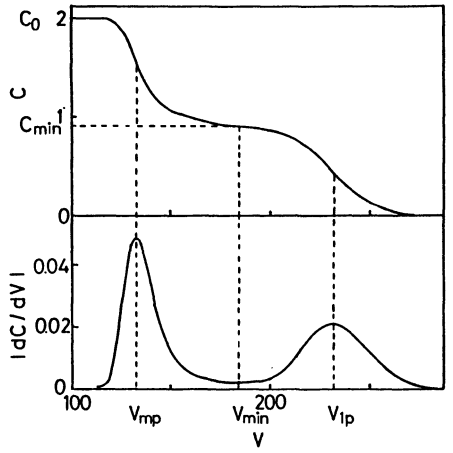

Fig. 1. Elution curve and its derivative simulated by using values of m=40 and C_0=2 and definitions of characteristic values.

Plate theory, based on phase separation model for micelle formation, was applied for simulation of gel chromatograms of surfactants.[5] This theory may predict a more realistic elution pattern than the above asymptotic theory, though no comparison has been reported for surfactants.

In this work, we develop plate theory based on mass action model for micellization of surfactants. This model is more rigorous than phase separation model and may also apply for proteins. Based on this theory, we investigate the effects of the total concentration and the aggregation number upon gel chromatographic patterns of self-associating systems. Derivative elution patterns are also simulated. These simulations make possible a better analysis of experimental results of gel chromatograms and reveal the scope and limitations of the asymptotic theory.

Methods

The procedure of computer simulation for plate theory developed by Nakagawa[5] was employed. It was assumed that the equilibrium of partition of solute between the mobile phase and the stationary phase is established instantaneously. At time zero, the column bed is saturated with surfactant solution of concentration C_0 and water as eluent begins to enter onto the gel bed. That is, the trailing boundary of frontal elution chromatography[6] is investigated.

For the monomer-m-mer equilibrium, the association constant K can be written as

$$K = (C_0 - C_1)/C_1^m \quad (3)$$

This reaction was assumed to be rapid. The value of C_1 was calculated by the Newton-Raphson method from Eq. 3.

To simulate a chromatogram, we must input the number N of plate, the void volume V_0, K, V_1, V_m, m, and C_0; N=100, K=1, V_1=230, V_m=130, and m=2, 3, 6, 10, 40, 80, 200, or ∞ were used together with a wide range of concentration C_0 Derivation of the elution curve was replaced by differentiation $\Delta C/\Delta V$.

Results and Discussion

Figure 1 shows a sample of simulation and definitions of C_{min}, V_{min}, V_{1p}, and V_{mp}. In general, derivative pattern has two peaks of V_{1p} and V_{mp} and a minimum of V_{min}. The C_{min} value is defined as the concentration at V_{min} on the elution curve. The V_c value can be calculated from the elution curve by using Eq. 2. For only cases of m=10, 40, and ∞, V_{1p}, V_c, and V_{mp} are shown as a function of C_0. Other cases are omitted, since we can infer such patterns from Fig. 2 roughly. For the case of m=2, derivative patterns had a single peak, regardless of C_0, whereas for cases of $m \geqq 3$, those patterns had two peaks. These results are consistent

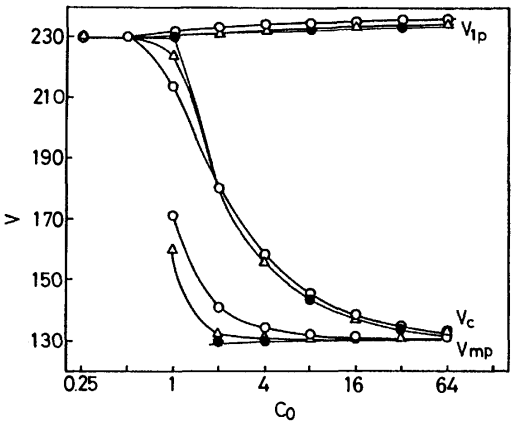

Fig. 2. Plots of V_{1p}, V_c, and V_{mp} against the logarithm of C_0 for cases of m=10 (○), m=40 (△), and m=∞ (●).

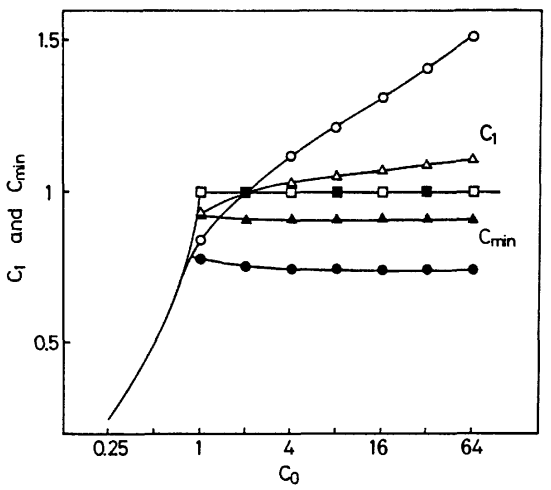

Fig. 3. Plots of C_1 (hollow symbols) and C_{min} (filled symbols) against the logarithm of C_0 for cases of m=10 (○,●), m=40 (△,▲), and m=∞ (□,■).

with predictions from asymptotic theory.[6] The V_c value simulated was in excellent agreement with that from Eq. 1: this equation, though obtained from asymptotic theory, holds rigorously for self-associating systems. As C_0 decreases, V_{1p} decreases and approaches V_1. This result indicates that V_1 should be evaluated at zero concentration. When m is small, V_{mp} decreases with increasing C_0 and approaches V_m. These results indicate that V_m should be evaluated at infinite concentration and that variation of V_{mp} with C_0 does not always reflect true size changes of the micelle. Concentration dependence of V_{mp} for hexamerization of α-chymotrypsin[7] is in qualitative agreement with the above prediction. Accurate estimation of micellar size of hexaethylene glycol dodecyl ether from V_{mp}[2] cannot be justified, though we do not deny micellar growth of this surfactant with C_0. According to asymptotic theory, V_{min} is expected to be $[(2m-1)V_1+(m-2)V_m]/(3m-3)$, regardless of C_0,[6] whereas the V_{min} value simulated increased with increasing C_0 (data are not shown). The latter prediction is in agreement with the experimental result.[8]

The C_1 value calculated from Eq. 3 is shown as a function of C_0 in Fig. 3. As is well known, the increase in C_1 decreased with increasing m above a concentration, called the critical micelle concentration. At $m \to \infty$, (phase separation model) C_1 was a constant of unity. As Fig. 3 shows, the C_{min} value simulated slightly decreased with increasing C_0 and increased with increasing m. According to asymptotic theory,

$$C_{min} = 2(m^2-1)[(m-2)/K]^{1/(m-1)}[m(2m-1)]^{m/(1-m)} \quad (4)$$

The C_{min} values calculated from Eq. 4 at m=10, 40, and ∞ were 0.733, 0.940, and 1, respectively. These values are close to the simulated values at large values of C_0 (see Fig. 3). Values of monomer concentration of hexaethylene glycol dodecyl ether were estimated from Eq. 1[4] and from C_{min}.[2] These values are different from each other, as expected.

The present results provide the basis for analysis of experimental chromatographic data. If V_1 and V_m can be estimated from the data, we can determine C_1 as a function of C_0. As we have shown herein, V_1 can be evaluated from V_{1p} or V_c at C_0=0 and V_m from V_{mp} or V_c at infinite concentration. Concentration dependence of C_1 changes with m, as shown in Fig. 3. This suggests the possibility for determination of m from the C_1 vs. C_0 relationship. In gel chromatography the elution volume of solute decreases with increasing size of the solute. For self-associating systems, however, the value of V_{mp} depends on C_0 as well as on size.[7] This must be taken into consideration, when we estimate micellar size from V_{mp}. Values of V_c and V_{mp} at infinite concentration correspond to correct micellar size. As m increases, the difference between C_{min} and C_1 decreases (Fig. 3). When $m>200$, C_{min} is practically equal to C_1 and then we can estimate C_1 from C_{min}, without use of Eq. 1. Asymptotic theory can predict a correct value of V_c and a rough value of C_{min}. Derivative elution patterns can provide useful information about micellar size and monomer concentration of surfactants. The above predictions based on plate theory are in agreement with experimental results, which will be published elsewhere.[8]

The CH-Surface Area of Sugar Molecules as a Measure of Their Potential Hydrophobicity

Yuki YANO,† Keiko TANAKA, Yukio DOI, and Masanobu JANADO*
Department of Food Science, Kyoto Women's University, Kyoto 605
(Received March 23, 1988)

Synopsis. Differential affinity of three groups of sugars (monosaccharides, glucodisaccharides and methyl glycosides) can reasonably be interpreted in terms of a molecular surface parameter, the ratio of the surface area of hydrophobic groups (CH, CH_2, and CH_3) to that of hydrophilic groups (OH and -O-) computed from the crystallographic data.

We reported several items of evidence indicating the potential hydrophobicity of sugars:[1-5] these include the configuration- and conformation-dependent affinity of sugars for polystyrene gel in aqueous solvents, which is also strongly affected by the type of salt (chaotropic or nonchaotropic) present, the cosolvent effect of sugars increasing the aqueous solubilities of hydrocarbons and 1-alkanols, and the strong affinity of *n*-aliphatic alcohols for dextran gel. In these studies, the hydrophobicity of sugars was measured in terms of their partition coefficients (K_{av}) between polystyrene gel (Bio-Beads SM-4, Bio-Rad Labs) and aqueous solvent. Inspection of the K_{av} spectrum of various sugars including monosaccharides, deoxy sugars, methyl glycosides and oligosaccharides led us to conclude that the hydrophobic behaviors of sugars are due to CH, CH_2, and CH_3 groups of the sugar molecules. Indeed, for monosaccharides, Miyajima et al.[6] showed that the polystyrene affinity ($\ln K_{av}$) is closely correlated with a CH-surface parameter, index A which is defined as the percent ratio of the total surface area of the hydrophobic groups (CH and CH_2) to that of the hydrophilic groups (OH and -O-). However, the CH index,[5] a CH-surface parameter defined on essentially the same basis as index A, totally fails to predict the order of the polystyrene affinity of glucodisaccharides and methyl glycosides where the effect of other molecular properties such as molecular planarity, rigidity and spatial segregation between OCH_3 and OH groups may become important.[5] Nevertheless, since the CH-surface effect seems to be the primary factor giving rise to the hydrophobic behaviors of sugars, it is of interest and profitable to examine the correlation between the polystyrene affinity and the CH index over a wide range of K_{av}.

The surface area is defined by the area of the surface traced out by the center of spherical water molecule of radius 1.4 Å sliding over the surface of sugar molecule.[7] The orthogonal atomic coordinates of sugar molecules were obtained from the Cambridge crystallographic data file (CAM), and the surface area was calculated using the computer program ASA written by H. Mizuno (Kyushu Univ.). The CH index was defined by

$$\text{CH Index} = \frac{\text{Total surface area of CH, } CH_2\text{, and } CH_3 \text{ groups}}{\text{Total surface area of OH, and -O- groups}}$$

which is formally identical to the Index A of Miyajima et al.[6] but differs in that, instead of assuming the free rotations of OH groups about the C-O linkages, the crystallographic atomic coordinates were used to calculate the surface area and that the parameters accounting for the 2α- and β- anomer equilibrium of glucodisaccharides were dropped out. Accordingly, the CH indexes of glucodisaccharides (Fig. 1) are those of β-anomers. The chromatographic partition coefficients (K_{av}) of sugars, obtained using a column of polystyrene beads (Bio-Beads SM-4) in 2 mol dm^{-3} NaCl,[2,5] can be correlated with the association constant (K) for sugar-polystyrene interaction by

$$K = \frac{1}{[B_o]}\left(\frac{K_{av} - K_{av}^{o}}{K_{av}^{o}}\right)$$

where $[B_o]$ is the total concentration of the independent and equivalent binding sites in the volume of the polystyrene gel phase accessible to sugar molecules,

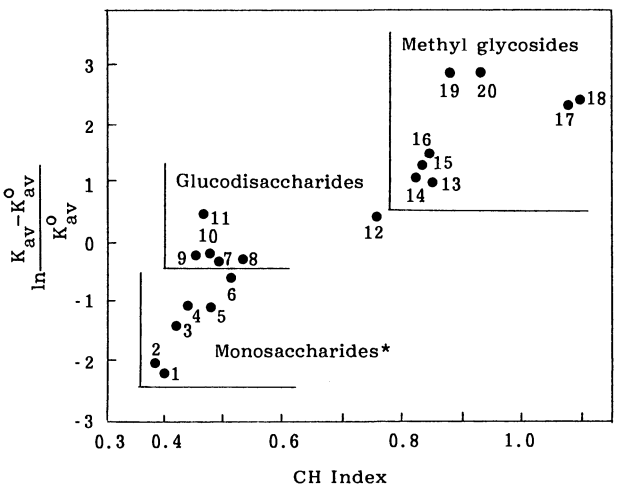

Fig. 1. Correlation between the polystyrene affinity and CH index. CH index=ratio of total surface area of CH, CH_2, and CH_3 groups to total surface area of OH and O groups. 1: galactose, 2: glucose, 3: mannose, 4: xylose, 5: arabinose, 6: ribose, 7: cellobiose, 8: maltose, 9: trehalose, 10: gentiobiose, 11: laminaribiose, 12: deoxyribose, 13: β-methyl D-galactoside, 14: α-methyl D-galactoside, 15: β-methyl D-glucoside, 16: α-methyl D-glucoside, 17: β-methyl D-xyloside, 18: β-methyl D-arabinoside, 19: α-methyl D-mannoside, 20: α-methyl D-xyloside. *: Data of CH-surface area from Miyajima et al. (Ref. 6).

† Present address: Department of Education, Kogakkan University, Ise-shi 516.

and K_{av}° is the partition coefficient in the absence of sugar-polystyrene interactions.[2] Accordingly, $\ln[(K_{av}-K_{av}^{\circ})/K_{av}^{\circ}]$ is a measure of the standard free energy of sugar-polystyrene interaction and hence it was taken as a measure of the polystyrene affinity of sugars in the present study.

Figure 1 shows the polystyrene affinity, $\ln[(K_{av}-K_{av}^{\circ})/K_{av}^{\circ}]$, of monosaccharides, glucodisaccharides and methyl glycosides plotted against the CH index. As previously noted,[5] the parallelism between the order of the polystyrene affinity and that of the CH index does not hold for glucodisaccharides and methyl glycosides. However, it is important to note that on the macroscale the CH index well correlates with the polystyrene affinity of sugars. Strictly, direct comparison of monosaccharides (methyl glycosides included) with disaccharides may not be valid as the multi-point interactions of sugar molecule with polystyrene will increase with increase of the molecular weight of sugars. (Note that the effect of the multi-point interactions, in which the hydrophobic surfaces on the glucose residues of the disaccharide molecules contribute cooperatively, but not additively, to the polystyrene affinity, is not taken into account in the formulation of K nor of the CH index.) Indeed, for monosaccharides and methyl glycosides an approximate linearity appears to exist between the two parameters. This strongly suggests that the hydrophobicity of sugars is primarily determined by the hydrophobic/hydrophilic surface balance. The failure of the CH index to predict the order of K_{av} of α and β-methyl D-mannosides ($\alpha(10.6) \gg \beta(4.3)$) indicates that the neglect of the anomeric equilibrium effect in the calculation of the CH index does not impose a serious limitaion on the validity of the CH index. Rather, more or less poor accuracy of the CH index compared with index A may be attributed to an increase in the conformational freedom of glucodisaccharides and methyl glycosides leading to an increased deviation from the crystalline state.

Preparation of Highly Pure Lithium and Sodium Fluorides Using Solvent Extraction

Kenji KOBAYASHI
NTT Opto-electronics Laboratories, Tokai-mura, Naka-gun, Ibaraki 319-11
(Received November 17, 1987)

Synopsis. LiF and NaF can be purified by solvent extraction. The impurity concentrations in the purified NaF are 2.5 ng g^{-1} for chromium, 60 ng g^{-1} for iron, 0.03 ng g^{-1} for cobalt, and 1.5 ng g^{-1} for copper. The concentrations in the purified LiF are 42 ng g^{-1} for nickel and 2.1 ng g^{-1} for copper.

For the fabrication of ultra-low-loss fluoride optical glass fibers (lower than 0.1 dB km^{-1}), it is necessary to decrease the amounts of impurities to a level of 1 ng g^{-1}. This is because the presence of more than 1 ng g^{-1} of a transition element in fluoride optical glass fibers causes transmission loss from the fibers.[1] LiF and NaF are used as raw materials in fiber production. Impurity concentrations of transition elements in LiF and NaF prepared by distillation and zone melting are at the 1 μg g^{-1} level.[2,3] Preparation of highly pure LiF and NaF in which transition elements are lower than 1 μg g^{-1} have not been reported yet.

In the determination of iron, copper, and nickel, chelate extractions of iron(III) with cupferron, copper(II) with dithizone, and nickel(II) with dimethylglyoxime have been used frequently.[4] The extraction technique can also be applied to the removal of iron(III), copper(II), and nickel(II) impurities from LiF and NaF, because lithium(I) and sodium(I) do not react with these reagents.

The determination of trace amounts of transition elements at 1 ng g^{-1} is difficult. Although ordinary analytical methods such as atomic absorption spectrometry and spark-source mass spectrometry, etc are sensitive to most elements, the application of these methods is limited when the concentrations of the transition elements are at a level of 1 ng g^{-1}. Neutron Activation Analysis(NAA) is a highly sensitive method for determining transition elements and the determination of chromium, cobalt, and copper of an order of ng g^{-1} in silica glass by NAA has been reported.[5] This paper describes the preparation of highly pure LiF and NaF by solvent extraction, and the NAA of transition elements in the purified LiF and NaF.

Experimental

Reagents and Apparatus. Reagent grade of LiCl and Na_2CO_3 were used as starting materials. Three chelate reagents (dithizone, cupferron, and dimethylglyoxime) were used without further purification. Highly pure 49% hydrofluoric, nitric, and hydrochloric acids, as well as ammonia, carbon tetrachloride, and chloroform were obtained commercially. Distilled water was produced by sub-boiling distillation. Radioactivity was measured by a Ge(Li) detector coupled with a 4096-channel pulse-height analyzer (4K-PHA), and a low-background gas-flow counter.

Tracer Experiment. $^{60}Co(T_{1/2}=5.27\ y)$, $^{65}Ni(T_{1/2}=2.52\ h)$, and $^{64}Cu(T_{1/2}=12.7\ h)$ tracers were prepared by irradiation of small amounts of cobalt nitrate, highly pure nickel and copper metals in the JRR-2 nuclear reactor and the product was dissolved in 1 mol dm^{-3} nitric acid. $^{59}Fe(T_{1/2}=44.6\ d)$ tracer($FeCl_3$ in 0.5 mol dm^{-3} hydrochloric acid solution; radiochemical purity=99%) was imported from USA and was diluted before use. Ten μg of each tracer was added to the solution containing 10 g of LiCl or Na_2CO_3. Then, ^{59}Fe(III), ^{60}Co(II) and ^{64}Cu(II), and ^{65}Ni(II) were extracted with cupferron into chloroform, dithizone into carbon tetrachloride, and dimethylglyoxime into chloroform, respectively. The radioactivity of the organic extract was measured and recovery for each element was calculated. Each recovery for extraction of iron(III) with cupferron at pH=0.4—6.1, cobalt(II) with dithizone at pH=4.0—6.5, nickel(II) with dimethylglyoxime at pH=9.0—10.0, and copper(II) with dithizone at pH=0.3—6.5 was more than 99%. Thus, iron(III), cobalt(II), and copper(II) can be extracted with the above chelate reagents at pH=4.0 and nickel(II) is extracted with dimethylglyoxime into chloroform at pH=9.0.

Preparation of LiF and NaF. LiCl (100 g) or Na_2CO_3 (100 g) was dissolved in 100 ml of distilled water. The LiCl solution was adjusted to pH=4.0, and extractions were carried out with cupferron into chloroform and dithizone into carbon tetrachloride. The residual aqueous solution was adjusted to pH=9.0, and the nickel impurity was extracted with dimethylglyoxime into chloroform. The impurities in the Na_2CO_3 solution were also extracted with the same reagents and at pH value as described above. A solution of 150 ml of 49% highly pure hydrofluoric acid was added to the residual aqueous solution and alkali metal fluoride was precipitated. The precipitate was aged for 1 d, washed with distilled water, dried in a vacuum oven at 100 °C for 2 d, and dehydrated at 400 °C for 5 h in argon atmosphere. The prepared LiF and NaF were identified by X-ray powder diffraction analysis.

Neutron Activation Analysis. LiF, LiCl, NaF, and Na_2CO_3 samples (0.2—2.0 g) and chromiun, iron, cobalt, nickel, and copper standards (1.0 μg—4.0 mg) were irradiated in the JRR-2 or JRR-4 nuclear reactor at a thermal neutron flux of $3—8\times10^{13}$ n cm^{-2} s^{-1}. In order to determine nickel and copper, the irradiation was carried out for 5—20 min, while for chromium, iron, and cobalt the irradiation time was 265 h. After irradiation for 265 h, the irradiated NaF was cooled 30 d until undesired radioactivities of $^{24}Na(T_{1/2}=15\ h)$ had almost decayed. The radioactivities of NaF and chromium, iron, and cobalt standards were measured by a Ge(Li) detector coupled with a 4K-PHA for $1\times10^4—3\times10^5$ s. The concentrations of chromium, iron, and cobalt were determined by the photopeaks from ^{51}Cr(320 keV), ^{59}Fe(1099 keV), and ^{60}Co(1332 keV). Trace amounts of nickel and copper were determined by the comparison method of substoichiometric radioactivation analysis. Carriers of nickel (0.5 mg) and copper (0.2 mg) were added to the irradiated samples, and the samples were dissolved in 0.1 mol dm^{-3} nitric acid. Substoichiometric extractions of copper with dithizone into carbon tetrachloride at pH 1.0 and nickel with sodium diethyldithiocarbamate into carbon tetrachloride at pH 9.0 were carried out.[6,7] The irradiated

a) Mean value ± standard deviation for five determinations.

nickel and copper standards were treated with exactly the same substoichiometric extraction as was described for the sample. The radioactivities of the extracts for the samples and standards were measured by a low-background gas-flow counter for 20 min.

Results and Discussion

The analytical results for chromium, iron, cobalt, nickel, and copper in LiF, LiCl, NaF, and Na_2CO_3 are shown in Table 1.

Results for the elements are mean values for five determinations. LiF-1 and NaF-1 were prepared samples. LiF-2-1, LiF-2-2, and NaF-2 were analytical grade commercial samples. The impurity concentrations in LiF-1 and NaF-1 were lower than those in LiCl and Na_2CO_3, which were the starting materials for the preparation of LiF-1 and NaF-1, and purified LiF and NaF could be prepared by the solvent extraction method. The concentration in LiF-1 was 42 ng g^{-1} for nickel, and 2.1 ng g^{-1} for copper. These values were lower than those in LiF-2-1 and LiF-2-2 by a factor of 2.2×10^{-1} to 3.8×10^{-3}. The impurity concentrations in NaF-1 were 2.5 ng g^{-1} for chromium, 60 ng g^{-1} for iron, 0.03 ng g^{-1} for cobalt, and 1.5 ng g^{-1} for copper and these values were lower than those in NaF-2 by a factor of 3.0×10^{-3} to 8.6×10^{-1}. The 40 ng g^{-1} detection limit for nickel was due to the interference by the radioactivity of ^{24}Na.

It was found that solvent extraction is a useful method for the preparation of highly pure LiF and NaF.

Solvatochromism of the Co(III) Complexes with Macrocyclic N_3O_3-Type Ligands

Mika FUJIWARA, Michiko YOSHITAKE,† Yutaka FUKUDA, and Kozo SONE*
Department of Chemistry, Faculty of Science, Ochanomizu University, Ohtsuka, Bunkyo-ku, Tokyo 112
(Received December 24,1987)

Synopsis. The color and visible spectrum of [Co(tacnta)] and [Co(tacntp)]·$3H_2O$ depend remarkably on the acceptor number of the solvent, as also do those of K[Co(edta)]·$2H_2O$ and related chelates. The changes are especially large in the case of [Co(tacntp)]·$3H_2O$, extending to solvents of high acidity. A plausible explanation is given for this solvatochromism.

Two types of solvatochromism are known to take place in solutions of metallic complexes.[1,2] They are: (i) the solvatochromism caused by structural changes in the first coordination sphere, for example, that of [Cu(acac)(tmen)]ClO_4 studied by Fukuda, Sone, and collaborators[1] which depends on the donor number (DN) of the solvent,[3] and (ii) the solvatochromism caused by the solute-solvent interactions in the second coordination sphere, for example, that of [Fe(bipy)$_2$-(CN)$_2$] studied by Schilt[4] which depends on the acceptor number (AN) of the solvent.[3]

Recently, we synthesized the Co(III) complexes of two macrocyclic N_3O_3-type ligands, 1,4,7-triazacyclononane-*N*,*N*′,*N*″-triacetate (tacnta) and 1,4,7-triazacyclononane-*N*,*N*′,*N*″-tripropionate (tacntp) (cf. Fig. 1). In the course of this work, we noticed that they show a characteristic solvatochromism in polar solvents, which seems to be related to that of K[Co(edta)]·$2H_2O$ and related complexes reported by Taura,[5] Ogino, and collaborators.[6] Since these are all inert 6-coordinated complexes, it seems that the observed solvatochromism is due to the solvent-solute interaction in the second coordination sphere. The outline of our spectral observations, and their plausible explanation, are given in this paper.

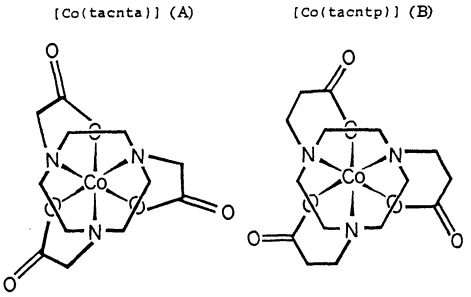

Fig. 1. Structures of the ligands and complexes.

Experimental

Preparation of Ligands. Tacnta was prepared according to the method described in the literature.[7] Tacntp was prepared similarly, but using 3-chloropropionic acid instead of chloroacetic acid. Because they were difficult to purify, the raw products obtained were directly converted to the Co(III) complexes.

Preparation of Complexes. [Co(tacnta)] was prepared according to the method described in the literature[7] (Found: C, 39.31; H, 5.12; N, 11.73%). To prepare [Co(tacntp)]·$3H_2O$, $CoCl_2 \cdot 6H_2O$ was added to the aqueous solution of tacntp. After adjusting the pH to ca. 5.5 with NaOH(aq), the mixture was stirred vigorously for several hours, and then evaporated to a small volume, and purified by passing into a column of Sephadex G-15. The eluent was evaporated to a small volume, and methanol was added to it to yield the complex as a violet powder. After washing twice with methanol, the residue was recrystallized from formamide-ethanol. Found: C, 38.78; H, 6.76; N, 9.14%. Calcd for $CoC_{15}H_{30}N_3O_9$: C, 39.57; H, 6.64; N, 9.23%.

Solvents. Methanol was purified by distillation over magnesium. Other solvents (Guaranteed Grade) were used without further purification.

Measurements. The electronic absorption spectra of the complexes were measured on a Hitachi 340 Recording Spectrophotometer using a 10-mm cell at room temperature (ca. 25 °C).

Results and Discussion

Some of the visible absorption spectra of [Co(tacnta)] (A) and [Co(tacntp)]·$3H_2O$ (B) obtained are shown in Fig. 2. Each of them shows two bands: the band I at ca. (19—20)×10^3 cm^{-1} and the band II at ca. (26—27)×10^3 cm^{-1}, as expected from their *fac*-N_3O_3-type structure.[8] Both bands shift slightly according to the solvent polarity, so that a remarkable color change from bluish violet to reddish violet comes about.

If the $\tilde{\nu}_{max}$ value of the band I is plotted against the Acceptor Number (AN) of the solvent, it can be seen that there is a good parallelism between these values,

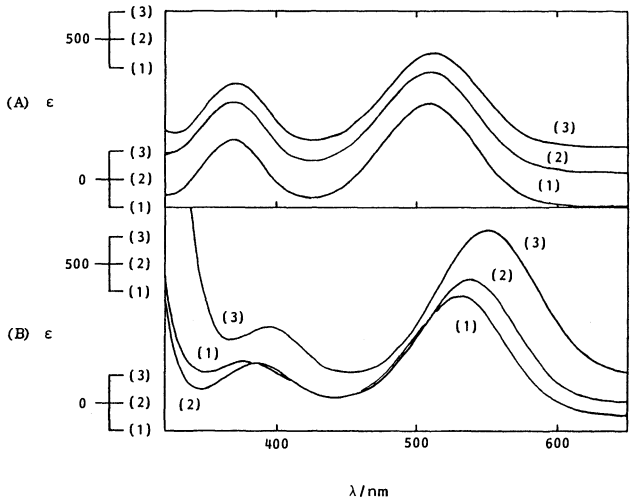

Fig. 2. Electronic spectra of the complexes. A: [Co(tacnta)]. Solvents: 1, HCOOH; 2, H_2O; 3, $HCONH_2$. B: [Co(tacntp)]·$3H_2O$. Solvents: 1, HCOOH; 2, H_2O; 3, $(CH_3)_2SO$.

† Present address: National Research Institute for Metals, 2-3-12 Nakameguro, Meguro-ku, Tokyo 153.

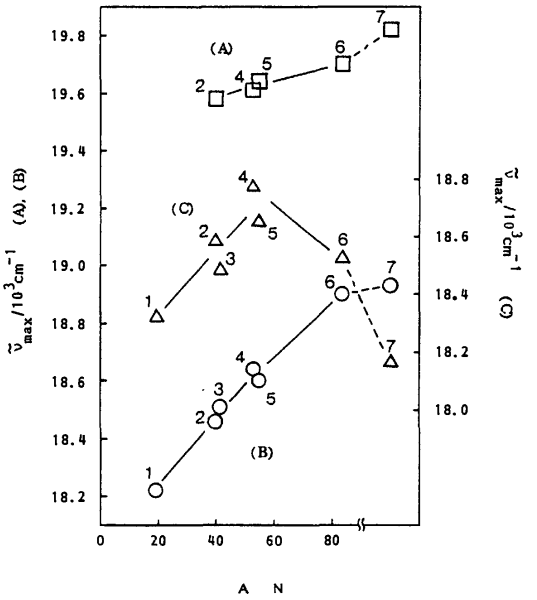

Fig. 3. Relation of $\tilde{\nu}_{max}$ with AN. A: [Co(tacnta)], B: [Co(tacntp)]·$3H_2O$, C: K[Co(edta)]·$2H_2O$.[a] Solvents: 1, $(CH_3)_2SO$; 2, $HCONH_2$; 3, CH_3OH; 4, CH_3COOH; 5, H_2O; 6, HCOOH; 7, H_3PO_4 (85%).[b] a) The AN of H_3PO_4 (85%) is expected to be higher than HCOOH, but is not exactly known. So the points 7 are given on a blank scale. b) The points 1, 2, and 3 on curve C were found to be slightly lower than those in the literature,[6] but the differences ($\Delta\tilde{\nu}$: $(0.03—0.06)\times10^3 cm^{-1}$) were mostly in the range of experimental error. The points 4, 6, and 7 on the same curve were newly obtained in the present study.

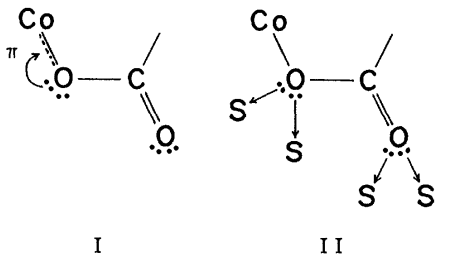

I II

Fig. 4. Effect of solvation by acceptor solvent molecules (S in II) on the structure of a coordinated COO^- group(I).

as that observed with K[Co(edta)]·$2H_2O$ and related complexes.[5,6] Figure 3 shows such a plot. It can be seen that the rise in $\tilde{\nu}_{max}$ with increasing AN is small with [Co(tacnta)], but with [Co(tacntp)]·$3H_2O$ it is much larger than with K[Co(edta)]·$2H_2O$, the curve of which tends to drop when the AN becomes very large.[9,10]

One can now explain the solvatochromism as follows. The COO^- groups of these complexes, which are most susceptible to outer influences, are solvated by the polar solvents which accept their lone-pair electrons. The strength of this solvation is governed by the AN of the solvent. This solvation weakens the (Co←O)σ and π bonds as shown in Fig. 4, by pulling out the lone-pair electrons on the O atoms toward the solvent molecules. The weakening of the σ bonds decreases the value of 10 Dq, but the weakening of the π bonds increases it.[11] Since the weaker π bonds will be more strongly affected by this kind of solvation, the value of the apparent 10 Dq tends to increase, shifting $\tilde{\nu}_{max}$ to a higher value.

It is also plausible that the large solvatochromism of [Co(tacntp)]·$3H_2O$ is related to the relative weakness of the COO^-–Co bonds in it which belong to the more deformable 6-membered chelate rings, as compared with those in the other complexes which belong to the rigid 5-membered chelate rings.

The authors are cordially grateful to Prof. Susumu Takamoto of Gakushuin University for his kind aid in the preparation of the macrocyclic ligands.

8) N. Matsuoka, J. Hidaka, and Y. Shimura, *Bull. Chem. Soc. Jpn.*, **40**, 1868 (1967).
9) This drop which was found in the present study is probably caused by the notable weakening of the (Co←O)σ bonds in very strong acceptor solvents, which eventually will lead to a decrease in 10 Dq; the fact that the tacnta and tacntp complexes do not show such a drop may be taken as proof of their robustness in such acceptor solvents.
10) A set of curves which are similar in shape, and in the magnitude of the shifts in $\tilde{\nu}_{max}$, to those in Fig. 3 can also be observed with the $\tilde{\nu}_{max}$ values of the band II. Here, however, the accuracy of the curves A and B is lower, since band II is weaker than band I and is more difficult to locate exactly in some cases.

Pheophytinization of Chlorophyll *a* and Chlorophyll *a'* in Aqueous Acetone

Hitoshi MAZAKI and Tadashi WATANABE*
Institute of Industrial Science, University of Tokyo, Roppongi, Minato-ku, Tokyo 106
(Received November 20, 1987)

Synopsis. Chlorophyll (Chl) *a* and its C-10 epimer, Chl *a'*, are compared for pheophytinization (demetallation) kinetics in aqueous acetone containing HCl. For each pigment the pheophytinization rate is of second order with respect to proton, and under identical conditions Chl *a'* is pheophytinized by roughly 50% faster than Chl *a*, due probably to weaker Mg-N bonds in Chl *a'*.

Our recent pigment composition analyses on higher plant chloroplasts, photosystem (PS) I and II particles, and several cyanobacteria showed for the first time that one molecule of Chl *a'*, or the C-10 epimer[1] of Chl *a*, is closely associated with the PS I reaction center (P700).[2,3] This has prompted us to carry out detailed physicochemical characterization of Chl *a'* against Chl *a*. In this Note we compare Chls *a* and *a'* for the kinetics of pheophytinization (replacement of the central Mg^{2+} ion with two protons), which would reflect the Mg-N bond strength in the chlorin macrocycle.

A few works have been reported on the pheophytinization of Chl derivatives. Following earlier observations by Mackinney and Joslyn,[4] Schanderl et al. compared Chl *a* and *b* pheophytinization rate constants in aqueous acetone at a single HCl concentration of 10^{-4} M (M=mol dm^{-3}).[5] A work of Berezin et al.[6] suggested indirectly that the Chl *a* pheophytinization rate is of second order with respect to proton in *t*-butyl alcohol containing trichloroacetic acid. The pheophytinization kinetics of Chl *a* in monomolecular films[7] and in heated green leaves[8] have been investigated. However, quantitative comparison between Chls *a* and *a'* with regard to pheophytinization kinetics has not been reported in the literature.

Experimental

Chls *a* and *a'*, with epimeric purity higher than 98%, were prepared by means of preparative scale high-performance liquid chromatography (HPLC) as described elsewhere.[9] Chl *a* or Chl *a'* was dissolved in an acetone/water (3/1, v/v) mixed solvent, and the solution was introduced in a temperature-controlled glass cell placed in a JASCO UVIDEC-650 spectrophotometer. The absorbance change due to the progress of pheophytinization was measured as a function of time at 430 nm [absorption peak for Chl *a*(*a'*)] or 409 nm [absorption peak for pheophytin (Pheo) *a*(*a'*)]. The concentration[10] of Chl *a*(*a'*) in aqueous acetone was 1.0×10^{-6} M, and that of HCl was varied in a range from 3×10^{-4} to 2×10^{-3} M. Thus the pheophytinization reaction

$$\text{Chl } a(a') + n\text{H}^+ \xrightarrow{k(k')} \text{Pheo } a(a') + \text{Mg}^{2+} \qquad (1)$$

can be regarded as pseudo-first-order with respect to Chl *a*(*a'*) concentration, with k and k' being the apparent rate constants for Chls *a* and *a'*, respectively. The k and k' values were obtained by fitting the time courses of Chl *a*(*a'*) concentration to the following kinetic formula:

$$\ln([\text{Chl}]_t/[\text{Chl}]_0) = -k(k')t \qquad (2)$$

where $[\text{Chl}]_0$ and $[\text{Chl}]_t$ are the concentrations of Chl *a*(*a'*) at the onset of measurement and at time t, respectively.

Results and Discussion

Figure 1 illustrates the temporal evolution of the relative concentration of Chl *a*(*a'*), observed at 430 nm, for different H^+ concentrations at 25 °C. The apparent rate constants are calculated from the slopes of the lines and Eq. 2. Under identical conditions, the k and k' values thus obtained were practically the same as those obtained by observing absorbance increase at 409 nm.

The rate constants from Fig. 1 are plotted in Fig. 2 against $-\log[H^+]$. The slope of −2.0 common for both Chl *a* and Chl *a'* indicates that the rate is indeed of second order with respect to proton (n=2 in Eq. 1). The pheophytinization rate of Chl *a'* is 1.4-fold higher than that of Chl *a* at a given $-\log[H^+]$ value; this is in contrast to a qualitative observation by Hynninen[11] that Chl *a'* was pheophytinized much more rapidly than Chl *a*. The higher tendency of Chl *a'* to be pheophytinized is due probably to its weaker Mg-N coordination bonds in the chlorin ring. A recent ^{13}C NMR

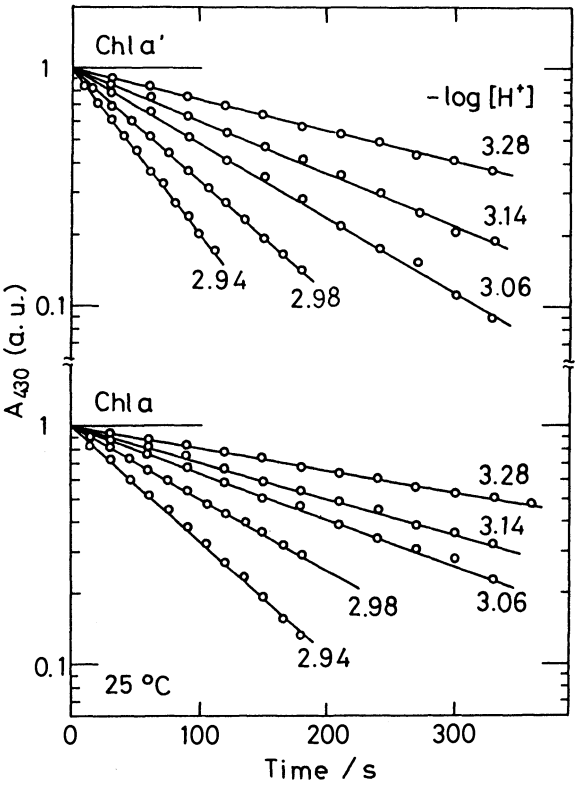

Fig. 1. Kinetic plots for the pheophytinization of Chls *a* and *a'* in aqueous acetone at different H^+ concentrations.

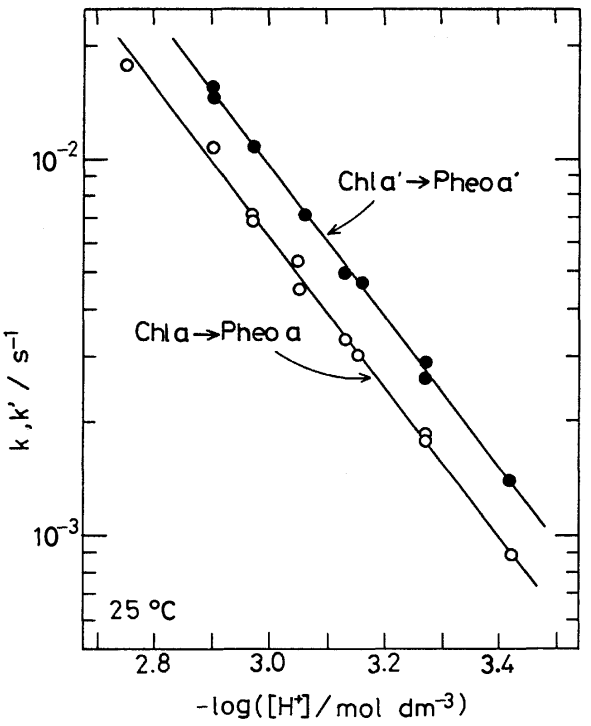

Fig. 2. Dependence of the pheophytinization rate constant k for Chl a (○) and k' for Chl a' (●) on H^+ concentration.

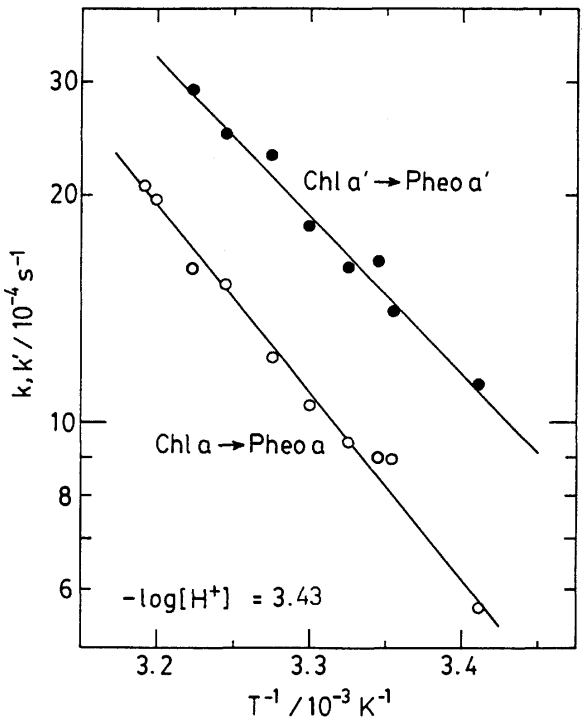

Fig. 3. Arrhenius plots over a temperature range 10—40 °C for the pheophytinization rate constants for Chl a (○) and Chl a' (●).

study on Chl derivatives[12] indicates that an enhanced steric hindrance between the bulky substituents (the C-7 phytyl chain and C-10 methoxycarbonyl group) in the Chl a' molecule induces a peripheral strain, especially in rings IV and V,[1] which in turn influences the conformation and stability of the whole macrocycle.

In aqueous acetone at 25 °C, though with a slightly different acetone/water volume ratio (4/1), Schanderl et al.[5] obtained a k value of 1.72×10^{-4} s^{-1} at $-\log[H^+]=4.0$. Extrapolation of our k vs. $-\log[H^+]$ plot in Fig. 2 to $-\log[H^+]=4.0$ yields $k=6.97\times10^{-5}$ s^{-1}. The 2.5-fold difference seen between these two values might reflect a difference in the solvent composition.[13]

The temperature dependence of the pheophytinization rates was examined in a range from 10 °C to 40 °C at a $-\log[H^+]$ value of 3.43. The Arrhenius plots in Fig. 3 gives the activation energies of 47.4 and 40.4 kJ mol^{-1} for Chls a and a', respectively. The former value compares well with a literature value[5] of 43.5 kJ mol^{-1}.

Based on the results presented above, the pseudo-first-order rate constants $k(k')$ for the Chl $a(a')$ pheophytinization in aqueous acetone are expressed as follows:

$$k\ /s^{-1} = 1.30\times10^{12}\,[H^+]^2\exp(-47400[J]/RT)$$
$$k'/s^{-1} = 1.20\times10^{11}\,[H^+]^2\exp(-40400[J]/RT)$$

The authors are grateful to Mr. M. Nakazato, Nampo Pharmaceutical Co., Ltd., for his help in preparing Chl a and a' samples. This work has been supported partially by a Grant-in-Aid from the Ministry of Education, Science and Culture (No. 62602508).

Sesquiterpene Lactones from Flowers of *Picris hieracioides* L

Takeshi KANAYAMA and Masahiro TADA*
Laboratory of Bio-organic Chemistry, Tokyo University of Agriculture and Technology, Fuchu, Tokyo 183
(Received February 17, 1988)

Synopsis. The isolation and structural elucidation of four guaianolides from the antimicrobial fractions of the flowers of *Picris hieracioides* L. (Compositae) are reported. Two of them are new compounds.

The flowers of *Picris hieracioides* L. var. *japonica* Regel (Compositae) are bitter and these cause a contact allergy for human skin. Schönbeck reported that the antibiotic activity of flowers of many higher plants is stronger than that of the other parts, leaves, roots and branches.[1] In the course of our investigation of antimicrobial compounds from flowers of higher plants,[2] we found that the extract of the flowers of *P. hieracioides* L. var. *japonica* Regel showed antimicrobial activity by the paper-disk method against *Bacillus subtilis*. Meanwhile, Nishimura et al. reported the isolation of some sesquiterpene lactone glycosides from whole plants of *P. hieracioides* L. var. *japonica* Regel.[3] We report here the isolation of two new sesquiterpene lactones, hieracin I and II with the known guaianolides, jacquilenin[4] and 8-deoxylactucin[5] from the antimicrobial fractions of methanol extract of the flowers of *P. hieracioides* L. var. *japonica* Regel.

The methanol extract of flowers (3.0 kg) of *P. hieracioides* L. var. *japonica* Regel. was concentrated in vacuo and the residue was partitioned with ethyl acetate and water. The antimicrobial activity [paper disk method against *B. subtilis* (IFO 3734)] was found in the ethyl acetate fraction. The residue of the ethyl acetate phase was chromatographed on silica gel with hexane-ethyl acetate. The active fractions were purified by HPLC to give an antimicrobial compound (**A**, 30 mg) and other compounds (**B**, 150 mg; **C**, 5.2 mg; and **D**, 0.5 mg).

8-Deoxylactucin (1). The spectroscopic properties (High resolution MS IR, ^{1}H NMR, and ^{13}C NMR) suggested that the compound **A** is a sesquiterpene lactone. The presumed structure from the ^{1}H-^{1}H COSY[6] and the J-resolved 2D[7] agreed with 8-deoxylactucin (**1**). The reported ^{1}H NMR data[5,8] of 8-deoxylactucin **1** corresponded with our data of the compound **A**.

Jacquilenin (2). The spectral data showed that compound **B** is very similar to 8-deoxylactucin (**1**) although one of the double bonds is saturated. Finally the structure of **B** was identified to be jacquilenin (**2**) by comparing the ^{1}H NMR (^{1}H-^{1}H COSY and NOESY[9]) and the ^{13}C NMR data with those of jacquilenin (**2**).[5,10]

Two new guaianolides, which were named hieracin I (**3**) and hieracin II (**4**), were isolated from a more polar fraction than 8-deoxylactucin (**1**).

Hieracin I (3). Compound **C** has a molecular formula $C_{15}H_{20}O_5$ (MS: *m/z* 280.1339, Calcd M, 280.1331). The IR [3450 (br), 1765, 1690, 1620 cm^{-1}] and ^{1}H NMR spectra suggested **C** should be a guaianolide similar to **1** and **2**. The MS (M^+-H_2O at *m/z* 262.1149, Calcd 262.1204), IR, ^{1}H NMR, and ^{13}C NMR spectra [δ 59.08 (d) and 71.90 (s)] proved that **C** has a tertiary hydroxyl group instead of a double bond (C1—C10) of jacquilenin **2**. The partial structure (**P**) was clearly revealed by the ^{1}H-^{1}H COSY spectrum of **C**. These observations led to the structure **3** for compound **C** which was named hieracin I. The chemical shift of H-13 (δ 1.24, d, J=7.0 Hz) and the coupling constant ($J_{7\alpha\text{-}11\beta}$=12.5

a) The coupling constants were estimated from the *J*-resolved 2D spectrum.

Hz) indicated that the methyl group at C-11 is α-oriented.[10] The stereochemistry at C-1, C-5, C-6, C-7 and C-10 was clarified by comparing the coupling constants ($J_{5\alpha\text{-}6\beta}$=9.6 and $J_{6\beta\text{-}7\alpha}$=9.6 Hz) with those of jacquilenin (**2**) ($J_{5\alpha\text{-}6\beta}$=10 Hz and $J_{6\beta\text{-}7\alpha}$=10 Hz) and the NOESY spectrum of hieracin I (**3**). The NOE were observed between H-14 and H-1α and between H-1α and H-5α. Whereas no NOE were observed between H-5α and H-6β, between H-6β and H-7α, and between H-7α and H-11β (Fig. 1).

Hieracin II (4). The spectral deta: MS (Found: *m/z* 278.1144; 260.1082, Calcd for $C_{15}H_{18}O_5$: M, 278.1152; M−H_2O, 260.1047), IR, and ^{1}H NMR [δ 6.23 (1H, d, *J*=3.7 Hz) and 5.55 1H, d, *J*=3.7 Hz)] suggested that compound **D** has an *exo*-methylene group (C11-C13) instead of a methyl group at C-11 of hieracin I (**3**). The novel compound **D** was named hieracin II (**4**).

8-Doxylactucin (**1**) showed moderate activity against *Bacillus subtilis* whereas jacquilenin (**2**) showed no activity against *B. subtilis*. Clearly the antimicrobial activity of **1** should depends on the α-methylene γ-lactone moiety.

Experimental

NMR spectra were measured with a JEOL GX-270 spectrometer in $CDCl_3$ solution containing tetramethylsilane as internal standard. IR spectra were measured on Jasco IR-810 spectrometer. Mass spectra were recorded by JEOL JMS-D300. HPLC was performed by JASCO BIP-1 HPLC system with UV detector on a silica-gel column (Lichrosorb Si-60 10 μm, 7.5×500 mm), an Asahipak-310 column, or an ODS column (INERTSIL 10 μm, 7.5×300 mm). Thin-layer chromatography was carried out on Kieselgel GF_{254} (Merck) in 0.25 mm thickness. Wakogel C-200 (Wako Pure Chemical Industries) was used for column chromatography.

Isolation of Sesquiterpene Lactones. The flowers (3.0 kg) of *Picris hieracioides* were collected in Yamanashi prefecture, Japan in September 1985 and extracted with methanol. The extract was concentrated in vacuo and the residue was partitioned with ethyl acetate and water. The antimicrobial activity was tested by paper-disk method against *Bacillus subtilis* (IFO 3734) for each fraction. The activity was found in the ethyl acetate phase. The residue of the ethyl acetate phase was chromatographed on silica gel with hexane–ethyl acetate. The repeated purification by HPLC on a silica-gel column (Lichrosorb Si-60, 10 μm, 7.53×500 mm) eluted with hexane–ethyl acetate (3:5) and ethyl acetate, and on an ASAHIPAK-310 column eluted with 40%-methanol and on an ODS column (INERTSIL 10 μm, 7.53×300 mm) eluted with 35%-methanol to give 8-deoxylactucin (**1**, 30 mg), jacquilenin (**2**, 150 mg), hieracin I (**3**, 5.2 mg), and hieracin II (**4**, 0.5 mg).

8-Deoxylactucin (1). MS: Found: *m/z* 260.1033, Calcd for $C_{15}H_{16}O_4$: M, 260.1048; IR (film) 3420, 1770, 1690, 1620, 1250, 1130, and 990 cm^{-1}.

Jacquilenin (2). Mp 147—152 °C; MS: Found: *m/z* 262.1194, Calcd for $C_{15}H_{18}O_4$: M, 262.1204; IR (KBr) 3350, 1750, 1660, 1260, and 995 cm^{-1}.

Hieracin I (3). MS: Found: *m/z* 280.1339; 262.1149, Calcd for $C_{15}H_{20}O_5$: M, 280.1311; M^+-H_2O, 262.1204; IR (neat) 3450, 1765, 1690, 1620, and 985 cm^{-1}.

Hieracin II (4). MS: Found: *m/z* 278.1144; 260.1082, Calcd for $C_{15}H_{18}O_5$: M, 278.1152; M^+-H_2O, 260.1047; IR 3400, 1760, 1680, 1620, and 985 cm^{-1}.

We are grateful Dr. H. Hirota (Department of Chemistry, The University of Tokyo) for the measurement of the high resolution mass spectra.

Synthesis of Bis[1,2-bis(methylseleno)vinylenedithio]-tetrathiafulvalene (TMSVT)

Hideyuki NAKANO, Takashi NOGAMI,* and Yasuhiko SHIROTA
Deparment of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadaoka, Suita, Osaka 565
(Received March 12, 1988)

Synopsis. The title molecule was synthesized as an effective donor molecule for highly conductive organic complexes. It is a TTF dirivative possessing four selenium atoms and eight sulfur atoms. Its oxidation potential ($E_{1/2}$) is 0.86 V vs. SCE in THF,which is slightly higher than that of VT and TMTVT.

TTF derivatives possessing multi-chalcogen atoms have recently been found to give materials of interesting solid-state electrical properties. For example, the ion radical salt (BEDT-TTF)$_2$Cu(SCN)$_2$ gave organic superconductors of high T_c (10.4 K)[1] without applying pressure. The superconductivity of various BEDT-TTF salts is a subject of extensive study.[2] Other aspects of the multi-chalcogen TTF derivatives are a molecular fastener effect[3] of a series of TTC$_n$-TTF and high mobility of TTeC$_1$-TTF.[4] One of the important factors governing the electrical properties of these materials is the existence of a chalcogen-chalcogen network in the solid. The syntheses of various TTF derivatives were reviewed by Krief.[5] We have synthesized bis[1,2-bis(methylthio)vinylenedithio]-tetrathiafulvalene (TMTVT)[6] which has twelve sulfur atoms. This molecule has the largest number of chalcogen atoms in TTF derivatives known at present. This paper reports the synthesis of bis[1,2-bis(methylseleno)vinylenedithio]tetrathiafulvalene (TMSVT) which also has twelve chalcogen atoms in the molecule.

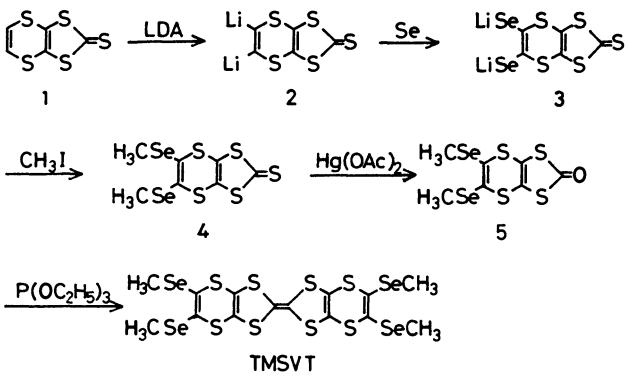
TMTVT

Results and Discussion

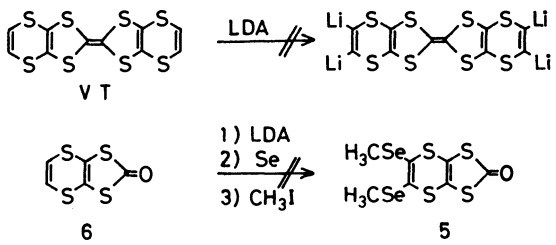
Synthesis of TMSVT. The synthetic route of TMSVT is shown in Scheme 1. 4,5-(Vinylenedithio)-1,3-dithiole-2-thione (**1**) was synthesized from 4,5-(ethoxyethylenedithio)-1,3-dithiole-2-thione as reported previously[7,8] with slight modifications.[9] It was lithiated by lithium diisopropylamide (LDA), followed by the selenium insertion reaction under supersonic wave irradiation for 2.5 h. Without supersonic wave irradiation, it took 4—5 h for the completion of the insertion reaction. The selenolate **3** was then reacted with methyl iodide to give 4,5-[1,2-bis(methylseleno)vinylenedithio]-1,3-dithiole-2-thione (**4**). The conversion of



Scheme 1.

the thiocarbonyl group of **4** to a carbonyl group was made by mercury(II) acetate[10] to give 4,5-[1,2-bis-(methylseleno)vinylenedithio]-1,3-dithiol-2-one (**5**). The coupling reaction of **5** was made by heating it in neat triethyl phosphite to give TMSVT.

Two other synthetic routes of TMSVT are conceivable. One is a reaction starting with the lithiation of bis(vinylenedithio)tetrathiafulvalene (VT). However, the poor solubility of VT in THF hampered this route. The other is the reaction starting from the lithiation of 4,5-(vinylenedithio)-1,3-dithiol-2-one (**6**) followed by the selenium insertion reaction and the subsequent reaction with methyl iodide. However, the carbonyl group of **6** was found to be decomposed after the reaction.



Cyclic voltammetry of TMSVT in THF gave a single and electrochemically irreversible wave. The separation of the redox peak positions was about 0.2 V, which is much larger than that of the reversible wave (0.059 V). In spite of this, if we define the oxidation potential as the mid-point of the redox peaks, $E_{1/2}$ was 0.86 V vs. SCE. This value was higher than those of TMTVT (0.83 V vs. SCE),[6] VT (0.83 V vs. SCE),[7] bis(methylvinylenedithio)tetrathiafulvalene (0.80 V vs. SCE),[7] bis(dimethylvinylenedithio)tetrathiafulvalene (0.80 V vs. SCE),[11] and BEDT-TTF ($E_{1/2}(1)$=0.69 V, $E_{1/2}(2)$=0.82 V vs. SCE). The order of the oxidation potential, TMSVT>TMTVT≈VT, seems to conflict with that reported for methylthio- and methylseleno-

derivatives of TTF or TSeF.[12] However, strict comparison can not be made, because VT, TMTVT, and TMSVT are electrochemically irreversible materials, and only one redox wave is observed for them unlike the cases of TTF, TTC_1-TTF, $TSeC_1$-TTF, TSeF, TTC_1-TSeF, and $TSeC_1$-TSeF;[12] all of the latter compounds gave two redox waves $E_{1/2}(1)$ and $E_{1/2}(2)$.

Experimental

All of the following reactions except the one from **4** to **5** were carried out in a nitrogen atmosphere. The mass spectra of the molecular ion peaks of the following products agreed with those calculated by computer simulation.

4,5-[1,2-Bis(methylseleno)vinylenedithio]-1,3-dithiole-2-thione (4). To the THF solution (150 ml) of diisopropylamine (0.94 g, 9.3 mmol) was added a hexane solution of butyllithium (9 mmol) at −78 °C, and the solution was stirred for 40 min at −78 °C. To this stirred solution was added **1** (1.00 g, 4.5 mmol) in one portion at −78 °C. The solution became dark red. The temperature of the solution was elevated gradually to 0 °C, and it was stirred for another 2 h at 0 °C to obtain the solution of **2**. It was then cooled to −78 °C, and well-ground selenium powder (0.711 g, 9.0 mmol) was added in one portion. The temperature of the stirred solution was elevated gradually to 0 °C under supersonic wave irradiation using a Bransonic 220 (Yamato Kagaku Co. Ltd). The solution was stirred for another 2.5 h at 0 °C to obtain a black solution. No selenium powder could be seen at this stage. The solution was then cooled to −78 °C, and methyl iodide (1.4 g, 9.9 mmol) was added with stirring. The temperature of the solution was then allowed to rise to room temperature, and the solution was stirred for another 1 h at this temperature to obtain a black solution. After evaporating the solvent, the residue was extracted with benzene, washed with water, and the benzene layer dried over Na_2SO_4. The crude product was chromatographed on silica gel using the mixed solvent of chloroform and hexane (1 : 4) as an eluent. The first pale yellow portion was discarded, and the second orange portion gave a yellow powder of **4** (0.338 g, 18.4%). It was recrystallized from the mixed solvent of THF and ethyl alcohol to obtain yellow needles. Mp: 126—127 °C. ^{1}H NMR δ=2.37 (s). MS m/z 410 (strongest M^+). Found: C, 21.03; H, 1.63%. Calcd for $C_7H_6S_5Se_2$: C, 20.59; H, 1.48%.

4,5-[1,2-Bis(methylseleno)vinylenedithio]-1,3-dithiol-2-one (5). The molecule **4** (0.2 g, 0.49 mmol) was dissolved in a mixed solvent of chloroform (40 ml) and acetic acid (40 ml), and mercury (II) acetate (0.312 g, 0.98 mmol) was added in one portion with stirring. The solution was stirred for 30 min at room temperature, and the pale yellow powder filtered off. The filtrate was washed with water, and the organic layer was dried over Na_2SO_4. After evaporating the solvent, the residue was chromatographed on silica gel using a mixed solvent of chloroform and hexane (1 : 1) as eluent, and the first pale yellow portion gave **5** (0.144 g, 75%). It was recrystallized from hexane or ethyl alcohol to obtain pale yellow needles. Mp: 96.5—97.5 °C. ^{1}H NMR δ=2.36 (s). MS m/z 394 (strongest M^+). Found C, 21.64; H, 1.72%. Calcd for $C_7H_6OS_4Se_2$: C, 21.44; H, 1.54%.

Bis[1,2-bis(methylseleno)vinylenedithio]tetrathiafulvalene (TMSVT). The reaction vessel containing **5** (0.204 g, 0.52 mmol) was purged with nitrogen gas, and triethyl phosphite (2.5 ml), which was distilled just before the reaction, was then added. The solution was stirred for a while to obtain a homogeneous solution. It was then heated with stirring, and red powder began to precipitate at around 100 °C. It was stirred at 110 °C for 2 h. After cooling to room temperature, the red powder was collected, washed with methyl alcohol, and dried in vacuum (0.155 g, 75.1%). The product was recrystallized from carbon tetrachloride to obtain red needles. Mp: 185 °C (decomp). ^{1}H NMR δ=2.31 (s). MS m/z 754 (strongest M^+). UV (THF): 338 nm (log ε 4.30) and 306 nm (log ε 4.37). Found: C, 22.24; H, 1.83%. Calcd for $C_{14}H_{12}S_8Se_4$: C, 22.35; H, 1.61%.

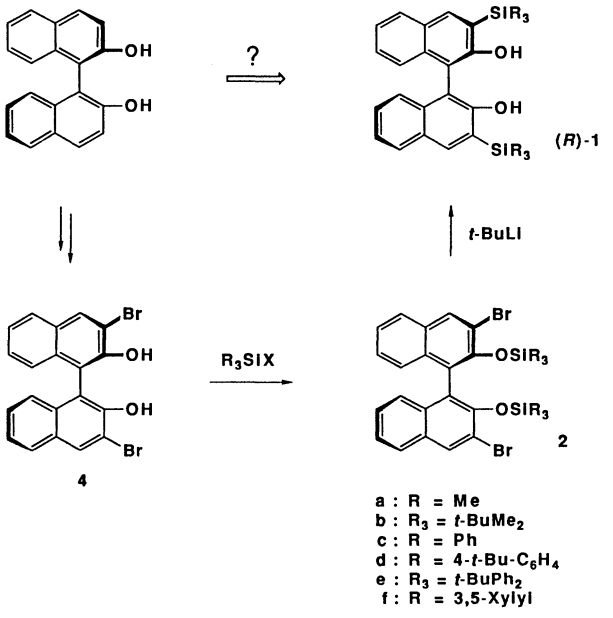
Efficient Synthesis of Sterically Hindered Chiral Binaphthol Derivatives

Keiji MARUOKA, Takayuki ITOH, Yoshitaka ARAKI, Tadashi SHIRASAKA, and Hisashi YAMAMOTO*
Department of Applied Chemistry, Faculty of Engineering, Nagoya University, Chikusa, Nagoya 464-01
(Received March 28, 1988)

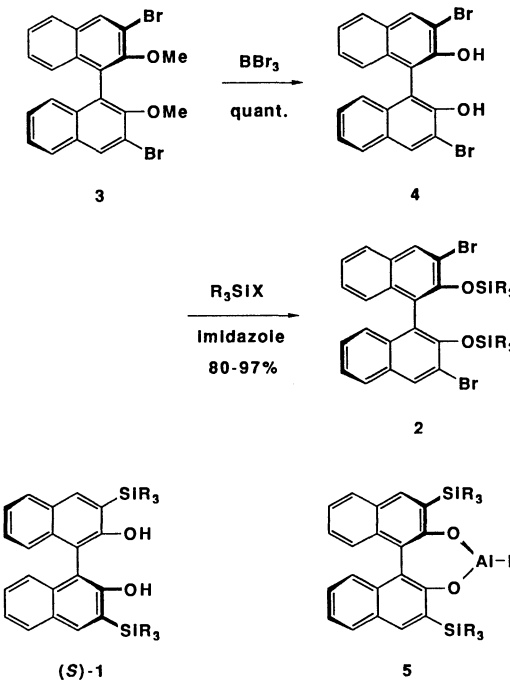
Synopsis. A highly effective method for preparation of a variety of sterically hindered chiral binaphthol derivatives has been described which involves the intramolecular 1,3-rearrangement of bis(trialkylsilyl ether) of chiral 3,3′-dibromo-1,1′-bi-2-naphthol with *t*-BuLi.

In connection with our recent study on the enantioselective activation of carbonyl moiety by complexing with the exceptionally bulky, chiral organoaluminum reagents,[1,2] it was required to synthesize certain sterically hindered, chiral phenol derivatives. An attractive possibility for the synthesis appeared to be the effective introduction of bulky trialkylsilyl substituents adjacent to hydroxyl groups of chiral binaphthols in view of the readily availability of a wide variety of trialkylsilyl derivatives. Here we report a new and highly effective approach to the synthesis of such sterically hindered, chiral 3,3′-bis(trialkylsilyl)-1,1′-bi-2-naphthol (*R*)-**1** and (*S*)-**1** based on the remarkably facile 1,3-rearrangement of bis(trialkylsilyl ether) of chiral 3,3′-dibromo-1,1′-bi-2-naphthol with *t*-BuLi as illustrated in Scheme 1.[3]

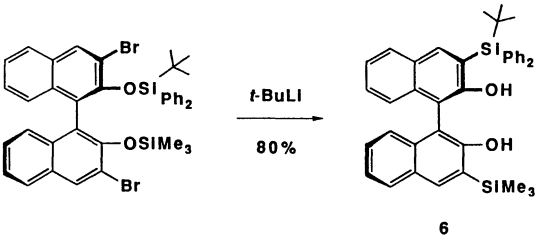


Scheme 1.

The requisite bis(silyl ether) **2** was readily obtainable from the known (*R*)-(+)-3,3′-dibromo-1,1′-bi-2-naphthol dimethyl ether (**3**)[4] in two steps. Thus, demethylation of **3** with BBr_3 (5.5 equiv) in CH_2Cl_2 at room temperature for 3 h afforded (*R*)-(+)-3,3′-dibromo-1,1′-bi-2-naphthol (**4**) quantitatively, which without purification was treated with trialkylsilyl halide (2.5—3 equiv) and imidazole (3—4 equiv) in DMF at 20—70 °C for several hours, producing the bis(silyl ether) **2** in 80—97% yield. Treatment of the bis(silyl ether) **2** with *t*-BuLi (3—3.5 equiv) under mild conditions furnished the corresponding (*R*)-(+)-3,3′-bis(trialkylsilyl)-1,1′-bi-2-naphthol (*R*)-**1** in 85—96% yield. The enantiomeric (*S*)-**1** can be prepared from (*S*)-(−)-1,1′-bi-2-naphthol in a same manner as described above. The readily obtainable, optically pure 3,3′-bis(silylated) binaphthol of type **1** should have vast synthetic potential as chiral bidentate ligands for designing of chiral metal catalyst or reagent as recently shown in our laboratory to be quite effective as a modified organoaluminum catalyst **5** (R=Ph or 3,5-Xylyl) for asymmetric hetero-Diels-Alder and ene reactions.[1]



Since the present 1,3-rearrangement proceeds rigorously in an intramolecular fashion, introduction of different trialkylsilyl groups at the 3,3′-positions of chiral binaphthols appeared feasible, thereby further enhancing the synthetic utility of the present method as exemplified by the facile synthesis of (*R*)-(+)-3-(*t*-butyldiphenylsilyl)-3′-(trimethylsilyl)-1,1′-bi-2-naphthol (**6**) in 80% yield.



Experimental

The IR spectra were measured on a Hitachi 260-10 spectrometer. The ^{1}H NMR spectra were recorded on a JNM-PMX 60 spectrometer, using TMS (tetramethylsilane) as an internal standard. Splitting patterns are indicated as s, singlet; m, multiplet. Melting points are not corrected. The microanalysis was performed at the Institute of Applied Organic Chemistry, Faculty of Engineering, Nagoya University. Tetrahydrofuran (THF) was distilled from benzophenone ketyl. Dichloromethane (CH_2Cl_2) and *N*,*N*-dimethylformamide (DMF) were stored over 4-A Molecular Sieves. All experiments were carried out under an argon atmosphere. Purification of the product was carried out by column chromatography on silica gel Fuji-Davison BW-300.

Preparation of (*R*)-(+)-3,3′-Bis(triphenylsilyl)-1,1′-bi-2-naphthol ((*R*)-1c): To a solution of (*R*)-(+)-3,3′-dibromo-1,1′-bi-2-naphthol dimethyl ether (**3**)[4] (2.78 g, 5.9 mmol) in CH_2Cl_2 (180 mL) was added BBr_3 (3.13 mL, 33 mmol) at 0 °C. The mixture was stirred at room temperature for 5 h. Then excess BBr_3 was decomposed by adding water carefully at 0 °C. The mixture was washed with water, extracted with CH_2Cl_2, dried over Na_2SO_4, and evaporated. The crude (*R*)-(+)-3,3′-dibromo-1,1′-bi-2-naphthol (**4**), thus obtained, was dissolved in DMF (36 mL), and imidazole (1.22 g, 18 mmol) followed by triphenylsilyl chloride (4.42 g, 15 mmol) was added at room temperature. The resulting mixture was stirred at room temperature for 5 h, poured into saturated $NaHCO_3$, and extracted with CH_2Cl_2. The organic layers were washed again with saturated $NaHCO_3$, dried over Na_2SO_4, and concentrated. The crude solid was applied to short-path column chromatography on silica gel (CH_2Cl_2/hexane=1 : 2 as eluent) to furnish bis(triphenylsilyl ether) **2** (5.48 g, 5.7 mmol) in 97% yield. To a solution of **2** in dry THF (80 mL) was added dropwise a 2.67 M pentane solution (1M=1 mol dm^{-3}) of *t*-BuLi (6.4 mL, 17.1 mmol) over a period of 10 min at 0 °C. The mixture was stirred at room temperature for 30 min, poured into saturated NH_4Cl, and extracted with CH_2Cl_2. The combined extracts were dried over Na_2SO_4 and concentrated. The crude product was chromatographed on silica gel (benzene/hexane=1 : 2 to 1 : 1 as eluent) to give (*R*)-(+)-3,3′-bis(triphenylsilyl)-1,1′-bi-2-naphthol ((*R*)-**1c**) (3.89 g, 85% yield) as white solids: $[\alpha]_D$ +125° (*c* 1.11, THF); mp 165—167 °C; IR ($CHCl_3$) 3540, 3065, 3015, 1590, 1428, 1359, 1305, 1105, 988, 910 cm^{-1}; ^{1}H NMR (CCl_4) δ=7.87 (s, 2H, Ar-H), 6.93—7.85 (m, 38H, Ar-H), 5.24 (s, 2H, OH); Anal. ($C_{56}H_{42}O_2Si_2$) C, H. If necessary, this material was further recrystallized from CH_2Cl_2/hexane at low temperature to furnish white crystals.

Other chiral 3,3′-bis(trialkylsilyl)-1,1′-bi-2-naphthols were prepared in a similar manner as described above. Their analytical and physical data are listed below.

(*R*)-(+)-3,3′-Bis(trimethylsilyl)-1,1′-bi-2-naphthol ((*R*)-1a): Yield: 86%; mp 68—71 °C; $[\alpha]_D$ +143° (*c* 0.985, THF); IR (CCl_4) 3540, 1584, 1356, 1305, 1248, 1181, 1149, 840 cm^{-1}; ^{1}H NMR (CCl_4) δ=7.97 (s, 2H, Ar-H), 7.63—7.96 (m, 2H, Ar-H), 6.84—7.43 (m, 6H, Ar-H), 5.15 (s, 2H, OH), 0.40 (s, 18H, CH_3); Anal. ($C_{26}H_{30}O_2Si_2$) C, H.

(*R*)-(+)-3,3′-Bis(*t*-butyldimethylsilyl)-1,1′-bi-2-naphthol ((*R*)-1b): Yield: 87%; mp 63—66 °C; $[\alpha]_D$ +136° (*c* 1.02, THF); IR (CCl_4) 3535, 1584, 1355, 1250, 1194, 830 cm^{-1}; ^{1}H NMR (CCl_4) δ=7.93 (s, 2H, Ar-H), 7.56—7.84 (m, 2H, Ar-H), 6.78—7.37 (m, 6H, Ar-H), 5.10 (s, 2H, OH), 0.97 (s, 18H, *t*-Bu), 0.41 (s, 12H, CH_3); Anal. ($C_{32}H_{42}O_2Si_2$) C, H.

(*R*)-(+)-3,3′-Bis[tris(4-*t*-butylphenyl)silyl]-1,1′-bi-2-naphthol ((*R*)-1d): Yield: 96% (amorphous solid); $[\alpha]_D$ +91.4° (*c* 1.22, THF); IR (CCl_4) 3550, 2980, 1395, 1270, 1095 cm^{-1}; ^{1}H NMR (CCl_4) δ=7.90 (s, 2H, Ar-H), 7.10—7.70 (m, 32H, Ar-H), 5.23 (s, 2H, OH), 1.31 (s, 54H, *t*-Bu); Anal. ($C_{80}H_{90}O_2Si_2$) C, H.

(*R*)-(+)-3,3′-Bis(*t*-butyldiphenylsilyl)-1,1′-bi-2-naphthol ((*R*)-1e): Yield: 95%; mp 145—147 °C; $[\alpha]_D$ +111° (*c* 1.01, THF); IR (CCl_4) 3530, 1430, 1360, 1150, 1110 cm^{-1}; ^{1}H NMR (CCl_4) δ=7.93 (s, 2H, Ar-H), 7.15—7.80 (m, 28H, Ar-H), 5.32 (s, 2H, OH), 1.23 (s, 18H, *t*-Bu); Anal. ($C_{52}H_{50}O_2Si_2$) C, H.

(*R*)-(+)-3,3′-Bis(tri-3,5-xylylsilyl)-1,1′-bi-2-naphthol ((*R*)-1f): Yield: 90%; mp 285—286 °C; $[\alpha]_D$ +135° (*c* 1.02, THF); IR (CCl_4) 3550, 2930, 1590, 1420, 1400, 1145 cm^{-1}; ^{1}H NMR (CCl_4) δ=7.73 (s, 2H, Ar-H), 6.83—7.33 (m, 26H, Ar-H), 5.13 (s, 2H, OH), 2.22 (s, 36H, Me); Anal. ($C_{68}H_{66}O_2Si_2$) C, H.

(*R*)-(+)-3-(*t*-Butyldiphenylsilyl)-3′-(trimethylsilyl)-1,1′-bi-2-naphthol (6): Yield: 80% (amorphous solid); mp 107—116 °C; $[\alpha]_D$ +128° (*c* 1.16, THF); IR (CCl_4) 3530, 1435, 1365, 1250, 1155 cm^{-1}; ^{1}H NMR (CCl_4) δ=7.03—8.01 (m, 20H, Ar-H), 5.25 (s, 1H, OH), 5.18 (s, 1H, OH), 1.22 (s, 9H, *t*-Bu), 0.41 (s, 9H, SiMe); Anal. ($C_{39}H_{40}O_2Si_2$) C, H.

(*S*)-(−)-3,3′-Bis(triphenylsilyl)-1,1′-bi-2-naphthol ((*S*)-1c): $[\alpha]_D$ −125° (*c* 1.10, THF). The spectral data is in consonance with those of (*R*)-**1c**.

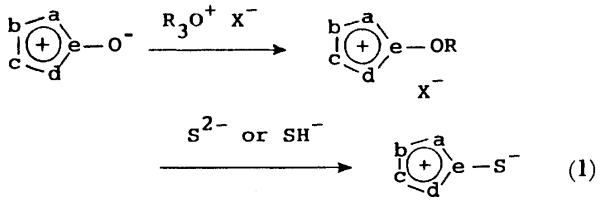
One-Step Conversion of Mesoionic Olate to Thiolate by Lawesson's Reagent

Shuki ARAKI,* Tetsuya GOTO, and Yasuo BUTSUGAN
Department of Applied Chemistry, Nagoya Institute of Technology, Gokiso-cho, Showa-ku, Nagoya 466
(Received March 29, 1988)

Synopsis. Treatment of mesoionic olates with Lawesson's reagent provides a convenient one-step conversion to mesoionic thiolates.

Mesoionic compounds, expressed by the general formula **1**, where a—f are suitably substituted carbons or heteroatoms, are an interesting family of heterocycles because of their unique structure, reaction behavior, and pharmaceutical activity.[1] Most of mesoions bear oxygen, sulfur, nitrogen, and carbon as the exocyclic group (f), and are called meso-ionic olate, thiolate, aminide, and methylide, respectively; and their interconversion is important from a synthetic standpoint. Mesoionic olates were hitherto converted to the corresponding thiolates via following two steps: alkylation with a trialkyloxonium salt and then replacement of the resulting alkylthio group by sulfide or hydrogensulfide anion (Eq. 1).[2]



(1)

Lawesson's reagent (**2**), 2,4-bis(*p*-methoxyphenyl)-1,3-dithiadiphosphetane-2,4-disulfide, is known as an excellent reagent for the conversion of various types of carbonyl group to the corresponding thiocarbonyl group.[3] However, the reaction of **2** with mesoionic olates has not to our knowledge been reported so far. Here, we describe the reaction of **2** with several mesoionic olates which provides a convenient method for the one-pot conversion of mesoionic olates to thiolates.

A mixture of 1,3-diphenyltetrazolium-5-olate (**3**) and Lawesson's reagent (**2**) in toluene was heated at reflux for 18 h. Purification by column chromatography gave 93% yield of the thiolate **4**, identical with the authentic sample prepared according to the literature method.[2a] Table 1 summarizes the results for other mesoionic olates. 3-Phenyl-1,2,3-thiadiazolium- (**5**) and 3-phenyl-1,2,3,4-thiatriazolium-5-olates (**7**) were converted to the corresponding thiolates **6** and **8** in high yields, whereas 3-*p*-methoxyphenyl-1,2,3-thiadiazolium-4-thiolate (**10**) was obtained in only 16%. The yields of the thiolates **4**, **6**, **8**, and **10** are much higher than or at least equivalent to those obtained by the existing method (Eq. 1).[2]

Treatment of 3-phenyl-1,2,3-oxadiazolium-5-olate (3-phenylsydnone) (**11**) with **2** gave 1,4-diphenyl-1,4-dihydro-1,2,4,5-tetrazine (**12**) quantitatively, and the expected thiolate **13** could not be obtained at all. The tetrazine **12** has been obtained from the reaction of **11** with P_4S_{10} in a low yield.[4] The thiolate **13** prepared by an independent method[2b] also gave **12** in 88% yield upon the treatment with **2**, suggesting the intermedi-

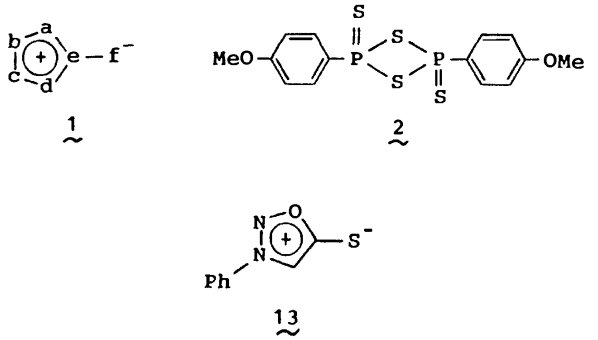


Table 1. Reaction of Mesoionic Olates with Lawesson's Reagent

Run	Olate	Product	Yield/%[a]
1	 **3**	 **4**	93 (59)[b]
2	 **5**	 **6**	98 (63)[c]
3	 **7**	 **8**	93 (25)[d]
4	 **9**	 **10**	16 (19)[e]
5	 **11**	 **12**	100
6	 **14**	 **15**	100

a) Numbers in parentheses refer to the reported yields of the existing two-step conversion (Eq. 1). b) Ref. 2a. c) Ref. 2b. d) Ref. 2c. e) Ref. 2d.

acy of **13** in the reaction of the olate **11** and **2**. Interestingly, the sulfur analog **5** of sydnone gave a high yield of the thiolate **6**. The reaction of a quinonoid mesoionic olate **14**[5] with **2** resulted in the cleavage of the pivotal carbon-carbon bond giving diphenylthiocarbazone (dithizone) **15** in a quantitative yield. Unfortunately, mesoionic olates of type B[1] such as 2,3-diphenyltetrazolium-5-olate and 3,5-diphenyl-1,2-dithiolium-4-olate gave complex mixtures of products on the treatment with **2**.

In summary, the thionation of mesoionic olates of type A by Lawesson's reagent (**2**) provides a convenient route to the corresponding mesoionic thiolates.

Experimental

Melting points were determined with a hot-stage apparatus and are uncorrected. Infrared spectra were recorded on a JASCO IRA-1 spectrophotometer. Mass spectra were recorded on a Hitachi M-52 instrument at 20 eV. ^{1}H and ^{13}C NMR spectra were recorded on a Hitachi R-24A spectrometer (60 MHz) and on a Varian XL-200 spectrometer (50 MHz), respectively, with Me_4Si as an internal standard.

Reaction of Mesoionic Olates with Lawesson's Reagent (2). Run 1. 1,3-Diphenyltetrazolium-5-olate (**3**) (103 mg, 0.43 mmol) and **2** (118 mg, 0.29 mmol) in toluene (5 cm^3) were heated at reflux for 18 h. The reaction mixture was cooled and adsorbed on a silica-gel column and eluted with dichloromethane. A yellow band was collected and the solvent was evaporated leaving yellow crystals of thiolate **4** (102 mg, 93%). Mp 151 °C (CH_2Cl_2) (lit,[2a] mp 155 °C); IR (KBr): 1494, 1374, 1302, 1266, 1190, 774, 764, 692, 686 cm^{-1}; MS m/z 254 (M^+).

Run 2. 3-Phenyl-1,2,3-thiadiazolium-5-olate (**5**) (100 mg, 0.56 mmol) and **2** (159 mg, 0.39 mmol) in toluene (6 cm^3) were warmed to 100 °C during the period of 30 min. The mixture was cooled and column chromatographed on silica gel (CH_2Cl_2) to give red crystals of thiolate **6** (107 mg, 98%). Mp 165 °C (CH_2Cl_2) (lit,[2b] mp 170—171 °C); IR (KBr): 1430, 1252, 1198, 1030, 898, 760 cm^{-1}; MS m/z 194 (M^+).

Run 3. 3-Phenyl-1,2,3,4-thiatriazolium-5-olate (**7**) (176 mg, 1.1 mmol) and **2** (300 mg, 0.74 mmol) in toluene (11 cm^3) were heated at reflux for 50 min. The mixture was cooled and column chromatographed on silica gel to give orange needles of thiolate **8** (178 mg, 93%). Mp 125 °C (CH_2Cl_2) (lit,[2c] mp 128 °C); IR (KBr): 1270, 1226, 1056, 922, 762, 660 cm^{-1}; MS m/z 195 (M^+).

Run 4. 3-*p*-Methoxyphenyl-1,2,3-thiadiazolium-4-olate (**9**) (121 mg, 0.58 mmol) and **2** (163 mg, 0.40 mmol) in toluene (6 cm^3) were heated at reflux for 16 h. Column chromatography on silica gel (ethyl acetate) gave red needles of thiolate **10** (20 mg, 16%). Mp 189 °C (MeOH) (lit,[2d] mp 193—194 °C); IR (KBr): 1512, 1394, 1306, 1254, 1176, 1152, 1078, 1022, 988, 834 cm^{-1}; MS m/z 224 (M^+).

Run 5. 3-Phenylsydnone (**11**) (110 mg, 0.68 mmol) and **2** (191 mg, 0.47 mmol) in toluene (6 cm^3) were refluxed for 3.5 h. The solvent was evaporated under reduced pressure and the residue was column chromatographed on silica gel (benzene) to give pale yellow plates of dihydrotetrazine (**12**) (80 mg, 100 %). Mp 191 °C (acetone) (lit,[4] mp 189—189.5 °C); IR (KBr): 1600, 1494, 1318, 1156, 906, 892, 754, 750, 700 cm^{-1}; MS: m/z 236 (M^+); ^{1}H NMR ($CDCl_3$): δ=6.90 (s, 2H, =CH–), 7.30 (m, 10H, Ph); ^{13}C NMR ($CDCl_3$): δ=115.3, 123.8, 129.4, 139.5, 142.3.

Run 6. 2,6-Di-*t*-butyl-4-(2,3-diphenyl-5-tetrazolio)phenolate (**14**)[5] (13 mg, 0.032 mmol) and **2** (9 mg, 0.022 mmol) in toluene (2 cm^3) were slowly heated to reflux during the period of 20 min. The solvent was removed under reduced pressure and the residue was purified by column chromatography on silica gel (benzene) to furnish dithizone **15** (8 mg, 100%). The melting point and spectral data were identical with those of a commercially obtained sample.

Reaction of 3-Phenyl-1,2,3-oxadiazolium-5-olate (13) with 2. A mixture of **13** (110 mg, 0.62 mmol) and **2** (177 mg, 0.44 mmol) in toluene (6 cm^3) was refluxed for 3.5 h. Column chromatography on silica gel (dichloromethane) gave dihydrotetrazine (**12**) (64 mg, 88%). The physical data were identical with those of the product of Run 5.

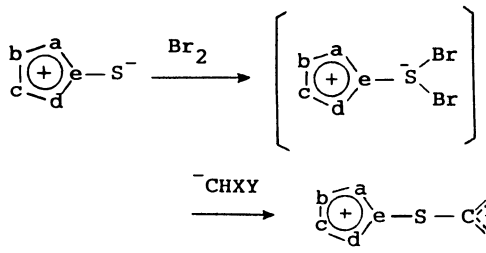
1,3,4-Thiadiazolines by a 1,5-Dipolar Ring Reconstruction of Mesoionic (2,3-Diphenyltetrazolio)thio Ylides

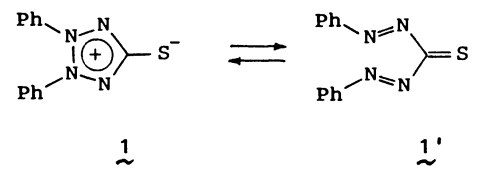
Shuki ARAKI,* Tetsuya GOTO, and Yasuo BUTSUGAN
Department of Applied Chemistry, Nagoya Institute of Technology, Gokiso-cho, Showa-ku, Nagoya 466
(Received March 29, 1988)

Synopsis. 4-Phenyl-2-phenylazo-2,3-dihydro-1,3,4-thiadiazoles were synthesized from 2,3-diphenyltetrazolium-5-thiolate by two methods. The formation of the thiadiazolines is rationalized by 1,5-dipolar ring closure of the intermediate mesoionic (tetrazolio)thio ylides.

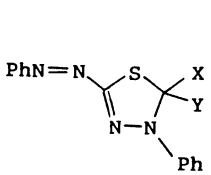
We have recently reported[1] the synthesis of mesoionic thiocarbonyl ylides by the treatment of mesoionic thiolates with bromine followed by the reaction of the conjugate anions of active methylene compounds (Eq. 1). Now, we have examined the reaction of the bromine adduct of 2,3-diphenyltetrazolium-5-thiolate (**1**) with various conjugate anions of active methylene compounds and found that several anions gave thiadiazoline derivatives **2** exclusively, instead of the expected thiocarbonyl ylides. Furthermore, same thiadiazoline derivatives were also obtained from the reaction of **1** with the diazo compounds of active methylene compounds.



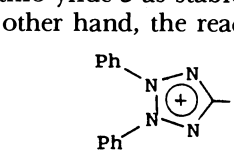
(1)



1 **1'**



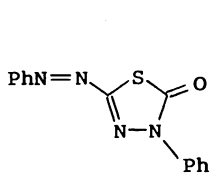
2a: X=Y=CO_2Et
b: X=CO_2Et, Y=CN
c: X=CO_2Et, Y=COMe
d: X,Y= 
The reaction of the bromine adduct of **1** with ethyl sodio-*p*-tolylsulfonylacetate gave the expected (tetrazolio)thio ylide **3** as stable crystals in a high yield. On the other hand, the reaction with diethyl sodiomalonate led to the exclusive formation of 5,5-bis(ethoxycarbonyl)-4-phenyl-2-phenylazo-2,3-dihydro-1,3,4-thiadiazole (**2a**) as deep red crystals in 94% yield, and the corresponding (tetrazolio)thio ylide was not obtained at all. The structure of **2a** was deduced from its analytical and spectral properties. The ^{13}CNMR spectrum showed two sets of phenyl signals and the absorptions of the thiadiazoline ring carbons at δ 83.0 and 154.6 ppm. Its ^1HNMR revealed the nonequivalency of the two ethoxycarbonyl groups. An intense absorption at 470 nm in the electronic spectrum is consistent with the presence of a phenylazo chromophore. Similar reactions with the sodium salt of ethyl cyanoacetate or ethyl acetoacetate gave the respective thiadiazolines **2b** and **2c** in good yields.



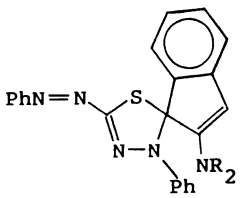
3

The thiadiazolines **2a** and **2c** were also prepared by refluxing of the thiolate **1** in chloroform with the diazo derivatives of diethyl malonate and ethyl acetoacetate, respectively.[2] A new thiadiazoline **2d** having a spirostructure was synthesized by the reaction of **1** with 10-diazo-9-anthrone.

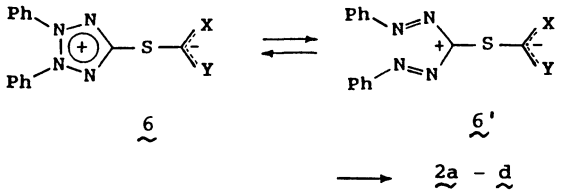
Two syntheses of 4-phenyl-2-phenylazo-2,3-dihydro-1,3,4-thiadiazole derivatives from mesoionic thiolate **1** are so far reported; treatment of **1** with iron pentacarbonyl gave 1,3,4-thiadiazol-2(3*H*)-one (**4**)[3] and reaction with 2-alkylaminoindenes yielded products with the general structure **5**.[4] The formation of these products **4** and **5** is thought to occur via the acyclic valence tautomer **1'** of thiolate **1**. In our reactions, the formation of thiadiazolines **2** can also be rationalized in terms of participation of the acyclic valence tautomer **6'** of intermediate thiocarbonyl ylide **6**. The tautomer **6'** undergoes 1,5-dipolar ring closure to furnish thiadiazolines **2** (Eq. 2). The isolation of (tetrazolio)thio ylide **6** is depend upon the nature of the substituents (X and Y) on the carbanionoid carbon; only in the



4



5



6 **6'**

(2)

cases of strongly electron-withdrawing substituents, the ylide **6** is thought to be isolated stably.

Experimental

General. Melting points were determined on a hot-stage apparatus and are uncorrected. Infrared spectra were taken for KBr discs with a JASCO IRA-1 spectrometer. Electronic spectra were run with a Hitachi 124 spectrophotometer. ^{1}H NMR spectra were recorded on a Hitachi R-24A spectrometer (60 MHz) or on a Varian XL-200 spectrometer (200 MHz) with Me_4Si as an internal standard. ^{13}C NMR spectra were determined on a Varian XL-200 spectrometer (50 MHz). Mass spectra were recorded on a Hitachi M-52 instrument at 20 eV or on an ESCO EMD-05B at 70 eV using a direct-inlet system. Elemental analyses were performed at the Elemental Analysis Center of Kyoto University.

Synthesis of Mesoionic (Tetrazolio)thio Ylide (3). To a stirred suspension of mesoionic thiolate **1** (127 mg, 0.5 mmol) in dry dichloromethane (1.5 cm^3) was added bromine (0.030 cm^3, 0.55 mmol) and the mixture was stirred at room temperature for 10 min. The sodium salt of ethyl *p*-tolylsulfonylacetate, prepared from ethyl *p*-tolylsulfonylacetate (242 mg, 1 mmol) and an equimolar amount of sodium hydride in tetrahydrofuran (THF) (1 cm^3), was added to the bromine adduct. After 5 min, the reaction was quenched by the addition of water (1 cm^3) and ether (20 cm^3) was added. Pale yellow precipitates were filtered and washed successively with ether, water, and THF, and then dried to give ylide **3** (220 mg, 89%), mp 125 °C (MeCN); IR: 1630, 1354, 1292, 1274, 1132, 1070, 764, 686, 662 cm^{-1}; UV (MeCN): λ_{max} 231 (log ε 4.34), 258 (sh) (4.12), and 343 nm (3.21); ^{1}H NMR (60 MHz, DMSO-d_6): δ=1.00 (t, J=7 Hz, $CH_2\underline{Me}$), 2.28 (s, 3H, Me), 3.80 (q, J=7 Hz, 2H, $C\underline{H}_2$Me), 7.10 (d, J=9 Hz, 2H, aryl H), 7.70 (m, 10H, Ph), 7.75 (d, J=9 Hz, 2H, aryl H); ^{13}C NMR (DMSO-d_6): δ=14.9 ($CH_2\underline{Me}$), 21.0 (Me), 57.6 ($\underline{C}H_2$Me), 60.4 (S-C$^-$), 126.5 (ortho), 127.2 (aryl), 128.0 (aryl), 130.1 (meta), 133.3 (ipso), 133.7 (para), 139.8 (C-Me), 145.0 (C-SO_2), 166.0 (C=O), 172.9 (S-C$^+$); Found: C, 56.38; H, 4.56; N, 10.79%. Calcd for $C_{24}H_{22}N_4S_2 \cdot H_2O$: C, 56.23; H, 4.71; N, 10.93%.

Reaction of the Bromine Adduct of 1 with the Conjugate Bases of Active Methylene Compounds. The following reaction with diethyl sodiomalonate is representative. To a suspension of the bromine adduct of **1**, prepared as above from **1** (127 mg, 0.5 mmol) and bromine (0.030 cm^3, 0.55 mmol) in dichloromethane (1.5 cm^3), was added diethyl sodiomalonate (1.5 mmol) in THF (1 cm^3). The mixture was stirred at room temperature for 10 min. Water was added and the product was extracted with dichloromethane. The extracts were dried over anhydrous sodium sulfate and the solvent was removed. The residue was chromatographed on silica gel (eluent: dichloromethane–hexane 1 : 1) to give thiadiazoline **2a** (198 mg, 96%) as red crystals, mp 91 °C (benzene–hexane); IR: 1772, 1554, 1490, 1250, 1234, 1150, 1130, 1038, 756, 682 cm^{-1}; UV-VIS (MeCN): λ_{max} 253 (log ε 4.08), 310 (4.03), and 470 nm (4.35), ^{1}H NMR (200 MHz, $CDCl_3$): δ=1.18 (t, J=7 Hz, 6H, Me), 4.30 (q, J=7 Hz, 2H, CH_2), 4.31 (q, J=7 Hz, 2H, CH_2), 7.13—7.52 (m, 8H, Ph), 7.92 (m, 2H, Ph); ^{13}C NMR ($CDCl_3$): δ=13.7 (Me), 63.5 (CH_2), 83.0 (C^5), 117.8 (ortho), 123.4 (ortho), 124.1 (para), 128.9 (meta), 129.2 (meta), 132.1 (para), 142.1 (ipso), 151.8 (ipso), 154.6 (C^2), 165.8 (C=O); MS (20 eV): m/z (rel intensity) 412 (M$^+$, 6), 77 (Ph, 100); Found: C, 58.43; H, 4.80; S, 7.79%. Calcd for $C_{20}H_{20}N_4O_4S$: C, 58.24; H, 4.89; S, 7.77%.

Similarly, thiadiazolines **2b** and **2c** were synthesized and obtained as red crystals.

2b: 62% yield; mp 98 °C (MeOH); IR: 1744, 1564, 1500, 1354, 1260, 1148, 748, 680 cm^{-1}; UV-VIS (MeCN): λ_{max} 245 (log ε 4.08), 315 (4.01), and 450 nm (4.36); ^{1}H NMR (60 MHz, $CDCl_3$): δ=1.23 (t, J=7 Hz, 3H, Me), 4.34 (q, J=7 Hz, 2H, CH_2), 7.40 (m, 8H, Ph), 7.85 (m, 2H, Ph); ^{13}C NMR ($CDCl_3$): δ=13.7 (Me), 65.1 (CH_2), 71.2 (C^5), 113.2 (CN), 116.3 (ortho), 123.7 (ortho), 124.6 (para), 129.6 (meta), 129.4 (meta), 133.0 (para), 140.5 (ipso), 151.5 (ipso), 155.0 (C^2), 163.4 (C=O); MS (20 eV): m/z (rel intensity) 365 (M$^+$, 34), 292 (M−CO_2Et, 100); Found: C, 59.23; H, 4.04; N, 19.37%. Calcd for $C_{18}H_{15}N_5O_2S$: C, 59.17; H, 4.14; N, 19.16%.

2c: 94% yield; mp 72 °C (hexane); IR: 1742, 1730, 1550, 1500, 1366, 1248, 1164, 1152, 774, 752, 686 cm^{-1}; UV-VIS (MeCN): λ_{max} 254 (log ε 4.06), 304 (4.02), and 477 nm (4.41); ^{1}H NMR (60 MHz, $CDCl_3$): δ=1.17 (t, J=7 Hz, 3H, $CH_2\underline{Me}$), 2.45 (s, 3H, COMe), 4.27 (q, J=7 Hz, 2H, CH_2), 7.35 (m, 8H, Ph), 7.80 (m, 2H, Ph); ^{13}C NMR ($CDCl_3$): δ=13.6 (Me), 25.5 (CO$\underline{Me}$), 63.2 ($\underline{C}H_2$Me), 86.7 (C^5), 116.5 (ortho), 123.3 (ortho), 123.7 (para), 129.0 (meta), 129.2 (meta), 132.2 (para), 141.8 (ipso), 151.7 (ipso), 153.5 (C^2), 166.5 ($\underline{C}O_2$Et), 196.0 ($\underline{C}$OMe); MS (70 eV): m/z (rel intensity) 382 (M$^+$, 2), 77 (Ph, 100); Found: C, 59.82; H, 4.66; N, 14.60%. Calcd for $C_{19}H_{18}N_4O_3S$: C, 59.67; H, 4.74; N, 14.65%.

Reaction of Thiolate 1 with Diazo Compounds. A solution of thiolate **1** (389 mg, 1.53 mmol) and diethyl diazomalonate[5] (549 mg, 2.95 mmol) in chloroform (12 cm^3) was heated at reflux for 24 h. The solvent was removed and the residue was column chromatographed on silica gel (eluent: chloroform) to afford red crystals of thiadiazoline **2a** (229 mg, 47%), identical with the compound obtained above. The reactions with ethyl diazoacetoacetate[5] and 10-diazo-9-anthrone[6] were similarly carried out and the corresponding thiadiazolines **2c** and **2d** were isolated in 5 and 65% yields, respectively.

2d: Mp 286 °C (benzene); IR: 1660, 1596, 1536, 1492, 1362, 1318, 1266, 1224, 1156, 930, 770, 746, 740, 710, 682 cm^{-1}; UV-VIS (MeCN): λ_{max} 253 (log ε 4.32), 279 (sh) (4.24), 302(sh) (4.11), and 476 nm (4.33); ^{1}H NMR (200 MHz, $CDCl_3$): δ=6.90—7.10 (m, 4H, aryl H), 7.50—7.70 (m, 8H, Ph and aryl H), 7.70—7.90 (m, 4H, Ph and aryl H), 8.41 (d, J=8 Hz, 2H, aryl H); ^{13}C NMR ($CDCl_3$): δ=81.1 (C^5), 116.9 (ortho), 122.9 (para), 123.3 (ortho), 127.5 (aryl CH), 127.8 (aryl CH), 129.0 (meta or aryl CH), 129.2 (meta or aryl CH), 129.4 (meta or aryl CH), 132.0 (para), 133.4 (aryl =$\underset{|}{C}$–), 134.9 (aryl CH), 140.5 (ipso or aryl =$\underset{|}{C}$–), 143.7 (ipso or aryl =$\underset{|}{C}$–), 151.9 (ipso), 154.8 (C^2), 181.8 (C=O); MS (20 eV): m/z (rel intensity) 446 (M$^+$, 100); Found: C, 72.62; H, 4.01; S, 7.24%. Calcd for $C_{27}H_{17}N_4OS$: C, 72.63; H, 4.06; S, 7.18%.

Potentiometric Study of Cadmium(II) Halide and Thiocyanate Complexes in Methanol. Determination of Thermodynamic Stability Constants of Third and Fourth Complexation Step

Khin Nwe SOE, Hidekazu DOE, and Toyokichi KITAGAWA*
Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka 558
(Received October 19, 1987)

Synopsis. The stability constants, K_3 and K_4, of $[Cd^{II}X_n]^{2-n}$ (X^-=Cl^-, Br^-, I^-, NCS^-) complexes in methanol have been determined by X^- ion measurements with Ag-AgX and NCS^- ion selective electrodes at 25 °C.

With the confirmation of the structural postulation, the formation of cadmium halide and thiocyanate complexes at any consecutive step accompanying the conformational change was earlier investigated by Ahrland and his co-workers in dimethyl sulfoxide.[1-3] Those investigations were performed at high ionic strength. We have previously studied the formation of mono- and dihalide and thiocyanate complexes in methanol at an ionic strength of 0.05 M (1 M=1 mol dm^{-3}).[4] The thermodynamic stability constants of mono- and dihalide and thiocyanate complexes, K_1 and K_2, have been studied. In this extended study, we aimed to determine the thermodynamic stability constants of tri- and tetrahalide and thiocyanate complexes, K_3 and K_4. In the present study, all potentiometric measurements were carried out at low ionic strength because it was extremely difficult to evaluate an ion activity coefficient at high ionic strength. The octahedral structure of both aquocadmium and solvated cadmium ion in dimethyl sulfoxide solution was postulated from an X-ray diffraction analysis.[5,6] Moreover, the tetrahedral structure postulation of cadmium tetrahalide complexes in aqueous solution were confirmed by X-ray diffraction studies.[5,7] Recently, the ambidentate coordination of N and S with cadmium at the formation of tri- and tetrathiocyanate complexes in aqueous solution has been postulated as $[Cd(SCN)(NCS)_2]^-$ and $[Cd(SCN)_2(NCS)_2]^{2-}$,[8,9] For these reasons, a conformational change will take place at any consecutive step of the formation of cadmium(II) halide and thiocyanate complexes.

Experimental

Materials. Cadmium(II) perchlorate hexahydrate was prepared by neutralizing cadmium carbonate (Nakarai, Guaranteed Grade) with perchloric acid.[10] This hexahydrate salt was purified by triple recrystallization from distilled water and was then dried on a vacuum line over diphosphorus pentaoxide for three days in order to obtain a dihydrate salt. The preparations of the other reagents were described in previous papers.[11,12]

Instrumentation. Outlines of the instrumentation and measurement procedure were described previously.[11,12] In the present study, the sensor for I^- was a Horiba iodide ion-selective electrode 8005-06T. All measurements were carried out in a closed cell thermostated at 25.0±0.1 °C. The cell contained 40 cm^3 of sample solution before titration.

Data Treatment and Results

In general, the following equilibria are established in methanol:

$$[CdX_{n-1}]^{3-n} + X^- \rightleftharpoons [CdX_n]^{2-n} \ (K_n;\ n=1—4) \quad (1)$$

$$Cd^{2+} + ClO_4^- \rightleftharpoons [CdClO_4]^+ \ (K_{1A}) \quad (2)$$

By considering these equilibria, a function, $\bar{n}$, defined as the average number of ligands, X^-, attached to the metal, M^{2+}, is written as:

$$\bar{n} = (C_X^\circ - [X^-])/C_M^\circ$$
$$= (y_1\beta_1[X^-] + 2y_2\beta_2[X^-]^2 + 3y_3\beta_3[X^-]^3 + 4y_4\beta_4[X^-]^4)/$$
$$(1 + y_1K_{1A}[ClO_4^-] + y_1\beta_1[X^-] + y_2\beta_2[X^-]^2 + y_3\beta_3[X^-]^3 + y_4\beta_4[X^-]^4). \quad (3)$$

C_M° and C_X° are the total concentrations of $Cd(ClO_4)_2$ and NaX respectively, and β_n is the overall stability constant ($\beta_n = \prod_{i=1}^{n} K_n$). It has been assumed that ions with an identical absolute value of charge have the same ion activity coefficient at I=0.05 M.[12] Thus, this assumption leads to $y_1=y_{2+}$, $y_2=y_3=y_{2+}y_\pm^2$, and $y_4=y_\pm^4$, where $y_\pm$ and y_{2+} are the ion activity coefficients of mono- and divalent ions, respectively. By rearranging Eq. 3, the following equation is obtained:

$$\bar{n}(1 + y_1K_{1A}[ClO_4^-]) = \beta_1(1-\bar{n})y_1[X^-] + \beta_2(2-\bar{n})y_2[X^-]^2 + \beta_3(3-\bar{n})y_3[X^-]^3 + \beta_4(4-\bar{n})y_4[X^-]^4. \quad (4)$$

Here, $\bar{n}$ and $[X^-]$ are measurable and K_{1A} has already been determined by conductometric measurements.[13]

Now, in consideration of the equilibria 1—3, the concentration of Cd^{2+} is:

$$[Cd^{2+}] = C_M^\circ/(1 + y_1K_{1A}[ClO_4^-] + y_1\beta_1[X^-] + y_2\beta_2[X^-]^2 + y_3\beta_3[X^-]^3 + y_4\beta_4[X^-]^4). \quad (5)$$

In order to calculate the y_1, y_2, y_3, and y_4 values, the Debye-Hückel second approximation has been used:

$$\ln y = -Az_i^2I^{1/2}/(1+BaI^{1/2}). \quad (6)$$

Data processing started with initial values of $[ClO_4^-] = 2C_M^\circ + C_I^\circ$ and of y_1, y_2, y_3, and y_4 values at I=0.05 M. By the use of these values, β_n were initially estimated by a multiple regression analysis with weighted terms according to Eq. 4. Those n values were used to calculate $[Cd^{2+}]$, $[CdX_n^{2-n}]$, and $[ClO_4^-]$. Then, I was calculated by the use of $[Cd^{2+}]$ and $[CdX_n^{2-n}]$. Since this calculated I value was slightly different from 0.05 M, $[X^-]$ was corrected by a $y_\pm$ value since the calibration

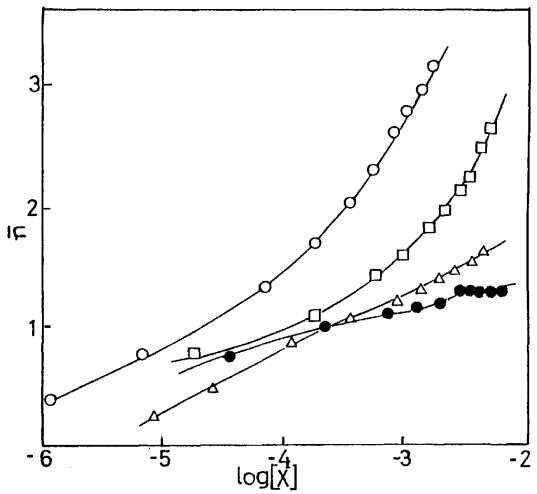

Fig. 1. Average coordination numbers, $\bar{n}$, as a function of log[X^-]: ● chloride; □ bromide; ○ iodide; △ thiocyanate. Dashed line: experimental line.

was made at I=0.05 M.[4] Here, we could return to Eq. 4 with new values of I, [ClO_4^-], and [X^-]. This series of processing was repeated until β_n values became constant.

Table 1 shows the stepwise stability constants, including K_1 and K_2. The y_{2+} and $y_{\pm}$ values at I=0.05 M are 0.08285 (a=5° A)[4] and 0.5110. The concentration stability constants are summarized in Table 2. The products of K_3K_4 are shown in Table 1.

Discussion

For the chloride system, K_3 and K_4 were so small that they could not be determined under this experimental conditions (Fig. 1), that $\bar{n}$ does not exceed 2. Similarly, in the bromide system, $\bar{n}$ does not exceed 3 due to the small values of K_3 and K_4. For the iodide system, the complex was formed up to tetraiodide under this experimental conditions and generally, thermodynamic stability constants decrease in the order $K_1>K_2>K_3>K_4$. Besides, the stabilities of halide complexes decrease in the order $I^->Br^->Cl^-$, as shown in Fig. 1, since cadmium(II) is a soft acid, preferring to coordinate with soft donor ligands.[14,15] In a protic solvent like water, the same sequence was found for cadmium(II) halides in various ionic media.[3]

The existence of $[Zn(MeOH)_6]^{2+}$ and $[Zn(MeOH)_5(ClO_4)]^+$ was postulated from a proton magnetic resonance investigation of the zinc-methanol system.[16] For this reason, the solvated cadmium ion probably has an octahedral $[Cd(MeOH)_6]^{2+}$ structure in this study. Additionally, according to the structural postulation described above (introduction), it can be obviously seen that the structural change of an octahedral coordination to tetrahedral coordination will certainly occur at any consecutive step of formation of cadmium(II) halide complexes in methanol.

According to the K_2 value, we have discussed earlier[4] how the steric hindrance of ligands in an octahedrally coordinated structure would suppress the formation of cadmium dihalide complexes; it would cause the value of K_2 to become small, making the ratio of K_1/K_2 extremely large. Therefore, it was impossible for a coordination change to take place at the second step. In other words, it will take place at the subsequent steps.

The coordination change at the subsequent steps was confirmed by a Raman study[17] on the C_{3v}, bent structure of $CdBr_3^-$ in an aqueous solution. For this reason, it is quite possible that $CdBr_3^-$ and CdI_3^- have a tetrahedral structure with a solvent molecule at an apex in methanol. Our results did not clearly indicate the step at which the conformational change occurs viz. the formation of a trihalide complex or the formation of a tetrahalide complex. However, an extremely small K_2 value may support a change at the third step. If data on enthalpy and entropy changes is available, they will be of great help in discussing the conformational change in greater detail.

K. N. S. thanks Professor Dr. Ko Ko Gyi of Rangoon University, Rangoon, Burma, for his kind permission to do research work in Japan.

(Received December 14, 1987)

Synopsis. Crystal structures of the titled compounds [Mn(Him)(salen)][ClO_4]CH_3OH (**1**) and [Mn(biim)(salen)][ClO_4] (**2**), have been determined by the single-crystal X-ray diffraction method. The molecular structure of the imidazole adduct (**1**) is a binuclear structure bridged by phenoxy oxygen atoms of salen ligand, while that of the 1,4-di(1-imidazolyl)butane adduct (**2**) is a polynuclear structure bridged by imidazole nitrogen atoms of 1,4-di(1-imidazolyl)-butane.

It is well-known that metal complexes with N,N'-ethylenebis[salicylideneamine] (well-known salen ligand) tend to assume a dimeric structure bridged by phenoxy oxygen atoms.[1] In this study the imidazole adduct and the 1,4-di(1-imidazolyl)butane adduct of [Mn(salen)][ClO_4] were prepared and their crystal structures were determined by a single-crystal X-ray diffraction technique in order to investigate their molecular structures.

Experimental

Synthesis. [Mn(Him)(salen)][ClO_4]CH_3OH (**1**). To a solution of [Mn(salen)][ClO_4]$2H_2O$ (2 mmol) in 30 cm^3 of methanol was added a solution of imidazole (3 mmol) in 10 cm^3 of methanol. The solution was gently warmed on a water bath for 10 min and cooled to room temperature. The solution was kept standing overnight. The dark-brown crystals precipitated were collected by suction filtration and dried. Found: C, 45.72; H, 4.31; N, 10.78%. Calcd for $MnClO_7N_4C_{20}H_{22}$: C, 46.13; H, 4.26; N, 10.76%. Mp >300 °C, Λ_M 88 S mol^{-1} cm^2 (methanol).

[Mn(biim)(salen)][ClO_4] (**2**). The complex (**2**) was prepared by a method similar to that of **1**, where 1,4-di(1-imidazoyl)butane instead of imidazole was used. Found: C, 51.07; H, 4.62; N, 13.75%. Calcd for $MnClO_6N_6C_{26}H_{28}$: C, 51.12; H, 4.62; N, 13.76%. Mp 253—257 °C, Λ_M 65 S mol^{-1} cm^2 (DMF).

Physical Measurements. Elemental analyses were performed by Mr. Shinichi Miyazaki at the Technical Service Center of Kumamoto University. Melting points were measured on a Yanagimoto micro-melting points apparatus and were uncorrected. Molar electrical conductivities were measured on a Denki Kagaku Keiki AOC-10 digital conductometer.

X-Ray Diffraction Study. Diffraction data for complexes **1** and **2** were obtained on a Rigaku Denki AFC-5 four-circle diffractometer at the Faculty of Science, Kyushu University, using graphite monochromatized Mo$K\alpha$ radiation at ambient temperature (20±1 °C). Pertinent crystallographic parameters are summarized below:

[Mn(Him)(salen)][ClO_4]CH_3OH (**1**). Formula=$MnClO_7N_4C_{20}H_{22}$, FW=520.8, triclinic, space group $P\bar{1}$, a=11.203(2) Å, b=11.565(2) Å, c=9.832(1) Å, α=112.25(1)°, β=107.50(1)°, γ=86.64(1)°, V=1119.9 Å^3, D_x=1.544 g cm^{-3} (Z=2), D_m=1.52 g cm^{-3}, crystal size 0.2×0.3×0.4 mm, scan mode θ-2θ, scan rate 6° min^{-1}, 2θ range 2.5°<2θ<48°, no. unique data used 2182, R=4.93%, R_w=5.16%.

[Mn(biim)(salen)][ClO_4] (**2**). Formula=$MnClO_6N_6C_{26}H_{28}$, FW=610.9, monoclinic, space group $P2_1/a$, a=16.566 (9) Å, b=16.141(4) Å, c=10.527(2) Å. β=102.81(2)°, V=2759.7 Å^3, D_x=1.470 g cm^{-3} (Z=4), D_m=1.46 g cm^{-3}, crystal size 0.2×0.2×0.4 mm, scan mode θ-2θ, scan rate 6° min^{-1}, 2θ range 2.5°<2θ<48°, no. unique data used 3204, R=5.62%, R_w=5.68%. One of two imidazole moieties of biim has been subjected to disorder. The occupancy factors for C(17) and C(18) atoms were assigned on the basis of the peak heights of the difference Fourier synthesis.

Reflection data were corrected for Lorentz-polarization effects but not for absorption. The structures were solved by the standard heavy-atom method and refined by a block-diagonal least-squares method using the Universal Crystallographic Computation Program System UNICS III.[2]

a) Occupancy factors: A 0.3; B 0.2; C 0.5.

The positions of hydrogen atoms were calculated. The hydrogen atoms were included in the structure factor calculation but not refined. The calculations were carried out on a FACOM M 200 computer at the Computer Center of Kyushu University. Positional parameters of non-hydrogen atoms for the complexes **1** and **2** are given in Tables 1 and 2, respectively. Tables of the anisotropic thermal parameters for non-hydrogen atoms, atomic parameters for hydrogen atoms, and F_o-F_c tables are given as supplementary data at the office of the Chemical Society of Japan as Document No. 8815.

Results and Discussion

Bond distances and angles with their estimated standard deviaitons of **1** and **2** are given in tables, which are deposited as supplementary data. Perspective drawings of the cations of **1** and **2** with the atom numbering scheme are shown in Figs. 1 and 2, respectively.

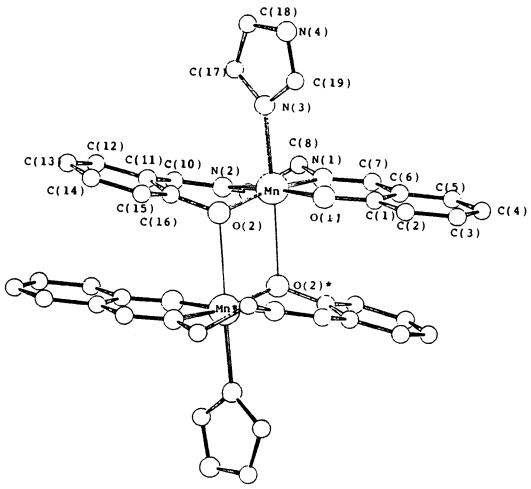

Fig. 1. Perspective drawing of **1** with the atom numbering scheme.

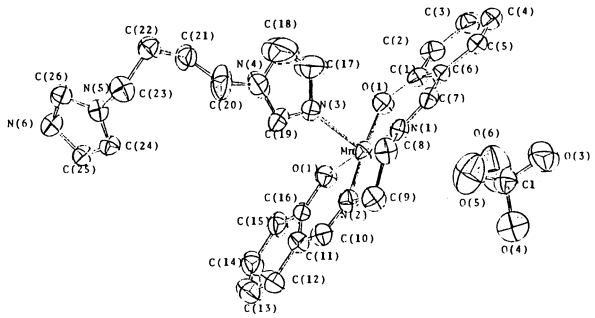

Fig. 2. Perspective drawing of unique molecule of [Mn(biim)(salen)][ClO_4] **2** with the atom numbering scheme.

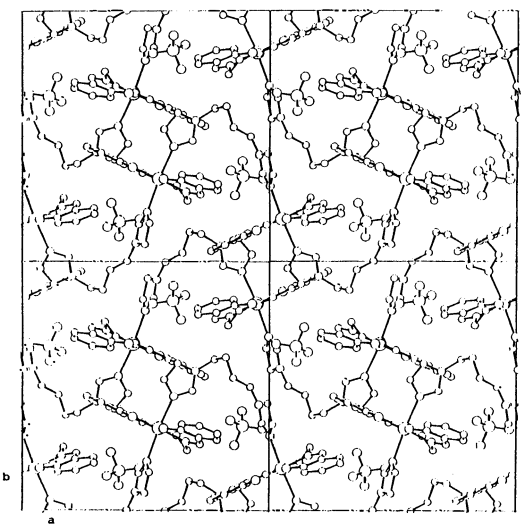

Fig. 3. Polynuclear structure of **2**.

Structural Description of [Mn(Him)(salen)][ClO_4] CH_3OH (1). As shown in Fig. 1, the structure of **1** is a binuclear structure bridged by phenoxy oxygen atoms

of salen ligands, in which two $[Mn(Him)(salen)]^+$ cations are related by an inversion center. The manganese(III) ion has a tetragonal bipyramidal coordination geometry, in which the basal coordination plane comprises N_2O_2 donors of quadridentate salen ligand; the two elongated axial positions are occupied by an imidazole nitrogen atom N(3) (Mn-N(3) 2.231(4) Å) and a phenoxy oxygen atom O(2)* of symmetry related salen ligand ($-x$, $-y$, $-z$) (Mn-O(2)* 2.635(3) Å). The imidazole plane lies on the Mn-O(1) and Mn-N(2) bonds.

Structural Description of [Mn(biim)(salen)][ClO_4] (2). The structure of **2** is a polymeric chain structure bridged by imidazole nitrogen atoms of 1,4-di(1-imidazolyl)-butane, as shown in Fig. 3. The manganese(III) ion has a tetragonal bipyramidal coordination geometry, in which the basl plane comprises N_2O_2 donors of the salen ligand; the two elongated axial positions are occupied by imidazole nitrogen atoms N(3) and N(6)* ($x+1$, $-y+1/2$, $z+1/2$) of biim ligands with the bond distances Mn-N(3) (2.278(5) Å) and Mn-N(6)* (2.283(4) Å).

Preparation and Resolution of Bis[tris(2-aminoethaneselenolato)-cobalt(III)-μ-Se, μ-Se', μ-Se'']cobalt(III) Complex

Shin MIYANOWAKI, Takumi KONNO,* Ken-ichi OKAMOTO, and Jinsai HIDAKA
Department of Chemistry, University of Tsukuba, Tsukuba, Ibaraki 305
(Received January 30, 1988)

Synopsis. The title *Se*-bridged complex, $[Co^{III}\{Co^{III}(aese)_3\}_2]^{3+}$ (aese=2-aminoethaneselenolate), was newly prepared by the reaction of *fac*-[Co(aese)$_3$] with Co^{2+} and separated into three isomers, *ΔΔ*, *ΔΛ*, and *ΛΛ*, by the ion-exchange chromatographic method. The isomers were characterized from their absorption, CD, and ^{13}C NMR spectra.

Thiolate ligands tend to form polynuclear metal complexes with μ-thiolato structure and several trinuclear cobalt(III) complexes with 2-aminoethanethiolate (aet) and L-cysteinate (L-cys) have been investigated.[1-12] This tendency is also expected for the selenolate ligand such as 2-aminoethaneselenolate (aese). However, up to now no study has appeared on the *Se*-bridged polynuclear cobalt(III) complexes. This note describes the preparation and resolution of the *Se*-bridged tricobalt(III) complex with 2-aminoethaneselenolate $[Co\{Co(aese)_3\}_2]^{3+}$ (Fig. 1). The isomers obtained are characterized from their absorption, CD, and ^{13}C NMR spectra in comparison with those of the corresponding tricobalt(III) complexes with 2-aminoethanethiolate, $[Co\{Co(aet)_3\}_2]^{3+}$.[3,4,9] The redox properties of $[Co\{Co(aese)_3\}_2]^{3+}$ and $[Co\{Co(aet)_3\}_2]^{3+}$ are also reported.

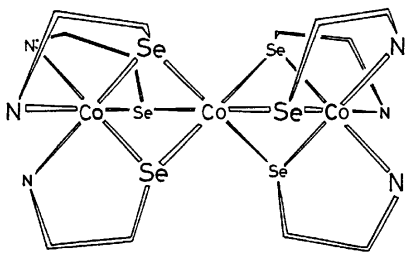

Fig. 1. The *ΔΔ* isomer of $[Co\{Co(aese)_3\}_2]^{3+}$.

Experimental

Preparation and Resolution of Complexes. 1) *fac*-[Co(aese)$_3$]: To a deoxygenated solution containing 0.7 g (18.2 mmol) of $NaBH_4$ in 45 cm^3 of water were successively added with stirring a deoxygenated solution containing 3.0 g (9.1 mmol) of $(NH_2CH_2CH_2Se-)_2\cdot 2HCl\cdot 0.5H_2O$[13] in 70 cm^3 of water and a deoxygenated solution containing 2.2 g (6.1 mmol) of $Na_3[Co(CO_3)_3]\cdot 3H_2O$ in 45 cm^3 of water. The mixture was continuously stirred at 60 °C for 5 h under nitrogen atmosphere. The resultant deep green complex was collected by filtration and washed with ethanol and ether. This complex is sparingly soluble in water. Found: C, 16.84; H, 4.24; N, 9.82%. Calcd for $[Co(aese)_3]=C_6H_{18}N_3Se_3Co$: C, 16.83; H, 4.21; N, 9.69%.

2) *meso*-$[Co\{Co(aese)_3\}_2]I_3$ and *rac*-$[Co\{Co(aese)_3\}_2]Cl_3\cdot 1.5H_2O\cdot NaCl$: To a suspension of 1.8 g (4.2 mmol) of *fac*-[Co(aese)$_3$] in 30 cm^3 of water was added a solution containing 0.5 g (2.1 mmol) of $CoCl_2\cdot 6H_2O$ in 10 cm^3 of water. The mixture was stirred at 40 °C for 1 h, whereupon the color of the solution became deep brownish green. Addition of a large amount of ethanol to the reaction solution in an ice bath yielded a deep green precipitate of $[Co\{Co(aese)_3\}_2]Cl_3$, which was collected by filtration.

One gram of $[Co\{Co(aese)_3\}_2]Cl_3$ was dissolved in a small amount of water and poured onto a column of SP-Sephadex C-25 (Na^+ form, 5.5 cm×45 cm). After the column had been swept with water, the adsorbed band was eluted with a 0.2 mol dm^{-3} aqueous solution of NaCl. A circulating-chromatographic technique was employed for the separation of the isomers. After circulating the eluate in the same column twice, two dark green bands, A-1 and A-2, were eluted in that order. It was found, from the result of the optical resolution procedure, that the A-1 and A-2 eluates contained *meso*- and *rac*-$[Co\{Co(aese)_3\}_2]^{3+}$, respectively. Each eluate was concentrated to a small volume with a rotary evaporator below 25 °C. On cooling the concentrated eluate in a refrigerator overnight, crystals of the A-2 isomer appeared and were collected by filtration. This isomer was recrystallized twice from water by adding ethanol in an ice bath. The crystals of the A-1 isomer were obtained as an iodide salt by adding a large amount of saturated NaI solution to the concentrated eluate. These aese tricobalt(III) isomers are unstable in aqueous solution in comparison with the aet tricobalt(III) ones. Found for A-1: C, 11.03; H, 2.78; N, 6.30%. Calcd for $[Co\{Co(aese)_3\}_2]I_3=C_{12}H_{36}N_6I_3Se_6Co_3$: C, 11.12; H, 2.80; N, 6.49%. Found for A-2: C, 13.11; H, 3.59; N, 7.64%. Calcd for $[Co\{Co(aese)_3\}_2]Cl_3\cdot 1.5H_2O\cdot NaCl=C_{12}H_{39}N_6O_{1.5}NaCl_4Se_6Co_3$: C, 13.02; H, 3.55; N, 7.59%.

3) Optical Resolution of $[Co\{Co(aese)_3\}_2]^{3+}$: The A-2 isomer was optically resolved by column chromatography, while the A-1 isomer could not be resolved. An aqueous solution of the A-2 isomer (0.2 g) was charged on the top of an SP-Sephadex C-25 column (Na^+ form, 4 cm×85 cm). Two bands were separated by eluting with a 0.2 mol dm^{-3} aqueous solution of $K_2[Sb_2(d\text{-tart})_2]\cdot 3H_2O$. After the separation into two bands, each adsorbed band was eluted with a 0.2 mol dm^{-3} aqueous solution of NaCl. It was found from the CD spectral measurements that the earlier moving band contained $(-)^{CD}_{680}$-$[Co\{Co(aese)_3\}_2]^{3+}$ and the later one contained $(+)^{CD}_{680}$-$[Co\{Co(aese)_3\}_2]^{3+}$. The $\Delta\varepsilon$ values of them were evaluated on the basis of the absorption spectrum of the racemic chloride salt.

4) Preparation and Resolution of $[Co\{Co(aet)_3\}_2](NO_3)_3$: This complex was prepared from *fac*-[Co(aet)$_3$] and $CoCl_2\cdot 6H_2O$ by the method of Busch et al.[3] Three isomers, *ΔΔ*, *ΔΛ*, and *ΛΛ*, were chromatographically separated according to the procedures described in 2) and 3).

Measurements. The electronic absorption spectra were recorded with a JASCO UVIDEC-610A spectrophotometer, the diffuse reflection spectra with a JASCO UVIDEC-1 spectrophotometer, and the CD spectra with a JASCO J-20 spectropolarimeter. The ^{13}C NMR spectra were recorded with a JEOL JNM-FX-90Q NMR spectrometer at the probe temperature in a D_2O solvent. Sodium 2,2-dimethyl-2-silapentane-5-sulfonate (DSS) was used as the internal reference. The cyclic voltammograms were recorded with a Hokuto Denko potentiogalvanostat, model HA-201, to which a linear potential scanner, model HB-103, was at-

tached. A grassy carbon electrode, a Pt wire counter electrode with a sufficiently large surface area, and a 3.33 mol dm^{-3} KCl calomel reference electrode were used for the potentiostatic measurements in a 0.01 mol dm^{-3} sodium nitrate solution at room temperature (20±1 °C). The electrode potential data were corrected to those for the standard hydrogen electrode (SHE).

Results and Discussion

Two geometrical isomers, *fac* and *mer*, are possible for the tris(2-aminoethaneselenolato)cobalt(III) complex, [Co(aese)$_3$]. The diffuse reflection spectrum of the selenolato complex which belongs to the [Co(N)$_3$(Se)$_3$] type is similar to that of the *fac* isomer of the corresponding thiolato complex, [Co(aet)$_3$] (Fig. 2). This suggests that the selenolato complex takes selectively the *fac* geometry as well as the corresponding thiolato complex.[3,14] The reflection spectrum of *fac*-[Co(aese)$_3$] shifts to lower energy than that of *fac*-[Co(aet)$_3$] in accordance with the fact that the ligand field strength is selenolate < thiolate.[15] Three isomers, *ΔΔ*, *ΔΛ*, and *ΛΛ*, are expected for [Co{Co(aese)$_3$}$_2$]$^{3+}$, considering the absolute configurations of two terminal *fac*-[Co(aese)$_3$] (Fig. 1), as in the case of [Co{Co(aet)$_3$}$_2$]$^{3+}$.[4] The A-1 and A-2 isomers exhibit similar absorption spectra, showing two intense d-d bands at ca. 17 and 21×10^3 cm^{-1} and more intense charge transfer bands at ca. 26 and 33×10^3 cm^{-1} (Fig. 3). This absorption spectral behavior coincides well with that of the tricobalt(III) complex with 2-aminoethanethiolate, [Co^{III}{Co^{III}(aet)$_3$}$_2$]$^{3+}$, whose molecular structure has been determined by single crystal X-ray analysis.[9] Therefore, both the A-1 and A-2 isomers can be assigned to the tricobalt(III) complex with 2-aminoethaneselenolate, [Co^{III}{Co^{III}-(aese)$_3$}$_2$]$^{3+}$. The absorption components of [Co{Co(aese)$_3$}$_2$]$^{3+}$ commonly shift to lower energy than those of [Co{Co(aet)$_3$}$_2$]$^{3+}$ (Fig. 3) and this behavior is consistent with that of the cobalt(III) complexes with selenium- or sulfur-containing ligands.[15-20]

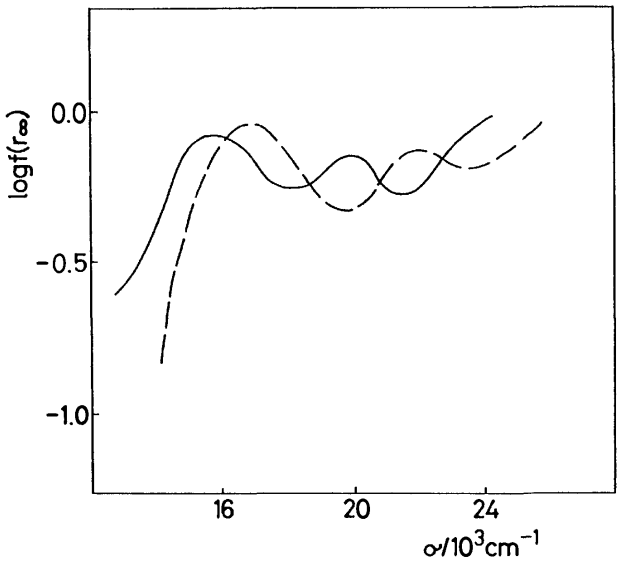

Fig. 2. Diffuse reflection spectra of *fac*-[Co(aese)$_3$] (——) and *fac*-[Co(aet)$_3$] (-----).

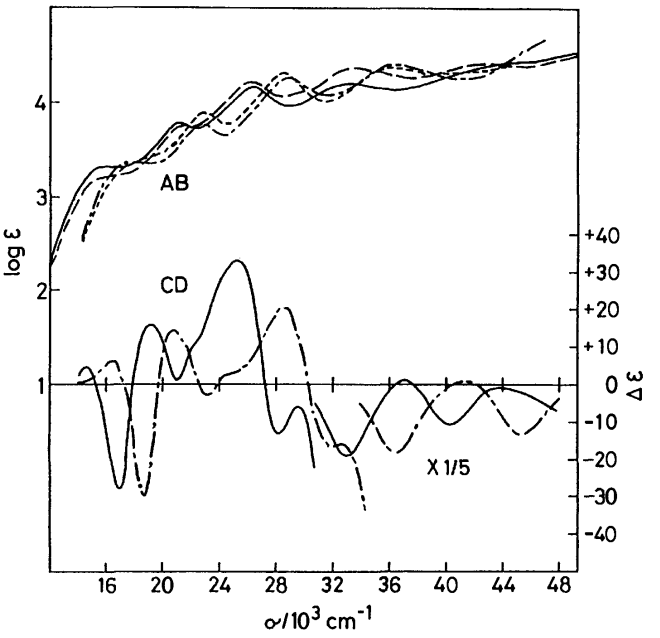

Fig. 3. Absorption and CD spectra of *ΔΔ*-[Co{Co(aese)$_3$}$_2$]$^{3+}$ (——), *ΔΛ*-[Co{Co(aese)$_3$}$_2$]$^{3+}$ (----), *ΔΛ*-[Co{Co(aet)$_3$}$_2$]$^{3+}$ (-·-·-), and *ΔΛ*-[Co{Co(aet)$_3$}$_2$]$^{3+}$ (------).

The A-2 isomer was optically resolved into the $(+)^{CD}_{680}$ and $(-)^{CD}_{680}$ ones, while the A-1 isomer could not. This result suggests that the A-1 and A-2 isomers take meso and racemic forms respectively, taking the similarity of their absorption spectra into consideration. This assignment is also supported by their ^{13}C NMR spectral behavior. Namely, both trinuclear isomers exhibit two ^{13}C NMR resonance lines due to two methylene carbons of the aese ligand; 27.09 and 49.68 ppm for the meso (A-1) isomer having S_6 symmetry, and 26.71 and 49.52 ppm for the racemic (A-2) isomer having D_3 symmetry. The $(+)^{CD}_{680}$ isomer exhibits the CD spectrum enantiomeric to the $(-)^{CD}_{680}$ one over the whole region. The CD spectral pattern of the $(+)^{CD}_{680}$ isomer agrees well with that of *ΔΛ*-[Co{Co(aet)$_3$}$_2$]$^{3+}$ (Fig. 3)[4] and furthermore, that of *Λ*$_{LLL}$*Λ*$_{LLL}$-[Co{Co(L-cys-*N*,*S*)$_3$}$_2$]$^{3-}$ whose absolute configuration has been determined by the single crystal X-ray analysis,[11] though the CD bands of the aese isomer shift significantly to lower energy than those of the aet isomer in parallel with their absorption spectral behavior. Accordingly, it is confidently assigned that the $(+)^{CD}_{680}$ isomer is *ΔΛ*-[Co{Co(aese)$_3$}$_2$]$^{3+}$ and the $(-)^{CD}_{680}$ isomer is the *ΔΔ* one.

The trinuclear complexes, [Co{Co(aese)$_3$}$_2$]$^{3+}$ and [Co{Co(aet)$_3$}$_2$]$^{3+}$, display a quasi-reversible cyclic response with $E_{1/2}$=−0.47 V for [Co{Co(aese)$_3$}$_2$]$^{3+}$ and $E_{1/2}$=−0.46 V for [Co{Co(aet)$_3$}$_2$]$^{3+}$, and no other redox process is observed in the potential range of −0.7—+0.5 V. The anodic and cathodic peaks separation, $E_{pa}-E_{pc}$, is 95 mV for [Co{Co(aese)$_3$}$_2$]$^{3+}$ and 65 mV for [Co{Co(aet)$_3$}$_2$]$^{3+}$, and the anodic peak current and the cathodic peak current are nearly equal for the two complexes. A similar redox reaction ($E_{1/2}$=−0.43 V, $E_{pa}-E_{pc}$=90 mV) was observed for the tricobaltate(III)

complex with L-cysteinate, $[Co\{Co(L\text{-}cys\text{-}N,S)_3\}_2]^{3-}$,[12] where the quasi-reversible redox reaction was assigned as the Co(III)/Co(II) redox process due to the central cobalt ion. Therefore, it is probable that the central cobalt ion is the active site of the redox reaction between Co(III) and Co(II) oxidation states for the present tricobalt(III) complexes with the aese and with the aet.

Ylide-Metal Complexes. XIV.[1] An X-Ray Photoelectron Spectroscopic Study on Tellurium Complexes of Methylenetriphenylphosphorane

Hidetaka KONNO† and Yoshihisa YAMAMOTO*
Faculty of Pharmaceutical Sciences, Higashi Nippon Gakuen University, Ishikari-Tobetsu, Hokkaido 061-02
†Faculty of Engineering, Hokkaido University, Sapporo 060
(Received February 4, 1988)

Synopsis. A series of new tellurium complexes of methylenetriphenylphosphorane, $(C_6H_5)_3P{=}CH_2$ (**L**), namely, dichlorobis(methylenetriphenylphosphorane)tellurium dichloride, $[L_2TeCl_2]Cl_2$, chlorotris(methylenetriphenylphosphorane)tellurium trichloride, $[L_3TeCl]Cl_3$, and tetrakis(methylenetriphenylphosphorane)tellurium tetrachloride, $[L_4Te]Cl_4$, were examined by XPS. Binding energies of Te 3d electrons for the complexes are considerably lower than those for common Te(IV) compounds such as $(C_6H_5)_2TeCl_2$, $TeCl_4$ (correctly Te_4Cl_{16}) and others, and they diminished with increasing number of **L**'s and decreasing number of bonded chlorine atoms, indicating that **L** is an electron donor. Bonded chlorine atoms and free chloride ions were clearly distinguished from the binding energy of Cl $2p_{3/2}$ electrons.

The preparation and properties of ylide metal complexes have been widely investigated in recent years. However, the electronic states of ylide metal complexes have not been reported except for the Cu and Au complexes.[1,2] In a previous paper,[3] we reported a series of new tellurium complexes of methylenetriphenylphosphorane, $(C_6H_5)_3P{=}CH_2$ (**L**), namely, dichlorobis(methylenetriphenylphosphorane)tellurium dichloride, $[L_2TeCl_2]Cl_2$, chlorotris(methylenetriphenylphosphorane)tellurium trichloride, $[L_3TeCl]Cl_3$, and tetrakis(methylenetriphenylphosphorane)tellurium tetrachloride, $[L_4Te]Cl_4$. The present paper deals with the electronic states of the above tellurium complexes by means of X-ray photoelectron spectroscopy (XPS).

Experimental

Preparation of dichlorobis(methylenetriphenylphosphorane)tellurium(IV) dichloride, $[\{(C_6H_5)_3P{=}CH_2\}_2TeCl_2]Cl_2$ (**1**), chlorotris(methylenetriphenylphosphorane)tellurium(IV) trichloride, $[\{(C_6H_5)_3P{=}CH_2\}_3TeCl]Cl_3$ (**2**), and tetrakis(methylenetriphenylphosphorane)tellurium(IV) tetrachloride, $[\{(C_6H_5)_3P{=}CH_2\}_4Te]Cl_4$ (**3**), were carried out as reported previously.[3]

For XPS measurements, samples were placed on a gold mesh holder and introduced into a spectrometer in a 99.9995% pure nitrogen atmosphere. After evacuating to a vacuum better than 2.7×10^{-5} Pa, the sample was cooled to 180—200 K. The instrument was a VG ESCA 3 electron spectrometer and Mg $K\alpha$ X-ray (50 W) was used. Peak separation was made by a nonlinear least squares method using a mixed Gaussian-Lorentzian curve shape. The background level was determined by a method proposed by Shirley,[4] in which the level was assumed to increase in proportion to the spectral intensity, and contributions by X-ray satellites were excluded. The electron-binding energies, E_B, were calibrated by assigning 285.0 eV to the C 1s peak of the phenyl carbons in methylenetriphenylphosphorane.[1,2]

Results and Discussion

Results of XPS Measurements: Binding energy, E_B, data for three complexes are summarized in Table 1. Apparently, no indication of decomposition of the complexes was observed in regard to the ligand ylide, since E_B values and relative peak widths for phosphorus were in a range comparable to those for the ylide or the ylide-gold complexes.[2] After peak separation, however, a second peak appeared in Te 3d spectra (peak (b) in Table 1) for complexes **1**—**3** and a third peak appeared in Cl 2p spectra (peak (c) in Table 1) for complexes **1** and **2**. This indicates that, in spite of

careful sample handling and measuring procedures, partial decomposition of the complexes could not be avoided. As expected from its instability,[3] decomposition was considerable for **1** judging from the intensity of the second peak of Te 3d. It is probable that the decomposition was caused by a trace amount of oxygen or water vapor during handling. Damage by X-ray irradiation can be disregarded, because no appreciable change in Te 3d spectra was observed after irradiating with 440 W-h of Mg$K\alpha$ X-ray, which is about four times the irradiation for taking all the spectra. Since the samples were contaminated by decomposition products, we shall only consider the binding energy data of the complexes and avoided quantitative discussion. It was unfortunate that the validity of the peak separation could not be supported by relative peak intensities. However it is unlikely that the accuracy of peak separation is less than the case of gold complexes previously reported,[1] where the results were examined quantitatively.

Electronic States of Ylide and Tellurium Atom: The E_B[P 2p] and E_B[P 2s] for ligand ylide in complexes **1—3** are practically identical as shown in Table 1. Further, E_B[P 2p] agrees with the values for ylide (**L**) (132.6 eV), triphenylmethylphosphonium bromide, $[(C_6H_5)_3PCH_3]Br$ (**4**), (132.6±0.4 eV), and chlorobis(methylenetriphenylphosphorane)gold(I), $[(C_6H_5)_3P{=}CH_2]_2AuCl$ (**5**), (132.4±0.4 eV), reported previously.[1,2] The E_B[P 2s] for **1—3** is also in agreement with that[2] (190.1 eV) for **L**, but is slightly higher than that[2] (189.6—8 eV) for **5**. The lower E_B[P 2s] for **5** was found to be due to the interference by X-ray satellite peaks of Cl 2p orbitals. After correction for the interference, E_B[P 2s] for **5** agreed with that for **1—3**; with the previous calculation program,[2] contributions by X-ray satellites could not be excluded. These results indicate that the electronic state of phosphorus in complexes **1—3** is identical to that in **L** and complex **5**.

It was not possible to separate the ylide methylene carbon peak from the phenyl carbon peak in **1—3**, precisely.[2] According to the ^{1}H NMR spectra,[3] however, the electronic state of the ylide methylene group in **1—3** is considered to be similar to that of the methyl group in **4**, that is, the chemical shift[3] (δ=3.15—3.30) of CH_2P in **1—3** agrees with that[5] (δ=3.17) of PCH_3 in **4**, but differs from the values of CH_2P in **L**[6] (δ=0.13) and **5**[7] (δ=1.7). This suggests that the carbanion of the ylides in **1—3** is donating electrons to the tellurium atom and the density of the electrons on the tellurium may be higher than that in common Te(IV) compounds.

An example of a Te 3d spectrum for **3** is shown in Fig. 1. The E_B[Te 3d] of peak (a) for each complex is assigned to the Te(IV) in each complex, and peak (b) to decomposition products. Since, as mentioned above, a methylene carbon in a ligand ylide is anionic[1,2,8] and a donor of electrons, it is able to raise the density of electrons on the central tellurium atom and lower the E_B. The E_B[Te 3d] values for **1—3** are lower than those[9-11] for common Te(IV) compounds: usually, E_B[Te $3d_{5/2}$]=575.3 eV and E_B[Te $3d_{3/2}$]=585.7 eV and two examples, diphenyltellurium(IV) dichloride, $(C_6H_5)_2TeCl_2$ (**6**), and $TeCl_4$ (**7**) (correctly, Te_4Cl_{16})[12] are shown in Table 2. In addition, E_B[Te 3d] values for **1—3** decrease slightly with increasing number of bonded ylides. The fall of E_B[Te 3d] can be caused both by increasing the number of bonded ylides and decreasing the number of bonded chlorine atoms. Further, it is considered that the donation of electrons from the ylides to the tellurium atom in **1—3** may be larger than in the case in gold complex **5**.[2] The conjecture is parallel to the results of ^{1}H NMR for CH_2P in tellurium[3] and gold[7] complexes. As a first approximation, the chemical shifts, ΔE_B, can be explained by a ligand chemical shift,[9,13] in which ΔE_B is a sum of each ligand chemical shift of bonded ligands, ΔE(j), that is, $\Delta E_B=\sum\Delta E(j)$. The ligand chemical shift by

Ph_2TeCl_2	576.2[a]		0.75	586.6[a]		0.75
$TeCl_4$	576.9		0.63[b]	587.3		0.63[b]
$(NH_4)_2TeCl_6$	576.9[a]		0.63	587.4[a]		0.63

Ph: C_6H_5.
a) Cited from Ref. 7 where original data[5] were converted by using E_B[C 1s]=284.8 eV for adventitious hydrocarbon. b) An average of six coordinated chlorine atoms.

the ylide, $\Delta E(\mathbf{L})$, can be calculated from E_B[Te $3d_{5/2}$] for **3** as follows by using E_B[Te $3d_{5/2}$] for metal Te, the mean value of which is calculated at 573.0±0.2 eV from compiled data:[11]

$$\Delta E(\mathbf{L}) = (574.3 - 573.0)/4 = 0.33 \text{ eV}.$$

As described above, the electronic states of bonded ylides in **1**—**3** are equivalent. Then, the ligand chemical shift by chlorine atom can be calculated as follows:

from complex **1**,

$\Delta E(\text{Cl}) = (574.7 - 573.0 - 0.33 \times 2)/2 = 0.52$ eV, and

from complex **2**,

$\Delta E(\text{Cl}) = 574.5 - 573.0 - 0.33 \times 3 = 0.51$ eV.

This agreement implies that the chlorine atoms in **1** and **2** are also equivalent in bonding. The ΔE(Cl) values in **1** and **2** are a little smaller than that in $(NH_4)_2TeCl_6$ (**8**) as shown in Table 2. In the case of $TeCl_4$ (**7**), which is a tetramer and should be expressed as Te_4Cl_{16},[12] each tellurium forms three short bonds to chlorine atoms (bond length 0.2312—0.2317 nm[12] and bond order 1.18[9]) and three long bonds to bridging chlorine atoms (bond length 0.2898—0.2959 nm[12] and bond order 0.11[9]), so that the contribution from the former chlorine atoms may be larger than 0.63 eV in Table 2 and that from the bridging atoms may be smaller. The structures of complexes **1** and **6** are essentially the same as for diphenyltellurium(IV) dibromide, $(C_6H_5)_2TeBr_2$ (**9**), whose structure is a distorted tetrahedron having nearly linear Br-Te-Br bonds.[14] In consideration of a smaller ΔE(Cl) in complex **1**, the Te-Cl bond length in **1** may be longer than that in **6**. The bond in complex **2** will be similar to that in **1**, as ΔE(Cl) is nearly the same.

Electronic States of the Bonded Chlorine Atom and the Free Chloride Ion: Only one chlorine species was identified in complex **3** (Table 1) and E_B[Cl $2p_{3/2}$] was close to those for $[(CH_3)_4]N^+Cl^-$[1] and similar type chloride ions in others.[15] Therefore, it is clear that peak (a) of Cl $2p_{3/2}$ for each complex is assigned to the free chloride ion. The reproducibility of E_B[Cl $2p_{3/2}$] of peak (b) for **1** and **2** is poorer compared with that of peak (a), but this peak can be assigned to bonded chlorine atom, since E_B[Cl $2p_{3/2}$] values are in a similar range with that for bonded chlorine atom in **5**.[1,2] Then, peak (c) is attributed to decomposition products. The E_B[Cl $2p_{3/2}$] of peak (c) is close to that[16] (199.9 eV) for a type of bridging chlorine atom, e.g., $Mo_6Cl_{12}(phen)_2$, phen: 1,10-phenanthroline, but it will be imprudent to conclude this at present. Due to partial decomposition of the complexes, the intensity ratios between peak (a) and (b) for **1** and **2** do not correspond to the atomic ratios of 2 : 2 and 3 : 1.

As a conclusion, all the XPS data obtained in the present work support the structures of the complexes which were constructed from the NMR data and the elemental analysis.[3]

Determination of Iodide Ion Using Alkali-Free Lead Phosphate Glasses as Potentiometric Detector Sensors in Nonsuppressed Ion Chromatography

Tsuyoshi NOMURA,* Yasuo HIKICHI, and Genkichi NAKAGAWA
Department of Materials Science and Engineering, Nagoya Institute of Technology, Gokiso-cho, Showa-ku, Nagoya 466
(Received February 8, 1988)

Synopsis. Alkali-free lead phosphate glasses containing silver oxide show a linear relationship with the Nernstian slope for iodide concentration. By using these glass membranes as potentiometric detector sensors for ion chromatography, the limit of detection for iodide ion was extended down to 0.05 $\mu g\,cm^{-3}$. The high sensitivity can be interpreted in terms of the strong interaction between iodide ion and the silver ion incorporated in the membrane material.

A wide variety of detectors are presently used for the determination of iodide ion in ion chromatography, and have been quantified by the conductimetric method[1] and the UV absorbsnce method,[2,3] in addition to the electrochemical detector methods such as the amperometric method[4] and the potentiometric method.[5] The potentiometric detector method, chiefly using ion-selective electrodes, has been reported by a number of workers.[6,7] Various types of ion-selective glass electrodes are available. However, most of those glasses respond to cationic species,[8,9] and no reports on anion-responsive glass electrodes have apparently been published to date. We have already investigated some alkali-free phosphate glasses as sensing materials for nitrate ion[10] and as potentiometric detector sensors for ion chromatography.[11]

This paper reports on properties of lead phosphate glass membranes containing silver oxide and on their application to the analysis of iodide ion as potentiometric detector sensors for ion chromatography.

Experimental

Apparatus. Alkali-free lead phosphate glasses were prepared as previously described.[11] Chemical compositions of some of the tested glasses, their potential changes per decade change in iodide ion activity, and their physical and chemical properties are listed in Table 1.

A schematic diagram for an ion-chromatographic system is shown in Fig. 1. It consists of a Toso Co. HLC-803D pump with a Rheodyne sample injector with a 100 mm^3 sample loop, a combination of a TSK IC-A guard column and duplicated TSK Gel IC anion SW anion separator columns, two valves (V1 and V2) of a column changing switch, and a DKK Co. ion-selective flow cell with some improvements. Under the ordinary circumstances, the guard column and only separator column SW 1 were used. However, when the iodide concentration in seawater was determined, most of chloride ion was eluted by column SW 1, valve 2 was switched back on the line after about an 8 min period, and the chromatogram of iodide ion was obtained by column SW 2.

Both of peak height (potential difference, mV) and peak area gave essentially straight lines against the logarithmic iodide concentration. Therefore, the peak height was routinely used for the determination of iodide concentration.

Solutions. Aqueous solutions of inorganic anions and sodium citrate eluent were prepared by the corresponding sodium salts of analytical reagent grade with twice distilled water. Before use, the eluent was degassed under vacuum with sonication. Artificial seawater was prepared as previously described.[12]

Recommended Procedure. A 10 cm^3 sample solution containing a 0.03 $\mu g\,cm^{-3}$ iodide species was taken in a 50 cm^3 beaker, and 1.0 cm^3 of 10^{-3} $mol\,dm^{-3}$ ascorbic acid was added to reduce the iodide species to iodide. Sodium citrate

Table 1. Chemical Compositions and Properties of Glasses

Glass no.	Chemical composition (Ag_2O : P_2O_5 : PbO : Al_2O_3, mol%)				Physical and chemical property: Transition temp	Softening temp	Thermal expansion	Membrane resist.	Chemical durability	Potential change
					°C	°C	$10^7/cm\,°C^{-1}$	$M\Omega\,cm^{-1}$	$10^4\,mg\,mm^{-2}$	mV/pI^-
1	—	55	35	10	433	506	102.4	37.6	8.96	35.2
2	5	55	30	10	447	536	118.1	24.4	7.78	52.3
3	10	55	25	10	506	567	113.4	29.6	16.5	58.2
4	15	55	20	10	493	552	120.6	39.2	14.6	48.9

eluent of 0.5 mmol dm^{-3} (pH about 5.0) was pumped at a flow rate of 1.0 cm^3 min^{-1}. For direct determination of iodide, a 100 mm^3 sample was injected and determined by comparison with the standard iodide concentration. Elution curves were obtained in the order: BrO_3^-, Cl^-, ClO_3^-, NO_2^-, Br^-, NO_3^- I^-, SCN^-, and ClO_4^-.

Results and Discussion

Properties of Glasses and Potential Response of Glass Electrodes. As is evident from Table 1, the values of physical and chemical properties of the lead phosphate glasses containing silver oxide are not so much different from those containing no silver oxide. The potential response for the glass number 3 in Table 1 is linear over the iodide ion activity range 10^{-1}—5×10^{-6} mol dm^{-3}, and it has a Nernstian response of about 58 mV per decade change in iodide activity at 25 °C. However, the glass electrode containing no silver oxide yields only a small unstable potential response for iodide.

Detection of Iodide Ion Using Lead Phosphate Glass Membrane Electrode in the Potentiometric Detector for Ion Chromatography. Figure 2 shows the chromatograms for 4 anions obtained with the potentiometric detectors for lead phosphate glass electrode No. 3(A) and No. 1(B) and with the conductivity detector (C), column SW 1 being used as the separator column and 0.5 mmol dm^{-3} sodium citrate (pH 4.96) as the eluent.

In measurement of peak heights for iodide ion, a negative dip peak is observed at the end of the iodide ion peak, and it increases with decreasing pH of the eluent and with increasing iodide ion concentration.

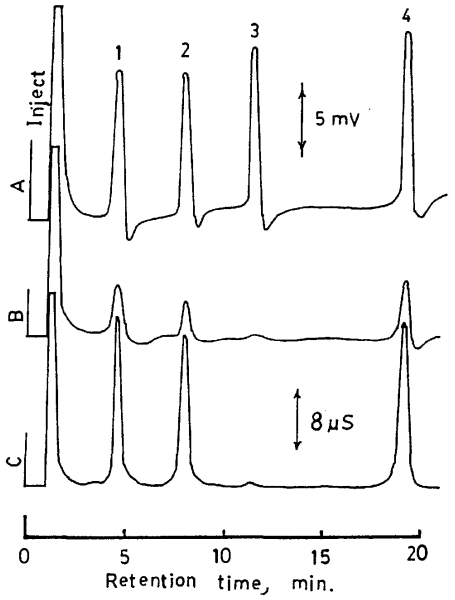

Fig. 2. Ion chromatograms of 4 anions with anion-exchange column. Eluent: 0.5 mol dm^{-3} sodium citrate (pH 4.96). Detector system: A: $10Ag_2O:55P_2O_5:25PbO:10Al_2O_3$ glass detector; B: $55P_2O_5:35PbO:10Al_2O_3$ glass detector; C: Conductivity detector. Anionic species: 1: 5 μg cm^{-3} Cl^-; 2: 10 μg cm^{-3} NO_3^-; 3: 0.4 μg cm^{-3} I^-; 4: 10 μg cm^{-3} ClO_4^-.

The glass number 3 detector is capable of detecting iodide ion with an extremely high sensitivity as compared with the other detectors. This suggests that the addition of silver ion in the glass material has led to the high sensitivity in potential response to iodide ion. Silver ion forms insoluble salts with anions such as Cl^-, Br^-, I^-, SCN^-, S^{2-}, and PO_4^{3-}, so that the insoluble silver iodide adsorbs strongly on the detector glass surface, resulting in the high sensitivity to iodide.

The sensitivity of UV absorbance method for the detection of iodide ion is as high as that of this method, but such anions as fluoride, chloride, and perchlorate ions will provide no sufficient absorbances for UV radiation.

Effect of Eluent pH on the Retention Time. Figure 3 shows the effect of eluent pH on the retention time of 5 anions. Decreasing the eluent pH produces good separation of peaks, but the accuracy for the measurement on these anions decreases due to the increase of the negative dip peak at the end of each peak. Therefore, the eluent pH around 5.0 yields only a small variation in the retention time for each anion, resulting in

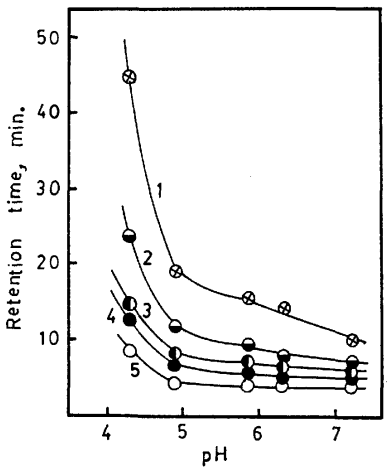

Fig. 3. Effect of pH on the retention time. Eluent: 0.5 mol dm^{-3} citric acid (pH 4.2—7.2). 1: ClO_4^-; 2: I^-; 3: NO_3^-; 4: Br^-; 5: Cl^-.

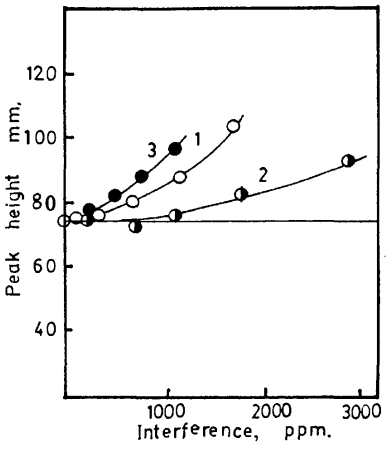

Fig. 4. Effect of diverse anions on the determination of 0.63 μg cm^{-3} iodide. Eluent: 0.5 mol dm^{-3} sodium citrate (pH≈5.0). 1: Br^-; 2: Cl^-; 3: NO_3^-.

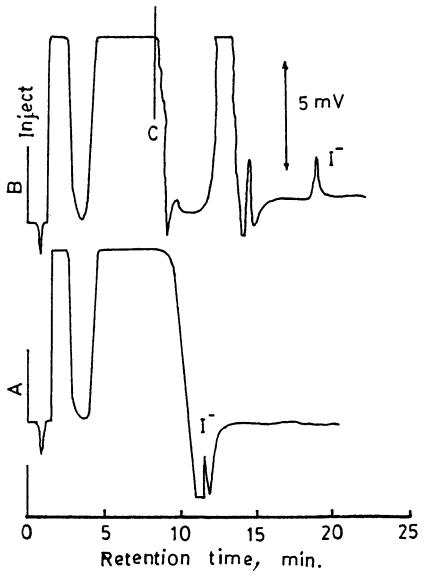

Fig. 5. Chromatograms of artificial seawater sample. Composition of artificial seawater: Cl^- 19 mg cm^{-3}, Br^- 65 μg cm^{-3}, I^- 0.06 μg cm^{-3} and IO_3^- 0.02 μg cm^{-3}. A: chromatogram of SW 1 column. B: chromatogram as similar to A when switched onto the line of SW 2 column after 8 minutes period. C: the place where the valve V 2 is switched onto the line of SW 2 column.

a favorable result will respect to the separation of each anion.

The peak height is considered to be proportional directly to the logarithmic concentration of iodide ion between 0.05 and 1.5 μg cm^{-3}. The relative standard deviation for five separate runs on 0.05 μg iodide ion in 100 mm^3 was about 4%. The detection limit of this procedure was estimated to be 3 ng for direct injection of 100 mm^3.

Interferences. Interferences of diverse ions, such as chloride, bromide, and nitrate ions, with the determination of 0.63 μg cm^{-3} of iodide ion are shown in Fig. 4. Of the anions examined, chloride, bromide, and nitrate ions cause interference if the specified amounts are exceeded (about 1500 for chloride, 400 for bromide, and 200 μg cm^{-3} for nitrate for the determination of 0.63 μg cm^{-3} of iodide). Iodate ion gives a small response and has a retention time different from that of iodide ion.

The amounts of the halogenic anions generally existing in seawater are about 0.05—0.06 μg cm^{-3} of total iodine, 65 μg cm^{-3} of bromide ion, and 19 mg cm^{-3} of chloride ion, so that the total iodine in seawater cannot be determined by the present procedure. When applying this procedure to the practical seawater, most of chloride ions must be removed by pretreatment.

The determination of total iodine in seawater is to be made as follows: (1) Ascorbic acid is added to reduce iodate to iodide, (2) a 200 mm^3 sample is injected, (3) chromatographic separation of anions is run with column SW 1 positioned as indicated in Fig. 1, (4) after most of chloride ions have passed through the detector (after 8 min), V2 valve is switched over to the line of column SW 2, and (5) the chromstogram of iodide ion is recorded with column SW 2.

Figure 5 shows typical chromatograms for the artificial seawater sample (Cl^- 19 mg cm^{-3} and Br^- 65, I^- 0.06, and IO_3^- 0.02 μg cm^{-3}) by both the ordinary method and the two column method. By the latter method, the large negative dip peak associated with chloride ion can be removed from the iodide peak, and the total iodide concentration can be determined accurately.

This work was supported by a Grant-in-Aid for General Scientific Research No. 62540433 from the Japanese Ministry of Education.

Synopsis. A flow-injection analysis method for the determination of a small amount of protein has been established by the use of the ultrasonic chemiluminescence of luminol. The present method was based on the phenomenon that the catalytic activity of cobalt(II) for the ultrasonic chemiluminescence of luminol decreased in the presence of protein. The apparatus consisted of only a luminol solution line equipped with an ultrasonic irradiation bath and a cobalt(II) catalyst solution line equipped with a sample inlet. Under optimum conditions, similar calibration curves were obtained for bovine serum albumin, bovine serum γ-globulin, human serum albumin, and human serum γ-globulin. According to the present method, these proteins could be determined in the concentration range 5.0×10^{-6}—1.0×10^{-1} g dm^{-3}, with a detection limit of 200 pg (injected sample volume 40 mm^3, S/N=2) and a coefficient of variation of 2.9% (n=8) at a rate of about 60 samples per hour.

The authors have already reported the flow-injection analysis (FIA) method for the determination of a small amount of protein using a 5-animo-2,3-dihydro-1,4-phthalazinedione (luminol) or a 1,10-phenanthroline (phen)-hydrogen peroxide (H_2O_2)-copper(II) system.[1,2] These methods were about 10^2—10^6 times as sensitive as the conventional methods, such as colorimetry and fluorometry for the determination of protein.[3,4] However, an improvement of the analytical capabilities and a simplification of the flow system have also been desired in these methods.

A selective, sensitive method for the determination of cobalt(II) (Co(II)) was established by Suzuki et al., in which the ultrasonic chemiluminescence (CL) reaction of luminol was utilized.[5] This method was carried out using a simple flow-injection system without a H_2O_2 line. On the other hand, the phenomenon that the catalytic activity of the cobalt(III) complex compound for the CL reaction between luminol and H_2O_2 decreased in the presence of protein was found by the authors in the previous paper.[6]

In the present study, a new FIA method for the determination of protein was established by the use of an ultrasonic CL reaction by which Co(II) at sub-pg levels could be detected and the complex formation between Co(II) and protein. Some improvements were achieved compared with the previous study,[2] regarding the following points: detection limit, coefficient of variation, sampling rate, and simplification of a flow system.

Experimental

Reagents. All the reagents used were of a commercially available special grade. Ion-exchange water was distilled for use. A 5.0×10^{-9} mol dm^{-3} Co(II) catalyst solution was prepared by diluting a Co(II) stock solution containing 1.0×10^{-3} mol dm^{-3} cobalt(II) chloride, 1.0×10^{-3} mol dm^{-3} hexadecyltrimethylammonium bromide (HTAB), and 1.0×10^{-1} mol dm^{-3} hydrochloric acid with a buffer solution (pH 10.2) containing 1.0×10^{-1} mol dm^{-3} boric acid, 1.0×10^{-1} mol dm^{-3} potassium hydroxide, and 1.0×10^{-3} mol dm^{-3} HTAB. A 5.0×10^{-5} mol dm^{-3} luminol solution containing 1.0×10^{-1} mol dm^{-3} sodium hydroxide (NaOH) was prepared for use. All the sample solutions of bovine serum albumin (BAS) from Nakarai Chemical Ltd., human serum albumin (HSA) from Chemical Dynamics Corporation, and bovine serum γ-globulin (BγG) and human serum γ-gulobulin (HγG) from Sigma Chemical Co. were prepared by dissolving and diluting them with the above-mentioned buffer solution.

Apparatus and Procedure. A schematic diagram of the FIA apparatus was shown in Fig. 1. The luminol solution (a) was fed at a flow rate of 1.5 cm^3 min^{-1} by means of a pump (P_1) (PERISTA MINI PUMP SJ-1211) and passed through a cooling bath (k), followed by the exposure to the ultrasonic irradiation in sonication cell (m) (0.7 cm i.d., 1.4 cm^3 volume) made of poly-propylene by mean of an oscillator (Tomy Seiko Co., Handy Sonic Model UR-20P; 28 kHz, max. 20W) equipped with an exponential horn (1). Then, the luminol solution was fed into a flow cell at a flow rate

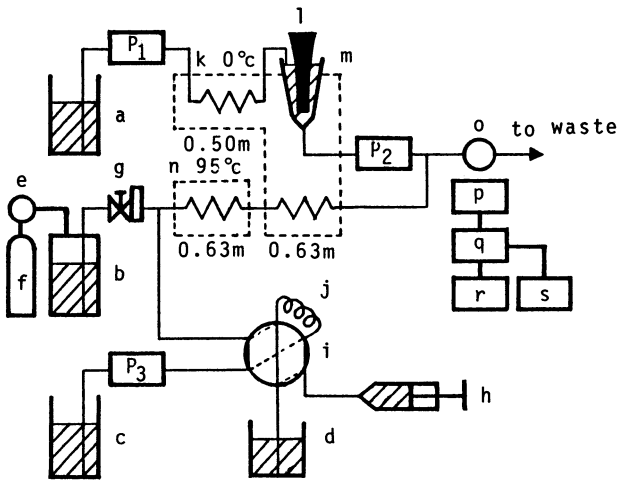

Fig. 1. Schematic diagram of the flow-injection system. a: Luminol solution, b: Co(II) catalyst solution, c: buffer solution, d: sample solution, e: regulator, f: N_2 cylinder, g: flowmeter equipped with a needle valve, h: syringe, i: six-way cock, j: sampling loop, k: cooling bath, l: exponential horn, m: sonication cell, n: heating bath, o: flow cell, p: photomultiplier, q: amplifier, r: recorder, s: integrator, and P_1, P_2, P_3: pump.

of 1.5 cm^3 min^{-1} by means of a pump (P_2) (PERISTA MINI PUMP SJ-1221).

The Co(II) catalyst solution (b) was fed at a flow rate of 1.0 cm^3 min^{-1} by means of an N_2 gas cylinder; the buffer solution (c) was fed at a rate of 1.5 cm^3 min^{-1} by means of a high-pressure pump (P_3) (Nishio kogyo Co., Ltd., SSP DM3M-2044). A definite volume (40 mm^3) of a protein sample solution (d) was injected into the buffer solution line through the sampling loop (j) and the six-way cock (i) (Reodyne). The injected protein sample solution was mixed with the Co(II) catalyst solution, passed through the heating bath (n) and the cooling bath, mixed with the luminol solution, and finally fed to the flow cell.

The CL intensity of the solution containing no sample was recorded as a base line, while the CL intensity of the solution containing protein was record as a negative peak because the catalytic activity of Co(II) decreased due to the formation of a complex compound between Co(II) and protein. The amount of protein was estimated from the peak area.

Results and Discussion

Optimization of Experimental Conditions. Prior to the determination of protein, the optimum concentrations of luminol, NaOH, Co(II), and HTAB were examined. Bovine serum albumin was used as a model protein.

The relationship between the luminol concentration and the peak area as well as the relationship between the NaOH concentration and the peak area were examined. Both the luminol concentration and the NaOH concentration did not affect the noise of the base line. From the experimental results, the optimum concentrations of luminol and NaOH were chosen as the concentrations which gave the maximum peak area. The relationship between the Co(II) concentration and the peak area or detection limit (S/N=2) are shown in Fig. 2. Both the peak area and the noise of the base line increased with increasing Co(II) the concentration; however, the optimum Co(II) concentration was chosen as the Co(II) concentration which gave a minimum detection limit.

In order to examine the catalytic effect of micelle on the CL intensity, HTAB (cationic surfactant), TritonX-100 (nonionic surfactant), and sodium dodecyl sulfate (SDS) (anionic surfactant) were used. The CL intensity in the presence of 1.0×10^{-3} mol dm^{-3} HTAB or 1.0×10^{-3} mol dm^{-3} TritonX-100 and in the absence of surfactant were 160, 27, and 75 mV respectively. Since SDS did not dissolve in the buffer solution (pH 10.2), HTAB was used in the present study. The relationship between the HTAB concentration and the peak area or detection limit (S/N=2) are shown in Fig. 3. Both the peak area and the noise of the base line increased with increasing HTAB concentration; however, the optimum HTAB concentration was chosen as the HTAB concentration which gave a minimum detection limit.

On the basis of these results, the following optimum

a) As BSA. b) Coefficient of variation.

concentrations of various reagents were used in the study thereafter: 5.0×10^{-5} mol dm^{-3} luminol, 1.0×10^{-1} mol dm^{-3} NaOH, 5.0×10^{-9} mol dm^{-3} Co(II), and 1.0×10^{-3} mol dm^{-3} HTAB.

Determination of Various Proteins. The calibration curves shown in Fig. 4 were obtained under the optimized conditions for a determination of various proteins. The responses for BSA, BγG, HSA, and HγG were almost similar. These proteins could be determined in the concentration range of 5.0×10^{-6}—1.0×10^{-1} g dm^{-3} with a detection limit 200 pg (injected sample volume 40 mm^3, S/N=2).

Since H_2O_2 was unnecessary in the present method, the FIA apparatus used in the present study consisted only of the luminol solution line equipped with an ultrasonic irradiation bath and the Co(II) catalyst solution line equipped with a sample inlet. The peak shape obtained by the present method was much sharper than that obtained by the previous method.[2] This seemed to be due to a reduction in the dilution degree of the sample solution in the simplified FIA system, which had two lines different from the previous system having three lines. The detection limit (S/N=2), coefficient of variation, and sampling rate are as follows: 1 ng (injected sample volume 50 mm^3), 4.9% (1.0×10^{-3} g dm^{-3} BSA, n=10), and about 20 samples per hour (1.0×10^{-2} g dm^{-3} BSA) in the previous method; 200 pg (injected sample volume 40 mm^3), 2.9% (1.0×10^{-3} g dm^{-3} BSA, n=8), and about 60 samples per hour (1.0×10^{-2} g dm^{-3} BSA) in the present one. Protein up to 250 pg could be detected using the previous method; however, it can be obtained only by the use of the amplifying effect of an amino acid. As can be seen from the above-mentioned results, the present method was superior to the previous one regarding analytical capabilities and a simplification of the flow system.

Comparison of the Present Method with the Other FIA Methods. Several FIA methods for a determination of protein have recently been reported. As can be seen from Table 1, the present method was superior regarding the detection limit and the concentration range for a determination of protein to the other FIA methods.

Ligand-Substitution Reaction Kinetics of Tris(8-quinolinolato)- and Bis-(2-methyl-8-quinolinolato)(8-quinolinolato)aluminum(III) Complexes with Ethylenediamine-*N,N,N',N'*-tetraacetic Acid

(Received February 22, 1988)

Synopsis. Ligand-substitution reactions of $[Al(hq)_3]$ and $[Al(hq)(mhq)_2]$ (H(m)hq: (2-methyl-)8-quinolinol) with H_4edta have been studied at 25 °C and 1.0 mol dm^{-3} NaCl by means of the stopped-flow spectrophotometric method. Three concurrent reaction pathways, a dissociative activation one and two parallel associative activation ones, to which H_2edta^{2-} and $Hedta^{3-}$ contribute, are elucidated.

Only one ligand-substitution reaction kinetics of aluminum(III) chelate complexes with multidentate ligands has been studied,[1] although they are of fundamental importance in the elucidation of the kinetic characteristics of aluminum(III). In our previous paper,[1] a ligand-substitution reaction of an aluminum(III) complex containing 7-[(2-carboxyphenyl)-azo]-8-hydroxy-5-quinolinesulfonic acid (H_3pqs) with 8-hydroxy-5-quinolinesulfonic acid was studied; it was found that the reaction proceeds with dissociative activation and with the liberation of one of the pqs^{3-} in $[Al(pqs)_2]^{3-}$ as the rate-determining step. In a subsequent investigation of the ligand-substitution reactions of an aluminum(III) complex containing 8-quinolinol (Hhq) and one containing Hhq and 2-methyl-8-quinolinol (Hmhq) with ethylenediamine-*N,N,N',N'*-tetraacetic acid (H_4edta); it was found, besides the dissociative activation process, which has been accepted as a general kinetic feature of aluminum-(III) (vide infra), that there exist processes in which the coordinating ligand participates and that these processes take place concurrently. This paper will be concerned with the ligand-substitution reaction kinetics and mechanisms of $[Al(hq)_3]$ and $[Al(hq)(mhq)_2]$ with H_4edta.

Experimental

Complexes. $[A(hq)_3]\cdot 1/2H_2O$. This complex was prepared from stoichiometric mixtures of aluminum(III) and Hhq in an ethanolic aqueous solution of pH 5—6.[2] Found: C, 69.75; H, 4.05; N, 8.80%. Calcd for $C_{27}H_{19}N_3O_{3.5}Al$: C, 69.22; H, 4.08; N, 8.97%.

$[Al(hq)(mhq)_2]\cdot 1/2H_2O$. Hmhq (3.2g, 0.020 mol) in 200 cm^3 ethanol was added to $AlK(SO_4)_2\cdot 12H_2O$ (4.7 g, 0.010 mol) in 200 cm^3 of an aqueous solution below pH 4. To the solution we then added Hhq (1.5 g, 0.010 mol) in 100 cm^3 of ethanol, and the resulting solution was adjusted to pH 5—6 with aqueous NH_3 to obtain a crystalline precipitate. The complex was recrystallized from acetone and was dried in vacuo at 140 °C for 7 h. Found: C, 70.38; H, 4.11; N, 8.87%. Calcd for $C_{29}H_{23}N_3O_{3.5}Al$: C, 70.15; H, 4.66; N, 8.46%.

Measurements. Kinetic runs were carried out in an ethanolic aqueous solution (ethanol, 10 vol%) of 1.0 mol dm^{-3} NaCl at 25.0±0.2 °C on a JASCO stopped-flow spectrophotometer[3] under pseudo-first-order kinetic conditions with respect to the H_4edta concentration. The change in the absorbance with the time was followed at 260 nm, where the aluminum(III) complexes of the 8-quinolinolate-type ligands (10^{-5}—10^{-3} mol dm^{-3}, λ_{max}: ca. 252 nm) showed a maximum absorbance against the free ligand. The rate constant, k_{obsd}, was calculated from Eq. 1:

$$\ln (A_0 - A_\infty)/(A_t - A_\infty) = k_{obsd}\, t \qquad (1)$$

Here, A_0, A_t, and A_∞ stand for absorbances at the initial state, at time t, and at equilibrium respectively. The hydrogen-ion concentration was measured, in principle, according to the literature procedure.[3] Analysis by the curve-fitting method (vide infra) was carried out with an NEC PC-9801VM2 personal computer.

Results and Discussion

The ligand-substitution reaction kinetics of $[Al(hq)_n(mhq)_{3-n}]$ (n=1 and 3) with H_4edta proceed in weakly acidic aqueous media (pH 3.0—4.5), where H_4edta is present mainly in the species of H_3edta^-, H_2edta^{2-}, $Hedta^{3-}$ and slightly in that of H_4edta.[4] The preliminary absorption spectral study gave evidence that $[Al(hq)_n(mhq)_{3-n}]$ turned quantitatively into $[Al(edta)]^-$ at equilibrium under the kinetic conditions specified in the experimental section. The dependence of the absorbance at a specified wavelength on the time

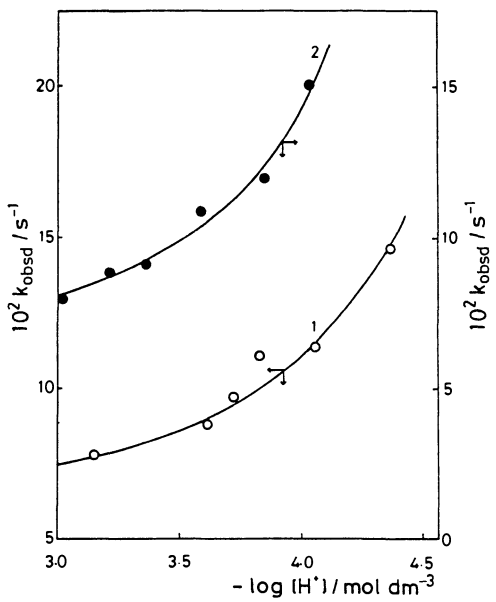

Fig. 1. Relation between k_{obsd} and $-\log[H^+]$. 1: $[Al(hq)_3]$, 1.49×10^{-5} mol dm^{-3}; and C_{edta}, 3.79×10^{-3} mol dm^{-3}. 2: $[Al(hq)(mhq)_2]$, 1.53×10^{-5} mol dm^{-3}; and C_{edta}, 3.78×10^{-3} mol dm^{-3}. 1.0 mol dm^{-3} NaCl (ethanol, 10 vol%), 25 °C.

conformed well to Eq. 1 for more than three half-life periods under a constant total H_4edta concentration, C_{edta}, and hydrogen-ion concentration, $-\log[H^+]$; this fact indicates that there is only one rate-determining step in the ligand-substitution reaction. The experimental data obtained under pseudo-first-order kinetic conditions with respect to C_{edta} are shown in Figs. 1 and 2. These data indicate that k_{obsd} depends not only on $-\log[H^+]$ but also on C_{edta}; k_{obsd} increases exponentially with the increases in $-\log[H^+]$ and in $\log C_{edta}$. The dependence of k_{obsd} on C_{edta} implies that H_4edta contributes to the ligand-substitution reaction. Hence, the rate equation can be given as follows (cf. Appendix):

$$-d[[Al(hq)_n(mhq)_{3-n}]]/dt = k_{obsd}[[Al(hq)_n(mhq)_{3-n}]]$$
$$k_{obsd} = \{k_d + [f_2([H^+]) + f_4([H^+])]C_{edta}/f_1([H^+])\}/[1 + f_3([H^+])]C_{edta}/f_1([H^+]) \quad (2)$$

Equation 2 indicates that the k_{obsd} vs. C_{edta} curve at a constant $-\log[H^+]$ should be asymptotic to a limiting line of:

$$k_{obsd,\infty} = [f_2([H^+]) + f_4([H^+])]/f_3([H^+]) \quad (2')$$

with an increase in C_{edta}. This is not the case for the present investigation, as is evident from Fig. 2 for $[Al(hq)_3]$. Therefore, the contribution of the $f_3([H^+])$ and $f_4([H^+])$ terms in Eq. 2 should be negligible; any possibilities can be excluded of the k_{osj} process and hence of any contribution of a mechanism in which a coordinated ligand is replaced by an entering ligand in the outer-sphere complex as the mechanistic rate-determining step. Accordingly, Eq. 2 can be simplified as follows:

$$k_{obsd} = k_d + [f_2([H^+])/f_1([H^+])]C_{edta} \quad (3)$$

It is reasonable to assume that the presence of H_4edta species and the contribution of the k_{i_4} pathway to the kinetics can be neglected above $-\log[H^+]$ of 3 (vide infra). Therefore, Eq. 3 can be modified to Eq. 4:

$$k_{obsd} = k_d + k_{i3}C_{edta} + \{(k_{i2} - k_{i3})K_{a2}[H^+] + (k_{i1} - k_{i3})\}C_{edta}/(K_{a3}K_{a2}[H^+]^2 + K_{a2}[H^+] + 1) \quad (4)$$

Equation 4 can be analyzed for the k_{obsd} vs. $-\log[H^+]$ relation by means of the curve-fitting method[5] with a normalized curve of:

$$Y = (av + b)/((K_{a3}/K_{a2})v^2 + v + 1\} + c,\ X = -\log v \quad (5)$$

with $a \equiv (k_{i2} - k_{i3})C_{edta}$, $b \equiv (k_{i1} - k_{i3})C_{edta}$, and $c \equiv k_d + k_{i3}C_{edta}$. Likewise, Eq. 4 can be analyzed for the k_{obsd} vs. $\log C_{edta}$ relation with a normalized curve of:

$$Y' = a'u + c',\ X' = \log u \quad (6)$$

with $a' \equiv f_2([H^+])/f_1([H^+])$ and $c' \equiv k_d$. Hence, the k_{ij}'s and k_d can be estimated from the a, b, c, and c' constants and the experimental parameter of C_{edta}. These rate constants can then be refined by using the a' constant, the K_{aj}'s, and the experimental parameter of $-\log[H^+]$. The k_{obsd} vs. $-\log[H^+]$ and the k_{obsd} vs. $\log C_{edta}$ relations in Figs. 1 and 2 were used for the analysis; the rate constants thus estimated are summarized in Table 1. The k_{i_3} rate constant was found to be negligibly smaller than k_d, which indicates that the k_{i_3} pathway, like the k_{i_4} one, does not contribute to the ligand-substitution processes. Hence, the substitution reaction of $[Al(hq)_n(mhq)_{3-n}]$ with H_4edta is concluded to proceed through the k_d and the k_{ij} (j: 1 and 2) pathways, to the latter of which H_2edta^{2-} and $Hedta^{3-}$ contribute, as the rate-determining steps.

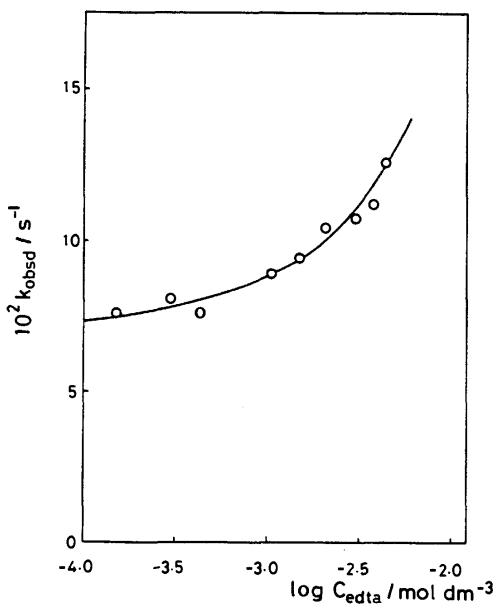

Fig. 2. Relation between k_{obsd} and $\log C_{edta}$. $[Al(hq)_3]$, 1.49×10^{-5} mol dm^{-3}; and $-\log[H^+]$, 3.83. 1.0 mol dm^{-3} NaCl (ethanol, 10 vol%), 25 °C.

It was found in the present investigation that the ligand-substitution reaction of $[Al(hq)_n(mhq)_{3-n}]$ with H_4edta proceeds through three reaction pathways, irrespective of the composition of the starting complex. The rate constants decrease in the following order: $k_{i1} > k_{i2} > k_d$ ($k_{i3} \fallingdotseq k_{i4} \fallingdotseq 0$). Each rate constant differs slightly with different compositions of the complex. Therefore, we would like to focus our attention first on the reaction kinetics of $[Al(hq)_3]$.

The dissociative activation pathway (k_d) of $[Al(hq)_3]$ is considered to originate from the nature of the aluminum(III) of an octahedral coordination.[6] In fact, the k_d of 7×10^{-2} s^{-1} of $[Al(hq)_3]$ is in fairly good agreement with that of 3×10^{-2} s^{-1} of $[Al(pqs)_2]^{3-}$,[1] when differen-

Table 1. Rate Constants for the Ligand-Substitution Reactions

Complex	k_d/s^{-1}	k_{i2}/mol^{-1} dm^3 s^{-1}	k_{i1}/mol^{-1} dm^3 s^{-1}	Remarks
$[Al(hq)_3]$	$(7.3\pm0.5)\times10^{-2}$	3.6±0.2	$(1.30\pm0.05)\times10^3$	This work[a]
$[Al(hq)(mhq)_2]$	$(7.5\pm0.5)\times10^{-2}$	4.0±0.2	$(2.38\pm0.05)\times10^3$	This work[a]
$[Al(pqs)_2]^{3-}$	$(3.00\pm0.43)\times10^{-2}$	—	—	Ref. No. 1[b]

a) 1.0 mol dm^{-3} NaCl (ethanol, 10 vol%), 25 °C. b) 0.1 mol dm^{-3} NaCl, 25 °C.

ces in the configuration and the chelate-ring structure of these two complexes are taken into consideration. The dissociative activation pathway may be initiated by a cleavage of the metal-oxygen bond of the coordinated quinolinolato ligand, for the Al-O bond of $[Al(hq)_3]$ has been estimated, by the ^1H NMR spectral[7] and the magnetic circular dichroism spectral[8] studies, to be dominantly ionic and highly labile.

There are two parallel associative activation pathways (k_{i1} and k_{i2}) in competition with the dissociative activation one (k_d). The k_{i1} rate constant, to which $Hedta^{3-}$ relates, is about three orders of magnitude larger than the k_{i2} rate constant, to which H_2edta^{2-} relates. This difference in the rate constants can not be ascribed simply to formation of the outer-sphere complex with the entering ligand by ionic or related interaction, because $[Al(hq)_3]$ has no formal charge and because no experimental evidence on the formation of the outer-sphere complex was obtained; the difference can, however, be ascribed to numbers of the protons blocking the coordination sites of the entering ligand.

Two associative activation mechanisms, the associative (A) and the associative interchange (I_a), can possibly explain the k_{i1} and k_{i2} pathways. However, the I_a mechanism may be more probable than the A one in view of the facts that aluminum(III) of a small ionic radius prefers intrinsically to take the dissociative interchange (I_d) mechanism[1,9] and that the k_{i1} and k_{i2} pathways do not become appreciable until the concentration of the entering ligand reaches a high point compared with that of the starting complex. These reaction pathways may be initiated by the substitutional interchange of the coordinated bulky quinolinolato ligand with the glycinate ligating group of H_4edta, probably to form an intermediate of the $[Al(hq)_2(Hedta\text{-}O,N)]^{2-}$ type.

No appreciable differences were noticed in the rate constants of $[Al(hq)_3]$ and $[Al(hq)(mhq)_2]$. These two ligands may take an equal opportunity to leave in the first step.

Appendix

The following general expression of k_{obsd} can be derived from the text:

$$k_{obsd} = \frac{k_d + \sum_{j=1}^{4} k_{ij}[H_j\,edta^{(4-j)-}] + \sum_{j=1}^{4} k_{osj}\,K_{osj}[H_j\,edta^{(4-j)-}]}{1+\sum_{j=1}^{4} K_{osj}[H_j\,edta^{(4-j)-}]}. \quad (A1)$$

Here, k_d, k_{ij}, and k_{osj} are the rate constants for the dissociative activation, the associative activation, and the outer-sphere complex related reaction processes, while K_{osj} is the formation constant for the outer-sphere complex. Equation A1 can, by using C_{edta} ($=\sum_{j=1}^{4}[H_jedta^{(4-j)-}]$), be rearranged to Eq. 2 with:

$$f_1([H^+]) \equiv (K_{a4}K_{a3}K_{a2}[H^+]^3 + K_{a3}K_{a2}[H^+]^2 + K_{a2}[H^+] + 1)K_{a1}[H^+], \quad (A2)$$

$$f_2([H^+]) \equiv (k_{i4}K_{a4}K_{a3}K_{a2}[H^+]^3 + k_{i3}K_{a3}K_{a2}[H^+]^2 + k_{i2}K_{a2}[H^+] + k_{i1})K_{a1}[H^+], \quad (A3)$$

$$f_3([H^+]) \equiv (K_{os4}K_{a4}K_{a3}K_{a2}[H^+]^3 + K_{os3}K_{a3}K_{a2}[H^+]^2 + K_{os2}K_{a2}[H^+] + K_{os1})K_{a1}[H^+], \quad (A4)$$

$$f_4([H^+]) \equiv (k_{os4}K_{os4}K_{a4}K_{a3}K_{a2}[H^+]^3 + k_{os3}K_{os3}K_{a3}K_{a2}[H^+]^2 + k_{os2}K_{os2}K_{a2}[H^+] + k_{os1}K_{os1})K_{a1}[H^+], \quad (A5)$$

where the K_{aj}'s are the protonation constants of H_4edta ($K_{aj}=[H_jedta^{(4-j)-}]/[H^+][H_{j-1}edta^{(5-j)-}]$, j: 1—4).[4]

(Received February 6, 1988)

Synopsis. Germanium vapor (atom) when co-condensated with THF at 77 K was found to be reactive toward organic halides. Several organogermanium halides were prepared by the addition of organic halides to the resultant germanium atom-THF slurry at ambient temperatures.

The co-condensation of metal vapor (atom) with certain solvents has been reported to make very reactive metal surfaces (slurries in solution).[2)] With this method it is becaming feasible to synthesize organometallic compounds, which would be difficult to prepare by other methods, at ambient conditions. However, there have been few reports on the reactivities of group 4B metal vapor-solvent slurries.[3)] Particularly no reports on silicon and germanium atoms-solvent slurries have appeared. In studying the reaction of germanium atoms in the condensed phase,[4-6)] we have found that germanium vapor (atom)-THF co-condensate is reactive toward organic halides. Here, we report on a new method for the preparation of organogermanium halides using germanium atom-THF co-condensate (slurry) at ambient temperatures.

Results and Discussion

A reactive germanium metal surface was conveniently produced by the co-condensation of germanium vapor with THF and by the use of essentially the same apparatus and conditions described previously (ca. 1200—1300 °C, 5×10^{-3} Torr, 1 Torr=133.322 Pa).[4)] Germanium metal was evaporated at a rate of ca. 10 mg min^{-1}, while an excess of THF was co-condensed on the wall of a quartz reaction flask containing the crucible and a perforated inlet tube through which THF was introduced. The reaction flask was immersed in liquid nitrogen during the germanium evaporation. Germanium atoms that co-condensed with THF were warmed to room temperature. The ensuing germanium atom-THF slurry was found to react with organic halides under argon. The size of particles in the germanium atom-THF slurry ranged from 0.7 to 18 μm as shown in Fig. 1.[7)]

Reactions of germanium atom-THF slurry with organic halides were examined. Germanium-containing products are summarized in Table 1. Bromotrichloromethane ($BrCCl_3$) reacted with this germanium atom-THF slurry at 50 °C for 5 h to give germanium tetrachloride ($GeCl_4$) (ca. 1.0%) and (trichloromethyl)-tribromogermane (CCl_3GeBr_3) The yields of germanium-containing products increased slightly at 50 °C for 20 h, as shown in Table 1. On the other hand, no reaction of $BrCCl_3$ took place with commercially available germanium powder (200 mesh) under these reaction conditions.

Reactions of germanium atom-solvent slurries with $BrCCl_3$ were also examined using various solvents. The yields of germanium-containing products were extremely low when a germanium atom-hexane slurry was used. No reaction of $BrCCl_3$ with germanium-benzene slurry occurred. The yields of germanium-containing products decreased roughly in the order: THF > DME ≃ hexane ≫ benzene. The differences of reactivities of solvents employed in this study might be attributed to the size and shape of particles in the germanium atom-solvent slurries. Similar results have been reported for nickel[1e)] and calcium atoms.[8)] Carbon tetrachloride (CCl_4) reacted with germanium atom-THF slurry to give $GeCl_4$ (ca. 1.0%) and (trichloromethyl)trichlorogermane (CCl_3GeCl_3) (3.0%). When $GeCl_4$ was used as a substrate, germanium atom-THF slurry produced hexachlorodigermane (Ge_2Cl_6) (10.0%) and octachlorotrigermane (Ge_3Cl_8) (3.0%). The reactions of germanium atom-THF slurry with sulfur monochloride (S_2Cl_2) and trichlorophophine (PCl_3) gave only $GeCl_4$ in 6.0 and 2.0% yields, respectively. No reaction of germanium atom-THF slurry with chloroform occurred.

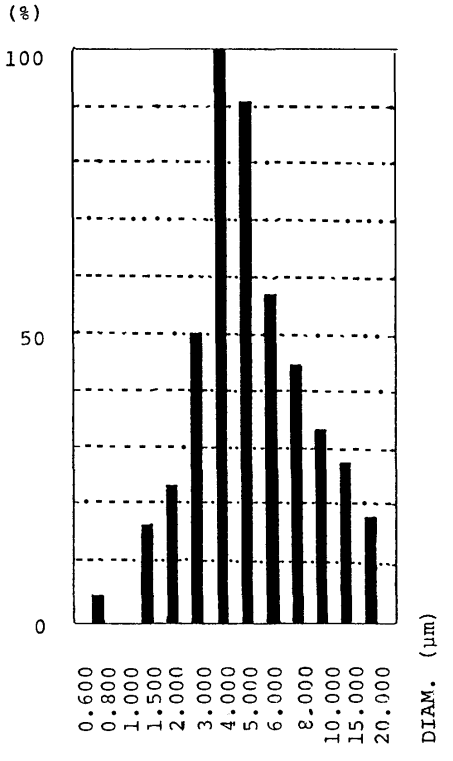

Fig. 1. Differential graph of germanium atom-THF slurry.

Table 1. Reactions of Germanium Atom-Solvent Slurries with Organic Halides

Halide (RX)	Solvent	Condition	Product (Yield/%)[a]
$BrCCl_3$	THF	50 °C, 5 h	$GeCl_4$ (ca. 1.0),[b] CCl_3GeBr_3 (2.5)
$BrCCl_3$	THF	50 °C, 20 h	$GeCl_4$ (ca. 1.0),[b] CCl_3GeBr_3 (3.5)
$BrCCl_3$	DME	50 °C, 5 h	$GeCl_4$ (trace), CCl_3GeBr_3 (1.5)
$BrCCl_3$	Hexane	50 °C, 5 h	$GeCl_4$ (trace), CCl_3GeBr_3 (1.0)
$BrCCl_3$	Hexane	50 °C, 20 h	$GeCl_4$ (trace), CCl_3GeBr_3 (1.5)
$BrCCl_3$	Benzene	50 °C, 20 h	No reaction
CCl_4	THF	50 °C, 5 h	$GeCl_4$ (ca. 1.0),[b] CCl_3GeCl_3 (3.0)
$GeCl_4$	THF	50 °C, 5 h	Ge_2Cl_6 (10.0), Ge_3Cl_8 (3.0)
S_2Cl_2	THF	50 °C, 5 h	$GeCl_4$ (6.0)
PCl_3	THF	50 °C, 5 h	$GeCl_4$ (2.0)
$CHCl_3$	THF	50 °C, 5 h	No reaction
MeI	THF	50 °C, 5 h	$MeGeI_3$ (1.0), Me_2GeI_2 (1.0)
EtI	THF	50 °C, 5 h	$EtGeI_3$ (1.0), Et_2GeI_2 (1.0)

a) Yields of products are based on the amount of germanium metal used. b) The retention time of $GeCl_4$ on GLC was partially overlapped with that of solvents.

Methyl iodide reacted with germanium atom-THF slurry to produce methyltriiodogermane ($MeGeI_3$) (1.0%) and dimethyldiiodogermane (Me_2GeI_2) (1.0%). With ethyl iodide, germanium atom-THF slurry produced ethyltriiodogermane ($EtGeI_3$) (0.5%) and diethyldiiodogermane (Et_2GeI_2) (0.5%).

The reactions of this germanium atom-THF slurry with organic halides proceed under milder conditions than a general direct synthesis of organogermanium halides,[9,10] although the yields of products are very low.

Experimental

GLC analyses were performed on a Shimazu GC-6A and 8A gas chromatograph equipped with a 2m×column packed with 20% SE-30 on celite 545. Infrared spectra were recorded on a Hitachi 260-10 spectrometer. GC-MASS spectra were obtained with a JEOL JMS-DX 303 mass spectrometer and data analyses were performed on a JMN-DA 5000 mass data system. ^1H NMR spectra were recorded on a Varian FT 80A, using tetramethylsilane as an internal standard.

Materials. The organic halides were commercially available products. THF and other solvents were dried over benzophenone ketyl and distilled before use. $MeGeI_3$,[11] Me_2GeI_2,[9] $EtGeI_3$,[11] and Et_2GeI_2[12] were prepared according to the cited literature.

Preparation of Gremanium Atom-Solvent Slurries. Germanium atom-solvent slurries were produced using essentially the same apparatus and conditions described previously.[4] A typical procedure is described below. Germanium metal (0.5 g, 6.9 mmol) was vaporized at a rate of ca. 10 mg min^{-1}, at a temperature of 1200—1300 °C using a resistence-heated, alumina-coated tungsten spiral crucible (5.0—6.0 V, 15 A) connected to copper electrodes, in vacuo (ca. 5×10^{-3} Torr). During the vaporization of germanium metal, a large excess of THF (20 cm^3) was introduced as a vapor through a perforated inlet tube. The THF was co-condensed onto the wall of a quartz reaction flask was immersed in liquid nitrogen during the entire operation. Then, the reaction flask was allowed to warm to room temperature and was left to stand for 1 h. The reaction flask was evacuated and then filled with argon.

Reactions of Germanium Atom-THF Slurry with Organic Halides. The reaction with $BrCCl_3$ is described as a typical example. The germanium atom-THF slurry was shaken vigorously and a given volume of the germanium atom-THF slurry was quickly placed in a two-necked 50-cm^3 flask equipped with a serum cap and a reflux condenser in an argon-filled glove box. Ten times molar amounts of $BrCCl_3$ were then syringed in. The reaction mixture was stirred at 50 °C for 5 h under argon. The products were identified by comparing their GC-MASS[4,5] and their retention times on GLC with those of authentic samples.

Identification of Products. The known compounds were identified by comparing their GC-MS and retention times on GLC with those of authentic samples. The unkown compounds were carefully identified by comparing their GC-MS with those of similar samples and by parent peaks and cleavage patterns considering natural abundance of germanium (ratio, $^{70}Ge/^{72}Ge/^{73}Ge/^{74}Ge/^{76}Ge=56/75/21/100/21$) and chlorine (ratio, $^{35}Cl/^{37}Cl=75.4/24.6$). $^{74}Ge_2{}^{35}Cl_6$[13] (parent ion peak at $m/z=358$), $m/z=323$ (6), 253 (12). $^{74}Ge_3{}^{35}Cl_8$ (parent ion peak at $m/z=502$), $m/z=327$ (21), 288 (7), and 253 (7).

The authors thank Dr. Kohji Ujiie, Messers. Hiroshi Yamashita and Hajime Takahashi of Ricoh Company Ltd., for measuring the size of germanium particles. We also thank Mitsubishi Metal Corporation for a gift of germanium metal. This work was supported in part by a Grant-in-Aid for Special Project Research (Nos. 61125004 and 62115003) provided by the Ministry of Education, Science and Culture.

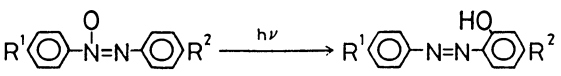
Facile Photorearrangement of Some Crowded Azoxyarenes via Two Concurrent Pathways

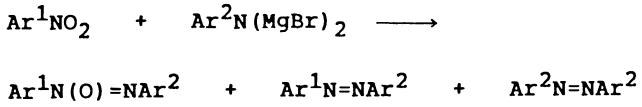
Masao Ōkubo,* Hayato Hyakutake, and Naoki Taniguchi
Department of Chemistry, Faculty of Science and Engineering, Saga University, Honjō-machi, Saga 840
(Received February 12, 1988)

Synopsis. Naphthalene-1-*ONN*-azoxybenzenes and some unsymmetrically ortho-substituted *ONN*- and *NNO*-azoxybenzenes were prepared, and their photochemical behavior in ethanol was compared. The crowded azoxyarenes tend to undergo a facile Wallach rearrangement via the known *azoxy-ortho* oxygen mirgation and a concurrent pathway involving *ONN–NNO* isomerization. The relative contribution of the two pathways was affected by substituents.

The photo-Wallach rearrangement of azoxyarenes via azoxy-ortho migration of oxygen (Scheme 1) is established.[1] However, neither systematic study on the steric repulsion effect nor that on the electronic effect of unsymmetrical (*unsym*-) azoxyarenes has appeared because their *ONN* and *NNO* isomers have so far been difficultly accessible. The difficulty has recently been overcome by a convenient method for the independent preparation of *unsym*-azoxyarene isomers by the condensation of nitroarenes with aryliminodimagnesium reagent ($ArN(MgBr)_2$, aryl-IDMg, Scheme 2).[2]



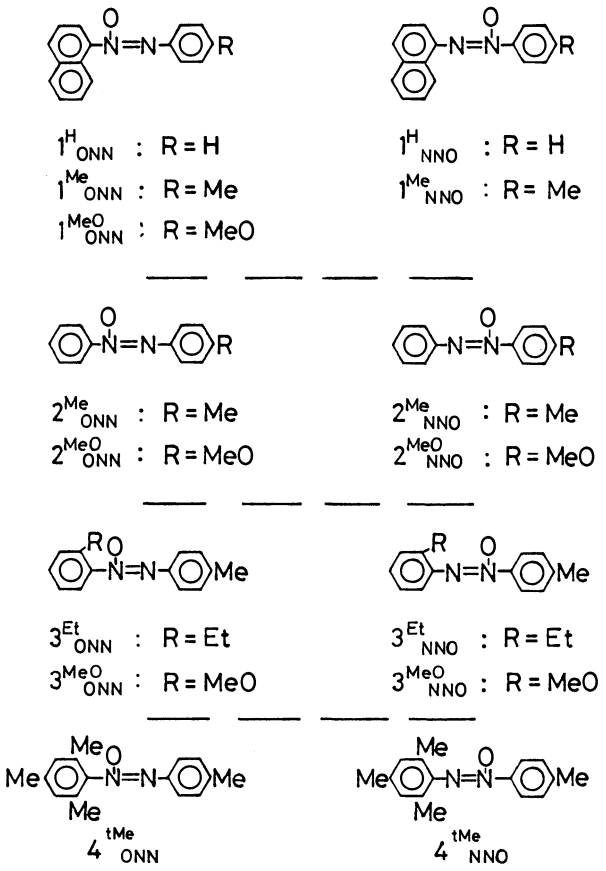
Scheme 1.



Scheme 2.

In this paper, the steric repulsion effect on the photoreactivity of crowded azoxyarenes and the directive effect of substituents on oxygen migration will be described. The azoxyarenes concerned are naphthalene-1-*NNO*-azoxybenzene ($\mathbf{1}^{H}_{NNO}$),[3] its more crowded *ONN*-isomer ($\mathbf{1}^{H}_{ONN}$), their *p*-Me and *p*-MeO derivatives ($\mathbf{1}^{Me}_{ONN}$ and $\mathbf{1}^{MeO}_{ONN}$), and some *o*-substituted *ONN*- and *NNO*-azoxybenzenes (**3** and **4**). The structure having an azoxy nitrogen combined to a bulky aryl group is indicated by *ONN*. Photochemical behavior was compared with one another and with that of non-crowded ones **2**. All the crowded and noncrowded azoxyarenes were prepared by the reaction of Scheme 2: $\mathbf{3}^{Et}_{NNO}$ was unavailable because of unsuccessful IDMg treatment (see Experimental).

The azoxyarenes were dissolved in ethanol, introduced into quartz cells, and irradiated for 30 min by a high-pressure mercury lamp. In addition to the azoxy isomers, two photo-Wallach products were isolated. The normal product has an *o*-OH group on the benzene ring nearer to the original "azo" nitrogen, and the isomeric one has an *o*-OH group on the ring nearer to



the original "azoxy" nitrogen (Scheme 1). Yields of isolated azoxy isomers, two Wallach products, and associated recoveries, based on amounts of azoxyarenes used, are given in Table 1 (Runs 1—11). When the azoxyarenes used in Runs 1—6 were irradiated in Pyrex glass cells of the same size, the yield of the normal Wallach product decreased by 4—11% and the recovery increased by 7—10%. By use of ordinary glass cells, additional decrease (1—5%) and increase (0—5%) were observed.

The higher reactivity of the crowded 1-naphthyl-*ONN* derivatives ($\mathbf{1}_{ONN}$), ascribable to the steric repulsion of *peri*-hydrogen, is shown by their recoveries (18 and 40%, Runs 1 and 2) lower than those of the non-crowded phenyl derivatives ($\mathbf{2}_{ONN}$ and $\mathbf{2}_{NNO}$, Runs 3—6). The latter are converted via the known pathway of Scheme 1. According to the "normal" pathway i) of Scheme 3, $\mathbf{1}^{Me}_{ONN}$ gave the normal Wallach product in higher yield (35%, Run 1) than $\mathbf{2}^{Me}_{ONN}$ (30%, Run 3). Participation of the other pathway ii) involving the *ONN–NNO* isomerization, probably via the oxadiaziridine intermediate **A**,[4,5] is shown by the isolation of an inseparable red oily mixture in 24% yield. The oil was composed of the less crowded $\mathbf{1}^{Me}_{NNO}$ and the "isomeric"

Table 1. Photochemical Rearrangement of Some Sterically Crowded Azoxyarenes

Run No.	Azoxyarenes $Ar^1N(O)=NAr^2$			Yield/%

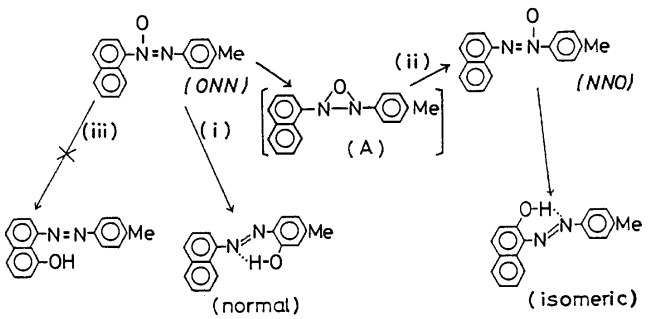
10	$\mathbf{4}^{tMe}_{ONN}$	2,4,6-Me_3Ph	*p*-MePh	22	42	9
11	$\mathbf{4}^{tMe}_{ONN}$	*p*-MePh	2,4,6-Me_3Ph	0	29[d]	29[e]

a) An oily mixture composed of the *NNO*-isomer and the corresponding Wallach product (see text). b) No *NNO*-isomer was isolated, but the formation was suggested (see text). c) Two isomeric Wallach products were obtained as an inseparable mixture. The minor one (5%) is the same as that obtained in Run 8. d) The product is the same as the Wallach product obtained in Run 10. e) Smaller overall amount due to unidentified decomposition products.



Scheme 3.

Wallach product (1-(4-methylphenylazo)-2-naphthol) in a molar ratio of 8 : 2 (see Experimental). Similarly, $\mathbf{1}^{MeO}_{ONN}$ gave the normal Wallach product in higher yield (33%, Run 2) than $\mathbf{2}^{MeO}_{ONN}$ (25%, Run 4). Neither the less crowded $\mathbf{1}^{MeO}_{NNO}$ nor the isomeric product was isolated from a small amount of complex mixture, but the second lowest amount of recovery among Runs 1—6 suggests a more or less participation of pathway ii). The conversion of *p*-MeO derivatives lower than that of the corresponding *p*-Me derivatives (Runs 1—6) is in accord with the electronic substituent effect of symmetrical azoxybenzenes.[6]

Also in solid state, $\mathbf{1}_{ONN}$'s are highly photosensitive as shown by color change of pure crystals from pale yellow into red even in an ordinary glass bottle placed under a fluorescent ceiling light. In the dark, their crystals or benzene solutions (even under refluxing) suffer no color change. All the other azoxyarenes used in this study were handled in the usual manner. Some effect of naphthalene ring sensitive to different wavelengths may also be responsible for the unique behavior of $\mathbf{1}_{ONN}$'s. No existence of the alternative pathway iii) (Scheme 3) via the *azoxy-peri* oxygen migration[7] was confirmed (see Experimental).

In the case of the *o*-substituted *ONN*-azoxybenzenes having a *p'*-Me group (Runs 7, 8, and 10) and their *NNO* isomers (Runs 9 and 11), the former are more reactive than the latter but the directive effects are somewhat complicated. Whereas $\mathbf{3}^{Et}_{ONN}$ reacts via the single pathway i), $\mathbf{3}^{MeO}_{ONN}$ reacts via the two pathways i) and ii). The highly crowded $\mathbf{4}^{tMe}_{ONN}$ was most easily converted, as shown by the lowest amount of recovery, to give the normal Wallach product and *NNO*-isomer via the two pathways. The lowest conversion of $\mathbf{1}^{MeO}_{NNO}$ is understandable because it may be electronically stabilized by the less hindered *o'*-MeO group[4] (vide infra), but the reaction proceeds via the two pathways. Since $\mathbf{4}^{tMe}_{NNO}$ has no ortho-hydrogen essential to the "normal" rearrangement, the exclusive formation of the "isomeric" product in lower yield is explicable. The lower combined yields and recovery in Runs 9 and 11 arise from the partial decomposition leading to some unidentified materials.

The primary conclusion is that the crowded azoxyarenes undergo the facile rearrangement via the two pathways, whereas the less crowded ones react sluggishly via the single and normal pathway. The conclusion is reasonable because the oxadiaziridine intermediate[4,5] is effective for the release of steric repulsion. With regard to the directive effect, the results of Runs 7 and 9 are exceptional to the conclusion, as seen from their contrast with those of Run 8. The comparably bulky *o*-Et and *o*-MeO groups exhibit the comparable reactivities but different directive effects. In conflict with no detection of the isomeric Wallach product from $\mathbf{2}^{MeO}_{NNO}$ (Run 6, vide supra), the normal and isomeric ones were previously isolated[4] probably due to different conditions of irradiation. The quite low reactivity of $\mathbf{2}^{MeO}_{NNO}$ suggests that the previous result arises from the electronic stabilization of oxadiaziridine by the *p'*-MeO group. The conversion of $\mathbf{1}^{MeO}_{ONN}$ lower than that of $\mathbf{1}^{Me}_{ONN}$ is similarly explaina-

Table 2. Melting Points and ^{1}H NMR Data of "Normal" Wallach Products (*o*-Hydroxyazoarenes)

Product formed from (Run No.)	Mp θ_m/°C	^{1}H NMR Data/δ
$\mathbf{1}^{Me}_{ONN}$(1)	112—113	12.88 (1H, s), 8.44—8.56 (1H, m), 7.45-8.04 (7H, m), 6.80—6.94 (2H, m), 2.40 (3H, s).
$\mathbf{2}^{MeO}_{ONN}$(2)	134—136	14.38 (1H, s), 8.50—8.62 (1H, m), 7.56—8.10 (7H, m), 6.56—6.78 (2H, m), 3.92 (3H, s).
$\mathbf{3}^{Et}_{ONN}$(7)	80.5—82	12.63 (1H, s), 7.80—7.66 (2H, m), 7.33—7.00 (3H, m), 6.80—6.56 (2H, m), 2.96 (2H, q), 2.33 (3H, s), 1.33 (3H, s).
$\mathbf{3}^{MeO}_{ONN}$(8)	128—128.5	13.13 (1H, s), 7.93—7.73 (2H, m), 7.63—6.60 (5H, m), 4.00 (3H, s), 2.36 (3H, s).
$\mathbf{3}^{MeO}_{NNO}$(9)[a]	—	Pairs of singlets at 13.53 and 13.13, 4.00 and 3.90, and 2.36 and 2.28 were observed.
$\mathbf{4}^{tMe}_{ONN}$(10)	104.5—105	12.30 (1H, s), 7.50 (2H, d), 6.70—6.43 (3H, m), 2.36 (6H, s), 2.33 (3H, s), 2.23 (3H, s).

a) The mixture gave three pairs of OH, OCH_3, and CH_3 singlets. Relative intensities are recognized as the composition of the mixture.

ble. The exceptions and conflict ascribable to the electronic directive effect on oxygen migration possibly involving the mutual conversion of *unsym*-azoxy isomers via oxadiaziridine[5] (see Scheme 3) remain to be studied.

Experimental

Azoxyarenes. The reactions of Scheme 2 were carried out as previously reported.[2] The azoxyarenes were separated from the reaction mixture by column chromatography, and purified by recrystallization. Attempts to prepare $\mathbf{3}^{Et}_{NNO}$ were unsuccessful because the treatment of *p*-$MeC_6H_4NO_2$ with *o*-EtC_6H_4-IDMg gave only a trace amount and the treatment of *o*-$EtC_6H_4NO_2$ with *p*-MeC_6H_4-IDMg afforded only $\mathbf{3}^{Et}_{ONN}$ (vide infra). The *NNO*-derivative, $\mathbf{1}^{tMe}_{NNO}$ (Run 11), was obtained by the photoreaction of Run 10; it was also obtained by a lucky *ONN-NNO* isomerization in the reaction of *p*-MeC_6H_4-IDMg with 2,4,6-$Me_3C_6H_2NO_2$.[8] The assignment of structures of *o*-substituted azoxyarenes and the product distributions in the reactions of Scheme 2 will be reported elsewhere.[8]

Procedures. The photoreactions were carried out using 0.002 M (1 M=1 mol dm^{-3}) solution in spectro-grade ethanol.[6] The quite low conversion in benzene and no effect of atmosphere were reported.[6] The solutions in quartz cells were placed at a distance of 4.5 cm from a water-jacketted mercury lamp of a merrygo-round UV-irradiation apparatus, and were irradiated for 30 min at room temperature (15—20 °C). The amounts of Wallach products and recovered and/or isomeric azoxyarenes were determined by chromatographic separation and/or by comparison of intensities of ^{1}H NMR signals with those of authentic samples.

Products. The authentic samples for photo-Wallach products, *o*-hydroxyazoarenes, were obtained as the minor products of coupling reactions of appropriate aryldiazonium salts with phenolates (except 2-naphthol derivatives, which were obtained as major products). They were isolated from the filtrates of crystallization of the major *p*-hydroxyazoarenes by column chromatography (Wako Gel C-200 and C-300), and were purified by recrystallization. The melting points (uncorrected) and ^{1}H NMR data of the "normal" products in Runs 1, 2, and 7—10 are summarized in Table 2. The elemental analyses gave satisfactory results. The minor isomeric product in Run 9 is the same as the normal one obtained in Run 8, and the product in Run 11 is the same as the normal one obtained in Run 10. The products obtained in Runs 3—6 are known.[4,9]

The composition of the inseparable mixture of $\mathbf{1}^{Me}_{NNO}$ and "isomeric" product (Run 1) was estimated from the relative intensities of two Me-proton ^{1}H NMR signals. The authentic sample of alternative *azoxy-peri* oxygen migration (cf. Run 1) was prepared in low yield by treating 8-nitro-1-naphthol[10] with a large excess of *p*-MeC_6H_4-IDMg.

The authors wish to thank Advanced Instrumentation Center for Chemical Analysis, Ehime University, for the elemental analyses. A part of this work is financially supported by a Grant-in-Aid for Scientific Research (60470026).

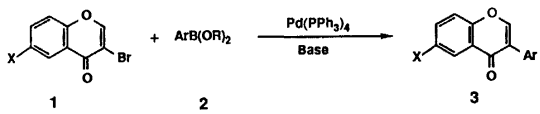
(Received February 26, 1988)

Synopsis. The synthesis of isoflavone derivatives by means of palladium-catalyzed cross-coupling reaction between 3-bromochromones and arylboronic acids or its butyl esters is described.

Isoflavones (3-phenyl-4*H*-1-benzopyran-4-ones) belong to the main categories of flavonoids, such as flavones (2-phenyl-4*H*-1-benzopyran-4-ones) and chalcones, which exist in plants, fruit, and flowers. Although many synthetic methods of isoflavones have been reported, including: (1) the oxidative rearrangement of chalcones with thallium(III) nitrate;[1] (2) the aryl migration of 2′-hydroxychalcone epoxides using $BF_3 \cdot OEt_2$;[2] and (3) the oxidation of products obtained by boiling *N*-styrylmorpholine and salicylaldehyde with CrO_3-pyridine in benzene;[3] no synthetic procedures of isoflavones have been presented hitherto using a direct arylation on a chromone framework. Recently, we have reported that the palladium-catalyzed cross-coupling reaction[4] of phenylboronic acids with haloarenes proceeds smoothly in the presence of bases to give corresponding biaryls. Thereafter, several articles[5] with respect to the application of this reaction have appeared. We report here the preparation of isoflavones (**3**) from 3-bromochromones (**1**) and arylboronic acids or its esters (**2**) by applying the above-mentioned cross-coupling reaction (Eq. 1).

Results and Discussion

The optimum conditions for carrying out the reaction of Eq. 1 were studied by using 3-bromochromone and phenylboronic acid or its butyl ester in the presence of 3 mol% of $Pd(PPh_3)_4$ and 2 equivs of various bases. The results are summarized in Table 1. From



1 2 3 (1)

the table, it is shown that the best yield of isoflavone can be obtained by using aqueous Na_2CO_3 as a base. The reaction is also effected with aqueous Tl_2CO_3[6] and found to be complete in the shorter reaction time compared with other bases (Entry 4). A more interesting use of Tl_2CO_3 may be the reaction of dibutyl phenylboronate with **1** under nonaqueous conditions (Entry 5). The desired isoflavone was obtained in 91% yield, whereas the reaction time had to be increased to 6 h. When the coupling reaction was carried out in the presence of NaOH or NaOAc, the formation of *o*-hydroxyacetophenone was observed in the GLC analysis. It has been known that chromones are subject to ring fission[7] by a strong base such as NaOH to give the corresponding *o*-hydroxyacetophenones. Furthermore, it has also been reported that arylboronic acids are protonized[5a,b] with water in the presence of a base. The low yields of isoflavone in those cases may be due to such side reactions.

Table 1. Effects of Bases on the Cross-Coupling Reaction of 3-Bromochromone with Phenylboronic Acid or Its Butyl Ester[a]

Entry	$PhB(OR)_2$	Base	Reaction time/h	Yield/%[b]
1	OH	3 M $NaOH/H_2O$	3	49
2	OH	3 M $NaOAc/H_2O$	8[c]	25
3	OH	2 M Na_2CO_3/H_2O	6	94
4	OH	1 M Tl_2CO_3/H_2O	1.5	85
5	OBu	Tl_2CO_3[d]	6	91

a) All the reactions were conducted under reflux temperature of benzene, using 3-bromochromone (1 mmol), phenylboron compound (1.1 mmol), $Pd(PPh_3)_4$ (0.03 mmol), and base (2 mmol). b) Isolated yield beased on 3-bromochromone. c) Reaction was not complete. d) Powdered Tl_2CO_3 was suspended in benzene.

To establish a generality of this method as a synthetic procedure of **3**, eleven isoflavone derivatives were prepared from the corresponding 3-bromochromones and arylboronic acids. Representative results are summarized in Table 2. The conditions using aqueous Na_2CO_3 as a base (Entry 3 in Table 1) were found to work for the most of phenylboronic acids with ortho and para substituents, and for the 3-bromochromones substituted with 6-Cl and 6-MeO groups. The yields of **3** seem to largely depend upon the functional groups on **2** rather than those of **1**. Namely, the reaction of *p*-nitrophenylboronic acid with **1** gave only 23% of 4′-nitroisoflavone after refluxing for 4 h. Mesitylboronic acid reacted only slowly (completed after 26 h) and gave less than 5% of 2′,4′,6′-trimethylisoflavone together with a substantial amount of mesitylene. The results indicated that the protonolysis of phenylboronic acids is competitive with the coupling even under the conditions using aqueous Na_2CO_3. Thus, such aqueous conditions are not suitable for the phenylboronic acids with electron-withdrawing substituents which accelerate the rate of protonolysis or two ortho substituents which retard the transmetallation step in the mechanism[8] of cross-coupling reaction. For these boronic acids, an alternative procedure (Entry 5 in Table 1) using the esters of boronic acids and Tl_2CO_3 was developed. Under these

Table 2. Synthesis of Isoflavones (Eq. 1)

Entry	1, X=	$ArB(OR)_2$	Base	Reaction time/h	Yield %[a]
1	H		2 M Na_2CO_3/H_2O	10	84
2	H		2 M Na_2CO_3/H_2O	3	94
3	H		2 M Na_2CO_3/H_2O	6	94
4	Cl		2 M Na_2CO_3/H_2O	23	71
5	MeO		2 M Na_2CO_3/H_2O	7	87
6	H		2 M Na_2CO_3/H_2O	6	80
7	H		Tl_2CO_3	9	88[b]
8	H		2 M Na_2CO_3/H_2O	7	90
9	H		Tl_2CO_3	48	47[b]

a) Isolated yields based on 3-bromochromones. b) Reaction was carried out under the nonaqueous conditions (Entry 5 in Table 1).

nonaqueous conditions, the protonolysis of arylboronic acids can be prevented. Indeed, the reactions of dibutyl mesitylboronate and *p*-nitrophenylboronate with **1** gave the corresponding coupling products in yields of 47 and 88% (Entries 7 and 9 in Table 2). Although it is necessary to further define the scope and limitations of this nonaqueous procedure, the conditions should be more useful for the coupling reactions[5] of the arylboron compounds which are sensitive to protonolysis or sterically hindered.

Since, the 3-bromochromones are readily prepared from commercially available *o*-hydroxyacetophenone and the arylboronic acids are also conventionally prepared by the reaction of aryl-Grignard reagents with trialkylborates followed by hydrolysis, it can be concluded that the present procedure is a general and straightforward method for isoflavone synthesis.

Experimental

All melting points are uncorrected. IR spectra were recorded on a JASCO-IRA-1 spectrometer by means of KBr pellet. ^1H NMR spectra were obtained with a Hitachi-R-90H Fourier Transform NMR spectrometer (90 MHz) and are reported in δ units using tetramethylsilane as an internal standard. Mass spectra were taken on a JEOL JMS-D300. GLC analyses were performed on a Hitachi 163 instrument using silicon OV-17 (2 m) on Uniport B.

Materials and Reagents. Benzene was the commercially available grade, and was distilled and dried over sodium before use. Tetrakis(triphenylphosphine)palladium(0) was prepared by the literature procedure.[9] Phenylboronic acid,[10] *p*-tolylboronic acid,[10] *p*-methoxyphenylboronic acid,[10] *p*-fluorophenylboronic acid,[11] 1-naphthylboronic acid,[12] *p*-nitrophenylboronic acid,[10] and mesitylboronic acid[13] were prepared by the known procedures.[14] 3-Bromochromones were also synthesized by the method reported by Gammill.[15] All isoflavones isolated and 3-bromo-6-methoxychromone were identified by IR, ^1H NMR, and mass spectra, and these physical data are as follows.

3-Bromo-6-methoxychromone: Mp 122.0—122.5 °C; IR (KBr) 1660 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ=3.90 (s, 3H, OCH_3), 7.20—7.48 (m, 2H, aromatic), 7.59 (d, 1H, J=2.6 Hz, C_5-H), and 8.20 (s, 1H, C_2-H); MS, Found: m/z 255.9566, Calcd for $C_{10}H_7BrO_3$: M, 255.9558.

Isoflavone: Mp 131.5—132.0 °C; IR (KBr) 1640 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ=7.32—7.78 (m, 8H, aromatic), 8.01 (s, 1H, C_2-H), and 8.31 (dd, 1H, C_5-H, J=7.5 and 1.8 Hz); MS, Found: m/z 222.0682, Calcd for $C_{15}H_{10}O_2$: M, 222.0681.

4′-Methylisoflavone: Mp 153.5—154.5 °C; IR (KBr) 1635 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ=2.38 (s, 3H, CH_3), 7.18—7.77 (m, 7H, aromatic), 7.99 (s, 1H, C_2-H), and 8.31 (dd, 1H, C_5-H, δ=8.4 and 1.8 Hz); MS, Found: m/z 236.0838, Calcd for $C_{16}H_{12}O_2$: M, 236.0838.

4′-Methoxyisoflavone: Mp 141—142 °C; IR (KBr) 1630 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ=3.84 (s, 3H, OCH_3), 6.92—7.77 (m, 7H, aromatic), 7.99 (s, 1H, C_2-H), and 8.31 (dd, 1H, C_5-H, J=7.5 and 1.9 Hz); MS, Found: m/z 252.0782, Calcd for $C_{16}H_{12}O_3$: M, 252.0787.

2′-Methylisoflavone: Mp 113.5—114.0 °C; IR (KBr) 1640 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ=2.26 (s, 3H, CH_3), 7.08—7.80 (m, 7H, aromatic), 7.87 (s, 1H, C_2-H), and 8.30 (dd, 1H, C_5-H, J=7.6 and 1.4 Hz); MS, Found: m/z 236.0821, Calcd for $C_{16}H_{12}O_2$: M, 236.0837.

6-Chloroisoflavone: Mp 186.0—186.5 °C; IR (KBr) 1635 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ=7.37—7.69 (m, 7H, aromatic), 8.01 (s, 1H, C_2-H), and 8.26 (d, 1H, C_5-H, J=2.4 Hz); MS, Found m/z 256.0276. Calcd for $C_{15}H_9ClO_2$: M, 256.0292.

6-Methoxyisoflavone: Mp 172—173 °C; IR (KBr) 1625 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ=3.91 (s, 3H, OCH_3), 7.19—7.64 (m, 7H, aromatic), 7.68 (d, 1H, C_5-H, δ=2.4 Hz), and 8.00 (s, 1H, C_2-H); MS, Found: m/z 252.0797, Calcd for $C_{16}H_{12}O_3$: M, 252.0787.

4′-Fluoroisoflavone: Mp 192.0—192.5 °C; IR (KBr) 1630 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ=7.02—7.79 (m, 7H, aromatic), 7.99 (s, 1H, C_2-H), and 8.30 (dd, 1H, C_5-H, J=7.4 and 1.8 Hz); MS, Found: m/z 240.0583, Calcd for $C_{15}H_9FO_2$: M, 240.0587.

4′-Nitroisoflavone: Mp 202—204 °C; IR (KBr) 1640 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ=7.38—8.46 (m, 8H, aromatic), and 8.13 (s, 1H, C_2-H); MS, Found: m/z 267.0533, Calcd for $C_{15}H_9NO_4$: M, 267.0532.

2′,3′-Benzoisoflavone: Mp 107.5—108.0 °C; IR (KBr) 1630 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ=7.35—7.96 (m, 10H, aromatic), 8.00 (s, 1H, C_2-H), and 8.34 (dd, 1H, C_5-H, J=7.9 and 1.5 Hz); MS, Found: m/z 272.0818, Calcd for $C_{19}H_{12}O_2$: M, 272.0837.

2′,4′,6′-Trimethylisoflavone: Mp 105.5—106.0 °C; IR (KBr) 1635 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ=2.13 (s, 6H, 2′-CH_3 and 6′-CH_3), 2.31 (s, 3H, 4′-CH_3), 6.94 (s, 2H, C_3-H, C_5-H), 7.24—7.80 (m, 3H, aromatic), 7.75 (s, 1H, C_2-H), and 8.28 (dd, 1H, C_5-H, J=7.8 and 1.8 Hz); MS, Found: m/z 264.1131, Calcd for $C_{18}H_{16}O_2$: M, 264.1151.

General Procedure. A 25 mL two-necked round-bottomed flask equipped with a reflux condenser, a septum inlet, and a magnetic stirring bar, was charged with 3-bromochromone (2.0 mmol), phenylboronic acid (2.2 mmol), and $Pd(PPh_3)_4$ (0.072 g, 0.06 mmol). The flask was flushed with nitrogen and filled with 4 ml of dry benzene and 2 ml of aqueous 2 M-Na_2CO_3 solution through the septum inlet with a syringe. For the reaction under nonaqueous conditions, dibutyl arylboronate (2.2 mmol) and powdered Tl_2CO_3 (2 mmol) were

used in place of phenylboronic acid and aqueous Na_2CO_3 solution. The mixture was refluxed in an oil bath with stirring. At suitable time intervals, a part of the reaction solution was sampled with a microsyringe and was subjected to GLC analysis. After the reaction was complete, the flask was cooled to room temperature. The product was extracted with benzene, washed with brine, and dried over anhydrous magnesium sulfate. Finally the product was isolated by silica gel column chromatography using a mixture of benzene, dichloromethane, and ether (2:2:1) as an eluent, followed by recrystallization from a mixture of hexane and a small amount of benzene.

