Invited Paper

Is Accurate X-Ray Analysis Worthwhile?

Jack D. DUNITZ

Organic Chemistry Laboratory, Swiss Federal Institute of Technology,
ETH-Zentrum, CH-8092 Zürich, Switzerland
(Received August 3, 1987)

Following a brief introduction to X-ray analysis, three areas are discussed where accurate measurements can lead to results of interest to chemistry. These areas are: (a) molecular geometry, (b) molecular motions in the solid state, (c) experimental electron density distributions. As the technical possibilities for accurate X-ray analysis improve, important developments in all three areas can be expected.

Most chemists nowadays are aware that the last two decades or so have seen a remarkable increase in the *ease* and *rapidity* with which X-ray crystal structure analyses can be accomplished; for this is a development that has transformed the tactics and strategies of preparative chemistry, both in the organic and organometallic areas. Almost as well known is the impressive increase in the *complexity* of the structures that can be elucidated at atomic or near atomic resolution, a development which is beginning to provide the structural basis for understanding and controlling many biochemical processes, with obvious implications for biology and medicine. Less well known, perhaps, is the remarkable improvement in the *accuracy* attainable in modern X-ray structure analysis. This particular improvement is due to instrumental and computational developments but also to the increased attention that has been paid to various sources of systematic error in the diffraction experiment.[1] Another most important factor is the sheer increase in the number of available diffractometers, thanks to which it no longer necessary to make the measurements in a hurry.

In this paper I shall mention three areas where this improved accuracy can lead to results of interest in chemistry: (a) small differences in bond length can be correlated with differences in chemical reactivity; (b) anisotropic displacement parameters can provide information about molecular motions in crystals and also about internal molecular motions; (c) electron density measurements provide an experimental approach to questions of chemical bonding. Before we discuss these developments, we first require a very brief introduction to X-ray crystallography in general.[2]

X-Ray Analysis in a Nutshell

When X-rays pass through matter they are scattered by the extra-nuclear electrons. In a crystal the electron density $\rho(\boldsymbol{X})$ is periodic and can therefore be represented as a Fourier series.

$$\rho(\boldsymbol{X}) = (1/V)\sum|F(\boldsymbol{H})|\cos[2\pi\boldsymbol{H}\cdot\boldsymbol{X}-\alpha(\boldsymbol{H})], \quad (1)$$

where V is the volume of the unit cell. The coefficients $|F(\boldsymbol{H})|$ of this series can be shown to correspond to the amplitudes of the diffracted beams in the directions of the scattering vector $\boldsymbol{H}(h_1, h_2, h_3)$. These amplitudes can be measured in an X-ray diffraction experiment. In order to reconstruct the electron density $\rho(\boldsymbol{X})$, we also need the corresponding phase angles $\alpha(\boldsymbol{H})$, as expressed in Eq. 1, that is, we need to know whether each Fourier wave starts at the origin with a maximum ($\alpha=0$) or a minimum ($\alpha=\pi$) or some intermediate value. This is the well known "phase problem," and methods are available for solving it.[3] For centrosymmetric crystals α is limited to the values 0 or π. Since $|F(\boldsymbol{H})|$ can be measured and $\alpha(\boldsymbol{H})$ can be obtained indirectly, there is nothing to stop us from evaluating the electron density $\rho(\boldsymbol{X})$ at each point $\boldsymbol{X}(x_1, x_2, x_3)$ of the unit cell by summation of the Fourier series in Eq. 1. Since the atomic nuclei are located at the points of maximum density (or, more correctly, at the centroids of the individual density peaks), the atomic arrangement can then be read off directly from $\rho(\boldsymbol{X})$. This is the way most crystal structures are solved.

Unfortunately, the electron density obtained from Eq. 1 is not quite true. In order to build up a faithful image of $\rho(\boldsymbol{X})$ we would need an infinite number of terms in the Fourier series. With a finite number of terms, the image is flawed by what is called "termination of series error," which consists mainly of spurious, more or less spherical, ripples of electron density emanating outwards from the atomic peaks. In most modern structure analyses, the set of atomic positions derived from $\rho(\boldsymbol{X})$ serves merely as a starting point for a series of non-linear least-squares refinements. Essentially, the parameters describing the atomic arrangement are adjusted to obtain optimal agreement with measured values of $|F(\boldsymbol{H})|$. The passage from the continuous electron density function $\rho(\boldsymbol{X})$ to the parametrized discrete-atom model runs something along the following lines.

By inversion of Eq. 1 we can express the complex structure amplitudes $F(\boldsymbol{H})$ as the Fourier transform of the continuous electron density within a unit cell,

$$F(\boldsymbol{H}) = \int \rho(\boldsymbol{X}) \exp[2\pi i\boldsymbol{H}\cdot\boldsymbol{X}]\mathrm{d}\boldsymbol{X}. \quad (2)$$

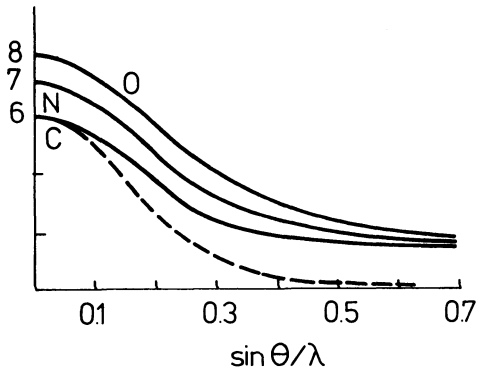

Fig. 1. Atomic scattering factors (form factors) for C, N, and O atoms at rest. The scattering factor is also shown for a C atom with mean-square displacement amplitude of 0.1 Å².

We now approximate $\rho(\boldsymbol{X})$ as a superposition of spherical density peaks associated with a set of non-interacting atoms at the positions $\boldsymbol{X}_j$ to obtain

$$\begin{aligned} F(\boldsymbol{H}) &= \int \Sigma \rho_j(\boldsymbol{X}-\boldsymbol{X}_j) \exp[2\pi i \boldsymbol{H}\cdot\boldsymbol{X}] \mathrm{d}\boldsymbol{X} \\ &= \Sigma \int \rho_j(\boldsymbol{X}-\boldsymbol{X}_j) \exp[2\pi i \boldsymbol{H}\cdot(\boldsymbol{X}-\boldsymbol{X}_j)] \\ &\qquad \times \exp[2\pi i \boldsymbol{H}\cdot\boldsymbol{X}_j] \mathrm{d}\boldsymbol{X} \\ &= \Sigma f_j(\boldsymbol{H}) \exp[2\pi i \boldsymbol{H}\cdot\boldsymbol{X}_j], \end{aligned} \tag{3}$$

where

$$f_j(\boldsymbol{H}) = \int \rho_j(\boldsymbol{X}) \exp[2\pi i \boldsymbol{H}\cdot\boldsymbol{X}] \mathrm{d}\boldsymbol{X}.$$

Since the atoms are assumed to have spherical symmetry, this integral can be written as

$$f_j(R) = 4\pi \int r^2 \rho(r) \frac{\sin 2\pi Rr}{2\pi Rr} \mathrm{d}r, \tag{4}$$

where r and R are radial distances in real and reciprocal space, respectively. The quantity $f_j(R)$ is the scattering power of the jth atom and is independent of the atomic position $\boldsymbol{X}_j$. Atomic scattering factors (form factors) for isolated neutral and ionic atoms have been calculated by many authors using various quantum mechanical models to obtain the appropriate electron densities; standard tabulations are given in International Tables for X-Ray Crystallography.[4] At zero scattering angle ($\boldsymbol{H}=0$), all electrons scatter in phase, so $f_j(0)$ equals the total number of electrons in the respective atom or ion. As the scattering angle increases ($|H|=2\sin\theta/\lambda$), interference between different regions of the electron cloud reduces the net scattering power, but even at large angles the inner core electrons are still scattering in phase (Fig. 1.)

Atomic Motion in Crystals

The atoms in a crystal are not stationary. From diffraction studies it is possible to obtain information not only about the mean atomic positions but also about the probability density functions (pdf's) of the atoms resulting from the time-averaged motion, averaged again over all unit cells in the crystal. In small molecule crystallography, the atomic pdf's are usually taken as trivariate Gaussian probability functions, except for hydrogen atoms which are taken as isotropic because their weak scattering power precludes the use of too many parameters in the description of their averaged motion. The atomic ellipsoids in the ORTEP diagrams[5] used to illustrate so many crystal structures are bounding surfaces that enclose some specific probability, usually 0.5, hence "50% probability ellipsoids." With these assumptions each atomic scattering factor has to be multiplied by the Fourier transform of the corresponding pdf, often referred to as the "anisotropic temperature factor," $T_j(\boldsymbol{H})$, which may be written in a compact form as

$$T(\boldsymbol{H}) = \exp(-2\pi^2 \boldsymbol{H}^T \boldsymbol{U} \boldsymbol{H}), \tag{5}$$

where $\boldsymbol{U}$ is a symmetric matrix, the matrix of second moments of the pdf. The second moment of the pdf in a given direction defined by a unit vector $\boldsymbol{n}$, i.e. the mean-square displacement of the atom in that direction, is then $\boldsymbol{n}^T\boldsymbol{U}\boldsymbol{n}$. The six components of $\boldsymbol{U}$ (or only one in the isotropic case) for each atom are included (as anisotropic displacement parameters or ADP's, together with the usual atomic positional parameters) in the least-squares analysis. In principle, higher cumulants of non-Gaussian pdf's can also be determined — 10 cubic terms, 15 quartic, and so on — but there are difficulties. The main problem is that these higher terms are only likely to be important when the second moments of the atomic pdf's are very large; however, the larger the second moments, the more rapidly the scattering from the atomic centre in question falls off with scattering angle. Thus, it is just when the higher terms become important that they become virtually impossible to measure.

Accuracy in Atomic Positions from X-Ray Diffraction

Atomic positions determined by X-ray diffraction correspond to centroids of distributions obtained by convoluting the atomic charge distributions with the corresponding pdf's. For small to medium sized molecules, these centroids are obtainable with nominal standard deviations of the order of a few thousandths of an Å, an uncertainty range that is usually considerably smaller than the built-in uncertainties involved in the derivation of averaged molecular structural parameters in systems where the

atoms are undergoing vibration. Since the relative phases of the vibrating atoms are generally unknown, separations between atomic centroids cannot be interpreted directly as interatomic distances.[6] The larger the mean-square displacements, the larger the uncertainties. In addition, atomic positions from X-ray analyses of molecular crystals based on low-angle[7] diffraction data are prone to systematic errors arising from asphericity in the distribution of the valency electrons. These errors can be reduced somewhat by appropriate weighting of the observations in the least-squares analysis.[8] However, it is much better to cool the crystals as far as possible to reduce the vibrational motion and try to measure the diffracted intensity at higher scattering angles. Atomic positions obtained from least-squares refinement of sufficiently extensive high-angle, low-temperature X-ray data can be expected to correspond closely to nuclear positions (as obtained from neutron diffraction data) and should be relatively free from systematic error. Indeed, for a small molecule, 2-aminopropenenitrile, atomic positions from 97 K X-ray diffraction data yield rotational constants very close to those obtained from a microwave spectroscopic study of the molecule in the gas phase.[9]

Accurate X-ray analysis can reveal subtle structural expressions of stereo-electronic effects.[10] In the dioxapropellane ketal **1** the two oxygen atoms O5 and O14 are chemically similar[11] but conformationally different (Fig. 2). From a crystal structure analysis at 98 K[12] the only pair of chemically equivalent bonds that shows an appreciable (>0.003 Å) difference in bond length is C6—O5, 1.412 Å, and C6–O14, 1.438 Å, difference 0.026 Å, with estimated standard deviation (esd) less than 0.003 Å. As seen in Fig. 2, the longer bond C6–O14 is synclinal (*sc*) to O5–C4 and hence antiperiplanar (*ap*) to a tetrahedral lone pair on O5, whereas the shorter bond C6—O5 is *ap* to O14—C13. The observed difference of 0.026 Å is in pleasing agreement with results of calculations on methanediol and methoxymethanol in the *sc,ap* conformation, which predict a relative lengthening by 0.025—0.030 Å of the C–O bond *ap* to a lone pair.[13]

Very similar results are observed for the tetraaza-tetraoxa-tricyclic molecule **2** from a crystal structure analysis at 96 K.[14] From the stereoview of the molecular conformation in Fig. 3, it is seen that the molecule as a whole is centrosymmetric and that the two sides of each seven-membered ring are conformationally different. The exocyclic N1–C1 bond is 0.025 Å shorter than N2–C2, while C1–O1 is 0.017 Å longer than C2–O2, differences that again clearly depend on stereoelectronic factors, the lone pair at N1 being *ap* to the C1–O1 bond while the lone pair at N2 is anticlinal (*ac*) to C2–O2. It is interesting that **2** must be thermodynamically more stable than the isomeric structure **3**, with which the compound was previously identified.[15] In the seven-membered ring the torsion angle about the O–O bond is 100°, close to the value in hydrogen peroxide.[16] In a six-membered ring, however, with normal bond lengths and approximately tetrahedral bond angles, it is impossible to obtain a torsion angle much greater than about 60°.

Bond-length differences of the magnitude we have been discussing may be associated with significant

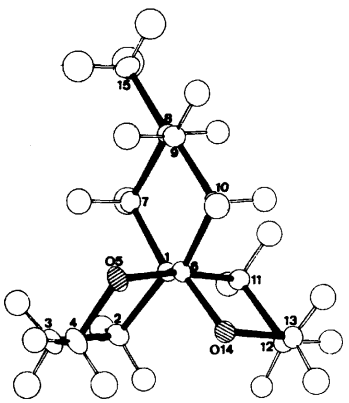

Fig. 2. View of molecule **1** at 98 K down the central C–C bond and showing atom numbering.[12]

changes in chemical reactivity. By combining crystallographic and kinetic data for acetals and related molecules, Kirby and Jones[17] found a linear relationship between the extension of a C–O bond (relative to some standard bond length) and the free energy of activation for heterolytic fission of the bond. For these reactions, and also for others,[18] it would appear that differences in the transition state are unimportant compared with differences in ground state structure. For axial aryl tetrahydropyranyl acetals **4** and for phosphate monoester anions $(ROPO_3)^{2-}$ the slope $\delta\Delta G^{\ddagger}/\delta r$ was found to be about 250 kcal mol^{-1} Å^{-1}. Thus, an increase of 0.02 Å in equilibrium bond length would correspond to a decrease of 5 kcal mol^{-1} in activation energy or to a 4000-fold increase in rate at room temperature. This astonishingly sharp sensitivity of activation energy of bond-breaking processes to quite small changes in ground-state structure can be accounted for in terms of a model involving a simple modification of the Morse equation, which is known to provide a good approximation to the potential energy of many classes of bonds.[19]

These results underline the need for accurate bond length measurements in structural studies bearing on questions of chemical reactivity.

Accuracy of Atomic Displacement Parameters from X-Ray Diffraction

Atomic displacement parameters (U values or ADP's) are calculated for thousands of crystal structure analyses each year, but the results do not seem to be generally regarded as being of any particular interest, at any rate not interesting enough to justify their publication in scientific journals. In fact, ADP's have practically disappeared from the published literature.[20] While one can sympathize with the reluctance of Journal Editors to publish long lists of numbers (six per atom for the usual Gaussian ADP's), the virtual disappearance of these data seems a pity because ADP's from reasonably careful routine analyses based on modern diffractometer measurements may often yield physically significant information about the atomic motions. Indeed, there is an ironical twist to the circumstance that most ADP's to be found in the literature are of poor quality. The reason for this is that just about the time when routine analyses were beginning to produce reasonably reliable numbers for these quantities, Editorial Boards were deciding against them. For the last few years ADP's have mostly been relegated to the category of supplementary information to be deposited and filed away in the vaults of scientific societies, publishing houses, libraries and similar depositaries.[21]

In the meantime, however, several studies have shown that ADP's from diffraction studies can yield important information not only about the molecular rigid-body motion but also about the internal molecular motion and other dynamical processes in crystals.[22] It is clear that for every pair of atoms A,B in a perfectly rigid grouping the mean-square displacements of both atoms must be exactly equal along the interatomic direction;

$$\Delta(\mathrm{A,B}) = \boldsymbol{n}^T\boldsymbol{U}_\mathrm{A}\boldsymbol{n} - \boldsymbol{n}^T\boldsymbol{U}_\mathrm{B}\boldsymbol{n} = 0, \qquad (6)$$

where $\boldsymbol{n}$ is the unit vector in the A,B direction. This condition is in effect a definition of rigidity, and if it is not satisfied within experimental accuracy there must be a relative motion of the atoms in the A,B direction. Note that the converse does not hold; Δ(A,B) may be zero if the relative motion of the atoms is perpendicular to the A,B direction. Thus, for example, the Δ values will not deviate significantly from zero for the out-of-plane vibrations of a planar molecule. Subject to this reservation, Eq. 6 provides a simple method of testing whether or not the ADP's obtained for a given molecule or molecular fragment are compatible with rigid-body behaviour.[23] Since bond-stretching vibrations typically have negligible amplitudes compared with other internal motions,[24] Eq. 6 should be valid for bonded pairs of atoms even in non-rigid molecules. Thus, evaluation of Δ(A,B) over all bonded pairs of atoms provides a useful estimate of the overall quality of the ADP's.[25] Failures of the rigid-bond criterion in certain structures have been used as a diagnostic to detect disorder among similarly shaped molecules with different bond lengths for corresponding bonds, e.g. different orientations of Jahn–Teller distorted complexes, and different spin-states of otherwise similar molecules.[26]

A visual impression of internal molecular motions can sometimes be gained simply from looking at ORTEP diagrams. Inspection of the matrix of Δ(A,B) values can reveal relative motion of rigid subgroups more objectively. Within the subgroups the Δ values should not differ significantly from zero, while relative motion of the subgroups will be manifested by much larger values of some of the inter-group Δ's. An example is given in Table 1, where Δ values for triphenylphosphine oxide in its orthorhombic crystal modification at 100 K[27] are shown. The triangles labelled A,B,C contain Δ values for the three phenyl groups (Fig. 4); the three blocks AB, AC, BC contain Δ values for pairs of atoms belonging to different rings. The esd's of the Δ's are about 7 units (Å$^2\times10^{-4}$) and the root-mean-square (rms) Δ's for the three individual rings are 11, 6, and 8 units respectively. Thus, the rings can be regarded as being essentially rigid. On the other hand, there is clear evidence of significant motion of the rings relative to one another, especially of ring A relative to rings B and C; the rms Δ values for blocks AB and AC are four or five times as large as those within the rings.

Two main methods for estimating amplitudes of

internal motion of non-rigid molecules, superimposed on the overall molecular motion,[28] have been proposed: (1) the segmented-body model, involving a network of coupled rigid bodies;[29] (2) addition of contributions from specified internal librations to those from rigid-body motion.[30] Although problems arise in connection with the correlations among internal and overall molecular librations,[31] mean-square amplitudes for torsional vibrations about bonds can be estimated reasonably well, especially when they are large compared with the overall molecular librations, and from this information (plus a knowledge of the crystal temperature) quadratic force constants for the motions in question can be derived.[32] A survey of ADP's from more than 125 crystal structures has shown that force constants estimated in this way for various librating groups are at least in the same range as those obtained by other techniques.[33]

Provided one is prepared to make a guess about the shape of the potential barrier hindering rotation of assumedly rigid groups, barrier heights can also be estimated from a knowledge of the mean-square libration amplitude $\langle\phi^2\rangle$ and the crystal temperature.

For example, rotation barriers estimated from ADP analysis for the cyclopentadienyl rings in crystalline metallocenes with the assumption of a fivefold sinusoidal potential agree well with those derived by solid-state NMR and other spectroscopic methods.[34]

Further developments in this direction could well lead during the next decade or so to an intrusion by crystallographers into the study of low-energy, large-amplitude molecular motions, a field that has traditionally been regarded as a preserve of molecular spectroscopy and gas-phase electron diffraction.

One possible use of accurate displacement parameters is to distinguish protium from deuterium in specifically labelled molecules by X-ray diffraction. This is no problem as far as neutron diffraction is concerned, since the neutron scattering powers of the two nuclei are very different, but neutron diffraction facilities are by no means so widely available. The problem with the distinction by means of X-rays is that the X-ray scattering powers of the two kinds of atom are identical. However, the heavier isotope is associated with a smaller vibrational amplitude. For a -CHD- methylene group, the difference between isotropic U_H and U_D can be estimated to be about 0.0035 Å^2, roughly double the standard deviation attainable today from low-temperature (liquid nitrogen) X-ray data of the highest quality.[35] In a practical test, it was possible to establish the relative configuration of the two stereogenic centres in deuterium-labelled malic acid **5** obtained by enzymatic addition of D_2O to fumaric acid.[36] The experiment was actually made with the crystalline mono ammonium salt and gave the same configuration as that established by neutron diffraction of the corresponding phenylethylammonium salt.[37] While it is clear that the X-ray method cannot possibly compete with neutron diffraction as far as isotope discrimination is concerned, its potentialities in this respect should not be altogether dismissed.

Another area where analysis of ADP's might be important includes studies of the nature and mechanism of phase changes, especially those involving order/disorder transformations. In ferrocene, for example, the cyclopentadienyl rings in the monoclinic high-temperature crystal modification are orientationally disordered down to the phase transition at 164 K.[38] Below this temperature the structure becomes triclinic, and the rings librate about well defined equilibrium orientations.[39]

Electron Density Maps

Electron density maps have been used for years to give images of molecules in crystals, and it has always been realized that such maps might also tell us something about the fundamental problem of the nature of the chemical bond. If only we could make those maps accurate enough they might help to illuminate for us the problem of how atoms are held together in molecules and crystals.

It was fortunate for the development of crystal structure analysis that the electron density in a molecular or ionic crystal is very closely similar to the superposition of the densities of the separated atoms, placed at the positions they occupy in the crystal. This similarity made it possible to use standard, spherically symmetric scattering factors (as expressed in Eq. 4 and Fig. 1) in solving crystal structures and also in refining them by least-squares methods. In fact, when crystallographers take pride in their low R factors,[40] they pay tribute to the goodness of the pro-crystal approximation as well as to the accuracy of their measurements. The difference $\Delta\rho(\boldsymbol{X})=\rho(\boldsymbol{X})-\rho_M(\boldsymbol{X})$ between the actual density and the pro-molecule density is known as the deformation density. It can be interpreted as representing the reorganization in the electron density that occurs when a collection of independent, isolated, spherically averaged atoms is combined to form a molecule in a crystal. Since $\Delta\rho$ is only a very small fraction of ρ in the region of the atoms, it is very susceptible to experimental error in the X-ray measurements and to inadequacies in the model (errors in the assumed atomic positions and ADP's).

The deformation density $\Delta\rho$ is conveniently obtained as:

$$\Delta\rho(\boldsymbol{X}) = (1/V)\sum\{|F(\boldsymbol{H})| - |F_M(\boldsymbol{H})|\} \times \cos[2\pi\boldsymbol{H}\cdot\boldsymbol{X} - \alpha_M(\boldsymbol{H})], \quad (7)$$

by analogy with Eq. 1, where $F_M(\boldsymbol{H})$ is calculated for the pro-crystal according to Eq. 3, suitably modified to allow for the atomic temperature factors (Eq. 5). The positions $\boldsymbol{X}_j$ and corresponding $\boldsymbol{U}_j$ components of the atoms in the pro-molecule (or pro-crystal) need to be estimated as accurately as possible by least-squares analysis, preferably using high-angle, low-temperature data, as described earlier in this article, or in a separate neutron-diffraction experiment.[41] Since the observed density $\rho(\boldsymbol{X})$ and the pro-molecule density $\rho_M(\boldsymbol{X})$ are both smeared by the vibrational motion of the atoms, so is the difference density obtained by subtracting one from the other.

In an alternative procedure, the deformation density is expressed in parametric form as the sum of a number of suitably designed functions, usually chosen as a set of multipoles, each multiplied by a radial function and centred at an atomic position. The Fourier transforms of the deformation functions are then added to the free-atom form factors with variable coefficients, which are refined, together with the atomic coordinates and ADP's, by least-squares analysis. The deformation density obtained in this way is, of course, restricted by the particular choice of deformation functions included in the model. Gen-

erally, it looks smoother than the difference density. The deformation density calculated with the multipole model is often called the static deformation density[42] since it represents the charge density reorganization in going from the vibrationless promolecule to the vibrationless molecule. This makes it more suitable for direct comparison with deformation densities obtained by quantum-mechanical calculations.

As recently discussed by Seiler,[1] it is becoming increasingly clear that dependable deformation densities require an expenditure in experimental time and effort far in excess of that involved in routine X-ray analysis. If the parameters describing the promolecule are to be obtained from X-ray data, accurate and extensive measurements of high-order reflections are required. To obtain such data, the atomic vibrations must be reduced as far as possible. It is therefore advisable to carry out the diffraction measurements with the crystal held at liquid nitrogen temperature or lower. And finally, even when all these conditions are fulfilled, the significant features of the deformation density are only a small fraction of the total density. We can maximize this ratio by dealing with light-atom structures. Indeed, until we understand how to obtain physically meaningful and interpretable maps for light-atom structures, it seems prudent to avoid crystals containing heavy elements as far as possible.

We mention here two examples of recent deformation density studies which have led to results of some chemical interest. The first example concerns tetrafluoroterephthalonitrile **6**. The molecule occupies a site of C_{2h} symmetry in the crystal, so that the asymmetric unit consists of only two atoms (C and F) in general positions plus three atoms (two C and one N) on a crystallographic mirror plane. For the deformation density study,[43] the intensities of *all* reflections within a limiting sphere of radius $\sin\theta/\lambda=1.15$Å^{-1} were measured with Mo $K\alpha$ radiation at 98 K; most reflections were measured in all symmetry-equivalent orientations, leading to a total of 17740 measurements. After averaging equivalent reflections, 2387 independent observations were left, nearly 700 per atom in the asymmetric unit. The difference map in the molecular plane, calculated with 1269 reflections with $F>20\sigma(F)$ is shown in Fig. 5. Prominent peaks occur close to the mid-points of the ring C–C bonds ($\approx$0.6 e Å^{-3}), of the exocyclic C–C bond ($\approx$0.4 e Å^{-3}), and of the C≡N triple bond ($\approx$0.75 e Å^{-3}), as well as in a region that is clearly associated with the *sp* lone pair of the N atom ($\approx$0.25 e Å^{-3}).[44] In contrast, the difference density along the polar C–F bond does not exceed 0.1 e Å^{-3}. Difference maps calculated with slightly different atomic form factors or with pro-crystal models obtained by varying details of the least-squares refinement were not significantly different from that shown in Fig. 5.

The static deformation density map calculated on the basis of the same experimental data is shown in Fig. 6A.[45] Compared with Fig. 5, the density peaks are of slightly different shapes and heights, but, allowing for the differences in the underlying assumptions, the main qualitative features of the two maps are remarkably similar.[46] There is also a close agreement between the experimental deformation

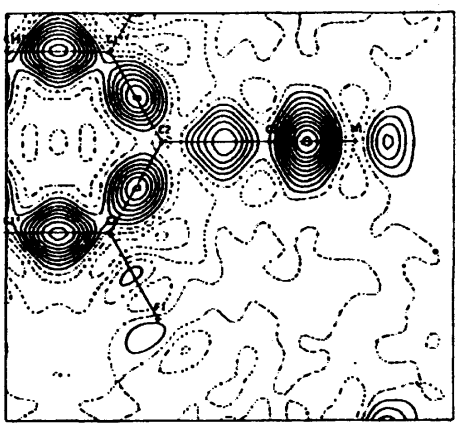

Fig. 5. Tetrafluoroterephthalonitrile. Electron density difference map $\Delta\rho$ in the molecular plane. Contour interval 0.075 e Å^{-3}, zero and negative contours broken.[43]

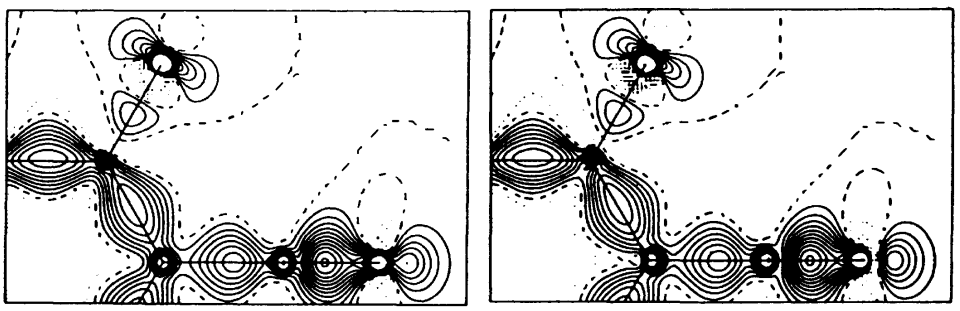

Fig. 6. Tetrafluoroterephthalonitrile. Static deformation density map in the molecular plane from (A) unconstrained, and (B) Hellmann-Feynman constrained refinements.[48] Contour interval 0.1 e Å^{-3}.

density and that calculated by density functional theory,[47] the main differences being in the lone-pair densities, which are somewhat smaller in the experimental map.

The Hellmann-Feynman theorem states that if the correct charge density is available, the forces on the atomic nuclei can be calculated by classical electrostatics; for a stable atomic arrangement, these forces must be zero. Hirshfeld has shown[48] that this condition is not fulfilled for the static deformation density shown in Fig. 6A. In particular, the electric field at the F nucleus was found to be strongly repulsive. The condition of zero net-force was then included as a constraint in the least-squares refinement with the same set of multipole terms, leading to the deformation map shown in Fig. 6B. At a first glance, the two maps look almost identical, and it may seem remarkable that one corresponds to appreciable forces on the atomic nuclei, the other to electrostatic equilibrium. The main difference is that sharp dipoles (core polarization) are produced at the nuclei, coupled with very small changes (less than 0.001 Å) in the atomic positions. Clearly, the electric field at the nuclear positions is extremely sensitive to features of the static deformation density close to the nuclei, features that are not easily determined from the X-ray data alone. The problem here is not so much the quality of the data as the strong correlation between the core polarization functions and the atomic coordinates.

For peroxides, difference maps show a density deficit at the mid-point of the O–O bond.[49,50] For example, Fig. 7 shows the difference density along the O–O bond in molecule **2**. The negative density along the bond axis contrasts with the positive density peaks corresponding to other bonding features seen in the Figure, such as the C–O and C–H bonds, as well as the O lone pairs.

In fact, from these and other studies, experimental "bonding density" seems to decrease in the order C–C>C–N>C–O≈N–N>C–F≈N–O>O–O, i.e., with increase in the number of valency electrons. This trend can be explained by comparing the tetrahedrally hybridized orbital occupation numbers for the bonded atoms with those of the spherically averaged atoms that are subtracted out.[51] It is also clear that the choice of reference states is to some extent arbitrary and that other kinds of trend could be produced by assuming non-spherical charge distributions for the atoms in the pro-molecule. Nevertheless, it may seem disturbing that the deformation-density results seem to contradict (or at least modify) the conventional wisdom about the nature of the chemical bond, namely that a build up of charge between the nuclei is necessary.[52,53] Indeed, the use of spherically averaged atoms to define the pro-molecule has come in for considerable criticism from theoreticians.[54,55] Difference densities more in line with theoretical views of chemical bonding could certainly be obtained by subtracting out suitably oriented ground-state or valence-state atoms, although such a procedure is also not without its difficulties. The choice of the reference state is clearly to some extent arbitrary. It can hardly be denied, however, that the spherically averaged density is the only choice that allows fully for the reduction in symmetry that occurs when a free atom becomes part of a molecule.

Our final example concerns the question: are ionic solids really built from ions? As Slater pointed out many years ago, the difference in charge distribution between the superposition of neutral atoms and the superposition of ions is "small and subtle, and difficult to determine by examination of the total density."[56] The main problem is that the difference between the charge densities of individual neutral atoms and corresponding ions only become appreci-

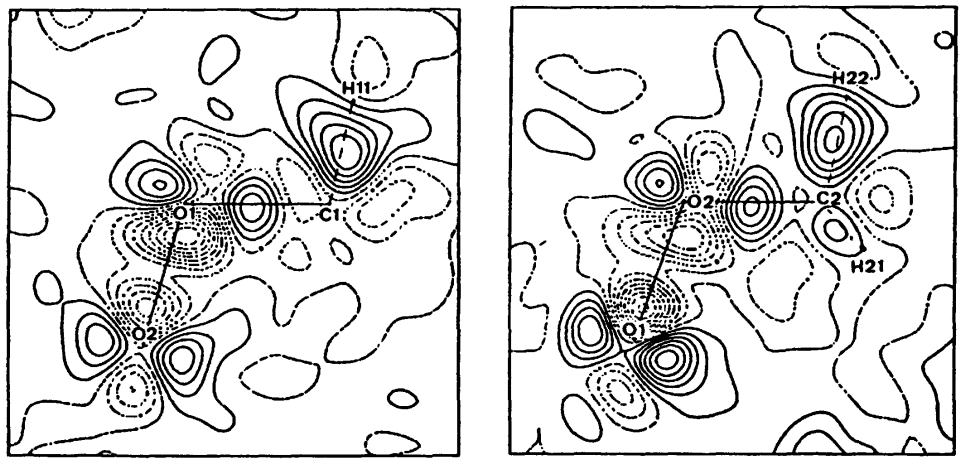

Fig. 7. Electron density difference maps $\Delta\rho$ in sections passing through the C–O–O planes of molecule **3**. Contour interval 0.075 e Å^{-3}, zero and negative contours broken.[50]

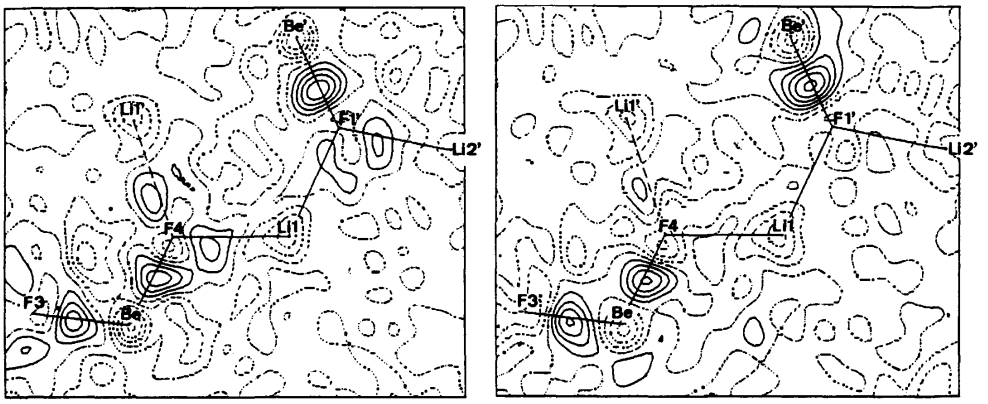

Fig. 8. Electron density difference maps $\Delta\rho$ for a chain of atoms in the Li_2BeF_4 crystal structure, based on the neutral-atom pro-crystal (left) and the ionic one (right). Contour interval 0.045 e Å^{-3}, zero and negative contours broken.[57]

able at large distances from the respective nuclei. In a crystal, where densities of neighbouring atoms overlap, this diffuse difference density cannot be unequivocally assigned to one atom or another. At these large distances, even if the density associated with a given atom may be quite small, the contribution of the spherical shell to the integrated charge may be considerable. The problem can also be expressed in terms of the respective form factors: the scattering powers (Eq. 4) of neutral atoms and of their corresponding ions differ appreciably only in a small region of reciprocal space close to the origin.

Indeed, in a new, accurate analysis of lithium tetrafluoroberyllate, Li_2BeF_4, at 81 K, both models yielded almost identical R factors[40] of 0.015 for all 6345 independent reflections out to $\sin\theta/\lambda$=1.35 Å^{-1}, an indication that the charge distribution is almost equally compatible with a superposition of neutral atom charge distributions and a superposition of ionic charges.[57] The two distributions are so similar that they can hardly be distinguished by examining the corresponding difference densities, shown in Fig. 8. Both maps show peaks of up to 0.2 e Å^{-3} along the Be–F bonds of the tetrahedral BeF_4 "anions" and still weaker ones along the Li–F directions.

Since the form factors of the neutral and ionic species differ only in the low-angle region, the intensities of the low-order reflections were re-measured in a separate experiment with a smaller crystal and with particular attention to the avoidance of systematic errors. When attention is focussed on 22 weak reflections in the region ($\sin\theta/\lambda$<0.25 Å^{-1}) where the form factors still show detectable differences, the neutral atom model reproduces the observed intensities better than the ionic one. This indicates that the diffuse charge density far from the nuclei is better represented by the superposition of outer tails of spherical distributions centred at the Li and Be atoms than by the tails of F-centred distributions.

However, since the charge distribution of the ionic model is so very similar to that of the neutral atom model, the two distributions must correspond to very similar energies. Thus, the cohesive energy estimated for an ionic model with integral charges will still be close to the correct result — and much simpler to calculate — even if the actual charge distribution happens to be slightly closer to that of the neutral atom model.[58] The fact that it is easier to calculate many properties of solids with integral point charges than with atomic charge distributions certainly makes the ionic model more convenient, but it does not necessarily make it more correct.

This work has been supported over the years by the Swiss National Foundation for Scientific Research. It has been made possible only through the dedicated collaboration of many students and colleagues, whose names are mentioned in the text and footnotes.

40) The crystallographic R factor, sometimes called the agreement factor, sometimes the disagreement factor, is usually defined as $R=\sum|F_H(\text{obs})-F_H(\text{calc})|/\sum F_H(\text{obs})$.

41) The use of neutron diffraction to obtain the parameters describing the pro-molecule completely avoids the bias associated with the use of isolated-atom form factors. Difference densities obtained in this way are known as X−N densities. The main disadvantage, apart from the extra work and inconvenience, is that one has to contend with two sets of experimental error instead of one. For investigations where the electron density around hydrogen atoms is of special interest, e.g., in studies of hydrogen bonding, etc., the additional work and complications involved in the double experiment are certainly justified.

42) A useful account of the concepts and terms used in experimental charge density studies has been provided by P. Coppens, "Electron Distributions and the Chemical Bond," ed by P. Coppens and M. B. Hall, Plenum, New York (1982), p. 61.

44) For comparison, the highest peak in the total electron density amounts to about 40 e Å^{-3} (at the F atom).

45) L. Hirshfeld, *Acta Crystallogr., Sect. B*, **40**, 484 (1984).

46) The main difference is that the static density (Fig. 6A) shows two lobes of a p-orbital like density at the F atom, whereas this feature is absent in the vibrationally smeared density (Fig. 5). Related to this difference, the U component of the F atom in the p-orbital direction is larger in the refinement without deformation density terms. Because of the high correlation in the least-squares calculation between vibrational and deformation parameters, this difference is not particularly serious.

Invited Paper

Compensation Effects in the Activation Parameters for the Homolytic Dissociation of Transition Metal-Alkyl Bonds

Jack HALPERN
Department of Chemistry, The University of Chicago, Chicago, Illinois 60637, U.S.A.
(Received August 14, 1987)

Determining the activation enthalpies of the homolytic dissociation of transition metal-alkyl bonds constitutes one of the most useful methods of deducing such bond dissociation energies. For several series of organocobalt compounds it has been found that trends of increasing enthalpies of activation for homolytic cobalt-carbon bond dissociation (i.e., of cobalt-carbon bond dissociation energies) are accompanied by partially compensating trends of increasingly positive entropies of activation. Evidence is advanced that these compensation effects are genuine. A suggested explanation is that, with increasing endothermicity of the bond dissociation process, the transition state becomes more "product-like," i.e., further along the path to dissociation.

In 1982[1] we described a method for the determination of transition metal-alkyl bond dissociation energies (D_{M-R}) based on determining the activation enthalpies of the bond-dissociation reaction (Eq. 1) and using the relation of Eq. 2.

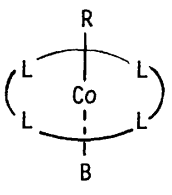
$$L_NM\text{-}R \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} L_NM\cdot + R\cdot \quad (1)$$

$$D_{M-R} = \Delta H_1^{\ddagger} - \Delta H_{-1}^{\ddagger} \quad (2)$$

In several cases where this has been tested, the reverse reaction of Eq. 1, i.e., the recombination of $L_NM\cdot$ and $R\cdot$, has been found to be diffusion-controlled.[2,3] Thus, $\Delta H_{-1}^{\ddagger}$ may be approximated by the value of the activation ethalpy for a diffusion-controlled reaction which, in organic solvents of low viscosity such as acetone or toluene, corresponds to about 2 kcal mol^{-1}. Accordingly, in practice, only $\Delta H_1^{\ddagger}$ needs to be determined in such solvents and D_{M-R} may be deduced from the relation,

$$D_{M-R} \approx \Delta H_1^{\ddagger} - 2 \text{ kcal mol}^{-1} \quad (3)$$

This approach has subsequently been extensively applied by ourselves and others and, indeed, has become one of the most successful and widely used methods for determining transition metal-alkyl bond dissociation energies in solution.[4-8] We have been interested in elucidating the factors that influence such bond energies and that could contribute to the enzyme-induced cobalt-carbon bond weakening and dissociation of coenzyme B_{12} that triggers the latter's biological role. For this purpose we have determined the Co-C bond dissociation energies of an extensive array of octahedral organocobalt(III) compounds [R-Co(Chel)B] (**1**) in which the alkyl group (R), the tetradentate equatorial ligand (Chel) and the trans-axial ligand (B) have been systematically varied.[1,3,8,9]



1 (L_4=Chel)

Results and Discussion

Our studies have encompassed various combinations of: R=$C_6H_5CH_2$, $C_6H_5CH(CH_3)$, $CH_3CH_2CH_2$, $(CH_3)_3CCH_2$; Chel=Bis(dimethylglyoximato) $(DH^-)_2$, *N,N'*-bis(salicylidene)-*o*-phenylenediamine (Saloph^{2-}), Octaethylporphyrin (OEP^{2-}); B=pyridine, 4-CN-pyridine, 4-CH_3-pyridine, 4-NH_2-pyridine, PMe_2Ph, PEt_2Ph, PBu_3^n, P(*cyclo*-C_6H_{11})$_3$ and PPh_3. The results of these measurements are summarized in Table 1.

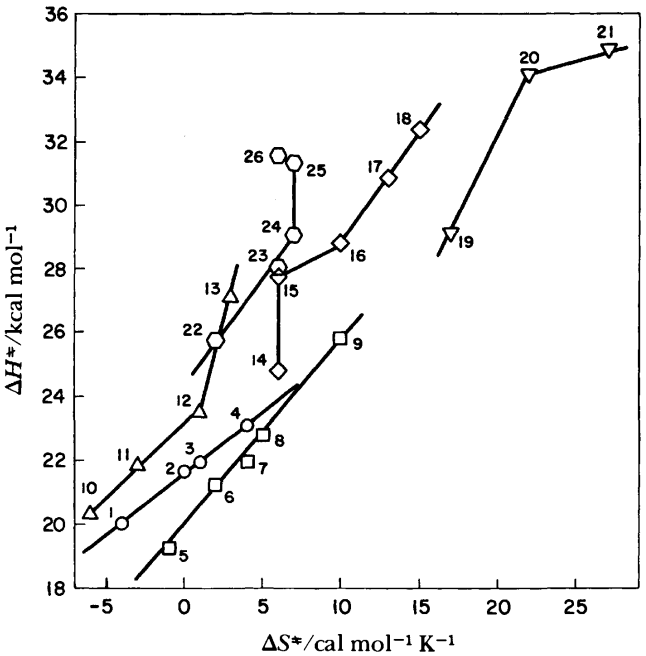


Fig. 1. Relations between enthalpies and entropies of activation for homolytic cobalt-carbon bond dissociation reactions. Numbers refer to entries in Table 1.

Examination of these data reveals that for each series of compounds with a given equatorial ligand, (Chel), variation of either R or B results in a systematic partial "compensation" of the activation parameters such that ΔS^* becomes increasingly positive as ΔH^* increases. The trends are depicted in Fig. 1.

There are well recognized grounds for treating such "compensation" effects with suspicion since they commonly have an artifactual origin reflecting the interdependence of ΔH^* and ΔS^*.[11-15] Thus, random errors in the determination of ΔH^* for a series of reactions, in which the variation of ΔG^* is small, will automatically be reflected in compensating variations in the interdependent variable ΔS^* through the relation, $\Delta G^*=\Delta H^*-T\Delta S^*$; hence for $\Delta\Delta G^*\approx 0$,

$$\Delta\Delta H^* \approx T\Delta\Delta S^* \tag{4}$$

or

$$\Delta H^* \approx \Delta H_0^* + T\Delta S^* \tag{5}$$

Several considerations, cited below, lead us to conclude that the trends of dependence of ΔS_1^* on ΔH_1^*, identified in Table 1 and Fig. 1, are genuine and not of such artifactual origin.

1. The variation of ΔH_1^* (and, correspondingly, of ΔS_1^*) in each series is not random but increases monotonically with ΔG^*. This is contrary to what would be expected if the compensating variations of ΔH_1^* and ΔS_1^* had their origins in random errors in the determination of ΔH_1^*.

2. According to Eq. 4 the slopes of plots of ΔH^* vs. ΔS^* should approximate the mean temperatures ($\overline{T}$) of the measurements. In fact, the slopes of the approximately linear plots of ΔH_1^* vs. ΔS_1^* in Fig. 1 are consistently significantly higher than $\overline{T}$. Thus, for the series [PhCH(CH_3)-Co(DH)$_2$(4-X-pyridine)] the slope is ca. 375 K whereas $\overline{T}$=298 K. Similarly, for the series [PhCH(CH_3)-Co(DH)$_2$(PR_3)] the slope is ca. 600 K whereas $\overline{T}$=293 K.

3. Similar trends of dependence of ΔH_1^* on ΔS_1^* are observed for several different series of compounds, namely for those in which (Chel)=(DH^-)$_2$, ($Saloph^{2-}$) and (OEP^{2-}) and for different procedures used to determine ΔH_1^*. Furthermore, for one of these series, [PhCH(CH_3)-Co(DH)$_2$(4-X-pyridine)], the validity of

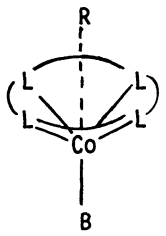
the ΔH_1^* values has been supported, using Eq. 2, by independent determinations of D_{Co-R} based on *thermodynamic* measurements.[3]

All of the above argue against the trends of compensating variations of ΔH_1^* and ΔS_1^*, in Table 1 and Fig. 1, having their origin in errors in the determination of ΔH_1^*. Accordingly, we conclude that these partial compensation effects are genuine and reflect systematic dependencies of structural features of the transition state on ΔH_1^*. The bond dissociation process associated with ΔH_1^* is substantially endothermic and the activation barrier (ΔH_{-1}^*) associated with the reverse (recombination) is small. Thus, the transition state for the dissociation reaction is anticipated to be "product-like" and to become more so with increasing endothermicity, i.e., with increasing D_{Co-R} and ΔH_1^* (Hammond postulate[16]). Since the entropy of the overall dissociation process is substantially positive, it is expected that this should be accompanied by an increase in the entropy of activation, ΔS_1^*, possibly associated with increasing relaxation of the originally octahedral configuration to the more product-like, less rigid, structure **2**. This provides a plausible explanation for the compensating dependence of ΔH_1^* on ΔS_1^* that we have identified as a general feature of such transition metal-alkyl bond dissociation reactions.



2

In this connection, it is of interest that for the series of complexes, $[C_6H_5CH_2\text{-}Co(OEP)PR_3]$, containing the octaethylporphyrin ligand, which we have previously concluded to be less flexible than the other equatorial ligands,[8] ΔS_1^* does indeed exhibit the smallest variation.

Thus it is seen that the relation between the bond dissociation rate and bond dissociation energy is not entirely simple. This is of some interest in the context of understanding the nature and origin of the "bond weakening" that is involved in the enzyme-induced Co-C bond dissociation of coenzyme B_{12}.[17] Clearly, entropic as well as enthalpic factors may contribute to such bond weakening.

Support of this research by grants from the National Institutes of Health, the National Science Foundation and the Petroleum Research Fund, administered by the American Chemical Society, is gratefully acknowledged.

11) Such grounds for concern are especially cogent with respect to claims of precisely linear dependence of ΔH^* on ΔS^*, i.e., manifestations of the so-called "isokinetic relationship," $\Delta H^* = \Delta H_0^* + \beta \Delta S^*$, particularly when the value of β is close to the temperature range of measurement. Indeed, there is reason to question the physical plausibility of such an isokinetic relation since it implies reversal of reactivity trends in passing through the "isokinetic temperature." For the purpose of the issues addressed in this paper the precise form of the dependence of ΔH^* on ΔS^* is not of primary importance and we have been careful to avoid claims of "isokinetic" behavior. We do, however, attach relevance to the qualitative monotonic dependence of ΔH^* on ΔS^* that we have observed consistently in the course of these measurements and that we conclude to be genuine.

Electrogenerated Chemiluminescence. 50. Electrochemistry and Electrogenerated Chemiluminescence of Micelle Solubilized $Os(bpy)_3^{2+}$

Jiangbo OUYANG and Allen J. BARD*
Department of Chemistry, The University of Texas Austin, TX 78712, U.S.A.
(Received August 20, 1987)

The oxidative electrochemistry and electrogenerated chemiluminescence (ECL) of $Os(bpy)_3^{2+}$ were studied in the presence of sodium dodecyl sulfate (SDS), Triton X-100, and cetyltrimethylammonium bromide (CTAB) in aqueous solutions. Variation of supporting electrolyte (NaCl) concentration affected the interaction between $Os(bpy)_3^{2+}$ and the surfactants. The measurement of oxidation peak current (i_{pa}) and ECL intensity at different NaCl concentrations suggested a strong interaction of $Os(bpy)_3^{2+}$ with SDS. Above the critical micelle concentration (cmc) the strong hydrophobic interaction of $Os(bpy)_3^{2+}$ and the SDS micelle core greatly suppresses both i_{pa} and the ECL intensity. The interaction of $Os(bpy)_3^{2+}$ with CTAB micelle is much weaker because of electrostatic effects. Triton X-100 micelles do not interact with $Os(bpy)_3^{2+}$.

We report studies of the effect of micelle-forming surfactants on the oxidative electrochemistry of $Os(bpy)_3^{2+}$ and its ECL in the presence of oxalate. Surfactants have been used in polarographic experiments and other electrochemical experiments. Most experiments deal with $E_{1/2}^{i}$ shifts and homogeneous electron-transfer kinetics of the substances solubilized in micelles.[1-3] Micelles have also been of interest in micellar catalysis and micellar models of biological membranes.[4] Micelles are dynamic aggregates of amphiphilic molecules and possess regions of hydrophilic and hydrophobic character.[5] The interactions that are operative between soluble substances and host micelles include electrostatic attractions,[6] surface adsorption,[7] pseudophase extraction,[8] and substrate/amphiphile coassembly to yield a unique micelle composition.[9] The specific nature of the interaction between a soluble species and the host micelle governs the effect of micellar microenvironment on the behavior of the substrate. This study was mainly motivated by our interest in the application of $Ru(bpy)_3^{2+}$ and other emitting centers as tags for analysis of species at low concentration.[10] In certain samples, e.g., biological fluids, the addition of surfactants can be helpful in suppressing the effects of interferences.

The present experiment was designed to elucidate the microenvironment effects of micelles on the electrochemical and ECL behavior of $Os(bpy)_3^{2+}$, which is a reasonably good luminescor.[11,12] The one-electron oxidation near +0.6 V vs. SCE allows the study of these compounds in aqueous solutions. Sodium dodecyl sulfate (SDS), Triton X-100, and cetyltrimethylammonium bromide (CTAB) were used as the representatives of anionic, neutral and cationic micelles, respectively. We also show that the electrolyte concentration affects the electrochemical and ECL behavior.

SDS = $CH_3(CH_2)_{11}OSO_3^-Na^+$

CTAB = $CH_3(CH_2)_{15}N^+(CH_3)_3Br^-$

Triton X-100 = $CH_3(CH_2)_7(OCH_2CH_2)_{9.5}$-  -OH

Structures of Surfactants

Experimental

SDS, CTAB, and Triton X-100 were obtained from Aldrich Chemicals (Milwaukee, WI) and were used without further purification. Sodium chloride was purchased from MCB (reagent grade, Cincinnati, OH) and Milli-Q water (Millipore Corp. El Paso, TX) was used to prepare all solutions. $Os(bpy)_3(PF_6)_2$ was prepared according to the procedure of Gaudiello et al.[13] The surface active compounds were dissolved in a very small volume of acetone to assist the solubility in water.

A three compartment cell was used to carry out all experiments. Electrochemical measurements were performed with a Princeton Applied Research (PAR) (Princeton, NJ) Model 175 universal programmer, a Model 173 potentiostat and a Model 179 digital coulometer equipped with positive feedback circuitry for IR compensation. Voltammograms were recorded on a Houston Instruments Model 2000 X-Y recorder. A BAS-100 electrochemical analyzer (Bioanalytical Systems, Lafayette, IN) was also used in the electrochemical measurements. ECL spectra were recorded on an Aminco-Bowman Spectrometer with a Hamamatsu R928 photomultiplier tube. Absorption spectra were obtained with a Hewlett-Packard Model 8450A dual-beam spectrophotometer.

Most of the experiments were performed under a purified nitrogen atmosphere. The electrochemical cell was adapted to a Schlenk line. Glassy carbon electrodes (0.07 cm^2) (BAS, Lafayette, IN) were employed as working electrodes for voltammetry and ECL. The electrodes were polished with a 0.05 μm alumina/water slurry on a felt surface and sonicated. A platinum mesh was used as counter electrode and all potentials were recorded against a saturated calomel electrode (SCE).

Results

Cyclic Voltammetry. Cyclic voltammetry (CV) experiments were carried out to study the effect of

SDS, Triton X-100, and CTAB micelles on the redox potentials and peak currents (i_p) for the oxidation of $Os(bpy)_3^{2+}$. The cyclic voltammogram of a 0.2 mM† aqueous solution of $Os(bpy)_3^{2+}$ in 50 mM NaCl in the absence and presence of surfactants is shown in Fig. 1. The waves observed are due to the one-electron oxidation[12] of $Os(bpy)_3^{2+}$, and, on reversal, the reduction of the +3 species:

$$Os(bpy)_3^{2+} \rightleftharpoons Os(bpy)_3^{3+} + e^- . \quad (1)$$

CV waves were observed in all three micellar solutions as shown in Fig. 1b—d. The value of ΔE_p, the separation between anodic and cathodic peak potentials ($E_{pa}-E_{pc}$), shows that the waves are essentially reversible in all solutions. ΔE_p is listed in Table 1 for all media. There are variations in the redox potentials associated with half reaction 1 in SDS media. In the presence of SDS, the $E_{1/2}$ (formal standard potential)

† 1 M=1 mol dm^{-3}.

shifted to slightly more positive values (see Table 1), especially at higher supporting electrolyte concentration; e.g., $E_{1/2}$ was 0.668 V vs. SCE at 300 mM NaCl with 70 mM SDS compared to 0.610 V in 300 mM NaCl alone. Both i_{pc} and i_{pa} were depressed about four times in the presence of SDS (50 mM NaCl in solution) and reduced slightly in the presence of Triton X-100 micelles and of CTAB micelles compared to that in an aqueous solution in the absence of surfactant (Fig. 2).

The supporting electrolyte concentration affects the oxidation of $Os(bpy)_3^{2+}$ as shown by i_{pa} vs. concentration of NaCl plots in Fig. 2. The variation of electrolyte concentration caused different responses for the three different micellar solutions. In 70 mM SDS (Fig. 2a), when the concentration of NaCl increased from 50 mM to 300 mM, the formal standard potential shifted from 0.615 to 0.688 V vs. SCE and the i_{pa} increased from 0.75 to 1.5 μA. In the absence of added NaCl, a solution with 0.2 mM $Os(bpy)_3^{2+}$ shows an i_{pa}=1.6 μA (with positive feedback iR compensation). However, under the same conditions in the presence of 70 μm SDS, no oxidation wave is seen ($i_{pa}\approx 0$). This indicates that all of the $Os(bpy)_3^{2+}$ in the SDS micelles becomes completely electrochemically inactive in the absence of supporting electrolyte. The peak current increased slightly upon the successive addition of NaCl with CTAB micelles, as shown in Fig. 2c. In the presence of Triton X-100 micelles, as well as without any surfactant added, the peak current decreased slightly as the concentration of NaCl increased.

The voltammetry was also studied at various concentrations of SDS. A plot of peak current vs. concentration of SDS is shown in Fig. 3a. SDS was gradually added to an aqueous solution containing 0.2 mM $Os(bpy)_3^{2+}$ and 50 mM NaCl. The oxidation peak current dropped from 3.0 to 1.9 μA upon the addition of 1.7 mM SDS, then continued decreasing, roughly linearly proportional to the SDS concentration, up to about 12 mM. Addition of more SDS depressed the peak current further until 30 mM SDS had been added. The peak current then leveled at 0.55 μA for SDS concentration up to 50 mM. The same phenomenon is observed for MV^+ reduction at different concentrations of SDS,[14] where the reduction current was depressed continually as the SDS concentration was raised above the critical micelle concentration (cmc) (which is 2.25 mM at 50 mM NaCl).

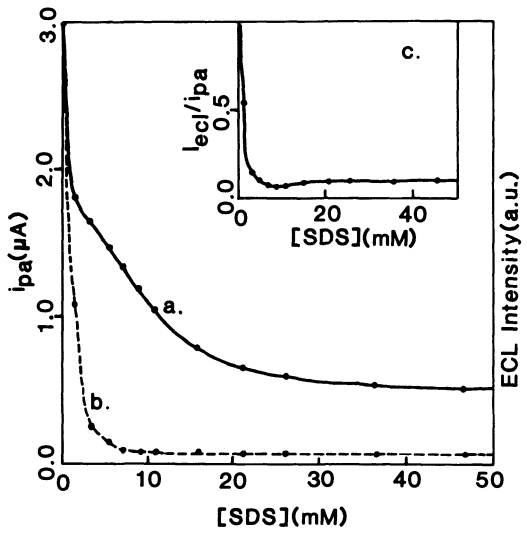

Fig. 3. (a) SDS concentration dependence of peak current for 0.2 mM $Os(bpy)_3^{2+}$ in 50 mM NaCl solution at GC electrode. Scan rate, 100 mV s^{-1}. (b) SDS concentration dependence of ECL intensity of $Os(bpy)_3^{2+}$ in 50 mM NaCl, 20 mM $C_2O_4^{2-}$; (c) ratio of the ECL intensity by the current at corresponding SDS concentration.

Diffusion Coefficients. The diffusion coefficient, D_o, is a measure of the association of electroactive molecules with the surfactant and micelles. Plots of i_{pa} vs. the square root of the sweep rate ($v^{1/2}$) in different media (Fig. 4) are linear, indicating that the electrode reaction of $Os(bpy)_3^{2+}$ is diffusion-controlled in the absence and presence of surfactant. This suggests that the electrochemically active species in the presence of SDS is the micelle-solubilized $Os(bpy)_3^{2+}$ in the bulk solution, since the slope of the i_{pa} vs. $v^{1/2}$ line corresponding to the SDS solution is significantly smaller than those corresponding to the other media. This observation is also clear from the decreased i_{pa} value in CV for a 0.2 mM solution of $Os(bpy)_3^{2+}$ in the presence of SDS micelles as compared to i_{pa}-values in the other media. D_o was 7.3×10^{-6} cm^2 s^{-1} in 50 mM NaCl aqueous solution, while D_o was 3.3×10^{-7} cm^2 s^{-1} in a 70 mM SDS and 50 mM NaCl solution. The decrease in D_o agrees with previous results of other species due to association with surfactants and in micellar assemblies[1a,3a,15] and an increase in the effective radius of the substrate.[16]

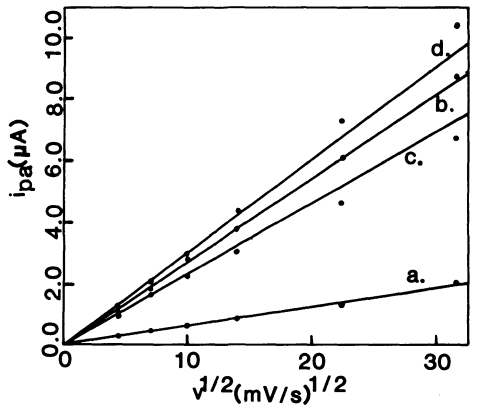

Fig. 4. Scan rate dependence of the anodic peak current for the oxidation of 0.2 mM $Os(bpy)_3^{2+}$. (a) 50 mM NaCl +70 mM SDS; (b) 50 mM NaCl +5% Triton X-100; (c) 50 mM NaCl +70 mM CTAB; (d) 50 mM NaCl aqueous.

The slopes of the i_p vs. $v^{1/2}$ lines in the presence of CTAB and Triton X-100 (50 mM NaCl) deviate little from those in aqueous solution and yield D_o-values of 4.4×10^{-6} and 5.9×10^{-6} $cm^2 s^{-1}$ for $Os(bpy)_3^{2+}$, respectively.

In general, the addition of electrolytes increases the size of ionic micelles.[17] As shown by other experiments[18] with no added salt, the SDS micelles are monodisperse with an aggregation number of 55. The aggregation numbers are 98.6 with 0.189 M NaCl and 162 with 0.424 M NaCl. The larger size of the micelles would suggest a smaller value for D_o. This is contrary to what is shown in Fig. 5, where the slopes of the i_p vs. $v^{1/2}$ line become steeper at higher concentration of NaCl in the presence of SDS micelles. The magnitude of i_{pa} in CV also increases with an increase in NaCl concentration in the presence of SDS. Thus, for example, the diffusion coefficient increased from 3.3×10^{-7} to 1.3×10^{-6} $cm^2 s^{-1}$ when the NaCl concentration increased from 50 to 300 mM. An explanation for this effect is proposed in the Discussion section. In all other media (surfactant-free solution, CTAB and Triton X-100 micellar solution), the addition of more NaCl caused only sight changes in the slopes of i_p vs. $v^{1/2}$ lines; i.e., diffusion coefficients showed only minor changes at higher concentrations of NaCl.

Electrogenerated Chemiluminescence. ECL of $Os(bpy)_3^{2+*}$ has been observed[12] upon the annihilation reaction between electrogenerated $Os(bpy)_3^{3+}$ and $Os(bpy)_3^{+}$ in acetonitrile solution. Because of the limited potential range of water, an alternative method, using oxalate oxidation,[19] to generate the ECL of $Os(bpy)_3^{2+*}$ was tried. When the potential was scanned to positive values in solutions of $Os(bpy)_3^{2+}$ and $C_2O_4^{2-}$, $Os(bpy)_3^{2+}$ was oxidized to $Os(bpy)_3^{3+}$ and $C_2O_4^{2-}$ generated CO_2^{-}, which in turn produced $Os(bpy)_3^{2+*}$.[19] Figure 6 shows the ECL intensity-potential profile for the system of 0.2 mM $Os(bpy)_3^{2+}$, 20 mM $C_2O_4^{2-}$, 50 mM NaCl in aqueous solution. ECL was first observed at the potential where $Os(bpy)_3^{2+}$ is oxidized. No emission was observed at this sensitivity in the absence of $Os(bpy)_3^{2+}$ (Fig. 6a). The addition of 70 mM SDS reduced the ECL intensity twenty-fold. When 5% (w/v) Triton X-100 or 70 mM CTAB was added (50 mM NaCl in solution), the ECL intensity decreased to two-thirds the value found in the absence of surfactant.

The effect of electrolyte concentration on the ECL intensity is shown in Fig. 7. In the SDS micellar media, increasing the NaCl concentration resulted in more intense ECL (Fig. 7a), in the same way that the

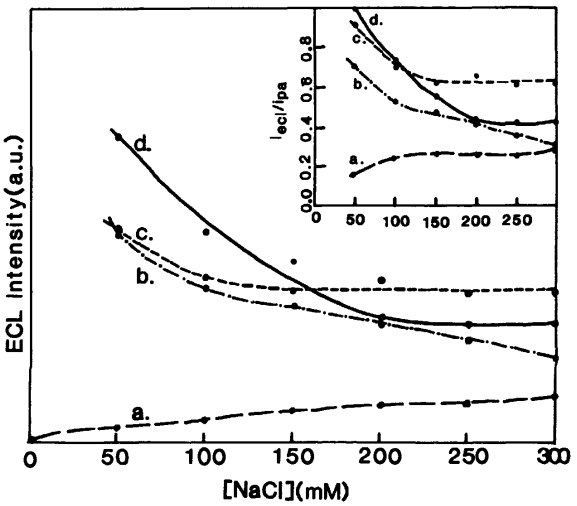

Fig. 7. NaCl concentration dependence of ECL intensity of 0.2 mM $Os(bpy)_3^{2+}$, 20 mM $C_2O_4^{2-}$. (a) 70 mM SDS; (b) 5% Triton X-100; (c) 70 mM CTAB; (d) pure aqueous.

i_{pa}-value increased with the electrolyte concentration. A zero ECL intensity was obtained by extrapolation to zero electrolyte concentration, which is expected from the zero peak current at zero electrolyte concentration (Fig. 2a). For CTAB solutions, the ECL intensity decreased as the NaCl concentration increased from 50 mM to 100 mM and reached a constant value at higher NaCl concentration (Fig. 7c). Similarly the ECL intensity decreased with an increase in NaCl concentration in the Triton X-100 micellar solution (Fig. 7b), which was similar to the ECL intensity change in aqueous solution (Fig. 7b).

The ratio of ECL intensity to peak current (I/i_{pa}) is much lower in an SDS solution than that in all other media at lower NaCl concentration as shown by the insert in Fig. 7. As the NaCl concentration increased, the I/i_{pa} ratio increased at higher NaCl concentration in SDS micellar solution. The ratio decreased for all other media as the NaCl concentration increased, except in the CTAB micellar solution, where the ratio reached a constant value and was larger than that in all other media at higher NaCl concentrations.

The ECL intensity vs. SDS concentration dependence is shown in Fig. 3b. It shows the same trend as the i_{pa}-SDS concentration plot. The presence of 1.7 mM SDS greatly reduced the ECL intensity. The greater the SDS concentration, the weaker was the ECL intensity. At an SDS concentration of 7 mM or higher, only very weak ECL was observed, and the intensities became essentially independent of SDS concentration. Figure 3c is a plot of the ratio of ECL intensity (Fig. 3b) to i_{pa} (Fig. 3a) at each SDS concentration.

Absorption and Luminescence Spectra. The spectroscopic properties of molecules are usually influenced by the environment. Since micelle formation produces a different environment for the solubilized $Os(bpy)_3^{2+}$, the spectroscopic behavior of $Os(bpy)_3^{2+}$ should change upon addition of SDS. Figure 8 shows the absorption spectra of $Os(bpy)_3^{2+}$ in different media. The spectra in CTAB and Triton X-100 micellar solutions were essentially the same as those in the pure aqueous solution. The absorption spectrum changed slightly upon addition of SDS, with the minimum at 460 nm becoming flat. The absorption spectra did not change when the NaCl concentration was varied.

The luminsecence spectra (Fig. 9) were also affected to a greater extent in the presence of SDS. The emission spectra of $Os(bpy)_3^{2+*}$ in 70 mM CTAB and 5% (w/v) Triton X-100 micelle solution were identical to that in aqueous solution with a maximum at about 730 nm. The position of the emission peak was shifted to 765 nm in a 70 mM SDS micellar solution. Since the concentration of $Os(bpy)_3^{2+}$ was the same in all of the solutions of different surfactants and in a 50 mM NaCl aqueous solution alone, and because the absorbances were the same, the fact that the emission intensities were about the same indicates that the quantum yields are about the same in different solutions. Variation of concentration of NaCl did not change the absorption or luminescence spectra in any of the solutions, nor did it affect the absorbance or emission intensities.

The shift in the emission peak for $Os(bpy)_3^{2+}$ in the SDS solution clearly shows an interaction between these species. The effect on the $Os(bpy)_3^{2+}$ emission depends upon whether the SDS concentration is above or below the cmc. The spectrum has a peak at 730 nm in pure aqueous solution. Addition of up to 3.4 mM SDS shifted the peak to 710 nm (a blue shift) (Fig. 9b). The turning point concentration of SDS for the large red spectral shift was near the critical micelle concentration of SDS (2.25 mM); i.e., when the concentration of SDS changed from below the cmc to above it, a large shift in peak position towards longer wavelengths (to 765 nm) resulted. As a comparison, the luminescence spectrum of $Os(bpy)_3^{2+}$ in hexane

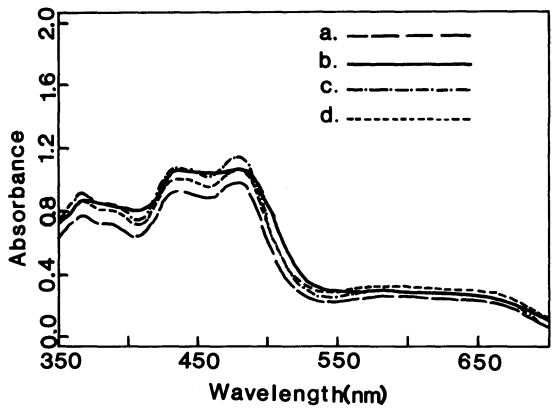

Fig. 8. Absorption spectra of $Os(bpy)_3^{2+}$, in (a) aqueous solution, (b) 70 mM SDS solution; (c) 5% Triton X-100 solution; (d) 70 mM CTAB solution. 1 cm path length cell.

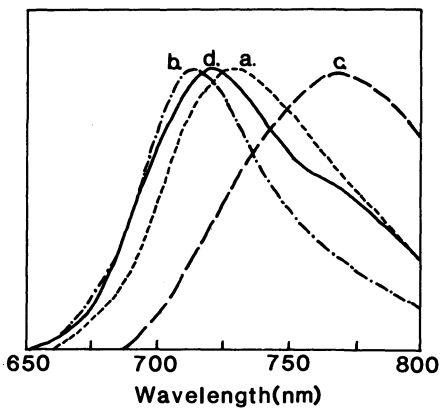

Fig. 9. Luminescence spectra of $Os(bpy)_3^{2+}$, in (a) pure aqueous, or 70 mM CTAB or 5% Triton X-100 solutions; (b) 2 mM SDS solution; (c) 70 mM SDS solution; (d) hexane solution. λ_{exc}=470 nm.

was measured; a shoulder appeared at 767 nm in addition to a peak at 720 nm. Note that a similar emission spectrum shift was reported for [11-(3-hexyl-1-indolyl)undecyl]trimethylammonium bromide around the cmc in an aqueous solution.[20]

Discussion

Dissolved species associate with surfactant molecules in different ways at different surfactant concentrations.[21] Below the critical micelle concentration (cmc), complexes can be formed between dissolved species and surfactant molecules (premicellar aggregates).[14,21] Above the cmc the surfactant exists in solution as micelles, and dissolved species, A, can partition between the micellar and the water phase. Scheme 1 is often used to describe a redox couple in which the oxidized and reduced forms interact with micellar aggregates (when the surfactant concentration is above the cmc).[1a]

$$\begin{array}{ccc} A_M^{(z+1)+} & \underset{-e}{\overset{+e}{\rightleftharpoons}} & A_M^{z+} \\ K_O \uparrow\downarrow & & \uparrow\downarrow K_R \\ A_W^{(z+1)+} + \text{Micelle} & \underset{-e}{\overset{+e}{\rightleftharpoons}} & A_W^{z+} + \text{Micelle} \end{array}$$

Scheme 1.

$K_O=[A_W^{(Z+1)+}][\text{micelle}]/[A_W^{(Z+1)+}]$ and $K_R=[A_W^{Z+}][\text{micelle}][A_M^{Z+}]$ are equilibrium constants, the subscripts M and W indicate the micellar and aqueous phases, respectively; and O and R indicate constants appropriate for the oxidant and reductant, respectively. For a simple reversible one-electron process, the formal standard potential can be represented as $E_W^\circ+(RT/F)\ln K_O(1+K_R)/K_R(1+K_O)$. When $A^{(Z+1)+}$ and A^{Z+} exist predominantly in the micelles, K_O, $K_R \ll 1$, the formal standard potential becomes $E_W^\circ+(RT/F)\ln[K_O/K_R]$. When $A^{(Z+1)+}$ and A^{Z+} exist predominantly in the water phase, K_O, $K_R \gg 1$, the logarithmic term disappears and the potential is E_W°, which represents the formal standard potential of the redox couple in the absence of micelles. The electrochemical evidence presented here indicates predominant existence of $A^{(Z+1)+}$ and A^{Z+} in the SDS micelles. The positive potential shift implies that $K_O > K_R$ and SDS micelles associate more strongly with $Os(bpy)_3^{2+}$ than with $Os(bpy)_3^{3+}$. Higher electrolyte concentrations resulted in a more positive potential shift, which indicates that the association of SDS with $Os(bpy)_3^{2+}$ was enhanced relative to that of $Os(bpy)_3^{3+}$; i.e., $(K_O/K_R)' > K_O/K_R$ where the prime denotes a higher electrolyte concentration. Two types of interactions can be considered between the Os-species and the SDS molecules: electrostatic and hydrophobic. The stronger interaction of the Os(II) species suggests that the hydrophobic interaction, involving the bpy ligands and the hydrocarbon chains on the SDS, is important. A similar phenomenon has been observed for association of SDS with methyl viologens of different oxidation states;[14,15] i.e., SDS associates more strongly with MV^+ than with the MV^{2+} form. Similarly $Ru(bpy)_3^{2+}$ is bound into Nafion more strongly than $Ru(bpy)_3^{3+}$.[22] This was also explained by the importance of hydrophobic interactions between the complex and the nonpolar regions of the Nafion.

The observed depression of the peak current for the oxidation of $Os(bpy)_3^{2+}$ at SDS levels below the cmc indicates that $Os(bpy)_3^{2+}$–surfactant aggregates are formed. By the same argument that has been applied to explain, for example, the shift in standard potential for 10-methylphenothiazine at premicellar concentrations of SDS,[21] the near independence of peak potentials for the oxidation of $Os(bpy)_3^{2+}$ at these levels of SDS indicates that $Os(bpy)_3^{2+}$–SDS and $Os(bpy)_3^{3+}$–SDS complexes have essentially equal formation constants.

At concentrations of SDS above the cmc, the aggregation number of the micelles can be altered by changing the electrolyte concentration in solution.[18] In general, both theoretical treatments[23] and experimental studies[18] show that higher electrolyte concentrations result in larger aggregation numbers. Thus with an increase of electrolyte (e.g., NaCl) concentration, the size of the micelle should increase and its diffusion coefficient should decrease. If the $Os(bpy)_3^{2+}$ contained in the micelle was reduced directly at the electrode, one would predict that the oxidation peak current and the measured D_R would decrease with an increase in NaCl concentration. However, the experimental results showed that i_{pa} (Fig. 2a) and D_R (Fig. 5) both increased with an increase of NaCl concentration. This finding can be explained, however, using the same model as that of Saji et al.,[24] for a similar finding for the oxidation of (11-ferrocenylundecyl)trimethylammonium bromide in the presence of SDS micelles. These authors showed that the ferrocenyl moiety incorporated in the micelle is not electroactive in the absence of added electrolyte. Earlier studies of others, given in this paper,[24] have similarly found that a species incorporated in a micelle could become electroinactive. In the case described here, when $Os(bpy)_3^{2+}$ penetrates the micellar surface, it associates strongly with the hydrocarbon core via hydrophobic interactions. This $Os(bpy)_3^{2+}$ would not be electroactive, since the micelle would prevent it from coming within electron transfer distance to the electrode and small anions would not be available to maintain electroneutrality. These micelle-bound $Os(bpy)_3^{2+}$ species would make no contribution to the anodic current. As found here, increasing the NaCl concentration increases the electroactivity of the micelle-bound $Os(bpy)_3^{2+}$, presumably because of a greater availability of anions to

balance the positive charge formed during the electrode reaction and maintain electroneutrality.

The decrease in i_{pa} in the presence of CTAB, as well as the effect of NaCl concentration on i_{pa}, is much smaller than for SDS. This suggests a much weaker interaction, perhaps because of the electrostatic repulsion between CTAB and $Os(bpy)_3^{2+}$, with the bulk of the current observed in the presence of CTAB originating from $Os(bpy)_3^{2+}$ present in solution. By similar arguments, the interaction of $Os(bpy)_3^{2+}$ and Triton X-100 is even weaker or absent.

In the present experiment, ECL was generated by the following mechanism:[19]

$$Os(bpy)_3^{2+}{}_{(W\text{ or }M)} \longrightarrow Os(bpy)_3^{3+}{}_{(W\text{ or }M)} + e^-, \quad (2)$$

$$Os(bpy)_3^{3+}{}_{(W\text{ or }M)} + C_2O_4^{2-} \longrightarrow CO_2^{-} + CO_2 + Os(bpy)_3^{2+}{}_{(W\text{ or }M)}, \quad (3)$$

$$CO_2^{-} + Os(bpy)_3^{3+}{}_{(W\text{ or }M)} \longrightarrow CO_2 + Os(bpy)_3^{2+*}{}_{(W\text{ or }M)}, \quad (4)$$

$$Os(bpy)_3^{2+*}{}_{(W\text{ or }M)} \longrightarrow Os(bpy)_3^{2+}{}_{(W\text{ or }M)} + h\nu, \quad (5)$$

where the subscripts W and M represent the aqueous and micellar phases, respectively. If we assume the luminescence yields of $Os(bpy)_3^{2+*}$ in the water and micellar phases are the same, there are two main factors affecting the ECL intensities: the amount of $Os(bpy)_3^{2+}$ oxidized to $Os(bpy)_3^{3+}$ and the nature of the environment of the reaction of CO_2^- with $Os(bpy)_3^{3+}$ to generate $Os(bpy)_3^{2+*}$. In aqueous solution in the absence of surfactant and in Triton X-100 micellar solution, the NaCl concentration strongly affected the observed ECL intensity (Fig. 7). While we have not investigated the mechanism of this decrease in intensity with NaCl concentration, it probably involves perturbation of the reaction of CO_2^- with $Os(bpy)_3^{3+}$ [or $Os(bpy)_3^{2+}$]. The ECL intensity of $Os(bpy)_3^{2+*}$ emission in an acetonitrile solution produced by generation of the +1 and +3 species, increases 2.5 times with an increase in tetrabutylammonium hexafluorophosphate from 50 mM to 200 mM. In SDS micellar solution the ECL intensity was lower than that in the other media. As discussed above, the amount of $Os(bpy)_3^{3+}$ generated, i.e., the oxidation current, is decreased in the presence of SDS. This leads to a strong decrease in the ECL intensity. The oxidation current was larger at higher NaCl concentrations, and in addition, the reaction of CO_2^- with $Os(bpy)_3^{3+}$ may take place in an environment that is less strongly perturbed by increases in ionic strength. This can account for the increase in ECL intensity as the NaCl concentration increased. The addition of CTAB decreased the intensity of ECL in 50 mM NaCl. In this case this decreased with added NaCl. The rate of decrease with increasing NaCl was not as high in the presence of CTAB as in aqueous NaCl solutions alone (Fig. 7), so that at NaCl concentrations above 200 mM, the ECL intensity in the presence of CTAB was larger than in its absence.

The luminescence spectra also indicate an interaction of $Os(bpy)_3^{2+}$ and SDS; the spectra strongly depend upon the SDS concentration. At the pre-cmc concentration level, the luminescence spectrum shows a peak wavelength at 710 nm, which is blue-shifted with respect to that at 730 nm in an aqueous solution without SDS. We ascribe this spectrum to an $Os(bpy)_3^{2+}$–SDS aggregate. When the SDS concentration was increased above the cmc, the spectrum showed a red shift with the peak wavelength at 765 nm. This apparently indicates a different type of interaction of $Os(bpy)_3^{2+}$ with SDS micelles than in premicellar aggregates. While the luminescence spectrum has only one peak at 730 nm in aqueous solution, there is additional shoulder at 767 nm in a hexane solution of $Os(bpy)_3^{2+}$. Thus the observed emission peak in SDS micelles at 765 nm can probably be attributed to a hydrophobic interaction.

Conclusion

Electrochemical techniques and ECL were used to study the interactions of the surfactants SDS, CTAB, and Triton X-100 with $Os(bpy)_3^{2+}$ at different concentrations of electrolyte. The $Os(bpy)_3^{2+}$ interacted most strongly with SDS, and at concentrations of SDS above the cmc and in the absence of added electrolyte (NaCl), both the electrochemical response and ECL (in the presence of oxalate) were suppressed. Addition of NaCl caused increases in both anodic current and ECL emission, although the levels remained below those under similar conditions in the absence of SDS. The interaction of $Os(bpy)_3^{2+}$ with CTAB was much weaker, while that with Triton X-100 was almost absent.

The support of this research by the Army Research Office is gratefully acknowledged.

Heat Capacity of CH_3D Adsorbed on Graphite at Monolayer Coverages between 0.3 and 7 K

Akira INABA[†,*] and (the late) James Alexander MORRISON[††]
Department of Chemistry, McMaster University, Hamilton, Ontario L8S 4M1, Canada
(Received August 28, 1987)

Heat capacity measurements have been made on CH_3D adsorbed on exfoliated graphite (Grafoil MAT) over the temperature range $0.3<T<7$ K at two surface coverages near a monolayer, to evaluate predictions of the energy states of the adsorbed molecules, based on earlier studies of the properties of bulk solid CH_3D and other isotopic methanes. Two Schottky-type anomalies are observed with maxima at 2 and 0.1 K; these are consistent with the predictions in a general way.

The heat capacities of bulk solid isotopic methanes have been studied over the years with the fundamental object of understanding molecular energy states—especially those associated with hindered rotational motion of the molecules in the solids. In addition to the original publications, several reviews of the studies are available in papers devoted to the discussion of molecular orientational ordering and related matters. For example, Bloom and Morrison published one such review[1] in 1973. More recently, Yamamoto et al. produced a summary of the theoretical and experimental investigation of solid methane[2] in terms of a specific quantum mechanical model, developed from a classical study.[3] The model is particularly valuable in showing how complicated and difficult the methane "problem" is from both the experimental and theoretical points of view. The methane system shows all of the features of the better-known example of the hydrogen/deuterium system[1] but with more solid phases and phase transitions and a greater number of nuclear spin symmetry species. Finally, a pertinent book on single particle rotations in molecular crystals should be mentioned.[4]

It is obvious that no one technique—either experimental or theoretical—will provide sufficient information to describe orientational motion in solids fully. In the case of the rotational energy of molecules, the characteristic temperature for rotation is generally low, e.g. $\theta_{rot}<87.5$ K for solid methane. (This can be worked out easily from data in Table 1 of Ref. 1.) Thus, contributions which rotational (orientational) motions make to thermodynamic properties and to the magnitude or separation of energy states depend upon θ_{rot}/T. In practical terms, this means that to exploit measured properties, such as heat capacities, to learn about quantum states of molecular solids, we need to make measurements at low temperatures, typically in the region $T<20$ K. Full details can be found in Refs. 1 and 2.

The so-called Schottky anomaly[5] has long been used to deduce information about arrays of energy levels from measured heat capacities and has been widely exploited for this purpose for the solid isotopic methanes.[6] The resulting energies have often been compared and correlated with estimates obtained from measurements of inelastic neutron scattering. In one extensive study[7] of the sequence of molecules, CH_4, CH_3D, CH_2D_2, CHD_3, and CD_4, expected results were obtained for CH_4 and CD_4 but not for the partially deuterated compounds in one of the solid phases, — viz. in phase III. It is the lowest temperature phase that exists under the equilibrium vapour pressure and is thought to have at least three different site symmetries,[8] but that is still not established in fact.[9] The investigation of the discrepancy brought out the following important conclusion which is contained in a direct quotation from Ref. 7.

> "The importance of the partial deuteration is that it defines a molecular axis. Thus, when the molecules interact with sites of lower symmetry, a distinction can be made between orientational levels, where the splitting stems from the change of the molecular axis relative to the site symmetry axes, and tunneling levels, where the splitting arises from overlap between equivalent molecular orientations. It turns out that the neutron scattering and thermodynamic experiments sample the manifolds of energy states in different ways. This is exploited through a model to yield a picture of orientational and tunneling states that is broadly consistent with experimental observation for all of the deuterated methanes including CD_4."

In other words, the combination of heat capacity and neutron scattering data for the solid methanes significantly refined our understanding of orientational and tunneling behaviour in them over what was obtainable from one type of data alone.

The work was extended by Maki in a theoretical study[10] of the much more anisotropic example of a monolayer of CH_3D adsorbed on the surface of a graphite crystallite. Information became available from neutron scattering measurements[11,12] to characterize vibrational/librational/orientational motion of

[††] Professor J. A. Morrison passed away on October 20, 1987. This became his last paper. (Editor)

the CH_3D molecules in this system. With that and his model for the bulk solid methanes, Maki was able to calculate the low temperature heat capacity to be expected for CH_3D on graphite.[10] He made a challenge to experimentalists to test his calculations and the present short paper is about a response to that challenge. The agreement between theory and experiment that is found is remarkably good and very satisfying.

For now, we are content to show that the Maki predictions are borne out by experiment. It will be possible in later publications to report the results of more detailed comparisons. There is also information contained in our measurements about conversion between nuclear spin symmetry species of CH_3D but we shall not deal with it here. The dynamics and mechanism of that process are still not known for certain.[13]

Experimental

The calorimeter assembly was installed in a rebuilt Mark V helium dilution refrigerator[14] (Oxford Instruments Ltd.). The calorimeter vessel was constructed of copper and contained graphite adsorbent in it. It carried a small specially designed needle valve[15] through which the gas to be adsorbed could be filled or emptied quantitatively. The germanium thermometer used had been calibrated by the supplier between 0.05 and 8 K based on the T-76[16] from 0.5 to 8 K and on the CMN magnetic scale below 0.5 K.

An exfoliated graphite called Grafoil MAT from Union Carbide was used after purification and outgassing as the adsorbent for the present measurements. It has a specific surface of 24 $m^2 g^{-1}$ and a bulk density of 0.3 g cm^{-3}.[17] The preparation and analyses of CH_3D of high isotopic purity by gas chromatography have been fully described.[18] The amount of the gas put into the calorimeter vessel was measured volumetrically with uncertainty of about ±0.2%.

One of the main experimental difficulties usually encountered in the heat capacity measurements for such adsorbed system or for small particles is long equilibrium time caused by poor thermal contact between adsorbent/sample and the calorimeter vessel. However, rather unexpectedly, it was found that our calorimeter system could be operated very satisfactorily as experienced many years ago in the heat capacity measurement of small particles of MgO.[19]

The heat capacity of two sub-monolayer samples with 3.014 and 2.590 mmol of the actual amount of CH_3D gas was measured between 0.3 and 7 K. The former corresponds to a coverage of 0.94 monolayer, which slightly exceeds a capacity of the commensurate ($\sqrt{3}\times\sqrt{3}$) structure, and the latter corresponds to a coverage of 0.81 monolayer. The contribution of the monolayer CH_3D to the total heat capacity including the calorimeter vessel was at least 7% at 7 K and amounted up to 95% at 0.3 K.

Results and Discussion

The after-drifts of all of the heat capacity measurements were fitted to an exponential time

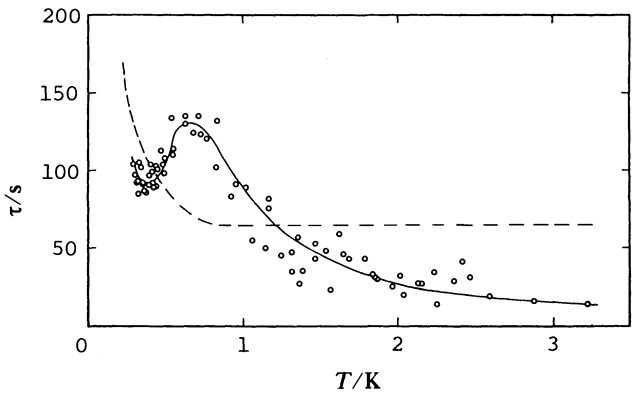

Fig. 1. Relaxation times for thermal equilibration as a function of temperature. ——, the present results for CH_3D/graphite; ------, for the bulk CH_3D.[21]

dependence in order to derive characteristic relaxation times that are plotted as a function of temperature in Fig. 1. About 3 K, they approached those obtained for the calorimeter vessel with graphite alone. The results for the two sets of measurements were indistinguishable and they had a structure with a maximum around 0.7 K, which is different from the behaviour of the bulk CH_3D as investigated by nuclear magnetic resonance[13] as well as by thermal measurements.[20,21]

Two sets of heat capacity measurements at different coverages are essentially indistinguishable from each other below 3 K. The shape of the Schottky anomalies observed is totally different from that of the bulk CH_3D.[20,21] The heat capacity has a broad maximum around 2 K and probably another one at 0.1 K. It means that the manifold of low-lying energy levels in CH_3D on graphite must be considerably different from that known for the bulk CH_3D.[7]

Complete understanding of the shape of the heat capacity curve would require to work out the energy levels of CH_3D molecules on the surface of graphite. Neutron scattering experiments which are being undertaken will certainly provide useful information toward that end, but the present experimental results alone are sufficient to give an insight into the structure of the energy level manifold. Fuller analysis of the heat capacities together with the experimental details will be reported elsewhere when the neutron scattering results have been rationalized.

The research was supported by a grant from the Natural Sciences and Engineering Research Council of Canada and, in part, by a Grant-in-Aid for Scientific Research administered by the Ministry of Education, Science and Culture of Japan. We are grateful to Dr. M. B. Dowell of the Union Carbide Corporation for the preparation of the Grafoil MAT. We thank Mr. W. Scott for supplying liquid helium efficiently. We also thank Dr. R. K. Thomas and Dr. K. Maki for stimulating discussions and helpful

correspondence. One of us (A.I.) would like to thank Professor H. Chihara and Professor M. L. Klein for their continuing advice and encouragement. The other (J.A.M.) wishes to express his long admiration for the high quality of the scientific contributions of Professor Tsunenobu Yamamoto of Kyoto University to our understanding of the methane "problem".

Invited Paper

Chemical Reaction Dynamics—The Study of Molecular Reactivity and Disequilibrium

Rephael David LEVINE

The Fritz Haber Research Center for Molecular Dynamics, The Hebrew University, Jerusalem 91904, Israel

(Received September 16, 1987)

Recent progress in molecular reaction dynamics is discussed with special reference to the selectivity in the reactivity and the specificity in product formation. Topics considered in some detail include dynamical aspects of stereochemistry, rotational state distributions in reactive collisions and intramolecular dynamics of larger molecules. The conceptual foundations of the thermodynamic-like approach to molecular disequilibrium are considered.

1. Introduction

On the molecular level, a chemical reaction occurs when atoms or groups of atoms rearrange themselves so as to result in a new configuration. The process can be intramolecular as in a unimolecular isomerization in the gas phase. It can be intermolecular as in a bimolecular reaction. It can involve several species as in a reaction in a liquid which may require some reorganization of the solvent molecules or as in a reaction catalysed by some surface site. Chemical reaction dynamics[1-15] seeks to understand the motions which occur during the chemical reaction. It asks what are the primary factors which govern these motions. When some understanding has been achieved it seeks to apply the new concepts. The question then becomes which factors are under our experimental control and how can we best manipulate these factors so as to influence the outcome of the chemical reaction on the molecular level.

It is the study of reactions on the elementary level of the isolated chemical act which makes dynamics distinct from its older sister, chemical kinetics. An example will perhaps best serve to illustrate the point. Chemical kinetics studies reactions under bulk conditions. In general, we find that increasing the temperature of the reagents will often increase the reaction rate. This general observation is also correct for example for the reaction

$$H_2 + OH \rightarrow H_2O + H$$

which is of importance in combustion.[16,17] The very concept of 'the temperature of the reagents' is a macroscopic one valid under special bulk conditions when the rate of the chemical reactions is slow as compared to the rate of inelastic energy transfer, collisions. One can then assume that the rapid inelastic collisions maintain the system in a state of thermal (but not chemical) equilibrium. For rapid chemical reactions and particularly so for very exothermic reactions, one typically needs to add to the mixture an excess of buffer gas whose role is to rapidly dissipate any deviations from equilibrium. In a real combustion process, the reagents will often be in marked deviation from thermal equilibrium. We are then faced with the need for dynamics for the following reason. As long as the reagents are in thermal equilibrium there is only one way of changing their energy and that is by heating the system. Temperature is the only relevant factor. Increasing the temperature leads to an increase in the energy content of each degree of freedom of the reagents. At higher temperatures we have the classical 'equipartition' result that each degree of freedom has an energy of $(1/2)RT$ where R is the gas constant ($\simeq$2 cal deg^{-1} mol^{-1}). At low temperatures, the energy content of the vibrational degrees of freedom will be somewhat below the classical value but can be readily computed, if need be, from equilibrium statistical mechanics. The key point is that for chemical kinetics, temperature is the only relevant operational variable for governing the distribution of the reagents over their different energy states (which are electronic, vibrational, rotational, and translational). One cannot selectively increase, say, the vibrational energy content of the reagents. Thermal heating is a democratic process where every degree of freedom receives on equal footing.

Once we need to deal with reagents not in thermal equilibrium, the required understanding changes in an essential way. One will now have to consider different ways in which the energy of the reagents can be changed. Putting a given amount of energy into the relative motion of the reagents (so that they collide with a higher relative velocity) need not change the rate of the reaction to the same extent as putting the same amount of energy in the vibrational excitation. Indeed, there are two modes of vibrational motion, that of H_2 and that of OH. We now know that vibrational excitation of H_2 is much more conducive to reaction than that of OH[18] and we have an interpretation of that selectivity based on the nature of the forces that operate during the collision.[19] One can consider many other types of selectivity. Even for our simple example, recall that OH is a radical with a lone electron in a p orbital. This orbital can be

aligned in space. Equally, OH as a rotating diatomic molecule has a plane of rotation. The p orbital can lie within that plane (a, so called, Π^- state) or be perpendicular to it (a Π^+ state). Are the two states equally reactive? My guess is that the Π^+ state is much more reactive. Much more so than the slight energy difference between the two states (Π^- is lower in energy) would suggest. As far as I know, there is not yet a definite answer but I am fairly certain about my intuitive guess. Yet another selectivity concerns the angle of approach. What is the optimal orientation for the molecular axes of H_2 and OH for reaction to take place. Here too, chemical intuition would lead one to expect that not all orientations are equally reactive and such stereoselectivity[10] can again be related to the nature of the forces during the reactive collision,[20] Fig. 1.

Chemical reaction dynamics is concerned not only with reagents in selected states. Equally of interest is the probing of the state of the products. Of course, this need be done immediately after the reactive collision prior to any secondary collisions. Otherwise the subsequent collisions will rapidly equilibrate the products. In chemical kinetics we characterize the reaction as, say, exothermic. In chemical dynamics we need to know in which modes of motion the excess energy will be found in the receeding products of the reaction. Historically, it was often experimentally easier to probe the products than to select the reagents. Hence much of our initial evidence came from product's analysis.[4] It should however be stressed that the two are obverse to one another. This can be best seen by considering microscopic reversibility as in the following analogy: Imagine a movie showing the motion of the atoms during the collision of the reagents. Repeat the movie many times by using reagents in different energy states. Sometimes, the collision will end up in a reaction having taken place. Other times, the reagents will separate, the collision being nonreactive. Say most of the reactive collisions originated from vibrationally excited reagents. Now run all those movies backwards. Those reactive collisions are now seen to preferentially produce vibrationally excited products. (Recall that for a reactive collision, the roles of reagents and products is reversed when the movie is run in the opposite direction in time). Hence, if the reaction of $OH+H_2$ proceeds preferentially from vibrationally excited H_2 molecules, the reverse reaction, that of $H+H_2O$ will preferentially produce vibrationally excited H_2 products.

It is important to bear in mind that dynamics studies not only scalar quantities such as energy but also vectors such as momenta. Indeed, one of the earliest questions asked in molecular reaction dynamics is what is the disposal of the momentum of the

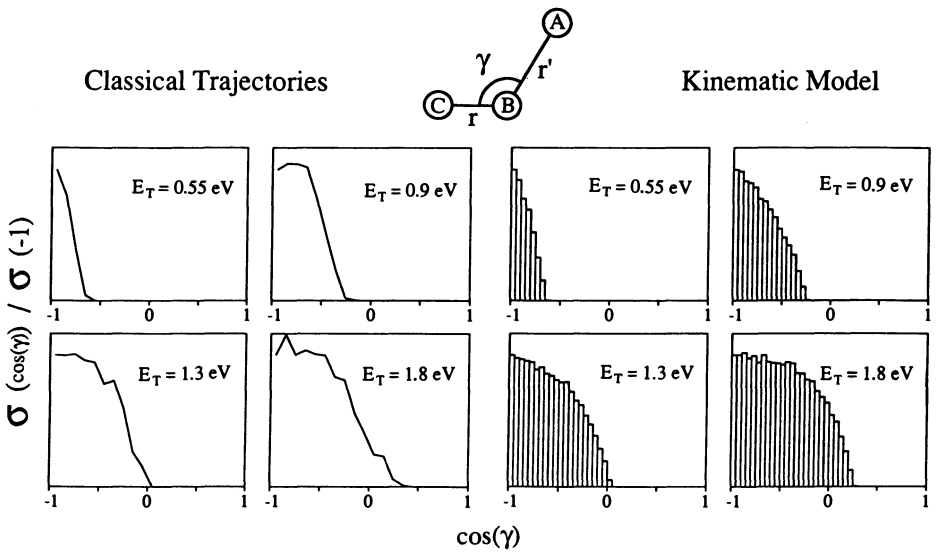

Fig. 1. An example of stereoselectivity. The reactivity in the $D+H_2 \rightarrow DH+H$ elementary reaction as a function of the angle of approach γ of the D atom to the axis of the H_2 molecule (see insert). Left panels: The reactivity computed using the method of classical trajectories[1] at a number of collision energies. Note how the 'cone of acceptance' for reaction opens up at higher collision energies. [For further details, see I. Schechter and R. D. Levine, *Int. J. Chem. Kinet.*, **18**, 1023 (1986)]. Right panels: The reactivity computed using a simple model where reaction takes place if the reactants can cross the barrier for reaction at the angle γ. [For further details, see I. Schechter, M. Prisant and R. D. Levine, *J. Phys. Chem.*, (1987)]. The success of the model shows that the cone of acceptance is governed primarily by the dependence of the height of the barrier to reaction on the angle of approach.

products. In particular, what is the direction of this momentum. To examine the question in detail we need to bear in mind that the motion of the systems' center of mass is unchanged during a chemical process in the gas phase. Hence it is the relative motion that we are really concerned with. So the issue is whether the (relative) momentum is distributed isotropically in space (suggesting that the collision has no memory of any preferred direction as would be the case for a long living collision complex), or not. One of the early indications of nonrandom dynamics was the observation that for many elementary reactions, the angular distribution of the products was strongly anisotropic indicating a very direct, brief process. It was indeed awhile before clear-cut examples of longer-duration reaction processes were discovered.[21] Nor is the study of products' angular distribution usful only for pure gas phase processes. Consider, for example, a beam of molecules incident on a surface at a given angle is the scattering mostly specular, with the angle of scattering about equal to the angle of incidence or is there a wide distribution in scattering angles? The latter is evidence for a trapping-desorption process where the scattered molecules spend some time at the surface prior to their 'evaporation' from the surface.

The study of the orientation dependence of

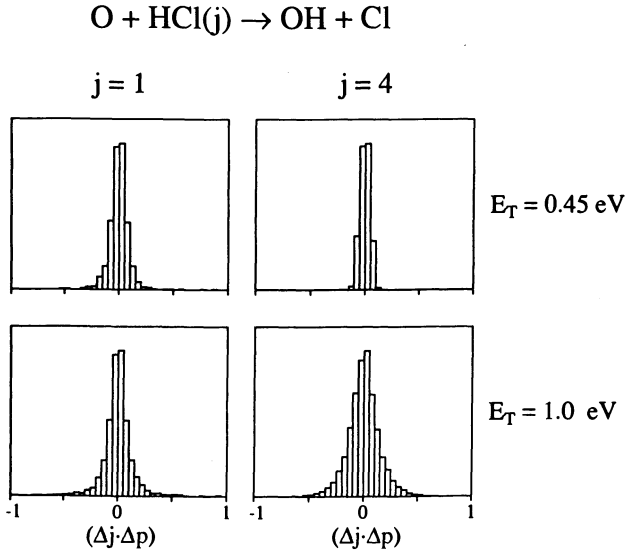

Fig. 2. Angular momentum correlations in the O+HCl→OH+Cl reaction. $\Delta\mathbf{j}$ is the change in the rotational angular momentum (j of OH minus j of HCl). $\Delta\mathbf{p}$ is the change in the linear momentum (momentum of the Cl-OH motion minus momentum of the O-HCl motion). The plot is vs. the scalar product of the unit vectors $\Delta\hat{\mathbf{j}}=\Delta\mathbf{j}/|\Delta j|$ and $\Delta\hat{\mathbf{p}}=\Delta\mathbf{p}/|\Delta p|$. The figure shows that for most collisions that result in reaction $\Delta\mathbf{j}$ is perpendicular to $\Delta\mathbf{p}$. This need *not* be the case in general and can be shown due to the lighter mass of the exchanged H atom. (I. Schechter and R. D. Levine, to be published).

chemical reactivity[10] also belongs to vector dynamics. More recently, the correlation amongst different vectors is also receiving much attention,[22,23] Fig. 2.

Experiments will typically select the reagents before the collision and/or probe the products after the collision. Theory is needed to bridge between these two ends. In their infancy are new experiments which use spectroscopic techniques to monitor the very process of the reactive collision.[24] Here, however, the need for theory is even more acute.

A generation ago, when I began work, the number of theorists actively interested in the field was so small that I could summarize everything I knew in one volume.[25] Less than ten years later two volumes were needed[26] and four volumes were required for a 1985 survey of the theory.[9] It is therefore no longer possible to overview the wide range of theoretical activity in the field. Instead, I have chosen to very briefly discuss one particular approach with which I have been closely associated.

2. The Distribution of Final States

Figure 3 shows the fraction of the total energy, E, carried by a CH_3 group as kinetic energy when an energy rich $Cd(CH_3)_2$ molecule dissociates.[27] The balance of the energy is in the other Cd–CH_3 bond and we have a distribution because a given total energy E can be partitioned in many different ways between the two bonds. Seemingly, the distribution is very asymmetic with the CH_3 group departing preferentially with either very little or with most of the available energy. Yet the theoretical analysis[27] suggested that

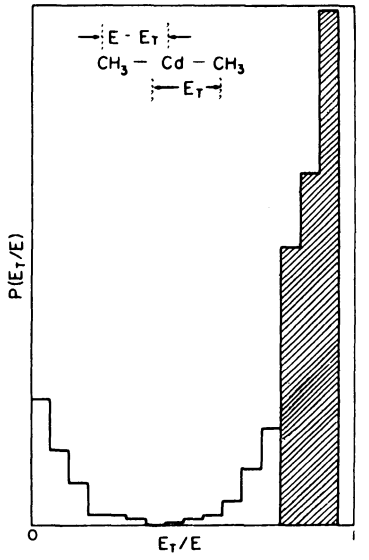

Fig. 3. The distribution of kinetic (E_T) and internal ($E-E_T$, see insert) energies in the dissociation of energy rich $Cd(CH_3)_2$.[27] The shaded region are those dissociating molecules where enough energy is taken by the dissociating CH_3 that $CdCH_3$ is stable.

this is *not* an example of specific energy disposal. Rather, this is what one should expect in the absence of specific effects. A uniform distribution, say, would have been much more surprising. It is not the shape of the distribution *per se* which one takes as evidence of specificity. What then is a disequilibrium distribution?

To answer this question we consider the complementary one: What is an equilibrium (or equipartition) distribution? The answer has been known in thermodynamics for a long time. At a given total energy, equilibrium is when all final quantum states are equally probable. It will take too much time to show that for the system of Fig. 3, the equilibrium distribution in kinetic energy E_T is [27]

$$P(E_T|E) \propto [E_T(E-E_T)]^{-1/2}, \tag{1}$$

which is indeed highly asymmetric. Instead, we consider a simpler case, say the products of the 'simplest' chemical exchange reaction

$$H + H_2 \rightarrow H_2(v=0,j) + H.$$

Here v and j are the vibrational and rotational quantum numbers of the product H_2 molecule. If the total energy is not too high only H_2 molecules in the ground vibrational state (i.e., $v=0$) can be formed. Of course, if reaction readily takes place then there need be enough energy to overcome the barrier along the reaction path.[28] In the products this energy is distributed between the rotation of H_2 about its center and the kinetic energy E_T of the motion of the H atom and the H_2 molecule. If we had to deal only with the H_2 molecule, the computation would be real simple: When H_2 is in the j'th rotational state it corresponds to $2j+1$ distinct quantum states. These correspond to the $2j+1$ distinct orientations in space of the angular momentum vector **j**. Another way of saying this is that a single rotational quantum state of a diatomic molecule is specified by two quantum numbers j and m_j and m_j can take up all integer values from $-j$ to $+j$ inclusive, i.e., $2j+1$ distinct values. When H_2 is in the rotational state j it has a rotational energy, E_j, which at lower j's is given by

$$E_j = Bj(j+1), \tag{2}$$

where B is the rotational constant. The energy which is then available for translation is $E_T=E-E_j$. The higher is the rotational energy of H_2, the less kinetic energy is available for the (relative) motion of H and H_2. Now the translational motion is also quantized. Just as for rotation, the larger the momentum **p**, the more quantum states are accessible. Since however the translational energy is, for all practical purposes, continuously varying, one typically speaks not of the number of such states but of their density, $\rho(E_T)$. It is defined so that there are $\rho(E_T)\delta E_T$ quantum states when the translational energy is confined to the short interval from E_T to $E_T+\delta E_T$. One shows that[1]

$$\rho(E_T) = A_T(E_T)^{1/2}, \tag{3}$$

where A_T depends on the mass. For the H+H_2 reaction we thus have that the density of final quantum states at the total energy E is

$$\begin{aligned}\rho(j,E) &= (2j+1)\rho(E_T) \\ &= A_T(2j+1)(E-E_j)^{1/2}\end{aligned} \tag{4}$$

At low j values, the dominant variation of $\rho(j,E)$ with j is the linear increase with j. As j increases, E_j increases even faster, (cf. (2)) and sooner or later E_j becomes a large fraction of E (Of course, $E_j \leq E$). When that happens, the square root term in (4) becomes rapidly variable and $\rho(j,E)$ decrease and becomes zero at $E_j=E$.

When the reaction is non-specific in its energy disposal we expect that the fraction $P^o(j)$ of H_2 product molecules in the state $(v=0,j)$ be proportional to $\rho(j,E)$

$$P^o(j) = (2j+1)(E-E_j)^{1/2}/\sum_j (2j+1)(E-E_j)^{1/2} \tag{5}$$

The denominator in (5) is simply there to insure normalization, i.e., that H_2 be found in some final j state

$$\sum_j P^o(j) = 1. \tag{6}$$

In both (5) and (6), the value of j is restricted by the

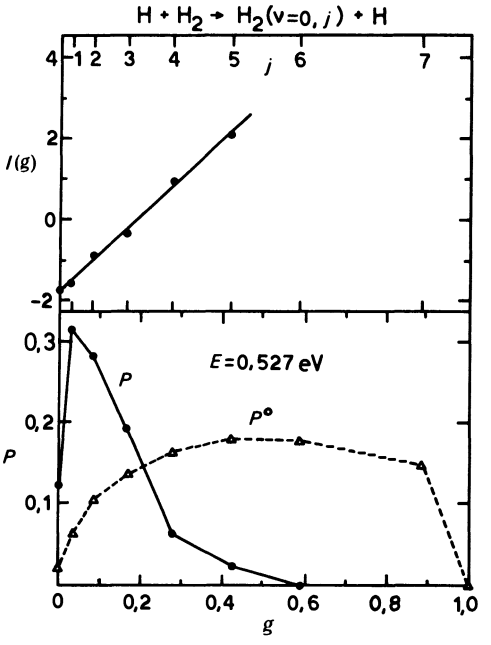

Fig. 4. Specificity of energy disposal. Bottom panel: Quantum mechanical computations (dots, from Ref. 29) and prior distribution (triangles, from Eq. 5) for the product H_2 rotational states vs. the reduced variable $g=E_j/E$. The two are quite different showing that lower rotational states are specifically populated by the reaction. Upper panel: The rotational surprisal, Eq. 7 vs. g. The line corresponds to $\theta_R=8$.

conservation of energy in a single collision, i.e., $E_j \leq E$.

How well does our equilibrium result (5) agree with the observed (or computed[29-32]) results? Not very well. Higher j values, as seen in Fig. 4 are far less probable than their fraction as given by (5). The reaction clearly selectively populates the final rotational states.

One can readily provide also an essentially quantitative characterization of the deviance from equilibrium. As in thermodynamics proper, a system can fail to reach complete equilibrium if it is subject to constraints. A simple example is compressed gas in a cylinder which is constrained from expansion by a piston which is firmly in place. If we free the piston, the gas will expand until its pressure equals the external pressure. A constraint can maintain a system in disequilibrium. This state of disequilibrium is really very simple to characterize: but for the constraint, the system is in equilibrium.

We find that precisely the same holds for disequilibrium in single collisions. The one difference is that the constraint(s), if any, is due to the preparation of the initial state and to the dynamics. The unexpected finding is that the dynamics gives rise to rather simple constraints. To see this, we shall return to the example of the $H+H_2$ reaction, and many others, in section 4.

As in thermodynamics proper we shall characterize the fraction of molecules in any given state by the chemical potential. This means that we regard the H_2 molecules in different quantum states as different and distinct chemical species. This give rise to no essential problem for it is known that a distinct chemical species is any molecule that can be distinguished from others and there are numerous spectroscopic and other methods whereby H_2 molecules in different rotational states can be sorted out. Even the $2j+1$ degenerate m_j states can be distinguished (e.g., by a Stern-Gerlach type experiment). Finally, the different orientations of the momentum $\mathbf{p}$ of the relative motion of H and H_2 can be studied by measuring the angular distribution of the products. Indeed, even in conventional, macroscopic thermodynamics it is sometimes useful to regard molecules in different states as distinct species.[33] Here however we are concerned with the nascent products of a single collision. We discuss the thermodynamics of a single collision in section 3 returning to our main theme in section 4. The reader willing to accept thermodynamic concepts can proceed directly to section 4.

3. Thermodynamics of Collision Processes

A single collision is a system of very finite number of degrees of freedom. Not only finite but often quite small (e.g., six for the three atom H_3 system, including the rotation). There is therefore a question of principle: Are we allowed to use thermodynamics for such a system? Is thermodynamics not a theory or systems of very many degrees of freedom? We have devoted considerable attention[33-38] to this question. Our starting point was information theory,[39] Thereby we have been able to extend the usual machinery of thermodynamics to small dynamical systems. Finally, we have been able to show[37,38] that exact quantum dynamics can be formulated as a thermodynamical theory. We shall return to this point in section 5 below.

The thermodynamical approach to dynamics that we have pioneered enables us to provide a dynamical justification to the procedures discussed section 4. One can wonder however, why do textbooks emphasize the 'large size' of thermodynamics systems. To clarify this point we need to discuss two conceps from probability theory. Since this is a point that many people are concerned about we would like to clarify it in some detail. We do this since the ideas are simple and the source of the confusion is semantic, that is the failure to properly distinguish between two, strictly distinct, concepts.

In the application of thermodynamics to finite, isolated systems it is essential to properly distinguish between the probability of an event (which is what is provided by the theory) and the frequency of an event (which is what is measured in an experiment). As an example we examine the most familiar example, that of tossing a coin. Take an honest coin. We assign a probability of 1/2 to each face. Let us call the two faces A and B. Now let us do an experiment-one tossing of the coin. Say the results is that face A is up. In our experiment the frequency of 'event A' is one and the frequency of 'event B' is zero. The frequency and the probability are quite distinct and both are well defined. Now consider another experiment: The coin is tossed twice. A possible outcome is that the coin fell 'face A up' in the first toss and 'face B up' in the second toss. In this experiment the frequency of 'event A' is 1/2 and so is the frequency of 'event B.' In this experiment the *numerical value* of the frequencies and the probabilities is the same. *However, an equally likely* outcome in our experiment is that the coin fell 'face A up' in both tosses. Then the numerical values of the frequencies and the probabilities would be quite different. Let us now toss the coin three times. A moment's reflection shows that whatever the outcome is, there is just no way for the *observed* frequency in such an experiment to be numerically equal to the *theoretical* probability. Indeed, it rapidly emerges that for any experiment where the coin is tossed an *odd* number of times, the frequency cannot equal the probability! The coin is but the simplest example. Take an honest die with six distinct but equivalent faces. The probability of each face coming up is 1/6. Unless we roll the die $6n$, n integer, times we will *never*

observe frequencies equal to the probabilities. Even if we do roll the die $6n$ times, there is no guarantee that all six faces will show up with exactly equal frequencies. In the great majority of all possible experiments with a die, the experimental frequency is not exactly equal to the probability.

Frequency and probability are thus two, quite distinct, concept which differ not only in their definition but also in their possible numerical values. What then gives rise to the confusion? The blame is on the law of large numbers. This theorem, very loosely stated, says that upon very many repetitions of an experiment, the observed frequencies will have numerical values very close to the theoretical probabilities. Hence the pragmatic result that the numerical value of the probability of an event can be determined as its frequency observed in a very large number of independent repetitions of the experiment. It must clearly however be understood that what the law of large numbers provides is a practical route to the assignment of a numerical value to the probability.

The purpose of the theory is to predict and explain observed results. What the law of large numbers tells us is that for the purpose of comparing observed frequencies with theoretical probabilities we require many repetitions. This is automatically insured if we carry an experiment on the distribution of H_2 rotational states on a macroscpic gaseous sample. Such a sample contains the order of Avogadro's number of molecules. We are thus assured that the observed frequency will be very close to the theoretical probability. The necessary conditions for the validity of the law of large numbers can also however be insured if the experiment is on the H_2 rotational state distribution after a single, isolated $H+H_2$ reactive collision. All that is necessary is that one observes many reactive collisions, each one isolated from the others. The experimenter knows this very well for if too few collisions are observed, the signal will not rise above the noise. The theorist is equally aware of this point on the pragmatic level. An instructive illustration is provided by the very common method — that of the study of the dynamics using classical trajectories.[40] Each one classical trajectory has a definite outcome. To simulate the inherent quantal uncertainty in the initial conditions and the resulting distribution of final states one needs to compute 'many' classical trajectories. How do we know how many is 'many'—by increasing the number of trajectories until the frequencies of the final states settles down to within the desired tolerance.

As a side comment we note the following implication. The method of classical trajectories is very extensively applied. However, as our experiments are reaching for higher and higher resolution we need to run more and more classical trajectories to achieve the corresponding computational resolution. We are already at a level where so many trajectories need be computed that fully quantal methods will soon become computationally more feasible!

4. Surprisal Analysis

As in thermodynamics, we characterize the observed distribution of products in terms of its deviance from a reference. Since we are typically dealing with collisions at a given value of the total energy, the typical reference is that of all final quantum states being equally probable. As discussed in section 2, one seldom fully resolves the final quantum states. Hence one needs to count the number of final states that correspond to the event of interest. For the $H+H_2 \rightarrow H_2(v=0,j)+H$ reaction we have performed the count in section 2 leading to Eq. (5) for $P^o(j)$, the reference or *prior* distribution of H_2 rotational states. We denote by $P(j)$ the actual, observed distribution. The corresponding thermodynamical potential known in this context as the *surprisal* is defined by

$$I_j = -\ln[P(j)/P^o(j)], \tag{7}$$

or

$$I_j = \ln[P^o(j)] - \ln[P(j)]. \tag{8}$$

Figure 4 shows a plot of I_j vs. the rotational energy of the H_2 molecule for a quantum mechanical computation of $P(j)$.[29–31] As is very clear, I_j is linearly dependent on E_j

$$I_j = \theta_o + \theta_R(E_j/E). \tag{9}$$

θ_o and θ_R are two constants, but θ_o is a function of θ_R as can be seen by combining (8) and (9)

$$P(j) = P^o(j) \exp(-\theta_o - \theta_R(E_j/E)). \tag{10}$$

Here $P^o(j)$ is given by (5) and since

$$\Sigma_j P(j) = 1, \tag{11}$$

it follows from (10) that θ_o can be computed from θ_R

$$\exp(\theta_o) = \sum_j P^0(j) \exp(-\theta_R(E_j/E)). \tag{12}$$

Hence the distribution of rotational states is fully characterized by the value of one (intensive) parameter, θ_R.

As in ordinary thermodynamics, one can use either θ_R or the corresponding (extensive) parameter, the mean value, $\langle E_j \rangle$,

$$\langle E_j \rangle = \sum_j E_j P(j), \tag{13}$$

of the rotational energy of the H_2 molecules. Since at a given total energy E, we have $E_j \leq E$, it is advantageous to work with the dimensionless reduced parameter $g \equiv E_j/E$ which spans the range from zero to

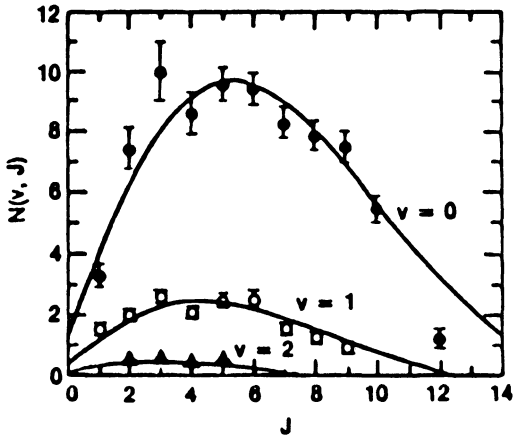

Fig. 5. The observed (points with error bars, from Ref. 41) HD vibrotational populations in the $H+D_2$ reaction using hot H atoms and the fit (curves) to the data using the functional forms (10) and (18) with a prior distribution given by (15). Note that the population scale is linear.

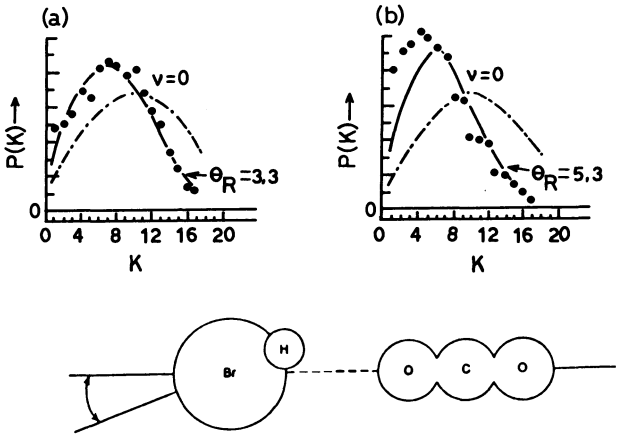

Fig. 6. The OH(v=0) rotational state distribution from the $H+CO_2 \rightarrow HO+CO$ reaction: (a) For a random approach; (b) For a geometry limited approach. Points are experimental data from Ref. 44. The line is Eq. 10 and the dashed line is the prior distribution. K is the OH rotational quantum number. The insert shows the principle of the geometry limited experiment. The $CO_2 \cdot HBr$ van der Waals adduct is photolyzed to yield hot H atoms. The angle of the HBr axis with respect to the CO_2 axis is largely confined to within the range indicated by a (weak, van der Waals) bending potential. Upon photolysis of HBr the H atom approaches CO_2 preferentially collinearly.

one. From (13) and (12) we see that there is a one-to-one relation between $\langle E_j\rangle/E$ and θ_R,

$$\langle (E_j/E)\rangle = \sum_j (E_j/E)P^o(j)\exp(-\theta_R(E_j/E))/\sum_j P^o(j)\exp(-\theta_R(E_j/E)). \quad (14)$$

If $\theta_R>0$ the population of the higher rotational states is below that expected on prior grounds and the value of $\langle E_j\rangle/E$ computed from (14) is below the value computed for $\theta_R=0$ which is the prior limit. If $\theta_R<0$, the higher rotational states are preferentially populated.

This distribution (10) provides an accurate fit for both quantal and classical computations[29-32] of product H_2 rotational distributions. More recently[41,42] using hot (i.e., fast) H atoms generated by laser-pulse photolysis of HBr, it was possible to experimentally resolve the H_2 product rotational states, Fig. 5. It is interesting to comment on the technique used to insure that the nascent products of a single collision are detected. This was achieved by using a second probe laser which is fired after the photolysis laser within a time short compared to the time between collisions. This second laser detects the H_2 products. The prior distribution used in Fig. 5 is not (5) but rather

$$P^o(j,v) \propto (2j+1)(E-E_v-E_j)^{1/2}. \quad (15)$$

The reason is that the hot H atoms carry sufficient energy for the H_2 products to be formed in excited vibrational states. When the H_2 molecule is in the vibrational state v,v=0,1$\cdots$ with an energy E_v, the energy released as kinetic energy is not $E-E_j$ but rather $E-E_v-E_j$. Hence (cf. (4)) is the change between (5) and (15). Otherwise, a single value of θ_R suffices to reproduce the experimental distribution.†

It is only recently that using laser probing, reliable nascent products' rotational distribution became available. Such results have been extensively analyzed using (10). A particularly interesting case, shown in Fig. 6 is the

$$H + CO_2 \rightarrow CO + OH(v,j)$$

reaction. This has been studied both for H atoms approaching CO_2 from all possible directions[43] and for H atoms confined to approach with a cone along the (linear) CO_2 axis. The geometry-limited initial state is achieved[44] by photolyzing the HBr bond in the van der Waals adduct[1] $BrH \cdot CO_2$ formed via a supersonic expansion of an HBr/CO_2 mixture. As can be seen in Fig. 6, both initial states give rise to an OH final rotational distribution which is well described by (10). The value of θ_R is higher for the geometry-limited initial state indicating a stronger preference for rotationally unexcited OH molecules.

Highly exoergic reactions can populate several products vibrational states. Much of the earlier work (reviewed in Ref. 45) in surprisal analysis examined these vibrational distributions which are more readily

† Note that since now $E_j \leq E-E_v$, the reduced variable in (10) is not (E_j/E) but $E_j/(E-E_v)$.

available from experiment. The prior distribution of vibrational states $P^o(v)$ is obtained by summing over all final quantum states where the vibrational state is v. From (15)

$$P^o(v) = \sum_j P^o(v,j) \propto \sum_j (2j+1)(E-E_v-E_j)^{1/2} \quad (16)$$

where summation is over all those rotational states allowed by conservation of energy, i.e., such that $E_j \leq E-E_v$. When the rotational constant B defined (in (2)) is very small compared to $E-E_v$ so that many terms contribute to the sum in (16) we can replace summation over j by an integration over E_j to get

$$P^o(v) \propto \int_0^{E-E_v} dE_j (E-E_v-E_j)^{1/2} \propto (E-E_v)^{3/2}. \quad (16')$$

The observed vibrational state distribution $P(v)$ defines the vibrational surprisal by

$$I_v = -\ln [P(v)/P^o(v)]. \quad (17)$$

Here too it is often the case that the surprisal is a linear function of the vibrational energy so that $P(v)$ can be well represented as

$$P(v) = P^o(v) \exp(-\lambda_0 - \lambda_v (E_v/E)). \quad (18)$$

A recent example, that of the

$$D_2 + F \rightarrow D + DF(v),$$

exoergic reaction at a well defined energy[46] is shown in Fig. 7. Here, as in many other reactions λ_v is negative showing a preferential disposal of the reaction exoergicity into the products vibration.

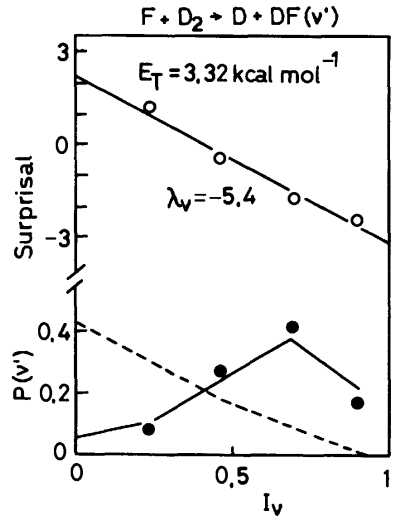

Fig. 7. Surprisal plot for the vibrational energy disposal in the F+D_2 reaction vs. $f_v \equiv E_v/E$. [Adapted from Y. M. Engel and R. D. Levine, *Chem. Phys. Lett.*, **123**, 42 (1986) using the experimental data (points) from Ref. 46]. The distribution (18) is shown as a solid line and the prior distribution (16) is the dashed line. $\lambda_v = -5.4$ as there is specific population of the higher vibrational states.

Microscopic reversibility, as discussed in section 1, can be used to show that the surprisal of the energy disposal equals the surprisal of the energy requirements in the reverse reaction.

Laser probing[7] of the states of molecules after a single collision has also provided much new information on inelastic, energy-transfer collisions. Typically, at energies in the chemical range such processes are constrained by the inefficient conversion of translational to internal energy.[47] Such an 'exponential gap'[1] behavior is illustrated in Fig. 8 for the

$$Xe + HgBr(v=52) \rightarrow Xe + HgBr(v')$$

process,[48] using thermal Xe atoms and HgBr in the $B^2\Sigma$ electronic state. The system 'resists' the change in the internal energy and the surprisal is linearly dependent on the magnitude of the 'gap' in vibrational energy $E_{v'}-E_v$ which is provided from the translation. Note that if $v'>v$, energy is taken out of the initial kinetic energy and the gap is positive, while if $v'<v$, energy is put into the final kinetic energy and the gap is negative. The surprisal which reflects the constraint on a change in energy is however a function of the absolute value of the gap, Fig. 8, and not on its sign.

We have centered attention on bimolecular, intermolecular processes. One can equally discuss intramolecular dynamics. Here we consider a particular aspect, that of optical excitation. When we excite the fundamental vibrational modes of a polyatomic molecule or the lower overtones, we have the limiting behavior familiar from spectroscopy. There are strong selection rules which limit the possible transitions and every spectral line can be assigned to a particular mode of excitation of the molecule. Newer experiments (e.g., Refs. 8 and 49) are preparing molecules with considerable excess energy.

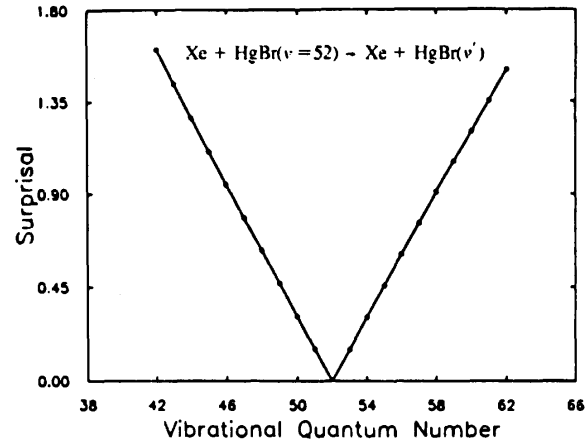

Fig. 8. Surprisal vs. the energy gap for the inelastic collision Xe+HgBr(v)→Xe+HgBr(v'). The surprisal is seen to be a function of the absolute value of the gap. From Ref. 48.

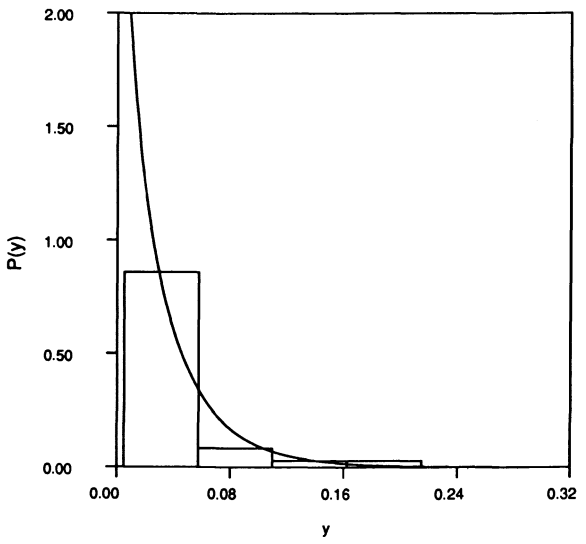

Fig. 9. The distribution of absorption intensities (data of Ref. 51) plottd as a histogram, for a fully resolved spectrum of pyrazine. The smooth curve is the corresponding prior distribution showing that the classical dynamics is chaotic.

There are numerous lines in the spectrum and it is by no means clear that the energy distribution in the optically excited molecule is very selective. It remains the case however that the intensity of lines in the spectrum gives the probabilities of the different transitions. Very recently[50] the thermodynamic approach has been applied to the distribution of intensities in optical spectra. Figure 9 shows the observed distribution[51] for pyrazine near the origin of the $^1Ag0_o^o \rightarrow {}^1B_{3u}$ transition. The coupling of the excited singlet $^1B_{3u}$ state to lower-lying triplet $^3B_{3u}$ states leads to vibrational energy redistribution, which, as shown by the analysis in Fig. 9 is totally non-selective (i.e., chaotic).

5. Thermodynamics

Surprisal analysis is used to quantitatively characterize the selectivity and specificity of chemical reactions and to identify the relevant variables. Can one however *predict* these variables and the parameters (e.g., θ_R, λ_v) directly from the forces that operate during the collision without computing the distributions first? It turns out[37,38] that this can be done if we center attention on the dynamics in phase space.[52,53] That is, we traceout the evolution of the distribution in phase space during the collision. The technical details will require too much space to be spelled out. The essential idea is that it proves possible to use the exponential forms as in (10) or (18) not only after the collision but also in the interaction region. The point of view we suggested earlier namely, that the state of a system is always one of equilibrium subject however to constraints is thereby shown to be equally valid for systems which evolve with time. It thus follows that thermodynamics is indeed also a theory of dynamics and not only of static equilibrium states.

Invited Paper

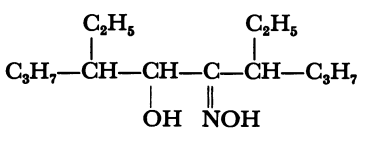
Role of the Interface in Solvent Extraction Processes

Henry FREISER
Strategic Metals Recovery Research Facility, Department of Chemistry,
University of Arizona, Tucson, AZ 85721, U.S.A.
(Received July 20, 1987)

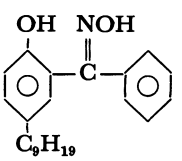
This paper reviews 25 years' investigation of kinetics of metal chelate extraction systems under high speed stirring conditions. Values of chelate formation rate constants for both analytical and hydrometallurgical extractants derived from such measurements using the assumption that the rate-determining step(s) occur in bulk aqueous phase, have been shown to be in reasonable agreement with expectations. Nevertheless, the introduction of the microporous Teflon phase separator in extraction kinetics resulted in clear evidence of reaction pathways involving the interface, as well as the bulk aqueous phase, even for simple chelating extractants.

For the first twenty years of our research into the kinetics and mechanisms of reactions of metal chelate formation and dissociation using solvent extraction techniques,[1] we did not believe that the liquid–liquid (L–L) interface played any significant role. At first, frankly, we simply did not give the matter too much thought. Using high speed stirring, which we believed would eliminate the need to consider mass transfer steps as rate determining, our results led us to conclude that the rate-determining step (rds) was the formation of an intermediate (usually a 1:1) metal chelate complex in the bulk aqueous phase.[2] This conclusion was greatly reinforced by the generally good agreement between the rate constants we calculated for such reactions with those in the literature obtained by a variety of experimental approaches. Since its introduction in 1962, Zangen[3] has successfully employed this technique for the kinetics of formation of Hg(II) complexes, Haraguchi et al. for the study of various Ni(II) complexes,[4,5] and it has also been utilized with kinetic studies of two organic chemical reactions, ester hydrolysis[6] and carbonium ion reactions.[7] While the technique we developed is uniquely useful for systems involving highly insoluble metal chelates, it was especially gratifying to note that it gave results that were in good agreement with those obtained by stopped-flow and other methods in at least two systems, Ni(II)–1,10-phenanthroline[8] and Ni(II)–8-quinolinol.[4]

The introduction of higher molecular weight chelating extractants for large scale, hydrometallurgical metal recoveries in the nineteen sixties and the subsequent study of some of the fundamentals of the behavior of these interesting reagents, served to focus attention on the interesting questions about the role of the interface in such extraction systems. For this reason, we conducted a detailed study of the kinetics of extraction of Cu(II) with aromatic (e.g. LIX 65N) and aliphatic (e.g. LIX 63) hydroxy oximes which were introduced in the 1960s by General Mills for the large scale extraction of copper.[9]



4,7-Diethyl-6-hydroxy-5-decanone oxime
LIX 63



2-Hydroxy-5-nonylbenzophenone oxime
LIX 65N

Previous workers, pointing to the low aqueous solubility of the LIX reagents, intuitively discarded the possibility of chelate formation in the aqueous phase and proposed that interfacial reaction kinetics, rather than homogeneous chemically controlled rates, are dominant.[10–12] Thus, in a review of the kinetics and mechanisms of Cu(II) extraction by LIX reagents, Flett[13] asserted that because these reagents are "so hydrophobic", their aqueous phase solubility could be totally ignored! Having taken this view, when chemical parameters appeared in the extraction rate expressions, these investigators had no choice but to invoke an "interfacial reaction" as the rate-determining step.

A key aspect of the extraction mechanism controversy lies in the nature of the experimental configuration used by various investigators. Under conditions of vigorous shaking[14,15] or high speed stirring,[16,17] mass transfer rates in metal chelate solvent extraction processes are much higher than chemical reaction rates. It is axiomatic that, in any multistep process, the overall kinetics of the process gives information about the slowest, i.e., the rate-determining step. Our high speed stirring apparatus is based on the classical Morton flask assembly[18] and is capable of speeds up to 20000 rpm. Our apparatus[16] is always operated at a stirring speed beyond the level at which the extraction rate becomes independent of the stirring speed. The plateau is a consequence of the balance between dispersion and coalescence, i.e., where further stirring energy does not reduce drop size of the dispersed phase, but simply contributes to overall convective movement in the reaction flask. The data we obtain are highly reproducible and

almost always result in simple experimental rate expressions having very nearly integral reaction orders. Furthermore, the values of chelation rate constants derived from the data are generally in accord with those expected for the substitution rates of metal ions in aqueous media and, where available, in good agreement with published values from studies utilizing independent methods.

In contrast, most others interested in mass transfer kinetics in liquid–liquid distribution systems start by considering diffusion as the primary source of "resistance" and then include slow chemical reaction kinetics as added "resistances", usually without attempting to account quantitatively for the reaction rate constants. These workers tend to favor experiments in which the interfacial area is well known but relatively small. Fixed interfacial area designs[19–24] are rooted in the assumption that the reaction is either diffusion or interfacially controlled. Inasmuch as rate constraints of such reactions must be expressed in terms of unit interfacial area, fixed-interface experiments permit this measurement to be made. Until recently, this has not been considered to be possible with high dispersion experiments because the interfacial contact area is unknown. Most fixed-interface experiments have been performed with either a series of single drops in a continuous phase or a Lewis cell. In the drop method, droplets of one phase are allowed to rise (or fall) through a column containing the second phase. This approach has been criticized for not overcoming diffusion effects in the droplet. The Lewis cell is designed so that both phases stand in contact with each other while each phase is stirred separately. Stirring supposedly overcomes diffusion problems by replenishing the interface with reactant from each bulk phase. Nevertheless, since the vigor of the stirring must be severely limited to avoid vortex formation, it is doubtful that diffusion effects totally eliminated.

We initiated our study of hydroxy oxime extractants with the LIX 65N-copper system. First, we determined the distribution equilibrium of LIX 65N between chloroform and water to be $10^{4.6\pm0.3}$,[17] which means that LIX 65N is significantly less hydrophobic than dithizone. The rate expression obtained from our kinetic data for the extraction of copper by LIX 65N can be quantitatively described by Eq. 1.

$$-\frac{d[Cu^{2+}]}{dt} = k'\frac{[Cu^{2+}][HL]_o^{2.0}}{[H^+]^{1.0}} \tag{1}$$

where HL represents LIX 65N.

From the observed kinetics, a reasonable mechanism for this system identifies the rds as the reaction of CuL^+ with HL (Eq. 4)

$$HL(o) \overset{K_{DR}}{\rightleftharpoons} HL \qquad \text{fast} \quad (2)$$

$$Cu^{2+} + HL \overset{\beta_1 K_a}{\rightleftharpoons} CuL^+ + H^+ \qquad \text{fast} \quad (3)$$

$$CuL^+ + HL \xrightarrow{k_1} CuL_2 + H^+ \qquad \text{slow} \quad (4)$$

$$CuL_2 \overset{K_{DC}}{\rightleftharpoons} CuL_2(o) \qquad \text{fast} \quad (5)$$

where K_{DR} and K_{DC} represent the distribution constants of ligand and chelate, K_a the acid dissociation constant of LIX 65N, and β_1 the equilibrium formation constant of CuL^+ from Cu^{2+} and L^-. The kinetic expression for the rds, Eq. 4, is

$$-\frac{d[Cu^{2+}]}{dt} = k_1[CuL^+][HL] \tag{6}$$

By substituting appropriately from Eqs. 2 and 3 into 6, one obtains Eq. 7, with which the observed dependence on metal ion, ligand, and pH are consistent.

$$-\frac{d[Cu^{2+}]}{dt} = \frac{k_1\beta_1 K_a[Cu^{2+}][HL]_o^2}{K_{DR}^2[H^+]} \tag{7}$$

The extraction of copper by LIX 65N is unusual in that the observed second-order dependence on ligand concentration contrasts sharply with the nearly universally observed first-order ligand dependencies.[25] This behavior is not unique, however, since for d^9 metal ions, the rate constants for the 1:1 and 1:2 complexes are not as different as they are for most other transition metal ions. Further, the observed reaction rate constant, k', is seen to be given in Eq. 8:

$$k' = k_1\beta_1 K_a/K_{DR}^2 \tag{8}$$

Together with the value of K_{DR} as $10^{4.6}$ and k' of 1.37, k_1 for LIX 65N is seen to be 2.2×10^7 M^{-1} s^{-1}, a value that is quite similar to rate constants for typical substitution reactions of Cu^{2+} (the corresponding rate constant for Cu and phenanthroline is only 3 times larger).[26]

Further proof of the mechanism described above was obtained by testing the validity of Eq. 8, using a series of organic solvents in parallel rate studies. Thus, Akiba and Freiser[27] found the observed rate of extraction of copper with LIX 65N, k', to vary by 3 orders of magnitude when seven organic solvents ranging from trichloromethane to heptane were used. The variation of log k' with log K_{DR} was linear and had a slope of -2, as required by Eq. 7. Similarly, in the case of the extraction kinetics of nickel with LIX 65N, which was found to be first order in ligand, the value of the slope of the log–log line of k' vs. K_{DR} is unity, in keeping with the mechanism having as the rate-determining step the formation of NiL^+ in the aqueous bulk phase.[27] The exact correspondence of variation of the observed rates to inverse first (with Ni) and second (with Cu) orders of the ligand distribution constants with the same set of solvents would seem to rule out any influence of interfacial effects in these systems.

Although all of our work to this point convinced us of the primary importance of the bulk aqueous phase

as the site of the rds, the chemical reaction of metal complex formation, this should not be taken to mean that an interfacial influence on extraction kinetics conducted under high-speed stirring conditions will **never** occur. Indeed, in collaboration with Watarai, we set about to search for systems in which just effects could occur by preparing and studying a series of symmetrically dialkylated dithizones, from methyl (HMeDz) to hexyl (HHxDz). An automated solvent extraction apparatus was developed,[28] of which a microporous teflon phase separator (MTPS) is a key element. With the MTPS, bulk organic phase is cleanly separated from a fine dispersion of the two phases in the flask, circulated through a spectrophotometric flow cell, and returned. It seemed appropriate to start with derivatives of dithizone, the extractant having the highest K_{DR} of all of the extractants studied to date. With use of the automated extraction apparatus, at high pH values, a drop in the alkylated dithizone concentration in chloroform was observed; this decrement increased with stirring speed up to a plateau region. The extent of the decrease in concentration varied with pH at stirring speeds in the plateau region in a manner parallel to the nonstirring experiment. The (stirring vs. nonstirring) difference in $pH_{1/2}$ values, $\Delta pH_{1/2}$, (pH at which 50% of the ligand remains in the organic phase) increased from 0.16, 0.66, 3.0, and 5.0 as the alkyl group varied from methyl to ethyl, butyl, and hexyl. No observable change was obtained with dithizone itself.

Interfacial tension (γ_i) measurements were carried out with aqueous phases at two pH values, 3.5 and 12.0, and the following organic phases: HDz in $CHCl_3$, HBuDz in CCl_4, and HBuDz in $CHCl_3$. In the acidic systems, there was no change in γ_i value that could be attributed to the presence of the solute. In the alkaline systems, however, a decrease in γ_i was observed which became linear with an increase of the logarithm of the solute concentration. The slopes of these curves were used to estimate the surface area occupied by one solute molecule, a_m, by means of one form of the Gibbs adsorption isotherm

$$a_m = -kT/(\delta\gamma_i/\delta \ln C)_T \qquad (9)$$

where K is the Boltzmann constant and C is the concentration of solute. The estimated values for a_m (Å^2 molecule^{-1}) were 90 for HDz in $CHCl_3$, 70 for HBuDz in CCl_4, and 150 for HBuDz in $CHCl_3$. The minimum solute concentration required for interfacial saturation, C_m, can also be estimated; the values for $\log C_m$ were -2.2 for HDz in $CHCl_3$, -3.7 for HBuDz in CCl_4, and -2.8 for HBuDz in $CHCl_3$. As might be expected, the greater effect is observed in the poorer solvent. The decrease in interfacial tension under alkaline but not acid conditions suggests that it is the reagent anion rather than the nonionized reagent that is surface active.

The reversible concentration change in organic phase, which was caused by stirring, suggests a significant participation of the liquid–liquid interface in the equilibrium. The interfacial component is less than 3% for dithizone and then rises rather rapidly from 26% in HMeDz to 82% in HEtDz, to 99.9% in HBuDz, and to all but 7×10^{-4}% in HHxDz. These changes are indicative of the dramatic change in the heterogeneous acid–base equilibrium constant (up to a factor of 10^5) that occurs because the anionic alkyldithizonate (but not the neutral ligand) is surface active and is adsorbed into the interfacial region.[29]

The extraction kinetics of nickel and zinc with the alkyldithizonates[29] closely resembled those with dithizone and its analogues studied earlier,[30] in that the rate was first order each in metal and ligand and inverse first order in hydrogen ion. If one were to assume that the mechanism remained the same, however, i.e., that the rds is the formation of the 1:1 complex from metal and ligand anion in the aqueous phase, the resulting second-order reaction rate constants increase with the size of alkyl group until, with the hexyldithizone, the values for both Ni and Zn would exceed the diffusion-limited rate constant for bimolecular reaction!

This unrealistic conclusion is avoided by accounting for the adsorption of the ligand anion in the interface, which is the probable locus for the formation of the 1:1 complex. Calculating the correct value of the ligand anion concentration in the interface from the observed differences in $pH_{1/2}$ values (vide supra) and assuming that since the metal ion is not surface active, its concentration in the interface is the same as it is in the bulk aqueous phase, we obtained values for rate constants that were eminently reasonable, i.e., essentially constant values for all the alkylated dithizones. Log k_1 for Ni and Zn are 5.13 and 8.80, respectively. These are consistent with those obtained from these metals in a broad cross section of ligand-substitution reactions. Essentially the entire cause of the unusual kinetic behavior, as well as of the unusual extraction equilibrium behavior, is the excess concentration of the ligand anion in the interfacial region, which is greatly enlarged by high-speed stirring.

From interfacial tension measurements, together with the use of MTPS, we were now able to interpret the variation of rates of extraction with stirring speed. We wished particularly to understand why, when the ligand anion was adsorbed into the interface, the rates reached maximum values at stirring speeds above 5000—6000 rpm. Combining the interfacial tension measurement of a particular system with the decrements in absorbance, ΔA, observed under stirring conditions, yields the expression:[31]

$$\Gamma a_i = \frac{\Delta A}{\varepsilon} V_o \left(1 + \frac{1}{K_D}\right) \sim \frac{\Delta A}{\varepsilon} V_o \qquad (10)$$

in which Γ is the surface excess in mol cm^{-2} (calculated using Eq. 9 with R instead of k), a_i the interfacial area, ΔA the absorbance decrement obtained with stirring, ε and K_D the molar absorbance and distribution constant of the extractant, and V_o the volume of the organic phase. Since every other parameter in Eq. 10 is experimentally determined, this now serves to evaluate, a_i, the interfacial area. Figure 1 summarizes the results of a study of the variation of interfacial area (recalculated as average drop size) with stirring speed for aqueous–$CHCl_3$ systems containing the extractant bis(*p*-butylphenyl)thiocarbazone (HBuDz), seen previously to function as an anionic surfactant, a neutral surfactant, either Triton X-45 (TX-45) or Triton X-100 (TX-100), or a cationic surfactant *N*-cetylpyridinium chloride (CPC).

As seen in Fig. 1, the average drop size (d) decreases with increasing stirring rate (ω), reaching a minimum at rates of about 80—100 rps, reflecting a balance between breakup and coalescence. It is interesting to note that while the minimum average drop size observed for the butyldithizone and the two Triton X systems was about the same, namely 210±10 μm, that for CPC, a more active surfactant, a measurably smaller average drop size, 160 μm, was achieved.

An interesting question arises about the fate of the adsorbed species when the droplets of organic phase pass through the MTPS. As the organic drops hit and penetrate the MTPS membrane, does the adsorbed species, in many cases relatively hydrophobic, accompany the organic phase, or is it desorbed and returned to be equilibrated with the two phase mixture in the flask? Our standard procedure cannot serve to decide this question because such a small fraction of the droplets of organic phase and their accompanying adsorbed material are removed at any point in time so that the fate of this adsorbate cannot be deduced from this experiment. If, instead of returning the separated organic phase to the reaction flask as before, the return stream goes to waste, however, the organic phase volume will be continuously reduced and the question can be resolved.

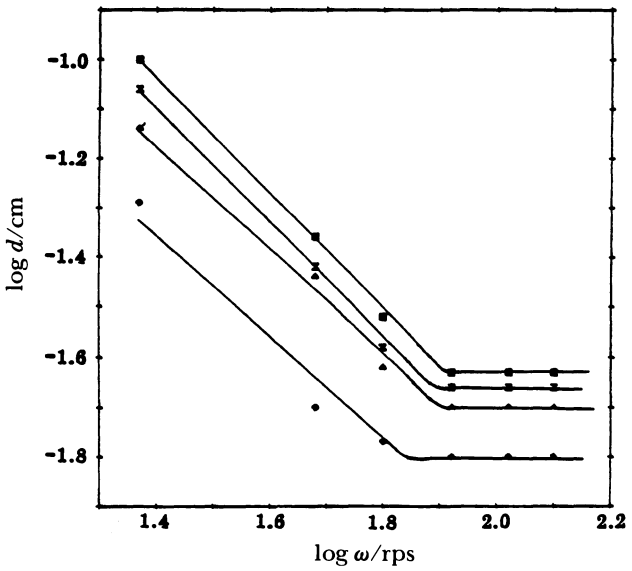


Fig. 1. Drop size as a function of stirring rate. (□) BuDz, (×) TX-100, (◆) TX-45 (▲) CPC.

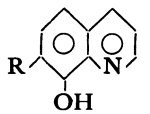
If the first of the two possibilities described above occurs, the observed absorbance should remain constant throughout the experiment. Alternatively, if the adsorbed species were stripped from the interface and returned to the reaction flask as the total organic phase volume and total interfacial area decreased, the absorbance should rise during the course of the experiment.

From such experiments conducted on three systems (LIX 65N in heptane–water, 7-dodecenyl-8-quinolinol [KELEX 100] in xylene–water, and 4,7-diphenyl-1,10-phenanthroline in $CHCl_3$–water) it was evident that the species adsorbed on the interface during the initial phase of the experiment, i.e., before any filtered organic phase is removed, is essentially all retained in the reaction flask.[32] This would be consistent with the positioning of the polar end of the adsorbed species in the aqueous side of the interface and the non-polar position in the organic side. As the phases separate on the MTPS, the adsorbed species are not retained in the aqueous interfacial region. This probably can be attributed to an energetically more unfavorable dehydration of the polar portion of the molecule than desolvation of the nonpolar portion required when the species leaves the organic interfacial region.

Armed with this technique, enabling us to measure and control reliably the interfacial area, we are now in the process of studying the effect of the interface on the overall extraction kinetics in a variety of chelate extraction systems. To begin with, we selected the system, Ni(II)–7-(5,5,7,7-tetramethyl-1-octen-3-yl)-8-quinolinol (KELEX 100) (B)[33] and NI(II)–8-quinolinol (A), because previous studies[34,35] have demonstrated that nickel extraction by 8-quinolinol (oxine) (A) occurs via two reaction pathways: (1) reaction between nickel and neutral oxine and (2) reaction of metal with ligand anion.



(A) R=H

(B) R=-CH(CH=CH$_2$)-CH$_2$-C(CH$_3$)$_2$-CH$_2$-C(CH$_3$)$_3$

In each case, it has been postulated in earlier studies that these rate-determining reactions occur in the bulk aqueous phase. Recent work in this laboratory[25,29] has revealed that, in cases where the ligand anion is a surface active species, the extraction may, at least partially, proceed through a reaction path involving

the interfacial region. Haraguchi and Freiser[36] have found that for KELEX 100 (B), the pH value is affected by high speed stirring, indicating that the distribution of the ligand anion is sensitive to changes in interfacial area. To help answer the question of whether the rate-determining steps for the extraction of nickel by oxine and its higher molecular weight analog, KELEX 100, are taking place in the bulk aqueous phase or in the interfacial region, this system has been studied with the MTPS apparatus.

The rates of extraction of nickel with oxine and KELEX 100 were found to be dependent on hydrogen ion concentration raised to a fractional power,[34,35] indicating two concurrent pathways whose rate determining steps involve either neutral and anionic forms of the ligand. These two paths had been previously presumed to occur strictly in the bulk aqueous phase. Finding that an increase in interfacial area can cause a drop in absorbance of the neutral reagent in the bulk organic phase under alkaline conditions, however, suggests that the ligand anion is surface active.[29] This leads to the possibility that the reaction of nickel with ligand anion may, at least in part, involve an interfacial reaction mechanism.

It was determined from the drop in absorbance of the species in the organic phase upon stirring, that at pH 11.3, the oxine anion exhibited an interfacial excess of 3×10^{-12} mol cm^{-2}, while for KELEX 100 the excess by 6×10^{-12} mol cm^{-2}, twice that of oxine. Even in the case of KELEX 100, the value of Γ is equivalent to each molecule occupying about 2800 Å^2 of interface, a value much larger than that expected for an interface saturated with a monolayer of the molecules. The rather small Γ values indicate that these species are only weakly surface active, yet even this leads to the kinetic effects observed.

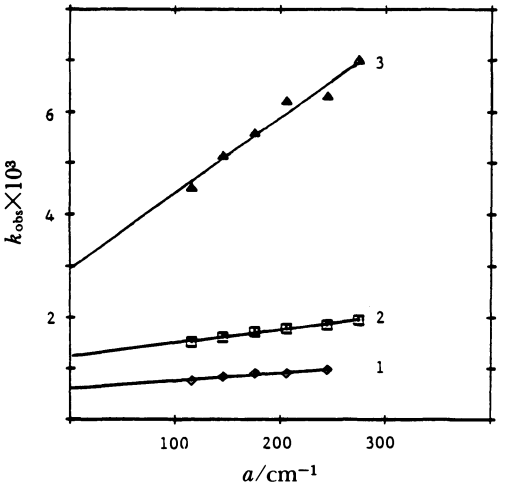


Fig. 2. Specific interfacial area dependency of nickel extraction by KELEX 100. (1) pH 7.27; (2) pH 7.7; (3) pH 8.45, Conditions: (KELEX)=1×10^{-2} M; ($NaClO_4$)=0.1 M; (Ni)=1×10^{-4} M.

In order to evaluate the role of the interface in the extraction kinetics of nickel with 8-quinolinols, the rates of reaction were measured as a function of specific interfacial area (interfacial area per unit volume of the organic phase). The results are illustrated in Fig. 2 for KELEX 100. The experiments were run over a range of pH values to see how the ratio of neutral to ligand anion would affect the balance between the two possible pathways (bulk and interfacial). The results, which indicate that the pH of extraction is very important in determining what combination of mechanisms is operative, can be rationalized by the reaction scheme illustrated in Fig. 3.

This scheme allows for three distinct concurrent reaction pathways: Path 1: Reaction between metal and neutral ligand in the bulk aqueous phase. Path 2: Reaction of metal with ligand anion in the bulk aqueous phase. Path 3: Reaction of metal and ligand anion in the interface.

Evidence in support of this reaction scheme is seen in Fig. 2. In the low pH range, the rate constants are relatively independent of specific interfacial area. In this range the neutral form of the ligand predominates, and its reaction with nickel ion occurs in the bulk (path 1). Inasmuch as the neutral ligand shows no observable surface activity lends support to the likelihood of a purely bulk phase reaction.

With increasing pH, increases in both slopes and intercepts is observed, indicating the dual anion mechanisms (paths 2 and 3). The significance of the increasing intercept is that, in the limit of zero interfacial area, the rate increases with pH, as required by a bulk phase reaction of the ligand anion.

The increase of the observed rate with interfacial area is heightened with increasing pH, demonstrating that the ligand anion participates in a rate-determining step at the interface (path 3).

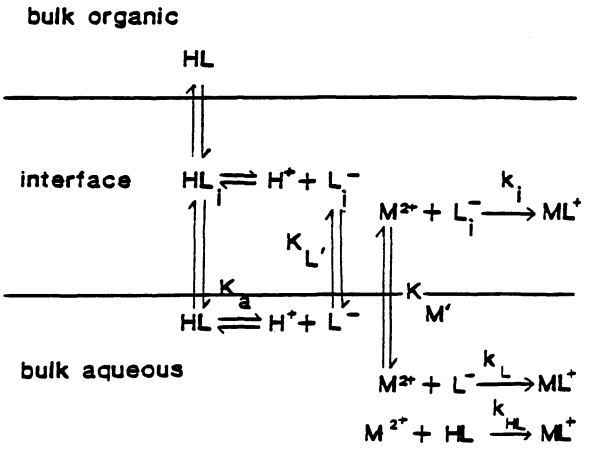

Fig. 3. Schematie mechanism of Ni(II)-8-quinolinol extraction system.

These findings can be represented quantitatively by the following derived relations:

$$-\frac{d[Ni]}{dt} = k_{obs}[Ni] \tag{11}$$

$$-\frac{d[Ni]}{dt} = \left(k_{HL} + k_L \frac{K_a}{[H^+]}\right)\frac{[HL]_o[Ni]}{K_D} + k_i K_{M'} K_{L'} ad \frac{K_a}{[H^+]} \frac{[Ni][HL]_o}{K_D} \tag{12}$$

$$k_{obs} = \left(k_{HL} + k_L \frac{K_a}{[H^+]}\right)\frac{[HL]_o}{K_D} + k_i K_{M'} K_{L'} ad \frac{K_a}{[H^+]} \frac{[HL]_o}{K_D} \tag{13}$$

where k_{obs} is the observed pseudo-first-order rate constant, k_{HL} is the second-order rate constant of metal plus neutral ligand in the bulk aqueous phase, k_L is the second-order rate constant for metal plus ligand anion in the bulk aqueous phase, k_i is the interfacial rate constant, K_a is the acid dissociation constant (pK_a 9.90 and 10.40 for oxine and KELEX 100, respectively[36]), K_D is the distribution constant of the neutral ligand ($10^{2.6}$ and $10^{5.52}$ for oxine and KELEX, respectively[39]), K_M is the distribution constant of the metal between the interface and bulk aqueous phase, K_L is the distribution constant of the ligand anion between the interface and the bulk aqueous phase, d is the thickness of the interface, and a is the specific interfacial area. A plot of k_{obs} vs. a (Fig. 2) permits the evaluation of all the rate constants, provided the other values are known. The excellent linearity seen in the plots confirms the applicability of Eq. 13.

The only unknown values in Eq. 13 are $K_{M'}$, $K_{L'}$, and d, since it is assumed that the metal is not surface active, $K_{M'}$ is taken as unity. The values of the produce of (K_L, d) can be obtained by measurement of $\Delta pH_{1/2}$. This relation[29] is

$$10^{\Delta pH_{1/2}} - 1 = K_{L'} ad \tag{14}$$

The $\Delta pH_{1/2}$ value for oxine was 0.03±0.01 and that for KELEX 100 was 0.8±0.6, yielding the values from Eq. 14 of ($K_{L'}$ ad) as $10^{-3.6\pm0.2}$ for oxine and $10^{-1.7\pm1.0}$ for KELEX 100.

The values of the slopes and intercepts of the lines in Fig. 2 can be used to evaluate all three rate constants, as well as the degrees of contribution of the three pathways. Results are tabulated in Table 1 along with values from other studies. A similar ligand, 8-mercaptoquinoline, is included for comparative purposes.

Table 1. Summary of Rate Constants for Nickel Extraction With Oxine and Its Analogs

Extractant	Log k_{HL} / $M^{-1}s^{-1}$	Log k_L / $M^{-1}s^{-1}$	Log k_i / $M^{-1}s^{-1}$
Oxine[a]	2.97	5.46	6.7±0.2
Oxine[b]	3.55	5.73	
Thiooxine[c]	3.45	5.45	
KELEX 100[a]	4.4	6.8	6.7±1.0
KELEX 100[d]	3.74		6.92

a) Present work. b) Reference 34. c) Reference 38. d) Reference 35.

These results are in fairly good agreement with Yamada et al.[34] for the Ni(II)-system, dispite the different assumptions about the reaction mechanism. The 10 fold higher interfacial rate constant we reported[33] can be accounted for in terms of the different environment in the bulk and interfacial phases. For example, the dielectric constant at the interface may be somewhere between that of the bulk solvents, and hence lower than that of bulk water. This would be expected to be a more conducive environment for the reaction involving charge neutralization, as is the case here. Also, the number of degrees of freedom for the adsorbed ligand should be lower at the interface, than the free anion in bulk water, resulting in a more positive entropy change. In addition, the geometric orientation of the weakly surface active chelating agent may be affected by the different environment that the interface provides. The polar chelating group is expected to be pointing towards the aqueous phase which will also enhance the chances of reaction. These factors would all lead to the observed larger interfacial rate constant found for oxine.

Although the more hydrophobic KELEX 100 anion is more highly adsorbed into the interfacial region than is the 8-quinolinolate (i.e., K'_L is higher) and thus a greater proportion of the reaction of the anion with Ni^{2+} takes place in that region, it is interesting to note that the corresponding rate constants, k_L and k_i, are not different. Thus, the interfacial region would seem to have an essentially aqueous character. Further investigation is necessary to obtain a general answer to the question of how the interfacial and bulk rate constants compare to one another.

The finding in this study of a three path reaction mechanism for the extraction of a well-known, simple, chelating system indicates the complexity that may be involved. The usefulness of the new extraction kinetics apparatus as a diagnostic tool for evaluating the role of the liquid–liquid interface in solvent extraction systems has been demonstrated. The ability to differentiate between bulk phase and interfacial reactions can be very important in the design of improved extractants, as well as in the understanding of the fundamental chemical properties of the liquid–liquid interface.

The interest in the role of the interface in solvent extraction processes will almost certainly result in significantly improved understanding of the details of the fundamental nature of such processes which will have positive benefits in practical applications of the

technique of solvent extraction, as well as to other fields of research involving surface forces.

Much of the research described here was conducted with the support of the National Science Foundation. In addition, I would like to express my appreciation to my Japanese coworkers for their great contributions to this and other aspects of my research.

(Received August 4, 1987)

This paper describes studies of a new class of cytochrome P-450 model compounds called the "picnic basket porphyrins." The picnic basket porphyrins are unsymmetrical porphyrins with one face sterically protected by a superstructure and the other unhindered. The manganese(III) porphyrins have been investigated as shape selective catalysts using oxygen atom donors in the presence of a sterically bulky imidazole. This paper presents ligand binding studies and competitive olefin epoxidations which lead to the surprising conclusion that catalysis by the manganese picnic basket porphyrins occurs exclusively on the sterically unhindered face indicating reaction by the minor catalyst component and not the selective major catalyst component.

Synthetic metalloporphyrins have received considerable attention as olefin epoxidation and alkane hydroxylation catalysts, and, thus, as models of the enzyme cytochrome P-450.[1,2,11,26,28] As catalysts metalloporphyrins are sometimes limited by their low turnover numbers and difficult syntheses, yet some have shown good shape selectivity (cis versus trans olefins) and modest asymmetric induction in olefin epoxidation.[2]

Most studies of catalysis have utilized oxygen atom donors including iodosylbenzene, hypochlorite, hydrogen peroxide, alkyl hydroperoxides, or amine *N*-oxides to generate the metalloporphyrin-based oxidant. In addition, several examples of apparent activation of dioxygen to oxidize substrates employing reducing agents and metalloporphyrins have been reported.[3] In most of these examples, however, it is not clear if metal-bound dioxygen is actually being activated or if catalysis is mediated by free hydrogen peroxide or peracids formed under these conditions.

While metalloporphyrins have limited practical applications, studies of oxygenations by metalloporphyrins and their selectivity have been useful in understanding the mechanism of cytochrome P-450 activity. This family of heme containing monooxygenases catalyze the oxygenation of organic substrates using dioxygen and NADH. Many key steps in the activation of oxygen by cytochrome P-450 and the subsequent oxidation of substrates are still not well-understood.

In an attempt to learn more about this important enzyme, we have prepared a new family of porphyrins called the "picnic basket" porphyrins, which are designed to exclude bulky axial ligands and yet allow small molecules like dioxygen to bind within the pocket.

In our investigation of these porphyrins we were particularly interested in probing the selectivity of the pocket toward axial ligands and olefin structure in catalytic epoxidations. Since we hope eventually to use the picnic basket porphyrins to activate dioxygen, information about the substrate selectivity within the pocket would allow us to determine whether bound dioxygen was activated in this cavity or whether catalysis was mediated by a free oxygen atom donor as discussed earlier. This paper describes the synthesis of the picnic basket porphyrins, ligand binding studies, and results from competitive olefin epoxidation. These studies led to unexpected conclusions about catalysis by manganese derivatives of the picnic basket porphyrins.

Experimental

Materials: Methylene dichloride, chloroform, tetrahydrofuran, 30% hydrogen peroxide and basic alumina (activity I) were purchased from J. T. Baker Chemical Company and used without further purification. Anhydrous manganese(II) bromide, 1-methylimidazole, (diacetoxyiodo)benzene, and *N*,*N*-dimethylformamide were purchased from Aldrich Chemical Co. and used as received. 2,6-Lutidine was purchased from Aldrich Chemical Co. and was dried by stirring over KOH and distilling from BaO. Manganese tetraphenylporphyrin (TPP) and tetramesitylporphyrin (TMP) were prepared as described in the literature. Iodosylbenzene was prepared from the diacetate by basic hydrolysis. 1,5-Diphenylimidazole was prepared by a modified literature procedure.[4] $\alpha,\alpha,\alpha,\alpha$-Tetrakis(*o*-aminophenyl)porphyrin was prepared as reported in the literature.[5] Manganese(III) porphyrin salts of various counterions were prepared from the corresponding bromide using the method of Bruice et al.[25]

Methods: Visible spectra were recorded either on a Varian Cary 219 Spectrometer or with a Hewlett Packard 8450A Diode Array Spectrometer with 7470A Plotter. In order to obtain reproducible spectral titrations, all glassware was treated with 5% aqueous NaOH for 12 h, rinsed, and then soaked in dilute aqueous HBr for 12 h. Spectra were recorded of CH_2Cl_2 solutions, at 25.0±0.5 °C, from 700 to

300 nm in a 1 cm pathlength cell. The concentration of Mn(PBP)Br was approximately 2×10^{-5} M and the imidazole concentration ranged from 0 to 20 mM. *N*-Substituted imidazoles were added to the cuvette from standard stock solutions via microliter syringe. Data were analyzed by the method of Dolphin and James.[6] Cyclic voltammograms were obtained using a Princeton Applied Research wave generator and a Hewlett Packard x-y recorder. $E_{1/2}$ values were measured for CH_2Cl_2 solutions containing 0.2 M tetrabutylammonium perchlorate (TBAP) as electrolyte at a glassy carbon electrode and are referenced to SSCE. All measured $E_{1/2}$ values are for reversible (ΔE_p=60—80 mV) or quasireversible waves (ΔE_p=80—110 mV). Epoxide production was monitored on a Hewlett Packard Model 5880A gas chromatograph fitted with a 15′×1/8″ column of OV-101 on Supelcoport. Chiral shift ^{1}H NMR was accomplished by adding Tris[3-(heptafluoropropylhydroxymethylene) (+)-camphorato]europium(III) [Eu(hfc)$_3$] (Aldrich) to a NMR sample of the isolated epoxide until the epoxide signals were resolved.[2a]

Synthesis: Bis(5-nitroisophthalamido)-α,α,α,α-tetrakis-(*o*-aminophenyl)porphyrin (2). The reaction was carried out under a rigorously dry nitrogen atmosphere using oven-dried glassware. 5-Nitroisophthaloyl chloride (3.968 g, 16.0 mmol) in dry CH_2Cl_2 (100 mL distilled from P_2O_5) was slowly added, with stirring, to a solution of α,α,α,α-TAMPP (340 mg, 0.50 mmol) in CH_2Cl_2 (1.0 L) containing pyridine (10 mL) in an ice bath. After stirring for 12 h at 0 °C the solution was treated with aqueous $NaHCO_3$ solution. The solution was filtered through a celite pad and the pad was washed with 9:1 EtOH-$CHCl_3$. After separation of the organic layer, the aqueous layer was extracted with two 100 mL portions of $CHCl_3$. The combined organic layers were washed with two 100 mL portions of saturated $NaHCO_3$ and with two 100 mL portions of water, reduced to a small volume, and purified by chromatography on a silica-gel column, eluting with $CHCl_3$ to 20:1 EtOH-$CHCl_3$. A purple band was cleanly separated. The product was crystallized by addition of EtOH and slow evaporation of the solvent and dried in vacuo (10^{-6} Torr) to yield 500 mg (24.4%) of purple crystals. ^{1}H NMR (CF_3CO_2D-$CDCl_3$) δ=9.06 (s, 4H), 8.81 (s, 4H), 8.57 (d, 4H), 8.43 (d, 4H), 8.16 (m, 4H), 7.97 (t, 4H), 7.72 (d, 4H), 7.01 (s, 2H). UV-vis (5% EtOH-$CHCl_3$) λ 449, 512 (sh), 545, 582, 618, 674 nm. IR (KBr) 3411 (vs), 1690 (vs), 1582 (s), 1526 (vs), 1449 (s), 1347 (m), 1313 (s), 967 (m), 812 (m), 800 (m), 759 (s), 723 (s) cm^{-1}. MS *m/z* 1025 (M+H).

Bis(5-aminoisophthalamido)-α,α,α,α-tetrakis(*o*-aminophenyl)porphyrin (3). The dinitro compound **2** (1.375 g, 1.34 mmol) was dissolved in a mixture of trifluoroacetic acid (20 mL) and acetic acid (50 mL) cooled in an ice bath. To this solution was added a concentrated hydrochloric acid solution (7.5 mL) of $SnCl_2\cdot2H_2O$ (9.07 g, 40.2 mmol); the mixture was then stirred for 6 h in an ice bath. The reaction mixture was slowly poured into aqueous $NaHCO_3$ in an ice bath. The resulting mixture was filtered through a celite pad. After removal of the water the celite pad was washed with 40% EtOH-$CHCl_3$ (about 500 mL) until the filtrate was nearly colorless. The organic solution was washed with saturated aqueous $NaHCO_3$ and then with water and dried over $MgSO_4$. The solution was concentrated in vacuo and the fine purple crystals which precipitated were centrifuged and washed with EtOH. After drying (10^{-6} Torr, 60—70 °C, 12 h) solvent-free diamine was obtained in 68% yield (884 mg). ^{1}H NMR (CF_3CO_2D-$CDCl_3$) δ=8.89 (s, 4H), 8.58 (s, 4H), 8.39 (d, 4H), 8.14 (m, 8H), 8.01 (t, 4H), 6.94 (s, 2H). UV-vis (5% EtOH-$CHCl_3$) λ 428, 490 (sh), 524, 563, 598, 653 nm. IR (KBr) 3453 (m), 3411 (s), 1681 (vs), 1579 (vs), 1520 (vs), 1446 (vs), 1341 (s), 1298 (s), 1239 (m), 964 (s), 884 (m), 806 (s), 791 (s), 757 (vs) cm^{-1}. MS *m/z* 964 (M−1).

General Method for the Synthesis of Amide-Strapped "Picnic Basket" Porphyrins 4a—e. The following reaction was carried out under a rigorously dry nitrogen atmosphere. To a dry $CHCl_3$ solution (50 mL) containing dry pyridine (0.5 mL), both a DMF solution (3 mL) of the diamine **3** (20 mg, 0.0207 mmol) and a CH_2Cl_2 solution (3 mL) of the diacid chloride (0.03 mmol) were added at the rate of about 10^{-2} mL min^{-1} by means of a syringe pump. After the addition was complete the mixture was stirred for an additional two hours. The reaction mixture was washed with two 20 mL portions of saturated $NaHCO_3$ and with two 20 mL portions of water. After the solvent was evaporated in vacuo, the residue was chromatographed on silica gel, eluting with 5% MeOH-CH_2Cl_2 (or EtOH-$CHCl_3$). A bright purple band was cleanly isolated. The fine red-purple crystals obtained on slow evaporation of the solvent were washed with EtOH and dried in vacuo (10^{-6} Torr, 60 °C, 12 h) to give the amide-strapped picnic basket porphyrins (**4a—e**).

General Procedure for Metallation of H_2(PBP) with Mn. Unmetallated picnic basket porphyrin (100 μmol), anhydrous $MnBr_2$ (215 mg, 1 mmol) and 20 drops of 2,6-lutidene were heated at reflux in 25 mL DMF under air in a 50 mL round bottom flask fitted with a magnetic stirrer and

a condenser. After 5 h at reflux, UV-vis spectral analysis indicated complete metallation. The reaction mixture was cooled to room temperature and poured into 600 mL deionized water. The precipitate was collected by filtration through a Celite pad and washed liberally with deionized water. The crude product was extracted from the Celite with $CHCl_3$ and the filtrate reduced on a rotovap. The green residue was dissolved in 20 mL CH_2Cl_2 and loaded onto a basic activity I Al_2O_3 column (3.5 cm diameter×8 cm) prepared from CH_2Cl_2 slurry. The desired green band was obtained by elution with $CHCl_3$. The $CHCl_3$ layer was washed three times with 100 mL saturated aqueous KBr in a separatory funnel and passed through crystalline KBr. Removal of solvent and drying the residue provided the desired Mn(PBP)Br in 80—85% yield.

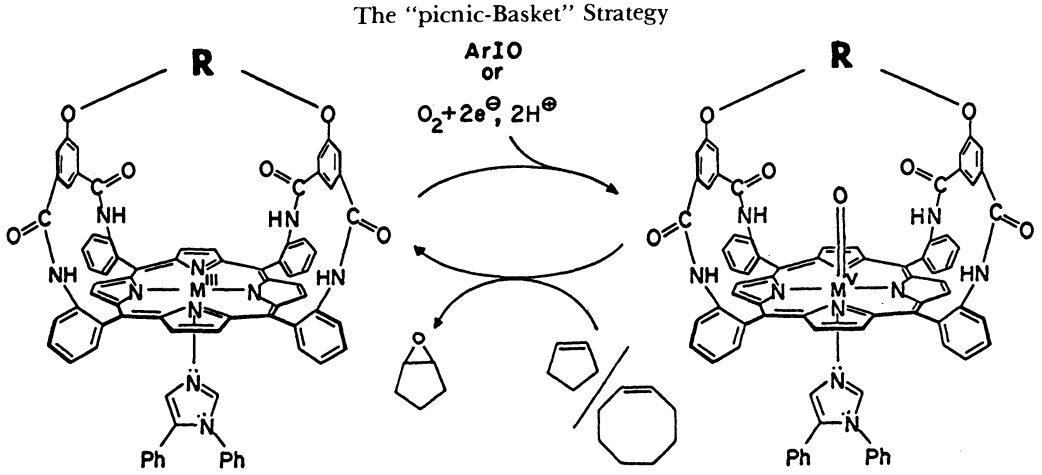
Results and Discussion

The "Picnic Basket" Approach: Our approach to a new cytochrome P-450 model compound is illustrated in Scheme 1. This approach utilizes synthetic porphyrins that are sterically protected on one face of the porphyrin macrocycle. A bulky ligand, which cannot fit into the pocket should block the axial site on the unhindered side of the porphyrin and force molecules such as O_2 or oxygen atom donors to bind within the cavity. Activation of bound dioxygen or O-atom transfer would then generate the metal oxo inside the pocket. A smaller (or cis) olefin, which has greater access to the sterically hindered metal oxo moiety, should then be epoxidized in preference to a larger (or trans) olefin. If R were made chiral catalytic, asymmetric epoxidation might be realized.

In the design of a sterically protected oxidation catalyst several factors must be considered. The cavity must be sufficiently hindered to prevent coordination of the bulky axial ligand but not so hindered as to exclude the oxidant or substrate. Since most of the sterically protected porphyrins reported to date were prepared as hemoglobin or myoglobin active site analogues, they were designed to bind dioxygen within very tight cavities. The cavities hinder coordination of ligands as small as 1-methylimidazole and even carbon monoxide. A crystal structure of Baldwin's capped porphyrin, for example, shows a separation of less than 4 Å between the phenyl "cap" and the porphyrin ring.[7] Porphyrins containing hindered pockets have also been prepared by Momenteau[8a] and Traylor.[8b] While the cavities in these porphyrins can control axial ligand coordination they can also restrict access of a substrate to the active site. In addition, several groups have observed the oxidation of alkyl groups on a porphyrin that are accessible to the metal oxo. Thus a sterically protected porphyrin was needed which had a large, permanent cavity within which O_2 could be bound and activated without oxidation of the superstructure.

We previously reported[9] good yields for the high dilution coupling of two equivalents of isophthaloyl chloride and the 4:0 atropisomer of tetrakis(*o*-aminophenyl)porphyrin (TAMPP) (Scheme 2). The

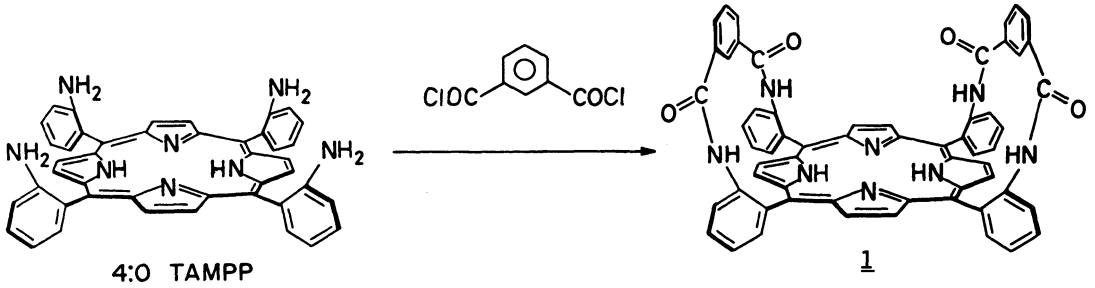


Scheme 1. Strategy for catalysis by "picnic-basket" porphyrins.

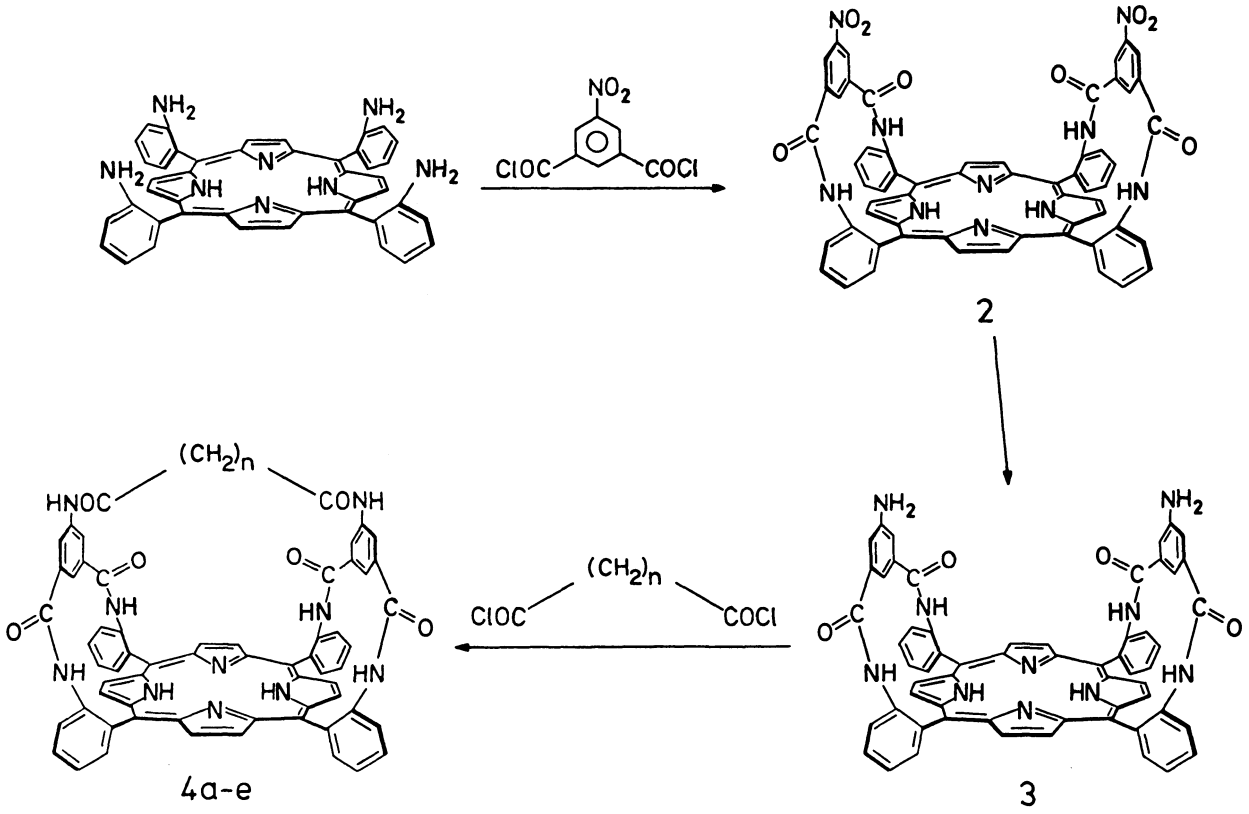
high yield was attributed to the complementary geometries of the isophthaloyl bridge and the aminophenyl groups on adjacent meso positions. No trans aminophenyl-bridged species were detected. Although the iron(II) derivative of **1** proved to be unsuccessful as a hemoglobin or myoglobin model it satisfied the above criteria since the rigid isophthalamido walls extend away from the porphyrin, forming a molecular cleft of large volume. By linking the 5 and 5′ positions the size of the cavity can be varied. Because of their shape we have given this class of molecules the trivial name "picnic basket" porphyrins.

Ligand Synthesis. The first picnic basket porphyrins were synthesized via the route outlined in Scheme 3. High dilution coupling of the 4:0 atropisomer of tetrakis(*o*-aminophenyl)porphyrin with 5-nitroisophthaloyl chloride yielded **2**, the 5,5′-dinitro derivative of **1**. Tin(II) chloride reduction to the 5,5′-diamino derivative **3** followed by high dilution coupling with a series of α,ω-diacid chlorides produced a family of porphyrins of general structure **4**. Derivatives with eight to twelve carbon atoms in the strap were synthesized in overall yields ranging from 10 to 22% based on the amount of 4:0 TAMPP used.

The solubility of these amide-strapped picnic basket porphyrins is very poor in nonprotic polar solvents such as methylene dichloride. This low solubility appears to result from intermolecular hydrogen bonding involving the amides in the strap. In addition to the solubility problem, this synthesis requires two high dilution reactions which severely limit reaction scale and introduce the most expensive

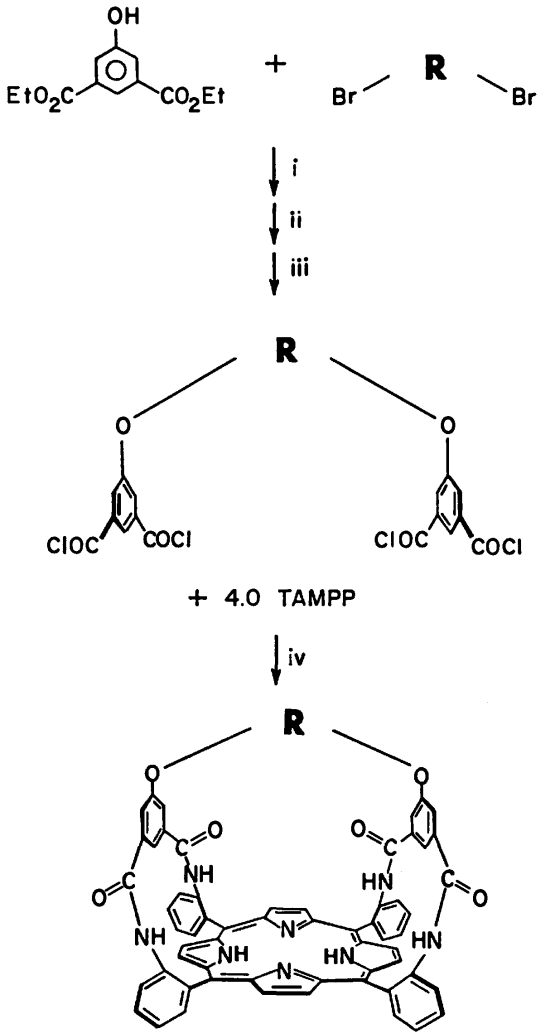


Scheme 2. Picnic basket precursor demonstrating complementary geometries between 4:0 TAMPP and isophthaloyl chloride.



Scheme 3. Synthesis of amide-strapped porphyrins **4a—e**.

reagent, the 4:0 TAMPP, three steps from the final product. In spite of these difficulties, the synthesis outlined in Scheme 3 has proven to be a viable route to this class of porphyrins.



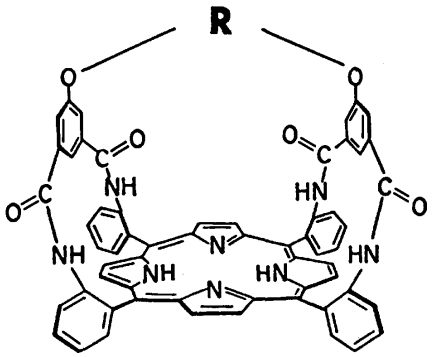
Scheme 4. Synthesis of ether-strapped porphyrins **5**—**9**.

Both of these problems were solved by replacing the amide linkages with ether linkages and through the use of a convergent synthesis as outlined in Scheme 4. This general synthesis has several advantages over that outlined in Scheme 3 in that it contains only one high dilution step and introduces the 4:0 TAMPP in the final step. The eight compounds depicted in Fig. 1 are available by this route. All of the following studies were performed on the ether strapped porphyrins whose synthesis and characterization have been described in detail.[10b] The various complexes of these ligands are specified by the following notation in this paper:

$$Mn(R\text{-}PBP)(L)_{in}(L')_{out}$$

where R=bridging group
C_n=normal alkane
PXY=*p*-xylene
DMB=2,6-dimethylbenzoate
BN=binaphthyl
PBP=picnic basket porphyrin
$(L)_{in}$=ligand coordinated within protected cavity
$(L)_{out}$=ligand bound on unencumbered porphyrin face

Manganese(III) Picnic Basket Porphyrins. Several recent studies have documented the beneficial effects of nitrogenous axial ligands in both Fe(III) and Mn(III) metalloporphyrin catalysts. Meunier[11a] and our group[11b] have observed dramatic increases in reaction rate, catalyst stability, epoxide yield, and stereospecificity in the epoxidation of alkenes by hypochlorite ion catalyzed by Mn(III) porphyrins with imidazoles and pyridine. Although the origin of these effects is not fully understood, they have been shown to result from nitrogenous base ligation.[12] Manganese porphyrin catalyzed epoxidations using



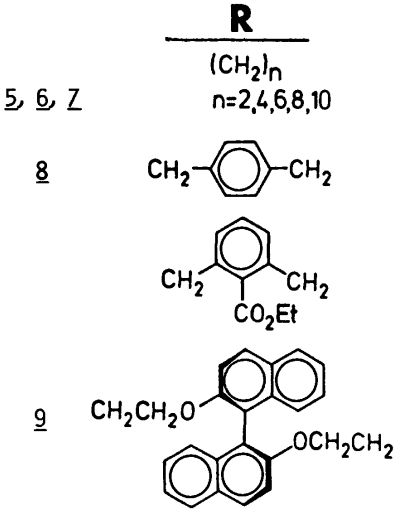


Fig. 1. Structures of ether-strapped porphyrins **5**—**9**.

other oxygen atom sources, such as iodosylbenzene[12] and peroxides,[13] are similarly affected by nitrogenous axial ligands. Since manganese porphyrins are well-behaved catalysts in the presence of nitrogenous ligands, we decided to investigate the selectivity of Mn(III) picnic basket porphyrins.