Synopsis. (1-2;5-6-η-Cyclooctadiene)(1-6-η-cyclooctatriene)ruthenium catalyzes the silylation of olefins at 60—140 °C to give allylsilanes with good selectivity in high yields. The reactions of trialkylsilane with 2-methyl-1-butene, 2-methyl-2-butene, and 3-methyl-1-butene give the same product, 3-methyl-1-trialkylsilyl-2-butene. Silylation of ethyl (*E*)-2-butenoate gives ethyl (*E*)-4-trialkylsilyl-2-butenoate in high yield.

Allylsilanes are highly versatile synthetic intermediates.[1] Allylsilanes are prepared by 1) the reaction of allyl chloride with copper-silicon powder at 250 °C,[2-4] 2) Ni or Pd complex-catalyzed reactions of dienes with disilanes,[5-7] 3) hydrosilylation of dienes,[8-11] 4) dissolving metal reductions of aromatic hydrocarbons,[12] 5) Wittig reactions,[13-16] 6) silylation of allylic organometallics.[17,18] Recently, Seki et al. reported the preparation of vinylsilanes and allylsilanes from olefins and triethylsilane catalyzed by $[Ru_3(CO)_{12}]$.[19] In the course of our study on the organic syntheses catalyzed by (1-2;5-6-η-cyclooctadiene)(1-6-η-cyclooctatriene)ruthenium(0) [Ru(cod)(cot)] and its derivatives,[20] we found that Ru(cod)(cot) catalyzes the selective silylation of olefins which provides a versatile method of the preparation of allylsilanes.

Results and Discussion

Triethylsilane and diethylmethylsilane readily reacted with 2-methyl-1-butene, 2-methyl-2-butene, 3-methyl-1-butene, 1-hexene, and ethyl (*E*)-2-butenoate in the presence of a catalytic amount of Ru(cod)(cot) at 60—140 °C to give the corresponding allylsilanes selectively. The results are summarized in Table 1.

The reactions of triethylsilane with 2-methyl-1-butene, 2-methyl-2-butene, or 3-methyl-1-butene gave 1-triethylsilyl-3-methyl-2-butene (**1**) as a major product in yields of 39—61% with 78—81% selectivity (Table 1, Runs 1—4). The minor products were regioisomers of **1**, (*E*)- and (*Z*)-1-trialkylsilyl-2-methyl-2-butene. Diethylmethylsilane also reacted with 2-methyl-2-butene to give 1-diethylmethylsilyl-3-methyl-2-butene (**2**) in a yield of 65% with 86% selectivity (Run 5). In all the reactions shown in Eq. 1, only small

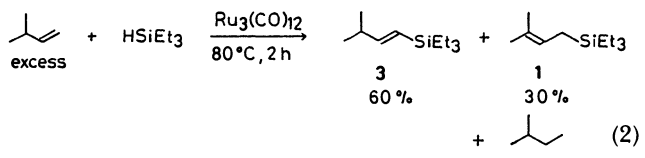
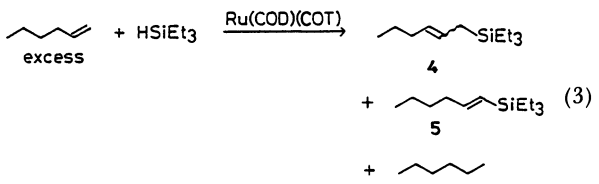
(1)

amounts of vinylsilanes were detected. Though Seki et al. reported that $[Ru_3(CO)_{12}]$ is an effective catalyst for the synthesis of vinylsilanes from olefins and hydrosilanes,[19] they did not mention the silylation of 2-methylbutenes. Several allylsilanes can be prepared by hydrosilylation catalyzed by Pd[8] and Rh[10] complexes. We confirmed that, in the presence of a catalytic amount of $[Ru_3(CO)_{12}]$, the reaction of triethylsilane with 3-methyl-1-butene gave (*E*)-1-triethylsilyl-3-methyl-1-butene (**3**) and **1** in yields of 60 and 30% respectively (Eq. 2). However, $[Ru_3(CO)_{12}]$ does not catalyze the reaction of triethylsilane with 2-methyl-1-butene and with 2-methyl-2-butene at 80 °C for 2 h; only the starting materials were recovered.



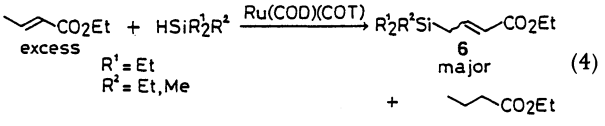
(2)

1-Hexene reacted with triethylsilane in the presence of Ru(cod)(cot) to give the product **4** in a yield of 67% (*E*/*Z*=65/35) with 82% selectivity (Run 6). (*E*)-1-Triethylsilyl-1-hexene (**5**) was also obtained in 15% yield. This result is almost the same as that of $[Ru_3(CO)_{12}]$-catalyzed reaction reported.[19] The reaction of triethylsilane with 1-hexene was rapid at 140 °C (Run 7). The yield and selectivity of products were the same as those in the reaction at 80 °C for 7 h (Runs 6, 7).



(3)

The reaction of ethyl (*E*)-2-butenoate with triethylsilane and with diethylmethylsilane gave the products **6** and **7** in yields of 63% (*E*/*Z*=91/9) and 66% (*E*/*Z*=92/8) with 85 and 89% selectivities (Runs 8, 9), respectively.

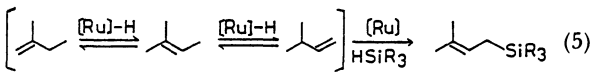


(4)

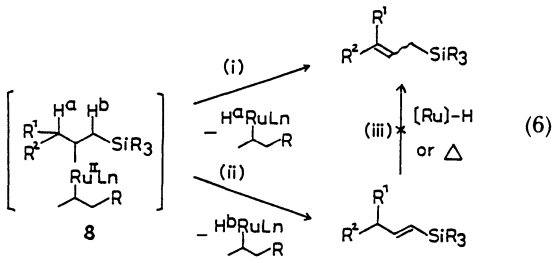
In these reactions, hydrogen did not evolve. In the reaction of ethyl (*E*)-2-butenoate, ethyl butanoate was formed in 92% yield based on triethylsilane.

When a catalytic amount of phosphorus ligands such as triphenylphosphine, tributylphosphine, triphenyl phosphite, and triethyl phosphite were added to the reaction mixture, no reaction occurred and starting materials, triethylsilane and olefins, were recovered. Dichlorotris(triphenylphosphine)ruthenium(II) $[RuCl_2(PPh_3)_3]$ was inactive in the reaction of triethylsilane with 2-methyl-2-butene. Silanes such as trimethoxysilane, triisopropylsilane, and dimethylphenylsilane, reacted with olefins. However, these reactions were very slow and only a trace amounts of the corresponding products were detected.

We consider the mechanism of the present reaction which is substantially the same as the $[Ru_3(CO)_{12}]$-catalyzed synthesis of vinylsilanes[19] except two features. The first one is a rapid equilibrium among three C_5 olefins, 2-methyl-1-butene, 2-methyl-2-butene, and 3-methyl-1-butene shown in Eq. 5. Probably a



(5)



(6)

catalytic amount of ruthenium hydride causes the isomerization of the double bond, then the silylation would occur. The second concerns a β-elimination step from an intermediate **8**[19] (Eq. 6). When two possible paths of β-elimination are considered in the last step of the present reaction, the path (i) would occur predominantly. The possibility of the isomerization of **3** to **1** was investigated. The reaction of a mixture of **3** and **1** (ratio **3**/**1**=68/32) in hexane was carried out in the presence of a catalytic amount of Ru(cot)(cod) and $HSiEt_3$ at 80 °C for 2 h; slight isomerization occurred (ratio **3**/**1**=54/46); however, the rate of the isomerization of vinylsilane to allylsilane (path (iii)) was very slow. Thus the product distribution would be determined by the direction of the β-elimination of **8**.

Experimental

All boiling points were uncorrected. Infrared spectra were recorded on a NICOLET 5-MX FT-IR spectrometer as films. Proton nuclear magnetic resonance spectra were obtained on a JNM-FX-90 spectrometer as 5—10% solutions with tetramethylsilane as an internal reference. Carbon-13 nuclear magnetic resonance spectra were obtained on a JNM-FX-100 (25.05 MHz) spectrometer as 40—50% solutions with tetramethylsilane and $CDCl_3$ as internal references. Mass spectra were taken on a Shimadzu QP-1000 GC-Mass spectrometer. Microanalyses were performed by the Laboratory for Organic Elemental Microanalysis of Kyoto University. Gas chromatographic analysis (GLC) were carried out on a 3 m×3 mm diameter column with OV 17 or a 2.9 m×3 mm diameter column with DEGA. All olefins, hydrosilanes, phosphines, and $[Ru_3(CO)_{12}]$ were commercial samples and were purified by distillation or by recrystallization under an atmosphere of argon before use. The complexes, Ru(cot)(cot)[21] and $[RuCl_2(PPh_3)_3]$[22] were prepared by the reported

methods. All catalytic reactions were carried out under an atmosphere of argon.

General Reaction Procedure. The reaction of triethylsilane with ethyl (*E*)-2-butenoate is representative. A mixture of triethylsilane (1.16 g, 10 mmol), ethyl (*E*)-2-butenoate (5.71 g, 50 mmol), and Ru(cod)(cot) (0.032 g, 0.1 mmol) was heated in a 50 cm^3 autoclave at 80 °C for 2 h. Careful vacuum distillation of the reaction mixture afforded 1.69 g (yield 74%) of ethyl 4-triethylsilyl-2-butenoate (**5**). Other reactions were carried out in a similar manner. Allylsilanes (**4** and **5**) are known compounds.[19]

1-Triethylsilyl-3-methyl-2-butene (1). Colorless liquid, bp 95 °C (22 mmHg) (1 mmHg=133.322 Pa); IR (neat) 1665 cm^{-1}; ^1H NMR ($CDCl_3$) δ=5.14 (1H, tqq, J=8.4 and 1.4 Hz), 1.68 (3H, s), 1.58 (3H, s), 1.41 (2H, d, J=8.4 Hz), 0.85—1.05 (9H, m), and 0.43—0.68 (6H, m); ^{13}C NMR ($CDCl_3$) δ=128.2 (s), 120.1 (d), 25.7 (q), 17.4 (q), 13.4 (t), 7.3 (q), and 3.3 (t). MS m/z: 184 (M^+). Found: C, 71.38; H, 13.37%. Calcd for $C_{11}H_{24}Si$: C, 71.65; H, 13.12%.

1-Diethylmethylsilyl-3-methyl-2-butene (2). Colorless liquid, bp 77 °C (22 mmHg); IR (neat) 1667 cm^{-1}; ^1H NMR ($CDCl_3$) δ=5.13 (1H, thep, J=8.5 and 1.3 Hz), 1.68 (3H, s), 1.56 (3H, s), 1.40 (2H, J=8.5 Hz, d), 0.84—1.04 (6H, m), 0.34—0.62 (4H, m), and −0.08 (3H, s); ^{13}C NMR($CDCl_3$) δ=128.2 (s), 120.0 (d), 25.7 (q), 17.4 (q), 15.2 (t), 7.2 (q), 5.1 (t), and −6.3 (q). MS m/z: 170 (M^+). Found: C, 70.65; H, 13.31%. Calcd for $C_{10}H_{22}Si$: C, 70.50; H, 13.02%.

1-Triethylsilyl-3-methyl-1-butene (3). Colorless liquid, bp 80 °C (22 mmHg); IR (neat) 1615 cm^{-1}; ^1H NMR ($CDCl_3$) δ=6.03 (1H, dd, δ=18.9 and 5.8 Hz), 5.45 (1H, dd, J=18.9 and 1.1 Hz), 2.25 (1H, m), 0.99 (6H, d, J=6.8 Hz), 0.84—1.04 (9H, m), and 0.36—0.67 (6H, m); ^{13}C NMR($CDCl_3$) δ=155.3 (d), 121.4 (d), 34.8 (d), 22.1 (q), 7.5 (q), and 3.9 (t). MS m/z: 184 (M^+). Found: C, 71.37; H, 13.38%. Calcd for $C_{11}H_{24}Si$: C, 71.65; H, 13.12%.

Ethyl (*E*)-4-Triethylsilyl-2-butenoate (6). Colorless liquid, bp 97 °C (2 mmHg); IR (neat) 1722 and 1644 cm^{-1}; ^1H NMR ($CDCl_3$) δ=7.07 (1H, td, J=9.0 and 15.4 Hz), 5.67 (1H, dt, J=15.4 and 1.3 Hz), 4.16 (2H, q, J=7.0 Hz), 1.76 (2H, dd, J=9.0 and 1.3 Hz), 1.28 (3H, t, J=7.0 Hz), 0.86—1.07 (9H, m), and 0.41—0.69 (6H, m); ^{13}C NMR ($CDCl_3$) δ=166.3 (s), 147.6 (d), 118.9 (d), 59.7 (t), 19.8 (t), 14.4 (q), 7.3 (q), and 3.3 (t). MS m/z: 228 (M^+). Found: C, 63.24; H, 10.76%. Calcd for $C_{12}H_{24}O_2Si$: C, 63.10; H, 10.59%.

Ethyl (*E*)-4-Diethylmethylsilyl-2-butenoate (7). Colorless liquid, bp 94 °C (3 mmHg); IR (neat) 1721 and 1644 cm^{-1}; ^1H NMR ($CDCl_3$) δ=6.96 (1H, dt, J=15.4 and 9.0 Hz), 5.57 (1H, dt, J=15.4 and 1.3 Hz), 4.06 (2H, q, J=7.2 Hz), 1.64 (2H, dd, J=9.0 and 1.3 Hz), 1.17 (3H, t, J=7.2 Hz), 0.70—0.96 (6H, m), 0.30—0.64 (4H, m), −0.10 (3H, s); ^{13}C NMR ($CDCl_3$) δ=165.4 (s), 146.6 (d), 118.5 (d), 58.8 (t), 20.5 (t), 13.6 (q), 6.4 (q), 4.2 (t), −7.1 (q). MS m/z: 214 (M^+). Found: C, 61.35; H, 10.64%. Calcd for $C_{11}H_{22}O_2Si$: C, 61.63; H, 10.34%.

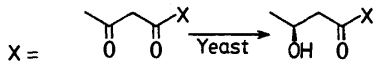
(Received March 24, 1988)

Synopsis. *N*-Ethylacetoacetamide and acetoacetanilide were enantioselectively converted into the corresponding (*S*)-3-hydroxy compounds by alginate- or polyurethane-immobilized bakers' yeasts, while without immobilization the yield of the yeast-mediated reaction was very low.

Microbial transformations of organic molecules are useful for the preparation of chiral compounds. One of the most intensively studied reactions is bakers' yeast-mediated conversion of β-keto esters into the corresponding optically active 3-hydroxy compounds. While ethyl acetoacetate (**1**) is reduced by bakers' yeast to afford ethyl (*S*)-3-hydroxybutanoate (**2**) possessing high optical purity,[1] chemical and optical yields of reactions of analogs of **1** fluctuate widely. Improvement of stereoselectivity of the microbial reduction of the analogs of **1** by chemical modification of the substrates[2] and stereochemical control of the reaction by the use of immobilized yeast[3,4] were described. In this note we will report microbial reduction of *N*-substituted acetoacetamides into the corresponding



X =		
OEt	**1**	**2**
NHEt	**3**	**4**
NHPh	**5**	**6**

alcohols and marked enhancement of the conversion by immobilizing bakers' yeast.

Bakers' yeast is commercially available in the form either of dried granules or of freshly prepared cake. The former is more convenient since it is stable and can be stored without significant deterioration. Microbial reduction of *N*-ethylacetoacetamide (**3**), a nitrogen analog of **1** was attempted using granular bakers' yeast. Under the conditions which assured efficient conversion of **1** to **2**, however, the amide **3** failed to give the corresponding alcohol, *N*-ethyl-3-hydroxybutanamide (**4**). Acetoacetanilide (**5**) was then subject to examination as a substrate of yeast-mediated reduction because of the ease of detection by TLC and separation of the expected reduction product, 3-hydroxybutananilide (**6**), as well as the unchanged **5**. Incubation of **5** for 7 days with fermenting yeast derived from granular dry yeast did not give the reduction product **6** but resulted in the recovery of **5** in 90% yield. When fresh yeast was used instead of dry yeast, however, the hydroxy derivative **6** was obtained in 11% yield. Brewers' yeast was also able to reduce **5** though in low yield (2%). Cultivated suspension of a strain, *Saccharomyces cerevisiae* H-194, was found to convert **5** into **6** in higher yield (48%) as given in Table 1.

The results described above leads to the following suggestion. The apparent inability of the dry bakers'

Table 1. Chemical Yield and Optical Purity of Yeast-Mediated Reduction of *N*-Substituted Acetoacetamides

yeast simply implies a low rate of the reaction and modification of the environment might improve the situation. Thus, attempts have been made to use the bakers' yeast in immobilized form. In fact, treatment of **5** with the dry yeast entrapped in calcium alginate gel[4,5] yielded **6** in 36% yield clearly demonstrating the effect of immobilization. The *N*-ethylamide **3** was also reduced by the alginate-immobilized yeast affording a 9% yield of **4**.

The optical purities of the reduction products, **4** and **6**, were determined by ^{1}H NMR spectral analysis using chiral shift reagents. The reduction was shown to proceed with considerably high stereoselectivity (>90% e.e.) as shown in Table 1. For the purpose of determining the absolute configuration of the hydroxyl group, **4** and **6** were converted into the *O*-benzoyl derivatives. The CD spectra of the benzoates showed the same sign of Cotton effects as those of the authentic compounds having *S*-configuration which were prepared from **2**, establishing the stereochemistry of **4** and **6**.

Microbial reduction of the acetoacetamides **3** and **5** was also studied using polyurethane-immobilized yeast.[6] Paste made of dry yeast and water was admixed with a prepolymer to yield the immobilized yeast entrapped in foaming polyurethane. The polyurethane-immobilized yeast was also found to convert **3** and **5** into the hydroxy compounds **4** and **6** in 9 and 28% yields, respectively. The optical purity of the product, however, was slightly lower than that using alginate-immobilized yeast. Modification of the nature of the polyurethane foams were attempted by the addition of acidic and basic polysaccharides, alginate and chitosan, respectively. But, essentially the same results were obtained as those without polysaccharide additives.

The results are all summarized in Table 1. The starting material, **3** or **5**, was recovered in 37 to 90% yield. Use of a larger amount of yeast can be expected to improve the chemical yield of the product, but was not undertaken in the present study. During the microbial reduction glucose was added daily, which may not be necessary when the reduction proceeded slowly.

In summary, acetoacetamides were enantioselectively reduced by bakers' yeast to the corresponding hydroxy derivatives in much lower yield than acetoacetic esters. However, improvement in conversion yield was attained by immobilization of the yeast with calcium alginate gel or polyurethane foam.

Experimental

^{1}H NMR spectra were recorded on a HITACHI R-24A (60 MHz) or on a Varian XL-200 (200 MHz) spectrometer. UV and CD spectra were measured in MeOH solutions with HITACHI 124 spectrophotometer and JASCO J-40C spectropolarimeter, respectively.

Dry granular yeast ("Active Dry Yeast", S. I. LeSaffre Co.) and fresh bakers' yeast (Oriental Yeast Co.) used in the study are commercially available. *S. cerevisiae* H-194 strain was provided by Professor N. Gunge of The Kumamoto Institute of Technology.

Preparation of Immobilized Yeast. Immobilization by calcium alginate gel was done following the reported procedure.[4] Polyurethane-immobilized bakers' yeast was prepared as follows: Prepolymer (20 g) containing ca. 2 mmol g^{-1} of free NCO group prepared from polyethylene oxide (mol wt ca. 1000) and methylphenylenediisocyanate was added to an intimate mixture of dry bakers' yeast (6.5 g) and H_2O (13 cm^3) and was stirred vigorously for 20 s. After standing for 1 h the resulting polyurethane foam (ca. 200 cm^3) was cut into pieces and washed with water. For the cases with polysaccharide additives, sodium alginate (83 mg) in H_2O (2.6 cm^3) or chitosan (86 mg) in 0.2 mol dm^{-3} AcOH aq (8 cm^3) was added to the yeast-H_2O mixture before the prepolymer addition.

Yeast-Mediated Reductions of Acetoacetamides. *N*-Ethyl-3-oxobutanamide (**3**) was prepared from diketene and ethylamine according to the literature.[7] Typical procedures for the microbial reductions of **3** and **5** are described below.

Reduction of 5 with Fresh Bakers' Yeast: A suspension of fresh bakers' yeast (20 g) in H_2O (125 cm^3) containing D-glucose (15 g) was preincubated at 30 °C for 1 h. A solution of **5** (708 mg) in EtOH (5 cm^3) was added to the suspension and the mixture was shaken at 30 °C for 7 d with daily addition of D-glucose (10 g).

Reduction of 3 with Alginate-Immobilized Bakers' Yeast: Calcium alginate-immobilized bakers' yeast, prepared from dry bakers' yeast (4.2 g) and sodium alginate (4.2 g),[4] and D-glucose (9 g) in H_2O (75 cm^3) were shaken at 30 °C for 1 h. A solution of **3** (774 mg) in EtOH (4 cm^3) was added to the mixture and shaking was continued at 30 °C for 7 d with daily addition of D-glucose (9 g).

Reduction of 5 with Polyurethane-Immobilized Bakers' Yeast: The immobilized yeast prepared from dry bakers' yeast (6.5 g) and prepolymer (20 g) was immersed in the mixture of **5** (992 mg) in EtOH (25 cm^3) and D-glucose (12 g) in H_2O (225 cm^3). The mixture was shaken at 30 °C for 7 d with daily addition of D-glucose (8 g).

Reduction of 5 with *S. cerevisiae* H-194: Sterilized culture medium (pH 5.5) comprising yeast extract (1.25 g), peptone (2.5 g), D-glucose (2.5 g), and H_2O (120 cm^3) was inoculated with *S. cerevisiae* H-194 and cultured at 30 °C for 2 d. The substrate **5** (124 mg) in EtOH (1 cm^3) was added to the culture and incubated further for 7 d with daily addition of D-glucose (7.5 g).

Extraction and Identification of the Products: The incubation mixture was filtered with the aid of celite when necessary, and the filtrate was extracted with Et_2O, AcOEt, and/or $CHCl_3$. The residue was washed with the same solvent and the washings were combined with the extract. The starting material and the reduction product were isolated by SiO_2 column chromatography ($CHCl_3$–MeOH) of the extract and were characterized by ^{1}H NMR spectra without further purification. The authentic samples of the racemic forms of **4** and **6** for the NMR and TLC comparisons were prepared from 3-butanolide by treatment with $EtNH_2$[8] and from **5** by $NaBH_4$ reduction,[9] respectively.

Determination of Optical Purity and Absolute Configuration. The optical purities of **4** and **6** were determined by 200 MHz ^{1}H NMR chiral shift studies using (+)-tris[bis-[perfluoro(2-propoxypropionyl)]methanate]europium(III) and tris[3-(heptafluoropropylhydroxymethylene)-*d*-camphorato]europium(III), respectively, in $CDCl_3$ solutions.

(*S*)-3-Benzoyloxy-*N*-ethylbutanamide: Ethyl (*S*)-3-hydroxybutanoate (**2**, 528 mg), prepared by the microbial reduction of **1** using fresh bakers' yeast, was benzoylated with benzoyl chloride (1 g) and pyridine (1 cm^3) at 0 °C for 1 h. Usual work-up and SiO_2 column chromatography ($CHCl_3$) afforded ethyl (*S*)-3-(benzoyloxy)butanoate (660 mg) as a colorless oil: ^{1}H NMR (CCl_4) δ=1.13 (3H, t, J=7 Hz), 1.36 (3H, d, J=6 Hz), 2.53 (1H, dd, J=15 and 6 Hz), 2.65 (1H, dd, J=15 and 6 Hz), 4.02 (2H, q, J=7 Hz), 5.36 (1H, hexad, J=6 Hz), 7.4 (3H, m), and 7.9 (2H, m). The benzoate (354 mg) in MeOH (4 cm^3) and 1 mol dm^{-3} NaOH aq (1.28 cm^3) was

stirred at 0 °C for 1 h. The mixture was acidified with HCl aq, evaporated, and extracted with $CHCl_3$ to afford crude (*S*)-3-(benzoyloxy)butanoic acid (200 mg). The free acid, without purification, was dissolved in $SOCl_2$ (1 cm^3) and stirred for 1 h. After evaporation of $SOCl_2$ the resulting acid chloride was dissolved in $CHCl_3$ and a solution of $EtNH_2$ in Et_2O was added until the mixture became alkaline towards moistened litmus paper. Usual work-up and preparative TLC (SiO_2, 5% MeOH/$CHCl_3$) gave (*S*)-3-benzolyoxy-*N*-ethylbutanamide (50 mg): mp 58 °C; ^1H NMR (CCl_4) δ=1.03 (3H, t, J=7 Hz), 1.35 (3H, d, J=6 Hz), 2.46 (1H, dd, J=13 and 6 Hz), 2.62 (1H, dd, J=13 and 6 Hz), 3.15 (2H, quint, J=6 Hz), 5.40 (1H, hexad, J=6 Hz), 7.3 (3H, m), 7.5 (1H, br s), and 7.9 (2H, m); UV 227 nm (ε 12500); CD $[\theta]_{225}$ −4300. Anal. ($C_{13}H_{17}NO_3$) C, H, N.

(*S*)-3-Benzoyloxy-*N*-phenylbutanamide: To an ice-cooled solution of (*S*)-3-(benzoyloxy)butanoic acid (100 mg) and aniline (137 mg) in $CHCl_3$ (4 cm^3) were added dicyclohexylcarbodiimide (206 mg) and 1-hydroxybenzotriazole (32 mg) and stirred for 1 h at 0 °C and for 1 d at room temperature. Usual work-up and SiO_2 column chromatography ($CHCl_3$) afforded (*S*)-3-benzolyoxy-*N*-phenylbutanamide (65 mg) as colorless crystals: mp 116 °C; ^1H NMR ($CDCl_3$) δ=1.38 (3H, d, J=7 Hz), 2.64 (1H, dd, J=14 and 7 Hz), 2.78 (1H, dd, J=14 and 7 Hz), 5.56 (1H, hexad, J=7 Hz), 7.1—7.9 (10H, m), and 8.6 (1H, br s); UV 232 nm (ε 25000); CD $[\theta]_{242}$ +22000, $[\theta]_{225}$ −17000. Anal. ($C_{17}H_{17}NO_3$) C, H, N.

***O*-Benzoyl Derivatives Derived from 4 and 6:** The microbial reduction products **4** and **6** were benzoylated with benzoyl chloride–pyridine and the benzoates were isolated by SiO_2 column chromatography ($CHCl_3$). The ^1H NMR spectra of the benzoyl derivatives and those of the corresponding authentic samples described above were indistinguishable and their CD spectra were also very similar having the same sign of the Cotton effects.

We are grateful to Professor Masanori Utaka of Okayama University for his advice on immobilization of bakers' yeast, to Professor Norio Gunge of The Kumamoto Institute of Technology for the gift of strains of yeast, and to Professor Ruka Nakashima of Tottori University for his helpful discussion and encouragement.

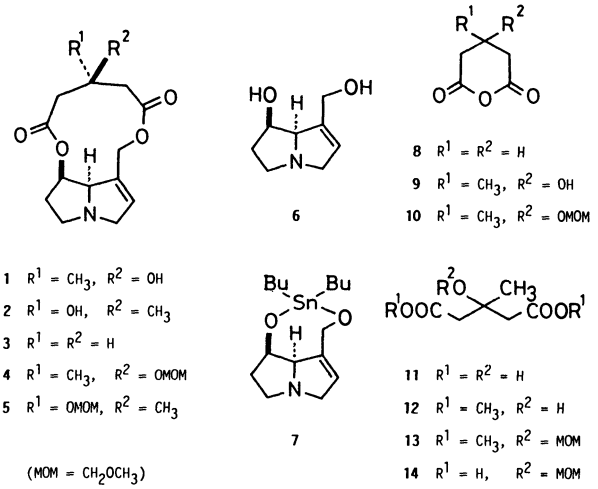
(Received March 24, 1988)

Synopsis. A new synthesis of (+)-dicrotaline (**1**), an 11-membered dilactonic pyrrolizidine alkaloid of retronecine (**6**) type has been achieved in one step by utilizing a tin-mediated lactonization process.

Macrocyclic pyrrolizidine alkaloids are attractive synthetic targets owing to interesting biological activities such as marked hepatotoxicity and carcinogenicity as well as intriguing chemical structures characterized by the presence of a large-ring dilactone.[1] The final crucial step in the total synthesis of these alkaloids is the formation of the large-ring dilactone from a pyrrolizidine diol ["necine," the most commonly (+)-retronecine (**6**)] and a diacid ("necic acid"). Overcoming this synthetic hurdle, some of the macrocyclic pyrrolizidine alkaloids have been synthesized recently by several research groups including us.[2,4a] Herein we wish to disclose a new, single-step synthesis of (+)-dicrotaline (**1**),[2b] an 11-membered dilactonic pyrrolizidine alkaloid of retronecine (**6**) type by virtue of a tin-mediated lactonization reaction.[3]

Shanzer et al. have reported the novel synthesis of macrocyclic tetralactones by the reaction of various cyclic anhydrides with stannoxanes derived from diols and dibutyltin oxide (Bu_2SnO).[3a] We envisioned that this tinmediated "template-driven" macrocyclization process would be applicable to the construction of macrocyclic pyrrolizidine dilactones. In fact, treatment of the stannoxane intermediate **7**[4a] prepared from **6**[4b] and Bu_2SnO, with glutaric anhydride (**8**) in refluxing xylene provided in one step an 11-membered dilactone **3**[5] in 32% yield. We therefore applied this tin-mediated dilactone formation process to the synthesis of **1**. Thus, dicrotalic anhydride (**9**)[2b,6] prepared from dicrotalic acid (3-hydroxy-3-methylglutaric acid) (**11**)[6] was treated with **7** in refluxing xylene to give **1**[2b] and the diastereomer **2**[2b] in 10 and 12% yields, respectively. Spectral (^{1}H NMR, IR, and mass spectra) and chiroptical properties of synthetic **1** were identical with those of natural **1**. Although **1** could be synthesized in one step, the diastereoselectivity and the chemical yield were unsatisfactory, which may be explained by the presence of the free hydroxyl group in the anhydride **9**. Therefore, we next examined the lactonization using the protected cyclic anhydride **10** and **7**. The anhydride **10** was prepared from the the dimethyl ester **12**[6] as follows: (i) conversion of **12** into the methoxymethyl (MOM) ether **13**;[7] (ii) hydrolysis of **13** into the diacid **14**; (iii) conversion of **14** into **10**. Treatment of **10** with **7** under the conditions described above, however, provided a 1 : 1 mixture of the dilactones **4** and **5** in 19% yield. No improvement on the diastereoselectivity and the chemical yield in the dilactone formation could be achieved even employing **10**.

In summary, a one-step synthesis of (+)-dicrotaline (**1**) has been achieved by using the tin-mediated lactonization process although there has been a limitation in view of the diastereoselectivity and the chemical yield.



Experimental

Melting points are uncorrected. Infrared (IR) spectra were obtained on a JASCO Model IR-810 spectrophotometer. Proton nuclear magnetic resonance (^{1}H NMR) spectra were recorded on a JEOL JNM-C675 (270 MHz) or a JEOL 90QE (90 MHz) spectrometer in $CDCl_3$ using tetramethylsilane (TMS) as an internal standard. Chemical shifts were expressed in parts per million (ppm) downfield from TMS (δ=0.0) and coupling constants in Hz. Optical rotations were measured on a JASCO DIP-181 polarimeter. The low- (CIMS and EIMS) and high-resolution (HRCIMS and HREIMS) mass spectra were recorded on a JEOL JMS-LG2000 instrument. Fuji-Davison silica gel BW-820-MH was used for column chromatography. Merck precoated silica gel 60 F_{254} plates, 0.25 mm thickness, were used for analytical and preparative thin-layer chromatography (TLC). Xylene and benzene were distilled from Na under nitrogen. Dichloromethane was distilled from CaH_2 under nitrogen. Tetrahydrofuran (THF) was distilled from Na-benzophenone ketyl under nitrogen. Chloroform was distilled from phosphorus pentoxide (P_2O_5).

17,18,19,20-Tetranorcrotalanan-11,15-dione (3). A mixture of **6**[4b] (25.9 mg, 0.167 mmol) and Bu_2SnO (49.9 mg, 0.200 mmol) in benzene (5 ml) was heated under reflux for 23 h with continuous removal of water by use of Molecular Sieves 4A (ca. 1 g). After cooling, the mixture was concentrated under reduced pressure to leave **7** as a pale yellow oil, which was suspended in xylene (3 ml). To the stirred suspension cooled at −25 °C was added a solution of **8** (21.0 mg, 0.184 mmol) in xylene (2 ml). The mixture was gradually warmed to room temperature for 3 h with stirring and then heated under reflux for 18 h. After cooling, the reaction mixture was concentrated under reduced pressure. Purifica-

tion of the residual oil by column chromatography on silica gel (2.5 g) with acetone–MeOH (1/0→5/1 volume ratio) afforded 13.5 mg (32% from **6**) of **3** as a colorless oil; $[\alpha]_D^{13}$ +37.8° (*c* 1.28, $CHCl_3$); lit,[5] $[\alpha]_D^{13}$ +39.0° (*c* 1.0, $CHCl_3$). The chiroptical and spectral (IR, ^1H NMR, and MS) properties of synthetic **3** were identical with those reported for **3**.[5]

(+)-Dicrotaline (1) and (+)-Epidicrotaline (2). The stannoxane **7** prepared from 20.2 mg (0.130 mmol) of **6** and 37.0 mg (0.150 mmol) of Bu_2SnO as described above was suspended in xylene (4.3 ml). To the stirred suspension was added **9**[2b,6] (19.3 mg. 0.134 mmol) at room temperature. The mixture was heated under reflux for 19 h. After cooling, the reaction mixture was concentrated under reduced pressure. Separation and purification of the residual oil with column chromatography on silica gel (3 g) with $CHCl_3$–MeOH (4/1→0/1 volume ratio) gave a mixture of **1** and **2** (11.6 mg) along with the unreacted **6** (16 mg, 79%). Further separation of the mixture of **1** and **2** by preparative TLC on silica gel with $CHCl_3$–MeOH–28% NH_3 aq (70/10/1 volume ratio) provided 3.8 mg (10% from **6**) of **1** as a colorless oil[8] and 4.2 mg (12% from **6**) of **2** as a colorless oil, respectively. **1**: $[\alpha]_D^{22}$ +11° (*c* 0.38, $CHCl_3$); lit,[2b] $[\alpha]_D^{18}$ +8.1° (*c* 1.18, $CHCl_3$). The hydrochloride of **1**: mp 198—200 °C decomp (EtOH); lit, mp 200 °C decomp (EtOH),[9] mp 211—212 °C decomp (EtOH).[2b] **2**: $[\alpha]_D^{22}$ +44° (*c* 0.32, $CHCl_3$); lit,[2b] $[\alpha]_D^{18}$ +43.3° (*c* 0.72, $CHCl_3$). Spectral (IR, ^1H NMR, and MS) properties of synthetic **1** and **2** were identical with those of natural **1** and those reported to synthetic **2**, respectively.[2b]

Dimethyl 3-(Methoxymethoxy)-3-methylglutarate (13). Dimethyl 3-hydroxy-3-methylglutarate (**12**) was prepared from **11** by the reported procedure.[6] To a solution of **12** (93.2 mg, 0.491 mmol) in $CHCl_3$ (3 ml) was added dimethoxymethane (methylal) (3 ml) and P_2O_5 (1.5 g).[7] The mixture was vigorously stirred at room temperature for 30 min. The reaction mixture was poured into a precooled, saturated aqueous $NaHCO_3$ solution (3 ml) and extracted with ether (3×8 ml). The extracts were combined, dried, and concentrated. Purification of the residual oil by column chromatography on silica gel (2 g) with hexane–EtOAc (6/1 volume ratio) gave 87.2 mg (76%) of **13** as a pale yellow oil; IR ($CHCl_3$) 1740, 1440, 1230, 1150, 1035 cm^{-1}; ^1H NMR (90 MHz) δ=1.49 (3H, s), 2.84 (4H, s), 3.35 (3H, s), 3.68 (6H, s), 4.76 (2H, s); CIMS (200 eV) *m/z* (rel intensity) 235 (M^++1; 100), 205 (40), 204 (95), 203 (51), 201 (57), 174 (92), 173 (40), 161 (46), 147 (96), 142 (90), 117 (65), 113 (40). HRCIMS. Found: *m/z* 235.1176. Cacld for $C_{10}H_{19}O_6$: M+H, 235.1181.

3-(Methoxymethoxy)-3-methylglutaric Acid (14). To a solution of **13** (47.6 mg, 0.203 mmol) in THF (2 ml) was added 0.5 M LiOH (2 ml) (1 M=1 mol dm^{-3}). The mixture was vigorously stirred at 40 °C for 24 h. The reaction mixture was neutralized by the addition of Amberlite CG-50 (acid form, 0.5 g). After being stirred for 10 min, the mixture was filtered through a column packed with Amberlite CG-50 (0.5 g). The column was washed thoroughly with MeOH. The filtrate and the column washings were combined and concentrated under reduced pressure. Purification of the residual oil by column chromatography on silica gel (4 g) with hexane–EtOAc–AcOH (15/15/1 volume ratio) gave 30.1 mg (76%) of **14** as a colorless oil; IR ($CHCl_3$) 3700—2400 (broad), 1720, 1025 cm^{-1}; ^1H NMR (90 MHz) δ=1.51 (3H, s), 2.89 (4H, s), 3.38 (3H, s), 4.80 (2H, s); CIMS (200 eV) *m/z* (rel intensity) 207 (M^++1; 3), 175 (100), 159 (40), 155 (37), 145 (84), 141 (65), 128 (20), 103 (37), 85 (21). HRCIMS. Found: *m/z* 207.0863. Calcd for $C_8H_{15}O_6$: M+H, 207.0868.

3-(Methoxymethoxy)-3-methylglutaric Anhydride (10). To a solution of **14** (46.2 mg, 0.224 mmol) in CH_2Cl_2 (1 ml) was added a solution of dicyclohexylcarbodiimide (46.2 mg, 0.224 mmol) in CH_2Cl_2 (1 ml) under nitrogen. The mixture was stirred at room temperature for 45 min and concentrated under reduced pressure. The residue was diluted with anhydrous acetone (5 ml) and insoluble materials were removed by filtration through a cotton plug. The filtrate was concentrated to leave 42.6 mg of crude **10** as a colorless oil; IR ($CHCl_3$) 1820, 1770, 1065, 1030 cm^{-1}; ^1H NMR (270 MHz) δ=1.44 (3H, s), 2.62 (2H, d, *J*=16.5), 3.16 (2H, d, *J*=16.5), 3.33 (3H, s), 4.72 (2H, s); CIMS (200 eV) *m/z* (rel intensity) 189 (M^++1; 22), 159 (100), 141 (87), 127 (55), 115 (33), 99 (38), 85 (37). HRCIMS. Found: *m/z* 189.0744. Calcd for $C_8H_{13}O_5$: M+H, 189.0763. The crude **10** was used for the next reaction without further purification.

13-(Methoxymethoxy)-17,19,20-trinorcrotalanan-11,15-diones (4 and 5). The stannoxane **7** prepared from 12.0 mg (0.0774 mmol) of **6** and 22.4 mg (0.0914 mmol) of Bu_2SnO as described before was suspended in xylene (3 ml). To the stirred suspension cooled at 0 °C was added a solution of **10** (16.0 mg, 0.0851 mmol) in xylene (1.0 ml). The mixture was stirred at 0 °C for 30 min and then at room temperature for 2 h. To the reaction mixture was added an another solution of **10** (5.8 mg, 0.030 mmol) in xylene (0.36 ml). After being stirred at 35 °C for additional 7 h, the mixture was heated under reflux for 36 h. After cooling, the reaction mixture was concentrated under reduced pressure. Separation of the residual oil by column chromatography on silica gel (2 g) with acetone→MeOH afforded 4.9 mg (19%) of a 1:1 mixture of **4** and **5** as a colorless oil. **4** and **5**: IR ($CHCl_3$) 1740, 1260, 1150, 1030 cm^{-1}; ^1H NMR (270 MHz) δ=1.57 (1.5H, s), 1.61 (1.5H, s), 2.2—2.3 (2H, complex pattern), 2.4—2.9 (5H, complex pattern), 3.43 (1.5H, s), 3.45 (1.5H, s), 3.5—3.6 (2H, complex pattern), 4.0—4.2 (2H, complex pattern), 4.56 (1H, m), 4.81 (2H, m), 5.22 (0.5H, m), 5.28 (0.5H, m), 5.32 (0.5H, d, *J*=12.9), 5.37 (0.5H, d, *J*=12.5), 5.92 (0.5H, br s), 5.95 (0.5H, br s); EIMS (70 eV) *m/z* (rel intensity) 325 (M^+; 45), 310 (7), 294 (26), 280 (6), 265 (53), 242 (28), 220 (23), 138 (51), 137 (71), 136 (86), 121 (74), 120 (75), 95 (78), 94 (100), 93 (63), 80 (55). HREIMS. Found: *m/z* 325.1535. Calcd for $C_{16}H_{23}O_6N$: M, 325.1526.

We thank Professor D. J. Robins, University of Glasgow, UK for providing us with the copies of IR, ^1H NMR, and mass spectra of natural **1**. Financial support from the Ministry of Education, Science and Culture [Grant-in-Aid for Special Project Research No. 62114007, Chemical Syntheses for Elucidation of Biological Functions] is gratefully acknowledged.

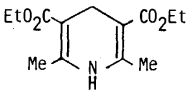
(Received April 15, 1988)

Synopsis. The carbon-carbon double bond in conjugated nitro and certain carbonyl compounds was reduced smoothly and selectively by Hantzsch ester (HEH), an NAD(P)H model, in the presence of a small amount of acetic acid.

Normally the reducing ability of NAD(P)H models is so modest that only strongly electron-deficient olefins are reduced[1] in contrast to certain enzymatic systems where NAD(P)H reduces smoothly the carbon-carbon double bond in a conjugated carbonyl compound with the aid of dehydrogenase.[2] In model systems, some cationic species such as proton,[3] Lewis acid,[4] or magnesium ion[5] have been used as an activator. For example, an NAD(P)H model, 3,5-bis-(ethoxycarbonyl)-1,4-dihydro-2,6-dimethylpyridine (Hantzsch ester: HEH) was demonstrated to reduce the carbon-carbon double bond in nitroalkenes smoothly with the aid of silica gel in benzene without any side reaction.[6]



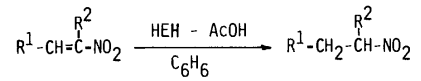
HEH

Nitroalkanes are useful intermediates because the nitro group can be easily converted to other functional groups, e.g., carbonyl,[7] nitrile oxide,[8] and amino group.[9] The synthetic method used widely for nitroalkanes is the reduction of conjugated nitroalkenes with $NaBH_4$.[10] The reaction proceeds smoothly for aliphatic nitroalkenes usually. However for aromatic nitroalkenes, side reactions such as dimerization take place affording low yields of the desired product.

In this paper we present another example of the selective reduction of conjugated aromatic nitroalkenes to nitroalkanes with HEH-acetic acid system[11] and also describe the extension of the scope to α,β-unsaturated carbonyl compounds.

Results and Discussion

The reduction of aromatic nitroalkene **1** to nitroalkane **2** was performed usually in benzene at 80 °C using 1.3 equivalent amounts of HEH under a nitrogen atmosphere. Other solvents such as ethanol and acetonitrile could be used in place of benzene.



As shown in Table 1, even a catalytic amount of acetic acid is enough as an activator for the selective reduction of various nitroalkenes. Besides acetic acid (pK_a=4.76), several carboxylic acids such as benzoic (pK_a=4.21), formic (pK_a=3.75), and chloroacetic (pK_a=2.87) acids showed efficient activation effects in catalytic amounts whereas dichloroacetic (pK_a=1.26) and trifluoroacetic (pK_a=0.3) acids did not exert sufficient effects in the reduction of β-nitrostyrene.

Table 1. Reduction of Nitroalkene **1**

1		AcOH/HEH	Yield of 2[a]

1; 1.0 mmol, HEH; 1.3 mmol: 80 °C, 15 h in benzene.
a) Isolated yield. b) GLC yield.

The products were obtained in excellent yields irrespective of the kind of the aromatic substituent in nitrostyrenes. In every case, no formation of dimer or other side products were observed.

To clarify the substituent effect, the reactions of substituted β-nitrostyrenes were carried out with HEH-trifluoroacetic acid system. Results are shown in Fig. 1. Apparently the yield of products increased with the increase in electron-withdrawing effect of the aromatic substituent.

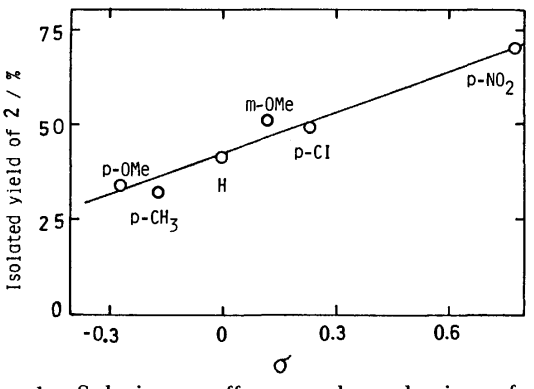

Fig. 1. Substituent effect on the reduction of β-nitrostyrenes **1**. **1**; 1.0 mmol, HEH; 1.3 mmol, CF_3COOH; 0.05 mmol: 80 °C for 15 h in benzene.

Reduction of α,β-unsaturated carbonyl compounds required more severe conditions than those of nitroalkene reduction in terms of reaction temperature and acid concentration. Thus the reactions were performed in toluene at 100 °C for 15 h using 2.3 equivalent amounts of acetic acid to HEH under a nitrogen atmosphere.

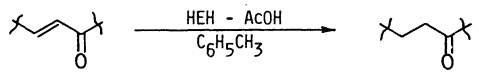

Table 2. Reduction of α,β-Unsaturated Carbonyl Compounds

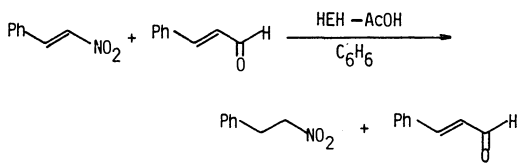
Carbonyl compound	AcOH/HEH molar ratio	Yield[a] %
PhCH=CHCHO	0	9[b]
	0.3	32[b]
	2.3	61[b]
	2.3	76
$CH_3(CH_2)_2CH=CHCHO$	2.3	83
$PhCH=CHCOCH_3$	2.3	54
	(0.05)[c]	33
$(CH_3)_2C=CHCOCH_3$	(0.05)[c]	35
2-Cyclohexen-1-one	2.3	trace
2-Cyclopenten-1-one	2.3	13

Carbonyl compound; 1.0 mmol, HEH; 1.3 mmol: 100 °C for 15 h in toluene. a) GLC yield. b) The reaction was run in benzene at 80 °C. c) The reaction was performed in benzene at 80 °C for 5 h employing CF_3COOH instead of CH_3COOH.

Results are given in Table 2. α,β-Unsaturated aldehydes were reduced smoothly yielding saturated aldehydes. α,β-Unsaturated linear ketones were moderately reactive whereas cyclic ketones such as 2-cyclohexenone reacted only scantily. Esters like methyl cinnamate, butyl acrylate, dimethyl fumarate, dimethyl maleate, and coumarin did not take part in the reaction.

The chemoselectivity between nitroalkene and α,β-unsaturated aldehyde is noteworthy. Thus an equimolar mixture of β-nitrostyrene and cinnamaldehyde was allowed to react with 0.9 equivalent amounts of HEH in the presence of a small amount of acetic acid (acetic acid/HEH=0.3) at 80 °C in benzene for 15 h. The reduction of the β-nitrostyrene to (2-nitroethyl)benzene took place selectively in 82% yield while the cinnamaldehyde was recovered unchanged in 98%.



As a whole, the present HEH-acetic acid system exhibited somewhat weaker reducing ability than that of HEH-silica gel system[6] in the reduction of a carbon-carbon double bond. In terms of this mildness, HEH-acetic acid system revealed the marked difference in reactivity toward the linear and cyclic α,β-unsaturated ketones. Since HEH is stable and obtained easily the present method has synthetic utility.

Experimental

HEH[12] and nitrostyrene derivatives[13] were prepared according to the literature. Other materials were commercially obtained. The structures of the products were confirmed by ^1H NMR and IR spectra.

General Procedure for the Reduction of Nitrostyrenes. Into a 50 cm^3 flask containing nitroalkene (1.0 mmol) and HEH (1.3 mmol) were added benzene (5 cm^3) and acetic acid (0.3 mmol) under a nitrogen atmosphere. The mixture was agitated at 80 °C for 15 h. After cooling, the reaction mixture was submitted to column chromatography on silica gel eluting with hexane-ethyl acetate to afford the reduced product. The results are given in Table 1.

General Procedure for the Reduction of α,β-Unsaturated Carbonyl Compounds. Into a 50 cm^3 flask containing α,β-unsaturated carbonyl compound (1.0 mmol) and HEH (1.3 mmol) were added toluene (5 cm^3) and acetic acid (3.0 mmol) under a nitrogen atmosphere. The mixture was agitated at 100 °C for 15 h. The product was analyzed by GLC. On the employment of trifluoroacetic acid (0.05 mmol), the reaction was performed in benzene (10 cm^3) at 80 °C for 5 h. The results are shown in Table 2.

Competitive Reaction of β-Nitrostyrene and Cinnamaldehyde. β-Nitrostyrene (1.0 mmol) and cinnamaldehyde (1.0 mmol) were agitated in the presence of HEH (0.9 mmol) and acetic acid (0.27 mmol) in benzene (5 cm^3) at 80 °C for 15 h under a nitrogen atmosphere. GLC analysis revealed the formation of (2-nitroethyl)benzene in 82% yield (based on HEH). The formation of 3-phenylpropionaldehyde was negligible (ca. 2%) and the most of the cinnamaldehyde remained unchanged (ca. 98%).

(Received November 25, 1987)

Synopsis. The catalytic oxygenation of cholesterol **1** with a platinum black catalyst under moderate pressure (20—25 atm) of oxygen yielded eleven oxidation products, **3**—**13a**. The reaction pathway of the catalytic oxygenation is discussed on the basis of the results for several reaction conditions.

Although the autoxidation of cholesterol (**1**) has been well-known for a long time, its mechanism has recently been clarified by Smith et al.[1a,b] On the other hand, Sneeden and Turner[2] performed the catalytic oxygenation of various steroidal alcohols with a platinum black catalyst (platinum catalyst) at ordinary pressures of oxygen and reported that the reaction proceeded easily, though their attempts concerning the catalytic oxygenation of **1** failed. However, in our previous paper[3] we reported success with the catalytic oxygenation of **1** with a platinum catalyst at room temperature under ordinary pressure of oxygen.

In this paper, we describe the structure of new products obtained by performing the catalytic oxygenation of **1** with a platinum catalyst at 80 °C under ordinary pressure and at 90 °C under moderate pressure (20—25 atm) of oxygen.

In the catalytic oxygenation of cholestanol with a platinum catalyst, the yield of cholestanone varied according to the method of preparing the platinum catalyst. Therefore, in order to investigate the catalyst activity, we performed the catalytic oxygenation of cholestanol using a platinum catalysts prepared under various conditions in ethyl acetate at room temperature for 24 h under ordinary pressures of oxygen, and obtained the results shown in Fig. 1. From the experimental results, it was found that the maximum yield (78%) of cholestanone was obtained when the platinum catalyst prepared by reducing platinum oxide (100 mg; 4.4×10^{-4} mol) with hydrogen (45 ml; 2.0×10^{-3} mol) was used.

For the catalytic oxygenation of **1** at moderate pressures of oxygen, we used the method of Sneeden and Turner.[2] The results of the catalytic oxygenation of **1** at ordinary pressure and at moderate pressure of oxygen performed using platinum catalyst under various conditions are given in Table 1. These oxidation products (**3**—**13a**) were directly identified by comparing them with the authentic samples by a known preparation method.[4-6]

The catalytic oxygenation of **1** with a platinum catalyst at 80 °C under ordinary pressure of oxygen gave oxidation products **3**—**9** with a good yield. In addition to the above products **3**—**9**, the reaction products **10**, **11**, and acidic substances **12a**, **13a** were newly isolated by the catalytic oxygenation of **1** using a catalytic amount of platinum catalyst under a moderate oxygen pressure. This was considered attributable to the effect of applying the moderate oxygen pressure, with the oxidation products **10**, **11**, and the acidic substances **12a**, **13a** being obtained only under a moderate pressure of oxygen.

According to the experimental results, the order on the oxidation position of cholesterol **1** is: hydroxyl group at C-3 > allylic hydrogen at C-7 > 5,6-double

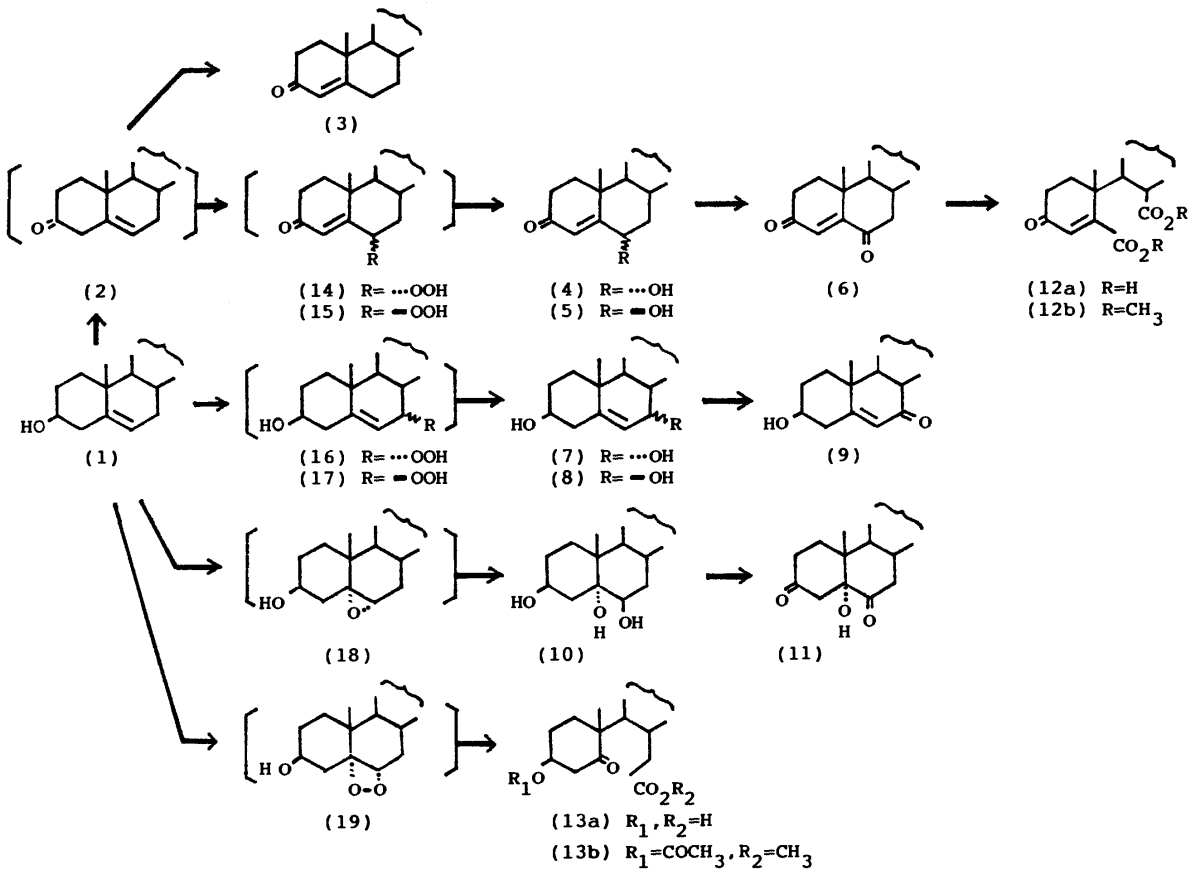

Fig. 2. Proposed pathways for the catalytic oxygenation of cholesterol (**1**).

bond.

The pathway of this catalytic oxygenation under moderate pressure of oxygen, presumed from the obtained oxidation product, is shown in Fig. 2. The courses of formation from **1** to **3** and **6** were shown in our previous paper.[3] In order to confirm the formation of the 6,7-seco acid **12a**, we performed catalytic oxygenation of diketone **6** with a platinum catalyst under a moderate pressure of oxygen with the result that **12a** was formed in a yield of 47%, as shown in Table 2. Therefore, **12a** was confirmed to be formed from **1** via **6**.

As for the formation of the 7-oxo compound **9**, it was assumed that there are two pathways: one is the pathway in which the 7α-hydroperoxide (**16**)[8] is directly formed and another is the course in which the 5α-hydroperoxide (**20**)[7a] is formed as is known to be formed by autoxidation[1a,b] and photoxidation.[7a,b] In order to confirm these pathways, the catalytic oxygenation of **16** with a platinum catalyst under ordinary pressure of oxygen was performed to give 3β,7α-diol **7** and **9** in yields of 56.2 and 39.7% respectively. On the other hand, 3β,5α-diol (**21**)[7a] was formed at a yield of 94% by catalytic oxygenation of **20** under these same conditions.

Therefore, in the catalytic oxygenation of **1**, it has become clear that the intermediate **16** is formed by the direct abstraction of the hydrogen of the allylic position at C-7 with the platinum catalyst, and an attack of oxygen; then **7** is formed with the reduction by hydrogen on the platinum catalyst and is further oxidized to give **9**.

In order to investigate the course of formation of hydroxy diketone **11**, catalytic oxygenation of 5,6α-epoxycholestan-3β-ol (**18**)[9] with a platinum catalyst in 2%-aqueous acetone at 80 °C under ordinary pressure of oxygen was performed to afford triol **10** with a yield of 59.6%. Furthermore, catalytic oxygenation of **10** with the platinum catalyst in *t*-butyl alcohol at room temperature under ordinary pressure of oxygen was performed to give **11** with a yield of 79.9%. These experimental results showed that the epoxide **18** was an intermediate in the formation of **11**.

Finally, regarding the pathway of the formation 5,6-seco acid **13a**, we have presumed that it is formed via the 5,6-dioxetane (**19**).[10a,b] We have inferred that the catalytic oxygenation of **1** with the platinum catalyst is considered a radical reaction, including the four pathways (Fig. 2).

Experimental

All melting points are uncorrected. IR spectra were obtained in KBr on a JASCO IR-G instrument. ^{1}H NMR were measured at 100 MHz using deuteriochloroform as the solvent. The chemical shift are given in ppm using tetramethylsilane (TMS) as an internal standard on a JNM-FX100 instrument. The mass spectra were recorded on a Hitachi RMU-7M system at 70 eV. GLC was performed on a Shimadzu GC-9A gas chromatography equipped 2%OV-17 (3 m×5 mm) at 300 °C and a SCOT OV-17 glass capillary column (30 m×0.3 mm).

Material and Authentic Specimens. Cholesterol (**1**) was a commercial source (Riken Vitamin Co. (Tokyo)) and purified by acetylation, hydrolysis and repeated recrystallization from methanol. The authentic specimens of cholest-4-en-3-one (**3**, mp 76—79 °C),[4a] 6α-hydroxycholest-4-en-3-one (**4**, mp 155—156 °C),[4b] 6β-hydroxycholest-4-en-3-one (**5**, mp 184—185 °C,[4b] cholest-4-ene-3,6-dione (**6**, mp 124—125 °C),[4b,c] cholest-5-ene-3β,7α-diol (**7**, mp 188—189 °C),[4d] cholest-5-ene-3β,7β-diol (**8**, mp 177—178 °C),[4d] 3β-hydroxycholest-5-en-7-one (**9**, mp 169—170 °C),[4d,e] cholestane-3β,5α,6β-triol (**10**, mp 236—238 °C),[4f] IR(KBr) ν 3400 cm^{-1} (OH); ^{1}H NMR ($CDCl_3$) (diacetate) δ=0.69 (3H, s, 18-CH_3), 1.15 (3H, s, 19-CH_3), 2.02 (3H, s, 6-OCOCH_3), 2.07 (3H, s, 3-OCOCH_3), 4.69 (1H, br.s *w*/2=6 Hz, 6-H), 5.15 (1H, m, *w*/2=24 Hz, 3-H); MS Found: *m*/*z* 420.3572. Catalytic Oxygenation of Cholesterol with Platinum Catalyst under Moderate Pressure of Oxygen. Platinum oxide (200 mg) was reduced to platinum black with hydrogen (60 ml) in *t*-butyl alcohol (10 ml) and then hydrogen was carefully replaced with air. The system filled with oxygen and catalyst was absorbed with oxygen (10 ml).

A solution of *t*-butyl alcohol (100 ml), platinum catalyst (200 mg), and cholesterol (**1**, 2g) was added to autoclave and the system was filled with oxygen (20—25 atm) and stirred at 90 °C for 24 hours. After reaction ceased, catalyst was removed by filtration and then the filtrate was concentrated to dryness at 40 °C under reduced pressure. Resulting reaction products were poured into ether and a treatment with 5%-Na_2CO_3 solution gave an acidic portion (160 mg, 8%) and a neutral portion (1.8 g, 90%). A portion of neutral product was separated on alumina column chromatography, TLC, and HPLC, while the other portion was analyzed by GLC as TMSE derivative. Acidic product was methylated with diazomethane and then acetylated with acetic anhydride-pyridine. A portion of the acidic products were separated on silica gel column chromatography, while the other portion was analyzed by GLC. All of the above oxidation products were identified by comparing with authentic sample by a known method.[4-6]

The authors wish to thank professor A. Nickon, Johns Hopkins University, for his kind donation of authentic samples and Dr. T. Iwadare, Sakura Fine-technical Co., Ltd., for his useful suggestion.

Synthesis of 1,4-Benzoquinone Derivatives Having Two Side-Armed Polyethers and Crown Ethers, and Their Electrochemical Study in the Presence of Alkali Metal Cations (Na^+ and K^+)

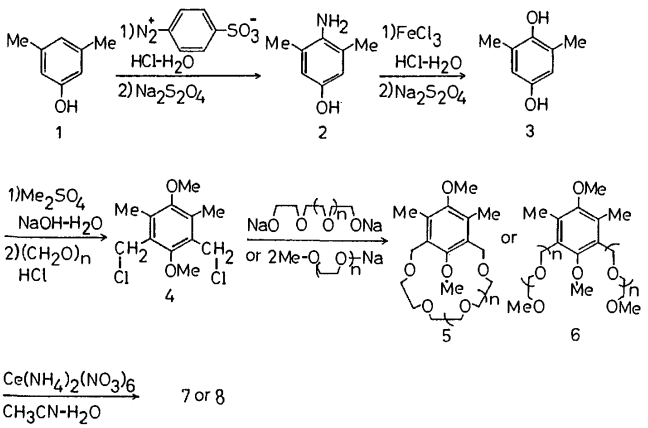
Hideo TOGO, Kiichi HASHIMOTO, Kenji MORIHASHI, and Osamu KIKUCHI*
Department of Chemistry, University of Tsukuba, Tsukuba, Ibaraki 305
(Received February 16, 1988)

Synopsis. Several crown ethers and two side-armed polyethers which have reducible quinonoid groups were prepared. Some of them, **7a**, **7b**, and **7d**, showed highly enhanced cation-binding properties for the Na^+ cation upon electrochemical reduction.

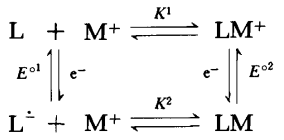
The design of redox-switched crown ethers and polyethers has been achieved by several researchers. The reducible functions involved in these compounds are disulfide,[1] quinone derivatives,[2] and nitrobenzene.[3] Their complexation abilities with metal cations are accelerated by the interaction of metal cations and polyether functions, and also by the ionic interaction of reduced functions with metal cations upon electrochemical reduction. In general, Li^+ has a large binding enhancement in most of the redox crowns or polyethers due to the strong affinity of Li^+ to heteroatoms, i.e. oxygen or nitrogen during electrochemical reduction.[2,3] In the case of Na^+ and K^+, the binding enhancements depend on the structures of the host compounds; it is a very interesting problem to determine the new redox-switched compounds which have large binding enhancements for Na^+ and K^+ cations. Here, we report on a series of crown ethers and two side-armed polyethers having quinonoid groups as well as their cyclic voltammetric studies, both in the presence and absence of metal cations (Na^+ and K^+).

Results and Discussion

We prepared the compounds **7a—d** and **8a—c**, which were obtained from 3,5-dimethylphenol by the following procedure.



Cyclic voltammetric studies of **7** and **8** in acetonitrile were carried out in the presence of metal cations, Na^+ and K^+, in order to examine the relative complexing abilities of the neutral ligand and the reduced one with metal cations; the binding enhancement, K^2/K^1, upon a one-electron reduction was obtained from the shift values ($E^{o1}-E^{o2}$) by Eq. 1.[3]



$$K^2/K^1 = \exp\left\{-\frac{F}{RT}(E^{o1}-E^{o2})\right\} \quad (1)$$

L : ligand, M^+: metal cation,
K^1 : binding constant for the neutral ligand,
K^2 : binding constant for the reduced ligand,
E^{o1} : redox potential for the free ligand,
E^{o2} : redox potential for the complex.

The binding enhancements and other electrochemical results are summarized in Table 1. In **7a**, the presence of Na^+ cation results in the observation of a new reduction peak, which corresponds to a one-electron reduction of the complex of crown **7a** and the Na^+ cation.

The cyclic voltammogram for the K^+ cation is reversible and the potential shift is small (0.10 V). Obviously, **7a** forms a 1-to-1 complex with Na^+ and K^+ cations during a one-electron reduction. Compounds **7b** and **7c** also form 1-to-1 complexes, both with Na^+ and K^+ cations, as shown in Table 1; compound **7b**, which has been reported by Cooper,[2a] exhibits large binding enhancements in both Na^+ and K^+ cations in acetonitrile, although Cooper used *N,N*-dimethylformamide as a solvent. Compound **7c** exhibits a small binding enhancement with both Na^+ and K^+ cations. Compound **7d** forms a 1-to-2 complex with the Na^+ cation, and its binding enhancement was the largest in the present ligands. On the other hand, **7d** forms a 1-to-1 complex with the K^+ cation and the binding enhancement was small. The binding enhancements of **8a—c** were found to be very small, though single-armed anthraquinone derivatives have large binding enhancements (ca. 10^2).[2c] We believe that one of the reasons is the result of a steric hindrance between two arms of **8** in the formation of a complex with metal cations during electrochemical reduction.

Experimental

Apparatus. ^1H NMR spectra were obtained on a JEOL FX-100 spectrometer. The chemical shifts are in ppm using TMS as an internal standard. IR spectra were measured on a

a) Quinone crown concentration 2 mM in CH_3CN containing 0.1 M Bu_4NClO_4 under Ar atmosphere. b) These peaks were broad. c) Quinone crown concentration 1 mM in DMF containing 0.1 M Et_4NClO_4 in the presence of 0.1 M $NaClO_4$ or KBF_4 (see to Ref. 2a). d) At 22 °C. e) At 23 °C. f) At 24 °C. g) Obtained from the difference between E^{c1} and E^{c2}. h) Obtained from the difference between E^{o1} (in the absence of metal cation) and E^{o2} (in the presence of metal cation).

Hitachi 260-50 spectrometer. Mass spectra were obtained with a Hitachi High MS M-80B mass spectrometer. Cyclic voltammograms were obtained by using a Hokuto Denko HB-104 and an HA-303.

Preparation of 1,4-Dimethoxy-2,6-bis(chloromethyl)-3,5-dimethylbenzene (4). Compound **4** was obtained by a known method from 3,5-dimethylphenol. 3,5-Dimethyl-4-aminophenol; mp 185—186 °C (lit,[4)] mp 181.5—182.5 °C). 2,6-Dimethylhydroquinone; mp 153—154 °C (lit,[4)] mp 150—151 °C). 1,4-Dimethoxy-2,6-dimethylbenzene; bp 90—93 °C/4 mmHg (lit,[5)] bp 80—82 °C/2 mmHg, 1 mmHg=133.322 Pa). 1,4-Dimethoxy-2,6-dimethylbenzene was treated with paraformaldehyde in concd hydrochloric acid solution under a closed system at about 60 °C overnight to give the desired chloromethylated compound **4** in 39% yield. 1,4-Dimethoxy-2,6-bis(chloromethyl)-3,5-dimethylbenzene; mp 143.0—143.5 °C (lit,[6)] mp 141.5—142.0 °C).

Preparation of Compounds 7 and 8. To the THF (100 ml) solution of 4506 mg (95%, 28.5 mmol) of triethylene glycol was added 3420 mg (60%, 85.5 mmol) of sodium hydride under cooling with an ice bath and stirred for 20 min. Then, both the above THF solution of disodium salt of triethylene glycol and the THF (100 ml) solution of 7500 mg (28.5 mmol) of 1,4-dimethoxy-2,6-bis(chloromethyl)-3,5-dimethylbenzene were added slowly with dropping funnels, respectively, to the THF (100 ml) solution in a three-necked flask which was cooled with an ice bath under an Ar atmosphere. After the addition, the reaction mixture was stirred at room temperature overnight. The solvent was removed and the residue was poured into water; the solution was then extracted with dichloromethane twice and the organic layer was dried over $MgSO_4$. After removing the solvent, the residue was chromatographed on silica gel (eluent; ethyl acetate) to give 2035 mg of **5a**.

5a; 21%; oil; ^{1}H NMR ($CDCl_3$) δ=2.35 (s, 6H, CH_3), 3.10—3.80 (m, 12H, $-CH_2CH_2-$), 3.67 (s, 3H, OCH_3), 3.68 (s, 3H, OCH_3), 4.58 (d, 2H, J=11.4 Hz, CH-H), and 4.76 (d, 2H, J=11.4 Hz, CH-H); IR (NaCl) 1080 and 1250 cm^{-1}; Found: C, 63.18; H, 8.30%. Calcd for $C_{18}H_{28}O_6$: C, 63.50; H, 8.29%.

5b; 30%; mp 97—99 °C; ^{1}H NMR ($CDCl_3$) δ=2.32 (s, 6H, CH_3), 3.40—3.70 (m, 20H, $-CH_2CH_2-$), 3.66 (s, 3H, OCH_3), 4.00 (s, 3H, OCH_3), and 4.60 (s, 4H, CH_2); IR (NaCl) 1115 cm^{-1}; Found: C, 62.21; H, 8.43%. Calcd for $C_{20}H_{32}O_7$: C, 62.48; H, 8.38%.

5c; 35%; mp 61—62 °C; ^{1}H NMR ($CDCl_3$) δ=2.32 (s, 6H, CH_3), 3.54 (s, 3H, OCH_3), 3.50—3.70 (m, 20H, $-CH_2CH_2-$), 3.93 (s, 3H, OCH_3), and 4.55 (s, 4H, CH_2); Found: C, 61.27; H, 8.49%. Calcd for $C_{22}H_{36}O_8$: C, 61.66; H, 8.46%; IR (NaCl) 1110 cm^{-1}.

5d; 10%; oil; ^{1}H NMR ($CDCl_3$) δ=2.32 (s, 6H, CH_3), 3.50—3.70 (m, 24H, $-CH_2CH_2-$), 3.66 (s, 3H, OCH_3), 3.86 (s, 3H, OCH_3), and 4.58 (s, 4H, CH_2); IR (NaCl) 1115 cm^{-1}; Found: C, 60.67; H, 8.65%. Calcd for $C_{24}H_{40}O_9$: C, 60.99; H, 8.53%.

Two side-armed polyethers were obtained by the same procedure.

6a; 100%; mp 142—143 °C: ^{1}H NMR ($CDCl_3$) δ=2.31 (s, 6H, CH_3), 3.41 (s, 6H, OCH_3), 3.66 (s, 3H, aromatic OCH_3), 3.77 (s, 3H, aromatic OCH_3), and 4.47 (s, 4H, CH_2); IR (NaCl) 1255 and 1080 cm^{-1}; Found: C, 66.14; H, 8.82%. Calcd for $C_{14}H_{22}O_4$: C, 66.11; H, 8.71%.

6b; 100%; oil; ^{1}H NMR ($CDCl_3$) δ=2.32 (s, 6H, CH_3), 3.37 (s, 6H, OCH_3), 3.50—3.70 (m, 8H, $-CH_2CH_2-$), 3.66 (s, 3H, aromatic OCH_3), 3.77 (s, 3H, aromatic OCH_3), and 4.58 (s, 4H, CH_2); IR (NaCl) 1090 cm^{-1}; Found: C, 63.07; H, 8.90%. Calcd for $C_{18}H_{30}O_6$: C, 63.13; H, 8.83%.

6c; 100%; oil; ^{1}H NMR ($CDCl_3$) δ=2.32 (s, 6H, CH_3), 3.37 (s, 6H, OCH_3), 3.77 (s, 3H, aromatic OCH_3), 3.66 (s, 3H, aromatic OCH_3), 3.50—3.70 (m, 16H, $-CH_2CH_2-$), and 4.57 (s, 4H, CH_2); IR (NaCl) 1110 cm^{-1}; Found: C, 61.32; H, 8.97%. Calcd for $C_{22}H_{38}O_8$: C, 61.37; H, 8.89%.

Dimethyl crown compound **5a**, 1.31 g (3.85 mmol), which was obtained above, was dissolved in 12 ml of acetonitrile; then, 12 ml of water solution of 5.30 g (9.63 mmol) of cerium (IV) diammonium nitrate was added to the solution and stirred for 45 min at room temperature. After the reaction, the reaction mixture was poured into dichloromethane and washed twice with water. The organic layer was dried over $MgSO_4$. After removing the solvent, the residue was chromatographed on silica gel (eluent: ethyl acetate) to give 0.94 g of **7a**. Compounds **7b—d** and **8a—c** were obtained by the same procedure.

7a; 79%; mp 56—59 °C; ^{1}H NMR ($CDCl_3$) δ=2.12 (s, 6H, CH_3), 3.50—3.70 (m, 12H, $-CH_2CH_2-$), and 4.53 (s, 4H, CH_2); IR (NaCl) 1655, 1135, and 1080 cm^{-1}; Found: C, 61.96; H, 7.13; MS (70 eV) m/z 310 (M^+). Calcd for $C_{16}H_{22}O_6$: C, 61.92; H, 7.14; M, 310.

7b; 31%; oil; ^{1}H NMR ($CDCl_3$) δ=2.13 (s, 6H, CH_3), 3.50—3.70 (m, 16H, $-CH_2CH_2-$), and 4.47 (s, 4H, CH_2); Found: C, 60.31; H, 7.43%; MS (70 eV) m/z 354 (M^+). Calcd for $C_{18}H_{26}O_7$: C, 61.00; H, 7.39%; M, 354; IR (NaCl) 1115 and 1650 cm^{-1}.

7c; 67%; oil; ^{1}H NMR ($CDCl_3$) δ=2.14 (s, 6H, CH_3), 3.60—3.70 (m, 20H, $-CH_2CH_2-$), and 4.48 (s, 4H, CH_2); IR (NaCl) 1650 and 1110 cm^{-1}; Found: C, 59.85; H, 7.64%; MS (70 eV) m/z 398 (M^+). Calcd for $C_{20}H_{30}O_8$: C, 60.28; H, 7.58%; M, 398.

7d; 60%; mp 48—51 °C; ^{1}H NMR ($CDCl_3$) δ=2.15 (s, 6H, CH_3), 3.50—3.70 (m, 24H, $-CH_2CH_2-$), and 4.49 (s, 4H, CH_2); IR (NaCl) 1650 and 1090 cm^{-1}; Found: C, 59.17; H, 7.69%; MS (70 eV) m/z 442 (M^+). Calcd for $C_{22}H_{34}O_9$: C, 59.71; H, 7.74%; M, 442.

8a; 94%; mp 47—48 °C; ^{1}H NMR ($CDCl_3$) δ=2.14 (s, 6H, CH_3), 3.38 (s, 6H, OCH_3), and 4.37 (s, 4H, CH_2); IR (NaCl) 1645 and 1095 cm^{-1}; Found: C, 64.11; H, 7.24%. Calcd for $C_{12}H_{16}O_4$: C, 64.27; H, 7.19%.

8b; 92%; oil; ^{1}H NMR ($CDCl_3$) δ=2.15 (s, 6H, CH_3), 3.36 (s, 6H, OCH_3), 3.50—3.70 (m, 8H, $-CH_2CH_2-$), and 4.47 (s, 4H, CH_2); IR (NaCl) 1640 and 1090 cm^{-1}; Found: C, 61.40; H, 7.77%. Calcd for $C_{16}H_{24}O_6$: C, 61.52; H, 7.74%.

8c; 84%; oil; ^{1}H NMR ($CDCl_3$) δ=2.15 (s, 6H, CH_3), 3.37 (s, 6H, OCH_3), 3.50—3.70 (m, 16H, $-CH_2CH_2-$), and 4.46 (s, 4H, CH_2); IR (NaCl) 1650 and 1110 cm^{-1}; Found: C, 59.82; H, 8.04%. Calcd for $C_{20}H_{32}O_8$: C, 59.98; H, 8.05%.

Reagents for Electrochemistry. Acetonitrile was distilled from CaH_2. Tetrabutylammonium perchlorate was twice recrystallized from ethyl acetate and alkali metal perchlorate salts were recrystallized from deionized water and dried over vacuum pumping at 100 °C. All these salts were stored in a desiccator, and samplings were carried out under an N_2 atmosphere in a dry box.

Cyclic Voltammetry Experiments. A 2 mM solution (1 M=1 mol dm^{-3}) of substrate was prepared by mixing of 0.1 mmol of quinone derivative, 1701 mg (5 mmol) of Bu_4NClO_4, and 50 ml of acetonitrile. Pt metallic working electrode (Beckman 39273) and Pt wire as the counter electrode were used. $E°$ values were reported vs. saturated calomel electrode (SCE). A scan rate of 200 mV s^{-1} was used. 25 ml of the solution was added to a cell equipped with a magnetic stirrer and an inlet for an Ar atmosphere. After 30 min of Ar purging and stirring, cyclic voltammograms were recorded under unstirred conditions. Also, 0.5, 1.0, 1.5, and 2.0 equiv metal perchlorate solutions were prepared by the same procedure with 0.1 mmol of quinone derivative, 5 mmol of Bu_4NClO_4, and 50 ml of acetonitrile.

The authors wish to express their thanks to Professor Naomichi Furukawa for his helpful advice and Professor Yasumasa Kuwabara for valuable help with MS measurements in University of Tsukuba.

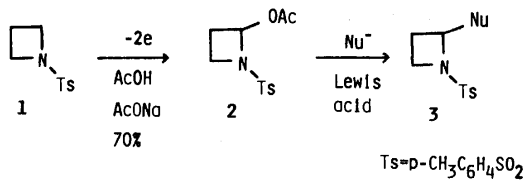
A Facile Syntehsis of 2-Substituted Azetidines[1)]

Tatsuya SHONO,* Yoshihiro MATSUMURA, Kenshi UCHIDA, and Fumihiko NAKATANI
Department of Synthetic Chemistry, Faculty of Engineering, Kyoto University, Yoshida Sakyo, Kyoto 606
(Received March 7, 1988)

Synopsis. A new method for the synthesis of 2-substituted azetidines has been exploited. The method consists of (1) anodic acetoxylation of 1-(*p*-tolylsulfonyl)azetidine at the 2-position and (2) subsequent nucleophilic substitution of the acetoxyl group with nucleophiles such as trimethylsilyl cyanide, allyltrimethylsilane, 2-acetoxyfuran, and trimethyl phosphite.

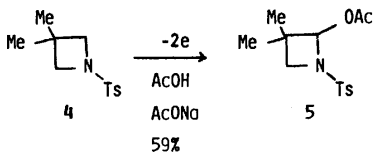
Although formation of 2-carbanions of azetidines followed by introduction of electrophiles to the 2-position has been recently reported,[2)] the opposite methods introducing nucleophiles (Nu^-) to the 2-position of azetidines have been unknown so far. We wish to report a new method for introducing Nu^- to the 2-position of azetidines. Our method consists of (1) anodic acetoxylation of 1-(*p*-tolylsulfonyl)azetidines **1** at the 2-position and (2) subsequent nucleophilic substitution of the acetoxyl group with a variety of Nu^- (Eq. 1).[3)]



(1)

The advantages of this method are (i) the starting compound **1** is easily available, and (ii) a variety of substituents can be introduced to the 2-position of the azetidine skeleton.

The procedure of anodic oxidation is simple as described in the experimental section. The yield of **2** was 70%. The anodic oxidation of **4** under similar conditions gave **5** in 59% yield (Eq. 2).



(2)

Although anodic oxidation of 1-formylazetidine and 1-(methoxycarbonyl)azetidine under similar conditions also gave the 2-acetoxylated products in 42 and 20% yields, respectively, compound **1** seems to be the most useful intermediate to the preparation of 2-substituted azetidines, since the synthesis of 1-formylazetidine and 1-(methoxycarbonyl)azetidine requires azetidine itself as the precursor, while **1** can easily be prepared from 3-amino-1-propanol.[6)] The anodic oxidation of **1** may proceed with direct electron transfer from **1** to anode, since the oxidation peak of **1**

Table 1. Reaction of **2** with Nucleophiles

Nucleophiles (equiv)		Lewis acid (equiv)		Condition	Product (Yield/%)
Me_3SiCN	(1.2)	$TiCl_4$	(1)	−70 °C, 2 h then r.t., 1 h	 **3a** (68)
	(1.5)	$TiCl_4$	(1)	−70 °C to r.t., 2.5 h	 **3b** (62)
6[a)]	(1.2)	$TiCl_4$	(1)	−70 °C, 5 h	 **3c** (38)
6[a)]	(1.2)	BF_3OEt_2	(1)	−18 °C, 15 min then r.t., 4 h	**3c** (36)
$P(OMe)_3$ **7**	(1.2)	$TiCl_4$	(1)	−70 °C, 2h	 **3d** (34)

a) See Ref. 7.

was observed at 2.60 V vs. SCE in acetonitrile.

The reaction of **2** with various Nu^- in the presence of Lewis acid catalysts gave **3a—d** in the yields shown in Table 1. In conclusion, this method provides a new synthetic route to various 2-substituted azetidines.

Experimental

Proton nuclear magnetic resonance spectra were measured on a Varian Associates EM-360 or EM-390 spectrometer with chemical shifts given in parts per million (δ) downfield from tetramethylsilane as an internal standard. Infrared spectra were recorded on a Hitachi 260-10 spectrometer. Elemental analyses were determined by the Center for Instrumental Analysis of Kyoto University. Electrooxidation was carried out using a DC power supply (GD 050-2) of Takasago Seisakusho. Ltd. 1-(*p*-Tolylsulfonyl)azetizine (**1**)[6] and 1-formylazetidine[8] were synthesized according to the reported methods.

1-(Methoxycarbonyl)azetidine was prepared similarly to the synthesis of 1-(ethoxycarbonyl)azetidine[8] (73% yield): bp 80 °C (20 mmHg (1 mmHg≈133.322 Pa), bulb-to-bulb); IR(neat) 2970, 2900, 1715, 1455, 1392, 1200, 1145, 1000, 780 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.16 (quint, 2H, J=7.0 Hz), 3.55 (s, 3H), 3.89 (t, 4H, J=7.0 Hz); MS, m/z 115(M^+), 100, 59, 56, 41(base); Found: C, 52.01; H, 7.93; N, 11.97%. Calcd for $C_5H_9NO_2$: C, 52.16; H, 7.88; N, 12.17%.

1-(*p*-Tolylsulfonyl)-3,3-dimethylazetidine (4) was prepared from 2,2-dimethyl-3-amino-1-propanol similarly according to the synthesis of **1**[6] (77% yield in two steps): mp 60—62 °C; IR(KBr) 2950, 2860, 1595, 1453, 1340, 1232, 1168, 1090, 1060, 825 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.70 (s, 6H), 2.47 (s, 3H), 3.49 (s, 4H), 7.47 (d, 2H, J=9.0 Hz), 7.82 (d, 2H, J=9.0 Hz); Found: C, 60.25; H, 7.07; N, 5.71; S. 13.32%. Calcd for $C_{12}H_{17}NO_2S$: C, 60.22; H, 7.16; N, 5.85; S, 13.40%.

Anodic Oxidation of 1. Into a cell equipped with a carbon rod cathode (8 mmϕ) and a platinum anode (2 cm×2 cm) was placed a solution of **1** (422 mg, 2 mmol) and sodium acetate (1g, 12 mmol) in acetic acid (20 mL). After having been passed 40 F mol^{-1} of electricity at room temperature (current density; 50 mA cm^{-2}, terminal voltage; 40 V), the mixture was poured into water and the organic portion was extracted with CH_2Cl_2. The solvent was removed in vacuo and the residue was subjected to preparative TLC (silica gel, AcOEt : hexane=1 : 2) to yield **2** (376 mg, 1.4 mmol, 70% yield): IR (KBr) 2950 (br), 1745, 1605, 1360, 1240, 1175, 1160, 1115, 1060, 850, 680 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.93—2.67 (m, 2H), 2.10 (s, 3H), 2.48 (s, 3H), 3.22—4.00 (m, 2H), 6.16 (t, 1H, J=6.0 Hz), 7.41 (d, 2H, J=9.0 Hz), 7.86 (d, 2H, J=9.0 Hz); Found: C, 53.55; H, 5.57; N, 4.91; S, 11.87%. Calcd for $C_{12}H_{15}NO_4S$: C, 53.52; H, 5.61; N, 5.20; S, 11.90%.

Anodic oxidation of 4, 1-formylazetidine, and 1-(methoxycarbonyl)azetidine in a similar manner to the anodic oxidation of **1** gave the corresponding 2-acetoxylated products.

5: 59% yield at 180 F mol^{-1} of electricity; IR (KBr) 2980, 1750, 1604, 1360, 1228, 1169, 1062 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.94 (s, 3H),1.16 (s, 3H), 2.12 (s, 3H), 2.49 (s, 3H), 3.16 (d, 1H, J=7.0 Hz), 3.41 (d, 1H, J=7.0 Hz), 5.75 (s, 1H), 7.45 (d, 2H, J=9.0 Hz), 7.85 (d, 2H, J=9.0 Hz); Found: C, 56.60; H, 6.62; N, 4.71; S, 10.50%. Calcd for $C_{14}H_{19}NO_4S$: C, 56.55; H, 6.44; N, 4.71; S, 10.78%.

2-Acetoxy-1-formylazetidine: 42% yield at 200 F mol^{-1} of electricity; IR (neat) 2980, 2900, 1745, 1675, 1460, 1405, 1228, 1100, 859 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.17 (s, 3H), 2.20—3.00 (m, 2H), 3.80—4.20 (m, 2H), 6.31—6.51 (m, 1H), 8.33—8.56 (br, 1 H); Found: C, 50.71; H, 6.30; N, 9.60%. Calcd for $C_6H_9NO_3$: C, 50.34; H, 6.34; N, 9.79%.

2-Acetoxy-1-(methoxycarbonyl)azetidine; 20% yield at 180 F mol^{-1} of electricity; ^1H NMR ($CDCl_3$) δ=2.00—2.90 (m, 2H), 2.13 (s, 3H), 3.73 (s, 3H), 3.70—4.10 (m, 2H), 6.25—6.43 (m, 1H); Found: C, 48.90; H, 6.31; N, 8.01%. Calcd for $C_7H_{11}NO_4$: C, 48.55; H, 6.40; N, 8.09%.

Reaction of 2 with Nucleophiles. A typical procedure is exemplified by the synthesis of 2-cyano-1-(*p*-tolylsulfonyl)-azetidine (**3a**): To a stirred solution of **2** (200 mg, 1.86 mmol) and trimethylsilyl cyanide (222 mg, 2.24 mmol) in CH_2Cl_2 was added dropwise $TiCl_4$ (0.2 mL, 1.86 mmol) at −70 °C under an atmosphere of nitrogen. The mixture was stirred at the temperature for 2 h and warmed to room temperature. Then, the reaction mixture was poured into water, and extracted with CH_2Cl_2. Drying and evaporation of the solvent gave a residue, which was subjected to a silica-gel chromatography (AcOEt : hexane=1 : 5) to yield **3a** (299 mg, 1.265 mmol, 68% yield): mp 106—108 °C; IR (neat) 2250, 1600, 1350, 1165, 1100, 820, 675 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.87—2.97 (m, 2H), 2.50 (s, 3H), 3.64—4.15 (m, 2H), 4.69 (t, 1H, J=9.5 Hz), 7.43 (d, 2H, J=8.3 Hz), 7.86 (d, 2H, J=8.3 Hz); MS, m/z 236 (M^+), 155, 91 (base), 81; Found: C, 55.75; H, 5.14; N, 11.54; S, 13.33%. Calcd for $C_{11}H_{12}N_2O_2S$: C, 55.92; H, 5.13; N, 11.86; S, 13.57%.

Data for new compounds **3b—d** are shown below.

3b: IR (neat) 3080, 2985, 1645, 1600, 1500, 1455 (br), 1345, 1305, 1295, 1240, 1163, 1100, 1000, 925, 820, 780, 735, 715, 670 cm^{-1}; ^1H NMR ($CDCl_3$); δ=1.59—2.12 (m, 2H), 2.28—2.60 (m, 2H), 2.41 (s, 3H), 3.18—4.13 (m, 3H), 4.72—5.15 (m, 2H), 5.37—6.06 (m, 1H), 7.23 (d, 2H, J=8.3 Hz), 7.63 (d, 2H, J=8.3 Hz); MS, m/z 251 (M^+), 210 (base), 155, 91; Found: C, 62.24; H, 6.89; N, 5.65; S, 12.51%. Calcd for $C_{13}H_{17}NO_2S$: C, 62.12; H, 6.82; N, 5.57; S, 12.76%.

3c: Mp 130—133 °C; IR (KBr) 1795, 1760, 1610, 1600, 1343, 1315, 1252, 1168, 1101, 1028, 900, 823 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.90—2.41 (m, 2H), 2.51 (s, 3H), 3.67 (t, 2H, J=8.0 Hz), 4.48—4.73 (m, 1H), 5.29—5.44 (m, 1H), 6.29—6.43 (m, 1H), 7.57 (d, 2H, J=9.0 Hz), 7.81—7.96 (m, 1H), 7.92 (d, 2H, J=9.0 Hz); Found: C, 57.49; H, 5.33; N, 4.77; S, 10.70%. Calcd for $C_{14}H_{15}NO_4S$: C, 57.32; H, 5.15; N, 4.78; S, 10.93%.

3d: Isolated by alumina chromatography; mp 86—87 °C; IR (KBr) 2960 (br), 1600, 1460 (br), 1355, 1250, 1170, 1100, 1075, 1030, 850, 825, 775, 720, 670 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.86—2.97 (m, 2H), 2.48 (s, 3H), 3.70 and 3.76 (2s, 3H), 3.89 and 3.94 (2s, 3H), 3.57—4.53 (m, 3H), 7.44 (d, 2H, J=9.0 Hz), 7.85 (d, 2H, J=9.0 Hz); Found: C, 45.20; H, 5.67; N, 4.28; P, 9.41%. Calcd for $C_{12}H_{18}NO_5SP$: C, 45.14; H, 5.86; N, 4.39; P, 9.70%.

Oxidation Potentials. Oxidation peak potential of **1** was measured at room temperature by using an H-type cell, a potentiostat HA-104 and function generator HB-107A (Hokuto Denko Ltd.) under the following conditions; scan rate: 100 mV s^{-1}; electrordes: platinum anode and cathode; E_p, 2.60 V vs. SCE (4.74×10^{-3} M (1M=1 mol dm^{-3})), 2.70 V vs. SCE (9.50×10^{-3} M) in CH_3CN–0.1 M $LiClO_4$.

Molecular Structure of Trimethylphosphine-Borane as Determined from Electron Diffraction and Microwave Spectroscopic Data

Kinya IIJIMA,* Yumi HAKAMATA, Takashi NISHIKAWA, and Shuzo SHIBATA
Department of Chemistry, Faculty of Science, Shizuoka University,
Oya, Shizuoka 422
(Received January 13, 1988)

The molecular structure of trimethylphosphine-borane has been determined from gas electron diffraction and spectroscopic data. The molecular parameters and their uncertainties are r_g(B-H)=1.225±0.011 Å, r_g(P-B)=1.899±0.006 Å, r_g(C-P)=1.815±0.003 Å, r_g(C-H)=1.103±0.002 Å, ∠HBH=108.6±0.6°, and ∠CPC=104.6±0.3°. The P-B distance of this complex is about 0.04 Å shorter than those of trimethylphosphine-boron trihalides.

Molecular structures of trimethylamine-borane and trimethylamine-boron trifluoride have been sudied by electron diffraction and microwave spectroscopic methods in the gas phase.[1-6] The molecular structures determined from microwave spectroscopic data, however, were found to be significantly different from those determined from electron diffraction data. Since a trimethylamine complex with borane or boron trifluoride has C_{3v} symmetry, the number of the rotational constants used in the structural analysis was limited and some molecular parameters had to be assumed in the microwave spectroscopic method. These assumptions were not necessary in electron diffraction, though electron diffraction data were less precise than microwave spectroscopic data. Therefore the joint analysis of electron diffraction and microwave spectroscopic data yielded highly accurate molecular parameters.[2,3]

The structural parameters of trimethylphosphine-borane have also been determined from the rotational constants of $(CH_3)_3P\cdot{}^{11}BH_3$, $(CH_3)_3P\cdot{}^{10}BH_3$, $CD_3(CH_3)_2P\cdot{}^{11}BH_3$, and $(CH_3)_3P\cdot{}^{11}BDH_2$.[7] We have reported in the study of $(CH_3)_3N\cdot BH_3$ that the substitution of D for H causes shortening of the B-H distance and opening of the HBH angle.[3] The microwave spectroscopic study, where isotopic molecules were assumed to have the same molecular dimension as the normal species, might have given incorrect molecular parameters as shown in the studies on trimethylamine complexes. Thus we reinvestigated the molecular structure of gaseous trimethylphosphine-borane by using both electron diffraction and microwave spectroscopic data.

Experimental

Diborane was prepared by the reaction of orthophosphoric acid and potassium tetrahydroborate,[8] and trimethylphosphine was obtained by the decomposition of trimethylphosphine-silver iodide complex at 200 °C.[9] The diborane and trimethylphosphine were allowed to react in a glass tube cooled by Dry Ice-acetone. The crude complex was purified by sublimation under reduced pressure. The purity was checked from the IR absorption spectra.

Electron diffraction photographs were taken by the use of an r³-sector on Kodak Electron-Image plates at camera distances of 293.79 and 143.85 mm. The sample was sublimed at 349 K by a high temperature nozzle. The accelerating voltage was about 40 kV and the wavelength was determined from the diffraction patterns of thallium(I) chloride.[10] The exposure times were about 30 and 105 s for the long and the short camera-distance photographs, respectively, with an electron-beam current of 0.8 μA. The pressure in the diffraction chamber was 1.5×10^{-3} Pa during the experiment. Two photographic plates taken at the long camera distance and three plates taken at the short camera distance were selected for the intensity measurement by a digital microphotometer. The electron diffraction unit and the digital microphotometer used in the present study have been described elsewhere.[11]

Analysis and Results

The scattering intensities in the range of q=10.0—53.5 Å^{-1} were obtained from the long camera-distance plates and those in the range of q=20.0—107.0 Å^{-1} from the short camera-distance plates. Here q represents $(40/\lambda)\sin(\theta/2)$, where λ is the wavelength

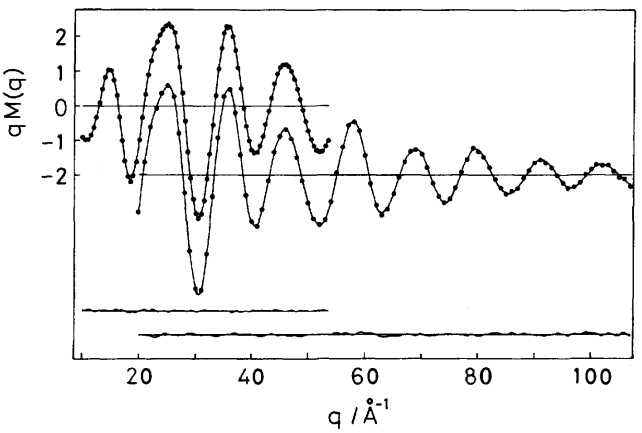

Fig. 1. Molecular intensities for trimethylphosphine-borane. The upper curve is the long camera-distance data and the lower the short camera-distance data. Dots represent the observed ones and solid curves the calculated ones. The residuals are shown at the lower part of the figure.

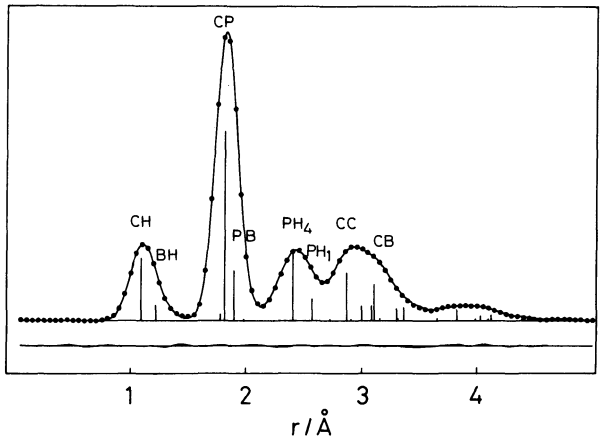

Fig. 2. Radial distribution curve for trimethylphosphine-borane. Dots represent the experimental one, solid curve the theoretical one, and the difference is shown below. The vertical bars represent bond distances and the scattering powers.

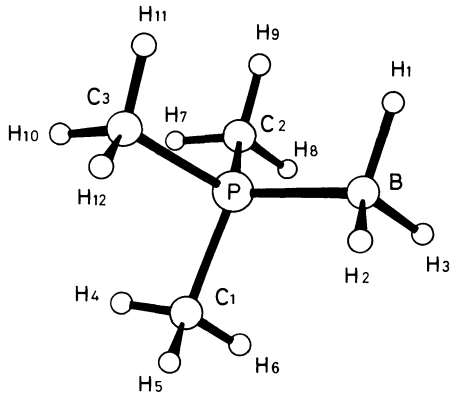

Fig. 3. Molecular model and numbering of atoms in trimethlphosphine-borane.

and θ is the scattering angle. They were leveled by using theoretical backgrounds, and the intensities for each camera distance were averaged. The elastic and inelastic scattering factors were taken from Refs. 12—14. The experimental molecular intensities obtained are shown in Fig. 1. Figure 2 shows the experimental radial distribution function. The molecular model of trimethylphosphine-borane and the numbering of the atoms are shown in Fig. 3.

It was assumed that the molecule of $(CH_3)_3P \cdot BH_3$ has C_{3v} symmetry in a staggered form and the methyl groups also have C_{3v} symmetry. The latter local C_3 axes were assumed to be coincident with the C-P bond. The r_α parameters[15] determined by least-squares analyses were r(B-H), r(P-B), r(C-P), r(C-H), r(C-C), r(H-(B)-H), and $\angle$PCH. Vibrational mean amplitudes and shrinkage corrections, $r_a - r_\alpha$,[15] were calculated from the reported force field,[16] where the force constants for the torsional vibration around the C-P and P-B bonds had not been estimated. The force

H_1-H_7	2087	110	H_5-H_8	2094	103
H_1-H_8	3190	−91	H_5-H_9	1474	148
H_1-H_9	2903	−3	H_5-H_{12}	2973	−47

The numbering of atoms is shown in Fig. 3.

constant for the C-P torsion was estimated to be 0.081×10^{-18} N m from the potential barrier height of 2.6 kcal mol^{-1} in trimethylphosphine.[17] From the preliminary analysis assuming a low potential barrier approximation[18] the potential barrier around the P-B bond was about 3 kcal mol^{-1}, though it might include a large error. The force constant for the torsional vibration around the P-B bond was 0.09×10^{-18} N m. Thus the torsional vibrations around the C-P and P-B bonds were treated in a high potential barrier approximation.[18] The calculated mean amplitudes and shrinkage corrections are listed in Table 1. The asymmetry parameters, κ, for the B-H, P-B, C-P, and C-H bonds were estimated to be 20, 4.3, 3.2, and 13×10^{-6} Å^3, respectively, by the diatomic approximation[19] and those for the other atomic pairs were ignored.

The results of the least-squares analysis from the electron diffraction data are listed in Table 2. The rotational constant of a normal species of trimethylphosphine-borane was calculated by using the r_α°[15] parameters transformed from the r_α parameters in Table 2. Although it was in good agreement with the observed one as shown in Table 3, the joint analysis of electron diffraction data and rotational constant was performed. The relative weight for the observed rotational constant in the least-squares calculation was estimated to be 1×10^7 in such a way that the standard deviation of the rotational constant obtained from the least-squares calculation is nearly equal to the uncertainty in B_z, which is a rotational constant corrected for the vibrational effect.[15] The geometrical parameters and the mean amplitudes obtained from the joint analysis are listed in Tables 2 and 4, respectively. The limits of error in the distances were taken to be the square root of the sum of the squares of the random and systematic errors, while those in the angles and the mean amplitudes were taken to be the

random errors. The random errors were assumed to be 2.6 times as large as the standard errors in the least-squares calculation. The systematic errors in the distances were estimated from the errors in both the measurements of camera distance (0.03%) and wavelength (0.11%). The best-fit molecular intensities and the radial distribution function are shown in Figs. 1 and 2, respectively. The experimental intensities, the experimental smooth backgrounds, and the correlation matrix for the molecular parameters are deposited in Document No. 8825 at the Office of the Editor of the Bulletin of the Chemical Society of Japan. The least-squares calculations were carried out on a HITAC M-682H computer in the Computer Center of the University of Tokyo.

Discussion

The molecular parameters of gaseous trimethylphosphine–borane obtained from the present study are in agreement with those from the microwave spectroscopic study[7] except the parameters of r(B–H) and ∠HBH. The P–B bond distance of $(CH_3)_3P \cdot BH_3$, 1.90 Å, is greater than that of $F_3P \cdot BH_3$, 1.84 Å,[20] but the former complex is more stable than the latter. The unusually short but weak P–B bond of the latter complex has been discussed elsewhere.[7,21] The P–B bond distance of $(CH_3)_3P \cdot BH_3$ is about 0.04 Å shorter than those of $(CH_3)_3P \cdot BX_3$ (X=Cl,Br,I),[22–24] which are in the range of 1.94—1.95 Å, though the sequence of the stability of the complexes is $(CH_3)_3P \cdot BBr_3 > (CH_3)_3P \cdot BH_3 > (CH_3)_3P \cdot BCl_3$.[25] This close approach of boron to phosphorus in $(CH_3)_3P \cdot BH_3$ is probably achieved by a relatively small steric hindrance of borane to the donor molecule.

The magnitude of structural changes of donor molecules on the complex formation is one of the measures of the acid strength of acceptors. The structural parameters of trimethylamine and trimethylphosphine in the complexes with boron compounds are listed in Table 5 in decreasing order of the CNC or CPC angles. This order is almost the same as the increasing order of the C–N or C–P distances.

The order of trimethylamine boron trihalides is the same as that of trimethylphosphine boron trihalides in Table 5, but a free trimethylamine molecule is at the top of the corresponding series and a free

trimethylphosphine molecule is at the bottom. The borane complexes are located at the position next to the free molecules. This fact means that both donor molecules require the least deformation energy on the complex formation with borane, and that the deformation energy of trimethylamine increases with the atomic number of halogens of the acceptor molecules while that of trimethylphosphine decreases. The different changes of the structures of trimethylamine and trimethylphosphine on the complex formation with boron trihalides will be explained by the ab initio molecular orbital calculation.

The authors express their thanks to Professor Teruhiko Ogata of Shizuoka University for his valuable discussion.

The ^{19}F Solid-State High-Resolution Nuclear Magnetic Resonance Study of K_2SiF_6, K_2GeF_6, and K_2SnF_6

Yoshichika YOSHIOKA,† Nobuo NAKAMURA, and Hideaki CHIHARA*
Department of Chemistry, Faculty of Science, Osaka University,
Toyonaka, Osaka 560
(Received January 21, 1988)

High-resolution ^{19}F NMR experiments were carried out on K_2SiF_6, K_2GeF_6, and K_2SnF_6, and the chemical-shift shielding tensors were determined. In all three substances, the shielding tensors are axially symmetric, and the most shielded direction is parallel to the MF (M=Si, Ge, and Sn) bond. The values of the shielding tensor elements ($\sigma_{//}$ and $\sigma_{\perp}$) change systematically from K_2SiF_6 to K_2SnF_6, except for the $\sigma_{\perp}$ component of K_2SiF_6, which is very large compared with those in the Ge and Sn-complexes. The analysis of σ's by a simple MO treatment indicates that π-backbonding is the strongest in the Si-F bond, probably because of the extraordinarily low electronegativity of Si. At room temperature, the reorientation of MF_6^{2-} anions is rapid enough to average out the shielding tensor components in the Si and Sn-complexes.

High-resolution NMR spectroscopy is a very useful technique for examining the structures and the chemical reactivities of such inorganic complex ions as MF_6^{2-} and is widely used for those ions in solutions. However, usual high-resolution NMR in solution gives only an averaged value of the chemical shift. In order to study the electronic structure and the reactivity of complex ions more closely, it is desirable to measure the anisotropy in the chemical-shift tensor by using crystalline materials. The temperature dependence of the chemical shift also provides valuable information about the very slow anisotropic molecular motion in the crystalline state.

It has been recognized that various types of compounds of Group IV_b metals, i.e., Si, Ge, and Sn, show unusual properties in that they do not obey the so-called law of corresponding states: the halogen nuclear quadrupole resonance frequencies in MX_4 (M=Si, Ge, and Sn) do not vary in a regular manner.[1] Also the ^{19}F chemical shift in MF_6^{2-} in solution does not change systematically from Si to Sn, etc.[2] These and other unique aspects of the behavior of the Group IV_b compounds have not yet been fully understood, although it can be inferred that the nature of the chemical bond changes abruptly on going from Si to Ge.[3] It is, therefore, interesting to determine the chemical shielding tensor completely using crystalline materials of Group IV_b compounds. Here we applied the solid-state high-resolution NMR technique to a series of K_2MF_6, where M=Si, Ge, and Sn, in an attempt to obtain detailed information on the electronic structure of MF_6^{2-} anions.

At room temperature, K_2SiF_6 is cubic,[4] while the other substances are trigonal,[5] as is shown in Figs. 1 and 2. The site symmetry at Si in K_2SiF_6 is O_h, while that of the central atoms in the other compounds is D_{3d}, which reflects the slight distortion of the MF_6 polyhedra from the regular octahedron. All the

anions in these crystals are crystallographically equivalent. Since MF_6^{2-} ions form an approximately regular octahedron, the electron distribution in the M-F bond must be close to the axial symmetry. Therefore, axially symmetric chemical-shift tensors at the F atoms may be expected.

Experimental Results and Discussion

1. Spectrometer. Measurements were made by a home-built spectrometer which operates at 40 MHz (suitable for ^{19}F resonance at 1 T). The MREV-8[6] pulse sequence was employed to obtain the high-resolution spectrum in the solid. The shortest interval between pulses was chosen as 6.7 μs, and the optimum resolution of the spectrometer was about 8 ppm (300 Hz). The details of the spectrometer, its operation, and the data-processing procedure have been described elsewhere.[7]

2. Potassium Hexafluorosilicate, K_2SiF_6.

i) Preparation and Measurements: Powdered K_2SiF_6 as purchased from the Nakarai Chemical Co., Ltd., was used for multiple-pulse NMR measurements at 300 and 77 K. The time-domain signals were accumulated 20 times and then Fourier-transformed to obtain a spectrum. The spectra thus obtained are shown in Fig. 3. The spectrum at 300 K has the half-height-width of 30 ppm (1.2 kHz) and does not appear to have any anisotropy. The line-width at 77 K is larger than that at 300 K, and a small additional hump appears on the high-field side.

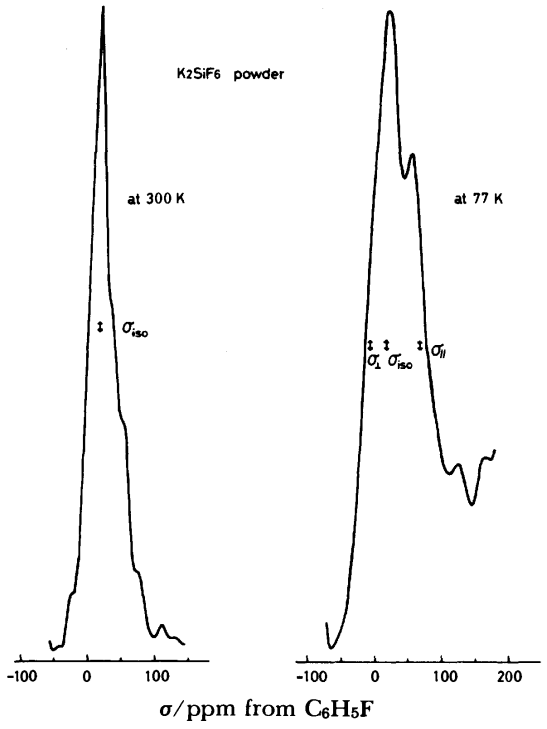

Fig. 3. High-resolution NMR spectra of ^{19}F in powdered K_2SiF_6 at 300 and 77 K. The reference material for the chemical shift is liquid C_6H_5F.

ii) Determination of Chemical-Shift Tensor: The spin-lattice relaxation time of ^{19}F was measured in the temperature range between 77 and 973 K by Moskvich et al.[8] According to them, the correlation time τ_c for the isotropic reorientation of SiF_6^{2-} is about 10^{-6} s at 300 K; therefore, it can be expected that this spherical reorientation will completely average the anisotropy of the chemical-shielding tensor of the ^{19}F nuclei. In fact, the spectrum at 300 K in the present work consists of a single, relatively narrow peak (shown in Fig. 3), which can be explained by such an averaging effect. The value of σ_{av} (isotropically averaged value) obtained is 16±5 ppm relative to the ^{19}F resonance in liquid C_6H_5F.

The spectrum at 77 K shown in Fig. 3 is different from the typical pattern for a rigid lattice: there is a small hump on the high-field side. The overall reorientation of SiF_6^{2-} will affect the line shape to some extent. Thus, Spiess[9] calculated the powder patterns for trigonal bipyramidal, tetrahedral, and octahedral molecules with an axially symmetric shielding tensor in the presence of a certain molecular reorientation in each case. He showed, based on the sudden-jump model, that a small hump may appear as the reorientational correlation time of the molecule approaches the inverse of the magnitude of the chemical-shift anisotropy. The powder pattern of K_2SiF_6 at 77 K was analysed according to the jump model; the chemical-shift anisotropy was estimated to be about 3 kHz, and the correlation time, to be about 3.3×10^{-3} s. The principal values of the shielding tensor were then determined as follows: $\sigma_{33}=66\pm5$ ppm and $\sigma_{22}=\sigma_{11}=-9\pm5$ ppm from liquid C_6H_5F ($\sigma_{33}\geqq\sigma_{22}\geqq\sigma_{11}$).

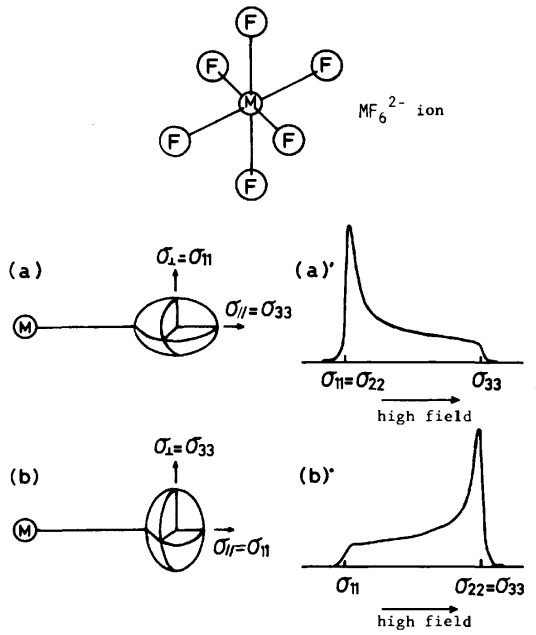

Fig. 4. Axially symmetric shielding tensor models and their powder patterns.

The SiF_6^{2-} ion forms a regular octahedron in the crystal;[4] therefore, the chemical-shielding tensor should be axially symmetric about the Si–F bond. In the case of an atom which forms a single bond, there are two possibilities of axially symmetric shielding tensors, as is shown in Fig. 4. In the **a** type, the maximum shielding direction is along the Si–F bond; in this case, the powder pattern of the **a′** type is obtained. In the case of the **b** type, the least shielded direction is along the Si–F bond, and so the powder pattern should be of the **b′** type. The analysis of the powder pattern of K_2SiF_6 indicates that the shielding tensor in this compound belongs to the **a** type. Therefore, its most shielded direction is along the Si–F bond, and the value of the chemical shift is 66 ppm. Its least shielded direction, on the other hand, is perpendicular to the Si–F bond, and its chemical shift is −9 ppm. The chemical shift of SiF_6^{2-} in a solution is 12 ppm,[2] slightly smaller than the isotropically averaged value in a solid (16 ppm) at room temperature.

3. Potassium Hexafluorogermanate, K_2GeF_6.

i) Preparation and Measurements: A colorless, transparent single crystal in the shape of a hexagonal plate was obtained by the slow evaporation at 30 °C of a solution of GeO_2 and KF in a stoichiometric ratio in 47% hydrofluoric acid. The crystal is of a trigonal symmetry, D_{3d}^3, with $Z=1$, and the C_3 axis of the GeF_6^{2-} ion is parallel to the crystallographic C axis[5] (see Fig. 2). The GeF_6^{2-} ion has the shape of a nearly regular octahedron, and so all the fluorines in the anion may be regarded as having nearly axially symmetric shielding tensors. Therefore, a pair of lines with the intensity ratio of 2:1 may be expected if the Zeeman field is rotated in the plane which is defined by the F_5, Ge, and F_1 atoms and the C_3 axis of the anion (see Fig. 2). A typical example of the spectrum at 300 K is shown in Fig. 5. The time-domain signals were accumulated 20 times at every 1800 s and then Fourier-transformed. When the Zeeman field was rotated in the above-mentioned plane of the crystal, the rotational patterns shown in Fig. 6 were obtained at 300 K. The line labelled by A is about twice as strong as the B line.

ii) Determination of the Chemical-Shift Tensor: From the ^{19}F second moment measured as a function of the temperature, Sergienko et al.[10] saw no sign of the reorientation of the GeF_6 anion, not even at 300 K. Therefore, we can use the rotational pattern of Fig. 6 to derive the rigid-lattice values of the shielding tensor components of ^{19}F. The dotted lines in Fig. 6 show the theoretical angular dependence of the shielding components on the assumption of the axially symmetric shielding tensor. The maximum point of the B curve (low-intensity line) corresponds to a Ge–F bond direction; that is, at this orientation the F_1–Ge–F_5 bond (see Fig. 2) is parallel to the Zeeman field. At the same orientation of the Zeeman field, the A curve (high intensity) has a minimum which indicates that the Zeeman field is perpendicular to both F_2–Ge–F_6 and F_3–Ge–F_4 bonds. Therefore, much as in the case of K_2SiF_6, the most shielded direction is along the Ge–F bond, while the least shielded direction is perpendicular to the Ge–F bond. The

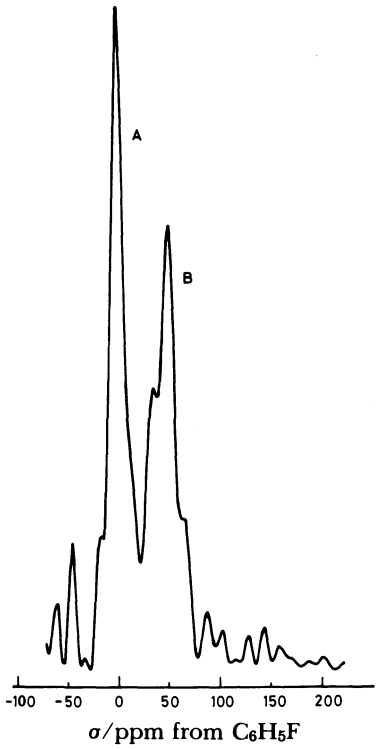

Fig. 5. ^{19}F NMR spectrum obtained by the Fourier transform of FID. The spectrum corresponds to the orientation, a* of Fig. 6.

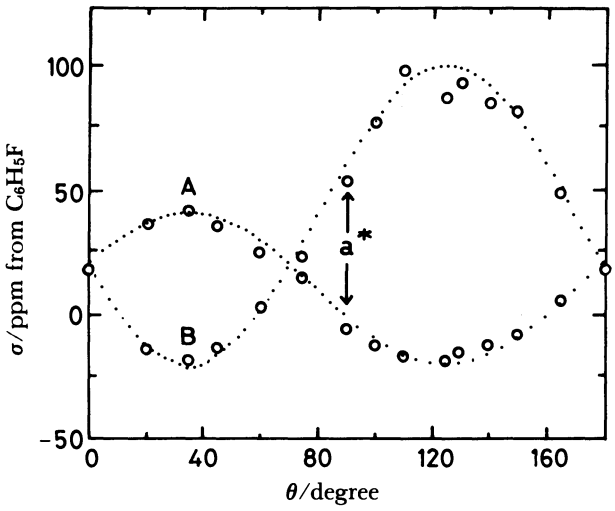

Fig. 6. Angular dependence of the ^{19}F chemical shifts of K_2GeF_6 single crystal. The pattern was obtained when the Zeeman field was rotated in the plane which is defined by F_5, Ge, and F_1 atoms and the C_3 axis (see Fig. 2). The angle θ is measured from the direction of the C_3 axis.

values of the shielding tensor components were thus determined as follows: $\sigma_{33}=99\pm3$ ppm and $\sigma_{22}=\sigma_{11}=-20\pm3$ ppm from liquid C_6H_5F. The isotropically averaged value is 19 ppm, significantly larger than that of ^{19}F in GeF_6^{2-} in solution (7 ppm).[2]

4. Potassium Hexafluorostannate, K_2SnF_6.

i) Preparation and Measurements: A K_2SnF_6 single crystal was obtained by the slow evaporation at 30 °C of a solution of $K_2Sn(OH)_6$ in 47% hydrofluoric acid. The crystal belongs to a trigonal system, and the site symmetry of Sn is D_{3d}.[5]

Multiple pulse measurements were made on the single crystal at 300 K in a manner similar to the case of K_2GeF_6. Contrary to the case of K_2GeF_6, no angular dependence of the shielding tensor was detected at 300 K, which indicates that the rapid molecular reorientation averages out the anisotropy in the shielding tensor, as in the case of K_2SiF_6. Then we carried out experiments on the powdered specimen at 300 and 77 K and reproduced the resulting spectra in Fig. 7. The spectrum at 300 K is a single, approximately symmetric peak, whereas the spectrum at 77 K corresponds to a typical powder pattern, involving some degree of anisotropy.

ii) Determination of the Chemical-Shift Tensor: The powder pattern at 300 K gives a motionally averaged, isotropic shielding with a σ_{av} value of 83 ± 5 ppm. The analysis of the powder pattern at 77 K, on the other hand, gives $\sigma_{33}=183\pm5$ ppm and $\sigma_{22}=\sigma_{11}=33\pm5$ ppm by assuming an axially symmetric shielding tensor. The most shielded direction is along the Sn–F bond, while the least shielded direction is perpendicular to the Sn–F bond. The averaged value, 83 ppm, is very different from that in SnF_6^{2-} in a solution (40 ppm).[2]

5. Discussion. Among the series of compounds of Group IV_b elements (C, Si, Ge, Sn, and Pb), silicon compounds show unusual behavior in several magnetic resonance properties, e.g., NMR chemical shifts[2,11] and NQR frequencies,[1] which reflect the electronic structures of atoms or molecules. The values of the chemical shielding of the compounds in this study are summarized in Fig. 8. To obtain some insight into the electronic structure of the molecules, the theory of Karplus and Das[12] will be used. The chemical-shift tensor consists of two contributions;

$$\sigma = \sigma^d + \sigma^p \tag{1}$$

where σ^d and σ^p are, respectively, the diamagnetic and paramagnetic parts of the chemical-shift tensor. Since it is the paramagnetic contribution that mainly gives rise to the experimentally observed variations in the chemical shifts of ^{13}C, ^{19}F, etc.,[12] only the paramagnetic part will be considered in investigating the electronic structure. According to the theory of Karplus and Das, the axially symmetric chemical-shift tensor for the atoms in this study can be given as follows:

$$\sigma_{//}^p = (3/2)\sigma_o(2\rho_\perp - \rho_\perp^2) \tag{2}$$

for the component along the M–F bond and

$$\sigma_\perp^p = (3/2)\sigma_o[\rho_\perp + (1-\rho_\perp)\varepsilon] \tag{3}$$

for the component perpendicular to the M–F bond, where σ_o is a semiempirical parameter, where $\rho_\perp$ is the π-bond character, and where

$$\varepsilon = 1 + IS - I - S. \tag{4}$$

I and S are the ionic character and the degree of sp hybridization respectively.

The $\sigma_{//}$ component increases regularly from K_2SiF_6 to K_2SnF_6, as is shown in Fig. 8. On the other hand, the $\sigma_\perp$ component of K_2SiF_6 seems to be anomalously large, presumably reflecting the anomalous character of the Si–F bond. Since $\sigma_{//}$ increases on going from K_2SiF_6 to K_2SnF_6, $|\sigma_{//}^p|$ must decrease in the same order. According to Eq. 2, it is concluded that the π-bond character, $\rho_\perp$, decreases regularly from K_2SiF_6 to K_2SnF_6. Such a tendency may be interpreted by

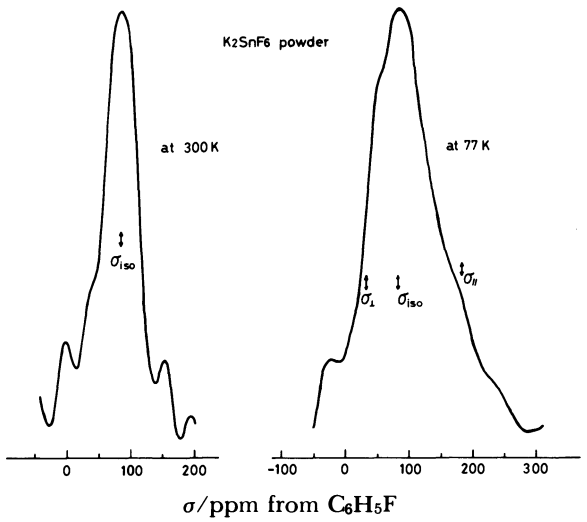

Fig. 7. Powder pattern of ^{19}F NMR in K_2SnF_6.

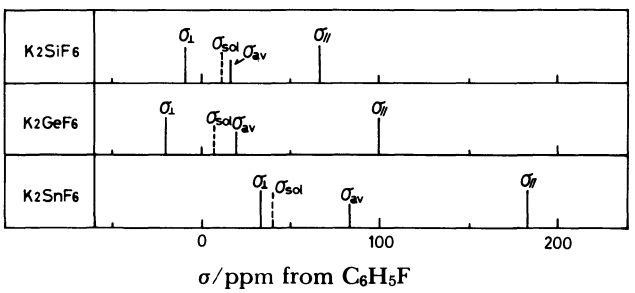

Fig. 8. Pictorial representation of the chemical shift tensor elements in K_2MF_6 (M=Si, Ge, and Sn) compounds. σ_{sol} is isotropic value in solution after Ref. 2.

introducing the concept of π-backbonding: the Group IV_b elements employ two d-orbitals in the octahedral d^2sp^3 hybridized orbitals for the framework of the MF_6^{2-} complex, and so the three remaining d-orbitals have the capability of forming π-bonding with orbitals of the ligand atoms. Through this π-bonding, partial electrons will be transferred from the ligands to the center atom. As $\rho_\perp$ is largest in the Si complex in the present series, we may consider that the π-backbonding is the strongest in K_2SiF_6.

An anomalously large $\sigma_\perp$ value was derived for SiF_6^{2-} compared with the other two compounds. According to Eq. 3, ε should be very small, so small as to cancel the effect of the large $\rho_\perp$ value in SiF_6^{2-}, which implies that the ionic or hybridyzation term in Eq. 4 should be large. Sanderson[13] and Hargittai and Bliefert[14] reexamined the electronegativity scale and showed that the electronegativity decreases in this order; C>Ge>Sn>Si. The anomalously large $\sigma_\perp$ value may be attributed to the high ionic character of the Si-F bond.

It may be noted in Fig. 8 that the difference between the trace of the chemical-shift tensor in the solid state, σ_{av}, and the isotropic chemical shift in a solution, σ_{sol}, is largest in K_2SnF_6. The large value shows that there is a large difference in the electronic structure of the MF_6^{2-} ion between the solid and liquid states. It is considered that the affinity of SnF_6^{2-} to water molecules in a solution is strongest, since the solubility of K_2SnF_6 is largest, and that this interaction causes a change in the electronic distribution in the SnF_6^{2-} anion.

Kinetics of the Denaturation of Ovalbumin and S-Ovalbumin by Alcohols

Kiyofumi MURAKAMI
Department of Chemistry, Faculty of Science, Yamaguchi University,
Yoshida 1677-1, Yamaguchi 753
(Received January 28, 1988)

The kinetics of denaturation of ovalbumin and S-ovalbumin by butyl alcohol isomers (butyl alcohol, isobutyl alcohol, *s*-butyl alcohol, and *t*-butyl alcohol) have been studied. The reactions were characterized as first order with respect to the protein and 11th order for the alcohols, irrespective of the kind of protein or alcohol. The rate constant was, however, significantly reduced by the branching of the alcohol structure and by the conversion of native ovalbumin to S-ovalbumin. The measurements were also performed on ovalbumin and S-ovalbumin whose SH groups were blocked from SH⇌S–S exchange reactions by modification with iodoacetamides. By the conversion to S-ovalbumin, the modified protein also exhibited a considerable resistivity against denaturation, suggesting that SH⇌S–S exchange reactions play no essential role in the formation of S-ovalbumin. On the basis of these results as well as determined activation parameters, the mechanism of the denaturation is discussed in the light of a combination of the hydrophobic interactions, between hydrophobic residues of the proteins and the alcohol molecules, and the fluctuations of the protein structures.

S-ovalbumin (stable ovalbumin) which is produced by a long-time storage of shell eggs[1] or by holding isolated ovalbumin in a warm and alkaline solution[2] is known to exhibit a considerable resistivity against various denaturation conditions, such as heat and urea.[2,3] Many attempts have been made in order to find some structural differences between ovalbumin and S-ovalbumin, which are very similar to each other.[2] (a) SH⇌S–S exchange reactions,[2-4] (b) an increase in the antiparallel β-sheet geometry with the expense of the same amount of the α-helical conformation,[5] (c) liberation of carboxyl groups,[6] (d) a reduced radias,[7] and (e) an increase in the surface hydrophobicity[7] have been suggested in explanation of the increased resistivity. However, it is still unclear that which of these plays an essential role for the conversion to S-ovalbumin.

Effects of alcohols on protein denaturation and as protein denaturants have extensively been studied for many proteins.[8-15] The main result of these studies is that the effectiveness of the alcohols increases with increase in the alkyl residue content while it reduces for branched alcohols. The result has been attributed to hydrophobic interactions between hydrophobic residues of the proteins and the alcohol molecules. On the other hand, it has also been pointed out that the effectiveness of the alcohols is highly correlated with their ability to disrupt water structure.[16,17] Furthermore, Bull and Breese[18] have recently studied the kinetics of the denaturation of many proteins by alcohols and reported an enhanced effect for alcohols having longer alkyl chains. However, the details of the kinetic aspects and the mechanism of the denaturation are still not fully elucidated.

The present paper describes the kinetics of the denaturation of ovalbumin and S-ovalbumin by butyl alcohol isomers and presents a possible denaturation mechanism as well as suggesting the difference between these proteins.

Experimental

Materials. The ovalbumin was prepared from fresh egg white by a method, essentially same with that of Kekwick and Cannan.[19] It was recrystallized three times from a $(NH_4)_2SO_4$ solution at pH=4.7 and stored at 4 °C. Before using, the preparation was exhaustively dialyzed against distilled water. The S-ovalbumin was prepared from the ovalbumin by the method of Smith and Back.[2]

The SH-blocked ovalbumin was prepared by the following method.[20] A stock solution of iodoacetamide was added dropwise to an aliquot of the dialyzed ovalbumin solution with stirring so as to make a final solution containing 10 moles of iodoacetamide per mole of SH group. The pH of the solution was then adjusted to 8.0 using a 0.2 M† NaOH solution. The solution was then kept at room temperature (about 18 °C) for 20 h, after which it was exhaustively dialyzed against water. This procedure was carried out in the dark. The SH group content of the preparation was determined according to the method of Boyer,[21,22] and it was found that two of the three SH groups which are exposed in the native ovalbumin[23] were blocked by the above method. For the conversion to the modified S-ovalbumin, this sample was also treated by the same method[2] as cited above.

The concentrations of the ovalbumin and S-ovalbumin solutions were determined spectrophotometrically, using the optical density $E^{1\%}_{1\,cm}=7.12$[24,25] at 280 nm.

p-Chloromercuribenzoic acid (guaranteed grade) was purchased from Katayama Chemicals. All other chemicals used were of reagent grade. Iodoacetamide, alcohols, sodium acetate and acetic acid were purchased from Wako Pure Chemical Industries and ammonium sulfate was from Katayama Chemicals.

Methods. The following procedure of the present kinetic measurements is similar to that of Bull and Breese.[18] All sample solutions were prepared in 0.2 M acetate buffer of pH=4.7. A 0.5 ml of ovalbumin solution (5×10^{-4} M) thermostated at 30 °C was rapidly mixed with 2 ml of an aqueous alcohol solution of an appropreate concentration,

† 1 M=1 mol dm^{-3}.

which was also thermostated at 30 °C: time=zero. It was found that the denatured protein began to precipitate in the course of time. After a time passage, the solution was diluted with 30 ml of the acetate buffer solution in order to stop the denaturation, and was kept at room temperature for 2 h for the full precipitation of the denatured protein. The solution was then centrifuged at 11000 rpm for 30 min, and an aliquot of the supernatant solution was subjected to the determination of the concentration of the remaining native protein. Blank measurements were also performed in the absence of the denaturants.

Analysis of Kinetic Data. Kinetics of the denaturation of the proteins by alcohols may be described by the equation:

$$P + m\,R\text{-}OH \longrightarrow D \qquad (1)$$

where R-OH, P, and D denote the alcohol molecule, the native protein, and the denatured one respectively and where m is the number of alcohol molecules required to denature one molecule of the protein. The rate of denaturation at any time can then be written by:

$$\frac{d\,[D]}{d\,t} = k\,[P]\,[R\text{-}OH]^m \qquad (2)$$

where [D], [P], and [R-OH] are the molar concentrations of the denatured and native proteins and alcohol, respectively and where k is the rate constant of the denaturation. The initial rate becomes in the logarithmic form as:

$$\log\left[\frac{d\,[D]}{d\,t}\right]_0 = m \log [R\text{-}OH]_0 + \log [P]_0 + \log k \qquad (3)$$

where the subscript 0 means the quantity at time zero: for instance $[P]_0$ is the initial concentration of the protein. According to this equation, m (the order of reaction) and k can be determined from the slope and the intercept of the plot of $\log[d[D]/dt]_0 - \log[P]_0$ vs. $\log[R\text{-}OH]_0$, respectively.

Results and Discussion

Kinetic Parameters. Figure 1 shows the time courses of the denaturation of ovalbumin and S-ovalbumin in the presence of *s*-butyl alcohol. As can be seen in this figure, S-ovalbumin is highly resistant to denaturation as compared to ovalbumin. In order to ensure the order of reaction with respect to the protein, the dependence of the initial rate of the denaturation on the concentration of ovalbumin was measured (see Eq. 3). The result shown in Fig. 2 yields the slope of 1.09, confirming that the reaction is first order with respect to the protein.

Figure 3 shows the plots of $\log[d[D]/dt]_0 - \log[P]_0$ vs. $\log[R\text{-}OH]_0$ for the denaturation of the four kinds of proteins by the butyl alcohol isomers. In accordance with Eq. 3, each plot exhibits a linear dependence; m and k determined from these plots are summarized in Table 1. The solubility of isobutyl alcohol is so small that the determination of the denaturation curve by the low alcohol concentration required an extremely long time (1 or 2 days) and the data were not collected.

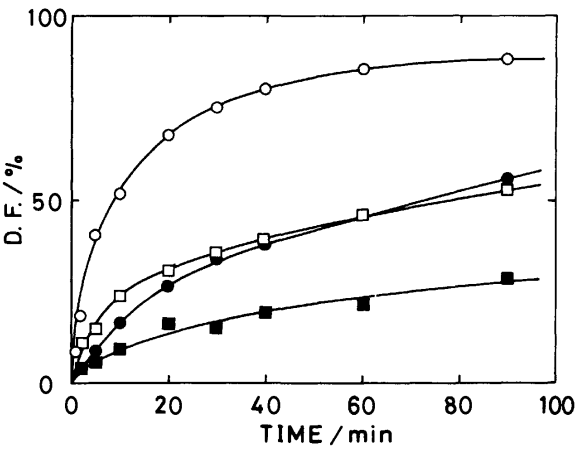

Fig. 1. Typical time courses of the denaturation of ovalbumin and S-ovalbumin by *s*-butyl alcohol. The ordinate shows the denatured fraction (D.F.) of the proteins. The initial concentrations of the alcohol are 1.1 M (○) and 0.95 M (●) for ovalbumin and 1.2 M (□) and 1.1 M (■) for S-ovalbumin.

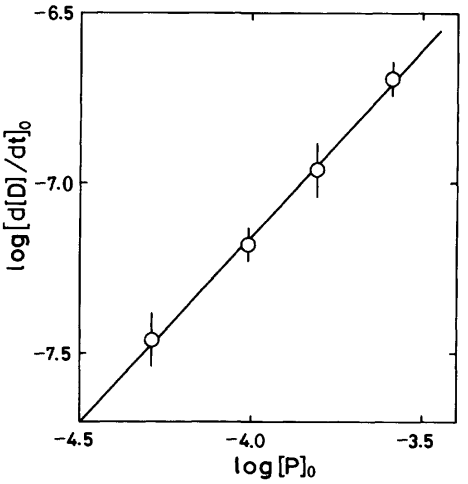

Fig. 2. Plot of $\log[d[D]/dt]_0$ vs. $\log[P]_0$ for ovalbumin in the presence of 1 M *s*-butyl alcohol. The solid line represents a least-square fit to the data, the slope of which is 1.09.

The following points can be seen from Table 1. At first, the order of reaction with respect to alcohols (m) is, within the experimental error, 11th, being irrespective of the kinds of protein or alcohol structure. The value of m for butyl alcohol is relatively in agreement with that reported by Bull and Breese.[18] They also reported that the order of the denaturation reaction by streight-chain alcohols decreases with the increase in the hydrocarbon content. Considering this together with the present results, it is suggestive for the denaturation mechanism that the number of alcohol molecules required for the denaturation depends on their hydrocarbon content

but is independent of the degree of branching.

Secondarily, k is, on the other hand, highly dependent on the structure of the denaturants and on the state of the protein. It progressively decreases with increase in the degree of branching of the denaturant's alkyl chain. Furthermore, it reduces by a factor from 3 to 10 on the conversion from ovalbumin to S-ovalbumin, that is, S-ovalbumin is highly resistant to the denaturation as compared to the native ovalbumin.

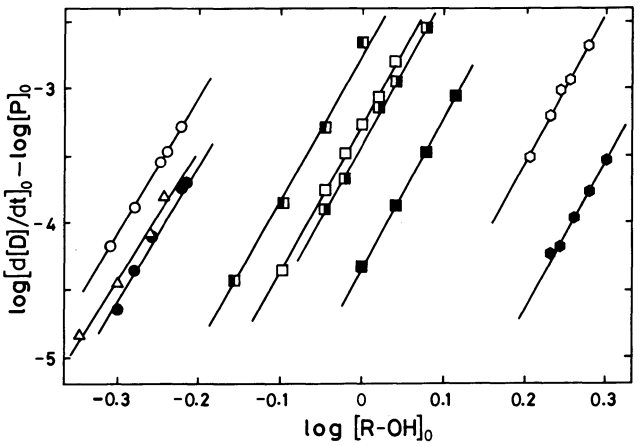

Fig. 3. Plot of $\log[d[D]/dt]_0-\log[P]_0$ vs. $\log[R\text{-}OH]_0$ for the denaturation of the proteins by butyl alcohol isomers. The denaturants are differentiated by the symbols as circle (butyl alcohol), triangle (isobutyl alcohol), square (*s*-butyl alcohol), and hexagon (*t*-butyl alcohol). Open symbols denote ovalbumin and filled ones S-ovalbumn. Half filled symbols ◧ and ◨ denote SH-modified native ovalbumin and S-ovalbumin produced from the SH-modified ovalumin respectively.

Table 1. Rate Constants and Orders of Reaction of the Denaturation by Butyl Alcohol Isomers at 30 °C[a)]

Alcohol	Ovalbumin	$k/M^{-m}S^{-1}$	m
n-BuOH	n-	2.14×10^{-1}	11.7
	S-	6.46×10^{-2}	11.5
i-BuOH	n-	2.95×10^{-2}	9.6
	S-	—	—
s-BuOH	n-	5.38×10^{-4}	11.1
	S-	4.68×10^{-5}	10.8
	n-mod.-	1.93×10^{-3}	11.3
	S-mod.-	3.89×10^{-4}	11.1
t-BuOH	n-	1.83×10^{-6}	11.0
	S-	2.36×10^{-7}	10.3

a) Abbreviations: *n*-BuOH=butyl alcohol, *i*-BuOH=isobutyl alcohol, *s*-BuOH=*s*-butyl alcohol, *t*-BuOH=*t*-butyl alcohol, n-=native ovalbumin, S-=S-ovalbumin, n-mod.-=SH-modified native ovalbumin, S-mod.-=S-ovalbumin produced from the SH-modified native ovalbumin. The error of m was estimated as ±1.

Activation Parameters. From the temperature dependence of k, the activation parameters of the denaturation of ovalbumin and S-ovalbumin by *s*-butyl alcohol were determined in the usual manner.[26)] Figure 4 shows the plot of $\ln[k/T]$ vs. T^{-1}. The slope and the intercept of the plot provide the activation enthalpy (ΔH^*) and the activation entropy

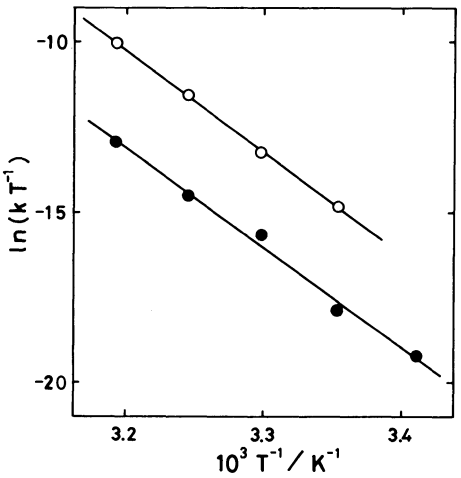

Fig. 4. Plots of $\ln(kT^{-1})$ vs. T^{-1} for the denaturation of ovalbumin and S-ovalbumin by *s*-butyl alcohol. Open circles denote ovalbumin and filled ones S-ovalbumin. The solid lines represent least-square fits to the data.

Table 2. Activation Parameters of the Denaturation by *s*-Butyl Alcohol[a)]

Protein	ΔG^*	ΔH^*	ΔS^*	$\Delta\Delta G^*$	$\Delta\Delta H^*$	$\Delta\Delta S^*$
	kJ mol^{-1}	kJ mol^{-1}	J K^{-1} mol^{-1}	kJ mol^{-1}	kJ mol^{-1}	J K^{-1} mol^{-1}
Ovalbumin	93	248	511			
S-ovalbumin	100	243	472	7	−5	−39

a) ΔΔ means the difference between the activation parameter for S-ovalbumin and that for native ovalbumin. The errors of ΔH^* and ΔS^* were estimated as 2—5% of those values.

(ΔS^*) of the denaturation respectively. The results are summarized in Table 2.

Denaturation Mechanism. The effects of alcohols on the protein denaturation and as the denaturants have been found to become pronounced with increasing alkyl residue content of the alcohols and to reduce with the increase in the degree of branching. They have been interpreted in terms of hydrophobic interactions:[8-15] bound alcohol molecules penetrate into the protein molecule, and interact with hydrophobic residues by replacing the native hydrophobic bonds between these residues and thereby destabilize the protein structures. These result have been derived from static information such as the effects on the transition temperature for thermal denaturation and on the denaturation midpoint, i.e., the concentration of a denaturant required to produce 50% change in the particular observable. The mechanism is, however, not sufficient to account for the present data for the effects of the branching of alcohol molecules on the kinetic parameters (Table 1).

It has been well-known that the structure of a globular protein is not rigid but fluctuates about its most stable conformation. The fluctuations may accompany an exposure of a part of hydrophobic regions to the solvent by openings of channels or crevices, the degree of which must necessarily depend on the degree of the spatial extent of the fluctuations. The so called "breathing"[27,28] motions may be involved in these fluctuations. A large fluctuation is expected to occur only rarely while small ones occur frequently. It is reasonable to assume that the alcohol molecules approach to the hydrophobic region by taking, among the possible conformations, the most fine-line-shape of the hydrophobic portion and by orienting along the channels or the crevices. Therefore, straight-chain molecules can easily approach the hydrophobic region through the frequently opening narrow channels or crevices. Thereby hydrophobic interactions between alcohol molecules and the hydrophobic residues will soon be achieved, resulting in the subsequent denaturation. This leads to large values of k for normal alcohols. On the other hand, branched alcohol molecules which have large diameters must, at the surface of the protein, wait for a wide channel or a wide crevice to open. Small values of k are, therefore, expected for the branched molecules. This mechanism seems to interpret well the observed correlation between the degree of branching of the alcohol molecules and the order of the value of k for these molecules, i. e., butyl alcohol > isobutyl alcohol > *s*-butyl alcohol > *t*-butyl alcohol (Table 1).

An alternative explanation for the effects of alcohols as protein denaturants is based on their ability to destabilize the structure of water.[16,17] Protein molecules, stabilized by hydration around their exposed hydrophobic residues, could be destabilized by the collapse of the hydrated water structure. It is likely that the collapse of the water structure enhances the fluctuations of the protein structure, and hence makes the alcohol molecules easily accesible to the hydrophobic region. The resultant hydrophobic interactions between alcohol molecules and the hydrophobic residues further destabilize the protein structure and amplify the structural fluctuations. Like this, the hydrophobic interactions and the collapse of the hydrated water structure may act cooperatively on the protein denaturation. Both the collapse of the water structure and the enhanced fluctuations will result in a large activation entropy. These considerations are consistent with the result of Segawa and Kume[29] that isopropyl alcohol enhances the fluctuations of the activated state of the thermal denaturation of lysozyme. A schematic illustration of the denaturation mechanism is shown in Fig. 5. Although it is well-known that alcohol molecules have, in general, the effect of increasing α-helix content of many proteins, the role of this fact on the potein denaturation is still unclear.[16] For the sake of simplicity, such a fact is not illustrated in Fig. 5.

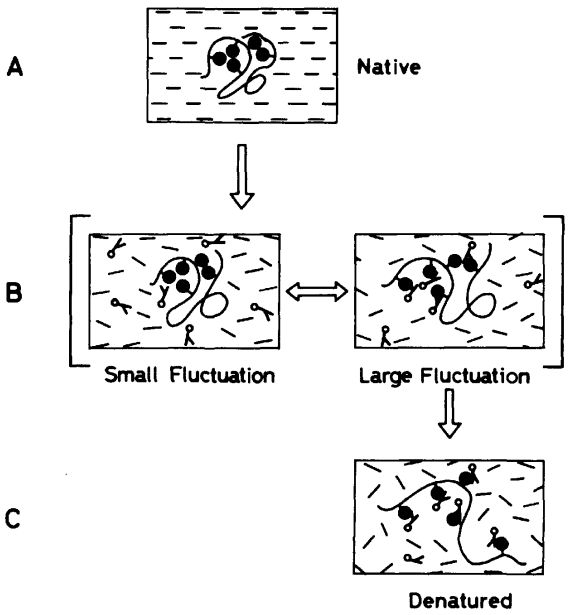

Fig. 5. A schematic illustration of the possible denaturation mechanism by alcohols. An addition of alcohol molecules (O—<) to the protein solution (A) destabilizes the structure of water, and hence enhances the fluctuations of the protein structure (B). When a large fluctuation takes place, alcohol molecules can approach so closely to the hydrophobic region of the protein that resultant hydrophobic interactions, between hydrophobic side chains (filled circles) and hydrophobic portions of alcohols, break the native hydrophobic bonds and thereby lead to the full denaturation of the protein structure (C).

According to the above mechanism, it may be concluded that S-ovalbumin is in a state in which the structural fluctuations are to some extent depressed as compared to the native ovalbumin. Nakamura and Ishimaru[7] reported that the Stokes radius of S-ovalbumin (25.5 Å) is smaller than that of ovalbumin (27.3 Å). The compact form of S-ovalbumin seem to be responsible for the depressed fluctuations. It can also be seen from Table 2 that the positive value of $\Delta\Delta G^*$ (7 kJ mol^{-1}) arises from the entropy term ($-T\Delta\Delta S^*$=12 kJ mol^{-1} at 30 °C) rather than the enthalpy term ($\Delta\Delta H^*$=−5 kJ mol^{-1}). This implies that the stability of S-ovalbumin is achieved by changes in the state of the structural fluctuations and/or in the hydration state of the protein rather than by any other strong bond formations. The increase in the surface hydrophobicity[7] and the change of a part (3—4%) of the protein from the α-helix to the antiparallel β-sheet conformation[5] in the conversion from ovalbumin to S-ovalbumin may also be closely related to the above changes. The fact that the number of alcohol molecules, required for the denaturation, decreases with the increase in the hydrocarbon content of the denaturant[18] but does not depend on the degree of branching for both of the ovalbumin and S-ovalbumin (Table 1) suggests that a definite amount of hydrophobic bonds must be broken in the activation process and it is not changed by the conversion of ovalbumin to S-ovalbumin. This is also supported by the small value of $\Delta\Delta H^*$ in Table 2.

The author wishes to thank Dr. Yasuo Fujisaki for his helpful discussion, and Mr. Tatsuhiro Sasaki for his support on the measurements.

A Peculiar Conformation of Normal-Chain Dicarboxylic Acid Salts in Aqueous Solutions

Kunio FUKUSHIMA,* Koichi ADACHI, and Kiyohisa WATANABE
Department of Chemistry, Faculty of Science, Shizuoka University,
836, Oya, Shizuoka 422
(Received January 29, 1988)

The Raman spectra of adipic acid, pimelic acid, and their salts were observed for various states. The spectra of the acids in aqueous sodium hydroxide solutions were found to be very different from those of the acids in organic solvents. The difference was interpreted, on the basis of normal vibration calculations, as being due to the helix formation of molecules in the former solutions. This tendency toward helical coiling is consistent with the same tendency found for the salts of azelaic acid and suberic acid in our previous study.

In our recent paper[1] on the measurements of the Raman spectra of suberic acid ($HOOC(CH_2)_6COOH$), azelaic acid ($HOOC(CH_2)_7COOH$) and their salts in solutions, we reported a remarkable spectral difference between the acids and their salts, especially for the C–C stretching bands in the region of 850 to 1000 cm^{-1}. On the basis of the normal-vibration calculation of the molecules, we ascribed the difference to the helix formation of the molecular chains of the acid salts. However, these molecules are rather complicated for clear vibrational analyses; in addition, the spectral difference might be ascribed to other factors including the end group difference, COOH and COO^-. In the present study, smaller molecules, adipic acid ($HOOC(CH_2)_4COOH$), pimelic acid ($HOOC(CH_2)_5COOH$) and their salts, which are more suitable for clear vibrational analyses, were treated in order to ascertain if the tendency of forming a helix of molecular chain found in our previous study is also observed in these smaller molecules; the spectral change due to the end group change, COOH to COO^-, was studied.

Experimental

The samples, adipic acid and pimelic acid, were commercial products (GR grade) of the Tokyo Kasei Kogyo Co. The Raman spectra of these samples were recorded for a solid, for solutions of organic solvents, and for aqueous sodium hydroxide solutions. The spectra were obtained with an R-800T Raman Spectrometer (Japan Spectroscopic Co.), using a 514.5 nm line (250 mW) of an NEC argon ion laser. 0.3 ml liquid cells were used for the measurements. The results are shown in Tables 1 and 2 and in Fig. 1.

Normal-Vibration Calculation

The normal-vibration calculation was carried out for pimelic acid according to Wilson's GF matrix method.[2] The following molecular parameters were used: C–C 1.53 Å, C–O 1.49 Å, C=O 1.25 Å, C–H 1.09 Å, O–H 1.07 Å, ∠CC=O=113°, ∠CCO=113°, ∠C–CO–C=124°, the other bond angles were equal to the tetrahedral angle. First, the normal-vibration calculation of a molecular model with an all-*ap* molecular chain (point group, C_{2v}) was calculated using the same force field as in the previous report[1] for force constants transferred from related molecules (Set I in Table 3). The calculated frequencies were then fitted to the observed frequencies of the solid by the method of least squares.[3] The results are shown for the region from 200 to 1700 cm^{-1} in Fig. 2. Then, using the refined force constants (Set II in Table 3),

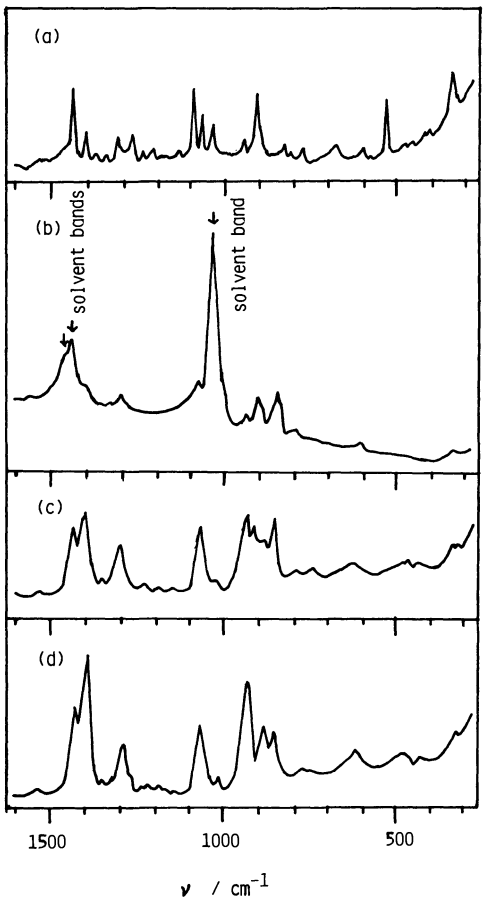

Fig. 1. Raman spectra of pimelic acid.
(a) Solid, (b) methanol solution (33.9 wt%), (c) aq. sodium hydroxide solution (mole ratio; NaOH: acid=1:1), (d) aq. sodium hydroxide solution (mole ratio; NaOH: acid=2.7:1).

normal-vibration calculations for various conformers were carried out. In Fig. 3, the results are compared with the observed C–C stretching bands.

Results and Discussion

Adipic acid was found to have an all-*ap* molecular chain in the crystalline state.[4] In addition, the infrared and Raman spectra were measured and analyzed based on the normal-vibration calculation by Suzuki and Shimanouchi.[5]

A pimelic acid is expected to assume an all-*ap* molecular chain in the solid state, a normal-vibration calculation was carried out for the model as has been described in the section of normal-vibration calculation. These calculations afford a basic information for the interpretation of the spectral difference of the solutions found in the present study; this information is shown in Tables 1 and 2 and in Fig. 1, in which the spectra of methanol solutions are shown as representatives of solutions of organic solvents (for adipic acid: methanol, pyridine, ethylacetate, 1,4-dioxane, dimethyl sulfoxide, acetic acid, formic acid; for pimelic acid: methanol, ethanol, pyridine, dimethyl sulfoxide, 1,4-dioxane).

The Spectra of Methanol Solutions. In Tables 1 and 2, the spectra in the regions from 1000 to 1080 cm^{-1} and from 1420 to 1500 cm^{-1} are not shown as the bands of the solvent overlap with the bands of the samples. Besides the bands corresponding to those of the solid conformer, new bands appear, showing that the conformer with an all-*ap* molecular chain and other conformer co-exist in methanol solutions. The prominent C–C stretching bands of pimelic acid at 807 and 854 cm^{-1} which are not ascribed to the all-*ap* conformation, correspond to the calculated frequencies of the TGTTGT, TTGGTT, TGGTGT conformers, as is shown in Fig. 3. Here, for example, TGTTGT represents the *ap-sc-ap-ap-sc-ap* conformation along the molecular chain of $CO-CH_2-CH_2-CH_2-CH_2-CH_2-CO$.

The Spectra of Aqueous Sodium Hydroxide Solutions. Even after excluding the spectral change arising from the end group change, COOH to COO^-, from the spectral changes shown in Tables 1 and 2 with reference to Table 4, the following spectral change still remains. Bands with frequency values entirely different from those of methanol solutions appear at 384, 775, 930, 1193, 1235, 1255, and 1275 cm^{-1} (adipic acid) and at 332, 434, 779, 864, 896, 1143, and 1194 cm^{-1} (pimelic acid). At the same time, the bands observed for methanol solutions, 372, 735, 790, 829, 895, 1106, and 1154 cm^{-1} (adipic acid) and 339, 755, 807, 854, 904, and 1211 cm^{-1} (pimelic acid) decrease in intensity. Although Table 4 suggests that the stretching frequency of the CC bond attached to the COOH group increases upon the group change from COOH to COO^-, the above-mentioned spectral change cannot be explained by the frequency change alone. These facts show that a peculiar molecular conformation which differs from those in methanol solutions and also in a solid becomes abundant in aqueous sodium hydroxide solutions. Therefore, in

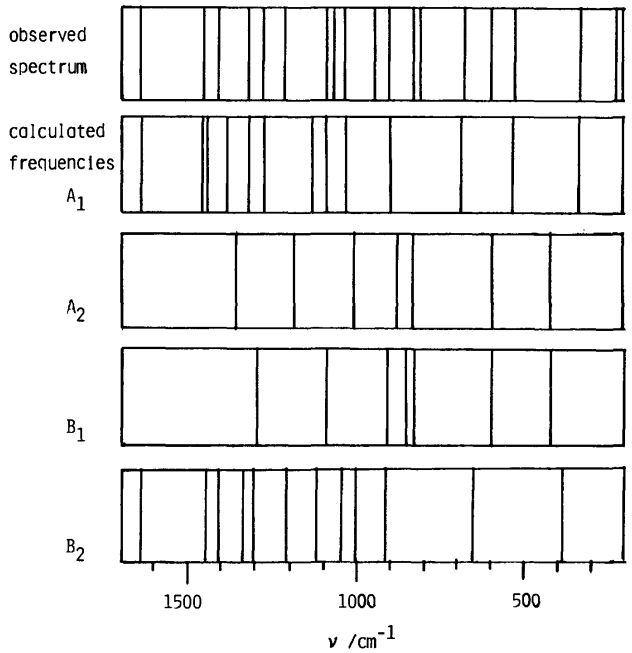

Fig. 2. Observed Raman spectrum of solid pimelic acid compared with calculated frequencies of the all-*ap* conformer.

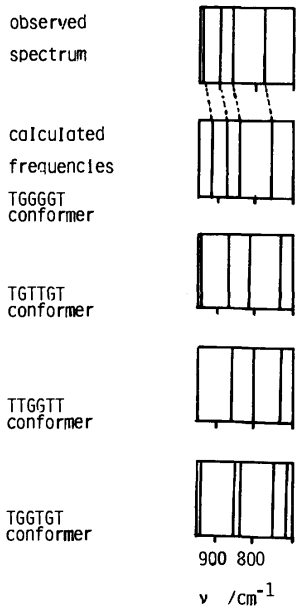

Fig. 3. Observed frequencies of C-C stretching bands of aq. hydroxide solution and calculated frequencies of various conformers for pimelic acid.

CH_2 group in pimelic acid compared with adipic acid shows an expected spectral difference between the acids. This correspondence suggests a similarity in the molecular conformations of the acids in aqueous sodium hydroxide solutions.

Molecular Conformation in Aqueous Sodium Hydroxide Solutions. Normal vibration calculations of various conformers were carried out using the refined force constants. For the C-C stretching vibrations, which give stronger bands in Raman spectra and which have remarkably different frequencies between methanol solutions and aqueous sodium hydroxide solutions, the calculated frequencies (Fig. 3) of various conformers are compared with the spectra of aqueous sodium hydroxide solutions. The bands of the spectrum of Fig. 1(c) correspond to the calculated frequencies of some conformers in Fig. 3; therefore, the solution corresponding to the figure might contain a mixture of those conformers. However, the pattern of the spectra (Fig. 1(d) and the top of Fig. 3) for a higher concentration of sodium hydroxide fits very well to the spectral pattern of the calculated frequencies of the TGGGGT conformer. Taking the similar situation found in the case of suberic acid and azelaic acid[1] into consideration, the conformer having the TGGGGT conformation of the skeleton is considerded to be abundant in aqueous sodium hydroxide solutions. This is in contrast to the case of some monocarboxylic acid salts, where the molecules may be supposed to gather to form micelles, taking an all-*ap* molecular chain.[6]

Interpretation of the Conformational Change. The remarkable conformational change from solutions of organic solvents to aqueous sodium hydroxide solutions may be interpreted as follows. In aqueous sodium hydroxide solutions, the carboxyl groups change to carboxylato groups, which are not capable of causing the intermolecular association of acid salt molecules. Therefore, the stabilization by hydrogen bonding, as in the case of the acids, is lost. Moreover, contact of the hydrophobic molecular chain of acid salt molecule with water molecules increases the instability of the molecular energy. In addition, the presence of a carboxylato group on each end of the molecular chain prevents the molecules from being stabilized by the formation of spherical micelles. These situations make the acid salt molecules take a conformation where the contact area of the hydrophobic molecular chain with water is minimized. The conformation with TGGGGT carbon-chain skeleton is a part of a helix in which the skeleton comes in contact with water molecules only at the outer surface of the helix; instability due to contact of the hydrophobic group and water is thus minimized. Therefore, this helical structure may be stable in aqueous solutions. This is consistent with the agreement of the observed frequencies for aqueous sodium hydroxide solutions with the calculated frequencies of the conformer with the helical structure.

Pulse Radiolysis Studies of Solvent Radical Cations in Liquid 1,2-Dichloroethane

Takashi SUMIYOSHI,* Naoki SUGITA, Kazuyuki WATANABE, and Meiseki KATAYAMA
Department of Atomic Science and Nuclear Engineering, Faculty of Engineering,
Hokkaido University, Sapporo 060
(Received February 20, 1988)

Transient absorption spectra with maxima at 270 and 550 nm were observed in liquid pure 1,2-dichloroethane by means of ps and ns pulse radiolysis. The broad absorption band with a maximum around 550 nm decayed according to a first-order reaction with $t_{1/2}$=0.2 ns in ps pulse radiolysis and $t_{1/2}$=200 ns in ns pulse radiolysis. These short lived species were attributed to solvent cations on the basis of scavenger experiments. The slowly decaying species with $t_{1/2}$=1.2 μs which absorbs around 400 nm superimposed on the 550 nm band, was tentatively assigned to carbocations. The 270 nm band formed during and after the electron pulse decayed over several microseconds by second-order kinetics. Those radicals which were produced by the dissociative electron attachment to the solvent and by the reaction of cations were responsible for this UV band.

Radiolysis of chlorinated hydrocarbonds such as carbon tetrachloride,[1] 1,2-dichloroethane (1,2-DCE),[2] and butyl chloride[3] has been applied to studies on solute cations by many workers. In these solvents electrons are dissociatively attached to solvent molecules to form stable chloride ions. The absorption spectra of solvent cations of carbon tetrachloride[4,5] and butyl chloride[6–8] have been observed and the rate constants of charge transfer with various solutes have been determined in pulse radiolysis experiments. However, it is reported that 1,2-DCE shows only a very weak absorption in the μs pulse radiolysis.[9] We initiated this study in order to obtain the spectral and kinetic information of 1,2-DCE cations. This paper reports the observation of radical cations of 1,2-DCE by means of ns and ps pulse radiolysis at room temperature and the rate constants of charge transfer for various cation scavengers.

Experimental

1,2-Dichloroethane was spectrograde of Wako Junyaku. The stroboscopic picosecond pulse radiolysis system[5] with a time resolution of 30 ps and the nanosecond pulse radiolysis system[10] with a time resolution of 10 ns were described earlier. Electron pulses of 45 MeV and 10 ns width from an S-band LINAC were used as a radiation source. The absorbed doses were determined with the KSCN dosimeter[11] for the 10 ns pulse and the hydrated electron dosimeter for the 30 ps fine-structure electron pulse applying $G(e_{aq}^-)$ at 30 ps as 4.8.[12] The detection system consisted of a monochromator (Bausch and Lomb, 33-86-25) and a photomultiplier (HTV, R928). The bandwidth of the monochromator was 10 nm. Samples were bubbled with argon in a quartz cell which has an optical path length of 1 or 2 cm and sealed with a teflon bulb for the ns pulse radiolysis. In the case of ps pulse radiolysis the solution was circulated through the 2 cm path length cell by a pump to prevent the deposition of radiation products. All experiments were carried out at 18 °C.

Results

Picosecond Pulse Radiolysis. Pure liquid 1,2-DCE was irradiated with a train of 30 ps fine structure electron pulses spacing at 350 ps each other. A typical kinetic trace observed at 550 nm is presented in Fig. 1. The solid line is the computer simulated first-order decay curve with parameters $G\varepsilon$=2.4×10^4 mol^{-1} dm^3 cm^{-1} and $t_{1/2}$=200 ps. The dose of the macro pulse whose time profile can be approximated as a gaussian with a half width of 10 ns was 38 Gy. Figure 2 shows the transient absorption spectra obtained immediately after the 30 ps pulse in the range of 350 to 700 nm. The spectrum exhibits a maximum at 550 nm.

Nanosecond Pulse Radiolysis. Figure 3 shows the

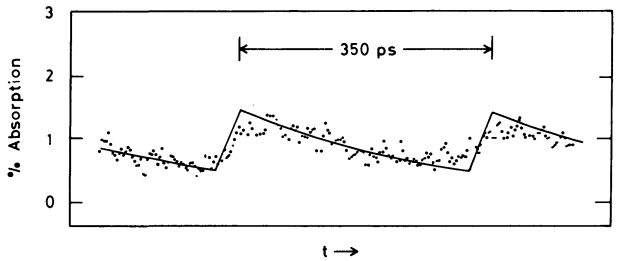

Fig. 1. The picosecond kinetic trace observed at 550 nm in pure 1,2-dichloroethane at 18 °C. The solid line is the simulated trace with $G\varepsilon$=2.4×10^4 mol^{-1} dm^3 cm^{-1} and $t_{1/2}$=200 ps.

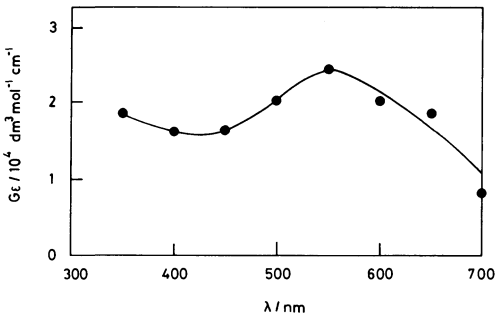

Fig. 2. The absorption spectrum obtained at the end of 30 ps electron pulse irradiation of pure 1,2-dichloroethane.

transient absorption spectra observed at the end of the 10 ns pulse, 120, 600 ns and 2 μs after the pulse in pure 1,2-DCE by the ns pulse radiolysis. Two distinguished transient absorption bands could be observed at 550 and 270 nm. However, the kinetic behavior is not identical for both absorption bands as shown in the insets of Fig. 3. The visible absorption spectrum immediately after pulse is quite similar to that was observed in the ps pulse radiolysis. The maximum of the visible band shifts from 550 to 500 nm in the first 120 ns then to 450 nm in 600 ns. This change can be also demonstrated by the different kinetic behavior observed at 400 and 650 nm as presented in Fig. 4. The decay trace at 650 nm consists two first-order components, i.e., $k_1=(2.5\pm0.5)\times10^7\ s^{-1}$ and $k_2=(3.5\pm0.5)\times10^6\ s^{-1}$. On the other hand, the kinetic trace at 400 nm is the superposition of these two components and a much slowly decaying component with $k_3=6\times10^5\ s^{-1}$. Therefore, the blue shift of the visible band is due to the rather long-lived species which absorbs near UV region.

The 270 nm band is formed during and after the pulse (Fig. 5a) and decays by a second-order reaction with $2k/\varepsilon=2\times10^7$ cm s^{-1}.

Typical electron scavengers such as N_2O, oxygen and CCl_4 have been added to the solution and it was found that they do neither reduce the initial absorbance of both 270 and 550 nm bands nor increase the decay rate. On the other hand, solutes which have a lower ionization potential than that of 1,2-DCE (11.41 eV)[14] increase the decay rate of 550 nm band and decrease the absorbance of the 270 nm band. Typical results obtained with cyclohexane (IP=10.32 eV)[14] as a cation scavenger are illustrated in Figs. 5a—c. The high concentration of cyclohexane ($>10^{-1}$ mol dm^{-3}) supresses the visible band almost completely

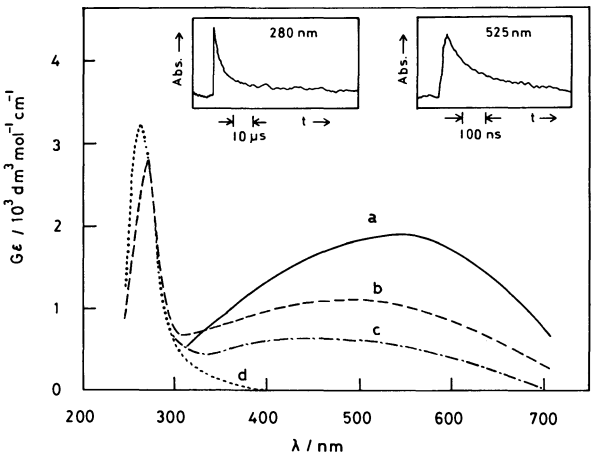

Fig. 3. Absorption spectra recorded at the end of the 10 ns electron pulse (a) and 120 ns (b), 600 ns (c) and 2 μs (d) after the pulse. Dose was 82 Gy and optical path length was 2 cm.

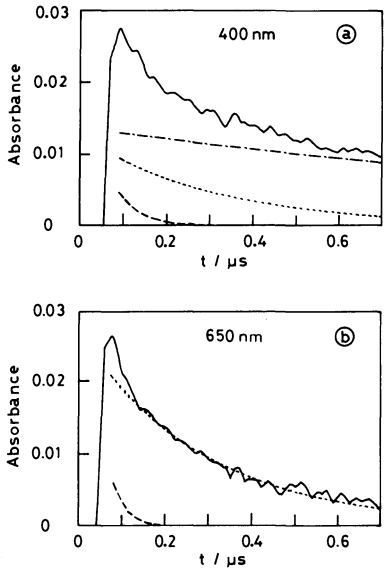

Fig. 4. Kinetic traces observed in pulse irradiated 1,2-DCE at 400 (a) and 650 nm (b). First-order components; (-----): $k_1=2.5\times10^7\ s^{-1}$, (------): $k_2=3.5\times10^6\ s^{-1}$, (—·—·—): $k_3=6\times10^5\ s^{-1}$.

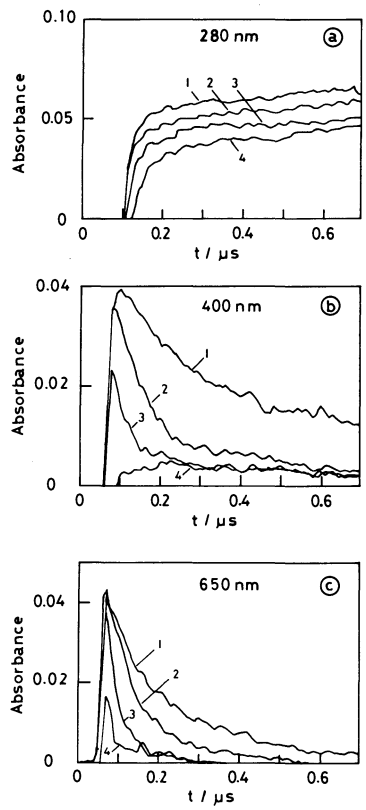

Fig. 5. Effects of cyclohexane on the transient absorption decay at 280 (a), 400 (b) and 650 nm (c). Dose was 110 Gy. Optical path length was 1 cm. Concentration of cyclohexane (in mol dm^{-3}); 1: 0; 2: 4.6×10^{-3}; 3: 1.8×10^{-2}; 4: 9.2×10^{-2}.

but the UV band to about a half. These results strongly indicate that the visible band is due to cationic species and reaction product of this primary cationic species contribute to the UV band to a certain extent. Obviously, the decay rate increases with increasing concentration of cyclohexane (Figs. 5b and 5c). Upon application of pseudo-first order kinetic treatment, the rate constant of positive charge transfer to cyclohexane was determined to be 1.5×10^{9} mol^{-1} dm^{3} s^{-1}.

In the case of pure 1,2-DCE, the absorbance vs. time profiles at 400 and 650 nm are different due to the contribution of the slowly decaying component as mentioned above. However, on addition of cyclohexane decay rate constants obtained at both wavelengths become same as shown in Figs. 5b and 5c. The initial signal intensity at 650 nm does not decrease significantly on addition of cyclohexane up to 2×10^{-2} mol dm^{-3}. On the contrary, the initial absorbance at 400 nm decreases with increasing cyclohexane concentration. These results suggest that the slowly decaying component at 400 nm reacts more rapidly with cation scavenger than the fast component or might be a secondary reaction product of cationic species.

The charge transfer rate constants have been obtained with 13 solutes. The rate constants determined are then correlated with the difference of ionization potential between 1,2-DCE and the added solute as shown in Fig. 6.

Aniline (IP=8.00 eV)[14] is well-known as a cation scavenger and the yield of the solvent cation can be estimated based on the maximum yield of aniline cation radicals.[15-17] The aniline cation radical exhibits an absorption maximum at 423 nm in aqueous solution[18] and at 385 nm in pure aniline.[19] Its extinction coefficient was established to be 2000 mol^{-1} dm^{3} cm^{-1}.[18] Figure 7 shows the typical transient absorption spectrum of the aniline cation radical observed in 2.75×10^{-2} mol dm^{-3} aniline solution. The spectral shape is the same with those observed in aqueous solution[18] and in pure aniline,[19] indicating that only one species is present. Figure 8 shows the decrease of the absorbance at 525 nm and the increase of 410 nm band with increasing aniline concentration. At higher concentration of aniline ($>10^{-2}$ mol dm^{-3}) the absorbance of aniline cation radical is too strong to determine the reduced absorbance of the solvent cations. In spite of this difficulty, the increase of aniline cation radical absorbance seems to correspond with the decrease of the absorbance at 525 nm. The yield of the aniline cation radical has been estimated to be G=2.8 based on the plateau yield of it (OD_{max}=0.088) at the concentration larger than 10^{-1} mol dm^{-3}.

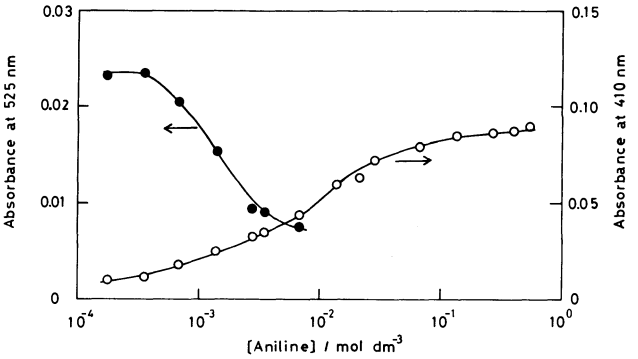

Fig. 8. Effect of aniline concentration on the absorbance at 525 nm of the 1,2-DCE radical cation and at 410 nm of the aniline cation. The absorbance was obtained at the end of pulse and 500 ns after the pulse, at 525 and 410 nm, respectively. Dose was 120 Gy. Optical path length was 1 cm.

Discussion

Assignment of the Transient Species. The transient absorbing species with a maximum at 550 nm has been observed in both ps and ns pulse radiolysis. This visible band can be assigned to 1,2-DCE radical cations based on the experimental evidence of the effects of the electron and cation scavengers on this band. This assignment is also supported by the relation between decay rate constants and the difference of ionization potential between 1,2-DCE and added solutes. The reaction rate constant of the added solute with the visible band increases with increasing difference of the ionization potential as illustrated in Fig. 6.

The $G\varepsilon$-value at 550 nm are 2.4×10^4 mol^{-1} dm^3 cm^{-1} at the end of 30 ps pulse and 1800 mol^{-1} dm^3 cm^{-1} at the end of 10 ns pulse. The higher G-value for ps pulse radiolysis and the short half lifetime of 200 ps indicate that more than 90% of primary 1,2-DCE radical cations disappears by geminate ion reactions. The faster decay observed at 400 and 650 nm during the first 120 ns is indicative of the tail of such geminate ion reactions.

The spectral shift from 550 to 500 nm in the first 120 ns can be due to the slowly decaying species with $k_3=6\times10^5$ s^{-1}. This species absorbs around 400 nm, and disappears almost completely by addition of cyclohexane larger than 5×10^{-3} mol dm^{-3}. These results show that the slow component is very reactive cationic species or has solvent cations as a precursor.

With respect to the spectral shift, it is interesting to note that the similar spectral change was observed in the case of butyl chloride cations.[6,7] Upon irradiation of butyl chloride the initial spectrum with a peak at 520 nm was obtained. However, the peak shifted to 450 nm within 80 μs at 133 K.[6] The short-lived species with a peak at 520 nm and the long-lived species with a peak at 450 nm were attributed to butyl chloride radical cations and butene radical cations, respectively. In that work, Arai et al. suggested that butene and butyl chloride cations must originate from a common precursor such as a vibrationally excited butyl chloride cations on the basis of cation scavenging experiments.

The formation of additional cationic species originating from the solvent was also suggested in the case of irradiated 1,2-DCE by Wang et al.[13] It was reported that there are two kinetically distinguishable cationic species of the 1,2-DCE solvent which react selectively with different solutes to form the phenylcarbenium ion. It was suggested that one is a 1,2-DCE radical cation and other a carbocation formed after C–Cl bond cleavage.

Therefore, we conclude that the fast decaying visible band with $k=(3.5\pm0.5)\times10^6$ s^{-1} is due to the 1,2-DCE radical cation and the slowly decaying visible band with $k=6\times10^5$ s^{-1} might due to cationic species such as $CH_2CHCl^{\ddagger}$ and $CH_2ClCH_2^+$ originates from 1,2-DCE.

The UV band with a peak at 270 nm was formed during and after pulse then decayed with a second-order reaction. This band can be ascribed to radicals which are produced by the dissociative electron attachment (reaction 1) and reactions of solvent cations such as deprotonation (reaction 2) and ion-molecular reactions (reaction 3).

$$CH_2ClCH_2Cl + e^- \longrightarrow CH_2ClCH_2\cdot + Cl^- \quad (1)$$

$$CH_2ClCH_2Cl^{\ddagger} \longrightarrow CH_2ClCHCl\cdot + H^+ \quad (2)$$

$$CH_2ClCH_2Cl^{\ddagger} + CH_2ClCH_2Cl \longrightarrow CH_2ClCH_2ClH^+ + CH_2ClCHCl\cdot \quad (3)$$

Yield of Solvent Cations. Wang et al.[13] estimated the yield of 1,2-DCE cations to be $G=0.87$ based on the yields of phenylcarbenium ions. The yield of solvent cations determined in the present experiment from the limiting absorbance of aniline cation radicals was $G=2.8$. Three times difference of cation yields can not be explained in the present situation. Since the extinction coefficient of the aniline cation radical was determined in water,[18] there might be a changing of the value depending on solvents. Also we have to consider the efficiency of cation scavenging. Since the yields of phenylcarbenium ion varies from $G=0.18$ to 0.87 depending on the solutes,[13] the solutes which were used by Wang et al. might be less effective than aniline to scavenge the solvent cation radical. Further experiments with various cation scavengers which have a well-defined extinction coefficient of cations are needed.

The authers wish to acknowledge Dr. Takeaki Enoto and Messrs. Hiroaki Tanida and Koichi Sato for their help in operating the LINAC.

(Received February 29, 1988)

The desorption of [1-^{14}C]octadecanoic acid molecules in vacuo from a Langmuir-Blodgett film, which is regarded as an extremely thin crystal, was studied by using three kinds of radioactive samples containing ten molecular layers: The first sample was labeled at the tenth (the outermost) layer; the second one, at the ninth layer and the third one, at both the ninth and tenth layers. From the initial slopes in the desorption curves for these samples it is suggested that most of the acid molecules desorb from the tenth layer and some acid molecules desorb as a dimer consisting of a pair of molecules from the ninth and tenth layers. The scanning electron micrographic observations were carried out for nonradioactive samples stored for a week at 298.2 or 278.2 K under atmospheric pressure; it was concluded that the fatty acid molecules jump back and forth between a boundary (stagnant) layer and the surface of the LB multilayer and coagulate into micron-size crystals.

Vapor pressure and heat of sublimation of long-chain fatty acid crystals at room temperature have been measured by only a few investigators in spite of their thermodynamical and practical utilities. This is attributable to the experimental difficulty in measuring the extremely low vapor pressure of the crystals. Some attempts[1-4] have been made by Knudsen's method to determine the vapor pressure for the long-chain compounds but only near their melting points in which relatively high vapor pressures are available.

The highly oriented Langmuir-Blodgett (LB) multilayer of octadecanoic acid takes on a C-type (monoclinic) crystal structure in the upper monolayers other than the first monolayer.[5] This is the most stable crystal form at room temperature. X-Ray diffraction and IR spectrum measurements indicated that the LB multilayer of octadecanoic acid consisted of its extremely small three-dimensional crystallites which are oriented so that their c-axes align with an angle of ca. 30° to the normal axis of the substrate plate.[5,6] The desorption of the acid molecules from the LB film is therefore regarded as that from the extremely thin and small crystals. Accordingly, the measurement of the desorption for the acid molecules labeled radioactively from the LB multilayer will give us useful information about the mechanism of the desorption process from the crystal. In the present study the desorption from the surface of the fatty acid multilayer was investigated by using the ^{14}C-samples labeled at arbitrary layers; the desorption mechanism was estimated and confirmed also by scanning electron micrographic observations for the nonradioactive LB films.

Experimental

Materials. [1-^{14}C]Octadecanoic acid (specific activity of 59.0 Ci mol^{-1}) from New England Nuclear, Inc., and the purest grade sample of octadecanoic acid from Wako Chemical Industry were used for the built-up process. Ferrotype plates (20×15×0.5 mm) were used as the substrate plate. The plates were washed in aqueous ethanol solution (ethanol:water=1:1 in volume ratio) containing 5% of potassium hydroxide and rinsed in triple distilled water, and their surfaces were pretreated with iron (III) octadecanoate (the purest grade of Tokyo Kasei Industry Co., Tokyo) to be hydrophobic. The subphase solution was triple-distilled water[7] whose pH was adjusted to 2 with twice distilled HCl. Under this pH condition, the monolayers consisting of only salt-free octadecanoic acid molecules are transfered onto the substrate plate even if some metal ions existed in the subphase solution.[8,9]

Troughs and Movable Barriers. Two sizes of Teflon troughs were used: The small one had inside dimensions of 260 mm^{length}×25 mm^{width}×15 mm^{depth} and large one, 282×155×5 mm. The large trough had a pocket (40×20×15 mm) in its bottom for vertical dipping of the substrate plate. The inside of the small trough was hydrophilic by the glow discharge in an oxigen atmosphere and the rims remained hydrophobic by protective adhesion tapes for a smooth movement[10] of a thin glass plate (32×24×0.5 mm) coated with paraffin. For the large trough a paraffin-coated silk thread of ca.20 cm in length was used as a movable barrier for the compression of the monolayers.

Built-up Procedure. A benzene solution (1×10^{-3} mol dm^{-3}) of nonradioactive octadecanoic acid was used as spreading solution for the large trough and hexane solutions (1×10^{-4} mol dm^{-3}) of radioactive or nonradioac-

†††† Present address: Nippon Paint Co., Ltd., Minami-shinagawa, Shinagawa-ku, Tokyo 140.

tive sample, for the small trough. The purest grade ethyl tetradecanoate (Wako Chemical Industry) as used as a piston oil whose surface pressure was about 20.7 mN m^{-1}.

The samples of LB film containing eight monomolecular layers of the nonradioactive acid were prepared by the conventional vertical-dipping method, using the large Teflon trough, at 285—290 K. Let us term the samples thus obtained LB-8 plates.

The substrate plate as dipped to a depth of 15 mm in the subphase solution and withdrawn through the nonradioactive monolayer at a velocity of 0.1—0.5 cm s^{-1} by means of a synchronous motor. In order to know the transfer ratio of the monolayer onto the substrate plate, we used the small Teflon trough and the floating glass plate (movable barrier) coated with paraffin. From the movement of the glass plate in the transfer process we evaluated the transfer ratio of the monolayer. The ratios for both upward and downward strokes were almost unity (0.97—1.00).

A modified horizontal-lifting method[10] was employed for the transfer of the additional two radioactive and/or nonradioactive monolayers on the LB-8 plates by using the small Teflon trough. The transfer process by the method is schematically shown in Fig. 1. After the solution surface was swept with Teflon barriers, the surface was divided into two equal parts with a narrow glass barrier **A** which was made hydrophobic by treatment with dimethyldichlorosilane. In order to prepare a radioactive sample labeled at the tenth layer, a nonradioactive octadecanoic acid monolayer was spread on one part of the divided surface. The monolayer was compressed with the floating glass plate by piston oil pressure. Then, the LB-8 plate on the monolayer (Fig. 1-a) was touched almost horizontally. A new glass barrier **B** was then placed near the end of the plate (Fig. 1-b),

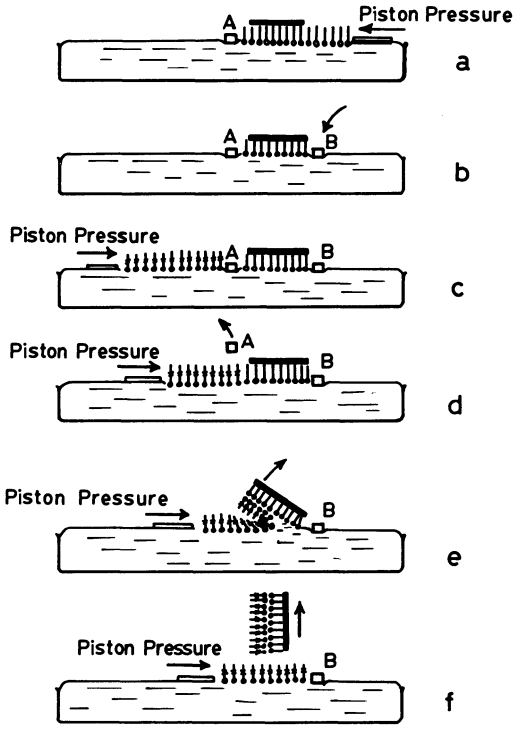

Fig. 1. Scheme of the transfer process of radioactive and/or nonradioactive monolayer onto LB-8 plate.

and the monolayer remaining around the plate was cleaned out with several hydrophobic glass barriers and an aspirator. Subsequently a [1-^{14}C]octadecanoic acid monolayer was spread on the other surface. The monolayer was also compressed with the second floating glass plate by a piston oil pressure. On removing the glass barrier **A** from the solution surface, the radioactive monolayer came from one part of the divided surface and spread around the plate (Fig. 1-d). The plate was then turned gradually by a mechanical operation controlled with a personal computer (NEC model PC-8001 MKII), lifted and finally removed from the surface (see Fig. 1-e and f). One molecular layer of the nonradioactive octadecanoic acid and an additional layer of [1-^{14}C]octadecanoic acid were transferred onto the LB-8 plate by this process. In order to prepare a sample labeled at the ninth layer, the LB-8 plate should be initially attached to the radioactive monolayer. For the preparation of a sample labeled simultaneously at both the ninth and tenth layer, the water surface should be occupied only by the radioactive monolayer: It is not necessary to use the glass barrier **A** to devide the solution surface into two parts. This depositing process gave Y-type films for the octadecanoic acid monolayer and the transfer ratios by this method were also almost unity.

The Measurement of the Desorption in Vacuo. The radioactive samples thus obtained were set in the vacuum chamber thermostated at ±0.1 K. After the samples had been set in the chamber, it took about 3 minutes to reach a pressure of 1×10^{-2} Pa with rotary and diffusion pumps. Isothermal desorption experiments were performed under this pressure and at a number of different temperatures (288—303.9 K). The radioactivity of each sample, being proportional to the remaining amount of [1-^{14}C]octadecanoic acid, was measured batchwise with a thin end-window Geiger-Müller tube, with a mica window of thickness 1.4 mg cm^{-2} at any given time.

Observation with Scanning Electron Micrographs. Scanning electron micrographic observation (SEM) of the nonradioactive samples containing ten monomolecular layers either freshly prepared or stored for a week under atmospheric pressure at 298.2 or 278.2 K were carried out with a JOEL JXA-840 scanning electron microscope.

Results and Discussion

Figure 2 shows the relative desorption profiles, $\ln(R/R_0)$-t, for the [1-^{14}C]octadecanoic acid from the LB films labeled at the tenth layer under the conditions of 1×10^{-2} Pa and various temperatures (288.6—303.8 K). R denotes the radioactivity due to the labeled molecules remaining in the LB film at time t and R_0, that at t=0. By assuming a first-order reaction for the desorption process, initial slopes in the curves were adopted to obtain the rate constants k_1 for the desorption of the acid molecules. Figure 3 show the Arrhenius plots for the rate constants. Five plots at lower temperatures (288.6—298.2 K) show good linearity, while a plot at 303.8 K deviates from this line. Not only desorption but also molecular exchange reactions most likely occur from and among

monolayers at the higher temperature. The apparent activation energy, 191.2 kJ mol^{-1}, for the desorption was obtained from the linear portion of the Arrheneus plots. This value is somewhat larger than the heat of sublimation for the octadecanoic acid crystal.[2] The heat of sublimation was calculated from the temperature dependence of its vapor pressure, which was obtained by Knudsen's method, near the melting point (342.2 K) of the crystal.

Figure 4 shows the desorption profiles for three kinds of samples in vacuo at 298.2 K. The first sample (▽) as labeled at the 9th layer, the second one (○), at the 10th layer, and the third one (□), at both the 9th and 10th layers. The desorption rate for the first sample is slower than that for the second one, but not zero. Some acid molecules seem to escape from the 9th layer as well as from the 10th layer even at the initial stage in spite of the existence of an additional monolayer on the 9th layer. The molecules is therefore thought to desorb as a dimer consisting of a pair of molecules across the 9th and 10th layers. One-half the sum (▲) of the relative radioactivities of the first and the second samples should be equal to the relative radioactivity of the third sample (□). However, the former was always larger than the latter.

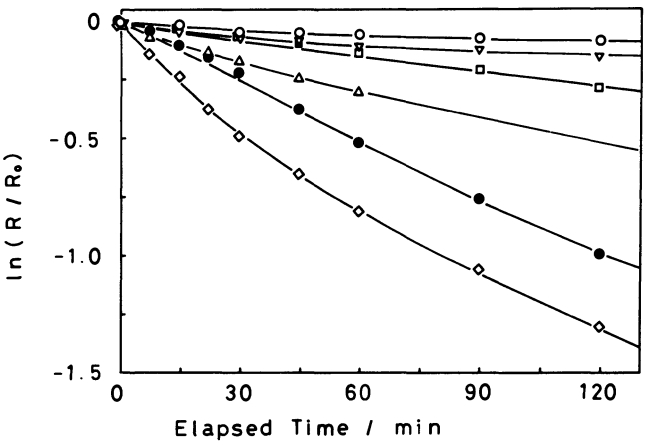

Fig. 2. Relationship between logarithm of relative radioactivity and evacuation time for the ^{14}C-sample labeled at the 10th layer under a pressure of 1× 10^{-2} Pa and various temperature. The mark ○ is at 288.7 K, ▽, at 290.7 K, □, at 293.4 K, △, at 296.3 K, ●, at 298.2 K, and ◇, at 303.9 K.

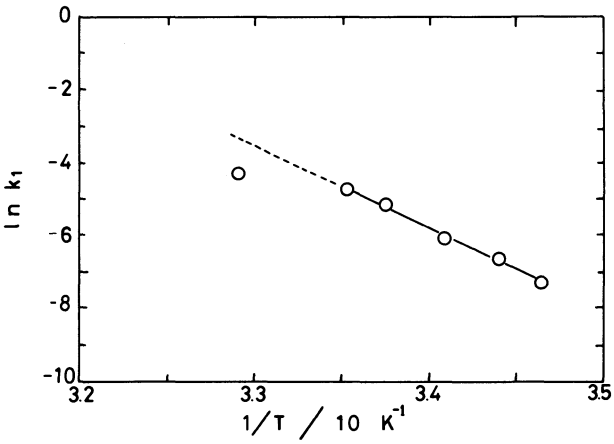

Fig. 3. The logarithm of the desorption rate for octadecanoic acid LB film labeled at the 10th layer vs. reciprocal temperature.

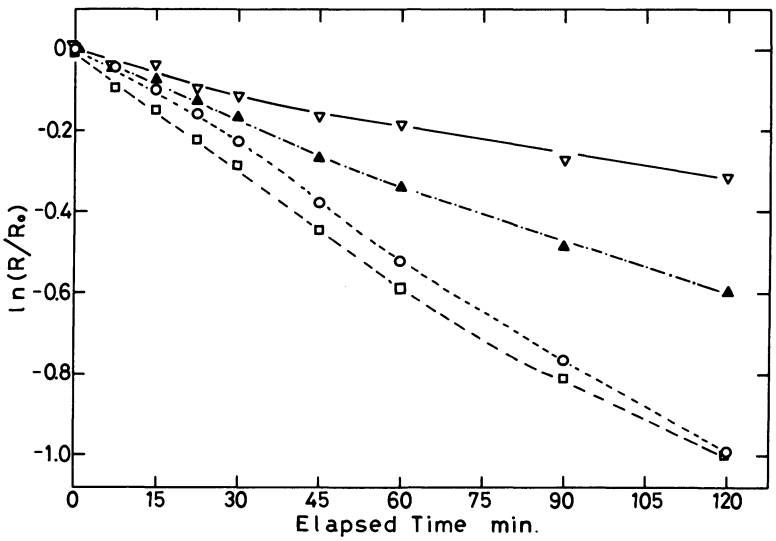

Fig. 4. Relationship between logarithm of relative radioactivity and evacuation time for various samples under a pressure of 1×10^{-2} Pa and at 298.2 K. ▽ denotes the sample labeled at the 9th layer, ○, the sample labeled at the 10th layer; □, the sample labeled simultaneously at the 9th and 10th layers; and ▲ one-half the sum of ▽ and ○.

Moreover, the relative radioactivity for the sample decreases significantly more than the relative radioactivities for the first and second samples. Consequently, the ^{14}C-labeled molecules appear to migrate among the layers even during the evacuation.

The radioactivity of another sample labeled at the 10 th layer was not altered after one-week storage under the conditions of atmospheric pressure and room temperature (298.2 K). The acid molecules, therefore, do not evaporate, but might migrate among and/or in layers under the above conditions. Fujihira et al.[11] observed the translayer diffusion in LB films by measuring the mobility of dyes. Such a translayer diffusion can be attributed to molecular exchange among the layers. To confirm the possibility of molecular exchange, four kinds of samples were prepared by the following procedure: Sample **a** was a LB film labeled at the 10 th layer; sample **b**, same as sample **a**, but stored for a week at 298.2 K and atmospheric pressure; sample **c**, a LB film labeled at the 9 th layer; sample **d**, same as sample **c**, but stored for a week at 298.2 K and atmospheric pressure. Desorption in vacuo for these four samples was observed. The $\ln(R/R_0)$-t relationship obtained is shown in Fig. 5. The desorption from sample **a** (◇) was faster than that from sample **b** (○), while the desorptions from the other samples **c** (□) and **d** (▽) were almost equal with that for sample **b** (○). Apparently, the acid molecules exchange their positions in and/or among monomolecular layers during the storage of the samples.

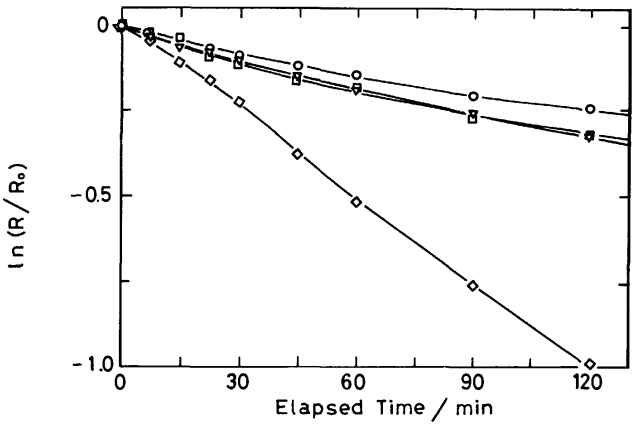

Fig. 5. Relationship between relative radioactivity and evacuation time for the various samples under a pressure of 10^{-2} Pa and 298.2 K. ◇ denotes sample **a** which is a LB film labeled at the 10th layer; ○, sample **b**, same as sample **a**, but stored for a week at 298.2 K and atmospheric pressure; □, sample c, LB film labeled at the 9th layer; ▽ sample **d**, same as sample c, but stored for a week at 298.2 K and atmospheric pressure.

The samples **b** and **d** stored for a week at 298.2 K and atmospheric pressure, showed a powdery appearance at their surfaces, while the sample just prepared or stored at lower temperature (278.2 K) did not have such an appearance. Figures 6-a and -b show the SEM pictures for two samples containing 10-monolayers of nonradioactive acid stored for a week at 278.2 K and at 298.2 K, respectively, under atmospheric pressure. The picture for the sample stored at 278.2 K (Fig.6-a) was as smooth as that for the sample just prepared, while that of the sample stored at 298.2 K (Fig. 6-b) had many white clusters having a diameter in the range of 0.2 to 3 μm. The clusters seem to be micron-

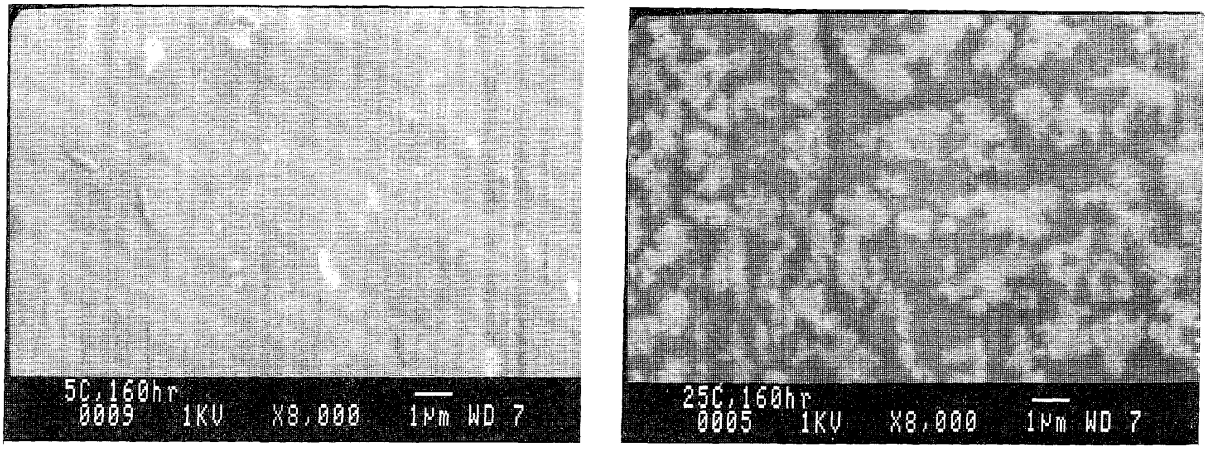

Fig. 6. Scanning electron micrographic (×5200) of the two samples containing 10 molecular layers of nonradioactive acid stored for a week under atmospheric pressure at 278.2 and 298.2 K. Photograph **a** is the sample stored at 278.2 K and photograph **b**, the sample stored at 298.2 K.

size crystals. The acid molecules in the LB film appear to migrate and aggregate to form the micron-size crystals during the storage at room temperature and under the atmospheric pressure. Let us examine the mechanism to produce such crystals.

The desorption of octadecanoic acid molecules in vacuo from its LB film is considerable:[12,13] Almost 90% of the [1-^{14}C]octadecanoic acid molecules in its monolayer on a quartz backing was evaporated after one hour evacuation at a pressure of 10^{-4} Pa.[12] Under atmospheric pressure, however, the radioactivity of the LB film of ^{14}C-labeled acid did not alter for a long time: There hardly occured any desorption of the acid molecules from the LB film under these conditions. The above two contradictory facts suggest the following for consideration: A thin boundary layer (stagnant layer) of the acid vapor occurs near the surface of the LB film as illustrated schematically in Fig. 7. In vacuo the molecules have a long mean-free path and can escape easily from the layer, while in air under the conditions of atmospheric pressure and room temperature the molecules, colliding frequently with air molecules or one another, have a short mean free path (10^{-7} m) and rarely escape (diffuse) from the layer into the air. Consequently, the desorption and adsorption of the molecules are continuously repeated between the LB film and the stagnant layer; the rates in the above two processes are in balance with one another. By repeated processes, an isothermal distillation[14] may occur from the extremely small crystallites (the LB film of multilayer of octadecanoic acid is, as mentioned before, an assembly of the extremely small crystallites),[6] to slightly larger crystallites. The extremely small crystallites would evaporate and disappear, while the slightly larger crystallites would become larger and larger during the one-week storage of the LB film. Thus film molecules can transfer over a long distance and coagulate into micron-size crystals. The "overturning" of octadecanoic acid molecules in monolayer[15,16] and the transference of ^{14}C-labeled acid from its LB film deposited on a solid surface onto other solid when the former solid was contacted with the latter one[17] might be due to the molecular migration by the desorption/adsorption process. Beischer,[18] and Rideal and Tadayon[19] reported the surface diffusion for the octadecanoic acid molecules in the monolayer deposited on mica surface the mobility of the molecules on the surface was found to be much greater than inside the bulk substance. The surface diffusion also seems to be attributed mainly to the desorption/adsorption process.

Estimation of Equilibrium Vapor Pressure. The desorption rate of an acid molecule from the LB film at time t is expressed as

$$-(d\Gamma/dt)_{des} = k_1\Gamma, \quad (1)$$

where Γ is the amount of radioactive octadecanoic acid in the LB film; k_1, the rate constant for the desorption. For the adsorption of molecules from the vapor layer onto a solid surface, the following equation is applicable,[20]

$$(d\Gamma/dt)_{ads} = k_2PS_o \quad (2)$$

where k_2 is the rate constant for the adsorption; P, the vapor pressure and S_o, the number of sites available for the adsorption of the film molecules.

From the constancy in the Γ-t relationship under atmospheric pressure it is concluded that the

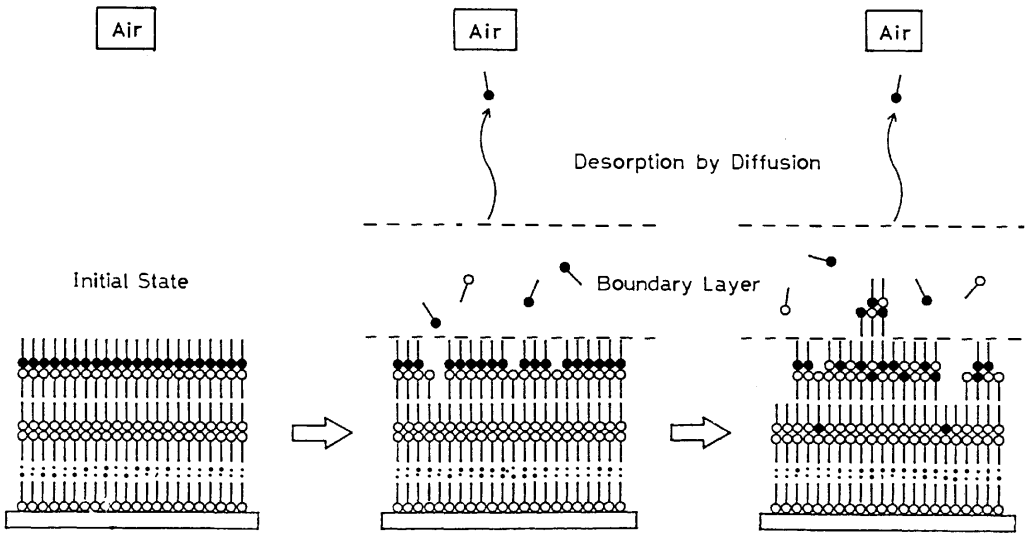

Fig. 7. Schematic drawing of molecular migration of the octadecanoic acid through the boundary (stagnant) layer near the surface of LB film.

adsorption and desorption rates are in balance with one another. Thus, we obtain

$$k_1\Gamma = k_2PS_o. \quad (3)$$

As Γ corresponds to the molecular density of octadecanoic acid at the outermost layer, S_o can be taken as equal to Γ, assuming that the adsorption occurs at any place in the outermost layer. According to the molecular kinetic theory, k_2 is proportional to the collision number of the molecules against the site having a definite area. Thus,

$$k_2 = N_aC\sigma_o\exp(-E_a^*/kT)/(2\pi MRT)^{1/2} \quad (4)$$

where N_a denotes the Avogadro number σ_o, the collision cross-section of octadecanoic acid molecule;[21] C, the sticking coefficient; M, the molar weight of octadecanoic acid and E_a^*, the apparent activation energy for the diffusion of the octadecanoic acid. Consequently, we obtain

$$P = k_1/k_2 = (2\pi MRT)^{1/2}k_1/N_aC\sigma_o\exp(-E_a^*/RT). \quad (5)$$

The average time τ which the molecule remains on the surface is calculated to be of the order of 10^{21} s.[20] from the apparent activation energy, 191.2 kJ mol^{-1}, for the desorption of octadecanoic acid. The sticking coefficient can therefore be taken as unity. By putting the experimental k_1 value, 1.51×10^{-4}s^{-1}, at 298.2 K into Eq. 5, P is expressed as the function of E_a^*,

$$P = 6.66 \times 10^{-8}\exp(-E_a^*/RT). \quad (6)$$

Unfortunately as there are no data about the activation energy for the diffusion of the octadecanoic acid molecule in air, we substituted, as a rough approximation, the E_a^* value, 3.83 kJ mol^{-1}, for the octadecane into Eq. 6. This E_a^* value was obtained from the temperature dependence of its the diffusion coefficient[21] in air. Equation 6 gives 3.12×10^{-7} Pa at 298.2 K as the vapor pressure of octadecanoic acid. On the other hand, 10.6×10^{-7} Pa is obtained as the vapor pressure of octadecanoic acid at room temperature by the extrapolation of the reference value[2] of its vapor pressure near its melting point to room temperature. The former value is smaller than the latter. However, the molecular arrangement in the solid near its melting point is thought to be more disordered than at room temperature; the molecules in the former solid appear to evaporate more easily than at room temperature.

The Heat of Immersion in Water and the Nature of the Surface Hydroxyl Group of Maghemite and Hematite

Haruo WATANABE* and Jun'etsu SETO
Sony Corporation Research Center, 174 Fujitsuka-cho, Hodogaya-ku, Yokohama 240
(Received March 5, 1988)

The heats of immersion in water of maghemite (γ-Fe_2O_3) were measured in comparison to those of hematite (α-Fe_2O_3) prepared from the same maghemite by crystal transformation with heat treatment, and outgassing up to 200 °C. The heats of immersion and the heat of hydration of maghemite were lower than those of hematite throughout the measurement conditions. These differences were concluded to be due to the differences in bulk crystal structure, especially the density of the crystal. That is, the heat of hydration at the stage of physisorption depends on the surface hydroxyl group density, corresponding to the bulk crystal density. Also the surface hydroxyl groups are strongly affected by the polarization of the bonds in the bulk, this results in the difference of the heat of hydration at the stage of chemisorption (formation of the hydroxyl groups) and the acidity of the hydroxyl groups. This view is confirmed on the polymorphs of other metal oxides.

Maghemite is widely used as a magnetic material for magnetic recording tape, and hence information on the surface properties of maghemite is essential for controlling the manufacturing conditions. However, little work has been reported on the surface properties of maghemite, and no work has been reported on the heat of immersion in water, whereas there have been many reports on hematite.[2-10] Our previous work[1] looked at the IEP (Isoelectric point) and the PZC (Point of zero charge) of maghemite, and clarified that the difference in these characteristics for maghemite and hematite arose from differences in the crystal structure. In the present work, the interaction between water and the surface of maghemite and the nature of the surface hydroxyl groups are investigated through the measurement of the heat of immersion and the adsorption isotherm, with hematite as a reference.

Experimental

Materials. The maghemite sample used in the present work was prepared from the acicular synthetic α-FeOOH (goethite) by sequential dehydration, reduction and oxidation processes. The hematite sample was prepared by heat treatment of the above maghemite sample in air at 550 °C. Impurities of the sample surface influence the value of the heat of immersion.[3] So in all cases the samples were purified as follows: First, washing with an alkali solution then distilled water and finally by electrodialysis. The samples and the purification procedure are the same as reported previously.[1]

Surface Area Measurements. The specific surface area of the samples was measured by applying the BET theory[11] to the nitrogen adsorption data obtained at the temperature of liquid nitrogen, assuming the cross-sectional area of nitrogen molecule to be 16.2 Å^2.

Heat of Immersion Measurements. A twin type heat conduction calorimeter (Tokyo Rikou MPC-2) was used. The sample was treated in a Pyrex glass ampoule at the desired temperature for 5 h in a vacuum of 2×10^{-4} Pa before sealing. The heat of immersion measurements were carried out with doubly distilled water at 25.0±0.1 °C. The heat of breaking of the ampoule was found to be 0.26 J.

Water Content Measurements. The water desorbed from the sample by evacuating at a given temperature was condensed in a cold trap of liquid nitrogen, followed by reevaporation and recondensation in a cold trap of dry ice. The water content of the sample was determined by the measurement of the amount of reevaporated water volumetrically, by using an all glass apparatus equipped with Baratron pressure gauge, assuming the water content to be zero at 1000 °C.

Water Adsorption Measurements. The sample was first prepared by evacuating at 25 °C for 5 h in a vacuum of 2×10^{-4} Pa. The adsorption of water on the sample was then measured gravimetrically at 25.0±0.1 °C, using a Cahn 2000 electrobalance housed in an all glass apparatus. Water vapor pressure was measured by Baratron pressure gauge.

Results and Disccusion

Adsorption of Water on the Surface. Maghemite is a less stable form of iron oxide[12] than hematite and becomes reduced under vacuum at temperatures higher than 250 °C, releasing oxygen and turning dark. Therefore, to measure the intrinsic surface properties, the heat treatment was always carried out under 200 °C. The samples treated under this condition were confirmed to contain no detectable divalent iron ions by analysis.

The specific surface areas (S_{N_2}) of the samples by BET method of nitrogen adsorption are shown in Table 1. The smaller value for the comparative hematite sample can be explained by the shrinkage due to the increase in crystal density caused by the crystal transformation. The change of the shape can not be detected by electron microscopic observation,[1] and no substantial change in the values of the samples was detected following the heat treatment.

The water content of the samples is shown in Fig. 1, where the amount of water is expressed by the number of water molecules per unit of surface area. Almost perfect desorption of the physisorbed water is

attained by the evacuation at 25 °C in a vaccum of 2×10^{-4} Pa. The number of chemisorbed water molecules is shown as the hydroxyl groups per unit area (V_c) in Table 1.

The water adsorption isotherms of the samples are shown in Fig. 2. The ordinate in the figure represents the amount of water adsorbed per unit area. These isotherms indicate that the water is physically adsorbed on the hydroxyl groups formed on the surface. By applying the BET method[11] to the isotherm, the amount of water per unit area in the physisorbed monolayer (V_p) was calculated and are shown in Table 1.

The samples in the present work have an acicular shape inherited from the starting goethite, this series of solid phase reactions follow the topotaxial rule.[14] The cylindrical face of the particle forms the main part of the total surface area, and is mainly the (lll) plane in the case of maghemite, and the (0001) plane in the case of hematite. The number of the surface iron ions per unit area ($S_{Fe^{3+}}$) for the (lll) plane of maghemite and the (0001) plane of hematite calculated crystallographically[15] are shown in Table 2. The values for the real surfaces of the samples may be larger than these values, because of the incorporation of the higher indexed planes due to the curvature of the surface. A convenient method to approximate the values is to calculate the average number of surface iron ions per unit area ($S_{Fe^{3+}}$) from the volume of unit cell per iron ion ($V_{Fe^{3+}}$) which is derived from the X-ray density data.[13] Values for the average number of surface iron ions per unit area ($S_{Fe^{3+}}$) are shown in Table 2. They are almost equal in number to the number of surface hydroxyl groups (V_c) in Table 1. This numerical correspondence was reported by Morimoto et al.,[16] and that the ratio V_p:V_c is nearly 1:2, which led them to suggest the model where one physisorbed water connects two neighboring surface hydroxyl groups through hydrogen bonds. The V_p:V_c ratio for maghemite and hematite from our result supports the above model.

Heat of Immersion and Heat of Hydration. The relation between the heats of immersion and the

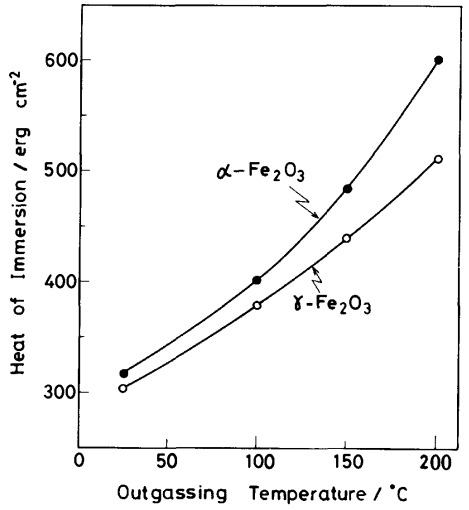

Fig. 3. Heat of immersion in water of maghemite (γ-Fe_2O_3) and hematite (α-Fe_2O_3) as a function of outgassing temperature.

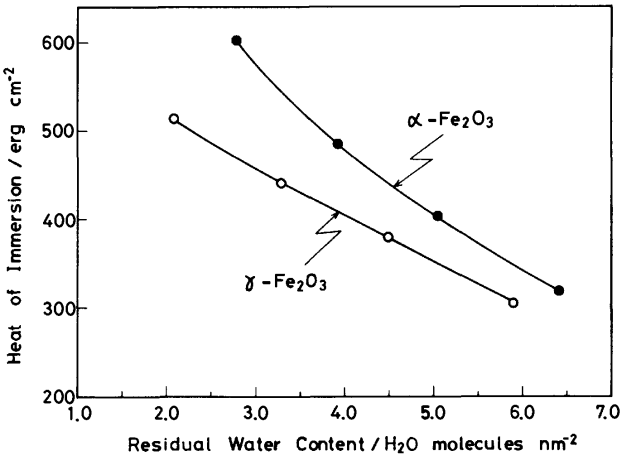

Fig. 4. Heat of immersion in water of maghemite (γ-Fe_2O_3) and hematite (α-Fe_2O_3) as a function of water content.

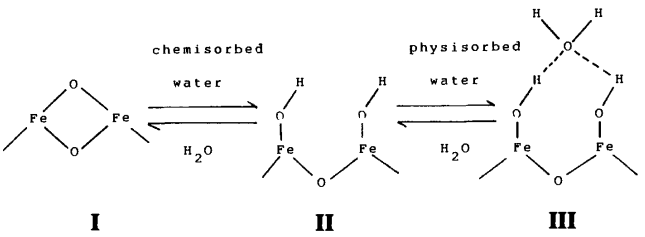
outgassing temperature for both samples is shown in Fig. 3. The amount of heat generated increased according to the outgassing temperature for both samples. Outgassing temperatures below 200 °C are low enough to allow complete rehydroxylation of the dehydrated sites.[6] The hematite sample shows a larger heat of immersion than the maghemite sample all through the temperature range of the measurement. The difference of the heat of immersion between the samples increased with increasing outgassing temperature.

The points for the highest water content of the samples corresponding to outgassing at 25 °C, indicate the heat of immersion for the completely hydroxylated state, that is, the surface is perfectly covered with chemisorbed water, as shown by the values of the $S_{Fe^{3+}}$, V_c and V_p. The value of the heat of immersion at this stage is 304 erg cm^{-2} for the maghemite, and 317 erg cm^{-2} for the hematite. The values of the heat of the immersion for hematite at this stage, are reported as 280 erg cm^{-2} by Jurinak and Burau,[3] 322 erg cm^{-2} by Furuichi et al.,[10] and 367 erg cm^{-2} by McCafferty and Zettlemoyer.[5] The present value for hematite compares favorably with other reported values, considering the differences of the samples and the conditions of measurement.

The heats of immersion for the lowest water content corresponding to outgassing at 200 °C, are 513 erg cm^{-2} for the maghemite and 602 erg cm^{-2} for the hematite. Healy and Fuerstenau[21] reported that the various metal oxides show a linear relation between the values of the heat of immersion (after outgassing at 200 °C) and the values of PZC. A metal oxide with a high value of PZC shows a large heat of immersion. The previous study[1] made it clear that the value of PZC of maghemite (pH 5.5) is lower than that of hematite (pH 6.7). The present results on the heats of immersion for samples outgassed at 200 °C fit the above relation.

Figure 4 shows the plots of the heat of immersion against the residual water content for both samples. The heat of surface hydration is calculated by the slope of these plots. At the stage of complete hydroxylation, shown in the below scheme [**II-III**], the heats of hydration are 32.2 kJ mol^{-1} for the maghemite and 37.6 kJ mol^{-1} for the hematite.



The heat of hydration at this stage corresponds to the physisorption of water, that is the construction of the hydrogen bonds, as in the above model **III**, between the oxygen atom of the physisorbed water and the two protons of the neighboring surface hydroxyl groups. The validity of this model in the present work is supported by the numerical correspondence of V_c and V_p in Table 1.

The average distance between the neighboring hydroxyl groups on the surface, relates to the density of hydroxyl groups on the surface (V_c), which is related to the average surface density of Fe^{3+} ($S_{Fe^{3+}}$) and the average bulk density of Fe^{3+} ($V_{Fe^{3+}}$) in Table 2. When the distance between the neighboring groups is long, the hydrogen bonds of the above model **III** are weak, and the heat of hydration is low. The average distance between the neighboring hydroxyl groups of maghemite is longer than that of hematite, as shown by the values of V_p and V_c. Thus, the heat of hydration

at the stage of physisorption of maghemite should be lower than that of hematite. This speculation is strongly supported by the experimental heats of hydration. The heat of the formation of the hydrogen bonds is given by halfing the value of the heat of hydration (one water molecule forms two hydrogen bonds). This gives values less than 20 kJ mol^{-1}, which is reasonable for hydrogen bond formation.

The heat of surface hydration for the stage when half of the surface is dehydrated, that is the heat of surface rehydration, is shown in the above scheme [I-II], and is 35.1 kJ mol^{-1} for the maghemite and 60.6 kJ mol^{-1} for the hematite. The maghemite shows the lower heat of hydration throughout the present study.

On the heat of hydration of the hematite, several different values have been reported, 101 kJ mol^{-1} by Healey et al.,[2] 66 kJ mol^{-1} by Furuichi et al.,[10] 47.2 kJ mol^{-1} by Morimoto et al.,[6] and 34.3 kJ mol^{-1} by Rossi et al.[9] These scattered values are caused by differing levels of ionic impurities, the difference of particle shape, differences in the preparation and outgassing conditions.

For comparing the intrinsic values of the heat of immersion and the heat of hydration for the maghemite and hematite, the above mentioned conditions were virtually identical. Consequently, the differences of the heat of immersion and the heat of hydration are due to the difference of the crystal structure.

The maghemite (γ-Fe_2O_3) has the spinel type crystal structure, and the hematite (α-Fe_2O_3) has the corundum type crystal structure.[17] These crystal structures correspond to γ-Al_2O_3 and α-Al_2O_3, respectively. In the comparative studies on the heat of immersion of γ- and α-Al_2O_3, γ-Al_2O_3 always shows a lower value for the heat of immersion than α-Al_2O_3.[18-20] These results are in good agreement with our results on maghemite and hematite.

The values for the heat of immersion of γ- and α-Al_2O_3 also follow the tendency described by Healy and Fuerstenau,[21] as the value of PZC for γ-Al_2O_3 is lower than that of α-Al_2O_3.[22]

Difference of the Nature of Surface Hydroxyl Groups Based on Difference of Crystal Structure. The average difference in the acidity of the surface hydroxyl groups between maghemite and hematite was reported as the difference of the IEP or the PZC of 1.1 to 1.2 pH units.[1]

The unit lattice of maghemite is expressed by the following formula:[23]

$$Fe^{3+}_8 \quad (Fe^{3+}_{40/3}\square_{8/3})\ O^{2-}_{32}$$

Coordination number = 4 Coordination number = 6

In the above formula a vacant lattice point of coordination number 6 is expressed by □, i.e. 6 oxygen ions adjacent to the Fe^{3+} ion site. Fe^{3+} ions are arranged at positions of coordination number 4 and 6 in a ratio of 3:5. On the other hand, hematite is a corundum-type oxide in which all of the Fe^{3+} ions have a coordination number of 6.

Parks[24] proposed a semiempirical equation for the PZC of metal oxides and metal hydroxides as follows:

$$PZC = A - 11.5(Z/R + 0.0029a)$$

where A is a constant depending on the coordination number of the metal ion and the hydration state of the surface. Z is the valency of the metal ion, R is the distance from the surface metal ion to the hydrogen ion in the surface hydroxyl group attached to the metal ion, and a is the crystal field stabilization energy of the metal ions by the hydroxide ions. The last term is zero when the metal ion is Fe^{3+} with a coordination number of 6 or 4.[25] The PZC value is more acidic by 2.4 pH units for four-coordinated than for six-coordinated metal ions, corresponding to the difference of the above constant A at the same hydration state. Thus the difference in the PZCs between maghemite and hematite is calculated to be 2.4×3/(3+5)=0.9, assuming that the additivity rule holds.[26]

Yoon et al.[27] has proposed improvements to Parks' equation: for complex oxides in which the correction of the crystal field stabilization energy is not required,

$$PZC = 18.43 - 53.12\sum f_i(v/L_s)_i - 0.5\sum f_i \log((2-v)/v)_i$$

where v is the bond valence, i.e., the valency of the metal ion per coordination number, and L_s ($=L+r$) is the sum of the mean M-O bond length (L) and the O-H distance (r), taken to be 1.01 Å. The f_i's are the ratio of the bonds to the total number of bonds. The value of PZC for maghemite is lower than that for hematite by 1.40 pH units as calculated by the above formula with the data for maghemite (γ-Fe_2O_3)[28] and hematite (α-Fe_2O_3).[17]

The above mentioned calculations support the proposition that the bonding energy between H^+ and O^{2-} of the surface hydroxyl groups of maghemite is lower than that of hematite, which is further supported by our experimental values.[1] As a matter of course, the difference in the heats of hydration at the [I-II] stage, shown in the previous scheme, further includes the difference in the bond formation energy of the Fe-O(-H) bonds for maghemite and hematite.

To discuss the Fe-O bond of the surface hydroxyl groups, it is necessary to examine the nature of this bond in the bulk. As aforementioned, the crystal density (D_x) of maghemite is lower than that of hematite, which means that the average bond length Fe-O of maghemite is longer than that of hematite. The ions are less ionic and the bonds are less polar[29] in maghemite than in hematite, which is supported by the lower electron density of the oxygen atoms of maghemite than of hematite as measured by XPS.[30]

(The same characteristics are also reported for γ- and α-Al_2O_3.[31]) The difference in the ionic characteristics of the bulk bonds should also be reflected in the surface hydroxyl groups.

From this point of the view, Healy et al.[32] introduced this ionic characteristics concept as "volume field strength", and successfully showed the linear relationship between the PZCs and the "volume field strength" for the polymorphs of manganese oxides. This electrostatic field is proportional to $(V_m)^{-2/3}$, where V_m is the volume of the unit cell per metal ion. And the value of PZC is given by the following formula:

$$PZC = A_1(V_m)^{-2/3} + B_1$$

This formula indicates that the value of PZC increases as V_m decreases, A_1 and B_1 are constants for the oxide series. The plots of this relation for maghemite and hematite are shown in Fig. 5. The plots of the polymorphs of manganese oxides from Healy et al.,[32] and of γ- and α-Al_2O_3 (PZC values[22] and V_m values from the crystal densities[33]) are also shown in Fig. 5. Almost the same slope can be found for the plot of each polymorph. This fact supports the view of Healy et al.[32] that the surface hydroxyl groups are strongly influenced by the electrostatic field within the lattice of the crystal. In other words, the surface hydroxyl groups are strongly affected by the polarization of the bonds in the bulk. The degree of the polarization becomes higher, as the bond length becomes shorter corresponding to an increasing the bulk crystal density. This increase in the polarization of the bonds in the bulk affects the surface hydroxyl groups, that is the acidity of the hydroxyl groups, which can be characterized by the parameter PZC, decreases.

In addition to this, it is suggested that the line of each metal ion has a different intercept, and this difference may be caused by the degree of the polarization of the bonds between the metal ion and the oxygen ion or the ionic characteristics of the metal ion, which is characterized by the electronegativity of the metal ion. The order of the intercept $Mn^{4+}>Fe^{3+}>Al^{3+}$ corresponds well to the electronegativity of the metal ion.[34]

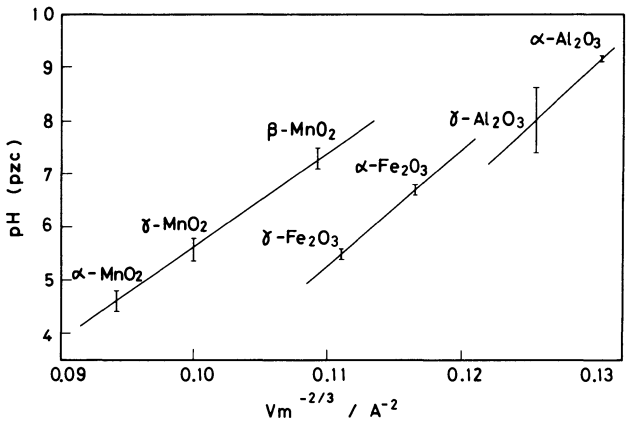


Fig. 5. Inter-relation of the values of the PZCs (pH_{pzc}) and the average volume of the unit cell per metal ion (V_m) for various metal oxides series.

Conclusion

(1) The surface density of hydroxyl groups for maghemite is lower than for hematite, corresponding to the difference in the density of the bulk crystal.

(2) The amount of the water physisorbed in a monolayer on maghemite is less than that for hematite, corresponding to the lower surface density of hydroxyl groups.

(3) The heat of the surface hydration at the stage of physisorption for maghemite is lower than for hematite, because the average distance between neighboring hydroxyl groups for maghemite is longer than for hematite.

(4) The heat of the surface hydration at the stage of chemisorption (the formation of the surface hydroxyl groups) for maghemite is lower than for hematite. This difference is caused by the different degree of the polarization of the bonds in the bulk which extends to the surface hydroxyl groups.

(5) The surface hydroxyl groups are strongly affected by the bulk, especially the polarization of the bonds in bulk. The degree of the polarization becomes higher, both as the bond length becomes shorter, corresponding to a higher bulk crystal density, and as the electronegativity of the metal ion becomes higher. This polarization of the bond in the bulk affects the surface hydroxyl groups, resulting in the dissociation of the hydroxyl groups, that is the acidity of the hydroxyl groups decreases.

The authors wish to thank Dr. Michael L. Hair of Xerox Research Centre of Canada for useful discussions, and Dr. Stephen Baker of Sony Corporation Research Center for reading the manuscript.

The Temperature Dependence of the Conductivities and Ion-Association Constants of Potassium Nitrate and Potassium Perchlorate in Water

Haruhiko YOKOYAMA* and Tomoko OHTA
Department of Chemistry, Yokohama City University, 22-2 Seto, Kanazawa-ku, Yokohama 236
(Received March 19, 1988)

The electric conductivities of potassium nitrate and potassium perchlorate in water have been measured at eleven temperatures from 0 to 50 °C and analyzed in order to obtain the ion-association constants and the limiting molar conductivities of these salts. It was found that the observed ion-association constants have a minimum value at 30 °C for KNO_3 and at 36 °C for $KClO_4$. Such a characteristic temperature dependence was considered to be due to the presence of specific short-range interactions within contact ion pairs, although the weak hydration of the ions seemed to help the formation of the contact ion pairs. The experimental standard enthalpies and entropies of ion association were discussed in comparison with the theoretical ones. The limiting molar conductivities of NO_3^- and ClO_4^- at each temperature were also evaluated and expressed as cubic equations of the temperature.

Potassium nitrate and potassium perchlorate have been known to be slightly associated in water.[1-4] It is of interest what interactions are concerned with their ion associations, since, from the electrostatic ion-association theories,[5,6] 1:1 electrolytes can be predicted to be almost completely dissociated in water. The detailed knowledge of the temperature dependence of their ion-association constants (K) should be useful in clarifing such a problem. At the present stage, however, we have no available information about this.

The limiting molar conductivities (λ^∞) of alkali metal ions and halide ions in water have been measured in detail at temperatures between 0 and 55 °C and expressed as cubic equations of the temperature.[7,8] However, the λ^∞ values of the nitrate ion and the perchlorate ion are known only for a few temperatures, although information on their temperature dependence would be valuable for the analysis of the conductivities of unsymmetrical electrolytes involving these anions and also for the investigation of the ion-solvent interactions in water.[8] For these reasons we performed conductivity measurements on aqueous solutions of potassium nitrate and potassium perchlorate at eleven temperatures between 0 and 50 °C and obtained the ion-association constants of KNO_3 and $KClO_4$ and the limiting molar conductivities of NO_3^- and ClO_4^- as a function of the temperature. On the basis of these results, we will discuss the character of the interactions between the ions.

Experimental

Materials. The potassium nitrate and potassium perchlorate (Wako Pure Chemical Industries, reagent-grade) were recrystallized twice from conductivity water and then air-dried at room temperature. The potassium perchlorate was then further dried at about 150 °C and kept over diphosphorus pentaoxide in a desiccator under reduced pressure. Small quantities of adsorption water (0.21 wt% for KNO_3 and 0.01 wt% for $KClO_4$) were found by the Karl-Fischer method with an AQ-5 Aquacounter of the Hiranuma Sangyo Co. and were corrected in the calculation of the concentrations of solutions.

Solutions. All the solutions were made by weight, and the molar concentration at each temperature was calculated by the use of the solution densities, which had been themselves estimated from those at 25 °C in the manner described previously.[9] The density measurements at 25 °C were carried out by using a vibrating-tube SS-D-200 twin-type densimeter of the Shibayama Scientific Co. Water purified by the use of Milli-Q Reagent-grade Water Systems of Japan Millipore was used for the preparation of the solutions. Its conductivity was always lower than 1×10^{-7} S cm^{-1} at 25 °C after the dissolved carbon dioxide had been removed. Ten solutions (from 0.0007 to 0.010 mol dm^{-3}) were examined.

Conductivity Measurements. The conductivity measurements were made with a Fuso 360 linear-bridge conductometer in the manner described previously.[10] The cell constant of the cell used was 0.13720 cm^{-1} at 25 °C. For the other temperatures, the change in the cell constant due to the thermal expansion of platinum and glass was corrected; it was regarded as −0.0014% for the elevation of 1 °C, which was estimated in the manner described by Robinson and Stokes.[8] The reproducibility of the conductivity measurements was within 0.03%, and the precision of the temperature measurements was ±0.003 °C. The accuracy of the temperature was ±0.01 °C.

Results and Discussion

Analysis of Conductivity Data. The observed molar conductivities (Λ)[11] were analyzed by assuming the ion association(ion-pair formation) of the salts in terms of the 1970 Fuoss-Justice equation,[12,13] with $E=E_1\Lambda^\infty-2E_2$:

$$\Lambda = \alpha[\Lambda^\infty - S(\alpha c)^{1/2} + E\alpha c\log(\alpha c) + J_1\alpha c - J_2(\alpha c)^{3/2}],$$

where S, E_1, E_2, J_1, and J_2 have the usual meanings and where α is the fraction of free ions. The values of the

closest distance of approach of the ions(a) involved in J_1 and J_2 and the Debye-Hückel equation of the activity coefficient were assumed to be equal to 3.38 and 3.63 Å for KNO_3 and $KClO_4$ respectively. These values were estimated from the crystallographic radius of K^+ (1.33 Å)[8] and the effective radii of NO_3^- and ClO_4^- (2.05 and 2.30 Å respectively, estimated from the ionic partial molar volumes[14] by the use of Glueckauf's equation[10,15]). The ion-association constant (K) and the limiting molar conductivity (Λ^∞) were determined by the least-squares procedure, minimizing σ, where $\sigma^2=\sum[\Lambda(\text{obsd})-\Lambda(\text{calcd})]^2/(n-2)$. The details of the calculations have been described previously.[10]

Ion-Association Constants and Their Temperature Dependence. The values of K, Λ^∞, and σ obtained are summarized in Tables 1 and 2.[16] The values of K and Λ^∞ at 25 °C are in practical agreement with the following values reported by Carman[2]: K=1.2—1.3 dm³ mol⁻¹ and Λ^∞=145.05 S cm² mol⁻¹ (a=3.46—3.83 Å) for KNO_3 and K=1.6 dm³mol⁻¹ and Λ^∞=140.65 S cm²mol⁻¹ (a=4.21 Å) for $KClO_4$. The experimentally obtained ion-association constants are larger than those predicted from the electrostatic ion-association theory[6], K=0.52 and 0.48 dm³ mol⁻¹ at 25 °C for a=3.38 and 3.63 Å respectively. The temperature dependence of the ion-association constant can be well characterized when $\log(K/\text{dm}^3\,\text{mol}^{-1})$ values are plotted against t/°C, as shown in Fig. 1. That is, the experimental ion-association constant has a minimum value at a certain temperature, while the theoretical one[6] increases with an increase in the temperature: for example, K/dm³ mol⁻¹=0.46 (0 °C), 0.48 (10 °C), 0.50 (20 °C), 0.53 (30 °C), 0.56 (40 °C), and 0.59 (50 °C) for a=3.38 Å and 0.43 (0 °C), 0.45 (10 °C), 0.47 (20 °C), 0.49 (30 °C), 0.52 (40 °C), and 0.55 (50 °C) for a=3.63 Å.

The experimental $\log K$ values can be reproduced well by a full line shown in Fig. 1 using this equation:

$$\log K = p(t - t_{\min})^2 + \log K_{\min}, \quad (1)$$

where the values of p, $t_{\min}$, and $K_{\min}$ are as given in Table 3. This equation is similar to that used by Harned and Embree[17,18] for the temperature dependence of the dissociation constants of such weak acids as acetic acid. The p values in Table 3 are near to the usual one, 5×10^{-5} K⁻², for the acid-dissociation constants reported by Harned and Embree.[17,18] The standard enthalpy and entropy of ion association ($\Delta H°$ and $\Delta S°$), which can be estimated by the use of Eq. 1, are shown for several temperatures in Tables 4 and 5. These values are smaller than the theoretical ones,[6] as shown in the same tables. Their deviation becomes remarkable with a decrease in the tempera-

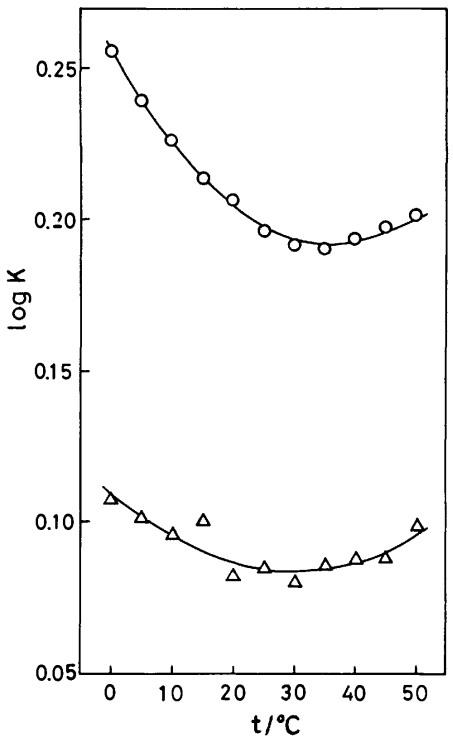

Fig. 1. Temperature dependence of ion-association constants of KNO_3 (△) and $KClO_4$ (○).

ture. Negative or small $\Delta H°$ values mean that exothermic interactions exist between the ions and become dominant at temperatures below t_{min}.

Although one may consider that the ion associations of KNO_3 and $KClO_4$ are due only to the weakness of the hydration of NO_3^- and ClO_4^-, this explanation is not necessarily adequate for the following reason. The hydration of I^- is supposed to be weaker than that of NO_3^- because of its more positive hydration free energy at 25 °C.[19] However, the ion-association constant between K^+ and I^- is 0.64 $dm^3\ mol^{-1}$ (a=4.5 Å, t=25 °C) smaller than that of KNO_3, and it decreases with the decrease in the temperature in the range from 5 to 55 °C.[20] This temperature dependence differs from that observed in the present study, although it is in agreement with the prediction from the electrostatic ion-association theory.[6]

Table 5. Experimental and Theoretical Values of Standard Enthalpy and Entropy of Ion Association Obtained for $KClO_4$ with a=3.63 Å

t	Experimental $\Delta H°$	Experimental $\Delta S°$	Theoretical[6] $\Delta H°$	Theoretical[6] $\Delta S°$
°C	kJ mol^{-1}	J K^{-1} mol^{-1}	kJ mol^{-1}	J K^{-1} mol^{-1}
5	−4.6±0.5	−12.0±1.6	2.53	2.2
15	−3.3±0.3	−7.5±0.9	3.05	4.0
25	−1.8±0.2	−2.4±0.6	3.59	5.9
35	−0.1±0.3	3.3±0.9	4.17	7.8
45	1.9±0.6	9.6±1.9	4.78	9.8

The exothermic interactions between the ions are considered to be specific interactions within contact ion pairs, independent of the macroscopic properties of a solvent such as the dielectric constant. The negative $\Delta S°$ values at lower temperatures suggest that the specific interactions require steric restrictions for the formation of contact ion pairs. The local charges of oxygen atoms are presumed to play an important role in such interactions within the contact ion pairs. The slightly large values of K and t_{min} of $KClO_4$ compared with those of KNO_3 mean that the specific interactions of K^+ with ClO_4^- are stronger than those with NO_3^-. This may be due to the relatively weak hydration of ClO_4^-[19] and also to the difference in the number of oxygen atoms of the anions.

The nitrate and perchlorate ions have been known to associate also with the other alkali metal ions.[2] Their ion-association constants increase with the ionic radii of the cations in the following sequences: $K(NaNO_3)<K(KNO_3)K(CsNO_3)$ and $K(KClO_4)<K(RbClO_4)<K(CsClO_4)$.[21] This may indicate that the formation of the contact ion pairs depends also on the ease of the release of the hydration water molecules of the cations, since the ion-association constants increase with a decrease in the hydration power of the alkali metal ions.[19]

The Temperature Dependence of the Limiting Molar Conductivities of NO_3^- and ClO_4^-. Harned and Owen represented the temperature dependence of the limiting molar conductivities (λ^∞) of alkali metal ions and halide ions between 5 and 55 °C by means of this cubic equation:[7]

$$\lambda^\infty = \lambda^\infty(25\,°C) + a(t-25) + b(t-25)^2 + c(t-25)^3. \quad (2)$$

The values of $\lambda^\infty(K^+)$ were calculated with this equation and then used to evaluate those of $\lambda^\infty(NO_3^-)$ and $\lambda^\infty(ClO_4^-)$ at the temperatures between 0 and 50 °C from $\Lambda^\infty(KNO_3)$ and $\Lambda^\infty(KClO_4)$. By using the resulting values, the parameters, a, b, c, and λ^∞(25 °C), for NO_3^- and ClO_4^- were determined; they are summarized in Table 6. With these parameter values, the experimental values of $\lambda^\infty(NO_3^-)$ and $\lambda^\infty(ClO_4^-)$ can be reproduced by the use of Eq. 2 within an accuracy of 0.01 S cm^2 mol^{-1}.

Table 6. Values of Parameters in Eq. 2 Representing the Temperature Dependence of the Limiting Ionic Molar Conductivities

Ion	λ^∞(25 °C) / S cm^2 mol^{-1}	a / S cm^2 mol^{-1} K^{-1}	$b\times10^3$ / S cm^2 mol^{-1} K^{-2}	$c\times10^6$ / S cm^2 mol^{-1} K^{-3}
NO_3^-	71.60	1.3670	3.776	−3.5
ClO_4^-	67.20	1.3159	3.833	−5.9

(Received March 28, 1988)

The surface pressure–area (π–A) curves for monolayers of four kinds of cation-anion triple long-chain salts [dialkyldimethylammonium alkanesulfonates] on the aqueous solution of 4.4 M NaCl were measured at various temperatures by the Langmuir method. Some π–A curves of these salts showed two transition points. Judging from the apparent molar entropy change on the transition, the first was assigned to the transition from the expanded state (E phase) to the condensed state (C-I phase) and the second to the transition from the C-I phase to another condensed state (C-II phase). In this paper, another condensed phase (C-I′) was newly observed over a certain temperature range on the phase diagram, which is the intermediate phase between the C-I phase and the C-II phase. There exist two triple points on the phase diagram at which three phases (i.e., E, C-I, and C-I′, and C-I, C-I′, and C-II) coexist. From the apparent molar entropy change, limiting area, compressibility, and phase diagram, the orientation of (2-1) long-chain salts in the monolayer state was assumed.

Many papers have been published on the adsorbed film at the air/water interfaces from the mixtures of cationic and anionic surfactant solutions.[1–11] Some studies concerning the mixed monolayers of cationic and anionic surfactants have also been reported.[12–16] We have recently investigated the surface chemical properties of the insoluble monolayers of double long-chain salts, which are composed of a long-chain cation and a long-chain anion, on water and/or electrolyte solutions.[17–20] The monolayers of double long-chain salts on 4.4 M NaCl solution (1 M=1 mol dm^{-3}) showed such outstanding behavior as some surface pressure–area (π–A) curves had two transition points.[19–20] To investigate the phase transitions of monolayer more deeply, it is necessary to extend the study from the viewpoint of molecular structure and to compare the results with those of other types of long-chain salts at the same experimental conditions, i.e., on 4.4 M NaCl solution.

In the present study then, dialkyldimethylammonium alkanesulfonates [which is denoted as (2-1)long-chain salt or as 2CnNCnS, in which n is the number of carbon atoms in the long-chain cation and anion, while a customary double long-chain salt will be described as (1-1) long-chain salt or as CnNCnS] were prepared, and the surface pressures of monolayers of these salts have been measured as a function of molecular area at various temperatures. The NaCl concentration of the substrate was fixed at 4.4 M throughout the experiments. The phase type in the monolayer states of the (2-1) long-chain salts could be judged from both the phase diagrams and thermodynamic quantities on the phase transition.

Experimental

The (2-1) long-chain salts (2CnNCnS), dialkyldimethylammonium alkanesulfonates, were prepared by mixing equimolar solutions of dialkyldimetylammonium bromides from Prof. T. Kunitake of Kyushu University and sodium alkanesulfonates from Tokyo Kasei Kogyo. The precipitates were purified by recrystallization from an acetone/water mixture (7:3 in v/v). The four salts of different hydrocarbon chain length are shown in Table 1. The purity of these salts was confirmed by elemental analyses. Each (2-1) long-chain salt was spread from hexane–ethanol mixture (4:1 in v/v, the former from Merck, Uvasol, and the latter from Nacalai Tesque) at the air/water interface.

The substrate solution of 4.4 M sodium chloride (Nacalai Tesque) was prepared using thrice distilled water. Sodium chloride was roasted at 973 K to remove any surface active impurities.

The surface pressure was measured by an automated Langmuir film balance, which was the same used in the previous study.[17–20] The concentration of NaCl in the substrate was held constant at 4.4 M throughout the experiments in order to observe the reproducible π–A curve and to compare the phase diagrams from the viewpoint of the molecular structures of the two kinds of salts [CnNCnS and 2CnNCnS].

Other experimental conditions were the same as described in the previous paper.[20]

Results and Discussion

The π–A curves obtained of 2CnNCnS salts with equal number of carbon atoms in three long chains, at

Table 1. Materials

Dialkyldimethylammonium alkanesulfonate	$(C_nH_{2n+1})_2N^+(CH_3)_2\,C_nH_{2n+1}SO_3^-$ where n=12, 14, 16, 18	2CnNCnS

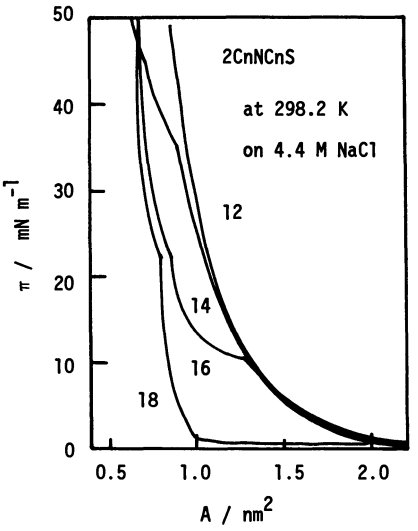

Fig. 1. The π–A curves of (2–1) long-chain salts on 4.4 M NaCl solution at 298.2 K. In the case of 2CnNCnS type; Curve 12, 2C12NC12S; 14, 2C14NC14S; 16, 2C16NC16S; 18, 2C18NC18S.

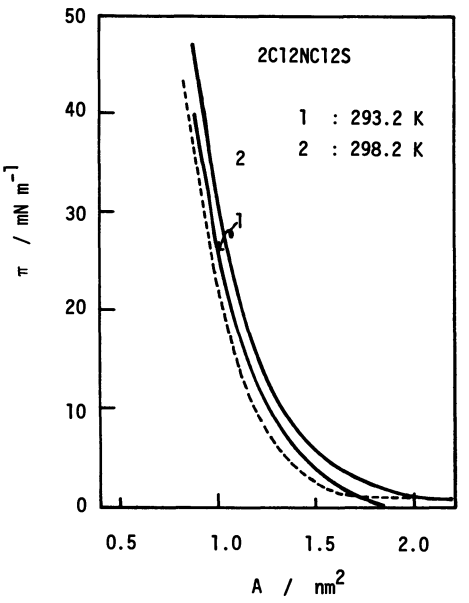

Fig. 2. The temperature dependence of π–A curves of 2C12NC12S salt. Substrate: 4.4 M NaCl solution. Dotted line: on pure water at 298.2 K.

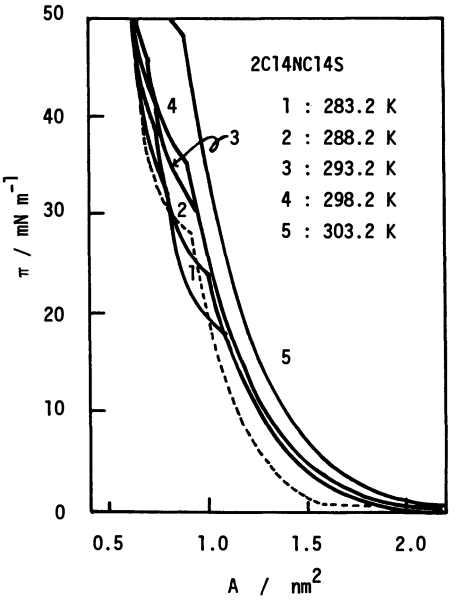

Fig. 3. The temperature dependence of π–A curves of 2C14NC14S salt. Substrate: 4.4 M NaCl solution. Dotted line: on pure water at 298.2 K.

298.2 K on 4.4 M NaCl are shown in Fig. 1. Numerical values in Fig. 1. refer to the number of carbon atoms in the long-chains. The longer the chain length of the salts, the smaller the value of the mean area per molecule at constant pressure. As seen from Fig. 1, all the π–A curves have one or two transition points at 298.2 K except for 2C12NC12S salt. Since the transition pressures remain constant irrespective of the compression rate,[19,20] all the transition points on the π–A curves can be regarded as the equilibrium point between two or three phases on the monolayer. The phase transition pressures (π^{eq}) change extensively with varying the chain length. Especially, both π–A curves of 2C14NC14S and 2C16NC16S revealed two distinct break points. The two transitions for these salts, however, have turned out to be different in phase; new intermediate phase appeared during the compression of the monolayer of 2C16NC16S. The first break point at a low surface pressure of the π–A curve for the 2C16NC16S salt indicates the transition from the expanded (E-phase) to the condensed film, and the second break point at a higher surface pressure is as the transition from a condensed film to another condensed film, as described in the previous papers.[19,20] These two condensed states are referred to the condensed phase I and the condensed phase II, respectively, in the same manner.[19,20] On the other hand, judging from the previous phase diagrams, the break point at a low surface pressure of 2C14NC14S can be assigned to the transition from the expanded phase (E-phase) to the condensed phase I′ (C-I′) which is different from the condensed phase I (C-I) on the monolayer phase diagram. The second break point at a higher surface pressure is regarded as the transition from the condensed phase I′ (C-I′) to the condensed phase II (C-II), which can be also assigned by the aid of thermodynamic quantities and the phase diagram as mentioned later.

On the other hand, the π–A isotherms of 2C18NC18S have only one transition point, which is the transition from one condensed state to another condensed state by the aid of thermodynamic quantities as mentioned later. The π–A curve of 2C12NC12S salt shows only an expanded film at 298.2 K.

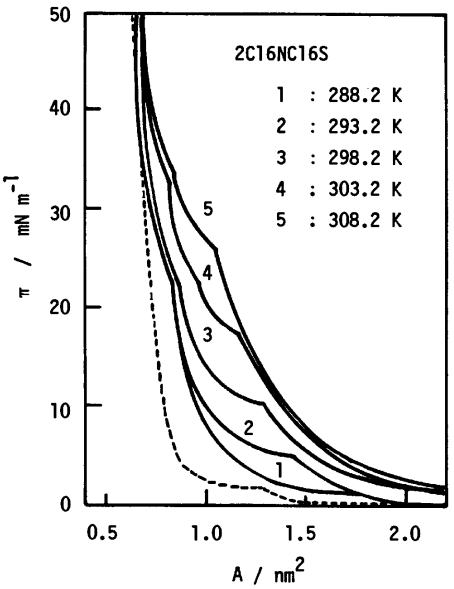

Fig. 4. The temperature dependence of π-A curves of 2C16NC16S salt. Substrate; 4.4 M NaCl solution. Dotted line: on pure water at 298.2 K.

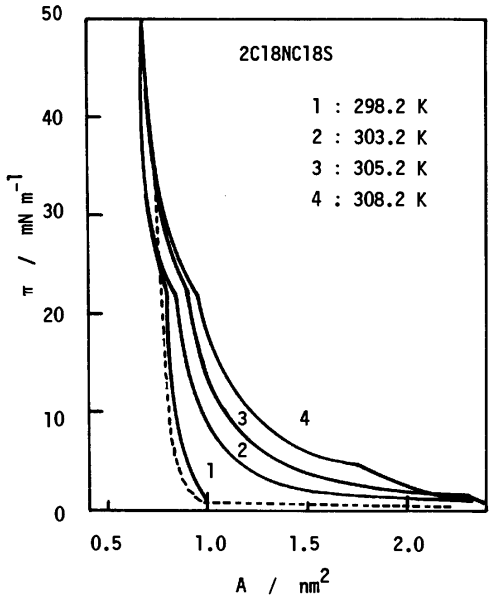

Fig. 5. The temperature dependence of π-A curves of 2C18NC18S salt. Substrate; 4.4 M NaCl solution. Dotted line: on pure water at 298.2 K.

In order to clarify the effect of the chain lengrh on the phase diagram, the π-A curves for the four (2-1) long-chain salts were compared at various temperatures in Figs. 2—5. The limiting area is found to be larger by about 0.6 nm² than threefold area of corresponding single long-chain fatty acids.[21] This is due to the bulky cationic head group. From these figures the π-A curves clearly have two or three transition points depending on the chain length of the cations and anions. In the previous experiments of (1-1) long-chain salt monolayer on 4.4 M NaCl solution, only two kinds transitions [E phase→C-I phase and C-I phase→C-II phase] have been observed. Therefore, the three kinds of transitions [E phase→C-I phase, C-I phase→C-I′ phase, and C-I′ phase→C-II phase] are characteristic of the present systems.

Table 2. Limiting Areas of (2-1) Long-Chain Salts and (1-1) Long-Chain Salts at 298.2 K (on 4.4 M NaCl)

Chain length (n) of salts	Limiting area (A/nm²)	
	C_nNC_nS	$2C_nNC_nS$
	Condensed phase I	
n=12	—	—
n=14	—	1.12(E→C-I′)[a]
n=16	0.728	1.06
n=18	0.700	—
	Condensed phase II	
n=12	—	—
n=14	—	0.910(C-I′→C-II)[b]
n=16	—	0.868
n=18	0.599	0.755

a) This value is the limiting area for the condensed phase I′(C-I′). b) This value is the limiting area for the condensed phase II(C-II).

In order to investigate the molecular orientation on the surface films, the limiting areas of the condensed film were estimated from the π-A curves by the same method described previously.[19,20] The values of the limiting area can be classified into two groups as shown in Table 2: one is the limiting area for the condensed phase I (for 2C14NC14S salt, the value is the limiting area for the condensed phase I′, this will be made clear later by the phase diagram), and the other is that for the condensed phase II. The π-A curves of 2C18NC18S (curve of n=18 in Fig. 1) and C16NC16S [curve of n=16 in Fig. 2 of Ref. 20], for example, have one transition point. As seen from Table 2, the limiting area (0.364 nm²) per alkyl chain for C16NC16S quite resembles the limiting area (0.350 nm²) per alkyl chain for the condensed phase I of the C18NC18S salt with two break points on the π-A curve, whereas the value of the limiting area (0.252 nm²) per alkyl chain for 2C18NC18S should be classified to another condensed phase, the condensed phase II of the $2C_nNC_nS$ salt.

As seen from Figs. 2 to 5, there exists evidently an appreciable difference in the limiting area of the π-A curves for (2-1) long-chain salt between on pure water and on the 4.4 M NaCl solution, which amounts to about 0.1 nm². The monolayer of the 2C18NC18S salt on pure water at 298.2 K exhibits a direct transition to condensed film and has no break point on the π-A curve. On the other hand, the monolayer on the 4.4 M NaCl solution is somewhat more loosely packed in the condensed state (C-I) than that on pure water and has a break point due to the transition from the condensed phase I to II at 298.2 K. The values of somewhat

expanded limiting area for the condensed phase I and the occurrence of the phase transition from the condensed phase I to II are attributable to the substrate of concentrated NaCl solution.

The film compressibilities of (2-1) long-chain salts are also useful for a discussion of the molecular interaction in the film. Compressibility is taken as $C_s=-1/A(\mathrm{d}A/\mathrm{d}\pi)\fallingdotseq(a_0-a_1)/a_0\pi_1$, where a_1 is the area at a certain surface pressure π_1, and a_0 is the area extrapolated to zero pressure. A suitable surface pressure was chosen 49 mN m^{-1} because above this surface pressure all the films are the state of the condensed phase II, as is clear from the π-A curves of Figs. 3 to 5. For the salts 2CnNCnS, the values of the compressibility decrease with increasing the chain length (n) of (2-1) long-chain salts (Table 3) and approach to that of octadecanoic acid. On the other hand, the condensed monolayer (C-II) of C18NC18S has twice the compressibility of the condensed films (C-II) of 2C18NC18S, and presents approximately similar compressibility to the 2C16NC16S monolayers (C-II), as seen in Table 3. This indicates that the cohesive interaction between the long chains increases with the number of alkyl chains, while decreasing with shortening of alkyl chain.

Table 3. Compressibilities of (2-1) Long-Chain Salts and (1-1) Long-Chain Salts in the Condensed Film at 298.2 K (on 4.4 M NaCl)

Chain length (n) of salts	Compressibility/m mN^{-1} [a]	
	CnNCnS	2CnNCnS
n=12	—	—
n=14	—	0.0056
n=16	—	0.0047
n=18	0.0039	0.0020

a) Octadecanoic acid, 0.0015 (m mN^{-1}); Dipalmitoyl phosphatidylcholine, 0.0064 (m mN^{-1}) at 298.2 K. Compressibility is taken as $(a_0-a_1)/a_0\pi_1$, where a_1 is the area at π_1=49 mN m^{-1}, and a_0 is the area extrapolated to zero pressure.

The studies of the temperature effect on the transition pressure are of much interest, since they provide us with thermodynamic information about the state of monolayers. Figures 3—5 show, the π-A isotherms of 2C14NC14S, 2C16NC16S, and 2C18NC18S at various temperatures, which have two break points. As for 2C16NC16S salt in particular, three break points are observed on the π-A isotherm. As was expected, the transitions pressures increased with an increase in the temperature.

In Fig. 6 are illustrated the three types of phase diagrams from the transition pressure (π^{eq}) and temperature for 2CnNCnS salts, where the slope of the π^{eq} against temperature is a key point to assign the phases.

The thermodynamic quantities on the phase transition of monolayers were calculated by the same method as described in our previous study.[17-20,22,23] The apparent molar entropy change (Δs^r) on the phase transition were evaluated by employing Eq. 29 of Ref. 22.

The apparent molar entropy changes on the various types of phase transition are given in Table 4 for (2-1) long-chain salts. As seen from in Table 4, the first

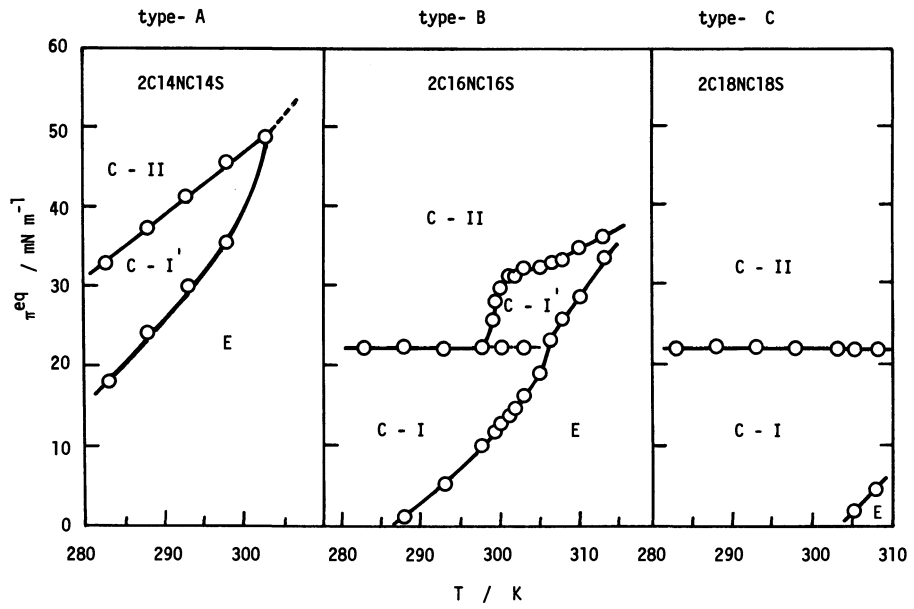

Fig. 6. The transition pressure (π^{eq}) as a function of the temperaure, and the transition pressure-temperature diagrams for the monolayers of 2C14NC14S, 2C16NC16S, and 2C18NC18S salts on the 4.4 M NaCl solution.

Table 4. The Apparent Molar Entropy Changes on the Phase Transition of (2-1) Long-Chain Salts at Various Temperature (on 4.4 M NaCl)

	Entropy change ($-10^{-2}\Delta s^{\gamma}$/J K^{-1} mol^{-1})					
	2C14NC14S	2C16NC16S			2C18NC18S	
Temp/K / Transition	298.2	298.2	303.2	308.2	298.2	305.4
E →C-I	—	2.9	5.0	—	—	9.6
E →C-I′	1.2	—	—	3.4	—	—
C-I →C-II	—	0.14	—	—	0.07	0.16
C-I →C-I′	—	—	0.2	—	—	—
C-I′→C-II	0.3	—	0.5	0.68	—	—

transition includes two kinds of transitions; one from the expanded phase (E) to the condensed phase I (C-I) and the other from the expanded phase (E) to the condensed phase I′ (C-I′). The values of the apparent molar entropy change of 2C16NC16S salt increases with the temperature. Normally, the value of the apparent molar entropy change increases with an increase in the temperature. The smaller value at 308.2 K than that at 303.2 K reflects the difference in type of the phase transition between the E→C-I and the E→C-I′. The phase transition for the 2C14NC14S salt at 298.2 K can be classified as the transition from the expanded phase (E) to the condensed phase I′ (C-I′) by the aid of the phase diagram (Fig. 6), and the slope of π^{eq} vs. T curves. The longer the chain length of the salt, the larger the apparent molar entropy on the transition from their expanded to their condensed states.

The apparent molar entropy changes on the other types of the phase transition are also given in Table 4. The second transition includes three kinds of transitions; C-I→C-II, C-I→C-I′, and C-I′→C-II. The apparent molar entropy change on the second phase transition decreased in magnitude by one order, compared with the apparent molar entropy change on the first phase transition (E→C-I, and E→C-I′). The column of 2C16NC16S salt at 303.2 K includes three numerical values. Especially in this case, the assignment of the type of phase transition is difficult only by the aid of the apparent molar entropy change. The values of the apparent molar entropy changes are too small to compare with those of other phase transitions. So, the phase transition for 2C16NC16S at 303.2 K was classified judging from the slope of π^{eq} vs. T curves in Fig. 6. The classification of the phase transitions on other salts were also done by the same method. The 2C18NC18S salt also has the transition from C-I to C-II on the π-A curve at 298.2 K. The longer the chain length of (2-1) long-chain salts, the smaller the apparent molar entropy change on the phase transition from C-I to C-II. The larger entropy change on the first transition (i.e.; E→C-I, and E→C-I′) suggests the considerable change of the molecular orientation in the monolayers, whereas the small entropy change on the second transition (i.e.; C-I→C-II, C-I→C-I′, and C-I′→C-II) suggests the slight change in the monolayer configuration. As a result, five types of classifications are possible for the phase transitions on the monolayers of (2-1) long-chain salts (2CnNCnS).

The monolayers of (2-1) long-chain salts turned out to have two or three transition points on their π-A curves. Figure 6 shows the phase diagrams of the monolayers of 2C14NC14S (type-A), 2C16NC16S (type-B) and 2C18NC18 (type-C) as expmples. Judging from the slope of the π^{eq} vs. T curve of the type B in Fig. 6, it is possible to distinguish between the phases of C-I and C-I′. But, there remains some question that the C-I and the C-I′ phases are distinguishable from the phase diagram of the types A and C in Fig. 6. This distinction may be made clearer by other techniques such as surface potential measurement and ellipsometric measurement. It is noteworthy that two triple points exist on the phase diagram of type-B and that three phase transitions, E→C-I, C-I→C-I′, and C-I′→C-II are possible depending on a particular temperature range. At higher temperature, the phase transition of E→C-II will be observed, which is a conventional phase transition in monolayer research. There are some studies on the polymorphism in monolayers of docosanoic acid and 1-octadecanol.[24,25] As for these compounds, the condensed phase I has not appeared on the 0.1 M NaCl solution or water, but it appears on the 4.4 M NaCl solution. Especially, in this (2-1) long-chain salt, another condensed phase I′ (C-I′) appears. The C-I′ phase is the intermediate phase between the C-I and C-II phases. In the condensed phase II, the (2-1) long-chain salts are probably aligned perpendicular to the water surface judging from the limiting area. From the small entropy change from the condensed phase I to II (Table 4), the hydrocarbon tail interaction in the condensed phase I might be similar to that in the condensed phase II. However, the limiting areas for the condensed phase I are considerably larger than those for the condensed phase II as shown in Table 2.

For the condensed phases I and I′, therefore, the elongated distance can be imagined between the ionic head groups, because Na^+ and Cl^- ions are probably incorporated into the two-dimensional ionic crystal structure, causing the pronounced cohesive interaction between the long chains. This model may be clarified by data from other techniques such as surface potential measurement and ellipsometric measurement, which will be reported in a separate paper.

In conclusion, the monolayer of a (2-1) long-chain salts on the concentrated NaCl solution was found to have two triple points in the phase diagram. From the phase transitions, the phase diagrams can be classified into three types: type-A is of two phase transitions, expanded phase (E) → the condensed phase II (C-II) via the condensed phase I′ (C-I′); type-B is of three phase transitions, namely the expanded phase (E) → the condensed phase I (C-I), the condensed phase I (C-I) → the condensed phase I′ (C-I′), and the condensed phase I′ → the condensed phase II (C-II); and type-C is two phase transitions, the expanded phase (E) → the condensed phase II (C-II) via the condensed phase I (C-I). New finding of this study is the appearance of the condensed phase I′ (C-I′) which wasn't present for the (1-1) long-chain salts.

One of authors (O. S.) wants to express his deep gratitude to Prof. Makoto Nakamura of College of General Education, Kyushu University and Dr. Akira Yamauchi of the Department of Chemistry, Kyushu University, for many valuable and most stimulating discussions during this work and would like to thank Dr. Yoshikiyo Moroi of the department of Chemistry, Kyushu University for help with preparation on this manuscript for publication.

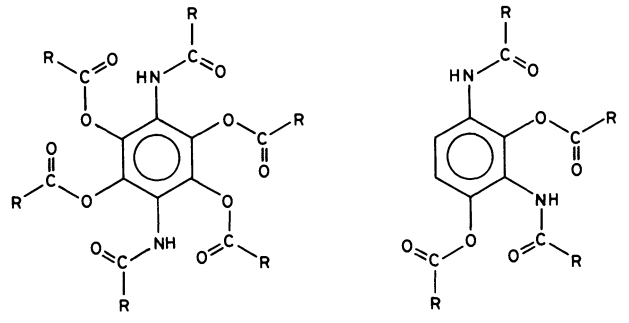
New Mesomorphic Compounds: *N,N'*-Dialkanoyl-2,4-bis(alkanoyloxy)-1,3-benzenediamines

Hiromitsu KAWADA and Yoshio MATSUNAGA*
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060
(Received March 31, 1988)

A series of *N,N'*-dialkanoyl-2,4-bis(alkanoyloxy)-1,3-benzenediamines has been synthesized. The high-temperature phases appearing in the heptanoyl to hexadecanoyl derivatives are viscous and are transformed into isotropic liquids with enthalpy changes of 20 kJ mol^{-1} or less. Their X-ray diffraction patterns are characteristic of the hexagonal disordered columnar phase. The second moment of the broad-line proton NMR spectrum measured in the mesophase region is 0.8 to 0.9 G^2 in the case of the octanoyl derivative and 0.04 G^2 in the case of the tetradecanoyl derivative, indicating the rather large difference in the motional behavior between these half-disk-shaped molecules.

As we reported earlier,[1] the mesomorphic behavior can be considerably enhanced by the replacement of the two $OCOC_nH_{2n+1}$ groups in the 1 and 4 positions of hexakis(alkanoyloxy)benzenes by $NHCOC_nH_{2n+1}$ groups; namely, the clearing point of discogenic *N,N'*-dialkanoyl-2,3,5,6-tetrakis(alkanoyloxy)-1,4-benzenediamine (**1**) is much higher than that of the corresponding hexakis(alkanoyloxy)benzene,[2,3] while the melting point of the former compound remains almost the same as that of the latter. These two compounds are composed of disk-like molecules in which the planar rigid core is densely surrounded by a planar ring of aliphatic chains. Although it is generally assumed that the distinctive feature common to all the mesomorphic compounds is the rod-like or disk-like shape of the molecule,[4-6] we have found that *N,N'*-dialkanoyl-2,4,6-trimethyl-1,3-benzenediamines are mesogenic.[7] These findings suggest that the presence of two $NHCOC_nH_{2n+1}$ groups per molecule is favorable to form stable mesophases and also that the molecule is not required to be rod-like or disk-like in order to form a mesophase. What is indispensable to the formation of mesophase is apparently the presence of a molecular core which keeps the molecules aligned up to relatively high temperatures and that of long flexible alkyl chains conformationally disordered at lower temperatures. Consequently, it seemed to us highly probable that *N,N'*-dialkanoyl-2,4-bis(alkanoyloxy)-1,3-benzenediamine (**2**), even though the molecule of which is half-disk-shaped, can produce some kind of mesophase.



1 R=C_nH_{2n+1} **2**

Experimental

Materials. 2,4-Dinitrosoresorcinol was prepared following the method described by Fitz,[8] but the addition of sodium nitrite at lower temperatures, −2 to −4 °C, was found to be recommendable. The wet product was added in small portions to tin(II) chloride dissolved in concentrated hydrochloric acid avoiding excessive raising of the temperature by the heat of the reaction. The warm solution was filtered and the amine was precipitated by the addition of concentrated hydrochloric acid. The acylation was carried out at room temperature by adding acyl chloride drop by drop to a pyridine solution of the diamine. The desired compounds were recrystallized from acetone or mixtures of benzene and diethyl ether. Found: C, 73.03; H, 10.65; N, 3.71%. Calcd for $C_6H_2(NHCOC_9H_{19})_2(OCOC_9H_{19})_2$: C, 72.97; H, 10.65; N, 3.70%. Found: C, 75.82; H, 11.49; N, 2.86%. Calcd for $C_6H_2(NHCOC_{13}H_{27})_2(OCOC_{13}H_{27})_2$: C, 75.87; H, 11.50; N, 2.85%.

Measurements. Calorimetric, X-ray, and NMR measurements were made mostly as described in our previous papers.[1,7] As the endothermic peaks due to melting and clearing are closely located in some derivatives, a rather slow rate of heating, 150 K h^{-1}, was employed throughout the present work in order to improve the separation between the peaks.

Results and Discussion

The thermal properties of the eight derivatives carrying heptanoyl to hexadecanoyl groups are summarized in Table 1. Here, crystalline, discotic, and isotropic phases are denoted by K, D, and I respectively. No solid-solid transition is found above room temperature for any homologous member. It may be noted that the temperature range of the mesophase is narrowed as the series is ascended. The mesophase appears over 35 °C range in the case of the heptanoyl and octanoyl derivatives but only over 11 °C in the case of the hexadecanoyl derivative. Compared with the corresponding homologous member in the series **1**, the present compounds melt at higher temperatures and are transformed into isotropic liquids at much lower temperatures. While the enthalpy change at the clearing point (D–I transition temperature) is in a narrow range

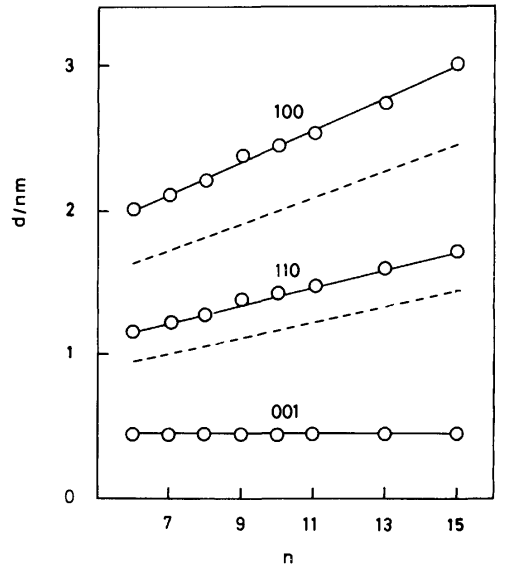

Fig. 1. Plots of spacings measured in the mesophases against the number of carbon atoms in the alkyl group for compounds **2**. Broken lines indicate the corresponding spacings of compounds **1**.

from 13 to 19 kJ mol^{-1}, that at the melting point (K-D transition temperature) increases rapidly with the increase of the alkyl chain length, from 9 to 60 kJ mol^{-1}. The entropy change at the clearing point is 83 J mol^{-1} K^{-1} for the heptanoyl derivative of the series **1** and 48 J mol^{-1} K^{-1} for the corresponding member of the series **2**. The value becomes smaller as both the series are ascended and 39 and 41 J mol^{-1} K^{-1} are obtained for the hexadecanoyl derivatives of the series **1** and **2** respectively. Thus, the entropy change in the present series is less dependent on the alkyl chain length than that in the hexasubstituted benzene series.

The isotropic liquid of all the derivatives may be supercooled as much as 20 °C. The mesophase of the heptanoyl to undecanoyl derivatives can be cooled to room temperature. No crystallization was observed even when the specimen was annealed at 5 °C below the melting point for four hours. On the other hand, three exothermic peaks are detected in the process of cooling for the dodecanoyl to hexadecanoyl derivatives. These metastable solid phases are easily transformed into the stable ones.

The X-ray diffraction pattern of the mesophase is essentially of the hexagonal disordered columnar structure; that is, there are two sharp inner peaks giving spacings in the ratio of $1:1/\sqrt{3}$ and one broad peak giving a spacing of 0.46 nm throughout the series. They may be assigned to 100, 110, and 001 reflections respectively. The innermost peak is accompanied in most cases by a weak peak assignable to the second order reflection. In addition, two weak extra peaks are detectable in the patterns given by the dodecanoyl derivative and the lower homologous members in the region between the sharp peaks and the broad one, indicating the appearance of some regularity in the molecular arrangement. The spacings d_{100} and d_{110} increase linearly with the alkyl chain length as shown in Fig. 1. For example, the heptanoyl derivative gives a d_{100} of 1.99 nm and the hexadecanoyl derivative 2.98 nm. They are much longer than those of the corresponding members in the series **1** represented by broken lines in the same figure. This suggests that the alkyl chains in compounds **2** are more extended and/or less interdigitated. In the mesophases formed by disk-like molecules, rotation of the whole molecule about the normal to the molecular plane and fluctuations of this axis around the preferred aromatic director are conceivable.[9] In order to achieve the hexagonal symmetry, the present half-disk-shaped molecule must be effectively disk-like in the mesophase. In other words, the molecules in a column must be oriented in various directions and rotating more freely than disk-like molecules do. Therefore, the interlocking of the alkyl chains must be less pronounced than that in the mesophase of compounds **1**. The supercooling of the mesophases of the heptanoyl to undecanoyl derivatives was confirmed by the X-ray measurements. The diffraction pattern recorded at room temperature for the once melted specimen is the same as that recorded in the temperature range of the stable existence.

The longest spacing in the crystalline phase is longer than that in the mesophase, d_{100} and changes linearly with the number of carbon atoms in the alkyl group; namely, 2.20 nm in the heptanoyl derivative and 4.70 nm in the hexadecanoyl derivative. The shrinkage at the melting point is only 0.21 nm in the former derivative and as much as 1.72 nm in the latter. This behavior is consistent with the remarkable increase in the enthalpy change as the series is ascended. The hexanoyl derivative is expected not to be mesomorphic because the shrinkage estimated by the linear relationship is nearly zero.

The liquid-like characteristics of alkyl chains in the mesophase are demonstrated by the small second moments of the broad-line proton NMR spectrum (the

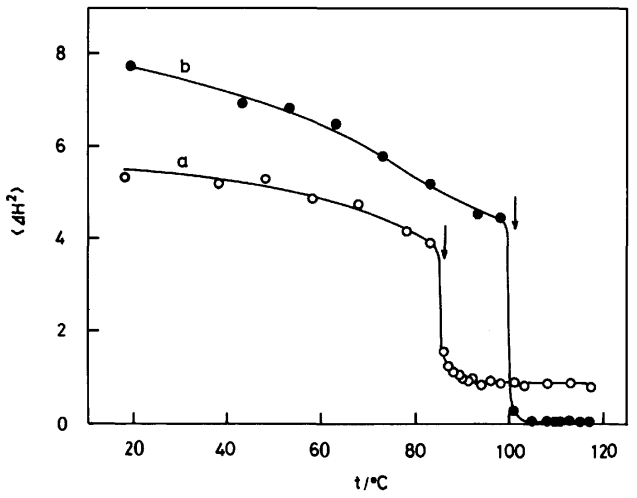

Fig. 2. Second moments of the broad-line proton NMR spectrum of compounds **2**, (a) n=7 and (b) n=13. The vertical arrows indicate the melting points determined by calorimetry.

mean-square width of the resonance line), $<\Delta H^2>$, measured above the melting point. As is shown in Fig. 2, the moment given by the octanoyl derivative is about 5.5 G^2 (1 G=10^{-4} T) at room temperature and about 4 G^2 just below the melting point which is indicated by a vertical arrow. An abrupt decrease of the moment occurs at the melting point and moments between 0.9 and 0.8 G^2 are shown by the mesophase. On the other hand, the tetradecanoyl derivative gives a moment of about 7.8 G^2 at room temperature and that of about 4.5 G^2 near the melting point. The moment observed above this temperature is only 0.04 G^2. Thus, the motional behavior in the hexagonal disordered columnar phase depends appreciably on the alkyl chain length. The similar but less pronounced tendency has been noted with compounds **1**; namely, the second moment observed for the mesophase of the octanoyl derivative was 0.3 G^2 and that of the hexadecanoyl derivative 0.03 G^2.[1] Judging from these values of the second moment, one may conclude that the alkyl chains in the lower homologous members are moving more slowly, in the time scale of NMR, than those in the higher members in both the series **1** and **2**. This conclusion is not incompatible with the entropy changes at the clearing point mentioned above.

According to the rule of selected miscibility of Sackmann and Demus,[10] an uninterrupted series of binary mixtures should be obtainable if the mesophases are of the same structural type. However, Dabrowski et al., employing a homologous series as one of the components, have shown that the smectic A phase in binary mixtures is more and more depressed and, in some extreme cases, separated by a gap as the layer spacing ratio is increased.[11,12] The mesophases given by the tetradecanoyl derivatives of series **1** and **2** were found not to be completely miscible by the contact method.[13] The d_{100} ratio of these two compounds is approximately 1.2. We also examined the combination of the hexadecanoyl derivative of series **1** and the decanoyl derivative of the series **2**. These two give the spacings similar to each other (see Fig. 1). In this combination too, the mesophases are not miscible. The results are apparently in contradiction to the above-mentioned rule and may be ascribed to the distinct difference in the shape of the molecules involved, disk-like and half-disk-like. We have examined the miscibility between the members in the present series. The mesophase of the tetradecanoyl derivative was found to be miscible in any ratio with those of the hexadecanoyl and dodecanoyl derivatives but not with those of undecanoyl derivative and the lower homologous members. The complete miscibility among the lower members is more severely restricted; that is, only the nearest neighboring members are miscible with each other. It may be too early to be certain of the situation, but these observations may imply that the similarity in the motional behavior is also of importance to provide complete miscibility.

The Brillouin Scattering of Highly Viscous Liquids-Triacetin and Propylene Glycol Diacetate

Ryuki HASHITANI, Hirohito MATSUI, Shinobu KODA, and Hiroyasu NOMURA*
Department of Chemical Engineering, School of Engineering, Nagoya University, Chikusa-ku, Nagoya-shi 464
(Received April 9, 1988)

The sound velocities of triacetin and propylene glycol diacetate were measured by means of Brillouin scattering in the temperature range from 200 to 350 K. The velocity dispersions due to the structural relaxation were observed in the gigahertz region. The relaxation behaviors could not be interpreted by the empirical equation proposed by Barlow et al., which holds in megahertz region and also the relaxation curves were located in higher frequency region than those predicted by the Maxwell model. The relaxation curves were well reproduced by single relaxation equation. In the temperature ranges of relaxation region, the temperature dependences of viscosity were expressed by Arrhenius' viscosity equation. The relaxation behaviors can be interpreted in terms of the weak cooperative motions of molecules.

Dynamic properties of liquids have been intuitively understood through observation of the viscous flow of liquids in an ordinary time scale. However, liquids behave as elastic media in a very short time scale, and so a definite time is needed for liquids to flow. The relaxation process is closely related to the collective translational motions and can occur in any liquids. The relaxation is called as viscoelastic and/or structural relaxation. In this sense, the relaxation process should reflect the dynamic nature of the local structure of liquid. In order to observe the relaxation process experimentally, one needs to measure the time- and frequency-dependences of viscosity and/or elastic modulus. The relaxation time in low-viscosity liquids is too short to measure by any experimental techniques available for us now. In this work we used highly viscous liquids or supercooled liquids as samples, because their relaxation times fall on the measurable frequency ranges.

The Brillouin scattering provides the sound velocity and the absorption coefficient of sound wave in the gigahertz region. In our previous papers, the structural relaxations of highly viscous liquids have been investigated by means of Brillouin scattering.[1-3] The relaxation behaviors in the GHz region have been discussed using the reduced variable method proposed by Lamb's school[4] which held very well in the MHz region and we pointed out that the distribution of relaxation times in GHz region was different from those in the MHz region, that is, Maxwellian relaxation curve reproduced our experimental results satisfactorily in the GHz region.

In this paper, the experimental results for two highly viscous liquids, triacetin (hereafter abbreviated as TAT) and propylene glycol diacetate (PGA), will be reported. Comparing with tri-*o*-tolyl phosphate (TOTP) and diisobutyl phthalate (DIBP) investigated before,[1-3] the molar volumes of TAT and PGA are small. In addition, the viscosity of PGA is much lower than that of TAT. The relaxation of PGA will appear in lower temperature region than those of TAT and the others.

Experimental

Samples. Triacetin(TAT), guaranteed grade, and propylene glycol diacetate (PGA), extra grade, were purchased from Kishida Chemical Co., Ltd. and Tokyo Chemical Industry Co., Ltd., respectively. They were purified by distillation under reduced pressure and were poured into scattering cells through a millipore filter with pore size of 0.2 μm.

Measurements. Rayleigh-Brillouin scattering spectra were observed by a pressure-scanning Fabry-Perot interferometer, using a He-Ne laser (NEC, GLG 5800, output 50 mW) as the light source. The detailes of experimental procedures were reported previously.[5] The range of scattering angle used was from 50° to 150°.

Refractive indexes were measured by an Abbe refractometer in the temperature range between 273 to 323 K. The values in the low temperature region were estimated by fitting the high temperature data to the Lorentz-Lorenz equation. The sound velocities at 5 MHz were measured by an ultrasonic interferometer in the temperature ranges from 268 to 318 K for TAT and from 248 to 318 K for PGA. The density and shear viscosity measurements were carried out by a buoyancy balance densitometer and rotational viscometer, respectively. These measurements were made in the temperature range from about 245 to 320 K for TAT and from 220 to 270 K for PGA.

Results

The sound velocity can be calculated from the Brillouin shift, Δf, which is the difference in the peak frequency between Rayleigh and Brillouin lines and is equal to the frequency of the sound wave, by following relation;

$$V=\frac{\lambda_i \Delta f}{2 n \sin(\theta/2)} \quad (1)$$

where λ_i is the wavelength of the incident light beam (632.8 nm). n is the refractive index of the sample, and θ is the scattering angle. The frequency dependences of sound velocity are shown in Fig. 1. The velocity dispersions are observed in the GHz region at 278, 298,

and 313 K for TAT. In the case of PGA, the sound velocity dispersions appear in the lower temperature region than for TAT. Figures 2 and 3 show the temperature dependence of sound velocity for the TAT and PGA, respectively. The temperature dependence for TAT changes around at 250 K and for PGA around at 220 K. Besides, the velocities of TAT at 253 K and those of PGA at 218 K are independent of the frequency, as shown in Fig. 1. Therefore, the velocities of TAT below ca. 250 K and those of PGA below ca. 220 K may be considered to be the high-frequency limiting values. It has been assumed in our previous paper that the high-frequency limiting velocity, V_∞, has the following temperature dependence:

$$V_\infty = \frac{a}{T} + b \qquad (2)$$

where T is the absolute temperature and a and b are fitting parameters; a=4.80×10^5 m·s^{-1}·K, b=57 m·s^{-1} for the TAT and a=3.97×10^5 m·s^{-1}·K, b=61 m·s^{-1} for the PGA, respectively.

As is seen in Figs. 2 and 3, the relaxation strength, $\varepsilon=(V_\infty^2-V_0^2)/V_\infty^2$, decreases with increasing temperature in the temperature ranges where the sound velocity dispersions were observed (ε=0.34 (273 K)—0.31 (313 K) for TAT and ε=0.24 (233 K)—0.18 (253 K) for PGA). If the sound dispersions were due to the vibrational relaxation, the temperature dependence of the relaxation strength, ε, should increase with increasing temperature. Therefore, the sound velocity

dispersions we observed here may be due to structural relaxation, and not to vibrational one.

Discussion

The storage modulus, M', which is the real part of complex longitudinal modulus, M^*, can be calculated from $M'=\rho V^2$ under the assumption of $(\alpha V/\omega)^2 \ll 1$, where α is the absorption coefficient and $\omega=2\pi\Delta f$. In the reduced variable method proposed by Lamb, reduced modulus, $(M'-M_0)/M_2$, is plotted against reduced frequency, $\omega\eta_s/G_\infty$, where $M_2=M_\infty-M_0=\rho V_\infty^2-\rho V_0^2$, η_s is the shear viscosity, and G_∞ is the high-frequency limit of shear modulus. We have no experimental data for G_∞ of TAT and PGA. For this reason, we adopt $\omega\eta_s/M_2$ instead of $\omega\eta_s/G_\infty$. If G_∞/M_2 is assumed to be independent of temperature, as usually done,[4] the plots of reduced modulus against $\omega\eta_s/G_\infty$ and $\omega\eta_s/M_2$ become the same, although plots as a whole are shifted by an amount of $\log(G_\infty/M_2)$ along the abscissa. Figures 4 and 5 show the reduced plots of M' for TAT and PGA, respectively.

Assuming the B.E.L. (Barlow-Erginsav-Lamb) equation[4] for both complex shear and bulk moduli, one can obtain the following expression for M^*;

$$\frac{M^*-M_0}{M_2}=C\left[1+\frac{1}{i\zeta\omega\tau_s}+2K\left(\frac{1}{i\zeta\omega\tau_s}\right)^{1/2}\right]^{-1}+(1-C)\left[1+\frac{1}{i\omega\tau_s}+2K\left(\frac{1}{i\omega\tau_s}\right)^{1/2}\right]^{-1} \quad (3)$$

and

$$C=\frac{K_\infty-K_0}{M_\infty-M_0}=1-\frac{4}{3}\frac{G_\infty}{M_\infty-M_0},\quad \tau_s=\frac{\eta_s}{G_\infty}$$

$$\zeta=\frac{\tau_v}{\tau_s}=\frac{\eta_v}{\eta_s}\frac{G_\infty}{K_\infty-K_0}=\frac{3}{4}\frac{\eta_v}{\eta_s}\frac{1-C}{C}$$

where η_v is the bulk viscosity and K is an empirical parameter concerned with the distribution of the relaxation times. The values of K given by means of ultrasonic method were reported to be unity for highly viscous pure liquids. On the other hand, Eq. 3 with $K=0$ corresponds to the Maxwellian model. The solid and broken curves in Figs. 4 and 5 are those calculated from Eq. 3 by putting respectively $K=0$ and $K=1.0$, into the equation and taking account of the shift along the abscissa by $\log(G_\infty/M_2)$ as mentioned above. It has been reported that the value of C lies between 0.35 and 0.5 and that of η_v/η_s, does between 1 and 3.[2,4,6] The differences in C and η_v/η_s in the ranges mentioned above do not affect the relaxation curve largely. We used $C=0.5$ and $\eta_v/\eta_s=3$, in drawing the lines in Figs. 4 and 5.

As is clear in Figs. 4 and 5, the relaxation curves of TAT and PGA obtained from Brillouin scattering are quite different from those calculated from Eq. 3 with $K=1$ (broken lines). At first sight, it may seem that data at the different temperatures are well superimposed on a single curve for each case of TAT and PGA. However, the composed relaxation curves are similar to that calculated by Eq. 3 with $K=0$ (solid curve) and the positions of composed curves in all cases investigated here deviate clearly from the solid curves toward the higher frequency side. The positions and the shapes of curves obtained from Eq. 3 with $K=0$ depend on the choice of the values of C and η_v/η_s. For example in the case of TAT, if we use the values of $C=0.6$ and $\eta_v/\eta_s=0.32$, we can reproduce the composed curve. However, $\eta_v/\eta_s=0.32$ is too small in comparison with the values reported ($\eta_v/\eta_s=1$—3) in literature.[2,4,6] In the case of PGA, the deviation can not be fully interpreted by the variation of C and η_v/η_s. This result indicates that the reduced variable method does not hold well in such wide frequency ranges as covering from MHz to GHz region and that the relaxation

●: 278 K, ○: 298 K, ⊖: 313 K.

behavior depends explicitly on the temperature in addition to the implicit temperature dependence involved in the reduced frequency. Thus it may be considered that the results obtained from Brillouin scattering reflect the high-temperature behavior, while those from ultrasonic method do the low-temperature one.

The shapes of relaxation curves obtained from Brillouin scattering are close to the Maxwellian model. If the reduced elastic modulus, $(M'-M_0)/M_2$, in the GHz region could be expressed by the following single (Maxwellian) relaxation equation:

$$\frac{M'-M_0}{M_2}=\frac{\omega^2\tau_M^2}{1+\omega^2\tau_M^2} \tag{4}$$

where τ_M is the relaxation time, the plot of $\{(M'-M_0)/M_2\}^{-1}$ against $1/\omega^2$ should be linear and its slope should be the square of the reciprocal relaxation time, $1/\tau_M$. As an example, Fig. 6 shows this relationship between $\{(M'-M_0)/M_2\}^{-1}$ and $1/\omega^2$ for the case of TAT at each temperature. As may be seen in Fig. 6, linear relationships are obtained within the limits of experimental error. Similar linear relationships are also obtained for the case of PGA at each temperature. If we use the relaxation times thus obtained, the reduced elastic moduli, $(M'-M_0)/M_2$, in the GHz region can be well expressed by a single relaxation equation (Eq. 4) within the frequency and temperature ranges investigated. This is shown in Fig. 7. The relaxation times of TAT obtained are 52, 25, and 20 ps at 278, 298, and 313 K, respectively and for PGA, 57, 33, and 20 ps at 233, 243, and 253 K, respectively.

It has been reported in some papers that single relaxation behavior or similar ones with narrow distribution of relaxation times appear when the temperature dependence of viscosity follows Arrhenius' viscosity equation.[1-3,7-9] At low temperature, where

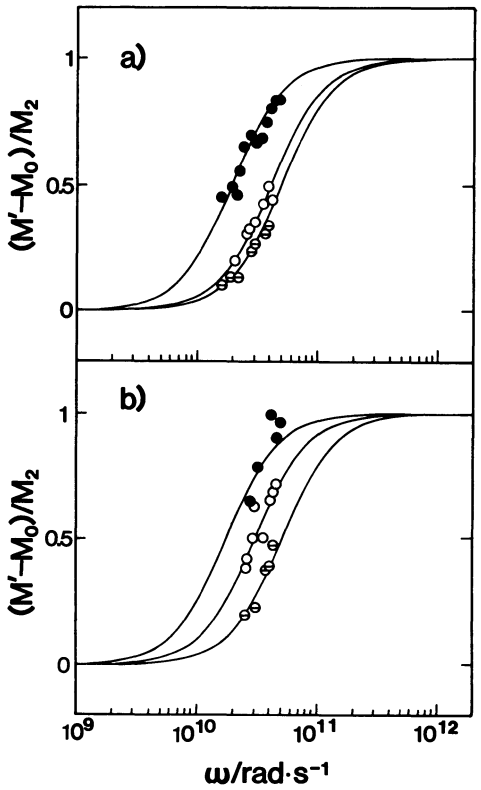

Fig. 7. Plots of $(M'-M_0)/M_2$ against angular frequency ω. a) TAT; ●: 278 K, ○: 298 K, ⊖: 313 K. b) PGA; ●: 233 K, ○: 243 K, ⊖: 253 K. Solid curves were drawn by single relaxation equation (Eq. 4).

relaxation behavior shows a broad distribution, the temperature dependence of viscosity can be understood in terms of the free volume theory. Litovitz and McDuffie suggest that if liquid viscosity obeys Arrhenius' equation, the cooperative character of molecular motions is weak in comparison with liquids which obey the free volume equation.[10] In the temperature region (278—313 K for TAT, and 233—253 for PGA). where the relaxation could be observed by the Brillouin scattering, the temperature dependence was close to the Arrhenius' equation, while in lower temperature, viscosity increased rapidly with decreasing temperature. Therefore, it is considered that the relaxation behavior investigated here is concerned with the weak cooperative motion of molecules, as well as in the cases of the samples we studied before.[1-3]

Topological Index and Thermodynamic Properties. IV.[3] Size Dependency of the Structure-Activity Correlation of Alkanes

Ying-duo GAO and Haruo HOSOYA*
Department of Chemistry, Ochanomizu University, Bunkyo-ku, Tokyo 112
(Received April 22, 1988)

Correlation coefficients between twelve thermodynamic properties (ΔS, ΔH_f, ΔG_f, bp, d, n_D, R_m, V_m, p_c, T_c, V_c, d_c) of 624 isomers of nonane through dodecane and five different topological indices (Z, p_3, w, p_2, A_3) were calculated, where the new index A_3 is proposed to be defined as the half sum of the off-diagonal elements of the cube of the adjacency matrix A. These properties can be classified into several types, according to the behavior of the two correlation coefficients, $\rho(Z)$ and $\rho(p_3)$, against the change of the size of molecules. ΔS and bp depend largely on Z, while d and n_D on p_3, irrespective of the size change of molecules. On the other hand, ΔH_f of smaller alkanes is largely dependent on Z, but for larger alkanes it turns out to be a p_3-dependent property. Various interesting behaviors of the structure-activity relationships including the "pentane effect" were observed and discussed.

There are two different standpoints in the study of structure-activity correlation for molecular properties, namely, application-oriented and theory-oriented, or in other words, practical and conceptual standpoints.[1,2] Choosing the latter road we showed, in paper III of this series,[3] that thermodynamic properties of the lower members ($N<9$) of alkanes can roughly be classified into a few types depending on their relative magnitudes of the correlation coefficients for the two different topological indices, Z and p_3. The former index Z[4] proposed by one of the present authors well reflect the dynamical topological features, such as rotational degree of freedom, while the latter index p_3,[5] Wiener's polarity number, represents the static topological factors governing the bulkiness of molecules. Boiling point and entropy are the typical quantities which depend largely on Z,[3,6] and density of liquid, refractive index, and some other properties form another type of thermodynamic properties whose topological characteristics are represented well by p_3.

However, it was observed in III that for several properties the correlation pattern fluctuates with the size of molecules. Do not these types of correlation of thermodynamic properties change all the way toward larger molecules? No systematic study for analyzing the size dependency of the structure-activity correlation patterns for alkanes has been reported. Further, correlations among the various topological indices for larger molecules have not yet been systematically analyzed. The purpose of the present paper is to study not only the behaviors of the thermodynamic properties of larger alkanes but also the size dependencies of these correlations and of the various topological indices of the corresponding graphs. The obtained results will be helpful both for further theoretical elucidation and quantitative prediction of the thermodynamic properties of molecular aggregates.

I. Definitions of Various Topological Indices

In this paper, only the topological indices of integer values will be considered. The Z index has been defined by one of the present authors.[4] Wiener's path number, (w), polarity number, (p_3),[5] and Gordon and Scantlebury's p_2[7] have been frequently introduced.[8-10] Besides them some new indices are introduced in this study. The quantity A_3 is the half sum of the cube of matrix A of a graph G. Namely,

$$A_3 = \sum_{i<j} (A^3)_{ij}.$$

The idea of Wiener's polarity number, p_3, can be extended to the definition of p_n as half the number of n in the off-diagonal elements of the distance matrix D of G.[11] However according to our experience, none of p_4, p_5, and p_6 was shown to be more effective than the above topological indices for analyzing the structure-activity relationship for alkanes. Thus in this paper, we will mainly deal with the five integral topological indices, Z, w, p_3, p_2, and A_3.

II. Thermodynamic Properties of Alkanes

In paper III of this series twenty-four different thermodynamic properties of lower members ($N<9$) of alkanes were classified into five types, A, B, C, W, and X, according to the relative magnitudes of the correlation coefficients for Z and p_3 parameters.[3] Namely, Type A properties, such as boiling point, are largely dependent on Z, whereas Type B (density of liquid etc.) and C (molar refraction etc.) properties have large positive and negative correlation with p_3, respectively. The correlation coefficients of Type W properties (critical temperature etc.) for both Z and p_3 are medium in value, and Type X properties such as melting point have really no correlation with either Z or p_3.

In this paper correlation coefficients of entropy (ΔS), heat of formation (ΔH_f), boiling point (bp),

liquid-state density (d), refractive index (n_D), molar refraction (R_m), molar volume (V_m), and free energy of formation (ΔG_f) with the above five indices for nonanes (35 isomers), decanes (75), undecanes (159), and dodecanes (355) were calculated. For critical pressure (p_c), critical temperature (T_c), critical volume (V_c), and critical density (d_c), analysis is not complete, because those data were available only up to decanes even in the up-dated version of the API Report.[12]

The data of the physical properties of isomers through nonane are almost all measured ones. For decane, the data of 42 isomers are the average of the independently calculated values obtained by Zwolinski,[13] Greenshields,[14] and Taylor, Pignocco, and Rossini.[15] By their methods, the calculated values of isomers are fairly in concordant with the measured ones, so that we think those calculated values are reliable. However, almost all the data of undecane and dodecane are calculated ones. Although we are doubtful about the reliability of those data, in order to analyze systematically, the correlation coefficients of twelve physical properties of the isomers of undecane and dodecane with the five indices are also calculated.

III. Liquid-State Density, Refractive Index and Related Properties

Correlation coefficients between each of the four properties (d, n_d, V_m, R_m) and various topological indices (Z, w, p_3, p_2, A_3) for the isomers of nonane, decane, undecane, and dodecane are given in Table 1.

Figure 1 shows the size dependency of the ρ values of d, n_D, V_m, and R_m. Although the majority of the data of undecane and dodecane are those calculated with a large set of structural parameters, the points of undecanes and dodecanes in Fig. 1 smoothly lie on the curves extended from the experimental ones for hexane through nonane. Thus we can conclude that there might be no large difference between the estimated and real values.

For these properties, correlation with Z and p_2 is too poor as compared with the case of smaller ($N<9$) alkanes. Actually liquid-state density and refractive

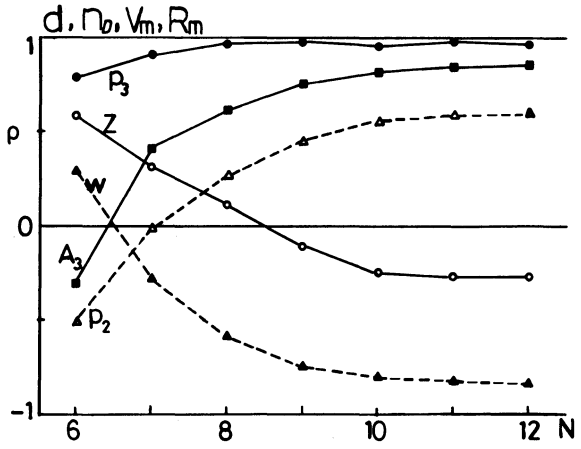

Fig. 1. The size dependency of the ρ values of d against the five topological indices for alkanes. The results for n_D, V_m, and R_m are identical to d.

Table 1. Correlation Coefficients between the Various Topological Indices and Several Thermodynamic Properties Depending Largely on p_3

Topological index	Property	C_9	C_{10}	C_{11}	C_{12}

	V_m	0.097	0.235	0.258	0.266
	R_m	0.069	0.165	0.209	0.236

d: liquid-state density (g ml^{-1}, 25 °C), n_D: refractive index (25 °C), V_m: molar volume (ml mol^{-1}, 25 °C), R_m: molar refraction (25 °C).

index were assigned to belong to B-type, while molar volume and molar refraction to C-type. All these properties have been known to be governed by the static topological features such as bulkiness of molecules.[3] Generally the absolute magnitudes of the $\rho(p_3)$ values for these properties increase quite similarly with the number of carbon atoms. It is surprizing to see that the absolute magnitudes of the linear correlation coefficients between p_3 and the four properties, d, n_D, V_m, and R_m, are all higher than 0.98 for the 355 isomers of dodecane. As seen in Fig. 1 for the size dependency of the $\rho(p_3)$ value for d, the Z index gradually loses its correlation with these Type properties with the increase of the molecular size. On the other hand, the ρ values for w and A_3 dramatically increase with the size of molecules but with opposite signs. The A_3 index was found to show remarkably good correlation with these properties when linearly combined with Z as aA_3+bZ, the ratio of b/a decreasing with the size of molecules. The results are listed in Table 2. It is interesting to see Fig. 2, where two randomly scattered correlation patterns of Z-p_3 and A_3-p_3 are seen to be merged into a fairly good linear plot when they are linearly combined with an appropriate ratio. If one carefully compares the $\rho(p_3)$ and the optimum $\rho(aA_3+bZ)$ values in Tables 1 and 2, no dramatic but fair improvement can be seen. So at this stage no merit is obtained by introducing the A_3 parameter for the QSAR analysis. However, as will be shown later the role of A_3 is highlighted for the correlation of A Type properties such as boiling point.

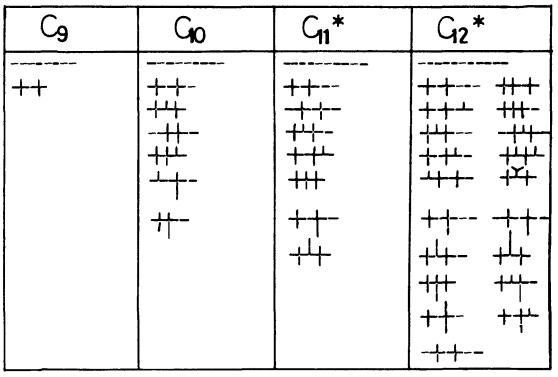
Table 2. Optimum Combinations of A_3 and Z Indices for Correlating the Four Topological Indices (A_3, w, p_2, Z)

Isomer	Property	Combination	ρ
C_9	d	A_3+0.39Z	*0.984*
	n_D	A_3+0.38Z	0.944
	V_m	A_3+0.38Z	*−0.983*
	R_m	A_3+0.38Z	−0.963
C_{10}	d	A_3+0.23Z	0.961
	n_D	A_3+0.22Z	*0.945*
	V_m	A_3+0.22Z	−0.958
	R_m	A_3+0.25Z	−0.897
C_{11}	d	A_3+0.15Z	*0.981*
	n_D	A_3+0.15Z	*0.964*
	V_m	A_3+0.15Z	*−0.981*
	R_m	A_3+0.16Z	−0.940
C_{12}	d	A_3+0.1Z	*0.983*
	n_D	A_3+0.1Z	*0.996*
	V_m	A_3+0.1Z	*−0.984*
	R_m	A_3+0.1Z	−0.967

The value in italic exceeds the corresponding correlation coefficients of p_3 parameter.

Now, let us take a closer look at the correlation between p_3 parameter and these four properties of B and C types. If we plot the values of d, n_D, V_m, and R_m of each group of isomers against p_3, most points are found to lie closely around a straight line, but a few points deviate from it, as exemplified in Figs. 3(a—d) for undecane isomers. For molar refraction the deviation is not obvious but can be detected from the correlation coefficients. The deviating points (the minority group) are represented with diamond marks.

Table 3. The Structures of Alkane Isomers (N=9—12) Deviating from the V_m-p_3 Plots. The Asterisks for Undecane and Dodecane Indicate that Except for Normal Alkanes the Data are Estimated Values



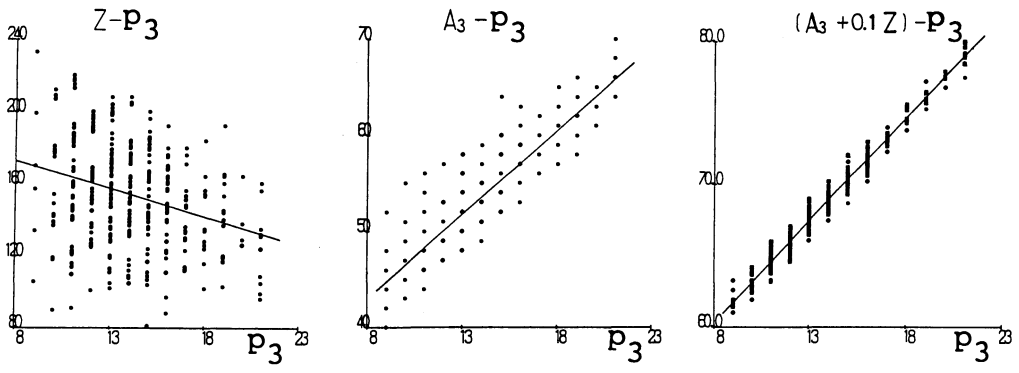


Fig. 2. The plots of Z—p_3, A_3—p_3, and (aA_3+bZ)—p_3, for dodecane isomers.

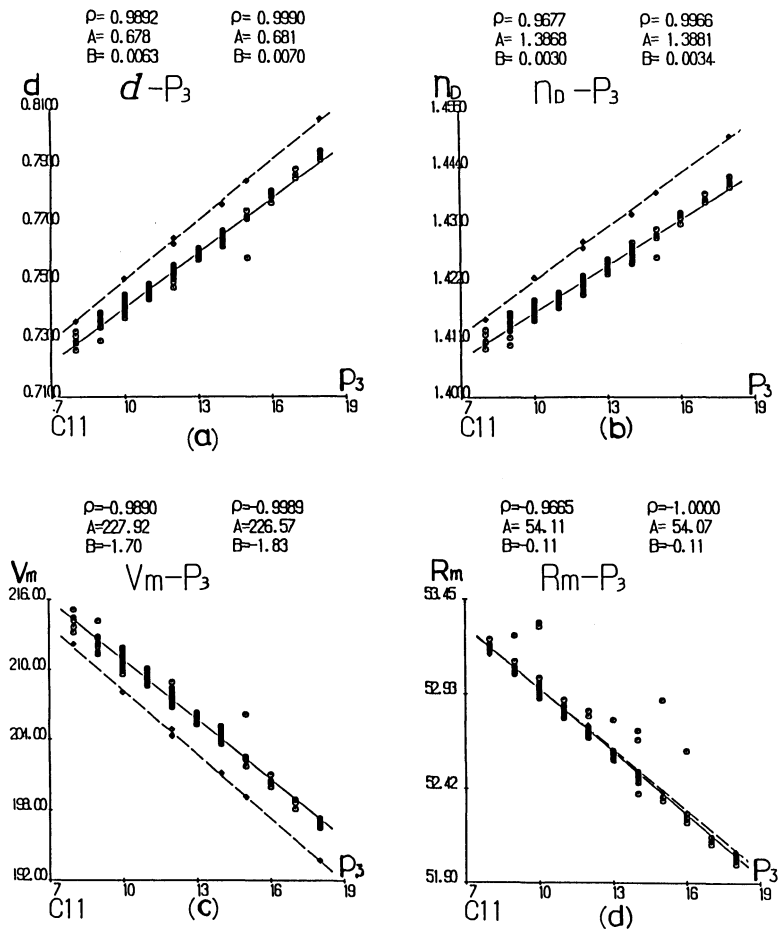

Fig. 3. The plots of d–p_3, n_D–p_3, V_m–p_3, and R_m–p_3 for undecane isomers. The ρ value and the coefficients A and B for $A+Bp_3$ corresponding to the majority and minority groups of undecane are, respectively, given in the top-left and right of each figrue.

The numerical results obtained from separate fittings are also given in the figures. For dodecane isomers quite a similar feature was found. We find that for these properties, except for R_m, all the deviating points correspond to a special group of compounds, whose structures are listed in Table 3.

It is remarkable that all the compounds but normal paraffins in Table 3 contain the common skeleton as ++. Further, among all the 624 alkanes studied, no compound other than those listed in Table 3 contains this skeleton. So we can safely assert that the ++ skeleton in alkanes works to decrease V_m, and increase d and n_D.†

IV. Pentane Effect

In general interactions between nonbonded pairs of alkane molecules in the liquid state are complicated enough to evade rigorous theoretical treatment. To simplify the question, we may consider only the dominant interactions. In calculating the conformational density of states of normal hydrocarbons, Terlin et al.,[16] proposed the so called "pentane effect". Namely, when four consecutive C–C bonds take the gauche–gauche conformation as those in cyclohexane, severe steric hindrance arises between the two methylene groups separated by four C–C bonds.

The measured volume of liquid compounds is interpreted to be composed of two factors. One is the volume which is really occupied by the component atoms, while the other is the spatial cavities, surrounded by either intra- or intermolecular group of atoms. The more efficient the molecules occupy the space, the smaller the cavities become. The skeleton of ++ is considered to decrease the V_m through the following two ways. First, a molecule with ++ skeleton generally tends to take a spherical shape compared to other isomers and is expected to expose

† In Table 3 those undecane and dodecane molecules are marked with asterisks whose thermodynamic properties are estimated. Even by omitting these data the present conclusion will not be changed.

lesser molecular surface than other molecules leading to smaller V_m value. Secondly, this is the most important, large steric hindrance within a molecule with a ++ skeleton causes the effective volume of the molecule to reduce considerably. As early as 1951, Platt[11] pointed out that steric hindrance reduces the effective volume of a molecule. Since under strong steric hindrance atoms are forced to get close to each other, the distance within nonbonding pair of atoms gets smaller than the van der Waals radii. Namely the so-called interpenetration occurs and the effective volume of a molecule is reduced.

Now, we can say without question that although the topological index p_3 is suitable for describing the "bulk" properties, such as liquid-state density molecular volume, and refractive index, etc., it fails in reflecting the effect of the ++ skeleton, or steric hindrance within a molecule.

The fact that normal paraffins belong to the minority group can be explained by the strong intermolecular interaction. Detailed discussion will be give in Section V.

We have attempted to get a single linear correlation for all the isomers. By assigning p_3+2 to the isomers with the ++ skeleton instead of p_3, all the isomers were found to lie on a straight line. The regression equations and correlation coefficients for d are obtained as follows:

For dodecane: $d = 0.68252 + 0.00600p_3'$
$\rho = 0.991$ (355 points)

For undecane: $d = 0.67790 + 0.00630p_3'$
$\rho = 0.990$ (159 points)

For decane : $d = 0.67754 + 0.00608p_3'$
$\rho = 0.973$ (75 points)

where

$$p_3' = \begin{cases} p_3+3 & \text{isomer which has ++ skeleton} \\ p_3 & \text{other} \end{cases}$$

All the correlations are of high quality including n_D and V_m, so that the p_3' index has a predictable power for these properties.

V. Entropy, Boiling Point, and Related Properties

The correlation coefficients between the topological indices and entropy (ΔS), boiling point (bp), heat of formation (ΔH_f), and free energy of formation (ΔG_f) of larger alkanes (N=9—12) are tabulated in Table 4. The size dependencies of these correlations are shown in Fig. 4(a—d).

For ΔS the $|\rho|$ values for Z, w, p_2, and A_3 do not change appreciably from hexanes to dodecanes. The discontinuous change at nonanes can be attributed to 3-methyl-4-ethylhexane, whose point deviates from the majority of their isomers. Although this molecule has no high symmetry, its entropy is extremely small compared with other isomers. So we deem that this data is erroneous. The recalculated ρ values by omitting this point are found to lie on more smoothed curves as marked with an asterisk in Fig. 4(a). Although the ρ value for p_3 gradually increases from hexane (0.1) to dodecane (0.7), one can safely conclude that entropy is governed by the dynamic feature of molecular topology and belongs essentially to A type.

For lower members of alkanes the correlation

Table 4. Correlation Coefficients between the Various Topological Indices and Several Thermodynamic Properties Depending Largely on Z

Topological index	Property	C_9	C_{10}	C_{11}	C_{12}

	ΔH_f	0.575	0.712	0.784	0.804
	ΔG_f	0.779	0.818	0.843	0.845

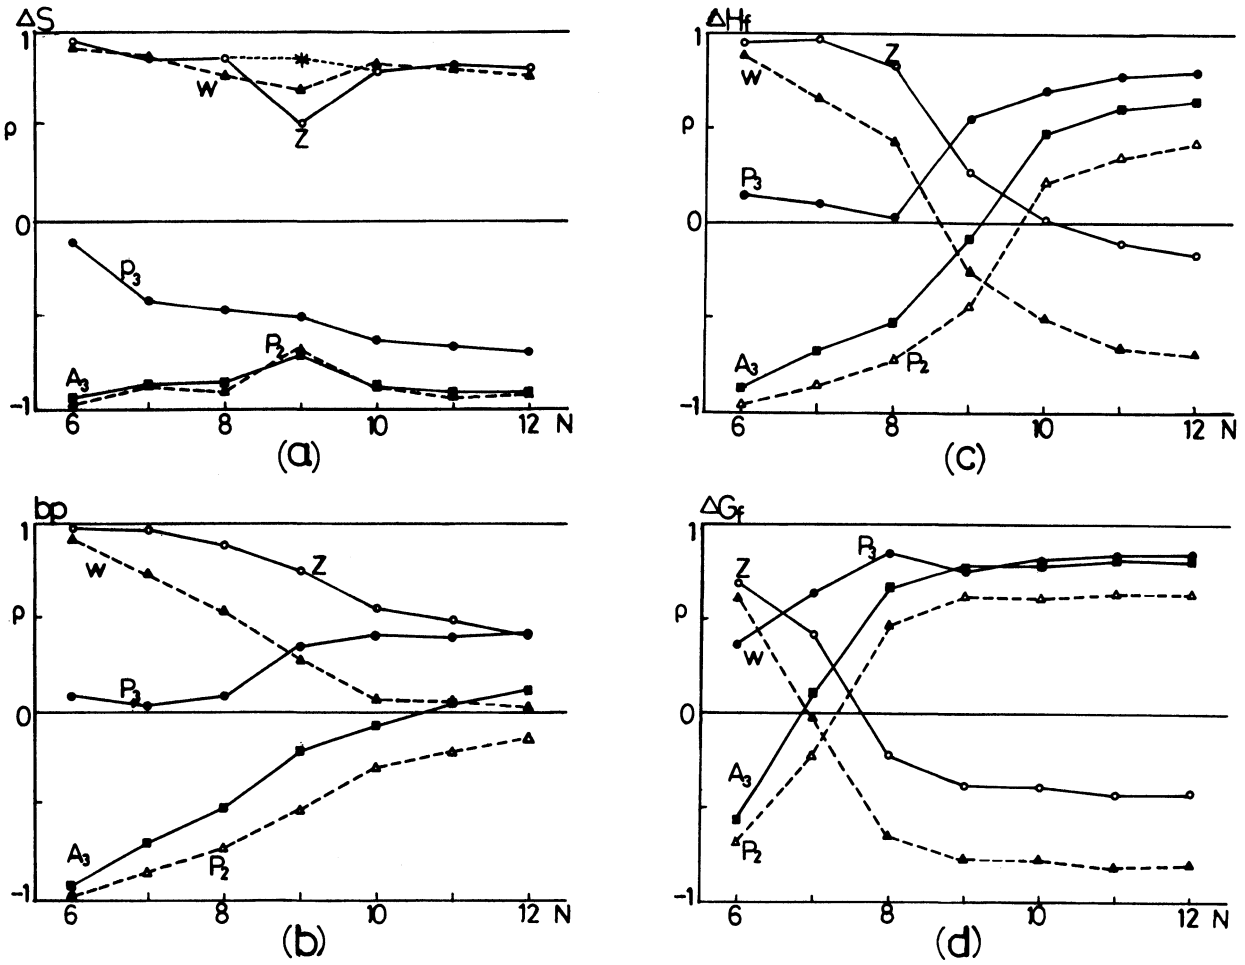

Fig. 4. The size dependency of the ρ values of ΔS, bp, ΔH_f, and ΔG_f against the five topological indices for alkanes. The asterisk for the Z curve in Fig. 4a was calculated by omitting one deviating point. The results for other topological indices are not shown.

pattern of boiling point, one of the typical A type properties, is very similar to that of entropy. However, as the size of molecules gets larger, the $|\rho|$ values of w and A_3 sharply drop down to zero while those of Z and p_2 slowly decrease. On the contrary $\rho(p_3)$ gradually increases but does not reach as high as 0.5. Thus boiling point of alkanes at least up to decane may well be classified into A-type. Although for dodecane isomers Z index still shows the largest $|\rho|$ value among all the indices studied, boiling point turns to belong to W-type, with medium $\rho(Z)$ and $\rho(p_3)$ values. It is to be noted that fairly large ρ value (>0.7) can be obtained by combining the Z and A_3 parameters as aA_3+bZ. (See Table 5 and Fig. 5). The ratio of b/a decreases with the size of molecules, whereas the $|\rho(A_3)|$ value decreases sharply down to zero.

Figure 5 shows that the deviant points correspond to the isomers with short branches. This is also the case with other properties, such as ΔS, ΔH_f, and ΔG_f. We have not found any appropriate topological index

Table 5. Optimum Combinations of A_3 and Z Indices for Boiling Point and Entropy, and Optimum Combination of p_3, p_4, p_5 for Heat and Free Energy of Formation

Isomer	Property	Combination	ρ
C_9	bp	$0.9A_3+Z$	0.886
	ΔS	$A_3+0.05Z$	−0.667
	ΔH_f	p_3+p_4	0.683
	ΔG_f	p_3-7p_5	0.958

to discriminate those short-branched isomers from others. If we can find such a topological index that can effectively characterize those kinds of molecules, all these problem will be solved.

Heat of formation, ΔH_f, for lower members of alkanes also belongs to A-type. The ρ values for the five parameters exhibit "cross-over" patterns as shown in Fig. 4(c). Namely ΔH_f changes its character into B-type above decane.

Free energy of formation, ΔG_f, of W-type, also shows a similar crossover pattern. (See Fig. 4(d)). However, the "transition point" to B-type for ΔG_f is lower than that of ΔH_f but is higher than that of the majority of B-Type properties shown in Fig. 1.

VI. Properties at the Critical Point

The correlation coefficients among the various topological indices for the four properties at the critical point, T_c, p_c, V_c and d_c, of nonane and decane isomers are presented in Table 6. However, data are not available for the higher members of alkanes.

In Fig. 6(a—d) are shown the size dependency of the ρ values of p_c, d_c, V_c, and T_c. Obviously w is the best for the description of d_c, V_c, whereas p_3 is the best for d_c and T_c. However, if they are to be classified, p_c belongs to B-type for all N and the remaining three properties change from W-type to B-type at around heptane and octane.

From the van der Waals equation of state, we get the

Table 6. Correlation Coefficients between the Various Topological Indices and Critical Constants

Topological index	Property	C_9	C_{10}
p_3	d_c	0.921	0.927
	V_c	−0.910	−0.922
	p_c	0.947	0.963
	T_c	0.850	0.848
A_3	d_c	0.871	0.859
	V_c	−0.870	−0.835
	p_c	0.912	0.904
	T_c	0.499	0.630
w	d_c	−0.931	−0.945
	V_c	0.938	0.933
	p_c	−0.881	−0.877
	T_c	−0.415	−0.551
p_2	d_c	0.639	0.641
	V_c	−0.647	−0.608
	p_c	0.680	0.684
	T_c	0.155	0.551
Z	d_c	−0.356	−0.374
	V_c	0.376	0.347
	p_c	−0.376	−0.393
	T_c	0.189	0.165

relations, $p_c=a/(27b^2)$, $T_c=8a/(27Rb)$, $V_c=3b$, giving $a=9RT_cV_c/8$ and $b=V_c/3$. The parameters a and b can be interpreted respectively to reflect the intermolecular interaction and molecular volume.[3] The values of a can be calculated from the data of T_c and V_c, as shown in Table 7 for nonane isomers. From this table, one may notice that those compact molecules with large steric hindrance, such as 2244m-4, 22m3e-4 23m3e-4, 24m3e-4, and 33e-4 (m and e, respectively stand for methyl and ethyl) have rather smaller value of a. Same thing also happens in decane isomers.

The more compact the molecule is, the weaker the molecules interact with each other in the liquid state. Further, it is noticed that the normal paraffin has the largest a value among all the isomers. As has been discussed in Section IV, we can further say that, the intermolecular interaction of molecules with high steric hindrance is weaker than for other molecules. The reason why the volume of those compounds decreases is not because they interact with each other strongly, but just as we discussed in Section IV.

Since "critical state" is a kind of state in which liquid phase and gaseous phase not only coexist, but also have the same density without any phase boundary between them, molecules in this state do not approach each other as in the liquid state. This means that the intermolecular interaction is not so strong that the volume of the bulk is determined mainly by the molecular size, as implied in the relation, $V_c=3b$. As shown in Table 7, each normal paraffin has actually the largest size (or V_c value) of all the isomers.

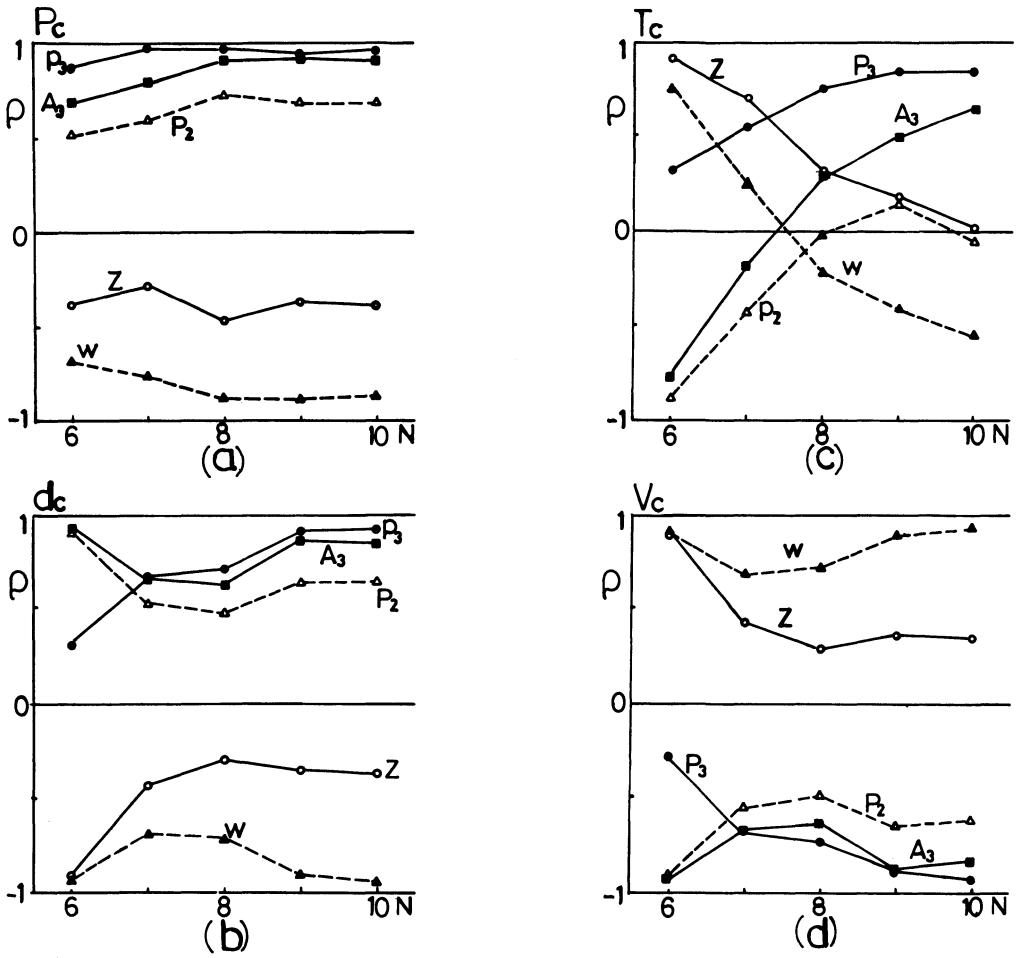

Fig. 6. The size dependency of the ρ values of p_c, d_c, T_c, and V_c against the five topological indices for alkanes.

But, liquid normal paraffin has the smallest volume among all the isomers having the same p_3 value. So it is clear that the decrease in volume of normal paraffins is due to the strong intermolecular interaction as to decrease the holes among molecules.

In liquid state, for alkanes, the most important intermolecular attraction is the London dispersion force, and its energy is proportional to the square of the polarizability and to inverse sixth power of the separation; i.e., $U_{\text{London}} \propto \alpha^2/\gamma^6$. Because of its loose structure, normal paraffin may have the largest polarizability and therefore it has the largest London dispersion force. We suppose this is the reason why the normal paraffins have the strongest intermolecular attraction.

VII. Concluding Remark

The size dependency of the correlations of twelve physical properties and topological types are summarized in Fig. 7. Since type C properties have large negative correlation with p_3, they can essentially be classified into type B. In Fig. 7, slant zebra indicates A-type, whose properties are largely dependent on Z index; stars indicate B-type, whose properties have large positive or negative correlations with p_3 index; checker and dots indicate W-type and X-type, respectively.

As seen from Fig. 7, the fact that entropy belongs essentially to A-type does not change even with the increase of molecular size. Boiling point can be classified into A-type up to decane, but it turns to belong to W-type above undecane. For heat of formation, as the number of cabon atoms in a molecule increases from six to twelve, its character changes from A-type to W-type for octane, and into B-type beyond decane. Liquid-state density, molar volume, refractive index, molar refraction and critical pressure are classified into B-type up to dodecane. Critical temperature, critical volume, and critical density turn to belong to B-type as the molecular size increases. Free energy of formation has almost no linear correlation both with Z and p_3 for lower members of alkanes, but it can be classified into B-type beyond undecane.

In paper III of this series, it has been pointed out that p_3 may be regarded as a kind of topological

Table 7. Critical Volume, Temperature and van der Waals' Constant a of Nonane Isomers

	2233m-5	0.478	607.5	292.39

bulkiness factor, or a static topological parameter, and Z may be regarded as a dynamical topological parameter. The present work confirms those inferences about Z and p_3 from the results of larger molecules.

We think p_3 is not a good parameter in reflecting the steric hindrance and complex interactions, and this conclusion is contrary to the results by some other authors.[11,17]

Boiling point, which is determined by the dynamical balance between the motion and interaction of molecules, has the best correlation with Z. This conclusion agrees with paper III. But for larger molecules, the correlation of Z with bp is not as good as that for smaller molecules. From Section V, it is revealed that the optimum linear combination among topological indices for bp is aA_3+bZ, and we have envisaged in Section III that aA_3+bZ has a certain

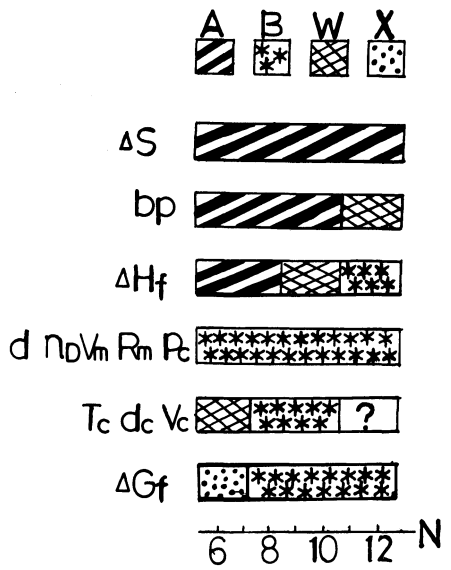

Fig. 7. Diagram showing the size dependency of the correlation types of physical properties and molecular topology for alkanes.

property close to p_3. Thus we may consider bp is also affected by bulkiness properties, and as the number of carbon atoms increases, the bulkiness properties become dominant. This is also the case with ΔH_f and ΔG_f.

The property of the parameter, A_3 is interesting, because when it is properly combined with Z, it will reflect various physical properties, whereas it has almost no correlation with any property by itself. It awaits further analysis.

Electrode Kinetics of Metal Complexes Confined in Perfluoro Polycarboxylate and Polysulfonate Coatings on Graphite Electrodes

Noboru OYAMA,* Takeo OHSAKA, Tooru USHIROGOUCHI, Sachiko SANPEI,† and Sadako NAKAMURA†

Department of Applied Chemistry for Resources, Tokyo University of Agriculture and Technology, Koganei, Tokyo 184

†Department of Chemistry, Japan Women's University, Mejirodai, Bunkyo-ku, Tokyo 112

(Received December 2, 1987)

A heterogeneous electron-transfer process of $[Os(bpy)_3]^{2+/3+}$ (bpy: 2,2′-bipyridine) and [(trimethylammonio)methyl]ferrocene/ferricinium ($TAF^{+/2+}$) redox couples, which were confined in perfluoro polycarboxylate and polysulfonate polyelectrolyte coatings on graphite electrodes, at the electrode/film interfaces as well as a homogeneous charge-transport process within the coating films were examined by means of potential-step chronoamperometry and chronocoulometry, normal pulse voltammetry and ac impedance measurements. The relevant kinetic parameters (i.e., the standard rate constant k° and the transfer coefficient of the heterogeneous electron-transfer process and the apparent diffusion coefficient D_{app} for the homogeneous charge-transport process) were determined at various concentrations of the redox species in the films at various pH's. The temperature dependences of D_{app}, k° and the formal potentials of the $[Os(bpy)_3]^{2+/3+}$ and $TAF^{+/2+}$ couples confined in the films were also examined and the relevant activation parameters for the heterogeneous electron-transfer and homogeneous charge-transport processes and the reaction entropies of these redox couples were evaluated. On the basis of the kinetic and thermodynamic data obtained, the mechanism of the charge-transport process within the films, the effects of polymer domain and pH on the rates of the heterogeneous electron-transfer and homogeneous charge-transport processes and on the incorporation of the redox species into the films, etc. are discussed.

Recently, much attention has been denoted to the electron-transfer processes at electroactive, thin polymer film-coated electrodes from the viewpoint of the fundamental studies on the mechanism and kinetics of electron transfer as well as the possible applications based on their interesting properties (e.g., electron-transfer catalysis (and mediation), redox conductivity and electrochromic property).[1] We have also been interested in this problem and have continued to conduct the kinetic and thermodynamic study of (i) the heterogeneous electron-transfer process between electrode and redox species (or sites) confined in polymeric domains and (ii) the homogeneous charge-transport process within polymer coatings for various types of redox polymer-coated electrode systems.[2-14] They involve (1) multiply-charged anionic metal complexes-electroinactive cationic polyelectrolyte film systems[2,4,7,8,11,13] (e.g., $[Mo(CN)_8]^{4-/3-}$, $[Fe(CN)_6]^{4-/3-}$ $[W(CN)_8]^{4-/3-}$ and $[IrCl_6]^{3-/2-}$-protonated poly(4-vinylpyridine) (PVP) systems and $[Fe(CN)_6]^{4-/3-}$, $[Mo(CN)_8]^{4-/3-}$, $[Fe(bp)_3]^{4-/3-}$ (bp: bathophenanthroline disulfonato) and $[W(CN)_8]^{4-/3-}$-electropolymerized poly(*N*,*N*-dialkylaniline) film systems), (2) polymer ligand-containing metal complex systems[2] (e.g., $[Fe(CN)_5]^{3-/2-}$-PVP system), (3) viologen polymer film systems[5,6,9] (e.g., *N*,*N*′-dimethyl-4,4′-bipyridinium-Nafion system, poly(xylylviologen) (PXV)-poly(*p*-styrenesulfonate) (PSS) system, poly(styrene-*co*-chloromethylstyrene) pendant viologen (PMV) film systems, and PMV-Nafion and -PSS systems) and (4) electropolymerized electroactive film systems[10,12,14] (e.g., poly(1-pyrenamine) and poly(*o*-phenylenediamine) film systems).

In the present report, we will describe the kinetic study concerning the electrode reactions ((i) and (ii)) of cationic redox couples (i.e., $[Os(bpy)_3]^{2+/3+}$ (bpy: 2,2′-bipyridine) and [(trimethylammonio)methyl] ferrocene/ferricinium ($TAF^{+/2+}$))-containing perfluoro polycarboxylate and polysulfonate polyelectrolyte coatings (Fig. 1) on graphite electrodes by means of potential-step chronoamperometry and chronocoulometry, normal pulse voltammetry and ac impedance measurements. Previously, Bard et al.[15] have examined the mechanism of charge transport through Nafion polymers (coated on glassy carbon electrodes)

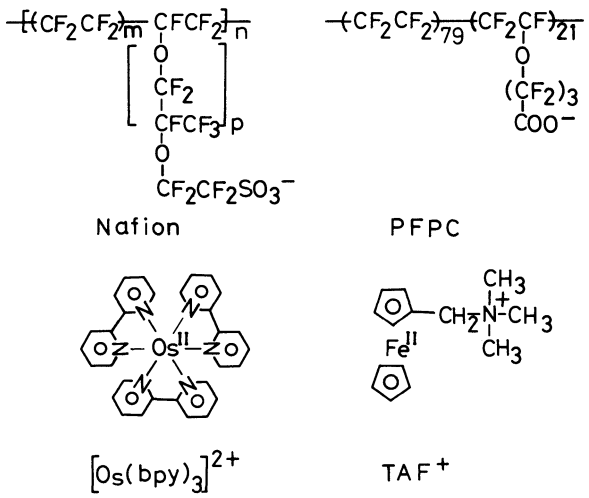

Fig. 1. Structures of the perfluoro polycarboxylate (PFPC) and polysulfonate (Nafion) polyelectrolytes, $[Os(bpy)_3]^{2+}$ and [(trimethylammonio)methyl]ferrocene (TAF^+) used in this study.

containing some redox species such as $[Os(bpy)_3]^{2+}$ and TAF^+ on the basis of the estimation of the apparent diffusion coefficient (D_{app}) for the charge-transport process within the films containing these redox species and the diffusion coefficients of actual mass transport of the same redox species through the polymer. Also, Anson et al.[16] have reported the shifts in formal redox potentials accompanying the incorporation of cationic complexes (including $[Os(bpy)_3]^{2+}$ and TAF^+) in perfluoro polycarboxylate and polysulfonate coatings on graphite electrodes. Our aim is to elucidate and understand the effect of polymer domain on the rates of both heterogeneous electron-transfer process and homogeneous charge-transport process and the dependences of the standard rate constant (k°) for the former process and the apparent diffusion coefficient (D_{app}) for the latter process upon concentration of redox species confined in the polymeric coatings. The temperature dependences of the formal redox potentials of the $[Os(bpy)_3]^{2+/3+}$ and $TAF^{+/2+}$ couples confined in the coatings, k° and D_{app} will be also examined in order to gain an additional insight into some possible factors controlling the rates of the heterogeneous electron-transfer and homogeneous charge-transport processes.

Experimental

Materials. Nafion membrane 125®, which is a perfluoro polysulfonate polyelectrolyte membrane, was obtained from E.I. du Pont de Nemours and Company (Wilmington, Delaware). According to a previous procedure,[5,6,17] the stock solution of Nafion was prepared from the membrane in order to facilitate the electrode coating. Then, an ethanol-dimethyl sulfoxide (EtOH-DMSO) mixture (50:50 volume percent) was used as a solvent and the concentration of Nafion was 3.6 mg ml^{-1}. Nafion coating films were prepared by evaporation of aliquots of the stock solution put on electrode surfaces. Perfluoro polycarboxylate polyelectrolyte (abbreviated as PFPC in this paper and shown in Fig. 1 together with Nafion) was obtained in the form of a fine suspension of the methyl ester from Asahi Glass Company (Tokyo). The suspension (15 mg) was dissolved in EtOH-DMSO (50:50 volume percent) mixture solution. The concentration of the prepared stock solution of PFPC (as the methyl ester form) was 3.6 mg ml^{-1}. To prepare the coating films on electrodes, aliquots (1—10 μl) of the stock solution were evaporated on freshly cleaved electrodes. The resulting deposite was exposed to 1 M (1 M=1 mol dm^{-3}) NaOH solution for 5 min to hydrolyze the ester to the carboxylate, and the electrode was then washed thoroughly with water. From the measurement of IR spectra of the PFPC film deposited on a glass slide, which was treated as mentioned above, it was confirmed that the extent of the hydrolysis under such a treatment is almost 100%.

$[Os(bpy)_3](ClO_4)_2$ (bpy: 2,2′-bipyridine) was synthesized according to the standard procedure.[18] [(Trimethylammonio)methyl] ferrocene bromide (abbreviated as TAF^+Br^-, see Fig. 1) was reagent grade (Tokyo Kasei Co.) and was used as received. The basal-plane pyrolytic graphite (BPG) (Union Carbide Co.) disk electrodes (area: 0.17 cm^2) were prepared and mounted into glass tube with heat-shrinkable polyolefin tube as previously described.[19] Aqueous solutions were prepared from doubly distilled water. The supporting electrolyte solution was 0.2 M CF_3COONa (Aldrich) adjust to pH 1.0, 2.0, and 3.0 with CF_3COOH and to pH 4.0 and 5.5 with 0.1 M CH_3COONa-CH_3COOH. Other chemicals were reagent grade and were used as received.

Apparatus and Procedures. A standard three-electrode electrochemical cell was used for all electrochemical experiments. The electrode assembly consisted of a film-coated BPG electrode as working electrode, a sodium chloride saturated calomel electrode (SSCE) as reference electrode and a spiral platinum as counter electrode. For cyclic voltammetry, potential-step chronoamperometry (and chronocoulometry), and normal pulse voltammetry, a home-made instrument was employed along with an X-Y recorder and a Nicolet digital oscilloscope (model 309).[2-14] Positive feed-back circuitry was employed to compensate the resistances (these were typically ca. 20—50 Ω) associated with the polymer coatings as much as possible. Potential-step chronoamperometric (and chronocoulometric) data (i.e., current-time and charge-time responses) were stored in the digital oscilloscope and then transferred via an interface (NEC, RSC-232C) to a microcomputer (NEC, PC-9801E) where an analysis of the data was performed. In normal pulse voltammetric experiments, the pulse width of 10—100 ms and the interval of 30—120 s between successive pulses were employed. Thus it can be safely considered that the depletion layer of reactants produced during the preceding pulse completely disappears before the following pulse starts. Normal pulse voltammetric measurements were confined to times (typically 1—10 ms) sufficiently short to ensure that semi-infinite linear diffusion prevailed. The ac impedance measurements were performed with a Frequency Response Analyzer (Solartron Model 1250) and a Potentiostat/Galvanostat 2000 (Toho Technical Research, Tokyo) as previously described.[7]

The Nafion or PFPC film-coated electrodes were soaked in 0.1—5.0 mM solutions (pH 1.0) (containing 0.2 M CF_3COONa) of metal complexes for 1—30 min in order to achieve the incorporation of desired quantities of metal complexes into the films. After that, the electrodes were replaced in a pure supporting electrolytic solution (0.2 M CF_3COONa, pH 1.0) and then the cyclic voltammograms were recorded. After the steady-state cyclic voltammograms were obtained, the quantity (Γ_p) of metal complexes incorporated into the films deposited on electrodes was estimated (in mol cm^{-2}) by measuring the charge required in a potential-step experiment to quantitatively oxidize or reduce the metal complexes and/or measuring the area of cyclic voltammograms (for the oxidation-reduction reactions of the incorporated metal complexes) obtained at slow potential scan rates. The Γ_p values estimated by the two procedures were the same within experimental error. The molar concentrations (C_p^0 in mol cm^{-3}) of the incorporated metal complexes were calculated from the Γ_p's thus obtained by using the thicknesses of the films which were estimated from their densities (mentioned below) under swelling state.

The film thicknesses under the "swelling" state were measured with a Surfcom 550 A (Surface Texture Measuring Instrument, Tokyo Seimitsu Co.). In this case, the samples

of wet Nafion films (thicknesses>2×10^{-5} cm) were produced by soaking the Pt-sputtered dry Nafion films coated on electrodes (the thickness of the Pt film coated<1×10^{-6} cm) in 0.2 M CF_3COONa solution (pH 1.0) for several hours and sorbing the water on the film surface by filter paper. The weight of the wet Nafion films (without Pt-sputtered films) coated on electrodes was also measured. The results indicated that the density of the wet Nafion film is 2.0 ± 0.3 g cm^{-3}, which is in good agreement with the previously reported value.[17,20] The wet thicknesses of the Nafion films incorporating various concentrations of the $[Os(bpy)_3]^{2+}$ (or TAF^+) complex were independent of the concentration of the incorporated $[Os(bpy)_3]^{2+}$ (or TAF^+) and were almost equal to those obtained for the swollen Nafion films containing no $[Os(bpy)_3]^{2+}$ (or TAF^+). With the PFPC film, at first by soaking the PFPC film-coated electrodes in 1 M NaOH for several tens of minutes for the hydrolysis of the methyl ester in the films and then by following the procedure similar to that used in the estimation of the densities of the swollen Nafion films, the density of the wet PFPC film was estimated to be 2.0 ± 0.4 g cm^{-3}, being independent of the incorporation of $[Os(bpy)_3]^{2+}$ (or TAF^+).

The experiments concerning temperature dependences of the formal potentials ($E^{0\prime}$), the apparent diffusion coefficients (D_{app}) for the diffusion-like charge-transport process within the films and the standard rate constant (k°) of the heterogeneous electron-transfer reaction at the electrode/film interfaces were carried out in a "non-isothermal electrochemical cell"[21-24] having a thermally jacketed compartment for the working and counter electrodes and a separate compartment for the reference electrode which was connected to the cell with a 3 M NH_4Cl salt bridge. The reference electrode was maintained at a fixed temperature (25 ± 0.2 °C). The temperature of the cell was varied in the range of 5—45 °C. The values of $E^{0\prime}$ were estimated as the average of the anodic and cathodic peak potentials of the cyclic voltammograms. The analysis of the data obtained was made according to the references[21-28] where the principles and assumption[21-24] involved in the use of such cells have been examined in detail and several recent experimental examples of their successful applications are available.[25-28]

Nitrogen gas was passed through the solutions to remove the dissolved oxygen before the experiments and over the solution during the experiments. Potentials were measured and are reported with respect to an SSCE. Experiments were conducted at ambient laboratory temperature (25 ± 1 °C), except for those concerning the temperature dependences of $E^{0\prime}$, D_{app}, and k°.

Results

Potential-Step Chronoamperometry and Chronocoulometry. Figure 2 shows the typical cyclic voltammograms for the $TAF^{+/2+}$ (or $[Os(bpy)_3]^{2+/3+}$) couple confined in the PFPC film on BPG electrodes in 0.2 M CF_3COONa solution (pH 5.5). The wave

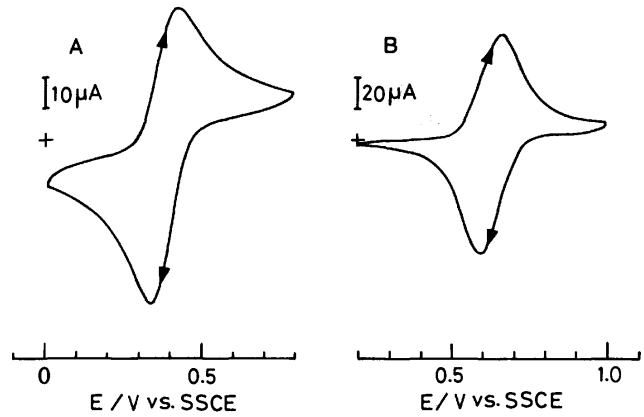

Fig. 2. Typical cyclic voltammograms for the redox reactions of (A) $TAF^{+/2+}$ and (B) $[Os(bpy)_3]^{2+/3+}$ couples confined in the PFPC films on BPG electrodes in 0.2 M CF_3COONa solution (pH 5.5) containing 0.1 M CH_3COONa/CH_3COOH buffer. Concentrations of redox species in the PFPC films (thickness: 2.1×10^{-5} cm): (A) 1.9×10^{-4} and (B) 2.3×10^{-4} mol cm^{-3}. Scan rate: 200 mV s^{-1}.

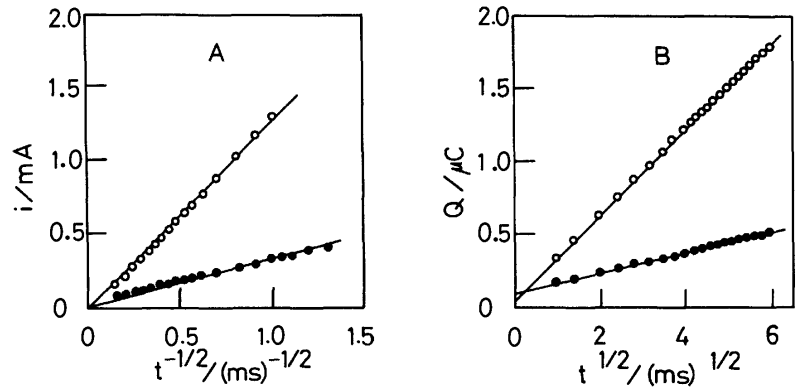

Fig. 3. Typical examples of the potential-step chronoamperometric and chronocoulometric Cottrell plots of (A) i vs. $t^{-1/2}$ and (B) Q vs. $t^{1/2}$ for the oxidation of the TAF^+ (●) and $[Os(bpy)_3]^{2+}$ (○) complexes confined in the PFPC film on BPG electrodes. Other experimental conditions are the same as in Fig. 2.

shapes are similar to those for the solution-phase $TAF^{+/2+}$ (or $[Os(bpy)_3]^{2+/3+}$) couple at a bare electrode, that is, the waves are diffusion-like, with broad peaks and diffusion tails. Typical examples of the potential-step chronoamperometric and chronocoulometric responses for the oxidation of the TAF^+ (or $[Os(bpy)_3]^{2+}$) complex confined in the PFPC film are shown in Fig. 3. These i vs. $t^{-1/2}$ and Q vs. $t^{1/2}$ plots (i: current Q: charge, t: time) are linear, indicating that the charge-transport processes within the films follow the Fick's diffusion laws.[2-14] Thus, the slopes of these plots yielded the values of the apparent diffusion coefficients (D_{app}) for the diffusional charge transport. The D_{app} values obtained from these both plots were almost the same. The linear i vs. $t^{-1/2}$ and Q vs. $t^{1/2}$ plots were also obtained at various concentrations of the $[Os(bpy)_3]^{2+}$ (or TAF^+) complex confined in the PFPC and Nafion films on electrodes in supporting electrolytic solutions of various pH's, and thus the relevant D_{app}'s were estimated from the slopes of these plots. The obtained data are summarized in Fig. 4.

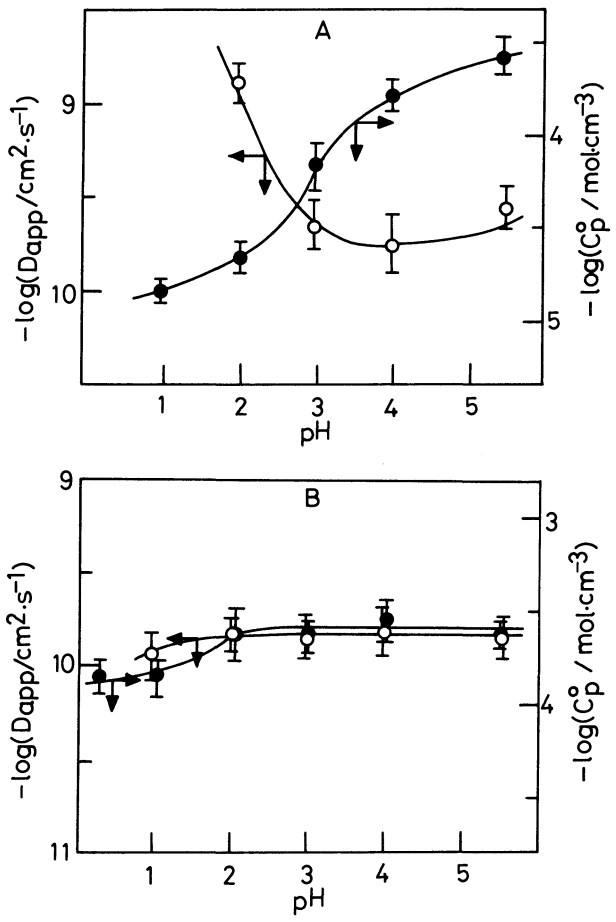

Fig. 4. pH dependences of C_p^0 and D_{app} for (A) $[Os(bpy)_3]^{2+}$-PFPC and (B) TAF^+-PFPC systems. The amount of the PFPC coatings: 4.2×10^{-5} g cm^{-2}. Supporting electrolyte: 0.2 M CF_3COONa. The values of D_{app} were estimated by potential-step chronoamperometry and chronocoulometry.

The D_{app}'s were found to depend on the incorporated redox species, their concentrations (C_p^0), the polymer films incorporating them, and the pH value of a solution.

Normal Pulse Voltammetry. Figure 5 shows the typical normal pulse voltammograms for the oxidation of the $[Os(bpy)_3]^{2+}$ (or TAF^+) complex confined in Nafion films on BPG electrodes in 0.2 M CF_3COONa solution (pH 5.5) at various sampling times (τ). These S-shaped waves are similar to those obtained for solution-phase redox species at an uncoated electrode[29,30] as well as for other redox compounds incorporated electrostatically into (or bound covalently to) polymer films on electrodes.[2-6,8-14] The half-wave potentials of the voltammograms shifted to more positive values with decreasing τ. Plots of the anodic limiting current (i_{lim}) of these

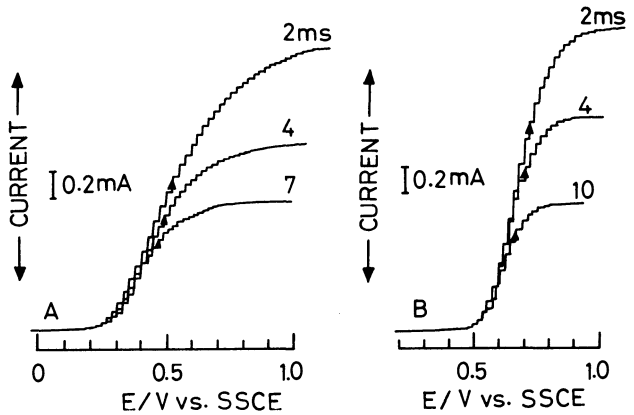

Fig. 5. Typical normal pulse voltammograms for the oxidation of (A) TAF^+ and (B) $[Os(bpy)_3]^{2+}$ complexes confined in the Nafion films on BPG electrodes at various sampling times. Concentration of SO_3^- group in Nafion films: 1.65×10^{-3} mol cm^{-3}. Film thickness: 4.3×10^{-5} cm. C_p^0: (A) 4.6×10^{-4}, (B) 3.2×10^{-4} mol cm^{-3}. Supporting electrolyte: 0.2 M CF_3COONa+0.1 M CH_3COONa/CH_3COOH (pH 5.5). Sampling times (ms) are given on each voltammogram.

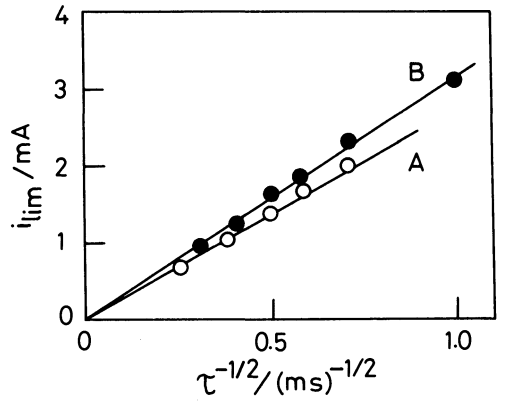

Fig. 6. Typical normal pulse voltammetric Cottrell plots of limiting current i_{lim} vs. $\tau^{-1/2}$ for the oxidation of (A) TAF^+ and (B) $[Os(bpy)_3]^{2+}$ confined in the Nafion film on BPG electrodes. Experimental conditions are the same as in Fig. 5.

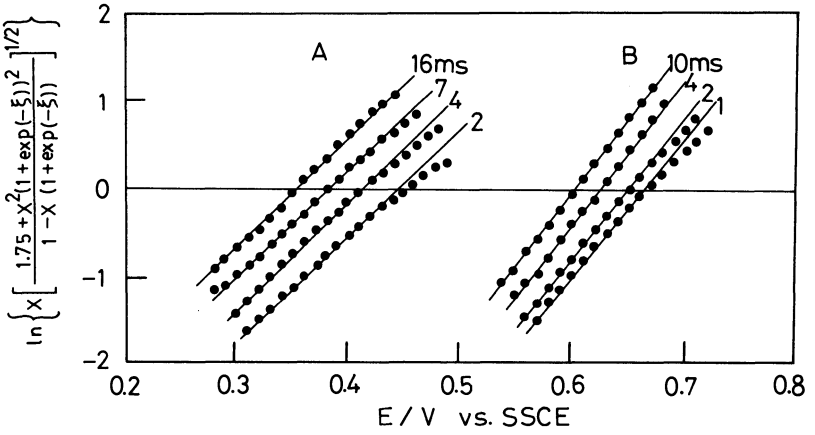

Fig. 7. Modified log plots of normal pulse voltammograms for the oxidation of (A) TFA^+ and (B) $[Os(bpy)_3]^{2+}$ complexes confined in the Nafion film. Sampling times (ms) are indicated on each straight line. other experimental conditions are the same as in Fig. 5.

normal pulse voltammograms against the inverse square root of τ were found to be linear as expected for a diffusion-controlled limiting current (Fig. 6).[2-6,8-14] Thus, the values of D_{app} were estimated from the slopes of the i_{lim} vs. $\tau^{-1/2}$ plots according to the normal pulse voltammetric Cottrell equation.[2-6,8-14,31] Further, the kinetic parameters (i.e., standard rate constant (k°) and transfer coefficient (α)) of the heterogeneous electron-transfer reaction at the electrode/film interfaces could be estimated from an analysis of the rising part of the current-potential curves shown in Fig. 5, as described previously.[2-6,8-14,29-31] The modified log plots for the normal pulse voltammograms of $\ln(x[\{1.75+x^2(1+\exp(-\xi))^2\}/\{1-x(1+\exp(-\xi))\}]^{1/2})$ vs. E were found to be linear (Fig. 7) and the slopes of the straight lines were constant at the different τ's in respective systems, where x is the ratio of the current at potential E to the anodic limiting diffusion current ($(i_d)_{Cott}$) expressed by the Cottrell equation and ξ is the dimensionless parameter expressed as $\{(nF/RT)(E-E^1_{1/2})\}$ ($E^1_{1/2}$: the reversible half-wave potential, n: the number of electrons involved in the heterogeneous electron-transfer reaction, F: the Faraday constant, R: the gas constant, T: the absolute temperature). Thus, according to the previously described procedures,[2-6,8-14,29-31] from the slopes of the straight lines and the intercepts of these lines with the axis, the values of k° and α were estimated. The values thus obtained of D_{app}, k°, and α are summarized in Fig. 9, together with those obtained by potential-step chronoamperometry (and chronocoulometry) and ac impedance measurements.

Alternating Current Impedance Measurements. In Fig. 8 are shown typical Cole-Cole plots (i.e., plots of the quadrature component of the ac impedance vs. its real component) for the redox reaction of the $[Os(bpy)_3]^{2+/3+}$ and $TAF^{+/2+}$ couples confined in the

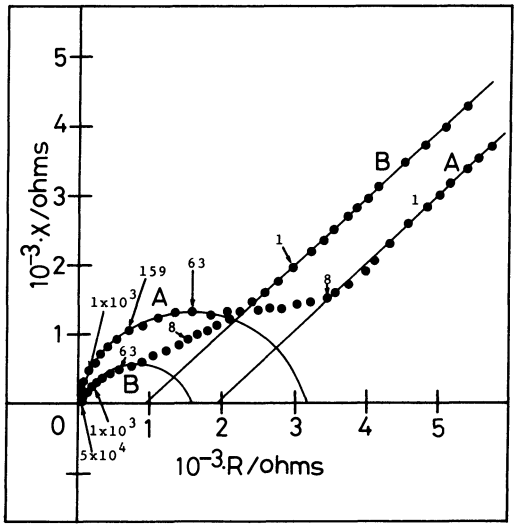

Fig. 8. Typical Cole-Cole plots for the redox reactions of (A) $TAF^{+/2+}$ and (B) $[Os(bpy)_3]^{2+/3+}$ couples confined in the PFPC film on BPG electrodes in a 0.2 M CF_3COONa solution (pH 5.5) containing 0.1 M CH_3COONa/CH_3COOH buffer. In both cases, the thicknesses of the PFPC films were 2.1×10^{-5} cm. C^0_P: (A) 2.9×10^{-5}, (B) 1.7×10^{-4} mol cm^{-3}. The dc potentials were set at (A) 0.328 and (B) 0.586 V vs. SSCE which are formal redox potentials in cases A and B, respectively. The amplitude of an imposed ac voltage was 5.0 mV. X and R show the quadrature and real components of the ac impedance, respectively. The numbers on each plot represent frequency in units of Hz.

PFPC films on BPG electrodes in a 0.2 M CF_3COONa solution (pH 5.5). The data in Fig. 8 show the complex plane impedance plots for the redox reactions of these couples at each formal redox potential. These plots are considered to consist of the semicircular part and the straight line which corresponds to the Warburg diffusional impedance.[32,34] It can be thus seen that the impedance loci of these

Confined redox couples: (○,◑,●) $[Os(bpy)_3]^{2+/3+}$, (▲,▲,▲,▲) $TAF^{+/2+}$. Coating films: (○,▲,△) PFPC film (Thickness: 2.1×10^{-5} cm) (◑,●,▲,▲) Nafion film (Thickness: 4.3×10^{-5}). Supporting electrolyte: (▲) 0.2 M CF_3COONa (pH 1.0); (○,◑,●,△,▲,▲) 0.2 M CF_3COONa +0.1 M CH_3COONa/CH_3COOH (pH 5.5). C_p^0: (○) 1.4×10^{-4}; (◑) 6.6×10^{-5}; (●) 2.6×10^{-5}; (▲) 1.9×10^{-4}; (△) 1.3×10^{-4}; (▲) 6.6×10^{-4}; (▲) 6.6×10^{-5} mol cm^{-3}.

plots correspond approximately to those expected for the electrochemical impedance represented by the well-known "Randles's equivalent circuit".[33] Thus, the diameter of the semicircle enabled us to estimate the heterogeneous electron-transfer resistance and thus k°.[32-34] The k° values thus obtained for the redox reactions of the $TAF^{+/2+}$ and $[Os(bpy)_3]^{2+/3+}$ couples confined in the Nafion or PFPC films at various C_p^0 values are shown in Fig. 9. The film resistances involving the solution resistance, obtained from the high-frequency intercept with the real axis, were in the range of ca. 20—50 Ω in both redox systems.

Temperature Dependences of $E^{0\prime}$, D_{app}, and k°. Figure 10 shows the temperature (T) dependences of the formal redox potentials ($E^{0\prime}$) for the $TAF^{+/2+}$ and $[Os(bpy)_3]^{2+/3+}$ couples confined in the Nafion and PFPC films. The linear relationships between $E^{0\prime}$ and T were obtained and thus the reaction entropy differences (ΔS_{rc}^0) for these couples were estimated by using the equation:[23,25-28]

$$\Delta S_{rc}^0 = S_{red}^0 - S_{ox}^0 = F(dE^{0\prime}/dT) \quad (1)$$

where S_{red}^0 and S_{ox}^0 are absolute ionic entropies of the reduced and oxidized halves of the redox couple and F is the Faraday constant. The temperature coefficient (dE_f^{ni}/dT) of the overall potential (E_f^{ni}) across the non-isothermal electrochemical cell consists of those of the Galvani metal-solution potential difference (ϕ_f^m), the potential difference across the thermal liquid junction within the 3 M NH_4Cl salt bridge (ϕ_{tlj}) and the thermocouple potential difference between the hot and cold regions of the working electrode (ϕ_{tc}), which are expressed by $d\phi_f^m/dT$, $d\phi_{tlj}/dT$, and $d\phi_{tc}/dT$, respectively.[23] The value of $d\phi_{tlj}/dT$ has been

Fig. 11. Film thicknesses: 4.3×10^{-5} cm. Supporting electrolyte: 0.2 M CF$_3$COONa+0.1 M CH$_3$COONa/CH$_3$COOH (pH 5.5). Widths of error bars indicate uncertainties in the measurements of D_{app} and $k°$.

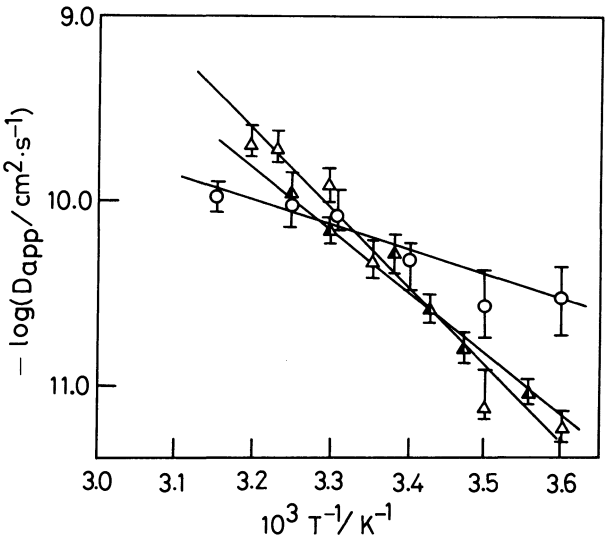

Fig. 13. Temperature dependences of D_{app} for the [Os(bpy)$_3$]$^{2+}$ and TAF$^+$ complexes confined in PFPC films. (○): [Os(bpy)$_3$]$^{2+}$ (C_p^0: 1.4×10^{-4} mol cm^{-3}), (▲): TAF$^+$ (C_p^0: 1.9×10^{-4} mol cm^{-3}), (△): TAF$^+$ (C_p^0: 1.3×10^{-4} mol cm^{-3}). Film thickness: 2.1×10^{-5} cm. Supporting electrolyte: (▲) 0.2 M CF$_3$COONa (pH 1.0); (○,△); 0.2 M CF$_3$COONa+CH$_3$COONa/CH$_3$COOH (pH 5.5). Widths of error bars indicate uncertainties in the measurements of D_{app}.

estimated to be less than 50 μV K^{-1}.[23,35] We have no data on the $d\phi_{tc}/dT$ for the BPG electrode, but it may be expected to be less than several tens of microvolts per degree from the $d\phi_{tc}/dT$ values for mercury and platinum which are 14 and 6 μV K^{-1}, respectively.[23,35] Thus we assumed that these temperature coefficients ($d\phi_{tlj}/dT$ and $d\phi_{tc}/dT$) can be negligible as compared with the experimental uncertainties (±2 cal mol^{-1} K^{-1} in ΔS_{rc}^0) in the present experiments.

In Fig. 11 is shown the typical dependence of the normal pulse voltammetric limiting current upon $\tau^{-1/2}$ for the oxidation of the TAF$^+$ confined in the Nafion film at different temperatures. From the slopes of such plots, the D_{app}'s at each temperature were obtained. Plots of the logarithm of D_{app} vs. T^{-1} were found to be linear over the temperature range 5—45 °C, indicating that the behaviors are of the Arrhenius type (see Figs. 12 and 13). Thus, according to Eyring et al.,[36,37] we can express the D_{app} as follows:

$$D_{app} = \lambda^2 \left(\frac{kT}{h}\right) \exp\left(\frac{\Delta S^{\ddagger}_{diffusion}}{R}\right) \exp\left(-\frac{\Delta H^{\ddagger}_{diffusion}}{RT}\right) \quad (2)$$

where $\Delta H^{\ddagger}_{diffusion}$ and $\Delta S^{\ddagger}_{diffusion}$ are the enthalpy and entropy, respectively, of activation for the homogeneous charge-transport process within the films, λ is the average distance between equilibrium positions in the process of diffusion, k is the Boltzmann constant, h is the Planck constant, and R is the gas constant. The values of λ have been unknown. Here, assuming that λ=1 and 10 Å, the values of $\Delta S^{\ddagger}_{diffusion}$ are estimated (Different investigators[37,38] have used values ranging

1 to 5 Å for λ). The obtained values of $\Delta H^{\neq}_{diffusion}$ and $\Delta S^{\neq}_{diffusion}$ are given in Table 2.

The temperature dependence of $k°$ for the $TAF^{+/2+}$ couple confined in the Nafion film is shown in Fig. 12, where the standard rate constants at the standard potential at each temperature are plotted against (temperature)$^{-1}$. According to Weaver et al.,[21-23] who have recently demonstrated in detail the possibility and significance of such measurements using a non-isothermal cell (see Experimental Section) for simple electrode reactions, the "real" enthalpy and entropy of activation of the heterogeneous electron-transfer reaction ($(\Delta H^0_{\neq})_{real}$ and $(\Delta S^0_{\neq})_{real}$) were estimated to be 9.6 ± 1.2 kcal mol^{-1} and -2 ± 1 cal mol^{-1} K^{-1}, respectively. In the estimation of $(\Delta S^0_{\neq})_{real}$, the transmission coefficient (κ) introduced in order to account for possible non-adiabaticity of the electrode reaction was assumed to be unity.[39]

Discussion

pH dependence of the Incorporation. From the data shown in Fig. 4, one can clearly see that the volume concentration (C^0_p) of the $[Os(bpy)_3]^{2+}$ incorporated into the PFPC film increases from 1.4×10^{-5} to 3.2×10^{-4} mol cm^{-3} with increasing pH from 1 to 5.5, while C^0_p of the incorporated TAF^+ is almost independent of pH in the range of pH ca. 2—5.5 and is ca. 2×10^{-4} mol cm^{-3}. This result for the $[Os(bpy)_3]^{2+}$ complex is explained by the equilibrium competition of protons and $[Os(bpy)_3]^{2+}$ ions for counterionic sites within the PFPC film. That is, at pH values as low as 1, protons compete quite successfully with $[Os(bpy)_3]^{2+}$ ions for counterionic sites within the PFPC, and with increasing pH $[Os(bpy)_3]^{2+}$ ions become dominantly trapped. The shape of the plot for the $[Os(bpy)_3]^{2+}$ resembles that of a typical pH titration curve. Thus, the effective pK_a of the carboxylic acid group in the PFPC is estimated to be ca. 2.9 from the pH at which the incorporation reaches one-half of its maximum value. This value is different from that (2,2) obtained from the incorporation experiments of $[Ru(NH_3)_6]^{3+}$ into the PFPC[16] and also from the pK_a of 1.9 measured directly for a similar perfluoro carboxylate polyelectrolyte.[40] As generally well-known, the effective pK_a of polyelectrolytes varies with the degree of protonation and with the ionic strength.[41] These are considered as main reasons for the different effective pK_a's.

On the other hand, the situation for the TAF^+ complex seems to be different from that for the above-mentioned $[Os(bpy)_3]^{2+}$ complex. The incorporation of TAF^+ complex changes slightly with pH, especially at pH<ca. 2. In this case, the effective pK_a, which is estimated from the C^0_p vs. pH curve by the same procedure as that used for the pK_a determination of the PFPC polyelectrolyte from the $[Os(bpy)_3]^{2+}$ incorporation experiments, is ca. 1, being clearly different from that obtained from the $[Os(bpy)_3]^{2+}$ incorporation experiments. The amount of the incorporation of the TAF^+ complex is comparable to the maximum value for the $[Os(bpy)_3]^{2+}$ complex, as seen from the C^0_p values for $[Os(bpy)_3]^{2+}$ and TAF^+ at pH 5.5.

These different pH-dependences of the incorporation of $[Os(bpy)_3]^{2+}$ and TAF^+ complexes into the PFPC film should be noted, because this result can be considered to suggest different interactions (between the complexes and the PFPC film) by which these complexes are incorporated into the film and confined in it. In the case of the Nafion (or poly(*p*-styrenesulfonate)) film, such a pH-dependence of the incorporation of the same complexes was not observed in the examined range of pH 1 to 5.5.[61] Thus, the observed pH-dependences of the incorporation are peculiar to the PFPC film. The feature to be noted on the basis of the above-mentioned incorporation experiments is that the morphology of the PFPC film changes from the non-ionic polymer film to the anionic polyelectrolyte film with cation-exchange properties with increasing pH from ca. 1 to 5.5. In the case of the $[Os(bpy)_3]^{2+}$ complex, the incorporation can be considered to be mainly due to "electrostatic interactions"[2-8,11,13,19,41-48,52] between anionic carboxylic sites in the PFPC and cationic $[Os(bpy)_3]^{2+}$ complexes. The C^0_p values were about 1.4×10^{-5} and 2.5×10^{-4} mol cm^{-3} at pH 1 and 5.5, respectively, where the PFPC films are in the nonionic and anionic states, respectively. Thus, the difference between the C^0_p values at pH 1 and 5.5 is considered to approximately correspond to the incorporation amount of $[Os(bpy)_3]^{2+}$ by electrostatic interactions. In addition, the C^0_p value of 1.4×10^{-5} mol cm^{-3} at pH 1 may be regarded as the amount of the $[Os(bpy)_3]^{2+}$ complex incorporated into the film by specific interactions other than such electrostatic interactions, for example, "hydrophobic interactions"[16,17,42] between the large fluorocarbon component of the polyelectrolyte coating and $[Os(bpy)_3]^{2+}$ complexes. On the other hand, in the case of the TAF^+ complex, the situation seems different. Unlike the $[Os(bpy)_3]^{2+}$ complex, there may be probably a minor contribution of electrostatic interactions to the incorporation. This is deducible from the fact that C^0_p scarcely depends on pH. In this case, the incorporation seems to be mainly due to "hydrophobic interaction".[16,17,42]

Apparent Diffusion Coefficients for Diffusion-Like Charge Transport within Nafion and PFPC Films. The data shown in Fig. 9 demonstrate the dependences of D_{app} on the redox complex confined in the film, its concentration (C^0_p) and the film confining it. For example, when C^0_p was increased from 3.2×10^{-5} to 3.2×10^{-4} mol cm^{-3}, D_{app} decreased from 4.7×10^{-9} to 4.5×10^{-10} cm^2 s^{-1} in the case of the Nafion-$[Os(bpy)_3]^{2+}$ system, while in the case of the Nafion-TAF^+ system D_{app} was found to slightly decrease. For the PFPC coatings, the dependences of D_{app} on C^0_p were

almost the same in both $[Os(bpy)_3]^{2+}$ and TAF^+ systems: D_{app} decreased from 8.3×10^{-10} to 5.1×10^{-11} $cm^2\,s^{-1}$ with an increase in C_p^0 from 3.2×10^{-5} to 3.2×10^{-4} mol cm^{-3}. These observed decreases of D_{app}'s with increasing C_p^0 may be understood by the same idea as that used to explain the concentration dependences of D_{app}'s found in the other previously reported redox polymer films:[2-14,42,46-48] These decreases are considered to be attributed to the effects of "electrostatic (or hydrophilic) cross linking"[2-8,11,13,16,17,19,41-48,52] of the films by the electrostatic (or hydrophilic) interactions between the redox ions and the polyelectrolytes containing them (as mentioned above) and/or of "single-file diffusion",[42,43,49] An increase of the electrostatic cross linking with increasing C_p^0 causes a decrease in the diffusion rate of redox ion itself as well as decreases in the rates of the charge-compensating counterion motion which is necessarily coupled to electron transfer, the motion of solvent and/or the segmental motion of the polymeric chain. Also, the diffusing species which must move between more or less fixed sites within a polymeric matrix are considered to have their rate of motion limited by the decreasing availability of sites as C_p^0 of the diffusing species increases. These result in the decrease of the overall rate of the charge transport with an increase in C_p^0 and thus the decreased D_{app}'s are observed. It is also apparent from Fig. 9 that at a given C_p^0 the values of D_{app} for the Nafion-TAF^+ and $[Os(bpy)_3]^{2+}$ systems are larger than those for the PFPC-TAF^+ and $[Os(bpy)_3]^{2+}$ systems. For example, at $C_p^0=1.0\times10^{-4}$ mol cm^{-3}, the values of D_{app} are 1.5×10^{-9} and 1.8×10^{-10} $cm^2\,s^{-1}$ for the Nafion-$[Os(bpy)_3]^{2+}$ and PFPC-$[Os(bpy)_3]^{2+}$ systems, respectively, and those are 6.2×10^{-10} and 1.0×10^{-10} $cm^2\,s^{-1}$ for the Nafion-TAF^+ and PFPC-TAF^+ systems, respectively.

The Dependence of D_{app} on pH is of interest in connection with the pH dependence of the incorporation of the $[Os(bpy)_3]^{2+}$ and TAF^+ complexes (Fig. 4). For the $[Os(bpy)_3]^{2+}$ system, the D_{app} decreased with increasing pH. This means that the decrease of D_{app} is owing to the increase of C_p^0, because C_p^0 increases with increasing pH as mentioned above. When pH was increased from 1 to 5.5, C_p^0 increased from 1.4×10^{-5} to 3.2×10^{-4} mol cm^{-3} and thus D_{app} decreased from 1.4×10^{-9} to 2.1×10^{-10} $cm^2\,s^{-1}$. For the TAF^+ system, on the other hand, D_{app}'s were almost independent of pH and were ca. 1.2×10^{-10} $cm^2\,s^{-1}$. Such a pH-independence of D_{app} can be expected, because C_p^0 rarely varies with pH in the examined range of pH.

Kinetic Parameters of Heterogeneous Electron-Transfer Reactions at Electrode/Film Interfaces. The k° values for a given system, estimated by normal pulse voltammetry and ac impedance method, were almost the same within experimental error as shown in Fig. 9.[55] It appears that k° depends, though slightly, on C_p^0. For example, when C_p^0 was increased from 3.2×10^{-5} to 3.2×10^{-4} mol cm^{-3}, k° decreased from ca. 3×10^{-4} to 7×10^{-5} cm s^{-1} in the case of the Nafion-$[Os(bpy)_3]^{2+}$ system and from ca. 2×10^{-5} to 7×10^{-6} cm s^{-1} in the case of the PFPC-$[Os(bpy)_3]^{2+}$ and TAF^+ systems. In the case of the Nafion-TAF^+ system, k° seemed almost independent of C_p^0. Further, the values of k° for the Nafion-$[Os(bpy)_3]^{2+}$ and TAF^+ systems are larger than those for the PFPC-$[Os(bpy)_3]^{2+}$ and TAF^+ systems, for example, at $C_p^0=1.0\times10^{-4}$ mol cm^{-3} the k° values (ca. 1×10^{-4} cm s^{-1}) for the former systems are about one order of the magnitude larger than those for the latter systems. The transfer coefficients were almost independent of the polymer films: The anodic transfer coefficients (α_+) for the oxidation of the $[Os(bpy)_3]^{2+}$ complex confined in the Nafion and PFPC films are 0.48 and 0.51, respectively, and those for the oxidation of the TAF^+ complex confined in the Nafion and PFPC films are 0.29 and 0.24, respectively.

Formal Potentials and Reaction Entropies for the $[Os(bpy)_3]^{2+/3+}$ and $TAF^{+/2+}$ Couples Confined in Films. The formal potentials ($E^{0\prime}$) of the $[Os(bpy)_3]^{2+/3+}$ and $TAF^{+/2+}$ couples largely varied with the films confining them (see Table 1), indicating that the relative equilibrium binding constants for two halves of a redox couple are not determined solely by the magnitudes of their positive charges. In the PFPC film, the less highly charged (i.e., reduced) form of each couple is stabilized larger, while in the Nafion film the more highly charged (i.e., oxidized) form is stabilized larger. As a result, the $E^{0\prime}$ values for the

Table 1. Formal Redox Potentials and Reaction Entropies for the $[Os(bpy)_3]^{2+/3+}$ and $TAF^{+/2+}$ Couples Confined in Nafion and PEPC Films

Film	Redox species	C_p^0/mol cm^{-3} [a]	$E^{0\prime}$/V vs. SSCE [b]	ΔS_{rc}°/cal $mol^{-1}\,K^{-1}$ [c]
Nafion	$[Os(bpy)_3]^{2+/3+}$ [d]	6.6×10^{-5}	0.587±0.003	−8±2
Nafion	$[Os(bpy)_3]^{2+/3+}$ [d]	2.6×10^{-4}	0.584±0.003	−9±2
Nafion	$TAF^{+/2+}$ [d]	6.0×10^{-5}	0.326±0.003	−11±2
Nafion	$TAF^{+/2+}$ [d]	6.0×10^{-4}	0.328±0.003	−7±2
PFPC	$[Os(bpy)_3]^{2+/3+}$ [d]	1.4×10^{-4}	0.637±0.003	5±2
PFPC	$TAF^{+/2+}$ [d]	1.9×10^{-4}	0.385±0.003	−5±2
PFPC	$TAF^{+/2+}$ [e]	1.3×10^{-4}	0.419±0.003	−19±2

a) Concentration of redox species confined in films. b) Formal redox potentials for the redox couples confined in films at 298 K. c) Reaction entropies for the redox couples confined in films (see text). d) Supporting electrolyte: 0.2 M CF_3COONa+0.1 M CH_3COONa/CH_3COOH (pH 5.5). e) Supporting electrolyte: 0.2 M CF_3COONa (pH 1.0).

$[Os(bpy)_3]^{2+/3+}$ and $TAF^{+/2+}$ couples confined in the PFPC film are more positive than those of these couples confined in the Nafion film. Further, in the PFPC film, the reduced form of the $TAF^{+/2+}$ couple is more stabilized at pH 1.0 than at pH 5.5. Thus, the values of $E^{0\prime}$ for these two couples indicate the more dominance of hydrophobic interactions for the $TAF^{+/2+}$ couple, compared with the $[Os(bpy)_3]^{2+/3+}$ couple where hydrophilic interactions are more dominant. This is also supported by the data of the incorporation of TAF^+ and $[Os(bpy)_3]^{2+}$ into the PFPC film (mentioned in the previous section). The present data seem to suggest that the hydrophobicity of the $TAF^{+/2+}$ couple is larger than that of the $[Os(bpy)_3]^{2+/3+}$ couple, in contrast to the previously reported results.[16]

The negative reaction entropy differences (ΔS^0_{rc}) were obtained except for the PFPC-$[Os(bpy)_3]^{2+}$ system. These negative ΔS^0_{rc} values may suggest that the net solvent ordering in the vicinity of the redox species is less extensive in the oxidized state than in the reduced state in qualitative disagreement with the expectations from an electrostatic treatment (e.g., by the Born model[50]). This is considered as a result of the hydrophobic interactions between the redox species and the surroundings (in the swollen Nafion and PFPC films) that are enhanced in the reduced state, leading to increased solvent ordering and a decrease in entropy compared with that for the oxidized state. Large negative values of ΔS^0_{rc} have been recently reported for the $[Ru(NH_3)_6]^{3+/2+}$ couple confined in the PFPC film on graphite electrodes[16] and the ferricinium-ferrocene couple attached to platinum electrodes.[28] Negative values of ΔS^0_{rc} have also been observed for the bulk-solution blue copper proteins[53] and ferricinium-ferrocene couple.[54]

On the other hand, the positive ΔS^0_{rc} value obtained for the PFPC-$[Os(bpy)_3]^{2+}$ system may be explained as follows: The increased polarization of water molecules adjacent to the aromatic rings of $[Os(bpy)_3]^{2+}$ ions occurs in the higher oxidation sate and, as a result, the positive ΔS^0_{rc} is obtained.

Activation Parameters for Homogeneous Charge-Transport Process and Heterogeneous Electron-Transfer Reaction. From the data in Table 2, some thermodynamic aspects on the homogeneous charge-transport process within the Nafion and PFPC films containing $[Os(bpy)_3]^{2+}$ or TAF^+ can be drawn as mentioned below. For a given film, the values of both $\Delta H^{\neq}_{diffusion}$ and $\Delta S^{\neq}_{diffusion}$ for the TAF^+ complex are larger than those for the $[Os(bpy)_3]^{2+}$ complex.[60] The values of D_{app} for the former complex are smaller than those for the latter complex. Thus, the charge-transport processes within the films containing TAF^+ are more favorable entropically and more unfavorable enthalpically, compared with those within the films containing $[Os(bpy)_3]^{2+}$ and as a whole the smaller values of D_{app} for the TAF^+ complex are due to the larger $\Delta H^{\neq}_{diffusion}$. In the case of the PFPC-TAF^+ system, the D_{app}'s obtained at pH 1.0 and pH 5.5 are almost the same. This results from the mutual compensation of the $\Delta H^{\neq}_{diffusion}$ and $\Delta S^{\neq}_{diffusion}$ terms, although the absolute values of $\Delta H^{\neq}_{diffusion}$ and $\Delta S^{\neq}_{diffusion}$ are largely different at these both pH's. As mentioned in the previous section, the incorporation of the TAF^+ complex into the PFPC film is due to mainly hydrophobic interactions, while in the case of the Nafion and PFPC-$[Os(bpy)_3]^{2+}$ systems an electrostatic interaction is the main force for the incorporation of the $[Os(bpy)_3]^{2+}$ (and $[Os(bpy)_3]^{3+}$) complexes

Table 2. Activation Parameters for Homogeneous Charge Transport in Nafion and PFPC Films

Film	Redox species	C°_p/mol cm^{-3} [a]	D_{app}/cm^2 s^{-1} [b]
Nafion	$[Os(bpy)_3]^{2+/3+}$ [g]	6.6×10^{-5}	21×10^{-10}
Nafion	$[Os(bpy)_3]^{2+/3+}$ [g]	2.6×10^{-4}	11×10^{-10}
Nafion	$TAF^{+/2+}$ [g]	6.0×10^{-5}	8.0×10^{-10}
Nafion	$TAF^{+/2+}$ [g]	6.0×10^{-4}	7.9×10^{-10}
PFPC	$[Os(bpy)_3]^{2+/3+}$ [g]	1.7×10^{-4}	7.9×10^{-10}
PFPC	$TAF^{+/2+}$ [g]	1.9×10^{-4}	0.9×10^{-10}
PFPC	$TAF^{+/2+}$ [h]	1.3×10^{-4}	1.7×10^{-10}

Film	$\Delta H^{\neq}_{diffusion}$/kcal mol^{-1} [c]	$\Delta S^{\neq}_{diffusion}$ cal mol^{-1} K^{-1} [d]	
Nafion	6.5±0.5	−13±2 [e]	−3±2 [f]
Nafion	4.9±0.6	−23±2 [e]	−13±2 [f]
Nafion	10 ±1.0	7±2 [e]	16±2 [f]
Nafion	10 ±1.0	7±2 [e]	16±2 [f]

into these films. From the combination of these facts and the data in Table 2, it may be concluded that in the case of the incorporation by hydrophobic interactions both $\Delta H^{\neq}_{diffusion}$ and $\Delta S^{\neq}_{diffusion}$ are larger than those in the case of the incorporation by electrostatic interactions. In the latter case, an increase in C^0_p causes a decrease in D_{app}, and in this case the $\Delta S^{\neq}_{diffusion}$ values are negative and decrease with increasing C^0_p. Similar results have been previously obtained for protonated poly(4-vinylpyridine) film-$[W(CN)_8]^{4-}$ and $[IrCl_6]^{3-}$ systems.[4] Electrostatic cross linking and single-file diffusion effects seem to mainly be reflected as "negative" $\Delta S^{\neq}_{diffusion}$ values. In the case of the Nafion-TAF^+ system, the D_{app} values are almost independent of C^0_p and the $\Delta H^{\neq}_{diffusion}$ and $\Delta S^{\neq}_{diffusion}$ values are also independent of C^0_p.

The "real" entropy ($(\Delta S^0_{\neq})_{real}$)[21-23] of activation for the heterogeneous electron-transfer reaction of the $TAF^{+/2+}$ couple confined in the Nafion film is negative (close to zero)(-2 ± 1 cal mol^{-1} K^{-1}). This fact seems to be remarkable,[51] although at the present stage we have no satisfactory explanation for this. In the estimation of $(\Delta S^0_{\neq})_{real}$, the transmission coefficient (κ)[39] was assumed as unity. Thus, it may be also probable that if $(\Delta S^0_{\neq})_{real}$ has a "normal" positive value, κ should be smaller than 1 and thus the heterogeneous electron-transfer reaction would be nonadiabatic.[39,51]

55) The conventional positive feedback techniques[56,57] were used to compensate the resistances associated with the polymer coatings as much as possible. That is, a normal pulse voltammetric experiment was carried out in a potential region preceding the wave corresponding to the oxidation of $[Os(bpy)_3]^{2+}$ (or TAF^+) confined in Nafion (or PFPC) films, where the current was due almost entirely to double-layer charging. The extent of compensation was increased until the onset of oscillation and then it was reduced slightly. Using these techniques, the residual uncompensated resistance can be, though not completely, decreased below typically ca. several ohms.[58,59] By comparing the uncompensated resistance with the heterogeneous electron-transfer resistances which were in the range of a few hundreds to thousands (in ohm) (as typically shown in Fig. 8), we conclude that uncompensated resistance is not a major contributor to error in the measurement.

60) The differences between $\Delta S^{*}_{diffusion}$ values obtained for the $[Os(bpy)_3]^{2+}$ and TAF^+ complexes confined in Nafion films were 29—30 cal mol^{-1} K^{-1} and those obtained for the same complexes confined in PFPC films were 17—26 cal mol^{-1} K^{-1} (Table 2). These differences in $\Delta S^{*}_{diffusion}$ values are fairly larger than those (4—5 cal mol^{-1} K^{-1}) between the $\Delta S^{*}_{diffusion}$ values estimated using λ values ranging 1 to 5 Å[37,38] which have usually been used in a quantitative analysis of the process of diffusion.
61) The sulfonate ion-exchange sites of Nafion perfluorosulfonate and poly(*p*-styrenesulfonate) films show strong acid behavior ($pK_a<1$).[40]

The α-Helical Conformation of the Aib-Containing Oligopeptide, Boc-(Leu$_3$-Aib)$_2$-OBzl

Kenji Okuyama,* Nobuo Tanaka, Masamitsu Doi, and Mitsuaki Narita
Faculty of Technology, Tokyo University of Agriculture and Technology, Koganei, Tokyo 184
(Received February 19, 1988)

The octapeptide Boc-(Leu$_3$-Aib)$_2$-OBzl crystallizes in the space group $P2_1$, with a=11.450(2), b=27.915(7), c=11.255(2) Å, β=116.95(1)°, and Z=2. The crystal structure has been solved by direct methods and refined to an R value of 0.08. The peptide back-bone, except for the C-terminal Aib residue, folds into a right-handed α-helical conformation, stabilized by four intramolecular (5→1) hydrogen bonds and two intermolecular hydrogen bonds between molecules related by the 2_1 symmetry along the b direction. In order to determine the helical conformation definitively, the helical parameters (unit height h and unit twist θ) at each amino-acid residue were derived from the bond lengths, bond angles, and torsional angles of the peptide main chain. The average values of these parameters for seven residues (h=1.57 Å and θ=99.0°) showed much better agreement with those for an α-helix (h=1.5 Å and θ=100°) rather than with those for a 3_{10}-helix (h=2.0 Å and θ=120°). Peptide helices are arranged in columns in head-to-tail fashion. These columns are packed in parallel with respect to their helical direction. Between neighbouring chains of helices only hydrophobic contacts are found.

The membrane-channel-forming polypeptides, alamethicin and suzukacillin, contain a high proportion of α-aminoisobutyric acid (Aib) residues. As a result of the steric hindrance of the two methyl moieties linked to a C_α atom, the torsional angles, ϕ and ψ, of an Aib residue are severely restricted to the values near those associated with either the right- or left-handed α-helix (ϕ=±57°, ψ=±47°) and the 3_{10}-helix (ϕ=±60°, ψ=±30°).[1] Therefore, Aib-containing oligopeptides have shown a high tendency to the above helical conformations,[1] especially the 3_{10}-helical conformation. At least, up to pentapeptides, they have all been shown to adopt the 3_{10}-helix with the exception of Boc-Aib-Pro-Val-Aib-Val-OMe, in which the helix is stabilized by two types of hydrogen bonds, 5→1 and 4→1, indicating an α-helix and a 3_{10}-helix respectively.[2] Although the difference in the torsional angles of ϕ and ψ between the α-helix and the 3_{10}-helix is very small, the type of helix is important in many aspects. For example, the helical type affects its length and radius and also the distribution of hydrophobic amino-acid residues on the surface of a helix. These factors are very important in any study of the design of three-dimensional structures of peptides using the Aib residues.

Recently, Narita and Doi succeeded in improving the solubility of protected peptide fragments by utilizing the nature of the Aib residue to promote helical folding in peptides.[3] Boc-(Leu$_3$-Aib)$_2$-OBzl is one of the oligopeptides they prepared to demonstrate the above usefulness of Aib residues. The IR absorption spectra of the peptide both in dichloromethane and in the single-crystal state showed strong intensity bands at 3340—3320 cm^{-1} (amide A) and 1665—1659 cm^{-1} (amide I). This indicated a helical conformation (3_{10}- or α-helix) in both the solution and the crystal state.[4]

In our preliminary single crystal study of Boc-(Leu$_3$-Aib)$_2$-OBzl, the α-helical conformation was deduced from the intensity distribution of the meridional ($0k0$) and near-meridional reflections with the spacing in the range of 1.4—2.2 Å and by comparison of the molecular size and the lattice dimensions.[4] In this paper, we will discuss in detail the molecular and crystal structure of this oligopeptide and will also discuss its helical type by using helical parameters calculated from the bond lengths, bond angles, and torsional angles of the peptide main chain for each residue.

Materials and Methods

The Boc-(Leu$_3$-Aib)$_2$-OBzl was prepared by the step-by-step elongation and fragment condensation methods. The procedures have been reported in detail elsewhere.[3] Boc-(Leu$_3$-Aib)$_2$-OBzl powder (40 mg) was dissolved in 30 ml of aqueous methanol (methanol:water=2:1 by volume) at 50 °C. Subsequently, the solution was cooled slowly to room temperature. After several days, transparent, plate-like single crystals were obtained. The lattice parameters and diffraction intensities were measured on a Rigaku four-circle diffractometer with Ni-filtered Cu $K\alpha$ radiation (λ=1.542 Å). The lattice parameters were refined by the least-squares fit using 20 reflections in the 2θ range of 40—50°. By using the ω-scan mode for reflections with 2θ values less than 30°, and by using the 2θ–ω-scan mode for the other reflections, the intensities of 3391 reflections were collected up to 100° in 2θ. The intensity measurements were carried out at scan speeds of 8° min^{-1} for reflections with $0<F_o^2<200$, 4° min^{-1} for $200<F_o^2<600$, and 2° min^{-1} for $600<F_o^2$. The scan width was $\Delta\omega=(1.2+0.45\tan\theta)°$. Three reference reflections, monitored every 100 reflections, showed no significant intensity deterioration during the data collection. Corrections were made for the

Lorentz and polarization factors, but not for the absorption effect. A total of 2863 reflections greater than $3\sigma(F_o)$ were used in the following analysis.

The density was measured by means of a flotation method using a solution of carbon tetrachloride and toluene. On the basis of the measured density and the unit cell volume, the unit cell can be said to contain two oligopeptide molecules.

Crystal Data: $C_{56}H_{96}N_8O_{11}$, F.W.=1057.4, monoclinic, space group $P2_1$, Z=2, a=11.450(2), b=27.915(7), c=11.255(2) Å, β=116.95(1)°, V=3207(1) Å^3, D_x=1.093, D_m=1.09 g cm^{-3}, ρ(Cu $K\alpha$)=5.7 cm^{-1}.

Determination and Refinement of the Structure

The direct method with the SAPI87[5] program based on MULTAN-80[6] was applied to the $P2_1$ space group. After several cycles of block-diagonal least-squares refinement starting from the coordinates of all the non-hydrogen atoms of the oligopeptide obtained by the direct method, difference Fourier syntheses revealed no significant peak. After an anisotropic refinement of the non-hydrogen atoms, the hydrogen atoms located on their calculated positions with isotropic temperature factors were included in the refinement. The quantity minimized was $\sum\omega(|F_o|-|F_c|)^2$, with w=1.0 for all reflections. After several cycles, some hydrogen atoms with unacceptable geometry were excluded from further calculations. The final R value was 0.083 (R_w=0.077) for all the non-hydrogen atoms and 28 hydrogen atoms. The final atomic parameters for the non-hydrogen atoms are given in Table 1.[7]

The atomic scattering factors were taken from International Tables for X-Ray Crystallography, Vol. IV.[8] Computations were done on a HITAC M-280H computer at the Computer Center, University of Tokyo, with the help of the programs in UNICS III.[9]

Results and Discussion

For the convenience of atom specification, all the residues are numbered in series from the N- to the C-terminus. Therefore, the molecule of Boc-(Leu$_3$ Aib)$_2$-OBzl is denoted as Boc-Leu1-Leu2-Leu3-Aib1-Leu4-Leu5-Leu6-Aib2-OBzl. The atomic names in the Leu and Aib residues are those given in the IUPAC-IUB recommendations,[10] while those in the protected groups at N- and C-termini are shown in Fig. 1.

Peptide-Backbone Conformation. A perspective view of the molecule is shown in Fig. 1, together with a part of the upper molecule related by the 2_1-symmetry. The bond distances, bond angles, and torsional angles (ϕ, ψ, ω) of the peptide main chain are given in Table 2. The bond lengths of C_i^α-C_i' in

Leu1 (1.43 Å), Leu2 (1.47 Å), Leu4 (1.43 Å), and Leu5 (1.46 Å) are slightly shorter, while those of C'_i–N_{i+1} in Leu2 (1.41 Å), Leu3 (1.36 Å), Leu5 (1.37 Å), and Leu6 (1.35 Å) are slightly longer, than the values of 1.53 Å and 1.32 Å respectively derived by Pauling et al.[11] Because of the contact between the two methyl moieties linked to the C^α_i atom and the carbonyl oxygen, the bond angles of C'_{i-1}–N_i–C^α_i (126° and 128°) and N_i–C^α_i–C'_i (108° and 108°) in the Aib residues are significantly different from those in the Leu residues.

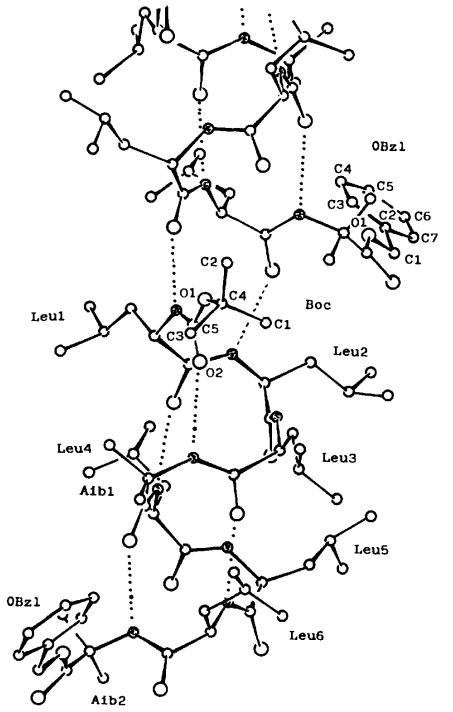

Fig. 1. Molecular structure of Boc-(Leu3-Aib)2-OBzl together with the atomic numbering in the terminal protected moieties (Boc and OBzl). The upper and lower side molecules are related to each other by a crystallographic 2_1 symmetry. Broken lines denote intra- and intermolecular hydrogen bonds.

All the peptide torsional angles, ω, showed a very good planarity. The values of the torsional angles, ϕ and ψ, showed that the octapeptide folds into a right-handed helix with the exception of the Aib2 residue at the C-terminus, in which the ϕ and ψ values belong to a left-handed helix. A change in the helical sense at the C-terminal Aib residue is usually observed in the oligopeptide helices with the protected moiety at the C-terminus.[12-14] This may be attributed to the bulky protected moiety linked to the Aib residue and the restricted conformation of the Aib residue. Since the ϕ and ψ values of an Aib residue are restricted to only two narrow regions, that is, near the right- or the left-handed α- (or 3_{10}-) helical regions, the helical sense of the C-terminus Aib residue has to be different from that of the preceding peptide region in order to avoid contact between the protected moiety and the rest of the molecule.

Since the allowed regions of torsional angles for the α-helix and the 3_{10}-helix almost entirely overlap in the ϕ–ψ map, it is not possible to decide a helical conformation on the basis of only the torsional angles in Table 2. Therefore, the helical conformation of Aib-containing oligopeptides have usually been determined by the intramolecular hydrogen bonding type, that is, the hydrogen bonds between the C=O group of Residue i and the N-H group of Residue i+3, which belong to the 3_{10}-helix, and those between Residue i and Residue i+4, which belong to the α-helix. However, even by the hydrogen-bonding type it is difficult to determine a helical structure definitively when the N-H groups of Residues i+3 and i+4 are both close to the C=O group of Residue i. In this study, therefore, the helical parameters were used as the criterion of the helical structure. They are the unit height (h) and the unit twist (θ), that is, the height per residue along the helical axis and the rotational angle per residue about the helical axis respectively. Assuming that each amino acid residue forms its own helix, the helical parameters are derived from its bond

Table 5. Hydrogen-Bond Parameters

Hydrogen bond	Bond length/Å (N···O)	Bond angle/° (N-H···O)
Intermolecular		
N(Leu 1)···O(Leu 5)	2.93	172
N(Leu 2)···O(Leu 6)	2.97	154
Intramolecular		
N(Aib 1)···O2(Boc)	3.22	162
N(Leu 4)···O(Leu 1)	3.01	167
N(Leu 6)···O(Leu 3)	3.02	175
N(Aib 2)···O(Leu 4)	3.06	176

lengths, bond angles, and torsional angles by the method of Sugeta and Miyazawa.[15] These values for each residue except for the C-terminus Aib2 are shown in Table 3. The average values are h=1.57 Å and θ=99.0°. Since the helical parameters for the α-helix and the 3_{10}-helix are h=1.5 Å and θ=100°, and h=2.0 Å, and θ=120°, respectively, it is obvious that the molecular conformation of Boc-(Leu$_3$-Aib)$_2$-OBzl is not a 3_{10}-helix, but an α-helix. This finding agreed with our previous conclusion from the X-ray intensity distribution of the meridional reflections and the consideration of the lattice dimensions.[4]

Side-Chain Conformations. The torsional angles in the Leu side chains are given in Table 4. The torsional angle of χ_1 (N-C_α-C_β-C_γ) is trans (Leu1, Leu2, and Leu3) or gauche (Leu4, Leu5, and Leu6), while those of χ_2 and χ_2' (C_α-C_β-C_γ-C_{δ_1} and C_α-C_β-C_γ-C_{δ_2}) are also trans or gauche, except in the Leu2 residue. The C_{δ_1} and C_{δ_2} atoms in the Leu2 residue cannot adopt either the trans or gauche conformation because of the short contact with the carbonyl oxygen atom of the Aib2 residue in the neighbouring molecule.

Hydrogen Bonds. The right-handed α-helical conformation of the peptide is stabilized by four intramolecular and two intermolecular hydrogen bonds (Fig. 1). The hydrogen-bond parameters are given in Table 5. All the lengths of the intramolecular hydrogen bonds are significantly longer than the mean value (2.9±0.1 Å)[16] usually observed in the peptide structures in which no Aib residues are included. This fact is also observed in other Aib-containing oligopeptides, such as Boc-(Ala-Aib)$_2$-Aib-OMe,[12] Boc-Leu-Aib-Pro-Val-Aib-OMe,[13] *p*-BrBz-(Aib)$_8$-O-*t*-Bu,[14] Boc-(Ala-Aib)$_2$-Ala-Glu(OBzl)-(Ala-Aib)$_2$-Ala-OMe,[17] and Boc-Leu-Aib-Pro-Val-Aib-Aib-Glu(OBzl)-Gln-Phl monohydrate.[18] This marked tendency of the Aib-containing peptides is probably due to the fact that the molecular conformations of these peptides are mainly determined by the stereochemical restrictions of the Aib residues rather than by the stabilization by the intramolecular hydrogen bonds. All the intramolecular hydrogen bonds listed in Table 5 are between the C=O group of Residue i and the N-H group of Residue i+4, which indicates the α-helical conformation. There is no hydrogen bond associated with N(Leu3) and N(Leu5). In the case of N(Leu3), there is no acceptor oxygen in the upper-peptide molecule because of the opposite helical sense at the C-terminal Aib2 residue. On the other hand, in the case of N(Leu5), the distance of 3.36 Å to the carbonyl oxygen in the Leu2 residue is

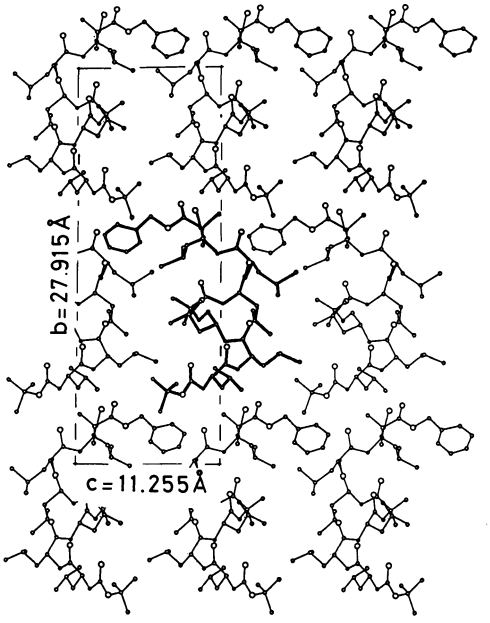

Fig. 2. Head-to-tail arrangement of Boc-(Leu$_3$-Aib)$_2$-OBzl molecules as viewed along the a direction. One molecule in a unit cell is drawn with bold lines.

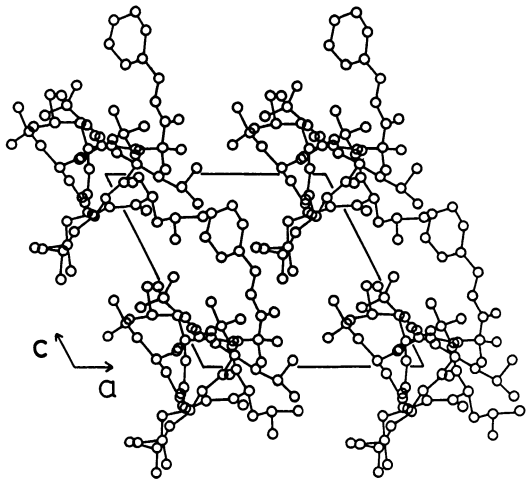

Fig. 3. Packing of octapeptide molecules in the crystal viewed along the *b* (helical) direction. For the sake of clarity only one molecule in the unit cell is shown.

fairly short, but too long as a hydrogen bond distance. In addition to the four intramolecular hydrogen bonds, two intermolecular hydrogen bonds, N(Leu1)···O(Leu5) of 2.93 Å and N(Leu2)···O(Leu6) of 2.97 Å, stabilize the helical conformation.

Crystal Structure of Boc-(Leu$_3$-Aib)$_2$-OBzl. Figure 2 shows the head-to-tail arrangement of the molecules as viewed along the *a* direction. The upper and lower molecules are related by the 2_1 symmetry along the *b*-axis and are linked head-to-tail by two intermolecular hydrogen bonds to form columns along this direction. These columns are arranged parallel with respect to their helical direction. The packing structure of Boc-(Leu$_3$-Aib)$_2$-OBzl molecules in the *ac*-plane is shown in Fig. 3. In this figure, only four equivalent molecules are illustrated; the molecules related by the 2_1 symmetry are omitted for the sake of clarity. Since the lattice dimensions of *a* and *c* are similar to each other, and since $\beta(=117°)$ is very close to 120°, the columns are packed pseudo-hexagonally. There is no hydrogen bond between laterally packed molecules, and only hydrophobic interactions stabilize the crystal structure. The benzyl moieties and the side chains of the Leu residues project from the helix core and interact with the neighbouring molecules (Figs. 2 and 3). The fairly short contacts between molecules are O(Leu5)···C7(OBzl) 3.47 Å, O(Leu5)···O1(Boc) 3.48 Å, O(Aib2)···C(Leu2) 3.39 Å, O(Aib2)···C(Leu1) 3.48 Å, and O(Leu6)···N(Leu1) 3.47 Å.

The authors wish to express their gratitude to Rigaku Corporation, for the permission to use a full-automatic X-ray structure analysis system (RASA-5RII) and to Mr. Toshihiko Hori, Rigaku Corporation, for his help with the intensity measurements.

Spectroscopic Studies on the Intramolecular Hydrogen Abstraction Reactions of *n*-Alkyl Anthraquinone-2-carboxylates

Yoshifumi TANIMOTO,* Megumu UEHARA, Masanobu TAKASHIMA, and Michiya ITOH
Faculty of Pharmaceutical Sciences, Kanazawa University, Takara-machi, Kanazawa 920
(Received March 30, 1988)

Chain length dependence of the intramolecular hydrogen abstraction reaction of *n*-alkyl anthraquinone-2-carboxylates (AQ-*n*, *n*=2—20) has been studied by steady-state photolysis, phosphorescence, laser flash photolysis, and two-step laser induced fluorescence spectroscopies. All the results indicate that the excited triplet of the anthraquinone chromophore abstracts a hydrogen atom from its methylene side chain, whose rate increases with increasing chain length. The rate constant of AQ-8 is 1×10^4 s^{-1} and the increase in the rate is about 1.5×10^4 s^{-1} per one additional methylene unit for $n\geqslant10$.

For many years chemistry and physics of bifunctional chain molecules have drawn much attention of polymer chemists, ESR and NMR spectroscopists, photochemists, photophysicists, and synthetic organic chemists, as reviewed in the literature.[1] It is because we can elucidate structural and energetic factors required in a reaction. Concerning with photochemistry, remote hydrogen abstraction of *n*-alkyl benzophenone-4-carboxylates, for example, have been extensively studied by Winnik and coworkers, to show how chain motion affects their photochemistry and photophysics.[2] In intramolecular excimer fluorescence of pyrene-$(CH_2)_n$-pyrene (*n*=2—22), fluorescence yields of the excimer were reported to be maximum at *n*=3 and minimum at *n*=7.[3] Switching of photochemical reaction pathways was found for redox reaction of a series of *N*-[ω-(*p*-nitrophenoxy)-alkyl]anilines.[4]

We have studied the magnetic field effects on the intermolecular hydrogen abstraction reaction of anthraquinones in aqueous sodium dodecyl sulfate (SDS) micellar solution, where a SDS surfactant acts itself as a hydrogen donor.[5] As intramolecular analogue of the reaction between excited triplet anthraquinone and SDS in a micelle, we designed a intramolecular reaction of anthraquinone with its methylene side chain. The excited triplet state is highly reactive compared with that of benzophenone so that the reaction processes may be followed precisely by time-resolved spectroscopic technique. This paper describes the effect of methylene chain lengths on photochemical and photophysical processes of *n*-alkyl anthraquinone-2-carboxylates, studied by steady-state photolysis, phosphorescence, laser flash photolysis, and two-step laser excitation fluorescence spectroscopies.[6]

Experimental

Chemicals. *n*-Alkyl anthraquinone-2-carboxylates (AQ-*n*, *n*=2—20) were synthesized by the condensation of anthraquinone-2-carboxylic acid sodium salt and *n*-alkyl bromides and purified by column chromatography and recrystallization. Typical analytical data of AQ-14 are as follows: mp 102 °C. IR(KBr) 2950—2840 (methylene), 1725 (aromatic ester), 1670 cm^{-1} (aromatic ketone). ^1H NMR (60 MHz, $CDCl_3$) δ=0.8—0.96 (t, 3H, CH_3-), 1.25 (s, 24H, $-CH_2-$), 4.23—4.45 (t, 2H, $-CO-O-CH_2-$), 7.63—8.80 (m, 7H, aromatic). Found: C, 77.64; H, 8.22%. Calcd for $C_{29}H_{36}O_4$: C, 77.64; H, 8.09%. Mass spectra; *m/z* 448 (M^+). Melting points of AQ-*n* are listed in Table 1.

EP Grade 1,1,2-trichloro-1,2,2-trifluoroethane (Freon 113) was purified by a column of basic aluminum oxide (1 m) and 3-methylpentane was distilled from $LiAlH_4$. Freon 113 was used in order to avoid intermolecular hydrogen abstraction reaction of AQ-*n* from solvent. Sample solutions were deaerated by several freeze-pump-thaw cycles, when necessary.

Apparatus. In steady-state photolysis, a 3 ml aliquote of the sample solution was irradiated with a 500 W xenon arc lamp filtered with a combination of a color glass (Toshiba UV-D33S) and a $NiSO_4$-$CoSO_4$ aqueous solution ($\lambda_{max}\approx330$ nm). The UV absorption spectral changes were recorded by a Hitachi U-3200 spectrophotometer.

Phosphorescence spectra were measured with a Hitachi MPF-4 spectrophotometer. The lifetimes were determined with an Ortec single photon counting system equipped with a PRA light pulser.

Transient absorption spectra were obtained by using an XeCl excimer laser (Lambda Physik EMG-50E, 308 nm) and a xenon arc lamp as an exciting and a probe light source, respectively. Transient signal on an Iwatsu TS-8123 storagescope was fed into a Fujitsu FM-11BS microcomputer for analysis.

Two-step laser induced fluorescence (TS-LIF) was measured by using an excimer laser (308 nm) and a N_2 laser-pumped dye laser (Molectron UV-12 and DL-14, 430 nm) as the first and the second laser. A homemade variable delay circuit was used for the timing of two lasers.

Table 1. Melting Points of *n*-Alkyl Anthraquinone-2-carboxylates (AQ-*n*)

n	Melting point/°C	*n*	Melting point/°C

Results

Steady-State Photolysis. Figure 1 shows a typical UV absorption spectral change of AQ-14 in Freon 113 solution upon photoirradiation, indicating photoreaction of this molecule. After photolysis, the solution becomes fluorescent as shown in the figure. Photoproducts, whose absorption and fluorescence bands appear around 350—500 and 450—600 nm, respectively, may be attributable to the cyclization products, since cyclic photoproducts in the photoinduced intramolecular hydrogen abstraction of *n*-alkyl benzophenone-4-carboxylates[2] and a fluorescent photoadduct of anthrasemiquinone to a SDS surfactant in the photoreaction of anthraquinone[5,7] were reported (see bellow).

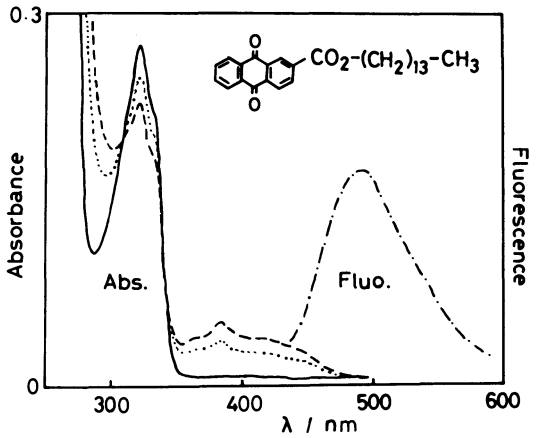

Fig. 1. Absorption and fluorescence spectra of AQ-14 in Freon 113 during photolysis. ——, before irradiation; -----, after 2 min irradiation, --- and —·—, after 4 min irradiation.

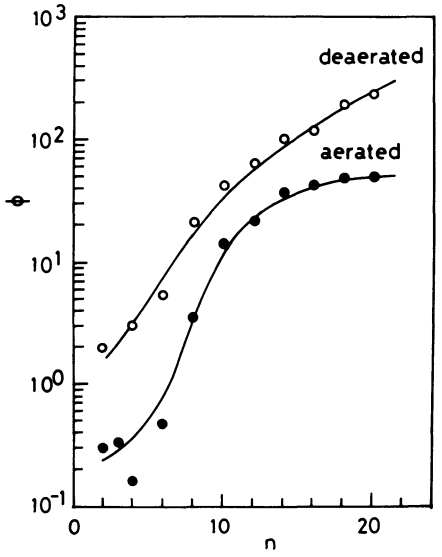

Fig. 2. Relative yields ϕ of disappearance of AQ-*n* in Freon 113.

Relative yield ϕ of disappearance of AQ-*n* were determined from the initial absorption intensity changes around 320 nm by the procedure described in a previous paper.[5] As shown in Fig. 2, ϕ is very small at shorter methylene chain length ($n<6$) and shows a sudden increase around $n=8$. Photolysis was also carried out in aerated Freon 113 solution of AQ-*n* (Fig. 2). The yields in aerated solutions are always smaller than those in deaerated solutions. The fact indicates that dissolved oxygen is also involved in the reaction though its mechanism is unknown at the present stage.

Phosphorescence. In order to clarify the primary step of the present photoreaction, we first examined the excited triplet of AQ-*n* by phosphorescence. Figure 3 shows phosphorescence spectra of AQ-*n* observed at room temperature and of AQ-2 at 77 K. In the spectra at room temperature, the band maxima appear at 435, 464, 502, 548, and 602 nm, and the shortest wavelength band at 435 nm disappears in the

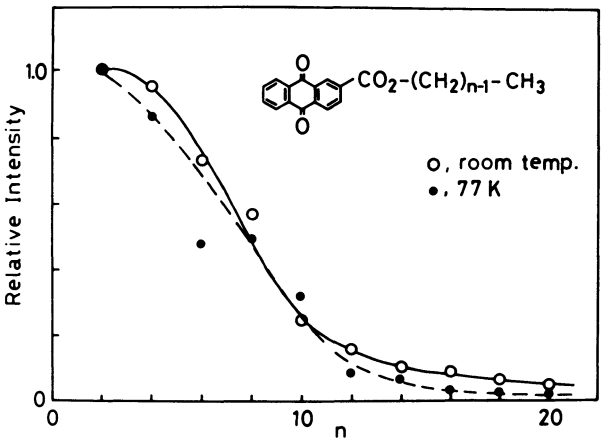

Fig. 4. Relative phosphorescence intensities of AQ-*n* at room temperature and 77 K. The intensities were normalized for that of AQ-2 at the respective temperature.

Table 2. Lifetimes (μs) of Excited Triplet State of AQ-n, Determined by Phosphorescence $\tau_P(n)$ and Laser Flash Photolysis $\tau_{LF}(n)$[a)]

n	τ_P	τ_{LF}	n	τ_P	τ_{LF}
2	75.8	48.7	12	11.9	10.0
4	70.4	42.9	14	7.9	7.3
6	52.3	38.1	16	6.8	6.0
8	40.7	30.4	18	5.5	5.2
10	19.0	12.6	20	4.3	4.5

Experimental errors are ±10 and ±20% for τ_P and τ_{LF}, respectively.

spectrum at 77 K. The energy difference between two successive bands are 1437, 1631, 1672, and 1637 cm^{-1}. Since the band progression from the second band is characteristic of the C=O stretching vibration, the 0–0 band of the phosphorescence is assigned to the one at 464 nm, and the lowest triplet state is of n,π^* nature. The assignment is compatible with the n,π^* nature of the lowest triplet state of anthraquinone.[8–11)] The shortest wavelength band at 435 nm, which disappears at 77 K, may be attributable to the emission from the thermally-populated higher triplet state. It is uncertain at the present stage whether it is the second triplet state or the vibronic state of the lowest one.[12)]

The relative phosphorescence intensities and lifetimes of AQ-n depend on the chain length n at room temperature as shown in Fig. 4 and Table 2, respectively. The lifetimes of AQ-n may be free from triplet-triplet (T–T) annihilation reaction, since they were obtained under low excitation density. Both phosphorescence intensities and lifetimes decrease with increasing the methylene chain length, n, suggesting that intramolecular reaction, i.e., hydrogen abstraction, is responsible for the lifetime of the excited triplet states. Furthermore, as shown in Fig. 4, the phosphorescence intensity dependence on the chain length observed at 77 K resembles that observed at room temperature. The facts may imply that the conformational distribution of the chain at room temperature is frozen at 77 K. Thus the phosphorescence lifetimes of AQ-n at 77 K may be determined by the intramolecular hydrogen abstraction. However, it is of interest that photoirradiation of AQ-14 in 3-methylpentane rigid matrix at 77 K did not show any appreciable change in its UV absorption spectrum. Probably, back reaction is fast in the rigid matrix because of conformational rigidity of the methylene chain in it.

Transient Absorption Spectra. Figure 5 shows transient absorption spectra of AQ-14 in Freon 113. As shown in the inset, decay of a transient absorption at 380 nm reaches a constant value around a 50 μs delay after laser excitation. In the transient absorption spectra at the present time scale (ca. 50 μs), there may be at least three species, i.e., excited triplet anthraquinone, semiquinone, and photoproducts. The absorption bands peaked around 380 and 500 nm, observed at a 1.2 μs delay, is mostly attributable to the T–T absorption of the anthraquinone chromophore. It is because similar spectra were observed for AQ-2, as shown in Fig. 5, and other molecules with n=3—20 in the μs time region, and the lifetime is comparable with its phosphorescence lifetime. On the other hand, the bands peaked around 380 and 450 nm, observed at a 33.5 μs delay, may be assigned to cyclization photoproducts, since they are similar to those of photoproducts observed in the steady-state photolysis (Fig. 1). The spectrum in the middle stage of the delay time might be attributable to the semiquinone radical, though its rigorous assignment is impossible. The decay of the semiquinone radical seems to be fast as observed in the reaction of the anthrasemiquinone radical in

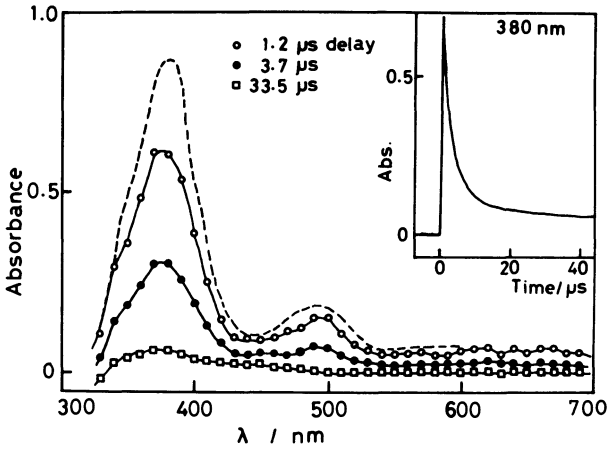

Fig. 5. Transient absorption spectra of AQ-14 in Freon 113. A broken line is the spectrum of AQ-2 at a 0.5 μs delay after laser excitation. Inset: A typical decay profile of transient absorption of AQ-14 monitored at 380 nm.

Table 3. Relative TS-LIF Intensities $I(n)$ and Risetimes $\tau_R(n)$ of AQ-n[a]

n	$I(n)$	$\tau_R(n)$ / μs
10	0.2	17.5
12	0.6	14.9
14	1.0	10.6
16	1.6	7.7
18	1.1	4.8
20	1.9	4.7

a) $I(n)$ are the intensities at a 70 μs delay after the first laser excitation. Experimental error is ±10—20%.

micellar solutions.[5]

In Fig. 6, transient absorption intensities at several delaytimes are shown as a function of n. The absorption intensities at a 4 μs delay decrease with increasing n, though those immediately after the laser excitation (1 μs delay) are almost independent of n. The n dependence of the absorption intensities at 4 and 20 μs delays is reflection of the lifetime shortening of the triplet states with increasing n. In contrast, the intensities at about 160 μs delay, which may be attributable to the photoproducts, gradually increases with increasing n, indicating the increase in the reaction yield with n.

The triplet lifetimes, estimated from the decay of the transient absorption at 380 nm, are listed in Table 2. The lifetimes estimated from the transient absorption are in good agreement with the phosphorescence lifetimes for longer methylene chain molecules (n=12—20). For the shorter chain molecules (n=2—6), triplet lifetimes estimated from the transient absorption is shorter than the phosphorescence lifetimes. This is mostly ascribed to the T–T annihilation due to the high excitation density in laser flash photolysis. Dependence of the lifetimes on n is almost the same as that of phosphorescence lifetimes. These observations present spectroscopic evidence that not physical but chemical quenching by methylene chain in the excited triplet determines its lifetime for long-chain molecules.

Two-Step Laser Induced Fluorescence. It was further attempted to monitor the initial yield of photoproducts with the aid of two-step laser induced fluorescence (TS-LIF) technique, since the cyclization products strongly fluoresce. This technique was proved to be effective to monitor the dynamics of fluorescent intermediates and products.[5,13] Figure 7 shows time-resolved TS-LIF spectra of AQ-14. The fluorescence band around 500 nm may be assigned to the photoproducts, since its spectrum and lifetime (22 ns) agree with those of photoproducts obtained from the steady-state photolysis (Fig. 1). As shown in the inset of Fig. 7, the fluorescence from photoproducts increases in intensity by increasing the delaytime between the first and second lasers, and

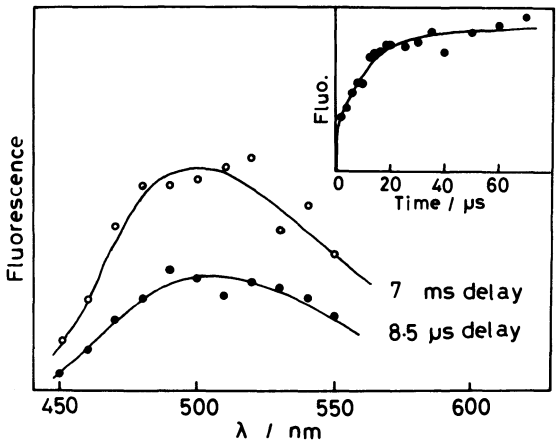

Fig. 7. Two-step laser induced fluorescence (TS-LIF) spectra of AQ-14 in Freon 113. Inset: Time profile of the TS-LIF intensity at 520 nm observed at several delaytimes.

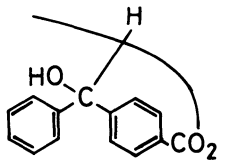
reaches a plateau around 50 μs or so.

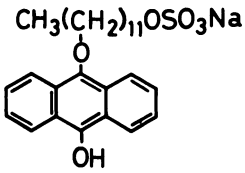
The relative yield and formation rate of the products were estimated from the relative TS-LIF intensities at a 70 μs delay and the growth curve of TS-LIF, respectively (Table 3). It is shown that the product yield determined by the TS-LIF increases with increasing n from 10 to 20, in accord with the increase in the formation rate (inverse of the risetime).

Discussion

A considerable effort has been made to elucidate photochemistry and photophysics of n-alkyl benzophenone-4-carboxylates (BP-n) by Winnik and coworkers.[2] According to their study, excited triplet benzophenone abstracts a hydrogen atom from its methylene side chain, leading to the cyclization products:



On the other hand, quite a few papers have been reported on the primary photochemical processes of quinones and benzophenones, in aqueous micellar solutions.[5,7,14–17] In micellar solution, their excited triplet states abstract a hydrogen atom from the methylene chain of a surfactant, resulting in the formation of an adduct of semiquinone (or ketyl radical) to the surfactant as a cage product. Upon photolysis of anthraquinone in micellar solution, the fluorescent products were obtained as the cage product:[7]



On analogy with the photoreactions mentioned above, photophysics and photochemistry of AQ-*n* may be described by the following scheme:

$$\text{AQ-}n \xrightarrow{h\nu} {}^1\text{AQ*-}n \quad (1)$$

$${}^1\text{AQ*-}n \longrightarrow {}^3\text{AQ*-}n \quad (2)$$

$${}^3\text{AQ*-}n \longrightarrow \text{AQ-}n + \text{phos.} \quad (3)$$

$${}^3\text{AQ*-}n \longrightarrow \text{AQ-}n \quad (4)$$

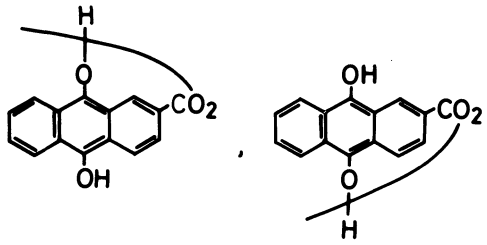
$${}^3\text{AQ*-}n \longrightarrow {}^3\text{BR} \quad (5)$$

$${}^3\text{BR} \rightleftharpoons {}^1\text{BR} \quad (6)$$

$${}^1\text{BR} \longrightarrow \text{P-}n. \quad (7)$$

The excited triplet state ^{3}AQ*-*n* of the anthraquinone chromophore is generated by the photoexcitation ((1) and (2)). While it phosphoresces (3), it abstracts a hydrogen atom from its methylene side chain, leading to a triplet biradical ^{3}BR. Triplet–singlet intersystem crossing of the biradical (6) results in the formation of a cage product P-*n*. Bimolecular reactions in the excited triplet ^{3}AQ*-*n* as well as those in triplet biradical might occur. A triplet biradical might be quenched by impurities. These reactions are not included in the scheme, though they might take place. In aerated solution, quenching of the excited triplet ^{3}AQ*-*n* as well as the biradical by dissolved oxygen may be responsible for the deactivation of the respective species.

As already shown for the reaction of *n*-alkyl benzophenone-4-carboxylates (BP-*n*),[2] the position of the hydrogen atom, which is abstracted by triplet anthraquinone, may spread over the polymethylenes, whose reaction probability seems proportional to the frequency of the collision of two sites. Further, in the present molecules, either one of two carbonyls at 9- and 10-positions, which are not equivalent with respect to the carboxyl group at 2-position, may abstract the hydrogen atom. Thus analysis of the reaction products is highly complicated. For example, in a thin-layer chromatogram of a photolyzed solution of AQ-14, at least four fluorescent products were detected, which may be isomers of different ring size, though chemical identification failed because of difficulty in isolation. These products change into nonfluorescent products upon aeration. This change is very similar to that described in the photoadduct of anthrasemiquinone to the surfactant in a SDS micellar solution, which may be attributable to the keto-enol isomerization.[7] Therefore, the main photoproducts are mostly ascribed to the coupling products at the two radical centers, i.e., cyclization products P-*n*:



All the observations mentioned in the previous section can be now discussed how the methylene chain length affects the intramolecular reaction efficiency between the excited triplet anthraquinone and the methylene side chain. In steady-state photolysis, the relative yield of disappearance of AQ-*n* increases with increasing the methylene chain lengths (Fig. 2), suggesting that the hydrogen abstraction of the excited triplet anthraquinone chromophore from its methylene side chain is responsible for the net photoreaction. This conclusion is confirmed from the phosphorescence, transient absorption, and TS-LIF measurements. Dependence of the phosphorescence intensities and lifetimes on methylene chain length *n* (Figs. 3 and 4, and Table 2) indicates that the excited triplet is quenched by the collision with its methylene chain. It is further verified, by transient absorption (Fig. 6 and Table 2) and TS-LIF (Table 3), that the quenching is not physical but chemical one, which generates biradicals, followed by the formation of fluorescent products. Collision between the carbonyl carbon atom at the anthraquinone chromophore in the excited state and the hydrogen atom at the methylene chain is a rate controlling step, whose frequency depends on the length of the chain. In the short-chain molecules, e.g., AQ-2, the steric hindrance avoids its reaction. In the long-chain molecules ($n \geqslant 10$), the reaction rate increases in accord with the collision frequency between the carbonyl and the methylene groups.

Now let's estimate the rate of hydrogen abstraction reaction. The lifetime $\tau_T(n)$ of the excited triplet ^{3}AQ*-*n* is given by the following equation,

$$1/\tau_T(n) = k_3 + k_4 + k_5(n). \quad (8)$$

By assuming that lifetime $\tau_T(2)$ of AQ-2 is determined only by the physical processes (3) and (4), the rate constant $k_5(n)$ of intramolecular reaction of AQ-*n* can be estimated as follows;

$$k_5(n) = 1/\tau_T(n) - 1/\tau_T(2). \quad (9)$$

Experimentally, lifetimes of the triplet state were obtained as phosphorescence lifetimes $\tau_P(n)$ and lifetimes $\tau_{LF}(n)$ of T–T absorption. Thus we can

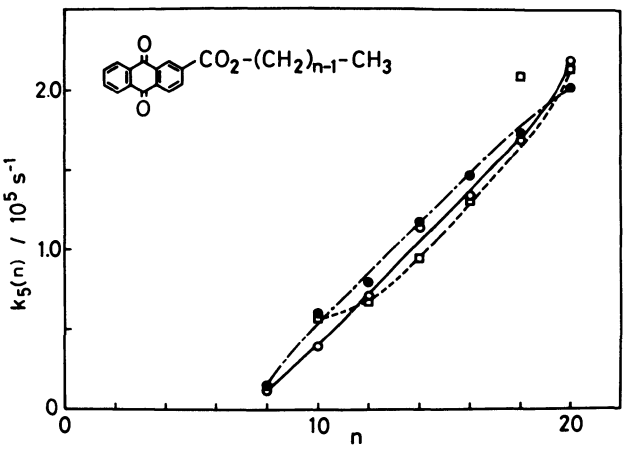


Fig. 8. Plots of the rate constant $k_5(n)$ of the intramolecular hydrogen abstraction against methylene chain length n. $k_5(n)$ were determined from phosphorescence lifetimes $\tau_P(n)$, ○, lifetimes $\tau_{LF}(n)$ of T–T absorption at 380 nm, ●, and risetimes $\tau_R(n)$ of photoproducts, □. See text.

determine $k_5(n)$ from the following equations:

$$k_5(n) = 1/\tau_P(n) - 1/\tau_P(2) \quad (10)$$

and

$$k_5(n) = 1/\tau_{LF}(n) = 1/\tau_{LF}(2). \quad (11)$$

The plots of Eqs. 10 and 11 against chain length n are given in Fig. 8. The $k_5(n)$ obtained by Eqs. 10 and 11 are in good agreement with each other as expected. In contrast with the phosphorescence lifetimes, triplet lifetimes of short-chain molecules ($n<8$) obtained from laser flash photolysis may be slightly shortened due to the T–T annihilation, which is not included in the above reaction scheme. For molecules with $n>8$, however, the triplet lifetimes are controlled predominantly by the rate $k_5(n)$ of intramolecular hydrogen abstraction.

In the TS-LIF measurements, the risetimes $\tau_R(n)$ of the fluorescence from the products may represent the formation rates. As discussed above, all the results indicate that the rate controlling step may be the reaction in the triplet state. If this is the case, the rate of product formation may be equal to the deactivation rate of the excited triplet,

$$1/\tau_R(n) = k_3 + k_4 + k_5(n). \quad (12)$$

Since $k_5(n) > k_3 + k_4$ for long-chain molecules as shown from the analysis of the excited triplet lifetimes, the following equation may approximately hold for $n \geqslant 10$:

$$k_5(n) \sim 1/\tau_R(n). \quad (13)$$

The plots of Eq. 13 against chain length n are also shown in Fig. 8. The k_5 values estimated from the risetimes of products (Eq. 13) coincide with those from lifetimes of the excited triplet states (Eqs. 10 and 11). The facts again demonstrate that the rate controlling step is the intramolecular hydrogen abstraction reaction in the excited state ^{3}AQ*-n for $n \geqslant 10$.

From the slope of the figure, we can conclude that the reaction rate of AQ-8 is 1×10^4 s^{-1} and the increase is 1.5×10^4 s^{-1} per one additional methylene unit for $n>8$.

Chain length dependence of intramolecular hydrogen abstraction of n-alkyl benzophenone-4-carboxylates (BP-n) has been studied by monitoring the disappearance yields and phosphorescence lifetimes of reactants.[2] BP-n shows methylene chain length dependence of the hydrogen abstraction rate in the triplet state similar to that of AQ-n mentioned above. In BP-n, the hydrogen abstraction rate of the benzophenone chromophore is 0.53×10^4 s^{-1} for $n=11$ and the increase is 0.46×10^4 s^{-1} per one additional methylene unit for $n>11$. When $n=14$, for example, the rates are 1×10^5 for AQ-14 and 0.18×10^5 s^{-1} for BP-14, respectively. Thus the rate constant of the former is about 5 times larger than that of the latter. The difference may be mainly attributable to the high reactivity of the anthraquinone triplet and partly to the existance of two reaction centers in the anthraquinone chromophore. Photochemical and photophysical similarity between AQ-n and BP-n implys that the photoreaction of AQ-n is conformationally controlled, in which conformational preequilibrium of the chain determines the reactivity, as theoretically analyzed for the latter.

Biomolecules Conform to the Rule of Topological Charge Stabilization

Jun-ichi AIHARA
Department of Chemistry, Faculty of Science, Shizuoka University, Oya, Shizuoka 422
(Received April 12, 1988)

Almost all biomolecules conform to the rule of topological charge stabilization. Heteroatoms are placed at the right sites in proteins, nucleoside bases, porphyrins, and related metabolites. It is noteworthy that typical redox-mediating coenzymes obey this rule both in the oxidized and reduced states. Thus, it is very likely that the rule of topological charge stabilization has been one of the most important guiding principles not only in chemical evolution but also in general biosynthesis.

Molecules containing one or more heteroatoms occur widely in nature. Nitrogen, oxygen, and sulfur are typical heteroatoms commonly found in biomolecules. These atoms are more electronegative than carbon and hydrogen.[1] Nucleic acids, proteins, coenzymes, and porphyrins all contain one or more π-electron subsystems containing heteroatoms. Considering that these molecules are biologically indispensable, it is a very important matter in chemistry and biochemistry to seek for the reason why they were chosen to construct living organisms. Why do the biomolecules contain many heteroatoms? What factors stabilize these molecules? Of course, it is never easy to answer these questions. Even partial answers will mark an important progress in the study of biosynthesis and molecular evolution.

In 1983 Gimarc pointed out that the pattern of charge densities in a molecule is determined mainly by the connectivity or the topology of the molecule.[2] Nature tends to place heteroatoms of great electronegativity in those positions where the isostructural, iso-π-electronic hydrocarbon has large charge densities.[2-4] Gimarc called the effect the rule of topological charge stabilization or the TCS rule. He showed that generally a molecule conforming to this rule is stable in our chemical sense.[2-4] In previous papers[5,6] the TCS rule was successfully used to explain the stability of so-called quasi-aromatic molecules and various organic molecules formed in primitive-Earth-simulation experiments.

This paper aims at rationalizing the stability of nucleoside bases and other important biomolecules in terms of Gimarc's TCS rule. We will show below that very many biologically important molecules are stable owing to the presence of heteroatoms at the right sites. As will be seen, most heteroatoms in every biomolecule are situated in such a manner that they attain the maximum thermodynamic stability of the whole conjugated system. Ketone oxygen and imine nitrogen contriburte one π electron to the conjugated system, whereas amine nitrogen and alcohol (or ether) oxygen contribute two π electrons instead of one.

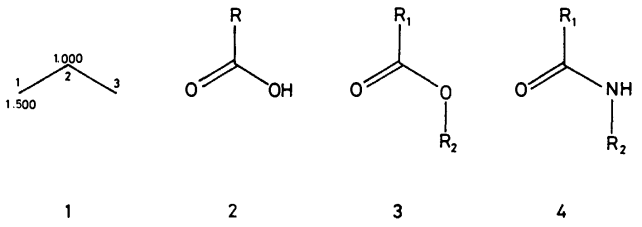
Results and Discussion

Charge densities calculated for a molecule containing heteroatoms depend on the choice of semiempirical parameters, but in the iso-π-electronic hydrocarbon all Coulomb integrals are uniform and charge densities are determined only by the topology of the molecule and the number of π electrons.[7] To emphasize this fact, Gimarc[2-4] referred to the isostructural, iso-π-electronic hydrocarbon as the uniform reference frame (URF). It is a (hypothetical) conjugated hydrocarbon obtained by replacing all the heteroatoms in a given molecule by sp^2 carbons and then by donating the same number of π electrons to the resulting conjugated system. The URF is, of course, not identical with a real molecule. It is charge densities in such URF's that the TCS rule adopts to estimate the stability of biomolecules containing heteroatoms. First-order perturbation theory has given a justification for the TCS rule.[3]

All charge densities given below will be those calculated for the π-electron systems of the URF's. We used the Hückel molecular orbital (HMO) model in its simplest form unless otherwise stated. The simple HMO model is known to yield exaggerated charges, but experience shows that they are adequate for the present purpose which requires only a qualitative pattern of charge distributions.[2] We assumed that the Coulomb integral has the same value for all carbons and that the resonance integral has the same value for all π bonds. All alkyl substituents will be disregarded for simplicity because they are scarcely conjugated with the parent π-electron framework.

Carboxylates and Peptides. Consider the allyl anion $C_3H_5^-$ (**1**), in which a central carbon is connected to two edge carbons. The conjugated system is composed of four π electrons moving through the three constituent carbons. The calculated charge density is greater at the edge carbons than at the central carbon. This anion represents the URF of the carboxyl group (**2**) not conjugated with the remainder of the molecule (R in **2**). Many carboxylic acids (**2**), carboxylic esters (**3**), and naturally occurring amino acids have this type of carboxyl groups. Here and hereafter R and R_i (i=1, 2, 3, ···) represent the substituents not conjugated with the π-electron system in question.

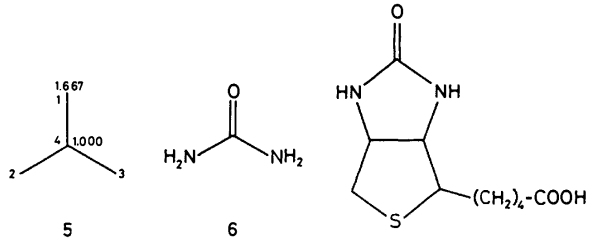
Topological charge stabilization says that electronegative heteroatoms prefer to occupy the sites where



1 2 3 4

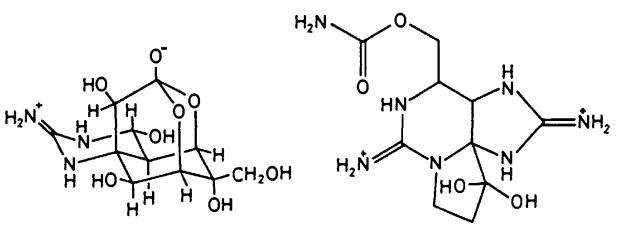
electron density is already very great in the iso-π-electronic URF.[2-4] Oxygen is much more electronegative than carbon.[1] Stability of carboxylic acids and carboxylates is attributable to the two constituent oxygens because these atoms occupy the two sites of greatest charge density in the URF. Individual peptide bonds in protein (**4**) are not conjugated with each other. They are also iso-π-electronic with the allyl anion (**1**). Stability of all proteins can thus be explained in terms of the TCS rule. This is possibly the primary reason why insulating methylenes intervene between adjacent peptide bonds.

Urea and Toxins. Gimarc considered the trimethylenemethane dianion $C(CH_2)_3^{2-}$ (**5**) as a URF of such common inorganic species as CO_3^{2-}, NO_3^- and SO_3.[2] The conjugated system of **5** is composed of six electrons moving through four carbons. The calculated charge density is greater at the peripheral carbons than at the central carbon. Naturally occurring CO_3^{2-}, NO_3^-, and SO_3 are very stable because all oxygens are located at the peripheral positions to achieve the maximum energy stabilization. Note that oxygen is more electronegative than nitrogen and sulfur.[1]

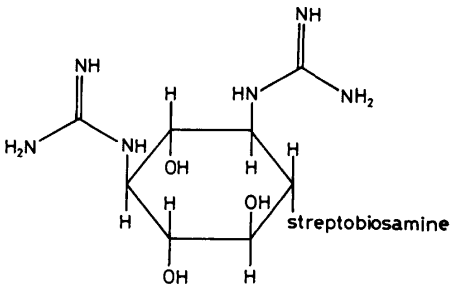


5 6 7

The trimethylenemethane dianion (**5**) also constitutes the URF's of urea (**6**) and biotin (**7**, growth factor). Analogous π-electron systems are found in many other biomolecules. For example, tetrodotoxin (**8**, swellfish toxin), saxitoxin (**9**, shellfish toxin), and streptomycin (**10**, antibiotic) have one, three, and two conjugated subsystems, respectively, which are all iso-π-electronic with urea. In these biomolecules nature puts oxygens and/or nitrogens at the peripheral positions of the trimethylenemethane framework where topology tends to distribute more charge density. These examples nicely illustrate the theory that the conformity to the TCS rule gives a stable molecular system.[2-4] Urea, biotin, tetrodotoxin, streptomycin, and saxitoxin are all Y-aromatic species.[8]

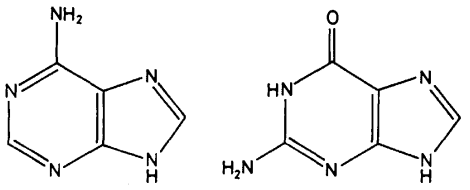


8 9

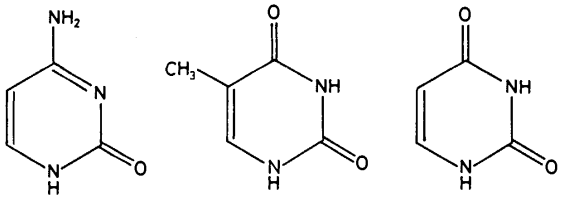


10

Nucleoside Bases. The purine and pyrimidine bases are key components of nucleic acids. Adenine (**11**), guanine (**12**), cytosine (**13**) thymine (**14**), and uracil (**15**) are principal nucleoside bases. The structural formulas **11**—**15** represent the bases in the tautomeric form which predominates according to spectroscopic analyses: the keto and amino form.[9,10] This form is favored in nucleic acids over the enol and imino form. In the present study, there is no need to discriminate between these two forms since both give the same URF. Even if a given base undergoes tautomerization, positions of the heteroatoms remain unchanged.



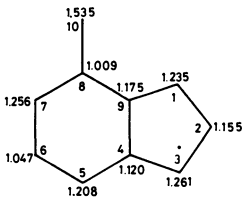
11 12



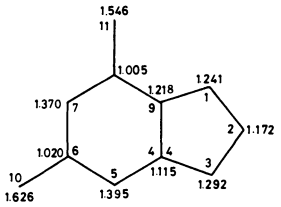
13 14 15

The URF's of two purine bases **11** and **12** are shown in **16** and **17**, respectively. Heteroatoms in these bases, without exceptions, are situated at the sites of large

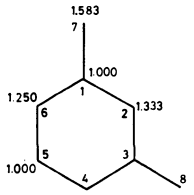
charge density in the corresponding URF's. It is noteworthy that all exomethylene carbons in these URF's (i.e., carbon 10 in **16** and carbons 10 and 11 in **17**) have high charge density. All these sites are occupied by amine nitrogens or ketone oxygens in the purine bases. All positions of high charge density in the URF's are occupied by heteroatoms in the corresponding purine bases. Three pyrimidine bases **13**, **14**, and **15** happen to have the same URF (**18**) with ten π electrons. It is clear that heteroatoms in these bases occupy the sites of high charge density in their common URF. Therefore it seems very likely that nature selected these nucleoside bases as parts of gene because they are not only stable but also easy to form.



16



17



18

The nucleoside bases in the keto and amino form fit the base-pairing scheme of Watson and Crick for double-stranded DNA, whereas those in the enol and imino form do not. However, the charge density distribution in the URF of each base is not consistent with the keto and amino form. All exomethylene carbons in the URF are high in charge density as compared with ring carbons. The enol and imino form is favorable from this point of view since alcohol (or ether) oxygen attracts much more charge than ketone oxygen. This discrepancy might represent the limitation of the TCS rule.

There are many biomolecules which have either a purine or pyrimidine nucleus. Among purine bases and alkaloids are hypoxanthine (**19**), xanthine (**20**), caffeine (**21**), theophylline (**22**), theobromine (**23**), and uric acid (**24**). The URF of hypoxanthine is the same as that of adenine (**16**). The URF's of xanthine, caffeine, theophylline, and theobromine are all identical with that of guanine (**17**). The URF of uric acid is shown in **25**. Among biological pyrimidines are 5-methylcytosine (**26**), 5-(hydroxymethyl)cytosine (**27**), and orotic acid (**28**). The URF's of **26** and **27** are identical with that of cytosine. The URF of orotic acid is shown in **29**. All these molecules conform to the TCS rule.

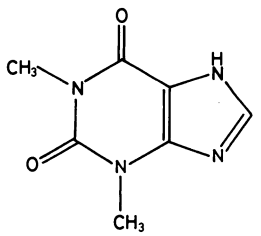
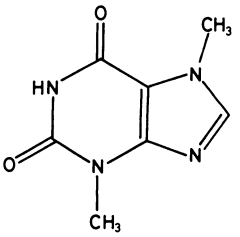
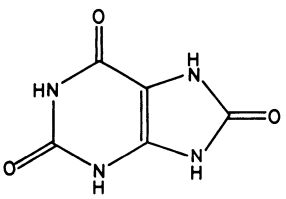
21



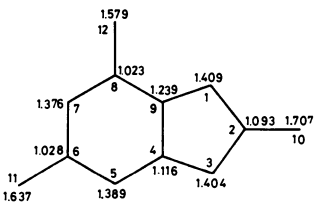
22



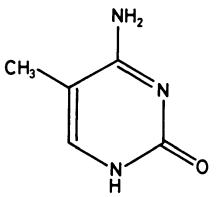
23



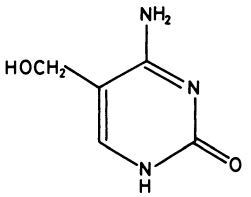
24



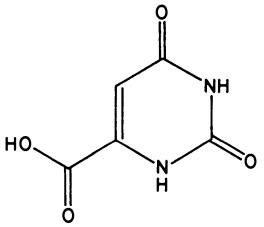
25



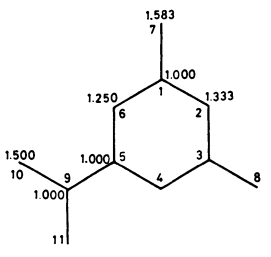
26



27

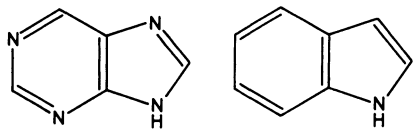


28

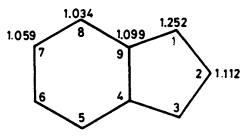


29

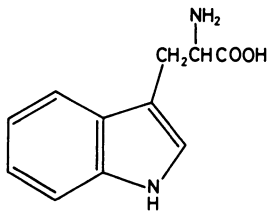
Unsubstituted purine and pyrimidine are not biomolecules. The calculated charge densities of the URF's of these molecules are not useful for rationalizing the positions of heteroatoms in nucleoside bases. The sites of high charge density in the URF's change by substitution. Furthermore, valence tautomerization sometimes occurs by substitution.[9,10] Unsubstituted purine (**30**) is iso-π-electronic with indole (**31**). Therefore, both have the same URF (**32**). A single indole nitrogen is located at one of the sites of greatest charge density in the URF. Thus, indole is stabilized by topological charge distribution, so are tryptophan (**33**) and many indole alkaloids. Indole is found in coal tar.



30 31



32

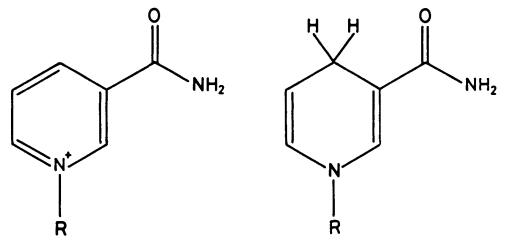


33

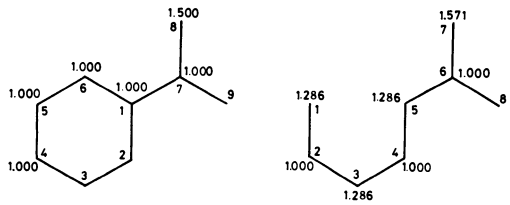
According to the original TCS rule,[2] one does not need to place heteroatoms at all sites of high charge density in the URF to stablize molecules. Indole indeed has one amine nitrogen at one of the sites of largest charge density in the URF. One nitrogen is enough to stabilize the indole conjugated system although there is one more site of largest charge density in the URF. Position 6 in the URF of pyrimidine bases (**18**) has high charge density, but these bases has no heteroatom there. In contrast, heteroatoms in **2**—**4**, **6**—**12**, and **19**—**24** are located at all sites of high charge density in the corresponding URF's. We might say that these biomolecules are extremely faithful to the TCS rule.

Coenzymes. Biological oxidation and reduction are catalyzed by enzymes, each of which functions in conjunction with a coenzyme which acts as an electron carrier. There are a number of oxidative enzymes but relatively few coenzymes.[11] These coenzymes are involved in many biological oxidation–reduction reactions. Biotin (**7**) acts as a coenzyme responsible for the transfer of carbon dioxide in carboxylation reactions.

There are two coenzymes which contain nicotinamide as an active center: namely, nicotinamide-adenine dinucleotide (NAD^+) and nicotinamide-adenine dinucleotide phosphate ($NADP^+$). NAD^+ ($NADP^+$) is reduced during the enzymatic reaction to give the dihydropyridine derivative NADH (NADPH). Their oxidized and reduced forms have the general formulas shown in **34** and **35**, respectively. The presence of a carbamoyl group ($-CONH_2$) in nicotinamide (**34**) is consistent with the charge density distribution in the URF (**36**, ten π electrons), whereas the ring nitrogen does not correspond to the site of high charge density in the URF. However, it seems unlikely that **34** is greatly destabilized by the ring nitrogen of the imine type.



34 35

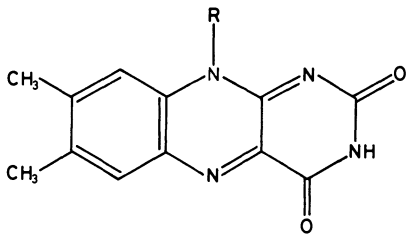


36 37

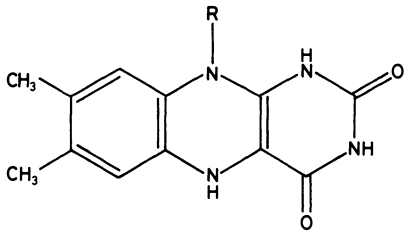
Let us consider the relative electron-attracting abilities of heteroatoms concerned. Amine nitrogen is a combination of N^{2+} and two π electrons, whereas imine nitrogen is a combination of N^+ and one π electron. Likewise, alcohol oxygen is a combination of O^{2+} and two π electrons, whereas ketone oxygen is a combination of O^+ and one π electron. The electron-attracting ability is then in the order: alcohol oxygen>amine nitrogen$\gg$ketone oxygen>imine nitrogen.[1] Considering that imine nitrogen is least electronegative, it seems unlikely that the imine nitrogen not situated at the right site destabilizes the π-electron system to a great extent. It is presumably for this reason that pyridine is as stable as benzene. The situation is essentially the same for nicotinamide (**34**). However, if alcohol oxygens and/or amine nitrogens are introduced into a given π-electron system, it is highly desirable for these atoms to occupy the sites of high charge density in the URF.

The URF of the reduced form of nicotinamide (**37**, ten π electrons) rationalizes the existence of three heteroatoms without any reservation. The ring nitrogen is now converted to amine nitrogen. It is then very desirable for this atom to occupy the site of high charge density in the URF. As shown in **37**, the amine nitrogen really occupys one of the sites of high charge density in the URF. Thus, three heteroatoms are required to stabilize both NAD^+ ($NADP^+$) and its reduced species.

There are two coenzymes which contain dimethylisoalloxazine as an active center: flavin mononucleotide (FMN) and flavin-adenine dinucleotide (FAD). These flavin coenzymes can be formulated as shown in **38**. They are formed in vivo from riboflavin (vitamin B_2), which can also be formulated as **38**. The isoalloxazine nucleus of a flavin coenzyme (oxidized form) is reduced during the enzymatic reaction to give the dihydro derivative or the reduced form (**39**). The yellow color of the flavin coenzyme disappears on reduction since the reduced form is colorless.

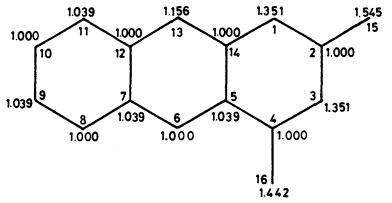


38

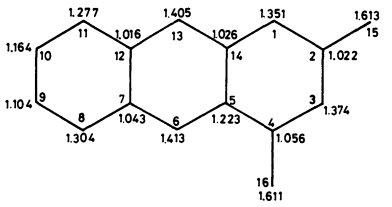


39

The URF of isoalloxazine (**40**, 18 π electrons) has large charge density at positions 1, 3, 13, 15, and 16. The corresponding positions in isoalloxazine are all occupied by electronegative heteroatoms. Position 6 in the URF is also occupied by a heteroatom (imine nitrogen) although it does not have very high charge density. This can again be rationalized by examining the charge density distribution in the URF of the reduced species (**41**, 20 π electrons). On reduction two imine nitrogens in isoalloxazine are converted into amine nitrogens. These amine nitrogens are assuredly placed at the sites of high charge density in the URF of the reduced form. Thus, imine nitrogen at position 6 in isoalloxazine is needed to stabilize its dihydro derivative. As mentioned above, imine nitrogens presumably influence the isoalloxazine conjugated system to a lesser extent. All sites of high charge density in **41** are occupied by heteroatoms in reduced isoalloxazine (**39**).

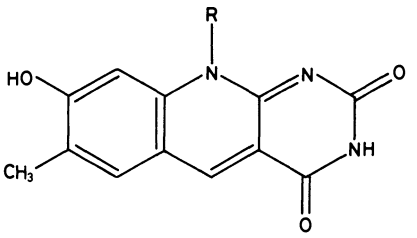


40

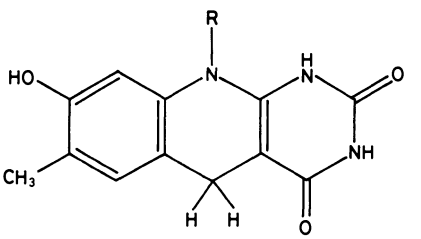


41

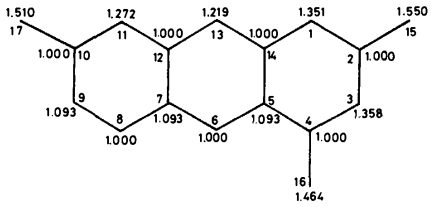
It is interesting to note that there are deazaflavin coenzymes,[12] which are structurally analogous to flavin coenzymes. It is a predominant cellular constituent in anaerobic methanogenic bacteria which biosynthesize methane. These bacteria are thought to be descendants of primordial organisms. Deazaflavin coenzymes (**42**) are likewise reduced during the enzymatic reaction to give the dihydro derivatives (**43**). The URF's of the oxidized and reduced forms are shown in **44** and **45**, respectively. Both forms have 20 π electrons each. All heteroatoms in **42** and **43** occupy the sites of high charge density in **44** and **45**, respectively. One carbon corresponding to position 6 in **44** is excluded from the conjugated system on



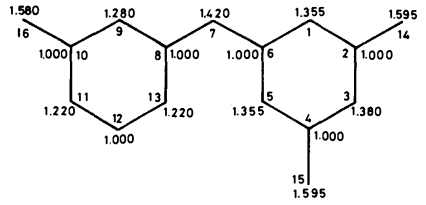
42



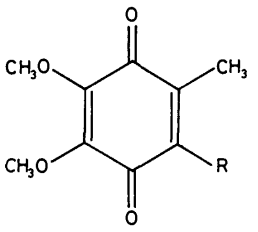
43



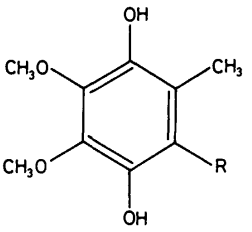
44



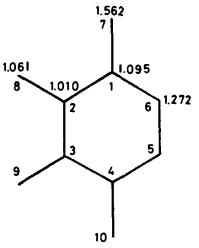
45



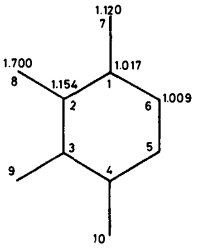
46



47



48



49

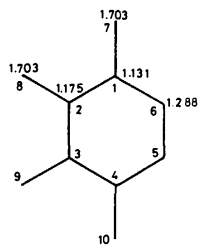
reduction. Therefore, there is no need to replace carbon 6 by nitrogen to stabilize the reduced form. Thus, the deazaflavin conjugated system is a functional hybrid between monocyclic nicotinamide and tricyclic flavin coenzymes.[12]

Mitochondria contain a quinone called ubiquinone which has the general structure **46**. The biological function of ubiquinone in redox reactions depends upon the reversible reduction to the corresponding hydroquinone (**47**). The URF of ubiquinone (**48**, 12 π electrons) has high charge density at positions 7 and 10. Two ketone oxygens are placed at the corresponding positions in the coenzyme. However, the positions of two methoxyl oxygens do not conform to the TCS rule. Charge density is not high at the corresponding positions (i.e, carbons 8 and 9) in the URF. Ubiquinone apparently constitutes an exceptional biomolecule, in the sense that highly electronegative methoxyl oxygens occupy the sites of low charge density in the URF.

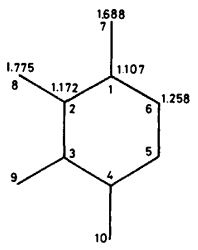
This difficulty may be resolved in the following manner. Remember that carbons 8 and 9 in the URF of ubiquinone are to be replaced by methoxyl oxygens, but not by ketone oxygens. In general, a resonance integral between ether oxygen and carbon is relatively small.[7] Therefore, it might be meaningful to decrease the resonance integrals between carbons 2 and 8 and between carbons 3 and 9 in the URF of ubiquinone tentatively to 80% of the standard value. Such modification of the URF can be justified by the fact that ubiquinone has no possibility of valence tautomerization. The charge densities in the modified URF is shown in **49**. Then, we have largest charge density at carbons 8 and 9, which can now be replaced reasonably by methoxyl oxygens to give the ubiquinone conjugated system. Such a drastic change in charge densities was caused by the exchange of the sixth and seventh molecular orbitals. These two orbitals are accidentally very close in energy to each other in the unmodified URF.

Unfortunately, another diffuculty arises with the modified URF of ubiquinone (**49**). Charge densities at carbons 7 and 10 are greatly reduced in this URF, and it seems that the presence of two ketone oxygens is not so effective for stabilizing the conjugated system. In this context, it is well-known that exomethylene carbons in an organic molecule generally are very reactive with high reactivity indices. For example, 3,6-dimethylene-1,4-cyclohexadiene cannot be isolated, whereas *p*-benzoquinone is fairly stable and isolable. Ketone oxygens are obviously helpful for stabilizing exocyclic doube bonds. The presence of two ketone oxygens in ubiquinone can be rationalized in this manner.

Methoxyl oxygens in ubiquinone play an important role when it is converted to the reduced form. The URF of the reduced form (**50**, 14 π electrons) has high charge density at positions 7, 8, 9, and 10. Thus, the four alcohol (or ether) oxygens are placed at these positions to stabilize the reduced form. The modified URF of the reduced form (**51**) was defined using the same resonance integrals as those in the modified URF of ubiquinone (**49**). It has a charge density distribution similar to **50**.