Metallation was accomplished by heating a DMF solution of the unmetallated picnic basket porphyrin with manganese bromide and the noncoordinating base, 2,6-lutidene, to give a compound with a visible spectrum similar to Mn(TPP)Br. The ^{1}H NMR spectrum shows severe paramagnetic broadening as is expected for a high spin d^4 system. Mass spectral analysis shows a molecular ion peak for Mn(PBP)$^+$. Loss of bromide ion is a result of the ionization method. Thus, the presence of a bromide counterion was inferred from the visible spectrum which is known to be counterion dependent.[24]

Ligand Binding. Since the picnic basket approach requires that the sterically unencumbered face of the porphyrin be made catalytically inactive by blocking that side of the porphyrin with a coordinated nitrogenous base, it is important to understand the thermodynamics and regiochemistry of nitrogenous base ligation. Unlike Mn(II) porphyrins, where crystallographic[14a] and solution[14b] studies have shown formation of only the mono-ligated complex, axial ligation to Mn(III) porphyrins is more complicated. Treatment of a five-coordinate Mn(III) porphyrin with an exogenous neutral ligand, L, can be expected to produce either a mono-L complex or a six coordinate bis-L complex, depending on the concentration of L and the relative magnitudes of the equilibrium binding constants K_L and $K_L{}^L$. The mono-ligated complex may be overall five or six-coordinate depending on the coordination properties of the counterion, X^-. This situation is depicted in Fig. 2. As the scheme in Fig. 2 suggests, equilibrium binding constants for neutral ligands will depend on the nature of the counterion. This has been demonstrated by isolation and structure determination of six-coordinate Mn(III) mono-L adducts with tightly coordinating anions such as azide[15a] or chloride,[15b] but only bis-L complexes have been isolated when a poorly coordinating counterion, perchlorate,[16] is present. Gravimetric analysis also indicates that a single pyridine binds to Mn(etioporphyrin)OAc.[17]

The spectral changes observed when a CH_2Cl_2 solution of Mn(PXY-PBP)Br is titrated with 1-methylimidazole are illustrated in Fig. 3. Six sharp isosbestic points indicate only two species, one of which is the starting material, are present over the course of the titration. The spectral changes are linear with the concentration of imidazole to the first power indicating that only one imidazole binds to each Mn(PXY-PBP)Br with an equilibrium constant of 2.7×10^3 M^{-1}. No evidence was found for binding of a

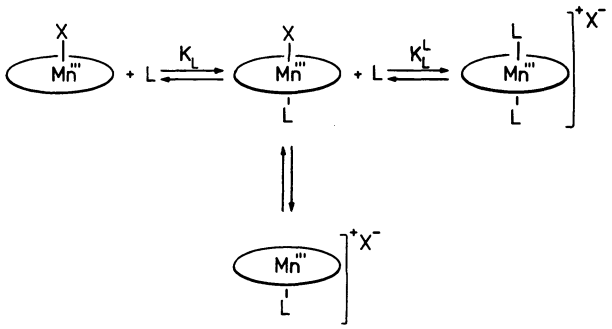

Fig. 2. Ligand binding to Mn(III) porphyrins.

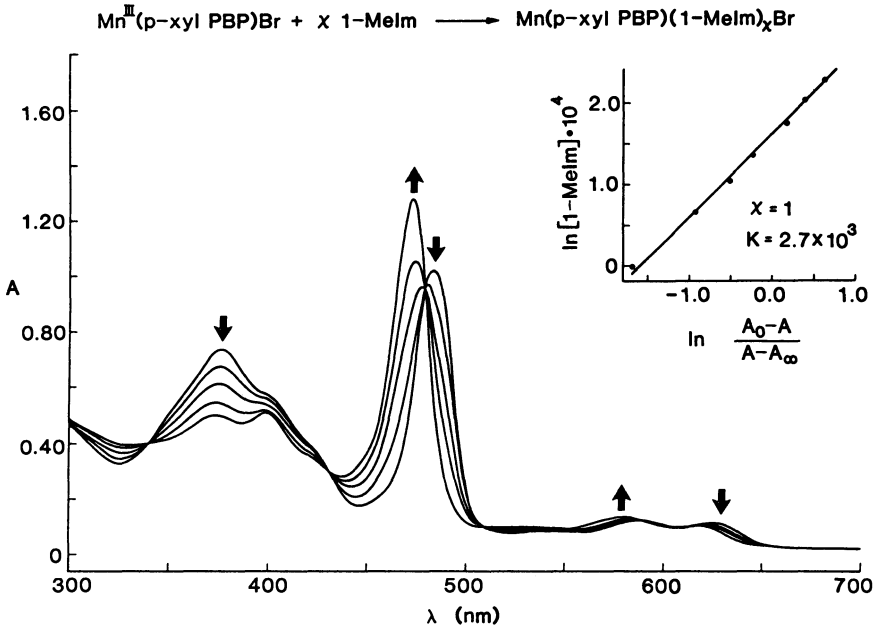

Fig. 3. Spectral titration of Mn(PXY-PBP)Br (**8**) with 1-methylimidazole.

second imidazole.

Similar changes are observed for a spectral titration using the bulky 1,5-diphenylimidazole but are complicated by two factors, that the ligand absorbs below 450 nm and, at high ligand concentrations, slow reduction to Mn(II) occurs. Reduction of Fe(III) porphyrins by excess nitrogenous ligand is well recognized. Despite these complications, the above analysis shows that a single 1,5-diphenylimidazole binds to each Mn(PXY-PBP)Br with an equilibrium constant estimated at $1.2\times10^3\ M^{-1}$.

In order to obtain spectral titrations which maintained sharp isosbestic points and did not change with time, all glassware had to be treated as described in the Experimental Section. Titrations performed in untreated glassware maintained isosbestic points only for the early part of the titration and showed spectral changes over time without addition of imidazole. As mentioned above, the visible spectrum of Mn(III) porphyrins depends strongly on the counterion. The behavior observed in untreated glassware is attributed to exchange of the bromide counterion for another counterion (probably chloride) adsorbed on the cuvette walls. Thus, the treatment described in the Experimental Section was designed to replace any anions which had leached into the glass with bromide.

Boucher studied the visible spectroscopy of Mn(III) porphyrins but reported no quantitative measure of equilibrium binding constants.[18] He does report that in the presence of excess ligand, Mn(III) porphyrins have the same visible spectrum, independent of the counterion in the starting material. Since the spectra of the starting materials do depend on the counterion, Boucher concludes a reaction with the neutral ligand has occurred and the anion is no longer coordinated. The product could be either the five-coordinate mono-L complex or the six-coordinate bis-L species.

La Mar has reported nonisosbestic spectral changes when Mn(III) porphyrins are treated with pyridine or 1-methylimidazole, and concluded that more than two species were present.[19]

Recently, Bruice has derived consecutive binding constants for 1-methylimidazole coordination to Mn(tpp)Cl from a spectral titration.[20] The lack of rigorous isosbestic points was considered evidence for the simultaneous presence of unligated, mono-L and bis-L species. K_L was determined to be $96.3\pm8.4\ M^{-1}$ and $K_LK_L^L$ to be $8530\pm330\ M^{-2}$ using Walker's method of analysis.[21] This analytical method, however, rests upon an unwarranted assumption — that the absorption coefficients of the mono-L and bis-L species are the same at the wavelength chosen for analysis. Several authors[22] have questioned this assumption in Walker's analysis. Thus, the results of Bruice, although consistent with those reported herein, must be considered questionable.

The present spectral study demonstrates that a single imidazole coordinates to Mn(PBP)Br and allows determination of the equilibrium binding constant but does not establish the site of ligation. To show that the hindered face of the picnic basket porphyrin can exclude a bulky axial ligand, an electrochemical study similar to that of Kadish[23] was undertaken.

Kadish examined nitrogenous base ligation to Mn(TPP)X complexes (X=N_3, Cl, ClO_4) by monitoring the Mn(II/III) half wave potential as a function of ligand concentration. For X=Cl or ClO_4, a cathodic shift in the half wave potential was observed as the concentration of pyridine increased. The magnitude of the shift, 53 mV per tenfold increase in pyridine concentration, is consistent with loss of a coordinated pyridine on reduction of Mn(III) to Mn(II), as shown in Eq. 1.

$$(1)\quad Mn^{III}(Por)(L)_n \xrightarrow{e^-} Mn^{II}(Por)(L)_{n-1} + L$$

Kadish concluded that the Mn(III) porphyrin is a bis(pyridine) adduct which, on reduction, becomes a monopyridine complex. The alternative explanation, that Mn(III) binds a single pyridine which is lost upon reduction to Mn(II), can be ruled out since Mn(II) porphyrins are known to exist as monopyridine complexes at these concentrations.[14b,24]

We repeated this experiment using Mn(TPP)Br or Mn(C8PBP)Br and varying concentrations of 1-methylimidazole or 1,5-diphenylimidazole. The results are plotted in Fig. 4. For two porphyrin/imidazole combinations, Mn(TPP)Br with the bulky 1,5-diphenylimidazole and the hindered Mn(C8PBP)-Br with 1-methylimidazole, no steric hindrance to imidazole coordination is expected by molecular models. For these combinations the Mn(II/III) half wave potential shifts cathodically 65 mV per tenfold increase in the imidazole concentration. This is consistent with the loss of a coordinated imidazole on reduction as observed by Kadish.[23]

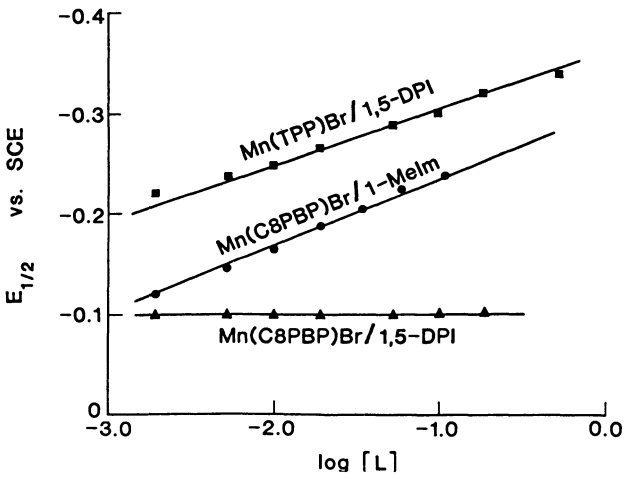

Fig. 4. Electrochemical study of Mn(III/II) half wave potential as a function of log[L].

For the porphyrin/imidazole combination where binding of a second imidazole is sterically disfavored, Mn(C8-PBP) with 1,5-diphenylimidazole, the Mn(II/III) half wave potential is independent of the imidazole concentration. Thus both the Mn(III) and the Mn(II) picnic basket porphyrins bind a single imidazole. This is direct evidence that the cavity in the picnic basket porphyrins will not accommodate 1,5-diphenylimidazole.

The electrochemical results indicate the binding of two imidazoles to Mn(III) in the unhindered cases while the spectral titrations indicate only one imidazole is bound. This apparent inconsistency can be explained by the fact that the electrochemical titration requires a supporting electrolyte, in this case tetrabutylammonium perchlorate, which supplies the perchlorate anion in concentrations 200 times that of the Mn(III) porphyrin. Under these conditions Bruice[25] and Kadish[23] have observed exchange of perchlorate for the counterion in the starting material. Thus, the manganese complex in the electrochemical titration is the perchlorate salt not the bromide salt used in the spectral titration. Since perchlorate is a weakly coordinating anion, perchlorate salts of Mn(III) porphyrins will bind two imidazoles unless sterically prevented from doing so.

Competitive Epoxidations. With knowledge of the regiochemistry and binding constant for imidazole ligation, we examined the substrate selectivity of the picnic basket porphyrin. Examination of molecular models showed that the unhindered face of the picnic basket porphyrin should be like TPP and the hindered pocket should resemble the sterically hindered TMP. As we have reported earlier,[26] Mn(TMP)Br is very selective for the epoxidation of cis olefins versus trans olefins. Mn(TPP)Br exhibits equal reactivity with cis and trans olefins. Table 1 shows the observed epoxide ratios for the hypochlorite oxidation of 1:1 olefin mixtures when catalyzed by Mn(TPP)Cl and Mn(TMP)Cl.[26] Thus, epoxidations of 1:1 mixtures of a cis and trans olefin, for example *cis*-2-octene and *trans*-β-methylstyrene, could be used to assay the

	15	1.4

amount of catalytic oxygen atom transfer that occurs inside the pocket of the picnic basket porphyrin.

The epoxide ratios for several competitive oxygenations are listed in Table 2. Despite changes in the pocket size, counter-ion, the 1,5-diphenylimidazole concentration, and the nature of the oxidant, the ratio of epoxides was similar to Mn(TPP)Cl. Control experiments with each oxidant catalyzed by Mn(TPP)Cl and Mn(TMP)Cl showed dramatic changes in epoxide ratios as discussed above. In all cases the yield of total epoxide or the conversion of olefin to epoxide was in the range reported in the literature. Rates of Mn(PBP)Br catalyzed reactions were never less than 60% of the rate for the Mn(TPP)Br catalyzed reaction. The epoxide ratio did not vary significantly over the course of the catalytic reaction. The Mn(PBP)Br was also more stable than Mn(TPP)Br under the same reaction conditions as determined by decay of their visible bands.

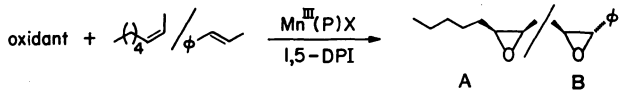
These observations all indicate that catalytic reaction is occurring on the unhindered, sterically nonselective face of the porphyrin despite the presence of a large excess of nitrogenous base. The alternative explanation, that all or some fraction of the catalytic reaction is occurring inside the pocket and the pocket is sterically unselective, seems unlikely given the demonstrated steric sensitivity of competitive oxygenation by Mn(TMP)Cl. Similar results were obtained for the competitive oxygenation of *cis,trans, trans*-cyclododecatriene supporting this conclusion. We have attributed the lack of shape selectivity to failure to control the regiochemistry of high-valent metal-oxo formation, as illustrated in Fig. 5.

Studies of the kinetics of ligand exchange on Mn(III) porphyrins, although limited, show extremely fast exchange rates. Jordan has determined rate constants of 1.5×10^7 and 6.4×10^7 s^{-1} respectively for the exchange of free methanol or *N,N*-dimethylformamide for ligand coordinated to Mn(III)(protoporphyrin IX dimethyl ester)(ClO_4).[27] Bruice has also shown rapid exchange of anionic ligands.[25]

In contrast, oxygen atom transfer to manganese porphyrins appears to be a much slower process.[28] Bimolecular rate constants for oxygen atom transfer from alkyl hydroperoxides to Mn(TPP)Cl, in the presence of 1-methylimidazole, are reported in the range of 200—300 M^{-1} s^{-1}.[20] Thus, interconversion of the Mn(III) porphyrins, **I** and **II** (Fig. 5), is probably rapid relative to conversion to the postulated oxo complexes, **III** and **IV**. The Mn(III) species, **I** and **II**, are therefore always in equilibrium; the ratio being given by the concentration of 1,5-diphenylimidazole and the equilibrium binding constant, which was determined spectrally. For the competitive alkene epoxidations, the ratio of species **II** to **I** is calculated to be 60:1.

The lack of shape selectivity in the competitive oxygenations must be due to the relative rates of formation of the high-valent manganese species, **III** and **IV**. Perhaps oxygen atom transfer to the minor Mn(III) component, **I**, is so much faster than transfer to the major component, **II**, as to outweigh the concentration difference. This rate difference may arise from the larger steric hindrance of the pocket encountered by the oxygen atom donor in reacting with **II**. As we have previously reported,[10] we have observed rate constants which differ by at least two orders of magnitude for reactions occurring inside versus outside the picnic basket porphyrin cavity. The possibility that species **IV**, which has the oxo ligand bound within the cavity, is formed but reacts with olefin much more slowly than does **III** is inconsistent with the constant rate of epoxidation by Mn(PBP)Br, which is similar to that of Mn(TPP)Br. Under these conditions **IV** should accumulate with time and the

Table 2. Cis/Trans Olefin Selectivity of Mn(PBP)X Under a Variety of Reaction Conditions



Oxidant	P	X⁻	[1,5-DPI]	A/B

catalyst should exhibit reduced activity. Thus **IV**, if it is formed, must be able to revert to **II** at a fairly rapid rate. Thus, the lack of shape selectivity is probably due to the minor, unselective component in the catalyst mixture being the more active catalyst.

Studies of the Chiral Picnic Basket Mn(BN-PBP)Br, 9. The chiral binaphthyl picnic basket porphyrin **9** was studied under conditions similar to those reported above with 1-octene or styrene as substrates and LiOCl/phase transfer agent or hydrogen peroxide as the oxygen atom donors in the presence of 1,5-diphenylimidazole. Since circular dichroism spectra of **9** showed bands in the 300—700 nm region the synthesis and Mn metallation did not racemize the porphyrin. Within experimental error no asymmetric induction was observed in the product epoxides by chiral shift ^{1}H NMR using Eu(hfc)$_3$; this result is consistent with oxo formation occurring on the unhindered, achiral face of the porphyrin as observed above and not within the chiral pocket.

Conclusion

While modest regio and enantioselectivities have previously been observed for oxygenations catalyzed by Mn(III) and Fe(III) porphyrins, the porpyrins used in these studies are symmetric with respect to the porphyrin plane. No attempts to observe reaction within the pocket of an unsymmetrical porphyrin have been reported. Studies on the unsymmetrical Mn(PBP)X have shown that metal oxo formation appears to occur only on the unhindered and unselective porphyrin face. Metal oxo formation must occur inside the cavity before shape selective oxygenations can be observed with the picnic basket porphyrins.

While we were unable to observed any olefin selectivity with oxygen atom donors that would indicate epoxidation within the pocket, we felt that dioxygen could still be bound and activated within the pocket. Both ruthenium(II)[10a] and iron(II) picnic basket porphyrins and similar iron(II) pocket porphyrins[29] exhibit reversible binding of dioxygen in the presence of a bulky axial ligand, but preliminary attempts to activate dioxygen using two reducing agent/metalloporphyrin systems provided no evidence for oxygen activation.[3a,c]

We are continuing to study other routes to dioxygen activation including a well-characterized ruthenium(II) picnic basket porphyrin O_2 adduct.[10a] Another possibility is to use oxygen atom donors with a kinetically less labile combination of metalloporphyrin and bulky ligand. One promising candidate is a ruthenium picnic basket porphyrin phosphine complex.

Support from the National Institutes of Health (Grants NIH GM17880-16,17) and the National Science Foundation (Grant NSF CHE83-18512) is gratefully acknowledged. The Nicolet NMC-300 and Varian XL-400 spectrometers were purchased with funds from the National Science Foundation (Grants NSF CHE81-09064 and NSF CHE84-14329). Ms. Patricia Bethel and the University of California, San Francisco Mass Spectrometry Facility supported by the National Institutes of Health (Grant RR01614) obtained all the mass spectral data reported. Dr. Ruth Records (Stanford) obtained the circular dichroism spectra. Mr. Ronald Nelson is gratefully acknowledged for synthetic help.

Pentaamminechromium(III) t_{2g}^3 Level Properties as Determined from Vibronic Spectra and Crystal Field Calculations

Hans-Herbert SCHMIDTKE,* Heribert ADAMSKY, and Thomas SCHÖNHERR
Institut für Theoretische Chemie der Universität Düsseldorf, D-4000 Düsseldorf 1, F.R.G.
(Received August 7, 1987)

Low temperature (~5 K) absorption and emission spectra of various halogenopentaamminechromium(III) salts have been recorded at high sensitivity in the intercombination region from pure microcrystalline powders and doped into corresponding rhodium complexes. Zero phonon and vibrational side bands are better resolved than reported in earlier investigations. They depend on the crystal lattice and allow a more detailed analysis of the vibrational fine structure. For carrying out reliable assignments to vibronic energy levels, the influence of the crystalline environment in different salts is found to be of major importance. Ligand field and angular overlap calculations are very helpful for solving the assignment problem, they can reproduce the proposed energy level scheme if symmetry adapted π-orbital expansion coefficients are introduced into the electron repulsion terms.

Since the pioneering work of A. E. Becquerel[1] who reported the luminescence lifetime of ruby in 1867, chromium(III) ion lattices and complexes have become the subject of increasing research activity in the field of photophysics and photochemistry. In particular, the theoretical work of Tanabe and Sugano[2] has greatly stimulated the understanding of processes which are connected with light absorption and emission of these systems. At present, the discovery of the room temperature tunable alexandrite laser[3] and the potential use of chromium(III) doped glass ceramics as solar concentrators[4,5] have additionally focused attention on electronic and vibrational properties of d^3 complexes. Whereas, in general, most of the properties of ionic systems are determined by their particular lattices formed on crystallization, common coordination compounds as $[Cr(NH_3)_6]^{3+}$ or $Cr(acac)_3$ are better described by isolated molecular species in the solid using theoretical methods which are appropriate for investigating chemical bondings.[6,7] For examining the photochemical reaction pathways, starting from the optical spectra as a basis, in the past twenty years predominantly chromium ammine compounds have been extensively used as sample cases.[8,9]

In an early attempt, Schläfer[10] related the energy gap between the ^2E_g and $^4T_{2g}$ levels (in O_h notation) derived from spectroscopically obtained ligand field (LF) parameters to the type of photophysical activity (fluorescence or phosphorescence), an observation which later has been named as Schläfer's rule. In an alternative point of view, the various ways of metal–ligand bonding have been considered for rationalizing the experimental results by classifying the ligands according to their extent of σ- and π-interactions towards the central metal.[11] More recently, this idea has been taken over for use in the angular overlap model (AOM) by which photosubstitution processes could be investigated calculating metal–ligand strengths in the excited state.[12] Although this procedure seems to account for the majority of results obtained from low symmetry chromium(III) ammine complexes, the predictions on photosubstitution concerning the leaving group have been claimed to be incorrect for some of the acidopentaammines.[13] Forster and coworkers have examined the emission spectra of more than 40 tetragonal ammine complexes.[14,15] They classified these compounds, by inspection of band shapes obtained, into ^2E_g and $^2T_{1g}$ emitters and expressed the energies of the lowest excited states by AOM antibonding parameters derived from level splittings as measured for spin-allowed transitions into quartet states. In addition, the doublet transition energy has been found to be of major influence on the nonradiative decay rate, and even a slight modification of the second coordination sphere could lead to drastic changes of luminescence properties.[16] "Although a considerable body of data has been collected···the relative importance of changes in electronic and vibrational factors that accompany ligand substitution is not yet clear" (quoted from Ref. 17). Compared to the amount of experimental results reported in the literature, theoretical investigations on electronic states arising from t_{2g}^3 electron configuration are more rare. For instance, the magnitude of the splitting of the lowest excited ^2E_g level due to lower symmetry is not clear and has been an object of controversy;[18–20] also information on the location of the spin-orbit split components of $^2T_{1g}$ and $^2T_{2g}$ is very scarce[21] and explanations for the in various complexes[22–24] anomalously large $^4A_{2g}$ ground state splitting is still unsatisfactory. On the other hand, since much of the experimental work cited above was performed on glassy solutions yielding poorly resolved spectra, the amount of information which can be obtained from these results is very limited.

Therefore, we want to report in the following some low temperature absorption and emission spectra of microcrystalline materials of pure halogenopentaammine complexes and doped in crystal lattices of

similar composition yielding much better resolved band patterns as obtained earlier. The characterization of zero phonon bands different from vibrational side bands supplies an improved basis for carrying out band assignments and determining level splittings due to the lower symmetry; it contributes to investigate the role of spin-orbit coupling and covalent bonding effects on the energy level scheme and transition probabilities. Distortions of the nuclear framework in the excited state and, eventually, changes of potential energy surfaces close to the equilibrium geometry may be obtained from an analysis of the vibrational fine structure yielding evidence on the strength of vibronic coupling, important for the energy transfer and reactivity of the molecule. Parallel to the experiments various calculations have been carried out using common theoretical models as LF theory and the AOM, introducing only minor modifications when proved to be necessary. The results supply important contributions to the discussion of the assignment problem.

Experimental

Preparation of Compounds. The chromium(III) complexes were synthesized according to methods given in the literature.[25] The chloro- and bromopentaammine salts, abbreviated by $[Cl]Y_2$ and $[Br]Y_2$, were purified by metathesis from saturated solutions in respective acids HY. Preparation of iodopentaammine is interfered by rapid hydrolysis processes which prevent further recrystallization. The quality of these samples was checked by recording their luminescence spectra which are very sensitive to decomposition. Deuterated materials were obtained by repeated treatment of saturated D_2O solutions with DY. Small single crystals (0.2—0.5 mm diameter) of $[Cl]Cl_2$ were grown from hot (60 °C) acidified aqueous solutions within several hours. Analogous rhodium(III) compounds for use as suitable host crystals were prepared from $[Rh(NH_3)_5Cl]Cl_2$ which was recrystallized following given procedures.[26]

Spectroscopic Measurements. Visible and ultraviolet spectra were recorded using an appropriately modified Cary 17 spectrophotometer equipped with an RCA 4832 photomultiplier. Polarized spectra obtained from a specially designed microscopic optical device[27] gave additional information only on the splittings of the broad quartet bands. Absorption and emission spectra due to intercombination transitions were measured using a McPherson 0.5 m double monochromator model 285 fitted with a 1200 lines/mm grating and a red sensitive GaAs photomultiplier. For comparing peak intensities the emission spectra are corrected for apparative response. Further parts of the equipment have been an argon laser and a helium flow cryostat allowing temperature to be reached at the sample down to 5 K. Low excitation intensities were necessary to prevent photodecomposition of the compounds. The 20 K Raman spectrum of $[Cl](NO_3)_2$ was recorded by T. Woike[28] using the 620 nm line of an optically pumped dye laser. Under these mild conditions the spectrum can be reproducibly recorded avoiding photodecomposition to a large extent.

Energy Levels

Electronic States. Octahedral complex compounds of transition metal ions with t_{2g}^3 electron configuration have $\binom{6}{3}=20$ electronic levels which due to the molecular symmetry are in part degenerate leading to the multiplet states $^4A_{2g}$ (ground state), ^2E_g, $^2T_{1g}$, and $^2T_{2g}$. At lower symmetry these states are split into a maximum of 10 energy levels leaving a residual twofold degeneracy (Kramers doublets) if magnetic fields are absent. For C_{4v} point symmetry pertinent for the present compounds, the level symbols and level splittings due to the various interactions considered are indicated in Fig. 1.

Electron transitions between these states exhibit, at least for helium temperature spectra of crystalline solids, well resolved vibrational fine structure which can be compared to the IR and/or Raman spectra, vibrational quanta in the t_{2g}^3 excited states being similar to those in the ground state since chemical bonding will not be changed very much on excitation into levels arising from the same electron configuration. An analysis of the fine structure identifying particular vibrational side bands is, nevertheless, not easy because band superpositions will occur to a large extent due to several electron transitions being located close to each other. In particular, the positions of the low symmetry spin-orbit levels arising from $^2T_{1g}$ and $^2T_{2g}$ are difficult to localize in the energy level scheme

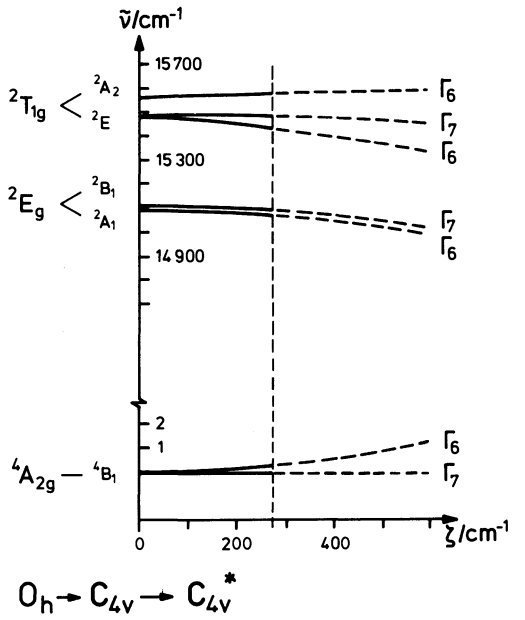

Fig. 1. Electronic t_{2g}^3 LF level scheme for C_{4v} symmetry chromium(III) complexes depending on the spin-orbit coupling coefficient ζ, for heavier ligands exceeding the parameter of the free ion (dotted lines). Model parameters chosen are σ_N= 7500, π_N=0, σ_X=5000, π_X=750, B=600, C=3500, all in cm^{-1}.

(see below); as far as the first excited ^2E_g level is concerned a splitting between 20 cm^{-1} for $[H_2O](ClO_4)_3$ and about 200 cm^{-1} for halogenopentaammine complexes [X] have been reported.[18,19] The latter result cannot be reproduced by conventional LF calculations[18,20] although level schemes of similar mixed halogeno-amine complexes of Cr(III) are explained very well by applying this model.[29] A substantial increase of ^2E_g level splitting is, however, calculated when different nephelauxetic effects are assumed for $b_2(d_{xy})$ and $e(d_{xz},d_{yz})$ orbitals of C_{4v} symmetry (see below). Since no crystal structural data had been available, earlier calculations could not use actual molecular geometries. Recently, however, the room temperature crystal structure of $[Cl]Cl_2$ has been reported[30] according to which the chromium ions occupy equivalent sites with approximately C_{4v} symmetry. The exact site symmetry is only C_s and the space group $D_{2h}^{16}\equiv Pnma$.

By spin-orbit coupling the multiplet levels are split by different amounts (see Fig. 1), the $^4B_1(C_{4v})$ ground state splitting being very small which cannot be resolved by electronic spectroscopy. ESR results report zero field splittings of the ground state of some 0.2 (chloro complex) to 0.9 cm^{-1} (iodo complex).[22,31,32] The experimental splittings thus obtained for the heavier halogeno complexes turn out to be much larger than those predicted from conventional LF calculations from which it was concluded that the effective spin-orbit coupling constants should be increased to unusual high values.[22] To what extent this assumption can be justified will be discussed when describing the LF calculations.

Vibrational Levels. In the infrared spectrum only vibrations of a_1 and e symmetry type will be expected on the basis of C_{4v} selection rules, in the Raman spectrum on the other hand all vibrational transitions of CrN_5X chromophore are allowed. Figure 2 illustrates the 20 K Raman spectrum of $[Cl](NO_3)_2$ which due to the easy photodecomposition of the compound is only obtained by a careful wave length selection of incident light. Assignments to internal complex vibrations were made on the basis of available infrared data, normal coordinate analyses,[33]

and results obtained from the present vibronic spectra. Table 1 compiles all normal vibrations of given symmetry type involving the chromium central atom; also an assignment of all vibrational frequencies together with their deuterium shifts measured for the chloro complex is given.

Results and Discussion

^2E_g and $^2T_{1g}$ Spectrum. In Fig. 3 the crystalline powder absorption spectra of three halogenopentaammine complexes recorded at low temperature (~5 K) in the $^4A_{2g} \rightarrow {}^2E_g$, $^2T_{1g}$ (O_h notation) energy region are illustrated. The dominating band peaks indicated by A, B, and C are assigned in agreement with earlier works[18-20] to zero phonon transitions; on deuteration they exhibit isotope shifts which are negligible compared to the other bands. The vibronic side band pattern can be explained in terms of σ(Cr-NH_3), σ(Cr-X), δ(H_3N-Cr-NH_3), and δ(Cr-N-H) atomic group vibrations of the chromophore (cf. Table 1). Assignment of zero phonon peaks to their octahedral parent states ^2E_g and $^2T_{1g}$ is, however, in dispute[18-20] (see above).

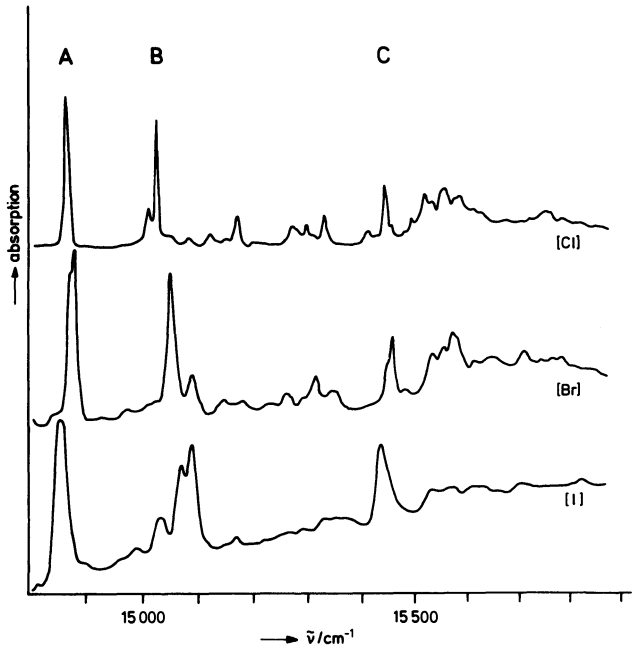

Fig. 3. Overall 5 K absorption spectra in the ^2E_g and $^2T_{1g}$ region of micro crystalline $[Cr(NH_3)_5X](NO_3)_2$.

The relative intensities of vibronic side bands obviously decrease in the series from [Cl] to [I] which may be explained by the larger perturbation of the octahedral symmetry by heavier halogen ligands breaking the d-d parity selection rule more efficiently and making pure electronic transitions allowed. It is further noticed that the band A belonging to the lowest transition energy is not much affected by the hetero ligands Cl, Br, or I which seems to be surprising in view of the fact that the energy gap to the ground state, approximately given by Racah parameters 9B+3C, ought to be subject to a varying nephelauxetic effect in this series of compounds. Also the energy difference between A and C peaks is almost unchanged in the spectra, only the position of the B bands varies to a certain amount. On the other hand crystalline effects are much larger than expected which becomes apparent from changing the anions of the salts, they even dominate the band shifts resulting from a variation of the hetero ligand (cf. Table 2).

$^2E_g(O_h)$ Splitting. The spectrum of crystalline $[Cl]Cl_2$ recorded with high resolution (better than 2 cm^{-1}) exhibits a splitting of the A band into two components A_I and A_{II} of different intensities (cf. Fig. 4). Half widths (8—10 cm^{-1}) and peak separations (12 cm^{-1}) are measured equally well for the deuterated complex (separation 14 cm^{-1}). In the emission spectrum the two peaks are found at almost identical frequencies, the intensity of the peak at higher energy increasing with temperature. For different counter ions the band profile changes, however, significantly. This applies for the degree of splitting and for the

Table 2. Zero Phonon Bands (in cm^{-1}) of $[Cr(NH_3)_5X]Y_2$ due to t_{2g}^3 Transitions Obtained from Low Temperature Absorption Spectra. I Refers to the Main Peak, II to a Satellite Peak or Shoulder

Compound	A_I	A_{II}-A_I	B-A_I	C_I-A_I	C_{II}-C_I

Proposed Assignment:	$^2A_1(^2E_g)$		$^2B_1(^2E_g)$	$^2A_2(^2T_{1g})$	

a) Broad band, splitting not resolved. b) Alternative assignment possible.

relative intensities of the peaks as well (see Table 2) which may have different explanations depending on the assignment made to the low symmetry level scheme (see later). Ligand field theory using common model parameters predicts the transition into the $\Gamma_6(^2A_1)$ component (cf. Fig. 1) to be lowest in energy. In addition, for some of the complex salts, e.g. $[Cl](NO_3)_2$, in this zero phonon region another much weaker transition is detected which in the absorption spectrum is observed as a shoulder.

The corresponding doublet band patterns could not be resolved in the case of $[NCO](NO_3)_2$[20] and $[I]I_2$ (Table 2), on the other hand in the spectra of most of the compounds investigated two transitions are observed which are located closely together in energy, one (A_I) with a higher intensity than the other (A_{II}). It is tempting to assign these peaks to the C_{4v} symmetry splitting of $^2E_g(O_h)$, i.e. to $^2A_1$ and $^2B_1$ which would be in agreement with the assignment proposed for the $[H_2O]$ and [OH] perchlorate.[19] However, pair interactions of paramagnetic Cr^{3+} centers could also give rise to additional peaks in the intercombination spectra.[34] Since these pair states are essentially determined by Cr–Cr distances we also investigated doped materials (0.1—3%Cr^{3+}) in corresponding Rh(III) complex salts. The spectra of these samples show, however, a quite similar A band pattern by which the occurrence of pair spectra can be excluded.

A further, more probable explanation is offered by the presence of different sites for Cr positions in the crystal. The space group *Pnma* obtained at room temperature for the $[Cl]Cl_2$ has only equivalent sites available for Cr atoms,[30] however, a temperature dependent X-ray investigation carried out on a powder sample distinctly reveals a structural phase transition between 220 and 230 K which cannot be detected in the electronic spectrum due to the lack of appropriate fine structure at these temperatures. Consequently we prefer to assign the band at A to only one of the ^2E_g split levels, the pair character being due to different sites; the other ^2E_g component then gives rise to the B band 150 to 300 cm^{-1} higher in energy. This interpretation would also explain the doublet structure of the zero phonon band C (cf. Table 2) although a similar pattern for B which equally well should be expected as a pair of bands could not be resolved. The varying band profile of A observed when changing the counter ion is then due to different environmental effects on crystalline Cr sites.

$^2T_{1g}(O_h)$ Splitting. From the six-fold degenerate $^2T_{1g}$ level which in octahedral complexes is located some 550 to 600 cm^{-1} higher than ^2E_g, at maximum three Kramers doublets can result (cf. Fig. 1) from which in tetragonal symmetry the $^2E(^2T_{1g})$ levels are appreciably decreased in energy due to interaction with the higher $^2E(^2T_{2g})$ levels of the same symmetry. The change in energy can be estimated from the AOM perturbation matrix by

$$\Delta E(^2E) = \frac{(\pi_L - \pi_X)^2}{6B + 2C} \quad (1)$$

with antibonding parameters π_L and π_X for the ligands L and X of a ML_5X chromophore. Since this expression is a negative contribution to the energy for any parameters associated to the ligands, $^2E(C_{4v})$ resulting from $^2T_{1g}(O_h)$ is always stabilized. On the other hand, the second $^2T_{1g}$ component, i.e. $^2A_2$, is almost unchanged on symmetry reduction since except for smaller spin-orbit coupling effects no interactions of neighboring levels are possible by symmetry reasons. As band C remains at almost equal position, e.g. in the series [Cl], [Br], and [I] of nitrate salts (see Table 2) for which π_X should essentially change, an assignment of this zero phonon band to $^2A_2$ seems to be straightforward (see crystal field calcula-

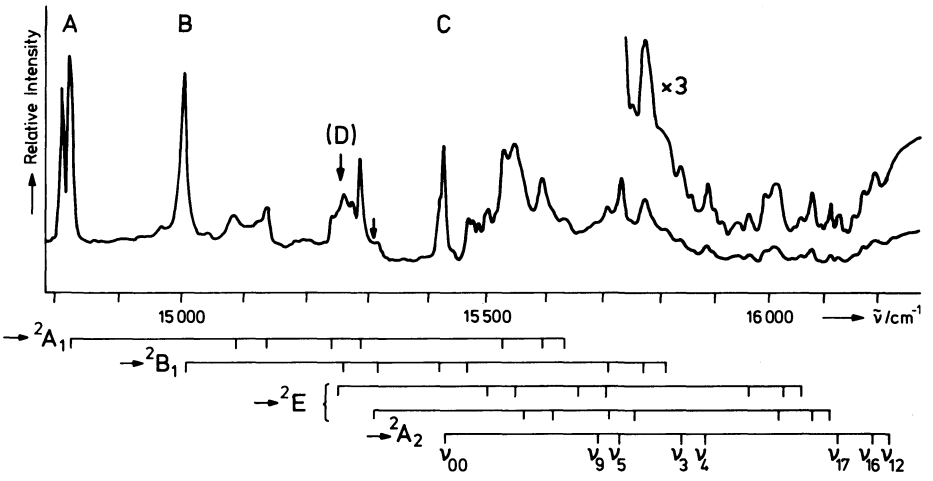

Fig. 4. High resolution absorption spectrum of $[Cr(NH_3)_5Cl]Cl_2$ at 5 K and vibronic assignments to C_{4v} symmetry levels (in the neighboring energy region narrow line spectra cannot be resolved).

tions).

Reliable assignments of $^4B_1 \rightarrow \Gamma_6, \Gamma_7(^2E)$ transitions in absorption spectra of low symmetry Cr(III) ammine complexes have not been carried out as yet because corresponding peaks are usually superimposed by vibrational side bands of $\Gamma_6(A_1)$ and $\Gamma_7(B_1)$ transitions arising from $^2E_g(O_h)$, the zero phonon peaks of which we have assigned to the A and B band. For localizing hidden zero phonon transitions in this region a vibronic band analysis must be performed assigning all vibronic intervals to normal vibrations known from Raman and luminescence spectra. In Fig. 4 the result of this analysis obtained for the [Cl]Cl_2 spectrum is presented by indicating the normal modes which give rise to absorption peaks in the side band spectrum. For this assignment only those vibrational quanta are used which are measured in the luminescence spectrum as main bands; by this virtually all satellite peaks can be explained. The same procedure is applied also to the corresponding deuterated compound which allows for checking each of the band assignments by regarding the expected isotope shifts of Table 1. As a result we conclude that a further zero phonon transition (D) should be present at 15246 cm^{-1} that is calculated from vibrational intervals belonging to ν_3, ν_5, ν_9, and ν_{16} to ν_{18} quanta. Indications for another zero phonon transition in this region also lower in energy than $^2A_2$ are found at a position marked by an arrow in Fig. 4 which could originate from the second split component of $^2E(C_{4v})$. However, these assignments are less certain.

$^2T_{2g}$ Spectrum. In Fig. 5 the spectrum of [Br]Br_2 is presented which includes also quartet transitions. Superimposed to one of these quartets the highest t_{2g}^3 intraconfigurational transitions can be detected with unusually large intensity. A similar band pattern has been reported[35] in this region for tr[Cr en_2Br_2](ClO_4) which was explained being due to the D_{4h} components ^2E_g and $^2B_{2g}$ of $^2T_{2g}(O_h)$. Güdel and co-workers, on the other hand, have assigned two narrow band shoulders they detected on the short wave length flank of the first quartet band of [OH]$(ClO_4)_2$ to the Γ_6 and Γ_7 components of $^2E(^2T_{2g})$, however, did not find any other fine structure close to these absorptions.[19] The present band profile obtained for [Br]Br_2 (similar features can be observed at high resolution also in the other halogenopentaammine spectra) with a relatively slowly decreasing progression of about 240 cm^{-1} is detected only at low temperatures. It cannot be assigned to a spin allowed transition, since quartet bands remain essentially unchanged on cooling to liquid helium temperatures. Higher intensities (extinction coefficients $\varepsilon \sim 10$) and larger band widths (~ 50 cm^{-1}) can be well explained from the interacting electronic energy level scheme considering spin-orbit coupling. Relevant finite off-diagonal perturbation matrix elements intermixing ^2E and $^4B_2$ wave functions of C_{4v} are

$$\langle \Gamma_6(^2E) | H_{SO} | \Gamma_6(^4B_2) \rangle = -\frac{\zeta}{2}$$

$$\langle \Gamma_7(^2E) | H_{SO} | \Gamma_7(^4B_2) \rangle = -\frac{\zeta}{\sqrt{12}} \qquad (2)$$

ζ being the one-electron spin-orbit coupling coefficient, while the corresponding matrix element with the second $^2T_{2g}(O_h)$ component, i.e. $\Gamma_7(^2B_2)$, is vanishing.[36] Other interactions of this kind involving the $^4E(C_{4v})$ state of $^4T_{2g}$ are small due to the energy denominator which is several thousand wavenumbers larger than for interactions with $^4B_2(C_{4v})$. Due to the larger mixing coefficient of $\Gamma_6(^4B_2)$ into $\Gamma_6(^2E)$ functions the transition into the $\Gamma_6(^2E)$ state should

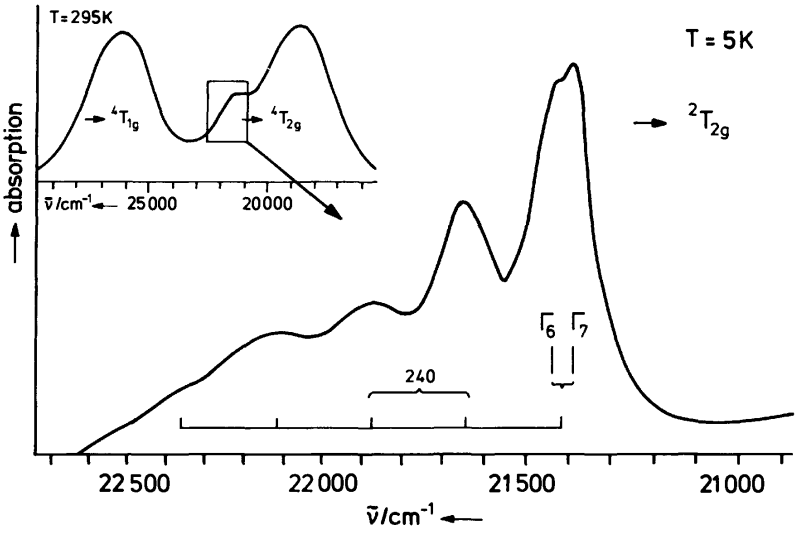

Fig. 5. Room temperature quartet absorption spectrum and 5 K high resolution $^2T_{2g}$ spectrum.

obtain higher intensity than for $\Gamma_7(^2E)$; the total splitting into Γ_6 and Γ_7 of ^2E is computed by a complete ligand field calculation to be some 50 cm^{-1} which is in good accordance with the assignment given in Fig. 5. The band widths, which are increased compared to usual doublet transitions of Cr(III), also indicate a higher contribution of quartet character which accounts for the occurrence of a vibrational progression due to larger nuclear distortions with respect to the ground state geometry.

The Fluoro Complex. In the series of halogenopentaammines of chromium(III) the fluoro complex spectrum obviously occupies a particular position. In the region of $^4A_{2g} \rightarrow {}^2E_g$ zero phonon transitions the absorption spectrum shows six intensive peaks, some with different half widths (cf. Fig. 6). In the emission spectrum corresponding bands are located at equal energies, their intensities being strongly temperature dependent which partly can be explained by Boltzmann distribution. The band pattern is repeated a few times shifted towards smaller wavenumbers into the vibrational side band region. These findings are best accounted for by the presence of a bunch of zero phonon transitions which arise from several nonequivalent sites in the crystal. Unfortunately no structural data is available for the fluoropentaamminechromium complex (as is not for other central metal ions). A preliminary powder X-ray recording at room temperature indicates a complicated super structure which is not unusual for perchlorate lattices. This would be in agreement with the given interpretation assuming nonequivalent chromium positions. A possible explanation may be given by the smaller size of the fluoride ion compared to NH_3 ligands preventing the hetero-ligand to favor a certain coordinate direction in the crystal lattice (the complex is considered to be built into the holes of the anion lattice) that would lead to a formation of different sites in the crystal.

An analysis of the vibrational side bands similar to the discussion carried out for the other halogeno complexes is not possible due to large band superpositions and a lack of sufficient peak resolution in this spectrum. Therefore also the zero phonon lines arising from $^2T_{1g}(O_h)$ split levels cannot be located. However, the slowly decreasing progressions in 530 cm^{-1} quanta clearly identified in the emission spectrum are explained being due to the metal-halogen stretching vibration $\nu_5(a_1)$ which is also observed in the spectra of the other pentaammine complexes. The intensity distribution in these progressions will be used for determining the geometric distortion of the emitting state (see below).

Crystal Field Calculations. Conventional LF and AOM calculations are, in general, able for the present compounds to account for the electronic energy level scheme verified from the experiment.[19,20,36] There are, however, some exceptions: e.g., the size of the low symmetry splitting of the $^4A_{2g}(O_h)$ ground and first excited state ^2E_g cannot be reproduced, i.e. in the experiment they are found about one order of magnitude larger than from theory even though when complete LF calculations are carried out considering all possible $\binom{10}{3}=120$ wave functions of the d^3 electron configuration. The highest level splittings calculated from usual model parameters which hold also for other chromium(III) complexes are ~0.3 cm^{-1} for $^4A_{2g}$ and ~50 cm^{-1} for ^2E_g. The results do not change very much if various improvements are implemented in the computer program:[21] consideration of the real

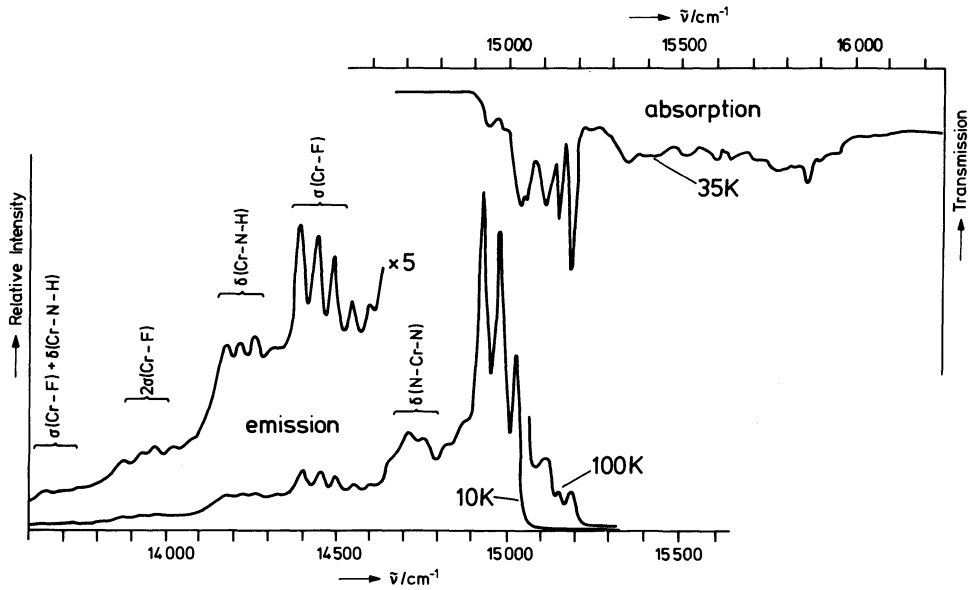

Fig. 6. Vibronic absorption spectrum (35 K) in the intercombination region and emission spectrum (10 K and 100 K, λ_{exc}=514.5 nm) of $[Cr(NH_3)_5F](ClO_4)_2$.

geometry, introduction of Trees correction, distinction of nephelauxetic effects for e_g and t_{2g} orbitals ($\beta_{55} \neq \beta_{35} \neq \beta_{33}$ according to Jørgensen[37]), and inclusion of potential interactions to the second coordination sphere by considering for hexacoordinated systems σ bonds between t_{2g} metal- and p-functions of the anions.[16] We have undertaken to check in detail all these influences by performing extensive ligand field calculations varying parameters within ranges being of physical significance which reproduce the correct quartet level sequences as derived from the polarized spectra, with the result that all these effects are not capable to explain the large ^2E_g splitting of these compounds. This is in agreement with earlier investigations.[16,18-20,36]

The incomplete treatment of the electron repulsion part that uses only parameters adapted to spherical symmetry has been criticized already earlier[18,37] and some founded extensions of the original models have been proposed to remove this shortcoming. A consequent consideration of electron repulsion leads, however, even at cubic symmetry to an inflation of parameters,[38] by which the convenient relations between theory and experiment, very useful in practice within the conventional models, are lost. The way out of this problem may be shown by the Stevens delocalization coefficients,[37] which in O_h symmetry consider differences in the LCAO expansion coefficients μ for e_g and t_{2g} orbitals,[39] i.e.

$$\psi = \mu\varphi_M + \lambda\varphi_L \qquad (3)$$

At this symmetry only two sets of μ,λ-coefficients are possible. The neglect of more center integrals justified by the strong localization of d-orbitals on the metal atom leads to various electron repulsion terms differing in symmetry

$$\mu_a\mu_b\mu_c\mu_d\langle ab|1/r_{12}|cd\rangle \qquad (4)$$

(each $\mu_i<1$) which can be expressed again by linear combinations of spherical Slater-Condon or Racah parameters.

For C_{4v} complexes the corresponding symmetry adapted μ-coefficients may be denoted by τ_ζ of d_{xy}, $\tau_\xi=\tau_\eta$ of d_{yz}, $d_{xz}(t_{2g})$ and ε_u of $d_{x^2-y^2}$, ε_v of $d_{z^2}(e_g)$. Since NH_3 ligands do not contribute to π-bonding ($\pi_N=0$), for present pentaammine complexes the corresponding π-coefficient is $\tau_\zeta=1$. A complete AOM calculation performed with a significant set of parameters shows that already a very small deviation of the other τ parameters from unity has a large effect on the ^2E_g splitting (cf. Fig. 7), the size of the ε-expansion coefficients chosen for e_g orbitals is found to be of minor importance for the splitting pattern of ^2E_g and $^2T_{1g}$ levels. Thus, a parameter value of $\tau_\xi=\tau_\eta=0.992$ can reproduce a level spacing of $\sim$200 cm^{-1} for ^2E_g determined from experiment.

The variation of level differences with the π-expansion parameter $\tau(=\tau_\xi=\tau_\eta)$ as demonstrated in Fig. 7 can be estimated also from the diagonal elements of the LF perturbation matrix of tetragonal symmetry given in terms of Racah parameters A, B, and C

$$\begin{aligned}
&^2E_g \text{ splitting} \quad \Delta E(^2B_1-{}^2A_1) = 2\tau^2(1-\tau^2)(3B+C)>0,\\
&^2T_{1g}-{}^2E_g \text{ separation} \quad \Delta E(^2A_2-{}^2A_1) = 0,\\
&^2T_{1g} \text{ splitting} \quad \Delta E(^2A_2-{}^2E) = (-0.5\tau^4+\tau^2-0.5)A\\
&\qquad + (2.5\tau^4-0.5\tau^2-2)B + 1.5(\tau^2-1)C<0,\\
&^4A_{2g} \text{ (ground state) splitting} \quad \Delta E(\Gamma_6-\Gamma_7) = 0. \qquad (5)
\end{aligned}$$

It is seen that for $\tau<1$ the ^2E_g level splitting is increased, the $^2T_{1g}-{}^2E_g$ spacing and ground state splitting remain unchanged but the $^2T_{1g}$ splitting tends to be smaller than calculated from conventional LF theory (cf. Eq. 1). The appearence of the A-parameter in the expression for the $^2T_{1g}$ splitting in Eq. 5, which in the spherically symmetric model cancels for any of the transition energies, does not cause difficulties: since its contribution to $\Delta E(^2A_2-{}^2E)$ is relatively small due to its coefficient dependent on τ even for large values of A the qualitative aspects of the results will not be changed.

As seen from the full LF calculation (Fig. 7) the total energy separation $\Delta E(^2A_2-{}^2A_1)$ is changed only slightly with varying τ which agrees with the observed positions of band C being at constant energy difference compared to A ($\sim$600 cm^{-1}) for all compounds considered as well as for the hexaammine complex.[7] Due to the avoided crossing of Γ_6 levels arising from $^2A_2$ and ^2E these states are strongly

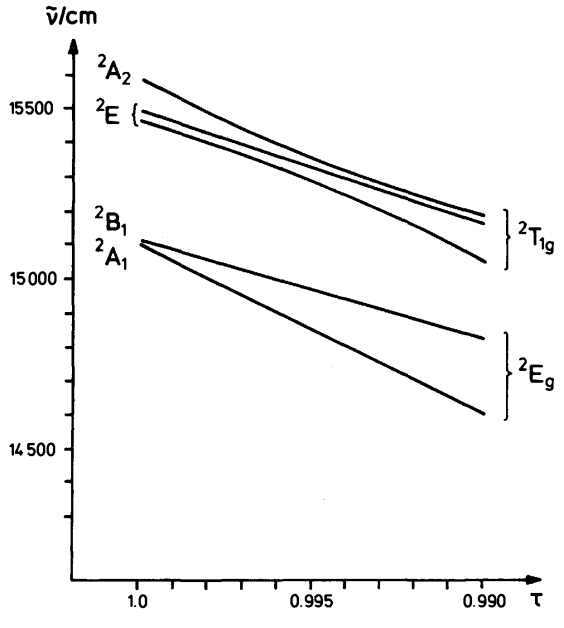

Fig. 7. Low symmetry ligand field splitting of ^2E_g, $^2T_{1g}$ levels depending on the π-orbital expansion factor τ (see text). Parameters are chosen as in Fig. 1 and ζ=200 cm^{-1}; $\varepsilon_u=\varepsilon_v$=1.0.

intermixed at $\tau<0.995$ by which the transition giving rise to band C should obtain an increased $^4B_1 \rightarrow {}^2E$ character. The situation is further complicated by a possible occurrence of a pseudo Jahn-Teller effect in the ^2E state[40] shifting the zero phonon transitions by virtue of vibronic coupling which has not been considered in the present model. A final decision on the assignment of band C can only be made on the basis of more detailed theoretical investigations.

Concerning the ground state $^4A_{2g}$, symmetry adapted expansion coefficients will not be able to calculate increased values for the splitting of this level since both Kramers doublets resulting from spin-orbit interaction have essentially identical orbital wave functions which hardly are affected differently by neighboring atoms that could lead to unequal energies. The large splittings for metal compounds with heavier halogen ligands observed from ESR spectra,[22-24] therefore, are only explained by a relativistic nephelauxetic effect which is described within the framework of LCAO theory in a similar way as Stevens expansion coefficients which allow the spin-orbit coupling parameters to be increased up to values higher than obtained for the free ions.[22,37]

Luminescence Intensity Analysis. The molecular structure of excited electronic states can be determined if in the vibronic spectrum at least partially resolved band profiles are obtained. For an analysis, the relative band intensities in the progression, e.g., of an emission spectrum

$$\nu_n = \nu_{00} - \nu_{pr} - n \cdot \nu_{ac} \tag{6}$$

are used where ν_{00} represents the zero phonon band gap, ν_{pr} a promoting mode which makes the transition electric dipole allowed, and ν_{ac} denotes the accepting mode forming the actual series of equally spaced band peaks.[41] If the pure electronic (zero phonon) transition is allowed, in general, some normal modes of given symmetry (which are totally symmetric if Jahn-Teller effects are absent) may act as promoting and accepting mode as well, a situation which leads to a rather complicated theoretical description of relative transition probabilities. In the Herzberg-Teller coupling scheme of electron-nuclear interaction the vibronic transition moment for g→a is expressed by

$$M^{ga} \approx \langle M_e^{ga} \rangle \langle \chi_v | \chi_{v'} \rangle + \sum_k \frac{\langle M_e^{gk} \rangle}{E_e^a - E_e^k} \sum_\mu \left\langle \left| \frac{\partial H_e}{\partial Q_\mu} \right|^{ka} \right\rangle \langle \chi_v | Q_\mu | \chi_{v'} \rangle + \cdots \tag{7}$$

where χ_v and $\chi_{v'}$ are total nuclear wave functions of the molecule in the ground and excited state, respectively, $\frac{\partial H_e}{\partial Q_\mu} Q_\mu$ is the linear vibronic coupling operator and E_e^k the energy of the wave function mixing into the states considered.[42] Due to the lack of appropriate electronic wave functions the size of these integrals are not known. Therefore relative Franck-Condon factors can only be compared to the spectra if some of the terms of Eq. 7 can be neglected, i.e., either the first contribution is zero if the pure electronic transition is strictly forbidden or χ_v refers to the zero phonon excitation and $\chi_{v'}$ belongs to a nontotally symmetric representation or the second and all higher terms are vanishingly small compared to the first term in the case of an allowed transition.

In the emission spectra of [X] complexes, apart from side bands assigned to fundamental vibrations, we can identify intensive transitions in combination with the Cr-halogen stretching vibration $\nu_5(a_1)$ as well as progressions in the same mode. Figure 8 depicts the luminescence spectrum of the $[Cl]Cl_2$ complex doped into the corresponding Rh(III) compound. This

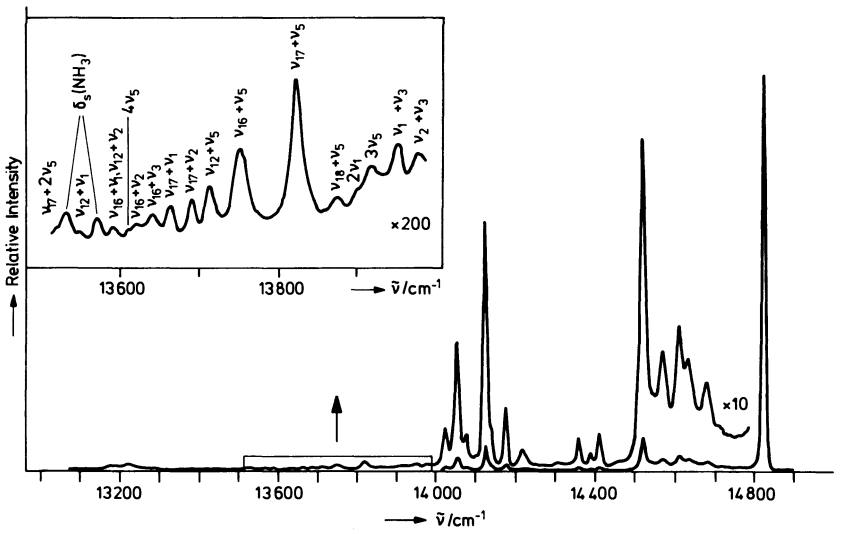

Fig. 8. ^2E_g emission spectrum of Cr^{3+} doped in $[Rh(NH_3)_5Cl]Cl_2$ at 5 K exhibiting low intensity members in the vibrational progression (λ_{exc}=514.5 nm).

Table 3. Intensity Relations in Vibrational Progressions and Nuclear Equilibrium Distortions in the First Excited State

X	σ_X/cm^{-1}	ν_5/ν_{00}	$2\nu_5/\nu_5$	$(\nu_{pr}^{a)}+\nu_5)/(\nu_{pr})$	ΔR(Cr-X)/pm
F	7400	0.11	0.12	0.08	≈ 3
Cl	5500	0.086[b)]	0.050[b)]	0.029[b)]	≈ 2
Br	5000	0.118[b)]	0.054[b)]	0.044[b)]	$\lesssim 1.5$[c)]
I	4500	0.12	0.06	0.07	$\lesssim 1.5$[c)]

a) $\nu_{pr}=\nu_{16}$ or ν_{17}, i.e. δ(Cr-N-H) of e-symmetry. b) Obtained from doped compounds (Rh-host). c) σ(Cr-X) is strongly mixed with the totally symmetric bending mode δ(N-Cr-N).

system has been chosen since intensity relations differing up to four orders of magnitude (1:10^4) could be determined in this case. Some of the intensity relations obtained are compiled in Table 3. Since ν_5 is at the same time promoting and accepting mode, the different numbers calculated for the two progressions considered are explained by the result of the discussion following Eq. 7. For a Franck-Condon analysis, therefore only the intensity relations in the ν_5-progression in combination with the nontotally symmetric vibrational modes δ(Cr-N-H), i.e. ν_{16} and ν_{17}, are evaluated since in these cases the first term in Eq. 7 vanishes for symmetry reasons. The fitting of experimental band intensities in the progression to a theoretical band profile function allows an intramolecular distribution function $I(n,\Delta,\beta)$ to be determined from which the parameter Δ is calculated containing the geometric distortion coordinates in the excited state.[43] The frequency factor $\beta=\nu_g/\nu_a$ is approximately unity since vibrational frequencies ν_a measured from the absorption spectra are almost equal to corresponding values ν_g obtained from IR and Raman data applying to the ground state.

Due to the rapidly decaying band intensities in the progression which moreover is obscured by many other vibrational side bands, a Franck-Condon analysis of the absorption spectrum cannot be carried out. On the other hand are emission spectra by far less perturbed by superpositions since transitions from only one or two of the lowest excited electronic states are involved; therefore they are more appropriate for these analyses. In the present spectra of halogenopentaammines, including the [F] compound, the most intense progressions are found to be due to the $\nu_5(a_1)$ mode which for [F] and [Cl] is an almost pure metal-halogen stretching vibration, but for [Br] and [I] it is appreciably mixed with the $\nu_6(a_1)$ bending mode (cf. Table 1).[33] As indicated in Table 3 the degree of the excited potential curve shift ΔR(Cr-X) proceeds with the size of the σ-antibonding parameter σ_X of the halogen ligand which is to be expected due the increased geometric distortion if the d_{z^2}-orbital (the hetero atom is located on the z-axis) is partially occupied on excitation.

From the distinctly longer progression observed in the $^2E(^2T_{2g})$ absorption spectrum (see Fig. 5) it can be concluded that this state exhibits a larger geometric distortion due to the intermixing of higher energy levels belonging to electron configurations which involve e_g orbitals. Actual numbers cannot be given since normal coordinates for the excited state would be required.

Conclusions

Since for many of the most common complex compounds, as the present halogenopentaammines of chromium(III), the electronic and vibrational energy level schemes are not known in detail, it is recommended to look more closely into well resolved vibronic spectra, i.e. to record low temperature crystalline absorption and emission spectra at high sensitivity. The measured band patterns are strongly dependent on the geometric properties of the crystals, possibly yielding in some instances more detailed information on local distortions than can be obtained from common X-ray investigations. In addition the analysis of the vibronic side bands, if vibrational fine structure is sufficiently well resolved, allows the geometry of some of the excited states to be determined which contributes for characterizing the emitting states being important for explaining photochemical processes.

Conventional ligand field and angular overlap calculations are very useful for carrying out band assignments but they are not in all cases appropriate models for reproducing values of energy levels derived from the experiment. However, small extension or variation of these models, e.g. as presently including symmetry restricted π-orbital expansion factors into the electron repulsion part, may lead to a satisfactory description of experimental results. It is these possible extensions of the model which should be considered in the near future in order to obtain a theory which is generally applicable to a larger variety of cases.

The authors are grateful to Dr. M. A. Atanasov, Sofia, for making us aware of the large level splittings due to orbital expansion factors, to Dr. T. Woike, Jülich, for recording the Raman spectrum, to Prof. R. Kniep and Mr. R. Seidel, Düsseldorf, for carrying out the X-ray investigations. We also appreciate the aid of

Degussa Company, Hanau, supplying us with the rhodium material.

Metal Complexes with Tetrapyrrole Ligands. 47.[1] Yttrium(III) Bis(octaalkylporphyrinate)s: Synthesis and Electron Spin Resonance Spectra of Earth Metal Porphyrin Sandwich Compounds

Johann Walter BUCHLER,* Jürgen HÜTTERMANN,† and Jürgen LÖFFLER
Institut für Anorganische Chemie, Technische Hochschule Darmstadt, D-6100 Darmstadt, F.R.G.
†Fachgebiet Biophysik und Physikalische Grundlagen der Medizin, Fachbereich Theoretische Medizin, Universität des Saarlandes, D-6650 Homburg/Saar, F.R.G.
(Received August 10, 1987)

Reaction of tris(2,4-pentanedionato)yttrium(III) with octaethylporhyrin, H_2oep in refluxing 1,2,4-trichlorobenzene (TCB) produces a trace (2%) of the double-decker, Y(oep)$_2$ (**3A**) besides major amounts (72%) of the yttrium(III) monoporphyrinate, Y(oep)(acac) which are separated by chromatography. Appreciable yields of Y(oep)$_2$ (**3A**) (25%) are obtained from dilithium octaethylporphyrinate, Li_2(oep), formed in situ and Y(oep)(acac) in refluxing TCB. The constitution of the double-decker **3A** is proved by UV/VIS, IR, ^{1}H NMR, ESR, ENDOR, and mass spectra. The well-defined composition Y(oep)$_2$ requires that one of the porphyrin rings is electron-deficient, i.e. the charge of the Y^{III} ion is compensated by the normal porphyrinate dianion and a porphyrinate monoanion radical. The magnetic moment in the solid state, μ_{eff}=1.5 B.M. (5—100 K), demonstrates the radical nature of **3A** as well. Under the time resolution of the methods used, the unpaired electron is delocalized between the two porphyrin rings. The wavenumber of the internal charge transfer absorption band in the near infrared (λ_{CTI} 1175 nm) agrees well with the value expected for the ionic radius of Y^{III} according the linear relationship of the energy of the CTI band and the ionic radius which has been established for the series of lanthanoid octaethylporphyrinates, Ln(oep)$_2$ (Ln=La···Lu). **3A** can be reduced to the diamagnetic sandwich anion, [Y(oep)$_2$]$^-$. Y^{III} double-decker radicals Y(omp)$_2$ (**3B**; λ_{CTI} 1100 nm) or Y(hbp)$_2$ (**3C**, λ_{CTI} 1100 nm) containing octamethylporphyrin or hexadecahydrotetrabenzoporphyrin have also been prepared.

Sandwich like metal bis(tetrapyrrole)s are known since the first description of tin(IV) bis(phthalocyaninate), Sn(pc)$_2$,[2,3] and the sandwich nature was demonstrated by crystallography in the case of Sn(pc)$_2$ and the actinoid sandwich systems, An(pc)$_2$ (An=Th, U),[4] or the lanthanoid double-deckers, Ln(pc)$_2$.[5] The latter compounds are intensively studied as prospective materials for electrical devices such as semiconductors or color displays.[6]

Synthetic investigations on the corresponding porphyrin sandwich systems have been initiated with the cerium(IV) bis[tetra(*p*-tolyl)porphyrinate], Ce(ttp)$_2$, and praseodymium(III) hydrogen bis[tetra(*p*-tolyl)-porphyrinate], PrH(ttp)$_2$.[7] Due to the limited solubility of the former species, the further investigation of the corresponding octaethylporphyrin derivatives M(oep)$_2$ (**A**; M=Ln; Ln=La···Lu save Pm) has been undertaken.[8] The diamagnetic parent compound, the Ce^{IV} sandwich Ce(oep)$_2$ (**1A**) has been fully described and the square antiprismatic geometry shown in **A** demonstrated by X-ray crystallography.[9]

The same geometry obtains for the paramagnetic Eu^{III} sandwich, Eu(oep)$_2$ (**2A**).[1] As in **2A**, the porphyrin rings in all the Ln^{III} double-deckers Ln(oep)$_2$ occur in two different oxidation states: There is a normal $(oep)^{2-}$ dianion, and an electron-deficient radical anion, $(oep\cdot)^{1-}$. These two rings show an internal charge transfer absorption band (CTI band) in the near infrared the energy of which is solely dependent on the ionic radius of the Ln^{III} ion.[10,11] As the radius of the Ln^{III} ion at coordination number 8 increases, the energy of the CTI band decreases,[11] and the redox potential of reaction (1) decreases likewise.[10,12]

$$Ln(oep)_2 + e^- \rightleftharpoons [Ln(oep)_2]^- \quad (1)$$

Obviously, interelectronic repulsion is less pronounced when the two porphyrin rings have a larger

distance. Hence, the electron-rich reduced species is the more stable the larger the Ln^{III} ion is.

The importance of the ionic radius in these double-deckers led to the hypothesis that yttrium(III) derivatives, e.g. $Y(oep)_2$ (**3A**), should be accessible and have redox potentials and energies of CTI bands close to those of $Ho(oep)_2$ (**4A**) or $Er(oep)_2$ (**5A**), because the ionic radii of these metal(III) ions are very similar: Y, 101.5 pm; Ho, 102 pm; Er, 100 pm.[13] Indeed, this idea has been realised. The synthesis and spectral properties of the yttrium(III) porphyrin sandwich compounds $Y(oep)_2$ (**3A**), $Y(omp)_2$ (**3B**), and $Y(hbp)_2$ (**3C**)[3] are described in this paper.

Experimental

Material and Methods. Chemicals and instruments used were the same as previously described[9] if not stated below. $Y(acac)_3 \cdot H_2O$ was prepared following literature methods.[14] Octamethylporphyrin, H_2omp, was a gift of Professor R. Guilard, Dijon. Hexadecahydrotetrabenzoporphyrin, H_2hbp, was prepared as described by Fuhrhop.[15] Near infrared spectra (Fig. 1) were taken with a Zeiss spectrophotometer DMR 21. The ESR spectra [Fig. 2; Varian X-band, E-line spectrometer; 9.25 GHz; diphenylpicrylhydrazyl (g=2.0036) as calibrant] and the magnetic susceptibility of $Y(oep)_2$ (5—100 K; vibrating reed magnetometer[16]) were obtained by Mr. Weißenberger and Mr. F. Arenz at the Institut für Festkörperphysik, Technische Hochschule Darmstadt (courtesy of Professor B. Elschner). A 0.25 M (1 M=1 mol dm^{-3}) solution of sodium anthracenide in THF was prepared as described elsewhere.[17]

Synthesis of 2,4-Pentanedionato(2,3,7,8,12,13,17,18-octaethylporphyrinato)yttrium(III), Y(oep)(acac). 300 mg (0.56 mmol) octaethylporphyrin and 500 mg $Y(acac)_3 \cdot H_2O$ (1.25 mmol) are heated to reflux in 50 ml TCB under a stream of nitrogen. After 5 h, the cherry-red solution is freed from TCB in vacuo, the residue dissolved in toluene, filtered and chromatographed at alumina (grade I, basic, column 4×6 cm). Elution with toluene yields Fraction 1: traces of Y(oep)(acac) and TCB. A second, red-brown Fraction 2 is eluted with toluene/methanol (100:1) and consists of H_2oep and $Y(oep)_2$. The alumina column is now deactivated with water,[8] dried and eluted with THF, whereupon the main product Y(oep)(acac) is obtained as Fraction 3 (bright red). This THF solution is diluted with dichloromethane and extracted several times with water for removal of THF. The dichloromethane phase is filtered, the solvent removed in vacuo and the red-violet powder of Y(oep)(acac) (290 mg, 72%) dried in vacuo. UV/VIS [λ_{max}]: 574 (I), 538 (II), 404 (III), 334 (IV) nm; rel. intens. III>IV≈I>II.[18] IR (KBr): 1605 and 1510 cm^{-1} (bands of the coordinated acetylacetonate ligand[19]). MS (FD): Calcd for Y(oep)(acac), M=720, Found M=720, Calcd for Y(oep)(OAc): M=680, Found M=680. (This peak is due to thermolysis of the coordinated acetylacetonate as observed previously with Sc(oep)(acac).[19])

Fraction 2 is rechromatographed at alumina (grade I, basic, 2×6 cm). With toluene, some H_2oep is eluted. With toluene–methanol (200:1), a brownish-red fraction containing 10 mg (2%) of $Y(oep)_2$ (**3A**; see below) is obtained.

Synthesis of Bis(2,3,7,8,12,13,17,18-octaethylporphyrinato)yttrium(III), Y(oep)$_2$ (3A). 4 ml of a 1.6 molar solution of butyllithium in hexane[8] is added dropwise to a solution of 135 mg (0.25 mmol) of H_2oep in 50 ml of TCB under argon. After stirring for 1 h at 20 °C, 180 mg (0.25 mmol) Y(oep)(acac) are added and heated to reflux under a rapid stream of argon. The color of the initially red-violet reaction mixture changes to brown after 5 h. The TCB is then removed in a high vacuum at 50 °C. The residue is chromatographed at an alumina column (grade I, basic, 4×8 cm) with toluene. After an orange-yellow forerun of unknown composition, a brown main fraction is eluted which at its end is increasingly contaminated with H_2oep. This eluate is evaporated to dryness and rechromatographed as above in order to remove the large amounts of H_2oep. The obtained solid is fractionately dissolved in benzene–TCB (5:1) leaving undissolved H_2oep which is filtered. Crystallization of the solution yields small black rhombs of **3A** (72 mg, 25%) which are dried in vacuo at 50 °C. Found: C, 74.12; H, 7.58; N, 9.68%. Calcd for **3A**, $C_{72}H_{88}N_8Y$: 1154.52: C 74.91; H 7.68; N, 9.70%. IR (KBr): 1535 cm^{-1} (oxidation state marker band[20]). MS(FD): Found, M=1154, Calcd for ^{89}Y, M=1153.6. UV/VIS [λ_{max}, (log ε), cyclohexane]: 674 (3.38), 538 (3.88), 374 (5.10), 340 (4.96). NIR [λ_{max} (log ε), cyclohexane]: 1175 (3.83). See also Fig. 1. TLC-R_f value: 0.68 (toluene).

Sodium Bis(2,3,7,8,12,13,17,18-octaethylporphyrinato)yttriate(III) in toluene/tetrahydrofurane. A solution of 5 mg (0.004 mmol) $Y(oep)_2$ (dried in vacuo at 50 °C) in 0.5 ml toluene-d_8 containing a trace of TMS was placed under Ar into a dry NMR tube and seald with a septum cap and Nescoe film. With a Hamilton syringe, 15 µl of 0.25 M sodium anthracenide in THF was added and a ^1H NMR spectrum taken (see Table 1); apart from the signals of $[Y(oep)_2]^-$, stronger signals of THF and weaker signals of anthracene, toluene, TMS, and H_2oep were noted. Afterwards, the red-brown solution was transferred (under air) to a cuvette for absorption spectroscopy. It did not show any absorption in the near infrared (900—2000 nm). UV/VIS (λ_{max}, toluene): 586 (I), 542 (II), 492 (III), 390 (IV) nm; rel. intens. IV>I>III>II. The relatively high intensity of band III is due to the presence of some H_2oep.

Synthesis of 2,4-Pentanedionato(2,3,7,8,12,13,17,18-octamethylporphyrinato)yttrium(III), Y(omp)(acac), and Bis(2,3,7,8,12,13,17,18-octamethylporphyrinato)yttrium(III), Y(omp)$_2$ (3B). As described for Y(oep)(acac), 300 mg (0.71 mmol) H_2omp and 600 mg (1.5 mmol) $Y(acac)_3 \cdot H_2O$ are reacted and the reaction products separated. After 5 h, besides the expected Y(omp)(acac) (170 mg, 40%) a notable part of the reaction product consisted of **3B**. After chromatography, **3B** (98 mg, 16%) was obtained as a dark brown powder which could not be recrystallized due to its very limited solubility. UV/VIS [λ_{max}], Y(omp)(acac) [dichloromethane]: 574 (I), 538 (II), 404 (III), 334 (IV) nm; rel. intens. III>IV≈I>II. $Y(omp)_2$ [toluene]: 670 (I), 536 (II), 374 (III), 340 (IV) nm, rel. intens. III>IV>II>I. NIR [λ_{max}, toluene]: $Y(omp)_2$, 1100 nm (about the same intensity as the VIS band II). MS (FD), Y(omp)(acac): Found, M=608, Calcd ^{89}Y, M=608; $Y(omp)_2$: Found, M=929, Calcd ^{89}Y, M=929. A TLC-R_f value could not be determined for $Y(omp)_2$: A spot of $Y(omp)_2$ was not visible on attempted chromatography with toluene.

Synthesis of 2,4-Pentanedionato(hexadecahydrotetrabenzo[*b,g,l,q*]porphyrinato)yttrium(III), Y(hbp)(acac). As described for Y(oep)(acac), 300 mg (0.57 mmol) H_2hbp and

500 mg (1.25 mmol) $Y(acac)_3 \cdot H_2O$ are reacted and the products separated. Fraction 2 yields 20 mg (3%) $Y(hbp)_2$, Fraction 3 270 mg (66%) Y(hbp)(acac).—UV/VIS (λ_{max}, dichloromethane): 572 (I), 536 (II), 404 (III), 334 (IV); rel. intens. III>IV≈I>II.—MS(FD): Found, M=712; Calcd ^{89}Y, M=712.

Synthesis of Bis(hexadecahydrotetrabenzo[*b,g,l,q*]porphyrinato)yttrium(III), Y(hbp)$_2$ (3C). As reported for **3A**, 135 mg (0.25 mmol) H_2hbp, 4 ml of a 1.6 molar solution of butyllithium, and 180 mg (0.25 mmol) Y(hbp)(acac) are reacted and the products separated. The resulting **3C** is less soluble than **3A** in all usual organic solvents and is obtained as a dark brown powder (51 mg; 18%) by recrystallization from toluene. UV/VIS (λ_{max}, toluene): 670 (I), 536 (II), 374 (III), 340 (IV) nm; rel. intens. III>IV>II>I. NIR (λ_{max}, toluene): 1100 nm (about the same intensity as the VIS band II). TLC-R_f: see note for $Y(omp)_2$.

ENDOR Spectroscopy. A Bruker ER 420 spectrometer was attached to a Dietz 621 computer and equipped with an ENDOR facility described previously[21]. Measurements between 1 and 20 MHz were performed at about 10 K and a ESR frequency of 9.4804 GHz with a sample of $Y(oep)_2$ in frozen toluene solution and recorded in the first derivative mode. The pattern of the weakly coupled proton signals (10—20 MHz; see Fig. 3) was not significantly changed when the measurement were not done at g=2.002(4), but at the tails of the ESR signal.

Results and Discussion

(a) Chemistry. The reaction of lanthanoid acetylacetonates $Ln(acac)_3$ with porphyrins H_2p is normally achieved by heating the reactants in boiling trichlorobenzene for 1—4 h and then produces the monoporphyrin complexes Ln(p)(acac)[22] according Eq. 2.

$$Ln(acac)_3 + H_2p \longrightarrow Ln(p)(acac) + 2Hacac \quad (2)$$

Prolonged heating (up to 20 h) yields the double-deckers in the tetraarylporphyrin series, e.g. $Ce(ttp)_2$[7] or the double-deckers $Ln(oep)_2$ with Ln=La···Tb[8-10,23] (Eqs. 3, 4).

$$Ln(p)(acac) + H_2p \longrightarrow LnH(p)_2 + Hacac \quad (3)$$

$$4LnH(p)_2 + O_2 \longrightarrow Ln(p)_2 + 2H_2O \quad (4)$$

The latter are accompanied by triple-deckers $Ln_2(oep)_3$[8-10,23] for Ln=La···Gd which emerge from reaction (5).

$$LnH(p)_2 + Ln(p)(acac) \longrightarrow Ln_2(p)_3 + Hacac \quad (5)$$

Obviously, the tendency to form double- and triple-deckers decreases with decreasing ionic radius of the lanthanoid ion and increasing bulkiness of the porphyrin. The later members of the series $Ln(oep)_2$ where Ln=Dy···Lu are not accessible from $Ln(acac)_3$. They have to be prepared by a modified "raise-by-one-story" reaction sequence 6—7 similar to Eqs. 3 and 4 using the monoporphyrin Ln(oep)(acac) and the dilithium complex of octaethylporphyrin, $Li_2(oep)$, which is an unstable material but easily obtained in situ from H_2oep and an excess of butyllithium in inert solvents.[8,24]

$$Ln(oep)(acac) + Li_2(oep) \longrightarrow LnLi(oep)_2 \quad (6)$$

$$4LnLi(oep)_2 + O_2 \longrightarrow 4Ln(oep)_2 + 2Li_2O \quad (7)$$

Other feasible starting materials for the synthesis of lanthanoid sandwich complexes would be the lanthanoid dialkylamides. While a uranium(IV) double-decker cannot be made from $U(oep)(acac)_2$ and $Li_2(oep)$,[8] $U(tpp)_2$ has been prepared from $U(NEt_2)_4$ and H_2tpp in refluxing toluene.[25]

Yttrium being similar to Holmium and Erbium as regards their ionic radii, the formation of a double-decker in the reaction of $Y(acac)_3$ with any porphyrin H_2p was not expected. At first, therefore, the monoporphyrinates Y(p)(acac) where prepared from octaethylporphyrin, octamethylporphyrin, and hexadecahydrotetrabenzoporphyrin.[15] However, when $Y(acac)_3$ is reacted with the octaalkylporphyrins, surprisingly, small amounts of double-deckers $Y(p)_2$ (**3A—3C**) are found besides the monoporphyrins Y(p)(acac) [(p)=(oep), (omp), (hbp)]: 2% for **3A**, 16% for **3B**, 3% for **3C**. The obtained yield of **3B** was sufficient to characterize the compound. Therefore, only the synthesis of **3A** and **3C** was performed with the "butyllithium raise-by-one-story" method (Eqs. 3 and 4).[8]

The monoporphyrins Y(p)(acac) are formed in reasonable yields, but have not been fully characterized because Y(tpp)(acac)[26] and Y(oep)(acac)[18] have already been described. It is more probable, however, that all the monoporphyrinates Ln(p)(acac) rather have the composition $Ln(p)(acac)(H_2O)_2$ or similar octacoordinate geometries in view of the known crystal structures[5,27] of lanthanoid phthalocyanines with bidentate acetate or acetylacetonate ligands. Furthermore, bridged binuclear structures may be formed from these monoporphyrinates in solution which still show the molecular ion of Ln(p)(acac) in the mass spectrum after crystallization but give inconsistent elemental analyses for this composition.[28] Therefore, the formula Y(p)(acac) is only used for simplicity.

Equations 4 and 7 imply that an oxidation is involved in the formation of the double-deckers $Ln(p)_2$. For an earth metal ion like Y^{III}, no other oxidation state is available. The oxidation must then involve the porphyrin ligand. Evidence for the presence of a porphyrin radical in $Y(p)_2$ is presented in the later sections.

All the properties of the porphyrin radical vanish in $Y(oep)_2$ when it is reduced to the diamagnetic anion $[Y(oep)_2]^-$. This reduction according Eq. 1[1,8] is done with sodium anthracenide in THF and easily followed by NMR spectroscopy. The oxidation-reduction potential for the pair $Y(oep)_2/[Y(oep)_2]^-$ is −0.21 V (cyclic voltammetry, SCE, DMF, NBu_4PF_6).[10,12]

$Y(oep)_2$ closely resembles its cerium analog: **3A** is

rather soluble even in alkanes. However, **3B** and **3C** only have a very limited solubility, like their parent porphyrins and the other metal complexes of the latter. This has precluded a more thorough investigation of **3B** and **3C**.

(b) Identification. $Y(oep)_2$ (**3A**), $Y(omp)_2$ (**3B**), and $Y(hbp)_2$ (**3C**) are identified by optical absorption (UV/VIS and NIR) and mass spectra. The optical absorption spectra of **3A—3C** do not have the "normal" appearence[29] of their cerium(IV) analogs, but are typical for species in which the porphyrin ligand is oxidized to a π-radical.[30] Specifically, the bands at 670 nm are reminiscent to strong absorption occurring in $Mg(oep)ClO_4$ (**7**) at about 660 nm.[30b] The bands found in **3A—3C** correspond well with those found with all compounds $Ln(oep)_2$ containing Ln^{III} ions.[11]

Furthermore, infrared spectra showing all the typical bands of octaethylporphyrin complexes lacking axial ligands, magnetic measurements and elemental analyses fully identify **3A**. As in the case of $Lu(pc)_2$[5a,31] and $Lu(oep)_2$ (**6A**),[8] the magnetic moment measured in the solid state clearly demonstrates the radical nature of $Y(oep)_2$: μ_{eff}=1.46—1.52 B. M. between 5.4 and 100 K (Curie-Weiss behavior, θ=1.5 K).

The most characteristical property of these double-decker radicals consisting of a noninteracting central metal ion M^{III} or M^{IV}, a porphyrinate dianion $(p)^{2-}$ and a porphyrinate monoanion radical $(p\cdot)^-$ is the NIR absorption band which occurs, e.g., for $La(oep)_2$ at 1480 nm,[10,11] $Eu(oep)_2$ at 1280 nm,[10,11,23] $Lu(oep)_2$ at 1135 nm,[10,11] $[Ce(oep)_2]^+$ at 1270 nm,[32] and $[Ce(ttp)_2]^+$ at 1340 nm.[32] This band is due to an internal charge-transfer complex (electron donor acceptor complex)[33] which is formed between the donor, $(p)^{2-}$, and the acceptor, $(p\cdot)^-$.[1,11] Donor and acceptor are combined in the same molecule. In an alternative view, these radicals could be "inverse mixed valence complexes," the mixed valencies not residing on two metals, but rather on two ligands.[1,11] The yttrium doubledeckers clearly fall into this class with their NIR bands for $Y(oep)_2$ (**3A**) at 1175 nm and $Y(omp)_2$ as well as $Y(hbp)_2$ at 1100 nm (see Fig. 1). The value for **3A** indeed coincides with the value for $Er(oep)_2$ (**5A**) at 1175 nm[11] and is very close to the value of $Ho(oep)_2$ (**4A**) at 1180 nm.[11]

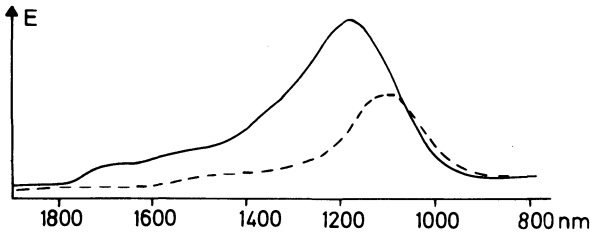

Fig. 1. Near infrared absorption spectra of $Y(oep)_2$ (**3A**) and $Y(omp)_2$ (**3B**) (extinction arbitrary).

A working hypothesis for a explanation of the lower wavelength found with **3B** and **3C** as compared with **3A** is the following: In the octamethyl or hexadecahydrotetrabenzo porphyrin sandwiches, the steric inter-ring repulsion is smaller than in the octaethyl porphyrin sandwich. Hence, the distance of the $C_{20}N_4$ mean planes is also smaller, and the electronic properties more closely resemble $Lu(oep)_2$ in which due to the smaller Lu^{III} ion the rings are forced more closely together.

The NIR band found in these double-deckers is reminiscent to the oxidized form $[(BChl)_2]^+$ of the "special pair" of bacteriochlorophyll b molecules $(BChl)_2$. $[(BChl)_2]^+$ is formed on illumination and has a NIR absorption at 1300 nm in Rhodopseumonas viridis.[34] The redox pair $[(BChl)_2]^+/(BChl)_2$ corresponds to the redox pairs $[Ce(oep)_2]^+/Ce(oep)_2$[32] or $Y(oep)_2/[Y(oep)_2]^-$ (see above). This relationship to the photosynthetic reaction center makes further studies of these double-deckers quite attractive.

(c) ^{1}H NMR Spectroscopy. The ^{1}H HMR spectrum of $Y(oep)_2$ (**3A**, data in Table 1) is much more complicated than the spectrum of $Ce(oep)_2$ (**1A**). This is seen in the chemical shifts and the linewidths of the signals. Most notable is a strong very broad peak at δ 3. This is reminiscent to a very broad peak in the spectrum of $[Ce(oep)_2]^+$[32] at δ 2.25 and a similar peak in the spectrum of $Lu(oep)_2$ (**6A**) at δ 3.06. In fact, these two peaks are the only ones in the spectra of **3A** and **6A** which point to paramagnetism of the compounds. All the other signals appear in regions where the proton signals occur in the diamagnetic reference **1A**. A detailed interpretation of the NMR spectra of **1A** and **2A** is given elsewhere.[1,8,9]

Even the methine signals of **3A** are duplicated, indicating a sandwich system in which one porphyrin ring is slightly different from the other, a situation which is also found in the diamagnetic anions, $[Y(oep)_2]^-$ and $[Lu(oep)_2]^-$.[8] In the latter, the duplication of the methine signals is due to the formation of an ion pair with a THF-solvated Na^+ counter ion which is thought to coordinate to the pyrrole nitrogen atoms on one side of the sandwich system. In the absence of any charges and ions, the diamagnetic species present in **3A** could be a centrally vacant quadruple-decker $[M(p)_2]_2$ formed in an association equilibrium (8):

$$2\,M(p)_2 \rightleftharpoons [M(p)_2]_2 \qquad (8)$$

Monoporphyrin π-radicals, e.g. $[Zn(oep)]ClO_4$,[35] tend to dimerize as well in concentrated solutions and thus form diamagnetic π-π-dimers. The diamagnetic component in the solution of **3A** (and **6A**[8]) can be removed by addition of the radical di-*t*-butyl nitroxide $(t\text{Bu})_2NO$, which otherwise acts as a "spin relaxer".[36] Generally, the line width of the NMR spectra of organic radicals is reduced in the presence of

Table 1. ^{1}H NMR Data (300 MHz) of Y(oep)$_2$ (**3A**), Its Reduction Product Na[Y(oep)$_2$], and Lu(oep)$_2$ (**6A**) Together with the Reference Data of Ce(oep)$_2$ (**1A**)

Compound	Chemical shifts δ, coupling constants J, or line widths $w(1/2)$[a]

a) δ [ppm] vs. int. TMS; J [Hz] or half widths $w(1/2)$ [Hz] (in italics). b) Methine protons of external (e) ring (outwards of the molecule). c) Methine protons of internal (i) ring (inwards to the molecule). d) 1 and 2 denote exo and endo methylene protons, respectively (assignment arbitrary). e) Presumed dimer present in the concentrated solution. f) Compound measured in presence of spin relaxer (tBu)$_2$NO. g) Isotropic shift of the radical $\delta_{iso}(rad)=\delta_{obs}-\delta_{ref}$ [Ce(oep)$_2$]. h) Reference is $1/2[\delta CH_2(e,1)+\delta CH_2(e,2)]$ because of ambiguity of assignment. i) Multiplicity of the signals observed.

other paramagnetic molecules acting as "spin relaxers". Hence, in the presence of (tBu)$_2$NO, the NMR spectrum of the radical **3A** alone becomes visible with all its four broad peaks that are to be expected in comparison to the diamagnetic **1A**. The assignments indicated in Table 1 are based on integrated intensity ratios. The multiplicity of the signals indicates only one set of methyl and two sets of diastereotopic methylene protons. On the NMR timescale, therefore, the two porphyrin rings are identical, and the π-electron hole seems to be delocalized.

The equilibrium (8) for **3A** obviously exists only in solution. Solid **3A** consists of paramagnetic monomers. Otherwise it should be diamagnetic (as is the solid phase of La(oep)$_2$[8]) and not exhibit an ESR spectrum as microcrystalline material in frozen matrices like **7**.[30b]

The isotropic shifts of the radical **3A** using **1A** as a diamagnetic reference are given in Table 1 as $\delta_{iso}(rad)=\delta_{obs}-\delta_{dia}$, along with the corresponding values of **6A**[8] and those calculated for the porphyrin radical contribution from the spectrum of **2A**.[1]

(d) Electron Spin Resonance and Electron Nuclear Double Resonance Spectra. ESR spectra of Y(oep)$_2$ at various temperatures in toluene or frozen toluene are shown in Fig. 2. With g=2.002(4), this is a typical signal of an organic radical. The line width ΔH_{pp} does not change very much on cooling to 70 K ($\Delta H_{pp}\simeq$4.11 G at 70 K, 3.52 G at 290 K), but on cooling below 40 K, shoulders appear causing an increase of total spectral extent to ~28 G at 4.2 K together with a slight increase in ΔH_{pp}(≃4.76) of the central line (see Fig. 2). The

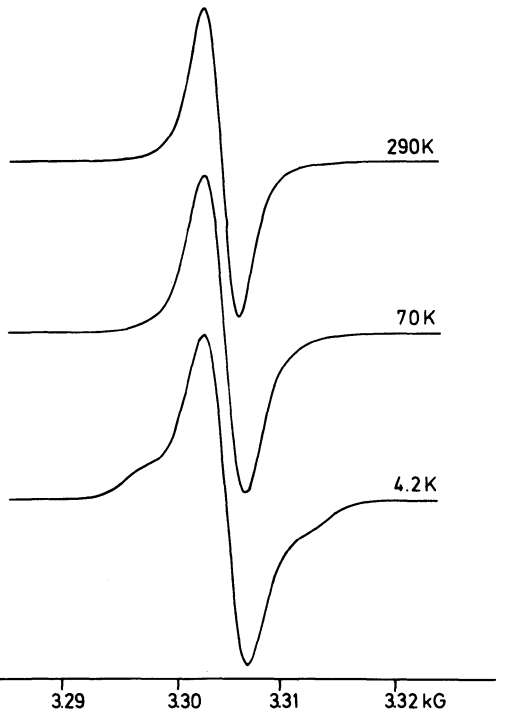

Fig. 2. Electron spin resonance spectrum of Y(oep)$_2$ (**3A**) (derivative mode).

reason for the additional lines is unclear. The slight asymmetry of the shoulders with respect to the central line could be indicative of the presence of a second, chemically different species. ΔH_{pp} at 70 K is slightly larger than that of the signal of the monoporphyrin radical [Mg(oep)]ClO$_4$ (**7**) [g=2.0025 at 223 K; $\Delta H_{pp}\approx$ 3.5 G].[30b]

While the spectrum of **7** shows a proton hyperfine structure (HFS) due to the methine H atoms [a_H=1.48 G=0.148 mT], such a fine structure is not distinguishable in the spectrum of **3A**. Under the assumption that the unpaired electron is delocalized between the two rings on the ESR time scale, a_H should be smaller for each contributing nucleus, and the total linewidth be reduced as compared with **7** although the number of contributing nuclei is doubled. The observed somewhat larger width of the signal of **3A** points to a coupling of the electron spin with another nucleus not present in **7**. This could be the ^{89}Y nucleus (100% natural abundance; spin 1/2; μ/μ_N=−0.237). Radicals derived from oep complexes, like **7**, bear the unpaired electron in the A_{1u} molecular orbital[30b] which has nodal planes at the four porphyrin nitrogen atoms. There is no spin density at these atoms and hence no ^{14}N-HFS seen. Likewise, in **3A** a ^{14}N hyperfine splitting is not observable. Hence, **3A** is probably also an A_{1u} radical. This is consistent with the visible absorption spectrum.[30b] Further investigations with meso-deuterated **3A** or Y(tpp)$_2$ would be useful, but the latter compound is hitherto not accessible via the butyllithium raise-by-one-story reaction.

The proton ENDOR spectrum is shown in Fig. 3. Three types of interaction can be distinguished. One is a sharp "matrix proton" line at the free nuclear frequency ν_n≃14.5 MHz; it gives no structural information. Next is a pair of lines displaced symmetrically about ν_n with a coupling of 0.45 MHz; its line shape indicates a dominantly isotropic interaction. The third coupling involves a broad, more powder-type anisotropic pair with 1.1 to 2.0 MHz. The absence of any larger interaction corroborates the notion of a distribution of spin density between the two porphyrin rings. The methine-H coupling in the monoporphyrin radical **7** translates into about 2.64 MHz for the double-decker **3A** whereas twice this value would be expected for the monoporphyrin radical.

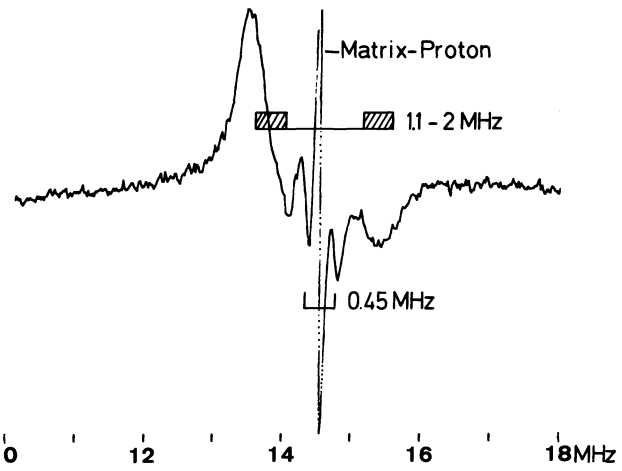

Fig. 3. Electron nuclear double resonance spectrum of Y(oep)$_2$ (**3A**) (proton range, 10—18 MHz).

If we assign the broad line pair in **3A** to the methine protons, the even lower observed (1.1—2.0 MHz) interaction again points to a contribution of the ^{89}Y nucleus onto which some spin density should be transferred. Such an interaction was looked for in the 1—10 MHz frequency region, but the data so far are not interpretable with reliability. The 0.45 MHz proton interaction could be due to the methylene protons of the ethyl groups.

(e) Conclusion. In view of the existence of yttrium(III) phthalocyaninate double-deckers Y(pc)$_2$[37] and probably also triple-deckers Y$_2$(pc)$_3$,[38] it is promising for further investigations to have the corresponding porphyrin sandwich **3A** which is much better soluble. With its NIR absorption, any redox reactions can be very easily followed. Indeed, not only the energies of the NIR absorption bands, but also the oxidation reduction potentials for the following steps (9a)—(9c) have been determined accurately in the

$$[M(oep)_2]^+ \underset{(a)}{\rightleftharpoons} M(oep)_2 \underset{(b)}{\rightleftharpoons} [M(oep)_2]^- \underset{(c)}{\rightleftharpoons} [M(oep)_2]^{2-} \quad (9)$$

porphyrin series for M=Ln (Ln=La···Lu save Pm) and for M=Y (**3A**).[10,12] The redox potentials associated with reactions (9a) [which is reaction (1) for M=Ln], (9b), and (9c) as well as the energy of the NIR band each lie on a straight line in the series M=La···Lu as the ionic radius decreases. The corresponding values obtained with **3A** fall onto these lines between Ho(oep)$_2$ (**4A**) and Er(oep)$_2$ (**5A**), demonstrating the importance of the ionic radius and the ring-ring distance in these sandwich systems.[10–12]

This work was supported by the Deutsche Forschungsgemeinschaft (Bonn), the Fonds der Chemischen Industrie (Frankfurt), and the Vereinigung von Freunden der Technischen Hochschule Darmstadt. We thank Professor Dr. B. Elschner, Mr. F. Arenz, and Mr. S. Weißenberger for magnetic and ESR measurements, Priv.-Doz. Dr. M. Veith and M. Fischer for the mass spectra, Dr. S. Braun for advice on the measurement of the NMR spectra, and Professor Dr. R. Guilard for a gift of octamethylporphyrin.

Invited Paper

Atom Trapping Atomic Absorption Spectrometric Determination of Some Trace Elements in Soils, Natural Waters, Seawater, and Bovine Liver

C. M. LAU, A. M. URE, and T. S. WEST*
Macaulay Land Use Research Institute, Aberdeen, AB9 2QJ, U.K.
(Received August 10, 1987)

The operational conditions for the determination of Ag, As, Au, Bi, Cd, Cu, Mn, Pb, Sb, Se, Tl, and Zn by atom trapping atomic absorption spectrometry are summarised. With this technique some of these trace elements can be determined in soils, natural waters, seawater and bovine liver at concentrations that are not possible by the conventional technique of flame AAS. For example, seawater is diluted ten-fold with distilled water to overcome nebulisation problems due to salt concentrations and the trace elements are collected for 2 min in situ in the air-acetylene flame before release and measurement. The attack of sodium on the hot silica atom trap tube in the flame gases is prevented by pre-aspiration of aluminium chloride into the flame, thus depositing a protective film of Al_2O_3. X-Ray diffraction, infrared spectroscopy, scanning electron microscopy, and spark source mass spectrometry are used to show that the protective alumina film consists of mainly σ alumina with a small amount of θ alumina spheroids of varying sizes <1 μm diameter and is highly pure. The nature of a similarly deposited Fe_2O_3 film is shown to be a more closely packed and irregular form of hematite with a small content of metallic iron. The results obtained by this simple new technique compare well with those obtained by spark source mass spectrometry and electrothermal AAS with a graphite furnace.

The development of atom trapping atomic absorption spectrometry[1] as a potential analytical technique for ultratrace element determination has been described in previous papers.[2-7] The surface of a water-cooled 4 mm o.d. silica tube traps and preconcentrates atomic species, or their precursors, within the body of an air–acetylene flame. When a sufficient amount has been collected (e.g. after 30 s—5 min) the trapped species are released into the flame subsequently by ejecting the water with a blast of air. The skin temperature of the silica tube attains that of the flame gases within 5—10 seconds. The trapped analyte is then atomised normally as a transient cloud of atoms within the flame. The tube is mounted permanently in the flame. Because of the uniquely low coefficient of thermal expansion of silica, the tube withstands the repeated thermal shocks produced by switching cold water back through the hot silica tube for the next trapping cycle for at least one hundred experiments before the surface becomes seriously etched. The atom trapping technique preserves the inherent simplicity, element-specificity and reliability of conventional flame AAS, as well as its ease of operation. In addition, it offers considerably higher sensitivity than the conventional technique whilst preserving most of its relative freedom from matrix interference when compared to other analytical methods of similar capacity. Hence we found it possible directly to determine selenium in plants,[4] and also lead and cadmium[5] in soils which would have been impossible by conventional flame AAS because of the low levels involved. This paper further explores the analytical applications of atom trapping AAS for the determination of some trace elements in fresh water, seawater, liver and soil samples, with particular attention to those containing very low analyte element concentrations. It also collates and summarises operational conditions for atom trapping AAS of Ag, As, Au, Bi, Cd, Cu, Mn, Pb, Sb, Se, Tl, and Zn.

Experimental

Equipment: The atom trapping AAS measurements were made with a Varian Techtron Model AA6 atomic absorption spectrophotometer equipped with background correction as described previously.[6] Instrumental parameters for each of the elements were optimised using standard solutions; these are summarised in Table 1. The possibility of background absorption and scattering effects occurring during atomic absorption measurements was examined in each case; only for elements with resonance lines below 240 nm was background correction necessary.

An Instrumental Laboratories Model 751 atomic absorption spectrophotometer fitted with a Model 555 controlled-temperature graphite furnace was used for electrothermal AAS determinations of some fresh water samples for the purposes of comparison.

Sample Preparation: Six Scottish top-soils (1 g samples) were digested with three 10 ml aliquots of aqua regia and taken to dryness each time on a steam bath, as previously described.[5] The final solutions were made up to 25 ml in 0.5 M nitric acid (1 M=1 mol dm^{-3}) and the arsenic concentrations in these solutions were measured by atom trapping AAS.

A nitric acid–hydrogen peroxide dissolution method was applied to the liver sample. In this method, a 1 g sample of the freeze-dried, powdered liver was digested with 10 ml of concentrated nitric acid on a steam bath and another 10 ml portion of the acid was added before the mixture was evaporated to less than 5 ml. The procedure was repeated with two 10 ml portions of 20 vol.(6%) hydrogen peroxide. The final mixture was filtered on Whatman No. 542 filter paper and the filtrate made up to 10 ml with 0.5 M nitric

acid.

Fresh water samples were collected and stored in polypropylene bottles and were acidified with 1% nitric acid prior to use. The samples were stored in a cold room (4 °C) and warmed up to room temperature for an hour before analysis.

The sea water was first filtered through a 50 μm sintered glass filter to remove suspended material and acidified with 1% hydrochloric acid before storing in a polypropylene bottle.

Standard Solutions: Stock solutions for the analyte elements were prepared from analytical reagent grade chemicals. Standard solutions with concentrations appropriate to the analysis were diluted from the stock solutions immediately before use. These standard solutions were prepared with an acid strength and matrix similar to the samples so that any interference effects of matrix elements on nebulisation of the solution or the trapping or release of the analyte could be minimised.

Preparation of Coated Tubes: The pre-deposited alumina and iron oxide coatings on the silica atom trap tubes were prepared by aspirating a 5000 μg ml^{-1} solution of aluminium (5 min) or iron(III) chloride (30 s) into the flame, and collecting the oxide formed on the surface of the water-cooled silica atom trap tube.

Procedure for Measurement. Arsenic in Aqua Regia Digests of Soils: Standard arsenic solutions were prepared in the range 0.1 to 0.5 μg ml^{-1} As and were made up in 0.5 M nitric acid with 200 μg ml^{-1} each of sodium and iron added to the solutions to match the approximate content of soil digests. Both the sample digests and standard solutions were collected for four minutes on an iron oxide-on-alumina-coated tube prior to atomic absorption measurement. The standard solutions were measured before and after the sample to ensure no change in sensitivity as a result of tube surface alteration. The concentrations of arsenic in the digests found from the standard calibration curve were checked by a standard addition method. Arsenic, 25 μg equivalent to 1.0 μg ml^{-1} arsenic in the digest, was added to the sample soils before the digestion procedure. The amount of arsenic recovered from the digest was measured as above.

Zinc in Seawater: Standard zinc solutions (0.8—8 ng ml^{-1} Zn^{2+}) were prepared by diluting from a zinc stock solution. The solutions were made up in 0.05 M hydrochloric acid and with the addition of 1000 μg ml^{-1} NaCl to simulate the main matrix constituent of seawater. The seawater sample was diluted ten times with double distilled water. The zinc in this diluted sample and the standard solutions were collected on an alumina coated tube for a period of 1 minute prior to atomic absorption measurement. The accuracy of the measurement was checked by testing the recovery of added zinc (2, 4, and 6 ng) to aliquots of the diluted seawater sample.

Trace Elements in a Bovine Liver Sample: Ag. Bi, Cd, and Pb were determined in nitric acid-hydrogen peroxide digests of freeze-dried bovine liver. Standard solutions of these elements were prepared to contain 500 μg ml^{-1} Fe, and 200 μg ml^{-1} each of Ca, K, and Na approximately to match the matrix of the sample digests. The sample and standard solutions were collected for a period of 2 min (except for Cd which required only 30 s) on an iron oxide-on-alumina-coated silica atom trap before atomic absorption measurements were made. The accuracy of the method was checked by calculating the % recovery of lead added to the liver sample solution, and also by comparing the values with previous spark source mass spectrometry results.

Trace Elements in Fresh Water Samples: Several elements (Ag, Cd, Cu, Mn, Pb, Tl, and Zn) were analysed in water samples. The standard solutions were prepared by freshly diluting from stock solutions and making up in 0.05 M nitric acid. Both the standard and sample solutions were collected on alumina coated tubes, usually with a four or five min. collection time, depending on the concentration of the elements in the samples, except for zinc where the concentration was adequate for conventional flame AAS. The accuracy of the method was checked by graphite furnace atomic absorption spectrometry in some cases.

Results and Discussion

The twelve elements (Ag, As, Au, Bi, Cd, Cu, Mn, Pb, Sb, Se, Tl, and Zn) were first determined by atom trapping AAS using a silica atom trap tube according to the instrumental conditions outlined in Table 1.

The characteristic concentration (μg ml^{-1} for 1% absorption) and detection limit for each element obtained by atom trapping AAS are compared with those of conventional flame AAS in Table 2. For all of these elements, even for Mn which has a relatively high melting point of 1244 °C, the atom trapping technique increased the sensitivity (characteristic concentration) considerably when ca. 2 min trapping periods were used. However, the loss of hollow cathode lamp signal due to partial obscuration of the optical path by the silica tube and light scattering noise on the tube surface, led to a somewhat poorer relative standard deviation. It will be seen that for elements with resonance lines below 200 nm, e.g. As and Se, this factor resulted in % relative standard deviations >10%. All the elements were determined using an air–acetylene flame except for arsenic which required the cooler air–butane flame to minimise volatilization losses of arsenic during the trapping cycle.

In order to minimise interference arising from the co-deposition of major matrix or chemically active species on the silica tube during the trapping of analyte species, alumina or iron oxide was pre-deposited on the silica tube before the sample solutions were analysed.[5] The determination of these elements by atom trapping AAS was, therefore, also made on alumina and iron oxide coated silica atom trap tubes. Table 3 summarises the results. Most elements were less sensitive when collected on these surfaces except for Cd, Pb, and Zn. The signals for Au, Cu, and Mn were depressed on the alumina coated tube and no signals were obtained from an iron oxide coated tube.

Nature and Structure of Alumina and Iron(III) Oxide Coating Materials: Investigations were made to identify the nature and structure of the alumina and iron oxide coatings, formed by rapid condensation of the vaporized products from an aluminium or iron(III) chloride solution on the ca. 200 °C silica

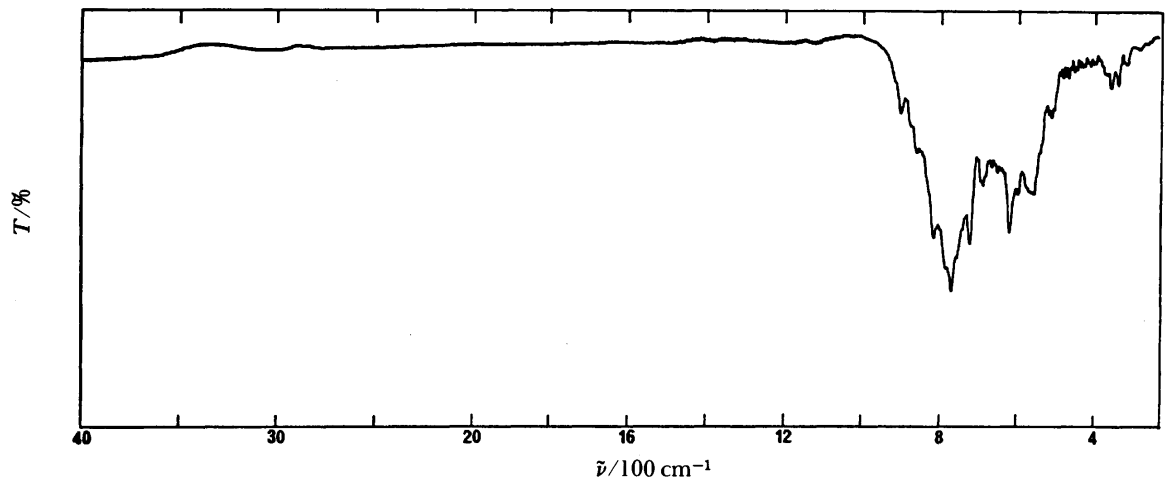

Fig. 1. Infrared absorption spectrum of alumina deposited on 'cold' surface of silica atom trap in air–acetylene flame. The Al_2O_3 is mainly δ but with a small amount of θ alumina.

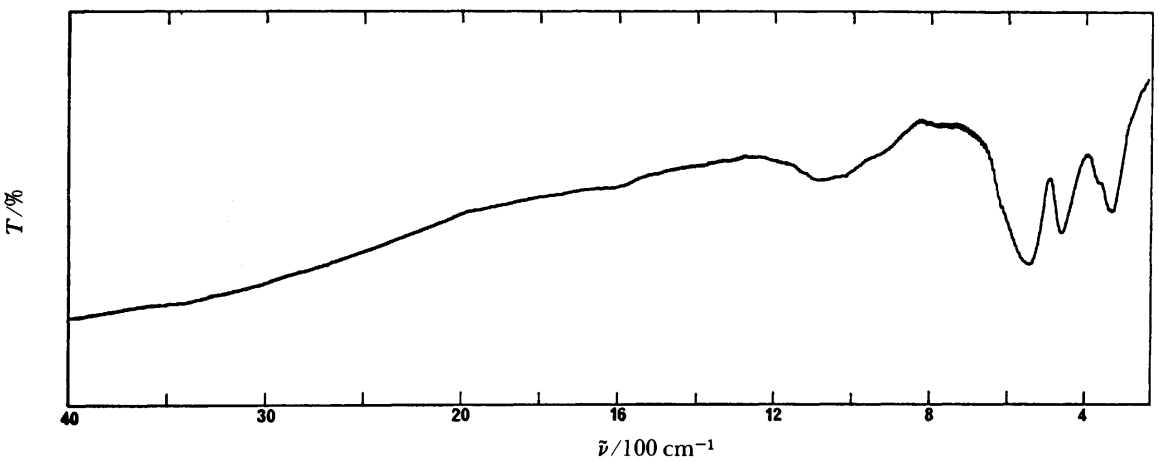

Fig. 2. Infrared absorption spectrum of iron oxide deposited on 'cold' surface of silica atom trap in air–acetylene flame. The deposit is mainly hematite with a small amount of metallic iron.

surface from flame gases ca. 3000 °C. Several techniques were employed, including infrared spectroscopy, X-ray diffraction, spark source mass spectrometry and scanning electron microscopy. The infrared spectra (Figs. 1 and 2) of the two coating materials showed that the alumina coating had a complicated absorption spectrum, but the iron oxide coating spectrum was identical to that of hematite.[8]

The X-ray diffraction pattern showed the alumina deposit to be dominated by delta (δ) alumina with a small amount of theta (θ) alumina. The same technique confirmed that the iron oxide coating was hematite with a trace of Fe metal. The spark source mass spectrometric analysis indicated that except for Cl, P, and Si, most other elements are present at less than the $\mu g\,g^{-1}$ level in the alumina coating material. This coating can, therefore, be considered relatively free from contamination for trace element analysis.

Further studies of the coatings were made using scanning electron microscopy to examine their microstructure. Under high magnification (×10000), Figs. 3 and 4, the alumina coating is seen to consist of loosely packed spheroids. Although the spheres were of different sizes, the largest was less than 1 μm in diameter. The iron oxide coating, however, was more compact, and more irregular in size and shape. Although the pre-deposition of these coating materials on the silica atom trap surface was an efficient way of minimising interference, the sensitivity for most elements was slightly decreased relative to collection on a clean silica tube surface. Broad peak signals were also observed for some elements when collected on the coated surface. It seems probable that these coatings greatly increased the surface area whilst simultaneously allowing some of the analyte species to become sequestered in the interstitial spaces of the coating, thus protracting the release time as shown by the broader release peaks and correspondingly lower peak heights.

Effects of Extraneous Elements: Interference effects in atom trapping AAS are more complicated than in conventional flame AAS. The presence of an extraneous element in the analyte solution may influence the proportion of free analyte atoms formed in the flame as in the conventional flame technique, but additionally cause physical alteration of the tube surface or alloy formation on the trap and subsequently affect the efficiency of trapping and/or release of analyte from the collector tube.

More than ten extraneous elements of concentrations up to $500\,\mu g\,ml^{-1}$ were added to each of the analyte solutions and their effects on the analyte signal were determined by atom trapping AAS with an alumina coated tube. According to the effects they produced on the analyte signal, the extraneous elements could be classified into two groups. For alkali and alkaline earth metals and other volatile elements, the highest concentration added caused less than ±30% interference on the analyte signal. The presence of the alumina on the collector tube prevented chemical attack (vitrification) of the silica surface by alkali metals and the volatile nature of the

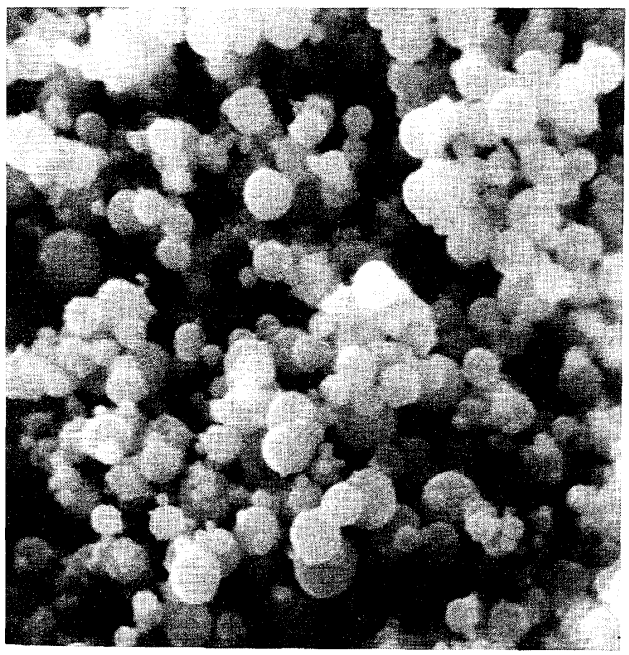

Fig. 3. Electron micrograph (×10000) of alumina deposited on 'cold' surface of silica atom trap following aspiration of $AlCl_3$ into air-acetylene flame.

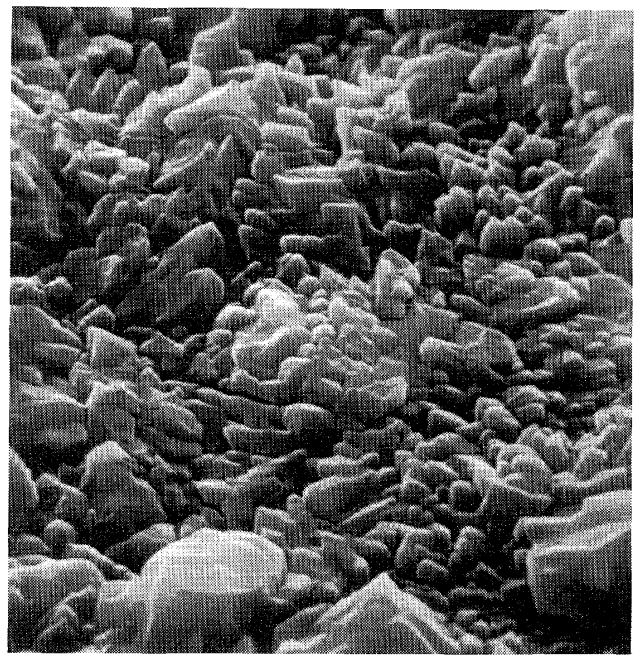

Fig. 4. Electron micrograph (×10000) of hematite deposited on 'cold' surface of silica atom trap following aspiration of $FeCl_3$ into air-acetylene flame.

metals also ensured their instant release together with the trapped analyte as the surface of the collector tube became hot without affecting the analyte signal to any marked extent. Such interference as occurred from these elements could be minimised by matrix matching and pre-conditioning of the tube with these elements before analysis.

The interference effects were more severe for involatile extraneous elements such as Fe, Co, Ni, Cu, Mn. For example, the presence of 500 μg ml^{-1} Fe, 500 μg ml^{-1} Co, or 500 μg ml^{-1} Ni reduced the copper signal by 40, 50, and 60% respectively. The effects of these elements were mainly due to their virtually permanent deposition on the alumina surface resulting in a gradual alteration in physical structure of the surface for the trapping of the analyte species. In the case of iron, the effect could be eliminated by pre-deposition of iron oxide on top of the alumina coated tube, and then collecting the high iron-containing analyte solutions on this modified tube surface. However, for *high* concentrations of other non-volatile elements such as Co and Ni, pre-deposition of these elements or their oxides on the tube surface did not lead to elimination or compensation. Alternative methods must, therefore, be used for samples containing *high* levels of Co or Ni in their matrix.

Sample Analysis. The results reported in Tables 4—7 are those of single individual determinations.

Arsenic in Aqua Regia Digests of Soils: The presence of the extremely toxic element arsenic in the environment is mainly of geological origin, although industrial processes have also made contributions. A recent survey gave the average content of arsenic of over 1000 soils to be 11.3 mg kg^{-1}.[9] A content of >50 mg kg^{-1} arsenic in a soil is regarded as potentially toxic to susceptible plants.[10] Several acid mixtures have been used for the extraction of arsenic from soil; these include nitric and sulphuric acids,[11] aqua regia,[12] perchloric and nitric,[13] and hydrofluoric and perchloric acids.[14] Aqua regia was used in this work because it is widely used for monitoring heavy metals in polluted soils.[15]

The arsenic contents of the six Scottish top-soils analysed in this study were found to range from 5—10 μg g^{-1}. The % recovery of added arsenic was 100% (±10%), Table 4.

Zinc in Seawater: The direct determination of trace elements in sea water by conventional AAS is difficult because of their low concentrations and the high salt matrix. One common procedure frequently used is preconcentration/separation by solvent extraction followed by electrothermal atomization AAS for analysis,[16] However, the sensitivity of the atom trapping method permits direct analysis of sea water diluted 10-fold to reduce nebulisation problems. The results of the analysis by atom trapping AAS are shown in Table 5. The concentration of zinc in the sample was found to be 9 μg l^{-1} compared to a literature value of 10 μg l^{-1}.[18] The % recovery of zinc added to the sample was also 100±10%.

Trace Elements in a Bovine Liver Sample: Flame atomic absorption spectrometry is often employed for the determination of trace elements in bovine liver tissue but, because of the high organic content in the sample, special sample treatments are required. Some

Zn	500	1.5	50

of the reported methods of sample preparation suitable for analysis by flame AAS included low temperature ashing (RF-excited oxygen plasma),[19] enzyme digestion,[20] or wet-oxidative digestion.[21] Amongst these, wet-oxidative digestion offers two main advantages over the other procedures. It is generally faster and, as it requires lower working temperatures (50—250 °C), the risk of losing volatile elements is reduced. The nitric acid–hydrogen peroxide procedure employed here was first tested by checking the recovery of lead added to the freeze-dried, powdered liver sample before digestion. The recovery was 100±10% of the quantity of the added lead. The concentrations of lead, cadmium, silver, and bismuth were then found by the method described, and the values were compared with those from previous spark source mass spectrometry results, Table 6. Apart from bismuth the other three elements showed consistent results by the two methods.

Trace Elements in Fresh Water Samples: Atomic absorption spectrometry is ideally suited to the analysis of fresh water for a wide range of elements. However, the extremely low levels of some elements in fresh water samples prevent their direct determination by conventional flame AAS, except for a few such as sodium, potassium, magnesium, calcium, and occasionally zinc. Several of these ultra-trace elements can, however, be determined directly by atom trapping AAS, e.g. in the three fresh water samples, featured in Table 7. Two elements (Mn and Pb) were also measured directly by electrothermal atomization AAS, which showed fair agreement with atom trapping.

Conclusion

Atom-trapping AAS can be applied to determine a wide range of elements with significant enhancement in sensitivity compared to conventional flame AAS. The successful analysis of trace elements in different types of sample showed the technique to be reliable for a range of matrices.

One of us (CML) is indebted to the Council of Management of this Institute for a grant in partial support of this work. We also thank M. J. Wilson, W. J. McHardy, A. R. Fraser, and C. A. Shand for assistance with the data on X-ray diffraction, electron microscopy, infrared absorption, and spark source mass spectrometry.

Invited Paper

Mass Spectrometry of Molecular Adsorbates Using Laser Desorption/Laser Multiphoton Ionization

Richard N. Zare,* Jong Hoon Hahn, and Renato Zenobi
Department of Chemistry, Stanford University, Stanford, CA 94305, U.S.A.
(Received August 20, 1987)

Current and potential applications of a new mass spectrometric technique for the analysis of nonvolatile and thermally labile substances are reviewed. The method is compared to other approaches and its advantages are discussed.

For the purposes of chemical analysis, gas chromatography combined with mass spectrometry (GC–MS) is often the method of choice for volatile compounds.[1] Here one relies on GC to separate components in a complex mixture and MS to identify them in terms of parent mass and daughter fragments. The GC–MS combination allows quantitation over a wide range of concentrations down to the parts per billion level. For nonvolatile compounds or compounds which decompose upon heating, one generally relies on liquid chromatography (LC) or electrophoresis. However, these techniques are not easily interfaced to mass spectrometers so that they generally do not partake of the identification powers of GC–MS. One effort to overcome this difficulty is to apply mass spectrometry to the analysis of molecular surface overlayers. Often this is accomplished by a one-step process in which molecules are ionized and ejected from the surface by bombardment with energetic particles, such as by electrons (ESD),[2] ions (SIMS),[3] fast neutral atoms (FAB),[4] fission fragments (plasma desorption),[5–7] and photons (laser desorption).[8–14] Compounds of major interest include peptides, proteins, polynucleotides, porphyrins, oligosaccharides, and biomolecules having strong acidic, basic, or polar side groups. However, it is necessary to understand in detail the ejection and ionization mechanism at the surface in order to relate the observed mass spectrum to the nature of the molecular adsorbate. Often this is obscured by matrix-dependent ionization as well as extensive fragmentation. We are exploring an alternative approach in which the desorption step is separated in time and in space from the ionization step.[15,16] This method has first been applied to the trace detection of atoms from surfaces,[17–22] then molecules from surfaces.[23–26] Many variations are possible, but our preferred embodiment of this method involves an infrared laser to desorb essentially intact molecules from a substrate opaque to this wavelength followed, after a suitable delay, by an ultraviolet laser to cause resonance-enhanced multiphoton ionization (REMPI) of those species absorbing the second wavelength. In comparison with other mass spectrometric methods, the two-step laser desorption/laser multiphoton ionization method has the advantages:

- short analysis time
- high sensitivity
- high selectivity in ionization
- no matrix ionzation effects
- simple mass spectrum often dominated by the parent ion peak
- large dynamic range of quantitation

In what follows we discuss these features and review our present efforts to develop this new mass spectrometric technique.

Two-Step Laser Desorption/Multiphoton Ionization Mass Spectrometry

A. Laser Desorption. Our two-step methodology has been described previously.[15,16] As a first step (Fig. 1a), a CO_2 laser pulse (10.6 μm; ca. 10 mJ pulse^{-1}; 10 μs pulse width; 10 Hz repetition rate) is directed onto a thin film of molecular adsorbate deposited on the surface of a suitable solid substrate, e.g., glass or machinable ceramic (MACOR). The substrate is rapidly heated and neutral molecules are desorbed from the surface (Fig. 1b).

The rate of heating induced by the CO_2 laser pulse is approximately 10^8 K s^{-1}. This should be compared to heating rates of 10 K s^{-1} or less, which can be obtained by traditional resistive heating. For adsorbates that undergo extensive molecular decomposition on the surface at a conventional heating rate, the rapid laser induced heating rates can favor desorption over decomposition.[27,28] It has been proposed[29] that the van der Waals type bonds between the physisorbed molecules and a solid substrate may serve as a "bottleneck" for energy transfer from a rapidly heated surface to the internal degrees of freedom of the adsorbed molecules, causing internally lukewarm intact molecules to be desorbed. There is much experimental evidence to support the claim that relatively cold molecules escape from a hot surface by laser-induced thermal desorption (LITD).[30–33] The same type of behavior in which evaporation dominates over decomposition has also been observed for large molecules desorbing from surfaces following

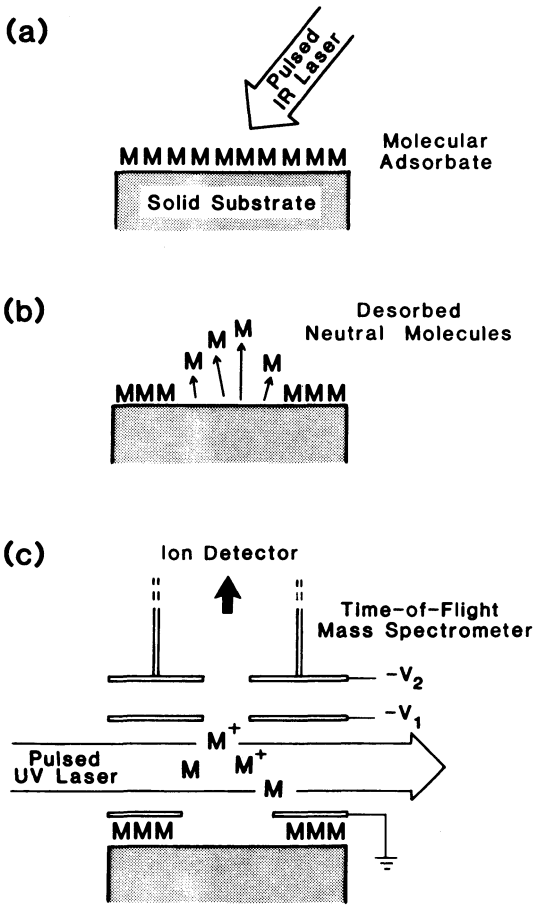

Fig. 1. Procedure for two-step laser desorption/laser multiphoton ionization mass spectrometry: (a) a CO_2 laser pulse is directed onto a film of molecular adsorbate; (b) neutral molecules escape from the surface by rapid thermal desorption; and (c) after a suitable time delay, the fourth harmonic of a Nd:YAG laser selectively ionizes neutral molecules, and the ions are then detected by a time-of-flight mass spectrometer.

pulsed laser heating.[8,9,15,16,26,27,34–37] Moreover, nonvolatile large molecules tend to desorb by LITD rather than by a resonant infrared absorption. For example, we have found that the parent ion signal of protoporphyrin IX dimethyl ester evaporated from a glass surface by a CO_2 laser pulse is 3×10^5 times stronger than that from a NaCl surface (which is transparent at the CO_2 laser wavelength).

B. Multiphoton Ionization. In the second step (Fig. 1c) of our methodology, desorbed molecules are ionized by 1+1 REMPI with the fourth harmonic (266 nm) of a Nd:YAG laser (ca. 1 mJ pulse^{-1}; 10 ns pulse width; 10 Hz repetition rate). The appropriate delay (70—90 μs) between the desorbing CO_2 laser and the ionizing Nd:YAG laser pulse is chosen so that the ionizing laser pulse intercepts as many molecules as possible.

In 1+1 REMPI, one photon causes a molecule to make a transition to an electronically excited state and a second photon ionizes the excited molecule. Wavelength selectivity results from the photon energy being resonant with an intermediate state while such selectivity is lost in the direct one-photon ionization process.[38] REMPI has other important attributes for mass spectrometry; it can provide very efficient "soft ionization"[15,16,34–42] in which the parent molecular ion dominates the mass spectrum. This is in sharp contrast to electron impact ionization where soft ionization can be obtained only with a significant decrease in ionization efficiency. In our experiments the Nd:YAG laser was slightly focused by a quartz lens to a 6 mm diameter spot size, resulting in a power density of about 10^6 W cm^{-2} in the ionization volume.

In contrast to direct one-step ionization of molecular adsorbates, the two-step laser methodology where the desorption and ionization processes are spatially and temporally separated allows a much larger fraction of the molecules to be converted to parent ions by optimizing separately the two laser sources. In addition, this technique avoids the variations of the ionization efficiency with surface substrate (matrix effect).

C. Ion Detection. Because the ion production is pulsed, it is natural to carry out mass analysis in a linear time-of-flight (TOF) system[15,16,26] or in a reflectron TOF mass spectrometer.[35–37,43] High-resolution Fourier-transform ion cyclotron resonance (FI-ICR) mass spectrometers may also be used as detectors.[44,45]

In our setup, the ions are mass-separated in a 30 cm flight tube and detected by an electron multiplier connected to two preamplifiers which feed a transient digitizer. Our typical mass resolution with this arrangement is about 100; we are presently modifying the TOF instrument into a reflectron configuration to provide much higher mass resolution.

D. Sample Preparation. In order to achieve the quantitative analysis of molecular adsorbates, it is essential to make a homogeneous film on a solid substrate. Figure 2a shows a schematic drawing of the system for preparing a thin sample film. Application of about 200 μl of the sample solution to a glass cup provides a convenient sample size for quantitative analysis. After application of the solution, the glass cup is spun horizontally by a motor and the solution spreads out as a layer over the inner cylindrical surface. A vacuum is applied to evaporate the solvent, resulting in a dry homogeneous film with known thickness. The glass cup is then mounted onto the tip of a 1/2 inch diameter Teflon rod, directly introduced into the main vacuum chamber (ca. 10^{-7} Torr) through a gate valve without breaking high vacuum, and placed in the center of the first electrode of our TOF instrument. The direct sample introduction

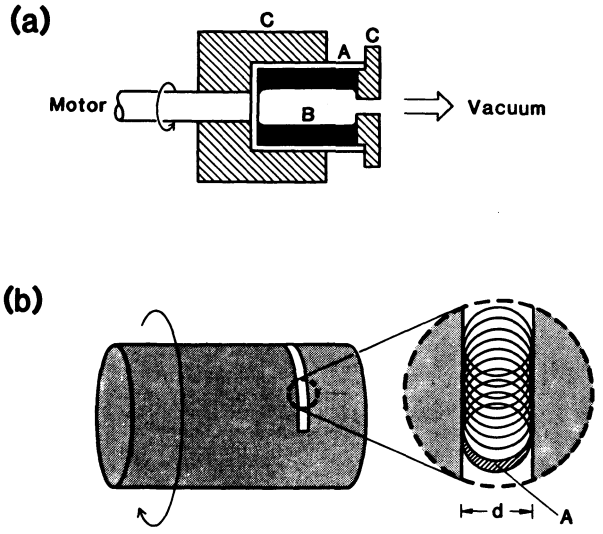

Fig. 2. (a) Apparatus for making a thin homogeneous sample film. Here A is a glass cup (12 mm×20 mm), B represents the sample solution layer formed as the glass cup is spun horizontally and by a motor, C is a Teflon clamp and cap assembly. (b) A CO_2 laser desorption track on the inner surface of the glass cup: d is the diameter of the desorption laser spot (ca. 1 mm) and A is the new area exposed in consecutive laser shots (ca. 5×10^{-2} mm^2).

method takes about one minute, and the mass spectrum can be recorded without further delay.

Representative Applications

Figure 3 shows typical laser desorption/laser multiphoton ionization mass spectra of a purine base, a dipeptide, a steroid, and a porphyrin. Common properties of these molecules are low volatility, high polarity, and a UV chromophore allowing for 1+1 REMPI (in the form of an aromatic or π-conjugated system). The most important features of these spectra are dominant parent ion peaks in all cases. Almost complete absence of fragmentation in Fig. 3c and 3d demonstrates the desorption of intact parent molecules in the laser evaporation step as well as the soft ionization capabilities of the REMPI process. The amount of fragmentation depends on the ionization laser fluence. For adenine, e.g., almost no fragmentation occurs at lower laser fluence.[16] Of course, fragmentation can also be a virtue in the identification of large molecules, and controlled fragmentation is easily achieved by increasing the fluence of the laser used in the ionization step. To some extent, fragmentation also depends on the nature of the surface/adsorbate bond: For gly-phe (Fig. 3b) and other dipeptides fairly intense fragments show up in the mass spectrum.[34] On the other hand, it is possible to observe parent ions of a decapeptide (MW=1295 amu)[36] and of proteins up to a mass of 23000 amu

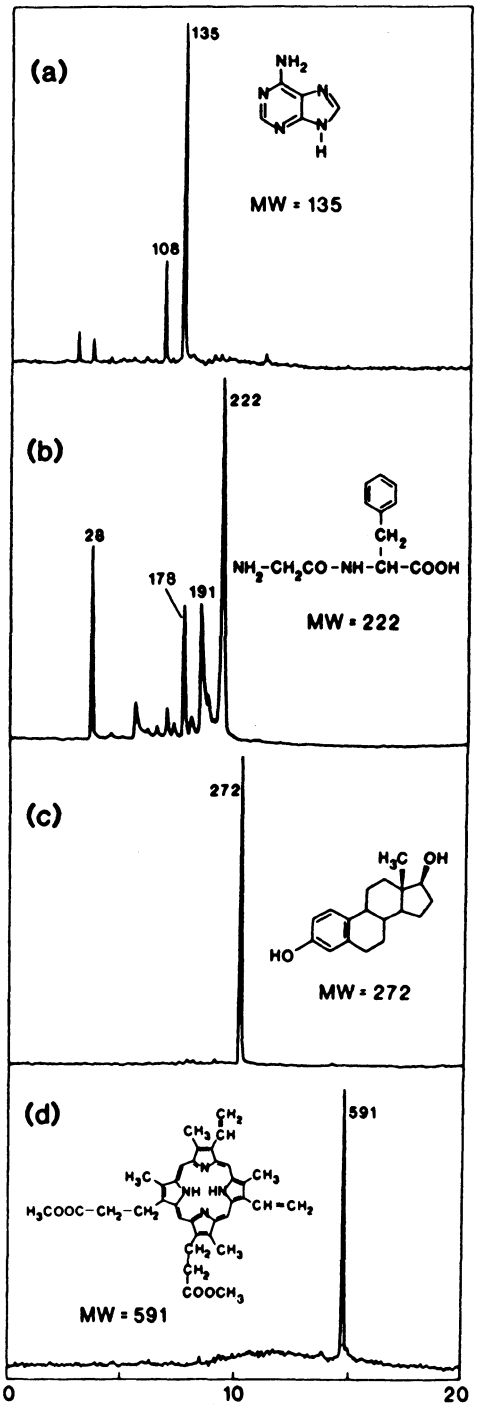

Fig. 3. Laser desorption/laser multiphoton ionization mass spectra of (a) adenine, (b) glycyl-L-phenylalanine (gly-phe), (c) β-estradiol, and (d) protoporphyrin IX dimethyl ester. Each mass spectrum represents an average over 200 laser shots.

(using ^{252}Cf bombardment).[6] We still lack a thorough understanding of various desorption mechanisms, and the examples above indicate that we need a better theoretical description in order to optimize the two-step process.

Higher-mass compounds are also tractable with our technique, as shown in Fig. 4. These two synthetic porphyrins again exhibit single parent ion peaks at 1132 and 1232 amu, respectively. This class of compounds is readily ionized by the fourth harmonic of the Nd:YAG laser. For protoporphyrin IX dimethyl ester (Fig. 3d) we have found[16] a detection limit of 4×10^{-17} mol.

Dominant parent ion peaks enable us to record spectra of mixtures. Figure 5 shows an example of an equimolar mixture of 5 phenylthiohydantoin (PTH)-amino acids. These compounds are the final products of the Edman degradation method used in protein sequencing. In our original work, all the 20 PTH-amino acids, corresponding to the 20 naturally occurring amino acids could be analyzed.[15] We were even able to distinguish between the leucine and isoleucine isomers owing to a difference in the fragmentation pattern. An example of a different sort is provided by the analysis of a meteorite sample.[46] Figure 6 shows a mass spectrum of material from Murchison, a meteorite rich in organic carbon compounds.[47] By spiking the sample with various standards, it was possible to identify a series of polynuclear aromatic compounds in the mass range from 120—300 amu, which is consistent with previous results.[48] Please note by its conspicuous absence the lack of porphyrins in this meteorite sample. This is now an accepted fact, but was the subject of a scientific debate for a long time.[49]

A particularly useful feature of our methodology is the linear quantitation we have achieved using the sampling technique described above. From experiments, where we exposed the same spot to the

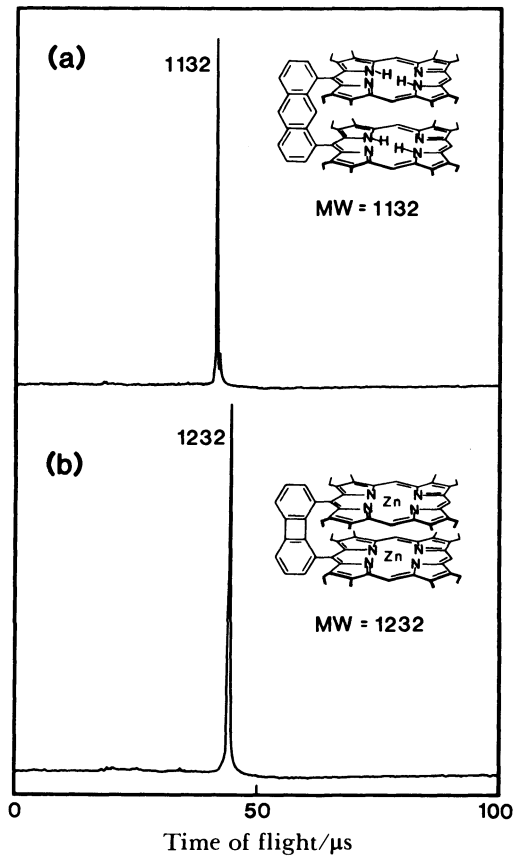

Fig. 4. Laser desorption/laser multiphoton ionization TOF mass spectra of (a) H_4(DPA) and (b) Zn_2(DPB).
DPA=1,8-bis(3,7,13,17-tetraethyl-2,8,12,18-tetramethyl-5-porphyrinyl)anthracene; DPB=1,8-bis(....)biphenylene.

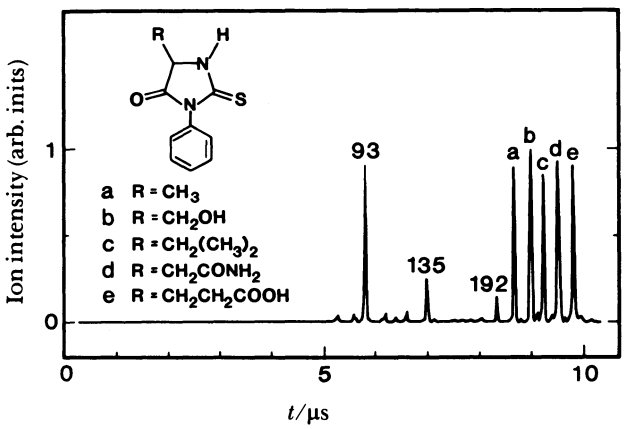

Fig. 5. A mixture of equimolar amounts of (a) PTH-alanine, (b) PTH-serine, (c) PTH-valine, (d) PTH-asparagine, and (e) PTH-glutamic acid analyzed by laser desorption/laser multiphoton ionization mass spectrometry. The peaks labeled a—e are the parent ions; some fragments of the compounds in the mixture superimpose in the lower mass region and give rise to the signals at 93, 135, and 192 amu.

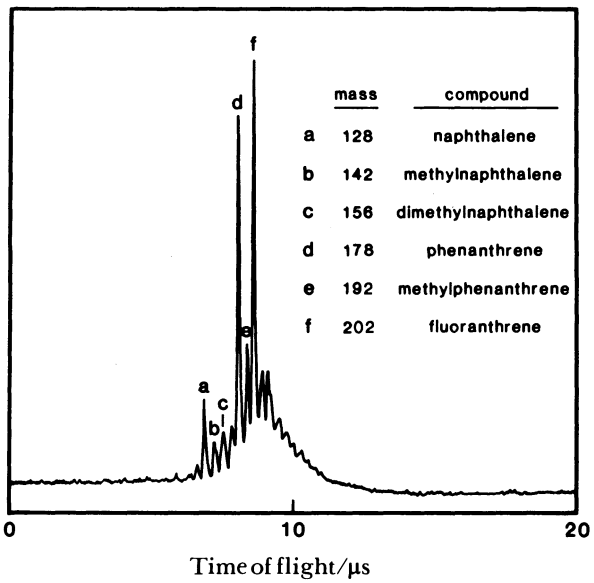

Fig. 6. Laser desorption/laser multiphoton ionization mass spectrum obtained from 1 μg of the Murchison meteorite.

desorption laser twice, we found that the desorption of the adsorbate is essentially complete after the first shot. Spectra taken for quantitative studies represent an average over many shots. Here we rotate the sample and expose a small surface area, A, to each new laser shot. This area can be calculated from a knowledge of the repetition rate of the desorption laser, the rotation speed of the sample, and the measured laser track width (cf. Fig. 2b). The amount of adsorbate which is removed per laser shot, n, is then calculated by

$$n = n_{tot} \cdot (A/A_{tot})$$

where n_{tot} is the total of amount of adsorbate deposited on A_{tot}, the total area covered. By monitoring how the signal height of the parent ion peak varies with adsorbate concentration, we found a linear dependence of n over a range of 5 orders of magnitude, as shown in Fig. 7.[16] The amount of adsorbate desorbed per laser shot ranges from nanomoles (100 monolayers) to femtomoles (10^{-4} monolayers).

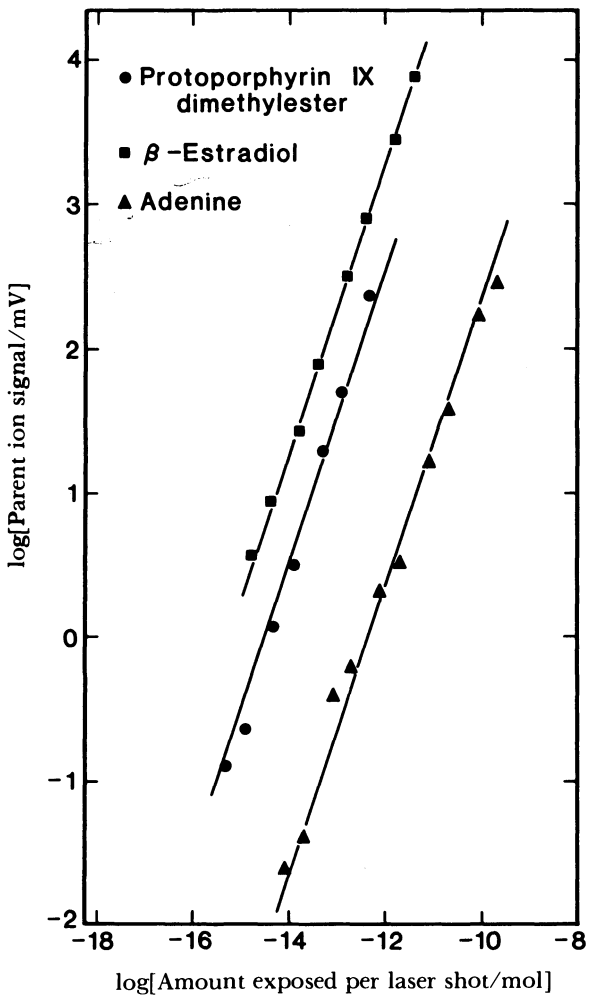

Fig. 7. Quantitation: Parent ion signal of protoporphyrin IX dimethyl ester, β-estradiol, and adenine vs. surface concentration.

Concluding Remarks

Laser desorption/laser multiphoton ionization has a number of appealing advantages for the mass spectrometric analysis of molecular adsorbates: high sensitivity, controlled fragmentation, selective ionization, rapid quantitation, and negligible matrix effects. This technique is in its early infancy but the applications to large biomolecules and other thermally labile and/or nonvolatile compounds are quite encouraging. More needs to be known about the desorption mechanism involving the adsorbate/substrate interaction before this method can be routinely applied. Nevertheless, this method has particular promise for the analysis of samples of limited availability, suggesting that some of its most dramatic uses may be in the analysis of rare samples, such as, fossils, lunar soils, meteorites, cosmic dust, and other cosmogeochemical materials.

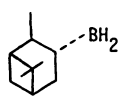
(Received May 28, 1987)

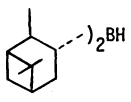
The hydroboration of representative 1-heteroarylcycloalkenes with monoisopinocampheylborane ($IpcBH_2$) was investigated systematically to establish the degree of asymmetric induction during hydroboration. The hydroboration of 1-heteroarylcyclopentene with $IpcBH_2$ at −25 °C proceeded cleanly to afford the corresponding dialkylboranes. These dialkylboranes, upon treatment with acetaldehyde and then oxidation, afforded the corresponding *trans*-2-heteroarylcycloalkanols of 85—86% ee. Similarly, 1-heteroarylcyclohexenes, upon hydroboration with $IpcBH_2$, followed by acetaldehyde treatment and oxidation, gave the corresponding alcohols in ca. 90% ee. The dialkylboranes or alkylboronic acids derived from 1-heteroarylcyclopentenes and $IpcBH_2$ can be recrystallized to furnish materials approaching 100% ee. From such dialkylboranes or alkylboronic acids, the corresponding boronates of ca. 100% ee were prepared and isolated. These are proving to be highly versatile synthetic intermediates for organic synthesis.

Asymmetric hydroboration, since its discovery in 1961,[2] proved to be a highly efficient reaction in synthetic organic chemistry.[3] Recently there has been intense interest in developing efficient methods for the preparation of organic compounds of high enantiomeric purities.[4] Of these procedures, asymmetric hydroboration is highly promising as a method for preparation of chiral compounds containing various functional groups.[5]

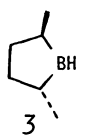
Monoisopinocampheylborane (**1**, $IpcBH_2$) hydroborates *trans*- and trisubstituted olefins with optical induction ranging from 53% to 100% ee.[6] The dialkylboranes derived from $IpcBH_2$ and trisubstituted olefins were crystallized to materials approaching 100% ee.[7] Recently heterocyclic olefins containing a double bond inside the ring were hydroborated with diisopinocampheylborane (**2**, Ipc_2BH) with quantitative asymmetric induction.[8,9a] Masamune and coworkers[10] have recently synthesized an asymmetric hydroborating agent, *trans*-2,5-dimethylborolane (**3**)



1



2



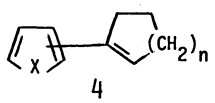
3

possessing a C_2 symmetry, which hydroborates *cis*-, *trans*- and trisubstituted olefins with an asymmetric induction ranging from 93—97% ee.

The wide range of biological activity, e.g., antitumor, carcinogenic, microbial growth inhibitor, plant growth inhibitor, antifeedant and antiflammatory displayed by a number of compounds possessing the furan and thiophene moiety has stimulated considerable effort to synthesize them.[11] In continuation of our studies on the asymmetric hydroboration of heterocyclic olefins,[8,9] various 1-heteroarylcycloalkenes were selected for study. This paper describes a systematic study of the hydroboration of 1-heteroarylcycloalkenes with $IpcBH_2$ to synthesize various chiral heterocyclic compounds.

Results and Discussion

In this study we consistently used monoisopinocampheylborane ($IpcBH_2$, 100% ee) from 92% ee (+)-α-pinene. A stock solution of $IpcBH_2$ was prepared from the TMED adduct of $IpcBH_2$ and boron trifluoride etherate in ethyl ether.[12] Representative 1-heteroarylcycloalkenes (**4**) were selected for the



4

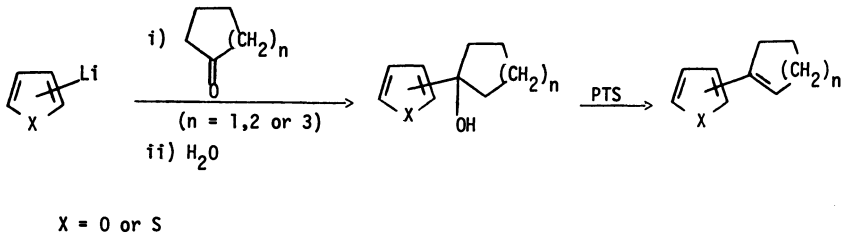
X = O or S

n = 1, 2 or 3

study. These alkenes, **4**, hitherto unreported, were prepared by the dehydration of the corresponding tertiary alcohols obtained from the addition of the heteroaryllithium to the cyclic ketone (Scheme 1). The olefins thus obtained were characterized by spectra and were 97—100% pure by GC examination.

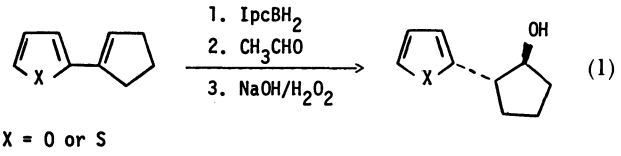
Hydroboration of 1-Heteroarylcycloalkenes with $IpcBH_2$. All of these representative olefins were hydroborated with an equimolar quantity of $IpcBH_2$. The reaction was monitored by quenching aliquots with methanol, followed by ^{11}B NMR spectra of the sample.

Hydroboration of 1-(2-Furyl)cycloalkenes. 2-Furylcycloalkenes of varying ring size were hydroborated



Scheme 1.

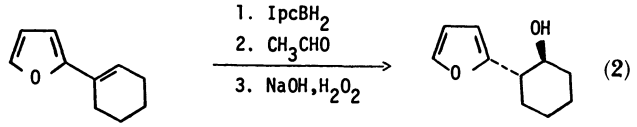
with $IpcBH_2$ in order to study the effect of ring size on asymmetric induction during hydroboration. The hydroboration of 1-(2-furyl)cyclopentene with (−)-$IpcBH_2$ [derived from (+)-α-pinene] proceeded smoothly at −25 °C in ethyl ether. The dialkylborane obtained was treated with acetaldehyde, then oxidation with alkaline hydrogen peroxide afforded *trans*-2-(2-furyl)cyclopentanol in excellent yield (Eq. 1, X=O).



(1)

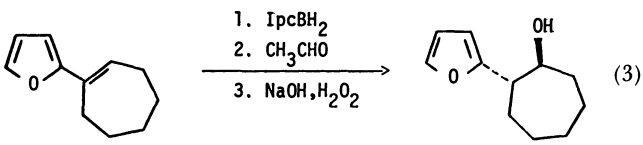
The optical purity of the alcohol by capillary GC analysis of its corresponding MTPA ester[13] was found to be of 86%.

The hydroboration of 1-(2-furyl)cyclohexene with (−)-$IpcBH_2$ proceeded slowly at −25 °C, achieving a 65% conversion in 10 days. The dialkylborane thus obtained was treated with acetaldehyde, followed by oxidation, affording *trans*-2-(2-furyl)cyclohexanol in 90% ee (Eq. 2). By increasing the temperature, i.e., to



(2)

0 °C, employed during hydroboration, 80% of the olefin could be hydroborated. However, the optical purity of the alcohol obtained after oxidation is lower, i.e., 80% ee. Similarly, 1-(2-furyl)cycloheptene could be hydroborated at −25 °C easily. Treatment with acetaldehyde, followed by oxidation, gave *trans*-2-(2-furyl)cycloheptanol in excellent yield (Eq. 3), with an

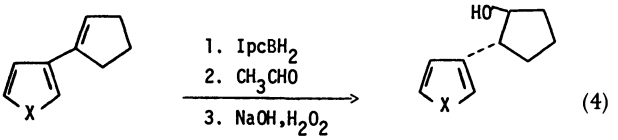


(3)

optical purity of the alcohol of 86%.

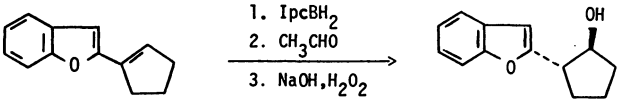
The asymmetric induction during hydroboration of 1-heteroarylcycloalkenes with $IpcBH_2$ increases slightly from the five-membered ring to the six-membered ring. The asymmetric induction in the seven-membered ring is, as expected, similar to that of the five-membered ring. Since the hydroboration of these cyclopentenes and cyclohexenes gave products with excellent asymmetric induction, various 1-heteroarylcyclopentenes and -cyclohexenes were hydroborated with $IpcBH_2$.

Hydroboration of 1-Heteroarylcyclopentenes. The hydroboration of 1-(3-furyl)cyclopentene with $IpcBH_2$ could be achieved at −25 °C. The dialkylborane obtained on treatment with acetaldehyde and then oxidation afforded *trans*-2-(3-furyl)cyclopentanol in 85% ee (Eq. 4, X=O). Similarly, 1-(2-thienyl)cyclopentene and 1-(3-thienyl)cyclopentene were hydroborated with $IpcBH_2$. The asymmetric induction during hydroboration was found to be 86% ee in both cases (Eqs. 1 and 4, X=S).



(4)

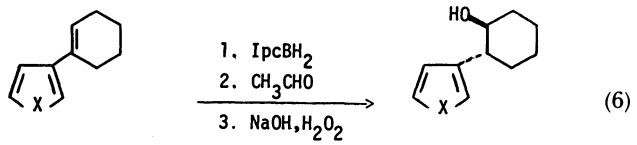
The hydroboration of 1-(2-benzofuryl)cyclopentene proceeded slowly at −25 °C. The dialkylborane was treated with acetaldehyde, followed by oxidation with alkaline hydrogen peroxide, giving *trans*-2-(2-benzofuryl)cyclopentanol in 85% ee (Eq. 5).



(5)

These results demonstrate the remarkable consistency in the asymmetric induction of these heterocyclic cyclopentenes during hydroboration with $IpcBH_2$. No significant change was observed in the asymmetric induction achieved during hydroboration with $IpcBH_2$, either by changing the heteroatom in the heterocycle (O or S), or by changing the position of the cyclopentene ring (2- or 3-position), or by altering substituents on the heteroaryl ring.

Hydroboration of 1-Heteroarylcyclohexenes. The hydroboration of 1-(3-furyl)cyclohexene proceeded similar to that of 1-(2-furyl)cyclohexene at −25 °C. The dialkylborane was treated with acetaldehyde and then oxidized to obtain *trans*-2-(3-furyl)cyclohexanol in 90% ee (Eq. 6, X=O). Similarly, 1-(3-thienyl)-



(6)

X = O or S

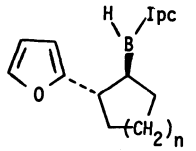
cyclohexene (Eq. 6, X=S) upon hydroboration with $IpcBH_2$, followed by acetaldehyde treatment, gave the boronic ester. Oxidation then afforded the corresponding *trans*-alcohol in 83% ee. The results are summarized in Table 1.

The absolute configuration of all product alcohols is not known. It was already established that $IpcBH_2$ attacks preferentially from one enantiotopic face of the alkene, realizing the alcohols of the same absolute configuration. Thus, the remarkable consistency of $IpcBH_2$ providing alcohols of the same absolute configuration was used to assign the absolute configurations of all of these alcohols. They are shown in Table 1.

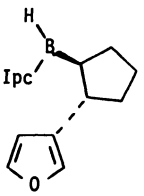
Upgrading the Optical Purities of Boranes. In all of the above examples, only 83—90% of asymmetric induction could be achieved. It is highly desirable to have materials approaching 100% ee. We selected the 2-heteroarylcyclopentylboranes to study upgrading to materials of essentially 100% ee.

The above mentioned *trans*-2-heteroarylcyclopentylisopinocampheylboranes[14] were found to be solids at −25 °C in ethyl ether. For example, *trans*-2-(2-furyl)cyclopentylisopinocampheylborane (**4**), obtained via hydroboration of 1-(2-furyl)cyclopentene with $IpcBH_2$ at −35 °C, crystallized in a well-defined form in 65% yield. The dialkylborane on oxidation produced *trans*-2-(2-furyl)cyclopentanol of essentially 100% optical purity.

Similarly, the selective crystallization of *trans*-2-(3-furyl)cyclopentylisopinocampheylborane (**5**) at −35 °C provided material of only 90% ee. However, a second crystallization in ethyl ether at 0 °C gave material approaching 100% ee.



4, n = 1
8, n = 2
9, n = 3



5

trans-2-(2-Thienyl)cyclopentylisopinocampheylborane (**6**) from 1-(2-thienyl)cyclopentene and $IpcBH_2$ showed unusual behavior. Although it is a dimer like the others (as evidenced by IR absorption at 1542 cm^{-1}), the major enantiomer accumulated in the mother liquor. The crystallized dialkylborane, **6**, showed reduced optical purity of only 7%. The dialkylborane in the mother liquor showed an optical purity of only 90%. It was further upgraded to 94% by cooling the reaction mixture to −78 °C, followed by the removal of crystalline borane. However, a

material of ca. 99% optical purity could be obtained by crystallizing its *trans*-2-(2-thienyl)cyclopentylboronic acid. *trans*-2-(3-Thienyl)cyclopentylisopinocampheylborane (**7**) crystallized at −35 °C, similar to **4**, to produce a material approaching 100% ee.

Further, in the case of *trans*-2-(2-furyl)cyclohexylisopinocampheylborane (**8**) and *trans*-2-(2-furyl)cycloheptylisopinocampheylborane (**9**), the dimer, $(R^*BHIpc)_2$, was not crystalline. The products are readily converted into boronic acid, $R^*B(OH)_2$, by treatment with acetaldehyde, followed by hydrolysis. A simple crystallization of these boronic acids in ether/pentane provided material of high optical purity. The corresponding *trans*-alcohols obtained after oxidation of these pure dialkylboranes or alkyl boronic acid were characterized and the results are summarized in Table 2.

Isolation of *trans*-3-Heteroarylcycloalkylboronates of High Enantiomeric Purities. Chiral alkylboronic esters containing only one alkyl group attached to boron are highly promising intermediates for asymmetric synthesis proceeding through boron

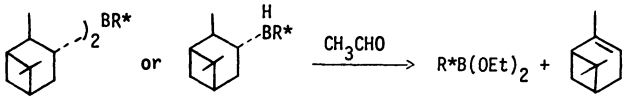
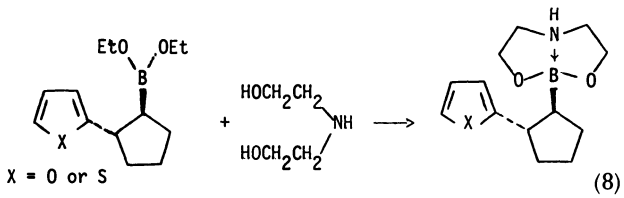
chemistry.[5,15,16] Previously, Brown, Jadhav and Desai[17] established the clean elimination of α-pinene from Ipc_2BR^* and IpcBHR* by treatment with acetaldehyde, giving $R^*B(OEt)_2$ without loss of optical activity (Eq. 7). A similar procedure provided



(7)

trans-2-heteroarylcycloalkylboronates. Simple distillation provided a pure boronate, characterized by ^{11}B NMR and ^1H NMR. The results are summarized in Table 3. From these esters, optically pure crystalline chelate esters stable in air were prepared by treating the ethyl boronates with diethanolamine (Eq. 8). From such derivatives, the corresponding boronic



(8)

acid can be easily regenerated by treating with hydrochloric acid.[18] These crystalline compounds showed a correct M^+ ion in the mass spectra. The results are summarized in Table 4.

Conclusion

The present method provides a simple and efficient method for the preparation of various *trans*-2-heteroarylcycloalkanols of high enantiomeric purity. Due to the availability of both enantiomers of α-pinene, both enantiomers of the heterocycles can be synthesized. The chiral auxiliary, α-pinene, can be recovered and recycled. The isolation of heterocyclic boronates of 100% ee provides a simple route to synthesize various heterocycles containing different functional groups in essentially 100% ee. The synthetic implications of such optically pure boronates are described elsewhere.[5] Moreover, using the known chemistry, these heterocycles can be converted to various other compounds.

Experimental

The reaction flasks and other glass equipment were stored in an oven at 150 °C overnight and assembled in a stream of dry nitrogen gas. Syringes were assembled and fitted with needles while hot and cooled in a stream of dry nitrogen gas. Special experimental techniques used in handling air-sensitive materials are described in detail elsewhere.[19]

Spectra. ^{11}B NMR spectra were recorded on a Varian FT-80A instrument. The chemical shifts are in δ relative to $BF_3 \cdot OEt_2$. ^1H NMR (60 MHz) were recorded on a Varian T-60. IR and mass spectra were recorded on Perkin-Elmer 137 and Finnegan GC/mass spectrometers respectively. Optical rotations were measured on a Rudolph polarimeter Autopol III.

GC Analysis. All GC analyses were carried out with a Hewlett Packard 5750 chromatograph using (a) 12 ft×0.125 in column packed with 10% Carbowax 20 M on Chromosorb W (100—120 mesh) or (b) 12 ft×0.125 in column packed with 10% SE-30 on Chromosorb W (100—120 mesh). For preparative GC, either (c) a 6 ft×0.5 in column packed with 20% Carbowax 20 M on Chromosorb W (60—80 mesh) or (d) a 6 ft×0.5 in column packed with 20% SP-2100 on Chromosorb W (60—80 mesh) was used.

Materials. Borane-methyl sulfide (BMS) purchased from Aldrich Chemical Company was estimated according to the standard procedure.[19] (+)-α-Pinene $[\alpha]_D^{23}$ +47.2° (neat) was purchased from Aldrich Chemical Company and distilled from a small excess of LAH. Anhydrous ethyl ether available from Mallinckrodt, Inc. was used directly. *N,N,N',N'*-Tetramethylethylenediamine (TMED) was distilled over excess calcium hydride. Tetrahydrofuran (THF) was distilled over anhydrous benzophenone ketyl and stored under nitrogen atmosphere in an ampule. The bis adduct of monoisopinocampheylborane with tetramethylethylenediamine (TMED·2IpcBH$_2$) and generation of (−)-IpcBH$_2$ of 100% ee from it was done as reported in the literature.[12]

Preparation of 1-Heteroarylcycloalkenes. Preparation of Tertiary Alcohols. Tertiary alcohols were prepared according to a similar procedure reported in the literature.[20] To a cooled (0 °C) solution of 16.32 g (240 mmol) of furan and ether (200 mL) was added *n*-BuLi in hexane, 76.8 mL (176 mmol) dropwise. The resulting mixture was stirred at 0 °C for 1 h, after which was added an ethereal solution of the corresponding ketone (152 mmol). After being stirred overnight, the reaction mixture was quenched with water (10 mL). The ether layer was decanted, dried ($MgSO_4$) and the solvent was removed under reduced pressure.

Preparation of 1-Heteroarylcycloalkenes. The crude alcohol taken in 100 mL benzene was treated with catalytic amount of *p*-toluenesulfonic acid for about 30 min at 40—50 °C. The benzene layer was dried over anhydrous K_2CO_3 and distilled to give the required olefins in 80—90% overall yield and >97% GC pure.

Preparation of 1-(3-Furyl/3-Thienyl)cycloalkenes. Following the general procedure used to prepare 3-furyl- or 3-thienyl-substituted cycloalkenes, 3-bromofuran or 3-bromothiophene (120 mmol) was taken in a 250-mL flask along with 150 mL of ether. It was cooled to −78 °C under N_2 and *n*-BuLi (144 mmol) was added dropwise. The reaction mixture was stirred at −78 °C for 1 h after which was added the corresponding ketone (120 mmol) slowly. It was further stirred 1 h at −78 °C, warmed to room temperature and quenched with water (10 mL). The ether layer was decanted, dried ($MgSO_4$) and the solvent was removed under reduced pressure. The crude product directly taken in benzene (100 mL) and treated with catalytic amount of *p*-toluenesulfonic acid for 30 min at 40—50 °C. The benzene layer was dried over anhydrous K_2CO_3 and distilled to give the corresponding olefins in 75—90% overall yield.

1-(3-Furyl)cyclopentene. Bp 88—90°/3.0 mmHg, n_D^{21} 1.5080, IR (neat on cm^{-1}) 2955, 2871, 1732, 1506, 1449, 1157, 1046, 1022, 1005, 905, 873, 784. ^1H NMR ($CDCl_3$) δ=1.35—2.80 (6H, m), 5.90 (1H, m), 6.55 (1H, m), 7.40 (2H, m). Mass spectrum *m/z* 134 (M^+).

1-(3-Furyl)cyclohexene. Bp 58—60°/0.3 mmHg, n_D^{21} 1.5100, IR (neat in cm^{-1}) 2990, 2920, 1580, 1480, 1190, 1170, 1090, 1070, 1000, 950, 905, 810, 760. ^1H NMR ($CDCl_3$) δ=1.30—2.40 (8H, m), 6.0 (1H, m), 6.50 (1H, m), 7.30 (2H, m). Mass spectrum *m/z* 148 (M^+).

1-(3-Thienyl)cyclopentene. Mp 59—60 °C. IR (Nujol in cm^{-1}) 2904, 2676, 1745, 1716, 1515, 1464, 1419, 1377, 1318, 1294, 1083, 1035, 954, 866, 838, 770, 722. ^1H NMR ($CDCl_3$) δ=1.80—2.80 (6H, m), 5.95 (1H, m), 6.80—7.25 (3H, m). Mass spectrum *m/z* 150 (M^+).

1-(3-Thienyl)cyclohexene. Bp 78—84°/0.05 mmHg, n_D^{21} 1.5650. IR (neat in cm^{-1}) 2927, 2857, 2833, 1447, 1435, 869, 841, 770, 714, 633. ^1H NMR ($CDCl_3$) δ=1.30—2.50 (8H, m), 6.15 (1H, m), 6.90—7.30 (3H, m). Mass spectrum *m/z* 164 (M^+).

Hydroboration of 1-(2-Furyl)cyclopentene. In a 250-mL flask equipped with septum inlet, magnetic stirring bar and a connecting tube leading to a mercury bubbler was placed 30 mL (25 mmol) of $IpcBH_2$ in ethyl ether and this was cooled to −25 °C. To the reaction flask was added with stirring 3.35 g (25 mmol) of 1-(2-furyl)cyclopentene over a period of 5 min. The reaction mixture was allowed to stir at −25 °C for 4 days. After completing the reaction (^{11}B NMR), the reaction flask was brought to 0 °C and 5.6 mL (10 mmol) of acetaldehyde was added dropwise and stirred at 25 °C for 6 h. Excess acetaldehyde was removed under reduced pressure (25 °C, 15 mmHg, 1 h) and to it 10 mL of THF was added. The boronate thus obtained was oxidized with 25 mL of 3 M sodium hydroxide and 3.7 mL of 30% H_2O_2. The reaction mixture was stirred at 25 °C for 5 h. The aqueous layer was saturated with potassium carbonate and extracted with 3×25 mL of ether, dried over $MgSO_4$ and the ether evaporated. The residue was passed through silica-gel column. The pentane eluent removed α-pinene, 5% ether in pentane removed unreacted olefins whereas the ether·pentane (20:80) afforded the alcohol, which, upon distillation, yielded 3.1 g of (1*S*,2*S*)-*trans*-2-(2-furyl)cyclopentanol, by 67—70°/0.02 mmHg, 82% isolated yield. GC purity >98%. It was further purified by preparative GC column c to furnish a GC pure material $[\alpha]_D^{23}$ +76.66° (*c* 2.215, MeOH), n_D^{21} 1.5065, 86% ee by capillary GC of its Mosher ester. IR (neat in cm^{-1}) 3358, 2959, 2975, 1594, 1504, 1451, 1147, 1069, 1045, 1010, 992, 800. ^1H NMR ($CDCl_3$) δ=1.80 (6H, m), 2.40 (1H, s), 3.0 (1H, m), 4.20 (1H, m), 6.0 (1H, m), 6.2 (1H, m), 7.25 (1H, m). Mass spectrum *m/z* 152 (M^+).

Hydroboration of 1-(2-Furyl)cyclohexene. With the usual experimental setup, 3.70 g (25 mmol) of 1-(2-furyl)cyclohexene was added dropwise to 35 mL (25 mmol) of $IpcBH_2$ in ethyl ether at −25 °C. The contents were stirred for 10 days at −25 °C and (5.6 mL) of acetaldehyde was added dropwise and stirred further for 6 h at room temperature. The boronate thus obtained was oxidized, worked up as usual, and purified by column chromatography as described in earlier cases to give 2.9 g of pure (1*S*,2*S*)-(+)-*trans*-2-(2-furyl)cyclohexanol, bp 75—80°/0.02 mmHg, 70% isolated yield. It was further purified by preparative GC column c to give GC pure material $[\alpha]_D^{23}$ +53.04 (*c* 1.795, MeOH), n_D^{21} 1.5080, 90% ee by capillary GC of its Mosher ester. IR (neat in cm^{-1}) 2931, 2858, 1591, 1448, 1170, 1146, 1122, 1060, 1009, 921, 802, 730. ^1H NMR ($CDCl_3$) δ=1.30—2.25 (8H, m), 2.40 (2H, m), 3.60 (1H, m), 6.0—6.40 (2H, m), 7.35 (1H, m). Mass spectrum *m/z* 166 (M^+).

Hydroboration of 1-(2-Furyl)cycloheptene. With the usual experimental setup, 4.05 g (25 mmol) of 1-(2-furyl)cycloheptene was added dropwise to 35 mL (25 mmol) of (−)-$IpcBH_2$ at −25 °C. The reaction mixture was stirred at −25 °C for 4 days. To the dialkylborane thus obtained was added 5.6 mL of acetaldehyde and the contents stirred 5 h at 25 °C. The excess of acetaldehyde was pumped off and the reaction mixture oxidized and worked up as described above to give 3.6 g of (1*S*,2*S*)-(+)-*trans*-2-(2-furyl)cycloheptanol, bp 78—80°/0.01 mmHg, 80% isolated yield. $[\alpha]_D^{21}$ +30.04 (*c* 2.43, MeOH), n_D^{21} 1.5115, 86% ee by capillary GC of its Mosher ester. IR (neat in cm^{-1}) 3400, 2928, 2860, 1502, 1457, 1444, 1146, 1046, 1024, 1010, 729. ^1H NMR ($CDCl_3$) δ=1.70 (10H, m), 2.0 (1H, s), 2.80 (1H, m), 3.85 (1H, m), 6.10 (1H, m), 6.30 (1H, m), 7.30 (1H, m). Mass spectrum *m/z* 180 (M^+).

Hydroboration of 1-(2-Thienyl)cyclopentene. With the usual experimental setup, 3.75 g (25 mmol) of 1-(2-thienyl)cyclopentene was added dropwise to 35 mL (25 mmol) of (−)-$IpcBH_2$ at −25 °C. The reaction mixture was stirred for 4 days at −25 °C. The dialkylborane thus obtained was worked up as usual, as described above, to give 3.6 g of distilled (1*S*,2*S*)-(+)-*trans*-2-(2-thienyl)cyclopentanol, bp 88—91°/0.02 mmHg, 86% isolated yield. n_D^{21} 1.5600. It was further purified by preparative GC to give pure product $[\alpha]_D^{22}$ 60.95 (*c* 2.3, MeOH), 86% ee by capillary GC of its Mosher ester. IR (neat in cm^{-1}) 3363, 2956, 2872, 1439, 1339, 1237, 1081, 1037, 824, 694. ^1H NMR ($CDCl_3$) δ=1.70—2.40 (7H, m), 3.10 (1H, m), 4.10 (1H, m), 6.80—7.30 (3H, m). Mass spectrum *m/z* 168 (M^+).

Hydroboration of 1-(3-Furyl)cyclopentene. With the usual experimental setup, 3.35 g of 1-(3-furyl)cyclopentene was added dropwise to 35.7 mL (25 mmol) of (−)-$IpcBH_2$ in ethyl ether at −25 °C. The contents after stirring for 4 days at −25 °C were worked up as usual and purified as described above to give 3.17 g of (1*S*,2*R*)-(+)-*trans*-2-(3-furyl)cyclopentanol, bp 75—80°/0.05 mmHg, 84% isolated yield. $[\alpha]_D^{22}$ +52.3 (*c* 2.2, MeOH), 85% ee by capillary GC of its Mosher ester. IR (neat in cm^{-1}) 3357, 2956, 2874, 1500, 1468, 1450, 1340, 1161, 1090, 1064, 1025, 814, 726. ^1H NMR ($CDCl_3$) δ=1.60—2.30 (6H, m), 2.70 (2H, m), 4.05 (1H, m), 6.35 (1H,

bs), 7.40 (2H, m). Mass spectrum *m/z* 152 (M^+).

Hydroboration of 1-(3-Thienyl)cyclopentene. With the usual experimental setup, 3.75 g (25 mmol) of 1-(3-thienyl)cyclopentene (in 5 mL of ether) was added dropwise to 30 mL (25 mmol) of (−)-IpcBH$_2$ at −25 °C. After stirring for 3 days at −25 °C, it was treated with acetaldehyde and worked up as described above to give 3.75 g of (1*S*,2*S*)-(+)-*trans*-2-(3-thienyl)cyclopentanol, bp 90—91 °C/0.04 mmHg, 89% isolated yield. It was further purified by preparative GC column c to give GC pure product n_D^{21} 1.5620, $[\alpha]_D^{22}$ +63.7 (*c* 2.05, MeOH), 86% ee by capillary GC of its Mosher ester. IR (neat in cm^{-1}) 3357, 2955, 2871, 1449, 1411, 1082, 1045, 844, 776, 645. ^{1}H NMR ($CDCl_3$) δ=1.4—2.35 (7H, m), 2.90 (1H, m), 4.0 (1H, m), 6.70—7.30 (3H, m). Mass spectrum *m/z* 168 (M^+).

Hydroboration of 1-(2-Benzofuryl)cyclopentene. With the usual experimental setup, 4.6 g (25 mmol) of 1-(2-benzofuryl)cyclopentene in 5 mL of ether was added dropwise to 30 mL (25 mmol) of (−)-IpcBH$_2$ at −25 °C. The reaction mixture was stirred at −25 °C for 10 days and worked up as described above to give 3.6 g of (1*S*,2*S*)-(+)-*trans*-2-(2-benzofuryl)cyclopentanol, bp 115—120 °C/0.02 mmHg isolated yield 71%, $[\alpha]_D^{22}$ +48.6° (*c* 2.74, MeOH), 85% ee by capillary GC of its Mosher ester. IR (neat in cm^{-1}) 3381, 2954, 2872, 1476, 1450, 1439, 1260, 1177, 1054, 787, 768, ^{1}H NMR ($CDCl_3$) δ=1.40—2.40 (6H, m), 2.90—3.40 (2H, m), 4.10—4.70 (2H, m), 6.60—7.10 (4H, m).

Hydroboration of 1-(3-Furyl)cyclohexene. With the usual experimental setup, 3.7 g (25 mmol) of 1-(3-furyl)cyclohexene was added dropwise to 35 mL (25 mmol) of (−)-IpcBH$_2$ at −25 °C. The reaction mixture was stirred at −25 °C for 10 days and worked up, purified as described above to give 3.2 g of (1*S*,2*R*)-(+)-*trans*-2-(3-furyl)cyclohexanol, bp 85—90 °C/0.02 mmHg, 77% isolated yield. It was further purified by capillary GC column c to give GC pure alcohol $[\alpha]_D^{22}$ +37.6° (*c* 2.11, MeOH), 90% ee by capillary GC of its Mosher ester. IR (neat in cm^{-1}) 3427, 2929, 2856, 1498, 1447, 1344, 1159, 1119, 1059, 1025, 736. ^{1}H NMR ($CDCl_3$) δ=1.20—2.0 (9H, m), 2.15 (1H, s), 4.0 (1H, m), 6.45 (1H, bs), 7.40 (2H, m). Mass spectrum *m/z* 166 (M^+).

Hydroboration of 1-(3-Thienyl)cyclohexene. With the usual experimental setup, 4.1 g (25 mmol) of 1-(3-thiethyl)-cyclohexene was added dropwise to 35 mL (25 mmol) of (−)-IpcBH$_2$ in ether at −25 °C. The contents, after being stirred for 10 days at −25 °C, were treated with excess acetaldehyde, worked up as usual to give 3.82 g of (1*S*,2*R*)-(+)-*trans*-2-(3-thienyl)cyclohexanol, bp 95—100 °C/0.02 mmHg, 84% isolated yield. It was further purified by preparative GC to give GC pure product $[\alpha]_D^{20}$ +31.93° (*c* 1.450, MeOH), 83% ee by capillary GC of its Mosher ester. IR (Nujol in cm^{-1}) 3272, 2928, 1465, 1378, 1350, 1232, 1063, 787, 722. ^{1}H NMR ($CDCl_3$) δ=1.30—2.0 (8H, m), 2.20 (1H, s), 2.60 (1H, m), 3.50 (1H, m), 6.80—7.45 (3H, m). Mass spectrum *m/z* 182 (M^+).

General Procedure for Upgrading and Isolation of Boronic Esters of High Optical Purity. Diethyl *trans*-2-(2-Furyl)cyclopentylboronate. A 250-mL round-bottom flask equipped with a sidearm, magnetic stirring bar and gas lead was flushed with nitrogen. In this flask 70 mL (50 mmol) of (−)-IpcBH$_2$ was taken and cooled to −35 °C. To it was added 6.7 g (50 mmol) of 1-(2-furyl)cyclopentene dropwise with magnetic stirring. The flask was maintained at −35 °C without stirring for 4 days. A white crystalline solid separated out. The supernatant liquid was removed by double-ended needle and the crystals were washed with cold ether (3×20 mL). The solid was dried under vacuum (ca. 15 mmHg) at 0 °C. It was then suspended in 20 mL of ether and treated with excess acetaldehyde (6 mL). The reaction mixture was stirred at room temperature for 5 h and (^{11}B NMR δ=30.97) showed the absence of dialkylborane. The excess of acetaldehyde pumped off and the residue distilled to give (+)-diethyl (1*S*,2*S*)-*trans*-2-(2-furyl)cyclopentylboronate, 7.05 g, bp 65—70°/0.02 mmHg, 60% isolated yield. $[\alpha]_D^{22}$ +51.58° (*c* 2.52, EtOH), >99% ee. ^{1}H NMR ($CDCl_3$) δ=1.20 (6H, m), 1.60—2.25 (7H, m), 3.25 (1H, m), 3.85 (4H, q), 5.90 (1H, m), 6.20 (1H, m), 7.25 (1H, m). A part of the sample was oxidized with NaOH, H_2O_2 to give the *trans*-2-(2-furyl)cyclopentanol which was further purified by preparative GC. $[\alpha]_D^{23}$ +88.2° (*c* 2.325, MeOH), >99% ee by capillary GC of its Mosher ester.

Diethyl *trans*-2-(3-Furyl)cyclopentylboronate. With the usual experimental setup, 6.7 g (50 mmol) of 3-furylcyclopentene was added dropwise to 70 mL (50 mmol) of IpcBH$_2$ at −35 °C. The flask was maintained at −35 °C without stirring for 4 days. The white crystalline solid separated out. The supernatant liquid was removed by double-ended needle and the crystals were washed with (3×20 mL) of cold ether. The solid was redissolved in 25 mL of ether at room temperature in about 10 min. A part of the solution (0.5 mL) was oxidized with NaOH and H_2O_2 and the optical purity checked by capillary GC of its Mosher ester showed 90% ee. The remaining whole solution was kept in a cold room for slow crystallization at 0 °C for 24 h. The white crystalline needles separated out. The supernatant liquid was removed by double-ended needle and the crystals washed with ice cold ether (3×5 mL). The crystals were dried under vacuum and treated with excess acetaldehyde. The usual workup as described above gave 5.9 g required boronate, bp 76—80°/0.04 mmHg, 50% yield. $[\alpha]_D^{22}$ +41.34° (*c* 2.38, EtOH), >99% ee. ^{1}H NMR ($CDCl_3$) δ=0.9—1.3 (6H, m), 1.4—2.0 (7H, m), 3.0 (1H, m), 3.8 (4H, q), 6.25 (1H, m), 7.20 (2H, m). A part of the diethyl *trans*-2-(3-furyl)cyclopentylboronate was oxidized to give the corresponding alcohol $[\alpha]_D^{22}$ +60.6° (*c* 2.29, MeOH), >99%ee by capillary GC of its Mosher ester.

Diethyl *trans*-2-(3-Thienyl)cyclopentylboronate. With the usual experimental setup as described above, diethyl *trans*-2-(3-thienyl)cyclopentylboronate was obtained bp 90—91°/0.05 mmHg, 50% isolated yield. $[\alpha]_D^{24}$ +46.72° (*c* 2.5, EtOH), >99% ee. ^{11}B NMR δ=31.42, ^{1}H NMR ($CDCl_3$) δ=0.9—1.4 (6H, m), 1.6—2.40 (7H, m), 3.15 (1H, m), 3.80 (4H, m), 6.8—7.4 (3H, m) its corresponding alcohol $[\alpha]_D^{22}$ +73.01° (*c* 2.3175, MeOH), >99% ee.

Diethyl *trans*-2-(2-Thienyl)cyclopentylboronate. With the usual experimental setup, 7.5 g (50 mmol) of 1-(2-thienyl)cyclopentene was added dropwise to 70 mL (50 mmol) of IpcBH$_2$ at −35 °C. The flask was maintained at −35 °C for 4 days without stirring and further kept at −78 °C for 5 h. The mother liquor containing the pure enantiomer was removed carefully without any crystalline particle and treated with excess of acetaldehyde (8 mL). The reaction mixture was stirred at room temperature for 5 h (^{11}B NMR δ=30.78) showed the absence of dialkylborane. The excess acetaldehyde and solvent was pumped off and the residue was taken up in 100 mL of pentane. The pentane layer was extracted with 3×25 mL of ether. The ether layer

was washed with water, dried over anhydrous $MgSO_4$ and the solvent removed to give *trans*-2-(2-thienyl)cyclopentylboronic acid, 7.15 g, 80% yield, 94% ee. It was crystallized with ether pentane at room temperature to give 5.7 g of pure boronic acid, 64% yield, which, upon treatment with ethanol, afforded the corresponding boronate, bp 85—90°/0.25 mmHg, 64% yield, $[\alpha]_D^{23}$ +36.10° (*c* 2.54, EtOH), 99% ee. ^1H NMR ($CDCl_3$) δ=0.9—1.4 (6H, m), 1.5—2.5 (7H, m), 3.20 (1H, m), 3.90 (4H, m), 6.7—7.10 (3H, m). The above boronate, upon oxidation, gave *trans*-2-thienylcyclopentanol $[\alpha]_D^{21}$ +70.6° (*c* 2.30, MeOH) >99% ee.

Diethyl *trans*-2-(2-Furyl)cyclohexylboronate. With the usual experimental setup, 7.4 g (50 mmol) of 1-(2-furyl)-cyclohexene was added dropwise to 70 mL (50 mmol) of $IpcBH_2$ in THF at −25 °C. The contents were stirred for 10 days at −25 °C and acetaldehyde (11.2 mL) was added dropwise and stirred further for 6 h at room temperature. The excess acetaldehyde and solvent were pumped off and the residue taken up in 100 mL of pentane. The pentane layer was extracted with 3×20 mL of 3 M sodium hydroxide. The alkaline solution was neutralized with 6 M HCl and extracted with 3×25 mL of ether. The ether layer was washed with water, dried over anhydrous $MgSO_4$ and solvent removed to afford 5.82 g of *trans*-2-(2-furyl)cyclohexylboronic acid, 60% yield, $[\alpha]_D^{22}$ +40.0° (*c* 1.05, CH_2Cl_2), 90% ee. The white crystalline boronic acid dissolved in ether pentane (2:3), 25 mL and kept at room temperature for slow crystallization. The supernatant liquid was removed by double-ended needle and crystals washed with cold ether pentane mixture (3×5 mL). After the usual workup, it gave 3.8 g of boronic acid, yield, 40%. $[\alpha]_D^{22}$ +44.5° (*c* 1.1, CH_2Cl_2). It was treated with ethanol to give its diethyl *trans*-2-(2-furyl)cyclohexylboronate, bp 100—105°/0.8 mmHg, $[\alpha]_D$ +36.2° (*c* 2.1, EtOH). ^1H NMR ($CDCl_3$) δ=0.9—1.35 (6H, m), 1.50—2.3 (9H, m), 3.2 (1H, m), 3.6—4.0 (4H, m), 6.2 (2H, q), 7.2 (1H, m). The boronate was oxidized to give the corresponding alcohol $[\alpha]_D^{22}$ +58.2° (*c* 1.8, MeOH) >98% ee by capillary GC of its Mosher ester.

Diethyl *trans*-2-(2-Furyl)cycloheptylboronate. With the usual experimental setup as described above, *trans*-2-(2-furyl)cycloheptylboronic acid was obtained 9 g, 87% yield. The solid was dissolved in ether pentane (2:3) 25 mL at room temperature. A part of the solution (0.5 mL) was oxidized with $NaOH/H_2O_2$ and the optical purity checked by capillary GC of its Mosher ester showed 86% ee. The remaining solution was crystallized and recrystallized at 0 °C for 24 h. The white crystalline needles separated out. The crystals were filtered and washed with pentane to give pure boronic acid, 4.7 g, 45% yield. It was treated with ethanol to give diethyl *trans*-2-(2-furyl)cycloheptylboronate, bp 120—125°/0.9 mmHg, $[\alpha]_D^{22}$ +24.6 (*c* 2.4, EtOH). ^1H NMR ($CDCl_3$) δ=0.9—1.3 (6H, m), 1.4—2.0 (11H, m), 3.1 (1H, m), 3.65—4.0 (4H, q), 5.9 (1H, m), 6.2 (1H, m) and 7.3 (1H, m). A part of the diethyl *trans*-2-(2-furyl)cycloheptylboronate was oxidized to give the corresponding alcohol $[\alpha]_D$ +34.9° (*c* 2.4, MeOH) >99% ee by capillary GC of its Mosher ester.

General Procedure for the Preparation of Diethanolamine *trans*-2-Heteroarylcycloalkylboronate. Ethyl heteroarylcycloalkylboronate (5 mmol) prepared as described above was taken in 15 mL of ether. To it 0.52 mL (5.4 mmol) of diethanolamine in 5 mL of 2-propanol was added and the reaction mixture was stirred at 25 °C for 1 h. A crystalline solid formed. It was filtered and removed by filtration and washed with 5 mL of cold ether. The results are shown in Table 4.

Reactivity† of Hypervalent Species: Reactions of Anionic Penta-Coordinated Silicon Complexes towards Nucleophiles

Alain BOUDIN, Geneviève CERVEAU, Claude CHUIT, Robert J. P. CORRIU,* and Catherine REYE

Institut de Chimie Fine, Université des Sciences et Techniques du Languedoc, Unité Associée CNRS UA N° 1097, Place E. Bataillon 34060 Montpellier Cedex, France

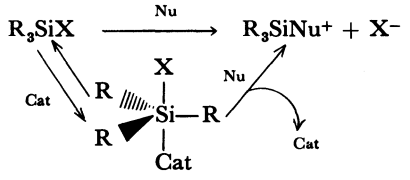
(Received July 17, 1987)

The reactivity of anionic penta-coordinated silicon complexes $[RSi(O_2C_6H_4\text{-}o)_2]^-Na^+$ **1** with nucleophilic reagents has been studied. **1** can be reduced to organosilanes $RSiH_3$ by metallic hydrides. Reactions with an excess of Grignard or organolithium reagents (R'MgX or R'Li) gave tetraorganosilanes $RSiR'_3$. When only two molar equivalents of Grignard reagents (R'MgX) or lithium reagents (R'Li) are added to complexes **1** functional silanes RR'_2SiX can be prepared.

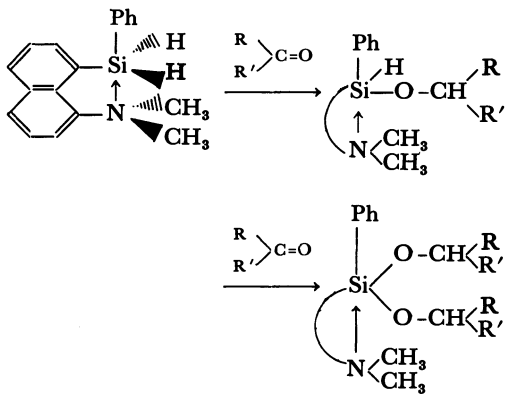
It has been known for a long time that silicon can expand its valence shell and several types of penta- and hexa-coordinated silicon compounds have been reported, in which silicon is surrounded by electronegative ligands[2-4] and more recently by nonelectronegative ones.[5] Numerous structural studies of hexa- and penta-coordinated silicon complexes have been reported[2,3,5,6] but little attention has been paid to the fundamental chemical behaviour of these species. Some reports which are in the literature suggested that these complexes may have unusual properties compared with those of their tetra-coordinated analogues. Kummer et al.[7] have observed that cationic bis(2,2'-bipyridine), 1,10-phenantroline, and pyridine *N*-oxide silicon complexes have unexpected properties. For instance $[SiX_2(bipy)_2]\,Cl_2$ may be dissolved in water or methanol without reaction of the SiX bond (X=Cl,Br). Kumada[4,8,9] has shown the unique reactivity of the carbon-silicon bond in organopentafluorosilicates and has exploited these properties in organic synthesis. Muller[10] has reported that reaction is possible between an organopentafluorosilicate and strong nucleophiles such as Grignard reagents:

$$[CH_3SiF_5]M_2 + 3C_2H_5MgBr \longrightarrow CH_3Si(C_2H_5)_3 \quad 25\%$$

Finally 1-hydrosilatrane has been shown to have some potential uses as a reducing agent.[11] All these examples illustrate very well the difference between the chemical behaviour of hypervalent silicon species and the tetra-coordinated ones. Moreover mechanistic studies of nucleophilic substitution at silicon performed in our laboratory[12] have established the nucleophilic activation of nucleophilic substitution at silicon. To explain these results, a mechanism has been proposed in which the rate-determining step is attack of the nucleophile, Nu, at a penta-coordinated silicon centre. This mechanism is now given further support by some recent results:



1) Reactivity of the Si–H bonds[13] in penta-coordinated silicon dihydrides towards nucleophiles is markedly greater than that of the corresponding tetra-coordinated species. For example these penta-coordinated silicon dihydrides react with carbonyl compounds without any catalyst as shown in the following reaction:



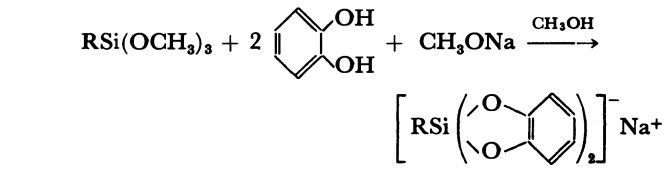
2) Other very recent experiments[14] have confirmed that penta-coordinated anionic trifluorosilicates $R_2SiF_3^-$ and difluorosilicates $R_3SiF_2^-$ react with nucleophiles faster than the corresponding fluorosilanes R_2SiF_2 and R_3SiF.

In this paper we describe the reactivity towards nucleophiles of anionic penta-coordinated silicon complexes of catechol $\left[RSi\left(\begin{smallmatrix}O\\O\end{smallmatrix}\!\!\bigcirc\right)_2\right]^-Na^+$ **1**. These derivatives have been prepared by Frye[15] and the structure of tetramethylammonium (1,2-benzenediolato)phenylsilicate has been determined by X-ray diffraction,[6a] but the chemistry of theses anions however has not yet been explored.

† Preliminary Communication Ref. 1.

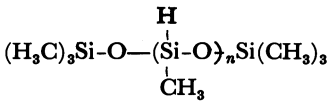
Results and Discussion

Synthesis of Anionic Penta-Coordinated Silicon Complexes of Catechol. The anionic penta-coordinated silicon complexes **1** have been synthesized according to the method described by Frye,[15]



1a : R=Ph, **1b** : R=CH_3, **1c** : R=1-naphthyl

The complex **1b** can be also prepared with 90% yield from the polymer polymethylhydrosiloxane (PMHS):



PMHS is obtained from methyldichlorosilane which is itself a by-product of the "direct synthesis" of dimethyldichlorosilane

Reactivity of Anionic Penta-Coordinated Silicon Complexes of Catechol towards Metal Hydrides. The reactivity of the anionic complexes **1a** and **1c** towards metal hydrides such as lithium aluminium hydride, diisobutylaluminium hydride and triethylaluminium/sodium hydride was investigated. The only product obtained is the monoorganosilane $RSiH_3$ in quite a good yield (Table 1).

Reactivity of Anionic Penta-Coordinated Silicon Complexes of Catechol towards Grignard and Organolithium Reagents. The reactivity of anionic complexes **1** with organometallic compounds (R'MgX and R'Li) has been studied. First, we have investigated the influence of the ratio complex/organometallic compound on the reaction products in order to examine the possible selectivty of the reaction.

Table 1. Reactions of Metalhydrides with Complexes **1**

Complex	Hydride	Reaction condition			Product (yield/%)[a]	
		Solvent	T/°C	t/h		
1a	$LiAlH_4$(excess)	Ether	20	2	$PhSiH_3$	(72)
1a	NaH/Et_3Al 4eq/3eq	Hexane	20	1	$PhSiH_3$	(68)
1a	i-Bu_2AlH(5eq)	CH_2Cl_2	0	1	$PhSiH_3$	(65)
1c	$LiAlH_4$(excess)	Ether	35	4	1-$NpSiH_3$	(73)

a) Yield of isolated product.

Table 2. Reaction of Methyllithium and Methylmagnesium Bromide with Complex **1a**. Influence of the Ratio Complex **1a**/Organometallic Compound on the Reaction Products[a]

CH_3M	Reaction condition			$PhSiH_3$	$PhCH_3SiH_2$	$Ph(CH_3)_2SiH$	$PhSi(CH_3)_3$
	Solvent	T/°C	t/h				
CH_3MgBr(1eq)	Ether	0	2, 5	79	9	12	0
CH_3MgBr(1eq)	Ether	35	2	56	7	36	0
CH_3MgBr(1eq)	THF	60	2	54	5	41	0
CH_3MgBr(2eq)	Ether	35	2	6	6	85	3
CH_3MgBr(3eq)	Ether	35	2	0	4	58	38
CH_3Li(1eq)	Ether	35	2	48	7	44	0
CH_3Li(2eq)	Ether	35	2	12	4	81	4
CH_3Li(2eq)	THF	60	2	9	10	49	32
CH_3Li(3eq)	Ether	35	2	0	0	0	100

a) The ratio of the different reaction products was determined by GLC after reduction of the reaction mixture with $LiAlH_4$.

The results obtained after reduction of the reaction mixture with an excess of lithium aluminium hydride are reported in Table 2. It appears that:

1) The addition of 1 or 2 molar equivalents of organometallic reagents R'MgX or R'Li results mainly in the formation of two Si–C bonds whatever the reaction conditions (solvent, temperature, nature of the organometallic compound). This implies that the first substitution is rate-determining step.

2) The reaction of 2 molar equivalents of organometallic reagents (R'MgX or R'Li) followed by reduction with lithium aluminium hydride gives mainly organosilanes of type RR'_2SiH.

3) 3 molar equivalents of organolithium reagent R'Li lead only to the tetra-substituted silanes $RSiR'_3$ while the reaction with 3 molar equivalents of Grignard reagent R'MgX followed by reduction with lithium aluminium hydride gives a mixture of RR'_2SiH and $RSiR'_3$. The results of the reactions carried out with 2 or 3 molar equivalents of organometallic reagents are summarised in Tables 3 and 4 respectively. The great reactivity of the allylic and alkynyl Grignard reagents towards complexes **1a** and **1b** should be pointed out in that the tetra-substituted compounds $RSi(CH_2CH{=}CH_2)_3$ or $RSi(C{\equiv}CR')_3$ are the main products whatever the stoichiometry of the reactants. It is worth noting the preparation in one step of 1-methyl-2,5-diphenylsilacyclopentadiene and 1,2,5-triphenylsilacyclopentadiene with satisfactory yield (Table 3). The reactivity of *t*-butylmagnesium bromide towards **1a** is low. One molar equivalent of *t*-butylmagnesium bromide in the

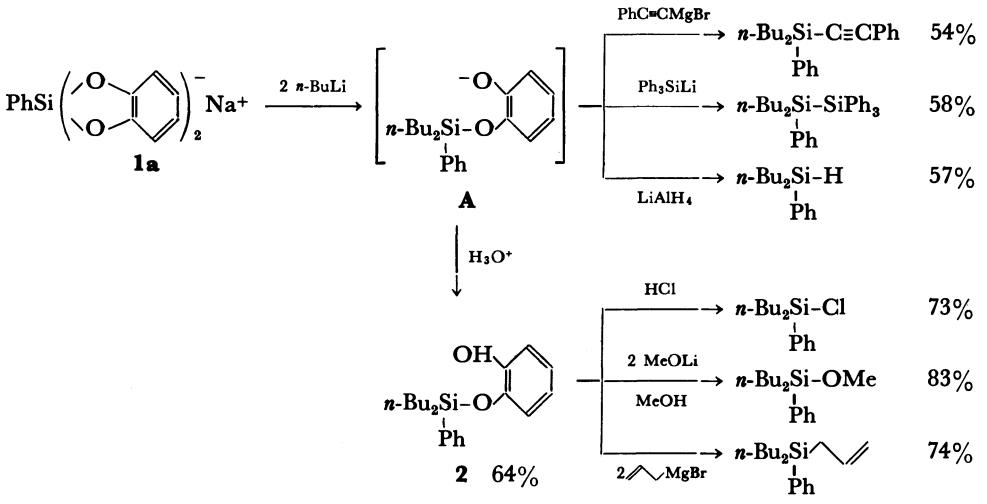

Scheme 1.

presence of one molar equivalent of the cryptand tris(3,6-dioxaheptyl)amine[16] (TDA-1) results in the formation of only one new Si–C bond giving after reduction with lithium aluminium hydride phenyl-*t*-butylsilane as the major product but in poor yield (16%) (Table 3) (without TDA-1 no reaction product at all was isolated). 3 molar equivalents of *t*-butylmagnesium bromide in the presence of 3 molar equivalents of TDA-1, react with **1a** to give after reduction with an excess of lithium aluminium hydride the unexpected product diphenyl-*t*-butylsilane in 31% yield.

$$\mathbf{1a} \xrightarrow[\text{2) } LiAlH_4]{\text{1) 3eq } t\text{-BuMgBr, 3eq TDA-1}} Ph_2SiH(t\text{-Bu})\ (31\%)$$

The formation of this product can be explained by a disproportionation of phenyl-*t*-butylsilane induced by $LiAlH_4$/TDA-1. Indeed other examples of disproportionation of silanes promoted by $LiAlH_4$/TDA-1 have been observed.[17]

$$PhSiH_3 \xrightarrow[\text{TDA-1}]{LiAlH_4} Ph_2SiH_2 \longrightarrow Ph_3SiH$$

Two different substituents can be introduced in successive steps into the complex **1a** without isolating the intermediate **A** (Scheme 1). This one can react with different nucleophilic reagents to give further organosilicon compounds with moderate to good yield. However in some cases, for purification purposes, it is better to hydrolyze the intermediate **A** and isolate **2** before adding the second nucleophile. Analogous results have been obtained with the dianionic hexa-coordinated silicon complex $\left[Si\left(O_2C_6H_4\right)_3\right]^{2-}\ 2Na^+$.[18]

In conclusion this work describes a new route to organosilicon compounds from penta-coordinated anionic species. From a mechanistic point of view the products obtained are the result of the reaction of a nucleophilic reagent with a negatively charged species. The mechanistic details of these nucleophilic reactions have yet to be elucidated. However these results open some new synthetic possibilities exploiting the reactivity of hypervalent silicon species.

Experimental

Reactions have been carried out under nitrogen. All solvents were purified by standard techniques before use. (All the compounds described in this paper have been characterized by usual techniques and analysis: CPV (Girdel,SE30). NMR spectra have been recorded with a Varian EM 360A spectrometer for ^1H, with a Bruker WP-80 for ^{13}C, with a Bruker WP-200 SY for ^{29}Si. All ^1H, ^{13}C, and ^{29}Si chemical shifts reported in ppm are relative to Me_4Si. IR spectra have been recorded with a Perkin Elmer 298 spectrophotometer, mass spectra with a JEOL JMS-DX 300 Mass Spectrometer. Microanalyses have been carried out by CNRS laboratories (Lyon).

Preparation of Complexes: Sodium Bis(1,2-benzenediolato)methylsilicate (1b) from $MeSi(OMe)_3$. A solution of $MeSi(OMe)_3$ (0.0475 mol) in 10 ml of MeOH was added at room temperature to a solution of MeONa (0.0475 mol) in 15 ml of MeOH. Then 10.34 g of catechol dissolved in 20 ml of MeOH were added dropwise at 25 °C. The mixture was heated for about 4 hours at 45 °C. MeOH was removed under vacuum. Complex was washed twice with ether and dried under vacuum at 100 °C for one day. 12 g (90%) of **1b** were obtained as a white powder. ^1H NMR (DMSO-d_6) δ=−0.1 (3H, s), 6.5—6.8 (8H,m); ^{13}C NMR (DMSO-d_6) δ=151.6, 120.8, 113.2, 1.2; ^{29}Si NMR (CD_3OD) δ=−73.77; IR (KBr) 1590, 1475, 1345, 1240, 1095, 1010, 895, 830, 750 cm^{-1}.

Sodium Bis(1,2-benzenediolato)methylsilicate (1b) from PMHS. 0.2 mol of catechol (22 g) and 0.2 mol of PMHS (12 g) were dissolved in about 50 ml of MeOH. 0.1 mol of MeONa dissolved in about 30 ml of MeOH was added slowly at room temperature. The reaction of MeONa with PMHS was exothermic. The mixture was stirred overnight during which time a precipitate from the polymer appeared. Then the solution was filtered and the solid washed twice

with methanol. The methanol was removed from the whole filtrate; 25.3 g (90%) of a grey powder was obtained. The spectral data were the same as those of the complex prepared from $MeSi(OMe)_3$.

Sodium Bis(1,2-benzenediolato)phenylsilicate (1a). The preparation of **1a** from $PhSi(OMe)_3$ was the same as that of **1b** from $MeSi(OMe)_3$. ^1H NMR (DMSO-d_6) δ=6.28—6.78 (8H, m), 6.95—7.22 (3H, m), 7.28—7.60 (2H, m); ^{13}C NMR (DMSO-d_6) δ=150.6, 140.8, 135.4, 129.4, 127.9, 119.9, 112.0; ^{29}Si NMR (DMSO-d_6) δ=−87.4; IR (KBr) 1600, 1475, 1340, 1240, 1220, 1110, 1100, 1010, 890, 825, 730, 700 cm^{-1}.

Sodium Bis(1,2-benzenediolato)-1-napthylsilicate (1c). The complex **1c** was prepared from $1\text{-}NpSi(OMe)_3$ as **1a** from $MeSi(OMe)_3$. ^1H NMR (DMSO-d_6) δ=6.1—6.7 (8H, m), 7.0—7.35 (3H, m), 7.35—7.78 (3H, m), 8.35—8.8 (1H, m); ^{13}C NMR (DMSO-d_6) δ=150.2, 132.7, 131.6, 130.1, 127.7, 127.1, 124.8, 124.6, 117.5, 110.1; ^{29}Si NMR (DMSO-d_6) δ=−84.64; IR (KBr) 1600, 1480, 1395, 1240, 1100, 1010, 890, 820, 740, 700 cm^{-1}.

Synthesis of Tetraorganosilanes $RSiR'_3$. The following is given as an example. **Methyltri(phenylethynyl)silane.** An excess of $PhC{\equiv}CMgBr$ (40 mmol) was added to a suspension of **1b** (10 mmol) in anhydrous ether (60 ml) at 20 °C. The mixture was stirred at 35 °C for about 4 hours, then hydrolyzed with aqueous 4M HCl. After 3 extractions with ether, the organic layer was washed 3 times with aqueous 2M NaOH then twice with water and once with brine. Evaporation of the solvent gave the crude $MeSi(C{\equiv}CPh)_3$ which was purified by recrystallization from pentane. 2.83 g (82%) of pure $MeSi(C{\equiv}CPh)_3$ was obtained, mp 125—6 °C (lit,[19] 126 °C).

The following products similarly prepared were: **Trimethylphenylsilane** (75%) bp 75—77 °C/30 Torr (lit,[20] 170.6 °C/760 Torr). **Triallylphenylsilane** (53%) bp 85—88 °C/0.4 Torr (lit,[21] 90—92 °C/0.8 Torr). **Tributylphenylsilane** (85%) bp 89—92 °C/0.05 Torr (lit,[22] 116—118 °C/0.9 Torr). **Tetraphenylsilane** (76%) mp 232—233 °C (lit,[23] 236.5—237 °C). **Tributylmethylsilane** (63%) bp 110—113 °C/14 Torr (lit,[24] 101—104 °C/9 Torr). **Triallylmethylsilane** (62%) bp 78—82 °C/35 Torr (lit,[25] 180.3 °C/745 Torr). **Methyltriphenylsilane** (63%) bp 150—160 °C/0.2 Torr (lit,[26] 196—200 °C/9 Torr). ***t*-Butylphenylsilane** (16%) bp 87 °C/30 Torr (lit,[27] 186—188 °C/760 Torr).

Synthesis of Triorganosilanes RR'_2SiH. The following is given as an example. **Dibutylphenylsilane.** Two molar equivalents of a molar solution of *n*-BuLi in ether were added to a suspension of **1a** (40 mmol) in 100 ml of ether at room temperature. The mixture was stirred at 20 °C about one hour then a suspension of 20 mmoles of $LiAlH_4$ in ether was added. The mixture was heated at 35 °C about 2 hours then hydrolyzed and extracted in the same way as for the isolation of $RSiR'_3$. 2.5 g (57%) of pure product was distilled at 75—79 °C/0.5 Torr (lit,[28]).

Similarly prepared were: **Dimethylphenylsilane** (37%) bp 89—91 °C/100 Torr (lit,[29] 159.3 °C/760 Torr). **Diethylphenylsilane** (40%) bp 115 °C/25 Torr (lit,[30] 97—100 °C/25 Torr). **Diisopropylphenylsilane** (45%) bp 120 °C/17 Torr (lit,[31] 58—60 °C/1.2 Torr). **Dicyclohexylphenylsilane** (83%) bp 145 °C/0.08 Torr (lit,[31] 124 °C/0.03 Torr). **Methyldiphenylsilane** (60%) bp 90—95 °C/1 Torr (lit,[32] 93.5 °C/1 Torr). **Dibenzylmethylsilane** (86%) bp 90—92 °C/0.05 Torr (lit,[33] 130—140 °C/3 Torr). **1-Methyl-2,5-diphenylsilacyclopentadiene** (51%) mp 97—99 °C (lit,[34] 97—98 °C). **1,2,5-Triphenylsilacyclopentadiene** (50%) mp 176—178 °C (lit,[35] 180—181 °C).

***t*-Butyldiphenylsilane.** 3 molar equivalents of *t*-BuMgCl in ether were added dropwise to a mixture of 20 mmoles of **1a** and 60 mmoles of TDA-1 in 100 ml of anhydrous ether. The pasty mixture was refluxed for 24 hours, then a suspension of 40 mmoles of $LiAlH_4$ in ether was added. The mixture was stirred at room temperature for one day, then hydrolyzed and extracted with ether. After the usual work-up the product was purified by silica-gel column chromatography to give 1.48 g of *t*-butyldiphenylsilane (31%). ^1H NMR (CCl_4) δ=1.0 (9H, s), 4.5 (1H, s), 7.05—7.55 (10H, m); IR (CCl_4) 2120 (SiH) cm^{-1} (lit,[36]).

Dibutylphenyl(2-hydroxyphenoxy)silane 2. 2 equivalents of *n*-BuLi in ether were added to a suspension of **1a** (20 mmol) in 150 ml of anhydrous ether at 20 °C. The mixture was stirred at room temperature for about one hour, then hydrolyzed with an aqueous solution of 4M HCl and extracted with ether three times. The combined organic extracts were washed 4 times with 2M NaOH, then with brine, dried ($MgSO_4$) and concentrated. The product was purified by distillation to give 4.2 g of **2** (64%). bp 153—5 °C/0.01 Torr. ^1H NMR (CCl_4) δ=0.42—2.02 (18H, m), 5.5 (1H, s), 6.5—7.0 (4H, m), 7.02—7.78 (5H, m); IR (CCl_4) 3560 (OH) cm^{-1}; Found: C, 73.21; H, 8.54; Si, 8,51%. Calcd for $C_{20}H_{28}O_2Si$: C, 73.17; H, 8.53; Si, 8.53%.

Dibutylphenyl(phenylethynyl)silane. 2 molar equivalents of *n*-BuLi in ether were added to a suspension of **1a** (20 mmol) in 150 ml of anhydrous ether at 20 °C. The mixture was stirred at room temperature for one hour then one equivalent of $PhC{\equiv}CMgBr$ was added at 20 °C. The mixture was heated at reflux about 6 hours then hydrolyzed with an aqueous solution of 4M HCl, and extracted with ether; the extracts were washed with 2M NaOH four times then with brine, dried ($MgSO_4$) and concentrated. The product was distilled to give 3.5 g (54%) of dibutylphenyl (phenylethynyl)silane, bp 150—153/0.01 Torr. ^1H NMR (CCl_4) δ=0.15—1.90 (18H, m), 6.65—7.90 (10H, m); IR (CCl_4) 2150 (-C≡C-) cm^{-1}; Found C, 82.39; H, 8.77; Si, 8.74%. Calcd for $C_{22}H_{28}Si$: C, 82.50; H, 8.75; Si, 8.75%.

Allyldibutylphenylsilane. An excess of allylmagnesium bromide was added to a solution of 15 mmoles of the organosilane **2** in 50 ml of anhydrous ether at 20 °C. The mixture was heated about 20 hours at reflux then hydrolyzed with an aqueous solution of 4 M HCl and extracted with ether three times. The combined organic extracts were washed with 2M NaOH four times then with brine, dried ($MgSO_4$) and concentrated. The product was distilled to give 2.8 g (74%) of allyldibutylphenylsilane; bp 167 °C/13 Torr; ^1H NMR (CCl_4) δ=0.63—1.67 (18H, m), 1.87 (2H, d), 4.60—6.05 (3H, m), 7.05—7.70 (5H, m); IR (CCl_4) 1625 (C=C) cm^{-1}; Found: C, 78,38; H, 10.74; Si, 10.77%. Calcd for $C_{17}H_{28}Si$: C, 78.46; H, 10.76; Si, 10.76%.

Dibutylphenylmethoxysilane. 2 molar equivalents of MeOLi dissolved in 15 ml of MeOH were added to a solution of 9.1 mmoles of the organosilane **2** in 100 ml of MeOH. The mixture was stirred about 1.5 h at 20 °C, then MeOH was removed. The residue was extracted with pentane, the salts were filtered and the solvent was removed under vacuum. The product was distilled to give 2.9 g of dibutylphenylmethoxysilane (83%); bp 113 °C/0.02 Torr; ^1H NMR (CCl_4) δ=0.8—1.8 (18H, m), 3.6 (3H, s), 7.3—7.8 (5H, m); Found: C, 72.11; H, 10.43; Si, 11.18%. Calcd for

$C_{15}H_{26}OSi$: C, 72.00; H, 10.40; Si, 11.20%.

Dibutylphenylchlorosilane. 5 molar equivalents of HCl diluted in ether (100 ml) were added to a solution of 15 mmoles of the organosilane **2** in 50 ml of ether. The mixture was stirred at 20 °C for about 15 hours, then the solvent was removed and the residue taken up in pentane. The catechol was filtered and the product was purified by distillation; bp 164 °C/13 Torr (yield 73%); ^{1}H NMR (CCl_4) δ: 0.45—1.90 (18H, m), 6.95—7.82 (5H, m); Found: C, 66.11; H, 9.02, Cl, 13.92; Si, 10.97%. Calcd for $C_{14}H_{23}ClSi$: C, 66.01; H, 9.03; Cl, 13.94; Si, 11.00%.

1,1-Dibutyl-1,2,2,2-tetraphenyldisilane. 2 equivalents of *n*-BuLi were added to a suspension of **1a** (10 mmol) in 50 ml of anhydrous ether at 20 °C. The mixture was stirred at room temperature for one hour, then 10 mmoles of Ph_3SiLi[37] in 30 ml of THF were added at 20 °C. The mixture was stirred under reflux during 36 hours. After this time the reaction mixture was completely colourless. The salts were filtered and washed with ether. The combined ether extracts were washed with water until the aqueous layer was colourless. The ethereal solution was dried over anhydrous $MgSO_4$ and concentrated. The solid residue was recrystallized from ethanol to give white crystals [2,77 g (58%)] of 1,1-dibutyl-1,2,2,2-tetraphenyldisilane; mp 108—110 °C; ^{1}H NMR (CCl_4) δ=0.75—1.65 (18H, m), 7.25—7.7 (20H, m); Found: C, 80.26; H, 7.98; Si, 11.75%. Calcd for $C_{32}H_{38}Si_2$: C, 80.33; H, 7.95; Si, 11.70%.

Invited Paper

Chemical Chameleons. Organosulfones as Synthetic Building Blocks

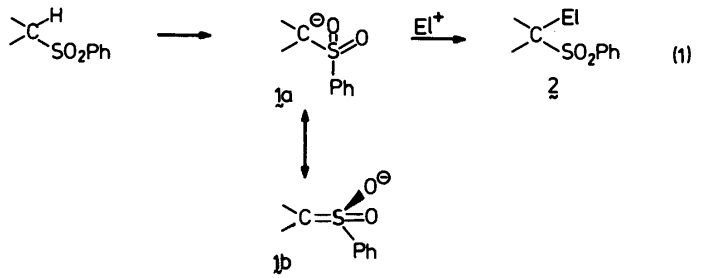
Barry Martin Trost
Department of Chemistry, University of Wisconsin-Madison, 1101 University Avenue, Madison, WI 53706, U.S.A.
(Received July 29, 1987)

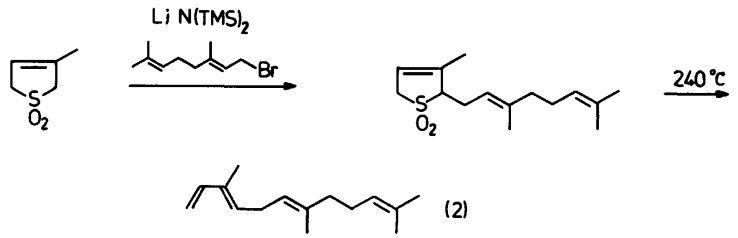
An overview of the duality of function of organosulfones as nucleophiles in basic media and electrophiles in Lewis acidic media, a change of reactivity for which they have been dubbed "chemical chameleons," is presented. In the first phase, transition metal catalysts activate allyl sulfones towards displacements. Use of palladium, molybdenum, and nickel catalysts allow stabilized anions to effect displacement; copper catalysts allow non-stabilized nucleophiles to be used. The use of the anion stabilizing and leaving group abilities of sulfones created a novel three carbon intercalation and a novel cyclocontraction-spiroannulation in which β-hydroxy sulfones participate in a Lewis acid catalyzed pinacol rearrangement. The lability of allyl and tertiary sulfones towards Lewis acids creates a wide array of electrophilic reactions such as Friedel-Crafts type cyclizations, intermolecular alkylations with organoalanes and enol silyl ethers, and ring expansions. The ability to design novel reagents for synthesis based upon this dual reactivity of organosulfones is illustrated by the use of an alkoxy-bis(phenylsulfonyl)methane as a synthon for a carbonyl 1,1-dipole.

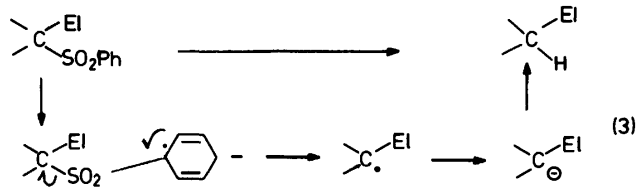
The utility of organosulfones for organic synthesis emerged with the evolution of non-nucleophilic strong bases like lithium dialkylamides and *n*-butyllithium which permit formation of a carbanion[1] (pK_a methyl phenyl sulfone 29[2]). The resulting organometallic appears to be enolate like (**1a**←→**1b**) based on both theoretical[3] and experimental data.[4] A notable discrepancy arises in the case of the organometallic generated from allyl phenyl sulfone where the carbanion center appears to be pyramidilized.[5] In contrast to enolates, sulfone stabilized anions have little propensity to react at oxygen.[6] Thus, treatment with electrophiles normally leads to smooth addition to carbon to give **2**. Since the sulfone functionality is rarely present in the final synthetic target, the major obstacle then becomes removal of the sulfone.

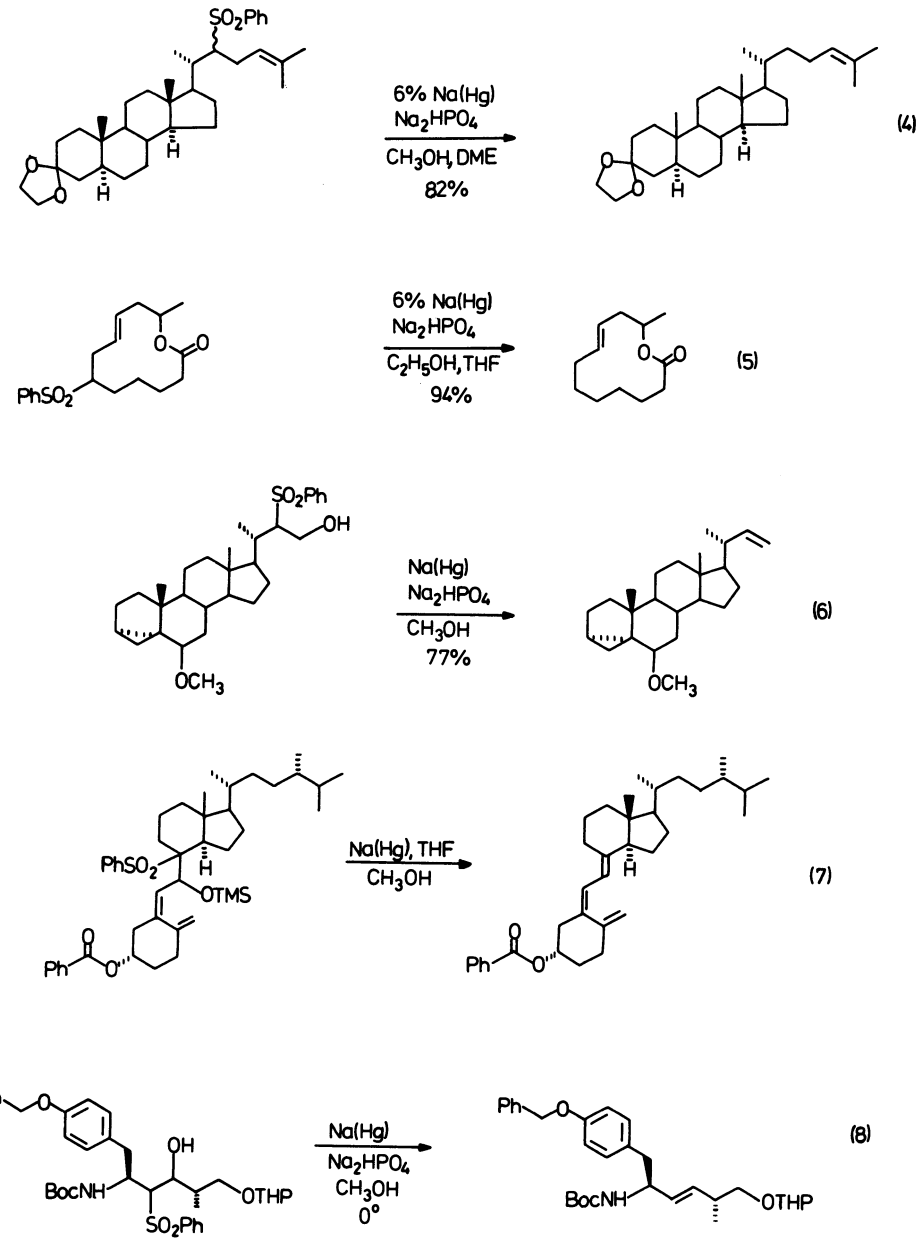
Early Applications. The early applications of organosulfones relied upon extrusions of sulfur dioxide in the base treatment of α-halo sulfones to give olefins (Ramberg-Bäcklund rearrangement)[7] or thermally in the case of sulfolenes as in a recent synthesis of farnesene (Eq. 2).[8]

A major advance arose by the recognition of







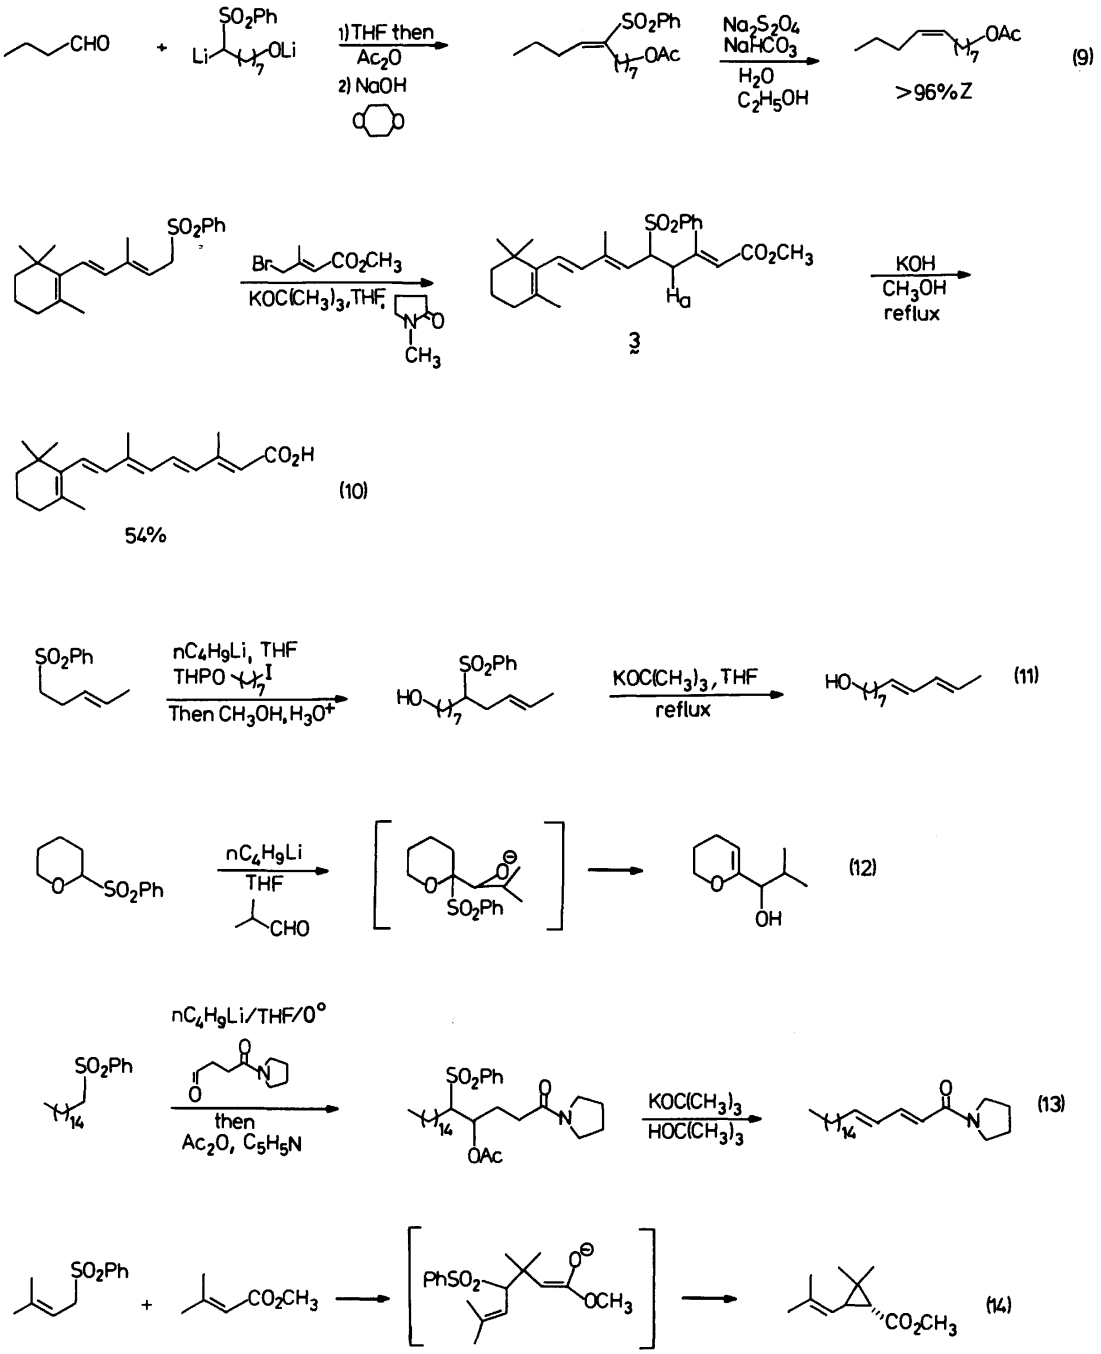


reductive desulfonation of aryl sulfones using dissolving metal reductions which permits the overall transformation shown in Eq. 3. Sodium amalgum in alcoholic solvents buffered with disodium hydrogenphosphate is a particularly mild way to effect such cleavages[9] (Eqs. 4[10] and 5[11]). In this reaction, the cleavage presumably occurs from the radical anion as depicted in Eq. 3. Its efficacy, therefore, depends upon the reduction potential of the sulfone and the stability of the resulting carbon radical. Thus, both "activated" sulfones, as in the case of an allyl system, and "unactivated" sulfones, represented by the saturated alkyl systems as in Eqs. 4 and 5, successfully cleave.

If the carbon β to the sulfones bears a potential leaving group, the reaction can be diverted to elimination to an olefin[12,16] (Eqs. 6[13] and 7[14]). Frequently, this method, originally introduced by Julia,[12] provides an olefin geometry complementary to that produced by Wittig type processes (cf. Eq. 8).[15]

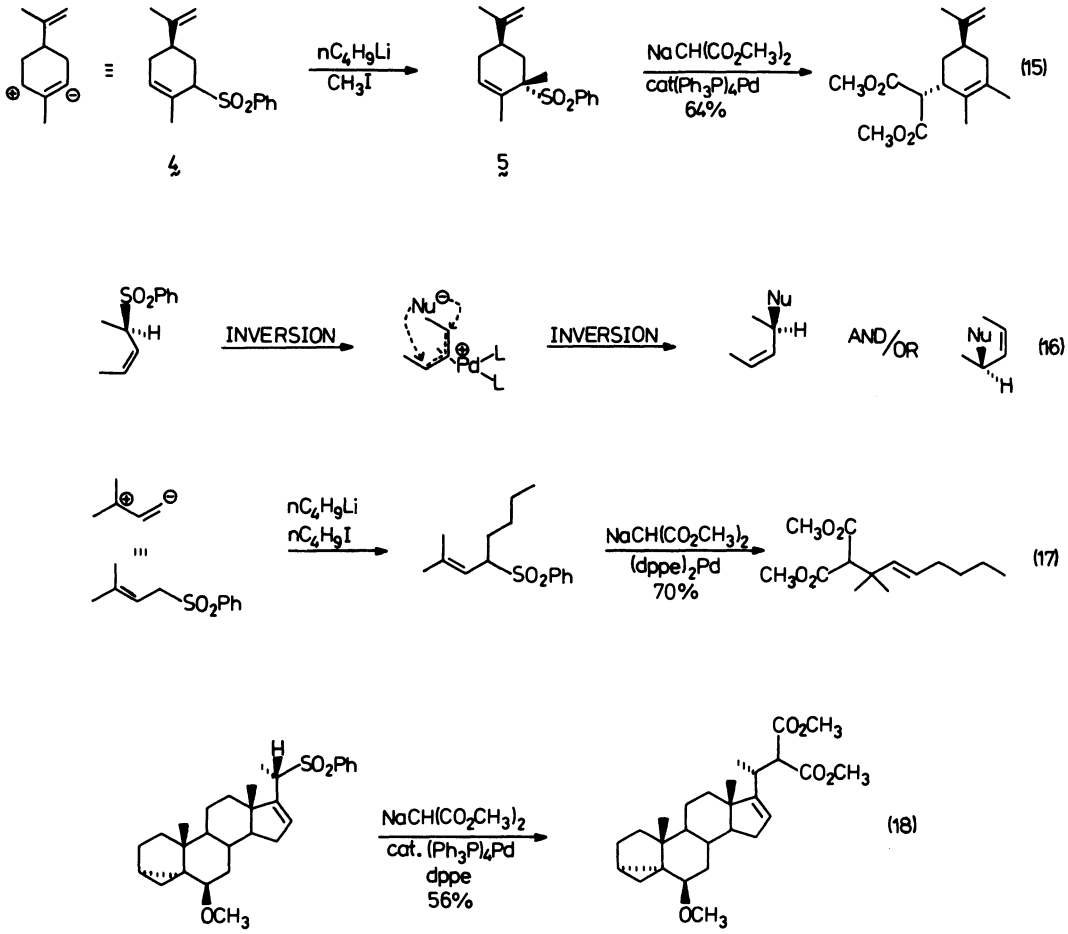
An alternative stereocontrolled introduction of an olefin via organosulfones, also introduced by Julia, relies on the steric bulk of the sulfone to direct placement of the larger alkyl group on the β-carbon of an α,β-unsaturated sulfone to be trans as in Eq. 9.[16] Stereocontrolled replacement of the C–S bond by a C–H using basic dithionite completes a stereoselective approach to (Z)-olefins.

The base-catalyzed elimination of aryl sulfones has also served as a useful approach to olefins. A synthesis



of vitamin A acid illustrates the alkylation-elimination sequence (Eq. 10).[17] The acidification of the proton to be removed (i.e. H_a in **3**) by virtue of its being vinylogously alpha to the ester facilitates the elimination but is not required. An allylic proton proved sufficient in a synthesis of a pheromone constituent of the false coddling moth (Eq. 11) but this elimination requires much harsher base conditions.[18] Activation of the sulfone as a leaving group by placing an electron donating group α to the sulfone has also proven effective (Eq. 12).[19] An interesting variant is a double elimination of β-acetoxy sulfones (Eq. 13)[20] which relies upon 1) facilitation of elimination of the elements of acetic acid by the sulfone, 2) the ease of converting a vinyl sulfone to an allyl sulfone and 3) the vinylogous elimination of the elements of benzenesulfinic acid.

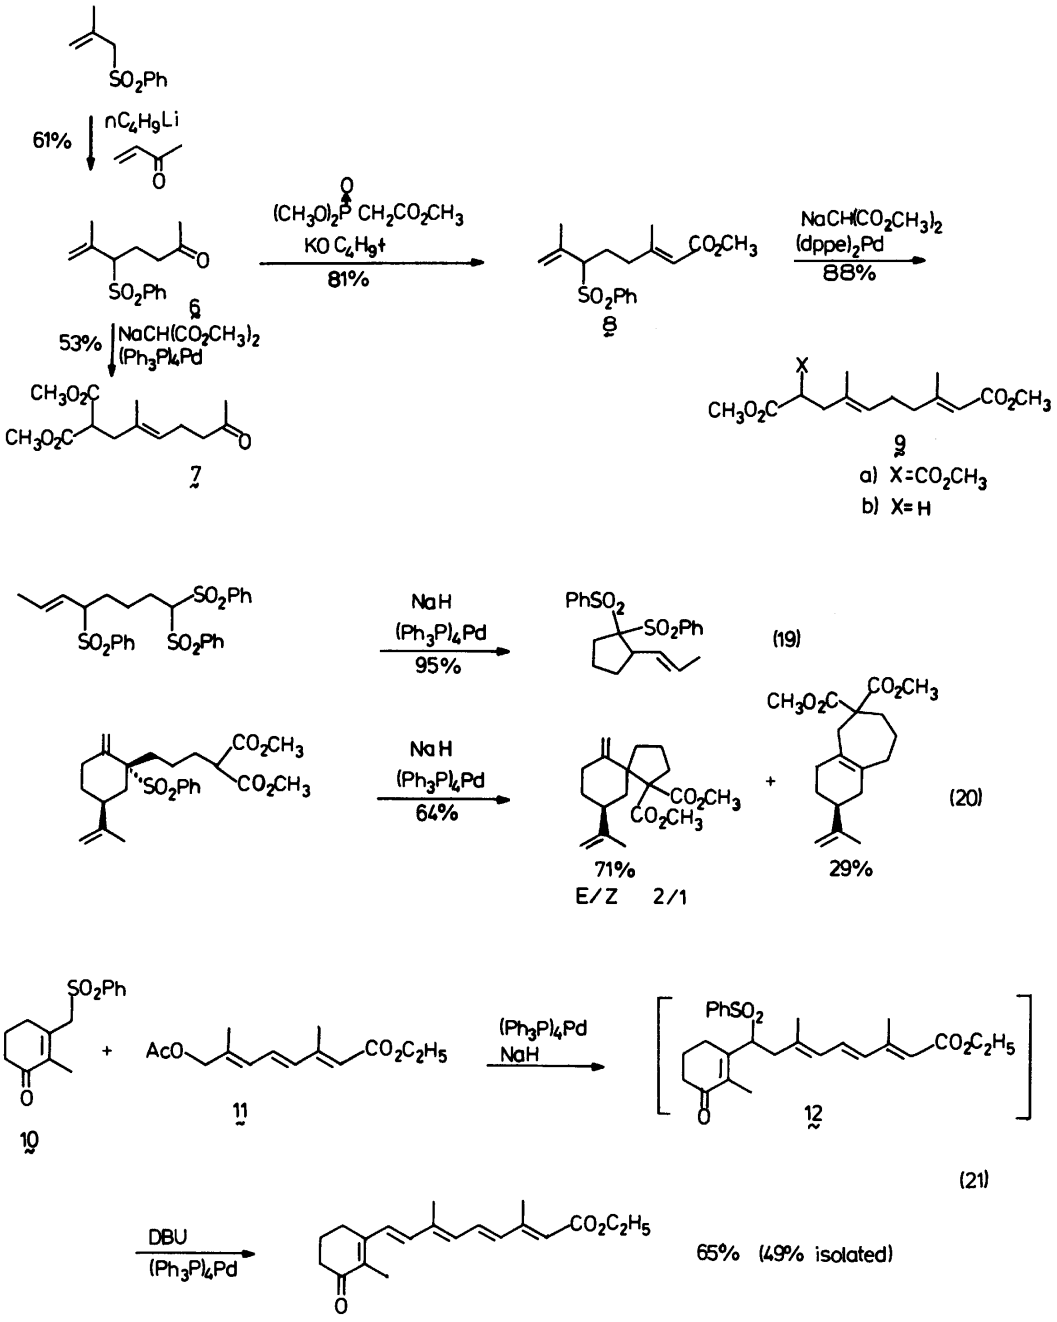
The elimination of the elements of arenesulfinic acid to form olefins relies upon the leaving group ability of sulfones. Although a phenylsulfonyl group has been estimated[21] to be a poorer leaving group than chloride by 10^9, it still functions viably in such a role. We became intrigued with the question of substituting the sulfone—a type of reaction which was



almost unprecedented. The earliest documented case involved formation of a cyclopropane[22] which evolved into a practical synthesis of methyl chrysanthemate according to Eq. 14.[23] Such a cyclopropanation proves to be rather limited and no other types of rings have been produced.

Transition Metal Promoted Substitutions. The poor leaving ability of an arylsulfonyl group has led to the exploitation of the trifluoromethylsulfonyl group which is 10^7 times better as a leaving group.[24] An alternative approach to overcome this lack of reactivity is to use a transition metal to activate the sulfone. The excellent ability of low valent palladium complexes to facilitate displacements of poor leaving groups at allylic positions led us to explore the reactions of allyl sulfones. Diastereoselective alkylation of allyl sulfone **4** leads predominately (88:12) to **5**.[25] Subjecting sulfone **5** to dimethyl sodiomalonate in the presence of a catalytic amount of a Pd(0) complex leads to regio- and diastereoselective substitution as depicted in Eq. 15. Since Pd(0) catalyzed alkylations involves initial substitution of the leaving group by palladium followed by displacement of the palladium by the nucleophile, the overall stereochemistry is net retention of configuration (Eq. 16). In principle, attachment can occur at either terminus of the allyl system independent of the original location of the sulfone. While formation of the new C–C bond at the less substituted position as depicted in Eq. 15 is most common, unhindered nucleophiles like malonate anion preferentially form the new C–C bond to the more substituted carbon when the competition is between a primary and a tertiary center or between a secondary and a tertiary center in an acyclic case (Eq. 17). This method has been employed to introduce a steroid side chain in a stereocontrolled manner (Eq. 18).[26]

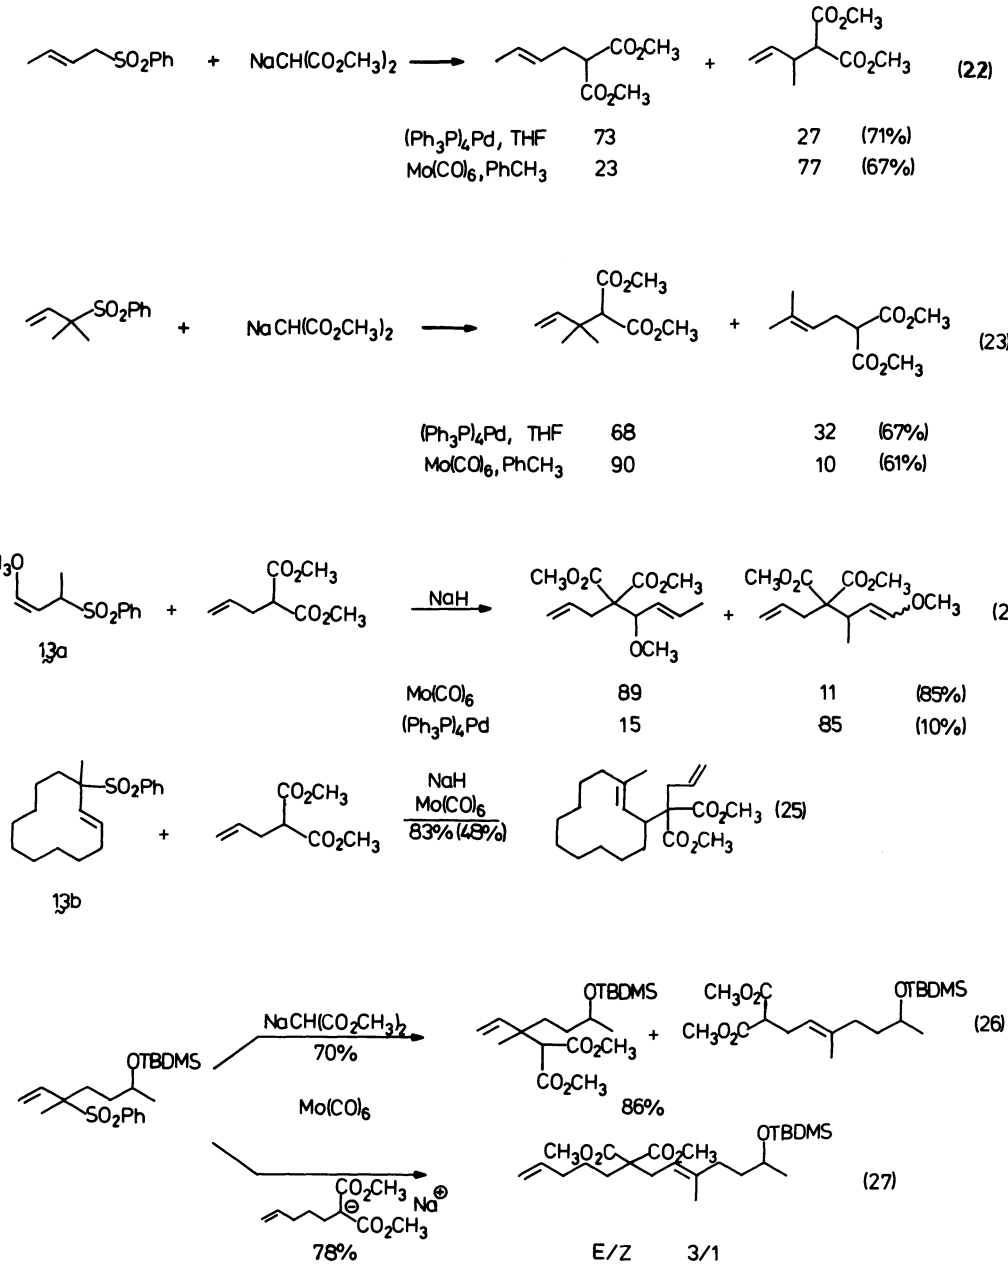
The chemoselectivity of this approach for C–C bond formation is highlighted by a short synthesis of the dimethyl ester of the sex pheromone of the Monarch butterfly (**9b**).[25] The keto sulfone **6** was a substrate for the palladium reaction, without the need to protect the carbonyl group, to give **7** with excellent regioselectivity. On the other hand, use of a typical carbonyl reagent, a phosphonate anion, led to the olefination product **8** without complications from the allyl sulfone. Addition of the sterically less demanding catalyst, $Pd(dppe)_2$, and dimethyl sodio-



malonate led in a regioselective alkylation to **9a** which has been previously decarbomethoxylated to the pheromone ester **9b**.

Whereas, all of the foregoing examples involve intermolecular alkylations, intramolecular alkylations also succeed as shown in Eqs. 19 and 20.[27] The choice of nucleophile may determine the regioselectivity. Thus, as Eq. 20 shows, the sterically undemanding malonate prefers to attack the sterically congested tertiary carbon although the selectivity is only moderate. In the absence of a nucleophile, eliminations to dienes occur. The ability of sulfone stabilized anions to serve as nucleophiles in palladium catalyzed alkylations of allylic acetates combined with the palladium catalyzed eliminations of allylic sulfones has led to a useful one pot alkylative elimination to polyenes according to Eq. 21.[25] In a model to vitamin A metabolites, the anion derived from allyl sulfone **10** is smoothly alkylated by allylic acetate **11** in the presence of a Pd(0) catalyst in DMSO at room temperature to give the intermediate **12**. DBU is added directly to the reaction mixture and the temperature raised to 80 °C to complete the sequence. Both steps, alkylation and elimination, require Pd(0) activation.

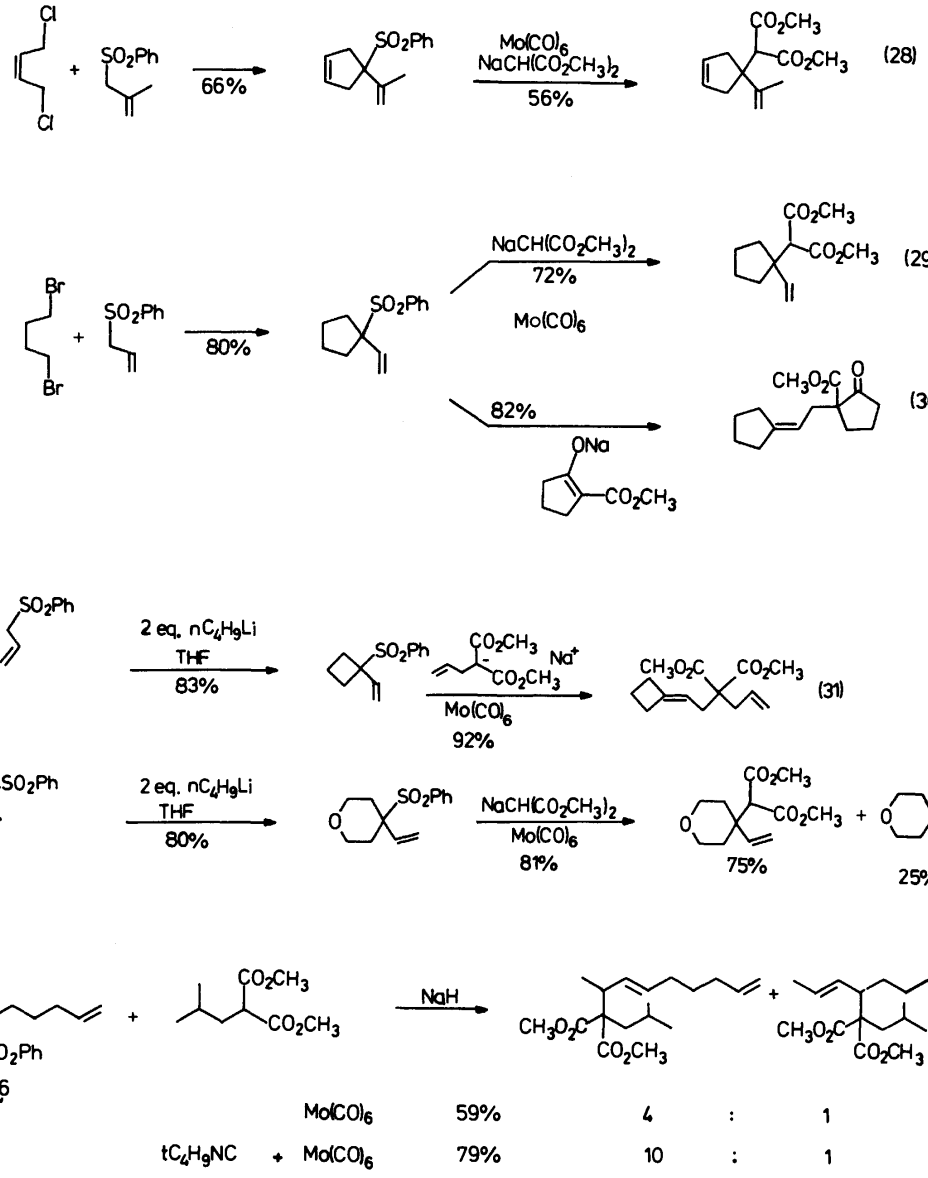
Molybdenum catalysts also activate allylic sulfones



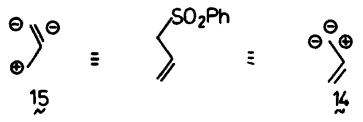
for alkylation.[27] Such catalysts usually complement the regiochemistry of the palladium catalyzed reactions as shown in Eq. 22. In the case of α,α-dimethylallyl phenyl sulfone, the propensity for alkylation at the tertiary position shown by the palladium catalyst is further enhanced by the molybdenum catalyst. In some cases, an allylic sulfone participates poorly in a Pd(0) catalyzed reaction but quite well in the Mo(0) version as in the case of **13a** and **13b** (Eqs. 24 and 25). In the case of Eq. 25, no reaction was observed with the Pd(0) catalyst; whereas, the Mo(0) catalyst gave an 83% yield at about 50% conversion. Normally, however, the Pd(0) catalyzed reaction is the more general.

Good diastereoselectivity may accompany these reactions as shown in Eq. 26 where only one diastereomeric product was observed although we have no basis for making an assignment of stereochemistry as yet. Increasing the steric bulk of the nucleophile by simply switching from the anion of dimethyl malonate (Eq. 26) to that derived from an alkylated malonate (Eq. 27) changes the regioselectivity from one dominated by the electronic distribution in the intermediate π-allylmolybdenum system to one dominated by the steric demands of the attacking nucleophile.

Combining alkylation of sulfone stabilized anions with molybdenum catalyzed reactions leads to a synthesis of 1,1-disubstituted cycloalkanes (Eqs. 28 and 29). As in all cases, use of a sterically more



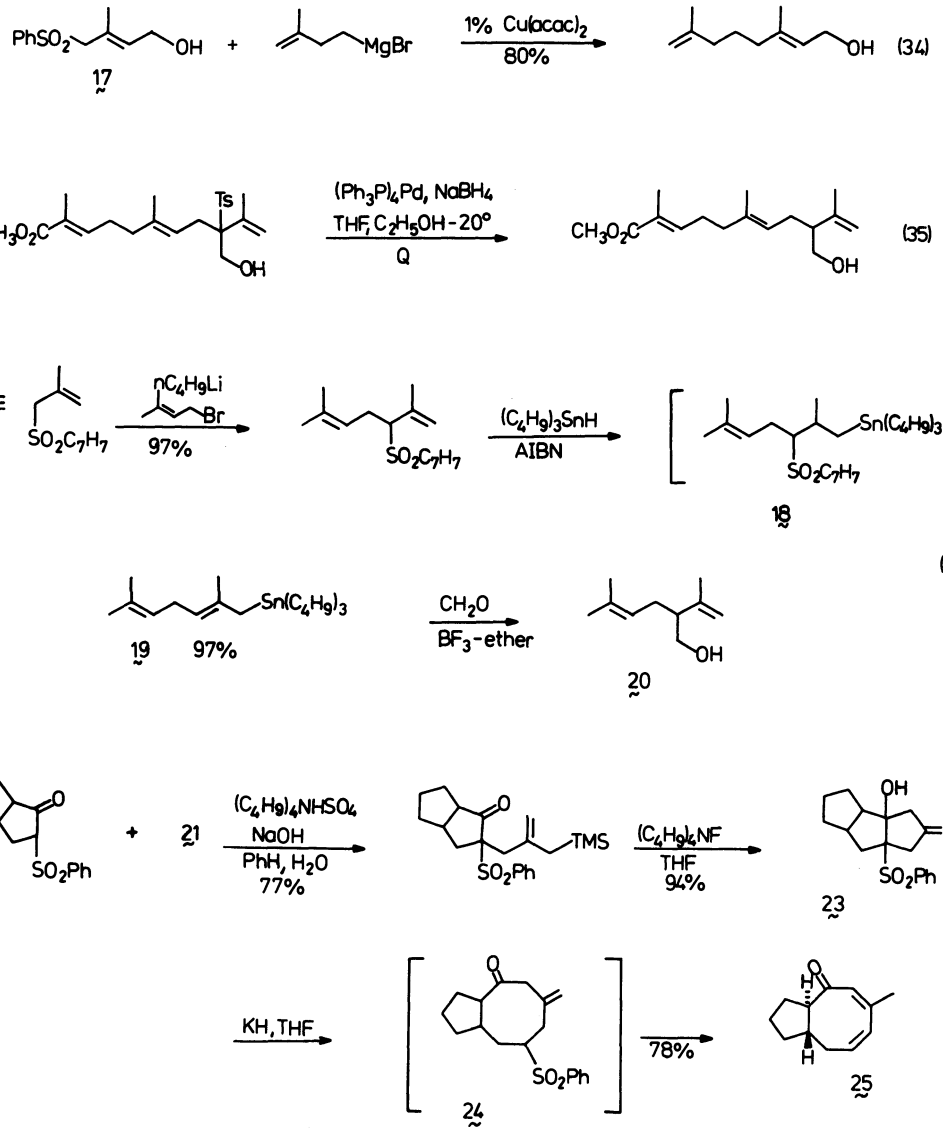
crowded nucleophile leads to attack at the primary carbon (Eq. 30). Both four membered rings (Eq. 31) and heterocycles (Eq. 32) can be made. Unlike other examples, dimethyl sodiomalonate gives poor regioselectivity in the four-membered ring case. This two step sequence illustrates the equivalency of an allyl sulfone to a 1,1,1-(i.e. **14**) or 1,1,3-(i.e. **15**) tripole.



The lability and volatility of the CO ligands limits the lifetime of the molybdenum hexacarbonyl catalysts. In a preliminary examination, we found that addition of a catalytic amount of *t*-butyl isocyanide indeed enhances the catalyst lifetime.[27] For example, the yield in the alkylation of allyl sulfone **16** increased substantially as did the degree of regioselectivity upon adding 3 eq. of *t*-butyl isocyanide per molybdenum.

Nickel catalysts also promote substitutions of allyl sulfones[28] but with lower regioselectivity than observed with either palladium or molybdenum catalysts. For example, the alkylation of α,α-dimethylallyl sulfone with dimethyl sodiomalonate gave a 91% yield of the two alkylation products depicted in Eq. 23 in almost a 2:3 ratio (with the major product derived from attack at the primary carbon) using $(dppe)_2Ni$.[27]

In all of the cases discussed, stabilized anions, were employed as nucleophiles. Substitutions by non-stabilized carbon nucleophiles occur smoothly using copper catalyzed additions of Grignard reagents. For example, a chemo- and regioselective displacement of

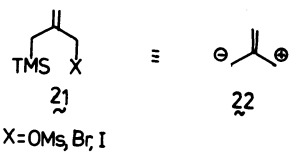


the sulfone moiety of the hydroxy sulfone **17** occurs as shown in Eq. 34.[29]

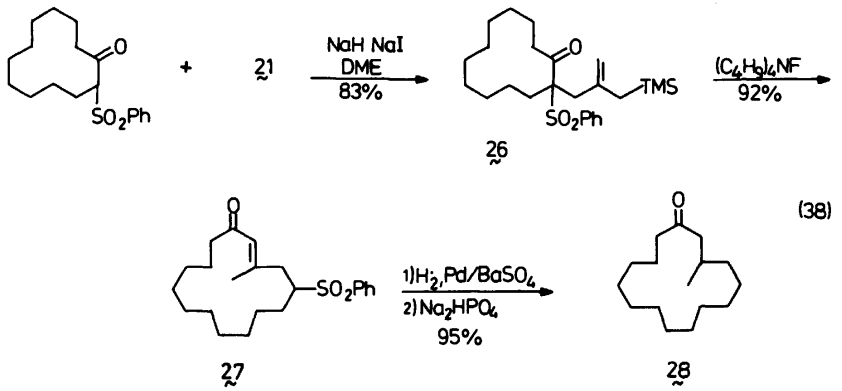
Reductive desulfonylations can also be achieved by using a hydride equivalent in metal catalyzed reactions. As shown in Eq. 35,[30] a synthesis of dehydrohelepuberinic acid ester took advantage of the sulfone stabilized anions to construct the carbon skeleton and then reductively cleaved the sulfone using Pd(0) catalysis in which the hydroxyl group dictated the regioselectivity.

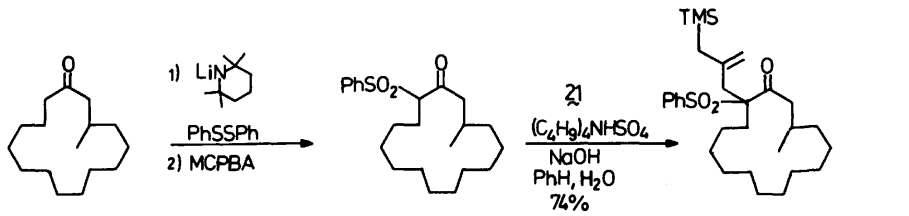
Radical Substitutions. An alternative way to overcome the sluggishness of sulfones to substitution takes advantage of the radicals bearing a β-sulfone. Thus, the allyl sulfone **18** undergoes radical substitution, presumably by an addition-elimination sequence, by tributyltin radical as depicted in Eq. 36.[31] The resulting allylstannane undergoes carbonyl addition to give the monoterpene lavandulol (**20**). In this case, the umpolung associated with converting an allyl sulfone **18** to an allylstannane **19** equates the starting methallyl phenyl sulfone to a 1,1-dianion.

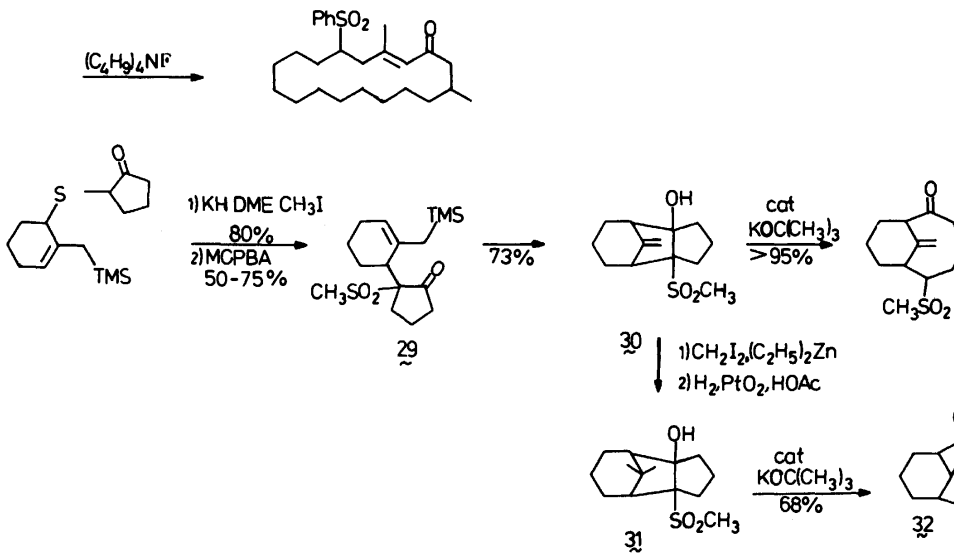
A Three Carbon Intercalation. The bifunctional conjunctive reagent **21** serves as a synthon for a 1,3-dipole **22**.[32] As depicted in Eq. 37, this zwitterionic



behavior allows straightforward methylenecyclopentane annulation.[33] By employing a β-keto sulfone as the starting meterial, the annulation creates a β-hydroxy sulfone **23**. Due to the anion stabilizing ability of the sulfone, converting the hydroxyl group into a "naked" alkoxide causes the common bond to cleave to create a ring enlarged β-keto sulfone **24**. Under the basic conditions for ring cleavage, the exocyclic double bond migrates into conjugation with the carbonyl group and, by so doing, facilitates the







base catalyzed elimination of the elements of benzenesulfinic acid to produce the eight membered ring dienone **25**.

The facility of fragmentation of the β-hydroxy sulfone **23** is related to ring size. If the starting β-keto sulfone is either acyclic or a cyclic system of more than seven carbons, cyclization of the allylsilane to create the methylenecyclopentane is accompanied by fragmentation as depicted for the 12-membered case **26** (Eq. 38). Thus, fluoride promoted cyclization leads directly to the enone **27** whereby fragmentation of the methylenecyclopentane and double bond migration occur concomitant with initial cyclization. Catalytic hydrogenation and desulfonylation complete a synthesis of muscone in an outstanding 62% overall yield from cyclododecanone, the precursor of the β-keto sulfone. This sequence lends itself to an iterative process. As shown in Eq. 39, muscone has been grown to an 18-membered ring.[34]

This method can also be used to create bridged bicyclic systems. In a model directed toward the bridged bicyclic portion of taxanes, the keto sulfone **29** was prepared by a sigmatropic rearrangement followed by oxidation (Eq. 40).[35] Fluoride initiated cyclization of the allylsilane led to substantial protodesilylation. On the other hand, ethylaluminum dichloride induces cyclization to the bridged bicyclic hydroxy sulfone **30**. Fragmentation occurred most smoothly with a catalytic amount of potassium *t*-butoxide in DMSO. More pertinent, the gem-

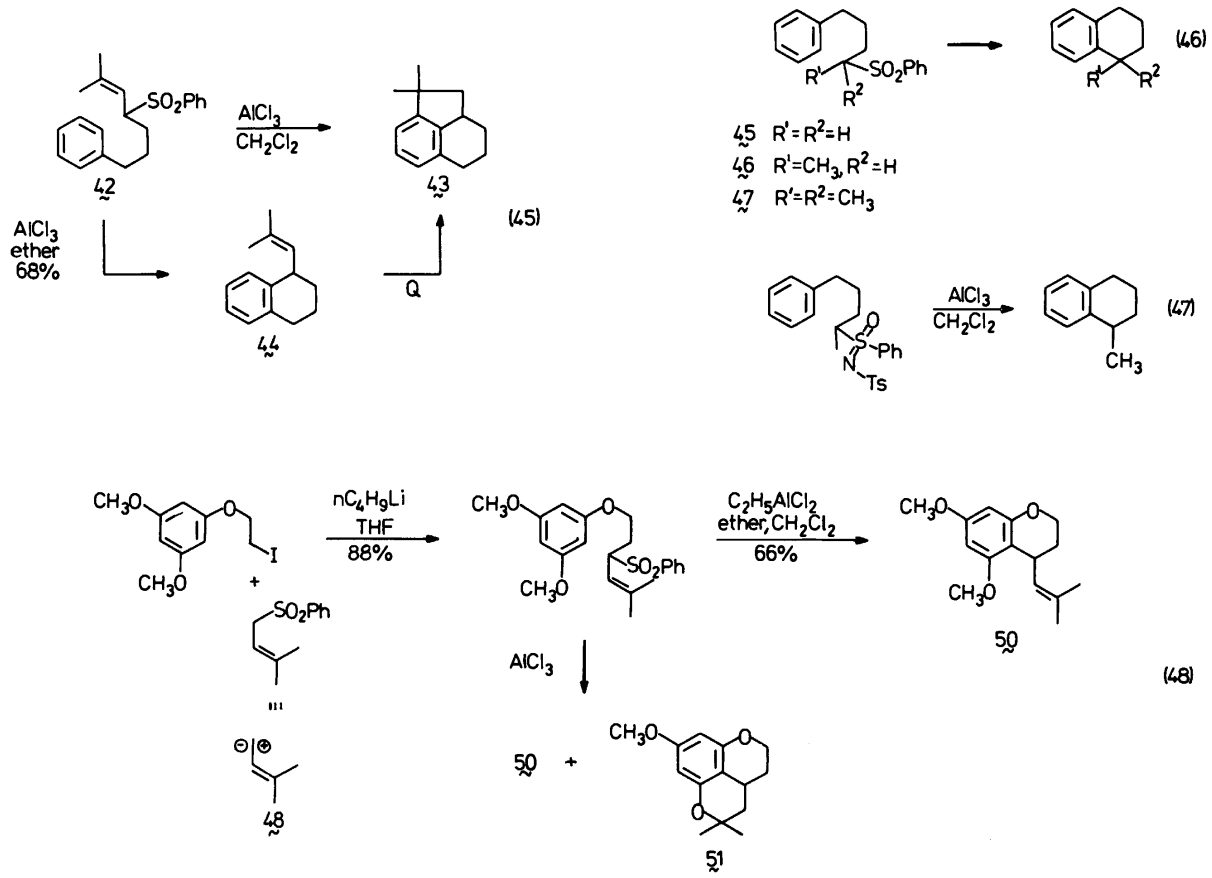
(44)

dimethyl compound **31**, available by hydrogenolysis of the cyclopropane derived from methylenation of the olefin of **30**, also fragments to the desired bicyclo-[5.3.1]undecane skeleton.[36]

In this version, the silyl chloride **33** serves directly as the 1,3-dipole synthon **34**. Lewis acids reveal both types of reactivity by, first, activating the allyl chloride **33** in its reaction with the enediol bis(silyl ether) and, second, by activating the carbonyl group of **35** towards addition by the allylsilane. Diol cleavage then completes the sequence.

The use of ethylaluminum chloride to cyclize the allylsilanes as in the cases of **29** and **35** proved limited. Applying the reaction to substrate **26** led to a totally different process as shown in Eq. 42.[37] In the presence of the Lewis acid, the initial cyclization product **37** apparently suffers a pinacol-type rearrangement to produce the ring contracted spiro ketone **38**. Isomerization of the exocyclic double bond into conjugation completes the sequence of this cyclocontraction-spiroannulation.

Excellent diastereoselectivity accompanies this novel approach to form spirocycles. Alkylation of the eight-membered ring keto sulfone **39** gives a single diastereomer **40** (Eq. 43). Ethylaluminum dichloride leads to cyclization and ring contraction to give the spirocycle **41** in which the migrating carbon completely retains its stereochemistry. Thus, depending upon the nature of the catalyst, two quite disparate reactions reflecting the multifaceted properties of sulfones can occur. As summarized in Eq. 44, a nucleophilic trigger promotes intercalation and an electrophilic trigger diverts the intermediate via a pinacol type rearrangement to a 2,2-disubstituted 4-



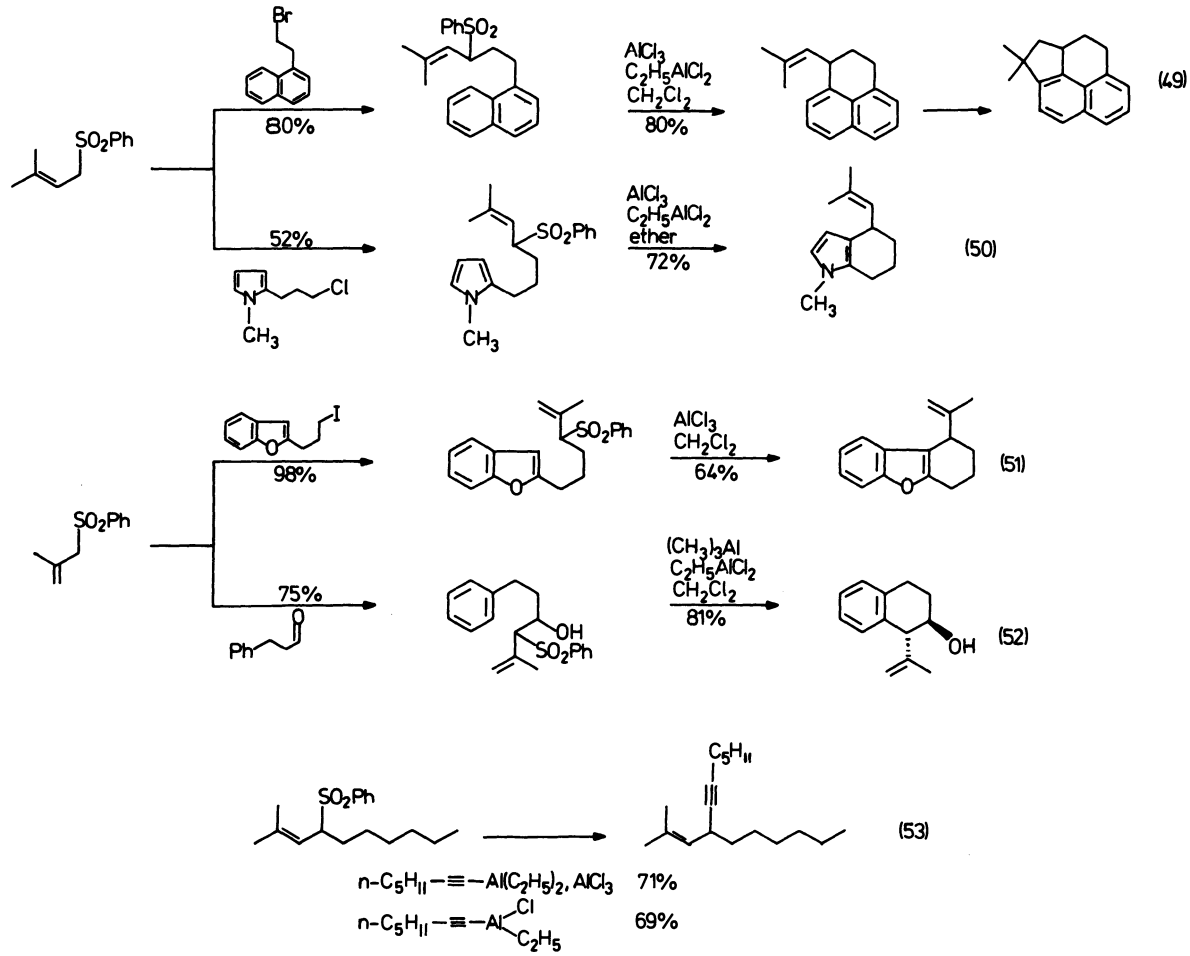
methylenecyclopentanone. The sensitivity of the β-hydroxy sulfone toward Lewis acid promoted rearrangement is quite remarkable considering the absence of any prior indication that Lewis acids induce ionization of organosulfones.[38]

Lewis Acid Induced Cyclizations. The ability to effect a pinacol-type rearrangement in which a phenylsulfonyl group ionizes in the presence of as weak a Lewis acid as ethylaluminum dichoride led to an investigation of the ionizing ability of simple organosulfones. Strikingly, the allyl sulfone **42** cyclized to the tricycle **43** even at −78°C in the presence of aluminum chloride in methylene dichloride.[39] Attenuating the reactivity of the aluminum chloride by using ether as a solvent requires 35°C for reaction, but the product is cleanly that of the simple cyclization **44**. Subsequent treatment with either aluminum chloride in methylene dichloride or trifluoroacetic acid quantitatively cyclizes the latter to the tricycle **43**.

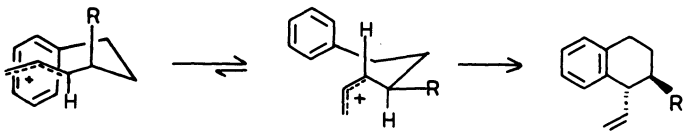
To determine how good a cation is necessary for ionization, the substrates **45**—**47** were treated with aluminum chloride (Eq. 46). Neither **45** nor **46** satisfactorily cyclizes; however, the tertiary sulfone **47** smoothly produces 1,1-dimethyltetralin in 70—80% yield with aluminum chloride in methylene dichloride. Increasing the Lewis basicity of the sulfone by using the sulfoximine extends the cyclization to secondary carbon centers (Eq. 47).[40] Competition studies indicate the sulfoximines are about twice as reactive as the corresponding sulfones.

The chameleon-type behavior of sulfones is readily apparent by the source of the cyclization substrates as revealed by a model study related to robustadials[41] and euglobals[42] (Eq. 48). The first step takes advantage of the nucleophilic properties of sulfone stabilized anions and the second step utilizes the propensity of allyl sulfones to ionize to the corresponding cations. In this way, prenyl sulfone serves as a synthon for the 1,1-dipole **48**. The choice of Lewis acid and solvent may be important. For example, aluminum chloride effects a second cyclization to **51** in competition with formation of the simple cyclization product **50**. By using ethylaluminum dichloride and further attenuating the Lewis acidity by using ether as a cosolvent, the second cyclization can be suppressed. Eqs. 49 and 50 reveal some of the generality of this cyclization strategy for both carbo- and heterocyclic cases. Equation 49 illustrates the further cyclization of the initial tricyclic product. Equation 50 reveals that the acid labile pyrrole ring survives when a HCl scavenger, ethylaluminum dichloride, is also employed although the benzofuran system of Eq. 51 does not require it.

Equation 52 shows the utility of the adducts from the metalated sulfone and an aldehyde participating



in the cyclization.[43] The alcohol is first reacted with trimethylaluminum before subjecting it to the stronger Lewis acid. Cyclization proceeds in excellent chemical yield and diastereoselectivity with only the (E)-product produced. The excellent diastereoselectivity is not limited to the hydroxyl substituent since the substrate bearing a methyl group in lieu of the hydroxyl group shows similar stereocontrol.[44] Viewing the cation generated upon ionization of the sulfone in a chair-type conformation suggests that placing this substituent in a pseudoaxial position as in **52** is less favorable than placing it in a pseudoequatorial one as in **53**.



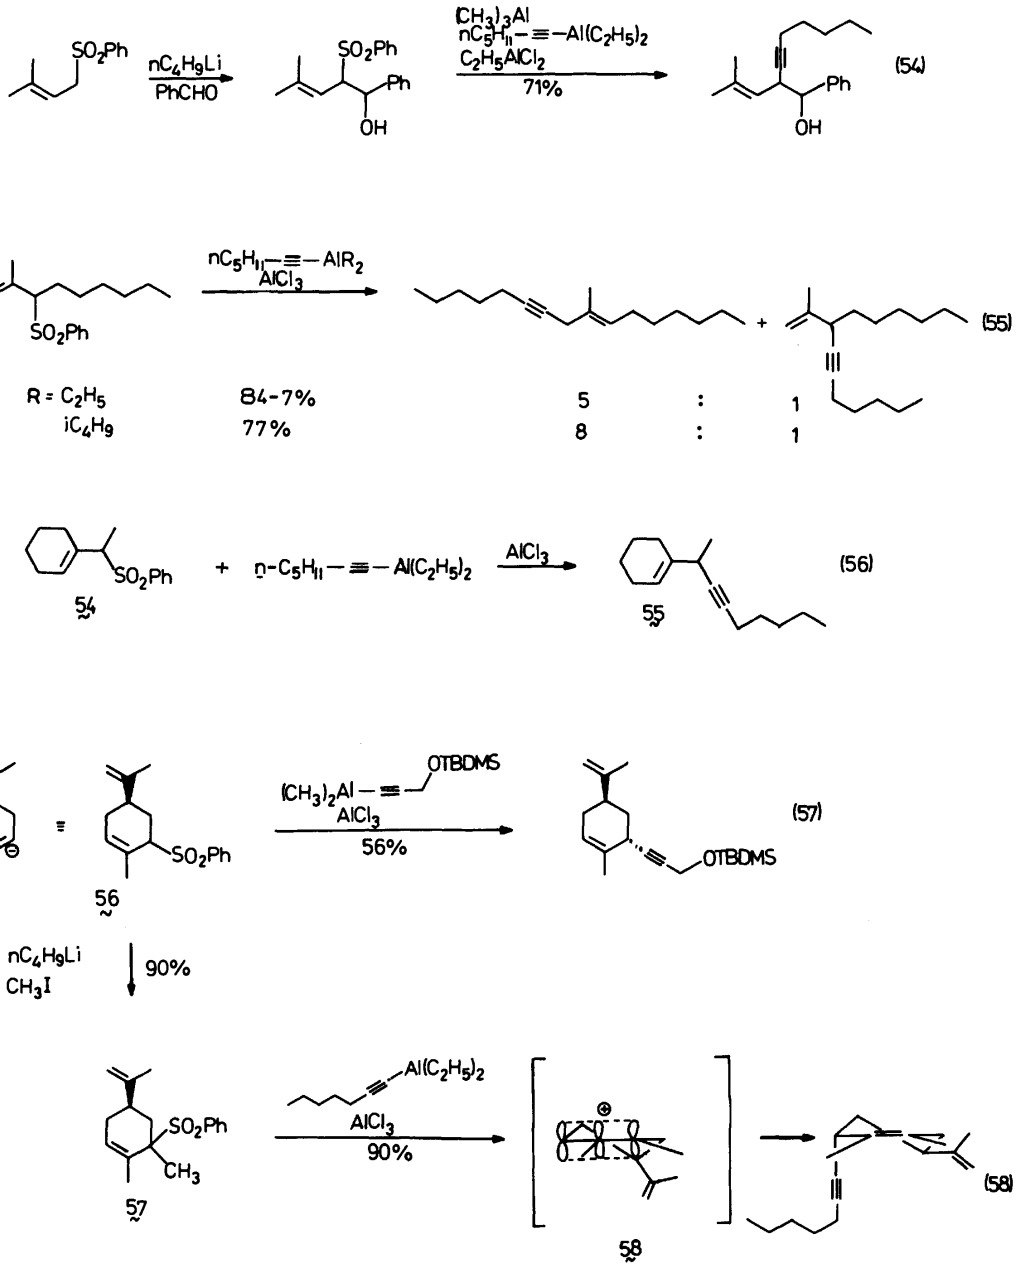
52 53

Lewis Acid Induced Condensations. The success of cyclization reactions led to a search of intermolecular condensations which require nucleophiles compatible with Lewis acids. Organoalanes have proven themselves as nucleophiles in the presence of Lewis acids and, in some cases, as both Lewis acid and nucleophile.[45]

Alkynylalanes, prepared by treating the lithiated alkyne with an appropriate chloroalane, smoothly condense with allyl sulfones. As shown in Eq. 53, use of a diethylalkynylalane requires aluminum chloride as a catalyst; whereas, an alkynylethylchloroalane serves as both the Lewis acid and nucleophile.[43] Unfortunately, the latter did not prove to be general and reactions frequently proceeded with only low conversions.

The high reactivity of the allyl sulfone is highlighted by the compatibility of the benzyl alcohol in the case of Eq. 54. As previously, smooth reaction requires initial treatment of the hydroxy sulfone with trimethylaluminum.

Even though the reaction proceeds through allyl cations, good regioselectivity normally accompanies this reaction. In the case of an unsymmetrical allyl system, competing a primary or secondary terminus with a tertiary one, very high selectivity for formation of the new C–C bond at the less substituted carbon occurs (cf. Eq. 53). In a primary versus secondary case, the selectivity for attack at the less substituted carbon

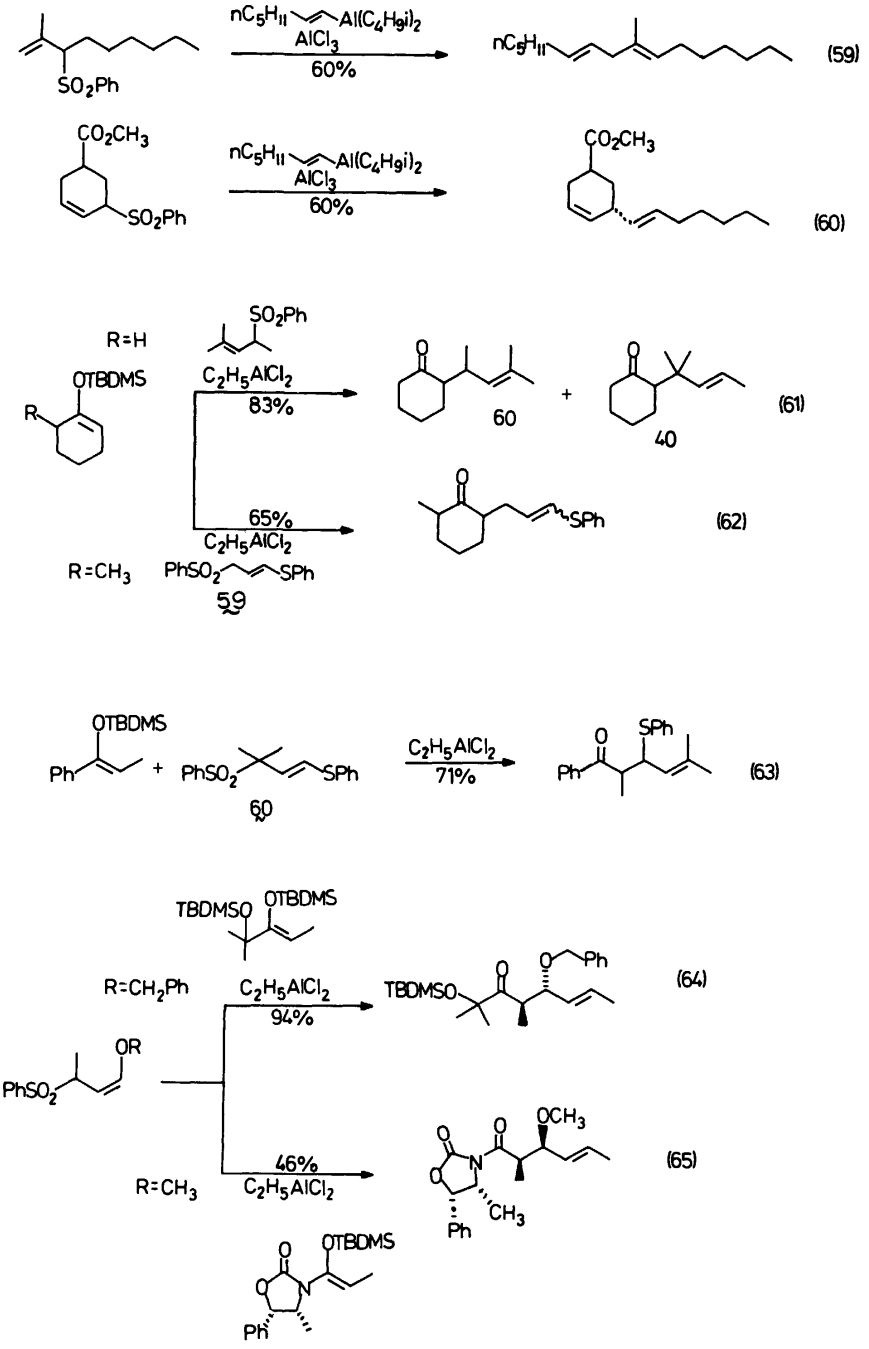


is somewhat lower (Eq. 55). By increasing the steric demands of the organoalane such as replacing ethyl by isobutyl, some improvement for attack at the primary terminus occurs. Allyl sulfone **54** competes two secondary carbons. The preference for the double bond to be endocyclic and the lower steric hindrance associated with attack at the exocyclic position leads to **55** as the dominant product (6:1, Eq. 56).

Good diastereoselectivity is obtained with cyclohexenyl phenyl sulfones (Eqs. 57 and 58). The preference for axial attack presumably derives from stereoelectronic factors.[46] Pseudoaxial attack on the intermediate allyl cation **58** allows the ring to directly distort toward the favorable half-chair conformation while maintaining good orbital overlap. Attack by the organoalane leading to the equatorial product requires distortion of the ring towards a boat—a less favorable process. The regioselectivity as shown in Eq. 58 demonstrates the preference for attack at the less hindered terminus of the allyl system regardless of the initial position of the sulfone. Since **57** arises by the methylation of the lithiated sulfone **56**, the latter is a synthetic equivalent to a 1,3-dipole **56a**.

Alkenylalanes, prepared by hydroalumination of acetylenes, behave in exactly analogous fashion as shown by Eqs. 59 and 60. Note that the intrinsically higher steric demands of an alkenylalane compared to an alkynylalane leads to higher regioselectivity (cf. Eqs. 55 versus 59).

The success of enol silanes as the nucleophilic

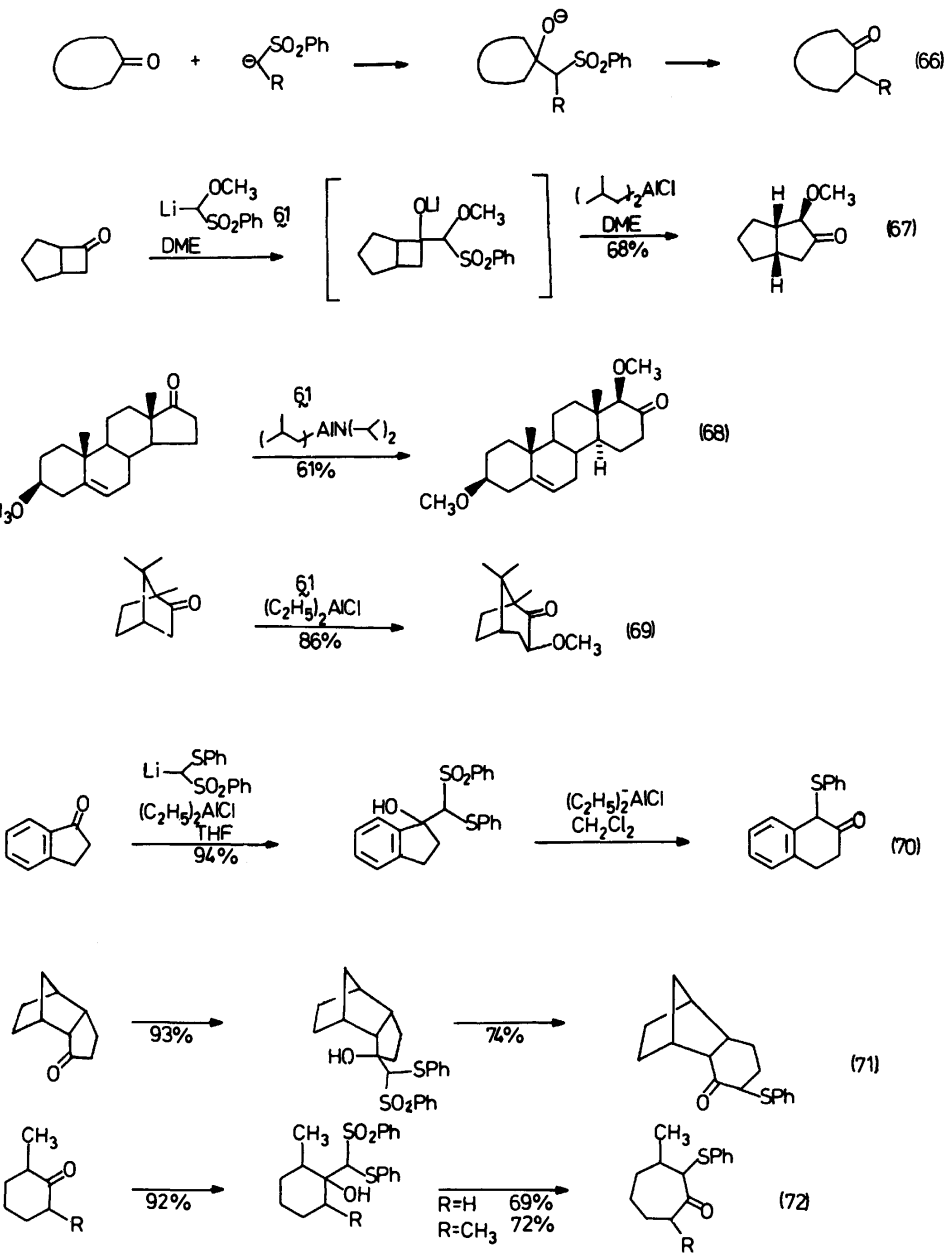


partners in Friedel–Crafts types of alkylations[47] led to their exploration as nucleophiles towards allyl sulfones. The most striking difference from the alkynyl- and alkenylalanes is the lower regioselectivity (cf. Eq. 61) unless the allyl sulfone has a strongly directing substituent (Eq. 62).[44] The regiochemistry in the latter case appears dictated by steric effects since the dimethyl analog **60** of the above sulfone **59** now proceeds by formation of the new C–C bond at the carbon bearing sulfur.

Modest diastereoselectivity accompanies this reaction. Whereas, the enol silyl ether of a ketone shows anti selectivity (Eq. 64, anti/syn 92/8); the enol silyl ether of an imide shows syn selectivity (Eq. 65, syn/anti 80/20).

The range of nucleophiles compatible with the conditions required for ionization of a sulfone remains yet to be defined. The success of organoalanes and enol silyl ethers indicated that we have reason to be optimistic that a rather broad variety will be feasible.

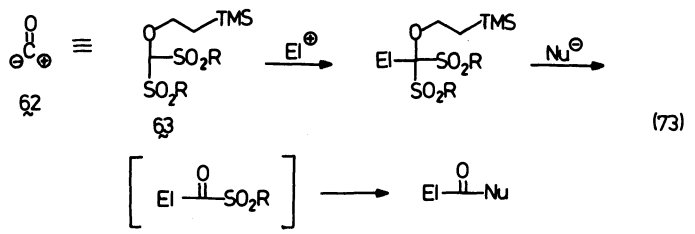
Lewis Acid Induced Ring Expansion. The duality of function of organosulfones corresponds to the type of reactivity necessary for ring expansions according to Eq. 66. The excellent acidifying properties of the sulfone should make this process feasible for



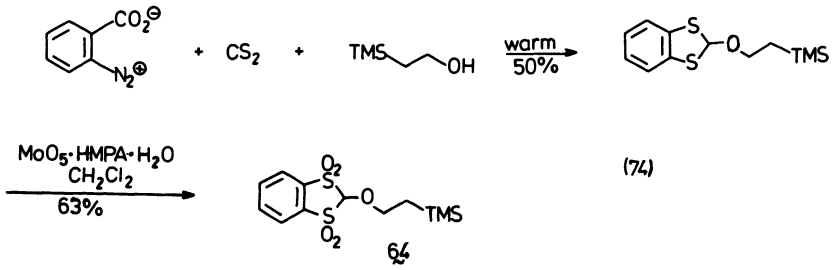
substrates in which R is a very poor anion stabilizing group or even anion destabilizing. Since few methods exist to expand rings directly to α-heteroatom substituted cycloalkanones, use of R=SPh and OCH_3 were first considered.[48]

As Eqs. 67—69 show, four- and five-membered ring ketones smoothly add methoxy(phenylsulfonyl)-methyllithium (**61**) in DME. Direct addition of a dialkylaluminum chloride to the lithium alkoxide effects ring enlargement in a one pot operation. While dialkylaluminum chlorides are normally employed (Eqs. 67 and 69), the steroid example required a milder Lewis acid which turned out to be diisobutylaluminum diisopropylamide (Eq. 68). As a carbonium ion process, the carbon α to the original carbonyl group that can best stabilize positive charge normally preferentially migrates (Eqs. 67 and 68). The case of camphor is an exception. Since migration of the bridgehead tertiary carbon would involve a boat-type transition state, the normally less favorable methylene group migrates since a favorable chair conformation can now be accomodated.[49]

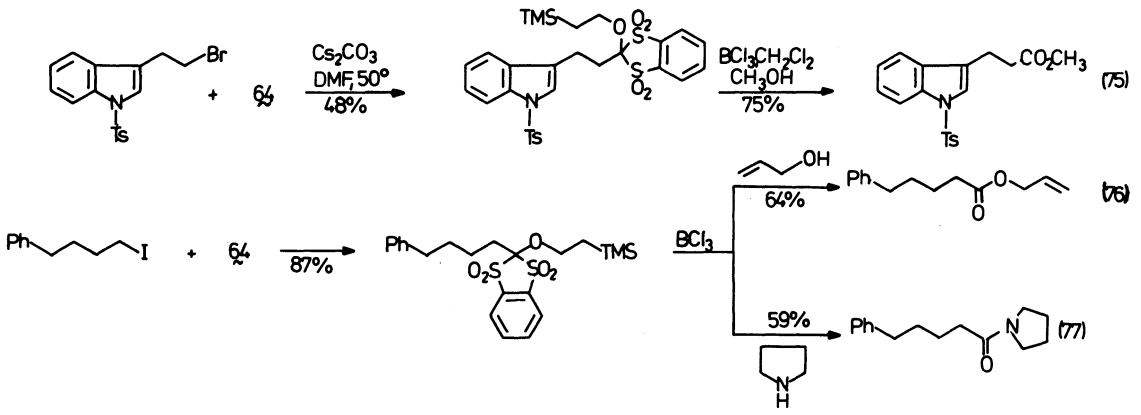
Extension of the above ring expansion to the phenylthio series proved problematic due to the fact that the equilibrium for carbonyl addition of phenylthiophenylsulfonylmethyllithium in THF was unfavorable. However, addition of diethylaluminum chloride to the THF solution resolves this problem and gives the simple carbonyl adducts without rearrangement (Eqs. 70—72). Subjecting the hydroxy sulfones to the same aluminum reagent but in methylene dichloride effects smooth rearrangement.



(73)



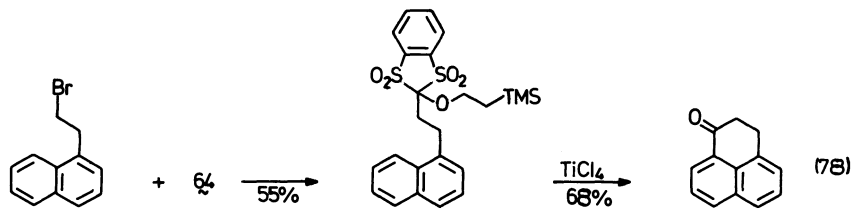
(74)



(75)

(76)

(77)

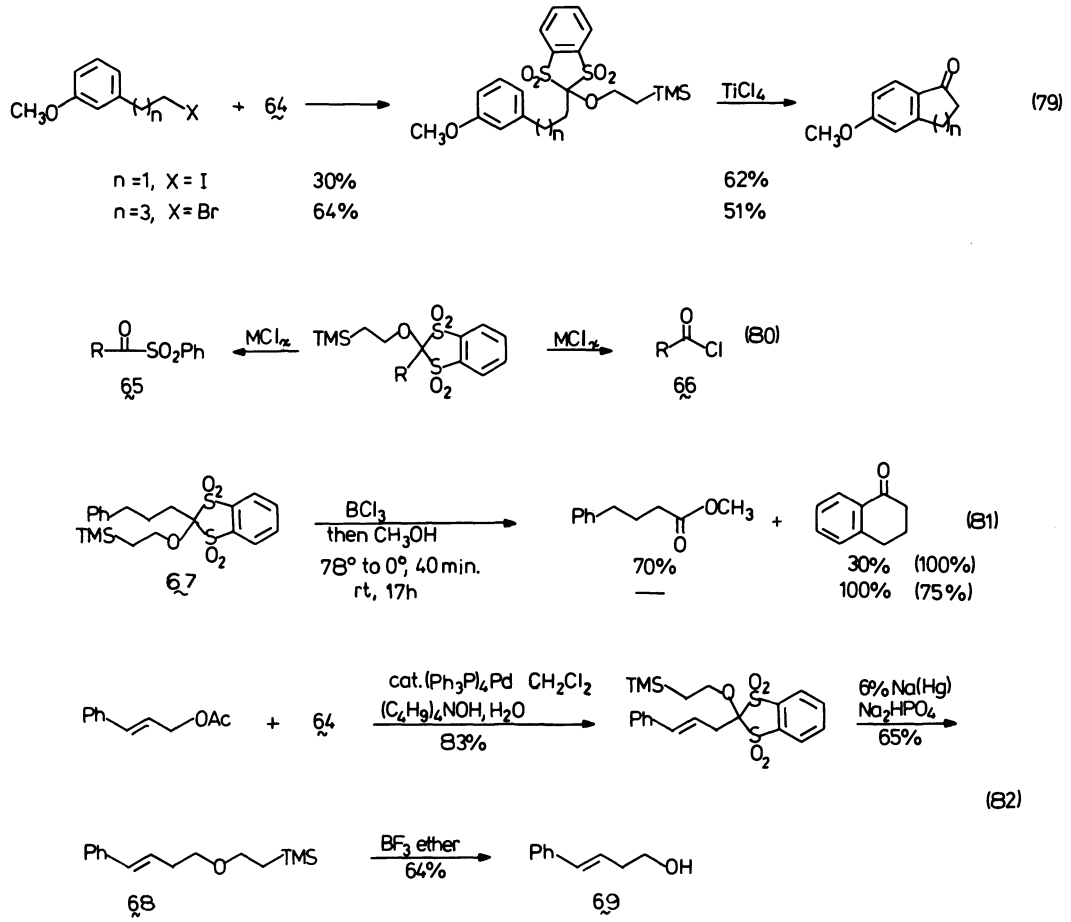


(78)

The migrating aptitude follows precisely the same pattern found for the methoxy reagent. The carbon that best stabilizes a positive charge normally migrates (Eqs. 70 and 72). On the other hand, conformational factors can overcome this electronic bias (Eq. 71). The ring expansion of the phenylthio reagent appears more general than that of the methoxy reagent **61**. Notably, ring expansion of six to seven (Eq. 72) occurs smoothly with the phenylthio reagent in contrast to the attempted reactions with **61**.

A Carbonyl 1,1-Dipole. The general importance of carbonyl compounds led to the extension of the above concepts to develop a controlled synthon for a carbonyl 1,1-dipole **62**. As revealed in Eq. 73, an alkoxy-bis(sulfone) **63** may be able to serve such a role. Such a reagent, **64**, was prepared as outlined in Eq. 74.[50]

The lability of the anion derived from **64** led to its formation in the presence of the appropriate electrophile. The examples of Eqs. 75—79 demonstrate that cesium carbonate in warm DMF best effects the alkylation. Exposure of the alkylation products to a Lewis acid such as boron trichloride followed by adding heteroatom nucleophiles such as an alcohol (Eqs. 75 and 76) or an amine (Eq. 77) completes the sequence. In these examples, a carbon group served as the electrophile and a heteroatom group served as the nucleophile. Thus, an ester and an amide synthesis is



available.

By using carbon groups as both nucleophile and electrophile, ketones are available. Equations 78 and 79 show how a carbonyl group can be stitched into place with appropriate arylalkyl halides. The demonstrated examples illustrate formation of five-, six-, and seven-membered rings.

The nature of the reactive electrophile in all of the above cases remains undefined. While it is tempting to speculate that acyl sulfones **65** may be involved, an acid chloride **66** may also be postulated (Eq. 80). That a reactive intermediate is indeed produced is strongly supported by treating **67** with boron trichloride at −78 to 0 °C followed by addition of methanol (Eq. 81) whereby the corresponding methyl ester and tetralone are both produced. Increasing the reaction time and temperature before adding methanol produces only tetralone.

The reductive desulfonylation of sulfones opens yet another avenue for application of this alkoxy-bis(sulfone) as shown in Eq. 82. The 2-(trimethylsilyl) ethyl group of **68** can be cleaved to produce the free saturated alcohol **69**. The overall transformation of Eq. 82 constitutes a homologation of an allyl alcohol to a homoallyl alcohol and corresponds to employment of the anion derived from **64** as a hydroxymethyl anion equivalent.

Conclusion

While it is always tempting to believe that a well explored path offers little opportunity for innovation, the tremendous subtleties that control reactivity undermine any such notion. Although the chemistry of sulfones extends back for over one hundred years, their utility as synthetic building blocks based upon their facilitation of carbanion formation strongly emerged in the 1960's. In spite of this extensive work, their high sensitivity to ionization to carbocations in the presence of Lewis acids, especially those derived from aluminum, had gone unnoticed. This reactivity of an inverse electronic sense opens new vistas. Their ability to function as nucleophiles in a basic environment and as electrophiles in a Lewis acidic environment aptly allows them to be called "chemical chameleons" from which many new applications and new synthetic reagents remain to be discovered.

We wish to thank the National Science Foundation and the National Institutes of Health for their generous support of our programs.

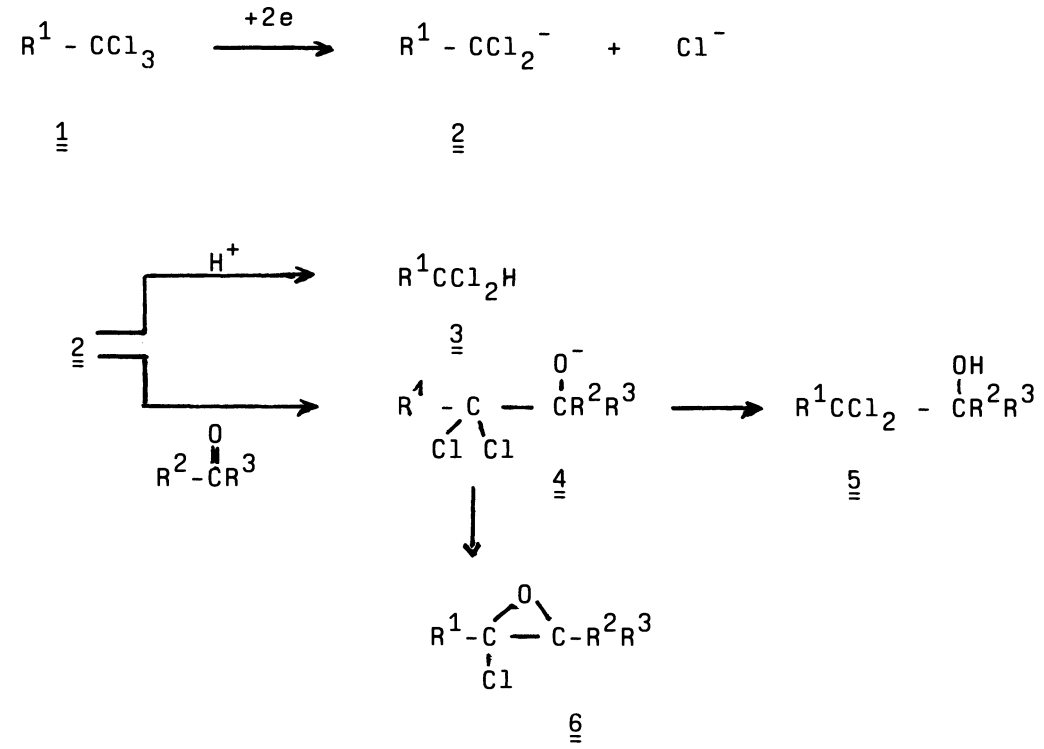
Invited Paper

Cathodic Addition of Benzylidyne Trichloride to Ketones and Aldehydes[1)]

Michael STEINIGER and Hans J. SCHÄFER*
Organisch-Chemisches Institut der Universität, Correns-Str 40, D-4400 Münster, F.R.G.
(Received August 3, 1987)

Ketones are converted to homologated enones **7a—g** in good yields by cathodic addition of benzylidyne trichloride (**1d**). As intermediates α-chlorooxiranes **6** are assumed, which rearrange via α-keto carbenium ions **9** to enones. The intermediacy of **9** is supported by the addition of **1d** to norcamphor, where the products indicate equilibrating norbornyl cations as intermediates. α,β-Unsaturated ketones lead depending on steric shielding of the double bond to the cyclopropane **23** as 1,4-adduct or the enone **26** as 1,2-adduct. With aldehydes and **1d**, α-chloro or α-hydroxy ketones, the conversion products of 2-chlorooxiranes, are obtained.

The electrochemical reduction of organic *gem*-trihalides **1** (Eq. 1) proceeds in two consecutive one-electron transfer steps and results in cleavage of the C–Halo bond to carbanions **2**,[2)] which can react with electrophiles. As electrophiles, protons,[3)] Michael acceptors,[4)] and carbonyl compounds[5)] have been used.



(1)

	R^1
a	Cl
b	CH_3
c	CO_2Et
d	C_6H_5

The electrochemical reduction of tetrachloromethane (**1a**) in the presence of carbonyl compounds produces trichloromethylcarbinols **5**[5a,b] and trichloroethane (**1b**) also forms analogous adducts in 19 to 34% yield.[6] The cathodic addition of ethyl trichloroacetate (**1c**) to cyclopentanone leads to a ring expansion to 2-chloro-2-(ethoxycarbonyl)cyclohexanone,[5a,6] this rearrangement points to 2-chlorooxirane **6** as intermediate. When **1c** is reduced in the presence of 2-methylpentanal 69% **6** (R^1=CO_2Et, R^2=H, R^3=$CH(CH_3)$-C_3H_7) can be isolated.[7] These results indicate, that the further reaction of **4** depends on R^1. For R^1=Cl, CH_3, **4** is not appreciably further converted. For R^1=CO_2Et an intramolecular nucleophilic substitution seems to be facilitated by the π-bond of the carbonyl group,[8] so that cyclization to **6** becomes the main reaction. To examine this assumption benzylidyne trichloride (**1d**) was reduced in the presence of carbonyl compounds. The addition of the benzyl anion **2d** should lead to **4d**, whose cyclization to **6d** should be favoured by the phenyl group.[8]

Results and Discussion

Cathodic Addition of Benzylidyne Trichloride (1d) to Ketones.[9] The reduction potential of **1d** was polarographically determined to be −0.8 V vs. Marple (−1.5 V vs. SCE). This is 0.5 V more cathodic than that of **1c**, which indicates that **2d** is more reactive than **2c** and therefore should add also to less reactive ketones. 5 to 10 mmol **1d** were electrolyzed at −0.8 V vs. Marple in the presence of 2 equiv of ketone until total conversion. After usual work up, the α,β-unsaturated ketones **7a—g** (Eq. 2) are isolated in good yields by LC (Table 1). Seen from the point of synthetic methodology, this reaction is a nucleophilic acylation with subsequent dehydration. Ketones are converted in this way to homologated enones.[10] The formation of **3d** at the expense of the wanted **7** is most probably due to protons of the anolyte passing the diaphragm. Addition of NaH to the anolyte and catholyte decreases the formation of **3d** and raises the yield to **7** significantly. The formation of the ketones **7** can be best explained with the 2-chlorooxirane **6d** as intermediate, which subsequently rearranges and eliminates HCl. The carbinol **5d** could be detected in 4% yield at the most. The exclusive cyclization of **4d** to **6d** is promoted besides by the phenyl group by the high nucleophilicity of the tertiary alcohol and the relief of its "back strain". Thermally or Lewis-acid catalyzed rearrangement of 2-halooxiranes to 2-halo ketones was accompanied mostly by migration of halogen. This can occur in a synchronous process via the transition state **8**[11] or via a α-keto carbenium ion **9**.[12] This means **6d** can be converted to **7** either via **8** or **9** and subsequent elimination of HCl (Eq. 3). A

Table 1. Cathodic Addition of Benzylidyne Trichloride (**1d**) to Ketones[a]

Ketone	Addition product **7**		Yield/%[b] **7**	Yield/%[b] **3d**
		**a** (40)[c]	(48)	(40)

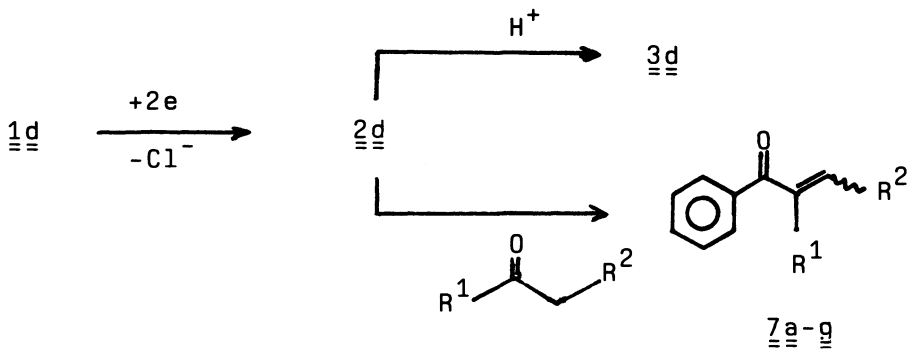
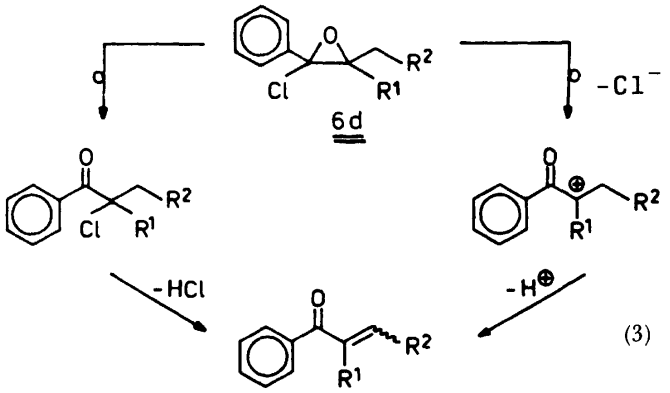
		**g**	64 (38)	22 (58)

a) Reduction at −0.8 V vs. Marple-electrode in 0.5 mol dm^{-3} $LiClO_4$ in THF with addition of NaH. b) Isolated yields; numbers in parenthesis are yields without addition of NaH. c) Relative yields.

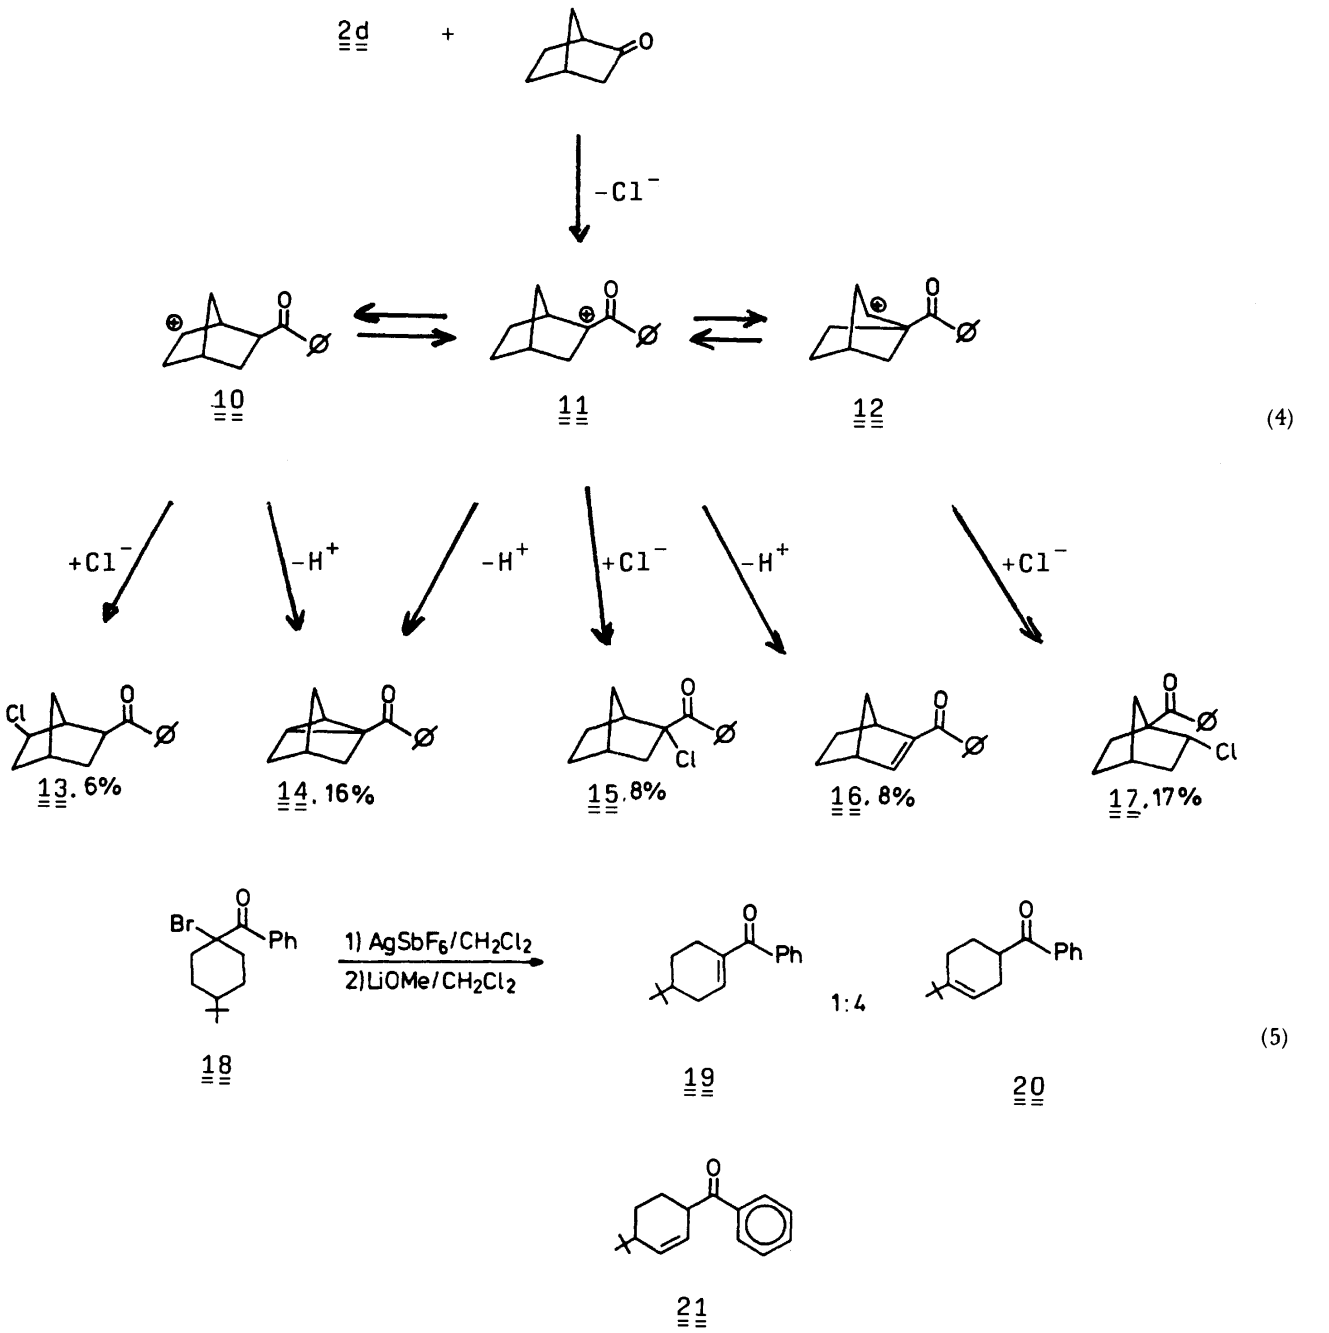


(2)

probe for the intermediacy of **9** should be the addition to norcamphor, where the intermediate 2-oxonorbornyl cation should lead to rearranged products. Reductive addition of **1d** to norcamphor produces the products **13**—**17**. Their formation supports the three equilibrating norbornyl cations **10**—**12** as intermediates (Eq. 4). A synchronous rearrangement of the



(3)



(4)

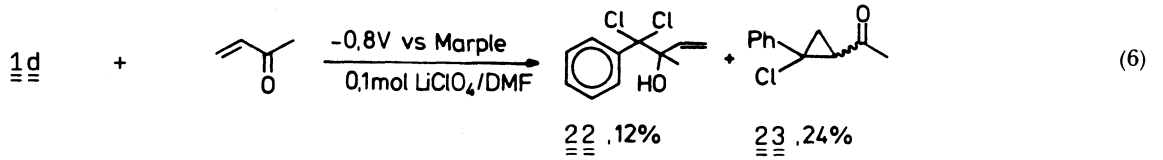
(5)

2-chlorooxirane should have led to **15** and **16** only. The intermediacy of the cations **10** to **12** is further supported by the acetolysis of *exo*-2-benzoyl-*endo*-2-norbornyl mesylate, where via an intermediate 2-benzoylnorbornyl cation acetates, corresponding to **13**, **14**, and **17**, are yielded.[13] A α-keto carbenium ion has been generated from **18** with $AgSbF_6$, its quenching with LiOMe leads to the ketones **19** and **20**.[14] The latter is formed by a transannular hydride shift, which converts the keto carbenium ion to a more stable tertiary carbocation (Eq. 5). Reductive addition of **1d** to 4-*t*-butylcyclohexanone formed, depending on the electrolyte, 21—36% **19**. Two minor products of about 5% yield were detected by GC/MS, whose structures are probably those of the isomers **20** and **21**. The different reaction behaviors could be attributed to the longer lifetime of the 2-keto carbenium ion in the first case, which favors the 1,4-hydride shift prior to deprotonation.

Structure Proofs: The MS spectra of all compounds exhibit besides the base peak *m/z* 105 ($C_6H_5CO^+$) intense M^+ ions. In the IR spectra the carbonyl group conjugated to a phenyl group and a double bond appears between 1660 and 1635 cm^{-1}. The chemical shifts of the olefinic protons in the ^1H NMR are found in the typical region of δ 5.45 to 6.65. The E/Z-isomers of **7b** were assigned using increments,[15] according to which the resonance of the olefinic proton in (*E*)-**7b** is found at higher δ-values. The ^1H NMR of **14** is due to the symmetry of the molecule and small coupling constants without much conclusiveness, but by its ^{13}C NMR the structure could be unambigously assigned. The chlorinated norbornyl compounds **13**, **15**, and **17** are isomers. Here the position of the chloro and the benzoyl substituent could be determined by ^1H NMR.

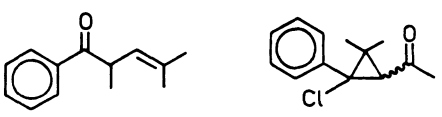
Cathodic Addition of 1d to α,β-Unsaturated Ketones. When **1d** is reduced as before in 0.1 mol dm^{-3} $LiClO_4$/DMF in the presence of methyl vinyl ketone, besides 8% **3d** the adducts **22** and **23** are isolated in the ratio 1:2 (Eq. 6). The low yields of adduct in spite of minor protonation of **2d** is possibly due to losses through extensive oligomer formation. **22** can be rationalized by 1,2-addition of **2d**, whilst **23** appears to be formed by 1,4-addition and subsequent cyclization. For the cathodic addition of **1c** to acrylonitrile or ethyl acrylate, the formation of analogous cyclopropane derivatives has been reported.[4] To decrease the 1,4-addition by steric shielding of the double bond **1d** was added to mesityl oxide. Although 2F(1F=96480C) mol^{-1} of charge had been passed, 20% of **1d** were recovered on work up, which indicated current consumption in a follow-up reduction of the product. The expected dienones **24**, **25** could be detected in only about 6% yield, main product with 30% was the enone **26** (44% by GLC). The 1,4-adduct **27** decreased to 6% as intended (Eq. 7). The enone **26** originates presumably from either **24**, **25**, or the chlorides **29**, **30**. They should be easily reducible at the applied potential to yield the carbanion **28**, which is protonated to **26** (Eq. 8).

Structure Proofs: For **23** the IR absorption of the carbonyl group at 1710 cm^{-1} and the base peak *m/z*=43 in the mass spectrum indicate the acetyl group. (*Z*)- and (*E*)-**23** can be distinguished by their ^1H NMR. The characteristic changes in the shifts for the E- and Z-isomer can be rationalized by the anisotropy effect of the phenyl ring. The correct

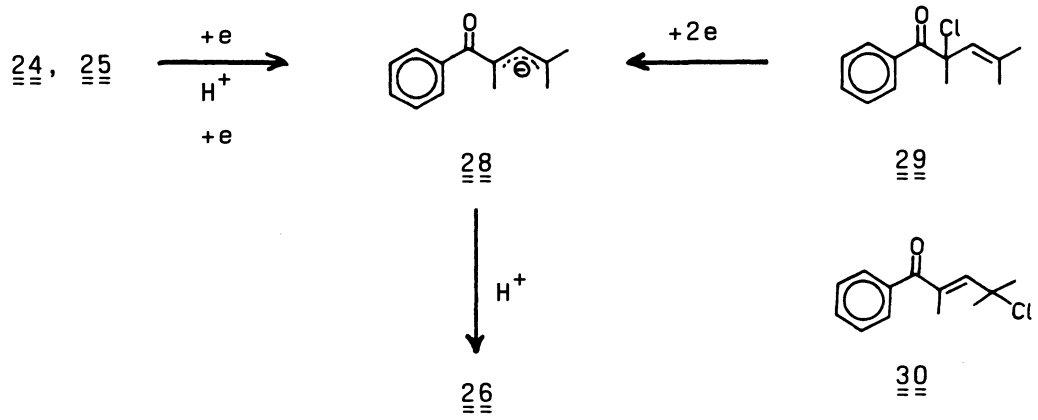


22 ,12% 23 ,24% (6)

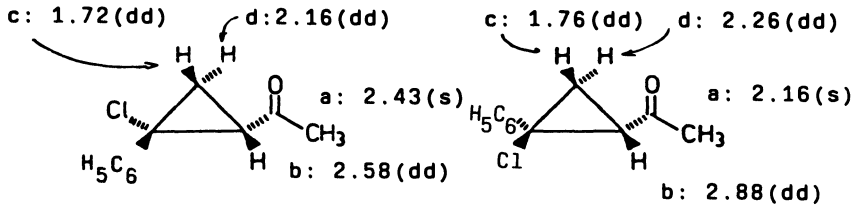
24 25



26 27 (7)



(8)



(*Z*)-**23** (*E*)-**23**

assignment was further checked by NOE. The IR spectrum of **26** with the carbonyl absorption at 1680 cm^{-1} indicates that the double bond is not conjugated with the benzoyl group. The assignment is supported by the appearance of two allylic methyl groups at δ 1.65 and 1.70 in the ^1H NMR.

Reductive Addition of 1d to Aldehydes. Reductive additions of **1d** to pentanal yielded the alcohol **31** and the chloro ketone **32** (Eq. 9). The suppressed formation of **3d** (9%) reflects the high reactivity of the aldehyde. The results further demonstrate that not only the π-system of the phenyl group,[8] but also "back strain" in **4** is necessary for the formation of the 2-chlorooxirane. It was therefore expected, that the addition to an α-branched aldehyde should lead to a higher portion of **6**. This proved indeed to be the case. Reduction of **1d** in the presence of 2-methylpentanal led besides a small amount of **3d** to the 2-chloro-oxirane **33** as a main product. Its structure was indicated by the mass spectrum and conversion to **34** and **35** (Eq. 10). Attempts to purify crude **33** by filtration over silica gel let to the α-chloro ketone **34** and the α-hydroxy ketone **35**. This conversion is not surprising, as 2-chlorooxiranes are easily hydrolyzed to mixtures of α-chloro and α-hydroxy ketones.[11b]

Structure Proofs: **31** shows in the mass spectrum the fragment ion m/z=160 from McLafferty-rearrangement. The other part of the molecule can be deduced from an α-cleavage to m/z=87. The structure of **32** is established from its carbonyl absorption at 1685 cm^{-1} in the IR, by the base peak of m/z=105 ($C_6H_5CO^+$) in the MS and the triplet for the chloromethine proton at δ 5.15 in the ^1H NMR. The ^1H NMR spectra for **34** and **35** are very similar. For **34** the chloromethine proton appears as doublet at δ 4.92, the hydroxymethine proton as multiplett between δ 4.87 and 5.16.

Experimental

IR spectra were obtained on Perkin-Elmer spectrometers 177 and 421. ^{1}H NMR spectra were recorded on a JEOL PMX 60, Varian HA 100 and Bruker WM 300. ^{13}C NMR spectra were measured on Bruker WH 90 and WM 300 spectrometers. Mass spectra were taken with the Varian instruments SM 1 and CH 7 at 70 eV ionization energy. Combined GC/MS-spectra were taken with the Varian instrument MAT 111. Elemental analyses were performed by M. Beller, Göttingen and on a Perkin-Elmer CHN-analyser. Gas chromatographic analyses were done with a Varian 1400 instrument, a Kipp & Zonen BD 7 recorder and the Minigrator Autolab of Spectra Physics. The following glass columns were used: 1.7 m, d=2 mm, 4% SE 30 on Chromosorb W, and 1.7 m, d=2 mm, 4% OV 225 on Chromosorb W. For TLC silica-gel plates 60 F 254 of Merck were used. HPLC was performed with a Waters 6000 A pump and an U6K injector together with a steel column (d=8 mm, l=50 cm) filled with LiChromosorb Si 60 (7 µm, Fa. Merck). For detection the Knauer differential refractometer type 51.78 coupled with a Abimed recorder Modell 300 was used. Eluent was in all cases CH_2Cl_2. Polarographic measurements were performed with the Bruker polarograph E 310, glass equipment and drop controller E 354 S from Metrohm and the Hewlett-Packard XY-recorder 7045 A; the following conditions were applied: drop time: 1 s, scan time: 10 mV s^{-1}, puls amphitude 50 mV. Preparative electrolyses at controlled potential were performed with the Wenking-potentiostat (3A/60 V). The electrolyses were operated in a double-walled glass cell (150 ml) with a Teflon stopper. Through this the anode compartment (glass tube with G4-frit), Luggin capillary, current feeder for the mercury pool cathode (d=4.5 cm) and nitrogen inlet were inserted. Reference electrode was the Marple electrode.[16] All electrolyses were conducted at 0 °C under nitrogen. The following electrolytes were used for polarography and preparative electrolyses: Electrolyte A: 0.2 mol dm^{-3} $LiClO_4$/DMF; electrolyte B, catholyte: 0.5 mol dm^{-3} $LiClO_4$/THF, 10 mg NaH, anolyte: 0.2 mol dm^{-3} $LiClO_4$/DMF, 10 mg NaH; electrolyte C: as B, but without NaH. For the work-up of the electrolyses, the catholyte was poured into the threefold amount of water, neutralized, extracted with ether (3×50 ml), the ether extracts were washed with water, dried ($MgSO_4$) and the ether was rotaevaporated. Benzene dried *N,N*-dimethylformamide (DMF) was stirred 24 h with P_2O_5, distilled at 18 Torr under nitrogen and stored over molecular sieve (4 Å).

Electrolysis of Benzylidyne Trichloride (1d) in Presence of 2-Butanone. 5 mmol (1.00 g) **1d** and 10 mmol (0.7 g) 2-butanone are electrolyzed in electrolyte A at −0.8 V vs. Marple until total conversion (10 mF). LC-separation of the crude product yielded 330 mg (2 mmol, 40%) **3d** and 390 mg (2.4 mmol, 48%) **7a, b**, which could be separated by analytical HPLC into **7a**, (*Z*)-**7b** and (*E*)-**7b**.

2-Ethyl-1-phenyl-2-propen-1-one (7a): Oil; IR and ^{1}H NMR spectra corresponded to those in the literature.[17]

(*Z*)-2-Methyl-1-phenyl-2-buten-1-one ((*Z*)-7b): Colorless oil; IR (neat 1655 (C=O) cm^{-1}; ^{1}H NMR (60 MHz, $CDCl_3$) δ=1.54 (d, 3H, ^4J=2 Hz), 1.95 (s, 3H, ^4J=1.5 Hz), 5.77 (q, 1H, ^4J=2 Hz), 7.15—8.05 (m, 5H); MS (70 eV) *m/z* (%) 160 (M$^+$; 32), 159 (28), 145 (38), 105 (100).

(*E*)-2-Methyl-1-phenyl-2-buten-1-one ((*E*)-7b): Oil; IR (neat) 1640 (C=O) cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.87 (d, 3H), 1.97 (s, 3H), 6.41 (q, 1H), 7.34—7.8 (m, 5H). **7b** is reported as E/Z-mixture in lit.[18]

Electrolysis of 1d in Presence of 3-Methyl-2-butanone. 5 mmol **1d** and 10 mmol (0.86 g) 3-methyl-2-butanone are electrolyzed in electrolyte B under efficient stirring at −0.8 V vs. Marple until 10 mF had been consumed. The catholyte is poured into ice water controlling the pH between 6—7 and worked-up. HPLC of the crude product yielded 130 mg (0.8 mmol, 16%) **3d**, 350 mg (2 mmol, 41%) **7c** and 160 mg (0.9 mmol, 18%) **7d**.

2-Isopropyl-1-phenyl-2-propen-1-one (7c): Colorless oil; IR (neat) 1655 (C=O) cm^{-1}; ^{1}H NMR (60 MHz, $CDCl_3$) δ=1.15 (d, 6H), 2.70—3.30 (m, 1H), 5.45 (s, 1H), 5.70 (s, 1H), 7.2—7.9 (m, 5H); MS (70 eV) *m/z* (%) 174 (M$^+$; 15), 173 (22), 159 (20), 105 (100); Found: C, 82.55; H, 8.15%. Calcd for $C_{12}H_{14}O$ (174.24): C, 82.72; H, 8.09%.

2,3-Dimethyl-1-phenyl-2-buten-1-one (7d): Oil; IR and ^{1}H NMR spectra agree with those in lit.[19]

Electrolysis of 1d in Presence of 3-Pentanone. 5 mmol (1.0 g) **1d** and 10 mmol (0.84 g) 3-pentanone are electrolyzed in electrolyte B or C at −0.8 V vs. Marple until 10 mF are consumed. Work-up of the crude product (1.1 g) and preparative HPLC yielded 490 mg (59%) **3d** and 300 mg (34%) **7e** (electrolyte C) or 190 mg (23%) **3d** and 580 mg (65%) **7e** (electrolyte B). **7d** was a 2:1 E/Z-mixture.

2-Ethyl-1-phenyl-2-buten-1-one (7d): Colorless oil; IR (neat) 1645 (C=O) cm^{-1}; ^{1}H NMR (60 MHz, $CDCl_3$) δ=1.00 (t, 3H), 1.80 (d, 3H), 2.45 (q, 2H), 6.25 (q, 1H), 7.25—7.75 (m, 5H); MS (70 eV) *m/z* (%) 174 (M$^+$; 20), 173 (20), 145 (81), 105 (100); Found: C, 82.64; H, 8.12%. Calcd for $C_{12}H_{14}O$ (174.24): C, 82.72; H, 8.09%.

Electrolysis of 1d in Presence of Acetophenone: As described above 5 mmol (1.0 g) **1d** were reduced in presence of 10 mmol (1.2 g) acetophenone to yield after HPLC 450 mg (56%) **3d** and 290 mg (28%) **7f** (electrolyte A) or 230 mg (29%) **3d**, 600 mg (58%) **7f** (electrolyte B). To prevent polymer formation solvents were rotaevaporated at room temp. The IR and ^{1}H NMR data of **1,2-diphenyl-2-propen-1-one (7f)**, oil, correspond to those in lit.[20]

Electrolysis of 1d in Presence of Cyclopentanone: 5 mmol (1 g) **1d** and 10 mmol (0.85 g) cyclopentanone are electrolyzed as above to afford after HPLC 450 mg (56%) **3d** and 310 mg (36%) **7g** (electrolyte A) or 170 mg (22%) **3d** and 550 mg (64%) **7g** (electrolyte B).

1-Benzoyl-1-cyclopentene (7g): Oil; IR and ^{1}H NMR spectra agree with those reported in lit.[21]

Electrolysis of 1d in Presence of Norcamphor: 10 mmol (2.0 g) **1d** and 20 mmol (2.2 g) norcamphor are electrolyzed in electrolyte B as above until 20 mF were consumed. HPLC yielded in order of elution: 500 mg (31%) **3d**, 200 mg (8%) **15**, 140 mg (6%) **13**, 400 mg (17%) **17**, 150 mg (8%) **16** and 320 mg (16%) **14**.

2-Benzoyl-6-chlorobicyclo[2.2.1]heptane (13): Oil; IR (neat) 1655 (C=O) cm^{-1}; ^{1}H NMR (300 MHz, $CDCl_3$) δ=0.98—1.75 (m, 4H), 2.1—2.28 (m, 2H), 2.46—2.57 (m, 1H), 2.68—2.80 (m, 1H), 3.92—4.04 (m, 1H), 4.54—4.66 (m, 1H), 7.40—7.62 (m, 3H), 7.83—8.04 (m, 2H); MS (70 eV) *m/z* (%): 234 (M$^+$; 4), 198 (17), 105 (100); Anal. by high resolution MS: Found: *m/z* 234.0811. Calcd for $C_{14}H_{15}ClO$: M, 234.0811.

1-Benzoyltricyclo[2.2.1.0^{2,6}]heptane (14): Oil; IR (neat)

1655 (C=O) cm^{-1}; ^1H and ^{13}C NMR correspond to lit;[12] MS (70 eV) *m/z* (%) 198 (M^+; 55), 105 (100); Found: C, 84.60; H, 7.10%. Calcd for $C_{14}H_{14}O$ (198.28): C, 84.81; H, 7.11%.

2-Benzoyl-2-chloro-bicyclo[2.2.1]heptane (15): Oil; IR (neat) 1675 (C=O) cm^{-1}; ^1H NMR (300 MHz, $CDCl_3$) δ=1.05—1.20 (m, 2H), 1.42—1.56 (m, 3H), 2.08—2.20 (m, 1H), 2.20—2.29 (m, 1H), 2.37—2.45 (m, 1H), 2.74—2.83 (m, 1H), 3.00—3.06 (m, 1H), 7.40—7.58 (m, 3H), 8.11—8.18 (m, 2H); MS (70 eV) *m/z* (%) 234 (M^+; 4), 105 (100); Found: C, 71.79; H, 6.68; Cl, 14.92%. Calcd for $C_{14}H_{15}ClO$ (234.7): C, 71.64; H, 6.82; Cl, 15.10%.

2-Benzoylbicyclo[2.2.1]hept-2-ene (16): Oil; IR (neat) 1635 (C=C, C=O) cm^{-1}; ^1H NMR (60 MHz, $CDCl_3$) δ=1.0—2.1 (m, 6H), 3.0—3.25 (m, 1H), 3.40—3.65 (m, 1H), 6.65 (d, 1H), 7.3—7.6 (m, 3H), 7.6—7.8 (m, 2H); MS (70 eV) *m/z* (%) 198 (M^+; 20), 170 (51), 105 (100); Anal. by high resolution MS: Found: *m/z* 198.1041. Calcd for $C_{14}H_{14}O$: M, 198.1044.

1-Benzoyl-2-chlorobicyclo[2.2.1]heptane (17): Oil; IR (neat) 1658 (C=O) cm^{-1}; ^1H NMR (300 MHz, $CDCl_3$) δ=1.28—1.48 (m, 1H), 1.65—2.46 (m, 8H), 4.34—4.50 (m, 1H), 7.35—7.58 (m, 3H), 7.78—7.96 (m, 2H); MS (70 eV) *m/z* (%) 234 (M^+; 7), 105 (100); Found: C, 71.70; H, 6.49; Cl, 14.88%. Calcd for $C_{14}H_{15}ClO$ (234.7): C, 71.64; H, 6.82; Cl, 15.10%.

Electrolysis of 1d in Presence of 4-*t*-Butylcyclohexanone. 5 mmol (1.0 g) **1d** and 10 mmol (1.3 g) 4-*t*-butylcyclohexanone were electrolyzed as above until total conversion in electrolyte A or B. LC (silica gel) afforded 250 mg (21%) **19** in electrolyte A or 430 mg (36%) **19** in electrolyte B. GLC shows about 5% of two double bond isomers of **19** with similar MS spectra.

1-Benzoyl-4-*t*-butyl-1-cyclohexene (19): Oil; IR (neat) 1635 (C=O) cm^{-1}; ^1H NMR (300 MHz, $CDCl_3$) δ=0.92 (s, 9H), 1.15—1.40 (m, 2H), 1.95—2.10 (m, 2H), 2.18—2.38 (m, 2H), 2.65—2.75 (m, 1H), 6.55—6.65 (m, 1H), 7.35—7.55 (m, 3H), 7.60—7.67 (m, 2H); MS (70 eV) *m/z* (%) 242 (M^+; 32), 185 (30), 105 (100); Found: C, 84.00; H, 9.27%. Calcd for $C_{17}H_{22}O$ (242.4): C, 84.25; H, 9.15%.

Electrolysis of 1d in Presence of Methyl Vinyl Ketone. 5 mmol (1.0 g) **1d** and 10 mmol (0.7 g) methyl vinyl ketone are electrolyzed in electrolyte A. Considerable loss of product (40%) during column filtration indicates polymer formation. HPLC yields 80 mg (10%) **3d**, 140 mg (12%) **22**, 80 mg (8%) (*E*)-**23** and 150 mg (16%) (*Z*)-**23**.

1,1-Dichloro-2-methyl-1-phenyl-3-buten-2-ol (22): Oil; IR (neat) 3500 (OH), 1635 (C=C), 995, 935 (C=CH_2) cm^{-1}; ^1H NMR (60 MHz, $CDCl_3$) δ=1.46 (s, 3H), 2.4 (s, 1H), 5.15—5.45 (m, 2H), 6.15 (dd, 1H), 7.20—7.90 (m, 5H); MS (70 eV) *m/z* (%) 159 ($M^+-C_4H_7O$; 8), 71 ($C_4H_7O^+$; 100); Found: C, 57.31; H, 5.51; Cl, 30.13%. Calcd for $C_{11}H_{12}Cl_2O$ (231.1): C, 57.17; H, 5.23; Cl, 30.68%.

1-Acetyl-2-chloro-2-phenylcyclopropane (23): Oil; IR (neat) 3060, 3030 (CH), 1710 (C=O) cm^{-1}; ^1H NMR (*E*-isomer, 300 MHz, $CDCl_3$) δ=1.76 (dd, 1H, *J*=6.3 Hz, *J*=8.5 Hz), 2.16 (s, 3H), 2.26 (dd, 1H, *J*=6.3 Hz, *J*=7.5 Hz), 2.88 (dd, 1H, *J*=7.5 Hz, 8.4 Hz), 7.24—7.40 (m, 5H); ^1H NMR (*Z*-isomer, 300 MHz, $CDCl_3$) δ=1.72 (dd, 1H, *J*=6.5 Hz, 8.6 Hz), 2.16 (dd, 1H, *J*=6.5 Hz, 7.5 Hz), 2.43 (s, 3H), 2.58 (dd, 1H, *J*=7.5 Hz, 8.6 Hz), 7.28—7.50 (m, 5H); MS (70 eV) *m/z* (%) 194 (M^+; 1), 159 (55), 43 (100); Found: C, 68.24; H, 5.76; Cl, 18.77%. Calcd for $C_{11}H_{11}ClO$ (194.7): C, 67.86; H, 5.70; Cl, 18.21%.

Electrolysis of 1d in Presence of 4-Methyl-3-penten-2-one. 7.5 mmol (1.5 g) **1d** and 15 mmol 4-methyl-3-penten-2-one are electrolyzed in electrolyte A until 15 mF are consumed. HPLC yielded 400 mg **1d** and **3d**, 528 mg (44%) **26** and 152 mg of a 1:1:1-mixture of **24**, **25**, **27**.

2,4-Dimethyl-1-phenyl-3-penten-1-one (26): Oil; IR (neat) 1680 (C=O) cm^{-1}; ^1H NMR spectrum corresponds to that reported in lit.[22]

4-Methyl-2-methylene-1-phenyl-3-penten-1-one (24): MS (70 eV) *m/z* (%) 186 (M^+; 23), 185 (20), 105 (100).

2,4-Dimethyl-1-phenyl-2,4-pentadien-1-one (25): MS (70 eV) *m/z* (%) 186 (M^+; 23), 185 (50), 171 (100), 105 (81).

1-Acetyl-2-chloro-3,3-dimethyl-2-phenylcyclopropane (27): MS (70 eV) *m/z* (%) 186 (M^+-HCl; 31), 179 (65), 43 (100).

Electrolysis of 1d in Presence of Pentanal. 10 mmol (2.0 g) **1d** are electrolyzed in presence of 20 mmol (1.72 g) pentanal. HPLC of the crude product (1.63 g) led to 140 mg (8.5%) **3d**, 480 mg (23%) **32** and 600 mg (24%) **31**.

1,1-Dichloro-1-phenyl-2-hexanol (31): Oil; IR (neat) 3400 (OH) cm^{-1}; ^1H NMR (300 MHz, $CDCl_3$) δ=0.84 (t, 3H), 1.16—1.44 (m, 4H), 1.44—1.66 (m, 2H), 4.10 (dd, 1H), 7.32—7.80 (m, 5H); MS (70 eV) *m/z* 210 (M^+-HCl; 5); **31** (+TMS−H) MS (70 eV) *m/z* (%) 303 (M^+-15; 1); Anal. by high resolution MS, Found: *m/z* 303.0739. Calcd for $C_{15}H_{24}Cl_2OSi$: $M-CH_3$ 303.0739.

2-Chloro-1-phenyl-1-pentanone (32): Oil; IR (neat) 1685 (C=O) cm^{-1}; ^1H NMR (60 MHz, $CDCl_3$) δ=0.93 (t, 3H), 1.28—1.67 (m, 4H), 1.83—2.30 (m, 2H), 5.15 (t, 1H), 7.28—8.20 (m, 5H); MS (70 eV) *m/z* (%) 210 (M^+; 3), 105 (100); Found: C, 68.49; H, 7.21; Cl, 16.97%. Calcd for $C_{12}H_{15}ClO$ (210.7): C, 68.40; H, 7.18; Cl, 16.82%.

Electrolysis of 1d in Presence of 2-Methylpropanal. 10 mmol (2.0 g) **1d** and 20 mmol (1.4 g) isobutyraldehyde were electrolyzed until conversion. GLC shows besides a small amount of **3d** about 60% **33**, attempted purification of **33** by filtration over silica converts it into **34** and **35**. HPLC afforded 130 mg (8%) **3d**, 290 mg (15%) **34**, and 590 mg (33%) **35**.

2-Chloro-3-methyl-1-phenyl-1-butanone (34): Oil; IR and ^1H NMR spectra agree with those in lit.[23] Found: C, 67.31; H, 6.64; Cl, 18.18%. Calcd for $C_{11}H_{13}OCl$ (196.7): C, 67.18; H, 6.66; Cl, 18.03%.

2-Hydroxy-3-methyl-1-phenyl-1-butanone (35): Oil; IR (neat) 3450 (OH), 1675 (C=O) cm^{-1}; ^1H NMR spectrum agreed with this in lit.[24]

1-Chloro-2-isopropyl-1-phenyloxirane (33): MS (70 eV) *m/z* (%) 196 (M^+; 3), 124 ($M^+-C_4H_8O$; 40), 105 (100).

We thank the Arbeitsgemeinschaft Industrieller Forschungsvereinigungen e.V. and the Fonds der Chemischen Industrie for financial support, H. Luftmann for interpretation of the mass spectra and H. Rennefeld for technical assistance.

(Received August 7, 1987)

The conformational flexibility of many of the native proteins facilitates their attainment of new reversible three-dimensional structures under well-specified conditions. Such structures appear to be of great importance in biological processes involving biologically active proteins, such as enzymes, receptors or protein hormones. Recently it was shown that the above conformational alterations can be followed not only by physicochemical methods but also immunochemically by the use of monoclonal antibodies (mAbs). mAbs are specific proteins, each capable of recognizing a corresponding well-characterized region (epitope) on the surface of a protein antigen. They are thus useful as tools in the study of the structure and properties of protein surfaces. Of particular interest is the fact that it is possible to prepare mAbs with predetermined specificities towards the different epitopes of a given protein. Such mAbs can thus be used to detect conformational alterations occurring at the different segments of a protein antigen. In the present review article we describe our own work and that of others on the use of mAbs as probes to detect the conformation and conformational alterations occurring in proteins exposed to different conditions, such as heat, adsorption onto solid surfaces, interaction with ligands and protein-protein interaction. The use of mAbs in the detection of protein folding intermediates is also described.

Powerful X-ray diffraction techniques developed for protein analysis have made it possible to elucidate the three-dimensional structure of approximately 300 proteins to date. In all of them it was noticed that the bending of the polypeptide backbone, leading to the formation of α-helices, β-pleated sheets and characteristic loops, brings about contact between amino acid residues located originally at relatively large distances from one another along the peptide chain. Because of the tertiary structure thus obtained, native protein molecules possess a characteristic "topography" when surveyed from the outside and a characteristic core when surveyed from the inside. The characteristic three-dimensional structure of a native protein seems to be derived from the primary amino acid sequence of the protein, since polypeptides possessing this primary sequence can coil, under appropriate conditions, into the native three-dimensional structure. Exposure of proteins to extreme conditions (high temperatures, extreme pH values or denaturating agents) is usually accompanied by disruption of the three-dimensional structure characterizing the native protein. The resulting denatured proteins possess physical, chemical, and biological properties which differ markedly from those of the native protein. Recently accumulated evidence shows that the three-dimensional structure of proteins is not rigid, but undergoes subtle reversible conformational fluctuations. Flexibility of amino acid side chains, mobility of peptide segments, and movement of structural domains as rigid bodies, have been demonstrated.[1] Physical methods (X-ray or neutron diffraction, NMR, fluorescence spectroscopy, hydrogen-deuterium exchange) have proved particularly useful in the determination of the amplitudes, time spans, and energies involved in these conformational oscillations. The conformational flexibility of many of the native proteins facilitates their acquisition of new reversible three-dimensional structures under well-specified conditions. Such structures seem to be of great importance in biological processes involving biologically active proteins, such as enzymes, receptors or protein hormones in which the conformational alterations in solution can be readily followed, not only by physicochemical methods but also immunochemically by the use of monoclonal antibodies (mAbs).

In the present review we describe the work of ourselves and others on the use of mAbs as probes to detect the conformation and conformational alterations occurring in proteins exposed to different conditions (heat, adsorption onto solid surfaces, interaction with ligands, protein-protein interaction). The use of mAbs in the detection of protein folding intermediates is also described.

Monoclonal Antibodies as Conformational Probes

The cell hybridization technique developed by Köhler and Milstein[2] enables the preparation of murine monoclonal antibodies (mAbs) capable of recognizing corresponding single well-characterized regions (epitopes) on the surface of the protein antigens used to elicit the immunological response. It thus seems that mAbs might serve as useful tools in the study of the structure and properties of protein surfaces. All antigenic determinants of proteins appear to be topographical, i.e., composed of

structures on the protein surface which may be contained within a single segment of the amino acid sequence or assembled from residues far apart in the amino acid sequence but brought together on the surface by the folding of the protein in its native conformation.[3] It is thus pertinent to note that mAbs are not only directed towards corresponding amino acid residues of the antigen, but seem also to recognize well-defined conformations of protein segments. Any alteration in the conformation of such a segment is usually accompanied by a marked change in the characteristic binding of the mAb with its protein antigen. It is obvious, however, that the use of mAbs as conformational probes of proteins will be reliable only if general information is available as to the antigenic determinant recognized by the mAb, and if no conformational alterations are induced in the antigen as a result of its interaction with the mAb.

The three-dimensional structure of an antigen-antibody complex was recently determined for the first time by X-ray crystallography using hen egg white lysozyme (HEL) and the Fab fragment of a mAb (D1.3) at a resolution of 2.8 Å.[4] The antigenic determinant was shown to be topographic, with the interface between antigen and antibody extending over an area having maximum dimensions of 30×20 Å. Complex formation with the mAb D1.3 did not produce any significant distortion in the structure of the lysozyme. This was also confirmed by the simultaneous binding of two different mAbs to the lysozyme[5] and the retention of enzymatic activity by the HEL-mAb D1.3 complex.[6] It is worth noting that mAbs towards different enzymes have been obtained which do not affect their catalytic activity.[7]

The three-dimensional structure of the HEL-D1.3 Fab complex suggests that the interaction between the enzyme and the mAb can be described by a "lock and key" model, in which complex formation is essentially an association between two rigid molecules. An absence of marked conformational changes (>2 Å) upon complex formation is, in fact, characteristic of nearly all protein-protein complexes studied to date at high resolution, in which the structure of the unbound form of at least one of the component proteins is also known. These complexes include bovine trypsin–pancreatic trypsin inhibitor;[8] porcine kallikrein A–bovine pancreatic trypsin inhibitor,[9] and carboxypeptidase A–potato inhibitor.[10]

The three-dimensional structure of another enzyme antibody complex, that formed between neuraminidase and a corresponding mAb, was recently elucidated by X-ray crystallography.[11] Unlike in the case of HEL mAb D1.3 Fab, the specific interaction was accompanied here by significant conformational changes in both the antigen and antibody. Conformational changes in proteins as a result of interaction with their corresponding antibodies have also been reported by others.[12] It is reasonable to assume that such changes occur in a region of the protein characterized by significant flexibility. If this is the case, one might explain the observed conformational alterations by assuming an "induced fit mechanism," whereby the antigen and/or the antibody achieve greater complementarity by undergoing conformational changes.

It is still too early to predict, on theoretical grounds, when the interaction between a protein antigen and its corresponding mAb proceeds according to the lock and key mechanism, and when it favors the induced fit mechanism. It is obvious, however, that determination of the parameters characterizing the binding of a protein antigen with its mAb in solution should supply valuable information on the conformational characteristics of the interacting protein antigen epitopes.

Recognition of the region of interaction of a protein antigen with a given mAb is necessary if the conformational alterations occurring under various conditions in that region are to be detected. Antigenic determinats can be delineated by means of a physical approach using X-ray diffraction methods as illustrated above, or by an immunochemical approach in which direct or competitive assays are used to determine the reactivity of the mAb with isoenzymes or natural variants, and with natural or synthetic fragments of the target proteins. It has recently become clear that antibodies against most regions of a protein can be induced by immunization with short synthetic peptides. This has permitted the generation of mAbs with predetermined specificity[13] which constitute excellent tools for probing surface conformations of proteins at precise locations.

Detection of Conformational Changes Induced by Ligands

The activity of many enzymes, and particularly of allosteric enzymes, is drastically modified by the binding of coenzymes, ligands, modulators, cofactors or inhibitors. Coenzymes are involved in many transfer reactions and may act by changing the molecular dynamics of specific biocatalysts.

Conformational alterations resulting from the binding of the β_2-subunit of *Escherichia coli* tryptophan synthase with its ligands were detected and analyzed by Djavadi-Ohaniance et al.[14] using mAbs as specific probes. Five mAbs recognizing five different epitopes of the β_2-subunit of *E. coli* tryptophan synthase were prepared and their apparent binding constants with the enzyme subunit determined in solution. Fixation of the coenzyme pyridoxal 5-phosphate and the substrate L-serine by the β_2-subunit modified the affinity constants of most of the mAbs for the enzyme, thus demonstrating the existence of extended conformational rearrangements of the

protein. Association of the α-subunit with the β_2-subunit, brought about an increase of the tryptophan synthase activity and abolished the serine deaminase activity of β_2; this was accompanied by important conformational changes readily detected with appropriate mAbs. The above changes are not limited to a small region near the ligand binding site of the protein but rather affect an extended area of the protein surface, as shown by the observation that each ligand modifies the association constant of at least four mAbs recognizing distinct and non-overlapping epitopes.

Conformational transitions induced by the binding of metal ions to specific sites of proteins have been monitored by various physicochemical methods. These transitions can also be localized by immunochemical methods. Specific mAbs directed against the calcium-stabilized structure of human prothrombin have been prepared and characterized by Lewis et al.[15] One of the mAbs was found to bind with prothrombin only in the presence of $CaCl_2$. It did not interact with abnormal prothrombin lacking the γ-carboxy-glutamate residues known to interact with metal ions. Replacement of the calcium cation by Mn^{2+}, Mg^{2+}, and Co^{2+} promoted binding. The conformational transitions in prothrombin occurring as a result of the metal binding have been monitored using circular dichroism and fluorescence techniques.[16,17] The above findings were corroborated by the earlier studies of Tai et al.[18] who used polyclonal antibodies in their immunochemical studies. Antigenic differences could be detected in bovine prothrombin in the presence or absence of Ca^{2+} with antibodies raised in rabbits and fractionated by affinity chromatography.

The value of mAbs as conformational probes is further illustrated by their use in the detection of the calcium-induced conformational change(s) in a C-reactive protein (a protein appearing in the serum in the acute phase of certain infections). Three out of four mAbs against C-reactive protein bind to the protein antigen in the presence of Ca^{2+}, but not in the presence of EDTA, indicating that the conformation of the antigenic determinant recognized by these mAbs is calcium-dependent. The Ca^{2+}-independent binding of the fourth mAb, however, suggests that the conformation of the epitope recognized by this mAb is independent of bound calcium.

Monoclonal antibodies possessing similar binding characteristics to those described above, and directed towards the various domains of protein C have been recently described by Wakabayashi et al.[19] The three mAbs which react with protein C only in the presence of Ca^{2+} were found to bind to the light chain of protein C, i.e. the chain possessing γ-carboxy-glutamic acid residues. Other mAbs which recognize the conformation of a protein in a medium devoid of Ca^{2+}, but not that in a medium containing Ca^{2+}, have been described by Dixit et al.,[20] who prepared and studied the characteristic of two such mAbs directed against thrombospondin.

The induction of different calcineurin conformations by metal ions could also be demonstrated by suitable mAbs.[21] The experimental data showed that the active conformational states of calcineurin are metal-ion-dependent, that the mAb VA_I affects the Ni^{2+}-induced conformational change of the enzyme, and that the β-subunit of calcineurin plays a critical role in the expression of Ni^{2+}-stimulated phosphatase activity. Conformational changes induced in myosin by Ca^{2+} could also be detected with appropriate mAbs. Particularly useful in the studies of Shimizu et al.[22] was a mAb capable of detecting conformational alteration in the light chain of myosin LC2.

Three mAbs that interact with carboxypeptidase-A with relatively high binding constants but without affecting the enzyme activity, were used in our laboratory[23] for the detection of subtle conformational alterations occurring in the enzyme molecule when exposed to various conditions. Of particular interest was the finding that the three mAbs can detect subtle reversible conformational alterations occurring on removal of zinc from the active site of the enzyme by 1,10-phenanthroline. Reconstitution of the enzymatic activity by addition of zinc to the apoenzyme led to full recovery of the antigenic characteristics of carboxypeptidase-A recognized by the three mAbs.

Use of Monoclonal Antibodies in the Detection of Protein Folding Intermediates

The "translation" of the amino acid sequence of a newly synthesized polypeptide chain into the well-ordered "native" three-dimensional structure of a functional protein is commonly referred to as "protein folding." This was clearly illustrated by the classical experiment of Anfinsen et al.[24] who demonstrated that reduced and urea-denatured pancreatic ribonuclease readily undergoes renaturation in an oxygen containing solution on removal of the denaturing agent. It should be pointed out, however, that the detailed mechanism involved in molecular renaturation and denaturing is still only poorly understood, though obviously of great interest to the molecular biologist. Up to quite recently the conformational processes occurring during renaturation or denaturation were studied mainly from a theoretical point of view as very few experimental techniques were available to tackle the problem. Rapid developments in the various physical methods, particularly X-ray and NMR, as well as the recently developed capacity for substituting different amino acid residues in proteins by site directed mutagenesis, have opened up new possibilities for the experimental study of the

process and the intermediate conformers appearing during protein renaturation and denaturation. Protein folding seems to proceed through a series of structural intermediates from short stretches of local, barely stable, secondary structures to compact "domains" that interact to yield the final tertiary structure. At each step on this pathway, the structural intermediates appear to undergo conformational rearrangements. In these protein folding studies mAbs can contribute as probes for detection of the early intermediates. The potential usefulness of mAbs in this connection was illustrated by the pioneer work of Blond and Goldberg[25] on the β_2 subunit of *E. coli* tryptophan synthase. Two mAbs were directed against the native β_2-subunit of the enzyme, and their association with either the intact β_2-subunit or its isolated domains was investigated using fluorescence energy transfer between the tryptophan residues of the antibodies and a dansyl group covalently linked to the antigen. Denaturation of the β_2-subunit was induced by a concentrated guanidine hydrochloride solution, and renaturation initiated by extremely rapid dilution of the denaturating agent. Association of both mAbs with the antigen occurred within a few seconds of intitiating the renaturation, while complete refolding of the β_2 subunit required several minutes. It was concluded that immunoreactive intermediates appear to be formed at an early stage of the folding process.

The β_2-subunit of *E. coli* tryptophan synthase is composed of two independently folding domains; F_1 (N-terminal) and F_2 (C-terminal) which can be isolated following mild proteolytic treatment of β_2 by trypsin. The effects of domain assembly on the conformations of the F_1 and F_2 domains were analyzed using six mAbs which recognize six different epitopes of the native β_2-subunit.[26] It was found that the association of the F_1 and F_2 domains within β_2 is accompanied by structural changes within the two domains, as detected by variations in their affinity constants for the mAbs.

The building of the quaternary structure of proteins composed of several protein subunits is often accompanied by corresponding subtle conformational changes in each of the subunits. Monoclonal antibodies can be used here to detect suspected conformational alterations. Such alterations have been observed, for example, in the case of glutamine synthetase, an enzyme composed of 12 identical subunits. Some of the mAbs prepared against this enzyme[27] were found to bind only to the monomeric form, whereas others recognize the full dodecameric form.

An interesting use of mAbs is in the detection of the assembly of mouse muscle acetylcholine receptors in vivo.[28] The receptor consists of α, β, γ, and δ subunits. With the aid of the mAbs prepared, one α-subunit species that may be an assembly intermediate has been identified.

Detection of Conformational Changes Induced by Heat and Absorption onto Solid Supports

The susceptibility of the tertiary structure of proteins to heat, to denaturants such as urea and guanidine hydrochloride, and to extreme pH value, is well-known. Such conformational alterations have been readily detected by means of polyclonal antibodies directed either to the native or to the denatured corresponding protein antigen. There is also considerable evidence that the binding of proteins to plastic surfaces, or to other organic or inorganic surfaces, may cause partial denaturation and lead to changes in protein conformation and antigenicity.[29–33] One might even predict that the specific environment to which enzymes, receptors and other biologically active proteins are exposed when embedded in native membranes could affect their conformation. Milne et al.[34] have recently demonstrated that mAbs can also be used to distinguish between the lipid dependent and reversible conformational states of human apolipoprotein B.

Vaidya et al.[32] reported marked modifications in the antigenic behavior of creatine kinase (CK) and lactate dehydrogenase (LDH) after their adsorption onto polystyrene plates, as revealed by their corresponding mAbs. Hybridomas producing anti-CK and anti-LDH antibodies were screened by an enzyme-linked immunosorbent assay (ELISA) with antigen coated onto plastic wells. Of seven antibodies that were positive for each isoenzyme of CK, four failed to bind to the native enzyme in solution. Moreover, none of the mAbs prepared against the various LDH isoenzymes, interacted with the corresponding enzyme in solution. These results strongly support the suggestion made that the conformation of protein-antigen in the solid phase may differ from that in solution. Observations similar to those of Vaidya et al.[32] were recorded in our own laboratory where it has been found that the mAb MF 30 against human lactate dehydrogenase isoenzyme 5 (HLDH5) was found to interact with HLDH5 adsorbed onto the polystyrene microtiter plate, but not with the enzyme in solution.[35] In contrast, mAb 2/66 prepared against porcine lactate dehydrogenase 5 (PLDH5) reacted equally well with HLDH5, when in solution and when adsorbed onto polystyrene. Following its denaturation by heating to 70 °C HLDH5 no longer reacted with mAb 2/66. The findings obtained are summarized in Table 1. Our data obtained suggest that the mAbs MF30 and 2/66 recognize two different antigenic sites of HLDH5. The antigenic site which is recognized by 2/66, and is present in the native enzyme both in solution and when adsorbed onto polystyrene, disappears on heating. The other antigenic determinant is recognized by mAb MF30 when the enzyme is adsorbed onto a polystyrene surface both before and after heat treatment.

Table 1. Qualitative Description of the Binding of the mAbs 2/66 and MF30 with Native and Heat Treated Human or Porcine Lactate Dehydrogenase Isoenzyme 5 (HLDH5 or PLDH5) when in Solution or Adsorbed onto Polystyrene

Monoclonal antibody	Solution[a]				Adsorbed onto polystyrene surface[b]			
	HLDH5		PLDH5		HLDH5		PLDH5	
	Nat.[d]	Ht.[d]	Nat.	Ht.	Nat.	Ht.	Nat.	Ht.
2/66[c]	+	−	+	−	+	−	+	−
MF30[c]	−	−	−	−	+	+	−	+

a) The native and heat-treated enzymes were allowed to interact with the corresponding monoclonal antibodies in solution. b) Interaction was allowed to take place between the native or heat-treated enzymes adsorbed onto polystyrene and corresponding antibodies kept in solution. c) 2/66 and MF30 denote the monoclonal antibodies obtained against porcine and human LDH5 isoenzymes, respectively. d) Nat. stands for native enzyme; Ht. stands for enzyme heated in PBS, pH 7.5, for 45 s at 70 °C (see Ref. 35).

Subtle conformational alterations in the antigenic region of carboxypeptidase-A(CPA) between the amino acid residues 209—218 following the adsorption of CPA onto polystyrene were also detected by our group with the aid of three mAbs directed towards this antigenic region.[23,36] The mAbs interacted with CPA with relatively high binding constants without affecting the enzyme's activity. Binding of the three mAbs with CPA adsorbed onto the polystyene plates was characterized by apparent binding constants which were higher by one or two orders of magnitude than the corresponding binding constants characterizing their interaction in solution. The conformational alterations occurring in CPA following its treatment with urea were also readily detectable by the mAbs employed.

Detection by mAbs of subtle conformational changes in proteins following their physical adsorption to solid supports has also been reported by the French school. Friguet et al.,[30] using mAbs directed against different epitopes of the β_2-subunit of *E. coli* tryptophan synthase, have shown that some of the antibodies bind very slowly to the native β_2-subunit in solution, but recognize the antigen quite rapidly when adsorbed onto a microtiter plate. Their observation imply that the ELISA test commonly used in screening for specific hybridomas may lead to the retention of antibodies not specific for the native conformation of the antigen.

Also investigated by our group was the interaction of mAbs raised against native hen egg white lysozyme (HEL) with the enzyme after its partial irreversible denaturation by heating. This antigen/antibody system was chosen because it has been well-characterized by the Pasteur group.[4] Irreversibly heat-denatured HEL (D. Kenett, unpublished results) was recognized by the mAbs D44.2 directed against the "loop" region of the native enzyme and by the mAb D1.3 directed against the amino and carboxyl termini of the enzyme. The mAb D74.3, which binds to an

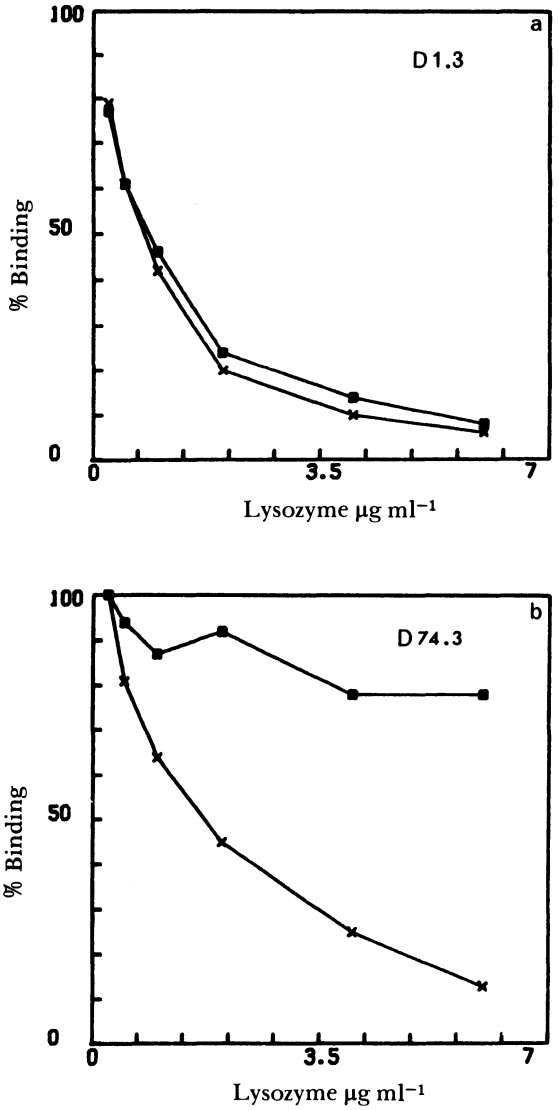

Fig. 1. Binding of the mAb D 1.3 (Fig. 1a) or mAb D 74.3 (Fig. 1b) onto HEL adsorbed on microtiter polystyrene plates in the presence of increasing concentrations of native (-X-X-) or partially heat denatured (-□-□-) (120 min at 95 °C, pH 5) enzyme.

epitope within the active site region of HEL, reacted only weakly with the denatured enzyme which lost most of its catalytic activity after heating (see Fig. 1). The active site of lysozyme is located in a cleft between two globular lobes which oscillate btween an open and a closed conformation during the catalytic cycle. As revealed by the mAbs, the active site appears to be more prone to conformational change than the rest of the molecule probably because of the hinge bending motion.

Monoclonal Antibodies as Topographical Probes

Monoclonal antibodies usually recognize a single well-characterized "surface" of a protein antigen. One might, therefore, expect to find them useful in building up a topographic picture of protein antigens, providing information about their orientation, attachment, ligand binding sites and carbohydrate attachment sites. They might be particularly useful in the elucidation of the molecular "surfaces" involved in subunit assembly, and the protein "surfaces" involved in the binding of a given protein with other proteins or with macro- or micro-environmental components.

The use of mAbs in the study of subunit assembly may be illustrated by the work of Moradi-Amel et al.[37] on the structure of mitochondrial F_1-ATPase. Four stable mAbs against pig heart mitochondrial F_1-ATPase were prepared. Three of them interact with the β-subunits and one binds strongly to the α-subunits. Quantitative analysis of the interaction of these mAbs with their corresponding subunits led to the prediction that mitochondrial F_1-ATPase consists of three α- and three β-subunits.

As an example of the use of mAbs in the topographical analysis of proteins, we might cite the elucidation of the position of the immunoglobulin (IgD) molecules within lymphocyte membranes using mAbs.[38,39] Treatment of intact cells with trypsin abolished the binding of mAb 11-6.3, but did not affect the binding of mAb 10-4.22. The mAb 11-6.3 was found to bind to the Fab portion of IgD, while mAb 10-4.22 bound to the Fc portion. It was thus conculded that IgD is enclosed within the lymphocyte cell membrane via its Fc portion.

The use of mAbs against subunits of human chorionic gonadotropin (hCG) in order to examine the orientation of the hormone in its complex with gonadal receptors, has been illustrated by Moyle et al.[40] hCG is a glycoprotein composed of α- and β-subunits which interact with gonadal receptors to stimulate steroid synthesis. The purified mAbs obtained were iodinated and used to determine which antigenic sites on hCG remained free in the hCG-receptor complexes. The resulting data indicated that portions of the β-subunit were buried (i.e. failed to bind with radiolabeled antibody), whereas other portions remained exposed (i.e., they bound with radiolabeled antibody). Those antibodies which interacted with portions of hCG that became inaccessible in the hCG-receptor complex also blocked the biological action of hCG, whereas those that interacted with exposed sites had little or no effect on its activity. A similar approach was used in order to determine the orientation of a human leukocyte interferon molecule on its cell surface.[41] Using a mAb against a synthetic interferon fragment, it was possible to show that the carboxyl terminus of the interferon remains accessible to the mAb even after its interaction with the corresponding cell surface receptor.

The use of mAbs as probes of the α-bungarotoxin (αBTx) and cholinergic-binding regions of the acetylcholine receptor (AcChR)[42] revealed the non-equivalence of the two αBTx binding regions of the AcChR molecule. Furthermore, it was possible to identify epitopes on the αBTx binding region that, when bound, produce differential effects on the binding of the agonist carbamyl-choline and the antagonist d-tubocurarine.

Concluding Remarks

We have shown here that mAbs might serve as useful probes in the detection of given protein conformations and conformational alterations. The high specificity of mAbs towards given antigen determinant conformations was recently illustrated by the preparation of "abzymes," i.e. mAbs that can catalyze a chemical reaction because they have been made to recognize the transition state of the reaction under consideration.[43] The value of mAbs as conformational probes will no doubt increase as more detailed information is acquired as to the structure of the antigenic epitopes which they recognize. In this respect, the production of mAbs of predetermined specificity by means of selected peptides might be of considerable importance.

Since mAbs prepared against a given protein recognize different antigenic sites of the antigen, it should be possible to use them in detecting the effect of amino acid substitution by site-directed mutagenesis on the conformation of different molecular regions. They may thus pave the way for the preparation of highly stable proteins under selected conditions.

In the section dealing with the use of mAbs as topographical probes, we have shown that they can be used in the elucidation of the quaternary structure of proteins, receptors and more complex biological systems. Their application in this area will undoubtedly increase in the future.

The use of mAbs as conformational probes is relatively new. Their use in conjunction with other methods in studies on structure and function is promising.

Invited Paper

Synthesis of Three Acyclic All-*trans*-Tetraterpene Diols, Putative Precursors of Bacterial Lipids

Bertrand CHAPPE,* Hélène MUSIKAS, Dominique MARIE, and Guy OURISSON
Institut de Chimie des Substances Naturelles du CNRS, 91198-Gif-sur-Yvette, France
(Received August 10, 1987)

Three acyclic all-*trans*-tetraterpene diols, **A**, **B**, and **C** have been synthesized from geraniol (**1**), by a convergent scheme involving six different C_{10} synthons derived from geraniol, and coupling by known reactions of three different types: substitution of allylic chlorides by carbanions α to sulfones, duplication of allylic alcohols, and Pd(0)-catalyzed coupling of allylic carbonates with doubly stabilized carbanions. **A**, **B**, and **C** represent postulated phylogenetic precursors of known membrane reinforcers, and are the three possible distally dihydroxylated dimers of geranylgeraniol: tail-to-tail, head-to-head, and head-to-tail.

We describe below the syntheses of three acyclic all-*trans*-tetraterpene diols **A**, **B**, and **C**, representing the three possible modes of coupling geranylgeraniol units (**A**: tail-to-tail, **B**: head-to-head, and **C**: head-to-tail). The diols thus obtained are distally dihydroxylated polyterpene chains about 40 Å long, and should therefore be able to form transmembrane inserts in normal biological phospholipid bilayers; they have been postulated[1] to be phylogenetic precursors of bacterial membrane-spanning carotenoids,[2] of the tricyclopolyprenols assumed from their known molecular fossils to be bacterial membrane lipids,[3] and of the known archaebacterial phospholipids.[4] **A**, **B**, and **C** are thus not known *per se* as natural products. We plan, and have begun, to test their membrane properties, either as such or as part of phospholipids or of other highly polar derivatives (phosphates, glucosides, ···), and also to test their effect on some lipid-dependent microorganisms.

The syntheses so far carried out have been limited to the all-trans substances; we plan to complete them later with syntheses of some of their Z-isomers, at least for the head-to-tail diol **C**: biologically important regular polyterpenols are often partially Z.

C

Methods and Results

The syntheses of carotenoids have illustrated the various ingenious ways to reach C_{40} by all possible arithmetic combinations of smaller units. We have chosen for our syntheses to start from the readily available geraniol (**1**), which was first modified in three ways to obtain the C_{10} properly functionnalized derivatives **5**, **7**, and **9**; the chloride **5** is the potential source of an allylic carbenium ion on one of the "head" methyl groups, and sulfones **7** and **9** function as potential sources of allylic carbanions on C-1, the "tail" of the geraniol unit, with different hydroxylation patterns at the "head". The practical synthetic problems have revolved around the proper choice of temporary protecting groups and of efficient coupling methods.

The protecting groups used have been chosen to permit selective removals; they include THP (tetrahydropyranyl), MEM (2-methoxyethoxymethoxy) and tBDMS (*t*-butyldimethylsilyl) ethers. The coupling methods involve base-catalyzed reaction of allylic chlorides with allylic sulfones, reductive dimerization of allylic alcohols with Ti(III), and Pd(0)-catalyzed reaction of allylic carbonates with allylic carbanions

Dedicated respectfully and with admiration to Professor Edgar Lederer, on the occasion of his approaching 80th birthday (G.O.).