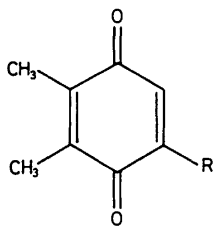


50

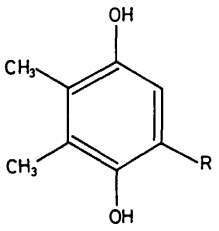


51

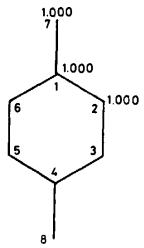
In photosynthesis plastoquinone (**52**) participates in reversible oxidation-reduction reactions. When plastoquinone is reduced during the reaction, the corresponding hydroquinone (**53**) is formed. Charge density is uniform over the URF of plastoquinone (**54**, eight π electrons). For the same reason as that given for ubiquinone, two exomethylene carbons in the URF are replaced by ketone oxygens in plastoquinone. The URF of hydroquinone (**55**, ten π electrons) has high charge density at positions 7 and 8. Two alcohol oxygens are placed at the corresponding positions in **53**. It follows that two oxygens are needed to stabilize both the oxidized and reduced forms of plastoquinone.



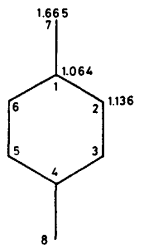
52



53



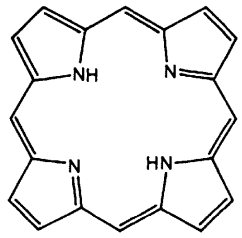
54



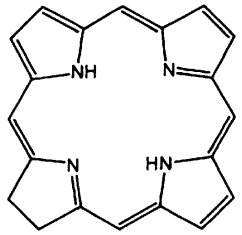
55

As has been seen above, it is very interesting that heteroatoms in representative redox-mediating coenzymes are arranged in such a manner that both the oxidized and reduced forms fulfill the TCS rule. Nature must have designed these molecular systems, taking into account the fact that amine nitrogen and alcohol (or ether) oxygen attract much more negative charge than imine nitrogen and ketone oxygen. The latter two atoms are sometimes introduced at sites of low charge density in the URF.

Porphyrins and Chlorophylls. All forms of life rely on the unique redox and electron-transfer abilities of hemoproteins and/or chlorophylls.[13,14] Active sites of hemoproteins and chlorophylls are the porphine (**56**) and chlorin (**57**) macrocycles, respectively, each acting as a ligand for a particular metal ion. Exactly speaking, chlorin represents a molecule formed by adding two hydrogens to the peripheral positions in the D-ring of any porphyrin. However, the term chlorin is here restricted to the unsubstituted chlorin nucleus (**57**). Although various substituents are usually attached to these molecules, we first disregard them all and evaluate the charge densities in metal-free porphine (**56**) and chlorin (**57**).

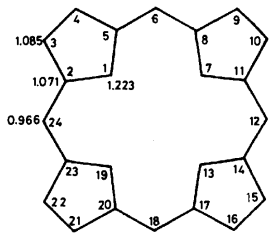


56

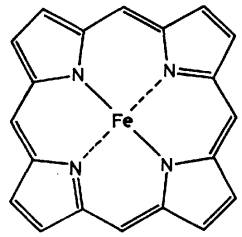


57

Pyrrole nitrogens in porphine (**56**) are located at those positions which have greatest charge density in the URF (**58**, 26 π electrons). Exactly the same observation was made over 35 years ago by Longuett-Higgins et al.[15] Historically, they were the first to introduce the idea of topological charge stabilization.[2] They noted that the great stability of porphine is largely due to the presence of nitrogens at positions in the skeleton where, for purely geometrical reasons, the π-electrons tend to congregate.[15] The TCS rule holds for **56**. Hemoproteins have an iron(II) ion at the center of every porphine nucleus. The metal ion is scarcely conjugated with the π-electron system of the porphine.[16] Therefore, there is no need to devise a different URF for the metal-porphine complex (**59**). In biosythesis the iron(II) ion is inserted after the formation of the porphine nucleus, and tightly bound to it.[13]



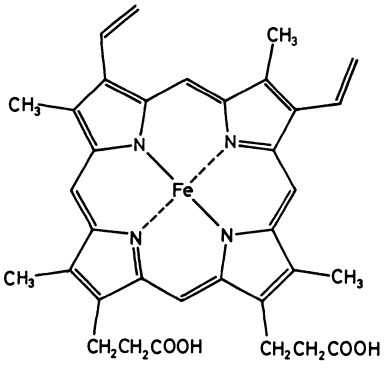
58



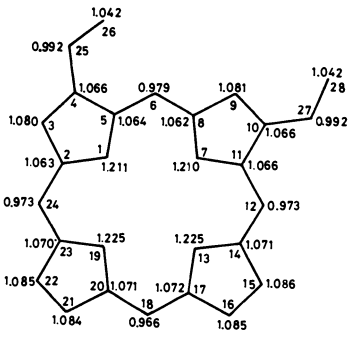
59

Substituted porphines have been referred to as porphyrins. All naturally occurring porphyrins have various substituents, most of which are not conjugated with the porphine nucleus. Heme (**60**) is an iron(II) complex of a porphyrin molecule called protoporphyrin. Human myoglobin and hemoglobin contain one and four heme molecules, respectively. The heme molecule not bound to protein has eight substituents, only two of which are conjugated with the porphine nucleus. As exemplified by **60**, vinyl and/or carbonyl groups in porphyrin are conjugated with the porphine nucleus. However, these substituents never displace the sites of large charge density in the URF. Compare the charge densities in the URF of porphine (**58**) with those in the URF of heme (**61**).

In generatal, a vinyl substituent is fairly reactive. Therefore, an alkyl group or the like is ofter attached to its β position. Otherwise, it is often replaced by the carbonyl substituent. When such a heme molecule is incorporated in protein, unsaturated substituents are used to bond the protein and become saturated ones.

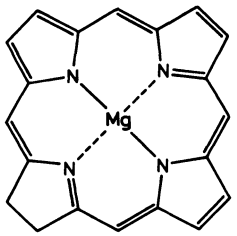


60

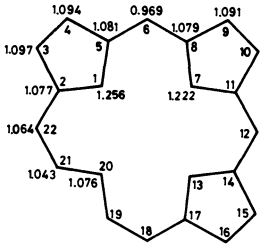


61

Chlorophylls have a magnesium-chlorin nucleus (**62**) with no carbon-carbon double bond in the D-ring. The calculated electron densities in the URF of chlorin (**63**, 24 π electrons) are highest at carbons 1, 7, and 13. There are nitrogens in the corresponding positions of chlorin. However, this molecule has one more nitrogen at position 20, the presence of which is not expectable from the URF (**63**). In the chlorophyll biosynthesis, the magnesium ion is inserted into the porphine nucleus in protoporphyrin.[13] After that, the reduction of the D-ring double bond occurs. Nitrogen at position 20 is thought to have been introduced to stabilize the metal-free porphine nucleus. After the reduction of the D-ring double bond all the four nitrogens are used to bind the magnesium ion tightly. If the magnesium ion is removed from chlorophyll, nitrogen at position 20 will be of the imine type. The magnesium ion is not conjugated with the π-electron system of chlorin.[17] Therefore, there is no need to devise a URF for the magnesium-chlorin complex (**62**).

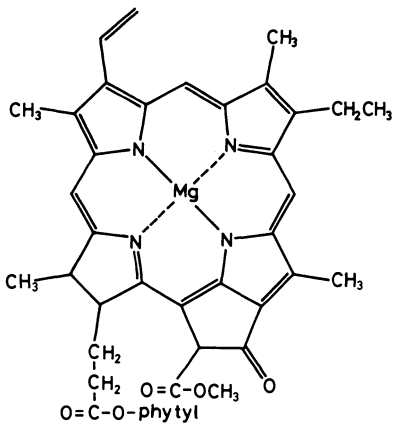


62

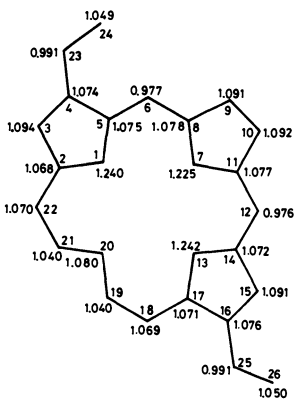


63

Naturally occurring chlorophylls have vinyl and/or formyl substituents in addition to alkyl substituents. Although photosynthetic organisms contain a variety of photosynthetic pigments, only chlorophyll *a* (**64**) performs a primary role in the photosynthetic act. This molecule has one vinyl and one carbonyl substituent attached to the chlorin nucleus. However, charge density is not large at all vinyl carbons of the URF (**65**). As in the case of porphyrins, vinyl substituents never change the sites of great charge density in the chlorin nucleus.



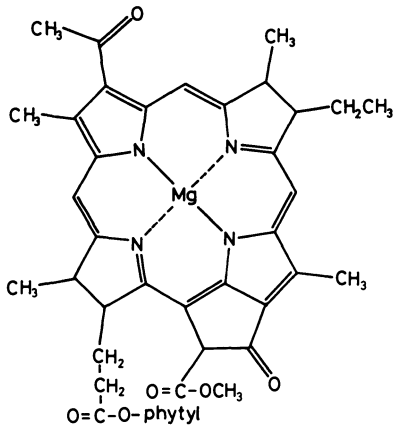
64



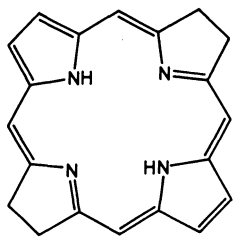
65

Photosynthetic bacteria produce a variety of photosynthetic pigments known collectively as bacte-

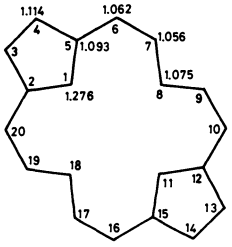
riochlorophylls.[13] Most bacteriochlorophylls have the same chlorin nucleus as those of chlorophylls. However, bacteriochlorophyll *a* (**66**) has a slightly different macrocycle (**67**), which has two additional hydrogens at the B-ring.[13] Two pyrrole nitrogens in **67** are located at sites of high charge density in the URF (**68**, 22 π electrons), but the other two are not. This again suggests that hydrogen addition at the B-ring must have occurred after the insertion of the magnesium ion. The URF of bacteriochlorophyll *a* itself is shown in **69**. The sites of high charge density in the URF are not displaced by the introduction of two unsaturated substituents. If the metal ion is removed from bacteriochlorophyll *a*, the two pyrrole nitrogens will be of the amine type, and the remaining two will be of the imine type.



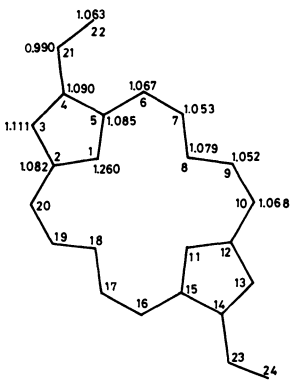
66



67

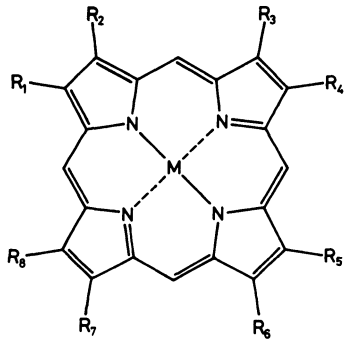


68

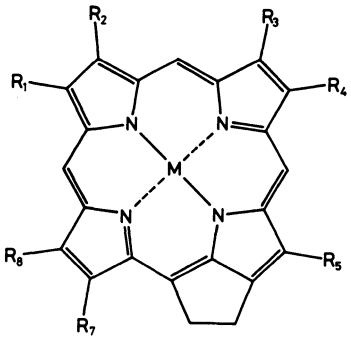


69

Porphyrins in geological samples[18] occur as complex mixtures of two major series: the etio and deoxophylloerythro types (**70** and **71**, respectively). In **70** and **71**, M represents an appropriate metal ion. These molecules are detectable in petroleum, shale, and coal. They have saturated substituents only, and the URF of porphine (**58**) applies. They were presumably derived from defunctionalization and full aromatization of naturally occurring chlorophylls.[18] This implies that unsaturated substituents attached to the original chlorophylls are not so stable as the porphine nucleus.



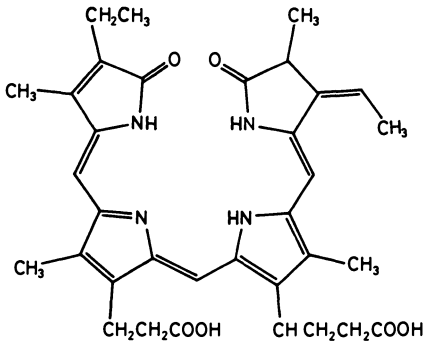
70



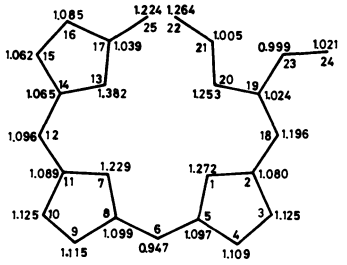
71

Phycobilins and bile pigments are formed in vivo by degradation of porphyrins.[14] Red and blue-green algae contain, in addition to chlorophyll *a*, blue or red pigments known as phycobilins, open-chain tetrapyrroles related to the chlorophylls but lacking the metal ion. These pigments absorb the sunlight effectively, and transfer its energy to chlorophyll *a*. Phycocyanobilin (**72**) is a phycobilin having the largest π-electron system. This blue compound has six heteroatoms except the isolated carboxyl groups. All heteroatoms occupy the sites of high charge density in the URF (**73**). Biliverdin (**74**) is one of the bile pigments, which is again an open-chain tetrapyrrole. A number of open tetrapyrroles are formed from biliverdin by reduction and oxidation reactions. The URF of biliverdin is shown in **75**. The locations of all heteroatoms in this molecule can be predicted from

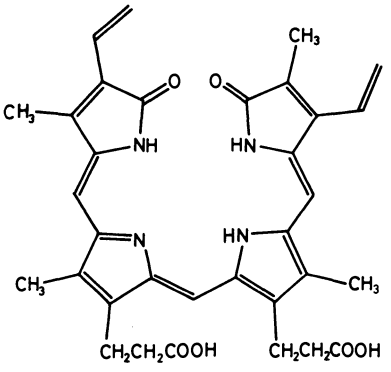
the charge density distribution in the URF. Thus, it is noteworthy that not only porphyrins but also their metabolites conform to the TCS rule very faithfully although their molecular structures are far from being simple.



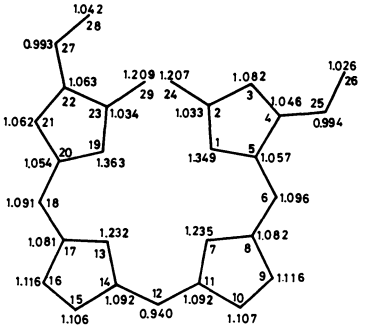
72



73



74



75

Concluding Remarks

Gimarc pointed out that the TCS rule has potential value as a guide for synthetic efforts to be made by organic chemists.[2] We have shown that many biologically important molecules conform to the TCS rule. Most heteroatoms in any biomolecule are placed at the sites of large charge density in its URF. In all examples shown above, highly electronegative alcohol (or ether) oxygens and amine nitrogens always occupy the sites of high charge density in the corresponding URF's. Nature obviously adopts the TCS rule as a general guide for biosynthesis. It should be noted that various coenzymes have been designed so that both the oxidized and reduced forms satisfy the TCS rule.

Chemical and biochemical evolution[19] must have occurred in harmony with the TCS rule.[6] As has been seen above, nucleoside bases, amino acids, and many other biomolecules are fully consistent with the TCS rule. This coincides with the fact that many of these molecules can be prepared by rather simple reactions intended to simulate chemical evolution.[17] Therefore, it is very probable that nature picked up molecules available readily in prebiotic chemistry to construct living organisms.[6] Some of the molecules must have exerted important functions incidentally in cellular systems. Conversely, nature has been so skillful as to choose biologically important molecules from the products of chemical evolution. For example, nucleoside bases are best suited for pairing in DNA and RNA. Such bases were chosen from a group of rather simple molecules which satisfy the TCS rule.

From a different point of view, we can say that living organisms adopted energetically very accessible ways of biosynthesis. In general, a stable molecule is associated with low activation energy of formation.[20] The resulting biomolecules are thermodynamically very stable as compared to their isomeric species. Many derivatives of indole (**31**) are prepared in vivo, but no structural isomers of indole, such as isoindole (**76**) and indolizine (**77**), are scarcely found in cellular systems. These isomers do not conform to the TCS rule, and are much less stable than indole. It is obvious that living organisms do not make much effort to prepare high-energy conjugated systems. Molecules with important biological functions must have been chosen from synthetically very accessible molecules. Thus, topological charge stabilization serves as a unifying principle for the systemization of biosynthesis.

Ab Initio Calculation for the Interaction Energy of He-H

Akira ICHIHARA,* Kohtoku SASAGANE, and Reikichi ITOH
Department of Chemistry, Faculty of Science and Engineering, Waseda University,
3-4-1 Ohkubo Shinjuku-ku, Tokyo 160
(Received April 25, 1988)

Using the help of an ab initio calculation with a configuration interaction (CI) treatment, the potential energies of a HeH system in the ground ($X^2\Sigma^+$) and the first three ($A^2\Sigma^+$, $B^2\Pi$, $C^2\Sigma^+$) excited electronic states were calculated, making due correction for the basis set superposition effect.

In recent years there have been several reports in which the radiative dissociation and predissociation of HeH were investigated.[1-8] Molecular calculations predict that the HeH system has a repulsive ground state, with only a van der Waals minimum,[9,10] and a series of bound Rydberg excited states.[11-13] Using a MRD-CI treatment, Theodorakopoulos et al.[11,12] calculated the potential energy curves of the ground and some excited electronic states of HeH. The theoretical radiative life times calculated by Petsalakis et al.[13] were in good agreement with the experimental values.[2,3]

In this paper we will report the results of full CI calculations of the potential energies of HeH in the ground ($X^2\Sigma^+$) and the first three ($A^2\Sigma^+$, $B^2\Pi$, $C^2\Sigma^+$) excited states, and the basis set superposition effect for these potential energies will be discussed. Then our results concerning the $A^2\Sigma^+ \rightarrow X^2\Sigma^+$ predissociation energy and the $B^2\Pi$ binding energy will be compared with the experimental values.[5-7]

In all the ab initio calculations, Gaussian basis sets [6S4P] for a H atom and [6S2P1D] for a He atom were employed. The hydrogen [6S4P] Gaussian basis set was composed of Schmidt (10s/4s) functions[14] augmented with the polarization and diffuse functions employed by Römelt et al.[15] and Theodorakopoulos et al.[11,12] The (10s/4s) contraction was performed so that the atomic energy with the contracted set came close to that with an uncontracted set. The Schmidt (10s) primitive functions were contracted to (6,2,1,1). The exponents of the polarization and diffuse functions were 0.025 and 0.01 for s-type orbitals and 0.7, 0.2, 0.035, and 0.01 for p-type orbitals. Moreover, the helium [6S2P1D] Gaussian basis set was composed of Schmidt (16s/6s) functions[14] augmented with the polarization functions employed by Römelt et al.[15] The Schmidt (16s) primitives were contracted to (6,5,2,1,1,1). The exponents of the polarization functions were 1.0 and 0.2 for p-type orbitals and 0.8 for the d-type orbital.

It has already been pointed out that the results of CI calculations for the interaction energy of the supermolecule system must be corrected in order to eliminate the type of error called a "basis set superposition error".[16-18] Boys et al. introduced the function counterpoise method[16] in order to overcome this error. In this method, the He–H interaction energy in the ground ($X^2\Sigma^+$) state ($E_{\rm int}^{X^2\Sigma^+}$) is calculated using the difference between the full CI energy of HeH ($E_{\rm HeH}^{X^2\Sigma^+}$) and an appropriate reference energy ($E_{\rm ref}$):

$$E_{\rm int}^{X^2\Sigma^+}(R) = E_{\rm HeH}^{X^2\Sigma^+}(R) - E_{\rm ref}(R), \tag{1}$$

where R is the internuclear distance of HeH. The reference energy is defined as the sum of the full CI energies of the ground H(1s) and ground He($1s^2$), with "ghost" orbitals at the expected location of the other atom:

$$E_{\rm ref}(R) = E_{\rm ghost}^{\rm H(1s)}(R) + E_{\rm ghost}^{\rm H(1s^2)}(R). \tag{2}$$

The term "ghost" represents an atom with a nuclear charge zero and without any electrons.

We also employed this method in the case of the $A^2\Sigma^+$, $B^2\Pi$, and $C^2\Sigma^+$ states of HeH in order to evaluate the "basis set superposition effect". As has been noted in the previous work by Theodorakopoulos et al.,[11,12] these three states are mainly described by a single configuration, the same one for the whole range of the internuclear distance, R, from 0.5 to 20.0 Bohr. These excited states have dissociation limits H(2s)+He($1s^2$) ($A^2\Sigma^+$) and H(2p)+He($1s^2$) ($B^2\Pi$ and $C^2\Sigma^+$) over R=20.0 Bohr. The interaction and reference energies may then be defined as:

$$\begin{aligned} E_{\rm int}^{\rm EXCITE}(R) &= E_{\rm HeH}^{\rm EXCITE}(R) - E_{\rm ref}(R), \text{ EXCITE} \\ &= A^2\Sigma^+, B^2\Pi, C^2\Sigma^+ \end{aligned} \tag{3}$$

$$\begin{aligned} E_{\rm ref}(R) &= E_{\rm ghost}^{\rm H(2s)}(R) + E_{\rm ghost}^{\rm H(1s^2)}(R) \quad \text{for } A^2\Sigma^+ \\ &= E_{\rm ghost}^{\rm H(2p\Pi)}(R) + E_{\rm ghost}^{\rm H(1s^2)}(R) \quad \text{for } B^2\Pi \\ &= E_{\rm ghost}^{\rm H(2p\Sigma)}(R) + E_{\rm ghost}^{\rm H(1s^2)}(R) \quad \text{for } C^2\Sigma^+ \end{aligned}$$

when there is the ghost He; the 2p orbitals of the H atom split into parallel ($2p\Sigma$) and perpendicular ($2p\Pi$) elements for the H—ghost He axis.

In the present work, the spatial symmetry considered in the CI treatment of the HeH system is $C_{\infty v}$. The CI calculations contain 6472 configurations for the $^2\Sigma$ symmetry and 7084 configurations for the $^2\Pi$ symmetry. These calculations were performed by using the graphical unitary group approach (GUGA) program of our group[19] and the HITAC M680H

system of the Computer Center of the Institute for Molecular Science (IMS).

Results and Discussion

Table 1 indicates the CI energies (E_H, E_{He}) of H(1s, 2s, 2p) and He($1s^2$), without ghost orbitals. These energies are equal to $E_{ghost}^{H(1s)}$, $E_{ghost}^{H(2s)}$, $E_{ghost}^{H(2p\Sigma,2p\Pi)}$, and $E_{ghost}^{He(1s^2)}$ at the internuclear distance of R=20.0 Bohr.

Tables 2—5 indicate the interaction energies of He–H in the ground $X^2\Sigma^+$ and excited $A^2\Sigma^+$, $B^2\Pi^+$, and $C^2\Sigma^+$ states, where the basis set superposition effect is evaluated by $E_{ref}-E_H-E_{He}$. It can be seen from Tables 2—5 that the basis set superposition effect grows with the electronic excitation level ($X^2\Sigma^+<A^2\Sigma^+<B^2\Pi^+<C^2\Sigma^+$). For the $X^2\Sigma^+$, $A^2\Sigma^+$, and $B^2\Pi$ states, the basis set superposition effect is less than 10^{-3} a.u. for the whole range of the R values

Table 6. $A^2\Sigma^+$ ($v'=0$) → $X^2\Sigma^+$ Predissociation and $B^2\Pi$ Binding Energies of HeH

	This work	Theodorakopoulos[a]	Experimental
		eV[b]	
$A^2\Sigma^+$ ($v'=0$) → $X^2\Sigma^+$ Predissociation	7.96[c]	7.91	7.9[d]
$B^2\Pi$ Binding	2.13	2.20	2.19±0.03[e]

a) From Ref. 12. b) 1 eV=1.6021892×10^{-19} J. c) The vibrational zero-point energy for the $A^2\Sigma^+$ state was estimated to be 0.2272 eV. d) Estimated from Fig. 3 in Ref. 5. e) From Ref. 7.

calculated and little effect on the shape of the interaction energy curves. This superposition effect changes the energy well depth by only 0.3—0.4 percent in the $A^2\Sigma^+$ and $B^2\Pi$ states. From these results, the basis set superposition effect can be said to be negligible for the $X^2\Sigma^+$, $A^2\Sigma^+$, and $B^2\Pi$ states. On the other hand, as may be seen in Table 5, the basis set superposition effect in the $C^2\Sigma^+$ state is about 0.002 a.u. in the energy minimum region and changes the well depth about 5 percent; therefore, it can not be neglected. The $C^2\Sigma^+$ state also has an upper boundary in the region of R=4.0 Bohr, where the basis set superposition effect is negligible.

Table 6 indicates the $A^2\Sigma^+(v'=0)\rightarrow X^2\Sigma^+$ predissociation and $B^2\Pi$ binding energies of HeH. In our calculation, the vibrational zero-point energy ($E_{vib}(v'=0)$) for the $A^2\Sigma^+$ state was estimated to be 0.2272 ev. The predissociation energy was calculated by the use of:

$$A^2\Sigma^+(v'=0) \rightarrow X^2\Sigma^+ \text{ predissociation energy}$$
$$= [\{E_{H(2s)} + E_{He(1s^2)} + E_{int}^{A^2\Sigma^+}(R = 1.5\,\text{Bohr}) + E_{vib}(v'=0)\} - \{E_{H(1s)} + E_{He(1s^2)}\}].$$

The results of the MRD-CI calculation by Theodorakopoulos et al.[11,12] and the experimental results reported by Peterson et al.[5] and by Möller et al.[7] are also listed in Table 6. Our calculated values are in good agreement with these other calculated and experimental values.

It may be concluded from the results of this investigation that our potential energies for the $X^2\Sigma^+$, $A^2\Sigma^+$, and $B^2\Pi$ states of the HeH system can give the $A^2\Sigma^+\rightarrow X^2\Sigma^+$ predissociation and $B^2\Pi$ binding energies. Moreover, the basis set superposition effect changes the interaction potential minimum about 5 percent for the $C^2\Sigma^+$ state.

We wish to thank professor Sigeru Huzinaga for suggesting this problem. Our study was based on the calculations by Giannoula Theodorakopoulos, Stavros C. Farantos, Ioannis D. Petsalakis, Cleanthes A. Nicolaides, Robert J. Buenker, and Sigrid D. Peyerimhoff.

Geometrical Isomers of Anionic Complexes Favorable to Chiral Discriminatory Ion-Pairing with Λ-$[Co(en)_3]^{3+}$ Ion and the Diastereomeric Ion-Pair Formation Constants in Solution[1)]

Akira TATEHATA* and Yasuyuki ASABA
Department of Chemistry, Faculty of Science, Shizuoka University, Ohya, Shizuoka 422
(Received September 5, 1987)

The stereoselectivities in the ion pairing of the geometrical isomers of anionic complexes, $[Co(ox)(gly)_2]^-$ and $[Co(ox)(edda)]^-$ (ox=oxalate dianion, gly=glycinate anion, and edda=ethylenediamine-*N*,*N*′-diacetate dianion) with $[Co(en)_3]^{3+}$ have been investigated by a chromatographic method. Only the C_1-*cis*(*N*) isomer of three geometrical isomers of $[Co(ox)(gly)_2]^-$ and the β-*cis* isomer of two of $[Co(ox)(edda)]^-$, in which three coordinated oxygen atoms are disposed triangularly along the pseudo C_3 axis, have been observed to interact more strongly with $[Co(en)_3]^{3+}$ than the other geometrical isomers. The diastereomeric ion-pair formation constants of C_1-*cis*(*N*)-$[Co(ox)(gly)_2]^-$ and β-*cis*-$[Co(ox)(edda)]^-$ with $[Co(en)_3]^{3+}$ in solution have been determined by a conductance method at 25 °C. The results were consistent with those of the chromatographic studies. An enhancement of the circular dichroism (CD) intensity of the A_2 component at the first d–d transition region of $[Co(en)_3]^{3+}$ has been observed upon the formation of ion pairing between the complex ions. Therefore, a favorable ion pair is considered to involve the hydrogen bonds between the coordinated oxygen atoms of the anionic complexes and the three N–H protons of $[Co(en)_3]^{3+}$ along the C_3 axis.

It is well-known that chromatography is an extremely valuable technique for the optical resolution of metal complexes.[2,3)] However, examples of a complete chromatographic resolution of anionic complexes are much fewer than those of cationic complexes because of a lack of effective eluting agents. We reported that the optically active $[Co(en)_3]^{3+}$ cation is an effective chiral discriminator for various complex anions and, hence, can serve as the highly promising eluting agent for the chromatographic resolution of many anionic complexes.[4,5)] It is thought that $[Co(en)_3]^{3+}$ can discriminate the chirality of anionic complexes by two different means: Λ-$[Co(en)_3]^{3+}$ prefers the Λ to the Δ isomer of $[Co(ox)_2(en)]^-$, whereas it prefers the Δ to the Λ isomer of $[Co(ox)_2(gly)]^{2-}$.[6–8)] The discrimination efficiency was shown to be largely different between the above two systems, though there is a difference in the electric charge on the anionic complexes. In order to explain why the absolute configurations of the favorable pairs of $[Co(ox)_2(en)]^-$ and $[Co(ox)_2(gly)]^{2-}$ with Λ-$[Co(en)_3]^{3+}$ are opposite to each other, our attention from an early stage was focused on the structural characteristics of the anionic complexes, especially on the difference in the spatial disposition of the coordinated oxygen atoms.[5,6)] It was therefore noted that $[Co(ox)_2(gly)]^{2-}$ has a triangular face comprising three coordinated oxygen atoms capable of forming three hydrogen bonds with N–H protons of Λ-$[Co(en)_3]^{3+}$ along its C_3 axis;[4)] however, $[Co(ox)_2(en)]^-$ has no such triangular face. It was then pointed out that the direction of the lone-pair electrons of coordinated oxygen atoms in Δ-$[Co(ox)_2(gly)]^{2-}$ is more favorable to the three hydrogen bonds with Λ-$[Co(en)_3]^{3+}$ than that in the antipode.[4,5)]

Subsequently, Miyoshi et al. investigated in detail the mechanism of chiral discrimination between metal complexes using a chromatographic method and proposed association models for the favorable pairs;[8,10)] chiral discrimination is effected along either the (pseudo) C_3 axis or the (pseudo) C_2 axis of the respective complexes. Thus, a homochiral (Λ–Λ or Δ–Δ) combination is favored when the cationic complex uses its C_3 axis, whereas a heterochiral (Λ–Δ or Δ–Λ) combination is favored when the cationic complex uses its C_2 axis, regardless of which axis (C_3 or C_2) of the anionic complex is directed to the cationic complex. Their proposal may explain the difference in the favorable association modes of $[Co(ox)_2(en)]^-$ and $[Co(ox)_2(gly)]^{2-}$. On the other hand, a crystal structure analysis of Δ-$[Co(l\text{-pn})_3]$ Λ-$[Cr(mal)_3]\cdot 3H_2O$ (*l*-pn=(R)-1,2-propanediamine, mal=malonate dianion) revealed that the cationic complex approaches the triangular face of Λ-$[Cr(mal)_3]^{3-}$ along the C_3 axis and makes face-to-face close contact through three hydrogen bonds.[9)] This indicates that the heterochiral combination mode can contribute effectively to chiral discrimination, even if the cationic complexes use the C_3 axis. Thus, their proposal may need to be tested further regarding many other metal complex systems.

In this paper the importance of the spatial disposition of coordinated atoms and the arrangement of chelate rings of anionic complexes are discussed in systems which involve the geometrical isomers of anionic complexes, $[Co(ox)(gly)_2]^-$ and $[Co(ox)(edda)]^-$. In order to obtain a measure of the discriminatory effect for strongly interacting ion pairs, the diastereomeric ion-pair formation constants are determined for $[Co(en)_3]^{3+}$–C_1-*cis*(*N*)-$[Co(ox)(gly)_2]^-$ and $[Co(en)_3]^{3+}$–β-*cis*-$[Co(ox)(edda)]^-$ systems. The favorable pair of these systems is Λ–Δ. It is then deduced from the CD change of Λ-$[Co(en)_3]^{3+}$ that the cationic complex uses its C_3 axis to discriminate the chirality of the anionic complexes, in disagreement with the proposal of Miyoshi et al. for the favorable pair containing the

heterochiral combination.

Experimental

Preparation of Complexes. The optically active $[Co(en)_3]I_3 \cdot H_2O$ was prepared by a method described in the literature[13] and converted to the chloride using an SP-Sephadex C-25 ion exchanger. Three geometrical isomers (*trans*(*N*), C_1-*cis*(*N*), and C_2-*cis*(*N*)) of $[Co(ox)(gly)_2]^-$ were prepared as described by Shimura and co-workers.[14] The C_1-*cis*(*N*) isomer for conductance measurements was resolved by a method described in the literature[15] (with a little modification) for obtaining the potassium salt.[16] Found for Λ-$(-)_{546}$ isomer ($[M]_{546}=-5530°$): C, 20.90; H, 2.64; N, 8.14%. Found for Λ-$(+)_{546}$ isomer ($[M]_{546}=+5540°$): C, 20.92; H, 2.63; N, 8.06%. Calcd for C_1-*cis*(*N*)-$K[Co(ox)(gly)_2] \cdot 0.5H_2O=C_6H_9N_2O_{8.5}KCo$: C, 21.00; H, 2.64; N, 8.16%. Two geometrical isomers (α-*cis* and β-*cis*) of $[Co(ox)(edda)]^-$ were prepared and separated by the method of Coleman et al.[17] Λ-$(-)_{589}$-β-*cis*-$K[Co(ox)(edda)] \cdot 2H_2O$ for conductance measurements was prepared according to the method of Jordan and Legg,[18] which was obtained as the dihydrate ($[M]_{589}=-3470°$, $\Delta\varepsilon_{544}=-2.22$ mol^{-1} dm^3 cm^{-1}) in this study though had been obtained as the monohydrate in Ref. 18 (The value of $\Delta\varepsilon_{544}$ reported for $(+)_{589}$ isomer was +2.05). Found: C, 24.35; H, 3.51; N, 7.04%. Calcd for β-*cis*-$K[Co(ox)(edda)] \cdot 2H_2O=C_8H_{14}N_2O_{10}KCo$: C, 24.25; H, 3.56; N, 7.07%.

Chromatographic Experiments. (*a*) Each sample of the racemic geometrical isomers of $[Co(ox)(gly)_2]^-$ and $[Co(ox)(edda)]^-$ was adsorbed on a column (1.9×60 cm) of DEAE-Sephadex A-25 anion exchanger and was eluted with an aqueous solution of NaCl (0.3 mol·dm^{-3}) or *rac*-$[Co(en)_3]Cl_3$ (0.1 mol·dm^{-3}) at a rate of 0.3—0.5 cm^{3}min^{-1}. The eluate was divided into fractions of 3-cm^3 portions and the concentration of the eluted isomer in each fraction was measured spectrophotometrically to obtain an elution curve.

(*b*) Each racemic isomer of the above anionic complexes was chromatographed in a similar manner as mentioned above, except for the length of the column (1.9×150 cm) and the use of an aqueous solution (0.05 mol·dm^{-3}) or 30% aqueous ethanol solution (0.05 mol·dm^{-3}) of Λ-$[Co(en)_3]Cl_3$ as the eluent.

(*c*) A column (1.9×60 cm) of SP-Sephadex C-25 cation exchanger which was converted completely to the Λ-$[Co(en)_3]^{3+}$ form was prepared. The bottom of the column was loaded with the cation exchanger in Na^+ form (10 cm long) in order to remove a small amount of Λ-$[Co(en)_3]^{3+}$ eluted from the upper part of the column. Each racemic anionic complex (5 ml of 20—30 mM; 1 M=1 mol dm^{-3}) was placed on the top of the column and eluted with water at a rate of 0.3 cm^3 min^{-1}. The concentration and the optical rotation of the partially resolved complex in each fraction (2.5 cm^3) were measured in order to determine percentage resolution.

Conductance Measurements. The complex anions of C_1-*cis*(*N*)-$[Co(ox)(gly)_2]^-$ and β-*cis*-$[Co(ox)(edda)]^-$, which were found to interact strongly with $[Co(en)_3]^{3+}$ by chromatographic studies, were selected for conductance measurements. The conductance of the mixed solutions containing various volume ratios of the chiral $[Co(en)_3]^{3+}$ and the chiral anionic complex (ionic strength, I=0.01 mol dm^{-3}) was measured at 25±0.01 °C using a conductometer (Type MY-8, Yanagimoto Mfg. Co. Ltd.) at a frequency of 800 Hz. The diastereomeric ion-pair formation constants were estimated according to the procedure described in various previous studies.[4,5,19]

CD Measurements. The CD spectra were measured on a Jasco J-500 spectropolarimeter using a 1-mm cell at room temperature. To an aqueous solution of Λ-$[Co(en)_3]I_3 \cdot H_2O$ (0.025 mol dm^{-3}) Λ- or *rac*-C_1-*cis*(*N*)-$K[Co(ox)(gly)_2]$ or *rac*-β-*cis*-$Na[Co(ox)(edda)] \cdot 2H_2O$ was added so as to prepare the solution of 0.025 (for Λ-complex) or 0.05 mol dm^{-3} (for *rac*-complex) with respect to the concentration of the anionic complex. Absorption spectra, absorbances of chromatographic fractions, and optical rotations were obtained on a Shimadzu MPS-50L recording spectrophotometer, a Jasco Uvidec-320 spectrophotometer, and a Union automatic polarimeter PM-101, respectively with 1 or 5 cm cells.

Results and Discussion

Chromatography of Geometrical Isomers of $[Co(ox)(gly)_2]^-$ and $[Co(ox)(edda)]^-$. Elution curves of geometrical isomers of $[Co(ox)(gly)_2]^-$ by anion-exchange chromatography are shown in Fig. 1. It can be seen that the C_1-*cis*(*N*)-isomer is eluted markedly faster when *rac*-$[Co(en)_3]Cl_3$ is used as an eluent than when sodium chloride is used, compared with *trans*(*N*)- and C_2-*cis*(*N*)-isomers.

By combining the ion-exchange equilibrium with the ion-pair formation equilibrium, the net retention volume, V, of the adsorbed anionic complex in the present anion-exchange chromatography can be

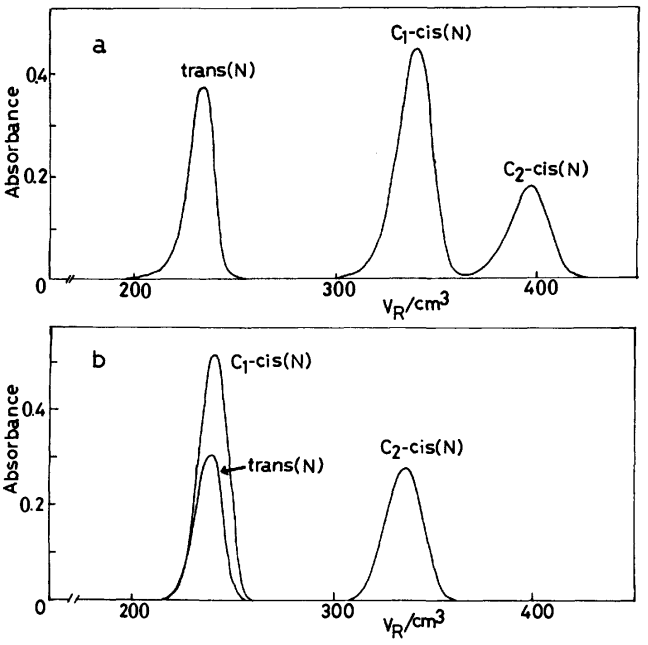

Fig. 1. Elution curves for geometrical isomers of $[Co(ox)(gly)_2]^-$ by chromatography using a column (1.9×60 cm) of DEAE-Sephadex A-25 and an aqueous solution of 0.3 mol dm^{-3} NaCl (a) and 0.1 mol dm^{-3} *rac*-$[Co(en)_3]Cl_3$ (b) as the eluent.

expressed by Eq. 1,[20]

$$V = V_s KQ/[Cl^-]\{1 + \beta[\text{cation}]\}, \quad (1)$$

where V_s is the volume of ion-exchange resin in the column, K the ion-exchange equilibrium constant for the reaction, $B^- + R\text{-}Cl \rightleftarrows Cl^- + R\text{-}B$ (B=anionic complex, R=ion-exchange group), Q the capacity of the ion-exchange resin, and β the ion-pair formation constant of the anionic complex with the cation contained in an eluting solution. We now consider the difference in the retention volumes of a certain anionic complex between elutions with sodium chloride and $[Co(en)_3]Cl_3$. The term $V_sKQ/[Cl^-]$ for a certain anionic complex is virtually identical in the two cases under the experimental conditions and the term β[cation] is expected to be negligibly small when the cation is sodium ion. Therefore, the ratio of the retention volumes is given by

$$V(Co(en)_3^{3+})/V(Na^+) = 1/\{1 + \beta[Co(en)_3^{3+}]\}, \quad (2)$$

where $V(Na^+)$ and $V(Co(en)_3^{3+})$ are the retention volumes observed when sodium chloride and $[Co(en)_3]Cl_3$ are used as an eluent, respectively. According to Eq. 2, the ratios of the retention volumes decrease with an increase in the value of the ion-pair formation constants between the anionic complexes and $[Co(en)_3]^{3+}$. This leads to the prediction that the anionic complex which forms a strong ion pair with $[Co(en)_3]^{3+}$ has a small value of the ratio, $V(Co(en)_3^{3+})/V(Na^+)$. Figure 1 indicates the decreasing order of the ratio for the three geometrical isomers of $[Co(ox)(gly)_2]^-$ to be *trans*(*N*)>C_2-*cis*(*N*)>C_1-*cis*(*N*)-isomer. Thus, it should be noted that C_1-*cis*(*N*)-$[Co(ox)(gly)_2]^-$ forms a stronger ion pair with $[Co(en)_3]^{3+}$ than do *trans*(*N*)- and C_2-*cis*(*N*)-isomers. This may be related to the observation that only a C_1-*cis*(*N*)-isomer is resolvable by usual anion-exchange chromatography using Λ-$[Co(en)_3]Cl_3$ as an eluent, as shown in Fig. 2. Figure 3 shows elution curves and percentage resolutions of three geometrical isomers in chromatography of which a column of SP-Sephadex C-25 in Λ-$[Co(en)_3]^{3+}$ form were employed (water: eluent). The complex anion of C_1-*cis*(*N*)-isomer was the last to be eluted, and a great degree of resolution was attained, being consistent with the results from the above-mentioned usual anion-exchange chromatography that C_1-*cis*(*N*)-isomer tends to form a strong ion pair with $[Co(en)_3]^{3+}$. The percentage resolution curve shows that the ion pair of Λ-$[Co(en)_3]^{3+}$-Λ-C_1-*cis*(*N*)-$[Co(ox)(gly)_2]^-$ is more favorable than Λ-$[Co(en)_3]^{3+}$-Λ-C_1-*cis*(*N*)-$[Co(ox)(gly)_2]^-$. Despite of the presence of an additional chelate ring between the coordinated nitrogen atoms in edda ligand, α-*cis* and β-*cis* isomers of $[Co(ox)(edda)]^-$ are the same as C_2-*cis*(*N*) and C_1-*cis*(*N*) isomers of $[Co(ox)(gly)_2]^-$, respectively, with respect to the spatial disposition of coordinated atoms around Co(III) (Scheme 1). Chromatograms of the geometrical isomers of $[Co(ox)(edda)]^-$ are shown in Fig.4.

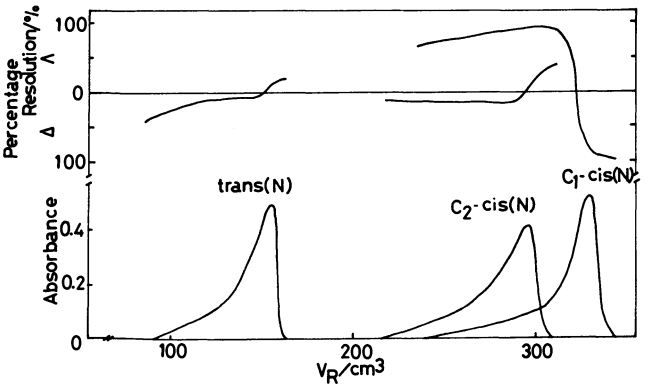

Fig. 3. Elution curves and percentage resolutions for geometrical isomers of $[Co(ox)(gly)_2]^-$ by chromatography using a column (1.9×60 cm) of SP-Sephadex C-25 in Λ-$[Co(en)_3]^{3+}$ form and water as an eluent.

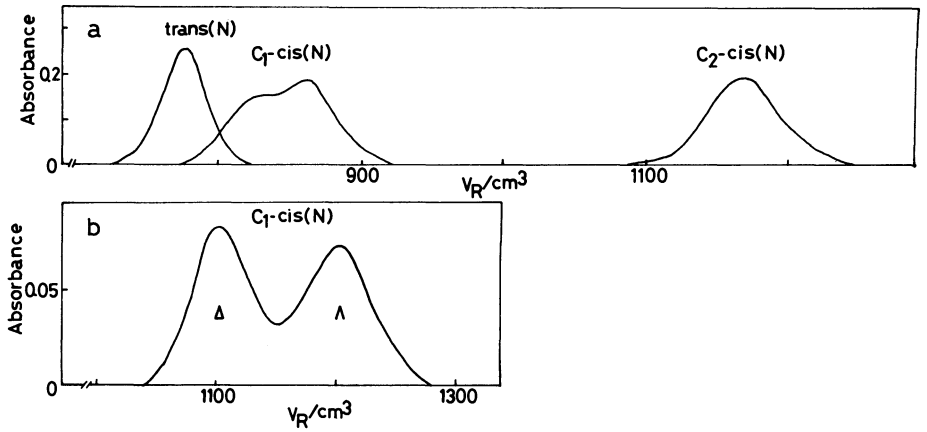

Fig. 2. Elution curves for geometrical isomers of $[Co(ox)(gly)_2]^-$ by chromatography using a column (1.9×150 cm) of DEAE-Sephadex A-25 and an aqueous solution (a) and a 30% ethanolic aqueous solution (b) of 0.05 mol dm^{-3} Λ-$[Co(en)_3]Cl_3$ as the eluent.

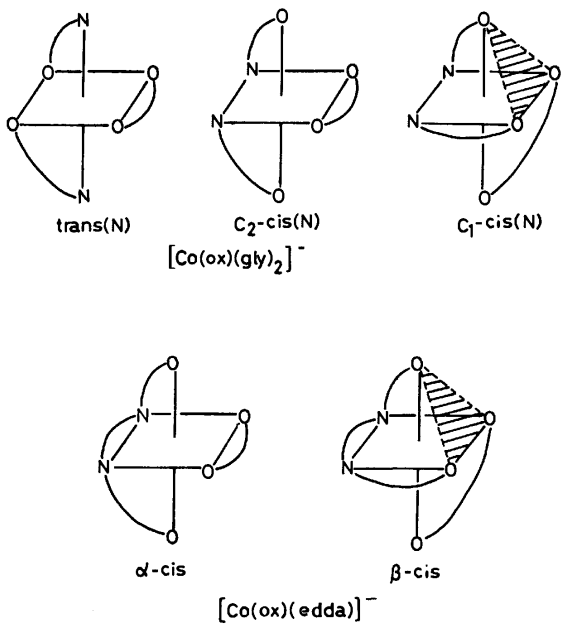

Scheme 1.

It can be seen that each chromatographic behavior of *α-cis* and *β-cis*-[Co(ox)(edda)]$^-$ is very similar to that of the corresponding geometrical isomer of [Co(ox)-(gly)$_2$]$^-$. The present observation suggests that the spatial disposition of the oxygen atoms in the complexes is important regarding both the ion pair formation and stereoselectivity. That is, *β-cis*-[Co(ox)(edda)]$^-$ and C$_1$-*cis*(*N*)-[Co(ox)(gly)$_2$]$^-$ are able to form a strong ion pair with [Co(en)$_3$]$^{3+}$ and to give a great degree of ion-pairing stereoselectivity since these isomers have a highly anionic triangular face consisting of three coordinated oxygen atoms (as shown by the shaded parts in Scheme 1). In order to obtain information about the structure of ion pair, especially about the direction of access of the complex anion to the complex cation, the CD changes of [Co(en)$_3$]$^{3+}$ in the first absorption band region were measured upon addition of C$_1$-*cis*(*N*)-[Co(ox)(gly)$_2$]$^-$ or *β-cis*-[Co(ox)(edda)]$^-$.

CD Changes and Ion Pair Structure. It is well-known that the addition of a chiral anion such as *d*-tartrate ion to such complexes as [Co(en)$_3$]$^{3+}$ and [Co(chxn)$_3$]$^{3+}$, which can form hydrogen bonds with the axial N-H protons along the C$_3$ axis, enhances the CD intensity of the A$_2$ component.[11,23] Yoneda and co-workers have shown by the CD studies of [Co-(sep)]$^{3+}$ (sep=1,3,6,8,10,13,16,19-octaazabicyclo[6.6.6]-icosane) and the related complexes that when the hydrogen bonds are formed by using equatorial N-H protons directed nearly along the C$_2$ axis, the effect leads to an enhancement of the E$_a$ rotational strength.[10-12] Therefore, we can determine the ion pair structure by observing which component (A$_2$ or E$_a$) of [Co(en)$_3$]$^{3+}$ is enhanced upon the addition of a chiral complex anion. Figure 5 shows the CD spectra

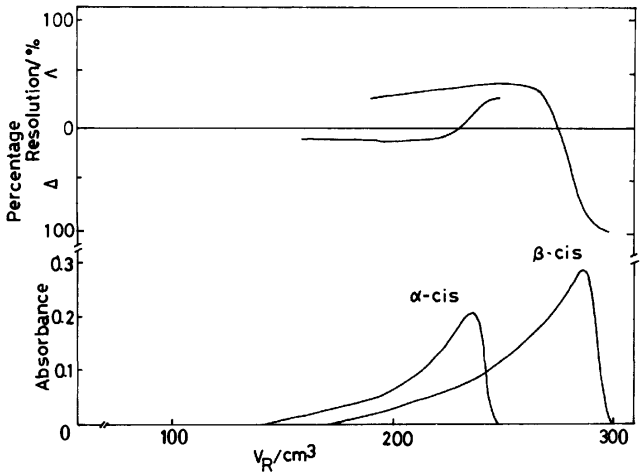

Fig. 4. Elution curves and percentage resolutions for geometrical isomers of [Co(ox)(edda)]$^-$ by chromatography using a column (1.9×60 cm) of SP-Sephadex C-25 in *Λ*-[Co(en)$_3$]$^{3+}$ form and water as an eluent.

(b) CD spectra of 0.025 mol dm^{-3} *Λ*-[Co(en)$_3$]$^{3+}$ in the absence (——) and the presence (----) of 0.05 mol dm^{-3} *rac*-C$_1$-*cis*(*N*)-[Co(ox)(gly)$_2$]$^-$. (c) CD spectra of 0.025 mol dm^{-3} *Λ*-C$_1$-*cis*(*N*)-[Co(ox)(gly)$_2$]$^-$ in the absence (——) and the presence (----) of 0.05 mol dm^{-3} *rac*-[Co(en)$_3$]$^{3+}$. All the samples were measured using a 1 mm cell.

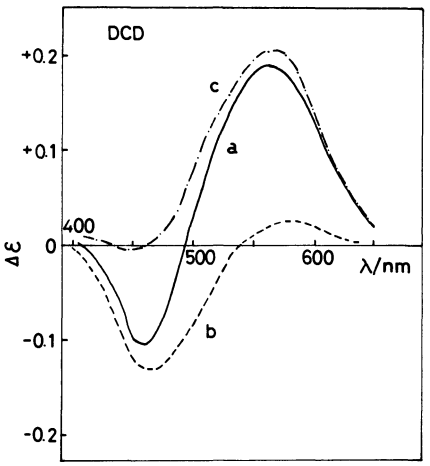

Fig. 6. The DCD spectra in the presence of *Λ*-$[Co(en)_3]^{3+}$ and *Δ*-C1-*cis*(*N*)-$[Co(ox)(gly)_2]^-$ (a), *Λ*-$[Co(en)_3]^{3+}$ and *rac*-C1-*cis*(*N*)-$[Co(ox)(gly)_2]^-$ (b), and *rac*-$[Co(en)_3]^{3+}$ and *Δ*-C1-*cis*(*N*)-$[Co(ox)(gly)_2]^-$ (c), respectively.

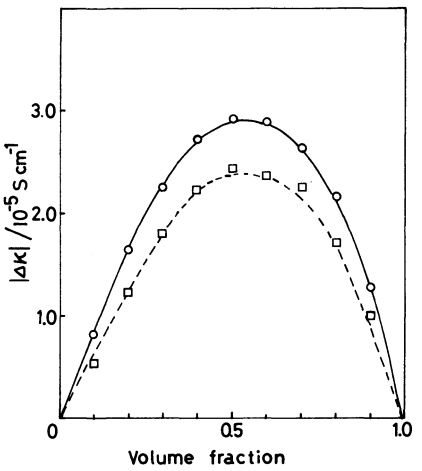

Fig. 7. The deviations, $|\Delta\kappa|$, of the measured conductivity from additivity as a function of the volume fraction, *x*, of *Λ*-$[Co(en)_3]I_3$ for the *Λ*-*Δ* (-O-) and the *Λ*-*Λ* (-□-) pairs in the $[Co(en)_3]^{3+}$-C1-*cis*(*N*)-$[Co(ox)(gly)_2]^-$ system at 25°C, I=0.01 mol dm^{-3}.

of aqueous *Λ*-$[Co(en)_3]^{3+}$ in the absence and the presence of *Δ*- or *rac*-C1-*cis*(*N*)-K$[Co(ox)(gly)_2]^-$ ion and the CD spectra of aqueous *Δ*-C1-*cis*(*N*)-$[Co(ox)(gly)_2]^-$ in the absence and the presence of *rac*-$[Co(en)_3]^{3+}$ ion. The difference CD (DCD) spectra, which are defined as the observed CD in the presence of both cationic and anionic complexes minus the simple sums of the component solution spectra, are shown in Fig. 6 in order to clarify the CD spectral changes due to ion pairing between these complex ions. The addition of *Δ*-C1-*cis*(*N*)-$[Co(ox)(gly)_2]^-$ to *Λ*-$[Co(en)_3]^{3+}$ not only enhances the CD intensity of the A_2 component at the first absorption band region of $[Co(en)_3]^{3+}$, but also produces a rather large decrease in the CD intensity of C1-*cis*(*N*)-$[Co(ox)(gly)_2]^-$ in the first d-d transition region ((*a*) in Figs. 5 and 6). Fortunately, the observed CD changes of $[Co(en)_3]^{3+}$ are not seriously disturbed by that of the anionic complex since the CD peaks of both the complex ions are very far apart from each other (at 430 nm(A_2) and 490 nm(E_a) for the cation, at 569 nm for the anion). The changes in the CD spectrum of *Λ*-$[Co(en)_3]^{3+}$ on addition of *Δ*- or *rac*-C1-*cis*(*N*)-$[Co(ox)(gly)_2]^-$ are remarkably similar to the case in which phosphate and *d*-tartrate ions are added. It has been established that three oxygen atoms of the phosphate[21,22] and *d*-tartrate ions[23,24] form hydrogen bonds with three N-H protons of the $[Co(en)_3]^{3+}$ along its C_3 axis, in solution as well as in crystal. The similarity in CD change detected in the present study suggests that the hydrogen bonds along the C_3 axis of the cation are formed between the three axial N-H protons of the $[Co(en)_3]^{3+}$ and the three coordinated oxygen atoms of the C1-*cis*(*N*)-$[Co(ox)(gly)_2]^-$. A similar existence of three N-H···O hydrogen bonds along the C_3 axis was reported for the diastereoisomer *Λ*-$[Co(l\text{-pn})_3]$*Λ*-$[Cr(mal)_3]\cdot 3H_2O$ in crystal.[9] The DCD spectrum for the solution involving *Λ*-$[Co(en)_3]^{3+}$ and *rac*-C1-*cis*-(*N*)-$[Co(ox)(gly)_2]^-$ has a small positive peak in the first d-d transition region of the complex anion ((*b*) in Fig.6). Since the ion-pairing interaction of the *Λ*-cation with the *Δ*-anion produces a large decrease in the CD intensity in the spectral region of the anion (a large positive DCD peak) ((*a*) in Figs. 5 and 6), the small positive DCD peak produced by the *Λ*-cation and the rac-anion indicates that the *Λ*-*Δ* interaction is stronger than the *Λ*-*Λ*; in other words, the favorable ion pair between $[Co(en)_3]^{3+}$ and C1-*cis*(*N*)-$[Co(ox)(gly)_2]^-$ is *Λ*-*Δ*.

Miyoshi et al. have reported that when the cationic complex uses its C_3 axis for hydrogen bonding to the anionic complex, a homochiral combination (*Λ*-*Λ* or *Δ*-*Δ*) is favored, whereas when the cationic complex uses its C_2 axis, a heterochiral combination (*Λ*-*Δ* or *Δ*-*Λ*) is favored.[8,10] However, in the present $[Co(en)_3]^{3+}$-C1-*cis*(*N*)-$[Co(ox)(gly)_2]^-$ system, it is strongly suggested from the CD spectral change (an enhancement of the A_2 component of $[Co(en)_3]^{3+}$) that the favorable pair is a heterochiral combination in which the cation uses its C_3 axis for hydrogen bonding. This is inconsistent with the discrimination mechanism proposed above by Miyoshi et al.

Diastereomeric Ion-Pair Formation Constants. We previously showed that the conductance method is useful for a determination of the diastereomeric ion-pair formation constants between chiral complex ions.[4,5] The conductance measurements were carried out for $[Co(en)_3]^{3+}$-C1-*cis*(*N*)-$[Co(ox)(gly)_2]^-$ and $[Co(en)_3]^{3+}$-*β*-*cis*-$[Co(ox)(edda)]^-$ systems. In Fig. 7 are shown the deviations ($\Delta\kappa$) of the measured conductivity from the additivity of the component conductivities at various volume fractions (*x*) of $[Co(en)_3]$-

$I_3 \cdot H_2O$ for the Λ-Δ and Λ-Λ pairs in the $[Co(en)_3]^{3+}$-C_1-*cis*(*N*)-$[Co(ox)(gly)_2]^-$ system at 25 °C, ionic strength I=0.01 mol dm^{-3}. The $\Delta\kappa$ value of the mixture, consisting of a solution of C_M mol dm^{-3} $[Co(en)_3]$-$I_3 \cdot H_2O$ and a solution of C_B mol dm^{-3} K-C_1-*cis*(*N*)-$[Co(ox)(gly)_2] \cdot 0.5H_2O$ at volume fractions of x and 1-x, respectively, is given by

$$10^3 \Delta\kappa = 10^3\kappa - C_M x \Lambda_m(MI_3) - C_B(1-x)\Lambda_m(KB), \quad (3)$$

where κ is the specific conductivity (S cm^{-1}) of the mixture and Λ_m is the molar conductivity (S cm^2 mol^{-1}) of the species specified in parentheses {M=$[Co(en)_3]^{3+}$, B=C_1-*cis*(*N*)-$[Co(ox)(gly)_2]^-$} at an ionic strength of 0.01 mol dm^{-3}. If a 1:1 ion pair, $M^{3+} \cdot B^-$, is assumed, $\Delta\kappa$ can be related to the molar concentration of the ion-pair by

$$[M^{3+} \cdot B^-] = 10^3 \Delta\kappa/\alpha \quad (4)$$

and

$$\alpha = 2\lambda(M^{3+} \cdot B^-) - 3\lambda(M^{3+}) - \lambda(B^-), \quad (5)$$

where λ is the ionic equivalent conductance at 25 °C, I=0.01 mol dm^{-3} of $M^{3+} \cdot B^-$, M^{3+}, and B^-, respectively. It can been seen in Fig. 7 that there exists a significant difference in the $|\Delta\kappa|$ values between the Λ-Δ and Λ-Λ pairs; that is, the $|\Delta\kappa|$ values for the Λ-Δ pair are invariably larger than those for the Λ-Λ pair at every volume fractions. The diastereomeric ion-pair formation constants, $K(\Lambda$-$\Delta)$ and $K(\Lambda$-$\Lambda)$, obtained by analyzing the $\Delta\kappa$ values according to procedures described in the literature[4,5,19] are given in Table 1 along with the relative formation constants (discrimination factors), $K(\Lambda$-$\Delta)/K(\Lambda$-$\Lambda)$, which is considered to be a measure of the stereoselectivity in ion pairing determined directly by conductance. The diastereomeric ion-pair formation constants and the discrimination factors for the $[Co(en)_3]^{3+}$-β-cis-$[Co(ox)(edda)]^-$ system are presented in Table 2. As can already be expected from the similarity of the chromatographic behavior to that of C_1-*cis*(*N*)-$[Co(ox)(gly)_2]^-$, the preference of the Λ-Δ combination was again observed in this system. However, it may be noteworthy that the discrimination factor for the $[Co(en)_3]^{3+}$-β-*cis*-$[Co(ox)(edda)]^-$ system is smaller than that for the $[Co(en)_3]^{3+}$-C_1-*cis*(*N*)-$[Co(ox)(gly)_2]^-$ system. In β-*cis*-$[Co(ox)(edda)]^-$ complex, the meridional acetate ring of the edda ligand is strained because of the presence of the "ethylenediamine" part of the edda, compared with the strain-free glycinate rings in C_1-*cis*(*N*)-$[Co(ox)(gly)_2]^-$. Consequently, both the anionic complexes are subtly different in the direction of the lone pair electrons on the coordinated oxygen atoms. Thus, as can be seen in Tables 1 and 2, this effect upon the ion-pair formation constants is more prominent for the favorable pairs ($K(\Lambda$-$\Delta)$=83.1 and 69.8 mol^{-1} dm^3 for $[Co(en)_3]^{3+}$-C_1-*cis*(*N*)-$[Co(ox)(gly)_2]^-$ and $[Co(en)_3]^{3+}$-β-*cis*-$[Co(ox)(edda)]^-$ systems, respectively) than for the unfavorable pairs ($K(\Lambda$-$\Lambda)$= 63.8 and $K(\Delta$-$\Delta)$=60.0 mol^{-1}dm^3 for the former and the latter systems, respectively) since the stabilization

of a favorable pair should greatly depend on the fitness of the hydrogen bonding. The importance of the direction of lone pair electrons on the oxygen atom employed for hydrogen bonding was also observed in chromatographic ion-pairing investigations of C_1-*cis*(*N*)-$[Co(ox)(gly)_2]^-$ and C_1-*cis*(*N*)-$[Co(ox)(\beta\text{-ala})_2]^-$ with Λ-$[Co(en)_3]^{3+}$ [5]; that is, the separation factor for C_1-*cis*(*N*)-$[Co(ox)(\beta\text{-ala})_2]^-$ with six-membered chelate rings has been shown to be slightly greater than that for C_1-*cis*(*N*)-$[Co(ox)(gly)_2]^-$ with five-membered chelate rings, where the separation factor is defined as the value of the retention volume of the later eluted enantiomer devided by that of the faster eluted one. This enhanced stereoselectivity for C_1-*cis*(*N*)-$[Co(ox)(\beta\text{-ala})_2]^-$ suggests that the direction of lone pair electrons on the carboxyl oxygen atom in the six-membered chelate ring is more favorable to hydrogen bonding along the C_3 axis with the N-H groups on the Λ-$[Co(en)_3]^{3+}$ than that in the five-membered chelate ring. The stereoselectivity was observed to increase for chelate rings of the related anionic complexes in the following order: strained five-membered chelate ring<less strained five-membered chelate ring<six-membered chelate ring. Thus, β-*cis*-$[Co(ox)(edda)]^-$ with the strained meridional acetate ring can be understood to show reduced ion-pairing stereoselectivity. The observation that the CD change of Λ-$[Co(en)_3]^{3+}$ on addition of β-*cis*-$[Co(ox)(edda)]^-$ is quite similar to that on addition of C_1-*cis*(*N*)-$[Co(ox)(gly)_2]^-$ but is slightly smaller in magnitude also supports the reduced stereoselectivity in $[Co(en)_3]^{3+}$-β-*cis*-$[Co(ox)(edda)]^-$ system.

Concluding Remarks

It has been shown that C_1-*cis*(*N*)-$[Co(ox)(gly)_2]^-$ and β-*cis*-$[Co(ox)(edda)]^-$ associate more strongly with $[Co(en)_3]^{3+}$ than the respective other geometrical isomers. An important structural characteristic of the anionic complexes is that they have a triangular face consisting of three coordinated oxygen atoms along the pseudo C_3 axis. In both $[Co(en)_3]^{3+}$-C_1-*cis*(*N*)-$[Co(ox)(gly)_2]^-$ and $[Co(en)_3]^{3+}$-β-cis-$[Co(ox)(edda)]^-$ systems a Λ-Λ combination was preferred over a Λ-Λ combination. This has also been confirmed by the diastereomeric ion-pair formation constants determined by the conductance method. The effect of C_1-*cis*(*N*)-$[Co(ox)(gly)_2]^-$ and β-*cis*-$[Co(ox)(edda)]^-$ on the CD spectra of $[Co(en)_3]^{3+}$ was very similar to that of phosphate and *d*-tartrate ions; that is, the A_2 rotational strength of $[Co(en)_3]^{3+}$ was enhanced upon the formation of ion pairing. This result strongly suggests that the hydrogen bondings formed between the cationic and the anionic complexes play an important role in the ion-pairing stereoselectivity and, further, that the anionic complex approaches a triangular face of $[Co(en)_3]^{3+}$ along the C_3 axis and makes a face-to-face close contact through three hydrogen bonds. The ion-pair structure is disagreement with the discrimination mechanism proposed by Miyoshi et al.

The sea bottom in the vicinity of the center of Lake Hamana in Japan forms a sea basin, and anoxic seawater appears in this bottom layer in summer. We examined the seasonal movements of phosphorus and iron compounds, dissolved hydrogen sulfide, and others in this anoxic seawater with a view to investigating their elution processes from the sediments of the sea basin into the anoxic seawater. Some parts of the elution phenomena of these components from the sediments of the sea basin in Lake Hamana into the anoxic seawater in summer will be described in the present work.

The sea bottom in the vicinity of the center of Lake Hamana in Japan forms a sea basin. Anoxic seawater appears in this bottom layer in summer because the hydrosphere in the basin becomes a reducing atmosphere at a high temperature as a result of the small tidal currents and the decomposition of dead marine organisms such as plankton deposited on the sea floor. However, very little information is available in the literature on the seasonal movements of phosphorus and iron compounds, dissolved hydrogen sulfide (DHS), and others, in the anoxic seawater occurring in a sea basin such as Lake Hamana.

We ourselves have reported previously analytical methods for dissolved inorganic phosphorus (DIP) and organic phosphorus (DOP)[1-3] and DHS[4,5] eluted from the sediments of the sea basin in Lake Hamana into the anoxic seawater. By applying mainly our analytical methods, we have now examined the seasonal movements of DIP, DOP, iron(II) and iron(III) ions, DHS, and others in the anoxic seawater occurring in the sea basin, with a view to investigating geochemically their elution processes from the sediments.

Experimental

Analytical Procedure for DHS. Sample solutions (4-ml volume) from different water depths are introduced from Kitahara's bottle into a 10-ml syringe containing 4 ml of an acetone solution of hydroxylamine hydrochloride(0.2%). After the removal of an air bubble, the syringe is shaken gently, then most of the mixed sample solution is transferred into a 7-ml dark plastic bottle. The bottle is immediately sealed and stored at 0 °C. The DHS in the stored solution is determined by means of gas chromatography under the conditions shown in Table 1.

§ A part of this paper was presented at the Symposium of Environmental Science held in Tokyo, November, 1986.

Table 1. Analytical Conditions for the Determination of Dissolved Hydrogen Sulfide by Means of Gas Chromatography

Column temperature	110 °C
Injection temperature	150 °C
H_2 pressure	0.75 kg cm^{-2}
Air pressure	1.30 kg cm^{-2}
Carrier gas	Nitrogen, 90 ml min^{-1}
Injection volume	2 μl
Glass column	1.1×3.2 mm i.d.
Packing material	Porapak N (50—80 mesh)

The initial DHS concentration in anoxic seawater is determined by reference to previously prepared calibration and decay curves for DHS at a rate of about 0.5% per hour over a 24-h period after sampling. For further details, the reader should refer to Refs. 4 and 5.

Analytical Procedure for DIP and DOP, and for Fe(II) and Fe(III). The DIP and DOP and the Fe(II) and Fe(III) in anoxic seawater are determined by the heteropoly-blue method[1,3] and by 1,10-phenanthroline spectrophotometry[6] respectively.

Results and Discussion

The water samples were taken using Kitahara's bottle from different water depths (at intervals of about 1 m) at two Stations, A and B, in Lake Hamana.[5] The sea bottom of Station A, in the vicinity of the center in Lake Hamana, forms the deepest sea basin (about 12 m) in the lake, while Station B, used as a control for A, stands at one end of this sea basin.

Figure 1 shows the seasonal variations in the dissolved oxygen (DO), the salinity, the pH, and the temperature at different water depths of Stations A and B at roughly monthly intervals for the year in 1983. It may be observed from the results shown in Fig. 1 that DO decreased gradually with the increase

in the water depth from near 4 m of Station A in March to September, closely approaching zero at the deep water depths of 7 to 11 m in May to September; the pH in seawaters of Station A showed a decreasing

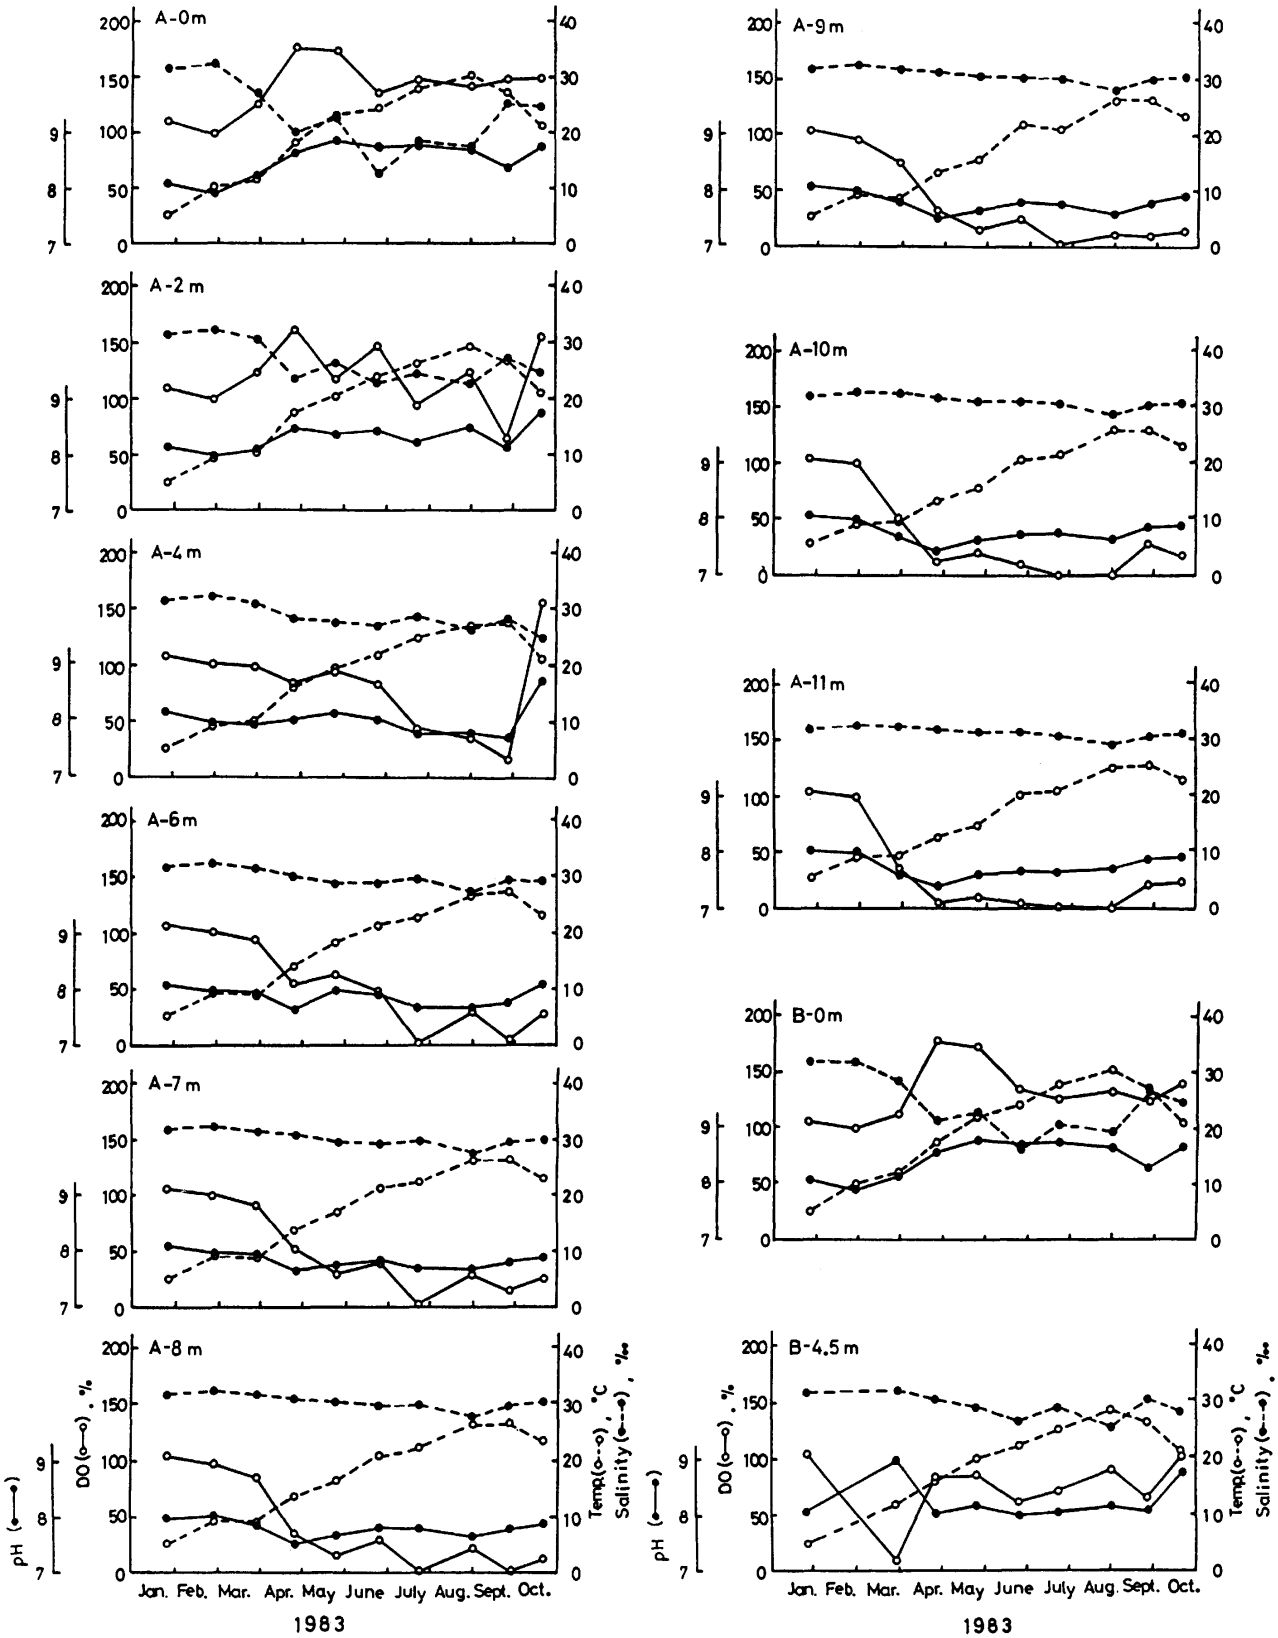

Fig. 1. Seasonal variations of dissolved oxygen, salinity, pH, and temperature in the seawater at different water depths of the stations A and B in 1983.

trend like DO with the increase in the water depth from near 4 m in March to September, while the water temperature reached a maximum near 30 °C at every water depth in August or September. From such changes in the DO and the pH, it can be estimated that the sea basin of Station A rises from a water depth of about 4 m and that its bottom layer presents a reducing atmosphere from March to September.

Figure 2 shows the seasonal variation in the contents of DIP, Fe(II), Fe(III), and DHS in the seawater at different water depths of Stations A and B at roughly monthly intervals for the year of 1983. The following points particularly attract attention among the results shown in Fig. 2:

(a) The DIP increased remarkably with the increase in water depth from near 3 m of Station A in roughly inverse interrelation to the DO and the pH in the summer season (June to September), while the DOP was 10 ppb or less at every water depth of both stations at all times. Therefore, the DOP was not

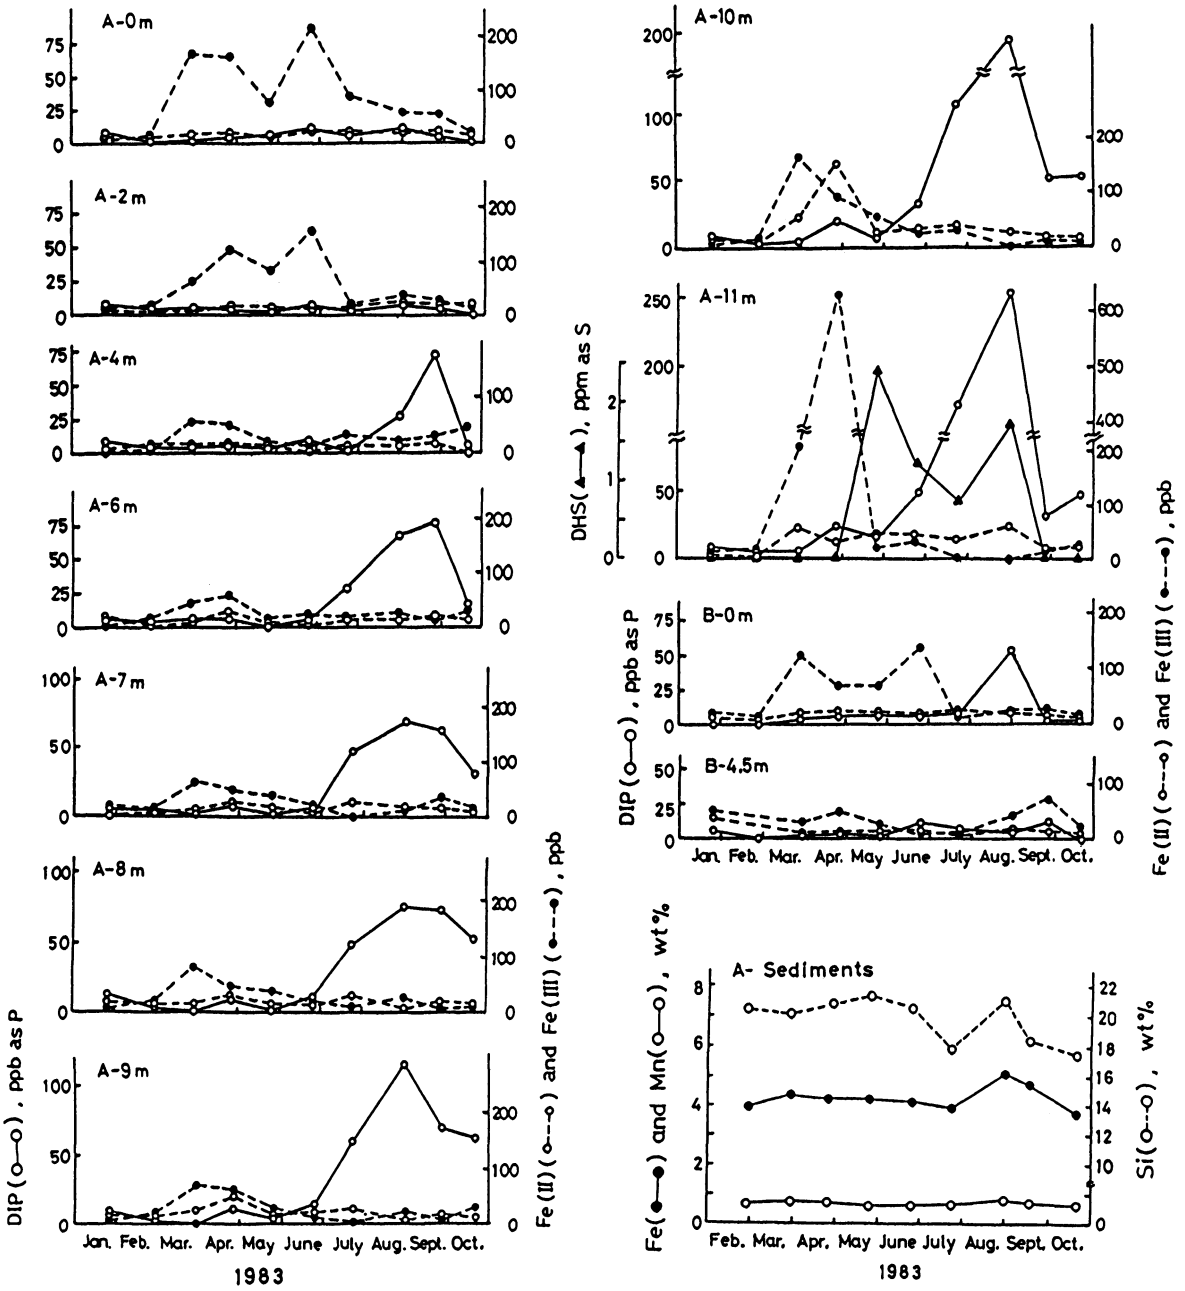

Fig. 2. Seasonal variations of dissolved inorganic phosphorus, Fe(II), Fe(III), and dissolved hydrogen sulfide in the seawater at different water depths of the stations A and B, and those of some elements in the sediments at the station A in 1983.

plotted in Fig. 2.

(b) The maxima of Fe(II) and DIP, even in a small peak, were simultaneously observed at the deep water depths from 7 to 11 m near the sediments of Station A around April.

(c) On the other hand, the peaks of Fe(III) at the same deep water depths appeared from March to April and had almost disappeared already when the DIP and a large amount of the DHS appeared in the anoxic seawater in the early summer season.

(d) However, the concentrations of Fe(III) in the seawater samples collected from the surface to a water depth of near 2 m of Stations A and B were higher than those in the anoxic seawater at the middle water depths of both stations from March to April, while they had the two maxima from March to the early summer season.

(e) The considerable amounts of DHS, which are several times as much as the DIP or Fe(II) contents, were detected at a water depth of 11 m of Station A in the summer season when the DIP appeared in the anoxic seawater.

(f) The seasonal variations of some elements in the surface layer of the sediments at the sea basin of Station A are shown in Fig. 2. It is evident from these results that considerable amounts of iron at least exist in the sediments, and that these seasonal curves of Fe and Si both have a miximum in summer. On the other hand, the Fe and Mn in plankton collected near the sea surface at Station A in August in 1983 constituted dry percentages of 3.5 and 0.05 respectively.

Figure 3 shows the vertical profiles of DIP, Fe(II),

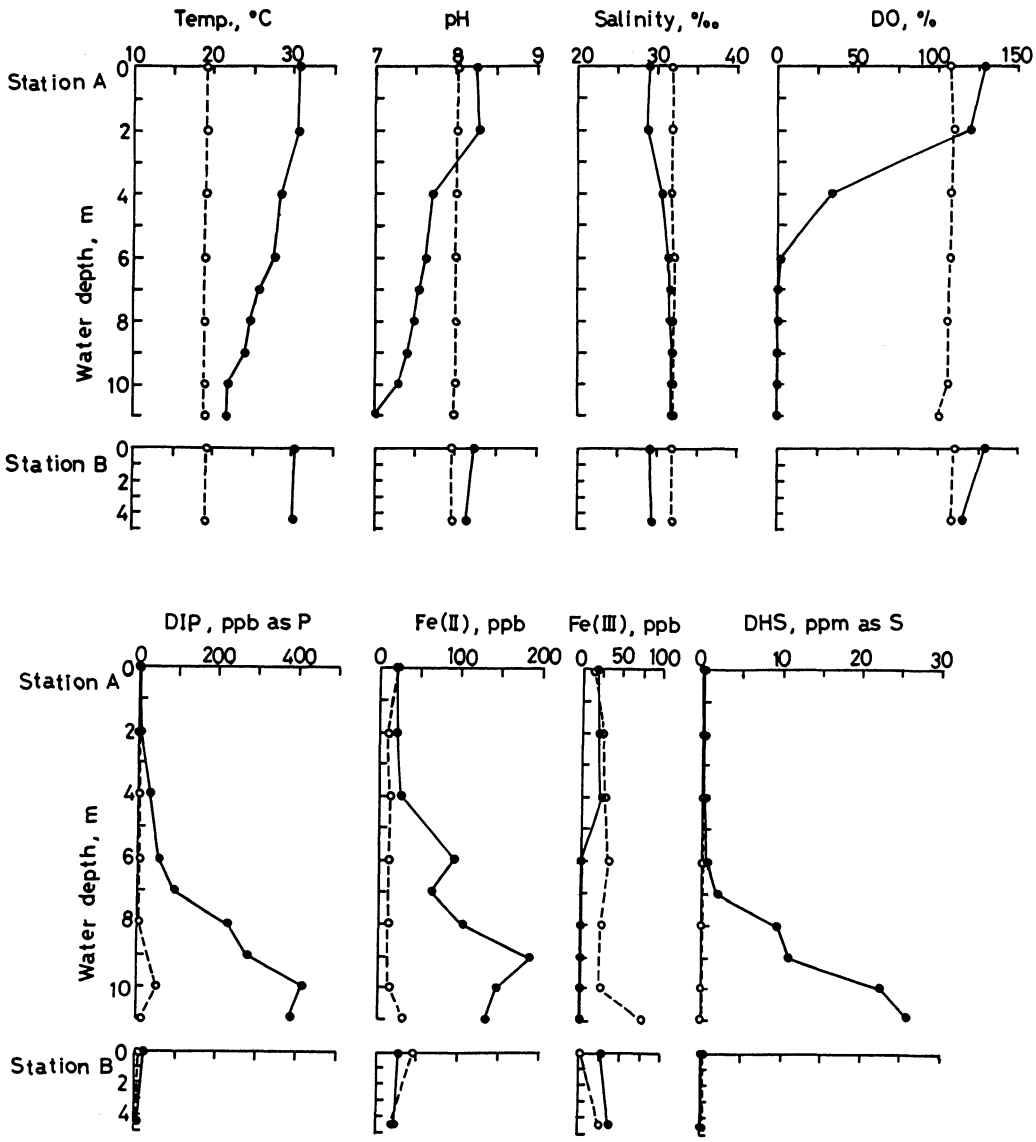

Fig. 3. Vertical profiles of dissolved inorganic phosphorus, Fe(II), Fe(III), dissolved hydrogen sulfide, and others in the seawater at the stations A and B in 1984. ●—●: in September, 1984, O---O in October, 1984.

Fe(III), DHS, and others in the anoxic seawater at Stations A and B in September and October in 1984. Since in Japan it was a relatively cold summer in 1984, and since, besides, some typhoons hit Lake Hamana in the summer, the anoxic seawater had not developed fully until the end of August that year. It is apparent from the vertical profiles shown in Fig. 3 that, in September at Station A, the DIP, Fe(II), and DHS were simultaneously eluted from the sediments of the sea basin into the anoxic seawater under the conditions at DO≈0, and that they then diffused gradually into the upper layer, whereas in October at Station A the DO has already reached saturation at every depth and so hardly any vertical changes with the water depth were observed. The variations shown in Fig. 3 correspond quite well to those shown in Fig. 2.

The molalities at each maximum in the seasonal-variation curves for DIP, Fe(II), Fe(III), and DHS at the water depth of A-11 m (Fig. 2) were 8.19, 1.07, 11.3, and 74.5 mmol m^{-3} respectively, while those for DIP, Fe(II), and DHS at the water depth of A-11 m in September (shown in Fig. 3) were 12.3, 2.38, and 754 mmol m^{-3} respectively.

Conclusion

On the basis of the above-mentioned experimental facts, we reached the following conclusions regarding the elution phenomena of DIP, Fe(II), Fe(III), and DHS from the sediments of the sea basin in Lake Hamana into the anoxic seawater in summer:

(1) The DIP is undoubtly eluted, together with a large amount of DHS and a small amount of Fe(II), from the sediments of the sea basin into anoxic seawater under the conditions of the water near the sediments at DO≈0 and at water temperatures≈20—30 °C in the summer season (see (a), (e) and Fig. 3 in Results and Discussion). The tendency for DIP to decrease with shallowing the water depth may be caused by the diffusion of the tidal current or by its being taken as nutrition by the plankton living in the shallow water layer. Such elutions of DIP and DHS from the sediments into the anoxic seawater in summer season might result mainly from the decomposition of dead plankton deposited on the surface of the sea basin according to a chemical reaction, represented by Richards,[7] which proceeds from the action of anaerobic bacteria in the sediments at the reducing atmosphere under the above-mentioned conditions.

Furthermore, the elutions of Fe(II) and DIP may occur by their changing chemically from very slightly soluble $FePO_4$ in water to hardly soluble $Fe_3(PO_4)_2$ in the sediments at the above-mentioned reducing state and by the dissociation of the $Fe_3(PO_4)_2$ with the drop in the pH(<7) of the interstitial water in the sediments according to the following Eqs. 1 and 2:[8]

$$FePO_4 \xrightarrow{\text{reducing state}} Fe_3(PO_4)_2 \quad (1)$$

$$Fe_3(PO_4)_2 \overset{pH<7}{\rightleftharpoons} 3Fe^{2+} + 2PO_4^{3-} \quad (2)$$

Such inference does not contradict the experimental fact that the maxima of Fe(II) and DIP at the deep water depths, even in a small peak accompanying the decrease in DO around April, appeared simultaneously in Fig. 2(see (b) and Fig. 3 in Results and Discussion).

(2) The Fe(II) appearing in the anoxic seawater from the sediments around April, as is shown in Fig. 2, and in August or September, as is shown in Figs. 2 and 3, may be rapidly oxidized to Fe(III) in the shallow water layer by the DO according to the following Eq. 3:

$$Fe(II) \xrightarrow{O_2(DO)} Fe(III) + e^- \quad (3)$$

(3) The peaks appearing in the seasonal-variation curves of Fe(III) at the deep water depths of Station A from March to April, as is shown in Fig. 2 (see (c) in Results and Discussion), may result from a slight dissociation of $Fe(OH)_3$ as a hardly soluble precipitate in water with the drop in the pH of the interstitial water in the sediments, as is shown in Fig. 1, and/or from the above-mentioned oxidation of Fe(II) by the DO (see (b) and (f)).

From the experimental findings that the concentrations of Fe(III) in the water near the surface of Stations A and B were higher than those in the anoxic seawater at the middle water depths of both stations for the above period, and that they had their two maxima in the season from March to early summer, as is shown in Fig. 2 (see to (d) in Results and Discussion), it can also be thought that some organic substances serving as chelators for Fe(III) which are produced from plankton living in the seawater near the sea surface may contain some Fe(III), or that on the occassion of sampling, a little plankton containing Fe(III) may be taken into the water samples (see (f) in Results and Discussion).

(4) The rapidly decaying phenomena, especially at the bottom layers, of Fe(II) and Fe(III) in the seasonal-variation curves at different water depths of Station A, as is shown in Fig. 2 (see (b), (c), and (d) in Results and Discussion) when the DIP and the large amounts of DHS appeared just in the anoxic seawater in the early summer season might be only an apparent decrease resulting from the formation[8] of FeS or FeS·S as a hardly soluble precipitate with the DHS, according to Eqs. 4 and 5:

$$2Fe^{3+} + H_2S \longrightarrow 2Fe^{2+} + S\downarrow + 2H^+ \quad (4)$$

$$Fe^{2+} + S^{2-} \longrightarrow FeS\downarrow \quad (5)$$

We wish to thank Professor Emeritus Dr. Hidehiro Gotô of Tohoku University, Professor Emeritus Dr. Michio Ôta of Yamanashi University, Professor Dr. Akira Murata of Shizuoka University, and Assistant Professor Dr. Mitsuru Sakamoto of Nagoya University for their kind and ever-continuing guidances.

Study of Polarographic Anodic Wave in the Presence of Chloride Ions by a New Numerical Method

Kenji KIKUCHI and Teisuke MURAYAMA*
Shiga Prefectural Junior College, Hikone, Shiga 522
Department of Applied Chemistry, Faculty of Engineering, Shizuoka University, Johoku, Hamamatu 432
(Received January 7, 1988)

A new numerical method is applied to the simultaneous diffusion equations describing the anodic process of mercury in solutions in the presence of chloride ions. The terms corresponding to precipitation and dissolution of mercury(I) chloride are included in the differential equations. It is found that the differential equation for precipitate particles should be rewritten using the backward space difference method for successful computation.

Kolthoff and Miller studied the anodic wave of mercury in the presence of chloride ions.[1] They observed that the diffusion current corrected for residual current is proportional to the concentration of chloride ions. They assumed that the concentration of chloride ions at the surface of mercury electrode is determined by the solubility product and by the concentration of mercury(I) ions at the electrode surface which is controlled by the electrode potential. Based on this assumption they derived an equation of the current-potential curve accompanying with formation of slightly soluble mercury(I) chloride salt as

$$E = E^0 + \frac{RT}{2F} \ln \frac{K_{sp}\gamma_A}{C_{B0}^2} = E' + \frac{RT}{2F} \ln K_{sp} - \frac{RT}{F} \ln (\bar{i}_d - \bar{i}), \quad (1)$$

where E is the potential of dropping mercury electrode, C_{B0} the concentration of chloride ion at the electrode surface, γ_A the activity coefficient of mercury(I) ion, K_{sp} the solubility product of mercury(I) chloride, $\bar{i}$ the average current, $\bar{i}_d$ the average diffusion current, F the Faraday constant, and E^0 the standard electrode potential of Hg_2^{2+}-Hg couple. The plot of $\log(i_d - i)$ vs. E should be a straight line with a reciprocal slope of −59.2 mV/unit at 25 °C. Their plot produced a straight line, however, with a reciprocal slope of −54 mV/unit, which did not agree with Eq. 1.

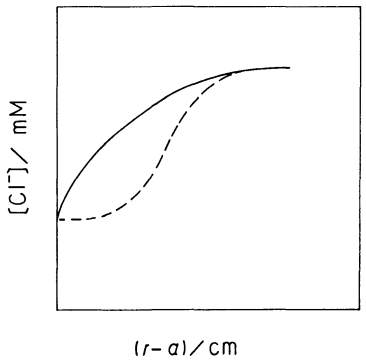

Fig. 1. Distance-concentration curves of chloride ions. A solid line represents a conception considered by Kolthoff and Miller. A dotted line represents a conception proposed by this paper.

After their study, the method and its variations have been generally used for analyzing anodic waves of electrode mercury in the presence of depolarizers which form slightly soluble mercury(I) compounds. The conception proposed by Kolthoff and Miller is that chloride ions are consumed only at the electrode surface and ionic concentration at the electrode surface can be determined by the solubility product and the electrode potential. Figure 1 schematically shows the concentration profile of chloride ions. A solid line was drawn according to their conception. However, chloride ions themselves do not receive any electrochemical change, but are consumed by the chemical reaction with mercury(I) ions produced through the electrochemical reaction. Hence the slope of concentration profile of chloride ions at the surface should be zero as illustrated by the dotted line in Fig. 1. These situations are not reflected in Eq. 1. The equation is a rather crude approximation to the phenomenon, which is waiting more detailed analysis.

This study has two purposes. One is application of a new numerical method,[2] and another is explicit consideration of formation and dissolution of precipitate particles in the process. No direct treatment of dissolution of precipitate particles has been found in literature.

Theory

In the anodic process, mercury is dissolved into solution as mercury(I) ions. When the concentration product of mercury(I) and chloride ions exceeds the solubility product, mercury(I) ions react with chloride ions producing mercury(I) chloride precipitate particles. These reactions are written as follows:

$$2Hg \rightleftharpoons Hg_2^{2+} + 2e^-, \quad (2)$$

and

$$Hg_2^{2+} + 2Cl^- \underset{k_b}{\overset{k_f}{\rightleftharpoons}} Hg_2Cl_2, \quad (3)$$

In Eq. 3, k_f and k_b are rate constants of formation and dissolution, respectively, of the precipitate particles. It is assumed that the effect of formation of mercury(II) ions on the anodic current is negligible in comparison with that of mercury(I) and chloride ions. Further it is assumed that Reaction 3 is rapid and in equilibrium. The solubility product is given by

$$K_{sp} = [Hg_2^{2+}][Cl^-]^2 = k_b[Hg_2Cl_2]/k_f = k_b^*/k_f. \quad (4)$$

Because the solubility of mercury(I) chloride is constant under experimental conditions, the product of the concentration and k_b is replaced by another constant k_b^* in Eq. 4.

In the following, subscripts A, B, and C denote, respectively, mercury(I) ion, chloride ion, and precipitate particle of mercury(I) chloride. Hence their concentrations are expressed as C_A, C_B, and C_C, respectively.

When precipitate particles exist in a volume element considered, or the condition that $C_AC_B^2 \geqq K_{sp}$ is satisfied in the volume element, the simultaneous equations governing concentrations of species appearing in Reactions 2 and 3 are

$$\frac{\partial C_A}{\partial t} = D_A\left(\frac{\partial^2 C_A}{\partial r^2}\right) + \left(\frac{2}{r}D_A - u\right)\frac{\partial C_A}{\partial r} - k_fC_AC_B^2 + k_b^*, \quad (5)$$

$$\frac{\partial C_B}{\partial t} = D_B\left(\frac{\partial^2 C_B}{\partial r^2}\right) + \left(\frac{2}{r}D_B - u\right)\frac{\partial C_B}{\partial r} - 2k_fC_AC_B^2 + 2k_b^*, \quad (6)$$

$$\frac{\partial C_C}{\partial t} = -u\frac{\partial C_C}{\partial r} + k_fC_AC_B - k_b^*, \quad (7)$$

and

$$u = m/(4\pi\rho r^2), \quad (8)$$

where D_h is the diffusion coefficient of species h, r the distance from the center of the electrode mercury drop, m the flow rate of mercury, and ρ the density of mercury. It is assumed that diffusion of the precipitate particles is negligible in comparison with that of ions. The precipitate concentration is expressed in formal concentration of the precipitate substance, which is assumed to be dispersed homogeneously in the volume element. As usually does, it is assumed that the center of mercury drop remains fixed.

When the precipitate does not exist in a volume element, that is $C_AC_B^2 < K_{sp}$, the simultaneous equations describing variation of concentrations are

$$\frac{\partial C_A}{\partial t} = D_A\left(\frac{\partial^2 C_A}{\partial r^2}\right) + \left(\frac{2}{r}D_A - u\right)\frac{\partial C_A}{\partial r}, \quad (9)$$

and

$$\frac{\partial C_B}{\partial t} = D_B\left(\frac{\partial^2 C_B}{\partial r^2}\right) + \left(\frac{2}{r}D_B - u\right)\frac{\partial C_B}{\partial r}. \quad (10)$$

Initial conditions are

$$C_A = 0,\ C_B = C^*_B, \text{ and } C_C = 0\ (t = 0, r > a). \quad (11)$$

Boundary conditions are as follows:

$$C_A = C_{A0},\ (\partial C_B/\partial r) = 0\ (t > 0, r = a), \quad (12)$$

and

$$C_A = 0,\ C_B = C^*_B,\ C_C = 0\ (t > 0, r = \infty). \quad (13)$$

In the above, a is the radius of mercury drop, C^*_B the concentration of chloride ions in bulk solution, and C_{A0} the concentration of mercury(I) ions at the surface of mercury electrode. The potential of mercury electrode dictates the value of C_{A0}. The instantaneous current, i, is given by

$$i = 2FD_AS(\partial C_A/\partial r)_{r=a}, \quad (14)$$

where S is the surface area of mercury drop.

Because the reaction proceeds in the neighborhood of electrode surface, numerical results most desired are those in the proximity of electrode surface. For this purpose, numerical integration of the differential equations is carried out more efficiently using a network, of which mesh is finer in near positions to the electrode surface and becomes coarser with the distance from the surface. Hence we introduce a parameter given by

$$s^P = 1 - 1/\{1 + (Hx)^P\}, \quad (15)$$

where H and P are constants. In the previous report,[2] the value of P is unity.

To facilitate calculation, we introduce the following transformations:[2]

$$y_A = C_A/C_{A0},\ y_B = C_B/C_{A0},$$
$$y_C = C_C/C_{A0},\ x = (r - a)/L,$$
$$d_A = D_A/D_A = 1,\ d_B = D_B/D_A,\ T = D_At/L^2,$$
$$U = Lur^2/(D_Aa^2),\ K_f = L^2k_fC_{A0}^2/D_A,$$

and

$$K_b = k_b^*L^2/C_{A0}D_A. \quad (16)$$

In the above, L is the representative length and H a constant. The maximum value of s is unity, where the value of r is infinite. With these transformations, Eq. 5 becomes

$$\frac{\partial y_A}{\partial T} = d_AH^2(1 - s^P)^{2(P+1)/P}\frac{\partial^2 y_A}{\partial s^2} + 2H(1 - s^P)^{(P+1)/P}\left\{\frac{2d_A}{x + a/L} + \frac{x(x + 2a/L)}{(x + a/L)^2}U - 2d_AH(P + 1)s^{P-1}(1 - s^P)^{1/P}\right\}\frac{\partial y_A}{\partial s} - K_fy_Ay_B^2 + K_b. \quad (17)$$

Derivation of Eq. 17 is carried out with the aid of the Crank-Nicolson's method[5] in a similar manner as the previous report. Space and time coordinates are expressed as

$$s_i = i\,\Delta s,\ T_j = j\Delta T,\ x_i = i\Delta s/H\{1 + (i\Delta s)^P\}^{1/P}, \quad (18)$$

and

$$y_A(s,T) = y_A(s_i, T_j) = y_{A,i,j}. \quad (19)$$

When the value of Δs is 0.01, the value of i ranges from 0, corresponding to the electrode surface, to 100, corresponding to infinite distance from the surface. The backward space difference method and the forward time difference method[2] are used in conversion of differential equations to difference equations.

In the case that $0<i<98$, the derivatives corresponding to both $\partial y_A(s,T)/\partial s$ and $\partial^2 y_A(s,T)/\partial s^2$ are expressed as

$$\left(\frac{\partial^2 y_A(s_i, T_{j+1})}{\partial s^2}\right) = \frac{1}{24(\Delta s)^2}\{(-y_{A,i+3,j+1} + 4y_{A,i+2,j+1} + 6y_{A,i+1,j+1} - 20y_{A,i,j+1} + 11y_{A,i-1,j+1}) + (-y_{A,i+3,j} + 4y_{A,i+2,j} + 6y_{A,i+1,j} - 20y_{A,i,j} + 11y_{A,i-1,j})\}, \quad (20)$$

and

$$\left(\frac{\partial y_A(s_i, T_{j+1})}{\partial s}\right) = \frac{1}{24\Delta s}\{(y_{A,i+3,j+1} - 6y_{A,i+2,j+1} + 18y_{A,i+1,j+1} - 10y_{A,i,j+1} - 3y_{A,i-1,j+1}) + (y_{A,i+3,j} - 6y_{A,i+2,j} + 18y_{A,i+1,j} - 10y_{A,i,j} - 3y_{A,i-1,j})\}, \quad (21)$$

with concentrations at the nodes $(i-1,j)$, (i,j), $(i+1,j)$, $(i+2,j)$, $(i+3,j)$, $(i-1,j+1)$, $(i,j+1)$, $(i+1,j+1)$, $(i+2,j+1)$, and $(i+3,j+1)$.

For the point that $i=98$, the outer nodes are ones with i of 99 and 100. Therefore, the backward space difference method was not applicable for conversion. The centered space difference method was used for this purpose. The derivatives are expressed as

$$\left(\frac{\partial^2 y_A(s_{98}, T_{j+1})}{\partial s^2}\right) = \frac{1}{24(\Delta s)^2}\{(-y_{A,100,j+1} + 16y_{A,99,j+1} - 30y_{A,98,j+1} + 16y_{A,97,j+1} - y_{A,96,j+1}) + (-y_{A,100,j} + 16y_{A,99,j} - 30y_{A,98,j} + 16y_{A,97,j} - y_{A,96,j})\}, \quad (22)$$

and

$$\left(\frac{\partial y_A(s_{98}, T_{j+1})}{\partial s}\right) = \frac{1}{24\Delta s}\{(-y_{A,100,j+1} + 8y_{A,99,j+1} - 8y_{A,97,j+1} + y_{A,96,j+1}) + (-y_{A,100,j} + 8y_{A,99,j} - 8y_{A,97,j} + y_{A,96,j})\}, \quad (23)$$

with concentrations at nodes $(96,j)$, $(97,j)$, $(98,j)$, $(99,j)$, $(100,j)$, $(96,j+1)$, $(97,j+1)$, $(98,j+1)$, $(99,j+1)$, and $(100,j+1)$.

For the point that $i=99$, the only outer node is a node with i of 100. Therefore, the forward space difference method was used for this purpose. The derivatives are expressed as

$$\left(\frac{\partial^2 y_A(s_{99}, T_{j+1})}{\partial s^2}\right) = \frac{1}{24(\Delta s)^2}\{(11y_{A,100,j+1} - 20y_{A,99,j+1} + 6y_{A,98,j+1} + 4y_{A,97,j+1} - y_{A,96,j+1}) + (11y_{A,100,j} - 20y_{A,99,j} + 6y_{A,98,j} + 4y_{A,97,j} - y_{A,96,j})\}, \quad (24)$$

and

$$\left(\frac{\partial y_A(s_{99}, T_{j+1})}{\partial s}\right) = \frac{1}{24\Delta s}\{(3y_{A,100,j+1} + 10y_{A,99,j+1} - 18y_{A,98,j+1} + 6y_{A,97,j+1} - y_{A,96,j+1}) + (3y_{A,100,j} + 10y_{A,99,j} - 18y_{A,98,j} + 6y_{A,97,j} - y_{A,96,j})\}. \quad (25)$$

with concentrations at the nodes $(96,j)$, $(97,j)$, $(98,j)$, $(99,j)$, $(100,j)$, $(96,j+1)$, $(97,j+1)$, $(98,j+1)$, $(99,j+1)$, and $(100,j+1)$.

By using the Crank-Nicolson method, the chemical kinetics term is reformulated as

$$K_f y_A y_b^2 = K_f(y_{A,i,j+1}y_{B,i,j+1}^2 + y_{A,i,j}y_{B,i,j}^2)/2. \quad (26)$$

Because the right-hand side of Eq. 26 contains square of $y_{B,i,j+1}$, the value of y_B at the next time coordinate, it is difficult to perform numerical computation without rewriting the term in linear form with respect to $y_{B,i,j+1}$. Linearization of the chemical kinetics term was treated in the previous report, where four methods were described. Larger reaction rate prevents computing by use of these methods because of truncation error. Considering large values of precipitation reaction rate constant (k_f) and dissolution rate constant (k_b) in the present system, the procedure proposed by Morihara and Cheng is applied to the present problem.[3]

By using the method of Morihara and Cheng, the chemical kinetics term is reformulated as follows:

$$K_f(y_{A,i,j+1}y_{B,i,j+1}^2 + y_{A,i,j}y_{B,i,j}^2)/2 = K_f y_{B,i,j+1}y_{B,i,j}(y_{A,i,j+1} + y_{A,i,j})/2. \quad (27)$$

When $0<i<98$, introduction of Eqs. 20, 21, and 27 to Eq. 17 gives

$$\begin{aligned}(1 &+ 20E_{A,i} + 10F_{A,i,j+1} + \Delta TK_f y_{B,i,j+1}y_{B,i,j}/2)y_{A,i,j+1}\\ &= (-E_{A,i} + F_{A,i,j+1})(y_{A,i+3,j+1} + y_{A,i+3,j})\\ &+ (4E_{A,i} - 6F_{A,i,j+1})(y_{A,i+2,j+1} + y_{A,i+2,j})\\ &+ (6E_{A,i} + 18F_{A,i,j+1})(y_{A,i+1,j+1} + y_{A,i+1,j})\\ &+ (11E_{A,i} - 3F_{A,i,j+1})(y_{A,i-1,j+1} + y_{A,i-1,j})\\ &+ (1 - 20E_{A,i} + 10F_{A,i,j+1}\\ &- \Delta TK_f y_{B,i,j+1}y_{B,i,j}/2)y_{A,i,j} + \Delta TK_b, \end{aligned} \quad (28)$$

$$E_{A,i} = \frac{\Delta T}{24\Delta s^2}\, d_A H^2\{1 - (s_i)^P\}^{2(P+1)/P}, \quad (29)$$

and

$$F_{A,i,j+1}=\frac{\Delta T}{12\Delta s}\left[H\{1-(s_i)^P\}^{(P+1)/P}+\frac{d_A}{x_i+a_{j+1}/L}\right.$$
$$\left.+\frac{x_i(x_i+2a_{j+1}/L)}{2(x_i+a_{j+1}/L)^2}U_{j+1}-\frac{d_A}{2}H(P+1)\{1-(s_i)^P\}^{1/P}\right]. \quad (30)$$

When i=98, introduction of Eqs. 22, 23, and 27 to Eq. 17 gives

$$\begin{aligned}&(1+30E_{A,98}+\Delta TK_f y_{B,98,j+1}y_{B,98,j}/2)y_{A,98,j+1}\\&=(-E_{A,98}-F_{A,98,j+1})(y_{A,100,j+1}+y_{A,100,j})\\&+(16E_{A,98}+8F_{A,98,j+1})(y_{A,99,j+1}+y_{A,99,j})\\&+(16E_{A,98}-8F_{A,98,j+1})(y_{A,97,j+1}+y_{A,97,j})\\&+(-E_{A,98}-3F_{A,98,j+1})(y_{A,96,j+1}+y_{A,96,j})\\&+(1-30E_{A,98}-\Delta TK_f y_{B,i,j+1}y_{B,i,j}/2)y_{A,i,j}\\&+\Delta TK_b. \quad (31)\end{aligned}$$

When i=99, introduction of Eqs. 24, 25, and 27 to Eq. 17 gives

$$\begin{aligned}&(1+20E_{A,99}-10F_{A,99,\,j+1}\\&+\Delta TK_f y_{B,99,j+1}y_{B,99,j}/2)y_{A,99,j+1}\\&=(11E_{A,99}+3F_{A,99,j+1})(y_{A,100,j+1}+y_{A,100,j})\\&+(6E_{A,99}-18F_{A,99,j+1})(y_{A,98,j+1}+y_{A,98,j})\\&+(4E_{A,98}+6F_{A,99,j+1})(y_{A,97,j+1}+y_{A,97,j})\\&+(-E_{A,99}-F_{A,99,j+1})(y_{A,96,j+1}+y_{A,96,j})\\&+(1-20E_{A,98}+10F_{A,99,j+1}\\&-\Delta TK_f y_{B,99,j+1}y_{B,99,j}/2)y_{A,99,j}+\Delta TK_b. \quad (32)\end{aligned}$$

The equation concerning species B is transformed as described below.

In the case that i=0, the boundary condition corresponding to $(\partial y_B/\partial s)_{r=a}$=0 is expressed as

$$\left(\frac{\partial C_B(s_0,T_{j+1})}{\partial s}\right)=\frac{1}{6(\Delta s)}(-11y_{B,0,j+1}+18y_{B,1,j+1}$$
$$-9y_{B,2,j+1}+2y_{B,3,j+1})=0, \quad (33)$$

with the concentration at nodes (0,j), (1,j), (2,j), (3,j), (0,j+1), (1,j+1), (2,j+1), and (3,j+1). The following equation is obtained from Eq. 33.

$$y_{B,0,j+1}=(18y_{B,1,j+1}-9y_{B,2,j+1}+2y_{B,3,j+1})/11 \quad (34)$$

In the case that i=1, the derivative corresponding to $\partial y_B/\partial s$ is expressed as

$$\begin{aligned}\left(\frac{\partial^2 y_B(s_1,T_{j+1})}{\partial s^2}\right)&=\frac{1}{276(\Delta s)^2}\{(-4y_{B,4,j+1}+6y_{B,3,j+1}\\&+159y_{B,2,j+1}-350y_{B,1,j+1}+189y_{B,0,j+1}\\&+30(\Delta s)y'_{B,0,j+1}+(-4y_{B,4,j}+6y_{B,3,j}\\&+159y_{B,2,j}-350y_{B,1,j}+189y_{B,0,j}\\&+30(\Delta s)y'_{B,0,j})\}, \quad (35)\end{aligned}$$

and

$$\begin{aligned}\left(\frac{\partial y_B(s_1,T_{j+1})}{\partial s}\right)&=\frac{1}{444(\Delta s)}\{(-4y_{B,4,j+1}+9y_{B,3,j+1}\\&+63y_{B,2,j+1}+175y_{B,1,j+1}-243y_{B,0,j+1}\\&-90(\Delta s)y'_{B,0,j+1})+(-4y_{B,4,j}+9y_{B,3,j}\\&+63y_{B,2,j}+175y_{B,1,j}-243y_{B,0,j}\\&-90(\Delta s)y'_{B,0,j})\}, \quad (36)\end{aligned}$$

with the first differential term at the mercury electrode surface ($y'_{B,0,j+1}$, $y'_{B,0,j}$) and with concentrations at nodes (0,j), (1,j), (2,j), (3,j), (4,j), (0,j+1), (1,j+1), (2,j+1), (3,j+1), and (4,j+1). Here values of $y'_{B,0,j+1}$ and $y'_{B,0,j}$ are zero because the chloride ions do not receive any electrochemical change. Introduction of Eqs. 27, 35, and 36 to Eq. 6 gives

$$\begin{aligned}&\{1+700E_{B,1}/23-350F_{B,1,j+1}/37\\&+\Delta TK_f y_{B,1,j}(y_{A,1,j+1}+y_{A,1,j})/2\}y_{B,1,j+1}\\&=(-8E_{B,1}/23-8F_{B,1,j+1}/37)(y_{B,4,j+1}+y_{B,4,j})\\&+(12E_{B,1}/23+18F_{B,1,j+1}/37)(y_{B,3,j+1}+y_{B,3,j})\\&+(318E_{B,1}/23+126F_{B,1,j+1}/37)(y_{B,2,j+1}+y_{B,2,j})\\&+(378E_{B,1}/23-486F_{B,1,j+1}/37)(y_{B,0,j+1}+y_{B,0,j})\\&+(1-700E_{B,1}/23+350F_{B,1,j+1})y_{B,1,j}+2\Delta TK_b. \quad (37)\end{aligned}$$

When 1<i, the equations concerning with species B are transformed in much the same way as species A. Equations correspoding to Eqs. 28, 31, and 32 are given as follows:

1<i<98,

$$\begin{aligned}&\{1+20E_{B,i}+10F_{B,i,j+1}\\&+\Delta TK_f y_{B,i,j}(y_{A,i,j+1}+y_{A,i,j})/2\}y_{B,i,j+1}\\&=(-E_{B,i}+F_{B,i,j+1})(y_{B,i+3,j+1}+y_{B,i+3,j})\\&+(4E_{B,i}-6F_{B,i,j+1})(y_{B,i+2,j+1}+y_{B,i+2,j})\\&+(6E_{B,i}+18F_{B,i,j+1})(y_{B,i+1,j+1}+y_{B,i+1,j})\\&+(11E_{B,i}-3F_{B,i,j+1})(y_{B,i-1,j+1}+y_{B,i-1,j})\\&+(1-20E_{B,i}-10F_{B,i,j+1})y_{B,i,j}+2\Delta TK_b. \quad (38)\end{aligned}$$

i=98,

$$\begin{aligned}&\{1+30E_{B,98}+\Delta TK_f y_{B,98,j}(y_{A,98,j+1}\\&+y_{A,98,j})/2\}y_{B,98,j+1}\\&=(-E_{B,98}-F_{B,98,j+1})(y_{B,100,j+1}+y_{B,100,j})\\&+(16E_{B,98}+8F_{B,98,j+1})(y_{B,99,j+1}+y_{B,99,j})\\&+(16E_{B,98}-8F_{B,98,j+1})(y_{B,97,j+1}+y_{B,97,j})\\&+(-E_{B,98}-3F_{B,98,j+1})(y_{B,96,j+1}+y_{B,96,j})\\&+(1-30E_{B,98})y_{B,i,j}+2\Delta TK_b. \quad (39)\end{aligned}$$

i=99,

$$\begin{aligned}&\{1+20E_{B,99}-10F_{B,99,j+1}+\Delta TK_f y_{B,99,j}(y_{A,99,j+1}\\&+y_{A,99,j})/2\}y_{B,99,j+1}\\&=(11E_{B,99}+3F_{B,99,j+1})(y_{A,100,j+1}+y_{B,100,j})\\&+(6E_{B,99}-18F_{B,99,j+1})(y_{B,98,j+1}+y_{B,98,j})\\&+(4E_{B,99}+6F_{B,99,j+1})(y_{B,97,j+1}+y_{B,97,j})\\&+(-E_{B,99}-F_{B,99,j+1})(y_{B,96,j+1}+y_{B,96,j})\\&+(1-20E_{B,98}+10F_{B,99,j+1})y_{A,i,j}+\Delta TK_b. \quad (40)\end{aligned}$$

In the volume element, where $C_A C_B^2 < K_{sp}$ is hold, Eqs. 5 and 6 are replaced by Eqs. 9 and 10, respectively. By neglecting chemical kinetics terms in Eqs. 28, 31, 32, 37, 38, 39, and 40, the finite difference equations are given as follows:

$0<i<98$,

$$\begin{aligned}(1 &+ 20E_{A,i} + 10F_{A,i,j+1})y_{A,i,j+1}\\ &= (-E_{A,i} + F_{A,i,j+1})(y_{A,i+3,j+1} + y_{A,i+3,j})\\ &+ (4E_{A,i} - 6F_{A,i,j+1})(y_{A,i+2,j+1} + y_{A,i+2,j})\\ &+ (6E_{A,i} + 18F_{A,i,j+1})(y_{A,i+1,j+1} + y_{A,i+1,j})\\ &+ (11E_{A,i} - 3F_{A,i,j+1})(y_{A,i-1,j+1} + y_{A,i-1,j})\\ &+ (1 + 20E_{A,i} + 19F_{A,i,j+1})y_{A,i,j}. \end{aligned} \quad (41)$$

$i=98$,

$$\begin{aligned}(1 &+ 30E_{A,98})y_{A,98,j+1}\\ &= (-E_{A,98} - F_{A,98,j+1})(y_{A,100,j+1} + y_{A,100,j})\\ &+ (16E_{A,98} + 8F_{A,98,j+1})(y_{A,99,j+1} + y_{A,99,j})\\ &+ (16E_{A,98} - 8F_{A,98,j+1})(y_{A,97,j+1} + y_{A,97,j})\\ &+ (-E_{A,98} - 3F_{A,98,j+1})(y_{A,96,j+1} + y_{A,96,j})\\ &+ (1 - 30E_{A,98})y_{A,98,j}. \end{aligned} \quad (42)$$

$i=99$,

$$\begin{aligned}(1 &+ 20E_{A,99} - 10F_{A,99,j+1})y_{A,99,j+1}\\ &= (11E_{A,99} + 3F_{A,99,j+1})(y_{A,100,j+1} + y_{A,100,j})\\ &+ (6E_{A,99} - 18F_{A,99,j+1})(y_{A,98,j+1} + y_{A,98,j})\\ &+ (4E_{A,99} + 6F_{A,99,j+1})(y_{A,97,j+1} + y_{A,97,j})\\ &+ (-E_{A,99} - F_{A,99,j+1})(y_{A,96,j+1} + y_{A,96,j})\\ &+ (1 - 20E_{A,98} + 10F_{A,99,j+1})y_{A,99,j}. \end{aligned} \quad (43)$$

$i=0$,

$$y_{B,0,j+1} = (18y_{B,1,j+1} - 9y_{B,2,j+1} + 2y_{B,3,j+1})/11. \quad (44)$$

$i=1$,

$$\begin{aligned}(1 &+ 700E_{B,1}/23 - 350F_{B,1,j+1}/37)y_{B,1,j}\\ &= (-8E_{B,1}/23 - 8F_{B,1,j+1}/37)(y_{B,4,j+1} + y_{B,4,j})\\ &+ (12E_{B,1}/23 + 18F_{B,1,j+1}/37)(y_{B,3,j+1} + y_{B,3,j})\\ &+ (318E_{B,1}/23 + 126F_{B,1,j+1}/37)(y_{B,2,j+1} + y_{B,2,j})\\ &+ (378E_{B,1}/23 - 486F_{B,1,j+1}/37)(y_{B,0,j+1} + y_{B,0,j})\\ &+ (1 - 700E_{B,1}/23 + 350F_{B,1,j+1})y_{B,1,j}. \end{aligned} \quad (45)$$

$1<i<98$,

$$\begin{aligned}(1 &+ 20E_{B,i} + 10F_{B,i,j+1})y_{B,i,j+1}\\ &= (-E_{B,i} + F_{B,i,j+1})(y_{B,i+3,j+1} + y_{B,i+3,j})\\ &+ (4E_{B,i} - 6F_{B,i,j+1})(y_{B,i+2,j+1} + y_{B,i+2,j})\\ &+ (6E_{B,i} + 18F_{B,i,j+1})(y_{B,i+1,j+1} + y_{B,i+1,j})\\ &+ (11E_{B,i} - 3F_{B,i,j+1})(y_{B,i-1,j+1} + y_{B,i-1,j})\\ &+ (1 - 20E_{B,i} - 10F_{B,i,j+1})y_{B,i,j}. \end{aligned} \quad (46)$$

$i=98$,

$$\begin{aligned}(1 &+ 30E_{B,98})y_{B,98,j+1}\\ &= (-E_{B,98} - F_{B,98,j+1})(y_{B,100,j+1} + y_{B,100,j})\\ &+ (16E_{B,98} + 8F_{B,98,j+1})(y_{B,99,j+1} + y_{B,99,j})\\ &+ (16E_{B,98} - 8F_{B,98,j+1})(y_{B,97,j+1} + y_{B,97,j})\\ &+ (-E_{B,98} - 3F_{B,98,j+1})(y_{B,96,j+1} + y_{B,96,j})\\ &+ (1 - 30E_{B,98})y_{B,98,j}. \end{aligned} \quad (47)$$

$i=99$,

$$\begin{aligned}(1 &+ 20E_{B,99} - 10F_{B,99,j+1})y_{B,99,j+1}\\ &= (11E_{B,99} + 3F_{B,99,j+1})(y_{B,100,j+1} + y_{B,100,j})\\ &+ (6E_{B,99} - 18F_{B,99,j+1})(y_{B,98,j+1} + y_{B,98,j})\\ &+ (4E_{B,99} + 6F_{B,99,j+1})(y_{B,97,j+1} + y_{B,97,j})\\ &+ (-E_{B,99} - F_{B,99,j+1})(y_{B,96,j+1} + y_{B,96,j})\\ &+ (1 - 20E_{B,98} + 10F_{B,99,j+1})y_{A,99,j}. \end{aligned} \quad (48)$$

In the above, the value of $y_{A,i,j+1}$ is calculated by Eqs. 28, 31, 32, and 41—43, and the value of $y_{B,i,j+1}$ by Eqs. 34, 37—40, and 45—48.

Equation 7 concerning species C contains a fluid flow term resulted from the growth of the mercury drop, but no diffusion term. The surface of electrode drop moves outward with time, and the solution around the drop flows from the outer regions to the surface of electrode. Hence concentrations at outer nodes control future concentrations at inner nodes. By this reason it is vital to use the backward space difference method for reformulation of the equation. This is contrary to other equations which contain diffusion terms. In diffusion, concentrations of both the inner and outer nodes are important factors determining their future concentrations. Hence, all the forward, centered, and backward space difference methods can be used for reformulation of an equation containing both the fluid flow and diffusion terms. In this paper, backward space difference method is used as shown in reformulation of Eqs. 5 and 6.

For transformation of Eq. 7 to difference equation, the derivatives are rewritten as shown below.

In the case that $i=1$, the derivative corresponding to $\partial C_C/\partial r$ is expressed as

$$\begin{aligned}\left(\frac{\partial y_C(s_1, T_{j+1})}{\partial s}\right) &= \frac{1}{24\Delta s}\{(-3y_{C,5,j+1} + 16y_{C,4,j+1}\\ &- 36y_{C,3,j+1} + 48y_{C,2,j+1} - 25y_{C,1,j+1}) + (-3y_{C,5,j+1}\\ &+ 16y_{C,4,j+1} - 36y_{C,3,j+1} + 48y_{C,2,j+1} - 25y_{C,1,j+1})\}, \end{aligned} \quad (49)$$

with the concentrations at the nodes $(1,j)$, $(2,j)$, $(3,j)$, $(4,j)$, $(5,j)$, $(1,j+1)$, $(2,j+1)$, $(3,j+1)$, $(4,j+1)$, and $(5,j+1)$.

When $1<i<98$, the derivative is expressed as

$$\begin{aligned}\left(\frac{\partial y_C(s_i, T_{j+1})}{\partial s}\right) &= \frac{1}{24\Delta s}\{(y_{C,i+3,j+1} - 6y_{C,i+2,j+1}\\ &+ 18y_{C,i+1,j+1} - 10y_{C,i,j+1} - 3y_{C,i-1,j+1})\\ &+ (-y_{C,i+3,j} - 6y_{C,i+2,j} + 18y_{C,i+1,j} - 10y_{C,i,j}\\ &- 3y_{C,i-1,j})\}, \end{aligned} \quad (50)$$

with the concentrations at the nodes $(i-1,j)$, (i,j), $(i+1,j)$, $(i+2,j)$, $(i+3,j)$, $(i-1,j+1)$, $(i,j+1)$, $(i+1,j+1)$,

$(i+2,j+1)$, and $(i+3,j+1)$.

When a point has i of 98, the outer nodes are those with i of 99 and 100. Therefore, application of the backward space difference method is impossible. The point is well distant from the electrode surface and the moment of the surface does not cause any significant effect. By this reason, the centered space difference method was used for transformation. The derivative is expressed with the concentrations at the nodes $(96,j)$, $(97,j)$, $(98,j)$, $(99,j)$, $(100,j)$, $(96,j+1)$, $(97,j+1)$, $(98,j+1)$, $(99,j+1)$, and $(100,j+1)$.

$$\left(\frac{\partial y_{C}(s_{98},T_{j+1})}{\partial s}\right)=\frac{1}{24\Delta s}\{(-y_{C,100,j+1}+8y_{C,99,j+1}-8y_{C,97,j+1}+y_{C,96,j+1})+(-y_{C,100,j}+8y_{C,99,j}-8y_{C,97,j}+y_{C,96,j})\}. \quad (51)$$

For the point that $i=99$, the only outer node is one with i of 100. Therefore, application of both the centered and backward space difference methods are impossible. The forward space difference method was used for this purpose. The derivative is expressed with the concentrations at the nodes $(96,j)$, $(97,j)$, $(98,j)$, $(99,j)$, $(100,j)$, $(96,j+1)$, $(97,j+1)$, $(98,j+1)$, $(99,j+1)$, and $(100,j+1)$.

$$\left(\frac{\partial y_{C}(s_{99},T_{j+1})}{\partial s}\right)=\frac{1}{24\Delta s}\{(3y_{C,100,j+1}+10y_{C,99,j+1}-18y_{C,98,j+1}+6y_{C,97,j+1}-y_{C,96,j})+(3y_{C,100,j}+10y_{C,99,j}-18y_{C,98,j}+6y_{C,97,j}-y_{C,96,j})\}. \quad (52)$$

Introducing Eqs. 49—52 into Eq. 7, we have the following equations:

$i=1$,

$$(1+25P_{C,1,j+1})y_{C,1,j+1}=P_{C,1,j+1}\{(-3y_{C,5,j+1}+16y_{C,4,j+1}-36y_{C,3,j+1}+48y_{C,2,j+1})+(-3y_{C,5,j}+16y_{C,4,j}-36y_{C,3,j}+48y_{C,2,j}-25y_{C,1,j})\}+y_{C,1,j}+\Delta TK_{f}y_{B,1,j+1}y_{B,1,j}(y_{A,1,j+1}+y_{A,1,j})/2-\Delta TK_{b}. \quad (53)$$

$1<i<98$,

$$(1+10P_{C,i,j+1})y_{C,i,j+1}=P_{C,i,j+1}\{(y_{C,i+3,j+1}-6y_{C,i+2,j+1}+18y_{C,i+1,j+1}-3y_{C,i-1,j+1})+(y_{C,i+3,j}-6y_{C,i+2,j}+18y_{C,i+1,j}-10y_{C,i,j}-3y_{C,i-1,j})\}+y_{C,i,j}+\Delta TK_{f}y_{B,i,j+1}y_{B,i,j}(y_{A,i,j+1}+y_{A,i,j})/2-\Delta TK_{b}. \quad (54)$$

$i=98$,

$$y_{C,98,j+1}=P_{C,98,j+1}\{(-y_{C,100,j+1}+8y_{C,99,j+1}-8y_{C,97,j+1}+y_{C,96,j+1})+(-y_{C,100,j}+8y_{C,99,j}-8y_{C,97,j}+y_{C,96,j})\}+y_{C,98,j}+\Delta TK_{f}y_{B,98,j+1}y_{B,98,j}(y_{A,98,j+1}+y_{A,98,j})/2-\Delta TK_{b}. \quad (55)$$

$i=99$,

$$(1-10P_{C,99,j+1})y_{C,99,j+1}=P_{C,99,j+1}\{(3y_{C,100,j+1}-18y_{C,98,j+1}+6y_{C,97,j+1}-y_{C,96,j+1})+(3y_{C,100,j}+10y_{C,99,j}-18y_{C,98,j}+6y_{C,97,j}-y_{C,96,j})\}+y_{C,99,j}+\Delta TK_{f}y_{B,99,j+1}y_{B,99,j}(y_{A,99,j+1}+y_{A,99,j})/2-\Delta TK_{b}. \quad (56)$$

$$P_{C,i,j+1}=\frac{\Delta TH(1-s_i)^2U_{j+1}x_i(x_i+2a_{j+1}/L)}{24\Delta s(x_i+a_{j+1}/L)^2}. \quad (57)$$

The value of $y_{C,i,j+1}$ is calculated with the aid of Eqs. 53—56.

The numerical computation described in the present method was programmed with the Gauss-Seidel method and the successive over relaxation method by using FORTRAN.

Converged values at $j\Delta T$ are usually used as initial values for computation of values at $(j+1)\Delta T$. This practice was successful when the concentration of chloride ions was lower than 1×10^{-4} mol dm^{-3}, where the difference between concentrations of mercury(I) and chloride ions was moderate. It produced, however, tremendous increase in the number of repetitions when the difference between concentrations of mercury(I) and chloride ions became large. It was nearly prohibitive. Therefore a new procedure was used instead of the practice described above. It was by use of estimated values at $(j+1)\Delta T$ as initial values for computation. The values at $(j+1)\Delta T$ are estimated roughly with the assumption that the converged values at $(j+1)\Delta T$ are situated on the extension of the line connecting two points, $y_{A,i,j-1}$ and $y_{A,i,j}$ The initial values at $(j+1)\Delta T$ are estimated with the following equations:

$$y_{A,i,j+1}=R(y_{A,i,j}-y_{A,i,j-1})+y_{A,i,j}, \quad (58)$$

where R is a constant ranging from 0.1 to 1.01.

Up to this point, consideration is confined solely to the current corresponding to the observed current. The residual current should be considered next. Because the residual current is the current in the absence of the chloride ion, the differential equation to be used for calculation of the residue current is Eq. 9, of which difference equation forms are Eqs. 41—43. Initial condition is

$$C_{A}=0 \quad (t=0,\quad r>a). \quad (59)$$

Boundary conditions are

$$C_{A}=C_{A0} \quad (t>0,\quad r=a), \quad (60)$$

$$C_{A}=0 \quad (t>0,\quad r=\infty). \quad (61)$$

The instantaneous anodic current in the absence of chloride ions, i_r, is given by

$$i_r=2FD_{A}S(\partial C_{A}/\partial r)_{r=a}. \quad (62)$$

Kolthoff and Miller corrected the observed current for residual current by

$$i_c=i-i_r. \quad (63)$$

The corrected current, i_c is the current mainly caused by precipitation reaction.

Results and Discussion

Any numerical method should be established by comparison of calculated results with observed data. The validity of the present method was examined under various experimental conditions. The anodic wave of mercury was measured in the presence of chloride ions of various concentrations.

The value of diffusion coefficient of mercury(I) ions for numerical computations was chosen so as to minimize difference between calculated and observed current.[2] This procedure produces a value of 0.847×10^{-5} cm^2 s^{-1}. The value of diffusion coefficient of chloride ions used is 2.03×10^{-5} cm^2 s^{-1}.[6]

Figure 2 shows the plots of $\log(i_d-i_c)$ vs. E constructed with observed data, where currents were measured at the end of life of mercury drop. The plots give straight lines. The slope of these lines ranges from −45 to −52 mV/unit. Experimental values of the reciprocal slope do not agree with Eq. 1. The half-wave potential shifts to anodic direction with increase of ionic strength. This shift is explained as follows: The concentration constant of the solubility product increases with ionic strength, because activity coefficients of ions decrease with ionic strength within the limit of the experimental conditions. The shift of half-wave potential is anodic direction as shown in Eq. 1. The value of anodic current corrected for residual current was proportional to the concentration of chloride ions.

Figure 3 shows the effect of concentration of ethanol added to the electrolyte. The concentration of ethanol does not influence on the value of reciprocal slope. However, the half-wave potential of anodic wave shifts to more negative by 52 mV with increase in the concentration of ethanol from 0 to 40 vol%, because the solubility product of mercury(I) chloride decrease with increase of ethanol concentration. The plots of $\log(i_d-i_c)$ vs. E produce straight lines with slopes ranging from −45 to −52 mV/unit.

Computation of the anodic current by the method described in Theory was successful when the concentration of chloride ions was within the range of 10^{-5} to 3×10^{-4} mol dm^{-3}. Values of parameters used are as follows: The value of L ranges from 10^{-5} to 10^{-2} cm and ΔT from 4.27×10^{-7} to 2.18×10^{-4} s. The rate constant of precipitate particle formation was chosen as the value of $C_AC_B^2$ in each volume element does not exceed the solubility product by as much as 10%. The computation failed, however, when the concentration of chloride ions was over 3×10^{-4} mol dm^{-3}. The reason of failure is as follows: The anodic wave caused by precipitation appears at the electrode potential ranging from 0.25 to 0.30 V vs. SCE. The concentration of mercury(I) ions in contact with mercury electrode at 0.30 V vs. SCE is 2.1×10^{-9} mol dm^{-3}, which is far lower than that of chloride ions. Remarkable imbalance between concentrations of mercury(I) and chloride ions prevents successful computation, even if it is performed with double precision.

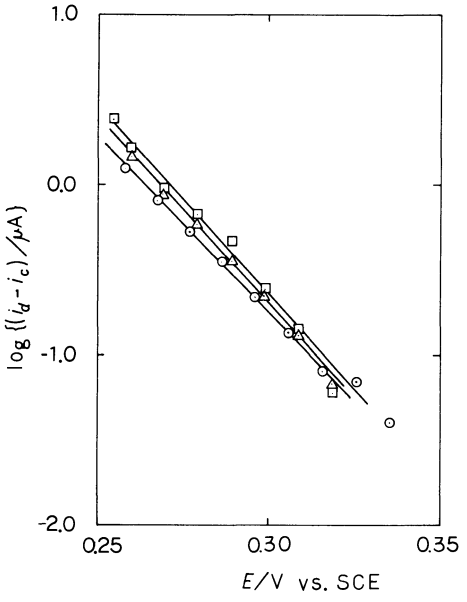

Fig. 2. Effect of ionic strength on the anodic wave in the solution of 0.5×10^{-3} mol dm^{-3} KCl and 0.005% gelatin. Value of ionic strength: ○, 0.05 M; △, 0.1 M; □, 0.2 M. The ionic strength is adjusted with potassium nitrate.

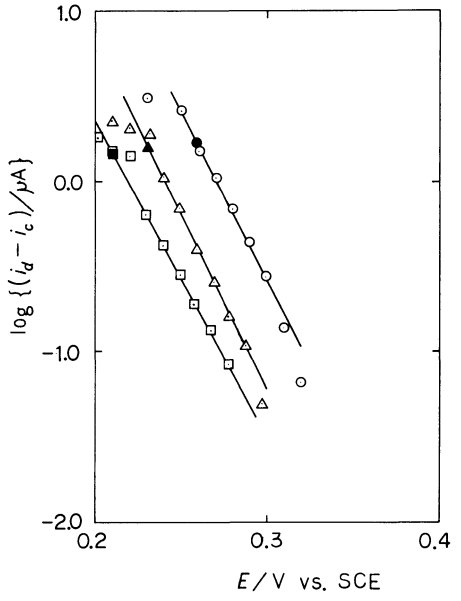

Fig. 3. Effect of the concentration of ethyl alcohol on the anodic wave in the solution containing 0.5×10^{-3} mol dm^{-3} KCl, 0.05 mol dm^{-3} KNO_3, and 0.005% gelatin. Concentration of ethyl alcohol: ○, 0 vol%; △, 20 vol%; □, 40 vol%. Filled symbols indicate the half-wave potentials.

Figure 4 shows the plots of $\log(i_d-i_c)$ vs. E constructed with calculated and observed data. The calculated data are consistent with the observed ones in the case that the concentration of chloride ions is 1×10^{-4} and 3×10^{-4} mol dm^{-3}.

Figure 5 shows the plot of the corrected limiting currents, i_l, vs. concentration of chloride ions. The current is proportional to the concentration. The points corresponding to calculated and observed limiting currents are on a straight line. The plot of observed half-wave potential against the logarithm of concentration of chloride ions produces another straight line. The value of slope of the straight line is -59 mV/unit, and this value agrees with the theoretical value given by Eq. 1. The calculated half-wave potential values are on this line. It indicates that the present method of the calculation reflects the phenomena going on in the vicinity of dropping mercury electrode. The value of the solubility product was chosen for the computed points to be on straight lines. A chosen value of solubility product of mercury(I) chloride is 2.0×10^{-17} mol^3 dm^{-9}. After making activity correction, the value of the activity product is given as 4.04×10^{-18} mol^3 dm^{-9}. This value is about three times as large as ones given in a standard literature.[4] It shows that the solubility of fresh precipitate, whose age is within the life of

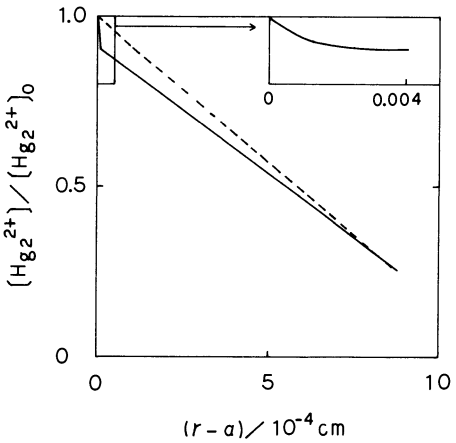

Fig. 7. Computed distance-concentration curves of mercury(I) ions at about the half-wave potential in the solution of 10^{-4} mol dm^{-3} chloride ions. The value of $\log(K_{sp})$: a solid line, -16.7; a dotted line, -11.7. The inset shows a graph with an enlarged abscissa.

electrode mercury drop, is larger than that of more aged precipitate.

Figure 6 shows the relation among the value of solubility product, the slope of logarithmic plot, and the half-wave potential of numerically-constructed polarograms. The concentration of chloride ions was kept at 10^{-4} mol dm^{-3}. The value of slope is almost constant when the half-wave potential is more positive than 0.40 V, whereas the slope decreases to approach to -59 mV/unit when the half-wave potential becomes more negative than 0.40 V vs. SCE.

Figure 7 shows numerically constructed concentration-distance curves of mercury(I) ions at about the half-wave potential. The concentration of mercury(I) ions at the surface of electrode is 5×10^{-4} mol dm^{-3} when a value of 2×10^{-12} mol^3 dm^{-9} is used for K_{sp}, and is 5×10^{-9} mol dm^{-3} when a value of 2×10^{-17} mol^3 dm^{-9} is used. The concentration of chloride ions is identical in the above two cases. It is found that the concentration-distance curve is divided into two parts. The interior and exterior curves correspond to the regions with and without mercury(I) chloride precipitate particles, respectively. The precipitation reaction proceeds in the interior region, but does not in the exterior one. It is found that the position of boundary between two regions approaches to the surface of electrode with decrease of K_{sp}. It indicates that the thickness of layer, in which the precipitation reaction proceeds, becomes small with decrease of K_{sp}. At the limit, it produces the concentration-distance curve of chloride ions by Kolthoff and Miller, who assumed that the precipitation reaction proceeds only at the surface of electrode. Therefore the value of slope becomes -59 mV/unit with the decrease of K_{sp} shown in Fig. 6.

Experimental

The chemicals used were of reagent grade. The concentration of chloride ion in stock solutions was calculated from amounts of sodium chloride or potassium chloride dissolved. The salts were dried at 110—120 °C for 2 h. Oxygen in test solutions were expelled by bubbling pure nitrogen for 50 min. The current of the anodic wave was measured just before the detachment of mercury drop. Measurements were carried out using a Hokuto Denko Model HA 104 Potentio-Galvanostat with three electrodes arrangement at 25 °C.

The dropping mercury electrode had the following characteristics (in 0.1 mol dm^{-3} sodium perchlorate at zero applied potential vs. SCE and at a mercury head of 80.0 cm): The flow rate of mercury (m), 2.08 mg s^{-1}; the drop time (t), 3.20 s; the capillary constant ($m^{2/3}t^{1/6}$), 1.978 mg$^{2/3}$ s$^{-1/2}$.

The numerical method described in the present paper was performed by an IBM 4361-L03 computer in Shiga Prefectural Junior College.

Conclusion

The anodic wave of mercury in the presence of chloride ions was studied by a new numerical method. The boundary condition, $(\partial C_B/\partial r)_{r=a}=0$, was used for computation, because chloride ions do not participate in the charge transfer at the electrode. The differential equation for precipitate particles was transformed to the difference equation with the backward space difference method which was chosen to reflect the relative motion of the solution around the electrode mercury drop. It was found that the transformation with the backward space difference method was vital for successful computation.

The results of numerical method indicate that the relations between the concentration of chloride ions and the half-wave potential, and those between the concentration of chloride ions and the limiting current corrected for residual current are in fair agreement with an equation derived by Kolthoff and Miller. However, the computed value of reciprocal slope of straight lines obtained by plotting $\log(i_d-i_c)$ against E does not agree with their theory but fairly agrees with observed data. Reason of this seems that the rate of production of mercury(I) ions is controlled both by the diffusion of chloride ions and by the potential of mercury electrode.

(Received January 9, 1988)

Iron supported on zeolite catalysts, prepared by treating NH_4Y with aqueous solutions containing Fe^{3+} or Fe^{2+} ions followed by calcination in air, were subjected to Mössbauer spectroscopic investigations before and after sulfiding treatments to elucidate the states and properties of Fe species supported. At least three types of Fe^{3+} species could be distinguished in the prepared samples. The first Fe^{3+} species were those located at the cation-exchange sites of zeolite. This type was reduced easily to Fe^{2+} species with the H_2S treatment, but was resistant to aggregation to form $Fe_{1-x}S$. The second Fe^{3+} species were those which had precipitated on the surface of zeolites as hydroxides. These were sulfided to crystalline $Fe_{1-x}S$ after H_2S treatment. Finally, the third Fe^{3+} species were those which were quite resistant to both reduction to Fe^{2+} and sulfiding to $Fe_{1-x}S$. These species were preferentially supported under the conditions where dealumination from zeolite framework took place simultaneously. Thus it was speculated that these species were bonded to zeolite framework to be stabilized. The distribution of the three Fe^{3+} species were quite different depending on the sample preparation. Comparison with the catalytic data clearly indicated that the third Fe^{3+} species acted as highly active sites for the toluene disproportionation reaction in the presence of H_2S.

Recently we reported that the iron supported on Y type zeolite (FeHY-1) prepared by treating NH_4Y with an aqueous $Fe(NO_3)_3$ solution showed high catalytic activity and low coke formation for the toluene disproportionation reaction in a flow of H_2S/H_2.[1] It was also shown that a FeHY-1 based catalyst was highly active for the hydrocracking of the atmospheric residual oil in the presence of H_2S.[2] There has been collected ample evidence to indicate that the iron species supported on FeHY-1 are clearly different from those on the other iron supported on zeolites prepared by conventional methods such as an ion-exchange method.[1,3] However, we still lack definite information as to the nature and state of iron species in FeHY-1.

It is known that Mössbauer spectroscopy is very useful to investigate the state of iron species on zeolites.[4] In this paper, we have studied the state of iron species after sulfiding treatment by using Mössbauer spectroscopy and the correlation between catalytic activity and the state of iron species supported on zeolite in the presence of H_2S.

Experimental

Preparation of Catalyst. To obtain FeHY-1-L, FeHY-1, FeHY-1-H, FeHY-2-L, and FeHY-2, ammonium-ion-exchanged Y type zeolite, NH_4Y (UCC; LZY-82), was mixed with the aqueous $Fe(NO_3)_3$ or $FeSO_4$ solution shown in Table 1 at room temperature, and stirred for 2 h at the specified temperatures. Then the suspension was filtered, washed with distilled water, dried in air at 363 K, and finally calcined in air at 773 K for 3 h.

For FeHY-3 and Fe/SiO_2, NH_4Y or silica gel(Fuji Davison) was suspended in water, to which aqueous $Fe(NO_3)_3$ solution was added as droplets while caution was paid to keep the pH of the suspension at 7 by adding droplets of aqueous ammonia solution simultaneously. This procedure was adopted in order to have Fe^{3+} ions precipitated as $Fe(OH)_3$. The subsequent procedures were the same as the above.

Measurements of Physicochemical and Catalytic Properties. The amount of supported Fe as well as the SiO_2/Al_2O_3 molar ratio of each sample were measured by Fluorescence spectrometer (Rigaku Denki; 3080E). The specific surface area was determined by BET method. The

a) SiO_2/Fe solution. b) 1 M=1 mol dm^{-3}.

unit cell dimension of zeolite lattice was determined by X-ray (Cu $K\alpha$) powder diffraction.

The toluene disproportionation reaction was carried out in a high-pressure fixed catalyst bed reactor. The loaded catalyst (1.8 g) was sulfided in a flow (60 $cm^3 m^{-1}$) of H_2S(0.2 vol%)/H_2 mixture at 523 K and 3 MPa for 16 h, before toluene was fed at a rate of 10 cm^3 (liquid) h^{-1} in a flow (200 $cm^3 m^{-1}$) of H_2S(0.2 vol%)/H_2 at 623 K and 6 MPa. The effluent, consisting mostly of unconverted toluene, xylene, and benzene was analyzed by FID gas chromatography. The amounts of coke deposition on spent catalysts were determined from increases in weight.

Mössbauer Measurement. Mössbauer spectroscopy was carried out by using a constant-acceleration spectrometer (Elscint, Inc.). Data were stored in a 1024-channel pulse height analyzer, TN-7200 (Tracor Northen, Inc.). A cobalt-57 source of 10 mCi diffused into a palladium foil (Amersham, Inc.) was used for the absorption measurement. Some of the spectra were fitted to the Lorentzian line shape by using a least-squares analysis. Isomer shift was referred to the center of the spectrum of metallic iron. In many cases samples were subjected to sulfiding treatments prior to the measurements: Samples were exposed to a flow of either H_2S(10 vol%)/He at 473 K or H_2S(10 vol%)/H_2 at 673 K for 2 h unless noted otherwise. The sulfied samples were measured in nitrogen atmosphere to prevent the reoxidation of sulfided iron species if any.

Results and Disscusion

Physicochemical Properties and Catalytic Activities. Some physicochemical and catalytic properties of the prepared samples as well as those of NH_4Y and HY are compared in Table 2. We have shown already that the treatment of NH_4Y with an aqueous solution of $Fe(NO_3)_3$ results in dealumination from zeolite framework.[1] The dealumination proceeds through

the attack of the protons which are produced from the hydrolysis of Fe^{3+} ions. As a result of the dealumination, SiO_2/Al_2O_3 molar ratio increases while the unit cell dimension of zeolite decreases. As seen from Table 2, FeHY-1 and FeHY-1-H showed larger SiO_2/Al_2O_3 ratios and smaller unit cell dimensions than the other samples, indicating the progress of significant degrees of dealumination. The amounts of supported Fe_2O_3 varied considerably with the samples, but these amounts were not directly related with the catalytic properties. As seen from the table, FeHY-1 and FeHY-1-H showed very high activities and very low coke depositions in a flow of H_2S(0.2 vol%)/H_2 compared with the other catalysts.

This clearly shows the importance of dealumination during the catalyst preparation. As stated previously, it is considered that the Fe species loaded on zeolite under the dealuminating conditions are present in a state significantly different from those loaded under the non-dealuminating conditions, and thus show unique acidic properties in the presence of H_2S.[1]

Mössbauer Spectra of Fresh Catalysts. Mössbauer spectra of prepared samples after calcination are shown in Fig. 1. The Mössbauer parameters estimated for the samples listed in Table 3. The spectra consisted of broad quadrupole doublets, denoted Type A hereafter. The doublets showed isomer shift (IS) 0.33—0.36 mm s^{-1} and quadrupole splitting (QS) 0.76—0.90 mm s^{-1}, which were in the anticipated ranges for octahedrally coordinated Fe^{3+} species.[5] However, the isomer shifts denied the existence of significant amounts of tetrahedrally coordinated Fe^{3+} ions in the samples. The absence of Zeeman splitting in the spectra assured that the particle sizes of the Fe^{3+} species were very fine, being 50—100 Å or less.[6]

As for the octahedrally coordinated Fe^{3+} species, several types are possible, such as Fe^{3+} ions located at the cation-exchange sites of zeolite,[4,7] oligomerized iron(III) oxide clusters located in supercages or on outer surface of zeolite, and fine Fe_2O_3 particles. The proportion of each type would depend on the sample preparation but more than a single type are likely to be loaded in each sample, as suggested from the broadness of the quadrupole doublet.

Mössbauer Spectra after H_2S/He Treatment at 473 K. The fresh samples were treated with H_2S(10 vol%)/He at 473 K (at 573 K for FeHY-1) and atmospheric pressure. Their Mössbauer spectra are

shown in Fig. 2. The Mössbauer parameters are listed in Table 3. The spectra are all composed of two or three types of quadrupole doublets.

A type of quadrupole doublet (Type B), with large IS of 0.92—1.70 mm s^{-1} and large QS of 1.77—2.31 mm s^{-1}, was typically observed in FeHY-1-L and FeHY-2-L. These samples were prepared by treating NH_4Y with either a dilute Fe^{3+} solution or a Fe^{2+} solution, conditions where the ion exchange of NH_4^+ with Fe^{3+} or Fe^{2+} was favored over the other types of loading. It has also been reported that such Fe^{3+} ions are easily reduced.[8] Thus Type B doublet is likely to be assigned to Fe^{2+} ions located at the cation-exchange sites of zeolite. This doublet was far weaker in FeHY-1 and FeHY-2, almost unvisible in FeHY-1-H and FeHY-3, and not visible in Fe/SiO_2.

A quadrupole doublet (Type C), with IS of 0.27—0.30 mm s^{-1} and QS of 0.54—0.77 mm s^{-1} appeared typically in FeHY-1-H, FeHY-2, FeHY-3, and Fe/SiO_2, and was assigned to fine particles of nonstoichiometric iron sulfide ($Fe_{1-x}S$) according to literature.[9] These samples were prepared under such conditions that the precipitation of iron hydroxides on zeolite was facilitated more or less. It is inferred that the precipitate changed to fine particles of Fe(III) oxide with the calcination and then to ferric sulfide with the H_2S/H_2.

Quite remarkably, Type C doublet was hardly visible in FeHY-1. The spectrum was dominated by Type A doublet responsible for Fe^{3+} species, with a minor contribution of Type B. The survival of Fe^{3+} species is still more remarkable when it is taken into account that the H_2S/H_2 treatment was carried out at a higher temperature (573 K) than that for the other samples (473 K). This fact indicates that a prevailing part of the Fe^{3+} ions in FeHY-1 are situated in a form which is quite resistive to reduction. Type A doublet was also present, but far less visible, in FeHY-1-H. It is considered that the reduction-resistant property arises from a strong interaction of Fe^{3+} species with zeolite lattice, and that such Fe^{3+} species are formed when Fe^{3+} ions are loaded on zeolite under the dealuminating conditions. The relative intensities of the three types of quadrupole doublets were estimated from the areas under the doublets and are indicated in Table 3.

Mössbauer Spectra after H_2S/H_2 Treatment at 673 K. Mössbauer spectra after H_2S(10 vol%)/H_2 treatment at 673 K are shown in Figs. 3 and 4, and Mössbauer parameters are listed in Table 3. Most of these spectra were drastically different from those described in the previous sections.

As shown in Fig. 3, the spectra of FeHY-1-H, FeHY-2, and FeHY-3 clearly showed a sextet of magnetic hyperfine structure with a paramagnetic doublet weakly superposing on it. The sextet was assigned to crystalline $Fe_{1-x}S$ of sufficiently large domains because the internal magnetic field (H_{int}) of about 28 T as well as the spectral shape coincided with those of commercially obtained $Fe_{1-x}S$ (Nippon Chikagaku Co., Ltd.).

As estimated from the area under the sextet, about 70% or more of iron species on these samples could be assigned to this kind of crystalline $Fe_{1-x}S$. It is considerd that fine particles $Fe_{1-x}S$, formed after sulfiding in H_2S(10 vol%)/He at 473 K, grew to large particles during sulfiding in H_2S(10 vol%)/H_2 at 673 K.

On the contrary, such a sextet magnetic hyperfine structure was not observed for FeHY-1-L, FeHY-1, and FeHY-2-L as shown in Fig. 4. This suggests that the crystal growth of $Fe_{1-x}S$ hardly proceeded. For FeHY-1-L and FeHY-2-L, a quadrupole doublet (Type B) due to Fe^{2+} ions at the cation-exchange sites of zeolite, remained predominant. While FeHY-1 exhibited not only this kind of quadrupole doublet (Type B) due to Fe^{2+} ions but also a quadrupole doublet (Type A) due to Fe^{3+} ions. As shown in Fig. 3, more than 40% of Fe^{3+} ions supported on FeHY-1 could survive after the treatment in H_2S(10%)/H_2 at 673 K. These results again indicate that the Fe^{3+} ions supported on FeHY-1 are resistant to reduction. This resistance should come from a strong interaction between the Fe^{3+} ions and zeolite lattice as described before.

States and Catalytic Activities of Supported Iron Species. The Mössbauer measurements mentioned above revealed that the states and properties of supported Fe^{3+} ions were largely different, depending on the preparation conditions.

When NH_4Y was treated with a dilute aqueous solution containing Fe^{3+} or Fe^{2+} at 323 K, as in the cases of FeHY-1-L and FeHY-2-L, most iron ions were loaded on zeolite by ion exchange and situated at the cationic sites. These Fe^{3+} ions were easily reduced to Fe^{2+} under the sulfiding conditions, but they were resistant to aggregation into crystalline $Fe_{1-x}S$.

When NH_4Y was treated with a Fe^{2+} or Fe^{3+} solution at higher temperature (363 or 373 K), as in the cases of FeHY-1-H and FeHY-2, a major part of Fe ions seemed to be loaded on zeolite by precipitation as hydroxides. Like FeHY-3 and Fe/SiO_2, the samples prepared in this way showed a superparamagnetic doublet due to finely dispersed $Fe_{1-x}S$ particles after the low temperature sulfiding (473 K) and a sextet hyperfine structure due to large particles of $Fe_{1-x}S$ after the high temperature sulfiding (673 K).

In contrast to these samples, FeHY-1 was shown to be very unique in the stability of Fe^{3+} ions loaded. In fact, more than 40% of the loaded Fe^{3+} ions could remain as Fe^{3+} even after the sulfiding treatment with H_2S(10%)/H_2 at 673 K. FeHY-1 was prepared under the conditions where dealumination from zeolite lattice took place. The hydrolysis of Fe^{3+} ions in the solution should produce protons and Fe^{3+} complexes. The released protons should attack zeolite lattice to dealuminate while the dealuminated sites would tend to be compensated by the Fe^{3+} complexes. In this way, Fe^{3+} complexes should be incorporated and partially bonded to zeolite lattice. It is assumed that such bonding should result in the remarkable resistivity of the Fe^{3+} ions to reduction.

It is interesting to compare these results with the catalytic activities for the toluene disproportionation reaction in the presence of H_2S. As already stated, FeHY-1 was the most active among the tested samples. This indicates the importance of the reduction-resistant Fe^{3+} species just mentioned. Moreover, the other two species dominating in the other samples, i.e., the ion-exchanged Fe^{3+} ions at the cation-exchange sites and the Fe species deposited on zeolite surface, which were easily reduced to Fe^{2+} or to crystalline $Fe_{1-x}S$ in the H_2S atmosphere, are judged to be not so active as the above one. A comment may be necessary for FeHY-1-H, which was active next to FeHY-1. Although the reduction-resistant Fe^{3+} could not be clealy revealed in this sample, probably due to the excessive amounts of the other species, one can expect its presence from the extent of dealumination of the sample. Therefore the high activity of FeHY-1-H can be assumed to result also from the reduction-resistant Fe^{3+} species.

Previously we estimated that the unique acidic properties of the Fe supported on zeolite in the toluene disproportionation reaction in the presence of H_2S were not associated with the formation of iron sulfide ($Fe_{1-x}S$) but with the adsorption of H_2S on a certain type of supported Fe^{3+} species.[1] This estimation has been confirmed with the above observation that the active sites are provided by the reduction-resistant Fe^{3+} species, although the mechanism for generating the unique acidity remains to be studied further.

Conclusion

Three types of Fe^{3+} species could be distinguished in the Fe supported on zeolite catalysts prepared. The Fe^{3+} located at cation-exchange sites of zeolite (the first type), dominating in FeHY-1-L and FeHY-2-L, are easily reduced to Fe^{2+} with the H_2S treatment, to give a characteristic quadrupole doublet with a large isomer shift. The second type, dominating in FeHY-

1-H, FeHY-2 and FeHY-3, consists of those which have precipitated on zeolite surface as iron hydroxides and have changed into Fe(III) oxide after calcination in air. This type is changed easily into well dispersed $Fe_{1-x}S$ with the H_2S treatment at 473 K, which further grows into sufficiently large particles of $Fe_{1-x}S$ to give a sextet hyperfine structure at higher temperature (673 K). The third type, typically formed in FeHY-1, is very resistant to chemical change, remaining almost intact even after the H_2S treatment at 673 K. The remarkable stability of this type is considered to arise from a strong interaction with the zeolite framework.

Comparison of these results with the catalytic performances, clearly indicates that it is the third type Fe^{3+} species which provide the highly active sites for the toluene disproportionation reaction in the presence of H_2S. The adsorption of H_2S on these Fe^{3+} species seems to produce the unique acidity required to the catalysis.

Cobalt(III) Complexes with Quadridentate Ligands. VII.[1] The Preparation and Properties of the Salicylato or Dichloro[tris-(2-aminoethyl)amine]cobalt(III) Complexes and the Related Complexes

Eiko TOYOTA, Yutaka YAMAMOTO,† and Yoshihisa YAMAMOTO*
Faculty of Pharmaceutical Sciences, Higashi Nippon Gakuen University,
Ishikari-Tobetsu, Hokkaido 061-02
†Tohoku College of Pharmacy, Komatsushima, Sendai 983
(Received March 7, 1988)

Salicylato- or 3-methyl(or 4-methyl)salicylato[tris(2-aminoethyl)amine]cobalt(III) complexes, [Co(R-sal)tren]Cl·nH$_2$O (R: H, CH$_3$) have been prepared from a reaction mixture of dichloro[tris(2-aminoethyl)amine]cobalt(III) chloride hydrate, [CoCl$_2$(tren)]Cl·H$_2$O, Ag$_2$O, and salicylic acid or 3-methyl- or 4-methylsalicylic acid. Two geometrical isomers (*t*- and *p*-) of their complexes were separated by Dowex 50W-X2 column chromatography. Their *t*- and *p*-isomers have been established by their ^{1}H NMR and absorption spectra. The formation ratio of *t*- and *p*-isomers is ca. 3:1. The isomerization between *t*-isomer and *p*-isomer was not observed in water and methanol. In the absorption spectra, the first absorption band for the *t*- and *p*-isomers was observed at 535 nm and 515 nm, respectively. In the ^{1}H and ^{13}C NMR spectra of [CoCl$_2$(tren)]Cl·H$_2$O, the signals of the tertiary amine, $-\overset{|}{\underset{|}{N}}-$, side methylene protons and methylene carbons have been assigned to the individual methylene protons and methylene carbons of the coordinated tris(2-aminoethyl)amine ligand.

In this series, the previous papers[1,2] have been concerned with the preparation, properties, and NMR spectra of isomers such as the *cis*-β_1, β_2-salicylato- or salicylaldehydato(triethylenetetramine)cobalt(III) chloride hydrates. In the NMR spectra, the signals for center, NH$_2$- side, -NH- side, and =N- side methylene protons and carbons for the cobalt(III) complexes with quadridentate amine ligands have been assigned.[3,4] The signals for $-\overset{|}{\underset{|}{N}}-$ side methylene protons and carbons have, however, so far remained unsolved. Octahedral cobalt(III) complexes with a tris(2-aminoethyl)amine (abbreviation: tren) ligand are suitable for NMR studies. In addition, the coordinated tren ligand to a metal ion has a tripodal-type configuration, and is different from a linear-type configuration such as trien ligand. We are therefore interested in the difference between tren and trien complexes. Many tren cobalt(III) complexes have been reported with such aliphatic compounds as NH$_2$CH$_2$COOH,[5] CH$_3$SCH(CH$_3$)COOH,[6] CH$_3$SCH$_2$CH$_2$NH$_2$,[7] CH$_3$SeCH$_2$CH$_2$NH$_2$,[8] and their related compounds;[9,10] however, little is known about the preparation and properties of tren cobalt(III) complexes with the organic ligands such as salicylic acid,[2,3] salicylaldehyde,[1] 8-quinolinol,[11] and their related compounds.[12]

The present paper deals with the preparation and properties of *t*- and *p*-salicylato or 3-methyl(or 4-methyl)salicylato(tren)cobalt(III) complexes, [Co(R-sal)tren]Cl·nH$_2$O (R: H, CH$_3$); it deals with the assignments of the configuration of *t*- and *p*-isomers,[13] and of ^{1}H and ^{13}C chemical shifts of the $-\overset{|}{\underset{|}{N}}-$ side methylene protons and carbons for [CoCl$_2$(tren)]-Cl·H$_2$O and [Co(R-sal)tren]Cl·nH$_2$O (R: H, CH$_3$).

Experimental

Measurements. The ^{1}H and ^{13}C NMR spectra were recorded with an FX90Q apparatus (JEOL) and an FX-60 spectrometer (JEOL), respectively. The visible absorption spectra were recorded with a Shimadzu UV-210 recording spectrophotometer. The electric conductivities in aqueous solutions were determined by the use of a conductometric meter, CM-30 (Shimadzu), at room temperature. The melting points were measured on a MP-500D apparatus (Yanaco). The magnetic susceptibilities were measured at room temperature by Faraday's method using a magnetic balance (Shimadzu).

Preparation of Complexes. Dichloro[tris(2-aminoethyl)-amine]cobalt(III) Chloride Hydrate (1): This complex was prepared by the method of Kimura et al.[9]

Mixture of *t*- and *p*-Salicylato[tris(2-aminoethyl)-cobalt(III) Chloride Dihydrate: Complex **1** (10.0 g, 30.3 mmol) was added to moistend fresh Ag$_2$O, which was made from silver nitrate (10.4 g, 61.2 mmol) and potassium hydroxide (3.44 g, 61.3 mmol). The mixture was stirred for several minutes at room temperature, then 20 cm^3 of water was added to the mixture. The mixture was stirred for about 30 min at 60 °C. Thus the precipitated silver chloride was filtered off and washed with a small amount of water. To the reddish violet filtrate was added 4.2 g (30.4 mmol) of salicylic acid. The solution was stirred at 50 °C for 24 h, and concentrated on a rotary evaporator. The concentrated solution was injected into a column chromatograph on alumina. Upon elution with methanol–ethanol (1:1), the first reddish violet band was collected and concentrated on a rotary evaporator. Yield: 3.4 g (27.2%).

Separation of *t*-Salicylato[tris(2-aminoethyl)amine]cobalt-(III) Chloride Dihydrate (2) and *p*-Salicylato[tris(2-amino-ethyl)amine]cobalt(III) Chloride Dihydrate (3): The separation of complexes **2** and **3** from the mixture complex of 0.5 g was achieved by a column of ion-exchange resin (Dowex

50W-X2, Na^+ form, ϕ2.5×25 cm). Upon elution with 0.4 mol dm^{-3} NaCl, the effluent of the first reddish violet band (*t*-isomer) and that of the second red band (*p*-isomer) was collected and concentrated, respectively. The separated NaCl was removed. The purification for the *t*- and *p*-isomers was recrystallized from methanol-ether, respectively. Color: russet for **2**, red for **3**. Yields: 2.15 g (17.2%) for **2**, 0.8 g (6.4%) for **3**. Found **2**: C, 38.02; H, 6.51; N, 13.74; Cl, 8.88%. **3**: C, 38.11; H, 6.16; N, 13.71; Cl, 8.87%. Calcd for $CoC_{13}H_{26}N_4O_5Cl$ (MW 412.76) C, 37.83; H, 6.35; N, 13.57; Cl, 8.59%. Mp: 240 °C for **2**, 242 °C for **3**. Λ=130 for **2** and 110 S cm^2 mol^{-1} for **3** in water.

***t*-3-Methylsalicylato[tris(2-aminoethyl)amine]cobalt(III) Chloride Hydrate (4) and *p*-3-Methylsalicylato[tris(2-aminoethyl)amine]cobalt(III) Chloride Hydrate (5):** A mixture of complexes **4** and **5** has been prepared from a reaction mixture of **1** (10.0 g, 30.3 mmol), Ag_2O (7.02 g, 30.3 mmol) and 3-methylsalicylic acid (4.6 g, 30.2 mmol) according to the method used for complexes **2** and **3**. A separation for complexes **4** and **5** was achieved by using a column of ion-exchange resin (Dowex 50W-X2, Na^+ form, ϕ2.5×25 cm). Upon ellution with 0.2 mol dm^{-3} NaCl, the effluent of the first reddish violet band (complex **4**) and the second red band (complex **5**) was collected and concentrated on a rotary evaporator, respectively. The precipitated NaCl was removed by filtration. The purification for the *t*- and *p*-isomers was recrystallized from methanol-ether. Color: russet for **4**, red for **5**. Yields: 1.86 g (15.0%) for **4**, 0.58 g (4.7%) for **5**. Found **4**: C, 40.88; H, 6.52; N, 13.54; Cl, 8.91%. **5**: C, 40.92; H, 6.61; N, 13.84; Cl, 8.97%. Calcd for $CoC_{14}H_{26}N_4O_4Cl$ (MW 408.77) C, 41.14; H, 6.41; N, 13.71; Cl, 8.67%. Mp: 244 °C for **4**, 246 °C for **5**. Λ=125 for **4** and 113 S cm^2 mol^{-1} for **5** in water.

***t*-4-Methylsalicylato[tris(2-aminoethyl)amine]cobalt(III) Chloride Hydrate (6) and *p*-4-Methylsalicylato[tris(2-aminoethyl)amine]cobalt(III) Chloride Hydrate (7):** The preparation and separation for complexes **6** and **7** are attempted using the method for complexes **4** and **5**. Color: russet for **6**, red for **7**. Yields: 2.04 g (16.5%) for **6**, 0.45 g (3.6%) for **7**. Found **6**: C, 40.95; H, 6.62; N, 13.81; Cl, 8.82%. **7**: C, 40.85; H, 6.59; N, 13.66; Cl, 8.89%. Calcd for $CoC_{14}H_{26}N_4O_4Cl$ (MW 408.77) C, 41.14; H, 6.41; N, 13.71; Cl, 8.67%. Mp: 248 °C for **6**, 249 °C for **7**. Λ=115 for **6** and 110 S cm^2 mol^{-1} for **7** in water.

***t*-Salicylato[tris(2-aminoethyl)amine]cobalt(III) Nitrate Hydrate (8) and *p*-Salicylato[tris(2-aminoethyl)amine]cobalt(III) Nitrate (9):** Complexes **8** and **9** were prepared from the reaction mixture of silver nitrate (0.21 g, 1.24 mmol) and **2** or **3** (0.5 g, 1.21 mmol), respectively. They were recrystallized from methanol-acetone. Color: russet for **8**, red for **9**. Yields: 0.34 g (66.7%) for **8**, 0.36 g (73.8%) for **9**. Found **8**: C, 37.06; H, 6.02; N, 16.88%. Calcd for $CoC_{13}H_{24}N_5O_7$ (MW 421.30) C, 37.06; H, 5.74; N, 16.62%. Found **9**: C, 38.73; H, 5.45; N, 17.11%. Calcd for $CoC_{13}H_{22}N_5O_6$ (MW 403.29) C, 38.72; H, 5.50; N, 17.37%. Mp: 237 °C for **8**, 243 °C for **9**. Λ=106 for **8** and 114 S cm^2 mol^{-1} for **9** in water.

Solubility. Complexes **2**—**9** are very soluble in water and DMSO, and soluble in methanol but insoluble in the other common organic solvents such as acetone, ether, and benzene.

Results and Discussion

Dichloro[tris(2-aminoethyl)amine]cobalt(III) Chloride Hydrate (1): The ^1H NMR spectrum of **1** was measured in 1.8 mol dm^{-3} D_2SO_4. The signals at δ 2.5—3.9 and δ 4.6—5.7 of **1** were assigned to the methylene and amine protons of the coordinated tren ligand, respectively. The methylene protons of the coordinated tren ligand showed two signals at δ 2.50—3.03 (4H) and 3.03—3.90 (8H), as shown in Fig. 1. The signals at δ 2.50—3.03 at the highest field are assigned to the NH_2- side methylene protons[3] of the tren ligand. The signals at δ 3.03—3.90 have been assigned to the tertiary amine, $-\overset{|}{N}-$, side methylene protons. Two protons of the NH_2- side methylene protons at δ 2.50—3.03 overlapped with the $-\overset{|}{N}-$ side methylene protons of the tren ligand; this might be due to the electronic effect of the N(3)H_2 group, which is in a trans position for the Cl(1) ligand. Then, the

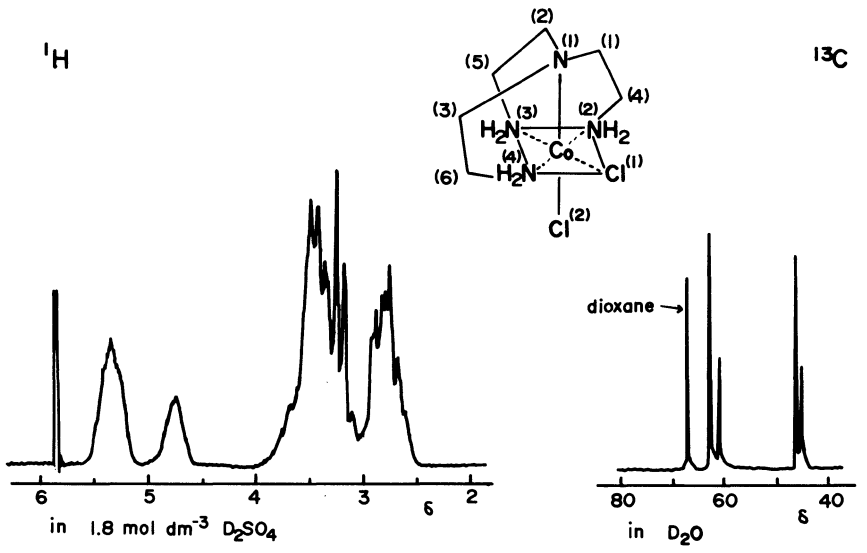

Fig. 1. The ^1H and ^{13}C NMR spectra of $[CoCl_2(tren)]Cl \cdot H_2O$.

methylene proton signals at δ 2.50—3.03 can be assigned to C(4)H_2 and C(6)H_2 protons, and those at δ 3.03—3.90 can be assigned to C(1)H_2, C(2)H_2, C(3)H_2, and C(5)H_2 protons.

The amine protons of the coordinated tren ligand showed two signals at δ 4.78 (2H) and 5.37 (4H), as shown in Fig. 1. The signal at δ 4.78 is assigned to the N(3)H_2 protons of the tren ligand in a position trans to the Cl(1) ligand. The signal at δ 5.37 is assigned to the N(2)H_2 and N(4)H_2 protons of the tren ligand in a position cis to the Cl(1) ligand. The above assignments were made in view of the following: studies of pentaammine(aniono)cobalt(III) ions, $[CoX(NH_3)_5]^{n+}$ (X: Cl, Br, OH···), have been reported by Buckingham,[14] Jolly,[15] Clifton,[16] who described that the chemical shift of the NH_3 group in a position trans to the electronegative atom (X) is at higher fields than those of NH_3 groups in a position cis to the electronegative atom.

The ^{13}C NMR spectrum of **1** was measured in D_2O. Both the signals at δ 45.4 and 46.6 are assigned to the NH_2- side methylene carbons[3] of the tren ligand, as shown in Fig. 1. The signals at δ 61.2 and 63.0 have been assigned to the -N< side methylene carbons. The methylene carbon signals at δ 45.4 and 61.2 are assigned to the C(5)H_2 and C(2)H_2 carbon, respectively, since both carbons are in a trans position for the Cl(1) ligand, and both carbon signals are smaller than those at δ 46.6 and 63.0. The signals at δ 46.6 and 63.0 are assigned to the C(4)H_2, C(6)H_2 and C(1)H_2, C(3)H_2, respectively.

Salicylato- or 3-Methyl(or 4-methyl)salicylato(tren)-cobalt(III) Chloride Hydrates (2—7): The abbreviations of the salicylato or 3-methyl(or 4-methyl)salicylato(tren)cobalt(III) complexes studied in this paper are listed in Table 1. The title complexes have *t*- and *p*-isomers, as shown in Fig. 2. A mixture of *t*- and *p*-salicylato(tren)cobalt(III) chloride dihydrate (**2**, **3**) or *t*- and *p*-3-methyl(or 4-methyl)salicylato(tren)-cobalt(III) chloride hydrate (**4**—**7**) has been isolated from a reaction mixture of complex **1**, Ag_2O, and salicylic acid or 3-methyl(or 4-methyl)salicylic acid. The separation of *t*- and *p*-isomers was attempted using an ion-exchange resin. The formation ratio of *t*- and *p*-isomers was ca. 3:1. The isomerization between *t*- and *p*-isomers is not observed in water and methanol. The corresponding nitrates (**8**, **9**) were prepared from the reaction mixture of complex **2** or **3** and silver nitrate, respectively. Complexes **2** and **3** were diamagnetic from the magnetic susceptibility. The electric conductivities for **2**—**9** in aqueous solutions were 106—130 S cm^2 mol^{-1}.

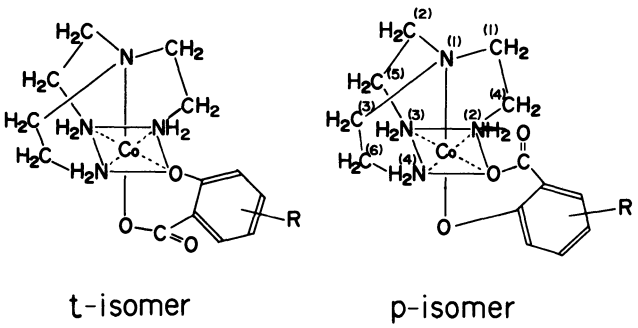

Fig. 2. Two geometrical isomers of [Co(R-sal)tren]-Cl·$n$$H_2O$ (R: H, CH_3).

In the ^1H NMR spectra, the signals at δ 2.5—4.0 and 4.6—5.3 of **2** and **3** were assigned to the methylene protons and the amine protons of the coordinated tren ligand, respectively, and the lowest field signals at δ 6.5—8.0 were assigned to the coordinated salicylato protons.[17] The methylene proton signals for the tren ligand in **2** are divided into two groups at the δ 2.6—3.1 and 3.1—4.0 regions. On the other hand, those for **3** are divided into three groups at the δ 2.5—2.8, 2.8—3.4, and 3.4—4.0 regions, as shown in Fig. 3. The methylene proton signals at δ 2.6—3.1 for **2** and at δ 2.5—2.8 for **3** are assigned to the NH_2- side methylene protons,[2,3] and those at δ 3.4—4.0 for **3** have been assigned to the -N< side methylene protons as shown in Table 2.

The amine protons for **2** showed one peak at δ 5.00, though those for **3** showed two peaks at δ 4.85 and 5.10 with an intensity ratio 2:1 as shown in Fig. 3. The signal at δ 4.85 of **3** is assigned to N(2)H_2 and N(3)H_2 protons, and that at δ 5.10 is assigned to the N(4)H_2 protons. The chemical shift (δ 4.85) of the proton signal of the NH_2 groups of **3** is at a higher field than that (δ 5.10) of **2**, i.e., the NH_2 group of **3** is considered to be at a position trans to the carboxyl oxygen of the coordinated salicylato ligand, which is more electronegative than the phenoxyl oxygen.[2,17] Thus, complexes **2** and **3** have been assigned to the *t*- and *p*-isomers, respectively. Also, the signals of the

Solvent and Standard: ^1H NMR spectra; 1.8 mol dm^{-3} D_2SO_4, internal DSS (δ=0), ^{13}C NMR spectra; D_2O, internal dioxane (δ=67.4), Absorption spectra; H_2O.

methylene protons of **3** are complicated signals compared with those of **2**. This can be due to the magnetic anisotropy between carbonyl oxygen of the coordinated salicylato ligand and methylene protons of the tren ligand, i.e., molecular models indicate that the carbonyl oxygen of the *p*-isomer has very near position for the methylene protons of the tren ligand, though that of the *t*-isomer has no such methylene protons around the carbonyl group. Also, the methylene protons for **3** showed two very sharp peaks in the δ 2.5—2.8 region, but those for **2** did not show the corresponding peaks. Thus, complexes **2** and **3** are assigned to the *t*- and *p*-isomers, respectively. In addition, a distinction between *t*- and *p*-isomers was found in the amine proton signals for **4** and **5**. The amine proton signal of **4** is different from those for **2** and **6**, but that for **5** is similar to those of **3** and **7** as shown in Fig. 3. This difference is attributed to the

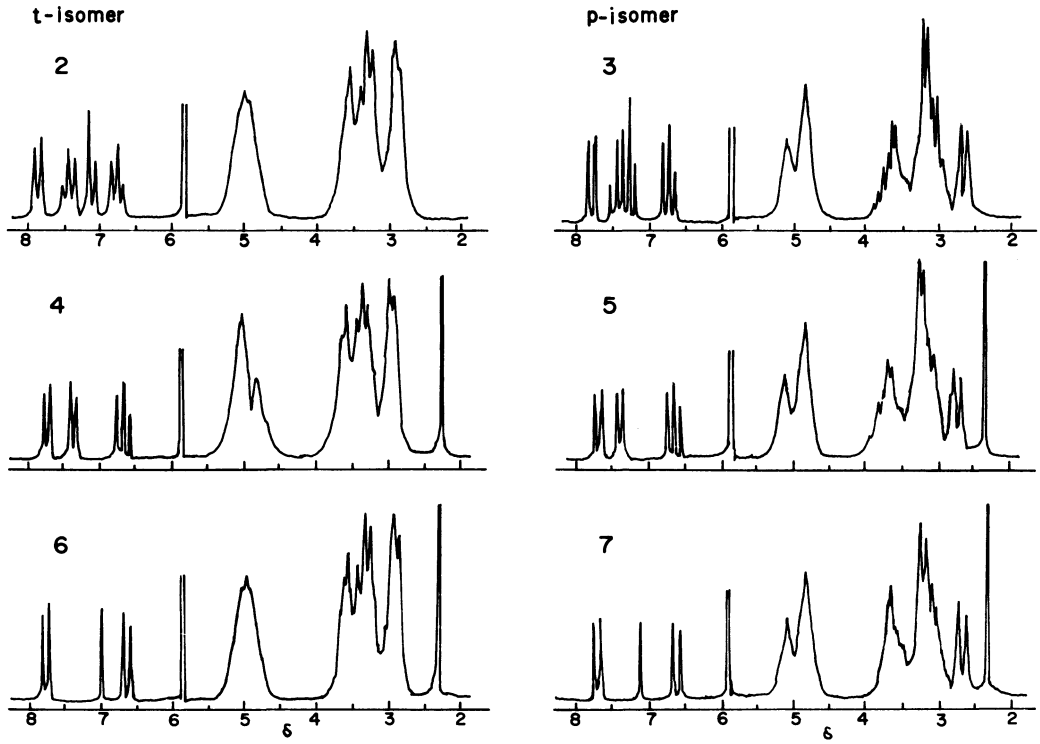

Fig. 3. The ^{1}H NMR spectra of complexes **2**—**7** in 1.8 mol dm^{-3} D_2SO_4.
2: *t*-[Co(sal)tren]Cl·2H_2O; **3**: *p*-[Co(sal)tren]Cl·2H_2O; **4**: *t*-[Co(3-Mesal)tren]Cl·H_2O; **5**: *p*-[Co(3-Mesal)tren]Cl·H_2O; **6**: *t*-[Co(4-Mesal)tren]Cl·H_2O; **7**: *p*-[Co(4-Mesal)tren]Cl·H_2O.

methyl group of the coordinated 3-methylsalicylato ligand. The methyl group of the 3-methylsalicylato ligand of **4** has the electronic effect to the phenoxyl oxygen, and the electronic state on the oxygen is a more electronegative, i.e., the amine protons split into two peaks. Accordingly, the N(3)H_2 group of **4** is considered to be at a position trans to the phenoxyl oxygen of the 3-methylsalicylato ligand. On the other hand, the N(3)H_2 group of **5** is considered to be at a position trans to the carboxyl oxygen from the results of the amine proton signals between **5** and **3**, **7**. Thus, complexes **4** and **5** have been assigned to the *t*- and *p*-isomers, respectively.

In the ^{13}C NMR spectra of complexes **2** and **3** in D_2O, there have been observed four signals for the coordinated tren ligand and seven signals for the coordinated salicylato ligand. The signals at δ 44.0, 45.4 for **2** are assigned to the NH_2– side methylene carbons. The signals at δ 60.7 and 61.4 for **2** have been assigned to the –N< side methylene carbons. The signals at δ 44.0 and 60.7 of **2** are assigned to the C(5) carbon and C(2) carbon, respectively, since both carbons are in the trans position for the phenoxyl oxygen, and their signals are smaller than those at δ 45.4 and 61.4. The signals at δ 45.4 and 61.4 are assigned to the C(4), C(6) and C(1), C(3) carbons, respectively. The distinction for *t*- and *p*-isomers is difficult from the results of the ^{13}C NMR spectra. The results of **3**, **8**, and **9** are collected in Table 2.

In the absorption spectra of complexes **2**—**7**, the absorption bands at ca. 330 nm for **2**—**7** were assigned to the specific absorption band.[3] The absorption bands at ca. 535 nm for **2**, **4**, and **6**, and those at 515 nm for **3**, **5**, and **7** were assigned to the first d–d absorption band ($^1T_{1g}\leftarrow{}^1A_{1g}$).[1] The first absorption bands of **2**, **4**, and **6** are at a longer wavelength than those of **3**, **5**, and **7**, respectively. This difference is agreement with that of the corresponding *cis*-β_1, β_2-salicylato- or 3-methyl(or 4-methyl)salicylato(trien)cobalt(III) complexes,[2,12] *cis*-β_1, β_2-[Co(R-sal)trien]Cl·*n*H_2O (R=H: β_1(**10**), β_2(**11**); R=3-CH_3: β_1(**12**), β_2(**13**); R=4-CH_3: β_1(**14**), β_2(**15**)). Thus, the NH_2 group of **3**, **5**, and **7** can be also considered to be at a position trans to the carboxyl oxygen of the coordinated salicylato ligand such as the *cis*-β_2 trien complexes (**11**, **13**, **15**). Also, the first absorption band (515 nm) of **5** is similar to those (515 nm) for **3** and **7**, but that (545 nm) of **4** is different from those (535 nm) for **2** and **6**, as is shown in Table 2. This can be due to the electronic effect of the methyl group of the coordinated 3-methylsalicylato ligand in complex **4** as previously described. Thus, complexes **2**, **4**, **6** and complexes **3**, **5**, **7** are assigned to *t*- and *p*-isomers, respectively.

The melting points, visible absorption spectra, colors of the solid state and solubilities of **2** and **3** are

almost similar to those of the trien complexes **10** and **11**. On the other hand, the isomerization between **2** and **3** is not observed, but complex **10** isomerizes to **11** in water at room temperature.

Some properties for complexes **2—9** are collected in Table 2 and the Experimental section.

Voltammetric Study of Organic Metals. I. The Determination of the Electrochemical Conditions for Crystal Growth

Sachiko SAKURA, Hideo IMAI, Hiroyuki ANZAI,*,† and Tetsuo MORIYA†

(Received March 14, 1987)

The metallic crystals of organic charge-transfer complexes are grown by means of the electrolytic oxidation of tetrathiafulvalene (TTF) derivatives in the presence of trihalide anions in organic solvents. In order to obtain a crystal of good quality, the optimal conditions for the growth have been searched for based on the data on the cyclic voltammetry. In this paper, the electrochemical conditions, such as the oxidation potential, the stability of the donor monocation radicals, and the redox behavior of the anions under the oxidation potential of the donors, are discussed in relation to the chemical reactions proceeding in the solution during the crystal growth.

The metal-like crystals (organic metals) of organic charge-transfer complexes have various interesting characteristics, such as electrical[1] and optical[2] anisotropies and metal-insulator phase transitions.[3-5] Especially, some of the organic metals obtained from bis(ethylenedithio)tetrathiafulvalene (BEDT-TTF) and tetramethyltetraselenafulvalene (TMTSF) with several inorganic anions have been found to become superconductors at low temperatures,[6,7] so that numerous physicists and chemists have been concentrating their attention on the crystals of their organic charge-transfer complexes. Therefore, it is extremely important to establish a systematic way of growing crystals of good quality so as to explore their physical properties and develop a new category of electronic materials. There have appeared, hitherto, four methods of crystal growth; by means of slow cooling,[8] condensation,[9] diffusion,[10] and electrocrystallization.[11] The crystal growth of organic metals or superconductors, which are composed of organic donors and inorganic anions, has thus far been obtained mainly by the electrocrystallization. The electrocrystallization is carried out by the electrochemical oxidation of the donor in the presence of supporting electrolytes in various organic solvents.

There are many kinds of counter-anions used for the crystallization of organic metals. From among these, trihalide anions with a linear structure have now been investigated, because the chemical nature of the trihalides can be gradually changed from Cl_3^- to I_3^- depending on the combination of the components.

Usually, an electrolytic reaction in a solution has been controlled under constant-current conditions (not under constant voltage conditions). However, it has not yet been clarified whether or not the crystal growth has thereby been carried out under optimal conditions, since the chemical reactions occurring at the electrodes are complicated. This problem will be discussed in this paper based on the data obtained by the cyclic voltammetry (CV) of the donors (D) and the trihalide anions (X^-).

Experimental

Electrochemical Measurement. The measurement of CV was carried out with a Fuso 312 polarograph and a Hokuto HB-104 function generator. The working and counter electrodes were a platinum disk (2 mmϕ) and a platinum wire (0.5 mmϕ, 3 cm) respectively. The supporting electrolyte was 0.1 M (M=mol dm^{-3}) tetrabutylammonium perchlorate (Bu_4NClO_4). An aqueous SCE was used as a reference electrode with a salt bridge of 0.1 M Bu_4NClO_4 dissolved in organic solvents. The measuring temperature was controlled at 25±0.1 °C. Tetrahydrofuran (THF) and benzonitrile (BN) were chosen as convenient solvents for CV, because in them both the donors and the supporting electrolyte were easily dissolved. When THF was used as a solvent, nitrogen gas saturated beforehand with a THF vapor was bubbled in order to remove the dissolved oxygen.

Crystal Growth. All the crystal-growth procedures employed were similar to the following example. 0.13 mmol (BEDT-TTF) was electrolytically oxidized in a 60-ml THF solution, in which 0.52 mmol Bu_4NI_3 had been dissolved, under a controlled current of 1 μA at 20 °C. The electrolysis was performed under an atmosphere of nitrogen gas. The working electrode was separated with a porous glass plate from the counter electrode; both were of platinum. The period of crystal growth was about 1—1.5 months.

Reagents. The TMTSF was purchased from Japan Carlit Co., Ltd. The TTF, BEDT-TTF, tetrakismethylthiotetrathiafulvalene (TMT-TTF), and bis(trimethylenedithio)tetrathiafulvalene (BTDT-TTF) were obtained from Tokyo Kasei Co., Ltd. The tetramethyltetrathiafulvalene (TMTTF) was synthesized by the coupling of 4,5-dimethyl-1,3-dithiolium perchlorate.[12] The Bu_4NX (X=Br_2Cl, $BrCl_2$, and Cl_3) were obtained from Tokyo Kasei Co., Ltd. The other tetrabutylammonium trihalides were synthesized by the addition reaction of tetrabutylammonium halides and halogens.[13,14] The donors and the supporting electrolytes were purified by recrystallization. The THF was purified as follows: powdered iron(II) sulfate was added to the solvent, and the mixture was stirred; if the color of the powder turned from green to brown, the old powder was replaced with a new one. This treatment was repeated until the green coloring of iron(II) persisted. Then the powder was removed

by filtration. The solvent was dehydrated by adding NaOH pellets for 12 hours. The solvent was then filtered and distilled. BN was purified as follows: After the solvent had been dried by adding powdered phosphorous pentoxide for 12 hours, the desiccant was removed by decantation; powdered anhydrous sodium carbonate was then added to the solvent, and the mixture was stirred for 3 hours. The solvent was filtered and distilled under a reduced pressure.

Results and Discussion

In the electrolytic crystallization, organic metals can be grown from the de-electronated D^+ and the dissolved X^-. In this process, information on the oxidation potential of D to D^+, the stability of D^+, and the electronic state of X^- at the oxidation potential of D is essential in order to obtain good crystals. Therefore, the electrolytic oxidation and reduction behavior of D and X^- have been studied in detail with CV.

If the electron-transfer process at the electrode is reversible, the oxidation potential (E_p^o) obtained by means of CV is more positive by $28.5/n$ mV than the standard oxidation potential (E^o), where n is the number of participating electrons.[15] On the other hand, the E_p^o value of the irreversible process shifts toward more positive values than that of the reversible case, depending on degree of irreversibility. The E_p^o value for irreversible cases is, therefore, only a semi-quantitative measure of the oxidizability. If both the oxidation peak and the re-reduction peak are observable, the mean value of these two peaks, $E^{o'}$, can be conveniently used as the effective potential, which is near E^o.

Electrolytic Oxidation of D. Generally, the electrode reaction of TTF derivatives occurs as a two-step oxidation process; in the first step, one electron is transferred, and then the second electron is transferred. The corresponding reduction processes occur in the reversed way:[16]

$$D \underset{+e,\ E_p^{r1}}{\overset{-e,\ E_p^{o1}}{\rightleftharpoons}} D^+ \underset{+e,\ E_p^{r2}}{\overset{-e,\ E_p^{o2}}{\rightleftharpoons}} D^{2+} \quad (1)$$

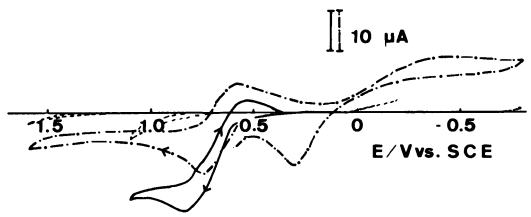

Fig. 5. Cyclic voltammograms of Bu_4NI_3; 20 mV s^{-1}. ——: 8.4 mM Bu_4NI_3 in THF, —·—·—: 6.5 mM Bu_4NI_4 in BN, ·····: blank.

Figures 1—4 show the CV measurements for TTF derivatives; the results are summarized in Table 1. It may be noted that the value of $\Delta E(=\lvert E_p^{o1} - E_p^{r1} \rvert)$ is the measure of the reversibility, which should be ≈60 mV for a reversible one-electron transfer process. In BN, the donors were oxidized quasi-reversibly to monocations ($\Delta E \approx 80$ mV). On the contrary, in THF, the donors were irreversibly oxidized; ΔE varies from 0.47 V to 0.16 V with an increase in the molecular weights of the donors. Though the irreversible reactions were carried out in THF, $E^{o'}$ can be obtained since re-reduction peaks were observed. It can be readily estimated whether or not the oxidation reaction really occurs under the applied potential from the E_p^{o1}, E_p^{o2}, and $E^{o'}$ values in Table 1. It seems that the pair of TMTTF and TMTSF, and the pair of BEDT-TTF and BTDT-TTF, which have very similar structures to each other, give similar CV profiles and similar oxidation potentials. No meaningful correlation of E_p^{o1} with the molecular weight of donors is found, however, as is plotted in Fig. 6.

In the electrolytic crystal growth, the applied potential should not exceed E_p^{o2} if only D^+ is to be generated in the solution.

The instability of D^+ can be judged from the CV data based on the following two viewpoints: i) If the ΔE value is large and the re-reduction peak is much distorted, or if the ratio of i_p^{r1}/i_p^{o1} is extremely small, then D^+ is chemically unstable and can easily be

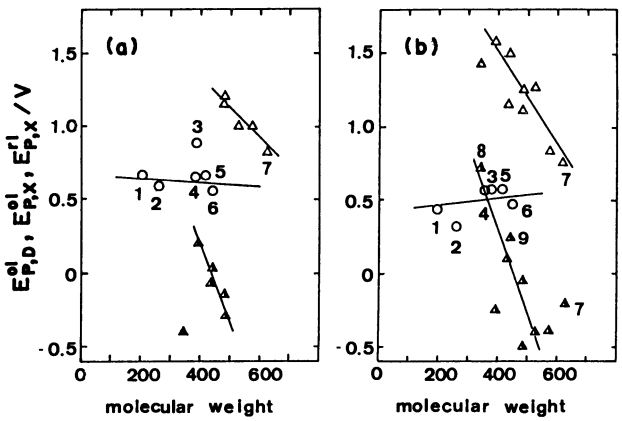

Fig. 6. Plots of E_p^{o1} of D, and $E_{p,X}^{o1}$ and $E_{p,X}^{r1}$ of X^- vs. the molecular weight. (a), in THF; (b), in BN. (○), $E_{p,D}^{o1}$; (△), $E_{p,X}^{o1}$; (▲), $E_{p,X}^{r1}$ 1: TTF, 2: TMTTF, 3: TMT-TTF, 4: BEDT-TTF, 5: BTDT-TTF, 6: TMTSF, 7: I_3^-, 8: Cl_3^-, 9: $BrCl_2^-$.

changed to other products. Therefore, most of the D^+ in BN are stable, while most of the D^+ in THF are unstable (Table 1). ii) D^+ is oxidized further to D^{2+} under relatively high potentials. If the value of $\Delta E_P(=\lvert E_p^{o1} - E_p^{o2} \rvert)$ is large, the proportionation reaction:

$$D^{2+} + D \rightarrow 2D^+ \qquad (2)$$

proceeds to the right and the D^{2+} will be transformed to D^+. Therefore, most of the D^{2+} in BN may be changed to D^+, while some of the D^{2+} in THF seem to persist in the solution and may become a cause of crystal defects or disorders.

Electronic State of Trihalide Anions in the Solution. As for the electrolytic crystal growth, the applied potential (E) must be an intermediate value between the oxidation peak potential ($E_{p,X}^{o1}$) and the reduction peak potential ($E_{p,X}^{r1}$) of X^- in order to keep X^- unchanged in the solution; of course, E should be more positive than the oxidation peak potential of D, $E_{p,D}^{o1}$, to generate D^+. Typical voltammograms for I_3^-

are shown in Fig. 5, while the results are summarized in Table 2. Figure 6 presents the plots of $E^{o1}_{p,X}$ and $E^{r1}_{p,X}$ vs. the molecular weight (MW) of the trihalide anions. The oxidation and reduction potentials of X^- decrease with an increase in the MW of trihalide anions; this can reasonably be understood by considering that the oxidation potential of halide anions decreases with an increase in MW, as $Cl^->Br^->I^-$ (Table 3). In Fig. 6 the plots of $E^{o1}_{p,D}$ vs. MW are also shown. Most trihalide anions were stable under the oxidation potential of D, except for the following cases.

Exception 1: When TMT-TTF is electrolytically oxidized in a THF solution containing I_3^-, the crystal growth is difficult, for such by-products from I_3^- as I_2 are produced[17]; the E_p^{o1} of TMT-TTF in THF is more positive than the E_p^{o1} of I_3^-. In a BN solution, Cl_3^- is reduced easily under the oxidation potential of the donors.

Exception 2: Generally, trihalide anions composed of lighter elements more easily decomposed in the organic solvent. Figure 7a shows the decomposition of $BrCl_2^-$ in THF. The reduction wave detected at 0.20 V in the first scan gradually decreased upon the repeated scanning, and eventually it disappeared. Moreover, a new oxidation wave appeared at 0.7 V on the disappearance of the yellow coloring in the solution; this new wave corresponds to the oxidation of Br^- (Table 3). These results suggest that $BrCl_2^-$ decomposes to other products containing Br^-. Since Cl_3^- is extremely unstable, the CV measurement in THF was difficult. Figure 7b shows such a situation; the CV peaks disappeared very rapidly on successive scannings. Figure 8 shows the change in the UV absorption spectra of Bu_4NCl_3 in THF after the dissolution of the reagent in the solution; the decrease in the absorption spectra may show the decomposition of Cl_3^- to Cl_2 and Cl^-, since the addition of Cl^- was found to suppress the change.

a) The data are taken from *Synth. Met.*, **19**, 611 (1987). b) The thickness is not measured. c) Only at the bottom of the crystal-growth cell. d) No crystals were obtained.

When the current was set at 1 μA, the apparent voltage between the two electrodes[11] became 0.3—1.2 V, depending on the D, the X^-, and the solvents. Because our cells for the electrocrystallization had been prepared so as to obtain a crystal of the highest purity and to avoid any impurities such as water molecules diffused from the reference electrode, it is practically impossible to introduce a reference electrode to measure the rigorous potential at each electrode. In spite of such a restriction on the experimental system, from our experimental results we can derive some conclusions that are essential to the crystal growth of the BEDT-TTF complexes.

As is shown in Table 4, we could not obtain any trace of the crystal from BEDT-TTF with Cl_3^-, $BrCl_2^-$, and Br_2Cl^- in either THF or BN, or with Br_3^- in BN. This result is reasonably explained by the above-mentioned unstable nature of the trihalide anions composed of lighter halogens, which leads to the production of Cl_2 and Br_2 by their decomposition. Before BEDT-TTF is electrolytically oxidized, these dihalogen molecules react with BEDT-TTF and/or the solvent; moreover, unnecessary oxidation and reduction reactions occur in the solution, which prevent the formation of the aimed-at crystals.

In the case of a BEDT-TTF–I_3^- system in THF, crystals of a good quality and a proper size were obtained, whereas in the case of a TMT-TTF–I_3^- system, it was difficult to obtain crystals,[18] possibly because of the oxidation of I_3^- in THF under the oxidation potential of TMT-TTF. On the other hand, in the case of the TMT-TTF–I_3^- system in BN, the crystal growth was very difficult,[18] although I_3^- is electrolytically stable in BN. The reason for this must be left to a forthcoming study.

Summary

The electrolytic oxidation and reduction behavior of donors (D=TTF, TMTTF, TMT-TTF, BEDT-TTF, BTDT-TTF, and TMTSF) and trihalide anions (X^-=I_3^-, I_2Br^-, IBr_2^-, $IBrCl^-$, ICl_2^-, Br_3^-, Br_2Cl^-, $BrCl_2^-$, and Cl_3^-) in organic solvents (THF and BN) were clarified by means of cyclic voltammetry.

It was found that 1) radical cations (D^+) of most of the donors were stable in BN, but unstable in THF, and 2) most trihalide anions (X^-) were stable under the oxidation potential of D, with a few exceptions.

The authors gratefully acknowledge the help of Dr. Madoka Tokumoto for his critical reading of the manuscript. This work was supported by the "R and D Project of Basic Technology for Future Industries" of the Ministry of International Trade and Industry, Agency of Industrial Science and Technology.

Molecular Structures of *cis*-[Co(CN)$_2$(acac)(dppe)] and *trans*(*C*,*N*)-[Co(CN)$_2$(acac)(edpp)]·H$_2$O and Trans Influence of Phosphine and Cyanide Ligands

Masakazu KITA, Kazuo KASHIWABARA, and Junnosuke FUJITA*
Department of Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya 464
(Received March 28, 1988)

Molecular structures of *cis*-[Co(CN)$_2$(acac)(dppe)] (**a**) and *trans*(*C*,*N*)-[Co(CN)$_2$(acac)(edpp)]·H$_2$O (**b**) have been determined by X-ray analysis, where acac, dppe, and edpp denote an acetylacetonate ion, 1,2-bis(diphenylphosphino)ethane and (2-aminoethyl)diphenylphosphine, respectively. Crystal data for **a**: monoclinic, $P2_1/a$, a=13.975(2), b=19.709(2), c=11.575(2) Å, β=109.71(1)°, V=3001.5(6) Å^3, Z=4, and R=0.049. Crystal data for **b**: monoclinic, $P2_1/c$, a=17.870(3), b=7.354(2), c=16.709(3) Å, β=105.45(2)°, V=2116.5(5) Å^3, Z=4, and R=0.056. The Co–O bonds trans to the phosphine and the cyanide ligands are longer, respectively, by ca. 0.06—0.08 Å and ca. 0.03—0.05 Å than those usually found in Co(III)-acac complexes such as [Co(acac)$_3$], indicating stronger trans influence of the former than the latter.

X-Ray structural studies of non-organocobalt(III)-phosphine complexes have been reported for [Co(O$_2$)-{(C$_6$H$_5$)$_2$PCHCHP(C$_6$H$_5$)$_2$}$_2$]$^+$,[1] [{P(CH$_3$)$_2$(C$_6$H$_5$)}$_2$(CN)-(O$_2$)Co(μ-CN)Co(CN)$_2${P(CH$_3$)$_2$(C$_6$H$_5$)}$_3$],[2] [Co(NCS)$_3$-{P(CH$_3$)$_3$}$_3$],[3] a number of bis(dimethylglyoximato)-cobalt(III) complexes containing unidentate phosphine ligands,[4] and a number of diphosphine-[5-8] and aminoalkylphosphine-cobalt(III) complexes[9-14] prepared in our laboratory. In this paper we have determined crystal structures of two cyanide-phosphine mixed ligand complexes of cobalt(III), [Co-(CN)$_2$(acac)(dppe)] and [Co(CN)$_2$(acac)(edpp)]. The complexes contain cyanide and phosphine ligands both of which give trans influence to many metal ions,[15] although the influence of the cyanide ligand in a cobalt(III) complex is not made clear.[15-21] The complexes studied here are suitable for examining trans influence of cyanide and phosphine ligands, since the magnitudes of influence can be compared within one complex molecule.

Experimental

X-Ray Analysis. ***cis*-[Co(CN)$_2$(acac)(dppe)].** The complex was prepared in a previous work.[22] Crystal data: monoclinic, $P2_1/a$, a=13.975(2), b=14.709(2), c=11.575(2) Å, β=109.71(1)°, V=3001.5(6) Å^3, Z=4, D_x=1.35 g cm^{-3}, D_m=1.36 g cm^{-3}, μ(Mo $K\alpha$)=7.055 cm^{-1}. An orange crystal of approximate dimensions 0.45×0.25×0.175 mm^3 was wrapped up in thin wax to protect it from moisture and used for X-ray work. Diffraction data were collected on a Rigaku AFC-5R diffractometer with graphite monochromatized Mo $K\alpha$ radiation (λ=0.71069 Å). Within the range $2\theta<60°$, 4006 independent reflections with $|F_o|>3\sigma(|F_o|)$ were obtained. No absorption correction was applied.

Calculations for the structure analysis were performed on a HITAC M-680H computer at the Computer Center of the Institute for Molecular Science with the Universal Crystallographic Computation Program System UNICS III.[23] Atomic scattering factors of neutral atoms were used.[24] The structure was solved by the usual heavy-atom method: The position of the cobalt atom was picked up by means of the

Patterson synthesis, and all the non-hydrogen atoms were located by the subsequent Fourier synthesis. The positions of 22 among 31 hydrogen atoms were identified in the subsequent difference-Fourier maps and others were not located. The structure was refined by a block-diagonal least squares method with anisotropic thermal parameters for nonhydrogen atoms and isotropic for hydrogens. The function minimized was $\sum w||F_o|-|F_c||^2$. Final R was 0.049 and R_w 0.055 for 4006 observed unique reflections. The atomic parameters of the non-hydrogen atoms are listed in Table 1. Complete lists of observed and calculated structure factors, hydrogen atomic parameters, and anisotropic thermal parameters for non-hydrogen atoms are preserved by the Chemical Society of Japan (Document No. 8829).

***trans*(*C*,*N*)-[Co(CN)$_2$(acac)(edpp)]·H$_2$O.** The complex was prepared in a previous work.[25] An orange rhombic crystal of approximate dimensions 0.37×0.40×0.55 mm^3 was used for X-ray work. Crystal data: monoclinic, $P2_1/c$, a=17.870(3), b=7.354(2), c=16.709(3) Å, β=105.45(2)°, V=2116.5(5) Å^3, Z=4, D_x=1.396 g cm^{-3}, D_m=1.39 g cm^{-3}, μ(Mo $K\alpha$)=9.368 cm^{-1}. Diffraction data were collected on a Rigaku AFC-5A diffractometer with graphite monochromatized Mo $K\alpha$ radiation (λ=0.71069 Å). Within the range $2\theta<55°$, 3525 reflections were measured. No absorption correction was applied.

Calculations for the structure analysis were performed on a FACOM M-382 computer at the Computer Center, Nagoya University. Atomic scattering factors of neutral atoms were used.[24] The structure was solved by the Monte Carlo direct method[26] with the aid of MULTAN 78[27] using 3464 non-zero unique reflections with $|F_o|>3\sigma(|F_o|)$, and refined on F^2 by the full-matrix least-squares program. Non-hydrogen atoms were refined anisotropically. All hydrogen atoms were located from a difference Fourier synthesis and refined with isotropic temperature factors. Final R and R_w were 0.056 and 0.039, respectively. The atomic parameters of the non-hydrogen atoms are listed in Table 2. Complete lists of observed and calculated structure factors, hydrogen atomic parameters, and anisotropic thermal parameters for non-hydrogen atoms are preserved by the Chemical Society of Japan (Document No. 8829).

nearly octahedrally. The dppe complex has a cis and the edpp one a trans(C,N) geometrical structure, as we have suggested by ^{1}H and ^{13}C NMR studies.[22,25] Other geometrical isomers were not yielded in the syntheses.[22,25]

Figure 2 shows schematic structures around the cobalt atoms of the dppe (**a**) and edpp (**b**) complexes, and a related complex, [Co(acac)(RR-chxn)(edpp)]$^{2+}$ (RR-chxn=(1*R*,2*R*)-1,2-cyclohexanediamine) (**c**)[13] with their bond distances. It is seen that both phosphine and cyanide ligands give remarkable trans influence to the cobalt-ligand bond. The Co–O bond distances of 1.955(3) Å in **a** and 1.968(2) Å in **b** both of which are trans to the phosphorus donor atom are longer by ca.

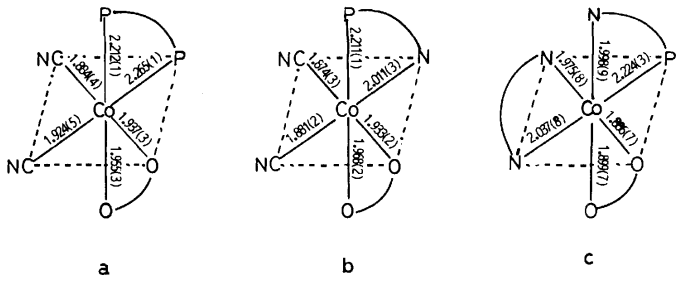

Fig. 2. Bond distances around the cobalt atom in the complexes, **a** $[Co(CN)_2(acac)(dppe)]$, **b** $[Co(CN)_2(acac)(edpp)]$, and c $[Co(acac)(RR\text{-}chxn)(edpp)]^{2+}$.[11]

0.06—0.08 Å than those in **c** (1.886(7) and 1.899(7) Å) and in $[Co(acac)_3]$ (1.883(4)—1.892(4) Å).[29] A similar elongation due to trans influence of phosphine ligands has been reported for Co-N bonds in a number of cobalt(III) phosphine-amine mixed ligand complexes.[5,6,9-14] The Co-O bond distances trans to the cyanide ligand in **a** (1.937(3) Å) and **b** (1.933(2) Å) are also longer by ca. 0.03—0.05 Å than those in **c** and $[Co(acac)_3]$, indicating trans influence of the cyanide ligand. However, the extent of elongation is somewhat small compared with that due to the phosphine ligand. The Co-N bond trans to the phosphine ligand in **c** (2.037(8) Å) is also longer than that trans to the cyanide ligand in **b** (2.011(3) Å). Although structural data are rather limited at present, a phosphine ligand seems to give stronger trans influence to cobalt(III)-ligand bonds than a cyanide ligand.

In complex **a** the Co-P bond distance of 2.265(1) Å and the Co-C bond distance of 1.924(5) Å, which are trans to each other, are fairly longer than the other Co-P and Co-C bond distances, respectively. The Co-C bond distances (1.927(2) and 1.930(2) Å) in *trans*-$[Co(CN)_2(tn)_2]^+$ (tn=trimethylenediamine)[30] are also longer than those (1.85(3) and 1.88(3) Å) in *cis*-$[Co(CN)_2(en)_2]^+$.[18] These results indicate that the two coordination bonds trans to each other are weakened by mutual trans influence of the phosphine and cyanide ligands. The results may also be related to the fact that the mixed cyano and

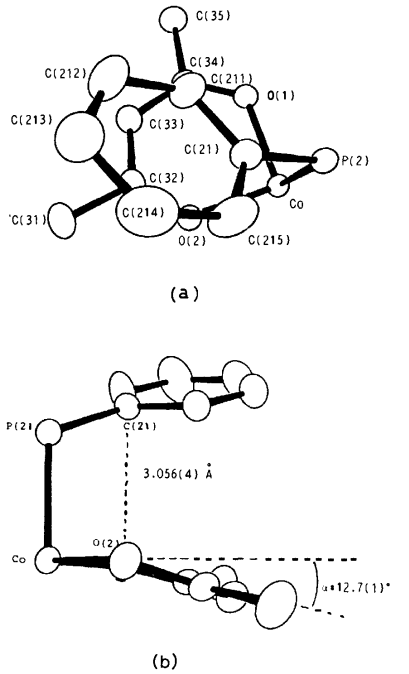

Fig. 3. A stacking structure of the acac and phenyl rings of [Co(CN)2(acac)(dppe)].

phosphine cobalt(III) complexes tend to form cis isomers for these ligands. The [Co(CN)2(acac)(edpp)] complex yielded selectively isomer **b**, in which two carbon and one phosphorus donor atoms are coordinated in a facial configuration. Two other possible isomers have these three donor atoms in a meridional configuration.

In complex **a** one of two phenyl groups is forced to be disposed over the acac chelate ring (Figs. 1(a) and 3). The O(2)···C(21) distance of 3.056(4) Å between two rings is shorter than the sum of their van der Waals radii (3.22 Å). A bent structure of the acac chelate ring with α=12.7(1)° as shown in Fig. 3(b) is probably attributable to such a stacking structure of these two rings. A similar bent structure has been observed in complex **c**.[13] On the other hand, complex **b** has no stacking structure of the phenyl and acac rings, and the acac chelate ring is nearly planar (α=4.1(5)°). All of the acac chelate rings in [Co(acac)3] are also nearly planar (α=1.6, 4.5, and 5.5°).[29] These results suggest that the interaction caused by stacking of the pseudo aromatic acac chelate and the phenyl rings is repulsive rather than attractive.

The dppe and edpp chelate rings in complexes **a** and **b** take a typical gauche conformation, and the tortion angle is 52.4(1)° (P(1)-C(13)-C(23)-P(2)) for the former and 49.9(1)° (P(2)-C(17)-C(16)-N(8)) for the latter.

The authors wish to thank the Ministry of Education for Science Reseach Grant-in Aid No. 61430013, and the Institute for Molecular Science (IMS), Okazaki National Reseach Institute for the use of X-ray and computation facilities. The authors are also grateful to Dr. Koshiro Toriumi (IMS) for his kind advice to X-ray structure analysis of [Co(CN)2-(acac)(dppe)].

Olefin Epoxidation Catalyzed by Sterically Bulky Metalloporphyrins (Metal=Fe,Mn) by Use of Sodium Hypochlorite as an Oxygen Source—A Kinetic Study

Hiroyuki AMATSU, T. Ken MIYAMOTO,* and Yukiyoshi SASAKI
Department of Chemistry, Faculty of Science, The University of Tokyo,
Hongo, Bunkyo-ku, Tokyo 113
(Received April 6, 1988)

Substituents around an active center give a variety of effects on metalloporphyrin catalyses. In order to examine the effects of a substituent on the kinetic parameters, several olefins (styrene derivatives, cyclooctene and 1-octene) have been epoxidized by iron(III) and manganese(III) complexes of *meso*-tetrakis(2,6-dimethylphenyl)porphyrin or *meso*-tetrakis(2,6-dichlorophenyl)porphyrin in the presence of sodium hypochrolite as an oxidant. As previously reported for a manganese porphyrin system, the rate-profile of an iron complex can be described by the Michaelis–Menten equation. Several examples of an anomalous rate dependence on the olefin concentration have been observed. The ortho substituents have little influence on the binding affinity of the oxo-iron complex to olefin, in contrast to the case of manganese complexes. It is additionally proposed that the *N*-alkylation of an iron porphyrin has some correlation to the kinetic parameters.

Metalloporphyrins, especially iron and manganese complexes, are capable of oxygenating hydrocarbons in a catalytic way, yielding alcohols from alkanes and epoxides from olefins. In these catalyses, several oxygen sources, either single oxygen donors such as iodosylbenzenes,[1–10] amine oxides,[11–13] and alkyl hydroperoxides,[14,15] or molecular oxygen in the presence of reducing agents such as sodium tetrahydroborate,[16] hydrogen and colloidal platinum,[17,18] or zinc powder and acetic acid[19] have been used. These reaction systems not only serve as models to cytochrome P-450 monooxygenase enzymes,[20] but have promising possibilities as catalysts. Several studies have been made to develop efficient metalloporphyrin catalysts for high-turnover oxygenation,[8,21,22] and to control the chemo-,[1,5,30,34] regio-,[1,23–26] and stereoselectivity.[27,28]

The use of manganese porphyrins with hypochlorite oxidant has recently been well-established for olefin epoxidation.[29–41] Nitrogen bases, such as pyridines and *N*-substituted imidazoles, enhance the reaction rate.[29,33,34,38] Kinetic studies have demonstrated that the rate can be described by the Michaelis–Menten equation and that the breakdown of an oxo-olefin intermediate (a proposed structure is a metallaoxetane **2**) is the rate-determining step of the catalytic cycle[35] (Fig. 1). The manganese–hypochlorite system has several advantages. First, sodium hypochrolite is a cheap oxidant and its concentration in solution can be determined by simple titration. Second, the rate is easy to measure since the reaction stops without adding a quencher when the aqueous and organic phases are separated. The observed kinetic parameters give information concerning catalyst-substrate interactions.

Although few iron porphyrins have been successful in oxygenation with hypochlorite, we found that a low catalytic activity results from an oxidative destruction of the catalysts and that the introduction of the electron-withdrawing substituents into the

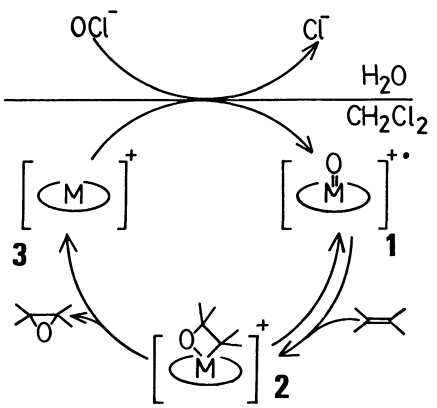

Fig. 1. Catalytic cycle of epoxidation by metalloporphyrin with hypochlorite oxidant.

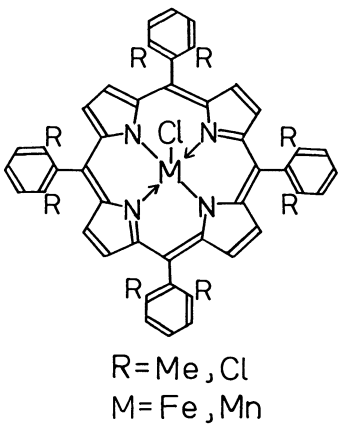

Fig. 2. The porphyrin complexes used as catalysts. Abbreviations: TPP=*meso*-tetraphenylporphyrin dianion; TMP=*meso*-tetramesitylporphyrin dianion; FeMe=[*meso*-tetrakis(2,6-dimethylphenyl)porphyrinato]iron(III) chloride; FeCl=[*meso*-tetrakis(2,6-dichlorophenyl)porphyrinato]iron(III) chloride; MnMe=[*meso*-tetrakis(2,6-dimethylphenyl)porphyrinato]manganese(III) chloride; MnCl=[*meso*-tetrakis(2,6-dichlorophenyl)porphyrinato]manganese(III) chloride.

ortho-position(s) of phenyl rings of TPP[42] reduces the catalyst decomposition; especially, an iron *meso*-tetrakis(2,6-difluorophenyl)porphyrin complex shows a sufficient epoxidation capability[39-41] (Fig. 2: R=F).

In order to obtain a greater undertstanding of olefin epoxidation by metalloporphyrin–hypochlorite systems, we used iron(III) and manganese(III) TPP derivatives carrying methyl- or chloro groups in the 2,6-positions of the phenyl rings (FeMe, FeCl, MnMe, and MnCl: Fig. 2).

Experimental

meso-Tetrakis(2,6-dimethylphenyl)porphyrin[42] and *meso*-tetrakis(2,6-dichlorophenyl)porphyrin[21] were prepared by methods described in the literature. The metals, iron(III) and manganese(III), were inserted by the procedure of Adler et al.[43]

Standard Conditions for Kinetics. A metalloporphyrin catalyst (4.6×10^{-5} M[44]), olefin (styrenes, cyclooctene, or 1-octene; 0.17 M), internal standard (*p*-dichlorobenzene; 0.014 M), phase-transfer reagent (benzyldimethyltetradecylammonium chloride; 0.010 M) were dissolved in 10 ml of dichloromethane. When manganese porphyrins were used, the addition of 4'-(1-imidazolyl)acetophenone was necessary; in the absence of the base, the reaction was too slow to obtain kinetic data. Sodium hypochlorite solution (20 ml, 0.42 M) was layered over the organic phase. The reaction was initiated by vigorous stirring. The temperature was maintained at 22 °C. The products were monitored periodically by gas chromatography.

Results and Discussion

Stabilities of Catalysts. When styrene was oxygenated catalytically by four metalloporphyrins (FeMe, FeCl, MnMe, and MnCl), phenylacetaldehyde could not be detected as a by-product. The same results were obtained in the styrene epoxidation, both by [(Mn(TMP)]$^+$–*N*-base–hypochlorite system[35] and by [Fe(TMP)]$^+$–iodosylbenzene system,[35] and by [Fe(TMP)]$^+$–iodosylbenzene system,[5] however, [Mn(TPP)]$^+$ produced a relatively large amount of phenylacetaldehyde (ca. 15%).[39-41] This tendency indicates that the steric hindrance of ortho substituents around the active site contributes to product selectivity.

In order to evaluate the ortho-substituent effect on the porphyrin catalyst stability, we measured the maximum yields of epoxides (Table 1). The reaction was continued until the catalyst was completely bleached or the epoxide formation stopped. (Both olefin and sodium hypochlorite were added, if necessary.) In Table 1, the yield of epoxide is expressed in turnovers (mol of produced epoxide per mol of catalyst). In styrene and cyclooctene epoxidation, all complexes, except for FeMe, showed quite high yields of the epoxidation compared with [Fe(TPP)]$^+$ and [Mn(TPP)]$^+$. In 1-octene epoxidation, all of the catalysts show low yields. In view of the fact that the TPP complexes have no reactivity, however, the R groups must contribute to the catalyst stability to a small extent.

It is well-known that metalloporphyrin, itself, suffers from oxidation at the meso-positions, followed by ring opening.[45] The ortho substituents of the meso-phenyl rings protect the meso-position from a bimolecular oxidative process, sterically or electronically (when the R is electron-withdrawing substituent). As far as iron porphyrin complexes are concerned, steric protection by the methyl groups is not efficient in stabilizing the catalyst against oxidative degradation.

Reaction Mechanism. The reaction rate was found to be first-order in the concentration of the iron or manganese porphyrin (0—1×10^{-4} M) and independent of the hypochlorite concentration (0.0043—0.42 M). With respect to the olefin concentration (0.002—2 M), the reaction order varied from zero to one. Plotting the reciprocal of the initial velocity vs. the reciprocal of the olefin concentration gave a straight line (Fig. 3). These results suggest that the mechanism of iron porphyrin-catalyzed epoxidation follows Michaelis–Menten kinetics, which has been proposed for the epoxidation by manganese complex-

hypochlorite system,[35] i.e., the high valent oxo-iron complex and olefin reversibly interact to form an oxo-olefin intermediate. A breakdown of the intermediate to epoxide is the rate-determining step.

Since the ortho-substituents prevent μ-oxo dimerization, a by-pass mechanism can be avoided. During the catalytic cycle all porphyrin molecules serve as a single catalyst.[46]

Although the epoxidation rate essentialy fitted Michaelis-Menten kinetics, we observed two anomalies of the rate dependence on the olefin concentration. One is the case using FeMe as a catalyst. As shown in Fig. 4, rate saturation was not found, even in the concentration range [cyclooctene]>1 M. An analogous rate dependence on the substrate concentration was found for styrene and 1-octene epoxidation. The other is the case of a MnCl catalyst, particularly for cyclooctene epoxidation (Fig. 5). The rate remarkably decreased with an increase in the concentration of the olefin above 0.2 M. A similar behavior was observed for styrene or 1-octene epoxidation. In the presence of cyclooctene in large excess, the UV-vis spectra of organic aliquots from the reaction mixtures showed a Soret band at 437 nm. This band could not be assigned to a common high valent manganese porphyrin which usually has a Soret band at 420—425 nm.[47-50] The observed kinetic behavior would result from the formation of a low reactive unknown intermediate under conditions of excess olefin. At present, we can not characterize this intermediate.[51]

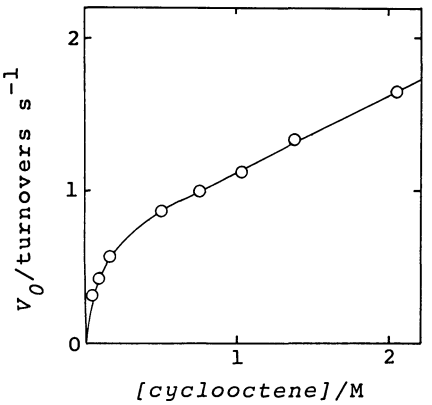

Fig. 4. Plot of initial velocity vs. cyclooctene concentration for FeMe-catalyzed epoxidation. The kinetic parameters were obtained from the linear part of double reciprocal plots at low cyclooctene concentration region.

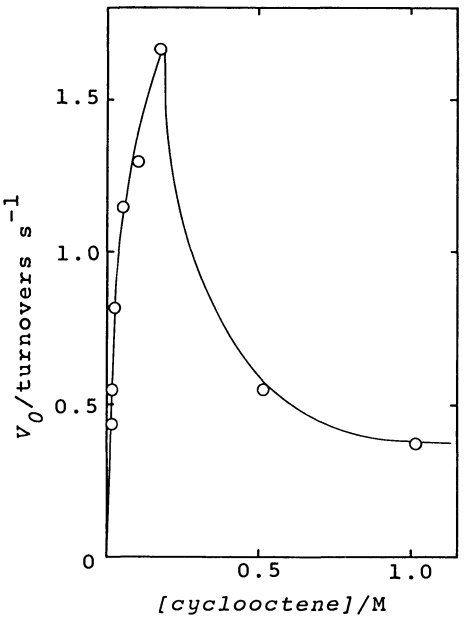

Fig. 5. Plot of initial velocity vs. cyclooctene concentration for MnCl-catalyzed epoxidation. The kinetic parameters were obtained from the linear part of double reciprocal plots at low cyclooctene concentration region.

Kinetic Parameters. In the Michaelis-Menten equation, the parameter V_{max} gives the rate-determining constant. The Michaelis constant K_m is a measure of the binding affinity of the olefin to a high valent metal-oxo complex: a large binding affinity corresponds to a low K_m value.

The values of V_{max} and K_m were calculated from the intercept and the slope of the straight line obtained by the Lineweaver-Burk plotting.[53]

In general, both the steric and electronic factors of porphyrin catalysts must govern the reactivity. On the assumption that both the methyl- and chloro-group would be nearly equal in steric hindrance, we expected to be able to obtain information concerning the electronic effect on the reaction. According to recent measurements of the CV redox potentials of iron porphyrin,[54] oxo $Fe^{IV}Cl^{+\cdot}$ is more oxidative than oxo $Fe^{IV}Me^{+\cdot}$ by 250 mV, reflecting the fact that the electron-withdrawing chloro groups might enhance the electrophilicity of the oxo-iron complex.

The above consideration encouraged us to examine the substituent effect on the binding affinity of the oxo-iron complex toward olefins. Table 2 gives the K_m values for the epoxidation of para-substituted styrenes(substituents: MeO-, Me-, H-, Cl-) by FeMe and FeCl. The K_m values decrease (i.e., the affinity toward the styrenes increases) as the styrene substituents become increasingly electron-donative, suggesting that the oxo-iron complexes are electrophilic.

Table 2. K_m Values for Para-Substituted Styrenes Epoxidation Catalyzed by Porphyrin Complexes

M	R	MeO-	Me-	H-	Cl-
		K_m/M	K_m/M	K_m/M	K_m/M
Fe	Me	0.0052	0.0095	0.40	0.5
	Cl	0.0077	0.017	0.065	0.6

The logarithm of the K_m values could be correlated with Hammett substituent constants σ_p (Fig. 6). The difference between the K_m values for FeMe and FeCl is small and the slopes of the two straight lines are almost equal; the difference in the ρ values is small. These results demonstrate that the difference between the methyl- and chloro-groups in the ortho-positions of TPP has little influence on the binding affinity of an oxo-iron complex to olefins. In other words, the electronic effect of oxo-iron complexes is not an important factor in epoxidation kinetics.