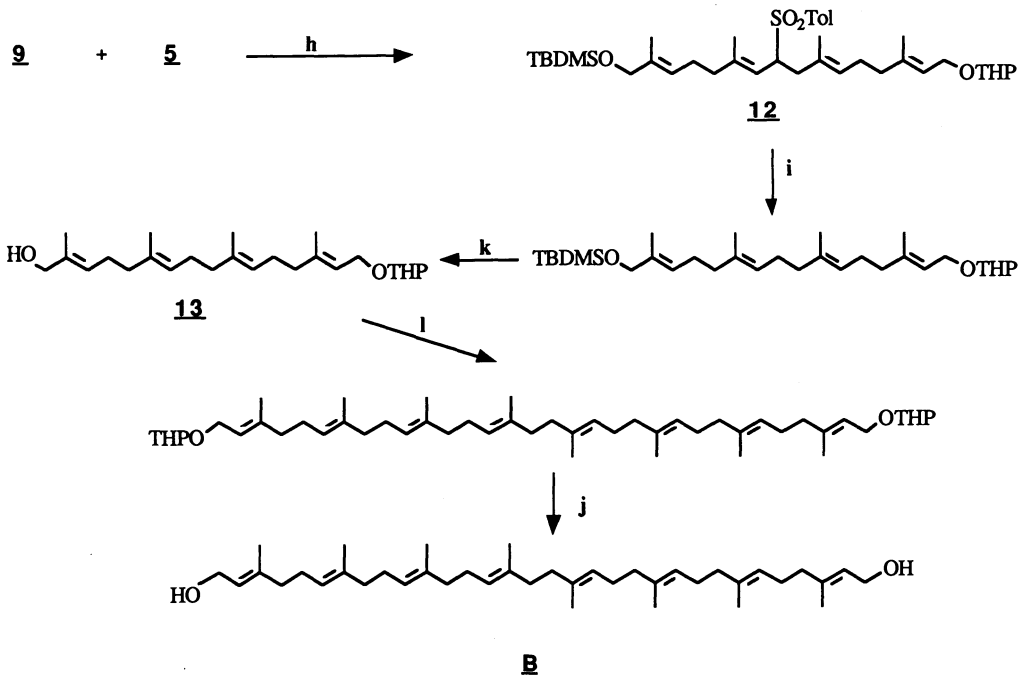
(in this case, with additional stabilization of the carbanion by a methoxycarbonyl group geminated with the sulfone).

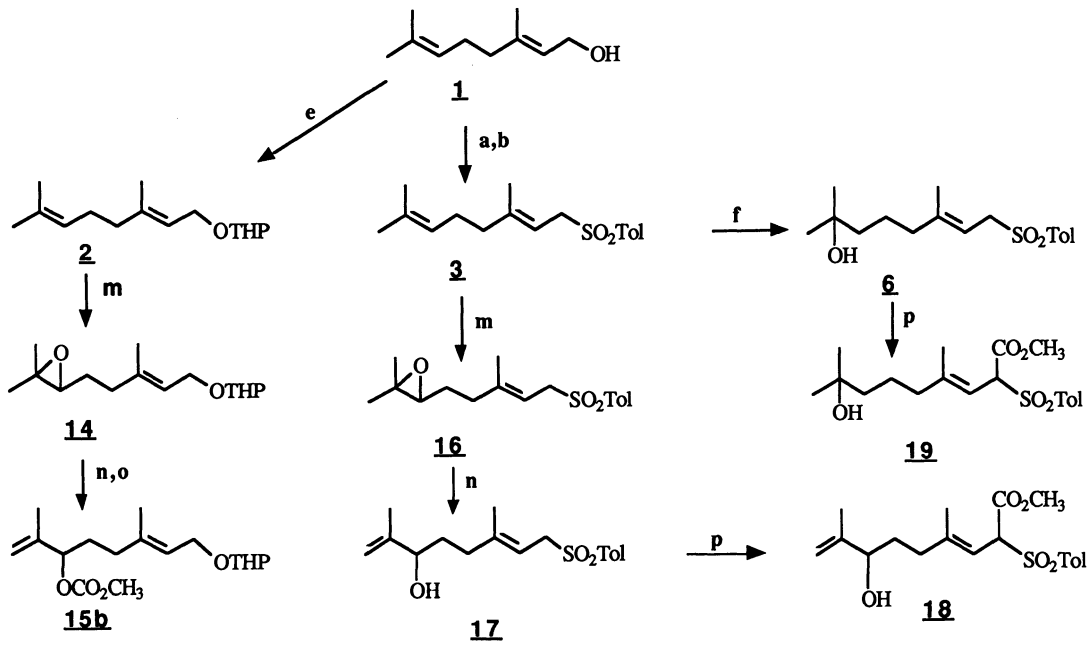
Chloride **5** was obtained by reaction of the THP-protected hydroxygeraniol **4** by reaction with tosyl chloride and triethylamine/4-dimethylaminopyridine.[5] The allylic oxidation of geranyl-THP ether **2** was efficiently achieved with *t*-butyl hydroperoxide with selenium dioxide as a catalyst;[6] this method is known to oxidize selectively the (E)-methyl group. Geraniol (**1**) itself gave, by the same chlorination method, geranyl chloride which was directly transformed into the *p*-tolyl sulfone **3** by reaction with sodium *p*-toluenesulfinate in DMF.[7] Geranyl *p*-tolylsulfone (**3**) was converted into the alcohols **6** and **8**, respectively by Brown's mercuration-reduction sequence,[8] and by the SeO_2-catalyzed allylic oxidation already mentioned.

The C_{10} sulfone **7** has next been converted with butyllithium into its carbanion, which reacted with the chloride **5** to give the C_{20} sulfone **10**; this was desulfonated by mild reduction with sodium amalgam in methanol, in the presence of disodium hydrogenphosphate.[9] After acid-catalyzed deprotection, the allylic alcohol **11b** was reductively duplicated with titanium trichloride and butyllithium,[10] to give the first C_{40} diol wanted, the tail-to-tail tetraterpenediol **A**.

The second goal, the head-to-head diol **B**, was similarly obtained, by identical reactions, from the same chloride **5** and the other sulfone **9**. In this case, the use of a tBDMS-ether permitted the selective deprotection with tetrabutylammonium fluoride (TBAF) of the silyl ether,[11] to unmask one only of the two allylic groups of the C_{20} chain, before the allylic



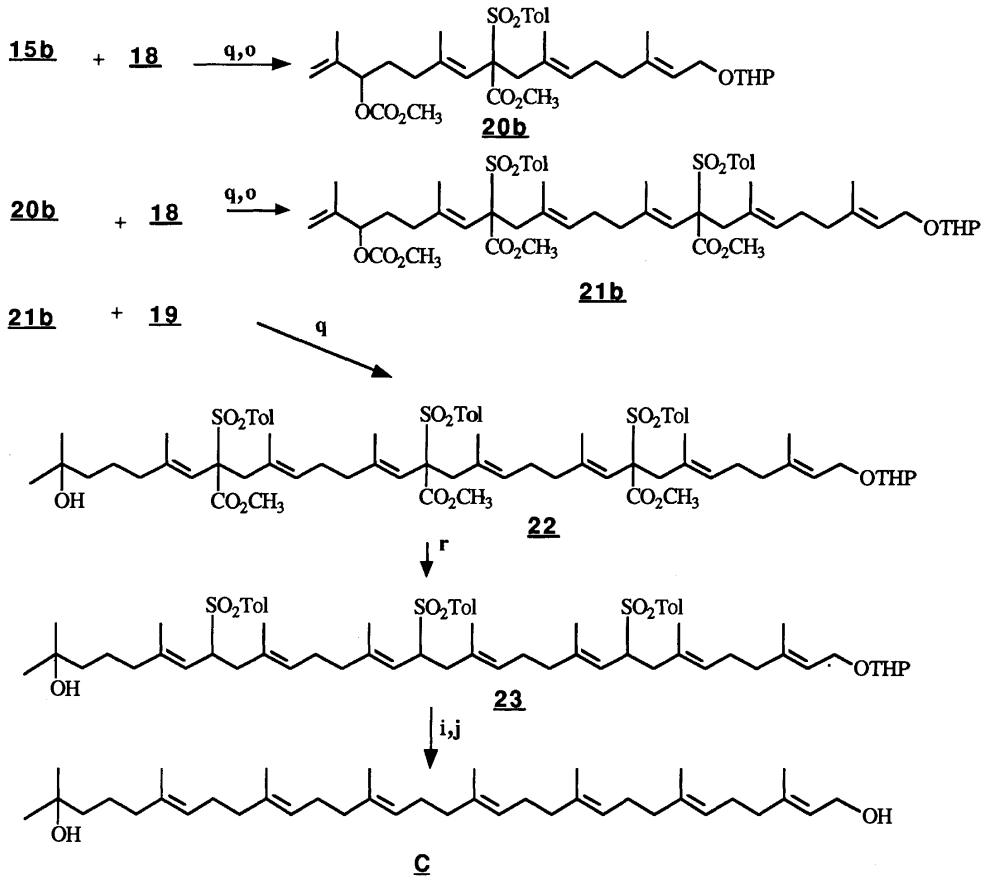
Scheme 3. h: *n*-BuLi/THF; i: Na/Hg, Na_2HPO_4/MeOH; j: TsOH/EtOH; k: TBAF/THF; l: $TiCl_3$, *n*-BuLi/Dimethoxyethane.



Scheme 4. a: TsCl, DMAP, TEA/CH_2Cl_2; b: *p*-$MeC_6H_4SO_2Na$/DMF; f: $(AcO)_2Hg$, NaOH, $NaBH_4$/THF, H_2O; m: mCPBA/CH_2Cl_2; n: $(C_3H_7O)_3Al$/*i*-PrOH/Tol; o: $ClCO_2Me$, Py/Tol; p: Me_2CO_3, *t*-BuOK/DMF.

alcohol **13** was coupled as before.

The third tetraterpene diol, **C**, has a regular head-to-tail polyprenyl chain. It was synthesized by iteration, according to a C_{10}–C_{20}–C_{30}–C_{40} sequence. The coupling reaction used was that developed by Keynan.[12] This required first the construction of the new C_{10} building blocks **15b**, **18**, and **19**; the known isomerization of epoxides into allylic alcohols with aluminium isopropoxide[13] paved the way for condensation, with the help of Pd(0) as its triphenylphosphine tetracoordinated complex, of the corresponding allylic carbonate. The demethoxycarbonylation was



Scheme 5. i: Na/Hg, Na_2HPO_4/MeOH; j: TsOH/EtOH; o: $ClCO_2Me$, Py/Tol; q: $(Ph_3P)_4Pd/Et_2O$; r: PATP, $CsCO_3$/DMF.

achieved with 4-aminothiophenol (PATP) and cesium carbonate, and the removal of the sulfone residues as above with sodium amalgam.

The convergent nature of this synthesis has made it possible to obtain sufficient amounts for the physical studies, which will be reported later.

Experimental

General Methods: NMR spectra were recorded in deuterochloroform with tetramethylsilane as internal standard on Bruker 80, 200 or 400 MHz spectrometers and are expressed as δ. Mass spectra: Kratos MS-80 or MS-9 spectrometers; expressed as m/z. Infrared spectra: chloroform solutions, Perkin-Elmer 297 spectrophotometer; date in agreement with the structures, available on request. Elemental analyses were carried out in the microanalytical laboratory of ICSN by Mlle C. Muller. Thin-layer chromatography (TLC): on Merck silica gel 60-F254 glass plates. Column chromatography: on Chromatogel 60ACC, 70—230 mesh or (for flash chromatography) 230—400 mesh silica gel. All solvents were freshly distilled; tetrahydrofuran (THF) was dried by distillation over sodium-benzophenone, ether by distillation over lithium aluminium hydride, *N,N*-dimethylformamide (DMF) by distillation over calcium hydride, methylene chloride by distillation over calcium chloride. All the substances obtained are oils, which gave however in general good analytical results after purification by flash chromatography monitored by TLC.

General Treatment of Ether Extracts: The usual treatment of ether extracts was to wash them successively with water, if necessary with dilute acid or alkali and again with water, and with saturated brine; they were then dried over anhydrous sodium sulfate and evaporated in vacuo.

General Procedure for Removal of *p*-Tolylsulfonyl Groups: To a mixture of sulfone (1 mol) and disodium hydrogenphosphate (4 mol) in anhydrous methanol, was added at 0 °C an excess of freshly prepared 6% sodium amalgam. Stirring was continued at 0 °C until the starting material had disappeared (TLC), and excess amalgam was destroyed with cold water. The ether extract of the reaction mixture was treated as usual and chromatographed on silica gel.

General Procedure for Terminal Allylic Oxidation: To a solution of selenium dioxide (0.03 mol) in methylene chloride, was added 70% *t*-butyl hydroperoxide (3 mol). The mixture was stirred at 25 °C for 30 min, then the substrate (1 mol) was introduced as a solution in methylene chloride, and stirring was continued for 20 h at 25 °C. Toluene was added, and the solvents were removed in a rotatory evaporator in vacuo. The residue was extracted three times with ether. The ether extract was treated as usual. The residue was dissolved in ethanol and treated with sodium borohydride at 0 °C for 1 h. Cold water was added, the

reaction mixture was extracted with ether, and the ether extract was treated as usual. Flash chromatography was used to isolate the allylic alcohol.

Geranyl Tetrahydropyranyl Ether (2). To a solution of geraniol (**1**) (15.4 g, 0.1 mol) in dry methylene chloride, were added dihydropyran (12.6 g, 0.15 mol) and *p*-toluenesulfonic acid (2.5 g, 0.01 mol). The mixture was stirred for 3 h at room temperature, and evaporated in vacuo. The ether extract of the residue was treated as usual. Filtration on silica gel gave the ether **2** (23.7 g, 99.5%). R_f=0.95 (hexane/ether 1/1). ^{1}H NMR: 5.39 (t, 1H), 5.10 (m, 1H), 4.65 (s, 1H), 4.31 (m, 2H), 3.60 (m, 2H), 2.08 (m, 4H), 1.73 (s, 6H), 1.60 (s, 9H); MS 238 (M^+), 137 (M^+−OTHP). Found: C, 75.4; H, 10.8; O, 13.5%. Calcd for $C_{15}H_{26}O_2$: C, 75.63; H, 10.92; O, 13.45%.

Geranyl *p*-Tolyl Sulfone (3). To a stirred solution of geraniol (**1**) (15.6 g, 0.101 mol) in dry methylene chloride (30 ml), were added at room temperature under an argon atmosphere 4-(dimethylamino)pyridine (DMAP, 7.15 g, 0.06 mol), *p*-toluenesulfonyl chloride (23.2 g, 0.12 mol) and triethylamine (14.09 ml, 0.1 mol). Stirring was maintained during 3 h, and methylene chloride was removed in vacuo. The ether extract of the residue was first washed with 10% $CuSO_4$, then with 10% $NaHCO_3$, and finally treated as usual, and purified by flash chromatography to give geranyl chloride (17.03 g, 97%), characterized by its ^{1}H NMR and mass spectra (*m/z* 172—174 M^+). R_f=0.96 (hexane/ether 1/1). Geranyl chloride (3.8 g, 22 mmol) in dry DMF (50 ml) was treated overnight at 25 °C with sodium *p*-toluenesulfinate (4.3 g, 24 mmol) under nitrogen. After evaporation of the solvent, addition of water and extraction with ether, the extract was treated as usual, and purified by flash chromatography (hexane/ether 1/1) to give geranyl *p*-tolyl sulfone (**3**) (5.6 g, 86%) as a colorless oil, apparently crystallizable at low temperature, but which we could not further purify (cf. analysis below). R_f 0.97 (ether). ^{1}H NMR 7.62 (d, 2H), 7.13 (d, 2H), 5.07 (m, 2H), 3.77 (m, 2H), 2.35 (s, 3H), 2.00 (d, 4H), 1.73 (s, 3H), 1.63 (s, 3H), 1.40 (s, 3H). MS 292 (M^+), 137 (M^+−$TolSO_2$). Found: C, 70.2; H, 8.5; S, 10.6%. Calcd for $C_{17}H_{24}O_2S$: C, 69.22; H, 8.5; S, 10.96%.

(2*E*,6*E*)-1-(Tetrahydro-2-pyranyloxy)-3,7-dimethyl-2,6-octadien-8-ol (4). Geranyl tetrahydropyranyl ether (**2**) (4.05 g, 17 mmol) was oxidized with *t*-BuOOH/SeO_2 according to the general procedure. After purification by flash chromatography on silica gel (hexane/ether 1/1), the mono THP-ether **4** was obtained (2.46 g, 57%). R_f 0.17 (hexane/ether 1/1). ^{1}H NMR 5.25 (m, 2H), 4.52 (s, 1H), 4.15—3.70 (m, 6H), 2.83 (s, 1H), 2.08 (m, 4H), 1.63 (m, 12H). MS 254 (M^+), 236 (M^+−H_2O), 153 (M^+−OTHP). Found: C, 70.6; H, 10.2; O, 19.2%. Calcd for $C_{15}H_{26}O_3$: C, 70.87; H, 10.24; O, 18.90%.

(2*E*,6*E*)-8-Chloro-1-(tetrahydro-2-pyranyloxy)-3,7-dimethyl-2,6-octadiene (5). To a solution of the mono THP-ether **4** (4.2 g, 16 mmol) in dry methylene chloride (40 ml) were added sequentially under nitrogen at 25 °C 4-(dimethylamino)pyridine (1.21 g, 10 mmol), tosyl chloride (3.8 g, 20 mmol) and triethylamine (2.22 ml, 16 mmol). The reaction mixture was stirred for 3 h, and methylene chloride was removed was removed in vacuo. The residue, diluted with water, was extracted 4 times with ether, with gentle magnetic stirring. Purification on silica gel afforded 4.55 g of pure chloride **5** (95%) as a colorless oil which could not be obtained analytically pure. R_f 0.97 (hexane/ether 1/1). ^{1}H NMR 5.27 (m, 2H), 4.50 (s, 1H), 4.15—3.70 (m, 6H), 2.08 (m, 4H), 1.67 (s, 3H), 1.57 (s, 3H), 1.67—1.57 (m, 6H). MS 274—272 (M^+), 236 (M^+−HCl).

(2*E*)-1-(*p*-Tolylsulfonyl)-3,7-dimethyl-2-octen-7-ol (6). To a magnetically stirred solution of sulfone **3** (3.1 g, 10.6 mmol) in THF (40 ml) and water (10 ml), was added with ice cooling mercuric acetate (3.38 g, 10.6 mmol). After 2 h, the reaction was completed by addition of 3 M sodium hydroxide (10 ml) and 0.5 M sodium borohydride in 3 M sodium hydroxide (10 ml). Stirring was continued for 30 min. The reaction mixture was saturated with potassium carbonate and extracted with ether. The extract was treated as usual, evaporated and purified on silica gel to give the hydroxy sulfone **6** (2.95 g, 89%). R_f 0.50 (ether). ^{1}H NMR 7.71 (d, 2H), 7.29 (d, 2H), 5.16 (t, 1H), 3.76 (d, 2H), 2.44 (s, 3H), 2.08 (m, 2H), 1.37 (s, 3H), 1.52—1.30 (m, 5H), 1.22 (s, 6H). MS 310 (M^+), 292 (M^+−H_2O). Found: C, 65.7; H, 8.7; O, 15.6; S, 10.05%. Calcd for $C_{17}H_{26}O_3S$: C,65.80; H, 8.38; O, 15.48; S, 10.32%.

(2*E*)-1-(*p*-Tolylsulfonyl)-7-(2-methoxyethoxymethoxy)-3,7-dimethyl-2-octene (7). To a stirred solution of the hydroxy sulfone **6** (2.8 g, 9 mmol) in dry methylene chloride (30 ml), were added at 25 °C *N,N*-diisopropylethylamine (DIPEA, 2.4 ml, 13.9 mmol) and MEM-chloride (1.6 ml, 14 mmol). Stirring was continued for 4 h (disappearance of the starting material, TLC), water and ether were added and the ether extract was treated as usual. Purification on silica gel afforded the MEM-ether **7** (3.45 g, 96%). R_f 0.72 (ether). ^{1}H NMR: 7.65 (d, 2H), 7.23 (d, 2H), 5.13 (m, 1H), 4.72 (s, 2H), 3.78 (d, 2H), 3.73—3.42 (m, 4H), 3.30 (s, 3H), 2.43 (s, 3H), 2.08—1.83 (m, 2H), 1.48—1.31 (m, 4H), 1.37 (s, 3H), 1.22 (s, 6H). MS 398 (M^+), 367 (M^+−31). Found: C, 63.0; H, 8.5; S, 7.74%. Calcd for $C_{21}H_{34}O_5S$: C, 63.31; H, 8.54; S, 8.04%.

(2*E*,6*E*)-1-(*p*-Tolylsulfonyl)-3,7-dimethyl-2,6-octadien-8-ol (8). Sulfone **3** (2.52 g, 8.6 mmol) was oxidized with *t*-BuOOH/SeO_2 in methylene chloride according to the general procedure, which afforded the hydroxy sulfone **8** (1.75 g, 66%). R_f 0.54 (ether). ^{1}H NMR 7.72 (d, 2H), 7.29 (d, 2H), 5.25 (m, 2H), 4.00 (s, 2H), 3.83 (d, 2H), 2.45 (s, 3H), 2.08 (m, 4H), 1.66 (s, 4H), 1.42 (s, 3H). MS 308 (M^+), 153 (M^+−$TolSO_2$). Found: C, 66.3; H, 7.8; O, 15.5; S, 10.2%. Calcd for $C_{17}H_{24}O_3S$: C, 66.23; H, 7.79; O, 15.58; S 10.39%.

(2*E*,6*E*)-1-(*p*-Tolylsulfonyl)-8-(*t*-butyldimethylsilyloxy)-3,7-dimethyl-2,6-octadiene (9). A stirred mixture of the hydroxy sulfone **8** (4.21 g, 13.6 mmol), *N,N*-diisopropylethylamine (3.56 ml, 20.5 mmol) and disodium hydrogenphosphate (7.75 g, 54.6 mmole) in dry DMF was treated at 25 °C with *t*-butyldimethylsilyl chloride (2.46 g, 16.4 mmol). Stirring was continued for 3 h at room temperature, water and ether were added and the ether extract was teated as usual. After evaporation in vacuo and flash chromatography on silica gel, the TBDMS-ether **9** was obtained (5.55 g, 96%). ^{1}H NMR 7.70 (d, 2H), 7.25 (d, 2H), 5.25 (m, 2H), 3.98 (s, 2H), 3.75 (d, 2H), 2.42 (s, 3H), 2.07 (m, 4H), 1.57 (s, 3H), 1.35 (s, 3H), 0.90 (s, 9H), 0.08 (s, 6H). MS (CI, NH_3) 423 (M^++1), 291 (M^++1−*t*-BuDMSiOH). Found: C, 65.5; H, 8.75%. Calcd for $C_{23}H_{38}O_3SiS$: C, 65.40; H, 9.00%.

(2*E*,6*E*,10*E*)-1-(Tetrahydro-2-pyranyloxy)-9-(*p*-tolylsulfonyl)-15-(2-methoxyethoxymethoxy)-3,7,11,15-tetramethyl-2,6,10-hexadecatriene (10). To a stirred solution of the MEM-sulfone **7** (3.35 g, 8.42 mmol) in dry THF (40 ml) and HMPA (10 ml), was added at −78 °C, under nitrogen, a solution of

n-BuLi (6.6 ml, 9.25 mmol). After 2h, was added at −78 °C, over 1 h a solution of the THP-chloride **5** (2.52 g, 9.25 mmol) in dry THF (8 ml) and HMPA (2 ml). The mixture was stirred overnight and worked up as usual. The crude product, after flash chromatography (ether/hexane 1/1) gave the triene **10** (3.2 g, 58%). R_f 0.3 (ether/hexane 1/1). ^{1}H NMR 7.70 (d, 2H), 7.26 (d, 2H), 5.57—4.98 (m, 3H), 4.78 (s, 2H), 4.58 (s, 1H), 4.37—3.78 (m, 5H), 3.78—3.45 (m, 4H), 3.38 (s, 3H), 2.43 (s, 3H), 2.32—1.78 (m, 8H), 1.75—1.46 (m, 6H), 1.67 (s, 9H), 1.46—1.32 (m, 4H), 1.22 (s, 6H). MS 634 (M^+), 603 (M^+-31). Found; C, 68.3; H, 9.0; O, 17.8; S, 4.8%. Calcd for $C_{36}H_{58}O_7S$: C, 68.14; H, 9.15; O, 17.67; S, 5.04%.

(2*E*,6*E*,10*E*)-1-(Tetrahydro-2-pyranyloxy)-15-(2-methoxyethoxymethoxy)-3,7,11,15-tetramethyl-2,6,10-hexadecatriene (11a). Elimination of the *p*-tolylsulfonyl group of the preceding product **10** (3.1 g, 4.9 mmol) was carried out according to the general procedure to give the THP-MEM-protected triene **11a** (2.12 g, 90%). R_f 0.55 (hexane/ether 1/1). ^{1}H NMR 5.47—4.95 (m, 3H), 4.78 (s, 2H), 4.58 (s, 1H), 4.37—3.80 (m, 4H), 3.80—3.46 (m, 4H), 3.38 (s, 3H), 2.22—1.80 (m, 10H), 1.75—1.55 (m, 15H), 1.55—1.38 (m, 4H), 1.22 (s, 6H). MS 480 (M^+), 404 ($M^+-HOCH_2CH_2OCH_3$), 374 ($M^+-HOMEM$). Found: C, 72.7; H, 11.0; O, 16.4%. Calcd for $C_{29}H_{52}O_5$: C, 72.50; H, 10.83; O, 16.67%.

(2*E*,6*E*,10*E*)-3,7,11,15-Tetramethyl-2,6,10-hexadecatriene-1,15-diol (11b). The THP-MEM ether **11a** (1.3 g, 2.7 mmol) was treated with *p*-toluenesulfonic acid in ethanol at 55 °C for 3 h. The solvent was removed in vacuo and water was added. The rection mixture was taken in ether and treated as usual. Flash chromatography afforded the diol **11b** (0.3 g) and two partially deprotected products, which were treated again with *p*-TsOH in the same conditions, to give 0.218 g more of the diol **11b**. Total yield 0.518 g (62%). ^{1}H NMR 5.52—4.95 (m, 3H), 4.11 (d, 2H), 2.63 (s, 1H), 2.26—1.83 (m, 10H), 1.68 (s)+1.60 (s)+1 OH (10H), 1.52—1.28 (m, 4H), 1.21 (s, 6H). MS (CI, NH_3): 291 (MH^+-H_2O), 273 (MH^+-2H_2O). Found: C, 78.1; H, 11.5; O, 10.6%. Calcd. for $C_{20}H_{36}O_2$: C, 77.92; H, 11.69; O, 10.39%.

(6*E*,10*E*,14*E*,18*E*,22*E*,26*E*,)-2,6,10,14,19,23,27,31-Octamethyl-6,10,14,18,22,26-dotriacontahexaene-2,31-diol (A). To a stirred solution of titanium trichloride (75 mg, 0.49 mmol) in dry 1,2-dimethoxyethane (2 ml), was added at −78 °C *n*-BuLi (1.1 ml, 1.40 mmol). After 5 min, alcohol **11b** (300 mg, 0.97 mmol) was added, and the reaction mixture was warmed to room temperature and retained for 15 min before addition of water and ether. The ether extract was treated as usual and silica gel chromatography gave the desired diol **A** (100 mg, 35%). ^{1}H NMR 5.25—4.91 (m, 6H), 2.60 (s, 2H), 2.17—1.87 (m, 24H), 1.62 (m, 18H), 1.47—1.31 (m, 8H), 1.22 (s, 12H). MS 582 (M^+), 564 (M^+-H_2O), 546 (M^+-2H_2O). Found: C, 82.1; H, 11.9%. Calcd for $C_{40}H_{70}O_2$: C, 82.47; H, 12.02%.

(2*E*,6*E*,10*E*,14*E*)-1-(*t*-Butyldimethylsilyloxy)-8-(*p*-tolylsulfonyl)-16-(tetrahydro-2-pyranyloxy)-2,6,10,14-tetramethyl-2,6,10,14-hexadecatetraene (12). The allylic cross-coupling reaction between the sulfone **9** (5.55 g, 13.15 mmol) and the chloride **5** (4.29 g, 15.77 mmol) was carried out in the same manner as for the synthesis of **10** from **5** and **7**. Yield: 6.85 g (72%). ^{1}H NMR 7.65 (d, 2H), 7.23 (d, 2H), 5.37—4.75 (m, 4H), 4.58 (s, 1H), 4.18—3.30 (m, 5H), 3.98 (s, 2H), 2.43 (s, 3H), 2.00—1.91 (m, 10H), 1.64 (s, 3H), 1.58 (s, 3H), 1.64—1.48 (m, 6H), 1.23 (s, 6H), 0.90 (s, 9H) 0.08 (s, 6H). MS 658 (M^+), 573 (M^+-THP), 557 (M^+-OTHP). Found: C, 69.2; H, 9.6; S, 4.9%. Calcd for $C_{38}H_{62}O_5SSi$: C, 69.30; H, 9.42; S, 4.86%.

(2*E*,6*E*,10*E*,14*E*)-16-(Tetrahydro-2-pyranyloxy)-2,6,10,14-tetramethyl-2,6,10,14-hexadecatetraen-1-ol (13). The TBDMS-THP ether **12** (3.07 g, 4.66 mmol) was treated with sodium amalgam according to the general procedure for sulfone removal. The reaction mixture was purified on silica gel and afforded the desulfonated product (2.05 g, 87%; R_f=0.9 in hexane/ether 7/3).

This product (1.84 g, 3.65 mmol) was treated for 3 h at 25 °C with N (*n*-Bu)$_4$NF in THF (10.7 ml, 3 equiv). The solvent was removed and the crude product, obtained from the ether extract in the usual way, was purified on sillica gel (hexane/ehter 7/3), to give the THP-monoprotected diol **13** (1.14 g, 81%). ^{1}H NMR 5.47—4.91 (m, 4H), 4.60 (s, 1H), 4.23—3.30 (m, 6H), 2.33—1.92 (m, 12H), 1.78—1.42 (m, 19H). MS (CI, NH_3) 408 ($M+NH_4^+$), 373 (MH^+-H_2O). Found: C, 76.75; H, 10.75; O, 12.3%. Calcd for $C_{25}H_{42}O_3$: C, 76.92; H, 10.77; O, 12.31%.

(2*E*,6*E*,10*E*,14*E*,18*E*,22*E*,26*E*,30*E*)-3,7,11,18,22,26,30-Octamethyl-2,6,10,14,18,22,26,30-dotriacontaoctaene-1,32-diol (B). The allylic coupling of the THP-monoprotected diol **13** (1 g, 2.56 mol) to give diol **B** was carried out with the same procedure as for the conversion of **11b** into **A**. The crude product was purified on silica gel (hexane/ether 7/3) to give the C_{40}-bis-THP-ether (0.22 g, 23%). This (0.18 g) was treated with *p*-TsOH in ethanol at 55 °C for 3 h. The solvent was evaporated in vacuo, the residue was extracted 4 time with ether and purified on silica gel (hexane/ether 1/1) to give the C_{40}-diol **B** (97 mg, 70%). ^{1}H NMR 5.55—4.98 (m, 8H), 4.72 (s, 2H), 4.17 (d, 4H), 2.32—1.91 (m, 28H), 1.70 (s, 12H), 1.62 (s, 12H). MS (CI, NH_3) 596 (MNH_4^+), 561 (MH^+-H_2O), 543 (MH^+-2H_2O). Found: C, 82.8; H, 11.6; O, 5.6%. Calcd for $C_{40}H_{66}O_2$: C, 83.04; H, 11.41; O, 5.53%.

(2*E*)-6,7-Epoxy-1-(tetrahydro-2-pyranyloxy)-3,7-dimethyl-2-octene (14). To a stirred solution of the THP-ether **2** (15 g, 63 mmol) in methylene chloride (100 ml), was added at 0 °C a solution of *m*-chloroperbenzoic acid (12 g) in the same solvent (100 ml). After 1 h, the reaction mixture was washed with a saturated solution of sodium hydrogencarbonate, water and brine, and was dried over sodium sulfate. The crude product was chromatographed on silica gel to give the epoxide **14** (12.3 g, 77%). R_f=0.83 (hexane/ether 1/1). ^{1}H NMR 5.30 (t, 1H), 4.52 (s, 1H), 4.30—3.23 (m, 4H), 2.60 (t, 1H), 2.11 (m, 2H), 1.62 (s, 3H), 1.96—1.30 (m, 8H), 1.22 (s, 3H), 1.18 (s, 3H). MS 254 (M^+), 169 (M^+-THP), 153 (M^+-OTHP). Found: C, 71.0; H, 10.15; O, 19.1%. Calcd for $C_{15}H_{26}O_3$: C, 70.87; H, 10.23; O, 18.90%.

(2*E*)-1-(Tetrahydro-2-pyranyloxy)-3,7-dimethyl-2,7-octadien-6-ol (15a). To a solution of the epoxide **14** (12.3 g, 48.4 mmol) in dry toluene (100 ml), was added a solution of aluminium isopropoxide in 2-propanol. The mixture was heated under reflux for 24 h, cooled, washed with N HCl (50 ml), water and brine, and dried over sodium sulfate. Flash chromatography (hexane/ether 1/1) on silica gel gave the allylic alcohol **15a** (10.7 g, 87%). R_f=0.45 (hexane/ether 1/1). ^{1}H NMR 5.31 (t, 1H), 4.85 (s, 1H), 4.76 (s, 1H), 4.52 (s, 1H), 4.32—3.26 (m, 5H), 2.35—1.87 (m, 2H), 1.87—1.35 (m, 3H+s, 6H at 1.68). MS 254 (M^+), 236 (M^+-H_2O), 170 (M^+-THP), 153 (M^+-OTHP). Found: C, 71.15; H, 10.1; O, 18.7%. Calcd for $C_{15}H_{26}O_3$: C, 70.87; H, 10.24; O, 18.90%.

(2*E*)-6-(Methoxycarbonyloxy)-1-(tetrahydro-2-pyranyloxy)-3,7-dimethyl-2,7-octadiene (15b). To a stirred solution of the alcohol **15a** (4.2 g, 16.5 mmol) in dry toluene (40 ml), were added at 25 °C, over 1 h, dry pyridine (2 ml) and methyl chloroformate (2 ml). Stirring was maintained for 12 h. The reaction mixture was washed with a dilute solution of ammonium chloride, water, a solution of copper sulfate, water and saturated brine, dried over sodium sulfate, evaporated and purified by chromatography over silica gel to give the mixed carbonate **15b** (5.06 g, 98%). ^{1}H NMR 5.31 (t, 1H), 4.97 (s, 1H), 4.88 (s, 1H), 4.58 (s, 1H), 4.37—3.31 (m, 5H), 3.75 (s, 3H), 2.20—1.42 (m, 10H), 1.73 (s, 3H), 1.67 (s, 3H). MS (CI, NH_3) 313 (MH^+), 237 (MH^+-HOCO_2Me), 211 ($MH^+-HOTHP$). Found: C, 65.4; H, 9.04; O, 25.45%. Calcd for $C_{17}H_{28}O_5$: C, 65.38; H, 8.97; O, 25.64%.

(2*E*)-6,7-Epoxy-1-(*p*-tolylsulfonyl)-3,7-dimethyl-2-octene (16) Epoxidation of sulfone **3** (6 g, 19.5 mmol) was carried out in the same manner as for the THP-ether **2** to give epoxide **16** (4.73 g, 75%). R_f=0.30 (hexane/ether 1/1). ^{1}H NMR 7.72 (d, 2H), 7.30 (d, 2H), 5.22 (t, 1H), 3.78 (d, 2H), 2.67 (t, 1H), 2.44 (s, 3H), 2.30—1.83 (m, 2H), 1.72—1.47 (m, 2H), 1.42 (s, 3H), 1.32 (s, 3H), 1.27 (s, 3H). MS 308 (M^+), 153 ($M^+-TolSO_2$), 135 ($M^+-TolSO_2-H_2O$).

(2*E*)-6-Hydroxy-1-(*p*-tolylsulfonyl)-3,7-dimethyl-2,7-octadiene (17). Isomerization of **16** was achieved in the same way as for **14** to afford sulfone **17** (1.8 g, 84%), identical with the known product.[12] R_f=0.30 (hexane/ether 1/1). ^{1}H NMR 7.73 (d, 2H), 7.32 (d, 2H), 5.21 (t, 1H), 4.49 (s, 1H), 4.85 (s, 1H), 3.99 (t, 1H), 3.79 (d, 2H), 2.43 (s, 3H), 2.11—1.95 (m, 2H), 1.71 (s, 4H), 1.66—1.48 (m, 2H), 1.35 (s, 3H). MS 308 (M^+), 153 ($M^+-TolSO_2$), 135 ($M^+-TolSO_2-H_2O$).

Methyl (3*E*)-7-Hydroxy-2-(*p*-tolylsulfonyl)-4,8-dimethyl-3,8-nonadienoate (18). This was prepared in 72% yield according to published procedures.[12] ^{1}H NMR 7.70 (d, 2H), 7.30 (d, 2H), 5.28 (d, 1H), 4.90 (s, 1H), 4.82 (s, 1H), 4.73 (d, 1H), 3.97 (t, 1H), 3.73 (s, 3H), 2.43 (s, 3H), 2.25—1.95 (m, 2H), 1.82—1.50 (m, 3H), 1.71 (s, 3H), 1.55 (s, 3H). MS (CI, NH_3) 349 (MH^+-H_2O), 309 ($MH^+-C_2H_2O_2H$).

Methyl (3*E*)-8-Hydroxy-2-(*p*-tolylsulfonyl)-4,8-dimethyl-3-nonenoate (19) Tertiary alcohol **6** (2 g, 6.5 mmol) was treated in the same manner as allylic alcohol **17** to give the sulfone carboxylate **19** (1.7 g, 65%). ^{1}H NMR 7.69 (d, 2H), 7.28 (d, 2H), 5.25 (d, 1H), 4.75 (d, 1H), 3.70 (s, 3H), 2.44 (s, 3H), 2.25—1.91 (m, 2H), 1.82 (s, 1H), 1.55 (s, 3H), 1.50—1.30 (m, 4H), 1.22 (s, 6H). MS (CI, NH_3) 351 (MH^+-H_2O), 293 ($MH^+-H_2O-C_2H_2O_2$), 197 ($MH^+-H_2O-C_7H_6O_2S$), 195 ($MH^+-H_2O-C_7H_8O_2S$). Found: C, 61.7; H, 7.5; O, 21.9; S, 8.7%. Calcd for $C_{19}H_{28}SO_5$: C, 61.96; H, 7.60; O, 21.74; S, 8.70%.

(2*E*,6*E*,10*E*)-9-Methoxycarbonyl-14-methoxycarbonyloxy-1-(tetrahydro-2-pyranyloxy)-9-(*p*-tolylsulfonyl)-3,7,11,15-tetramethyl-2,6,10,15-hexadecatetraene (20b). To a mixture of the THP-ether **15b** (1.45 g, 4.1 mmol) and the allylic alcohol **18** (1.70 g, 4.65 mmol) in dry THF (6 ml), was added at 25 °C 0.268g of tetrakis(triphenylphosphine)palladium(0). After 2 h, ether and water were added, the ether extract was washed with N sodium cyanide, and treated as usual. The crude product was dissolved in dry toluene (20 ml); pyridine (0.5 ml, 6.5 mmol) and methyl chloroformate (0.5 ml, 6.5 mmol) were added. Stirring was continued overnight, and the mixture was washed with dilute ammonium chloride, water, dilute copper sulfate, water, and saturated brine, then dried over sodium sulfate, evaporated and chromatographed (hexane/ether 1/1) to give product **20b** (1.9 g, 62%). R_f=0.45 (hexane/ether 1/1). ^{1}H NMR 7.72 (d, 2H), 7.30 (d, 2H), 5.35 (s, 1H), 5.31 (t, 1H), 5.15 (m, 1H), 5.00 (s, 1H), 4.95 (s, 1H), 4.61 (s, 1H), 4.11 (m, 2H), 3.88 (t, 1H), 3.78 (s, 3H), 3.70 (s, 3H), 3.51 (m, 2H), 3.10 (d, 1H), 2.90 (d, 1H), 2.44 (s, 3H), 2.17—1.95 (m, 6H), 1.83—1.53 (m, 8H, incl. 1.73 s, 1.65 s, 1.57 s), 1.48 (s, 3H). MS (CI, NH_3) 661 (MH^+), 559 ($MH^+-HOTHP$), 505 ($MH^+-C_7H_8O_2S$), 483 $MH^+-HOTHP-HOCO_2Me$), 403 ($MH^+-HOTHP-C_7H_8O_2S$). Found: C, 65.3; H, 8.0; O, 21.9; S, 4.9%. Calcd for $C_{36}H_{52}O_9S$: C, 65.45; H, 7.88; O, 21.82; S, 4.85%.

(2*E*,6*E*,10*E*,14*E*,18*E*)-1-(Tetrahydro-2-pyranyloxy)-9-17-bis(methoxycarbonyl)-22-methoxycarbonyloxy-9,17-bis(*p*-tolylsulfonyl)-3,7,11,15,19,23-hexamethyl-2,6,10,14,18,23-tetracosahexaene (21b). The Pd(0)-catalyzed coupling between the allylic carbonate **20b** (1.7 g, 2.6 mmol) and the allylic alcohol **18** (1.1 g, 3.0 mmol) was run as above to give the expected product **21b** (1.6 g, 61%) and starting materials. R_f=0.26 (hexane/ether 3/7). ^{1}H NMR 7.69 (d, 4H), 7.28 (d, 4H), 5.31 (m, 2H), 5.25—5.06 (m, 3H), 4.95 (s, 2H), 4.61 (s, 1H), 4.41—3.90 (m, 3H), 3.78 (s, 3H), 3.68 (s, 6H), 3.52 (m, 2H), 3.20—2.90 (m, 4H), 2.44 (s, 6H), 2.20—1.92 (m, 10H), 1.82—1.52 (m, 23H, incl. s 1.75, 1.65, 1.60), 1.49 (s, 3H). MS (FAB, NaCl) 1031 (MNa^+), 907 ($MH^+-HOTHP$), 853 ($MH^+-TolSO_2$), 751 ($MH^+-TolSO_2-HOTHP$), 675 ($MH^+-TolSO_2-HOTHP-MeOCOOH$) Found: C, 65.6; H, 7.6; O, 20.7; S, 6.6%. Calcd for $C_{55}H_{76}O_{13}S_2$: C, 65.47; H, 7.54; O, 20.63; S, 6.35%.

(2*E*,6*E*,10*E*,14*E*,18*E*,22*E*,26*E*)-31-Hydroxy-1-(tetrahydro-2-pyranyloxy)-9,17,25-tris(methoxycarbonyl)-9,17,25-tris(*p*-tolylsulfonyl)-3,7,11,15,19,23,27,31-octamethyl-2,6,10,14,18,22,26-dotriacontaheptaene (22). The same Pd(0)-catalyzed coupling was achieved between substrates **19** (1 g, 2.7 mmol) and **21b** (1.5 g, 1.5 mmol) to give the expected product **22** (1.7 g, 88%). ^{1}H NMR 7.73 (d, 6H), 7.30 (d, 6H), 5.37—5.08 (m, 7H), 4.62 (s, 1H), 4.27—3.41 (m, 4H), 3.68 (s, 9H), 3.25—2.66 (m, 6H), 2.44 (s, 9H), 2.15—1.82 (m, 14H), 1.70—1.25 (m, 32H, incl. s 1.64, 1.60, 1.58, 1.56, 1.46, 1.25), 1.22 (s, 6H). MS (FAB, NaCl) 1323 (MNa^+), 1167 (MNa^+-HSO_2Tol), 1013 ($MNa^+-HSO_2Tol-TolSO_2$). Found: C, 66.2; H, 7.6; O, 18.5; S 7.35%. Calcd for $C_{72}H_{100}O_{15}S_3$: C, 66.46; H, 7.69; O, 18.64; S, 7.38%.

(2*E*,6*E*,10*E*,14*E*,18*E*,22*E*,26*E*)-31-Hydroxy-1-(tetrahydro-2-pyranyloxy)-9,17,25-tris(*p*-tolylsulfonyl)-3,7,11,15,19,23,27,31-octamethyldotriaconta-2,6,10,14,18,22,26-heptaene (23). To a solution of the above tricarboxylate **22** (400 mg, 0.3 mmol) in dry DMF (10 ml), were added *p*-aminothiophenol (230 mg, 1.85 mmol) and cesium carbonate (100 mg). The mixture was stirred at 85 °C for 3 h, poured into water and extracted with ether. The usual treatment gave, after purification on silica gel the decarboxylated product **23** (203 mg, 60%). ^{1}H NMR 7.73 (m, 6H), 7.31 (d, 6H), 5.43—4.86 (m, 7H), 4.60 (s, 1H), 4.36—3.46 (m, 7H), 2.46 (s, 9H), 2.11—1.78 (m, 20H), 1.63—1.43 (m, 6H), 1.43—1.30 (m, 4H), 1.65 (s, 4H), 1.51 (s, 9H), 1.25 (s, 9H), 1.21 (s, 6H). MS (FAB, NaCl) 1149 (MNa^+), 993 (MNa^+-HSO_2Tol). Found: C,70.15; H, 8.4; O, 12.8; S, 8.3%. Calcd for $C_{66}H_{94}O_9S_3$: C, 70.34; H, 8.35; O, 12.79; S, 8.52%.

(2*E*,6*E*,10*E*,14*E*,18*E*,22*E*,26*E*)-3,7,11,15,19,23,27,31-Octamethyl-2,6,10,14,18,22,26-dotriacontaheptaene-1,31-diol (C). Desulfonation of the preceding substance **23** (200 mg, 1.18 mmol) by the general procedure gave the THP-ether of diol **C**, which was prepared irectly by treatment with

a trace of *p*-TsOH in ethanol at 55 °C for 3 h, to give after purification the desired product **C** (60 mg, 58%). ^{1}H NMR 5.58—4.92 (m, 7H), 4.18 (d, 2H), 3.05—2.92 (m, 2H), 2.54—1.83 (m, 24H), 1.67—1.65 (m, 21H), 1.51—1.33 (m, 6H), 1.24 (s, 6H). MS (CI, NH_3) 598 (MNH_4^+), 563 (MH^+-H_2O), 545 (MH^+-2H_2O). Found: C, 82.7; H, 11.9; O, 5.75%. Calcd for $C_{40}H_{68}O_2$: C, 82.75; H, 11.72; O, 5.52%.

One of us (H. M.) thanks Ecole Normale Supérieure for a fellowship-at-large. We thank CNRS (PIRMED programme) for a partial grant. We thank Dr. B. Das and his staff for the mass spectra and Mlle C. Muller for the microanalyses.

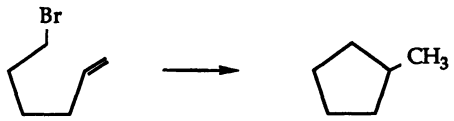
Radical Cyclization in the Control of Regio- and Stereochemistry

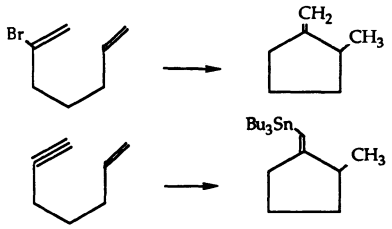
Gilbert STORK
Department of Chemistry, Columbia University, New York, New York 10027, U.S.A.
(Received August 25, 1987)

This article presents a review of the control of regio- and stereochemistry which is now possible by the use of the recently introduced haloacetal and the related halosilyl ether cyclizations, starting from a cyclohexenol or a cyclopentenol. The hydroxyl group is the control element which permits the addition of two carbon chains to the double bond of the allylic alcohol system, with complete regiospecificity and stereospecificity at the near end of the double bond, and with complete regiospecificity and high stereoselectivity at the far end of the bond. Examples of the use of the new methodology from the field of alkaloid, steroid and prostaglandin synthesis are given.

It is remarkable that the long-known radical-mediated cyclization of 6-bromo-1-hexene to methylcyclopentane[1] has not seen much application to specific problems of synthesis. Perhaps this is because the process is intrinsically limited to the construction of structures which specifically include a substituted cyclopentane (or, less frequently, a substituted cylcohexane).[2]



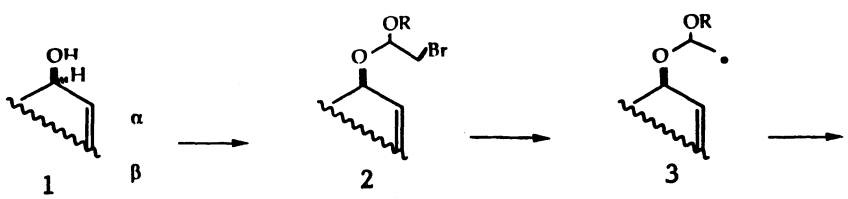
A potentially much broader field of application opened up with the introduction of the vinyl radical cyclization,[3] since the resulting five- or six-membered ring now contains a double bond in a predetermined position, where it can serve as the basis for subsequent synthetic elaboration. A further increase in scope followed the discovery[4] that the vinyl radical which leads to ring formation can be produced not only by the classical removal of a halogen atom, but also by selective addition of a stannyl radical to an alkyne.



These developments have been important. What I wish to review here, however, are radical-mediated cyclizations which we believe to be of much wider application. The new methodology followed the realization that the stereochemistry of the hydroxyl group of a cyclic allylic alcohol, most commonly a cyclopentenol or a cyclohexenol (cf. 1), could be used to add functional carbon chains at the near (α), as well as at the far (β) end of the double bond. And this proceeds with *complete* regiospecificity and stereospecificity at the α end, as well as complete regiospecificity and high stereoselectivity at the β end. In other words, any of the four possible arrangements of two functional chains on adjacent carbon atoms could be produced at will.

The principle of the method involves *connecting to the allylic hydroxyl a detachable radical precursor capable of cyclizing to a five-membered ring.*[5] The *regiospecificity* at the α-center follows because of the great preference (magnified here, for obvious reasons) for the formation of a five-membered ring. The *stereospecificity* at the α-center follows from the Bürgi-Dunitz-like[6] ($\sim 109^{\circ}_{\pm}$) approach of the radical center to the plane of the double bond.[7] When the olefinic double bond is in a six-membered or smaller ring, this necessarily results in the cis fusion of the new ring. Eventual removal of the detachable connection concludes the regio- and stereospecific attachment of the α-chain, cis to the controlling hydroxyl group.

This is illustrated, using an acetal link as the detachable connector.



Obviously, the epimeric stereochemical attachment of the α-chain is accessible by starting with the epimeric allylic alcohol.

Not only can regio- and stereospecific addition of a functional chain be accomplished at the α-center, it can simultaneously be achieved at the β-center. Three requirements had to be met to make this a useful process: a) The radical generated at the β-center by the initial cyclization has to be trapped in an *intermolecular* reaction within the lifetime of that radical. This is not a problem when the required β-substituent is a hydrogen (e.g. from a stannane). It becomes a problem when the trap must be a functional carbon atom or a functional carbon chain. Such a trap should not be so efficient that it would trap the initiator itself (e.g. $Bu_3Sn\cdot$) or the initial primary radical before it cyclizes, but efficient enough to trap the β-center (which may be secondary or tertiary) faster than the latter either acquires a hydrogen from some component of the medium, or disproportionates. b) The species capable of trapping the β-center must be as versatile as possible. The most useful trap would result in the delivery of a one carbon functional species. c) The stereochemistry must be controlled.

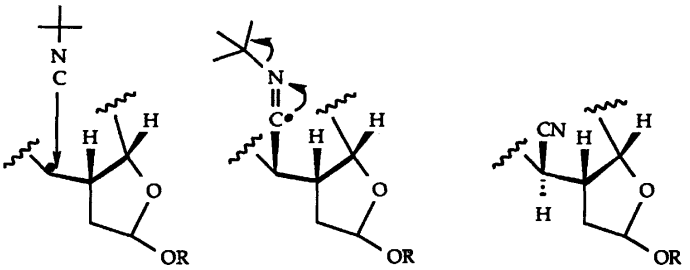
We eventually concluded that *t*-butyl isocyanide would answer the second requirement by transferring a cyano group to the β-center.[8] That this proved successful is fortunate because isocyanides are known to react with stannyl radicals, as shown.[9]

$$R_3Sn\cdot + R'\text{-}N{=}C \rightarrow R_3Sn(C{\equiv}N) + R'\cdot$$

This process is, however, considerably slower than reaction of the stannyl radical with the halo acetal (**2**→**3**). It is, of course, necessary to keep the stannane concentration low enough if one wishes to deliver a carbon species, rather than a hydrogen, at the β-center.

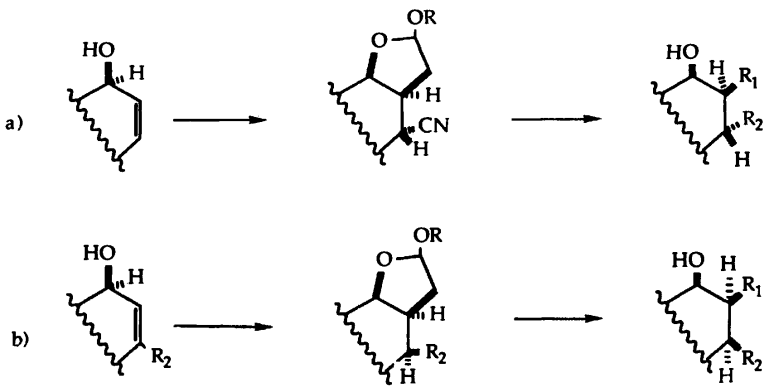
A convenient way to achieve the required low concentration involves producing the necessary stannane by conducting the radical cyclization-trapping in the presence of sodium cyanotrihydroborate in refluxing *t*-butyl alcohol.[10] This procedure regenerates tributylstannane from the small concentration of tributylstannyl halide produced as the reaction proceeds. An important added advantage is that only ~0.1 equiv of halostannane needs to be added to carry out the whole process.

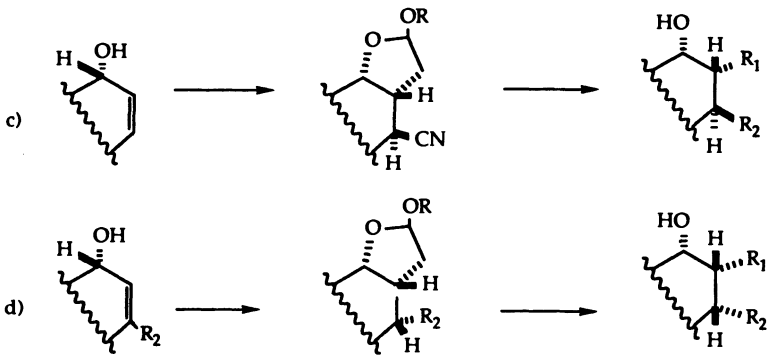
Note that the use of *t*-butyl isocyanide cannot lead to telomer formation because the adduct once formed loses its radical nature simply by ejection of a *t*-butyl radical.



With respect to the final requirement of stereoselectivity at the β-center, we made use of the fact that the cis fusion of the five-membered acetal ring would produce a molecule with a clear-cut differentiation between its convex and its concave faces. As we anticipated, attachment of the trap takes place on the more accessible convex face with high selectivity.

The result of this cyclization-trapping process, therefore, is that the allylic hydroxyl controls the attachment of the vicinal substituent (an acetaldehyde equivalent in the bromo acetal version of the general

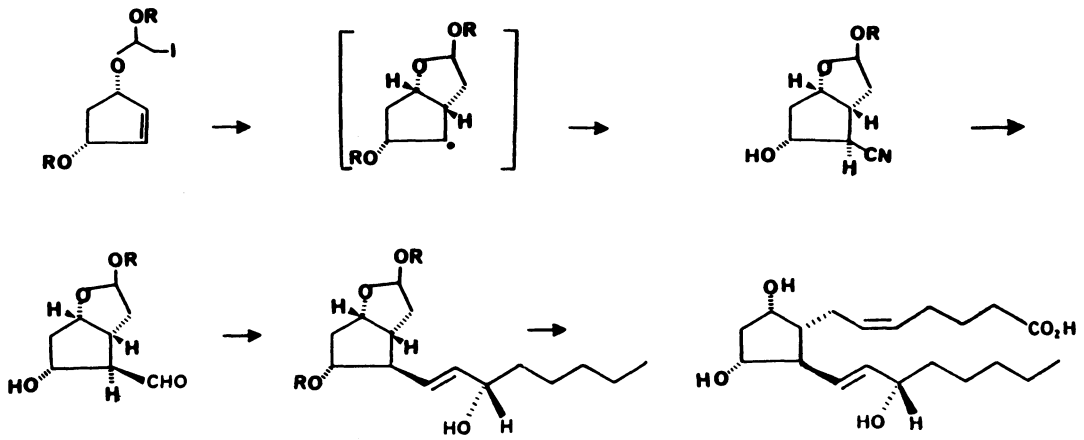




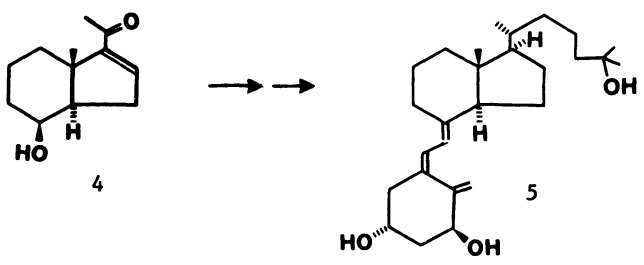
scheme) cis, and that of the substituent at the far end of the double bond trans to it. Because the far end substituent can be either a functional carbon (e.g. cyano group) or a hydrogen (in the absence of carbon trap), all four possible arrangements at the site of the original double bond can be produced at will. This is shown in a)—d) above. Of course, after it has served its control function, the hydroxyl can eventually be kept, inverted, oxidized or removed entirely, as the situation requires.

Note also that the halo acetal sequence delivers the acetaldehyde chain in a protected acetal form. This allows various organometallic transformations to be carried out on the substituent (e.g. cyano) before liberating and elaborating the acetaldehyde chain.

The synthesis of prostaglandins,[11] which is illustrated below, is one of the simplest and most obvious applications of the general principles that have just been outlined.



This is an archetype for this type of construction since it simply requires the addition of two chains of defined stereochemistry to the double bond of a cyclic allyl alcohol. One further illustration, in a less obvious situation, will serve to emphasize the generality of this reaction sequence. Consider the problem of constructing the hydrindan **4** a useful starting material for the synthesis of calcitriol (**5**) and other D vitamins.

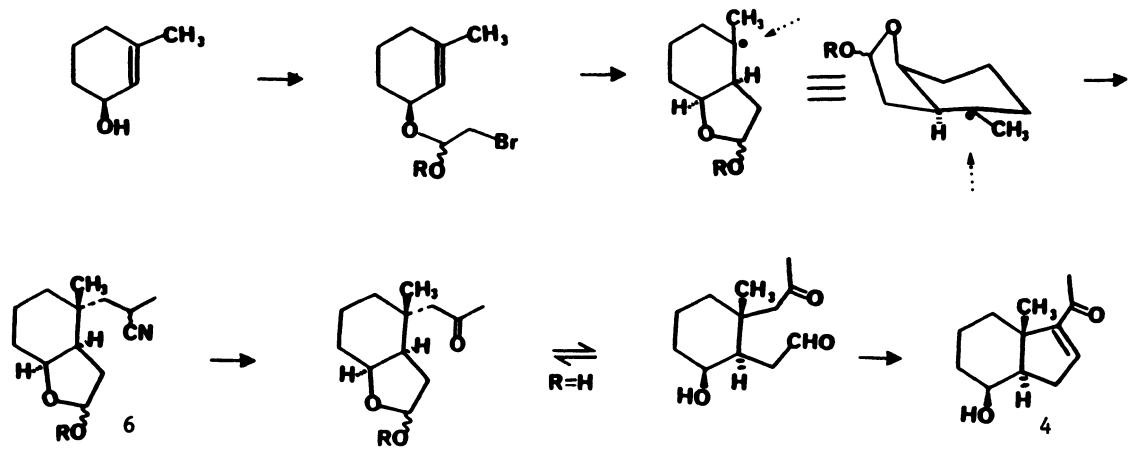


4 5

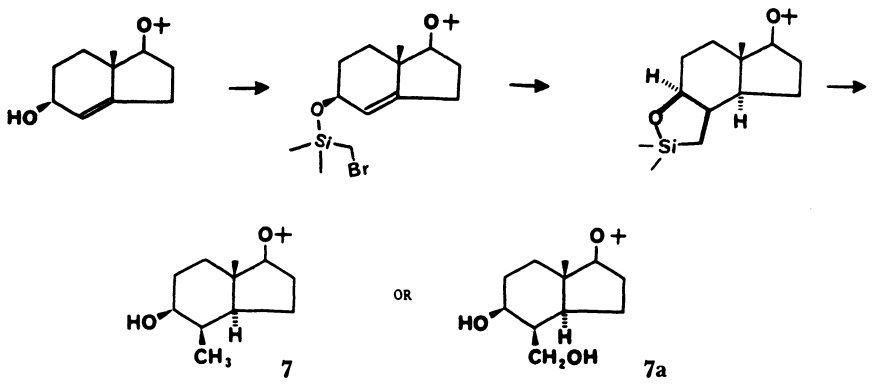
This requires the assembly of a *trans*-hydrindan system, and it is not immediately obvious that this target could, nevertheless, be reached easily by the general bromo acetal route. This is, however, again simply a matter of controlling the regio- and stereochemistry of two vicinal functional chains: only four steps are required to make **4**, starting with 3-methyl-2-cyclohexenol,[12] as is shown below.

In this particular construction, we see again the protection afforded by the acetal function during the transformation (reaction of **6** with LDA, then with oxygen) of the functional chain trapped at the far center (methacrylonitrile, rather than t-butyl isocyanide, was used as the trap in this particular case, as a convenient precursor of the required acetonyl residue).

This is not the only way that the problem of ring junction stereochemistry can be solved using the



principles outlined here. The trapping from the convex side at the far center means that if it is a hydrogen atom which is delivered at that center (no carbon trap present), it will be delivered anti to the controlling allylic hydroxyl (cf. b) and d) above). An important corollary of that simple fact is that cis or trans ring fusions can be generated at will.[13] An example[14] is shown below.



Note that the cis junction would be produced, if desired, merely by starting with the epimeric alcohol.

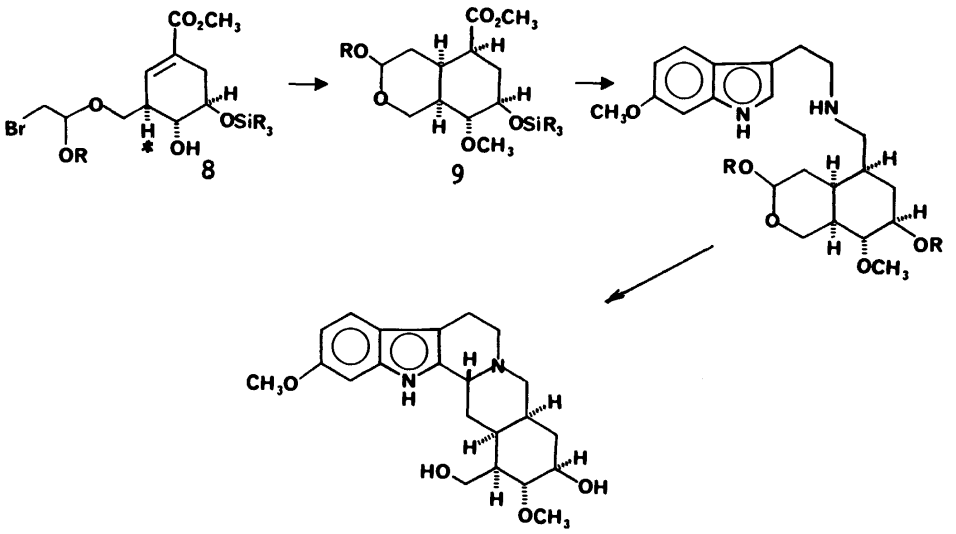
This particular case illustrates the use of a silyl ether rather than an acetal as the detachable connection. This is a useful variant when either a one carbon functional group[15] (cf. **7a**), or even a methyl group, is required adjacent to the original allylic hydroxyl, rather than an acetaldehyde chain.

Two special features should be pointed out here: 1) The ring junction is produced, cis or trans at will, by a process which does not depend on the thermodynamic stability of the particular bicyclic system. Either cis- or trans-hydrindans can thus be produced, as well as cis or trans decalins. 2) The regio- and stereochemistry of the newly added substituent, either hydroxymethyl or methyl, is also kinetically determined so that, in the trans series, it ends up axial even if, as in **7** and **7a** this happens to produce a 1,3-diaxial interaction with an angular methyl group.[16] This is particularly useful because it is often a simple matter to invert the axial substituent to the more stable epimeric position, via the adjacent ketone.

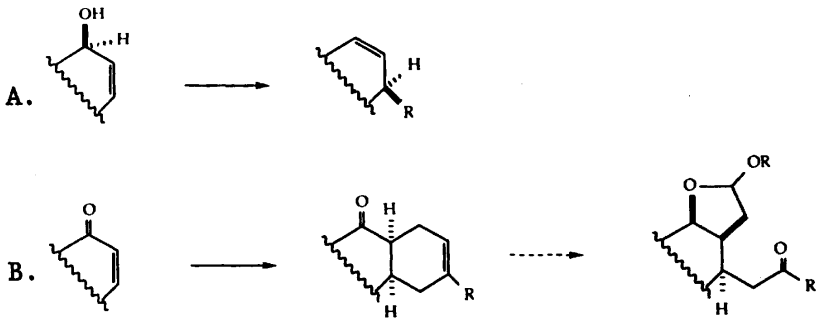
Let us end by showing an example which further emphasizes the variety of synthetic targets which can take advantage of the features that we are illustrating here. This concerns again setting up vicinal stereochemistry on a double bond via the bromo acetal route, but it now involves a homoallylic rather than an allylic alcohol as we see in **8**. This raises a new problem because abstraction of the starred allylic hydrogen by the radical derived from the bromo acetal would now compete with cyclization. This is circumvented by increasing the cyclization rate, in this particular case by making the olefin more electron poor by conjugation with the carbonyl group.

The radical cyclization-trapping process (trapping at the far center is now by a hydrogen; cf. case b above) thus controls the last two centers in ring E of the alkaloid reserpine. That these are correctly placed, as anticipated, is shown by transformation of the major cyclization product **9** to reserpinol.[17]

There are other processes which make use of the stereochemistry of an allylic hydroxyl to direct the formation of a carbon-carbon bond. The best known of these is the Claisen rearrangement (cf. A below). This very important reaction transfers



stereochemistry from an allylic hydroxyl to the far end of the related double bond, but loses the hydroxyl in the process. There are multiple-step schemes which can control two adjacent centers, as the bromo acetal radical process can. The Diels-Alder reaction, for instance, using a conjugated cyclic ketone, leads to a cyclohexene which can be cleaved to give two different chains adjacent to the carbon oxygen bond (cf. **B**). The stereochemistry is, however, not broadly controllable in this special application of a reaction which



has, of course, many other important uses. We believe, however, that the concise transformations we have just discussed (cf. a)—d) above) have considerable potential in synthesis.

I want to acknowledge my indebtedness to the members of my group, some cited here, some not, who have helped shape the work described here. I am also pleased to thank the United States National Science Foundation and the National Institutes of Health for their financial support, without which this work would not have been possible.

Syntheses and Dynamic Behavior of Chiral Heptalenes

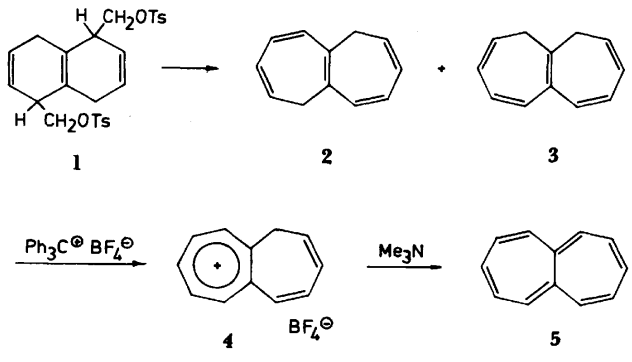
Klaus HAFNER,* Günter L. KNAUP, and Hans Jörg LINDNER
Institut für Organische Chemie der Technischen Hochschule Darmstadt,
Petersenstrasse 22, D-6100 Darmstadt, F.R.G.
(Received August 31, 1987)

Cycloaddition reactions of azulenes with dimethyl acetylenedicarboxylate afford an excellent access to a large variety of substituted dimethyl 1,2-heptalenedicarboxylates. These can be converted into various methylheptalenes, which proved to be remarkably stable. This allowed for the first time a separation of the bond shift isomers as well as an optical resolution of derivatives of this axial chiral 12π-electron system. Kinetic studies of bond shifting and ring inversion provide information on the transition states of these dynamic processes.

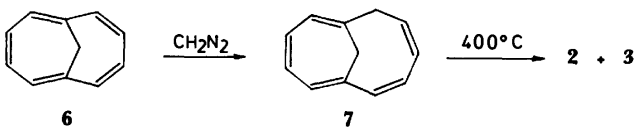
Since Hückel introduced his famous rule[1] that a monocyclic planar π-electron system should be aromatic if it contains $[4n+2]$ π-electrons, a large number of neutral and ionic ring systems[2] had been prepared in order to test the validity of this aromaticity concept. The investigations verified a clear distinction in the chemical and physical properties between the $[4n+2]$ and $4n$ π-electron systems and completely justified Hückels rule. For instance, the two species differ characteristically in the ^{1}H NMR spectra. While the outer protons of the $[4n+2]$ π-systems show a low field shift caused by a diamagnetic ring current,[3] those of the $4n$ π-systems show a high field shift, which could be attributed to a paramagnetic contribution arising from the mixing of excited states with the ground state.[4] Whereas the HMO-theory originally only predicted that $[4n+2]$ π-systems should be more stable than $4n$ π-systems, later theories suggested that the $4n$ π-systems should be destabilized by delocalization and should be in fact antiaromatic.[5] This is valid not only for annulenes, but also for bicyclic systems derived from annulenes bridged by an essential single bond. Indeed, the smallest members of the mono- and bicyclic annulenes, cyclobutadiene[2] and pentalene,[6] are so reactive, that they can not be isolated. Another significant difference is the fact that mono- and bicyclic systems with $4n$ π-perimeters possess localized double bonds in the ground states. Therefore, the structures with delocalized bonds are only transition states on the potential surfaces which connect the localized bond systems with one another. This could be established for tetra-*t*-butylcyclobutadiene,[7] 1,3,5-tri-*t*-butylpentalene,[8] cyclooctatetraene,[9] and heptalene.[10] In contrast to cyclobutadiene and pentalene, the higher homologues, cyclooctatetraene and heptalene, are characterized by nonplanar structures. Thus, from each of these systems exist four isodynamic structures, which are, via bond shifting and ring inversion, in a dynamic equilibrium with one another. A study of both dynamic processes should provide information on their transition states and, therefore, also on the antiaromaticity of the delocalized systems. Assuming planar delocalized transition states for the bond shift and planar localized transition states for the ring inversion, the difference between the activation enthalpies of both processes should be equal to the delocalization energies for the planar ring systems. For cyclooctatetraene, Oth[9] determined by NMR measurements of the ethoxy derivative a difference of 3.5 kcal mol^{-1}, which he attributed to the energy required for the delocalization of the planar 8π-perimeter. A similar value was calculated by Paquette et al.[11] from the differences of the activation enthalpies of methyl-substituted cyclooctatetraenes taking into account different steric strains in the assumed planar localized and delocalized transition states. In the case of the 1,2,3-tri- and 1,2,3,4-tetramethylcyclooctatetraenes, even a separation of the bond shift isomers and an enrichment of the enantiomers was possible.[12]

Syntheses and Physical Properties of Heptalenes

Dauben and Bertelli[13] demonstrated in 1961 that the dihydroheptalenes **2** and **3** can be transformed into heptalene **5** by hydride abstraction and subsequent



Scheme 1.



Scheme 2.

deprotonation of the resulting heptalenium salt **4** (Scheme 1). Since then, additional syntheses of the bicyclic 12π-system **5** were published[14] using this method. While Dauben and Bertelli[15] prepared a mixture of **2** and **3** by solvolytic rearrangement of the isotetralin **1**, Vogel et al.[10] obtained a similar mixture by pyrolysis of **7**, which was prepared by ring expansion of 1,6-methano[10]annulene **6** (Scheme 2).

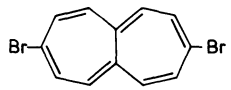
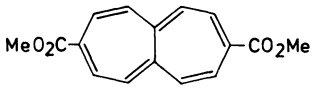
a) and 1% dimethyl 3-methylazulene-1,2-dicarboxylate b) and 3% dimethyl 6-methylheptalene-1,2-dicarboxylate, 1% dimethyl 4-methylazulene-2,3-dicarboxylate, 4% dimethyl 5-methyl-3,4-dihydrocyclopent[*cd*]azulene-1,2-dicarboxylate c) and 7% dimethyl 3,4-dihydrocyclopent[*cd*]azulene-1,2-dicarboxylate.

In 1979, both Vogel et al.[16] and Paquette et al.[17] developed heptalene syntheses based on dibromocarbene additions to isotetralin. Similarly 3,8-dibromoheptalene **8**[18] and dimethyl heptalene-3,8-dicarboxylate **9**[19] can be prepared. In contrast to these multistep



8



9

syntheses, we developed an extremely simple, onepot synthesis, which allows the preparation of numerous substituted heptalene-1,2-dicarboxylates.[20] Cycloaddition of dimethyl acetylenedicarboxylate to azulenes **10** in boiling tetralin affords the dimethyl heptalene-1,2-dicarboxylates **16** in yields up to 64%. Side products of these reactions are the dimethyl heptalene-2,3-dicarboxylates **17**, the dimethyl azulene-1,2-dicarboxylates **18** and the dimethyl 3,4-dihydrocyclopent[*cd*]azulene-1,2-dicarboxylates **19** in varying yields (Scheme 3). The formation of all these compounds can be rationalized by invoking **11** as an intermediate formed by an electrophilic attack of the electron-deficient alkyne to the azulene. Ring closure of **11** should lead to the adducts **12**—**15**, which then isomerize to the heptalenes **16**, **17**, and the azulene derivatives **18**, **19**, respectively. The drastic reaction conditions required for the cycloaddition did not allow the detection of the proposed intermediates. However, if the reaction is carried out at 7 kbar and 50 °C, the [4+2] adduct **14** becomes the main product.[22]

In contrast to the parent compound **5**, the 3,8-disubstituted derivatives **8**, **9**, and the heptalenedicarboxylates **16**, **17** are remarkably stable. However, in boiling tetralin **16** undergoes a slow irreversible rearrangement to heptalene-1,3-dicarboxylates **20** and a ring contraction to the azulene derivatives **18**, **21**, and **22**. The rate of this reaction and the ratio of the products depend strongly on the substituents.[23] While the thermolysis of the dimethyl heptalene-1,2-dicarboxylate **16a** yields predominantely the azulenes **18a**, **21a**, and **22a**, and only traces of the heptalene-1,3-dicarboxylate **20a**, compounds of this type become the main products by the thermolyses of methyl-substituted heptalenedicarboxylates (Scheme 4). As we could show, the stability of heptalenes not only increases by electron-withdrawing substituents in the 1- or 3-position (the positions with high electron densities) but also by alkyl substituents in the peri-positions. Therefore, reduction of the dimethyl heptalenedicarboxylates **16** with diisobutylaluminum hydride (DIBAH) afford the 1,2-bis(hydroxymethyl)-heptalenes **23** as thermally and air-stable yellow crystals[24,25] (Scheme 5). Due to the chiral heptalene system, the diastereotopic hydroxymethyl groups appear in the ^{1}H NMR spectra as AB spin systems with vicinal coupling constants around 15 Hz. The tetramethyl derivative **23k** can be converted into the dichloride **24b**, which can be reduced with lithium triethylborohydride to the hexamethylheptalene **26**.[24] In contrast to **24b**, the trimethyl derivative **24a** is unstable at room temperature but rather eliminates HCl spontaneously to the dimethylidene compound **25**[25] (Scheme 6). Similarly to the HCl elimination of **24a**, the diols **23** can be dehydrated by treatment with catalytic amounts of *p*-toluenesulfonic acid in boiling benzene.[25] These reactions lead (probably via an enolic structure similar to **25** to the heptalene-2-carbaldehydes **27**. Decarbonylation of **27** with chlorotris(triphenylphosphin)rhodium(I) yields the methylheptalenes **28** as thermally and airstable compounds[25] (Scheme 7). In addition to **28a**—**d** we also synthesized 1,6-dimethylheptalene **31** by an

entirely different pathway after the dimethyl *cis*-1,5a,6,10a-tetrahydroheptalenedicarboxylate **29** became readily available by a new rearrangement reaction.[26]

Reduction of **29** with DIBAH and subsequent twofold dehydration of the resulting alcohol **30** affords the heptalene **31** as a yellow oil[25] (Scheme 8). In contrast to the extremely air-sensitive and thermally unstable parent compound **5**, the described methylheptalenes — even the dimethyl derivatives **28a** and **31** — are surprisingly stable. This could not only be a result of a kinetic stabilization due to a steric shielding of the heptalene system, but rather to an enhancement of twisting of the nonplanar 12π-perimeter caused mainly by the steric interaction of the substituents in the peri-positions. This reduces the cyclic conjugation and increases the HOMO-LUMO gap and, therefore, reduces the reactivity of the $4n$ π-system.

Resolution and Chiroptical Properties of Chiral Heptalenes

Heptalenes, as most other $4n$ π-systems, show in the ground state π-bond fixation. Therefore, from unsymmetrically substituted heptalenes exist two nonequivalent bond shift isomers. The ratio of these isomers depends on the substituents. For the un- and

monosubstituted dimethyl heptalene-1,2-dicarboxylates **16a—d** and the bridged derivatives **16r—t** only the bond shift isomers with a single bond between the ester groups can be observed in the ^{1}H NMR spectra. However, for **16g—o**, which have two or three alkyl substituents in the peri-positions, 10—30% of the other bond shift isomers can be detected. The preference of the isomers with a single bond between the ester groups can be explained by the tendency of the carboxylate groups to assume a coplanar arrangement to the adjacent double bonds of the ring system, which is sterically hindered in the other isomers. In contrast to some heptalene-1,2-dicarboxylates **16**, both bond shift isomers of the diols **23**, the 2-carbaldehydes **27** as well as the methylheptalenes **26** and **28** can be detected in varying ratios in the ^{1}H NMR spectra. Although a unique trend has not been found so far, an effect is evident. The isomer with the lowest number of substituents in the peri-positions having a double bond to the bridge atoms C-5a and C-10a is thermodynamically more stable than the other. This might be due to a smaller steric interaction across the peri-positions in this bond shift isomer.

X-Ray analyses[27] of the heptalene dicarboxylates **9** and **16a** confirmed a C_2-geometry for the heptalene system with the two annelated seven-membered rings in boat conformations. Therefore, for heptalenes should, according to Oth et al.,[28] exist four isodynamic axial chiral structures which are, via bond shift (BS) and ring inversion (RI), in a dynamic equillibrium with one another (Scheme 9). So far, π-bond shift has been investigated in heptalene itself (E_a=3.5 kcal mol^{-1}),[10] heptalene-1,6-dicarbaldehyde ($\Delta G^{\ddagger}$=9.9 kcal mol^{-1}),[16] dimethyl heptalene-1,6-dicarboxylate ($\Delta G^{\ddagger}$=14 kcal mol^{-1}),[16] and dimethyl 6,8,10-trimethylheptalene-1,2-dicarboxylate **16i** ($\Delta G^{\ddagger}$=21.7 and 21.0 kcal mol^{-1}, respectively).[29] For the latter, the bond shift isomers can even be separated by low temperature chromatography. As these results indicate, the energy barrier for the bond shift increases with the number of substituents in the peri-positions of the heptalenes. In fact, for the dimethyl 5,6,8,10-tetramethylheptalene-1,2-dicarboxylate **16k** we succeeded for the first time in isolating in pure form all four isomers (+)-M-**A**, (+)-M-**B**, (−)-P-**A**, and (−)-P-**B** of a $4n$ π-system.[30,31] The bond shift isomers rac-**A** and rac-**B** of **16k** can be separated by simple chromatography on alumina at room temperature. Both bond shift isomers differ characteristically in their NMR and UV spectra. While the protons H-3 and H-4 of **16kA** show a coupling constant of 6.9 Hz, those of **16kb** appear as an AB spin-system with a coupling constant of 11.8 Hz. These values are characteristic for coupling constants via single and double bonds in substituted heptalenes and allow a simple assignment of the positions of the double bonds. The structures of the bond shift isomers A and B of **16k** were also established by X-ray analyses.[30] Although the optical resolution can be carried out by HPLC on triacetylcellulose,[32] for a preparative scale separation we prefered the classic method of fractional crystallization of diastereomeric salts. For that the diesters **16kA**

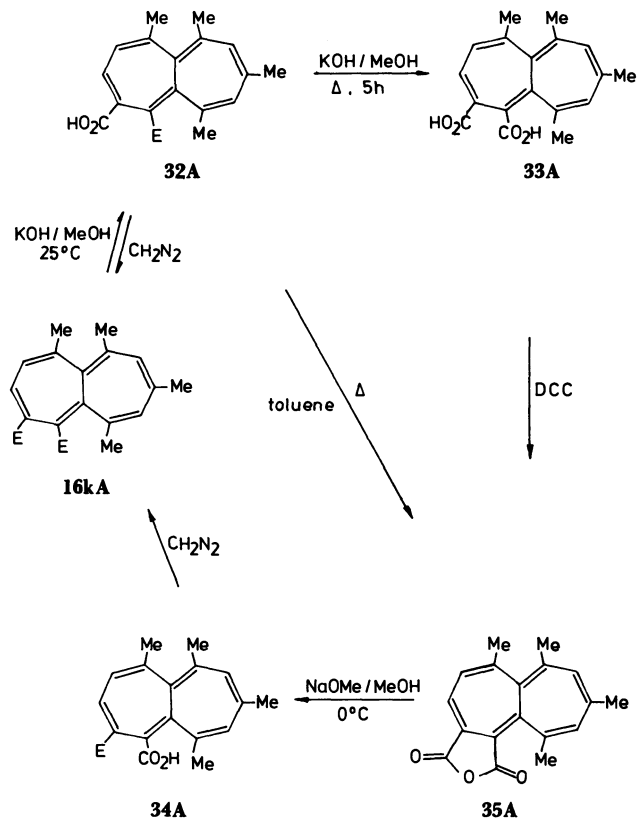

Scheme 10.

and **16kB** were converted into the free acids with potassium hydroxide in methanol. If the reactions are carried out at room temperature, selectively **32A** and **32B** with the carboxylic acid group in 2-position are obtained without bond shift isomerization. On the other hand, the preparation of the dicarboxylic acid **33A** requires considerably higher temperatures. Both the mono-**32A** and the dicarboxylic acid **33A** can be converted into the anhydride **35A**, which selectively affords the 1-carboxylic acid **34A** by treating with sodium methoxide (Scheme 10). The selectivity of the saponification of **16k** and the esterification of **35A** might be due to a steric shielding of the carboxylate group in the 1-positions caused by the methyl groups in the 8-position. In fact, heptalene-1,2-dicarboxylates without substituents in the 8-position, i.e. **16a**—**d**, yield under the same reaction conditions mixtures of the corresponding 1- and 2-carboxylic acids. By our experience, the best optically active amines suitable for the resolution of the 2-carboxylic acids **32** are cinchonine and (+)-1-phenylethylamine for **32A** and (+)- and (−)-ephedrine for **32B**. With these amines, the heptalenes (+)-M-**32A**, (+)-M-**32B**, (−)-P-**32A**, and (−)-P-**32B** were obtained with an enantiomeric purity of greater than 98%, as determined by NMR spectroscopy of the diastereomeric ephedrine salts. The optically active heptalenecarboxylic acids **32** and the diesters **16k**, prepared from **32** with diazomethane without racemization, have very high specific optical rotations (Table 1), typical for systems with helical chiral chromophores. The absolute configuration of the chiral heptalenes was achieved by X-ray analysis of the (+)-ephedrine salt of (+)-M-**32A**. Since both bond shift isomers of (+)-M-**32** show very similar CD-spectra (characterized by two positive Cotton effects at 358, 321 nm, and 380, 312 nm, respectively, and two negative Cotton effects at 280, 252 nm, and 278, 224 nm, respectively) (Fig. 1), the two bond shift isomers must have the same absolute configuration. Although the bond shift isomers of the dimethyl 6,8,10-trimethylheptalene-1,2-dicarboxylate **16i** undergo at room temperature in solution a fast interconversion, they are stable in the crystalline form. NMR spectra taken of solutions of these crystals show each to be isomerically pure. While crystallization from hexane/ether of **16i** and the 4-isopropyl- and 4-*t*-butyl derivatives **16m** and **16n** affords selectively the thermodynamically more stable isomers (single bond between the ester groups), the tetramethyl derivative **16l** crystallizes to give only the other isomer. So far, all attempts for an optical resolution, or at least an enrichment of one of the enantiomeres, of **16i** by fractional crystallization of salts of the carboxylic acid **36** with optically active amines have failed. This is probably due to the existence of both bond shift isomers of **16i** in solution. Nevertheless, a resolution could be achieved with the (−)-menthyl ester **38**, prepared from the anhydride **37** with (−)-menthol and subsequent esterification with diazomethane (Scheme 11). Crystallization at room temperature leads selectively to the (−)-menthyl-(−)-P-heptalene diastereomer (−)-**38A**. However, the ^{1}H NMR spectra at room temperature clearly show that the four diastereomers (−)-**38A**, (+)-**38A**, (−)-**38B**, and (+)-**38B** exist in the equilibrium in a ratio of 5.5:3.3:1.2:1. Reduction of the enantiomerically pure diesters (−)-P-**16kA** and (−)-P-**16kB** with diisobutylaluminium hydride affords the alcohols (−)-P-**23kA** and (−)-P-**23kB** with enantiomeric purities of greater than 98%, as shown by ^{1}H NMR spectra using the chiral shift reagent Eu(hfc)$_3$. Since these optically active alcohols, which have no electron-withdrawing substituents, show CD-spectra very similar to the heptalene-1,2-

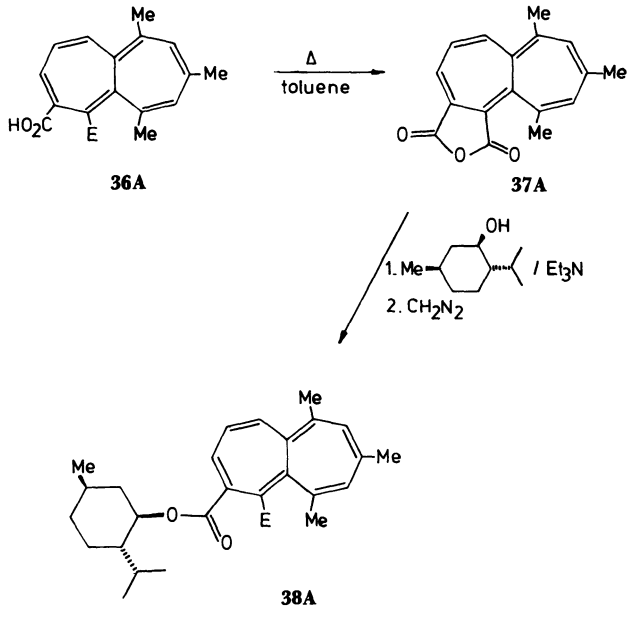
dicarboxylates **16k** and **27**, the chiroptical properties of the chiral heptalenes are caused mainly by the inherent chiral heptalene system and depend, only to a small degree, on the substituents.

The reaction of a mixture of rac-**23kA** and **B** with phosphorus pentachloride and subsequent reduction of the resulting dichloride rac-**24b** affords a mixture of the hexamethylheptalenes rac-**26A** and **B** in good yields. However, all attempts to prepare the enantiomerically pure (−)-P-**26** starting with the pure (−)-P-**23kA** or (−)-P-**23kB** have failed. Instead of the pure compounds, only mixtures of the bond shift isomers of **24k** and of **26** were obtained with specific optical rotations of at most 50, equivalent to an ee of at most 5%. A possible explanation for these results is that the chlorination of **23k** proceeds via an almost planar tropylium cation, which may also be responsible for the instability of the trimethyl derivative **24a**. In fact, the chlorination of **23kA** leads selectively to the bond shift isomer **24kB**, which then is acid-catalyzed equilibrated with the isomer **24bA**. This was shown by isolating the pure isomer **24bB** after quenching the reaction at −60 °C with $NaHCO_3$. A similar tropylium cation may also be responsible for the readily acid-catalyzed dehydration of the alcohols **23** to the aldehydes **27**. This reaction is also accompanied by a racemization. Thus, it is not possible to prepare enantiomerically pure methylheptalenes by this reaction sequence, starting with enantiomerically pure heptalene-1,2-dicarboxylates.[24,25] However, it has been shown recently that the optical resolution of the 1,5,6,10-tetramethylheptalene rac-**28c** can be carried out in good yields by HPLC on triacetylcellulose.[34] As expected, the chiroptical properties of the enantiomers of **28c** are very similar to those of the corresponding optically active heptalene carboxylates and diols.



Scheme 11.

The Dynamic Behavior of Chiral Heptalenes

The separation of the bond shift isomers and the resolution of the enantiomers of the dimethyl 5,6,8,10-tetramethylheptalene-1,2-dicarboxylate **16k** allowed for the first time a determination of the kinetic parameters of both the bond shift and the ring inversion of a substituted heptalene. According to the corresponding studies of cyclooctatetraenes,[9,11,12] this should provide information about the delocalized heptalene system and, therefore, about the antiaromaticity of this 12π-system. However, the energy barrier for the ring inversion of **16k** is considerably higher than that for the bond shift (Table 2). These results are inconsistent with planar transition states for both processes as proposed for the dynamic behavior of all cyclooctatetraenes investigated so far.[9,11] Rather the bond shift must occur via a nonplanar, helical chiral transition state. Therefore, it seems impossible to determine the delocalization energy for the antiaromatic systems from the difference of the activation enthalpies of both processes as done by Oth[9] and Paquette et al.[11] for cyclooctatetraene. Also for the hexamethylheptalene **26** the bond shift occurs with retention of the configuration, but both energy barriers are higher than those for the corresponding dicarboxylate **16k** (Table 2). This might be due to a larger steric hindrance of the spherical methyl groups in comparison with the ester groups. This assumption is corroborated by the fact that the value for the ring inversion, which requires an almost planar transition state, increases more than those for the bond shift. In order to obtain more detailed information about the geometries of the transition states, we calculated the dynamics of both processes for the substituted heptalenes **39**, **40**, **28a**, and **28c** having methyl groups in the peri-positions and also for the parent compound **5** by π-SCF-force field calculations.[35] According to these calculations, the bond shift of the

Scheme 12.

1,5,6,10-tetramethylheptalene **28c** should occur via helical chiral, delocalized transition states with an activation enthalpy of 30 kcal mol^{-1}. On the other hand, the ring inversion should occur via partly planar, localized transition states with an activation enthalpy of 31 kcal mol^{-1} (Fig. 2). This value is in good agreement with recent experimental results (Table 2).[36] In contrast to this, planar transition states for both processes should require activation enthalpies of 62 and 72 kcal mol^{-1}, respectively. Therefore, the calculated conformations of the transition states seem to represent a good model for the dynamic behavior of highly substituted heptalenes. As the calculated values for the activation enthalpies for the dynamic processes (Table 3) indicate, the bond shift of the methylheptalenes **39**, **40**,

and **28a** should also occur via nonplanar transition states. However, the difference of the activation enthalpies of both processes should decrease with the number of substituents. Furthermore, for heptalenes with two or less substituents in the peri-positions the ring inversion should be faster than the bond shift. While we could demonstrate that the bond shift of the (−)-menthyl heptalenecarboxylate **38** is not accompanied by racemization, we have not yet investigated the lower substituted heptalenes. However, the necessary data can be obtained by NMR measurements of heptalenes with diastereotopic substituents, i.e. the hydroxymethylheptalenes **23**. Similarily, Paquette et al.[11,12] found that the activation enthalpies of both dynamic processes for methyl-substituted cyclooctatetraenes were also dependend on the degree of substitution. While these authors explained this exclusively by the different steric interaction of the substituents in the assumed planar localized and delocalized transition states, our results for substituted heptalenes suggest that this may be due to different conformations of the transition states and, therefore, different steric strains of the ring system. In fact, calculations by Dewar et al.[37] suggest that the bond shift of cyclooctatetraene also proceeds via a nonplanar transition state.

Conclusion

Our investigations of the dynamic behavior of chiral heptalenes established that the ring inversion and the bond shift, at least of highly substituted heptalenes, occur via nonplanar transition states with different conformations. Thus, it seems very questionable to determine the delocalization energies of heptalenes (even of the parent compound) from the difference of the activation parameters of both dynamic processes. The same should be valid for cyclooctatetraenes.

Antioxidants

Gerald SCOTT
Polymer Group, Aston University, Birmingham, B4 7ET, U.K.
(Received September 3, 1987)

Antioxidants can be classified by the way in which they interfere with the process of autoxidation. Two main types can be identified; the chain-breaking antioxidants which either reduce the alkylperoxyl radical or oxidise the alkyl radical and the preventive antioxidants which either retard the breakdown of hydroperoxides (metal deactivators, UV absorbers) or destroy them by non-radical mechanisms. Synergism results from the complementary action of antioxidants when used together. Recent studies of antioxidant mechanisms have led to the discovery of "stable" redox systems which are able to catalytically scavenge alkyl and alkylperoxyl radicals in competition with the normal reactions of these species in autoxidation. The physical behaviour (solubility, volatility etc.) of antioxidants can dominate their behaviour under certain conditions and the development of polymer-bound antioxidants is believed to be a solution to antioxidant migration and loss.

The Significance of Autoxidation in Technological and Biological Processes. Most carbon-based materials deteriorate as a result of chemical reaction with oxygen of the environment. During the past century autoxidation has been shown to be a common factor in the loss of physical properties of rubbers and plastics, in the rancidification of fats and oils, in the deterioration of lubricating properties of hydrocarbon oils[1] and more recently reactive species involved in autoxidation have been implicated in a variety of diseases in vivo.[2–12]

The phenomenon of rubber "ageing" and the effects of very small amounts of added chemicals which were given the name "antioxygens" or "antioxidants" in inhibiting this process were observed at an early stage in the development of rubber as a technological material. Ageing of rubber was recognized by Ostwald to be associated with the absorption of oxygen in the early 1900's.[13] However, the understanding of the mechanism of oxidative deterioration remained obscure until the free radical chain reaction of autoxidation was proposed by Bäckström for benzaldehyde in the mid 1920's.[14] A key feature of the process (reactions (1)—(6)) is the formation of an intermediate peroxide[15] since this provided an explanation for the autoaccelerating oxidation rate curve which had first been observed by Genthe in 1906 in a study of the autoxidation of linseed oil.[16] The rate of autoxidation is now known to be directly related to the concentration of this species in many organic substrates and once it is present in the autoxidising system, no other initiator is required (reaction (1)).

Initiation

$$\mathrm{ROOH} \xrightarrow[(a)]{\Delta,\,h\nu} \mathrm{RO}\cdot + \cdot\mathrm{OH} \qquad (1)$$

$$\mathrm{RH} + \left.\begin{matrix}\cdot\mathrm{OH}\\ \cdot\mathrm{OR}\end{matrix}\right] \xrightarrow[(b)]{} \mathrm{R}\cdot + \left.\begin{matrix}\mathrm{H_2O}\\ \mathrm{ROH}\end{matrix}\right]$$

Propagation

$$\mathrm{R}\cdot + \mathrm{O_2} \longrightarrow \mathrm{ROO}\cdot \qquad (2)$$

$$\mathrm{ROO}\cdot + \mathrm{RH} \longrightarrow \mathrm{ROOH} + \mathrm{R}\cdot \qquad (3)$$

Termination

$$2\mathrm{R}\cdot \longrightarrow \mathrm{R\text{-}R} \qquad (4)$$

$$\mathrm{R}\cdot + \mathrm{ROO}\cdot \longrightarrow \mathrm{ROOR} \qquad (5)$$

$$2\mathrm{ROO}\cdot \longrightarrow \text{Disproportionation products} \qquad (6)$$

Since reaction (3) is normally rate determining, termination generally occurs by reaction (6) but important exceptions to this will be discussed below.

The oxidation of fats and oils has been studied by chemists for almost as long as polymeric materials. The pure linoleate esters were frequently used as chemical models of more complex oils and fats and indeed the understanding of the chemistry of cross-linking of drying oils and the deterioration of food stuffs resulted from early observations of the effects of oxygen on the 1,4 unsaturated fatty acids and their esters.[17,18] In recent years the full significance of this chemistry has begun to be appreciated by biologists and biochemists and to the scientist concerned with the durability of relatively stable systems it is a cause of wonder that nature has been able to develop such highly effective antioxidant systems in vivo. The chemical constituents of the lipids when isolated from their natural antioxidants undergo oxidative breakdown and cross-linking extremely rapidly and it is clear that man has much to learn from nature about the preservation of organic materials. Nevertheless, evidence is accumulating that the natural antioxidant defences of the body become less effective with age.[11] This results in increasing free radical activity in the cells and associated loss of elasticity of the cell tissues. There is strong evidence too that many of the diseases of old age, notably Alzheimer's disease,[10] Parkinsons disease,[12] artherio-sclerosis[12] and cancer[12] are associated with decreased oxidation resistance of the organisms involved.

There is clearly then a powerful motivation on the

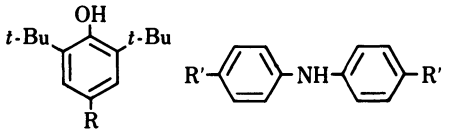
Scheme 1. Antioxidant mechanisms.

part of both technologists and biologists to a better understanding of how destructive oxidation processes may be inhibited. The following review aims to bring together the most important developments in antioxidant mechanisms that have occurred during the past thirty years.

Inhibition of Autoxidation. The autoxidation chain reaction outlined in reactions (1)—(6) can be conveniently reformulated in a way (Scheme 1) that illustrates in principle the means by which the kinetic chain can be inhibited.[19] It is clear from Scheme 1 that the process of autoxidation involves two distinct but interacting cyclical processes. The primary kinetic chain reaction involves the continuous regeneration of the chain propagating species, R· and ROO· but this cycle is continually replenished with new alkyl radicals as a result of homolysis (which may be light or metal ion catalysed) of hydroperoxides. From this formulation antioxidants may be broadly categorised into those which intercept the primary chain reaction, the chain breaking (CB) antioxidants, or those which prevent or retard the formation of initiating radicals, the preventive (P) antioxidants.[20]

Chain-Breaking Mechanism of Antioxidant Action. The alkyl and alkylperoxyl radicals display complementary behaviour.[21] Alkylperoxyl, ROO·, is an electron acceptor and can be readily reduced by hydrogen (or electron) donors. Provided the radical species produced by oxidation is stable and cannot continue the kinetic chain, this constitutes the chain-breaking hydrogen (or electron) donor (CB-D) mechanism of antioxidant action. Most CB-D antioxidants are hindered phenols or aromatic amines and representative examples used in technological systems are the 2,6-di-tert-butyl phenols (**1**) or diphenylamine derivatives (**2**).



1 **2**

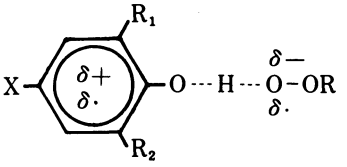
In the former, -R varies from a simple alkyl group as in BHT (R=methyl) to the much more complex multifunctional group (e.g. $C(CH_2OCOCH_2CH_2-)_4$ designed to meet the physical requirements (solubility, low volatility) of a polymeric substrate. In the diphenylamines, again the group -R′ varies widely and is frequently attached through nitrogen or oxygen.

A large amount of semiempirical information based on studies in hydrocarbon substrates has provided the following generalisation on the relationship between CB–D activity and structure.[20]

1. Electron releasing groups in the aromatic ring increase antioxidant activity, whereas electron attracting groups decrease it.

2. Substituents that delocalise the electron in the aryloxyl or arylaminyl radicals increase antioxidant activity.

These "rules" can be rationalised on the basis of the transition state (**3**) involved in hydrogen abstraction



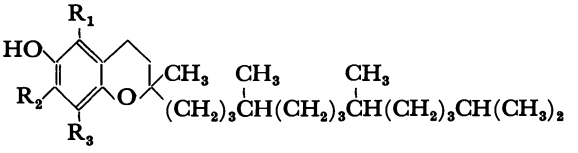
3

by alkylperoxyl. There is both partial separation of charge between the alkylperoxyl and the aromatic ring and partial delocalisation of the electron in the π bond system. Thus, groups in X and R_1,R_2 which release electrons or delocalise the impaired electron decrease the transition state energy.

A third generalization which has proved useful is that bulky groups which hinder the group from which hydrogen abstraction occurs improve antioxidant activity. This has been related to the steric stabilisation (non-reactivity) of the radical produced.[22]

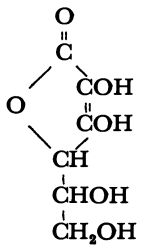
The biological antioxidants, the tocopherols

Tocopherols	R_1	R_2	R_3
α	CH_3	CH_3	CH_3
β	CH_3	H	CH_3
γ	H	CH_3	CH_3
δ	H	H	CH_3



4

Ascorbic acid



5

(Vitamin E) (**4**) and ascorbic acid (**5**) both act by the CB–D mechanism.

Although the aryloxyl derived from α-tocopherol is not as stable as many hindered phenoxyls, there is evidence that it can be readily reduced back to the parent phenol by ascorbic acid[23,24] and this cooperative interaction is believed to account for the synergism that has been obseved between these two CB–D antioxidants in the unsaturated fatty esters. Similar synergism has been observed in technological media.[25]

Although the chain-breaking donor mechanism of antioxidant action has been known for many years following the pioneering studies in the 1930s of Lowry and his co-workers,[26] very little attention was paid to the complementary chain-breaking acceptor mechanism until relatively recently. The main reason for this is that any oxidising agent for alkyl radicals is in competition with oxygen (see Scheme 2) and the CB–A process will only occur if alkyl radicals are present in the system at a concentration that makes this competition possible. CB–A antioxidants involve essentially the same radical trapping chemistry as polymerization inhibition in the absence of oxygen.[27] Among the more effective are quinones, nitro compounds and "stable" radicals; they are effective electron acceptors. These are precisely the species now recognised to be important as CB–A antioxidants.[28,29]

It was suggested some years ago[30] that an antioxidant which was capable of reversible oxidation and reduction could in principle behave as a catalytic antioxidant. The example quoted was the Cu^{2+}/Cu^{+} system since cupric salts were known to be antioxidants in some substrates. This antioxidant mechanism was subsequently shown to occur in paint media[31] where cupric acetate, which is used as a blue-green pigment, was shown to lead to the formation of conjugated polyunsaturation and brown discolouration in the paint medium.

The mechanism proposed is summarized in reactions (7) and (8) and was subsequently shown to

$$R\cdot + Cu^{2+} \longrightarrow [RCu^{+}] \longrightarrow \text{>C=C<} + Cu^{+} + H^{+} \quad (7)$$

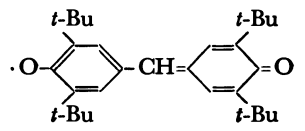
$$ROO\cdot + Cu^{+} + H^{+} \longrightarrow ROOH + Cu^{2+} \quad (8)$$

operate in polypropylene subjected to oxidation in a high shearing mixer when the oxygen concentration is low.[32] A side reaction which competes with this process and limits its practical usefulness at higher oxygen pressures when the hydroperoxide concentration is appreciable, is the well-known redox sequence involving hydroperoxide.

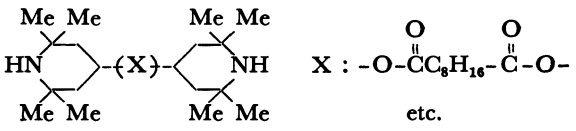
$$Cu^{+} + ROOH \longrightarrow Cu^{2+} + RO\cdot + OH^{-} \quad (9)$$

$$Cu^{2+} + ROOH \longrightarrow Cu^{+} + ROO\cdot + H^{+} \quad (10)$$

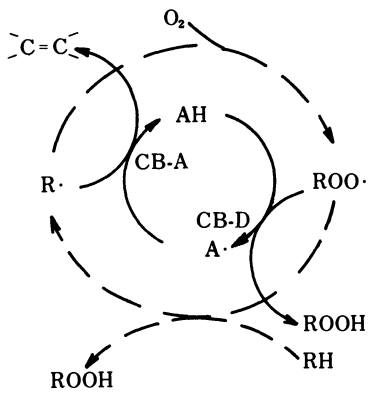
Nevertheless, the catalytic cycle summarised in reactions (7) and (8) has proved to be a useful model to explain the behaviour of a variety of oxidising species as antioxidants in oxygen deficient systems. Particularly interesting is the very high efficiency of "stable" oxyl radicals as melt stabilisers for polypropylene.[27] Galvinoxyl (**6**) and the nitroxyls derived from "hindered" piperidines (**7**) have been studied in



6



7



A· = Phenoxyl, nitroxyl, quinone, Cu^{2+}, I_2, ETC

Scheme 2. The chain-breaking antioxidant mechanisms.

Scheme 3. Mechanism of catalytic chain-breaking antioxidants.

some detail.[28,33–35] and the mechanism proposed is generalised in Scheme 3. Scheme 3 shows the competition between oxygen and the CB–A antioxidant (A·) for alkyl radicals and between the CB–D antioxidant (AH) and the substrate for alkylperoxyl radicals. The catalytic CB–A/CB–D mechanism has been shown to occur in polymeric substrates when the diffusion of oxygen into the system is limited and the oxygen concentration is therefore low.[28] The general conditions for its operation are:

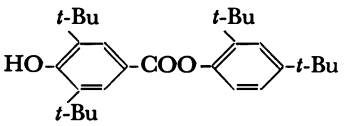
(i) The antioxidant has two relatively stable oxidation states which can coexist in the substrate. These include aryloxyl and their cognate phenols, nitroxyls and their cognate hydroxylamines, quinones and their cognate semiquinones, iodine and hydrogen iodide and cupric, and cuprous ions.

(ii) Termination can occur through alkyl. It has been known for many years, since the pioneering studies of Bateman and his co-workers,[36] that hydrocarbons which oxidise to give resonance stabilised radicals terminate in part by reactions (4) and (5) up to relatively high oxygen concentrations. Limitation of oxygen diffusion which occurs widely in polymeric substrates also increases termination through alkyl radicals so that in photo-oxidation at ambient oxygen pressure, termination of macroalkyl by nitroxyl can readily occur.[28,37] A high rate of initiation by UV light may also lead to a higher macroalkyl concentration, again favouring the CB–A/CB–D process.

Nitroxyl radicals can be generated in situ in polymers by the spin trapping procedure.[38] Mechanical shear in polyolefins during processing gives rise to macroalkyl radicals which subsequently react with spin traps.[39,40] Thus 2-methyl-2-nitrosopropane (NTB) processed into polypropylene is an effective light stabiliser. Its photoantioxidant activity is directly related to the amount of nitroxyl produced in the polymer.[40]

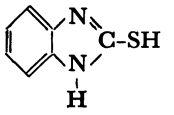
The Preventive Mechanism. Scheme 1 indicates three main mechanisms of preventive antioxidant action. Two of these, the deactivation of metal ions and the absorption of UV light, are palliative and are therefore of limited effectiveness since they retard rather than inhibit the generation of free radicals from hydroperoxides. Many such compounds are in commercial use but most of them operate by more than one mechanism, thus displaying the phenomenon of autosynergism (i.e. they contain two complementary inhibitory functions in the same molecule). Thus the copper deactivator, **8**[41] and the UV stabiliser, **9**[42] are both CB–D antioxidants and the

8

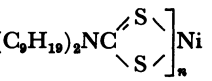


9

copper deactivator **10**[43] and the UV stabiliser **11**[44] are

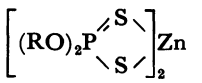


10



11

both effective peroxide decomposers. The decomposition of hydroperoxides by chemical reactions which do not lead to the formation of free radicals is by far the most important preventive mechanism of antioxidant action. It was first observed in hydrocarbon oils[45] and most modern lubricating oils contain a zinc dialkyl dithiophosphate (**12**) as a key stabilizing component. The mechanism of the metal dithiolates of which the dithiocarbamates (**11**) dithiophosphates (**12**) are typical has been extensively investigated in recent years[44] and they have been shown to function by being oxidised by hydroperoxides formed in the substrate to sulfur acids which in turn act as ionic catalysts for the further and complete destruction of hydroperoxides. Simple aliphatic sulphides (**13**) also act

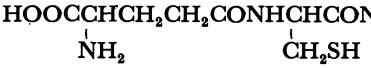


12

$(ROCOCH_2CH_2)_2S$

13

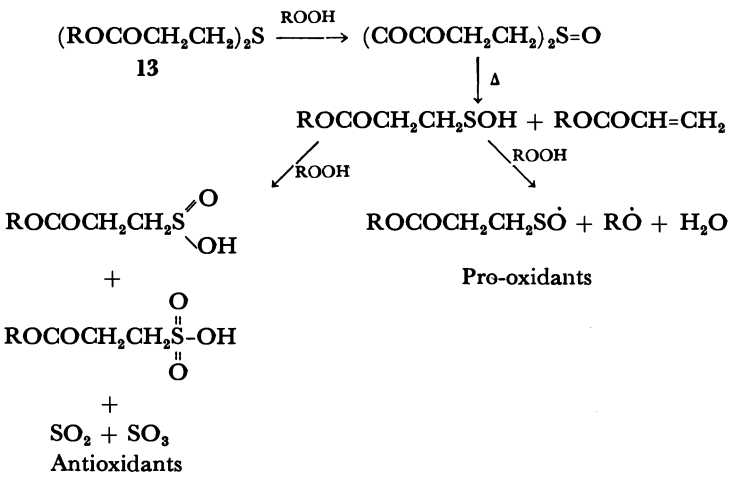
in the same way.[46] The chemistry is complex and the generation of the antioxidant species is preceded by the formation of intermediates which destroy hydroperoxides in a free radical process (Scheme 4). The early stages of the action of peroxide decomposing antioxidants are therefore often associated with prooxidant effects. Other sulphur antioxidants including the dithiolates, generate sulphinic, sulphonic and sulphuric acids in analogous processes.[44] Prior oxidation of the sulphur precursors has been shown in some cases to give rise to more effective stabilising systems.[47,48] Glutathione peroxidase (**14**) is a



14

biological antioxidant with a formal resemblance to the synthetic peroxidases. However, it seems that its hydroperoxide decomposing mechanism is quite different from the latter, involving coupled single electron-transfer steps which reduce hydroperoxides to alcohols.[49]

Synergism. Reference to Scheme 1 suggests that preventive antioxidants and chain-breaking antioxidants should have a mutual protective effect on one another. This phenomenon, commonly referred to as



Scheme 4. Mechanism of sulfide antioxidants.

"synergism" has in practice proved to be of considerable importance in technological systems. A typical synergist used in the thermal-oxidative stabilisation of polypropylene is a combination of a typical high molecular weight hindered phenol (**1**) and a 3,3′-thiodipropionate ester.[50] However, synergism can also occur between preventive antioxidants. Thus, for example, it is known that the primary initiator in photo-oxidation is the hydroperoxide which is inevitably present as a result of the processing operation.[51] The generation of radicals by this process (reaction (1)) places a very severe strain on other antioxidants present. However, many peroxide decomposers and chain-breaking antioxidants are photolytically unstable and cannot survive for very long unless they are themselves protected against UV light.[52] UV absorbers have the ability to protect chain-breaking and peroxidolytic antioxidants against photo-oxidation and some of the most effective systems condtain a combination of peroxide decomposer, chain-breaking antioxidant (sometimes as in the case of the nitroxyls, catalytic) and a UV absorber.[53]

Physical Aspects of Antioxidant Action. In recent years, attention has turned from the organic chemistry to the physical chemistry of antioxidant behaviour. Homologous antioxidants containing the same functional group frequently behave very differently in technological systems and this phenomenon can be related to their physical behaviour, particularly solubility and volatility which determine their effectiveness.[54] In order to minimise such effects a good deal of attention is being directed to the chemical attachment of antioxidants and UV stabilisers to the polymer backbone. This can be done conveniently by copolymerization or by grafting of antioxidants to the polymer chain.[55,56] Considerable success has been achieved in producing polymers which are much less susceptible to high-temperature oxidation but which will also stand up to the rigorous conditions of oil or solvent extraction to which rubbers and plastics are often exposed in the technological environment.[56,57]

An important by-product of research into polymer-bound antioxidants is the discovery that in rubber modified plastics (e.g. ABS), antioxidants chemically attached to the more oxidisable rubber phase are several times more effective than conventional antioxidants. This is due to the fact that the antioxidants are located in much higher concentration in the rubber domains where they are required to act.[57]

Future Perspective. The study of antioxidants which began as an empirical art has now become a systematic scientific discipline to interpret disparate technological phenomena by unified chemical and physical concepts. The mechanisms elaborated over the past twenty years permit the selection of antioxidants to solve specific technological problems.

As polymers and other technological media are used under more and more severe conditions, it seems inevitable that durability will in the future be an important design factor. In the field of biology too, the prevention of random oxidation is seen to be increasingly desirable in the fight against disease. In the design of synergistic antioxidant mixtures and in the targeting of antioxidants to specific sites, the biochemist can profit from research in vitro. However, man has yet to learn how to mimic the complex single electron transfer peroxidases developed by nature.

Invited Paper

Insertion of Carbon-Heteroatom Multiple Bonds into Bis(η^5-cyclopentadienyl)titanacyclobutenes

James Douglas MEINHART and Robert Howard GRUBBS*
Contribution No. 7667 from the Arnold and Mabel Beckman Laboratory of Chemical Synthesis, California Institute of Technology, Pasadena, California, 91125, U.S.A.
(Received September 17, 1987)

Titanacyclobutenes that are readily produced by the reaction of Tebbe reagent with disubstituted acetylenes react with a variety of heteroatom multiple bonds. The reaction with aldehydes and ketones is particularly clean and has been studied mechanistically. The aldehyde or ketone carbonyl oxygen coordinates to the titanium center in a preequilibrium step before ring expansion to the product metallaoxacyclohexenes.

Introduction

Insertion of unsaturated organic molecules into transition-metal carbon bonds has received much attention during the past thirty years. Insertion of carbon-carbon multiple bonds into transition-metal alkyl .complexes has been the focus of many laboratories due to the economic importance of polyolefins.[1] Carbon-heteroatom multiple bonds (i.e. ketone, ester, nitrile, and imine) also insert into transition-metal alkyl complexes.[2] Application of transition-metal alkyl complexes rather than main group complexes for nucleophilic addition to carbon-heteroatom bonds has the potential to alter the reactivity and selectivity by the appropriate combination of ancillary ligands.

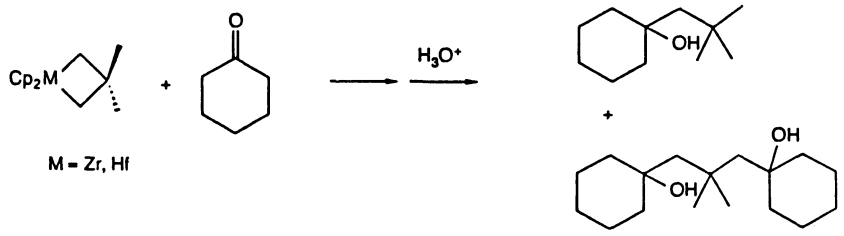
Organic chemistry contains many examples of metal alkyl addition to carbon-heteroatom multiple bonds. The Grignard reaction is a classic example of this type of reaction. Alkyl and aryl compounds derived from Li, Na, Al, and Cd are commonly used in organic synthesis.[3] The reactivity of these complexes is generally 1,2 addition to carbonyl groups, with varying selectivity.

Few transition-metal organometallic reagents have been developed for addition to carbon-heteroatom functionality. Dialkylcuprate complexes (R_2CuLi) add to α,β-unsaturated ketones in a 1,4 sense to yield a γ-alkylated ketone.[4] In contrast, an alkyllithium reagent adds in a 1,2 sense to the same ketone to yield an alcohol. This modified selectivity of a main group complex via a transition metal may provide new methods for regio- and stereo-controlled reactions.

Likewise, $(Pr^iO)_3TiCl$, when treated with a Grignard reagent, forms an alkyl titanium derivative, which is selective for aldehydes in the presence of ketones and nitriles.[5] Thus, the need for protection-deprotection of sensitive functionality may be reduced. This same titanium reagent also reacts in a highly diastereoselective manner with ketones and aldehydes. Transition-metal alkyl complexes from the left half of the transition block are highly reactive toward carbonyl compounds due to the oxophilicity of the metal.

Several reactions are known where a transition metal complex serves as a catalyst, transferring or coupling alkyl groups from a donor complex to the unsaturated substrate.[6]

Recently, 1,2-addition of carbonyl compounds to metallacyclobutane complexes has been postulated by product analysis.[7]

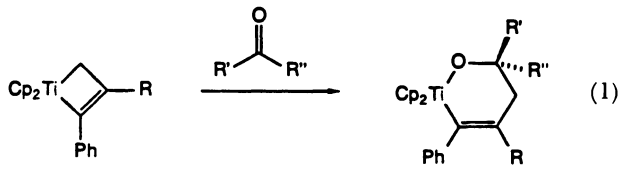


Due to the lack of methylene transfer chemistry of titanacyclobutenes, the reactivity of titanacyclobutenes with carbon-heteroatom bonds was investigated. Titanacyclobutenes[8] offer a unique template for the study of insertion into titanium-carbon bonds.

Results

Treatment of a solution of 2,3-diphenyltitanocenacyclobutene, **1a**, with acetone at room temperature for 2 days yields titanocenaoxacyclohexene, **2a**, in quantitative yield (Eq. 1). The reaction is greatly accelerated by warming the sample to 80 °C for

approximately 10—15 minutes. The 3-methyl-2-phenyltitanacyclobutene, **1b**, works equally well.[9] The titanaoxacyclohexenes, **2**, are isolated as yellow solids.



(1)

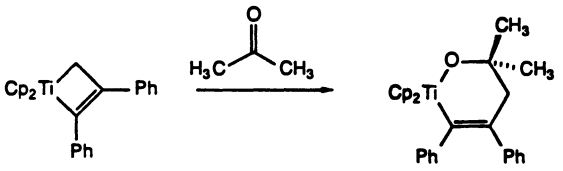
1a : R = Ph
1b : R = CH_3

2

The reaction is general for a variety of organic ketones (Table 1). Methylene transfer reaction to the ketone is not observed. Enolization of the ketone by the titanacyclobutene is not a significant side reaction.

However, titanacyclobutenes with β-hydrogens do not insert ketones to an appreciable extent. The metallacycle begins to react, and the insertion product decomposes rapidly at room temperature.

The kinetics of the insertion reaction of acetone into **1a** was monitored by NMR (Eq. 2). The rate expression was first order in metallacycle and ketone, second order overall. At 50 °C a second-order rate constant was calculated, $k_{323}=5.94(3)\times10^{-4}\ M^{-1}\ s^{-1}$.



(2)

1a **2a**

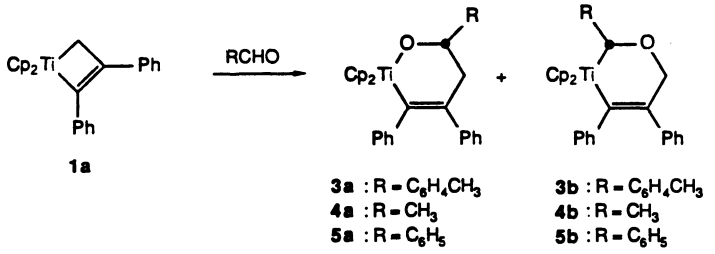
Table 1. Ketone Insertion into Titanacyclobutenes

Ketone	Titanacycle	Product		Ketone	Titanacycle	Product	
	1a		**2a**		**1a**		**2i**
	1a		**2b**		**1a**		**2j**
	**1a**		**2c**		**1a**		**2k**
	**1a**		**2d**		**1a**		**2l**
	1a		**2e**		**1a**		**2m**
	**1a**		**2f**		**1b**		**2n**
	**1a**		**2g**		**1b**		**2o**
	**1a**		**2h**				

The activation parameters were determined by Eyring analysis of the rate constants over a 40 °C temperature range (Table 2).

The NMR of the reaction solution at room temperature shows sharp signals for the metallacycle but a broad signal for the acetone. Upon cooling, the acetone signal broadens and disappears at ca. −40 °C at 90 MHz. Upon further cooling to −80 °C, the acetone signal begins to sharpen but does not split into a resolved doublet.

Aldehydes also insert cleanly into titanacyclobutenes (Eq. 3). Treatment of a solution of **1a** with *p*-tolualdehyde at room temperature cleanly results in disappearance of the starting material. Examination of the reaction mixture by NMR reveals the formation of two products in a 2:1 ratio. The major product is the expected isomer **3a** containing a titanium-oxygen bond. However, the second product appears to be a regioisomer, **3b**, in which the aldehyde has inserted in the opposite sense, forming a titanium-carbon bond. The dialkyl-substituted oxatitanacyclohexene, **3b**, is much less stable than **3a**. The titanaoxacyclohexenes are moderately air-stable and may be chromatographed on silica. The dialkyl isomers, **3b**, are air-sensitive and decompose upon warming to 80 °C. Insertion of acetaldehyde also yields two isomeric insertion products **4a** and **4b** in a nearly 1:1 ratio.



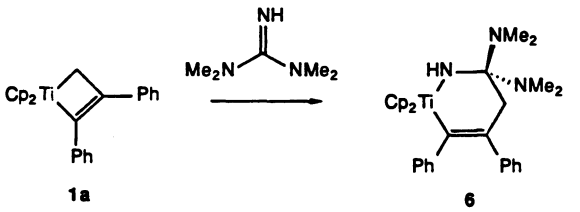
1a

3a : R = $C_6H_4CH_3$ **3b** : R = $C_6H_4CH_3$
4a : R = CH_3 **4b** : R = CH_3
5a : R = C_6H_5 **5b** : R = C_6H_5

(3)

The insertion of benzaldehyde into **1a** has also been studied by Brown-Wensley.[9] Again, two products **5a** and **5b** were observed in a 2:1 ratio. The isomers were physically separated and hydrolyzed with HCl. The organic products were identified and are consistent with proposed regiochemistry.

Several other carbon-heteroatom multiple bonds add to titanacycles **1a**. Tetramethylguanidine inserts to yield an azatitanacyclohexene **6** (Eq. 4). The 90 MHz ^{1}H NMR exhibits a broad singlet for the $N(CH_3)_2$ groups at room temperature. The signal passes through coalescence at +15 °C, and becomes two singlets ($\Delta\nu$=47.8 Hz) at −80 °C. The η^5-cyclopentadienyl resonance also is a singlet until −47 °C when it passes through coalescence and becomes two singlets ($\Delta\nu$=73.5 Hz) at −80 °C.



1a **6**

1a **7**

(5)

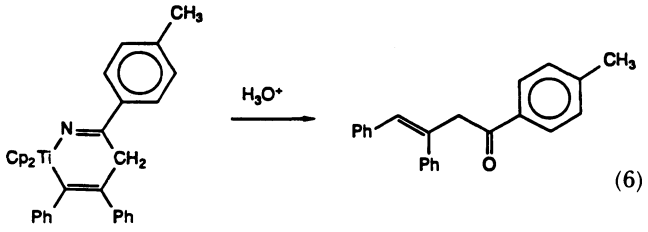
Table 2. Rate Constants and Activation Parameters for Acetone Insertion into **1a**

Temperature/K	k/$M^{-1}s^{-1}\times10^4$
293	3.51(7)
301	5.9(1)
313	16.8(2)
323	29.5(4)

$\Delta G^{\ddagger}_{301}$ = 22.0(5) kcal mol^{-1}. $\Delta H^{\ddagger}$ = 13.1(4) kcal mol^{-1}. $\Delta S^{\ddagger}_{301}$ = −29(1) eu.

Nitriles also react with titanacyclobutenes (Eq. 5); however, the reactions are not as clean as ketone insertions, and the products are not as stable. Treatment of a solution of **1a** in 400 μL of C_6D_6 with one equivalent of benzonitrile yielded, over 24 hours, a 1-aza-2-titanacyclohexa-3,6-diene complex, **7**. The product was stable for days in solution but eventually decomposed. The insertion reaction works for a variety of nitriles: *p*-tolyl, 1-methylpropyl, 1-phenylpropyl, and methacrylonitrile. Acetonitrile yielded

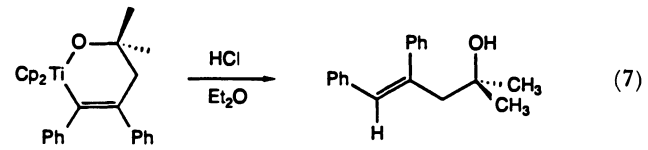
several products that decomposed rapidly at room temperature. Insertion of nitriles into titanacycle **1b** was also facile. Hydrolysis of the insertion products yields the corresponding ketones (Eq. 6).



(6)

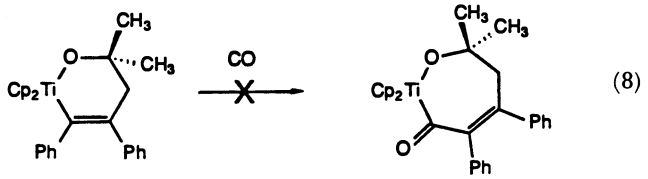
A variety of substrates do not react with the titanacyclobutenes: esters, carbonates, CO_2, CS_2, and imines.

The titanaoxacyclohexenes **2a** can be removed from the metal fragment by hydrolysis with HCl to yield a homoallylic alcohol in high yield (Eq. 7).



(7)

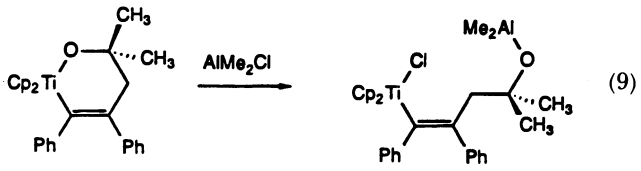
We had hoped to insert CO into the remaining titanium–carbon bond of **2a** to eventually yield a lactone (Eq. 8). However, all attempts to react **2a** with CO either thermally or photochemically failed.



(8)

2a

Lewis acids are known to accelerate migratory insertions of CO into metal–carbon bonds.[10,11] Treatment of **2a** with one equivalent of dimethylaluminum chloride results in immediate formation of a new complex. The new complex was dark-red and the NMR spectrum was very complex. Treatment of this complex with CO yield starting material **2a**. The deep-red color of the reaction mixture and analysis of the NMR spectrum suggest that the Ti–O bond transmetallates to the dimethylaluminum chloride, forming a titanocene alkenyl chloride and aluminum alkoxide (Eq. 9). Trimethyltin chloride did not react with **2a**.



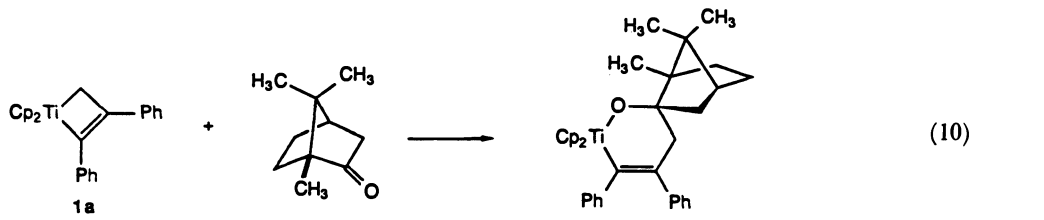
(9)

Discussion

Titanocenacyclobutenes readily insert ketones to yield titanocenaoxacyclohexenes. The reaction is quite general for many ketones, and a few examples deserve mention.

The insertion shows very little facial selection for cyclohexenone derivatives. Insertion of 2-methylcyclohexanone yields two diastereomeric products in nearly equal ratios. Insertion of *l*-carvone gives two diastereomeric products in a 62:38 ratio. The lack of diastereoselection reflects both a lack of adverse steric interactions at the transition state and the relatively high reaction temperature. Attempting to increase the diastereoselection by reducing the temperature is impractical because of the slow reaction rate at room temperature.

Titanacyclobutenes will add very sterically crowded ketones, such as *d*-camphor, although the reaction is much slower. The NMR data and difference NOE experiments suggest that the metallacycle adds to the *endo*-face of the camphor molecule (Eq. 10).[12]



(10)

Phenyl cyclopropyl ketone inserts without any rearrangement to produce a single product in high yield. If the insertion mechanism involved a one-electron reduction or oxidation of the ketone, the cyclopropyl carbinyl radical could open.[13] Although rearrangement is not observed, this experiment does not conclusively rule out a radical mechanism.

Ethyl levulinate reacts exclusively at the methyl ketone to yield the expected oxacyclohexene, **2m**. Simple esters such as methyl benzoate do not react with the titanacyclobutenes. This selectivity for ketones over esters may arise from two factors. Esters are slightly weaker bases than ketone (1–2 pK_a units).[14] The carbonyl carbon of an ester is less electrophilic compared to a ketone, due to resonance from the other oxygen atom.[15] Both factors, the less

basic carbonly oxygen and the less electrophilic carbon, contribute to the selectivity. Steric factors are not significant. Unlike ketones, which display an exchanged broadened NMR signal for the ketone during reaction, the NMR signals of the ester remain sharp.

The NMR spectra during the reaction suggest that the ketone is associated with the metallacycle prior to reaction. Titanacyclobutenes are formally 16-electron complexes and have a vacant orbital into which the carbonyl may coordinate. Variable temperature NMR experiments confirm a dynamic process with a very low activation barrier, possibly ketone coordination, occurs. Kinetic data and activation parameters (Table 2) are consistent with a second-order reaction. A rapid pre-equilibrium does not change the observed rate analysis.[16]

The regiochemistry of aldehyde insertion also provides information about the mechanism. Formation of a titanium–carbon bond compared to a more thermodynamically stable titanium-oxygen bond is very unusual. The estimated energy difference of a Ti–C and Ti–O bond is ca. 50 kcal mol^{-1}.[17] The formation of a Ti–C bond has been observed in the head-to-tail coupling of diphenylketene units in a titanium diphenylketene complex.[18]

A possible explanation for the product distribution is kinetic control of the insertion proceeding via a π-bound aldehyde complex. An organic carbonyl group can coordinate either in a π-sense or σ-sense to the metallacycle. A $Cp_2V(acetone)^+$ complex in which the acetone molecule is η^1-coordinated through the sp^2 lone pair of the oxygen atom has been structurally characterized.[19] The variable temperature NMR results may be explained, by a reversible coordination of the carbonyl group in either geometry. However, a π-complex is the necessary transition state for the insertion due to orbital overlap constraints.[20] If η^1-coordination of the oxygen atom lead directly to product, then only **3** should be formed because the carbon would never interact with the titanium. A π-complex could give two isomeric complexes, one with the oxygen atom toward the metallacycle and one with the oxygen away from the metallacycle. Due to steric interactions, ketones react only with the alkyl substituents directed away from the η^5-cyclopentadienyl rings, resulting in the observed regiospecificity. Since aldehydes have only one alkyl group, they can twist slightly to accommodate reaction in either direction (Fig. 1). Larger substituents on the aldehyde

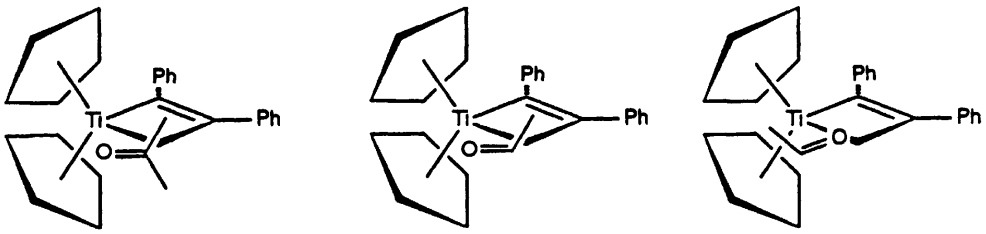


Fig. 1. Proposed carbonyl complexes of **2a**.

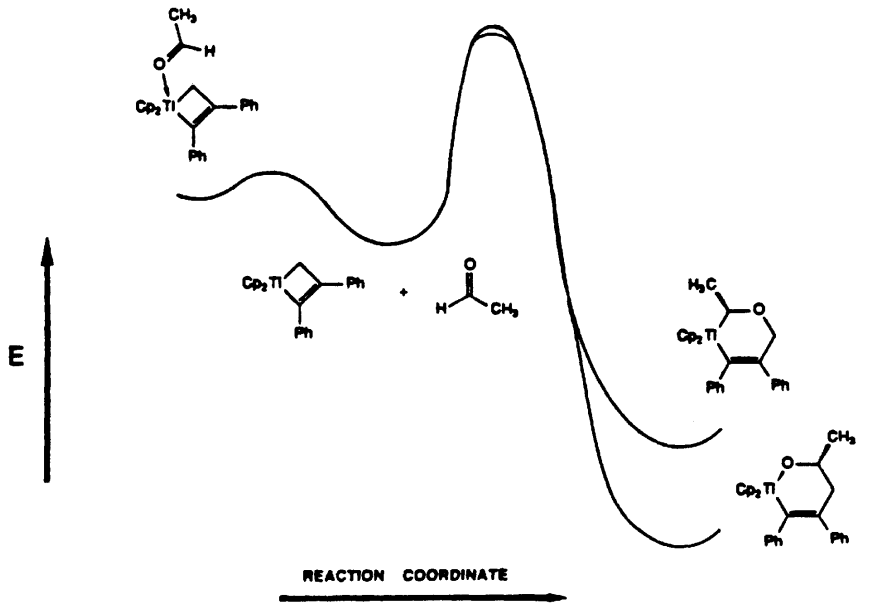

Fig. 2. Proposed energy profile for aldehyde and ketone insertion.

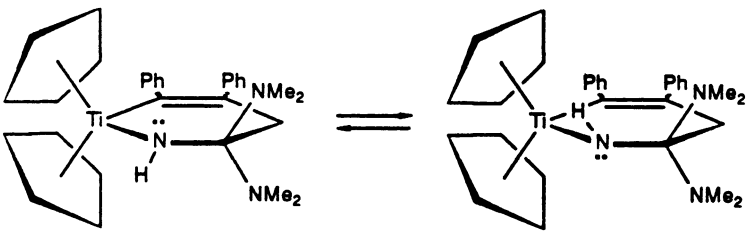
favor the Ti–O product as predicted. The metal center is d^0, and a rotation barrier resulting from back-bonding to the π^* orbital should not exist.

The products are also consistent with an early transition state. Based on the Hammond postulate, an early transition state should be "reactant-like" and not reflect the relative stability of the products.[21] A substituents-effect study of the kinetics may provide information about the polarization of the transition state. A proposed reaction coordinate is shown in Fig. 2.

Insertion of nitriles is analogous to insertion of ketones. However, the products appear to be less stable. The remaining methylene group at the γ-position may be quite acidic due to resonance delocalization (Eq. 11), and deprotonation could lead to decomposition. Nitrile insertions into zirconocene hydride and alkyl complexes yield stable complexes.[22] If the nitrile insertion product is immediately hydrolyzed, the expected ketone is isolated in low yield.

(11)

The most unusual substrate that inserts into titanacyclobutenes is tetramethylguanidine. The insertion product, **6**, has two fluxional processes by NMR.[23] The higher-energy process coalesces at +15 °C at 90 MHz, yielding a $\Delta G^*=14.2\pm0.3$ kcal mol^{-1}. This process is attributable to hindered rotation of the $N(CH_3)_2$ groups. The lower-energy process coalesces at −47 °C, yielding a $\Delta G^*=10.9\pm0.3$ kcal mol^{-1}. This process is attributable to the inversion of the NH group bonded to the titanium. The nitrogen pair presumably interacts with the vacant LUMO on the metal (Eq. 12).[24] This interaction would lead to inequivalent η^5-cyclopentadienyl rings, if the rate were slowed below the NMR time scale.



(12)

The lack of carbonylation of **2a** is consistent with other titanium and zirconium alkyl alkoxide complexes. The lack of carbonylation is usually explained by invoking donation of the oxygen lone pair into the LUMO on the titanium. Dative interaction from the oxygen fills the orbital, which would be used for coordination of the CO. This π-donation from the oxygen of titanium alkoxides has been structurally verified.[25] Attempts to complex the oxygen to another Lewis acid failed. Dimethylaluminum chloride appeared to transmetallate the Ti–O bond, although the resulting complex did not react with CO.

Conclusion

Titanacyclobutenes readily insert ketones, aldehydes, and nitriles to form new organometalic complexes. These reactions proceed in good yield with titanacyclobutenes that have a phenyl grouped at the α-position. Titanacyclobutenes that have alkyl substituents at the α-position form unstable products.

The reaction is general for many ketones and highly selective for ketones and aldehydes over esters. Aldehydes yield two products, the predicted Ti–O bound isomer but also the Ti–C bound isomer. The product distribution is consistent with a π-bound carbonyl group at the rate-determining transition state. A detailed kinetics study of the insertion, including substituent effects, would be useful in understanding the mechanism.

Insertion of nitriles forms an analogous product; however, they are less stable than the ketone products.

The titanaoxacyclohexenes, **2**, may be hydrolyzed to the corresponding homoallylic alcohols in high yield. Unfortunately, the titanaoxacyclohexenes would not insert CO under any of the conditions used. Extensions of this work utilizing functionalized titanacyclobutenes and different Lewis acids may find use in organic synthesis.

Experimental

General Considerations. All manipulations were performed with the use of standard Schlenk techniques under argon or in a Vacuum Atmospheres Co. glovebox under nitrogen. Argon was purified by passage through columns of BASF R3-11 (Chemalog) and Linde 4 Å molecular sieves. Carbonylations were performed in Lab-Glass pressure bottles (60 or 100 mL) fitted with two inlet valves and a pressure gauge. Toluene, benzene, THF, and diethyl ether were vacuum-transferred from sodium benzophenone ketyl and stored in Teflon-valve sealed vessels under argon. Pentane and hexane were stirred over concentrated H_2SO_4, dried, vacuum-transferred from sodium benzophenone ketyl and stored in Teflon-valve sealed vessels under argon.

Methylene chloride was vacuum-transferred from P_2O_5 or CaH_2 and stored under argon. Benzene-d_6, toluene-d_8, and THF-d_8 were vacuum-transferred from sodium benzophenone ketyl. Carbon monoxide (CP) was obtained from Matheson. ^{13}C-enriched carbon monoxide (90% ^{13}C) was obtained from Monsanto-Mound Laboratories. Trimethylphosphine was obtained from Strem Chemicals. Acetylenes were obtained from Aldrich, Farchan Laboratory, or Wiley Organics and dried or distilled before use.

Instrumentation. Infrared spectra were recorded on either a Beckman 4240, Shimadzu IR-435, or Perkin-Elmer 1310 spectrophotometer. ^{1}H NMR were recorded on a Varian EM-390, JEOL FX-90Q, Varian XL-200, JEOL GX-400, or Brüker WM-500 and referenced to residual solvent (C_6D_6, δ 7.15; C_7D_8, δ 2.09; THF-d_8, δ 3.58 or 1.73; $CDCl_3$, δ 7.24). ^{31}P{^{1}H} NMR were recorded on a JEOL FX-90Q and referenced to external 85% H_3PO_4 (positive δ, lower field). ^{13}C{^{1}H} NMR were recorded on a JEOL FX-90Q, Varian XL-200, or JEOL GX-400. Difference NOE spectra were recorded on a JEOL GX-400 or a Brüker WM-500 at the Southern California Regional NMR Facility located at the California Institute of Technology. Reaction kinetics were performed on the JEOL FX-90Q using an automated routine. Elemental analyses were performed by Dornis and Kolbe, Mulheim, West Germany, and the analytical facility of the California Institute of Technology.

Kinetics. The rates of the reaction were determined by NMR in septum capped tubes. At least 12 data points were taken by integration of the methylene signals in the starting material and products. The complex **1a** varied in concentration from 0.12 to 0.24 M and the acetone was always in excess varying from 0.17—0.34 M in C_6D_6. Probe temperature was determined at each temperature by a standard second order kinetic calculation.

Materials. Titanacyclobutenes were synthesized as previously described.[8] Ketones, aldehydes, and nitriles were purchased from Aldrich Chemical Co. and used as received. Tetramethylguanidine was obtained from Kodak and dried over 4 Å molecular sieves.

Insertion of Ketones into Titanacyclobutenes 1a and 1b. All reactions were performed by the same general procedure. A stirred solution or suspension of the titanacyclobutene (typically 0.5 M in toluene) was treated with the ketone. The mixture was stirred for 24—48 hours at room temperature, at which time the solution was clear orange. As an alternate method, the reaction mixture was heated to 80 °C for 10—15 minutes and cooled to room temperature. The orange solution was filtered and the volatiles removed, the solid washed with pentane or ether, and dried in vacuo to yield the product.

3,3-Dimethyl-5,6-diphenyl-2-oxa-titanocenecyclohex-5-ene, 2a. Yield: 93%. ^{1}H NMR (90 MHz, C_6D_6) δ=7.08—6.64 (m, 10H), 5.77 (s, 10H), 2.67 (s, 2H), 1.21 (s, 6H). ^{13}C{^{1}H} NMR (22.5 MHz, C_6D_6) δ=190.32, 154.32, 147.23, 134.30, 129.82, 127.55, 124.68, 122.87, 113.64 (Cp), 88.16, 58.79, 28.64. IR (KBr, cm^{-1}) 3010 (w), 2960 (m), 2920 (m), 1650 (w), 1155 (s), 995 (s), 800 (s). Anal. Calcd for $C_{28}H_{28}OTi$: C, 78.50; H, 6.59%. Found: C, 78.50; H, 6.72%.

3-Methyl-3,5,6-triphenyl-2-oxa-titanocenecylohex-5-ene, 2b. Yield: 87%. ^{1}H NMR (400 MHz, C_6D_6) δ=7.267—6.789 (m, 15H), 5.954 (s, 5H), 5.591 (s, 5H), 3.089 (d, J=15.4 Hz, 1H), 2.962 (d, J=15.4 Hz, 1H), 1.578 (s, 3H). Difference NOE experiments: irradiation of δ 5.954 enhances δ 7.220, 6.789, 5.591, 3.089; irradiation of δ 5.591 enhances δ 6.789, 5.954. ^{13}C{^{1}H} NMR (22.5 MHz, C_6D_6) δ=190.7, 154.2, 150.6, 147.3, 133.9, 129.8, 128.3, 127.7, 126.4, 124.9, 123.1, 114.9 (Cp), 113.2 (Cp), 90.8, 58.3, 29.3. IR (KBr, cm^{-1}) 3025 (m), 2975 (m), 1600 (w), 1090 (s), 1068 (s), 1000 (s), 804 (s). Anal. Calcd for $C_{33}H_{30}OTi$: C, 80.81; H, 6.16%. Found: C, 79.70; H, 6.06%.

Reaction of Cyclohexanone with 1a, 2c. Yield: 90%. ^{1}H NMR (400 MHz, C_6D_6) δ=7.029 (m, 6H), 6.883 (t of t, J=7.0, 2.0 Hz, 1H), 6.767 (m, 3H), 5.775 (s, 10H), 2.646 (s, 2H), 1.710 (m, 2H), 1.472 (m, 5H), 1.349 (m, 2H), 1.239 (m, 1H). Difference NOE experiments: irradiation of δ 5.775 enhances δ 6.767, 2.646, 1.710; irradiation of δ 2.646 enhances δ 5.775, 1.349. ^{13}C{^{1}H} NMR (50 MHz, C_6D_6) δ=189.4, 154.7, 147.6, 133.6, 129.9, 128.3, 124.6, 122.8, 113.5 (Cp), 89.9, 57.1, 37.8 (×2), 26.6, 23.6 (×2). IR (KBr, cm^{-1}) 3030 (m), 2925 (s), 1068 (s), 995 (s), 800 (s).

Reaction of 2-Cyclohexen-1-one with 1a, 2d. Yield: 57%. ^{1}H NMR (400 MHz, C_6D_6) δ=7.062—7.046 (m, 6H), 6.868 (m, 1H), 6.804 (m, 3H), 6.044 (d, J=10.0 Hz, 1H), 5.841 (s, 5H), 5.742 (s, 5H), 5.74 (d, overlapping Cp, 1H), 2.838 (d, J=15.4 Hz, 1H), 2.750 (d, J=15.4 Hz, 1H), 1.932—1.755 (m, 3H), 1.641—1.518 (m, 3H). Difference NOE experiments: irradiation of δ 5.841 enhances δ 6.84, 2.838; irradiation of δ 5.742 enhances δ 6.044, 2.750. ^{13}C{^{1}H} NMR (50 MHz, C_6D_6) δ=190.7, 154.2, 147.2, 133.3, 133.6, 129.9, 128.7, 128.3, 127.8, 124.8, 122.9, 113.9 (Cp), 113.7 (Cp), 87.4, 57.8, 36.6, 25.9, 25.4, 20.3. IR (KBr, cm^{-1}) 3015 (w), 2920 (m), 1068 (s), 993 (s), 805 (s).

3-Cyclopropyl-3,5,6-triphenyl-2-oxa-titanocenecyclohex-5-ene, 2e. Yield: 77%. ^{1}H NMR (400 MHz, C_6D_6) δ=7.23—6.76 (m, 15H), 5.842 (s, 5H), 5.673 (s, 5H), 3.381 (d, J=15.4 Hz, 1H), 3.283 (d, J=15.4 Hz, 1H), 1.472 (m, 1H), 0.430 (m, 2H), 0.295 (m, 1H), 0.198 (m, 1H). Difference NOE experiments: irradiation of δ 5.842 enhances δ 7.06, 6.77, 3.28; irradiation of 5.673 enhances δ 6.77, 1.47, 0.43, 0.198. ^{13}C{^{1}H} NMR (22.5 MHz, C_6D_6) δ=189.3, 154.4, 147.6, 146.7, 133.7, 130.1, 127.5, 127.7, 126.4, 124.9, 123.0, 115.1 (Cp), 112.8 (Cp), 91.7, 57.1, 22.8, 2.19, 1.47. IR (KBr, cm^{-1}) 3010 (m), 2930 (w), 1030 (s), 810 (s).

Reaction of α-Tetralone with 1a, 2f. Yield: 96%. ^{1}H NMR (400 MHz, C_6D_6) δ=7.940 (d, J=7.6 Hz, 1H), 7.237 (m, 1H), 7.108 (m, 1H), 7.044 (m, 8H), 6.860 (m, 2H), 6.796 (m, 1H), 5.998 (s, 5H), 5.673 (s, 5H), 3.150 (d, J=16.1 Hz, 1H), 2.920 (s, J=16.1 Hz, 1H), 2.643 (m, 1H), 2.588 (m, 1H), 2.320 (m, 1H), 1.923 (m, 1H), 1.815 (m, 2H). Difference NOE experiments: irradiation of δ 5.998 enhances δ 7.940, 6.860, 5.673, 3.150; irradiation of δ 5.673 enhances δ 6.860, 5.998, 2.920, 1.923.

Reaction of β-Tetralone with 1a, 2g. Yield: 77%. ^{1}H NMR (400 MHz, C_6D_6) δ=7.236—6.911 (m, 14H), 5.961 (s, 1H), 5.561 (s, 5H), 3.270 (d, J=16.3 Hz, 1H), 2.942 (m, 1H), 2.920 (d, J=15.6 Hz, 1H), 2.880 (d, J=16.6 Hz, 1H), 2.722 (d, J=15.6 Hz, 1H), 1.825 (m, 1H), 1.780 (m, 1H). Difference NOE experiments: irradiation of δ 5.961 enhances δ 6.91, 5.561, 2.920; irradiation δ 5.561 enhances δ 6.91, 5.961, 3.270.

3-Methyl-5,6-diphenyl-3-vinyl-2-oxa-titanocenecylohex-5-ene, 2h. Yield: 62%. ^{1}H NMR (400 MHz, C_6D_6) δ=7.03—6.76 (m, 10H), 5.97 (d of d, J=10.5, 17.1 Hz, 1H), 5.938 (s, 5H), 5.612 (s, 5H), 5.100 (d of d, J=17.1, 2.2 Hz, 1H), 4.970 (d

of d, J=10.5, 2.2 Hz, 1H), 2.910 (d, J=15.4 Hz, 1H), 2.58 (d, J=15.4 Hz, 1H), 1.34 s 3. Difference NOE experiments: irradiation of δ 5.940 and 5.970 enhances δ 6.76, 5.61, 2.91; irradiation of δ 5.61 enhances δ 6.76, 5.94; irradiation of δ 1.34 enhances 7.02, 5.97, 5.61, 5.10, 2.58. $^{13}C\{^1H\}$ NMR (22.5 MHz, C_6D_6) δ=190.7, 154.3, 147.0, 146.1, 133.4, 129.9, 127.6, 124.8, 123.0, 114.5, 113.4, 110.3, 89.7, 57.0, 26.2. IR (KBr, cm^{-1}) 3005 (m), 2910 (s), 1015 (s), 987 (s), 800 (s).

Reaction of Ethyl Levulinate with 1a. Synthesis of 2m. ^1H NMR (400 MHz, C_6D_6) δ=7.02—6.69 (m, 6H), 6.88 (t of t, J=7.0, 2.0 Hz, 1H), 6.75 (m, 3H), 5.901 (s, 5H), 5.596 (s, 5H), 4.010 (m, 2H), 2.720 (d, J=15.4 Hz, 1H), 2.460 (d, J=15.4 Hz, 1H), 2.315 (m, 2H), 2.138 (m, 1H), 2.01 (m, 1H), 1.77 (m, 1H), 1.134 (s, 3H), 1.020 (t, J=7.1 Hz, 3H). Difference NOE experiments: irradiation of δ 5.901 enhances δ 6.75 and 2.72; irradiation of δ 5.596 enhances δ 6.75. $^{13}C\{^1H\}$ NMR (22.5 MHz, C_6D_6) δ 190.52, 173.51, 154.27, 147.18, 133.85, 129.84 (CH), 127.62 (CH), 124.75 (CH), 122.96 (CH), 114.19 (Cp), 113.59 (Cp), 89.38 (quat), 60.07 (CH_2), 57.52 (CH_2), 37.53 (CH_2), 30.11 (CH_2), 24.64 (CH_3) 14.34 (CH_3).

Reaction of *l*-Carvone with 1a. Synthesis of 2j. Major isomer: ^1H NMR (400 MHz, C_6D_6) δ=7.31—6.75 (m, 10H), 6.076 (s, 5H), 5.441 (s, 5H), 5.32 (br s, 1H), 5.05 (t, J=1.0 Hz, 1H), 4.91 (t, J=1.0 Hz, 1H), 3.16 (d of d, J=15.8, 1.7 Hz, 1H), 2.70 (m, 1H), 2.69 (d, J=15.8 Hz, 1H), 2.50 (m, 2H), 1.95 (m, 1H), 1.83 (br s, 3H), 1.79 (s, 3H). Difference NOE experiments: irradiation of δ 6.074 enhances δ 6.880, 5.441, 3.16; irradiation of δ 5.441 enhances δ 6.076. $^{13}C\{^1H\}$ NMR (22.5 MHz, C_6D_6) δ 190.95, 154.22, 149.51, 147.45, 140.13, 134.34, 130.11, 129.95, 127.67, 125.94, 125.40, 124.08, 123.18, 123.07, 113.37 (Cp), 114.51 (Cp), 109.71, 93.33, 53.68, 40.89, 39.27, 31.89, 20.52, 19.22.

Minor isomer: ^1H NMR (400 MHz, C_6D_6) δ=7.31—6.75 (m, 10H), 6.032 (s, 5H), 5.665 (s, 5H), 5.44 (br d, J=12 Hz, 1H), 5.01 (t, J=1.0 Hz, 1H), 4.89 (t, J=1.0 Hz, 1H), 3.35 (d, J=15.6 Hz, 1H), 2.41 (d, J=15.6 Hz, 1H), 2.70 (m, 1H), 2.50 (m, 2H), 1.95 (m, 1H), 1.88 (br s, 3H), 1.78 (s, 3H). Difference NOE experiments: irradiation of δ 6.032 enhances δ 6.75, 5.665, 3.35; irradiation of δ 5.665 enhances δ 6.75, 6.032. $^{13}C\{^1H\}$ NMR (22.5 MHz, C_6D_6) δ=190.14, 154.44, 149.78, 147.12, 137.86, 134.23, 130.11, 129.95, 127.67, 125.94, 125.40, 124.08, 123.18, 123.07, 114.51 (Cp), 113.48 (Cp), 109.64, 91.00, 56.06, 41.81, 38.72, 32.33, 20.95, 19.54. (Some signals of the isomers overlap.)

Reaction of Norcamphor with 1a. Synthesis of 2k. ^1H NMR (400 MHz, C_6D_6) δ=7.05—6.99 (m, 6H), 6.86 (t of t, J=7.1, 2.0 Hz, 1H), 6.78 (m, 3H), 5.825 (s, 5H), 5.692 (s, 5H), 2.84 (d, J=15.4 Hz, 1H), 2.73 (d, J=15.4 Hz, 1H), 2.18—2.15 (m, 2H), 1.81 (m, 1H), 1.73 (m, 1H), 1.53 (m, 1H), 1.35—1.15 (m, 4H), 0.93 (m, 1H). Difference NOE experiments: irradiation of δ 5.825 enhances δ 6.78, 5.692, 2.84; irradiation of δ 5.692 enhances δ 6.78, 5.825, 2.73, 1.35. $^{13}C\{^1H\}$ NMR (22.5 MHz, C_6D_6) δ=190.30, 154.92, 147.34, 134.12, 129.90, 127.62, 127.51, 124.70, 122.85, 113.59 (Cp), 113.48 (Cp), 97.45, 57.52, 48.26, 45.44, 38.24, 37.42, 29.29, 22.85.

Reaction of *d*-Camphor with 1a. Synthesis of 2l. ^1H NMR (400 MHz, C_6D_6) δ=7.14—6.99 (m, 6H), 6.86—6.78 (m, 4H), 5.961 (s, 10H), 5.641 (s, 10H), 2.940 (d, J=15.4 Hz, 1H), 2.360 (d, J=15.4 Hz, 1H), 2.195 (d of t, J=12.9, 1.5, 1H), 1.72 (t, J=4.6 Hz, 1H), 1.68 (d, J=13.2 Hz, 1H), 1.56 (m, 2H), 1.32 (m, 2H), 1.017 (s, 3H), 0.932 (s, 3H), 0.852 (s, 3H). Difference NOE experiments: irradiation of δ 5.961 enhances δ 5.641, 2.96, 1.72, 0.932; irradiation of δ 5.641 enhances δ 5.961, 2.360, 2.195, 1.017. $^{13}C\{^1H\}$ NMR (22.5 MHz, C_6D_6) δ 190.57, 154.82, 147.77, 134.39, 129.95, 128.49, 127.67, 127.57, 124.75, 122.96, 113.64 (Cp), 113.37 (Cp), 100.80, 54.65, 54.43, 49.40, 45.88, 31.57, 27.51, 21.55, 21.39, 12.12.

Reaction of 2-Methylcyclohexanone with 1a. Synthesis of 2i. First isomer: ^1H NMR (400 MHz, C_6D_6) δ=7.06—6.75 (m, 10H), 6.000 (s, 5H), 5.644 (s, 5H), 2.80 (d, J=15.6 Hz, 1H), 2.56 (d, J=15.6 Hz, 1H), 2.01 (m, 1H), 1.56—1.10 (m, 8H), 0.995 (d, J=6.6 Hz, 3H). Second isomer: ^1H NMR (400 MHz, C_6D_6) δ=7.06—6.75 (m, 10H), 5.943 (s, 5H), 5.601 (s, 5H), 2.96 (d, J=15.6 Hz, 1H), 2.53 (d, J=15.6 Hz, 1H), 2.01 (m, 1H), 1.56—1.04 (m, 8H), 0.950 (d, J=7.1 Hz, 3H). Difference NOE experiments: irradiation of δ 6.000 enhances δ 6.75, 2.80; irradiation of δ 5.943 enhances δ 6.75, 2.96; irradiation of δ 5.664 enhances δ 6.75, 2.56, 2.01, 1.53; irradiation of δ 5.601 enhances δ 6.75, 2.53, 2.01. $^{13}C\{^1H\}$ NMR (22.5 MHz, C_6D_6) δ 189.60, 189.27, 154.82, 154.55, 147.94, 147.61, 134.45, 134.28, 129.95, 127.62, 124.75, 122.91, 114.19, 114.02, 113.32, 113.05, 93.4, 92.52, 55.68, 50.15, 41.76, 41.43, 35.25, 31.79, 24.53, 24.42, 24.09, 23.94, 16.46.

3,3-Bis(dimethylamino)-5,6-diphenyl-2-aza-titanocenecyclohex-5-ene, 6. Yield: 92%. ^1H NMR (90 MHz, C_7D_8) δ=7.30—6.24 (m, 10H), 5.72 (s, 10H), 2.56 (br s, 6H), 2.45 (s, 3H). $^{13}C\{^1H\}$ NMR (22.5 MHz, C_7D_8) δ=178.70, 161.09, 158.76, 150.15, 129.29, 127.88, 127.34, 127.07, 124.09, 121.71, 110.28 (Cp), 39.20 (br), 30.96. IR (KBr, cm^{-1}) 3060 (w), 3020 (w), 2920 (m), 2870 (m), 1570 (s), 1485 (s), 1455 (s), 1425 (s), 1360 (s), 1122 (s), 1022 (s), 805 (s). Anal. Calcd for $C_{30}H_{35}N_3Ti$: C, 74.21; H, 7.27; N, 8.65%. Found: C, 74.05; H, 7.18; N, 8.52%.

3,3,5-Trimethyl-6-phenyl-2-oxa-titanocenecyclohex-5-ene, 2n. Yield: 74%. ^1H NMR (90 MHz, C_6D_6) δ=7.38—6.87 (m, 5H), 5.74 (s, 10H), 2.26 (s, 2H), 1.64 (s, 3H), 1.13 (s, 6H). $^{13}C\{^1H\}$ NMR (22.5 MHz, C_6D_6) δ=186.8, 155.0, 123.0, 113.6, 88.0, 57.4, 28.5, 24.2. IR (KBr, cm^{-1}) 3020 (w), 2980 (m), 2910 (m), 1000 (s), 805 (s). Anal. Calcd for $C_{23}H_{26}OTi$: C, 75.41; H, 7.15%. Found: C, 75.16; H, 7.03%.

3,5-Dimethyl-3,6-diphenyl-2-oxa-titanocenecyclohex-5-ene, 2o. Yield: 85%. ^1H NMR (90 MHz, C_6D_6) δ=7.33—6.95 (m, 10H), 5.88 (s, 5H), 5.62 (s, 5H), 2.83 (d of d, J=15.3, 1.0 Hz, 1H), 2.42 (d, J=15.3 Hz, 1H), 1.70 (d, J=1.0 Hz, 3H), 1.42 (s, 3H). $^{13}C\{^1H\}$ NMR (22.5 MHz, C_6D_6) δ=187.05, 154.87, 150.81, 128.27, 126.54, 126.37, 124.91, 123.40, 114.67 (Cp), 113.10 (Cp), 90.78, 56.82, 28.64, 24.42. IR (KBr, cm^{-1}) 3060 (w), 2990 (m), 2890 (m), 1100 (s), 1070 (s), 808 (s).

Acidolysis of 2a. A stirred suspension of **2a** (115 mg, 0.268 mmol) in 2 ml of diethyl ether at 0 °C was treated with anhydrous HCl gas (15 ml, 0.67 mmol). The mixture immediately turned red and a red precipitate formed. The reaction was warmed to room temperature over 15 minutes, diluted with 10 ml more diethyl ether, filtered through a 1-inch plug of silica gel and the filtrate concentrated at reduced pressure to yield an orange residue. The residue was extracted with petroleum ether: ether (3:1), the extract filtered through glass wool, and concentrated at reduced pressure to yield the product 2-methyl-4,5-diphenyl-4-penten-2-ol (61 mg, 0.242 mmol, 90%) as yellowish crystals. ^1H NMR (400 MHz, $CDCl_3$) δ=7.279—7.198 (m, 5H), 7.100—7.052 (m, 3H), 6.940—6.921 (m, 2H), 6.522 (s, 1H),

2.768 (s, 2H), 1.497 (br s, 1H), 1.155 (s, 6H). $^{13}C\{^1H\}$ NMR (22.5 MHz, $CDCl_3$) δ=141.41, 139.35, 137.13, 130.68, 129.00, 128.63, 127.82, 127.11, 126.35, 71.53, 53.71 (CH_2), 29.76 (CH_3).

Reaction of *p*-Tolualdehyde with 1a. To a stirred suspension of titanacyclobutene **1a** (365 mg, 0.986 mmol) in 2 ml toluene at room temperature was added *p*-tolualdehyde (140 ml, 1.18 mmol). The mixture was stirred at room temperature for 12 hours, then the volatiles removed in vacuo to yield a red-orange form. The foam was triturated with diethylether, the yellow precipitate filtered from the red solution, and both fractions taken to dryness. The yellow fraction (150 mg, 0.307 mmol) was the insertion product **10a**: ^1H NMR (90 MHz, C_6D_6) δ=7.37—6.67 (m, 14H), 6.06 (s, 5H), 5.59 (s, 5H), 5.48 (m, 1H), 3.05 (s, 1H), 2.97 (d, J=3.2 Hz, 1H), 2.18 (s, 3H). ^1H NMR (400 MHz, C_6D_6) δ=7.29—6.95 (m, 10H), 6.89 (t of t, J=7.1, 0.8 Hz, 2H), 6.78 (t, of t, J=7.1, 0.8 Hz, 2H), 6.119 (s, 5H), 5.610 (s, 5H), 5.53 (d of d, J=10.1, 2.8 Hz, 1H), 3.07 (d of d, J=16.6, 2.9 Hz, 1H), 2.985 (d of d, J=16.6, 10.2 Hz, 1H), 2.18 (s, 3H). $^{13}C\{^1H\}$ NMR (22.5 MHz, C_6D_6) δ=191.44, 153.03, 146.71, 136.51, 136.29, 130.06, 129.08, 128.43, 127.62, 125.72, 124.97, 123.28, 114.35 (Cp), 113.86 (Cp), 88.67, 57.09, 21.11. The diethyl ether-soluble fraction revealed a 2:1 ration of products. The major product was the same as the yellow precipitate; the minor product had ^1H NMR η^5-cyclopentadienyl resonances at δ 5.91, 5.82.

Reaction of Acetaldehyde with 1a. To a stirred suspension of titanacyclobutene **1a** (320 mg, 0.864 mmol) in 3 ml of toluene at room temperature was added acetaldehyde (60 ml, 1.07 mmol) via syringe. The reaction vessel was wrapped in Al foil and the mixture stirred for 12 hours. The reaction mixture was taken to dryness and the red-orange solid was extracted with 2 ml toluene at −78 °C. Both fractions were dried in vacuo. The extract was red-orange and the residue was dark-red. The red-orange extract material was a 2:1 ratio of the Ti-O product. Orange isomer: ^1H NMR (90 MHz, C_6D_6) δ=7.34—6.57 (m, 10H), 5.98 (s, 5H), 5.60 (s, 5H), 4.66—4.29 (m, 1H), 2.70 (s, 1H), 2.64 (d, J=2.9 Hz, 1H), 1.06 (d, J=5.8 Hz, 3H). ^1H NMR (400 MHz, C_6D_6) δ=7.406—6.728 (m, 10H), 5.982 (s, 5H), 5.592 (s, 5H), 4.498 (m, 1H), 2.70 (d of d, J=16.4, 2.8 Hz, 1H), 2.60 (d of d, J=16.4, 9.5 Hz, 1H), 1.06 (d, J=5.9 Hz, 3H). $^{13}C\{^1H\}$ NMR (22.5 MHz, C_6D_6) δ=191.11, 153.30, 136.18, 130.49, 130.06, 128.33, 127.57, 124.91, 123.12, 114.19 (Cp), 113.54 (Cp), 83.25, 55.95, 23.77. Red isomer: ^1H NMR (400 MHz, C_6D_6) δ=7.336—6.944 (m, 10H), 5.890 (s, 5H), 5.883 (s, 5H), 5.641 (q, J=6.35 Hz, 1H), 4.470 (d of d, J=10.0, 4.2 Hz, 1H), 1.48 (d, J=9.8 Hz, 1H), 1.215 (d, J=6.35 Hz, 3H). $^{13}C\{^1H\}$ NMR (22.5 MHz, C_6D_6) δ=181.76, 148.32, 146.09, 144.63, 143.06, 130.44, 130.00, 128.27, 127.57, 126.05, 125.67, 113.54 (Cp), 111.29 (Cp), 87.97, 59.42, 22.41.

Reaction of Benzonitrile with 1a. A solution of titanacycle **1a** (34 mg, 0.092 mmol) in 400 μL of C_6D_6 in an NMR tube was treated with benzonitrile (10 μL, 0.098 mmol). After 24 hours the solution was dark orange and NMR analysis revealed a new compound: ^1H NMR (90 MHz, C_6D_6) δ=7.50—6.80 (m, 15H), 5.64 (s, 10H), 4.03 (s, 2H).

Reaction of *p*-Tolunitrile with 1a. A solution of titanacyclobutene **1a** (38 mg, 0.103 mmol) in 400 μL of C_6D_6 in an NMR tube was treated with *p*-tolunitrile. After 18 hours the color had changed to dark-orange, and the NMR spectrum revealed the reaction as 90% complete: ^1H NMR (90 MHz, C_6D_6) δ=7.50—6.80 (m, 14H), 5.66 (s, 10H), 4.01 (s, 2H), 2.13 (s, 3H).

Reaction of α-Phenylpropionitrile with 1a. A solution of **1a** (38 mg, 0.103 mmol) in 400 μL of C_6D_6 in an NMR tube was treated with α-phenylpropionitrile (14 μL, 0.105 mmol) at room temperature. The color changed slowly over 24 hours from red to dark-orange. NMR analysis revealed a single product and some remaining starting materials: ^1H NMR (90 MHz, C_6D_6) δ=7.15—6.60 (m, 15H), 5.63 (s, 5H), 5.61 (s, 5H), 3.54 (br s, 2H), 3.08 (q, J=7.0 Hz, 1H), 1.32 (d, J=7.0 Hz, 3H).

Reaction of α-Methylpropionitrile with 1a. A solution of **1a** (38 mg, 0.103 mmol) in 400 μL of C_6D_6 in an NMR tube was treated with α-methylpropionitrile (10 μL, 0.11 mmol) at room temperature. The color changed slowly over 24 hours from red to dark-orange. NMR analysis revealed a single product and some remaining starting materials: ^1H NMR (90 MHz, C_6D_6) δ=7.15—6.60 (m, 10H), 5.60 (s, 10H), 3.51 (s, 2H), 1.94 (septet, J=7.1 Hz, 1H), 0.93 (d, J=7.1 Hz, 6H).

Reaction of Methacrylonitrile with 1a. A solution of **1a** (26 mg, 0.071 mmol) in 400 μL of C_6D_6 was treated with methacrylonitrile (6 μL, 0.071 mmol) at room temperature. After 12 hours the reaction was ca. 60% complete by NMR analysis: ^1H NMR (90 MHz, C_6D_6) δ=7.16—6.50 (m, 10H), 5.60 (s, 5H), 5.58 (s, 5H), 5.03 (m, 2H), 3.87 (s, 2H), 1.82 (br s, 3H).

Hydrolysis of the Insertion Product of 1a and *p*-Tolunitrile. To a stirred solution of metallacycle **1a** (200 mg, 0.54 mmol) in 3 ml of THF was added *p*-tolunitrile (75 μL, 0.627 mmol) at room temperature. The reaction was stirred at room temperature for 24 hours. The volatiles were removed in vacuo and the solid suspended in diethyl ether and hydrolyzed with 5% aqueous HCl for 30 minutes. The aqueous phase was separated and extracted with diethyl ether 3×5 ml, the organic phases combined, dried over $MgSO_4$, and concentrated in vacuo. The product was flash-chromatographed ($CHCl_3$) to yield 41 mg of the product ketone: ^1H NMR (90 MHz, $CDCl_3$) δ=7.80—7.00 (m, 14H), 6.55 (br s, 1H), 4.11 (d, J=1.2 Hz, 2H), 2.37 (s, 3H).

Reaction of *p*-Tolunitrile with 1b. A solution of metallacycle **1b** (97 mg, 0.315 mmol) in 500 μL of C_6D_6 was treated with *p*-tolunitrile (36 μL, 0.32 mmol) at room temperature. The reaction was complete within 4 hours to yield a dark-orange solution: ^1H NMR (90 MHz, C_6D_6) δ=7.50—6.80 (m, 9H), 5.70 (s, 10H), 3.68 (s, 2H), 2.20 (s, 3H), 1.65 (s, 3H).

(Received May 18, 1987)

The Electron Spin Resonance(ESR) spectra of ten 5-formazanyl copper(II) complexes in toluene solutions have been observed at room temperature and at that of liquidnitrogen. The ESR($g_{//}$ and $A_{//}$) and bonding(α^2) parameters of the copper ion were greatly affected by substituting several groups at the ortho position of 1-phenyl ring of formazan. Based on these results, the complexes are classified into three groups: Group I, in which $A_{//}\simeq 0.012$—$0.013\,cm^{-1}$ and $\alpha^2\simeq 0.5$; Group II, in which $A_{//}\simeq 0.017\,cm^{-1}$ and $\alpha^2\simeq 0.7$, and Group III, in which two copper ions are interacting. It is clarified that they correspond nicely to three types of copper-containing proteins previously investigated.

Since Kuhn and Jerchel studied the tetrazolium salts of formazan in a program of research on invert soap,[1] these compounds, with their remarkable biological potentialities, have been extensively investigated. Especially, formazans obtained by the reduction of the corresponding tetrazolium salts have been widely utilized to check enzyme activity in plant and animal tissues.[2]

Formazans have been known to form complexes with some transition metals having the stoichiometries of 2:1 and 1:1.[3-5] Previously, we ourselves reported that some copper complexes of formazan show small isotropic splitting constants of the copper ion in the ESR spectra of these complexes and that their magnetic properties change drastically with different kinds of substituents to the 1-phenyl ring of 1,3,5-triphenyl-5-formazan (Fig. 1).[6] These results have motivated us to undertake a thorough examination of the substituent effects on the electronic states and magnetic properties of these complexes.

Many studies of copper complexes have established that the structural configuration around the copper ion is affected by the inductive property of the substituent group,[7,8] the distortion due to the bulky substituents,[9,10] and the apical coordination of the solvent molecules, in addition to the symmetry of the ligand field.[11,12] The change in the ESR parameters has been discussed in relation to various kinds of binding sites of copper proteins. A comparison of ESR data of the binding sites of copper proteins with those of well-defined model complexes enables us to suppose micro-structural information about the area around the copper ion in proteins.[13-17] Thus, the copper ions in the various copper proteins thus far investigated have been classified into three types, based on ESR spectroscopic studies.[18-21]

The effects of the substituent groups on the copper complexes mentioned above have thus far been found in the range of a perturbation within each type of copper-containing protein. However, we have now found that the copper-ion environment in 5-formazanyl copper(II) complexes is much affected by the introduction of different substituent groups into formazan and that the change in the spectroscopic behavior due to these substituents extends over all three types. Therefore, we have attempted to establish the micro-structural details of the present complexes and the analogy to the binding site of copper-containing proteins.

In this paper, we will report the results of our ESR spectroscopic study of copper complexes of formazan with several kinds of substituents. The results obtained are examined based on the inductive, distortional, and coordinational effects. Finally, the configulational change suggested by the ESR and bonding parameters will be discussed in relation to three types of copper-containing proteins.

Experimental

Preparation of Samples. 1,3,5-Triphenyl-5-formazan, which has no substituent in the 1-phenyl ring, is shown in Fig. 1. Formazans with a para or ortho substituent in the 1-phenyl ring were obtained by the reaction of the diazonium salts of para- or ortho-substituted aniline with benzaldehyde phenylhydrazone by a method described elsewhere.[22] (Hereafter, we will abbreviate the substituent as X.) The copper complex was prepared by mixing ethanol solutions of formazan and copper acetate monohydrate.[4] The precipitate was obtained by the addition of water to the ethanol solution. Recrystallization was also carried out in the ethanol solution. The complexes obtained consisted of a fine powder and so could not be submitted to X-ray crystallographic measurements. The analytical data of the complexes prepared for the present study are listed in Table 1. The complexes obtained are abbreviated as *p*-X-Cu (2:1) for bis[1-(*p*-X phenyl)-3,5-diphenyl-5-formazanyl]copper and *o*-X-Cu (1:1) for bis[1-(*o*-X phenyl)-3,5-diphenyl-5-formazanyl]dicopper.

Physical Measurements. The X-band (9 GHz) ESR spectra were obtained in the toluene solutions of the

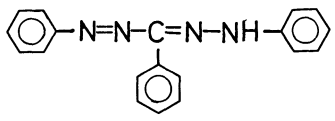

Fig. 1. 1,3,5-Triphenyl-5-formazan.

complex at room temperature and in frozen glasses at 77 K with a JEOL ME-3X spectrometer equipped with 100 KHz field modulation. The Mn^{2+} in MgO was used as a standard sample for the calibration of the magnetic field. The optical spectra of the complexes were measured in toluene solutions at room temperature by the use of a Shimazu Double-beam Spectrophotometer, UV200, in the range of 300—700 nm and by the use of a Shimazu Multi-purpose Spectrophotometer, MPS50L, in the range of 600—2000 nm.

Results

The 5-formazanyl copper complexes obtained are classified into two categories on the basis of the stoichiometry of formazan and the copper ion from the results of the elemental analyses; one is of a 2:1 stoichiometry of formazan and the copper ion, while the other is of 1:1. Based on the ESR parameters to be described below, the former is further divided into two groups, Group I and Group II; the latter is abbreviated as Group III. The molecular structures of the complexes tentatively suggested by the elemental analyses are shown in Fig. 2(a) for the complexes in Groups I and II and in Fig. 2(b) for those in Group III. The latter shows the dimer structures of the complex. The complexes belonging to each group are listed in Table 2.

Group I. The ESR spectrum of *p*-H-Cu (2:1), **1**, in a toluene solution at room temperature is shown in Fig. 3(a) as a typical example of the spectra of the complexes belonging to Group I. The spectra of the complexes of Group I consisted of four ill-resolved resonance lines attributable to one copper ion (I=3/2). In some complexes, further splittings around 0.0005 cm^{-1} were observed at the absorption line in the highest field; they were unambiguously assigned to the superhyperfine interaction between the unpaired electron of the copper ion and the ligand-nitrogen nuclei. The isotropic copper splitting constants, A_{iso}(Cu), are around 0.004 cm^{-1}. These values are extremely small compared with those of the ordinary copper complexes with a planar configuration.[23,24]

The ESR spectrum of **1** obtained in a frozen toluene solution at 77 K is shown in Fig. 3(b), which is also typical of monomeric copper species. The g values, g_1, g_2, and g_3, which were experimentally determined in the ESR spectra at 77 K, are tabulated in Table 2. The g_1 clearly corresponds to the usual notation, $g_{//}$.

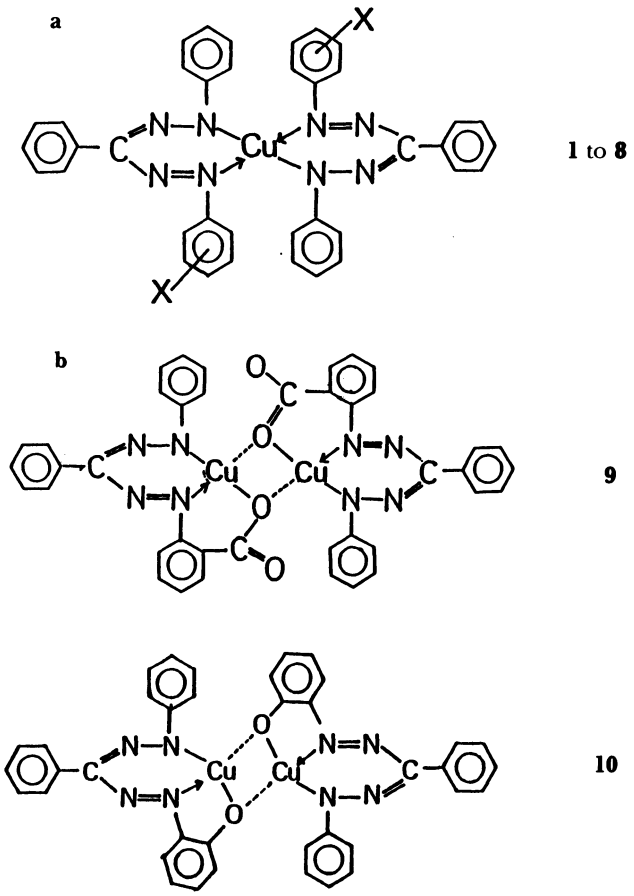

Fig. 2. **a**, Bis[1-(*p*-X phenyl)-3,5-diphenyl-5-formazanyl]copper, **1**: X=H; **2**: X=Cl; **3**: X=Br; **4**: X=NO_2; **5**: X=CH_3. a) "sh" designates shoulder.

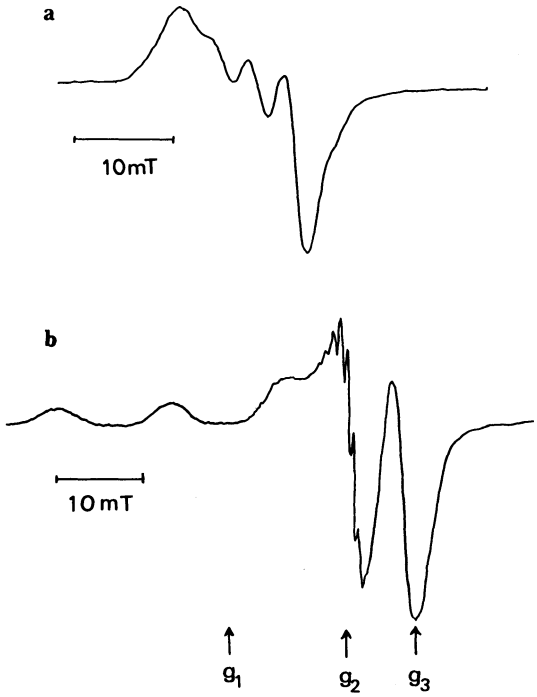

Fig. 3. ESR spectra of **1** in toluene solution at (a) room temperature and (b) liquid-nitrogen temperature. Further splittings were not observed in (a).

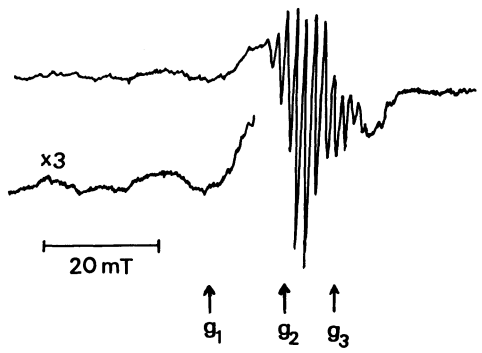

Fig. 4. ESR spectrum of **7** in toluene solution at liquid-nitrogen temperature.

The g_2 and g_3 can not, however, be uniquely assigned to g_x and g_y. The splitting of 0.012 cm^{-1} at the g_1 position, A_1(Cu), can reasonably be assigned to the parallel component of the copper hyperfine splittings, $A_{//}$(Cu). This value is also small compared with those of the usual planar copper complexes. Further splitting constants at the g_2 and g_3 positions are represented as A_2 and A_3 respectively. These can not be uniquely assigned to the splittings due to the x and y components of the copper ion, for the splittings due to the four equivalent nitrogen nuclei may overlap. However, in view of the apparent intensity ratios of the absorption lines at the g_2 and g_3 positions, the assignment of these splittings to the ligand nitrogens seems most plausible. The ESR parameters of the other complexes of Group I, **2**, to **6**, are also tabulated in Table 2. These parameters of Group I are almost all the same in spite of the various kinds of substituents.

Group II. Figure 4 shows the ESR spectrum of *o*-Cl-Cu (2:1), **7**, in a toluene solution at 77 K. The ESR spectral patterns of this complex at room temperature and 77 K were similar with those of Group I except for the fact of the larger values of A_1(Cu), A_2, A_3, and A_{iso}(Cu). A_1(Cu) and A_{iso}(Cu) are 0.017 cm^{-1} and 0.0077 cm^{-1} respectively. A_2 and A_3 are 0.0015 cm^{-1}. These are usual values in copper complexes with planar or pseudo-planar configurations.[23,24] Their g values are also similar to those of the complexes of Group I. In the ESR spectrum of *o*-Br-Cu (2:1), **8**, in a toluene solution at 77 K, the splitting constants of the copper ion and the g values are similar with those of **7** except for the property of the axial symmetry with $g_2=g_3$ and $A_2=A_3$.

Group III. As has previously been reported, the ESR of *o*-COOH-Cu (1:1), **9**, in a toluene solution showed only one sharp single line and did not reveal any hyperfine structure at either room temperature or

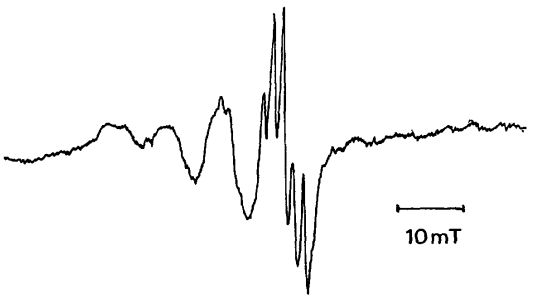

Fig. 5. ESR spectrum of **10** in toluene solution at room temperature. Superhyperfine splittings due to ligand nitrogens are observed in the absorption line at the highest field.

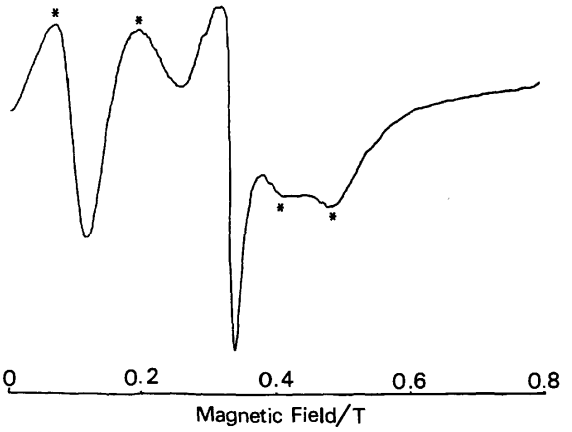

Fig. 6. ESR spectrum of **10** in microcrystalline state at room temperature. The asterisks in the spectrum show the absorptions due to the excited triplet state of the dimer. These disappear at liquid-nitrogen temperature. The central part of the spectrum is due to the monomeric species.

the temperature of liquidnitrogen. The temperature dependence of the magnetic susceptibility of the powdered sample could well be interpreted on the basis of the ground triplet-excited singlet model for the dimeric species of the copper ions.[25] Therefore, one absorption line was attributed to the exchange interaction between two copper ions. In order to get further information about the copper monomer, the addition of pyridine to the toluene solution was attempted. As a result, the hyperfine structure due to the copper monomer appeared at room temperature and that of liquidnitrogen. The data in Table 2 are what were obtained in this way: The g_{ave}(Cu) of **9** is slightly larger than those of Group II, but A_{iso}(Cu) and A_1(Cu) are similar to those of Group II. These values of **9** might, by the addition of pyridine, have been varied from those without the solvation of pyridine.[26] However, the visible absorptions did not show any appreciable change by the addition of pyridine. Therefore, it is conceivable that the configurational change around the copper ion may be small in the pyridine-added toluene solution.

The ESR spectrum of *o*-OH-Cu (1:1), **10**, in the toluene solution at room temperature consisted of four lines attributable to the copper monomer (Fig. 5). Further splittings to five lines at the absorption in the highest field provide firm evidence that the two nitrogens of the ligand take part in the superhyperfine interaction. At the temperature of liquidnitrogen the typical spectrum of the usual copper ion with an anisotropy was observed. The ESR parameters of the monomer were similar to those of Group II. In the microcrystalline state, on the other hand, the ESR spectrum of the triplet state was observed at room temperature on both sides of the absorption line attributable to the monomeric species of the copper ion, as is shown in Fig. 6. The absorption line without the asterisk around 0.3 T corresponds to that of the copper monomeric species. The signal intensity of the triplet state became too weak to be recognized at 77 K. It is obvious from these facts that the two copper ions are interacting with each other through exchange interaction. The details of the triplet state, including the estimation of the zero-field-splitting parameter, D, will be reported elsewhere.

Discussion

Table 2 indicates that the unsubstituted 5-formazanyl copper, **1**, and all of the complexes with para substituent groups, **2** to **6**, belong to Group I. The symmetry around the copper ion in these complexes can plausibly be considered to be planar or pseudo-planar, based upon the g values and the hypothetical molecular structures. On the other hand, the complexes with ortho substituent groups belong to all three groups, suggesting that the substitution results in a different ligand configuration around the copper ion.

The change in the electronic state of the copper ion has been discussed on the basis of: 1) The electron-inductive effect caused by the substituent groups, 2) the distortional effect caused by the substituent groups, and 3) the apical coordination effect, caused mainly by the solvent molecules. The effects of the increased electron-donating ability of the substituent groups on the ESR parameters are to decrease $g_{//}$ and to increase $A_{//}$(Cu). The ESR behavior of Group I did not depend upon the electron-donating ability of the para substituent groups. The trend of the change in $g_{//}$ and $A_{//}$(Cu), expected from the increase in the electron-donating ability (-Cl, -Br, -H, and -CH_3), was not observed in the complexes with the ortho substituent groups. Therefore, the electron-inductive effect of the substituent groups is not dominant in the para and ortho substituents. Yokoi et al. reported that the distortional effect becomes dominant when the substituent groups are bulkier.[9] In such a case, $A_{//}$(Cu) decreases and $g_{//}$ increases with the degree of

distortion from the plane containing the copper ion. The facts that *o*-H-Cu (2:1), **1**, and *o*-CH_3-Cu (2:1), **6**, are in Group I, while *o*-Cl-Cu (2:1), **7**, and *o*-Br-Cu (2:1), **8**, are in Group II obviate the importance of the distortional effect caused by the substituent groups on the electronic state of the copper ion. The apical coordination of the solvent molecules is weak in the case of the toluene solution. Therefore, it may be concluded that the three effects mentioned above are not adequate to interpret the drastic change in the ESR parameters shown in Table 2.