It is highly desirable that epoxidation by manganese catalyst should be carried out in the absence of an *N*-base, in comparison with that of iron catalysts. In all cases concerning our manganese system, the addition of an *N*-base was, however, required in order to monitor the reaction by gas chromatography. Moreover,in epoxidation by MnMe a determination of the initial velocity was very difficult because of the peculiar time course for epoxide production without any catalyst or *N*-base loss (Fig. 7). (The behavior has not yet been rationalized.) This prevented us from carrying out a manganese catalyzed epoxidation of a series of para substituted styrenes. In a calculation of the kinetic parameters for MnMe (Table 3), the initial velocities were obtained from the tangent slopes of the time course curves at time $T=0$.

The V_{max} and K_m values for the epoxidation of three different olefins to the four iron and manganese porphyrins are also listed in Table 3. Although large differences in the K_m values between the two different metals or between the two different subsituents to each olefin were not observed, a slight tendency is noticeable, as described below.

When iron porphyrins are used for olefin epoxidation, the difference in the K_m values between FeMe and FeCl to each olefin is not very large, compared with the difference obtained by using manganese complexes. This result indicates a small electronic effect

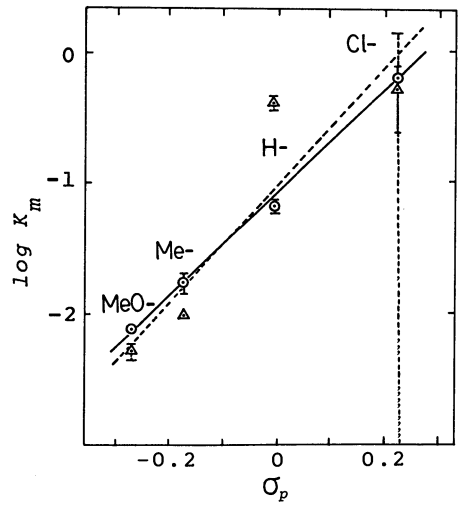

Fig. 6. Plot of log K_m for para-substituted styrenes vs. Hammett substituent constants σ_p for iron porphyrin-catalyzed epoxidation: —O— for FeCl catalyst; ---△— for FeMe catalyst. The two straight lines are drawn by the least squares method.

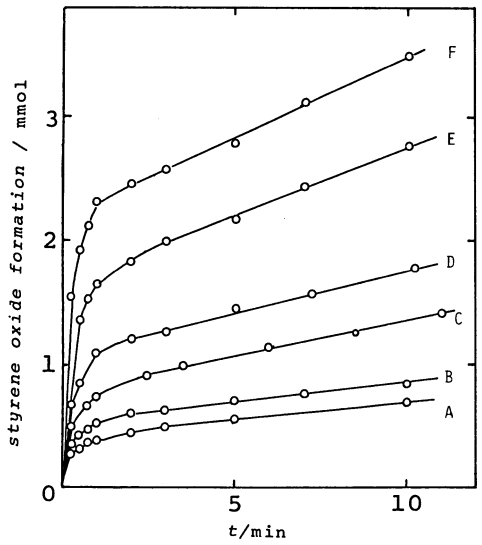

Fig. 7. Time course for styrene oxide production catalyzed by MnMe. [styrene]=A 0.21; B 0.31; C 0.75; D 1.3; E 2.7; F 3.9 M. By use of other complexes the plots of time course for epoxide production give straight lines.

Table 3. Kinetic Parameters for Epoxidation Catalyzed by Iron and Manganese Porphyrin Complexes

M	R	V_{max}[a]	K_m	V_{max}[a]	K_m	V_{max}[a]	K_m
		turnovers s^{-1}	M	turnovers s^{-1}	M	turnovers s^{-1}	M
Fe	Me	1.3	0.40	1.1	0.16	0.13	0.26
	Cl	1.4	0.065	2.8	0.30	0.37	0.06
Mn + *N*-base	Me	10.3	0.51	3.8	0.051	4	2
	Cl	2.8	0.06	1.9	0.036	2.1	0.09

a) V_{max} (in turnovers s^{-1}) here is identical to the rate-determining constant k_2.[35]

on the binding affinity of oxo-iron complex to olefin, as mentioned above. With respect to the manganese complexes, the K_m value for MnCl to each olefin is smaller than that of MnMe (by a factor of 8.5 for styrene; 22 for 1-octene). The electron-withdrawing chloro groups enhance the binding affinity of the oxo-manganese complex to olefin.

Taking all these facts together, we presently propose a speculative mechanism. One possible explanation for the difference between the iron and the manganese catalysts is that steric interactions between an ortho substituent and the olefin differ. According to previous EXAFS results regarding oxo-metal complexes, the distance Fe-O is 1.64 Å[55] and Mn-O is 1.84 Å.[56] Fe-O is shorter than Mn-O by 0.2 Å. Thus, when olefin approaches the oxygen atom of an oxo-metal complex, a relatively large steric interaction between the olefin and ortho substituents of oxo-iron complexes would be expected, compared with the case of manganese complexes. In iron complexes, owing to a large steric interaction, the electronic effect of the ortho-substituents has little influence on the binding affinity to the olefins. On the other hand, in manganese complexes, the steric interaction is not so large that the electronic effect reflects the binding affinity.

N-Alkylation of an Iron Porphyrin. Both cytochrome P-450 enzymes[57] and iron porphyrin-iodosylarene systems[58-62] undergo an *N*-alkylation of porphyrin in the epoxidation of 1-olefins. Although *N*-alkylation causes a "suicide" inactivation of P-450, a reduced activity is still retained in a model system.[59]

We observed an *N*-alkylaiton of FeCl in the course of the epoxidation of 1-octene. Under hypochlorite oxidant conditions FeCl and excess 1-octene were stirred for 4 min. The organic phase turned green. The UV-vis spectrum (λ_{max} 435, 578, 641 nm) was similar to that of the previously reported iron *N*-alkylporphyrins.[58,59]

For each of the two iron porphyrins the difference of K_m values among the three different olefins is small, as shown in Table 3. The V_{max} values for 1-octene are, however, about 1/10 of the V_{max} values for other two olefins. These kinetic data suggest that the oxo-1-octene intermediate has a relatively long lifetime. Therefore, a rearrangement of the intermediate may occur while affording *N*-alkylporphyrin.

Conclusively, we have demonstrated that: (1) the mechanism for the catalytic reaction by iron porphyrins is the Michaelis-Menten type as well as that by manganese complexes, (2) the differences of the metals or the ortho substituents give effects on oxidative catalyst destruction and on the Michaelis-Menten parameters, V_{max} and K_m, and (3) *N*-alkylation of an iron porphyrin has a relationship to the kinetic parameters.

This work was supported in part by a Grant-in-Aid for Scientific Research (No. 61470041) from the Ministry of Education, Science and Culture.

(Received April 13, 1988)

A characteristic second peak appears at about 10 eV from a main peak in the XANES (X-ray Absorption Near Edge Structure) spectrum of aqueous 3d transition metal complex of divalent state. This second peak is prominent in solid samples. The peak intensity depends on the kind of central metal or counter anion in solid. Theoretical calculations based on the full multiple scattering formalism provide the information regarding the origin and property of the second peak in XANES. The second peak can be reproduced by the multiple scattering calculation considering only six first coordinating oxygen atoms. The intensity and the position of the peak vary with the charge on the first coordinating oxygen atoms which is affected by the ions or solvent molecules contacting with the metal complex.

The coordination structures of hydrated complexes of 3d transition metals have been studied by X-ray diffraction technique[1] and EXAFS (Extended X-ray Absorption Fine Structure)[2,3] which investigate the pair correlation functions. Recently, it has been demonstrated that XANES spectroscopy directly provides higher order correlation function containing the information on geometries around the X-ray absorbing atom.[4] In the region of XANES are involved the electron transitions from a core level to unoccupied valence levels and multielectron effects (shake up and shake off). This complexity makes the XANES difficult to be applied to the characterization of materials.

We have found that there is a characteristic peak at about 10 eV higher from the main peak in the XANES spectra of hexaaqua 3d transition metal complexes of divalent state and the peak is stronger for solid samples than for aqueous solutions. Such a peak has also been reported in the XANES spectra of $MnCl_2$, $FeCl_2$, and $CoCl_2$, at about 5 eV higher from the main peak. Stern[5] explained it in terms of multielectron excitation such as shake up process by referring to the results of XPS. Sham[6] has observed an analogous peak at 6.8 eV higher from the main peak for L_{III}-edge of Pt in K_2PtCl_4 solid. This peak is not present in the spectrum of solution state. He concluded that this peak is most likely due to the density of state effects involving Pt–Pt interaction. In the XANES of Ge, a similar peak is more prominent in crystal state than in amorphous state. Proietti et al.[7] have attributed the peak to the multiple scattering effect by the second and the third coordination shell.

In this paper, we study the origin of the second peak in K-edge XANES of hexaaqua complexes of 3d transition metals by means of multiple scattering calculation. The XANES calculations are performed according to the scheme described in detail elsewhere[8] in which the full multiple scattering effect is taken into consideration. The scattering property of each atomic pair is described by a set of scattering phase shifts which depends on the electronic structure of the atom. Thus the charge distribution around the X-ray absorbing atom can be obtained by means of XANES analysis.

Experimental

$Mn(ClO_4)_2 \cdot 6H_2O$ and $Co(ClO_4)_2 \cdot 6H_2O$ were purchased from Kishida Chemicals, Ltd. and $Ni(NO_3)_2 \cdot 6H_2O$ and $Fe(ClO_4)_3 \cdot 6H_2O$ from Nakarai Chemicals, Ltd. $CrSO_4 \cdot 5H_2O$, $Cr(ClO_4)_3 \cdot 6H_2O$, $Fe(ClO_4)_2 \cdot 6H_2O$, $Cu(ClO_4)_2 \cdot 6H_2O$, and $Zn(ClO_4)_2 \cdot 6H_2O$ were prepared according to the text.[9] The solution of Ti^{3+}, Cr^{2+}, and Fe^{2+} were prepared by the electrolytic reductions of each sulphate (Ti^{4+}, Cr^{3+}) or perchlorate (Fe^{3+}) solutions. The solution of V^{3+} ion was prepared by mixing equal amounts of V^{4+} and V^{2+} sulphate solutions. Since these low valence state ions are very sensitive to air and are easily oxidized, all the procedures for the preparations as well as the X-ray absorption measurements were performed under a dry nitrogen gas atmosphere.

The solid powdered samples were held on adhesive tapes and the liquid samples were placed in airtight polyethylene pouches. The concentrations of metal ions in solution were 1.0 mol dm^{-3}.

All of the K-edge absorption spectra were recorded at BL-7C of the Photon Factory of National Laboratory for High Energy Physics (KEK) in Tsukuba. A Si(111) double crystal monochromator was used. The storage ring was operated at 2.5 GeV and the ring current was 150—200 mA.

Method of XANES Calculation

The XANES theory used in this paper is based on the short range order multiple scattering theory proposed by one of the present authors.[10] The $\chi(k)$ is calculated by the same method as the one for EXAFS. $\chi(k)$ is defined as

$$\chi(k) = (\sigma(k) - \sigma_o(k))/\sigma_o(k),$$

where $\sigma_o(k)$ is the photo-absorption cross section of the core orbital of a free atom, $\sigma(k)$ is the cross section in the presence of surrounding atoms, and k is the wave vector of the ejected photoelectron.

For semiconductors and insulators, the core holes

are not fully screened and the hole potential felt by a photoelectron is too large to be neglected.[11] One of the simplest models for the hole potential is a $Z+1$ potential. In this paper it is assumed that the system is fully relaxed in the final state and the photo-absorbing atom is replaced with a $Z+1$ atom.

The phase shifts are obtained under the Hartree-Fock approximation by using Pendry's program.[12] Practically it requires the charge densities of atoms calculated from the interatomic distances and the charges of atoms. Usually the distances are obtained from X-ray diffraction data and the charges are from Pauling's method.[13] In the present work, the charges are treated as the unknown parameters for the XANES calculations in order to clarify their contribution to the XANES.

Results and Discussion

XANES Spectra. The structures of the hexaaqua complexes of 3d transition metals are normally octahedral, except for Cr^{2+} and Cu^{2+} in which there are a Jahn-Teller distortion.

The K-edge XANES spectra for trivalent 3d metal complexes are shown in Fig. 1. There is a weak dipole-forbidden 1s–3d transition peak in the pre-edge region of each XANES spectrum. The energy scale refers to this pre-edge peak. The shapes of the XANES for trivalent hexaaqua complexes, especially Ti^{3+}, V^{3+}, and Cr^{3+}, resemble each other. Figure 2 shows the XANES spectra for divalent 3d metal complexes in solid and solution. It is interesting to note that the XANES spectra for hexaaqua complexes in solution (Fig. 2 right) are quite similar to each other, except for Cr^{2+} and Cu^{2+}. The shapes of XANES for Cr^{2+} and Cu^{2+} are different from those for other metal complexes possibly because of the Jahn-Teller distortion. Garcia et al.[14] reported that the theoretical calculation for a CuO_6 cluster, taking into account the Jahn-Teller distortion (>0.3 Å), predicted the presence of the peaks on both low- and high-energy sides of a main peak. In our spectra, there are two peaks on high-energy side of the main peak B in Fig. 2 for Cr^{2+} and Cu^{2+}, and there is a single peak on the edge for $CrSO_4 \cdot 5H_2O$ in which the difference in bond length between those for axial and equatrial amounts to 0.43 Å.[15] The distances between peaks in XANES are listed in Table 1. The main peak B shifts to high-energy side with the increase of atomic number of central metal.

Another characteristic spectral feature for aqua complexes of divalent metals is that the peak C at about 10 eV higher energy side from the main peak is stronger in solid than in solution. This peak is especially strong in the spectra of Zn^{2+} as shown in

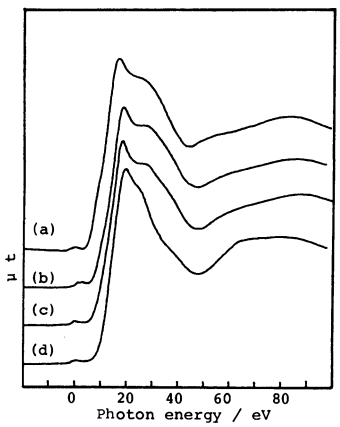

Fig. 1. K-edge XANES spectra for trivalent 3d metal complexes in aqueous solution of (a) Ti^{3+}, (b) V^{3+}, (c) Cr^{3+}, and (d) Fe^{3+} ions. The energy scale refers to the pre-edge peak.

Table 1. Intervals between Peaks in eV

	Cr^{2+}	Mn^{2+}	Fe^{2+}	Co^{2+}	Ni^{2+}	Cu^{2+}	Zn^{2+}
A–B (solid)	14.3	13.7	16.2	16.9	17.1	19.2	—
A–B (solution)	14.3	12.5	15.1	16.9	15.9	18.9	—
B–C (solid)	6.1 11.3	10.5	11.3	11.2	12.6	5.4 13.9	11.9

Fig. 3. The order of the intensities of this peak is $Zn^{2+}>Mn^{2+}>Fe^{2+}>Co^{2+}>Ni^{2+}$. Regarding the origin of the peak C, the possibility of the multielectron effect observed in XANES for 3d metal chlorides[5] can be ruled out because (1) the peak intensities are different in solids and solutions and (2) the peak appears remarkably in Zn^{2+} compounds in which 3d orbitals are filled with valence electrons exhibiting no shake up peak in XPS. It has also been reported[16] that the plasmon satellites are featureless and probably lost in the background in the low kinetic energy region in XPS and this would make the shake up phenomenon quite weak in XANES region. It is possible that the appearance of the peak C is caused by the multiple scattering effect of photoelectrons. The multiple scattering calculation for ZnSe by Matsuura,[17] reproduces the second peak at about 10 eV higher from the main peak when the second shell scattering is included for the calculation. In the case of Ge crystal,[7] the peak is caused presumably by the multiple scattering by the shell extending further than the second shell. The XANES spectra for Zn^{2+} crystals having various counter anions are shown in Fig. 3. The second peak is observed in each spectrum, with the intensity order of $ClO_4^->NO_3^->SO_4^{2-}$. The peak is also observed in solution though it is rather weak. The XANES spectra for Zn^{2+} solutions are the same regardless of the kind of the anion. From the results of solutions, it is inferable that the second shell is less important, and that the electron scattering by only nearest six coordinating oxygen atoms would make the peak appear.

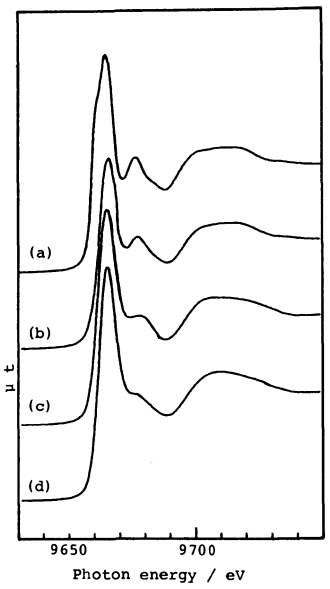

Fig. 3. K-edge XANES spectra for Zn^{2+} compounds, (a) $Zn(ClO_4)_2\cdot 6H_2O$, (b) $Zn(NO_3)_2\cdot 6H_2O$, (c) $ZnSO_4\cdot 7H_2O$, and (d) Zn^{2+} aqueous solution.

Multiple Scattering Calculation. $[Zn(OH_2)_6]^{2+}$ complex is chosen as a model in order to reveal the character of the second peak or the peak C in XANES, because the second peak for Zn^{2+} is the most prominent among the 3d transition metals and the calculation is expected to be the simplest owing to the fully occupied 3d orbitals.

First, the cluster consisting of 35 atoms having Zn at the center, $ZnO_{26}N_8$, is adopted as the model for solid $Zn(NO_3)_2\cdot 6H_2O$. The positions of the selected atoms are within 5 Å from Zn and fixed according to the X-ray diffraction results.[18] For the phase shift calculations of the central Zn atom and the first coordinating oxygen atoms, a diatomic molecule, Zn–O, is considered and its bond length is assumed to be 2.08 Å which is observed in solution.[1] The charges on Zn and O atoms are unknown parameters. They are determined by putting the trial values to get the best fit between the theoretical result and the experimental spectrum. Figure 4 (a) shows the

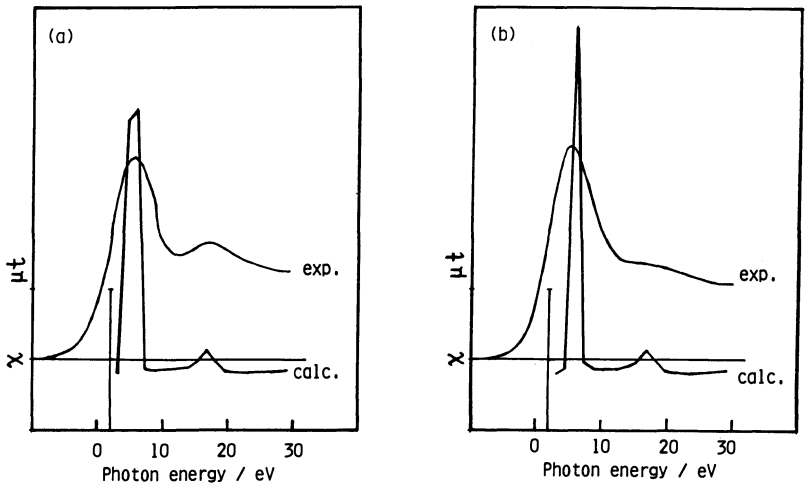

Fig. 4. Theoretical and experimental XANES spectra for (a) $Zn(NO_3)_2\cdot 6H_2O$ crystal and (b) Zn^{2+} aqueous solution.

XANES spectrum of $Zn(NO_3)_2 \cdot 6H_2O$ and the calculated XANES spectrum for the $ZnO_{26}N_8$ cluster model when the charge of Zn atom is 1.2 (that of O atom is −1.2). The charge of NO_3 is fixed as neutral. The charges of Zn and the first coordinating O atoms are determined so as to reproduce the positions of the main B and the second peak C of the experimental spectrum. In the present work, only the intensity and the position of the second peak are important. Therefore the theoretical XANES spectra are not corrected for the absolute intensity and the widths of the peaks, which can be estimated by considering the absorption cross section of free atom and the life time of the excited state.

Next, the calculation was performed on the model of a ZnO_6 cluster representing the complex present in aqueous solution. The second coordinating atoms are those in solvent molecules and they cannot contribute to produce the fine structure in XANES and EXAFS because their positions are randomly distributed. The shape of the cluster is octahedral and the distance of Zn–O is 2.08 Å.[1] The calculated XANES spectrum for the solution model is shown in Fig. 4 (b). This is a very important result which indicates that the multiple scattering effect confined only in the ZnO_6 moiety gives rise to the second peak. We had expected that the intensity of the second peak in the calculated spectrum for the solid model should be stronger than that for the aqueous solution model. The intensities and the positions of the second peaks are, however, almost the same.

Subsequently, the effect of solvent molecules in this calculation is studied just in case. Twelve oxygen atoms of water molecules are added to the ZnO_6 cluster. It is assumed that the water molecules bond to the complex through the hydrogen bonding and that the distance of O–O in Zn–O–H···O–H and the angle of Zn–O–H are 2.5 Å and 140° in this model. Further, the multiple scattering calculations are performed for the models having the water molecules at various places which simulate the distribution of the solvent molecules. However, the results are not different from those of the ZnO_6 cluster and the solid. We conclude that the second shell atoms and/or the atoms outside of the second coordination shell atoms should not contribute much to the appearance of the second peak in XANES for the 3d metal aqua complexes.

The Effect of the Charge on Oxygen. From the full multiple scattering calculation the following conclusions are derived. (1) In order to produce the second peak in XANES only the first coordination shell atoms are neccessary. (2) Addition of the second shell atoms results in no alteration in the strength or in the position of the second peak. (3) Thus it is impossible only by placing the scattering atoms around the central atom to reproduce the experimental facts that the second peak is lower for solution

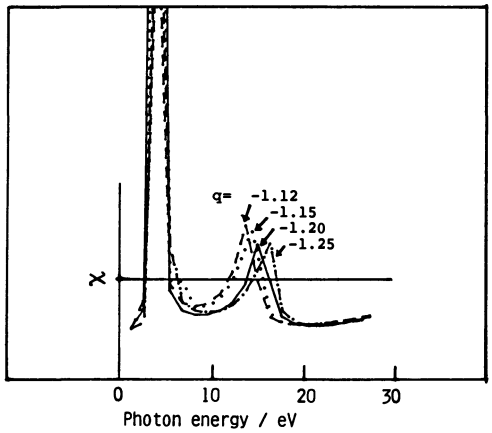

Fig. 5. Calculated XANES spectra for various charges (−1.12—−1.25) on the first coordinating oxygen atoms. The charge on Zn atom is fixed at 1.2.

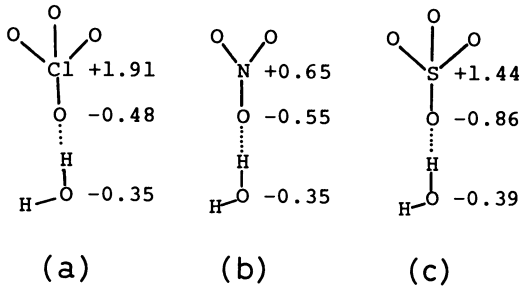

Fig. 6. Charge distributions on water molecule and counter anions determined by MNDO calculations: (a) ClO_4^-, (b) NO_3^-, and (c) SO_4^{2-}.

sample than that for solid sample and that the peak height for the solid sample is quite sensitive to the kind of counter anion.

In order to explain the effect of the counter anion on the second peak in XANES, the charge of the first coordinating oxygen atoms should be incorporated into the calculation. Figure 5 shows the calculated XANES spectra for the various charges (−1.12—−1.25) of the first coordinating oxygen atoms in ZnO_6 cluster model, where the charge of Zn is fixed to be 1.2. The intensities and positions of the second peak change according to the charge of the first coordinating oxygens. The more the negative charge on oxygens, the lower the second peak height and the lower the peak position in energy. Then, in order to estimate the charge on the oxygen atoms, or the alteration of the charge due to the anions, we perform MNDO calculations, which are recognized as the useful quantum chemical method to predict the charges of the atoms up to Cl atom in periodic table.[19,20] The calculations performed here consider only the counter anion and water molecule. The results of the calculations are shown in Fig. 6. The lengths of the hydrogen bondings between H_2O and counter anions are optimized by the calculations so

that they are not necessarily the same as those for the crystals. The calculations indicate that SO_4^{2-} ion induces more negative charge on the oxygen atom than ClO_4^- or NO_3^- does. The experimental result that the crystal with the ClO_4^- or NO_3^- counter ion gives the stronger second peak is in accordance with the theoretical prediction that these anions induced less negative charge on the oxygens, thus the intensities for these crystals are stronger. The peak shifts are also well-predicted with the present model calculation. In this way, the characteristics of the intensity and the position of the second peak can be explained qualitatively by taking into account the variation of the charge on the first coordinating oxygens.

In the case of solution sample, the second coordinating water molecules take various positions around the first coordinaing water molecules. Thus, the charge on the first coordinating oxygens fluctuates depending on the length of the hydrogen bonding between the first and the second water molecules. It may be concluded that the fluctuation of the charge on the first coordinating oxygen atoms would smooth out the second peak in XANES because the position of the peak shifts according to the charges of the first coordinating oxygens. In conformity with this view, the reason why the second peak for Mn^{2+} or Zn^{2+} having a larger ionic radius is stronger than the other complexes is understandable. That is, the negative charge induced by the central metal cation on the oxygen atoms of the first coordinating water molecules must be smaller for larger ionic radius cations.

In conclusion, we believe that the second peak in XANES of the aqueous 3d metal complex appears due to the multiple scattering effect in the system consisting of the central metal and only six first coordinating oxygen atoms, and that its intensity and position vary with the charge on the first-coordinating oxygen atoms which is affected by the second and/or further coordinating atoms. The feature at the higher energy region of several eV from the main peak in XANES seems to contain the information concerning the second coordinating atoms which are too far from the central atom to be studied by means of EXAFS.

The authors thank Drs. Tadashi Matsushita and Masaharu Nomura of the National Laboratory for High Energy Physics (KEK) for their help and suggestions on EXAFS measurements. This work was supported by the Grant-in-Aid for Special Project Research No. 62124039 from the Ministry of Education, Science and Culture.

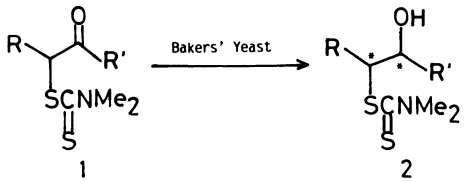
Asymmetric Reduction of α-(Dimethylthiocarbamoylthio) Carbonyl Compounds with Bakers' Yeast

Sadao Tsuboi,* Noriyuki Kohara, Katsumi Doi, Masanori Utaka, and Akira Takeda
Department of Synthetic Chemistry, School of Engineering, Okayama University, Tsushima, Okayama 700
(Received February 15, 1988)

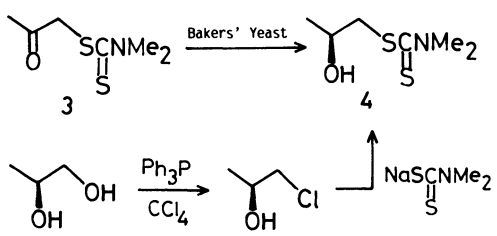
Treatment of α-(dimethylthiocarbamoylthio) ketones with bakers' yeast afforded the corresponding chiral alcohols in high yields with high enantiomeric excess (in most cases, more than 96% ee). α-(Dimethylthiocarbamoylthio) aldehydes were reduced to give chiral α-(dimethylthiocarbamoylthio) alcohols in 69—92% yields with 32—63% ee, which were converted to chiral 1,2-epithio derivatives.

Recently, asymmetric reduction of ketones with bakers' yeast (Saccharomyces cerevisiae) has been widely utilized for the preparation of chiral building blocks.[1] It is well-known that the reduction of β-keto esters by bakers' yeast affords optically active β-hydroxy esters.[1] Generally speaking, ketones α-substituted by an electron-withdrawing group are inclined to be reduced with bakers' yeast. Ketones α-substituted by sulfur atoms are also reduced to give chiral alcohols. For example, asymmetric reductions of compounds such as 1,3-dithians,[2] sulfides,[3] sulfones[4] with bakers' yeast are reported. Here, we describe an asymmetric reduction of α-(dimethylthiocarbamoylthio) ketones **1** with bakers' yeast, leading to chiral alcohols **2**. Ketones **1** can be obtained in high yield by the reaction of α-halo ketones with sodium dimethyldithiocarbamate, which is commercially available and can be easily prepared by the reaction of dimethylamine and carbon disulfide in the presence of sodium hydroxide.[5]



1 2

Various ketones **1** were prepared and treated with bakers' yeast in tap water in the presence of glucose. The reaction gave chiral alcohols **2** in good yield. Enantiomeric excess of the chiral alcohols obtained was determined by ^{1}H NMR analysis in the presence of chiral shift reagent (Eu(hfc)$_3$) and/or by HPLC analysis for the corresponding esters of (*S*)-(+)-α-methoxy-α-(trifluoromethyl)phenylacetic acid (MTPA).[6] These results are shown in Table 1.



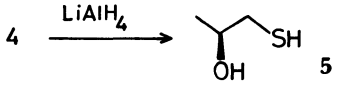
Treatment of α-(dimethylthiocarbamoylthio)acetone (**3**) with bakers' yeast gave the corresponding chiral alcohol **4** with more than 96% ee in unusually

Table 1. Asymmetric Reduction of α-(Dimethylthiocarbamoylthio)-Substituted Carbonyl Compounds with Bakers' Yeast

Ketone	Product	Reaction time/day	Yield[a] %	ee %
 3	 4	6	91	>96
 6	 7	6	39	>96
 8	 9	4	82[b]	>96[c]
 10	3	4	25	—
	4	4	39	77
 11	 12	5	92	55
 13	 14	9	69	32
 15	 16	10	78	46
 17	 18	9	75	63

a) Isolated yield. b) Isolated as a diastereomeric mixture: erythro/threo=72/28. c) Both of erythro and threo.

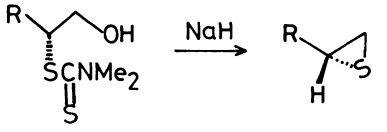
high yield (91%). The absolute configuration was determined to be *S* by the independent synthesis of **4** via (*S*)-1-chloro-2-propanol from (*S*)-(+)-1,2-propanediol, as shown in experimental section. Reduction of **4** with $LiAlH_4$ gave 1-mercapto-2-propanol (**5**) in 83%



yield. Chiral reduction of 1-(dimethylthiocarbamoylthio)-2-heptanone (**6**) with bakers' yeast afforded optically pure (*S*)-(+)-1-(dimethylthiocarbamoylthio)-2-heptanol (**7**) in 39% yield. Treatment of 3-(dimethylthiocarbamoylthio)-2-butanone (**8**) with bakers' yeast yielded the diastereomeric mixture of the corresponding alcohols **9** with the ratio of erythro/threo (72/28) in 82% yield. Optical purities of each isomer separated by preparative HPLC were more than 96% ee. Treatment of 3-(dimethylthiocarbamoylthio)-2,4-pentanedione (**10**) with bakers' yeast gave a mixture of hydrolysis product **3** and its reduced product **4**. Absolute configuration of the chiral alcohols **7** and **9** was presumed to be *S* by comparison of the symbol of the optical rotation of **4**. This fact consists with the results obtained on the reduction of other sulfur-substituted ketones.[3,4]

Furthermore, α-(dimethylthiocarbamoylthio) aldehydes were also reduced with bakers' yeast to give chiral alcohols unexpectedly, although the optical purity was not high. For example, 2-(dimethylthiocarbamoylthio)pentanal (**11**) was reduced with bakers' yeast to give the corresponding alcohol **12** in 92% yield with 55% ee. As shown in the table, some aldehydes such as **13**, **15**, and **17** were also reduced with bakers' yeast to give the corresponding chiral alcohols **14**, **16**, and **18** in good yields.

Some optically active epithio compounds are synthesized because they are important for the preparation of chiral polymers containing sulfur.[7] The reduced products were converted to the thioepoxides and the absolute configuration was determined as *R* by comparison of the direction of the optical rotation with that of known epithio compounds.[7] Compound **12** was treated with sodium hydride to give (*R*)-(+)-1,2-epithiopentane (**19**) in 40% yield. Compound **14** was also treated with sodium hydride to give a known compound, (*R*)-(+)-3-methyl-1,2-epithiobutane (**20**).[7]



12, R=$CH_2CH_2CH_3$ **19**, R=$CH_2CH_2CH_3$
14, R=$CH(CH_3)_2$ **20**, R=$CH(CH_3)_2$

The present reduction with bakers' yeast afforded chiral (dimethylthiocarbamoylthio) alcohols in good yield, which would be useful for the synthesis of sulfur containing natural products[8] and chiral thiiranes[7] because the reaction conditions are mild and the procedures are simple and economically feasible.

Experimental

The melting points and boiling points are uncorrected. Elemental analyses were carried out by Eiichiro Amano in our laboratory. Analytical spectra were obtained with the following instruments: IR, Jasco Model A-102; ^1H NMR (60 MHz), JEOL JNM-PMX60SI apparatus; ^1H NMR (100 MHz) and ^{13}C NMR (25 MHz), JEOL JNM-FX100 apparatus. Optical rotations were measured on a Jasco DIP-4 spectrometer. HPLC analysis was performed with a Yanagimoto liquid chromatograph L-2000 fitted with a Yanapak SA-I (6-mm o.d.×250-mm length) and with a Sumipax OA-3000 (4-mm o.d.×250-mm length) for the determination of enantioselectivity.

Fermentation was carried out at 31—35 °C by using industrial bakers' yeast purchased from Oriental Yeast Co., Ltd. All glasswares were sterilized by boiling water before use. The amount of consumed glucose was checked by test paper for that of glucose in urine. During the fermentation, additional glucose was added when the concentration became less than 0.5%. α-Chloro aldehydes were prepared by the reaction of aldehydes with sulfuryl chloride.[9]

α-(Dimethylthiocarbamoylthio)acetone (3). To a solution of 5 g (35 mmol) of sodium dimethyldithiocarbamate in 30 ml of methanol was added dropwise 3.9 g (42 mmol) of chloroacetone with cooling. The mixture was stirred overnight at room temperature and then poured into water. After the mixture was concentrated in vacuo, the organic material was extracted with dichloromethane. The combined extracts were washed with water, dried over $MgSO_4$, and concentrated to give 5.46 g (88%) of **3**: mp 50—51 °C (from ethyl acetate); IR (KBr) 1715, 1498, 1355, 1255, 1155, and 980 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.33 (s, 3H, $COCH_3$), 3.49 (s, 6H, $N(CH_3)_2$), 4.18 (s, 2H, CH_2). Found: C, 40.78; H, 6.17; N, 7.68%. Calcd for $C_6H_{11}NOS_2$: C, 40.65; H, 6.26; N, 7.90%.

(*S*)-(+)-1-(Dimethylthiocarbamoylthio)-2-propanol (4). To a mixture of KH_2PO_4 (1 g), $NH_4H_2PO_4$ (1 g), $MgSO_4$ (0.5 g), $CaCO_3$ (2.5 g), glucose (90 g), and boiled water (450 ml) was added 9 g of bakers' yeast at 32 °C. After bubbles formed (ca. 20 min), 3 g (16.9 mmol) of **3** was added and then the mixture was stirred at 32 °C for 57 h. The organic layer was extracted with ethyl acetate. The combined extracts were washed with water, dried ($MgSO_4$), and concentrated to give 3.22 g of an oil, which was chromatographed on SiO_2 (hexane/CH_2Cl_2=5/1) to give 2.74 g (91%) of **4**: bp 240 °C (10 mm) (short-pass distillation); mp 50—51 °C (from ether); $[\alpha]_D^{13}$ +52.2° (*c* 0.20, $CHCl_3$); IR (neat) 3400, 2990, 2940, 1500, 1375, 1255, 1145, 1120, 980 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.28 (d, *J*=6 Hz, 3H, CH_3CHOH), 2.97 (s, 1H, OH), 3.43 (m, 8H, $(CH_3)_2N$, CH_2S), 4.00 (m, 1H, CH_3CHOH). Found: C, 39.78; H, 6.88; N, 7.20%. Calcd for $C_6H_{13}NOS_2$: C, 40.19; H, 7.31; N, 7.81%.

Independent Synthesis of 4. To 1.15 g (4.4 mmol) of triphenylphosphine was added a solution of 313 mg (4.12 mmol) of (*S*)-(+)-1,2-propanediol ($[\alpha]_D^{26}$ +16.9° (neat))

in 3 ml of CCl_4 under an atmosphere of nitrogen. The mixture was heated under reflux for 4 h and then cooled to room temperature. A mixed solvent of hexane and ether (3/1) was added and the mixture was filtered. After concentration of the filtrate, the residue was added dropwise into a solution of 630 mg (4.4 mmol) of sodium dimethyldithiocarbamate in 5 ml of methanol and then the mixture was heated under reflux for 4 h. After evaporation of the solvent, the residue was poured into water. The organic layer was extracted with ethyl acetate. The extracts were washed with water, and dried over $MgSO_4$. Evaporation of the solvent gave 256 mg of the crude product, which was purified by preparative TLC (hexane/ethyl acetate, 1/1) to give 43 mg (5.8%) of **4**: R_f 0.34—0.51; $[\alpha]_D^{27}$ +33.3° (*c* 0.96, $CHCl_3$). IR and ^1H NMR data were identical with those of an authentic sample prepared above.

(*S*)-(+)-1-Mercapto-2-propanol (5). To a stirred mixture of $LiAlH_4$ (150 mg, 3.95 mmol) and dry ether (5 ml) was added a solution of **4** (471 mg, 2.63 mmol) in 5 ml of dry ether at −20 °C. The mixture was stirred for 2 h at −20 °C and then quenched with dilute HCl. The organic layer was extracted with ether and the combined extracts were washed with water, dried over $MgSO_4$, and concentrated. Removal of the solvent gave 142 mg (59%) of **5**: $[\alpha]_D^{22}$ +86.1° (*c* 2.42, $CHCl_3$); IR (neat) 3400, 3000, 1260, 1125, 1070 cm^{-1}. ^1H NMR data were identical with those of the literature.[10]

1-(Dimethylthiocarbamoylthio)-2-heptanone (6). To a solution of 1.92 g (16.9 mmol) of 2-heptanone in 15 ml of ether was added 2.70 g (0.87 ml, 16.9 mmol) of bromine at 0 °C. After the brown color disappeared, the mixture was poured into water and the organic materials were extracted with ether. The combined extracts were washed with saturated $NaHCO_3$ and water, and dried over $MgSO_4$. Concentration of the solvent gave 3.17 g (97%) of a mixture of 3-bromo-2-heptanone and 1-bromo-2-heptanone (4/1): IR (neat) 1720, 1460, 1350, 1220 cm^{-1}; ^1H NMR (CCl_4) δ=0.91 (t, 3H, CH_3), 1.10—1.65 (m, 4H, $(CH_2)_2$), 1.70—2.20 (m, 2H, $C\underline{H}_2CHBr$), 2.27 (s, 3H, $C\underline{H}_3CO$), 4.17 (t, 1H, $C\underline{H}Br$). To a solution of 1.43 g (10.0 mmol) of sodium dimethyldithiocarbamate in 10 ml of methanol was added dropwise 1.50 g of the brominated 2-heptanone described above and the mixture was stirred overnight. After evaporation of the solvent, the residue was poured into water. The organic materials were extracted with CH_2Cl_2. The combined extracts were washed with water, dried over $MgSO_4$, and concentrated. The crude oil (2.55 g) was chromatographed on SiO_2 to give 1.06 g (74%) of 3-(dimethylthiocarbamoylthio)-2-heptanone: IR (neat) 1710, 1500, 1250, 1150, 1050, 980 cm^{-1}; ^1H NMR (CCl_4) δ=0.91 (t, 3H, CH_3), 1.10—2.00 (m, 6H, $(CH_2)_3$), 2.19 (s, 3H, $C\underline{H}_3CO$), 3.47 (s, 6H, $N(C\underline{H}_3)_2$), 4.82 (t, 1H, $C\underline{H}SCSN$). The last fraction gave 60 mg (16%) of **6**: ^1H NMR (CCl_4) δ=0.92 (t, 3H, CH_3), 1.1—2.0 (m, 6H, $(CH_2)_3$), 2.65 (t, 2H, $C\underline{H}_2CO$), 3.50 (s, 6H, $N(C\underline{H}_3)_2$), 4.20 (s, 2H, $C\underline{H}_2SCSN$). Found: C, 51.68; H, 7.94; N, 6.01%. Calcd for $C_{10}H_{19}NOS_2$: C, 51.46; H, 8.20; N, 6.00%.

(*S*)-(+)-1-(Dimethylthiocarbamoylthio)-2-heptanol (7). To a mixture of KH_2PO_4 (0.2 g), $NH_4H_2PO_4$ (0.2 g), $MgSO_4$ (0.1 g), $CaCO_3$ (0.5 g), glucose (10 g), and boiled water (100 ml) was added 1 g of bakers' yeast at 32 °C. After bubbles formed (ca. 15 min), 0.125 g (0.534 mmol) of **6** was added and then the mixture was stirred at 35 °C. After 84 h, 1 g of bakers' yeast was added. After 113 h, 2 g of glucose was added. After 5.5 h, the organic layer was extracted twice with ethyl acetate and CH_2Cl_2. The combined extracts were washed with water and dried over $MgSO_4$. Concentraion of the solvent gave 0.116 g of the crude product, which was purified with column chromatography to give 55 mg (39%) of **7**: ^1H NMR (CCl_4) δ=0.9 (t, 3H, CH_3), 1.1—1.8 (m, 8H, $(CH_2)_4$), 3.1—3.6 (m, 9H, $C\underline{H}_2C\underline{H}OH$, $N(C\underline{H}_3)_2$), 3.68 (d, 2H, $CHOHC\underline{H}_2$); $[\alpha]_D^{32}$ +12.0° (*c* 0.50, $CHCl_3$); >95% ee by ^1H NMR analysis in the presence of Eu(hfc)$_3$. Found: C, 51.07; H, 8.69; N, 5.83%. Calcd for $C_{10}H_{21}NOS_2$: C, 51.02; H, 8.99; N, 5.95%.

3-(Dimethylthiocarbamoylthio)-2-butanone (8). To a mixed solution of sodium dimethyldithiocarbamate in 10 ml of methanol was added 1.50 g of a mixture of 3-chloro-2-butanone and 3,3-dichloro-2-butanone (5/6)[9] with ice cooling. The mixture was stirred overnight and concentrated. The organic layer was extracted with CH_2Cl_2, washed with water, dried over $MgSO_4$, and concentrated. The residual oil (1.93 g) was purified with column chromatography (hexane/ethyl acetate, 10/1) to give 0.545 g (52%) of **8**: IR (neat) 1710, 1500, 1250, 1050, 980 cm^{-1}; ^1H NMR (CCl_4) δ=1.44 (d, *J*=8 Hz, 3H, CH_3), 2.25 (s, 3H, CH_3CO), 3.50 (s, 6H, $N(CH_3)_2$), 4.87 (q, 1H, $C\underline{H}SCSN$). Found: C, 43.85; H, 6.71; N, 7.24%. Calcd for $C_7H_{13}NOS_2$: C, 43.95; H, 6.85; N, 7.32%.

3-(Dimethylthiocarbamoylthio)-2-butanol (9). To a mixture of $NH_4H_2PO_4$ (0.6 g), KH_2PO_4 (0.6 g), $MgSO_4$ (0.3 g), $CaCO_3$ (1.28 g), glucose (30 g), and boiled water (300 ml) was added 3 g of bakers' yeast at 32 °C. After bubbles formed (ca. 20 min), 0.722 g (4.52 mmol) of **8** was added and then the mixture was stirred at 35 °C. After 64 h, 10 g of glucose was added. After 96 h, the organic layer was extracted twice with ethyl acetate and CH_2Cl_2. The combined extracts were washed with water, dried over $MgSO_4$, and concentrated. The residual oil (0.285 g) was chromatographed on SiO_2 to give 0.60 g (82%) of **9** as a mixture of erythro and threo (72/28): IR (neat) 3340, 1500, 1370, 1050, 980 cm^{-1}; ^1H NMR (CCl_4) δ=1.25 (m, 6H, $2CH_3$), 2.20 (s, 1H, OH), 3.43 (s, 6H, $N(CH_3)_2$), 4.03 (m, 2H, $C\underline{H}OHC\underline{H}SCS$). Found: C, 43.59; H, 7.96; N, 7.12%. Calcd for $C_7H_{15}NOS_2$: C, 43.49; H, 7.82; N, 7.25%. Each component was separated by preparative HPLC (column, SA-I(6ϕ×25 mm); eluent, hexane/ethyl acetate/ethanol (20/5/1)). *erythro*-**9**: $[\alpha]_D^{25}$ +109.4° (*c* 1.70, $CHCl_3$); IR (neat) 3430, 1500, 1381, 1260, 990, 980 cm^{-1}; ^1H NMR (CCl_4) δ=1.15 (d, *J*=6 Hz, 3H, $C\underline{H}_3CHOH$), 1.32 (d, *J*=6 Hz, 3H, $C\underline{H}_3CHSCS$), 2.55 (s, 1H, OH), 3.45 (s, 6H, $N(CH_3)_2$), 4.10 (m, 2H, $C\underline{H}C\underline{H}$); $J_{CH\text{-}CH}$=3.2 Hz, determined by ^1H NMR in the presence of 10% Eu(hfc)$_3$; >96% ee, no paired peaks in the presence of 40% Eu(hfc)$_3$. *threo*-**9**: $[\alpha]_D^{25}$ −51.4° (*c* 1.07, $CHCl_3$); IR (neat) 3420, 1500, 1372, 1250, 980, 962 cm^{-1}; ^1H NMR (CCl_4) δ=1.19 (d, *J*=6 Hz, 3H, $C\underline{H}_3CHOH$), 1.36 (d, *J*=6 Hz, 3H, $C\underline{H}_3CHSCS$), 2.40 (s, 1H, OH), 3.44 (s, 6H, $N(CH_3)_2$), 3.98 (m, 2H, >CH-CH<); $J_{CH\text{-}CH}$=4.8 Hz, determined by ^1H NMR in the presence of 10% Eu(hfc)$_3$; >96% ee, no paired peaks in the presence of 40% Eu(hfc)$_3$.

3-(Dimethylthiocarbamoylthio)-2,4-pentanedione (10). To a solution of 2.18 g (15.2 mmol) of sodium dimethyldithiocarbamate in 10 ml of methanol was added dropwise 2.01 g (15 mmol) of 3-chloro-2,4-pentanedione[11] with ice cooling. The mixture was stirred for 9 h at room temperature. After concentration of the solvent, the residue was poured into water and the organic layer was extracted with CH_2Cl_2. The combined extracts were washed with

water, dried over $MgSO_4$, and concentrated. The crude product (3.56 g) was purified with column chromatography (hexane/ethyl acetate, 20/1) to give 2.20 g (67%) of **10**: ^1H NMR (CCl_4) δ=2.06 (s, 6H, $2CH_3$), 3.50 (s, 6H, $N(CH_3)_2$), 17.32 (s, 1H, C=C-OH). Found: C, 43.49; H, 5.85; N, 6.12%. Calcd for $C_8H_{13}NO_2S_2$: C, 43.81; H, 5.97; N, 6.39%.

Reduction of 10 with Bakers' Yeast. Compound **10** (1.01 g, 4.59 mmol) was treated with bakers' yeast for 4 days, as described in the preparation of **9**. The crude product was chromatogaphed on SiO_2 (hexane/ethyl acetate, 20/1) to give 0.206 g (25%) of **3** as the first fraction. The second fraction gave 0.318 g (39%) of **4**: $[\alpha]_D^{25}$ +40.2 (*c* 2.56, $CHCl_3$): 77% ee. Spectral data were identical with those of the samples prepared above.

2-(Dimethylthiocarbamoylthio)pentanal (11). To a solution of 12.0 g (83.9 mmol) of sodium dimethyldithiocarbamate in 40 ml of methanol was added dropwise 9.57 g (79.4 mmol) of 2-chloropentanal with ice cooling. The mixture was stirred for 12 h at 25 °C and then for 1 h at 30—40 °C. After concentration of the solvent, the organic layer was extracted with CH_2Cl_2. The combined extracts were washed with water, dried over $MgSO_4$, and concentrated. The residue (14.9 g) was distilled to give 10.2 g (63%) of **11**: bp 127—129 °C (0.3 mm); IR (neat) 1720, 1500, 1380, 1250, 980 cm^{-1}; ^1H NMR (CCl_4) δ=1.00 (t, *J*=6 Hz, 3H, CH_3), 1.20—2.20 (m, 4H, $(CH_2)_2$), 3.50 (s, 6H, $N(CH_3)_2$), 4.75 (t, *J*=6 Hz, 1H, C<u>H</u>SCS), 9.37 (s, 1H, C<u>H</u>O). Found: C, 47.08; H, 7.34; N, 6.62%. Calcd for $C_8H_{15}ONS$: C, 46.79; H, 7.36; N, 6.82%.

Other aldehydes (**13**, **15**, **17**) were also prepared by the method described above.

2-(Dimethylthiocarbamoylthio)-3-methylbutanal (13): 53% yield; bp 133—135 °C (0.3 mm); IR (neat) 2950, 1720, 1500, 1470, 1250 cm^{-1}; ^1H NMR (CCl_4) δ=0.95 (d, *J*=6.5 Hz, 3H, CH_3), 1.10 (d, *J*=6.5 Hz, 3H, CH_3), 2.45 (m, 1H, $(CH_3)_2C\underline{H}$), 3.50 (s, 6H, $N(CH_3)_2$), 4.85 (d, *J*=5 Hz, 1H, C<u>H</u>CHO), 9.42 (s, 1H, CHO). Found: C, 46.72; H, 7.18; N, 7.03%. Calcd for $C_{18}H_{15}NOS_2$: C, 46.79; H, 7.36; N, 6.82%.

2-(Dimethylthiocarbamoylthio)hexanal (15): 63% yield; bp 80 °C (1.5 mm) (bath temperature); IR(neat) 2950, 1720, 1500, 1380, 1255, 980 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.89 (t, 3H), 1.11—2.13 (m, 6H), 3.46 (d, 6H), 4.75 (t, *J*=6.5 Hz, 1H), 9.50 (s, 1H). Found: C, 49.52; H, 7.80, N, 6.21%. Calcd for $C_9H_{17}NOS_2$: C, 49.28; H, 7.81; N, 6.39%.

2-(Dimethylthiocarbamoylthio)heptanal (17): 96% yield; IR (neat) 1720, 1500, 1380, 1250, 1150, 980 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.86 (t, *J*=6 Hz, 3H), 1.07—1.56 (m, 8H), 3.45 (s, 6H), 4.70 (t, *J*=6 Hz, 1H), 9.36 (s, 1H).

***(R)*-(+)-2-(Dimethylthiocarbamoylthio)-1-pentanol (12).** To a mixture of $NH_4H_2PO_4$ (1 g), KH_2PO_4 (1 g), $MgSO_4$ (0.5 g), $CaCO_3$ (2.5 g), glucose (40 g), and boiled water (500 ml) was added 5 g of bakers' yeast at 35 °C. After bubbles formed, 1.77 g (8.63 mmol) of **11** was added and then the mixture was stirred at 35 °C. After 21, 47, 69, 94, and 106 h, 5 g of bakers' yeast was added. After 5 days, the organic layer was extracted twice with ethyl acetate and CH_2Cl_2. The combined extracts were washed with water, dried over $MgSO_4$, and concentrated. The residual oil (1.85 g) was chromatographed on SiO_2 (hexane/ethyl acetate, 10/1) to give 1.64 g (92%) of **12**: $[\alpha]_D^{35}$ +30.3° (*c* 4.02, $CHCl_3$): IR (neat) 3300, 1500, 1362, 1240, 980 cm^{-1}; ^1H NMR (CCl_4) δ=1.10 (t, 3H, CH_3), 1.30—2.00 (m, 4H, $(CH_2)_2$), 3.50 (s, 6H, $N(CH_3)_2$), 3.61 (d, 2H, $C\underline{H}_2OH$), 4.10 (m, 1H, C<u>H</u>SCS). Found: C, 46.40; H, 8.15; N, 6.46%. Calcd for $C_8H_{17}ONS$: C, 46.34; H, 8.27; N, 6.76%.

MTPA Ester of 12. To a solution of **12** (0.248 g, 1.20 mmol), CCl_4 (5 ml), and pyridine (5 ml) was added 0.146 g (0.577 mmol) of (*S*)-(+)-α-methoxy-α-(trifluoromethyl)phenylacetyl chloride.[6] The mixture was stirred for 27 h at room temperature and then poured into water. The organic layer was extracted with ether and the combined extracts were washed with dilute HCl, saturated $NaHCO_3$, and water, and dried over $MgSO_4$. After removal of the solvent, the residue (0.34 g) was purified with preparative TLC (hexane/ethyl acetate, 2/1) to give 91 mg (39%) of MTPA ester of **12**: R_f 0.36—0.53; IR (neat) 1755, 1250, 1165, 1020, 980 cm^{-1}; ^1H NMR (CCl_4) δ=0.95 (t, *J*=6 Hz, 3H, CH_3), 1.1—1.9 (m, 4H, $(CH_2)_2$), 3.40 (s, 6H, $N(CH_3)_2$), 3.50 (s, 3H, OCH_3), 4.0—4.5 (m, 3H, OCH_2CHSCS), 7.3 (m, 5H); ^{13}C NMR ($CDCl_3$) δ=13.8 (q), 20.1 (t), 32.6 (t), 50.8 (d), 51.0 (d), 55.5 (q), 68.0 (t), 127.5 (d), 128.4 (d), 129.6 (d), 132.3 (s); 54.6% ee, determined by the peak ratio of δ 50.8 and 51.0 (<u>C</u>HSCS). Found: C, 51.18; H, 5.84; N, 3.28%. Calcd for $C_{18}H_{24}O_3NS_2F_3$: C, 51.04; H, 5.71; N, 3.31%.

***(R)*-(+)-2-(Dimethylthiocarbamoylthio)-3-methyl-1-butanol (14).** Compound **13** (4.09 g, 19.9 mmol) was treated with bakers' yeast as shown in the preparation of **12**. The crude product (3.76 g) was chromatographed on SiO_2 (hexane/ethyl acetate, 10/1—2/1) to give 1.58 g (39% yield, 69% yield based on the consumed **13**): TLC (hexane/ethyl acetate, 2/1), R_f 0.26; $[\alpha]_D^{26}$ +29.6° (*c* 1.34, $CHCl_3$); 32% ee, determined by ^1H NMR in the presence of Eu(hfc)$_3$; IR (neat) 3450, 1500, 1375, 1255, 980 cm^{-1}; ^1H NMR (CCl_4) δ=1.01 (d, *J*=6 Hz, 3H, CH_3), 1.05 (d, *J*=6 Hz, 3H, CH_3), 2.12 (s, 1H, OH), 2.30 (m, 1H, $C\underline{H}(CH_3)_2$), 3.44 (s, 6H, $N(CH_3)_2$), 3.69 (d, *J*=6 Hz, 2H, CH_2), 4.08 (m, 1H, CHSCS). Found: C, 46.41; H, 8.15; N, 7.02%. Calcd for $C_8H_{17}NOS_2$: C, 46.33; H, 8.27; N, 6.76%. The later fraction gave 1.80 g of **13**: TLC (hexane/ethyl acetate, 2/1), R_f 0.44.

***(R)*-(+)-2-(Dimethylthiocarbamoyl)-1-hexanol (16).** Aldehyde **15** (0.370 g, 1.69 mmol) was treated with bakers' yeast, as shown in the preparation of **12**. The crude product (2.9 g) was chromatographed on SiO_2 (hexane/ethyl acetate, 10/1) to give 0.29 g (78%) of **16**: $[\alpha]_D^{17}$ +39.6° (*c* 1.39, $CHCl_3$); IR (neat) 3400, 2940, 1500, 1250, 985 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.94 (t, *J*=6 Hz, 3H, CH_3), 1.14—2.00 (m, 6H), 2.41 (s, 1H), 3.50 (s, 6H), 3.66 (d, *J*=5.5 Hz, 2H), 4.00 (m, 1H); 46% ee, determined by ^{13}C NMR spectrum of the MTPA ester. Found: C, 48.79; H, 8.74; N, 6.44%. Calcd for $C_9H_{19}NOS_2$: C, 48.83; H, 8.65; N, 6.33%.

MTPA Ester of 16. To a mixture of **16** (0.1 g, 0.457 mmol), CCl_4 (5 ml), and pyridine (5 ml) was added 0.115 g (0.455 mmol) of (*S*)-(+)-α-methoxy-α-(trifluoromethyl)phenylacetyl chloride.[6] The mixture was stirred for 20 h at room temperature. After quenched with water, the organic layer was extracted with ether. The ethereal layer was washed with dil HCl, saturated $NaHCO_3$, and water, and then dried over $MgSO_4$. Concentration of the solvent gave the crude product, which was purified with preparative TLC (hexane/ethyl acetate, 2/1) to afford 68 mg (34%) of MTPA ester of **16**: R_f 0.45—0.55; IR (neat) 2950, 1750, 1500, 1250, 1165, 980 cm^{-1}; ^1H NMR (CCl_4) δ=0.89 (t, *J*=6 Hz, 3H), 1.1—2.0 (m, 6H), 3.40 (s, 6H), 3.51 (s, 3H), 3.9—4.6 (m, 3H), 7.32 (m, 5H); ^{13}C NMR ($CDCl_3$) δ=13.8 (q), 22.4 (t), 28.9 (t), 30.1 (t), 41.4 (q), 45.5 (q), 50.8 (d), 51.1 (d), 57.9 (t), 127.4 (d), 128.4 (d), 129.6 (d), 132.2 (s), 166.2 (s), 195.6 (s); 46% ee,

determined by the peak ratio of δ 50.8 and 51.1 (CHSCS). Found: C, 52.03; H, 6.12; N, 3.11%. Calcd for $C_{19}H_{26}F_3NO_3S_2$: C, 52.16; H, 5.99; N, 3.20%.

(*R*)-(+)-2-(Dimethylthiocarbamoylthio)-1-heptanol (18). Aldehyde **17** (2.23 g, 9.56 mmol) was treated with bakers' yeast for 9 days, as shown in the preparation of **12**. The crude product (2.2 g) was chromatographed on SiO_2 (hexane/ethyl acetate, 20/1) to give 1.69 g (75%) of **18**: $[\alpha]_D^{26}$ +39.6° (*c* 5.00, $CHCl_3$): IR (neat) 3425, 1500, 1375, 1255, 980 cm^{-1}; ^1H NMR (CCl_4) δ=0.95 (t, 3H), 1.13—1.90 (m, 8H), 2.82 (s, 1H), 3.50 (s, 6H), 3.70 (m, 2H), 4.00 (m, 1H). Found: C, 51.23; H, 8.89; N, 6.12%. Calcd for $C_{10}H_{21}NOS_2$: C, 51.02; H, 8.99; N, 5.95%.

MTPA ester of 18 was prepared by the reaction of **18** (116 mg, 0.498 mmol) with (*S*)-(+)-α-methoxy-α-(trifluoromethyl)phenylacetyl chloride[6] as described above. The crude product (0.25 g) was purified by preparative TLC (hexane/ethyl acetate, 2/1) to give 117 mg (52%) of MTPA ester of **18**: $[\alpha]_D^{26}$ +3.16° (*c* 3.16, $CHCl_3$); IR (neat) 2950, 1755, 1380, 1250, 1165 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.89 (t, *J*=5.5 Hz, 3H), 1.05—2.0 (m, 8H), 3.35 (s, 3H), 3.41 (s, 3H), 3.55 (s, 3H), 4.0—4.7 (m, 3H), 7.4 (broad S, 5H): ^{13}C NMR ($CDCl_3$) δ=13.9 (q), 22.3 (t), 26.4 (t), 30.4 (t), 31.5 (t), 41.4 (q), 45.3 (q), 50.9 (d), 51.1 (d), 55.5 (q), 68.0 (t), 127.5 (d), 128.3 (d), 129.5 (d), 132.2 (s), 166.2 (s), 195.5 (s); 63% ee, determined by the peak ratio of δ 50.9 and 51.1 (CHSCS). Found: C, 53.26; H, 6.17; N, 3.04%. Calcd for $C_{20}H_{28}F_3NO_3S_2$: C, 53.20; H, 6.25; N, 3.10%.

(*R*)-(+)-1,2-Epithiopentane (19). To a stirred mixture of NaH (0.661 g, 16.5 mmol) and THF (3 ml) was added a solution of 2.75 g (13.3 mmol) of **12** in 5 ml of THF at 0 °C during a period of 45 min. The mixture was stirred for 30 min at 0 °C and for 2 h at room temperature. After the mixture was poured into water, the organic layer was extracted with ether, washed with water, dried over $MgSO_4$, and concentrated. Short-pass distillation of the residue gave 0.523 g (40%) of **19**: $[\alpha]_D^{24}$ +8.0° (*c* 1.0, $CHCl_3$); IR (neat) 2890, 1460, 1261, 1040, 915 cm^{-1}; ^1H NMR (CCl_4) δ=0.98 (t, *J*=6 Hz, 3H, CH_3), 1.11 (m, 4H, CH_2CH_2), 2.04 (apparent d, *J*=5 Hz, 1H, CH_2S), 2.38 (apparent d, *J*=6 Hz, 1H, CH_2), 2.78 (m, 1H, CHS); ^{13}C NMR ($CDCl_3$) δ=13.7 (q), 22.5 (t), 25.8 (t), 35.7 (d), 38.6 (t); mass spectrum (70 eV) *m/z* 102 (M^+), 87, 74, 73, 70, 69, 64, 59. Found: C, 58.68; H, 9.57%. Calcd for $C_5H_{10}S$: C, 58.77; H, 9.86%.

(*R*)-(+)-3-Methyl-1,2-epithiobutane (20).[7] To a stirred mixture of 0.20 g (5.00 mmol) of NaH (60% in oil) and 1 ml of ether was added dropwise a solution of 1.03 g (4.98 mmol) of **14** in 3 ml of ether at 0 °C. The mixture was stirred for 2 days at 0 °C and then poured in ice water, and acidified with 10% HCl. The organic layer was extracted with ether, washed with water, dried over $MgSO_4$, and concentrated. Short-pass distillation of the residue afforded 18 mg (4%) of **20**: bp 70—90 °C (100 mm)(bath temperature); $[\alpha]_D^{26}$ +4.2° (*c* 3.52, $CDCl_3$); IR (neat) 2950, 1660, 1460, 1260, 1040 cm^{-1}: ^1H NMR ($CDCl_3$) δ=1.06 (d, *J*=6 Hz 6H, $2CH_3$), 1.22 (m, 1H, $CH(CH_3)_2$), 2.14 (apparent d, *J*=5 Hz, 1H, CH_2S), 2.42 (apparent d, *J*=5 Hz, 1H, CH_2S), 2.65 (m, 1H, CHS).

We thank Drs. Yoshitomo Yamamoto and Taizo Sako of Ouchi Shinko Chemical Industry Co., Ltd. for their generous gift of sodium dimethyldithiocarbamate.

Stereochemical Behavior of Intermediary Compounds in the Amine-Catalyzed Knoevenagel Reaction

Rikuhei TANIKAGA,* Naoto KONYA, Kazumasa HAMAMURA, and Aritsune KAJI
Department of Chemistry, Faculty of Science, Kyoto University,

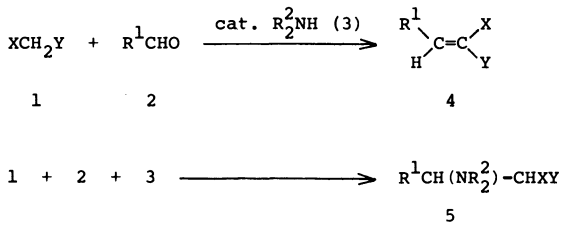
(Received March 1, 1988)

Treatment of the active methylene compounds and aldehydes with a catalytic amount of a secondary amine produces thermodynamically stable alkenes, and the intermediary amino compounds are isolated. The reaction involves many reversible steps, and the stereochemistry of products is determined in the elimination step from the intermediary compounds via stable planar carbanions, in which the small difference in the steric requirements of two electron-withdrawing groups is effective. Steric and electronic effects in the intermediates sometimes bring about the carbon–carbon bond fission with recovery of active methylene compounds, and these effects prevent the Knoevenagel reaction from occurring.

Among a number of synthetic methods for carbon–carbon bond formation the amine-catalyzed Knoevenagel reaction is frequently employed because of its high reactivity under mildly basic conditions.[1-5] The main preparative application of the reaction has been condensation of aldehydes and ketones with easily enolizable compounds usually containing two electron-withdrawing groups. The reaction, though easy to operate, seems to involve a complicated mechanism. Previously we observed that simple treatment of methyl arylsulfinylacetate **1a** (X=CO_2Me, Y=S(O)Ar) and aldehydes **2** with a catalytic amount of a secondary amine **3** produced thermodynamically stable (*E*)-alkenes (*E*)-**4**, and assumed that the stereochemistry of the reaction was determined in the elimination step from intermediary amino compounds **5** via planar carbanions **6**[5] stabilized by both a sulfur atom and a carbonyl group (Scheme 1).



Scheme 1.

However, it remains obscure whether the presence of a sulfur atom is essential for stabilization of **6**. Here we wish further to clarify what factors influence the behaviors of the intermediate **5** in the amine-catalyzed Knoevenagel reaction starting from the active methylene compound **1** containing two electron-withdrawing groups (X and Y) in general.

Results and Discussion

The following amine-catalyzed reactions were carried out with the intention of examining the stereochemistry of products. Simple treatment of **1** (10 mmol) and **2** (12 mmol) with piperidine (0.5 mmol) in acetonitrile (50 ml) produced alkenes **4** as shown in Table 1.

Thermodynamically stable **4** were always obtained regardless of the absence of a sulfinyl group, and their formation was much influenced by the small difference in the steric requirements of X and Y groups, especially near a reaction center. Although such a selectivity was not observed in the presence of small X and Y groups (e.g., X=CO_2Me, Y=COMe), the *E*:Z ratio was slightly improved by using, instead of piperidine, larger 2,6-dimethylpiperidine or dicyclohexylamine (34:66, 36:64, respectively).

These findings can be rationalized by the explanation that the steric effects of X and Y groups are more

Table 1. Preparation of Alkenes **4**

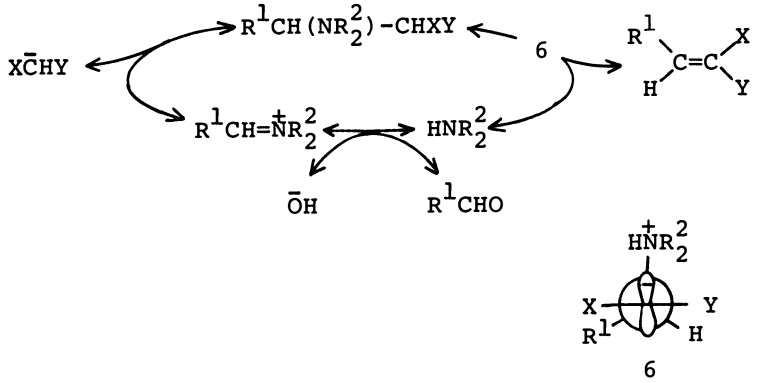
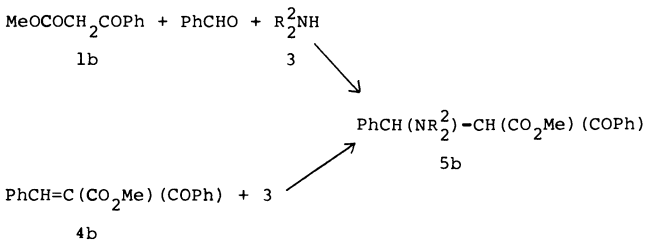


Scheme 2. Reaction mechanism (X<Y).

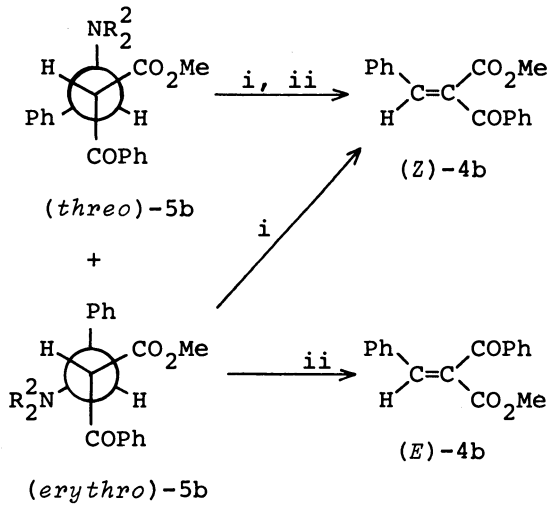


Scheme 3.

effective in planar carbanions **6**, in which two groups R^1 and X, or R^1 and Y are brought close together (Scheme 2).[5,6] Interestingly, the formation of **6** did not accompany loss of enantiomercal purity of a sulfinyl group (Y=(*R*)-S(O)C_6H_4Cl-*p*).

When a solution of methyl benzoylacetate (**1b**)(10 mmol), benzaldehyde (12 mmol), and secondary amine **3** (12 mmol) in a small quantity of acetonitrile was allowed to stand at 0 °C, the diastereoisomeric amino compounds *threo*- and *erythro*-**5b** crystallized directly with time in 70—92% yields. The amino compounds **5b** were also obtained with the same threo:erythro ratio from alkenes **4b** (10 mmol) and **3** (12 mmol) (Scheme 3).

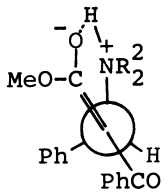
Previously we reported that thermodynamically stable (*E*)-alkenes (*E*)-**4**, that is, the Knoevenagel reaction products were obtained simply by dissolving **5a** derived from **1a** in acetonitrile at 20—60 °C, whereas on treatment with acetic acid anti-elimination occurred to afford mixtures of (*E*)- and (*Z*)-**4a**.[5] Similar treatment of mixtures of *threo*- and *erythro*-**5b** lead to the results as listed in Table 2.



Scheme 4. Reaction conditions: i, MeCN; ii, AcOH

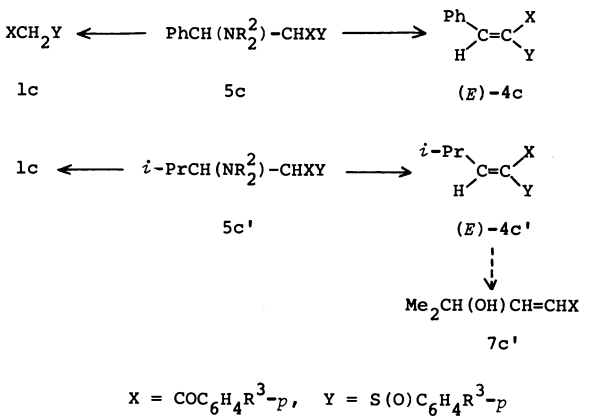
High selectivity in the Knoevenagel reaction was realized in an elimination step from **5b** rather than in its formation probably because steric repulsion between COPh and Ph groups is considerable in a planar carbanion **6** if R^1=Ph and Y=COPh in Scheme 2. Since the carbanion **6** is enolizable, the elimination may occur via an intermediate such as **6b′**. The stereochemistry in the elimination step can be interpreted essentially in the same way.

Similar treatment of 1-aryl-2-(arylsulfinyl)ethanone (**1c**) and an aldehyde (R^1=Ph or *i*-Pr) with a secondary amine **3** gave the amino compounds **5c**, **5c′** as crystalline solids, and interestingly **5c** or **5c′** appeared



6b′

to be well suited for studies of the intermediate in the amine-catalyzed Knoevenagel reaction because both **1c** and (*E*)-alkenes (*E*)-**4c**, (*E*)-**4c′** were obtained by dissolving **5c** or **5c′** in a suitable solvent. Since a secondary amine is known to cause (*E*)-**4c′** to undergo further reactions yielding an allylic alcohol **7c′**,[7] it is important to neutralize the amine **3** formed as a by-product. Therefore, **5c′** was dissolved in dichloromethane containing aqueous ammonium chloride in which the Knoevenagel reaction proceeded as usual. These results are given in Table 3 (Scheme 5).



Scheme 5.

Table 3. Formation of **1c** and (*E*)-**4c**, **4c′** from **5c**, **5c′**[a,b]

R^1	R^2_2	R^3	Yield/%[c]

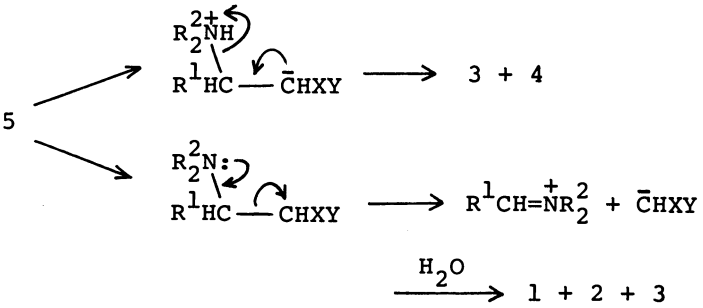
i-Pr	Me, Me	Me	92	1
i-Pr	$-(CH_2)_4-$	Me	84	0
i-Pr	$-(CH_2)_5-$	Me	100	0
i-Pr	$-(CH_2)_2CHMe(CH_2)_2-$	Me	100	0

a) A mixture of threo- and erythro-isomers was used. b) Reaction conditions: **5c**; MeCN, 60 °C, 6 h; **5c′**; CH_2Cl_2, 20 °C, 12 h. c) Isolated yield. d) No (*Z*)-isomer was obtained.

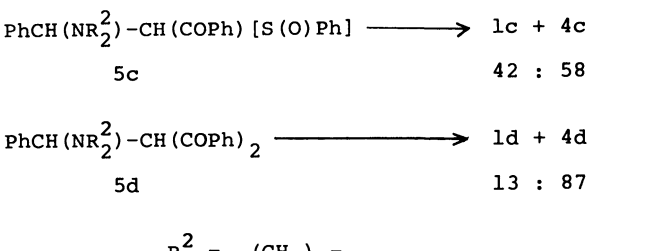
The absence of (*Z*)-**4c**, (*Z*)-**4c′** means that the elimination is affected by the difference in the steric requirements of C=O and S→O groups [bond distance, 1.23 (C=O) and 1.44 Å (S→O);[8] van der Waals radius, 1.55 (C atom) and 1.85 Å (S atom)[9]]. Construction of a molecular model suggests considerable steric restraints for the formation of **5**, and actually preparation of **5** with bulky R^1 and R^2 [e.g., R^1=*i*-Pr, and R^2=$-CHMe(CH_2)_4-$] was impossible. This steric hindrance may also have contributed to weakening the linkage of both C–N and C–C bonds though the C–C bond fission mechanism has not yet been clarified (Scheme 7).

The **1c**/(*E*)-**4c** or **1c**/(*E*)-**4c′** ratio increased with the relative bulkiness of R^2_2 in the order; $-(CH_2)_4-$ < Me_2 ≈ $-(CH_2)_5-$ < $-(CH_2)_2CHMe(CH_2)_2-$, that is, a bulky R^2_2N group favored the C–C bond fission. Since the elimination reaction from **5** might be initiated by removal of the proton at the α-position of X and Y groups, the formation of the alkene **4** was depressed by the presence of an electron-donating group, e.g., R^1=*i*-Pr or R^3=Me, and accelarated by replacement of a sulfinyl group by a carbonyl group (Scheme 7).

The reversibility of the amine-catalyzed Knoevenagel reaction is supported by the findings that the intermediate **5** was obtained from both the starting compound **1** and the product **4** (Scheme 3), and at the same time, **5** produced **1** and **4** (Scheme 5). Solidification of **5** might make it possible to shift the equilibrium yielding **5**. In a solution, however, the equilibrium between **1c** and **5c** (or **5c′**) was sometimes found to be more in favor to **1c** (e.g., R^1=*i*-Pr in Table 3), and in fact the Knoevenagel reaction never occurred from **1c** and *i*-PrCHO. Neither usage of an equimolar



Scheme 6.



Scheme 7.

amount of an amine nor removal of water from the reaction mixture improved the yield of **4**.

In conclusion, the amine-catalyzed Knoevenagel reaction involves many reversible steps as shown in Scheme 2, the stereochemical behavior of an intermediary amino compound plays an important role, and the usage of a catalytic amount of a secondary amine forces this thermodynamically-controlled reaction to completion giving the most stable product.

Rappoport has studied the stereochemical behavior in vinylic substitution (via addition-elimination) of halosubstituted electrophilic olefins containing two electron-withdrawing groups by a nucleophile such as ArS^- and ArO^-, and interestingly proposed the planar carbanion similar to **6** in the elimination step.[10,11] Our present results may provide significant information concerning an addition-elimination reaction.

Experimental

^1H NMR spectra were determined at 100 MHz with a JEOL JNM-PS-100 or at 400 MHz with a JEOL JNM-GX-400 spectrometer, and refer to deuteriochloroform solution with tetramethylsilane as internal standard. IR spectra were recorded with a Hitachi 215 spectrometer, and MS with a JEOL JMX-DX-300 instrument. GLPC analysis was carried out with a Varian 920 instrument using a column packed with 20% silicone DS-550. Column chromatography and TLC were performed, using Wakogel 200 silica gel and Merck plastic sheets silica gel 60 F_{254} respectively. HPLC analysis was carried out with a Shimadzu LC-6A system containing a column packed with a commercially-available chiral cellulose derivative (Daicel Chemical Industry's CHIRALCEL-OC) or a ODS column.

Commercial 1-phenyl-1,3-butanedione, methyl benzoylacetate (**1b**), methyl acetoacetate, 1,3-diphenyl-1,3-propanedione (**1d**), aldehydes **2**, and amines **3** were purified before use. 4-Methyl-1-phenyl-1,3-pentanedione, 1-phenyl-2-(phenylsulfinyl)ethanone, and 1-(*p*-tolyl)-2-(*p*-tolylsulfinyl)ethanone were prepared by the reported methods.[12,13]

***t*-Butyl (*R*S)-*p*-Chlorophenylsulfinylacetate.** To a stirred solution of ethylmagnesium bromide [prepared from Mg (2.43 g, 0.1 mol) and bromoethane (10.9 g, 0.1 mol) in diethyl ether (50 ml)] under argon atmosphere was added diisopropylamine (14 ml, 0.1 mol). The resulting solution was refluxed for 30 min and cooled to −40 °C. To the solution was added successively a solution of *t*-butyl acetate (8.13 g, 0.07 mol) in tetrahydrofuran (THF) (5 ml) and a solution of menthyl (*S*S,*S*C)-*p*-chlorobenzenesulfinate[14] (9.45 g, 0.03 mol) in diethyl ether (80 ml)–THF (8 ml). The solution was stirred for further 10 h at −40 °C, and quenched with saturated aqueous ammonium chloride (50 ml). The aqueous layer was extracted with chloroform, and the combined organic phases were washed with water, and dried (anhydrous magnesium sulfate). After having removed the solvent column chromatography on silica gel eluting with hexane–ethyl acetate (3:1) and recrystallized from hexane–ethyl acetate (5:1) gave *t*-butyl (*R*S)-*p*-chlorophenylsulfinylacetate (6.26 g, 76%): mp 123.5 °C; $[\alpha]_D^{23.5}$ +169.7° (*c* 1.09, MeOH)(100% e.e. by HPLC); IR (KBr) 1720 (C=O) and 1040 cm^{-1} (S→O); ^1H NMR ($CDCl_3$) δ=1.40 (9H, s, Me), 3.57 (1H, d, *J*=13 Hz, CH_2), 3.81 (1H, d, *J*=13 Hz, CH_2), 7.51 (2H, d, *J*=7 Hz, Ar), and 7.67 (2H, d, *J*=7 Hz, Ar); Found: C, 52.25; H, 5.32%. Calcd for $C_{12}H_{15}ClO_3S$: C, 52.44; H, 5.50%.

Knoevenagel Reaction of Compounds 1 and Aldehydes 2. A solution of **1** (10 mmol), **2** (10 mmol), and an amine **3** (0.5 mmol) in acetonitrile (50 ml) was kept under the conditions given in Table 1. After having removed the solvent under the reduced pressure the residue was chromatographed on silica gel using hexane–ethyl acetate (4:1) to give the alkene **4** in the yield as shown in Table 1. A minimum quantity of the reaction mixture was withdrawn prior to isolation to determine the *E*:*Z* ratio of **4** by GLPC, HPLC, or ^1H NMR. The enantiomeric excess was determined by HPLC using a chiral derivative. By this route the following compounds were obtained.

(2*E*)-1,3-Diphenyl-2-phenylsulfinyl-2-propen-1-one [(*E*)-4c]: Mp 90 °C; IR (Nujol) 1640 (C=O) and 1060 cm^{-1} (S→O); ^1H NMR ($CDCl_3$) δ=6.9—7.8 (11H, m, Ph, CH=C); MS *m*/*z* 332 (M^+, 8%); Anal. ($C_{21}H_{16}O_2S$) C, H.

***t*-Butyl (*R*S, 2*E*)-2-(*p*-Chlorophenylsulfinyl)-2-hexenoate:** Liquid; $[\alpha]_D^{22}$=166.9° (*c* 1.10, MeOH)(100% e.e.); IR (neat) 1720 (C=O) and 1050 cm^{-1} (S→O); ^1H NMR ($CDCl_3$) δ=0.98 (3H, t, *J*=7 Hz, Me), 1.35 (9H, s, Me_3C), 1.6—2.7 (4H, m, CH_2), 7.11 (1H, t, *J*=8 Hz, CH=C), 7.48 (2H, d, *J*=8 Hz, Ar) and 7.69 (2H, d, *J*=8 Hz, Ar); MS *m*/*z* 328 (M^+, 10%); Anal. ($C_{16}H_{21}ClO_3S$) C, H.

(4*E*)-4-Benzoyl-2-methyl-5-phenyl-4-penten-3-one: Liquid; IR (neat) 1675 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ=1.13 (6H, d, *J*=6 Hz, Me), 3.13 (1H, hept, CH), 7.76 (1H, s, CH=C), and 7.1—8.1 (10H, m, Ph); MS *m*/*z* 278 (M^+, 6%); Anal. ($C_{19}H_{18}O_2$) C,H.

4-Benzoyl-2-methyl-4-octen-3-one: Liquid; IR (neat) 1715 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ=0.5—2.7 (7H, m, Me, CH_2), 1.08 (6H, d, *J*=7 Hz, Me_2C), 3.11 (1H, m, CH), 6.46 (1H, t, *J*=7 Hz, *Z* CH=C), 6.96 (1H, t, *J*=7 Hz, *E* CH=C), and 7.2—8.1 (5H, m, Ph); MS *m*/*z* 244 (M^+, 1%); Anal. ($C_{12}H_{20}O_2$) C, H.

(3*E*)-3-Benzoyl-4-phenyl-3-buten-2-one: Mp 98 °C (lit,[15] mp 98—99 °C).

(3*E*)-3-Benzoyl-5-methyl-3-hexen-2-one: Liquid; IR (neat) 1700 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ=1.00 (6H, d, *J*=6 Hz, Me_2C), 2.32 (3H, s, MeCO), 3.10 (1H, hept, *J*=6 Hz, CH), 6.71 (1H, d, *J*=10 Hz, CH=C), and 7.2—8.1 (5H, m, Ph); MS *m*/*z* 216 (M^+, 12%); Anal. ($C_{14}H_{16}O_2$) C, H.

(3*E*)-3-Benzoyl-3-hepten-2-one: Liquid; IR (neat) 1720 cm^{-1}; (C=O); ^1H NMR ($CDCl_3$) δ=0.6—2.2 (7H, m, Me, CH_2), 2.31 (3H, s, MeCO), 6.96 (1H, t, *J*=7 Hz, CH=C), and 7.2—8.1 (5H, m, Ph); MS *m*/*z* 216 (M^+, 18%); Anal. ($C_{14}H_{16}O_2$) C, H.

Methyl (2*Z*)-2-Benzoyl-3-phenyl-2-propenoate [(*Z*)-4b]: Liquid; IR (neat) 1740(O-C=O) and 1680 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ=3.68 (3H, s, MeO), 7.92 (1H, s, CH=C), and 6.9—8.1 (10H, m, Ph); MS *m*/*z* 266 (M^+, 7%); Anal. ($C_{17}H_{14}O_3$) C, H.

Methyl 2-Acetyl-3-phenyl-2-propenoate: Liquid; IR (neat) 1730 (O-C-O) and 1660 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) (*E*)-isomer δ=2.30 (3H, s, MeCO), 3.81 (3H, s, MeO), 7.0—7.5 (5H, m, Ph), and 7.66 (1H, s, CH=C), (*Z*)-isomer δ=2.40 (3H, s, MeCO), 3.87 (3H, s, MeO), 7.2—7.6 (5H, m, Ph), and 7.57 (1H, s, CH=C).

Methyl 2-Acetyl-2-hexenoate: Liquid; IR (neat) 1730 (O-C=O) and 1690 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) (*E*)-isomer δ=0.9—2.8 (7H, m, Me, CH_2), 1.16 (3H, s, MeCO), 3.80 (3H, s, MeO), and 6.68 (1H, d, J=11 Hz, CH=C), (*Z*)-isomer δ=0.9—2.8 (7H, m, Me, CH_2), 1.30 (3H, s, MeCO), 3.85 (3H, s, MeO), and 6.60 (1H, d, J=11 Hz, CH=C).

The elemental analyses found were in good agreement with the calculated values throughout.

Formation of the Amino Compounds 5. A solution of **1** (10 mmol), **2** (15 mmol), and **3** (15 mmol) in acetonitrile (20 ml) was kept at 0 °C for 24 h. The product precipitated was filtered off, washed several times with cold acetonitrile, and dried in vacuo. Almost pure diastereoisomeric **5** was obtained as a colorless solid. Further purification by recrystallization or column chromatography proved to be impossible owing to ready elimination reactions. The configuration of *threo*- and *erythro*-**5** were assigned on the basis of the results obtained by anti-elimination using acetic acid,[5] and their ratio was determined by ^1H NMR. Mass spectra of **5** indicated the absence of M^+ peaks.

By this route the following compounds were obtained.

Methyl 2-Benzoyl-3-pyrrolidino-3-phenylpropionate: Yield 70%; mp 128 °C; IR (Nujol) 1730 (O-C=O) and 1685 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ=1.3—1.9 (4H, m, CH_2), 2.1—3.0 (4H, m, CH_2-N), 3.30/3.76 (3H, s, threo/erythro MeO), 4.71—4.81 (1H, d, J=12 Hz, CH-N), 5.15/5.27 (1H, d, J=12 Hz, threo/erythro CH-CO), and 7.0—8.2 (10H, m, Ph); Anal. ($C_{21}H_{23}O_3N$) C, H, N.

Methyl 2-Benzoyl-3-phenyl-3-piperidinopropionate: Yield 92%; mp 145—146 °C; IR (Nujol) 1730 (O-C=O) and 1685 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ=0.9—1.8 (6H, m, CH_2), 1.8—2.9 (4H, m, CH_2-N), 3.51/3.79 (3H, s, threo/erythro MeO), 4.66/4.71 (1H, d, J=11 Hz, threo/erythro CH-N), 5.28/5.25 (1H, d, J=11 Hz, threo/erythro CH-CO), and 7.0—8.2 (10H, m, Ph); Anal. ($C_{22}H_{25}O_3N$) C, H, N.

Methyl 2-Benzoyl-3-(4-methylpiperidino)-3-phenylpropionate: Yield 78%; mp 130—132 °C; IR (Nujol) 1725 (O-C-O) and 1690 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ=0.6—1.9 (8H, m, Me, CH, CH_2), 2.0—3.1 (4H, m, CH_2-N), 3.46/3.76 (3H, s, threo/erythro MeO), 4.47/4.73 (1H, d, J=11 Hz threo/erythro CH-N), 5.24/5.33 (1H, d, J=11 Hz, threo/erythro CH-CO), and 7.0—8.1 (10H, m, Ph); Anal. ($C_{23}H_{27}O_3N$) C, H, N.

Methyl 2-Benzoyl-3-(perhydro-1-azepinyl)-3-phenylpropionate: Yield 82%; mp 128—129 °C; IR (Nujol) 1730 (O-C-O) and 1685 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ=0.9—1.8 (8H, m, CH_2), 2.1—3.1 (4H, m, CH_2-N), 3.46/3.77 (3H, s, threo/erythro MeO), 4.74/4.83 (1H, d, J=11 Hz, threo/erythro CH-N), 5.22/5.28 (1H, d, J=11 Hz, threo/erythro CH-CO), and 7.1—8.2 (10H, m, Ph); Anal. ($C_{23}H_{27}O_3N$) C, H, N.

3-Dimethylamino-1,3-diphenyl-2-phenylsulfinyl-1-propanone: Yield 84%; mp 139 °C; IR (Nujol) 1650 (C=O) and 1060 cm^{-1} (S→O); ^1H NMR ($CDCl_3$) δ=2.04 (3H, s, Me), 2.52 (3H, s, Me), 4.6—5.2 (2H, br, CH), and 6.8—7.7 (15H, m, Ph); very slightly soluble in $CDCl_3$; Anal. ($C_{23}H_{23}O_2NS$) C, H, N.

1,3-Diphenyl-2-phenylsulfinyl-3-(1-pyrrolidinyl)-1-propanone: Yield 94%; mp 139—140 °C; IR (Nujol) 1660 (C=O) and 1060 cm^{-1} (S→O); ^1H NMR ($CDCl_3$) δ=1.6—1.9 (4H, m, CH_2), 2.5—2.9 (4H, m, CH-N), 5.0—6.3 (2H, br, CH), and 6.9—7.8 (15H, m, Ph); very slightly soluble in $CDCl_3$; Anal. ($C_{25}H_{25}O_2NS$) C, H, N.

1,3-Diphenyl-2-phenylsulfinyl-3-piperidino-1-propanone: Yield 70%; mp 154—155 °C; IR (Nujol) 1660 (C=O) and 1055 cm^{-1} (S→O); ^1H NMR ($CDCl_3$) δ=1.0—2.0 (6H, m, CH_2), 2.0—3.0 (4H, m, CH_2-N), 4.21 (1H, d, J=11 Hz, CH-N), 5.90 (1H, d, J=11 Hz CH-SO), and 6.9—7.9 (15H, m, Ph); slightly soluble in $CDCl_3$; Anal. ($C_{26}H_{27}O_2NS$) C, H, N.

1,3-Diphenyl-3-(4-methylpiperidino)-2-phenylsulfinyl-1-propanone: Yield 91%; mp 147—149 °C; IR (Nujol) 1660 (C=O) and 1055 cm^{-1} (S→O); ^1H NMR ($CDCl_3$) δ=0.6—3.2 (12H, m, Me, CH, CH_2), 4.6—5.5 (2H, br, CH), and 6.8—7.9 (15H, m, Ph); very slightly soluble in $CDCl_3$; Anal. ($C_{27}H_{29}O_2NS$) C, H, N.

3-Dimethylamino-4-methyl-1-phenyl-2-phenylsulfinyl-1-pentanone: Yield 80%; mp 87—79 ° C; IR (Nujol) 1660 (C=O) and 1055 cm^{-1} (S→O); ^1H NMR ($CDCl_3$) δ=0.72—1.28 (6H, m, Me), 2.0 (1H, m, CH), 2.50/2.59 (6H, s, threo/erythro Me_2N), 3.22/3.61 (1H, d, J=11 Hz, threo/erythro CH-N), 4.82/5.26 (1H, d, J=11 Hz, threo/erythro CH-SO), and 6.8—7.9 (10H, m, Ph); Anal. ($C_{20}H_{25}O_2NS$) C, H, N.

4-Methyl-1-phenyl-2-phenylsulfinyl-3-piperidino-1-pentanone: Yield 94%; mp 99—101 °C; IR (Nujol) 1660 (C=O) and 1050 cm^{-1} (S→O); ^1H NMR ($CDCl_3$) δ=0.6—1.9 (6H m, CH_2), 2.1 (1H, m, CH), 2.4—3.1 (4H, m, CH_2-N), 3.23/3.57 (1H, dd, J=11, 6 Hz, threo/erythro CH-N), 4.71/5.21 (1H, d, J=11 Hz, threo/erythro CH-SO), and 6.9—7.9 (10H, m, Ph); Anal. ($C_{23}H_{29}O_2NS$) C, H, N.

4-Methyl-3-(4-methylpiperidino)-1-phenyl-2-phenylsulfinyl-1-pentanone: Yield 93%; mp 96—98 °C; IR (Nujol) 1660 (C=O) and 1055 cm^{-1} (S→O); ^1H NMR ($CDCl_3$) δ=0.5—1.8 (14H, m, Me, CH, CH_2), 2.0 (1H, m, CH), 2.2—3.3 (4H, m, CH_2-N), 3.30/3.62 (1H, dd, J=12, 7 Hz, threo/erythro CH-N), 4.72/5.21 (1H, d, J=12 Hz, threo/erythro CH-SO), and 6.9—7.9 (10H, m, Ph); Anal. ($C_{24}H_{31}O_2NS$) C, H, N.

3-Dimethylamino-3-phenyl-1-(*p*-tolyl)-2-(*p*-tolylsulfinyl)-1-propanone: Yield 77%; mp 148—149 °C; IR (Nujol) 1660 (C=O) and 1055 cm^{-1} (S→O); ^1H NMR ($CDCl_3$) δ=2.06/2.17 (3H, s, Me), 2.31 (1H, s, Me), 2.2—2.5 (6H, Me_2N), 4.1—5.1 (2H, CH), and 6.8—8.0 (13H, m, Ph, Ar); slightly soluble in $CDCl_3$; Anal. ($C_{25}H_{27}O_2NS$) C, H, N.

3-Phenyl-3-pyrrolidino-1-(*p*-tolyl)-2-(*p*-tolylsulfinyl)-1-propanone: Yield 99%; mp 145—147 °C; IR (Nujol) 1665 (C=O) and 1055 cm^{-1} (S→O); ^1H NMR ($CDCl_3$) δ=1.5—1.8 (4H, m, CH_2), 2.16/2.22 (3H, s, Me), 2.36 (3H, s, Me), 2.5—3.0 (4H, m, CH_2-N), 4.1—5.1 (2H, CH), and 6.8—7.9 (13H, m, Ph, Ar); slightly soluble in $CDCl_3$; Anal. ($C_{27}H_{29}O_2NS$) C, H, N.

3-Phenyl-3-piperidino-1-(*p*-tolyl)-2-(*p*-tolylsulfinyl)-1-propanone: Yield 66%; mp 165—166 °C; IR (Nujol) 1660 (C=O) and 1060 cm^{-1} (S→O); ^1H NMR ($CDCl_3$) δ=1.0—1.9 (6H, m, CH_2), 2.16/2.21 (3H, s, Me), 2.36 (3H, s, Me), 2.0—2.2 (4H, m, CH_2-N), 4.2—5.9 (2H, br, CH), and 6.7—8.0 (13H, m, Ph, Ar); very slightly soluble in $CDCl_3$; Anal. ($C_{28}H_{31}O_2NS$) C, H, N.

3-(4-Methylpiperidino)-3-phenyl-1-(*p*-tolyl)-2-(*p*-tolylsulfinyl)-1-propanone: Yield 68%; mp 167—168 °C; IR (Nujol) 1660 (C=O) and 1060 cm^{-1} (S→O); ^1H NMR ($CDCl_3$) δ=0.5—3.2 (18H, m, Me, CH, CH_2), 4.6—5.4 (2H, m, CH), and 6.7—8.0 (13H, m, Ph, Ar); very slightly soluble in $CDCl_3$; Anal. ($C_{29}H_{33}O_2NS$) C, H, N.

4-Methyl-3-dimethylamino-1-(*p*-tolyl)-2-(*p*-tolylsulfinyl)-

1-pentanone: Yield 68%; mp 104—105 °C; IR (Nujol) 1660 (C=O) and 1060 cm^{-1} (S→O); ^1H NMR ($CDCl_3$) δ=0.6—1.3 (6H, m, Me), 1.8—2.8 (13H, m, Me, CH), 3.17/3.61 (1H, dd, J=10, 5 Hz, CH-N), 4.69/5.22 (1H, d, J=10 Hz, CH-SO), and 6.8—7.9 (8H, m, Ar); slightly soluble in $CDCl_3$; Anal. ($C_{22}H_{29}O_2NS$) C, H, N.

4-Methyl-3-(1-pyrrolidinyl)-1-(*p*-tolyl)-2-(*p*-tolylsulfinyl)-1-pentanone: Yield 74%; mp 89—90 °C; IR (Nujol) 1660 (C=O) and 1060 cm^{-1} (S→O); ^1H NMR ($CDCl_3$) δ=0.7—3.2 (21H, m, Me, CH, CH_2), 4.0—4.8 (2H, m, CH), and 6.8—7.9 (8H, m, Ar); slightly soluble in $CDCl_3$; Anal. ($C_{24}H_{31}O_2NS$) C, H, N.

4-Methyl-3-piperidino-1-(*p*-tolyl)-2-(*p*-tolylsulfinyl)-1-pentanone: Yield 85%; mp 108—109 °C; IR (Nujol) 1660 (C=O) and 1060 cm^{-1} (S→O); ^1H NMR ($CDCl_3$) δ=0.7—3.1 (23H, m, Me, CH, CH_2), 3.20/3.58 (1H, dd, J=10, 4 Hz, CH-N), 4.65/5.26 (1H, d, J=10 Hz, CH-SO), and 6.8—7.4 (8H, m, Ar); slightly soluble in $CDCl_3$; Anal. ($C_{25}H_{33}O_2NS$) C, H, N.

4-Methyl-3-(4-methylpiperidino)-1-(*p*-tolyl)-2-(*p*-tolylsulfinyl)-1-pentanone: Yield 88%; mp 109—110 °C; IR (Nujol) 1655 (C=O) and 1060 cm^{-1} (S→O); ^1H NMR δ ($CDCl_3$) δ= 0.6—3.3 (25H, m, Me, CH, CH_2), 4.0—4.8 (2H, CH), and 6.8—7.9 (4H, m, Ar); slightly soluble in $CDCl_3$; Anal. ($C_{26}H_{35}O_2NS$) C, H, N.

2-Benzoyl-1,3-diphenyl-3-piperidino-1-propanone: Yield 90%; mp 150 °C; IR (Nujol) 1680 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ=1.0—1.7 (6H, m, CH_2), 2.0—2.6 (4H, m, CH-N), 4.70 (1H, d, J=13 Hz, CH-N), 5.38 (1H, d, J=13 Hz, CH-CO), and 7.0—8.1 (15H, m, Ph); Anal. ($C_{27}H_{27}O_2N$) C, H, N.

The elemental analyses found were in good agreement with the calculated values throughout. Assignment between threo and erythro isomers sometimes was difficult because the compound **5** was slightly soluble in $CDCl_3$.

Reaction of Compounds 5b in Acetic Acid. A solution of **5b** (5 mmol) in acetic acid (10 ml) was stirred at 20 ° C for 10 min. Water (50 ml) was added and the mixture was extracted twice with diethyl ether (50 ml). The organic phase was washed with three portions of saturated aqueous $NaHCO_3$ and NaCl, and dried (anhydrous $MgSO_4$). After the solvent had been removed, the residue obtained was purified by column chromatography on silica gel eluting with hexane-ethyl acetate (4:1). The *E*:*Z* ratio was determined by GLPC using a diastereoisomeric mixture of **4b**.

Methyl (2*E*)-2-Benzoyl-3-phenyl-2-propenoate [(*E*)-4b]: Liquid; IR (neat) 1740 (O-C=O) and 1680 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ=3.68 (3H, s, MeO), and 6.9—8.1 (11H, m, Ph, CH); MS *m/z* 266 (M^+, 5%); Anal. ($C_{17}H_{14}O_2$) C, H.

Reaction of Compounds 5b, 5c, 5c′ in Acetonitrile. A solution of **5b** or **5c** (5 mmol) in acetonitrile (100 ml) or **5c′** (5 mmol) in dichloromethane-saturated aqueous NH_4Cl (4:1, 50 ml) was kept under the reaction conditions given in Tables 2 and 3. Dichloromethane (100 ml) was added and the organic phase was washed with 10% hydrochloric acid (50 ml) and aqueous NaCl (50 ml). The aqueous layer was extracted with two portions of dichloromethane (50 ml), and the combined organic phases were again washed with aqueous NaCl before being dried (anhydrous $MgSO_4$). Removal of the solvent gave the residue which was chromatographed on a silica-gel column eluting hexane-ethyl acetate (4:1) to afford **1** and (*Z*)-**5b**, (*E*)-**5c**, or (*E*)-**5c′**. These results are given in Tables 2 and 3.

(2*E*)-3-Phenyl-2-(*p*-toluenesulfinyl)-1-(*p*-tolyl)-2-propen-1-one: Mp 83 °C; IR (Nujol) 1670 (C=O) and 1050 cm^{-1} (S→O); ^1H NMR ($CDCl_3$) δ=2.25 (6H, s, MeO) and 6.8—7.8 (14H, m, Ph, Ar, CH); MS *m/z* 360 (M^+, 2%); Anal. ($C_{23}H_{20}O_2S$) C, H.

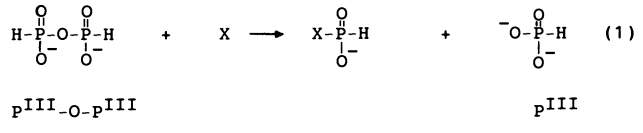
(Received March 4, 1988)

Inorganic diphosphonate phosphonylated predominantly phosphate groups on nucleoside 5′-monophosphates (=NMP's: AMP, GMP, IMP, CMP, and UMP), deoxynucleoside 5′-monophosphates (=dNMP's: dAMP and dTMP), and sugar phosphates (=SP's: Glc1P, Glc6P, and Rib5P) in aqueous solutions under mild conditions (50—70 °C, pH 6). The chemical structures of phosphonylated products were discussed on their ^{31}P NMR spectra and high-performance liquid chromatograms. The main phosphonylated products from NMP's and dNMP's were analogous in structure to nucleoside 5′-diphosphates. The rate of phosphonylation of phosphate groups on NMP's, dNMP's, and SP's varied strongly depending on reaction conditions: pH, reaction temperature, and initial concentration of inorganic diphosphonate. The maximum yields of phosphonylated products were ca. 70% for all NMP's, dNMP's, and SP's under the following conditions: initial concentration of inorganic diphosphonate is 1.5 mol dm^{-3}; each initial concentration of NMP's, dNMP's, or SP's is 0.1 mol dm^{-3}; 70 °C; pH 6.

Blaser and Worms reported[2,3] that disodium inorganic diphosphonate (P^{III}–O–P^{III}), $Na_2P_2H_2O_5$, reacted with several nucleophiles (X) such as orthophosphate and fluoride to form new compounds (X–$\overset{\overset{O}{\|}}{\underset{\underset{O^-}{|}}{P}}$–H) and inorganic phosphonate (P^{III}) according to Eq. 1. Hypophosphate,[2,4] diphosphate,[3,5] triphosphate,[5,6] and ammonia[7] were also found to react



with inorganic diphosphonate to form new compounds. In such reactions a "phosphonyl" group ($\overset{\overset{O}{\|}}{\underset{\underset{O^-}{|}}{H\text{–}P}}$–) on P^{III}–O–P^{III} is transferred to a nucleophile to form a "phosphonylated" product. We called this type of reaction "phosphonyl transfer reaction" or "phosphonylation" rather than "transanhydrization" proposed by Blaser and Worms,[2,3] because of its similarity to phosphoryl transfer reaction or phosphorylation of biological importance.[8]

Much attention has recently been focused on phosphonylation of biomolecules in the field of nucleic acid syntheses and kinetic research of enzymatic reactions. Successful examples are the application of nucleoside H-phosphonate to automatic syntheses of DNA and RNA,[9,10] and the wide use of phosphonate analogues of biomolecules as a metabolic regulator.[11] On the other hand, no successful attempts with inorganic diphosphonate as a phosphonylating agent have been reported for the synthesis of phosphonylated analogues of "biophosphates" such as nucleotides and sugar phosphates. The main reason is the lack of analytical techniques for simultaneous determination of biophosphates and inorganic phosphonates. We have developed the HPLC system coupled with flow injection analysis for simultaneous determination of biophosphates and inorganic phosphonates.[12–16]

The purpose of our project in this series was to characterize the formation of phosphonylated analogues of biophosphates by means of the HPLC technique[12–16] and ^{31}P NMR spectroscopy. We have already reported[17] that adenosine 5′-monophosphate was phosphonylated by P^{III}–O–P^{III} to give an analogue of adenosine 5′-diphosphate as a main product, with some by-products phosphonylated at the 2′- or 3′-position of the ribose. We also reported in a preliminary paper that a phosphate group on glucose 1-monophosphate was phosphonylated selectively by P^{III}–O–P^{III}.[1] This paper deals mainly with phosphonylation of phosphate groups on nucleoside 5′-monophosphates (=NMP's: AMP, GMP, IMP, CMP, and UMP),[18] deoxynucleoside 5′-monophosphates (=dNMP's: dAMP and dTMP),[18] and sugar phosphates (=SP's: Glc1P, Glc6P, and Rib5P)[18] under various conditions.

Experimental

Chemicals. Disodium salt of AMP from Boehringer-Mannheim, disodium salts of GMP, IMP, CMP, UMP, dAMP, and dTMP from Yamasa Shoyu, and disodium salts

of Glc1P, Glc6P, and Rib5P from Sigma were commercially available.

Disodium inorganic diphosphonate, $Na_2P_2H_2O_5$, was prepared according to the literature[6] with a slight modification. In an Erlenmeyer flask with a glass stopper, 300 ml acetic anhydride, $(CH_3CO)_2O$, was added to a mixture of 18.5 g of phosphonic acid, H_2PHO_3, and 48.6 g of disodium phosphonate pentahydrate, $Na_2PHO_3 \cdot 5H_2O$. The resulting mixture was agitated for 1 h and allowed to be incubated in an ultrasonic cleaner for 3 h at room temperature to give a white precipitate. After the supernatant was removed, the precipitate was suspended in 300 ml acetone, filtered, and washed with acetone in order to remove acetic anhydride and acetic acid. The precipitate was dissolved in 150 ml of water and recrystallized by addition of 210 ml of ethanol. The precipitate was filtered, washed with acetone, and dried at 50 °C to get about 15 g of disodium inorganic diphosphonate. The purity of the disodium inorganic diphosphonate thus obtained was checked by HPLC[12] to be 97—99% (as P).

Reaction of NMP, dNMP, or SP with Inorganic Diphosphonate. Unless otherwise stated, initial concentration of inorganic diphosphonate varied form 0.5 to 1.5 mol dm^{-3}, keeping the initial concentration of NMP's, dNMP's, or SP's at 0.1 mol dm^{-3} constant. The reaction mixture was adjusted to the prescribed pH value (10, 8, 6, or 4) with a sodium hydroxide or hydrochloric acid solution and was allowed to react at 50, 60, 70, and 80 °C. The pH change during the reactions was not controlled strictly.

HPLC Measurement. The HPLC manifold and technique were described in previous papers.[12-16] An HLC-601 system (Toyo Soda) was used as a main pumping system. The separations were performed on a column (100×4.0 mm I.D.) packed with an anion exchanger (TSKgel SAX, 10 μm, Toyo Soda). Flow rate was 1.0 ml min^{-1} and column temperature was kept at 30, 40, or 50 °C. Separated NMP's or dNMP's were detected at 260 nm by use of UV spectrophotometer located at the outlet of the separation column. Phosphate and phosphonate groups on reactants and products were monitored by the on-line coupled flow injection system designed for the differential detection of phosphate and phosphonate groups.[12]

^{31}P NMR Measurement. Pulse FT ^{31}P NMR spectra were recorded at the room temperature by use of JEOL JNM-FX100 (40.25 MHz), VARIAN XL-300 (121 MHz), and JEOL JNM-GX400 (161 MHz) spectrometers. Chemical shifts were measured in comparison with the 85% orthophosphoric acid external standard.

Results and Discussion

Characterization of Phosphonylation by HPLC. An aqueous mixture of AMP and P^{III}-O-P^{III} was incubated at 80 °C. After 3 h incubation, aliquots of the reaction mixture were diluted and analyzed by an HPLC system designed for the simultaneous determination of nucleotides, sugar phosphates, and inorganic phosphonates.[12-16]

Figure 1 shows HPLC profiles for a 100-fold-diluted sample solution. With UV-detection at 260 nm (Fig. 1a), one main product (A) and two by-products (B and C) were observed in addition to a peak for AMP. A small peak for adenosine (Ado), probably as an impurity in AMP, was also recorded.

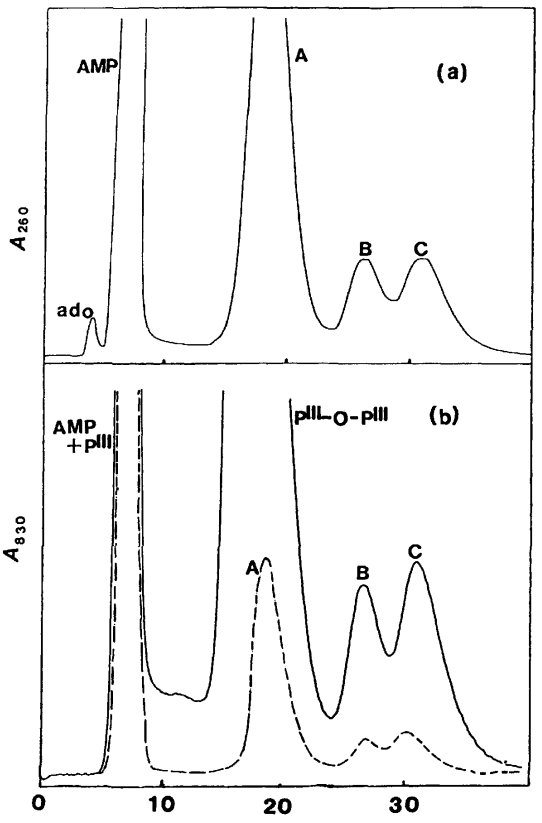


Fig. 1. HPLC profile for AMP (0.15 mol dm^{-3}) phosphonylated by inorganic diphosphonate (0.23 mol dm^{-3}) at 80 °C (pH 6) after 3 h incubation. The reaction mixture was diluted 100-fold. Eluent: 0.12 mol dm^{-3} KCl and 0.1% EDTA 4Na.

The solid lines in Figs. 1b and 2b indicate the sum of the absorbances (830 nm) due to phosphate and phosphonate groups measured in the presence of an oxidizing agent and the broken lines in Figs. 1b and 2b indicate the absorbance (830 nm) due to phosphate group measured in the absence of the oxidizing agent.

The peaks for P^{III} and P^{III}-O-P^{III} in Fig. 1b overlapped with those for AMP and a main product A, respectively. By lowering the sample concentration with 1000-fold dilution, the peaks for P^{III}-O-P^{III}, P^{III}, and A can well be resolved as shown in Fig. 2b. The results in Figs. 1 and 2 indicate that each of species A, B, and C is composed of phosphate, phosphonate, and adenosine, suggesting the formation of derivatives of AMP.

^{31}P NMR Spectra of Phosphonylated Products. No information was available from the HPLC profiles about the chemical structures of the products. To characterize the chemical structures of three phosphonylated products, ^{31}P NMR spectra of the reaction mixture were measured at room temperature on a JEOL JNM-FX100 spectrometer.

A proton-decoupled spectrum of the phosphonylated

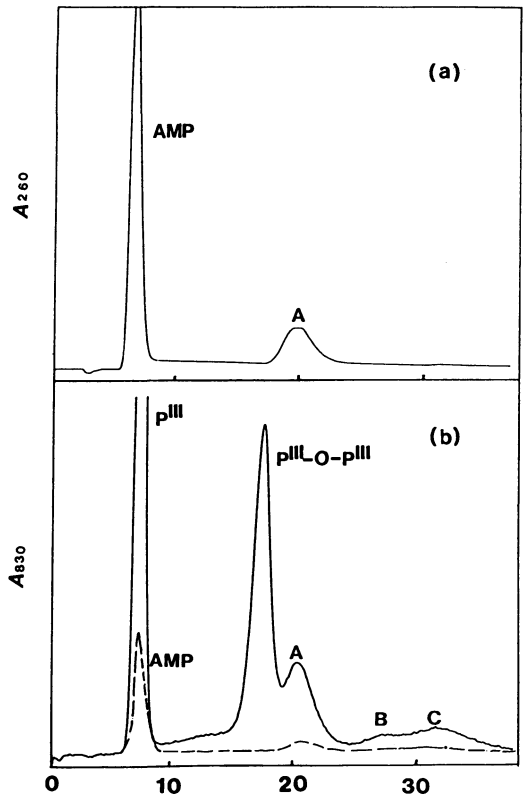

Fig. 2. HPLC profile for AMP (0.15 mol dm^{-3}) phosphonylated by inorganic diphosphonate (0.23 mol dm^{-3}) at 80 °C (pH 6) after 3 h incubation. The reaction mixture was diluted 1000-fold. Eluent: 0.12 mol dm^{-3} KCl and 0.1% EDTA 4Na.

Chart 1.

product of AMP (Fig. 3a) shows five singlets and two doublets. Three singlets are assigned to P^{III} (3.93 ppm), AMP (3.30 ppm), and P^{III}-O-P^{III} (−3.93 ppm) on the basis of the chemical shifts for the authentic samples. Two unknown doublets (D and E, −9.55 and −4.00 ppm) and two unknown singlets (G and F, 7.10 and 5.90 ppm) are expected to be the signals for phosphonylated products. One of the signals for the doublet (E) overlapped with that of P^{III}-O-P^{III}. The doublet could be separated from the signal for P^{III}-O-P^{III} by the experiment using a high magnetic field NMR spectrometer (JEOL JNM-GX400). Since the intensities of NMR signals are proportional to phosphorus contents, the main peak (A) in Fig. 1 can be assigned to the doublet (D and E), and the other peaks (B and C) correspond to signals F and G.

The new POP bond is likely to be formed by phosphonylation of AMP because the doublets (D and E) have the same J value of 19.8 Hz and the magnitudes of these J values are approximately equal to the geminal coupling constant ($^2J_{PP}$=21.7 Hz)[19] in adenosine 5′-diphosphate (ADP). The POP bond formation and the intensities of the doublets (D and E) suggest that phosphate group on AMP is predominantly phosphonylated to form product **1** (Chart 1) similar in structure to ADP.

Further splitting of the doublet (E) into a double-doublet is shown in a proton-coupled spectrum (Fig. 3b), while the doublet (D) is not split. The double-doublet (E) is assigned to the phosphorus atom (P_β of **1**) of phosphonyl group (H-$\overset{\overset{O}{\|}}{\underset{\underset{O^-}{|}}{P}}$-) transferred from P^{III}-O-P^{III} to the phosphate group on AMP because the double-doublet (E) shows a splitting of 665.5 Hz for the hydrogen atom attached directly to a phosphorus atom.[20]

If the doublet (D) can be assigned to the signal of P_α of **1**, the doublet (D) is expected to be further split into double-triplets caused by spin-spin coupling with two 5′-hydrogen atoms. The doublet (D) is not split in Fig. 3b, however, the band widths are broadened

compared with the signal observed in the proton-decoupled spectrum. The magnitude of J value can be estimated to be 4 Hz from band broadening. This value is similar to the vicinal coupling constant ($^3J_{PH}$) in AMP (4.9 Hz).[21] Therefore, the doublet (D) is assigned to the signal of P_α of **1**. Phosphate groups on other NMP's (Chart 2), dNMP's (Chart 3), and SP's (Chart 4) were also confirmed to be phosphonylated predominantly. Table 1 lists NMR parameters for phosphonylated products.

Chart 4.

The signals corresponding to G and F in Fig. 3a cannot be observed in a proton-coupled spectrum as shown in Fig. 3b, owing to a complex splitting and a low yield. Signals G and F are assigned to compounds **11** and **12** (Chart 5) produced by phosphonylation of

a) Estimated from the band broadening.

2′- or 3′-OH group, because the double-doublets (+5.9 and +7.1 ppm, $^1J_{PH}$=650 Hz and $^3J_{PH}$=10 Hz each) are observed in a proton-coupled spectrum by other experiments under alkaline conditions (pH 10). Phosphonylation of AMP in an alkaline solution gave **11** and **12** predominantly, but in a neutral solution, **11** and **12** were formed in small amounts (<2%). Phosphonylation of OH groups will be described in detail in a subsequent paper of this series.

Kinetic Profiles for Phosphonylation. Figures 4 and 5 show kinetic HPLC profiles for phosphonylation of AMP and Rib5P. The reaction mixture (P^{III}–O–P^{III}; 1.5 mol dm^{-3}, AMP or Rib5P; 0.1 mol dm^{-3}) was incubated at 60 °C in the pH range from 6 (0 min) to 5.5 (after 100 min) without any buffer solution. Aliquots (0.1 ml) of mixed solutions were withdrawn at 10 or 20 min intervals and diluted with 100 ml of distilled water. An aliquot (0.1 ml) of diluted solutions was introduced into an HPLC system designed for determination of nucleotides and both phosphate and phosphonate groups on reactants and products.[12–16] In the reaction of NMP's and dNMP's, the reactant and the product were detected simultaneously at 260 nm as shown in Fig. 4. On the other hand, phosphate groups were detected in the reaction of SP's to determine SP's and a phosphonylated product simultaneously as shown in Fig. 5, since SP's and their products **8**, **9**, and **10** have no UV-absorption.

The HPLC profiles at time 0 in Figs. 4 and 5 showed the peaks of only AMP and Rib5P. The elution peaks (H and I) appearing after 10—20 min represent the peaks of the phosphonylated products **1** and **8**. The peak areas of the products increased with time at the expense of AMP and Rib5P. The yields of

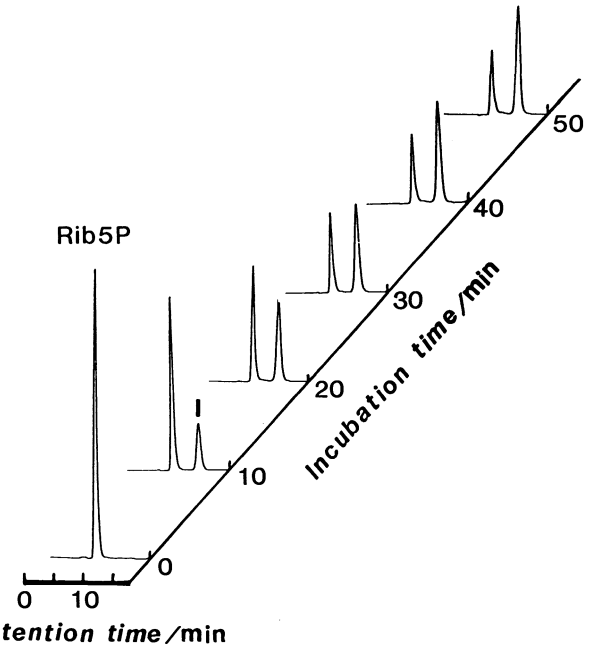

Fig. 5. Kinetic HPLC profile for phosphonylation of Rib5P (0.1 mol dm^{-3}) with inorganic diphosphonate (1.5 mol dm^{-3}) at 60 °C and pH 6. Eluent: 0.20 mol dm^{-3} KCl and 0.1% EDTA 4Na.

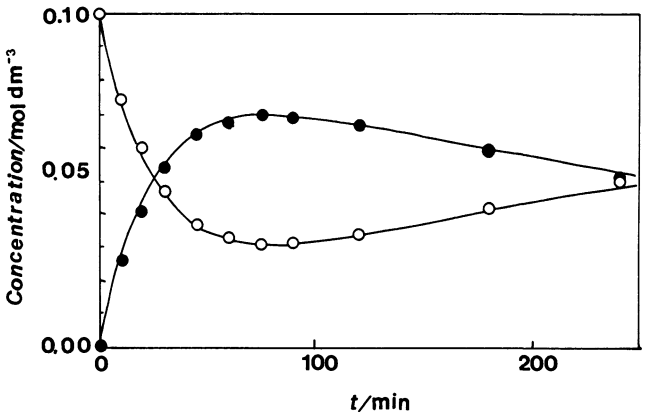

Fig. 6. Time dependence of the reaction components of phosphonylation for AMP with inorganic diphosphonate. Plot of the observed molar concentrations of AMP and product **1** vs. time/min in aqueous solution containing initially 0.1 mol dm^{-3} AMP and 1.0 mol dm^{-3} P^{III}–O–P^{III} at 60 °C and pH 6. (○): AMP, (●): product **1**. Eluent: 0.20 mol dm^{-3} KCl and 0.1% EDTA 4Na.

Table 2. Phosphonylation of AMP with P^{III}–O–P^{III}

Reaction condition					Yield/%
Molarity/mol dm^{-3}		pH	Temp/°C	Time/min	
P^{III}–O–P^{III}	AMP				
0.5	0.1	6	50	480	41
			60	300	43
			70	180	49
1.0	0.1	4	60	60	18
		6	50	300	59
			60	120	60
			70	60	62
		8	60	120	53
		10	60	0—120	0
1.5	0.1	6	50	180	69
			60	75	70
			70	30	69

the products reached a maximum after 50—60 min, and then gradually disappeared.

Effects of pH and Temperature on the Phosphonylation of NMP's. Figure 6 illustrates the time-dependent utilization of AMP and formation of product **1**. With the progress of the reaction, the amount of **1** increased gradually to a maximum (about 70% after 60 min), and then gradually decreased. Table 2 lists maximum yields and reaction times required to reach maximum yields under various reaction conditions.

The pH effect on the maximum yield was examined in the reaction of AMP at 60 °C and 1.0 mol dm^{-3} of initial concentration for P^{III}–O–P^{III}. In the pH range studied here, products were obtained in higher yields at neutral pH region, compared to a lower yield in both acidic and alkaline pH regions. The optimal pH was confirmed to be 6, because the reaction at pH ca. 6 gave a maximum yield, and the mixed solutions of P^{III}–O–P^{III} and NMP's, dNMP's, or SP's were kept at pH ca. 6 without any buffer solutions.

The maximum yield increased with increasing initial concentration of P^{III}–O–P^{III}: 50% at 0.5 mol dm^{-3}, 60% at 1.0 mol dm^{-3}, and 70% at 1.5 mol dm^{-3}. The increase in reaction temperature decreased the time required to reach a maximum yield, but did not contribute to an increase in a maximum yield. The optimal conditions for phosphonylation of AMP with P^{III}–O–P^{III} were found to be initial concentration of P^{III}–O–P^{III} 1.5 mol dm^{-3}, pH 6, and 60 °C.

Table 3. Yields/% of Phosphonylated Products of NMP's[a]

NMP[b]	[P^{III}–O–P^{III}]/mol dm^{-3}	Time/min		
		30	60	120
GMP	1.0	26	42	56
IMP	1.0	26	43	59
	1.5	43	61	66
UMP	1.0	25	42	57
	1.5	44	61	66
CMP	1.0	29	46	62
	1.5	50	68	73

a) Reaction temperature: 60 °C; pH: 6. b) Initial concentration of NMP is 0.1 mol dm^{-3}.

To examine effects of bases of NMP's on maximum yields, the maximum yields of GMP, IMP, UMP, and CMP were compiled in Table 3. The maximum yields and reaction times were almost the same as that obtained for the reaction of AMP. Therefore, we concluded that differences in bases on NMP's did not change the reactivity of NMP's even in the purine and pyrimidine nucleotides.

Effects of pH and Temperature on the Phosphonylation of dNMP's and SP's. Both dNMP's and SP's were also phosphonylated with P^{III}–O–P^{III} under various conditions and the maximum yields were listed in Tables 4 and 5.

dNMP was phosphonylated after 2 h in the yield of 59% at pH 6 and 60 °C when the initial concentration of P^{III}–O–P^{III} was 1.0 mol dm^{-3}. The yield increased and the reaction time decreased with an increase in initial concentration of P^{III}–O–P^{III} as well as in the reaction of NMP. In the reaction of dAMP the yield of **7** was found to be 57 and 70% at 1.0 and 1.5 mol dm^{-3} of P^{III}–O–P^{III}, respectively. The optimum conditions for the phosphonylation of dNMP's are at 1.5 mol dm^{-3} of P^{III}–O–P^{III}, pH 6, and 60 °C.

In the reaction of Rib5P, the yield of **8** at pH 6 was higher than that at pH 4 and 8 under the conditions of 1.0 mol dm^{-3} of P^{III}–O–P^{III} and 60 °C. At 1.5 mol dm^{-3} of P^{III}–O–P^{III}, Rib5P was phosphonylated in the yield of 70% at pH 6 and 60 °C, while the yields of **8** were 43 and 59% when the initial concentrations of P^{III}–O–P^{III} were 0.5 and 1.0 mol dm^{-3}, respectively. Initial concentration affected yields strongly, but reaction temperature did not contribute to changes in the yield in spite of decreasing reaction time. At pH 6 and 60 °C, other SP's were also phosphonylated by P^{III}–O–P^{III}. About 70% of Glc1P or Glc6P was phosphonylated after 1 h at 1.5 mol dm^{-3} of P^{III}–O–P^{III}. The optimal conditions for the phosphonylation of SP's are at 1.5 mol dm^{-3} of P^{III}–O–P^{III}, pH 6, and 60 °C as well as in the reaction of NMP's and dNMP's.

The results obtained in the reaction of dNMP's or SP's showed that the 2′-OH and bases on NMP's affected slightly the reactivity of phosphate groups on NMP's, dNMP's, and SP's.

(Received March 7, 1988)

Two new triterpenoids, skimmiarepin A and B, which both exhibit an insect growth inhibitory activity against the silkworm, *Bombyx mori* L., have been isolated from the leaves and the fruit of *Skimmia japonica* Thunb. var. *intermedia* Komatsu f. *repens* (Nakai) Hara. Their structures have been determined by extensive 2D NMR studies and chemical methods.

The shrub *Skimmia japonica* Thunb. var. *intermedia* Komatsu f. *repens* (Nakai) Hara (Rutaceae)[1] is widely distributed in Japan and its leaves are relatively free from insect attack. In our preliminary screening for the biological activities of plant materials, the methanol extracts of the leaves and fruit of this plant exhibited an insect growth inhibitory activity against the silkworm, *Bombyx mori* L. Monitoring the fractionations of the methanol extracts by artificial diet feeding bioassay against silkworm larvae[2] led to the isolation of two new triterpenoids responsible to the observed activity.[3] This paper deals with the structures of these new compounds, named skimmiarepin A and B.

Skimmiarepin A (**1**), $C_{35}H_{56}O_6$, mp 164.5—165.5 °C, $[\alpha]_D^{20}$ −22.7° (*c* 0.20, EtOH), was isolated from the methanol extract of the leaves in 0.013% yield as colorless needles by conventional silica-gel column chromatography and preparative high-performance liquid chromatography. It had IR absorptions indicative of hydroxyl (3580 and 3320 cm^{-1}) and ester (1725 cm^{-1}) groups, and formed a couple of diacetates **3**, $C_{39}H_{60}O_8$, mp 79.0—80.0 °C, and **4**, $C_{39}H_{60}O_8$, mp 191.5—192.5 °C, on acetylation with 4-dimethylaminopyridine–acetic anhydride. The oxidation of **1** with pyridinium chlorochromate gave a keto lactone **5**, $C_{35}H_{52}O_6$, mp 135.0—136.0 °C, the IR spectrum of which showed the presence of the newly introduced γ-lactone (1780 cm^{-1}). These facts and the appearance of a pair of ^{13}C NMR signals due to a hemiacetal carbon atom in **1** (δ_C 98.12 and 102.00) suggested that **1** is an epimeric mixture with respect to the hemiacetal carbon atom which constitutes a five-membered cyclic ether. At first our attention was directed to the simplest compound **5**.

The 400 MHz ^1H NMR spectrum of **5** showed signals due to a cyclopropyl methylene group at δ 0.45 and 0.58 (1H each, d, *J*=5.6 Hz), six tertiary methyl groups at δ 0.84, 0.93, 1.09, 1.32, 1.34, and 1.37 (3H each, s), a trisubstituted epoxide at δ 2.80 (1H, d, *J*=7.3 Hz), and two oxygen-bearing methine groups at δ 4.17 (1H, ddd, *J*=10.5, 7.3, and 6.1 Hz) and 4.70 (1H, t, *J*=2.9 Hz). The presence of an isovaleric ester was also evident from the ^1H NMR signals at δ 0.96 (6H, d,

a) The spectrum was determined at 25 °C in $CDCl_3$ solution, with TMS as the internal standard. Assignments were based on the ^1H–^1H and ^1H–^{13}C COSY, and NOESY experiments. b) m#: Overlapped multiplets.

J=6.6 Hz), 2.09 (1H, m), and 2.17 (2H, d, J=6.6 Hz), and the MS fragment at m/z 466 ($M^+-C_5H_{10}O_2$). In addition, an ^1H–^1H COSY analysis and simple homo-decoupling experiments, as summarized in Table 1, revealed the presence of four partial structures, **A**, **B**, **C**, and **D**, all suggesting a carbon framework analogous to those of glabretal (**6**)[4] and ailanthol (**7**)[5] for **5**. The ^1H–^{13}C COSY spectrum of **5** led to straightforward assignments of the ^{13}C NMR signals, except for those of the quaternary carbon atoms at δ_C 28.88, 34.02, 37.12, 37.23, and 50.53 (Table 2). Complete assignments of these quaternary carbon signals as well as ^1H NMR signals of tertiary methyl groups could be accomplished by NOE measurements and ^1H–^{13}C long-range COSY experiments. Namely, observations of NOEs between $H_{3\beta}$ and two methyl groups (δ_H 0.84 and 0.93; $C_{4\alpha}$- and $C_{4\beta}$-Me), between $H_{5\alpha}$ and one of the above methyl groups (δ_H 0.84), between the other one (δ_H 0.93) and $H_{6\beta}$ as well as the third methyl group at δ_H 1.09 (C_{10}-Me), and between the third (δ_H 1.09) and the fourth one at δ_H 1.32 (C_8-Me) defined the positions of all the tertiary methyl groups. The ^{13}C NMR signal at δ_C 37.23 (C_4) showed long-range correlations with methyl proton signals at δ_H 0.84 and 0.93, while the signal at δ_C 37.12 (C_{10}) showed a correlation with that at δ_H 1.09. Further, the methyl proton signal at δ_H 1.32 was long-range-coupled with the carbon signals at δ_C 50.53 (C_8) and

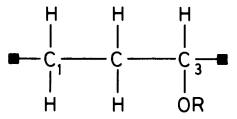
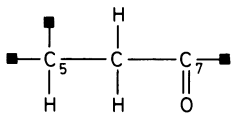
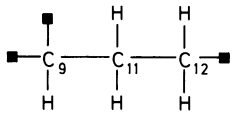
a) The spectra were measured at 100 MHz in $CDCl_3$ solutions and the shifts are given in δ(ppm) relative to the internal TMS. Assignments were made by means of INEPT, ^1H–^{13}C COSY, and ^1H–^{13}C long-range COSY experiments. Values in parentheses are attributable to the $C_{21}\alpha$-OH epimer.



A



B



C

34.02 (C_{14}). The remaining quaternary carbon signal at δ_C 28.88 could, therefore, be assigned to C_{13}.

These facts inevitably led to an understanding of the gross structure of **5** for the keto lactone and, hence, structure **1** for skimmiarepin A. The locations of the isovaleric ester and the secondary hydroxyl group in **1** were apparently at $C_{3\alpha}$ and $C_{7\alpha}$, respectively, according to the chemical shifts and the coupling pattern of ^{1}H NMR signals due to their carbinyl protons [$H_{3\beta}$: δ 4.66 (t, J=2.8 Hz); $H_{7\beta}$: δ 3.76 (br s)].[4,6] The final confirmation of the assigned structure was achieved by a chemical correlation of **1** with **6**. Thus, a partial methanolysis of the diacetate **3** with triethylamine–methanol yielded an amorphous hemiacetal **8**, $C_{37}H_{58}O_7$. A treatment of **8** with ethyl vinyl ether–pyridinium *p*-toluenesulfonate and a selective methanolysis of the product with sodium methoxide–methanol, followed by a treatment with pyridinium *p*-toluenesulfonate, afforded a diol, the spectral data of which are identical with those of **6**. The stereochemistry at C_{21} of **3** and **4** was deduced from scrutinizing the ^{13}C NMR data for the carbon atoms on the side chains of both compounds.[6]

7

Skimmiarepin B (**2**) was obtained from a methanol extract of the fruit in 0.001% yield as fine needles, $C_{40}H_{60}O_6$, mp 168.0—169.0 °C, $[\alpha]_D^{18}$ −39.8° (*c* 0.11, $CHCl_3$), and exhibited spectral data quite similar to those of **1**, except for following observations. The IR and UV spectra of **2** showed the presence of an unsaturated carboxylic ester [ν_{max} 1705 and 1615 cm^{-1}; λ_{max} 303 nm (ε 21000)]. The ^{1}H NMR spectrum did not show any signal due to the isovaleric ester present in **1** but, instead, showed the presence of a 2,4,6-decatrienoic ester [δ 7.43 (1H, dd, J=14.6 and 11.4 Hz), 6.57 (1H, t, J=11.4 Hz), 6.46 (1H, dd, J=14.6 and 10.6 Hz), 6.27 (1H, dd, J=14.8 and 10.6 Hz), 5.91 (1H, dt, J=14.8 and 7.2 Hz), 5.69 (1H, d, J=11.4 Hz), 2.12 (2H, q, J=7.2 Hz), 1.46 (2H, sext, J=7.2 Hz), and 0.91 (3H, t, J=7.2 Hz)]. The relatively small coupling constant (11.4 Hz) between H_2' and H_3' and the appearance of the H_4' signal at a lower field (δ 7.43)[7] revealed the *Z*-geometry of the C_2' double bond. On the other hand, the *E*-configuration of the C_4' and C_6' double bonds was deduced from the trans ethylenic coupling constants between H_4' and H_5' (14.6 Hz) and between H_6' and H_7' (14.8 Hz), respectively. From this evidence and the pertinent ^{13}C NMR data (Table 2), the structure **2** was proposed for skimmiarepin B.

Experimental

All mps were determined on a Mitamura micro melting-point apparatus and are uncorrected. The IR and UV spectra were recorded on a JASCO model A-302 spectro-

photometer and a JASCO UVIDEC-670 spectrophotometer, respectively. The ^{1}H NMR (400 MHz) and ^{13}C NMR (100 MHz) spectra were taken on a JEOL JNM-GX400 instrument in $CDCl_3$ solutions, with TMS as the internal standard. Mass spectra as well as high-resolution mass spectra were measured with a JEOL JMS-D300 spectrometer at 70 eV of ionization energy. A Union Gikken apparatus, model PM-101, was used for measuring the rotations. High-performance liquid chromatographic separation was performed on a Waters Associates HPLC model 6000A, with a TSK-GEL LS-410KG (ODS) column.

Isolation. The leaves and the fruit of *Skimmia* japonica Thunb. var. *intermedia* Komatsu f. *repens* (Nakai) Hara were collected from Mt. Kuishi, Kochi Prefecture, in December 1985. Fresh leaves (1.82 kg) were chopped up and extracted with methanol (6 l) at room temperature for one week. The methanol solution was concentrated up to about 0.5 l, water (0.5 l) was added, and the resulting aqueous suspension was extracted with dichloromethane (3×0.3 l). The dichloromethane layer was washed with water, dried over sodium sulfate, and evaporated to dryness. The residue (65.1 g) was subjected to chromatography over silicic acid (800 g); upon eluting with hexane–ethyl acetate mixtures, ethyl acetate increased from 20 to 80%. Elution with 50% ethyl acetate in hexane gave a fraction (12.0 g) which was rechromatographed over neutral alumina (250 g), using 50% ether in hexane as the eluent, to yield skimmiarepin A (**1**) (347 mg). The fresh fruit (1.44 kg) was extracted in the same manner as described above and the dichloromethane extract (8.3 g) was subjected to chromatography over silicic acid (300 g); upon eluting with hexane–ethyl acetate mixtures, ethyl acetate increased from 20 to 80%. Elution with 50% ethyl acetate in hexane afforded a fraction (155 mg) which was further purified by high-performance liquid chromatography (TSK-GEL LS-410KG, 10% water in methanol) to give skimmiarepin B (**2**) (23 mg).

Skimmiarepin A (1). The crude material was recrystallized from ethanol to give colorless prisms (234 mg); mp 164.5—165.5 °C; $[\alpha]_D^{20}$ −22.7° (*c* 0.20, EtOH); IR (Nujol) 3580, 3320, 1725, 1270, and 1025 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.48 and 0.72 (1H each, d, *J*=4.7 Hz, 18-H_2), 0.96 and 0.97 (3H each, d, *J*=6.6 Hz, 4′- and 5′-H_3), 0.85, 0.88, 0.89, 1.05, 1.31, and 1.32 (3H each, s, 28-, 19-, 29-, 30-, 27-, and 26-H_3), 2.11 (1H, m, 3′-H), 2.23 (2H, d, *J*=6.6 Hz, 2′-H_2), 2.84 (1H, d, *J*=7.3 Hz, 24-H), 3.76 (1H, br s, 7-H), 3.88 (1H, ddd, *J*=9.5, 7.3, and 7.3 Hz, 23-H), 4.66 (1H, t, *J*=2.8 Hz, 3-H), and 5.44 (1H, t, *J*=3.2 Hz, 21-H); ^{13}C NMR (see Table 2); MS (70 eV) *m/z* (rel intensity) 572 (M^+, 3), 554 (M^+-H_2O, 22), 536 (M^+-2H_2O, 7), 470 ($M^+-C_5H_{10}O_2$, 11), 452 ($M^+-H_2O-C_5H_{10}O_2$, 32), 398 (45), 312 (78), 202 (87), and 187 (100). Found: *m/z* 572.4086. Calcd for $C_{35}H_{56}O_6$: M, 572.4077.

Skimmiarepin B (2). The crude substance was recrystallized from acetone to yield white needles (16 mg); mp 168.0—169.0 °C; $[\alpha]_D^{18}$ −39.8° (*c* 0.11, $CHCl_3$); IR (CCl_4) 3600, 3400, 1705, 1615, and 1170 cm^{-1}; UV (EtOH) 303 nm (ε 21000); ^{1}H NMR ($CDCl_3$) δ=0.45 and 0.71 (1H each, d, *J*=5.2 Hz, 18-H_2), 0.87, 1.05, 1.30, and 1.32 (3H each, s, 28-, 30-, 27-, and 26-H_3), 0.90 (6H, s, 19- and 29-H_3), 0.91 (3H, t, *J*=7.2 Hz, 10′-H_3), 1.46 (2H, sext, *J*=7.2 Hz, 9′-H_2), 2.12 (2H, q, *J*=7.2 Hz, 8′-H_2), 2.85 (1H, d, *J*=7.6 Hz, 24-H), 3.77 (1H, br t, *J*=3.2 Hz, 7-H), 3.88 (1H, ddd, *J*=9.5, 7.2, and 7.2 Hz, 23-H), 4.73 (1H, t, *J*=2.7 Hz, 3-H), 5.43 (1H, t, *J*=3.4 Hz, 21-H), 5.69 (1H, d, *J*=11.4 Hz, 2′-H), 5.91 (1H, dt, *J*=14.8 and 7.2 Hz, 7′-H), 6.27 (1H, dd, *J*=14.8 and 10.6 Hz, 6′-H), 6.46 (1H, dd, *J*=14.6 and 10.6 Hz, 5′-H), 6.57 (1H, t, *J*=11.4 Hz, 3′-H), and 7.43 (1H, dd, *J*=14.6 and 11.4 Hz, 4′-H); ^{13}C NMR (see Table 2). Found: C, 74.99; H, 9.51%. Calcd for $C_{40}H_{60}O_6 \cdot 1/4H_2O$: C, 74.90; H, 9.51%.

Acetylation of 1. To a solution of **1** (160 mg) in acetic anhydride (0.3 ml) and pyridine (0.6 ml) was added a catalytic amount of 4-dimethylaminopyridine. The mixture was stirred overnight at room temperature and then worked up in the usual way. The product was chromatographed over silicic acid (20 g), with 75% ether in hexane as the eluent, to give diacetates, **3** (72 mg) and **4** (105 mg).

Diacetate 3. The former fraction was recrystallized from hexane–ethyl acetate to yield colorless prisms (66 mg); mp 79.0—80.0 °C; IR (CCl_4) 1730 and 1250 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.37 and 0.74 (1H each, d, *J*=5.6 Hz, 18-H_2), 0.76, 0.87, 0.91, 1.10, 1.30, and 1.33 (3H each, s, 28-, 19-, 29-, 30-, 27-, and 26-H_3), 1.00 and 1.01 (3H each, d, *J*=6.4 Hz, 4′- and 5′-H_3), 2.04 and 2.06 (3H each, s, 2Ac), 2.12 (1H, m, 3′-H), 2.22 (2H, d, *J*=6.4 Hz, 2′-H_2), 2.75 (1H, d, *J*=7.6 Hz, 24-H), 3.90 (1H, ddd, *J*=10.2, 7.2, and 6.0 Hz, 23-H), 4.67 (1H, t, *J*=2.8 Hz, 3-H), 5.00 (1H, t, *J*=2.8 Hz, 7-H), and 6.29 (1H, d, *J*=3.4 Hz, 21-H); ^{13}C NMR (see Table 2); MS (70 eV) *m/z* (rel intensity) 596 (M^+-AcOH, 52), 536 (M^+-2AcOH, 29), 434 (M^+-2AcOH−$C_5H_{10}O_2$, 27), and 135 (100). Found: *m/z* 596.4049. Calcd for $C_{39}H_{60}O_8$−AcOH: M, 596.4076.

Diacetate 4. The latter fraction was recrystallized from aqueous methanol to afford white needles (89 mg); mp 191.5—192.5 °C; IR (CCl_4) 1730, 1250, and 1230 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.32 and 0.72 (1H each, d, *J*=5.7 Hz, 18-H_2), 0.76, 0.87, 0.91, 1.09, 1.27, and 1.32 (3H each, s, 28-, 19-, 29-, 30-, 27-, and 26-H_3), 1.00 (6H, d, *J*=6.4 Hz, 4′- and 5′-H_3), 2.04 and 2.08 (3H each, s, 2Ac), 2.12 (1H, m, 3′-H), 2.22 (2H, d, *J*=6.4 Hz, 2′-H_2), 2.67 (1H, d, *J*=7.6 Hz, 24-H), 3.88 (1H, ddd, *J*=10.0, 7.6, and 7.0 Hz, 23-H), 4.67 (1H, t, *J*=2.7 Hz, 3-H), 4.98 (1H, t, *J*=2.8 Hz, 7-H), and 6.27 (1H, d, *J*=3.4 Hz, 21-H); ^{13}C NMR (see Table 2); MS (70 eV) *m/z* (rel intensity) 596 (M^+-AcOH, 38), 536 (M^+-2AcOH, 21), 434 (M^+-2AcOH−$C_5H_{10}O_2$, 22), and 135 (100). Found: *m/z* 596.4095. Calcd for $C_{39}H_{60}O_8$−AcOH: M, 596.4076.

Oxidation of 1. To a suspension of pyridinium chlorochromate (50 mg) in dichloromethane (0.5 ml) was added a solution of **1** (30 mg) in dichloromethane (0.5 ml). The mixture was stirred for 6 h at room temperature and then worked up in the usual manner. The product was subjected to chromatography over silicic acid (3 g). Elution with 30% ethyl acetate in hexane gave a keto lactone **5** (22 mg) which was recrystallized from ether–hexane to yield white needles (15 mg); mp 135.0—136.0 °C; IR (CCl_4) 1780, 1738, and 1710 cm^{-1}; ^{1}H NMR (see Table 1); ^{13}C NMR (see Table 2); MS (70 eV) *m/z* (rel intensity) 568 (M^+, 8) and 413 (100). Found: *m/z* 568.3765. Calcd for $C_{35}H_{52}O_6$: M, 568.3764.

Partial Methanolysis of 3. A mixture of **3** (60 mg) and triethylamine (30 mg) in methanol (1.2 ml) was stirred under a nitrogen atmosphere at room temperature for 10 days and then evaporated to dryness. The residue was subjected to chromatography over silicic acid (5 g), with 30% ethyl acetate in hexane, to give a hemiacetal (**8**) as an amorphous solid (34 mg); IR (CCl_4) 3600, 3440, 1730, and 1255 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.35 and 0.65 (1H each, d, *J*=5.4 Hz, 18-H_2), 0.76, 0.87, 0.91, 1.10, 1.30, and 1.31 (3H each, s, 28-, 19-, 29-, 30-, 27-, and 26-H_3), 1.00 (6H d, *J*=6.6 Hz, 4′- and

5′-H_3), 2.04 (3H s, Ac), 2.12 (1H, m, 3′-H), 2.23 (2H, d, J=6.6 Hz, 2′-H_2), 2.83 (1H, d, J=7.6 Hz, 24-H), 3.87 (1H, ddd, J=9.5, 7.6, and 7.3 Hz, 23-H), 4.66 (1H, t, J=2.8 Hz, 3-H), 5.01 (1H, t, J=3.2 Hz, 7-H), and 5.41 (1H, t, J=3.4 Hz, 21-H); MS (70 eV) m/z (rel intensity) 596 (M^+-H_2O, 31), 536 ($M^+-H_2O-AcOH$, 17), 434($M^+-H_2O-AcOH-C_5H_{10}O_2$, 24), and 135 (100). Found: m/z 596.4093. Calcd for $C_{37}H_{58}O_7-H_2O$: M, 596.4077.

Conversion of 8 into Glabretal (6). A mixture of **8** (32 mg), ethyl vinyl ether (0.2 ml), and a catalytic amount of pyridinium *p*-toluenesulfonate was stirred overnight under a nitrogen atmosphere at room temperature. After dilution with dichloromethane (10 ml), the solution was washed with a saturated sodium hydrogencarbonate solution and saturated brine, successively, dried over magnesium sulfate, and evaporated to dryness. The residue, which no longer showed a hydroxylic band in the IR spectrum, was dissolved in methanol (0.5 ml); then, a 0.57 M sodium methoxide solution in methanol (1.0 ml) was added under a nitrogen atmosphere with ice cooling. The mixture was stirred at room temperature for 10 days and then worked up in the usual way. The resulting product was chromatographed over silicic acid (3 g), with 50% ethyl acetate in hexane, to afford a deisovaleryl compound (21 mg). A mixture of the product and a catalytic amount of pyridinium *p*-toluenesulfonate in methanol (0.5 ml) was stirred for 6 h at room temperature under a nitrogen atmosphere and then worked up in the usual manner. The product was chromatographed using a Lobar Column (Merck, LiChroprep Si 60, size B) and 50% ethyl acetate in benzene as the solvent to yield a diol (12 mg) which was identified by comparison of spectral data with those of **6** [IR ($CHCl_3$) 3500, 1715, and 1260 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.35 and 0.63 (1H each, d, J=5.6 Hz, 18-H_2), 2.04 (3H, s, Ac), 2.83 (1H, d, J=7.3 Hz, 24-H), 3.42 (1H, br s, 3-H), 3.84 (1H, ddd, J=9.5, 7.6, and 7.3 Hz, 23-H), 5.01 (1H, t, J=3.2 Hz, 7-H), and 5.42 (1H, d, J=3.2 Hz, 21-H)].

(Received March 10, 1988)

A 5–8–5-membered tricyclic diterpene, cycloaraneosene, has been totally synthesized via a stereoselective condensation of two units of optically active iridoids, a Cope rearrangement, a chemical reduction of the tetrasubstituted double bond, and the formation of an eight-membered ring. The proposed structure of natural hydroxycycloaraneosene should be revised to 8β-hydroxycycloaraneosene, judging from the NMR spectral data.

In 1975, Borschberg reported the isolation and structure determination of a 5–8–5-membered tricyclic diterpene, cycloaraneosene (**1**),[3] from *Sordaria araneosa* Cain. Obviously, **1** is the biogenetic precursor of the congener diterpenoids of a fungus, such as sordaricin[4] and hydroxycycloaraneosene.[3] In this paper we describe the total synthesis of **1** using the condensation of two functionalized iridoids, in which the synthetic strategy is similar to our previous synthesis of fusicoccatriene.[5] Although several studies on this subject have been appeared, no total synthesis of natural 5–8–5-membered tricyclic compounds has been reported.[6]

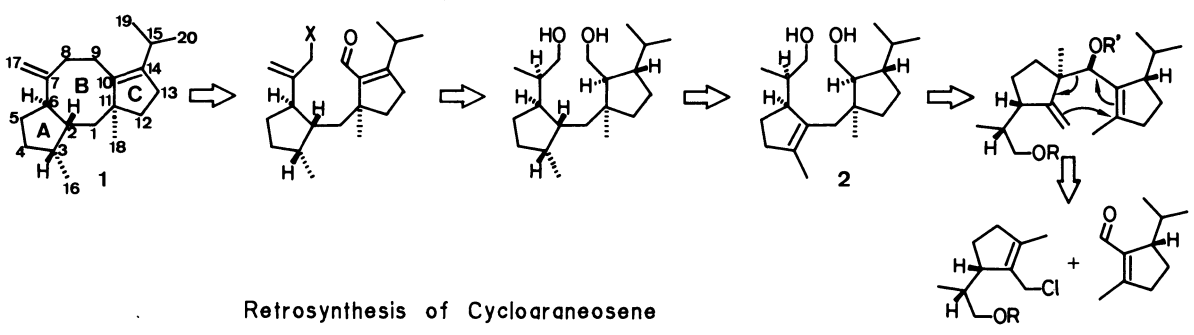
Results and Discussion

Among the natural 5–8–5-membered compounds, the stereochemistry of **1** has two outstanding features: i) the syn-relation between the hydrogen at C-6 and the methyl group C-11 is reverse to that of cotylenins[7] and fusicoccins[8] and ii) the hydrogens at C-2 and C-3 of the saturated ring A have a cis-β-geometry (i.e., (2*R*,3*R*)-structure). The former arrangement can be created by a stereospecific Cope rearrangement of the dimeric condensate of appropriate iridoids.[9] Therefore, in order to synthesize **1**,[10] a stereoselective reduction of the tetrasubstituted double bond, which is indispensable for a Cope rearrangement, is crucial. This reduction must be performed prior to the formation of double bonds and the B-ring.

With the regard to those facts, the key compounds for a reduction must be the diol **2** or its equivalents, the stereochemical framework of which should be inherited from the condensation of (3*S*)-iridenals and (3*S*)-iridenyl chlorides.

In order to obtain **2**, we carried out further conversions of the Cope rearrangement product **3**, prepared from the chromium(II) chloride condensation[11] of (3*S*)-1-iriden-7-al and (3*S*,8*R*)-9-benzyloxy-7-chloro-1-iridene[5] as follows. The hydrolysis of **3** and the epimerization of the resulting aldehyde were consecutively performed with potassium fluoride on silica gel and on Florisil to give thermodynamically stable aldehyde **4** in good yield. The lithium aluminum hydride (LAH) reduction of **4** gave the corresponding primary alcohol **5**. The catalytic hydrogenolysis of **5** with palladium on carbon gave the desired **2**, which was further transformed to diacetate **6** and bis(tetrahydropyranyl) (THP) ether (**7**).

In order to generate the correct stereochemistry of the A-ring, the hydrogenation must occur from the β-side of **2**; this procedure was shown to be promising from observations of the Dreiding's Stereomodels; i.e., the α-side of the A-ring is more hindered than the β-side by substituents on the C-ring. However, all attempts to hydrogenate **2** failed, except for hydrogenation under Adam's conditions, platinum(IV) oxide in acetic acid, which gave a mixture of acetylated dihydro derivatives in low yields. This



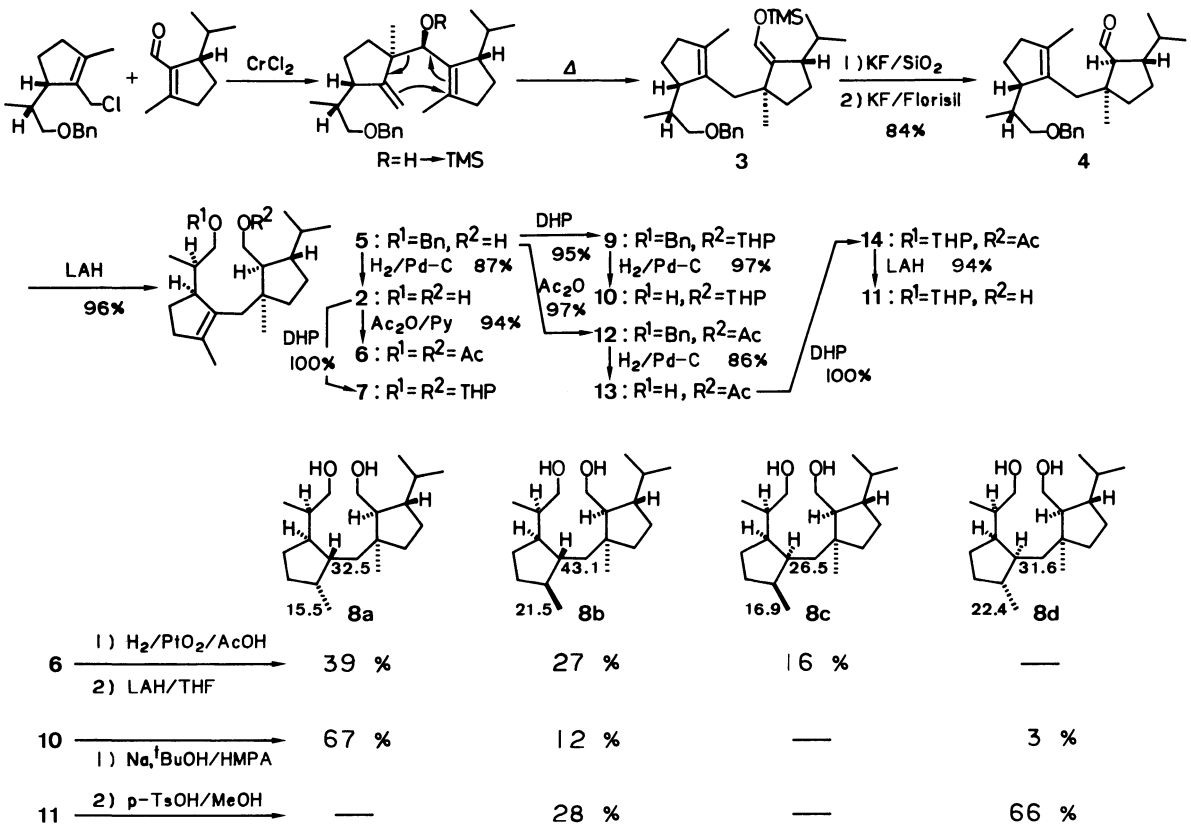
Retrosynthesis of Cycloaraneosene

Scheme 1.

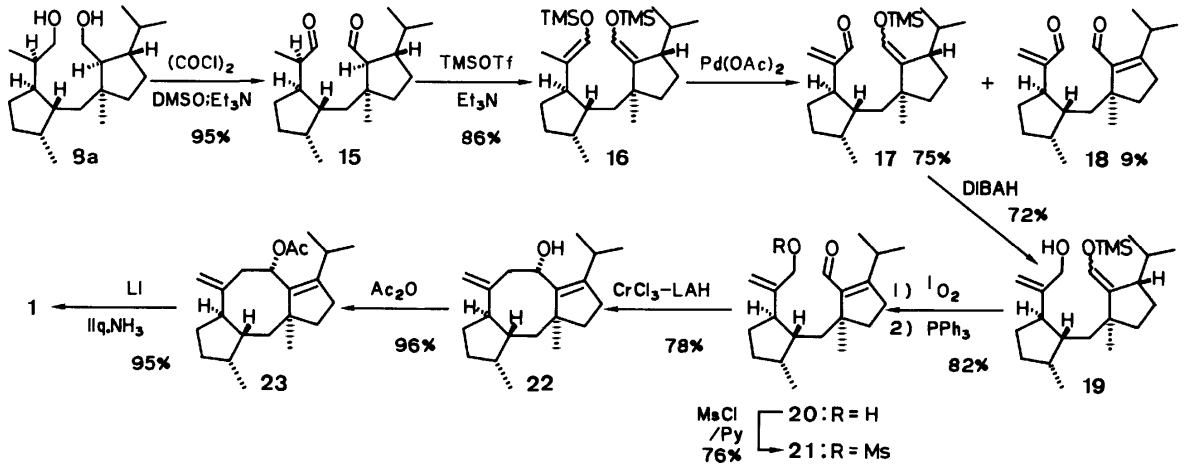
should indicate that the hydrogenation of the acetate might be facile; indeed, when **6** was reduced in acetic acid at 70 °C, three dihydro derivatives were formed. Although this mixture was inseparable, hydrolyzed dihydro diols were fractionated through a silica-gel column chromatography; the yield (39%) of the major dihydro diol (**8a**) was still insufficient for a synthetic purpose. However, a ^{13}C NMR chemical shift comparison of the stereomers, **8b** and **8c** (27 and 16% yields, respectively), disclosed reliable information for selecting the correct isomer for the synthesis.

Interestingly, the catalytic deuteration of **6** under comparable conditions also afforded three products; these reduction products contained more than two deuterium atoms. This finding indicated that the hydrogen (deuterium) exchange via π-allyl complexation is very rapid. Furthermore, the complete disappearance of the signals due to C-2, C-3, and C-16 from the olefinic carbon region indicated the distributions of deuterium; the intactness of the C-6 signal for all isomers assured the original (6*R*)-configuration. According to the well-known relationship of the ^{13}C chemical shift and the stereochemistry, the configurations of the isomers were as follows: **8a** and **8c** having relatively higher secondary methyl signals suggested a cis-configuration between these methyls and the vicinal substituent.[12] The same criteria could be applied to deduce the geometries of C-2 and C-6 from the chemical shifts of C-1 methylene carbons to assign trans and cis, respectively, for **8a** and **8c**. Thus, the major diol, **8a**, is the required (2*R*,3*R*)-isomer, and **8c** is (2*S*,3*S*)-isomer. The remaining **8b**, exhibiting both methyl and methylene signals at a lower field, must be the (2*R*,3*S*)-isomer.

In order to improve the selectivity, an alkali metal reduction of the derivative of **2** in a polar aprotic media under forced conditions seems to be promising.[13] Thus, THP ether **9** prepared from **5** was hydrogenolyzed in order to furnish an alcohol **10**. A sodium metal reduction of **10** in hexamethylphosphoric triamide (HMPA) with added 1,1-dimethylethanol at room temperature yielded **8a** in moderate yield, accompanied by small amounts of **8b** and **8d** (**8a**:**8b**:**8d**=22:4:1). The absence of thermodynamically unstable **8c** was predictable from a mechanistic view point, and the ^{13}C NMR spectrum of **8d** is reasonable as a (2*S*,3*R*)-isomer based on the above-mentioned criteria.[12] These figures are found in illustrations **8a—d**. It is noteworthy that **7**, having no hydroxyl group, did not react under the above conditions. Therefore, a hydrogen-donating hydroxyl group is required in the molecule, and the direction of hydrogenation must be controlled by the orientation of the hydroxyl group. This must be an important factor for an improved selectivity. Further proof for this mechanistic assumption was obtained from a reduction of **11**, which was prepared from **5** in four steps: acetylation of **5** gave **12** which was hydrogeno-



Scheme 2.



Scheme 3.

lyzed to **13**, and etherification of **13** by dihydropyran gave **14**. Finally, an LAH reduction of **14** yielded **11**. The product distributions of the sodium-1,1-dimethylethanol-HMPA reduction of **11** were completely different from the case of **10**. Namely, **8d** was produced as the major product accompanied by **8b** (**8d**:**8b**=7:3), and **8a** was not detected at all. This result can be explained in terms of the directional control of the hydroxyl group, which was conformationally oriented on the α-side of the A ring in **11**. Thus, the dissolving metal reduction of **10** provided the required stereochemistry for the present aim, while the reduction of a compound similar to **11** has been used in our recent synthesis of dictymal.[14]

Subsequently, to construct the tricyclic skeleton with proper functionalities for **1**, **8a** was oxidized to dialdehyde **15**, which was then converted to an isomeric mixture of bis(silyl enol ether)s **16**. Upon palladium(II) acetate-treatment,[15] the less-hindered enol ether of **16** was preferentially oxidized to give **17**; the yield of the accompanying dialdehyde **18** was only 9%. Diisobutylaluminum hydride (DIBAH) reduction gave an allyl alcohol **19**, and its sensitized photooxidation yielded a hydroxy aldehyde **20**. The mesylate **21** derived from **20** was treated with chromium(II) chloride to give a tricyclic compound **22**. The chemical shift of the singlet methyl, δ=1.20, indicated a syn-relationship with the allylic hydroxyl group.

The final transformation was achieved through a reductive elimination of the allylic hydroxyl group via the acetate **23**. The physical properties of **1**, thus obtained, were in accord to those of natural (−)-cycloaraneosene in all respects, including the optical rotation, ($[\alpha]_D$ −37.5° (lit,[3] −38.4°)), and the ^{13}C NMR chemical shifts.[3]

Incidentally, the structure of **22** is same as that proposed for a congener metabolite, hydroxycycloaraneosene (**22A**).[3] However, the physical data of **22** were clearly different from those recorded for the natural product or its epimer derived by chemical transformations.[3] Thus, our **22**, colorless scales, mp 64—65 °C, revealed a negative rotation ($[\alpha]_D$ −21.8°); however, **22A**, a colorless oil, was reported to be positive ($[\alpha]_D$ +7.5°). The reported ^1H NMR chemical shift for the singlet methyl of **22A** was δ=1.02. Presumably, **22A** is 8β-hydroxy derivative of **1**.

Syntheses of other members of terpenoids via this strategy is currently in progress.

Experimental

The elemental analyses were carried out by Miss S. Hirashima, of Institute of Advanced Material Study, Kyushu University. The NMR spectra were measured by a JEOL FX 100 Spectrometer in a $CDCl_3$ solution, unless otherwise specified, and the chemical shifts expressed were in δ units. The mass spectra were measured with a JEOL 01SG-2 Spectrometer. The IR spectra were taken as KBr disks or as a liquid film inserted between NaCl plates using a Jasco IR-A 102 Spectrometer. Optical rotations were measured with a Union Model PM-101 apparatus. The solvents for the reactions were carefully purified by distillation under an N_2 atmosphere immediately before use, and absolutely anhydrous unless otherwise specified. The stationary phase for the column chromatography was Wako Gel C 300 throughout, and elusion systems were mixtures of hexane and ethyl acetate (99:1 to 90:10).

Hydrolysis and Epimerization of 3 to 4. To a tetrahydrofuran (THF) solution (50 cm^3) of **3**[5] (1.69 g), silica gel (11 g), and KF (5.5 g) were added and stirred at 15—25 °C for 2 d. The mixture was then passed through a Florisil column and the residue, obtained by removing the solvent, was dissolved in MeOH (80 cm^3), to which Florisil (6 g) and KF (6 g) were added and kept at 15—25 °C for 1 d. The mixture was filtered on a Florisil column and the residue obtained by removing the solvent was chromatographed on a silica-gel column to give **4** [a colorless oil, 1.27 g; 84%. Found: C, 82.05; H, 10.40%. Calcd for $C_{27}H_{40}O_2$: C, 81.77, H, 10.12%. $[\alpha]_D^{24}$: −20.9° (*C* 2.29, $CHCl_3$). MS *m/z*, 396 (M^+). ^1H NMR δ=0.82 (3H, d, *J*=7 Hz), 0.87 (3H, d, *J*=7 Hz), 1.00 (3H, d, *J*=7 Hz), 1.18 (3H, s), 1.60 (3H, br s), 1.2—2.5 (13H, m), 2.5—2.9 (2H, m), 3.06 (1H, t, *J*=9 Hz), 3.21 (1H, dd, *J*=9, 4 Hz), 4.35 (1H, d, *J*=12 Hz), 4.40 (1H, d, *J*=12 Hz), 7.25 (5H,

br s), and 9.74 (1H, d, J=3 Hz). ^{13}C NMR δ=14.94 (q), 17.00 (q), 20.35 (q), 21.41 (q), 23.35 (t), 27.47 (t), 28.12 (q), 31.47 (t), 33.00 (d), 34.65 (d), 37.36 (t), 38.06 (t), 45.89 (d), 50.30 (s), 52.95 (d), 67.59 (d), 72.12 (t), 73.12 (t), 127.54 (d, 3C), 128.36 (d, 2C), 134.25 (s), 136.25 (s), 139.01 (s), and 205.72 (d). IR ν: 2950, 1715, 1455, 1370, 1100, 730, and 695 cm^{-1}].

LAH Reduction of 4 to 5. To a THF solution (20 cm^3) of **4** (1.18 g), added at 15—25 °C for 2 h was LAH (120 mg). The mixture was then treated with small portions of aq NH_4Cl and the resulting supernatant was dried on $MgSO_4$. After evaporation of the solvent, the residue was purified by silica-gel column chromatography to give **5** [a colorless oil, 1.15 g; 96%. Found: C, 81.24; H, 10.75%. Calcd for $C_{27}H_{42}O_2$: C, 81.35; H, 10.62%. $[\alpha]_D^{24}$: −39.3° (c 2.16, $CHCl_3$). MS m/z, 398 (M^+). ^{1}H NMR δ=0.84 (3H, d, J=7 Hz), 0.90 (3H, d, J=6 Hz), 1.02 (3H, d, J=7 Hz), 1.09 (3H, s), 1.60 (3H, br s), 1.2—2.0 (11H, m), 2.0—2.3 (4H, m), 2.75 (1H, m), 3.10 (1H, t, J=9 Hz). 3.29 (1H, dd, J=9, 4 Hz), 3.5—3.8 (2H, m), 4.40 (1H, d, J=12 Hz), 4.44 (1H, d, J=12 Hz), and 7.26 (5H, br s). ^{13}C NMR δ=14.94 (q), 17.06 (q), 17.71 (q), 22.30 (q), 23.47 (t), 24.41 (t), 28.53 (q), 29.88 (t), 31.00 (d), 34.71 (d), 37.36 (t), 37.53 (t), 46.53 (s), 47.83 (d), 53.18 (d), 56.24 (d), 63.95 (t), 72.48 (t), 73.18 (t), 127.48 (d), 127.66 (d, 2C), 128.42 (d, 2C), 135.30 (s, 2C), and 139.13 (s). IR ν: 2950, 1450, 1370, 1100, 1030, 730, and 695 cm^{-1}].

Catalytic Hydrogenolysis of 5 to 2. To an ethanol (EtOH) solution (6 cm^3) of **5** (310 mg), Pd/C (5%, 100 mg) was added and the mixture was stirred under an H_2 atmosphere at 15—25 °C for 24 h. After removing the catalyst and the solvent, the residue was chromatographed on a silica-gel column to give **2** [colorless crystals, mp 100—101.5 °C, 209 mg; 87%. Found: C, 77.96; H, 11.97%. Calcd for $C_{20}H_{36}O_2$: C, 77.87; H, 11.76%. $[\alpha]_D^{20}$: −30.8° (c 2.53, $CHCl_3$). ^{1}H NMR δ=0.83 (3H, d, J=6 Hz), 0.90 (3H, d, J=7 Hz), 0.95 (3H, d, J=7 Hz), 1.12 (3H, s), 1.61 (3H, br s), 1.2—2.4 (15H, m), 2.82 (2H, br s), 3.19 (1H, dd, J=11, 8 Hz), 3.48 (1H, dd, J=11, 5 Hz), and 3.6—3.8 (2H, m). ^{13}C NMR δ=15.06 (q), 16.71 (q), 17.82 (q), 22.18 (q), 23.00 (t), 24.47 (t), 28.83 (q), 29.36 (t), 30.83 (d), 36.47 (d), 37.36 (t), 37.71 (t), 46.59 (s), 47.18 (d), 53.24 (d), 56.30 (d), 63.18 (t), 64.36 (t), 135.48 (s), and 135.78 (s). IR ν: 3610, 2950, 1460, and 1010 cm^{-1}].

Diacetate 6 of 2. A pyridine solution (4 cm^3) of **2** (310 mg) was treated with Ac_2O (1 cm^3), and usual workup afforded a diacetate **6** [a colorless oil, 369 mg; 94%. Found: C, 73.36; H, 10.43%. Calcd for $C_{24}H_{40}O_4$: C, 73.43; H, 10.27%. MS m/z, 392 (M^+). ^{1}H NMR δ=0.84 (3H, d, J=6 Hz), 0.91 (3H, d, J=7 Hz), 0.97 (3H, d, J=7 Hz), 1.08 (3H, s), 1.61 (3H, br s), 1.3—1.9 (10H, m), 2.01 (3H, s), 2.04 (3H, s), 1.9—2.4 (4H, m), 2.75 (1H, m), 3.69 (1H, dd, J=10, 9 Hz), 3.85 (1H, dd, J=10, 5 Hz), and 4.0—4.2 (2H, m). ^{13}C NMR δ=14.88 (q), 16.65 (q), 17.59 (q), 20.88 (q, 2C), 22.00 (q), 22.88 (t), 24.41 (t), 28.12 (q), 29.59 (t), 30.65 (d), 33.36 (d), 37.24 (t, 2C), 46.47 (s), 47.94 (d), 52.47 (d), 53.00 (d), 65.59 (t), 66.30 (t), 134.36 (s), 136.01 (s), and 171.18 (s, 2C). IR ν: 2950, 1740, 1460, 1365, 1235, and 1030 cm^{-1}].

Bis(tetrahydropyranyl) Derivatives 7 of 2. A CH_2Cl_2 solution (4 cm^3) of **2** (209 mg) was treated with dihydropyran (0.2 cm^3) and pyridinium p-toluenesulfonate (PPTS, 20 mg) at 15—25 °C for 15 h. The mixture was then extracted with ether, washed with aq $NaHCO_3$, and dried over $MgSO_4$. After evaporation of the volatile material, the residue was chromatographed on a silica-gel column to give **7** [a colorless oil, 323 mg; 100%. Found: m/z, 476.3860 (M^+). Calcd for $C_{30}H_{52}O_4$: 476.3863. ^{1}H NMR δ=0.7—1.1 (9H, m), 1.09 (3H, s), 1.58 (3H, br s), 1.3—2.4 (26H, m), 2.75 (1H, m), 3.2—3.6 (4H, m), 3.6—4.0 (4H, m), and 4.4—4.6 (2H, m). IR ν: 2950, 1450, 1195, 1115, 1025, and 970 cm^{-1}].

Catalytic Reduction and Subsequent LAH-Reduction of 6 to 8a, 8b, and 8c. An AcOH solution (15 cm^3) of **6** (889 mg) was reduced with PtO_2 (95 mg) at 15—25 °C for 24 h under an H_2 atmosphere to give an oily stereoisomeric dihydro derivatives (866 mg; 97%), which was dissolved in a THF solution (10 cm^3) and reduced with LAH (250 mg) to give a stereoisomeric mixture. High-pressure liquid chromatography (Micropolasil, hexane-EtOAc (10:1)) of the mixture afforded **8a** [colorless crystals, mp 113—114 °C, 252 mg; 40%. Found:C, 77.31; H, 12.26%. Calcd for $C_{20}H_{38}O_2$: C, 77.36; H, 12.33%. MS m/z, 310 (M^+). ^{1}H NMR δ=0.82 (3H, d, J=7 Hz), 0.84 (3H, d, J=7 Hz), 0.89 (3H, d, J=7 Hz), 0.99 (3H, d, J=6 Hz), 1.05 (3H, s), 1.1—2.4 (19H, m), 3.35 (1H, dd, J=10, 8 Hz), and 3.5—3.8 (3H, m). ^{13}C NMR δ=15.53 (q), 17.06 (q), 18.06 (q), 22.35 (q), 24.18 (t), 24.88 (t), 27.71 (q), 31.47 (d), 32.47 (t), 33.24 (t), 36.83 (d), 37.41 (d), 38.00 (t), 41.65 (d), 44.89 (s), 47.00 (d), 47.89 (d), 56.06 (d), 64.12 (t), and 65.36 (t). IR ν: 3300, 2950, 1445, 1370, and 1020 cm^{-1}], **8b** [colorless crystals, mp 69—70.5 °C, 188 mg; 28%. Found: m/z, 310.2882 (M^+). Calcd for $C_{20}H_{38}O_2$: 310.2870. ^{1}H NMR δ=0.84 (3H, d, J=6 Hz), 0.90 (3H, d, J=6 Hz), 0.91 (3H, d, J=6 Hz), 1.00 (3H, d, J=6 Hz), 1.06 (3H, s), 1.1—2.2 (19H, m), 3.37 (1H, dd, J=10, 7 Hz), and 3.5—3.8 (3H, m). ^{13}C NMR δ=16.53 (q), 18.06 (q), 21.47 (q), 22.41 (q), 24.83 (t), 27.94 (t), 28.12 (q), 31.41 (d), 33.12 (t), 38.06 (t), 40.12 (d), 41.00 (d), 43.12 (t), 45.36 (s), 45.94 (d), 47.89 (d), 52.42 (d), 56.18 (d), 63.95 (t), and 66.42 (t). IR ν: 3250, 2950, 1460, 1370, and 1030 cm^{-1}], and **8c** [colorless crystals, mp 94—95.5 °C, 119 mg; 17%. Found: m/z, 310.2882 (M^+). ^{1}H NMR δ=0.85 (3H, d, J=6 Hz), 0.90 (3H, d, J=7 Hz), 0.94 (3H, d, J=7 Hz), 1.00 (3H, d, J=6 Hz), 1.04 (3H, s), 1.0—2.2 (19H, m), 3.39 (1H, br dd, J=10, 6 Hz), and 3.5—3.8 (3H, m). ^{13}C NMR δ=16.87 (q), 17.85 (q), 18.44 (q), 22.30 (q), 24.61 (t), 25.47 (t), 26.48 (t), 28.40 (q), 30.51 (t), 31.05 (d), 35.04 (d), 37.58 (t), 39.10 (d), 40.20 (d), 44.49 (s), 47.66 (d), 50.90 (d), 55.82 (d), 63.75 (t), and 67.38 (t)].

Catalytic Deuteration of 6. Similarly, **6** (207 mg) was reduced with deuterium gas in the presence of PtO_2 (20 mg) in AcOD (4 cm^3) and, without isolation, consecutively reduced with LAH to give the deuterio derivatives of **8a**, **8b**, and **8c** in similar product distributions. Silica-gel column chromatography of the mixture afforded analytically pure samples.

THP-Ether 9 from 5. As a manner similar to the formation of **7**, **5** (1.10 g) was treated with dihydropyran (0.5 cm^3) and PPTS (20 mg) to give **9** [a colorless oil, 1.24 g; 95%. Found: C, 79.82; H, 10.56%. Calcd for $C_{32}H_{50}O_3$: C, 79.62; H, 10.44%. MS m/z, 482 (M^+). ^{1}H NMR δ=0.83 (3H, d, J=7 Hz), 0.90 (3H, d, J=7 Hz), 1.02 (3H, d, J=7 Hz), 1.08 (3H, s), 1.58 (3H, br s), 1.2—2.0 (16H, m), 2.0—2.4 (4H, m), 2.75 (1H, m), 3.09 (1H, t, J=9Hz), 3.27 (1H, dd, J=9.4 Hz), 3.3—3.6 (2H, m), 3.6—4.0 (2H, m), 4.37 (1H, d, J=12 Hz), 4.43 (1H, d, J=12 Hz), 4.54 (1H, m), and 7.25 (5H, br s). IR ν: 2950, 1450, 1365, 1200, 1115, 1025, 730, and 695 cm^{-1}].

Catalytic Hydrogenolysis of 9 to 10. An EtOH solution (12 cm^3) of **9** (1.26 g) was hydrogenated with Pd/carbon (5%, 120 mg) at 15—25 °C for 23 h to give **10** [a colorless oil, 997 mg; 97%. Found: C, 76.29; H, 11.49%. Calcd for

$C_{25}H_{44}O_3$: C, 76.48; H, 11.30%. MS *m/z*, 392 (M^+). ^1H NMR δ=0.8—1.0 (9H, m), 1.08 (3H, s), 1.61 (3H, br s), 1.2—1.9 (16H, m), 1.9—2.4 (5H, m), 2.78 (1H, m), 3.1—3.7 (4H, m), 3.7—4.0 (2H, m), and 4.53 (1H, m). IR ν: 3450, 2950, 1460, 1370, 1200, 1120, 1030, and 980 cm^{-1}].

Na-*t*-BuOH-HMPA-Reduction of 10 to 8a, 8b, and 8d. To HMPA (60 cm^3), metallic Na (350 mg) was added under an N_2 atmosphere. To a blue solution, thus formed, *t*-BuOH (1 cm^3) was added with stirring. Then, **2** (1.30 g) was introduced at 15—25 °C under an N_2 atmosphere and stirring continued for further 15 h. The mixture was then extracted with ether, washed with water, and dried on $MgSO_4$. Silica-gel column chromatography of the organic material gave an oily mixture (1.24 g; 95%), which was subsequently dissolved in MeOH (12 cm^3) containing *p*-TsOH (120 mg) and refluxed for 3 h. The mixture was then extracted with EtOAc and chromatographed on a silica-gel column to give **8a** (660 mg; 70%), **8b** (126 mg; 13%), and **8d** [colorless crystals, mp 142—143 °C, 31.3 mg; 3%. Found: *m/z*, 310.1905 (M^+). Calcd for $C_{20}H_{38}O_2$: 310.2870. ^1H NMR δ=0.84 (3H, d, *J*=6 Hz), 0.91 (3H, d, *J*=7 Hz), 0.94 (3H, d, *J*=7 Hz), 0.97 (3H, d, *J*=6 Hz), 1.06 (3H, s), 2.02 (2H, br s), 1.2—2.2 (17H, m), 3.32 (1H, dd, *J*=10, 7 Hz), and 3.5—3.8 (3H, m). ^{13}C NMR δ=16.64 (q), 18.20 (q), 22.30 (q), 22.38 (q), 25.23 (t), 27.50 (t), 27.81 (q), 31.41 (d), 31.60 (t, 2C), 36.13 (d), 37.85 (t), 39.10 (d), 44.41 (d), 44.80 (s), 45.66 (d), 47.58 (d), 56.21 (d), 64.02 (t), and 67.62 (t). IR ν: 3250, 2950, 1450, 1365, and 1020 cm^{-1}], **8a**, and **8b** were identical with the sample prepared from **2**.

Acetate 12 of 5. A pyridine solution (3 cm^3) of **5** (296 mg) was treated with Ac_2O (0.5 cm^3) to give, after a usual workup, **12** [a colorless oil, 317 mg; 97%. Found: C, 79.15; H, 10.14%. Calcd for $C_{29}H_{44}O_3$: C, 79.04; H, 10.06%. MS *m/z*, 440 (M^+). ^1H NMR δ=0.83 (3H, d, *J*=7 Hz), 0.90 (3H, d, *J*=7 Hz), 1.02 (3H, d, *J*=7 Hz), 1.07 (3H, s), 1.56 (3H, br s), 1.2—1.9 (10H, m), 2.00 (3H, s), 1.9—2.3 (4H, m), 2.71 (1H, m), 3.08 (1H, t, *J*=9 Hz), 3.25 (1H, dd, *J*=9, 4 Hz), 4.10 (2H, br d, *J*=7 Hz), 4.36 (1H, d, *J*=12 Hz), 4.43 (1H, d, *J*=12 Hz), and 7.24 (5H, br s). IR ν: 2950, 1740, 1450, 1360, 1240, 1100, 1025, 730, and 695 cm^{-1}].

Catalytic Hydrogenolysis of 12 and 13. A mixture of **12** (303 mg) and Pd/C (5%, 30 mg) in EtOH (6 cm^3) was stirred under an H_2 atmosphere at 15—25 °C for 24 h. After removing the catalyst and the solvent, the residue was chromatographed on a silica-gel column to give **13** [a colorless oil, 208 mg; 86%. Found: C, 75.48; H, 11.19%. Calcd for $C_{22}H_{38}O_3$: C, 75.38; H, 10.93%. MS *m/z*, 350 (M^+). ^1H NMR δ=0.83 (3H, d, *J*=6 Hz), 0.90 (3H, d, *J*=7 Hz), 0.94 (3H, d, *J*=7 Hz), 1.07 (3H, s), 1.61 (3H, br s), 2.03 (3H, s), 1.2—2.3 (15H, m), 2.74 (1H, m), 3.23 (1H, dd, *J*=11, 8 Hz), 3.49 (1H, dd, *J*=11, 6 Hz), and 4.13 (2H, br d, *J*=6 Hz). IR ν: 3450, 2950, 1740, 1460, 1370, 1240, and 1030 cm^{-1}].

THP-Ether 14 of 13. A CH_2Cl_2 solution (4 cm^3) of **13** (208 mg) was treated with dihydropyran (0.1 cm^3) and PPTS (20 mg) to give **14** [a colorless oil, 257 mg; 100%. Found: C, 74.63; H, 10.83%. Calcd for $C_{27}H_{46}O_4$: C, 74.61; H, 10.67%. MS *m/z*, 434 (M^+). ^1H NMR δ=0.8—1.1 (9H, m), 1.09 (3H, s), 1.60 (3H, br s), 1.2—2.0 (16H, m), 2.03 (3H, s), 2.0—2.3 (4H, m), 2.74 (1H, m), 2.8—4.0 (4H, m), 4.11 (2H, br d, *J*=6 Hz), and 4.46 (1H, m). IR ν: 2950, 1745, 1460, 1370, 1240, 1125, 1035, and 970 cm^{-1}].

LAH-Reduction of 14 to 11. A THF solution (2 cm^3) of **14** (257 mg) was treated with LAH (23 mg) at 0 °C for 1 h. A small amount of aq NH_4Cl was added, and the resulting supernatant was dried on $MgSO_4$ and evaporated in vacuo. The residue was chromatographed on a silica-gel column to give **11** [a colorless oil, 220 mg; 94%. Found: *m/z*, 392.3288 (M^+). Calcd for $C_{25}H_{44}O_3$: 392.3288. ^1H NMR δ=0.8—1.1 (9H, m), 1.10 (3H, s), 1.56 (3H, br s), 1.1—2.0 (17H, m), 2.0—2.4 (4H, m), 2.76 (1H, m), 2.9—3.9 (6H, m), and 4.50 (1H, m). IR ν: 3450, 2950, 1460, 1370, 1120, 1030, 980, 905, 870, and 810 cm^{-1}].

Na-*t*-BuOH-HMPA-Reduction of 11 to 8b and 8d. Similar to the reduction of **10**, **11** (180 mg) was treated with Na (42 mg) and *t*-BuOH (0.14 cm^3) in an HMPA (6 cm^3). Successive treatments with *p*-TsOH (20 mg) in refluxing MeOH (4 cm^3) afforded a mixture of dihydro-diols. Silica-gel column chromatography of the mixture gave **8b** (40 mg; 28%) and **8d** (94 mg; 66%). Despite careful inspections of every chromatographic fraction, no **8a** was detected.

Swern's Oxidation of 8a to Dial (15). To a CH_2Cl_2 solution (16 cm^3) of $(COCl)_2$ (0.68 cm^3), DMSO (1.10 cm^3) was added drop by drop at −78 °C for 15 min. Then, a THF solution (5 cm^3) of **8a** (801 mg) was added and stirred for another 30 min; after the introduction of Et_3N (7.2 cm^3), the temperature was gradually raised to −10 °C, and treated with aq $NaHCO_3$. The mixture was extracted with EtOAc, and the organic extract was chromatographed on a silica-gel column to give **15** [a colorless oil, 747 mg; 95%. Found: *m/z*, 306.2561 (M^+). Calcd for $C_{20}H_{34}O_2$: 306.2557. ^1H NMR δ=0.80 (3H, d, *J*=7 Hz), 0.82 (3H, d, *J*=7 Hz), 0.87 (3H, d, *J*=7 Hz), 1.11 (3H, d, *J*=7 Hz), 1.17 (3H, s), 1.2—2.5 (17H, m), 9.67 (1H, d, *J*=2 Hz), and 9.70 (1H, br s). ^{13}C NMR δ=13.12 (q), 15.12 (q), 20.41 (q), 21.41 (q), 24.65 (t), 27.24 (q), 27.59 (t), 33.00 (t, 2C), 33.71 (d), 36.65 (d), 38.41 (t), 42.36 (d), 45.77 (d), 45.89 (d), 47.71 (d), 48.94 (s), 67.59 (d), 205.60 (d), and 205.83 (d). IR ν: 2950, 1720, 1460, and 1380 cm^{-1}].

Bis(TMS-Enol Ether) 16 of 15. To a CH_2Cl_2 solution (8 cm^3) of **15** (747 mg), Et_3N (1.7 cm^3) and trimethylsilyl triflate (2.26 cm^3) were added under an N_2 atmosphere, and stirred for 15 h. The mixture was then washed with aq K_2CO_3 and extracted with ether. Florisil-column chromatography of the organic material afforded **16** [a colorless oil, 942 mg; 86%. Found: *m/z*, 450.3368 (M^+). Calcd for $C_{26}H_{50}O_2Si_2$: 450.3338. ^1H NMR δ=0.16 (18H, s), 0.74 (3H, d, *J*=6 Hz), 0.80 (3H, d, *J*=7 Hz), 0.87 (3H, d, *J*=7 Hz), 0.97 (3H, s), 1.2—2.8 (18H, m), and 5.9—6.0 (2H, m). IR ν: 2950, 1665, 1445, 1250, 1155, 870, 840, and 750 cm^{-1}].

$Pd(OAc)_2$-Oxidation of 16. Formation of 17 and 18. To an acetonitrile solution (5 cm^3) of **16** (216 mg) was added $Pd(OAc)_2$ (160 mg) under N_2 atmosphere. After stirring at 15—25 °C for 6 h, the mixture was filtered on a Florisil column, and washed with ether. The residue obtained by removing the solvent was chromatographed on a silica-gel column to give **17** [a colorless oil, 136 mg; 75%. Found: C, 73.17; H, 10.91%. Calcd for $C_{23}H_{40}O_2Si$: C, 73.34; H, 10.70%. MS *m/z*, 376 (M^+). ^1H NMR δ=0.14 (9H, s), 0.73 (3H, d, *J*=7 Hz), 0.86 (6H, d, *J*=7 Hz), 0.96 (3H, s), 1.1—2.8 (15H, m), 5.9—5.95 (2H, m), 6.22 (1H, s), and 9.50 (1H, s). IR ν: 2950, 1690, 1660, 1250, 1150, 865, and 845 cm^{-1}] and **18** [a colorless oil, 13.2 mg; 9%].

DIBAH-Reduction of 17. Formation of 19. To a toluene solution (5 cm^3) of **17** (494 mg), DIBAH dissolved in hexane (1.8 M, 1 cm^3) was added under an N_2 atmosphere and kept at −78 °C for 30 min with stirring. The mixture was then diluted with aq NH_4Cl and extracted with ether. After

removing the solvent, the residue was chromatographed on a silica-gel column to give **19** [a colorless oil, 359 mg; 72%. Found: C, 72.91; H, 11.25%. Calcd for $C_{23}H_{42}O_2Si$: C, 72.95; H, 11.18%. MS *m/z*, 378 (M^+). ^1H NMR δ=0.15 (9H, s), 0.74 (3H, d, *J*=7 Hz), 0.83 (3H, d, *J*=7 Hz), 0.87 (3H, d, *J*=7 Hz), 0.99 (3H, s), 1.1—2.5 (15H, m), 2.65 (1H, br s), 4.04 (2H, br s), 4.86 (1H, br s), 5.04 (1H, q, *J*=1.5 Hz), and 5.98 (1H, d, *J*=2 Hz). IR ν: 3300, 2950, 1660, 1450, 1375, 1250, 1155, 1055, 870, 840, and 750 cm^{-1}].

$^1O_2$-Oxygenation of 19 to 20. An acetone solution (10 cm^3) of **19** (359 mg), pyridine (30 mg), and Rose Bengal (30 mg) was irradiated by means of 500-W tungsten lamp with an air stream at 0—5 °C. After 20 min, the mixture was treated with PPh_3 (373 mg) and kept at 15—25 °C for 15 h. The residue obtained by removing the solvent was then purified with silica-gel column chromatography to give **20** [a colorless oil, 236 mg; 82%. Found: *m/z*, 304.2399 (M^+). Calcd for $C_{20}H_{32}O_2$: 304.2401. $[\alpha]_D^{25}$: −57.8° (*c* 1.28, $CHCl_3$). ^1H NMR δ=0.86 (3H, d, *J*=7 Hz), 1.09 (3H, d, *J*=7 Hz), 1.10 (3H, d, *J*=7 Hz), 1.17 (3H, s), 1.2—2.4 (14H, m), 3.40 (1H, sept, *J*=7 Hz), 3.96 (2H, br s), 4.80 (1H, br s), 5.06 (1H, q, *J*=1.5 Hz), and 9.90 (1H, s). ^{13}C NMR δ=16.00 (q), 21.59 (q, 2C), 26.24 (t), 26.83 (d), 28.94 (q), 30.06 (t), 33.41 (t), 35.59 (t), 36.06 (t), 36.06 (d), 44.71 (d), 48.00 (d), 49.94 (s), 64.42 (t), 108.89 (t), 142.19 (s), 152.30 (s), 172.78 (s), and 188.96 (d). IR ν: 3450, 2950, 1660, 1650, 1450, 1050, 1020, and 890 cm^{-1}].

MsCl-Treatment of 20 to 21. A toluene solution (3 cm^3) of **20** (31.2 mg) was treated with MsCl (0.12 cm^3) and pyridine (0.24 cm^3) at 0 °C under an N_2 atmosphere for 15 h. The mixture was then diluted with aq $NaHCO_3$ and extracted with ether. The extract was chromatographed on a silica-gel column to give **21** [a colorless oil, 29 mg; 76%. Found: *m/z*, 382.2141 (M^+). Calcd for $C_{21}H_{34}O_4S$: 382.2176. ^1H NMR δ=0.88 (3H, d, *J*=7 Hz), 1.10 (6H, d, *J*=7 Hz), 1.19 (3H, s), 1.2—2.6 (13H, m), 3.00 (3H, s), 3.41 (1H, sept, *J*=7 Hz), 4.58 (2H, br s), 5.01 (1H, br s), 5.16 (1H, br s), and 9.94 (1H, s). IR ν: 2950, 1660, 1610, 1460, 1360, 1170, 830, and 730 cm^{-1}].

$CrCl_2$-Cyclization of 21. Formation of 22. A THF solution (5 cm^3) of $CrCl_2$ (prepared from $CrCl_3$, 158 mg, and LAH, 19 mg), was diluted with *N*,*N*-dimethylformamide (DMF, 30 cm^3) and then **21** (29 mg) in THF (2 cm^3) was added at 0 °C under N_2 atmosphere, and kept stirring for 15 h. The mixture was then diluted with water, extracted with ether, and dried on $MgSO_4$. Silica-gel column chromatography of the organic material gave **22** [colorless scales, mp 64—65 °C, 12.4 mg; 78%. Found: C, 83.27; H, 11.46%. Calcd for $C_{20}H_{32}O$: C, 83.27; H, 11.18%. $[\alpha]_D^{24}$: −21.8° (*c* 2.66, $CHCl_3$). MS *m/z*, 288 (M^+). ^1H NMR δ=0.84 (3H, d, *J*=7 Hz), 0.91 (3H, d, *J*=6 Hz), 0.96 (3H, d, *J*=7 Hz), 1.20 (3H, s), 1.2—2.6 (16H, m), 2.73 (1H, sept, *J*=7 Hz), 4.77 (1H, dd, *J*=8, 7 Hz), 4.79 (1H, br s), and 4.95 (1H, m). ^{13}C NMR δ=17.59 (q), 21.47 (q), 21.94 (q), 27.12 (d), 27.94 (t), 28.65 (t), 29.83 (q), 31.41 (t), 38.18 (d), 38.71 (t), 40.65 (t), 41.00 (d), 45.06 (d), 50.36 (d), 51.53 (s), 69.06 (d), 113.48 (t), 139.30 (s), 148.19 (s), and 148.72 (s). IR ν: 3350, 2950, 1640, 1455, 1380, 1000, 885, and 730 cm^{-1}].

Acetylation of 22 to 23. A pyridine solution (1 cm^3) of **22** (79.1 mg) was treated with Ac_2O (0.2 cm^3) at 15—25 °C to give **23** [a colorless oil, 80.8 mg; 96%. $[\alpha]_D^{26}$: −39.8° (*c* 2.31, $CHCl_3$). Found: C, 80.19; H, 10.39%. Calcd for $C_{22}H_{34}O_2$: C, 79.95; H, 10.34%. MS *m/z*, 330 (M^+). ^1H NMR δ=0.85 (3H, d, *J*=7 Hz), 0.89 (3H, d, *J*=7 Hz), 0.94 (3H, d, *J*=7 Hz), 1.17 (3H, s), 1.2—2.6 (16H, m), 2.85 (1H, sept, *J*=7 Hz), 1.97 (3H, s), 4.80 (1H, br s), 4.90 (1H, br s), and 5.84 (1H, dd, *J*=10, 7 Hz). ^{13}C NMR δ=17.35 (q), 21.06 (q), 21.47 (q, 2C), 27.30 (d), 27.94 (t, 2C), 30.00 (q), 31.00 (t), 38.36 (t), 38.71 (t), 38.71 (d), 42.77 (t), 45.36 (d), 49.83 (d), 51.12 (s), 71.83 (d), 112.24 (t), 133.60 (s), 147.31 (s), 151.31 (s), and 170.30 (s). IR ν: 2950, 1750, 1650, 1470, 1390, 1255, 1040, 975, and 910 cm^{-1}].

Li-NH_3 Reduction of 23. Formation of 1. At −78 °C, to liq NH_3 containing **23** (11.5 mg), an excess of Li metal, two drops of *t*-BuOH, and THF (1 cm^3) were added. After stirring for 30 min, the mixture was diluted with hexane, and sodium benzoate was added until the solution became yellow. Then, NH_4Cl was added and NH_3 was allowed to vaporize in a hood; the residue, thus obtained, was diluted with hexane, washed with aq $NaHCO_3$, and dried on $MgSO_4$. Silica-gel column chromatography of the organic material gave **1** [9.8 mg; 95%. Found: *m/z*, 272.2527 (M^+). Calcd for $C_{20}H_{32}$: 272.2502. $[\alpha]_D^{27}$: −37.5° (*c* 0.21, $CHCl_3$). ^1H NMR δ=0.82 (3H, d, *J*=7 Hz), 0.87 (3H, s), 0.89 (3H, d, *J*=7 Hz), 0.97 (3H, d, *J*=7 Hz), 1.1—2.5 (17H, m), 2.59 (1H, sept, *J*=7 Hz), 4.67 (1H, m), and 4.76 (1H, d, *J*=2 Hz). ^{13}C NMR δ=16.36 (q), 21.19 (q), 21.34 (q), 24.22 (t), 26.90 (q), 27.10 (t), 27.39 (d), 31.69 (t), 33.06 (t), 35.89 (t), 36.03 (t), 39.16 (d), 40.48 (t), 47.17 (d), 49.32 (d), 50.78 (s), 110.59 (t), 138.91 (s), 142.43 (s), and 155.95 (s). IR ν: 3070, 2955, 2860, 1635, 1450, 1375, 1360, 1330, 1100, and 880 cm^{-1}].

Reactivities of Stable Rotamers. XXII. Lewis Acid-Catalyzed Reactions of 3-(1,4-Disubstituted 9-Triptycyl)-3-methylbutanoyl Chloride: Isolation of Rotameric Ketones and Competition between Cyclizations to Substituted and to Unsubstituted Benzene Rings[1,2]

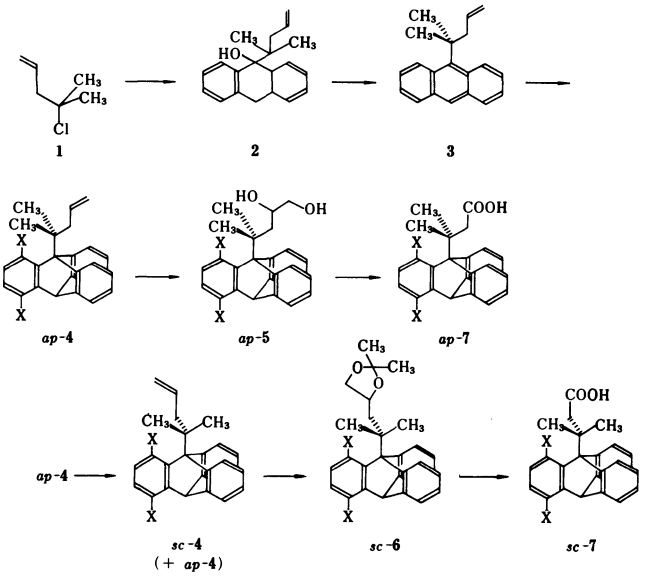
Toshimasa TANAKA, Katsumi YONEMOTO, Yasufumi NAKAI, Gaku YAMAMOTO, and Michinori ŌKI*,†
Department of Chemistry, Faculty of Science, The University of Tokyo, Bunkyo-ku, Tokyo 113
(Received March 18, 1988)

Rotational isomers of 3-(1,4-disubstituted 9-triptycyl)-3-methylbutanoic acid, where the substituent is either a methoxyl or a methyl, have been prepared, starting from 1,4-disubstituted 9-(1,1-dimethyl-3-butenyl)triptycene. Lewis acid-catalyzed reactions of the *ap*-acid chloride afforded corresponding ketones expected from the intramolecular Friedel–Crafts reaction. The *sc* form of the 1,4-dimethoxy compound gave a ketone that was formed by the reaction of the unsubstituted benzene ring and a lactone which was derived by the attack of the acylium ion on the methoxy-oxygen followed by demethylation. The *sc* form of the 1,4-dimethyl compound afforded a ketone which was expected from cyclization to the unsubstituted benzene ring and another ketone that was derived from the ipso attack of the acylium ion followed by 1,2-methide migration. In both cases, the ketone derived from the *ap* form of the acid chloride was different from that obtained from the *sc*. The barriers to isomerization of the *ap*-ketone to the *sc*-ketone was 29.6 kcal mol^{-1} at 100.5 °C and 25.6 kcal mol^{-1} at 56.0 °C for the methoxy and the methyl compounds, respectively. In both cases, the ketone derived from the *sc*-form was more stable than that from the *ap*, the *sc*/*ap* ratio at the equilibrium being 20.0 (56.0 °C) and 5.9 (100.5 °C), respectively, for the methyl and the methoxy compounds. In the reaction of the *sc* form, the competitive results between the cyclization toward the unsubstituted benzene ring and that toward the substituted vary according to the solvent and the Lewis acid used.

Since the isolation of rotational isomers in the triptycene and 9-arylfluorene series,[3] we have been interested in the study of reactivities of rotational isomers.[3] Due to the difficulty in the syntheses of the triptycene series, the examples that have been studied are rather limited: halogenation of a *t*-butyl group,[5] and some radical reactions[6] and cation-forming reactions[7] of the halogenated compounds. We now wish to report successful isolation of 3-(1,4-disubstituted 9-triptycyl)-3-methylbutanoic acid rotamers where the substituents are methyls or methoxyls and Lewis acid-catalyzed reactions of the corresponding acid chlorides.

Results

Syntheses of the compounds were carried out in the following ways. A Grignard reagent prepared from 4-chloro-4-methyl-1-pentene (**1**) was added to 9-anthrone and the adduct (**2**) was treated with phosphorus pentaoxide to form 9-(1,1-dimethyl-3-butenyl)anthracene (**3**). Addition of benzynes to the anthracene afforded the corresponding olefinic triptycenes (**4**), the *ap* isomer being the major product. Recrystallization of the product from hexane–dichloromethane afforded pure *ap*-form of **4**. The *ap*-olefins were oxidized with trimethylamine oxide in the presence of osmium tetraoxide[8] to the corresponding diols which were successively oxidized with periodic acid[9] and then with potassium permanganate to yield the desired *ap*-carboxylic acid (*ap*-**7**). Separation of the *sc*-isomers was tried at various stages of the synthesis of the carboxylic acid (**7**) but none of them was promising. Thus, although the number of steps required for the synthesis increased, we derived the corresponding diols to acetonides which were separated by chromatography. The best route to the prepartion of the *sc*-acid (*sc*-**7**) was the following. The



Scheme 1. Synthetic routes to 3-(1,4-disubstituted 9-triptycyl)-3-methylbutanoic acid rotamers: X is a methoxyl or a methyl. Only one form of the *sc* is shown.

† Present address: Department of Chemistry, Faculty of Science, Okayama University of Science, Ridaicho, Okayama 700.

olefin (**4**) was heated in 1-chloronaphthalene to isomerize and the *sc*-enriched olefin was oxidized with trimethylamine oxide as above and the resulted diols **5** were converted to acetonides in the presence of *p*-toluenesulfonic acid. The acetonides (**6**) were separated by medium-pressure chromatography on silica gel, the *sc* form giving two diastereomers (two pairs of enantiomers) due to the fact that a new chiral center was formed in addition to the chirality due to the frozen rotation about the C_9-to-substituent bond. The separated two forms of *sc*-acetonides were hydrolyzed to regenerate the diols (*sc*-**5**) which were similarly oxidized with periodic acid and then with potassium permanganate to yield the *sc*-carboxylic acid (*sc*-**7**).

3-(1,4-Dimethoxy-9-triptycyl)-3-methylbutanoic acid (**7a**) was treated with oxalyl dichloride to produce the corresponding chloride which was then treated with titanium(IV) chloride in benzene. *ap*-**7a** gave the corresponding ketone (*ap*-**8a**) in a good yield, whereas *sc*-**7a** afforded the corresponding ketone (*sc*-**8a**) and a lactone (**9**) which was formed by the reaction of intervening acylium ion on the methoxy-oxygen followed by demethylation. The formation ratio, *sc*-**8a**/**9**, varied when the solvent and/or the catalyst was varied and the results are shown in Table 1. *ap*-**8** and *sc*-**8** were definitely different, though they melted at the same temperature and their analytical data as well as the spectral data were all consistent with the proposed structure, 8,11-dimethoxy-1,1-dimethyl-1,2-dihydro-7*H*-7,11b-*o*-benzeno-3*H*-benz[*de*]anthracen-3-one.

The similar treatment of *ap*-3-(1,4-dimethyl-9-triptycyl)-3-methylbutanoic acid (*ap*-**7b**) afforded the corresponding ketone (*ap*-**8b**) as a sole product. By contrast, *sc*-**7b** yielded under the similar conditions a ketone (*sc*-**8b**) which was conformationally isomeric with *ap*-**8b** and another ketone to which we assign structure **10** from spectroscopic evidence and from consideration of reaction mechanisms. The formation ratio, *sc*-**8b**/**10**, was affected again by the reaction conditions, solvent and Lewis acid. The results are summarized in Table 2.

Heating *ap*-**7b** with thionyl chloride afforded *ap*-**8b** and a vinyl chloride type compound (**11**) which could be independently synthesized from *ap*-**8b** and thionyl chloride. Similarly *sc*-**7b** afforded **11** and another vinyl chloride type compound(**12**)in addition to *ap*-**8b** and **10**, when it was heated with thionyl chloride. **12** was independently synthesized from **10** and thionyl chloride.

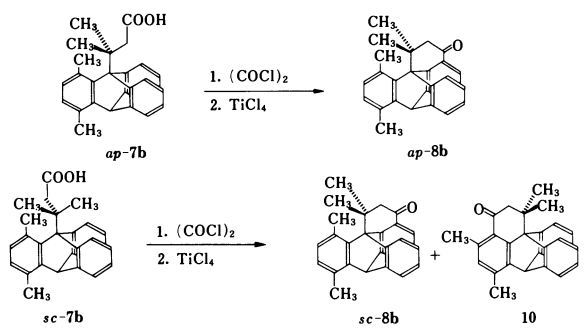
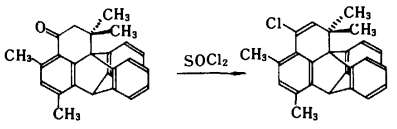
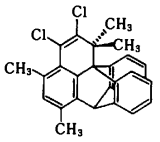


Scheme 3. Reaction of *ap*-**7b** and *sc*-**7b** under the Friedel-Crafts conditions. Only one enantiomeric form is shown.



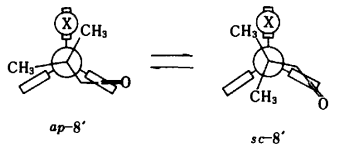
9 12

Further heating of the chloro compound (**12**) with thionyl chloride afforded further-chlorinated compounds, the main product being a dichloro compound to which we assign the structure of 2,3-dichloro-1,1,4,6-tetramethyl-7*H*-7,11b-*o*-benzeno-1*H*-benz[*de*]-anthracene (**13**). The reason for the assignment is the loss of the olefinic proton signal in its ^{1}H NMR spectra. However, the compound could not be purified to give the correct elemental analyses. Mass spectra of the enriched dichloro compound **13** showed that there were even trichlorinated and tetrachlorinated compounds as contaminants. Interestingly **11** did not give further-chlorinated compound on the same treatment as above.



13

The ketone **8** obtained from the *ap*-form and the *sc* of the acids could be isomerized by heating. The rate constants for isomerization, thermodynamic parameters, and activation parameters are shown in Tables 3 and 4. Apparently, the barrier to rotation in the methyl series was lower than that of the methoxyl series and at the equilibrium the *sc*-ketone was favored over the *ap*, the preference being greater in the methyl series than in the methoxyl series.



ap-8′ *sc*-8′

Scheme 4. Isomerization of ketones (**8**): X is either a methoxyl or a methyl.

Table 3. Rate Constants for Isomerization, *ap*-**8a** → *sc*-**8a**, Equilibrium Constants, Thermodynamic Parameters and Activation Parameters

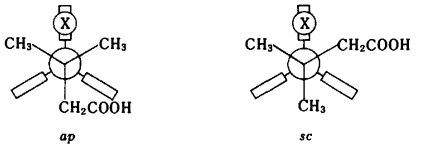
Temperature/°C	$k\times10^5$/s^{-1}	K(*sc*-**8a**/*ap*-**8a**)
77.5	0.31±0.01	6.2
90.0	1.24±0.04	6.0
100.5	3.8 ±0.1	5.9
111.5	11.1 ±0.4	5.6

ΔH^*=27.6±0.6 kcal mol^{-1}; ΔS^*=−5±2 cal mol^{-1} K^{-1}; $\Delta H°$=−0.8±0.6 kcal mol^{-1}; $\Delta S°$=1±2 cal mol^{-1} K^{-1}.

The gem-dimethyl groups in **9**, **10**, and **12** were found to be diastereotopic in ^{1}H NMR spectra, suggesting that there are enantiomers. The barriers to racemization were investigated but are apparently higher than 26 kcal mol^{-1} (1 cal=4.184 J), because their ^{1}H NMR spectra did not change up to 130 °C.

Discussion

When one looks at the Newman-type projections of the *ap*-acid and the *sc*, it is clear why the *ap*-acid gives a ketone as a sole product, because the cyclization to one benzeno bridge gives an enantiomer of the one that is obtained by cyclization to another benzeno bridge. The carboxyl group in the *ap* is too far to have any significant interactions with the substituted benzeno bridge. By contrast,the carboxymethyl group in the *sc* isomer is flanked by an unsubstituted and a substituted benzeno bridge. If cyclization takes place to the unsubstituted benzeno bridge, the ketone (**8**) is formed, whereas the acid gives another product if it reacts with the other substituted benzeno bridge.



ap *sc*

The structures of the products other than the normal ketones were elucidated in the following ways. Compound **9** showed in its ^{1}H NMR spectra the loss of one methoxy-methyl group: that is consistent with the high resolution MS. Infrared spectrum showed an absorption at 1750 cm^{-1} to indicate the presence of an ester group. This is confirmed by ^{13}C NMR spectra. To accommodate these spectral information together with consideration of reaction mechanisms described below, we are compelled to assume the structure of the lactone (**9**). Although the IR absorption at 1750 cm^{-1} is a little low for phenolic esters,[10] we believe this is due to abnormal bond angles and conformations that are needed because of the congestedness of the molecular structure. The ketone other than that which can be isomerized to the ketone **8b**, both of which were obtained by the reaction of *sc*-**7b**, showed the presence of four methyl groups, two aromatic and two

Table 4. Rate Constants for Isomerization, *ap*-**8b** → *sc*-**8b**, Equilibrium Constants, Thermodynamic Parameters and Activation Parameters

ΔH^*=22.4±0.9 kcal mol^{-1}; ΔS^*=−10±3 cal mol^{-1} K^{-1}; $\Delta H°$=−0.7±0.7 kcal mol^{-1}; $\Delta S°$=4±2 cal mol^{-1} K^{-1}.

aliphatic, and loss of an aromatic proton that shows absorption at high magnetic fields in its ^{1}H NMR spectra. It is most reasonable to assume that a proton on the dimethylbeneno bridge is lost, because these give absorptions at a high field among aromatic protons. The IR spectrum indicates the presence of a carbonyl group by the absorption at 1673 cm^{-1}. Although this absorption seems to be at a too low frequency for the normal noncoplanar aromatic carbonyl group,[11] this anomaly may again be attributed to abnormal molecular structure of this kind of congested molecules. Thus we assign structure **10** to this compound that accommodates all of spectroscopic, analytical, and mechanistic implications.

Formation of a lactone (**9**) from *sc*-**7a** is interesting because it is a reaction of an ether with an acyl chloride to form an ester in the presence of a Lewis acid. However, there are some literatures that reported this type of reactions.[12] The mechanism of the reaction must be the attack of the acylium ion produced from the acyl chloride in the presence of the Lewis acid on the 1-methoxy-oxygen atom followed by demethylation by a nucleophile. In *sc*-**7b**, the basicity of the methyl group at 1-position is too low to be attacked by the acylium ion, instead the π-system at the 1-position is attacked (ipso attack).[13] The benzenonium ion thus produced undergoes 1,2-methide shift to afford the product.

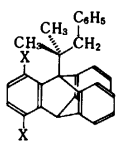
The results in Tables 1 and 2 reveal that, whereas the ratio of *sc*-**8b**/**10** is not much affected by the reaction conditions, that of *sc*-**8a**/**9** changes dramatically by the conditions. Therefore, we should like to discuss the results of *sc*-**7a** first.

The results in Table 1 indicate that the *sc*-**8a**/**9** ratio is generally small if the solvent is nonpolar: in dichloromethane with titanium(IV) chloride catalyst *sc*-**8a** is practically the sole product, whereas in cyclohexane *sc*-**8a** and **9** are almost equally produced. This tendency is again observed when tin(IV) chloride is used as a catalyst: this time, the lactone becomes an overwhelming product when cyclohexane is used as a solvent. The reaction rates, though it was not possible to determine exactly, were large in dichloromethane and small in benzene and further smaller in cyclohexane. Since titanium(IV) chloride is known to be a stronger Lewis acid than tin(IV) chloride,[14] we should like to propose the following mechanisms for the explanation of the results.

The acid chloride and the Lewis acid form a complex and then an ion pair, $RCO^+MCl_5^-$. The ion pair must be tighter, when the acidity of the Lewis acid is low and when the solvent polarity is low. When the ion pair is loose, the steric effects on the approach of the acylium ion to the reaction site will be small, whereas the steric effects will be great, when the ion pair is tight, because the acylium cation as well as the MCl_5^- anion must approach the reaction site. Thus the reaction with less steric hindrance will be favored when the ion pair is tight. In the Lewis acid-catalyzed reaction of *sc*-**7a**, there are two sites of reaction: though in principle it is possible to consider the ipso attack of the acylium ion to the 1-position where the methoxyl group is borne, the electron density at this position is too low[15] for the reaction. The reaction that occurs at the methoxy-oxygen suffers less steric hindrance than that occurring at the benzeno bridge, because the acylium cation must approach the peri-carbon, penetrating into the triptycene skeleton, if it reacts at the 8-position. The results with aluminium chloride are confusing in that aluminium chloride is a stronger Lewis acid than others. However, there is a possibility that the reaction with aluminium chloride is very complex and may even be taking place under heterogeneous conditions. We defer the discussion of the results until further information becomes available.

Examination of Table 2 reveals that, firstly, the ratio *sc*-**8b**/**10** is relatively insensitive to the conditions and, secondly, the attack to the 1-position is slightly favored in dichloromethane but, in cyclohexane, cyclization to the 8-position is slightly favored. We should like to attribute this difference between the methoxy compound and the methyl compound to the difference in the reaction sites. Namely, in the methyl compound, both reactions are occurring to the π-system of the triptycene skeleton. The steric effects given at the 1-position may not be much different from that given at the 8-position, although the methyl group at the 1-position gives additional steric effects on the attack. These steric effects together with the fact that the π-electron density at the 1-position must be slightly higher than at the 8-position where no substituent is present are reflected in the product ratio. However, the tendency seen in the methoxy compound, that is a less crowded site is more favorably attacked in nonpolar solvents and in the presence of less acidic Lewis acid is again reproduced.

As to the barriers to isomerization of the ketones **8**, we may compare them with those in similarly substituted 9-(1,1-dimethyl-2-phenylethyl)triptycenes (**14**),[16] because they are structurally similar and the substituent at the β-position of the 9-substituent is



14

known to affect the barrier to rotation little, if any.[5] Table 5 compiles free energies of activation, calculated by using the reported activation parameters and the equilibrium constants, at 150 °C that is an interim point for the two series. The barriers are strikingly

reduced in the ketones (**8**) relative to the open chain analogs (**14**). This must reflect the instability of the ground state of the ketone. However, the order of the height of barriers is the same: in both series, the methyl compound gives a lower barrier to isomerization than the methoxy compound. According to our discussion previously made,[16] this is a reflection of the fact that the ground state of the methyl compound is more congested than the methoxy compound because of the steric size of the methyl and the methoxyl groups.

The congestedness of the methyl compound seems to be reflected as well in the population ratio: the *sc*-**8b**/*ap*-**8b** is 18.6 at 80 °C, whereas the *sc*-**8a**/*ap*-**8a** is 6.0 at 90 °C. As the first approximation, we would assume that the ketones are planar with the benzeno bridge to which it is attached and the gem-dimethyl groups would eclipse the benzeno bridges. However, it is not the case, because a pair of isomers is isolated for each compound, **8a** and **8b**. To the next approximation, one would think that the ketone moiety avoids coplanarity with the benzeno bridge and the carbonyl moiety taking the planar structure, as is seen in the Newman type projections (*ap*-**8′** and *sc*-**8′**). However, the dihedral angle made by the benzeno bridge and the carbonyl cannot be very large if one considers the carbonyl absorption in the IR spectra. This model also fails to show why *ap*-**8b** and *sc*-**8b** are so much different in their stabilities. Since good crystals of these compounds have not been obtained so far, we decided to carry out molecular mechanics calculations to find possible answers to these questions.

Since MM2 calculations with the parameters originally given gave far larger differences in the total energies of the *ap*- and *sc*-ketones than the observed,[2] we have modified some parameters which are concerned with the carbonyl-to-aromatic ring bond for the calculation here. The results are compiled in Table 6.

Table 5. Comparison of Free Energies of Activation for Rotation at 423 K in **8** and **14** (kcal mol^{-1})

X	Process	Compound **8**	Compound **14**
CH_3O	*ap* → *sc*	29.9	42.5
	sc → *ap*	31.2	42.0
CH_3	*ap* → *sc*	26.5	37.7
	sc → *ap*	28.8	36.1

The calculations predict that *sc*-**8a** is more stable than *ap*-**8a** by 2.74 kcal mol^{-1} and *sc*-**8b** more stable than *ap*-**8b** by 3.27 kcal mol^{-1}. Thus the calculations still overestimate the energy difference of the rotamers but the difference is smaller than the results using the standard parameters and the tendency is correctly predicted. Of particular interest in the calculated structures of the ketones is the large distorsion of the triptycene skeleton. The geometries are far different from those expected from molecular models. The dihedral angles about the bridgehead to substituent bond are about 45° at the smallest. The difference in the stabilities between *ap*-**8** and *sc*-**8** is mainly ascribed to the difference in the torsion term, suggesting that the distorsion of the triptycene skeleton is severer in *ap*-**8** than in *sc*-**8**.

This predicted distorsion of the triptycene skeleton by the calculation is supported by the ^{1}H NMR spectra. The most interesting feature in the ^{1}H NMR spectra of these ketones is that one of the aliphatic methyl groups gives its signal at a considerably high field of δ ca. 1.65, compared with the other methyl, as a doublet because of the long range coupling of ca. 1.5 Hz with one of the methylene protons. The molecular mechanics calculations show that the relevant methyl group (-*sc*-methyl in *ap*-**8′** and *ap*-methyl in *sc*-**8′** in Scheme 4) and one of the methylene hydrogens are exactly antiperiplanar, ideally located for the W-letter coupling. It further indicates that the methyl group is located in the shielding region of the highly distorted benzene ring and also in the shielding region of the carbonyl moiety, in conformity with the ^{1}H NMR spectra.

Although cyclization of the acid (**7b**) on heating with thionyl chloride might seem odd, there is a precedence of this type of reactions. Namely, 3-(9-triptycyl)propionic acid is known to cyclize when it is heated with thionyl chloride.[17] The proximity of the carbonyl

moiety to the triptycene skeleton must be the cause for this reaction. Easily enolizable ketones are known to afford vinyl chloride type compounds, when they are heated with thionyl chloride.[18,19] The formation of **11** and **12** can be rationalized by the analogies of this reaction, because acetophenone is known to undergo this reaction.[19]

Experimental

Spectral Measurements. The ^{1}H NMR spectra were recorded on a JEOL GX270 spectrometer which operates at 270 MHz. The infrared spectra were obtained on a Hitachi IR-260-30 spectrophotometer with KBr discs.

9-(1,1-Dimethyl-3-butenyl)-9,10-dihydro-9-anthracenol (2). A solution of 6.2 g (56.6 mmol) of 4-chloro-4-methyl-1-pentene (**1**)[20] and 5.15 mL (56.6 mmol) of 1,2-dibromoethane in 60 mL of tetrahydrofuran was added to 2.75 g (113 mmol) of magnesium covered with 10 mL of tetrahydrofuran in 2 h under a nitrogen atmosphere. After the formation of the Grignard reagent was completed, the mixture was diluted with 50 mL of tetrahydrofuran and 5.0 g (26 mmol) of 9-anthrone was added. The mixture was stirred for 1 h at room temperature and then heated under reflux for 1 h. After cooling, the mixture was decomposed with aqueous ammonium chloride. The mixture was extracted with benzene and the solvent was evaporated from the combined extract. After removal of the unreacted anthrone that deposited from the mixture, the products were submitted to medium-pressure chromatography on silica gel (hexane eluent) to give the desired material in 10% yield. The pure sample was obtained by recrystallization from hexane, mp 76.0 °C. Found: C, 86.01; H, 7.94%. Calcd for $C_{20}H_{22}O$: C, 86.29; H, 7.97%. ^{1}H NMR ($CDCl_3$) δ=0.83 (6H, s), 2.01 (1H, s), 2.11 (2H, d, J=7.3 Hz), 3.87 and 4.16 (2H, ABq, J=20 Hz), 4.86—4.98 (2H, m), 5.66—5.79 (1H, m), 7.23—7.34 (6H, m), 7.80—7.84 (2H, m).

9-(1,1-Dimethyl-3-butenyl)anthracene (3). A solution of 1.45 g (5.2 mmol) of the preceding alcohol (**2**) in 40 mL of carbon tetrachloride was heated under reflux with 11 g of phophorus pentaoxide for 15—20 min. The carbon tetrachloride solution was decanted and the residue was extracted several times with hot carbon tetrachloride. The solvent was evaporated from the carbon tetrachloride solution and the residue was chromatographed on silica gel (7:1 hexane-dichloromethane eluent) to give the desired product in 90% yield. The pure sample was obtained by recrystallization from hexane, mp 57.5—59.5 °C. Found: C, 92.11; H, 7.71%. Calcd for $C_{20}H_{20}$: C, 92.26; H, 7.74%. ^{1}H NMR ($CDCl_3$) δ=1.82 (6H, s), 3.13 (2H, d, J=7.3 Hz), 4.88—5.07 (2H, m), 5.54—5.67 (1H, m), 7.26—7.35 (4H, m), 7.88—7.92 (2H, m), 8.23 (1H, s), 8.48—8.52 (2H, m).

1,4-Dimethoxy-9-(1,1-dimethyl-3-butenyl)triptycene (4a). To a solution of 4.5 g (17 mmol) of **3** and 3.5 mL (26 mmol) of isopentyl nitrite in 300 mL of dichloromethane, were simultaneously added from two dropping funnels 7.0 g (34 mmol) of 3,6-dimethoxyanthranilic acid[21] in 130 mL of acetone and 5 mL (37 mmol) of isopentyl nitrite in 40 mL of dichloromethane in 6 h, with stirring and refluxing under a nitrogen atmosphere. After the addtion was over, the whole was refluxed for another hour and cooled. The solvents were evaporated and the residue was submitted to chromatography on silica gel (5:1 hexane-dichloromethane eluent) to afford 35% of the desired material as a ca. 5.5:1 mixture of *ap* and *sc* isomers. The pure *ap*-**4a** was obtained by recrystallization of the product from dichloromethane-hexane, mp 245.5—246.5 °C. Found: C, 84.64; H, 6.91%. Calcd for $C_{28}H_{28}O_2$: C, 84.81; H, 7.12%. ^{1}H NMR ($CDCl_3$) δ=2.04 (6H, s), 3.29 (2H, d, J=6.9 Hz), 3.71 (3H, s), 3.80 (3H, s), 5.20—5.29 (2H, m), 5.87 (1H, s), 6.22—6.38 (1H, m), 6.57 and 6.60 (2H, ABq, J=8.8 Hz), 6.92—7.00 (4H, m), 7.37—7.41 (2H, m), 7.83—7.87 (2H, m).

1,4-Dimethyl-9-(1,1-dimethyl-3-butenyl)triptycene (4b). This compound was similarly prepared as described above, starting from **3** and 3,6-dimethylanthranilic acid.[22] The yield of the crude product (ca. 5.5:1 mixture of *ap*-**4b** and *sc*-**4b**) was 96%. Recrystallization of the product from hexane-dichloromethane afforded pure *ap*-**4b**, mp 208.5—209.0 °C. Found: C, 92.10; H, 7.62%. Calcd for $C_{28}H_{28}$: C, 92.26; 7.74%. ^{1}H NMR ($CDCl_3$) δ=2.22 (6H, s), 2.49 (3H, s), 2.64 (3H, s), 3.31 (2H, d, J=7.0 Hz), 5.23—5.57 (2H, m), 5.58 (1H, s), 6.19—6.34 (1H, m), 6.73 (2H, s), 6.93—7.02 (4H, m), 7.24—7.38 (2H, m), 7.83—7.88 (2H, m).

***ap*-3-(1,4-Dimethoxy-9-triptycyl)-3-methylbutanoic Acid (*ap*-7a).** A solution of 20 mg of osmium tetraoxide in 1 mL of *t*-butyl alcohol was added to a solution of 1.0 g (2.5 mmol) of the olefin (*ap*-**4a**), 3.7 g (49 mmol) of trimethylamine oxide dihydrate and 2 mL of pyridine in 15 mL of water and 50 mL of *t*-butyl alcohol and the whole was refluxed for 12 h. The mixture was cooled and treated with 20 mL of 20% aqueous sodium sulfite. Most of the *t*-butyl alcohol was evaporated and the aqueous layer was extracted with dichloromethane after being saturated with sodium chloride. The extract was washed with dilute hydrochloric acid to remove pyridine. Evaporation of the solvent afforded practically pure *ap*-4-(1,4-dimethoxy-9-triptycyl)-4-methyl-1,2-pentanediol (*ap*-**5a**) in almost quantitative yield. ^{1}H NMR ($CDCl_3$) δ=2.10 (3H, s), 2.23 (3H, s), 2.55 (1H, dd, J=15 and 2.6 Hz), 2.68 (1H, dd, J=15 and 7.3 Hz), 3.52 (1H, m), 3.73 (3H, s), 3.75—3.80 (1H, m), 3.80 (3H, s), 4.30—4.47 (1H, m), 5.87 (1H, s), 6.58 and 6.61 (2H, ABq, J=9.2 Hz), 6.90—7.02 (4H, m), 7.38—7.42 (2H, m), 7.66—7.70 (1H, m), 7.98—8.01 (1H, m).

Periodic acid (750 mg or 3.5 mmol) was added to a solution of 400 mg (0.93 mmol) of the diol (*ap*-**5a**) in 15 mL of tetrahydrofuran and 3 mL of water and the whole was stirred for 1 h at room temprature. The mixture was poured into

water and extracted with dichloromethane. Evaporation of the solvent afforded *ap*-3-(1,4-dimethoxy-9-triptycyl)-3-methylbutanal in 75% yield. ^{1}H NMR ($CDCl_3$) δ=2.26 (6H, s), 3.65 (2H, d, J=2.6 Hz), 3.74 (3H, s), 3.80 (3H, s), 5.88 (1H, s), 6.58 and 6.62 (2H, ABq, J=9.1 Hz), 6.97—7.00 (4H, m), 7.40—7.44 (2H, m), 7.76—7.82 (2H, m), 10.25 (1H, t, J=2.6 Hz).

To a solution of 100 mg (0.25 mmol) of the *ap*-aldehyde in 4 mL of acetone were added 4 mg of sodium hydrogencarbonate and 40 mg (0.25 mmol) of potassium permanganate with ice-cooling and the mixture was stirred for 50 min. The mixture was treated with an aqueous solution of sodium hydrogensulfite to destroy the excess of potassium permanganate, acidified with hydrochloric acid, and extracted with dichloromethane. After evaporation of the solvent the residue was recrystallized from tetrahydrofuran-pentane to give pure *ap*-**7a**, mp 198.5 °C (decomp). The yield was 60%. Found: C, 77.98; H, 6.49%. Calcd for $C_{27}H_{26}O_4$: C, 78.24; H, 6.32%. ^{1}H NMR ($CDCl_3$) δ=2.25 (6H, s), 3.62 (2H, s), 3.73 (3H, s), 3.81 (3H, s), 5.89 (1H, s), 6.59 and 6.62 (2H, ABq, J=8.1 Hz), 6.99—7.03 (4H, m), 7.41—7.44 (2H, m), 7.86—7.90 (2H, m).

***ap*-3-(1,4-Dimethyl-9-triptycyl)-3-methylbutanoic Acid (*ap*-7b).** This compound was prepared similarly as described above from *ap*-**4b**. The NMR data and yield, where appropriate, are given. *ap*-4-(1,4-Dimethyl-9-triptycyl)-4-methyl-1,2-pentanediol (*ap*-**5b**): ^{1}H NMR ($CDCl_3$) δ=2.27 (3H, s), 2.42 (3H, s), 2.49 (3H, s), 2.67 (3H, s), 2.45—2.84 (2H, m), 3.48 (1H, dd, J=11 and 2.1 Hz), 3.69 (1H, dd, J=11 and 2.1 Hz), 4.3—4.5 (1H, m), 5.58 (1H, s), 6.74 (2H, s), 6.85—7.10 (4H, m), 7.29—7.41 (2H, m), 7.60—8.22 (2H, m); yield>95%. *ap*-3-(1,4-Dimethyl-9-triptycyl)-3-methylbutanal: ^{1}H NMR ($CDCl_3$) δ=2.43 (6H, s), 2.49 (3H, s), 2.67 (3H, s), 3.74 (2H, d, J=2.2 Hz), 5.60 (1H, s), 6.76 (2H, s), 6.90—7.01 (4H, m), 7.36—7.42 (2H, m), 7.78—7.81 (2H, m), 10.19 (1H, t, J=1.9 Hz); yield>95%. *ap*-**7b**: ^{1}H NMR ($CDCl_3$) δ=2.43 (6H, s), 2.50 (3H, s), 2.68 (3H, s), 3.67 (2H, s), 5.60 (1H, s), 6.76 (2H, s), 7.01—7.13 (4H, m), 7.37—7.40 (2H, m), 7.85—7.87 (2H, m); yield 95%. This compound did not give correct analyses of elements, the phenomenon being often observed in the compounds in triptycene series probably because of inclusion of solvent or other molecules. The methyl ester, mp 204—205 °C, however, gave correct analytical results. Found: C, 84.70; H, 7.00%. Calcd for $C_{28}H_{28}O_2$: C, 84.81; H, 7.12%. ^{1}H NMR ($CDCl_3$) δ=2.36 (6H, s), 2.48 (3H, s), 2.65 (3H, s), 3.59 (2H, s), 3.80 (3H, s), 5.58 (1H, s), 6.73 (2H, s), 6.97—7.00 (4H, m), 7.35—7.38 (2H, m), 7.84—7.88 (2H, m).