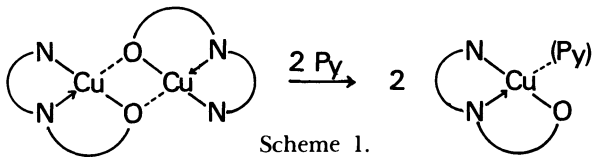
For the probable structure with the square-planar symmetry and with the ground orbital of $d_{x^2-y^2}$,[27] Kivelson and Neiman defined a bonding parameter, α^2.[28] Here we will use α^2 expressed semiempirically by Bryce:[29]

$$\alpha^2 = \frac{A_{//}}{P} + (g_{//}-2.0023) + \frac{3}{7}(g_{\perp}-2.0023) + 0.04$$

where P=0.04 cm^{-1}. In order to ascertain the bonding characters of the copper ion under the assumption of the square-planar symmetry around the copper ion, the bonding parameters of Group I and II are compared. In a previous paper, the square-planar structure around the copper ion in the microcrystalline state of **1** was presumably adopted with reference to the *g* values of the other copper complexes with the square-planar symmetry.[6] Though the three different values of the *g* component in the frozen toluene solutions of the present complexes suggest a deviation from the square-planar symmetry around the copper ion, the structure is presumed not to be much changed from the planarity, for the difference between g_2 and g_3 is not very large. Under these assumptions, the bonding parameters, α^2, of Group I and II were calculated; they are tabulated in the last column of Table 2.

The deviation from 1.0 shows the degree of covalency of the bonding. The fact that α^2 in Group I, about 0.5, is extremely small indicates the strong covalency in the bonding between the copper ion and the ligands. Such small values have previously been reported with respect to the complexes with sulfur coordination and to plastocyanine, in which the sulfur coordination was determined by means of X-ray analyses.[30,31] On the other hand, the α^2 around 0.7 of Group II is not so small and is comparable to those of Cu-phthalocyanine (0.73) and Cu-tetraphenylporphyrine (0.79).[21] Therefore, it may be concluded that the bonding conditions of Group I and Group II differ considerably.

The toluene solution of **9** showed only a single line, without any hyperfine splitting, at room temperature and at that of liquidnitrogen. These results can be well-interpreted by assuming that, even in a toluene solution, the dimeric structure shown in Fig. 2(b) is retained and that the exchange interaction between the two copper ions in the dimer smears out the lines caused by the hyperfine splittings. Upon the addition of one drop of pyridine, however, the ESR spectrum characteristic of the monomeric copper ion was observed. Therefore, it is adequate to mention that the addition of pyridine to the toluene solution of **9** has led to the dissociation of the dimer to the monomer, probably ligated by the pyridine molecule, as is shown in Scheme 1. Previously it has been shown that the



Scheme 1.

temperature dependence of the magnetic susceptibility of **9** could be well-interpreted by the dimeric model with ferromagnetic exchange interaction of the order of 20 K. Therefore, it is plausible to consider that **9** retains the dimeric structure even in the toluene solution. On the other hand, the ESR spectrum of the triplet state observed in **10**, indicates that **10** makes a dimer in the microcrystalline state. However, the ESR spectrum of **10** in the toluene solution showed the hyperfine structure characteristic of the monomeric copper ion at room temperature and at that of liquidnitrogen. The half-field resonance giving one evidence of the dimeric interaction was not observed in the toluene solution, even at the temperature of liquidnitrogen. These results suggest that the dimer of the **10** formed in the microcrystalline state dissociates into two monomeric species in the toluene solution, as is shown in Scheme 1. Such a difference between **9** and **10** in the toluene solutions may be due to the difference in ligation ability between -COOH and -OH. Consequently, the complexes belonging to Group III can be characterized as those in which the complexes have the dimeric structure in the solid state.

Unfortunately, we could not obtain the useful information from the ESR spectra of **9** and **10**, about the circumstances of the copper ions in the dimer. However, the fact that the ESR parameters of the dissociated species of **9** and **10** are very similar to those of the complexes in Group II indicates that the ligand configurations of the copper ions in the dimers are not so different as those of the copper ions belonging to Group II. The substituents of formazan, -COOH and -OH, can be regarded as bases, $-COO^-$ and $-O^-$. On the other hand, the substituent groups in Group I and II can not be bases, though they are electronegative. Therefore. only the ortho substituents, which can be bases for the copper ion, have the possibility of forming magnetically interacted dimeric species.

It is interesting to compare the α^2 and $A_{//}$(Cu) of the present complexes with those of copper-containing proteins. Copper-containing proteins have been classified into three types from the spectroscopic point of view:[20]

Type I: Blue copper proteins. $A_{//}$(Cu) is less than

0.008 cm^{-1}, and there is an abnormally strong absorption maximum around 600 nm.

Type II: Normal copper proteins. The copper splitting constants are of the order of 0.017 cm^{-1}, and the other spectroscopic parameters are similar to those of the copper complexes with a planar structure.

Type III: ESR nondetectable copper proteins. It is generally said that a strong antiferromagnetic or ferromagnetic coupling between two copper ions leads to the ESR spectra becoming nondetectable.

X-Ray analyses were carried out in several kinds of **Type I** copper proteins; the sulfur coordination was thus authenticated.[30,31] Their bonding conditions have become clear.[32] Though sulfurs do not exist in the ligands of the present complexes, the ESR parameters and α^2 values of Group I correspond well to those of **Type I** copper proteins. Therefore, the nitrogens of formazan would constitute strong covalent bondings with the copper ion in the complexes of Group I, as in the case of **Type I** copper proteins. The α^2 values of the ordinary copper complexes with peptide bondings, in which the copper ions have the square-planar symmetry, are in the range from 0.81 to 0.82. The α^2 and $A_{/\!/}$(Cu) values of the complexes of Group II are 0.7 and 0.017 cm^{-1} respectively. Therefore, the complexes of Group II correspond well to the **Type II** copper proteins. It had been considered that the two copper ions were so strongly coupled in the **Type III** copper proteins that ESR observation was difficult. However, the observation of the ESR of the triplet state was accomplished first in the Met derivative of hemocyanine copper, showing clear evidence of the interaction of the two copper ions. As has previously been mentioned in the Results section, the exchange-narrowing was observed in **9** and the ESR spectrum of the triplet state was observed in **10**, in each microcrystalline state. They are characterized as the species with the dimeric interaction, corresponding to **Type III**.

The most characteristic point of these results is that the three types of ESR behaviour, depending upon the different substituent groups to the ortho position of 1-phenyl ring, correspond to the three types of copper proteins. These results may be useful in elucidating the micro-structural details around the copper ions in **Types I, II,** and **III** copper proteins. The 5-formazanyl copper(II) complexes with a flexible molecular structure have the possibility of being plausible model compounds of copper-containing proteins.

The authors wish to thank Dr. Takaharu Matsubara for the measurements of the absorption spectra and also Professor Noboru Hirota for his valuable discussions. This work was partially supported by the Grant-in-Aid for Scientific Research on Priority Area of "Macromolecular Complexes (No. 62612005)" from the Ministry of Education, Science and Culture.

(Received June 4, 1987)

The electrolytic removal of phosphoric acid and mono-, di-, and tripotassium phosphates from aqueous solution was attemped using improved active charcoal electrodes which proved more effective in removing these electrolytes than the previous one. The degree of removal of phosphoric acid and phosphates exceeded 90% after 80 min's electrolysis, tending to 100% after sufficient time of electrolysis. The mechanism of removal of phosphoric acid and potassium phosphates was confirmed to be the entrapment and concentration of these substances as potassium hydroxide and phosphoric acid in the pores of the active charcoal. The processes of removal of phosphoric acid and phosphates were found to be complicated due to hydrogen and hydroxide ions formed by the dissociation of phosphoric acid and hydrolysis of phosphates respectively which explained the initial rate of removal of these substances decreasing in the order of phosphoric acid through potassium dihydrogen- to tripotassium phosphate. Regeneration of active charcoal electrode was further inferred.

Present authors have reported in a previous paper that alkali and sulfate ions were effectively removed from alkali sulfate solution by the electrolysis using active charcoal electrodes.[1] In the present paper, the removal of potassium phosphates and phosphoric acid from an aqueous solution by this technique was reported. These salts require detailed study from the viewpoints of both water pollutant[2] and the complicated behavior exhibited during their removal by electrolysis, due mainly to the hydrolysis of polybasic phosphate salts and dissociation of phosphoric acid. The improvement of the electrodes used for the measurement of removal of electrolytes was also devised in comparison with the former one.[1]

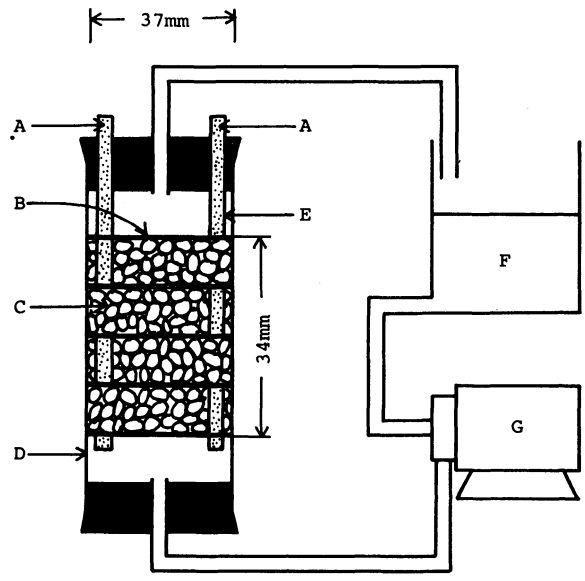

Fig. 1. Apparatus.
A: Graphite electrode, B: perforated plastic plate, C: active charcoal, D: glass tube, E: tape-insulated part, F: sample reservoir G: circulation pump.

Experimental

Materials. The phosphoric acid and potassium phosphates used were guaranteed-grade products of Wako Pure Chemical Co. Ltd. which were used without further purification. The active charcoal used as electrodes was a guaranteed-grade product of Wako, charcoal activated, granulated, the size being about 4 mm in diameter and 4 to 10 mm in length, which was washed with conductivity water until it showed no increase in electric conductance.

Apparatus and Procedure. The apparatus used is similar as a whole to that used in a previous paper:[1] It consists of three parts, an electrode chamber, a circulation pump, and a reservoir, as shown in Fig. 1. But the electrode chamber is different from the former one. The electrode consists of four layers of packed charcoal granules, 15 g in total weight. The layers are separated from each other by perforated plastic plates of 2 mm in pore diameter and 1 mm in thickness, perforated portion covering two third of the area of plastic plate. The electrode is constructed by alternately connecting charcoal layers to a cathode and an anode carbon rods.

To carry out the electrolytic removal of phosphoric acid and potassium phosphates, each 1 dm^3 solution of phosphoric acid, potassium dihydrogenphosphate, dipotassium hydrogenphosphate, and tripotassium phosphate containing 20 ppm of phosphate ions as PO_4^{3-} was introduced in the apparatus. The solution was circulated at the rate of 7.9 $dm^3\ min^{-1}$ † and a direct current was applied. The voltage was controlled so as to keep a constant current of 50 mA. During the electrolysis, small portions of the solution were withdrawn from the reservoir at intervals of 20 min, and the concentrations of phosphate and potassium ions were measured by Shimazu LC-5A Liquid Chromatograph and by Hitachi 508 type Atomic Absorption Spectrophotometer respectively. From the concentration thus obtained the degree of removal of each ions was calculated as a percent of initial concentration and was plotted against the time of electrolysis to study the rate of

† The degree of removal was found nearly the same for the flow rate down to 3 $dm^3\ min^{-1}$: 4 $dm^3\ min^{-1}$ may be sufficient for practical application of 80 min's electrolysis.

removal. Further, in order to study the mechanism and to obtain the optimum conditions of electrolytic removal of phosphoric acid and potassium phosphates, measurements of electrolytic removal were carried out in detail.

Results and Discussion

Performance of Electrode. In the former case of removal of potassium sulfate from an aqueous solution by using active charcoal electrode,[1] the porous porcelain septum used consumed a large electric power due to a large electric resistance between the electrodes. To confirm the efficiency of the improved electrode used to overcome this loss, aqueous dipotassium hydrogenphosphate solution was electrolyzed under the conditions mentioned above and the results obtained were compared with those obtained using previous electrode for the same amount of active charcoal and current conditions. The degree of removal vs. time curves agreed with each other up to 93% removal within the difference of 2% for the period of 80 min while the applied voltage was markedly reduced in the present measurement as shown in Fig. 2: Electric power consumed during this period was calculated to be about 24 to 31 Wh for the former electrode and about 3 Wh for the present electrode. The marked reduction of electric power consumption proved the effectiveness of the improved electrode used in the present study.

The degree of removal of phosphate ions obtained for phosphoric acid, and potassium phosphates was plotted against time of electrolysis as shown by solid lines in Fig. 3. The broken lines show the degree of removal by active charcoal without electrolysis.

Mechanism of Removal without Electrolysis. In the case of phosphate ions without electrolysis, the degree of removal was low as a whole compared with the case of electrolysis. The degree of removal was most marked for phosphoric acid and gradually decreased from potassium dihydrogenphosphate to tripotassium phosphate. As regards such an adsorption of phosphate ions, it may be pertinent to refer to the fact that the addition of hydrogen ions to the salt of weak acid strongly increase the adsorption of corresponding anion.[3] In the present case, as shown later in Fig. 4, hydrogen ion concentration of aqueous solutions decreased from phosphoric acid through potassium dihydrogenphosphate to tripotassium phosphate. This fact together with the above mentioned tendency of adsorption explain the order of adsorption of phosphate ion shown in Fig. 3.

Mechanism of Removal by Electrolysis. In the case of removal by electrolysis both initial rate and maximum value of the degree of removal were larger than those obtained without electrolysis as shown in Figs. 3 and 5. The removal of phosphate ions after 80 min was 100% for phosphoric acid and was least value of 90% for tripotassium phosphate. The degree of removal after sufficient time of electrolysis tended towards 100%, irrespective of the salts used. The difference between the removals with and without electrolysis is evident since the latter is affected by the

hydrogen ion concentration as mentioned above while the former is determined mainly by the movement of ions in the solution in an electric field mentioned as follows.

Hydrolysis and Dissociation of Phosphates and Phosphoric Acid: As for the initial rate of removal of phosphate ions, decreasing order of phosphoric acid, potassium dihydrogen-, dipotassium hydrogen-, and tripotassium phosphates was confirmed which is considered to be closely related to hydroxide and hydrogen ions produced respectively by the hydrolysis of phosphates and dissociation of phosphoric acid since these ions are expected to remarkably influence the transference of both potassium and phosphate ions. This was confirmed by the measurement of pH change of the solution against time of electrolysis as shown in Fig. 4.

In this figure pH value after 80 min agreed with pH value of distilled water after sufficient time of electrolysis. As was evident from a high initial value of pH and its rapid decrease in the initial stage of electrolysis of tripotassium salt, high electric mobility of hydroxide ions[††] produced by hydrolysis and their discharge at the anode was dominant which reduced both the initial ionic transport and the rate of removal of potassium and phosphate ions.[4] As seen in Fig. 4 such a tendency was most marked for tripotassium phosphate, less marked for dipotassium hydrogenphosphate and almost negligible for potassium dihydrogenphosphate. Initial rate of removal of phosphate ions is explained to increase in parallel with this. The decreasing order of initial concentration of potassium ions from tripotassium phosphate to potassium dihydrogenphosphate is also in accord with this increase. In the case of potassium dihydrogenphosphate, both hydrolysis and dissociation of phosphate ions are calculated to be negligible, and the salt simply dissociate to form potassium and dihydrogenphosphate ions which migrate towards electrodes with the least hindrance by hydroxide ions. A slight decrease of pH after sufficient time of electrolysis, as mentioned above may come from dissolved carbon dioxide which could not be removed from distilled water used. The larger initial rate of removal of phosphate ions in the case of phosphoric acid than that of potassium salts may be due to the overlapping of a large initial rate of adsorption exhibited even without electrolysis which was already shown by the broken line in Fig. 3. Thus, phosphate ions both in the form of free acid and in various forms of potassium salts can be confirmed to be removed effectively by the electrolysis using active charcoal electrode.

The degree of removal of potassium ions was measured at the same time with phosphate ions and was plotted against the time of electrolysis as shown in Fig. 5, together with the degree of removal without electrolysis. As seen, initial rate of removal increased from tripotassium phosphate through dipotassium hydrogen- to potassium dihydrogenphosphate and about 95% of potassium ions was removed after 80 min's electrolysis of these salts similarly to the degree of removal of phosphate ions. The order of the initial rate of removal of potassium ions mentioned above may be similarly explained by taking account of hydrolytic formation of hydroxide ions of large ionic mobility and resulting decrease of the transference number of potassium ion.[4] No removal of potassium ions by the circulation of solution without electrolysis is distinctly shown in Fig. 5. The phenomena may have some relation with the negative adsorption of potassium hydroxide towards charcoal[3] but it was not studied in detail in the present paper.

Up-Take of Ions by Charcoal Electrode: Phosphoric acid and potassium phosphates removed from the solution are considered to be entrapped and concentrated in the pores of active charcoal electrodes similarly to the case of the removal of potassium sulfate reported in a previous paper.[1]

To confirm this, extraction of potassium and phosphate ions from active charcoal electrodes which are considered to entrap these ions was carried out by treating the charcoal with acid or alkali. The amount of ions extracted was expressed as the percentage of the total amount of each ions entrapped. The results showed that from active charcoal used as the anode for the removal of potassium dihydrogenphosphate, phosphate ions could not be extracted with acid solution but more than 90% was extracted with concentrated potassium hydroxide, and nearly 100% of potassium ions were extracted from the cathode with concentrated hydrochloric acid. Further, active

[††] Mobility of ions at 25 °C (unit in $S\,cm^2\,mol^{-1}$); OH^- 198.3, $H_2PO_4^-$ 36, HPO_4^{2-} 57, PO_4^{3-} 69.0, K^+ 73.5.

charcoal electrode used for removing potassium dihydrogenphosphate was put in conductivity water together with a platinum wire electrode, and the direct current was applied in the reverse direction to that applied during the removal experiment. The amounts of potassium and phosphate ions thus extracted were nearly 100% and 65% of the amount entrapped respectively.

These results confirmed the fact similar to the case of potassium sulfate[1] that phosphate and potassium ions were entrapped respectively as phosphoric acid and potassium hydroxide in each electrode. But different from the case of alkali sulfate, polyvalency of phosphate ion and formation of hydroxide ions due to its hydrolysis complicated the process of electrolytic removal as mentioned. However, even under such conditions, complete removal could be established after sufficient time of electrolysis, irrespective of the phosphates used.

Regeneration of Active Charcoal Electrodes. As mentioned above phosphate and potassium ions taken up by the charcoal electrodes can be easily released by treating them with acid, alkali, and by electrolysis. These facts may suggest the possibility of regeneration and repeated use of active charcoal as the electrode. The problem should be paid attention when the present method is applied for the practical problem, details of which are under study.

Excitation Wavelength Dependence of Phosphorescence and Hydrogen-Bonding Formation of Thioxanthone and 2,4-Diisopentylthioxanthone

Hiroshi MORITA,* Shigeyasu MORI, and Tsuguo YAMAOKA
Department of Image Science and Technology, Faculty of Engineering, Chiba University, Yayoi-cho, Chiba 260
(Received June 8, 1987)

Phosphorescence spectra of the ethanol solutions of thioxanthone(TX) and 2,4-diisopentylthioxanthone (DITX) exhibited excitation wavelength dependence at 77 K. In addition to the normal phosphorescence observed at 450 nm for TX and at 460 nm for DITX, a new red-shifted phosphorescence was resolved at 470 nm and 485 nm, respectively, when TX and DITX were excited at the absorption tail. The lifetimes and excitation spectra of the red-shifted phosphorescence were found to differ from those of the normal phosphorescence. Based on the study on UV absorption spectra and phosphorescence spectra measured with hydrated species of TX and DITX in ethanol–water solution at 77 K, the red-shifted phosphorescence is ascribed to the hydrogen-bonded species with water. In 2-methyltetrahydrofuran, phosphorescences of TX and DITX shift to the longer wavelengths and the lifetimes become longer when excited at the longer absorption tail, although the phosphorescence excitation spectra do not change appreciably.

In polymer photochemistry, thioxanthone[9*H*-thioxanthen-9-one](TX) and its derivatives are effective sensitizers in radical polymerization of vinyl monomers,[1–3] in photocrosslinking of polyacrylates and polystyrenes,[4,5] and in photocuring of coating systems.[6] In order to understand the sensitization mechanisms, photophysical and photochemical properties of TX and its derivatives have been studied extensively.[1,3,5,7,8] As is widely recognized in aromatic carbonyl compounds,[9–12] TX has close-lying $S_1(\pi\text{-}\pi^*)$ and $S_2(n\text{-}\pi^*)$, and $T_1(\pi\text{-}\pi^*)$ and $T_2(n\text{-}\pi^*)$ states.[13–15] Due to the proximity of the S_1 and S_2 states, S_1–S_0 internal conversion rate of TX is influenced significantly by the solvent polarity, and hence fluorescence intensity, peak position, and lifetime largely change depending on solvents.[16]

Nature of the triplet state of TX and its derivatives is of particular interest in relation to the photochemical behavior as a sensitizer. Because the T_1 state of TX is assigned to $\pi\text{-}\pi^*$ state even in nonpolar solvents,[13–15] the phosphorescent behavior of TX and its derivatives is not expected to change significantly depending on solvents in contrast to the case of xanthone.[12]

Recently, however, we have observed that the phosphorescence spectra observed with the ethanol and 2-methyltetrahydrofuran (MTHF) solutions of TX and 2,4-diisopentylthioxanthone (DITX) change significantly depending on excitation wavelengths. To investigate this in detail, we have measured in the present paper, the phosphorescence and UV absorption spectra of TX and DITX in ethanol, in ethanol–water, and in MTHF at 77 K, and found that TX and DITX form hydrogen-bonded(H-bonded) species with water even in freshly distilled ethanol solution.

Experimental

TX (Kanto G.R. grade) and DITX (Toshin Kayacure) were purified by repeated recrystallization from benzene three times and finally by vacuum sublimation. Ethanol (Wako G.R. grade) used as a solvent was purified by fractional distillation, and MTHF (Tokyo Kasei G.R. grade), by fractional distillation immediately before use in the dark. Degassed solutions of TX and DITX were prepared by freeze-pump-thaw cycles under a background pressure of 6×10^{-3} Pa.

Phosphorescence spectra and phosphorescence excitation spectra were measured at 77 K with the combination of a phosphoroscope, a monochromator (JASCO CT-50), and a photomultiplier tube (EMI 6256S), exciting light from a 150 W xenon arc lamp (Ushio UXL-150D) being monochromatized with a monochromator (Nikon G250). Phosphorescence decay curves were recorded with the use of a transient memory (Kawasaki Electronica MR100E). UV absorption spectra were measured at 77 K and at room temperature with a Hitachi 200-20 and a Hitachi 330 recording spectrophotometers in cells of 1 and 10 mm light path lengths. The effect of photoproducts[5,7] of the ethanol and MTHF solutions of TX and DITX on phosphorescence lifetimes and spectra, and on UV spectra is negligible under the present experimental conditions.

Results and Discussion

Phosphorescence of TX and DITX in Ethanol. Phosphorescence spectrum observed with the ethanol solution of TX (2.4×10^{-4} M†) excited at 380 nm is shown in Fig. 1A. Observed spectrum is broad and has a peak at 450 nm and a shoulder at ≈480 nm (hereafter this phosphorescence is called the normal phosphorescence). Phosphorescence excitation spectra of TX monitored at 450 and 480 nm are shown in Fig. 1B; the excitation spectrum monitored at 450 nm has peaks at 384, 366, and 299 nm, and coincides well with the UV absorption spectrum of TX measured at 77 K (Fig. 1C). On the other hand, the excitation spectrum monitored at 480 nm shows an additional new band at ≈400 nm. Hence, phosphorescence spectrum was further measured by exciting TX at

† 1 M=1 mol dm^{-3}.

400 nm; the result is also shown in Fig. 1A. The weak and broad phosphorescence spectrum with a peak at ≈470 nm and a shoulder at ≈500 nm was observed (referring to the normal phosphorescence, this is called the red-shifted phosphorescence). The red-

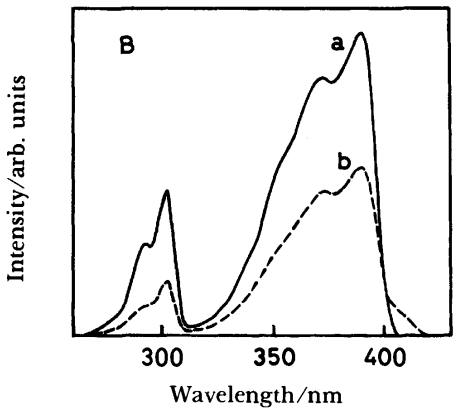

Fig. 2B. Phosphorescence excitation spectra measured with the ethanol solution of DITX (4.4×10^{-4} M) monitored at (a) 460 nm and (b) 490 nm.

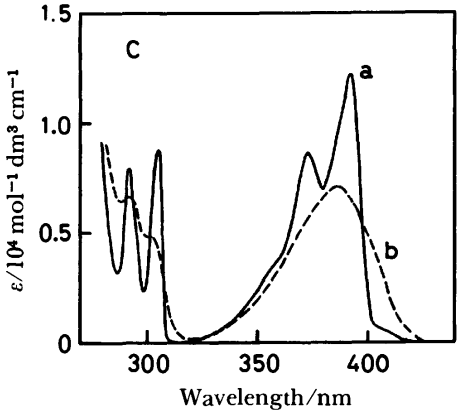

Fig. 2C. UV absorption spectra measured with the ethanol solutions of (a) DITX (7.3×10^{-5} M) at 77 K and (b) DITX (8.3×10^{-5} M) at room temperature.

shifted phosphorescence monitored at 480 nm decays single-exponentially, and the lifetime is 213 ms. This is longer than the one (160 ms) of the normal phosphorescence monitored at 450 nm and also at 475 nm which decays single-exponentially. From the lifetime measurement, the normal and the red-shifted phosphorescences can be assigned to different species of TX.

As in the case of TX, phosphorescence observed with the ethanol solution of DITX exhibits excitation wavelength dependence. Phosphorescence spectrum of DITX excited at 392 nm (near an absorption maximum) has a peak at 460 nm and a shoulder at ≈490 nm, whereas the one excited at 410 nm has a peak at 485 nm and a shoulder at ≈520 nm (Fig. 2A). The lifetime of the latter (i.e., of the red-shifted phosphorescence) is 226 ms and is longer than the one (173 ms) of the former (i.e., of the normal phosphorescence). In phosphorescence excitation spectrum, a new 410 nm band was observed when monitored at ≈490 nm (Fig. 2B). From these results, the normal and the red-shifted phosphorescences can be assigned to different species of DITX.

It is worthwhile to notice that the red-shifted phosphorescence can be observed with the ethanol solution of such a low concentration as 6×10^{-6} M of TX. The extra 400 nm(or 410 nm) band in the excitation spectrum of TX(or DITX) corresponds to the tail of the strong UV absorption measured at 77 K (Figs. 1C and 2C). Intensity of the absorption tail (in terms of apparent extinction coefficient) is rather unaffected by the concentration change of TX from 6×10^{-5} M to 2×10^{-3} M. These results indicate that the new chemical species which gives rise to the red-shifted phosphorescence is neither an associate such as a dimer or an aggregate, nor triplet excimer state which is suggested in naphthoquinones and anthraquinones.[17] Furthermore, the phosphorescence lifetimes were measured with degassed solutions. The lifetimes for the normal and the red-shifted phosphorescences of TX and DITX agree well with the values of the corresponding aerated solutions. The result suggests that a radical species and a light-absorbing transient (LAT) therefrom[7,18,19] are not responsible for the observation of the red-shifted phosphorescence. Judging from the experimental results mentioned above, formation of a hydrated species due to a little dissolved water in ethanol as an impurity is suggested.

Hydrogen-Bonded Species of TX and DITX. To investigate the nature of the hydrated species of TX and DITX in ethanol, UV absorption spectra of TX and DITX were measured at 77 K in ethanol-water mixed solutions; the results are shown in Fig. 3. As the water content is increased, a new band appears at ≈398 nm in the spectrum of TX and at ≈405 nm in the spectrum of DITX with isosbestic points.

The spectral change can be analysed on the basis of

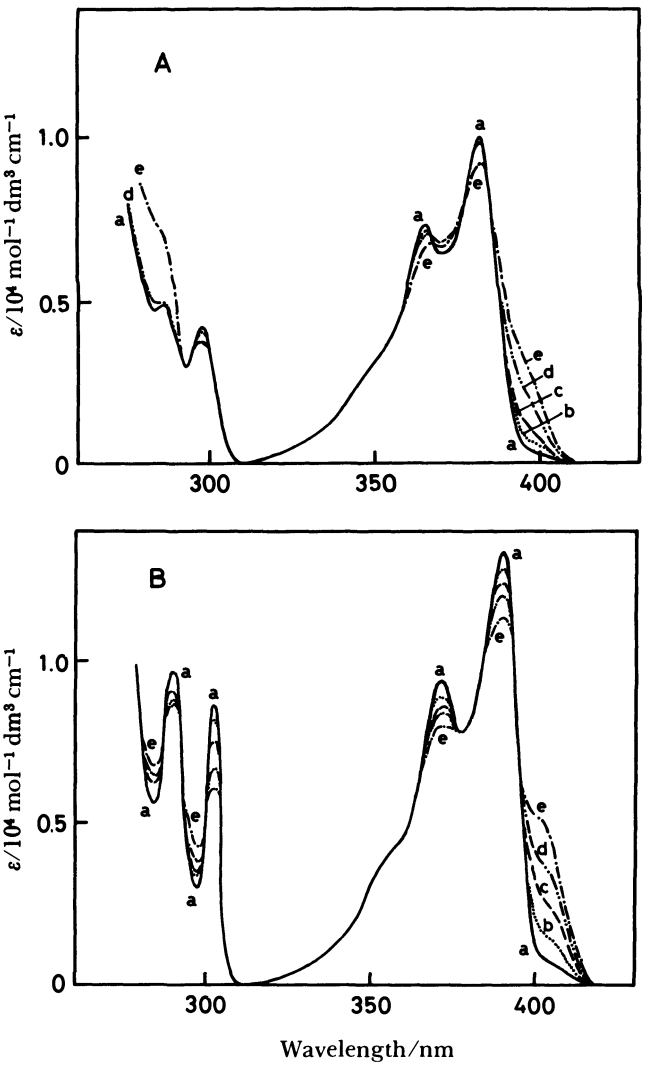

Fig. 3. UV absorption spectra measured with the ethanol-water solutions of (A) TX (9.0×10^{-5} M) and (B) DITX (9.7×10^{-5} M) at 77 K. Water content is (A):(a) 0, (b) 1, (c) 2, (d) 4, and (e) 6 vol%; and (B):(a) 0, (b) 1, (c) 2.5, (d) 4, and (e) 6 vol%.

formation of an associate between TX(or DITX) (A) and water (B):A+B→AB(or C). The association constant, K, was evaluated by the use of the equation;[20,21]

$$(d/[A]_0-\varepsilon_A)^{-1} = ((\varepsilon_C-\varepsilon_A)K[B]_0)^{-1} + (\varepsilon_C-\varepsilon_A)^{-1}, \quad (1)$$

where d is the apparent absorbance (per 1 cm light path length) for the system, ε_A and ε_C, the molar extinction coefficients of TX(or DITX) and the associate, respectively, and $[A]_0$ and $[B]_0$, the initial concentrations of TX(or DITX) and water, respectively. The equation is applicable to the case where $[B]_0 \gg [A]_0$ and $\varepsilon_B \approx 0$ are satisfied. Taking into account of the volume change of ethanol-water mixed solution at 77 K, $(d/[A]_0-\varepsilon_A)^{-1}$ was plotted against $[B]_0^{-1}$ at several wavelengths; the results are shown in Fig. 4. Linear relationship holds for both TX and

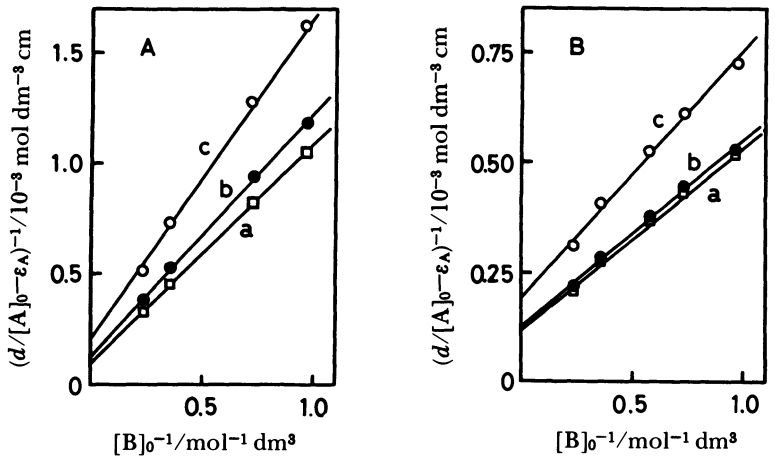

Fig. 4. Plots of $(d/[A]_0-\varepsilon_A)^{-1}$ against $[B]_0^{-1}$ for (A) TX at (a) 392.5 nm, (b) 397.5 nm, and (c) 400 nm; and (B) DITX at (a) 402 nm, (b) 404 nm, and (c) 408 nm in ethanol-water solution at 77 K.

DITX, indicating that the 1:1 associated species between TX(or DITX) and water is predominantly formed in ethanol. From the slopes and intercepts of the straight lines in Fig. 4, K and ε_C values were evaluated; the average of K's evaluated for TX-water in 392.5—400 nm region is 0.11±0.03, and the one evaluated for DITX-water in 400—408 nm region is 0.29±0.05. The observed K values are small in ethanol. In the case of xanthone in ethanol-water mixed solvent, a strongly hydrated species in which water molecule is H-bonded to carbonyl group was also reported from the measurement of time-resolved EPR spectrum at 77 K.[22] Considering the similarity between TX(or DITX) and xanthone in H-bond formation, and also considering the small K values in protic solvents being characteristic for H-bond formation,[23,24] the associate between TX(or DITX) and water may be assigned to the H-bonded species. By the use of the ε_C values, absorption spectra of the H-bonded species are shown in Fig. 5. The H-bonded species of TX-water has an absorption maximum at ≈394 nm, and the one of DITX-water, at ≈402 nm. It is noticed that as the water content is decreased, a slight shift to the longer wavelengths was observed with the absorption peak as is easily seen in Fig. 3.

The electronic structure of TX was calculated theoretically by the Pariser-Parr-Pople method in π-electron approximation.[25,26] The first π-π^* state (i.e., 384 nm band in ethanol) of TX is rich in intramolecular charge-transfer character from sulfur atom to carbonyl group as in the case of xanthone.[27] In the calculation procedure of π-electron structure, H-bond formation with water mainly affect the core Coulomb integral, α_P, of the H-bonded atom.[25] In TX, the H-bond, =O···H-O, between the carbonyl oxygen and water is thought to be more stable than the H-bond, S···H-O, between the sulfur atom and water.[23] Actual calculations have been done for the above two cases; theoretical results predict that the first π-π^* band shifts to longer wavelengths for =O···H-O H-bonding formation and to shorter wavelengths for S···H-O H-bonding formation. The observed longer wavelength shift of the first π-π^* band in Fig. 5 qualitatively supports the =O···H-O H-bond formation between TX and water.

The hydrated species between TX(or DITX) and water is also formed at room temperature as is shown in Fig. 6. The UV spectral change can be attributed to the formation of H-bonded species as in the case at 77 K, and K and ε_C values were evaluated from Eq. 1. The average K value is 0.26±0.03 for TX-water and 0.16±0.04 for DITX-water. By the use of the ε_C values, absorption spectra of the H-bonded species are also shown in Fig. 5.

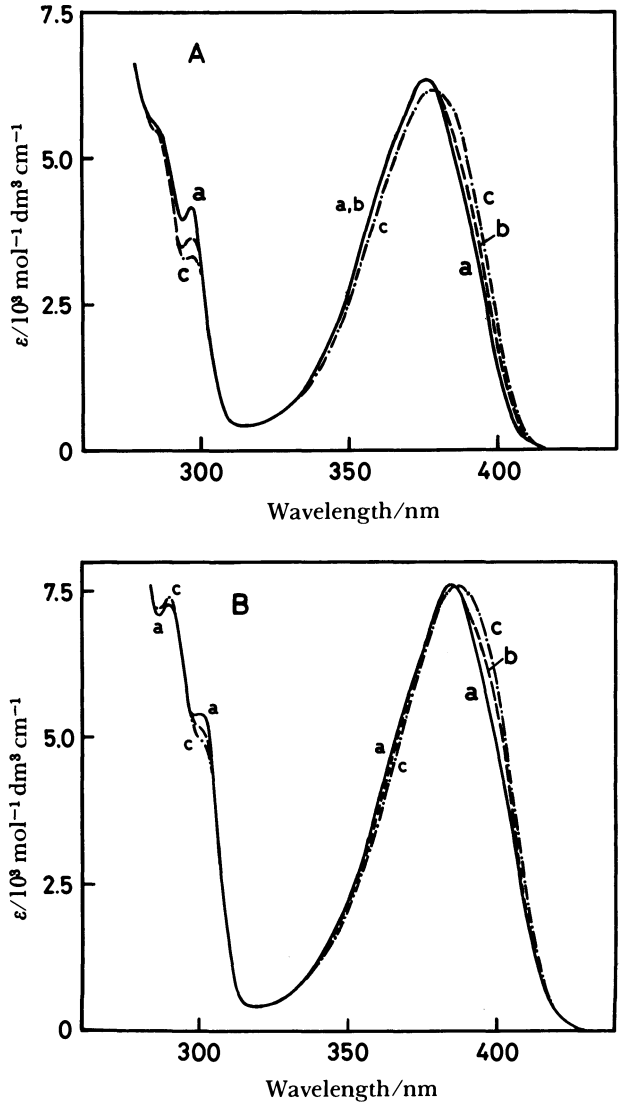

Fig. 6. UV absorption spectra measured with the ethanol-water solutions of (A) TX (7.2×10^{-5} M) and (B) DITX (7.9×10^{-5} M) at room temperature. Water content is (A):(a) 0, (b) 2, and (c) 10 vol%, and (B):(a) 0, (b) 4, and (c) 10 vol%.

Phosphorescence of TX and DITX in Ethanol-Water Solution. Phosphorescence spectra observed with the ethanol-water mixed solution of TX excited at 385 nm are shown in Fig. 7A. As the water content is increased, ≈470 nm and ≈442 nm regions increase their intensities relative to the 452 nm band. This result suggests that at least two phosphorescent species coexist in ethanol-water solution. This is confirmed by measuring the excitation wavelength dependence of phosphorescence spectrum (Fig. 7B) and also by observing excitation spectrum at several monitoring wavelengths (Fig. 7C). In Fig. 7B, besides the normal phosphorescence observed at 452 nm, ≈470 nm phosphorescence was resolved by exciting TX at 400 nm. The ≈470 nm phosphorescence increases its intensity as the water content is increased.

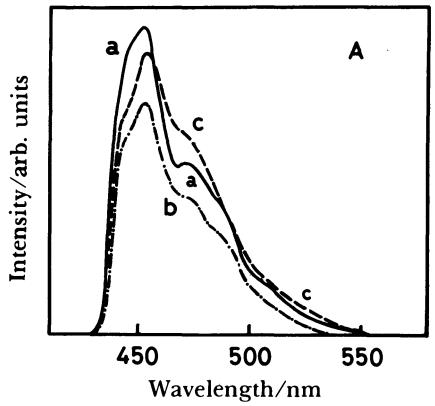

Fig. 7A. Phosphorescence spectra measured with the ethanol-water mixed solutions of TX (2.0×10^{-4} M) excited at 385 nm. Water content is (a) 1.0, (b) 4.8, and (c) 9.1 vol%.

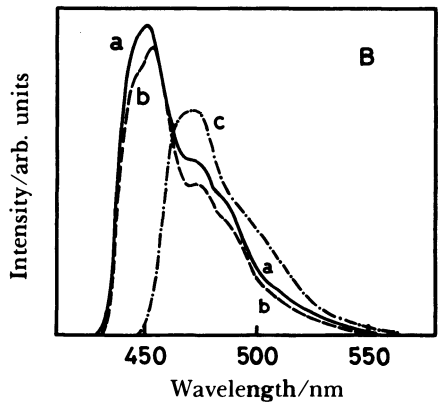

Fig. 7B. Phosphorescence spectra measured with the ethanol-water (100:1 by volume) solution of TX (2.7×10^{-4} M) excited at (a 350 nm, (b) 385 nm, and (c) 400 nm.

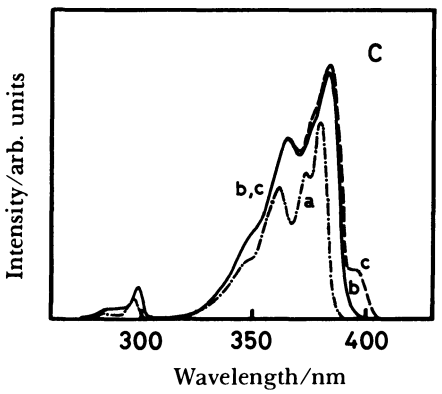

Fig. 7C. Phosphorescence excitation spectra measured with the ethanol-water (100:1 by volume) solution of TX (2.7×10^{-4} M) monitored at (a) 433 nm, (b) 450 nm, and (c) 475 nm.

The same intensity increase was also observed for 397 nm band in the excitation spectrum. Referring to the UV absorption spectrum of TX in ethanol-water at 77 K (Fig. 3), the ≈470 nm phosphorescence is safely

assigned to the hydrated (H-bonded) species. The phosphorescences monitored at 475 nm and at 450 nm decay single-exponentially, and the lifetimes are 212 ms and 160 ms, respectively, in good agreement with the corresponding values of the red-shifted and the normal phosphorescences of TX in pure ethanol. From these results, the red-shifted phosphorescence observed weakly in ethanol can be assigned to the H-bonded species between TX and water.

To understand the phosphorescent behavior in the 442 nm region, the phosphorescence excitation spectra were measured at several monitoring wavelengths; the result monitored at 433—435 nm (Fig. 7C) shows a new distinct band at 374 nm, revealing that the 442 nm phosphorescence can be ascribed to another (i.e., the third) chemical species. Coexistence of three chemical species in ethanol-water solution was also reported in the case of xanthone.[22]

In Fig. 7C, ≈380 nm band in the excitation spectrum shifts to shorter wavelengths (from 384 nm to 380 nm) as the monitoring wavelength becomes shorter (from 475 nm to 433 nm). This may suggest that the normal phosphorescence of TX shows inhomogeneous broadening by solute-solvent interaction.

Phosphorescent behavior of DITX in ethanol-water solution is similar to the one of TX mentioned above. In addition to the normal phosphorescence at 458 nm,

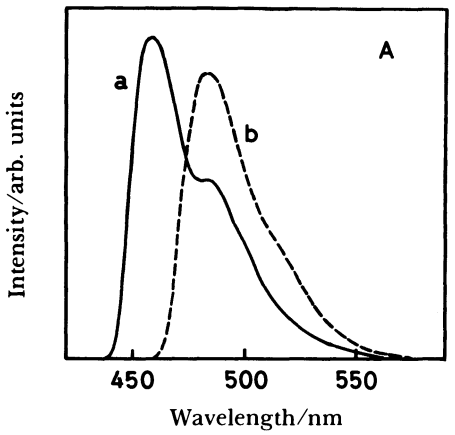

Fig. 8A. Phosphorescence spectra measured with the ethanol-water (100:1 by volume) solution of DITX (3.0×10^{-4} M) excited at (a) 392 nm and (b) 410 nm.

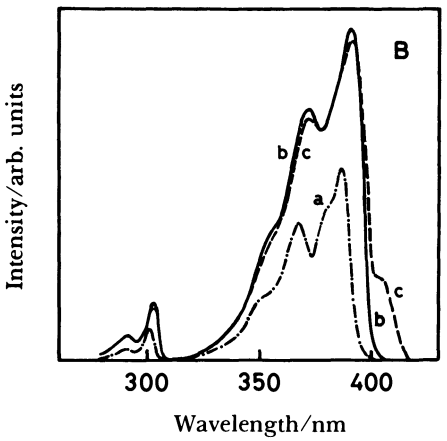

Fig. 8B. Phosphorescence excitation spectra measured with the ethanol-water (100:1 by volume) solution of DITX (3.0×10^{-4} M) monitored at (a) 442 nm, (b) 458 nm, and (c) 490 nm.

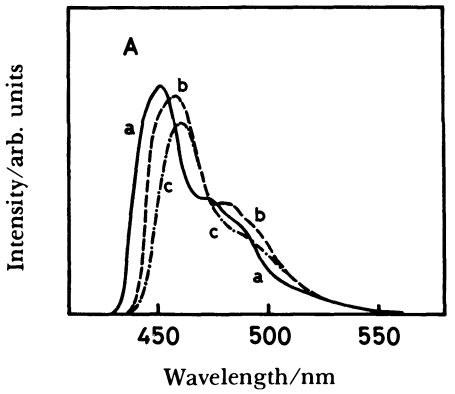

Fig. 9A. Phosphorescence spectra measured with the MTHF solution of TX (3.1×10^{-4} M) excited at (a) 385 nm, (b) 395 nm, and (c) 398 nm.

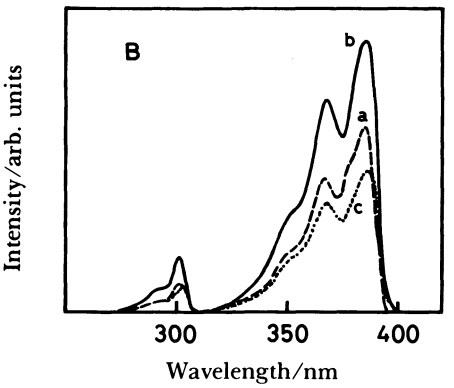

Fig. 9B. Phosphorescence excitation spectra measured with the MTHF solution of TX (3.1×10^{-4} M) monitored at (a) 440 nm, (b) 450 nm, and (c) 475 nm.

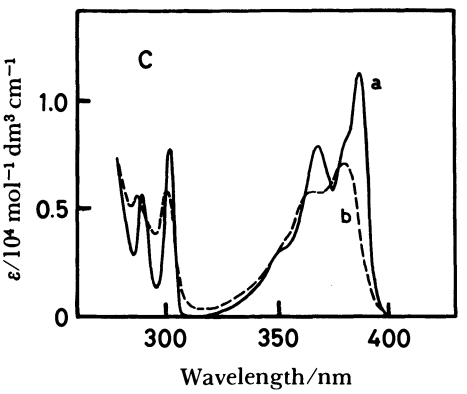

Fig. 9C. UV absorption spectra measured with the MTHF solutions of (a) TX (5.2×10^{-5} M) at 77 K and (b) TX (1.6×10^{-4} M) at room temperature.

phosphorescence due to the H-bonded species is resolved at 485 nm by exciting DITX at 410 nm (Fig. 8A). Furthermore, excitation spectrum monitored at 442 nm shows a new band at ≈380 nm as a shoulder

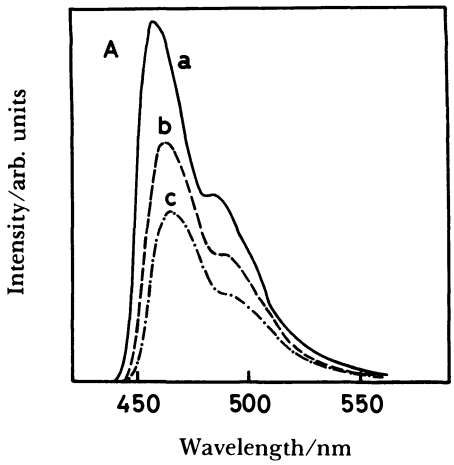

Fig. 10A. Phosphorescence spectra measured with the MTHF solution of DITX (1.7×10^{-4} M) excited at (a) 394 nm, (b) 400 nm, and (c) 403 nm.

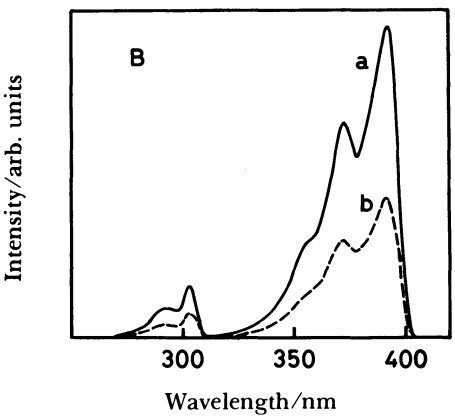

Fig. 10B. Phosphorescence excitation spectra measured with the MTHF solution of DITX (1.7×10^{-4} M) monitored at (a) 458 nm and (b) 490 nm.

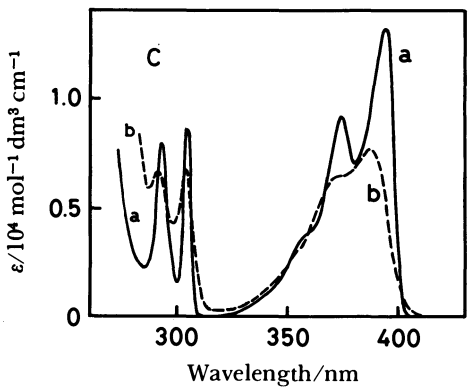

Fig. 10C. UV absorption spectra measured with the MTHF solution of DITX (8.6×10^{-5} M) at (a) 77 K and (b) room temperature.

(Fig. 8B), revealing that the third chemical species exists and phosphoresces in shorter wavelength region of the normal phosphorescence.

As in the case of TX, ≈390 nm band in the excitation spectrum shifts to shorter wavelengths (from 391 nm to 386 nm) as the monitoring wavelength becomes shorter (from 490 nm to 442 nm), suggesting that phosphorescence of DITX exhibits inhomogeneous broadening by solute–solvent interaction.

Phosphorescence of TX and DITX in MTHF. Phosphorescence spectra being excited at several wavelengths were measured with the MTHF solutions of TX and DITX. The results are shown in Figs. 9A and 10A. As the longer excitation wavelength is used, the phosphorescence shifts to the longer wavelengths (by ≈10 nm for TX, and by ≈6 nm for DITX), and the longer is the phosphorescence lifetime. The lifetime of TX varies from 150 ms (excited at 385 nm) to 177 ms (excited at 398 nm), and the one of DITX, from 163 ms (excited at 394 nm) to 186 ms (excited at 403 nm). In phosphorescence decay of DITX excited at 403 nm, a slight deviation from a single-exponential decay was observed. Although the phosphorescence excitation spectra and UV absorption spectra in MTHF (Figs. 9B, 9C, 10B, and 10C) did not exhibit any new band in ≈400 nm region in contrast to the cases of TX and DITX in ethanol, these results may suggest that another chemical species, phosphorescence of which can be resolved poorly in the present study, may coexist in MTHF, too.

Photoacoustic Study of 280 nm Band of Acetone Vapor

Takefumi OKA,* Humiyo KOBAYASHI, Naoki OGUMA, and Makoto MOROHASHI
Department of Electrical Engineering, Nagaoka Technical College, 888 Nishikatakai Nagaoka, Niigata 940
(Received June 8, 1987)

Relaxation of the energy absorbed by acetone vapor (200 Torr) on excitation with UV (230—340 nm) was investigated by the photoacoustic technique. The presence of two relaxation paths was found by their difference in heat production rates: The faster path is $S_0 \rightarrow S_1 \rightarrow T_1 \rightarrow S_0$ and the slower path is $S_0 \rightarrow$ radicals→recombination products. The PA spectra corresponding to these paths were determined separately. The spectrum for the T_1 path has a peak around 295 nm and extends to longer wavelengths beyond 310 nm. The spectrum for the decomposition path has a peak around 275 nm and overlaps with the spectrum for the T_1 path in the region of $\lambda<310$ nm. The study of frequency dependences of PA signals showed the presence of faster and slower heat releasing steps in each path. In the T_1 path, the faster and the slower steps are due to vibrational deactivation of hot T_1 formed from S_1 and of hot S_0 formed from T_1 respectively. In the radical path, the faster and slower steps are the deactivation of the hot radicals and the recombination of the thermalized radicals respectively. The addition of O_2 to the system accelerated the heat release process via the relaxed T_1 and also converted the slow heat release process of recombination into a fast process of addition reactions of O_2 to the radicals.

When a gas in a closed space is irradiated with intensity modulated radiation, generally some of the energy absorbed is released as modulated heat. This in turn produces a modulated pressure change, an acoustic wave. This is known as Photo Acoustic Effect (PA hereafter).

The frequency of the PA signal is the same as that of the excitation radiation but the PA signal has a phase lag behind the radiation. The phase lag as well as the amplitude of the PA signal bears information about the relaxation of the absorbed energy to heat.

By comparison of in-phase and out-of-phase PA spectra which are observed at phase angles separated by 90°, we can distinguish parts of an absorption band relaxing at different rates. Biacetyl,[1] azabenzenes,[2] and aromatic ketones[3] have been studied in this way. If the PA spectrum and the absorption spectrum of a particular gas are different, it also indicates the presence of different relaxation processes in that absorption band. This kind of technique has been used to determine the fluorescence quantum yield of benzene[4] and to investigate nonradiative processes of benzene.[5]

The frequency dependence of the phase lag provides chance to determine the rate constant of the relaxation process involved. Hunter et al. have developed a multi-state relaxation model[6] and have determined the triplet lifetimes of biacetyl,[7] benzenes,[8] and alkyl iodides[9,10] by applying the model to the frequency dependence of phase lag and/or amplitude.

In the present study, acetone is investigated by the PA technique measuring the PA spectra and the frequency dependence of the phase lag.

Acetone has an absorption band ranging from 220 nm to 330 nm with a maximum around 275 nm. The fluorescence quantum yield is very low (<0.002)[11] and nonradiative processes dominate the decay process. For low vibrational levels of S_1, the quantum yield of the $S_1 \rightarrow T_1$ intersystem crossing is 1 and $k_{isc}=3.8\times10^8\ s^{-1}$.[12] The intersystem crossing $S_1 \rightarrow T_1$ should form a hot triplet. On decreasing the excitation wavelength below 310 nm, k_{isc} decreases but the decomposition rate constant k_d increases.[13] Recently, Copeland and Crosley have reported the barrier height for decomposition into CH_3 and $COCH_3$ to be 385 kJ mol^{-1} above the ground state S_0 (50 kJ mol^{-1} above T_1). They have also shown the vibrational deactivation rate constant of the hot triplet by S_0 to be 7.59×10^{10} mol^{-1} dm^3 s^{-1} ($\approx10^9\ s^{-1}$ with 200 Torr of acetone (1 Torr=133.322 Pa)) and the lifetime of the thermal triplet to be 0.225 ms.[14] Since the quantum yield of the phosphorescence is small (≈0.02),[15] the lifetime of T_1 is ascribed to intersystem crossing to S_0.

Therefore we expect two paths of heat production in acetone: fast heat ($\approx50+\alpha$ kJ mol^{-1}) followed by slow ($\tau\approx0.2$ ms) heat (≈335 kJ mol^{-1}) for the $S_0 \rightarrow S_1 \rightarrow T_1 \rightarrow S_0$ path and fast heat ($\approx50+\alpha$ kJ mol^{-1}) followed by very slow heat (≈335 kJ mol^{-1})[16] for the $S_0 \rightarrow$ radicals→recombination products path. The α depends on the excess energy above the barrier. T_1 is quenched by oxygen with the rate constant of 8.4×10^9 mol^{-1} dm^3 s^{-1} ($5\times10^7\ s^{-1}$ with 100 Torr of O_2). Consequently the rate of heat production due to T_1 should increase in the presence of O_2.

Method

In order to analyze the PA spectra and the frequency dependence of the phase lag, equations to describe them are derived below. We assume a sinusoidally amplitude modulated light beam:

$$I(\lambda) = I_0(\lambda)(\delta+\sin\omega t)$$

where $I_0(\lambda)$ is the beam intensity at a wavelength of λ, ω is the angular frequency of modulation and δ is the relative intensity of the DC component. The light absorption process is expressed as

$$S_0 + h\nu \xrightarrow{I(\lambda)A(\lambda)} S_1$$

where $A(\lambda)$ is the fraction of the absorption over the full path length divided by the path length, and S_0 and S_1 refer to the ground and excited state respectively.

First, we shall deal with the PA spectra for a system which has two heat production processes with different rate constants. We assume two paths for heat production characterized by $\{r_1(\lambda),X_1,k_1,q_1\}$ and $\{r_2(\lambda),X_2,k_2,q_2\}$ as shown in the equations below.

$$\begin{array}{l} S_1 \xrightarrow{r_1(\lambda)} X_1 \xrightarrow{k_1} S_0 + q_1 \\ S_1 \xrightarrow{r_2(\lambda)} X_2 \xrightarrow{k_2} S_0 + q_2 \end{array}$$

where r_1 and r_2 refer to branching ratios from S_1 to the states X_1 and X_2 respectively, and X_1 and X_2 are only symbolic. They may or may not be real states. The point is that there are two parallel processes producing heat q_1 with a rate constant k_1 and heat q_2 with k_2. The heat production process may not be a single step in each path, but we assume so here. This assumption is adequate for the purpose of spectral analysis. Later we will employ a two-step model for the analysis of the frequency dependence.

The acoustic pressure $p(t)$ expected for the above scheme is as follows.

$$p(t) = K\frac{I_0(\lambda)}{\sqrt{\omega^2+k_t^2}}\{A_1(\lambda)b_1(\omega)\sin(\omega t-\phi_a-\phi_1) + A_2(\lambda)b_2(\omega)\sin(\omega t-\phi_a-\phi_2)\}$$

where $A_i(\lambda)=A(\lambda)r_i/(r_1+r_2)$, $b_i(\omega)=k_iq_i/\sqrt{\omega^2+k_i^2}$, $\phi_i=\tan^{-1}(\omega/k_i)$, k_t is a reciprocal of the time of thermal relaxation of the heated gas onto the cell walls and ϕ_a represents a phase lag due to the apparatus including a phase lag due to a thermal diffusivity effect. K is a constant independent of t, ω, and λ.

Then, the output of a lock-in amplifier $p(\lambda)$ is

$$p(\lambda) = K\frac{I_0(\lambda)}{\sqrt{\omega^2+k_t^2}}\{A_1(\lambda)b_1(\omega)\cos(\phi_r-\phi_a-\phi_1) + A_2(\lambda)b_2(\omega)\cos(\phi_r-\phi_a-\phi_2)\} \quad (1)$$

where ϕ_r is an adjustable phase lag of a reference signal. The in-phase spectrum with respect to the heat q_1 can be obtained by setting $\phi_r=\phi_a+\phi_1$:

$$p_{in}(\lambda) = K\frac{I_0(\lambda)}{\sqrt{\omega^2+k_t^2}}\{A_1(\lambda)b_1(\omega) + A_2(\lambda)b_2(\omega)\cos(\phi_1-\phi_2)\}. \quad (2)$$

The out-of-phase spectrum is given by setting $\phi_r=\phi_a+\phi_1+90°$ as

$$p_{out}(\lambda) = K\frac{I_0(\lambda)}{\sqrt{\omega^2+k_t^2}}\{0-A_2(\lambda)b_2(\omega)\sin(\phi_1-\phi_2)\}. \quad (3)$$

Since we know the shape of $I_0(\lambda)$ from a PA spectrum of carbon black,[18] the shape of the spectrum $A_2(\lambda)$ can be obtained from the out-of-phase spectrum of Eq. 3. Generally, the other spectrum $A_1(\lambda)$ can not be determined from $p_{in}(\lambda)$ of Eq. 2 even if the shape of $A_2(\lambda)$ is known. In the present study, however, we can find the shape of $A_1(\lambda)$ because $A_2(\lambda)b_2(\omega)$ term in $p_{in}(\lambda)$ is negligibly small compared to $A_1(\lambda)b_1(\omega)$ at particular frequencies.

Next we shall deal with the frequency dependence of the PA signal. In the spectrum analysis (Eqs. 1—3), we assumed for simplicity a single step, and consequently one rate constant for each heat producing path. The frequency analysis is only effective for a single path mechanism. Usually, a real path has many steps in series.

Here we assume a single path model consisting of two steps in series which are characterized by different rate constants as shown in Fig. 1. This model is essentially the same as the one used by Hunter et al.[6] In the first step, the fast heat F is released with a rate constant of $1/\tau_f$ and the slow heat S is released with a rate constant of $1/\tau_s$ in the second step.

When $\tau_f \ll \tau_s$, the PA signal can be approximated by

$$p(t) = K\frac{I_0(\lambda)}{\sqrt{\omega^2+k_t^2}}A(\lambda)b(\omega)\sin(\omega t-\phi_a-\phi) \quad (4)$$

where

$$b(\omega) = S\sqrt{(F/S)^2+\{1+2(F/S)\}/\{1+(\omega\tau_s)^2\}} \quad (5)$$

$$\phi = \mathrm{Tan}^{-1}\frac{\omega\tau_s}{(F/S)\{1+(\omega\tau_s)^2\}+1} \quad (6)$$

ϕ_a: a phase lag of the apparatus including that due to the thermal diffusivity effect. The $b(\omega)$ can be interpreted as the effective heat detected at ω. If this two-step model is applicable to each path in the previous model for spectral analysis, then the $b_i(\omega)$ terms in Eqs. 1—3 must be replaced by $b(\omega)$ of Eq. 5. Of course, S, F, and τ_s are different for each path.

To use frequency dependence of the PA amplitude, a logarithmic function of the amplitude, excluding the thermal diffusivity factor, is useful:

$$\log\{b(\omega)/S\} = \frac{1}{2}\log\left\{(F/S)^2+\frac{1+2(F/S)}{1+(\omega\tau_s)^2}\right\}. \quad (7)$$

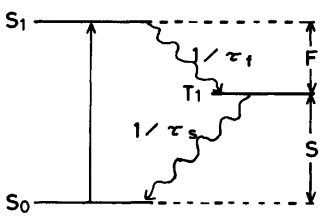

Fig. 1. A model of a relaxation path consisting of two steps in series. τ_f and F refer to the lifetime and the heat released in the first(fast) step; τ_s and S those in the second (slow) step. T_1 is not necessarily a triplet state and can be any state.

This quantity decreases as the frequency increases. The limiting values at lower frequencies and at higher frequencies are $\log\{1+(F/S)\}$ and $\log(F/S)$ respectively. Therefore we can determine the ratio of the fast heat(F) to the slow heat(S) if the relative amplitudes are obtained over a wide frequency range.

The phase lag ϕ is a more sensitive function of ω than the amplitude. To extract information on the relaxation due to the sample gas from the experimentally observed phase lag ($\phi+\phi_a$), ϕ_a must be determined and be subtracted. This can be done using a gas which has no slow heat, i.e. $S=0$ and consequently no phase lag, i.e. $\phi=0$. With this gas the observed phase lag is equal to ϕ_a.

The function ϕ of Eq. 6 has a maximum of $\tan^{-1}\frac{1}{2\sqrt{(F/S)\{1+(F/S)\}}}$ at $\omega=\{1+(S/F)\}/\tau_s$ and takes small values at lower and higher frequencies. When we observed this maximum, we can determine both the ratio F/S and the lifetime τ_s.

Experimental

The apparatus used is schematically shown in Fig. 2. The light source was a 500W xenon arc lamp (Ushio, UXL500D). The light beam was modulated at a frequency between 10 and 1000 Hz by a rotating disk chopper (Scetic Instruments, 300C) and then was passed through a 20 cm scanning monochromator (Ritsu, MC-20L) with a bandpass of 4.2 nm. The modulated monochromatic light beam was passed through a cylindrical PA cell (18 mm diameter, 70 mm long) along its axis to a solar blind phototube (HTV R1384).

The body of the PA cell was made of Pyrex, and two quartz windows were attached to the cell with epoxy resin. This cell also had two gas ports with greaseless stop cocks. PA signals were sensed by an electret microphone with a built-in FET preamplifier. The microphone was mounted in a small cavity adjacent to the cell body at its middle by using electron wax. The back side of the microphone was sealed with epoxy resin to make it vacuum tight. The microphone was polarized by a battery (9 V).

The output of the microphone (or of the phototube) was sent to a lock-in amplifier (Stanford Research Inc., SR 510) where a signal from a photocoupler on the chopper was used as a reference signal. The output of the lock-in amplifier was fed into a strip chart recorder.

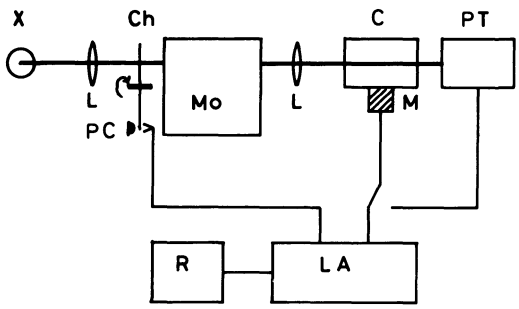

Fig. 2. Block diagram of the apparatus.
X, Xe lamp; L, lens; Ch, chopper; Mo, monochromator; C, cell; M, microphone; PT, photo tube; PC, photo coupler; LA, lock-in amplifier; R, recorder.

Sample gases were mixtures of acetone 200 Torr and a buffer gas (Ar or air) 560 Torr. The cell was filled on a conventional vacuum line. Filling and pumping of the cell was done slowly ($\approx$1 Torr s^{-1}) to prevent rupturing the diaphragm of the microphone.

To test the performance of this cell, measurements were made on mixtures of benzene vapor and a buffer gas (Ar or air). The cell showed no resonance below 1.5 kHz. The phase lag obtained with the mixtures showed chopping frequency dependence, but this was used as a phase lag of the apparatus (ϕ_a in Eq. 4).

To obtain corrected PA spectra, apparent PA spectra were divided by a PA spectrum of carbon black.[18] The spectra in Figs. 5, 9, and 10 are so corrected.

Three kinds of measurements were done in the present work.

1. PA spectra were measured by scanning the wavelength with a fixed chopping frequency at two fixed phase angles separated by 90° from each other.
2. The frequency dependence of the phase lag was obtained by a null reading at various chopping frequencies between 10 and 1000 Hz at a fixed wavelength.
3. Optical absorption spectra were obtained by division of a spectrum of the transmitted light intensity with a sample gas mixture in the cell by that with a buffer gas alone.

All the measurements were done at room temperature.

Results and Discussion

PA Spectra in Ar. The PA spectra of acetone (200 Torr) with Ar as a buffer gas at a frequency of 20 Hz are shown in Fig. 3. The out-of-phase spectrum (ϕ=90° in Fig. 3) was taken with the phase angle to null PA signal at 310 nm. The in-phase spectrum (ϕ=0°) was taken with a phase lead of 90° in front of the phase angle of the out-of-phase spectrum. At wavelengths longer than 310 nm, the signal appears

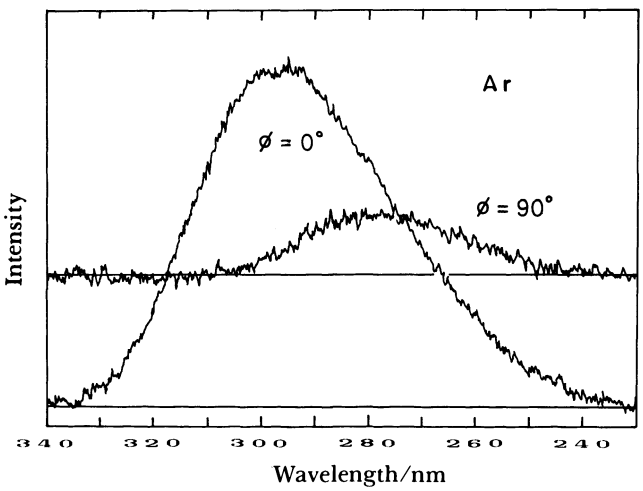

Fig. 3. PA spectra of acetone with Ar as a buffer gas (f=20 Hz). Acetone 200 Torr and Ar 560 Torr. Phase angles are of relative values.

only in the in-phase spectrum. This means that at $\lambda>310$ nm, there is only one relaxation process. On the other hand, there are two processes at $\lambda<310$ nm. In other words, the situation of Eqs. 2 and 3 is achieved in Fig. 3; Eq. 2 corresponds to the in-phase spectrum in the figure and Eq. 3 to the out-of-phase spectrum. The out-of-phase spectrum represents the spectral shape of one ($I_0(\lambda)A_2(\lambda)$ in Eq. 3) of two relaxation processes, which is a relatively slower one because the positive value of the out-of-phase spectrum results in $\phi_2>\phi_1$ in Eq. 3.

According to Eq. 2, the in-phase spectrum should be a mixture of two spectra $I_0(\lambda)A_2(\lambda)$ and $I_0(\lambda)A_1(\lambda)$. To confirm this interpretation, we examined the PA spectra at various frequencies (20—700 Hz). When the frequency was increased, the out-of-phase spectrum quickly decreased its relative intensity to that of the in-phase spectrum. This is consistent with the out-of-phase spectrum being that of slower relaxation: in Eqs. 2 and 3 the amplitude ratio $b_2(\omega)/b_1(\omega)$ is mathematically expected to become smaller as ω increases in the range of $k_1>\omega>k_2$.

In order to confirm the presence of a relatively faster heat releasing process and to determine its spectral shape $I_0(\lambda)A_1(\lambda)$, a trial spectrum for the faster process is tested in Fig. 4. Actually the trial spectrum is the in-phase spectrum at 35 Hz. In Fig. 4, the trial spectrum was so adjusted in its intensity to fit the long wavelength part of the mixture spectrum (the in-phase spectrum at 20 Hz) and was then subtracted from the latter. The difference between the mixed and the trial (the solid line in Fig. 4) reproduces the shape of the spectrum of the slower process which is actually the out-of-phase spectrum at 20 Hz. Therefore this trial spectrum is the spectrum of the faster process ($I_0(\lambda)A_1(\lambda)$ in Eq. 2).

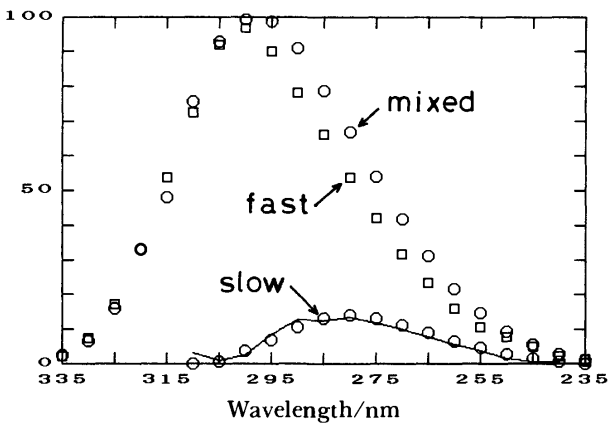

Fig. 4. Decomposition of the in-phase PA spectrum of Fig. 3 into a faster and a slower components. ○ (upper): the in-phase (ϕ=0°) PA spectrum in Fig. 3 (normalized to 100 at the peak).
□: trial spectrum for a faster component. ○ (lower): the out-of-phase (ϕ=90°) PA spectrum in Fig. 3 (height adjusted to fit the solid curve).
Solid curve: difference of ○ (upper) and □.

The corrected spectra of the slower ($A_2(\lambda)$) and the faster ($A_1(\lambda)$) heat releasing processes are shown in Fig. 5. Their shapes are frequency independent but their relative intensities in the in-phase and out-of-phase spectra depend on the frequency.

Since the slower process is absent at 310 nm, we can determine the rate constant for the faster process by measuring phase lags ϕ_1 at 310 nm as a function of frequency. Figure 6 shows the results. It is seen in Fig. 6 that the curve calculated by using Eq. 6 with τ_s=0.2 ms and F/S=0.2 fits the data well. The lifetime of the relaxed triplet state (T_1) of acetone has been reported to be 0.225 ms.[14] The expected values for F and S are 50 and 335 kJ mol^{-1} respectively for the relaxation path $S_1\rightarrow T_1\rightarrow S_0$ (excited at 310 nm). Therefore we assign the faster heat releasing process to

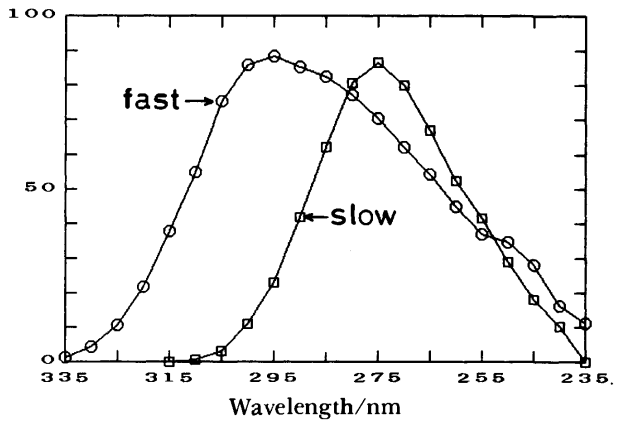

Fig. 5. Corrected PA spectra corresponding to the faster (T_1) and the slower (radicals) heat releasing processes. Normalized at their peaks. The correction was made by division with PA spectrum of carbon black.

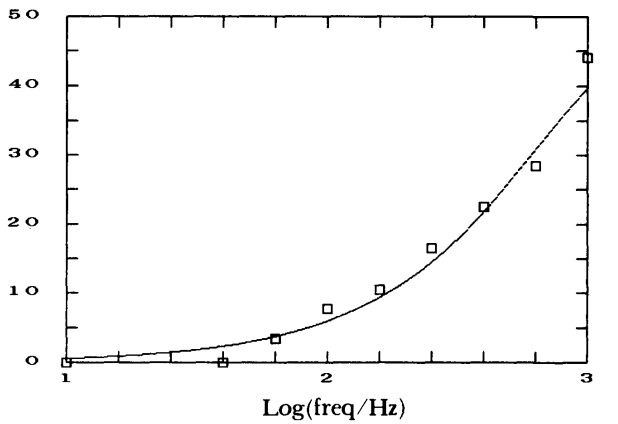

Fig. 6. Frequency dependence of phase lag of the heat released by T_1 observed at 310 nm.
Correction was made for the phase lag due to the apparatus. The solid line is the curve of Eq. 6 with τ_s=0.2 ms and F/S=0.2.

the relaxation path via the triplet state (T_1).

On the other hand, the slower process can be assigned to the heat release on the recombination of radicals formed by photolysis of acetone because its heat releasing rate is slower than that of T_1 and its excitation wavelength ($\lambda<310$ nm) corresponds to the energy above the barrier height of decomposition, i.e. 385 kJ mol^{-1}.[14]

This slower process can not be studied directly in the same manner as the faster one, because its entire spectrum overlaps with that of the faster one. However, we can get some idea about the frequency dependence of the slower process indirectly from analyses of the PA spectra obtained at various frequencies. It should be mentioned here that in the following analysis of the slower process, we approximate second order recombination reactions by a pseudo first order reaction assuming a constant steady state concentration of the radicals.

We now know the spectral shape of the faster process $A_1(\lambda)$ and the slower $A_2(\lambda)$ as well as the phase lag of the faster process $\phi_1(\omega)$. We should therefore be able to determine $\phi_2(\omega)$ and $b_2(\omega)/b_1(\omega)$ of Eq. 1 by decomposing the in-phase spectrum into the two components (as done in Fig. 4) and comparing the resulting component spectra and the out-of-phase spectrum. To calculate the relative values of $b_2(\omega)$ from the ratio $b_2(\omega)/b_1(\omega)$, we used $b_1(\omega)$ calculated by using Eq. 5 with $F/S=0.2$ and $\tau_s=0.2$ ms for we did not measure $b_1(\omega)$. The calculated $b_1(\omega)$ is constant between 10 and 200 Hz and then gradually decreases down to 0.4 of the constant value as the frequency increases to 1000 Hz. The values of $\log\{b_2(\omega)\}$ and $\phi_2(\omega)$ thus obtained are shown in Fig. 7 (circles) as a function of $\log f$.

These curves are typical forms of the theoretical Eqs. 6 and 7; and are indications of the presence of two steps in the heat production process due to radicals. We estimate $F/S\lesssim 0.35$ from the highest and the lowest values of $\log\{b_2(\omega)\}$ and the approximate frequency of $\phi_2(\omega)$ peak of 35 Hz. These values lead to a very slow lifetime of $\tau_s\gtrsim 6$ ms. Equation 6 with these parameter values can reproduce the shape of $\phi_2(\omega)$ curve in Fig. 7 but predicts the peak of $\phi_2(\omega)\gtrsim 30°$. This discrepancy in the peak value of ϕ_2 may be due to the large errors in the determination of ϕ_2 by the spectrum subtraction method.

The two steps found in the heat production process due to radicals are interpreted as follows: heat release during the primary photodecomposition is the faster step remaining even at high frequencies ($f\leqq 100$ Hz) while the heat release on radical recombination is the slower one, present only at low frequencies ($f\leqq 20$ Hz).

PA Spectra in Air. PA spectra at 20 Hz with air as a buffer gas are shown in Fig. 8. As the PA spectra in Ar at 20 Hz (Fig. 3), these spectra also have two components. We decomposed the in-phase spectrum into a faster and a slower component spectra and found that the shapes of both component spectra were the same as those in Ar. Therefore we assign the out-of-phase spectrum to that due to radicals and the in-phase spectrum to a mixture of spectra due to radicals and to T_1.

The phase lags at 310 nm were found to be null in the frequency range of 10 to 1000 Hz. This indicates that the lifetime of T_1 is shortened (<20 μs) by the presence of about 100 Torr of O_2.

The frequency dependences of ϕ_2 and $\log b_2$ determined by spectral subtraction method as before are shown in Fig. 7 (squares). We used $\phi_1=0$ and $b_1=1$ for the heat production rate of T_1 in air because the rate is supposed to be much larger than that in Ar. A tail of a peak is observed in the ϕ_2 curve.

Therefore the heat production process due to radicals also has two steps: A faster one and a slower

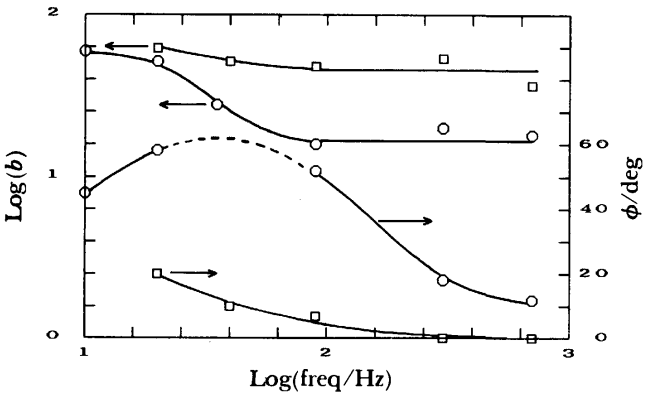

Fig. 7. Frequency dependences of PA signals due to the heat released by radicals.
O: Ar as a buffer gas, □: air as a buffer gas. ϕ: phase lag, b: amplitude. All the data were obtained indirectly from frequency dependence of spectral shape.

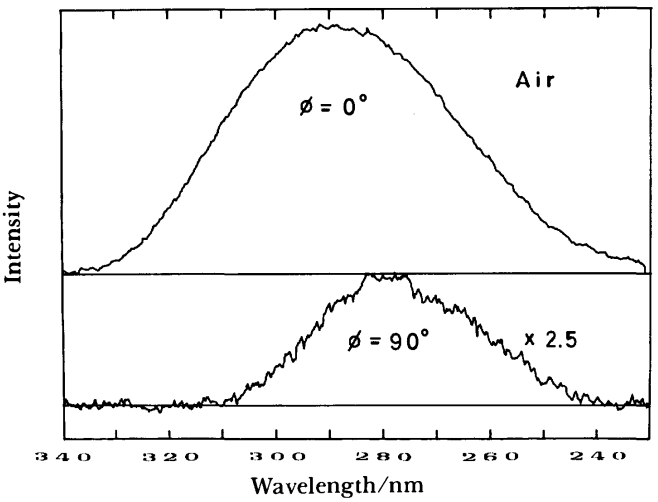

Fig. 8. PA spectra of acetone with air as a buffer gas (f=20 Hz).
Acetone 200 Torr and air 560 Torr. Phase angles are of relative values.

one. The faster step remaining at high frequencies (f>100 Hz) may be the primary photodecomposition and the reactions of the radicals so produced with O_2. For example, the pseudo first order rate constant of CH_3 with 100 Torr of O_2 is calculated to be 5×10^7 s^{-1} according to the literature.[19] The slower step observed at very low frequencies (f<20 Hz) could be heat release on recombination reactions of heavier radicals which are formed by addition of O_2 to primary radicals such as CH_3O_2.

Comparison of PA Spectra (PAS) with Absorption Spectra (ABS). In Fig. 9 the in-phase PAS at 423 Hz and the ABS with Ar as a buffer gas are compared. In Fig. 10 the in-phase PAS at 508 Hz and the ABS with air as a buffer gas are compared. The same sample was used in the measurements of the corresponding PAS and ABS. These PAS are corrected for $I_0(\lambda)$.

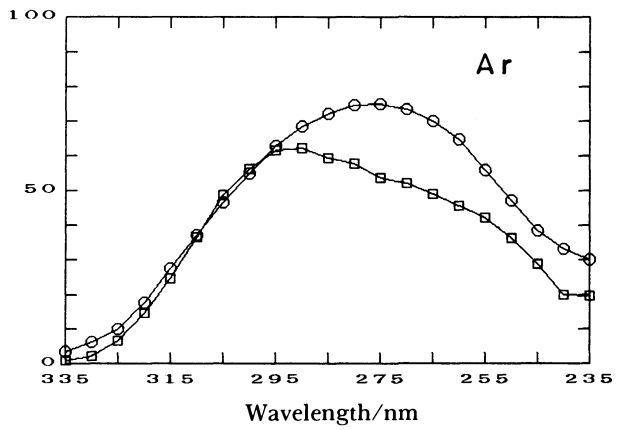

Fig. 9. Comparison of the absorption spectrum and the corrected PA spectrum of acetone with Ar as a buffer gas (f=423 Hz).
Acetone 200 Torr and Ar 560 Torr. The absorption-(○) is in % unit. PAS(□) is normalized to fit ABS at longer wavelengths.

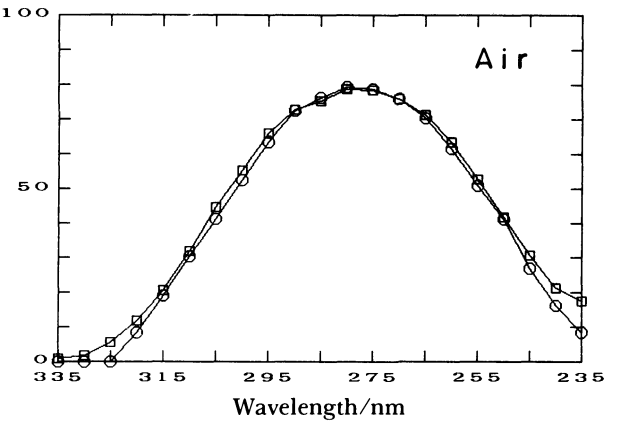

Fig. 10. Comparison of the absorption spectrum and the corrected PA spectrum of acetone with air as a buffer gas (f=508 Hz). See the legend of Fig. 9.

An ABS represents energy absorbed but a PAS represents energy released as heat. The heat defect in Fig. 9 can be considered due to failure to observe the slowly released heat at the high frequency.

The ABS in Fig. 10 as well as in Fig. 9 is proportional to $A(\lambda)$ in Eq. 2: $A(\lambda)=A_1(\lambda)+A_2(\lambda)$. The PAS in air (Fig. 10) can be also expressed by Eq. 2 as $A_1(\lambda)b_1(f=508)+A_2(\lambda)b_2(f=508)\cos(0)$. The effective heat at 508 Hz for T_1 path, i.e. $b_1(f=508)$ is equal to the total energy absorbed because the total energy of T_1 is released by the faster process in the presence of O_2: $b_1(508)$=430 kJ mol^{-1} at 280 nm. Judging from Fig. 7, $b_2(508)$ is the heat released by the faster process in the radical path: $b_2(508)=100+Q$ kJ mol^{-1} at 280 nm. Here the Q represents a sum of the heat released by the addition reactions of the two primary radicals to O_2. The coincidence of ABS and PAS in air (Fig. 10) requires Q to be about 330 kJ mol^{-1}.

Summary

It was found that there are two heat production paths in the 280 nm absorption band of acetone: one via T_1 and the other via radicals.

The spectral shapes for T_1 formation and photodecomposition were determined (Fig. 5).

The assignments of the heat observed in PA signals are summarized in Table 1 and the following reaction scheme.

$$S_0 \longrightarrow S_1$$
$$S_1 \longrightarrow T_1 + q_1$$
$$S_1 \longrightarrow \text{decomposition}(R_1+R_2) + q_2$$
$$T_1 \longrightarrow S_0 + q_3$$
$$R_1, R_2 \text{ recombination} \longrightarrow \text{products} + q_4$$
$$T_1 + O_2 \longrightarrow S_0 + O_2 + q_3' \quad (q_3=q_3')$$
$$R_1 + R_2 + 2O_2 \longrightarrow R_1O_2 + R_2O_2 + q_5$$
$$R_1O_2 + R_2O_2 \longrightarrow \text{products} + q_6$$

where q_i refers to heat released.

Table 1. Assignments of the Heat Observed[a]

Buffer	Path via T_1		Path via radicals	
	Fast	Slow	Fast	Slow
Ar	q_1 (50+α)	q_3 (335)	q_2 (50+α)	q_4 (335)
air	q_1+q_3' (385+α)	—	q_2+q_5 (385+α)	q_6

a) The numbers in parentheses are rough estimates of the amount of heat released in kJ mol^{-1} unit. $\alpha=1.2\times10^5/\lambda-385$ kJ mol^{-1}. λ is the excitation wavelength in nm.

Design of Novel Mesomorphic Compounds: *N,N′,N″*-Trialkyl-1,3,5-benzenetricarboxamides

Yoshio MATSUNAGA,* Nobuhiko MIYAJIMA, Yuichi NAKAYASU, Satoshi SAKAI, and Michihiro YONENAGA
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060
(Received June 12, 1987)

N,N′-Dialkyl-1,4-benzenedicarboxamides melt with anomalously small enthalpy changes. The 1,3-analogs behave similarly but at lower temperatures. These observations provide a clue to design novel mesomorphic compounds; *N,N′,N″*-trialkyl-1,3,5-benzenetricarboxamides. The compounds carrying pentyl to octadecyl groups melt at temperatures between 49 and 119 °C depending upon the alkyl chain length. The clearing points are located above 200 °C. The unoriented liquid crystals show X-ray diffraction patterns consisting of two major peaks. The inner sharp peak gives a spacing, which increases as the series is ascended, from 1.40 to 2.26 nm. The outer one is sharp in the pentyl and hexyl derivatives but diffuse in the higher homologous members. The second moments of the broad-line proton NMR spectra measured above the melting points are as small as a few hundredths G^2 and firmly establish the liquid-like characteristics of the alkyl chains.

Our earlier study on the phase diagrams of a number of binary systems composed of *N*-(4-propoxybenzylidene)-4-hexylaniline and *N*-alkyl-4-nitrobenzamide or *N*-(4-nitrophenyl)alkanamide revealed that these *p*-disubstituted benzenes would form smectic liquid crystals near room temperature if the melts were sufficiently supercooled.[1] Thus, the substituents $CONHC_nH_{2n+1}$ and $NHCOC_nH_{2n+1}$ appeared to be outstandingly efficient to promote the thermal stability of liquid crystals. This conclusion is in accordance with the placement of the $NHCOCH_3$ group by Gray at the top of the order of efficiency in promoting both nematic and smectic liquid crystals.[2] He suggested that hydrogen bonding is possibly of importance in this case in retaining the molecular order in the mesophases. Therefore, we have looked into the thermal properties of benzene derivatives carrying two or more $CONHC_nH_{2n+1}$ or $NHCOC_nH_{2n+1}$ groups with the hope of finding new ways to design mesomorphic compounds.[3,4] The present paper records details of our work on *N,N′*-dialkyl-1,4- and 1,3-benzenedicarboxamides and *N,N′,N″*-trialkyl-1,3,5-benzenetricarboxamides.

Experimental

Materials. The isophthaloyl dichloride, terephthaloyl dichloride, 1,3,5-benzenetricarbonyl trichloride, and alkylamines were obtained from commercial sources. The condensation reaction between the acyl chloride and the amine was carried out in boiling benzene by the addition of pyridine. The products were purified by repeated recrystallizations from appropriate solvents and were carefully dried. For example, Found: C, 68.91; H, 9.43; N, 10.08%. Calcd for $C_6H_3(CONHC_5H_{11})_3$: C, 69.03; H, 9.41; N, 10.06%. Found: C, 77.43; H, 11.93; N, 5.10%. Calcd for $C_6H_3(CONHC_{15}H_{31})_3$: C, 77.36; H, 11.90; N, 5.01%.

Measurements. Calorimetric, X-ray, and NMR measurements were made as described in our previous papers.[3-5]

Results and Discussion

Thermal Properties of *N,N′*-Dialkylbenzenedicarboxamides. As ordinary liquid crystals are known to be formed by elongated molecules, the compounds initially examined by us were *N,N′*-dialkyl-1,4-benzenedicarboxamides (**1**). Their transition temperatures and associated enthalpies are presented in Table 1. It must be noted that the enthalpy of melting decreases as the series is ascended and also that the values are rather small. For comparison, dioctadecyl terephthalate, which is closely-related in molecular structure to the octadecyl derivative, melts at 86 °C with an enthalpy change of 136 kJ mol^{-1}. This value is 2.2 times the corresponding one of octadecane, 62 kJ mol^{-1}. These observations imply that the *N,N′*-dialkyl-1,4-benzenedicarboxamide crystal is considerably disordered just below the melting point. In other words, the high-temperature form is in a stage

intermediate between the isotropic liquid and the well-organized solid state. The compound is not very soluble in most organic solvents. Moreover, the endothermic peaks are broadened in a second and subsequent heatings indicating that the compound is prone to thermal decomposition.

We extended our examination to *N,N'*-dialkyl-1,3-benzenedicarboxamides (**2**) expecting depression of melting points and also improved solubilities. These compounds are polymorphic (see Table 2). The enthalpies of melting are as small as those of the 1,4-analogs; however, the value increases with the increase of alkyl chain length in contrast to the aforementioned series. The compounds dissolve well in benzene and are easily recrystallized from mixtures of benzene and ethanol. Thus, both compounds **1** and **2** are promising as starting materials to obtain mesomorphic compounds but the latter are easiler to handle. Our next step to approach the emergence of liquid crystals was the introduction of an extra $CONHC_nH_{2n+1}$ group into the *N,N'*-dialkyl-1,3-benzenedicarboxamide molecule. As will be described in the following paragraphs, *N,N',N''*-trialkyl-1,3,5-benzenetricarboxamides (**3**) are truly mesomorphic.

Thermal Properties of *N,N',N''*-Trialkyl-1,3,5-benzenetricarboxamides. The thermal properties are summarized in Table 3. Here, K, M, and I stand for crystal, mesophase, and isotropic liquid respectively. The stable form of the hexadecyl derivative melts at about 90 °C. As this form is always contaminated by the metastable form melting at 73 °C which is easily crystallized from the melt, the data for the latter are presented in this table. Most of the compounds exhibit two transitions above room temperature. The pentyl derivative and higher homologs form viscous birefringent fluids upon the transition located between 49 and 119 °C. The enthalpy change associated with the transition increases on ascending the series. The presence of a large difference between the nonyl and decyl derivatives must be noted. The mesophase covers a wide temperature range and the transformation into an isotropic liquid occurs above 200 °C in all cases. The transition is accompanied by enthalpy changes from 6 to 22 kJ mol^{-1}. The supercooling of the isotropic liquid is not detectable at a cooling rate of 5 K s^{-1}. The odd-even alternation of clearing point is found in the whole series and is particularly remarkable when the alkyl group is octyl or longer.

The butyl derivative shows a solid-solid transition in the temperature range where the higher homologs are transformed into liquid crystals and melts at a temperature higher than the clearing points of any other members. It may be added that trioctadecyl 1,3,5-benzenetricarboxylate melts at 79 °C with an enthalpy change of 133 kJ mol^{-1}. Therefore, the mesophase of the octadecyl derivative appears in the temperature range where the corresponding ester is liquid.

No identifiable texture is shown by the liquid crystals when the crystals melt. However, the texture observed for liquid crystals of low homologous members appearing by slow cooling of the isotropic liquid is likely to be fan or broken fan shaped.

X-Ray Diffraction. Figure 1 presents plots of spacings against the number of carbon atoms in an alkyl group, n. The longest spacing given by the butyl derivative is 1.20 nm at room temperature. No abrupt change is found at the solid-solid transition located at 98 °C. The spacing increases gradually upon further heating and reaches 1.26 nm at 150 °C. The higher members in the crystalline state can be classified into three groups by the alkyl chain length dependence. The pentyl and hexyl derivatives give nearly the same values, 1.67 and 1.68 nm. From the heptyl to decyl derivatives, the spacing increases by 0.17 nm per methylene group. There is an abrupt increase between the decyl and undecyl derivatives. Then, the spacing changes again linearly with n by as much as 0.20 nm per methylene group. The tetradecyl derivative is the only exception to this group.

The diffraction patterns recorded at 150±10 °C for the "unoriented" liquid crystals consist of two major peaks. In fact, the specimen spread in the form of a thin film over an aluminum holder cannot be free from orientation; therefore, "unoriented" here means not intentionally oriented. The inner peak is sharp and strong and gives a spacing of 1.63 nm for the heptyl derivative and 2.26 nm for the octadecyl derivative. The outer peak is diffuse in these homologous members. The maximum remains at the same Bragg angle throughout the series as shown in Fig. 1. This feature is consistent with not only a nonordered smectic phase but also a hexagonal disordered columnar structure. The enthalpy changes at the clearing points, 6 to 22 kJ mol^{-1}, are in the range of values for the nonordered smectic-isotropic transitions collected by Demus et al.[6] They are also comparable with the enthalpy changes given at the hexagonal disordered columnar-isotropic transitions of hexakis(alkanoyloxy)benzenes but appreciably smaller than the corresponding values of *N,N'*-dialkanoyl-2,3,5,6-tetrakis(alkanoyloxy)-1,4-benzenediamines.[5,7,8]

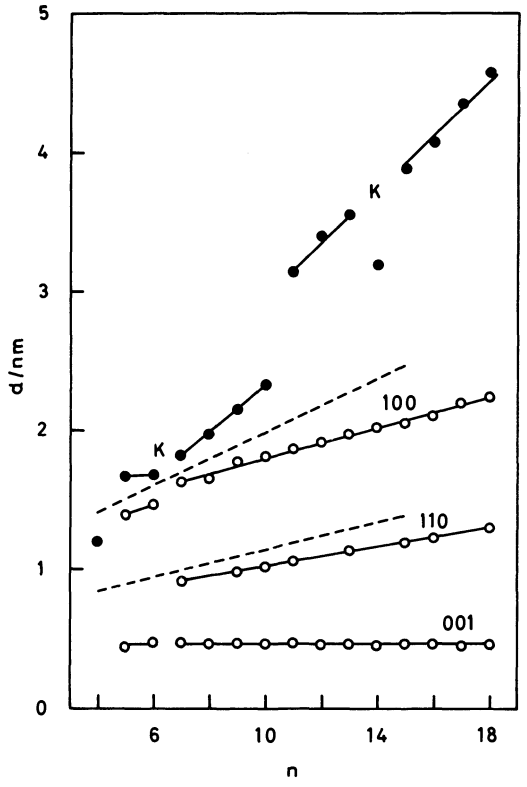

Fig. 1. Plots of spacings against the number of carbon atoms in the alkyl group of compounds **3**. The open circles show the spacings measured in mesophases. Broken lines indicate the corresponding spacings of *N,N'*-dialkanoyl-2,3,5,6-tetrakis(alkanoyloxy)-1,4-benzenediamines in the hexagonal disordered columnar phase.

Levelut has assumed that a disk-like molecule must be made of a planar rigid core surrounded by a more or less planar ring of aliphatic chains.[9] According to this view, the paraffinic crown of the *N,N',N''*-trialkyl-1,3,5-benzenetricarboxamide molecule cannot be considered to be dense enough to form columnar liquid crystals. However, a careful examination of many diffraction patterns revealed the presence of a peak, although not in all the cases, the spacing of which is about $1/\sqrt{3}$ times the longest one. The peak is very weak possibly due to the unfavorable orientation of the liquid crystals. This ratio is characteristic of a hexagonal columnar structure. The longest spacing may be assigned to the first order 100 reflection and the other one to 110 reflection. In Fig. 1, broken lines show the spacings d_{100} and d_{110} in the mesophase of *N,N'*-dialkanoyl-2,3,5,6-tetrakis(alkanoyloxy)-1,4-benzenediamines taken from our previous work.[5] Compared with them, not only the spacings themselves but also the increments per methylene group of compound **3** are shorter suggesting that the alkyl chains are more liquid-like and/or more interdigitated. Because the molecule carries only three alkyl groups, the chains attached to neighboring molecules must be differently oriented in order to achieve hexagonal packing of the columns. The molecules in each column are irregularly spaced. The average distance 0.47 nm agrees well with the values estimated for the above-mentioned hexasubstituted benzenes.[5,7,8]

While the d_{100} value in the heptyl to octadecyl derivatives varies linearly with n, the longest spacings exhibited by the pentyl and hexyl derivatives are smaller by about 0.1 nm than those expected by a linear relationship. The two compounds give sharp outer peaks and the whole diffraction patterns bear

strong resemblances to those reported for smectic B phase. The intermolecular distance (d) is estimated to be 0.47 nm by Bragg's formula and 0.54 nm when one employs the formula $2d \sin\theta = 1.1547\lambda$ proposed by de Vries specifically for smectic B phase.[10] The latter value is slightly longer than those reported for ordinary smectic B liquid crystals. If this identification is accepted, the longer spacing is assigned to the 001 reflection and the shorter one to the overlap of the 110 and 200 reflections. The molecules must be in a high degree of rotational disorder around the axis in the plane of the benzene ring and are in hexagonal packing within the layers. Such a motion may be possible only when the alkyl chains are not long. One might assume that the mesophases exhibited by these two are also hexagonal columnar. As the outer peak is sharp, the molecules in each column are equally spaced. It must be noted that the observed distance between parallel molecules, 0.47 nm, is unusually large compared with those known for some ordered columnar phases; namely, 0.36 nm of hexaalkoxytriphenylenes and hexaalkoxytruxenes.[11,12] Evidently, further studies are required to yield precise information regarding the molecular arrangement in these mesophases.

NMR Spectra. The liquid-like characteristics of alkyl chains in the mesophases are well demonstrated by small second moments of broad-line proton NMR spectrum (the mean-square width of the resonance line), $\langle \Delta H^2 \rangle$, above the melting point. Values of the order of 0.01 G^2 ($G=10^{-4}$ T) for the mesophases of the octyl and hexadecyl derivatives are almost indistinguishable from those of isotropic liquids because of the resolution limit of our spectrometer. The increase in the enthalpy change of melting with the increase of alkyl chain length is clearly manifested by the magnitude of the second moment decrease at the transition temperature; that is, about 2 G^2 at 116 °C and about 6 G^2 at 90 °C. The depression of the moment by about 2 G^2 in the non-mesogenic butyl derivative occurs in a temperature range higher by 10 to 20 °C than the calorimetric transition point located at 98 °C, indicating that the chains are not moving fast enough on an NMR time scale at the transition temperature. Moreover, the moment remains at about 3 G^2 in the high-temperature form.

The molecules examined in the present work are neither rod-like nor disk-like; nevertheless, the behavior reported above fully confirms the formation of liquid crystals. The primary requirement for the appearance of liquid crystals is not the specific geometrical anisotropy of the molecules but the anisotropy of the intermolecular forces maintaining order in the crystal and liquid crystals. The interaction between the benzenetricarboxamide units keeps the molecules in columns or layers up to relatively high temperatures. The N–H stretching vibrational band is shifted by 15 to 35 cm^{-1} to the lower wavenumber by melting and the C=O band slightly to the opposite direction, suggesting that the hydrogen bonding is strengthened upon the transition. On the other hand, the long flexible alkyl chains are conformationally disordered at lower temperatures. This molecular feature seems sufficient to fulfill the above-mentioned requirement.

Finally, it must be added that mesomorphic 1,3,5-trisubstituted benzenes are not entirely new. However, the compounds so far reported carry substituents such as cholesteryloxycarbonyloxy groups or 4-alkyl- and 4-alkoxybenzoyl groups.[13–15] They are not as simple as the present compounds and may be classified into different families of liquid crystal materials.

(Received June 17, 1987)

The pressure-induced superconductivity in black phosphorus was measured along five different paths in a P–T phase diagram. The effect of the pressure on the superconducting transition temperature-(T_c) depends strongly on the path in the P–T phase diagram. The results for several paths were compared with those obtained by Wittig et al. If black phosphorus was pressurized at the temperature of liquid helium, the T_c went up to 10.7 K and the onset temperature of transition was beyond 13 K at very high pressures. When red phosphorus was used as the starting material and pressurized at 4.2 K, T_c steeply increased with an increase in the pressure; it increased up to 13 K, while the onset temperature of transition reached 18 K at 30 GPa. This is the highest superconducting transition temperature among the elements. Pressure-induced phase transitions have also been studied by the X-ray techniques using synchrotron radiation at the temperature of liquid nitrogen. The pressure of the transition at 77 K was higher than that at room temperature. Two or three phases coexisted in a wide pressure (6—14 GPa) at 77 K.

The anomalous superconductivities of black phosphorus (black P) have been investigated at low temperatures and high pressures.[1-4] The superconducting transition temperature (T_c) of black P reaches to about 11 K under very high pressures. The T_c vs. pressure curve depends on the path in the P–T phase diagram.[1,2] Wittig et al. have found double maxima in the T_c–P curve.[3] Yokovlev et al. have studied the superconductivity under pressure using a red phosphorus as the starting material.[4]

Black P is transformed from an orthorhombic structure to a rhombohedral structure, and then further to a simple cubic form, with the increase in the pressure at room temperature.[5] The transition from the orthorhombic form to the rhombohedral one is very slow, and these phases coexist over a wide pressure range. The simple cubic form is very stable under pressure and exists at least up to 60 GPa.[6] The mechanism of phase transitions in black P has already been discussed by many authors.[7-12] Iwasaki et al. have determined the P–T phase diagram of black P above room temperature by means of X-ray study with synchrotron radiation.[13] However, the phase diagram has not yet been studied below room temperature. An X-ray beam of synchrotron radiation is quite suitable for high-pressure experiments because of such excellent characteristics as brightness, a small divergence, and a constant energy.[14] By using synchrotron radiation, we have investigated the pressure-induced phase transitions of black P at the temperature of liquid nitrogen.

In this paper we wish to report our results on the pressure-induced superconductivity and phase transitions in black P obtained by the use of new high-pressure apparatuses that can continuously change the pressure at low temperatures.

Experimental

In determining the pressure dependence of T_c by the resistive method, we used the apparatus described in a previous paper.[15] The system consists of a diamond-anvil pressure cell mounted on a booster which is actuated by helium gas. The pressure can continuously be changed at the temperature of liquid helium.

Figure 1 illustrates the sample assembly for the measurement of the resistance. Each diamond anvil was convered by polyvinyl chloride films to a thickness of about 25 μm; these films were used as a pressure medium. Copper electrical leads with a thickness of 10 μm were set between two anvils. The gap width between two electrodes was about 30 μm. This configuration is similar to that is Sakai's method.[16]

A thin rectangular plate of black P was cut from a single crystal in the air and put on the gap between electrodes. The resistance was measured along the *ac* plane of the crystal. The measurement of the resistance under high pressure was carried out along the five different paths depicted in Fig. 2. Path (A1): After the sample was transformed into the simple

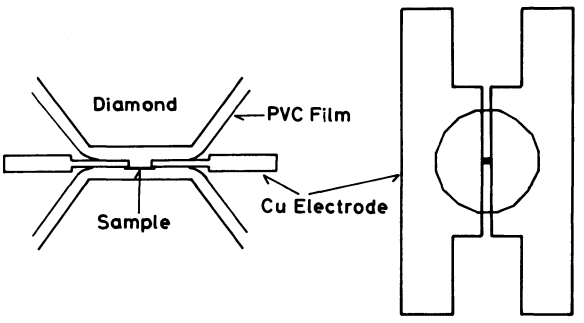

Fig. 1. Sample assembly used for the measurement of the electrical resistance.

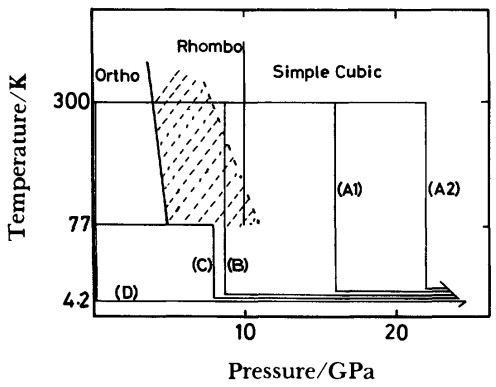

Fig. 2. Schematic phase diagram of black phosphorus: Hatched region shows the pressure range where two or three phases coexist. Five paths along which T_c was measued are also illustrated.

cubic phase by a pressure of 16 GPa at room temperature, the pressure cell was cooled to the temperature of liquid helium, keeping the pressure constant. Then, the pressure was raised further at the temperature of liquid helium. The T_c's were measured at constant pressures. Path (A2): After pressure was applied up to 22 GPa at room temperature, the cell was cooled. Then, the T_c was measured by the same procedure as above. Path (B): Pressure was applied up to 8.7 GPa at room temperature, whereupon the sample was trans formed into the rhombohedral phase. Then, it was cooled to the temperature of liquid helium. Path (C): Pressure was increased to 8 GPa at the temperature of liquid nitrogen. Both orthorhombic and rhombohedral phases coexist under this condition. Then, the cell was cooled to the temperature of liquid helium. Path (D): After the sample had been cooled to the temperature of liquid helium at almost the ambient pressure, pressure was applied. The T_c's were measured at constant pressures. The resistance of the high-purity red phosphorus was also measured along this path. The red P was provided by the Mitsubishi Metal Corporation; its purity was over 99.9999%.

The pressure was determined by means of fixed points for the Bi, ZnS, and GaP transitions at room temperature. To estimate the pressure at low temperatures, we adopted the calibration curve between the generated pressure and the applied force, as determined at room temperature.

A new diamond-anvil pressure cell was developed for X-ray measurement which makes possible a continuous change in the pressure at low temperatures. The details of the high-pressure system have been reported elsewhere.[17] The X-ray measurement at high pressures and 77 K was carried out using a bending-magnet beam line at the Photon Factory (Synchrotron Radiation Laboratory) in Tsukuba. An energy-dispersive X-ray diffraction system was adopted in this experiment. The diffraction patterns of black P and NaCl were recorded at $2\theta=21°$. The diffraction lines of NaCl were used to determine the pressure value according to Decker's scale.

Single crystals of black P were grown at about 1100 °C and at 1 GPa using a wedge-type cubic anvil high-pressure apparatus.[18]

Results and Discussion

1. Pressure-Induced Phase Transitions at 77 K.

X-Ray diffraction for black P under quasi-hydrostatic conditions has already been studied using a cubic anvil press at room temperature. A cube made of a mixture of boron and epoxy resin is used as the pressure-transmiting medium. The transition from the orthorhombic form to the rhombohedral one begins to occur at about 4.5 GPa. A rate of the transition is very slow. Both phases coexist between 4.5 and 8.1 GPa under quasi-hydrostatic condition.[2] Recently, we have obtained some results on the phase transition in black P under hydrostatic pressure at room temperature by means of an X-ray study with synchrotron radiation.[14] When a 4:1 solution of methanol to ethanol was used as the pressure-transmitting medium, the phase transition occured sharply at around 4.6 GPa, and the pressure range of the coexistence became narrow under hydrostatic

conditions. The phase transition from orthorhombic to rhombohedral is very sensitive to the degree of hydrostaticity of the solid and liquid pressure media, even at room temperature.

Figure 3 shows the energy-dispersive X-ray diffraction profiles of black P in the pressure range of 0—7 GPa at 77 K. The pressure was continuously increased at 77 K under quasi-hydrostatic conditions. The (*hkl*) of the diffraction lines for P and NaCl is indicated in Fig. 3. A single-phase pattern of the orthorhombic form was observed at 3.2 GPa. The five peaks in the phase shifted to higher energies with the increase in the pressure. The transition from orthorhombic to rhombohedral started at around 6 GPa. The two diffraction lines of the rhombohedral black P, (014) and (110), were clearly observed at around 6.6 GPa. The diffraction lines of the orthorhombic phase did not disappear at this pressure.

Figure 4 shows energy-dispersive X-ray diffraction patterns in the pressure range of 8—14 GPa at 77 K. The diffraction lines of the orthorhombic and rhombohedral structures were also found to coexist at 8.5 GPa. The transition to the cubic phase appeared at around 10 GPa. The intensity of the (110) line in the simple cubic phase increased with an increase in the pressure. The pattern of the simple cubic became dominant above 13 GPa at 77 K. The coexistence of two or three phases was observed in the pressure range of 6—14 GPa at 77 K under quasi-hydrostatic conditions.

Figure 5 exhibits the X-ray diffraction patterns at 77 K under a decrease in the pressure. As the pressure was reduced to 11.7 GPa at 77 K, the simple cubic phase began to be transformed into the rhombohedral structure, which became dominant at around 10 GPa. The simple cubic rhombohedral transition was nearly reversible with either an increase or a decrease in the pressure at 77 K. The rhombohedral phase was stable on a decrease in the pressure. The diffraction line of the orthorhombic structure could not be observed, even in the very low pressure region, at 77 K.

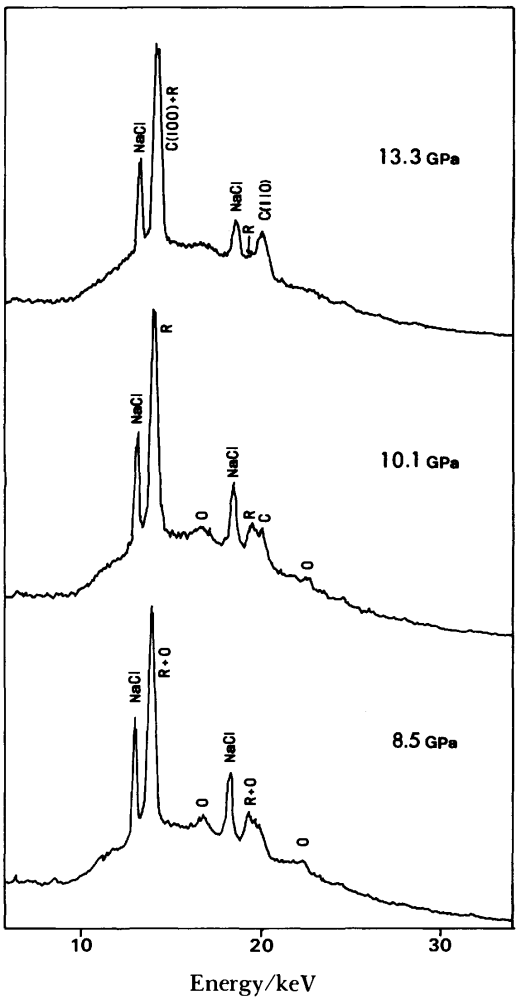

Fig. 4. Energy dispersive X-ray diffraction profiles of black Phosphorus in the pressure range 8—14 GPa at 77 K.

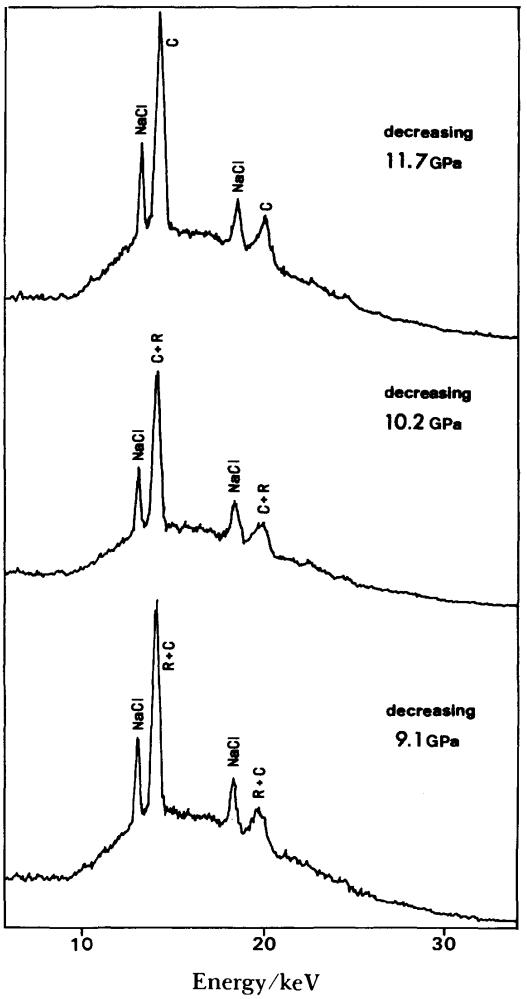

Fig. 5. X-Ray diffraction patterns at 77 K under decreasing pressure.

2. Superconductivity. Figure 6 depicts the pressure-dependence of the T_c along five different paths. Path (A1): Black P shows the metallic behavior at 16 GPa. The ratio of the resistance at room temperature to that just above T_c is about 2.5. The element becomes a superconductor at the T_c of about 6 K at this pressure. The T_c slightly increases with an increase in the pressure. Path (A2): After pressure was raised to 22 GPa at room temperature, the sample was cooled to the temperature of liquid helium at this pressure. The superconductivity of the simple cubic phase was observed at 8.1 K under 22 GPa. The T_c is increased from 5.9 K at 16 GPa in Path (A1) to 8.1 K at 22 GPa in Path (A2) by applying pressure at room temperature. The T_c at 27 GPa was 8.7 K when the pressure was increased from 22 GPa to 27 GPa at 4.2 K. Wittig et al. have reported that the T_c of the simple cubic phase is increased to 10 K at very high pressure.[3] In their experiment, the pressure was always changed at room temperature, and the pressure cell was cooled only for the measurement of T_c. The results for Path (A2) and Wittig's path are shown in Fig. 7. The T_c of the simple cubic phase rapidly increased with the increase in the pressure. On the other hand, the T_c is not sensitive to pressure, as it is pressurized at 4.2 K. The origin of this difference can not be elucidated at present. Path (B): The superconductivity was observed around 5.7 K at 9 GPa. The T_c–P curve along Path (B) is similar to that along Path (A1). Path (C): As is shown in Fig. 4, both orthorhombic and rhombohedral phases coexist at 8 GPa and the temperature of liquid nitrogen. The sample was cooled to the temperature of liquid helium from this condition. The superconductivity was found at around 5.2 K under about 10 GPa. It should be noted that the T_c is higher than that along Path (D) at this pressure. Path (D): The T_c rapidly increased with the increase in the pressure; it went up to 10.7 K, and the onset temperature of the transition was beyond 13 K at very high pressures.

Figure 8 shows the critical current at 4.2 K and at 29 GPa. The value of dI_c/dT along Path (A1) is about one order of magnitude higher than that along Path (D). The pressure dependence of the residual resistance greatly differs from Path (A1) to Path (D). These results suggest that systems along the paths do not coincide with each other, even under the same pressure.

A red phosphorus (red P) is directly transformed to a black modification at around 8 GPa at room temperature.[20] Yakovlev et al. have studied the superconductivity of black P converted from red P at room temperature and high pressures; they have thus obtained a high superconducting transition temperature.[4] We have also measured the resistance of the high-purity red P along Path (D). The resistance suddenly decreased at about 7 GPa and 4.2 K. The red P had to be converted to the black P under these

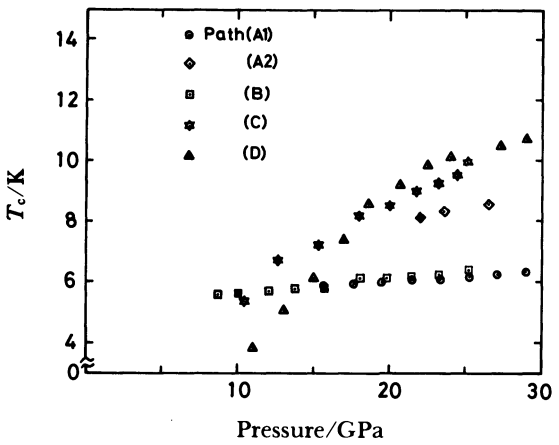

Fig. 6. Pressure dependence of the T_c along five different paths depicted in the Fig. 1.

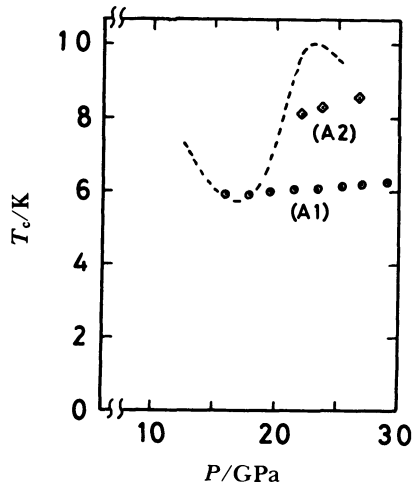

Fig. 7. T_c–P curves of the simple cubic phase: The dashed curve is obtained by Wittig et al.

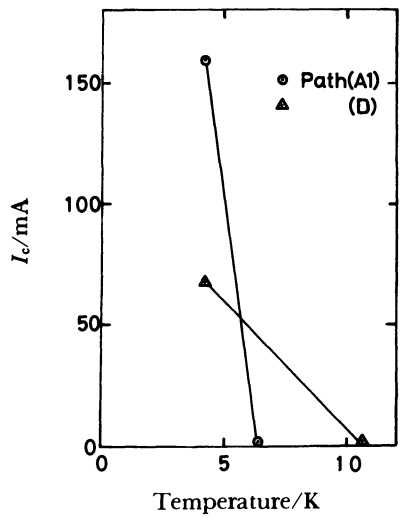

Fig. 8. Critical current of black phosphorus along the path (A1) and (D) at 4.2 K and 29 GPa.

conditions. The superconductivity was observed at around 10 GPa. Figure 9 shows the superconducting transition curves along Path (D). The T_c steeply increased with the increase in the pressure; it went up to 13 K, and the onset temperature of transition reached 18 K at 30 GPa. The T_c somewhat differed for several samples. The transition from superconductivity to the normal state does not readily terminate on the high-temperature side. The width of this transition was 6—7 K. This is very broard compared with the results of black P along Path (D). Figure 10 shows the T_c–P curves along Path (D) when the red P and black P were used as the starting materials. The T_c of the "red P" is much higher than that of black P at very high pressures. Here, the value of the superconducting transition temperature is the highest among the elements. The T_c of the phosphorus along Path (D) is higher than that of the simple cubic phase

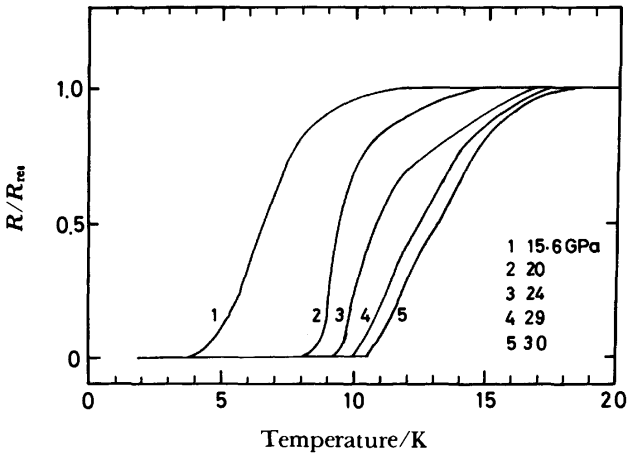

Fig. 9. The superconducting transition curves for the "red phosphorus" along the path(D). The red P was converted to the black P at about 7 GPa and 4.2 K.

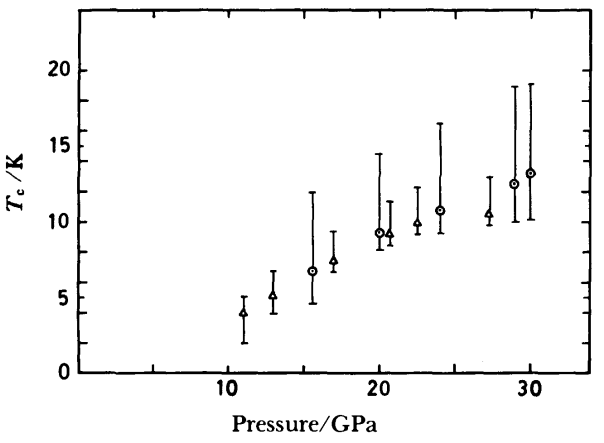

Fig. 10. T_c–P curves along the path (D) when the red P and black P as the starting materials were used; O: red P, Δ: black P. Vertial arrow heads shows the transition width.

obtained by Wittig et al.

The X-ray diffraction of black P with synchrotron radiation has been studied at the temperature of liquid helium and at high pressures. We thus obtained some preliminary results: The orthorhombic form began to be transformed to the rhombohedral form at about 10 GPa; several phases coexist in a wider pressure range.[21]

These experimental results suggest that the high T_c-superconductivity observed when pressure is applied at 4.2 K is not due to the simple cubic phase only.

Structural Studies of Liquid 1,1,1-Trichloroethane by Means of X-Ray Diffraction[1)]

Keiko NISHIKAWA* and Takao IIJIMA
Department of Chemistry, Faculty of Science, Gakushuin University, Mejiro, Toshima-ku, Tokyo 171
(Received July 8, 1987)

The X-ray scattering intensities from liquid 1,1,1-trichloroethane (TCE) were measured at room temperature by the energy-dispersive method. By the use of the real space expansion and the reciprocal space expansion based on the local lattice structure model, structure simulation studies for TCE were carried out. A bcc model with a random orientation of the methyl group reproduces the experimental intensities well. The number of molecules in the structure region, n, was determined by a trial-and-error method, and a least-squares refinement was carried out to determine the following four parameters; the lattice constant of the bcc cell, a; the Prins parameter, D; the radius up to the continuous region, R_c; and its damping factor, l_c. The refined parameters with the standard deviations in parentheses are: a=6.78 (0.11) Å, D=0.049 (0.009) Å, R_c=12.70 (0.48) Å, and l_c=1.76 (1.22) Å with n=51.

In order to understand the orientational correlation of molecular liquids, it has been proved to be useful to construct a local lattice structure model[2-4)] and to test it against the experimental intensity. The present authors previously reported that the scattering intensities of tetrahedral molecular liquids, such as carbon tetrachloride[3-5)] and neopentane,[6)] were reproduced well by the bcc (body-centered cubic) local-lattice-structure model.

In the bcc model, a chlorine atom (or a methyl group) of one molecule lies in a hollow formed by three off-axis chlorine atoms (or methyl groups) of the neighboring molecule, and the three-fold axes of these molecules are aligned. This packing has been named "head-tail head-tail packing." By the repetition of the packing over a three-dimensional space, a bcc lattice is obtained.[3)]

In the present work a structural study of 1,1,1-trichloroethane (TCE) has been carried out. A molecule of TCE is a quasi- tetrahedral molecule; it is obtained by replacing one of the chlorine atoms of carbon tetrachloride by a methyl group. Because the radius of the van der Waals spheres of a methyl group is almost equal to that of a chlorine atom, an appropriate structure model for liquid TCE can be expected to be similar to that of liquid carbon tetrachloride[3-5)] or liquid neopentane.[6)]

Both the real space expansion and the reciprocal space expansion are applied in the simulation study. The former expansion is a traditional calculation. However, it has the limitation that it is difficult to simulate scattering intensities in the small-s region because of the inevitable appearance of ghosts. The reciprocal space expansion was previously pesented by the present authors to overcome this difficulty in the real space expansion.[5,7)]

It is reported that the scattering intensities of liquid TCE can be simulated well by the same bcc model as is used for liquid carbon tetrachloride, where one of the chlorine atoms of carbon tetrachloride is replaced at random by a methyl group. This random replacement of a methyl group is called "random orientation of a methyl group" in the present paper.

Experimental

The sample, TCE (Kanto Kagaku), was purified by careful distillation. The scattering intensities from liquid TCE were measured at 20 °C. An energy-dispersive diffractometer with a horizontal scattering plane and a θ—2θ scanning system was used. A fine-focus X-ray tube with a tungsten target was used under the operating condition of 47.5 kV and 25 mA (or 20 mA). The scattered photons were detected by means of a pure Ge SSD (ORTEC) equipped with a multichannel pulse height analyzer (NAIG). The transmission method was applied to the collection of the data at the scattering angles (2θ) of 2.5, 5, 10, 20, and 40°. The details of the experimentation by the energy-dispersive method and the analysis of the intensity data have been reported elsewhere.[8)]

Intensity Simulation of Liquid TCE

In constructing a local lattice structure model,[2,4)] we assume a certain nearest-neighbor configuration around a central molecule and repeat this structural unit by some specific rule. According to this model the average molecular positions, as viewed from the location of a given central molecule, conform to a certain lattice structure and any molecule in the liquid can be a central molecule. Unlike the crystalline case, however, the repetition of the structural unit is imperfect and is, therefore, accompanied by a rapid loss of positional correlation as the distance between the central molecule and the surrounding ones increases. This loss of correlation may be embodied in the model in the form of a mean-square deviation of the distribution of the separation between atoms, which increases rapidly with the distance. At least beyond a few molecular radii away from any starting point, the structure can be regarded as a continuum. This distance is denoted by R_c in the present paper.

By using the group scattering factor for a methyl group introduced by Narten,[9)] a methyl group is

treated as an "atom" in the following calculations.

The coherent scattering intensity per molecule from liquid TCE in the form of the real-space expansion[4] is given by:

$$I(s) = \sum_i \sum_m f_i f_m j_0(s r_{im}) \exp(-l_{im}^2 s^2/2) + I_c \quad (1)$$

where $j_0(x)$ is given by $\sin(x)/x$, f_i is the atomic scattering factor of the i-th atom and l_{im} is the root mean-square deviation of the mean interatomic distance, r_{im}. The notation s is the scattering parameter defined by $4\pi\sin\theta/\lambda$ (2θ: scattering angle, λ: wavelength of X-rays). The summation for i is over all the atoms of the central TCE molecule, while the summation for m is over all the atoms in the discrete structure region within the radius R_c. I_c is the contribution from the region where the structure is regarded as a continuum. The expression of I_c is given by:

$$I_c = \sum_i f_i \langle F \rangle n \frac{3[sR_c\cos(sR_c) - \sin(sR_c)]}{(sR_c)^3} \exp(-l_c^2 s^2/2) \quad (2)$$

where $\langle F \rangle$ is the mean scattering amplitude of a molecule given by:

$$\langle F \rangle = \sum_i f_i \quad (3)$$

and n is the number of molecules within the discrete-structure region.[4] For the mean-square deviation the Prins relation:[2,10]

$$l_{im}^2 = 2Dr_{im} \quad (4)$$

was employed.

By the application of the Poisson summation formula,[11] we can obtain the following expression as the reciprocal space expansion:

$$I(s) = \frac{1}{v}\sum_{\nu}{}' \frac{2\pi D s}{b_\nu} \left[\frac{1}{(Ds^2)^2 + (s-b_\nu)^2} - \frac{1}{(Ds^2)^2 + (s+b_\nu)^2}\right] \times \sum_\alpha \sum_\beta f_\alpha f_\beta \exp(-i\boldsymbol{b}_\nu \cdot \boldsymbol{a}_{\alpha\beta}) + \sum_{\alpha \neq \beta} \sum f_\alpha f_\beta [\exp(-l_{\alpha\beta}^2 s^2/2) - \exp(-Dr_{\alpha\beta} s^2)] j_0(s r_{\alpha\beta}) \quad (5)$$

where $\boldsymbol{b}_\nu$ is the reciprocal-lattice-point vector. The notation α indicates the α-th atom and $\boldsymbol{a}_{\alpha\beta}$ is the vector between α and β atoms. The summation for α in the first term is carried out over all the atoms in a molecule and the summation for β over all the atoms in a unit cell. The second term in Eq. 5 is the correction term due to the mean-square deviations of intramolecular distances which are not given by the Prins relation. The summation for α and β in the second term is carried out over all the atoms in a molecule. The notation $l_{\alpha\beta}$ is the root mean-square amplitude of the intramolecular distance, $r_{\alpha\beta}$. The details of the derivation of Eq. 5 has been described in the previous papers.[5,7]

Results and Discussion

The experimental total coherent intensity, $I(s)$, from liquid TCE is shown in Fig. 1 by a solid curve, with the calculated self-scattering intensity shown by a broken curve. The weighted structure function is shown in Fig. 2; it is defined by:

$$si(s) = s(I(s) - \sum_i f_i(s)^2). \quad (6)$$

The weighted structure function for a free TCE

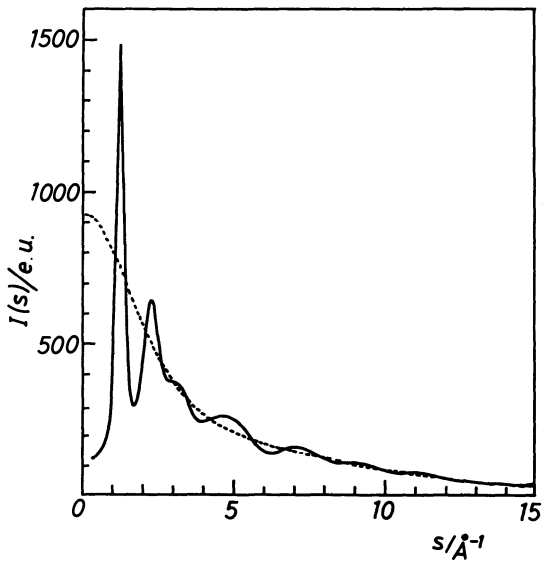

Fig. 1. The observed total coherent intensity $I(s)$ for liquid TCE (solid curve) and the self-scattering intensity from the constituent atoms (dotted curve).

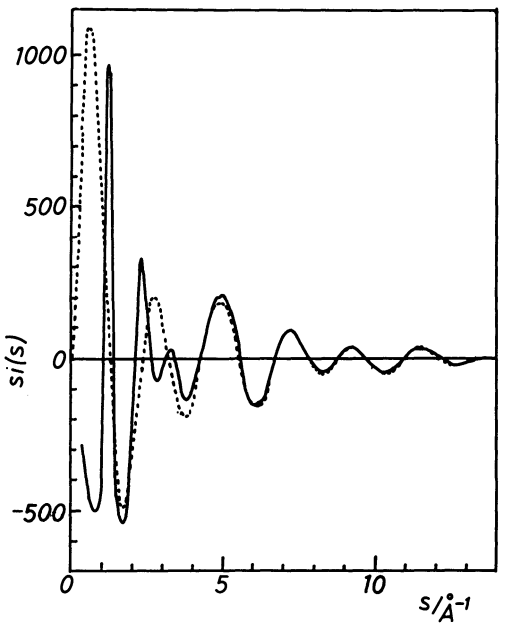

Fig. 2. Observed weighted structure function $si(s)$ for liquid TCE (solid curve) and the calculated one for a free molecule of TCE (dotted curve).

molecule is shown by a broken curve. For the intramolecular parameters, r_{ij} and l_{ij}, the data for a gaseous molecule[12] were utilized. The experimental weighted structure function is in good agreement with the calculated one for the free molecule in the range of $s>6$ Å^{-1}. The pattern of the scattering intensity from liquid TCE is very similar to that from liquid carbon tetrachloride,[3,4,8] i.e., a very sharp peak at $s\approx1.3$ Å^{-1} the successive peak at $s\approx2.3$ Å^{-1} and a small peak at $s\approx3.2$ Å^{-1}. However, the relative intensity of the second peak of TCE at $s\approx2.3$ Å^{-1} is lower.

The Fourier transform of the weighted structure function, $si(s)$, as defined by:

$$4\pi r^2(\rho-\rho_0)=\frac{2r}{\pi\sum_i Z_i^2}\sum si(s)\sin sr\cdot\Delta s \qquad (7)$$

gives the distribution function, including the weight of the electron cloud of each atom. The distribution function is shown in Fig. 3. The peaks at $r\approx1.8$ Å and 2.9 Å are attributed to the intramolecular distances of the carbon and chlorine atoms and of the chlorine and chlorine atoms, respectively. The peak at $r\approx3.9$ Å shows the nearest distance between the atoms belonging to the neighboring molecules. The peaks with respect to the long-range correlation of the molecular arrangement appear at integral multiples of about 5.9 Å; i.e., r=6.3, 11.5, 16.5, and 21.5 Å. This may show that the TCE molecules are arranged linearly. The peak at $r\approx3.9$ Å is a probe to know the distance of the neighboring molecules. When the head-tail head-tail packing is assumed, the distance of the centers of neighboring molecules is obtained as 5.9 Å by using the value of 3.9Å; the second nearest neighbor distance is 6.8 Å, which corresponds to the lattice constant of the bcc lattice. The pile of the first nearest neighbors at 5.9 Å and the second nearest neighbors at 6.8 Å forms a large peak centered at 6.3 Å in the distribution function of Fig. 3.

As has been mentioned above, the most probable packing for the molecules of liquid TCE is the head-tail head-tail packing. In fact, the calculated intensity based on the bcc model with the random orientation of a methyl group has reproduced the experimental intensity well. The intensity calculation for the random orientation of a methyl group was performed as follows; a central molecule was placed on the lattice point of the bcc, four possible arrangements of a methyl group being considered. The first nearest neighbor molecules were put on the next lattice points with the four arrangements of a methyl group in the same way. The intensities for the 16 ways of molecular arrangement were calculated by the use of Eq. 1, and then the total was divided by 16. For molecules farther than the first nearest neighbors, similar calculations were carried out.

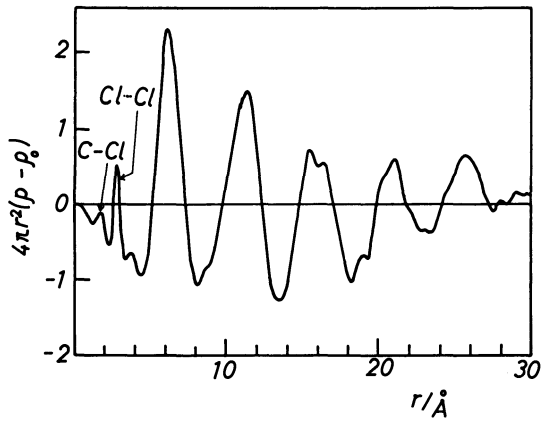

Fig. 3. The radial distribution function of liquid TCE.

Next, the least-squares refinements for the weighted structure function $si(s)$, based on the bcc local-lattice structure with the random orientation of a methyl group were carried out. The refined parameters were as follows; the number of molecules (n) in the discrete structure region, the lattice constant of the bcc cell (a), the Prins parameter (D) which gives the mean-square deviation of the distance of atoms belonging to different molecules (see Eq. 4) and the radius of the discrete-structure region (R_c) and its damping factor (l_c) (see Eq. 2). For the determination of the number n, a trial-and-error method was applied. The other four parameters were refined by the least-squares method. The weighted structure function obtained by the use of the following values showed the best agreement with the experimental values: n is 51, which corresponds to the inclusion up to the fourth nearest neighbors, a=6.78 (0.11) Å, D=0.049 (0.009) Å, R_c= 12.70 (0.48) Å and l_c=1.76 (1.22) Å, where the numerals in the parentheses are the standard deviations. The reliability factor, $\mathscr{R}$, as defined by:

$$\mathscr{R}=\left[\frac{\sum w(s)[si(s)_{exp}-si(s)_{calc}]^2}{\sum w(s)[si(s)_{exp}]^2}\right]^{\frac{1}{2}} \qquad (8)$$

was 0.23, where $w(s)$ was the weight function. The values of $w(s)$ were chosen as 0.1 for $0<s\leqslant1$ Å^{-1} and 1.0 for $s>1$ Å^{-1}. From the refined value of a, the distance of the first nearest neighbors becomes 5.87 Å. The weighted-structure function calculated by the use of these refined values is shown in Fig. 4 by the solid curve together with the experimental one (broken curve). The calculated intensity is in good agreement with the experimental one in the region of $s\geqslant1$ Å^{-1}.

The discrepancy in the region of $s<1$ Å^{-1} originates from the sudden onset of the continuum region to the discrete-structure region.[5,7] In order to overcome the difficulty of the real space expansion, the reciprocal space expansion was carried out. Because it is impossible to simulate the intensity for the random orientation exactly in the case of the reciprocal space expansion, the following approximation was adopted: the bond distance between a centered carbon atom

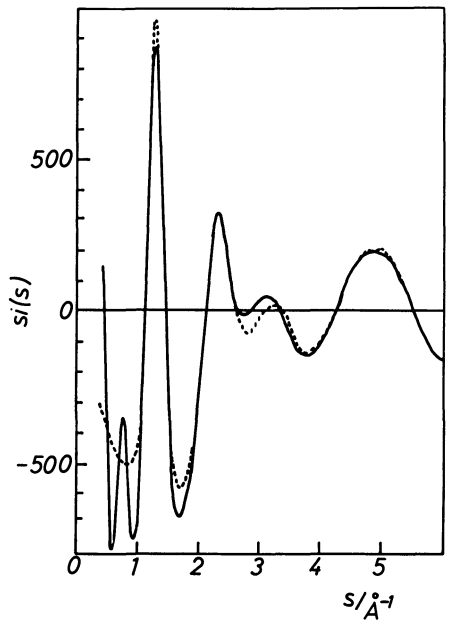

Fig. 4. The weighted structure function $si(s)$ for liquid TCE. The solid curve is the calculated one for the bcc model with the random orientation of the methyl group and the dotted curve is the experimental one.

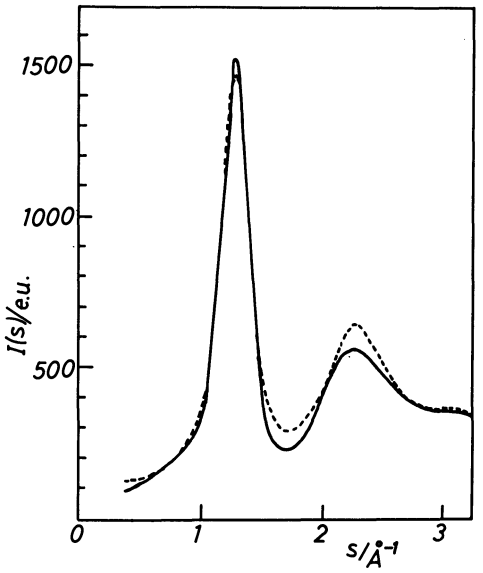

Fig. 5. The total coherent intensity of liquid TCE. The solid curve is the calculated intensity based on the bcc model by the use fo the "reciprocal space expansion." The broken curve is the experimental intensity.

and a methyl group (1.54 Å) was changed to that between the carbon atom and a chlorine atom (1.77 Å) and hypothetical atoms with the scattering factor of $(3f_{Cl}+f_{Me})/4$ were equally placed at the positions of chlorine atoms and a methyl group. The other structural parameters used in the reciprocal-space expansion were identical with those obtained by the least-square refinement in the real-space expansion. Reciprocal lattice points up to $\nu=(600)$ ($b_\nu=5.56$ Å^{-1}) were included. The results of the application to TCE based on the bcc local-lattice structure shows an excellent agreement of the calculated intensity with the experimental value in the region of s smaller than 2 Å^{-1} (see Fig. 5). The total coherent intensity is shown in Fig. 5, because it demonstrates the discrepancy between the experimental and the simulated intensities in the small-s region. Contrary to the real space expansion, the convergence becomes worse with an increase in the s. By the use of both the real space and the reciprocal space expansion, the observed scattering intensity of liquid TCE in the whole range of s is satisfactorily accounted for on the basis of the bcc local-lattice model.

Molecules with an octupole moment, such as carbon tetrachloride and neopentane, are highly stabilized by the head-tail head-tail packing.[13] Because a TCE molecule has a dipole moment, the bcc model in the liquid TCE with the random orientation of a methyl group is not consistent with the electrostatic interaction of the molecule. Some of the other orientations of the methyl group were, therefore, attempted in the simulation study. As was shown in the structure study of the plastic crystal of carbon tetrachloride,[14] the calculated intensity curve for packings other than the head-tail head-tail packing has peaks and valleys at entirely different positions from the experimental curve. Therefore, we can restrict the model for liquid TCE to the head-tail head-tail packing. The head-tail head-tail packing with the parallel orientation of a methyl group gives the same pattern, but the first peak at $s\approx1.3$ Å^{-1} becomes much higher than the experimental one and the reliability factor becomes worse. Of course, the parallel orientation of the methyl group can not be permitted physically because of the unstabilization caused by the interaction between the dipole moments. However, the fact mentioned above shows that the height of the first peak in the intensity curve is fairly sensitive to the orientation of the methyl groups. Next, the intensity for another model was calculated, where molecular arrangements with a parallel dipole moment to that of the central molecule are omitted in the arrangements of the first neighbors and molecules farther than the first nearest neighbors have the random orientation for the methyl groups. The intensity curve for this model was in very good agreement with that for the random orientation of the methyl group, and the reliability factor was 0.235 (cf. 0.230 in the random orientation.)

Though the TCE molecules may be arranged so as to stabilize the dipole interaction, the information on the orientation of the methyl group is smeared in the

liquid; it may, however, be said that the orientation is random in the liquid on the average. In the case of liquid TCE, the agreement between the experimental intensity and the calculated one based on the bcc model is of the same degree as in liquid carbon tetrachloride or liquid neopentane.

TCE has two plastic crystal phases, i.e., a fcc phase and a rohmbohedral phase,[15] just like carbon tetrachloride. In the structure analysis of Phase Ia (plastic crystal fcc) of carbon tetrachloride, it has been shown that the head-tail head-tail packing is dominant.[14] The simulation study in the plastic crystal is easier than in the liquid, because the nearest neighbor distance of molecules can be determined from the unit-cell dimensions and so only the orientational correlation needs to be investigated. The structure study of plastic crystal of TCE is now under way and it will give further information on the structure of liquid TCE. It will be reported in the near future.

Why Does the Hückel Rule Hold for a Variety of Monocyclic Conjugated Systems?

Jun-ichi AIHARA* and Hiroshi ICHIKAWA†
Department of Chemistry, Faculty of Science, Shizuoka University, Oya, Shizuoka 422
†Hoshi College of Pharmacy, Shinagawa, Tokyo 142
(Received July 9, 1987)

Hückel's $4n+2$ rule is shown to be applicable to diverse monocyclic π systems by means of graph theory and frontier orbital theory. All monocyclic $(4n+2)$-π-electron systems are proved to have both kinetic and thermodynamic stabilities. They are predicted to be diatropic in nature.

In 1931 Hückel presented so-called Hückel molecular orbital (HMO) theory.[1] He applied it to annulene π systems, and established the well-known Hückel rule for aromaticity, according to which all annulenes with $4n+2$ π electrons are predicted to be chemically stable or aromatic, and all annulenes with $4n$ π electrons are predicted to be rather reactive or antiaromatic. The Hückel rule is applicable not only to neutral annulenes but also to annulene ions.[1-3] Hückel suggested that it is also applicable to such heteroconjugated systems as pyridine and pyrrole.[1] As a matter of fact, the Hückel rule has been successfully applied to many monocyclic heteroconjugated systems and their ions.[4]

Hückel pointed out that the highest occupied molecular orbitals (HOMO's) of [$4n+2$]annulene are completely filled.[1] He then associated the closed-shell π system with the stability or aromaticity of an entire conjugated system. The HOMO's of [$4n+3$]annulene cations and [$4n+1$]annulene anions are also completely filled. In contrast to them, the HOMO's of [$4n$]annulene are relatively high in energy, and not completely filled. Hückel predicted that it must be reactive for this reason.[1]

A number of attempts have been made to test the validity of the Hückel rule. Various perturbational MO methods have been used to explain stabilization or destabilization of annulenes due to cyclic conjugation.[5-8] Breslow compared the energy of a cyclic π system with that of an open-chain reference system.[9] The applicability of the Hückel rule to annulenes has been confirmed by these attempts.

Dewar et al. devised an olefinic reference system of the same geometry as a real π system, using such bonds as scissored off from acyclic π systems,[10] and evaluated the so-called Dewar resonance energy relative to the energy of such a reference system. Hess and Schaad defined this type of resonance energy within the framework of HMO theory.[11,12] Aihara found that for monocyclic π systems Dewar resonance energy is definable using π bond energies of infinitely large cyclic π systems.[13] Two research groups formulated the Dewar resonance energy graph-theoretically.[14-18] All these attempts revealed that very many heterocyclic compounds obey the Hückel rule.

However, it has not been clarified yet whether or not the Hückel rule is applicable to all monocyclic π systems conceivable. There has been no general proof for the validity of the Hückel rule. This paper aims at elucidating the applicability and the physical meaning of the Hückel rule by means of graph theory[14-20] and frontier orbital theory.[7,21-23] The HMO model is used throughout this paper. Arbitrary integers are represented by N, m, n, p, or q.

Kinetic Aspect of the Hückel Rule

First, an aromatic molecule must be chemically stable or preferably unreactive. This kind of stability has been referred to as kinetic stability. We show below that the Hückel rule can be used reasonably to predict the kinetic stability of any monocyclic π system.

A given monocyclic π system formed by N conjugated atoms is denoted by G. We assume that there is no substituent in G. A characteristic polynomial $P_G(X)$ for G can be obtained by means of Sachs graph theory.[14-20] A reference polynomial $R_G(X)$ is a characteristic polynomial constructed graph-theoretically for a hypothetical olefinic reference structure of G.[14-18] Both $P_G(X)$ and $R_G(X)$ are the polynomials of degree N. The reference structure defined by $R_G(X)$ is assumed to have exactly the same geometry as G. However, the π bonds in it are tacitly assumed to have the same π bond energies as the analogous π bonds in acyclic polyenes.

For monocyclic π systems, $P_G(X)$ is obtainable simply by subtracting a constant from $R_G(X)$, namely,[14-18]

$$P_G(X) = R_G(X) - K_G, \tag{1}$$

where $K_G > 0$ is the constant given by

$$K_G = 2\prod_{(ij)}^{G} k_{ij}. \tag{2}$$

Here, k_{ij} is the Hückel parameter for the i-j π bond, and (ij) runs over all π bonds in G. The curves $Y=P_G(X)$ and $Y=R_G(X)$ coincide exactly in the X-Y plane by displacing the former curve upward by K_G. There are N zeroes in $P_G(X)$ and $R_G(X)$, which represent the energies of N molecular orbitals (MO's)

in G and its reference structure, respectively.[14-18] For example, K_G is 1.3122 for 1,4-dihydropyrazine, and $P_G(X)$ and $R_G(X)$ are

$$P_G(X) = X^6 - 3X^5 - 2.99X^4 + 10.86X^3 + 2.3644X^2 - 7.86X - 0.3744, \quad (3)$$

$$R_G(X) = X^6 - 3X^5 - 2.99X^4 + 10.86X^3 + 2.3644X^2 - 7.86X + 0.9378. \quad (4)$$

Here, the Hückel parameters of Hess, Schaad, and Holyoke[11] were used. The curves $Y=P_G(X)$ and $Y=R_G(X)$ for this eight-π-electron system are drawn in Fig. 1.

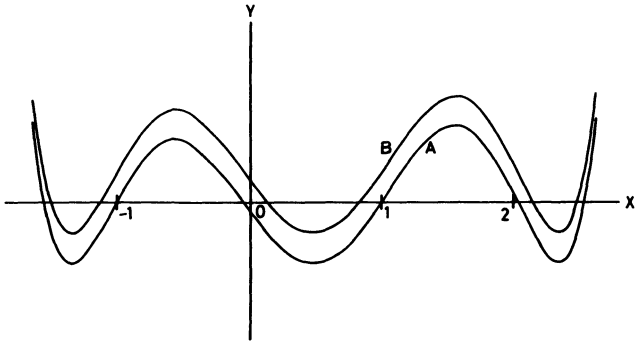

Fig. 1. The curves $Y=P_G(X)$ (A) and $Y=R_G(X)$ (B) for 1,4-dihydropyrazine.

Fikui et al.[7,21-23] named the HOMO and the lowest unoccupied molecular orbital (LUMO) frontier MOs, the energies and phases of which are closely related to the reactivity of the molecule. The HOMO and the LUMO contribute much more to such reactivity indices as superdelocalizabilities than any other MO's.[22] Therefore, it is instructive to examine the locations of these MO's in the energy scale.

The mth largest root X_m of the equation $P_G(X)=0$ represents the energy of the mth MO in G. The mth largest root X_m° of the equation $R_G(X)=0$ represents the energy of the mth MO in an olefinic reference system of G.[14-18] In general, positive and negative roots correspond to bonding and antibonding MOs, respectively. As can be seen from Fig. 1, the following two inequalities hold:

$$\begin{aligned} X_m &> X_m^\circ \text{ for } m = 2p+1 \\ X_m &< X_m^\circ \text{ for } m = 2p \end{aligned} \quad (5)$$

It is clear from Eq. 5 that the HOMO of a monocyclic $(4n+2)$-π-electron system is always lower in energy than that of the olefinic reference system, but that the LUMO is always higher in energy than that of the reference system. Such a $(4n+2)$-π-electron system must have much smaller superdelocalizabilities than its olefinic reference system defined by $R_G(X)$. This indicates that a $(4n+2)$-π-electron system must be much more resistant both to electrophilic and nucleophilic substitutions than a hypothetical olefinic system of the same geometry (i.e., the reference system). On the other hand, a monocyclic $4n$-π-electron system has a higher HOMO and a lower LUMO, both of which contribute much to the increase in reactivity. It has thus been confirmed that the Hückel rule holds in a kinetic sense for all kinds of monocyclic π systems. Therefore, it is very possible that most monocyclic species classified as aromatics are less reactive than those classified as antiaromatics.

Figure 1 shows that even if the $(2p)$th and $(2p+1)$th MO's of a monocyclic π system are degenerate in energy, the $(2p+1)$th and $(2p+2)$th MO's are never degenerate. If the $(2p+1)$th and $(2p+2)$th MO's were degenerate, the corresponding roots of the equation $R_G(X)=0$ would become complex numbers. This never occurs since the realness of these roots has been proved mathematically.[24] Therefore, a monocyclic conjugated species with $4n+2$ π electrons always has a closed-shell π system with a doubly occupied HOMO. As mentioned, Hückel showed that [$4n+2$]annulene has a closed-shell π system.[1] The present graph-theoretical analysis happens to constitute an extension of this viewpoint to all monocyclic conjugated systems. There is no open-shell $(4n+2)$-π-electron system as far as monocyclic conjugated molecules are concerned.

A singly occupied molecular orbital (SOMO) is also one of the frontier orbitals.[7,22,23] As seen above, Hückel's original interpretation of aromaticity is based on the kinetic instability of an open-shell π system with SOMO's.[1] It is very true that an open-shell π system is very reactive. Aside from [$4n$]annulenes, however, there are few monocyclic systems with SOMO's. Even in [$4n$]annulenes the degeneracy of the SOMO's are in fact lifted by the introduction of bond-length alternation. Since most heterocyclic systems with $4n$ π electrons have no degenerate SOMO's, the interpretation of antiaromaticity in terms of SOMO's is of limited use.

Thermodynamic Aspect of the Hückel Rule

Ideally, an aromatic molecule must exhibit not only kinetic but also thermodynamic stabilities.[3-9] Haddon and Fukunaga showed that [$4n+2$]annulenes meet the thermodynamic and kinetic criteria of aromatic character.[25] We next prove that any monocyclic $(4n+2)$-π-electron system is thermodynamically stabilized by cyclic conjugation. Fukui's frontier MO theory[7] is again useful for this purpose.

The Schrödinger equation defined in HMO theory for a linear π system is essentially of one-dimensional character, and can formally be reduced to the one-dimensional form:

$$-\frac{\hbar^2}{2m}\frac{d^2}{dX^2}\Psi(X) + \{V(X) - E\}\Psi(X) = 0, \quad (6)$$

where $\Psi(X)$ is the eigenfunction (i.e., the MO), E is the

eigenvalue (i.e., the energy of the MO), $V(X)$ is the electrostatic potential felt by an electron, m is the mass of an electron, and $\hbar$ is the Planck constant divided by 2π. The interatomic distances and the form of $V(X)$ can in principle be chosen in such a manner that Eq. 6 yields the Hückel secular determinant for a given linear π system. In other words, $V(X)$ may be an unrealistic function as far as Eq. 6 reproduces the Hückel matrix elements within the Hückel approximation. $V(X)$ may be assumed to be a differentiable function. In this treatment, we tacitly use hypothetical one-dimensional AO analogues as the LCAO basis functions.

Such a Schrödinger equation is mathematically identical with the eigenvalue problem of the Sturm-Liouville type.[26] The mth eigenfunction obtained by solving this problem has $m-1$ zeroes in the defined region. In the present case, the mth eigenfunction corresponds to the mth MO of a linear π system, which necessarily has $m-1$ nodes. The number of nodes increases one by one on going to higher MOs. Accordingly, LCAO coefficients of the $(2p+1)$th MO have the same sign at the two edge atoms, whereas those of the $(2p)$th MO at the edge atoms differ in sign. This sign rule holds for all kinds of linear π systems.

Fukui indicated that any conceivable division of benzene into two fragments produces segments whose HOMO and LUMO overlap in-phase at the original two junctions.[7] HOMO–LUMO interactions then give rise to stabilization by cyclic conjugation. We adopt this way of reasoning. An arbitrarily chosen monocyclic π system is first divided into two segments, both of which are linear conjugated subsystems. These two segments are assumed to have an even number of π electrons. Figure 2 shows the case in which a monocyclic aromatic molecule is divided into two segments, the one with two conjugated atoms and two π electrons and the other with the remaining conjugated atoms and π electrons.

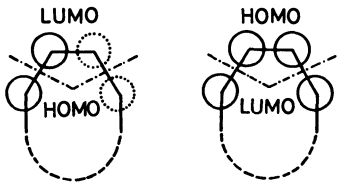

Fig. 2. Stabilizing HOMO–LUMO interactions in a monocyclic $(4n+2)$-π-electron system.

It follows that if the HOMO and the LUMO concerned are the $(2p+1)$th MO of one segment and the $(2q+1)$th MO of the other segment, respectively, both MO's overlop in-phase at the original two junctions. If the HOMO and the LUMO are the $(2p)$th MO of one segment and the $(2q)$th MO of the other segment, respectively, both MO's overlap in-phase, too. Then, the entire cyclic π system is predicted to gain stabilization energy by HOMO–LUMO interactions. Such a situation occurs only if the entire cyclic system has $4n+2$ π electrons.

On the other hand, if the HOMO and the LUMO concerned are the $(2p)$th MO of one segment and the $(2q+1)$th MO of the other segment, respectively, both MO's do not overlap in-phase at one of the junctions. In this case, the HOMO of the latter segment necessarily does not overlap in-phase with the LUMO of the former segment, either. The entire cyclic π system is predicted not to be stabilized by HOMO–LUMO interactions. Such a situation occurs only if the entire cyclic π system have $4n$ π electrons.

We can also assume that an odd number of π electrons reside at each segment.[5,7] This time the SOMO's of the two segments become interacting frontier MO's. Exactly the same proof can be achieved for the thermodynamic aspect of the Hückel rule by examining whether or not a phase dislocation occurs between the SOMO's at the original two junctions. Unless the total number of π electrons is equal to $4n+2$, the two SOMO's do not overlap in-phase at one of the junctions.

The above frontier MO analyses apply not only to all neutral monocyclic species but also to all charged ones. It is monocyclic $(4n+2)$-π-electron systems alone that are stabilized by HOMO–LUMO interactions. This is the very reason why the Hückel rule can be interpreted in thermodynamic terms. We can safely say on this basis that all kinds of $(4n+2)$-π-electron systems are thermodynamically stable.

Thermodynamic stability of a molecule due to cyclic conjugation is given numerically by the graph-theoretically defined resonance energy, RE.[14–18] It is defined as the difference in total π-electron energy between a given conjugated system and its reference system. RE is expressed explicitly as

$$\mathrm{RE} = \sum_{m=1}^{N} g_m(X_m - X_m^\circ), \tag{7}$$

where g_m is the occupation number for the mth MO. The mth orbital resonance energy, ORE_m, is defined as[27]

$$\mathrm{ORE}_m = X_m - X_m^\circ. \tag{8}$$

Since Eq. 5 holds, ORE_m is positive if $m=2p+1$, and negative otherwise. Therefore, the HOMO resonance energy of a $(4n+2)$-π-electron system is positive, whereas that of a $(4n)$-π-electron system is negative. RE is obtainable by adding up twice the orbital resonance energies of all occupied MO's.[27]

Figure 1 indicates that $P_G(X)$, in general, has a rather steep gradient at $X=X_1$ and X_N, compared to those at other zeroes of $P_G(X)$. This implies that the absolute values of ORE_1 and ORE_N are in general smaller than those of other orbital resonance energies. ORE_1 always has a small positive value. ORE_m is

positive in sign if m=even, and negative otherwise. Except the cases of m=1 and N, the absolute values of the orbital resonance energies are rather comparable with each other. This might be understandable from Fig. 1. Since any monocyclic π system behaves as such, the sign of the overall resonance energy (i.e., RE) is determined primarily by the sign of the HOMO resonance energy, i.e., the orbital resonance energy of the HOMO.

We have calculated RE's of many monocyclic heteroconjugated systems.[14,18] Resonance energies and orbital resonance energies for four typical monocyclic π systems are listed in Table 1. Here, the Hückel parameters determined by Hess, Schaad, and Holyoke were employed.[11] For all these molecules, the sign of RE is really determined by the sign of HOMO resonance energy. No exceptions were found in accordance with the above frontier MO analyses. As predicted by the frontier MO analyses, monocyclic $(4n+2)$-π-electron systems alone have positive RE due to cyclic conjugation. There seems to be no monocyclic aromatic species which has a destabilized HOMO and no monocyclic antiaromatic species which has a stabilized HOMO.

For most neutral monocyclic systems, all bonding MO's are filled, and all antibonding MOs vacant. For these systems, aromaticity can be estimated by comparing the values of $|P_G(i)|$ and $|R_G(i)|$, where $i=\sqrt{-1}$.[15,28] If $|P_G(i)|>|R_G(i)|$ for a given species G, it is aromatic thermodynamically. Logarithms of $|P_G(i)|$ and $|R_G(i)|$ are roughly proportional to the total π-electron energies of G and its olefinic reference structure, respectively.[15] K_G increases or decreases the value of $|P_G(i)|$ according to the Hückel rule. If G has $2n+1$ bonding MO's with $4n+2$ π electrons, K_G makes $|P_G(i)|$ larger than $|R_G(i)|$, and positive RE results. There are no exceptions.

Table 1. Orbital Resonance Energies of Monocyclic π Systems

m	X_m	X_m°	ORE$_m/\beta$[a]

a) β is an absolute value of β.

Magnetotropic Aspect of the Hückel Rule

It has widely been accepted that aromatic and antiaromatic annulenes are diatropic and paratropic, respectively.[29] Magnetotropism of annulens is simply determined by the number of π electrons. Therefore, it is predictable from the Hückel rule. Let us examine whether or not the magnetotropism of an arbitrarily chosen monocyclic π system is predictable from the Hückel rule.

When the magnetic field is applied to a monocyclic π system, only the term K_G in $P_G(X)$ changes.[16,27,30] All coefficients of $R_G(X)$ are not dependent upon the external field. If the field is perpendicular to the molecular plane, K_G is expressed as

$$K_G = 2\cos\left(\frac{eSB}{\hbar}\right)\prod_{(ij)}^{G} k_{ij}, \tag{9}$$

where B is the field strength, S is the area of the ring, and e is the charge of an electron.

Since K_G slightly decreases in the magnetic field, $P_G(X)$ displaces slightly downward toward the location of $R_G(X)$. Accordingly, every MO with positive orbital resonance energy is destabilized by the field, whereas every MO with negative orbital resonance energy is stabilized by the field. The former MO contributes to the exaltation of molecular diamagnetism.[27,31] The latter MO is paramagnetic in nature, decreasing molecular diamagnetism. The HOMO of a monocyclic system with $4n+2$ π electrons is always diamagnetic or diatropic in nature. These magnetic effects arise from the ring current induced in a cyclic system.

Haddon[32] and Aihara[33] proved that the ring current intensity is proportional to the product of the resonance energy and the ring area for all aromatic annulenes and annulene ions. Aihara extended this idea to all monocyclic π systems, and found that the induced ring current is approximately proportional to the resonance energy, multiplied by the area of the ring.[34] Since it has been proved that monocyclic systems with $4n+2$ π electrons have positive RE, they all are necessarily diatropic. Those with $4n$ π electrons have negative RE, so they must be paratropic. Thus, magnetotropism is an excellent index for determining the degree of aromatic

stabilization. Conversely, the Hückel rule can be used assuredly to determine the sign of magnetropism for all monocyclic π systems.

Concluding Remarks

The Hückel rule has been used successfully to identify innumerable monocyclic π systems as aromatic or antiaromatic species. The above treatments based on graph theory and frontier orbital theory revealed novel physical implications of the Hückel rule, and justified well the use of it. It has been established that any monocyclic $(4n+2)$-π-electron system has not only kinetic but also thermodynamic stabilities. The sign of the overall resonance energy is determined simply by the number of π electrons. Ichikawa and Ebisawa[35] recently found a nice correlation between the Hückel resonance energy[11] and the kinetic energy of π electrons.

If a given monocyclic molecule has a singly twisted π system (i.e., a Möbius ring system),[36] the sign of K_G in Eq. 2 becomes negative.[17,37] The curve $Y=P_G(X)$ for a Möbius system displaces upward from the curve $Y=R_G(X)$. When a $(4n+2)$-π-electron Möbius system is divided into two segments, a phase dislocation occurs between the frontier MO's of the two segments. For a $(4n)$-π-electron Möbius system, however, it does not occurs. The Hückel rule is thus reversed. Any Möbius system with $4n+2$ π electrons then becomes antiaromatic, and any Möbius system with $4n$ π electrons aromatic.

The Hückel rule and the above explanation of it do not apply to highly charged molecules since electrostatic interactions are far from being balanced. Thus, such species as tetraanions and tetracations of monocyclic π systems may be very unstable even if they have $4n+2$ π electrons. We might say that the Hückel rule is universally applicable as far as intramolecular electrostatic interactions are well-balanced.

If the Hückel rule seems not to be applicable to a given neutral molecule, the validity of its bonding scheme, rather than that of the Hückel rule, should be questioned. For example, phosphole does not behave like an aromatic molecule although it appears to be iso-π-electronic with pyrrole.[4] Cyclophosphazene of any size is neither aromatic nor antiaromatic.[38] Its diamagnetic susceptibility can be estimated additively with respect to constituent atoms and bonds.[39] There must be no cyclic conjugation in these compounds, and the Hückel rule is not applicable.

We are grateful to Professor Haruo Moriguchi (Shizuoka University) for helpful discussions.

Raman Spectral Characteristics of Cobalt(III) Complexes with Quadridentate Ligands

Tatsuya KAWAMOTO,* Jinsai HIDAKA, and Hisahiko EINAGA†
Department of Chemistry, University of Tsukuba, Tsukuba, Ibaraki 305
†Institute of Materials Science, University of Tsukuba, Tsukuba, Ibaraki 305
(Received April 16, 1987)

The Raman spectra of cobalt(III) complexes with quadridentate ligands such as triethylenetetramine (trien), ethylenediamine-*N*,*N*′-diacetate (edda), tris(2-aminoethyl)amine (tren), and *N*-(2-aminoethyl)iminodiacetate (aeida), were measured for the skeletal vibration region of 200—700 cm^{-1} in order to obtain general information on the relation between the spectra and the structures of these complexes. The Raman bands can be classified into four vibration modes; a totally symmetric stretching vibration mode in the 420—670 cm^{-1} region, a stretching vibration mode excluding the totally symmetric one in the 390—450 cm^{-1} region, a metal-ligand skeletal bending deformation mode in the 300—420 cm^{-1} region, and the chelate ring deformation mode in the 240—290 cm^{-1} region. The skeletal vibrations of cis-α and cis-β isomers of the cobalt(III) complexes with linear quadridentate ligands correspond to those of the tris(bidentate)cobalt(III) and the mer isomers of bis(terdentate)cobalt(III) complexes, respectively. In addition, the skeletal vibrations of the cobalt(III) complexes with tripodlike quadridentate ligands also correspond to those of the mer isomers of bis(terdentate)cobalt(III) complexes. The Raman spectra of the present complexes depend primarily on the configuration of the quadridentate ligands and the effect due to the bidentate ligands is of secondary importance.

In the last few years, it has been recognized that Raman spectra in the skeletal vibration region can be applied successfully to the differentiation of geometrical isomers of cobalt(III) complexes.[1] The main interest has been focused on the low frequency region where the Raman bands for the skeletal vibrations appear. However, little systematic investigations had been reported at this time concerning the relation between the Raman spectra and the structural characteristics of the metal complexes.

In the previous papers, we reported the Raman spectral characteristics of the $[Co(gly)_x(ox)_y(en)_z]$-type complexes (gly, glycinate; ox, oxalate; and en, 1,2-ethanediamine),[2] the $[Co(ida)_n(dien)_{2-n}]$-type complexes (ida, iminodiacetate and dien, diethylenetriamine),[3] and the cobalt(III) complexes containing the six-membered chelate ring.[4] The Raman spectra of the $[Co(gly)_x(ox)_y(en)_z]$-type complexes have been treated in terms of the effective symmetry,[2] which was mainly specified by the arrangement of the coordinated atoms around the cobalt(III). It has been found that the striking differences in the Raman spectral characteristics of the mer and fac isomers of the $[Co(ida)_n(dien)_{2-n}]$-type complexes reflect the structural distortion in the isomeric pairs.

In this paper, the Raman spectra in the skeletal vibration region of the cobalt(III) complexes with quadridentate ligands, triethylenetetramine (trien), ethylenediamine-*N*,*N*′-diacetate (edda), tris(2-aminoethyl)amine (tren), and *N*-(2-aminoethyl)iminodiacetate (aeida), are measured and the relation between the stereochemical properties and Raman spectra of these complexes is discussed in relation to the Raman spectral characteristics of the tris(bidentate)- and bis(terdentate)cobalt(III) complexes.

Experimental

Complexes. The following complexes were prepared and characterized according to procedures in the literature *cis*-α-[Co(en)(trien)]I_3,[5] *cis*-β-[Co(en)(trien)]Cl_3,[5,6] *cis*-α-[Co(edda)(en)]ClO_4,[7] *cis*-β-[Co(edda)(en)]ClO_4,[7] *cis*-α-[Co(edda)$(NH_3)_2$]NO_3,[7] *cis*-α-[Co(edda)(gly)],[8] and *cis*-α-Na[Co(edda)(ox)].[9]

[Co(ox)(trien)]Cl. *cis*-α- and *cis*-β-[Co(ox)(trien)]I, which were prepared in the same way as has been reported,[10] were converted to the chloride by passing the solution through a column of Dowex 1-X8 anion-exchange resin in the chloride form. Found for the cis-α isomer: C, 28.27; H, 5.63; N, 16.47%. Calcd for $[Co(ox)(trien)]Cl \cdot 1/2H_2O = CoC_8H_{18}N_4O_4Cl \cdot 1/2H_2O$: C, 28.46; H, 5.67; N, 16.59%. Found for the cis-β isomer: C, 25.98; H, 5.92; N, 15.18%. Calcd for $[Co(ox)(trien)]Cl \cdot 9/4H_2O$: C, 26.03; H, 6.14; N, 15.18%.

[Co(en)(tren)]Cl_3. This complex was prepared by a procedure alternative to that described in the literature.[11] To a solution of $[CoCl_2(tren)]Cl$[12] (3.3 g) in 20 cm^3 of water on a steam bath was added 1,2-ethanediamine (0.6 g). Heating was continued for 30 min. After cooling, [Co(en)(tren)]Cl_3 was isolated by the column chromatographic method using SP-Sephadex C-25 (Na^+ form, 4 cm×20 cm) and a 0.2 mol dm^{-3} aqueous solution of NaCl as an eluent. Found: C, 23.47; H, 7.48; N, 20.50%. Calcd for $[Co(en)(tren)]Cl_3 \cdot 2H_2O = CoC_8H_{26}N_6Cl_3 \cdot 2H_2O$: C, 23.57; H, 7.42; N, 20.62%.

[Co(ox)(tren)]Cl. This complex was prepared by a procedure similar to that used for $[Co(ox)(trien)]^+$. A solution containing $[CoCl_2(tren)]Cl$ (0.5 g) and oxalic acid (0.4 g) in 10 cm^3 of water was warmed on a steam bath for 30 min. After cooling, the resulting red solution was passed through a column of SP-Sephadex C-25 (Na^+ form, 3 cm×40 cm) with a 0.05 mol dm^{-3} aqueous solution of NaCl as an eluent. The red eluate was concentrated and then cooled in an ice bath in order to obtain [Co(ox)(tren)]Cl. Found: C, 27.69; H, 5.88; N, 16.23%. Calcd for $[Co(ox)(tren)]Cl \cdot H_2O = CoC_8H_{18}N_4O_4Cl \cdot H_2O$: C, 27.72; H,

5.82; N, 16.16%. Absorp. max. $10^{-3}\sigma/cm^{-1}$($\log \varepsilon/mol^{-1}$ $dm^3\,cm^{-1}$): 20.12 (2.13) and 28.17 (2.16).

[Co(edda)(tn)]ClO_4. The preparation procedure was identical with that of [Co(edda)(en)]$^{+}$[7] except that 1,3-propanediamine (tn) was used instead of en. The reaction mixture was poured onto a column of Dowex 50W-X8 (200—400 mesh, Na^+ form, 3 cm×60 cm) and the three main red bands were eluted. It was found that the second eluate was *cis*-*α*-[Co(edda)(tn)]$^+$ and the third one was *cis*-*β*-[Co(edda)(tn)]$^+$ from their absorption, ^1H NMR, and ^{13}C NMR spectra. Found for the cis-*α* isomer: C, 26.48; H, 4.87; N, 13.61%. Calcd for [Co(edda)(tn)]ClO_4=$CoC_9H_{20}N_4O_8Cl$: C, 26.58; H, 4.96; N, 13.78%. Found for the cis-*β* isomer: C, 25.43; H, 5.18; N, 13.00%. Calcd for [Co(edda)(tn)]-$ClO_4\cdot H_2O$: C, 25.45; H, 5.22; N, 13.19%. Absorp. max. $10^{-3}\sigma/cm^{-1}$ ($\log \varepsilon/mol^{-1}dm^3cm^{-1}$): the cis-*α* isomer: 18.59 (2.00), 21.69sh (1.73), 27.55 (2.18) and the cis-*β* isomer: 19.92 (2.14), 27.86 (2.23).

***cis*-α-[Co(edda)(β-ala)].** This complex has been prepared by Nakazawa et al.,[13] but the synthesis in the present work was carried out according to the procedure of the complex with the glycinate ligand,[8] except that *β*-alanine was used in place of glycine. Found: C, 32.02; H, 5.24; N, 12.67%. Calcd for [Co(edda)(*β*-ala)]$\cdot 3/4H_2O$=$CoC_9H_{16}N_3O_6\cdot 3/4H_2O$: C, 32.30; H, 5.27; N, 12.56%. Absorp. max. $10^{-3}\sigma/cm^{-1}$ ($\log \varepsilon/mol^{-1}dm^3cm^{-1}$): 17.99sh (1.99), 19.69 (2.05), and 26.74 (2.09).

[Co(aeida)(en)]Cl. Two isomers were separated by an SP-Sephadex C-25 column chromatography using an aqueous solution of NaCl in place of that of $NaClO_4$ as an eluent given in literature.[14] Found for the trans(O) isomer: C, 25.00; H, 6.27; N, 14.70%. Calcd for [Co(aeida)(en)]Cl$\cdot 3H_2O$=$CoC_8H_{18}N_4O_4Cl\cdot 3H_2O$: C, 25.11; H, 6.32; N, 14.64%. Found for the cis(O) isomer: C, 26.27; H, 5.91; N, 15.29%. Calcd for [Co(aeida)(en)]Cl$\cdot 2H_2O$: C, 26.35; H, 6.08; N, 15.36%.

Measurements. The Raman spectra were recorded on a JASCO Laser Raman spectrometer, which was constructed specially with a double monochromator, model CT-25, a He-Ne laser, model NEC GLG-8500, and a data processor, model DP-500, as the main components. The sample solution was excited at 632.8 nm, and the Raman spectra were calibrated with indene. The electronic absorption spectra were recorded with JASCO UVIDEC-1 and -610 spectrophotometers, and the ^1H NMR and ^{13}C NMR spectra were recorded in deuterium oxide on a JEOL JNM-FX-100 NMR spectrometer at the probe temperature. Sodium 2,2-dimethyl-2-silapentane-5-sulfonate (DSS) was used as internal reference.

Results and Discussion

General Aspect. [Co(quadridentate)(bidentate)]-type complexes used in this work for Raman spectral study are depicted in Fig. 1. The Raman spectral data in the skeletal vibration region of the cobalt(III) complexes with quadridentate ligands such as trien, tren, edda, and aeida, are summarized in Table 1, together with those of $[Co(NH_3)_6]^{3+}$,[2] $[Co(en)_3]^{3+}$,[2] *unsym-fac*-$[Co(dien)_2]^{3+}$,[3] and *trans*(O)-$[Co(gly)_2(en)]^{+}$[2] for comparison.

Figure 2 shows the Raman spectrum of *cis*-*α*-

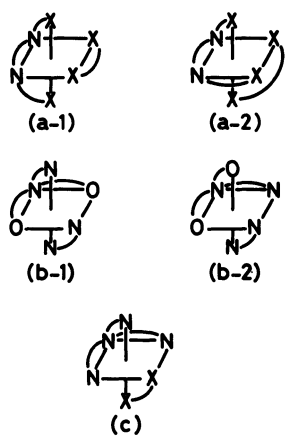

Fig. 1. Structures of [Co(quadridentate)(bidentate)]-type complexes. Cis-*α* (a-1) and cis-*β* (a-2) isomers of the complexes with trien (X=N) and edda (X=O), trans(O) (b-1) and cis(O) (b-2) isomers of [Co(aeida)-(en)]$^+$, and the complexes with tren (c).

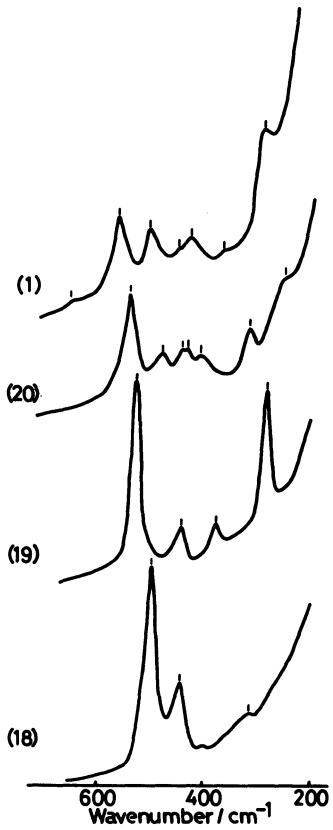

Fig. 2. Raman spectra of *cis*-*α*-[Co(en)(trien)]$^{3+}$, *unsyn-fac*-$[Co(dien)_2]^{3+}$ (Ref. 3), $[Co(en)_3]^{3+}$ (Ref. 2), and $[Co(NH_3)_6]^{3+}$ (Ref. 2). Numbers in parentheses correspond to those in Table 1.

[Co(en)(trien)]$^{3+}$ as a typical example of the cobalt(III) complexes with quadridentate ligand, together with those of *unsym-fac*-$[Co(dien)_2]^{3+}$, $[Co(en)_3]^{3+}$, and $[Co(NH_3)_6]^{3+}$. These complexes all possess an O_h

a) The following abbreviations are used: s, strong; m, medium; w, weak; vw, very weak; sh, shoulder; p, polarized; dp, depolarized. b) Ref. 2. c) Ref. 3. d) These bands correspond to the breathing vibration mode which is characteristic for the bis(terdentate)cobalt(III) complexes. e) ν_{ts} denotes the totally symmetric stretching vibration mode; ν, the stretching vibration mode excluding the totally symmetric one; δ_{sbd}, the metal-ligand skeletal bending deformation mode; δ_{crd}, the chelate ring deformation mode, and L, the donor atom (N and/or O).

symmetry with respect to the coordinated atoms. From their Raman frequencies and intensities, it seems that the Raman bands at 555, 420—500, 354, and 282 cm^{-1} of *cis*-α-$[Co(en)(trien)]^{3+}$ correspond to those at 546, 430—490, 321, and 255 cm^{-1} of *unsym-fac*-$[Co(dien)_2]^{3+}$ and to those at 525, 440, 378, and 283 cm^{-1} of $[Co(en)_3]^{3+}$, respectively. However, the depolarization ratio of the Raman band at 498 cm^{-1} of *cis*-α-$[Co(en)(trien)]^{3+}$ is different from that of the corresponding Raman bands of *unsym-fac*-$[Co(dien)_2]^{3+}$ (485 cm^{-1}), $[Co(en)_3]^{3+}$ (440 cm^{-1}), and $[Co(NH_3)_6]^{3+}$ (440 cm^{-1}) (Table 1, Fig. 2); the band at 498 cm^{-1} of *cis*-α-$[Co(en)(trien)]^{3+}$ is polarized, while the band at 485 cm^{-1} of *unsym-fac*-$[Co(dien)_2]^{3+}$ and the bands at 440 cm^{-1} of $[Co(en)_3]^{3+}$ and $[Co(NH_3)_6]^{3+}$ are depolarized. This spectral feature is unique for the cobalt(III) complexes with quadridentate ligands: The polarized Raman bands at 440—510 cm^{-1} are regarded as characteristic of the cobalt(III) complexes with quadridentate ligands, because they were not observed for bis(terdentate)- and tris(bidentate)cobalt(III) and related complexes.[2,3] On the contrary, the polarized Raman bands around 400 cm^{-1}, characteristic for the cobalt(III) complexes with terdentate ligands, could not be observed for the cobalt(III) complexes with quadridentate ligands.

It is evident from Fig. 2 and Table 1 that the Raman spectral characteristic of *cis*-α-$[Co(en)(trien)]^{3+}$ is similar to that of $[Co(en)_3]^{3+}$ rather than that of *unsym-fac*-$[Co(dien)_2]^{3+}$. Accordingly, the Raman spectrum of *cis*-α-$[Co(en)(trien)]^{3+}$ can be assigned on the basis of the Raman spectrum of $[Co(en)_3]^{3+}$ except for the Raman band at 498 cm^{-1}. This deduction is supported by comparison of *cis*-α-$[Co(edda)(en)]^+$ with *trans*(O)-$[Co(gly)_2(en)]^+$ which have a D_{4h} symmetry with respect to the coordinated atoms; that is, Table 1 shows that the Raman bands at 520—620, 420—470, 349, and 262 cm^{-1} of *cis*-α-$[Co(edda)(en)]^+$ correspond to those at 520—600, 450—510, 368, and 275 cm^{-1} of *trans*(O)-$[Co(gly)_2(en)]^+$, except for the difference in the depolarization ratio between the Raman band at 461 cm^{-1} of the former and that at 504 cm^{-1} of the latter. Furthermore, taking the Raman frequency and the depolarization ratio into account, it is considered that the polarized bands at 498 cm^{-1} of *cis*-α-$[Co(en)(trien)]^{3+}$ and at 461 cm^{-1} of *cis*-α-$[Co(edda)(en)]^+$ can be assigned to the totally symmetric vibration mode.

On the basis of the above discussion and the Raman spectral characteristics summarized in Table 1, it can be concluded that the Raman spectra of the cobalt(III) complexes with quadridentate ligands can be classified into four categories similar to those of tris(bidentate)cobalt(III) complexes;[2] polarized bands in the 420—670 cm^{-1} region, depolarized ones in the 390—450 cm^{-1} region, depolarized ones in the 300—420 cm^{-1} region, and polarized ones in the 240—290 cm^{-1} region. These can be assigned to the totally symmetric stretching vibration mode, the stretching vibration mode excluding the totally symmetric one, the metal-ligand skeletal bending deformation mode, and the chelate ring deformation mode, respectively.

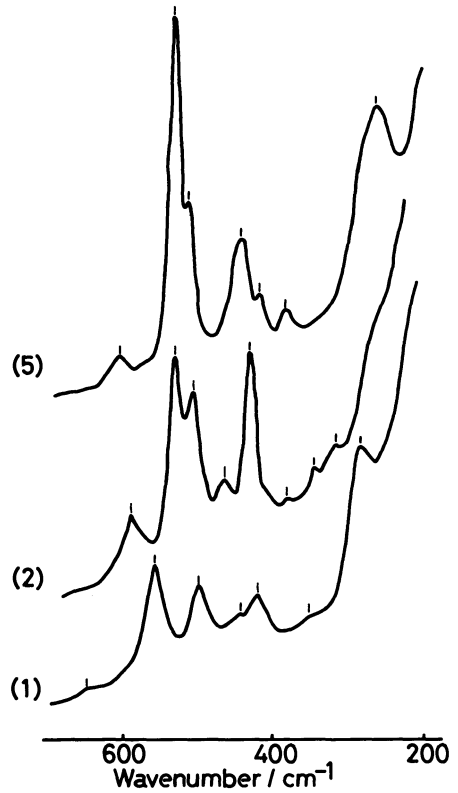

Fig. 3 Raman spectra of *cis*-α- and *cis*-β-[Co(en)(trien)]$^{3+}$ and [Co(en)(tren)]$^{3+}$. Numbers in parentheses correspond to those in Table 1.

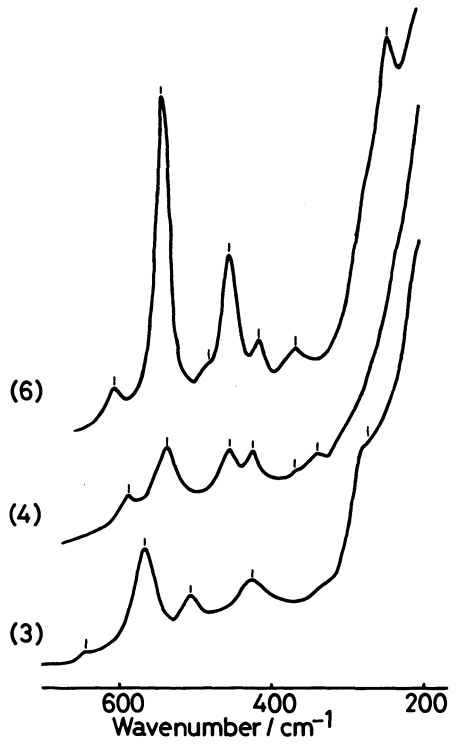

Fig. 4. Raman spectra of *cis*-α- and *cis*-β-[Co(ox)(trien)]$^{+}$ and [Co(ox)(tren)]$^{+}$. Numbers in parentheses correspond to those in Table 1.

Raman Spectra of [Co(trien)(bidentate)]- and [Co(tren)(bidentate)]-type Complexes. It can be seen from Fig. 3 and Table 1 that *cis*-α- and *cis*-β-[Co(en)(trien)]$^{3+}$ show different Raman spectral feature in each skeletal vibration region; the Raman spectrum of *cis*-β-[Co(en)(trien)]$^{3+}$ is similar to that of [Co(en)(tren)]$^{3+}$ rather than that of the cis-α isomer. The significant aspect in structures of *cis*-β-[Co(en)(trien)]$^{3+}$ and [Co(en)(tren)]$^{3+}$ is that the coordinated N-N-N portion of the quadridentate ligands (trien and tren) have equally meridional configuration toward the central metal atom. It is obvious that this meridional configuration greatly influences the normal vibration modes in the skeletal vibration region of the Raman spectra of *cis*-β-[Co(en)(trien)]$^{3+}$ and [Co(en)(tren)]$^{3+}$, because the mer isomers of the bis(terdentate)cobalt(III) complexes have shown the Raman spectral feature quite different from that of the fac isomers.[3] This type of Raman spectral feature can also be observed for the two geometrical isomers of [Co(ox)(trien)]$^{+}$ and [Co(ox)(tren)]$^{+}$; the Raman spectrum of *cis*-β-[Co(ox)(trien)]$^{+}$ can not be correlated to that of cis-α isomer, but, that of [Co(ox)(tren)]$^{+}$ (Fig. 4).

As shown in Figs. 3 and 4, the cobalt(III) complexes with quadridentate ligands, *cis*-β-[Co(en)(trien)]$^{3+}$, *cis*-β-[Co(ox)(trien)]$^{+}$, [Co(en)(tren)]$^{3+}$, and [Co(ox)(tren)]$^{+}$, which have equally meridional configuration with respect to the coordinated N-N-N portion in the quadridentate ligands, exhibit multiple polarized bands in the stretching vibration region, which is characteristic for the mer isomers of bis(terdentate)-cobalt(III) complexes.[3] These findings suggest that their Raman spectra are mainly regulated by the normal vibrational modes of the meridional configuration of the quadridentate ligands. Especially, the polarized Raman bands around 450 cm^{-1} are regarded as characteristic for cis-β isomers of the [Co(trien)-(bidentate)]- and [Co(tren)(bidentate)]-type complexes since the corresponding bands could not be observed in the spectra of the tris(bidentate)cobalt(III) complexes and the fac isomers of the bis(terdentate)-cobalt(III) complexes.

Hence, in the cobalt(III) complexes with trien and tren ligands, so far as skeletal vibrations are concerned, the Raman spectra of the cis-α isomers can be correlated with those of the tris(bidentate)cobalt-(III) complexes, and those of the cis-β isomers and the complexes with the tripodlike quadridentate ligands can be correlated with those of the mer isomers of the bis(terdentate)cobalt(III) complexes, respectively.