***sc*-3-(1,4-Dimethoxy-9-triptycyl)-3-methylbutanoic Acid (*sc*-7a).** Thermal isomerization of *ap*-**4** was accomplished by heating a solution of *ap*-**4** in 1-chloronaphthalene at 250 °C for 12 h under a nitrogen atmosphere. The solvent was removed by chromatography on silica gel. The residue showed the presence of isomers in *sc*/*ap*=1.4 ratio. It was possible to enrich the *sc*-isomer up to 95% by recrystallization from dichloromethane-hexane. ^{1}H NMR ($CDCl_3$) δ=1.97 (3H, s), 2.02 (3H, s), 3.31 and 3.54 (2H, AB of ABX, J=6.2 and 7.3 Hz), 3.74 (3H, s), 3.82 (3H, s), 5.17—5.24 (2H, m), 6.23—6.38 (1H, m), 6.55 and 6.63 (2H, ABq, J=8.8 Hz), 6.90—7.02 (4H, m), 7.38—7.42 (2H, m), 7.66—7.70 (1H, m), 7.98—8.01 (1H, m).

Dihydroxylation of the olefin mixture with osmium tetraoxide and trimethylamine oxide was carried out similarly as described for the *ap*-isomer. The *sc*-olefin gave two isomers (I and II) due to the fact that a new chiral center was formed, the ratio, I/II, being ca. 1.0. The yield was quantitative. ^{1}H NMR data ($CDCl_3$, δ) of *sc*-diols which were separated from the *ap* at the acetonide stage (see below): *sc*-**5a**(I) 2.09 (3H, s), 2.13 (3H, s), 2.67 (1H, dd, J=15 and 2.6 Hz), 2.68 (1H, dd, J=15 and 7.3 Hz), 3.52 (1H, m), 3.73 (3H, s), 3.75—3.87 (1H, m), 3.78 (3H, s), 3.82 (3H, s), 4.30—4.47 (1H, m), 5.87 (1H, s), 6.58 and 6.61 (2H, ABq, J=8.8 Hz), 6.90—7.02 (4H, m), 7.38—7.42 (2H, m), 7.66—7.70 (1H, m), 7.98—8.01 (1H, m); *sc*-**5a**(II) 2.06 (3H, s), 2.21 (3H, s), 2.64 (1H, dd, J=15 and 8.1 Hz), 2.69 (1H, dd, J=15 and 2.9 Hz), 3.49—3.56 (1H, m), 3.64—3.75 (1H, m), 3.70 (3H, s), 3.82 (3H, s), 4.37—4.45 (1H, m), 5.88 (1H, s), 6.57 and 6.64 (2H, ABq, J=9.2 Hz), 6.92—7.03 (4H, m), 7.35—7.42 (2H, m), 7.88—7.91 (1H, m), 8.01—8.04 (1H, m).

A solution of 300 mg of the mixture of diols **5a** in 15 mL of acetone was heated under reflux for 4 h with a catalytic amount of *p*-toluenesulfonic acid, the formed water being trapped by Molecular Sieves 5A. After cooling, the mixture was poured into aqueous sodium hydrogencarbonate and extracted with dichloromethane. After evaporation of the solvent, the residue was submitted to flash column or medium-pressure column chromatography on silica gel (9:1 hexane–ether eluent). The order of elution was *ap*-**6a**, *sc*-**6a**(I), and *sc*-**6a**(II). The separation of the two *sc* forms was not complete. The following ^{1}H NMR data ($CDCl_3$, δ) were recorded. *ap*-**6a**: 1.45 (3H, s), 1.49 (3H, s), 2.07 (3H, s), 2.18 (3H, s), 2.68 (1H, dd, J=15 and 6.8 Hz), 2.92 (1H, dd, J=15 and 3.6 Hz), 3.59 (1H, t, J=8.1 Hz), 3.72 (3H, s), 3.79 (3H, s), 4.26 (1H, dd, J=8.1 and 5.9 Hz), 4.64—4.74 (1H, m), 5.88 (1H, s), 6.57 and 6.60 (2H, ABq, J=9.2 Hz), 6.93—6.99 (4H, m), 7.38—7.41 (2H, m), 7.70—7.73 (1H, m), 8.00—8.03 (1H, m). *sc*-**6a**(I): 1.55 (6H, s), 2.04 (3H, s), 2.10 (3H, s), 2.70 (1H, dd, J=15 and 4.8 Hz), 3.24 (1H, dd, J=15 and 6.6 Hz), 3.64 (1H, dd, J=8.4 and 7.7 Hz), 3.77 (3H, s), 3.82 (3H, s), 4.27 (1H, dd, J=7.7 and 5.5 Hz), 4.67—4.73 (1H, m), 5.88 (1H, s), 6.59 and 6.64 (2H, ABq, J=8.8 Hz), 6.92—7.00 (4H, m), 7.35—7.41 (2H, m), 7.71—7.75 (1H, m), 7.84—7.87 (1H, m). *sc*-**6a**(II): 1.50 (3H, s), 1.51 (3H, s), 2.04 (3H, s), 2.16 (3H, s), 2.82 (1H, dd, J=11 and 8.1 Hz), 2.88 (1H, dd, J=11 and 2.6 Hz), 3.56 (1H, t, J=7.7 Hz), 3.70 (3H, s), 3.81 (3H, s), 4.16 (1H, dd, J=7.7 and 5.9 Hz), 4.68—4.72 (1H, m), 5.88 (1H, s), 6.63 and 6.65 (2H, ABq, J=8.8 Hz), 6.94—7.00 (4H, m), 7.36—7.40 (2H, m), 7.88—7.91 (1H, m) 8.06—8.10 (1H, m).

The mixture of *sc*-**6a**(I) and *sc*-**6a**(II) (1.0 g) in 25 mL of tetrahydrofuran was added to 25 mL of 1 M hydrochloric acid (1 M=1 mol L^{-1}) and the mixture was stirred at room temperature for 2.5 h. The mixture was poured into water and extracted with dichloromethane. Evaporation of the solvent afforded a mixture of two forms of *sc*-**5a**.

The oxidation of the mixture of *sc*-**5a** was carried out as described for the *ap*-form to afford the *sc*-aldehyde. ^{1}H NMR ($CDCl_3$) δ=2.19 (3H, s), 2.25 (3H, s), 3.57 and 3.97 (2H, ABdq, J=16 and 2.6 Hz), 3.72 (3H, s), 3.82 (3H, s), 5.90 (1H, s), 6.59 and 6.65 (2H, ABq, J=9.2 Hz), 6.94—7.02 (4H, m), 7.38—7.43 (2H, m), 7.74—7.82 (2H, m), 10.19 (1H, t, J=2.6 Hz).

The oxidation of the *sc*-aldehyde was caried out similarly as described for the *ap* form to afford 60% *sc*-**7a**, mp 270 °C (decomp). ^{1}H NMR ($CDCl_3$) δ=2.22 (3H, s), 2.24 (3H, s), 3.50 and 4.28 (2H, ABq, J=15 Hz), 3.79 (3H, s), 3.83 (3H, s), 5.90 (1H, s), 6.59 and 6.69 (2H, ABq, J=9.2 Hz), 6.96—7.03

(4H, m), 7.38—7.44 (2H, m), 7.81—7.85 (1H, m), 7.91—7.94 (1H, m). This compound did not give correct analyses but its methyl ester, mp 231—232 °C, did the correct data. Found: C, 78.38; H, 6.47%. Calcd for $C_{28}H_{28}O_4$: C, 78.48; H, 6.39%. ^{1}H NMR ($CDCl_3$) δ=2.14 (3H, s), 2.15 (3H, s), 3.60 (2H, ABq, J=15 Hz), 3.73 (3H, s), 3.79 (3H, s), 3.81 (3H, s), 5.89 (1H s), 6.56 and 6.62 (2H, ABq, J=9.2 Hz), 6.93—7.00 (4H, m), 7.36—7.42 (2H, m), 7.80—7.83 (1H, m), 7.90—7.94 (1H, m).

***sc*-3-(1,4-Dimethyl-9-triptycyl)-3-methylbutanoic Acid (*sc*-7b).** This compound was prepared as described for the preparation of *sc*-**7a**. The ^{1}H NMR data ($CDCl_3$, δ) and yield, where appropriate, are given. *sc*-**4b**: 2.07 (3H, s), 2.13 (3H, s), 2.52 (3H, s), 2.63 (3H, s), 3.21—3.70 (2H, m), 5.28 (2H, d, J=5.1 Hz), 5.68 (1H, s), 6.14—6.36 (1H, m), 6.78 (2H, s), 6.92—7.02 (4H, m), 7.32—7.41 (2H, m), 7.82—7.90 (2H, m); *sc*/*ap* ratio 0.69. *sc*-**5b (I)**: 2.12 (3H, s), 2.36 (3H, s), 2.52 (3H, s), 2.55 (3H, s), 2.65—2.97 (2H, m), 3.47—3.86 (2H, m), 4.3—4.4 (1H, m), 5.57 (1H, s), 6.73 and 6.77 (2H, ABq, J=6.1 Hz), 6.85—7.10 (4H, m), 7.29—7.41 (2H, m), 7.60—8.22 (2H, m). *sc*-**5b**(II): 2.12 (3H, s), 2.34 (3H, s), 2.52 (3H, s), 2.77 (3H, s), 2.65—2.97 (2H, m), 3.47—3.86 (2H, m), 4.3—4.4 (1H, m), 5.57 (1H, s), 6.73 and 6.77 (2H, ABq, J=6.1 Hz), 6.85—7.10 (4H, m), 7.29—7.41 (2H, m), 7.60—8.22 (2H, m). The ratio *sc*-**5b**(I)/*sc*-**5b**(II) was ca. 2:1. *ap*-**6b**: 1.45 (3H, s), 1.48 (3H, s), 2.25 (3H, s), 2.38 (3H, s), 2.48 (3H, s), 2.66 (3H, s), 2.60—3.01 (2H, m), 3.55 (1H, dd, J=10.0 and 7.1 Hz), 4.24 (1H, dd, J=10.0 and 7.1 Hz), 4.63—4.75 (1H, m), 5.55 (1H, s), 6.74 (2H, s), 6.91—7.20 (4H, m), 7.32—7.40 (2H, m), 7.68—7.75 (1H, m), 7.98—8.06 (1H, m). *sc*-**6b**(I): 1.53 (6H, s), 2.20 (6H, s), 2.51 (3H, s), 2.56 (3H, s), 2.65—3.16 (2H, m), 3.60 (1H, dd, J=7.9 and 5.9 Hz), 4.19 (1H, dd, J=7.9 and 5.9 Hz), 4.68—4.82 (1H, m), 5.58 (1H, s), 6.73 and 6.76 (2H, ABq, J=7.9 Hz), 6.90—7.10 (4H, m), 7.28—7.42 (2H, m), 7.76—8.20 (2H, m). *sc*-**6b**(II): 1.46 (3H, s), 1.48 (3H, s), 2.09 (3H, s), 2.31 (3H, s), 2.52 (3H, s), 2.77 (3H, s), 2.63—3.15 (2H, m), 3.58 (1H, dd, J=8.0 and 5.9 Hz), 4.19 (1H, dd, J=8.0 and 5.9 Hz), 4.68—4.82 (1H, m), 5.58 (1H, s), 6.60—6.70 (2H, m), 6.85—7.05 (4H, m), 7.30—7.42 (2H, m), 7.65—8.08 (2H, m). *sc*-Aldehyde: 2.31 (3H, s), 2.36 (3H, s), 2.53 (3H, s), 2.62 (3H, s), 3.79 (2H, m), 5.60 (1H, s), 6.78—6.79 (2H, m), 6.97—7.02 (4H, m), 7.35—7.40 (2H, m), 7.78—7.84 (2H, m), 10.24 (1H, m). *sc*-**7b**: mp 149—160 °C, yield>95%. Found: C, 84.51; H, 6.61%. Calcd for $C_{27}H_{26}O_2$: C, 84.78; H, 6.85%. ^{1}H NMR ($CDCl_3$) δ=2.30 (3H, s), 2.37 (3H, s), 2.53 (3H, s), 2.75 (3H, s), 3.75 and 3.94 (2H, ABq, J=16 Hz), 5.60 (1H, s), 6.80 (2H, s), 6.98—7.05 (4H, m), 7.35—7.41 (2H, m), 7.84—7.87 (1H, m), 7.91—7.94 (1H, m). *sc*-**7b** methyl ester: mp 210—211 °C. Found: C, 85.02; H, 7.00%. Calcd for $C_{28}H_{28}O_2$: C, 84.81; H, 7.12%. ^{1}H NMR ($CDCl_3$) δ=2.21 (3H, s), 2.28 (3H, s), 2.50 (3H, s), 2.70 (3H, s), 3.7—3.8 (2H, m), 3.81 (3H, s), 5.56 (1H, s), 6.75 (2H, s), 6.9—7.1 (4H, m), 7.2—7.5 (2H, m), 7.75—7.95 (2H, m) at 90 MHz.

Lewis Acid-Catalyzed Reaction of 3-(1,4-Dimethoxy-9-triptycyl)-3-methylbutanoic Acid (7a). The carboxylic acid (100 mg or 0.24 mmol) in 7.5 mL of benzene was stirred with 0.3 mL (3.5 mmol) of oxalyl dichloride at room temperature for 2 h and the solvent and the excess of oxalyl dichloride were evaporated in vacuo. The residue showed the following ^{1}H NMR spectra ($CDCl_3$, δ). *ap*: 2.22 (6H, s), 3.73 (3H, s), 3.80 (3H, s), 4.29 (2H, s), 5.89 (1H, s), 6.55 and 6.65 (2H, ABq, J=9.1 Hz), 6.98—7.05 (4H, m), 7.36—7.44 (2H, m), 7.73—7.77 (2H, m). *sc*: 2.17 (3H, s), 2.22 (3H, s), 3.79 (3H, s), 3.83 (3H, s), 4.32 and 4.82 (2H, ABq, J=19 Hz), 5.90 (1H, s), 6.60 and 6.70 (2H, ABq, J=10 Hz), 6.96—7.05 (4H, m), 7.35—7.46 (2H, m), 7.72—7.88 (2H, m).

The acid chloride produced in the above reaction was dissolved in 10 mL of benzene and 0.050 mL (2 equiv) of titanium(IV) chloride was added. The mixture was stirred for 4 h at room temperature and decomposed with water. The aqueous layer was extracted with dichlomethane and the solvents were evaporated from the combined organic layers.

The *ap*-acid afforded, after purification by recrystallization from tetrahydrofuran-pentane, 8,11-dimethoxy-1,1-dimethyl-1,2-dihydro-7*H*-7,11b-*o*-benzeno-3*H*-benz[*de*]-anthracen-3-one (*ap*-**8a**), mp 283.0—284.0 °C, in 70% yield. Found: C, 81.52; H, 5.85%. Calcd for $C_{27}H_{24}O_3$: C, 81.79; H, 6.10%. ^{1}H NMR ($CDCl_3$) δ=1.67 (3H, d, J=1.4 Hz), 2.10 (3H, s), 2.71 (1H, d, J=15 Hz), 3.37 (1H, app dd, J=15 and 1.4 Hz), 3.75 (3H, s), 3.87 (3H, s), 5.93 (1H, s), 6.62 and 6.71 (2H, ABq, J=9.0 Hz), 6.88—7.00 (2H, m), 7.06—7.13 (1H, m), 7.32—7.35 (1H, m), 7.56—7.62 (2H, m), 7.79—7.82 (1H, m), IR (KBr disc): 1690 cm^{-1}.

The *sc*-acid afforded a ketone (*sc*-**8a**) and a lactone (**9**) which were not easily separated. The pure ketone was obtained by recrystallization of the product, obtained with the use of dichloromethane or benzene as a solvent, from tetrahydrofuran-pentane. The pure lactone was obtained by chromatography on silica gel (1:2 hexane-dichloromethane) after conversion of the ketone into its oxime. The combined yields of the lactone and the ketone were ca. 70%.

sc-**8a**: mp 283.0—284.0 °C. Found: C, 81.54; H, 6.34%. Calcd for $C_{27}H_{24}O_3$: C, 81.79; H, 6.10%. ^{1}H NMR ($CDCl_3$) δ=1.63 (3H, d, J=1.5 Hz), 2.07 (3H, s), 2.62 (1H, d, J=16 Hz), 3.91 (1H, app dd, J=16 and 1.5 Hz), 3.75 (3H, s), 3.76 (3H, s), 5.94 (1H, s), 6.51 and 6.55 (2H, ABq, J=8.1 Hz), 7.09—7.25 (3H, m), 7.47—7.64 (3H, m), 7.86—7.89 (1H, m). IR (KBr disc): 1690 cm^{-1}.

9: mp 238.5—240.0 °C. This compound failed to give correct analysis, the phenomenon being often observed in the triptycene series as mentioned in the analysis of *ap*-**7b**. High resolution MS: M^+ 382.1549 (82.9%) and 383.1590 (25.6%) in accordance with the calculated values 382.1567 for $C_{26}H_{22}O_3$ and 383.1601 for $C_{25}{}^{13}CH_{22}O_3$. ^{1}H NMR ($CDCl_3$) δ=1.97 (3H, s), 2.19 (3H, s), 3.13 and 3.90 (2H, ABq, J=15 Hz), 3.87 (3H, s), 5.93 (1H, s), 6.69 and 6.82 (2H, ABq, J=9.2 Hz), 6.98—7.10 (4H, m), 7.39—7.58 (3H, m), 7.82—7.85 (1H, m). IR (KBr disc): 1750 cm^{-1}. ^{13}C NMR ($CDCl_3$): 170.6 ppm from TMS.

Lewis Acid-Catalyzed Reaction of 3-(1,4-Dimethyl-9-triptycyl)-3-methylbutanoic Acid (7b). The reaction was carried out as described for **7a**. The following ^{1}H NMR data ($CDCl_3$, δ) were recorded at 90 MHz.

***ap*-Acid Chloride:** 2.41 (6H, s), 2.47 (3H, s), 2.61 (3H, s), 4.30 (2H, s), 5.56 (1H, s), 6.72 (2H, s), 6.8—7.1 (4H, m), 7.2—7.5 (2H, m), 7.5—7.8 (2H, m).

***sc*-Acid Chloride:** 2.27 (3H, s), 2.34 (3H, s), 2.61 (3H, s), 2.70 (3H, s), 4.37 and 4.52 (2H, ABq, J=19.8 Hz), 5.56 (1H, s), 6.78 (2H, s), 6.8—7.2 (4H, m), 7.3—7.4 (2H, m), 7.6—7.9 (2H, m).

The *ap*-acid chloride afforded 1,1,8,11-tetramethyl-1,2-dihydro-7*H*-7,11b-*o*-benzeno-3*H*-benz[*de*]anthracen-3-one (**8b**), mp 192.0—192.5 °C, in 70% yield. Found: C, 88.64; H, 6.55%. Calcd for $C_{27}H_{24}O$: C, 88.97; H, 6.64%. ^{1}H NMR ($CDCl_3$) δ=1.70 (3H, d, J=1.8 Hz), 2.18 (3H, s), 2.52 (3H, s),

2.61 (3H, s), 2.72 (1H, d, J=15 Hz), 3.31 (1H, dd, J=15 and 1.8 Hz), 5.56 (1H, s), 6.76 and 6.81 (2H, ABq, J=8.1 Hz), 6.85—6.96 (2H, m), 7.02—7.08 (1H, m), 7.23—7.29 (1H, m), 7.46—7.57 (2H, m), 7.72—7.75 (1H, m). IR (KBr disc): 1678 cm^{-1}.

The *sc*-acid chloride gave two ketones which were separated by preparative TLC on silica gel (1:2 hexane–dichloromethane eluent).

1,1,8,11-Tetramethyl-1,2-dihydro-7*H*-7,11b-*o*-benzeno-3*H*-benz[*de*]anthracen-3-one (*sc*-8b): mp 247.0—248.0 °C. Yield 33%. Found: C, 88.75; H, 6.57%. Calcd for $C_{27}H_{24}O$: C, 88.97; H, 6.64%. ^1H NMR ($CDCl_3$) δ=1.65 (3H, d, J=1.5 Hz), 2.21 (3H, s), 2.43 (3H, s), 2.65 (3H, s), 2.73 (1H, d, J=15 Hz), 3.74 (1H, dd, J=15 and 1.5 Hz), 5.66 (1H, s), 6.66 and 6.67 (2H, ABq, J=8.1 Hz), 7.04—7.14 (3H, m), 7.43—7.46 (1H, m), 7.52—7.55 (1H, m), 7.63—7.67 (1H, m), 7.79—7.83 (1H, m). IR (KBr disc): 1692 cm^{-1}.

1,1,4,6-Tetramethyl-1,2-dihydro-7*H*-7,11b-*o*-benzeno-3*H*-benz[*de*]anthracen-3-one (10): mp 262.5—263.0 °C, yield 37%. Found: C, 88.85; H, 6.52%. Calcd for $C_{27}H_{24}O$: C, 88.97; H, 6.64%. ^1H NMR ($CDCl_3$) δ=1.69 (3H, s), 2.09 (3H, s), 2.51 (3H, s), 2.53 (3H, s), 2.60 and 3.55 (2H, ABq, J=16 Hz), 5.51 (1H, s), 6.75 (1H, s), 6.91—6.96 (2H, m), 7.04—7.08 (2H, m), 7.30 and 7.46 (2H, ABq, J=6.8 Hz), 7.75 and 7.83 (2H, ABq, J=7.3 Hz). IR (KBr disc): 1673 cm^{-1}.

Effects of Solvent and Catalyst. The reactions were carried out in essentially the same manner as described in the reaction of **7a**. Although the results were irregular when the amount of the catalyst was less than 1.0 equivalent to the acid chloride, they were essentially the same when the catalyst was 1.0—10 equivalents. When the solvent was cyclohexane, the reaction was slow. The results are given in Tables 1 and 2. The analysis of the products were caried out by ^1H NMR spectra using the signals due to the methyl or methoxyl protons.

3-Chloro-1,1,8,11-tetramethyl-7*H*-7,11b-*o*-benzeno-1*H*-benz[*de*]anthracene (11). A mixture of 100 mg of *sc*-**8b** and 5 mL of thionyl chloride, which was distilled over triphenylphospine, was heated under reflux for 2 h under a nitrogen atmosphere. The excessive thionyl chloride was evaporated in vacuo and the residue was treated with water. The mixture was extracted with dichloromethane, and the extract was washed with aqueous sodium hydrogencarbonate and dried over magnesium sulfate. After evaporation of the solvent, the residue was submitted to preparative TLC on silica gel with 2:1 hexane–dichloromethane as an eluent. **11** was obtained as crystals, mp 264.0—266.0 °C, in 50% yield. High resolution MS: M^+ 382.1480 and 384.1468. Calcd for $C_{27}H_{23}{}^{35}Cl$ and $C_{27}H_{23}{}^{37}Cl$: 382.1486 and 384.1458. ^1H NMR ($CDCl_3$) δ=1.72 (3H, s), 2.21 (3H, s), 2.34 (3H, s), 2.54 (3H, s), 5.54 (1H, s), 6.40 (1H, s), 6.49 and 6.62 (2H, ABq, J=8.1 Hz), 6.99—7.28 (5H, m), 7.47—7.50 (1H, m), 7.80—7.83 (1H, m).

3-Chloro-1,1,4,6-tetramethyl-7*H*-7,11b-*o*-benzeno-1*H*-benz[*de*]anthracene (12): mp 223.0—225.0 °C, was similarly obtained in ca. 50% yield from **10**. High resolution MS: M^+ 382.1468 and 384.1443. Calcd for $C_{27}H_{23}{}^{35}Cl$ and $C_{27}H_{23}{}^{37}Cl$: 382.1468 and 384.1458. ^1H NMR ($CDCl_3$) δ=1.74 (3H, s), 2.12 (3H, s), 2.44 (3H, s), 2.46 (3H, s), 5.43 (1H, s), 6.41 (1H, s), 6.64 (1H, s), 6.80—6.88 (2H, m), 7.02—7.24 (3H, m), 7.47—7.54 (2H, m), 7.76—7.82 (1H, m).

Further Heating of 11 and 12 with Thionyl Chloride. **12** and thionyl chloride for 12 h afforded a product which was almost pure on the ^1H NMR spectral ground. The structure of the product was assigned as 2,3-dichloro-1,1,4,6-tetramethyl-7*H*-7,11b-*o*-benzeno-1*H*-benz[*de*]anthracene (**13**). ^1H NMR ($CDCl_3$) δ=1.85 (3H, s), 2.28 (3H, s), 2.43 (3H, s), 2.46 (3H, s), 5.44 (1H, s), 6.65 (1H, s), 6.84—6.93 (2H, m), 7.05—7.25 (3H, m), 7.38—7.53 (2H, m), 7.84—7.87 (1H, m). High resolution MS: M^+ 416.1072 and 418.1049. Calcd for $C_{27}H_{22}{}^{35}Cl_2$ and $C_{27}H_{22}{}^{35}Cl^{37}Cl$: 416.1097 and 418.1067. The mass spectrum also showed the presence of peaks which indicated the contamination of **13** by trichloro and tetrachloro compounds.

11 did not react with thionyl chloride any more under the conditions.

Heating *ap*-7b and *sc*-7b with Thionyl Chloride. The *ap*-acid (100 mg) was heated with 5 mL of thionyl chloride similarly as mentioned above. The reaction afforded *sc*-**8b**, **11**, and *ap*-**8b** in 70, 11, and 3% yields, respectively.

sc-**7b**, on a similar treatment, afforded **10**, *sc*-**8b**, **12**, and **11** in 21, 42, 20, and 5% yields, respectively. In addition, **13** and *ap*-**8b** were detected by ^1H NMR spectra, the yields being ca. 1 and 2%, respectively.

Thermal Equilibration of Ketones 8. The *ap*-ketone was dissolved in toluene-d_8 to make up a ca. 25 mmol L^{-1} solution. The sample solution was heated in an appropriate boiling solvent bath except for the cases at 70 and 90 °C, when a thermostatted bath was used. The solvents used for the bath were toluene (111.5 °C), water (100.5 °C), and acetone (56.0 °C). The rates of isomerization were followed by ^1H NMR spectra by observing methyl signals. The rate constants were obtained by assuming the first order reaction which is reversible. The error limit in Tables 3 and 4 are given at the 95% confidence.

Calculation of the Data in Table 5. It was assumed that the thermodynamic parameters obtained at about or below 100 °C could be extrapolated to 150 °C for the ketones (**8**) and those obtained at 200 °C or higher temperatures for **14** could as well be extrapolated to 150 °C. Then the equilibrium contants at 150 °C could be calculated and were used for the calculation of the reverse reaction rates. Free energies of activation for the forward and backward reactions were thus calculated and listed.

Molecular Mechanics Calculations. Calculations were performed on Hitachi M-680H computer system at the Computer Center of the University of Tokyo (CCUT) using a modified version[23] of the MM2 program.[24] Some of the force field parameters were modified in order to properly reproduce deformations about the bond which connects a benzene ring with a carbonyl function attached to it and are listed in Table 7.

Asymmetric Synthesis of Axially Chiral, Unsymmetrical Diphenic Acids via Intramolecular Ullmann Coupling Reaction[1)]

Sotaro MIYANO,* Hiroshi FUKUSHIMA, Shigeru HANDA, Hiromitsu ITO, and Harukichi HASHIMOTO
Department of Applied Chemistry, Faculty of Engineering, Tohoku University, Aramaki-Aoba, Sendai 980
(Received March 22, 1988)

A practical route to unsymmetrical diphenic acids is described. Successive esterification of ethylene glycol with two different 2-halobenzoyl chlorides gave the corresponding mixed diester, which was treated with copper powder in boiling DMF under dilution conditions. Silica-gel column chromatography allowed ready separation of the intramolecularly coupled cyclic diester (30—60% yield) from other by-products accompanying the Ullmann reaction, and alkaline hydrolysis gave unsymmetrical diphenic acid. Axially chiral, unsymmetrical diphenic acids of more than 99% enantiomeric excess were obtained from the reaction of mixed diesters prepared from (*R*)-1,1′-bi-2-naphthol.

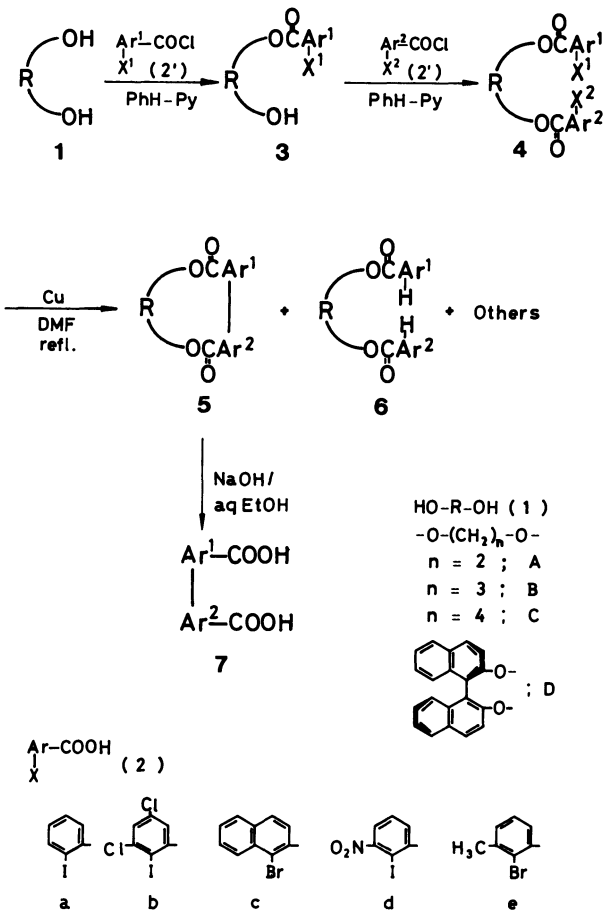
The formation of aryl–aryl bond continues to be an important problem in organic synthesis.[2)] Among a number of methods currently available, nucleophilic addition of aryl Grignard reagents to aryl halides in the presence of nickel–phosphine complex (Kumada-Tamao reaction)[3)] or 2-(*o*-alkoxyaryl)-2-oxazolines (Meyers reaction)[4)] has become widely utilized in the last decade. However, efforts have still been devoted to develop novel methodologies, because procedures are severely limited when one wants regioselective aryl–aryl bond formation between two differently substituted aromatic nuclei bearing substituents such as nitro or carbonyl which are incompatible with organomagnesium reagents.[5)] It is known that, for the aryl halides bearing such functionalities, the Ullmann coupling reaction is complementary to the organometallic routes.[6)] However, when applied to a mixture of two different aryl halides, the reaction rarely works well to give the unsymmetrical biaryl in good yield because of the inevitable formation of the symmetrically coupled products which are difficult to separate from the desired one.[7)]

In the course of our study on the asymmetric reaction by use of axially chiral biaryl auxiliaries, we encountered an occasion where unsymmetrical diphenic acids were needed.[8)] Herein we wish to report that the intramolecular Ullmann coupling reaction of mixed diester of 2-halobenzoic acids provides a convenient route to unsymmetrical diphenic acids, and if desired, with complete axial chirality.

Results and Discussion

Synthesis of Racemic Diphenic Acids. Newman and Cella had tried the synthesis of unsymmetrical diphenic acid via intramolecular Ullmann coupling of a mixed acid anhydride of 2-halobenzoic acids,[9)] but their attempt was not fully realized because of the rapid disproportionation of the anhydride before coupling, resulting in the formation of the corresponding symmetrical diphenic acids along with the unsymmetrical acid in a statistical ratio. Attempted intramolecular coupling of *N*-phenyl-2,2′-dibromodibenzimide or 2,2′-dibromobenzil also failed to cyclize to give *N*-phenyldiphenimide or phenanthrenequinone.

As we had succeeded in the intramolecular Ullmann coupling of diol diesters of 2-halobenzoic acids to give, after hydrolysis, symmetrical diphenic acids,[10)] we tried to extend the reaction to the unimolecular



Scheme 1.

Table 1. Intramolecular Ullmann Coupling of Mixed Diesters of 2-Halobenzoic Acids[a]

	4					5

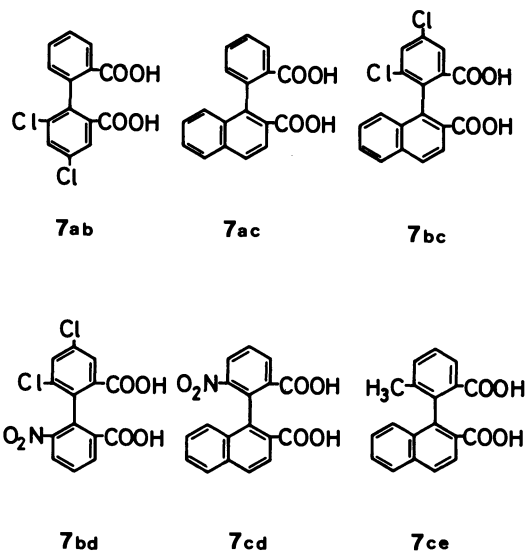
a) A solution of **4** in 40 ml of DMF was added to a vigorously stirred, gently refluxing suspension of Cu powder (20 equiv) in 60 ml of DMF during 6-h period. After the addition, the reaction was continued for 2 h. b) Eluent for the separation of **5** by silica-gel column chromatography; **5** was obtained as the first eluting component.

coupling of mixed diester of two different 2-halobenzoic acids for the synthesis of unsymmetrical diphenic acids (Scheme 1).

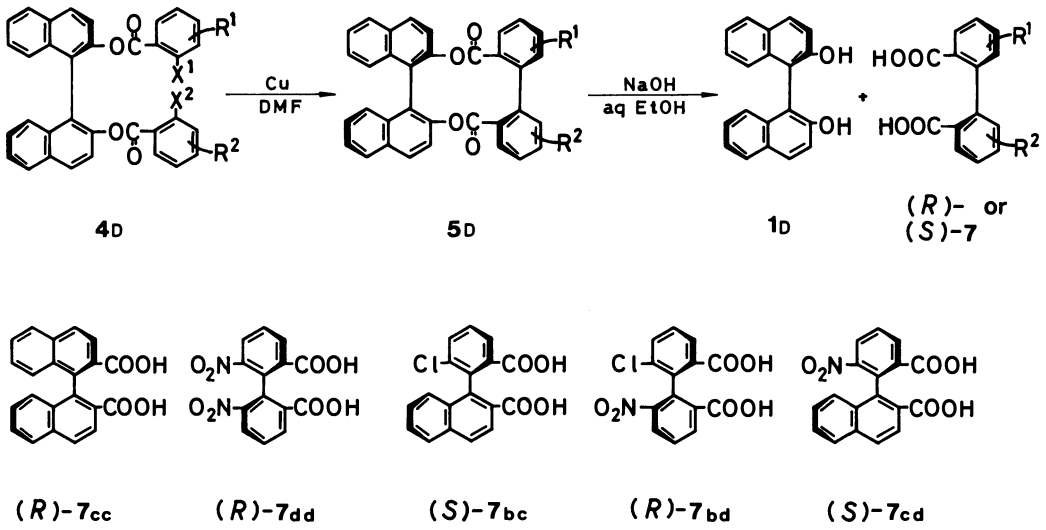
Treatment of a 2-halobenzoyl chloride **2′** with excess diol **1** in benzene–pyridine gave mono ester **3**. After purification by silica-gel column chromatography, **3** was in turn treated with a second 2-halobenzoyl chloride again in benzene–pyridine to give the corresponding unsymmetrical diester **4** in good yields.

The Ullmann reaction was carried out as before[10] by slowly adding a solution of **4** in *N,N*-dimethylformamide (DMF) to a vigorously stirred suspension of an activated copper powder in DMF heated at reflux. TLC analysis of the reaction mixture showed the presence of intramolecularly coupled cyclic diester **5** and of reduced, open chain diester **6** as the unimolecular reaction products accompanied by several oligomeric products originated from intermolecular coupling. It was shown that the monomeric cycle **5** was the first eluting component on silica-gel column, which enabled ready separation of **5** from the reduction product **6** and other by-products. Table 1 lists the results of the column-chromatographic separation of the intramolecularly coupled products, where yields refer to analytically pure samples.[11] This chromatographic behavior may reflect rather rigid, slightly strained cyclic structure of **5** as judged by higher IR absorption frequencies of the carbonyl function of **5** (1740—1750 cm^{-1}) than that of **6** (ca. 1720 cm^{-1}). CPK molecular models of **5** indicate that linking of two *o,o′*-positions of a biaryl by $-COO(CH_2)_2OCO-$ chain fixes the dihedral angle between the two phenyl rings to ca. 80°,[12] which disposes the $-OCH_2CH_2O-$ protons in diastereotopic positions, placing two of the vicinal protons near the shielding cones of the aromatic planes: ^1H NMR of **5** showed AA′BB′ pattern centered at around δ 4.1 and 5.1, while **6** showed a singlet at around δ 4.6 for these protons.

Hydrolytic removal of the bridging ethylenedioxy group from **5** was a trivial procedure, and afforded six unsymmetrical diphenic acids **7ab—7ce** listed.



Steric bulk of the *o,o′*-substituents in biphenyl system is estimated by Adams to be in the order of $H<CH_3<Cl<NO_2$.[13] The inferior result of the reaction of **4Ace** should be ascribed to the electronic effects of the methyl substituent, as is known that electron-donating substituents disfavor the Ullmann coupling. The yield of the intramolecular coupling seems to be improved by the use of somewhat longer methylene chain, which will impose less steric constraints on the cycle (compare the reaction of **4Ace** with that of **4Bce** and **4Cce**). The advantage was offset by the reduced separability of **5Cce** from **6Cce** on silica-gel column; the enlargement of the bridging chain seemed to reduce the difference of the chromatographic behavior between the cycle **5** and the open chain diester **6**.



Scheme 2.

Asymmetric Synthesis of Axially Chiral, Unsymmetrical Diphenic Acids. We have reported virtually complete asymmetric synthesis of axially chiral, symmetrical diphenic acids ((*R*)-**7cc**[14] and (*R*)-**7dd**[10]) via the intramolecular Ullmann coupling of diesters (**4Dcc** and **4Ddd**, respectively) prepared from (*R*)-1,1′-bi-2-naphthol ((*R*)-binaphthol, **1D**) (Scheme 2). The remarkable stereoselectivity in the joining of two aryl rings has been explained on the basis of the steric requirements in assembling the 12-membered cyclic diester **5D** which contains two sets of biaryl skeletons connected each other by –COO– bridges on *o,o′*-positions.[15] This means that the sense of axial chirality of the one biaryl unit determines that of the other in such ring systems, which can be utilized for the determination of axial chirality of relevant biaryl skeletons.[16]

The high stereoselectivity and predictability of the axial chirality were utilized for the synthesis of axially chiral, unsymmetrical diphenic acids of known absolute configurations ((*S*)-**7bc**, (*R*)-**7bd**, and (*S*)-**7cd**) (Scheme 2 and Table 1). Enantiomeric purity of these acids (>99%) were readily confirmed by HPLC analyses carried out on chiral stationary phases prepared from axially chiral binaphthyl derivatives.[8] Further confirmation of the assignment of absolute configurations of these acids by use of ^{1}H NMR spectral studies will be presented elsewhere.

It is known that the Ullmann reaction is susceptible to the reaction conditions, especially the nature of the copper used and accidental moisture, which makes reproducibility difficult. Although we could not fully clarify at present the reason why the reaction of **4Dbd** gave exceptionally good results, we are inclined to say that it was not accidental considering the fact that duplicate runs in this work gave practically analogous results with the deviation range of around ±15%; the combination of two 2-halobenzoic acids as well as the choice of the linking bridge may play a significant role in the reaction.

Previous synthesis of unsymmetrical diphenic acids is only limited.[6] Meyers et al. reported the synthesis of 6-methoxydiphenic acid in high yield by the oxazoline route, which, however, needed somewhat troublesome transformation of the two carboxyl groups to oxazolines for protection and activation, and deprotection after aryl coupling to regenerate them.[17] Although the method disclosed herein needed chromatographic purification, it gave moderate to good yields in the key intramolecular coupling. The procedure is operationally rather simple, and seems to have synthetic utility, especially where the Meyers reaction can not be applied, or where axially chiral diphenic acids are needed.

Experimental

Measurements. IR spectra were measured on a Shimadzu IR-430 grating spectrophotometer. ^{1}H NMR spectra were recorded on a JEOL JNM-FX60 instrument using tetramethylsilane as internal standard and $CDCl_3$ as solvent. Optical rotations were recorded on a Union PM-101 automatic digital polarimeter in a 1-cm cell at 23—25 °C. HPLC was carried out on a JASCO TRIROTAR-III and/or a Shimadzu LC-5A, with UV detection at 254 nm. Melting points were uncorrected.

Materials. Analytical TLC was performed using Merck silica gel 60G or $60F_{254}$. Merck silica gel 60H was used for preparative TLC. Silica-gel columns were prepared by use of Wako Gel C-200, while alumina columns by Wako activated alumina (ca. 300 mesh). DMF was distilled from CaH_2 just prior to use under nitrogen. Solvents for experiments requiring anhydrous conditions were purified by the usual methods. Enantiomerically pure (*R*)-binaphthol was obtained as before;[14] $[\alpha]_D$+34.6 ° (*c* 0.905, THF). Copper powder (Junsei Chemical Co., 200 mesh) was

pretreated for activation before the Ullmann reaction.[14]

2-Halobenzoic Acids (2). **2a** was used as purchased. **2b** was prepared according to the literature;[18] mp 179—181 °C (lit,[18] 175—180 °C), IR(KBr) 1705 cm^{-1}. Preparation of **2c**,[19] **2d**,[10] and **2e**[20] were reported before. These acids were converted to acid chlorides **2'** by boiling in thionyl chloride for several hours. After the reaction, volatiles were removed in vacuo, and a small amount of benzene was added and distilled off in vacuo. The latter procedure was repeated two more times, and the remaining acid chlorides were used directly for esterification.

Monoesters 3A—3C of Glycols 1A—1C. The synthesis of 2-(3,5-dichloro-2-iodobenzoyloxy)ethanol (**3Ab**) is representative for the preparation of glycol monoesters. To a stirred mixture of ethylene glycol (**1A**) (30 ml), benzene (30 ml), and pyridine (10 ml) was added dropwise a solution of **2'b** (prepared from 4.50 g of **2b**, 14.2 mmol) in benzene (30 ml). The mixture was stirred overnight at ambient temperature, and then heated at reflux for 3 h. To the cool mixture were added 30 ml of benzene and 100 ml of 2 M† HCl, and phases were separated. Aqueous phase was extracted with portions of benzene. Combined organic phase was washed with 2 M HCl, 1M Na_2CO_3, and water, and then dried over Na_2SO_4. After volatiles were removed in vacuo, the residue was subjected to silica-gel column chromatography eluting with $CHCl_3$ to give 4.72 g of **3Ab** (92%); mp 85—86 °C; IR (KBr) 3250 (br) and 1720 cm^{-1}; ^1H NMR δ=1.9 (1H, s, OH), 3.8—4.2 (2H, m, $\underline{CH_2}$-OH), 4.2—4.6 (2H, m, COO-CH_2), and 7.2—7.9 (2H, m, Ar-H).

3Ac was obtained from **2c** in 87% yield using benzene as the eluent for silica-gel column chromatography; mp 74—76 °C; IR (KBr) 3500 (br) and 1710 cm^{-1}; ^1H NMR δ=2.2 (1H, s, OH), 3.7—4.1 (2H, m, $\underline{CH_2}$-OH), 4.3—4.6 (2H, m, COO-CH_2), and 7.3—8.6 (6H, m, Ar-H).

3Ae was obtained from **2e** as an oil in 82% yield, using chloroform as the eluent for silica-gel column chromatography; IR (liq. film) 3400 (br) and 1720 cm^{-1}; ^1H NMR δ=2.4 (4H, s, OH and CH_3), 3.6—3.9 (2H, m, $\underline{CH_2}$-OH), 4.4—4.7 (2H, m, COO-CH_2), and 7.1—7.6 (3H, m, Ar-H).

3Be was prepared from **2e** and 1,3-propanediol; 83% yield, benzene as the eluent; oil; IR (liq. film) 3400 (br) and 1720 cm^{-1}; ^1H NMR δ=2.0 (1H, s, OH), 2.0 (2H, tt, J_1=J_2=6.0 Hz, $CH_2\underline{CH_2}CH_2$), 2.4 (3H, s, CH_3), 3.77 (2H, t, J_1=6.0 Hz, $\underline{CH_2}$-OH), 4.46 (2H, t, J_2=6.0 Hz, $COOCH_2$), and 7.0—7.6 (3H, m, Ar-H).

3Ce was obtained from **2e** and 1,4-butanediol; 79% yield, benzene-ethyl acetate (3/1) as the eluent; oil; IR (liq. film) 3350 (br) and 1730 cm^{-1}; ^1H NMR δ=1.7 (1H, s, OH), 1.7—2.0 (4H, m, $CH_2(\underline{CH_2})_2CH_2$), 2.42 (3H, s, CH_3), 3.68 (2H, t, J_1=6.0 Hz, $\underline{CH_2}$-OH), 4.34 (2H, t, J_2=6.0 Hz), and 7.0—7.6 (3H, m, Ar-H).

Monoesters 3D of (*R*)-Binaphthol 1D. 3Db: **2b** (7.50 g, 23.7 mmol) was converted to **2'b**, which was treated with **1D** (5.75 g, 20.1 mmol) as above. The reaction mixture was chromatographed on alumina; after diester **4Dbb** had been eluted out with toluene (0.30 g, 1.7% based on **1D**), elution with toluene-ethanol (10/1) and crystallization from toluene gave **3Db**, 9.94 g (85% based on **1D**); mp 175—177 °C; $[\alpha]_D$ +86.8° (*c* 0.852, $CHCl_3$); IR (KBr) 3450 and 1730 cm^{-1}; ^1H NMR δ=5.0 (1H, s (br), OH) and 7.0—8.2 (14H, m, Ar-H). Found: C, 55.19; H, 2.61; halogen, 34.11%. Calcd for $C_{27}H_{15}Cl_2IO_3$: C, 55.42; H, 2.58; Cl+I, 33.80%.

3Dc was obtained from **2c** (3.60 g, 14.3 mmol) and **1D** (4.20 g, 14.7 mmol) as above; 6.03 g (81% based on **2c**); mp 192—193 °C (lit,[14] 179—180 °C); $[\alpha]_D$ +33.2° (*c* 0.918, acetone) (lit,[14] $[\alpha]$+ 34.1° (*c* 1.38, acetone)), $[\alpha]_D$ +140.9° (*c* 1.35, $CHCl_3$); IR (KBr) 3400 and 1730 cm^{-1}; ^1H NMR δ=5.4 (1H, s (br), OH) and 6.5—8.4 (18H, m, Ar-H). Found: C, 71.36; H, 3.96; Br, 15.11%. Calcd for $C_{31}H_{19}BrO_3$: C, 71.69; H, 3.69; Br, 15.38%.

Diesters 4. The synthesis of 1-(1-bromo-2-naphthoyloxy)-2-(3,5-dichloro-2-iodobenzoyloxy)ethane (**4Abc**) is representative. A mixture of **2'c** (prepared from 1.50 g (5.98 mmol) of **2c**) and **3Ab** (1.81 g, 5.01 mmol) in benzene (80 ml) and pyridine (10 ml) was stirred overnight at ambient temperature, and then heated at reflux for 3 h. The reaction was worked up as was stated for the synthesis of monoesters. Silica-gel column chromatography eluting with benzene gave 2.68 g of **4Abc** (90%); mp 105—106 °C; IR (KBr) 1720 cm^{-1}; ^1H NMR δ=4.6 (4H, s, $(CH_2)_2$) and 7.0—8.5 (8H, m, Ar-H). Found: C, 40.52; H, 2.38; halogen, 46.52%. Calcd for $C_{20}H_{12}BrCl_2IO_4$: C, 40.44; H, 2.04; Br+Cl+I, 46.75%.

Similar reactions gave the following diesters; silica-gel column was used for purification of the diester unless otherwise noted.

4Aab: 89% yield, toluene as the eluent; mp 52—54 °C; IR (KBr) 1730 and 1700 cm^{-1}; ^1H NMR δ=4.65 (4H, s, $(CH_2)_2$) and 6.9—8.2 (6H, m, Ar-H). Found: C, 32.88; H, 1.89; halogen, 54.72%. Calcd for $C_{16}H_{10}Cl_2I_2O_4$; C, 32.52; H, 1.71; Cl+I, 54.95%.

4Aac: 90% yield, benzene as the eluent; oil; IR (liq. film) 1720 cm^{-1}; ^1H NMR δ=4.65 (4H, s, $(CH_2)_2$) and 6.9—8.6 (10H, m, Ar-H). Found: C, 45.76; H, 3.08; halogen, 39.71%. Calcd for $C_{20}H_{14}BrIO_4$: C, 45.74; H, 2.69; Br+I, 39.38%.

4Abd: 83% yield, cyclohexane-ethyl acetate (20/1) as the eluent; mp 105—108 °C; IR (KBr) 1720 cm^{-1}, ^1H NMR δ=4.65 (4H, s, $(CH_2)_2$) and 7.0—7.8 (5H, m, Ar-H). Found: C, 30.83; H, 1.67; N, 2.20; halogen; 50.56%. Calcd for $C_{16}H_9Cl_2I_2NO_6$: C, 30.22; H, 1.43; N, 2.02; Cl+I, 51.06%. The discrepancy of the elemental analysis seemed to be caused by deiodination during the column chromatography as judged by coloring.

4Acd: 86% yield, benzene as the eluent; mp 110—112 °C; IR (KBr) 1720 cm^{-1}; ^1H NMR δ=4.65 (4H, s, $(CH_2)_2$) and 7.1—8.5 (9H, m, Ar-H). Found: C, 42.56; H, 2.46; N, 2.15; halogen, 36.66%. Calcd for $C_{20}H_{13}BrINO_6$: C, 42.13; H, 2.30; N, 2.46; Br+I, 36.27%.

4Ace: 90% yield, toluene-hexane (3/1) as the eluent; mp 72—73.5 °C; IR (KBr) 1720 cm^{-1}; ^1H NMR δ=2.4 (3H, s, CH_3), 4.6 (4H, s, $(CH_2)_2$), and 7.0—8.6 (9H, m, Ar-H). Found: C, 51.53; H, 3.36; Br, 32.31%. Calcd for $C_{21}H_{16}Br_2O_4$: C, 51.25; H, 3.28; Br, 32.47%.

4Bce: 87% yield, toluene as the eluent; oil; IR (liq. film) 1720 cm^{-1}; ^1H NMR δ=2.1—2.6 (2H, m, CH_2-$\underline{CH_2}$-CH_2), 2.40 (3H, s, CH_3), 4.4—4.7 (4H, m, O$\underline{CH_2}$-$CH_2\underline{CH_2}$O), and 7.0—8.6 (9H, m, Ar-H). Found: C, 52.03; H, 3.72; Br, 31.37%. Calcd for $C_{22}H_{18}Br_2O_4$: C, 52.20; H, 3.58; Br, 31.57%.

4Cce: 81% yield, benzene-hexane (4/1) as the eluent; mp 73—77 °C; IR (KBr) 1710 cm^{-1}; ^1H NMR δ=1.7—2.1 (4H, m, CH_2-$(\underline{CH_2})_2$-CH_2), 2.3 (3H, s, CH_3), 4.2—4.6 (4H, m, O$\underline{CH_2}$-$(CH_2)_2$-$\underline{CH_2}$O), and 7.0—8.6 (9H, m, Ar-H). Found:

† 1 M=1 mol dm^{-3}.

C, 53.34; H, 3.95; Br, 30.41%. Calcd for $C_{23}H_{20}Br_2O_4$: C, 53.10; H, 3.88; Br, 30.72%.

4Dbc: The monoester **3Dc** (2.50 g, 4.82 mmol) was treated with **2'b** (prepared from 1.90 g of **2b** (5.99 mmol)) in benzene–pyridine in the presence of 50 mg of 4-(dimethylamino)pyridine to give 2.68 g (68% yield) of **4Dbc**; toluene as the eluent on alumina column; mp 99—102 °C; IR (KBr) 1750 cm^{-1}; $[\alpha]_D$ +29.9° (*c* 0.735, $CHCl_3$). Found: C, 55.78; H, 2.38; halogen, 34.11%. Calcd for $C_{38}H_{20}BrCl_2IO_4$; C, 55.78; H, 2.46; Br+Cl+I, 33.94%.

4Dbd: 93% yield, toluene–hexane (3/1) as the eluent; mp 85-90 °C; IR (KBr) 1745 cm^{-1}; $[\alpha]_D$ +46.0 ° (*c* 0.891, $CHCl_3$). Found: C, 47.20; H, 2.08; N, 1.58; halogen, 37.94%. Calcd for $C_{34}H_{17}Cl_2I_2NO_6$:C, 47.47; H, 1.99; N, 1.63; Cl+I, 37.74%.

4Dcd: 86% yield, toluene as the eluent; mp 103—106 °C; IR (KBr) 1745 cm^{-1}; $[\alpha]_D$ +29.4 ° (*c* 0.782, $CHCl_3$). Found: C, 57.81; H, 2.45; N, 1.89; halogen, 25.67%. Calcd for $C_{38}H_{21}BrINO_6$: C, 57.46; H, 2.66; N, 1.76; Br+I, 26.03%.

Synthesis of Unsymmetrical Diphenic Acids 7. General procedure for the Ullmann reaction was the same as that described in the previous paper unless otherwise noted.[10] To a vigorously stirred suspension of the activated copper powder (40—100 mg-atom) in DMF (60 ml) heated at gentle reflux, was added a solution of **4** (2—5 mmol) in 40 ml of DMF over a 6-h period under a nitrogen atmosphere. After 2-h heating at reflux, the reaction was treated as before:[10] The reaction mixture was filtered, products were taken into benzene, worked up as usual, and solvents were removed in vacuo. Organic residue was chromatographed on silica-gel column with eluent depicted in Table 1 to isolate the intramolecularly coupled cycle **5**, which was obtained as the first eluting component. Alkaline hydrolysis of **5** (0.3—1.6 mmol) was performed by boiling with KOH (1—2 g) in ethanol(50 ml)–water(3 ml).

Synthesis of 7ab: The treatment of **4Aab** (3.02 g) with 6.5 g of copper powder gave, after usual workup, 1.60 g of organic residue, which was chromatographed on silica-gel column with toluene as the eluent to give 0.878 g of **5Aab** (R_f=0.41 on Merck 60G/toluene) and 50 mg of **6Aab** (R_f=0.31). **5Aab**; mp, 165—167 °C; ^1H NMR δ=3.8—4.3 (2H, m, CHH-CHH), 4.8—5.3 (2H, m, CHH-CHH), and 7.1—8.0 (6H, m, Ar-H). Found: C, 57.17; H, 3.22; Cl, 21.34%. Calcd for $C_{16}H_{10}Cl_2O_4$: C, 57.00; H, 2.99; Cl, 21.03%. **6Aab**: IR (KBr) 1720 cm^{-1}; ^1H NMR δ=4.6 (4H, s, $(CH_2)_2$) and 7.1—8.0 (8H, m, Ar-H).

After a sample of **5Aab** (0.50 g, 1.48 mmol) had been boiled with KOH (1 g) in aq ethanol for 4 h, the mixture was diluted with water, and most of the ethanol was removed under reduced pressure. The aqueous phase was extracted with ether, made acidic by adding concd HCl, and then extracted with ether. After the usual workup, evaporation of the solvent afforded **7ab** as white powder; 0.41 g, 89% yield; mp 204—205 °C; IR (KBr) 2900 (br), 1690, 1400, 1260, 1080, 1000, 800, and 700 cm^{-1}. Found: C, 53.91; H, 2.65; Cl, 23.03%. Calcd for $C_{14}H_8Cl_2O_4$: C, 54.05; H, 2.59; Cl, 22.79%.

Synthesis of 7ac: Treatment of 2.56 g of **4Aac** gave 0.667 g of **5Aac**; mp 58—59 °C; ^1H NMR δ=3.8—4.4 (2H, m, CHH-CHH), 4.8—5.4 (2H, m, CHH-CHH), and 7.1—8.2 (10H, m, Ar-H). Found: C, 75.31; H, 4.30%. Calcd for $C_{20}H_{14}O_4$: C, 75.46; H, 4.43%.

Hydrolysis of 0.50 g of **5Aac** gave 0.39 g of **7ac**; 85% yield; mp 228—230 °C; IR (KBr) 2900 (br), 1680, 1400, 1280, 1240, and 750 cm^{-1}. Found: C, 73.81; H, 4.20%. Calcd for $C_{18}H_{12}O_4$: C, 73.96; H, 4.14%.

Synthesis of 7bc: Treatment of 2.12 g of **4Abc** gave 0.843 g of **5Abc**; mp 60—61 °C; ^1H NMR δ=3.8—4.4 (2H, m, CHH-CHH), 4.9—5.3 (2H, m, CHH-CHH), and 7.1—8.1 (8H, m, Ar-H). Found: C, 61.66; H, 3.26; Cl, 17.98%. Calcd for $C_{20}H_{12}Cl_2O_4$: C, 62.04; H, 3.12; Cl, 18.31%.

Hydrolysis of 0.55 g of **5Abc** gave 0.46 g of **7bc**: 89% yield; mp 238—239 °C; IR (KBr) 2950 (br), 1690, 1280, 1250, 1080, 1010, and 790 cm^{-1}. Found: C, 59.57; H, 2.94; Cl, 19.34%. Calcd for $C_{18}H_{10}Cl_2O_4$: C, 59.86; H, 2.79; Cl, 19.63%.

Synthesis of 7bd: Treatment of 1.95 g of **4Abd** gave 0.661 g of **5Abd**; mp 172—173 °C; ^1H NMR δ=3.7—4.3 (2H, m, CHH-CHH), 4.7—5.4 (2H, m, CHH-CHH), and 7.0—8.3 (5H, m, Ar-H). Found: C, 50.58; H, 2.57; N, 3.45; Cl, 18.25%. Calcd for $C_{16}H_9Cl_2NO_6$: C, 50.29; H, 2.37; N, 3.67; Cl, 18.55%.

Hydrolysis of 0.50 g of **5Abd** gave 0.45 g of **7bd**; 96% yield; mp 276—277 °C; IR (KBr) 2900 (br), 1690, 1530, 1280, 1240, 820, and 690 cm^{-1}. Found: C, 47.63; H, 2.21; N, 3.65; Cl, 20.19%. Calcd for $C_{14}H_7Cl_2NO_6$: C, 47.22; H, 1.98; N, 3.93; Cl, 19.91%.

Synthesis of 7cd. Treatment of 2.15 g of **4Acd** gave 0.520 g of **5Acd**; 260—262 °C; ^1H NMR δ=3.8—4.4 (2H, m, CHH-CHH), 4.8—5.5 (2H, m, CHH-CHH), and 7.2—8.3 (9H, m, Ar-H). Found: C, 65.76; H, 3.66; N, 3.99%. Calcd for $C_{20}H_{13}NO_6$: C, 66.12; H, 3.61; N, 3.86%.

Hydrolysis of 0.35 g of **5Acd** gave 0.31 g of **7cd**: 95% yield, mp 249—250 °C; IR (KBr), 2950 (br), 1690, 1530, 1350, 1280, 1070, and 790 cm^{-1}. Found: C, 63.76; H, 3.63; N, 3.91%. Calcd for $C_{18}H_{11}NO_6$: C, 64.10; H, 3.29; N, 4.15%.

Synthesis of 7ce: Treatment of 1.10 g of **4Ace** gave 0.212 g of **5Ace**; mp, 196—199 °C; ^1H NMR δ=1.92 (3H, s, CH_3), 3.8—4.4 (2H, m, CHH-CHH), 4.7—5.4 (2H, m, CHH-CHH), and 7.1—8.0 (9H, m, Ar-H). Found: C, 76.10; H, 4.94%. Calcd for $C_{21}H_{16}O_4$: C, 75.89; H, 4.85%.

Hydrolysis of 0.15 g of **5Ace** gave 0.12 g of **7ce**; 87% yield; mp 211—215 °C; IR (KBr) 3000 (br), 1690, 1400, 1290, 1250, and 760 cm^{-1}. Found: C, 74.42; H, 4.81%. Calcd for $C_{19}H_{14}O_4$: C, 74.50; H, 4.61%.

From 2.60 g of **4Bce** was obtained 0.55 g of **5Bce**; mp, 180—182.5 °C; ^1H NMR δ=1.9 (3H, s, CH_3), 1.8—2.4 (2H, m, $CH_2CH_2CH_2$), 3.7—5.0 (4H, m, $OCH_2CH_2CH_2O$), and 7.2—8.0 (9H, m, Ar-H). Found: C, 76.53; H, 5.26%. Calcd for $C_{22}H_{18}O_4$: C, 76.29; H, 5.24%.

From 1.73 g of **4Cce** was obtained 0.59 g of **5Cce**; mp, 165—168.5 °C; ^1H NMR δ=1.6—2.0 (4H, m, $CH_2(CH_2)_2CH_2O$), 1.9 (3H, s, CH_3), 3.8—4.6 (4H, m, $OCH_2(CH_2)_2CH_2O$), and 7.1—8.0 (9H, m, Ar-H). Found: C, 76.23; H, 5.81%. Calcd for $C_{23}H_{20}O_4$: C, 76.65; H, 5.59%.

Synthesis of (*R*)-7bd: Treatment of 1.65 g of **4Dbd** gave 0.93 g of **5Dbd**; mp 195—198 °C; $[\alpha]_D$ +151.3 ° (*c* 0.840, $CHCl_3$). Found: C, 67.46; H, 2.81; N, 2.02; Cl, 11.95%. Calcd for $C_{34}H_{17}Cl_2NO_6$: C, 67.34; H, 2.83; N, 2.31; Cl, 11.69%.

A portion of the **5Dbd** (0.53 g, 0.875 mmol) was treated with KOH in aq ethanol as above. The reaction mixture was diluted with 50 ml of water, and most of ethanol was removed in vacuo. The residue was extracted with ether, and the aqueous phase was made acidic with concd HCl, followed by extraction with diethyl ether. Ether extracts were combined, and then extracted with 2 M sodium hydrogencarbonate solution, leaving binaphthol in ether

phase. The diphenic acid and binaphthol were recovered by the usual procedure. Recovered (*R*)-binaphthol (0.22 g, 88%) showed no sigh of racemization as judged by its optical rotation; $[\alpha]_D$ +35.0° (*c* 0.813, THF).

(*R*)-**7bd:** 0.28 g (90% yield); mp 237—238°C; $[\alpha]_D$ +35.0° (*c* 0.485, 95% EtOH); IR (KBr) 3000 (br), 1700, 1530, 1350, 1280, 1240, 820, and 790 cm^{-1}. Found: C, 47.63; H, 2.21; N, 3.65; Cl, 20.19%. The enantiomeric purity of the acid (>99% ee) was confirmed by HPLC analysis by comparing the corresponding racemic acid; the details of the experiment have been reported.[8]

Diphenic acids were converted to *N,N'*-dibutyldiphenamides for HPLC analysis as follows: A mixture of a diphenic acid (5—10 mg) in 0.5 ml of thionyl chloride in a screw-capped bottle was stirred under sonication for 1.5 h at 60 °C. Excess thionyl chloride was removed in vacuo, and then 0.5 ml of butylamine was added. After the mixture had been stirred for 1 h at ambient temperature, excess amine was removed in vacuo. The residue was purified by preparative TLC (ethyl acetate-hexane (2/1)).

Synthesis of (*S*)-7bc: Treatment of 1.55 g of **4Dbc** gave 0.38 g of **5Dbc**; mp 205—208 °C; $[\alpha]_D$+272° (*c* 2.22, $CHCl_3$). Found: C, 75.01; H, 2.94; Cl, 11.35%. Calcd for $C_{38}H_{20}Cl_2O_4$: C, 74.64; H, 3.30; Cl, 11.60%.

Hydrolysis of 0.20 g of **5Dbc** gave 0.11 g of (*S*)-**7bc**; 93% yield; mp 238—239 °C; $[\alpha]_D$ −1.3° (*c* 1.57, THF), −18.6° (*c* 1.02, $CHCl_3$); IR (KBr) 2900 (br), 1700, 1440, 1400, 1270, 1230, 790, and 760 cm^{-1}. Found: C, 59.41; H, 2.73; Cl, 19.26%.

Synthesis of (*S*)-7cd: Treatment of 1.45 g of **4Dcd** gave 0.47 g of **5Dcd**; mp 324—326 °C; $[\alpha]_D$ +201° (*c* 0.762, $CHCl_3$). Found: 78.04; H, 4.01; N,2.26%. Calcd for $C_{38}H_{21}NO_6$: C, 77.68; H, 3.60; N, 2.38%.

Hydrolysis of 0.25 g of **5Dcd** gave 0.13 g of (*S*)-**7cd**; 91% yield; mp 210—212 °C; $[\alpha]_D$ +42.0° (*c* 1.95, THF), +30.4° (*c* 0.520, 95% EtOH); IR (KBr) 2900 (br), 1690, 1530, 1345, 1300, 1070, 1010, 790, 770, and 750 cm^{-1}. Found: C, 64.10, H, 3.19; N, 4.09%.

Regio- and Stereoselective Ring Opening of ω-Alkenyllactones Using Organocopper Reagents[1)]

Masatoshi KAWASHIMA, Toshio SATO, and Tamotsu FUJISAWA*
Chemistry Department of Resources, Mie University, Tsu, Mie 514
(Received April 2, 1988)

New synthetic methods are described for the preparation of (*E*)-3-, (*E*)-4-, and (*E*)-5-alkenoic acids by the regio- and stereoselective ring opening of β, γ, and δ-lactones with unsaturated substituents at the ω-position using organocopper reagents such as halomagnesium diorganocuprates or Grignard reagents in the presence of copper(I) iodide. Both the organocopper reagents with primary, secondary, tertiary alkyl, and phenyl groups gave the corresponding carbon homologated alkenoic acids in good yields. Alkadienoic acids were also obtained in good yields by the reactions of ω-alkenyllactones with divinyl- and diallylcuprates. Utilizing the ring opening of β-isopropenyl-β-propiolactone, homoterpenoid carboxylic acids were easily obtained in good yields. The ring opening of β-(1-chlorovinyl)-β-propiolactone afforded 4-chloro-3-alkenoic acids which were easily transformed to 4-oxoalkanoic acids and 4-oxo-2-alkenoic acids.

Nucleophilic displacement reactions of allylic compounds have received considerable attention[2)] because of their synthetic and mechanistic importance on the regio- and stereochemistry. Recently their attentions have been poured into the applications of organometallic reagents to selective carbon homologation with newly formed carbon–carbon double bond. Among organometallic reagents, organocopper reagents have been most widely used for the substitution reactions and applied to the synthesis of various kinds of alkenes. The regio- and stereoselective synthesis of alkenes is very important but not so easy since the selectivity is affected by many factors such as the structure of substrate, the nature of organocopper reagent, solvent, temperature and so on.[3,4)] On the other hand, there were many reports on the synthetic methods of alkenoic acids which are useful building blocks for the synthesis of natural products. The representative methods such as Ramberg-Bäcklund rearrangement of ω-halo-ω-(alkylsulfonyl)alkanoic acids,[5)] Knoevenagel condensation of malonic acid with aldehyde,[6)] and the reduction of the alkynoic acid[7)] are capable for disubstituted alkenes, but not for trisubstituted alkenes such as terpenoid carboxylic acid. Moreover, there is no sufficient method, to our knowledge, in all of aspects of stereoselectivity of carbon–carbon double bond, the product yield, the applicability, and the convenience of the synthetic procedure.

Previously the synthetic methods of 3-substituted propanoic acids by the reactions of β-propiolactones with organocopper reagents were reported.[8)] The high regioselectivity of the ring opening of the lactone was achieved by the attack of organocopper reagents, considered as "soft base", to the "soft" β-carbon atom of the lactone rather than the attack to the "hard" carbonyl carbon atom.[9)] Therefore, if β-propiolactone possesses a vinyl group at β-carbon, it is expected that the "softer" organocopper reagent attacks the "softer" terminal vinyl carbon of the lactone in the S_N2' manner to afford 4-substituted 3-alkenoic acid. Moreover, this concept seems to be capable for the new synthetic method of alkenoic acid **1** by the ring opening of ω-alkenyllactones **2** using organocopper reagents. Actually ring opening of γ- and δ-lactones possessing ω-unsaturated substituent with organocopper reagents have been reported.[10)] The present paper shows the detail on the regio- and stereoselective ring opening of ω-alkenyllactones such as β-vinyl-β-propiolactone, β-isopropenyl-β-propiolactone, β-(1-chlorovinyl)-β-propiolactone, γ-vinyl-γ-butyrolactone, and δ-vinyl-δ-valerolactone with organocopper reagents to afford various kinds of alkenoic acids.

7

When β-vinyl-β-propiolactone (**3**), prepared by the cycloaddition of acrylaldehyde with ketene,[11)] was treated with butylmagnesium bromide in the presence of copper(I) iodide (2 mol%) in THF at −30 °C, two kinds of carboxylic acids, 3-nonenoic acid (**4b**) and 3-butyl-4-pentenoic acid (**5b**), formed by both S_N2' and S_N2 reactions respectively, were obtained in 91% yield

Table 1. Reactions of β-Vinyl-β-propiolactone with Butylmetallic Compounds

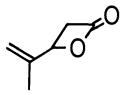
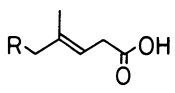
a) Isolated yield. b) Determined by GLC analysis. c) For the case of butylcopper-dimethyl sulfide and copper-catalyzed butyl Grignard reagent, the ratio of THF to Me$_2$S was 5:1 and 20:1, respectively.

without accompanying the products **6** and **7** by the attack to the carbonyl carbon. GLC analysis of the acids showed the ratio of **4b** to **5b** as 98:2, indicating that the reaction regioselectively proceeds through S_N2' pathway. Butyl Grignard reagent and other butylcopper reagents were used in this ring opening of the lactone **3**. It should be noted that the reaction of the lactone **3** with butylmagnesium bromide in the absence of copper catalyst in THF at −30 °C gave only 11% of **4b** along with **6** and **7**. Although three kinds of monoorganocopper complexes with tributylphosphine, trifluoroborane,[12] and dimethyl sulfide gave only carboxylic acids **4** and **5** in high yields, the ratio of the S_N2' product to the S_N2 product was somewhat inferior to that of the reaction of Grignard reagents in the presence of copper(I) iodide. Even lithium diorganocuprate which is commonly used in the allylic substitutions did not reveal the selectivity as high as copper-catalyzed Grignard reagent. Therefore optimum conditions were examined in the reaction of the lactone **3** with Grignard reagent in the presence of copper(I) iodide. The solvent and temperature effects on both the regioselectivity and the stereochemistry of the newly formed double bond of **4b** were examined. When homogeneous reaction was carried out by adding dimethyl sulfide as a co-solvent of THF to dissolve the copper catalyst, the yield of the acids increased from 91% to 96% with the same ratio of **4b** to **5b** (98:2). Ether, instead of THF, was employed as a solvent to result in decreasing both the yield (68%) and regioselectivity (**4b**:**5b**=80:20). High regio- and stereoselectivity by the S_N2' reaction was exhibited at a lower temperature. When the reaction was carried out at −100 °C, **4b** was obtained in a high yield of 94% along with only a trace amount of **5b** and the ratio of the *E*- to *Z*-isomer of **4b** was 90:10. These results are shown in Table 1. Since it was reported that the active species in copper-catalyzed Grignard reaction were halomagnesium cuprates,[3,13] the reaction of the lactone **3** with dibutylcuprate, prepared from one equivalent of copper(I) iodide and two equivalents of butylmagnesium bromide, was examined. Expectedly the reaction proceeded regio- and stereoselectively to afford the acid **4b** in a yield of 92% (E:Z=89:11) along with a small amount of **5b**. The reactions of several representative Grignard reagents in the presence of copper catalyst and diorganocuprates with the lactone **3** were examined. Both of the reactions of diorganocuprates and of Grignard reagents in the presence of a catalytic amount of copper(I) iodide proceeded with similar selectivity to afford the corresponding 3-alkenoic acids **4a—g** in similar good yields, when the organic groups of organocopper reagents are primary, secondary, and tertiary alkyl ones. In contrast to the poor result of the copper-catalyzed reaction of allylmagnesium bromide, the reaction using diallylcuprate proceeded with higher regio- and stereoselectivity to give the corresponding dienoic acid. The result was not improved in the case of divinylcuprate. These results are summarized in Table 2.



8



9

Synthesis of 4-methyl-5-substituted 3-pentenoic acids **9** was performed by using regio- and stereoselective ring opening of β-isopropenyl-β-propiolactone (**8**) prepared by the cycloaddition of methacrylaldehyde with ketene.[11b] Grignard reagents with primary, secondary, and tertiary alkyl groups, and with phenyl group furnished the acids **9a—e** in good yields, respectively. Although copper-catalyzed Grignard reagents with vinyl and allyl groups gave the acids **9f** and **9g** in poor yields, the use of divinyl- and diallylcuprate increased the yield of **9f** and **9g** in similar to the case of the lactone **3**. On the stereochemistry of the products, the ratio of *E*-isomer to *Z*-isomer was ranging from 82:18 to 66:34.

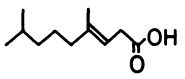
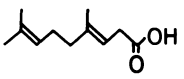
a) All products were isolated and the isomer ratios were determined by GLC analysis. b) Reactions were performed in THF-Me_2S (20:1). In the ring opening of **3** and **8**, 2 mol% of CuI was used. In the ring opening of **10**, 4 mol% of CuI was used. c) Reactions were performed in THF-Me_2S (10:1).

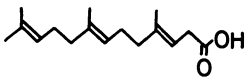
Compared with the ring opening of the vinyllactone **3**, the reaction of the isopropenyllactone **8** was found to give exclusively regioselective products by S_N2' reaction without any products through S_N2 pathway, but the stereoselectivity of newly formed carbon–carbon double bond somewhat decreased. These results are also summarized in Table 2.



9h

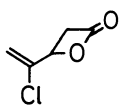


9i

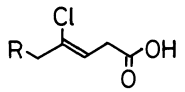


9j

Ring opening of the lactone **8** was applied to the synthesis of homoterpenoid carboxylic acids which were useful for the synthesis of terpenoid natural products.[14] 4,8-Dimethyl-3-nonenoic acid (**9h**) was obtained in 85% yield by the reaction of the lactone **8** with isopentylmagnesium bromide in the presence of copper(I) iodide (2 mol%). Homogeranic acid (**9i**) and homofarnesylic acid (**9j**) were obtained by the reaction of the lactone **8** with halomagnesium diprenylcuprate and digeranylcuprate in 89% and 68% yields, respectively. The isomer ratios of (*E*) to (*Z*) of newly formed carbon–carbon double bond of these acids **9h—j** were ca. 75:25.

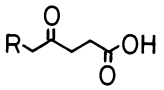


10



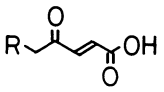
11

The synthesis of 4-chloro-3-alkenoic acid **11** was tried by the ring opening of β-(1-chlorovinyl)-β-propiolactone (**10**) prepared by the cycloaddition of α-chloroacrylaldehyde with ketene.[11b] When the lactone **10** was treated with various kinds of Grignard reagents in the presence of 4 mol% of copper(I) iodide, in THF–Me_2S at −78 °C, only S_N2' products, **11a—g** were formed in high yields. As the substituents of Grignard reagents, not only primary, secondary, and tertiary alkyl groups, but also phenyl and vinyl groups could be used to give good results. Diphenyl-, divinyl-, and diallylcuprates gave the corresponding acids **11e—g** in much higher yields than the corresponding Grignard reagents in the presence of copper(I) iodide. Stereochemistry of the newly formed carbon–carbon double bond of **11a—g** was determined to be predominant *Z* configuration in all cases, by comparing the NMR spectra with those of *E*- and *Z*-isomers of ethyl 4-chloro-3-pentenoate[15] and by capillary GLC analysis. Although the major isomer of obtained acid is named as *Z*-isomer in nomenclature, the relative configuration of the carbon–carbon double bond is same as that of (*E*)-3-alkenoic acid obtained by the ring opening reaction of the lactone **3**. These results are summarized also in Table 2.

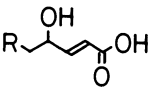


12

13



14



15

The utility of the acids **11** was demonstrated by the transformation to 4-oxoalkanoic acids **12** which are well-known as important precursors for γ-substituted γ-butyrolactones (**13**) as natural products.[16] According to the reported method of the hydrolysis of vinyl chloride to ketones,[17] treatment of **11b** with $TiCl_4$, MeOH, H_2O, and acetone in CH_2Cl_2 gave 4-oxononanoic acid (**12b**) in 82% accompanied with 8% yield of methyl 4-oxononanoate. The other acids **11** were also hydrolyzed to the corresponding keto acids **12** in good yields except for the cases of chlorodienoic acids such as **11f** and **11g**, which gave complex mixture. Moreover the transformation of **11** to 4-oxo-2-alkenoic acid **14**, which is incorporated in the macrolide antibiotics[18] such as A26771B, pyrenophorin, and vermiculine, was also achieved by the convenient method as follows. Hydrolysis of **11b** with refluxing 2 M NaOH (1 M=1 mol dm^{-3}) afforded 4-hydroxy-2-nonenoic acid (**15b**). Without any purification, **15b** was converted to 4-oxo-2-nonenoic acid (**14b**) by the Jones oxidation in a yield of 61% from **11b**. In this transformation, all of the other acids **11** were transformed to the corresponding keto alkenoic acids **14** in moderate yields. These results were summarized in Table 3.

γ-Butyrolactone and δ-valerolactone do not react with diorganocuprate and these lactones have been used for the synthesis of keto alcohol by the addition of alkyllithium to the carbonyl carbon of the lactones.[19] Nevertheless the ring opening of γ-vinyl-γ-butyrolactone and δ-vinyl-δ-valerolactone using organocopper reagents proceeded in S_N2' reaction leading to 4- and 5-alkenoic acids in a similar way to the case of four-membered lactones. Several papers concerning the reactions of the related γ-lactones

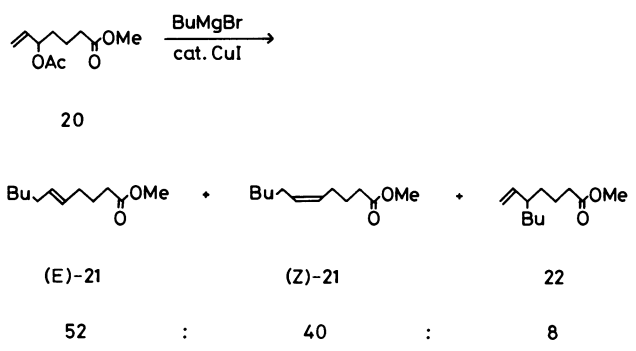
a) All products were isolated and the isomer ratios were determined by GLC analysis. b) Reactions were performed in THF–Me_2S (20:1). In the ring opening of **16** and **18**, 2 and 3 mol% of CuI were used, respectively. c) Reactions were performed in THF–Me_2S (10:1).

the S_N2' reaction. GLC analysis of the acid **17b** showed the predominance of the *E*-isomer (*E*:*Z*= 86:14). Both of copper-catalyzed Grignard reagents with primary, secondary, and tertiary alkyl groups and the corresponding dialkylcuprates attacked regioselectively the terminal vinyl carbon of the lactone to afford (*E*)-4-alkenoic acids **17a—d** in high yields. Diphenyl-, divinyl-, and diallylcuprates gave the acids **17e—g** in higher yields than the corresponding copper-catalyzed Grignard reagents. These results are summarized in Table 4.

δ-Vinyl-δ-valerolactone (**18**)[22] was also found to react regio- and stereoselectively with organocopper reagents as shown also in Table 4. In a similar way to the case of the reaction of vinylbutyrolactone **16**, (*E*)-5-alkenoic acids **19a—d** as the S_N2' products were predominantly obtained in the reaction of the lactone **18** with alkyl Grignard reagents in the presence of copper(I) iodide and with dialkylcuprates. The use of divinyl- and diallylcuprate resulted in increasing the yields and the geometrical purity of the dienoic acids **19f,g**.

In the synthetic methods of alkenoic acids described above, the cyclic structure of the lactones **3**, **8**, **10**, **16**, and **18** as the starting materials seems to be essential for high regio- and stereoselectivity as confirmed by the following control experiment. When methyl 5-acetoxy-6-heptenoate (**20**) was treated with butylmagnesium bromide in the presence of copper(I) iodide (3 mol%) in THF–Me_2S (20:1) at −45 °C for 1 h, methyl (*E*)- and (*Z*)-5-undecenoates (**21**) (S_N2' products) and methyl 5-vinylnonanoates (**22**) (S_N2 product) were obtained in 98% yield in the ratio of 52:40:8, while the reaction of the corresponding lactone **18** gave only S_N2' product with (*E*):(*Z*) ratio of 88:12. Anderson et al. reported that S_N2':S_N2 and (*E*)-S_N2':(*Z*)-S_N2' ratios of the substitution products of allylic esters were enhanced with leaving groups of lower acidity of the conjugate acid.[23] In also the above example, the acidity of the conjugate acids of ω-alkenyllactones is lower than that of methyl 5-acetoxy-6-heptenoate. Therefore the ring opening of three kinds of β-vinyllactones **3**, **16**, and **18** seemed to indicate almost similar selectivity regardless the number of the ring construction atoms, since it is thought that there is no large difference among the acidity of the conjugate acids of three kinds of β-vinyllactones **3**, **16**, and **18**.



The above description defines a new convenient synthetic method of (*E*)-3-, (*E*)-4-, and (*E*)-5-alkenoic acids by the reactions of β-, γ-, and δ-lactones possessing ω-alkenyl group with organocopper reagents. Advantages of these C_5—C_7 carbon homologation methods are specified as follows: (1) starting materials are easily accessible, (2) the reaction procedure is simple, (3) the introduction of various kinds of organic groups to the alkenoic acid is possible because of the easy availability of Grignard reagent, (4) carboxyl group and carbon–carbon double bond are easily transformed to other functional groups. Synthetic utilities of these methods were represented in previous communications on the synthesis of natural products.[1b-d,24]

Experimental

General. Boiling points were measured at the pressure indicated and are uncorrected. Infrared spectra were recorded on a Hitachi EPI-G2 spectrometer. ^1H NMR spectra were recorded on a Varian A-60 spectrometer and on a Jeol JNM-PMX60SI spectrometer and are reported in parts per million (δ) from TMS. Samples were dissolved in CCl_4 containing TMS as an internal standard. GLC analysis were performed on a Yanaco G-180 Gas Chromatograph using a 0.25 mm×50 m FFAP column. Preparative thin-layer chromatography (TLC) was performed on 20×20 cm glass plates coated with 1.5 mm of silica gel (Wakogel B-5F). Distillation of reaction products was performed on a Kugelrohr apparatus.

All reactions were run under a positive pressure of dry argon. Reactions requiring anhydrous conditions were performed in a flame-dried glassware that was cooled under argon. Anhydrous solvents were transferred by an oven-dried syringe. Solvents were distilled before use: diethyl ether from lithium aluminium hydride; tetrahydrofuran (THF) from sodium benzophenone ketyl. Dimethyl sulfide (Me_2S) was used without purification. Grignard reagents and butyllithium were standardized by titration with 2-butanol using 1,10-phenanthroline as an indicator.[25] Copper(I) iodide was purified by a known method.[26] All ω-alkenyllactones were prepared by published procedures.[11,21,22]

Procedure for the Reaction of Butylmagnesium Bromide in the Presence of 2 mol% CuI with β-Vinyl-β-propiolactone (3). In a typical experiment a flask equipped with a magnetic stirring bar and a septum was charged 9.3 mg (0.04 mmol) of CuI. After flushing with dry argon, 6 ml of anhydrous THF and 0.5 ml of Me_2S were added and the solution was chilled to −100 °C. A THF solution (2 ml) of 200 mg (2.00 mmol) of **3** was added to the flask. After stirring the mixture for 10 min, a solution of 2.40 mmol of BuMgBr in 2 ml of THF was added over 5 min. The reaction mixture was stirred for 15 min at −100 °C and then quenched with 2 ml of 3 M HCl and extracted with ether. The separated organic layer was extracted with three 5 ml

portions of 3 M NaOH. The alkaline solution was acidified with 3 ml of 6 M HCl, and then extracted with ether. The ethereal extracts were washed with brine and dried ($MgSO_4$). Removal of the solvent followed by vacuum distillation gave 295 mg (94%) of clear oil. Regio- and stereoisomer ratios were determined by GLC analyses of the corresponding methyl ester using a FFAP 50 m column. Regioisomers were separated by TLC (hexane:AcOEt:AcOH=60:20:1).

The same procedure was used for the copper-catalyzed reactions of Grignard reagents with ω-alkenyllactones shown in Tables 2 and 4.

Procedure for the Reaction of Dibutylcuprate with the Lactone 3. In a typical experiment a flask equipped with a magnetic stirring bar and a septum was charged 420 mg (2.20 mmol) of CuI. After flushing with dry argon, 4 ml of anhydrous THF and 1 ml of Me_2S were added and the solution was chilled to −30 °C. A solution of 4.40 mmol of BuMgBr in 4 ml of THF was added. After stirring for 30 min at −30 °C, the mixture was chilled to −78 °C and a THF solution (2 ml) of 200 mg (2.00 mmol) of **3** was added to the flask. The reaction mixture was stirred for 60 min at −78 °C, worked up, purified, and analyzed as the case of copper-catalyzed reaction. The same procedure was used for the reactions of diorganocuprates with ω-alkenyllactones shown in Tables 2 and 4.

3-Hexenoic Acid (4a).[27] Bp 80 °C (bath temp)/1.5 mmHg (1 mmHg=133.322 Pa).

3-Nonenoic Acid (4b):[28] Bp 130 °C (bath temp)/1.5 mmHg; IR (neat) 1710 (s) and 965 (s) cm^{-1}; ^1H NMR δ=0.90 (t, J=6.5 Hz, 3 H), 1.07—1.80 (m, 6H), 1.80—2.30 (m, 2H), 2.83—3.17 (m, 2H), 5.33—5.68 (m, 2H), 10.84 (s, 1H).

3-Butyl-4-pentenoic Acid (5b). R_f=0.3 (Hexane:AcOEt:AcOH=60:20:1); IR (neat) 1710 (s), 995 (s), and 920 (s) cm^{-1}; ^1H NMR δ=0.87 (t, J=6.5 Hz, 3H), 1.05—1.52 (m, 6H), 2.13—2.76 (m, 3H), 4.69—5.84 (m, 3H), 10.83 (s, 1H); Anal. ($C_9H_{16}O_2$) C, H.

6-Methyl-3-octenoic Acid (4c). Bp 130 °C (bath temp)/1.5 mmHg; IR (neat) 1715 (s) and 970 (s) cm^{-1}; ^1H NMR δ=0.86 (d, J=6.5 Hz, 3H), 0.88 (t, J=6.5 Hz, 3H), 1.08—1.77 (m, 3H), 1.77—2.25 (m, 2H), 2.90—3.24 (m, 2H), 5.28—5.68 (m, 2H), 10.93 (s, 1H); Anal. ($C_9H_{16}O_2$) C, H.

6,6-Dimethyl-3-heptenoic Acid (4d). Bp 130 °C (bath temp)/1.5 mmHg; IR (neat) 1715 (s) and 970 (s) cm^{-1}; ^1H NMR δ=0.90 (s, 9H), 2.04—2.16 (m, 2H), 2.95—3.22 (m, 2H), 5.27—5.68 (m, 2H), 10.81 (s, 1H); Anal. ($C_9H_{16}O_2$) C, H.

5-Phenyl-3-pentenoic Acid (4e). Bp 200 °C (bath temp)/1.5 mmHg; IR (neat) 1710 (s), 965 (s), 740 (s), and 700 (s) cm^{-1}; ^1H NMR δ=2.85—3.15 (m, 2H), 3.15—3.50 (m, 2H), 5.44—5.70 (m, 2H), 7.08 (s, 5H), 11.30 (s, 1H); Anal. ($C_{11}H_{12}O_2$) C, H.

3,6-Heptadienoic Acid (4f). Bp 110 °C (bath temp)/1.5 mmHg; IR (neat) 1710 (s), 990 (s), 965 (s), and 910 (s) cm^{-1}; ^1H NMR δ=2.58—2.93 (m, 2H), 2.93—3.20 (m, 2H), 4.78—6.25 (m, 5H), 11.56 (s, 1H); Anal. ($C_7H_{10}O_2$) C, H.

3,7-Octadienoic Acid (4g). Bp 120 °C (bath temp)/1.5 mmHg; IR (neat) 1710 (s), 990 (s), 965 (s), and 915 (s) cm^{-1}; ^1H NMR δ=1.97—2.33 (m, 4H), 2.87—3.23 (m, 2H), 4.75—6.41 (m, 5H), 10.68 (s, 1H); Anal. ($C_8H_{12}O_2$) C, H.

4-Methyl-3-hexenoic Acid (9a). Bp 110 °C (bath temp)/1.5 mmHg; IR (neat) 1710 (s) and 835 (w) cm^{-1}; ^1H NMR δ=1.00 (t, J=7 Hz, 3H), 1.63 (s, 1.8H), 1.72 (s, 1.2H), 2.03 (q, J=7 Hz, 2H), 3.00 (d, J=7 Hz,, 2H), 5.22 (t, J=7 Hz, 1H), 10.87 (s, 1H).

4-Methyl-3-nonenoic Acid (9b). Bp 150 °C (bath temp)/1.5 mmHg; IR (neat) 1710 (s) and 830 (w) cm^{-1}; ^1H NMR δ=0.90 (t, J=6 Hz, 3H), 1.17—1.67 (m, 6H), 1.71 (s, 2.1H), 1.80 (s, 0.9H), 1.88—2.33 (m, 2H), 3.06 (d, J=7 Hz, 2H), 5.23 (t, J=7 Hz, 1H), 10.43 (s, 1H); Anal. ($C_{10}H_{18}O_2$) C, H.

4,6-Dimethyl-3-octenoic Acid (9c). Bp 150 °C (bath temp)/1.5 mmHg; IR (neat) 1710 (s) and 840 (w) cm^{-1}; ^1H NMR δ=0.85 (t, J=6 Hz, 3H), 0.90 (d, J=6 Hz, 3H), 1.14—1.55 (m, 3H), 1.60 (s, 2.1H), 1.69 (s, 0.9H), 1.79—2.09 (m, 2H), 3.00 (d, J=7 Hz, 2H), 5.27 (t, J=7 Hz, 1H), 10.90 (s, 1H); Anal. ($C_{10}H_{18}O_2$) C, H.

4,6,6-Trimethyl-3-heptenoic Acid (9d). Bp 150 °C (bath temp)/1.5 mmHg; IR (neat) 1710 (s) and 840 (w) cm^{-1}; ^1H NMR δ=0.90 (s, 6.3H), 0.93 (s, 2.7H), 1.67 (s, 2.1H), 1.76 (s, 0.9H), 1.94 (s, 2H), 3.00 (d, J=7 Hz, 2H), 5.23 (t, J=7 Hz, 0.7H), 5.42 (t, J=7 Hz, 0.3H), 11.30 (s, 1H); Anal. ($C_{10}H_{18}O_2$) C, H.

4-Methyl-5-phenyl-3-pentenoic Acid (9e). Bp 200 °C (bath temp)/1.5 mmHg; IR (neat) 1710 (s), 845 (w), 735 (s), and 700 (s) cm^{-1}; ^1H NMR δ=1.53 (s, 2.1H), 1.62 (s, 0.9H), 3.03 (d, J=7 Hz, 2H), 3.23 (s, 2H), 5.37 (t, J=7 Hz, 1H), 7.09 (s, 5H), 11.53 (s, 1H); Anal. ($C_{12}H_{14}O_2$) C, H.

4-Methyl-3,6-heptadienoic Acid (9f). Bp 120 °C (bath temp)/1.5 mmHg; IR (neat) 1710 (s), 990 (m), 910 (s), and 830 (w) cm^{-1}; ^1H NMR δ=1.60 (s, 2.1H), 1.69 (s, 0.9H), 2.82 (d, J=7 Hz, 2H), 3.14 (d, J=7 Hz, 2H), 4.77—6.27 (m, 4H), 11.42 (s, 1H); Anal. ($C_8H_{12}O_2$) C, H.

4-Methyl-3,7-octadienoic Acid (9g). Bp 130 °C (bath temp)/1.5 mmHg; IR (neat) 1710 (s), 990 (m), 910 (s), and 830 (w) cm^{-1}; ^1H NMR δ=1.70 (s, 2.1H), 1.79 (s, 0.9H), 2.20 (br s, 4H), 3.10 (d, J=7 Hz, 2H), 4.77—6.25 (m, 4H), 10.81 (s, 1H); Anal. ($C_9H_{14}O_2$) C, H.

4,8-Dimethyl-3-nonenoic Acid (9h).[28] R_f=0.6 (CH_2Cl_2:AcOEt:AcOH=200:20:1); IR (neat) 1710 (s) and 830 (w) cm^{-1}; ^1H NMR δ=0.87 (d, J=5.5 Hz, 6H), 1.11—1.55 (m, 4H), 1.63—1.86 (m, 3H), 3.03 (d, J=7 Hz, 2H), 5.35 (t, J=7 Hz, 1H); 11.21 (s, 1H).

4,8-Dimethyl-3,7-nonadienoic Acid (9i).[30] R_f=0.6 (CH_2Cl_2:AcOEt:AcOH=200:20:1)

4,8,12-Trimethyl-3,7,11-tridecatrienoic Acid (9j).[14b] R_f=0.4 (CH_2Cl_2:AcOEt:AcOH=200:20:1); ^1H NMR δ=1.60 (br s,3H), 1.67 (br s, 9H), 2.05 (br s, 8H), 3.00 (d, J=7 Hz, 2H), 4.65—5.30 (m, 3H), 10.85 (s, 1H).

4-Chloro-3-hexenoic Acid (11a). Bp 130 °C (bath temp)/1.5 mmHg; IR (neat) 1710 (s) and 820 (m) cm^{-1}; ^1H NMR δ=1.13 (t, J=7 Hz, 3H), 2.40 (q, J=7 Hz, 2H), 3.09 (d, J=6.5 Hz, 0.2H), 3.25 (d, J=6.5 Hz, 1.8H), 5.64 (t, J=6.5 Hz, 1H), 11.13 (s, 1H); Anal. ($C_6H_9ClO_2$) C, H.

4-Chloro-3-nonenoic Acid (11b). Bp 170 °C (bath temp)/1.5 mmHg; IR (neat) 1715 (s) 850 (m), and 810 (m) cm^{-1}; ^1H NMR δ=0.91 (t, J=6 Hz, 3H), 1.07—2.00 (m, 6H), 2.00—2.67 (m, 2H), 3.08 (d, J=7 Hz, 0.2 H), 3.24 (d, J=6.5 Hz, 1.8H), 5.62 (t, J=6.5 Hz, 0.9H), 5.69 (t, J=7 Hz, 0.1H), 11.22 (s, 1H); Anal. ($C_9H_{15}ClO_2$) C, H.

4-Chloro-6-methyl-3-octenoic Acid (11c). Bp 170 °C (bath temp)/1.5 mmHg; IR (neat) 1715 (s), 830 (m), and 800 (m) cm^{-1}; ^1H NMR δ=0.93 (t, J=6 Hz, 3H), 0.98 (d, J=6 Hz, 3H), 1.05—2.00 (m, 3H), 2.00—2.65 (m, 2H), 3.06 (d, J=7 Hz, 0.2H), 3.22 (d, J=6.5 Hz, 1.8H), 5.61 (t, J=6.5 Hz, 0.9H), 5.69 (t, J=7 Hz, 0.1H), 11.49 (s, 1H); Anal. ($C_9H_{15}ClO_2$) C, H.

4-Chloro-6,6-dimethyl-3-heptenoic Acid (11d). Bp 150 °C

(bath temp)/1.5 mmHg; IR (neat) 1715 (s) and 820 (m) cm^{-1}; ^1H NMR δ=0.98 (s, 9H), 2.27 (s, 2H), 3.07 (d, J=7 Hz, 0.2H), 3.26 (d, J=6.5 Hz, 1.8H), 5.57 (t, J=6.5 Hz, 0.9H), 5.85 (t, J=7 Hz, 0.1H), 11.32 (s, 1H); Anal. ($C_9H_{15}ClO_2$) C, H.

4-Chloro-5-phenyl-3-pentenoic Acid (11e). Bp 230 °C (bath temp)/1.5 mmHg; IR (neat) 1715 (s), 825 (m), 790 (m), 740 (s), and 700 (s) cm^{-1}; ^1H NMR δ=3.13 (d, J=7 Hz, 0.4H), 3.23 (d, J=6.5 Hz, 1.6H), 3.57 (s, 2H), 5.67 (t, J=6.5 Hz, 0.8H), 5.84 (t, J=7 Hz, 0.2H), 7.16 (s, 5H), 11.45 (s, 1H); Anal. ($C_{11}H_{11}COl_2$) C, H.

4-Chloro-3,6-heptadienoic Acid (11f). Bp 140 °C (bath temp)/1.5 mmHg; IR (neat) 1710 (s), 990 (s), and 810 (m) cm^{-1}; ^1H NMR δ=3.08 (d, J=6.5 Hz, 2H), 3.24 (d, J=6.5 Hz, 2H), 4.60—6.23 (m, 5H), 11.41 (s, 1H); Anal. ($C_7H_9ClO_2$) C, H.

4-Chloro-3,7-octadienoic Acid (11g). Bp 150 °C (bath temp)/1.5 mmHg; IR (neat) 1710 (s), 990 (s), and 845 (m) cm^{-1}; ^1H NMR δ=2.40 (s, 4H), 3.08 (d, J=7 Hz, 0.2H), 3.26 (d, J=6.5 Hz, 1.8H), 4.77—6.12 (m, 4H), 11.41 (s, 1H); Anal. ($C_8H_{11}ClO_2$) C, H.

4-Heptenoic Acid (17a).[7] Bp 110 °C (bath temp)/1.5 mmHg; IR (neat) 1715 (s) and 970 (s) cm^{-1}; ^1H NMR δ=0.94 (t, J=7 Hz, 3H), 1.68—2.17 (m, 2H), 2.17—2.45 (m, 4H), 5.40—5.74 (m, 2H), 11.01 (s, 1H).

4-Decenoic Acid (17b).[31] Bp 150 °C (bath temp)/1.5 mmHg.

7-Methyl-4-nonenoic Acid (17c). Bp 150 °C (bath temp)/1.5 mmHg; IR (neat) 1715 (s) and 970 (s) cm^{-1}; ^1H NMR δ=0.86 (t, J=6 Hz, 3H), 0.91 (d, J=6 Hz, 3H), 1.01—1.70 (m, 3H), 1.70—2.17 (m, 2H), 2.20—2.53 (m, 4H), 5.25—5.59 (m, 2H), 11.62 (s, 1H); Anal. ($C_{10}H_{18}O_2$) C, H.

7,7-Dimethyl-4-octenoic Acid (17d). Bp 150 °C (bath temp)/1.5 mmHg; IR (neat) 1715 (s) and 970 (s) cm^{-1}; ^1H NMR δ=0.84 (s, 9H), 1.73—2.05 (m, 2H), 2.23—2.43 (m, 4H), 5.26—5.52 (m, 2H), 11.53 (s, 1H); Anal. ($C_{10}H_{18}O_2$) C, H.

6-Phenyl-4-hexenoic Acid (17e).[32] Bp 200 °C (bath temp)/1.5 mmHg; IR (neat) 1715 (s), 970 (s), 740 (s), and 700 (s) cm^{-1}; ^1H NMR δ=2.20—2.50 (m, 4H), 3.04—3.43 (m, 2H), 5.23—5.59 (m, 2H), 7.02 (s, 5H), 11.49 (s, 1H).

4,7-Octadienoic Acid (17f). Bp 120 °C (bath temp)/1.5 mmHg; IR (neat) 1715 (s) 990 (s), 970 (s), and 915 (s) cm^{-1}; ^1H NMR δ=2.16—2.58 (m, 4H), 2.58—3.08 (m, 2H), 4.82—6.17 (m, 5H), 11.06 (s, 1H); Anal. ($C_8H_{12}O_2$) C, H.

4,8-Nonadienoic Acid (17g).[33] Bp 130 °C (bath temp)/1.5 mmHg.

5-Octenoic Acid (19a).[5b] Bp 120 °C (bath temp)/1.5 mmHg; IR (neat) 1715 (s) and 970 (s) cm^{-1}; ^1H NMR δ=0.96 (t, J=7 Hz, 3H), 1.42—2.50 (m, 8H), 5.20—5.50 (m, 2H), 10.21 (s, 1H).

5-Undecenoic Acid (19b).[34] Bp 170 °C (bath temp)/1.5 mmHg.

8-Methyl-5-decenoic Acid (19c). Bp 170 °C (bath temp)/1.5 mmHg; IR (neat) 1715 (s) and 970 (s) cm^{-1}; ^1H NMR δ=0.85 (t, J=6 Hz, 3H), 0.90 (d, J=6 Hz, 3H), 1.01—2.54 (m, 11H), 5.30—5.48 (m, 2H), 11.71 (s, 1H); Anal. ($C_{11}H_{20}O_2$) C, H.

8,8-Dimethyl-5-nonenoic Acid (19d). Bp 170 °C (bath temp)/1.5 mmHg; IR (neat) 1715 (s) and 970 (s) cm^{-1}; ^1H NMR δ=0.89 (s, 9H), 1.45—2.54 (m, 8H), 5.30—5.63 (m, 2H), 11.39 (s, 1H); Anal. ($C_{11}H_{20}O_2$) C, H.

7-Phenyl-5-heptenoic Acid (19e). Bp 220 °C (bath temp)/1.5 mmHg; IR (neat) 1715 (s), 970 (s), 740 (s), and 700 (s) cm^{-1}; ^1H NMR δ=1.45—2.57 (m, 6H), 3.12—3.41 (m, 2H), 5.21—5.64 (m, 2H), 7.08 (s, 5H), 9.97 (s, 1H); Anal. ($C_{13}H_{16}O_2$) C, H.

5,8-Nonadienoic Acid (19f). Bp 130 °C (bath temp)/1.5 mmHg; IR (neat) 1715 (s), 990 (s), 970 (s), and 915 (s) cm^{-1}; ^1H NMR δ=1.47—2.57 (m, 6H), 2.57—2.94 (m, 2H), 4.72—6.14 (m, 5H), 11.56 (s, 1H); Anal. ($C_9H_{14}O_2$) C, H.

5,9-Decadienoic Acid (19g). Bp 140 °C (bath temp)/1.5 mmHg; IR (neat) 1715 (s), 990 (s), 970 (s), and 910 (s) cm^{-1}; ^1H NMR δ=1.45—2.57 (m, 10H), 4.75—6.40 (m, 5H), 11.53 (s, 1H); Anal. ($C_{10}H_{16}O_2$) C, H.

Procedure for the Transformation of 4-Chloro-3-alkenoic Acids (11) to 4-Oxoalkanoic Acids (12). According to the reported method,[17] to a solution of $TiCl_4$ 1.95 g (10.3 mmol), MeOH 68.7 mg (2.14 mmol), H_2O 80.6 mg (4.47 mmol), and acetone 354 mg (6.09 mmol) in CH_2Cl_2 (4 ml), a solution of **11b** 385 mg (2.02 mmol) in 2 ml of CH_2Cl_2 was added at room temperature. The mixture was stirred at the same temperature for 64 h. Then the reaction was quenched by pouring into ice-water, and the organic layer was separated. The aqueous phase was washed twice with CH_2Cl_2 and the combined organic layers were washed with water and brine, dried with $MgSO_4$, and concentrated. The crude product was purified by preparative TLC (CH_2Cl_2:AcOH=20:1) to give 4-oxononanoic acid (**12b**) 285 mg (1.66 mmol) (82%) and methyl 4-oxononanoate 30.1 mg (0.162 mmol) (8%).

In the exactly same manner as above, the other 4-oxoalkanoic acids were obtained.

4-Oxohexanoic Acid (12a).[16] Mp 37—40 °C.

4-Oxononanoic Acid (12b).[16] Mp 68—70 °C.

4-Methyl-4-oxooctanoic Acid (12c).[35] IR (neat) 1740 (s), 1720 (s), and 1710 (s) cm^{-1}; ^1H NMR δ=0.86 (d, J=2.5 Hz, 3H), 0.92 (br s, 3H), 1.08—1.58 (m, 2H), 1.58—2.14 (m, 1H), 2.14—2.48 (m, 2H), 2.63 (br s, 4H), 11.10 (s, 1H).

6,6-Dimethyl-4-oxoheptanoic Acid (12d). IR (neat) 1735 (s), 1720 (s), and 1710 (s) cm^{-1}; ^1H NMR δ=1.00 (s, 9H), 2.32 (s, 2H), 2.40—2.92 (m, 4H), 13.17 (br s, 1H); Anal. ($C_9H_{16}O_3$) C, H.

4-Oxo-5-phenylpentanoic Acid (12e).[36] Mp 53—55 °C; IR (neat) 1720 (s), 1700 (s), 740 (m), and 700 (m) cm^{-1}; ^1H NMR δ=2.55 (br s, 4H), 3.58 (s, 2H), 7.15 (s, 5H), 10.68 (s, 1H).

Procedure for the Transformation of 11 to 4-Oxo-2-alkenoic Acid (14). A solution of **11b** 502 mg (2.63 mmol) in 13 ml of 2 M NaOH was refluxed with stirring for 20 min. After the mixture was cooled to room temperature and acidified with concd HCl, the mixture was extracted twice with ether. The extracts were washed with water and brine, dried with $MgSO_4$, and concentrated to give viscous oil. The crude 4-hydroxy-2-nonenoic acid was used for the following oxidation without any purification. To a solution of the hydroxy acid in acetone (5 ml) was added a solution of CrO_3 263 mg (2.63 mmol) in concd H_2SO_4 (0.3 ml) and water (1.0 ml) at 0 °C. After the mixture was stirred at the same temperature for 10 min, the products were extracted with ether. The extracts were washed with water and brine, dried with $MgSO_4$, and concentrated. Purification of the residue by preparative TLC (CH_2Cl_2:AcOH=20:1) gave 4-oxo-2-nonenoic acid (**14b**) 272 mg (1.60 mmol) (61%).

In the exactly same manner as above, the other 4-oxo-2-

alkenoic acids were obtained.

4-Oxo-2-hexenoic Acid (14a).[37] Mp 110—112 °C; IR (KBr) 1720 (s), 1690 (s), and 1670 (s) cm^{-1}; ^1H NMR δ=1.13 (t, J=7 Hz, 3H), 2.72 (q, J=7 Hz, 2H), 6.82 (AB, H_A=6.60, H_B=7.05, J=16 Hz, 2H), 11.55 (s, 1H).

4-Oxo-2-nonenoic Acid (14b). Mp 115—117 °C; IR (KBr) 1720 (s), 1680 (s), and 1660 (s) cm^{-1}; ^1H NMR δ=0.90 (t, J=5 Hz, 3H), 1.12—1.97 (m, 6H), 2.65 (t, J=6 Hz, 2H), 6.90 (AB, J=16 Hz, 2H), 11.62 (br s, 1H); Anal. ($C_9H_{14}O_3$) C, H.

6-Methyl-4-oxo-2-octenoic Acid (14c). Mp 78—80 °C; IR (KBr) 1710 (s), 1680 (s), and 1660 (s) cm^{-1}; ^1H NMR δ=0.87 (br s, 3H), 0.97 (br s, 3H), 1.13—1.63 (m, 2H), 1.63—2.30 (m, 1H), 2.30—2.88 (m, 2H), 6.87 (AB, J=16 Hz, 2H), 11.52 (br s, 1H); Anal. ($C_9H_{14}O_3$) C, H.

6,6-Dimethyl-4-oxo-2-heptenoic Acid (14d). Mp 91—93 °C; IR (KBr) 1710 (s), 1685 (s), and 1670 (s) cm^{-1}; ^1H NMR δ=1.06 (s, 9H), 2.55 (s, 2H), 6.88 (AB, H_A=6.60, H_B=7.17, J=16 Hz, 2H), 10.71 (br s, 1H); Anal. ($C_9H_{14}O_3$) C, H.

4-Oxo-5-phenyl-2-pentenoic Acid (14e). Mp 95—97 °C; IR (KBr) 1705 (s), 1680 (s), 1675 (s), 735 (m), and 695 (m) cm^{-1}; ^1H NMR δ=3.87 (s, 2H), 6.88 (AB, J=16 Hz, 2H), 11.03 (br s, 1H); Anal. ($C_{11}H_{10}O_3$) C, H.

4-Oxo-2,6-heptadienoic Acid (14f). Mp 80—82 °C; IR (neat) 1720 (s), 1685 (s), 1665 (s), 1000 (s), and 915 (s) cm^{-1}; ^1H NMR δ=3.40 (d, J=7 Hz, 2H), 4.93—6.30 (m, 3H), 6.88 (AB, J=16 Hz, 2H), 10.88 (br s, 1H); Anal. ($C_7H_8O_3$) C, H.

4-Oxo-2,7-octadienoic Acid (14g). Mp 100—102 °C; IR (neat) 1710 (s), 1685 (s), 1665 (s), 1005 (s), and 910 (s) cm^{-1}; ^1H NMR δ=2.43 (t, J=5.5 Hz, 2H), 2.63—3.03 (m, 2H), 4.80—6.23 (m, 3H), 6.85 (AB, J=16 Hz, 2H), 11.56 (s, 1H); Anal. ($C_8H_{10}O_3$) C, H.

We thank Messrs. Masashi Takeuchi, Toshiyuki Itoh, Masakuni Nakagawa, Kouichi Naruse, and Kouichi Tamai for their invaluable assistance in the experimental work. The present work was partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture.

Dehydrooligopeptides. X. Useful Synthetic Method for (*E*)- and (*Z*)-Isomers of Dehydroaspartic Acids, and Their $\Delta^{1,2}$-Dehydrodipeptides by the Base-Catalyzed β-Elimination[1]

Chung-gi SHIN,* Takumi OBARA, Shigeru MORITA, and Yasuchika YONEZAWA
Laboratory of Organic Chemistry, Faculty of Technology, Kanagawa University, Rokkakubashi, Kanagawa-ku, Yokohama 221
(Received April 12, 1988)

Various kinds of *N*-benzyloxycarbonyl (*E*)- and (*Z*)-dehydroaspartic acid (Cbz-ΔAsp) derivatives were successfully synthesized by both a base-catalyzed β-elimination of β-hydroxyaspartic acid esters (HyAsp) via their β-mesyloxy Asp derivatives and several modes of the cleavages of α-(*N*-Cbz)-aminomaleic acid anhydride. Moreover, for high-yield synthesis of $\Delta^{1,2}$-dehydrodipeptides (DHP) containing a ΔAsp residue, a similar β-elimination was applied to Δ^{1}-DHP with a C-terminal HyAsp residue. The configuration of all the new ΔAsp derivatives and their $\Delta^{1,2}$-DHPs were confirmed mainly on the basis of ^{1}H NMR spectral data.

In the course of our work regarding the synthesis of α-dehydroamino acid (DHA; ΔAA) and dehydrooligopeptide (DHP), in particular, various kinds of DHA derivatives, which corresponded to the proteinic α-amino acid (AA), have so far been synthesized.[2-7] Recently, the reason why much attention has been directed on the synthesis and the chemical property of DHA is because the *N*-carboxy α-dehydroamino acid anhydride (ΔNCA), derived from *N*-benzyloxycarbonyl (Cbz)–DHA and thionyl chloride, has very effective and extensive coupling abilities with H–AA–OH and oligopeptide for the DHP synthesis, as already reported.[3,5,8-10]

A synthesis of the (*Z*)-isomer of *N*-protected dehydroaspartic acid dimethyl ester [ΔAsp(OMe)–OMe] has already been reported by Kolasa and Gross.[11] However, simple synthetic routes to the various kinds of (*E*)- and (*Z*)-ΔAsp derivatives have not yet appeared in the literature. Particularly, in order to synthesize the important partial skeleton of phomopsin A containing (*E*)-ΔAsp moiety (Fig. 1), isolated from the culture of *Phomopsis leptostromiformis*,[12] a high-yield syntheses of (*E*)-ΔAsp derivatives and their $\Delta^{1,2}$-dehydrodipeptides (DHP)[13] containing dehydroisoleucine (ΔIle) residue must be accomplished by all means.

In the present paper, we wish to report on a useful syntheses of (*E*)- and (*Z*)-ΔAsp derivatives from both β-hydroxyaspartic acids (HyAsp–OH) and α-(*N*-Cbz)-aminomaleic acid anhydride, and those of $\Delta^{1,2}$-DHP (ΔAA-ΔAsp) by the coupling of appropriate ΔNCA with HyAsp–OMe, followed by a base-catalyzed β-elimination. Moreover, based on ^{1}H NMR spectral data, the configurational structure of ΔAsp derivatives and the corresponding $\Delta^{1,2}$-DHPs could be clearly determined.

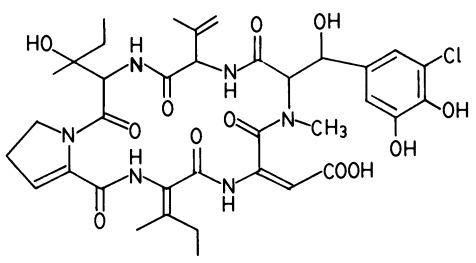

Fig. 1. Phomopsin A.

Results and Discussion

Syntheses of (*E*)- and (*Z*)-ΔAsp Derivatives. It has already been reported that the β-elimination of Cbz-β-(tosyloxy)aspartic acid dimethyl ester, derived from Cbz–β-(hydroxy)aspartic acid dimethyl ester [Cbz–HyAsp(OMe)–OMe] (**1a**) and *p*-toluenesulfonyl (tosyl) chloride, with organic base such as 1,4-diazabicyclo-[2.2.2]octane (Dabco) or 1,8-diazabicyclo[5.4.0]undec-5-ene (DBU) gave only the (*Z*)-isomer of Cbz-ΔAsp(OMe)-OMe [(*Z*)-**3a**].[11] In addition, detailed formation on the mechanism of (*Z*)-**3a** and its DHP was also discussed. However, syntheses of not only the (*E*)-isomer of **3a** but also its peptides have not been described.

At first, in order to investigate the synthesis of various (*E*)- and (*Z*)-isomers of ΔAsp derivatives **3**, instead of the above tosylation, the mesylation of **1a** was carried out, followed by a similar base-catalyzed β-elimination, by a previously reported method.[14]

The reaction of *threo*- and *erythro*-**1a**, respectively, which were freshly prepared (Table 1), with methanesulfonyl (mesyl; Ms) chloride in tetrahydrofuran (THF), was performed to yield the corresponding β-mesyloxy Asp derivatives (**2a**). Subsequently, the leaving mesyloxy group of **2a**, formed as an intermediate, was eliminated in situ with a base, such as triethylamine (TEA) or DBU, to give first an (*E*)-isomer of **3a** as a mixture with (*Z*)-**3a**. At the same time, the intermediate **2a** was also obtained purely. However, as can be seen in the summary given in Table 2, as long as the present method is used, the yield of (*E*)-**3a** was found to be less than 43%, although that of (*Z*)-**3a** was more than 72%. In any event, as a result, the expected (*E*)-**3a** was ultimately obtained, even though the yield was slightly low. Fortunately,

	DBU	2	29	29	0	38

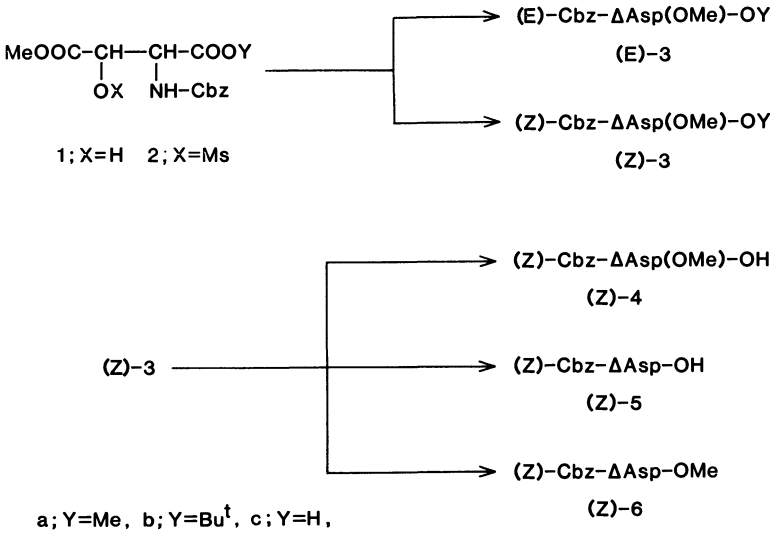
according to the another method described later, various (*E*)-isomer of ⊿Asp derivatives could be successfully synthesized in good yields.

A subsequent ester hydrolysis of (*Z*)-**3a**, thus obtained, with an equimolar 1 M LiOH (1 M=1mol dm^{-3}) was carried out in dioxane under cooling to give three kinds of products. The three compounds could be readily isolated by a silica-gel column chromatogram method and were identified as being (*Z*)-Cbz-⊿Asp(OMe)-OH [(*Z*)-**4**] and (*Z*)-Cbz-⊿Asp-OH [(*Z*)-**5**] in 45 and 3% yields, respectively, along with a trace of a by-product, also identified as (*Z*)-Cbz-⊿Asp-OMe [(*Z*)-**6**], as was illustrated in Scheme 1.

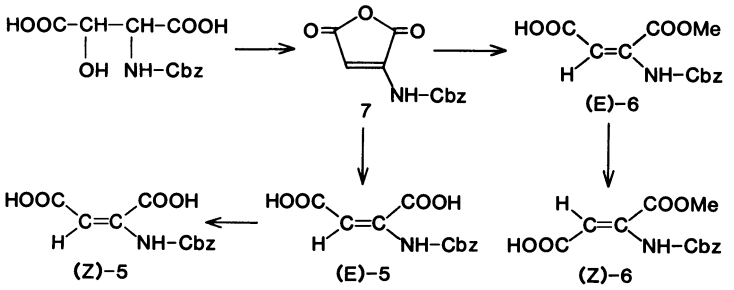
Furthermore, when three moles of 1 M LiOH was used, compound (*Z*)-**5** alone was found to be obtained in 71% yield. In the above case, although it was difficult to confirm whether the structure of mono ester of ⊿Asp (**4** and **6**) is α-methyl or β-methyl ester, an independent preparation of (*Z*)-**4** was successfully tried in the following manner.

First, according to the method mentioned above, (*E*)- and (*Z*)-Cbz-⊿Asp(OMe)-OBu^t (**3b**) were synthesized in 35 and 40% yields, respectively, by the successive mesylation and β-elimination of Cbz-HyAsp(OMe)-OBu^t (**1b**), which was derived from Cbz-HyAsp(OMe)-OH (**1c**)[15] and isobutene. On the other hand, it was found that a small amount of the expected Cbz-β-(Bu^{t}O)-Asp(OMe)-OBu^t was also obtained. Subsequently, the *t*-butyl ester decomposition of both (*E*)- and (*Z*)-**3b**, respectively, with HCl was carried out in ethyl acetate to give only one chemical species almost quantitatively, which was in complete accord with (*Z*)-**4**.

From the above results, the structural determination of **4** was exactly accomplished; it can be seen that the



Scheme 1.



Scheme 2.

isomerization of (*E*)-**3b** took place during the ester decomposition.

Moreover, in order to obtain the (*E*)-isomers of **4**—**6** in high yields, the authentic 2-(*N*-Cbz)-aminomaleic acid anhydride (**7**)[16] was cleaved with 1 M LiOH in the absence of methanol to give (*Z*)-**5** in an almost quantitative yield, while the treatment of **7** with base such as dicyclohexylamine (DCA) or TEA was carried out in methanol to give a hitherto unknown kind. Concerning the configurational structure of the unknown compound, thus obtained, from both the spectral data (IR and ^{1}H NMR) and the satisfactory elemental analysis ($C_{13}H_{13}NO_6$), it was supposed that a kind of the possible total four regio and geometric isomers of the corresponding ⊿Asp monomethyl esters [(*Z*)-**4**, (*E*)-**4**, (*Z*)-**6**, and (*E*)-**6**] was formed. Furthermore, by a comparison with various ⊿Asp derivatives already obtained (see above), it could be concluded that the expected (*E*)-Cbz-⊿Asp-OMe [(*E*)-**6**] was first synthesized in 84% yield. Subsequent isomerization of (*E*)-**6** with HCl was completely performed in ethyl acetate to yield (*Z*)-**6**, which was in accord with the product derived by the hydrolysis of (*Z*)-**3a**. In addition, (*Z*)-**6** was also found to be obtainable quantitatively by a treatment of **7** with methanol in the presence of TEA. Accordingly, the configurational structure of (*E*)-**6** could be unambiguously determined.

On the other hand, more interestingly, it was also found that a treatment of **7** with a saturated $NaHCO_3$ aqueous solution gave (*E*)-Cbz-⊿Asp-OH [(*E*)-**5**] in 95% yield, which was readily isomerized with 1 M LiOH in dioxane to give (*Z*)-**5** quantitatively, according to Scheme 2. Consequently, as summarized in Table 3, all of the (*E*)- and (*Z*)-isomers of **3**—**6**, except for (*E*)-**4**, were obtained purely.

The yields, physical constants, and spectral data of ⊿Asp derivatives **3**—**6** are summarized in Table 3. Particularly, based on the fact that the olefin proton signal of (*E*)-isomer (δ 6.17) of DHA shifted always at lower magnetic field than that of (*Z*)-isomer (δ 5.54), similar to the results reported previously,[17] the configuration of all the ⊿Asp derivatives, thus obtained, could be clearly confirmed.

Synthesis of $\Delta^{1,2}$-DHP Containing ⊿Asp Residue. It has already been reported that the successive mesylation and base-catalyzed β-elimination of Δ^1- or Δ^2-DHP containing N- and C-terminal threonine residues respectively were carried out to give $\Delta^{1,2}$-

DHP.[14] By taking advantage of the above-mentioned useful procedure, the desired various ⊿^{1,2}-dehydrodipeptides containing C-terminal ⊿Asp(OMe) residue were successfully synthesized as follows.

Firstly, for a high-yield synthesis of ⊿^{1}-DHP with a C-terminal HyAsp residue as the substrates, the so-called ⊿NCA method developed by us was carried out with very good results. Various (*Z*)-isomer of ⊿NCA derivatives (**8**: **a**; ⊿Abu,[18] **b**; ⊿Val, **c**; ⊿Ile)[2,3,5] were treated with di-*t*-butyl dicarbonate [$((CH_3)_3COCO)_2O$; $(Boc)_2O$] in the presence of pyridine and then with *threo*- or *erythro*-HyAsp(OMe)-OMe as an amine component in the presence of *N*-methylmorpholine (NMM) at pH 9 to give the corresponding (*Z*)-*t*-butoxycarbonyl (Boc)-⊿^{1}-dehydrodipeptide dimethyl ester [Boc-⊿AA-HyAsp(OMe)-OMe] (**10**) in ca. 36% overall yield.

From the above result, it is obvious that the acylation of **8** with $(Boc)_2O$ occurred at first to form Boc-⊿NCA (**9**) as an intermediate, which was immediately coupled with HyAsp(OMe)-OMe in one-pot to give **10**. Even though the overall yield of **10** was lower (at present) these procedures seem to be very useful for the synthesis of ⊿^{1}-dehydrodipeptide esters (**10**), as summarized in Tables 4 and 5.

Subsequently, the mesylation of **10** with mesyl chloride and then the β-elimination of the mesyloxy derivatives (**11**), formed as unstable intermediates, were carried out in situ in THF in the presence of TEA or DBU to give first the expected Boc-⊿^{1,2}-dehydrodipeptide dimethyl ester [Boc-⊿AA-⊿Asp(OMe)-OMe] (**12**). In the case of **10a—c** containing a *threo*-HyAsp

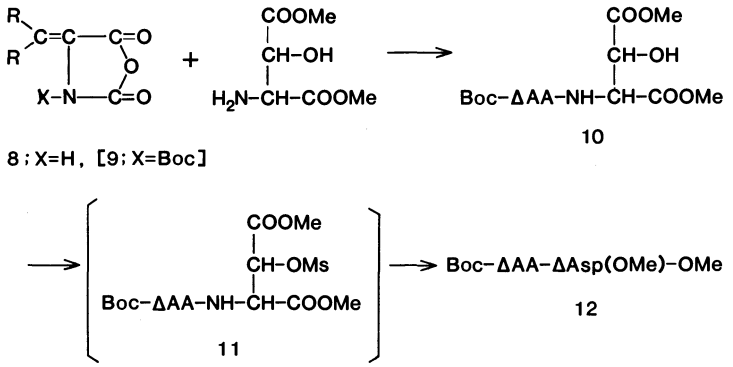

Scheme 3.

residue, the above-mentioned successive reactions were performed in the presence of TEA for 24 h to give only a (*Z,Z*)-isomer of **12a—c** in 51—92% yield, as summarized in Table 6. On the other hand, when compound **10b** containing *erythro*-HyAsp residue was similarly worked up in the presence of DBU for 4.5 h, Boc-⊿Val-(*E*)-⊿Asp(OMe)-OMe [(*E*)-**12b**] was obtained in a 20% yield, whereas the similar reaction of *erythro*-**10c** gave Boc-(*E*)- and (*Z*)-⊿Ile-(*Z*)-⊿Asp-(OMe)-OMe [(*E,Z*)- and (*Z,Z*)-**12c**] in a 23% yield. In this case, the N-terminal (*Z*)-⊿Ile of **10c** containing either *threo*- or *erythro*-HyAsp residue was found to be isomerized partially to give a mixture of (*E,Z*)- and (*Z,Z*)-**12** during β-elimination.

As Table 8 shows, the chemical shifts of the olefin proton of two isomers, (*Z,E*)- and (*Z,Z*)-**12**, are clearly distinguishable from each other; that is, the signal of (*E*)-⊿Asp (δ 6.72) shifts at a considerably lower magnetic field than that of (*Z*)-⊿Asp (δ 5.40) residue.[17] From this fact, the configurations of **12** could be readily confirmed. Furthermore, from the above results, it can be seen that the formation and yield of each geometric isomers of **12** results from differences between the structure of substrates, which contain *erythro*- or *threo*-HyAsp(OMe)-OMe residue, and the reaction conditions. Accordingly, if only product (*Z,Z*)-**12** is desired, the reaction time must necessarily to be prolonged in the presence of TEA, although only an example is shown. On the contrary, if an appropriate **12** containing (*E*)-⊿Asp residue is expected, it seems to be preferable to shorten the reaction time in the presence of DBU. Unfortunately, however, it is not understandable why the similar β-elimination of **10** containing *erythro*-HyAsp residue gave either (*Z, E*)- or (*Z,Z*)-**12**, as summarized in Tables 6, 7, and 8. Consequently, at present, it is difficult to

obtain selectively and quantitatively only one of the geometric isomers.

In conclusion, it is noteworthy that various kinds of (*E*)- and (*Z*)-⊿Asp derivatives and their dehydrodipeptides were readily synthesized from several routes and that their configurations could be completely determined. Moreover, it is firmly believed that these obtained results will contribute to the synthesis of the important partial skeleton of phomopsin A.

Experimental

General. Melting points were determined with a Yamato micro melting-point apparatus MP-21 model and were uncorrected. The IR spectra were recorded with a Hitachi EPI-G2 grating spectrometer. The ^{1}H NMR spectra were measured with a JEOL JMN PS 100 spectrometer in a $CDCl_3$ solution with tetramethylsilane as the internal standard.

Preparation of 1c. To a solution of β-HyAsp(OMe)-OH (4.0 g, 24.5 mmol) in a saturated $NaHCO_3$ aqueous solution (61 ml) was added a solution of Cbz-Cl (5 ml, 29.4 mmol) in dry diethyl ether (20 ml), with vigorous stirring, drop by drop under cooling. After continuous stirring at room temperature for 1.5 h, Cbz-Cl (2.7 ml, 16.0 mmol) and $NaHCO_3$ (2.6 g, 30.0 mmol) were further added to the resultant solution at room temperature for 2 h. The reaction solution was poured into water (100 ml) and washed with ethyl acetate. The aqueous layer was made to pH 2 with 1 M HCl and then extracted three times with ethyl acetate (30 ml). The combined extracts were washed with saturated NaCl aqueous solution and then dried over anhydrous Na_2SO_4. After removing the solvent under reduced pressure, the residue was solidified with hexane and then the crude crystals were collected. Recrystallization from a mixture of hexane and ethyl acetate gave **1c** as colorless needles.

Reaction of 1c with Isobutene. Into a suspension of **1c** (3.56 g, 1.2 mmol) in dry CH_2Cl_2 (50 ml) was introduced isobutene gas below −40 °C, until the suspension volume increased to about 75 ml. After adding concentrated sulfuric acid (0.12 ml), the resulting suspension was put into a sealed tube and then allowed to stand at room temperature for 10 days until becoming homogeneous. The reaction solution was poured into a saturated $NaHCO_3$ aqueous solution (150 ml) and the resultant solution was extracted three times

with $CHCl_3$. The combined extracts were washed with water and then dried over anhydrous Na_2SO_4. After removing the solvent, the residue was purified on a silica-gel column using a mixture of benzene and acetone (30:1 v/v) as the eluent. The first fraction gave **1c** (0.6 g) and the second **2b** (0.9 g) in 19% yield.

Preparation of (*E*)- and (*Z*)-3a. To a solution of **1a** (2g, 6.43 mmol) and MsCl (1.1 g, 9.7 mmol) in dry THF (20 ml) was added drop by drop a solution of DBU or TEA (19.3 mmol) in dry THF (10 ml) at 0 °C. After stirring at 0 °C for 1 h, the resulting chilled solution was returned to room temperature and then allowed to stand. After removing the solvent, the residue was dissolved in ethyl acetate (100 ml) and the resultant solution was washed successively with 10% citric acid aqueous solution, saturated $NaHCO_3$ solution, water and finally dried over anhydrous $MgSO_4$. After concentrating the solution under reduced pressure, the residual syrup was chromatographed on a silica-gel column using a mixture of benzene and acetone (30:1 v/v) as the eluent. Three or four fractions were always obtained, as summarized in Table 2. The expected (*E*)- and (*Z*)-**3a** and intermediates Cbz-β-(MsO)Asp(OMe)-OMe (**2a**) are listed in Table 3.

Preparation of (*E*)- and (*Z*)-3b. In a similar manner, a treatment of **1b** with MsCl in the presence of DBU was worked up to give (*E*)- and (*Z*)-**3b**, no accompanying the corresponding β-mesyloxy derivative (**2b**). See Table 3.

Hydrolysis of 3a with LiOH. To a solution of (*Z*)-**3a** (4.26 g, 14.5 mmol) in dioxane (15 ml) was added 1 M LiOH (15 ml) drop by drop at 5—8 °C. The resulting solution was slowly returned to room temperature and then stirred continuously for 3.5 h. The reaction solution was poured into water (100 ml) and then washed with diethyl ether. The aqueous layer was acidified to pH 1 with 6 M HCl and extracted three times with ethyl acetate (50 ml). The combined extracts were washed with saturated NaCl aqueous solution and then dried over anhydrous Na_2SO_4. After removing the solvent under reduced pressure the residual crude crystals obtained were recrystallized from benzene to give (*Z*)-**4** as colorless needles. The filtrate was concentrated under reduced pressure to give a viscous syrup, which was chromatographed on a silica-gel column using a mixture of $CHCl_3$, methanol and ethyl acetate (200:1:1 v/v) to give three fractions. Compound (*Z*)-**4** was further obtained in a 45% yield from the first fraction and small amounts of (*Z*)-**5** and **6** were also obtained in 3 and 2% yields, respectively, from the second and the final fractions. On the other hand, from the ether layer (*Z*)-**3a** was recovered in 40% yield.

Similarly, the hydrolysis of (*Z*)-**3a** was worked up with 1 M LiOH (45 ml) at room temperature for 24 h to give (*Z*)-**5** in 71% yield. In addition, in a similar manner, treatment of (*E*)-**3a** was performed to give (*Z*)-**4**, **5**, and **6** in almost the same ratio obtained above.

Ester Decomposition of 3c. A solution of (*Z*)- or (*E*)-**3c** (1.0 g, 3.3 mmol) in ethyl acetate (30 ml) saturated with gaseous HCl was stirred at room temperature for 1.5 h. After removing the solvent and excess HCl under reduced pressure, the residue was dissolved in ethyl acetate (30 ml) and the resulting solution was again concentrated under reduced pressure. The residue,thus obtained, was crystallized by treating with hexane. The collected crystals were recrystallized from small quantity of ethyl acetate to give (*Z*)-**4** alone in 91% yield.

Preparation of (*E*)-5 from 7. a) Method A: A solution of **7** (2.47 g, 10.0 mmol) in saturated $NaHCO_3$ aqueous solution (50 ml) was stirred at room temperature for 1 h. The reaction solution was washed with diethyl ether and the aqueous layer was made to pH 2 with 1 M HCl and then extracted three times with ethyl acetate (50 ml). The combined extracts were washed with a saturated NaCl aqueous solution and then dried over anhydrous Na_2SO_4. After concentrating the solution under reduced pressure, the residue, thus obtained was crystallized by treating with diisopropyl ether. The collected crude crystals were recrystallized from a mixture of diisopropyl ether and ethyl acetate (5:2 v/v) to give (*E*)-**5** as colorless needles quantitatively.

b) Method B: To a solution of **7** (2.47 g, 10.0 mmol) in dioxane (30 ml) was added 1 M LiOH (13.5 ml) under cooling. After stirring for 1 h, ice-water (100 ml) was added to the reaction solution and the resulting solution was washed with chilled diethyl ether and then made to pH 2 with 1 M HCl. The acidified solution was similarly worked up to give (*E*)-**5**, according to Method A.

Preparation of (*Z*)-5. a) Method A: To a solution of **7** (2.47 g, 10.0 mmol) in dioxane (25 ml) was added 1 M LiOH (25 ml) at room temperature. After stirring for 1 h, the reaction solution was made to pH 2 with 1 M HCl and then extracted three times with ethyl acetate (50 ml). The combined extracts were washed with a saturated NaCl aqueous solution and dried over anhydrous Na_2SO_4. After removing the solvent under reduced pressure, the residue was crystallized by treating with hexane. Recrystallization from a mixture of ethyl acetate and hexane gave (*Z*)-**5** as colorless needles quantitatively.

b) Method B: The treatment of the solution of (*E*)-**5** (2.65 g, 10.0 mmol) in dioxane (30 ml) with 1 M LiOH (25 ml) was similarly worked up to give (*Z*)-**5** quantitatively by the isomerization.

Preparation of (*E*)-6. a) Method A: To a solution of **7** (1.0 g, 4.05 mmol) in dry methanol (10 ml) was added drop by drop a solution of DCA (0.8 ml, 4.05 mmol) in dry methanol (5 ml). After stirring for 30 min and then for 1.5 h at room temperature, the reaction solution was concentrated under reduced pressure. The crystalline residue, thus obtained, was dissolved successively in 10% citric acid (30 ml) and ethyl acetate (30 ml); then the resulting solution was vigorously shaken. The aqueous layer was extracted with ethyl acetate. The combined organic layers were dried over anhydrous Na_2SO_4. After removing the solvent under reduced pressure, the crude crystals collected by using diisopropyl ether were recrystallized from small amount of ethyl acetate to give (*E*)-**6** as colorless needles. 83% yield.

b) Method B: To a solution of **7** (1.0 g, 4.05 mmol) in dry methanol (10 ml) was added drop by drop a solution of TEA (0.57 ml, 4.05 mmol) in dry methanol (5 ml) under cooling. The resultant solution was stirred for 30 min and then at room temperature for 30 min. The treatment of the reaction solution was similarly worked up to give (*E*)-**6** almost quantitatively.

Preparation of (*Z*)-6. a) Method A: To a solution of **7** (1.0 g, 4.05 mmol) in dry methanol (10 ml) was added drop by drop TEA (0.86 ml, 6.08 mmol) under cooling. The

resulting solution was allowed to stand at room temperature and then stirred continuously for 12 h. After removing the solvent, the residue was dissolved in 10% citric acid (30 ml) and the resultant solution was extracted twice with ethyl acetate (30 ml). The combined extracts were washed with saturated NaCl aqueous solution and then dried over anhydrous Na_2SO_4. The concentration of the solution under reduced pressure gave crude crystals, which were collected by using hexane and then recrystallized from a mixture of hexane and ethyl acetate to give (*Z*)-**6** as colorless needles quantitatively.

b) Method B: A solution of (*E*)-**6** (1.0 g, 4.06 mmol) in ethyl acetate (30 ml) saturated with gaseous HCl was stirred at room temperature for 6 h. The reaction solution was concentrated under reduced pressure to give crude residue, which was again dissolved in ethyl acetate (30 ml). This procedure was repeated until HCl gas was completely taken off. The crude crystals collected by using hexane were similarly worked up to give (*Z*)-**6** quantitatively.

Preparation of 10. To a solution of ΔNCA (7.04 mmol) and $(Boc)_2O$ (8.45 g, 8.45 mmol) in THF (7 ml) was added drop by drop pyridine (0.15 ml, 1.85 mmol) under cooling. The resulting solution was slowly returned to room temperature and then stirred continuously overnight. To the solution,thus prepared, was further added a solution of HyAsp(OMe)-OMe·HCl (2.25 g, 10.6 mmol) and TEA (1.48 ml, 10.6 mmol) in dry THF (7 ml) at room temperature. After making the solution pH 9 with NMM (1.0 ml, 9.1 mmol), the resulting solution was stirred for more 2.5—4.0 h and then concentrated under reduced pressure to give a crude residue, which was dissolved in ethyl acetate (100 ml). This solution was successively washed with 10% citric acid, water, saturated aqueous $NaHCO_3$ solution and water and finally dried over anhydrous Na_2SO_4. After removing the solvent under reduced pressure, the crude residue obtained was crystallized and collected by using diisopropyl ether. In the case of a syrup, which did not crystallize, purification on a silica-gel column using a mixture of $CHCl_3$ and acetone (20:1 v/v) as the eluent was carried out to give crystals, which were recrystallized from a mixture of petroleum ether and ethyl acetate to give **10**. The dipeptide containing a *threo*-HyAsp residue, thus obtained, was colorless prisms; the one with an *erythro*-HyAsp residue was colorless needles.

Preparation of 12. To a solution of **10** (1.60 mmol) and MsCl (0.19 ml, 2.40 mmol) in dry THF (7 ml) below 0 °C. After stirring for 1 h and then at room temperature for 24 h in the case of TEA, or for 4.5 h in the case of DBU, the reaction solution was concentrated under reduced pressure. The residue, thus obtained, was dissolved in ethyl acetate (50 ml) and the resulting solution was washed successively with 10% citric acid, water, saturated aqueous $NaHCO_3$ solution, and then water and finally dried over anhydrous Na_2SO_4. After removing the solvent under reduced pressure, the obtained residual crystals were recrystallized from a mixture of petroleum ether and ethyl acetate to give **12** as colorless prisms [(*Z*)-isomer] or colorless needles [(*E*)-isomer].

The present work was partially supported by a Grant-in-Aid for Scientific Research No. 62540394 from the Ministry of Education, Science and Culture.

Retentive Solvolysis. 16.[1] Reinvestigation of the Retentive Phenolysis of 1-Phenylethyl Chloride. The Mechanism and the Structure of Ion Pair Intermediate

Tomomi KINOSHITA,* Takuya UENO, Keizo IKAI, Masataka FUJIWARA, and Kunio OKAMOTO†

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Kyoto 606

(Received April 12, 1988)

The effect of added aniline on the polarimetric (k_p) and titrimetric rate constants (k_t) has been reexamined for the phenolysis of 1-phenylethyl chloride (RCl) in phenol–benzene (1:1 w/w). The k_p–k_t plot against the aniline concentrations exhibited the pattern C, instead of A which was the previous results in our laboratory. It has been revealed that the previous rate constants at the lower aniline concentrations, including the case of absence of aniline, were underestimated due to overlooking the reverse reaction caused by the liberated hydrogen chloride. The pattern C indicates that the first ion pair intermediate, not the second one, is nucleophilically attacked by solvent phenol molecule. The major products were the partially retained *o*-RC_6H_4OH, the partially inverted *p*-RC_6H_4OH, together with the partially retained ROPh. The same k_p–k_t pattern C has been observed for the competitive solvolysis of RCl in phenol–methanol (85:15 w/w), which produced the partially retained ROMe and ROPh, the partially inverted *o*- and *p*-RC_6H_4OH, and styrene. Such stereochemical outcomes for both solvolyses demonstrate that the major first ion pair intermediate should be a rear-side-shielded ion pair intermediate.

On the basis of the pattern of salt effect of added aniline on the polarimetric and titrimetric rate constants (k_p and k_t, respectively),[2] the retentive phenolysis of 1-phenylethyl chloride[2–5] (RCl), the first example of the retentive phenolysis, has been hitherto recognized to be one of a few solvolysis systems,[1,6–9,††] which exhibited the pattern A[1,6,9] in the k_p–k_t plot against the concentration of added salt.

However, there have been left two problems for the phenolysis of 1-phenylethyl chloride. First, the pattern of k_p–k_t diagram, previously reported for the phenolysis of RCl,[2] exhibited an "unusually" steep slope of the special salt effect[7,10,11] on k_t. Although such a steep slope has been often reported for S_N1 solvolyses in some solvents[11] other than phenol, it has not been known for the phenolyses examined so far.[1,6,8,9,12,13]

The steep increase in the k_t is characterized by the use of the parameters proposed by Winstein and his co-workers.[11a] The parameters are: $k^0_{t,ext}/k^0_t$=5.0 and $[salt]_{1/2}$=0.0036 M (1 M=1 mol dm^{-3}) for RCl, whereas 1.09—2.69 and 0.01—0.03 M, respectively, for the other systems.[1,6,8,9,12,13] The $k^0_{t,ext}$ designates the k_t value extrapolated at zero salt concentration from the linear part at higher salt concentrations, k^0_t is the actual k_t value at zero salt concentration, and $[salt]_{1/2}$ is the salt concentration corresponding to $\frac{1}{2}\cdot(k^0_{t,ext}+k^0_t)$.

Secondly, it has been known that the phenolysis accompanies the reverse reaction in the absence of an added base,[14,15] which results in retardation of the apparent rate (k_t)[14] and rearrangement of ROPh to *o*- and *p*- RC_6H_4OH by the liberated strong acid such as hydrogen chloride.[15] Such an effect of reverse reaction was sometimes overlooked.[16]

We have therefore reinvestigated the k_p–k_t pattern for the phenolysis of 1-phenylethyl chloride with suspicions on the pattern A,[1,6,9] under the conditions where the effect of reverse reaction is completely eliminated.

Although we briefly mentioned the results in the footnotes of the preceding papers,[1,6,13] we now report in details that the k_p–k_t diagram for the phenolysis of RCl in the presence of $PhNH_2$, Et_3N, and NaOPh does exhibit the pattern C,[1,6] which specifies Int-1, not Int-2, for the ion pair stage of product formation. Furthermore, adding the stereochemical outcomes for the reinvestigated methanol-perturbed phenolysis of RCl,[17] we also report that the structure of the major Int-1 should be a rear-side-shielded ion pair intermediate.

Results and Discussion

Reexamination of Phenolysis Rates. Optically active 1-phenylethyl chloride (RCl) has been subjected to the phenolysis under the identical conditions with those employed previously,[2] i.e., in phenol–benzene (1:1 w/w) at variable concentrations (0—0.391 M) of added aniline at 25 °C, except the concentration of RCl, 0.10 M instead of previous 0.55 M[2] for the k_p measurements. The phenolysis rate has been reexamined both titrimetrically and polarimetrically. Titrimetric rate measurements have been carried out by the use of 0.05 M aqueous HCl (or NaOH) solution as a titrating reagent, cold acetone (ca. −15 °C) as a stop solution, and lacmoid as an indicator, instead of previous 0.1 M $HClO_4$ (or NaOAc) acetic acid

† Current address: Meisei Chemical Works, Ltd., 1 Nakazawacho, Ukyo-ku, Kyoto 615.

†† Although the acetolysis of 2-(*p*-methoxyphenyl)-propyl tosylate was previously reported to proceed via Int-2,[10] reexamination of the pattern of salt effect by us[6] has clarified that the product source is Int-1, not Int-2.

solution, acetic acid (ca. 10 °C), and Crystal Violet, respectively.[2] All the rate data are summarized along with those in the presence of Et_3N, NaOPh, lithium perchlorate, and a hindered pyridine in Table 1 and they are plotted against the concentration of aniline in Fig. 1 together with the previously-reported data.[2]

In the absence of aniline, the k_t^0 value had a tendency to decrease as the reaction proceeded at 1—25% conversion. After ca. 25% conversion, the reaction retarded much more. This phenomenon can be ascribed to the occurrence of competing reverse reaction, i.e., the cleavage reaction of the aralkyl phenyl ether by the liberated hydrogen chloride to give the starting RCl.[14,15] The initial k_t^0 value at zero % reaction, therefore, has been extrapolated from k_t^0 values at 1—13% reaction. The new k_t^0 value coincides within experimental errors with a k_t value (Table 1) in the presence of a hindered amine, 2,6-di-*t*-butyl-4-methylpyridine, which plays only as a neutralizer for the liberated acid, not as a phenoxide donor. The new k_t^0 value is 5.0 (±0.4) times larger than the previously-reported value,[2] which had been measured at 12—27% reaction. An approximately identical value with the previous one[2] could be obtained at such 10—25% reaction. The k_p^0 value, k_p value in the absence of the base, exhibited a little acceleration with an increase in the reaction %, most probably due to the cleavage reaction of the aralkyl phenyl ether.[14,15] The initial k_p^0 value was determined, therefore, by the extrapolation method similar to that described above. The new k_p values are 1.1 times larger than the previous ones over the whole range of $PhNH_2$ concentration (Fig. 1). The discrepancy can be mainly ascribed to the difference of the phenol concentration

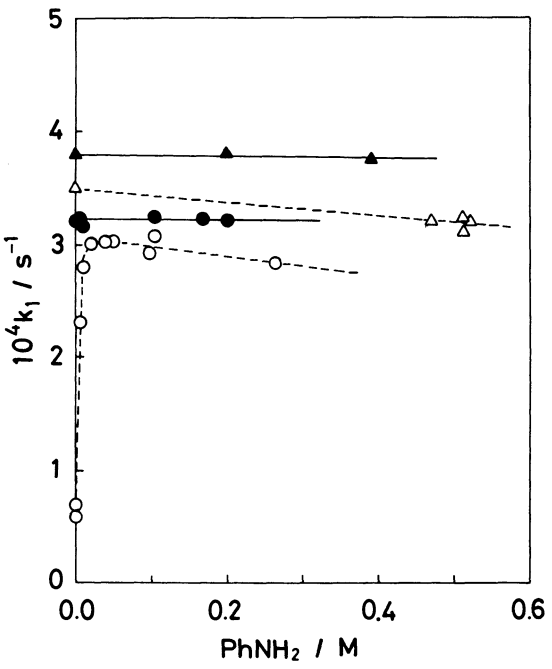

Fig. 1. Effect of added $PhNH_2$ concentration on the titrimetric and polarimetric rate constants (k_t and k_p) for the phenolysis of 1-phenylethyl chloride in phenol-benzene (1:1 w/w) at 25°C.

in the respective solvents owing to that of the substrate concentrations between in this work (0.10 M) and in the previous work (0.55 M).[2]

The k_t value at 0.0050 M $PhNH_2$ (0.050 M RCl) was obtained from the data at 1—8% reactions. The new value is 1.4 times larger than the previously-reported value which had been estimated at 5.8% reaction.[2] For each run in the presence of 0.106—0.198 M $PhNH_2$, a smooth first-order linear relationship (correlation coefficient≧0.9997) has been obtained until at least 80% reaction and the new values are somewhat larger than the previous ones.[2] In view of the conditions and the accuracy of rate measurements, the new data are much more reliable than the previously-reported data.[2]

Reexamination of the k_p–k_t Pattern for Phenolysis. The new pattern of the salt effect of $PhNH_2$ on the k_p–k_t diagram exhibits no special salt effect on k_t, differently from the previous one[2] (Fig. 1). The k_p/k_t ratio is constant, 1.19, over the whole range of the concentration of $PhNH_2$. The analogous k_p–k_t patterns have been also observed in the presence of Et_3N and NaOPh (Fig. 2) instead of $PhNH_2$. Lithium perchlorate also exhibits no special salt effect on k_t[†††] (Table 1). Such patterns were classified as pattern C in one of our previous reports.[1,6]

Thus, the k_p–k_t patterns indicate that the first ion pair intermediate (Int-1), not the second one (Int-2), partially reacts with the solvent phenol molecule, partially returns to the substrate, and partially racemizes by itself,[1,6] whereas the previously-reported k_p–k_t profile[2] suggested that all the products derived from the reaction of Int-2 with the phenoxide at higher base concentrations.[1,6]

The same k_p–k_t pattern C[1,6] has been reported for the phenolyses of 1-phenylethyl,[8] 1-phenylpropyl,[9] 1-methyl-1-phenylpropyl,[9] 2-methyl-1-phenylpropyl,[9] and *p*-chlorobenzhydryl *p*-nitrobenzoates[9] in the presence of NaOPh or Et_3N, and 2,2-dimethyl-1-phenylpropyl *p*-nitrobenzoate in the presence of $(n\text{-}Bu)_4NClO_4$,[6] for the hydrolysis of RCl in 60% aqueous dioxane in the presence of $LiClO_4$,[18] and for the acetolysis of *exo*-2-norbornyl brosylate in the presence of KOAc.[19,§]

Product Distribution for the Phenolysis. Product distribution for the phenolysis of RCl was analyzed by the use of GLPC in the presence of $PhNH_2$ under the conditions identical with those employed in the

††† 2,6-Di-*t*-butyl-4-methylpyridine was added in order to neutralize the liberated acid which might cause the reverse reaction.

§ Although the rates for the acetolysis of *exo*-2-norbornyl brosylate were measured only at two concentrations of added KOAc,[19] the k_p–k_t pattern can be estimated to be the same as the corrected one for this system.[6]

Table 2. The Product Distribution for the Phenolysis of 1-Phenylethyl Chloride (RCl) in the Presence of Aniline in Phenol–Benzene (1:1 w/w) at 25 °C[a]

0.408[c]	69.0[d]	16.3[d]	14.7[d]	—	—	—	—

a) [RCl]=0.10 M. b) Determined by GLPC; (ROPh+o-RC_6H_4OH+p-RC_6H_4OH+RNHPh+o-$RC_6H_4NH_2$+p-$RC_6H_4NH_2$)%=100%: in parentheses; (ROPh+o-RC_6H_4OH+p-RC_6H_4OH)%=100%. c) In the presence of Et_3N instead of $PhNH_2$ at 40 °C; cited from Ref. 3. d) Isolated yield %.

kinetic measurements. Together with the usual phenolysis products, i.e., ROPh, o- and p-RC_6H_4OH, and styrene, the phenolysis produces minor amounts of RNHPh, o- and p-$RC_6H_4NH_2$ which were not previously detected[2] (Table 2). In the absence of aniline, no ROPh was obtained because of the rearrangement of ROPh to o- and p-RC_6H_4OH by the liberated acid.[15]

With an increase in the concentration of added $PhNH_2$, the yield% of the aniline derivatives increases, albeit still minor amounts. The yield% ratio of the phenol derivatives to the aniline ones in products can be regarded as approximately comparable with the composition of phenol and aniline in the solvolysis media. Furthermore, the ratio of ROPh to RC_6H_4OH (o- and p-) is almost invariable.§§

Such results of product analyses suggest that the added aniline in this system does not play a role of phenoxide donor, but roles of a scavenger of the liberated acid and of a competing nucleophile with an almost identical nucleophilicity with that of phenol. The effect of added $PhNH_2$ on the product distribution is compatible with the k_p–k_t profile.

Stereochemical Courses of the Phenolysis. All the substitution products for the phenolysis of optically active RCl in the presence of $PhNH_2$ (0.110 and 0.290 M) were isolated by MPLC and preparative TLC (silica gel), although ROPh alone had been isolated in the previous work.[2] The net stereochemical course was deduced for the formation of each substitution product from its optical rotation. The results are summarized along with the previously-reported ones[2] in Table 4. The absolute configurations and maximum rotations for the related 1-phenylethyl derivatives are shown in Table 3.

The configuration is partially retained for the ROPh formation and partially inverted for the p-RC_6H_4OH formation with predominant racemization, respectively, and highly inverted for the RNHPh[20] and o-$RC_6H_4NH_2$[21] formations with less racemization (Scheme 1).

a) The maximum rotations for relevant compounds in this table are shown in Table 3. b) Neat, 1 dm. c) In benzene unless otherwise noted. d) In methanol. e) In $CHCl_3$. f) Cited from Ref. 2. g) Cited from Ref. 3.

retentive solvolyses have been reported in 90% aqueous acetone,[22] 2,2,2-trifluoroethanol,[23] 97% aqueous 2,2,2-trifluoroethanol,[23] trifluoroacetic acid[24] other than in phenol solvents, whereas many inversive results have been observed.[18,23,25]

The partial retention for *o*-RC_6H_4OH formation in the presence of $PhNH_2$ is in marked contrast to the partial inversion for that in the presence of Et_3N. The direct and retentive ortho-alkylation have not been known in the phenolysis[16] except those for 1-phenylethyldiazonium salt[4] and for 2,2-dimethyl-1-(*p*-methoxyphenyl)propyl *p*-nitrobenzoate.[13] The inversion % for *p*-RC_6H_4OH formation is much lower in the presence of $PhNH_2$ than that in the presence of Et_3N. The inversion % for RNHPh and *o*-$RC_6H_4NH_2$ formation is higher than that for *p*-RC_6H_4OH and is somewhat smaller than that (87.9±9.1%) for the anilinolysis of RCl in aniline, although the reaction conditions are different from each other.§§§

The stereochemical courses for all substitution products are approximately constant within experimental errors with an increase in the concentration of added aniline (Table 4), which is consistent with the salt effects on k_p–k_t diagram and on the product distribution.

The extent of racemization is variable for each product, from 36.0% (for RNHPh) to 92.6% (for *o*-RC_6H_4OH), which indicates that the racemization can not be attributed to a simple reason.

Methanol-Perturbed Phenolysis. The competitive solvolysis of RCl has been carried out at 25 °C in phenol–methanol (85:15 w/w) solvent, which was one of binary mixture solvents adopted in the previous work.[17] The solvolysis, i.e., methanol-perturbed phenolysis, has been followed both titrimetrically and polarimetrically in the presence of Et_3N (0—0.30 M) and NaOPh (0—0.25 M), although the solvolysis was not kinetically examined before.[17]

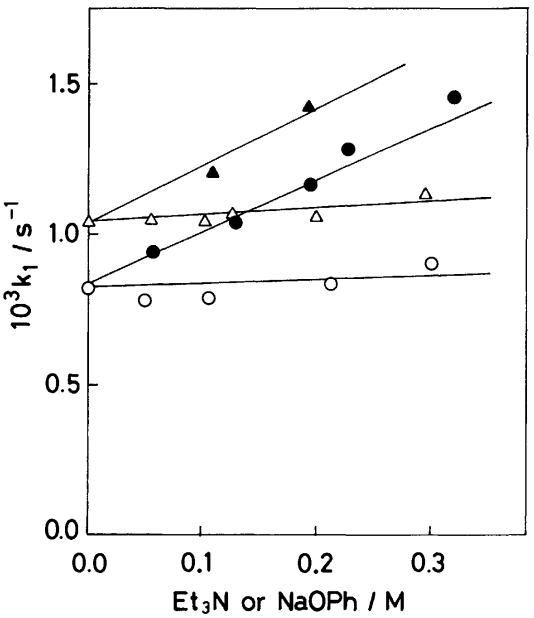

Fig. 3. Effect of added base concentration on the titrimetric and polarimetric rate constants (k_t and k_p) for the competitive solvolysis of 1-phenylethyl chloride in phenol–methanol (85:15 w/w) at 25 °C. ○ k_t, △ p_p; in the presence of Et_3N. ● k_t, ▲ k_p; in the presence of NaOPh.

The pattern of k_p–k_t diagram with k_p/k_t=1.24 (Fig. 3), analogous to that for the phenolysis in the phenol–benzene solvent (Figs. 1 and 2), indicates that all the products are derived from the reaction of Int-1 with solvent molecules, phenol and methanol, despite of the presence of the phenoxide.

The competitive solvolysis afforded ROMe together with the phenolysis products, ROPh, *o*- and *p*-R-C_6H_4OH, and styrene. The product distribution (Fig. 4) is similar to that at 50 ° C which was previously reported[17] and is invariable over the whole range of added base concentrations (0.05—0.3 M), which is consistent with the k_p–k_t profile.

§§§ Although the retentive nucleophilic substitution by aniline was recently mentioned for 1-phenylethyl benzenesulfonate in methanol,[26] the actual detailed data of stereochemical courses have not been reported.

The constancy of product distribution in the course of reaction (26.9—100%) has been confirmed at 0.110 M Et_3N concentration, showing that all the products were formed via a same reaction pathway.

Although RCl usually undergoes net inversion when solvolyzed in methanol–benzene[5] like in other common solvents,[18,23,25] the methanol-perturbation product, ROMe, and ROPh have the partially retained configurations, whereas *o*- and *p*-RC_6H_4OH's have the partially inverted ones (Table 5). These stereochemical results are approximately same as the previous results at 50 °C.[17] The stereochemical outcomes for the product formation in the presence of Et_3N (0.110 and 0.291 M) and NaOPh (0.13 M) are identical with each other within experimental errors.

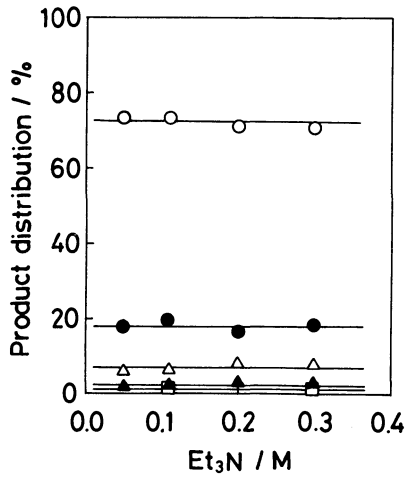

Fig. 4. Effect of added Et_3N concentration on the product distribution for the competitive solvolysis of 1-phenylethyl chloride in phenol–methanol (85:15 w/w) at 25 °C.
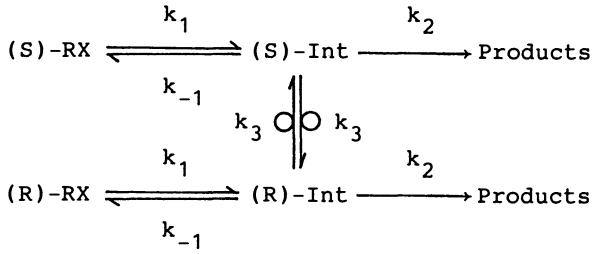
○ ROPh, ● ROMe, △ *o*-RC_6H_4OH, ▲ *p*-RC_6H_4OH, □ $C_6H_5CH{=}CH_2$.

That is consistent with the salt effect on the k_p–k_t diagram and on the product distribution.

For the formation of phenolysis products, ROPh, *o*- and *p*-RC_6H_4OH, the extents of racemization can be regarded as approximately identical with each other, suggesting that the phenolysis products might be derived from a single ion pair intermediate (Int-1).

Mechanism. The k_p–k_t profiles for the phenolysis and the methanol-perturbed phenolysis indicate that (i) all the products are derived from the first ion pair intermediate (Int-1), not from the second one (Int-2), (ii) the Int-1 is so reactive that it reacts with the solvent phenol or methanol molecule before it does with the added phenoxide, and (iii) the Int-1 partially returns to the substrate and partially racemizes by itself.[1,6] No contribution of phenoxide ion as a nucleophile has been confirmed by the constancy of product distribution for the phenol derivatives and that of the stereochemical course for each substitution product against an increase in added base concentration (vide supra).

These kinetic features can be expressed by the following reaction scheme, which contains a single ion pair intermediate.



Scheme 2.

According to Scheme 1, the total rate expressions for k_p and k_t can be derived as following Eqs. 1 and 2.[1]

Table 5. The Stereochemical Courses for Products of the Competitive Solvolysis of 1-Phenylethyl Chloride (RCl) in Phenol–Methanol (85:15 w/w) in the Presence of Et_3N and NaOPh at 25 °C[a]

a) The maximum rotations for relevant compounds in this table are shown in Table 3. b) Neat, 1 dm. c) In benzene unless otherwise noted. d) Cited from Ref. 14.

$$k_p = \frac{k_1}{1 + \{k_{-1}/(k_2 + 2k_3)\}} \quad (1)$$

$$k_t = \frac{k_1}{1 + (k_{-1}/k_2)} \quad (2)$$

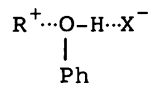
where $k_2 = k_2' + k_2''[\mathrm{PhOH}] + k_2'''[\mathrm{MeOH}]$.

Structure of the Ion Pair Intermediate. For the retentive ROPh formation in the solvolysis systems, solvent-separated ion pair model (a),[7,11,27] four-center ion pair model (b),[3,4,28] and rear-side-shielded ion pair model (c)[5,13,27i] could provide reasonable explanations as a key intermediate. Althogh they were all proposed for Int-2, not for Int-1, the models (b) and (c) are also applicable to Int-1. However, the model (a) might be inapplicable to Int-1, because it should be generated only via a contact ion pair (d)[7,11,27] as Int-1 (Scheme 3).

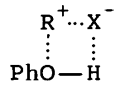
The stereochemical courses for all the other products in the phenolysis and in the methanol-perturbed phenolysis could be explained by the use of the model (b) and its analogues, i.e., six-center ion pair models (e),[4,17] or the model (c) and its analogues, i.e., ion pairs shielded by aniline molecule from the rear-side.

Models for ion pair intermediate structure:

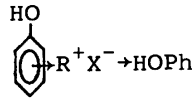
(a) solvent-separated ion pair model[7,11,27]



(b) four-center ion pair model[3,4,28]



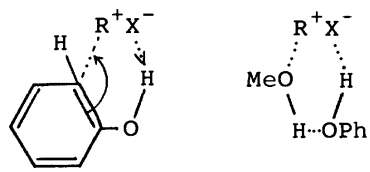
(c) rear-side-shielded ion pair model[5,13,27i]



and its analogues

(d) contact ion pair model[7,11,27] $R^+X^- \rightarrow HOPh$

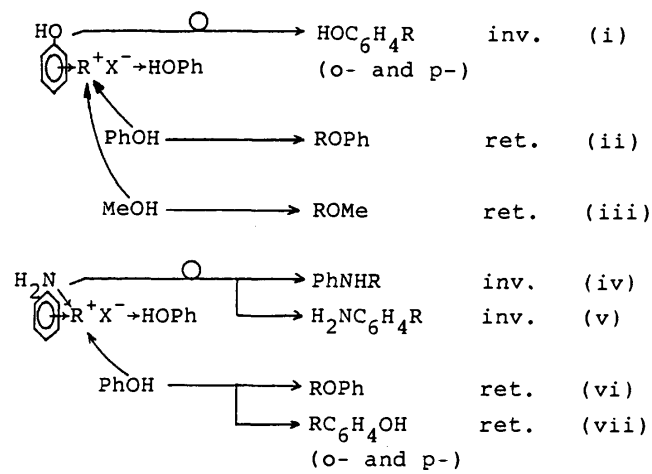
(e) six-center ion pair models[4,17]



Scheme 3.

In view of the rear-side attack of phenol molecule toward R^+ of Int-1 which is predominantly occupied by the C-alkylation in the presence of Et_3N or NaOPh, the Int-1 should have an ion pair structure shielded by a phenol molecule from the rear-side. It is probable that the retentive methanolysis proceeds via models (c) ((iii) in Scheme 4).

In the presence of $PhNH_2$, the inversive alkylations of $PhNH_2$ give an indication that model (c) shielded by $PhNH_2$ might coexist with another model (c) shielded by PhOH ((iv) and (v) in Scheme 4). The aniline-shielded ion pair (c) could produce the retained alkylphenols ((vii) in Scheme 4); the *o*-isomer might be more easily formed via a six-center conformation (cf. (e) in Scheme 3) than the *p*-isomer. The formation of retained *o*-alkylphenol in the presence of $PhNH_2$ (Table 4) could suggest that the aniline-shielded ion pair (c) might be predominant. These are consistent with the other fact that the inverted *p*-alkylphenol accompanies more racemization in the presence of $PhNH_2$ than in the presence of Et_3N (Table 4). From such rear-side-shielded ion pair models, predominant formation pathway for each product may be expressed in Scheme 4.



Scheme 4.

The Int-1 in this system, therefore, have an analogous ion pair structure to that for Int-2 in the phenolysis of 2,2-dimethyl-1-(*p*-methoxyphenyl)propyl *p*-nitrobenzoate.[13]

More racemization for ROMe than that for the other products suggests that a rear-side-open, not shielded, ion pair intermediate, e.g., a four-center ion pair (b) and/or a contact ion pair (d), might contribute as a minor Int-1 to the product formation.

In conclusion, (i) the reexamination of k_p–k_t profile for the phenolysis system has clarified that all the products are produced by the reaction of Int-1 with solvent phenol molecule, and (ii) the features of stereochemical outcomes for both solvolyses, the phenolysis in phenol-benzene (1:1 w/w) and the competitive solvolysis in phenol-methanol (85:15 w/w), indicate that the Int-1 might be composed of multiple ion pair intermediates with various types, not of a single one, but that the major Int-1 should be

a rear-side-shielded ion pair intermediate.

Experimental

^{13}C and ^{1}H NMR spectra were taken with a JEOL model JNM FX-100 25 MHz (FT) and Hitachi R-24 and R-600 (FT) 60 MHz instruments, respectively. IR spectra were recorded with a Hitachi model 215 spectrophotometer. Optical rotations were measured with a JASCO model DIP-SL polarimeter. GLPC was performed with a Hitachi model 163 instrument. MPLC was done with a chromatograph system composed of a FMI model RP-SY-2 pump system and a Merck silica gel 60 column. Melting points were measured on a Yamato model MP-21 apparatus.

Materials. Optically active 1-phenylethanol was obtained both by the resolution of the racemic alcohol according to the Pope-Peachey method[29] and by asymmetric reduction of acetophenone.[30] Optically active and racemic 1-phenylethyl chlorides were prepared by reactions of respective 1-phenylethanols with thionyl chloride as previously described.[2,3] Sodium phenoxide was prepared in the previously-reported manner.[31] 2,6-Di-*t*-butyl-4-methylpyridine was synthesized by a known method.[32] All the other organic reagents were of an analytical reagent grade, dried, and fractionated prior to use.

Titrimetric Rate Measurements. The usual aliquot technique[5] was employed, using cold acetone (ca. −15 °C) as a stop solution, 0.05 M NaOH (or HCl) solution as a titrating reagent, and lacmoid as an indicator. In the presence of a base, the reaction was followed to at least 80% reaction; smooth first-order linear relationships (correlation coefficient ≥0.9997) were obtained. In the absence of a base, the reaction was followed to ca. 30% completion; the initial rate constant was taken by extrapolation from rate constants at 1—13% reaction.

The rate data are shown along with polarimetric rate data in Table 1 and Figs. 1, 2, and 3.

Polarimetric Rate Measurements. (A) Phenolyses: The previous method[2] was followed. A reaction solution, prepared at the reaction temperature (25.0±0.1 °C), was immediately placed into a jacketed polarimeter tube (1 dm) maintained at 25 °C by circulation of water from a constant temperature bath kept at 25.0±0.1 °C. In each run, the reaction was followed to at least 80% conversion; a smooth first-order linear relationship was obtained (the correlation coefficients≥0.9997).

(B) Methanol-Perturbed Phenolyses: Each reaction solution ([RCl]=0.1 M, [Et_3N]=0—0.30 M; 10 ml) was kept at 25.0±0.1 °C. After a specified time, the solution was poured onto an ice-cooled mixture of 10% aq. NaOH solution (200 ml)–diethyl ether (400 ml) and immediately shaked. The ether layer was promptly separated, washed with cold 10% aq. NaCl solution, and dried. After subsequent removal of the solvent by rotary evaporation, the optical rotation of benzene solution (5 ml) of the concentrate was measured. Thus, the optical rotations at five or more specified times were graphically treated, and a smooth first-order linear relationship was obtained (the correlation coefficient≥ 0.9993).

The rate data are summarized in Table 1 and Figs. 1, 2, and 3 along with the titrimetric rate data.

a) δ; in $CDCl_3$.

the phenolyses were analyzed by GLPC in a manner similar to that reported earlier.[1,33]

The data are shown for the phenolysis in Table 2 and for the methanol-perturbed phenolysis in Fig. 4.

Isolation of Phenolysis Products. The previous procedures[5] were followed. All substitution products were separated by MPLC and preparative TLC (silica gel). As a representative run, isolation of the products in the phenolysis of RCl in the presence of $PhNH_2$ (0.110 M) is described in the following. A solution (350 ml) of (*R*)-(+)-RCl (5.021 g, 0.03571 mol; $\alpha_D^{23.5}$ +24.2±0.1° (neat, 1 dm)), in phenol-benzene (1:1 w/w) containing aniline (0.110 M) was kept at 25.0±0.1 °C for 6 h. After usual working-up,[5] (*R*)-(−)-ROPh (4.994 g, $\alpha_D^{21.5}$ −1.55±0.08° (neat, 1 dm)), (*R*)-(+)-*o*-RC_6H_4OH (0.318 g, $[\alpha]_D^{25.8}$ +0.398±0.035° (*c* 5.773, benzene)), and (*S*)-(+)-*p*-RC_6H_4OH (0.339 g, $[\alpha]_D^{26.0}$ +0.235±0.043° (*c* 4.673, benzene)), were obtained from the organic solution. Simultaneously, (*S*)-(+)-RNHPh[20](0.132 g; mp 46.8—47.9 °C (lit,[20b] 47.5—48.1 °C); $[\alpha]_D^{31.0}$ +2.43±0.13° (*c* 2.391, methanol)), (*S*)-(+)-*o*-$RC_6H_4NH_2$[21] (0.0249 g; mp 57.0—58.2 °C (lit, 57.5—58.5 °C,[20b] 58—59 °C,[34] 58.5—59.0 °C[35]); $[\alpha]_D^{24.9}$ +4.4±0.6° (*c* 0.32, benzene)), and *p*-$RC_6H_4NH_2$(0.0073 g) were isolated from an aqueous acidic solution used for washing the organic solution.

The stereochemical data for products are tabulated along with those at 0.29 M $PhNH_2$ and the previously-reported ones in Table 4. Those for the methanol-perturbed phenolysis are summarized in Table 5.

Each solvolysis product was identified on the basis of ^1H and ^{13}C NMR and IR spectral data and chromatographic data. ^{13}C NMR spectral data for all substitution products are shown in Table 6.

Anilinolysis of 1-Phenylethyl Chloride. An aniline solution (100 ml) of (*S*)-(−)-RCl (1.505 g, 0.0107 mol; $\alpha_D^{21.2}$ −51.90±0.08° (neat, 1 dm)) was maintained at 50.0±0.1 °C for 4.5 h (ca. $t_{1/2}$×10). After removing the solvent by distillation at a reduced pressure and a usual work-up, (*R*)-(−)-RNHPh[20](1.853 g, 87.8% yield; mp 46.7—47.8 °C; $[\alpha]_D^{19.4}$ −12.6±1.3° (*c* 0.150, cyclohexane)) was isolated by chromatographic separation and distillation in vacuo.

The authors thank the Ministry of Education, Science, and Calture for a Grant-in-Aid for Scientific Research.

The Catalytic Reduction of Aldehydes and Ketones with 2-Propanol over Hydrous Zirconium Oxide

Makoto SHIBAGAKI,* Kyoko TAKAHASHI, and Hajime MATSUSHITA
Life Science Research Laboratory, Japan Tobacco INC.,
6-2 Umegaoka, Midori-ku, Yokohama, Kanagawa 227
(Received April 20, 1988)

Reduction of aldehydes with 2-propanol proceeded efficiently by catalysis with hydrous zirconium oxide to give the corresponding alcohols. Most ketones also were reduced efficiently, but conjugated or sterically hindered ketones resisted the reduction. The reduction was carried out with primary, secondary, or tertiary alcohols, and only secondary alcohols served as hydrogen donors. Kinetic experiments have indicated that the reaction rate is of first-order dependence on each of the concentrations of the carbonyl compound, 2-propanol, and the catalyst. An observation of the primary isotope effect has suggested that a step of hydride transfer from absorbed 2-propanol to absorbed carbonyl compound constitutes the rate-determining step for the reduction.

The reduction of multiple bonds using an organic molecule as a hydrogen donor in place of hydrogen gas or metal hydride is known as hydrogen-transfer reaction.[1] One example is the reduction of aldehydes and ketones with metal alkoxide and alcohol. This is called the Meerwein-Ponndorf-Verley reduction. It was discovered in 1925 and has been used successfully in a number of instances.[2] Aluminium isopropoxide has been found to be the best reagent for this reduction. However, this method calls for both addition of at least 100 to 200% excess aluminium isopropoxide and neutralization of alkoxide salt with strong acid. As other catalysts for this reduction, complexes of cobalt,[3] iridium,[4,5] rhodium,[6-8] ruthenium,[8,9] indium,[10] molybdenum,[11] and zirconium[12] have been reported. Although these catalysts have many advantages over conventional metal alkoxides, the isolation of products is always attended by tedious workups.

Heterogeneous methods for the reduction are known, and zeolite[13] and oxides of aluminium,[14] magnesium,[15] silicon,[15] calcium[15,17] barium,[15] strontium,[15] zirconium,[16] titanium,[16] vanadium,[16] molybdenum,[16] zinc,[16] thorium,[16] and lanthanoid groups[18] have been reported to be successful catalysts. These methods have several advantages in the isolation of products. However, they need to be carried out in the vapor phase, and require high reaction temperatures and flow reactor systems.

Posner et al.[19] reported that dried chromatographic alumina served as a catalyst in the liquid phase. Several aldehydes and ketones could be reduced by use of this catalyst, and products were easily isolated by filtering-off of catalyst and subsequent evaporation of solvent. However, this reduction requires water-free conditions and a large amount of catalyst. In our previous paper,[20] we briefly reported that the reduction of aldehydes and ketones with 2-propanol proceeded efficiently over hydrous zirconium oxide in the liquid phase. The hydrous oxide is available in the form of hard and translucent granules, of which X-ray diffraction analysis has shown to be amorphous.

Reduction with hydrous zirconium oxide has the following advantages: 1) the reduction does not call for strong acid treatment; 2) the products are easily isolated by filtering-off of catalyst and subsequent evaporation of solvent, because this catalyst is insoluble in any solvents; 3) hydrous zirconium oxide is stable at room temperature in air for 7 years, and can be used for repeated reductions; 4) hydrous zirconium oxide is not sensitive to air or water, and the reduction does not require water-free conditions.

In this paper, we will report the scope and limitation of the reduction of carbonyl compounds with alcohols catalyzed by hydrous zirconium oxide. A proposition of the mechanism of this reaction also will be described.

Experimental

Materials. Commercial reagents were used for the reduction without further purification. 2-Propan-2-*d*-ol was prepared by the reduction of acetone with sodium borodeuteride.

Hydrous Zirconium Oxide. To a solution of zirconium(IV) dichloride oxide ($ZrOCl_2 \cdot 8H_2O$) (200 g of solid in 10 dm^3 deionized water) was slowly added an aqueous solution of sodium hydroxide (1 mol dm^{-3}) at room temperature. Constant gentle stirring was maintained and the addition was continued until the pH of the resulting solution reached 6.80. The solution was allowed to stand for 48 h at room temperature. The resulting product was filtered and washed free from chloride ions. The gel was spread on a glass plate and dried in air at room temperature for 10 h and at 80 °C for 2 h. Fifty four grams of hydrous zirconium oxide was obtained in the form of granules, and was heated at 300 °C for 5 h.

General Procedure for the Reduction of Aldehydes and Ketones with 2-Propanol. In a 25 cm^3 round-bottom flask equipped with a reflux condenser was placed hydrous zirconium oxide (24—60 mesh; 1.0 or 2.0 g), an aldehyde or ketone (5 mmol), 2-propanol (10 cm^3), and a hydrocarbon (0.5 mmol) as an internal standard. The contents were heated under gentle reflux. The reaction mixture was collected at appropriate times after refluxing, and the

concentration of the products were analyzed by GLC (a capillary column PEG 20M 30 m). The identification of the products was made by comparison of retention times in gas chromatography with those of authentic samples.

Reduction of Hexanal with Several Alcohols. In a 10 cm^3 round-bottom flask equipped with a reflux condenser was placed hydrous zirconium oxide (24—60 mesh; 0.2 g), hexanal (1.0 mmol), an alcohol (2.0 cm^3), and dodecane (0.1 mmol) as an internal standard. The contents were placed in an oil bath kept at 78.0 °C (±0.1 °C). The analysis of the products was performed in a simlar manner as described above.

Kinetic Experiment. All experiments are carried out in a 10 cm^3 round-bottom flask equipped with a reflux condenser. The concentrations of a carbonyl compound and a hydrocarbon as an internal standard were always 0.5 and 0.05 mol dm^{-3}, respectively, and 2 cm^3 of 2-propanol was used as both reductant and solvent. In the case of the reduction of hexanal, benzaldehyde, cyclohexanone, and acetophenone, the amount of catalyst was usually 0.2, 0.2, 0.1, 0.4 g, respectively. The reaction was performed in a similar manner as described above.

Results and Discussion

Reduction of Aldehydes. The reduction of aldehydes yielded the corresponding alcohols. Essentially no by-products could be detected. A linear correlation between the natural logarithm of the carbonyl concentration and the reaction time was obtained. This result indicates that the reduction rate is of pseudo-first-order in the carbonyl concentration. The rate of the reaction is represented by

$$r = k' \cdot [C], \quad (1)$$

where k' and [C] are the pseude-first-order rate constant and the concentration of carbonyl compound, respectively. The rate constants and yields are listed in Table 1. Generally, the reduction of aldehydes proceeds efficiently, and the steric hindrance around the carbonyl group does not interfere with the reduction. The reduction of conjugated aldehydes also proceeds efficiently to give allylic alcohols selectively.

Reduction of Ketones. Rate constants for the reduction of ketones were obtained in the similar manner as those for aldehydes and are listed in Table 2. Cyclohexanone and 4-methylcyclohexanone were reduced faster than 2-methylcyclohexanone. An α-substituted methyl group seems to interfere with the access of a carbonyl group to the active site of the catalyst. The slow reduction of camphor, 3-decanone, and benzophenone can be attributed to the steric

hindrance. The presence of a double bond conjugated to the carbonyl group serves to slow down the rate of some reactions, although the reduction of 2-cyclohexen-1-one, 3-methyl-2-cyclohexen-1-one, and 2,6,6-trimethyl-2-cyclohexene-1,4-dione did proceed. The chloride substitution at the α-position increased the reduction rate, but at the γ-position it did not affect the rate. This suggests that electronic factors have some influence on the reaction.

Alcohols as Hydride Sources. The reduction of hexanal was carried out with some alcohols as well as with 2-propanol. The results are listed in Table 3. When primary alcohols were used, the acetalization proceeded faster than the reduction. Hexanal diethyl acetal and hexanal dimethyl acetal were obtained in 91 and 100% yields, respectively. Tertiary alcohol or methanol did not work as hydride donors. Basically, only secondary alcohols could be used.

Dependence on Catalyst Amount. For determining the order in catalyst amount, reduction rates of hexanal, cyclohexanone, and acetophenone were measured with 0.02—1.0 g of the catalyst. As shown in Fig. 1, the pseudo-first-order rate constants, k', were proportional directly to the amount of catalyst. Hence the specific rate constant, k, is to be introduced as

$$r = k'/[\text{cat.}], \quad (2)$$

where [cat.] is the concentration of catalyst.

Dependence on Reaction Temperature. In order to investigate the dependence on reaction temperature,

the reduction of hexanal, benzaldehyde, cyclohexanone, or acetophenone was carried out at 59.0—82.5 °C. The natural logarithm of the specific rate constant, k, vs. the reciprocal of the absolute temperature, that is, the Arrhenius plot, is shown in Fig. 2. As can be seen from the figure, a good straight line is obtained. From the inclination of the line, the activation energies of these reductions were estimated, which are listed in Table 4.

Effect of Alcohol Concentration. The influence of the concentration of 2-propanol upon the reduction rate was investigated for the reduction of hexanal, benzaldehyde, cyclohexanone, and acetophenone under the following conditions: the amount of 2-propanol was changed in the range from 2 to 0.5 cm^3 and toluene as a diluent was added in order to keep the volume of reaction mixture constant. The correlation between the concentration of 2-propanol and the specific rate constant, k, is shown in Fig. 3. In all cases, similar rate constants were obtained, and the concentration of 2-propanol did not affect the reaction rate under the present experimental conditions. However, decreasing the ratio of 2-propanol to the carbonyl compound changed the reaction rate. When

Benzaldehyde	0.2	2.29
Acetophenone	0.4	2.46

a) Carbonyl compound 1 mmol, alcohol 2 cm^3 reaction temperature 78.0 °C.

tion of the carbonyl compound and the reaction time was observed in the early stage of reaction. This result indicates that the initial reaction rate is of second order under these conditions. Furthermore, when their ratio was 2 to 1, the following relationship was obtained:

$$\log_e\{([C_0]-[C])/(2\cdot[C_0]-[C])\} = k''\cdot[C_0]\cdot t, \quad (3)$$

where $[C_0]$, $[C]$, and k'' are the initial carbonyl concentration, the carbonyl concentration, and the pseude-second-order rate constant, respectively.

Isotope Effect. The reduction of hexanal, benzaldehyde, cyclohexanone, and acetophenone was performed with 2-propan-2-*d*-ol in place of 2-propanol. The primary isotope effects k_H/k_D of the reactions, which are listed in Table 5, are larger than 2, which indicates that the C–H bond at the 2-position in 2-propanol is broken in the transition state.

Kinetic Discussion. As described above, the reaction rate is of first-order dependence on each of the concentrations of the carbonyl compound, 2-propanol, and the catalyst, as represented by

$$r = k\cdot[C]\cdot[A]\cdot[\text{cat.}], \quad (4)$$

where k, [C], [A], and [cat.] are the rate constant and the concentrations of the carbonyl compound, 2-propanol, and the catalyst, respectively. These results suggest that the rate-determining step is to be assigned to the step subsequent to the adsorption of 2-propanol and carbonyl on the catalyst. Taking the mechanism into account, we should like to propose a scheme. Based on the proposed scheme, the reduction rate is expressed by

$$r = \frac{k_1\cdot k_2\cdot k_3\cdot[C]\cdot[A]\cdot[\text{cat.}]}{k_{-1}\cdot(k_2+k_{-2})+k_2\cdot k_3[C]}. \quad (5)$$

The observation of the primary isotope effect suggests that the step of the hydride transfer from 2-propanol to a carbonyl compound, that is, the third step in the scheme, constitutes the rate-determining step. Therefore, k_3 is far less than k_{-2}, and the rate equation is rewritten to

$$r = \frac{k_1\cdot k_3\cdot[C]\cdot[A]\cdot[\text{cat.}]}{k_{-1}/K_2+k_{-3}\cdot[C]}. \quad (6)$$

where $K_2=k_2/k_{-2}$. Furthermore, $k_{-1}/K_2 \gg k_3\cdot[C]$, hence the rate equation becomes

$$r = K_1\cdot K_2\cdot k_3\cdot[C]\cdot[A]\cdot[\text{cat.}], \quad (7)$$

where $K_1=k_1/k_{-1}$. This equation apparently corresponds to Eq. 4, and the proposed scheme may be concluded to be reasonable. A similar mechanism[17] has been proposed for the Meerwein–Ponndorf–Verley reduction with hydroapatite catalyst, leading to estimation of its activation energy as 12±2 kcal mol^{-1}, which is the same with our case (see Table 4).

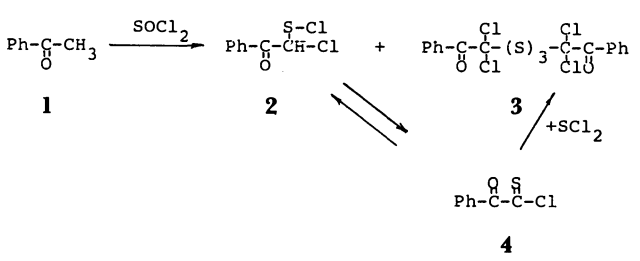
Reaction of 2-Hydroxyacetophenones with Thionyl Chloride in the Presence of a Catalytic Amount of Pyridine[1)]

Syed Mashhood ALI, Mohd ILYAS,† and Shigeo TANIMOTO
Institute for Chemical Research, Kyoto University, Uji, Kyoto 611
(Received April 22, 1988)

Reaction of 2-hydroxyacetophenone (**5**) with excess thionyl chloride in the presence of a catalytic amount of pyridine at room temperature afforded a thiirane **6**, while 2-hydroxy-4-methoxyacetophenone (**7**) furnished **8** when subjected to almost identical conditions. The products were characterized by microanalyses data and spectroscopic techniques including the mass spectroscopy. Plausible mechanisms for the conversions have been proposed in the light of available literature.

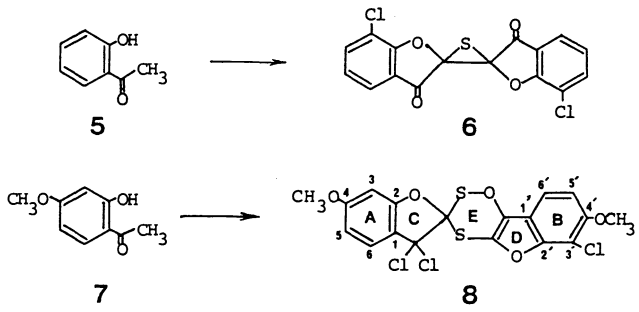
Thionyl chloride is routinely used as a chlorinating agent for many different substrate types.[2)] The course of the reaction of active methylene compounds with thionyl chloride seems unpredictable and so-called abnormal products have been reported in many cases[3)] often without further detailed investigations. The reaction of acetophenone (**1**) with $SOCl_2$ in the presence of a catalytic amount of pyridine furnishes **2** and **3**.[4,5)] The mechanism proposed for this reaction involves the intermediacy of α-oxobenzenethionyl chloride (**4**). However, the literature reveals that there is controversy over the existence of **4**[4,5)] and that little is known about the chemistry of related compounds with adjacent C=O and C=S functions.



We have investigated the reaction of some 2-hydroxyacetophenones with excess of thionyl chloride in the presence of a catalytic amount of pyridine in an attempt to obtain cyclic α-oxothiocarboxylic esters with the aim to further the available information on the reaction intermediates and also to explore the synthetic potential of the products. We wish to report our results in this manuscript.

Results and Discussion

The reaction of 2-hydroxyacetophenone (**5**) with excess of thionyl chloride in the presence of a catalytic amount of pyridine at room temperature afforded a red gummy mass which was subjected to column chromatography. Elution with petroleum ether–benzene (1:1) yielded **6**. Further elution of the column with more polar solvents gave a gummy mixture which could not be resolved even on repeated column chromatography. When 2-hydroxy-4-methoxyacetophenone (**7**) was treated with excess $SOCl_2$, under almost identical conditions, also a red gummy mass was obtained which was subjected to column chromatography. Elution of the column with petroleum ether–benzene (4:1) furnished a white solid which was crystallized from petroleum ether–benzene to give white crystals of **8**. Attempts to resolve the complex tar obtained on further elution with more polar solvents were not successful. The structures of **6** and **8** were established with the help of microanalyses and spectroscopic data.



Compound **6** analyzing for $C_{16}H_6Cl_2O_4S$ gave a positive Beilstein test indicating the presence of halogen. The presence of chlorine in **6** was clearly shown by the isotopic clusters in the mass spectrum and confirmed by microanalysis. Its IR spectrum displayed bands at 1725 (five membered ketone) and 690 (C–Cl). The ^1H NMR spectrum exhibited only the signals for aromatic protons as a multiplet in the region δ 7.00—8.00 displaying the 1,2,3-trisubstituted nature of the aromatic rings. The actual structure could only be elucidated by taking into account the mass fragmentation pattern of **6**. The mass spectrum did not exhibit the molecular ion peak expected at *m/z* 364, however, the peak with the highest mass to charge ratio was recorded at *m/z* 332 along with the isotopic peaks at *m/z* 334 and 336 whose relative intensities supported the presence of two chlorine atoms in this fragment. The formation of this fragment can be explained by the elimination of sulfur from the molecular ion (Chart 1). The most

† Department of Chemistry, Aligarh Muslim University, Aligarh, India.

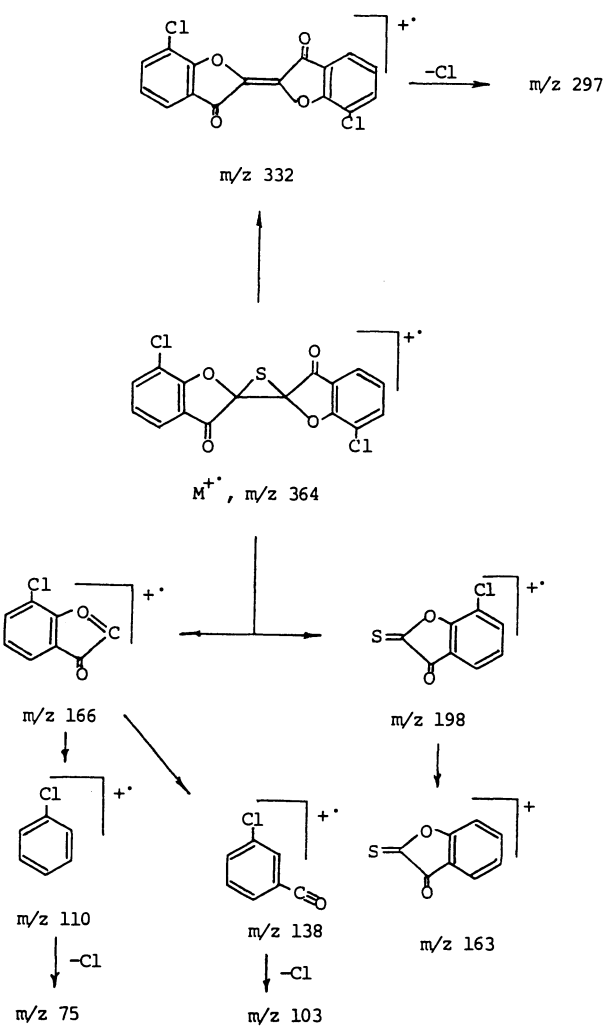


Chart 1.

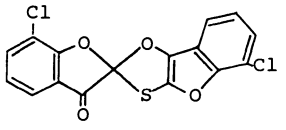
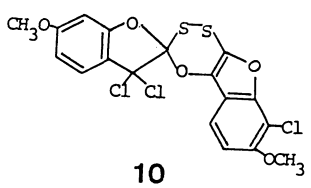
diagnostic fragmentation was the fission of the molecule into two fragments recorded at *m/z* 166 (base peak) and 198 (11.52) accompanied by the isotopic peaks at *m/z* 168 (33.00) and 200 (3.84), respectively. The loss of chlorine from the ion at *m/z* 198 can give an ion at *m/z* 163, while the fragments at m/z 103, 110, and 138 can be derived either directly from the molecular ion or from the fragments with *m/z* 166 and 198. The position of the chlorine in the aromatic rings was located with the help of NMR data and taking into account the mechanistic considerations. On the basis of above discussion, two possibilities can be drawn, either a thiirane **6** or a 1,3-oxathiole **9**. The absence of an enol ether band in the IR spectrum, characteristic of 1,3-oxathiole skeleton,[6] helped in eliminating this possibility. The compound was, therefore, characterized as thiirane **6**.



9

Compound **8** analyzing for $C_{18}H_{11}Cl_3O_5S_2$ also gave a positive Beilstein test. The presence of chlorine was confirmed by microanalysis and mass spectral data. Its IR spectrum displayed bands at 1610 (C=C), 1230 (enol ether), and 690 (C–Cl). The NMR spectrum proved comparatively more useful and clearly showed the presence of a chlorine in one of the aromatic rings. Two ortho-coupled doublets (J=9 Hz), each for one proton, at δ 7.44 and 7.80 were attributed to the protons at C-6 and C-6′, respectively. A high-field singlet at 6.54 ppm for one proton was due to C-3 proton. The signal for the C-5 and C-5′ protons merged and appeared as a multiplet centered at δ 6.75. Though the two methoxyl groups have slightly different environment, their signals appeared as a broad singlet at δ 3.80. The actual structure was, however, elucidated with the help of mass fragmentation pattern of **8** (Chart 2). The molecular ion peak could not be recorded in this case also and the peak at *m/z* 441 was the one with the highest mass to charge ratio accompanied by isotopic peaks at *m/z* 443 and 445, whose relative intensities showed the presence of two chlorine in this fragment. The formation of this fragment can be explained by the loss of a chlorine atom from the molecular ion. The most diagnostic peaks were those resulting by the retro-Diels–Alder fission of the ring E recorded at *m/z* 213 and 228. Another significant peak at *m/z* 214 was attributed to the doubly charged ion formed by the loss of sulfur monoxide from the $M^{+\cdot}$. The fragments derived from this ion were recorded at *m/z* 323, 358, 378, and 393. The above data grossly confirms the structure **8**. There are however few points which should be mentioned here. The assignment of chlorine on the ring A rather than on ring B is fully supported by the mass fragmentation pattern. Compound **10** was also taken into consideration. The possibility was however ruled out because there are few peaks which can only be explained by the loss of SO from the $M^{+\cdot}$ and this is not possible from **10**.



10

The reaction of active methylene compounds with $SOCl_2$ proceeds either by *O*- or *C*-sulfinylation. *O*-Sulfinylation of carbonyl compounds leads to either *gem*-dichlorides[7] or α-monochloro ketones, while *C*-sulfinylation gives rise to α-chlorosulfinyl ketones. These products may then undergo further transformations to give a variety of products. The formation of **6**

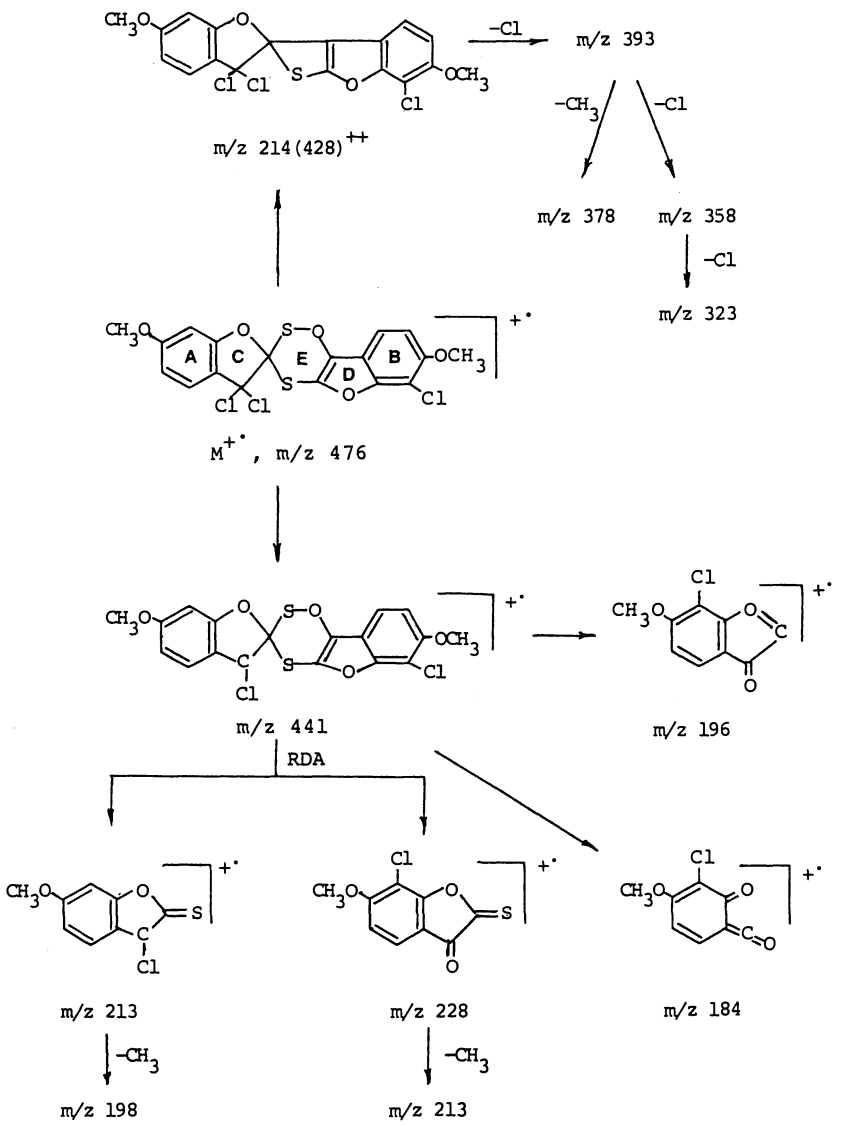


Chart 2.

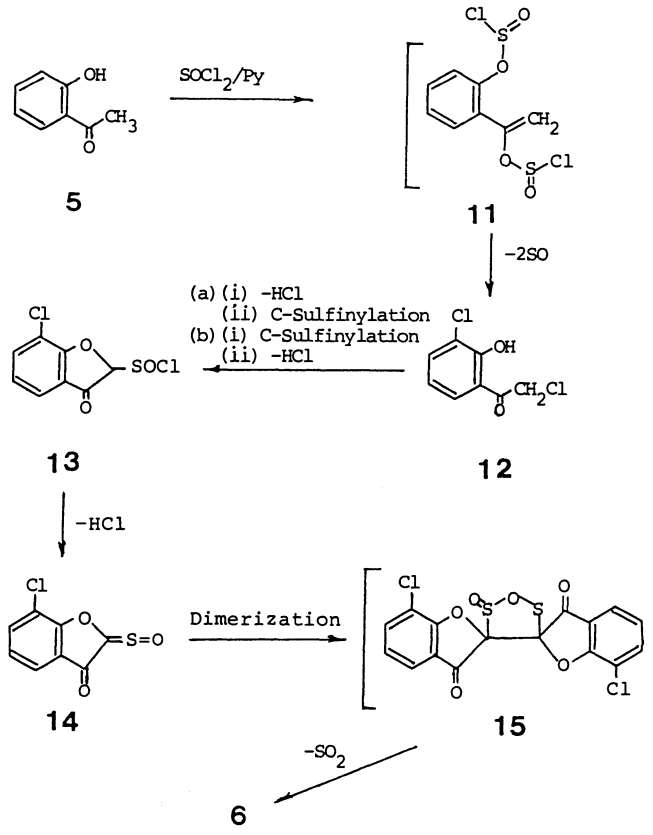
and **8** can be explained by a combination of these processes.

There are some reports on the formation of thiirane from active methylene compounds by the reaction with $SOCl_2$.[8] A plausible mechanism for the formation of **6** from **5** can be outlined as in Scheme 1, in analogy to the precedent examples. *O*-Sulfinylation of both the hydroxyl as well as carbonyl functions of **5** can lead to **11** which can yield **12** by Cl migration accompanied by the loss of sulfur monoxide. Compound **13** can be obtained from **12** either by route (a) or (b). The loss of HCl from **13** followed by dimerization accompanied by the loss of SO_2 may furnish thiirane **6**.[8] It is important to mention here that the chlorination of phenol with $SOCl_2$ has never been observed and there is only one recent report which describes the chlorination of an aromatic compound with $SOCl_2$.[9]

The mechanism for the formation of **8** is not very clear, however, a probable mechanism can be outlined as in Scheme 2. α-Chlorosulfenyl chlorides **17** and **20** can be obtained from sulfinyl chlorides **16** and **19**, respectively, by the Pummerer rearrangement.[10] α-Oxo thiocarboxylic esters **18** and **21** can be obtained from **17** and **20**, respectively, by the loss of two molecules of HCl. [4+2]Cyclodimerization of **18** and **22** can lead to **8**. Though the probability of conversion of $\rangle C{=}O$ to $\rangle CCl_2$ after the dimerization also exists, we think that in such a case [4+4] addition would have been more preferable. It is not clear why the other mode of cyclization which could give compound **10** was not preferred. Though the mechanism proposed is purely speculative, it is most appropriate in the light of available data. It is clear that the two substrates show different behavior towards the reagent and since there are many factors such as nature of the substrate, amount and



Scheme 1.

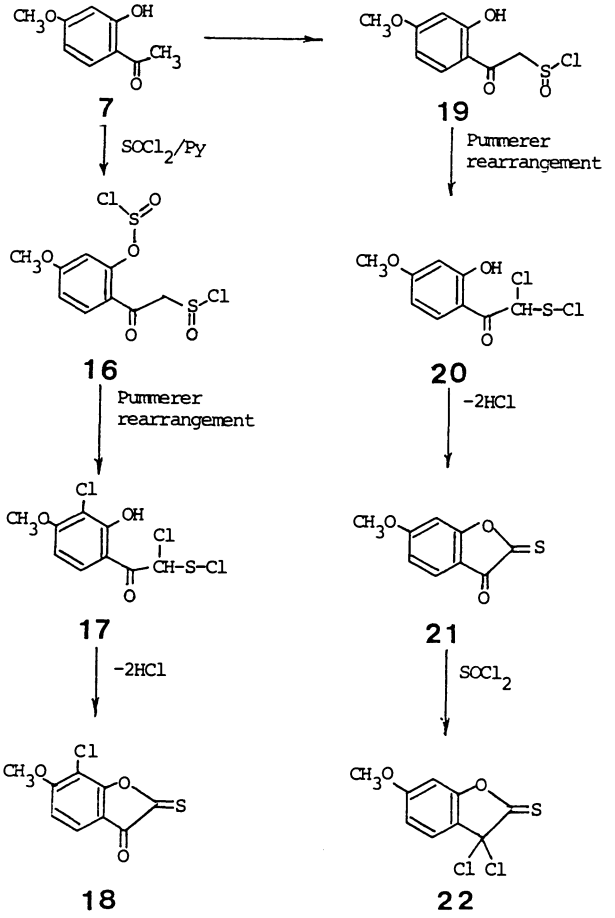
concentration of the reagent used, the order of addition, solvent and temperature, which affect the course of the reaction, it is difficult to explain the difference in their behavior at this stage.

In conclusion, the present manuscript describes the reaction of two 2-hydroxyacetophenones **5** and **6** with excess $SOCl_2$ in the presence of a catalytic amount of pyridine to furnish **6** and **8**, respectively. Though the yields are not high, the accomplishment of these complicated spiro skeleton in a single step from readily available starting materials is quite significant. The plausible mechanisms and their fragmentation patterns have been discussed. Nuclear chlorination with $SOCl_2$ of the aromatic systems has been observed which has only one precedence.

Experimental

All melting points were recorded on a Kofler microscopical hot stage and are uncorrected. Infrared spectra were obtained on a Pye Unicam SP3-100 spectrophotometer. Ultraviolet spectra measured on a Pye Unicam PU 8800 instrument. NMR spectra were recorded on a 60 MHz Varian A60D instrument using TMS as internal standard. Mass spectra were recorded with a JEOL JMS-D300 spectrometer at 70 eV.

Reaction of 2-Hydroxyacetophenone (5) with Thionyl Chloride in the Presence of a Catalytic Amount of Pyridine. 2-Hydroxyacetophenone (4.0 g, 29.4 mmol) was



Scheme 2.

dissolved in thionyl chloride (52.5 g, 44.0 mmol) and a catalytic amount of pyridine (0.46 g, 0.58 mmol) was added. The contents were stirred at room temperature for 3 h. Excess $SOCl_2$ was removed at room temperature under reduced pressure to give a red gummy mass which was subjected to column chromatography over silica gel. Elution with petroleum ether–benzene (1:1) afforded a light pink solid, crystallized from $CHCl_3$–MeOH mixture to furnish white crystals of thiirane **6** (1.45 g, 27%), mp 160—162 °C; IR (KBr): ν_{max} 2940, 1725, 1610, 1590, 1470, 1450, 1320, 1295, 1215, 1190, 1140, 1100, 1060, 1000, 860, 830, 750, 730, 690, 640 cm^{-1}; UV (MeOH): λ_{max} 240, 290 nm; ^1H NMR ($CDCl_3$): δ=7.00—8.00 (m, Ar-H); MS (rel. int.): *m/z* 336 (4.01), 335 (3.68), 334 (21.76), 333 (3.05), 332 (33.27), 298 (1.94), 200 (3.84), 198 (11.52), 168 (33.00), 167 (2.50), 166 (100.00), 163 (18.21), 137 (10.30), 112 (8.90), 110 (35.32), 103 (18.45), 92 (15.00), 75 (40.35). Found: C, 52.52; H, 1.51; Cl, 19.18%. Calcd for $C_{16}H_6Cl_2O_4S$: C, 52.62; H, 1.66; Cl, 19.42%.

Reaction of 2-Hydroxy-4-methoxyacetophenone (7) with Thionyl Chloride in the Presence of a Catalytic Amount of Pyridine. To a solution of 2-hydroxy-4-methoxyacetophenone (3.0 g, 18 mmol) in thionyl chloride (32.26 g, 27.0 mmol) was added a small amount of pyridine (0.03 g,

0.36 mmol). The reaction mixture was stirred at room temperature for 3 h. Excess $SOCl_2$ was then removed at room temperature under reduced pressure to get a red gummy mass which was subjected to column chromatography over silica gel. Elution with petroleum ether–benzene (4:1) afforded a white solid which was crystallized from a mixture of petroleum ether–benzene to yield white crystals of **8** (1.46 g, 34%), mp 129—130 °C; IR (KBr): ν_{max} 2960, 1610, 1585, 1526, 1490, 1440, 1420, 1345, 1325, 1260, 1230, 1180, 1130, 1100, 1030, 1020, 975, 940, 930, 850, 830, 810, 785, 740, 690, 640, 620 cm^{-1}; ^1H NMR ($CDCl_3$): δ=3.80 (6H, s, 2×OMe), 6.54 (1H, s, H-3), 6.75 (2H, m, H-5,5′), 7.44 (1H, d, J=9 Hz, H-6), 7.80 (1H, d, J=9 Hz, H-6′); MS (rel. int.): m/z 445 (4.12), 443 (8.10), 441 (11.26), 397 (3.80), 395 (7.42), 394 (2.15), 393 (11.32), 382 (2.00), 380 (4.20), 378 (6.12), 360 (4.52), 359 (3.00), 358 (13.28), 324 (7.20), 323 (20.40), 230 (8.00), 229 (10.00), 228 (24.54), 216 (8.95), 215 (42.15), 214 (23.50), 213 (100.00), 198 (12.51), 196 (16.54), 184 (2.55), 150 (14.50). The Retardation of Methanol Oxidation at a Platinum Electrode in an Acid Solution

Hiroshi MATSUI
Department of Applied Chemistry, Faculty of Engineering, The University of Tokushima, Minami-josanjima-cho, Tokushima 770
(Received March 22, 1988)

The rate retardation of the oxidation of methanol at the potential range of about 0.65—0.8 V vs. a reversible hydrogen electrode on a platinum electrode in 0.5 mol dm^{-3} H_2SO_4 was studied. The rate retardation of the overall oxidation was caused by that of the oxidation, Reaction D, not via CO_{ad}. From the relationship among the rate of Reaction D, the CO_{ad} coverage, and the potentials, three types of rate retardation were found out: Type 1— Reaction D is not accelerated by the potential, and the rate of the reaction is determined by the CO_{ad} coverage and the methanol concentration. Type 2— the rate of Reaction D decreases at stationary CO_{ad} coverages as the oxidation is prolonged. Type 3— the rate decreases at CO_{ad} coverages close to the limiting value. It is proposed that Types 1 and 2 of the rate retardations take place when the adsorption of methanol molecules is rate-determining, and when the formaldehyde and formic acid formed from methanol are accumulated in the vicinity of the electrode, respectively. Type 3 of the rate retardation has been explained in a preceding paper in terms of the aggregate damaging effect of CO_{ad}.

It has been known[1-3] that a plot of log i vs. E gives a straight line for the oxidation of methanol at a platinum electrode in an acid solution in the potential range lower than about 0.6—0.7 V, but the downward deviation from the straight line takes place at higher potentials than about 0.65 V. Such a deviation for the rate of the methanol oxidation has been interpreted in terms of the formation of stably chemisorbed species (SCS),[2,4,5] the formation of platinum surface oxide,[6] and the accumulation of adsorbed impurities from a solution.[7,8] Furthermore, the rate deviation has been reported[1,9] to occur when the dissociative adsorption of methanol is rate determining. This information was based on the assumption that methanol was always oxidized to CO_2 via SCS. However, recent investigations[2,4,5] have revealed that methanol is oxidized via at least two parallel reactions; one via SCS (Reaction B), and the other not via SCS (Reaction D).

Two types of SCS are generally proposed: COH_{ad},[10,11] and CO_{ad}.[12,13] For example, mass spectroscopic measurements[10,11] gave results suggesting COH to be adsorbable. On the other hand, in situ IR spectroscopic investigations[12] gave strong evidence for the existence of CO_{ad}. Furthermore, our results[13] obtained by means of the electrochemical methods confirmed that SCS is CO_{ad}. In the present paper, therefore, the downward deviation of methanol oxidation is discussed by assuming CO_{ad} as SCS. Of course, the conclusions derived by the present investigation are not altered even when another chemical kind of SCS instead of CO_{ad} is assumed.

The present investigation was undertaken in order to determine the origin of such a downward deviation, i.e., the rate retardation in the electrooxidation of methanol to carbon dioxide at platinum in a 0.5 mol dm^{-3} H_2SO_4 solution in the potential range of 0.65—0.8 V vs. RHE. The upper limit of 0.80 V was taken in order to eliminate the rate retardation of methanol oxidation due to the formation of platinum oxide.

Experimental

The coverage θ, with CO_{ad} is expressed as:

$$\theta = (Q_H^0 - Q_H)/Q_H^0 \quad (1)$$

where Q_H^0 and Q_H are the charge required to cover fully the electrode surface with adsorbed hydrogen atoms in the absence and in the presence of CO_{ad} respectively. These charges were determined by the conventional hydrogen deposition method.

The rate of Reaction D was determined by the following procedure. As has been reported in a previous paper,[5] the overall rate, i_T, of the methanol oxidation can be expressed by:

$$\begin{aligned} i_T &= i_A + i_B + i_D \\ &= 2\,dQ^{ox}/dt + 3i_B + i_D \end{aligned} \quad (2)$$

where i_A and i_B are the rates of the formation and the further oxidation of CO_{ad} respectively. i_D is the rate of the methanol oxidation not via CO_{ad}, and Q^{ox} is the charge required to oxidize CO_{ad} to CO_2. When the methanol concentration is smaller than about 0.5 mol dm^{-3}, $i_B \ll i_T$ at potentials below about 0.8 V, as has been described in the previous work[5]. Consequently,

$$i_D \fallingdotseq i_T - 2\,dQ^{ox}/dt \quad (3)$$

Here, Q^{ox} can be approximated by $Q_H^0\,\theta$ (see Fig. 8 in Ref. 15). Thus,

$$i_D \fallingdotseq i_T - 2\,Q_H^0\,d\theta/dt \quad (4)$$

In the present investigation, i_D was determined under both potentiostatic and potentiodynamic conditions.

(A) Potentiostatic Conditions: The current and θ at a constant potential were measured by using the potential sequence of (a) in Fig. 1. i_T at the potential is equal to the observed current for the methanol oxidation, while $d\theta/dt$ was determined from the time-variation in θ. Then, i_D was

calculated according to Eq. 4.

(B) Potentiodynamic Conditions: The i-E curves and θ values were obtained by using the potential sequence of (b) in Fig. 1. The potential was scanned after the preadsorbed CO species had been removed at Step C of the pretreatment in Fig. 1. Curves 1 and 3 in Fig. 2 show examples of i-E curves in the presence and the absence of methanol

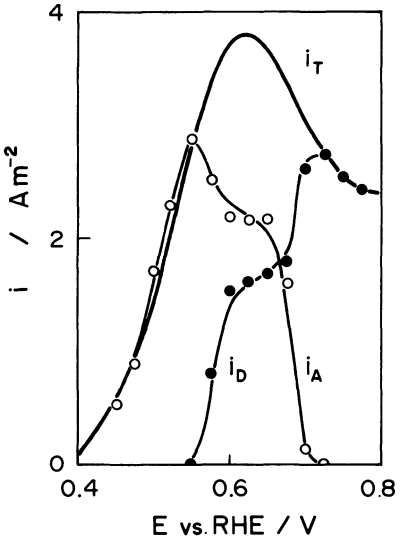

Fig. 3. Variation in i_A, i_D, and i_T with potential, 0.1 mol dm^{-3} CH_3OH+0.5 mol dm^{-3} H_2SO_4, scan rate 1 V s^{-1}. These values were obtained on the basis of Fig. 2.

respectively, when the scan rate is 1 V s^{-1} and the methanol concentration is 0.1 mol dm^{-3}. The values of i_T were determined from the differences in the current between Curves 1 and 3. Curve 2 in Fig. 2 is the θ-E curve obtained under the same experimental conditions as Curve 1. $d\theta/dt$ during the anodic scan is proportional to $d\theta/dE$, because the scan rate, s, is constant:

$$d\theta/dt = s\, d\theta/dE \quad (5)$$

Thus, $d\theta/dt$ was determinable from the slope of the θ-E curve, and then i_D was calculated from Eqs. 4 and 5. Figure 3 shows the potential dependence of the i_D value thus obtained. The i_D was approximately equal to i_T in the potential range of about 0.7—0.8 V, while $i_T \fallingdotseq i_A$ at potentials below about 0.55 V. Therefore, the order of Reaction D with respect to the methanol concentration was determined from the relationship between i_T at 0.7 V and the concentration.

The effects of the presence of formaldehyde and formic acid on the i-E curve and θ were also examined by using the potential sequence of (b) in Fig. 1. The other experimental conditions and procedures were almost the same as those used in the previous studies.[5,14] All the reaction rates and the charges were measured at 0 °C. The potentials were referred to a reversible hydrogen electrode (RHE) in 0.5 mol dm^{-3} H_2SO_4.

Results and Discussion

Figure 4 shows the relationship between the potential and i_D in the prolonged oxidation of methanol under potentiostatic conditions. Since the methanol oxidation, Reaction D, not via CO_{ad} does not occur at the electrode surface occupied by CO_{ad}, the rate of Reaction D was expressed by the current per the surface not occupied by CO_{ad}, $i_D/(1-\theta)$. As may be seen from Fig. 4, there is a linear relationship between

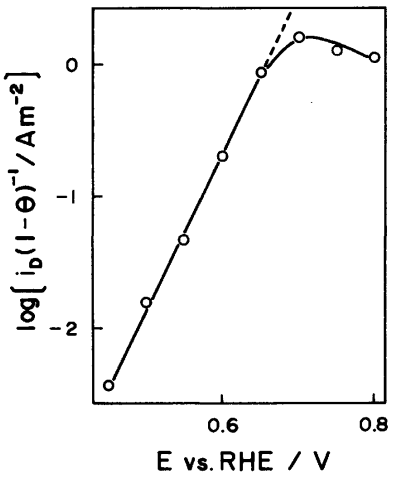

Fig. 4. Variation in stationary i_D with potential, oxidation time at a constant potential 300 s, 0.1 mol dm^{-3} CH_3OH+0.5 mol dm^{-3} H_2SO_4.

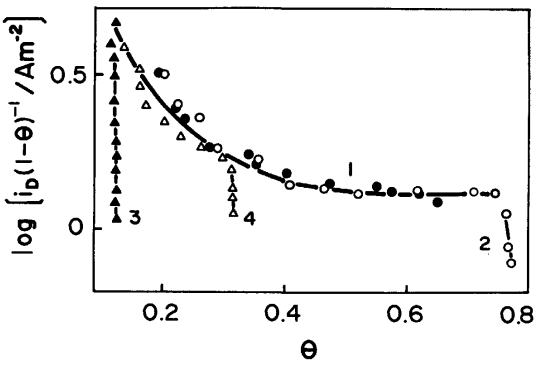

Fig. 5. Variation in $i_D/(1-\theta)$ with CO_{ad} coverage, 0.1 mol dm^{-3} CH_3OH+0.5 mol dm^{-3} H_2SO_4. Potential (V): ○ 0.65; ● 0.70; △ 0.75; ▲ 0.80. All of part of the rates at every potential belong to curve 1.

the potential and the logarithm of $i_D/(1-\theta)$ in the potential range of 0.45—0.65 V. The rate of Reaction D at the higher potentials, however, deviates downward from the straight line. In order to clarify the causes of this rate deviation, the relationship between $i_D/(1-\theta)$ and θ during the controlled potential oxidation of methanol at different potentials was examined. The results are presented in Fig. 5.

Figure 5 indicates three types of rate retardation: Type 1; $i_D/(1-\theta)$ directly deviates from the Tafel straight line without any other rate retardations at potentials above about 0.7 V. The resulting $i_D/(1-\theta)$ is at constant surface coverages, independent of the potential, as Curve 1 in Fig. 5 shows. Type 2: at potentials above about 0.75 V, the CO_{ad} coverage soon becomes stationary, although with small values, and then $i_D/(1-\theta)$ falls, as in indicated by Curves 3 and 4. Type 3: at a coverage close to about 0.8, $i_D/(1-\theta)$ begins to fall abruptly, as Curve 2 shows.

The rate retardation of Type 3 has already been presented in the preceding paper[15] as being due to the aggregate demaging effect on reaction sites indispensable for the methanol oxidation. The causes of the rate retardations of Types 1 and 2 will be discussed below.

Rate Retardation of Type 1. As Curve 1 in Fig. 5 shows, the rate retardation of Type 1 occurs at the same CO_{ad} coverage, although CO_{ad} has a retarding effect on Reaction D. Hence, the rate retardation of Type 1 is explicitly caused by some factor other than the formation of CO_{ad}.

Breiter et al.[7,8] reported that the rate of the oxidation of methanol at platinum electrodes could be retarded by the presence of not only CO_{ad}, but also easily desorbable surface substances, such as chloride anions. Although such desorbable adsorbates can not be detected by the conventional hydrogen-deposition method, the adsorbates are detectable by an anodic stripping method in which the potential scan is very rapid. In this method,[9] the hardly and easily oxidizable adsorbates are detected by the hindrance of the formation of the platinum oxide and the appearance of a new oxidation wave in the potentiodynamic *i-E* curve. In the present investigation, a potential scan of 718 V s^{-1} was applied to the electrode immediately after the methanol oxidation at 0.8 V in 0.01 mol dm^{-3} CH_3OH+0.5 mol dm^{-3} H_2SO_4. The wave of the dotted line 3 around 1.5 V is due to the formation of the platinum oxide, while the wave of the solid line 1 around 1.8 V is due to both the formation of the surface oxide and the oxidation of the CO_{ad} which was formed during the previous oxidation at a constant potential. The presence of methanol had little effect on the formation of the oxide; also, no appreciable wave for the oxidation of new adsorbates was detected. Hence, both hardly and easily oxidizable surface substances, even if these substances are easily desorbable, can be eliminated as possible causes of the rate retardation of Type 1. The remaining cause of the rate retardation is a change in the reaction mechanism.

In Fig. 5, $i_D/(1-\theta)$ goes down on Curves 2—4 as the oxidation time passed. Consequently, the extent of the rate retardations of Types 2 and 3 were slight at a short oxidation time. Hence, provided that the oxidation time is short, the reaction order with respect to the methanol concentration can be examined without any effect of rate retardations of Types 2 and 3. These experimental conditions were approximately satisfied by oxidizing methanol at a potential scan of a few V s^{-1} after the removal of CO_{ad}. That is, the oxidation time was short at this scan rate, and the retardation of Type 1 occurred at potentials of about 0.7—0.8 V, as is indicated by Fig. 3. Figure 7 shows the dependence of $i_D/(1-\theta)$ at 0.7 V on the methanol concentration obtained when the scan rate is 3 V s^{-1}. As may be seen from this figure, there was a

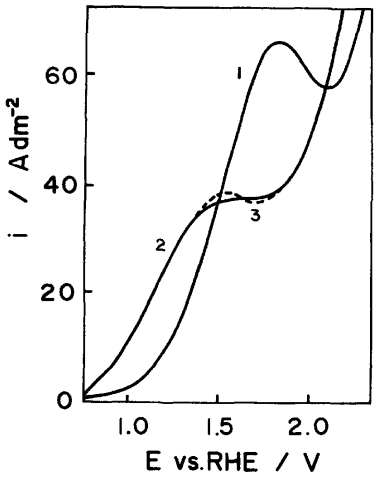

Fig. 6. i-E curves at rapid potential scan after 100 second oxidation of methanol at a constant potential, scan rate 718 V s^{-1}, 0.01 mol dm^{-3} CH_3OH +0.5 mol dm^{-3} H_2SO_4, smooth platinum. Potential (V): (1) 0.6; (2) 0.8; (3) in the absence of CH_3OH.

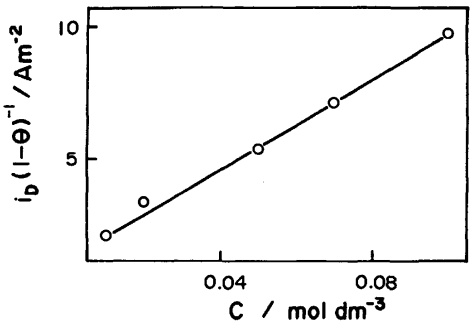

Fig. 7. Variation in i_D with methanol concentration, C. The rates were taken from potentiodynamic (3 V s^{-1}) i-E curves.

linear relationship between $i_D/(1-\theta)$ and the methanol concentration; i.e., the reaction order with respect to the methanol concentration was first.

An $i_D/(1-\theta)$ value independent of the potential and the first reaction order with respect to the methanol concentration would result, when one of the following nonelectrochemical processes of methanol molecules becomes rate-determining: (1) the diffusion to an electrode, (2) the adsorption on an electrode, and (3) a chemical reaction at the electrode surface, e.g., the dehydrogenation of methanol molecules. The maximum value of the observed rate of the methanol oxidation was smaller by a few orders of magnitude than the limiting diffusion rate previously estimated.[16] For example, the maximum value of i_D in Fig. 4 is less than about one hundredth of the estimate. Consequently, Process 1 can be rejected as a possible rate-determining step. Process 3 can also be ruled out as the rate-determining step, because no product of the surface reaction involved in Reaction D could be detected at the open circuit. Furthermore, the

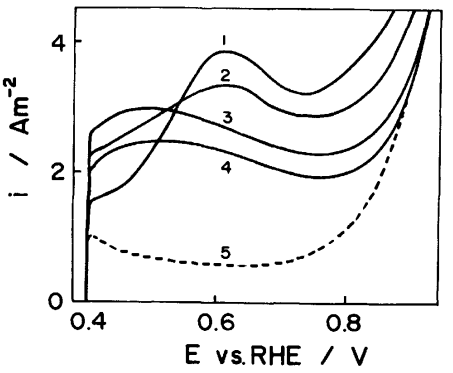

Fig. 8. Potentiodynamic i-E curves immediately after preoxidation at 0.8 V, 0.1 mol dm^{-3} CH_3OH +0.5 mol dm^{-3} H_2SO_4, scan rate 1 V s^{-1}. Preoxidation times (s): (1) 0; (2) 1; (3) 10; (4) 100; (5) in the absence of CH_3OH.

Table 1. Current Efficiencies for the Formation of Formaldehyde and Formic Acid in CH_3OH+ 0.5 mol dm^{-3} H_2SO_4; Oxidation Time, (300 s)

0.7	0.1	13	6
0.8	1.0	35	15
0.8	0.1	14	7

adsorption of methanol molecules has been proposed[2,4,17] as an elementary process in the electrooxidation. From these facts, it was concluded that the rate retardation of Type 1 is caused when the adsorption of methanol molecules is rate-determining.

Rate Retardation of Type 2. In order to clarify the cause of the rate retardation of Type 2, the effect of the preoxidation on i_D was examined by means of the potential scan of 1 V s^{-1}. Figure 8 shows the potentiodynamic i-E curves for the oxidation of methanol when a prolonged oxidation at 0.8 V is undertaken prior to the potential scan. By the preoxidation, i_T at 0.7—0.8 V, i.e., i_D decreased, and a new wave appeared at about 0.4—0.5 V. This finding suggests that some products retarding Reaction D are formed from methanol and are accumulated in the vicinity of the electrode.

Formaldehyde and formic acid are known[4,16] to be formed in the anodic oxidation of methanol. Under the present experimental conditions also, their formation was confirmed, as Table 1 shows. The effect of the presence of these substances on i_D was examined in mixed systems of methanol-formaldehyde and methanol-formic acid. As Table 1 shows, the current efficiencies for the production of these

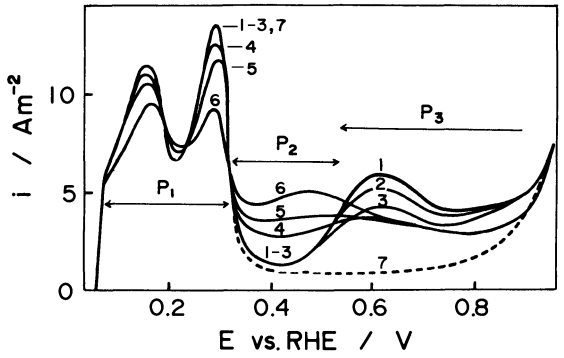

Fig. 9. Potentiodynamic i–E curves in the presence of formaldehyde added to solution, HCHO +0.1 mol dm^{-3} CH_3OH+0.5 mol dm^{-3} H_2SO_4, scan rate 1 V s^{-1}. HCHO (mol dm^{-3}): (1) 0; (2) 0.001; (3) 0.002; (4) 0.01; (5) 0.02; (6) 0.05; (7) in the absence of HCHO and CH_3OH.

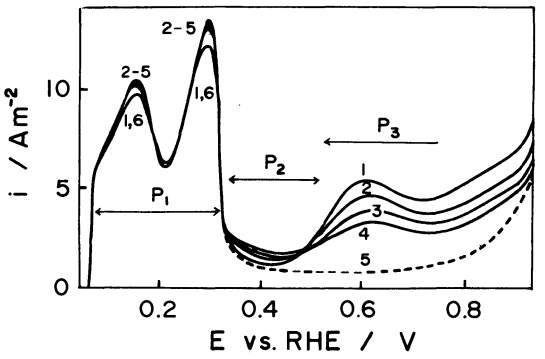

Fig. 10. Potentiodynamic i–E curves in the presence of formic acid added to solution, HCOOH +0.1 mol dm^{-3} CH_3OH+0.5 mol dm^{-3} H_2SO_4, scan 1 V s^{-1}. HCOOH (mol dm^{-3}): (1) 0; (2) 0.0005; (3) 0.002; (4) 0.005; (5) in the absence of HCOOH and CH_3OH.

substances are small at low methanol concentrations. Therefore, in order to reduce the accumulation of formaldehyde and formic acid from methanol, the methanol concentration of 0.1 mol dm^{-3} was used to examine the effect of the addition of formaldehyde and formic acid.