Raman Spectra of [Co(edda)(bidentate)]-type and [Co(aeida)(en)]$^{+}$ Complexes. Figure 5 shows the Raman spectra of cis-α and cis-β isomers of [Co(edda)(en)]$^{+}$ and [Co(edda)(tn)]$^{+}$. In view of the Raman spectra of the tris(bidentate)cobalt(III)[2] and

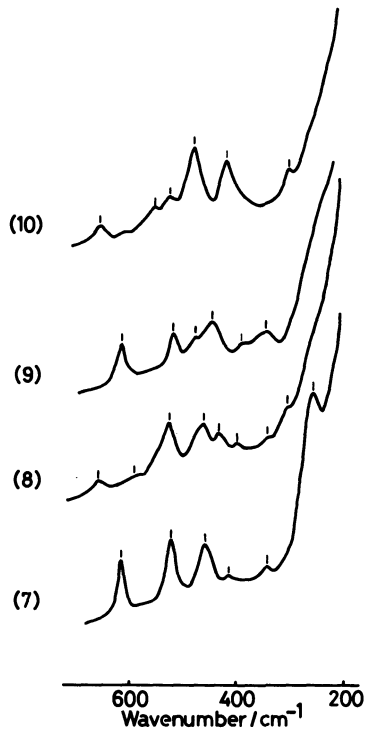

Fig. 5. Raman spectra of cis-α and cis-β isomers of $[Co(edda)(en)]^+$ and of $[Co(edda)(tn)]^+$. Numbers in parentheses correspond to those in Table 1.

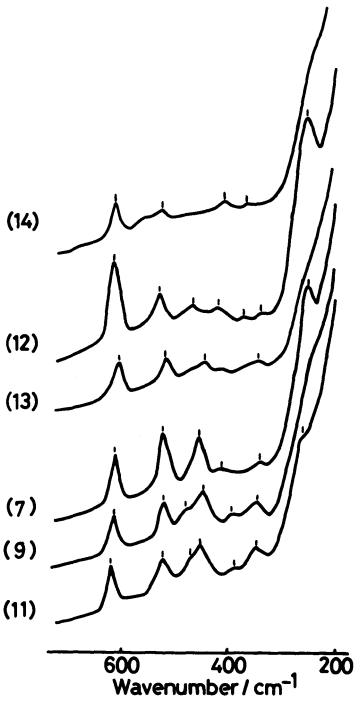

Fig. 6. Raman spectra of cis-α isomers of $[Co(edda)(ox)]^-$, $[Co(edda)(gly)]$, $[Co(edda)(\beta\text{-ala})]$, $[Co(edda)(en)]^+$, $[Co(edda)(tn)]^+$, and $[Co(edda)(NH_3)_2]^+$. Numbers in parentheses correspond to those in Table 1.

bis(terdentate)cobalt(III)[3] complexes, the Raman band at 617 cm^{-1} of the cis-α isomer of $[Co(edda)(en)]^+$ and that at 660 cm^{-1} of the cis-β isomer are closely associated with the coordinated oxygen atom. Furthermore, the shift of these bands is most prominent for the Raman spectra of *cis*-α- and *cis*-β-$[Co(edda)(en)]^+$ and is useful for differentiation between the cis-α and cis-β isomers. A similar feature is also observed for the Raman spectra of the cis-α and cis-β isomeric pairs of $[Co(edda)(tn)]^+$ (Fig. 5) and $[Co(edda)(ox)]^-$ (Table 1).

The Raman spectra of *trans*(O)- and *cis*(O)-$[Co(aeida)(en)]^+$ exhibit unique differences around 400 cm^{-1} from the Raman spectrum of *cis*-β-$[Co(edda)(en)]^+$ with the different chelate ring structure (Table 1). The trans(O) and cis(O) isomers of $[Co(aeida)(en)]^+$ show polarized bands at 400 and 409 cm^{-1}, respectively, but the cis-β isomer of $[Co(edda)(en)]^+$ shows no polarized band in the corresponding region. These polarized bands around 400 cm^{-1} can be assigned to the skeletal breathing mode on the basis of the Raman spectral characteristics of the mer isomers of $[Co(ida)(dien)]^+$, $[Co(mida)(mdien)]^+$, $[Co(ida)(mida)]^-$, and $[Co(mida)_2]^-$,[3] where mida and mdien denote *N*-methyliminodiacetate and *N*,*N*-bis(2-aminoethyl)methylamine, respectively. The skeletal breathing mode of the cobalt(III) complexes with a tripodlike quadridentate ligand, $[Co(en)(tren)]^{3+}$ and $[Co(ox)(tren)]^+$, are also detectable at 442 and 453 cm^{-1} by comparison with the mer isomers of $[Co(dien)_2]^{3+}$, $[Co(ida)(dien)]^+$, and $[Co(mida)(mdien)]^+$.[3]

Role of Bidentate Ligands. It can be seen by comparison of Figs. 3 and 4 that *cis*-α-$[Co(en)(trien)]^{3+}$ and $[Co(en)(tren)]^{3+}$ exhibit Raman spectral characteristics similar to *cis*-α-$[Co(ox)(trien)]^+$ and $[Co(ox)(tren)]^+$, respectively. Furthermore, the Raman spectral behavior of the same geometrical isomers of the cobalt(III) complexes with edda ligand in the higher frequency region resemble each other as shown in Figs. 5 and 6. Accordingly, it is evident that the Raman spectra of the [Co(quadridentate)(bidentate)]-type complexes depend mainly on the configuration of the quadridentate ligands and the role of the bidentate ligands is of minor importance.

Some unsymmetrical azoxy- and azoferrocenes and *N*-(ferrocenylarylmethylene)anilines were obtained by the reactions of aryliminodimagnesium reagents ($ArN(MgBr)_2$) with nitro- and aroylferrocenes. The types of products were same as those obtained in the similar reactions with nitrobenzenes and benzophenones. The different distribution of products arising from quite mild reactions was understood by the effect of bulky and electron-rich ferrocenyl group which retards the initial coordination and electron transfer processes, in comparison with that of phenyl group. The characteristic molecular structures of the new ferrocene compounds were studied by means of electronic absorption, ^1H NMR, and X-ray crystallography. The results were summarized and discussed.

In the electron transfer initiated fifteen reactions of various magnesium reagents with aromatic nitro and carbonyl compounds, the distribution of normal and abnormal (radical) products was recently correlated with the combination of electron-donating and -accepting abilities (EDA and EAA) of reactants,[2)] which represent the efficiency of electron transfer, and was estimated by the difference (ΔE) between the oxidation and reduction potentials of reactants.

Among the fifteen reactions, the deoxygenative condensation of aryliminodimagnesium reagents

a) $Ar^1NO_2 + ArN(MgBr)_2 \rightarrow Ar^1N(O)=NAr + Ar^1N=NAr + \underline{ArN=NAr}$

b) $Ar^1COAr^2 + ArN(MgBr)_2 \rightarrow Ar^1CAr^2 + Ar^1CHAr^2$
$\quad\quad\quad

2) and benzoylferrocenes (Scheme 3), the types of products are same as those in the reactions 1a and 1b. The product distribution in the reactions 2 and 3 is noticeably different reflecting their much milder natures due to the retarding effect of bulky and electron rich ferrocenyl group in comparison with that of phenyl group: Some modification of the EDA-EAA concept is necessary. The azoxy- and azoferrocenes as well as *N*-(ferrocenylarylmethylene)-anilines are new compounds, and the molecular structures were studied by means of ^{1}H NMR, electronic absorption, and X-ray crystallography. The results will be summarized and discussed.

Results and Discussion

The EDA-EAA concept deals with the efficiency of initial processes essential to the reactions, i.e., the σ-complex formation and the subsequent electron transfer.[2] The product distributions in reactions 2 and 3 will be elucidated partly by the simple concept and additionally by modifying it by the effect of ferrocenyl group on the two processes. The phenyl-IDMg reagents used are *p*-MeO-, *p*-Me-, and *p*-Cl-substituted ones: The normalized oxidation peak potentials measured in THF–Bu_4NClO_4 system are 0.912V, 0.941V, and 1.056V, respectively.[8] The large positive value indicates a weak EDA.

IDMg Reaction with Nitroferrocene. The product distribution in reaction 2 under fixed conditions is given in Table 1 (Runs 1—5); the two previous results of reaction 1a with *p*-MeO-nitrobenzene[3] are listed for comparison (Runs 6 and 7). The unavoidable formation of symmetrical (*sym*-) azoarene (**3**) indicates involvement with electron transfer.[3,9] The reactivity of azoxyarenes in the IDMg deoxygenation, influencing on the relative yields of azoxy and unsymmetrical azo compounds, was also correlated to EDA and EAA.[5]

For discussing the character of reaction 2, some normalized reduction potentials of nitro and azoxy substrates are given below. The large negative value indicates weak EAA. The ΔE value of 2.6—2.8, estimated from the potential of nitroferrocene, corresponds to the borderline of "electron transfer"

(Fc=ferrocenyl)

$FcNO_2$	−1.693V
$FcN(O)=NC_6H_4Cl$-*p*	−1.604V
p-$MeOC_6H_4NO_2$	−1.508V
p-$MeOC_6H_4N(O)=NC_6H_4Cl$-*p*	−1.563V

and "coordination" controlled reactions.[2] The hybrid character may be one of the reasons of the small effect of EDA indicated by slight variation of yields of azoxy- and azoferrocenes (**1** and **2**) and **3** (Runs 1, 2, 4, and 5). The weaker EAA of nitroferrocene than that of *p*-MeO-nitrobenzene, as shown by remarkably different (185 mV) potentials, seems responsible for the noticeably different yields between Runs 2 and 6 using *p*-MeC_6H_4-IDMg. The small EDA effect, including the almost same yields in Runs 5 and 7 using *p*-ClC_6H_4-IDMg, is understood by the nature of **1** which is resistant to deoxygenation as described below.

Even in Runs 1 and 2 using 5.0 mol of IDMg's having stronger EDA's the yield of **1** is still higher than that of **2**: A larger amount of IDMg is needed for effective deoxygenation (Run 3). The sluggish deoxygenation is in accord with weaker EAA of **1** than that of azoxybenzene (vide supra), but is not in accord with noticeably stronger EAA of **1** than that of nitroferrocene. The neighboring bulky ferrocenyl group of **1** will cause steric repulsion against the attack of anionic IDMg nitrogen on the positive azoxy nitrogen.[5] However, as shown in the final section, the planar molecular structure of **1** is the most reliable reason for the sluggish deoxygenation.

IDMg Reaction with Benzoylferrocenes. The yields of *N*-(ferrocenylarylmethylene)anilines (**4**, anils)[4] and amounts of recovered substrates in reaction 3 are summarized in Table 2 (Runs 1—30). Benzoylferrocenes have weaker EAA than that of benzophenone (reduction potential: −1.989V[2]): their potentials were undetermined, because they are over the potential window of THF–Bu_4NClO_4 system.[2] The ΔE value of reaction 3 is larger than 3.1, suggesting the "coordination controlled" character[2,5] accompanying a much milder electron transfer. This is supported by the almost negligible formation of radical products, ferrocenylarylmethanol and *sym*-azoarene. The

a) Yields obtained after heating at 55 °C for 3 h. b) Fc=ferrocenyl. c) Cf. Ref. 1).

former, formed via hydrogen abstraction from the solvent by ketyl radical,[3] was detected by ^{1}H NMR (see Experimental). The formation of the latter will be discussed later. The reaction 3 is clean as shown by high combined amounts of anil and the recovery, and it proceeds very slowly (vide infra). By comparing the relative yields of **4** (Table 2), reflecting the reactivity of reactants, some new type substituent effects depending on the molar ratio were disclosed in the field of Grignard and IDMg reactions.

By use of 1.2 mol of IDMg and unsubstituted benzoylferrocene, the conversion was quite low after treating at 55 °C for 2 h (Runs 1, 6, and 11) and at room temperature (8—12 °C) for 16 h (Runs 16, 21, and 26). In contrast to the reaction 1b giving sufficient conversion at 55 °C for 2 h,[4] reaction 3 is notably sluggish and leads to disclosure of an expected but new type substituent effect of reagent. At both the temperatures, the conversion becomes greater as the substituent changes from MeO via Me and H to Cl. Thus the conversion manner indicates the substituent effect on positive charge of the reagent's Mg atom; the strong charge of Cl reagent is favorable for the σ-complex formation. For estimating the acceleration by temperature elevation, the conversion per 1 h at 55 °C was compared with that at room temperature. A rough estimate, 33-, 13-, and 11-folds for accelerations by MeO, Me, and Cl reagents, respectively, indicates the "coordination controlled" character of reaction 2.

By use of 2.4 mol of IDMg, the conversion became fairly high, and the substituent effect of reagent was unobservable. These facts suggest a cooperation of two IDMg molecules;[10] the σ-complex is formed by one and electron-donating addition of the other, in which substituent effect may compensate with each other. Instead, the effect of substrate appears in a novel U-shaped manner shown in Fig. 1 by the typical results of Runs 2—5 using MeO-substituted IDMg. The conversion is higher in the cases of MeO and Cl substrates and is lower in the cases of Me and H substrates. The U-shaped variation is common to almost all the runs using fixed substituent of IDMg at both the temperatures (Runs 7—10, 12—15, 17—20, 22—25, and 26—30). The variation is conceivable if

a) The condition A: at 55 °C for 3 h; B: at room temperature for 16 h.

we assume that the σ-complex formed at the most essential process of reaction 3 is a "loose" one due to steric repulsion by the ferrocenyl group with reference to that expected in reaction 1b. As the substituent changes from MeO via Me and H to Cl, the EAA becomes stronger,[2] while the σ-complex becomes more loose. Thus the high reactivity of the Cl substrate is ascribed to its strong EAA, whereas the reactivity of the MeO substrate is ascribed to formation of a fairly tight σ-complex which assists the substrate in accepting electrons.[7]

The formation of small amount of *sym*-azoarene, observed also for the first time among IDMg reactions of type 1b, becomes appreciable at lower temperatures. The formation, in spite of the much milder electron transfer, is not unexpected according to the mechanism of two electron oxidation of IDMg molecules proposed recently.[9] At lower temperatures favorable for accumulating the "loose" σ-complex, a small part of which tends to dissociate, after electron transfer, into ketyl and arylaminyl radicals due to steric repulsion. The latter radicals produced in proximity to each other undergo disproportionation and dimerization affording *sym*-azoarenes.[9]

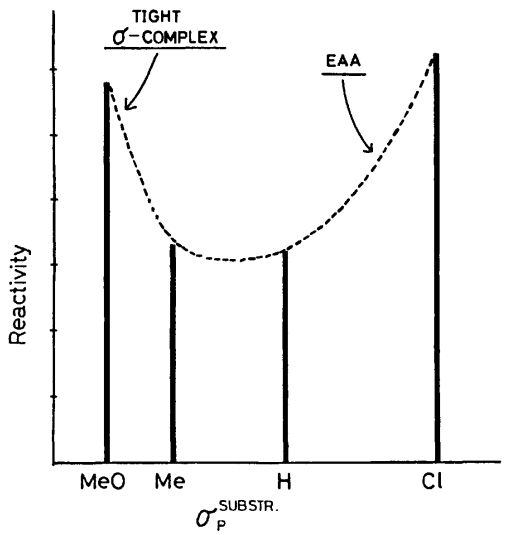

Fig. 1. Schematic diagram for the relative reactivities of *p*-substituted benzoylferrocenes.

Electronic Absorption of Deeply Colored Azoxy- and Azoferrocenes. The azoxy- and azoferrocenes (**1** and **2**) form deep-red crystals. The electronic absorption maxima obtained by measurements in 1,4-dioxane are summarized in Table 3; those of azoxy- and azobenzenes are listed for comparison. The deep color of **1** and **2** is ascribed to the d-d transition[11] as shown below.

The azoxyferrocenes have two absorption maxima: λ^A in the region of 320—350 nm and λ^B in that of 475—495 nm. As shown in Table 3, λ^A shifts toward red depending on the electron-repelling resonance effect of the substituent in the manner similar to that of λ^C of azoxybenzenes; both λ^A and λ^C are assigned to the $\pi\rightarrow\pi^*$ transition. In contrast, λ^B shifts toward blue depending on the inductive effect of the substituent, and is assigned to the d-d transition.

The azoferrocenes have also two absorption maxima: λ^D in the region of 320—340 nm and λ^E in that of 520—540 nm. As shown in the table, λ^D as well as λ^F of azobenzenes shift in the manner similar to λ^A and λ^C, and is assigned to the $\pi\rightarrow\pi^*$ transition. While λ^G of azobenzene in the region of 430—440 nm is assigned to the $n\rightarrow\pi^*$ transition, λ^E shifts in the manner similar to λ^B and is assigned to the d-d transition. The possibility that the λ^E band overlaps with the $n\rightarrow\pi^*$ band can, however, not be excluded.

Molecular Structures of Azoxyferrocene (1), Azoferrocene (2), and *N*-(Ferrocenylarylmethylene)aniline (4). An unexpected chemical shift of cyclopentadienyl protons was disclosed from comparison of azoxy- and azoferrocenes (**1** and **2**, Fig. 2). Usually in *p*-substituted azoxybenzenes, both the two doublets of AB-quartet appear at lower magnetic fields compared to those of the corresponding azobenzenes.[3] In a similar manner, one of the two narrow triplets of cyclopentadienyl protons of **1** appears at a lower field

aniline, Table 5) was also carried out.

The structure of the three molecules is shown in Fig. 3; the numbering schemes of atoms and the definition of planar groups are given in the figure. The structures are viewed from the direction perpendicular to the plane passing through C(1), N(1), and N(2) atoms in $\mathbf{1}^{MeO}$ and $\mathbf{2}^{Cl}$, whereas C(1), C(41), and N atoms in $\mathbf{4}^{MeO}_{H}$. The dihedral angles between the planar groups are shown in Table 6. Crystal data, selected bond lengths and angles are summarized in Tables 7—9. Tables of atomic coordinates, thermal parameters, and observed and calculated structure factors are kept at the Chemical Society of Japan, Document No. 8767.

A common structural feature of the three molecules is that cyclopentadiene and -dienyl rings in ferrocenyl moiety are in an eclipsed conformation, which was reported previously in the case of ferrocenecarboxylic acid.[12] The presence of oxygen atom attached to diazo group in $\mathbf{1}^{MeO}$ seems to have a little effect on the overall conformation of molecule (vide infra), judging from the tabulated values of molecular dimensions. The effective delocalization of π-electrons of diazo and phenyl groups in $\mathbf{1}^{MeO}$ and $\mathbf{2}^{Cl}$ is shown by the

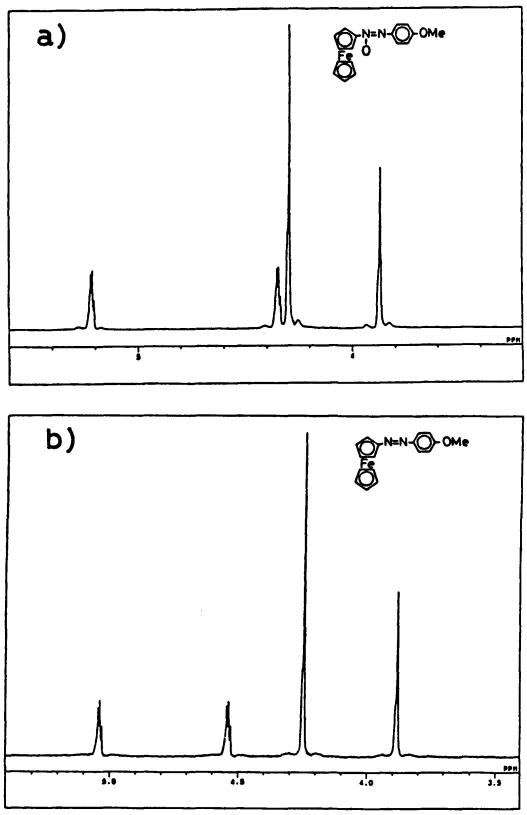

Fig. 2. Cyclopentadienyl proton chemical shift of azoxy- and azoferrocenes.

tabulated values of bond length.

The structure of 4^{MeO}_{H} is quite different from those of 1^{MeO} and 2^{Cl}, mainly because of the steric repulsion between the two phenyl rings. These rings are perpendicular to C(1), C(41), and N planes. No delocalization of π-electrons is indicated by the

C(41)-N bond length of 1.272(5) Å which is comparable to the value of the pure C=N bond.

The projection of diene plane(2) on dienyl plane(1) of 1^{MeO} and 2^{Cl} is shown in Fig. 4. In contrast to almost completely eclipsed conformation of 2^{Cl}, the plane 2 in 1^{MeO} is slightly twisted from the plane 1 seemingly due to steric repulsion with the negative azoxy oxygen caused by planarity. The twist, however, does not provide any clue to elucidation of the abnormal chemical shift of 3- and 4-protons of dienyl ring observed in solution (vide supra), because the singlet signal of the diene protons (δ 4.22—4.24, Fig. 2 and Table 4) indicates the free rotation. The low barrier to internal rotation of diene planes in ferrocene was reported.[13] It is significant that both the pairs of narrow triplets of 1^R and 2^R have almost the same centers at δ 4.73—4.84, and that the splitting by ca. 0.43 ppm from the center of 1^R is notably larger than that by ca. 0.26 ppm of 2^R. The large splitting suggests a participation of polarized resonance structure of the dienyl ring of 1^R caused by positive azoxy nitrogen. The polarization may be the true reason causing the ^1H NMR anomaly (Fig. 2) as well as the twist (Fig. 4).

Data of ^1H NMR summarized in Tables 4 and 5 are similar to each other. Thus it may be concluded that all the products, 1^R, 2^R, and $4^{R^1}{}_{R^2}$, have the molecular structures same as those described above.

General Discussion. The simple EDA-EAA concept, useful for understanding the reactions of magnesium reagents with noncrowded benzene derivatives,[2] seems unsuitable for extending directly to the IDMg reactions with somewhat bulky and electron rich ferrocene derivatives. However, new type substituent effects were disclosed and elucidated, in line with the previous discussion,[2] by modifying the concept based on the effect of ferrocenyl group retarding two initial processes of the reactions.

The elucidation of the results of reactions is compatible with the structure analyses of products. The coplanar structure of 1^R is distinct from twisted ones of azoxybenzenes; an example of the latter having the dihedral angle of ca. 23 degree between the two phenyl rings was reported.[14] The planarity and effective π-electron delocalization of 1^R lead to reduction of the positive charge on azoxy nitrogen making it unfavorable to the attack of anionic IDMg nitrogen (vide supra).[9] Thus the quite sluggish deoxygenation of 1^R in reaction 2 is most plausibly ascribed to its planar structure involving the electron rich ferrocenyl group. The perpendicular twist between ferrocenyl and phenyl planes in $4^{R^1}{}_{R^2}$ reflects the steric repulsion responsible for the sluggishness of reaction 3.

The synthetic aspect of formation of **1**, **2** (reaction 2), and **4** (reaction 3) should be noted, though the optimum conditions for preparing them were undetermined. Azo-substituted ferrocene is so far difficult to access because of the instability of ferrocene ring under diazotization conditions. The symmetrical diferrocenyl diazene is known,[15] and only one phenylazo derivative was prepared in a low yield by treating an equimolar mixture of phenylazo- and unsubstituted cyclopentadienyllithiums with iron(II) chloride.[16] Neither symmetrical nor unsymmetrical azoxyferrocene has been reported. Thus the IDMg procedure will provide a convenient route for preparing unsymmetrical azoxy- and azoferrocenes if the method for preparing nitroferrocene (See Experi-

mental) is improved. Concerning the condensation of diaryl ketones with anilines, a Lewis acid catalyst (e.g., BF_3) gives sufficient yields of anils only when the carbonyl component is a strong electrophile, e.g., fluorenone and its nitro derivatives.[3] In contrast, the IDMg procedure applied to the moderate electrophiles such as benzophenones can be extended to the extremely weak electrophile, i.e., benzoylferrocenes.

Experimental

Materials and Reaction Procedures. Nitroferrocene was obtained in yields lower than 20% by lithiation of ferrocene with BuLi followed by nitration with N_2O_4.[17] Benzoylferrocenes were prepared in good yields by Fridel-Crafts method using appropriate aroyl chlorides.[18] The IDMg reactions were carried out by adding the substrate (1.3 mmol) dissolved in THF (10 ml) to a solution of reagent in THF (35 ml) at 0 °C, and the resulting mixture was stirred at 55 °C or at room temperature (8—12 °C); the reaction times are given in Tables 1 and 2. The products were separated by column chromatography on silica gel (Wako Gel C-200 and C-300). The melting points, the elemental analysis results, and ^1H NMR data are summarized in Tables 4 and 5. The melting points are uncorrected. The trace amount of ferrocenylarylmethanols in reaction 3 was confirmed by ^1H NMR signal of benzylic proton appearing at δ 4.05—4.25.

Crystallographic Analyses. The three dimensional structures of $\mathbf{1}^{MeO}$, $\mathbf{2}^{Cl}$, and $\mathbf{4}^{MeO}{}_H$ were established by X-ray diffraction. The intensity data were collected on an automated single-crystal diffractometer by use of graphite-monochromated Mo $K\alpha$ radiation. The structure was solved by combined use of the direct method with MULTAN 78 and heavy atom method, and then refined by the block-diagonal least-squares procedure. Anisotropic temparature factors are assigned for non-hydrogen atoms except for methyl carbon atom in $\mathbf{1}^{MeO}$. Hydrogen atoms were not considered in structure factor calculation for $\mathbf{1}^{MeO}$ and $\mathbf{2}^{Cl}$, whereas they could be located in the difference map for $\mathbf{4}^{MeO}{}_H$ and were included in the least-squares computations. Absorption correction was not applied; it may limit the accuracy of the present structure analyses. Crystal data and some indices concerning the results of structure determination were listed in Tables 7—9.

The authors wish to thank Dr. Shuji Emori, Saga University, for his helpful discussion on the molecular structures of azoxy- and azoferrocenes. The authors are grateful to the Ministry of Education, Science and Culture for a financial support by a Grant-in-Aid for Scientific Research (No. 60470026).

(Received June 9, 1987)

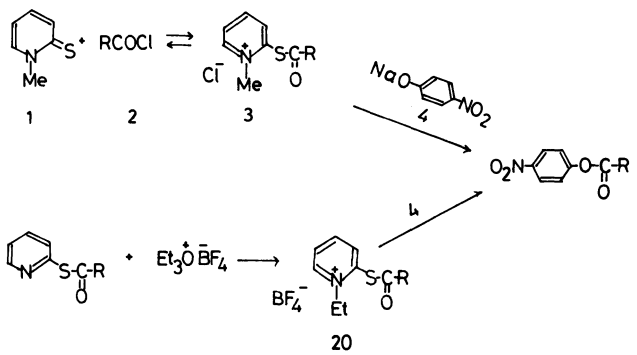
Reaction of phenols, amines, and acids with 2-benzoylthio-1-methylpyridinium chloride prepared in situ from benzoyl chloride and 1-methyl-2(1*H*)-pyridinethione, afforded the corresponding benzoyl derivatives in good yields. In the reaction of *p*-nitrophenol, even a catalytic amount of 1-methyl-2(1*H*)-pyridinethione proved to be effective. Similar reactions of *p*-nitrophenol with isobutyryl chloride and acetyl chloride in the presence of 1-methyl-2(1*H*)-pyridinethione afforded *p*-nitrophenyl isobutyrate and *p*-nitrophenyl acetate in 63 and 44% yields, respectively. 2-Benzoylthio-, 2-acetylthio-, and 2-isobutyrylthio-1-ethylpyridinium tetrafluoroborates were prepared by treatment of the corresponding 2-acylthiopyridines with triethyloxonium tetrafluoroborate. These pyridinium salts also acted as acylating agents in an aqueous phase. Some competitive reactions of 2-aminoethanol and phenols with 2-benzoylthio-1-methylpyridinium chloride were also investigated.

Conversion of the reaction medium from a nonaqueous phase into an aqueous phase can be useful, especially for treatment of enzymes or proteins, because they are generally more or less denatured in organic solvents. On the other hand, esters of carbothioic *S*-acids are much more reactive than the corresponding carboxylic acid esters and frequently serve as acylating agents in biological reactions, e.g., acetyl-CoA.[1] As one of the candidates for water-soluble acylating agents, we chose 2-acylthio-1-alkylpyridinium salts;[2] the pyridinium moiety should not only activate the *S*-thioester but also make the compounds water-soluble.[3]

Results and Discussion

Treatment of 1-methyl-2(1*H*)-pyridinethione (**1**) with benzoyl chloride (**2a**) in refluxing acetonitrile for 2 h afforded 2-benzoylthio-1-methylpyridinium chloride (**3a**) as a highly hygroscopic precipitate. Its ^{1}H NMR spectrum showed that the salt **3a** was stable in D_2O, at least for 1 h, suggesting that it might act as a benzoylating agent in an aqueous layer. In fact, addition of sodium *p*-nitrophenoxide (**4**) to an aqueous solution containing a crude **3a** gave *p*-nitrophenyl benzoate (**5a**) in 50% yield. The salt **3a**, however, was in equilibrium with the starting materials (**3a**:**1**=ca. 1:4) in chloroform-*d*.

When **1** and **2a** were mixed in $CDCl_3$–D_2O, it is shown later that the salt **3a** formed in the organic layer is selectively extracted into the aqueous layer. This led to a more convenient 'one-pot' procedure; without isolation of **3a**, direct addition of water-soluble sodium *p*-nitrophenoxide (**4**) to a chloroform–water solution of **1** and **2a** afforded the ester **5a** in 81% yield. Similar treatment of phenol, 2,4-dinitrophenol, and 2-aminoethanol in the presence of an equimolar amount of 1 M NaOH (1 M=1 mol dm^{-3}) gave phenyl benzoate (**6**), 2,4-dinitrophenyl benzoate (**7**), and *N*-(2-hydroxyethyl)benzamide (**8**) in 83, 73, and 67% yields, respectively.



a: R=Ph, b: R=CHMe$_2$, c: R=Me, d: R=OEt

Since 1-methyl-2(1*H*)-pyridinethione (**1**) regenerates after benzoylation, a catalytic amount of **1** might promote the reaction.[4] Benzoylation of **4** was performed, therefore, in changing the amounts of **1**. As shown in Table 1, benzoylation was accelerated with the increase of **1**, but even 0.01 equimolar amount of **1** was found to be effective, giving **5a** in 65% yield.

If a product formed in an aqueous phase is extracted smoothly into an organic phase, a heterogeneous system is applicable for the preparation of such a fairly water-sensitive compound as an acid anhydride. Sodium acetate, therefore, was added to a chloroform–water solution of **1** and **2a**, providing acetic benzoic anhydride **10** in 83% yield as estimated from ^{1}H NMR spectroscopy. Formation of acetanilide (59%) by addition of aniline to the crude product proved that acid anhydride **10** had been generated. Similar reactions of **3a** with several acids in the

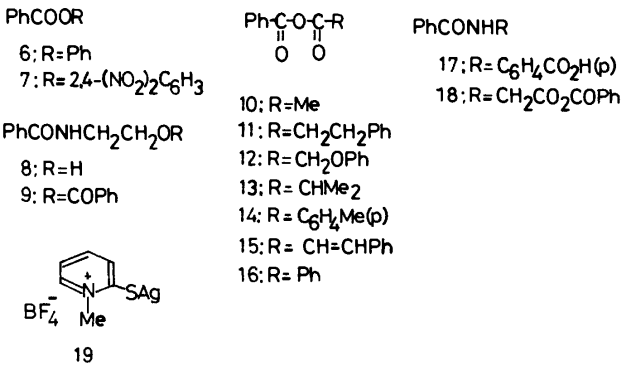
a) Prepared in situ from **1** and **2a** in $CHCl_3$–H_2O. The reaction mixture was stirred for 1.5 h at room temperature, except for the case of sodium *p*-nitrophenoxide (2 h). b) Equimolar amount of base was used. c) Estimated by ^1H NMR spectroscopy; figures in parentheses showed the yields isolated as the corresponding anilides; besides the anilides, benzanilide was obtained in 6, 18, trace, 26, and 55% yields, respectively, from **10**—**14**. d) Small amounts (5%) of dibenzoyl derivative **9** was isolated.

presence of an equimolar amount of sodium hydrogencarbonate or sodium hydroxide afforded the corresponding mixed acid anhydrides in moderate to good yields (Table 2). Furthermore addition of sodium hydroxide to a chloroform-water solution of **1** and **2a** yielded benzoic anhydride (**16**) in 79% yield. This reaction should involve hydrolysis of **2a**, followed by nucleophilic attack of the benzoic acid thus produced on **3a**. Under the same conditions, but in the absence of **1**, hydrolysis of **2a** occurred predominantly to give benzoic acid together with small amounts of benzoic anhydride and benzoyl chloride.

When **3a** was similarly treated with trifluoroacetic acid, only the hydrolysis was observed. This is reasonable because benzoic trifluoroacetic anhydride was hydrolyzed within 10 min by stirring it in a benzene-water solution.

Reaction of *p*-aminobenzoic acid with **3a** gave the *N*-benzoyl derivative **17** in 75% yield, whereas benzoylation of glycine yielded the *N,O*-dibenzoyl derivative **18** (19%), which was partially converted into *N*-benzoylglycine during column chromatography or recrystallization.



19

An aqueous solution of sodium *p*-nitrophenoxide (**4**) was added to a chloroform–water solution of **1** and isobutyryl chloride, giving the ester **5b** in 63% yield based on isobutyryl chloride. Similar reaction of **4** with acetyl chloride provided the acetate **5c** in 44% yield. Under the same conditions, but in the absence of **1**, the acetate **5c** could not be obtained.

In order to obtain some information about the partition of **3** between chloroform and water as well as the stability of **3**, the following ^1H NMR spectral investigation was performed. (i) In a NMR sample

Table 3. The Ratios of **3** to **1** in Chloroform-*d* and Partition of **3** between Chloroform-*d* and Deuterium Oxide

a) In the absence of D_2O: Calculated by method (i). b) Calculated by method (ii). c) The chemical shift of the 1-methyl signal of **3**. d) Most acyl chloride was hydrolyzed, since strong signals of the methyl groups of isobutyric acid and acetic acid were observed, respectively.

tube, **1** (0.2 mmol) and acyl chloride (0.2 mmol) were dissolved in $CDCl_3$ (0.2 ml) and the reaction was monitored by ^1H NMR spectroscopy; the ratio of **1** and **3** was calculated on the basis of area-ratios due to the 1-methyl signal of **1** (δ=4.00) and that of **3** (see, Table 3). (ii) After 1 h, D_2O (0.2 ml) was added to the sample tube and the ratios of **1** to **3** in both the layers were determined by comparing the integration of the methyl signals due to **1** and **3** with that of toluene (added as an internal standard). The results are shown in Table 3. The salts **3a**—**c** were formed immediately and equilibrated with the starting material within 10 min, whereas formation of **3b** was slow and even after 1 h, equilibrium was not attained. Under the same conditions, however, *p*-toluenesulfonyl chloride did not afford the corresponding salt. The salts **3a** and **3d** were fairly stable in an aqueous layer, but the salt **3c** was sensitive to water. In accord with expectation, the stability of **3b** stood between **3a** and **3c**.

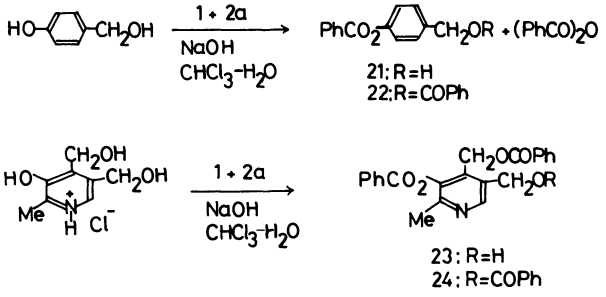
Treatment of sodium *p*-nitrophenoxide with ethyl chloroformate in the presence of **1** afforded the carbonate **5d** in 32 and 70% yields, respectively, after 1.5 h and 5 h. In the absence of **1**, however, the carbonate **5d** formed in 61% yield after 5 h.

Several attempts to purify **3a** failed, mainly owing to its reversibility in solution. Therefore, the counter ion was changed to a less nucleophilic tetrafluoroborate. After reflux of an acetonitrile solution of **1** and **2a** for 2 h, silver tetrafluoroborate was added to give water-insoluble precipitates. Its IR and/or ^1H NMR spectra indicated the absence of a carbonyl group, but the presence of a *N*-methyl group (δ=4.07, DMSO-d_6) and the characteristic absorption band for tetrafluoroborate (1000—1150 cm^{-1}). The same compound was obtained by treatment of **1** with silver tetrafluoroborate, as judged by IR spectroscopy. From these results the product was tentatively assigned to **19**.

The intending tetrafluoroborate **20a** was prepared by *N*-ethylation of 2-benzoylthiopyridine with triethyloxonium tetrafluoroborate in 85% yield. The salt **20a** is fairly stable at room temperature even in an open vessel and is soluble in chloroform as well as in water. Similar treatment of 2-isobutyrylthiopyridine and 2-acetylthiopyridine afforded the corresponding salts **20b** and **20c** as a syrup, respectively. The latter two salts gradually turned yellow even in a desiccator over phosphorus pentaoxide and they were soluble in water but insufficiently soluble in chloroform. By this route water-soluble acylating agents could be synthesized from carboxylic acid, since 2-acylthiopyridines were prepared by treatment of the corresponding carboxylic acid with 2-pyridinethiol in the presence of di-2-pyridyl sulfide-triphenylphosphine[5] or dicyclohexylcarbodiimide.[6]

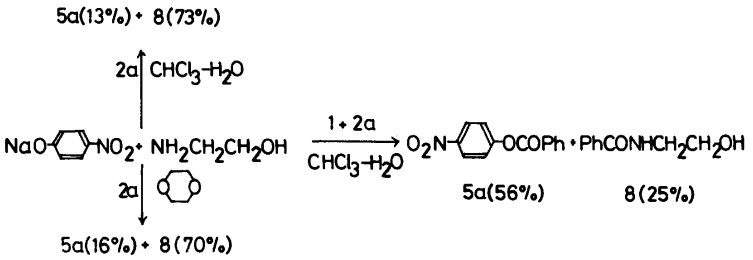
Treatment of the phenoxide **4** with the salts **20a**—**c** in water yielded the corresponding esters in 95, 80, and 73% yields, respectively.

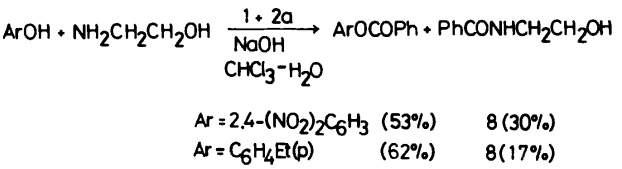
Addition of an equimolar amount of 1 M sodium hydroxide and either methanol or benzyl alcohol to a chloroform–water solution of **1** and **2a** gave the corresponding esters in only 2.4 and 10% yields, respectively. These results suggested that it may be possible to achieve selective benzoylation of the phenolic hydroxyl group, if the compounds have both alcoholic and phenolic hydroxyl groups. In fact benzoylation of *p*-hydroxybenzyl alcohol with **3a** afforded *p*-(hydroxymethyl)phenyl benzoate (**21**) (49%) and dibenzoate **22** (3%).[7] Similar reaction of pyridoxol hydrochloride gave 3,α^4-dibenzoate **23** in 36% yield. Since migration of the acyl group from C-3 to C-4 was known to occur,[8] two equimolar amounts of **3a** were used; the yield of **23** was raised to 75%, together with the perbenzoate **24** (7%).



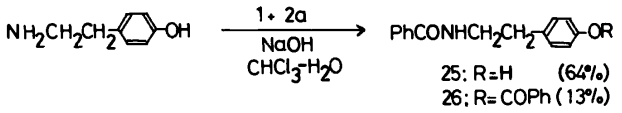
Addition of an equimolar amount of sodium *p*-nitrophenoxide and 2-aminoethanol to **3a** (generated in situ) provided the benzoate **5a** and benzamide **8**

(isolated as the acetate) in 56 and 25% yields, respectively. On the other hand, in the absence of **1** similar heterogeneous or homogeneous reactions with **2a** gave **5a** and **8** in 13 and 73% or 16 and 70% yields, respectively. In similar competitive reactions between 2-aminoethanol and 2,4-dinitrophenol or *p*-ethylphenol, predominant benzoylation of phenolic hydroxyl groups was also observed in the presence of **1**.





Contrary to the competitive reactions described above, benzoylation of tyramine, having both amino and phenolic hydroxyl groups in the same molecule, with **3a** preponderant gave the *N*-benzoyl derivative **25** (64%) together with the *N,O*-dibenzoyl derivative **26** (13%) and unreacted tyramine (11%, recovery).[9]



Such a difference may be explained as follows. The amino group might be more reactive than the phenoxide ion towards **3a**. Benzoylation of phenoxide ion, however, should be entropically favorable, since the phenoxide ion could become the counter ion of the pyridinium salt, but 2-aminoethanol could not. But, in the case of tyramine, which should be captured as the counter ion of pyridinium salt, such an entropical predominance seems to be negligible and the more reactive amino group would be preferentially benzoylated.

Experimental

General. All melting points are uncorrected. ^{1}H NMR spectra were recorded with a Varian EM-360A Spectrometer in $CDCl_3$ and D_2O solution with tetramethylsilane and DSS, respectively, as an internal standard. IR Spectra were determined with a Hitachi 285 Infrared Spectrophotometer. Column chromatography was performed on silica gel (Wako, C-300). The organic solutions were dried over magnesium sulfate and distilled under reduced pressure.

2-Benzoylthio-1-methylpyridinium Chloride (3a). A solution of 1-methyl-2(1*H*)-pyridinethione (**1**) (1.81 g, 14.5 mmol) and benzoyl chloride (**2a**) (2.04 g, 14.5 mmol) in acetonitrile (15 ml) was heated under reflux for 2 h and cooled at room temperature. Addition of diethyl ether to the mixture caused hygroscopic precipitates; ^{1}H NMR ($CDCl_3$) δ=4.00 (s, N-Me), 4.80 (s, N^+-Me), 6.70 (d, pyridine ring proton at 6), and 7.10—8.85 (m, ring protons); ^{1}H NMR (D_2O) δ=4.05 (s, N-Me), 4.37 (s, N^+-Me), 7.35—8.80 (m, ring protons), and 9.18 (d, pyridinium ring proton at 6). Attempts to purify the precipitate failed. The ^{1}H NMR spectrum in $CDCl_3$ showed that the salt **3a** attained an equilibrium with the starting material (**3a**:**1**=ca. 1:4).

Benzoylation of Sodium *p*-Nitrophenoxide with 3a. (a) The precipitate of **3a** (61 mg) and sodium *p*-nitrophenoxide (**4**) (37 mg, 0.23 mmol) was dissolved in water (2 ml). After being stirred for 30 min at room temperature, the mixture was extracted with chloroform. The extracts were combined and evaporated. The residue was chromatographed with dichloromethane to afford 28 mg (50%) of *p*-nitrophenyl benzoate (**5a**). (b) To an ice-cooled solution of the pyridinethione **1** (126 mg, 1.01 mmol) and benzoyl chloride (142 mg, 1.01 mmol) in chloroform (5 ml) was added water (5 ml) and the mixture was stirred for 5 min. After addition of **4** (163 mg, 1.01 mmol) at 0 °C, the mixture was stirred for 2 h at room temperature and extracted with chloroform. Similar processing as described above afforded 199 mg (81%) of **5a**.

Benzoylation of Phenol. To a solution of **1** (136 mg, 1.09 mmol) and benzoyl chloride (153 mg, 1.09 mmol) in chloroform (5 ml) was added water (3 ml) and the mixture was stirred for 5 mim and cooled with ice-water. A solution of phenol (103 mg, 1.09 mmol) in water (8 ml) containing 1 M NaOH (1.09 ml) was added over 15 min and the mixture was stirred for an additional 1.5 h at room temperature and then extracted with chloroform. The combined extracts were dried, and evaporated to a syrup, which was chromatographed with dichloromethane, to give 178 mg (82%) of phenyl benzoate (**6**).

Similar treatment of 2,4-dinitrophenol (201 mg, 1.09 mmol) gave 2,4-dinitrophenyl benzoate (**7**) in 73% (229 mg) yield.

Benzoylation of 2-Aminoethanol. Similar treatment of 2-aminoethanol (67 mg, 1.1 mmol) described for the pre-

paration of **6** afforded a syrup, which was chromatographed with chloroform, to give successively 17 mg (7%) of benzoic anhydride, 15 mg (5%) of the *N,O*-dibenzoyl derivative **9**, and 38 mg (21%) of the *N*-benzoyl derivative **8**. The residue obtained by evaporation of the aqueous layer was extracted with chloroform and the extracts were evaporated to give 83 mg of **8** (total yield 67%).

Typical Procedure for the Preparation of Acid Anhydride; Acetic Benzoic Anhydride (10): To an ice-cooled solution of **1** (179 mg, 1.43 mmol) and **2a** (201 mg, 1.43 mmol) in chloroform (10 ml) were added 5 ml of water and the solution was stirred for 5 min. To the mixture was added sodium acetate (117 mg, 1.43 mmol) at 0 °C. After being stirred for 1.5 h at room temperature, the mixture was extracted with chloroform and the combined extracts were dried, and evaporated to a syrup. The yield of acetic benzoic anhydride (83%) was deduced on the basis of signals due to the 1-methyl group of **1** (δ=4.00) and the acetyl group of **10** (δ=2.35). In its spectrum, the acetyl signals of acetic acid (δ=2.09) and acetic anhydride (δ=2.20) were negligible. Purification by column chromatography with benzene provided 61 mg (26%) of **10**, together with 87 mg (50%) of benzoic acid. Sublimation of the anhydride was found to be unsuitable because of the co-sublimation of **1**. To a chloroform solution (2 ml) of the crude product was added aniline (133 mg, 1.43 mmol). The mixture was kept for 3.5 h at room temperature, diluted with chloroform and washed successively with dilute HCl, aq $NaHCO_3$, and water, dried, and evaporated. The syrup was chromatographed with dichloromethane to yield acetanilide (114 mg, 59%) and benzanilide (17 mg, 6%).

Similar treatment of the acid, except for the addition of an equimolar amount of sodium hydrogencarbonate, afforded the corresponding acid anhydride. The estimated yield of benzoic 3-phenylpropionic anhydride (**11**) (based on the ethylene signals at δ=3.00) and benzoic phenoxyacetic anhydride (**12**) (methylene signals at δ=4.91) were 82 and 79%, respectively.

Similar treatment of the acid, except for the use of sodium hydroxide instead of sodium hydrogencarbonate, provided benzoic isobutyric anhydride (**13**) (61%, methyl signals at δ=1.36 and 1.25), benzoic *p*-toluic anhydride (**14**) (91%, methyl signal at δ=2.45), benzoic cinnamic anhydride (**15**) (66%, signals of olefinic proton at δ=6.70 and 6.43).

Benzoic Anhydride (16). To a stirred solution of **1** (1.12 mmol) and **2a** (1.12 mmol) in 10 ml of chloroform was added 4 ml of water at room temperature and the solution was stirred for 5 min. To the solution was added over 5 min 1 M NaOH (1.12 ml) and the mixture was stirred for 1.5 h and extracted with chloroform. The extracts were evaporated and the residue was chromatographed with chloroform, to give 100 mg (79%) of **16**.

Benzoylation of *p*-Aminobenzoic Acid and Glycine. Similar treatment of *p*-aminobenzoic acid (196 mg, 1.43 mmol) described for the preparation of **11** afforded 259 mg (75%) of **17**.

Glycine (107 mg, 1.43 mmol) was similarly benzoylated. After chromatography with dichloromethane, the *N,O*-dibenzoyl derivative **18** was isolated in 77 mg (19%); IR (KBr) 1810, 1655, and 1450 cm^{-1}; ^1H NMR ($CDCl_3$) δ=4.42 (4H, s, $-CH_2-$), 7.35—7.75 and 7.90—8.25 (10H, m, 2×Ph). Purification of **18** failed because of partial hydrolysis to *N*-benzoylglycine during recrystallization from benzene.

Acylation of Sodium *p*-Nitrophenoxide. (a) To an ice-cooled solution of **1** (120 mg, 0.96 mmol) and isobutyryl chloride (102 mg, 0.96 mmol) in chloroform (5 ml) and water (5 ml) was added sodium *p*-nitrophenoxide (**4**) (155 mg, 0.96 mmol). After being stirred for 1 h at room temperature, the mixture was extracted with chloroform. The combined extracts were dried, and evaporated. The residue was chromatographed with chloroform to give 126.4 mg (63%) of **5b**.

(b) Similar treatment of acetyl chloride (75 mg, 0.96 mmol) with **4** (0.96 mmol) afforded 76 mg (44%) of *p*-nitrophenyl acetate (**5c**).

Ethyl *p*-Nitrophenyl Carbonate (5d). Similar treatment of ethyl chloroformate (104 mg, 0.96 mmol) with **4** as described above gave **5d** in 32% yield. When the reaction time was extended to 5 h, the yield was raised to 70%.

Similar treatment in the absence of **1** for 5 h afforded **5d** in 61% yield.

Attempt at Preparation of 20a by Exchange of the Counter Ion. Compound **1** (2.06 mmol) and **2** (2.06 mmol) was stirred for 5 min in chloroform (10 ml)–water (10 ml) and the organic layer was drawn off. To the aqueous layer was added silver tetrafluoroborate (2.06 mmol). After filtration of the precipitates, the filtrate was freeze-drying to give 230 mg of hygroscopic powder; IR (KBr) 1620, 1540, 1490, 1420, 1400, 1260, 1050, 760, and 700 cm^{-1}.

The same product, as judged from IR spectroscopy, was obtained by treatment of **1** with silver tetrafluoroborate.

2-Benzoylthio-1-ethylpyridinium Tetrafluoroborate (20a). A suspension of benzoic acid (3.66 g, 30 mmol) and 2-pyridinethiol (3.33 g, 30 mmol) in dry ethyl acetate (18 ml) was cooled with ice-ethanol (ca. −12 °C). To the solution was added over 10 min a solution of dicyclohexylcarbodiimide (6.18 g, 30 mmol) in dry ethyl acetate (15 ml) with stirring. After being cooled at ambient temperature, the mixture was kept overnight at room temperature . After filtration, the filtrate was evaporated and the residue was purified by bulb to bulb distillation, bp 145 °C (oven temperature)/0.1 Torr (1 Torr=133.322 Pa), to afford 5.03 g (78%) of 2-benzoylthiopyridine. The same compound was also prepared from sodium 2-pyridinethiolate with benzoyl chloride.[10]

To an ice-cooled solution of triethyloxonium tetrafluoroborate (190 mg, 1 mmol) in dichloromethane (1 ml) was added a solution of 2-benzoylthiopyridine (210 mg, 0.98 mmol) in dichloromethane (1.5 ml) with stirring. The mixture was stirred overnight at room temperature and filtered (14 mg of a precipitate was obtained, which had no ethyl group). The filtrate was washed with diethyl ether (decantation). Reprecipitation from acetone–diethyl ether afforded 276 mg (85%) of **20a**, mp 79—80 °C; IR (KBr) 1695, 1600, 1490, and 1060 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.58 (3H, t, J=7.0 Hz, Et), 4.90 (2H, q, Et), 7.35—8.90 (8H, m, Ph and H-3, H-4, and H-5 of the pyridine ring), and 9.36 (1H, d, J=7.0 Hz, H-6 of the pyridine ring). Found: C, 50.38; H, 4.17; N, 4.22; S, 9.98%. Calcd for $C_{14}H_{14}NOSBF_4$: C, 50.78; H, 4.26; N, 4.23; S, 9.68%.

1-Ethyl-2-isobutyrylthiopyridinium Tetrafluoroborate (20b). Similar treatment of isobutyrylthiopyridine with triethyloxonium tetrafluoroborate as described above afforded a syrup. It was partially purified by repeated decantation with dichloromethane–diethyl ether (ca. 70%), but complete purification was unsuccessful, because it

gradually turned yellow in a desiccator containing phosphorus pentaoxide, IR(KBr) 1740 and 1060 cm^{-1}; ^1H NMR (CD_3COCD_3) δ=1.36 (6H, d, J=7.0 Hz, $CHMe_2$), 1.68 (3H, t, J=7.0 Hz, Et), 3.30 (1H, m, $CHMe_2$), 5.03 (2H, q, Et), 8.30—9.05 (3H, m, ring protons), and 9.51 (1H, q, ring proton).

2-Acetylthio-1-ethylpyridinium Tetrafluoroborate (20c). Similar treatment of 2-acetylthiopyridine with triethyloxonium tetrafluoroborate gave **20c** as a syrup in ca. 88% yield, which also gradually turned yellow and failed to purify, IR (KBr) 1745, 1615, and 1060 cm^{-1}; ^1H NMR (CD_3COCD_3) δ=1.62 (3H, t, J=7.0 Hz, Et), 2.82 (3H, s, COMe), 4.98 (2H, q, Et), 8.22—9.05 (3H, m, ring protons), and 9.47 (1H, q, ring proton).

Acetylation of Sodium *p*-Nitrophenoxide with 2-Acylthio-1-ethylpyridinium Tetrafluoroborate. To a stirred solution of **20a** (166 mg, 0.53 mmol) was added sodium *p*-nitrophenoxide (81 mg, 0.50 mmol). After being stirred for 1 h at room temperature, the mixture was extracted with chloroform and the extracts were evaporated. The syrup was chromatographed with chloroform, to afford the ester **5a** in 95% yield.

Similar treatment of **20b** and **20c** with sodium *p*-nitrophenoxide provided the corresponding esters **5b** and **5c** in 80 and 73% yields, respectively.

Benzoylation of *p*-Hydroxybenzyl Alcohol. To an ice-cooled solution of **1** (2.86 mmol) and **2a** (2.86 mmol) in chloroform (10 ml) was added 10 ml of water and the mixture was stirred for 10 min. To the solution was added over 20 min a solution of *p*-hydroxybenzyl alcohol (355 mg, 2.86 mmol) and 1 M NaOH (2.86 ml) in 10 ml of water. After being stirred for 1.5 h at room temperature, the mixture was extracted with chloroform and the extracts were dried and evaporated. The residue was chromatographed with dichloromethane, to give successively benzoic anhydride (22% based on **2a**), *p*-(hydroxymethyl)phenyl benzoate (**21**) (320 mg, 49%), and *p*-[(benzoyloxy)methyl]phenyl benzoate (**22**) (29 mg, 3% based on the alcohol).

Benzoylation of Pyridoxol. Similar treatment of pyridoxol hydrochloride (588 mg, 2.86 mmol) as described above, but using two equimolar amounts of NaOH, yielded 389 mg (36%) of 3,α^4-dibenzoate (**23**). When two equimolar amounts of **1** and **2a** were used, the yield of **23** was raised to 75%, together with the tribenzoate **24** (7%).

Hydrogen chloride was bubbled into a solution of **23** in methanol-diethyl ether to give white crystals of the salt of **23**, mp 151—152 °C (lit, 152—153 °C).[8] The tribenzoate was recrystallized from ethanol; mp 120—121 °C (lit, 122 °C).[11]

Competitive Benzoylation between 2-Aminoethanol and Sodium Phenoxide. (a) In the Presence of 1. To a solution of **1** (1.96 mmol) and **2a** (1.96 mmol) in chloroform (10 ml) was added over 15 min a solution of sodium *p*-nitrophenoxide (**4**) (1.96 mmol) and 2-aminoethanol (1.96 mmol) in 10 ml of water at room temperature. After being stirred for an additional 1 h, the mixture was extracted with chloroform and the extracts were evaporated to a syrup, which was chromatographed with dichloromethane, to give 267 mg (56%) of **5a**. To the residue obtained by evaporation of the aqueous layer was added acetic anhydride (10 ml) and 0.5 ml of BF_3 etherate and the mixture was stirred overnight. After conventional work up, the residue was chromatographed with chloroform, to provide 101 mg (25%) of 2-(benzamido)ethyl acetate. An analytical sample was prepared by recrystallization from cyclohexane, mp 50—51 °C; IR(KBr) 3350 (NH), 1715 (CO), 1617 and 1513 cm^{-1} (NHCO). Found: C, 63.78; H, 6.36; N, 6.70%. Calcd for $C_{11}H_{13}NO_3$: C, 63.75; H, 6.32; N, 6.76%.

(b) In the Absence of 1. To a solution of **4** (1.96 mmol) and 2-aminoethanol (1.96 mmol) in 10 ml of water was added benzoyl chloride (**2a**) (1.96 mmol) in 10 ml of dichloromethane and the mixture was stirred for 24 h. Processing as described above afforded the ester **5a**, amide **8**, and 2-(benzamido)ethyl acetate in 13, 52, and 21% yields, respectively.

Similar benzoylation in 1,4-dioxane afforded **5a**, **8**, and 2-benzamidoethyl acetate in 16, 40, and 30% yields, respectively.

To a solution of **1** (2.07 mmol) and **2a** (2.07 mmol) in chloroform (20 ml)–water (4 ml) at ca. 5 °C was added an aqueous solution (24 ml) of 2,4-dinitrophenol (2.07 mmol), sodium hydroxide (2.07 mmol), and 2-aminoethanol (2.07 mmol). After being stirred for 1.5 h, the mixture was worked up as described above, to give the ester **7** (53%) and 2-(benzamido)ethyl acetate (30%).

Similar competitive reaction of 2-aminoethanol (2.02 mmol) and *p*-ethylphenol yielded *p*-ethylphenyl benzoate (62%) and 2-benzamidoethyl acetate (17%).

The possibility of benzoyl migration from *p*-nitrophenyl benzoate to 2-aminoethanol was excluded as follows. To a chloroform solution of **5a** (2.23 mmol) was added an aqueous solution (10 ml) of 2-aminoethanol (2.23 mmol) and the solution was stirred for 24 h. The organic layer separated was evaporated to afford the unchanged **5a** in 95% yield.

Benzoylation of Tyramine. To a solution of **1** (0.97 mmol) and **2a** (0.97 mmol) in chloroform (10 ml) was added a solution of tyramine (133 mg, 0.97 mmol) containing 1 M NaOH (0.97 ml) in water (10 ml) at room temperature. After being stirred for 1 h, the mixture was diluted with chloroform. The organic layer was washed with water and evaporated to a syrup, which was chromatographed with chloroform, to give 44 mg (13%, based on tyramine) of the dibenzoate **26** as the first fraction, mp 171—172 °C (lit, 172 °C).[12] The second fraction (150 mg, 64%) was the *N*-benzoyl derivative **25**, which was recrystallized from acetonitrile, mp 163—164 °C (lit, 162 °C).[13]

The aqueous layer was evaporated and the residue (870 mg) was acetylated to give 24 mg (11%) of the *N,O*-diacetyl derivative of tyramine, which was isolated by column chromatography with chloroform. The acetate was recrystallized from benzene, mp 97—98 °C; IR (KBr) 3300 (NH), 1770 and 1760 (CO), and 1643 (NHCO) cm^{-1}. Found: C, 64.86; H, 6.81; N, 6.29%. Calcd for $C_{12}H_{15}NO_3$: C, 65.14; H, 6.83; N, 6.33%.

The present work was partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education.

The Chiral Recognition of Optically Active Poly(triphenylmethyl methacrylate) Derivatives as Stationary Phases for HPLC[1)]

Yoshio Okamoto,* Eiji Yashima,† Motoshi Ishikura, and Koichi Hatada
Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560
(Received June 30, 1987)

Four *meta*-halogen- or *meta*-methyl-substituted optically active poly(triphenylmethyl methacrylate) [poly(TrMA)] derivatives with a one-handed helical structure were coated on macroporous silica gel and their chiral-recognition abilities as stationary phases for high-pherformance liquid chromatography were investigated with methanol or hexane–2-propanol (95:5(v/v)) as the eluent. The chiral-recognition abilities of poly(*m*-fluorophenyldiphenylmethyl methacrylate) and poly(*m*-chlorophenyldiphenylmethyl methacrylate) were slightly low compared with that of poly(TrMA) when methanol was used as the eluent. Poly[tris(*m*-chlorophenyl)methyl methacrylate] [poly(*m*-Cl_3TrMA)] showed no resolving ability, although poly[tris(*m*-tolyl)methyl methacrylate] [poly(*m*-Me_3TrMA)] had an effective chiral recognition ability and resolved some racemates more efficiently than poly(TrMA). When hexane–2-propanol (95/5) was used as the eluent, the optical-resolution abilities of all these chiral polymers except for poly(*m*-Cl_3TrMA) were rather similar to that of poly(TrMA) under the same eluent system. The chiral-adsorbing sites are considered to be the chiral triarylmethyl propellers in the methanol system; carbonyl groups may also be involved in the hexane–2-propanol system. The difference in the chiral-recognition abilities of the two tri-substituted chiral polymers were ascribed to their different propeller structures and/or the different conformations of their carbonyl groups. The optical-resolution abilities of poly[TrMA-*co*-(*m*-Cl_3TrMA)] and poly[TrMA-*co*-(*m*-Me_3TrMA)] were also investigated. From the results, the mechanism of the separation of enantiomers on poly(TrMA) was discussed.

Optically active poly(TrMA) is a unique polymer whose chirality is caused only by helicity; it is directly prepared by the asymmetric polymerization of TrMA with chiral anionic initiators, such as (−)-sparteine-butyllithium[2)] and (+)-(2*S*,3*S*)- or (−)-(2*R*,3*R*)-dimethoxy-1,4-bis(dimethylamino)butane (DDB)–lithium amide complexes[3)] in toluene at a low temperature. The polymer, especially when coated on macroporous silica gel,[4)] can resolve many racemic compounds, including hydrocarbons, esters, amides, and alcohols, most of which were first resolved on a poly(TrMA) column.[5)] As eluents, polar solvents like methanol are more effective than nonpolar solvents like hexane, indicating that the nonpolar interaction between the polymer, probably triphenylmethyl groups, and nonpolar groups of enantiomers plays an important role in chiral recognition.[5)] However, when methanol is used as the eluent, the ester groups of poly(TrMA) are slowly solvolyzed to form methyl triphenylmethyl ether.[6)] In order to improve this defect, we prepared (*m*-fluorophenyl)diphenylmethyl methacrylate (*m*-F_1TrMA), (*m*-chlorophenyl)diphenylmethyl methacrylate (*m*-Cl_1TrMA), tris(*m*-chlorophenyl)methyl methacrylate (*m*-Cl_3TrMA), tris(*m*-tolyl)methyl methacrylate (*m*-Me_3TrMA), and tris(*p*-chlorophenyl)methyl methacrylate (*p*-Cl_3TrMA), and then measured the rates of methanolysis by means of ^{1}H NMR spectroscopy.[7)] The methacrylates with electron-withdrawing substituents like halogen were much more stable against methanolysis than those with electron-donating substituents like the methyl group. All the methacrylates except for *p*-Cl_3TrMA gave optically active isotactic one-handed helical polymers with chiral anionic initiators in toluene at −78 °C.[7)] The CD spectra of these chiral polymers were greatly different from each other. We assumed that the difference is attributable to the different propeller structures and/or conformations of ester groups, including carbonyl groups.

In this article, we will investigate the optical-resolution abilities of these chiral polymers and chiral copolymers of TrMA; we will also discuss the mechanism of enantiomer recognition.

Experimental

Materials. Optically active poly(triphenylmethyl methacrylate) derivatives were prepared by the asymmetric polymerization of the corresponding monomer with chiral lithium initiators in toluene at −78 °C;[3,7)] the $[\alpha]_D^{25}$ values of the polymer in tetrahydrofuran (THF) were +343° [poly(TrMA)], +330° [poly(*m*-F_1TrMA)], +356° [poly(*m*-Cl_1TrMA)], −284° [poly(*m*-Cl_3TrMA)], and $[\alpha]_{546}^{25}$ −310° [poly(*m*-Me_3TrMA)]. The fractions which were soluble in THF and insoluble in benzene–hexane (1:1(v/v)) were used for the preparation of the chiral stationary phases.

Poly(TrMA-*co*-*m*-Cl_3TrMA) and poly(TrMA-*co*-*m*-Me_3TrMA) were prepared by asymmetric copolymerization with (+)- or (−)-DDB and *N*,*N*′-diphenylethylenediamine monolithium amide complex in toluene at −78 °C, as previously reported.[7)]

Most racemic compounds were commercially available or were prepared by the usual procedures.

Preparation of Stationary Phase. Macroporous silica gels, (Merck, LiChrospher SI 1000 (diameter, 10 μm; pore size, 100 nm) and SI 4000 (10 μm; 400 nm)), were treated

† Present address: Department of Applied Chemistry, Faculty of Engineering, Kagoshima University, Korimoto, Kagoshima 890.

with a large excess of dichlorodiphenylsilane in toluene at 110 °C for 24 h and with (3-aminopropyl)triethoxysilane in benzene at 80 °C for 24 h respectively. After the reaction, the silica gels were poured into methanol, filtered, and dried. Found for SI 1000: C, 2.93; H, 0.54%. Found for SI 4000: C, 0.23; H, 0.07%.

A chiral polymer (0.75 g) was dissolved in 10 ml of THF and the silanized silica gel (3.0 g) was wetted with the polymer solution (ca. 5 ml) as uniformly as possible. Then, the solvent was evaporated under reduced pressure. This process was repeated with the remaining polymer solution. The stationary phases contained 20—24.5 wt% of polymer on silica gel, judging from the elemental analyses. The packing materials thus obtained were packed in a stainless-steel column (25×0.46 (i.d.) cm) at 300 kg cm^{-2} by means of a slurry method using methanol. The plate number of a column was 3000—4500 for acetone when methanol (0.5 ml min^{-1}) was the eluent at 15 °C. The void volume (V_0) of the column was estimated to be 3.3 ml, with water as a non-retained compound.

Measurements. Chromatographic resolution was accomplished on a JASCO TRIROTAR-II chromatograph equipped with UV (JASCO UVIDEC-100-III) and polarimetric (JASCO DIP-181C) detectors. The optical rotation was followed in a flow cell (5×0.2 (i.d.) cm) at full lamp (mercury) intensity without filters. Resolution was carried out with methanol or a hexane-2-propanol (95:5 (v/v)) mixture at a flow-rate of 0.5 ml min^{-1} at 15 °C, unless otherwise stated.

Results and Discussion

Figure 1 shows the chromatogram of the resolution of *trans*-2,3-diphenyloxirane (**1**) on a poly(*m*-F$_1$TrMA) column. The enantiomers were eluted at the retention volumes, V_1 and V_2. The capacity factors, k_1' and k_2', were determined to be 0.66 and 1.20 respectively by using the following relations:

$$k_1' = \frac{(V_1 - V_0)}{V_0} \qquad k_2' = \frac{(V_2 - V_0)}{V_0}$$

The separation factor, α, and the resolution factor, R_s, were estimated to be 1.82 and 2.51 respectively from these equations:

$$\alpha = \frac{k_2'}{k_1'} \qquad R_s = \frac{2(V_2 - V_1)}{(W_1 + W_2)}$$

Table 1 shows the results of the optical resolution of racemates **1**, *trans*-cyclopropanedicarboxylic acid dianilide (**2**), the Tröger base (**3**), benzoin (**4**), 2,2′-dihydroxy-1,1′-binaphtyl (**5**), 2,2′-(2,2-dimethyl-2-silapropane-1,3-diyl)-1,1′-binaphthalene (**6**),[8] and tris(acetylacetonato)cobalt(III) (Co(acac)$_3$), with methanol as the eluent. All the compounds were almost completely resolved by the use of a (+)-poly(TrMA) column. When a polar solvent like methanol was used as the eluent, the driving force for the separation of the enantiomers on (+)-poly(TrMA) has been considered to be nonpolar interaction between the polymer, probably the chiral propeller of the triphenylmethyl group, and nonpolar groups of

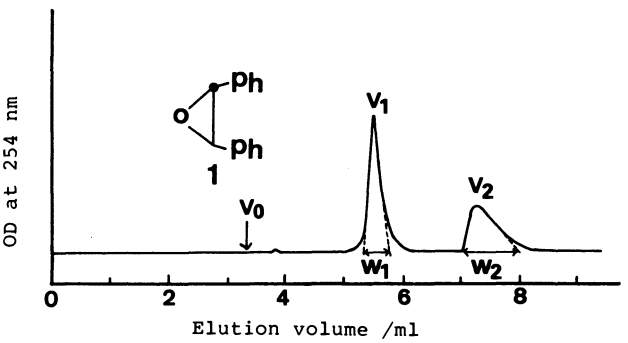

Fig. 1. Chromatographic resolution of *trans*-2,3-diphenyloxirane (**1**) on (+)poly(*m*-F$_1$TrMA) column. (Column: 25 cm×0.46 (i.d.) cm, eluent: methanol (0.5 ml min^{-1}), 15 °C).

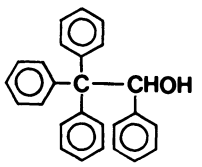
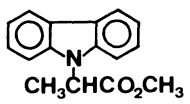
enantiomers.[5] The capacity factors (k_1') and the chiral-recognition abilities (α) decrease with an increase in the size and number of halogen substituents of the stationary phases. Poly(*m*-Cl_3TrMA) having a specific rotation as high as those of other chiral polymers, could not resolve any racemic compounds. However, poly(*m*-Me_3TrMA) showed a complete separation for Compounds **1** and **6** and a partial separation of **3**. Moreover, poly(*m*-Me_3TrMA) resolved 1,2,2,2-tetraphenylethanol (**7**, α=1.16) and methyl 2-(1-carbazolyl)propionate (**8**, α=1.45) more effectively than poly(TrMA) by using a mobile phase of methanol-H_2O=85/15 (v/v). These results indicate that the effects of the halogen and methyl substituents are greatly different from each other; this will be discussed later.



7



8

In the resolution of **1**, all the (+)-polymers adsorbed the (+)-isomer more strongly than the (−)-isomer, while the two negative polymers adsorbed the (−)-isomer more strongly. Similar results were also obtained for the other compounds, indicating that the sign of the optical rotation of polymers reflects the helicity of the polymer chains.

In Table 2 are collected the results of the resolution of racemates **1**, **3**, **4**, and Co(acac)$_3$ on the chiral polymers, using hexane-2-propanol (95:5 (v/v)) as the eluent at 15 °C. Poly(TrMA) resolved all the racemates with a slightly low separation factor in comparison to that with the methanol eluent. The chiral-recognition abilities of the other polymers did not always decrease in hexane-2-propanol, and **3**, **4**, and Co(acac)$_3$ were more effectively resolved on the poly(*m*-F_1TrMA) and poly(*m*-Cl_1TrMA) columns than on the poly(TrMA) column. In this non-polar system, the ester group (COO) and the triarylmethyl group may both more effectively participate in chiral discrimination. This might bring about the similar optical resolving powers of poly(TrMA), poly(*m*-F_1TrMA), poly(*m*-Cl_1TrMA), and poly(*m*-Me_3TrMA). The extremely low chiral-recognition ability of poly(*m*-Cl_3TrMA) in both the eluent systems may be attributed to a different structure of the triarylmethyl group.

Previously, we proposed that the triphenylmethyl groups on the optically active poly(TrMA) may take either left- or right-handed propeller structures, accompanied by the formation of a one-handed helical polymer chain.[9] (+)-Poly(TrMA) has been considered to possess a right-handed helix on polymer chains and a left-handed propeller on the triphenylmethyl group, based on the results of the optical resolution of various racemic compounds.[5,9] Such a chiral propeller structure of the triphenylmethyl group has been demonstrated by Empirical Force Field Calculations,[10,11] while perchlorotriphenylamine has been

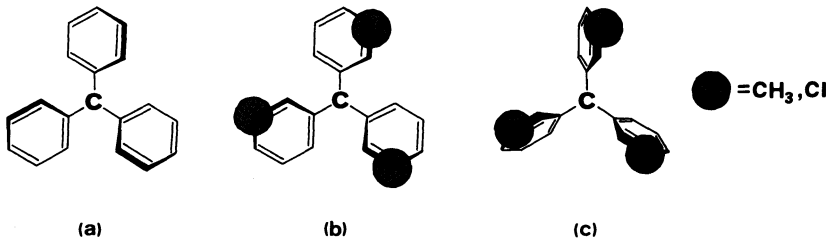

Fig. 2. Possible propeller structures of triphenylmethyl group (a), tris(*m*-tolyl)methyl group (b), and tris(*m*-chlorophenyl)methyl group (c).

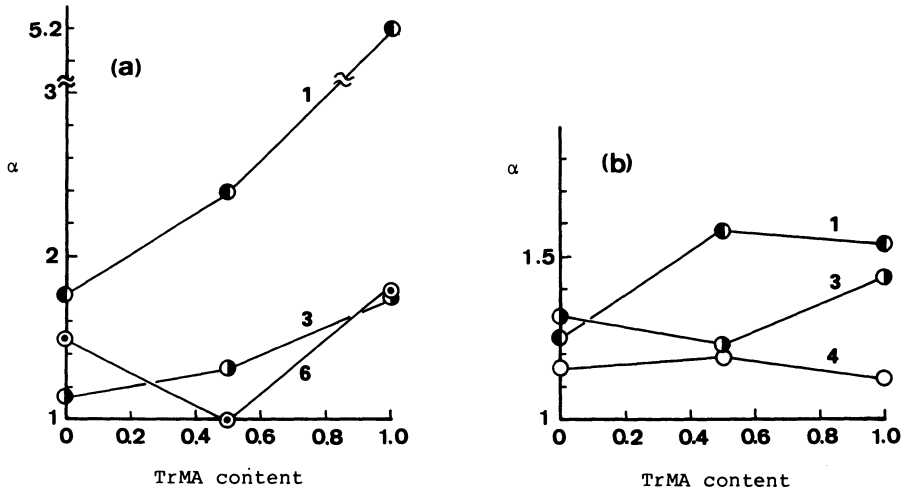

Fig. 3. Influence of TrMA content on separation factor (α) of poly(TrMA-*co*-*m*-Me$_3$TrMA). Eluent: (a), methanol; (b), hexane–2-propanol (95/5).

proved to take a stable propeller structure by its optical resolution.[12]

Figure 2 shows the possible left-handed propeller structures of the triphenylmethyl group and its derivatives. Three phenyl rings are likely to be twisted at some intermediate angle to each other for steric hindrance (Fig. 2(a)); the dihedral angle formed by the planes of the phenyl rings was calculated to be 35.7° for the most stable structure of triphenylmethane.[10] These chiral propeller faces must play the most important role in recognizing enantiomers, at least when methanol is used as the eluent. The three *m*-tolyl rings may also be twisted (Fig. 2(b)), because poly(*m*-Me$_3$TrMA) showed an effective chiral-recognition ability, similar to that of poly(TrMA) to some enantiomers. On the other hand, three *m*-chlorophenyl rings seem to be more upright, as is illustrated in Fig. 2(c). Therefore, enantiomers can not interact with chiral propeller faces and will be less retained in the stationary phase. This must lead to a poor separation of the enantiomers, regardless of the eluents.

The chiral recognition of the poly(triarylmethylmethacrylate)s must be governed not only by a single triarylmethyl propeller but also by adjacent propellers. In order to investigate this, copolymers of TrMA and *m*-Cl$_3$TrMA or *m*-Me$_3$TrMA were prepared[7] and used as chiral stationary phases in the same manner as homopolymers. All the copolymers in our experiments showed almost the same optical rotation, regardless of the molar ratios, as has previously been reported.[7] Figure 3 shows the relationships between the TrMA content in poly(TrMA-*co*-*m*-Me$_3$TrMA) and the separation factors (α) for the three racemates **1**, **3**, and **4**. When methanol was used as the eluent (Fig. 3(a)), the α values for **1** and **3** were nearly equal to the average values of those on the two homopolymers. These compounds may be recognized on a single propeller unit. The copolymer could not resolve Compound **6**, although both the homopolymers resolved it well, indicating that continuous, same monomer units in polymer chains are necessary for the separation of **6**. On the other hand, **1** and **4** were better resolved on the copolymer than on either of the homopolymers in the hexane–2-propanol system (Fig. 3(b)). Those compounds seem to be recognized more effectively on chiral sites lying between TrMA and *m*-Me$_3$TrMA units.

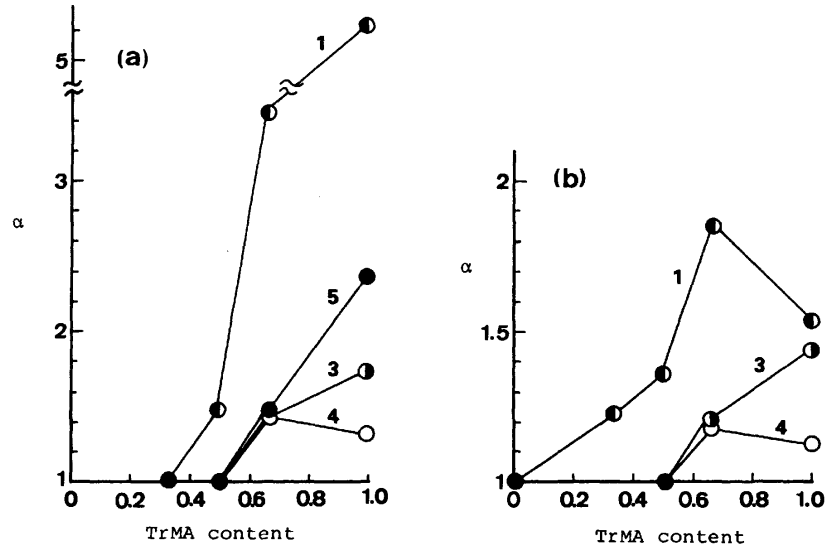

Fig. 4. Influence of TrMA content on separation factor (α) of poly(TrMA-*co*-*m*-Cl_3TrMA). Eluent: (a), methanol; (b), hexane–2-propanol (95/5).

Figure 4 shows the relationships between the TrMA content in poly(TrMA-*co*-*m*-Cl_3TrMA) and the α values for the four racemates **1**, **3**, **4**, and **5**. In both eluent systems, all of the racemates except **1** were not resolved on the copolymers containing less than 50% TrMA units; the resolution of **1** could be attained on the copolymers containing 50 and 33% TrMA units. These results suggest that two or more continuous TrMA units are necessary for the resolution of **3**, **4**, and **5**, while **1** can be resolved by only one TrMA unit in the copolymer.

The authors are grateful to Professor Ryoji Noyori of Nagoya University and Professor C. G. Overberger of the University of Michigan for providing the two racemic compounds **6** and **8** respectively. This work was partially supported by a Grant-in-Aid for Scientific Research on Priority Area, Advanced Molecular Conversion, from the Ministry of Education, Science and Culture.

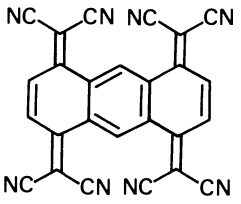
The title compound (OCNAQ) was synthesized. Treatment of 1,2,3,4,5,6,7,8-octahydroanthracene with *N*-bromosuccinimide (NBS) under irradiation using a 100-W light bulb in refluxing CCl_4 followed by dicyanomethylation with excess of $NaCH(CN)_2$ in Me_2SO gave an isomeric mixture of 1,4,5,8-tetrakis(dicyanomethyl) derivatives. The mixture was subjected by repetition of the successive bromination-dehydrobromination procedure giving OCNAQ in 20% overall yield. The cyclic voltammogram of OCNAQ exhibits four redox waves ($E_{1/2}^1$ 0.26, $E_{1/2}^2$ 0.05, $E_{1/2}^3$ −0.44, and $E_{1/2}^4$ −0.53 V vs. SCE in MeCN), indicating that OCNAQ is a stronger acceptor than tetracyanoquinodimethane (TCNQ, $E_{1/2}^1$ 0.17 V vs. SCE). Both 1:1 and 2:1 salts, (Et_4N)(OCNAQ) and $(Et_4N)_2$(OCNAQ), were obtained from reactions of Et_4NI with potassium and lithium salts of OCNAQ, respectively. The X-ray crystal analyses of these salts indicate that the TCNQ moieties are boat-shaped bent to opposite directions. With the 1:1 salt, which behaves as a semiconductor (4×10^{-4} Ω^{-1} cm^{-1} at room temperature, E_a 0.22 eV), the OCNAQ molecules are arrayed in the segregated stacking mode, while the 2:1 salt (10^{-7} Ω^{-1} cm^{-1}) has no columnar structure of the OCNAQ molecules.

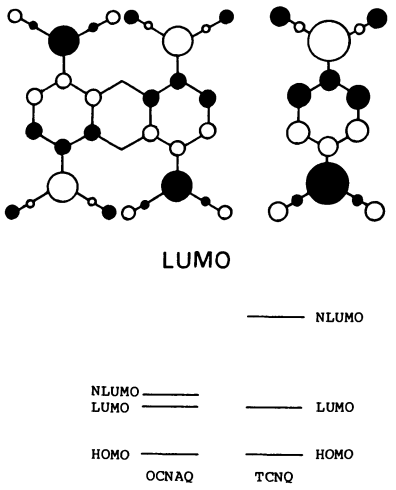
A large number of tetracyanoquinodimethane (TCNQ) derivatives have appeared in the past few decades; however, twin-TCNQ-type acceptors had not as yet been presented.[1] The compound **1** (abbreviated as OCNAQ) is one of the simplest examples of this



OCNAQ
1

type in which a pair of TCNQ nuclei are linked together through two methylidyne (-CH=) groups. The simple Hückel molecular orbital theory predicts that the lowest unoccupied molecular orbitals (LUMO) of OCNAQ and TCNQ are equal in energy and upon introduction of an electron into the OCNAQ molecule, the charge density is shared equally by both TCNQ nuclei.[2] Such charge dispersal would result in the reduction of on-site Coulomb repulsion and thus OCNAQ is expected to accept a second electron more easily than TCNQ.

Another factor that is not expected from TCNQ is the nonbonded interaction between cyano groups at positions 11 and 14 or 12 and 13 as well as that between a cyano group and a methylidyne group at position 9 or 10. Such a steric interaction



undoubtedly affects not only the molecular and crystal structures of the OCNAQ salts but also their electronic states.

In view of these considerations, it seems worthwhile to synthesize OCNAQ and to compare its physical and chemical properties with those of TCNQ which have been accumulated numerously since this intriguing acceptor was reported by Du Pont chemists.[3] This paper describes the synthetic route to OCNAQ and its fundamental properties obtained mainly from the mono- and dianion tetraethylammonium salts, a part of which has recently been reported in preliminary form.[4]

Results and Discussion

Synthesis. A number of synthetic strategies have been developed in order to construct the TCNQ-type-framework.[3,5-18] Survey of literature procedures suggested 1,4,5,8-tetrakis(cyanomethyl)anthracene and 1,4,5,8-tetrachloroanthraquinone to be most promising starting materials of the OCNAQ synthesis;[8] however, such approaches were unsuccessful. One of the key intermediates would be 1,4,5,8-tetrakis-(dicyanomethyl)-1,2,3,4,5,6,7,8-octahydroanthracene (**4**). It has been found that **4** is obtainable by simple substitution reactions and can be converted into OCNAQ by repetition of the successive bromination-dehydrobromination procedure in an overall yield of 20% as outlined in Scheme 1. The starting material, 1,2,3,4,5,6,7,8-octahydroanthracene (**2**), is readily available in one step from cheap, commercial compounds.[19] A mixture of **2** and *N*-bromosuccinimide (NBS) in refluxing carbon tetrachloride was irradiated with a 100-W unfrosted light bulb to afford an isomeric mixture of the 1,4,5,8-tetrabromo derivatives **3** as a white solid in 81% yield. The bromides **3** are unexpectedly stable at room temperature and can be stored in a freezer (−20 °C) without decomposition for a couple of days. Although **3** underwent dehydrobromination on treatment with sodium acetate in refluxing acetic acid to give anthracene in ca. 80% yield, the satisfactory dicyanomethylation of **3** was achieved by the use of a large excess of the sodium salt of malononitrile in Me_2SO to afford an isomeric mixture of **4** in 95% yield.

The active hydrogen atom of dicyanomethyl groups of **4** was easily replaced by bromine on treatment with NBS in MeCN in the presence of acetic acid. A difficulty with which the present procedure was confronted was the subsequent dehydrobromination, since even the action of such a weak base as pyridine led to the formation of polymerized products. One way out of the difficulty might be to carry out the dehydrobromination using a very weak base under slightly acidic conditions. A combination of *N*,*N*-dimethylformamide (DMF), acetic acid, and a small amount of ethanol was found to be suitable for the conversion of the bromination product from **4** into the tetrakis(dicyanomethylene) derivative **5** although the yield was moderate (35% based on **4**). The treatment of **5** with pyridine in MeCN followed by the addition of a solution of excess of bromine in 50% acetic acid gave OCNAQ as a yellow powder in 75% yield. The resulting crude product is sparingly soluble in MeCN but can be used directly for the preparation of charge-transfer complexes. OCNAQ reacted easily with potassium iodide in MeCN to afford the potassium salt of OCNAQ, which was then treated with tetraethylammonium iodide in refluxing MeCN giving the (Et_4N)(OCNAQ) salt (**6**) as black needles. Oxidation of **6** with bromine followed by recrystallization from MeCN gave an analytically pure sample of

$$\mathbf{1} \xrightarrow{KI} K^+OCNAQ^- \xrightarrow{Et_4NI} \underset{\mathbf{6}}{Et_4N^+OCNAQ^-} \xrightarrow{Br_2} \mathbf{1}$$

OCNAQ as fine golden yellow plates, which did not melt upon heating up to 400 °C but gradually turned brown above 180 °C. The infrared spectrum of OCNAQ as well as that of **5** exhibits a very strong absorption band due to the cyano stretching vibration at 2225 cm^{-1} indicating the presence of conjugated cyano groups.

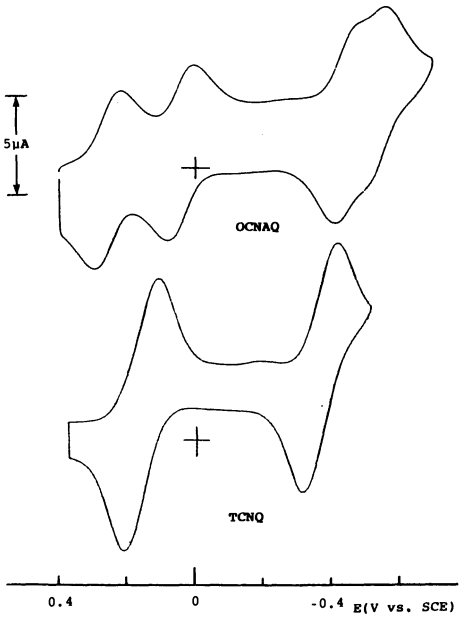


Fig. 1. Cyclic voltammograms of OCNAQ and TCNQ: solvent, MeCN; supporting electrolyte, Et_4NClO_4 (0.1 mol dm^{-3}); reference electrode, calomel; working electrode, platinum; sweep, 250 mV s^{-1}.

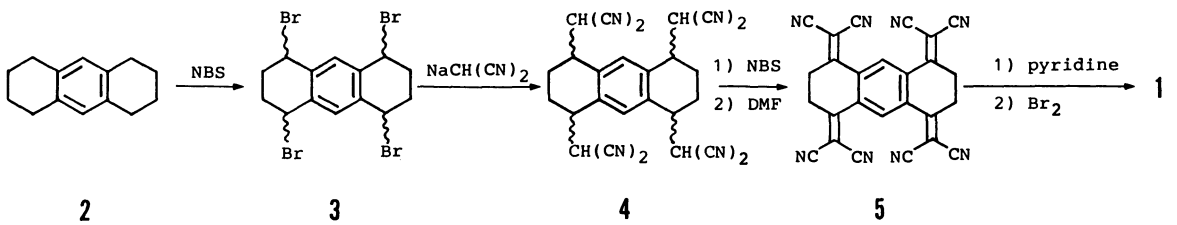

Scheme 1.

Electrochemical Studies. Figure 1 shows the cyclic voltammogram of OCNAQ with tetraethylammonium perchlorate as the supporting electrolyte in MeCN together with that of TCNQ measured under the same conditions. Four reversible redox waves appear at the potentials ($E_{1/2}$) 0.26, 0.05, −0.44, and −0.53 V vs. SCE. A comparison of the first redox potential of OCNAQ with that of TCNQ ($E_{1/2}$ 0.17 V vs. SCE)[20] reveals that OCNAQ is a stronger electron acceptor than TCNQ and thus the result is not exactly in accord with the expectation based on the simple Hückel molecular orbital calculation. Considerable deformation observed in the OCNAQ framework as described below as well as the stabilization due to charge dispersal present in the actual anion radical would result in such a discrepancy. Another interesting feature is that the second redox potential of OCNAQ is close to the first rather than the second redox potential of TCNQ ($E_{1/2}$ −0.36 V vs. SCE).[20] As mentioned in the introductory part, such a higher value of the second redox potential can be predicted by the simple Hückel MO theory combined with a consideration of Coulomb repulsive interaction.[21] In consequence, it is evident that the electron affinity of the anion radical $OCNAQ^{\cdot-}$ is stronger than that of $TCNQ^{\cdot-}$.

ESR Spectrum of the Radical Anion $OCNAQ^{\cdot-}$. A highly resolved ESR spectrum was obtained from the salt (Et_4N)(OCNAQ) **6** in MeCN with a *g*-factor of 2.0044. Figure 2 shows the observed spectrum and its simulation. The salt is completely ionic, because no hyperfine splitting due to the tetraethylammonium moiety has been observed. The hyperfine data derived from the spectrum together with the modified McLachlan calculation[22] provides the following coupling constants for the radical anion $OCNAQ^{\cdot-}$: a_H(2,3,6,7), 0.054±0.002 mT; a_H(9,10), −0.053±0.004 mT; a_N, 0.047±0.002 mT. Since a pair of acceptors are linked together through a conjugated system in OCNAQ, the charge in its anion radical $OCNAQ^{-\cdot}$ is expected to be highly delocalized. In fact, compared with the coupling constants for the radical anion $TCNQ^{\cdot-}$ [a_H (mT), 0.142[22] or 0.144;[23] a_N (mT), 0.099[22] or 0.102[23]], the value for the protons at positions 2,3,6,7 is about one-third and the value for the nitrogen atoms half as much.

X-Ray Structure of the (Et_4N)(OCNAQ) Salt (6). The structure of the OCNAQ framework was definitely confirmed by X-ray diffraction analysis of the salt **6** (Fig. 3). The crystal data are collected in Table 1. The final atomic parameters are listed in Table 2.[24] It is noteworthy that a quinonoid structure still remains in the OCNAQ framework of the salt, since the C–C distances between positions 2 and 3 and between positions 6 and 7 (1.33 Å) are shorter than those of aromatic rings and $TCNQ^{\cdot-}$ (1.38 Å;[25] 1.36 Å[26]) but are close to the corresponding distances of the neutral TCNQ (1.35 Å),[27] benzo-TCNQ (1.35 Å),[28] and $(Me)_4$TCNQ (1.34 Å)[17] in which the delocalization of π electrons of the bonds is depressed as a result of deformation from planarity. The result

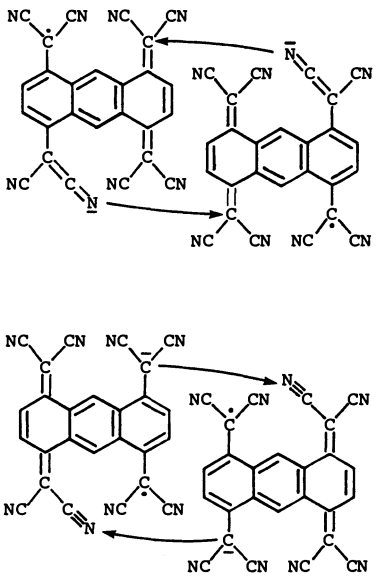
suggests that OCNAQ has the ability to accept a second electron more easily than TCNQ, in agreement with a higher value of the second redox potential of OCNAQ. The benzene ring is essentially planar but the TCNQ nuclei are distorted into boat forms, and the bows and sterns of the two boats face in opposite directions. The $C(CN)_2$ groups are twisted about the exo CC axes (10—11°). The boat forms are bent by 10—12° and the dihedral angles between the plane of the benzene ring and that of the bottom of the boat form are ca. 10° (Table 3).[24]

Figure 4 shows the crystal structure. Clearly, the OCNAQ molecules stack nearly along a-axis to form a column with an alternate arrangement of slightly different interplanar spacings between the benzene rings of the adjacent molecules; the longer one (3.81 Å) appears between molecules (a) and (b) in Fig. 4, and the shorter (3.70 Å) between molecules (b) and (c), both of which are longer than the sum of the van der Waals radii (3.40 Å)[29] and thus much longer than those of the usual TCNQ columns (3.2—3.3 Å). In contrast, the shortest and the next shortest interatomic distances between nitrogens of the inside cyano groups of one molecule and exo-methylene carbons of the adjacent molecule, i.e., 3.05 (1) and 3.14 (1) Å, are shorter than the sum of the van der Waals radii (3.25 Å).[29] Interestingly the interatomic distances N(a)5···C(b)13 and C(a)11···N(b)1, which are placed between a pair of the molecules showing the longer interplanar spacing, are the shortest (3.05 Å), and hence the next shortest distance (3.14 Å) is allocated to the distances N(b)8···C(c)14 and C(b)12···N(c)4 belonging to a pair of the molecules with the shorter interplanar spacing.[30] This fact implies that the intermolecular charge delocalization in the column is



Scheme 2.

mainly caused by overlapping of orbitals of thses nitrogen and carbon atoms rather than that of the carbon atoms constituting anthracene nuclei, as can be illustrated by Scheme 2.

Solid State ESR Measurements of 6. Generally the ground state of the TCNQ salts is singlet and the singlet-triplet energy difference J ranges from 0.03 to 0.4 eV.[31-35] To evaluate the extent of intermolecular interaction in the OCNAQ column, the temperature dependence of ESR absorption intensity of the powdered salt was examined. As shown in Fig. 5, the intensity is increased by a factor of 10 on changing the temperature from −166 °C to −19 °C and the

equation[31,36] $I \propto [\exp(-J/kT)]/T$ holds in this temperature range, giving J=0.052 eV. The result suggests that there exist distinct intermolecular attractive forces other than those of the van der Waals type, which hold the columnar structure of the OCNAQ molecules and lead to the ground state singlet.

Electrical Conductivity of 6. The single crystal resistivity of **6** was measured with a two-probe technique. The room-temperature conductivity is ca. $4\times10^{-4}\,\Omega^{-1}\,cm^{-1}$. Unfortunately no information on the single crystal conductivities of 1:1 TCNQ ammonium salts is available. However, their compacted powder pellets exhibit much lower conductivities ($\sigma \leqq 10^{-6}\,\Omega^{-1}\,cm^{-1}$).[3,37] It seems reasonable to assume that the reduction of on-site Coulomb repulsion in $OCNAQ^{-}$ is responsible for the high conductivity of **6** as compared with those of simple TCNQ ammonium salts. The salt **6** behaves as a semiconductor. Figure 6 shows the temperature dependence of the resistivity. The conductivity is increased by a factor of 8 on changing the temperature from 300 to 400 K with an activation energy of 0.22 eV.

a) $B_{eq}=4/3(\sum_i\sum_j \beta_{ij} a_i \cdot a_j)$.

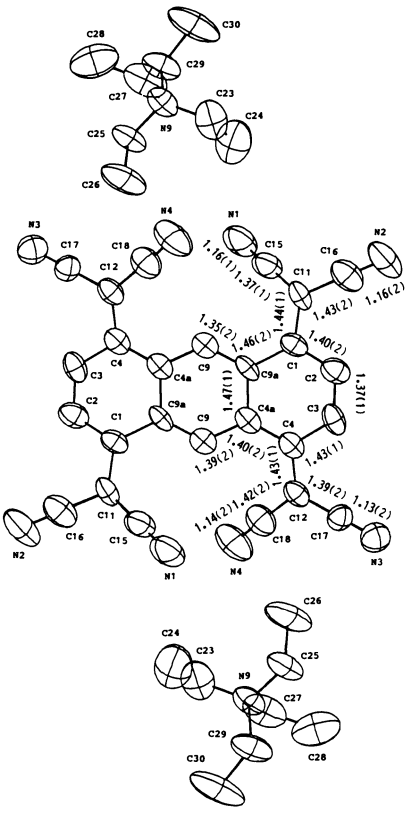

Fig. 7. ORTEP view of $(Et_4N)_2$(OCNAQ), **7**, showing the atom numbering scheme and bond lengths (Å).

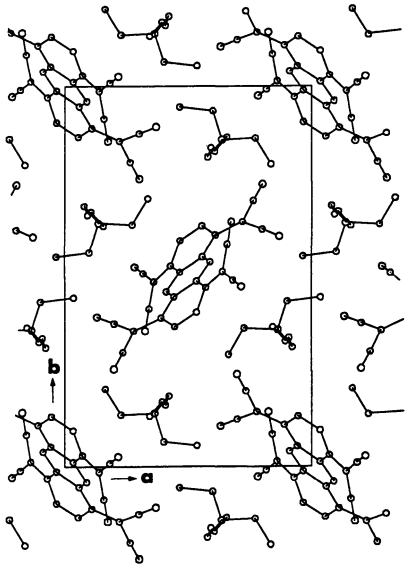

Fig. 8. Crystal structure of **7** (c-axis projection).

OCNAQ in hot methanol gave the 2:1 $(Et_4N)_2$-(OCNAQ) salt (**7**) as blue-black needles, reflecting a higher value of the second redox potential or the presence of a pair of TCNQ moieties. The salt **7** is readily soluble in hot methanol in which the salt **6** is insoluble. Its conductivity ($1.2\times10^{-7}\,\Omega^{-1}\,cm^{-1}$ at room temperature) is much lower than that of the 1:1 salt **6**. The crystal data and final atomic parameters of the salt are listed in Tables 1 and 4,[24] respectively. The salt has a center of symmetry in the OCNAQ molecule (Fig. 7). In contrast to the monoanion salt **6**, the C(2)-C(3) distance (1.37 Å) is within the range of the above-mentioned values of $TCNQ^-$ (1.35—1.38 Å), suggesting that the quinonoid geometry of the acceptor seems almost lacking. Such a geometrical change implies much difficulty in introducing a third electron into the OCNAQ molecule, in agreement with a considerably lower value of the third redox potential of OCNAQ, and would be responsible for a dramatic change in the crystal structure of the salt in which a columnar structure of the OCNAQ molecules is no longer present (Fig. 8). Deformation of the anthracene framework of **7** is, however, similar to that of **6**: The boat-shaped TCNQ nuclei in **7** are bent by 10—12° and the dihedral angle between the plane of the benzene ring and that of the bottom of the boat form is ca. 10° (Table 3).[24]

Experimental

Instruments. The following spectrometers were used: IR, Hitachi 260-30; ^1H NMR, Varian EM-390; ESR, Varian E-112/V 7800 for an MeCN solution, which was degassed in a quartz tube (4 mm o.d.) by three freeze-thaw cycles, and JEOL FE1X for a solid sample; Cyclic voltammograms were measured by a potentiostat (Yanaco V8-3010PG) equipped with a function generator (NF FG-121B) and an XY recorder (Watanabe WX 4401). MeCN (special grade) was distilled over P_2O_5 and subsequently over K_2CO_3. Resistivity measurements were performed by a two-probe (gold paste electrodes) technique.

X-Ray Structure Analyses. The structure analyses were made with a Rigaku Denki AFC-4 automatic four-circle diffractometer [Cu $K\alpha$ radiation (1.54184 Å), graphite monochromator, ω—2θ scan technique, $2\theta\leqq120°$, scan speed 4° min^{-1} (θ), scan range (1.1+0.5 tan θ)°]. Three standard reflections measured every 50 reflections showed no significant X-ray damage or crystal decay. Of 2595 (for **6**) and 2166 (for **7**) independent reflections observed, unique 1647 (for **6**) and 1007 (for **7**) reflections with $|F_o|>3\sigma(|F_o|)$ were used for structure determination. The structure was solved by direct methods with MULTAN 78[38] (with atomic scattering factors from International Tables for X-ray Crystallography)[39] and refined by full-matrix least squares (UNICS III)[40,41] with anisotropic thermal parameters for non-hydrogen atoms and isotropic for hydrogen atoms. **6**: $R=0.064$ and $R_w=0.074$, where $w=(4.155-0.274|F_{obs}|+0.006F_{obs}^2)^{-1}$. **7**: $R=0.072$ and $R_w=0.070$, where $w=(2.343-0.092|F_{obs}|+0.004F_{obs}^2)^{-1}$.

Elemental analyses were performed by Mses Toshiko Seki and Kimiyo Saeki of the analytical section of the Department of Chemistry, The University of Tokyo.

Preparation of 1,4,5,8-Tetrabromo-1,2,3,4,5,6,7,8-octahydroanthracenes (3). 1,2,3,4,5,6,7,8-Octahydroanthracene (**2**) was prepared by the action of $AlCl_3$ on a mixture of tetralin and 1,4-dichlorobutane (special grade) according to the literature procedure[19] and was recrystallized repeatedly from ethanol: mp 71.5 °C [lit,[19] mp 72 °C]. A solution of **2** (5.0 g, 26.8 mmol) in 250 ml of CCl_4 was placed in a 500-ml round-bottomed pyrex flask, and NBS (21 g, 117 mmol) was added. The flask was immersed in an oil bath preheated at 90 °C. The mixture was refluxed with stirring and was exposed to the light of an ordinary 100-W unfrosted bulb placed 1 cm from the flask. Vigorous reaction took place within 5 min. After irradiation for 45 min, the reaction mixture was cooled with water and filtered. The isolated solid mass was washed with CCl_4 and the washings were combined with the filtrate. The solid was then washed with water and ethanol to remove succinimide, and the residue was washed finally with hexane to give the first crop of the bromide **3** as a white solid (2.5 g, 19%), which was rather stable and decomposed only very slowly with loss of HBr at room temperature; IR (KBr, cm^{-1}) 2950 w, 2900 w, 1630 w, 1495 w, 1430 s, 1345 w, 1225 s, 1190 s, 1000 w, 985 w, 915 s, 895 m, 765 w, 740 m, 630 s, 520 m; ^1H NMR ($CDCl_3$) δ=2.3—2.8 (m, 8H), 5.4—5.8 (m, 4H), 7.33 (s, 2H). Found: C, 33.14; H, 2.57%. Calcd for $C_{14}H_{14}Br_4$: C, 33.50; H, 2.81%. The filtrate and the CCl_4 washings were concentrated under reduced pressure, and the viscous residue was triturated with 10 ml of $CHCl_3$, diluted with 10 ml of hexane, and cooled in a refrigerator. The resulting precipitate was isolated by filtration and washed with ethanol and hexane, affording the second crop of the bromide **3** as a white solid (8.3 g, 62%), which showed satisfactory elemental analysis after recrystallization from benzene. Found: C, 33.64; H, 2.60%. Calcd for $C_{14}H_{14}Br_4$: C, 33.50; H, 2.81%. These two crops of the crude bromide were combined, pulverized in a mortar, and used in the next step.

Preparation of 1,4,5,8-Tetrakis(dicyanomethyl)-1,2,3,4,5,6,7,8-octahydroanthracenes (4). To a mechanically stirred suspension of 20 g (0.5 mol) of sodium hydride (60% oil dispersion) in 60 ml of Me_2SO, which was placed in a 1000-ml three-necked flask, was added a solution of 35 g (0.53 mol) of malononitrile in 40 ml of Me_2SO at 25 °C under an atmosphere of nitrogen. After the addition was complete, stirring was continued for 15 min. To the resulting homogeneous solution was added 10.8 g (21.5 mmol) of the above powder of the bromide **3** in one portion and stirring was continued for 3 h. To the reaction mixture was added 500 ml of 10% aqueous acetic acid with stirring. The resulting light brown paste was collected, washed successively with water, benzene, and hexane and treated with 100 ml of hot acetic acid followed by addition of 500 ml of water. The resulting precipitate was isolated by filtration, washed with water and hexane, and dried in vacuo, affording a white solid (9.0 g, 19.2 mmol, 95%). The NMR spectrum in MeCN showed the solid to be an isomeric mixture of **4**. In a separate experiment under the same conditions, the bromide obtained as the first crop described above gave only one isomer of **4**: colorless needles from MeCN (dried at 80 °C in vacuo); mp 355 °C decomp; IR (KBr, cm^{-1}) 2900 s, 2245 m (CN), 2200 w (CN), 1620 m, 1510 m, 1440 m, 1400 w, 1320 m, 1260 w, 1230 m, 1145 m, 1040 w, 1000 w, 980 m, 920 m, 905 m, 795 m, 760 w, 720 m. ^1H NMR (Me_2SO-d_6) δ=1.5—2.6 (m. 8H), 3.6—3.9 (m, 4H), 5.56 (d, 4H, J=4.5 Hz), 7.52 (s, 2H). Found: C, 70.71; H, 4.04; N, 25.47%. Calcd for $C_{26}H_{18}N_8$: C, 70.57; H, 4.10; N, 25.33%. The second crop of the bromide afforded an isomeric mixture of **4**.

Preparation of 1,4,5,8-Tetrakis(dicyanomethylene)-1,2,3,4,5,6,7,8-octahydroanthracene (5). To a mixture of 60 ml of MeCN and 10 ml of acetic acid were added **4** (9.0 g) and NBS (20 g, 112 mmol), and the mixture was stirred at room temperature for 1 h and at 45 °C for 2 h and then filtered. To the well-stirred and water-cooled filtrate a mixture of 50 ml of DMF, 25 ml of acetic acid, and 3 ml of ethanol was added dropwise over a period of 1 h. The reaction mixture was stirred overnight and diluted with 100 ml of 50% aqueous acetic acid. The dark brown mixture was stirred for an additional 1 h. The product was separated by filtration and washed with MeCN until the filtrate became bright yellow. The yield of **5** was 3.1 g (7.1 mmol, 35%): mp 320—325 °C decomp, as yellow crystals from MeCN; IR (KBr, cm^{-1}) 3065 w, 2920 m, 2225 vs (CN), 1640 m, 1590 s, 1560 s, 1550 s, 1480 m, 1440 m, 1410 w, 1350 w, 1320 m, 1295 m, 1220 m, 1205 m, 1100 w, 980 w, 970 w, 915 m, 880 m, 800 s, 775 w. Found: C, 71.74; H, 2.44 N, 25.69%. Calcd for $C_{26}H_{10}N_8$: C, 71.88; H, 2.32; N, 25.80%.

Preparation of 11,11,12,12,13,13,14,14-Octacyano-1,4:5,8-anthradiquinotetramethane (1).[42] To a stirred suspension of 3.1 g of **5** in 100 ml of MeCN was added a solution of 3 g of pyridine in 50 ml of MeCN under an atmosphere of nitrogen. After 30 min, the dark blue-black mixture was ice-cooled and then an ice-cooled solution of 3.5 g of bromine in 250 ml of 50% aqueous acetic acid was added in one portion and stirred for 5 min. The product was separated by filtration and washed successively with 50% aqueous acetic acid, water, ethanol, and finally MeCN until the filtrate became bright yellow. The yield of **1** thus obtained was 2.3 g (5.3 mmol, 75%) as a yellow powder, and the overall yield starting from **2** was therefore 20%. This crude product was used without further purification. An analytical sample of **1** was obtained by two recrystallizations (from MeCN) of **1** regenerated from the bromine oxidation of the salt **6** as described below: fine golden yellow plates; mp>400 °C (its appearance gradually turned brown above 180 °C and dark brown above 380 °C); IR (KBr, cm^{-1}) 3060 w, 2930 vw, 2225 vs (CN), 1640 m, 1590 w, 1555 vs, 1480 w, 1335 w, 1300 m, 1260 vw, 1205 m, 1100 w, 970 w, 935 vw, 895 m, 800 m, 775 w. Found: C, 72.85; H, 1.40; N, 26.20%. Calcd for $C_{26}H_6N_8$: C, 72.56; H, 1.41; N, 26.04%.

Preparation of the Salt (Et_4N)(OCNAQ)(6) To a suspension of 0.5 g of OCNAQ in 40 ml of MeCN was added 0.5 g of potassium iodide and the mixture was stirred for 2 h. The black deposit was separated by filtration and washed with MeCN. A mixture of the crude potassium salt (0.55 g) and tetraethylammonium iodide (0.4 g) in 20 ml of MeCN was refluxed for 5 min. The resulting precipitate (0.58 g) was recrystallized twice from MeCN to give **6** as black needles. Found: C, 73.04; H, 4.43; N, 22.56%. Calcd for $C_{34}H_{26}N_9$: C, 72.84; H, 4.67; N, 22.49%. OCNAQ was regenerated upon addition of excess of an aqueous bromine solution to a suspension of **6** in MeCN.

Preparation of the Salt (Et_4N)$_2$(OCNAQ)(7). The crude lithium salt of OCNAQ, which was prepared analogously as described above, was dissolved in methanol and filtered. To the dark blue filtrate was added an excess of Et_4NI (more than 2.5 equiv) and the mixture was heated to boiling, filtered, and then the filtrate was cooled. The resulting precipitate was collected and recrystallized from methanol to give **7** as blue-black needles. Found: C, 73.02; H, 6.55; N, 20.42%. Calcd for $C_{42}H_{46}N_{10}$: C, 73.01; H, 6.71; N, 20.27%. A 1:1 mixture of **7** and OCNAQ was heated in MeCN to yield **6**.

We are grateful to Drs. Gaku Yamamoto, Akiko Kobayashi, and Shigeru Murata for many helpful discussions.

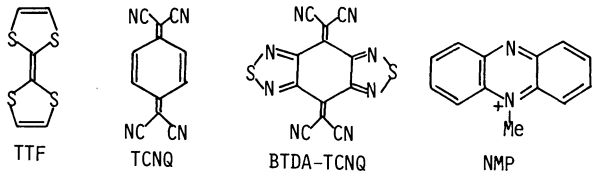
(Received July 2, 1987)

Tropylium ions have been found to be good cations for forming highly conductive salts of $TCNQ^{-}$. Tropylium ions with different reduction potentials were prepared. The first reduction potentials which are correlated with the substituent constants σ_p^+ control the formation of the salts. The cations with higher reduction potentials underwent a reaction with $TCNQ^{-}$ to give neutral TCNQ and coupling products. The molar ratios of the initially formed salts are also dependent on the reduction potentials. The simple salts are only formed when the reduction potentials are lower than −0.43 V. This fact is rationalized by the difference in the ease of electron transfer from $TCNQ^{-}$ to tropylium ions which is determined by the reduction potentials. Some simple salts show significantly low electrical resistivities compared with usual $TCNQ^{-}$ simple salts. BTDA-$TCNQ^{-}$ also gave conductive salts of tropylium ions, indicating that BTDA-TCNQ is useful for forming organic semiconductors.

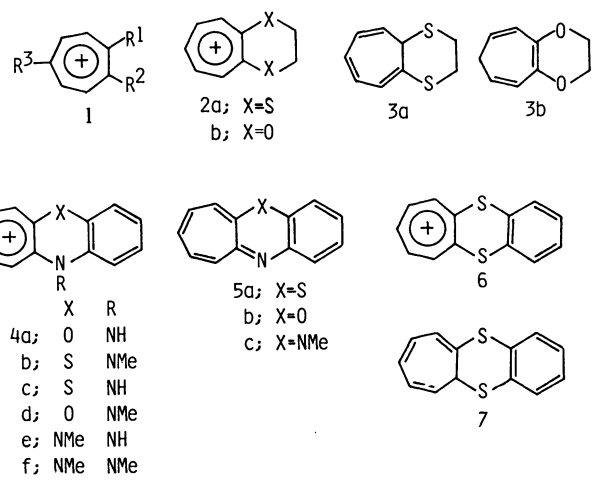
Recently much attention has been focused on organic conductors and the requirements for them have been proposed.[1] In the tetrathiafulvalene (TTF)-tetracyanoquinodimethan (TCNQ) system, the redox potentials are the most important factors to determine conductivity, where the difference between the first oxidation potentials for donors [E_1^{ox}(D)] and the first reduction potentials for acceptors [E_1^{red}(A)] is $-0.02<E_1^{ox}(D)-E_1^{red}(A)<0.34$ V for giving organic metals.[2] The difference in the redox potentials is related to the degree of charge transfer.[3] On the other hand, simple $TCNQ^{-}$ salts of cations usually exhibit low conductivity because of the complete charge transfer.[3,4] Therefore, the systematic study on the factors governing the conductivities of simple $TCNQ^{-}$ salts has not been done although the effect of the reduction potentials of cations has been pointed out by Torrance.[3] *N*-Methylphenazinium (NMP) which has a higher reduction potential compared with those for other cations is an exceptional cation whose 1:1 $TCNQ^{-}$ salt is an organic metal.[5] Tropylium ion whose reduction potential is close to that of NMP[6] has been reported to undergo a reaction with $TCNQ^{-}$ without formation of salts.[7] However, its derivatives still seemed attractive cations for preparing highly conductive salts as well as for the systematic study on the substituent effects for the following reasons. First, they are stable aromatic cations and can be easily functionalized to change electron affinity. Second, they have high polarizability which is related to the high conductivities of the complex salts of $TCNQ^{-}$ with heterocyclic cations.[8] Third, they are desirable cations for the investigation of substituent effects since substituents are directly attached to the delocalized cation ring. Finally, heteroatoms which increase intra- and interstack interactions for stabilizing the metallic state are easily introduced in the substituents. From these viewpoints, we have investigated the salt formation of tropylium ions with $TCNQ^{-}$ [9] as well as bis[1,2,5]thiadiazolotetracyanoquinodimethan anion radical (BTDA-$TCNQ^{-}$) which we prepared recently.[10]



Results and Discussion

Preparation of Tropylium Ions. Monocyclic tropylium ions **1a,b,g,j,k,o,r** are new compounds which were prepared by the following methods.[11] Reaction of 5-bromo-2-methoxytropone with trimethyloxonium tetrafluoroborate in nitromethane gave **1a** and **1b** in 12% and 61% yields, respectively. The similar reaction of 4-methoxytropone and 2-aminotropone led to the formation of **1k** and **1r** in 85% and 36% yields, respectively. Methylthio derivatives **1g,j,o** were synthesized by the reaction of the corresponding tropothiones with methyl iodide in ether in 70%, 25%, and 48% yields, respectively. Bicyclic cations **2a,b** were synthesized by deprotonation of the corresponding cycloheptatriene derivatives **3a**[12] and **3b**[13] with $NOBF_4$ in 72% and 80% yields, respectively. This method using $NOBF_4$ is useful for the deprotonation of cyclic cycloheptatrienes to give tropylium ions.[14] Tricyclic cations **4b—f** whose structures are analogous to that of NMP were prepared from the corresponding heterocycles, cyclohepta[*b*][1,4]benzothiazine (**5a**),[15] cyclohepta[*b*][1,4]benzoxazine (**5b**),[16] and *N*-methylcyclohepta[b][1,4]benzodiazine (**5c**)[17] by protonation with hydrogen chloride or methylation with methyl iodide. Cation **4a** was prepared as the BF_4^{-} salt according to Nozoe's method.[15b] Heterocyclic cation **6**

with two sulfur atoms were prepared as the BF_4^- salt by deprotonation of heterocycle **7**[12] in acetonitrile.



Reduction Potentials for Tropylium Ions. The first reduction potentials (E_1^{red}) for tropylium ions were measured by cyclic voltammetry. The data for monocyclic tropylium ions summarized in Table 1 show that electron-donating substituents lower the first reduction potentials. The values are linearly correlated with the sum of the substituent constants σ_p^+ as shown in Fig. 1.[18] This linear relationship means the presence of the additive properties of substituent effects on the reduction potentials. Introduction of an SMe group decreases the reduction potentials by −0.10—−0.15 V, while introduction of an OMe group decreases them by −0.20—−0.26 V.[19] The reduction potentials for bicyclic cations **2a,b** are also shown in Table 1. Their higher reduction potentials compared with those for the corresponding monocyclic cations

1g,m by 0.09 V may be attributed to the nonplanar structures of **2a,b**. The redox potentials for the tricyclic cations **4** are shown in Table 2. The values are higher than those for the corresponding monocyclic or bicyclic cations and even oxidation potentials are observed. These results show that tropylium ions with different reduction potentials can be readily prepared.

Reaction of Tropylium Ions with $TCNQ^{-}$. When a boiling ethanol or acetonitrile solution of the salts of monocyclic tropylium ions **1** was treated with $TCNQ^{-}$ lithium salt in boiling ethanol, **1j,k,l,m,n,q** gave simple salts and **1d,f,g,h,p** gave complex salts. The molar ratios are shown in Table 3. Cation **1g** which formed a complex salt by direct mixing gave a simple salt when the metathesis was carried out in the presence of lithium iodide. Treatment of the simple salts with TCNQ in boiling acetonitrile gave their complex salts. These salts are the first $TCNQ^{-}$ salts of tropylium ion species.

In contrast, nonsubstituted one **1c** underwent a reaction with $TCNQ^{-}$ to give **8** (R=H) and neutral TCNQ without the formation of salts as reported by Melby.[7] Tropylium ions **1b,i** underwent the same type of reaction to give **8** and neutral TCNQ. The bicyclic cations **2a** also underwent the same type of reaction, while **2b** gave a complex salt. In the case of tricyclic cations, **4a,c—f** gave simple salts and **4b** gave a 1:2 salt by metathesis, while **6** underwent the reaction with $TCNQ^{-}$. It should be noted that the cations **1b,c,i,2a** and **6** which underwent the reaction have higher reduction potentials. This fact shows that the reduction potentials strongly affect the formation of salts. The molar ratios of the initially formed salts are also related to the reduction potentials. Figure 2 clearly shows the effects of the reduction potentials. The tropylium ions in region I ($E_1^{red}>-0.2$ V) underwent the reaction. The ions in region II (-0.43 V$<E_1^{red}<-0.2$ V) formed complex salts, while the ions in region III ($E_1^{red}<-0.43$ V) formed simple salts. There are some exceptions, indicating that the salt formation is also affected by other factors. For example, the bicyclic cation **2a** in region II underwent the reaction and **2b** in region III formed a complex salt. This can be attributed to the nonplanar structures which make it difficult to form salts. The reason for the formation of the complex salt of **1p** which is in region III may be attributed to the large size of **1p**. Decrease in the Coulomb force due to the low electron affinity of **1r** may be the reason for the formation of the complex salt of **1r**.

These findings suggest the reaction mechanism shown in Scheme 1. When the salt formation takes place faster than the coupling reaction or electron transfer, simple salts are formed. When electron transfer competes with the salt formation, complex salts are formed since electron transfer leads to the formation of neutral TCNQ which reacts with simple salts to give complex salts. The effect of lithium

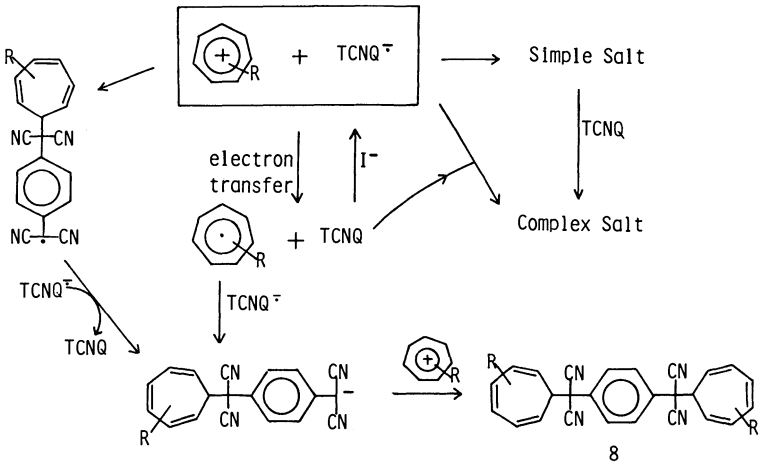
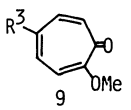


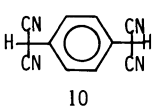
Scheme 1.

iodide can be explained by considering that neutral TCNQ which was formed by the electron transfer reaction was reduced by I^- to give $TCNQ^-$. On the other hand, highly reactive tropylium ions undergo the reaction to give the adducts **8** by the mechanism shown in Scheme **1** instead of the salt formation. The reduction potentials for the cations play an important role in determining the reactivities, since the reduction potentials of tropylium ions are related to their pK_R^+ values and electron affinities.[19]

This mechanism is supported by the following results. When each ethanol solution of cations and Li^+TCNQ^- (1 equiv) at low concentration (ca. 10^{-4} M) were mixed, the green color due to $TCNQ^-$ immediately disappeared in the case of cations which belong to region I and II, while in the case of cations which belong to region III the green color remained. The molar ratios of the cations to TCNQ can be determined by measuring the intensity ratios of the absorbance at 400 nm to that at 842 nm in the absorption spectra in which those for the simple salts are shown to be 0.5.[5,20] In fact, ratios in the above green solutions were about 0.5. The ratios for the **1p,r** which belong to region III but form complex salts were 0.50 and 0.54, respectively, indicating that the cations **1p,r** as well as other cations which belong to region III are stable under these conditions. These findings suggest that the reactivity of cations to $TCNQ^-$ is determined by the reduction potentials, but the salt formation is also affected by the factors other than the reactivity of cations.



9



10

On the other hand, hydroxy derivatives **1a,e** underwent a proton transfer to give tropone derivatives **9** and dihydrodihydroxy-TCNQ **10**, indicating that hydroxy derivatives cannot be used for the formation of salts.

The properties of $TCNQ^-$ salts are summarized in Table 3. Electrical resistivities are relatively low, indicating that tropylium ions are good cations for forming highly conductive $TCNQ^-$ salts. It is interesting that even alkyl derivative **11** forms conductive $TCNQ^-$ salts. The 1:2 salts are more conductive than the corresponding 1:1 salts as found in usual $TCNQ^-$ salts.[3,4] It should be noted here that the simple salts of **1m** and **4c** show significantly low resistivities compared with those for $TCNQ^-$ simple salts of other cations except NMP.[3,4] Resistivities of the simple salts seem to be related to the structures of cations as well as the reduction potentials as shown in Fig. 2. For example, the resistivity of 1,4-dimethoxy derivative **1k** is higher than that of 1,2-dimethoxy derivative **1m**. This can be accounted for by the nonplanar structure of **1k** which is deduced from the higher reduction potential compared with that for **1m**. The high resistivity of the $TCNQ^-$ simple salt of tetramethyl derivative **11** may also be explained in terms of the steric factor. In addition, the fact that the cations **1q** and **4f** having lower reduction potentials form lower conductive salts indicates that there is a lower limit of the reduction potentials for the cations to show good conductivities. In the salts of cations having lower reduction potentials, the ions seem to be completely charged due to the poor electron affinity of the cations. This is supported by the finding that the anion radical of $TCNQF_4$ which is a strong electron acceptor than TCNQ forms a low conductive simple salt with tricyclic cation **4c** (ρ; $1.8\times10^5\ \Omega$ cm).

Another interesting feature is that the nitrile stretching frequencies for 1:1 salts are lower than those for the metal salts[21] even if the salts show high conductivities. Nitrile stretching frequencies for TCNQ complexes or salts are reported to be linearly correlated with the degree of charge transfer[22] and are

conventionally used for determining it. It has recently been reported that when a salt or a complex takes a mixed stack, there is no linear correlation between them.[23] Our result shows that even in the case of good conductive salts which are considered to form segregated stacks, nitrile stretching frequencies are not always linearly correlated with the degree of charge transfer.

BTDA-TCNQ$^-$ Salts of Tropylium Ions. Bis-[1,2,5]thiadiazolotetracyanoquinodimethan (BTDA-TCNQ) has been found to afford highly conductive charge transfer (CT) complexes with some donors.[10,24] BTDA-TCNQ which forms a two dimensional network by a strong S···N≡C interaction[25] is expected to give two- or three-dimensional CT complexes or anion radical salts. The first reduction potential of BTDA-TCNQ (−0.02 V vs. SCE) is a little lower than that of TCNQ (+0.18 V vs. SCE), indicating that the electron transfer from BTDA-TCNQ$^-$ to cations more easily takes place than that from TCNQ$^-$. On the other hand, the nucleophilicity of BTDA-TCNQ$^-$ is considered to be weaker than that of TCNQ$^-$ since negative charge is delocalized in the thiadiazole rings.[26]

When a boiling ethanol or acetonitrile solution of monocyclic tropylium ions was treated with Li$^+$ BTDA-TCNQ$^-$ in boiling ethanol, salts whose molar ratios are shown in Table 4 precipitated. Most of salts contain water, indicating that BTDA-TCNQ$^-$ tends to uptake water. It should be noted that the cations **1b** and **1i** which underwent the coupling reaction with TCNQ$^-$ gave salts with BTDA-TCNQ$^-$. Bicyclic cation **2a** which underwent the coupling reaction with TCNQ$^-$ also formed a salt with BTDA-TCNQ$^-$. These facts can be explained in terms of the low nucleophilicity of BTDA-TCNQ$^-$ which reduces the reactivity for the coupling reaction. The electrical resistivities of the BTDA-TCNQ$^-$ salts summarized in Table 4 show that these salts are conductive, indicating the usefulness of BTDA-TCNQ$^-$ for forming organic semiconductors with cations. The nitrile stretching frequencies are lower than those for the metal salts.[27] This may be accounted for by the strong S···N≡C interaction.

Table 4. Properties of TCNQ$^-$ Salts

Cation	Molar ratio	ν/cm^{-1}	ρ/Ω cm[a]
1b	3:4	2173	3.7×10^2
1d	1:1	2172	2.5×10^3

a) Measured under the same conditions as those of TCNQ$^-$ Salts

Conclusion

Tropylium ions with different reduction potentials were prepared. The first reduction potentials are correlated with the substituent constants σ_p^+ and the substituent effects are additive. The tropylium ions were found to form conductive salts with TCNQ$^-$. The reduction potentials for cations affect the salt formation. The tropylium ions with higher reduction potentials (E_1^{red}>−0.2 V) undergo the reaction with TCNQ$^-$. When the reduction potentials are between −0.2 V and −0.43 V, complex salts are formed. When they are lower than −0.43 V, simple salts are formed. Electrical resistivities of the salts are relatively low and particularly, those of the simple salts of **1m** and **4c** are much lower than those of usual TCNQ$^-$ simple salts. The nitrile stretching frequencies for the salts are not linearly correlated with the degree of charge transfer. BTDA-TCNQ$^-$ also gave conductive salts of tropylium ions. Due to the low nucleophilicity, BTDA-TCNQ$^-$ formed salts with even tropylium ions which have high reduction potentials and underwent the reaction with TCNQ$^-$.

Experimental

General Methods. IR spectra were taken on a Shimadzu IR-27G spectrometer or a Shimadzu IR-435 spectrometer equipped with a Shimadzu DR-1 data recorder. UV spectra were measured with a Hitachi 340 spectrophotometer and mass spectra with a Hitachi M-52 mass spectrometer. ^{1}H NMR spectra were obtained at 60 MHz on a Varian EM-360, at 90 MHz on a Varian EM-390, at 200 MHz on a Varian XL-200 spectrometer. Redox potentials were measured on a Yanako Voltammetric Analyzer p-1000. All reaction solvents were distilled prior to use. Melting points were measured on a Laboratory Devices MEL-TEMP apparatus and are uncorrected.

Preparation of 5-Bromo-1-hydroxy-2-methoxytropylium Tetrafluoroborate and 5-Bromo-1,2-dimethoxytropylium Tetrafluoroborate. A solution of 900 mg (4.19 mmol) of 5-bromo-2-methoxytropone and 743 mg (7.03 mmol) of trimethyloxonium tetrafluoroborate in 5 ml of anhydrous nitromethane was stirred under nitrogen for 58 h at room temperature. After 1 ml of methanol was added to quench the excess of the methylating reagent, addition of 15 ml of absolute ether precipitated pale yellow crystals which were collected by filtration followed by washing with absolute ether to give 810 mg (61% yield) of the BF_4^- salt of **1b**. From the filtrate, pale yellow crystals were precipitated on cooling. Filtration followed by washing with absolute ether gave 150 mg (12% yield) of the BF_4^- salt of **1a**. **1a**-BF_4^-: mp 155—158 °C; IR (KBr) 3400—3300, 3100—3000, 1592, 1570, 1500, 1450, 1350, 1275, 1150—980, 830, 530 cm^{-1}; ^{1}H NMR (CD_3CN, 90 MHz) δ=4.05 (s, 3H), 5.75—5.95 (brs, 1H), 7.31 (d, 1H, J=12 Hz), 7.41 (d, 1H, J=12 Hz), 8.10 (d, 2H,

J=12 Hz). **1b**-BF_4^-: mp 157—159 °C; IR (KBr) 3100, 1530, 1475, 1445, 1280, 1150-950, 923, 840, 700 cm^{-1}; MS m/z 316 (M^+); ^1H NMR (CD_3CN, 90 MHz) δ=4.28 (s, 6H), 8.07 (d, 2H, J=12 Hz), 8.73 (d, 2H, J=12 Hz).

Preparation of 1,4-Dimethoxytropylium Tetrafluoroborate. A solution of 80 mg (0.588 mmol) of 4-methoxytropone and 100 mg (0.647 mmol) of trimethyloxonium tetrafluoroborate in 3 ml of dichloromethane was stirred under nitrogen for 12 h. Addition of 50 ml of absolute ether precipitated 80 mg (85% yield) of **1k**-BF_4^- as colorless crystals which were used for the salt formation without further purification due to the deliquescent property. **1k**-BF_4^-: mp 93—95 °C; IR (KBr) 3100—2950, 1570, 1490, 1431, 1305, 1205, 1150—950, 862, 682 cm^{-1}; MS m/z 150 (M^+-BF_4); ^1H NMR (CD_3CN, 90 MHz) δ=4.12 (s, 6H), 7.95 (d, 2H, J=11 Hz), 8.11 (s, 2H), 8.70 (t, 1H, J=11 Hz).

Preparation of 1-Methylamino-2-methoxytropylium Tetrafluoroborate. 300 mg (2.83 mmol) of 2-aminotropone and 460 mg (3.11 mmol) of trimethyloxonium tetrafluoroborate in 5 ml of anhydrous nitromethane was stirred at room temperature for 82 h. After methanol was added to quench the excess of trimethyloxonium salt, addition of 30 ml of absolute ether precipitated yellow crystals. Filtration followed by washing with absolute ether gave 225 mg (36% yield) of **1r**-BF_4^- which was used without further purification due to the strongly deliquescent property. **1r**-BF_4^-: mp 93—98 °C, IR (KBr) 3200—2900, 1640, 1590, 1500, 1440, 1275, 1218, 1150—950, 940, 745 cm^{-1}; MS m/z 150 (M^+-BF_4); ^1H NMR (CD_3CN, 90 MHz) δ=4.19 (s, 3H), 4.73 (s, 3H), 7.40—7.95 (m, 5H).

Preparation of Methylthio Derivatives 1g,j,o. These tropylium ions were prepared by the reaction of corresponding tropothiones with methyl iodide. 2-Methyltropothione[28] and 2-aminotropothione[29] were prepared according to Nozoe's method. 2-Methoxytropothione was synthesized by the following method. To a suspension of 1.63 g (7.35 mmol) of phosphorus pentasulfide and 0.800 g (8.09 mmol) of triethylamine in 50 ml of carbon disulfide, a solution of 1.00 g (7.35 mmol) of 2-methoxytropone in 50 ml of carbon disulfide was added and stirred under nitrogen for 12 h at room temperature. The precipitated deep orange crystals were separated by decantation and washed with 10 ml of carbon disulfide 3 times. The combined carbon disulfide solution was evaporated under reduced pressure below 20 °C to give 670 mg (60% yield) of 2-methoxytropothione which was used without further purification. The structure of 2-methoxytropothione was confirmed by the ^1H NMR spectrum. ($CDCl_3$, 60 MHz) δ=3.90 (s, 3H), 6.5—7.0 (m, 4H), 8.15 (d, 1H, J=12 Hz).

When a solution of tropothiones and methyl iodide (10—30 equiv) in absolute ether was stirred under nitrogen for 12—15 h at room temperature, red solids deposited. Filtration followed by washing with absolute ether gave the iodides of tropylium ions **1g,j,o** in 70%, 25%, and 48% yields, respectively. **1g**: mp 178—180 °C; IR (KBr) 3100—2900, 1490, 1472, 1400, 1389, 1320, 1278, 1240, 1090, 1045, 735, 550 cm^{-1}; MS m/z 183 (M^+-I); ^1H NMR (CD_3CN, 90 MHz) δ=2.92 (s, 6H), 8.13—8.47 (m, 5H). **1j**: mp 93—95 °C; IR (KBr) 3000—2950, 1510, 1488, 1450, 1420, 1280, 1220, 1020, 938, 750, 560 cm^{-1}; ^1H NMR (CD_3CN, 90 MHz) δ=2.79 (s, 3H), 4.40 (s, 3H), 8.2—8.5 (m, 5H). **1o**: mp 130 °C (decomp); ^1H NMR (CD_3CN, 90 MHz) δ=2.78 (s, 3H), 7.6—8.1 (m, 5H).

Since the solubility of the iodide of **1g** in ethanol or acetonitrile was too low to be used for the salt formation, the counter anion was substituted for BF_4^-. To a solution of 200 mg of the iodide in 5 ml of absolute acetonitrile, 126 mg (0.645 mmol) of $AgBF_4$ was added. After the solution was stirred at room temperature for 1 h, the deposited AgI was filtered off and washed with absolute acetonitrile. The combined acetonitrile solution was evaporated to give 147 mg (84% yield) of the BF_4^- salt: mp 205—210 °C (decomp).

Preparation of Bicyclic Tropylium Ions 2. These ions were prepared by the deprotonation of the corresponding cycloheptatrienes **3a**[12] and **3b**.[13] To a solution of 200 mg (0.338 mmol) of bicyclic cycloheptatriene **3a** in 10 ml of anhydrous acetonitrile, 236 mg (2.02 mmol) of $NOBF_4$ in 5 ml of anhydrous acetonitrile was added with nitrogen bubbling. After the solution was stirred at room temperature for 15 min, addition of 50 ml of absolute ether precipitated yellow crystals. Filtration followed by washing with absolute ether gave 65 mg of **2a**-BF_4^-. The residue which was obtained by evaporation of the filtrate was treated with absolute ethanol. From the soluble part in ethanol, 130 mg of **2a**-BF_4^- was obtained by removal of the solvent. The total yield was 72%. **2a**-BF_4^-: mp 138—140 °C, IR (KBr) 3050—2950, 1500, 1470, 1425, 1285, 1150—950, 730 cm^{-1}; ^1H NMR (CD_3CN, 90 MHz) δ=3.61 (s, 4H), 8.02 (d, 2H, J=11 Hz), 8.10 (t, 1H, J=11 Hz), 8.45 (dd, 2H, J=11, 11 Hz).

Similarly, the reaction of 150 mg (1 mmol) of bicyclic cycloheptatriene **3b** with $NOBF_4$ (2 equiv) gave 189 mg (80% yield) of ethylenedioxytropylium ion **2b**: mp 128—130 °C; IR (KBr) 3100—3000, 1480, 1468, 1284, 1185, 1150—950, 750, 700 cm^{-1}; ^1H NMR (CD_3CN, 90 MHz) δ=4.70 (s, 4H), 8.40 (s, 5H).

Preparation of 5-Methyl-5*H*-cyclohepta[*b*]quinoxaline. A solution of 4.69 g (33.4 mmol) of 2-chlorotropone and 4.50 g (36.9 mmol) of *N*-methyl-1,2-phenylenediamine[30] in 60 ml of absolute ethanol was refluxed under nitrogen for 48 h. Removal of the solvent gave black tarry matter to which 2 M hydrochloric acid was added. The solution was washed with benzene to remove the recovered 2-chlorotropone, made basic with 2 M sodium hydroxide, and extracted with 100 ml of benzene 3 times. The extract was washed with sat. aqueous $NaHCO_3$ and dried over Na_2SO_4. Evaporation of the solvent followed by column chromatography on alumina (2:1 ether-hexane) gave 2.38 g of dark green crystals which were recrystallized from pentane-hexane to give 1.80 g (26% yield) of **5c** as dark green needles: mp 92—93 °C; IR (KBr) 3050, 2900, 1620, 1570, 1480, 1330, 720 cm^{-1}; MS (25 ev)(relative intensity) 208 (M^+, 92), 193 (M^+,$-CH_3$); ^1H NMR ($CDCl_3$, 200 MHz) δ=2.74 (s, 3H), 4.42 (ddd, 1H, J=9.5, 2.0, 0.8 Hz), 5.29 (dddd, 1H, J=11.0, 8.0, 2.9, 2.0 Hz), 5.57 (ddd, 1H, J=12.0, 2.9, 1.0 Hz), 5.85 (dddd, 1H, J=12.0, 8.0, 1.2, 0.8 Hz), 5.86 (dddd, 1H, J=11.0, 9.5, 1.2, 1.0 Hz), 6.19 (dd, 1H, J=8.0, 1.2 Hz), 6.63 (ddd, 1H, J=10.0, 7.0, 1.2 Hz), 6.66 (dd, 1H, J=10.0, 2.3 Hz), 6.73 (ddd, 1H, J=8.0, 7.0, 2.3 Hz). Found: C, 80.74; H, 5.81; N, 13.45%. Calcd for $C_{14}H_{12}N_2$: C, 80.46; H, 5.81; N, 13.51%.

Preparation of Tricyclic Cation 4b,d,f by Methylation of the Corresponding Heterocycles 5. Methylation of **5a** using methyl iodide or dimethyl sulfate gave a complex mixture of products. However, reaction of **5a** with trimethyloxonium tetrafluoroborate gave the methylated

a) The molar ratio could not be determined on the basis of the analytical data.

compound **4b**. 99 mg (0.711 mmol) of trimethyloxonium tetrafluoroborate was added under nitrogen to a solution of 150 mg (0.711 mmol) of **5a** in 5 ml of dichloromethane. Stirring at room temperature for 24 h gave 180 mg (80% yield) of **4b**-BF_4^-: mp 158—160 °C (decomp); ^{1}H NMR (CD_3CN, 60 MHz) δ=3.67 (s, 3H), 6.97—7.67 (m, 9H).

Methylation of **5b** with methyl iodide in absolute ether readily gave **4d**-I^-: mp 196—198 °C (decomp); ^{1}H NMR (CD_3CN, 90 MHz) δ=3.33 (s, 3H), 6.67—9.96 (m, 9H).

Methylation of **5c** with methyl iodide in absolute ether gave deep green crystals which were recrystallized from ethanol to give **4f**-I^- in 75% yield as deep green plates: mp 267—268 °C (decomp); ^{1}H NMR (DMSO-d_6, 90 MHz) δ=3.13 (s, 6H), 6.46 (m, 2H), 6.55 (m, 1H), 6.67—7.10 (m, 4H), 7.30 (m, 2H). Found: C, 51.26; H, 4.36; N, 7.94%. Calcd for $C_{15}H_{15}N_2I$: C, 51.45; H, 4.32; N, 8.00%.

Preparation of Heterocyclic Cation 6. In a similar manner as the preparation of bicyclic cations **2a,b**, heterocyclic cation **6** was prepared by the dehydrogenation of heterocycle **7**[12] with $NOBF_4$. The reaction of 100 mg (0.434 mmol) of **7** with 51 mg (0.434 mg) of $NOBF_4$ in anhydrous acetonitrile gave 51 mg (37% yield) of **6**-BF_4^-: mp 40—42 °C; IR (KBr) 3020, 1604, 1510, 1457, 1440, 1270, 1100—980, 755, 730, 560 cm^{-1}; MS *m/z* 230 (M^+-BF_4) ^{1}H NMR (CD_3CN, 90 MHz) δ=7.4—7.9 (m, 4H), 8.3—8.7 (m, 5H). Found: C, 47.40; H, 3.48; S, 19.82%. Calcd for $C_{13}H_{10}S_2BF_4(H_2O)_{0.5}$: C, 48.02; H, 3.10; S, 19.72%.

Preparation of TCNQ$^-$ salts. The following is a general procedure to prepare salts. A boiling saturated absolute ethanol or acetonitrile solution of cations and a boiling saturated absolute ethanol solution of Li$^+$TCNQ$^-$ were mixed. The solution was allowed to stand at room temperature until crystals precipitated. Filtration followed by washing with a small amount of absolute ethanol and then absolute ether gave salts. The reaction of 1:1 salts with another equivalent of TCNQ in boiling acetonitrile gave their complex salts. Melting points, forms of crystals, and analytical data of salts are shown in Table 5.

Preparation of BTDA-TCNQ$^-$ Salts. BTDA-TCNQ$^-$ of tropylium ions were prepared by metathesis of tropylium ions and Li$^+$BTDA-TCNQ$^-$ in a similar manner as TCNQ$^-$ salts. The properties along with analytical data are shown in Table 6.

The Solubility of Peptide Intermediates in Organic Solvents.[1] Solubilizing Potential of Hexafluoro-2-propanol

Mitsuaki NARITA,* Shinya HONDA, Hiroshi UMEYAMA, and Satoshi OBANA
Department of Industrial Chemistry, Faculty of Technology, Tokyo University of Agriculture and Technology, Koganei 184
(Received July 29, 1987)

The solubility of peptides to be insoluble in EtOH, MeOH, DMF, DMA, NMP, DMSO, and HMPA was examined in HFIP, sulfolane, TMP, PC, and a mixture of 5—10% HFIP-CH_2Cl_2 (v/v). HFIP has the highest solubilizing potential, followed by HMPA and DMSO, while the solubilizing potential of sulfolane, TMP, and PC is lower than that of HMPA, DMSO, DMF, and NMP and is close to that of MeOH and EtOH. The solubility of the peptides in the mixture of HFIP-CH_2Cl_2 marvelously is as high as that in HFIP alone. The solvent-titration study in CH_2Cl_2-polar solvents clearly indicated that the solubility of peptides having a β-sheet structure in organic solvents was independent of the polarity of the solvents but was strongly dependent on their hydrogen donating and accepting ability. The conformation of the peptides in the mixture of HFIP-CH_2Cl_2 and in HFIP alone was examined using the IR and CD spectroscopies, respectively.

The search for effective solvents for peptide and protein synthesis is of practical significance since the insolubility of peptide intermediates, protected peptides, is a serious problem for peptide and protein synthesis.[2] In many cases, the insolubility of peptide intemediates in high-polar organic solvents, namely, DMA, DMF, NMP, DMSO, and HMPA is caused by a β-sheet aggregation consisting of peptide chains equal to or larger than an octa- or nonapeptide sequence.[3-10] Therefore, it is of paramount significance to elucidate what plays an important role in disrupting a β-sheet aggregation.

In this paper, we first examine the solubility of the peptides **1—15** (Fig. 1) in high-polar organic solvents shown in Table 1. Next using a solvent-titration technique, we exemplify that the hydrogen donating and accepting ability of solvent plays an important role in disrupting a β-sheet aggregation.

The peptides **1—15** have a β-sheet structure in the solid state, and their solubility was already examined in low-, medium-, and high-polar solvents such as benzene, carbon tetrachloride, ethyl acetate, tetrahydrofuran, dichloromethane, chloroform, AN, EtOH, MeOH, DMF, DMA, NMP, DMSO, and HMPA.[3-6] Generally, the solubility of peptides having a β-sheet structure in medium-polar solvents decreases extremely at a hexa- or heptapeptide level and their solubility in high-polar solvents, at an octa- or nonapeptide level.

Experimental

Materials. The samples of the peptides **1—15** are those prepared before.[3-6] The purity of the peptides was confirmed by elemental and amino acid analyses. The peptides soluble in DMF gave a single peak on high-performance liquid chromatography.

IR Measurements. The IR absorption spectra of the samples in dichloromethane were recorded at room temperature with a JEOL Model JIR-100 FT-IR spectrometer by employing 0.5 mm-path length cells with sodium chloride windows. The concentration of the peptides was kept 1.0×10^{-3} M (1 M=1 mol dm^{-3}).

CD Measurements. The CD spectra were recorded using a JASCO model J-40AS recording spectropolarimeter. Experimental details have been reported elsewhere.[11] The concentration of the peptides was kept 1.0 mg ml^{-1}.

Results and Discussion

The Solubility of the Peptides 1—15 in High-Polar Organic Solvents. The solubility of the peptides **1—15** was examined in the high-polar solvents shown in Table, namely, HFIP, sulfolane, PC, TMP, and a mixture of 5—10% HFIP-CH_2Cl_2 (v/v). The results are summarized in Table together with the solubility of the peptides **1—15** in HMPA, DMSO, DMF, DMA, NMP, EtOH, MeOH, AN, and CH_2Cl_2.[3-6] The solubility (c=1.0 g dl^{-1}) was divided into the following four classes: (A) completely soluble at room temperature, (B) completely soluble at 80°, (C) partially soluble at 80° and (D) nearly insoluble at 80°. In the cases of HFIP, EtOH, MeOH, 5% and 10% HFIP-CH_2Cl_2 mixtures, and CH_2Cl_2, the classes (B), (C), and (D) were decided at refluxing temperature. As shown in Table, among the solvents examined, HFIP has the highest solubilizing potential, followed by the second class of HMPA and DMSO and the third one of DMF, DMA, and NMP, while the solubilizing potential of sulfolane, TMP, and PC is lower than that of DMF, DMA, and NMP and is close to that of EtOH and MeOH. It is marvelous that the solubilizing potential of the mixture of HFIP-CH_2Cl_2 is higher than that of HMPA and DMSO and is close to that of HFIP alone. The last result is of great significance for peptide and protein synthesis since it suggests that we can use a mixture of HFIP and CH_2Cl_2 instead of quite expensive HFIP for further peptide-chain elongation.

Solvent-Titration Study of Boc-Val-Gly-Phe-Gly-Leu-Ile-Leu_2-OBzl 16. Octapeptides having a β-sheet structure in the solid state are usually insoluble

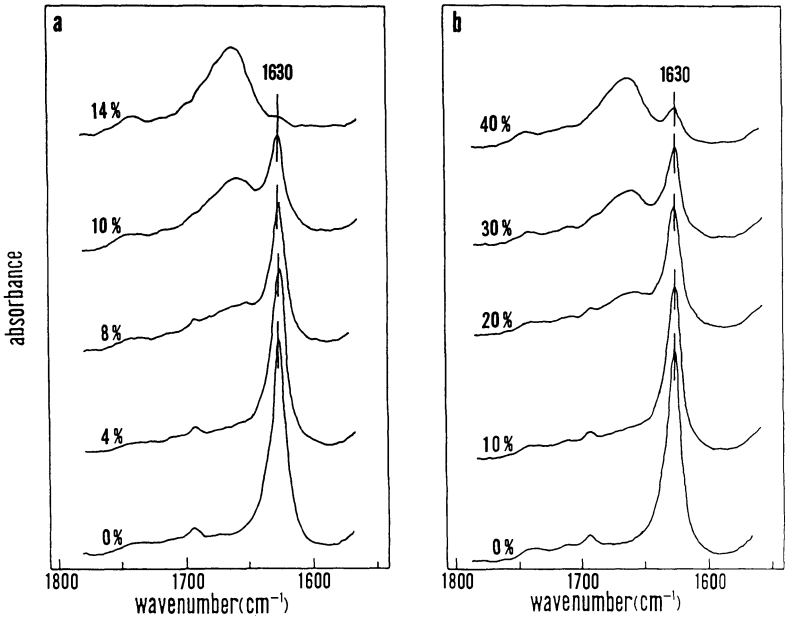

Fig. 2. Typical IR absorption spectra in the amide I region of the peptide **16** in CH_2Cl_2-DMSO (a) and CH_2Cl_2-TMP (b). The percentages in Fig. 2 indicate v/v-%.

in CH_2Cl_2,[3-6] but the octapeptide **16** is a novel one to be soluble in CH_2Cl_2. It has an antiparallel β-sheet structure in CH_2Cl_2 solution.[4] Figure 2 shows typical IR absorption spectra of the peptide **16** in CH_2Cl_2–DMSO and CH_2Cl_2–TMP solutions in the amide I region. Weak and strong bands at 1690 and 1630 cm^{-1} in CH_2Cl_2 solution, respectively, are assigned to an antiparallel β-sheet structure.[12] Successive addition of DMSO or TMP to the CH_2Cl_2 solution induces a dramatic decrease in the strong band at 1630 cm^{-1} and an increase in the broad band at 1660 cm^{-1}, indicating that the β-sheet aggregation of the peptide **16** is easily disrupted by increasing amounts of DMSO and TMP. Both solvents are known to function as hydrogen acceptor and to form effective hydrogen bonds with peptide N–H bonds, thereby disrupting the β-sheet aggregation. Figure 3 illustrates the solvent-titration curves of the peptide **16** in the CH_2Cl_2 solution. By adding increasing amounts of the high-polar solvents, namely, HFIP, HMPA, DMSO, TMP, and PC, similar trends as a function of solvent composition are observed among the high-polar solvents. These solvent-titration curves indicate that, among the solvents examined, HFIP has the highest potential for disrupting a β-sheet aggregation in the CH_2Cl_2 solution, followed by the second class of HMPA and DMSO, and the third one of TMP and PC. The similar trends were also observed among DMSO, HMPA, and TMP in the solvent-titration study of N-protected C-terminal sequences of substance P.[13] PC has the highest polarity (see footnotes in Table), but its solubilizing potential is low, while the polarity of HFIP is estimated to be similar to that of HMPA and DMSO, but its solubilizing potential is the highest. Similarly, AN with higher polarity than HMPA has remarkably lower solubilizing potential than HMPA. These results distinctly denote that the solubility of the peptides **1**—**15** in the high-polar solvents is independent of the polarity of solvent but is strongly dependent on the hydrogen donating and accepting ability of solvent.

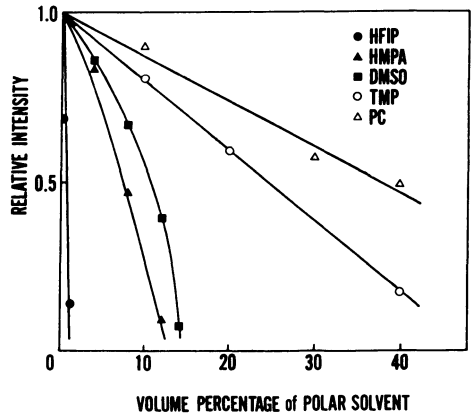

Fig. 3. Relative intensity of the amide I carbonyl stretching 1630-cm^{-1} band related to the β-sheet structure in the IR absorption spectra of the peptide **16** in CH_2Cl_2–HFIP (●) CH_2Cl_2–HMPA (▲), CH_2Cl_2–DMSO (■), CH_2Cl_2–TMP (○), and CH_2Cl_2–PC (△).

Conformation of the Peptides 6, 8—10, and 12 in 5% HFIP–CH_2Cl_2 (v/v) Solution and in HFIP Solution. Figure 4 presents the IR absorption spectra of the peptides **6**, **8—10**, and **12** in a 5% HFIP–CH_2Cl_2 solution in the amide I region. These spectra show that the 1630-cm^{-1} band disappears completely and the strong 1660-cm^{-1} band appears. These results distinctly indicate that HFIP having a strong proton donating ability effectively disrupts a β-sheet aggrega-

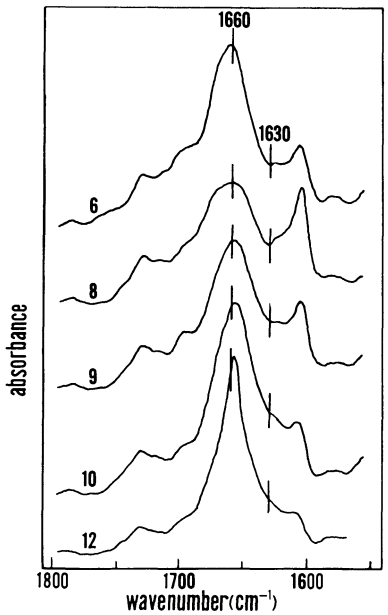

Fig. 4. IR absorption spectra in the amide I region of the peptides **6**, **8—10**, and **12** in 5% HFIP–CH_2Cl_2 solution.

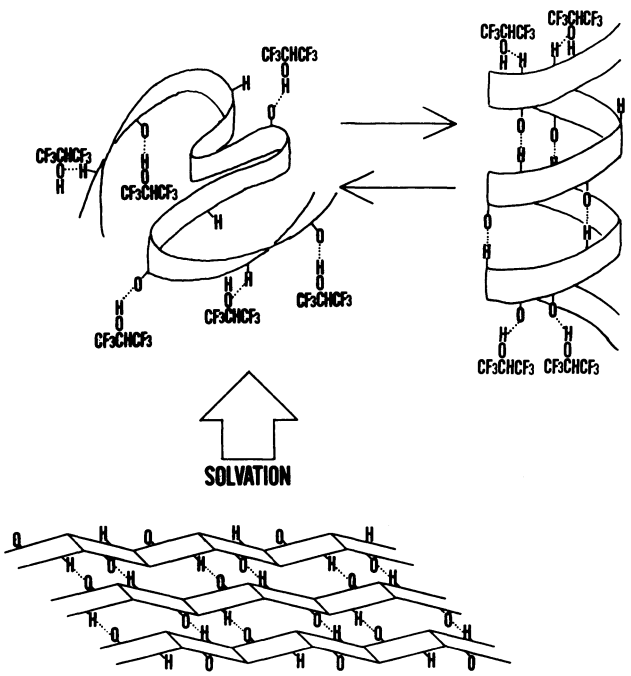

Fig. 5. Scheme in eqeuilibrium between unordered and helix structures.

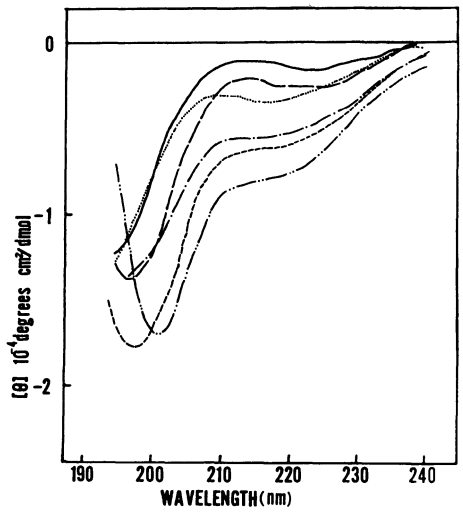

Fig. 6. CD spectra of the peptides **8**—**12** and **14** in HFIP solution. **8**, ——; **9**, ··; **10**, ------; **11**, —— **12**, —·—·—; **14**, —··—··—.

tion formed by peptide chains equal to or smaller than a dodecapeptide sequence. Since HFIP is known to promote helical folding of peptide chains, the conformation of the peptides **6**, **8**—**10**, and **12** in the 5% HFIP-CH_2Cl_2 solution might be in equilibrium between helical and unordered structures (Fig. 5), and the peptide to have unordered structures is justly subjected to solvation to form hydrogen bonds effectively shown in Fig. 5. As shown in Fig. 6, the CD spectra of the peptides **8**—**12** and **14** in HFIP practically indicate these peptides to be in equilibrium between helix and unordered structures. The equilibrium constant is properly dependent on the nature of amino acid sequences.

Conclusion

The solubilizing potential of high-polar organic solvents for peptide intermediates was in fairly good agreement with the hydrogen donating and accepting ability of solvents. Namely, the solubilizing potential was in the following order: HFIP≫HMPA and DMSO>DMF, DMA, and NMP≫TMP, PC, EtOH, and MeOH≫AN, while the hydrogen donating and accepting ability was also in the following order: HFIP≫HMPA>DMSO≫TMP>PC. The solubility of peptides equal to or larger than octapeptides having a β-sheet structure in the solid state in the mixture of 5—10% HFIP-CH_2Cl_2 (v/v) was marvelously close to their solubility in HFIP alone, indicating that HFIP behaves itself like a denaturant in CH_2Cl_2 solution although HFIP has a high potential as a promoter of helical folding of peptides. The results obtained in this paper afford the powerful basis for exploration of effective solvents for peptide and protein synthesis. Use of a mixture of HFIP and CH_2Cl_2 as a solvent in peptide chain elongation, in many cases, will also overcome the serious problem for peptide and protein synthesis, namely, the insolubility of peptide intermediates. Now, we are working on the peptide chain elongation in a mixture of HFIP-CH_2Cl_2.

The authors wish to thank Central Glass Co., Ltd., for the generous gift of HFIP.

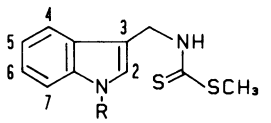
Novel Sulfur-Containing Phytoalexins from the Chinese Cabbage *Brassica campestris* L. ssp. *pekinensis* (Cruciferae)[1]

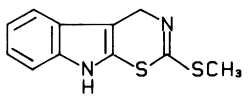
Mitsuo TAKASUGI,* Kenji MONDE, Nobukatsu KATSUI, and Akira SHIRATA†,††
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060
†National Institute of Agro-Environmental Sciences, Yatabe-machi, Tsukuba 305
(Received July 29, 1987)

The first isolation and structure elucidation of four sulfur-containing indole phytoalexins from Chinese cabbage inoculated with *Pseudomonas cichorii* are described.

Accumulation of phytoalexins, antimicrobial compounds synthesized by plants after their exposure to micro-organisms,[2] has been described from over 20 plant families,[3] Because of their antimicrobial properties, an important role of phytoalexins in host defense mechanisms has been suggested.[4] We recently reported the isolation of two sesquiterpenoids,[5] a bibenzyl,[6] and two polyacetylenes[7] as phytoalexins from lettuce (*Lactuca sativa* var. *capitata*, Compositae), Chinese yam (*Dioscorea batatas*, Dioscoreaceae), and burdock (*Arctium lappa*, Compositae), respectively. The plant family Cruciferae includes many vegetables of economic importance such as cabbage, Chinese cabbage, radish, turnip, and so on.[8] However, no phytoalexins have been reported from this family. We reported, in a preliminary communication,[9] on the isolation and structures of three cruciferous phytoalexins, named methoxybrassinin (**1**), brassinin (**2**), and cyclobrassinin (**3**), from Chinese cabbage (*Brassica*



1 : R=OCH3
2 : R=H



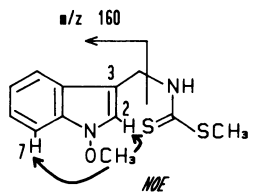
3

campestris L. ssp. *pekinensis*) inoculated with the bacterium *Pseudomonas cichorii*. In this paper we describe the details of the study and the isolation of an additional new phytoalexin, methoxybrassitin (**4**), together with a related compound **5**.

Results and Discussion

Sliced heads of Chinese cabbage were inoculated with the suspension of the bacterium *Pseudomonas cichorii* and incubated at 20 °C for 3 days. After being dried, the incubated tissue was extracted with acetone. Two-dimensional TLC bioassay[9] of the extracts revealed the presence of several antifungal compounds not detected in uninoculated control tissue. The acetone extracts from the inoculated tissue were submitted to sequential chromatography on silica gel and Sephadex LH-20 columns, giving five antifungal compounds **1**, **2**, **3**, **4**, and **5** in the yields (based on dry weight of the tissue) of 0.018%, 0.0022%, 0.0098%, 0.0011%, and 0.00047%, respectively.[10]

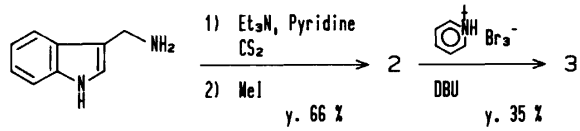
Methoxybrassinin (**1**) was obtained as a viscous oil. The molecular formula of **1** was determined to be $C_{12}H_{14}N_2OS_2$ by high-resolution mass spectrometry (HR-MS), together with ^1H and ^{13}C NMR spectral information. Its UV [λ_{max} (CH_3OH) 218 and 267 nm] spectrum suggested the presence of an *N*-methoxyindole nucleus[11] in **1**. The ^1H NMR spectrum ($CDCl_3$) showed signals for five aromatic protons, of which four [δ 7.60 (d, J=8 Hz, 4-H), 7.17 (ddd, J=8, 8, and 2 Hz, 5-H), 7.30 (ddd, J=8, 8, and 2 Hz, 6-H), and 7.45 (d, J=8 Hz, 7-H)] were assigned successively by spin-decoupling experiments and their locations were confirmed by nuclear Overhauser enhancement (NOE) difference experiments. Irradiation of N-OCH_3 protons at δ 4.10 resulted in enhancements of both the signals at δ 7.45 (7-H) and 7.34 (2-H), indicating that the position 2 of the indole nucleus is unsubstituted. Therefore, the position 3 of the nucleus should have a substituent. The ^1H and ^{13}C NMR spectra further indicated that the substituent contains one each of $-CH_2-$ [δ_H 5.02 (d, J=4 Hz) and δ_C 42.8], >NH [δ_H 7.0 (br s)], >C=S (δ_C 198.3), and $-SCH_3$ [δ_H 2.65 (s) and δ_C 18.2]. Its mass spectrum showed a base peak at *m/z* 160.0733 $(M-C_2H_4NS_2)^+$, indicating that the methylene in the substituent is attached to C-3 of the nucleus. Since ^1H NMR signals of the methylene changed from a doublet to a singlet on exchange with D_2O, it is further connected to the >NH leading to the whole structure **1**. The dithiocarbamate structure in **1** was further supported by the presence of a minor rotational isomer [δ 2.75 (s, $-SCH_3$), 4.75 (br d, J=4 Hz, $-CH_2-$), and 7.6 (br s, >NH)] due to hindered C-N rotation.[12] 1-Methoxyindole derivatives are rather rare as natural products[11] although the occurrence of indole alkaloids has been observed in many plants.[13]



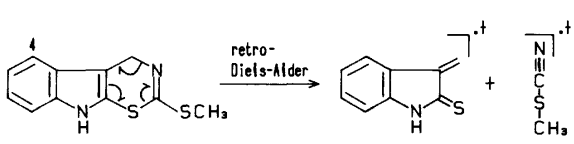
1

†† Present address: Sericultural Experiment Station, Yatabe-machi, Tsukuba 305.

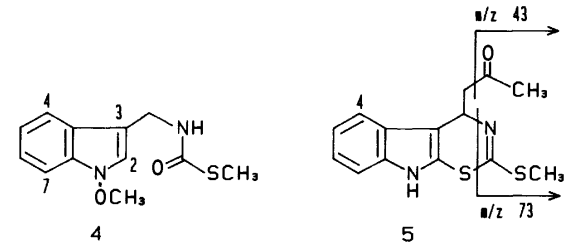
Brassinin (**2**), mp 132—133 °C, has the molecular formula $C_{11}H_{12}N_2S_2$ by HR-MS. Its spectral data indicated **2** as a demethoxy derivative of **1**. The ^{1}H NMR spectrum was similar to that of **1** except that **2** showed a signal due to an indolic NH (δ 8.16) in place of the methoxyl group. The IR spectrum showed a sharp absorption (ν_{max} 3490 cm^{-1}) due to the indolic NH. The UV spectrum [λ_{max} (CH_3OH) 218 and 268 nm] was similar to that of **1**. The mass spectrum showed a base peak at *m/z* 130.0679 $(M-C_2H_4NS_2)^+$ and implied that the indole ring of **2** is connected to a methylene group of a side chain as in **1**. Similarly, NOE experiment confirmed the position of the side chain at C-3. Namely, irradiation of the indolic NH induced the enhancements of signals at δ 7.25 (2-H) and 7.42 (7-H). The side chain was shown to be the same as that of **1** based on ^{1}H and ^{13}C NMR spectra [δ_H 5.07 (d, J=4 Hz) and δ_C 43.2 (t), $-CH_2-$; δ_H 7.0 (br), >NH; δ_C 198.2, >C=S; δ_H 2.65 (s) and δ_C 18.2 (q), $-SCH_3$]. Therefore, the whole structure of brassinin should be represented by **2**. The structure of **2** was confirmed by the following synthesis. Treatment of 3-(aminomethyl)indole[14] with carbon disulfide in the presence of pyridine and triethylamine gave a dithiocarbamate salt, which was methylated with methyl iodide to give **2** in 66% yield. The both synthetic and natural specimens were identical in all respects.



Cyclobrassinin (**3**), mp 136—137 °C, has the molecular formula $C_{11}H_{10}N_2S_2$ by HR-MS and showed a slightly different UV [λ_{max} (CH_3OH) 204, 227, 284, and 294 nm] spectrum from those of **1** and **2**. Its ^{1}H NMR spectrum showed signals for 2,3-disubstituted indole. In NOE difference experiment, irradiation of an indolic NH at δ 7.91 caused enhancement of the only one proton signal at δ 7.33 (7-H, indole numbering). Consecutive spin-decoupling experiments assigned the three remaining indole ring protons [δ 7.18 (6-H), 7.14 (5-H), and 7.49 (4-H)]. The spectrum further showed the presence of a methylene (δ 5.09, 2H, s) and a methylthio (δ 2.56, 3H, s) groups. The presence of nine sp^2 carbon atoms in the ^{13}C NMR spectrum, together with eight degrees of unsaturation implied a tricyclic structure of **3**. Its mass spectrum showed two peaks at *m/z* 161 $(M-C_2H_3NS)^+$ and 73 (C_2H_3NS), which suggested a retro-Diels-Alder fission of the third ring in **3**. This fragmentation and the presence of a >C=N- group (δ_c 152.0; ν_{max} 1600 cm^{-1}) suggested that **3** contained a 4*H*-1,3- or a 4*H*-1,2-thiazine moiety. The former was preferred when we considered the low carbon chemical shift (δ 48.8) of the methylene and the co-occurrence of **3** with **2** in the inoculated Chinese cabbage tissue. In NOE difference experiment irradiation of the indole ring proton at δ 7.49 (4-H) resulted in the signal enhancement of the methylene protons and supported the proposed structure **3**. The structure was confirmed by transforming brassinin (**2**) to **3**. Bromination of **2** with pyridinium bromide perbromide, followed by dehydrobromination, gave **3** in 35% yield, which was identical with natural cyclobrassinin.

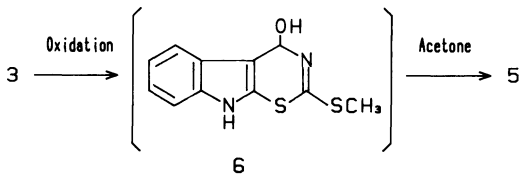


Methoxybrassitin (**4**). mp 94—96 °C, has a molecular formula of $C_{12}H_{14}N_2O_2S$. Comparison of its ^{1}H NMR spectral feature [δ 7.60 (4-H), 7.15 (5-H), 7.28 (6-H), 7.43 (7-H), 7.25 (2-H), and 4.07 (1-OCH_3)] with those of **1** suggested that **4** was also a 3-substituted *N*-methoxyindole. This view was supported by spin-decoupling and NOE difference experiments. Irradiation of the methoxyl protons and of the aromatic proton at δ 7.60 (4-H) caused signal enhancements of 2-H and 7-H protons, and methylene protons at δ 4.61 (d, J=5 Hz), respectively. The mass spectrum of **4** showed a base peak at *m/z* 160 $(M-C_2H_4NOS)^+$, indicating that the *N*-methoxyindole nucleus links a methylene group as in **1**. Since the methylene proton signals changed from a doublet to a singlet on exchange with D_2O, the methylene was further connected to a >NH. Namely, methoxybrassitin (**4**) differs from **1** in a substituent at the >NH. The substituent (C_2H_3OS) was assigned $-(C=O)SCH_3$ based on IR (1662 cm^{-1}, >C=O) and ^{13}C NMR [δ 167.6 (s), >C=O; 12.4 (q), $-SCH_3$] spectral data giving the structure **4**.



The fifth compound **5**, amorphous solid, has a molecular formula of $C_{14}H_{14}N_2OS_2$ and showed a very similar UV [λ_{max} (CH_3OH) 202, 227, 282, and 294 nm] spectrum to that of cyclobrassinin (**3**). The ^{1}H NMR spectrum [δ 7.59 (4-H), 7.14 (5-H), 7.17 (6-H), 7.31 (7-H), and 7.96 (br s, indole NH)] of **5** also showed characteristic of 2,3-disubstituted indole. The same ring system as in **3** was postulated when the IR (**5**: 1598 cm^{-1}; **3**: 1600 cm^{-1}) and ^{13}C NMR (**5**: δ_c 151.8; **3**: δ_c 152.0) absorptions of >C=N- groups were compared

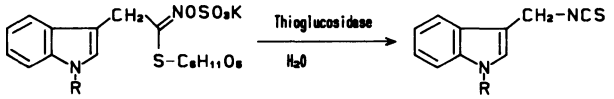
with those of **3**. The NMR spectra of **5** further showed the presence of a methylthio group (δ_H 2.51 and δ_C 15.1) attached probably to the above >C=N- and also of a moiety CH_3COCH_2- [δ_H 2.21 (3H, s) and δ_C 30.9, $-CH_3$; δ_C 206.5, >C=O; δ_H 2.87 (dd, J=8 and 15 Hz) and 2.99 (dd, J=6 and 15 Hz), and δ_C 49.0, $-CH_2-$] attached to a methine group [δ_H 6.00 (dd, J=6 and 8 Hz) and δ_C 56.0]. In NOE difference experiments, irradiation of the proton at δ 7.59 (4-H) resulted in enhancements of signals due to both the methine and the methylene protons. Therefore, the structure **5** was proposed. Two diagnostic mass fragments at m/z 43 (C_2H_3O) and 73 (C_2H_3NS) were reasonably explainable by the structure **5**. The compound **5** may be an artefact derived from **3**, since it showed no optical activity and acetone was used as a solvent for extraction. The artefact-forming process, however, requires an oxidation step. Long time stirring of **3** with acetone in the presence of air showed no indication of the formation of **5**. Therefore, **5** might be a condensation product of



6

acetone with a hydroxy derivative **6** produced in the inoculated tissue, although such compound has not been isolated to date.

Cruciferous plants, including Chinese cabbage, contain thioglucosides called glucosinolates,[15] which undergo enzymic hydrolysis on crushing of the plant tissues to give isothiocyanates. Since Chinese cabbage contains neoglucobrassicin and glucobrassicin (**7** and **8**, respectively)[15] the formation of methoxybrassinin (**1**) and brassinin (**2**) might be explained by reactions of the respective isothiocyanates (**9** and **10**) derived from the glucosinolates (**7** and **8**) with methanethiol



7: R=OCH₃
8: R=H

9: R=OCH₃
10: R=H

possibly generated in the course of cutting the tissue. This possibility was ruled out, however, from the following experiments: i) crushed uninoculated Chinese cabbage tissue gave none of these compounds when they were incubated for 0, 1, 2, 3, and 4 days at 20 °C; ii) none of these compounds **1** to **4** were detected when the excised Chinese cabbage tissue without the bacterium inoculation was incubated under the same conditions as those of the inoculated tissue (20 °C, 3 days); iii) production of these compounds was also induced by ultraviolet irradiation. In this case, tissue is not mechanically injured.

It is interesting to note that Nomoto and Tamura reported the isolation of 1-methoxyindoleacetonitrile from clubroots of Chinese cabbage.[11] They supposed it to be a metabolite of the roots infected with *Plasmodiophora brassicae*. We have also observed the presence of this compound in *P. cichorii*-inoculated daikon (*Raphanus sativus* L. var. *hortensis*).[16]

These four compounds **1**, **2**, **3**, and **4** exhibited broad, moderate antifungal activity against over 31 plant pathogenic fungi, e. g. *Pyricularia orizae*, with complete inhibition at 400 ppm, and moderate inhibition at 100 ppm.

Although many phytoalexins (over 200 compounds) have been isolated to date,[3] this is the first report of sulfur-containing phytoalexins.

Experimental

All the melting points were uncorrected. IR spectra were recorded with a JASCO A-120 spectrometer, UV spectra with Shimadzu UV 240 spectrometer, ^1H and ^{13}C NMR spectra with JEOL JNX-GX400 or JEOL JNM-FX200 spectrometer in deuteriochloroform solution containing tetramethylsilane as an internal standard, low and high resolution mass spectra with a JEOL JMS-D300 spectrometer, with direct inlet system operating at 70 eV. HPLC separation was performed with a Hitachi 635S equipped with a JASCO UVIDEC-100V detector, using an analytical or a preparative μ-Porasil column (Waters Associates).

Method of Bioassay. For two-dimensional TLC bioassay, developed silica-gel sheet (i, Et_2O; ii, CH_2Cl_2-CH_3OH, 98:2) was sprayed with a dense conidial suspension of *Bipolaris leersiae* in a potato-glucose medium, and incubated in a moist box at 25 °C for 2 days. Fungitoxic spots appeared white against a dark gray background. Antifungal activity of each chromatographic fraction was monitored by one-dimensional TLC bioassay using the solvent system i or ii.

Induction and Isolation of the Phytoalexins. Chinese cabbage heads (*Brassica campestris* L. ssp. *pekinensis*) were cut into small pieces and kept in a moist chamber at 20 °C for 1 day, and then inoculated with *Pseudomonas cichorii* (ca. 10^8 cells ml^{-1}). After being incubated at 20 °C for 3 days they were air-dried at 60 °C. The dried tissue (1418 g) was extracted twice with acetone at room temperature. The extracts were evaporated under reduced pressure below 35 °C to give an acetone extract (20.0 g), which was triturated with ethyl acetate to remove inactive insoluble material (2.27 g). The filtered ethyl acetate solution was passed through a short silica-gel column and the column was eluted with ethyl acetate. The eluate (14.15 g) from the column was separated into three fractions by chromatography on silica gel: F-1-1 (0.97 g), inactive fraction eluted with CH_2Cl_2-CH_3OH (99.5:0.5); F-1-2 (4.55 g), less polar active fraction eluted with the above eluent; F-1-3 (8.87 g), more polar active fraction eluted with CH_2Cl_2-CH_3OH (99.5:0.5, and 7:3). Further fractionation of F-1-3 will be reported in future.

Fraction F-1-2 was separated into five fraction (F-2-1—F-2-5) by chromatography on Sephadex LH-20 with CH_3OH-EtOAc (1:1). Fraction F-2-3 (525 mg) was further separated

into 6 fractions (F-3-1—F-3-6) by chromatography on silica gel with hexane-diethyl ether (4:1). Fraction F-3-2 (265 mg) was further purified by chromatography on silica gel with CH_2Cl_2-CH_3OH (99.5:0.5) to give methoxybrassinin **1**, 250 mg). Fraction F-3-4 (15.8 mg) was purified by three sequential preparative HPLC on a μ-Porasil column using CH_2Cl_2-CH_3OH (99.5:0.5), benzene-EtOAc (20:1), and hexane-diethyl ether (4:1) to give a compound **5** (6.7 mg). Fraction F-3-5 (40.2 mg) was purified by a silica-gel column with benzene-EtOAc (10:1), followed by preparative HPLC on a μ-Porasil column using CH_2Cl_2-hexane-CH_3OH (800:200:1), yielding methoxybrassitin (**4**, 15.9 mg). Fraction F-2-4 (226 mg) was fractionated by chromatography on silica gel with CH_2Cl_2 to give cyclobrassinin (**3**, 139.1 mg) and brassinin (**2**, 30.8 mg).

Characterization of the Compounds 1—5. Methoxybrassinin (1): $C_{12}H_{14}N_2OS_2$ (*m/z* 266.0550, M^+); viscous oil; IR ($CHCl_3$) 3380, 1475, 1452, 1352, 1298, 1088, 958, and 922 cm^{-1}; UV (CH_3OH) 218 (ε 37300), 241 (trough, 11500), 267 (15800), 287 (sh, 9470), and 297 (sh, 5740) nm; ^1H NMR δ=2.65 (s, $-SCH_3$), 4.10 (s, $-OCH_3$), 5.02 (d, *J*=4 Hz, $-CH_2-$), 7.0 (br, >NH), 7.17 (ddd, *J*=8, 8, and 2 Hz, 5-H), 7.30 (ddd, *J*=8, 8, 2 Hz, 6-H), 7.34 (s, 2-H), 7.45 (d, *J*=8 Hz, 7-H), and 7.60 (d, *J*=8 Hz, 4-H). The spectrum showed minor signals (1/4 intensity of the major signals) due to a rotamer at δ= 2.75 (s, $-SCH_3$), 4.75 (br d, *J*=4 Hz), and 7.6 (br, >NH); ^{13}C NMR δ=18.2 (q, $-SCH_3$), 42.8 (t, $-CH_2-$), 66.0 (q, $-OCH_3$), 106.4 (s), 108.6 (d), 119.0 (d), 120.5 (d), 122.7 (d), 123.0 (s), 123.1 (d), 132.3 (s), and 198.3 (s, >C=S); MS *m/z* (%) 266 (4, M^+), 235 [54, $(M-OCH_3)^+$], 218 [16, $(M-SCH_3-H)^+$], 160 (100, $C_{10}H_{10}NO$), 145 (28), 129 (57), and 91 (23, $C_2H_3S_2$).

Brassinin (2): $C_{11}H_{12}N_2S_2$ (*m/z* 236.0418, M^+); mp 132—133 °C (CH_2Cl_2-hexane); IR ($CHCl_3$) 3490, 3380, 1480, 1455, 1092, and 922 cm^{-1}; UV (CH_3OH) 218 (ε 38300), 236 (trough, 8740), 268 (16100), and 287 (9070) nm; ^1H NMR δ=2.65 (s, $-SCH_3$), 5.07 (d, *J*=4 Hz, $-CH_2-$), 7.0 (br, >NH), 7.18 (ddd, *J*=8, 8, and 1 Hz, 5-H), 7.25 (ddd, *J*=8, 8, and 1 Hz, 6-H overlapped with 2-H), 7.42 (d, *J*=8 Hz, 7-H), 7.64 (br d, *J*=8 Hz, 4-H), 8.16 (br s, 1-H), and minor signals (1/4 intensity of the major ones) due to a rotamer at δ=2.75 (s, $-SCH_3$), 4.80 (d, *J*=4 Hz, $-CH_2-$), and 7.6 (br, >NH); ^{13}C NMR δ=18.2 (q, $-SCH_3$), 43.2 (t, $-CH_2-$), 110.9 (s), 111.5 (d), 118.7 (d), 120.4 (d), 122.8 (d), 124.0 (d), 126.5 (s), 136.3 (s), and 198.2 (s, >C=S); MS *m/z* (%) 236 (46, M^+), 188 [3, $(M-SCH_3-H)^+$], 162 (16, C_9H_8NS), and 130 (100, C_9H_8N).

Synthesis fo Brassinin (2): To a mixture of 3-(aminomethyl)indole[14] (730 mg), pyridine (2.0 ml), and triethylamine (0.70 ml) was added carbon disulfide (330 µl) at 0 °C and the mixture was kept at the temperature for 1 h. The reaction mixture was then treated with methyl iodide (312 µl), kept at 3 °C for 24 h, and poured into 1.5 M H_2SO_4 (1 M=1 mol dm^{-3}) (50 ml).[17] The crude product extracted from the reaction mixture with diethyl ether was crystallized from CH_2Cl_2-hexane to yield **2** (782 mg), mp 132—133 °C, in 66% yield.

Cyclobrassinin (3): $C_{11}H_{10}N_2S_2$ (*m/z* 234.0264, M^+); mp 136—137 °C (CH_2Cl_2-hexane); IR ($CHCl_3$) 3450, 1600, 1450, 1430, 1338, 980, and 910; UV (CH_3OH) 204 (ε 24700), 227 (34000), 259 (trough, 6330), 284 (7830), and 294 (8170) nm; ^1H NMR δ=2.56 (3H, s, $-SCH_3$), 5.09 (2H, s, $-CH_2-$), 7.14 (1H, ddd, *J*=7, 7, and 2 Hz, 5-H), 7.18 (1H, ddd, *J*=7, 7, and 2 Hz, 6-H), 7.33 (1H, dd, *J*=7 and 2 Hz, 7-H), 7.49 (1H, dd, *J*=7 and 2 Hz, 4-H), and 7.91 (1H, br, 1-H); ^{13}C NMR δ=15.2 (q, $-SCH_3$), 48.8 (t, $-CH_2-$), 103.9 (s), 110.7 (d), 117.2 (d), 120.3 (d), 122.0 (d), 122.4 (s), 125.2 (s), 136.7 (s), and 152.0 (s, >C=N); MS *m/z* (%) 234 (10, M^+), 161 (100, C_9H_7NS), 117 (47, C_8H_7N), and 73 (6, C_2H_3NS).

Synthesis of Cyclobrassinin (3): To a solution of **2** (237 mg) in CH_2Cl_2 (24 ml) was added pyridinium bromide perbromide (336 mg) in small portions at room temperature and the mixture was kept at the temperature for 20 min and then basified with 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) and refluxed for 10 min. The reaction mixture was evaporated and the residue was applied on a silica-gel column and eluted with CH_2Cl_2 to give crystalline material (107 mg), which on recrystallization from CH_2Cl_2-hexane gave **3** (81 mg) in 35% yield, indistinguishable from natural cyclobrassinin.

Methoxybrassitin (4): $C_{12}H_{14}N_2O_2S$ (*m/z* 250.0772, M^+); mp 94—96 °C (Et_2O-EtOH); IR ($CHCl_3$) 3430, 1662, 1482, 1455, and 1182 cm^{-1}; UV (CH_3OH) 219 (ε 32100), 247 (trough, 2360), 273 (5200), 287 (5200), 295 (sh, 4250) nm; ^1H NMR δ=2.38 (3H, s, $-SCH_3$), 4.07 (3H, s, $-OCH_3$), 4.61 (2H, d, *J*=5 Hz, $-CH_2-$), 5.51 (1H, br s, >NH), 7.15 (1H, ddd, *J*=8, 8, and 1 Hz, 5-H), 7.25 (1H, s, 2-H), 7.28 (1H, ddd, *J*=8, 8, and 1 Hz, 6-H), 7.43 (1H, br d, *J*=8 Hz, 7-H), and 7.60 (1H, br d, *J*=8 Hz, 4-H); ^{13}C NMR δ=12.4 (q, $-SCH_3$), 36.8 (t, $-CH_2-$), 65.9 (q, $-OCH_3$), 108.0 (s), 108.5 (d), 119.1 (d), 120.3 (d), 122.1 (d), 122.8 (s), 123.0 (d), 132.5 (s), and 167.6 (s, >C=O); MS *m/z* (%) 250 (42, M^+), 219 (33), 202 [43, $(M-SCH_3-H)^+$], 176 (48), 171 [33, $(M-SCH_3-OCH_3-H)^+$], 160 [100, $(M-NHCOSCH_3)^+$], 145 (36), 129 (57), 102 (31), 75 (54), and 47 (66).

Compound 5: $C_{14}H_{14}N_2OS_2$ (*m/z* 290.0550, M^+); IR ($CHCl_3$) 3460, 1705, 1598, 1445, 1423, 1355, 1338, 1260, 1158, 965, and 918 cm^{-1}; UV (CH_3OH) 202 (ε 18900), 227 (28000), 259 (trough, 5740), 282 (6490), and 294 (6690) nm; ^1H NMR δ=2.21 (3H, s, $-COCH_3$), 2.51 (3H, s, $-SCH_3$), 2.87 (1H, dd, *J*=15 and 8 Hz), 2.99 (1H, dd, *J*=15 and 6 Hz), 6.00 (1H, dd, *J*=8 and 6 Hz, >CH-), 7.14 (1H, ddd, *J*=7, 7, and 2 Hz, 5-H), 7.17 (1H, ddd, *J*=7, 7, and 2 Hz, 6-H), 7.31 (1H, dd, *J*=7 and 2 Hz, 7-H), 7.59 (1H, dd, *J*=7 and 2 Hz, 4-H), and 7.96 (1H, br, >NH); ^{13}C NMR δ=15.1 (q, $-SCH_3$), 30.9 (q, $\underline{C}O\underline{C}H_3$), 49.0 (t, $-CH_2-$), 56.0 (d, >CH-), 106.3 (s), 110.7 (d), 117.8 (d), 120.6 (d), 122.2 (s), 122.3 (d), 124.8 (s), 136.6 (s), 151.8 (s, >C=N-), and 206.5 (s, >C=O); MS *m/z* (%) 290 (21, M^+), 275 (14), 217 (31), 199 (31), 184 (74), 175 (100, $C_{10}H_9NS$), and 73 (32, C_2H_3NS), and 43 (62).

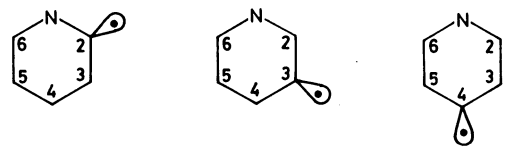
An Ab Initio Molecular Orbital Study of Pyridyl Radicals

Osamu KIKUCHI,* Yuji HONDO, Kenji MORIHASHI, and Mitsunobu NAKAYAMA
Department of Chemistry, The University of Tsukuba, Tennodai, Tsukuba 305
(Received July 4, 1987)

Synopsis. Open-shell RHF and UHF ab initio calculations were carried out for 2-, 3-, and 4-pyridyl radicals in order to determine their molecular structures and relative energies. The minimal STO-3G basis set was used for the structure optimization, while the 4-31G basis set was used for the energy evaluation. The 2-pyridyl radical has the lowest energy, although the energy differences among these three isomers were very small. The possibility of a Π-ground state in pyridyl radicals was rejected.

Pyridyl radicals are typical aryl radicals and are derived formally from the homolytic cleavage of the CH bond of pyridine. Three isomers, 2-, 3-, and 4-pyridyl radicals, have been detected by ESR,[1,2] and the reactivity of 2-pyridyl has recently been discussed.[3] An interesting aspect from the theoretical point of view is the relative energies of the three isomers, since the interaction between the singly-occupied molecular orbital (SOMO) and the nonbonding orbital at the nitrogen atom can be expected to affect the stability of



2 3 4

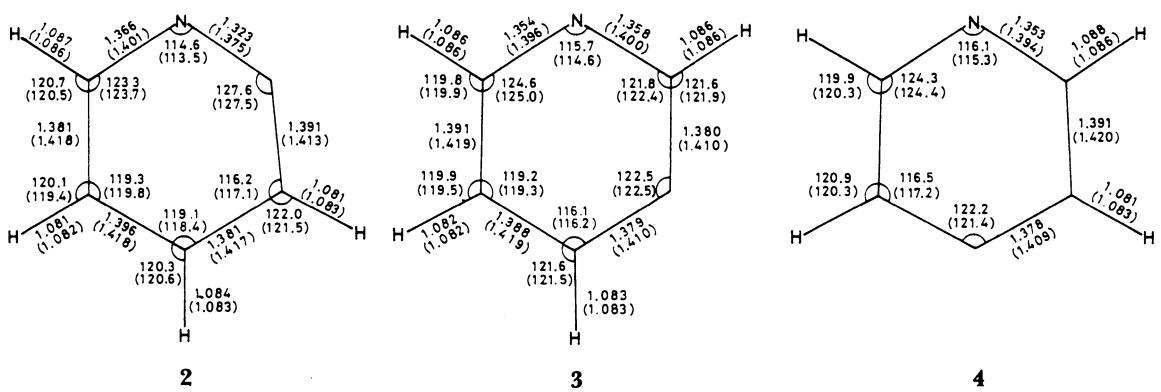
these radicals. Another interesting point is to examine the possibility of the Π-ground state, in which the π_4 orbital is occupied by the unpaired electron, although ESR has suggested the Σ-ground states for these radicals.[2] There have been only a few theoretical studies of pyridyl radicals;[2,4] all of them are semiempirical calculations applied to idealized or assumed molecular structures. In the present study, the molecular structures of three pyridyl radicals, **2**—**4** were optimized by ab initio MO methods, and their relative energies were compared.