Figures 9 and 10 shows the potentiodynamic i–E curves in mixed systems of methanol–formaldehyde and methanol–formic acid. As these curves indicate, methanol was oxidized at potentials above about 0.45 V, while formaldehyde and formic acid were oxidized at potentials above 0.35 V, at the scan rate of 1 V s^{-1}. Consequently, the new wave observed around 0.4 V in Fig. 8 is ascribed to the oxidation of the formaldehyde and formic acid which are formed during the oxidation of methanol at 0.8 V. It is particularly interesting that, in the mixed system, the overall rate in the potential range of about 0.5—0.8 V decreased as the concentration of formaldehyde and formic acid increased up to about 0.02 mol dm^{-3}. As

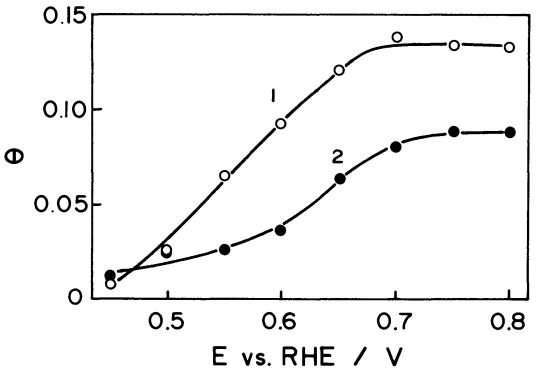

Fig. 11. Potentiodynamic θ–E curves for oxidation of methanol in (2) 0.02 mol dm^{-3} HCOOH +0.1 mol dm^{-3} CH_3OH; (1) in the absence of HCOOH, scan rate 1 V s^{-1}.

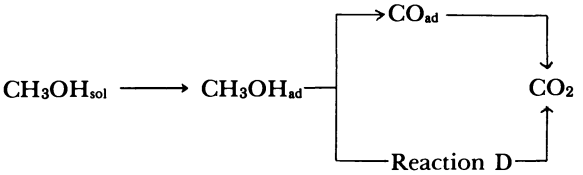
has been described in the Experimental section, the i_T values in the potential range of 0.7—0.8 V are approximately equal to i_D. Therefore, it seems certain that Reaction D is retarded by the formation of formaldehyde and formic acid. The effects of these substances are most remarkable in the concentrations of 0.02—0.03 mol dm^{-3}. At higher concentrations, the overall rate increased with an increase in the concentration. Since the oxidation of formaldehyde and formic acid was enhanced at high concentrations, the increase in the overall rate at the higher concentrations is probably due to the oxidation of these substances.

As has been described above, the adsorption of methanol molecules precedes both the CO_{ad} formation and Reaction D, and the accumulation of adsorbed molecules is very slight:



Consequently, the rate of the adsorption of methanol molecules, r_{ad} is the sum of the rates of the CO_{ad} formation and Reaction D, when each rate is expressed in mol s^{-1} m^{-2}:

$$r_{ad} = i_A/4F + i_D/6F \quad (6)$$

where i_A can be expressed in terms of $d\theta/dt$ by the same method as in the Experimental section:

$$i_A \fallingdotseq 2s Q_H{}^0 d\theta/dE \quad (7)$$

Figure 11 shows the relationship between the CO_{ad} coverage and the potential in the presence and in the absence of formic acid under potentiodynamic conditions. In the potential range of about 0.7—0.8 V, the slope of the θ–E curve, i.e., $d\theta/dE$ was little

influenced by the presence of formic acid, and i_D decreased, as may be seen from Fig. 9. Consequently, i_D and also r_{ad} are decreased by the presence of formic acid. A smilar decrease in r_{ad} was observed also in the case of formaldehyde, so long as the formaldehyde concentration was lower than about 0.05 mol dm^{-3}. At higher concentrations, however, the CO_{ad} formation from formaldehyde was remarkable at the pretreatment step D in Fig. 1b; therefore the effect of the presence of formaldehyde on i_D could not be examined.

To sum up, the rate retardation of Type 2 was related to the retardation of the adsorption of methanol molecules. The retardation occurred when small amounts of formaldehyde and formic acid were added to a solution of methanol, or when these substances were formed at the electrode by the preoxidation of methanol, although the adsorption of these substances was not confirmed by either the method of hydrogen deposition and by that of anodic stripping. From these results, it was concluded that the rate retardation of Type 2 was due to the accumulation of formaldehyde and formic acid in the vicinity of the electrode without adsorption.

16) The limiting current density, i_L, for the linear diffusion was determined by means of the following equation:

$$i_L = nFDC/\delta$$

where each of the symbols represents its ordinary meaning. When n, D, C, and δ are 6, 1×10^{-9} m^2 s^{-1}, 0.1 mol dm^{-3}, and 5×10^{-4} m respectively, one obtains $i_L=1\times10^2$ A·m^{-2}. With a platinized platinum electrode, the limiting diffusion current per unit of apparent surface area would be equal to or a little larger than, this value* because of the roughened surface, though it appears that any exact estimation would be very complicated.

Apparent Molal Volumes of Urea Derivatives in Water-Methanol Mixtures

Kiyoshi MIZUTANI and Motoo YASUDA*
Department of Chemistry, College of General Education, Nagoya University,
Chikusa-ku, Nagoya 464-01
(Received April 1, 1988)

Apparent molal volumes (ϕ_v) at 25 °C have been obtained for the following urea derivatives in water–methanol mixtures from measurements of the density using an Anton Paar digital densimeter: urea (U), methylurea (MU), ethylurea (EU), 1,1-dimethylurea (1,1-DMU), 1,3-dimethylurea (1,3-DMU), 1,1-diethylurea (1,1-DEU), and 1,3-diethylurea (1,3-DEU). The limiting values ϕ_v° were calculated by linear extrapolation using the least-squares method. A plot of ϕ_v° vs. X_2, the mole fraction of methanol, showed a minimum for each alkylurea studied at low methanol concentrations ($X_2 \simeq 0.1$), but none for unsubstituted urea: the more alkyl-substituted the urea was, the sharper the minimum. Inspection of the data shows that the assumption of independent solvation on both sides of the urea molecules also holds to a good approximation to the apparent molal volumes both in the pure solvents and in the mixtures.

It has long been known that alcohol–water mixtures often show abnormalities in their properties, such as the viscosity-composition and the ultrasonic velocity-composition maximum. Although they are not fully understood, such peculiarities are considered to be structural in origin. Thus, Franks and Ives postulated an enhancement of the structure of water by interactions between alkyl groups and water in the water-rich region; they therefore surveyed the properties of these systems with special reference to their structural implications.[1] Aqueous urea also has long been the subject of study, in particular the effect of urea on the water structure, and many biophysicochemical studies have been carried out on aqueous urea. The theoretical treatment of the mixture has been performed by Frank and Franks, who pictured dissolved urea as acting like a statistical water-structure breaker.[2] It is generally accepted that urea does not appreciably interact with either hydrophobic or hydrophilic molecules or groups, and so several thermodynamic and transport properties of aqueous urea solutions with added electrolytes or nonelectrolytes have been interpreted in terms of the nonspecific interaction of urea with the solute, as has been noted by Mathieson and Conway.[3] We feel that, in order to understand the effect of urea on the structure of water, it would now be useful to carry out the systematic study of urea solutions over the whole mole-fraction range of alcohol and water. Since the infinite-dilution apparent molal volumes are independent of solute–solute interactions, being determined only by the respective intrinsic value and solute–solvent interactions, they can be used to examine the solute–solvent interactions.

In the present work, densities were measured at 25 °C for the urea(or alkylurea)–methanol–water ternary system at various concentrations. The apparent molal volumes and their limiting values were obtained from these data.

Experimental

The density of the methanol, which was a guaranteed reagent from Wako Chemical Industries, Ltd., was 0.78663 g cm^{-3} at 25 °C; the reported densities are 0.78665[4] and 0.78660.[5] As will be seen later, the infinite apparent molal volume of urea in this solvent was 36.98 cm^3 mol^{-1}, which was in excellent agreement with the value (36.97) reported by Hamilton and Stokes.[5] The methanol, therefore, was used without further purification as a solvent or cosolvent. The urea (Wako Chemical Industries, Ltd.) and 1,1-dimethylurea (Sigma Chemical Company) were used as received. The methylurea (Wako Chemical), and the 1,1-diethylurea and 1,3-diethylurea, which have both been obtained from the Aldrich Chemical Company, Inc., were recrystallized from ethanol. The ethylurea and 1,3-dimethylurea, which were both from the Tokyo Kasei Kogyo Co., Ltd., were recrystallized from an ethanol–ethyl ether mixture.

Ternary systems are very complicated, and special interest is usually taken in their properties in the water-rich region. Thus, the densities of the urea solutions were measured at 25 °C in 0, 0.1, 0.2, 0.3, 0.4, 0.6, 0.8, and 1.0 by the use of mole-fraction methanol X_2 in water. All the solutions were prepared by weight in the concentration range of 0.2—0.9 mol kg^{-1} (the number of moles of urea per kg of the mixed solvent whenever the mixed solvent was used). The mixed solvent was prepared for each series of measurements, and its density was determined respectively. The densities were measured to $\pm 2 \times 10^{-6}$ g cm^{-3} with an Anton Paar DMA 02D Densimeter as before.[6] The temperature control of the thermostated bath system regulating the densimeter was better than ±0.005 °C.

Results

The apparent molal volumes were obtained using Eq. 1:

$$\phi_v = \frac{M}{d} + \frac{1000(d_o - d)}{m d_o d} \quad (1)$$

where M is the molecular weight of the urea; m, its molal concentration, and d_o and d, the densities of the solvent and the solution respectively. The apparent

molal volumes of a nonelectrolyte such as urea are usually expressed as in Eq. 2 below ca. 1 mol kg^{-1}:

$$\phi_v = \phi_v^\circ + S_v m \quad (2)$$

where ϕ_v° is the infinite-dilution apparent molal volume and where S_v is the experimental slope. At an infinite dilution, ϕ_v° is equal to $\overline{V}^\circ$ (the infinite-dilution partial molal volume). The ϕ_v° values were calculated by a linear extrapolation using the least-squares fit to Eq. 2. The derived values for ϕ_v° are summarized in Table 1. The standard deviations are less than 0.03 cm^3 mol^{-1}. Those for amino-acid–alkali-chloride–water ternary systems previously reported by the present authors were mostly less than 0.02 cm^3 mol^{-1};[6] the volatility of methanol probably makes the standard deviations a little larger in the present work. The ϕ_v° values in water for U, 1,1-DMU, and 1,3-DMU are reported by Philip et al. as 44.24, 78.88, and 80.04 cm^3 mol^{-1} respectively.[7] Our value for U is in excellent agreement, and for 1,1-DMU and 1,3-DMU our values are in good agreement, with the literature values. For the other alkylureas no accurate ϕ_v° values have yet been reported, although Herskovits and Kelly evaluated the partial specific volumes for the ureas using the density data;[8] their densities, however, were measured with 10-cm^3 pycnometers in order to obtain viscosity coefficients for the ureas and so can not be compared with our data. As has been mentioned earlier, the ϕ_v° value of urea in methanol was reported to be 36.97 cm^3 mol^{-1} by Hamilton and Stokes,[5] a value in excellent agreement with ours. As for the others, however, no comparable data have been reported.

Discussion

Apparent Molal Volume of Urea. First of all let us consider the results for the unsubstituted urea. The thermodynamic properties of aqueous urea solutions, including the volume, were intensively discussed by Stokes,[9] who reported apparent molal volumes of urea at 0, 40, and 50 °C to supplement the existing volume data. He showed that ϕ_v° is strongly temperature-dependent; 41.75 cm^3 mol^{-1} at 0 °C, 44.20 at 25, 44.55 at 30, 45.10 at 40, and 45.60 at 50. The estimated thermal expansion coefficient α of the limiting apparent molal volumes, defined by:

$$\alpha(\phi_v^\circ) = \mathrm{d} \ln \phi_v^\circ / \mathrm{d}T$$

is abnormally large at low temperatures, but decreases as the temperature is raised. The ϕ_v° values measured by Hamilton and Stokes[5] in various organic solvents, such as methanol, ethanol, and formamide, show a large variation in different solvents, though the temperature dependence of the limiting apparent molal volumes in nonaqueous solvents is slight, in marked contrast to the situation in water. Of the several properties of the solvents they examined, the compressibility of the solvent has the only clear correlation with the ϕ_v° values of urea; the ϕ_v° value increases as the compressibility of the solvent decreases. Regarding the compressibility as a measure of the void space in the liquid, they argued that the solute molecule does not have to create a hole for itself of the full dimensions demanded by its intrinsic size. Thus, methanol, with the largest compressibility of the solvents studied by them at 25 °C, gave the smallest ϕ_v° value of urea, 36.97 cm^3 mol^{-1}. As has been mentioned earlier, water–alcohol systems are well-known to enhance the structure of water considerably when alcohol is added to water in low mole fractions; as a result, the water–alcohol systems show often abnormalities in their properties. The isentropic compressibilities of water–methanol mixtures studied separately by Kiyohara and Benson[10] and by Lara and Desnoyers[11] show a minimum around X_2=0.13—0.14 at 25 °C. As is shown in Fig. 1, in which the volumes of the transfer of urea from water to the mixtures are plotted against X_2, U shows a volume maximum in the water-rich region. Though the maximum of the volume does not agree with that of its adiabatic compressibility, there is an indication that urea has a larger volume in the less compressibility solvents, as has been noted by Hamilton and Stokes.

Table 1. Limiting Apparent Molal Volumes ϕ_v° in Water-Methanol Mixtures

X_2	ϕ_v°/cm^3 mol^{-1}						
	U	MU	EU	1,1-DMU	1,3-DMU	1,1-DEU	1,3-DEU
0.0	44.24	62.40	79.26	78.53	80.32	111.63	113.74
0.1	44.34	61.64	77.86	77.11	78.53	109.33	110.86
0.2	44.89	62.18	78.84	77.77	79.18	110.48	112.34
0.3	45.16	62.45	79.64	78.06	79.73	111.80	114.20
0.4	44.65	62.51	80.26	78.10	80.02	112.42	115.47

ϕ_v° in Water. The ϕ_v° values of the six alkylsubstituted ureas studied here are listed in Table 1. The contribution of a methyl or ethyl group to the apparent molal volume can be thought of as the intrinsic volume of the group plus volume terms originating from interactions between the solute and solvent molecules. Thus, when a hydrogen atom bonded to a nitrogen of a urea molecule is replaced by a methyl group, which is hydrophobic in nature, the ϕ_v° values of the urea molecules are influenced by the following: (1) a contribution from the methyl group itself (intrinsic and hydrophobic), (2) a hindrance of the hydrogen-bonding ability of the substituted amino group, and (3) finally a decrease in the hydrogen-bonding ability of the carbonyl group.[7] By comparing the ϕ_v° values of two pairs of isomers, 1,1-DMU and 1,3-DMU, and 1,1-DEU and 1,3-DEU, the 1,3-isomers are seen to have definitely larger volumes than the corresponding 1,1-isomer, as Table 1 shows. In accounting for this difference the second effect mentioned above may be most important. The 1,1-isomer has one unsubstituted amino group, and so it has more hydrogen-bonding ability than the corresponding 1,3-isomer; that is, the former exhibits a greater volume decrease due to hydrogen-bonding. Next, half of the sum of the ϕ_v° values of U and 1,3-isomer is roughly equal to the value of the corresponding mono-substituted urea: (44.24+80.32)/2=62.28 and 62.40 for methylderivatives, (44.24+113.74)/2=78.99 and 79.26 for ethyl derivatives. This fact supports the assumption of independent solvation on both sides of the urea molecules, as reported by Rouw and Somsen from their measurements of the enthalpies of solutions.[12] From the additivity of the group contributions to the partial molar volumes for various kinds of organic analogues, such as carboxylic acids, alkylamines, amino acids, ketones, and alcohols, the group volume increment of CH_2 was calculated as 16.0±0.2 cm^3 mol^{-1} by Shahidi[13] except for cyclic compounds, for which the group volume increment is ca. 2 cm^3 mol^{-1} smaller than for acyclic compounds.[14] Thus, for open-chain compounds, a volume increment of 16 cm^3 mol^{-1} is usually brought about by the replacement of a hydrogen atom by a methyl group. As may be seen from Table 1, the volume difference between urea and methylurea in water is 18.16 cm^3 mol^{-1}, much larger than 16. In the case of alkylamines, this large volume increment may be due to the hindrance of hydrogen-bonding formation of the substituted amino group, as well as to the contribution from the methyl group itself, mentioned above: this brings about a smaller volume decrement. In this connection, it is very interesting to note the volume-change relationships of alkylamine compounds. The partial molal volumes at an infinite dilution reported by Verrall and Conway for the compounds are as follows:[15] CH_3NH_2 40.0, $(CH_3)_2NH$ 58.6, $(CH_3)_3N$ 77.9, and $(C_2H_5)_3N$ 119.7 cm^3 mol^{-1}. A value of 18.6 cm^3 mol^{-1}, much larger than 16, is observed in passing from CH_3NH_2 to $(CH_3)_2NH$, and one of 19.3, in passing from $(CH_3)_2NH$ to $(CH_3)_3N$.

ϕ_v° in Methanol. As may be seen from Table 1, the ϕ_v° values in methanol are smaller than the corresponding values in water except for 1,3-DEU. By comparing the transfer volumes from water to methanol, urea is found to have a more negative value than the other alkylureas studied. The transfer volumes at an infinite dilution from water to methanol $\Delta\bar{V}^\circ_{tr}$ increase in the following order:

U<1,1-DMU<MU<EU<1,3-DMU<1,1-DEU<1,3-DEU.

Thus, alkyl groups, methyl and ethyl, make a larger contribution to the volume in methanol than in water. In other words, a larger volume increment is observed in methanol than in water when urea is substituted by the methyl group, i.e., 20.40 $cm^3\,mol^{-1}$ from U to MU in methanol compared with 18.16 in water.

The assumption of the independent solvation of both sides of the urea molecules mentioned above can be applied also to the volume in methanol and in each water–methanol mixture studied as well.

Recently, Edward et al. have expressed volumes in CCl_4 and other organic solvents by using this equation:[16]

$$\bar{V}^\circ = V_c + \sum n_i I_i + \delta Z_g \qquad (3)$$

where V_c is independent of the solute and is defined as the co-volume, and where n_i and I_i are the number of and characteristic volume of group i. Z_g is the average number of gauche conformations of a molecule at a given temperature, and δ is the volume decrement associated with a gauche interaction. More recently, it has been demonstrated by French and Criss that the group-additive relationships can be expressed for volumes of organic nonelectrolyte solutes, such as alkanes, amines, ethers, and alkanols, in methanol also at 25 °C.[4,17] They obtained a V_c value of 15.8 $cm^3\,mol^{-1}$ and the I_i values by analyzing the volume data in methanol. Some of the I_i values in $cm^3\,mol^{-1}$ are as follows:

$$-CH_3\ 25.83;\ -CH_2-\ 17.72;\ -\underset{|}{\overset{|}{C}}H\ 10.44;\ -\underset{|}{\overset{|}{C}}-\ 3.4;\ -NH_2\ -0.8;$$
$$-OH\ -1.1;\ \diagdown\!\!\diagup C{=}O\ 3.8;\ -CONH-\ 6.4;\ -H\ 8.1.$$

As was pointed out by these authors, the group parameters for volumes are based upon the key assumption that each group contribution is independent of the location of the group and the nature of other groups in the molecule. As may be seen from the data, $I(NH_2)+I(CO)$ are not equal to $I(CONH)+I(H)$. This fact may suggest that amino and carbonyl groups adjacent each other do interact. In fact, as for U with no gauche interaction, the calculated values of the partial molal volume are 18.0 ($V_c+2I(NH_2)+I(CO)$) and 29.5 ($V_c+I(CONH)+I(H)+I(NH_2)$), compared with the experimental value of 36.98 $cm^3\,mol^{-1}$. Group additivity is apparently not applicable to the urea molecule, although the assumption of the independent solvation of both sides of the urea derivatives produced a good approximation of the molal volume.

ϕ_v° in the Mixed Solvents. In Figs. 1 and 2 volumes of the transfer from water to the methanol-water mixtures are plotted against the mole fraction of methanol in the mixture. As may be seen from these figures, each curve of $\Delta\bar{V}^\circ_{tr}$ in the water-rich region goes through a minimum and then turns upward except for the non-hydrophobic solute U. Upon the introduction of more or larger alkyl groups into the urea molecule, the curves gradually come to show deeper minima. The order of decreasing (more negative) $\Delta\bar{V}^\circ_{tr}$ values at $X_2=0.1$ is:

U<MU<1,1-DMU≃EU<1,3-DMU<1,1-DEU<1,3-DEU.

It is considered that this reflects the order of the hydrophobicity of the compounds. In this connection, it is interesting to note Rouw and Somsen's report concerning the enthalpies of transfer, $\Delta\bar{H}^\circ_{tr}$, from water to mixtures of DMF+H_2O for various alkyl-substituted ureas.[12] They show that the enthalpies of solution of these compounds (except for U) show an endothermic shift (i.e., $\Delta\bar{H}^\circ_{tr}>0$) upon the addition of small amounts of DMF to the water. The order of increasing $\Delta\bar{H}^\circ_{tr}$ values in the water-rich region is:

U<MU<1,1-DMU≃EU<1,3-DMU<TMU,

where TMU indicates tetramethylurea. These two sequences agree perfectly with each other, demonstrating that the 1,3-isomer is more hydrophobic than the 1,1-isomer and that 1,1-DMU has about the same hydrophobicity in nature as ethylurea. On the other hand, a volume increment is brought about upon the addition of a small amount of water to methanol. The volumes of transfer from CH_3OH to CH_3OH+H_2O increase in the following sequence:

1,3-DEU<1,1-DEU<1,3-DMU<EU<1,1-DMU<MU<U.

Here, the less hydrophobic the solute is, the more the volume increases. More studies will be necessary in order to elucidate further the behavior of the ternary water–methanol–urea system.

The Addition Effect of CH_3Br and CH_3Cl on Ignition of CH_4 by Shock Wave

Kazuo TAKAHASHI, Tadaaki INOMATA,* Takao MORIWAKI, and Satiko OKAZAKI
Department of Chemistry, Faculty of Science and Technology, Sophia University,
Kioi-cho 7-1, Chiyoda-ku, Tokyo 102
(Received April 23, 1988)

Ignition delay times were measured in the CH_4–CH_3X (X: Cl or Br)–O_2 system diluted in Ar using a shock tube. The times were shorter than those without CH_3X, indicating that CH_3X accelerates the ignition of CH_4. A theoretical model including 8 elementary reactions concerning CH_3X, with a CH_4 oxidation mechanism consisting of 93 reactions, was used to examine the role of halogen for the ignition. The compounds containing Br formed a chain reaction with CH_4 and accelerated the decomposition of CH_4, while CH_3Cl acted only as a fuel which was easily decomposed.

Ignition delays in mixtures involving CH_4 and additives have been studied under various experimental conditions.[1–6] The results showed that additives generally promoted ignition in a CH_4–O_2 mixture, except for substances like N_2 which act as diluents only. The addition effect of some hydrocarbons or hydrocarbon derivatives can be attributed principally to a chemical reaction due to the alkyl radicals generated from the decomposition of the additives.

The ignition delay in CH_4–O_2 strongly depends on the rate of initiation reaction (R1) and the rate of CH_3 generation (R2 and R4), as reported previously.[7] The promotion of ignition by CH_3Br, well-known as an inhibitor for flame propagation, was caused by the additional production of the CH_3 radical, because the activation energy in CH_3Br decomposition (R94) was smaller than that in CH_4 decomposition. However, in addition to insufficient discussion for the role of Br atom, other problems remain, including how other halomethanes influence the ignition of CH_4 and what happens in the reaction mechanism due to the differences of kinds of halogen.

In this investigation, the measurements of ignition delay by using a shock tube and the analytical treatments are performed in the mixtures containing CH_3Br or CH_3Cl, to understand the reaction of halogenated compounds through the induction period. Although the CH_4–CH_3Br–O_2 system has already been studied,[7] CH_3Br had acted as a part of the main fuel, because the test mixture had involved a large amount of CH_3Br (about 30% of CH_4). So this system involving a small amount of CH_3Br was reexamined.

Experimental

The shock tube used in the experiment was made of 6.2 cm i.d. stainless steel pipe. The reaction and driver sections were 3.8 m and 1.7 m long, respectively, so dwell time above 1.5 ms could be obtained in all experimental regions. Other apparatus for measurements of shock velocity and of ignition delay time and the procedures were already reported in detail.[7] The composition of the gas mixtures in Table 1 was employed; the accuracy for preparation of gas mixture is below 0.01%, because silicone oil and mercury manometers were used. The pressure and temperature behind the reflected shock wave were 1.9—3.9 atm and 1500—2000 K, respectively.

Analytical Treatment

To clarify the role of halogen atoms for the ignition, ignition delay times were calculated based on the reaction mechanism presented in Table 2, under the constant pressure conditions.[8] Figure 5 shows that the OH concentration as a function of the time after the arrival of the shock wave increased gradually in the middle stage of the induction period, while the concentration in the last stage rose rapidly. These two sections are regarded as linear, and the ignition delay time was defined as the intersection of the two straight lines. When the profile between time and concentration of H atom, concentration of CH_4, or temperature was used, the ignition delay times were the same as that from the concentration profile of OH.

Rate constants for forward reactions accumulated by Westbrook[9] were used, except R94 and R102, which are not involved in Ref. 9. Most of these rate constants which had been used for the calculation of burning velocity are regarded as being reasonable at present. However, the rate constants of reactions involving CHCO, CH_2CO, or CH_2 are uncertain and more exact values need. In this calculation, reactions involving CHCO, CH_2CO, or CH_2 did not greatly affect an ignition delay time, so the values in Ref. 9 were used as presented. Rate constants for reverse reactions were calculated from forward ones and equilibrium constants.

R94 and R102 were estimated as calculated induction times so as to agree with experimental ones in 1500—2000 K. The rate constant of R94 in high pressure limit was expressed by

$$k_{94} = 1.58 \times 10^{14} \exp(-71700/RT).$$[10]

However, the agreement of experimental and calculated values could not be attained by using this expression. This experimental conditions are

correspond to the so called fall-off region for R94, so the ratio of k/k_∞ was estimated by unimolecular reaction theory. The ratio was 0.07—0.11; then the one-tenth of pre-exponential factor of the above expression was most suitable. Because the data for k_{102} could not be obtained, the expression in Table 2 was estimated. The estimated activation energy of R102 is located between the bond energy of CH_3–Cl and the activation energy of R94 and the pre-exponential factor is reasonable for a unimolecular reaction in fall-off region. Because the variation below 3% of k_{94} or k_{102} does not cause any important change to calculated ignition delay times, both estimated expressions include errors of ±3%.

Although most thermochemical and thermodynamic data which were needed to calculate induction time or reverse rate constants were obtained from Refs. 11 and 12, the data for nine compounds shown below, which were not published, were evaluated by the general statistical method.[11] From the moments of inertia and fundamental vibrational frequencies for C_2H_3 and C_2H_5,[12] C_2H_6,[13] CH_3O,[14] CH_3Cl and CH_3Br,[15] H_2O_2,[16] CHCO,[17] and CH_2CO,[18] we calculated the data for these compounds in the 0—4000 K range. The data in the 0—1500 K range was reported for the former seven compounds;[12–16] calculated values in the 0—1500 K range agree well with the data in the references, supporting the adequacy of calculated values for 1500—4000 K, because values in high temperature can be estimated more exactly. On the other hand, the calculated data for CHCO and CH_2CO may involve some error, because of using unreliable fundamental vibrational frequencies, but small changes of thermodynamic data for CHCO and CH_2CO do not affect calculations of ignition delay times.

Results and Discussion

Additives used in this study are a kind of fuel, so we must determine how a small additional amount of fuel changes the ignition delay. As shown in Fig. 1, ignition delay times are slightly longer in mixture 2 than that in mixture 1; namely, CH_4 acts as a self-inhibitive compound. Therefore, to discuss the role of halogen, we used the mixture containing only CH_4 as fuel and some mixtures in which a part of CH_4 was replaced by halomethane. For example, the concentrations of O_2 and Ar and the number of C atoms are constant in mixtures 2, 3, and 4 (Table 1) and it is proper to use them to examine the role of the halogen atom, as previously reported.[7]

Ignition delay times of mixtures including CH_3Br or CH_3Cl (in Fig. 1) are short in comparison with the times for the mixtures 1 and 2, indicating that these compounds accelerate an ignition of CH_4; the acceleration effect of CH_3Br is more predominant than CH_3Cl. The lines between $1/(10^{-4}\,T_5)$ and $\log(\tau/s)$

Table 1. Test Gas Mixture Composition (%)

1	2.00	—	—	4.00	94.00
2	2.10	—	—	4.00	93.90
3	2.00	0.10	—	4.00	93.90
4	2.00	—	0.10	4.00	93.90

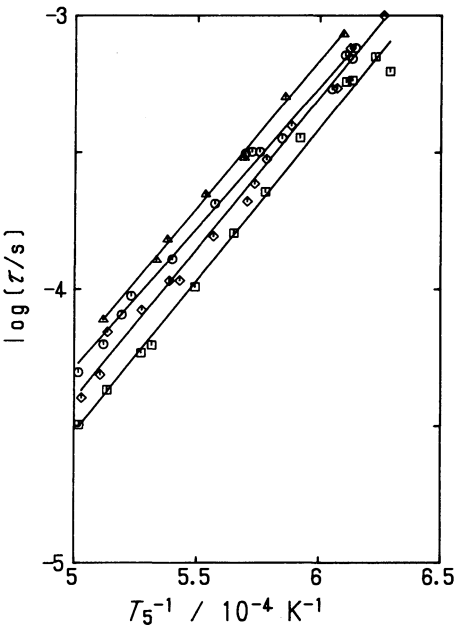

Fig. 1. Observed ignition delay times. ○, mixture 1; △, mixture 2; □, mixture 3; ◇, mixture 4.

are straight. The slopes are 1.04, 1.02, 1.08, and 1.09 K for the mixtures 1, 2, 3, and 4, respectively; namely, the addition effect is quite different absolutely each case but the dependence on temperature is almost identical in all mixtures. The fact that ignition delay times in mixtures 3 and 4 are shorter than that in mixtures 1 or 2 may be explained qualitatively by only the difference of bond energies of C–H and C–X. However it is hardly possible that only the initiation reactions (R1, R94, R102) control the ignition delay, even though they are the main factor.

We indicated[7] that the main reactions controlling the ignition of CH_4 are R1, R2, R4—R6, R8, R9, R13, R14, R22, and R69. CH_3, CH_3O, CH_2O, and CHO species participate in all these reactions, except for R69, which is the most important one to chain branching: These results suggest that the ignition reactions progress through the route of $CH_3 \rightarrow CH_3O \rightarrow CH_2O \rightarrow CHO$. When CH_3Br is added, the reaction scheme will differ; the initiation reaction is not R1 but R94, R1 does not contribute to ignition at all, and R95 and R98, known as inhibition ones, compete with R69 in the consumption of H atoms. Moreover, in CH_4–O_2, the behavior of CH_3 and of H atom made extremely important contribution to an ignition. CH_3, generated by the initiation reaction (R1), reacts

$CH_4 + M = CH_3 + H + M$ (R1)
$CH_4 + OH = CH_3 + H_2O$ (R2)
$CH_4 + O = CH_3 + OH$ (R4)
$CH_3 + HO_2 = CH_3O + OH$ (R5)
$CH_3 + O_2 = CH_3O + O$ (R6)
$CH_3 + O = CH_2O + H$ (R8)
$CH_3 + CH_3 = C_2H_6$ (R9)
$CH_3O + M = CH_2O + H + M$ (R13)
$CH_2O + OH = HCO + H_2O$ (R14)
$HCO + M = CO + H + M$ (R22)
$H + O_2 = O + OH$ (R69)
$CH_3Br = CH_3 + Br$ (R94)
$CH_3Br + H = CH_3 + HBr$ (R95)
$HBr + H = H_2 + Br$ (R98)

with O_2 or O atom. R6 is predominant in the early stage of the induction period and R8 becomes important later, while the concentration of H atom increased continuously. These facts are important in order to comprehend the role of halogen atoms.

Calculated induction times are in good agreement with the observed values, as shown in Fig. 2, indicating that the reaction mechanism in Table 2 is reasonable. Although a large number of reactions for halogen containing compounds have been reported, the set of R94—R109 for halogen containing compounds is enough to explain the ignition delay time. As is obvious from experimental results, additive effects are similar in all temperature regions; therefore, model calculations and various parametric analyses were performed in all mixtures at 1800 K. Calculated induction times are shown in Table 3. This includes the results which were calculated by the reaction mechanism in Table 2 and by deleting reactions concerning halogen species one by one from it.

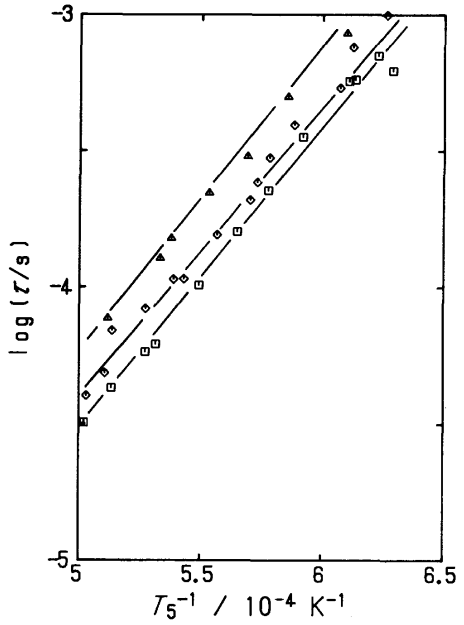

Fig. 2. Comparison of calculated and observed ignition delay times. △, mixtures 2; □, mixture 3; ◇, mixture 4. Straight lines are calculated ones.

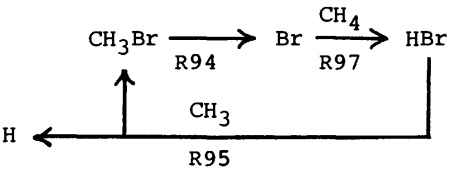
In eight reactions involving bromine containing species, the reactions, R94, R95, R97, and R98 influence upon ignition delay time. When R94, R95, or R97 is deleted from the complete mechanism (Table 2), the ignition delay is longer than that in the complete mechanism, while deletion of R98 made it shorter, showing that R94, R95, and R97 promote an ignition and R98 inhibits an ignition.

The calculated ignition delay time without R94 is longer than that in mixture 2. This result is caused by R98, in addition, R95 can also inhibit an ignition, when R94 is deleted. R95 proceeds in the reverse direction in a greater part of the induction period, while R94, R97, and R98 proceed in the forward direction, in the complete mechanism. When R94 is deleted, R95 proceeds in the forward direction through the whole induction period, leading to the inhibition of ignition. Of course, the conditions in which R94 does not exist cannot occur in these experiments, but the result suggests that a reaction like R95 has some possibility to act as an inhibition one or as an acceleration one, depending on the rate of thermal decomposition of the halogenated hydrocarbons.

The initiation reaction is, of course, R94, because the rates of other initiation reactions (R1, R74, R92) did not contribute much to the ignition delay time. While CH_3 is consumed through R6 and R8, which are the main reactions for CH_3 consumption, Br atom consumed CH_4 through R97 and then CH_3Br was regenerated through the reverse reaction of R95. R97, including the same species as R95 on its right side, progresses forward, namely CH_4 is not regenerated by R97. Therefore, the next chain cycle is formed and promotes the decomposition of CH_4. Moreover, in the



(I)

cycle, H atoms are produced, so that the chain branching reaction, R69, or the reaction of CH_4 consumption, R3, is accelerated catalytically. In brief, the net reaction of R94, R95, and R97 corresponds to a process having a fast rate in which CH_4 is decomposed to CH_3 and H atom instead of process R1 having a slow rate.

The effect of CH_3Cl as ignition promoter is low in comparison to that of CH_3Br; the effective reactions on ignition are R102, R103, R105, and R106. Al-

X+H+M=HX+M(R101, R109)			118	153

a) Reaction which is delected from the complete mechanism. X is Br or Cl.

though the initiation reaction is changed from R1 to R102, the chain reaction like (I) does not exist. This is because R102 is 100 times faster than R1 and R105 proceeds in the forward direction and promotes the decomposition of CH_4, but R103 progresses forward (Fig. 4), so CH_3Cl could not be regenerated during the whole induction period. The difference of rates between R95 and R103 depends on the rate constant. The forward and net rates of R103 are about 1/10 of R95 and the reverse rate of R103 is about 1/500 of R95, while the concentration of HCl is two times that of HBr (Figs. 5 and 6).

$$CH_3Cl = CH_3 + Cl \quad (R102)$$
$$CH_3Cl + H = CH_3 + HCl \quad (R103)$$
$$CH_4 + Cl = CH_3 + HCl \quad (R105)$$
$$HCl + H = H_2 + Cl \quad (R106)$$

As R103 proceeds in the forward direction and the

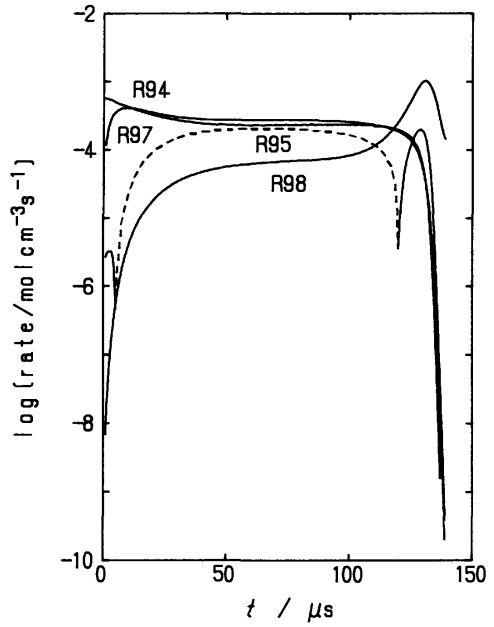

Fig. 3. Net reaction rates of R94, R95, R97, and R98 at 1800K in mixture 3. t is time after the arrival of shock wave. Solid line: net reaction proceeds in forward direction, dotted line: in reverse direction.

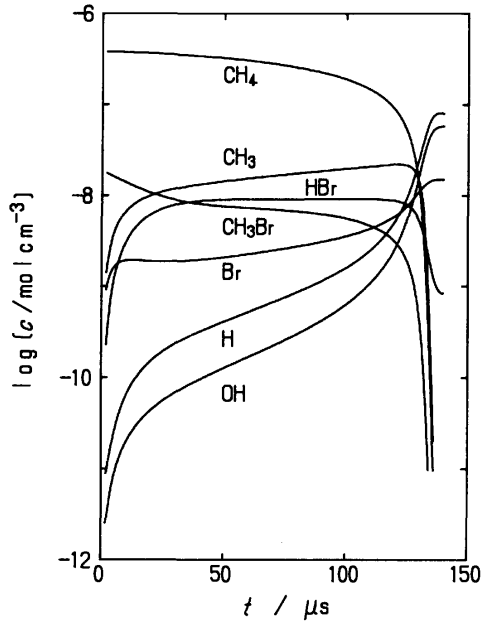

Fig. 5. Calculated concentration profiles of CH_4, CH_3, H, OH, CH_3Br, HBr, and Br at 1800K in mixture 3.

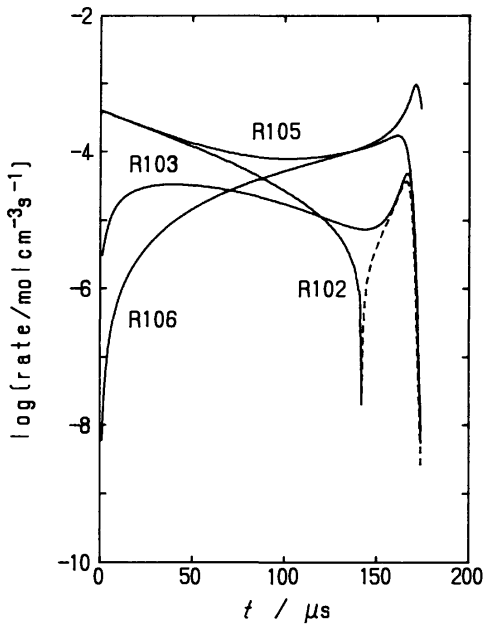

Fig. 4. Net reaction rates of R102, R103, R105, and R106 at 1800K in mixture 4.

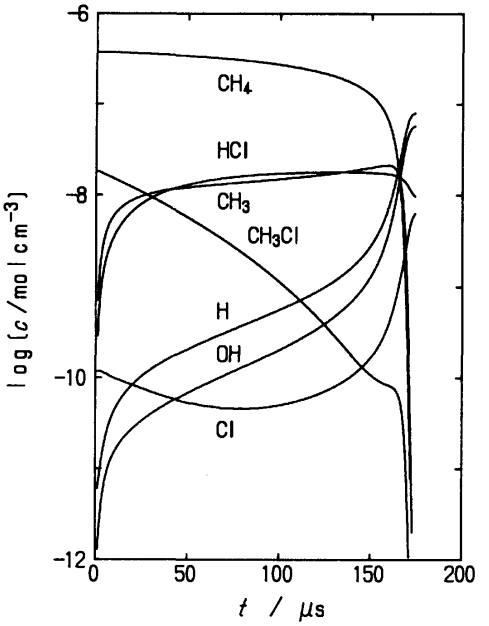

Fig. 6. Calculated concentration profiles of CH_4, CH_3, H, OH, CH_3Cl, HCl, and Cl at 1800 K in mixture 4.

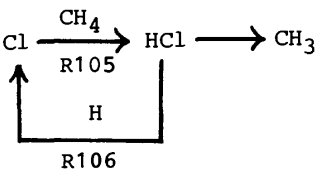
reverse rate of R105 is very slow, HCl generated by R103 reacts through R106; as a result, R105 and R106, which have comparable rates, form chain (II). The



(II)

chain promotes the decomposition of CH_4, while consumes H simultaneously. H atom promotes R69 directly, while CH_3 needs two or more steps, which have low rate constants, to generate H atom, so the chain (II) inhibits the ignition. In CH_3Br, the chain like (II) is probably created too, but it contributes little to an ignition as the reverse rate of R96 is faster than that of forward rate of R98 through the whole induction period.

When R102 is deleted, the ignition delay is almost equal to that in mixture 3, as shown in Table 3. If R102 does not exist, it is predicted that CH_3Cl should consume H through R103; H is consumed furthermore by the chain (II), causing inhibition of an ignition. Exclusion of R103, R105, or R106 makes the ignition delay shorter by a few percent; this result indicates that these reactions certainly inhibit an ignition and that H atom has more effect on the ignition than CH_3 does.

The concentration profile of CH_3Br or of Br differ from that of CH_3Cl or of Cl, respectively. On the other hand, the profiles of CH_4, CH_3, OH, H, or HX (X: Br or Cl) are very similar in the mixtures 3 and 4. When the reaction is initiated, Br is first generated by R94 and then HBr rapidly increases, following Br, until it reaches a constant value at about 30 μs. The consumption of CH_3Br is retarded practically with increase of concentration of HBr. CH_3Cl is consumed gradually through the induction period and its concentration did not become constant. Moreover, Cl atom is produced in the early stages of induction period, but it generates HCl soon because of fast R105, resulting in the greater parts of Cl existing as HCl even in early stages. Although these profiles may be easily expected from Figs. 3 and 4, they express fully the difference of addition effect between CH_3Br and CH_3Cl. At the same time, they show that both additives change the rate of ignition reaction but not the main ignition mechanism.

In conclusion, the promotion mechanism by the addition of CH_3Br and CH_3Cl to methane is because of the relatively fast decomposition rates in both additives, which lead to easy generation of CH_3 radical; this is especially clear in CH_3Br, because of the existence of the chain reaction constructed by R94, R95, and R97. The fundamental discrepancy in CH_3Br and CH_3Cl depends on the relative rates of R95 or R103 and R98 or R106, in addition to the low rate in R102.

Determination of Ionic Partial Molar Volumes of Bolaform Electrolytes by Means of Sedimentation Potential Measurements

Hiromitsu HIRAKAWA,* Hiroyasu NOMURA,† and Fumio KAWAIZUMI†
Department of Electronics, Faculty of Engineering, Kagoshima University, Kagoshima 890
†Department of Chemical Engineering, School of Engineering, Nagoya University, Nagoya 464
(Received March 31, 1988)

Synopsis. Sedimentation potentials (SP) and electrical conductivities have been measured in aqueous solutions of three kinds of bolaform electrolytes, $[R_3N-(CH_2)_n-NR_3]Br_2$ where R stands for ethyl group and n is equal to 4, 6, and 10. Using the SP and conductivity data the partial molar volumes of the bolaform salts were divided into cationic and anionic parts. Two ionic sites of the bolaform electrolytes behave independently.

Partial molar quantities of a dissolved electrolyte are known to give much information on various aspects of solute–solvent interactions. Among them, partial molar volumes V_2^0 is perhaps one of the most familiar and useful quantities, since its accurate values can be determined directly from density measurements. Inspection of the temperature dependence of partial molar volumes of electrolytes indicates that significant differences in ion–water interactions exist for cations and anions. For detailed discussion of V_2^0 data, ionic division of V_2^0 of electrolytes is indispensable. A number of workers have carried out the ionic division based on various theoretical and/or empirical criteria. The criteria or assumptions adopted and the results obtained are given in a review.[1)]

Method of ionic division founded on a firm theoretical ground has long been restricted to the ultrasonic vibration potential (UVP) measurement. Unfortunately, special techniques are needed to use this valuable method. An alternative to the UVP method is the sedimentation potential (SP) measurement. Recently a sedimentation potential generating apparatus (SPGA) was designed by one of the present authors (H.H) and the sedimentation potentials were measured with sufficient accuracy for aqueous solutions of ordinary inorganic electrolytes.[2)] In this note, we will report first the results of sedimentation potential measurement on bolaform electrolytes in aqueous solutions and then discuss the ionic partial molar volumes evaluated.

Bolaform electrolyte is a class of salts with general formula $[R_3N-(CH_2)_n-NR_3]Br_2$. Following the official nomenclature it is expressed as bis(tetraalkylammonio)alkaline dibromide. In this work three kinds of bolaform salts were used as samples for which R=ethyl, and n is equal to 4, 6, and 10. These samples will be abbreviated as J4, J6, and J10, respectively. Samples were prepared and purified as described elsewhere.[3)]

The experimental procedures of SP measurements are the same as those in our previous paper.[2)] For the ionic division of V_2^0 transference numbers are necessary. These values are not found in the literature. For this reason as part of this work, electric conductivities were measured using a Fuso 360 linear-bridge conductometer. The cell constant of the cell used in the present study was 0.1240 cm^{-1} and the concentration ranges were 10^{-4} to 10^{-3} mol dm^{-3}.

All measurements were done at 25 °C.

The concentration dependences of SP of bolaform electrolytes in aqueous solutions are shown in Fig. 1. Negative values of SP were observed for all samples investigated and the values decreased with increasing concentration. At lower concentrations, the SP values became independent of concentration of the salts. With increasing molecular weight, the absolute values of SP increased.

The limiting conductivities of bolaform electrolyte were evaluated from the least squares fitting of the following Debye–Hückel–Onsager equation;

$$\Lambda = \Lambda^\infty - (B_1\Lambda^\infty + B_2)c^{1/2} \quad (1)$$

where c is the concentration in mol dm^{-3} and B_1 and B_2 are the parameters given by the theory. For the sample J4, down ward deviation from Eq. 1 was observed, suggesting that ion-pairing occurs for this salt. But no further discussion on the conductivity will be done, since the conductivity data at infinite dilution are needed at this stage for the evaluation of the transference number only. The limiting values Λ^∞ obtained are summarized in the third column of Table 1.

The SP generated in aqueous electrolyte solutions

Table 1. Sedimentation Potential (SP) and Limiting Molar Conductivity of Bolaform Salts in Aqueous Solutions and Calculated Partial Molar Volumes for Cation and Anion

	SP	Λ^∞	V_2^0	V_+^0	V_-^0
	μV	S cm^2 mol^{-1}	cm^3 mol^{-1}	cm^3 mol^{-1}	cm^3 mol^{-1}
J4	−2.16	232.7	322.28[a]	267.0	27.5
J6	−2.30	237.6	356.50[a]	303.3	26.6
J10	−2.35	240.5	420.26[a]	365.3	27.5

a) Ref. 4.

using our apparatus is expressed as follows;[2]

$$V = 1.015 \times 10^{-6}\left[\frac{t_+}{z_+}(m_+ - V_+^0\rho) - \frac{t_-}{z_-}(m_- - V_-^0\rho)\right]x_0 \quad (2)$$

where t is the transference number, z is the charge, m is the molecular weight of the ion, ρ is the density of solvent, x_0 is the velocity amplitude, and the other symbols have their usual meanings. Since $V_2^0 = \nu_+V_+^0 + \nu_-V_-^0$, by combining the partial molar volume and the SP of an electrolyte, one can evaluate the partial molar volumes of the constituent ions without relaying on any kind of extra-thermodyamic or semiempirical assumptions. The partial molar volumes of J4, J6, and J10 are found in the literature.[4] The transference numbers t_+ and t_- were calculated from the limiting ionic conductivities given in Table 1 and the literature value[5] of $\Lambda^\infty(Br^-) = 78.14$ S cm^2 mol^{-1}. The estimated transference numbers of bolaform ions are 0.4944, 0.5100, and 0.5187, for J4, J6, and J10, respectively. The individual ionic partial molar volumes obtained are included in Table 1. The values of $V_-^0(Br^-)$ in Table 1 are all around 27.2 cm^{3}mol^{-1}. These values are a little smaller than those generally accepted; $V_-^0(Br^-) = 29.2$—30.9 cm^3 mol^{-1} according to the compilation of Millero.[1] However, in view of the precision of SP measurements[4] this difference has no significance. Rather, our work can serve as experimental evidence that ionic additivity of partial molar volume holds for these bolaform electrolytes. The ionic additivity corresponds to the independent behavior of the two separated ionic sites in the bolaform cations in aqueous solutions. The relationship for increment of partial molar volume and number of methylene groups in bolaform salts has been discussed elsewhere.[4]

The Magnetic Properties of the Copper(II) Alkanoate Adducts with Benzimidazole and Related Nitrogen Donors

Shuji EMORI,* Hikari KURIHARA, and Yoneichiro MUTO
Department of Chemistry, Faculty of Science and Engineering, Saga University,
Honjo-machi, Saga 840
(Received February 10, 1988)

Synopsis. Various copper(II) alkanoate adducts with benzimidazole, *N*-acetylbenzimidazole, and benzoxazole have been prepared. The influence of the hydrogen bonded structure in the benzimidazole adducts on their magnetic properties are discussed.

A number of magnetic studies concerning dinuclear copper(II) carboxylates have revealed that the magnitude of the spin-exchange coupling between copper(II) ions is affected by the donor characteristics of both the bridging carboxylato and axial donor ligands.[1-3] For example, the room-temperature magnetic moments of the copper(II) alkanoate adducts with cyclic tertiary amines and cyclic ethers can be expressed according to

$$\mu_{eff} = -0.052(pK_a - 0.068pK_a' - 4.56) + \Delta\mu_\alpha + 1.38_5, \quad (1)$$

where pK_a and pK_a' are the acidities of the conjugate acids of alkanoate and axial ligands, respectively. $\Delta\mu_\alpha$ is the correction term for the substitution in the methyl group of acetic acid (-0.05_8 and -0.07_0 BM for the series of mono- and disubstituted acetates, respectively),[4] including the corrections for steric strain, field effect, and hyperconjugation.[4] Also, for the hydrates[1,5,6] and the ammonium chloride adducts,[7-9] a similar relationship can be demonstrated by plots of their corrected magnetic moments, $\mu_{eff}-\Delta\mu_\alpha$, against $pK_a-0.068pK_a'$, when -7.0 and -1.74 are used for the pK_a' values of chloride ion[10] and water molecule, respectively. However, the intercept obtained in this way (1.39_9 BM at $pK_a=4.56$ and $pK_a'=0$) is slightly larger than that in Eq. 1. This difference seems to be caused by the following two structural backgrounds: (1) the hydrogen bonding between the carboxylato oxygen atom and the neighboring proton donor, such as ammonium ion or water molecule,[11,12] decreases the electron density on the oxygen atom, and (2) the steric repulsion resulting from the bulky nature of the axial ligand, such as tertiary amines,[13] weakens its coordination bond. In order to clarify which factor plays a more important role in the above difference, we carried out preparations and magnetic susceptibility measurements of the copper(II) alkanoate adducts with benzimidazole, *N*-acetylbenzimidazole, and benzoxazole. These compounds are appropriate for studying the effect of hydrogen bonding on their magnetic properties, since all of these ligands have a similar bulkiness around their coordination sites, while only the benzimidazole adducts have hydrogen-bonded structures.[14,15]

Benzimidazole and benzoxazole are commercially available and were used without further purification.

Table 1. Analytical Data and Effective Magnetic Moments at 20°C

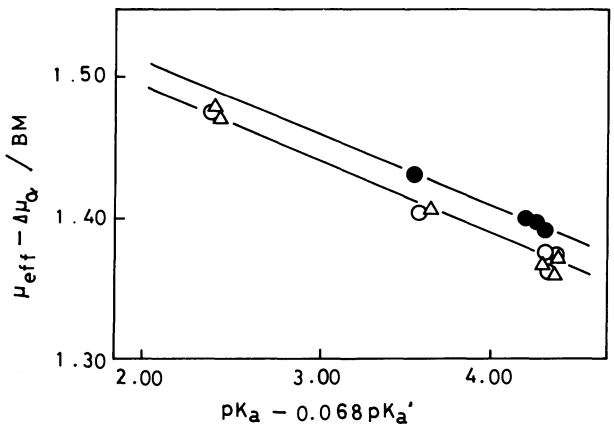

Fig. 1. The corrected magnetic moments at 20 °C plotted against the acidities of the ligands for the copper(II) alkanoate adducts with benzimidazole (●), *N*-acetylbenzimidazole (○), and benzoxazole (△).

N-Acetylbenzimidazole was prepared by the procedure of Reddy et al., mp 113 °C (lit, mp 113 °C).[17] Various copper(II) alkanoate adducts were obtained by a general procedure for synthesizing adducts with heterocyclic amines.[16,18]

The effective magnetic moments of these compounds (Table 1) were evaluated from the room-temperature magnetic susceptibilities, which were corrected for the diamagnetism of the ligands using Pascal constants,[19] and for $N\alpha$ using 60×10^{-6} emu mol^{-1} (1 emu=$4\pi\times10^{-6}$ m^3). The IR spectra of these compounds show characteristic bands in the ranges 1675—1615 and 1435—1405 cm^{-1} associated with unsymmetric and symmetric COO stretching vibrations of the carboxyl groups.[21] In the crystal of the copper(II) acetate adduct with benzimidazole, its dinuclear structure and the interdinuclear hydrogen-bond contact between the carboxylato oxygen atom and the benzimidazole ligand have been established by an X-ray analysis.[14] The magnetic and IR spectral data indicate that the present compounds also have bridged dinuclear structures similar to that of copper(II) acetate monohydrate.[11,12] In addition, the broad NH stretching bands[22] at about 3250—3200 cm^{-1} indicate that hydrogen bonding is involved in the benzimidazole adducts.

In order to confirm the linear correlation, the corrected magnetic moments, $\mu_{eff}-\Delta\mu_\alpha$, of the present compounds together with those of the corresponding acetates,[15,18] are plotted against $pK_a-0.068pK_a'$ in Fig. 1, using the pK_a' value of 5.46, 4.74, and 3.96, (the last two values are estimated by the Branch-Calvin equation[23]) for benzimidazole, *N*-acetylbenzimidazole, and benzoxazole, respectively. The error in the estimation of pK_a' values is practically permissible, since the coefficient of pK_a' in Eq. 1 is very small. As can be seen from Fig. 1, the points for the benzimidazole adducts and the rest are on different lines from each other, which have the same slope of −0.052 BM and intercepts of 1.37_9 and 1.36_3 BM, respectively. The intercepts obtained here are somewhat smaller than that of Eq. 1, and may be explained in terms of a steric hindrance for axial ligation. However, the present ligands have a similar bulkiness around the donor atoms. Thus, the difference in the intercepts apparently indicates the effect of hydrogen bonding in the benzimidazole adducts. The reported singlet-triplet separation values for the benzimidazole and benzoxazole adducts of copper(II) acetate (324 and 344 cm^{-1} respectively)[15,18] indicate that the hydrogen bonding weakens the intradinuclear antiferromagnetic interaction. The magnitude of the difference (ca. 0.01_5 BM) is comparable to that of the difference between the tertiary amine adducts and the ammonium chloride adducts of copper(II) alkanoate. Although both the strength and number of hydrogen bonds have been disregarded, this coincidence indicates that the difference between those of the tertiary amine and the ammonium chloride adducts is mainly attributable to hydrogen bonding and that the steric hindrance to an axial coordination of the tertiary amines is negligible, probably due to considerably long sp^3 hybridized orbitals at their coordination sites.

Specific Binding of Substrates Containing Nitrogen and Oxygen Donor Groups to Copper(II)-Gadolinium(III) Hetero-Metal Center

Masatomi SAKAMOTO,* Tomitaro ISHIMORI, and Hisashi ŌKAWA†
Department of Industrial Chemistry, Faculty of Engineering, Ehime University, Bunkyo-cho, Matsuyama 790
†Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812
(Received April 15, 1988)

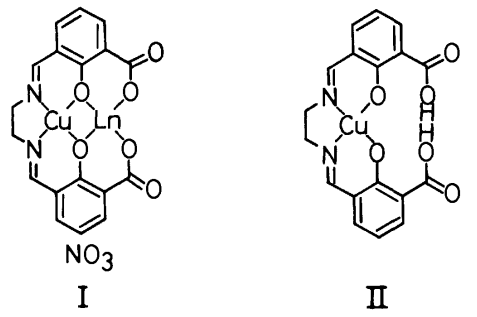
Synopsis. Substrate binding to the Cu(II)–Gd(III) hetero-metal complex of *N,N'*-bis(3-carboxysalicylidene)ethylenediamine was studied in *N,N*-dimethylformamide. It was suggested that substrates with a nitrogenous and an oxygenous groups (amino alcohols, 8-quinolinol, amino acids, and amino acid esters) were specifically bound to the Cu(II)-Gd(III) center, with the nitrogen to the copper and with the oxygen to the gadolinium.

Recently we have reported[1] that the copper(II)-lanthanoid(III) hetero-metal complexes (Fig. 1, I) of *N,N'*-bis(3-carboxysalicylidene)ethylenediamine (H_4-fsaen) show "solvation selectivity" associated with the copper or lanthanoid center depending upon the nature of solvents. That is, in pyridine solution the solvation occurs at the copper center to afford a pentacoordination around the metal, whereas in dimethyl sulfoxide or *N,N*-dimethylformamide solutions the solvation occurs exclusively at the lanthanoid center while maintaining the planar configuration around the copper ion. It should be emphasized that the mononuclear precursor complex (Fig. 1, II) takes a pentacoordination with a solvent molecule at an apical site in all of these solvents. The above findings prompted us to examine if the Cu(II)–Ln(III) center functions as a specific binding site for substrates containing both nitrogenous and oxygenous donating groups. In this study the Cu(II)–Gd(III) complex of H_4fsaen, in which gadolinium is located at the center of lanthanoid series, was adopted and the binding of various substrates (amino alcohols, 8-quinolinol, amino acids, and amino acid esters) to the complex was investigated in *N,N*-dimethylformamide (DMF).

Experimental

Materials. The Cu(II)-Gd(III) complex of H_4fsaen was synthesized according to the method reported previously.[1] 2-Amino-1-butanol was purchased from Tokyo Kasei Co. Other reagents used as substrates were purchased from Wako Pure Chemical Industries. Methyl esters of the amino acids were obtained as hydrochloride after the literature method[3] and used for the following experiments without neutralization.

Methods. A solution of the Cu(II)–Gd(III) complex in DMF (2.5×10^{-2} mol·dm^{-3}) was prepared. To 2 cm^3 of this solution was added a weighed amount of a substrate (except for amino acids), and the total volume was made up to 10 cm^3 with DMF. Visible spectra of the mixture were determined with a HP 8452A Spectrophotometer. For amino acids as substrates, a suspension of an amino acid in the complex solution was stirred for 2 h, and the supernatant solution was submitted to the spectral measurements. The CD spectra were determined with a JASCO J-20 Automatic Recording Spectropolarimeter.



I II

Fig. 1. Chemical structures of copper(II)-lanthanoid(III) hetero-metal complexes(I) and copper(II) mononuclear complex(II) of *N,N'*-bis(3-carboxysalicylidene)ethylenediamine.

Results and Discussion

In general the axial coordination of a substrate to the copper center results in a red shift of the d–d band maximum, along with a color change from purple to green or blue. For example, when an amino alcohol (2-aminoethanol, 3-amino-1-propanol, 1-amino-2-propanol, 2-amino-1-butanol) was added as the substrate to the complex solution, the d–d band maximum shifted by 1×10^3—2×10^3 cm^{-1} to lower frequency.

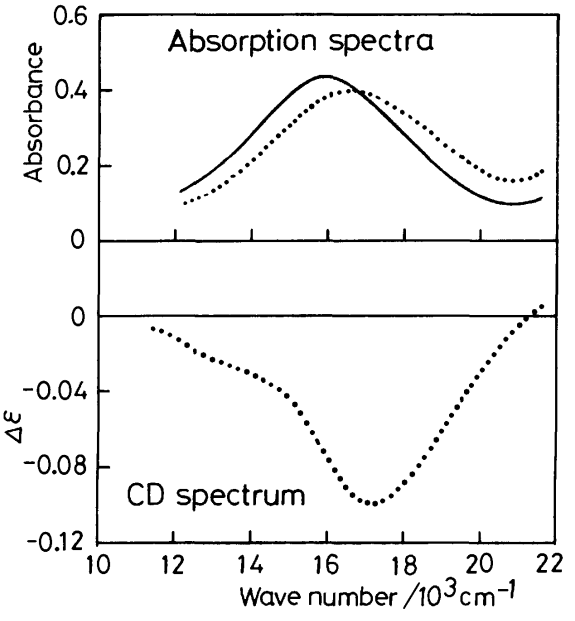


Fig. 2. Absorption and CD spectra in DMF. Concentration of the binuclear complex is 5×10^{-3} mol dm^{-3}. (——): with 2-aminoethanol (10 mol dm^{-3}); (……): with (*R*)-(−)-2-amino-1-butanol (10 mol dm^{-3}).

Table 1. The d–d Band Maxima of Cu(II)–Gd(III) Binuclear Complex in DMF Solution of Various Substrates[a]

Substrate	$\tilde{\nu}_{max}/10^3$ cm^{-1}
No substrate	17.86
1,2-Ethanediol[b]	18.08
1,3-Propanediol[b]	17.89
2-Aminoethanol[b]	15.97
3-Amino-1-propanol[b]	16.50
1-Amino-2-propanol[b]	16.19
(*R*)-(−)-2-Amino-1-butanol[b]	16.67
8-Quinolinol[c]	17.33
Glycine[d]	17.86
β-Alanine[d]	17.67
4-Aminobutyric acid[d]	17.48
Glycine methyl ester[e]	17.64
β-Alanine methyl ester[e]	17.73
Methyl 4-aminobutyrate[e]	17.67

a) Concentration of binuclear complex is 5×10^{-3} mol·dm^{-3}. b) Concentration is 10 mol·dm^{-3}. c) Concentration is 1 mol·dm^{-3}. d) Spectra were measured for the supernatant solution after these substrates were suspended with stirring for 2 h. e) Hydrochlorides were used. Concentration of glycinate, alaninate, and butyrate are 5.26×10^{-3}, 5.01×10^{-3}, and 5.40×10^{-3} mol·dm^{-3}, respectively.

Typical spectra are shown in Fig. 2 and the numerical data are given in Table 1. The largest red shift of the d–d band is observed for 2-aminoethanol and the shift tends to decrease when the alkane chain is lengthened or a substituent is introduced on the ethylene chain. When (*R*)-(−)-2-amino-1-butanol was added as the substrate, the solution showed significant circular dichroism at the d–d transitions of the copper(II) ion (Fig. 2). The addition of 1,2-ethanediol or 1,3-propanediol as the substrate, on the other hand, showed no indication of the coordination to the copper center (see Table 1). All these facts indicate that the amino alcohols coordinate to the copper center at the nitrogen atom. The coordination at the lanthanoid center, however, cannot be monitored spectroscopically, because electronic structures of lanthanoid ions are little affected by the change in the coordination geometry or the ligand field strength.[4] However, it is expected that oxygenous substrates such as alcohols, phenols, carboxylic acids, or esters have a high affinity towards lanthanoid ions compared with DMF (amide) used as the solvent. This is probably the case of 1,2-ethanediol and 1,3-propanediol; these substrates may exclusively coordinate to the gadolinium ion at both oxygen atoms. Therefore, we presumed that the amino alcohols are bound to the Cu(II)–Gd(III) center, with the nitrogen to the copper and with the oxygen to the gadolinium.

The addition of quinoline as the substrate showed no indication of the coordination to the copper(II) ion, whereas the addition of 8-quinolinol caused a significant red shift of the d–d band. This is rationalized in terms of that the binding of quinoline to the copper center is sterically hindered but the binding of 8-quinolinol to the Cu(II)–Gd(III) center is not subjected to any steric hindrance when the hydroxyl group is concerned with the coordination to the gadolinium(III) ion. This adds a support to our presumption that amino alcohols are bound as bidentate bridge to the Cu(II)–Gd(III) center.

Somewhat different feature of binding was recognized for amino acids. When glycine was added to the complex solution, no indication of the nitrogen coordination to the copper was observed from its electronic spectrum. When β-alanine was added, no apparent color change occurred but its electronic spectrum showed a slight red shift of the d–d band. When 4-aminobutyric acid was the substrate, apparent color change occurred and its spectrum showed a larger red shift of the d–d band. Therefore, the nitrogen coordination to the copper center becomes feasible on lengthening the alkane chain of amino acid. This trend differs from that found for amino alcohols. Conceivably carboxylate group of amino acids coordinate bidentately to the gadolinium center. Such bidentate carboxylates were reported for some lanthanoid(III) acetate hydrates.[5] If this is the case, the coordination of the terminal nitrogen to the copper should be difficult for glycine but is easier for amino acids with a longer methylene chain.

In order to gain an insight into the binding mode of amino acids, we also examined the binding of amino acid esters (methyl aminoacetate, methyl 3-aminopropionate, methyl 4-aminobutyrate) to the Cu(II)–Gd(III) center. As seen in Table 1, the substrate binding to the copper center was evidenced spectroscopically for all the cases. We assume that in these cases, the ester group functions as a unidentate donor so that the amino acid esters are bound to the Cu(II)–Gd(III) center in the essentially the same way as that of amino alcohols.

From the above discussions it is suggested that the substrates possessing a nitrogenous and an oxygenous donor groups are specifically bound to the Cu(II)–Gd(III) center, though their binding constants have not yet been determined.

Facile Conversion of Aldehydes into 1-Substituted 2-Chloro-3,3-difluoro-2-propen-1-ols with 1,1-Dibromo-1-chloro-2,2,2-trifluoroethane/Magnesium Reagent

Makoto FUJITA and Tamejiro HIYAMA*
Sagami Chemical Research Center, 4-4-1 Nishiohnuma, Sagamihara, Kanagawa 229
(Received May 13, 1988)

Synopsis. Aldehydes RCHO are converted in excellent yields into chlorodifluoroallyl alcohols $RCH(OH)CCl=CF_2$ upon treatment with $CClBr_2CF_3$ and magnesium in tetrahydrofuran at 0 °C.

Aldehyde adducts of halogenated ethenyl anions $^-CX=CF_2$ (X=Cl or F) have been shown to be useful intermediates for the synthesis of α-halo-α,β-unsaturated ketones and acid derivatives,[1] as well as artificial pyrethroids.[2] The aldehyde addition of $CX=CF_2$ anions was earlier realized at −130 °C with $LiCX=CF_2$,[1a-c] and recently achieved under milder conditions using $R_3SiCX=CF_2/F^-$,[3] $CF_3CCl_3/Zn/AlCl_3$(cat),[4] or CF_3CCl_3/Pb[1h] reagent. Even these reagents possess problems from practical viewpoints. For example, preparation of the fluorinated vinylsilanes is tedious;[5] the zinc and lead reagents seem to lack wide applicability.[6] Reported herein is an alternative facile way to 1-substituted 2-chloro-3,3-difluoro-2-propen-1-ols **2** through the reaction of aldehydes **1** with $CClBr_2CF_3$ and magnesium, both of which are commercially readily available and economical (Eq 1).

$$\underset{\mathbf{1}}{RCHO} + CClBr_2CF_3 \xrightarrow[THF]{Mg} \underset{\mathbf{2}}{RCH(OH)CCl=CF_2} \quad (1)$$

f: R = 
Results and Discussion

The adducts **2** were produced in excellent yields, when aldehydes were treated with 3 molar equivalents of 1,1-dibromo-1-chloro-2,2,2-trifluoroethane and 6 mol of magnesium chips in tetrahydrofuran (THF). Results are summarized in Table 1. In addition to common aliphatic and aromatic aldehydes, readily enolizable aldehydes (e.g. **1d** and **1f**) give the desired adducts. Cinnamaldehyde (**1c**) afforded a 1,2-adduct only. The adduct **2f** is a versatile intermediate for synthetic pyrethroids having a $CH=C(Cl)CF_3$ side chain.[2]

The reaction course of the transformation deserves particular comments. When 1:1 mole ratio of $CClBr_2CF_3$ and Mg was applied, any kinds of aldehyde adducts were not detected, but formation of $CClBr=CF_2$ was observed by ^{19}F NMR of the crude reaction mixture. Thus, the organomagnesium reagent responsible for the carbonyl addition is concluded to be a Grignard reagent $BrMgCCl=CF_2$ generated in situ by the reaction of magnesium metal and the $CClBr=CF_2$.[7] In this sense, the mechanism of the total transformation contrasts sharply to that of the $CF_3CCl_3/Zn/AlCl_3$ (cat) reagent, which first gives aldehyde adducts $RCH(OH)CCl_2CF_3$ and then reduces the adducts to give products of type **2**.

Although the Grignard reagent $BrMgCCl=CF_2$ is recorded by Stelin et al.,[7] its carbonyl addition has never been achieved due possibly to the instability of the reagent. Noteworthy is that the in situ prepared reagent can do the transformation at 0 °C as reported herein.

Experimental

Materials. Magnesium chips and 1,1-dibromo-1-chloro-2,2,2-trifluoroethane were purchased from Nakarai Chemicals Co. Ltd. and PCR Co. Ltd., respectively, and used directly. Aldehydes were purchased from Tokyo Kasei Kogyo Co. Ltd. Ethyl 2-formyl-3,3-dimethylcyclopropanecarboxylate was prepared by a procedure previously reported.[2b] Tetrahydrofuran was dried over benzophenone ketyl and freshly distilled before use.

Reaction of Aldehydes with $CClBr_2CF_3$/Mg Reagent. A Typical Procedure. Magnesium chips 144 mg (6.0 mmol) were suspended in THF 2 mL solution of benzaldehyde (**1a**) 106 mg (1.0 mmol). The whole was cooled at 0 °C, and THF 2 mL solution of 1,1-dibromo-1-chloro-2,2,2-trifluoroethane 825 mg (3.0 mmol) was added dropwise. After 3 h at 0 °C, sat ammonium chloride aq solution 15 mL was added, and the mixture was extracted with diethyl ether (10 mL×3). The ethereal extract was dried over anhydrous magnesium sulfate, concentrated under reduced pressure, and subjected to preparative TLC (silica gel, dichloromethane–hexane 1:1) to give 2-chloro-3,3-difluoro-1-phenyl-2-propen-1-ol 144 mg (**2a**) (70%) as a colorless oil. Spectral data are completely in accord with those of the authentic sample.[4b]

Table 1. Transformation of RCHO to $RCH(OH)CCl=CF_2$[a]

Helix Formation of Poly(L-ornithine) in Decyl and Dodecyl Sulfate Solutions

Kunio TAKEDA* and Kazuo YAMAMOTO
Department of Applied Chemistry, Okayama University of Science,
1-1 Ridai-cho, Okayama 700
(Received January 20, 1988)

Synopsis. Structural changes in poly(L-ornithine)[$(Orn)_n$] were studied in solutions of sodium decyl sulfate ($NaDecSO_4$) by the curve-fitting method of circular dichroism. In the $NaDecSO_4$ concentration range from 4 to 9 mmol dm^{-3}, only the β-structure was found. Below and above this concentration range, however, the α-helical structure was formed slightly, its fraction being less than 20%. The addition of 1-octanol enhanced the helix formation in the $(Orn)_n$–$NaDecSO_4$ complex.

Many investigations have been conducted in the past three decades that have dealt with the conformational changes in homopolypeptides such as poly(L-ornithine)[$(Orn)_n$] homologs in anionic surfactant solutions.[1-13] However, few attempts have been made to estimate quantitatively the presence of α-helix, β-structure, and random coil in these homologs in the surfactant solutions. Recently, we computed the fractions of α-helix, β-structure, and random coil of $(Orn)_n$ in a sodium dodecyl sulfate ($NaDodSO_4$) solution[12] using a simulation of the circular dichroism (CD) spectra similar to Greenfield and Fasman.[14] This method may make possible a quantitative study when a slight amount of helical structure in the polypeptide chain is induced by another surfactant solution. We now report proportional changes of α-helix, β-structure, and random coil in $(Orn)_n$ induced by sodium decyl sulfate ($NaDecSO_4$), together with the effect of added 1-octanol on the formation of helical structure in the same surfactant solution.

Experimental

The $(Orn)_n$ sample employed was described in a previous study.[12] The $NaDecSO_4$ was prepared from 1-decanol (purity: 99.8%), essentially according to the method of Dreger et al.[15] The critical micelle concentration of the surfactant, as determined by the electric conductivity method, was 31.5 mM (1 M=1 mol dm^{-3}) at 25 °C.

The CD measurements were carried out with a Jasco J-500A spectropolarimeter equipped with a Jasco DP-501 data processor. Details of the experimental procedures have been described elsewhere.[10,12] The CD measurements were made under the same conditions as have been described previously: temperature, 20 °C; pH, neutral; the residue concentration of $(Orn)_n$, 9.2×10^{-5} M.[12] The simulation of the CD spectrum was made over the wavelength region of 190—250 nm with the assumption that the $(Orn)_n$ assumes only three structures: α-helix, β-structure, and random coil. The relative proportions of these three structures were calculated by the same method as in a previous study.[12]

Results and Discussion

The CD spectra of $(Orn)_n$ at various $NaDecSO_4$ concentrations are shown in Fig. 1. Figure 1 also shows two CD spectra of the polypeptide in a 0.8 mM $NaDecSO_4$ solution containing slight amounts of 1-octanol. The addition of 1-octanol enhanced helix formation in $(Orn)_n$, as can be seen by the increase in the magnitude of the α-helical-type CD spectrum. In the $NaDecSO_4$ concentration range from 4 to 9 mM, the surfactant solution containing $(Orn)_n$ became slightly turbid, but this turbidity did not interfere in the CD measurements (the same phenomenon is observed in the $NaDodSO_4$.[12] In this concentration range, the CD spectra of $(Orn)_n$ were typically of β-structure (not shown, refer to Fig. 1 in Ref. 12). These CD spectra were analyzed using the same reference spectra as in the previous study.[12] The proportional

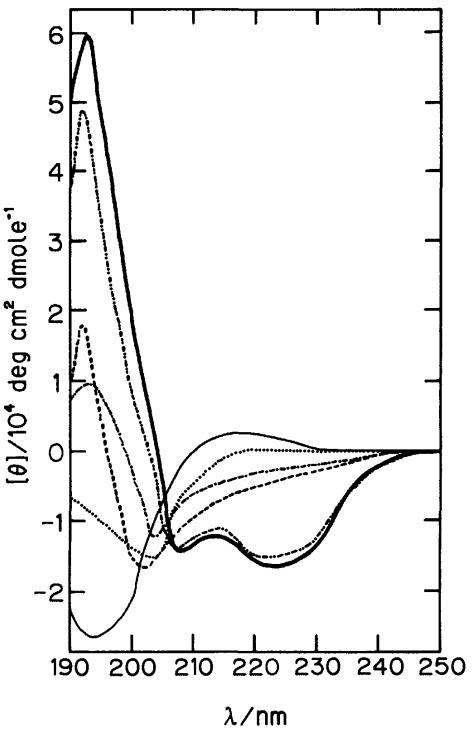

Fig. 1. CD spectra of $(Orn)_n$ in $NaDecSO_4$ solutions in the absence and the presence of 1-octanol. $NaDecSO_4$ concentrations in the absence of octanol: 0.3 (—); 0.4 (·····); 0.8 (-·-·-·) and 14 mM (-----). Added octanol concentrations to 0.8 mM $NaDecSO_4$ solution: 1.02 (-·-·-·-·-) and 1.28 mM (——). The polypeptide concentration: 9.2×10^{-5} M (residue). The CD spectra of $(Orn)_n$ were time-dependent in the order of hour in 0.4 and 0.8 mM $NaDecSO_4$ solutions without the octanol. All the measurements of spectra were carried out within 10 min after mixing the $(Orn)_n$ solution with the surfactant solution.

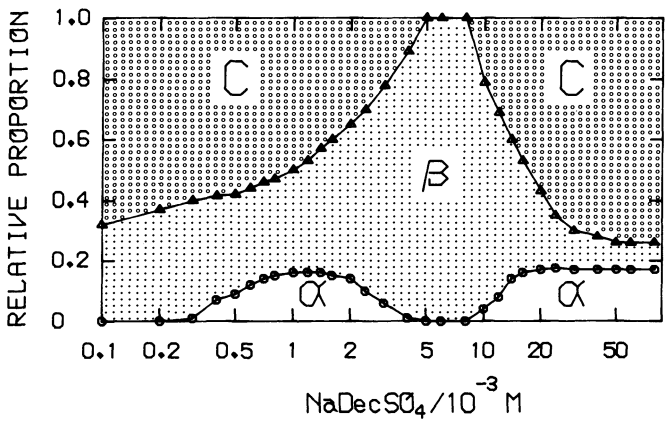

Fig. 2. Proportional changes of α-helix (α), β-structure (β), and random coil (C) in $(Orn)_n$ as a function of $NaDecSO_4$ concentration. The proportions were estimated using the CD spectra measured under the same conditions as mentioned in Fig. 1. The boundary between the α-helix and the β-structure is plotted (-⊖-) and that between the β-structure and the random coil done (-△-). Then, each area gives the fraction of the corresponding structure. The same method was used in the following figure.

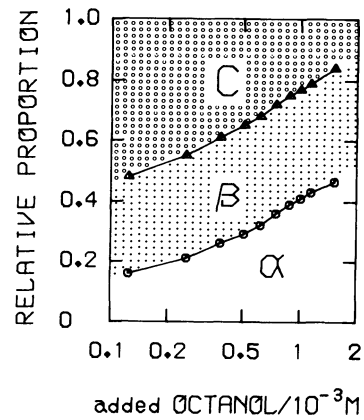

Fig. 3. Proportional changes of α-helix, (α), β-structure (β), and random coil (C) in $(Orn)_n$ as a function of added 1-octanol to 0.8 mM $NaDecSO_4$ solution.

changes in the secondary structure of $(Orn)_n$ as a function of concentration of $NaDecSO_4$ are presented in Fig. 2. As is seen, $(Orn)_n$ assumes a 100% β-structure in the $NaDecSO_4$ solutions of 5 to 9 mM. The data in this figure also show that the helical structure is assumed in two concentration ranges of $NaDecSO_4$; between 0.3 and 4 mM and above 9 mM $NaDecSO_4$. The $(Orn)_n$ assumes the helical structure also in two concentration ranges of $NaDodSO_4$.[12] However, higher concentrations of $NaDecSO_4$ were required than was the case with $NaDodSO_4$.[12] In the lower concentration range of $NaDodSO_4$, the polypeptide assumes an unstable helix. This unstable helix changes to β-structure within a matter of minutes.[12] The helical structure formed in the lower concentrations of $NaDecSO_4$ was also unstable, but not to the same extent; several hours were required for the change to the β-structure. The helical proportion was much lower in $NaDecSO_4$ than in $NaDodSO_4$; the proportion was less than 12 and 17% in the two $NaDecSO_4$ concentration ranges as seen in Fig. 2, whereas the maximal proportions of the unstable and the stable helical structures in $NaDodSO_4$ are 50 and 73% respectively.[12]

This difference between the helical proportions of $(Orn)_n$ formed in the two surfactant solutions must be necessarily due to the difference in the number of carbons in the hydrophobic portion of the two surfactants. As is seen in Fig. 1, the presence of slight amounts of octanol in 0.8 mM $NaDecSO_4$ greatly enhanced the double-minimum of the helical-type CD spectrum of $(Orn)_n$. The proportional changes in the three structures are plotted as a function of 1-octanol concentration in Fig. 3. The helical proportion increased to 46%, which is comparable with the maximal fraction of the unstabale helix in $NaDodSO_4$.[12] The increment of hydrophobicity due to 1-octanol (which probably leads to the formation of mixed micelle of $NaDecSO_4$ with 1-octanol) clearly correlates with the increase in helical proportion. The proportion of β-structure, however, was not affected by the addition of 1-octanol (Fig. 3). A similar increase in the helical proportion of $(Orn)_n$ was observed by the addition of 1-octanol to $NaDecSO_4$ solutions at other concentrations. For example, the addition of 2 mM 1-octanol increased helical proportion from 4 to 12% in 0.4 mM $NaDecSO_4$.

The positive charges in the side groups of $(Orn)_n$ or poly(L-lysine)[$(Lys)_n$] are generally considered to be eliminated by the electrostatic interaction with the hydrophilic groups of anionic surfactant ions such as alkyl sulfate ions.[4,7] The neutralization of the charges of polypeptide by the surfactant ions, however, is not enough to cause the formation of α-helix and β-structure, as is expected from the previous studies of the effect of the hydrocarbon chain length of a surfactant.[4,10,11] It is reasonable to speculate that the hydrocarbon chain may be involved in the formation of secondary structure in the surfactant-polypeptide complexes. Tseng and Yang have suggested that the hydrocarbon chains of surfactants bound to polypeptide might be juxstapositioned to other hydrocarbon chains of the excess surfactant molecules, thus forming a micelle-like structure.[7] In this regard, it is worth noting that the proportion of β-structure of $(Orn)_n$ reaches 100% in $NaDecSO_4$ as well as in $NaDodSO_4$.[12] $(Lys)_n$ also assumes 100% β-structure in $NaDodSO_4$.[13] In the antiparallel β-sheet structure, the polypeptide chains run in opposite directions, being hold together by hydrogen bonds of peptide linkage with the amino acid side groups alternatively sticking up and sticking down (see Fig. 6 in Ref. 16). This means that the alkyl sulfate ions bound to the side groups of β-structural polypeptide stretch out perpendicularly to both the polypeptide backbone and the hydrogen bonds. When such a β-sheet is formed, the alkyl chains of surfactants bound to the residues might stand close together on both sides of the sheet.

This might lead to the formation of the McBain lamellar micelle[17] with alkyl chains. These alkyl chains may belong to the excess surfactant molecules or to the surfactants bound to other β-structural polypeptides (or to other distant β-structural segments of the identical polypeptide). As mentioned above, when $(Orn)_n$ and $(Lys)_n$ predominantly assume the β-structure in these surfactant solutions, the solutions become slightly turbid. The turbidity might be due to the accumulation of the sheets through the formation of the lamellar micelle. On the other hand, when the polypeptide assumes the α-helical structure, the side groups of amino acids are considered to stretch out in every direction around the helical rod.[18] This feature suggests that alkyl sulfate ions bound to side groups of α-helical polypeptide might stretch out in every direction in a different manner from those bound to β-structural polypeptides. How these complexes assume the α-helical structure remains unknown.

Vapor Pressures of Diethyl, Diisopropyl, and Dibutyl Phthalates at Reduced Pressures

Hirotake KATAYAMA
Department of Mechanical Engineering, College of Engineering, Hosei University, Kajino-cho, Koganei, Tokyo 184
(Received January 26, 1988)

Synopsis. Vapor pressures of the three phthalates noted above were measured over the ranges 0.3—30, 0.3—10, and 0.3—9 kPa, respectively. The correlations of vapor pressures using the Cragoe equation with 4 constants give the percent root mean square deviations of 0.21, 0.33, and 0.28, respectively.

Few experimental data of vapor pressure for dialkyl phthalates have been published. Their accuracies are not good. Accordingly the vapor pressures of diethyl, diisopropyl, and dibutyl phthalates were measured over the ranges 0.3—30, 0.3—10, and 0.3—9 kPa, respectively. The results were checked by the Chebyshev polynomial[1] and the Cragoe,[2] Frost-Kalkwarf,[3] and Antoine[4] equations. The enthalpies of vaporization for the phthalates were also obtained from the slopes of the vapor pressure against the temperature (dP/dt).

Experimental

Special grade materials from Tokyo Kasei Co., Ltd., were used without further purification. The purity of each was determined by gas chromatographic analyses with a 3 mm I.D. and 2 m length column of 5% Silicone SE-52 on Celite. In all cases it exceeded 99%.

Table 1 shows the densities and refractive indices compared with published values.[5-8]

The experimental apparatus and procedure have already been described elsewhere.[9-11] The part of the equilibrium still unit with the Cottrell pump, which was of the vapor circulation type, was made of Pyrex glass. The measurement and the control of pressure were carried out with the Multi-Range Model 157/100 pressure standard from Texas Instruments Inc., which had a spiral quartz Bourdon guage and a servo controlled valve in a vacuum line. The accuracy of the gauge was ±0.002 kPa for 10—34 kPa range and ±0.001 kPa for 0.24—10 kPa. The variation of the pressure control on the operation was read from the attached deviation meter. It was found to be within ±0.00003 kPa for the 1—34 kPa, and within ±0.0004 kPa for the 0.3—1 kPa.

Four mercury thermometers with immersion lines marked at the 18 cm points from their bulb ends, i.e., the set of 40—100, 100—150, 150—200, and 200—250 °C graduations, were used for temperature measurements. They were calibrated at 5 °C intervals with accuracies of ±0.04 K by Watanabe Keiki Seisakusho Co., Ltd., Tokyo. The intermediate temperatures in the intervals were interpolated. After the circulation of vapor for one hour, no fluctuations of the thermometers were observed greater than 0.02 K.

Results and Discussion

The experimental results are presented in Table 2. The results are also plotted in Fig. 1 including a comparison with values from the literature.[5,12–18]

The Chebyshev polynomial,[1] and the Cragoe,[2] Frost-Kalkwarf,[3] and Antoine[4] equations were used to fit the results.

The Chebyshev polynomial is :

$$t\ln(P) = a_0/2 + \sum a_i E_i(X). \quad (1)$$

where P kPa, $t(=T-273.15)$°C, T K, $E_1(x)=x$, $E_2(x)=2x^2-1$, $E_i(x)=2xE_{i-1}(x)-E_{i-2}(x)$, and x is a function of temperature defined as

$$x = \frac{2T - (T_{max} + T_{min})}{T_{max} + T_{min}} \quad (2)$$

where T_{max} and T_{min} are the maximum and minimum temperatures of the related substances, respectively. The polynomial with 4 parameters is identical to the Cragoe equation.

The Cragoe equation is:

$$\ln(P) = A_c + B_c/t + C_c t + D_c t^2 \quad (3)$$

or

$$t\ln(P) = A_c t + B_c + C_c t^2 + D_c t^3. \quad (4)$$

The Frost-Kalkwarf equation is:

$$\ln(P) = A_f + B_f/t + C_f \ln t + D_f P/t^2 \quad (5)$$

or

$$t\ln(P) = A_f t + B_f + C_f t \ln t + D_f P/t. \quad (6)$$

The Antoine equation is:

$$\ln(P) = A_a - B_a/(t + C_a) \quad (7)$$

or

$$t\ln(P) = A_a t + D_a - C_a \ln(P) \quad (8)$$

where $D_a=A_aC_a-B_a$.

All the constants of the expressions mentioned above were determined by least-square fits of $t\ln(P)$.

The percent root mean square deviations of pressure (prms) using Cragoe, Frost-Kalkwarf, and Antoine equations were estimated as 0.21, 0.21, and 1.25 for diethyl phthalate, respectively; 0.33, 0.33, and 1.88 for diisopropyl phthalate, respectively; and 0.28, 0.30, and 2.14 for dibutyl phthalate, respectively.

The prms using the Chebyshev polynomial for diethyl phthalate were taken as 0.33 with 3 parameters, 0.21 with 4 parameters, 0,20 with 5 parameters, 0.15 with 6 and 7 parameters, 0.14 with 8 and 9 parameters, and 0.11 with 10 parameters. The prms of diisopropyl phthalate were 0.34 with 3 parameters, 0.30 with 4 and 5 parameters, 0.24 with 6 parameters, 0.13 with 7 parameters, and 0.12 with 8—10 parameters. The prms of dibutyl phthalate were 0.37 with 3 parameters, 0.28 with 4 parameters, 0.26 with 5 and 6 parameters, 0.25 with 7 parameters, 0.18 with 8 parameters, and 0.15 with 9 and 10 parameters.

Conversely the temperatures were calculated from the pressures by using the Cragoe, Frost-Kalkwarf, and Antoine equations. The mean temperature differences of the Cragoe, Frost-Kalkwarf, and Antoine equations with the experimental values were taken as 0.04, 0.04, and 0.28 K for diethyl phthalate, respectively; 0.07, 0.06, and 0.32 K for diisopropyl phthalate, respectively; and 0.06, 0.06, and 0.46 K for dibutyl phthalate, respectively.

The constants of the Cragoe and Frost-Kalkwarf equations are listed in Table 3. The constants of the Antoine equation are not listed, because they give large errors. Those of the Chebyshev polynomial are omitted, because the polynomial with 4 parameters gives satisfactory fits.

The enthalpies of vaporization, ΔH_v, were calculated from the Clapeyron equation via the slopes of the

The Cathodic Desulfonylation of 1-Ethoxycarbonyl- and 1-Cyano-1-(*p*-tolylsulfonyl)-2-phenylethenes at the Mercury Electrode in Nonaqueous Solvents

Akira KUNUGI* and Kyo ABE†

(Received March 25, 1988)

Synopsis. The cathodic reduction of 1-ethoxycarbonyl-1-(*p*-tolylsulfonyl)-2-phenylethene in MeCN and DMF is characterized by the selective elimination of the *p*-tolylsulfonyl group, resulting in the formation of ethyl (*E*)-cinnamate in good yields, in the presence of such efficient proton donors as benzoic acid and acetic acid. On the other hand, the cathodic desulfonylation of 1-cyano-1-(*p*-tolylsulfonyl)-2-phenylethene proceeds with low efficiencies, even in the presence of acetic acid and benzoic acid.

The cathodic desulfurization of organosulfur compounds has received considerable attention because most of them are valuable synthetic precursors. In general, α,β-unsaturated sulfides, sulfoxides, and sulfones are much more subject to cathodic desulfurization than to the hydrogenation of the double bond.[1-6] For example, the previous paper[6] showed that the cathodic reduction of 1-methylthio-1-(*p*-tolylsulfonyl)-2-arylethenes in nonaqueous solvents involves the selective cleavage of a carbon–sulfur bond, resulting in the formation of (*E*)-1-methylthio-2-arylethenes in moderate yields with the consumption of about 2 electrons per molecule, in the presence of such efficient proton donors as phenol and benzoic acid. The cathodic reduction of vinyl sulfones with the electron-withdrawing group at Position 1, such as the title compounds, 1-ethoxycarbonyl-1-(*p*-tolylsulfonyl)-2-phenylethene (**1**) and 1-cyano-1-(*p*-tolylsulfonyl)-2-phenylethene (**2**), is also of interest in connection with the reductive desulfonylation. Moreover, they may be expected to afford the corresponding desulfonylated compounds in a manner similar to the cathodic reduction of 1-methylthio-1-(*p*-tolylsulfonyl)-2-phenylethene.[6]

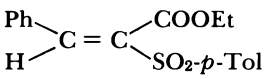
In the present work, the electrolytic reductions of **1** and **2** at a mercury electrode in nonaqueous media, such as acetonitrile (MeCN) and *N*,*N*-dimethylformamide (DMF), were studied by means of polarography, coulometry, and controlled-potential macroelectrolysis. The substrates, **1** and **2**, gave the corresponding desulfonylated compounds, (*E*)-ethyl cinnamate (**3**) and (*E*)-cinnamonitrile (**4**) respectively, but their yields were greatly dependent on the kind of electrolytic solution.

Experimental

The title compound, **1**, was synthesized by a condensation of benzaldehyde with ethyl (*p*-tolylsulfonyl)acetate according to a method described in the literature.[7] Ethyl (*p*-tolylsulfonyl)acetate was prepared starting from ethyl bromoacetate and sodium *p*-toluenesulfinate according to the published method:[8]

$$BrCH_2COOEt + p\text{-}TolSO_2Na \xrightarrow[\text{in DMF}]{} EtOOCCH_2SO_2\text{-}p\text{-}Tol$$

$$EtOOCCH_2SO_2\text{-}p\text{-}Tol + PhCHO \xrightarrow[\text{in benzene}]{\text{Piperidine}}$$

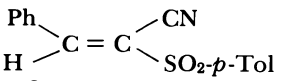


1

Similarly, **2** was synthesized from benzaldehyde and (*p*-tolylsulfonyl)acetonitrile,[7] which had itself been prepared starting from chloroacetonitrile and sodium *p*-toluenesulfinate according to the published method:[8]

$$ClCH_2CN + p\text{-}TolSO_2Na \xrightarrow[\text{in EtOH}]{} NCCH_2SO_2\text{-}p\text{-}Tol$$

$$NCCH_2SO_2\text{-}p\text{-}Tol + PhCHO \xrightarrow[\text{in DMF}]{\text{Triton B}}$$



2

The substrates, **1** and **2**, were purified by recrystallization from a benzene–hexane mixture and from ethanol respectively; they were identified by means of their ^{1}H NMR spectra.

The nonaqueous acetonitrile solutions were prepared from predeoxygenated MeCN and tetrabutylammonium tetrafluoroborate (TBAB) or tetrabutylammonium perchlorate (TBAP), which had been purified and dried as has been described previously.[4] The nonaqueous *N*,*N*-dimethylformamide solutions were similarly prepared from the predeoxygenated DMF and TBAB or TBAP. DMF was purified in a manner similar to that described in the literature.[9] The concentration of the supporting electrolyte was 0.1 mol dm^{-3}. The phenol, acetic acid, and benzoic acid used as proton donors were purified by means of distillation or sublimation.

A Ag/0.1 mol dm^{-3} $AgNO_3$ in MeCN reference electrode (Ag/Ag^+) and a Ag/AgI, 0.1 mol dm^{-3} TBAI in DMF reference electrode (Ag/AgI) were used respectively, depending on the kind of solvent used. Polarography, coulometry, and controlled potential macroelectrolysis were carried out, using the same experimental set-up and procedure as were reported in the previous paper.[6]

Results and Discussion

Polarography. The influence of the proton donor on the dc polarograms of **1** and **2** at a dropping mercury electrode was examined in MeCN/TBAP and DMF/TBAP. Phenol, acetic acid, and benzoic acid were used as the proton donors. Among the media studied, the strongest influence on the polarogram was observed in the medium of MeCN/benzoic acid. Table 1 summarizes the half-wave potential ($E_{1/2}$) and the wave height (i_d) of the first reduction wave in various electrolytic solutions. As may be seen from Table 1, there is some difference among the proton donors used with respect to the influence of the proton donor on $E_{1/2}$ and i_d. That is, the $E_{1/2}$ of the first wave of **1** in MeCN was shifted to more positive values by the addition of acetic acid or benzoic acid, but $E_{1/2}$ in DMF was not changed. On the other hand, the $E_{1/2}$ of **2** was not influenced, not even in the medium of MeCN/benzoic acid. The influence of the proton donor on i_d was also observed; these results are also presented in Table 1.

Macroelectrolysis. A series of controlled potential macroelectrolyses of **1** and **2** at each plateau potential of the first reduction wave were carried out at the stirred mercury pool electrode in MeCN/TBAB and DMF/TBAB in the absence and in the presence of proton donors at room temperature. The results are summarized in Table 2. The coulometric n-values (electrons per molecule) were obtained from the amount of the substrate added and the quantity of electricity passed through before the termination of the electrolysis. Table 2 shows that the substrate with the COOEt group, **1**, affords the desulfonylated compound, **3**, and methyl p-tolyl sulfone (**5**) in good yields, in MeCN and DMF containing excess acetic acid and benzoic acid, whereas the yields of **3** and **5** were low in the absence of the proton donor and even

		Benzoic acid (4.0)	1.1	**4** (8)	**5** (Trace)

a) **3**:  , **4**:  , **5**: p-TolSO$_2$Me.

in the presence of excess phenol. **5** was obtained as a product by a CH_3I methylation of the *p*-toluenesulfonyl anion formed upon electrolysis. It is worth noting that phenol is an effective proton donor in the cathodic desulfonylation of 1-methylsulfonyl-1-methylthio-2-phenylethene in both MeCN and DMF, but not in the case of **1**.

On the other hand, the electrolytic reduction of **2** afforded the desulfonylated compounds, **4** and **5**, in low yields, even in the presence of acetic acid. The yields of **4** and **5**, although still low, were increased to 29 and 22% respectively in the medium of MeCN/benzoic acid. Even though **2** was easier to reduce than **1**, the cathodic desulfonylation proceeded with a low efficiency compared with **1**. This seems to be not because the desulfonylated compound is subject to further reduction, but because the polymerization of a reduction intermediate of **2** proceeds in preference to the desulfonylation, although the polymeric products could not be characterized. This is supported by the evidence that coulometric *n*-values are low and that **4** is not easier to reduce than **2**. The stereochemical structures of **3** and **4** was determined on the basis of the NMR spectra of their olefinic protons. A perusal of the NMR spectra of the reaction mixtures indicated no formation of (*Z*)-isomers of **3** and **4** in any experiment.

The combination of Tables 1 and 2 indicates that the proton donor causing an increase in i_d by its addition has a tendency to bring about the cathodic desulfonylation with a high efficiency.

Electrical Properties of the Organic Conductor, (BEDT-TTF)$_3$(ClO$_4$)$_2$

Kenichi IMAEDA,* Toshiaki ENOKI,† Gunzi SAITO,†† and Hiroo INOKUCHI
Institute for Molecular Science, Okazaki 444
††The Institute for Solid State Physics, The University of Tokyo,
Roppongi, Minato-ku, Tokyo 106
(Received April 16, 1988)

Synopsis. Electrical conductivity and thermoelectric power have been measured for (BEDT-TTF)$_3$(ClO$_4$)$_2$. The electrical conduction is two-dimensional in the bc plane. The metal–insulator transition temperature is lowered by pressure at a rate of -8 K kbar^{-1}. The negligible thermopower at high-temperatures indicates that (BEDT-TTF)$_3$(ClO$_4$)$_2$ is the system with large on-site Coulomb repulsion.

Since our presentation on a two-dimensional metallic conductivity for (BEDT-TTF)$_2$ClO$_4$(C$_2$H$_3$Cl$_3$)$_{0.5}$ (BEDT-TTF: bis(ethylenedithio)tetrathiafulvalene),[1] BEDT-TTF radical salts have been actively investigated because they show a polymorphism and novel electronic properties due to the thermal vibrations of the ethylene groups. Interestingly, β-(BEDT-TTF)$_2$I$_3$ became a superconductor near 8 K.[2,3] Recently, Urayama et al. found a superconductivity at 10.4 K under ambient pressure in (BEDT-TTF)$_2$Cu(NCS)$_2$.[4] This transition temperature is the highest among organic superconductors hitherto known.

There are two crystalline phases in (BEDT-TTF)–ClO$_4$ salts, (BEDT-TTF)$_2$ClO$_4$(C$_2$H$_3$Cl$_3$)$_{0.5}$ and (BEDT-TTF)$_3$(ClO$_4$)$_2$. The former remaines metallic down to 0.8 K for a rapid cooling, while it shows a nesting transition at 25 K for a slow cooling, which is associated with the ordering of the C$_2$H$_3$Cl$_3$ molecules.[5,6] On the other hand, the latter shows a metal–insulator transition around 170 K.[7] As to (BEDT-TTF)$_3$(ClO$_4$)$_2$, the structural analysis presents that the BEDT-TTF molecules form a two-dimensional network with the face-to-face stacks along the [0$\bar{1}$1] direction and the side-by-side arrangements along not only the [012] direction but also the [021] direction.[7,8] The band calculation suggests the semimetallic band structure and the two-dimensional intermolecular interactions with a small anisotropy of transfer integral (t[012]/t[021]$\approx$3).[8] The polarized reflectance measurement gives the two-dimensional optical spectra.[9] ESR studies also suggest the two-dimensionality with large linewidth.[5] In this note, we report the experimental results of the anisotropy and pressure effect of electrical conductivity, and thermoelectric power for (BEDT-TTF)$_3$(ClO$_4$)$_2$.

Experimental

The black thin plate crystals of (BEDT-TTF)$_3$(ClO$_4$)$_2$ were prepared in C$_2$H$_3$Cl$_3$ solvent by a standard electrochemical technique. The anisotropy of electrical conductivity in the bc plane (see Ref. 7 for the definition of the crystal axes) was measured with a Montgomery method. Electrical conductivity under pressure up to 10 kbar along the c-axis was measured by a four-probe method in a BeCu clamp cell using Idemitsu Daphne oil #7373 as a pressure medium liquid. The pressure at room temperature was monitored with a manganin sensor. Thermoelectric power along the c-axis was measured with the method described by Chaikin and Kwak.[10]

Results and Discussion

Figure 1 shows the result of the anisotropy of the resistivity. The small anisotropy ($\rho_b/\rho_c\approx2$) at room temperature means that electrical conduction is two-dimensional in the bc plane, which is consistent with the results of X-ray analysis, band calculation, optical and ESR experiments. ρ_b/ρ_c is entirely independent of temperature in the metallic region. Below the metal–insulator (M–I) transition at 172 K, ρ_b/ρ_c increases gradually and then increases abruptly below 110 K. The ESR study has presented that the g-value for the applied field parallel to the b′-axis changes from 2.002 to 2.006 below the metal–insulator transition temperature (T_{MI}).[5] The shift of $g_{b'}$ suggests the displacement of the BEDT-TTF molecules. Therefore, the increase of ρ_b below T_{MI} is considered to be associated with such a displacement unfavorable for electron transport along the b direction.

Figure 2 shows the result of the thermoelectric power S. The value of S is almost zero in the high-temperature region. Then, S falls off sharply below 172 K. The thermopower for intrinsic semiconductors depends on temperature with the relation of $S\propto-(k/|e|)((b-1)/(b+1))(E_g/2kT)$, where b is mobility ratio μ_e/μ_h between electron and hole carriers and E_g is

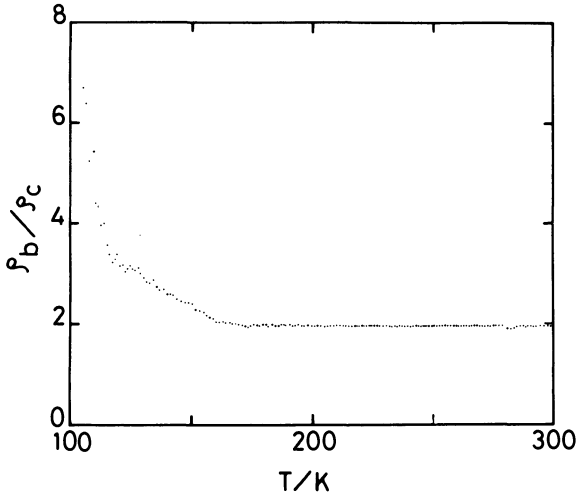

Fig. 1. Temperature dependence of the anisotropy ρ_b/ρ_c of the resistivity.

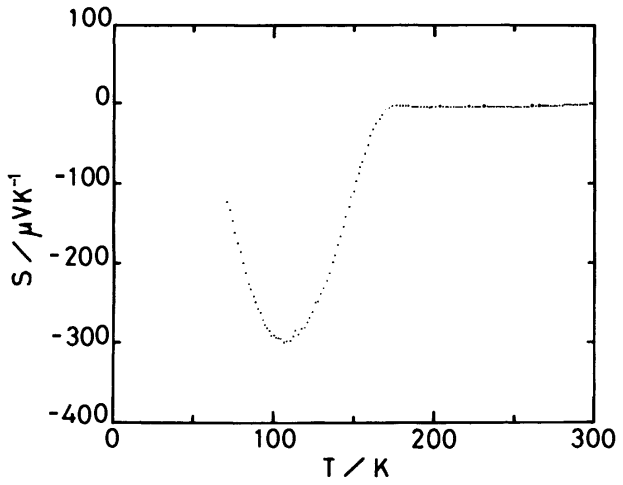

Fig. 2. Temperature dependence of the thermoelectric power.

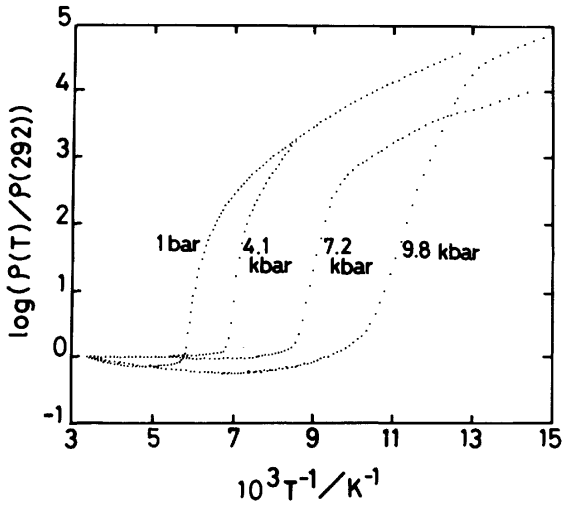

Fig. 3. Temperature dependence of the resistivities under 1 bar, 4.1 kbar, 7.2 kbar, and 9.8 kbar.

the energy band gap. The decrease proportional to T^{-1} below 172 K suggests that the M-I transition takes place at this temperature, which is just the same to T_{MI} observed in the resistivity. The constant thermopower in the metallic region and the sharp decrease below T_{MI} resemble those of α-(BEDT-TTF)$_2$I$_3$[11] and (BEDT-TTF)$_2$PF$_6$.[12] In the semiconducting region, S shows a minimum around 110 K with a large value of -300 μV K^{-1} and increases again with lowering temperature. The sign of the slope in the plot between S and T^{-1} depends on the magnitude of b (μ_e/μ_h). The negative slope above 110 K means that $b>1$, namely $\mu_e>\mu_h$, while the positive slope below 110 K means $\mu_e<\mu_h$. Therefore, the anomaly at 110 K, which corresponds to the temperature with a rapid increase in the anisotropy ρ_b/ρ_c, is considered to be caused by a some modulation in the electronic structure associated with the change in the magnitude of the mobility between electron and hole carriers.

Next, we present the result of the pressure effect on the M-I transition. Figure 3 shows the temperature

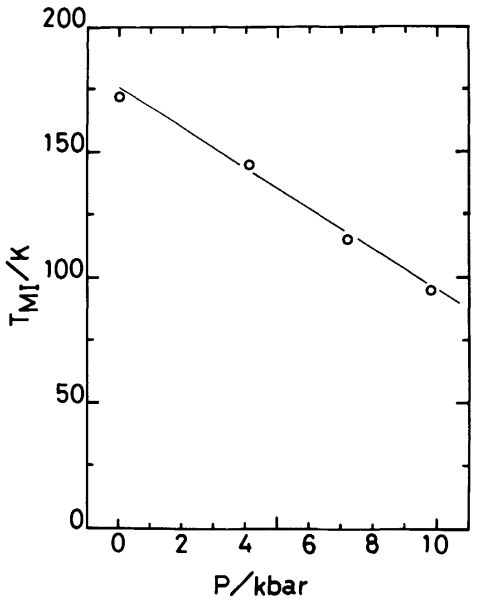

Fig. 4. Pressure dependence of the metal-insulator transition temperature (T_{MI}). The solid line corresponds to $dT_{MI}/dP=-8$ K kbar^{-1}.

dependence of the resistivities under several pressures. As the different samples are employed due to thin fragile crystals, the resistivity behaviors in the metallic region are somewhat different for each pressure. The M-I transition is suppressed as the pressure is increased. T_{MI} was determined to be the temperature with the maximum of $-d\log\rho/dT$. Figure 4 shows the correlation between T_{MI} and pressure. T_{MI} is lowered linearly with pressure at a rate of -8 K kbar^{-1}. This rate is approximately the same as those of other BEDT-TTF salts; $dT_{MI}/dP=-10$ K kbar^{-1} for (BEDT-TTF)$_2$ReO$_4$[13] and -11 K kbar^{-1} for α-(BEDT-TTF)$_2$I$_3$.[14] (BEDT-TTF)$_3$(ClO$_4$)$_2$ is expected to become a metal above ca. 22 kbar corresponding to the pressure at which T_{MI} is extrapolated to zero.

Finally, we mention the evidence of strong on-site Coulomb repulsion in the (BEDT-TTF)$_3$(ClO$_4$)$_2$ system. The thermopower in the high-temperature limit for a system with a strong on-site Coulomb repulsion U can be given by the following equation, according to the statistical-mechanical treatment by Chaikin and Beni;[15]

$$S=-\frac{k}{|e|}\ln(2(1-\gamma)/\gamma),$$

where γ is the degree of charge transfer. We obtain $S=0$ from the above equation using $\gamma=2/3$. The complete agreement of the magnitude of S with the experimental result suggests the importance of electron-electron Coulomb interactions in the present system. This fact is in good accordance with the result by Parkin et al.[16] They have reported that the spin susceptibility of (BEDT-TTF)$_3$(ClO$_4$)$_2$ is enhanced by Coulomb interactions beyond the Pauli paramagnetism expected for noninteracting electrons with $4t_{//}=0.75$ eV and U is estimated to be 3—4 eV according to the formalism presented by Torrance et al. for

$U \gg 4t$.[17]

The authors wish to thank Dr. Koichi Kikuchi of Tokyo Metropolitan University and Dr. Keizo Murata of Electrotechnical Laboratory for their advices about the conductivity measurement under pressure.

(Received April 30, 1988)

Synopsis. The reaction mechanism for photosensitized reduction of methylviologen, MV^{2+} through the triplet-triplet energy transfer from organic dyes to 9-anthracenecarboxylate, AC^- was investigated. From the kinetic analysis on MV^{+} formation, it was estimated that both efficiencies of the energy transfer and of the electron transfer from $^3AC^-$ to MV^{2+} were close to unity.

The mechanistic investigation of highly efficient photosensitized reactions has been required for the utilization of light energy and the application to the optical devices in technology. As for the ideal sensitizer in the reaction, there are three requirments; (a) a light absorption in the wide range of wavelength, (b) an efficient utilization of absorbed light energy and (c) the complete turnover of the light absorber. We have investigated the mechanism of electron-transfer reaction for sensitized formation of methylviologen radical by xanthene dyes, where the initial process is started through electron transfer from triplet dyes, ^{3}Dye to MV^{2+}. This is followed by electron transfer to the resulting semioxidized dyes from triethanolamine, TEOA (oxidation-cycle mechanism for three component system of Dye/MV^{2+}/TEOA).[1,2] The maximum yields for MV^{+} formation were equal to 0.16 and 0.045 in case of Eosine Y, $C_{20}H_6O_5Br_4Na_2$ and Erythrosine, Ery, $C_{20}H_6O_5I_4Na_2$ as the sensitizer, respectively. Although this sensitized reaction satisfied the requirement (c), much higher yield was expected by the excitation in the range of visible wavelength, i.e., requirements (a) and (b). In the present paper, attention is focused on the achievement of all requirements of (a)—(c) for the sensitized reaction mentioned above.

Experimental

Materials. Fluorescein, Eosine Y, Erythrosine, Proflavine and Acriflavine were recrystallized three times from ethanol. Methylviologen (Nakarai,G.R.) and triethanolamine (Tokyo kasei,G.R.) were used as received. Each sample was degassed by bubbling argon gas (99.9%) for at least 30 min or by repeating freezing and evacuation 5—7 times under vacuum.

Procedures. A degassed sample in a cell (1 cm×1 cm×4 cm) was irradiated at 25 °C in a steady-light illumination apparatus with a 300 W tungsten lamp. The quantum yield of MV^{+} formation was determined by the conventional actinometry using Eosine Y or potassium ferrioxalate solution.[2,3] Laser flash photolysis was carried out by using a pulsed dye laser (Phase R, 2100B; dye G4: excitation 500 nm and dye B1: excitation 440 nm; FWHM of pulse: 500 ns) and a usual monitoring system composed of a light source, a monochromator, and a transient recorder.

Results and Discussion

Using AC^- as a sensitizer instead of xanthene dyes, the steady light irradiation to three component system of AC^-/MV^{2+}/TEOA was carried out. The dependence of the quantum yield of MV^{+} formation, Φ^A on MV^{2+} concentration is shown in Fig. 1.
The maximum value of 0.9±0.1 was obtained at MV^{2+} concentration of ca. 1 mM (1 M=1 mol dm^{-3}) in aqueous solution (pH=8.3) and there was no decomposition of AC^- during the irradiation. Although the competitive reactions of $^3AC^-$ with MV^{2+} or with TEOA were considered, the decay rate of $^3AC^-$ was not affected by an addition of 3 mM TEOA in a laser-flash experiment. On the other hand, the rate constant of $^3AC^-$ reacting with MV^{2+} was obtained as 3.1×10^9 M^{-1} s^{-1}. Thus, at the concentrations of MV^{2+} in Fig. 1, the initial process occurred by the electron transfer from $^3AC^-$ to MV^{2+}, which leads to formation of MV^{+} and AC· followed by the electron transfer from TEOA (the oxidation cycle mechanism). The kinetical treatment for Φ^A could be performed in a similar manner to that reported in the case of Dye/MV^{2+}/TEOA system, since the linear relationships between $1/\Phi^A$ and $1/[MV^{2+}]$, and between $1/\Phi^A$ and 1/[TEOA] were held, respectively.[2] Then, Φ^A can be written in the following equation:

$$\Phi^A = \phi_{st}{}^A \frac{\alpha_2 k_{qA}^{r}[MV^{2+}]}{k_{dA} + k_{qA}[MV^{2+}]} \frac{k_2'[TEOA]}{k_2 + k_2'[TEOA]} \quad (1)$$

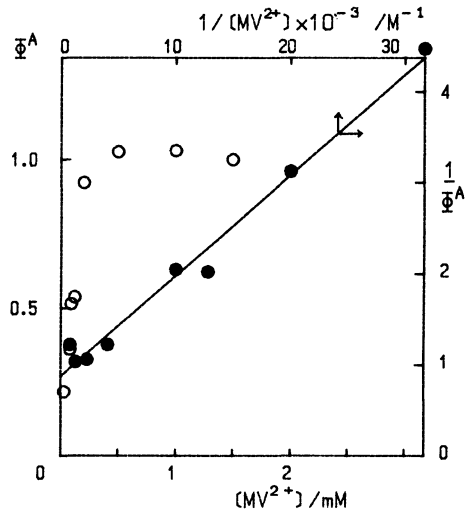

Fig. 1. MV^{2+} concentration effect on the quantum yield of MV^{+} formation, Φ^A. [AC^-]: 75 μM; [TEOA]: 3 μM; pH=8.5; μ=0.03.

where α_2 represents the formation efficiency of $MV^{+\cdot}$. k_{dA}, k^r_{qA} (k_{qA}), k_2 and k_2' are the rate constants for $^3AC^-$ decay, for the genuine (and total) reaction between $^3AC^-$ and MV^{2+}, for AC· decomposition and for the electron transfer reaction between AC· and TEOA, respectively. Maximum value of Φ^A was close to the values of an intersystem crossing probability to $^3AC^-$, ϕ_{st}^A. From the fact, it seems that the electron transfer from $^3AC^-$ to MV^{2+} occurred without any deactivation i.e., $k^r_{qA}=k_{qA}$ and that the production efficiency of radicals of $MV^{+\cdot}$ and AC· separated from its radical pair complex was unity, approximately i.e., $\alpha_2=1$.[4] The reaction system of AC^-/MV^{2+}/TEOA satisfies requirements, (b) and (c).

In order to achieve the requirement, (a), it is very useful to introduce the concept of an energy transfer from organic dyes. Many studies about triplet-triplet energy transfer have been carried out. Concerning the present system, the kinetical investigations on energy transfer from the triplet dyes to several anthracene derivatives have been reported.[5-7] The quantum yield of $MV^{+\cdot}$ formation through the energy transfer, Φ^T on

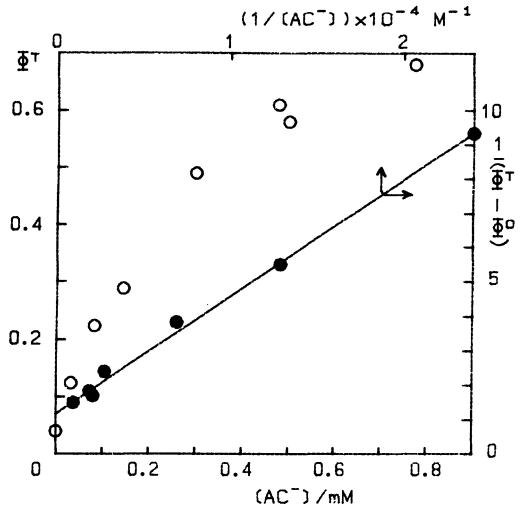

Fig. 2. AC^- concentration effect on the quantum yield of $MV^{+\cdot}$ formation through the energy transfer from $^3Ery^{2-}$ to AC^-, Φ^T. [Ery^{2-}]: 5 μM; [MV^{2+}]: 0.1 mM; [TEOA]: 3 mM; pH=8.5; μ=0.1.

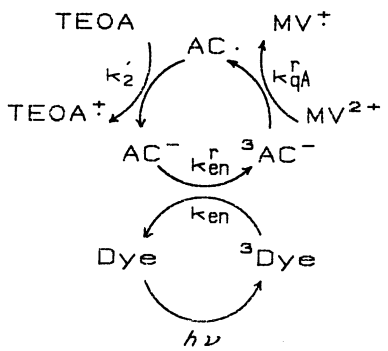

Fig. 3. The proposed reaction scheme for the sensitized reduction of MV^{2+} through the energy transfer from triplet dyes to AC^-.

four-component system of Dye/AC^-/MV^{2+}/TEOA by steady-light illumination increased both with MV^{2+} concentration and with AC^- concentration. For the AC^- concentration effect, an effective enhancement in about 16-fold on Φ^T was observed by the addition of 0.78 mM AC^- using Erythrosine as a sensitizer. The results on Φ^T are shown in Fig. 2 (Sens: Ery). The essential mechanism in Fig. 3 can be proposed which is applicable to the present system by referring to the results in Figs. 1 and 2. Depending on the concentrations of MV^{2+} and AC^-, the electron transfer from triplet dyes to MV^{2+} competes with the energy transfer.[1,2] Therefore, the quantum yield of free radical formation of $MV^{+\cdot}$ is given as follows:

$$\Phi^T = \phi_{st}^D \frac{1}{k_{dd} + k_q[MV^{2+}] + k_{en}[AC^-]} \left(\gamma_1 k^r_q[MV^{2+}] + \gamma_2 \frac{k^r_{qA}[MV^{2+}]}{k_{dA} + k_{qA}[MV^{2+}]} k^r_{en}[AC^-]\right) \quad (2)$$

and

$$\gamma_1 = \alpha_1 k_1'[TEOA]/(k_1 + k_1'[TEOA])$$

$$\gamma_2 = \alpha_2 k_2'[TEOA]/(k_2 + k_2'[TEOA])$$

where γ_1 and γ_2 refer to the reaction efficiency through the processes of dye-sensitized electron transfer and to that through the process of AC^- sensitized one, respectively. ϕ_{st}^D represents the intersystem crossing probability of dye. k_{dd}, k^r_q(k_q), k^r_{en} (k_{en}), k_1 and k_1' are the rate constants for ^{3}Dye decay, for the genuine (and total) reaction of electron transfer between ^{3}Dye and MV^{2+}, for the genuine (and total) reaction of energy transfer from ^{3}Dye to AC^-, for $Dye^{+\cdot}$ decomposition and for the electron transfer reaction between $Dye^{+\cdot}$ and TEOA, respectively. Putting Φ^T at $[AC^-]=0$ as Φ^0, the approximate equation, Eq. 3, is obtained under the condition of $k_{dd} \ll k_q[MV^{2+}]$, $k_{en}[AC^-]$ and $k_{dA} \ll k_{qA}[MV^{2+}]$ in Eq. 2:

$$\Phi^T - \Phi^0 = \phi_{st}^D \frac{(\gamma_2 k^r_{en} k^r_{qA}/k_{qA} - \gamma_1 k_{en} k^r_q/k_q)[AC^-]}{k_q[MV^{2+}] + k_{en}[AC^-]} \quad (3)$$

The linear relationship between $1/(\Phi^T - \Phi^0)$ and $1/[AC^-]$ is obtained as shown in Fig. 2. The values of interception are 1.7 and 1.1 for Eosine Y (ϕ_{st}^D=0.64) and Erythrosine ($\phi_{st}^D \approx 1$) sensitization, respectively. Since the interception equals to the value of $1/\phi_{st}^D$, the relation of $k^r_{en}=k_{en}$ is suggested. This means that the

Table 1. Maximum Quantum Yield of $MV^{+\cdot}$ Formation (Φ^T_{max}) through the Energy Transfer from Dyes to AC^- and the Rate Constants of the Energy Transfer (k_{en})

Dyes(concentration/μM)	Φ^T_{max}	$k_{en}/M^{-1}s^{-1}$
Fluorescein(10)	0.045	4.5×10^9
Eosine Y(10)	0.55	4.7×10^9
Erythrosine(10)	0.77	3.2×10^9
Proflavine(22)	0.23	2.7×10^9
Acriflavine(17)	0.28	7.4×10^9

energy transfer from triplet dye to AC^- occurs without any deactivation as is shown in Fig. 3.

Under the higher concentrations of AC^-, the following approximate equation can be derived from Eq. 2 and the effect of MV^{2+} concentration on Φ^T is analyzed.

$$\Phi^T = \phi_{st}^D \frac{k_{en}^r}{k_{en}} \frac{k_{qA}^r[MV^{2+}]}{k_{dA} + k_{qA}[MV^{2+}]} \quad (4)$$

From the interception of linear relationship between $1/\Phi^T$ and $1/[MV^{2+}]$, k_{en}^r/k_{en} values was also estimated to be unity using ϕ_{st}^D value of sensitizer. This result coincides with the fact ($k_{en}^r = k_{en}$) obtained from AC^- concentration effect on Φ^T.

Using xanthene dyes and acridine dyes as energy donors, the observed values of maximum yield of Φ^T_{max} and the values of the rate constant, k_{en} are summarised in Table 1. These reaction systems of Dye/AC^-/MV^{2+}/TEOA satisfy all requirements of (a), (b), and (c) since a light absorption extends in the range of wavelength from 370 nm to 550 nm.

Photochemical Generation of μ-Amido-μ-peroxo-bis[bis(ethylenediamine)-cobalt(III)] Complex from the Corresponding μ-Hyperoxo Complex in Neutral Aqueous Solution

Nobuyoshi SHINOHARA,* Emiko KOSE, and Wataru OHKUBO
Department of Chemistry, Yokohama City University,
Seto, Kanazawa-ku, Yokohama 236
(Received October 20, 1987)

Synopsis. A μ-amido-μ-hyperoxo complex, $[(en)_2Co(NH_2,O_2^-)Co(en)_2]^{4+}$, was found to generate the corresponding μ-peroxo complex, together with mononuclear cobalt(III) complexes upon irradiation with near-ultraviolet light in a neutral aqueous solution. The result is different from that obtained in an acidic aqueous solution, in which the products are $[Co(NH_3)(en)_2(H_2O)]^{3+}$ and Co_{aq}^{2+}. The photochemical reaction mechanisms are discussed.

The photosensitivity of the μ-hyperoxo-bis[pentaamminecobalt(III)] complex, $[(NH_3)_5Co(O_2^-)Co(NH_3)_5]^{5+}$, first observed by Sykes,[1] has been investigated by Barnes, et al.,[2] and by Valentine and Valentine.[3-5] The μ-hyperoxo cobalt(III) complexes are photosensitive, and photodecomposition occurs upon irradiation with near-ultraviolet light (i.e. light with wavelengths longer than 300 nm).

Photochemical reactions of μ-amido-μ-hyperoxo-bis[bis(ethylenediamine)cobalt(III)] complex, $[(en)_2Co(NH_2,O_2^-)Co(en)_2]^{4+}$, in acidic aqueous solutions were studied by Valentine and Valentine,[4] who established the stoichiometry of the reactions as follows:

$$[(en)_2Co(NH_2,\ O_2^-)Co(en)_2]^{4+} \xrightarrow[H^+,\ H_2O]{h\nu(>300\ nm)} cis\text{-}[Co(NH_3)(en)_2(H_2O)]^{3+} + O_2 + Co^{2+} + 2enH_2^{2+} \quad (1)$$

We have studied the photochemistry of the same complex in a neutral aqueous solution, and found that the corresponding μ-peroxo cobalt(III) complex is formed together with mononuclear cobalt(III) complexes, which is different from the result obtained in an acidic aqueous solution.

Experimental

$[(en)_2Co(NH_2,O_2^-)Co(en)_2](ClO_4)_4$ and $[(en)_2Co(NH_2,O_2^{2-})Co(en)_2](NO_3)_3\cdot 2.5H_2O$ were obtained by methods described in the literature,[4,6] and recrystallized. The deaerations of the solutions used for photolysis were carried out by bubbling with pure nitrogen. A sample solution containing the μ-amido-μ-hyperoxo complex was irradiated continuously in a 1-cm quartz cell using a high-pressure mercury lamp, UM-102 (100 W), or an ultrahigh-pressure mercury lamp, USH-500D (500 W) (Ushio Electric Co.), at room temperature. Monochromatic light (313, 365, and 436 nm) was obtained by a combination of solution and glass filters. The absorption spectra were recorded on a Shimadzu MPS-2000 spectrophotometer.

For investigating the reaction products, about 20 ml of the solution in a fused silica cell was irradiated with light. The number of components of the photochemical decomposition products and their identities were determined by spectrophotometric analyses of the photolyzed solutions and by ion-exchange chromatography on a cation-exchange resin (CM-Sephadex C-25 in the sodium form). A portion of the irradiated solution was passed through a cation-exchange column. The absorbed band was eluted with 1.2 mol dm^{-3} sodium perchlorate solution. The first group eluted consisted of two mononuclear complexes which could not be separated from each other for the acid-base equilibria in a neutral aqueous solution as described later. After removing mononuclear complexes, μ-peroxo and μ-hyperoxo complexes were successively eluted in this order. Another portion of the irradiated solution was passed through a column for the separation of two mononuclear complexes. The absorbed band was eluted with a 0.01 mol dm^{-3} sodium hydroxide solution containing 0.3 mol dm^{-3} sodium perchlorate. The first two bands corresponded to mononuclear complexes, *cis*-$[Co(OH)_2(en)_2]^+$ and *cis*-$[Co(OH)(NH_3)(en)_2]^{2+}$. The μ-peroxo complex was identified by comparing the absorption spectrum with that of an authentic sample synthesized by a method described in the literature.[6] The mononuclear products were identified spectrophotometrically.[7,8] Oxygen was determined by gas chromatography.

Results and Discussion

The absorption spectrum of $[(en)_2Co(NH_2,O_2^-)Co(en)_2]^{4+}$ in an aqueous solution has two peaks (466 and 686 nm) in visible region. The electronic structure was studied by Lever and Gray.[9] The absorption spectral changes are shown in Fig. 1 for irradiation of the deaerated aqueous solution at the $O_2^-\rightarrow Co(III)$ charge-transfer band (351 nm). The absorption at 466 and 686 nm decreased with an increase in the irradiation time. Valentine and Valentine[4] proposed Eq. 1 in order to account for the photodecomposition reaction by determining the photolyzed products chromatographically. We can suggest that more

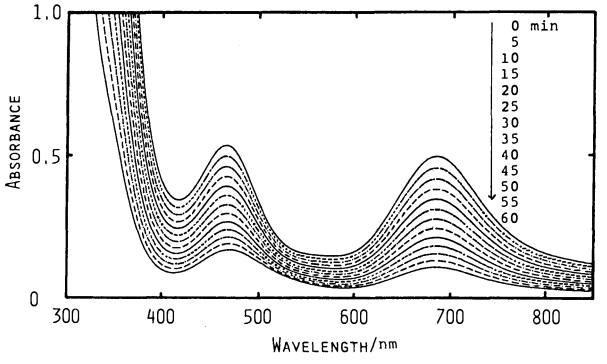

Fig. 1. Absorption spectral changes of 1.00×10^{-3} mol dm^{-3} $[(en)_2Co(NH_2,\ O_2^-)Co(en)]^{4+}$ in deaerated aqueous solution of 0.1 mol dm^{-3} $HClO_4$ upon irradiation at 365 nm light.

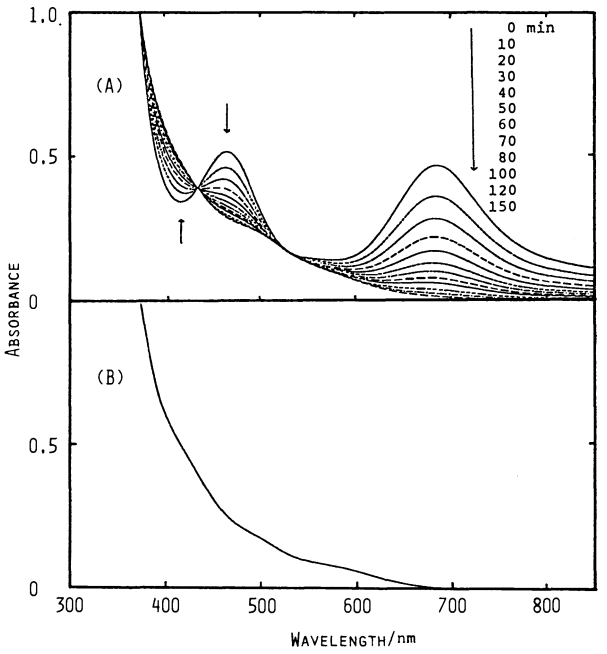

Fig. 2. UV and visible absorption spectra.
A: Absorption spectrtal changes of 1.00×10^{-3} mol dm^{-3} $[(en)_2Co(NH_2, O_2^-)Co(en)_2]^{4+}$ upon irradiation of the neutral deaerated solution at 365 nm light.

detailed photodecomposition reactions in aqueous solutions are as follows. In the excited state that can be formulated as $*[(en)_2Co(III)(NH_2,O_2^0)Co(II)(en)_2]^{4+}$, the oxygen molecule should be released by a kinetically labile Co(II) species (Eq. 2), which then undergoes a very rapid aquation leading to the Co_{aq}^{2+} (Eq. 3) in an acidic aqueous solution. Since

$$[(en)_2Co(NH_2, O_2^-)Co(en)_2]^{4+} \xrightarrow{h\nu} *[(en)_2Co(NH_2, O_2^0)Co(en)_2]^{4+} \xrightarrow{H_2O} cis\text{-}[Co(OH)(NH_3)(en)_2]^{2+} + cis\text{-}[Co(en)_2(H_2O)_2]^{2+} + O_2 \quad (2)$$

$$cis\text{-}[Co(en)_2(H_2O)_2]^{2+} \xrightarrow{H^+} Co^{2+} + 2enH_2^{2+} + 2H_2O \quad (3)$$

the ligand dissociation reaction in Co(II)–polyamine complexes becomes slower as the pH is increased,[10,11] it appears that $[Co(en)_2(H_2O)_2]^{2+}$ reacts with μ-hyperoxo complex before the dissociation in neutral solution as stated below.

When the μ-amido-μ-hyperoxo complex was irradiated with light at 365 nm in a neutral aqueous solution, the absorption changes were different from those obtained in acidic aqueous solutions, as shown in Fig. 2A. The intensity of the absorption in the 432—850 nm range decreased with an isosbestic point at 432 nm. The absorbance at 686 nm disappeared after 150 min irradiation with a high-pressure mercury lamp under our experimental conditions. The spectrum in Fig. 2A changed with the irradiation time and approached a final form, which was very similar to the spectrum of the corresponding μ-peroxo complex (Fig. 2B). Similar results were obtained for 313 and 436 nm irradiation. Such an attainment of the limiting spectrum is due to the inertness of the resulting μ-peroxo complex, compared to the photosensitive μ-hyperoxo complex, upon irradiation in the range of the wavelength examined. The decomposition reaction was independent of the presence or absence of dissolved oxygen.

The number of components and their identities were determined by spectrophotometric analyses of photolyzed solutions and by ion-exchange chromatography. It was found that μ-amido-μ-peroxo complex and two kinds of mononuclear complexes could be generated in neutral solutions. The photodecomposition of μ-hyperoxo complex is also accompanied by the generation of oxygen. Accordingly, we concluded that Eq. 4 describes the stoichiometry for the photochemical decomposition of μ-amido-μ-hyperoxo complex in a neutral aqueous solution.

$$2[(en)_2Co(NH_2, O_2^-)Co(en)_2]^{4+} + 3H_2O \xrightarrow{h\nu} [(en)_2Co(NH_2, O_2^{2-})Co(en)_2]^{3+} + cis\text{-}[Co(OH)(NH_3)(en)_2]^{2+} + cis\text{-}[Co(OH)(en)_2(H_2O)]^{2+} + O_2 + H^+ \quad (4)$$

The resulting mononuclear hydroxo complexes in Eq. 4 are in equilibria with aqua complexes, *cis*-$[Co(NH_3)(en)_2(H_2O)]^{3+}$ and *cis*-$[Co(en)_2(H_2O)_2]^{3+}$, whose acid ionization constants are $pK=6.05$ (25 °C) and $pK=6.06$ (25 °C), respectively.[8,12]

The absorption near 500 nm of the final spectrum in Fig. 2A is a little larger than that in Fig. 2B, which is due to a contribution of the mononuclear complexes formed together with a μ-peroxo complex. The contribution is very small for the small molar extinction coefficient of the mononuclear cobalt(III) complexes, compared with that of the μ-peroxo complex.

We believe that in neutral aqueous solution the *cis*-$[Co(en)_2(H_2O)_2]^{2+}$, formed by the photodecomposition of the μ-hyperoxo complex (Eq. 2), reacts with the remaining μ-hyperoxo complex to give *cis*-$[Co(OH)(en)_2(H_2O)]^{2+}$ and μ-peroxo complex:

$$cis\text{-}[Co(en)_2(H_2O)_2]^{2+} + [(en)_2Co(NH_2, O_2^-)Co(en)_2]^{4+} \longrightarrow cis\text{-}[Co(OH)(en)_2(H_2O)]^{2+} + [(en)_2Co(NH_2, O_2^{2-})Co(en)_2]^{3+} + H^+ \quad (5)$$

The rate of the dissociation of en from $[Co(en)_2(H_2O)_2]^{2+}$ is slower in a neutral solution than in an acidic solution.[10,11] Therefore, it appears that the reaction shown by Eq. 5 occurs before the decomposition of $[Co(en)_2(H_2O)_2]^{2+}$ to $[Co(en)(H_2O)_4]^{2+}$ or Co_{aq}^{2+}.

(Received December 17, 1987)

Synopsis. An enzyme electrode for creatine consisting of a single glass electrode and immobilized creatine kinase was prepared, and the effects of various conditions on the calibration curve obtained with this electrode were examined. Creatine in the range of 0.42—3.3 mmol dm^{-3} could be determined at 37 °C and pH 9.

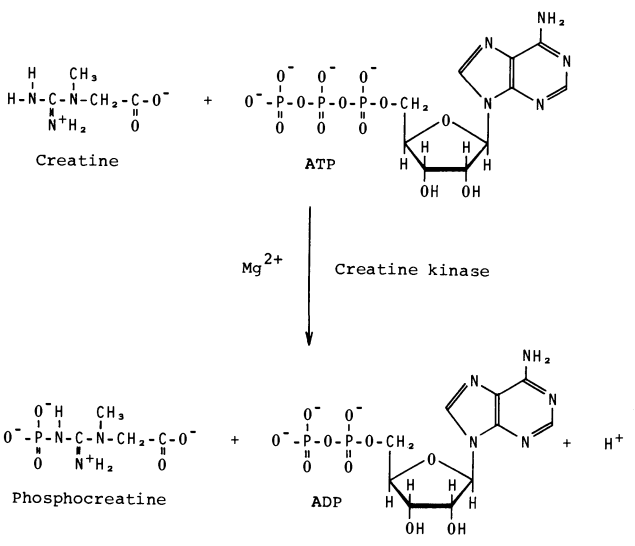
Creatine is a nitrogenous compound produced by protein metabolism. It is found in muscle in combination with phosphoric acid as phosphocreatine and is intimately associated with the chemical changes which take place during muscle contraction. Creatine is not found in any appreciable amount in the urine. There is a little in the urine of women and children, but not normally in that of men.[1] It is increased by the destruction and denaturation of muscles. The creatine content in urine or serum can thus be used clinically.

There has been much recent progress in the study of enzyme electrodes,[2-8] but an enzyme electrode for creatine has not yet been developed. In this work, we prepared an enzyme electrode for the determination of creatine. The enzyme reaction is shown in Scheme 1.

Experimental

Apparatus and Reagents. A glass electrode, Model GST-155C (TOA Electronics, Ltd.), was employed to prepare the enzyme electrode. The pH was measured with a digital pH/mV meter, Model TSC-10A (TOA Electronics, Ltd.), connected with an electronic recorder, Model R-102 (Rikadenki Kogyo Co., Ltd.). All the measurements were carried out at 37±0.2 °C.

The creatine kinase (from rabbit muscle; specific activity, 800 units per mg at 38 °C) was obtained from Boehringer Mannheim Yamanouchi, and the adenosine 5′-triphosphate (ATP)(Purity is 98±3%), from the Oriental Yeast Co. The creatine (analytical-reagent grade), bovine serum albumin (BSA)(Fraction V powder; purity, 98.5±0.5%), and glutaraldehyde(25%) were obtained from Wako Pure Chemical Industries. The ATP(10^{-1} mol dm^{-3}), creatine (3×10^{-2} mol dm^{-3}), BSA(10 w/w%), and glutaraldehyde (12.5 v/v%) solutions were prepared with distilled water.



Scheme 1. Enzyme reaction of creatine.

Preparation of the Enzyme Electrode. The electrode consisted of a glass electrode with an immobilized creatine kinase membrane fitted to its detector end. A cross-linking method was used for the immobilization of the creatine kinase. That is, 30 µl of a 10 w/w% BSA solution was spread on a polycarbonate membrane (0.1 µm caliber), after which 5 mg of creatine kinase and 4 µl of 12.5 v/v% glutaraldehyde were added with prompt mixing. They were spread at a thickness of 0.05 mm. The membrane was then left to stand for at least 2 hours at 4 °C and then attached to the glass electrode by means of an O-ring.

Determination of Creatine. The enzyme electrode for creatine was immersed in 10 ml of a 2 mmol dm^{-3} ATP-0.1 mmol dm^{-3} magnesium sulfate (pH 9) solution in a thermostat-regulated cell. Then 2 ml of the creatine solution was injected into the cell, and the ion-production by the enzyme reaction during the first 10 minutes, unless otherwise indicated, was monitored as the change in the pH. The electrode was washed with distilled water in each measurement.

Results and Discussion

Immobilization of Enzyme. A cross-linking method and matrix-entrapping methods of enzyme immobilization were also examined. (A) Cross-linking method: The membrane was prepared as has been described in the experimental sections. (B) Matrix-entrapping method: On a glass plate, 10 µl of a 20 w/w% cellulose acetate–acetone solution and 30 µl of a creatine kinase aqueous solution (5 mg/30 µl) were mixed quickly and spread at a thickness of 0.05 mm. This immobilized enzyme membrane and a polycarbonate membrane with a caliber of 0.1 µm were attached to a single glass electrode by means of an O-ring.

The response curves of the two types of electrodes are shown in Fig. 1. The response curves of Electrodes A and B were similar. The ΔpH value (0.18) of Electrode A after 10 min was greater than that (0.11) of Electrode B. The caribration curve of Electrode A was also compared with that of Electrode B [Fig. 2, Curves (A) and (D)]. Both methods (cross-linking and matrix-entrapping) could be employed. Further studies were made on the cross-linking method with greater ΔpH values.

Effects of Alkaline Solutions. In the enzyme reaction shown in Scheme 1, the optimum pH of creatine kinase is pH 8—9.[9] The sample solution was adjusted to this pH with sodium hydroxide, aqueous

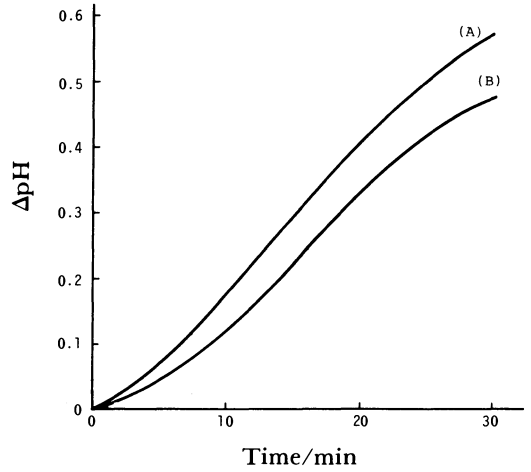


Fig. 1. Response curves of creatine enzyme electrode. (A) Cross-linking method. (B) Matrix-entrapping method. The sample (12 ml) contained 1.67 mmol dm^{-3} creatine, 1.67 mmol dm^{-3} ATP, and 8.33 mmol dm^{-3} magnesium sulfate. Temp 37 °C.

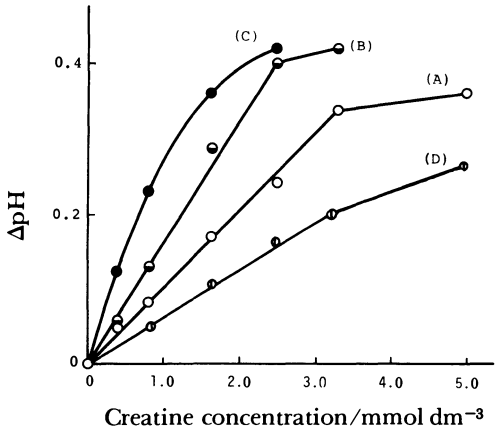

Fig. 2. Calibration curves of creatine. (A) Cross-linking method (after 10 min). (B) Cross-linking method (after 20 min). (C) Cross-linking method (after 30 min). (D) Matrix-entrapping method (after 10 min). The sample (12 ml) contained the indicated amount creatine, 1.67 mmol dm^{-3} ATP and 8.33 mmol dm^{-3} magnesium sulfate. Temp 37 °C.

ammonia, or potassium hydroxide. The response (ΔpH) was greatest with potassium hydroxide (0.18) and least with sodium hydroxide (0.03), because sodium hydroxide inactivated creatine kinase.[10] Potassium hydroxide was used in the subsequent experiments.

Effects of ATP and Magnesium Sulfate Concentrations. ATP plays an important part in energy metabolism, and the magnesium ion functions as a cofactor of creatine kinase.[11] The responses were measured with concentrations of 8.3×10^{-3}—8.33 mmol dm^{-3} ATP and 0.833—41.7 mmol dm^{-3} magnesium sulfate for 1.67 mmol dm^{-3} of creatine. The ΔpH values increased with the ATP concentration in the range of 8.33×10^{-3}—1.67 mmol dm^{-3} and was constant in the range of 1.67—8.33 mmol dm^{-3} (the amount required theoretically was 1.67 mmol dm^{-3} ATP), because at higher concentrations the amount of ATP passing through the membrane became constant. Similarly, the ΔpH increased with up to 8.33 mmol dm^{-3} magnesium sulfate, and then became constant because the magnesium-ion concentration was in excess of the amount required as a cofactor for the creatine kinase. Accordingly, 1.67 mmol dm^{-3} ATP and 8.33 mmol dm^{-3} magnesium sulfate were used.

Effect of the Temperature. The effect of the temperature on the ΔpH was also examined in the range of 20—40 °C. The ΔpH value (0.180 after 10 min) was the greatest at 37—38 °C. The creatine kinase was inactivated at 40 °C (ΔpH was 0.120). The optimum temperature for creatine kinase was 37—38 °C. Therefore, all subsequent measurements were done at 37 °C.

Effect of the Amount of Immobilized Creatine Kinase. The effects of the amount of immobilized enzyme will also be discussed. Creatine kinase in the range from 2000 units (2.5 mg) to 8000 units (10 mg) was immobilized with 6 μl of a 10 w/w% BSA solution and 0.8 μl of a 12.5 v/v% glutaraldehyde solution per 1 mg of enzyme. The value of ΔpH increased in the range of 2000—4000 units of the enzyme and remained constant with larger amounts. The enzyme activity was low with small amounts of enzyme because a part of the active site reacted with the cross-linking agent.[12] On the basis of these results, 5 mg (4000 units) of creatine kinase were immobilized with 30 μl of a 10 w/w% BSA solution and 4 μl of a 12.5 v/v% glutaraldehyde solution.

Calibration Curve. Linear plots of the creatine concentration vs. the ΔpH were obtained at concentrations of 0.42—3.3 mmol dm^{-3} at 10 min [Curve (A)], 0.42—2.5 mmol dm^{-3} at 20 min [Curve B)] and 0.42—1.6 mmol dm^{-3} at 30 min [Curve (C)], as is shown in Fig. 2. The plots fit these three equations; $Y=96.66X+0.006$ [Curve (A)], $Y=165.8X-0.006$ [Curve (B)], and $Y=183.3X-0.06$ [Curve (C)], where Y is ΔpH and X is the creatine concentration in mmol dm^{-3}. The correlation coefficients were 0.999, 0.998, and 0.991 respectively. The coefficients of variation were less than 7.2%.

Life-Time of the Electrode. The life-time of the prepared enzyme electrode for creatine was also considered. The stability of this electrode is good for 0—3 days (ΔpH was 0.18) after the preparation. However, the sensitivity of this electrode decreased after 4 days (the ΔpH values were 0.169, 0.150, 0.135, 0.117, 0.103, and 0.086 after 4, 5, 6, 7, 8, and 9 days respectively) because of the decrease in the activity of the enzyme. Just this electrode was used 10—20 times a day.

Effects of Concomitant Compounds. The creatine was determined in the presence of eight other compounds (creatinine, β-D-glucose, cholesterol, sodium chloride, urea, L-ascorbic acid, iodine, and citric acid), as is shown in Table 1. Creatinine, glucose, cholesterol, and sodium chloride were present in mole amounts about 10, 100, and 1000 times respectively

Table 1. Effects of Concomitant Compound on the Determination of Creatine

Concomitant compound	Molar ratio creatine : concomitant compound (mol : mol)	Relative error (%)
Creatinine	1 : 1	−1.0
	1 : 10	0.4
	1 : 100	0.9
β-D-Glucose	1 : 1	0.5
	1 : 10	0.3
	1 : 100	0.5
Cholesterol	1 : 0.01	−0.2
	1 : 0.05	−0.4
Sodium chloride	1 : 1	0.7
	1 : 100	−0.5
	1 : 1000	0.9
L-Ascorbic acid	1 : 1	0.6
	1 : 3	1.1
	1 : 5	−1.3
Iodine	1 : 0.1	−3.0
	1 : 0.5	−2.4
Citric acid	1 : 0.1	−2.2
	1 : 0.5	−3.0
Urea	1 : 1	−1.0
	1 : 10	−1.7
	1 : 100	2.9

Sample, 12 ml, of 1.67 mmol dm^{-3} creatine 1.67 mmol dm^{-3} ATP and 8.33 mmol dm^{-3} magnesium sulfate. Temp 37 °C.

that of creatine in human serum. Creatine could be determined with a relative error of less than ±1.7% in the presence of molar ratios of 1—100 creatinine, 1—100 β-D-glucose, 0.01—0.05 cholesterol, 1—1000 sodium chloride, 1—5 L-ascorbic acid, and 1—10 urea. The effect of cholesterol was examined at less than the presence ratio in human serum, because the solubility of cholesterol was small (0.2 mg/100 ml H_2O). Creatine could be determined with a relative error of less than −3% in the presence of molar ratios of 0.1—0.5 iodine as the SH reagent and 0.1—0.5 citric acid as the chelating agent.

The Second Dissociation Constant of Sulfuric Acid at Elevated Temperatures from Potentiometric Measurements

Yoshiyuki MATSUSHIMA and Akitsugu OKUWAKI*
Department of Molecular Chemistry and Engineering, Faculty of Engineering, Tohoku University, Sendai 980
(Received December 28, 1987)

Synopsis. The second dissociation constant of sulfuric acid in 1 *m* KCl media has been determined from 25 to 200 °C using Debye-Hückel equation from the data on the electromotive force of a hydrogen ion-concentration cell. The thermodynamic values for the $HSO_4^-=H^++SO_4^{2-}$ reaction and the KSO_4^- ion-pair association constant are also presented.

The sulfate ion plays an important role in the equilibrium,[1,2] rate,[3] and morphology[4] of the precipitation of inorganic compounds at elevated temperatures through complex formation with metal ions. However, the formation constants for sulfate complexes are very limited except for the hydrogensulfate ion.

Cobble and Criss[5–7] developed a method of estimating the equilibrium constant applicable up to the critical temperature using the entropy-corresponding principle. Recently, Helgeson[8] has proposed another method applicable to 600 °C and 5 kbar for geological applications. Such an estimation, however, can be applied only for simple single ions. Consequently, the formation constants for many complexes must be known to understand the effect of chemical species on the nature of reactions in solutions at elevated temperatures.

The second dissociation constant for sulfuric acid at elevated temperatures has been determined by solubility measurements[9,10] and conductivity measurements,[11,12] but not yet by emf measurements. A hydrogen ion-concentration cell at an elevated temperature was first used to determine the pH of the buffer solutions by Le Peintre et al.[13] Mesmer and Baes have since reviewed the hydrolysis of metal ions at a high ionic strength.[14] MacDonald has also investigated this reaction using the electrochemical method.[15] In the present study, we have determined the second dissociation constant of sulfuric acid at elevated temperatures by using potentiometric measurements as the first step to determine the formation constants of multivalent metal ions with sulfate ions.

Experimental

Materials. A stock solution of 0.1 mol dm^{-3} HCl was prepared from reagent-grade hydrochloric acid diluted with doubly distilled water. Reagent-grade KCl and K_2SO_4 were used without further purification. Ultrapure hydrogen (99.99999%) was used for the hydrogen electrode.

Hydrogen Ion-Concentration Cell.[16] The hydrogen ion-concentration cell consisted of a 300-cm^{-3} titanium autoclave containing a 180-cm^{-3} outer quartz beaker and an inner PTFE compartment, the two being joined by a liquid junction and each containing a platinized platinum hydrogen electrode. Figure 1 shows a cross-sectional view of the inner compartment. The porous PTFE disk (pore size, 0.2 μm; thickness, 1 mm) provides a liquid junction between the two compartments. The side of this compartment has a pin hole 0.7 mm in diameter which allows a rapid pressure-equilibration of hydrogen gas. Thus, the cell may be represented as:

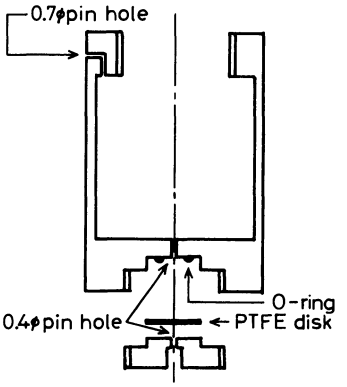

Fig. 1. Schematic of PTFE inner compartment.

$$\mathrm{Pt,H_2}\left|\begin{array}{l}\mathrm{HCl}(m_1)\\ \mathrm{K_2SO_4}(m_2)\\ \mathrm{KCl}(m_3=1)\end{array}\right\|\begin{array}{l}\mathrm{HCl}(m_4=0.001)\\ \mathrm{KCl}(m_5=1)\end{array}\left|\right.\mathrm{H_2,Pt} \qquad \text{(I)}$$

where m represents the molalities. The HCl concentration in the reference solution was 0.001 *m* in each experiment. The emf measurement was carried out for the 14 sets of composition as follows: m_1=0.0100—0.0240 and m_2= 0.0100—0.0250. In order to minimize the liquid junction potential and keep the ionic strength constant, KCl was added as a supporting electrolyte in both solutions (1 *m*). Because the PTFE is not wetted, the saturated KCl solution does not permeate the porous disk. We treated the disk using the following procedure: 1) wetting the porous disk with acetone and expelling air from the pores in the disk; 2) replacing the acetone with distilled water for a few days; 3) exchanging the water with a saturated KCl solution for two weeks. The cell was degassed after assembly by alternately pressurizing it with hydrogen and by venting it to atmospheric pressure several times. Finally, the cell was pressurized to about 0.5 MPa with hydrogen. The potential of the cell was measured over the temperature range from 25 to 200 °C at 25 °C intervals with a digital voltmeter. The voltage was recorded after a values had remained constant for several minutes (≧±1 mV).

Results and Discussion

Since the pressure of hydrogen is equal in the two compartments, the potential of the cell (I) is given by Eq. 1:

$$E=(RT/F)\ln(a_{\mathrm{H^+},t}/a_{\mathrm{H^+},r})+E_j \qquad (1)$$

where a_{H^+} is the activity of the hydrogen ion and where the subscripts t and r refer to the test solution and the reference solution respectively. E_j is the liquid junction potential, which can be estimated using the Henderson equation:[17]

$$E_j = -\sum D_i([i]_t - [i]_r) \quad (2)$$

$$D_i = RT|Z_i|\lambda_i/(Z_iF\sum(|Z_i|[\bar{i}]\lambda_i) \quad (3)$$

where $[i]$ denotes the molality of the species i and λ_i is the limiting equivalent conductance of the i th ion. The values of λ_i are available over the above temperature range.[18]

The Debye-Hückel equation was used to calculate the activity coefficient:

$$\log\gamma_i = -Z_i^2S\sqrt{I}/(1 + A\sqrt{I}) \quad (4)$$

where S is the Debye-Hückel limiting slope, Z_i is the charge of the ionic species, and A is the adjustable parameter experimentally determined from the solubilities of various $M_m(SO_4)_n$ at elevated temperatures.[19,20] In the test solution, the major equilibrium reactions are as follows:

$$HSO_4^- \rightleftarrows H^+ + SO_4^{2-} \quad (5)$$

$$K^+ + SO_4^{2-} \rightleftarrows KSO_4^- \quad (6)$$

The equilibrium constants of the above reactions, expressed in logarithmic form, and combined with Eq. 4 are thus related to the concentrations and ionic strength respectively:

$$\log K_2 = \log([H^+][SO_4^{2-}]/[HSO_4^-]) - 4S\sqrt{I}/(1 + A\sqrt{I}) \quad (7)$$

$$\log K_K = \log([KSO_4^-]/[K^+][SO_4^{2-}]) + 4S\sqrt{I}/(1 + A\sqrt{I}) \quad (8)$$

The total analytical concentrations of H^+, SO_4^{2-}, and K^+ are expressed as $[H^+]+[HSO_4^-]=m_1$ (9), $[SO_4^{2-}]+[HSO_4^-]+[KSO_4^-]=m_2$ (10), and $[K^+]+[KSO_4^-]=2m_2+m_3$ (11). From Eqs. 7—11 we obtain the calculated concentration of $[H^+]_{cal}$ by the Newton-Raphson method. Combining $[H^+]_{cal}$ with Eq. 1 produces the calculated values of the potential at each temperature. Then we employed a computer program to analyze the equilibrium constants of sulfate complexes, i.e., the pair of K_2 and K_K which best account for all the observed potential data. The values obtained in this work are listed and compared with the literature values in Table 1, while they are illustrated in Fig. 2. Except for 298 K, the standard deviation between E_{obsd} and E_{calcd} increased with the increase in the temperature as follows: 298 K ±1.2%; 323 K ±0.6%; 348 K ±0.5%; 373 K ±0.6%; 398 K ±0.8; 423 K ±1.6%; 448 K ±2.3%; 473K ±3.1%.

Assuming that ΔC_p° varied as a quadratic function of the temperature, the values of log K_2 and log K_K obtained as functions of temperature were fitted by the least-squares method to give a five-parameter equation:

Table 1. Values of log K_2 and log K_K as a Function of the Temperature

T/K	$-\log K_2$	$-\log K_2$[a]	$\log K_K$	$\log K_K$[b]
298	1.99	1.988	0.27	0.28
323	2.35	2.246	0.32	0.31
348	2.72	2.539	0.35	0.38
373	3.08	2.855	0.45	0.45
398	3.44	3.189	0.52	0.52
423	3.81	3.534	0.61	0.60
448	4.18	3.887	0.71	0.73
473	4.58	4.246	0.94	0.94

a) Marshall and Jones.[10] b) Calculated from Eq. 12.

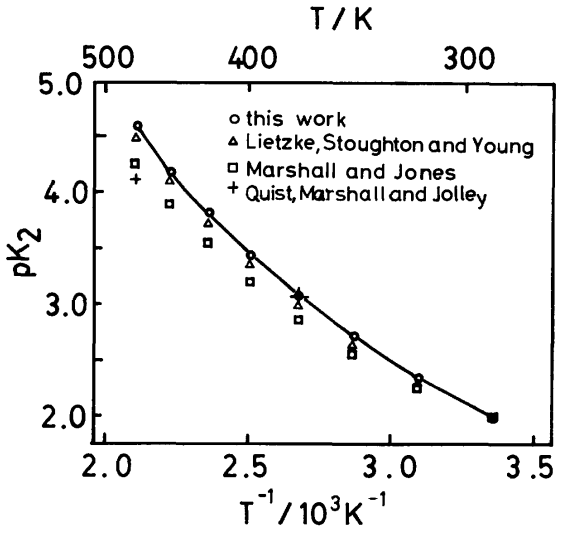

Fig. 2. pK_2 vs. T^{-1} for the second dissociation of sulfuric acid. Solid line is from Eq. 12.

$$\log K = a + b\log T + c/T + dT + eT^2 \quad (12)$$

where T is the absolute temperature. For log K_2, the parameters a, b, c, d, and e are:

a=577.214, b=−246.01, c=−12717, d=0.283133, e=−1.37566×10^{-4} and for log K_k their values are:

a=−3072, b=1310.68, c=68881, d=−1.56182, e= 7.1513×10^{-4}.

Usually, it is necessary to evaluate the A parameter as well as log K_2 to extrapolate the plots of log K_{app} vs. $\sqrt{I}/(1+A\sqrt{I})$ into an infinite dilution at each temperature. In the present study, however, the ionic strength in the test solution was fixed at 1 m in order that a liquid-junction potential should not exceed 1 mV. Thus, we used the literature value of the A parameter.[19,20] Nevertheless, the pK_2 values are substantially in agreement with the values determined by the solubility measurement at elevated temperatures[10] as well as with those reported by other investigators,[9-11] at 25 °C. In one earlier paper[10] the association of the calcium ion with sulfate was not assumed, but the existence of the $CaSO_4$ ion pair was pointed out later.[21] If the ion pair is present in the solution, it seems that the pK_2 values become higher,

Table 2. Thermodynamic Values for the $HSO_4^- \rightleftharpoons H^+ + SO_4^{2-}$ Reaction

T	$\Delta G°$	$\Delta H°$	$\Delta S°$	ΔC_p
K	kJ mol^{-1}	kJ mol^{-1}	J mol^{-1} K^{-1}	J mol^{-1} K^{-1}
298	11.4	−24.1	−119	−218
323	14.6	−29.2	−136	−192
348	18.1	−33.9	−149	−187
373	22.0	−38.7	−163	−200
398	26.3	−43.9	−176	−234
423	30.9	−50.6	−192	−287
448	35.9	−58.6	−211	−361
473	41.5	−68.6	−233	−452

as in the present work, than when without association.

The ion-pair association constant of KSO_4^- in the present study was somewhat lower than that determined by conductivity measurements.[22,23] There was some difficulty in obtaining a log K_K value for the present system. The log K values for the association of the univalent metal ion with the sulfate ion are considerably smaller than those of bi- and tervalent metal ions.[24] Thus, a weak complex of KSO_4^- results in a small contribution to the potential.

From the treatment of Eq. 12, the standard thermodynamic functions for changes in free energy ($\Delta G°$), enthalpy ($\Delta H°$), entropy ($\Delta S°$), and heat capacity ($\Delta C_p°$) were obtained for the temperature range from 25 to 200 °C. The values are given in Table 2. These values depend on the assumption of the dependency of $\Delta C_p°$ on the temperature. It is generally known that the standard heat capacities of ionic species in an aqueous solution show maximum values near 100 °C;[8] the $\Delta C_p°$ value in the present study indeed showed a maximum value at approximately 80 °C, in accordance with the maxima for $\Delta C_p°$ obtained for other ionization reactions.

The authors wish to thank Sumitomo Electric Industries, Ltd., for providing the porous PTFE membranes.

(Received February 25, 1988)

Synopsis. The title complex (**1**), which is two-dimensional polymeric and an allotrope of the previously reported linear polymeric complex (**2**), was obtained and its crystal and molecular structure was determined by means of a single-crystal X-ray diffraction method. Since **1** is more soluble in organic solvents, **1** and **2** could be prepared, separately. The crystal of $CdC_{16}H_{18}N_4S_2$, F. W. 442.9, is monoclinic, space group $P2_1/c$, a=13.958(2), b=5.759(1), c=11.466(2) Å, β=99.24(1)°, U=909.8(3) Å^3, Z=2, D_m=1.61(3), D_x=1.62 g cm^{-3}, μ(Mo $K\alpha$)=14.2 cm^{-1}. The cadmium atom is in a trans-2*S*4*N*-hexa-coordinated octahedral geometry. Each cadmium atom is at the center of symmetry, and it is bridged to four cadmium atoms by an thiocyanate ion, respectively, and the complex network is extended on the bc-plane.

There have aleady been several structural reports concerning the one-, two-, and three-dimensional polymeric thiocyanato (SCN) complexes of metals.[1-4] In the case of thiocyanato complexes of cadmium, Cs[Cd(SCN)$_3$] has a three-dimensional,[5] Rb[Cd(SCN)$_3$] a two-dimensional,[5] and [(CH$_3$)$_4$N][Cd(SCN)$_3$] a one-dimensional network,[6] respectively. However, in the Lewis base adducts of cadmium(II) thiocyanates, they are in a double-SCN-ion-bridging one-dimensional polymeric form,[7-10] like cobalt thiocyanate.[4]

Recently, we found that other types of crystals were mixed in the sample of the benzylamine adduct of cadmium(II) thiocyanate, previously reported,[10] which gave the same chemical analysis and almost the same infrared spectrum, though they were found to have a different unit-cell.

Therefore, we investigated how to separated the previously reported adduct **2** and this new compound **1**; moreover, the crystal and molecular structure of **1** was determined by a single-crystal X-ray diffraction method.

Experimental

Syntheses of Both Types of Bis(benzylamine)bis(thiocyanato)cadmium(II), (1,2). The product obtained by mixing cadmium thiocyanate and benzylamine in the stoichiometric ratio in methanolic medium was always a mixture of **1** and **2**. Although the crystals of **2** were almost insoluble in methanol and ethanol after once precipitated, while the solubility of the crystals of **1** was also very low, the yield of **1** after recrystallization from methanol was poor. The process to obtain **1**, found empirically, is as follows.

Cadmium(II) thiocyanate (0.9 g, 4 mmol) and benzylamine (0.9 g, 8.4 mmol) were dissolved into 30 and 10 cm^3 of methanol–ethanol mixture (2:1=v/v), separately (the mixing of ethanol lowers the solubility of deposited **2**). They were warmed to about 80 °C and mixed. After the mixture was refluxed about 2 h, it was filtered off while hot in order to remove **2** (a part of **1** was also removed). The filtrate was slowly cooled to 6 °C, and deposited crystals of **1** were separated, washed with a little portion of the ethanol–methanol mixture, and dried in open air. Yield: 0.80 g, 1.8 mmol, 45%. Found: Cd, 25.30; C, 42.99; H, 4.00; N, 12.55%. Calcd for ($CdC_{16}H_{18}N_4S_2$) Cd, 25.38; C, 43.39; H, 4.10; N, 12.65%.

On the other hand, the precipitated crystals were almost pure **2**, when being added benzylamine a little less than the calculated quantity, using methanol–water mixture as the solvent (98:2=v/v) to increase the solubility of **1**, and being left standing the mixed solution overnight at room temperature. Yield: 0.48 g, 1.1 mmol (59%) from 2 mmol of Cd(SCN)$_2$ and 3.7 mmol of benzylamine in 40 cm^3 of the solvent.

Although both crystals of **1** and **2** appear commonly in a spatula-like plate form (as shown in Fig. 1**A**) relatively large crystals of **1** and **2** appear in the forms shown by Figs. 1**B** and 1**C**, respectively: this is the best simple method for distinguishing both types of the crystals. From an X-ray photographic study, the respective unit-cell axes of **1** and **2** are found to be in the directions shown in the figure captions.

Single Crystal X-Ray Structure Analysis. The crystal used for the structural analysis was colorless, and parallelepiped in shape (0.3×0.3×0.15 mm^3). The intensities in the range of $3<2\theta<67°$ (2θ) were collected on a Rigaku AFC-6A automated four-circle X-ray diffractometer using graphite monochromated Mo $K\alpha$ radiation (λ= 0.71073 Å) by means of ω–2θ scan technique (scan speed 4° min^{-1}; scan width 1.25+0.5 tanθ (°/θ)). The intensities were corrected for Lorentz and polarization factors, but not for absorption and extinction. Of 3891 independent intensities collected, 2457 reflections with $|F_o|>3\sigma(|F_o|)$ were used for the structure determination.

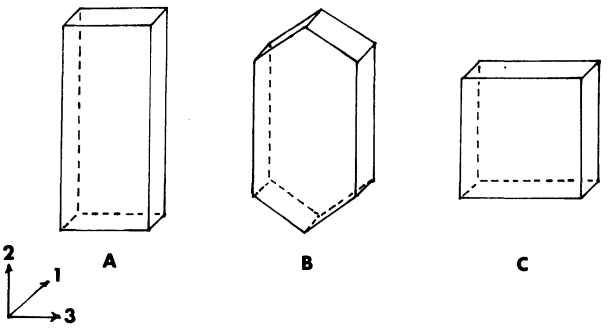

Fig. 1. The apparent features of the complexes **1** and **2** crystals. The directions of the unit-cell axes of **1** and **2** are as follows, respectively. **1**: 1, a; 2, b; 3, c. **2**: 1, a; 2, −c; 3, b.

All the calculations were carried out on a HITAC M-682H computer at the Computer Center of the University of Tokyo, using a local version of the UNICS program.[11] The scattering factors were taken from Ref. 12.

The structure was solved by the heavy-atom method (positional, and thermal parameters were refined by a block diagonal least-squares method). The final R value applying an anisotropic temperature factors was 0.057 (all the hydrogen atoms were not included into the structure factor calculations).

Results and Discussion

The selected bond lengths and bond angles are shown in Table 1. A perspective drawing of the complex including the four SCN ions bridging to the neighboring four metal atoms, together with the numbering scheme of the atoms, is shown in Fig. 2, and a packing diagram of a unit cell in Fig. 3.[13] Each cadmium atom is at the center of symmetry (0,0,0 and 0,0.5,0.5), and is bridged to four neighboring metal atoms with a SCN ion, respectively, and the two-dimensional network of the complex is expanded on the bc-plane. This type of the planar-polymeric structure is the first example found in a Lewis base adduct of cadmium(II) thiocyanates.

Table 1. Selected Bond Lengths and Bond Angles of the Complex **1**

Bond length	(l/Å)	Bond length	(l/Å)
Cd-S^{iii}	2.753(2)	Cd-N(1)	2.339(8)
Cd-N(2)	2.322(5)	S-C(1)	1.637(10)
N(1)-C(1)	1.157(13)	N(2)-C(2)	1.477(7)
Cd$\cdots$Cd^{ii}	6.416(1)		
Bond angle	**(ϕ/°)**	**Bond angle**	**(ϕ/°)**
N(1)-Cd-N(2)	86.8(2)	N(1)-Cd-S^{iii}	90.8(2)
N(2)-Cd-S^{iii}	89.20(14)	Cd-N(1)-C(1)	146.3(7)
Cd^{ii}-S-C(1)	98.39(16)	S-C(1)-N(1)	179.3(9)
Cd-N(2)-C(2)	117.0(4)	N(2)-C(2)-C(3)	113.9(6)

Key to the symmetry operations: ii, x, 0.5−y, 0.5+z; iii, −x, −0.5+y, 0.5−z.

As shown in Fig. 2, around a cadmium(II) atom, two SCN sulfur, two SCN nitrogen, and two benzylamine nitrogen atoms are coordinated, where each pair of the same kind of the ligating atoms are in a trans-configuration. The configuration of the complex, as well as the respective bond lengths around the metal atom (Cd-S(SCN), 2.753(2); Cd-N-(SCN), 2.339(8); Cd-N(benzylamine), 2.322(5) Å) are not much different from those of **2**. The Cd-N-C-(SCN) angle of **1**, 146.3(7)°, is much smaller than the other common thiocyanato complexes (160—180°), while the angles Cd-S-C (98.39(16)°) and S-C-N (179.3(4)°) are in the common range of the other

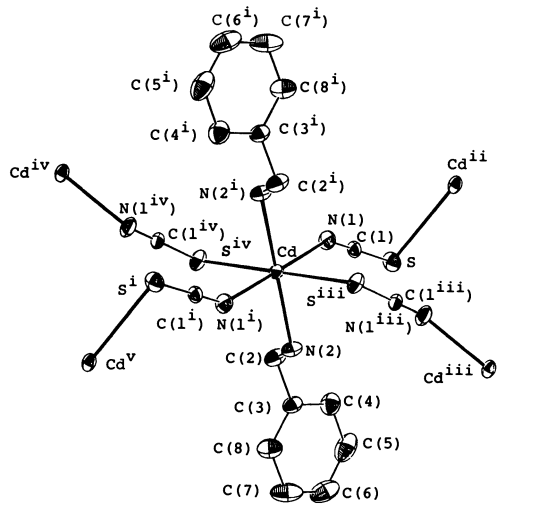

Fig. 2. The perspective drawing of the complex **1** around the central metal atom and thiocyanate ion bridgings: the numbering scheme of the atoms are shown in the figure. The key to the symmetry operations: i, −x, −y, −z; ii, x, 0.5−y, 0.5+z; iii, −x, −0.5+y, 0.5−z; iv, x, 0.5−y, −0.5+z; v, x, −0.5−y, −0.5+z.

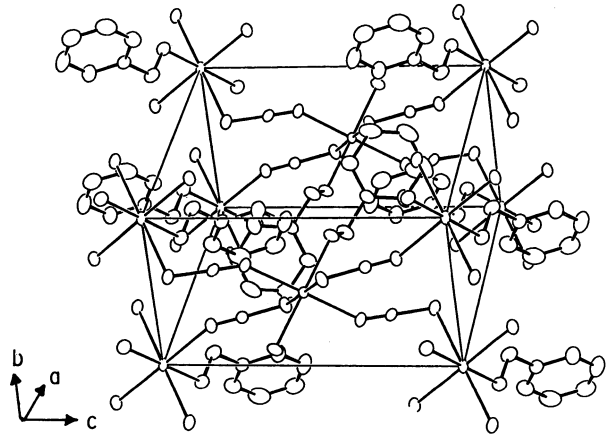

Fig. 3. Crystal packing diagram of the complex **1**.

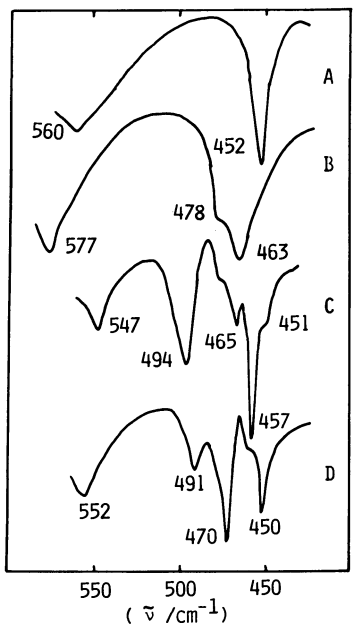

Fig. 4. Infrared absorption spectra of the complexes **1** and **2** near their δ(SCN) peak together with the spectra of some related compounds. (A) Benzylamine, (B) cadmium thiocyanate, (C) complexes **2**, (D) complexes **1**.

cadmium thiocyante complexes.[7-10] These data are the same for the cases of **2**. The inter-bridging-metal-atomic-distance of **1**, 6.416(1) Å, is much longer than that of **2**, 5.873(1) Å.

The infrared absorption spectra of **1** and **2** were found to be aproximately the same: ν(CN), 2080; ν(CS), 752(s), and 720(sh) cm^{-1}. However, as shown in Fig. 4, the features of the δ(SCN) bands of **1** and **2** are a little different from each other: the former peak is more clearly separated. This is another way to distinguish crystals of **1** and **2**.

The Synthesis and the Crystal and Molecular Structure of Tris(*N*-ethyl-2-pyrrolidone)tetrakis(thiocyanato)cobalt(II)mercury(II), $[CoHg(SCN)_4(C_6H_{11}NO)_3]$

Hisashi KINOSHITA* and Akira OUCHI†

†Department of Chemistry, College of Arts and Sciences, The University of Tokyo, Komaba, Meguro-ku, Tokyo 153
(Received March 1, 1988)

Synopsis. The title complex, which has a new-type layer structure, has been obtained, and its crystal and molecular structure has been determined by the X-ray diffraction technique. The crystallographic data are: monoclinic, space group $P2_1/n$, a=18.264(7), b=16.223(7), c=10.623(5) Å, β=92.77(5)° and Z=4. The final R value was 0.059. The cobalt atoms are in an octahedral geometry, ligated by three thiocyanato(SCN) nitrogen atoms and three oxygen atoms (*N*-methyl-2-pyrrolidone) in a meridional configuration; these cobalt atoms are cross-linked to adjacent mercury atoms by SCN ions, forming a characteristic layer structure which consists of twenty-four-membered rings of the $[Co_3Hg_3(SCN)_6]$ unit. The mercury atoms are in the tetrahedral geometry, ligated by four sulfur atoms of SCN ions, three bridging and one unidentate. The complex layers in parallel are piled up in the a-axis direction, and there are no bridgings or hydrogen bondings between them.

Previously, the present authors[1-3] have reported the crystal structures of some Lewis base adducts of tetrakis(thiocyanato)cobalt(II)mercury(II), $CoHg(SCN)_4$ (**1**), with the general formula of $CoHg(SCN)_4L_2$ (L= *N*-methyl-2-piperidone(mpp) (**2**)[1] or dimethyl sulfoxide(dmso) (**3**)[1]) and of $CoHg(SCN)_4(H_2O)_2\cdot 2L$ (L= *N*,*N*-dimethylacetamide(dma) (**4**)[2] or *N*-methyl-2-pyrrolidone(mpd) (**5**)[3]). These complexes were found to have two-dimensional planar networks consisting of sixteen-membered rings of the $Co_2Hg_2(SCN)_4$ unit. By continuing this line of research using *N*-ethyl-2-pyrrolidone(abbr.; epd) as the Lewis base, the title complex was obtained. From the preliminary test, its chemical composition ($CoHg(SCN)_4L_3$), its crystal system, and its unit cell size were found to be different from those of **2**—**5**. Therefore, we have investigated the crystal and molecular structure of this complex by means of the X-ray diffraction method.

Experimental

Synthesis of Tris(*N*-ethyl-2-pyrrolidone)tetrakis(thiocyanato)cobalt(II)mercury(II) (6). The crystalline powder of **1** (1.0 g, 2.0 mmol) was dissolved into epd (10 cm³), and 10 cm³ of tetrahydrofuran was added to the solution. The mixture was then left standing for several days; thereby red-purple crystals of **6** were deposited. They were filtered off and dried over silica gel. Yield: 0.6 g, 28%. Found: Co, 7.07; C, 31.68; H, 3.81; N, 11.82%. Calcd for $CoHgC_{22}H_{33}N_7O_3S_4$: Co, 7.09; C, 31.79; H, 4.00; N, 11.79%.

X-Ray Structure Analysis. A crystal of **6**, red-purple in color and in the shape of a parallelepiped (0.3×0.3×0.2 mm³), was used for the intensity measurement. Crystallographic data: $CoHgC_{22}H_{33}N_7O_3S_4$ $F.W.$=831.33, monoclinic, with the space group of $P2_1/n$, a=18.264(7), b=16.223(7), c=10.623(5) Å, β=92.77(5) ,U=3144.0(9) Å³, Z=4, D_m=1.75(3) g cm⁻³, D_x=1.76 g cm⁻³, μ(Mo $K\alpha$)=5.75 mm⁻¹. Reflections within the range of $3°<2\theta<60°$ were collected on a Rigaku AFC-6A automated four-circle X-ray diffractometer with graphite-monochromatd Mo $K\alpha$ radiation (λ=0.71073 Å): the $\omega-2\theta$ scan technique was employed (scan speed, 4° min⁻¹ (θ); scan width, 1.12+0.5 tan θ(θ/°)). Of the 3841 independent reflections measured, 3023 $|F_o|>3\sigma(|F_o|)$ reflections were used for the structure determination. The intensities were corrected for the Lorentz and polarization factors as well as for the absorption. The last correction was made using a numerical Gaussian integration.[4] The structure was solved by the heavy atom method. The positional and thermal parameters were refined by the block-diagonal least-squares method. Hydrogen atoms were not included in the structure factor calculation. The final R value obtained by applying the anisotropic temperature parameters was 0.059.[5]

All the calculations were carried out on a HITAC M-682H computer apparatus at the Computer Center of the University of Tokyo, using the local version of the UNICS program system.[6] The atomic scattering factors were taken from Ref. 7.

Results and Discussion

The selected bond lengths and bond angles, and also some interatomic distances, are shown in Table 1.[8] A perspective drawing of the complex around a cobalt atom is sown Fig. 1. The projection of the structure along the a axis is shown in Fig. 2.

Each mercury atom is coordinated tetrahedrally by four SCN sulfur atoms. The cobalt atom is six-coordinated and is in an octahedral geometry, where three SCN nitrogen atoms and three carbonyl-oxygen atoms of the *N*-ethyl-2-pyrrolidone molecule are ligated in a meridional configuration. Therefore, one of the four SCN ions, which are ligated to each mercury atom with their sulfur atom, has a free nitrogen terminal. The bond lengths of Co–O and Co–N (on the average, 2.080 and 2.131 Å respectively) are not very different from the respective sums of Shannon's ionic radii (Co–O: 2.00, and Co–N: 2.11 Å).[9] The Hg–S bond lengths (2.531 Å, on the average) are shorter than the sum of the Shannon ionic radii, 2.80 Å; especially, the bond length Hg–S(4) of the unidentate SCN ion, 2.455(7) Å, is a little shorter than the other three Hg–S bonds.

The bond angles, Co–N–C (160.5° on the average), deviate a little from 180°, while the N–C–S angles (177° on the average) are almost 180°. In this complex, three mercury(II), three cobalt(II), and six SCN ions make a twenty-four-membered ring unit which forms a two-dimensional polymeric network which is quite different from those of **2**, **3**, **4**, and **5**. In

Table 1. Selected Bond Lengths and Bond Angles, with Estimated Standard Deviations in Parentheses

Bond length	l/Å	Bond length	l/Å

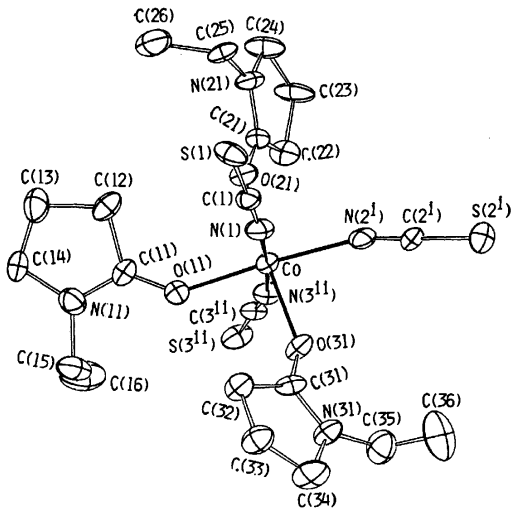

Fig. 1. The perspective drawing of the complex around a cobalt atom.

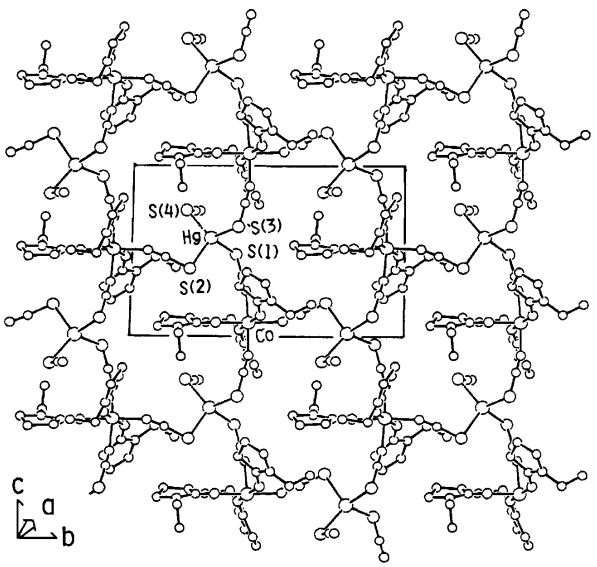

Fig. 2. The projection of the unit cell of the complex to the (100) plane.

the latter four complexes, the planar networks are composed of sixteen-membered ring units, including two mercury, two cobalt and four SCN^- ions.[1,2] Therefore, the present complex was found to have a new type of layer structure. In a unit cell there are two layers which spread out parallel to the (1 0 0) plane. The interlayer distance is 9.12 Å, which is much longer than those of **2** and **3**, where the distances are 8.21 and 6.85 Å respectively.[1] The ethyl group of epd may cause the steric hindrance, resulting in the bulky structure with the relatively small specific gravity of 1.76 g cm^{-3}; the specific gravities of **2**, **3**, **4**, and **5** are 2.03, 2.22, 1.99, and 2.04 g cm^{-3} respectively.

Regarding the metal atoms only, this complex layer has an obvious structural feature; it is of the so-called "graphite" type, consisting of the six-membered ring

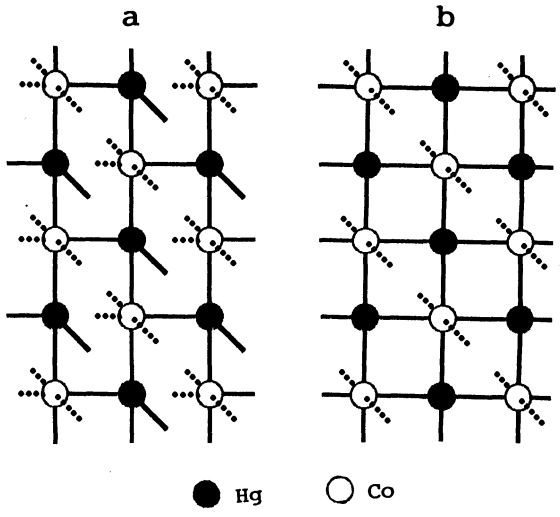

Fig. 3. The schematic presentation of the projection of the metal atomic arrangements of the complexes. a. $CoHg(SCN)_4(epd)_3$ projected to (100) plane. b. $CoHg(SCN)_4L_2$-type[1] or $CoHg(SCN)_4(H_2O)_2$·L-type[2,3] complexes projected to an appropriate plane. Each solid line indicates the thiocyanate ion. The dotted lines indicate the Lewis base (or water) molecules.

unit shown in Fig. 3(a), which is deduced from the "diamond" type structure of $CoHg(SCN)_4$, the starting material. On the other hand, in all of the layer structures of **2—5**, the units of the positions of the metal atoms are the four-membered ring units of Co_2Hg_2, as is shown in Fig. 3(b).

(Received April 16, 1988)

Synopsis. Thiolate-bridged dinuclear cobalt(II), iron(II), and Manganese(II) complexes and trinuclear manganese(II) complexes of thiolic ligands, 2-[(2-aminoethyl)amino]ethanethiol, 2-[(3-aminopropyl)amino]ethanethiol, 2-[(2-pyridylmethyl)amino]ethanethiol, and 2-[[(2-pyridylethyl]amino]ethanethiol, were prepared and their magnetic properties were examined in the temperature range 80—300 K. The results indicated a significant antiferromagnetic spin-exchange interactions through the bridging sulfur atom for all the complexes.

Sulfur-bridged polynuclear metal complexes are of interest in view of magnetic spin-exchange interaction through the sulfur bridge. Some thiolate-bridged polynuclear metal complexes have been synthesized.[1] However, magnetic investigations on thiolate-bridged polynuclear metal complexes are still limited. In this study we have obtained two types of thiolate-bridged complexes of cobalt(II), iron(II), and manganese(II) ions using tridentate thiolic ligands with an NNS-donor set, 2-[(2-aminoethyl)amino]ethanethiol (HL^1), 2-[(3-aminopropyl)amino]ethanethiol (HL^2), 2-[(2-pyridylmethyl)amino]ethanethiol (HL^3), and 2-[[(2-pyridyl)ethyl]amino]ethanethiol (HL^4). This paper reports the magnetic study of dinuclear complexes $[M_2(L)_2X_2]$ ($M=Co^{2+}$, Fe^{2+}, Mn^{2+}; X=Cl, NO_3) and trinuclear complexes $[Mn_3(L)_4]X_2$ ($X=ClO_4$, NO_3).

Experimental

Preparations. The thiolic ligands were obtained by the methods described previously.[2]

$[M_2(L)_2X_2]$ (M=Co, Fe, Mn; $L=L^1$—L^4; X=Cl, NO_3). A methanolic solution of equimolar amounts of a metal salt and a ligand was stirred overnight at room temperature under nitrogen atmosphere. Microcrystals separated were collected by filter suction, washed with methanol, and dried in vacuo. The cobalt, iron, and manganese complexes are violet, yellow, and colorless, respectively.

$[Mn_3(L)_4]X_2$ ($L=L^1$, L^2; $X=ClO_4$, NO_3). The complexes were obtained as almost colorless microcrystals in nearly the same way as described above, except for the use of an excess of a ligand (about 1.5 times).

Elemental analyses of the complexes are given in Table 1.

Measurements. IR spectra were recorded on a JASCO IR-800 spectrometer on KBr disks or Nujol mulls. Electronic spectra were recorded on powder samples by the use of a Simadzu MPS-5000 spectrometer. Magnetic susceptibilities were determined by the Faraday method over the temperature range 80—300 K.

Results and Discussion

$[M_2(L)_2X_2]$. The complexes have the stoichiometry of M:L:X=1:1:1 and are presumed to be dinuclear bridged by the thiolate group, because such a dimeric structure has been shown for the nickel(II) complexes with HL^4 [3] and 3-[[(2-pyridyl)ethyl]amino]-propanethiol (HL′)[4] by single-crystal X-ray analysis. Further, similar alkoxo-bridged dinuclear structures are known for the copper(II) complexes of tridentate alcoholic ligands.[5]

In the case of $[Co_2(L^4)_2(NO_3)_2]$ the unidentate coordination of the nitrate ion to the metal was evidenced by the split NO_3^- vibrations (1460, 1380, 1290, and 1030 cm^{-1}).[6] Further, the diffuse reflectance

$[Mn_3(L^1)_4](ClO_4)_2$	22.72	5.26	13.25	22.86	5.28	13.33
$[Mn_3(L^2)_4](ClO_4)_2$	26.48	5.84	12.46	26.79	5.85	12.50
$[Mn_3(L^2)_4](NO_3)_2$	28.90	6.41	16.66	29.38	6.38	17.05

spectra of the cobalt(II) complexes showed three d–d bands in the region 10000—20000 cm^{-1} (e.g., $[Co_2(L^4)_2Cl_2]$: 13000, 15800, and 18200 cm^{-1}), indicating a pentacoordination around the metal.[7] The manganese(II) complexes showed no spin-allowed d–d transition and any reliable spectra could not be obtained for the iron(II) complexes because of their sensitivity toward dioxygen. However, we believe that in both the manganese(II) and iron(II) complexes the chloride ion coordinates to the metal ion to complete a penta-coordination around the metal.

The magnetic moment (per metal ion) of each complex is subnormal at room temperature for high-spin metal ion (Table 2), and the cryomagnetic susceptibility determined in the range 80—300 K did not obey the Curie-Weiss law below 150 K. This is probably due to an intramolecular antiferromagnetic spin-exchange interaction. Typical examples of the temperature-variation of magnetic susceptibility are given in Figs. 1 and 2.

The χ_A vs. T curve of $[Co_2(L^3)_2Cl_2]$ shows a maximum at 160 K. Based on the isotropic exchange Hamiltonian (Heisenberg model) for a dimer ($\mathscr{H} = -2J\hat{S}_1 \cdot \hat{S}_2$), the maganetic susceptibility for the (S_1=3/2)–(S_2=3/2) dimer is given by the equation,[8]

$$\chi_A = (Ng^2\beta^2/kT)[14 + 5\exp(-6J/kT) + \exp(-10J/kT)]/[7 + 3\exp(-10J/kT) + \exp(-12J/kT)] + N\alpha \quad (1)$$

In this equation J is the exchange integral, N the Avogadro number, g the Lande g-factor, β the Bohr magneton, T absolute temperature, and $N\alpha$ the temperature-independent paramagnetism. As is seen

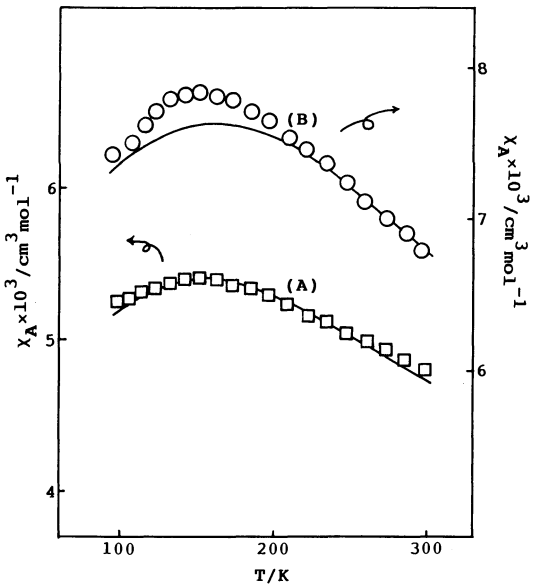

Fig. 1. Temperature variations of magnetic susceptibility of (A) $[Co_2(L^4)_2Cl_2]$ and (B) $[Fe_2(L^4)_2Cl_2]$. The solid curves are drawn based on the susceptibility equations based on the Heisenberg model (J=−35.1 cm^{-1}, g=2.20, $N\alpha$=220×10^{-6} cm^3mol^{-1} for (A) and J=−25.0 cm^{-1}, g=2.20, $N\alpha$=0 for (B)). The discrepancy in the case (B) is presumed to be due to an orbital contribution to the susceptibility.

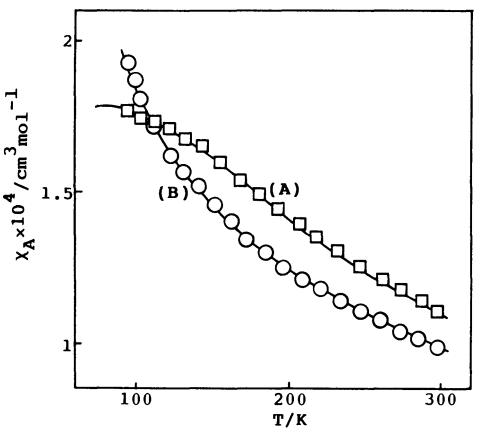

Fig. 2. Temperature variations of magnetic susceptibility of (A) $[Mn_2(L^4)_2Cl]$ and (B) $[Mn_3(L^2)_4](NO_3)_2$. The solid curves are drawn in terms of the Heisenberg model (Eqs. 2 and 3, respectively) using the magnetic parameters given in Table 2.

Table 2. Magnetic Data of the Complexes

Complex	g	J/cm^{-1}	$N\alpha$×10^6/cm^3 mol^{-1}	$\mu_{eff}/\mu_B(T/K)$
$[Co_2(L^3)_2Cl_2]$	2.20	−36.5	200	3.33(297.8)
$[Co_2(L^4)_2Cl_2]\frac{1}{2}H_2O$	2.20	−35.1	220	3.39(297.8)
$[Fe_2(L^1)_2Cl_2]$	—	—	—	3.58(299.0)
$[Fe_2(L^3)_2Cl_2]$	—	—	—	4.02(297.8)
$[Fe_2(L^4)_2Cl_2]\frac{1}{2}H_2O$	—	—	—	4.02(297.8)
$[Mn_2(L^1)_2Cl_2]$	2.00	−11.8	0	4.88(297.8)
$[Mn_2(L^2)_2Cl_2]$	2.00	−9.8	0	5.01(297.8)
$[Mn_2(L^3)_2Cl_2]$	2.00	−10.4	0	4.94(297.8)
$[Mn_2(L^4)_2Cl_2]\frac{1}{2}H_2O$	2.00	−9.0	0	5.14(297.8)
$[Mn_2(L^4)_2(NO_3)_2]$	2.00	−8.5	0	5.21(297.8)
$[Mn_3(L^1)_4](ClO_4)_2$	2.06	−14.7	0	4.71(297.8)
$[Mn_3(L^2)_4](ClO_4)_2$	2.05	−8.9	0	5.16(295.4)
$[Mn_3(L^2)_4](NO_3)_2$	2.03	−11.1	0	4.85(297.8)

in Fig. 1(A), the cryomagnetic behavior of this complex can be well simulated with the Eq. 1 using magnetic parameters given in Table 2, clearly demonstrating the dinuclear structure of this complex. Similarly, the magnetism of $[Co_2(L^4)_2Cl_2]$ obeyed the Eq. 1 in the temperature range 80—300 K.

The χ_A vs. T curves for the manganese(II) complexes show no maximum in the range 80—300 K but show an apparent decrease at lower temperature (Fig. 2(A)). The magnetic susceptibility for the $(S_1=5/2)$-$(S_2=5/2)$ system based on the Heisenberg model is given by the equation,[9]

$$\chi_A = (Ng^2\beta^2/kT)[55 + 30\exp(-10J/kT) + 14\exp(-18J/kT) + 5\exp(-24J/kT) + \exp(-28J/kT)]/[11 + 9\exp(-10J/kT) + 7\exp(-18J/kT) + 5\exp(-24J/kT) + 3\exp(-28J/kT) + \exp(-30J/kT)] + N\alpha, \quad (2)$$

where each simbol has the same meaning as in the Eq. 1. The magnetism of the manganese(II) complexes can be well explained with this equation, as exemplified in Fig. 2(A), using reasonable magnetic parameters given in Table 2. Thus, cryomagnetic investigations add a support for the dinuclear structure of the manganese(II) complexes.

Each χ_A vs. T curve of the iron(II) complexes shows a maximum near 120 K as seen in Fig. 1(B). Such a cryomagnetic behavior seemed to be characteristic of dimeric iron(II), but the exact magnetic simulation with the susceptibility equation for the $(S_1=2)$-$(S_2=2)$ system based on the Heisenberg model could not be attained as shown in Fig. 1(B). We believe that the complexes are indeed dinuclear but the magnetic simulation in terms of the Heisenberg model is not valid because of a significant orbital contribution, as suggested for related dinuclear iron(II) complexes.[10]

$[Mn_3(L)_4]X_2$. This type of complexes was obtained only with manganese(II) ions. The magnetic moment (per metal ion) of those complexes is also subnormal for high-spin manganese(II) ion and decreased with lowering of temperature. The most plausible structure for those complexes is trinuclear where each terminal metal is sixcoordinated with the two ligands, and the central metal is tetrahedrally coordinated with bridging thiolate sulfurs. Such a linear, trinuclear structure is known for nickel(II) complexes of amino thiolic ligands.[11] The evidence supporting this structure has been obtained by cryomagnetic investigations. The magnetic susceptibility equations for the $(S_1=5/2)$-$(S_2=5/2)$-$(S_3=5/2)$ system was derived Kambe's method[12] on assuming $J_{12}=J_{23}=J$ and $J_{13}=0$ and is expressed as follows:

$$\chi_A = (Ng^2\beta^2/36kT)[A/B] + N\alpha \quad (4)$$

where A=2040exp(55J/kT)+1365exp(50J/kT)+858exp(45J/kT)+1860exp(40J/kT)+858exp(37J/kT)+252exp(35J/kT)+495exp(34J/kT)+252exp(31J/kT)+105exp(30J/kT)+105exp(28J/kT)+858exp(27J/kT)+495exp(26J/kT)+252exp(25J/kT)+105exp(24J/kT)+30exp(23J/kT)+30exp(19J/kT)+105exp(18J/kT)+252exp(17J/kT)+498exp(16J/kT)+30exp(13J/kT)+108exp(10J/kT)+252exp(7J/kT)+30exp(5J/kT)+105

and B=8exp(55J/kT)+7exp(50J/kT)+6exp(45J/kT)+12exp(40J/kT)+6exp(37J/kT)+4exp(35J/kT)+5exp(34/kT)+4exp(31J/kT)+3exp(30J/kT)+3exp(28J/kT)+6exp(27J/kT)+5exp(26J/kT)+4exp(25J/kT)+3exp(24J/kT)+2exp(23J/kT)+2exp(19J/kT)+3exp(18J/kT)+4exp(17J/kT)+6exp(16J/kT)+2exp(13J/kT)+4exp(10J/kT)+4exp(7J/kT)+2exp(5J/kT)+3.

As shown in Fig. 2(B) good agreements were obtained between the experimental and theoretical magnetic susceptibilities. To our knowledge these are the first example of linear trinuclear manganese(II) complexes bridged by thiolate sulfurs.

In conclusion it was revealed that the thiolate bridge mediates a significant antiferromagnetic spin-exchange interaction between cobalt(II), iron(II), or manganese(II) ions.

A Short Step Synthesis of 3-Deoxy-D-*manno*-2-octulosonic Acid (KDO)

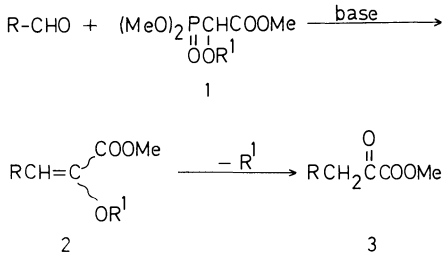
Hiroshi ITOH,* Tuyoshi KANEKO, Kazuhiro TANAMI, and Kazue YODA
The Noguchi Institute, 1-8-1 Kaga, Itabashi-ku, Tokyo 173
(Received October 16, 1987)

Synopsis. 3-Deoxy-D-*manno*-2-octulosonic acid (KDO) 1,4-lactone was synthesized from *aldehydo*-D-mannose derivatives by Horner–Emmons reaction in two steps.

3-Deoxy-D-*manno*-2-octulosonic acid (2-keto-3-deoxy-octonic acid; KDO) is an integral component of the lipopolysaccharides (LPS) of gram-negative bacteria and connects the lipophilic part of LPS, lipid A, to the core region of polysaccharide through its ketosidic bonds.[1]

Following an identification of the important and unique function of KDO and a determination of its structure, several partial syntheses from simpler sugars could be accomplished. The published methods regarding the synthesis of KDO involve a Wittig reaction of D-mannose derivatives[2] or a reaction of D-arabinose derivatives with di-*t*-butyl oxalacetate.[3] However, these methods required either many steps for the completion of the structure of KDO or a separation of KDO and its isomers.

We now wish to describe a synthesis of KDO involving fewer steps by a Horner–Emmons reaction. The condensation of Horne's phosphonate **1**[4] with aldehydes afforded a carboxymethyl enol ether derivative **2**. We attempted to convert this enol ethers **2** into a keto carboxymethyl derivative **3**, which corresponds to the C-1—C-3 part of KDO.

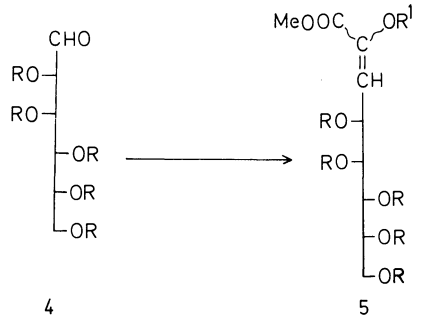


Reactions of acetylated or benzylated *aldehydo*-D-mannose derivatives **4** with **1** using lithium bis(trimethylsilyl)amide as a base in tetrahydrofuran (THF) afforded the expected methyl 3-deoxy-D-*manno*-oct-2-enoate derivatives **5** in reasonable yields; the results are summarized in Table 1. In most cases, the *E*-isomers were formed, predominantly, as judged from the ^{1}H NMR spectra.[6]

In contrast, the reaction of 3,4:5,6-di-*O*-isopropylidene-*aldehydo*-D-mannose, which was not purified after a dethioacetal reaction, with **1** (R^1=–$SiMe_2CMe_3$) did not afford the corresponding **5**, resulting in a complex mixture. 2-*O*-Acetyl-3,4:5,6-di-*O*-isopropylidene-*aldehydo*-D-mannose afforded **5**, though in low yield (25%). When butyllithium or DBU–$LiClO_4$[5] was used as a base, **5** was also obtained, but the yield was lower.

The deprotection step from **5** to KDO 1,4-lactone (**6**) was first investigated by using methyl 4,5,6,7,8-penta-*O*-acetyl-2-*O*-(*t*-butyldimethylsilyl)-3-deoxy-D-*manno*-oct-2-enoate (**5a**). When **5a** was treated with tetrabutylammonium fluoride, the solution immediately became dark brown, indicating a complex mixture. A treatment of **5a** with sodium methoxide in methanol and a subsequent addition of a cation-exchange resin afforded the expected **6**, though in low yield.

Table 1. Yields of 3-Deoxy-D-*manno*-oct-2-enoate Derivatives (**5**)



R	R^1	5 (%)
-Ac	$-SiMe_2Bu^t$	68 (**5a**)
	-Ac	29 (**5b**)
	$-COOCMe_2CCl_3$	56 (**5c**)
-Bn	$-SiMe_2Bu^t$	70 (**5d**)
	$-COOCMe_2CCl_3$	56 (**5e**)
	-Bn	77 (**5f**)

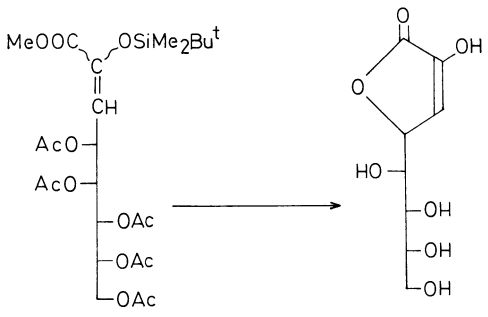
Bn=benzyl.

To improve the yield of **6**, other alkoxides or other methods[7] were investigated. The results are summarized in Table 2. Among these results, the best yield (45%) was obtained with sodium ethoxide in ethanol at −20 °C. The product **6** was readily separated from the reaction mixture by crystallization.

Conversions of other enoates **5b—f** to **6** were also examined, but proved to be unsatisfactory. A trace amount of **6** was obtained from **5c** upon a similar treatment with alkoxide, but not at all from **5b**. Attempts to convert **5d—f** into **6**, involving various methods reported for the removal of benzyl protecting groups (i.e., catalytic hydrogenolysis,[8] reductive cleavage with sodium in ethanol,[9] iodotrimethylsilane,[10] or ethanethiol–boron trifluoride etherate[11]) failed, always resulting in the formation of complex mixtures. When **5d** was first treated with tetrabutylammonium fluoride, the desired 4,5,6,7,8-penta-*O*-benzyl-3-deoxy-D-*manno*-octulosonic acid (66%) was obtained. However, it could not be converted into **6** by catalytic hydrogenolysis, a complex mixture being formed.

One method already described in the literature was used to give an ammonium salt of KDO from **6**[3]

Table 2. Conversion of **5a** into **6**



5a 6

Reagent	Temp	Time/h	Yield/%

ammonium salt of KDO

Experimental

General Procedure. Melting points are uncorrected. NMR spectra were recorded in the solvents noted (Me_4Si, 0.00 ppm) with a JEOL FX 90A spectrometer. Column chromatography was performed by flash chromatography with silica gel. Specific rotations were measured with a JASCO DIP-360 polarimeter. IR spectra were recorded with a JASCO A-102 spectrometer.

2,3,4,5,6-Penta-*O*-acetyl-*aldehydo*-D-mannose. This compound was prepared as described by Miljikovic's method[12] from 2,3,4,5,6-penta-*O*-acetyl-*aldehydo*-D-mannose diethyl dithioacetal. The product was purified by column chromatography (ethyl acetate: hexane 1:5) as oil (it gradually crystallized). This compound could not be stored after purification, since it decomposed rapidly while in storage. ^1H NMR ($CDCl_3$) δ=2.00 (3H, s), 2.05 (3H, s), 2.10 (3H, s), 2.12 (3H, s), 2.17 (3H, s), 4.00—4.30 (2H, m), 4.90—5.25 (2H, m), 5.40—5.55 (2H, m), 9.42 (1H, d, J=1.0 Hz); IR (KBr) 1750, 1710 cm^{-1}.

Methyl α-(Dimethoxyphosphinyl)glycolate *t*-Butyldimethylsilyl Ether (1, R¹=*t*-butyldimethylsilyl). To a solution of methyl α-(dimethoxyphosphinyl)glycolate (0.198 g, 1.00 mmol) in DMF (1 ml) were added *t*-butyldimethylsilyl chloride (0.181 g, 1.20 mmol) and imidazole (0.082 g, 1.20 mmol) at room temperature. After stirring for 17 h at room temperature, the resulting mixture was extracted with diethyl ether; the product was purified by column chromatography (ethyl acetate: hexane 1:4) to give 0.255 g (82%) as oil; ^1H NMR ($CDCl_3$) δ=0.13 (6H, s), 0.93 (9H, s), 3.70 (3H, s), 3.77 (3H, s), 3.88 (3H, s), 4.58 (1H, d, J=18.0 Hz).

Methyl α-(Dimethoxyphosphinyl)glycolate Benzyl Ether (1, R¹=benzyl). To a solution of methyl α-(dimethoxyphosphinyl)glycolate (1.98 g, 10.0 mmol) in cyclohexane (60 ml) and dichloromethane (30 ml) were added benzyl trichloroacetimidate[13] (5.10 g, 20 mmol) and trifluoromethanesulfonic acid (0.44 ml, 5.0 mmol) at room temperature; the mixture was stirred for 23 h. The resulting mixture was extracted with dichloromethane and the product was purified by column chromatography (ethyl acetate:hexane 3:2) to give 2.73 g (95%) as oil; ^1H NMR ($CDCl_3$) δ=3.67 (3H, s), 3.73 (3H, s), 3.83 (3H, s), 4.37 (1H, d, J=18.4 Hz), 4.75 (1H, d, J=9.0 Hz), 4.83 (1H, d, J=9.0 Hz), 7.25 (5H, s).

Methyl 2-*O*-Acetyl-α-(dimethoxyphosphinyl)glycolate (1, R¹=acetyl). ^1H NMR ($CDCl_3$) δ=2.18 (3H, s), 3.73 (3H, s), 3.75 (3H, s), 3.92 (3H, s), 5.38 (1H, d, J=17.2 Hz).

Methyl 4,5,6,7,8-Penta-*O*-acetyl-2-*O*-(*t*-butyldimethylsilyl)-3-deoxy-D-*manno*-oct-2-enoate (5a). To a solution of methyl α-(dimethoxyphosphinyl)glycolate *t*-butyldimethylsilyl ether (0.225 g, 0.720 mmol) in THF (3 ml) was added 1 M lithium bis(trimethylsilyl)amide (1 M=1 mol dm^{-3}) in THF solution (0.660 ml) at −78 °C under an argon atmosphere. After 10 min, 2,3,4,5,6-penta-*O*-acetyl-*aldehydo*-D-mannose (0.234 g, 0.600 mmol) in THF (25 ml) solution was added dropwise over 20 min at −78 °C; the mixture was stirred for 2 h at −78 °C. The resulting mixture was extracted with diethyl ether and the products were separated by column chromatography (ethyl acetate:hexane 1:8). The faster moving compound was (*Z*)-**5a** (0.005 g, 1%) obtained as oil; ^1H NMR ($CDCl_3$) δ=0.20 (6H, s), 1.00 (9H, s), 1.99 (3H, s), 2.02 (3H, s), 2.04 (6H, s), 2.07 (3H, s), 3.72 (3H, s), 4.07—4.18 (1H, m), 5.00—5.22 (1H, m), 5.28—5.95 (5H, m); ^{13}C NMR ($CDCl_3$) δ=−4.2, 18.7, 20.4, 20.6, 20.7, 25.8, 52.3, 62.0, 65.5, 67.5, 68.1, 69.8, 114.1, 144.0, 169.4,

169.5, 169.8, 170.4. The slower moving compound was (*E*)-**5a** (0.231 g, 67%) obtained as colorless crystals; mp 56—59 °C. ^{1}H NMR ($CDCl_3$) δ=0.14 (6H, s), 0.92 (9H, s), 2.00 (3H, s), 2.04 (6H, s), 2.12 (3H, s), 2.16 (3H, s), 3.82 (3H, s), 4.06—4.21 (2H, m), 5.00—5.20 (1H, m), 5.28 (1H, d, J=9.8 Hz), 5.34 (1H, dd, J=2.1, 7.5 Hz), 5.50 (1H, dd, J=2.1, 9.0 Hz), 6.23 (1H, dd, J=7.5, 9.8 Hz); ^{13}C NMR ($CDCl_3$) δ=−5.0, 18.2, 20.6, 20.8, 20.9, 25.5, 52.0, 62.0, 67.7, 68.3, 69.9, 115.0, 145.6, 164.0, 169.4, 169.6, 169.7, 169.9, 170.5. IR (KBr) 1750, 1640, 1220 cm^{-1}; $[\alpha]_D^{28}$=31.2° (*c* 1.67, acetone); Found: C, 52.45, H, 7.11%. Calcd for $C_{25}H_{40}O_{13}Si$: C, 52.07, H. 6.99%. Other methyl 3-deoxy-D-*manno*-oct-2-enoate derivatives (**5**) were also obtained in a similar manner. ^{1}H NMR data of the main products are listed as follows.

Methyl 2,4,5,6,7,8-Hexa-*O*-acetyl-3-deoxy-D-*manno*-oct-2-enoate (5b); ^{1}H NMR ($CDCl_3$) δ=2.02 (12H, s), 2.08 (6H, s), 3.76 (3H, s), 3.73—4.18 (2H, m), 4.93—5.50 (1H, d, J=10.0 Hz), 6.22 (1H, dd, J=8.0, 10.0 Hz).

Methyl 4,5,6,7,8-Penta-*O*-acetyl-2-*O*-(2,2,2-trichloro-1,1-dimethylethoxycarbonyl)-3-deoxy-D-*manno*-oct-2-enoate (5c); ^{1}H NMR ($CDCl_3$) δ=2.02 (12H, s), 2.12 (3H, s), 3.82 (3H, s), 4.00—4.30 (2H, m), 5.00—5.60 (3H, m), 5.81 (1H, d, J=9.6 Hz), 6.23 (1H, dd, J=6.6, 9.6 Hz).

Methyl 4,5,6,7,8-Penta-*O*-benzyl-2-*O*-(*t*-butyldimethylsilyl)-3-deoxy-D-*manno*-oct-2-enoate (5d); ^{1}H NMR ($CDCl_3$) δ=0.13 (6H, s), 0.93 (9H, s), 3.58 (3H, s), 3.60—4.00 (5H, m), 4.20—4.70 (10H, m), 5.13 (1H, dd, J=2.4, 9.2 Hz), 5.58 (1H, d, J=9.2 Hz).

Methyl 4,5,6,7,8-Penta-*O*-benzyl-2-*O*-(2,2,2-trichloro-1,1-dimethylethoxycarbonyl)-3-deoxy-D-*manno*-oct-2-enoate (5e); ^{1}H NMR ($CDCl_3$) δ=3.66 (3H, s), 3.72—4.24 (5H, m), 4.40—4.82 (10H, m), 5.32 (1H, dd, J=5.0, 10.0 Hz), 6.15 (1H, d, J=10.0 Hz).

Methyl 4-*O*-Acetyl-2-*O*-(*t*-butyldimethylsilyl)-5,6:7,8-di-2-enoate (5f); ^{1}H NMR ($CDCl_3$) δ=3.68 (3H, s), 3.68—3.95 (5H, m), 4.25—4.78 (10H, m), 5.12 (1H, dd, J=2.5, 9.5 Hz), 5.32 (1H, d, J=9.5 Hz).

Methyl 4-*O*-acetyl-2-*O*-(*t*-butyldimethylsilyl)-5,6:7,8-di-*O*-isopropylidene-3-deoxy-D-*manno*-oct-2-enoate; ^{1}H NMR ($CDCl_3$) δ=0.17 (6H, s), 0.93 (9H, s), 1.35 (3H, s). 1.40 (9H, s), 2.03 (3H, s), 3.75 (3H, s), 3.75—4.33 (5H, m), 5.40 (1H, d, J=5.0 Hz), 6.22 (1H, dd, J=3.0, 5.0 Hz).

KDO 1,4-Lactone (6). To a solution of sodium ethoxide (0.106 g, 1.55 mmol) in ethanol (20 ml) was added **5a** (0.447 g, 0.775 mmol) in ethanol (32 ml) at −20 °C. This solution was stirred for 20 h at −20 °C. Then, Dowex 50 WX (H^+) was added at room temperature and the mixture stirred for 2.5 h. After filtration, the filtrate was evaporated under reduced pressure and ethanol–diethyl ether was added. Compound **6** was collected by filtration and dried to give 0.077 g (45%) of colorless crystals, mp 191—194 °C (lit,[3b] 192—194 °C). $[\alpha]_D^{28}$ +34.3° (*c* 1.4 water) (lit,[3b] $[\alpha]_D^{24}$ +31.8° (*c* 1.4, water).

Synthesis of Mixed Trialkyl Phosphates: Oxidative Phosphorylation of Alcohols with Dialkyl Phosphonates in the Presence of Copper(II) Chloride

Yoshiki OKAMOTO,* Tetuya KUSANO, and Setsuo TAKAMUKU
The Institute of Scientific and Industrial Research, Osaka University,
Ibaraki, Osaka 567
(Received January 13, 1988)

Synopsis. Mixed trialkyl phosphates were synthesized by oxidative phosphorylation of alcohols with dialkyl phosphonates and oxygen in the presence of copper(II) chloride in fairly good yields.

Various methods for the phosphorylation of alcohol have been reported.[1] The most frequently used method to prepare mixed trialkyl phosphate (**1**) involves the phosphorylation of alcohol with dialkyl phosphorochloridate (**2**), which is generally prepared by the chlorination of dialkyl phosphonate (**3**) with chlorine. Some modifications have been designed so as to avoid handling potentially hazardous chlorine gas. One is the reaction of alcohol with **3** in carbon tetrachloride and tertiary amine.[2] The other is an anodic phosphorylation of alcohol with **3** in the presence of lithium chloride.[3] In these reactions, **2** is presumed to be involved as an intermediate.

In the present paper, we report a more convenient procedure for preparation of **1** by the oxidation of **3** with oxygen by coupling with oxidation-reduction cycle of Cu(II) and Cu(I) chlorides in alcohol. This procedure possesses several advantages over the known methods: (1) handling potentially hazardous substances can be avoided, (2) water is the sole by-product, and (3) expensive reagents and special apparatus are unnecessary. Therefore, this method could be satisfactorily employed for the technical production of **1**. This procedure probably consists of three unit processes: (1) the chlorination of **3** with copper(II) chloride to give **2** and hydrogen chloride,[4] (2) the phosphorylation of alcohol with **2** to afford **1** and hydrogen chloride, and (3) the oxidation of hydrogen chloride and copper(I) chloride with oxygen to reproduce copper(II) chloride.[5] Consequently, in the presence of a catalytic amount of copper(II) chloride and by bubbling oxygen, alcohol is phosphorylated with **3** to give the corresponding **1**.

$$\underset{\mathbf{3}}{(RO)_2P(O)H} + 2CuCl_2 \longrightarrow \underset{\mathbf{2}}{(RO)_2P(O)Cl} + HCl + 2CuCl \quad (1)$$

$$\mathbf{2} + R'OH \longrightarrow \underset{\mathbf{1}}{(RO)_2P(O)OR'} + HCl \quad (2)$$

$$4CuCl + 4HCl + O_2 \longrightarrow 4CuCl_2 + 2H_2O \quad (3)$$

Table 1. Results of Oxidative Phosphorylation of Ethanol with **3b**[a]

EtOH/**3b**	$CuCl_2$[b]	Temp	Conv.[c]	Yield[c]
mole ratio	mol%	°C	%	%
1.2	10	5	84	19
1.2	10	17	86	44
1.2	10	50	98	97
1.2	10	70	95	34
3.0	10	50	98	95
10.0	10	50	98	78
1.2	2	50	33	32
1.2	3	50	90	88
1.2	5	50	98	97
1.2	7	50	98	82

a) Conditions; 10 ml of mixture EtOH/**3b** was charged in a reaction tube (ϕ=10 mm) and oxygen was bubbled through it at flow rate 30 ml min^{-1} for 5 h. b) Based on **3b** used. c) Conversion and yield based on **3b** were determined by GLC using biphenyl as an internal standard.

The results obtained on the reaction of ethanol with diethyl phosphonate (**3b**) under several conditions are shown in Table 1. At a lower temperature (5 °C), the yield of triethyl phosphate (**1b-Et**) was low, despite the large conversion of **3b**. The intermediate, diethyl phosphorochloridate (**2b**), remained almost unreacted. The yield of **1b-Et** increased remarkably upon raising the temperature, and reached a maximum at 50 °C. At a higher temperature (70 °C), the yield was again reduced due to the formation of tetraethyl pyrophosphate (**4**), which may have been formed by a reaction between **1b-Et** and **2b** (Eq. 4).

$$\underset{\mathbf{1b\text{-}Et}}{(EtO)_2P(O)OEt} + \underset{\mathbf{2b}}{(EtO)_2P(O)Cl} \longrightarrow (EtO)_2P(O)OP(O)(OEt)_2 + EtCl \quad (4)$$

It has been reported that Eq. 4 may be catalyzed with a small amount of copper.[6] Figure 1 shows the conversion of **3b** and the yield of **1b-Et** under optimum conditions as the function of the reaction time. The consumption of **3b** was completed within 5 h, and the yield of **1b-Et** became quantitative. Table 2 shows the obtained results regarding reactions of the other **3** with alcohols. With an increasing number of carbons of the alkyl group, the conversion of **3** decreased slightly; however, the yield of **1** decreased to

a great extent. This result suggests that an increase in the bulkiness of alkyl groups affected the phosphorylation rate of **2** (Eq. 2) more than the chlorination rate of **3** (Eq. 1). When isopropyl or *t*-butyl alcohol was used, the yield of **1** became reduced and **4** was yielded in substantial quantity. The phosphates (**1**) of these alcohols may particularly tend to dimerize while easily liberating the corresponding alkyl chlorides, according to the reaction similar to Eq. 4. The phosphorylation of phenol with **3b** gave only a 3% yield of diethyl phenyl phosphate. In this case, the reaction mixture became turbid and a white precipitate was observed. Since phenol is more acidic than aliphatic alcohol, this precipitate may be the copper salt of phenol. The formation of the salt impaired the catalytc activity of copper. However, diphenyl phosphonate (**3e**) reacted with ethyl alcohol to give a similar result as in the cases of dipropyl phosphonate (**3c**) or dibutyl phosphonate (**3d**). Reactions using other copper(II) salts, such as bromide, acetate, and sulfate, failed. This suggests that chloride is necessary in order to propagate the reaction. The reaction (Eq. 1) can be explained by using the following radical mechanism:

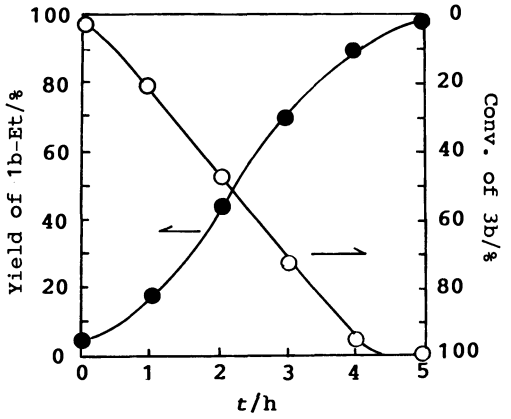

Fig. 1. Yield of **1b-Et** and conversion of **3b** as a function of reaction time.
Conditions: Ten ml of reaction mixture (EtOH/**3b** mole ratio=1.2 and $CuCl_2$ 10% based on **3b**) was bubbled with oxygen gas (flow rate 50 ml min^{-1}) at 50 °C. ●; Yield of **1b-Et**, ○; conversion of **3b**.

$$CuCl_2 \longrightarrow CuCl + Cl\cdot \quad (5)$$

$$Cl\cdot + \mathbf{3} \longrightarrow HCl + \cdot P(O)(OR)_2 \quad (6)$$

$$CuCl_2 + \cdot P(O)(OR)_2 \longrightarrow CuCl + \mathbf{2} \quad (7)$$

An electron transfer from the chloride to copper(II) occurs (Eq. 5), and the hydrogen atom of **3** is abstracted by the chlorine atom (Eq. 6). Since the oxidation potentials of the sulfate and acetate ions are higher than that of the chloride ion (oxidation of these ions are more difficult), consequently, the reactions using copper(II) sulfate and acetate did not occur. When copper(II) bromide is used, the resulting dialkyl phosphorobromidate (**5**) gives dialkyl hydrogenphosphate (**6**) and

$$\underset{\mathbf{5}}{(RO)_2P(O)Br} + ROH \longrightarrow \underset{\mathbf{6}}{(RO)_2P(O)OH} + RBr \quad (8)$$

alkyl bromide in place of **1** and hydrogen bromide (Eq. 8).

Upon the addition of triethylamine, the reaction was interrupted. Since hydrogen chloride may be consumed while binding the triethylamine, the progress of the reaction (Eq. 3) finally stopped. When acetonitrile was used as a solvent, **3** did not react, probably because of the extremely low solubility of

a) Conditions: R'OH/**3** mole ratio; 1.3, $CuCl_2$; 10% based on **3**, oxygen flow rate; 30 ml min^{-1}, 50 °C, 5 h. b) Yields and conversion based on **3** were determined by GLC. Yields indicated in parentheses were for isolated product by distillation (**1b-Et**; bp 92—94 °C/12 mmHg, **1b-Bu**; bp 123—124 °C/15 mmHg, **1c-Et**; bp 110—112 °C/23 mmHg). In all cases, the phosphates were identified by comparison with authentic samples.[1] c) Tetraethyl pyrophosphate (**4**, 45%), which was assigned by comparison with an authentic sample[1] by means of GLC, yielded. d) The yield of **4** was 48%.

copper(I) chloride.

Experimental

Typical Procedure: A mixture of diethyl phosphonate (**3b**, 13.8 g, 0.1 mmol), propyl alcohol (7.2 g, 0.12 mmol), and copper(II) chloride (1.3 g, 0.01 mmol) was placed in a cylindrical reaction vessel (ϕ=10 mm). Copper(II) chloride was easily soluble in the mixture; however, after some time, white copper(I) chloride gradually precipitated due to its poor solubility. With bubbling of oxygen (flow rate 30 ml min^{-1}) at 50 °C, the precipitates soon disappeared and the solution became blue. The progress of the reaction was monitored by GLC (a 1-m glass column packed with Silicone OV 17 (2%) on Chromosorb W AW DMCS) at prescribed time intervals. After the conversion of **3 b** was complete, the reaction mixture was distilled in vacuo to afford diethyl propyl phosphate (**1b-Pr**, 78%, 100—101 °C/0.1 mmHg (1 mm Hg=133.322 Pa)).

(Received February 5, 1988)

Synopsis. Tricarbonyliron complexes of 3-buten-2-one, 3-penten-2-one, and 4-phenyl-3-buten-2-one reacted with organolithium and Grignard reagents to afford 1,4-diketones in one step, some of the products are amenable to convertion to natural products.

Much attention has been devoted in recent years to the chemistry of iron carbonyl complexes of dienes and polyenes.[1] Recently, the reaction of tricarbonyl-(4-phenyl-3-buten-2-one)iron and its derivatives with organolithium and Grignard reagents to give the corresponding 1,4-diketones has been reported.[2] This has prompted us to report our similar results and their application to the synthesis of some natural products.[3]

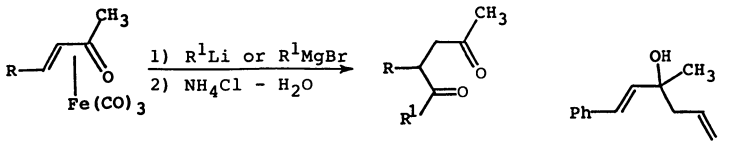
(3-Buten-2-one)tricarbonyliron (**1**)[4] was reacted with 2.5 molar equivalents of butyllithium in THF at −78 °C for 25 min. The reaction mixture was quenched with diluted H_2SO_4 or with saturated NH_4Cl aqueous solution to give 2,5-nonanedione **2** (R^1=*n*-Bu) in 62% yield. The reaction of **1** with *t*-BuLi and PhLi afforded the corresponding 1,4-diketones in 29% and 75% yields, respectively.

The similar reaction of (3-penten-2-one)tricarbonyliron (**3**)[5] and tricarbonyl(4-phenyl-3-buten-2-one)iron (**5**)[6] with organolithium and Grignard reagents also yielded the corresponding 1,4-diketones **4** and **5**, respectively; the results are shown in Table 1. The reaction of **5** with allylmagnesium bromide, however, afforded a 1,2-addition product **7** in 80% yield.

The structures of these products were determined by spectroscopic analyses or by the comparison of their ^1H NMR and/or IR spectra with those of authentic samples.

As has already been reported,[2] the reactions probably proceed by acyl transfer from a metal acyl intermediate to the, α,β-unsaturated ketone followed by protonation. Therefore, we attempted a quenching of a reaction mixture of **1** and *n*-BuLi with excess MeI instead of NH_4Cl aqueous solution, however, no methylated product could be obtained, only **2** (R^1=*n*-Bu) was produced.

The reaction of **1** with hexyl- and *p*-methylbenzylmagnesium bromide afforded the corresponding 1,4-diketones **8** and **9** in 82% and 19% yields, respectively, as shown in Table 1. The compound **8** was then



1 R = H 2 R = H 7

3 R = CH_3 4 R = CH_3

5 R = Ph 6 R = Ph

Table 1. Synthesis of 1,4-Diketones (in THF, −78 °C)

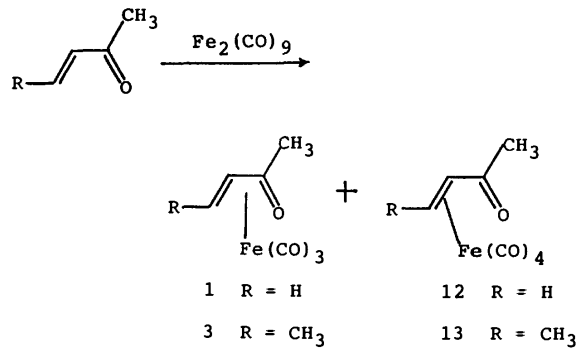
transformed by cyclization in basic medium conditions to dihydrojasmone **10**.[9] The compound **9** was reported to be converted to cuparene **11**.[10]

Thus it is found that this one-step synthesis of 1,4-diketones by nucleophilic reaction to tricarbonyliron complexes of α,β-unsaturated ketones will be widely useful to natural product syntheses. However, from these limited examples, we can not conclude which of the two reagents, alkyllithium and Grignard reagent, is the better in this 1,4-diketone synthesis.