The open-shell RHF and UHF methods were employed. The RHF orbitals are appropriate for understanding the orbital shape, while the UHF orbitals involve the spin-polarization effect. The molecular structures were optimized with the STO-3G basis set,[5] and the energies were calculated with the 4-31G basis set.[6]

The RHF calculation showed that the SOMO of each radical is localized mainly on the carbon atom at the radical center; the atomic-spin populations at the carbon atoms in **2**, **3**, and **4** are 0.879, 0.918, and 0.916 respectively. The molecular structures optimized by RHF and UHF (in parentheses) calculations are shown in Fig. 1. The CC and CN bonds calculated by the UHF method are longer than those calculated by the RHF method by 0.02—0.05 Å. The RHF N–C(2) bond length in **2**, 1.323 Å, is very short in comparison with those in **3** and **4**, which are in the range of 1.35—1.36 Å. This is caused by the interaction between the nitrogen nonbonding orbital and the unpaired electron at the adjacent carbon atom in **2**. This interaction is also reflected in the calculated orbital energies of the SOMO and the nonbonding orbital. As may be seen from Fig. 2, the SOMO energy of **2** is higher than those of **3** and **4**, while the nonbonding orbital of **2** lies lower than those of **3** and **4**. These facts indicate an appreciable interaction between the two orbitals in 2-pyridyl.

The 2-pyridyl radical has the lowest energy of the three isomers, as is shown in Table 1. The energy differences among the three isomers, however, are not large. The origin of the stability of **2** is not clear, although the interaction between SOMO and the nonbonding orbital may contribute to some extent.

Since the SOMO of **2** lies higher than those of **3** and **4**, the Π state of 2-pyridyl, in which the σ_{18} electron is



2 3 4

excited to the π_4 orbital, may be expected to lie low. The Π state of 2-pyridyl was thus examined. The optimized structure is shown in Fig. 3. The structure of the Π state of 2-pyridyl is very different from that of the Σ state in Fig. 1. The N–C_2 bond, 1.221 Å, is extremely short, while the N–C_2–C_3 bond angle is very large. These facts suggest that the N–C_2 bond may be written formally as a triple bond, $-N^+{\equiv}C-$. The Π state was calculated to lie 376 kJ mol^{-1} above the Σ-ground state (STO-3G energy difference). It is thus concluded that the Π state is not expected for the

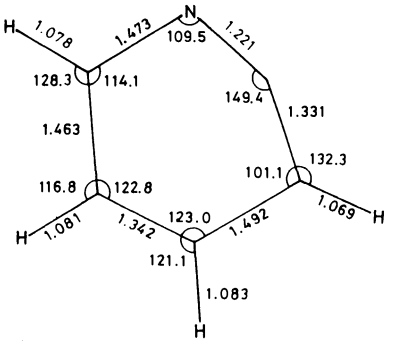

Fig. 3. Molecular structure of the excited Π state of 2-pyridyl radical optimized by open-shell RHF method with STO-3G basis set.

ground state of 2-pyridyl, even if the substitution and/or environmental effects are changed.

The calculated spin distribution of pyridyl radicals did not agree with the experimental values estimated from the ESR spectra. The proton hyperfine coupling constants[7)] of 2-pyridyl, for example, were calculated by means of the RHF method to be very small (0.4—2.1 G (1G=10^{-4} T)); experiments have shown the coupling constants of 10 and 6 G to two protons.[2)] The UHF method gave larger values: $a(H_3)$=36, $a(H_4)$=−30, $a(H_5)$=33, $a(H_6)$=−33. The disagreement may come from the method of calculation. The UHF values are generally larger than the experimental values because of the failure of the spin-polarization contribution.[8)]

All the calculations were carried out with the ABINIT program written by our group. The work was supported by the University of Tsukuba Project Research.

Effects of Crown-Type Host-Guest Complexation on Electrochemical Profiles of Pb^{2+} Ion

Hiroshi Tsukube,* Kentaro Takagi, Tatsuo Higashiyama, Tadashi Iwachido, and Naomi Hayama
Department of Chemistry, College of Liberal Arts & Science, Okayama University, Okayama 700
(Received July 6, 1987)

Synopsis. Crown ethers, cryptands, and related synthetic host molecules modified electrochemical profiles of Pb^{2+} ion by host-guest complexations. The reduction potentials of the Pb^{2+} complexes were significantly correlated with their complex stabilities.

Crown ethers, cryptands, and other synthetic host molecules specifically bind guest cations and often modify their physicochemical properties and chemical reactivities. For example, solubility, spectroscopic profile, and catalytic activity of the guest cation were demonstrated to be varied by host-guest complexation.[1]

Here we examined electrochemical properties of a series of Pb^{2+} complexes with tripodes, crown ethers, double armed crowns, and cryptand molecules, and revealed an interesting relationship between thermodynamic stabilities and reduction potentials of Pb^{2+} complexes. Since electrochemical properties of the Pb^{2+} complexes were significantly influenced by the natures and the structures of ligating host molecules, the present study may provide further possibilities in controlling redox chemistry of active guest species at will.

Results and Discussion

We employed a series of tripodes, crown ethers, and cryptands, which had various distributions, numbers, and types of donor groups (Fig. 1).[2,3] Typical cyclic voltammograms for aqueous solutions of Pb^{2+} ion in the presence and absence of double armed crown ether **8** are shown in Fig. 2. When 0.5 equiv of double armed crown ether **8** was added to a solution of Pb^{2+} ion, new reduction peak B appeared at more negative potential than that of initially observed peak A. Then peak A disappeared in the presence of ca. 1.0—2.0 equiv of **8** to Pb^{2+} ion, and only peak B remained in the presence of excess of **8**. Similar successive changes were observed in the other examined systems, and crown-type host-guest complexation may be essentially involved in such a heterogeneous electrochemical reaction.[4] Although free Pb^{2+} ion showed more positive reduction peak potential (−0.51 V) than Cd^{2+} and Zn^{2+} ions (−0.83 and −1.27 V) under the employed conditions (see Experimental), double armed crown ether **8**, and cryptands **10** and **11** modified Pb^{2+} ion less reducible than Cd^{2+} ion.

Figure 3 shows relationship between induced shifts of reduction peak potentials by complexation and stability constants for corresponding Pb^{2+} complexes.[5] It clearly indicates that redox reaction of

*Log K for aza-crown ether **7** was obtained as higher than 8.7.
Since aza-crown ether **5** and/or its Pb^{2+} complex were suspended under the employed electrochemical conditions. The shift value indicated was estimated as smaller.

Pb^{2+} complex largely depended on the nature and the structure of the ligating molecule. The relationship is almost sigmoidal and provides some indication of the structures of the Pb^{2+} complexes with the various ligands. Interestingly, double armed crown ethers **6**—**8** and cryptands **10**—**11** showed greater induced shifts in the reduction potentials than tripodes and simple crown ethers. Since ^{13}C NMR studies have strongly suggested that these host molecules could completely wrap around the electroactive Pb^{2+} ion and effectively shield it from the surroundings,[6] they markedly inhibited electron transfer reaction and offered much negative reduction potentials. These observations offer an interesting method for correlating the stability constants and electrode potentials for the Pb^{2+} ion, and further possibilities that electrochemistry of other kinds of guest species may be controlled by appropriate choice of crown ethers and/or related host molecules.

Experimental

1. Host Molecules. Host molecules **2**, **6**, **7**, and **8** were prepared by the literature methods,[2,3] and showed satisfactory mass, ^1H NMR, and IR spectroscopic data as well as physical properties.

Other employed host molecules and reagents were commercially available and used as received.

2. Cyclic Voltammetry Experiments. Electrochemical measurements were conducted under an Ar in a buffered aqueous solution (0.1 M CH_3CO_2H/0.1 M CH_3CO_2Na, 1 M=1 mol dm^{-3}, pH=6.22). A standard H-cell, glassy carbon (working electrode), and a platinum wire (counter-electrode) were used. All the cyclic voltammograms were recorded at room temperature after several scans (scan rate; 20 mV s^{-1}), and reduction peak potentials were obtained vs. Ag/AgCl electrode.

3. Determination of Stability Constant for Pb^{2+} Complex. Stability constants of host molecules **1**, **2**, **5**, and **7** for Pb^{2+} ion were determined potentiometrically at 17 °C by a modification of the Frensdorff method:[7] log K=3.6 for **1**; 2.1 for **2**; 7.4 for **5**; and >8.7 for **7**. Pb^{2+} ion specific electrode (Denki Kagaku Keiki, Model 7180) was used to ascertain stability constants, and the reference electrode was Ag/AgCl (Orion, Model 90-01). The activities of Pb^{2+} ion were measured in an aqueous solution of $Pb(ClO_4)_2$ both in the absence and presence of each host molecule: $Pb(ClO_4)_2$, 1.0×10^{-3} M; host, 3.0×10^{-3} M. The stability constants for other host molecules were found in the literature:[5] Log K=5.85 for **3**; 6.90 for **4**; 8.39 for **6**; 10.70 for **8**; 7.93 for **9**; 13.12 for **10**; 12.72 for **11**; 1.85 for **12**; and 4.27 for **13**.

The authors are grateful to Drs. Nakao (Okayama Univ.) and Satoh (Osaka Prefectural Univ.) for helpful discussion.

Effect of Pore Diffusion in Liquid-Phase Enantioselective Hydrogenation with Ni-SiO_2 Catalysts

Yuriko NITTA* and Toshinobu IMANAKA
Department of Chemical Engineering, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560
(Received June 5, 1987)

Synopsis. A series of Ni-SiO_2 catalysts, having a constant Ni loading and different Ni crystallite sizes, were prepared by using series of silica supports with controlled wide-pore structure. The crystallite size effect in enantioselective hydrogenation was found to hold also for the reactions controlled by the pore diffusion.

Since Izumi et al.[1] developed the modified Raney-Ni catalysts for the enantioselective hydrogenation of methyl acetoacetate (MAA) to optically active methyl 3-hydroxybutyrate (MHB), much effort has been devoted to the understanding of the reactions on metal catalysts.[2-5] The reaction is known to be highly sensitive to the catalyst-surface structure and modifying conditions. As to unsupported Ni catalysts modified under fixed conditions, we reported that amorphous catalysts have only low enantioselectivity and that the selectivity increased with increasing crystallite size of Ni up to around 10 nm.[6] Harada et al.[7] also suggested that amorphous and crystalline parts of H_2-reduced catalysts obtained from NiO provides nonselective and selective sites, respectively. With SiO_2-supported Ni catalysts, the observation that higher Ni loadings result in higher enantioselectivities was also explained by the crystallite size effect similarly to the case of unsupported catalysts.[8,9]

On the other hand, Sachtler interpreted the effect of Ni loading in terms of pore diffusion during catalyst modification.[5] He suggested that, to verify the crystallite size effect, one should change the size of Ni crystallites while keeping the Ni loading of the catalyst constant. Woerde et al.[10] reported that the liquid-phase hydrogenation is also a pore-diffusion process. Therefore, in order to establish the crystallite size effect, we should clarify the effect of pore diffusion on the apparent enantioselectivity, although we have already confirmed the crystallite size effect with Ni-SiO_2 catalysts having constant Ni loading.[9,11,12] For this purpose, the use of a series of wide-pore silica with controlled pore structure looks promising. The preparation of Rh catalysts using these silica supports provided series of Rh-SiO_2 catalysts with desired metal particle size.[13]

In this work, we prepared a series of Ni-SiO_2 catalysts, which have a constant Ni loading and different Ni crystallite sizes, by using a series of silica supports with controlled pore structure and examined the enantioselective hydrogenation of MAA with these catalysts under different reaction conditions.

Experimental

The Ni-SiO_2 catalysts were prepared by the pore-filling procedure with aqueous solution of nickel nitrate and a series of silica (Super Micro Bead Silica Gel, Fuji-Davison Chemical Ltd.) having different pore diameters. The Ni loading was kept constant at 7.5 wt% unless otherwise stated. The samples were dried in air at 383 K for 16 h. Two grams of a sample were reduced in flowing hydrogen at 673 K for 3 h and then modified with aqueous (2*R*,3*R*)-tartaric acid solution (pH=5.1). The enantioselective hydrogenation of MAA was carried out for 17 h either with a glass autoclave (No. 1) (TEM-U-50, Taiatsu Glass Industry Co.) equipped with a vigorous-stirring system under an initial H_2 pressure of 10 kg cm^{-2} at 333 K, or with a stainless-steel autoclave (No. 2) (TVS-2, Taiatsu Glass Industry Co.) attached to a shaking apparatus of 100 times per minute under an H_2 pressure of ca. 100 kg cm^{-2} at 350 K. The detailed procedures of the catalyst modification and the hydrogenation reaction were described elsewhere.[8]

The hydrogenation activity of the catalyst was determined from the pressure decrease during the initial 15 min of the reaction. The optical yield (OY) of (−)-MHB determined from the optical rotation of the distilled product was used as a measure of the enantioselectivity of the catalyst. The mean crystallite size of Ni (D_c) in the catalyst was obtained from the half-width of the peak on (111) plane of Ni metal in the X-ray diffraction pattern of the catalyst.

Results and Discussion

The physical properties of the silica supports employed here are listed in Table 1. These wide-pore supports were found to provide a series of suitable catalysts for studying the effects of pore diffusion and the Ni crystallite size.

The silica support (Silica Gel No. 1, Nakarai Chemicals, Ltd.) having been employed in our previous works[8,11,14] had only micropores with a

mean diameter of 3 nm,[9] and the supported catalysts were prepared by the precipitation method. Under these conditions, the contribution of Ni in pores to the overall reaction was negligible.[9] In such a case, the hydrogenation reactions carried out under vigorous stirring (i.e., in autoclave No. 1) were controlled by the surface reaction, whereas the diffusion process was not neglected in the reactions carried out under mild stirring (i.e., in autoclave No. 2).[14]

With the catalysts prepared here by the pore-filling method using the wide-pore supports, Ni particles are regarded to exist mainly in the pores, based on the models proposed by Dorling et al.[15,16] and Dafler.[17] When the Ni loading was kept constant, the mean crystallite size of Ni increased with an increase in the pore diameter of the silica support as shown in Table 2. This tendency is the same as that observed in the preparation of Rh-SiO_2 catalysts with desired metal-particle size.[13]

The apparent enantioselectivity of these Ni-SiO_2 catalysts observed in the reactions carried out in the autoclave No. 1 decreased with an increase in the pore diameter of silica support in spite of an increase in the mean crystallite size of Ni in these catalysts. On the other hand, when hydrogenations were carried out by using another autoclave (No. 2) with a mild shaking system, the enantioselectivity of the catalysts increased with an increase in the mean crystallite size of Ni just as with the catalysts reported previously (Fig. 1). In this case, the reactions are regarded to be diffusion controlled as already pointed out,[10,14] probably because of the slow mass transfer from gas-liquid interface to the catalyst surface under a low stirring intensity. Accordingly, the higher selectivity of the catalyst with the larger Ni crystallites reflects the increase in the fraction of selective sites in the catalyst surface.

As shown in Fig. 1, the catalysts with different Ni loadings (4.1 to 11.3 wt%), prepared by using S-4 silica with the widest pore (72.8 nm) as the support, exhibited an increased enantioselectivity with an increase in the mean crystallite size of Ni even in the case using the autoclave No. 1. Therefore, the results shown in Table 1 suggest that the reaction on the catalysts with narrower pores is retarded by the pore diffusion. Since the surface reaction rate on nonselective sites is higher than that on selective sites under our reaction conditions,[14] the reaction on nonselective sites becomes more limited when the concentration of reactants in pores is lowered by the slow diffusion, which leads to a higher enantioselectivity of the catalyst with narrower pores.

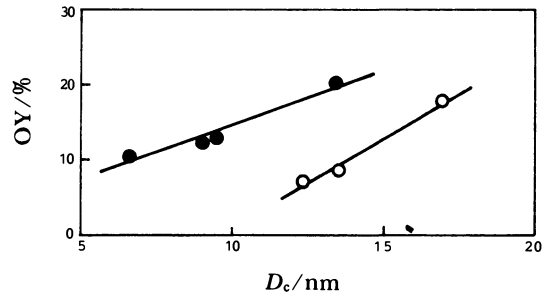

Fig. 1. Enantioselectivity of modified Ni-SiO_2 catalysts as a function of the mean crystallite size of Ni. Reactions were carried out either with the catalysts having different Ni loadings in autoclave No. 1 (○) (surface reaction controlled), or with 7.5 wt% Ni-SiO_2 catalysts in autoclave No. 2 (●) (pore diffusion controlled).

In the liquid-phase reaction carried out by using autoclave No. 1 with a vigorous-stirring system, the rate of mass transfer of H_2 from gas phase to the pellet surface is fast enough and the concentration ratio MAA/H_2 is in the order of 10^2. Under these conditions the modulus Φ can be estimated as follows:[18]

$$\Phi = \eta\phi^2 = R_p^2 \frac{r_{obs}}{D_{eff} C_{H2}}$$

where η is the effectiveness factor, ϕ is the Thiele modulus, R_p is the radius of the spherical catalyst pellet (5 μm), and D_{eff} is the effective diffusion coefficient of H_2. With $D_{eff}=3.5\times10^{-4}$ cm^2 s^{-1} and $C_{H_2}=3.6\times10^{-5}$ mol cm^{-3} at 333 K in ethyl acetate, Φ was calculated from the observed highest rate and found to be in the order of 10^{-4}. Since Φ is so small, the effectiveness factor for mass transfer inside the catalyst particle is essentially unity and so the reaction is essentially intrinsic. However, D_{eff} in liquid phase is difficult to estimate especially in narrower pores with relatively large Ni particles in them and might be much smaller than the value assumed above. Even values in the order of 10^{-10} to 10^{-14} have been reported for D_{eff} in Zeolites.[18] Therefore, the possibility that the pore diffusion interferes with the reactions on the catalysts with narrower pores cannot be denied.

These findings and discussion strongly suggest that the crystallite size effect holds for the reactions controlled by either the surface reaction or the pore diffusion. However, we should be careful in estimating the surface properties of supported

catalysts from the apparent enantioselectivities when the rate determining step varies with the catalysts.

The authors are greatly obliged to the Fuji-Davison Chemical Ltd. for presenting them with a series of silica supports, Super Micro Bead Silica Gel, and the data of their physical properties.

Terplex Formation in the Excited Triplet State. The Chloranil and Mesitylene System

Harumichi KOBASHI,* Ken-ichi HIRATSUKA, and Kazuaki MOTEGI
Department of Chemistry, Faculty of Engineering, Gunma University, Kiryu, Gunma 376
(Received July 1, 1987)

Synopsis. The enthalpy and entropy changes have been estimated for the formation of a triplet-state (1:2) terplex as well as an ordinary (1:1) exciplex between triplet chloranil (^{3}CA) and mesitylene (M) in carbon tetrachloride. Results indicate that the terplex is energetically less stable than the bimolecular exciplex, while the stabilization of the terplex is compensated by the positive entropy change associated with transformation from the exciplex to the terplex.

There are many reports on the formation of a ternary component exciplex (terplex) in the excited singlet state of electron donor-acceptor systems.[1-4] On the other hand, only little is known the terplex formation in the excited triplet state.[5] In addition, it was reported recently that not only termolecular interaction but also the existence of an ordinary triplet exciplex could not be reconfirmed for some systems such as the zinc etioporphyrin I and *p*-nitrotoluene system, which had been believed for a long time as a representative of a locally excited (LE-type) triplet exciplex.[6] Under these circumstances, it will be very important to study a triplet-state terplex as well as ordinary (1:1) exciplex and the contribution of the terplex to a dynamic behavior of the exciplex.

In a previous paper,[7] one of us reported both spectroscopic and kinetic results concerning the formation of the LE-type triplet exciplex between ^{3}CA and M, ^{3}(CA-M), which is an intermediate for the hydrogen atom transfer from M to ^{3}CA in 1,2-dichloroethane (DCE). During the course of our study concerning solvent effects on the reactivity of this triplet exciplex,[8] we have found that a termolecular interaction occurs between the exciplex and the exess donor M in less polar solvents.[9]

In this paper, we describe results of thermodynamic and kinetic properties of the terplex ^{3}(CA-M_2) as well as the exciplex ^{3}(CA-M) in the nonpolar solvent CCl_4. This is, to our knowledge, the first report presenting thermodynamic data of a terplex formed in the excited triplet state. After this work had been completed, we knew a report concerning the (1:1) exciplex formation for the same system in CCl_4.[10] However, there was no information concerning the terplex formation.

Experimental

A nanosecond laser photolysis was carried out using the same ruby laser as used previously.[7] A transient signal was memorized to a strage oscilloscope (Iwatu, TS-8123) and displayed on a recorder (Rikadenki, RW-11T). Temperature was varied in the range 5—55 °C by circulating water into a sample cell holder using a thermostat (Taitec, Jr-80) combined with a cooling pipe (Taitec, 150L). Chloranil (tetrachloro-*p*-benzoquinone) and mesitylene (1,3,5-trimethylbenzene) were purified by the same methods as used before.[7,11] Carbon tetrachloride (*Cica*-Merk, Uvasol) as a solvent was fractionally distilled after purification through an alumina column. All samples were carefully degassed by the usual freeze-pump-thaw method.

Results and Discussion

Figure 1 shows transient absorption spectra observed for a CCl_4 solution of CA (0.0025 mol dm^{-3}) and M (0.030 mol dm^{-3}). A broad band in the wavelength region longer than 800 nm is attributed to the CT band of the LE-type triplet exciplex ^{3}(CA-M).[7] The relative intensity of this band to the band at 510 nm increased apparently for the case [M]=0.60 mol dm^{-3}, although no other new band was observed. The band around 510 nm, which is due to both free ^{3}CA and ^{3}(CA-M), decays rapidly and the bands attributable to chloranil semiquinone radical (CAH·) emerge at 427.5 and 360 nm. The rise time of CAH· followed at 427.5 nm was identical to the decay time of the triplet species monitored at 510 nm as well as at 1000 nm. These spectral features are quite similar to those observed in DCE. Namely, the hydrogen atom transfer from M to ^{3}CA proceeds through the exciplex;

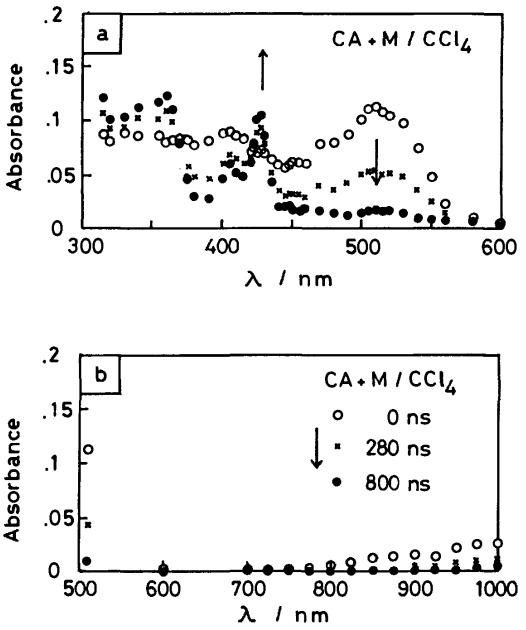

Fig. 1. Transient absorption spectra for the CCl_4 solution containing CA(0.0025 mol dm^{-3}) and M(0.030 mol dm^{-3}) in the wevelength regions of (a) 320—600 nm measured using an R636 photomultiplier and (b) 510—1000 nm measured using an R406 photomultiplier. Time after the pulsing: (○) 0, (×) 280, and (●) 800 ns. The absorbances of the 0 ns spectra in (a) and (b) were normalized to each other at 510 nm.

the same mechanism as revealed previously in DCE.[7]

Figure 2 shows the dependence of the decay rate (τ^{-1}) at the 510 nm band on [M] ranging from 0.0025 to 1.2 mol dm^{-3}. The decay rates were not dependent on the laser power for excitation (ca. 3—15 mJ). In the low concentration region of [M] less than ca. 0.1 mol dm^{-3}, the quenching curve bends downward with an increase of [M], while in the more concentrated region the decay rate becomes slow gradually passing through the maximum value with increasing [M]. The decay features can not be interpreted only by taking into account the (1:1) exciplex formation. This finding suggests that there exists the interaction between the exciplex and another M molecule. Since the triplet species at 510 nm decays exactly with a single exponential function, it is reasonable to consider that a dynamic equilibrium may be established rapidly among triplet species including a terplex under the present experimental conditions. The reaction scheme is written as follows:

$$^3CA + M \underset{}{\overset{K_1}{\rightleftharpoons}} {}^3(CA^{\delta-} - M^{\delta+}) \underset{-M}{\overset{+M}{\rightleftharpoons}} {}^3(CA^{\delta'-} - M_2^{\delta'+})$$

$$\downarrow k_0 \qquad \downarrow k_1 \qquad \downarrow k_2$$

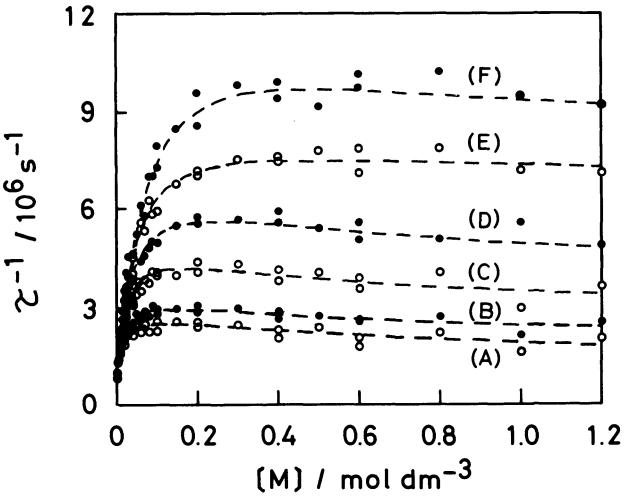

Fig. 2. Relations of τ^{-1} vs. [M] ranging from 0.0025 to 1.2 mol dm^{-3} at several temperatures: (○) and (●) Observed values measured at (A) 10, (B) 15, (C) 25, (D), 35, (E) 45, and (F) 55 °C. (----) Calculated curves.

In this case, the decay rate of ^{3}CA can be expressed by the following Eq. 1.

$$\tau^{-1} = \frac{k_0 + k_1K_1[M] + k_2K_1K_2[M]^2}{1 + K_1[M] + K_1K_2[M]^2} \quad (1)$$

where k_0, k_1, and k_2 are the decay rate parameters of free ^{3}CA, ordinary exciplex ^{3}(CA-M) and terplex ^{3}(CA-M$_2$), respectively, and K_1 and K_2 are the equilibrium constants for formation of the exciplex and terplex, respectively.

As exemplified in Fig. 2, the calculated curve according to Eq. 1 reproduces well the experimental values. Then, five parameters k_0, k_1, k_2, K_1, and K_2 can be estimated by a nonlinear least-square regression analysis using a combination of damping Gauss-Newton and Marquardt methods for 32 experimental points. Results are listed in Table 1. The k_1 and K_1 values are obtained with a good accuracy at each temperature. The corresponding parameters for the terplex, k_2 and K_2, are also estimated although the errors are relatively large. The k_0 values have large errors in the present 5-parameters fitting and tend to be estimated somewhat largely; e.g., the decay rate of ^{3}CA in the absence of M is ca. 0.1×10^6 s^{-1} at 25 °C. The van't Hoff plots for K_1 and K_2 values in Table 1 yield the enthalpy (ΔH) and entropy (ΔS) changes for the formation of both (1:1) and (1:2) exciplexes. These thermodynamic parameters together with equilibrium constants (K_e) and lifetimes (τ_e) of both exciplexes are summarized in Table 2.

The noticeable results in Table 2 are the positive enthalpy and entropy changes for the terplex formation. That is, the terplex formation from the

55	1.04±0.10	13.0±0.4	8.0±0.6	11±1	2.1±1.0

bimolecular exciplex is energetically unfavorable but the positive entropy change contributes largely to decreasing the free energy change. The latter result may be attributed to an increase in entropy of solvation on going from the exciplex state to the terplex state or attributed to a conformational change between ^{3}(CA–M) and ^{3}(CA–M_2) accompanied by a solvent reorientation. A similar discussion about such contribution of entropy has been given for the stabilization of an ordinary (1:1) triplet exciplex[12] and the conformational change has been suggested for a terplex formed in the excited singlet state.[2]

Other results are summarized as follows: 1) The triplet-state terplex formation becomes significant in a concentrated solution of M over ca. 0.2 mol dm^{-3}, although no distinct absorption due to the terplex was observed. 2) The deactivation rate of the terplex is smaller than that of the ordinary exciplex. This fact suggests that H-atom transfer in the terplex takes place more slowly than that in the exciplex, because it is considered that the reaction rate of H-atom transfer must depend on the mutual orientation between ^{3}CA and M in each exciplex but a competing deactivation, i.e., intersystem crossing, would be relatively unaffected. 3) The thermodynamic quantities for the (1:1) exciplex are similar to those for an usual electron donor–acceptor complex in the ground state.[13] 4) The lifetime of ^{3}(CA–M) in CCl_4 is considerably longer than that in DCE (32 ns at 25 °C).[7] It is presumed from this result that the solvent polarity affects significantly on the H-atom transfer reaction.

This work was financially supported in part by the Gunma University Foundation for Science and Technology. The authors also thank to Professor Haruo Shizuka for his interest and manuscript reading.

Determination of a Small Amount of a Biological Constituent by the Use of Chemiluminescence. XII. Highly Sensitive Immunoaffinity Chromatography

Tadashi HARA,* Kazuhiko TSUKAGOSHI, Akihiro ARAI, and Takeshi IHARADA
Department of Chemical Engineering, Faculty of Engineering, Doshisha University, Karasuma Imadegawa, Kamigyo-ku, Kyoto 602
(Received June 16, 1987)

Synopsis. Highly sensitive immunoaffinity chromatography was established by combining a micro-bore affinity column with a chemiluminescence detector for protein monitored by a flow-injection method using a 1,10-phenanthroline–hydrogen peroxide–copper(II) system. After having optimized the bed volume of a column, the flow rate of a buffer solution which was used for an immune reaction, and the time necessary for an immune reaction in a column, human serum albumin in the range of 3×10^{-4}—1×10^{-1} g dm^{-3} could be determined, with the detection limit of 15 ng as the injected amount. Human serum γ-globulin and bovine serum γ-globulin showed somewhat nonspecific adsorption onto an affinity column with values of 0.16 and 0.14 based on the specific adsorption 1.00 of human serum albumin onto a column, whereas bovine serum albumin, bovine serum α-globulin, and ovalbumin showed no nonspecific adsorption.

Cyclic immunoaffinity chromatography was previously established by the authors by combining an affinity column with a chemiluminescence (CL) detector for protein using the chemiluminescent reaction of a 5-amino-2,3-dihydro-1,4-phthalazinedione (luminol)–hydrogen peroxide (H_2O_2)–copper(II) (Cu(II)) system.[1,2] According to this method, a small amount of protein could be determined continuously and selectively without using a labeling procedure. However the sensitivity of this method was not yet satisfactory for the determination of a trace amount of α-fetoprotein (AFP) as a tumor marker. Furthermore, some problems as to both nonspecific adsorption onto an immunoaffinity column and the cycling of a sample solution still remained undissolved.

On the other hand, a highly sensitive CL detector for protein monitored by a flow-injection method using a 1,10-phenanthroline (phen)–H_2O_2–Cu(II) system was established by the authors in the previous paper[3]. This method was 40 times superior to the previous one using a luminol–H_2O_2–Cu(II) system in their detection limits of protein.

In the present study, the above mentioned CL detector using a phen–H_2O_2–Cu(II) system was used for the determination of protein together with a micro-bore immunoaffinity column which required no cycling of the sample solution. Experimental conditions such as the bed volume of an affinity column, the flow rate of a buffer solution which was used for an immune reaction, and the time necessary for an immune reaction in a column were optimized, followed by the determination of human serum albumin. The result showed that marked improvement could be achieved compared with the previous work in the following points: The detection limit of protein, the nonspecific adsorption onto a column, the time necessary for a measurement, and the durability of a column.

Experimental

All reagents were of commercially available special grade. Ion exchanged water was distilled for use. A phen solution, a H_2O_2 solution, and a Cu(II) catalyst solution containing L-arginine hydrochloride were prepared as in the previous paper.[3] Human serum albumin (HSA) (Miles Laboratories, Inc.), bovine serum albumin (BSA) (Nakarai Chemicals, Ltd.), human serum γ-globulin (HγG) (Sigma Chemical Co.), bovine serum γ-globulin (BγG) (Sigma Chemical Co.), bovine serum α-globulin (BαG) (ICN Pharmaceuticals, Inc.), ovalbumin (Ova) (Sigma Chemical Co.), and human control serum (Q-PAK-Chemistry Control Serum I; Hyland) were diluted with a 8.34×10^{-3} mol dm^{-3} phosphate buffer solution (Buff-A, pH 7.3) consisting of a 2.78×10^{-3} mol dm^{-3} potassium dihydrogenphosphate solution and a 5.56×10^{-3} mol dm^{-3} disodium hydrogenphosphate solution.

Rabbit anti-HSA (DAKO) was immobilized onto CNBr-Activated Sepharose 4B (Pharmacia Fine Chemicals) in accordance with the instruction paper. About 5 mg of antibody was immobilized onto 1 cm^3 of support. This value was obtained by the measurement of the remaining antibody by the UV monitor (Hitachi, Ltd., wavelength-

tunable effluent monitor, 634A). This immunosorbent was packed in a micro-bore column (1 mm i.d. ×50 mm) which was manufactured using a Teflon tube (2 mm o.d. ×1 mm i.d.) and a Teflon line-filter (Nishio Kogyo, Ltd.) (Fig. 1).

A flow diagram of the immunoaffinity chromatography system equipped with the CL detector devised by the authors is shown in Fig. 2. A buffer solution which was used for an immune reaction (Buff-A) (a) was fed at the flow rate of 0.2 cm^3 min^{-1} by the pump (e) (Atto, SJ1211), and an eluent (Buff-B, pH 2.2) (b) consisting of a 8.0×10^{-3} mol dm^{-3} hydrochloric acid solution and a 2.5×10^{-2} mol dm^{-3} potassium chloride solution was fed at the flow rate of 1.0 cm^3 min^{-1} by the pump (d) (Pharmacia Fine Chemicals, High-precision Pump, P-500). A 50 mm^3 portion of HSA solution was injected into the Buff-A line through a sampling loop (i) and a six-way cock (g), and passed through an affinity column (f). The immune reaction was performed by feeding Buff-A to the column for 10 min after the injection of a sample solution. Then Buff-B was fed to the column to liberate HSA by operating a six-way cock (h). HSA in the eluate from the column was detected by the CL detector (k). Subsequently Buff-A was fed again to the column for 2 min to regenerate it by operating a six-way cock (h).

Results and Discussion

The optimum pH value of an eluent was determined so as to liberate sufficient HSA from an affinity column (Fig. 3). The gel immobilized with antibody was packed in a column (3 mm i.d. ×50 mm, Omnifit), and to it, 200 mm^3 of 1.0×10^{-1} g dm^{-3} HSA solution was loaded. Then HSA was liberated by feeding the eluent at various concentrations of hydrochloric acid (the concentration of potassium chloride was constant: 2.5×10^{-2} mol dm^{-3}). HSA in the eluate from the column was detected by means of the UV monitor, and the peak area was measured by use of an integrator (Shimadzu Chromatopac E1A). Judging from Fig. 3, 8.0×10^{-3} mol dm^{-3} hydrochloric acid–2.5×10^{-2} mol dm^{-3} potassium chloride buffer solution (pH 2.2) was employed as an eluent.

In the previous work, the equipment and the procedure for analysis were complicated since it required the cycling of a sample solution for an immune reaction. Moreover, the cycling of a sample solution was thought to badly influence the time necessary for a measurement, the durability of the column, the coefficient of variation, and nonspecific adsorption onto the column. Therefore, a micro-bore immunoaffinity column in the present study was manufactured using a Teflon tube (1 mm i.d.) and a Teflon line-filter (pore size=10 μm) which required no cycling of a sample solution (Fig. 1). The flow rate of Buff-A was selected to be 0.2 cm^3 min^{-1}, the minimum flow rate achieved by the pump used, so as to perform the immune reaction sufficiently on a column during a single passage of a sample solution. Using this flow rate, the bed volume of a column and the reaction time (the time of feeding Buff-A) required were investigated using a 4.0×10^{-3} g dm^{-3} HSA solution. The relationship between the immune reaction time and the peak area of the liberated protein is shown in Fig. 4 using several columns of various bed volume (1 mm i.d. ×15, 30, and 50 mm). In case of a 1 mm i.d. ×70 mm column, the blank value was so large that the measurement was disturbed. Therefore a 1 mm i.d. ×50 mm column was employed so as to reduce the blank value and to obtain the maximum peak area at the same time. The immune reaction time was

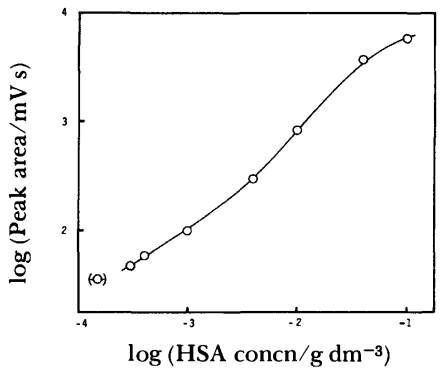

Fig. 5. Calibration curve of HSA.
(—O—): Blank value.

Table 1. Selectivity of an Affinity Column

Protein	Selectivity
HSA	1.00
HγG	0.16
BSA	0.00
BγG	0.14
BαG	0.00
Ova	0.00

Protein concn = 1.0×10^{-2} g dm^{-3}.

selected to be 10 min. A 1.0×10^{-1} g dm^{-3} BSA solution was analyzed under the above mentioned conditions, but no protein peak was observed. Liberation of HSA was performed by feeding Buff-B at the flow rate of 1.0 cm^3 min^{-1}. HSA less than 1.0×10^{-2} g dm^{-3} could be completely eluted within 5 min. Then the column was regenerated for 2 min at the flow rate of 1.0 cm^3 min^{-1} by feeding Buff-A corresponding to the volume of 50 times as large as the bed volume. The time necessary for an overall measurement (immune reaction-liberation-regeneration) was 17 min.

Under the condition mentioned above, the calibration curve of HSA obtained by the present method is shown in Fig. 5. As can be seen from Fig. 5, HSA in the range of 3×10^{-4}—1×10^{-1} g dm^{-3} could be determined with the lower limit of 15 ng. The coefficient of variation for six analyses of 4.0×10^{-3} g dm^{-3} HSA was 4.0%, and the affinity column was durable for about 40 replicate analysis.

The selectivity of the affinity column is indicated on the basis of the analytical value of HSA (Table 1). Each 1.0×10^{-2} g dm^{-3} of protein was used throughout this experiment. HγG and BγG showed somewhat nonspecific adsorption with values of 0.16 and 0.14 based on the specific adsorption 1.00 of HSA, whereas BSA, BαG, and Ova showed no nonspecific adsorption. The determination of HSA in a serum sample was next examined. Various amounts of HSA were estimated in either the presence or absence of a definite amount of control serum (containing about 6×10^{-3} g dm^{-3} HSA, diluted to a volume of 5000 times with a buffer solution), and the relationship between HSA concentration and the analytical value was obtained by the use of the calibration curve shown in Fig. 5

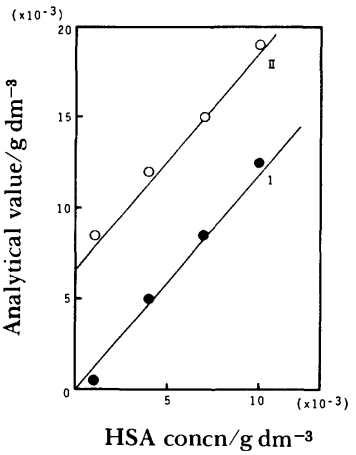

Fig. 6. Relationship between HSA concn and analytical value.
●: HSA and O: HSA+control serum.

(Fig. 6). The difference between straight lines I and II in the graph was approximately equal to the amount of HSA in the added control serum. This means that the present method was applicable to the selective determination of protein in a serum sample.

According to the previous cyclic immunoaffinity chromatography using a luminol-H_2O_2-Cu(II) chemiluminescence system, the detection limit of protein, nonspecific adsorption onto a column, the time necessary for a measurement, durability of a column, and the coefficient of variation were 100 ng, 0.00—0.63 (5 kinds of protein, on the basis of the analytical value of HSA), 34 min, about 20 times, and 5.7% (n=5, 1.0×10^{-2} g dm^{-3} HSA) respectively. In the present study, they were as follows; 15 ng, 0.00—0.16, 17 min, about 40 times, and 4.0% (n=6, 4.0×10^{-3} g dm^{-3} HSA) respectively.

Recently a small amount of protein such as AFP has attracted public attention as a tumor marker. As for AFP, Single Radial Immunodiffusion method and Reverse Passive Haemagglutination method have been generally used for simple screening. Their detection limits are 5000 and 200 ng cm^{-3} respectively, and the latter method is only qualitative.[4] Though HSA was analyzed in the present study by immobilizing anti-HSA on agarose gel, a trace amount of protein such as AFP might be analyzed continuously and selectively with the sensitivity required for practical use if suitable antibody should be immobilized.

^{17}O NMR Study of Metal Carbonyl Cluster Compounds. III.[1] ^{17}O NMR Spectra of Mixed Metal Carbonyl Cluster Compounds, $R_2Sn[M(CO)_x][M'(CO)_y]$, $R_2Sn[M(CO)_x][M'(CO)_yCp]$, and $ClSn[Mn(CO)_5][Fe(CO)_2Cp]_2$

Satoru ONAKA* and Yoshio KATO
Department of Chemistry, Nagoya Institute of Technology, Gokiso-cho, Showa-ku, Nagoya 466
(Received July 6, 1987)

Synopsis. A series of mixed metal carbonyl cluster compounds of $R_2Sn[M(CO)_x][M'(CO)_y]$ and $R_2Sn[M(CO)_x][M'(CO)_yCp]$ were synthesized and their ^{17}O NMR spectra were measured to demonstrate how ^{17}O NMR spectroscopy is superior to IR spectroscopy to study the electronic nature of the oxygen atoms in CO groups. For these mixed metal clusters, ^{17}O NMR spectral assignments were easily made and the electron distribution around the O atoms was concluded to be only slightly changed compared with those of homo-dinuclear $R_2Sn[M(CO)_x]_2$ and $R_2Sn[M'(CO)_yCp]_2$.

In previous papers,[1] we have demonstrated that ^{17}O NMR is an eligible alternative to ^{13}C NMR or IR (ν(CO) region) for elucidating the change of electron distribution and/or structures of metal carbonyl cluster derivatives. This trait of ^{17}O NMR spectroscopy is now applied to a series of $R_2Sn[M(CO)_x]_2$, $R_2Sn[M'(CO)_yCp]_2$, $R_2Sn[M(CO)_x][M'(CO)_y]$, and $R_2Sn[M(CO)_x][M'(CO)_yCp]$ type derivatives. The present paper reports the syntheses of a series of $R_2Sn[M(CO)_x][M'(CO)_y]$, $R_2Sn[M(CO)_x][M'(CO)_yCp]$ type compounds and $ClSn[Mn(CO)_5][Fe(CO)_2Cp]_2$ and the results of ^{17}O NMR measurements for a sereis of aforementioned homo-dinuclear and hetero-dinuclear or hetero-trinuclear metal carbonyl derivatives.

Experimental

All the manipulations were made under a purified nitrogen atmosphere. Solvents were distilled from benzophenone ketyl under N_2 before use. Literature methods were employed to obtain the following homo-dinuclear metal carbony derivatives, $Me_2Sn[Mn(CO)_5]_2$ (**1**),[2] $Ph_2Sn[Mn(CO)_5]_2$ (**2**),[3] $Me_2Sn[Re(CO)_5]_2$ (**3**),[3] $Me_2Sn[Co(CO)_4]_2$ (**4**),[4] $Ph_2Sn[Co(CO)_4]_2$ (**5**),[4] $Cl_2Sn[Co(CO)_4]_2$ (**6**),[5] $Me_2Sn[Mo(CO)_3Cp]_2$ (**7**),[6] $Me_2Sn[Fe(CO)_2Cp]_2$ (**8**)[7], and $Cl_2Sn[Fe(CO)_2Cp]_2$ (**9**).[7]

Synthesis of $Me_2Sn[Mn(CO)_5][Re(CO)_5]$ (10). A 850 mg sample (2 mmol) of $BrMe_2SnMn(CO)_5$[8] was allowed to react with an equimolar amount of $NaRe(CO)_5$ in THF at room temperature and the reaction mixture was stirred overnight. Then the solvent was vacuum-stripped from the yellow-orange solution to leave yellow solid. This solid was recrystallized from hexane to yield 620 mg of pale yellow sample (yield 46%). Found: C, 21.77; H, 0.95%. Calcd for $C_{12}H_6MnO_{10}ReSn$: C, 21.52; H, 0.90%. ν(CO) (ligroine solution): 2117 (w), 2095 (w), 2080 (m), 2077 (m, sh), 2010 (vs), and 1982 (s) cm^{-1}.

Synthesis of $Ph_2Sn[Mn(CO)_5][Co(CO)_4]$ (11). A similar method as the above was employed; a 960 mg (2 mmol) sample of $ClPh_2Sn$-$Co(CO)_4$[9] was allowed to react with an equimolar amount of $NaMn(CO)_5$ in THF at room temperature. Similar treatment as the above and recrystallization from pentane to give 300 mg (yield 23%) of pale yellow crystals. Found: C, 39.53; H, 1.52%. Calcd for $C_{21}H_{10}CoMnO_9Sn$: C, 39.48; H, 1.56%. ν(CO) (Nujoll mull): 2105 (w), 2100 (w), 2080 (s), 2030 (m), 2018 (s), 2010 (vs), and 1985 (m) cm^{-1}.

Synthesis of $Me_2Sn[Mn(CO)_5][Mo(CO)_3Cp]$ (12). A 0.76 g (2 mmol) sample of $ClMe_2Sn$-$Mn(CO)_5$[10] was treated with an equimolar amount of $NaMo(CO)_3Cp$ in THF as above described and recrystallization from petroleum ether gave 0.90 g sample of pure product (yield 76%). The purity of this sample was checked by spectroscopic data (IR, and ^1H NMR)[11].

Synthesis of $ClSn[Mn(CO)_5][Fe(CO)_2Cp]_2$ (13). A 220 mg (0.55 mmol) sample of $Mn_2(CO)_{10}$ was dissolved into 50 ml of THF and the solution was stirred over 1% Na amalgam for 2 h. After filtration of this solution, a THF solution (50 ml) which contains a 400 mg (1.1 mmol) sample of $Cl_2Sn[Fe(CO)_2Cp]_2$ was added to this filtrate and the reaction mixture was stirred overnight at room temperature. From the resulting red solution, the solvent was vacuum-stripped and red-orange residue was extracted three times with each 20 ml of benzene. From the combined extracts, the solvent was partially vacuum-distilled off and 20 ml of petroleum ether was added. Storage of this solution in a refrigerator for a few days gave orange-red crystals (220 mg; yield 28%). So far analytically pure sample has not yet been obtained. However, several spectroscopic data suggest that this sample is spectroscopically pure. ν(CO) (CCl_4 solution): 2089 (s), 2060 (vw), 2025 (m, sh), 2010 (vs), 2000 (s), 1990 (s), and 1949 (m) cm^{-1}. ^1H NMR: δ=4.5 (C_5H_5).

Spectral Measurements. ^{17}O NMR spectra were recorded on a Varian XL-200 spectrometer operated at 27.12 MHz for ca 0.5 mol dm^{-3} THF, benzene, and/or chloroform solutions at 30 °C with Fourier transform mode for naturally abundant level (0.037%). The spectra were measured using a 10 mm o.d. sample tube with 0.01 s acquisition time and 90° pulse. Chemical shifts were measured in parts per million with reference to external $H_2{}^{17}O$ standard contained in a 1 mm capillary. IR spectra were recorded on a Jasco 701G spectrometer and proton NMR spectra were obtained with a Hitachi-Perkin-Elmer R-24A spectrometer (60 MHz). Absorption spectra were recorded on a Hitachi 220A double-beam spectrophotometer with a 1.0 mm quartz cell in cyclohexane. All the spectral results are tabulated in Table 1.

^{17}O NMR Spectral Results and Assignment

The manganese and rhenium carbonyl unit, $M(CO)_5$ (M=Mn and Re) has four equatorial and one axial carbonyls. Therefore, two peaks wth relative intensity of 4:1 are observed for compounds **1**—**3** (Fig. 1a). The cobalt carbonyl unit, $Co(CO)_4$, has three equatorial and one axial carbonyls. However, compounds **4**—**6** show unresolved ^{17}O NMR spectra. Molybdenum cyclopentadienyl derivative **7** has two carbonyl groups (Scheme) and therefore two peaks with relative intensity of 2:1 are observed (Fig. 1b). Two carbonyls in iron cyclopentadienyl derivatives **8** and **9** are equivalent and only one resonance is

detected in ^{17}O NMR spectra of these derivatives. With all these assignments in mind for homodinuclear metal carbonyl derivatives, **1—9**, ^{17}O NMR spectral assignments are easily made for hetero-

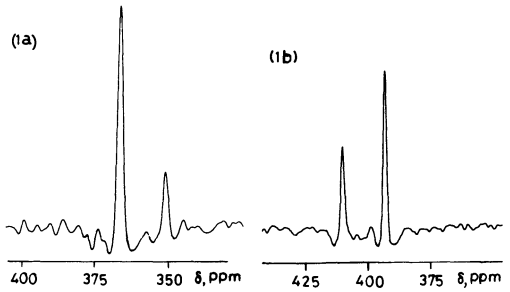

Fig. 1. ^{17}O NMR spectra of: (1a) $Me_2Sn[Re(CO)_5]_2$ and (1b) $Me_2Sn[Mo(CO)_3Cp]_2$.

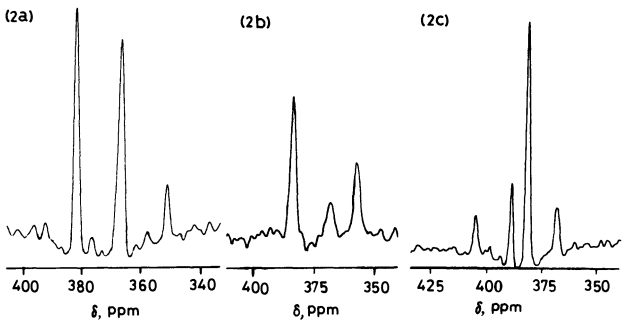

Fig. 2. ^{17}O NMR spectra of: (2a) $Me_2Sn[Mn(CO)_5]$-$[Re(CO)_5]$, (2b) $Ph_2Sn[Mn(CO)_5][Co(CO)_4]$, and (2c) $Me_2Sn[Mn(CO)_5][Mo(CO)_3Cp]$.

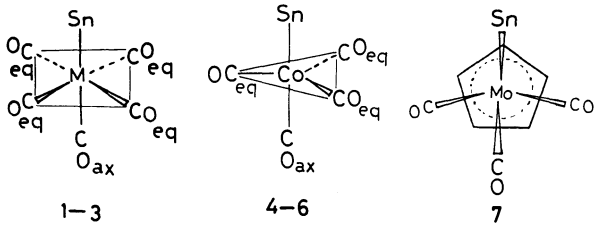

Scheme

dinuclear or hetero-trinuclear metal carbonyl derivatives **10—13**; $Me_2Sn[Mn(CO)_5][Re(CO)_5]$ (**10**) shows two intense and one weak resonances (Fig. 2a) and the most intense peak is assigned to the equatorial carbonyls in the $Mn(CO)_5$ moiety. The line width of the next intense peak at δ 366.8 is broader than that of the most intense peak at δ 382.1 and the chemical shift is quite close to the resonance of the axial carbonyls in $Me_2Sn[Mn(CO)_5]_2$ (**1**) at δ 365.9. Therefore, this peak is assigned to the equatorial carbonyls in the $Re(CO)_5$ moiety and the axial carbonyl in the $Mn(CO)_5$ moiety. The weak peak at 351.5 ppm is assigned to the axial carbonyl in the $Re(CO)_5$ moiety. $Ph_2Sn[Mn(CO)_5][Co(CO)_4]$ shows three peaks at δ 383.0, 367.5, and 357.1 in THF (Fig. 2b). The most intense peak at δ 383.0 is assigned to the four equatorial carbonyls and the weakest peak at δ 367.5 is assigned to the axial carbonyl in the $Mn(CO)_5$ moiety. The medium intensity peak at δ 357.1 is assigned to the carbonyls in the $Co(CO)_4$ moiety. Here again the resonance due to the three equatorial carbonyls and the resonance due to the axial carbonyl in the $Co(CO)_4$ moiety are not resolved. Although the most complex

spectrum is displayed for $Me_2Sn[Mn(CO)_5][Mo(CO)_3Cp]$ (**12**) (Fig. 2c), spectral assignment is easily made with reference to the assignments of (**1**) and (**7**). The weak peak at δ 405.6 is assigned to the trans CO with respect to Sn and the medium intensity peak at δ 388.8 to the two cis CO with respect to Sn on the $Mo(CO)_3Cp$ moiety. The most intense peak at δ 381.7 is assigned to the equatorial four CO and the weak peak at δ 367.8 to the axial CO in the $Mn(CO)_5$ moiety. $ClSn[Mn(CO)_5][Fe(CO)_2Cp]_2$ (**13**) shows two intense peaks at δ 382.1 and δ 367.2. The peak at δ 382.1 is assigned to the four equatorial carbonyls in the $Mn(CO)_5$ moiety and the peak at δ 367.2 is assigned to the axial CO in the $Mn(CO)_5$ moiety and the four carbonyls in the two $Fe(CO)_2Cp$ units.

Discussion

As for absorption spectra, we have previously suggested that the absorption between 300 and 400 nm is assignable to $\sigma \rightarrow \sigma^*$ transition of the Sn–Mn bonds in $Me_2Sn[Mn(CO)_5]_2$ and $MeSn[Mn(CO)_5]_3$.[2] To supplement this suggestion, absorption spectral measurements are examined for a present series of derivatives, **1**—**13**. All these derivatives exhibit absorptions between 300 and 400 nm and these absorptions are assignable to $\sigma \rightarrow \sigma^*$ transition of the Sn–M bonds in the present series of derivatives.

As is shown in the Table 1, all the derivatives which are employed for the present study show very complex IR spectra in the ν(CO) region. On the other hand ^{17}O NMR spectra for these derivatives are generally simpler than the corresponding ν(CO) spectra and the ^{17}O NMR spectral assignments are easily achieved as is mentioned in the previous section. The investigation for the change of electron distribution around the oxygen atom(s) of interest are easily made in terms of the ^{17}O chemical shift, whereas normal coordinate treatments by use of a computer are necessary in order to make similar investigation in terms of force constants for IR spectroscopy in the ν(CO) region.[12] In this sense, the superiority of ^{17}O NMR spectroscopy to IR spectroscopy is again demonstrated for present more complex systems than those simpler systems which were demonstrated in the previous studies.[1]

Then, ^{17}O NMR spectroscopy is applied to investigate the effect of substitution of one of the $M(CO)_x$ or $M'(CO)_yCp$ unit in the homo-dinuclear $R_2Sn[M(CO)_x]_2$ or $R_2Sn[M'(CO)_yCp]_2$ system with other metal carbonyl unit, $M'(CO)_y$ on the electron distribution around the O atom(s) of interest; that is, ^{17}O-chemical shifts for **10**—**13** are compared with those for **1**—**3**, **5**, **7**, and **9**. The substitution, however, causes only slight changes of the chemical shifts except for $Me_2Sn[Mo(CO)_3Cp]_2$ (**7**); several ppm shifts are observed for the $Mo(CO)_3Cp$ moiety by substitution of one of the $Mo(CO)_3Cp$ unit with a $Mn(CO)_5$ unit. The fact that the substituent is on the third atom from the O atoms of interest explains this range of small shift. Todd et al. reported a larger down-field shift, that is, 14.4 ppm, in the substitution of bromine atoms for triphenylphosphines in $Mn_2(CO)_8(PPh_3)_2$;[13] in this system, the substituent is on the second atom from the O atoms of interest. The effect of the substituents, R, on the ^{17}O-chemical shift is also studied for a series of $R_2Sn[Co(CO)_4]_2$ (R=Me, Ph, and Cl) (**4**—**6**) and $R_2Sn[Fe(CO)_2Cp]_2$ (**8**, **9**) (R=Me and Cl). For a series of Co derivatives, 5.5 ppm lower-field shift is observed by substitution of Ph with Cl and 11.6 ppm lower-field shift is observed by substitution of Me with Cl for a series of Fe derivatives. Here again, the substituent is on the third atom from the O atoms of interest and only slight lower-field shifts are observed. These lines of evidence suggest that ^{17}O-chemical shift of CO groups is sensitive to the metal atom to which the CO groups are coordinated and the effect of the substituent on the ^{17}O-chemical shift, that is, on the electron distribution around the oxygen atom(s), is small, if any, in the case that the substitution is made on the third atom from the O atoms of interest. We are now applying this trait of ^{17}O NMR spectroscopy for higher nuclearity mixed metal carbonyl clusters.

We would like to express our gratitude to professor Kensuke Takahashi of this Institute for his kind help to get ^{17}O NMR spectra.

Novel Racemization of Atropisomeric Flavins and 5-Deazaflavins via Adduct Formation[1)]

Seiji SHINKAI,*, Hideki NAKAO, Toshiro YAMAGUCHI, and Osamu MANABE
Department of Industrial Chemistry, Faculty of Engineering, Nagasaki University, Nagasaki 852
(Received April 18, 1987)

Synopsis. The molecular structures of covalent adducts derived from flavins and 5-deazaflavins are discussed on the basis of racemization of atropisomeric flavins and 5-deazaflavins. The 5-adducts with SO_3^{2-} and CN^- underwent facile racemization, indicating that the molecular structure changes from the "tense" planar state to the "relaxed" bent state. On the other hand, the 4a-adduct prepared by the photo-alkylation method did not racemize at room temperature. This indicates that the structure of the 4a-adduct is different from the bent 5-adduct. These results provide an information useful to discuss the reduced state of flavoproteins.

A number of papers have reported on the synthesis and the resolution of optical isomers caused by restricted rotation about a C–C single bond.[2–7)] The typical examples are sterically-hindered binaphthyls and biphenyls.[3–5)] In contrast, only a few precedents exist for such optical isomers including restricted rotation about a C–N single bond,[8–11)] and the characteristics arising from the C–N axis are not understood well. We recently synthesized several isoalloxazines (**1NR** and **2NR**) and 5-deazaisoalloxazines (**1CHR** and **2CHR**) with restricted rotation about the C(1′)–N(10) single bond.[12,13)] They were optically resolved by a liquid chromatographic method using a chiral packing column. It was found that these atropisomers did not recemize thermally (below 70 °C) or by visible light irradiation (at 30 °C) but the (5-deaza)isoalloxazines with a 2′-substituted phenyl group or a naphthyl group at N(10) racemized invariably when they were reduced to 1,5-dihydro forms.[13,14)] Detailed examination established that the facile rotation in the reduced state is due to conversion of the "planar" oxidized forms to the "bent" reduced forms by which the steric restriction is partically relaxed:[14)] that is, reduction changes the molecular geometry from the "tense" steric state to the "relaxed" steric state.

1,5-dihydro form — Y=CN^-, SO_3^{2-} (1)

It is known that flavins and 5-deazaflavins reversibly form covalent adducts (i.e., 5-adducts) with nucleophiles such as CN^- and SO_3^{2-} at 5-position.[14)] It would be of value to examine whether the racemization is also induced by the adduct formation. If they recemize, it provides unambiguous evidence for the bent structure. With this object in mind, we treated optically-pure **1XR** and **2XR** with the nucleophiles and checked whether recovered (5-deaza)isoalloxazines recemized.

Experimental

Materials. Preparations of 3-methyl-10-(2-phenylphenyl)isoalloxazine (**1NPh**), 3-methyl-10-(2-phenylphenyl)-5-deazaisoalloxazine (**1CHPh**), 3-methyl-10-(1-naphthyl)isoalloxazine (**2NH**), 3-methyl-10-(2-methoxy-1-naphthyl)isoalloxazine (**2NOMe**), and 3-methyl-10-(2-methoxy-1-naphthyl)-5-deazaisoalloxazine (**2CHOMe**) were described previously.[12,13)] The method of optical resolution was also described.[12,13)]

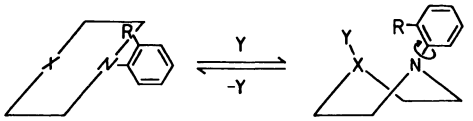
Reactions with KCN or K_2SO_3. The aqueous reactions of (5-deaza)isoalloxazines with KCN or K_2SO_3 were conducted aerobically in the quartz cuvette at 30 °C. The concentrations of the reactants are recorded in footnotes to Table 1. The progress of the reactions was followed spectrophotometrically by monitoring the disappearance of the absorption band at around 440 nm for isoalloxazines and 400 nm for 5-deazaisoalloxazines. The reaction of 5-deazaisoalloxazines and K_2SO_3 was finished immediately after mixing. Other reactions took 1—2 h. After completion of the reactions the solution (5 ml) was acidified with concd HCl (15 ml) and stirred for 1 h at room temperature. By this treatment the adducts decomposed to the oxidized forms, which were easily monitored by the recovery of the yellow solution color. Then, the solution was adjusted to pH 4 with 0.1 M Na_2HPO_4 (1 M=1 mol dm^{-3}) and extracted with chloroform. The chloroform solution was concentrated in vacuo and the residue (about 1 ml) was analyzed by HPLC using a chiral packing column (Sumipax OA-2000). The results are summarized in Table 1. We confirmed in a separate experiment that in the absence of the nucleophiles these (5-deaza)isoalloxazines do not racemize by the treatment described above.

Photo-Alkylation. (+)-**1NPh** (6.17×10^{-5} M) and ammonium phenylacetate (5.44×10^{-2} M) were dissolved in a mixed solvent of methanol–water (1.3:2.0 v/v). The solution pH was 7.1. The anaerobic solution in a Thunberg cuvette was photoirradiated by a 17-W flourescent lamp for 30 min at

room temperature. The absorption spectra taken every 5 min were very similar to those reported in Ref. 20 in which "pure" 4a-benzyl-4a,5-dihydroflavin resulted: That is, the absorption maximum (440 nm) decreased with photoirradiation with an isosbestic point (315 nm) giving rise to a new absorption maximum (350 nm). The solution was diluted with water and then extracted with chloroform. The chloroform layer was separated and dried over Na_2SO_4. The solution was concentrated in vacuo to dryness. The residue (dissolved in 0.5 ml chloroform) was subjected to HPLC analysis using a chiral packing column (Sumipax OA-2000) connected to a photo-diode array UV-VIS detector (Shimadzu SPD-M1A). In a separate study, we confirmed that photoirradiation in the absence of ammonium phenylacetate at room temperature does not induce racemization.

Results and Discussion

It is clearly seen from Table 1 that **1NPh**, **1CHPh**, and **2NH** racemize when they form the 5-adducts. It is firmly established by X-ray crystallographic studies that oxidized flavins are planar, whereas reduced 1,5-dihydroflavins are folded along a line through N(5) and N(10) like butterfly wings.[15,16] This is because the nitrogen atoms N(5) and N(10) have a high degree of tetrahedral sp^3 hybridization in the reduced state.[15,16] Although there exists no firm evidence for the molecular structure of 5-adducts, it has been expected that 5-adducts would be bent like 1,5-dihydro forms on the basis of the spectral similarity. Our finding that the 5-adducts derived from chiral (5-deaza)isoalloxazines with a 2′-phenylphenyl group or a naphthyl group easily racemize at room temperature clearly supports that the 5-adducts employ the bent structure which can relax the steric restriction (Eq. 2).



(2)

In contrast, the optical purities of 2NOMe and 2CHOMe are essentially unaffected by this treatment, indicating that racemization does not occur either in the 5-adduct state or in the transition state.[17] We have found that the redox treatment of these (5-deaza)isoalloxazines (Y=H in Eq. 2) does not change the optical purities.[12,13] This means that the steric bulkiness of the 2′-methoxy-1′-naphthyl group (but not of Y) is responsible for the retention of the optical purities. Therefore, the difference between the 2′-methoxy-1′-naphthyl group and the 2′-substituted phenyl group can be explained as follows: In the 2′-methoxy-1′-naphthyl group which would be comparable sterically with the 2′,6′-disubstituted phenyl group both 2′-methoxyl group and 8′-hydrogen provide steric hindrance to restrict the rotation, whereas in the 2′-substituted phenyl group the steric bulkiness is not enough to suppress the rotation.

The foregoing racemization trend is completely in accord with that observed for the redox treatment of the chiral (5-deaza)flavins.[12,13] Therefore, the 5-adducts should employ the bent structure with butterfly-like wings similar to the 1,5-dihydro forms.

Racemization may also take place via 4a-adducts (covalent adducts at 4a-position) if they employ the bent structure. The thermal nucleophilic attack usually occurs at 5-position of the isoalloxazine ring except a few cases.[18,19] It is known, on the other hand, that light-induced alkylation occurs at 4a-position.[20] By means of this photo-alkylation method we examined whether racemization takes place via 4a-adducts.

Accoding to Bruice et al.,[18,19] λ_{max} for 5-adducts characteristically appears between 296 and 330 nm and λ_{max} for 4a-adducts appears between 360 and 370 nm. In photo-alkylation of 6,7-dimethyl-10-(tetra-*O*-acetylribityl)isoalloxazine by phenylacetate, Walker et al.[20]

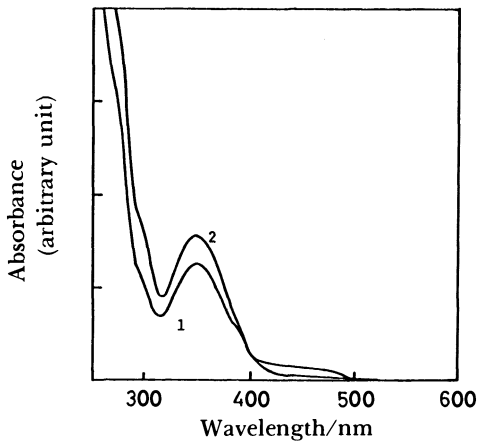


Fig. 1. Absorption spectra of the first peak (1) and the second peak (2) measured by a photo-diode array UV-VIS detector connected to a chiral peaking column.

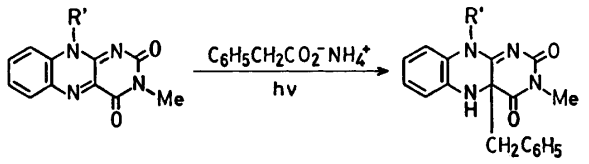
Table 1. Racemization via Adduct Formation

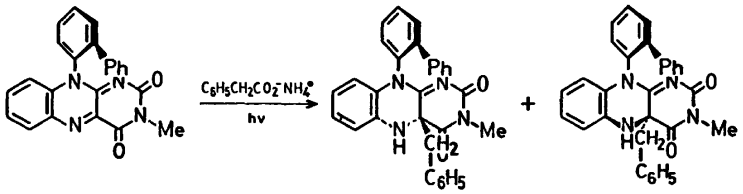
Flavin[a]	Optical purity of (+)-Isomer/e.e.%	Nucleophile[b]	Recovered flavin	
			(+)-Isomer/%	(−)-Isomer/%
1NPh	100	K_2SO_3	46.6	52.4
1CHPh	100	K_2SO_3	55.0	45.0
1CHPh	100	KCN	54.4	45.6
2NH	100	K_2SO_3	52.8	47.2
2NOMe	98.0	K_2SO_3	98.0	2.0
2CHOMe	100	K_2SO_3	100	0
2CHOMe	100	KCN	100	0

a) [1NPh]=6.20×10^{-5} M, [1CHPh]=4.74×10^{-5} M. The concentrations of other flavins were 5.00×10^{-5} M. b) [K_2SO_3]=0.752 M for isoalloxazines and 0.125 M for 5-deazaisoalloxazines, [KCN]=1.10×10^{-3} M. The reaction between 5-deazaisoalloxazines and KCN was not completely reversible because in the HPLC analysis we detected a small amount of some unknown products in addition to recovered 5-deazaisoalloxazines.



(3)

observed a new absorption maximum at 364 nm which was attributed to the 4a-adduct. In HPLC we observed two large peaks which gave the identical absorption spectra (λ_{max} 350 nm: Fig. 1). Therefore, these two peaks are attributed to the optically-isomeric 4a-adducts of 1NPh. The peak intensity ratio of the first vs. the second peak was 1.0:2.1. The ratio was affected neither by heating in chloroform for 2 h at 60 °C nor by keeping at room temperature in the dark for 3 days. These results suggest that the C(1')–N(10) axis in the 4a-adduct cannot racemize at room temperature and that the peak separation in HPLC is due to the chirality at 4a position. The absolute configuration of (+)-1NPh is not determined yet. If it could be drawn as in Eq. 4, it would result in two optical isomers, A and B. The attack from the 2'-phenyl side results in A while that from the 6'-hydrogen side results in B. Presumably, the attack from the sterically-crowded 2'-phenyl side is less advantageous. If so, the first weak peak (32%) is attributed to A and the second strong peak (68%) is attributed to B.



A B

(4)

Recently, Yoneda et al.[21] reported an X-ray crystallographic structure of 4a,5-dihydro-4a-hydroxy-3,10-dimethyl-5-deazaisoalloxazine, a 4a-adduct of 5-deazaisoalloxazine. The picture shows that N(10) with sp^2 nitrogen is almost planar while C(5) with sp^3 carbon is bent to the chair-like form, totally resulting in a half-chair conformation. On the other hand, almost nothing is known with certainty as to the 4a-adduct of isoalloxazine. If it is bent along the N(5)–N(10) like butterfly wings, the 4a-adduct of (+)-1NPh should racemize easily at room temperature. Thus, the present result suggests that N(10) in the 4a-adduct should be planar with sp^2 nitrogen which does not allow facile racemization.

According to Massey and Hemmerich,[22] a large number of flavoproteins may be classified into two groups from a viewpoint of their regiospecific reactivities, a 5-activated group and a 4a-activated group. The first group which uses the N(5) in the redox reactions is characterized by red semiquinone, high sulfite affinity, and *bent structure of reduced form*, whereas the second group which uses the C(4a) in the redox reactions is characterized by blue semiquinone, low sulfite affinity, and *almost planar structure of reduced form*. As demonsrated in the present study, the 5-adduct employs the bent structure while the 4a-adduct employs the almost planar N(10). The difference is well-correlated with the classification in flavoenzymes: that is, the reactions including N(5) take the bent intermediates while those including C(4a) take the planar intermediates not only in the flavoenzymes but also in the model systems. Therefore, the present results could provide a significant cross-link between enzymic reactions and model organic reactions.

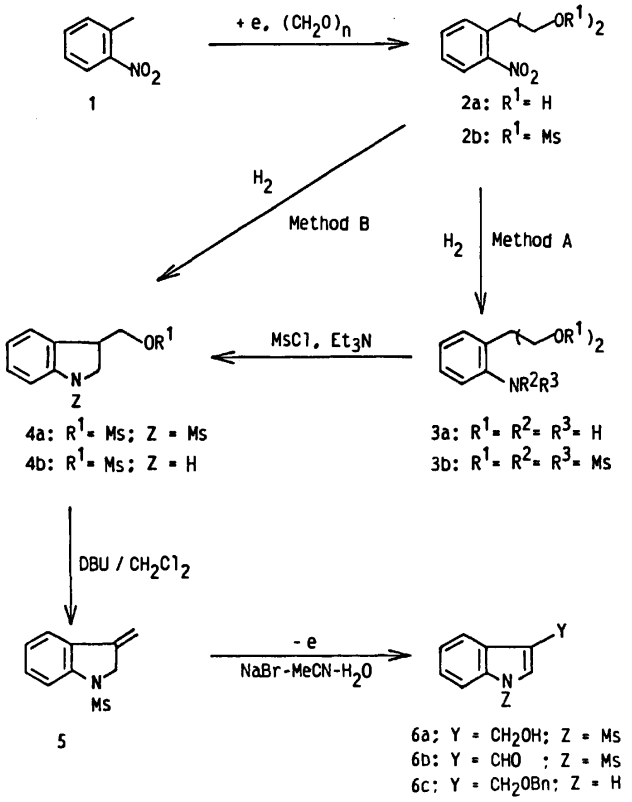
A Facile Synthesis of 3-Hydroxymethyl- and 3-Formylindoles from *o*-Nitrotoluene

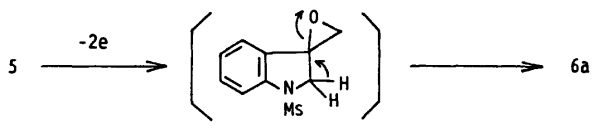
Hideo TANAKA, Yasuo MURAKAMI, Koichi OKAMOTO, Takao AIZAWA, and Sigeru TORII*
Department of Industrial Chemistry, School of Engineering, Okayama University, Okayama 700
(Received July, 3, 1987)

Synopsis. A synthesis of 3-hydroxymethyl- and 3-formylindoles has been performed by manipulation of the side chain of 3-hydroxymethylindoline derived from *o*-nitrotoluene. Electro-reductive cyclization of 2-(2-nitrophenyl)-1,3-bis(methylsulfonyloxy)propane to 3-(benzyloxymethyl)indole, is also discussed.

The conversion of readily available *o*-nitrotoluene (**1**) into useful 3-substituted indoles **6** is of current interest.[1] We have recently reported an efficient electrogenerated base (EG Base) induced double hydroxymethylation of the methyl group of *o*-nitrotoluene (**1**) with formaldehyde.[2] The adduct **2a** (R^1=H) possesses all of the framework elements required for the formation of 3-hydroxymethyl- or 3-formylindole (**6a**, **6b**), which are intermediates for the synthesis of useful indole derivatives.[3] Herewith, we describe a convenient synthesis of **6a** (Y=CH_2OH, Z=Ms) and **6b** (Y=CHO, Z=Ms) by manipulation of the C(3)-side chain of indolines **4**, derived from **2a**, together with electroreductive transformation of **2b** (R^1=Ms) to **6c** (Y=CH_2OCH_2Ph, Z=H).



Scheme 1.



Scheme 2.

Our approach to indoles **6** is outlined in Scheme 1. The key intermediate **4a** (R^1=Z=Ms) was prepared by two different pathways (Methods A and B).[4,5] Thus, hydrogenation of **2a** over Pd/C catalyst gave amine **3a** (R^1=R^2=R^3=H; 96%) which, upon treatment with methanesulfonyl chloride (MsCl) and Et_3N in CH_2Cl_2, was converted to indoline **4a** (85%) along with **3b** (R^1=R^2=R^3=Ms, 3%) (Method A).[4] Cyclization of the by-product **3b** to **4a** was successfully performed in 91% yield by the electroreduction in DMF containing ascorbic acid and anthracene.[6] Alternatively (Method B), hydrogenation of methanesulfonate **2b** over PtO_2 in benzene containing K_2CO_3 afforded indoline **4b** (R^1=Ms, Z=H) exclusively (80%).[5] Treatment of **4b** with MsCl/Et_3N in CH_2Cl_2 afforded **4a** (88%).

Next task is the introduction of the C=C double bond at the C(2)-position of indoline **4a**. At first, we investigated the direct dehydrogenation of **4a** using catalysts, e.g., PtO_2 and Pd/C. All attempts, however, resulted in the formation of a complex mixture and failed in obtaining an appreciable amount of the desired products **6**.[7] Finally, we found a new route involving two-step operation (**4a**→**5**→**6a**); heating **4a** with diazabicyclo[5.4.0]undec-7-ene (DBU) in CH_2Cl_2 afforded 3-methyleneindoline (**5**) (94%), which was, in turn, electrolyzed in an aqueous CH_3CN solution containing NaBr to give indole **6a** (Y=CH_2OH) in 85% yield. The electrochemical transformation (**5**→**6a**) can be explained by assuming that the intermediary epoxide **7** (Scheme 2), formed by an electrolytic epoxidation of **5**,[8] is isomerized to **6a** in the electrolysis media. In fact, treatment of **5** with *m*-chloroperbenzoic acid and CH_2Cl_2 also afforded alcohol **6a** (49%). Aldehyde **6b** was obtained in 89% yield by oxidation of **6a** under O_2 (1 atm) in the presence of $RuCl_2(PPh_3)_3$ catalyst.[9]

As an alternative route to 3-substituted indoles, transformation of **2b** (R^1=Ms) to indole **6c** was performed by electroreduction of **2b** (R^1=Ms) in a benzyl chloride/Et_4NBr/DMF (Pt electrodes) system, affording **6c** (60%) after passage of 3.2 F mol^{-1} (1 F=96480C) of electricity. The presence of benzyl chloride in the electrolysis media is indispensable since absence of benzyl chloride resulted in the formation of a complex mixture. Although the mechanism is still unclear, it is likely that anion species, generated from electroreduction of the nitro group,[10] attack the methylsulfonyloxy group on the side chain.

Experimental

Apparatus and Procedures. IR spectra were recorded on a JASCO IRA-1 grating spectrometer. ^{1}H NMR spectra were measured at 60 MHz with a Hitachi R-24 spectrometer and ^{13}C NMR spectra were recorded with a JEOL FX-100 (25.05 MHz) spectrometer. Melting and boiling points are uncorrected. Column chromatography was carried out using Wako C-200 (silica gel) with hexane–EtOAc as an eluent. Elemental analysis were performed in our laboratory.

2-(2-Nitrophenyl)-1,3-bis(methylsulfonyloxy)propane (2b). To a mixture of **2a** (2.27 g, 11.5 mmol)[2] and Et_3N (10 ml) in CH_2Cl_2 (20 ml) was added MsCl (5 ml) at 0 °C. After stirring for 2 h at room temperature, usual workup of the mixture followed by chromatography (3:1 hexane–EtOAc) afforded **2b** (3.92 g, 97%) as colorless crystals: mp 90—91 °C (from benzene–CH_2Cl_2); IR (Nujol) 1355, 1175 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=2.89 (3H, s, CH_3SO_3), 3.9—4.2 (1H, m, CH), 4.56 (4H, d, J=5 Hz, CH_2O), 7.4—7.9 (4H, m, Ar). Anal. ($C_{11}H_{15}NO_8S_2$) C, H.

2-(2-Aminophenyl)-1,3-propanediol (3a). A mixture of **2a** (1.02 g, 5.2 mmol) and 5% Pd/C (100 mg) in EtOAc (20 ml) was stirred at room temperature under H_2 (1 atm) for 15 h. After the catalysts were removed by filtration, evaporation of the solvent afforded **3a** (840 mg, 96%) as colorless crystals: mp 72—75 °C (from benzene–CH_2Cl_2); IR (Nujol) 3360, 3330, 3300, 3200 cm^{-1}; ^{1}H NMR ($CDCl_3$–acetone-d_6) δ=3.0—3.4 (1H, m, CH), 3.6—4.1 (8H, m, NH_2, CH_2OH), 6.4—7.1 (4H, m, Ar). Anal. ($C_9H_{13}NO_2$) C, H.

1-Methylsulfonyl-2-(methylsulfonyloxymethyl)indoline (4a). Method A: To a mixture of **3a** (179 mg, 1.1 mmol) and Et_3N (0.6 ml, 4.3 mmol) in dry CH_2Cl_2 (4 ml) was added MsCl (0.18 ml, 2.3 mmol) at −10 °C. After being stirred at room temperature for 2 h, MsCl (0.08 ml, 1.0 mmol) was added at 10 °C and stirring was continued for an additional 1 h at room temperature. Usual workup of the mixture followed by chromatography (4:1 hexane–EtOAc) afforded **4a** (278 mg, 85%) as colorless crystals along with **3b** (16 mg, 3%). Compound **4a**: mp 99—101 °C (from benzene–CH_2Cl_2); IR ($CHCl_3$) 1370, 1355, 1175, 1160 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=2.89 (3H, s, CH_3SO_2N), 2.95 (3H, s, CH_3SO_3), 3.6—4.1 (3H, m, $CHCH_2N$), 4.32 (2H, dd, J=6, 1 Hz, CH_2O), 7.0—7.4 (4H, m, Ar). Anal. ($C_{11}H_{15}NO_5S_2$) C, H. Compound **3b**: mp 184—186 °C (from benzene–CH_2Cl_2); IR (Nujol) 3330—3380, 1190, 1185, 1170, 1160 cm^{-1}; ^{1}H NMR ($CDCl_3$–acetone-d_6) δ=2.95 (6H, s, CH_3SO_3), 3.51 (6H, s, CH_3SO_2N), 3.8—4.1 (1H, m, CH), 4.53 (4H, d, J=6 Hz, CH_2O), 7.4—7.7 (4H, m, Ar). Anal. ($C_{13}H_{21}NO_{10}S_4$) C, H.

Method B: To a solution of **2b** (1.13 g, 3.2 mmol) in benzene (80 ml) were added K_2CO_3 (800 mg) and $PtO_2 \cdot 3H_2O$ (120 mg). After stirring at room temperature under H_2 (1 atm) for 4 h, the catalysts were removed by filtration. Evaporation of the solvents followed by chromatography (2:1 hexane–EtOAc) afforded **4b** (580 mg, 80%): IR (neat) 3360, 1360, 1180 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=2.90 (3H, s, SO_2CH_3), 3.3—3.8 (2H, m, CH_2N), 3.55 (1H, br. s, H, NH), 3.3—3.8 (1H, m, CH), 4.1—4.4 (2H, m, CH_2O), 6.5—7.3 (4H, m, Ar). The structure of **4b** was confirmed by the following transformation into **4a**. To a mixture of **4b** (39 mg, 0.17 mmol) and Et_3N (0.2 ml) in CH_2Cl_2 (3 ml) was added MsCl (0.06 ml, 1.43 mmol) at −10 °C. After stirring for 3 h at room temperature, usual workup of the mixture followed by chromatography (3:1 hexane–EtOAc) afforded **4a** (46 mg, 88%), whose IR spectra and ^{1}H NMR were fully identical with those of **4a** described above.

1-Methylsulfonyl-3-methyleneindoline (5). A mixture of **4a** (125 mg, 0.41 mmol) and 1,8-diazabicyclo[5.4.0]undec-7-ene (0.25 ml, 1.67 mmol) in CH_2Cl_2 (4 ml) was heated at reflux for 15 h. Usual workup of the mixture followed by chromatography (3:1 hexane–EtOAc) afforded **5** (81 mg, 94%) as colorless crystals: mp 114—116 °C (from benzene); IR ($CHCl_3$) 1640, 1355, 1160 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=2.83 (3H, s, CH_3SO_2N), 4.55 (1H, dd, J=3 Hz, HC=C), 6.8—7.5 (4H, m, Ar). Anal. ($C_{10}H_{11}NO_2S$) C, H.

3-Hydroxymethyl-1-(methylsulfonyl)indole (6a). A solution of **5** (35 mg, 0.17 mmol) in MeCN (10 ml)–H_2O (2 ml) contaning NaBr (27 mg, 0.26 mmol) was electrolyzed under a constant current density of 3.3 mA cm^{-2} at room temperature in a beaker type cell fitted with two platinum electrodes (3 cm^2).[12] After passage of 3 F mol^{-1} of electricity (2.8 h), workup of the electrolytes followed by chromatography (4:1 hexane–EtOAc) afforded **6a** (33 mg, 85%) as colorless crystals: mp 117—120 °C (from benzene–CH_2Cl_2); IR ($CHCl_3$) 3400, 1370, 1170, 1110 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=2.45 (1H, br. s, OH), 3.02 (3H, s, CH_3SO_2N), 4.79 (2H, br. s, CH_2O), 7.2—7.9 (5H, m, Ar, HC=C). Anal. ($C_{10}H_{11}NO_3S$) C, H.

3-Formyl-1-(methylsulfonyl)indole (6b). A mixture of **6a** (240 mg, 1.1 mmol) and $RuCl_2(PPh_3)_3$ (310 mg, 0.3 mmol)[10] in CH_2ClCH_2Cl (10 ml) was stirred under O_2 (1 atm) at 50—60 °C for 4 h. After evaporation of the solvent, the residue was passed through short Florisil column (hexane–EtOAc). The eluents were concentrated and chromatographed (4:1 hexane–EtOAc), affording colorless crystals **6b** (192 mg, 80%): mp 170—171 °C (from benzene–CH_2Cl_2); IR (Nujol) 1690, 1380, 1185 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=3.25 (3H, s, CH_3SO_2N), 7.4—8.4 (4H, m, Ar), 8.04 (1H, s, HC=C), 10.07 (1H, s, CHO). Anal. ($C_{10}H_9NSO_3$) C, H.

Electroreductive Cyclization of 2-[2-[Bis(methylsulfonyl)-amino]phenyl]-1,3-bis(methylsulfonyloxy)propane (3b). Electrolysis was carried out in an H-shaped divided cell fitted with Pt-cathode (3 cm^2) and Pt-anode (3 cm^2).[12] Into both anode and cathode compartments was charged a DMF solution of Et_4NOTs (6 ml/133 mg each). To the catholyte were added **3b** (48 mg, 0.1 mmol), ascorbic acid (35 mg, 0.2 mmol), and anthracene (18 mg, 0.1 mmol). The mixture was electrolyzed under a constant current density of 3.3 mA cm^{-2} at room temperature for 2.4 h (4.5 F mol^{-1}). The catholyte was worked up in the usual manner, yielding colorless crystals **4a** (28 mg, 90%), whose IR and ^{1}H NMR spectra were fully identical with those of **4a** described above.

3-(Benzyloxymethyl)indole (6c). Electrolysis was carried out in the same cell as described above. Into both the anode and cathode compartments was placed a DMF solution of Et_4NBr (6 ml, 315 mg each). To the catholyte were added **2b** (107 mg, 0.3 mmol) and benzyl chloride (0.17 ml, 1.48 mmol). The mixture was electrolyzed under a constant current (1.7 mA cm^{-2}) at room temperature for 5.2 h (3.2 F mol^{-1}). Usual workup of the catholyte followed by chromatography on Florisil (10:1 hexane–EtOAc) afforded 3-(benzyloxymethyl)indole (**6c**)[13] (43 mg, 60%): IR (neat) 3340, 1455, 1105 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.86 (1H, br. s, NH), 4.67 (2H, s, C=CCH_2O), 5.07 (2H, s, OCH_2Ph), 6.9—7.7 (5H, m, Ar, NCH=C), 7.29 (4H, s, Ph); ^{13}C NMR ($CDCl_3$) δ=56.8 (t), 80.2 (t), 108.6 (d), 111.5 (s), 119.2 (d), 120.0 (d), 122.6 (d), 122.8 (d), 122.8 (s), 128.6 (d), 129.1 (d), 129.5 (d), 132.9 (s), 134.6 (s).

The Infrared Spectrum of Dioxygen Bound to the Synthetic Porphinatoiron in an Aqueous Medium

Makoto YUASA, Kimiko YAMAMOTO, Hiroyuki NISHIDE, and Eishun TSUCHIDA*
Department of Polymer Chemistry, Waseda University, Tokyo 160
(Received June 29, 1987)

Synopsis. A highly concentrated aqueous solution of heme ([heme]=25 mM) was prepared by embedding the 5,10,15,20-tetrakis(α,α,α,α-*o*-(2′,2′-dimethyl-20′-(2″-trimethylammonio)ethylphosphonatoxy)eicosanamido)phenyl)porphinatoiron(II) complex of 1-dodecylimidazole in bilayer of polymerized 1,2-bis(2,4-octadecadienoyl)-*sn*-glycero-3-phosphocholine liposome (poly-lipid liposome/heme). The dioxygen-binding mode of the poly-lipid liposome/oxy-heme in the aqueous medium was then measured by means of infrared difference spectroscopy: The ν_{O-O} value at 1161 cm^{-1} was found to correspond to those of the oxy picket-fence heme in Nujol mulls, oxy myoglobin, and oxy hemoglobin in an aqueous medium.

The present authors previously found and reported that the heme derivatives incorporated into a bilayer of natural, synthetic, or polymerized lipid liposome could bind dioxygen reversibly under physiological conditions.[1-3] We could also prepare a highly concentrated aqueous heme solution by embedding the 5,10,15,20-tetrakis(α,α,α,α-*o*-(2′,2′-dimethyl-20′-(2″-trimethylammonioethylphosphonatoxy)eicosanamido)phenyl)porphinatoiron(II) complex of 1-dodecylimidazole in bilayer of polymerized 1,2-bis(2,4-octadecadienoyl)-*sn*-glycero-3-phosphocholine liposome (abbreviated as poly-lipid liposome/heme). In this note, we described the dioxygen-binding mode of the poly-lipid liposome/oxy-heme in an aqueous medium, as measured by means of infrared difference spectroscopy and discussed it in comparison with those of the picket-fence oxy-heme[4] in Nujol mulls, and of oxy myoglobin (oxy-Mb) and oxy hemoglobin (oxy-Hb) in an aqueous medium.

Experimental

Meterials. The heme derivative and 1-dodecylimidazole were synthesized as previously reported.[2] The lipid derivative was prepared according to the procedure in the literature.[5] The Mb from Horse Skeletal Muscle was purchased from Sigma (special grade). The $^{18}O_2$ gas was purchased from the Takachiho Shouji Co., Ltd.

Preparation of samples. A mixture (methanol-benzene) of the heme (1.45 g), the imidazole (0.354 g), and the lipid (3.91 g) (molar ratio 1/3/10) was freeze-dried to give a reddish powder. Oxygen-free distilled water (pH 7, adjusted with a dil. NaOH solution, 10 ml) was then added, and the mixture was shaken by means of a Vortex mixer. It was ultrasonicated and homoginized in an ice-water bath under a nitrogen atmosphere (60 W×1 h, using a probe-type sonicator; Nihon-Seiki US-600) to yield a deep red-colored and concentrated liposome/heme solution ([heme]=25 mM†). The solution thus prepared was allowed to stand under ultraviolet (UV) irradiation (Rika-Seiki UVL-32LB, 64 W×3 day) at 40 °C under a nitrogen atmosphere in order to polymerize the lipid and to give a concd poly-lipid liposome/deoxy-heme solution. The pH and volume of the aqueous solution were adjusted to pH 7 and 20 ml with a dil. NaOH solution and oxygen-free distilled water. The reduction of the Fe(III)-heme derivative to the deoxy-heme spontaneously occurred during the polymerization. The complete polymerization and reduction were confirmed by means of UV and Vis absorption and ^{13}C NMR spectroscopical measurements, as has been reported previously.[3] The poly-lipid liposome/heme looked like a small unilammelar vesicle (SUV), and its diameter was estimated to be ca. 350 A by means of transmission electron microscopic measurements.

The oxy- and carboxy-Mb solutions were prepared as reported in the literature.[6] ([Mb]=20 mM, pH 9, 0.1 M Tris buffer solution).

Measurements. The infrared difference spectra were measured for the poly-lipid liposome/heme and Mb in the aqueous media at 10 °C under $^{16}O_2$ vs. $^{18}O_2$, $^{16}O_2$ vs. $^{12}C^{16}O$, and $^{12}C^{16}O$ vs. a nitrogen atmosphere. The cells used were precisely matched in terms of path-length (25 μm) and calcium fluoride (CaF_2) window thickness. The spectra were recorded with a Japan Spectroscopic Co., ltd. Model IR-810-type infrared spectrophotometer in the absorbance mode, using a double beam, an expanded ordinate and abscissa, and a resolution of 2 cm^{-1}, with a data processor.

The UV and Vis absorption spectra were measured with a double- beam UV and Vis absorption spectroscophotometer (Shimazu MPS-2000). The cells with CaF_2 windows could be used for both the UV and Vis and infrared absorption spectroscopy, recorded in the same cell.

Results and Discussion

The values of the O-O and C-O stretching frequencies (ν_{O-O} and ν_{C-O}) of oxy- and carboxy-Mb were 1103 cm^{-1} (band width at 1/2 height=ca. 10 cm^{-1}) and 1944 cm^{-1} (ca. 16 cm^{-1}) respectively: these values were consistent with those reported

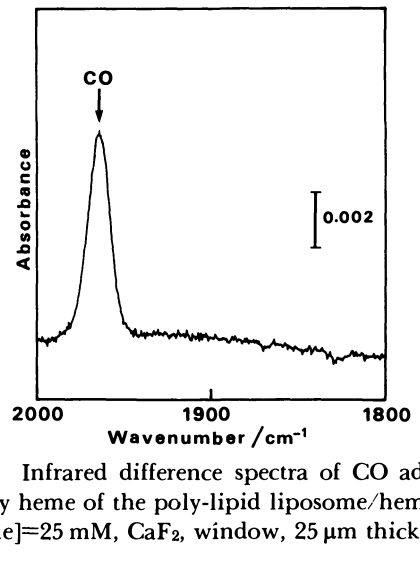

Fig. 1. Infrared difference spectra of CO adduct vs. deoxy heme of the poly-lipid liposome/heme. [heme]=25 mM, CaF_2, window, 25 μm thickness.

† 1 M=1 mol dm^{-3}.

previously.[6] The intensity relative to the CO band was also similar to the reference data. The UV and Vis absorption spectra of oxy- and carboxy-Mb did not change before and after infrared absorption spectroscopic measurements and agreed with those reported in the literature.[7] This result supports the validity of the measuring procedure used in the present experiment.

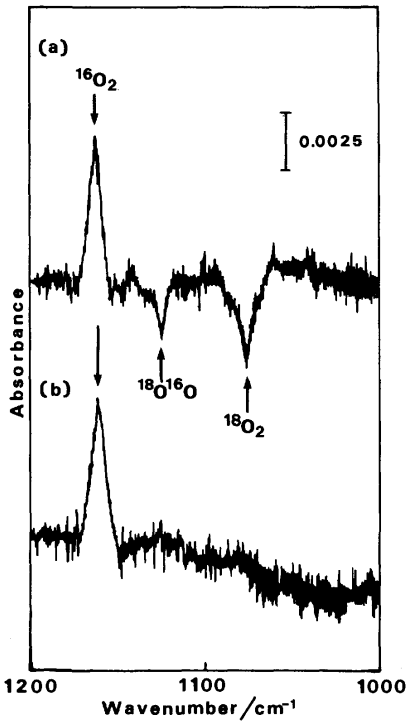

Fig. 2. Infrared difference spectra of $^{16}O_2$ vs. $^{18}O_2$ adducts (a) and $^{16}O_2$ vs. $^{12}C^{16}O$ adducts (b) of the poly-lipid liposome/heme. [heme]=25 mM, CaF_2 window, 25 μm thickness.

The UV and Vis absorption spectrum (λ_{max}; 426, 535 and 562 nm) of the poly-lipid liposome/deoxy-heme changed to the spectrum that was assigned to the oxygen adduct (λ_{max}; 422 and 544 nm) upon exposure to oxygen. The spectrum of the oxygen adduct changed to that of the carbon monoxide (CO) adduct (423 and 540 nm) on bubbling through CO and then returned to that of the deoxy-heme on bubbling through nitrogen. The half-lifetime of the oxygen adduct was ca. 30 hr in the aqueous medium 10 °C.

Figure 1 shows the infrared spectrum of the CO adduct of the poly-lipid liposome/heme, as corrected with the spectrum of the corresponding deoxy-heme in the reference cell. The intense band with a maximum at 1966 cm^{-1} is similar to that of the picket-fence heme-CO complex of 1-methylimidazole in Nujol mulls (ν_{CO}=1969 cm^{-1}).[8] Similarly, the difference spectrum of the CO vs. the $^{16}O_2$ adducts of the poly-lipid liposome/heme showed an intense bond at 1966 cm^{-1}.

The difference spectrum (Fig. 2a) of the $^{16}O_2$ adduct vs. the CO adduct of the poly-lipid liposome/heme shows an intense band at 1161 cm^{-1} with a band-width of 14 cm^{-1} at 1/2 height, a value which agrees with those of the picket-fence heme complex in Nujol mulls and of oxy-Mb and oxy-Hb in aqueous media.[6,8,9] The intensity ralative to be CO band of the poly-lipid liposome/heme was similar to those of Mb and Hb. For the difference spectra of the $^{16}O_2$ vs. the $^{18}O_2$ adducts of the poly-lipid liposome/heme, the $^{16}O_2$ adduct shows an intense band at 1161 cm^{-1} while the $^{18}O_2$ adduct shows prominent bands at 1125 and 1076 cm^{-1} based on the frequency of ^{16}O–^{18}O and ^{18}O–^{18}O respectively (Fig. 2b). The UV and Vis absorption spectra supported the gaseous molecule-binding ability of the ploy-lipid liposome/heme after

the infrared-spectroscopic measurement.

The data of the infrared and UV and Vis absorption spectra are summarized in Table 1. The O–O stretching frequency of the poly-lipid liposome/oxy-heme differs from that of the gaseous oxygen molecule (ν_{O-O}=1556 cm^{-1}),[10] but is similar to that of superoxide (O_2^-, 1145 cm^{-1}).[10] Metal dioxygen complexes with both oxygen atoms bound to a metal (side-on type) have an O–O stretch between 800 and 900 cm^{-1} [12,13] and an O–O bond order of about 1.0. On the other hand, both cobalt dioxygen complexes with a configuration such as the bent end-on type[14] and an O–O bond order of 1.5 exhibit an O–O stretching frequency between 1000 and 1500 cm^{-1}.[15,16] Thus, it may be concluded that molecular dioxygen obviously coordinates to the synthetic lipid-heme, even in an aqueous medium, and that its coordination structure is a bent end-on type one similar to oxy-Mb, oxy-Hb, and the oxygen adduct of the picket-fence heme.

This work was partially supported by Grant-in-Aids for Scientific Research on Priority Area of Macromolecular Complexes, and Encouragement of Young Scientists from the Ministry of Education, Science and Culture.

Structures of New [4+2]-Cycloadducts from Diels-Alder Reactions of Methyl 2-Oxo-2*H*-pyran-5-carboxylate with 2-Methyl- and 2-Methoxy-1,3-butadienes[1)]

(Received July 2, 1987)

Synopsis. A Diels-Alder reaction of methyl 2-oxo-2*H*-pyran-5-carboxylate (**1**) with isoprene gave two stereoisomers, methyl 8-methyl-8-vinyl- and 8-isopropenyl-3-oxo-2-oxabicyclo[2.2.2]oct-5-ene-6-carboxylates. On the other hand, only a stereoisomer from a reaction of **1** with 2-methoxy-1,3-butadiene, methyl 8-methoxy-8-vinyl-3-oxo-2-oxabicyclo[2.2.2]oct-5-ene-6-carboxylate was obtained. The stereostructures of these adducts were determined by NMR spectral data and single-crystal X-ray analyses.

Diels-Alder reactions[2)] using 2-pyrones can be used to prepare such versatile products as various [4+2]-cycloadducts, polycyclic compounds, and benzene derivatives since 2-pyrones might serve as either dienes or dienophiles and the primary adducts undergo succeeding thermal conversions through their secondary reactions, e.g., decarboxylation, hydrogen migration, and intramolecular cycloaddition. In the course of our study on the thermal cycloaddition reactions of enone compounds, we became interested in the use of methyl 2-oxo-2*H*-pyran-5-carboxylate (**1**) as a substrate bearing two enone systems with the expectation that it might selectively react as a diene or a dienophile to the reaction partner and that the products potentially serve as synthetic intermediates. Previous papers[3)] have demonstrated that the Diels-Alder reactions of **1** with 2-substituted 1,3-butadienes **2** afford tetrahydrocoumarins **3**—**5** and that they can be used as one approach to the synthesis of trichothecane sesquiterpenes.[3b,4)] In addition to the documented products resulting from the reaction of **1** acting as a dienophile, we have tried to isolate hitherto unidentified cycloadducts of **1** as a diene. We now report on the structures of the newly isolated [4+2]-cycloadducts **6**, **7**,[5)] and **8**.

7 R_1=H, R_2=Me
8 R_1=OMe, R_2=H
9 R_1=H, R_2=OMe

Cycloadditions of **1** with isoprene or 2-methoxy-1,3-butadiene were carried out at 90—114 °C in an autoclave. The crude products were repeatedly column-chromatographed and recrystallized to afford three pure bicyclic lactones **6**—**8**, along with some other known products **3**—**5**. However, in the present reactions the regioisomer (**9**) of **8** could not be detected.[6)] The combined yield and the ratio of **6** to **7** were seriously effected by the reaction temperature since further conversions of these initial adducts occurred under applied conditions.[7)] As shown in Table 1, the IR and ^{1}H NMR spectra of the three compounds indicated characteristic of absorption bands (1635—1640 and 950—990 cm^{-1}) and signals

due to vinyl and isopropenyl groups. The ^{1}H NMR spectra also revealed the presence of one olefinic proton (C_5-H) at the lowest field with the splitting pattern of a doublet of doublets (J=6 and 2 Hz) and two methine protons (C_1-H and C_4-H) at positions α to the oxygen and carbonyl of the lactone. The similality of these spectral data indicates that they possess the same structural skeleton formed presumably by an endo addition; however, they differed in regiochemistry. Furthermore, the stereochemistry of **6** and **7** could be confirmed by X-ray crystal structure analyses; these were performed with single crystals prepared from methanol solutions. Perspective views are depicted in Figs. 1 and 2.[8] Thus, their structures were determined to be **6**, **7**, and **8**. The results obtained here show that **1** can react both as a dienophile and a diene toward 2-methyl- and 2-methoxy-1,3-butadienes to furnish [4+2]-cycloadducts **3**—**5** and **6**—**8**.

Experimental

Melting points are uncorrected. IR spectra were measured in $CHCl_3$ with a Hitachi 260-50 spectrometer. NMR spectra were obtained with JEOL JNM MH-100, JEOL JNM-PMX 60, and JEOL JNM-FX 60 spectrometers for ^{1}H and ^{13}C in $CDCl_3$, respectively. Chemical shifts are given in δ values (ppm) downfield from the internal TMS reference. Mass spectra were measured with a JEOL JMS-D 300S spectrometer. Column chromatography was performed with Fuji-Davison BW-300 silica gel.

Methyl 8-Methyl-8-vinyl- and 8-Isopropenyl-3-oxo-2-oxabicyclo[2.2.2]oct-5-ene-6-carboxylates (6 and 7). A mixture of 1.0 g (6.5 mmol) of **1** and 2.2 g (32 mmol) of isoprene in 100 ml of benzene was heated at 110—114 °C for 10 h in an autoclave under a nitrogen atmosphere. After removing the solvent and excess diene, the residue was chromatographed on silica gel with hexane-ethyl acetate (19:1) as an eluent to give a mixture of **6** and **7** (0.56 g; 50% yield based on **1** consumed) along with a mixture of **3** and **4** (0.32 g), and **1** (0.22 g). A mixture of **6** and **7** was repeatedly column-chromatographed and finally recrystallized from methanol to afford each pure compound (ratio of **6**/**7** was about 1:3); the elevation of the reaction temperature (above ca. 120 °C) led to a decrease of a total yield of **6** and **7**, and to change of the isomer ratio. The high reaction temperature also improved the yield of the known product, tricyclo[3.2.1.0^{2,7}]-octene compound.[3a] **6**: Mp 115—116 °C (methanol); MS: m/z 222 (M^+) and 223 [M+1]$^+$); Found: C, 64.65; H, 6.24%. Calcd for $C_{12}H_{14}O_4$: C, 64.85; H, 6.35%. **7**: Mp 106—106.5 °C (methanol); MS: 222 (M^+) and 223 [M+1]$^+$); Found: C, 64.80; H, 6.43%. Calcd for $C_{12}H_{14}O_4$: C, 64.85; H, 6.35%.

Methyl 8-Methoxy-8-vinyl-3-oxo-2-oxabicyclo[2.2.2]oct-5-ene-6-carboxylate (8) and the Related Adducts. A mixture of 5.0 g (32 mmol) of **1** and 5.1 g (60 mmol) of 2-methoxy-1,3-butadiene in 50 ml of toluene was heated at 90—100 °C for 3 h in an autoclave under a nitrogen atmosphere. Removing the solvent and excess diene gave 9.5 g of a yellow viscous oil. The crude products were column-chromatographed on silica gel using hexane-ethyl acetate (4:1) as an eluent to afford 9-methoxy-6-methoxycarbonyl-2-oxabicyclo-[4.4.0]deca-4,8-dien-3-one (**5**; 5.0 g), and its 9,10-dehydro isomer (0.78 g). The other fractions were further chromatographed under similar conditions to give **8** as a colorless solid (ca. 10% yield) together with unidentified materials. **5**: Mp 104.5—105.5 °C (hexane-acetone) (lit,[3b] mp 96—98 °C); IR: 1730—1740 and 1675 cm^{-1}; ^{1}H NMR: 2.15—2.95 (4H, m, 2X-CH_2-), 3.50 (3H, s, -OCH_3), 3.78 (3H, s, -CO_2CH_3), 4.67 (1H, m, -$CH_2\underline{C}\underline{H}O$-), 5.02 (1H, dd, J=7 and 2 Hz, -$C\underline{H}$=$\underline{C}OCH_3$), 6.04 and 6.94 (each 1H, d, J=11 Hz, -CH=CH-); ^{13}C NMR: 29.6, 31.4, 46.2, 53.0, 54.2, 77.0, 89.9, 121.0, 149.3, 152.2, 163.1, and 171.5; MS: m/z 238 (M^+). 9,10-Dehydro isomer of **5**: Mp 100—103 °C (hexane-ethyl acetate); IR: 1730—1740 and 1675 cm^{-1}; ^{1}H NMR: 1.72—2.24 (4H, m, 2X-CH_2-), 3.49 (3H, s, -OCH_3), 3.70 (3H, s, -CO_2CH_3), 4.72 (1H, d, J=5 Hz, =$CH\underline{C}\underline{H}O$-), 5.38 (1H, d, J=5 Hz, =$C\underline{H}\underline{C}HO$-), 5.91 and 6.57 (each 1H, d, J=11 Hz, -CH=CH-); MS: m/z 238 (M^+); Found: C, 60.41; H, 5.82%. Calcd for $C_{12}H_{14}O_5$: C, 60.49; H, 5.92%. This enol compound was transformed into the corresponding keto compound, 6-methoxycarbonyl-2-oxabicyclo[4.4.0]dec-4-ene-3,9-dione through the column chromatography using silica gel; mp 128—129 °C (ether) (lit,[3b] 121—122 °C); IR: 1730—1740 cm^{-1}; ^{1}H NMR: 2.00—2.89 (6H, m, 3X-CH_2-), 3.90 (3H, s, -CO_2CH_3), 5.18 (1H, t, J=4 Hz, -$CH_2\underline{C}\underline{H}O$-), 6.09 and 7.00 (each 1H, d, J=11 Hz, -CH=CH-); ^{13}C NMR: 29.5, 37.3, 43.7, 46.8, 53.6, 78.7, 121.3, 148.0, 162.0, 171.1, and 205.0; MS: m/z 224 (M^+); Found: C, 58.79; H, 5.46%. Calcd for $C_{11}H_{12}O_5$: C, 58.92; H, 5.40%. **8**: Mp 105—106.5 °C (hexane-methanol); MS: m/z 208 ([M+1]$^+$−31) and 207 (M^+−31); Found: C, 60.70; H, 6.01%. Calcd for $C_{12}H_{14}O_5$: C, 60.50; H, 5.92%.

X-Ray Analyses of 6 and 7.[9] The single crystals used for X-ray analyses were recrystallized from methanol solutions. The diffraction data for compounds **6** and **7** were collected on an Enraf-Nonius CAD-4 automated four-circle diffractometer with graphite-monochromated Mo $K\alpha$ radiation (λ=0.71073 Å). The unit-cell constants and diffraction intensities were measured by the ω-2θ scan method. The intensities were corrected for the Lorentz and polarization factors, but no corrections were made for the absorption. The structures were solved by direct method using the program MULTAN 82[10] and the refinement were done by full-matrix least-squares method with anisotropic temperature factors for the non-H atoms and isotropic temperature factors, B=5, for the H atoms. The atomic-scattering factors taken from the International Tables for Crystallography[11] were used on a SDP program package.[12] The crystal data are as follows.

6: $C_{12}H_{14}O_4$, M=222.24, colorless single-crystal size 0.4×0.1×0.05 mm^3, monoclinic, space group $P2_1/n$, a=6.150(6), b=6.7759(8), c=26.680(3) Å, γ=95.91(3)°, V=1106(1) Å^3, Z=4, D_C=1.335 g cm^{-3}, μ(Mo $K\alpha$)=0.936 cm^{-1}. A total of 3228 reflections in the range $2°<2\theta<60°$ were collected for the structure analysis. The final R value was R=0.049, R_W=0.053 for 145 valiables and 1007 reflections with $I>3.0\sigma(I)$.

7: $C_{12}H_{14}O_4$, M=222.24, colorless single-crystal size 0.8×1.0×0.3 mm^3, triclinic, space group $P\bar{1}$, a=6.234(2), b=7.91(1), c=12.248(5) Å, α=101.93(5), β=97.41(3), γ=107.76(4)°, V=551(1) Å^3, Z=2, D_C=1.340 g cm^{-3}, μ(Mo $K\alpha$)=0.985 cm^{-1}. A total of 4827 reflections in the range $2°<2\theta<70$ were collected for the structure analysis. The final R value was R=0.104, R_W=0.136 for 144 valiables and 3074 reflections with $I>3.0\sigma(I)$. The molecules of **7** take randomly one of the two possible conformations which differ in the methyl group orientation around the C–O ester linkage.

The authors wish to thank Professor Kiyohisa Imada for X-ray crystallographic analyses and correcting this manuscript, and to Miss Kimiko Tanabe for mass spectral measurements. We are also thankful to the Research Center for Material Analysis in Miyazaki University for the use of the NMR, MS, and X-ray apparatus.

(Received July 16, 1987)

Synopsis. The title compound was prepared and hydrogenated by using a Ru(II)- or Rh(I)-phosphine catalyst precursor with excellent *anti*-selectivity, the results indicating that a ligating group, $NHCO_2Me$, may direct the addition of hydrogen to an olefinic diastereoface proximate to this group which binds the catalyst.

Recently, highly anti-selective preparation of the Aldol-type α-substituted β-hydroxy esters has been reported[2] via diastereoselective hydrogenation of α-(hydroxyalkyl)acrylates, and the selectivity stems from the hydroxyl-directed olefin hydrogenation of these chiral allylic alcohols.[3]

We report here that a ligating group, $NHCO_2Me$ in an allylic position of certain olefinic substrates, can bind the catalyst and direct effectively addition of hydrogen from one olefinic diastereoface of the molecule.

Very recently, Brown et al.[4] have reported the same directed hydrogenation of N-substituted α-(aminoalkyl)acrylates closely related to the present substrate, even with the kinetic resolution by using a chiral rhodium(I)–phosphine complex.

Results and Discussion

Methyl 2-[α-(methoxycarbonylamino)benzyl]acrylate (**1**) was readily prepared from methyl benzylidenecarbamate[5] and methyl acrylate (Eq. 1).

$$PhCH{=}NCO_2Me + H_2C{=}CHCO_2Me \xrightarrow{DABCO} \underset{\displaystyle CH_2}{\overset{\displaystyle \overset{\displaystyle NHCO_2Me}{|}}{PhCHCCO_2Me}}{\overset{\displaystyle \|}{}} \quad (1)$$

We have found that the amine-catalyzed reaction of acrylates with the imine compound is much faster than that with common aldehydes[6] at room temperature in the presence of 1,4-diazabicyclo[2.2.2]octane (DABCO) to give **1** in ca. 80% yield.

Acrylate **1** thus obtained was hydrogenated under various conditions by using 1 mol% of $Ru(OCOCF_3)_2(PPh_3)_2$ (**2**) or $[Rh(cod)(dppe)]^+ClO_4^-$ (**3**) as a catalyst precursor. The Ru(II) complex **2** was prepared by a reported procedure with slight modification.[7] All data for conversion and selectivity of the present hydrogenation of **1** are given in Table 1.

Hydrogenation of **1** was markedly dependent on the solvent used, less polar solvent such as dichloromethane, benzene or THF being found to behave either inhibitive or a little less selective (Entries 1—3, 8 and 9).

Methanol was generally the best solvent. Hydrogen pressure also played a crucial role for acceptable rate of hydrogenation (at 25 °C in two days) and 30 atm or above of hydrogen pressure was necessary for both catalysts **2** and **3** (Entries 4—6 and 10) or $[Rh(cod)(dppb)]^+ClO_4^-$ (**5**) (Entries 11 and 12). Thus, under selected conditions, excellent diastereoselective hydrogenation was achieved in two cases (99.1% anti

in Entry 4 and 98.0% anti in Entry 10, respectively).

As is seen in Entry 13, 5% palladium on charcoal (**6**) was active enough for complete hydrogenation of **1** under 10 atm of hydrogen in 3 h, to result in low but reverse selectivity.

Since stereochemistry of the diastereomeric hydrogenation products **4** was hardly determined on the basis of coupling constants of vicinal protons (5.9 and 6.4 Hz, respectively), they were converted to the corresponding 2-azetidinone derivatives in the following manner: Two samples of **4** obtained from Entries 10 and 13 were independently converted into 3-methyl-4-phenyl-2-azetidinone (**7**) by unambiguous three-step procedures as depicted in Scheme 1.

A sample of **4** from Entry 10 (diastereomer ratio=50:1) afforded *trans*-**7** in exclusive preference (trans:cis=70:1), indicating that the present hydrogenation of **1** proceeded with anti-selectivity.

A plausible explanation of the observed selectivity could derive from the presence of a ligating $NHCO_2Me$ group in **1**, which directs efficiently the attack of the hydrogenation catalyst, Ru(II) or Rh(I)/H_2/MeOH, on one diastereoface of the molecule proximate to the directing group.

It should be noted that an *N*-tosylated analog of **1**[8] was found to be very reluctant to the hydrogenation under conditions employed.

Furthermore, the alkyl analogs of **1**, i.e. methyl (**8**), isopropyl (**9**), isobutyl (**10**), and *t*-butyl (**11**) instead of phenyl group in **1**, were prepared (see **Experimental**). However, these analogs were found, at the present time, to undergo hydrogenation under the comparable conditions with much inferior anti-selectivity (54—93%).

Experimental

General Comments. All boiling and melting points are uncorrected. ^1H and $^{13}C\{^1H\}$ NMR spectra were obtained on a JEOL FX-90Q spectrometer with Me_4Si as an internal standard in $CDCl_3$. IR spectra (mostly neat) were recorded on JASCO IRA-2 spectrophotometer.

Catalyst Precursors. $Ru(OCOCF_3)_2(PPh_3)_2$ (**2**)[7], [Rh(dppe)(cod)]$^+ClO_4^-$ (**3**)[9] (dppe=1,2-bis(diphenylphosphino)ethane, cod=1,5-cyclooctadiene), and [Rh(dppb)(cod)]$^+ClO_4^-$ (**5**)[9] (dppb=1,4-bis(diphenylphosphino)butane) were prepared according to the reported procedures, respectively. Complex **2** was prepared by the reaction of $RuCl_2(PPh_3)_3$ with $AgOCOCF_3$ in acetone.

Preparation of Methyl 2-[α-(Methoxycarbonylamino)benzyl]acrylate (1). Methyl benzylidenecarbamate[5] (7.23 g, 44 mmol) and DABCO (1.00 g, 9 mmol, 20 mol%) were dissolved in methyl acrylate (5 mL) and the mixture was stirred overnight at room temperature. Excess acrylate was removed by evaporation and crystalline materials remained were dissolved in $CHCl_3$ (150 mL). The $CHCl_3$ solution was washed with 3 M† HCl, aq $NaHCO_3$, and water to remove DABCO, and dried ($MgSO_4$). Solvent was removed and fairly clean product (80% yield) was recrystallized (hexane-$CHCl_3$) to give analytically pure **1**: Mp 120—121 °C; ^1H NMR (90 MHz) δ=3.67 and 3.70 (s, MeO×2), 5.67 (br. s, NH and CH-N), 5.91 (br. s, =CH), 6.37 (d, *J*=0.9 Hz, =CH), and 7.28 (br. s, Ph). IR (KBr) 1715 and 1690 cm^{-1}; Found: C, 62.49; H, 6.01; N, 5.53%. Calcd for $C_{13}H_{15}NO_4$: C, 62.64; H, 6.07; N, 5.62%.

Preparation of Methyl 2-[α-(Methoxycarbonylamino)alkyl]acrylates (8—11). In a typical reaction, methyl (1-ethoxyethyl)carbamate (2.50 g, 17 mmol), obtained from acetaldehyde diethyl acetal and methyl carbamate, and methyl 3-(dimethylamino)propionate (2.22 g, 17 mmol) were treated with 2 equiv. of lithium diisopropylamide (LDA) (40 mmol) in hexane-THF (1:2, 75 mL) at −78 °C for 15 min.[10] The whole mixture was allowed to warm up to 0 °C and stirred for additional 2 h. Usual workup and removal of the solvents afforded a precursor of the requisite acrylate.

The crude precursor (17 mmol) was treated overnight with excess MeI (90 mmol) in MeOH (5 mL) and the resulting ammonium salt was then treated with 1,8-diazabicyclo-[5.4.0]undec-7-ene (DBU) (20 mmol) in acetone (15 mL). Workup and distillation as usual gave methyl 2-[α-(methoxycarbonylamino)ethyl]acrylate (**8**) (1.40 g, 43% overall yield): Bp 82—84 °C/2 Torr††; ^1H NMR δ=1.35 (d, *J*=7 Hz, Me), 3.65 and 3.77 (s, MeO×2), 4.60 (m, CH), 5.10 (br. d, NH), 5.76 (s, =CH), and 6.17 (d, *J*=0.9 Hz, =CH); IR (neat) 1715 and 1695 cm^{-1}; Found: C, 51.39; H, 7.30; N, 7.31%. Calcd for $C_8H_{13}NO_4$: C, 51.33; H, 7.00; N, 7.48%.

In exactly the same manner as above, isopropyl (**9**), isobutyl (**10**), and *t*-butyl (**11**) analogs were prepared starting with respective acetals of *i*-PrCHO, *i*-BuCHO, and *t*-BuCHO. (**9**) (61% yield): Bp 98—100 °C/2 Torr; ^1H NMR δ=0.84 and 0.95 (d, *J*=6.6 Hz, 3H×2), 1.95 (m, 1H), 3.66 (s, 3H), 3.76 (s, 3H), 4.08 (t, *J*=9 Hz, 1H), 5.42 (br. d, 1H), 5.71 (br. s, 1H), and 6.22 (d, *J*=1.1 Hz, 1H); Found: CHN. (**10**) (74% yield): Bp 75—78 °C/2 Torr; ^1H NMR δ=0.94 and 0.96 (d, *J*=6.4 Hz, 3H×2), 1.54 (m, 3H), 3.65 (s, 3H), 3.76 (s, 3H), 4.50 (q, *J*=9 Hz, 1H), 5.33 (br. d, 1H), 5.75 (br. s, 1H), and 6.18 (d, *J*=1.1 Hz); Found: CHN. (**11**) (53% yield): Bp 112—113 °C/2 Torr; ^1H NMR δ=0.90 (s, 9H), 3.66 (s, 3H), 3.76 (s, 3H), 4.39 (d, *J*=10 Hz, 1H), 5.65 (br. s, 1H), 5.90 (br. d, 1H), and 6.28 (d, *J*=1.1 Hz, 1H); Found: CHN.

Hydrogenation Procedures. In a 50-mL micro autoclave containing a glass lining tube and a stirring magnetic bar, under an argon atmosphere, were placed a catalyst precursor (1×10^{-2} mmol) and the substrate **1** (1 mmol) dissolved in a given solvent (5 mL). The inert atmosphere was replaced with hydrogen, the initial pressure of hydrogen being adjusted to 5—30 atm in each run. The reaction mixture was stirred at room temperature for 15—48 h depending on the other reaction conditions. The mixture was then filtered

† 1 M=1 mol dm^{-3}.

†† 1 Torr=133.322 Pa.

through a short plug of silica gel to remove the catalyst complex and the filtrate was evaporated to leave an oil. Conversion of the reaction was determined by capillary GLC (HR-20M, 30 m×0.2 mm, at 200 °C). Purification of the product by column chromatography (silica gel, hexane–ether) afforded a major component (**4a**) from the diastereomeric mixtures. ^{1}H NMR δ=1.23 (d, J=7.0 Hz, Me), 2.93 (qd, J=7.0 and 5.9 Hz, CH), 3.58 and 3.65 (s, MeO×2), 4.84 (dd, J=9.4 and 5.9 Hz, CHN), 6.00 (br. d, J=9.4 Hz, NH), and 7.26 (br. s, Ph). The vicinal coupling of the minor component (**4b**), J=6.4 Hz. Data of hydrogenation of **1** were given in Table 1. Hydrogenation of alkyl analogs of **1** (**8**—**11**) was also carried out in essentially the same procedure as described above (in methanol). Antiselectivity in each analog was given in parentheses: **8** (93%), **9** (69%), **10** (54%), and **11** (77%).

Preparation of 3-Methyl-4-phenyl-2-azetidinone (7). Iodine (0.76 g, 3 mmol) and hexamethyldisilane (0.51 g, 3.5 mmol) were stirred at 70 °C for 30 min. To trimethylsilyl iodide thus formed was added **4** (obtained from Entry 10) (1 mmol) dissolved in MeCN (5 mL) and the mixture was heated under reflux for 4 h. All volatile materials but disilylated product were evacuated under 2 Torr, and the residue was treated through a short silica gel column with MeOH. The eluent was evaporated to leave crude β-amino acid, $PhCH(NH_2)CHMeCO_2H$. The latter was treated with 2-chloro-1-methylpyridinium iodide (0.28 g, 1.1 mmol) and Et_3N (0.3 mL, 2.2 mmol) in dry MeCN (100 mL) under reflux for 8 h.[11] After evaporation of the solvent, the residue was extracted with ether and the extracts were washed with water and dried ($MgSO_4$). The crude product was purified by column chromatography (silica gel, hexane–ether) to give **7** (86.6 mg, 54% overall yield). The ratio of cis/trans=1/70 was determined by capillary GLC (HR-20M, 30 m×0.2 mm at 200 °C): T_R(trans) 18 min, T_R(cis) 23 min.

In the same manner as above, a sample of **4** from Entry 13 was converted into **7**. In this case, the cis/trans ratio was 80/20, and the isomers were separated by column chromatography. NMR spectral data of *cis*- and *trans*-**7**[12] were given below. *cis*-**7**: ^{1}H NMR δ=0.82 (d, J=7.5 Hz, 3H), 3.58 (ddq, J=1.8, 5.5, and 7.5 Hz, 1H), 4.88 (d, J=5.5 Hz, 1H), 6.14 (br., 1H), and 7.13—7.48 (m, 5H). ^{13}C NMR (22.5 MHz) δ=10.1, 51.0, 55.2, 126.6, 127.9, 128.6, 137.6, and 173.8. *trans*-**7**: ^{1}H NMR δ=1.42 (d, J=7.5 Hz, 3H), 3.06 (dq, J=2.2 and 7.5 Hz, 1H), 3.61 (d, J=2.2 Hz, 1H), 6.20 (br., 1H), and 7.35 (br. s, 5H). ^{13}C NMR δ=13.0, 56.5, 59.3, 125.5, 128.0, 128.8, 140.3, and 171.7.

A Novel Chiral Stationary Phase for Optical Resolution of Amino Acids and Their Derivatives by Ligand-Exchange High-Performance Liquid Chromatography

Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113
†Research Center, Daicel Chemical Industries Ltd., Shinzaike, Aboshi-ku, Himeji, Hyogo 671-12
(Received July 28, 1987)

Synopsis. A novel chiral stationary phase, [(1*R*,2*S*)-2-hydroxy-1-methyl-2-phenylethylamino]acetic acid, was prepared from (−)-norephedrine, and its sodium salt was bound to silica gel pretreated with [3-(glycidyloxy)propyl]trimethoxysilane. The chiral stationary phase was found to be effective for the optical resolution of amino acids and their derivatives by ligand-exchange high-performance liquid chromatography using aq copper(II) sulfate solution as an eluent.

The chromatographic resolution of amino acids is achieved by ligand-exchange chromatography using copper(II) complexes of chiral stationary phases (CSPs). Gübitz and his co-workers developed practically useful packings for high-performance liquid chromatography (HPLC), in which copper(II) complexes of various amino acids are covalently bonded to silica gel pretreated with [3-(glycidyloxy)-propyl]trimethoxysilane.[1–5] Among these CSPs, L-hydroxyproline shows the best chiral recognition ability. Moreover, recently we developed and reported new CSPs consisting of optically active *erythro*- and *threo*-2-carboxymethylamino-1,2-diphenylethanol moieties.[6,7] These results indicate that hydroxyl group in the chiral amino acid moieties may play an important role for the chiral recognition and that optically active 2-aminoalkanols would be applicable as chiral moieties for CSPs.

On the basis of this consideration, we prepared a novel CSP, [(1*R*,2*S*)-2-hydroxy-1-methyl-2-phenylethylamino]acetic acid, from (−)-norephedrine and applied it for ligand-exchange HPLC.

Sodium [(1*R*,2*S*)-2-hydroxy-1-methyl-2-phenylethylamino]acetate (sodium salt of N-carboxymethylated norephedrine) (**2**) was easily prepared by ethoxycarbonylmethylation of (−)-norephedrine (**1**) with ethyl bromoacetate, followed by hydrolysis with aq NaOH solution. Without further purification, the sodium salt was allowed to react with silica gel pretreated with [3-(glycidyloxy)propyl]trimethoxysilane to give a new covalently-bonded CSP (**3**). The CSP was converted to copper(II) complex (**4**) by treatment with aq $CuSO_4$ solution. The silica gel, bonded with the CSP, was packed in a stainless steel column by the ascending slurry technique.

A number of amino acids and *N*-benzyloxycarbonylated (Z-) amino acids could be resolved on the copper(II) complex of this CSP by means of ligand-exchange HPLC using an aq copper(II) sulfate solution as a mobile phase. But, this CSP could not resolve amino acids such as alanine, leucine, methionine, phenylglycine, glutamine, glutamic acid, citrulline, and histidine. Typical chromatograms for the resolution of amino acids by HPLC are shown in Fig. 1, and the corresponding chromatographic parameters are given in the Table 1.

The CSPs, derived from *erythro*- and *threo*-2-amino-1,2-diphenylethanol, have quite different chiral recognition ability each other for amino acids and their derivatives, namely, amino acids and their derivatives resolved can be devided into two groups.[6,7] But, **4** could resolve amino acids and their derivatives of the two groups, although the scope of application and the α values obtained are smaller than those showed when *erythro*- and *threo*-2-amino-1,2-diphenylethanol moieties were used as CSPs.[6,7] This difference in the chiral recognition should result from the difference of the substituent at C2. In the case of *erythro*- and *threo*-2-amino-1,2-diphenylethanol, the

π–π interaction between the phenyl groups at C1 and C2 play an important role to fix the comformation of the copper(II) chelates. On the other hand, the chelate of **4**, in which the π–π interaction is absent, would be flexible. The flexibility would result in the samller α values for amino acids and their derivatives in the two groups.

Moreover, the CSP, derived from (*R*)-2-amino-2-phenylethanol showed no chiral recognition ability, indicating that the phenyl group at C1 plays also an important role for the chiral recognition.

Experimental

Materials. (−)-Norephedrine was purchased from Aldrich Chemical Company, silica gel, Develosil 100-5 from Nomura Chemical Co., [3-(glycidyloxy)propyl]trimethoxysilane from Shin-Etsu Chemical Co., amino acids from the Peptide Institute, and *N*-benzyloxycarbonylated amino acids from Sigma Chemical Company.

All solvents were of reagent grade.

Instruments. Melting point was measured by a Laboratory Devices MEL-TEMP apparatus and is uncorrected. IR spectra were recorded on a JASCO IR-810 spectrometer. ^{1}H NMR was recorded on a JOEL JNM-PMX60 at 60 MHz using TMS as an internal standard. A JASCO TRIROTAR-V, a Rheodyne 7125 injector, a JASCO UVIDEC-100-IV UV detector, and a NIHON CROMATO CDS 86 Ver. 2.7 data processor were used for HPLC. The column temperature was maintained at 35 °C by a JASCO TU-100 column oven.

Ethyl [(1*R*,2*S*)-2-Hydroxy-1-methyl-2-phenylethylamino]-acetate. To a solution of (−)-norephedrine (1.21 g, 8 mmol) in dichloromethane (10 ml) was added drop by drop a solution of ethyl bromoacetate (1.50 g, 9 mmol) in dichloromethane (10 ml) in a period of 30 min at room temperature. After stirring at the temperature for additional 2.5 h, triethylamine (1.2 ml, about 9 mmol) was added to the solution, and the reaction mixture was stirred for 2.5 h. Then, the solvent was evaporated, and benzene (ca. 100 ml) was added to the residue. The benzene solution was washed with water and sat. NaCl solution and dried with Na_2SO_4. After evaporation of the solvent under reduced pressure, crude product was purified by silica-gel chromatography

(eluent: hexane/ethyl acetate=1/1) to give ethyl [(1*R*,2*S*)-2-hydroxy-1-methyl-2-phenylethylamino]acetate in 78% yield. Glassy oil. $[\alpha]_D^{22.4}$ +2.4° (*c* 0.414, EtOH). IR (KBr): 3470, 1747, 1455, 1241, 1148, and 703 cm^{-1}. ^1H NMR ($CDCl_3$): 0.78 (d, 3H, *J*=7 Hz), 1.22 (t, 3H, *J*=7 Hz), 2.74 (m, 3H), 3.30 (s, 2H), 4.08 (q, 2H, *J*=7 Hz), 4.57 (d, 1H, *J*=4 Hz), and 7.23 (s, 5H).

Calcd for $C_{13}H_{19}NO_3$: C, 65.80; H, 8.07; N, 5.90%. Found: C, 65.43; H, 8.02; N, 5.94%.

Sodium [(1*R*,2*S*)-2-Hydroxy-1-methyl-2-phenylethylamino]-acetate (2). To a solution of ethyl [(1*R*,2*S*)-2-hydroxy-1-methyl-2-phenylethylamino]acetate (1.66 g, 7 mmol) was added 7.2 ml of 1 $mol \cdot dm^{-3}$ NaOH solution at room temperature, and the solution was stirred overnight at room temperature. Evaporation of the solvent gave 1.60 g of slightly yellow-colored solid mass. The mass was identified to be **2** by IR spectroscopy. IR (KBr): 3400, 1600, 1415, 1000, 760, 700 cm^{-1}.

Coating on Silica Gel. A suspension of silica gel (50 g), dried for 3 h at 120 °C, in dry benzene (500 ml) was refluxed, and the benzene (ca. 50 ml) was distilled off. Then, [3-(glycidyloxy)propyl]trimethoxysilane (25 ml) was added to the suspension. The suspension was refluxed for 8 h with removal of methanol formed from the mixture. After cooling, the benzene was removed by filtration, and the silica gel was thoroughly washed with dichloromethane. To a solution of **2** in methanol (20 ml) was added the silica gel (7.0 g), and the mixture was stirred for 6 d at 30 °C. The CSP-bonded silica gel was collected by filtration, washed with methanol, and poured into 1 w/v% $CuSO_4$ solution (150 ml). The copper(II)-loaded silica gel was collected by filtration and washed thoroughly with 2.5×10^{-4} $mol \cdot dm^{-3}$ $CuSO_4$ solution. Elemental analysis for the copper-loaded silica gel gave C, 6.00; H, 1.35; N, 0.32% (C, 4.20; H, 1.25% for the silanized silica gel).

Chromatography. The copper-loaded silica gel, suspended in 2.5×10^{-4} $mol \cdot dm^{-3}$ $CuSO_4$ solution, was packed in a stainless steel column (25×0.46 (i.d.) cm) by the slurry technique under the pressure of 250 $kg \cdot cm^{-2}$.

The chromatography was carried out at 35 °C at a flow-rate of 0.5 $ml \cdot min^{-1}$ using 2.5×10^{-4} $mol \cdot dm^{-3}$ $CuSO_4$ solution as a mobile phase. The dead volume of the column was estimated to be 3.00 cm^3 with water.

The *k'* values of unresolved amino acids were as follows; alanine (5.96), leucine (9.35), methionine (7.95), phenylglycine (8.77), glutamine (10.53), glutamic acid (9.68), citrulline (6.10), and histidine (13.67).

Cobalt-Catalyzed Hydrohydroxymethylation of Formaldehyde: Effect of $Ru_3(CO)_{12}$ and Phenol

Kazuhisa MURATA,* Akio MATSUDA, and Takashi MASUDA
National Chemical Laboratory for Industry, Yatabe, Tsukuba, Ibaraki 305
(Received July 1, 1987)

Synopsis. A catalyst system, containing $Co_2(CO)_8$, $Ru_3(CO)_{12}$, and phenol, was found to be effective for the hydrohydroxymethylation of formaldehyde to give ethylene glycol with the yield of ca.65%, better than those previously reported.

The hydrohydroxymethylation, by which ethylene glycol(EG) is produced directly from formaldehyde, is receiving increasingly wider attention as an attractive route to C_2 compounds.[1] So far, stoichiometric,[2] and catalytic[3] hydroformylation of formaldehyde to glycolaldehyde(GLA) has been achieved by using cobalt and rhodium catalysts with reasonable selectivity. However, these require a successive hydrogenation of GLA to obtain EG. Recently, the hydrohydroxymethylation of CH_2O has been reported with moderate EG yield(ca. 25%) using rhodium-cobalt system.[4]

In the course of our study on a syngas conversion to EG, where cobalt catalyst is employed under high pressure, we have found that the addition of $Ru_3(CO)_{12}$ is effective for enhancing the glycol productivity,[5] in addition to the effectiveness of phenol as solvent.[6] In this study, the effects of addition of $Ru_3(CO)_{12}$ and phenol on the cobalt-catalyzed hydrohydroxymethylation of CH_2O will be described.

Results and Discussion

In the preliminary stage of our study, we examined the behavior of cobalt catalyst under the conditions of 200 atm at 180 °C. The results are given in Table 1. Ethylene glycol was produced in ca. 20% yield after the reaction in dioxane solvent for 7 h, where 37% formaldehyde aqueous solution was used as formaldehyde source (Run 1): Methanol (9%) was obtained as by-product and small amounts of ethanol (1.5%) and methyl cellosolve (18%) were detected. The addition of phosphine (1,2-bis(diphenylphosphino)-ethane (dpe), P/Co=0.5(molar ratio)) caused the EG yield to be slightly enhanced (Run 2). Paraformaldehyde was less favorable than CH_2O (aq.) (Run 3), but

a) Conditions: $Co_2(CO)_8$ 2 mmol, solvent 50 ml, CH_2O(aq.) 5 mmol, 180 °C, 200atm(H_2/CO=1). b) $Ph_2P(CH_2)_2PPh_2$. c) Based on CH_2O initially added(50 mmol). d) Paraformaldehyde(50 mmol). e) Paraformaldehyde(50 mmol)/H_2O(60 mmol). f) EG+$EtOCH_2CH_2OH$. g) EG+*i*-$PrOCH_2CH_2OH$. h) EG+$AcOCH_2CH_2OH$+$AcOCH_2CH_2OAc$. i) Two-stage reaction: 60 °C, 6 h→190 °C, 2.5 h. j) EG+$HOCH_2CHO$. k) EG+$AcOCH_2CH_2OH$. l) EG+$HCOOCH_2CH_2OH$. m) EG+$PhCOOCH_2CH_2OH$.

the addition of H_2O, in this case, raised the EG yield(Run 4). By use of alcohol solvents, alkyl cellosolves[7] were produced in high yields with a small amount of EG (Runs 5,6). In case of acetic acid solvent, ethylene glycol and its acetate esters were formed in ca. 28% yield, but a partial decomposition of $Co_2(CO)_8$ occurred (Run 7).

When organic acids were used as additives but not solvent, the enhancement of the EG yield was also observed (Table 1, Runs 9—14). The yield decreased by the addition of excess acid (Run 14). Also the yield was influenced by total pressure and temperature: the yield increased with the increases in pressure up to 200 atm (Fig. 1,● and in temperature to 180 °C (Fig. 2,●), whereas methanol formation decreased with the increase in pressure (Fig. 1,▲) and increased with the increase in temperature (Fig. 2,▲).

We have found the Co-Ru system, which is active for syngas conversion to EG;[5] so, effect of ruthenium was examined using cobalt-phenol system, the results of which are given in Table 2. The EG yield as well as MeOH increased with the increase in Ru concentration: EG and MeOH accounts for up to ca. 88% of products (Runs 4,5). Other metal carbonyls such as $Re_2(CO)_{10}$, $Mo(CO)_6$, $Fe(CO)_5$, and $Cr(CO)_6$ were unfavorable.

Figure 2 (○) shows the effect of reaction temperature. The maximum EG yield of ca. 65%, which is the highest value of those previously reported,[1a] was achieved at 180 °C: The yield of MeOH increased with the increase in temperature. As shown in Fig. 1, the pressure effect of Co-Ru-PhOH system was analogous to that of Co-AcOH system: The EG yield increased with the increase in pressure up to 500 atm (○). The effect of H_2 pressure was similar to that of total pressure (Fig. 3) and the EG yield was little affected by CO pressure (Fig. 3,●).

4	0.20	55.9(60.8)	25.5(27.7)
5	0.233	56.8(60.4)	26.1(27.8)

a) Conditions: $Co_2(CO)_8$ 2.5 mmol, CH_2O(aq.) 40 mmol, PhOH 106 mmol, Toluene 12 ml, 500 atm(H_2/CO=9), 140 °C, 2 h. b) See footnote (c) of Table 1. c) Selectivity=Product(mol)×100/Converted CH_2O(mol).

In the absence of organic acid and ruthenium, the EG yield was ca. 20% (Table 1, Runs 1,2). The low EG yield might be that the aldol condensation of CH_2O and/or GLA takes place to form higher molecular weight by-products.[3] Glycolaldehyde was produced in ca. 70% yield[2] after the hydroformylation of CH_2O at 60 °C for 6 h: When the resulting solution was further treated at 190 °C for 2.5 h, the EG formed was ca. 43% (Table 1, Run 8), indicating that the condensation as well as hydrogenation of GLA could occur. Therefore, in order to increase the yield of EG formed by one-batch process at 180 °C, it seems to be important that the hydrohydroxymethylation of CH_2O predominates over the condensation at temperature as high as 180 °C.

Considering the schemes of syngas conversion[6-8] and of Rh-catalyzed hydroformylation of CH_2O,[3] this cobalt-catalyzed reaction may be assumed to proceed by the Scheme 1, in which hydroxymethylcobalt complex a,[9] the formation of which might be prompted by phenol,[10,11,12] (steps I—III), is involved as a key intermediate: The complex a thus formed undergoes CO insertion(IV) and subsequent hydrogenation(V) to give GLA, which is reduced to EG(VI) by catalysis of cobalt and/or ruthenium. MeOH could be produced via hydrogenolysis of methoxycobalt complex b(VIII) as well as of the complex a(IX).

An acceleration of MeOH formation as well as EG formation was observed in the presence of Ru (Table 2). So, ruthenium, at least, appears to be responsible for the reduction of GLA and/or CH_2O.[13] The Halcon Group suggested that Ru-phosphine complex could be a catalyst effective for the reduction of GLA to EG.[14] In hydrocarbonylation of MeOH to EtOH, it

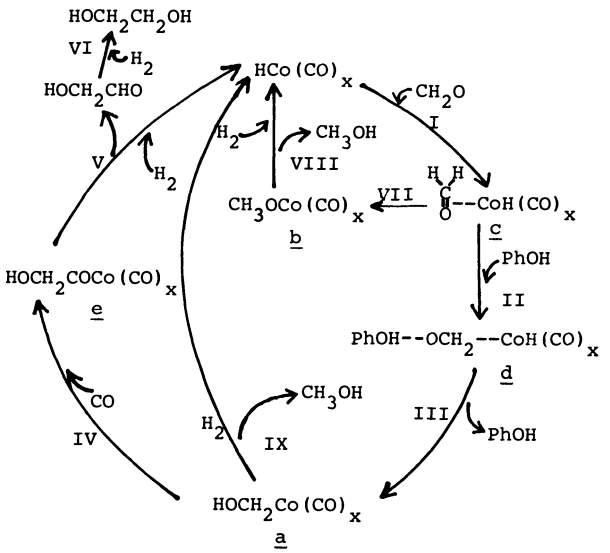
$Co_2(CO)_8$ 2.5 mmol, $Ru_3(CO)_{12}$ 0.167 mmol, PhOH 106 mmol, CH_2O(aq) 40 mmol, toluene 12 ml, Pco=100 at, 180 °C, 2 h. ●▲ Pco=75 atm.



Scheme 1.

has been reported that hydrogenation of CH_3CHO occurs readily by Ru catalysis.[15]

The hydroformylation of CH_2O occurs even at 60 °C (Table 1, Run 8) and also the hydrohydroxymethylation activity is little affected by CO pressure (Fig. 3,●), indicating that CO insertion step(IV) is rapid under the conditions employed. Therefore, it is probable that the EG formation could be accelerated by an increased hydrogen pressure (Fig. 3).

Experimental

Materials. $Ru_3(CO)_{12}$, solvents, and organic acids were obtained commercially and used with no further purification. $Co_2(CO)_8$ was prepared according to an usual procedure. Aqueous 37% formaldehyde solution and paraformaldehyde were commercial products.

Reaction Procedure. A typical experiment can be described as follows: A catalyst solution containing $Co_2(CO)_8$, $Ru_3(CO)_{12}$, PhOH, and CH_2O(aq) in solvent (50 ml) was placed in a stainless steel autoclave (100 ml), which was subsequently charged with syngas (H_2/CO=4). When the system was heated to a desired temperature, the total pressure was adjusted to a desired pressure by introducing more syngas mixture. After the reaction, the vessel was cooled to room temperature and the solution was analyzed by GLC.

The two-stage reaction was carried out, first at 60 °C for 6 h to produce glycolaldehyde, then by increasing the temperature to 190 °C for another period of 2.5 h giving EG.

Development and Applications for the Simulater of Intermolecular Potentials. II.† Hydration Effects on the Conformation of Tyramine

Tatsuya TAKAGI,* Akito TANAKA, Mika TANI, Hironobu MAEZAKI, Hideaki FUJIWARA, and Yoshio SASAKI
Faculty of Pharmaceutical Sciences, Osaka University, 1-6 Yamada-Oka, Suita, Osaka 565
(Received May 22, 1987)

Conformational energy maps of the tyramine monocation and its hydrated species were calculated using the SIMP system. The populations of the trans conformer were calculated to be 18% and 53% for the isolated monocation and the hydrated one respectively. The computational results was supported by the results of conformational analysis based on ^{1}H NMR spectroscopy.

Recently, the conformations of compounds which possess physiological activity have been studied widely in order to estimate the structural requirements for the active compounds and to reveal the chemical environments around the active sites of receptors.[2,3] For example, Pullman et al.[2] reported PCILO calculations in connection with conformational studies of the derivatives of phenethylamine, which is a basic skeleton of biological and medicinal interest. They concluded that the phenethylamines exist as a mixture of two nearly equally populated conformers in vacuo. Chuman[3] also reported, from a computational analysis of molecular mechanics, that the active form of enkephaline was similar to that proposed by Hudson et al.[4] However, these analyses have a common defect that the compounds are treated in vacuo and not in solution. Indeed, Chuman's active conformer of enkephaline was calculated to be located 25 kcal mol^{-1} above the global minimum. He claimed that such an energy difference was understandable if the computational accuracy, the conformational change by an induced fitting, and the differences in surroundings were considered (the virtual molecules for these calculations are in vacuo, whereas practical molecules are dissolved in solution). To overcome this defect, Pullman et al.[5] attempted conformational analyses of some hydrated models, which resemble actual states more closely in surroundings than do the molecules in vacuo, using the semiempirical PCILO and ab initio MO methods. Nevertheless, the PCILO method was not accurate enough with respect to the interaction energy, and the CPU time was not sufficient for a full ab initio MO calculation.

In a previous report,[1] we ourselves have developed the SIMP (Simulater of Intermolecular Potentials) system for the calculation of intermolecular interactions with sufficient accuracy and within a reasonably short CPU time. In the present study, we have estimated the preferred conformations of hydrated tyramine by this method and have compared them with those from NMR measurements. Tyramine has the ability to displace noradrenaline from a cytoplasmic mobile pool in adrenergic nerve terminals, leading to sympathomimetic effects. A similar displacement can also occur from granular storage sites. Since the structural specificity of this displacement is quite distinct[6] from that reported for the α-and β-receptors,[7] the preferred conformations of tyramine in an aqueous solution have attracted much attention.

We also explored the applicability of SIMP to the estimation of solvent effects on the conformational energies of this molecule.

Experimental

D_2O, $CDCl_3$, and CD_2Cl_2 (Uvasol reagents from E. Merck) were used as received. Tyramine (a special grade reagent) was used without any special purification. The saturated solutions of tyramine in the above solvents were used for the NMR measurements. The ^{1}H NMR spectra were observed with a HITACHI R-900M FT NMR spectrometer operating at 90 MHz and at 35 °C using 16k data points. Satisfactory signal-to-noise ratios were obtained after the accumulation of 128 transients for the D_2O solution, 5036 transients for the $CDCl_3$ solution, and 1024 transients for the CD_2Cl_2 solution. Programs for the SIMP and MNDO MO[8] calculations were the same as those in previous reports.[1,9] The MOPAC program system,[10] as updated by us for the SIMP calculations, was also used. The ^{1}H NMR spectra were analyzed by the use of the LAOCN5 program.[11] The numerical computations were done with the NEAC S1000 plus SX-1 system at the Computation Center Osaka University, with the M-780 plus VP-200 system at the Data Processing Center Kyoto University, and with the M680H plus S810/10 system at the Computer Center of the Institute for Molecular Science.

Results and Discussion

Since tyramine is known to take a monocation form in the neighbourhood of pH7, we have made computations with the monocation form. The structural parameters used for the MNDO MO calculations were taken from the X-ray crystallographic structures,[12] except for those relating to the hydrogen atoms. The distance of O-H, the angle of C-C-H, etc. were optimized using the MNDO MO method. The numbering of atoms in the tyramine monocation and the structural parameters are shown in Fig. 1 and Table 1 respectively. Tyramine has three flexible dihedral angles, as is defined in Fig. 1. Since the dihedral angles of θ_1 and

θ_2 are considered to be more significant than that of θ_3 with respect to the overall molecular shape, we varied θ_1 and θ_2 for the computation of the conformational energy maps, while θ_3 was optimized in order to minimize the conformational energy for each set of θ_1 and θ_2 values. The other structural parameters were kept unchanged from the monomer values throughout the computations. Here, we will define the two regions of the conformations of tyramine. One is a gauche region which is defined by θ_2 being equal to 0°—120° or 240°—360°. The other is a trans region defined by θ_2=120°—240°, which is considered to be a structure similar to that of noradrenaline in an aqueous solution.[13]

The conformational energy map for the tyramine monocation obtained is shown in Fig. 2. Although the 'bulk repulsive concept,'[14] which is the basis of organic stereochemistry, would lead to a trans conformer as the preferred one, this map shows that the gauche conformer is more preferable than the trans one. In fact, the most stable values of θ_1 and θ_2 were calculated to be in a gauche region (75° and 57° respectively), though the conformational energy for the most stable conformation in the trans region was higher than the global minimum by only 3.9 kJ mol^{-1}. This profile is qualitatively consistent with that of the conformational energy map obtained by Pullman et al.[2] We have previously reported[15] that alkyl/aryl interac-

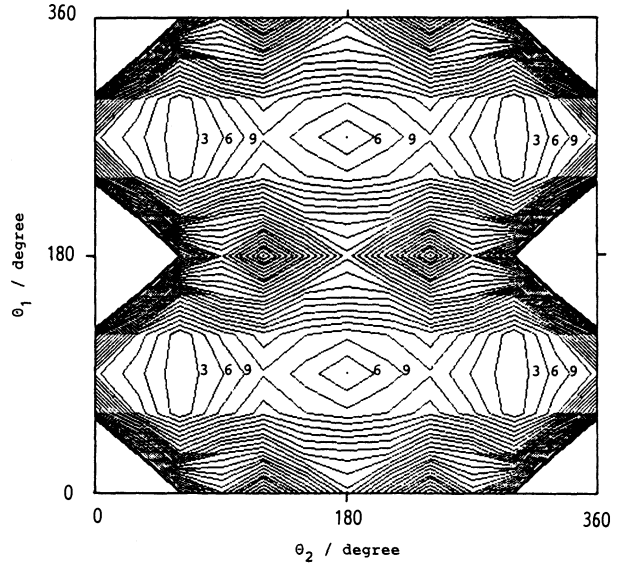

Fig. 2. The conformational energy map of tyramine monocation (kJ mol^{-1} with respect to the global minimum).

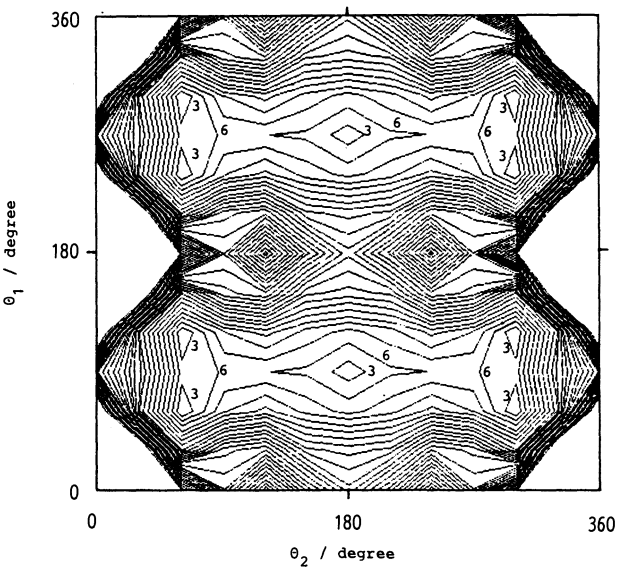

Fig. 3. The conformational energy map of hydrated tyramine monocation (kJ mol^{-1} with respect to the global minimum).

tions, called CH/π interactions by Nishio et al.,[16] can dominate the conformation of molecules, leading to a gauche conformer with respect to the alkyl and aryl groups. We have also reported, on the basis of the results of the energy decomposition analysis proposed by Kitaura et al.,[17] that the CH/π intramolecular interactions resemble the weak hydrogen bondings, as exemplified by the OH/π interactions. Since the most strong intramolecular interaction for the tyramine monocation in nature is an NH/π interaction, which is thought to be much stronger than the CH/π interaction, the preference of the gauche conformer may be reasonable.

In order to explore the hydration effects on the conformational energy map, four H_2O molecules were placed around the two polar sites of OH and NH_3. The angle of θ_3 and the distances between the polar sites and the H_2O molecules were optimized. The resulting conformational energy map of hydrated tyramine is shown in Fig. 3. Although the total profile of the energy map for the hydrated system was similar to that for the isolated system, the difference in energies was sufficiently large to change the population of each conformer. The difference in energies of the most stable conformations in the gauche and trans regions was calculated to be 2.4 kJ mol^{-1}, about half of that for the isolated system calculated above. In addition, the conformational energy increases around the regions of the global minimum more abruptly for the hydrated system than for the isolated system. In order to compare the population of trans and gauche conformers in detail, the populations were calculated by defining the trans conformer as θ_2=120°—240°, and the gauche one, as θ_2=0°—120° and θ_2=240°—360°. Under these conditions, the following equations hold:

$$P_t = \frac{1}{P_0} \int_{\frac{2}{3}\pi}^{\frac{4}{3}\pi} \int_0^{2\pi} \exp\{-\Delta E(\theta_1, \theta_2)/RT\} \, d\theta_1 \, d\theta_2 \quad (1)$$

$$P_g = 1 - P_t \quad (2)$$

$$P_0 = \int_0^{2\pi} \int_0^{2\pi} \exp\{-\Delta E(\theta_1, \theta_2)/RT\} \, d\theta_1 \, d\theta_2 \quad (3)$$

where P_t is the population of the trans conformer and P_g is that of the gauche conformer. The double integrations and the necessary interpolation of ΔE (θ_1, θ_2) were carried out using spline functions. The resultant populations at 35 °C are shown in Table 2. From these results, the trans conformer of tyramine is estimated to be more preferable in an aqueous solution than in vacuo. The reason for this populational change should be as follows: the NH/π interactions, which are considered to be the main origin of the preference of the gauche conformer, are replaced by the stronger interactions of the NH/H_2O interactions.

In order to confirm these computational results, we have analyzed the ^{1}H NMR spectra of tyramine in an aqueous solution as well as in several organic solvents. Examples of the calculated and observed NMR spectra of tyramine are shown in Fig. 4. The shift values and the vicinal coupling constants obtained using the LAOCN5 program are listed in Table 3. The rms errors between the observed and calculated coupling constants for tyramine in H_2O, CD_2Cl_2, and $CDCl_3$ are 0.11, 0.14, and 0.11 Hz respectively. As is shown in Fig. 5, the observed coupling constants, J_{AB} and $J_{AB'}$, may be represented by the following equations:

$$J_{AB} = P_t J_t + P_g J_g + \varepsilon \quad (4)$$

$$J_{AB'} = P_t J_g + \frac{1}{2} P_g (J_g + J_t) + \varepsilon' \quad (5)$$

$$P_t + P_g = 1 \quad (6)$$

where J_g and J_t are the ideal coupling constants for the gauche conformer and the trans conformer respectively, and where ε and ε' are the error terms. The values of J_g and J_t were assumed to be 2.0 and 13.0 Hz

Table 2. Rotamer Populations of Tyramine at 35 °C as Calculated by SIMP

System	Trans/%	Gauche/%
Isolated	18	82
Hydrated	53	47

Table 3. ^{1}H NMR Parameters for the AA'BB' Part of Tyramine

Solvent	$\nu_A - \nu_B$/Hz	J_{AB}/Hz	$J_{AB'}$/Hz
CD_2Cl_2	21.12	6.70	6.68
$CDCl_3$	22.61	6.80	6.53
D_2O	23.40	9.17	2.84

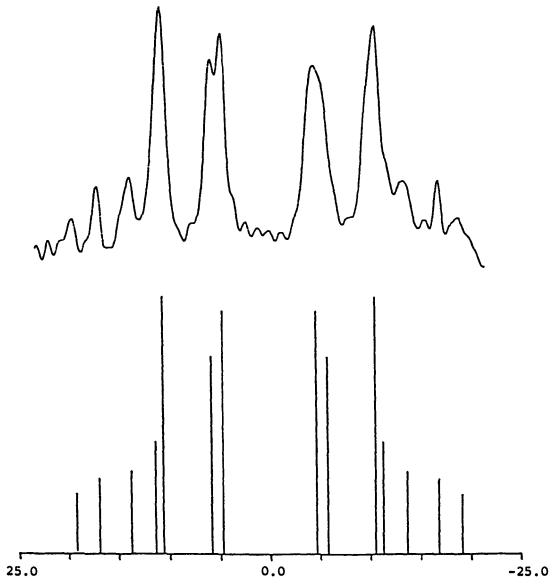

Fig. 4. The observed (upper) and the calculated (lower) NMR spectra of tyramine in CD_2Cl_2. The AA'BB' part from the alkyl side chain is shown. Lines at the higher field side are broadened by the small couplings with the aromatic protons.

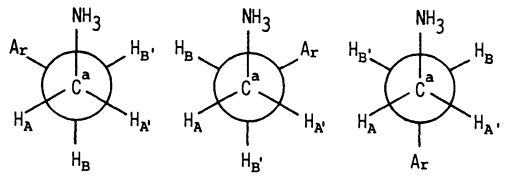

Fig. 5. Three possible conformations relating to the dihedral angle of θ_2.

Table 4. Rotamer Populations of Tyramine in Various Solvents

Solvent	Trans/%	Gauche/%
CD_2Cl_2	37	63
$CDCl_3$	38	62
D_2O	69	31

respectively, these values were cited from the literature.[18] When the value of $\varepsilon^2+\varepsilon'^2$ was minimized, P_t and P_g are determined experimentally as follows:

$$P_t = \frac{4J_{AB} - 2J_{AB'} + J_t - 3J_g}{5(J_t - J_g)} \quad (7)$$

$$P_g = 1 - P_t \quad (8)$$

Note from the definition (Fig. 5) that J_{AB} is larger than $J_{AB'}$ in Eq. 7. The resulting populations are listed in Table 4, which indicates that the trans conformer is preferable in D_2O, this is in agreement with the above SIMP calculations. In this way, our SIMP system is expected to offer a powerful method for determining hydration effects on the conformations of biologically significant molecules.

In Table 4, populations are also determined experimentally in CD_2Cl_2 and $CDCl_3$. The preference for the gauche conformer, which is indicated by the calculation for the isolated system in Table 2, is supported by the experiments.

The authors wish to thank the Institute of Molecular Science for allotting them CPU time on the HITAC M-680H plus S810/10 computer system. This investigation was supported as one of the Special Projects for Program Development at the Computation Center Osaka University using the NEAC S-1000 plus SX-1 computer system.

Relationship between Solubility and Micellization of Surfactants; Micelle Temperature Range (MTR) Instead of Krafft Point

Yoshikiyo Moroi* and Ryohei Matuura
Department of Chemistry, Faculty of Science, Kyushu University, Higashi-ku, Fukuoka 812
(Received June 5, 1987)

In order to clarify the relation between the solubility and micellization of surfactants, the micellar temperature range (MTR) is proposed instead of the usually used Krafft point. The physicochemical meaning of cmc defined by Phillips was examined from a mathematical point of view. As a result, it became clear that the temperature range for MTR is based on the concentration range for cmc, which in turn results from the polydispersity of micelles. The mass-action model of multiple association can be used to explain these facts. The MTR, thus determined by solubility and by cmc, was found to be able to explain a leveling of the MTR for homologous surfactants with an increase of the alkyl chain length and its increase of sodium dodecyl sulfate with increasing concentration of added sodium chloride.

In a previous paper,[1] the authors discussed the dissolution, micellization of surfactants, and solubilization in their aqueous solution from the viewpoint of degrees of freedom based on the phase rule and reached the conclusion that the mass action model for micelle formation can perfectly elucidate the above phenomena of surfactant solutions. It was also found from a series of studies on anionic surfactants with divalent cationic gegenions[2-5] that the Krafft point is not a single point but is a diffuse temperature range which might be called the micelle temperature range (MTR) or the Krafft range.[3] That is, the MTR is a narrow temperature range over which the surfactant solubility as monomer becomes sufficiently high for monomers to start micellization notably; it is consistent with the mass-action model of micelle formation.

Up to now, two concepts have been reported concerning the Krafft point: one is a phase transition at the Krafft point and the other is a solubility increase up to the cmc for micellization at the Krafft point. Recent examples of the former concept are a melting point model of hydrated surfactant solid,[6,7] and the phase transition from a stable coagel to a composite state of gel and micelles.[8] As for the latter, the most direct approach to the Krafft point absolutely rests on the solubility and cmc measurements of surfactants with temperature, as was often pointed out in our preceding papers. From the measurements, the concept of the Krafft point can be made clear.

The authors have studied the effects of both the alkyl chain length of a surfactant ion[3] and the extent of charge separation of divalent genenion on dissolution and micelle formation[5] of surfactants and have concluded that the Krafft point should be replaced by the new term "MTR" of surfactants, which is physicochemically correct. In this study, the technical terms and concepts which had been presented in order to relate the dissolution of surfactants with their micellization are reviewed. Also, it is confirmed that the term "MTR" can be used to successfully elucidate various phenomena concerning the dissolution and micellization of surfactants, not only from a view point of the phase rule but also experimentally.

Progress of Concepts of the Krafft Point

Since 1895, Krafft and Wiglow[9] have worked with soap solutions and have used the term "Ausscheidungstemperatur" which means the temperature at which a new phase separates from the soap solutions upon cooling, colloid chemists have studied the problem with deep concern. Above all, McBain and Elford[10] have studied the potassium oleate-water system and drew a phase diagram in which the minimum temperature at which heterogeneous systems just turned into a homogeneous isotropic liquid was recorded. Also, Lawrence[11] in 1935 called this transition temperature the "Krafft point" for the first time and showed that the Krafft point represents a phase change of the adhesion between hydrocarbon chains throughout the micelle (from solid to liquid). Shinoda and Hutchinson[6]

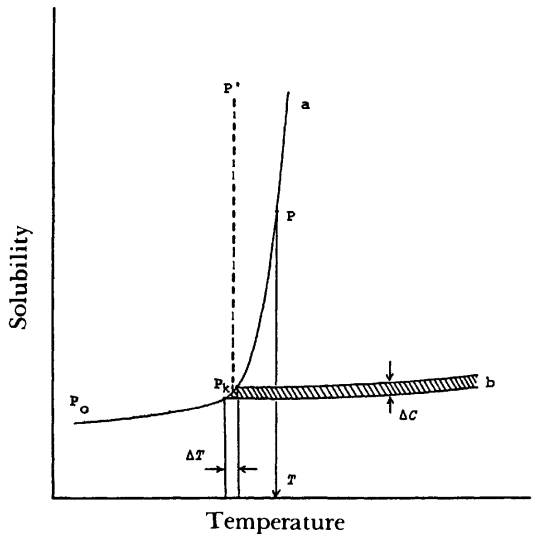

Fig. 1. Changes of solubility and cmc with temperature: (a) solubility curve, (b), cmc curve, ΔC narrow concentration range of cmc, ΔT narrow temperature range of MTR, $P_o \rightarrow P_k \rightarrow P'$ solubility for phase separation model.

presented an interpretation that the Krafft point represented a freezing of micelles or the melting point of a hydrated solid of surfactants; they said "the Krafft point now can be interpreted as a point at which solid hydrated agent and micelles are in equilibrium with monomers: in terms of phase, with two components the equilibrium hydrated solid⇄monomers⇄micelles is univariant, so that at given pressure the point is fixed."

On the other hand, in 1951 Eggenberger and Harwood[12] performed conductometric studies on the solubility and micelle formation of dodecylammonium chloride and found a point on the solubility curve corresponding to a very sharp break in the solubility vs. temperature curve which could be attributed to the "Krafft effect" or a solubilization of the undissociated molecule by the micelle. Significantly, the cmc vs. temperature curve intersected the precipitation curve at this point. Thereafter, a view of the Krafft point seemed to have been established as described in a paper by Phillips,[13] in which the Krafft point was defined as the temperature at which the cmc is equal to the saturation solubility. Alexander and Johnson[14] interpreted the "Krafft phenomenon" as an unusual property in that the solubility of soaps increased enormously over a small temperature range (Krafft point). Other technical terms, "critical solution temperature (cst)[15]" and "critical micellar temperature (cmt),[16]" appeared to designate this characteristic phenomenon.

As mentioned in the above review, the concept of the Krafft point can be divided into two different aspects: a phase transition of solid surfactant and a solubility increase up to cmc for micellization. Then, the Krafft point becomes a definite temperature, a point, for the former concept and a small temperature range for the latter. The existence of two different views concerning the same phenomenon is quite confusing. Therefore, it is very necessary to solve the present conflict.

Physicochemical Meaning of Critical Micelle Concentration (cmc)

The striking characteristic of a surfactant solution is the fact that monomeric surfactant molecules aggregate to form micelles above a certain concentration, leading to an abrupt change in such solution properties as the surface tension, osmotic pressure, intensity of scattered light, electrical conductivity, and so on. The narrow concentration range for these changes is called the critical micelle concentration.[17,18] There have been reported a number of methods for determining the cmc, all of which, of course, depend on abrupt changes in the concentration dependence of several properties of surfactant solutions. Taking the changes into consideration, Phillips defined the cmc as being the concentration corresponding to the maximum change in the gradient in the property-concentration (ϕ–C_t) curve:[13]

$$\left(\frac{d^3\phi}{dC_t^3}\right)_{C_t=cmc} = 0 \quad (1)$$

where

$$\phi = \alpha[S] + \beta[M] \quad (2)$$

α and β are proportionality constants, and [S] and [M] are the concentrations of the monomeric surfactant and the micelle, respectively. In reality, however, the property of a solution can not be expressed so simply as in Eq. 2, although Eq. 1 is correct.

Suppose that a surfactant molecule ($G_{\nu_g}S_{\nu_s}$) is composed of ν_g counterions (G) with charge z_g and ν_s surfactant ions (S) with charge z_s. For the electrical neutrality condition to be satisfied,

$$z_g\nu_g + z_s\nu_s = 0 \quad (3)$$

As is well-known, micelles are not monodisperse but polydisperse; thus, the following equilibria between counterions and surfactant ions can be given for micellization:

$$\begin{aligned} m_1G + n_1S &\overset{K_1}{\rightleftharpoons} M_1 \\ m_2G + n_2S &\overset{K_2}{\rightleftharpoons} M_2 \\ &\cdots\cdots\cdots\cdots \\ m_iG + n_iS &\overset{K_i}{\rightleftharpoons} M_i \end{aligned} \quad (4)$$

Also, the electroneutrality of a solution holds:

$$z_g[G] + z_s[S] + \sum_i (z_g m_i + z_s n_i)[M_i] = 0 \quad (5)$$

where the brackets refer to the concentration of chemical species. From Eq. 4 the micellization constant can be written as

$$K_i = [M_i]/([G]^{m_i}[S]^{n_i}) \quad (6)$$

It is important at present to examine the number of degrees of freedom using Gibbs' phase rule ($f = C-P+2-r$) for the succeeding discussion. The total number of components (C) is $i+3$ (solvent, G, S, M_1, M_2, $\cdots$ M_i), the number of phases (P) is one (surfactant solution), and the number of equilibrium equations (r) is $i+1$ (Eqs. 5 and 6). Therefore, the degrees of freedom becomes three, and the total surfactant concentration (C_t) determines the concentrations of every chemical species at constant temperature and pressure. The mass balance for the counterion and surfactant ion can be expressed, respectively, as

$$\nu_g C_t = [G] + \sum_i m_i[M_i] \quad (7)$$

$$\nu_s C_t = [S] + \sum_i n_i[M_i] \quad (8)$$

From an analogy with Eq. 2 the solution property (ϕ) becomes a composite of the contributions from every chemical species:

$$\phi = \alpha_1[S] + \alpha_2[G] + \sum_i \beta_i[M_i] \quad (9)$$

where α_1, α_2, and β_i are the contribution factors of each chemical species. Their magnitudes depend on the solution properties used for a cmc determination. The solvent contribution is omitted here, since the surfac-

tant concentration is relatively small and the solution property without a solvent contribution is usually employed. Equations 8 and 9 can be rewritten in terms of the concentrations of the monomeric surfactant ion and counterion with the help of Eq. 6;

$$\nu_s C_t = [S] + \sum_i n_i K_i [G]^{m_i} [S]^{n_i} \quad (10)$$

$$\phi = \alpha_1 [S] + \alpha_2 [G] + \sum_i \beta_i K_i [G]^{m_i} [S]^{n_i} \quad (11)$$

From Eqs. 6, 7, 8, and 10, C_t and ϕ turn out to be functions of common variable [S] or [G]. The next step for a cmc determination is to obtain a solution of Eq. 1, in which the derivative of ϕ with respect to C_t can be calculated through a common variable [S]. Then, cmc (C_t) can be automatically determined from the [S] value thus determined. What must be stressed here is that the cmc value determined as a solution of Eq. 1 is a function of the contribution factors: α_1, α_2, and β_i. In other words, cmc depends on the solution property employed for a cmc determination and is naturally different, depending on a method used. Therefore, the cmc turns out to have a value with a narrow concentration range. As a matter of fact, the cmc values obtained from the solution properties mainly due to a monomeric surfactant contribution are less than those due to a surfactant micelle contribution,[17,18,19] as can be seen in Figs. 2a and 2b. In this case random errors are taken into account for the cmc determination methods. For example, the cmc from the surface tension is less than that from turbidity.[20] Contrary to the above expectation, however, the cmc has often come to be presented as a definite concentration,[21,22] especially after the appearance of a phase-separation model for micellization.[6] It is pertinent to

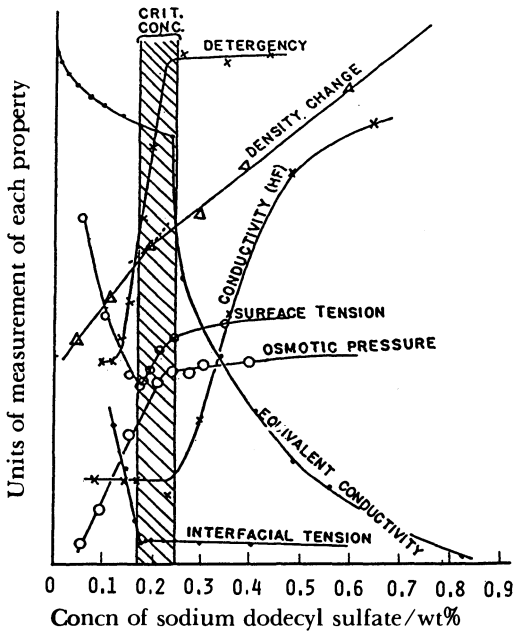

Fig. 2a. Physical property curves for sodium dodecylsulfate. Temperature=25—38°C.[17]

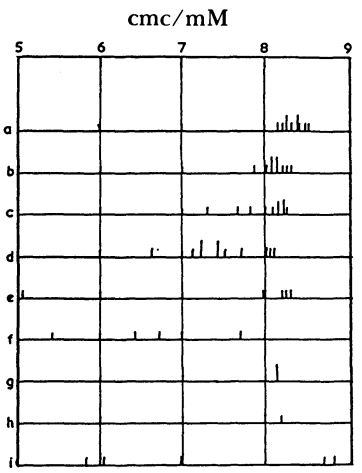

Fig. 2b. Variation of cmc of sodium dodecyl sulfate at temperature between 20 and 30°C by various experimental methods.[19] a) Specific conductivity, b) equivalent conductivity, c) other conductance, d) surface tension vs. logarithm of concentration, e) other relationships between surface tension and concentration, f) absorbance, g) solubilization of OT dye, h) light scattering, i) other methods such as refractive index, emf, vapor pressure, sound velocity, and viscosity.

demonstrate in this paper, therefore, the fact that the cmc can vary for a narrow concentration range in terms of the above discussion.

Monodisperse Micelle of Nonionic Surfactant. The most simplified example is monodisperse micelle of a nonionic surfactant, in which $\nu_g=0$, $z_s=0$, and $n_i=n$. Then, Eqs. 10 and 11 become, respectively,

$$C_t = [S] + nK_n[S]^n \quad (12)$$

and

$$\phi = \alpha[S] + \beta K_n [S]^n. \quad (13)$$

The third derivative of ϕ with respect to C_t becomes

$$\frac{d^3\phi}{dC_t^3} = (\beta - \alpha n)\, n(n-1) K_n [S]^{n-3} \times \{(n-2)(1+n^2 K_n [S]^{n-1}) - 3n^2(n-1)K_n[S]^{n-1}\} / (1+n^2 K_n [S]^{n-1})^5. \quad (14)$$

The solution of $d^3\phi/dC_t^3=0$ gives

$$[S] = \left\{\frac{n-2}{(2n^3-n^2)K_n}\right\}^{1/(n-1)} \quad (15)$$

and

$$C_t = \left\{\frac{n-2}{(2n^3-n^2)K_n}\right\}^{1/(n-1)} \times \frac{2n^2-2}{2n^2-n}. \quad (16)$$

The two important implications of the above are (1) cmc (C_t) does not depend on the contribution factors and (2) the micellization constant (K_n) can be estimated in terms of the values of cmc and the aggregation number of the micelle. The former clear-cut result

Table 1. Micellization Constant (K_n) of Nonionic Surfactants of Oxyethylene Type Based on Monodisperse Micelle

Lipophile	Oxyethylene unit	cmc / μmol dm^{-3}	n	log K_n
1-Dodecanol[24]	8	110	123	478

	15	150	38	138
	22	196	28	97

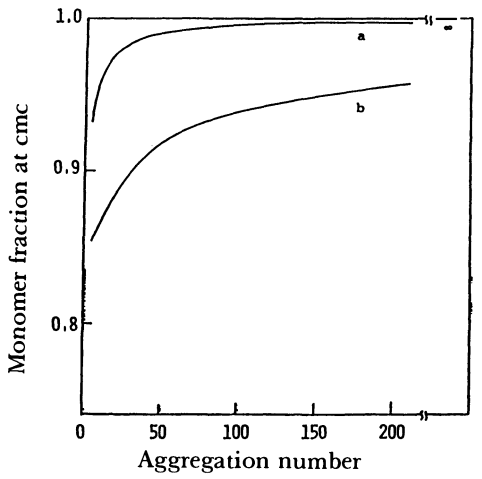

Fig. 3. Monomer fraction at cmc with aggregation number for monodisperse micelle of nonionic surfactant: a Eq. 17, b Eq. 18.

arises from the monodispersity of micelles, and cmc becomes independent of the method used for a cmc determination. In Table 1 are given many K_n values evaluated using Eq. 16 for nonionic surfactants of the oxyethylene type whose cmc and aggregation number are known.[23-26] As expected, K_n values increase with increasing aggregation number. From Eqs. 15 and 16 the fraction of nomomeric surfactants against the total surfactant concentration at cmc becomes

$$\frac{[S]}{C_t} = 1 - \frac{n-2}{2n^2-2}. \tag{17}$$

This fraction is illustrated against n in Fig. 3. On the other hand, Desnoyers et al. have already and independently presented the monomer fraction at the cmc and obtained a different expression from the same standpoint; he derived it in terms of the second derivative of the monomer fraction with respect to the total surfactant concentration.[27] However, the reason why the cmc can be defined as the total concentration at an inflection point of the monomer fraction is not clear. The fraction by Desnoyers,

$$\frac{[S]}{C_t} = \frac{n}{n-1} \times \{1 - (1/2n)^{1/2}\}, \tag{18}$$

is also shown in Fig. 3. The monomeric fraction has been found to be more than 99% at the cmc for the usual nonionic surfactant micelles with aggregation numbers greater than 50.

Monodisperse Micelle of Ionic Surfactant. Next, we consider the monodisperse micelle of an ionic surfactant. From the electroneutrality of a solution (eq. 5), the micelle concentration $[M_n]$ becomes

$$[M_n] = K_n[S]^n[G]^m = -x[S] - y[G] \tag{19}$$

where

$$x = z_s/(z_g m + z_s n) \tag{20}$$

and

$$y = z_g/(z_g m + z_s n) \tag{21}$$

Then, the equations corresponding to Eqs. 10 and 11 read, respectively, as

$$\nu_s C_t = (1-nx)[S] - ny[G] \tag{22}$$

and

$$\phi = (\alpha_1 - \beta x)[S] + (\alpha_2 - \beta y)[G] \tag{23}$$

The third derivative of ϕ with respect to C_t can likewise be obtained as

$$\frac{1}{\nu_s^3}\frac{d^3\phi}{dC_t^3} = (\alpha_2 - \beta y - \alpha_2 nx - \alpha_1 ny + 2\beta nxy) \times \{G'''(1 - nx - nyG') - 3nyG''^2\}/(1 - nx + nyG')^5 \tag{24}$$

where G′, G″, and G‴ are, respectively, the first, second, and third derivatives of [G] with respect to [S]. The solution then becomes

$$G'''(1 - nx + nyG') - 3nyG''^2 = 0 \tag{25}$$

In this case, too, the monomer concentration at the cmc turns out not to include any contribution factor at all. Hence, it becomes evident that the cmc theoretically does not depend on the method of cmc determination, regardless of whether an ionic or nonionic micelle is considered, as long as micelles are monodispersed. Experimentally, however, there must be random errors for the cmc values. In other words, the cmc values coincide with one another, independent of the cmc determination method, whether it is based on a solution property due to the surfactant monomer or due to the micelle. In reality, however, cmc's have been determined within a narrow concentration range.[18] This experimental fact means that the micelles formed in a surfactant solution are not monodisperse but, rather, polydisperse.

Polydisperse Micelle of Nonionic Surfactant. Now

that monodisperse micelles have been considered, the succeeding discussion should be about polydisperse micelles. Consider the simplest example in which micelles having only two kinds of aggregation numbers (n_1 and n_2) are formed in a solution. In this case, Eqs. 10 and 11 become, respectively,

$$C_t=[S]+n_1K_1[S]^{n_1}+n_2K_2[S]^{n_2} \quad (26)$$

and

$$\phi=\alpha_1[S]+\beta_1K_1[S]^{n_1}+\beta_2K_2[S]^{n_2} \quad (27)$$

Thus, from Eqs. 26 and 27,

$$\frac{d^3\phi}{dC_t^3}=N/(1+n_1^2K_1[S]^{n_1-1}+n_2^2K_2[S]^{n_2-1})^5, \quad (28)$$

where the numerator is given by

$$\begin{aligned}N &=(\beta_1-\alpha_1n_1)n_1(n_1-1)K_1[S]^{n_1-3}\times\{n_1-2\\ &+n_1^2(1-2n_1)K_1[S]^{n_1-1}\\ &+n_2^2(1+n_1-3n_2)K_2[S]^{n_2-1}\}\\ &+(\beta_2-\alpha_1n_2)n_2(n_2-1)K_2[S]^{n_2-3}\times\{n_2-2\\ &+n_1^2(1-3n_1+n_2)K_1[S]^{n_1-1}+n_2^2(1-2n_2)K_2[S]^{n_2-1}\}\\ &+n_1n_2(n_1-n_2)(\beta_1n_2-\beta_2n_1)K_1K_2[S]^{n_1+n_2-4}\\ &\times\{n_1+n_2-3+n_1^2(-2n_1+n_2)K_1[S]^{n_1-1}\\ &+n_2^2(n_1-2n_2)K_2[S]^{n_2-1}\} \quad (29)\end{aligned}$$

It turns out from Eq. 29 that the monomer concentration [S] satisfying $d^3\phi/dC_t^3=0$ depends on the contribution factors: α_1, β_1, and β_2. That is, the cmc value (C_t) obtained from the monomer concentration depends on a method for cmc determination. Thus, the cmc difference due to the method of determination is a systematic difference, just as systematic errors are different from random errors. The micelle aggregation number in a real system is much more dispersed than in the present case: two kinds of aggregation numbers.[28-33] Therefore, as a matter of fact, the cmc depends on the method used for a cmc determination and the cmc value should be defined as a narrow concentration range. From the above discussion, the relationship between the solubility and the cmc can be schematically illustrated (Fig. 1). The solubility is determined only by the temperature at atmospheric pressure and the cmc is given by a narrow concentration range, even at a specified temperature. As for the phase rule on a solubility curve, an excess surfactant phase coexists in the system and the number of phases becomes two. Thus, the number of degrees of freedom turns out to be two, as should be clear from the above discussion. The temperature determines the concentration of every chemical species at a specified pressure. This fact is in total agreement with the experimental fact that the solubility is determined only by the temperature at atmospheric pressure. For more details, reference to the literature[1] is recommended. The cmc change with temperature, on the other hand, is due to the variation of K_n, α, and β with temperature. As a result, the micelle temperature range (MTR) must be defined as the temperature within a narrow temperature range, for which the solubility vs. temperature curve intersects the cmc range vs. temperature curve although a single temperature within the MTR can be obtained from one cmc determination method. In other words, MTR is determined by balancing between the cmc range and the solubility and by their dependence on the temperature. In this sense, MTR is a phenomenological temperature range rather than a strict physical quantity.

Elucidation of MTR Changes

At present, it is very important to show that some experimental facts can be elucidated by the above definition of MTR, since the validity of the definition should be examined by this approach. The following are two typical examples of MTR changes.

Leveling of MTR for Homologous Surfactants with an Increase in Their Alkyl Chain Length. The Krafft point of homologous ionic surfactants has been reported to increase with an increase in the alkyl chain length of a surfactant ion.[3,34-36] The important feature is that MTR does not increase linearly with the carbon number of an alkyl chain, but with gradual leveling. On the other hand, the logarithms of both the solubility and the cmc decrease linearly with an increase in the carbon number.[3] Of course this applies for cases in which the logarithm of the solubility is less than that of the cmc at low temperature. In addition, the heat of dissolution below MTR becomes more positive with an increasing carbon number of surfactant ions; the rate of solubility increase with temperature is more rapid for a surfactant ion with a longer alkyl chain.[3] On the contrary, the cmc change with temperature is relatively small, irrespective of the alkyl chain length (Fig. 4). From the definition of MTR, in which solubility and cmc curves should intersect each other,

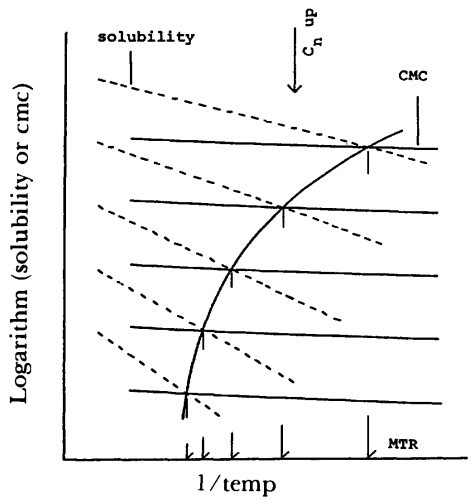

Fig. 4. Schematic illustration of MTR change with increase of carbon number of surfactant ion.

the leveling of MTR is easily understood from the figure.

MTR Increase of Sodium Dodecyl Sulfate (SDS) with Increase of Counterion Concentration. The addition of a salt having an ion in common with a counterion into an ionic surfactant solution leads to both a decrease in the cmc and an increase in the aggregation number of micelles. The presence of excess counterions also leads to a solubility decrease of the surfactant due to the constant solubility product of the counterion and the surfactant ion, as long as an excess surfactant phase coexists in the system, even when the surfactant concentration is above the cmc. Then, an MTR change is expected from an addition of excess salt into the system. In fact, the MTR of sodium dodecylsulfate increases with an increase in the concentration of sodium chloride in the solution. The aim of this section is to elucidate the movement of the MTR to higher temperature from the viewpoint of the present concept as to MTR and to compare the evaluated results with the reported ones.[16]

Let us suppose a monodisperse micelle formation, sicne the mass-action model of a single micellar size has been well applied to ionic surfactants.[37] The relation between the cmc and the counterion concentration then, according to Eq. 6, becomes

$$\ln \text{cmc} = -\frac{m}{n}\ln[\text{G}] - \frac{1}{n}\ln K_n + \frac{1}{n}\ln[\text{M}_n] \qquad (30)$$

since the concentration of the monomeric surfactant ion at the cmc can be replaced by the total surfactant concentration with more than 99% confidence, according to Phillips' definition of cmc.[37] In the usual case ($n > 50$; $K_n \gg [\text{M}_n]$) the last term on the right-hand side is less than a few percent of the constant term of association constant, and Eq. 30 can be well approximated by

$$\ln \text{cmc} = -\frac{m}{n}\ln[\text{G}] + \text{constant}. \qquad (31)$$

Here, m/n is the association degree of gegenion to the micelle. The linear relataionship between ln cmc and ln [G] has been ascertained from a number of experiments; this indicates that the above approximation is correct. The cmc of SDS is 8.4×10^{-3} mol dm^{-3} and m/n was extrapolated to be 0.72—0.75[38] at its MTR (9 °C).[39] The value of the constant was evaluated to be −8.22 and −8.36 for 0.72 and 0.75 of m/n, respectively. On the other hand, the solubility of SDS decreases with an increase in the counterion concentration, while maintaining the solubilty product constant at 9 °C;

$$C(C + C_{\text{Na}^+}) = (8.4\times10^{-3})^2, \qquad (32)$$

where C is the concentration of the surfactant or the solubility. From Eqs. 31 and 32 the difference between ln cmc and ln C at 9 °C can be evaluated at different C_{Na^+} concentrations. A cmc change with temperature

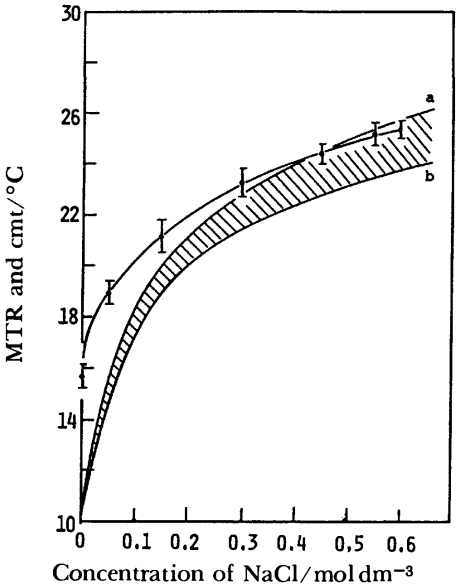

Fig. 5. MTR increase of sodium dodecylsulfate with increase of sodium chloride concentration: ⊖ cmt change, a m/n=0.72, b m/n=0.75.

is negligibly small compared with a solubility change. Then, it can be presumed that the difference ln cmc—ln C can be made zero only by a solubility increase with temperature. Then, MTR is the temperature at which the above difference becomes zero. The heat of dissolution (Δh) is necessary for the present calculation; Δh was estimated to be 50 kJ mol^{-1} from the solubility data of Nakayama and Shinoda.[40] The range of MTR thus obtained from two m/n values, 0.72 and 0.75, is shown in Fig. 5 together with the experimental results. The difference is less than a few degrees between the MTR and the critical micellar temperature (cmt)[16] by Mazer and Benedek; this is quite reasonable, judging from the definition of cmt. In spite of the difference between MTR and cmt, the present agreement can be said to be excellent.

The conclusions reached from the above discussion are (1) the micelle temperature range (MTR) is a better technical term than the Krafft point for expressing the relation between the solubility and micelle formation, (2) MTR can be determined only by balancing between the cmc range and the solubility and their dependence on temperature, and (3) these can be well explained by the mass-action model of micelle formation and the size distribution of micelles.

The Preparation of Organo Colloidal Precious Metal Particles

Kenjiro MEGURO, Makoto TORIZUKA, and Kunio ESUMI*
Department of Applied Chemistry, Institute of Colloid and Interface Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162
(Received June 17, 1987)

Platinum particles were prepared by reducing the hydrogen hexachloroplatinate extracted in organic solvents from an aqueous solution by these extractants:dioctadecyldimethylammonium chloride(DDAC), trioctylmethylammonium chloride(TMAC), and trioctylphosphine oxide(TOPO). The extraction ratio of platinum(IV) increased in chloroform, isobutyl methyl ketone, and cyclohexane with an increase in the concentrations of the extractants, and then approached a constant state. The extracts were reduced by formaldehyde or benzaldehyde in the presence of water and a base (sodium hydroxide or triethylamine) for several hours at 65 °C. The platinum particles obtained in chloroform and isobutyl methyl ketone were very stable; their diameters were 15—25 Å.