In the course of the synthesis of **1** and **3** by the reaction of 3-buten-2-one and 3-penten-2-one with $Fe_2(CO)_9$ in benzene, we isolated new complexes [3-4-η-(3-buten-2-one)]tetracarbonyliron (**12**) and [3-4-η-(3-penten-2-one)]tetracarbonyliron (**13**) as orange oils along with tricarbonyl complexes **1** and **3**, respectively. The yield of **12** was dependent on the reaction temperature, thus, **1** and **12** were obtained in 7% and 47% yields, respectively at 60 °C and in 53% and 3% yields at 80 °C. Furthermore, **12** was gradually



changed to **1** by heating in benzene. The structures of **12** and **13** were determined by the above fact as well as the analyses of ^{1}H NMR, IR and/or mass spectra (see Experimental).

Experimntal

General. The IR spectra were obtained with a Hitachi 260-50 spectrophotometer, ^{1}H NMR spectra were recorded with JEOL JNM-270 (270 MHz) or JNM-H60 (60 MHz) spectrometer in $CDCl_3$ solutions, and mass spectra were measured with JEOL JMS D-200 spectrometer.

Syntheses of (3-Buten-2-one)tricarbonyliron (1) and [3-4-η-(3-Buten-2-one)]tetracarbonyliron (12). A solution of 3-buten-2-one (0.41 ml, 5.0 mmol) and $Fe_2(CO)_9$ (2.728 g, 7.5 mmol) in anhydrous benzene (25 ml) was heated at 80 °C overnight. The precipitate was filtered off, solvent was removed under reduced pressure, the residue was purified by column chromatography on silica gel (45 g) using benzene as eluent to give complexes **1** (554 mg, 53% yield) and **12** (40 mg, 3% yield) as orange oils.

When the same reaction was carried out at 60 °C, **1** and **12** were obtained in 7% and 47% yields, respectively.

1:[4] IR (neat), 2080, 2010, 1990 cm^{-1}; MS *m/z* 210 (M^+), 182, 154; ^{1}H NMR ($CDCl_3$) δ=1.36 (d, d, J=2, 12 Hz, H-4(Z)), 2.07 (d, d, J=2, 7 Hz, H-4(E)), 2.48 (s, CH_3), 5.54 (d, d, J=7, 12 Hz, H-3).

12: IR (neat), 2110, 2030, 1960 cm^{-1}; MS *m/z* 238 (M^+), 210, 182, 154; ^{1}H NMR ($CDCl_3$) δ=2.35 (s, CH_3), 2.56 (d, d, J=2, 7 Hz, H-4(E)), 2.98 (d, d, J=2, 12 Hz, H-4(Z)), 3.53 (d, d, J=7, 12 Hz, H-3).

The patterns of the C=O stretching region in the IR spectra of **1** and **12** are very similar to those of tricarbonyliron and tetracarbonyliron complexes of styrene, respectively.[12]

Similarly, complexes **3** and **13** were obtained by the reaction of 3-penten-2-one and $Fe_2(CO)_9$ as orange oils.

3:[5] IR (neat), 2065, 1990, 1972 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.52 (d, J=6 Hz, CH_3), 1.9—2.4 (m, H-4), 2.48 (s, CH_3), 5.47 (d, J=9 Hz, H-3).

13: unstable orange oil; IR (neat), 2105, 2030, 1980 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.81 (d, J=6 Hz, CH_3), 2.33 (s, CH_3), 3.5—4.2 (m, 2H).

General Procedure of the Reaction of Complexes with Organolithium and Grignard Reagents. The general procedure will be illustrated below by using the reactions of (3-buten-2-one)tricarbonyliron (**1**) and *n*-BuLi, and tricarbonyl(4-phenyl-3-buten-2-one)iron (**5**) and vinylmagnesium bromide as example.

A stirred solution of **1** (106.6 mg, 0.5 mmol) in anhydrous THF (2 ml) was cooled at −78 °C under N_2 atmosphere and was added dropwise 2.34 M hexane solution (1 M=1 mol dm^{-3}) of *n*-BuLi (0.54 ml, 1.25 mmol). After 25 min, the reaction mixture was quenched with saturated aqueous solution of NH_4Cl (5 ml), extracted with CH_2Cl_2 three times, the extract was dried over anhydrous Na_2SO_4, the solvent was removed, and the residue was purified by preparative TLC on silica gel using a mixture of hexane and AcOEt (3:1) as eluent to give 2,5-nonanedione **2** (R^1=*n*-Bu) (49.1 mg, 62% yield) as colorless oil.

A stirred solution of **5** (143.1 mg, 0.5 mmol) in anhydrous THF (2 ml) was cooled at −78 °C under N_2 atmosphere and was added dropwise 0.9 M ethereal solution of vinylmagnesium bromide (1.5 ml, 1.25 mmol). After 80 min, the reaction mixture was quenched with saturated NH_4Cl (5 ml) and extracted with CH_2Cl_2. The extract was dried over anhydrous Na_2SO_4, the solvent removed, and the residue purified by preparative TLC using a mixture of hexane and AcOEt (5: 1) to give 4-phenyl-1-heptene-3,6-dione (**6**) (R^1=CH=CH_2) (66.7 mg, 64% yield) as colorless oil.

IR (neat), 1708, 1675 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=2.15 (s, CH_3), 2.63 (1H, d, d, J=4, 19 Hz, H-5), 3.58 (1H, d, d, J=11 19 Hz, H-5), 4.46 (d, d, J=4, 11 Hz, H-4), 5.68 (d, d, J=3, 10 Hz, H-2), 6.23—6.42 (2H, m, H-1), 7.10—7.40 (m, Ph).

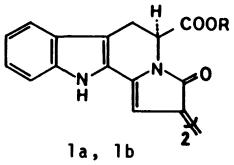
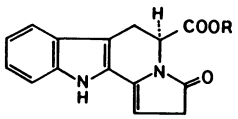
(Received March 8, 1988)

Synopsis. A dimeric blue pigment was formed by the autoxidation of a dihydropyrrolo[2,1-*a*]isoquinolin-3(2*H*)-one derivative.

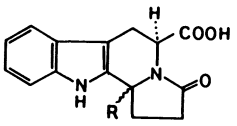
A blue pigment, trichotomine (**1a**, R=H), was isolated from *Clerodendron trichotomum* Thunb.[1] It was suggested that the biosynthesis of **1a** involved an oxidative dimerization of **2a** (R=H) formed from L-tryptophan and 2-oxoglutaric acid.[1,2] In the synthesis of **1a**, **1b** (R=Me) was obtained by the autoxidation of **2b** (R=Me).[3] We examined the extracts of the above plant, and isolated **3a** (R=α-H), **3b** (R=β-H), **3c** (R=α-COOH), and **3d** (R=β-COOH), which were other plausible precursors of **1a**.[4] Kapadia et al. reported the isolation of **4a** (R=H) and **4b** (R=Me); these formations were proposed to result from the condensation of 2-oxoglutaric acid with 3-demethylmescaline and mescaline, respectively.[2,5] The biosynthesis of **1a** caused us to anticipate the occurrence of natural dimeric pigments derived from such compounds as **4a,b**. In this paper, we wish to report on the oxidative dimerization of a dihydropyrrolo[2,1-*a*-]isoquinolin-3(2*H*)-one derivative **5** as a model compound.



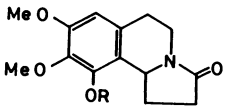
1a, 1b



2a, 2b



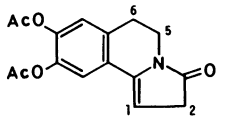
3a–3d



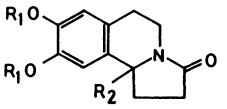
4a, 4b

The known compound, **6**[6], prepared from dopamine hydrochloride and 2-oxoglutaric acid, was acetylated with acetic anhydride and pyridine to an acetate **7**. Upon electrolysis in methanol containing $(n\text{-Bu})_4$NCl as a supporting electrolyte, **7** underwent decarboxylative methoxylation[7] to a methoxy lactam **8**. The ^{1}H NMR spectrum of **8** showed a singlet (δ=3.16) of the methoxyl group on C-10b and an octet (δ=4.18) of the equatorial C_5-proton deshielded by the carbonyl group at C-3.[8] On electrolysis in methanol containing Et_4NOTs as an electrolyte, **7** yielded **8** and a methoxy α,β-unsaturated lactam **9** in a ratio of 5:2. The structure of **9** was in line with the ^{1}H NMR spectrum [a singlet at δ=3.17 (OCH_3), two doublets at δ=6.23 (C_2–H) and 7.13 (C_1–H), and a characteristic octet at δ=4.29 (equatorial C_5–H)]; **9** seemed to be formed via an intermediate **5**. Using a large excess of lead tetraacetate in the presence of methanol, **9** was also obtained from **7**; **9** may be similarly formed by an oxidative decarboxylation of **7** to **5**, followed by further oxidation. Upon heating at 85—90 °C for 7 h, **8** was converted to a β,γ-unsaturated lactam **5** after a loss of methanol [^{1}H NMR δ=3.25 (d, J=2.9 Hz, C_2–2H) and 5.57 (t, J=2.9 Hz, C_1–H)].

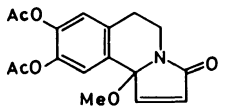
The oxidative dimerization of **5** was achieved by heating a solution of **5** in 1,1,2,2-tetrachloroethane under an oxygen atmosphere at 123—127 °C for 3 h to give a blue pigment **10**. The described structure of **10** is in agreement with the spectral data; UV 634 nm, SIMS m/z 599 $(M+H)^+$, ^{1}H NMR δ=3.04 (t, J=6.4 Hz, C_6–2H×2) and 3.83 (t, J=6.4 Hz, C_5–2H×2). Under similar conditions to those used for **5**, **9** also afforded **10**, which might be formed by an initial homolytic fission of the C_{10b}-oxygen bond in **9**, followed by coupling at C-2 of the resulting allylic radical **11** and dehydrogenation. The coloration of **5** and **9** upon heating at their melting points was due to the formation of **10**, respectively, as confirmed by the TLC R_f values.



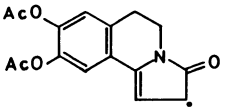
5



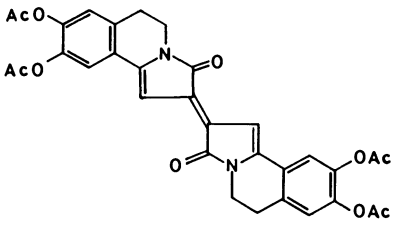
6 R_1=H R_2=COOH
7 R_1=Ac R_2=COOH
8 R_1=Ac R_2=OMe



9



11



10

The formation of **10** from **5** may also proceed via **11**; this is another type of well-known oxidative dimerization of indoxyl to indigo.[9]

Experimental

All melting points were determined on a Yanagimoto micro melting point apparatus and are uncorrected. IR spectra were recorded on a Hitachi EPI-G_3 using Nujol. ^{1}H NMR spectra were obtained on a JNM-GSX-400 (400 MHz) and ^{13}C NMR spectra on a JNM-PFT-60 (15 MHz) or a JNM-GSX-400 (100 MHz). UV spectra were measured on a JASCO-UVIDEC-510. Mass spectra were obtained on a Hitach M-52 or M-80 mass spectrometer at an ionization energy of 70 eV. Analytical TLC was carried out on silica-gel plates (Kieselgel 60 F_{254}, E. Merk).

Preparation of 7. According to the literature,[6] a solution of dopamine hydrochloride (5.70 g) and 2-oxoglutaric acid (5.84 g) in water (50 ml) was refluxed for 9 h, and cooled to room temperature to give **6** (4.03 g, 51%). A solution of **6** (2.26 g) in acetic anhydride (20 ml) and pyridine (20 ml) was allowed to stand at 20 °C for 23 h, and concentrated under reduced pressure. The residue was crystallized from $CHCl_3$–CH_3OH to afford **7** (2.77 g, 93%); mp (in a sealed tube) 239—241 °C; UV (CH_3OH) 205 (ε 28400), 269 (1150), and 275 nm (1150); IR 1760, 1720, and 1632 cm^{-1}; ^{1}H NMR (DMSO-d_6) δ=2.06 (1H, m), 2.26 (3H, s), 2.27 (3H, s), 2.30—2.50 (2H, m), 2.77—2.88 (3H, m), 3.22 (1H, m), 4.02 (1H, ddd, J=12.9, 5.5, and 4.0 Hz), 7.10 (1H, s), and 7.31 (1H, s); ^{13}C NMR (DMSO-d_6) δ=20.1, 26.8, 30.0, 32.1, 35.1, 66.1, 121.5, 123.2, 132.2, 134.6, 140.3, 141.1, 168.0, 172.1, and 173.2. Anal. ($C_{17}H_{17}NO_7$) C, H, N.

Anodic Oxidation of 7. 1) A mixture of **7** (150 mg, 0.43 mmol), (n-Bu)$_4$NCl (0.50 g), and CH_3OH (50 ml) was placed in a beaker-type undivided cell, and glassy carbon rods were used as an anode and a cathode, respectively.[10] After ca. 3.6 F mol^{-1} (1F=96480 C) of electicity (the voltage between the anode and cathode=2.1 V), the electrolytic solution was concentrated under reduced pressure to give a residue which was dissolved in benzene (80 ml). The solution was washed with water, and brine, and then dried over Na_2SO_4. Evaporation of the solvent and crystallization from CH_3OH gave **8** (67 mg, 47%); UV (CH_3OH) 205 (ε 26400), 268 (1220), and 274 nm (1230); IR 1780 and 1701 cm^{-1}; ^{1}H NMR (CD_3OD) δ=2.21 (1H, m), 2.26 (3H, s), 2.27 (3H, s), 2.42 (1H, m), 2.63—2.90 (4H, m), 3.16 (3H, s), 3.23 (1H, dddd, J=13.0, 10.0, 6.2, and 1.1 Hz), 4.18 (1H, ddd, J=13.0, 5.5, and 3.3 Hz), 7.08 (1H, s), and 7.27 (1H, s); ^{13}C NMR ($CDCl_3$) δ=20.6, 28.1, 30.7, 32.3, 35.2, 50.5, 90.7, 121.2, 123.5, 132.8, 135.8, 141.1, 141.8, 168.2, and 174.7; MS m/z 301 (M^+−32). Anal. ($C_{17}H_{19}NO_6$) C, H, N.

Compound **8** melted at 160—168 °C with decomposition and changed into **5**.

2) Using Et_4NOTs (0.48 g) as a supporting electrolyte, **7** (138 mg, 0.40 mmol) was electrolyzed under similar conditions to those described above (electricity: ca. 3 F mol^{-1}). The work-up mentioned above and crystallization from CH_3OH afforded a mixture of **8** and **9** (76 mg) in a ratio of 5:2, which was separated after column chromatography (SiO_2–$CHCl_3$). **9**; mp 138—140 °C; UV (CH_3OH) 212 (ε 18300) and 277 nm (sh, 2170); IR 1779 and 1713 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=2.27 (3H, s), 2.29 (3H, s), 2.72 (1H, ddd, J=16.6, 4.2, and 1.5 Hz), 2.92 (1H, ddd, J=16.6, 11.9, and 6.1 Hz), 3.17 (3H, s), 3.23 (1H, ddd, J=13.0, 11.9, and 4.2 Hz), 4.29 (1H, ddd, J=13.0, 6.1, and 1.5 Hz), 6.23 (1H, d, J=5.9 Hz), 7.01 (1H, s), 7.13 (1H, d, J=5.9 Hz), and 7.33 (1H, s); ^{13}C NMR ($CDCl_3$) δ=20.6, 28.6, 34.5, 50.4, 90.8, 122.9, 123.9, 128.3, 132.5, 133.2, 140.7, 142.1, 147.9, 168.0, and 170.0. Found: m/z 331.1065. Calcd for $C_{17}H_{17}NO_6$: M, 331.1055.

Upon heating at the mp, **9** gave a colored oil, which showed a blue spot of **10** (R_f 0.55) and a spot of **9** (R_f 0.41) on TLC (CH_3OH:CH_2Cl_2=1:30).

Oxidation of 7 with Lead Tetraacetate (LTA). LTA (0.41 g, 0.93 mmol) was added to a solution of **7** (50 mg, 0.14 mmol) in benzene (20 ml), CH_3OH (0.5 ml), and pyridine (0.1 ml). The reaction mixture was stirred at 26 °C for 15 min, and washed successively with 0.5 wt% HCl, water, and brine, and then dried over Na_2SO_4. Evaporation of the solvent and crystallization from CH_3OH afforded **9** (18 mg, 38%), which was identical with that obtained as described above by spectroscopic (^{1}H NMR, IR) and TLC comparisons.

Preparation of 5. The crystals of **8** (58 mg, 0.17 mmol) were heated at 85—90 °C for 7 h under reduced pressure to give **5** almost quantitatively. Recrystallization from CH_3OH gave needles of **5**; mp 170—174 °C; UV (CH_3OH) 205 (ε 35700), 237 (21300), and 293 nm (5250); IR 1767, 1711, and 1626 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=2.30 (3H, s), 2.31 (3H, s), 2.95 (2H, t, J=6.2 Hz), 3.25 (2H, d, J=2.9 Hz), 3.75 (2H, t, J=6.2 Hz), 5.57 (1H, t, J=2.9 Hz), 7.08 (1H, s), and 7.40 (1H, s); ^{13}C NMR ($CDCl_3$) δ=20.6, 20.7, 28.5, 36.6, 38.2, 97.8, 119.1, 123.5, 125.7, 132.3, 138.5, 141.2, 142.2, 168.2, 168.3, and 176.3. Found: m/z 301.0913. Calcd for $C_{16}H_{15}NO_5$: M, 301.0948.

Upon heating at the mp, **5** gave a colored oil, which showed a blue spot of **10** (R_f 0.55) and a spot of **5** (R_f 0.35) on TLC (CH_3OH:CH_2Cl_2=1:30).

Dimerization of 5. A solution of **5** (30 mg, 0.10 mmol) in 1,1,2,2-tetrachloroethane (20 ml) was stirred at 123—127 °C for 3 h under oxygen atmosphere. The resulting blue solution was concentrated under reduced pressure. The residue was washed with CH_3OH and purified with column chromatography (SiO_2, 1 vol% CH_3OH–$CHCl_3$) to give **10** (5 mg, 17%) as amorphous powder; UV ($CHCl_3$) 316 (ε 28500), 590 (29900), and 634 nm (26500); IR 1767 and 1668 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=2.31 (3H×2, s), 2.34 (3H×2, s), 3.04 (2H×2, t, J=6.4 Hz), 3.83 (2H×2, t, J=6.4 Hz), 7.13 (1H×2, s), 7.19 (1H×2, s), and 7.60 (1H×2, s); MS (SIMS) m/z 599 $(M+H)^+$. Found: C, 63.87; H, 4.31; N, 4.60%. Calcd for $(C_{16}H_{13}NO_5)_2$: C, 64.21, H, 4.38, N, 4.68%.

Dimerization of 9. A solution of **9** (40 mg, 0.12 mmol) in 1,1,2,2-tetrachloroethane (20 ml) was stirred at 121—123 °C for 1 h. The resulting blue solution was worked up as described above to afford **10** (15 mg, 42%), which was identical to that obtained from **5** by spectroscopic (^{1}H NMR, IR) and TLC comparisons.

We would like to thank Dr. Hiroshi Sakurai of Meijo University for obtaining the mass spectra.

Simple Synthesis of (*Z*)-12-Nonadecen-9-one, (*Z*)-13-Icosen-10-one, the Sex Pheromone of Peach Fruit Moth, and (*Z*)-5-Undecen-2-one, a Biologically Active Molecule from the Pedal Gland of the Bontebok[1)]

Synopsis. A simple and convenient synthesis of (*Z*)-12-nonadecen-9-one, (*Z*)-13-icosen-10-one, the sex pheromone of the peach fruit moth, and (*Z*)-5-undecen-2-one, the pheromone from the pedal gland of the bontebok, is described. These pheromones were readily synthesized using successive alkylation of acetone dimethylhydrazone in one-pot.

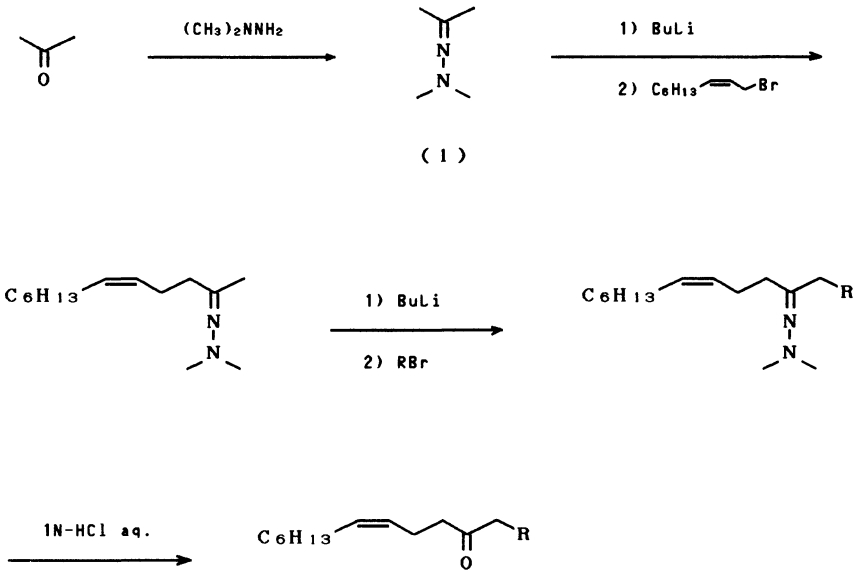
(*Z*)-12-Nonadecen-9-one (**2a**) and (*Z*)-13-icosen-10-one (**2b**) are the sex pheromones of the Japanese peach fruit moth (*Carposina niponensis* Walsingham), and have been isolated and identified by Tamaki et al. in 1977.[2)] Since these pheromones have attracted practical interest, several syntheses of these compounds have been reported.[2,3)]

On the other hand, we have previously reported a facile synthetic method of unsymmetrical ketones using acetone dimethylhydrazone (**1**) and the application of this method to the synthesis of jasmones.[4)]

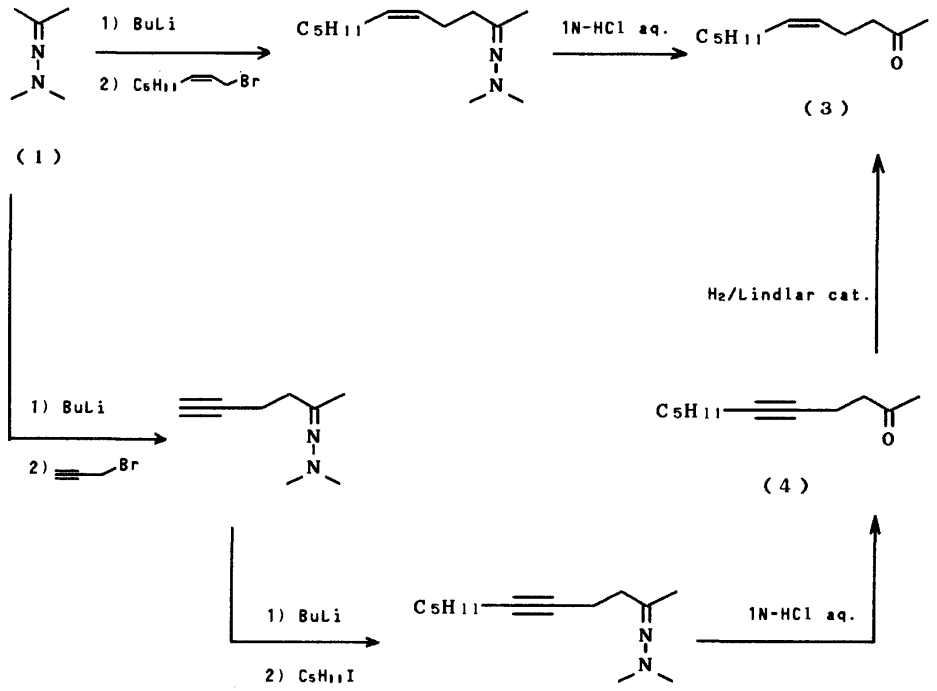
In this paper, we wish to report on a simple and convenient synthesis of the pheromones **2a** and **2b** via acetone dimethylhydrazone (**1**). Using this method, (*Z*)-5-undecen-2-one (**3**), which is known as a principal volatile component contained in the pedal gland exudate of the bontebok, *Damaliscus dorcas dorcas*,[5)] could also be synthesized.

The synthetic route of (*Z*)-12-nonadecen-9-one (**2a**) and (*Z*)-13-icosen-10-one (**2b**) from acetone as a starting material is described in Scheme 1. Acetone dimethylhydrazone (**1**), easily prepared from acetone and *N*,*N*-dimethylhydrazine in 80% yield, was allowed to react with 1 equiv. of butyllithium in tetrahydrofuran (THF) at −5 °C and then with (*Z*)-1-bromo-2-nonene to give the α-monoalkylated hydrazone. The hydrazone was then alkylated regioselectively at the α′ methyl carbon using 1 equiv. of butyllithium and 1-bromoheptane to afford the corresponding α,α′-dialkylated hydrazone, which was readily converted to the desired pheromone **2a** by hydrolysis under an acidic condition. These reactions were carried out successively in one-pot and the overall yield of the product **2a** was 70% from **1**. Similarly, after successive alkylation of the hydrazone **1** and hydrolysis of the product, (*Z*)-13-icosen-10-one (**2b**) was obtained in 62% overall yield from **1**.

The synthesis of (*Z*)-5-undecen-2-one (**3**) was carried out as follows. Acetone dimethylhydrazone (**1**) was treated successively with 1 equiv. of butyllithium and (*Z*)-1-bromo-2-octene, and the product was hydrolyzed to give the desired compound **3** in 98% yield (Scheme 2).[6)] The alternative synthetic route is also shown in Scheme 2, although the yield was low. Treatment of the hydrazone (**1**) with 1 equiv. of butyllithium at −5 °C, followed by the addition of 3-bromopropyne,



Scheme 1.



Scheme 2.

gave a monoalkylated hydrazone. To the hydrazone, without isolation, 1 equiv. of butyllithium was again added, followed by 1-iodopentane. The product was readily hydrolyzed by hydrochloric acid to afford 5-undecyn-2-one (**4**) in 14% yield from **1**. By partial hydrogenation of **4** over Lindlar catalyst, the expected pheromone **3** was obtained in 36% yield.

The corresponding (*E*)-isomers of **2a**, **2b**, and **3** were not detected by GC.

Experimental

The IR spectra were recorded on a Hitachi 260-10 Infrared Spectrophotometer. The NMR spectra were measured on a Hitachi R-600 FT-NMR Spectrometer at 60 MHz, using tetramethylsilane (δ=0.00) as an internal standard, and chemical shifts are given in ppm. The mass spectra (MS) were determined on a Hitachi RM-50 GC-MS spectrometer. The analytical gas chromatography was carried out on a Yanagimoto G-8 gas chromatograph with a column of 10% Silicone gum SE-30 on Chromosorb, and the column chromatography was performed on Merck silica gel 60 (230—400 mesh). All the boiling points were uncorrected, and all the yields were isolated ones.

Materials. Tetrahydrofuran (THF) was dried over potassium-benzophenone under argon and distilled just before use. Benzene was also purified by distillation over sodium-benzophenone under argon, and stored over 4A Molecular Sieves. 3-Bromopropyne, 1-bromoheptane, 1-bromooctane, 1-iodopentane, acetone, *N*,*N*-dimethylhydrazine, and Lindlar catalyst were commercial products of the highest available purity, and were used without further purification. Butyllithium in hexane, also a commercial product, was titrated with *s*-butyl alcohol using 1,10-phenanthroline as an indicator just before use. (*Z*)-1-Bromo-2-octene was prepared by the hydrogenation of 2-octyn-1-ol[7] over Lindlar catalyst[8] followed by bromination. By the same procedure, (*Z*)-1-bromo-2-nonene was obtained from 2-nonyn-1-ol.[7]

Acetone Dimethylhydrazone (1). The hydrazone **1** was prepared by refluxing of acetone and *N*,*N*-dimethylhydrazine in 80% yield. IR (neat): 1660, 1170, 1090 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.93 (3H, s, CCH_3), 1.97 (3H, s, CCH_3), 2.04 (6H, s, $N(CH_3)_2$); MS *m*/*z* (%): 100 (M^+, 8), 44 (90), 42 (83), 28 (100).

(*Z*)-12-Nonadecen-9-one (2a). Butyllithium (3.0 mmol) was added via syringe at −5 °C with stirring under argon to a solution of acetone dimethylhydrazone (**1**) (0.30 g, 3.0 mmol) in THF (10 ml). After standing for 1 h, (*Z*)-1-bromo-2-nonene (0.61 g, 3.0 mmol) was added; the mixture was stirred for 20 h at room temperature. After cooling the mixture at −5 °C again, butyllithium (3.0 mmol) was added dropwise; 1 h later, 1-bromoheptane (0.47 ml, 3.0 mmol) was added, and the reaction mixture was stirred for 20 h at room temperature. After 1 mol dm^{-3} hydrochloric acid was added, the mixture was refluxed at 80 °C for 2 h, cooled to the room temperature, and extracted with ethyl acetate. The organic layer was washed with brine, dried over anhydrous magnesium sulfate, filtered and concentrated. The residual liquid was distilled by Kugelrohr to give (*Z*)-12-nonadecen-9-one (**2a**) (0.59 g) in 70% yield, bp 210 °C/2 Torr (bath temp; Torr≈133.322 Pa). IR (neat): 2850, 1720, 1470 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.87 (6H, t, CH_3), 1.08—2.18 (20H, m, CH_2), 2.20—2.60 (8H, m, CH_2), 5.20—5.48 (2H, m, CH=CH); MS *m*/*z* (%): 280 (M^+, 6), 195 (7), 141 (100), 125 (15).

(*Z*)-13-Icosen-10-one (2b). In a manner similar to the above, (*Z*)-13-icosen-10-one (**2b**) was prepared by the successive alkylations of acetone dimethylhydrazone (**1**) using (*Z*)-1-bromo-2-nonene and 1-bromooctane and the hydrolysis in 62% yield. IR (neat): 2900, 1725, 1480 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.87 (6H, t, CH_3), 1.05—2.20 (22H, m, CH_2), 2.20—2.70 (8H, m, CH_2), 5.20—5.48 (2H, m, CH=CH) MS *m*/*z* (%): 294 (M^+, 10), 157 (100), 125 (22), 85 (18).

5-Undecyn-2-one (4). By the same procedure, using 3-bromopropyne and 1-iodopentane, successive alkylations of acetone dimethylhydrazone (**1**) and the hydrolysis were carried out. After the usual work up, column chromatography (hexane:ethyl acetate=9:1) gave 5-undecyn-2-one (**4**) in 14% yield. IR (neat): 1725 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.89

(3H, t, CH_3), 1.08—1.72 (6H, m, CH_2), 1.80—2.82 (6H, m, CH_2), 2.16 (3H, s, CH_3); MS *m/z*: 166 (M^+).

(*Z*)-5-Undecen-2-one (3). According to a manner similar to that described above, (*Z*)-5-undecyn-2-one (**3**) was obtained by the monoalkylation of acetone dimethylhydrazone (**1**) with (*Z*)-1-bromo-2-octene and the hydrolysis in 98% yield. On the other hand, the ketone **3** was also prepared by hydrogenation of 5-undecyn-2-one (**4**) over Lindlar catalyst[8] in 36% yield. IR (neat): 2930, 1735, 1360, 1160 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.90 (3H, t, CH_3), 1.06—1.70 (6H, m, CH_2), 2.14 (3H, s, CH_3), 1.80—2.75 (6H, m, CH_2), 5.20—5.50 (2H, m, CH=CH); MS *m/z* (%): 168 (M^+, 13), 109 (38), 81 (33), 43 (100).

The Structure and Absolute Stereochemistry of a Halogenated Chamigrene Derivative from the Red Alga *Laurencia* Species[1)]

Minoru SUZUKI,* Etsuro KUROSAWA, and Akio FURUSAKI*
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060
(Received April 13, 1988)

Synopsis. The structure of a halochamigrene derivative, 2,10-dibromo-3-chlorochamigran-7-en-9-ol, isolated from the red alga *Laurencia* species has been determined by spectral and chemical methods as well as X-ray crystallographic analysis of the ketone derivative. Furthermore, the conformations of this compound and its derivatives are briefly discussed.

During the course of our continuing search for the constituents of the red alga *Laurencia nipponica* Yamada, we have isolated a halogenated chamigrene derivative **1** from the specimens collected at Hamamasu[2)] and other locations[3)] in Hokkaido. In this paper, we report the structural determination of this compound.

Compound **1** was analyzed for $C_{15}H_{23}OBr_2Cl$ by elemental analysis together with low and high resolution mass spectrometry. The ^1H NMR spectrum of **1** presented signals at δ=0.99 (3H, s), 1.22 (3H, s), 1.70 (3H, s), and 2.05 (3H, dd, J=1.5, 1.5 Hz) due to four methyl groups and at δ=4.27 (1H, br d, J=9 Hz), 4.37 (1H, d, J=9 Hz), 4.90 (1H, dd, J=10, 8 Hz), and 5.44 (1H, dddd, J=3, 1.5, 1.5, 1.5 Hz) due to three methine protons and an olefinic proton. Acetylation of **1** with acetic anhydride and pyridine gave the corresponding acetate **2**, $C_{17}H_{25}O_2Br_2Cl$. Double resonance experiments on the ^1H NMR spectrum of the acetate **2** indicated the presence of ■–C(CH_3)=CH–CH(OAc)–CH(Br or Cl)–■ (■; quaternary carbon) grouping in the molecule. Oxidation of **1** with Jones reagent yielded an α,β-unsaturated ketone **3**, $C_{15}H_{21}OBr_2Cl$. In view of the above-mentioned data coupled with the coexistence of **1** with many other halochamigrenes in the same alga,[2,3)] it was strongly suggested that compound **1** would be a halochamigrene derivative. Comparison of the physical properties of **1** with those of previously reported halochamigrene derivatives suggested that compound **1** is 2,10-dibromo-3-chlorochamigran-7-en-9-ol,[4)] which has been obtained as the major metabolite from *Laurencia pacifica* Kylin collected at near Ensenada, Mexico. The IR and ^1H NMR spectra of both compounds along with their derivatives were identical. The proposed structure **1** for 2,10-dibromo-3-chlorochamigran-7-en-9-ol, however, has been deduced mainly from spectral analysis.[4)] Therefore, in order to confirm the structure of **1** including the absolute configuration, a single crystal of the ketone **3** was subjected to X-ray crystallographic analysis.

The crystal data for **3** were as follows: $C_{15}H_{21}OBr_2Cl$, mol wt 412.59, monoclinic, space group $P2_1$, a=9.773(4), b=10.897(5), c=7.616(2) Å, β=92.40(3)°, Z=2, D_c=1.691 g cm^{-3}. The structure was solved by the Monte Carlo direct method,[5)] and refined by the block-diagonal least-square method with anisotropic thermal parameters. The absolute configuration was determined by Hamilton's method;[6)] the R-factor ratio for the two enantiomeric structures, 1.037, excluded one of them at the 99.5% confidence level. After all the hydrogen atoms had been located in a difference Fourier map, further full-matrix least-squares refinements were carried out including the hydrogen atoms with the same fixed isotropic temperature factors of 2.5 Å^2. The final R-value was 0.054.[7)] The molecular framework obtained is shown

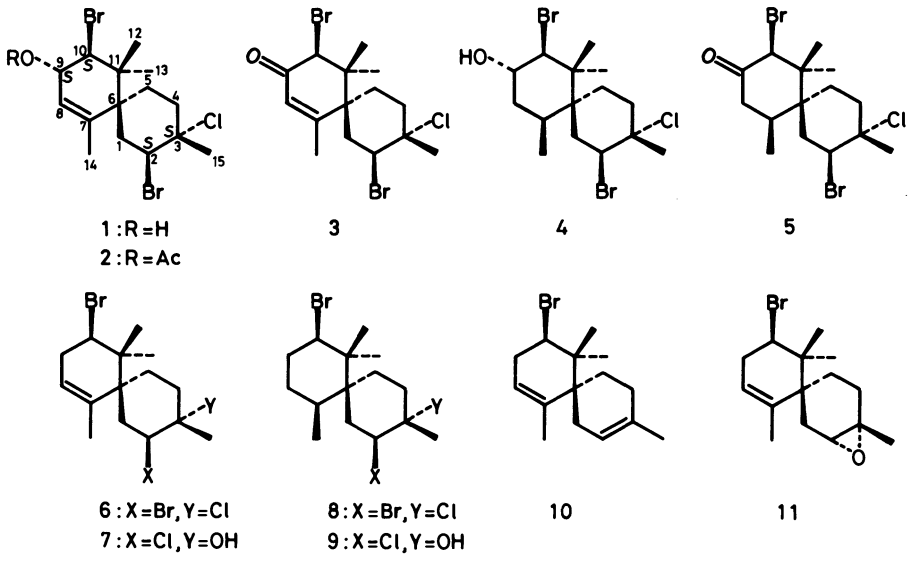

Fig. 1.

in Fig. 2. Thus, the molecular structure has been established as formula **3**.[8]

The C-9 configuration in **1** could be established on the basis of the coupling constant of the pertinent proton at C-9 in the ^{1}H NMR spectrum of the hydrogenated product **4**.[9] The J-value, J=11 Hz, between the protons at C-9 and C-10 indicated that the stereochemistry of the substituents at C-9 and C-10 is trans diequatorial to each other, thus showing that the absolute configuration at C-9 is *S*. Consequently, the absolute structure of 2,10-dibromo-3-chlorochamigran-7-en-9-ol is represented by formula **1**.

In the previous paper,[10] we have reported that the conformations of the B-ring in the halochamigrene derivatives, such as **6** and **7**, are not chair form (formulae **6C** and **7C**) (Fig. 3) but rather twist boat form (formulae **6B** and **7B**). Compound **1**, which has the same structural feature as **6** except for the hydroxyl group at C-9, seemed to adopt a conformation, formula **1B**, very similar to those of **6** and **7** (**6B** and **7B**). In fact, in the ^{1}H NMR spectra the signals of the methyl group at C-7 in **1** and **2** were shifted downfield compared with those[10] of compounds **10** and **11**. Furthermore, the coupling constants of the protons at C-2 in **1** and **2** indicated that these protons are neither axial nor equatorial proton on the cyclohexane ring with the normal chair conformation as observed in the case of **6** and **7**. Since the situation was almost same for the ketone **3**, the ketone **3** seemed to take conformation **3B**. However, as described above, the X-ray analysis of the ketone **3** showed that the B-ring conformation is a somewhat deformed chair form (Fig. 2). Detailed analysis of the ^{1}H NMR spectra of the ketone **3** and its dihydro derivative **5** gave the following information. In the ^{1}H NMR spectrum of **3**, some signals were rather broad at room temperature, whereas measuring at −30 °C sharpened the signals. In the spectrum measured at −30 °C, the signal due to the C_2–H was observed at δ=4.89, whose coupling constant, J=11 and 7 Hz, was compatible with those of **1** and **2**. This indicates that the ketone **3** exists in solution at room temperature as a mixture of interconverting conformers, reflecting the broad signals in the ^{1}H NMR spectrum. On the other hand, the ^{1}H NMR spectrum of **5** showed the signal due to the C_2–H at δ=4.43 (J=13 and 4 Hz), thus indicating that the B-ring conformation of the dihydro derivative **5** is represented by formula **5C** which is very similar to the conformations **8C** and **9C** of the compounds **8** and **9**.[10] Above results suggest that, although the B-ring conformation of the ketone **3** took the chair form (**3C**) in the solid state, a preferred conformation in solution would be twist boat form (**3B**).

2,10-Dibromo-3-chlorochamigran-7-en-9-ol (**1**) is the first example of the halochamigrene derivatives from *Laurencia* species with a trans-diequatorial bromohydrin moiety at C-9 and C-10 instead of cis-bromohydrin at C-9 and C-10 which have unexceptionally been encountered in a number of halogenated chamigrane-type sesquiterpenoids.[11]

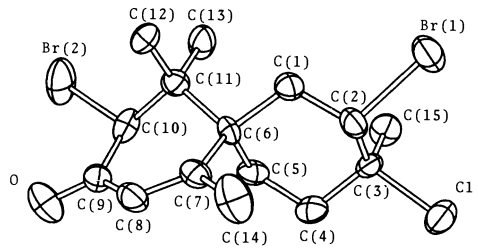

Fig. 2. A perspective view of the **3** molecule.

Experimental

All the mps were uncorrecterd. The IR spectra were recorded on a JASCO A-102 spectrophotometer and the UV spectrum on a Shimadzu UV-240 spectrophotometer. The ^{1}H and ^{13}C NMR spectra were measured on a JEOL JNM-FX 200 or a JEOL JNM-FX 100 spectrometer, using tetramethylsilane as an internal reference in $CDCl_3$. The low and high resolution mass spectra were taken at 70 eV with a JEOL JMS-D300 spectrometer. Optical rotations were determined on a JASCO DIP-140 polarimeter in $CHCl_3$. Silica gel (Merck, Kieselgel 60, 70—230 mesh) and silica gel (Merck, Kieselgel GF_{254} (Type 60)) were used for column and thin-layer chromatography, respectively.

1: Mp 119—120 °C (diisopropyl ether); $[\alpha]_D^{19}$ +25.3° (*c* 1.39); IR (Nujol), ν_{max} 3330, 1310, 1220, 1143, 1112, 1079, 1041, 1018, 999, 985, 850, and 810 cm^{-1}; ^{1}H NMR, in the text; ^{13}C NMR (25.0 MHz), δ=17.8 (q), 24.1 (q), 25.1 (q), 25.7 (q), 31.5 (t), 39.1 (t), 40.1 (t), 45.5 (s), 47.9 (s), 62.4 (d), 70.6 (s), 70.9 (d), 73.0 (d), 124.0 (d), and 143.0 (s); MS, *m/z* (rel intensity) 337, 335, 333 (0.3:0.9:0.7; M^+−Br), 319, 317, 315 (0.3:0.9:0.7; M^+−Br−H_2O), 164, 162 (3:3), 157 (2), 145 (2), 135 (3), 133 (2), 119 (23), 107 (3), 105 (4), 93 (3), 91 (5), 83 (100), 81 (2), 79 (3), 77 (3), 69 (3), 67 (2), 65 (2), 55 (5), 53 (3), 43 (2), and 41 (6). $C_{15}H_{21}{}^{79}Br^{79}Br^{35}Cl$: M−$H_2O$, 393.9699.

Found: C, 43.34; H, 5.63%. Calcd for $C_{15}H_{23}OBr_2Cl$: C, 43.45; H, 5.59%.

Acetylation of 1. Acetylation of **1** (17 mg) was carried out with acetic anhydride and pyridine by the usual method. The acetylated product was purified by column chromatography over silica gel to yield **2** (22 mg); colorless gum; $[\alpha]_D^{19}$ +75.6° (*c* 1.75); IR ($CHCl_3$), ν_{max} 1732, 1310, 1237, 1162, 1142, 1115, 1081, 1021, 991, 966, 957, 850, and 813 cm^{-1}; ^1H NMR, δ=1.03 (3H, s), 1.25 (3H, s), 1.71 (3H, s), 2.04 (3H, dd, *J*=1.5, 1.5 Hz), 4.42 (1H, d, *J*=9 Hz), 4.88 (1H, dd, *J*=11, 7 Hz), 5.36 (1H, dq, *J*=3, 1.5 Hz), and 5.44 (1H, ddq, *J*=9, 3, 1.5 Hz); MS, *m/z* 400, 398, 396, 394 (0.1:0.3:0.4:0.2; M^+−CH_3COOH), 378, 376, 374 (2:14:6; M^+−Br), 336, 334 332 (15:100:62; M^+−Br−CH_2CO), 119 (25), 105 (15), 91 (23), 83 (91), 55 (15), 43 (94), and 41 (24). Found: *m/z* 393.9701. Calcd for $C_{15}H_{21}{}^{79}Br^{79}Br^{35}Cl$: M−$CH_3COOH$, 393.9700.

Saponification of 2. A solution of **2** (9 mg) and potassium carbonate (15 mg) in methanol (1 ml) was stirred at room temperature for 50 min and then worked up in the usual way to give **1** (8 mg); The spectral data were identical with those of natural alcohol (**1**).

Oxidation of 1. To a solution of **1** (14 mg) in acetone (3 ml) was added Jones reagent dropwise with swirling at room temperature. After the usual work-up, the oily product was chromatographed on a silica-gel plate to give **3** (11 mg); crystals; mp 133—134 °C (diisopropyl ether); $[\alpha]_D^{17}$ −3.28° (*c* 1.54); UV (EtOH), λ_{max} 244 nm (ε 11800); IR (CCl_4), ν_{max} 1680, 1620, 1215, 1172, 1080, 970, 880, and 860 cm^{-1}; ^1H NMR, δ=1.02 (3H, br s), 1.35 (3H, br s), 1.74 (3H, s), 2.30 (3H, d, *J*=1.5 Hz), 4.85 (1H, m), 4.93 (1H, br s), and 6.01 (1H, br s); ^1H NMR (100 MHz, at −30 °C), δ=1.02 (3H, s), 1.37 (3H, s), 1.75 (3H, s), 2.34 (3H, br s), 4.89 (1H, dd, *J*=11, 7 Hz), 5.00 (1H, s), and 6.05 (1H, br s); MS, *m/z* 416, 414, 412, 410 (0.02:0.09:0.12:0.06; M^+), 335, 333, 331 (1:9:4; M^+−Br), 280 (13), 278 (76), 276 (60), 199 (28), 197 (100), 161 (58), 119 (12), 105 (16), 91 (31), 83 (19), 79 (14), 77 (18), 69 (18), 55 (33), 53 (27), 41 (27), and 39 (23). Found: *m/z* 409.9646. Calcd for $C_{15}H_{21}O^{79}Br^{79}Br^{35}Cl$: M, 409.9652.

Hydrogenation of 1. Hydrogenation of **1** (8 mg) was performed in ethyl acetate over PtO_2-catalyst. After the usual work-up, the residual oil was chromatographed on a silica-gel plate to afford **4** (7 mg); colorless oil; $[\alpha]_D^{19}$ +46.3° (*c* 0.72); IR ($CHCl_3$), ν_{max} 3550, 1300, 1120, 1095, 1047, 905, 890, 880, 873, 861, 838, and 810 cm^{-1}; ^1H NMR, δ=1.10 (3H, s), 1.16 (3H, s), 1.22 (3H, d, *J*=7.5 Hz), 1.71 (3H, s), 3.93 (1H, ddd, *J*=11, 11, 5 Hz), 4.17 (1H, d, *J*=11 Hz), and 4.41 (1H, dd, *J*=13, 4 Hz); MS, *m/z* 339, 337, 335 (1:5:4; M^+−Br), 321, 319, 317 (2:7:5; M^+−Br−H_2O), 149 (7), 121 (7), 109 (6), 105 (7), 93 (9), 91 (9), 85 (100), 83 (7), 81 (7), 79 (6), 77 (6), 69 (6), 67 (7), 57 (8), 55 (25), 53 (6), 43 (9), and 41 (40). Found: *m/z* 335.0776. Calcd for $C_{15}H_{25}O^{79}Br^{35}Cl$: M−Br, 335.0776.

Oxidation of 4. Oxidation of **4** (10 mg) was carried out with Jones reagent in acetone in the usual manner to give **5** (9 mg); crystals; mp 181—183 °C (diisopropyl ether); IR ($CHCl_3$), ν_{max} 1730, 1305, 1280, 1147, 1095, 867, and 859 cm^{-1}; ^1H NMR, δ=1.05 (3H, s), 1.16 (3H, d, *J*=7 Hz), 1.23 (3H, s), 1.75 (3H, s), 4.43 (1H, dd, *J*=13, 4 Hz), and 4.81 (1H, s); MS, *m/z* 337, 335, 333 (1:5:4; M^+−Br), 121 (14), 119 (55), 105 (9), 93 (13), 91 (13), 87 (11), 83 (100), 79 (12), 77 (11), 69 (12), 67 (10), 55 (30), 53 (19), 45 (13), 43 (9), 41 (36), and 39 (16). Found: *m/z* 333.0619. Calcd for $C_{15}H_{23}O^{-79}Br^{35}Cl$: M−Br, 333.0620.

X-Ray Experiment. A single crystal with dimensions of ca. 0.2×0.3×0.5 mm^3 was used for the X-ray measurement. The cell dimensions and diffraction intensities were measured on a Rigaku four-circle diffractometer at the High Brilliance X-Ray Diffraction Laboratory of Hokkaido University, using graphite-monochromated Mo $K\alpha$ radiation (λ=0.71073 Å). The θ–2θ scan technique was applied at a θ scan speed of 4° min^{-1}; the background was counted for 10 s at each end of the scan range. The intensities of three standard reflections, measured at intervals of every 100 reflections, decreased gradually during the course of data collection; the final-intensity/initial-intensity ratios were ca. 0.988—0.994. The intensities were corrected for this damage to the sample as well as for the Lorentz and polarization factors, but not for the absorption or the extinction effect. In the range of 2θ values up to 50°, 1274 independent structure factors above the 3σ(F) level were selected for the structure determination.

We are grateful to Professor William Fenical, University of California, Scripps Institution of Oceanography, for providing us with copies of the IR and ^1H NMR spectra of 2,10-dibromo-3-chlorochamigran-7-en-9-ol and its derivatives; the acetate, the ketone, and the dihydro derivative.

†Medicinal Research Laboratory, Toyo Jozo Co., Ohito-cho, Shizuoka 410-23
(Received April 19, 1988)

Synopsis. C-Terminal hexapeptide analogs of substance P (SP) were synthesized by a solid-phase method. These analogs, [Dab^6]-SP(6-11), [Orn^6]-SP(6-11), and [Lys^6]-SP(6-11), showed a contractile activity on an isolated guinea-pig ileum.

Substance P (SP) is a smooth muscle-contracting peptide having a sequence H–Arg–Pro–Lys–Pro–Gln–Gln–Phe–Phe–Gly–Leu–Met–NH_2. In studies of the relationships between chain length and activity of SP,[2,3)] it was found that the potency of the C-terminal hexapeptide of SP was similar to that of SP. We reported the relative potencies of C-terminal hexapeptide analogs of SP each having either Gly, γAbu (4-aminobutyric acid), δAva (5-aminovaleric acid), or εAcp (6-aminocaproic acid) at the N-terminus.[4)] In this paper,[5)] we would like to report the synthesis and structure-activity relationships of the other C-terminal hexapeptide analogs, **1**, **2**, and **3**, N-terminus of which is Dab, Orn,[6)] or Lys, respectively. These analogs were synthesized by a solid-phase method according to Merrifield's procedure.[7)]

H-Dab-Phe-Phe-Gly-Leu-Met-NH_2 **1**
H-Orn-Phe-Phe-Gly-Leu-Met-NH_2 **2**
H-Lys-Phe-Phe-Gly-Leu-Met-NH_2 **3**

For the synthesis, one of the present authors[8)] designed a manually operated apparatus with a Diflon vessel. The coupling was performed on a 2% cross-linked benzhydrylamine (BHA) resin support[9)] using Boc-amino acids. First of all, Boc–Met–OH was coupled with the BHA group on the resin by DCC. The resulting resin was treated with Ac_2O and Et_3N in CH_2Cl_2 in order to mask the residual free BHA groups. Then, the Boc-group was removed with 30% TFA/CH_2Cl_2 containing anisole as a scavenger. Boc–Leu–OH, Boc–Gly–OH, Boc–Phe–OH, and Boc–Phe–OH were coupled to the N-terminus on the resin, successively. In each case, for the first coupling a 2.5-fold excess of Boc-amino acid was used and for the second a 1.25-fold excess. The Boc–Phe–Phe–Gly–Leu–Met–BHA resin was divided into several parts. After deprotection of the N-terminus of the peptide-resin, Boc–Dab(Boc)–OH, Boc–Orn(Boc)–OH, and Boc–Lys(Boc)–OH were coupled with each. The peptide-resin bond of H–Dab–Phe–Phe–Gly–Leu–Met–BHA resin derived from Boc–Dab(Boc)-derivative by treatment with TFA was cleaved with liquid HF containing anisole and methionine.[10)] Column chromatography on Bio-Gel P-2 was used to separate the methionine from analog **1**. For further purification, partition chromatography was performed by using the upper phase of the mixture of *n*-BuOH and 0.1% AcOH (1 : 1) as an eluent on a column of Sephadex G-25. The other two analogs, **2** and **3**, were prepared from Boc–Orn(Boc)–Phe–Phe–Gly–Leu–Met–BHA resin and Boc–Lys(Boc)–Phe–Phe–Gly–Leu–Met–BHA resin by the same procedure respectively. The homogeneities of the analogs (**1**, **2**, and **3**) were confirmed by HPLC on an ODS column. The analogs were highly soluble in water and showed that the CD spectra had one peak at 220 nm and one trough at 235 nm. Their molar ellipticity values are summarized in Table 1. These CD spectra are referred to as an "unordered structure" by Mehlis et al.[11)] Their contractile activities, as measured on an isolated guinea-pig ileum, showed the relative potencies compared with the authentic SP in Table 2. Among them, [Orn^6]-SP(6-11) had the highest potency, though it was still less than that of SP. These results suggest that Dab, Orn, and Lys at the N-terminus of these analogs have a capability to increase the activity of H–Phe–Phe–Gly–Leu–Met–NH_2;[2)] and that the potency of each depends upon the length of the side chain of each basic amino acid.

Table 1. Circular Dichroism of SP(6–11) Analogs

Compound	[θ] (10^3 deg cm^2/dmol)[a)]	
	Peak (220 nm)	Trough (235 nm)
[Dab^6]-SP$^{6-11}$ (**1**)	+10.8	−1.4
[Orn^6]-SP$^{6-11}$ (**2**)	+10.8	−1.4
[Lys^6]-SP$^{6-11}$ (**3**)	+15.4	−1.5

a) Molar ellipticity value in water at room temp.

Table 2. Contractile Activities of SP and SP(6–11) Analogs on an Isolated Guinea-Pig Ileum

Compound	EC_{50}(M)[a)]	Relative Potencies
SP	4.4×10^{-9}	100
1	2.0×10^{-8}	22
2	9.7×10^{-9}	45
3	1.1×10^{-8}	40

a) EC_{50}: effective concentration (half maximal contraction).

Experimental

All coupling steps were carried out with a manual peptide synthesizer (TSP-D type, Taiatsu Scientific Glass Co., Ltd.). The cleavage of the peptide-resin was achieved with a HF reaction apparatus (Type II, Peptide Institute, Inc. and

Toho Kasei Co., Ltd.). The melting points were determined on a Mel-Temp apparatus and are uncorrected. The homogenity of the synthetic peptides was confirmed by TLC on Merck silica gel F_{254} plates and HPLC. HPLC was performed with 4.6 mm×25 cm Finepak SIL ODS column with UV detection at 215 nm. The following solvent system was used for HPLC: *n*-PrOH-10% $NaClO_4$aq (1:4) at a flow rate of 1.5 ml min^{-1}. TLC was developed in the following solvent system: *n*-BuOH-AcOH-pyridine-water (4:1:1:2). Ninhydrin and Rydon[12] reagents were used for detection on TLC plates. Amino acid analyses were performed with a JEOL automatic amino acid analyzer, after the samples had been hydrolyzed with constant-boiling HCl in evacuated sealed ampoules for 20 h at 110 °C. The CD spectrum was measured with a JASCO model J-20 spectrometer.

Preparation of Boc-Met-BHA Resin. BHA resin hydrochloride[13] (5 g, 0.4 mequiv of NH_2 group/g) was placed in the Daiflon vessel of a peptide synthesizer, and operations were carried out as shown in Table 3.

Preparation of Boc-Phe-Phe-Gly-Leu-Met-BHA Resin. According to the series of operations outlined in Table 4, the above Boc-Met-BHA resin was treated in the vessel succesively. The pentapeptide resin, thus derived, was dried in a vacuum desiccator; it weighed 6.45 g.

[Dab^6]-SP(6-11). Boc-Phe-Phe-Gly-Leu-Met-BHA resin (1.63 g, 0.5 mequiv) was placed in the vessel, and the coupling of Boc-Dab(Boc)-OH (1.25 mmol)[14] was carried out, as shown in Table 4. After the second coupling (steps 12—15 in Table 4) used 0.625 mmol of Boc-Dab(Boc)-OH, the Boc groups on Dab were removed by steps 1—3. H-Dab-Phe-Phe-Gly-Leu-Met-BHA resin was treated with anhydrous liquid HF (ca. 15 ml) containing anisole (2 ml) and D,L-methionine (171 mg) at 0 °C for 1 h. After evaporation of HF in vacuo, the mixture of peptide and

resin was washed with ethyl ether. The peptide was extracted with 30% AcOH and the extract was concentrated by lyophilization. The crude peptide was charged on a column (2×100 cm) of Bio-Gel P-2 and eluted with 2% AcOH. The main fractions (132 mg) were further chromatographed on a column (2×35 cm) of Sephadex G-25 eluted with the upper phase of the system 0.5% AcOH-*n*-BuOH (1:1). The fractions collected were evaporated in vacuo. The aqueous solution of the residue was lyophilized and a white crystalline peptide was obtained. Yield, 67 mg (15%); mp 177—178 °C; amino acid ratio: Dab 1.06, Phe 1.93, Gly 0.97, Leu 1.01, Met 1.03; TLC: R_f 0.69; HPLC: t_R(min) 11.4.

Found: C, 53.01; H, 6.95; N, 12.50%. Calcd for $C_{35}H_{52}N_8SO_6 \cdot 2AcOH \cdot 3H_2O$: C, 52.81; H, 7.50; N, 12.63%.

[Lys^6]-SP(6-11). This peptide was synthesized by the same procedure as described for the preparation of [Dab^6]-SP(6-11). Boc-Phe-Phe-Gly-Leu-Met-BHA resin (1.63 g, 0.5 mequiv) and Boc-Lys(Boc)-OH (1.25 mmol for the first coupling and 0.625 mmol for the second) were used and the yield was 18% (93 mg). Mp 188—191 °C; amino acid ratio: Lys 0.99, Phe 1.82, Gly 1.06, Leu 1.08, Met 1.05; TLC: R_f 0.63; HPLC: t_R(min) 9.8.

Found: C, 53.37; H, 7.05; N, 11.19%. Calcd for $C_{37}H_{56}N_8SO_6 \cdot 4AcOH \cdot 1.5H_2O$: C, 53.61; H, 7.50; N, 11.11%.

[Orn^6]-SP(6-11). Another Boc-Phe-Phe-Gly-Leu-Met-BHA resin (1.3 g, 0.61 mequiv) was used for the coupling with Boc-Orn(Boc)-OH (the first, 1.83 mmol and the second, 0.92 mmol). The procedure used was the same as that for the cases of the above two analogs. The purified analog weighed 38 mg (7%) and the mp was 168—171 °C. Amino acid ratio: Orn 0.96, Phe 1.98, Gly 1.01, Leu 1.01, Met 1.04; TLC: R_f 0.66; HPLC: t_R(min) 10.4.

Found: C, 54.55; H, 7.17; N, 12.41%. Calcd for $C_{36}H_{54}N_8SO_6 \cdot 2AcOH \cdot 2H_2O$: C, 54.41; H, 7.53; N, 12.69%.

Bioassay. Isolated ileum preparations from male guinea pigs (430—480 g) were suspended in a bath containing Tyrode's solution, bubbled with air and maintained at 37 °C. Contractions were recorded isotonically. The relative potencies of the test peptides were calculated from the EC_{50}(M) values.

14) This derivative was prepared by the method of L. Morder, A. Hallett, E. Wünsch, O. Keller, and G. Wersin, *Hoppe-Seyler's Z. Physiol. Chem.*, **357**, 1651 (1976). L-2,4-Diaminobutyric acid dihydrochloride was purchased from Fluka AG, Switzerland and Boc-Dab(Boc)-OH·DCHA (DCHA=dicyclohexylamine) was obtained in a 62% yield; mp 118—120 °C. Anal. ($C_{26}H_{49}N_3O_6$) C, H, N.

A Facile Method for the Preparation of γ-Alkenyl-γ-butyrolactones

Masatoshi KAWASHIMA and Tamotsu FUJISAWA*
Chemistry Department of Resources, Mie University, Tsu, Mie 514
(Received April 28, 1988)

Synopsis. Methyl substituted γ-alkenyl-γ-butyrolactones were prepared from easily available α,β-unsaturated aldehydes such as acrylaldehyde, methacrylaldehyde, crotonaldehyde, and 3-methyl-2-butenal.

The structure of γ-alkenyl-γ-butyrolactones belongs to a kind of allylic esters and the lactones have been utilized to many synthetic reactions. For example, allylic substitutions of the lactones with organocopper reagents,[1] with ester enolate,[2] and with allylsilanes[3] leading to 4-alkenoic acids and 4,8-alkadienoic acid esters have been developed. Moreover γ-alkenyl-γ-butyrolactones have been incorporated in important key compounds for the synthesis of natural products such as ipsdienol,[4] biotin,[5] urinary metabolites of retinoic acid,[6] chrysanthemic acid,[7] avenaciolide,[8] marmelo oxide,[9] and dihydromevinolin.[10] The lactones have been prepared by many methods[11] such as condensation of vinyl epoxide with ethyl cyanoacetate and with diethyl malonate, decarboxylation of 2-vinyl-1,1-cyclopropanedicarboxylic acid prepared from 1,4-dibromo-2-butene and diethyl malonate, and reaction of 1,3-diene with carboxylic acid in the presence of metal oxide, however, these methods seem to have a limitation at the point of generality in which the kinds of applicable starting materials are confined. Here we wish to report the convenient method for the synthesis of methyl-substituted γ-alkenyl-γ-butyrolactones by the combination of easily available starting materials, two molecules of α,β-unsaturated aldehydes such as acrylaldehyde, methacrylaldehyde, crotonaldehyde, and 3-methyl-2-butenal.[12] General synthetic route was outlined in Scheme 1.

Although all of the aldehydes **1** are easily converted to the corresponding bromo acetal according to the published method for the preparation of 2-(2-bromoethyl)-1,3-dioxane (**2a**) from acrylaldehyde, 1,3-propanediol, and anhydrous hydrogen bromide,[13] crotonaldehyde and 3-methyl-2-butenal were transformed into the corresponding chloro acetals, which are preferable in the preparation of secondary and tertiary Grignard reagents rather than the corresponding bromo acetal. In the acetalization of 3-methyl-2-butenal, hydrochlorination was carried out in the presence of tetrabutylammonium chloride and Molecular Sieves 3A to improve the yields. These bromo and chloro acetals **2** were converted into the corresponding Grignard reagents **3** by the usual method.[13] Then the reactions of Grignard reagents **3** with aldehydes **4** gave the allylic alcohols **5** in high or moderate yields. An attempt of direct hydrolysis of **5** to lactol **7** in aqueous media unfortunately did not succeed even in a mixed solvent such as acetone–water because of the poor solubility in water except for the case of **5a**. Therefore the alcohols **5** were converted to lactol ether **6** in acidic methanol followed by hydrolysis of **6** in acidic aqueous acetone to give lactol **7** in moderate yields without accompanying a tautomer of the lactol, γ-hydroxy aldehyde. In the last oxidation step of **7** to **8**, silver oxide, prepared in situ from silver nitrate and sodium hydroxide, was used as the suitable oxidant which did not oxidize carbon–carbon double bond. The diastereomer ratios of the lactones **8b** and **8c** were determined by GLC analysis as 43:57 and 79:21, respectively. Unfortunately, assignment of the configurations of these lactones did not succeed. To reveal the utility of this method for the preparation of γ-alkenyl-γ-butyrolactone, a precursor **8e**[7] of chrysanthemic acid was synthesized from 3-methyl-2-butenal as the starting material.

e	H	Me	Me	H	Me	Me	68(X=Cl)	41	61	66	68	43

a) The yields were calculated from **1a**. b) The yield was calculated from **5a**.

Results for the synthesis of **8** were summarized in Table 1.

As described above, this method for the preparation of γ-alkenyl-γ-butyrolactone has the following advantages; (i) easy availabilities of starting materials and the other reagents, (ii) simple procedure and operations, (iii) generality for the preparation of various substituted γ-alkenyl-γ-butyrolactones.

Experimental

General. Boiling points were measured at the pressure indicated and are uncorrected. Infrared spectra (neat) were recorded on a Hitachi EPI-G2 spectrometer. ^{1}H NMR spectra were recorded on a JEOL JNM-PMX60SI spectrometer with Me_4Si as an internal standard in CCl_4. GLC analysis was performed on a Yanaco G-180 Gas Chromatograph.

Materials. Acrylaldehyde, methacrylaldehyde, crotonaldehyde, 3-methyl-2-butenal, 2-(2-bromoethyl)-1,3-dioxane, and the other reagents were commercially available.

Acetalization of Aldehydes 1b,c,e to 2b,c,e. According to the reported procedure[13] for the preparation of **2a**, 2-(2-bromo-1-methylethyl)-1,3-dioxane (**2b**) was prepared from methacrylaldehyde, 1,3-propanediol, and anhydrous HBr. In the similar manner as the preparation of **2b**, the other chloro acetals **2c** and **2e** were prepared from crotonaldehyde and 3-methyl-2-butenal, respectively, by the treatment with 1,3-propanediol saturated with anhydrous HCl in the presence of a half mole of tetrabutylammonium chloride. **2b**: bp 61—62 °C/0.5 mmHg (1 mmHg=133.322 Pa); ^{1}H NMR δ=1.02 (d, J=7 Hz, 3H), 0.83—2.43 (m, 3H), 3.08—4.28 (m, 6H), and 4.39 (d, J=5 Hz, 1H); IR 1145 (s), 1110 (s), and 1015 (s) cm^{-1}; Found: C, 40.46; H, 6.48%. Calcd for $C_7H_{13}BrO_2$: C, 40.21; H, 6.27%. **2c**: bp 63—64 °C/5 mmHg; ^{1}H NMR δ=1.05—2.53 (m, 2H), 1.48 (d, J=7 Hz, 3H), 1.93 (dd, J=5 Hz, 6 Hz, 2H), 3.47—4.50 (m, 5H), and 4.68 (t, J=5 Hz, 1H); IR 1140 (s), 1105 (s), 1080 (s), 1030 (s), 1000 (s), and 620 (s) cm^{-1}; Found: C, 50.94; H, 8.00%. Calcd for $C_7H_{13}ClO_2$: C, 51.07; H, 7.96%. **2e**: bp 68—70 °C/1.5 mmHg; ^{1}H NMR δ=0.82—2.43 (m, 2H), 1.55 (s, 6H), 1.96 (d, J=4.5 Hz, 2H), 3.40—4.21 (m, 4H), and 4.65 (t, J=4.5 Hz, 1H); IR 1145 (s), 1130 (s), 1115 (s), 1085 (s), and 990 (s) cm^{-1}; Found: C, 53.84; H, 8.46%. Calcd for $C_8H_{15}ClO_2$: C, 53.78; H, 8.46%.

Preparation of Grignard Reagents 3a—e. Grignard reagents **3a—e** were prepared from **2a—e**, respectively, by the treatment with magnesium turning in gently refluxing THF in the similar manner to the published procedure[13] and standardized by titration with 2-butanol using 1,10-phenanthroline as an indicator.[14]

Preparation of the Allylic Alcohols 5a—e. To the THF solution of **3a** (145 ml, 170 mmol) was added a solution of **1a** (10.0 g, 178 mmol) in THF (50 ml) at 0 °C and stirred at the same temperature for 3 h. Then the mixture was quenched by pouring into saturated aq. NH_4Cl and the layer were separated. The aqueous phase was washed three times with ether and the combined organic layers were washed with brine, dried with anhydrous $MgSO_4$, and concentrated. Distillation of the residue under a reduced pressure gave 2-(3-hydroxy-4-pentenyl)-1,3-dioxane (**5a**) (18.6 g, 108 mmol): bp 100—102 °C/1.5 mmHg; ^{1}H NMR δ=1.00—2.48 (m, 6H), 3.17 (s, 1H), 3.40—4.30 (m, 5H), 4.30—4.73 (m, 1H), and 4.85—6.14 (m, 3H); IR 3450 (s), 1145 (s), 1090 (s), 990 (s), and 925 (s) cm^{-1}; Found: C, 62.92; H, 9.48%. Calcd for $C_9H_{16}O_3$: C, 62.77; H, 9.36%.

In exactly the same manner as above, methyl-substituted analogues **5b—e** were prepared. **5b**: bp 125—127 °C/1.5 mmHg; ^{1}H NMR δ=0.75—2.47 (m, 5H), 0.93 (d, J=6 Hz, 3H), 1.70 (br s, 3H), 3.10 (s, 1H), 3.40—4.56 (m, 6H), 4.75 (br s, 1H), and 4.88 (br s, 1H); IR 3450 (s), 1145 (s), 1120 (s), 1100 (s), 1050 (s), 1000 (s), and 890 (s) cm^{-1}; Found: C, 65.68; H, 10.17%. Calcd for $C_{11}H_{20}O_3$: C, 65.97; H, 10.07%. **5c**: bp 102—104 °C/0.4 mmHg; ^{1}H NMR δ=0.83 (d, J=6 Hz, 3H), 1.05—2.45 (m, 5H), 1.63 (s, 3H), 3.04 (s, 1H), 3.28—4.25 (m, 5H), 4.51 (t, J=5 Hz, 1H), and 4.65—5.00 (m, 2H); IR 3425 (s), 1140 (s), 1105 (s), 1070 (s), 1015 (s), 990 (s), and 890 (s) cm^{-1}; Found: C, 65.70; H, 10.17%. Calcd for $C_{11}H_{20}O_3$: C, 65.97; H, 10.07%. **5d**: bp 116—118 °C/1 mmHg; ^{1}H NMR δ=0.77—2.47 (m, 9H), 2.83 (s, 1H), 3.30—4.30 (m, 5H), 4.33—4.63 (m, 1H), 4.76 (d, J=1.5 Hz, 1H), and 4.88 (d, J=1.5 Hz, 1H); IR 3450 (s), 1140 (s), 1085 (s), 990 (s), and 890 (s) cm^{-1}; Found: C, 64.56; H, 9.90%. Calcd for $C_{10}H_{18}O_3$: C, 64.49; H, 9.74%. **5e**: bp 135—138 °C/1.5 mmHg; ^{1}H NMR δ=0.75—2.47 (m, 4H), 0.90 (s, 3H), 0.93 (s, 3H), 1.67 (s, 3H), 1.75 (s, 3H), 2.91 (s, 1H), 3.47—4.33 (m, 5H), 4.67 (t, J=5 Hz, 1H), and 5.25 (d, J=9 Hz, 1H); IR 3500 (s), 1140 (s), 1085 (s), 1035 (s), 1000 (s), 985 (s), and 820 (m) cm^{-1}; Found: C, 68.08; H, 10.66%. Calcd for $C_{13}H_{24}O_3$: C, 68.38; H, 10.60%.

Preparation of Lactol Ether 6b—e. A solution of **5b** (1.70 g, 8.49 mmol) in MeOH (40 ml) was acidified with 2 drops of 6 M HCl (1 M=1 mol dm^{-3}) and stirred at room temperature for 12 h. After neutralization with saturated aq. $NaHCO_3$, ether was added to the mixture. The organic layer was separated and the aqueous layer was washed three times with ether. The combined extracts were washed with water. After the solution was dried with anhydrous $MgSO_4$ and concentrated, distillation of the residue under the reduced pressure afforded 2-methoxy-3-methyl-5-isopropenyltetrahydrofuran (**6b**) (940 mg, 6.01 mmol): bp 69—71 °C/24 mmHg; ^{1}H NMR δ=1.01 (br d, J=7 Hz, 3H), 1.23—2.37 (m, 3H), 1.69 (br s, 3H), 3.27 (s, 3H), 4.13—4.63 (m, 2H), 4.70 (br s, 1H), and 4.90 (br s, 1H); IR 1100 (s), 1070 (s), 1010 (s), and 895 (s) cm^{-1}; Found: C, 69.11; H, 10.48%. Calcd for $C_9H_{16}O_2$: C, 69.19; H, 10.32%.

In the same manner as above, methyl-substituted analogues **6c—e** were prepared. **6c**: bp 75—78 °C/22 mmHg; ^{1}H NMR δ=0.63—1.17 (m, 3H), 1.33—2.63 (m, 6H), 3.23 (s, 3H), 3.67—3.97 (m, 0.6H), 4.18—4.45 (m, 0.6H), and 4.67—5.10 (m, 2.8H); IR 1100 (s), 1070 (s), 1030 (s), and 895 (s) cm^{-1}; Found: C, 68.91; H, 10.37%. Calcd for $C_9H_{16}O_2$: C, 69.19; H, 10.32%. **6d**: bp 73—75 °C/30 mmHg; ^{1}H NMR δ=1.42—2.33 (m, 7H), 3.32 (s, 3H), 4.42 (br t, J=7 Hz, 1H), 4.77 (br s, 1H), and 4.85—5.13 (m, 2H); IR 1205 (s), 1105 (s), 1050 (s), 1035 (s), and 895 (s) cm^{-1}; Found: C, 67.33; H,

10.06%. Calcd for $C_8H_{14}O_2$: C, 67.57; H, 9.92%. **6e**: bp 105—110 °C/33 mmHg; ^{1}H NMR δ=0.85 (s, 3H), 0.98 (s, 3H), 1.47—2.17 (m, 2H), 1.70 (s, 3H), 1.77 (s, 3H), 3.25 (s, 3H), 4.07—4.40 (m, 1H), 4.82 (t, J=5 Hz, 1H), and 5.05 (d, J=8 Hz, 1H); IR 1100 (s), 1050 (s), 1030 (s), 1000 (s), 980 (s), and 840 (s) cm^{-1}; Found: C, 71.98; H, 11.00%. Calcd for $C_{11}H_{20}O_2$: C, 71.70; H, 10.94%.

Hydrolysis of 5a and 6b—e to Lactol 7a—e. A solution of **5a** (1.34 g, 7.77 mmol) in 10% H_2SO_4 (45 ml) and stirred at room temperature for 12 h. The mixture was extracted three times with ether. After the extracts were washed with brine, dried with anhydrous $MgSO_4$, and concentrated, distillation of the residue under a reduced pressure afforded 2-hydroxy-5-vinyltetrahydrofuran (**7a**) (474 mg, 4.15 mmol): bp 80—100 °C/1.5 mmHg (Kugelrohr); ^{1}H NMR δ=1.00—2.65 (m, 4H), 3.75 (br s, 1H), 4.17—4.80 (m, 1H), and 4.83—6.25 (m, 4H); IR 3420 (s), 1050 (s), 1020 (s), 990 (s), and 925 (s) cm^{-1}; Found: C, 63.37; H, 9.02%. Calcd for $C_6H_{10}O_2$: C, 63.14; H, 8.83%.

In the same manner as above, methyl-substituted analogues **7b—e** were prepared. **7b**: bp 60—70 °C/1.5 mmHg (Kugelrohr); ^{1}H NMR δ=1.05 (br d, J=6 Hz, 3H), 1.23—2.57 (m, 3H), 1.70 (br s, 3H), and 4.05—5.43 (m, 5H); IR 3425 (s), 1075 (s), 1040 (s), 1000 (s), 990 (s), and 895 (s) cm^{-1}; Found: C, 67.47; H, 9.96%. Calcd for $C_8H_{14}O_2$: C, 67.57; H, 9.92%. **7c**: bp 65—70 °C/1.5 mmHg; ^{1}H NMR δ=0.73—1.17 (m, 3H), 1.17—2.76 (m, 6H), and 3.65—5.75 (m, 5H); IR 3425 (s), 1090 (s), 1070 (s), 1050 (s), 1010 (s), 980 (s), and 895 (s) cm^{-1}; Found: C, 67.37; H, 9.97%. Calcd for $C_8H_{14}O_2$: C, 67.57; H, 9.92%. **7d**: bp 100—120 °C/1.5 mmHg (Kugelrohr); ^{1}H NMR δ=1.50—2.17 (m, 7H), 4.10—5.13 (m, 4H), and 5.17—5.73 (m, 1H); IR 3425 (s), 1060 (s), 1045 (s), 1000 (s), 980 (s), and 895 (s) cm^{-1}; Found: C, 65.55; H, 9.47%. Calcd for $C_7H_{12}O_2$: C, 65.60; H, 9.44%. **7e**: mp 65—70 °C; bp 70-85 °C/1.5 mmHg; ^{1}H NMR δ=0.87 (s, 3H), 1.00 (s, 3H), 1.50—2.07 (m, 2H), 1.70 (s, 3H), 1.77 (s, 3H), and 4.12—5.67 (m, 4H); IR 3375 (s), 1095 (s), 1050 (s), 1025 (s), 1000 (s), 985 (s), and 840 (s) cm^{-1}; Found: C, 70.39; H, 10.72%. Calcd for $C_{10}H_{18}O_2$: C, 70.55; H, 10.66%.

Oxidation of 7a—e to γ-Alkenyl-γ-butyrolactone 8a—e. To a solution of silver nitrate (780 mg, 4.59 mmol) in water (1 ml), 6.51 M NaOH solution (1.80 ml, 11.7 mmol) was added at room temperature. The mixture was heated to 50 °C and methanol (1 ml) was added. After being cooled to 0 °C, a solution of **7a** (262 mg, 2.29 mmol) in MeOH (2 ml) was added to the suspension of silver oxide. The reaction mixture was stirred at 40 °C for 12 h. After being cooled to room temperature and acidified with 10% H_2SO_4, the mixture was extracted with $CHCl_3$. The extracts were washed with water and brine, dried with anhydrous $MgSO_4$, and concentrated. Distillation of the residue gave 5-vinyltetrahydro-2-furanone (**8a**)[11b] (232 mg, 2.07 mmol): bp 100—120 °C/1.5 mmHg (Kugelrohr); ^{1}H NMR δ=1.78—3.15 (m, 4H), 4.78—6.20 (m, 4H); IR 1775 (s) and 980 (s) cm^{-1}.

In the same manner as above, methyl-substituted analogues **8b—e** were prepared. Determination of the diastereomer ratios of the lactones **8b** and **8c** was performed by analytical GLC (0.25 mm×50 m FFAP column, 120 °C, relative retention time was 1.00:1.01 and 1.00:1.07, respectively. **8b**: bp 120—130 °C/1.5 mmHg (Kugelrohr); ^{1}H NMR δ=1.25 (d, J=7 Hz, 3H), 1.50—3.05 (m, 3H), 1.75 (s, 3H), 4.54—5.20 (m, 3H); IR 1775 (s) and 900 (s) cm^{-1}; Found: C, 68.77; H, 8.55%. Calcd for $C_8H_{12}O_2$: C, 68.55; H, 8.63%. **8c**: bp 120—130 °C/1.5 mmHg (Kugelrohr); ^{1}H NMR δ=0.79—1.27 (m, 3H), 1.75 (s, 3H), 1.80—2.93 (m, 3H), 4.25—4.60 (m, 1H), 4.98 (br s, 2H); IR 1780 (s) and 910 (s) cm^{-1}; Found: C, 68.36; H, 8.74%. Calcd for $C_8H_{12}O_2$: C, 68.55; H, 8.63%. **8d**: bp 110—130 °C/1.5 mmHg (Kugelrohr); ^{1}H NMR δ=1.76 (s, 3H), 1.80—2.77 (m, 4H), 4.70—5.18 (m, 3H); IR 1770 (s) and 900 (s) cm^{-1}; Found: C, 66.54; H, 8.11%. Calcd for $C_7H_{10}O_2$: C, 66.65; H, 7.99%. **8e**:[7] mp 45—50 °C; bp 130—150 °C/1.5 mmHg (Kugelrohr); ^{1}H NMR δ=1.00 (s, 3H), 1.12 (s, 3H), 1.73 (s, 3H), 1.80 (s, 3H), 2.31 (s, 1H), 2.34 (s, 1H), 4.78 (d, J=9 Hz, 1H), 5.19 (br d, J=9 Hz, 1H); IR 1775 (s) and 850 (m) cm^{-1}.

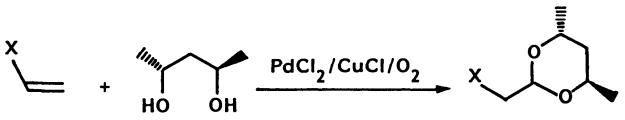
Machikaneyama, Toyonaka, Osaka 560
(Received May 9, 1988)

Synopsis. The diastereoselectivity of the carbonyl addition of organolithium reagents to β-keto acetals was examined. Addition of MeLi to β-keto acetal derived from Pd(II)-catalyzed acetalization of phenyl vinyl ketone with (*R*,*R*)-2,4-pentanediol gave (4*R*,6*R*)-4,6-dimethyl-2-[(2*R*)-2-hydroxy-2-phenylpropyl]-1,3-dioxane in 75%de.

We have recently found that terminal olefins bearing electron-withdrawing substituents such as COR, COOR, and CN are regioselectively acetalized at the terminal olefinic carbon with diols by using a catalyst system of $PdCl_2$–CuCl–O_2.[1] The reaction with readily available (*R*,*R*)-2,4-pentanediol gives homochiral acetals having functional groups at the side chain.



X= electron-withdrawing group

Homochiral cyclic acetals derived from (*R*,*R*)-2,4-pentanediol may be regarded as one of the useful precursors for the synthesis of homochiral alcohols. This stems from the basic finding that one of the diastereotopic acetal bonds is stereoselectively cleaved by nucleophiles in the presence of Lewis acids.[2] Described herein is a fundamental reaction using the acetal moiety as the chiral auxiliary, that is the diastereofacial differenciating addition[3] of alkyllithium reagents to β-keto acetal **1** leading to β-hydroxy acetal **2**.

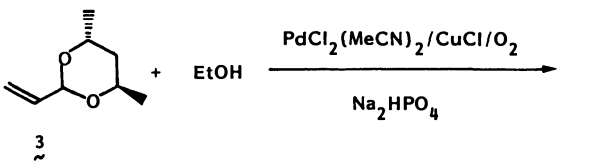
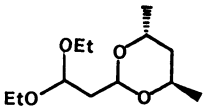
Results and Discussion

The keto acetals **1a** and **1b** were prepared by the Pd(II)-catalyzed acetalization of the corresponding vinyl ketones with (*R*,*R*)-2,4-pentanediol. Acetalization of vinyl acetal **3** with ethanol led to bis-acetal **4**, which upon hydrolysis gave the homochiral acetal **1c**.[4] The bis-acetal **4** can be also prepared by partial acetal-exchange reaction of 1,1,3,3-tetraethoxypropane with (*R*,*R*)-2,4-pentanediol.



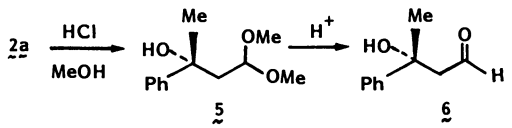
3



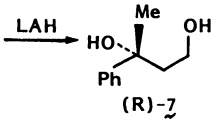
4

Commonyl used organometallic reagents such as RLi and RMgX were allowed to react with the carbonyl group of **1** under various conditions. In contrast to the carbonyl addition to α-keto acetals derived from (+)-tartaric acid,[5] RLi was found to react more selectively than RMgX. Thus, the reaction of **1a** (R=Ph)(5×10^{-2} M, 1 M=1 mol dm^{-3}) with 2 equiv of MeLi at −78 °C in ether gives **2a** as crystals in a relatively high diastereomeric excess (75% de), while the selectivity is extremely low with MeMgI (Table 1, Entries 1 and 2). The alcohol **2a** obtained was purified by recrystallizations to give a single diastereomer. Although the differenciation is significantly dependent on the nature of substituent R at β-carbon and reagents (Table 1, Entries 4—7), it is remarkable that a 75% differenciation is attained with **2a**, in spite of the reaction site being far from the chiral center.

The configuration of newly created chiral center in **2a** was determined to be (*R*) by the following transformations. The acetal exchange of recrystallized **2a** ($[\alpha]_D^{27}$ +22.0°) with methanol followed by hydrolysis (Amberlyst 15, acetone–H_2O) gave β-hydroxy aldehyde **6**, which upon reduction with $LiAlH_4$ afforded *R*-(+)-diol **7** ($[\alpha]_D^{26}$ +65.2°, 97.7% ee) of the known configuration.[6] Of note is that direct hydrolysis of **2a** to **6** by using HCl and *p*-TsOH was unsuccessful.



5 **6**



(R)-**7**

There is no doubt that the 1,3-dioxane **1** is conformationally most stable when the $RCOCH_2$ group at the C-2 carbon is in equatorial. If the C=O group in this moiety occupies the conformation as depicted

Table 1. Addition Reaction of Organometallic Reagents to Keto Acetals **1**

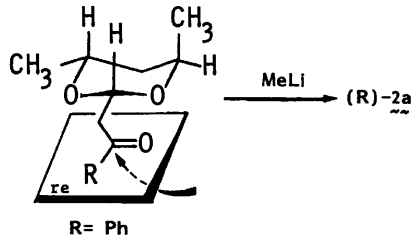
a) Determined by capillary column GLC analysis. b) Determined by GLC analysis. c) In contrast to Entry 1, the formation of predominant diastereomer was reversed. d) Determined by NMR (FX-100).

in Scheme 1, the backside (*si*-face) of the diastereoplane of **1a** (R=Ph) is obviously less hindered. Coordination of Li to the oxygen atoms and subsequent attack of the methyl anion to the C=O bond from the *si*-face creates (*R*)-chiral carbon in **2a**. If this is the case, the conformational preference of $RCOCH_2$ group is determined by the nature of the substituent R and reagent.



Scheme 1.

Experimental

Preparation of **1a** and **1b** was reported previously.[1] The keto acetal **1b** is also obtained by the reaction of 4-methoxy-3-butene-2-one with (*R,R*)-2,4-pentanediol.[7] Preparation of **1c** was described below.

(4*R*,6*R*)-4,6-Dimethyl-2-ethenyl-1,3-dioxane (3). Into a solution of (*R,R*)-2,4-pentanediol (Wako Pure Chemical Ind.) (1.00 g, 9.60 mmol), acrylaldehyde (1.30 mL, 19.4 mol), and *p*-TsOH (190 mg, 1.0 mmol) in anhydrous ether (20 mL) was added Molecular Sieves 4A (1.0 g). The mixture was stirred for 17 h at room temperature, and filtered. After addition of saturated aqueous $NaHCO_3$ (5 mL), the mixture was extracted with ether and dried ($MgSO_4$). Kugelrohr distillation gave **3** (1.14 g, 84% yield): bp 76—83 °C (64 mmHg); ^1H NMR (60 MHz, $CDCl_3$) δ=1.22 (3H, d, J=6.2 Hz, CH_3), 1.39 (3H, d, J=6.8 Hz, CH_3), 1.57—2.20 (m, 2H, C_5-H), 3.72—4.60 (2H, m, C_4- and C_6-H), 5.05—5.42 (2H, m, H_2C=C), and 5.45—6.20 (2H, m, C=CH and C_2-H); MS *m/z* 141 (M^+-1).

Found: C, 67.40; H, 9.91%. Calcd for $C_8H_{14}O_2$: C, 67.57; H, 9.92%.

(4*R*,6*R*)-4,6-Dimethyl-2-(2,2-diethoxyethyl)-1,3-dioxane (4). i) Pd(II)-Catalyzed Acetalization of 3 with Ethanol. To a test tube were placed a magnetic stirring bar, CuCl (10 mg, 0.10 mmol), Na_2HPO_4 (71 mg, 0.50 mmol), and ethanol (0.36 mL, 6.13 mmol), and there was added a solution of acrylaldehyde acetal **3** (143 mg, 1.00 mmol) and triethyl orthoformate (296 mg, 2.00 mmol) in DME (1 mL) and then $PdCl_2(CH_3CN)_2$ (26 mg, 0.10 mmol). The test tube was placed into an autoclave (10 mL) into which a 10 kg cm^{-2} pressure of O_2 was introduced. After stirring for 24 h at 50 °C, the resulting solution was cooled to room temperature, diluted with ether, and filtered. Florisil column chromatography (2.0 g, 1.5×1 cm) with ether (60 mL) gave oily material (221 mg), from which the product **4** (103 mg, 44%) was isolated by preparative TLC (SiO_2, hexane-EtOAc=7:3). **4**: R_f 0.64; ^1H NMR (500 MHz, $CDCl_3$) δ=1.19 (3H, d, J=6.3 Hz, C_4-Me_{eq}), 1.20 (6H, t, J=7.0 Hz, -$CH_2\underline{CH_3}$), 1.31—1.43 (1H, m, C_5-H), 1.35 (3H, d, J=6.9 Hz, C_6-Me_{ax}), 1.83 (1H, ddd, J=6.3, 11.4, and 13.4 Hz, C_5-H), 1.87 (1H, dt, J=14.1 and 6.7 Hz, $C_{1'}$-H), 1.94 (1H, dt, J=14.1 and 6.7 Hz, $C_{1'}$-H), 3.51 (1H, dq, J=9.7 and 7.0 Hz, -$OC\underline{H_2}CH_3$), 3.53 (1H, dq, J=9.7 and 7.0 Hz, -$OC\underline{H_2}CH_3$), 3.63 (1H, dq, J=9.3 and 7.0 Hz, -$OC\underline{H_2}CH_3$), 3.68 (1H, dq, J=9.3 and 7.0 Hz, -$OC\underline{H_2}CH_3$), 3.95 (1H, ddq, J=2.7, 6.3, and 11.4 Hz, C_6-H_{ax}), 4.28 (1H, dq, J=6.3 and 6.3 Hz, C_4-H_{eq}), 4.67 (1H, t, J=6.7 Hz, $C_{2'}$-H), and 4.96 (1H, t, J=6.7 Hz, -OCHO-); MS *m/z* 231 (M^+-1).

Found: C, 61.81; H, 10.19%. Calcd for $C_{12}H_{24}O_4$: C, 62.04; H, 10.41%.

ii) Partial Acetal Exchange of 1,1,3,3-Tetraethoxypropane with (*R,R*)-2,4-Pentanediol. To a solution of 1,1,3,3-tetraethoxypropane (Nakarai Kagaku) (1.43 g, 6.49 mol) and (*R,R*)-2,4-pentanediol (320 mg, 3.07 mmol) dissolved in THF (6 mL) was slowly added concd H_2SO_4 (10 µl), and the acidic solution was stirred for 4 h at 50 °C. The resulting mixture was neutralized with saturated aqueous $NaHCO_3$ (10 mL×2), and the aqueous layer was extracted with ether. The extract was dried ($MgSO_4$) and evaporated to give oily material (1.351 g), which was subjected into SiO_2 column chromatography (45 g, 17×0.9 cm). Unreacted 1,1,3,3-tetraethoxypropane (0.478 g) was recovered from 210 mL of elution with a 9:1 solution of hexane-EtOAc. Further elution (80 mL) gave **4** (0.520 g, 73%).

In this reaction 2,2'-methylene bis[(4*R*,6*R*)-4,6-dimethyl-1,3-dioxane] was formed as the byproduct.

(4*R*,6*R*)-4,6-Dimethyl-2-(2-oxoethyl)-1,3-dioxane (1c). Into a solution of the acetal **4** (200 mg, 0.86 mmol) in acetone (5 mL) and water (40 µL, 2.2 mmol) was added Amberlyst 15 (10 mg), and the mixture was stirred for 24 h at room temperature and filtered. The product was extracted with ether, dried ($MgSO_4$), and concentrated to give **1c** (75 mg, 55%): ^1H NMR (500 MHz, $CDCl_3$) δ=1.20 (3H, J=6.2 Hz, C_6-Me_{eq}), 1.38 (3H, d, J=6.9 Hz, C_4-Me_{ax}), 1.34—1.38 (1H, m, C_5-H_{eq}), 1.85 (1H, ddd, J=6.2, 11.9, and 13.3 Hz, C_5-H_{ax}), 2.62 (2H, dd, J=2.3 and 4.7 Hz, $C_{1'}$-H), 4.00 (1H, ddq, J=2.3, 11.9, and 6.2 Hz, C_6-H_{ax}), 4.31 (1H, dq, J=6.2 and 6.9 Hz, C_4-H_{eq}), 5.32 (1H, t, J=4.7 Hz, 1H, C_2-H), and 9.79 (1H, t, J=2.3 Hz, HC(O)-); Found: *m/z* 158.0953. Calcd for $C_8H_{14}O_3$: M, 158.0943.

General Procedure for Addition of Organometallic Reagents to Keto Acetal 1. Into a solution of ketoacetal **1** in

ether (5×10^{-2} M) was added organolithium or magnesium reagent (2.0—2.8 equiv) at −78 °C. The concentration of reagent used is as follows; MeLi (1.1 M in ether), Bu^{n}Li (1.5 M in ether), PhLi (0.6 M in ether), and MeMgI (2.3 M in ether). After the above mixture was stirred at −78 °C for 4 h, it was allowed to warm to room temperature, and the product was extracted by usual manner. The diastereomeric excess of crude product was determined by capillary column GLC analysis (base line separation) using SCOT OV-17 capillary column (30 m×0.3 mm, Wako Pure Chemical Ind.) or PEG-20M Bonded (25 m×0.25 mm, Chemical Bonded Column, GASUKURO KOGYO Inc.) with a Shimadzu Model GC-MINI 2, or 100 MHz NMR spectrometer. The results were shown in Table 1, and the spectral and analytical data of products are as follows.

(4*R*,6*R*)-4,6-Dimethyl-2-(2-hydroxy-2-phenylpropyl)-1,3-dioxane (2a). Recrystallization of the product from hexane gave a single diastereomer of **2a** (45% recovery): mp 97—98 °C; IR (neat) 3500 cm^{-1}; ^{1}H NMR (500 MHz, $CDCl_3$) δ=1.08 (3H, d, J=6.9 Hz, C_4-Me_{ax}), 1.16 (3H, d, J=6.0 Hz, C_6-Me_{eq}), 1.27 (1H, ddd, J=1.2, 2.4, and 13.3 Hz, C_5-H_{eq}), 1,15 (3H, s, $C_{2'}$-Me), 1.84 (1H, ddd, J=6.2, 11.8, and 13.3 Hz, C_5-H_{ax}), 2.12 (1H, J=8.3 and 14.2 Hz, $C_{1'}$-H), 2.25 (1H, dd, J=3.2 and 14.2 Hz, $C_{1'}$-H), 3.79 (1H, ddq, J=2.4, 11.8, and 6.0 Hz, C_6-H_{ax}), 4.29 (1H, ddq, J=1.2, 6.19, and 6.9 Hz, C_4-H_{eq}), 4.41 (1H, br s, -OH), 4.60 (1H, dd, J=3.2, and 8.3 Hz, C_2-H), 7.22—7.37 (3H, m, ArH), and 7.44—7.47 (2H, m, ArH); $[\alpha]_D^{27}$ +22.0° (*c* 0.528, $CHCl_3$).

Found: C, 71.75; H, 8.72%. Calcd for $C_{15}H_{22}O_3$: C, 71.97; H, 8.86%.

(4*R*,6*R*)-4,6-Dimethyl-2-(2-hydroxy-2-phenylhexyl)-1,3-dioxane (2b). R_f 0.47 (SiO_2, hexane-EtOAc=8:2); IR (neat) 3500 and 1140 cm^{-1}; ^{1}H NMR (60 MHz, CCl_4) δ=0.52—1.53 (17H, m, *n*-Bu, C_5-H, and Me), 2.14 (5H, d, J=5 Hz, $C_{1'}$-H), 3.33—4.03 (1H, m, C<u>H</u>CH$_3$), 4.03—4.53 (1H, m, C<u>H</u>CH$_3$), 4.30 (1H, s, OH), 4.70 (1H, t, J=5 Hz, C_2-H), 6.90—7.86 (5H, m, ArH).

Found: C, 73.68; H, 9.61%. Calcd for $C_{18}H_{28}O_3$: C, 73.93; H, 9.65%.

(4*R*,6*R*)-4,6-Dimethyl-2-(2-hydroxy-2-methylhexyl)-1,3-dioxane (2c). Bp 110 °C (3 mmHg); IR (neat) 3550 and 1140 cm^{-1}; ^{1}H NMR (60 MHz, $CDCl_3$) δ=0.87 (3H, m, C<u>H</u>$_3$-CH$_2$CH$_2$C<u>H</u>$_2$), 1.1—1.6 (12H, m, C<u>H</u>$_3$CH and CH$_3$C<u>H</u>$_2$C<u>H</u>$_2$-C<u>H</u>$_2$), 1.17 (3H, s, -CH$_2$C<u>H</u>$_3$), 1.5—2.0 (2H, m, C_5-H), 1.75 (2H, d, J=6.0 Hz, $C_{1'}$-H), 3.12—3.66 (1H, s, O<u>H</u>), 3.76—4.09 (1H, m, CH$_3$C<u>H</u>), 4.09—4.46 (1H, m, CH$_3$C<u>H</u>), 5.14 (1H, t, J=6.0 Hz, C_2-H).

(4*R*,6*R*)-4,6-Dimethyl-2-(2-hydroxypropyl)-1,3-dioxane (2d). R_f 0.63 (SiO_2, hexane-EtOAc=2:8); IR (neat) 3430 and 1140 cm^{-1}; ^{1}H NMR (100 MHz, $CDCl_3$) δ=1.17 (3H, 1d, J=6.0 Hz, CHC<u>H</u>$_3$), 1.21 (3H, d, J=6.0 Hz, CHC<u>H</u>$_3$), 1.38 (3H, d, J=7.0 Hz, CH(OH)C<u>H</u>$_3$), 1.60—2.02 (4H, m, C_5-H and $C_{1'}$-H), 3.24 (1H, br s, O<u>H</u>), 3.80—4.46 (3H, m, -C<u>H</u>CH$_3$ and $C_{1'}$-H), 5.08 (1H, t, J=6.0 Hz, C_2-H); MS *m/z* 173 (M^+-1).

Transformation of 2a into 7. Into a solution of **2a** ($[\alpha]_D^{27}$ +22.0°, 0.250 g, 1.00 mmol) in anhydrous methanol (5 mL) was added a solution (10 mL) of methanol saturated with dry HCl. After the solution was stirred for 3.5 h at 50 °C, the acidic solution was neutralized to pH ≈8.5 with 5% aqueous $NaHCO_3$ solution. Usual workup followed by a short path column chromatography (SiO_2, 0.1 g, hexane) gave a mixture (169 mg) of **5**, the starting material **2a**, and 2-phenyl-2,4,4-trimethoxybutane in a ratio of 7:1:1 by NMR. **5**: R_f 0.44 (SiO_2, hexane-EtOAc=7:3); IR (neat) 3450 and 1110 cm^{-1}; ^{1}H NMR (60 MHz, $CDCl_3$) δ=1.50 (3H, s, Me), 1.80 (1H, s, OH), 2.17 (2H, d, J=5.5 Hz, C_3-H), 3.19 (3H, s, OMe), 3.22 (3H, s, OMe), 4.12 (1H, t, J=5.5 Hz, C_4-H), 7.07—7.57 (5H, m, ArH). The above mixture was then dissolved in acetone (3 mL) and water (0.3 mL), into which Amberlyst 15 (30 mg) was added. After stirring for 3 h at 50 °C, the mixture was filtered, extracted with ether, and dried (Na_2SO_4) to give oily material (144 mg) containing **6** in 61% purity (NMR). **6**: ^{1}H NMR (60 MHz, $CDCl_3$) δ=1.67 (3H, s, Me), 2.40 (1H, s, OH), 2.75 (2H, d, J=3 Hz, CH_2), 6.60—7.90 (5H, m, ArH), 9.63 (1H, t, J=3 Hz, CHO); MS *m/z* 163 (M^+-1). The oily material was then dissolved in ether (1.5 mL), into which was added a suspended solution of $LiAlH_4$ (99 mg, 2.6 mmol) in ether (1.5 mL) at 0 °C. The mixture was stirred for 1 h at 0 °C and 3 h at room temperature. Usual workup followed by preparative TLC (SiO_2, chloroform) gave (3*R*)-3-phenyl-1,3-butanediol (**7**) (75 mg, 28% yield from **2a**). The compound **7** was further purified by preparative TLC (SiO_2, chloroform-ether=8:2, R_f=0.39) to give **7** (47 mg) of $[\alpha]_D^{26}$ +65.2° (*c* 0.406, benzene). The $[\alpha]_D$ value corresponds to be 97.7% ee based on the reported maximum rotation ($[\alpha]_D^{26}$ −66.7°).[6] **7**: ^{1}H NMR (100 MHz, $CDCl_3$) δ=1.54 (3H, s, Me), 2.01 (1H, dd, J=4.8 and 0.8 Hz, C_2-H), 2.42 (1H, br s, OH), 3.60 (3H, m, C_1-H and OH), and 7.9—7.4 (5H, m, ArH); IR (neat) 3500 cm^{-1}; MS *m/z* 166 (M^+).

The Long-Term Testing of ZSM-5-Type Zeolite Containing Strontium for the High-Temperature Conversion of Methanol to Olefin

Hideo OKADO,* Tsuneji SANO,† Kunio SUZUKI,† Kiyomi OKABE,† and Haruo TAKAYA†
Maruzen Petrochemical Co., Ltd., Goi, Ichihara-shi, Chiba 290
†National Chemical Laboratory for Industry, Higashi, Tsukuba-shi, Ibaraki 304
(Received January 14, 1988)

Synopsis. Using ZSM-5-type zeolites containing alkaline earth metals (Mg, Ca, Sr), long-term tests for methanol conversion were carried out for up to 1000 h at 550 °C under a methanol LHSV of 2.3 h^{-1}. Strontium-containing zeolite showed the most stable activity. This was attributed to the effect of strontium on the acidity of the zeolite.

ZSM-5-type zeolites are excellent for the conversion of methanol to light olefins and gasoline.[1-7] It is well-known that a high selectivity to light olefins has been attained at high temperatures over highly siliceous zeolites.[8,9] However, catalyst deactivation is a serious problem under high reaction temperatures. The deactivation occurs predominantly for two causes; one is the poisoning of active sites due to the accumulation of carbonaceous deposits, and the other is the structure degradation of the zeolites by dealumination from the framework. In the former case, the deactivated catalyst can be regenerated by burning off the carbonaceous deposits, while in the latter case a practical method for regeneration has not yet been established. The deactivation due to the dealumination is, therefore, more serious than the coke deposition. Furthermore, it is known that the dealumination is accelerated in a moisture-rich atmosphere such as methanol conversion. In order to improve the catalyst life under high temperatures, the resistance against steaming must be much improved.

Recently, we reported that the ZSM-5-type zeolites containing alkaline earth metals (AE-ZSM-5, AE= Mg, Ca, Sr) showed an increased selectivity to olefins at temperatures above 500 °C.[10-12] Hence, we carried out a long-term life test of AE-ZSM-5, and compared the results of Sr-ZSM-5 with those of Mg-ZSM-5 and Ca-ZSM-5.

Experimental

The protonated zeolite catalysts (AE-ZSM-5, AE= Mg, Ca, Sr) with a SiO_2/Al_2O_3 ratio of 200 were prepared by the method described in our previous papers.[10,12]

Methanol-conversion runs were carried out under atmospheric pressure over a fixed bed in a quartz tube reactor (10 mm i.d.), and the product gas was analyzed by the use of TCD- and FID-type Yanaco AG-1000TFH auto gas chromatographs.[10] The reactant gas consisted of methanol/argon (1/1 mol/mol), while the argon served as a diluent as well as an internal standard for analysis. The products obtained will be abbreviated in the present paper as follows: ethylene=$C_2^=$; propylene=$C_3^=$;C_4-olefins=$C_4^=$; C_5-olefins=$C_5^=$; dimethyl ether=DME.

The catalyst regeneration was performed by burning off carbonaceous deposits under a stream of air/argon (0.8/1.0 v/v), just after DME appeared in the products. The temperature was maintained at 400 °C for the first 2 h, then raised to 550 °C, and finally maintained at 550 °C for 2 h.

The elemental composition, the ^{27}Al-MAS NMR spectra, and the diffuse reflectance FT-IR spectra of the hydroxyl groups of the zeolites were measured according to the methods described in our previous papers.[10,12]

Results and Discussion.

A long-term life test for the methanol conversion was carried out at a temperature of 550 °C and at a methanol LHSV value of 2.3 h^{-1}. For Sr-ZSM-5, a long-term life test was carried out for 1000 h, as is shown in Fig. 1. The catalyst was regenerated 12 times with intervals of from 74 to 79 h, while the methanol conversion was kept nearly constant (ca. 100%). The total yield of $C_2^=$ to $C_5^=$, the maximum value of which was 80 to 83%, decreased with time on-stream, but it was almost completely recovered by regeneration. Thus, the Sr-ZSM-5 catalyst was found to be stable and

Reaction conditions: MeOH LHSV=2.3 h^{-1}, MeOH/Ar=1/1 mol/mol, temp=550 °C. *1) R is composed of paraffins, C_6^+-olefins, benzene, toluene, xylene, CO, and CO_2.

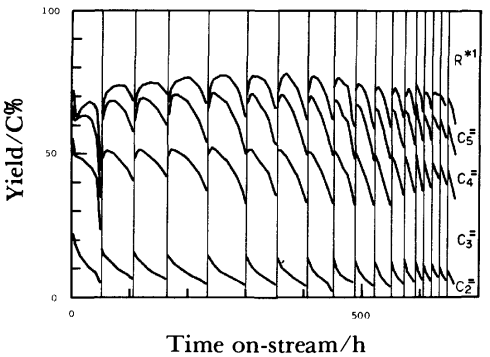

Fig. 2. Long-term life test over Mg-ZSM-5.
Reaction conditions: MeOH LHSV=2.3 h^{-1}, MeOH/Ar=1/1 mol/mol, temp=550 °C. *1) R is composed of paraffins, C_6^+-olefins, benzene, toluene, xylene, CO, and CO_2.

to show a high selectivity to light olefins.

On the other hand, for Mg-ZSM-5, a long-term life test was terminated at 660 h; the catalyst should be regenerated at shorter intervals because of the ease of deactivation, as is shown in Fig. 2. The maximum total yield of $C_2^=$ to $C_5^=$ during the regeneration interval ranged from 68 to 77% during the first 400 h time on-stream and decreased slightly after that. It is, therefore, concluded that the Mg-ZSM-5 catalyst is less stable and shows a lower selectivity to light olefins than that of Sr-ZSM-5.

For Ca-ZSM-5, a long-term life test was carried out for 1000 h, as is shown in Fig. 3. The total yield of $C_2^=$ to $C_5^=$ changed in a manner similar to that of Sr-ZSM-5. The number of regenerations, 10 times, was less than that of Sr-ZSM-5. The maximum total yield of $C_2^=$ to $C_5^=$ was 83 to 86%, higher than that of Sr-ZSM-5. However, the regeneration interval should be gradually shortened from 120 to 75 h along with the time on-stream. This implies that the active sites are rather unstable for Ca-ZSM-5 and that the life time for Ca-ZSM-5 is shorter than that of Sr-ZSM-5.

The three catalysts used in the long-term life tests were characterized by means of ^{27}Al-MAS NMR spectroscopy. The intensities of the peak at about 53 ppm assigned to tetrahedrally coordinated aluminium[13] were also measured. The intensity ratios, which means the percentage of a 53 ppm peak intensity of the used catalysts relative to that of the corresponding fresh catalysts, are listed in Table 1.

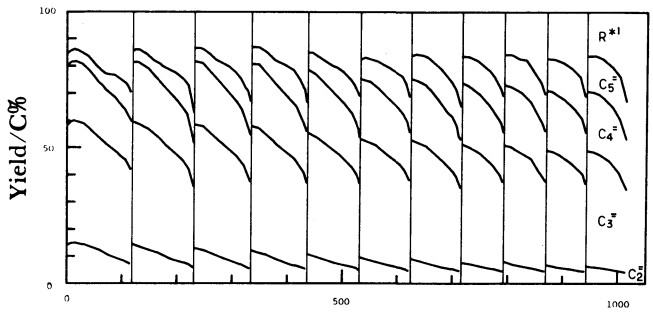

Fig. 3. Long-term life test over Ca-ZSM-5.
Reaction conditions: MeOH LHSV=2.3 h^{-1}, MeOH/Ar=1/1 mol/mol, temp=550 °C. *1) R is composed of paraffins, C_6^+-olefins, benzene, toluene, xylene, CO, and CO_2.

The ratio for Sr-ZSM-5 is 94%, distinctly higher than those of both Mg-ZSM-5 (18 to 19%) and Ca-ZSM-5 (32 to 56%). This implies that Sr-ZSM-5 has a higher resistance against the dealumination of the framework. It is considered that the acidity of zeolites originates from tetrahedrally coordinated aluminium, so that the long catalytic life of Sr-ZSM-5 (Fig. 1) is based on the greater resistance against the dealumination of the aluminosilicate framework.

Figure 4 shows the diffuse reflectance FT-IR spectra of hydroxyl groups for the three catalysts before and after the life tests. As has previously been reported,[14] each of the spectra is characterized by two well-defined peaks at 3605 and 3730—40 cm^{-1}. The low-frequency peak is assigned to an acidic bridged OH of Si(OH)Al, and the high-frequency one, to a terminal Si–OH or OH of the extra-framework silica. The broad peak near 3500 cm^{-1} is attributed to hydrogen bonding

Table 1. Characteristics of AE-ZSM-5 before and after the Long-Term Life Test

Catalyst	Chemical composition[a] (Molar ratio)		Particle size (μm)	Relative intensity of the 53 ppm peak[b] after life test[c] (%)	
	SiO_2/Al_2O_3	AE/Al_2		Upper-layer[d]	Lower-layer[d]
Mg-ZSM-5	212	0.25	3—4	18	19
Ca-ZSM-5	200	2.63	4—6	32	56
Sr-ZSM-5	218	2.81	4—6	94	94

a) After proton ion-exchange. AE=Mg, Ca, and Sr. b) The intensity ratio (×100) of the 53 ppm peak of the used zeolite to the corresponding fresh one was determined by means of ^{27}Al-MAS NMR. c) The life tests were carried out at 550 °C under a MeOH LHSV of 2.3 h^{-1}, diluted with argon (MeOH/Ar=1/1 mol/mol). The total life times are 660 h for Mg-ZSM-5, 1000 h for Ca-ZSM-5 and 1000 h for Sr-ZSM-5. d) The upper-layer is 25% of the total volume of the catalyst, while the lower-layer is 75%.

between adjacent hydroxyl groups.[14] For Mg-ZSM-5, the peak at 3605 cm^{-1}, which was clearly observed in the fresh catalyst, disappeared nearly completely after the life test for 660 h, as is shown by Curves 1 and 2. This disappearance seems to be consistent with the release of a large number of aluminium atoms from the framework.

For the fresh Ca-ZSM-5 (Curve 3), the intensity of the peak at 3605 cm^{-1} was very low. We ourselves have previously reported[11] that the addition of calcium or strontium to the starting materials in the zeolite synthesis decreases the strong acid sites, corresponding to the peak at 3605 cm^{-1}, observed for the as-made zeolite catalyst because of the partial replacement of the H^+-acid sites for the calcium or strontium ions. On the other hand, the strong acid sites of the working catalyst gradually increase with the time on-stream in the methanol-conversion run because of the migration of the calcium ions from the initial sites. As compared to the 3605 cm^{-1} peak intensity of the fresh catalyst, that of the upper-layer catalyst of the reactor (Curve 4) remained almost unchanged, while that of the lower-layer one (Curve 5) increased. It is plausible that the deterioration of the catalyst, its dealumination, would take place in a greater degree at the upper-layer catalyst, since methanol was fed from the top of the reactor. The results for ^{27}Al-MAS NMR (Table 1) clearly support this possibility; that is to say, the relative intensity of the 53 ppm peak at the upper-layer catalyst (32%) is lower than that of the lower-layer one (56%). It is concluded, therefore, that the very low intensity for the upper-layer part is due to dealumination, while the increase in the intensity for the lower-layer part is due to the release of calcium ions from the strong acid sites, as has been mentioned above. This conclusion is also supported by the previous report that steam produced by methanol conversion accelerated the release of calcium ions from the acid sites.[15]

On the other hand, the peak at 3605 cm^{-1} was not observed for either the fresh Sr-ZSM-5 or the used one, as is shown by Curves 6 and 7. These observations of the FT-IR and ^{27}Al-MAS NMR spectra indicate that Sr-ZSM-5 is a remarkably stable catalyst for methanol conversion. From these results, it was confirmed that among AE-ZSM-5 Sr-ZSM-5 was the best catalyst in both the yield of light olefins and the catalyst life.

This work is a part of the "C_1 Chemistry Project," a National Research and Development program of the Agency of Industrial Science and Technology, Ministry of International Trade and Industry (M.I.T.I), Japan.

We wish to thank Dr. S. Shin (National Chemical Laboratory for Industry) for his helpful discussion.

(Received December 3, 1987)

The decomposition mechanisms were studied for ionized species of ethane and propane in the low-energy region by using an ab initio molecular orbital method. Calculations show that rather complex fragmentation processes may occur in addition to a simple cleavage of C-C and C-H bonds. In order to examine the possibility of an elimination of H_2 or CH_4 from the radical cation of saturated hydrocarbons, the potential energy curves were calculated for both 1,1- and 1,2-eliminations. An energy barrier of 1,2-elimination was estimated to be small, but a 1,1-elimination can also possibly occur. It was also found that a single C-H bond scission of the parent radical cation may occur with the same order of energy for the H_2 loss. The present results are qualitatively in a good agreement with the experiments.

The mass spectra of saturated hydrocarbons give a complex pattern for the fragment species caused by ionization under electron bombardment,[1] although there are only two different kinds of bonds: C-C and C-H. Since saturated hydrocarbon molecules are fundamental organic molecules constructed with σ-frameworks, it is important to investigate the behavior of the ionized species produced by removing a σ-bonding electron in order to understand the fragmentation pattern of the mass spectra.

The unimolecular decomposition processes of radical cation species are strongly related to the electronic structure of the parent molecules. When molecules have a double bond or heteroatoms, a characteristic mass spectrum can be observed; this result can be effectively used for a molecular identification. In the case of saturated hydrocarbon, however, mechanistic studies have been very few, since various types of fragment ions are observed. In this respect, we carried out a quantum chemical investigation and theoretically explored the mechanism of the fragmentation processes for saturated hydrocarbon. In this paper, we look at for ethane and propane as the simplest system.

Theoretical Procedure

The molecular geometries of radical cations are calculated by using an analytical gradient method based on an unrestricted Hartree-Fock (UHF) method with STO-3G and 6-31G basis sets.[2] In order to determine whether the structures obtained by geometry optimization are located at equilibrium or a transition state, we carried out vibrational analysis by using an analytical second derivative method.[3]

Results and Discussion

Experimental data resulting from electron impact and photoionization studies for propane and butane show that cation species are mainly produced by a simple cleavage of the C-C bond in the high-energy region. In the low-energy region, however, it seems that there are rather complex processes, such as H_2 or CH_4 loss, or isomerization.[4,5] Before discussing the fragmentation mechanisms of propane, we consider the potential energy surfaces for the fragmentation processes of the ethane radical cation, especially in the lowest electronic state.

$C_2H_6^{+\cdot}$. The experimental data for ethane by electron impact shows that various kinds of fragment ions are produced and $C_2H_5^+$, $C_2H_4^{+\cdot}$, $C_2H_3^+$, $C_2H_2^{+\cdot}$, and CH_3^+ are observed in the electron energy from 10 to 23 eV.[6] It should be noted that the appearance potential of $C_2H_5^+$ (12.5 eV) is nearly the same as that of $C_2H_4^{+\cdot}$ (12.1 eV). This evidence is also shown by photoionization,[7] and suggests that the H_2 elimination competes with the hydrogen atom loss from an ethane radical cation.

Unimolecular fragmentation takes place by breaking two C-H bonds which can be distinguished as 1,2-elimination and 1,1-elimination. The products are an ethylene radical cation CH_2=$CH_2^{+\cdot}$ and a methylcarbene radical cation CH_3-$CH^{+\cdot}$, respectively. Table 1 summarizes the energies of the parent ion $C_2H_6^{+\cdot}$ and fragments $C_2H_5^+$, $C_2H_4^{+\cdot}$, CH_3^+, etc. calculated at their equilibrium structures. Since the electron correlation effect is important for estimating the energy barrier, we also calculated the energies by using the MP3 method, as shown in Table 1. However, the qualitative feature of the product distribution for ionized species may be read from the SCF results.

Table 1 shows that the most stable fragments are CH_2=$CH_2^{+\cdot}$+H_2 and that the energy is 0.8 eV lower than that of $CH_3CH_2^+$+H·. This result seems to be consistent with the fact that the appearance potential of $C_2H_4^{+\cdot}$ is lower than that of $C_2H_5^+$. However, we must consider the barrier height to dissociate two hydrogens from ethane radical cation.

Let us discuss the energy barrier for the H_2 loss via a 1,2-elimination:[8]

$$C_2H_6^{+\cdot} \rightarrow C_2H_4^{+\cdot} + H_2. \quad (1)$$

a) Equilibrium geometries are obtained by Hartree-Fock method (UHF method for radicals and RHF method for closed-shell molecules). The energies by MP3 method (third-order Møller-Plesset perturbation theory) are calculated at the geometries optimized by HF method with STO-3G basis set. b) Ref. 15.

In the case of a neutral ethane molecule, a reaction in which two hydrogens synchronously dissociate is known to be symmetry forbidden in the sense of the Woodward-Hoffmann rule. On the other hand, if one electron is removed from the system, one may expect that the barrier height of the 1,2-H_2 elimination for the ethane radical cation would be less than that in the case of a neutral molecule. Since an ethane radical cation is a potentially high energy species, the energy of a C-H bond dissociation of $C_2H_6^{+\cdot}$ has been calculated to be only 1.1 eV (6-31G). When we calculate the potential energy curve for a hydrogen abstraction reaction,

$$C_2H_5^{+} + H\cdot \rightarrow C_2H_4^{+\cdot} + H_2, \quad (2)$$

the reaction is found to be exothermic and to proceeds without an energy barrier. Therefore, we could estimate that the barrier height of a 1,2-H_2 elimination process,

$$C_2H_6^{+\cdot} \rightarrow [CH_3\text{-}CH_2\cdots H]^{+\cdot} \rightarrow [CH_2\text{=}CH_2]^{+\cdot} + H_2 \quad (3)$$

should not be greater than that of a two-step 1,2-H_2 elimination process:

$$C_2H_6^{+\cdot} \rightarrow [CH_3\text{-}CH_2]^{+} + H\cdot \rightarrow [CH_2\text{=}CH_2]^{+\cdot} + H_2. \quad (4)$$

Such an energy relation may explain why the appearance potential of $C_2H_4^{+\cdot}$ is slightly lower than that of $C_2H_5^{+}$ (see the dashed line in Fig. 2).

The other possibility of H_2 loss is a 1,1-elimination in which two hydrogens are removed from one carbon atom of ethane. Although a methylcarbene radical cation, being a product, seems to be a very unstable species, the energy of $CH_3CH^{+\cdot}+H_2$ is calculated to be only 0.6 eV higher than that of $CH_3CH_2^{+}+H\cdot$. This means that a 1,1-elimination can also occur. While electron-impact experiments for CH_3CD_3 at 70 eV show that $C_2H_2D_2^{+\cdot}$, $C_2H_3D^{+\cdot}$, and $C_2D_3H^{+\cdot}$ are all observed,[9)] experimental evidence for such mechanisms has not been reported in the low-energy region. The present calculation strongly suggests evidence for the formation of a carbene radical cation due to a H_2 or D_2 loss from $CH_3CD_3^{+\cdot}$. Such species have been men-

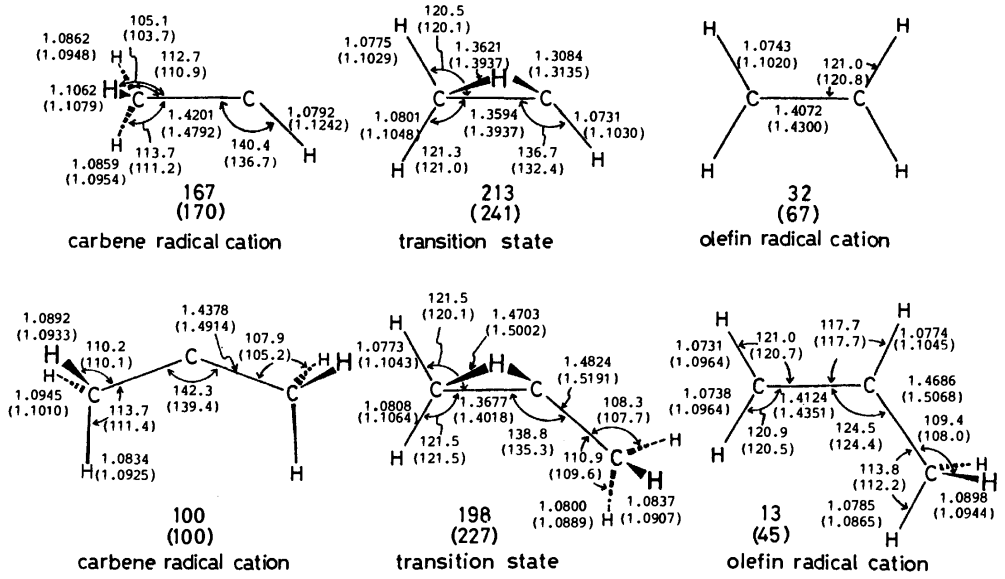

Fig. 1. The structures of methylcarbene radical cation and dimethylcarbene radical cation and their transition states of hydrogen migration calculated by using the UHF method with 6-31G (STO-3G) basis set. The units of bond lengths and bond angles are in Angstrom and degrees. The values shown in each geometry are the relative energies ($kJ\,mol^{-1}$) from the energy of the radical cation of ethane or propane at equilibrium structure. The values in parentheses are obtained with STO-3G basis set.

tioned as non-symmetric ethylene ions by von Koch[10] as the major precursor of acetylene ions. The methylcarbene radical cation may isomerize to a more stable ethylene radical cation; this energy barrier has been calculated to be ca. 0.5 eV. Figure 1 shows the geometries of the carbene radical cation and its transition state to an ethylene radical cation. The energy profile of this isomerization is shown by the curved line in Fig. 2. Most of the structures of other species have already been published elsewhere.[11,12,15]

Figure 2 summarizes the energy relations of the species formed by the ionization of ethane, as is discussed in this section. The ground state of an ethane radical cation was calculated to be a C-C σ-type radical cation which diabatically correlates to the cleavage of a C-C bond. The dissociation reaction of a C-C bond, however, requires more energy than the loss of H· or H_2. Since the energy of a C-C σ-type radical cation is very close to that of a C-H pseudo π-type radical cation, it would be expected that internal energy dispensation should rapidly occur during decomposition reactions.

$C_3H_8^{+\cdot}$. We have shown that there are two possibilities for removing two hydrogens from an ethane radical cation: 1,1- and 1,2-eliminations. In the case of propane, there are CH_3· and CH_4 losses as well as H· and H_2 losses. Table 1 also summarizes the energies of the possible fragments generated from propane. The potential energy surfaces are illustrated for H· and H_2 losses from $C_3H_8^{+\cdot}$ in Fig. 3(a) and for CH_3· and CH_4 losses in Fig. 3(b).

The experiment by Chupka and Berkowitz[7] shows that $C_3H_7^+$, $C_3H_6^{+\cdot}$, $C_2H_5^+$, and $C_2H_4^{+\cdot}$ are observed

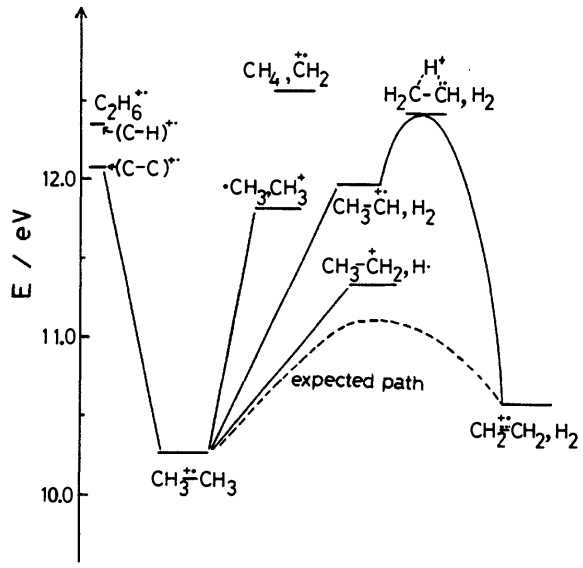

Fig. 2. The energy relations of the radical cation species caused by the ionization of ethane in the lowest state. The energies are calculated by UHF method at the optimized geometries with 6-31G basis set relative to the neutral ethane molecule.

over a narrow range: 11.3—11.9 eV. This means that losses of H·, H_2, CH_3·, and CH_4 from $C_3H_8^{+\cdot}$ occur at almost the same energy.[13]

As demonstrated in Fig. 3, the most stable product is an isopropyl cation. Due to the strong hyperconjugation by two methyl groups, the cation center prefers the central carbon to the terminal one. From Table 1, the dissociation of the central C-H bond in $C_3H_8^{+\cdot}$ is

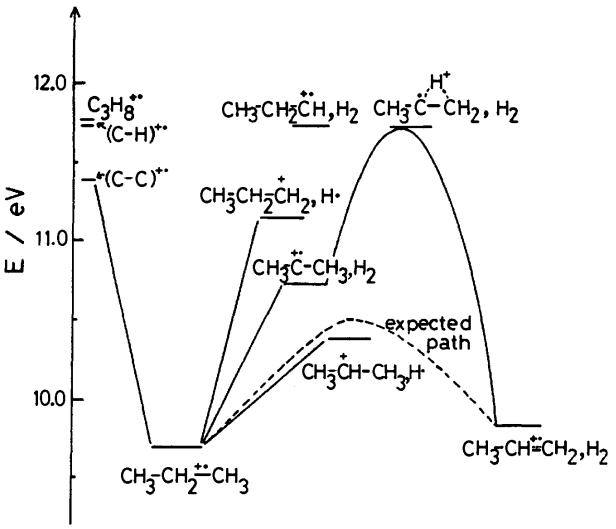

Fig. 3(a). The energy relations for H· and H_2 elimination from propane radical cation.

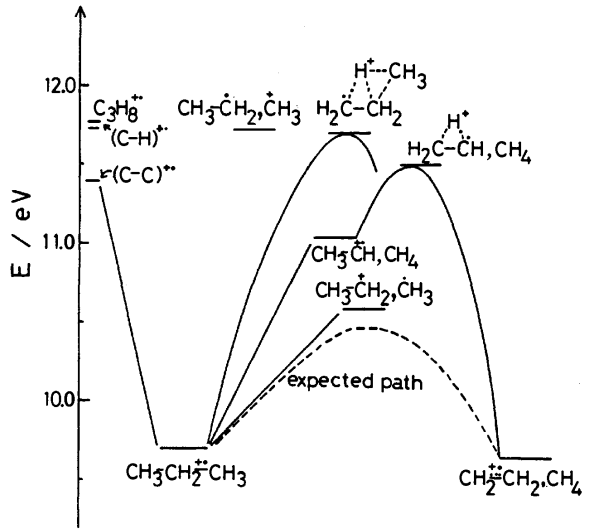

Fig. 3(b). The energy relations for CH_3· and CH_4 elimination from propane radical cation.

calculated to be only 0.7 eV (6-31G), while 1.4 eV is obtained for a terminal C-H bond dissociation.

Although an olefin π radical cation is energetically more stable, there is an energy barrier to be formed from a saturated hydrocarbon radical cation. It should be noted that the energy of the hydrogen atom loss of an ethane radical cation (1.1 eV) is in the middle of those of the central and terminal H· losses of $C_3H_8^{+\cdot}$ (0.7 eV and 1.4 eV). When the energy barrier of the H_2 loss of $C_3H_8^{+\cdot}$ is comparable to that in the case of $C_2H_6^{+\cdot}$, one can expect that the H· loss occurs more easily than the H_2 loss for $C_3H_8^{+\cdot}$. This expectation is in accord with the experimental results.[7]

Moreover, one can not neglect the two processes in which CH_4 or H_2 eliminates from the same carbon atom (1,1-elimination) and a different carbon atom (1,2-elimination). It is interesting that the energy of a dimethylcarbene radical cation is located between the energies of an isopropyl cation and a propyl cation. The molecular structure of a dimethylcarbene radical cation is illustrated in Fig. 1. Although the equilibrium geometry takes a C_2 symmetry, two methyl groups almost freely rotate internally. Since the carbene radical cation center is stabilized by two methyl groups, the energy barrier of the 1,2-hydrogen shift is calculated to be much higher than in the case of a methylcarbene radical cation. The dimethylcarbene radical cation is one of the strong candidates for a H_2 loss of the propane radical cation.

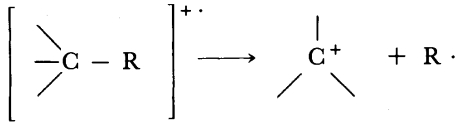
Molecular Orbitals and Ionization Potentials. The I.P. (ionization potential) from the high-lying occupied molecular orbitals of ethane is observed at 12.0—13.5 eV.[14] The degenerate C-H pseudo π-type bonding orbital ($1e_g$) and the C-C σ-type bond orbital ($3a_g$) are included in this energy region; these orbitals are energetically very close. Similar patterns of I.P. were measured at 11.5—12.6 eV in the case of propane. Although the highest occupied molecular orbitals of ethane and propane were assigned to be a C-H π-type molecular orbital through an RHF calculation,[14] a UHF calculation shows that the energy of a C-C σ-type radical cation is slightly lower than that of a C-H pseudo π-type radical cation. The energies of the vertical ionized states of ethane were estimated to be 12.1 eV for the C-C σ orbital and 12.4 eV for C-H π-type MO with the present UHF calculation.

As a result of geometry optimization, the lowest state of the ionized parent molecule was found to be a C-C σ-type radical cation for both ethane and propane. Since the energy difference is very small between C-C σ and C-H pseudo π-type radical cations, the electronic coupling between them becomes large through a geometrical relaxation. This fact would lead to the complex fragmentation profiles of ethane and propane radical cations.

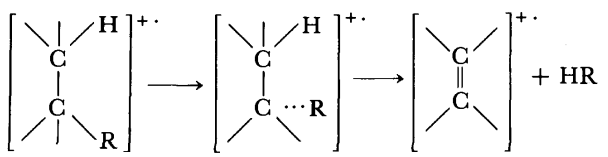
Concluding Remarks

The fragmentation mechanisms of the saturated hydrocarbon in the low-energy region may be summarized as follows:

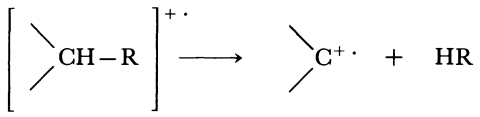
1) Hydrogen or alkyl radical (R·) elimination



2) 1,2-HR elimination



3) 1,1-HR elimination



where R=H or CH_3. Mechanism 1 is a simple bond cleavage process. Mechanism 2 proceeds with a small energy barrier. Although a reverse 2+2 type reaction is symmetry forbidden in the case of a neutral system, the energy barrier is substantially reduced for the HR loss of a radical cation. The 1,2-HR elimination process is expected to compete with a simple C-R bond scission, since the expected transition-state energy of mechanism 2 is very close to the energy of the product by mechanism 1 (see Figs. 2 and 3). Our calculation also shows that a carbene radical cation could be produced via HR loss by 1,1-elimination in the low-energy region.

This research was carried out by using an HITAC M680-H at the computer center of Institute for Molecular Science. This work was supported by Grant-in-Aid for Scientific Research (No. 62470013).

Kinetic Studies by Means of the NMR Techniques. I. Acid-Catalyzed Proton-Exchange Reactions of Some Substituted Phenols

Akihiro YOSHINO, Yasuki NAKASHIMA, and Kensuke TAKAHASHI*
Department of Applied Chemistry, Nagoya Institute of Technology, Gokiso-cho, Showa-ku, Nagoya 466
(Received March 11, 1988)

A kinetic study was conducted on the acid-catalyzed proton-deuteron-exchange reactions of several substituted phenols. The rates of the exchange were determined by using the two-bond isotope shifts ($^2\Delta$) on the carbons and the pattern-fitting analyses for the ^{13}C NMR signals. The observed reaction rates can be expressed additively with substituent parameters. The parameters of the para positions are linearly correlated to the σ_p^+ with ρ=−3.6.

The proton-deuteron-exchange reaction is a typical ionic reaction. Therefore, its study can provide useful indices for various ionic reactions. In the cases of the title reactions, the reactions proceed through the σ-complex, whose formation is a rate-determining step. Katritzky et al. reviewed such acid-catalyzed hydrogen-exchange reactions.[1]

In studies of hydrogen-exchange reactions, knowledge of the isotopic fractionation (D in %) is necessary. This fractionation can be obtained by various methods, such as IR,[2] ^{1}H NMR,[3] ^{2}H NMR,[4] MS,[4] and ^{13}C NMR.[4-8] The organic reaction rates have been discussed in terms of the substituent parameters presented by Hammett[9] and extended by Brown-Okamoto,[10] Taft,[11] and Yukawa-Tsuno.[12] The Hammett equation has been applied to many reaction rates of the meta- and para-substituted benzenes.[13] However, its application is limited in the cases of multiply substituted benzenes. Therefore, the parameters must be considered with regard to steric or mutual interactions between substituents.

In the present article, we present a method to evaluate simultaneously the title reaction rates for different sites of the substituted benzenes. The rates were obtained for thirty-eight sites of twenty unsubstituted and substituted phenols.

Experimental

The materials used were commercially available and were used without further purification. The reaction vessels were hand-made Pyrex ampules. A sample consisting of 0.01 mol of phenol was added to 1 g of a HCl/D_2O (0.1 wt%) solution, and the mixture was sealed into the Pyrex ampule with a stirring bar. The ampule was then kept at 80±1 °C in a DN-42 oven (Yamato Scientific Co.,Ltd.). The solution was stirred to produce the reaction. After the reaction had reached an extent of about 5—50 D%, the sample was cooled by immersing it in water; the contents were then separated into aqueous and oily (or solid) phases. The latter phase was used for the NMR measurement. The concentration of the NMR sample solution was neat for the liquid sample and ca. 50 wt% in dioxane for the solid sample. The samples were not degassed, since the presence of oxygen made T_1 short, which reduced the time needed to repeat its NMR measurement. The ^{13}C and ^{2}H NMR spectra were obtained with a Varian XL-200 FT-NMR spectrometer operating at 50.31 and 30.71 MHz respectively. The ^{13}C NMR spectra were measured by using the gated decoupling technique with no NOE pulse sequence. Data acquisition was carried out under the following conditions: flip angle of pulse, 45°: number of transients, 24—128: data points, 32000: delay time, 40 s, and spectral width, 2600—3500 Hz. The isotopic fractionation was obtained by the use of the Lorentzian lineshape-fitting procedure within an accuracy of ±0.5%. The computer-assisted lineshape simulations were run on a Sharp personal computer MZ-80B with a BASIC program, while the linear regressions were run on a Hitachi M-260H computer in our Institute using a FORTRAN program with double precision.

Results and Discussion

NMR Spectra. The NMR signal intensities of the deuterons meta to the hydroxyl or within the methyl group(s) did not change: that is, the natural abundance intensities remained even after the title reactions had been carried out for 200 h under the experimental conditions used. Those of the deuterium at the ortho and para positions were clearly observed with an increased intensity, but not separately, because of the broadening caused by the quadrupole interactions. In this system especially, the large solvent signal of D_2O sometimes interferes with the signals of the products. Therefore, the ^{2}H NMR signals of the products were not convenient for the product analyses. The NMR observation in the present study was, then, carried out only for the ^{13}C NMR spectra in the region of the aromatic carbons.

Figure 1 shows a typical ^{13}C NMR spectrum, which was observed for a solution obtained for 2-methylphenol. In this case, there are two reactive sites, C_4 and C_6, whose labeled carbon signals overlap with the unlabeled ones. The signal of the labeled carbon splits into three lines with coupling to deuterium, as may be seen in Fig. 1. It is also more shielded than that of the unlabeled carbon because of the so-called one-bond isotope shift, $^1\Delta$. The carbon atoms adjacent to the labeled one also suffer a high-field shift from the two-

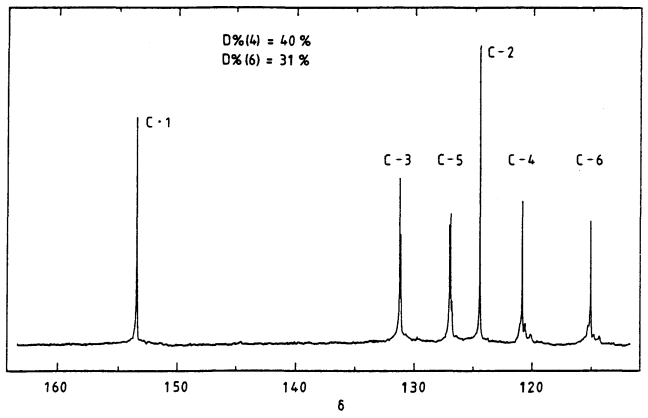

Fig. 1. The aromatic carbon regions of the 50.3 MHz ^{13}C NMR spectrum of the reaction mixtures of 2-methylphenol in the D_2O-HCl system. The spectrum was measured with the parameters of SW= 2600 Hz, 32 k data points, AT=6.154s, D1=40s, and 64 aquisitions (NT).

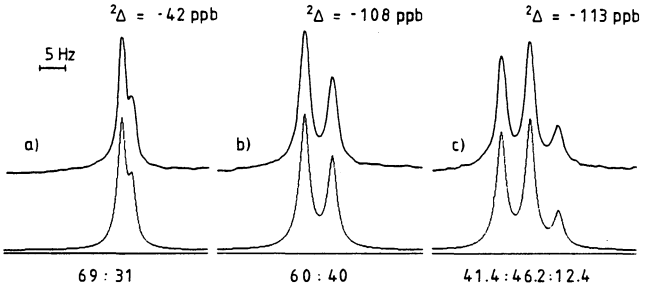

Fig. 2. ^{13}C NMR Spectra of (a) the C_1, (b) the C_3, and (c) the C_5 regions partly expanded from the spectrum of Fig. 1. The upper value gives the two-bond isotope shift and the lower one gives the intensity ratio of the signals. Data points were 427 points and half-height widths were 1.8, 2.3, and 2.4 Hz for a, b, and c, respectively.

bond isotope shift ($^2\Delta$). Therefore, both the C_1 and C_3 signals appear as two lines, and the C_5 signal, as three lines, as is shown in Fig. 2, though the C_2 signal does not split because it has no adjacent labeled carbon. The intensities of the signals are consistent with those obtained in each site, within an error of 1%.

Determination of *D* (%). In this article, the deuterium atom% is expressed as *D* (%). Reuben has reported a method of evaluating the deuterium/protium ratio by using the two-bond isotope shifts ($^2\Delta$).[6] His examples contain several equivalent labeled sites. However, in our cases, where the site in question has two nonequivalent adjacent site, its ^{13}C signal appears as three lines. This phenomenon may be ascribed to similar contributions from the two labeled deuterium atoms. In the cases of the method described here, the signals were sharp enough for the line separation to be observed and the *D*(%) could be determined accurately. As only the ortho and para protons of a phenol derivative undergo exchange reaction, the ^{13}C signals of C_1, C_3, and C_5 split into three or two lines only by means of adjacent labeled carbons. Thus, when the *D* (%) on the C_2, C_4, and C_6 of a phenol derivative are expressed as *p*, *q*, and *r*, the C_1, C_3, and C_5 signals split as follows:

$$C_1;\ (100-p)(100-r):(100-p)r+p(100-r):pr$$
$$C_3;\ (100-p)(100-q):(100-p)q+p(100-q):pq$$
$$C_5;\ (100-q)(100-r):(100-q)r+q(100-r):qr$$

If any one of C_2, C_4, or C_6 has a substituent, the *D*(%) of the substituted carbon is defined as zero. Then, in the case of 2-methylphenol, the *D*(%) of C_2 is equal to zero. Therefore, the two C_1 singlets have an intensity ratio of $(100-r):r$, while the two C_3 singlets have a ratio of $(100-q):q$. The three C_5 singlets have a ratio of $(100-q)(100-r):(100-q)r+q(100-r):qr$. Using these theoretical ratios, the pattern-fitting analyses were made for the experimental pattern, as is shown in Fig.2, by assuming that each signal fits the Lorentzian lineshape. The analyses need a parameter concerned with line widths. This is determined by a visual fitting of the calculated and observed spectra. The deuterium isotope shifts were determined from the spectra without any window function. As these parameters were determined independently, the *D*(%) of the sample can be obtained within an error of ±0.5% by means of the pattern-fitting analyses used. The values of *p*, *q*, and *r* can be determined by this method.

Evaluation of Reaction-Rate Constants. The exchange reaction between two reactants, AX and BX*, can be expressed as follows:

$$AX + BX^* \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} AX^* + BX, \qquad (1)$$

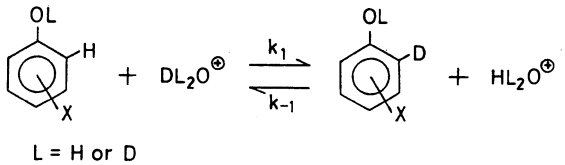
where X* represents a labeled X atom. The reaction is first-order with respect to the concentration of the isotope X*. Let the concentrations be: [AX]+[AX*]=*a*, [AX*]=*x*, [BX]+[BX*]=*b*, [BX*]=*y*, and *x*+*y*=*z* (constant). Then, the rate will be expressed as:

$$\ln(x_0-x_e)-\ln(x-x_e)=kt((a+b)/ab) \qquad (2)$$

where x_0 and x_e are the values of *x* at $t=0$ and ∞ respectively and where

$$x_e=az/(a+b). \qquad (3)$$

The total exchange rate *k* is equal to the sum of k_1 and k_{-1}. Equation 2 has been named McKay's equation.[14] In this article, the hydrogen-deuterium-exchange reactions of the substituted phenols proceed as follows (Scheme 1):



L = H or D

Scheme 1.

Table 1. ^2H Distributions and Reaction Rates as Calculated from ^{13}C NMR Lineshape Analyses of 3-Methoxyphenol in HCl-D_2O at 80 °C

Run No.	Time	HCl	D/%			D_e/%
	h	mmol dm^{-3}	C-2	C-4	C-6	
1	2.00	8.85	7	29	32	71.6
			(1.61)[a)]	(8.14)	(9.31)	
2	3.00	15.9	18	57	59	74.9
			(1.60)	(8.33)	(9.03)	

a) The values in parentheses are the reaction rates (k) calculated from Eq. 4 in the text: they are divided by the concentration of HCl and are given in units of 10^{-3} s^{-1} dm^3 mol^{-1}.

Table 2. Exchange Rate Constants (k_1) Observed for the Reactions in HCl-D_2O at 80 °C in Units of 10^{-6} dm^3 mol^{-1} s^{-1}

Compd. No.	Substituent	Site of exchange		
		H-2	H-4	H-6
1	H	8.97	16.7	8.97
2	2-CH_3	—	7.51	5.83

18	3,4-$(CH_3)_2$	53.7	—	61.3
19	3,5-$(CH_3)_2$	546	1370	546
20	2,3-$(OCH_3)_2$	—	132	87.6

When the concentrations of the reactants are expressed by D(%), 0, D_e, and D can be substituted for x_0, x_e, and x in Eq. 2. Then, it is shown as follows:

$$((a+b)/ab)kt = \ln(D_e/(D_e-D)) = -\ln(1-(D/D_e)). \quad (4)$$

If k_1 is equal to k_{-1}, D_e can be calculated from the initial concentrations of the reactants. However, if k_1 is not equal to k_{-1}, where the reaction has the kinetic isotope effect (KIE), K ($=k_1/k_{-1}$) and D_e must be observed directly. In this case,

$$k_1 = k/(1+1/K),\ k_{-1} = k_1/K. \quad (5)$$

In the reactions studied for the 19 substituted phenols, no kinetic isotope effects (KIE) were observed except for that of 3-t-butylphenol. One reason seems to be the high reaction temperature used (80 °C). Two examples of evaluations of D(%) and the reaction rates are shown in Table 1. The error of log k is considered to be within ±0.03. The first-order rate constants evaluated for thirty-eight different sites of twenty phenols are given in Table 2. From the data in Table 2, it must be said that the rates of all the 3-substituted phenols are larger than those of the corresponding 2- or 4-substituted ones and that of the unsubstituted one. However, the rates of the 2- or 4-substituted phenols are smaller than that of phenol. These trends are to be expected from the electronic properties of the substituents. KIE was observed for the case of 3-t-butylphenol (**9**: hereafter compounds will be referred to using the numbers given in Table 2), and the K's were determined to be 0.0671, 0.206, and 0.119 for the 2-, 4-, and 6-positions respectively.

Substituent Parameters. The reaction rates for the substituted phenols are assumed to be expressed as the sum of the substituent parameters as follows:

$$\log k_x = \log k_H + \sum n_i S_i + \sum n_{jab} S_{jab}, \quad (6)$$

where k_x's are the observed rate constants k_1's for unsubstituted or substituted phenols. The value of log k_H on the right hand side of Eq. 6 can be determined as a parameter in a regression analysis of the parameters in Eq. 6. S_i(X) (for example, S_o, S_m, or S_p) is a substituent parameter for the i-position with respect to the substituent X. The notation of S_{jab}(X,Y) is used to express an interaction effect of the a- and b-positioned substituents, X and Y, to the j-positioned rate. These are correction terms for the interactions between the substituents, and n_i or n_{jab} is a weight factor for S_i or S_{jab}. For example, in the case of 3,5-dimethylphenol, the rates for two different sites can be calculated from Eq. 6 as follows:

2-position; $\log k_1 = \log k_H(\text{ortho}) + S_o + S_p + S_{213}$;
4-position; $\log k_1 = \log k_H(\text{para}) + 2S_o + S_{435}$.

A correction term, S_{213} or S_{435}, appears in the case where the observed site is sandwiched with two substituents, OH and X, or X and X, as in the present example. In the case of 3-methylphenol, the rates can be expressed as follows:

2-position; $\log k_1 = \log k_H(\text{ortho}) + S_o + S_{213}$;
4-position; $\log k_1 = \log k_H(\text{para}) + S_o$;
6-position; $\log k_1 = \log k_H(\text{ortho}) + S_p$.

In the case of 4-methylphenol, the rates can be expressed as follows:

2-(or 6-)position; $\log k_1 = \log k_H(\text{ortho}) + S_m$.

The observed data in Table 2 were analyzed except for those of Compounds **14**, **17**, and **20**, where three sub-

Table 3. Substituion Parameters of Eq. 6 Evaluated for the Reactions in HCl-D_2O

Parameter	Substituent			
	CH_3	CH_3O	t-C_4H_9	Cl

$S_{435}(X,X)$	−0.055	—	—	—
$S_{412}(OH,X)$	−0.295	−1.303	−0.393	−1.382
$S_{612}(OH,X)$	−0.113	−1.239	0.124	−1.103

log k_H(ortho)=−5.066. log k_H(para)=−4.788. Standard deviation=0.096. Probable error=0.011. Calculated from 33 data with 27 parameters.

stituents are adjacent to each other. Corrections for such three adjacent substituents can not be determined at the present stage. The $S_i(X)$ and $S_{jab}(X,Y)$ parameters thus obtained are given in Table 3. The parameters of log k_H in Eq. 6 were evaluated to be −5.066 and −4.788 for the two sites, ortho and para respectively. The values of log k_H(ortho) and log k_H(para) are in good agreement with the experimentally observed rates of phenol, within the limits of probable error. These parameters express S_o and S_p for the OH group. This group's k_H(ortho):k_H(para) ratio was obtained as 0.527:1. Thirty-three experimental data in Table 2 were correlated with 27 parameters with a standard deviation of 0.096. The reaction rates, log k_1, can be calculated within an error of ±0.03. S_o contains three contributions from the mesomeric, inductive, and steric effects of the substituents. S_m is evaluated from the data of the *p*-substituted phenols; it contains two contributions from the mesomeric and inductive effects of the substituents. S_p is essentially similar to Hammett's σ_p^+ and contains two contributions from the mesomeric and the inductive effects of the substituent. S_{213} appears in the cases of the meta-substituted phenols in which the two substituents interact sterically with each other in their activated states. As has been shown before in the example of 3-methylphenol (**3**), the log k_1's of the 2- and 4-positions of 3-substituted phenols are the same if S_{213} is not taken into consideration. The k_1's of phenol (**1**) are different for the two sites, the 2- and 4-positions. Therefore, the k_1's of 3-substituted phenols must be compared with each other after they have been divided by the corresponding k_1's of **1**. As a matter of fact, the k_1's of the 2-position are smaller than those of the 4-position except for one example. The ratios are, then, 0.579, 0.372, 0.639, and 1.100 for the 3-substituents of t-C_4H_9, CH_3O, CH_3, and Cl respectively. The bulkiness of the substituents is considered to be t-C_4H_9>CH_3O>CH_3>Cl, but the S_{213} of a methoxyl group shows a larger negative value than that of the t-C_4H_9 group. However, no details are known at present. The S_{435} appears in the case of the 4-position of **19**, much as with S_{213}. However, the S_{435} values of the two methyl groups are

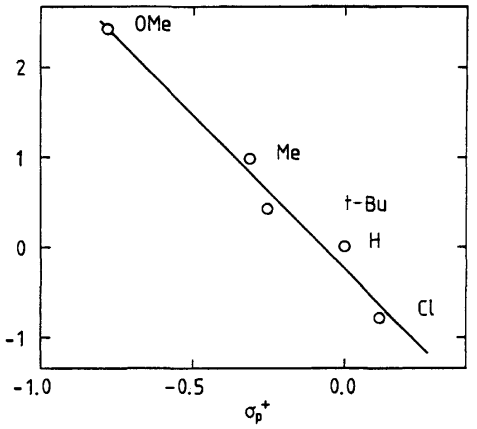

Fig. 3. Plot of S_o based on the σ_p^+ constants.

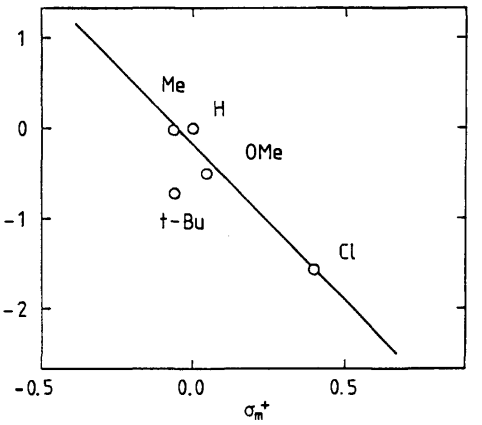

Fig. 4. Plot of S_m based on the σ_m^+ constants.

nearly zero. This shows that the hydoxyl group is more sterically effective than the methyl group in the present reaction. This is consistent with the fact that the methoxyl group is more effective than the *t*-butyl group for S_{213}. It is also considered that the presence of oxygen atom in the group has some effect. S_{412} and S_{612} appear in the cases of 2-substituted phenols. The two k_1's of the 4- and 6-positions of 2-substituted phenols must be compared with each other after the k_1's are divided by those of **1**. Their ratios are 0.692, 0.878, 0.312, and 0.537 for CH_3, CH_3O, t-C_4H_9, and Cl respectively. The k_1's at the 4-positions are affected more than those at the 6-positions by the introduction of 2-substituents. As may be seen in Table 3, the S_{412} and S_{612} values are especially large for the CH_3O and Cl groups. This contribution is probably due to the interference of the resonance effect of the hydroxyl group with the 2-substituents.

Correlation between Substituent Parameters and Hammett's Constants. The substituent parameters, S_o, S_m, and S_p, can be correlated with Hammett's constants, as is shown in Figs. 3—5. The S_o's are, however, plotted on a straight line with the σ_p^+ in Fig. 3, because no σ_o's are given in the Hammett relation. The straight line shows S_o=−3.4 σ_p^+−0.2, (r=0.986). In

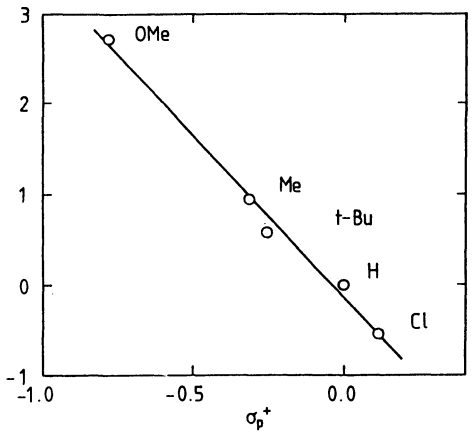

Fig. 5. Plot of S_p based on the σ_p^+ constants.

Fig. 4, the S_m of the *t*-butyl group is beneath the straight line. The straight line shows $S_m=-3.4\ \sigma_m^+-0.2$ ($r=0.979$) except for the point of the *t*-butyl group. In the case of S_p, all the values are correlated well with σ_p^+ by the use of the relation $S_p=-3.6\ \sigma_p^+-0.1$ ($r=0.995$), as is shown in Fig. 5. These values may be compared with that of $\rho=-3.51$ observed for similar reactions of 4-substituted anilines.[15]

It may be concluded that the method used in this article can be applied to ascertain the reaction rates in similar hydrogen-deuterium-exchange reactions with a good precision and with simplicity.

The substituent parameters can be expressed with the Hammett relation. Especially, it must be said that the additive relation can be applied even to ortho-substituted phenols with small deviations. This may be ascribed to the small size of the reagent, that is, a proton or deuteron, in the hydrogen-deuterium exchange reaction.

(Received March 14, 1988)

X-band and Q-band ESR measurements of Mn(II) ions contained in Japanese cultured marine pearls and pearl oyster (*Pinctada fucata*) were carried out at room temperature. The ESR spectra observed for the powdered samples of nacreous and prismatic layers revealed the ESR hyperfine structures typical to Mn(II) in an aragonite lattice and a calcite lattice, respectively. The ESR spectra were interpreted with the following spin Hamiltonian.

$$\mathcal{H} = g\beta \boldsymbol{H}\cdot\boldsymbol{S} + a\boldsymbol{S}\cdot\boldsymbol{I} - g_n\beta_n\boldsymbol{H}\cdot\boldsymbol{I} + D[S_z^2 - S(S+1)/3] + E(S_x^2 - S_y^2)$$

The resonance fields for all the $M=+1/2 \leftrightarrow M=-1/2$ ESR transitions were derived, with the third-order corrections all taken into account. The zero-field splitting parameters D and E for Mn(II) ions in these biominerals were estimated by computer simulations of the ESR line shapes. The estimated parameters for the nacreous Mn(II) ion (D=20.8 mT, E=6.9 mT) are apparently different from those for the prismatic Mn(II) ion (D=8.5 mT, E=1.4 mT).

First observation of the ESR of marine seed pearls was recently reported by Ishizu et al.[1] They found that pearls containing the blackish materials gave a more intense ESR signal of an organic free radical assignable to that of melanin, as justified from the isotropic g-factor, line width, and microwave saturation behavior. It has also been reported that the blackish pearls revealed ESR spectra resemblant to those of the Mn(II) ion in the calcite lattice, whereas the ESR spectra of the Mn(II) ion in satin white and pale yellow pearls resemble those of Mn(II) ion in the aragonite lattice. Accordingly one will expect that a detailed analysis of the Mn(II) ESR spectrum will provide useful information to characterize the crystal structure of the calcification phase in terms of the ESR crystal field parameters. In this paper, the ESR spectra of the Mn(II) ion contained in typical Japanese marine pearls have been analyzed and their detailed parameters have been discussed. Those of pearl oyster (*Pinctada fucata*) have also been examined, as typical ESR spectra of the Mn(II) ion in the calcite lattice.

The crystal field characters of the Mn(II) ion are discussed based on a spin Hamiltonian involving an isotropic g-factor, isotropic hyperfine structure term a, and zero-field splitting parameters D and E, where the third-order perturbation corrections were all calculated. The D and E values have been obtained by computer simulation of the observed ESR line shapes.

Experimental

The pearls and pearl oyster (*Pinctada fucata*) were respectively cultured and collected at Uwa Sea, Ehime Prefecture, Japan. The pearls were pulverized after removal of their artificial nuclei. The shells were washed to remove the sludge and scales of acorn barnacles that covered them, then the powdered sample was collected from the outer surface, i.e. the prismatic layer, of the shell. Satin white and blackish pearls were used as typical reference materials.

X-band and Q-band ESR spectra were respectively recorded by a JEOL-FE-2XG X-band spectrometer and by a JEOL-ES-SQ4 Q-band spectrometer operating with 100 kHz magnetic-field modulation. Li-TCNQ (g=2.0025) and Cr(III) in MgO (g=1.9800) were used as standard g markers. The magnetic fields were calibrated with the hyperfine splitting of Mn(II) in MgO (8.69 mT).

The computer program used for simulation of the observed ESR spectra of the powdered samples is similar to those of Pilbrow et al. and Belford et al.[2] The calculations were carried out on a FACOM M-180II AD computer at the Data Processing Center of this University.

Results and Discussion

The spin Hamiltonian appropriate for Mn(II) ion (S=5/2, I=5/2) can be written by

$$\mathcal{H} = g\beta\boldsymbol{H}\cdot\boldsymbol{S} + a\boldsymbol{S}\cdot\boldsymbol{I} - g_n\beta_n\boldsymbol{H}\cdot\boldsymbol{I} + D[S_z^2 - S(S+1)/3] + E(S_x^2 - S_y^2) \quad (1)$$

where all symbols have their usual meaning, and we assume that g and a are both isotropic, which is a good approximation for an S state ion.

Approximate solutions of the spin Hamiltonian have been reported by various authors. In the ESR spectra of Mn(II) ions, forbidden transitions ($\Delta M=\pm1$, $\Delta m=\pm1$) have been usually observed in addition to the allowed transitions ($\Delta M=\pm1$, $\Delta m=0$). Bleaney et al.[3] previously explained the positions of the forbidden lines and their remarkably large intensity relative to the allowed transition, with application of the perturbation procedure, where they have restricted their third-order corrections to the terms of aD^2. Later, although the theoretical calculations have been reviewed by several authors. Their results were obtained by assuming some third-order corrections to be zero but these were not suitable for the simulation of the present spectra.[4] Therefore, we have derived the general solution which includes all the third-order corrections.

Theoretically, the spectrum of Mn(II) ion with D, $a \ll g\beta H_0$ exhibits fine structure due to five transitions with transition probability ratio of 5 : 8 : 9 : 8 : 5, each of which splits into six hyperfine lines and five pairs of forbidden hyperfine lines. However, we have not observed any clear fine structure due to the transition other than the strongest central fine structure transition ($M=1/2 \leftrightarrow M=-1/2$). One of the reasons for this may be that the concentrations of Mn(II) ions in the samples were too low to observe all the transitions. In fact, the contents of manganese ions in marine pearls and shells are one order less than those in fresh water ones.[5]

When the angle between the magnetic field direction and the z axis, and the angle between the projection of the magnetic field direction on the x-y plane and the x axis (θ and φ) are employed, the resonance fields concerned with the central fine structure transition are given for the allowed transitions $[(+1/2, m) \leftrightarrow (-1/2, m)]$ by,

$$H = H_0 - am/g\beta + [8(16v-2w)+a^2(4m^2-35)]/8g^2\beta^2H_0 - am[a^2(4m^2-65)+16(72v-w+2au)]/8g^3\beta^3H_0^2 \quad (2)$$

for the forbidden transitions $[(+1/2, m-1) \leftrightarrow (-1/2, m)]$,

$$H = H_0 - a(2m+1)/2g\beta - g_n\beta_nH_0/g\beta + [8(16v-2w)+a^2(4m^2+4m-67)]/8g^2\beta^2H_0 - a(2m+1)[a^2(4m^2+4m-195) + 16(72v-w+4au)]/16g^3\beta^3H_0^2 \quad (3)$$

and for the forbidden transitions $[(+1/2, m) \leftrightarrow (-1/2, m-1)]$,

$$H = H_0 - a(2m+1)/2g\beta + g_n\beta_nH_0/g\beta + [8(16v-2w)+a^2(2m+1)^2]/8g^2\beta^2H_0 - a(2m+1)[a^2(4m^2+4m+73) + 16(72v-w)]/16g^3\beta^3H_0^2 \quad (4)$$

where

$$H_0 = h\nu/g\beta \quad (5)$$

$$u = D(3\cos^2\theta-1)+3E\sin^2\theta\cos2\varphi \quad (6)$$

$$v = (D-E\cos2\varphi)^2\sin^2\theta\cos^2\theta+E^2\sin^2\theta\sin^22\varphi \quad (7)$$

$$w = [D\sin^2\theta+E\cos2\varphi(\cos^2\theta+1)]^2+4E^2\cos^2\theta\sin^22\varphi \quad (8)$$

The transition probabilities of the above forbidden transitions relative to the allowed transitions are given by

$$I = 64v[35-4m(m+1)]/g^2\beta^2H_0^2 \quad (9)$$

It has been well documented that the prismatic layer, or the outer surface, of the shell has the form of calcite. The calcite lattice has a symmetry octahedral unit. This reflects to the typical ESR spectrum with relatively high axial symmetry of the zero-field splitting as shown in Fig. 1(a). The six main lines arise from the allowed transitions, and five weak pairs of lines between the main lines are ascribed to the forbidden transitions. This spectrum is the same as that of the shell (*Balanus balanoides*) but some difference can be seen in the line width of the shell (*Mytilus edulis*), both reported by Chasteen et al.[6,7] In the case of the marine shell (*Mytilus edulis*) reported so far, the ESR line width is sharp because of the longer spin-lattice relaxation. The zero-field splitting parameters can therefore be determined from the observed spectrum. However, in the present case, those parameters have been estimated by computer simulation of the ESR line shape, since the fine structures are poorly observed. The apparent ESR intensities for the allowed transitions are decreased on the higher magnetic field side, as the D value is increased. For convenience, the E value is usually taken to be zero in the calcite case. However, the line shape of the spectrum simulated by taking account of the E term is similar to the observed one, Fig. 1(b), in comparison with that which is simulated by omitting the E term, Fig. 1(c).

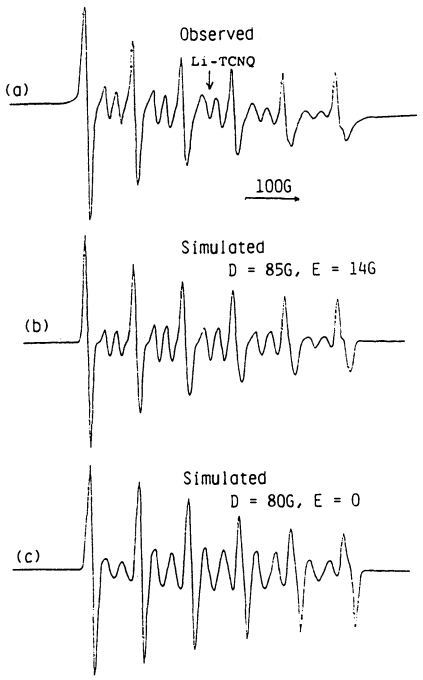

Fig. 1. (a): The X-band ESR spectrum observed at room temperature for Mn(II) ion in the prismatic layer of shell (*Pinctada fucata*). (b) and (c): The computer simulated ESR spectra for (a).

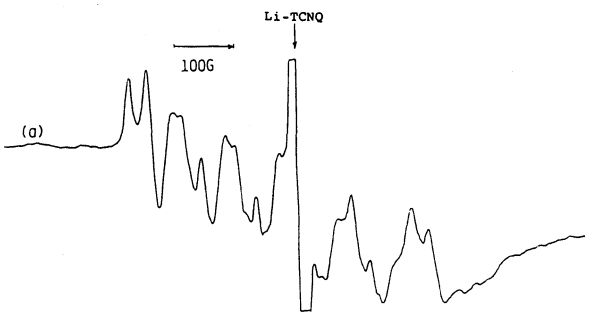

Fig. 2. The X-band ESR spectrum observed at room temperature for Mn(II) ion in the nacreous layer of the cultured marine pearl.

In contrast to the ESR spectrum of the prismatic layer, the X-band ESR spectrum of the nacreous layer of the cultured pearls appears to be very complicated, as shown in Fig. 2. The nacreous layer is composed of calcium carbonate in the form of aragonite. Because a metal ion in the aragonite lattice takes an unusual lower symmetrical nine-coordinate geometry,[8] the Mn(II) ion possesses the large zero-field interaction which brings the strong forbidden transition on the observed ESR spectrum. Consequently, the allowed and forbidden transition absorptions are overlapped each other; thus the Mn(II) ESR spectra become complicated with high anisotropy. According to Eq. 9, the forbidden transition intensity will be effectively reduced and the ESR hyperfine structure much simplified when the magnetic field increases. Actually, the Q-band ESR spectrum observed for the powdered sample of the nacreous layer is less complex and an effective reduction in the forbidden transition absorptions can be observed, Fig. 3(a). A similar Q-band ESR spectrum was reported for clam shell (*Mya arenaria*) by Chasteen et al.,[9] where the zero-field splitting parameters were determined from the hyperfine lines due to the second- and third-order terms in the perturbation equations. The spectrum for the pearl is less resolved than that for the clam shell. Therefore, the computer simulation of the Q-band ESR line shape has also been carried out to estimate the D and E values, as summarized in Table 1.

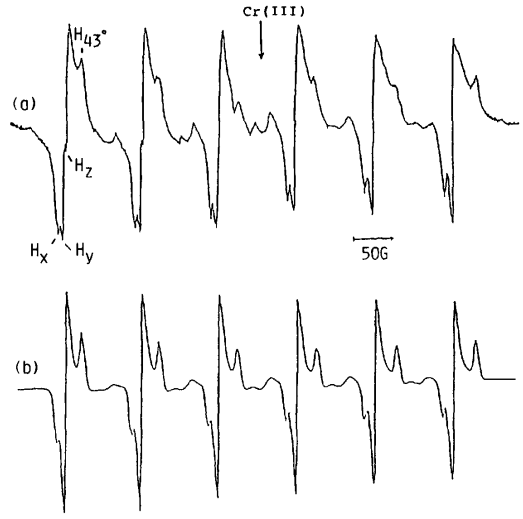

Fig. 3. (a): The Q-band ESR spectrum observed at room temperature for Mn(II) ion in the nacreous layer of the cultured marine pearl. (b): The computer simulated ESR spectrum for (a).

Table 1. ESR Parameters for Mn(II) Ions in the Calcite Lattice in the Prismatic Layer of Marine Shell (*Pinctada fucata*) and in the Aragonite Matrix in Nacreous Layer of the Marine Pearl

	g	a/mT	D/mT	E/mT	E/D	
Calcite	2.006	9.40	8.50	1.40	0.16	This work
	2.001	9.38	8.63	—	—	Ref. 7
Aragonite	2.004	9.60	20.80	6.90	0.33	This work
	2.006	9.40	25.00	4.20	0.17	Ref. 9

In the case of calcite, the present D value is similar to that reported by Chasteen et al.,[9] although the method used to determine the zero-field splitting parameters are different. The contribution of the E value was found to be larger than what we had expected from the usual approximation of setting the same term to zero. Thus the importance of the E term is demonstrated for the metal ion doped in a calcite lattice. The estimated D and E values for the Mn(II) ion in the aragonite phase of the marine pearl are different from those reported for the same phase in clam shell (*Mya arenaria*) by Chasteen et al.[9] The present D and E values for the marine pearl are respectively less and larger than the values for their shell, as shown in Table 1.

The range of ratio $r(=E/D)$ is distributed from 0 to 1/3, and it is taken to be a parameter which indicates a degree of ligand field symmetry. When the r value is zero, the ligand field has perfect axial symmetry, and if the r value is 1/3, that means perfect rhombic symmetry. It is interesting that the r value of the Mn(II) ion determined for the marine pearl is about 1/3. This means that the nacreous layer of the marine pearl is composed of aragonite which is highly distorted by the metal coordination geometry.

As described earlier, the satin white and the pale yellow pearls revealed ESR hyperfine structure ascribed to the Mn(II) ion contained in the aragonite matrix of the nacreous layer. The pearls containing blackish materials usually gave a mixed hyperfine splitting of prismatic Mn(II) and that of Mn(II) ascribed to the species in the aragonite matrix. In this case, the detailed analysis of the line shape is difficult, because the line shape analysis of the X-band ESR of Mn(II) in the aragonite lattice is much more complicated due to the overlapping of the multi-forbidden transition. The further calculation of the line shape in this case is now under way.

The authors wish to express their sincere thanks to Mr. Terumi Kobata who provided the valuable samples of pearls and shells, we also gratefully acknowledge Professors Noboru Hirota and Hiroaki Ohya-Nishiguchi of Kyoto University for their measurement of Q-band ESR spectra. This work was partially supported by the Grant-in-Aid for Scientific Research (No. 63540491) from the Ministry of Education, Science and Culture. The X-band ESR measurements were carried out at the Advanced Instrumentation Center for Chemical Analysis of this University.

XRD Characteristics of Na-ZSM-5 Synthesized from an Organic-Free System

Feng-Yuen DAI,* Minoru SUZUKI, (the late) Hiroshi TAKAHASHI, and Yasukazu SAITO
Institute of Industrial Science, University of Tokyo, 7-22-1 Roppongi, Minato-ku, Tokyo 106
(Received March 15, 1988)

XRD profiles of as-synthesized Na- and TPA-ZSM-5 were not identical. They became similar to each other, however, when both zeolites were converted into organic-free or organic-contained forms. In terms of the framework topology, Na-ZSM-5 resembled TPA-ZSM-5 but differed from so-called ZSM-8. SEM images revealed the Na-ZSM-5 crystal to exhibit a hexagonal-lath-shaped morphology. Due to the preferred orientations, the intensities of (0k0) and (h0l) reflections were intensified and diminished, respectively. The hexagonal flat plane of the Na-ZSM-5 crystal was (010). Therefore, the 10-membered-ring straight channels were strongly indicated to penetrate perpendicularly to the hexagonal flat plane of the as-synthesized Na-ZSM-5 crystal.

Powder X-ray diffraction (XRD) is commonly used for identifying the structure of as-synthesized zeolites, because this technique is very simple and suitable for the small crystals of synthetic zeolites (ca. 0.5—15 μm).

Care should be taken on XRD characterization, since certain zeolites with different frameworks exhibit similar profiles, as has been pointed out previously by Breck[1] for phillipsite, harmotome and gismondine. Lechert[2] gave another example recently for structurally related zeolites of ZSM-5, ZSM-8, and ZSM-11, and stated that a splitting of the highest peak (2θ=23.0—23.5°; Cu $K\alpha$ radiation) was observed for ZSM-8 only.

ZSM-5 zeolite has been synthesized generally from the tetrapropylammonium (TPA)-contained aluminosilicate gel;[3] nevertheless, it is possible to obtain ZSM-5 without adopting expensive and toxic TPA components.[4-8] Grose et al.[5] mentioned that the XRD pattern and adsorption property of a novel zeolite synthesized from an organic-free system (designated as Na-ZSM-5 hereafter) resembled those of typical TPA-ZSM-5. According to our preliminary examinations, however, as-synthesized Na-ZSM-5 gave a splitting similar to ZSM-8 in the main peak region (2θ=23.0—23.5°). A new question arises therefore whether as-synthesized Na-ZSM-5 belongs to TPA-ZSM-5 or so-called ZSM-8.

XRD profiles of zeolites are well-known to be affected easily without changing the framework topology. For example, dehydration of chabazite brought about framework distortion.[10] According to Baerlocher and Meier,[11] synthetic tetramethylammonium gismondine with tetragonal crystal symmetry changed continuously to a pseudocubic form upon thermal decomposition of the organic cation. Wu et al.[12] showed that conversion of as-synthesized TPA-ZSM-5 into its ammonium or hydrogen form caused a symmetry change from orthorhombic to monoclinic, whereas the orthorhombic symmetry was regenerated by ammonia adsorption on the hydrogen form. The XRD profiles of zeolites are thus affected by guest substances in the skeleton, such as water or organic species.

The present study is an attempt to attribute the structure of as-synthesized Na-ZSM-5 zeolite to TPA-ZSM-5 or ZSM-8 and also to elucidate the correlation between its characteristic morphology and the crystal structure.

Experimental

Sample Preparation. TPA-ZSM-5 zeolite (designated sample A_1 hereafter) was synthesized from a starting composition of 2.0 TPA_2O-4.0 Na_2O-1.0 Al_2O_3-65 SiO_2-3000 H_2O under hydrothermal conditions of 170 °C for 48 h with stirring. Tetrapropylammonium bromide (TPABr) was adopted as the TPA source. The sample A_1 was calcined in air at 620 °C for 3 h to give a calcined (TPA)-ZSM-5 (sample B_1). The sample B_1 was then treated with 1 M NH_4Cl aqueous solution (1 M=1 mol dm^{-3}) at room temperature for 12 h, followed by calcination at 540 °C for 4 h to convert it into a hydrogen form. After this hydrogen form was degassed in vacuo at 150 °C for 1 h in a glass tube, an excess amount of prepurified diethylamine (DEA) was vacuum-transferred into the glass tube to immerse the zeolite at 15 °C for 12 h, producing a DEA-contained zeolite (sample A_1').

As-synthesized Na-ZSM-5 was prepared from a composition of 8.75 Na_2O-1.0 Al_2O_3-70 SiO_2-3150 H_2O by following the procedure reported previously.[8] Conversion of as-synthesized Na-ZSM-5 into its hydrogen form (sample B_2) was carried out by ion-exchange with 1 M NH_4Cl aqueous solution, followed by calcination at 540 °C for 4 h. Immersion with DEA changed the sample B_2 into another DEA-contained zeolite (sample A_2). The other organic-free ZSM-5 (sample B_2') was prepared by calcining the sample A_2 at 620 °C for 3 h.

Characterization. The XRD profiles of zeolites were measured by an X-ray diffractometer (Rigaku Denki Co. Ltd., D-9 C, equipped with a scintillation counter) under the conditions: Cu $K\alpha$ radiation (Ni-filter) at the intensity of 30 kV-10 mA with the slit system of RS=0.15 mm and DS=SS=1/2°; the 2θ scanning rate of 1/4 or 1/8° min^{-1}.

Silicon powder (300 mesh-pass) was adopted as the internal standard for adjusting 2θ values (22—25°) accurately with reference to the Si(111) reflection.

Crystal morphologies of zeolites were observed by means of scanning electron microscopy (SEM) (Akashi Co., Ltd., Alpha-10).

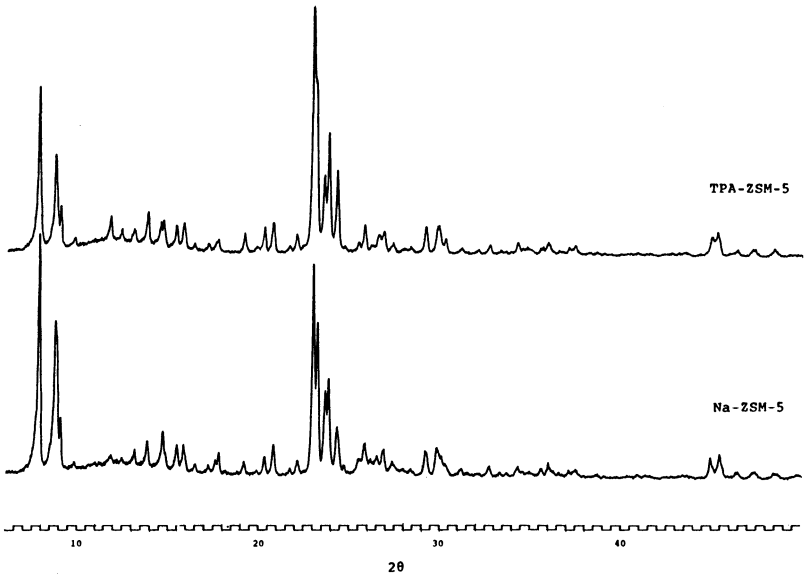

Fig. 1. XRD profiles of Na-ZSM-5 and TPA-ZSM-5 synthesized from organic-free and TPABr systems, respectively; XRD 2θ scanning rate of $1/4°\ min^{-1}$.

Results and Discussion

Effects of Organic Species on XRD Profiles. Typical XRD profiles of as-synthesized TPA-ZSM-5 and Na-ZSM-5 are contrasted in Fig. 1. Although it was once stated that almost all the diffraction peaks of as-synthesized Na-ZSM-5 coincided with those of typical TPA-ZSM-5,[5] these XRD profiles were not exactly identical. Firstly, peak intensity differences were apparent at 2θ=7.94, 8.87, 11.90, 12.50, 13.19, 14.70—14.88 (doublet), 20.34, 23.68, and 23.91°. Secondly, the splitting in the main peak region (2θ=23.0—23.5°) was much clearer for Na-ZSM-5 than for TPA-ZSM-5. Calcination of as-synthesized TPA-ZSM-5, however, resulted in a well-resolved profile of the main peak splitting,[13] accompanying the intensified peaks at 2θ=7.94, 8.87, 13.19, and 14.82°, and the diminished ones at 11.90, 12.50, 20.34, 23.68, and 23.91°.[14] Consequently, the XRD profile of calcined-(TPA)-ZSM-5 (B_1) well resembles that of as-synthesized Na-ZSM-5.

Readsorption of organic species onto either calcined-(TPA)-ZSM-5 or as-synthesized Na-ZSM-5 was attemped therefore to clarify the effect of organic guest substances on XRD profiles.

The XRD region of 2θ=22—25° was enlarged and shown in Figs. 2 and 3. Hydrogen forms of both kinds of as-synthesized ZSM-5 were prepared in order to minimize the steric hindrances for the adsorption of organic species. Diethylamine (DEA) was adopted as absorbate, because its molecule size is small enough to diffuse freely into the zeolite channel (size of ZSM-5 window: 5—6 Å).[15]

The XRD profile of five significant peaks of as-synthesized TPA-ZSM-5 was varied by sequential treatments of $A_1 \rightarrow B_1 \rightarrow A_1'$ (Fig. 2).

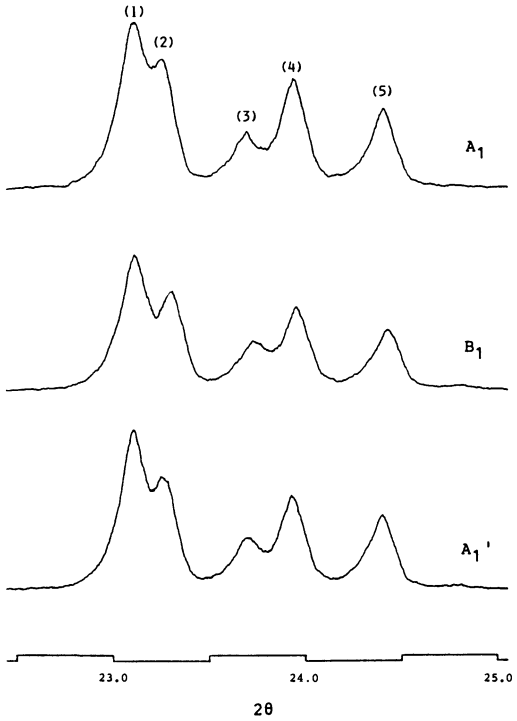

Fig. 2. Variation of XRD profiles: as-synthesized TPA-ZSM-5 (A_1) changed to calcined-TPA-ZSM-5 (B_1) by calcination at 620°C for 3 h, and finally to DEA-ZSM-5 (A_1') by loading diethylamine (DEA) at 15°C for 12 h; XRD 2θ scanning rate of $1/8°\ min^{-1}$.

As converting A_1 into B_1, the position of the strongest peak (marked as (1)) remained unchanged, whereas the others of (2)—(5) were shifted slightly toward high angles. As the peak (2) shifted to higher angle, the profile became well-resolved, which was accepted as grounds for the ZSM-8 assignment. On the contrary,

incorporation of DEA into H-ZSM-5 (B_1) induced peak shifts again toward lower angles, as shown for the (2)—(5) peaks of DEA-ZSM-5 (A_1'). The XRD profile was thus changed reversibly between as-synthesized TPA-ZSM-5 (A_1) and DEA-ZSM-5 (A_1').

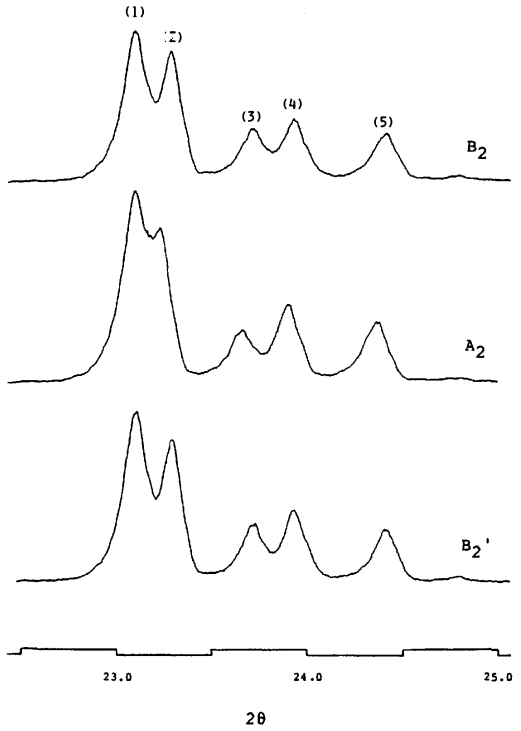

Fig. 3. Variation of XRD profiles: H-ZSM-5 (B_2), ion-exchanged from as-synthesized Na-ZSM-5, changed to DEA-ZSM-5 (A_2) by loading diethylamine (DEA) and finally to calcined-DEA-ZSM-5 (B_2') by calcination at 540°C for 4 h; XRD measurement conditions are the same as those of Fig. 2.

The hydrogen form of Na-ZSM-5 was loaded with DEA, then calcined to reproduce the organic-free form. These treatments brought the changes of XRD profiles as $B_2 \rightarrow A_2 \rightarrow B_2'$ (Fig. 3).

Conversion of H-ZSM-5(B_2) to DEA-ZSM-5(A_2) induced peak shifts toward lower angles except foi the main peak (1). The splitting profiles due to the main peaks of (1) and (2) were similar between DEA-ZSM-5 (A_2) and as-synthesized TPA-ZSM-5 (A_1 in Fig. 2). Thermal decomposition of guest organic substances contained in the sample A_2 yielded the sample B_2', which gave again the XRD profile similar to H-ZSM-5 (B_2).

The following aspects are deduced from Figs. 2 and 3.

(1) Either occluded during hydrothermal synthesis or absorbed by ammine immersion, organic species inside the zeolite skeleton exert an influence upon XRD profiles, irrespective of the ZSM-5 zeolite synthesized from the system with or without using organic templates.

(2) The adsorption and decomposition of guest organic subtances induce XRD profiles to change reversibly, as apparent from the resemblance between A_1' and A_1 (Fig. 2) or between B_2 and B_2' (Fig. 3).

(3) The shape of the main peaks around $2\theta = 23.0—23.5°$ is sensitive to the involvement of organic species in the zeolite skeleton; the well-resolved profile of the organic-free form (B_1, B_2, and B_2') is in sharp contrast to the poorly-resolved profile of those incorporated with organic species (A_1, A_1', and A_2).

(4) Certain diffraction peaks are induced to shift by the incorporation of organic species into both kinds of ZSM-5 skeletons.

Since both kinds of silicious zeolites exhibit high

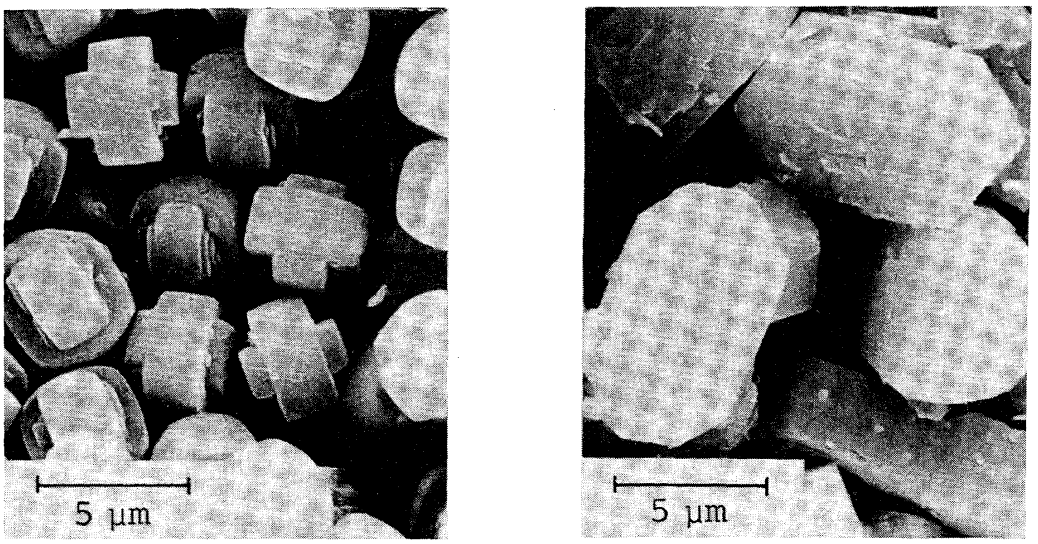

Fig. 4. Typical SEM morphologies of ZSM-5 zeolites synthesized from TPABr (B_1) and organic-free (B_2) systems; notations are common to those of Figs. 2 and 3.

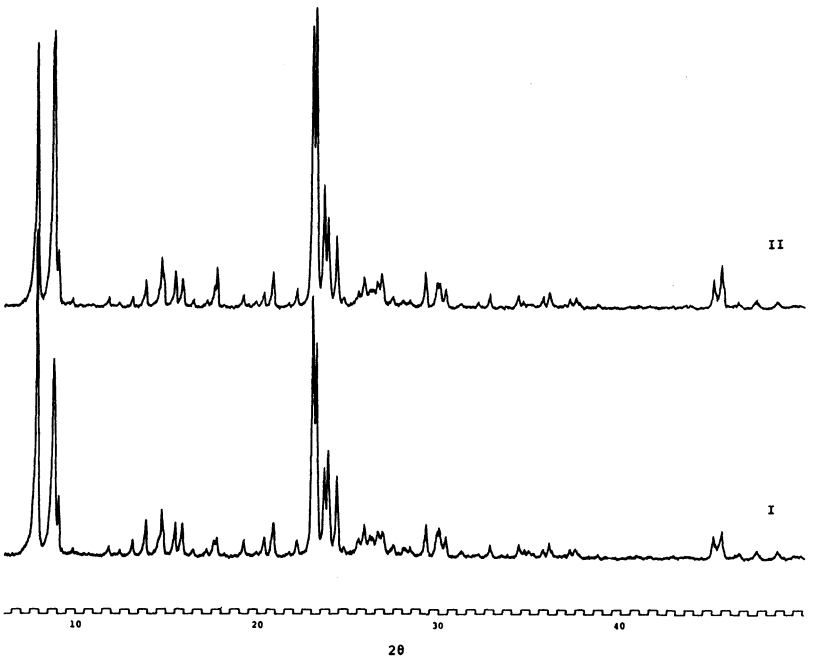

Fig. 5. Variation of XRD profiles for H-ZSM-5, ion-exchanged from as-synthesized Na-ZSM-5: specimen set with the normal manner (I) and extremely pressurized manner (II); XRD 2θ scanning rate of $1/4°\ min^{-1}$.

thermal stability against calcination (620 °C for 3 h), as evident from the reversible changes of those XRD profiles (point (2)), no topological changes occur throughout these conversion processes. These XRD profile changes (Figs. 2 and 3) can therefore be attributed to lattice expansion induced by the guest organic amine.

Throughout the XRD region of 2θ=5—50°, all the peak positions of calcined-(TPA)-ZSM-5 (B_1) coincided well (within an error of ±0.02°) with those of H-ZSM-5 (B_2). No doublet peaks were observed at the regions around 24.4, 29.2, and 48.6° for either Na-ZSM-5 or TPA-ZSM-5 during the conversion processes, suggesting both of them to belong commonly to the orthorhombic symmetry.[12] On these grounds, as-synthesized Na-ZSM-5 is concluded to possess an isostructure with TPA-ZSM-5, different from the so-called ZSM-8[9] in framework topology.

Crystal Characteristics of Na-ZSM-5 Synthesized from Organic Free System. Crystal Morphology. Typical SEM morphologies of Na- and TPA-ZSM-5 zeolites are shown in Fig. 4. Spherical-like or crossed-discus crystals (B_1) were easily formed with use of TPABr, whereas hexagonal-lath-shaped crystals (B_2) were always obtained from the organic-free system. Each crystal morphology remained unchanged throughout sequential treatments of ammonium ion exchange, calcination and DEA adsorption.

Effect of Preferred Orientation on XRD Profiles. Characteristic to the hexagonal-lath-shaped ZSM-5 crystals (B_2) synthesized from the organic-free system, certain XRD peak intensities were sensitive to the manner of mounting the specimen onto an X-ray sample holder. With regard to the spherical-like ZSM-5 zeolite (B_1), such changes of XRD spectra have never been experienced previously.

Table 1. Specific XRD Peak Intensities of Hexagonal-Lath-Shaped Na-ZSM-5 Crystals Sensitive to Specimen Setting Manner

$(h$	k	$l)$[a]	2θ[b]	(I/I_0)[c] Normal setting	(I/I_0)[c] Extreme pressing
1	0	2	13.90	76	47
2	0	2	15.86	69	49
1	0	3	20.34	40	28
3	0	3	23.91	219	156
0	4	0	17.79	38	69
0	5	1	23.25	436	526
1	5	1	23.68	186	213
0	10	0	45.46	57	73

a) See Ref. 18. b) Cu $K\alpha$ radiation ±0.02°. c) The intensity of isotropic (111) reflection (2θ=9.08°) was adopted as I_0, because this was the strongest peak insensitive to the preferred orientation.

Figure 5 illustrated the XRD profiles of hexagonal-lath-shaped ZSM-5 (B_2) measured in different conditions; one of the specimen was set by a standard procedure[16] (I) and the other was set in excess amount with extra pressure(II). The peaks located at 2θ=8.85, 17.79, 23.25, 23.68, 26.85, and 45.46° were intensified, whereas those of 7.92, 13.90, 15.86, 20.34, 23.01, and 23.91° were diminished, by pressing. Extra pressure induced the change of the total peak area within the region of 2θ=22.0—25.0°. Improper specimen pressing must be

avoided, since the peak area is often adopted for estimating the degree of crystallization.[17]

The diffraction peaks sensitive to the specimen pressing were specified (Table 1), together with the corresponding Miller Indices of ZSM-5.[18]

As evident from Table 1, the peaks diminished in intensity were classified to the group of ($h0l$) reflection, whereas the peaks intensified belonged to the ($0k0$) group.

Since the lath-shaped crystals were apt to deviate from random orientation, it is conceivable that the orientation of hexagonal-flat planes become parallel to the plane of the XRD sample holder. The XRD peaks of the diffraction planes parallel to the hexagonal-flat surface would therefore be intensified. This supports the view that the hexagonal-flat plane of Na-ZSM-5 crystal belong to the (010) plane.

In the ZSM-5 skeleton, the straight 10-membered-ring channel elongates along the 'b' axis, whereas the zigzag channel extends toward the 'a' axis.[15] Since the diffraction planes with ($0k0$) Miller Indices intersect perpendicularly with the 'b' axis, the straight channels are concluded to penetrate perpendicularly to the flat plane of the hexagonal-lath-shaped crystals.

Conclusion

(1) Na-ZSM-5 possesses an isostructure with TPA-ZSM-5 but differs from the so-called ZSM-8 in framework topology. XRD profiles of Na- and TPA-ZSM-5 were controlled by incorporation or decomposition of organic amine in the ZSM-5 skeleton.

(2) XRD intensities of ($0k0$) and ($h0l$) reflections for hexagonal-lath-shaped Na-ZSM-5 are sensitive to the preferred orientation. The hexagonal-flat plane of Na-ZSM-5 crystal is (010). Therefore, the 10-membered-ring straight channels of ZSM-5 are strongly indicated to penetrate perpendicularly to the hexagonal-flat plane of the crystal.

We are grateful to Mr. Hiromi Nakamoto (Catalysts & Chemical Industry, Co., Ltd.) for helpful advice on zeolite syntheses and to Mr. Shigeji Hagiwara (Institute of Industrial Science, University of Tokyo) for valuable comments on the XRD characterization.

^{1}H NMR Study of the Regioisomers of Primary *O*-Di- and Trisubstituted α-Cyclodextrins

Yoshihisa MATSUI,* Masahiko FUJIE, and Hiroshi SAKATE
Faculty of Agriculture, Shimane University, Nishikawatsu, Matsue 690
(Received March 24, 1988)

The regioisomers of bis- and tris[C(6)-*O*-sulfonylated] α-cyclodextrins were converted in satisfactory yields to the corresponding C(6)-pyridinio derivatives, which afforded the characteristic splitting patterns of ^{1}H NMR signals available for a regioisomer determination. Electrostatic repulsive interactions between the positively charged pyridinio groups play an important role in the remarkable splitting of the ^{1}H NMR signals observed for some regioisomers.

O-Arylsulfonylated cyclodextrins are the key intermediates from which a number of other cyclodextrin derivatives have been prepared.[1] In particular, primary *O*-bis- or poly(arylsulfonylated) cyclodextrins have attracted much attention regarding the construction of refined artificial enzymes[2] or artificial receptors.[3] Polysubstituted cyclodextrins generally involve a fair number of regioisomers. For example, bis- and tris[C(6)-*O*-sulfonylated] α-cyclodextrins involve three and four regioisomers, respectively. They are designated as 6A,6B-, 6A,6C-, and 6A,6D-isomers for disubstituted α-cyclodextrins and 6A,6B,6C-, 6A,6B,6D-, 6A,6B,6E-, and 6A,6C,6E-isomers for trisubstituted α-cyclodextrins. Recently, Fujita et al.[4] have succeeded in separating a mixture of the regioisomers of C(6) polysulfonylated α-cyclodextrins from one another and determining the position of the substituents in them. In this regioisomer determination, however, ^{1}H NMR spectroscopy played only a minor role, owing to the similarity and/or complexity of the spectra.

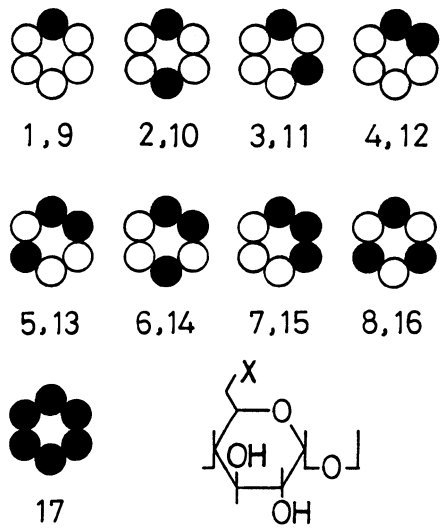

Fig. 1. α-Cyclodextrin derivatives examined.

●: X= -OSO$_2$-(Me, Me) (**1**—**8**)
●: X= -N$^+$ (**9**—**17**)

In the course of an investigation of charged cyclodextrins,[5] we recently found that the regioisomers of bis- and tris[C(6)-*O*-arylsulfonylated] α-cyclodextrins are converted in satisfactory yields to the corresponding pyridinio derivatives, the ^{1}H NMR spectra of which afford more abundant structural information than those of the *O*-arylsulfonylated α-cyclodextrins. The present article deals with the structural information obtained from the ^{1}H NMR spectra of the hydrogencarbonate salts of mono-, bis-, and tris[6-(1-pyridinio)-6-deoxy]-α-cyclodextrins (**9**—**16**) as well as the ^{1}H NMR spectra of mono-, bis-, and tris(6-*O*-mesitylsulfonyl)-α-cyclodextrins (**1**—**8**), as shown in Fig. 1. The ^{1}H NMR spectra of the hydrogencarbonate salts of hexakis[6-(1-pyridinio)-6-deoxy]-α-cyclodextrins (**17**) and methyl 6-(1-pyridinio)-6-deoxy-α-D-glucopyranoside (**18**) were also examined for the sake of comparison. Brief ^{1}H and ^{13}C NMR data for **2**—**8** have been reported by Fujita et al.[4b]

Experimental

Materials. α-Cyclodextrin was kindly supplied by Nihon Shokuhin Kako Co., Ltd., and was dried overnight in vacuo at 110 °C. Reagent-grade pyridine was dried over calcium hydride and distilled in the presence of fresh calcium hydride just before use. Reagent-grade mesitylenesulfonyl chloride was used without further purification. Deuterium oxide (Merck, 99.75%), dimethyl-d_6 sulfoxide (DMSO-d_6, CEA, 99.8%), tetramethylsilane (TMS), and sodium 2,2-dimethyl-2-silapentane-5-sulfonate (DSS) were available for NMR use.

Apparatus. ^{1}H NMR spectra were recorded using a JEOL Model JNM-GX270 FT NMR spectrometer (270 MHz). Absorption spectra and optical rotation were measured with a Hitachi Model 220 spectrophotometer and a Union Giken Model PM-101 polarimeter, respectively. High-performance liquid chromatography (HPLC) was performed on a Hitachi Model 683-56 chromatograph.

Preparation of 1—8. *O*-Mesitylsulfonylated α-cyclodextrins **1**—**8** were prepared and separated from one another according to the method of Fujita et al.[4] A prepacked column (Merck, Lober column LiChroprep RP-8, 25×310 mm) was used for reversed-phase column chromatography to separate

a mixture of **1**—**8** from one another. Aqueous methanol solutions were used as eluents. A silica-gel column (Wako, C-200, 50×350 mm) was used for a further separation of **8** from **7**.[4b] The eluates of these column chromatographies were assayed by UV spectrophotometry at 275 nm. In addition, the main fractions were analyzed by HPLC with a LiChrosorb RP-18 column (Merck, 4×250 mm) and aqueous acetonitrile solutions as eluents. Typical chromatograms are shown in Fig. 2. All the peaks, except peaks 5 and 6, have been assigned in terms of their regiochemistries:[4] Peak 1 corresponds to monosulfonylated α-cyclodextrin **1**, peaks 2, 3, and 4 to disulfonates **2**, **3**, and **4** respectively, and peaks 7 and 8 to trisulfonates **7** and **8**, respectively. Peaks 5 and 6 have been attributed to the trisulfonylated regioisomers, **5** and **6**, but a discrimination between them has not been accomplished. As will be mentioned later, the ^{1}H NMR spectra of tripyridinio-α-cyclodextrins **13** and **14** derived from **5** and **6**, respectively, suggested that **5** is a 6A,6B,6E-isomer and **6** is a 6A,6B,6D-isomer. Here, we tentatively assume that peak 5 corresponds to regioisomer **5** and peak 6 to **6**. Purified samples of **5**—**8** were obtained by a repeated collection of the main peak fractions in the HPLC, followed by an evaporation of the fractions to dryness.

Preparation of 9—16. A typical run was as follows: A purified sample of **2** (140 mg, 0.105 mmol) was dissolved in dry pyridine (10 cm^3) and the resulting solution was refluxed with stirring for 5 h. After removing pyridine by evaporation in vacuo at 40 °C, a mixed solvent of acetone-water [9 : 1 (v/v)] was added to the residue. A resulting precipitate (156 mg) was separated by filtration, dissolved in water (2 cm^3), and chromatographed on a 15×130 mm CM-cellulose (Serva) column with the stepwise elution of 0.05, 0.10, 0.25, and 0.50 mol dm^{-3} aqueous ammonium hydrogencarbonate solutions. The elution was followed by UV-spectrophotometry at 270 nm and polarimetry at 589 nm. The eluates of 0.10 mol dm^{-3} ammonium hydrogencarbonate were combined and evaporated to dryness at 40 °C to give **10** (113 mg, 0.093 mmol, 89% yield). Likewise, **9** was obtained from the eluates of 0.05 mol dm^{-3} ammonium hydrogencarbonate in 80% yield, **11** and **12** from the eluates of 0.10 mol dm^{-3} ammonium hydrogencarbonate in 88 and 86% yields, respectively, and **13**, **14**, **15**, and **16** from the eluates of 0.25 mol dm^{-3} ammonium hydrogencarbonate in 82, 85, 73, and 23% yields, respectively. Each product gave a virtually single peak in HPLC on a TSKgel CM-5PW column (Toyo Soda, 7.5×75 mm) with 0.40 or 0.50 mol dm^{-3} ammonium hydrogencarbonate as an eluent.

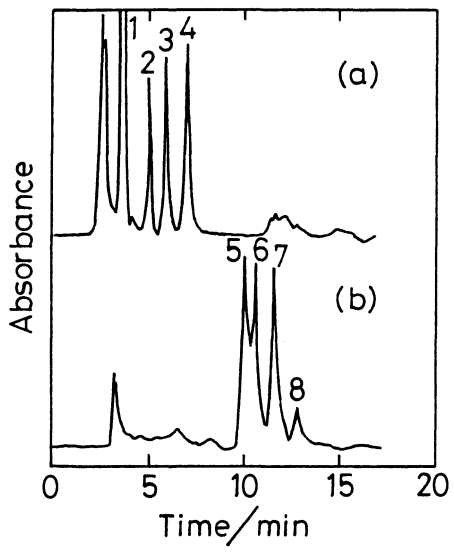

Fig. 2. The HPLC of **1**—**8** with a LiChrosorb RP-18 column and 40% (a) or 50% (b) aqueous acetonitrile as an eluent. The eluates were assayed by UV spectrophotometer at 275 nm.

Preparation of 17. Hexakis(2,3-di-*O*-acetyl-6-bromo-6-deoxy)-α-cyclodextrin (**19**) was prepared by the method of Takeo et al.[6] A solution of **19** (5.00 g, 2.7 mmol) in dry pyridine (50 cm^3) was refluxed with stirring for 30 h. A tar-like material was separated out from the solution during refluxing and was solidified upon cooling to room temperature. The solid was separated by filtration, dissolved in 25% aqueous ammonia solution, and allowed to stand for 0.5 h at room temperature to complete deacetylation. The solution was evaporated to dryness in vacuo to give a dark-brown residue (4.47 g). An aliquot (1.20 g) of the residue was chromatographed on a 20×280 mm Toyopearl CM 650S column (Toyo Soda). A stepwise elution was applied with 0.05, 0.10, 0.15, 0.20, 0.25, 0.30, and 0.50 mol dm^{-3} aqueous ammonium hydrogencarbonate solutions. Each fraction (10 cm^3) was assayed by UV spectrophotometry at 270 nm and polarimetry at 589 nm. Eluates given by 0.20 mol dm^{-3} ammonium hydrogencarbonate were combined and evaporated to dryness in vacuo at 40 °C to afford crude **17** (0.92 g, 0.54 mmol, 74% yield based on **19**). The HPLC of the product with a TSKgel CM-5PW column and 0.40 mol dm^{-3} hydrogencarbonate as an eluent gave a high main peak, though a few additional low peaks were also observed before and after the main peak. A purified sample of **17** was obtained by a repeated collection of a main peak fraction in the HPLC; then, the fraction was evaporated to dryness.

Preparation of 18. Methyl 6-*O*-(*p*-tolylsulfonyl)-α-D-glucopyranoside (5.00 g, 14.4 mmol) was dissolved in dry pyridine (100 cm^3) and heated at 100 °C for 5 h. After removal of pyridine by evaporation in vacuo at 40 °C, the residue was dissolved in 50 cm^3 of distilled water. To the solution was added Amberlite IR-120B (Na form, 15 cm^3); the mixture was stirred overnight at room temperature. The ion-exchange resin was separated by filtration, washed well with distilled water, and then added to 0.5 mol dm^{-3} aqueous ammonium hydrogencarbonate solution (100 cm^3). The mixture was stirred overnight at room temperature. After removal of the ion-exchange resin by filtration, the filtrate was evaporated to dryness in vacuo at 40 °C to give a crude product (4.23 g, 92% yield) of **18**. A purified sample of **18** was obtained by column chromatography with a 45×430 mm CM-cellulose (Serva) column and 0.05 mol dm^{-3} ammonium hydrogencarbonate as an eluent.

Results and Discussion

^{1}H NMR Spectra of 1—8. The ^{1}H NMR spectrum of the 6A,6B,6C-trisulfonylated isomer **7** (43 mmol dm^{-3}) in DMSO-d_6 at 50 °C is shown in Fig. 3 as being typical. In the spectrum, the absorptions at about δ=7.1, 2.5, and 2.3 were assigned to the meta-H's, ortho-methyl-H's, and para-methyl-H's, respectively, of the mesityl groups on the basis of a comparison with the spectrum of sodium mesitylenesulfonate.

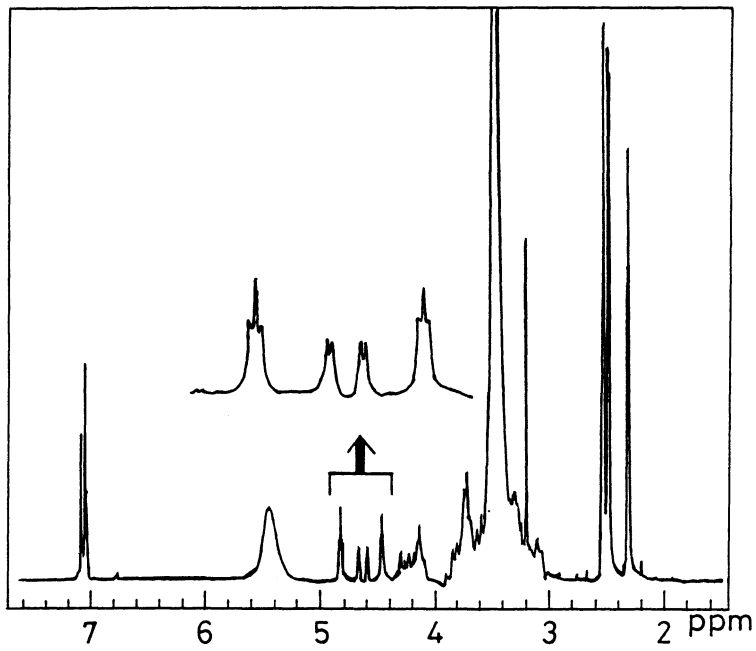

Fig. 3. 270 MHz ^{1}H NMR spectrum of **7** in DMSO-d_6 at 50 °C.

a) Chemical shift (δ/ppm from TMS) in DMSO-d_6 at 50 °C. The number of protons in a molecule were evaluated by the integration of peak area and were shown in parentheses. b) Singlet signal. c) Doublet signal with J=3.20±0.03 Hz. d) Higher field than δ=4.55. e) δ=4.55—4.75. f) Lower field than δ=4.75.

Protons involved in the glucopyranose (GP) moieties gave complex signals at δ=3—5. Among them, doublet signals at δ=4.4—4.9 (J=2.8—3.4 Hz) were relatively distinct and were assigned to anomeric C(1)-H's.

Table 1 shows the chemical shifts (δ) and the numbers of protons for the singlets of meta-H's and para-Me-H's, together with those for the doublets of C(1)-H's, in **1**—**8**. The δ values for ortho-Me-H's were ambiguous in some cases, owing to an overlapping of the signals with solvent signals; thus, data for the signals are omitted from the table. The effect of sample concentrations on the NMR spectra, examined for **1**—**4**, indicated that the δ values shown in the table were virtually independent, within a standard error of 0.01 ppm, of sample concentrations ranging from 10 to 44 mol dm^{-3}.[7)] The A,D-isomer **2** or A,C,E-isomer **8** gave

only a singlet at δ=ca. 7.1 for meta-H's and a singlet at δ=ca. 2.3 for para-Me-H's, suggesting that two mesityl groups of **2** or three mesityl groups of **8** are equivalent (isochronous). On the ^{1}H NMR time scale, the molecular structures of **2** and **8** in solution are regarded as being symmetrical, as would be expected from their structural formula. On the other hand, essentially asymmetrical molecules, such as **3**—**7**, gave two or three signals for meta-H's and one or two signals for para-Me-H's (within the resolution limit of the apparatus). The splitting of the signals indicates that the mesityl groups in the compounds are not equivalent. However, the width of the splitting was too narrow to obtain more information regarding their regiochemistries.

More detailed information was available from the splitting patterns of the doublets due to C(1)-H's. All the C(1)-H's of **1**—**8** gave doublets in the region of δ=4.45—4.85, which could be subdivided into three regions, i.e., higher field than δ=4.55 (Region 1), δ=4.55—4.75 (Region 2), and lower field than δ=4.75 (Region 3). It was found that the numbers (m) of C(1)-H's giving doublets in Regions 1—3 reflect the structural characteristics of **1**—**8**: Thus, the ratio of the m's in Regions 1, 2, and 3 was equal to 0 : 2 : 4 for the monosulfonate **1**, 0 : 4 : 2 for the disulfonates **2** and **3**, 1 : 2 : 3 for another disulfonate **4**, 1 : 4 : 1 for the trisulfonates **5** and **6**, 2 : 2 : 2 for **7**, and 0 : 6 : 0 for **8**. These characteristic splitting patterns are well explained on the basis of the following assumptions:

1) The C(1)-H's of unsubstituted GP rings generally give doublets in Region 3.[8]

2) If the A ring [GP(A)] of the GP's in α-cyclodextrin is sulfonylated at C(6)-OH, the C(1)-H of GP(A) is subject to significant shielding by the sulfonylation to give a doublet in Region 2. Furthermore, one of the C(1)-H's involved in GP's adjacent to GP(A) is also significantly shielded by a remote substituent effect to give another doublet in Region 2. The C(1)-H, thus shielded, may belong to GP(B), but not to GP(F), since the substituent is favorably oriented to GP(B) and not to GP(F).[9]

3) If both of vicinal GP(A) and GP(B) are sulfonylated, the C(1)-H of GP(B) is subject to strong shielding by both of the substituents in GP(A) and GP(B) to give a doublet in Region 1. The C(1)-H of GP(A) is significantly shielded by the substituent of GP(A), but little by that of GP(B), and give a doublet in Region 2.

Based on these assumptions, we estimated the number (n) of C(1)-H's belonging to each δ region for **1**—**8** (Table 2). For example, the GP's of A,C,E-isomer **8** are alternatingly sulfonylated, so that all the C(1)-H's should give doublets in Region 2. The A,B,C-isomer **7** bears three sulfonylated-GP's which are bound in series. Then, two C(1)-H's of GP(B) and GP(C) should give doublets in Region 1, those of GP(A) and GP(D) in Region 2, and those of GP(E) and GP(F) in Region 3. The n values, thus estimated, agreed entirely with those observed (Table 1), indicating that the above assumptions are reliable. These results also mean that the regioisomer determination by Fujita et al.[4] is substantiated by ^{1}H NMR spectroscopy, though a distinction between A,B,E-isomer **5** and A,B,D-isomer **6** still remained impossible owing to the similarity of their splitting patterns.

^{1}H NMR Spectra of 9—18. Upon refluxing pyridine solutions containing **1**—**8**, the mesitylenesulfo-

a) Chemical shift (δ/ppm from DSS) in D_2O at 50 °C. The unit of J is Hz.

nyloxy groups were replaced by the positively charged pyridinio groups to give **9**—**16** in satisfactory yields. Figure 4 illustrates the ^{1}H NMR spectrum of the monopyridinio derivative **9** (14 mmol dm^{-3}) in D_2O at 50 °C.[10] The ortho-, meta-, and para-protons of the pyridinio group gave a doublet at δ=8.76 (2H, J=5.6 Hz), a triplet at δ=7.99 (2H, J=7.0 Hz), and a triplet at δ=8.52 (1H, J=7.4 Hz), respectively. The protons of the GP moieties gave complex absorptions at δ=2.5—5.1. Among them, the following absorptions were relatively distinct: Doublets at δ=4.8—5.0 (6H, J=ca. 3.2 Hz) due to anomeric C(1)-H's, a pair of a double doublet signal (dd-signal) (1H, δ=4.64, J=13.3 and 9.6 Hz) and an apparently doublet signal (1H, δ=5.12, J=12.9 Hz) due to diastereotopic geminal C(6)-H's, and a pair of a dd-signal (1H, δ=2.54, J=12.0 and 2.9 Hz) and an apparently doublet signal (1H, δ=2.81, J=12.0 Hz) due to another diastereotopic geminal C(6)-H's. The pairing of the absorptions was confirmed by spin-spin decoupling experiments. The dd-signals reflect spin-spin coupling between the geminal C(6)-H's (J=12—13 Hz), together with that between vicinal C(5)-H and C(6)-H(trans) (J=3—10 Hz). The magnitude of coupling constants between vicinal C(5)-H and C(6)-H(gauche) is too small to be detected with the apparatus used, so that another C(6)-H apparently gives a doublet signal. Upon assigning the GP rings involving these C(6)-H's, the ^{1}H NMR spectra of **17**, **18**, and unsubstituted α-cyclodextrin (**20**) were instructive. They gave clear signals, most of which could be assigned (Table 3).[10] The geminal C(6)-H's of **20** gave signals around δ=3.7—3.9, whereas those of **17** or **18** gave a pair of signals in the lower-field region of δ=4—5, but no signal in the higher-field region of δ=2.5—2.8. Based on these data, we assigned the lower-field pair of **9** to the C(6)-H's of the substituted GP ring [GP(A)] and the higher-field pair to those of the unsubstituted GP [GP(B)] adjacent to GP(A). A molecular model study showed that the pyridinium ring is located in the close vicinity of the C(6)-H's of GP(B), when the C(5)-C(6) bond of GP(A) is held in the gauche-trans conformation, as illustrated in Fig. 5.[11] The striking upfield shift of the absorptions for

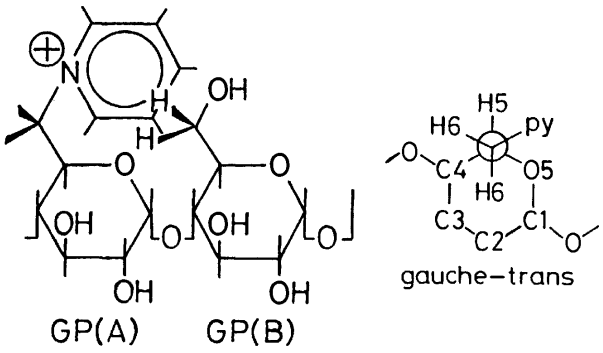

Fig. 5. The schematic diagram for the orientation of the pyridinio group in **9**.

the C(6)-H's of GP(B) in **9** compared with those for the C(6)-H's of **20** is attributable to the strong shielding by the ring current of the adjacent pyridinio group. On the other hand, the remarkable downfield shift observed for the C(6)-H's of GP(A) in **9** may be due to the deshielding effect of the positively charged pyridinio group directly bound to the C(6)-carbon. The vicinal coupling constant between C(5)-H and C(6)-H (trans) is larger in GP(A) (J=9.6 Hz) than in GP(B) (J=2.9 Hz), indicating that the rotation about the C(5)-C(6) bond is significantly restricted to a gauche-trans conformation in GP(A), but little in GP(B).[11]

Characteristic splitting patterns were observed for ^{1}H NMR signals due to the protons involved in the pyridinio groups of the di- and trisubstituted regioisomers of **10**—**16** (Table 4).[10] The A,D-isomer **10** gave the signals similar to those of **9**: A doublet at δ=8.75 for ortho-H's, a triplet at δ=7.97 for meta-H's, and a triplet at δ=8.49 for para-H's. The A,C-isomer **11** and A,B-isomers **12** gave more complex signals than **10**. Signals for ortho- and para-H's of **11** were split into two doublets at δ=8.79 and 8.70 ($\Delta\delta$=0.09) and two triplets at δ=8.49 and 8.46 ($\Delta\delta$=0.03) respectively, though meta-H's gave only a triplet at δ=7.96. The splittings of the signals for ortho- and para-H's were markedly enlarged in **12** to give two doublets at δ=8.79 and 8.46 ($\Delta\delta$=0.33) and two triplets at δ=8.47 and 8.12 ($\Delta\delta$=0.35). Furthermore, signals for meta-H's were

Table 4. ^{1}H NMR Data for Ortho-, Meta-, and Para-H's of the Pyridinio Groups in **9**—**17**[a)]

Compound	Ortho-H	Meta-H	Para-H
9	8.76 (2H, d, J=5.6)	7.99 (2H, t, J=7.0)	8.52 (1H, t, J=7.4)

a) Chemical shift (δ/ppm from DSS) in D_2O at 50 °C. The unit of J is Hz.

also split into two triplets at δ=7.94 and 7.80 ($\Delta\delta$=0.14) in **12**. Somewhat similar splittings of signals have been observed for the regioisomers of disulfonylated α-cyclodextrins **2**—**4**, as described above. However, there is a large difference in the splitting mode of the signals between the pyridinio and mesitylsulfonyl derivatives. Thus, the splitting in **11** and **12** are much larger than those in **3** and **4** ($\Delta\delta$ less than 0.04), indicating that interactions between two pyridinio groups are much stronger than those between two mesitylsulfonyl groups. Moreover, the width of the splitting in the pyridinio derivatives increased with decreasing distance between the substituents, whereas that in the mesitylsulfonyl derivatives was not parallel to the distance. The splitting in the former may be caused mainly by strong electrostatic repulsive interactions between the positively charged pyridinio groups, which enlarge differences in the electronic and/or stereochemical structures between two pyridinio groups in a molecule.

The splitting patterns of the signals due to the protons involved in the pyridinio groups of trisubstituted regioisomers **13**—**16** were also characteristic. For example, the para-H's of A,C,E-isomer **16** gave only a triplet at δ=8.62, those of A,B,E-isomer **13** and A,B,D-isomer **14**, two triplets at δ=8.6—8.7 and one triplet at δ=8.3, and those of A,B,C-isomer **15**, one triplet at δ=8.64 and two triplets at δ=8.3—8.4. These results indicate that, if the C(6)-OH's of vicinal GP's [GP(A) and GP(B)] are displaced by the pyridinio groups, one of the para-H's of the pyridinio groups is subject to significant shielding to give a triplet in the higher-field region of δ=8.3—8.4, though another para-H is little affected to give a triplet at δ=8.6—8.7. In A,B,C-isomer **15**, two para-H's of the pyridinio groups are significantly shielded to give two triplets at the higher field-region. Similar splittings of the signals were also observed for the ortho-H's of **13**—**16**. These characteristic splitting patterns serve to distinguish the regioisomers from one another, though the distinction between A,B,E- and A,B,D-isomers are still impossible.

Table 5. ^{1}H NMR Data for the C(6)-H's of **9**—**17** Giving Double Doublet Signals in the High-Field Region of δ=2.4—2.7

Compound	δ[a)]
9	2.54 (1H, dd, J=12.0 and 2.9 Hz)
10	2.63 (2H, dd, J=13.0 and 4.6 Hz)
11	2.60 (1H, dd, J=12.9 and 4.7 Hz)[b)]
12	2.42 (1H, dd, J=11.6 and 4.3 Hz)
13	2.50 (1H, dd, J=12.4 and 4.3 Hz)[c)]
14	2.73 (1H, dd, J=13.2 and 4.6 Hz)[b)]
15	2.63 (1H, dd, J=12.6 and 4.1 Hz)
16	No Signal[d)]
17	No Signal

a) Chemical shift (ppm from DSS) in D_2O at 50 °C. b) Another C(6)-H gave a double doublet signal at δ=ca. 2.9. Details were ambiguous owing to overlapping with the other signals. c) Another C(6)-H gave a signal at δ=2.99 (1H, dd, J=11.7 and 5.3 Hz). d) The C(6)-H gave a signal at δ=2.99 (3H, dd, J=12.8 and 6.1 Hz).

There are another signals which are available for a regioisomer determination. They are the dd-signals appearing in the upfield region of δ=2.4—2.7 (Table 5). As described above, the dd-signal for **9** is attributable to one of the geminal C(6)-H's involved in an unsubstituted GP [GP(B)] adjacent to a substituted GP [GP(A)]. Similar dd-signals were observed for **10**—**15**, but not for **16** and **17**. It is reasonable that **17** gives no such dd-signal, since **17** has no unsubstituted GP. The A,C,E-isomer **16** gave no dd-signal in this region, though a dd-signal was found at a significantly lower field (δ=2.99). The A,C-isomer **11** also gave a dd-signal in the lower-field region (δ=ca. 2.9), together with a dd-signal in the higher-field region (δ=2.60). On the other hand, either A,D-isomer **10** or A,B-isomer **12** gave a dd-signal only in the higher-field region and

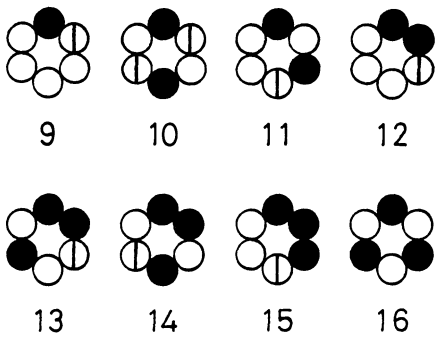

Fig. 6. Assigned glucopyranose rings (Ⓓ) which involve the C(6)-H's affording the high-field dd-signals at δ=2.4—2.7.

no dd-signal in the lower-field region. These facts indicate that the dd-signal of **11** in the lower-field region is due to the C(6)-H of GP(B) which is interposed between two substituted GP's [GP(A) and GP(C)]. The downfield shift of the dd-signal may be caused by electrostatic repulsive interactions between the pyridinio groups in GP(A) and GP(C) which compel the pyridinium ring of GP(A) to move away from the C(6)-H's of GP(B) and to weaken the ring current shielding effect. Upon this assumption, we assigned the GP rings which involve the C(6)-H's affording the upfield dd-signals (Fig. 6). The number of the GP's assigned was two for **10**, one for **9** and **11**—**15**, and zero for **16** and **17**, which agreed well with those observed (Table 5). This assignment also affords a clue to the distinction between regioisomers **13** and **14**. As Fig. 6 shows, GP(C) in **13** and GP(E) in **14** are responsible for the dd-signals in the higher-field region. It is worthwhile to point out that the intramolecular environments of GP(C) in **13** and GP(E) in **14** are significantly different from each other: The former is adjacent to two vicinal substituted-GP's [GP(A) and GP(B)] and the intramolecular environment is very similar to the GP(C) in A,B-isomer **12**. On the other hand, the latter is linked to an isolated substituted-GP [GP(D)] similar to the GP(E) in A,D-isomer **10**. If the intramolecular environments of GP(C) in **13** is similar to those of GP(C) in **12** and those of GP(E) in **14** to those of GP(E) in **10**, it is anticipated that the GP(C) of **13** gives the dd-signal at higher field than that for the GP(E) of **14**, since the dd-signal for the GP(C) of **12** was found at higher field by 0.21 ppm than that for the GP(E) of **10**. The upfield shift of the dd-signal for **12** compared with that for **10** may be attributed to strong electrostatic repulsive interactions between the pyridinio groups of the vicinal GP's [GP(A) and GP(B)], which force the pyridinium ring of GP(B) to come close to the C(6)-H's of GP(C) and strengthen the shielding by the ring current of the pyridinio group. Thus, the regioisomers which gave dd-signals at δ=2.50 (**13**) and δ=2.78 (**14**) are ascribable to the A,B,E- and A,B,D-isomers, respectively. The basis of the assignment described here is not necessarily rigid for a definite regioisomer determination. However, it must be one clue in solving this puzzling problem.

All the pyridinio derivatives **9**—**17** also gave distinct doublet signals at δ=4.7—5.3 due to C(1)-H's. The splitting patterns of the doublets reflected the structural features of the derivatives. However, details are omitted here, since they offer no further information concerning the regiochemistries than that which is described above.

7) This fact suggests that no aggregation of host molecules occurs in solution. The size of the mesityl group may be too large to be deeply included in a cavity of another host molecule. The relatively apolar solvent DMSO-d_6 may also contribute to weakening the hydrophobic interactions between the host molecules.

8) The unsubstituted α-cyclodextrin gives a doublet at δ=4.81 (J=3.0 Hz) due to C(1)-H's in DMSO-d_6: B. Casu and M. Reggiani, *Tetrahedron*, **22**, 3061 (1966).

9) A study with the CPK molecular model suggested that the orientation of the mesitylsulfonyl group to GP(F) is unfavorable due to steric hindrance from the C(5)-oxygen of GP(F).

10) The effect of sample concentrations on the NMR spectra was examined for **9**—**12**. The δ values obtained were virtually independent, within the standard error of 0.02 ppm, of the sample concentrations ranging from 10 to 60 mmol dm^{-3}. This fact indicates that no aggregation of the host molecules occurs in solution. Electrostatic repulsive interactions between positively charged host molecules may be responsible for the repression of aggregation. The δ values for **13**—**17** were determined in dilute solutions of 2—3 mmol dm^{-3}, where the aggregation hardly occurs.

Evaluation of Kinetic Parameters from Steady-State Voltammograms at Ultramicrodisk Electrodes

Takayuki ABE, Kingo ITAYA,* Isamu UCHIDA, Koichi AOKI,† and Koichi TOKUDA†
Department of Applied Chemistry, Faculty of Engineering, Tohoku University, Aoba, Aramaki, Sendai 980
†Department of Electronic Chemistry, Graduate School at Nagatsuta, Tokyo Institute of Technology, Nagatsuta, Midori-ku, Yokohama 227
(Received March 29, 1988)

Platinum ultramicrodisk electrodes 0.8 μm in radius were constructed by anodic electropolishing of a platinum wire followed by sealing it with soft glass. Voltammograms for oxidation of $[Mo(CN)_8]^{4-}$, Fe^{2-}, and $[Fe(CN)_6]^{4-}$, being of a sigmoidal form, were measured at these electrodes and microdisk electrodes with 7.5 μm in radius under the essentially steady-state condition. A voltammogram of Fe^{2+} at 7.5 μm electrode was drawn out, exhibiting a halfwave potential shifted from the formal potential. This trend was more distinctive for a wave at 0.8 μm electrode. Radii of the electrodes and diffusion coefficients of the electroactive species were determined consistently from the limiting currents. The conventional log-plot showed that electrode reactions of Fe^{2+} and $[Fe(CN)_6]^{4-}$ were, respectively, totally irreversible and almost reversible at these electrodes. Application of the modified log-plot to the voltammograms yielded straight line, of which slope allowed us to evaluate the transfer coefficient and of which intercept gave values of the charge-transfer rate constant. Simulated voltammograms at these values were in good agreement with experimental ones.

Since mass transport at ultramicroelectrodes is caused by two- or three-dimensional diffusion rather than linear diffusion, the diffusional flux at ultramicroelectrodes is larger than that at electrodes on a conventional scale. This trend becomes remarkable as electrolysis time is long. For example, the ratio of the diffusional flux at a microdisk electrode 10 μm in diameter to that at conventional electrodes is 5.3, 11, and 46, respectively, at 0.1, 1, and 10 s.[1] Thus overall electrode reactions at ultramicroelectrodes are often complicated by charge-transfer kinetics even at a long time electrolysis. Investigations on the charge-transfer kinetics have been undertaken at very small mercury droplets on a vitreous carbon electrode,[2] microring electrodes,[3-5] microdisk electrodes,[6-10] microcylinder electrodes[11-16] and at microband electrodes.[17,18] Since measurements of voltammograms at these electrodes can be made under the quasi-steady state or the steady-state conditions, they are free from complication associated with current transient.