The preparation of colloidal metals has long been studied extensively.[1-4] Recently, many investigations of the preparation of particles have concentrated upon precious metals because of their many applications, e.g., as catalysts.[5,6] The greater part of the experiments have been made in an aqueous solution in the presence of surfactants or polymers in order to stabilize the colloidal particles.[5-7] Further, it has been reported[8,9] that the precious metal particles can be prepared in water in oil microemulsions. However, there have been only a few reports on the preparation of precious metal particles in organic solvents, since the solubility of most particle precursors is very low in organic solvents.

On the other hand, metal salts can be transferred into organic solvents by means of solvent extraction.[10-13] This method allows precious metal salt to be extracted in organic solvents as particle precursors of organic precious metal.

The aim of the present work was to prepare platinum metal particles from their salts extracted into organic solvents.

Experimental

Materials. Hexachloroplatinic(IV) acid was supplied by Tanaka Kikinzoku Kogyo K.K. as a hexahydrate ($H_2PtCl_6 \cdot 6H_2O$). As extractants, dioctadecyldimethylammonium chloride (DDAC), trioctylmethylammonium chloride (TMAC), and trioctylphosphine oxide (TOPO) were employed. The DDAC was obtained from the Lion Co., Ltd., and was purified once by recrystallization from 2-propanol. The TMAC and TOPO were commercial, extra pure grades from the Tokyo Chemical Industry Co., Ltd., and were used without further purification. The other chemicals were commercial, extra pure grades from Wako Pure Chemical Industries, Ltd. The water used in this experiment was deionized by means of the MILLI-Q Water Purification System.

Procedure. For the extraction, two kinds of solutions were mixed; one was a 10 ml aqueous solution of 0.5 mmol dm^{-3} hexachloroplatinic(IV) acid, while the other was 0—3.0 mmol dm^{-3} of the extractant in chloroform, isobutyl methyl ketone (MIBK), or cyclohexane (in the case of TOPO, 0—2.0 mol dm^{-3} HCl was used). Then, the mixed solution was shaken at 25°C for 12 h to attain an equilibrium of extraction. After the extraction, the concentration of platinum(IV) remaining in the aqueous solution was determined photometrically by means of the tin chloride method. The extraction ratio was calculated from the difference between the initial concentration of Pt(IV) and that remaining in the aqueous phase.

In order to obtain Pt particles, each of the platinum(IV) salts extracted in an organic solvent was directly reduced by several reductants: formaldehyde, benzaldehyde in the presence of sodium hydroxide, triethylamine (TEA) and water, hydrazine, and hydrogen (through bubbling). The subsequent refluxing of the solution under nitrogen gas on a water bath (65 °C) between 15 min and 10 h gave a homogeneous dark brown solution of platinum sols.

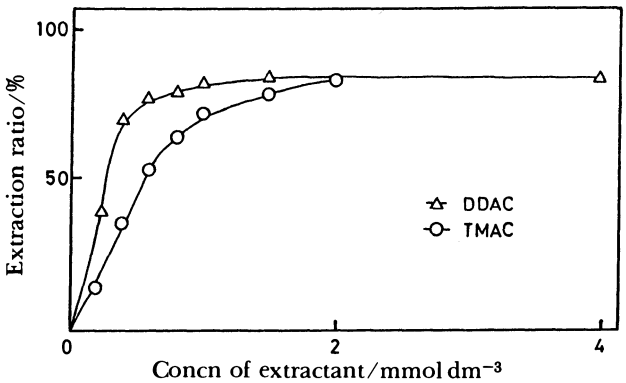

Fig. 1. Effect of concentration of DDAC and TMAC in chloroform on the extraction of platinum(IV).

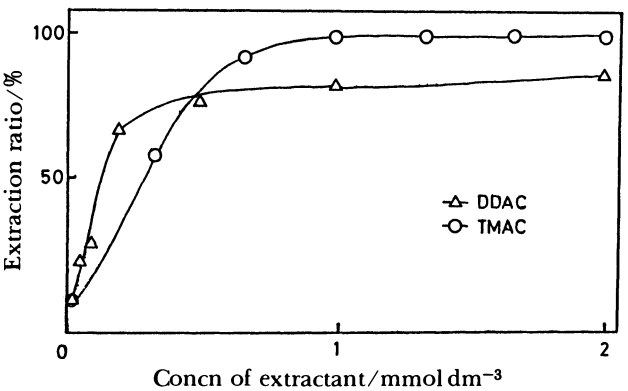

Fig. 2. Effect of concentration of DDAC and TMAC in MIBK on the extraction of platinum(IV).

The Pt-particle sizes were determined by means of transmission electron microscopy with a Hitachi H-800 microscope. The magnification of the electron microscope was 70000—200000. The particle size distribution and the average diameter of the Pt particles were obtained on the basis of these enlarged electron-microscope photographs.

Results and Discussion

The effect of the extractant concentration on the transfer of platinum(IV) salt to an organic solvent was studied. The efficiency of extraction is usually defined as the ratio of the platinum(IV) concentration in an organic solvent against the total platinum(IV) concentration: This is named the "extraction ratio." The extraction ratios of platinum(IV) to chloroform by

Table 1. Properties of Precursors of Platinum Sols by Extraction

Initial concn of Pt	Extractant and concn	Organic solvent	Extraction ratio	Concn of Pt in organic phase
mmol dm^{-3}	mmol dm^{-3}		%	mmol dm^{-3}
0.5	DDAC 1.5	Chloroform	83.6	0.42[D/C]
	TMAC 2.0		82.6	0.42[T/C]
	DDAC 0.5	MIBK	77.0	0.39[D/M]

DDAC and TMAC are plotted against the concentration of the extractant in Fig. 1. It can be seen that the extraction ratios for both extractants increase with an increase in the concentration of the extractant and then approach to a constant state. In the case of DDAC, the extraction ratio reaches above 85% above the concentration of 1.5 mmol dm^{-3}, while the concentration of more than 2 mmol dm^{-3} of TMAC gave a

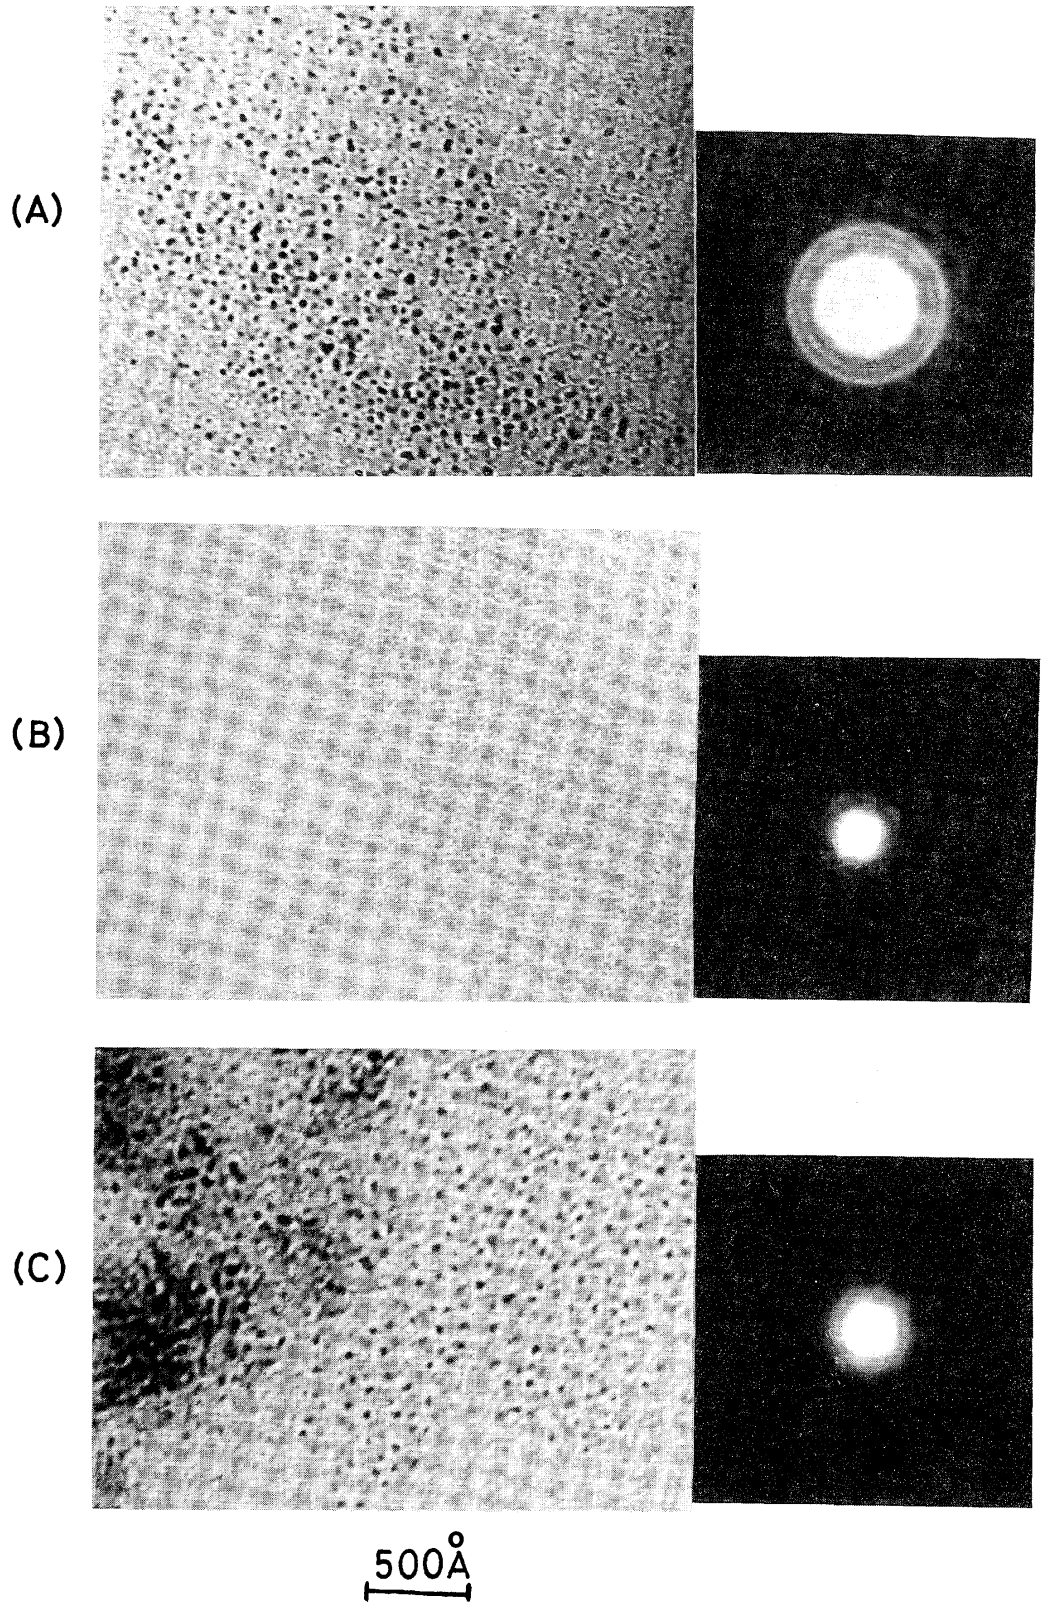

Fig. 4. Electron micrograph and electron diffractogram of platinum sols reduced with formaldehyde from various extracts: (A) D/C, (B) T/M, (C) T/H.

ratio of more than 83%. Similarly, the extraction ratios of platinum(IV) to MIBK by DDAC and TMAC are shown in Fig. 2. When the DDAC and TMAC concentrations were above 1 mmol dm^{-3}, the extraction ratio for the former became more than 80%, while that for the latter was almost 100%. Figure 3 shows the extraction ratio of platinum(IV) in cyclohexane as a function of the concentration of TOPO. It is found that the extraction ratio of platinum(IV) increases with an increase in the concentration of TOPO without any addition of hydrochloric acid, but it is still very low. Upon the addition of hydrochloric acid, however, the extraction ratio increased remarkably: it was almost 100% when the TOPO concentration was 0.05 mol dm^{-3} in the presence of 1.0 mol dm^{-3} hydrochloric acid in water. Thus, it was confirmed that the platinum(IV) salt in an aqueous solution is efficiently transferred to an organic solvent by using adequate extractants.

The particle precursors were prepared under the conditions shown in Table 1. Table 2 shows the conditions of sols preparation from extracts in chloroform and the stability of the sols. The extracts of platinum salt were not reduced by only formaldehyde or benzaldehyde, without any base or water. However, upon the addition of a base and water, very stable Pt sols were obtained. From Table 3 it is apparent that the extracts in MIBK are reduced by formaldehyde or benzaldehyde in the presence of a base and water and that the sols obtained are stable for TMAC, but not for DDAC. In the case of extracts with TOPO in cyclohexane, the sols were also obtained only upon the addition of a base and water, but they were not stable.

The platinum sols particles prepared by the reduction with formaldehyde or benzaldehyde were almost spherical. The extracts obtained by DDAC in chloroform, TMAC in chloroform, DDAC in MIBK, TMAC in MIBK, and TOPO in cyclohexane are abbrevated D/C, T/C, D/M, T/M, and T/H respectively. The electron micrograph and electron diffractogram of particles formed by the reduction of D/C with formaldehyde and sodium hydroxide are shown in Fig. 4(A); their particle-diameter distribution is shown in Fig. 5(A), where the mean particle diameter is 17.5 Å, with a standard deviation of 3.23 Å. Similarly, Figs. 4(B) and 5(B) show the electron micrograph, the electron diffractogram, and the diameter distribution of the platinum particles prepared by the reduction of T/M with formaldehyde and sodium hydroxide; the mean particle diameter was 19.3 Å, with a standard deviation of 3.99 Å. The mean particle diameter of the platinum prepared by the reduction of T/H with formaldehyde and sodium hydroxide was 19.0 Å, and the standard deviation was 4.94 Å, as is shown in Figs. 4(C) and 5(C). The platinum particles prepared by the above method are crystalline, with a diffraction pattern corresponding to the fcc structure of platinum.

The effect of the reaction time on the particle-diameter distribution of the platinum particles produced by the reduction of T/C with benzaldehyde,

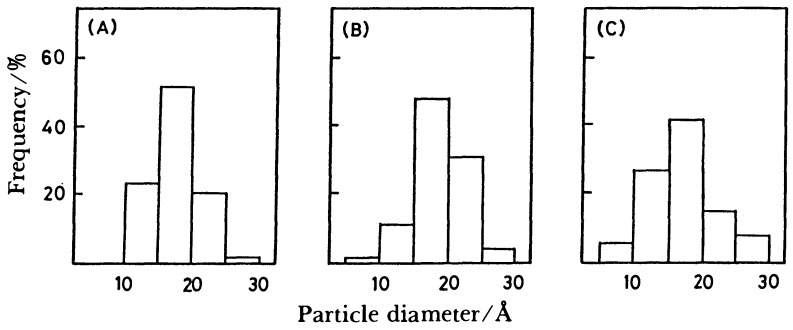

Fig. 5. Particle diameter distribution of platinum sol particle: (A) D/C, (B) T/M, (C) T/H.

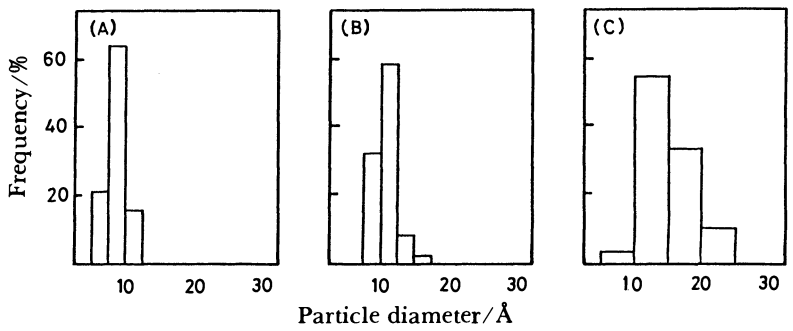

Fig. 6. Particle diameter distribution of platinum sol particles by reduction of T/C with benzaldehyde, triethylamine and water: reaction time; (A) 15, (B) 30, (C) 120 min.

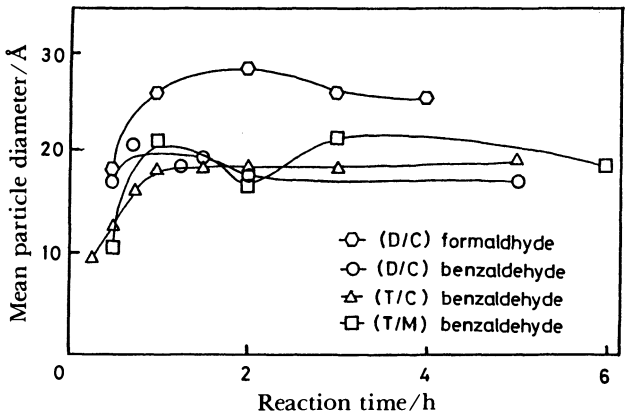

Fig. 7. Relationship between reaction time and mean particle size of platinum sol.

triethylamine, and water was also studied. In Fig. 6 it can be seen that the size of the platinum particles increases with an increase in the reaction time; the mean particle diameters are 8.3, 10.5, and 15.1 Å for 15, 30, and 120 min respectively, while the corresponding deviations are 1.39, 1.62, and 3.07 Å. Further, the plots of the mean particle diameter vs. the reaction time for the four systems are shown in Fig. 7. It is found that the mean particle diameter increases with an increase in the reaction time until about 1 h, and then becomes constant, suggesting that the nucleation of the platinum particle occurs and that the nucleus has grown into a certain constant value during the initial hour. Compared with the reduction of D/C by formaldehyde and benzaldehyde, the former provides larger platinum particles than the latter. This result is, presumably, attributably to the difference between the solubilities of benzaldehyde and formaldehyde in chloroform; benzaldehyde has a higher solubility than formaldehyde.

As a conclusion, it can be said that the preparation of platinum particles in an organic solvent needs water to facilitate the reduction of platinum(IV) with formaldehyde or benzaldehyde. It seems that the reduction of platinum(IV) occurs at the interface between the water and the organic solvent and that the platinum nucleus is produced and grows quickly (in about one hour) at this interface. As a result, platinum particles with diameters in the range of 15—25 Å are obtained. This method can also be used in the preparation of other precious metal particles in organic solvents.

The Preparation of Colloidal Precious Metal Particles Using Copolymers of Vinyl Alcohol-*N*-Vinylpyrrolidone

Kenjiro MEGURO, Yukari NAKAMURA, Yoshihiro HAYASHI, Makoto TORIZUKA, and Kunio ESUMI*

Department of Applied Chemistry, Institute of Colloid and Interface Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162

(Received June 18, 1987)

Precious metal particles of platinum and silver have been prepared by the reduction of metal salts dissolved in an aqueous solution of a copolymer of vinyl alcohol and *N*-vinylpyrrolidone with methanol. The stable platinum sols were obtained in the presence of poly(vinyl alcohol), poly(*N*-vinylpyrrolidone), and their copolymers, but their particle sizes hardly changed with the ratio of *N*-vinylpyrrolidone in the copolymer. On the other hand, colloidal stable silver sols were obtained only in the presence of a copolymer. Further, with an increase in the ratio of *N*-vinylpyrrolidone in the copolymer, the particle size of silver became small.

Precious metal particles have been attractive as catalysts[1-3] when it is desirable to use fine monodispersed particles. On the preparation of fine particles, precious metal ions have often been reduced in a mixture of precious metal ions, protective colloids, and a reducing agent. As protective colloids, poly(vinyl alcohol), poly(*N*-vinylpyrrolidone), and poly(methyl vinyl ether)[4-9] have been employed. However, homopolymers are not easily adsorbed on precious metal particles, so monodispersed particles are hard to obtain when they are used.

The objective of this work was to prepare fine monodispersed precious metal particles using copolymers of vinyl alcohol-*N*-vinylpyrrolidone.

Experimental

Materials. The $H_2PtCl_6 \cdot 6H_2O$ was supplied by Tanaka Kikinzoku K.K., while the $AgNO_3$ was obtained from the Tokyo Kasei Co. Ltd. The poly(vinyl alcohol)(PVA) and poly (*N*-vinylpyrrolidone)(PVP) were obtained from Kishida Chemicals Co., Ltd., and the Tokyo Kasei Co., Ltd., respectively. As monomers, vinyl acetate (VAc) and *N*-vinylpyrrolidone(VP) were obtained from Wako Chemical Industries: They were distilled under reduced pressure before use. The other chemicals were of extra pure grades. The water used was purified through the Milli-Q Reagent Water System.

Preparation of Copolymers: Mixtures of VAc and VP in various ratios were added to acetone, and the polymerization was carried out under a nitrogen gas atmosphere at 70 °C, using α,α'-azobisisobutyronitrile as the initiator. Then, the products, as purified with petroleum ether, were dissolved into methanol and saponified upon the addition of sodium methoxide at 40 °C under a nitrogen-gas atmosphere. The samples thus obtained were purified with diethyl ether and acetone.

Measurements: The molecular weights of the samples were determined by means of gel permeation chromatography (Japan Optical Co.) with a column of Shodex OH Pak B800P and B804 (Showa Denkou Co.): Pullulan was used as the standard sample, and a mixture of methanol and water (1 : 1) was used as the solvent.

Determination of the Content Ratio of the Copolymer of Vinyl Alcohol-*N*-Vinylpyrrolidone: Some VAc-VP copolymers were dissolved into acetone, and then sodium hydroxide was added for saponification. After the complete saponification, the remaining sodium hydroxide was back-titrated with hydrochloric acid. From the results of a subsequent titration, the ratio of VA-VP in the copolymers was determined.

Preparation of Colloidal Particles: A polymer (7.5—200 mg) as a protective colloid and a metal salt (0.033 mmol dm^{-3}) were dissolved in a mixed solvent consisting of methanol (25 ml) and water (25 ml). The resulting solution was refluxed to prepare a colloidal dispersion of the metal. In the case of silver nitrate, the concentrations ranged between 0.033 and 0.33 mmol dm^{-3}.

The particle sizes of the precious-metal particles obtained were determined by means of transmission electron microscopy with a Hitachi H 800 microscope.

Results and Discussion

Platinum Sol. Figure 1 shows the relationship between the amount of PVP added and the number-average particle size of platinum. When the amount of PVP was 75 mg, the particle size was smallest in the case of the highest molecular weight of PVP. However, upon the addition of 150—200 mg of PVP, the particle size increased with an increase in the molecular weight of PVP. Similar experiments were also carried out in the case of PVA. It was found that the

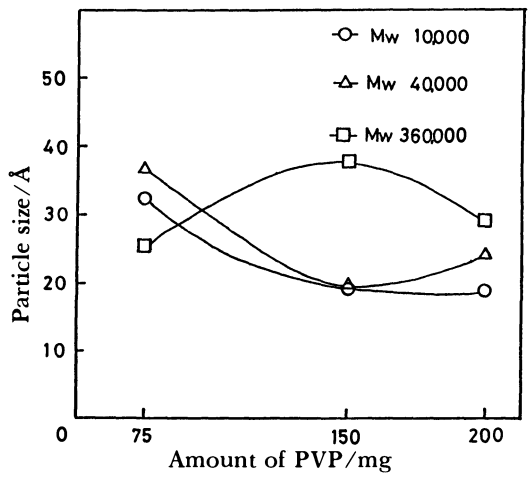

Fig. 1. Mean particle size of platinum sols as a function of molecular weight of PVP.

particle size hardly changed with an increase in the amount of PVA added (M.W.=20000). Further, using PVA (M.W.=88000), stable platinum sols were obtained, but their particle size could not be determined by transmission electron microscopy because extensive coagulation resulted from the evaporation of the solvent from a drop of solution on the support. Accordingly, in order to study the effect of copolymers on the particle size of platinum particles, the molecular weight of the copolymer was controlled to within the range of 30000—60000. The pertinent properties of the copolymers are given in Table 1.

Figure 2 shows the number-average particle size of platinum with the molar ratio of VA or VP in the copolymers. Here, the amount of the copolymers added was 150 mg. From Fig. 2 it can be seen that, except for PVA, the particle sizes of platinum are almost the same for the other copolymers, indicating that the copolymers of VA-VP do not provide a different colloidal protective action from homopolymers (PVA or PVP).

Silver Sol. Keeping constant the amount of copolymers added (150 mg), silver sols were prepared as a function of the amount of silver nitrate. In the case of PVA alone, stable silver sols were not obtained and the

Table 1. Pertinent Properties of Copolymers

Copolymer	Molar ratio in copolymer		Molecular weight
	VA	VP	
A2	0.15	0.85	4.4×10^4
A4	0.35	0.65	6.4×10^4
A8	0.74	0.26	3.1×10^4

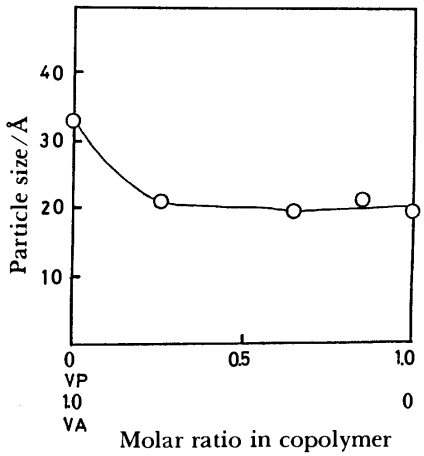

Fig. 2. Mean particle size of platinum sols as a function of molar ratio of VA or VP in copolymers.

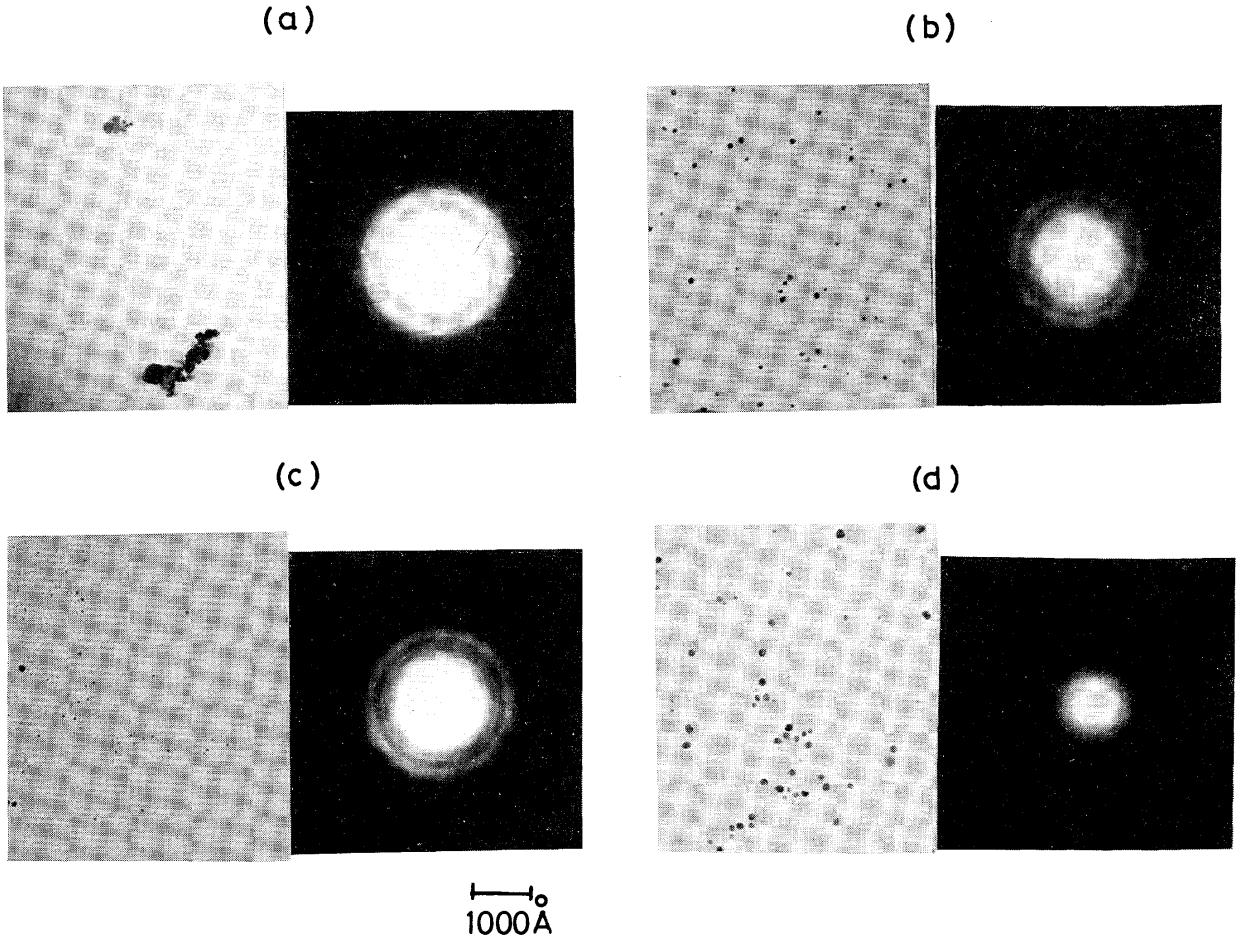

Fig. 3. Electron micrograph and electron diffractogram of colloidal silver sols: (a) PVP, (b) A2, (c) A4, (d) A8.

colloidal dispersions were turbid. This result coincided with that obtained by Hirai et al.[8] Similarly, PVP alone did not provide any stable silver sols. The electron photograph and electron diffractogram of these particles are shown in Fig. 3(a), where their particle sizes range from 300 to 400 Å.

On the other hand, with the copolymers of VA-VP, a transparent silver dispersion was obtained, where the copolymers of A2 and A8 gave yellow sols, and the others, red sols. The electron photograph and electron diffractogram of these stable sols are shown in Fig. 3(b), (c), and (d). The particle size of the silver sols prepared with the copolymers of A2 and A8 was rather monodispersed, being 80—170 Å of diameter, while those of the sols prepared with the copolymer of A4 were both large and small; the former was about 150 Å, and the latter, 50 Å. From the electron diffractogram, the particles can be said to be crystalline, with a diffraction pattern corresponding to the f.c.c. structure of silver.

Thus, the above results confirm that stable silver sols are obtained only by the use of the copolymer of VA-VP.

In order to elucidate the effect of the copolymer on the formation of silver sols, the silver sols were prepared as a function of the amount of copolymer added. In the case of the copolymer A2 (shown in Table 2), yellow silver sols were obtained in the range of 7.5—200 mg. When 15 and 7.5 mg portions were added, the particle sizes were divided into two regions; one was 100—200 Å, and the other, 30—40 Å. In the case of the copolymer A4 (shown in Table 3), the color of sols changed with the amount of the copolymer added; the red sols were obtained in the range of 100—200 mg and 7.5—15.0 mg, and the yellow sols, in the range of 25—75 mg. The electron microscopy shows that, upon the addition of 37.5—75 mg, and 200 mg of the copolymer A4, monodispersed sols are prepared, but the addition of 100—175 mg of the copolymer A4 leads to a broad particle size distribution. Table 4 shows the properties of the silver sols prepared in the presence of the copolymer A8. Upon the addition of less than 37.5 mg of the copolymer A8, no stable sols were obtained, but the addition of 75 mg of the copolymer A8 allowed the preparation of monodispersed sols. Upon the further addition of the copolymer A8, the stable sols were still obtained. Thus, with an increase in the ratio of *N*-vinylpyrrolidone in the copolymers, the particles of silver sols became smaller.

Table 2. Color, Dispersion, and Particle Size of Colloidal Silver with the Copolymer A2

Added amount/mg	Color	Dispersion	Particle size/Å
200	Yellow	Stable	70—120
175	Yellow	Stable	50—200
150	Yellow	Stable	100—160
100	Yellow	Stable	60—150
75	Yellow	Stable	80—150
37.5	Yellow	Stable	70—100
15	Yellow	Stable	100—180, 30—40
7.5	Yellow	Stable	150—200, 30

Table 3. Color, Dispersion, and Particle Size of Colloidal Silver with the Copolymer A4

Added amount/mg	Color	Dispersion	Particle size/Å
200	Red	Stable	60—110
175	Red	Stable	20—180
150	Red	Stable	100—200, 50
100	Red	Stable	100—200
75	Yellow	Stable	60—110
37.5	Yellow	Stable	60—110
25	Yellow	Stable	30—150
15	Red	Stable	20—150
7.5	Red	Stable	100—300, 30—70

Table 4. Color, Dispersion, and Particle Size of Colloidal Silver with the Copolymer A8

Added amount/mg	Color	Dispersion	Particle size/Å
200	Yellow	Stable	50—110, 250
175	Yellow	Stable	50—130
150	Yellow	Stable	80—150
100	Red	Stable	60—170
75	Yellow	Stable	60—110
37.5	Gray	Instable	20—300
25	Gray	Instable	Coagulate
15	Gray	Instable	Coagulate
7.5	Gray	Instable	Coagulate

Consequently, it can be summarized that, upon the addition of the copolymer A2 in the range of 0.5—4 wt%, rather monodispersed silver sols are prepared, while the addition of the copolymer A4 or A8 also leads to the formation of monodispersed silver sols, although the additive concentration is restricted to some degree.

Protective colloids, such as PVA, and PVP, have been used to prepare colloidal precious metal particles because they adsorb on metal particles, resulting in stable sols. In this study, PVA and PVP are found to be effective as a protective colloid for the preparation of colloidal platinum sols. Although Jirgensons et al.[10] have reported that decreasing the degree of the polymerization of PVP results in a depression of the aggregation of precious metal particles, an opposite result is obtained in this study.

In the case of the preparation of silver sols, the copolymers of VA-VP give rather monodispersed silver sols, suggesting that the copolymers of VA-VP are adsorbed effectively on the silver sols. In fact, Ueno[11] has reported that the surface tension of the copolymers of VA-VP decreases with an increase in the VP content and is lower than that of each homopolymer. This result leads to the conclusion that the copolymers of VA-VP can adsorb on a solid surface more easily than

homopolymers, resulting in the formation of monodispersed particles as an effective protective colloid.

(Received June 22, 1987)

The valence electronic structures of poly(dimethylsilane)(PDMS) $(Si(CH_3)_2)_n$ and polysilane $(SiH_2)_n$ were studied. PDMS was experimentally studied by X-ray photoelectron spectroscopy (XPS) and UV photoelectron spectroscopy (UPS), and band calculations were performed for both compounds. The observed spectral features and calculated band structures were assigned and discussed through a comparison with theoretical and experimental results for oligomers and other polymers. These analyses have demonstrated how the electronic structures of these compounds are correlated through factors such as (i) change in the chain length, (ii) methylation, and (iii) the substitution of Si by C. PDMS has a small ionization energy (5.9 eV) almost as low as that of poly(*p*-phenylene) (5.6 eV). This small value comes from the combined contribution from the small electronegativity of silicon, σ-conjugation, and the inductive effect of methyl groups. The small ionization energy and large σ-conjugation explain the reported high conductivity of PDMS and its derivatives upon acceptor doping.

Recently the electronic properties of polysilane $(SiH_2)_n$ and their derivatives have attracted considerable interest from various viewpoints such as the strong delocalization of σ-electrons (σ-conjugation),[1-3] a new class of conducting polymers,[1,4,5] photoresists,[1] photoinitiators for polymerization,[1] and species found in the films of plasma-deposited Si:H alloy.[6,7] The permethylated or other organo-substituted compounds are used for protecting the polysilane backbone from unstability to air.

The elucidation of the electronic structures of polysilane and poly(dimethylsilane) $(SiMe_2)_m$ (PDMS), which is the simplest poly(organosilane), is the basis for such studies. However, the electronic structures of these compounds have not been investigated experimentally, although shorter members of silanes Si_nH_{2n+2} $(n \leqslant 5)$[8,9] and permethylated silanes $Si_m(CH_3)_{2m+2}$ $(m \leqslant 5)$[8,10] have been extensively studied by gas phase UV photoelectron spectroscopy (UPS). On the theoretical side, there have been several band calculations for polysilane and their derivatives.[11-13] A recently reported UPS study of polysilanes with complex pendants[14] clarified several important points such as the dominant contribution of the large pendants to their electronic structure and the relation of chain-pendant interaction with their ability as photoresists. Unfortunately, however, the topmost part of the valence band could not be studied in detail, and there is a large uncertainty in the energy axis due to sample charging.

In this paper we report on a study of the whole valence electronic structures of PDMS and polysilane. PDMS is studied by X-ray photoelectron spectroscopy (XPS) and UPS. Such experiments could not be performed on unstable unsubstituted polysilane, but band calculations were performed on both compounds; the results are discussed in terms of the relevant data for oligomers. A comparison is also made with polyethylene $(CH_2)_n$, the carbon analogue of polysilane, and conducting polymers with π-conjugated carbon chains.

Furthermore, in the process of sample preparation we found that thin films of PDMS can be prepared by vacuum-evaporation, a technique which has been successfully applied to other polymers such as polyethylene and polypropylene.[15] This technique may also be applicable for the thin-film preparation of other polysilanes.

Experimental

The PDMS powder was supplied from Shinnisso-Kako Co. Ltd., and used without further purification. The XPS spectra were measured on a VG ESCALAB 5 photoelectron spectrometer using Al $K\alpha$ radiation ($h\nu$=1486.6 eV). The sample powder was supported on a Nichiban double-sided adhesive tape.

The UPS spectra were measured using two photoelectron spectrometers with different light sources, i.e. (i) rare-gas resonance lines (He I, $h\nu$=21.2 eV; Ne I, $h\nu$=16.8 eV, and Ar I, $h\nu$=11.7 eV), and (ii) the combination of a Hinteregger-type hydrogen discharge lamp with a 0.5-m Seya-Namioka-type monochromator ($h\nu$=7.7—10.5 eV). The base pressure of the chamber was ca. 5×10^{-8} Pa and ca. 2×10^{-4} Pa for spectrometers (i) and (ii), respectively. In both cases, the energy analyzer of photoelectrons was a retarding-potential type one. The photoelectron spectra were obtained using an ac moduation technique,[16,17] with a modulation of 0.2 V peak to peak.

One advantage of the retarding-potential-type analyzer is that we could accurately determine the absolute binding energy.[16,17] In order to use this advantage for insulators, however, a thin film of several tens nm thickness was necessary for avoiding sample charging. Such a film was obtained by in-situ vacuum-evaporation in the photoelectron spectrometer to a thickness of 25 nm, which was monitored by a quartz oscillator.

The evaporated film was examined by IR spectroscopy.

The IR spectrum of PDMS before evaporation was measured with a KBr pellet, and agreed well with the reported spectrum.[18] It exhibits bands due to adsorbed water at 3440 cm^{-1} and 1650 cm^{-1}, and a band due to Si-O bond at 1035 cm^{-1}. We also observed a weak oxygen 1s peak in the XPS spectrum of the powder, which corresponds to a few per cent of O atom per Si atom. Such a small amount of oxygen is not expected to affect the observed UPS and valence-XPS spectra. A weak band due to the Si-H stretching also appears at 2100 cm^{-1}. In the spectrum of a film evaporated onto a KBr disk, water-derived bands are completely removed and the Si-O band becomes weak. On the other hand, the Si-H band becomes stronger, and the band around 700 cm^{-1}, which is related to the Si-C bonds, becomes weaker. From these results, we conclude that some of the CH_3 groups are replaced by H atoms upon evaporation: however, main structure of PDMS is preserved.

The evaporated film did not sublime away, even after a long storage in high vacuum. This indicates that the molecular weight of PDMS in the evaporated film is much larger than those of the short oligomers ($n \leqslant 5$) studied in gas-phase UPS experiments.[8,10]

Calculation

The band structure calculations were performed with an extended Hückel approximation using a program described elsewhere.[19] Parameters by Nguyen et al.[20] (Table 1) were used.

The validity of this method was examined by comparing the observed gas phase UPS spectra of small silanes[8] and methylated silanes[10] with the calculated energy levels by this method without Si 3d orbitals. The calculated results compare reasonably well with the observed UPS spectra, when we shift the calculated results by about 2 eV to the lower-energy side. The character of calculated levels also agree well with the experimentally assigned ones by Bock et al.[8-10] These results indicate that we can use this rather primitive method for discussing the gross features of the electronic structures of polysilane and PDMS.

We also calculated the molecular orbitals of Si_2H_6 with (i) the use of a slightly smaller orbital exponent ζ=1.2 for Si and (ii) an extended basis set including the Si 3d orbital. The results showed that these changes have little effect on the calculated results. Since the calculated band structures of PDMS and polysilane are also little affected by these changes, we report here only the results without 3d orbitals and ζ=1.383.

Band structure calculations of polymers were performed for polysilane, PDMS, and polyethylene. All three polymers were taken to be in a planar-zigzag conformation: The bond angles and bond lengths are listed in Table 1(b). This conformation has not yet been experimentally verified for polysilane and PDMS, and other possibilities are also suggested.[23] However, UPS and XPS experiments on crystalline and gaseous alkanes[24] indicate only a minor difference of the density-of-states between extended planar-zigzag and random-coil conformations. Therefore, the results for an adopted conformation will be at least a good first-

order approximation to the real systems.

Results and Discussion

Polysilane. The calculated band structure of polysilane is shown in Fig. 1(a). Due to the assumption of a planar-zigzag conformation, the bands form pairs degenerate at the edge of the Brillouin zone ($k=\pi/a$), where a is the lattice constant. The same kind of pairing also occurs in the results for other polymers in Figs. 1(b) and (c). The Si 3s orbitals form a broad band 1+1′. Si-H and Si-Si bonds form separated bands 2+2′ and 3+3′, respectively. These results agree with other calculations,[11-13] except that some of them indicate an overlap of the bands 2+2′ and 3+3′. We discuss this point later.

This band structure is fairly similar to that of polyethylene (Fig. 1(c)), which is the same as that by McCubbin and Manne.[25] However, the bands in polysilane show lower binding energies than corresponding ones in polyethylene. This should be due to the smaller electronegativity of Si (1.8 in Pauling scale[26]) than that of C (2.5), which appear as the smaller H_{ii} of Si 3p than that of C 2p in Table 1. Another difference is the overlap of the C-H and C-C bands (2+2′ and 3+3′) in polyethylene, which is well verified by photoemission experiments[27] and other calculations.[22]

In Fig. 2(c) we show the density of states (DOS) of polysilane derived from Fig. 1(a). The peaks in the DOS correspond to the bands in Fig. 1(a); their characters are also shown. For a comparison, in Figs. 2(a) and (b) we show the reported gas-phase UPS spectra of SiH_4[28,29] and Si_5H_{12}.[8] The peak energies in these spectra are listed in Table 2. In this comparison, the calculated DOS is rigidly shifted by 2.0 eV as described in Calculation. The studies of Si_nH_{2n+2} from n=1 to 5 by Bock et al.[8] revealed that the spectra of these compounds consist of (i) a largely unchanged intense peak due to the SiH bonds and (ii) split levels below and above the SiH peak, which are derived from interacting Si3s orbitals and SiSi bonds, respectively. These characters are shown in the figure.

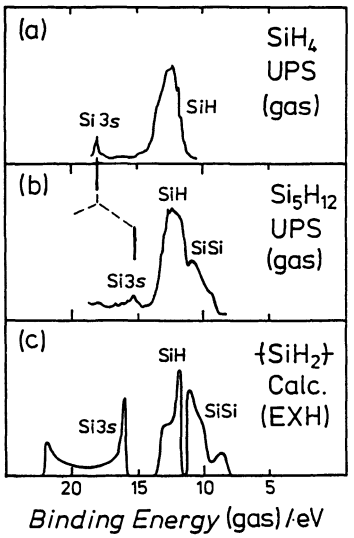

Fig. 2. Gas phase UPS spectra of SiH_4[35] (a) and Si_5H_{12}[8] (b) compared with the calculated density of states of polysilane derived from Fig. 1(a).

Since previous studies have shown that electronic structures of oligomers of 5 units already resemble that of a polymer,[30-32] a comparison between the theory and the spectrum of Si_5H_{12}, the longest silane oligomer so far measured, is meaningful for the discussion of polysilane. In Fig. 2 a good correspondence can be seen between these two, as well as an agreement of the peak assignments.

We also see a good correspondence between the band calculation and the n-dependence reported by Bock et al.[8] The large shift of the uppermost Si3s level from n=1 to 5 (2.86 eV) corresponds to the wide dispersion of the Si 3s band in Fig. 1(a), which reflects the strong interaction between the directly bonded Si atoms. Further, the insensitivity of the SiH peak to the chain length corresponds to the narrow width of the calculated SiH bands in Fig. 1(a), which indicates a weak interaction among the SiH bonds. These results support the absence of an overlap between the SiSi and

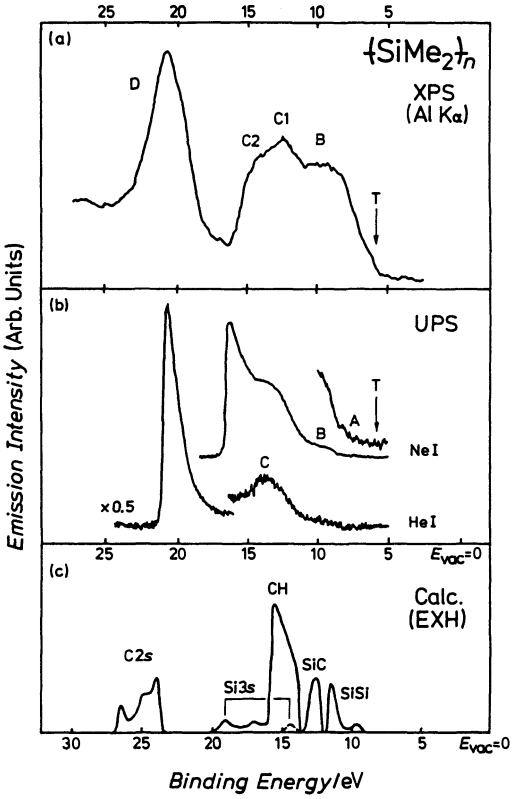

Fig. 3. X-Ray (a) and ultraviolet (b) photoelectron spectra of poly(dimethylsilane) solid compared with (c) the density of states deduced from the extended Hückel calculation in Fig. 1(b) by making a histogram of 0.5 eV steps. The abscissa is 2.5 eV shifted as described in the text. The ionization threshold and peaks are labelled T and A—D, respectively.

SiH bands in the present calculation. This absence also agrees with a recent calculation using realistic semiempirical parameters.[13] In contrast to this, the UPS spectra of short alkanes[33] show no stationary peak, because of the mixing among the electronic states derived from the CH and CC bonds.

Thus we can conclude that the important aspects of the electronic structure of polysilane are reproduced in the calculated band structure in Fig. 1(a).

Poly(dimethylsilane). In Figs. 3(a) and (b), we show the XPS and UPS spectra of PDMS. The abscissa is the binding energy relative to the vacuum level. The absolute energy scale could be accurately determined for the UPS spectra by taking the left-hand cutoff of each spectrum to be zero kinetic energy of photoelectrons.[17] The absence of charging is verified; by the sharpness of this cutoff. The energy scale of the XPS spectrum is adjusted to fit the spectral features with those in the UPS spectra.

In the XPS spectra we can see four features labelled B, C1, C2, and D. In the UPS spectra, three valence band features (A, B, and C) can be seen. Feature C corresponds to the broad band formed by C1 and C2 in the XPS spectrum. The sharp intense peak near the left-hand cutoff in the UPS spectra are due to secondary electrons. The topmost part of the valence band is not clearly seen in the UPS spectra in Fig. 3, possibly due to an incomplete cleanliness of the sample surface. Fortunately, this part (feature A) can be more clearly seen in the UPS spectra at lower photon energies (Fig. 4) with a clear onset T at 5.9±0.1 eV corresponding to the ionization threshold. The binding energies of these spectral features are listed in Table 2.

We now analyze these spectra with the aid of the calculated band structure of PDMS and the theoretical and experimental results of the relevant compounds.

The calculated band structure of PDMS is shown in Fig. 1(b). The highest occupied bands 9+9′ originate from interacting Si-Si bonds, as in polysilane. The

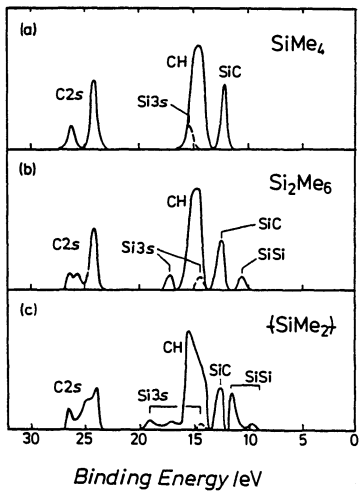

Fig. 5. Calculated density of states of $Si(CH_3)_4$ (a), $Si_2(CH_3)_6$ (b), and poly(dimethylsilane) (c).

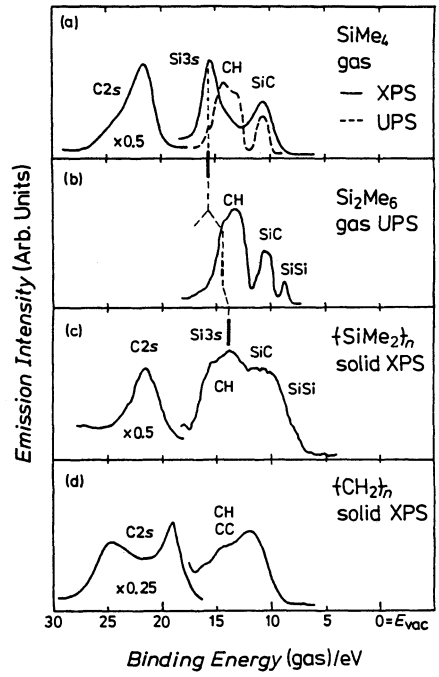

Fig. 6. Photoelectron spectra of permethylated silanes[10,34,35] and n-$C_{36}H_{74}$.[36] Solid state spectra are shifted by 1.0 eV for compensating the polarization energy. The location of the upper edge of the Si3s band is indicated.

dispersion is also farily similar to that of polysilane. The next bands 8+8′ are derived from the Si-C bonds. The next four pairs of narrow bands 4+4′—7+7′ at 15 eV originate mainly from the C-H bonds. The linear combination of Si3s orbitals form the wide band 3+3′ at ca. 17 eV. The character analysis of the bands revealed that the top of the Si band is not in 3′ at k=0 but in 6′ at k=0. This splitting originates from the avoided crossing with the CH bands with the same symmetry. Finally, the two pairs of bands 2+2′ and 1+1′ around 25 eV are derived from the C2s orbitals.

The DOS of PDMS obtained from this band calculation is shown in Fig. 3 (c) with the characters of the contributing bands. Further, in Fig. 5 we compare this DOS with those of $Si(CH_3)_4$ and $Si_2(CH_3)_6$. For the latter two, the functions located at MO binding energies are convoluted with a Gaussian function of 0.7 eV FWHM for simulating the photoelectron spectra.

As a counterpart from experimental observations, in Fig. 6 we compare our XPS and UPS spectra with the reported photoelectron spectra of permethylated silanes[10,34,35] and a long alkane n-$C_{36}H_{74}$,[36] a good model compound of polyethylene. The binding energies of the features in these spectra are listed in Table 2. The characters of each band in the reported spectra are taken from the original papers.

It is known that the photoelectron spectrum of a molecular solid fits well with the gas phase spectrum of a constituent molecule, when due allowance is made for a shift in the binding energy scale and for peak broadening.[37] Thus we can compare the observed XPS and UPS results of solid state with the gas-phase spectra and theoretical calculations (for an isolated chain) by rigidly shifting the energy scale. Since the shift comes from the polarization of the molecules surrounding the cation, it is called the polarization energy.[38] In Fig. 6, the solid spectra are shifted by 1.0 eV, which is a common value observed for other compounds.[39] In Fig. 5, the calculated DOS is shifted by 2.5 eV for the best overall fit with the XPS and UPS results. This shift contains contributions from the polarization energy and from the shift described in Calculation.

From Figs. 5 and 6, the intense feature D in the XPS spectrum can be easily assigned to the calculated C2s bands 2+2′ and 1+1′, the latter probably corresponding to the tail at the higher-binding-energy side. The observed width (FWHM 3.3 eV) is much smaller than that of polyethylene (7.6 eV at half height) (Fig. 6(d)). Correspondingly, the calculated total width of the 1+1′ and 2+2′ bands are much smaller than that of the 1+1′ band of polyethylene. This difference can be explained by the fact that the interaction among the C2s orbitals is small in PDMS where the carbon atoms are not directly bonded, while the interaction is strong in the directly-bonded carbon chain of polyethylene.

In discussing the lower binding energy region, we at first note that the photoionization cross section of the Si3s orbital is almost negligible in the UPS region, as can be seen from a comparison of the XPS and UPS spectra of $Si(CH_3)_4$ in Fig. 6(a). Thus, we can analyze the UPS spectra in terms of the bands derived from the CH-, SiC-, and SiSi-bonds.

The calculation shown in Fig. 1(b) indicates that these bands do not overlap. In particular, each CH- and SiC-derived band shows a small dispersion. Reflecting this situation, the energies of the DOS peaks of CH and SiC character in Fig. 5 are almost

independent of the silicon number, m.

The trends in the UPS spectra of $Si(CH_3)_4$ and $Si_2(CH_3)_6$ in Fig. 6 verify this theoretical expectation. The CH-, SiC-, and SiSi-peaks are well separated, and the energies of the former two are almost the same. We can thus assign peaks C, B, and A in the UPS spectra of PDMS to the CH-, SiC-, and SiSi-bands, respectively.

Next we discuss the levels derived from the Si 3s orbitals. The band calculation of PDMS in Fig. 1(b) shows a large dispersion of the Si3s-derived bands 3+3′, which corresponds to the strong 3s-3s interaction by the Si-Si bonds. This situation can also be seen as an increasing splitting of the DOS peaks in Fig. 5 with increasing m (note that the upper edge of the Si3s band is at 6′ at k=0). Thus, we expect a significant overlap of the CH- and Si3s-derived bands.

By comparing the UPS and XPS spectra in Figs. 2(a) and (b), we find that the upper-binding-energy part of peak C in the UPS spectrum becomes enhanced as C1 in the XPS spectrum. Thus. we can assign this enhanced peak to the upper edge of the Si3s band, and the broad background peak C1+C2 to the CH bands. The shift of the Si3s level from that of $Si(CH_3)_4$ (ca. 2 eV) due to the band formation is a little smaller than the corresponding value for polysilane (ca. 3 eV), in accordance with the calculation. The lower edge of the Si3s band is difficult to distinguish, even in the XPS spectrum. It may be buried in the tail of the intense C2s band on the low-energy side.

Finally, we discuss the inductive effect of the methyl groups. It shifts the Si-Si and Si3s levels of PDMS to a lower binding energy than those of polysilane. This shift is evaluated to be 1.6 eV from a comparison of the observed spectra of oligomers, while calculations in Fig. 1 gives a value of about 1 eV. A similar shift is also found in a recent calculation on alkyl-substituted polysilanes.[13]

Ionization Thresholds and Electrical Conductivity. Two important parameters of the uppermost band in discussing the electrical conductivity of polymers are (i) the energy of the upper edge (ionization threshold energy) and (ii) the bandwidth. The former is related to the feasibility of carrier (hole) generation by acceptor doping, while the latter is a measure of the degree of delocalization in a single chain.

In Table 3, we compare the solid ionization thresholds I_s^{th} and the widths of the highest occupied bands of PDMS, polysilane, and polyethylene.[40] Relevant data of poly(p-phenylene)[32] and polyacetylene[41] are also included as representatives of conduct-

Table 3. Ionization Threshold Energies and Bandwidths of Polysilane, PDMS, and Related Polymers (in eV)

Polymer	I_s^{th}/eV	Width of the highest occupied band
PDMS	5.9	2.0[e]
Polysilane	(7.5)[a]	2.0[e]
Polyethylene	8.5[b]	4.0[f]
Polyacetylene	5.24[c]	5—6[c]
Poly(p-phenylen)	5.6$_5$[d]	3.9[d]

a) Estimated from the value of PDMS assuming a shift of 1.6 eV. b) Ref. 40. c) Ref. 41. d) Ref. 32. e) Estimated from the UPS spectra of oligomers. f) Ref. 27.

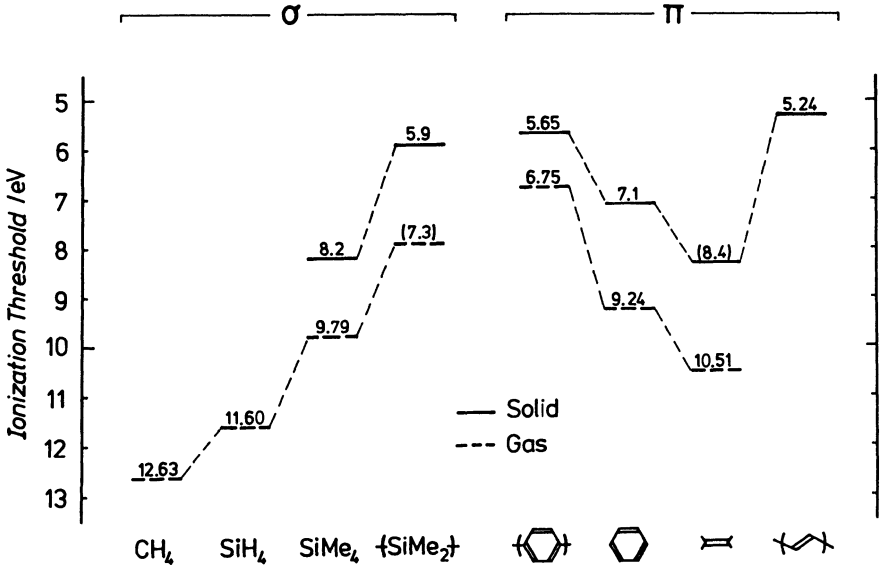

Fig. 7. Ionization thresholds of σ-conjugated silanes and π-conjugated hydrocarbons. For comparison, the data of CH_4 is included in the σ-system. The data in the parentheses are estimated by assuming a gas-to-solid difference in the adjacent compound in the figure. Values not listed in Tables 2 and 3 are taken from the following: CH_4: Ref. 43 (gas); $Si(CH_3)_4$: Ref. 44 (solid); poly(p-phenylene): Ref. 32 (gas); benzene: Refs. 43 (gas) and 45 (solid); ethylene: Refs. 43 (gas) and 46 (solid).

ing polymers with a π-conjugated carbon principal chain. The ionization threshold of polysilane is estimated from the value of PDMS, assuming a 1.6-eV shift due to the inductive effect by the methyl groups. Although a precise determination of the band widths is difficult for PDMS and polysilane, we can still estimate them to be of the order of ca. 2 eV from the spectra of PDMS (Fig. 4) and oligomers. The value of polyacetylene was also deduced from the data of oligomers.[42]

In Table 3 we can see that the threshold of polysilane is 1 eV smaller than that of polyethylene due to the smaller electronegativity of Si than C (as discussed above). Further, the value of PDMS is 1.6 eV smaller than that of polysilane by the inductive effect of methyl groups, and almost comparable to that of poly(*p*-phenylene). However, it is still significantly larger than that of polyacetylene, which can be doped with iodine. This is consistent with the experimental results that doping of PDMS needs strong acceptors, such as AsF_5 and SbF_5.[1]

In Fig. 7 the change of ionization thresholds of σ-conjugated systems from CH_4 to PDMS are compared with analogous change in π-conjugated hydrocarbon systems. In the latter, the orbital energies of the highest occupied orbital is lowered by a strong (4 to 5 eV bandwidth) π conjugation. Note that the ionization threshold of the solid polymers are smaller than the value of gas phase due to the polarization energy.

The bandwidths of polysilane and PDMS are less than those of π-conjugated polymers. However, such bandwidths should still be sufficient for realizing a good intrachain conductivity, since they are already much larger than the bandwidths of conducting molecular complexes.[47] Therefore, the origin of the limited conductivity of doped PDMS (7×10^{-3} S cm^{-1})[1] may be a small interchain conductivity. Although permethylation is advantageous for a high intrachain conductivity by lowering the ionization threshold, the methyl groups hinder the hole transport from chain to chain. The increased conductivity of photo-crosslinked polymers[1] supports this idea. Another possible way of increasing the interchain conductivity will be the partial substitution of PDMS by some pendant group which can "shake hands" to transport the holes. However, the conductivities of doped phenyl-substituted PDMS are lower than that of doped PDMS.[1] Therefore, the choice of an appropriate pendant for such a purpose needs further consideration.

Concluding Remarks

In this paper we reported a combined theoretical and experimental study of polysilane and poly(dimethylsilane) (PDMS). Observed XPS and UPS spectra of PDMS could be analyzed in a detailed way by theoretical band calculations. Further, a comparison with oligomers confirmed the assignments and also revealed how the electronic structures of these polymers evolve from those of constituent units. Such a successful use of oligomers for studying the Si-backboned polymers is an extension of similar studies for polymers with carbon-derived backbones, where the usefulness of oligomers has been already well demonstrated.[27,30-32]

Polysilane and PDMS have rather small ionization energies due to the small electronegativity of Si, σ-delocalization and the inductive effect of methyl groups. Although the one-dimensional delocalization makes the ionization energy still larger than that of a three-dimensionally connected Si solid (5.35 eV),[48] the value of PDMS is already comparable to those of π-conjugated carbon-derived polymers. This fact explains the good conductivity to PDMS and its derivatives upon doping. Further, the linear structure offers useful properties such as the solubility to organic solvents.

Thus, the introduction of Si as a constituent atom of the principal chain offers an exciting prospect for designing materials of interesting electronic properties. Although in this work we have dealt with the most basic two polymers of this group, other interesting derivatives, e.g. with π-pendants, have also been synthesized.[1] A study of the electronic structures of such polymers will give more insight into the full possibilities of polysilanes. The work of Loubriel and Zeigler[14] pioneered this direction, and recently we have also examined the chain-pendant interaction in poly(methylphenylsilane) in some detail.[49]

We thank Dr. Kyozaburo Takeda of Nippon Telegram and Telephone Corporation for helpful discussions. The Photocatalytic Activity of a Platinized Titanium Dioxide Catalyst Supported over Silica

Kazunari DOMEN, Yoshihisa SAKATA, Akihiko KUDO, Ken-ichi MARUYA, and Takaharu ONISHI*
Research Laboratory of Resources Utilization, Tokyo Institute of Technology,
4259 Nagatsuta, Midori-ku, Yokohama 227
(Received July 4, 1987)

The effect of the amount of TiO_2 loading on the photocatalytic activity of H_2 evolution from aqueous methanol solution over a platinized TiO_2/SiO_2 catalyst was studied. UV diffuse reflectance spectra of TiO_2/SiO_2 showed the blue shift of absorption edge for the catalyst of lower amount of TiO_2 loading, which suggested the higher dispersion of TiO_2 on SiO_2. The activity decreased monotonously with the decrease of the amount of TiO_2 loading over SiO_2, i.e. with the increase of the dispersion.

Various photo-induced reactions over TiO_2 powder have been studied by many workers. For example the photo-oxidation of hydrocarbons by O_2,[1,2] photo-adsorption and desorption of O_2,[3-5] and hydrogenation of unsaturated hydrocarbons[6,7] were reported. On the other hand, the platinized TiO_2 powder is known as an effective photocatalyst for some reactions, such as photo-Kolbe reaction[8,9] and the H_2 evolution from aqueous solutions containing organic compounds.[10,11] In the latter system, the catalyst is generally regarded as a micro-photoelectrochemical cell. In that model, both the electron in the conduction band and the hole in the valence band are produced by the band gap irradiation, and then the excited electron reduces a reactant over the platinum surface, and the hole oxidizes a reactant over the TiO_2 surface. Therefore the electron and the hole have to be separated and to migrate to those reaction sites. On such "charge-separation" type reactions, the effects of the particle size[12,13] and also the crystal structures of TiO_2 (anatase, rutile, or amorphous)[14,15] upon the photocatalytic activities were reported.

Recently Anpo et al. studied the photocatalytic activities of hydrogenation of unsaturated hydrocarbons with H_2O over titanium-silicon oxides[16] and titanium oxide anchored onto porous Vycol glass.[17] They concluded that the high dispersion of titanium oxide resulted in the high activity for the reaction. In their system, localized electron-hole pair excited by photon seems to be an active species. For the "charge-separation" type reaction, however, the effect of the loading of the photoactive materials over an insulator with a large surface area has been scarcely studied.[18,19] In this paper, the activity of platinized TiO_2 supported over SiO_2 for the H_2 evolution from aqueous methanol solution is reported.

Experimental

A titanium sulfate solution (24.0% as $Ti(SO_4)_2$) was purchased from Kanto Chemical Co. and hexachloroplatinic acid was obtained from Wako Pure Chemical Ind. SiO_2 with ca. 200 $m^2 g^{-1}$ of BET surface area (Degussa) was used. A TiO_2/SiO_2 catalyst was prepared by an impregnation method: SiO_2 powder impregnated with aqueous titanium sulfate solution was stirred for 1 h and then it was dried by a rotary evaporator, followed by calcination at various temperatures for 2 h in air.

The reaction was carried out using a closed gas circulation system (ca. 300 ml) attached with a vacuum line. A reaction vessel (200 ml) made of Pyrex glass was irradiated through a flat window. An aqueous methanol solution suspended with the catalyst was stirred magnetically. The measurement of the activity of the H_2 evolution was carried out as follows. The aqueous methanol solution (typically 100 ml of methanol and 100 ml of water) containing TiO_2/SiO_2 and H_2PtCl_6 was degassed until no air peaks were detected in the gas phase by gas chromatography. Then, the solution was irradiated by an Xe lamp (USHIO, UXL 500D-O, 500 W), which was used at 300 W for obtaining a stable intensity of light for a long time. The amount of evolved H_2 was measured by gas chromatography (MS 5A column, Ar carrier) attached directly to the closed circulation system.

Catalysts were characterized using X-ray diffraction (Rigaku), X-ray photoelectron spectroscopy (Shimadzu, ESCA-750) and UV diffuse reflectance spectroscopy (JASCO UVIDEC-505). The surface area of the catalyst was determined by BET measurement. The quantum yield at 365 nm was measured using a monochrometer (H. 20, ISA JOBIN YVON Instrument) and thermopile (The Eppley Laboratory Inc.)

Results and Discussion

Characterization of TiO_2/SiO_2 Calcined at Various Temperatures. SiO_2 impregnated with aqueous $Ti(SO_4)_2$ solution was dried and calcined at various temperatures. Titanium sulfate began to decompose at about 673 K. In Table 1, the BET surface areas and

Table 1. BET Surface Areas and Ratios of XPS Peak Area of TiO_2(5 wt%)/SiO_2 Calcined at Various Temperatures

Calcination temperature	BET surface area	Ratio of peak area	
K	$m^2 \cdot g^{-1}$	Ti/Si	O/Si
673	126	0.61	0.73
833	170	0.61	0.70
998	180	0.56	0.70
1073	170	0.55	0.72

The surface area of SiO_2 used in the experimental was 202 $m^2 \cdot g^{-1}$.

the results of XPS of TiO_2(5 wt%)/SiO_2 calcined at various temperatures are shown. The surfase area increased with the increase of calcination temperature from 673 K to 833 K and it was almost constant above 833 K. Sulfur was observed on the sample calcined at 673 K by XPS, while no sulfur remained on those calcined above 998 K.

The signal intensity ratio of Ti(2p3/2)/Si(2s), decreased ca. 10% at high calcination temperatures (998 K and 1073 K), probably due to the sintering of supported TiO_2, which resulted in the decrease of the surface area. In the X-ray diffraction (XRD) pattern, no clear peak of TiO_2 was observed in TiO_2 (5 wt%)/SiO_2 at any calcination temperatures.

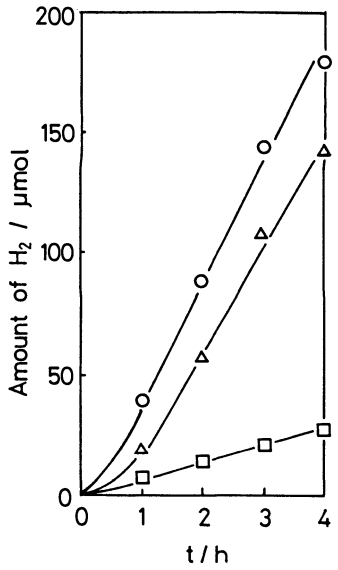

Fig. 1. H_2 evolution from aqueous methanol solution (50 vol%) over Pt-TiO_2/SiO_2 catalysts. ○: Pt(1 wt%)-TiO_2(2 wt%)/SiO_2, △: Pt(0.5 wt%)-TiO_2(2 wt%)/SiO_2, □: Pt(0.1 wt%)-TiO_2(2 wt%)/SiO_2, catalyst: 0.5 g, solution: 200 ml, an Xe lamp (500 W) was used at 300 W.

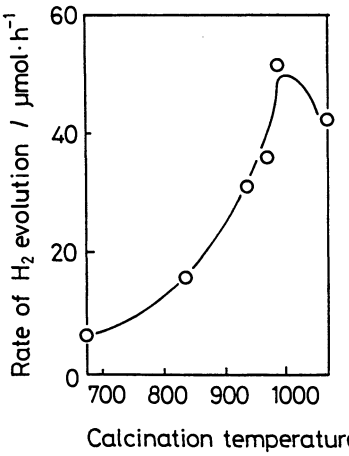

Fig. 2. Dependence of the rate of H_2 evolution from aqueous methanol solution (50 vol%) over Pt-(1 wt%)-TiO_2(5 wt%)/SiO_2 upon the calcination temperature for TiO_2/SiO_2. Catalyst: 0.5 g, solution: 200 ml.

Dependence of the Activity upon the Calcination Temperature of TiO_2/SiO_2. Typical H_2 evolution behaviours are shown in Fig. 1. The rate of the H_2 evolution was a little slower at the beginning than that at the steady state, probably due to the reduction of platinum. Therefore, the rate of the H_2 evolution at the steady state was regarded as the activity of the catalyst.

The dependence of the activity of the Pt (1 wt%)-TiO_2 (5 wt%)/SiO_2 catalyst upon the calcination temperature of TiO_2/SiO_2 is shown in Fig. 2. Pt (1 wt%)-TiO_2 (5 wt%)/SiO_2 denotes the catalyst which contains 1 wt% of Pt against TiO_2, and 5 wt% of TiO_2 against SiO_2. The activity increased markedly with the increase of the calcination temperature up to 998 K, and decreased slightly at higher temperature. Thus, in this study all the catalysts were calcined at 998 K.

UV Diffuse Reflectance Spectra of TiO_2/SiO_2. In Fig. 3, UV diffuse reflectance spectra of TiO_2/SiO_2 samples calcined at 998 K are shown. With the decrease of the amount of TiO_2, the absorption edge shifted monotonously to shorter wavelength. Similar blue shifts were previously reported in TiO_2/SiO_2 mixed oxide[16] and TiO_2 anchored on porous Vycor glass.[17] This phenomenon is interpreted by the so-called quantization effect,[20,21] which arises from the confinement of charge carriers in a semiconductor of a small volume. Thus, the blue shift of absorption spectra shown in Fig. 3 could be attributed to the change of the dispersion of supported TiO_2 on SiO_2, i.e. for the lower loading of TiO_2, higher dispersion

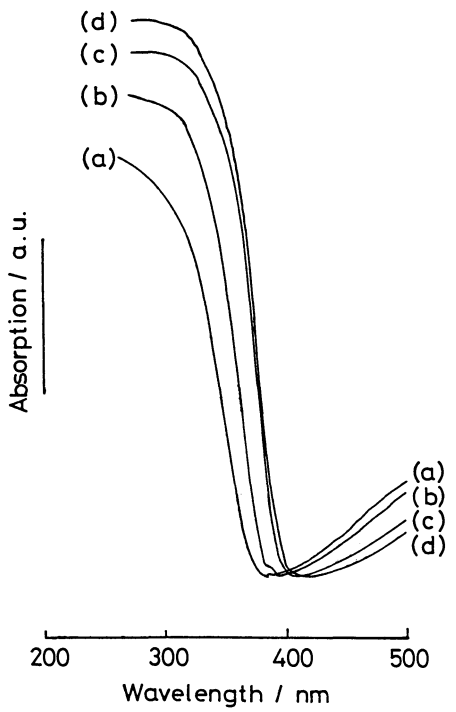

Fig. 3. UV diffuse reflectance spectra of various TiO_2/SiO_2 catalysts calcined at 998 K. (a); TiO_2(0.5 wt%)/SiO_2, (b); TiO_2(2 wt%)/SiO_2, (c); TiO_2(10 wt%)/SiO_2 (d); TiO_2(20 wt%)/SiO_2.

was achieved and, electrons and holes were confined in a smaller volume of TiO_2. Thus, it is concluded that TiO_2 is supported on SiO_2 and that the degree of the dispersion is controlled by changing the amount of the loading of TiO_2.

Dependence of the Activity upon the Amount of Pt Supported on TiO_2/SiO_2. The dependence of the activities upon the amounts of supported Pt over several kinds of TiO_2/SiO_2 catalysts are shown in Fig. 4. The activities increased in proportion to the amounts of supported platinum in the region of small platinum loading on TiO_2. This may suggest that most part of Pt, added as H_2PtCl_6, was reduced and worked as the catalyst for the H_2 evolution on TiO_2. In the higher loading region, the activities decreased gradually with the increases of the amounts of platinum. Since the color of the catalyst changed from gray to dark gray or black with the increase of Pt loading, one of the reasons for the decrease of the activity is due to the decrease of the amount of photons absorbed in TiO_2 because of the absorption of UV photons by Pt metal particles. Another one is the increase of the possibility of the recombination of an electron and a hole over platinum.

The optimum amount of Pt was different in each catalyst, as shown in Fig. 4. With the decrease of the amount of supported TiO_2 over SiO_2, the optimum ratio of Pt to TiO_2 increased.

Comparison of the Intrinsic Photocatalytic Activities of the H_2 Evolution among Pt-TiO_2/SiO_2 Catalysts. To compare the intrinsic photocatalytic activities, the amount of Pt loading was fixed at the value

which each catalyst showed the maximum activity as indicated in Fig. 4. Figure 5 depicts the dependence of the rates of the H_2 evolution upon the amounts of catalysts in aqueous methanol solution. For all catalysts, the activity increased with the increase of the amount of the catalyst and reached the value which was almost independent of the amount of the catalyst. Under the condition of the saturated amount of catalyst, almost all photons, which had larger energy than the band gap of TiO_2 and entered into the reaction vessel, should be absorbed by TiO_2 although a small part of photons might go out by scattering. Therefore, the rate at the saturated amount of the catalyst was regarded as the intrinsic activity for the Pt-TiO_2/SiO_2 catalyst, which was normalized by the number of the absorbed photons. It should be noted that the number of the absorbed photons is different in each catalyst, because the UV absorption edge shifted to the shorter wavelength region with the decrease of TiO_2 loading as shown in Fig. 3. It was estimated that TiO_2 (0.5 wt%)/SiO_2 absorbed by about 30% smaller number of photons than TiO_2 (20 wt%)/SiO_2 did. On the other hand, the activity of TiO_2 (20 wt%)/SiO_2 was higher by ca. 3 times than that of TiO_2 (0.5 wt%)/SiO_2 under the same irradiation condition as shown in Fig. 5.

Thus, it is concluded that the activity of the H_2 evolution decreased monotonously with the decrease of the amount of supported TiO_2 over SiO_2. In other words, a higher dispersion catalyst exhibited the quantum efficiency of H_2 evolution lower than the lower dispersion catalyst did. In Table 2, the quantum yields are also summarized. This result is seemingly contra-

Table 2. Comparison of the Maximum Activities over Various TiO_2/SiO_2 Catalysts

Catalysts	Amounts of catalyst[a)]	Pt wt%	Amounts of TiO_2 on SiO_2	Rate of H_2 evolution	Quantum yield
	g/200 ml	wt%/TiO_2	g/200 ml	10^{-6} mol · h^{-1}	% at 365 nm
TiO_2(0.5wt%)/SiO_2	2.5	10	0.0125	29	8
TiO_2(2wt%)/SiO_2	2	2.5	0.04	58	16
TiO_2(10wt%)/SiO_2	1	0.5	0.1	86	23
TiO_2(20wt%)/SiO_2	0.5	0.25	0.1	132	35

a) The amounts of catalysts are indicated by arrows in Fig. 5.

dictory to those previously reported, i.e. the high efficiency of highly dispersed TiO_2 in SiO_2[16] and also anchored onto porous Vycor glass[17] for hydrogenation of alkyne with water. The active species for alkyne hydrogenation was regarded as localized electron-hole pairs. On the other hand, in the present case, electrons and holes have to be separated well enough to react with substrates at different sites, i.e. Pt and TiO_2 surfaces. As the detailed structure of the catalyst, Pt-TiO_2/SiO_2, is not clear one can only surmise the explanation of the result. One of the interpretations for the decrease of the activity at low TiO_2 loading region may be the low efficiency of the electron transfer from the conduction band of TiO_2 into Pt particles, which might be caused by the formation of mixed oxide of TiO_2 and SiO_2 due to the calcination at 998 K. If a part of loaded TiO_2 formed the mixed oxide with SiO_2, the diffusion length of the conduction band electron could be reduced and the effect would be more dominant for the lower TiO_2 loading catalyst.

Thus, the high dispersion of a photoactive material over an inert material with a large surface area does not simply result in the increase of the efficiency of the photocatalytic reaction for the "charge-separation" type reaction. To reveal the reason for the low efficiency of the highly dispersed TiO_2 on SiO_2, the detailed structual study of the catalyst will be of importance.

We thank Prof. Yasuhiro Iwasawa and Dr. Tetsuya Aruga, Faculty of Science, The University of Tokyo, for the measurements of UV diffuse reflectance spectroscopy.

A Consideration of the Charge Density of Polyelectrolytes Based on a Layer Model in Solution

Tetsuo KANEKO
1-16, Kogane, Kazusa-cho, Matsudo-shi, Chiba-ken 270
(Received July 10, 1987)

In a model system where layers formed by aggregations of polyelectrolyte molecules are mutually parallel in a solvent, the surface-charge density of the layers is estimated by solving the one-dimensional Poisson-Boltzmann equation. The surface-charge density at a over temperature, T, can be determined depending on the number, n_g, of charged groups per unit of the volume in a layer of polyelectrolytes and on the thickness, Δx, of the layer, if the distance between layers of polyelectrolyts is sufficiently large. This surface-charge density is evaluated by assuming that n_g is given by the reciprocal of the cubed mean length between neighboring charged groups in a polyelectrolyte molecule and that Δx is of the order of an ion diameter, possibly including the hydration sheath. The surface-charge density given by the layer model agrees well with that semiempirically given by a rod-like polyelectrolyte model. Also, the ratio of the total charge of a layer to the total charge of the charged groups in the layer agrees well with the degree of the ionic dissociation of ionene polymers in a salt-free solution.

Polyelectrolytes in aqueous solutions form a strong electric field which attracts counter ions, because the molecules of the polyelectrolytes have ionizable groups with high densities. Because of the strong electric field, counter ions may condense in the charged macromolecules, and counter ions condensed in polyions may affect the charge density of the polyions. In order to interpret some properties of polyelectrolyte solutions as exhibited in the phenomenon of osmotic pressure, it is important to know the charge density of polyions. The phenomenon of the condensation of counter ions due to polyions is well-known,[1] although the charge density of polyions after the condensation of counter ions has not yet been obtained obviously on a priori grounds. Lately, Manning deduced that the condensation of counter ions on polyions composed of wormlike chains depended on the charge (of charged groups) per unit of length in a chain of polyelectrolytes.[2] If the solution of the Poisson-Boltzmann equation can be obtained in a system consisting of not freely mobile charges and freely mobile ions, the charge density of the polyion should be given. Manning noted that the statistical-mechanical phase integral for an infinite line-charge model diverges for all values of a uniform linear-charge density greater than the critical value, and he was able to estimate the condensation of counter ions on a polyion,[2] although he did not solve the Poisson-Boltzmann equation.

The purpose of the investigation in this paper is to determine the polyion-charge density by solving the Poisson-Boltzmann equation. Although the Poisson-Boltzmann equation is not readily solved, an analytically rigorous solution of the one-dimensional Poisson-Boltzmann equation for two parallel charged plates in a solution containing only counter ions has been given by Engström and Wennerström.[3]

The polyelectrolyte solution model treated in this investigation is a system in which the layers formed by aggregations of polyelectrolyte molecules are immersed in a solvent and in which the layers are parallel to each other. The charge density of the polyions in this investigation is taken as the surface-charge density on these layers; this surface-charge density is obtained by using an analytically rigorous solution given by Engström and Wennerström. The magnitute of the surface-charge density in this paper is determined from the electrostatic interaction between a polyion and counter ions. Knowledge with respect to its magnitude determined by means of the contribution of the electrostatic interaction would be useful in ascertaining the dominant factor which determines polyion-charge density. Thus, it would be valuable to estimate the surface-charge density attributable to the electrostatic contribution, although the surface-charge density in the rod-like polyelectrolyte model of Lifson and Katchalsky[4] can be estimated by using an experimentally given osmotic coefficient.

The density, n_g, of charged groups of polyelectrolytes taken into the model used in this paper is the number of charged groups per unit of volume in an aggregation of polyelectrolytes. A net-like polyelectrolyte, an ion-permeable membrane (which contains ionizable groups in its structure), etc. can be regarded as aggregations of the chains of polyelectrolytes. Therefore, their surface-charge density in water may be readily estimated if the surface-charge density of an aggregation of polyelectrolytes can be determined as a function of n_g. In addition, the thickness of a layer formed by the aggregation of polyelectrolytes must be determined in order to estimate the surface-charge density. It is considered, becuase of the size of the charged groups, that this layer thickness should have a minimum value which is not zero. The surface-charge density of a layer is estimated by assuming the minimum thickness of a layer and a sufficiently large distance between layers. As a result, it is found that the ratio of this surface-charge density to the charges attributed to charged groups in the layer is comparable with the degree of the ionic dissociation of ionene

polymers.[5]

Model

Structure of a Layer Model. A model which represents polyelectrolyte solutions as charged plates immersed in a simple salt solution has been used in order to describe the properties of polyelectrolyte solutions.[6] In this investigation, instead of the charged plates, layers consisting of polyelectrolytes are placed in a solvent, and layers of a salt-free solution interleave the layers of polyelectrolytes, as is shown in Fig. 1. This polyelectrolyte-solution model of the layer structure may be described as follows:

1) A model system is comprised of many layers consisting of layers of polyelectrolytes and layers of the solution, and these layers are parallel to each other.

2) The distances between the layers of polyelectrolytes equal $2a$.

3) All the layers of polyelectrolytes are Δx thick.

4) The number of charged groups per unit of volume in all layers of polyelectrolytes is n_g.

Electrostatic Potential. The electrostatic potential, ψ, in this layer model is described by the one-dimensional Poisson-Boltzmann equation. In accordance with the assumption of a salt-free solution, the Poisson-Boltzmann equation (SI units) within the layer of polyelectrolyte (Region 1 : $0 \leqq x \leqq \Delta x/2$) is:

$$\frac{d^2\psi_1}{dx^2} = -\frac{1}{\varepsilon}\cdot\{-z'e n_g + z e n_0 \exp[-ze\psi_1/kT]\}, \quad (1)$$

while outside the layer of polyelectrolytes (Region 2: $\Delta x/2 \leqq x \leqq 2a+\Delta x/2$) it is:

$$\frac{d^2\psi_2}{dx^2} = -\frac{z e n_0}{\varepsilon}\cdot \exp[-ze\psi_2/kT], \quad (2)$$

where ze is the charge of a counter ion, $-z'e$ is the charge of a charged group, n_0 is a normalization constant, ε is the dielectric constant of the pure solvent, k is Boltzmann's constant, and T is the absolute temperature. In addition, it has been assumed that the dielectric constant within a layer of polyelectrolytes is the same as that outside.

The boundary conditions for Eq. 2 are:

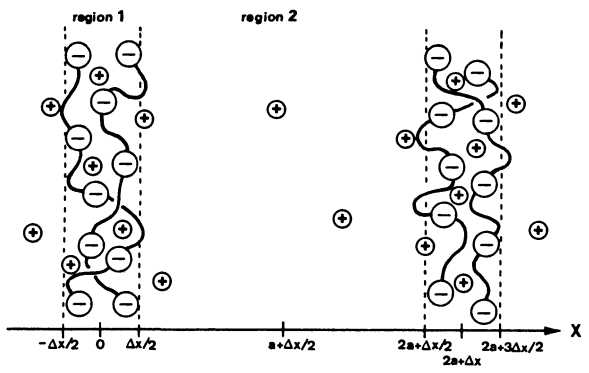

Fig. 1. Layer model of polyelectrolyte solution. Charged groups and counter ions are represented by (−) and (+) respectively.

$$\psi_2(a+\Delta x/2) = 0, \quad -\left.\frac{d\psi_2}{dx}\right|_{x=a+\Delta x/2} = 0,$$

and:

$$-\left.\frac{d\psi_2}{dx}\right|_{x=\Delta x/2} = \left.\frac{d\psi_2}{dx}\right|_{x=2a+\Delta x/2} = -\frac{\sigma}{\varepsilon}, \quad (3)$$

where $-\sigma$ is the surface-charge density on a polyelectrolyte layer.

A rigorous solution for Eq. 2 can be obtained analytically by integrating Eq. 2 twice in a manner similar to that in which a rigorous solution for two parallel charged plates was given by Engström and Wennerström.[3] As a result, the electrostatic potential in the Region 2 ($\Delta x/2 \leqq x \leqq a+\Delta x/2$) is given as follows:

$$\psi_2 = \frac{2kT}{ze}\cdot \ln\{\cos\frac{s}{a}\cdot((a+\frac{\Delta x}{2})-x)\}, \quad (4)$$

where $$s \equiv a\cdot\left(\frac{n_0 z^2 e^2}{2kT\varepsilon}\right)^{1/2}$$

On the basis of Eq. 3 and the first derivative of Eq. 4, the dimensionless parameter s can also be represented as:

$$s\tan s = \frac{\sigma z e a}{2kT\varepsilon}, \quad (5)$$

and for a sufficiently large value of the right side of Eq. 5, s approaches $\pi/2$; then the above formula becomes:

$$\tan s = \frac{\sigma z e a}{\pi kT\varepsilon}. \quad (6)$$

On the other hand, it is difficult to solve Eq. 1 analytically and rigorously. On the basis of a perturbation method used by Lifson in order to obtain an approximate analytical solution for the electrostatic potential of spherical polyelectrolytes,[7] an approximate solution of Eq. 1 can, however, be obtained.

A first approximation, v, to ψ_1 in this perturbation method means that the total charge density is zero everywhere; v must satisfy:

$$\frac{d^2v}{dx^2} = 0, \quad (7)$$

Moreover, in order to satisfy Eq. 1 v should be:

$$v = -\frac{kT}{ze}\ln f, \quad (8)$$

where:

$$f \equiv \frac{z' n_g}{z n_0}.$$

A correction function, w, for v is defined as satisfying the following equation:

$$\psi_1 = v + w. \quad (9)$$

If Taylor's expansion is carried out as follows:

$$\exp[-\frac{ze\psi_1}{kT}] = \exp[-\frac{ze}{kT}v] - \frac{ze}{kT}\cdot \exp[-\frac{ze}{kT}v]\cdot w + \cdots,$$

when Eq. 9 is substituted into Eq. 1, by considering Eqs. 7 and 8 the following differential equation for w is obtained:

$$\frac{d^2w}{dx^2} = \mu^2 w, \tag{10}$$

where $\mu^2 \equiv zz'e^2n_g/\varepsilon kT$. An approximation of w is given by solving Eq. 10.

The continuity of the electrostatic potential at $x=\Delta x/2$ and the continuity of the electrostatic field at $x=\Delta x/2$ require the following conditions, based on Eqs. 3 and 4:

$$\psi_1(\frac{\Delta x}{2}) = \frac{kT}{ze} \cdot \ln(\cos^2 s) \tag{11}$$

$$-\frac{d\psi_1}{dx}\Big|_{x=\Delta x/2} = -\frac{\sigma}{\varepsilon}.$$

The electrostatic potential, ψ_1, which is obtained by substituting the solution of w from Eq. 10 into Eq. 9 and which satisfies the above conditions, is given as follows:

$$\psi_1 = -\frac{kT}{ze}\cdot\ln f + \frac{kT}{ze}\cdot\{\frac{1}{2}(\ln(\cos^2 s)+\ln f)+\frac{\Lambda\sigma}{\sqrt{2}}\}\cdot \exp[-\mu(\frac{\Delta x}{2}-x)] + \frac{kT}{ze}\cdot\{\frac{1}{2}(\ln(\cos^2 s)+\ln f) - \frac{\Lambda\sigma}{\sqrt{2}}\}\cdot\exp[\mu(\frac{\Delta x}{2}-x)], \tag{12}$$

where $\Lambda^2 \equiv z/(2z'kT\varepsilon n_g)$.

Surface-Charge Density. The demand of electrostatic field continuity in Region 1 ($-\Delta x/2<x<\Delta x/2$) imposes a restriction on the exponential coefficients in Eq. 12. The demand is:

$$-\frac{d\psi_1}{dx}\Big|_{x=0} = 0, \tag{13}$$

because the sign of the electrostatic field at $x>0$ differs from that at $x<0$ in the region close to $x=0$ if the distribution of counter ions on the right side of a layer equals that on the left side of the layer. Equation 13 requires that the exponential coefficients in Eq. 12 satisfy the following equation:

$$\ln f = \sqrt{2}\Lambda\sigma\cdot\{\tanh[\mu\Delta x/2]\}^{-1} - \ln\cos^2 s. \tag{14}$$

The continuity of counter-ion distribution in all regions of the system leads to a formula independent of Eq. 14 on the basis of the electrostatic potential at $x=\Delta x/2$, the second derivative of the potential, and the definition of f. By considering Eq. 11, the density of counter ions $n(x)$ at $x=\Delta x/2$ is:

$$n(\Delta x/2) = n_0\cdot\exp[-\frac{ze\psi_1(\Delta x/2)}{kT}] = \frac{n_0}{\cos^2 s}. \tag{15}$$

On the other hand, by considering Eq. 5, the second derivative of $\psi_2(x)$ given by Eq. 4 yields:

$$n(\Delta x/2) = \frac{\sigma^2}{2kT\varepsilon} + \frac{2kT\varepsilon s^2}{(zea)^2}. \tag{16}$$

If the magnitude of a is of the order of 10^2 Å and the magnitude σ is of the order of 10^{-2} C·m^{-2}, even though the magnitude of s is the maximum $\pi/2$, the second term on the right side of Eq. 16 is much smaller than the first term. Hence, under the condition that the second term can be neglected, the following equation is obtained:

$$n(\Delta x/2) = \frac{\sigma^2}{2kT\varepsilon}. \tag{17}$$

By substituting Eq. 17 into Eq. 15, the following formula is obtained:

$$n_0 = \frac{\sigma^2}{2kT\varepsilon}\cdot\cos^2 s. \tag{18}$$

When, Eq. 18 is substituted into the definition of f,

$$\ln f = -2\ln\Lambda\sigma - \ln\cos^2 s. \tag{19}$$

By equating Eq. 14 with Eq. 19, we obtain the following formula for the surface-charge density of the layer of polyelectrolytes:

$$\frac{\Lambda\sigma}{\ln\Lambda\sigma} = -\sqrt{2}\tanh[\mu\Delta x/2]. \tag{20}$$

In addition, in accordance with the sign on the right side of Eq. 20 and its magnitude, the magnitude of $\Lambda\sigma$ is close to 1 and must satisfy $\Lambda\sigma<1$. Therefore, $\ln\Lambda\sigma$ may be represented approximately as follows:

$$\ln\Lambda\sigma = -2(1-\sqrt{\Lambda\sigma}).$$

On the basis of this approximation and Eq. 20, the surface-charge density can be described as:

$$-\sigma = -\frac{Y}{2\Lambda}\{(Y+2)-\sqrt{(Y+4)Y}\}, \tag{21}$$

where: $Y \equiv 2\sqrt{2}\tanh[\mu\Delta x/2]$.

Parameters in $-\sigma$. Both the surface-charge density, $-\sigma$, given by Eq. 20 and that given approximately by Eq. 21 depend on only three parameters: n_g, Δx, and T, when Eq. 17 is satisfied. f depends on four parameters: n_g, Δx, a, and T, as may be seen in both Eq. 14 and Eq. 19 because s depends on four parameters: n_g, Δx, a, and T, as may be seen in Eq. 5. Hence, the electrostatic potential, the electrostatic field, and the density of counter ions at a certain position x depend on four parameters: n_g, Δx, a, and T.

In order to estimate $-\sigma$, the n_g and Δx parameters must be determined. It is considered that the density n_g must be equivalent to the density of charged groups in a polyion dispersed in a solution, if we are to describe the charged circumstance of the polyion according to the layer model, and it is assumed that, while the distance, b, between neighboring charged groups in a polyion dispersed in a salt-free solution is held constant, charged groups in polyelectrolyte molecules are packed in a layer of polyelectrolytes. Thus, n_g is given as follows:

$$n_g = 1/b^3. \tag{22}$$

The density n_g given by Eq. 22 is regarded as the density approximately equivalent to the density of charged groups in a polyion. In addition, Fujii has found[5] that the distance between neighboring charged groups (obtained by substituting the degree of ionic dissociation, ξ^{-1}, of polyions found experimentally in a sufficiently dilute salt-free solution of ionene polymers into the formula given by Manning: $\xi^{-1}=(e^2/\varepsilon kTb)^{-1}$ (CGS-esu)) is approximately equal to the mean distance between neighboring charged groups in the polyion chain, which is regarded as a freely rotating methylene chain. Therefore, the density n_g, obtained on the basis of Eq. 22 by assuming that the distance, b, between neighboring charged groups in a flexible polyelectrolyte can be taken as the mean distance between neighboring ionizable groups in a freely rotating methylene chain, is used to calculate $-\sigma$ when a polyelectrolyte solution described by the layer model is a sufficiently dilute salt-free solution.

The thickness, Δx, of a layer is another parameter affecting $-\sigma$ and must be determined in order to calculate $-\sigma$. This thickness, Δx, should have a minimum which is not zero because of the size of the charged groups. The most dilute condition in the layer model system corresponds to the condition that Δx is at its minimum and the distance between layers is infinite. Therefore, it is considered that $-\sigma$, compared with the charge density of a polyion in a sufficiently dilute salt-free solution, should be calculated under the condition that Δx is at its minimum; in order to calculate this surface-charge density, $-\sigma$, it is assumed that Δx is at its minimum and that Δx is of the order of an ion diameter, possibly including the hydration sheath, when the polyelectrolyte is flexible.

Results and Discussion

Surface-Charge Density. The electrostatic potential, the electrostatic field, and the density of counter ions in the layer model treated here depend on these parameters: n_g, Δx, a, and T.

The surface-charge density $-\sigma$ depends on these parameters: n_g, Δx, and T, when the magnitude of a is larger than the order of 10^2 Å. Moreover, when the magnitude of Δx is larger than several angstroms, the $-\sigma$ value given by Eq. 21 becomes independent of, Δx, as is shown in Fig. 2. This independence from Δx is hardly affected by the magnitute of n_g, and it is interesting that the magnitude of Δx at which the independence begins to appear nearly equals the order of an ion diameter, possibly including the hydration sheath. The behavior of $-\sigma$, which become independent of Δx, suggests that, although several polyelectrolytes are associated with one another, the charge density of polyions may be invariable in a sufficiently dilute solution.

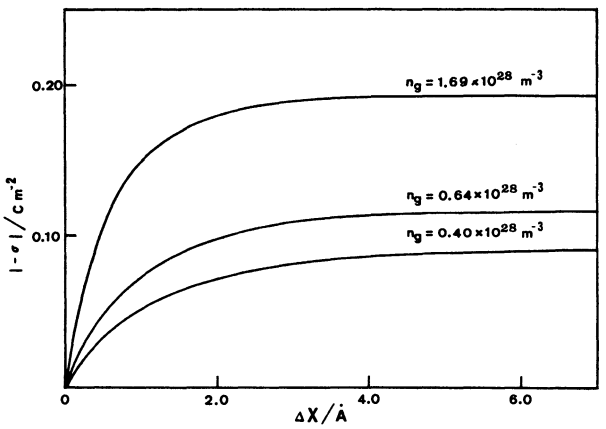

Fig. 2. The dependence of $-\sigma$ on Δx at 298 K on the basis of Eq. 21. The physical meaning of $-\sigma$ is incomplete at the magnitude of Δx which is smaller than a minimum thickness.

Electrostatic Potential. The dependence of the electrostatic potential on a may be seen from the following formulae, which are obtained from Eq. 4 and Eq. 12 by considering Eqs. 6 and 19, when a is sufficiently large: at $0 \leqq x < \Delta x/2$ (in a layer of polyelectrolytes):

$$\psi_1(x) = -\frac{2kT}{ze}\cdot\ln\left(\frac{\sqrt{2}}{\pi}\mu a\right) - \frac{kT}{ze}\cdot\left\{\left(\frac{\Delta\sigma}{\sqrt{2}}+\ln\Delta\sigma\right)\cdot\exp\left[\mu\left(\frac{\Delta x}{2}-x\right)\right] - \left(\frac{\Delta\sigma}{\sqrt{2}}-\ln\Delta\sigma\right)\cdot\exp\left[-\mu\left(\frac{\Delta x}{2}-x\right)\right]\right\} \quad (23)$$

and at $\Delta x/2 \leqq x$ (in the vicinity of the layer surface where $\{\pi(x-\Delta x/2)/2a\}^2 \ll 1$ is satisfied):

$$\psi_2(x) = -\frac{2kT}{ze}\cdot\ln\left(\frac{\sqrt{2}}{\pi}\Delta\sigma\mu a\right)+\frac{2kT}{ze}\cdot \ln\left\{1+\frac{1}{\sqrt{2}}\Delta\sigma\mu\left(x-\frac{\Delta x}{2}\right)\right\}. \quad (24)$$

The increase in the absolute value of the potential in accordance with the increase in a, as noted by Engström and Wennerström,[3] is shown in Eqs. 23 and 24. Equations 23 and 24, however, indicate that the difference in potential $\psi(x_1)-\psi(x_2)$ between the x_1 and x_2 positions which satisfies $\{\pi(x-\Delta x/2)/2a\}^2 \ll 1$ is independent of a.

Electric Field. As is suggested by the property of the potential mentioned above, when a is sufficiently large the electrostatic field $-\varepsilon\,d\psi/dx$ at a position which satisfies $\{\pi(x-\Delta x/2)/2a\}^2 \ll 1$ is independent of a, as is shown in the following formulae:
at $0 \leqq x < \Delta x/2$ (in a layer of polyelectrolytes):

$$-\varepsilon\cdot\frac{d\psi_1}{dx} = \frac{-1}{\sqrt{2}\Delta}\cdot\left\{\frac{\Delta\sigma}{\sqrt{2}}+\ln\Delta\sigma\right\}\cdot\exp\left[\mu\left(\frac{\Delta x}{2}-x\right)\right] - \frac{1}{\sqrt{2}\Delta}\cdot\left\{\frac{\Delta\sigma}{\sqrt{2}}-\ln\Delta\sigma\right\}\cdot\exp\left[-\mu\left(\frac{\Delta x}{2}-x\right)\right], \quad (25)$$

and at $\Delta x/2 \leqq x$ (where $\{\pi(x-\Delta x/2)/2a\}^2 \ll 1$ is satisfied):

$$-\varepsilon\cdot\frac{d\psi_2}{dx} = -\sigma\cdot\left\{1+\frac{1}{\sqrt{2}}\cdot\Delta\sigma\mu\left(x-\frac{\Delta x}{2}\right)\right\}^{-1}. \quad (26)$$

The property of this electrostatic field suggests that the number of counter ions which are distributed within a closed surface covering a polyion and close to the polyion itself is independent of the concentration of polyelectrolytes in a sufficiently dilute salt-free solution.

Density of Counter Ions. As is suggested by the property of the electrostatic field mentioned above, when a is sufficiently large the density of counter ions $n(x)$ at a position which satisfies $\{\pi(x-\Delta x/2)/2a\}^2 \ll 1$ is independent of a, and $n(x)$ is given by the following formulae: at $0 \leqq x < \Delta x/2$ (in a layer of polyelectrolytes):

$$n(x) = \frac{z'}{z} \cdot n_g \cdot \exp\left[\left\{\frac{\Delta\sigma}{\sqrt{2}} + \ln \Delta\sigma\right\} \cdot \exp\left[\mu\left(\frac{\Delta x}{2} - x\right)\right]\right.$$
$$\left. - \left\{\frac{\Delta\sigma}{\sqrt{2}} - \ln \Delta\sigma\right\} \cdot \exp\left[-\mu\left(\frac{\Delta x}{2} - x\right)\right]\right], \quad (27)$$

and at $\Delta x/2 \leqq x$ (where $\{\pi(x-\Delta x/2)/2a\}^2 \ll 1$ is satisfied):

$$n(x) = \frac{1}{\sqrt{2}} \cdot \Delta\sigma\mu \cdot \left(\frac{\sigma}{e}\right) \cdot \left\{1 + \frac{1}{\sqrt{2}} \cdot \right.$$
$$\left. \Delta\sigma\mu \cdot \left(x - \frac{\Delta x}{2}\right)\right\}^{-2}. \quad (28)$$

Equation 27 is given by substituting Eq. 23 into $n_0 \cdot \exp[-ze\psi/kT]$ and by considering Eqs. 6 and 18. Similarly, Eq. 28 is obtained by substituting Eq. 24 into $n_0 \cdot \exp[-ze\psi/kT]$. The property of $n(x)$ mentioned here suggests that the density of counter ions close to a polyion is independent of the concentration of polyelectrolytes in a sufficiently dilute salt-free solution.

Evaluation of $-\sigma$. The surface-charge density $-\sigma$ and the $\sigma/(en_g\Delta x/2)$ ratio, calculated under the conditions that Δx is the minimum thickness and a is sufficiently large, agree well with the polyion-charge density[8] (given by the rod-like model of a polyelectrolyte) and the degree of ionic dissociation[5] of a polyelectrolyte (found experimentally in a sufficiently dilute salt-free solution) respectively, as may be seen in Tables 1 and 2. These results suggest that the layer model is a good approximate description of a polyelectrolyte solution. Also, the charged-groups packing density n_g assumed in the Model and the determination of Δx mentioned in the Model both seem reasonable when a sufficiently dilute salt-free solution of flexible polyelectrolytes is described according to the layer model. As a result, although the layer model is a one-dimensional model system, it seem that this model can lead to a quantitative description of the charged circumstance of a polyion.

The values of $-\sigma$ and σ shown in Tables 1 and 2 were calculated by determining n_g from Eq. 22 and by using Eq. 21, at 298 K. It is assumed that the minimum thickness of a layer of polyelectrolytes is 3 Å,[3] regarded as the order of an ion diameter, possibly including its hydration sheath. $-\sigma_{rod}$ in Table 1 is the surface-charge density given by the rod-like model of a polyelectrolyte. $-\sigma_{rod}$ is obtained by using the dimensionless parameter λ[8] in CGS-esu as follows:

$$-\sigma_{rod} = -(\varepsilon kT/2\pi re) \cdot \lambda,$$

where r is the radius of the rod-like model. λ may be calculated[4] on the basis of the osmotic coefficient of a salt-free polyelectrolyte solution. The λ calculated as described here is $\lambda_{effective}$[8] in Table 1. The $\sigma/(en_g\Delta x/2)$ ratio, shown in Table 2, represents the charged rate of a layer of polyelectrolytes, because σ is the total charge within a cylinder of unit cross section; it ends at $x=0$ and $x=\Delta x/2$ and is parallel to the x-axis.

In the layer model, counter ions permeate into a layer of polyelectrolytes. Consequently, the condensation of counter ions implies that counter ions are condensed between charged groups. The counter ions located between charged groups contribute to the relaxation of the positive electrostatic energy and to the relaxation of tension induced in a methylene chain by the repulsion between charged groups. If it is noted that the $\sigma/(en_g\Delta x/2)$ ratio agrees well with the degree of dissociation ξ^{-1} given experimentally, it may be considered that the counter ions mentioned above are located between the charged groups, even though a

Table 1. $-\sigma_{rod}$ and $-\sigma$ for Polyacrylate at 298 K

α[a]	r / Å	$\lambda_{effective}$	$-\sigma_{rod}$[c] / C·m^{-2}	$-\sigma$[d] / C·m^{-2}
0.8	6	4	−0.24	−0.17

polyelectrolyte solution is a sufficiently dilute salt-free solution.

Conclusion

The layer model of a polyelectrolyte solution treated here has a structure in which layers of polyelectrolytes are arranged in a parallel manner in a solvent. The electrostatic potential, the electrostatic field, and the density of counter ions within and outside the layers are determined on the basis of solutions of the one-dimensional Poisson-Botzmann equation; they depend on the thickness, Δx, of the layers; the distance, $2a$, between the layers; the density, n_g, of charged groups in the layers; and the absolute temperature T. When a is sufficiently large, the electrostatic field and the density of counter ions within a layer of polyelectrolytes become independent of a. Outside the layer also, the electrostatic field and the density of counter ions become independent of a at positions which satisfy $\{\pi(x-\Delta x/2)/2a\}^2 \ll 1$. These results suggest not only that the charge density of a polyion is independent of the concentration of polyelectrolytes in a sufficiently dilute salt-free solution, but also that the distribution of counter ions close to a polyion is independent of thier concentration.

The surface-charge density $-\sigma$ on a layer of polyelectrolytes in the layer model depends only on Δx, n_g, and T, as determined from the properties of the electrostatic field when a is sufficiently large. The surface-charge density $-\sigma$ given by Eq. 21 for polyacrylate when a is sufficiently large is comparable to the $-\sigma_{rod}$ value semiempirically givien by the rod-like model of polyelectrolytes. Also, the charged rate, $\sigma/(en_g\Delta x/2)$, of layers of polyelectrolytes calculated by using the σ value given by Eq. 21 agrees with degree of dissociation of counter ions in salt-free solutions of ionene bromides at an infinite dilution. In addition, it has been assumed that the methylene chain of polyelectrolyte rotates freely and that n_g is given by the reciprocal of the cubed mean length between neighboring ionizable groups in the chain in calculating $-\sigma$ and $\sigma/(en_g\Delta x/2)$; also, it has been assumed that Δx is of the order of an ion diameter, possibly including the hydration sheath.

The surface-charge density $-\sigma$ comparable to $-\sigma_{rod}$ and the $\sigma/(en_g\Delta x/2)$ ratio comparable to the degree of the ionic dissociation of the ionene polymer suggest that, although the layer model is one-dimensional, the charged circumstance of a polyion may be quantitatively described according to the layer model. Therefore, it may be concluded that the layer model can lead to a quantitative estimation of the charged circumstance of a polyion, while $-\sigma$ in the layer model can be determined from Δx, n_g, and T when the solution of polyelectrolytes is salt-free and is sufficiently dilute.

Appendix

The mean distance, $(\overline{d^2})^{1/2}$, between the neighboring ionizable groups in a freely rotating methylene chain is given by the following formula:

$$\overline{d^2} = n l^2 \cdot \left\{\frac{1-\cos\theta}{1+\cos\theta} + \frac{2-\cos\theta}{n} \cdot \frac{1-(-\cos\theta)^n}{(1+\cos\theta)^2}\right\},$$

where n is the number of bonds between neighboring ionizable groups, l is the bond length, and θ is the bond angle. $\overline{d^2}$ is calculated by assuming that both C-C and C-N bond lengths are 1.5 Å, while both C-C-C and C-C-N bond angles are 109.5°.

The author wished to express his thanks to Dr. Kazumi Kogure for her many helpful discussion and to Hideo Mizutani for his valuable discussion.

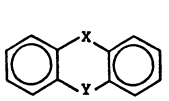
Solution Structure and Preferred Orientation of 3,7-Dibromo-10*H*-phenothiazine Dissolved in Nematic Liquid Crystal†

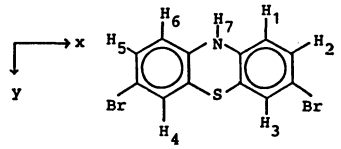
Hideaki FUJIWARA*, Masayuki WATANABE, Iwao YAMANAKA, Tatsuya TAKAGI, and Yoshio SASAKI
Faculty of Pharmaceutical Sciences, Osaka University, 1-6 Yamadaoka, Suita, Osaka 565
(Received August 14, 1987)

The NMR spectrum of the title compound has been measured in nematic phase ZLI1167 and analyzed to obtain the direct couplings. The direct couplings were interpreted by assuming a folded structure of the tricyclic framework. The dihedral angle of the two phenyl rings is determined to be 149.1±2.5° and a value of 170±3° is obtained for the angle of S···N-H. The NH proton is concluded to occupy a "equatorial" position on the central ring in a boat form. The preferred orientation of the molecule in ZLI1167 is discussed by comparing the principal axes of order tensor with those of the moment of inertia.

NMR studies of molecules oriented in liquid crystals provide important information on the molecular structure and preferred orientation in mobile state. These studies for some tricyclic compounds **1** folded along a symmetry axis have proved that the angle of



1
The tricyclic framework

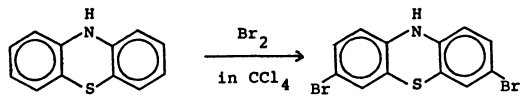


2
3,7-Dibromo-10*H*-phenothiazine

folding (dihedral angle) changes depending on the state of compound investigated.[1-5] For example, dihedral angles of 131.4° in gaseous state,[6] 128° in crystals,[7,8] and 141.6°[2] and 140.6°[1] in solution (of nematic liquid crystals) have been reported for thianthrene (X=Y=S in **1**). These facts stimulate systematic works on structural parameters including the dihedral angle in the mobile state. In the present study, 3,7-dibromo-10*H*-phenothiazine (**2**) is taken up among derivatives of the phenothiazines. The tricyclic compounds phenothiazines are interested because they include a number of important drugs with tranquilizing, antihistaminic, and antiemetic activities.

Experimental

3,7-Dibromo-10*H*-phenothiazine was synthesized by the bromination of 10*H*-phenothiazine.[9] The raw product was



recrystallized from toluene after decolorizing by sodium dithionite $Na_2S_2O_4$. Melting point of the final product (pale green) was 206—209 °C (lit, 197—198 °C,[9] 190—196 °C,[10] and 206—207 °C[11]).

3,7-Dibromo-10*H*-phenothiazine was dissolved in nematic solvent ZLI1167 (Merck) by 5.2 wt%. ^{1}H NMR spectrum was measured on a XL-200 NMR spectrometer operating at 200 MHz. The temperature of measurement was 34.1 °C. Fids of 5000 transients were accumulated using a 40° (4 μs) pulse at an interval of 0.4 s and Fourier transformed to obtain a spectral width of 8 kHz for the data point of 16k. A convolution difference was taken to remove very broad background signals originating from the solvent. The resulting line width was ca. 10 Hz in the center and ca. 20 Hz at the edges of the spectrum. The preliminary spectra were considerably broadened probably because of a contamination with some metallic or radical impurities, and hence a small amount of 1,10-phenanthroline was added to obtain the final sharp spectrum. Normal spectrum in an isotropic medium was taken on a Hitachi R-22 NMR spectrometer in CW mode at 90 MHz and at the probe temperature of 34.1 °C. The solvent used was a mixture (20/80 in volume) of dimethyl sulfoxide and carbon tetrachloride which was suited for a better separation in chemical shifts.

Analysis of NMR spectra obtained in the nematic phase was made by the programs LAO3D9 and LAO3D9D. These programs are modified versions of LAOCN3 and applicable up to 9 spins. These versions have been written in double precision and LAO3D9D includes a damping route as reported by the authors.[5] The resulting direct couplings were analyzed by the program SHAPE[12] to obtain structural and order parameters. Only the variance in LAOCN calculation was input for the error analysis. All the above calculations were done on NEAC S-1000 and SX-1 computers at the Computation Center in Osaka University.

Results

3,7-Dibromo-10*H*-phenothiazine has C_s symmetry and exhibits spectra with the seven spin system of AA'BB'CC'D. It includes four chemical shifts (δ_1, δ_2, δ_3, and δ_7) and twelve direct couplings (D_{12}, D_{13}, D_{14}, D_{15}, D_{16}, D_{17}, D_{23}, D_{24}, D_{25}, D_{27}, D_{34}, D_{37}) besides the twelve indirect couplings J_{ij} as independent variables. Among these parameters the indirect couplings were fixed at the values observed in an isotropic medium as usually done[13] when the indirect couplings show no discernible solvent dependency. The values used were J_{12}=8.20 and J_{23}=2.20 Hz observed in the mixed solvent above mentioned, other indirect couplings being negligibly small. The LAOCN iteration calculation has given rms error of 1.35 Hz for the ninety seven of the observed and the simulated transition frequencies.

D_{23}	98.65±0.20	ν_3	68.36±0.23
D_{24}	23.77±0.21	ν_7	331.08±0.35
D_{25}	21.77±0.29		
D_{27}	135.22±0.22		

a) Given in Hz at 200 MHz relative to the carrier frequency. Positive toward the low field side.

The simulated spectrum is shown in Fig. 1 together with that observed. The experimental line width is broader at the edges of the spectrum. This is caused by a temperature fluctuation on the sample and also probably by a trace amount of impurities which remain unmasked even on addition of 1,10-phenanthroline. The NMR parameters determined are listed in Table 1. The chemical shifts of H_2 and H_3 are reversed in order in the nematic phase compared to those in an isotropic medium where $\delta_2-\delta_1=0.356$ ppm, $\delta_3-\delta_1=0.267$ ppm, and $\delta_7-\delta_1=1.889$ ppm have been obtained in the above mixed solvent. This may be due to a solvent effect. The direct couplings obtained are analyzed by the program SHAPE. The resulting order parameters and the structural parameters are listed in Table 2 (case 1).

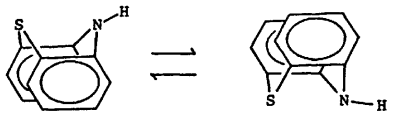
Discussion

The framework of phenothiazine is known to be

folded and to interconvert very rapidly between two equivalent structures:



The barrier to inversion is reported to be 2.87[14] and 2.4[15] kcal mol^{-1} for 10*H*-phenothiazine from dielectric relaxation studies, but no data are available for the dibromo derivative. In the above calculation (case 1 in Table 2), the barrier to this inversion is assumed to be so high that only the ground state is occupied at the measurement temperature. In this regard, correlation between the internal motion and the overall molecular reorientation[16-18] can affect the calculation. When the barrier to internal motion is very low and the rate of internal motion is much faster than that of the whole molecular reorientation, only a set of the order parameters is sufficient to describe the orientational behavior of the molecule and the molecular structure reflects a statistical average of the fast internal motion. This is the case for the internal rotation of methyl group. But when the rate of internal motion is comparable to or slower than that of the whole molecular reorientation, order parameters can differ in each step of the internal motion and in principle an infinite number of the order parameters are needed. In the present study, calculations were also attempted under the fast inversion limit: a potential function of Eq. 1 was adopted,

$$V=V_0\{(\psi/\psi_0)^4-2(\psi/\psi_0)^2\},\quad \psi=(\pi-\phi)/2 \qquad (1)$$

where V_0 is the inversion barrier and ϕ is the dihedral angle between the two phenyl rings, ϕ_0 being this angle at ground state. An alternative function is proposed by Higashi et al.,[15] which has a singular point at $\phi=\pi$ and is not used here. Statistical averaging of the direct couplings under such inversion motion can be achieved by following equation

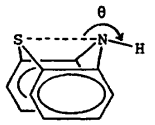
$$\langle D_{ij}\rangle=\int D_{ij}(\psi)P(\psi)\,d\psi \qquad (2)$$

where $\langle\ \rangle$ means the statistical average and where $D_{ij}(\psi)$ and $P(\psi)$ are the direct coupling and the distribution function, respectively, calculated under a dihedral angle of ϕ. This distribution function is given by Eq. 3.

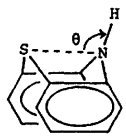
$$P(\psi)\,d\psi=\exp(-V/RT)\,d\psi/\int\exp(-V/RT)\,d\psi \qquad (3)$$

To perform the integration in above equations, ϕ was changed from 80° to 180° in 0.1° step and integrated numerically. Subroutines were added to SHAPE for this calculation: DIHED to calculate the dihedral angle for the ground state, XYZIM to give new coordinates for the dihedral angles changed stepwise, and CALCUD to derive the direct couplings for the variable dihedral angles. Only one set of the order parameters are defined since the very rapid rate of the inversion motion is assumed. The barrier was set equal to 2.4 kcal mol^{-1}. An effort to determine this barrier from the simulation of the direct couplings was unsuccessful. The results of calculation are also summarized in Table 2 (case 2). The weighted rms error between the observed and the simulated direct couplings was almost the same in the two cases, i.e., 0.240 Hz (case 1) and 0.239 Hz (case 2). In fact, the recalculated values of D_{ij} were the same in the two cases, and only those of D_{15}, D_{24}, and D_{25} deviated from the experimental values by slightly more than their probable errors, i.e., D_{15}=46.45, D_{24}=23.30, and D_{25}=21.19 Hz. Therefore, it may be concluded that the experimental values of D_{ij} have failed to distinguish between the two cases because of their relatively large errors coming from the line broadening in the spectrum. A more elaborate analysis of the direct couplings assuming a correlation between the inversion and the whole molecular reorientation was not attempted, since the barrier to inversion was not known for the dibromo derivative and the experimental values of D_{ij} were not so accurately obtained as to make the barrier determinable in that analysis. However, the structural parameters and the order parameters derived above deserve further discussion as described below.

Molecular Structure of 3,7-Dibromo-10*H*-phenothiazine Dissolved in ZLI1167. The dihedral angle (ϕ_0) and the angle of S···N-H (θ) in the ground state are listed in Table 2. The latter angle is determined assuming that N and S atoms lie just on the coplanar line made by the two planes of phenyl ring and assuming that r_{NH}=1.09 Å.[19] This angle is also determined for the case when N and S stoms deviate from the coplanar line by 0.03 and 0.18 Å, respectively, and r_{SN} equals 3.03 Å as reported in crystal.[19] This value is listed in parenthesis in Table 2. Also listed in the Table are structural parameters in an orthorhombic crystal of 10*H*-phenothiazine for reference. The dihedral angle in a little smaller in the dibromo derivative than that in the parent molecule in Table 2. This angle in the latter compound is also reported to be 153.3°[20] in monoclinic crystal and 144±7°[21] in solution. Hitherto, much effort has been devoted to study the conformation of phenothiazines. However, some controversies still remain unresolved especially regarding the conformation of the NH proton. For 10*H*-phenothiazine a molecular orbital calculation predicted superiority of the "H-intra" conformer in the stability compared to the "H-extra" one,[22] and this



"H-intra" form



"H-extra" form

was proved in crystal.[19,20] However, the conformation in the crystal does not necessarily indicate the stability of a molecule in itself since the molecule is embedded

in a rigid lattice in the crystal. In solution a molecular Kerr constant study supported the "H-intra" conformation[21] and NMR chemical shifts did not conflict with this conclusion.[23] However, coexistence of "H-intra" and "H-extra" conformers was suggested from a dipole moment study.[24] In the present case of 3,7-dibromo-10*H*-phenothiazine, the angle of S ··· N-H is less than 180° and might indicate the "H-extra" conformation.[25] However, in a pure "H-extra" conformation, the angle of S ··· N-H needs to be in close vicinity to 90° since the proton is situated at an "axial" position of the central ring in the boat form. In this sense, discussion of the stability of the two conformers made on the basis of the S ··· N-H angle is confusing.[26] This angle lies between 150° and 185° in various phenothiazines[25] including the present case. These values deviate far from 90° and it may be said that the phenothiazine derivatives are supported to be in the "equatorial" conformation irrespective of the substituent attached to nitrogen, although the position of the substituent is changed from one derivative to another. With regard to the dihedral angle and the conformation of NH proton, a similar NMR study using liquid crystal solvent is interested for 10*H*-phenothiazine itself. However, some special techniques such as multiple quantum NMR spectroscopy or high power decoupling for some deuterated compounds are needed to simplify the spectrum.

Preferred Orientation of 3,7-Dibromo-10*H*-phenothiazine Dissolved in ZLI1167. The authors have demonstrated on an interrelation between the principal axes for the order tensor and those for the moment of inertia in the studies of hexachlorocyclohexane isomers.[27,28] In the present case, principal axes x',y',z' for the order tensor can be derived as follows. The axis x' coincides with x from symmetry. The axes y' and z' are those which makes $S_{y'z'}$ equal to zero. $S_{y'z'}$ is expressed as in Eq. 4,

$$S_{y'z'}=\sum_{p,q}\cos\theta_q^{z'}S_{pq},\quad p,q=x,y,z \tag{4}$$

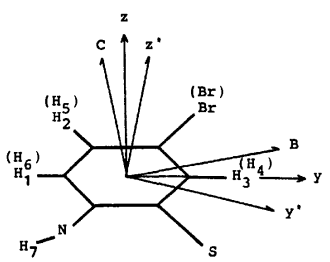


Fig. 2. Principal axis systems for the order tensor (x',y',z') and for the moment of inertia(A,B,C) in 3,7-dibromo-10*H*-phenothiazine (side view).
The x' and A axes coincide with the x axis from the C_s symmetry, but these three axes are abbreviated in the Figure for simplicity. The x, y, and z axes are defined so as to place the protons of H_1, H_3, H_4, and H_6 on the xy plane. Angles of rotation are −11.7° for y' and z' axes and 11.3° for B and C axes with regard to the y and z axes.

where $\theta_p^{y'}$ means the angle between axes p and y'. From this equation, an angle of rotaion ω which moves y and z on to y' and z', respectively, can be obtained as,

$$\tan(2\omega)=2S_{yz}/(S_{yy}-S_{zz}) \tag{5}$$

and also the relevant principal values turn out to be: $S_{x'x'}=S_{xx}$ and $S_{z'z'}=\sin^2\omega S_{yy}+\cos^2\omega S_{zz}-\sin(2\omega)S_{yz}$. From these equations, $\omega=-11.7$, $S_{x'x'}=-0.1223$, and $S_{z'z'}=0.1995$ are reached (Fig. 2). Principal axes A, B, C for the moment of inertia were determined by the program XYZ[29] modified by the present author, principal values being $I_A=513.0$, $I_B=5671.3$, and $I_C=6003.7$ amu·Å^2. In this calculation, bond lengths obtained in a crystal,[19] bonding angles of 120° for carbons, an angle of 170.5° for S ··· N-H, and the dihedral angle of 149.1° were used together with the angles of 66.0° for <S-N-C and 54.0° for <N-S-C. The B and C axes are seen to be rotated by 11.3° from y and z axes (Fig. 2). Therefore, the two principal axis systems differ 23° from each other, suggesting a special steric effect of Br atoms on the phenyl rings as observed[27,28] for Cl stoms in hexachlorocyclohexane.

The author (H. F.) is grateful to Professor Kensuke Takahashi of Nagoya Institute of Technology for facilities for the NMR measurements

26) Bonding angles around the N atom change considerably reflecting the degree of conjugation of N with the phenyl rings. And so, the two conformers are better differentiated from whether the H atom is located closer to the phenyl rings ("H-intra") or the lone pair electrons are ("H-extra"). This condition is well judged on a basis of the angle between the N-H bond and the plane made by the N atom and the two phenyl carbons attached to it.

Emission Spectrum of Acetylene by Controlled Electron Impact

Toshifumi YOSHIDOME, Masaharu TANIGUCHI, Keiji NAKASHIMA, Hirofumi KAWAZUMI, and Teiichiro OGAWA*

Department of Molecular Science and Technology, Kyushu University, Kasuga-shi, Fukuoka 816

(Received September 10, 1987)

Emission spectra of C_2H_2 and C_2D_2 excited by collisions with electrons of 7—20 eV show a broad and diffuse band in the 240—400 nm region and this band was assigned to the S_1(lower vibrational levels)-S_0 transition of acetylene on the basis of its wavelength, excitation function (threshold: 5.5 eV) and lifetime (323±30 ns). Their emission cross sections are on the order of 10^{-19} cm^2. Among intense fragment emissions at higher electron energies, band of C_2H has also been observed and its lifetime is 3.9±0.8 μs.

Fluorescence of acetylene is very weak. A discrete fluorescence was observed in a high frequency discharge,[1] in a matrix[2] and in the gas phase under a laser excitation.[3,4] These fluorescence was assigned to the transition from the lowest excited state to the ground state. The fluorescence quantum yield in the gas phase was estimated to be 10^{-4}, and it decreased sharply with decreasing exciting wavelength.[5]

The electron is an efficient excitation source and is able to excite both optically-allowed and forbidden transitions.[6] Aromatic molecules exhibit characteristic emission upon excitation by electrons similar to optical fluorescence.[7] However, their vibrational structure is different and optically-forbidden vibrational levels are predominant in the benzene spectrum.[8] Meanwhile, emission spectrum of acetylene excited by electrons showed only bands of fragments and no parent emission was detected in the previous investigation.[9]

In order to clarify spectroscopic properties of acetylene, we have again measured emission spectrum of acetylene under controlled electron-impact excitation and analyzed its decay curve.

Experimental

The apparatus is similar with the one described previously.[7] In brief, the collision chamber (8″) was evacuated with a 4″ oil-diffusion pump with a liquid nitrogen trap. The base pressure was of the order 10^{-6} Torr (1 Torr=133 Pa) and the operating pressure was about 1×10^{-3} Torr. The sample gas was jetted into the collision region through a mass flow controller (Standard Tech. 400MKII) and a multichannel nozzle, and was collided with the electron beam from a tungsten filament.

The optical emission was observed through a quartz window at an angle of 45° with respect to the electron beam. The spectrum was obtained with a SPEX 1670 monochromator equipped with a 1200 grooves/mm grating blazed at 300 nm and a Hamamatsu R585 photomultiplier and with an NF PC545 photoncounter. The electron beam was pulsed so as to subtract the stray radiation from the hot filament.

The instrumental response of the optical system was calibrated with a Hamamatsu L591 standard deuterium lamp. The corrected spectrum was expressed in units of relative number of photons per wavenumber. The electron energy was calibrated with the peak of N_2^* (337.1 nm) at 14.5 eV and its energy resolution was 0.8 eV at 10 eV.

Fluorescence decay was measured with an Ortec 457 time-to-amplitude converter, an Ortec 473A constant-fraction discriminator, a Norland Ino-tech 5300 multichannel analyzer, and an NEC PC 9801VF microcomputer. The pulse width of the electron beam was 1 μs, and its repetition rate was 50 kHz. The system was calibrated with the lifetime (1.7 ns) of the 3^1P-2^1S transition of He (501.4 nm).

C_2H_2 was commercially obtained (Eto Sanso, 99.6%) and was used as supplied. C_2D_2 was prepared from CaC_2 and D_2O, and its isotopic purity was > 96% according to a mass spectrometric analysis.

Results and Discussion

There are bands of H (Balmer lines), CH (the A-X and B-X transitions), CH^+ (the B-A and b-a transitions) and C_2 (the d-a transition) on the emission spectrum by controlled electron impact on acetylene, as are reported previously.[9,10] But no feature assignable to C_2H_2 was observed previously,[9] partly because measurements were carried out at higher electron energies. Typical emission spectra of C_2H_2 and C_2D_2 excited at electron energies of 14 and 7 eV are shown in Fig. 1;

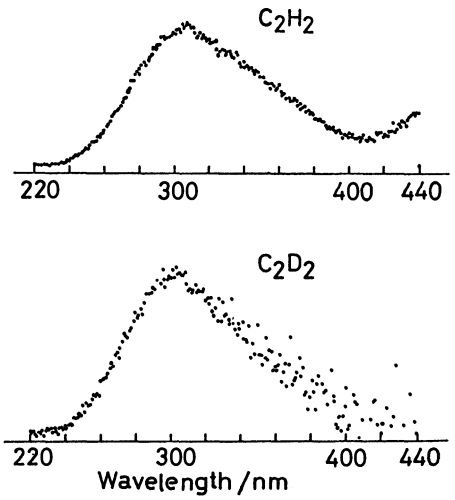

Fig. 1. Emission spectra of C_2H_2 and C_2D_2 by controlled electron impact. Electron energy: 14 eV (C_2H_2) and 7 eV (C_2D_2). Optical resolution: 5 nm.

the optical resolution was 5 nm and the optical response of the instrument was corrected. The spectra are broad and diffuse, and the peak appears at 307 nm for C_2H_2 and at 300 nm for C_2D_2.

The similarity of the observed spectra with those by the optical excitation[2-4] shows that the observed emission is due to the transition from the lowest excited state ($^1\Sigma_u$) to the ground state($^1\Sigma_g$), as is optical fluorescence. However, the present spectrum was measured at a much lower pressure than that in the laser excitation and collisional effects can be ignored. The spectrum of C_2H_2 shifts to the red than that of C_2D_2, probably because the vibrational spacing of the latter in the ground electronic state is smaller.

There is no contribution of any fragment species at 7 eV and only C_2H and CH(C) may appear at 14 eV, because the calculated dissociation limits of C_2H(B) and CH(C) are 9.29[11,12] and 13.91[11,13] eV, respectively. The increase at 400 nm region toward longer wavelength in the C_2H_2 spectrum can be assigned to the band of C_2H*.

The excitation function of C_2H_2 measured at 280 nm is shown in Fig. 2. A peak at 14.5 eV is due to N_2 (the C-B transition) measured together for a calibration of the electron energy. The rise toward higher electron energy is due to fragments such as C_2H* and CH(C-X). The excitation function above 9.0 eV was obtained by subtracting the contribution from the fragment emission, and is shown by triangles. It has a maximum at about 10 eV and decreases smoothly to higher electron energies. The C_2H_2* emission was not distinguishable from the fragment emissions at higher electron energies. The threshold energy is found to be 5.5±0.6 eV. The 0-0 transition of C_2H_2 is located at 5.23 eV,[14] and this agreement is consistent with the assignment. Because this threshold energy is much lower than the dissociation limit of any fragment, the observed emission is certainly not due to any fragment species.

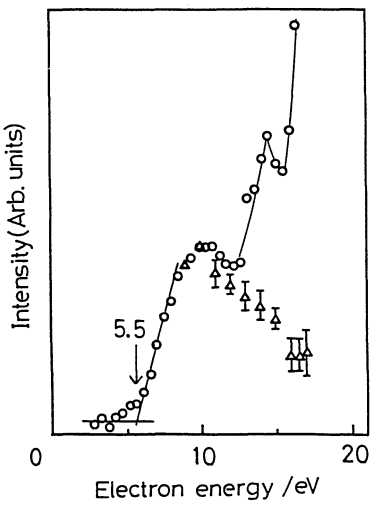

Fig. 2. Excitation function of C_2H_2 at 280 nm.
O: Total optical emission. Δ: C_2H_2* above 10 eV.
Total optical emission should be due to C_2H_2* below 9.5 eV.

The electron excitation is nonresonant in principle and many vibrational levels may be excited together. Thus, the acetylene spectra may be diffuse, though it exhibits banded fluorescence under a dye-laser excitation. The peak of the spectra seems to locate in the identical region with that excited at the 0-0 transition by the laser,[3] if we take instrumental response into consideration. However, the present spectrum is broader than the 0-0 fluorescence by the laser excitation, and this finding indicates that not only the 0 level but also some lower vibrational states are also excited by controlled electron impact.

The 0-0 transition is forbidden due to the geometry change between the ground and the excited states, and excitation to the higher vibrational levels had larger intensity in the optical excitation.[3,14] Nevertheless, the 0-0 transition seems to be prominent under electron excitation. This is also the case in benzene.[8] The higher intensity of the 0-0 transition should be due to a specific interaction between the molecule and the electron.

The emission cross sections of acetylene emission were determined by measuring the band areas relative to that of the C-B transition of N_2; the emission cross section of the latter was determined to be 1.6×10^{-18} cm^2 at 12.4 eV.[15] They were 2.2×10^{-19} cm^2 for C_2H_2 and 3.2×10^{-19} cm^2 for C_2D_2 at the incident electron energy of 12.4 eV. Uncertainty of these values would be 50% mainly due to uncertainty in the pressure measurements; however, relative values of C_2H_2 and C_2D_2 should be more accurate.

The decay curve of the C_2H_2 emission at 300 nm is

Table 1. The Lifetime of C_2H_2* by Controlled Electron Impact at an Electron Energy of 17 eV

Wavelength/nm	Lifetime/ns
280	313±26
290	322±20
300	336±30
315	319±41

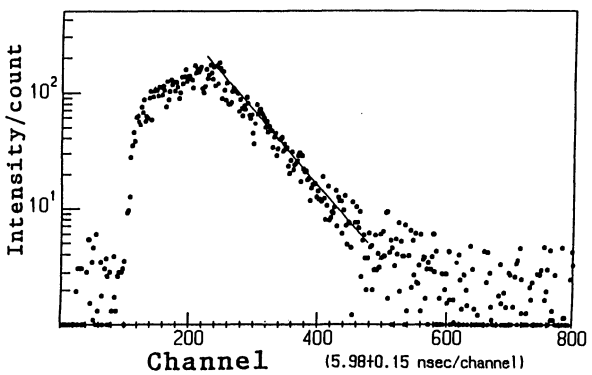

Fig. 3. Fluorescence decay curve for C_2H_2 at 300 nm.
The electron energy: 10 eV.

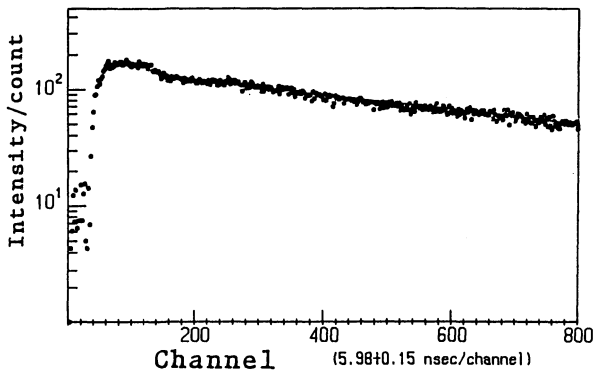

Fig. 4. Fluorescence decay curve for C_2H at 500 nm. The electron energy: 50 eV.

Table 2. The Lifetime of C_2H^* by Controlled Electron Impact

Wavelength /nm	Lifetime at 19eV/μs	Lifetime at 50 eV/μs
300		3.5±0.5
450	3.6±1.0	3.9±0.7
500	3.9±0.8	4.4±0.7

shown in Fig. 3; the incident electron energy was 10 eV. The lifetime of the excited state was determined to be 328±50 ns by a least-square fitting of the decay curve. The results of the decay curve analysis is shown in Table 1. The lifetime was independent of the electron energy between 10 and 50 eV and of the wavelength between 280 and 315 nm within experimental uncertainties. Then, we can conclude that the lifetime of $C_2H_2^*$ is 323±30 ns by taking the average of all data. This lifetime agrees with that to lower vibrational levels measured by laser excitation[3] within experimental uncertainties, and disagree with that to higher vibrational levels.[4] This finding confirms the assignment that the observed emission arises mainly from the lower vibrational levels of the A state of acetylene.

There is another band above 410 nm in Fig. 1(a). This band is also broad and diffuse and is extended to longer wavelength region. Since its threshold is about 10 eV and the calculated threshold for C_2H is 9.29 eV, this band can be assigned to C_2H^*, as was reported by a VUV photolysis of acetylene.[16] The decay curve of the C_2H emission at 500 nm is shown in Fig. 4 and the lifetime was determined to be 4.4±0.7 μs. The lifetimes measured are shown in Table 2; lifetime does not vary with wavelength within experimental uncertainties. The lifetime of C_2H was determined to be 3.9±0.8 μs by taking an average of these results. This lifetime is approximately in agreement with those obtained in a VUV photolysis;[16] however, the latter values were measured at higher pressures by extraporating observed lifetime to zero pressure. Since the present measurements were carried out at 10^{-3} Torr, our values should be more accurate.

The electron excitation is a useful technique to investigate the molecular excited state at a very low pressure where collisional effect can be ignored.

The authors thank to professor Yukio Nishimura for the use of his standard deuterium lamp and to Dr. Teijiro Ichimura of Tokyo Institute of Technology for his comments.

The Thermal Decomposition and Hydrolysis of Calcium Carbamoyl Phosphate

Choichiro SHIMASAKI* and Hiroki SUZUKI
Department of Industrial Chemistry, Faculty of Engineering, Toyama University, Gofuku, Toyama 930
(Received May 18, 1987)

Calcium carbamoyl phosphate (**1**) was prepared by adding an aqueous calcium chloride solution to a reaction solution of KH_2PO_4 with KOCN. **1** was unstable at room temprature. **1** was dehydrated to make anhydrous salt and thermally decomposed to liberate ammonia, cyanic acid, and carbon dioxide, finally resulting in the formation of calcium pyrophosphate in air. The apparent activation energies for the three endothermic peaks of the DTA curve were estimated to be 50.0, 83.9, and 148.3 kJ mol^{-1} respectively. The hydrolysis of **1** in an aqueous solution apparently obeyed the first-order kinetics. The activation parameters for the hydrolysis of **1** were evaluated by using the ^{31}P NMR spectra of **1** with the lapse of the reaction time. The activation energy was 92.2 kJ mol^{-1}; the activation enthalpy, 89.7 kJ mol^{-1}, and the activation entropy, −6.3 e.u.

Some phosphor-nitrogen compounds are already used as industrial materials and obtained as industrial products. There are a series of phosphorus-nitrogen compounds which have amino groups on a P atom. There compounds have the potential for use as new flameproofing and glow-retardant agents on a large number of cellulosic materials; further, they can be used as the starting materials in the preparation of many organic and inorganic phosphorus compounds.

In our previous papers,[1-3] the thermal behavior of many phosphoramidates were reported. This paper will describe the synthesis, thermal behavior, and hydrolysis of calcium carbamoyl phosphate (**1**) containing nitrogen and carbon. This compound was instable even at room temperature, and its thermal product resulted in calcium pyrophosphate. It was found by ^{31}P NMR measurements that the hydrolysis of **1** apparently obeys the first-order kinetics.

Experimental

Preparation of Calcium Carbamoyl Phosphate. **1** was synthesized by reference to the method described in the literature.[4] Potassium dihydrogenphosphate (0.1 mol) and potassium cyanate (0.1 mol) were dissolved in 100 cm^3 of water. To the resulting mixture, which had been cooled in an ice bath, two solutions of 60 ml of 1 mol dm^{-3} $BaCl_2$ and 50 ml of 1 mol dm^{-3} NaOH were slowly added, drop by drop with continuous stirring. During the treatment, the pH of the solution was kept at 9.0—9.3. The resulting cream-colored precipitate of barium monohydrogenphosphate was removed by suction filtration. The filtrate was transferred to a flask, and 50 ml of 1 mol dm^{-3} $CaCl_2$ was added, drop by drop. To the resulting solution was slowly added 100 ml of ethanol. The resulting white precipitate was collected by suction filtration, washed with several small portions of water, ethanol, and acetone, air-dried, and finally dried in a vacuum over diphosphorus pentaoxide for 48 h.

Chemical Analysis. The phosphorus in a sample was determined colorimetrically by the molybdenum-blue method. The calcium in a sample was estimated by the atomic-absorption-analysis technique. The nitrogen, carbon, and hydrogen in a sample were determined by using a Hitachi C, H, N analyser-026 at the Toyama Medical and Pharmacy University.

Measurements. The thermal analysis measurements were made in air by using a Rigakudenki TG-DTA, DSC apparatus, at the heating rates of 3, 5, 6, 8, and 10 K min^{-1} for TG-DTA and 5 K min for DSC respectively. The IR spectra of the sample were recorded on a Nipponbunko IR-810 apparatus using the KBr-disc method. For the ^{31}P NMR spectra, a sample of about 100 mg was put in 5.0 cm^3 of a 6% EDTA deuterated-water solution and stirred for several minutes. A JNM-FX 90 Fourier transform spektrometer was used to measure the ^{31}P NMR spectra. An X-ray diffraction diagram of a powder sample was taken with nickel-filtered Cu $K\alpha$ radiation using a Shimazu X-ray diffractometer XD-5, XD-3A, and a Rigaku RAD-RVB apparatus.

Results and Discussion

Thermal Behavior. The DTA and TG curves of **1** are shown in Fig. 1. The DTA curve indicated four endothermic peaks in this range: r.t.—362, 362—430, 430—465, and 465—541 K, while the TG curve indicated a slow decrease in the weight. For each type of peak (E_{D1}, E_{D2}, E_{D3}, and E_{D4}) shown in Fig. 1, two temperatures are recorded; the first one is the point of departure from the base line, while the second one is the end point of the peak temperature. The indication of "temperature" on the DTA curve in Fig. 1 means the temperature at which samples were removed from a furnace prior to being cooled in a silicagel desiccator and subjected to further research. The results of the elemental analyses of the thermal products are shown in Table 1. It can be seen from Table 1 that the nitrogen, carbon, and hydrogen contents of the thermal product decreased in the heating process and that the

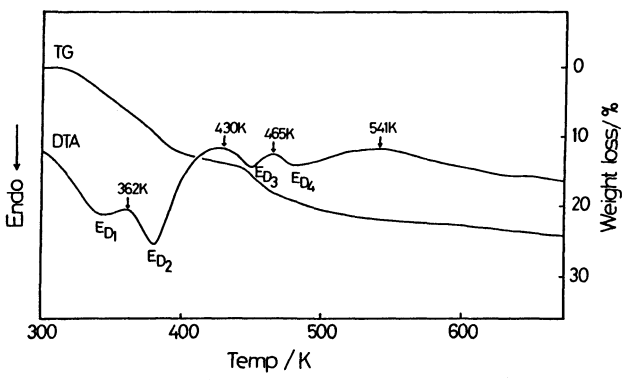

Fig. 1. DTA and TG curves of CaCAP·1.5H_2O. Heating rate: 5 K min^{-1}.

thermal product at 541 K contained no nitrogen and hydrogen. These data on the reduction in weight after 30 min at each endothermic peak temperature were not always in agreement with those calculated from the TG curve. The results showed that carbon dioxide, ammonia, and cyanic acid are exhausted in the case of the thermal condensation of **1**.

The IR spectra of the thermal products are shown in Fig. 2. For the IR spectrum of **1**, the absorption band at about 3400 cm^{-1} is assigned to the N-H stretching vibration; those at 1680 and 1730 cm^{-1}, to the C=O stretching vibration; those at 1610 and 1630 cm^{-1}, to the N-H deformation vibration; that at 1400 cm^{-1}, to the C-N stretching vibration; that at 1150 cm^{-1}, to the P=O stretching vibration; that at 980 cm^{-1}, to the P-O-C stretching vibration, and that at 570 cm^{-1}, to the $(PO_2)^-$ or $(PO_3)^{2-}$ deformation vibration. These absorptions grew weaker with an increase in the temperature, and they disappeared in the thermal product at 430 K. At about 910 cm^{-1}, the absorption band attributed to the P-O-P antisymmetric stretching vibration grew strong. This showed that the condensation polymerization was proceeding. For the thermal product at 362—673 K, the absorption band of carbon dioxide was observed at 2350 cm^{-1}. Also, for the thermal product at 1073 K, the absorption observed at 900—1250 cm^{-1} was very complex, with strong peaks. This complexity of absorption was attributed to the progress of the crystallization.

Table 1. Elemental Analysis of the Thermal Products of $CaCAP \cdot 1.5H_2O$

Sample	Ca/%	P.%	N/%	C/%	H/%
r.t.[a]	19.1	15.0	6.2	5.4	2.3
	(19.4)	(15.0)	(6.8)	(5.8)	(2.5)
362 K	21.5	16.1	5.4	5.1	2.1
430 K	25.2	19.3	3.4	3.1	1.3
465 K	25.4	20.9	2.1	2.9	0.5
541 K	27.2	21.7	0.0	2.1	0.0
673 K	30.1	23.7	0.0	1.6	0.0
1273 K[b]	32.5	24.5	0.0	0.0	0.0
	(32.8)	(25.4)			

a) Calculated values in parentheses as $CaCAP \cdot 1.5H_2O$.
b) Calculated values in parentheses as $Ca_2P_2O_7$.

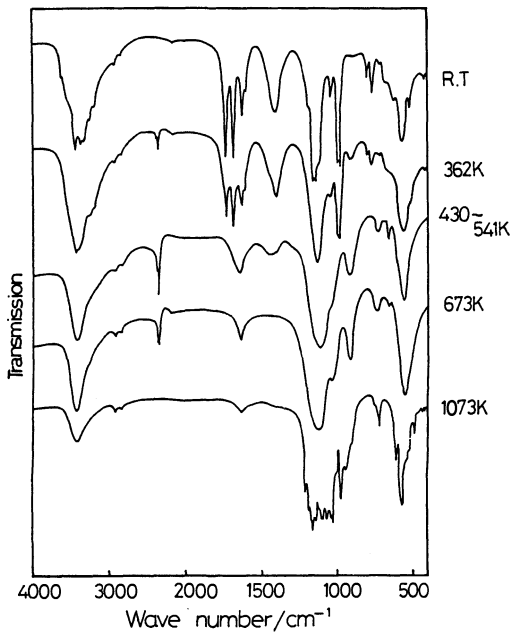

Fig. 2. IR spectra of the thermal products of $CaCAP \cdot 1.5H_2O$.

The ^{31}P NMR spectra of the thermal products are shown in Fig. 3. As has been mentioned previously, **1** is very instable at room temperature; therfore, the

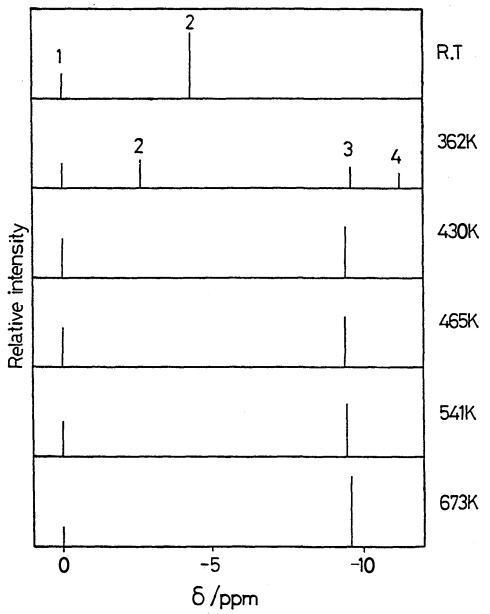

Fig. 3. ^{31}P NMR spectra of the thermal products of $CaCAP \cdot 1.5H_2O$. 1: Orthophosphate, 2: carbamoylphosphate, 3: diphosphate, 4: end PO_4 group of intermediate polyphosphate ($n>3$).

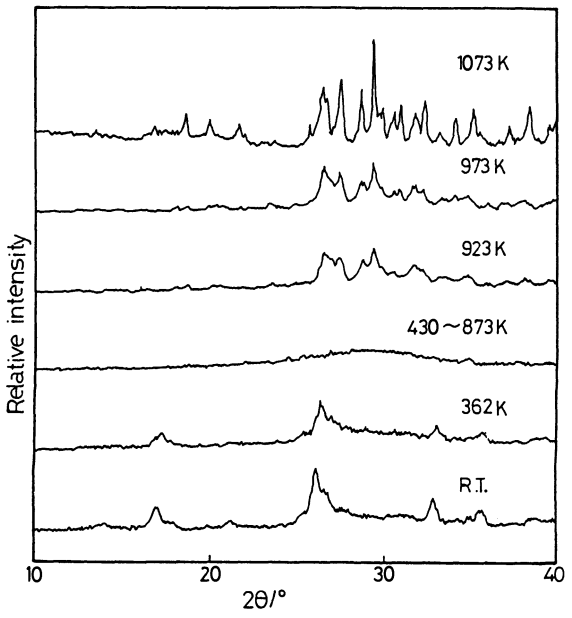

Fig. 4. X-Ray diffraction diagrams of the thermal products of $CaCAP \cdot 1.5H_2O$. Heating rate: 2 K min^{-1}.

^{31}P NMR spectrum of **1** indicated peaks caused by a carbamoyl phosphate (CAP) and an orthophosphate (PO_4). The molar ratio CAP/(CAP+PO_4), is calculated by means of the signal area, was 0.88 for **1**. The ^{31}P NMR spectrum of the thermal product at 362 K indicated peaks attributable to a PO_4, a CAP, a diphosphate (P_2O_7), and an intermediate of the thermal condensation. The thermal product at 430 K indicated no CAP peak, but peaks of PO_4 and P_2O_7 were both registered. These results agreed with those of the IR spectra. The peak of P_2O_7 grew stronger above 430 K.

The X-ray diffractions of the thermal product at a given isothermal temperature, as obtained by using XD-3A, are shown in Fig. 4. No diffraction patterns on the thermal products were observed at room temperature at 430—873 K. The X-ray diffraction of the thermal product at 973 K indicated weak patterns, but these patterns were much clearer than those at 923 K. The X-ray diffraction patterns of the thermal products at the temperature interval from 465 to 673 K, as obtained using the Rigaku RAD-RVB apparatus, were similar to the amorphous solid compositions, as is shown in Fig. 4. The thermal product at 1073 K showed strong X-ray diffraction patterns of α-$Ca_2P_2O_7$.[5]

Decomposition at Room Temperature. The stability of **1** was checked at room temperatue (283—303 K) in air. Figure 5 should the IR and ^{31}P NMR spectra of the decomposition of **1** at room temperature. **1** was very instable at room temperature. At 910 cm^{-1}, the absorption of the P-O-P antisymmetric stretching vibration appeared, and its intensity increased with the lapse of the reaction time. Therefore, either the polymerization or the condensation of **1** seemed to be progressing. This agrees with the results of the IR and ^{31}P NMR spectra. A peak attributable to P_2O_7 appeared after the lapse of 8 dyas, and its intensity increased with the lapse of the reaction time. A peak due to CAP decreased with the lapse of the reaction time. A peak due to CAP decreased with the lapse of the reaction time, on the other hand, and disappeared at 133 days.

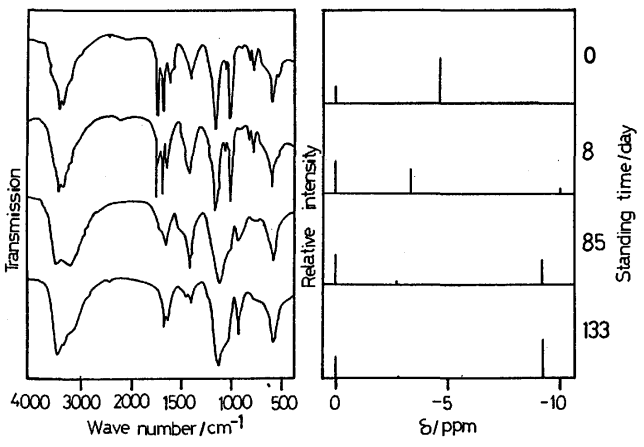

Fig. 5. IR and ^{31}P NMR spectra of the decomposition of CaCAP·1.5H_2O at room temperature.

Kinetic Studies of Thermal Process. Kinetic studies of the pyrolysis (i.e., dehydration and condensation) of **1** were done by the Kissinger method[6] on the basis of the DTA peaks E_{D1}—E_{D4}, as is shown in Fig. 1. As the heating rate increased, both the initial transition and the peak maximum for dehydration and condensation were shifted to higher temperatures. The theoretical work of Kissinger indicated that the activation energy of the pyrolysis process of **1** was defined by the following form:

$$\frac{d \ln (\phi/T_m^2)}{d(1/T_m)} = -E/R$$

where ϕ stands for the heating rate; T_m, for the temperature of the DTA-maximum, E, for the activation energy, and R, for the gas constant. These plots of $\ln(\phi/T_m^2)$ against $1/T_m$ are linear, the slop being equal to $-E/R$. Thus, the apparent activation energies of each pyrolysis process were obtained from this slop. The apparent activation energies for the three endothermic peaks (=E_{D1}, E_{D2}, and E_{D3}) were estimated to be 50.0, 83.9, and 148.3 kJ mol^{-1} respectively. The results are shown in Fig. 6 and Table 2. As the heating rate increased, the peak maximum for E_{D4} was not appreciably shifted. It was found that the E_{D4} peak was caused by the heat of crystallization.

According to these results, the pyrolysis mechanism of **1** may be written as Scheme 1. **1** is dehydrated to

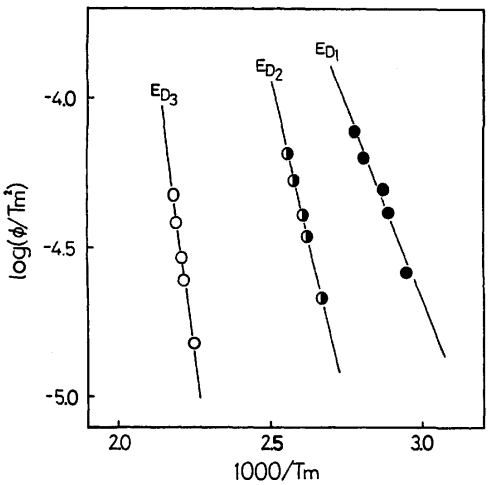

Fig. 6. The Kissinger's plots for E_{D1}, E_{D2}, and E_{D3} in DTA curves for CaCAP·1.5H_2O.

Table 2. Kinetic Data for the Pyrolysis of CaCAP·1.5H_2O

DTA peak	Equation of straight line	$r^{a)}$	E/kJ·mol^{-1}
E_{D1}	$\log(\phi/T_m^2)=-2.609\cdot1000/T_m+3.147$	0.985	50.0
E_{D2}	$\log(\phi/T_m^2)=-4.378\cdot1000/T_m+7.019$	0.996	83.9
E_{D3}	$\log(\phi/T_m^2)=-7.735\cdot1000/T_m+12.550$	0.999	148.3

make anhydrous salts. Next, the anhydrous salts are bimolecularly condensed to liberate ammonia, cyanic acid, and carbon dioxide. Finally, calcium pyrophosphate is formed.

Hydrolysis of Calcium Carbamoyl Phosphate in an Aqueous Solution. The hydrolysis of **1** in an aqueous solution seems to progress as follows:

$$OPO_3 \cdot CO \cdot NH_2^{2-} + H_2O \rightarrow PO_4H_2^- + CO_2NH_2^-,$$

$$CO_2NH_2^- + PO_4H_2^- + H_2O \rightarrow CO_3H^- + NH_4^+ + PO_4H^{2-}.$$

^{31}P NMR measurement was used to investigate the hydrolysis reaction of **1** at temperatures from 299.0 to 315.2 K. The ^{31}P NMR spectra of **1** with the lapse of the reaction time at 302.6 K are shown in Fig. 7. These spectra indicated peaks attributable to CAP and PO_4; the former decreased and shifted to a low magnetic field with the lapse of the reaction time. The chemical shifts of the ^{31}P NMR spectra at various temperatures, taken at intervals, are shown in Fig. 3. Smooth curves were obtained at all temperatures. The speed of shifting grew rapidly with the rise in the temperature. After the lapse of an infinite time, the peak due to CAP was shifted by about −2.6 ppm. This phenomenon is independent of the pH, as was shown in the pH measurement of a solution[7] with the lapse of the reaction time over a period of 307 min. As Fig. 7 shows, the peak attributable to CAP decreased and that attributable to PO_4 increased with the lapse of the reaction time (apparently obeying the first-order kinetics). The first-order kinetics can represented as follows:

$$kt = \ln \frac{a_o - a_\infty}{a_t - a_\infty},$$

where a_o and a_∞ are the CAP/(CAP+PO_4) molar ratios at the beginning and when the reaction is complete respectively; a_t, the value after time t, and k, the rate constant. a_o, a_∞, and a_t were determined by measuring the integral intensities of the ^{31}P NMR spectrum for CAP and PO_4 respectively. The first-order kinetic

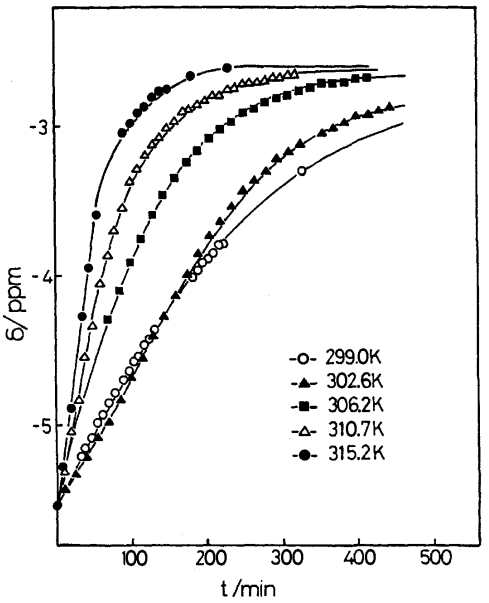

Fig. 8. The chemical shift of ^{31}P NMR spectra at various temperatures.

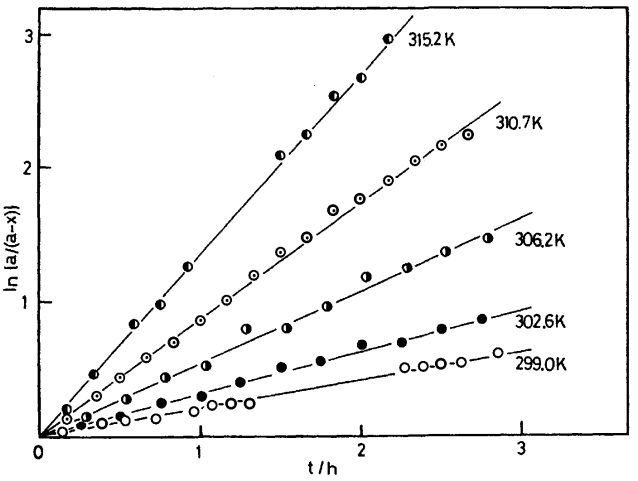

Fig. 9. The first order kinetic plots of ln $a/(a-x)$ vs. t for the hydrolysis of CaCAP·1.5H$_2$O in aqueous solution.

plots of $\ln[(a_0-a_\infty)/(a_t-a_\infty)]$ vs. t at various temperatures were found to be linear, as is shown in Fig. 9. The rate constants for the hydrolysis of **1** are shown in Table 3. Arrhenius plots (Fig. 10) give us the activation energy and the frequency factor. The activation enthalpy and entropy were obtained by using the values of the activation energy and the frequency factor. These kinetic data are tabulated in Table 4.

One of the most significant treatments of the theory of reaction rates is based on the concept of the existence of an activated complex as an intermediate stage in all chemical reactions. In a reaction involving two or more molecules, the reactants, possessing sufficient energy, must approach one another closely. Since in any bimolecular reaction except in the dissociation of two molecules, a reaction with $A \fallingdotseq 10^{11}\,M^{-1}\cdot s^{-1}$ is generally regarded as a standard bimolecular reaction,[8] the value of the frequency factor in this paper suggests a bimolecular reaction. Even in a unimolecular reaction, in which a single molecule takes part in each chemical act, it is necessary for some rearrangement of atoms and energy to occur, thus giving the requisite activated complex, before a reaction can take place. From the results of Table 4, the value of the activation energy can be said to be approximately identical to that of the activation enthalpy. By supposing that an equilibrium exists between the reacting molecules and the activated complex, which decompose at a definite rate, it has been found possible to estimate the apparent ΔS^* value for the hydrolysis reaction. Such a ΔS^* value suggests that mechanism of the hydrolysis reaction consists of two main complicating steps which can be described by the above chemical equations.

Pressure and Temperature Effects on Octahedral-Tetrahedral Equilibria in 4-Methylpyridine and 2-Methylpyridine Solutions of Some Cobalt(II) Halides

Kazuo KOJIMA
Department of Chemistry, Faculty of Science and Engineering, Ritsumeikan University, Kita-ku, Kyoto 603
(Received May 18, 1987)

The visible absorption spectra of CoX_2 (X=Cl, Br) in solutions of both 4-methylpyridine (4-Me-py) and 2-methylpyridine (2-Me-py) have been measured in the pressure range of 1 bar —3 kbar at room temperature, and in the temperature range of ≈6—≈75 °C at 1 bar. In the 4-Me-py solution system, the configuration equilibrium, $[CoX_2(4\text{-Me-py})_2]$ (tetrahedral) $+2(4\text{-Me-py}) \rightleftarrows [CoX_2(4\text{-Me-py})_4]$ (octahedral), was found to exist over the experimental pressure range. Increasing the pressure shifted the equilibrium toward the octahedral species side with volume changes of -26 cm^3 mol^{-1} for the chloro complex and -25 cm^3 mol^{-1} for the bromo complex at 1 bar. The above equilibrium held fairly well over the whole experimental temperature range for the chloro complex, but in the restricted temperature range for the bromo complex. Increasing the temperature tended to increase the formation of the tetrahedral species, the heats of reaction, being 53.3 kJ mol^{-1} and 62.6 kJ mol^{-1} for the chloro and bromo complexes, respectively. On the other hand, in the 2-Me-py solution system, increasing the pressure or temperature could hardly confirm the existence of the octahedral-tetrahedral configuration equilibrium. A charge-transfer band between the solvent molecule 2-Me-py and the free ion X^- decreased in intensity with increasing temperature. The above results in the 4-Me-py and 2-Me-py systems were compared with those of the pyridine (py) and 3-methylpyridine (3-Me-py) systems mentioned in the literature.

As a typical configuration equilibrium between the tetrahedral and octahedral complexes of Co(II), the following reaction is known in some nonaqueous solvents

$$[CoX_2(R\text{-py})_2] + 2(R\text{-py}) \overset{K}{\rightleftarrows} [CoX_2(R\text{-py})_4], \quad (1)$$
(tetrahedral) (octahedral)

where K is the equilibrium constant, X=Cl, Br, or I, and R-py=py or methylpyridines.

By means of spectrophotometric measurements of the $CoCl_2$-py system, Katzin[1] could study the temperature effect on the equilibrium and determined the value of ΔH. Using a series of R-py, Nelson et al.[2,3] have obtained thermodynamic data related to the equilibrium by means of spectroscopic, electrical, and calorimetric measurements. They interpreted the data in terms of the dative π-bonding from Co(II) to the pyridine base, which depends first on the kind of X^- and R-py and, secondly, on the hydrogen bond between the ligand and the solvent molecule. However, Libus et al.[4] have pointed out the importance of the hydrogen bond. Sawada et al.[5,6] have spectrophotometrically investigated the equilibrium of Eq. 1 for 1,2-dihaloethane solutions and found a linear correlation between the strength of the Co(II)-N bond and pK_b of R-py. On the other hand, the kinetic parameters related to the equilibrium have been determined by using nitrogen-14 NMR[7] and the temperature-jump method.[8,9]

All of the above reports, except for Katzin's,[1] have dealt with the equilibrium of Eq. 1 at atmospheric pressure and near room temperature. On the other hand, the effects of pressure and temperature on the equilibrium of Eq. 1 in the systems of R-py=py and 3-Me-py have been reported in previous papers.[10-12] There have been many studies[13] of high-pressure effects on inorganic reactions which involve ionic species. In these reactions, the contribution of electrostriction to the reaction volume or the activation volume is significant. However, the reaction of Eq. 1 involves no ionic species; therefore, the effect of electrostriction seems to be negligible.

Both the py[10,11] and 3-Me-py[12] systems under high pressures favored the octahedral species; however, at high temperatures the tetrahedral species was favored. Thus, from the variation of K with pressure and temperature, the values of ΔV and ΔH could be estimated. In the 3-Me-py system,[12] the 400-nm band which becomes stronger with increasing temperature was assigned to a charge-transfer transition between the solvent molecule (3-Me-py) and X^- arising from a dissociation of the tetrahedral species $[CoX_2(3\text{-Me-py})_2]$.

In the present paper, the pressure and temperature effects on the equilibrium of Eq. 1 (X=Cl, Br, R-py=4-Me-py, 2-Me-py) are described. The results are discussed in comparison with those of the py[10,11] and 3-Me-py[12] systems.

Experimental

$CoCl_2$ and $CoBr_2 \cdot 6H_2O$ were used after drying and 4-Me-py and 2-Me-py were used after drying and distillation. Sample solutions of CoX_2 in 4-Me-py or in 2-Me-py were prepared just before spectroscopic measurements.

High-pressure spectra were recorded at room temperature on a Shimadzu UV-365 spectrophotometer equipped with a clamp-type cell[14] (optical path length: 1.6 cm). High-temperature spectra were recorded at atmospheric pressure on a Shimadzu MPS-2000 instrument equipped with a pair of thermostated quartz cells (optical path length: 0.98 cm).

The experimental details were described in a previous paper.[10]

Results and Discussion

Spectra at Atmospheric Pressure and Room Temperature. The positions of the visible absorption spectra of CoX_2 in 4-Me-py and 2-Me-py solutions at atmospheric pressure and room temperature are listed in Table 1 together with those of the py[10,11] and 3-Me-py[12] systems. In the 4-Me-py system, the spectra are composed of both the O- and T-bands. This feature is similar to that in the py[10,11] or 3-Me-py[12] system. The O-band is due to the $^4T_{1g}(F) \rightarrow {}^4T_{1g}(P)$ electronic transition of the octahedral complex and the T-band is due to the $^4A_2(F) \rightarrow {}^4T_1(P)$ transition of the tetrahedral complex. On the other hand, in the spectra of the 2-Me-py system, a strong T-band is observed, but an O-band is hardly found. Similar results have been mentioned in the earlier reports[2,5,6,15-17] which described how the $[CoX_2(2\text{-Me-py})_4]$ complex seems to be little formed owing to a steric hindrance by the methyl group in 2-Me-py.

It can be seen in Table 1 that for octahedral or tetrahedral halo complexes having different ligands of amine bases, the energy of the strongest peak decreases in the order: py $\geqslant$ 4-Me-py > 3-Me-py > 2-Me-py. The position of the strongest peak could be a rough measure for the strength of the ligand field, though the position of the center of a band should be an exact measure of that. Therefore, the above order of R-py also reveals roughly a decreasing order of the ligand-field strength. This dependence of the ligand-field strength on R-py may result from a steric effect. This result is in contrast with earlier results.[5,6,16-18] The positions of the T-band have been reported to remain almost unchanged regardless of ligand R-py, namely, $[CoX_2(4\text{-Me-py})_2]$ or $[CoX_2(2\text{-Me-py})_2]$ in chloroform[16] and $[CoX_2(py)_2]$ or $[CoX_2(2\text{-Me-py})_2]$ in py or 2-Me-py solution.[17] Sawada et al.[5,6] have also found that the peak positions of $[CoX_2(R\text{-py})_2]$ in 1,2-dihaloethane solutions do not depend on the kind of ligand R-py. As for octahedral complexes, Goodgame and Hayward[18] have shown that for solid complexes the O-band of $[CoBr_2(4\text{-Me-py})_4]$ lies at longer wavelength than that of $[CoBr_2(3\text{-Me-py})_4]$.

sh: shoulder.
a) In each complex, the peaks and shoulders are aligned in the order of decreasing intensity on going from left to right.

Pressure Effect. Figure 1 shows the pressure dependence of the spectra of $CoCl_2$ in 4-Me-py. For both chloro and bromo (not shown) complexes, the intensities of the T-band decrease, but those of the O-band increase with increasing pressure. Therefore, it can be concluded that the equilibrium of Eq. 1 shifts toward the octahedral species $[CoX_2(4\text{-Me-py})_4]$ with increasing pressure. A similar feature has been also found in the py[10] or 3-Me-py[12] system.

The absorption spectra of $CoCl_2$ in 2-Me-py at various pressures are shown in Fig. 2. Two bands were found in addition to the T-band: a weak band at about 510 nm, and a weak, broad band ranging from $\approx$360 to $\approx$410 nm (see also Fig. 5). These two bands are discussed below in the section concerning the tempera-

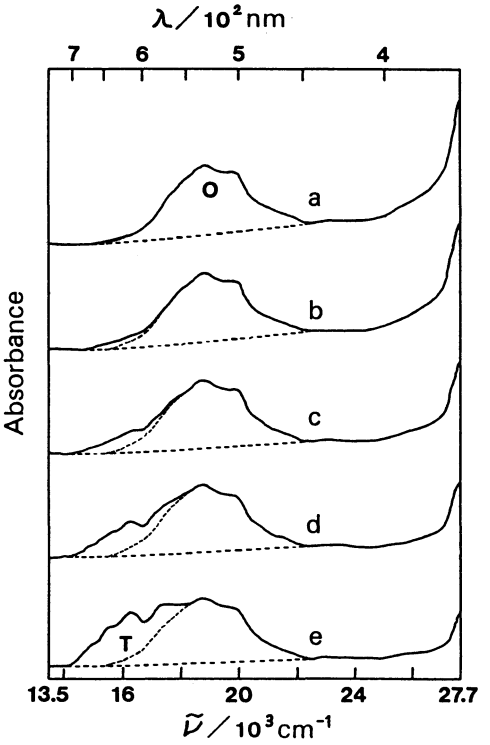

Fig. 1. Absorption spectra of $CoCl_2$ in 4-Me-py at high pressures (28.2°C), uncorrected for compression of solution. Each broken line shows the separation of the bands. Concn: 8.16×10^{-4} mol dm^{-3}. a: 3.0 kbar, b: 2.1 kbar, c: 1.0 kbar, d: 0.5 kbar, e: 1 bar.

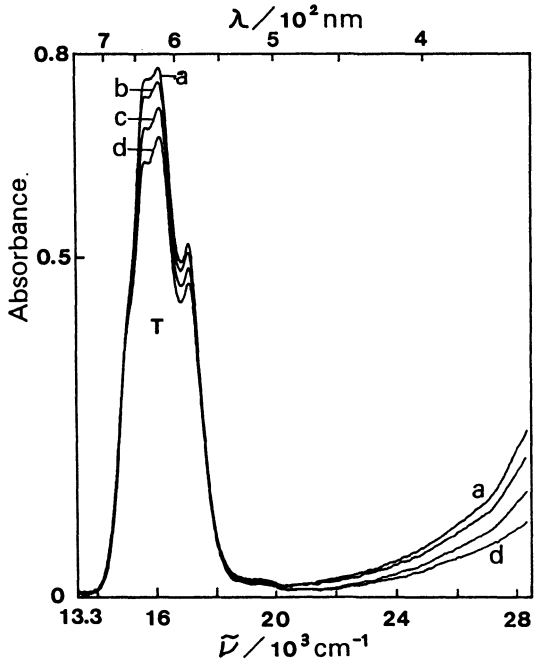

Fig. 2. Absorption spectra of $CoCl_2$ in 2-Me-py at high pressures (27.7°C), uncorrected for compression of solution. Concn: 7.70×10^{-4} mol dm^{-3}. a: 3.0 kbar, b: 2.0 kbar, c: 1.1 kbar, d: 1 bar.

ture effect. Contrary to the 4-Me-py system, the T-band in the 2-Me-py system apparently becomes stronger with increasing pressure. This tendency has also been observed in the high-pressure spectra of the tetrahedral complex $[CoCl_4]^{2-}$ in CH_3NO_2.[19] Even if the spectra are corrected for a compression of the solution, the T-band intensity changes little with pressure. Therefore, in the 2-Me-py system, the equilibrium of Eq. 1, if it exists, may be scarcely affected by the pressure.

Consider the equilibrium of Eq. 1 in the 4-Me-py system described above. When the pressure increases, the equilibrium shifts toward the octahedral complex side with a volume change (ΔV) of the system. ΔV is calculated by the equation[10]

$$\Delta V = -RT\frac{d}{dP}\ln(I_o/I_T), \qquad (2)$$

where R is the gas constant and I_o and I_T are the integrated intensities of the O- and T-bands, respectively.

As described in Ref. 10, Eq. 2 is derived by assuming that the molar absorption coefficients of both the $[CoX_2(4\text{-Me-py})_4]$ and $[CoX_2(4\text{-Me-py})_2]$ complexes hardly depend on the pressure at relatively low pressures.[20] The activity coefficient of solvent 4-Me-py is also assumed to be independent of pressure; this seems to be reasonable at relatively low pressures.

The plots of $\ln(I_o/I_T)$ vs. pressure in Fig. 3 were fitted to the following equations by a least-squares method:

$$\ln(I_o/I_T) = 0.565 + 1.017P, \text{ for the chloro complex, and}$$
$$\ln(I_o/I_T) = 0.0254 + 0.995P - 0.209P^2 + 0.0211P^3, \text{ for the bromo complex.} \qquad (3)$$

a) This work. b) Ref. 12. c) Ref. 10. d) Ref. 11.

From Eqs. 2 and 3, the values of ΔV were estimated to be all negative; these are listed in Table 2 together with those of the py[10,11] and 3-Me-py[12] systems.

From Eq. 1, ΔV equals $V_{oct}-(V_{tet}+2V_{sol})$, where V_{oct}, V_{tet}, and V_{sol} are the intrinsic molar volumes of the octahedral species, the tetrahedral species, and the solvent, respectively. The values of V_{oct} and V_{tet} are not available, but the molar volumes of some related complexes in solutions have been reported. Libus et al. have estimated the molar volumes of $[ZnCl_2(py)_2]$ and $[NiCl_2(py)_4]$ in py solutions to be 198.7 ± 1.3 cm^3 mol^{-1} [21] and 333 ± 10 cm^3 mol^{-1},[22] respectively. Narbutt and Siekierski[23] have obtained the molar volume of $[Co(NCS)_2(4\text{-Me-py})_4]$ in benzene solutions as 428 ± 15 cm^3 mol^{-1}. The molar volumes of py and methylpyridines can be estimated from their densities to be of the order of 80 and 100 cm^3 mol^{-1}, respectively. On the basis of the above values, the magnitude of $|\Delta V|$ at 1 bar (Table 2) seems reasonable.

The values of $|\Delta V|$ at 1 bar were found to decrease

according to the ligand sequence py>4-Me-py>3-Me-py. This sequence shows that V_{oct} relative to the sum of V_{tet} and $2V_{sol}$ becomes large in the order, py<4-Me-py<3-Me-py, owing to the steric hindrance of R-py ligands in each octahedral complex.

The differences in $|\Delta V|$ at 1 bar between the chloro and bromo complexes are large in the py system, but are small in the 4-Me-py and 3-Me-py systems. This fact suggests that the contribution of X to both V_{oct} and V_{tet} is smaller in the methylpyridine systems than in the py system.

It can be seen in Table 2 that for both the chloro and bromo complexes the ratios of the values of $|\Delta V|$ at high pressures to those at 1 bar increase in the order, py<4-Me-py<3-Me-py. It is impossible to discuss further this pressure dependence of $|\Delta V|$, since the activities and compressibilities of solvents R-py were not obtained at high pressures.

Temperature Effect. The absorption spectra of $CoCl_2$ in 4-Me-py at various temperatures are shown in Fig. 4. The intensity of the T-band increases steeply with increasing temperature. Although the change in the O-band with temperature could be obscured due to the intense T-band, the equilibrium of Eq. 1 probably shifts toward the tetrahedral species $[CoCl_2(4\text{-Me-py})_2]$ with increasing temperature, contrary to the pressure effect described above. A similar result was obtained

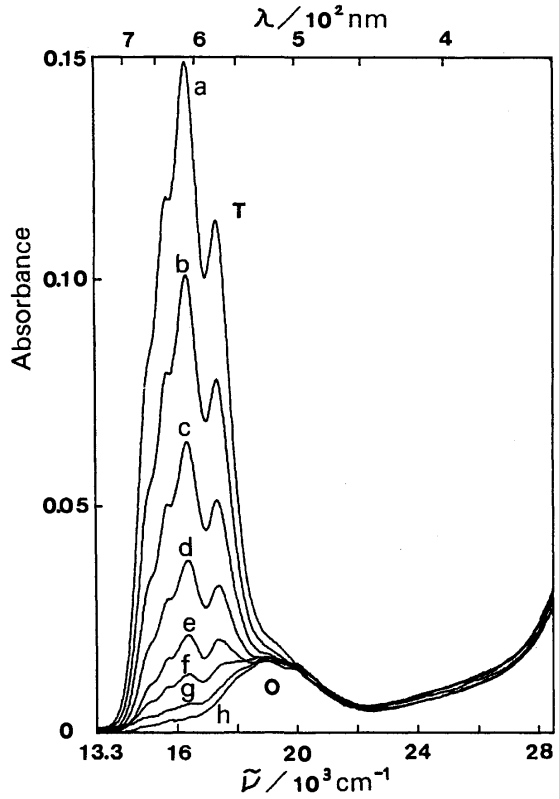

Fig. 4. Absorption spectra of $CoCl_2$ in 4-Me-py at various temperatures, uncorrected for thermal expansion of solution. Concn: 7.39×10^{-4} mol dm^{-3}. a: 74.8°C, b: 64.4°C, c: 54.6°C, d: 44.8°C, e: 35.2°C, f: 25.0°C, g: 14.9°C, h: 5.8°C.

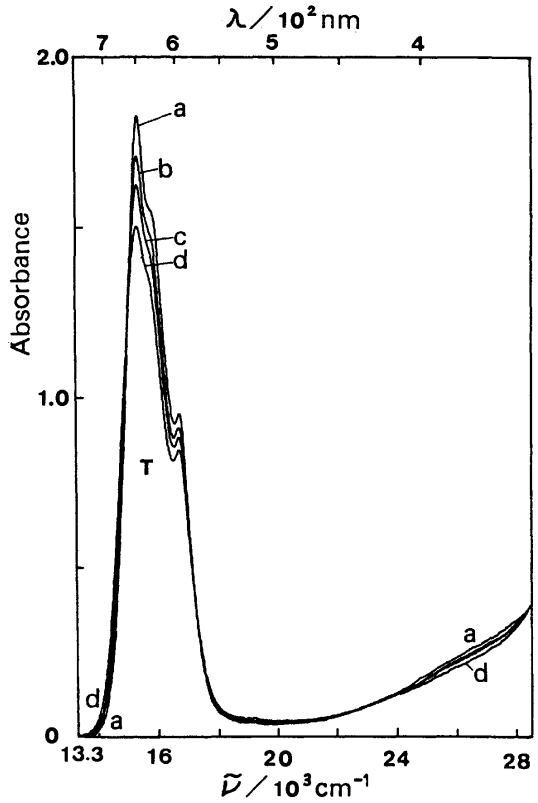

Fig. 5. Absorption spectra of $CoBr_2$ in 2-Me-py at various temperatures, uncorrected for thermal expansion of solution. Concn: 2.18×10^{-3} mol dm^{-3}. a: 5.5°C, b: 26.3°C, c: 44.5°C, d: 75.3°C.

for the bromo complex (not shown). Such a tendency is similar to that of the py[10] or 3-Me-py[12] system.

Figure 5 shows the absorption spectra of $CoBr_2$ in 2-Me-py at various temperatures. Contrary to the 4-Me-py system, the intensity of the T-band apparently decreases slightly with increasing temperature. Therefore, the equilibrium of Eq. 1 in the 2-Me-py system may be hardly shifted with increasing temperature.

In the 4-Me-py system, the heat of reaction for $[CoX_2(4\text{-Me-py})_4] \rightleftarrows [CoX_2(4\text{-Me-py})_2]+2(4\text{-Me-py})$, ΔH, can be obtained by the method described in Ref. 10: The variation of the equilibrium constant for the reaction of $[CoX_2(4\text{-Me-py})_4] \rightleftarrows [CoX_2(4\text{-Me-py})_2]+2(4\text{-Me-py})$ with temperature can be approximately followed by the change of the T-band intensity. As the intensity of the T-band, the absorbance of the 664-nm shoulder for the chloro complex and that of the 646-nm peak for the bromo complex are used. In Fig. 6, the logarithm of the corrected absorbance A' is plotted against the reciprocal absolute temperature. In order to obtain A', the observed absorbance is corrected by use of the thermal expansion coefficient for solvent 4-Me-py (1.038×10^{-3} K^{-1}[24]). The plots in Fig. 6 can be fitted to straight lines, indicating that each value of ΔH is constant over each temperature range. The slopes of the lines give ΔH as follows: 53.3 kJ mol^{-1} for the chloro complex over the range of 5.8—74.8 °C and 62.6 kJ mol^{-1} for the bromo complex over the range of

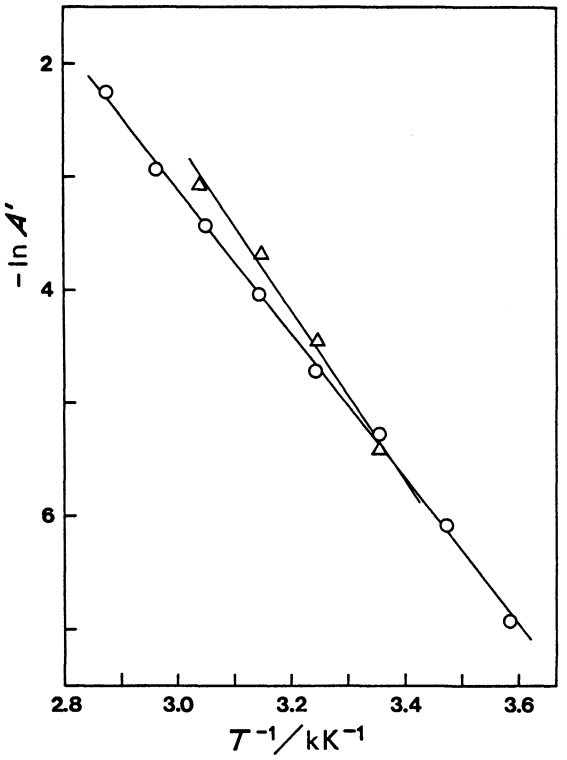

Fig. 6. Logarithm of the corrected absorbance A' vs. reciprocal absolute temperature in the 4-Me-py solution system. O: $CoCl_2$, Δ: $CoBr_2$, ——: calculated fitting lines.

Table 3. ΔH for the Reaction of $[CoX_2(R\text{-}py)_4] \rightleftarrows [CoX_2(R\text{-}py)_2]+2(R\text{-}py)$

R-py (ligand)	Solvent	ΔH / kJ mol^{-1}			Reference
		Cl	Br	I	
py	py	57.3	60.7	65.3	10, 11
	$CHCl_3$	63.6	65.3	69.5	2
4-Me-py	4-Me-py	53.3	62.6		This work
	$CHCl_3$	65.7			3
3-Me-py	3-Me-py	56.7	58.6		12
	$CHCl_3$	56.1			3

25.0—55.8 °C These values are listed in Table 3 together with the values for the py and 3-Me-py complexes in each R-py solution[10-12] and in $CHCl_3$ solutions.[2,3]

As described above, the values of ΔH are determined by the same method as that described in the literature,[1,8,9,25] by assuming that the concentration of the octahedral complex is constant in the experimental temperature range.[10] This assumption seems reasonable when the concentration of the octahedral complex is much larger than that of the tetrahedral complex. In order to examine the validity of this assumption, in the $CoCl_2$-4-Me-py system (Fig. 4), for example, the decrease in the concentration of $[CoCl_2(4\text{-}Me\text{-}py)_4]$ with increasing temperature was attempted to be taken into account by subtracting the concentration of $[CoCl_2(4\text{-}Me\text{-}py)_2]$ from the total concentration of Co(II). The concentration of $[CoCl_2(4\text{-}Me\text{-}py)_2]$ was determined by using the molar absorption coefficient at 615 nm of 663 dm^3 mol^{-1} cm^{-1} for $[CoCl_2(4\text{-}Me\text{-}py)_2]$ in $CHCl_3$-4-Me-py mixtures,[16] since the value in the 4-Me-py solution could not be obtained. Using the spectral data in Fig. 4, the above procedure gives a ΔH which is larger by 2.5 kJ mol^{-1} than 53.3 kJ mol^{-1} in Table 3.

In spectroscopic studies of solution equilibrium, few studies have taken into account the temperature dependence of the activity of the solvent. Exceptionally, in an aqueous solution system, Swaddle and Fabes[26] regarded the relative density $\rho_r(=\rho_{T,P}/\rho_{298\,K,1\,bar})$ as an activity of the solvent water at high temperatures and high pressures on the basis of the solvent effect on the oscillator strength of the absorption band. In addition to the above consideration concerning the concentration of $[CoCl_2(4\text{-}Me\text{-}py)_4]$, taking the activity of solvent 4-Me-py into account with the method by Swaddle and Fabes,[26] the value of ΔH is 53.8 kJ mol^{-1}. This is only by 0.5 kJ mol^{-1} larger than 53.3 kJ mol^{-1} in Table 3.

Since the above procedures give similar effects concerning the values of ΔH in the other CoX_2-R-py systems, the values of ΔH in Table 3 seem to be reasonable.

It seems to be difficult at present to determine the values of the absorption coefficients of the octahedral and tetrahedral complexes in solutions of py, 3-Me-py, and 4-Me-py and the values of the activities of solvents at high temperatures. However, the method for determining ΔH used in the present and previous[10-12] reports seems to be reasonable.

As Table 3 shows, ΔH of the 4-Me-py system is larger for ligand Br^- than for ligand Cl^-, which is similar to the py,[10,11] 3-Me-py,[12] and $CHCl_3$[2,3] solution systems. This trend seems to be explained in terms of the dative π-bonding from Co(II) to the pyridine base proposed by King et al.:[2] Charge is readily transferred from ligand X^- to Co(II) in the order $Cl^- < Br^- < I^-$. This enhances the release of non-bonding d-electrons of Co(II) to antibonding pyridine base π-orbitals, thereby strengthening the Co(II)-N bond in the order $Cl^- < Br^- < I^-$.

The heats of dissociation of the solid complexes $[CoX_2(R\text{-}py)_4]$ in the reaction, $[CoX_2(R\text{-}py)_4](solid) \rightleftarrows [CoX_2(R\text{-}py)_2](solid)+2(R\text{-}py)(gas)$, have been reported to increase in the order $I^- < Br^- < Cl^-$ for the 4-Me-py[3,27] and 3-Me-py[3] complexes. The fact that this order for the heats of dissociation is opposed to the order for ΔH seems to be important in a further discussion of the X^- dependence of the dative π-bonding in solutions.

In the $CoBr_2$-R-py systems ΔH decreases in the order of ligand R-py: 4-Me-py > py > 3-Me-py (Table 3). This order agrees with that of the $CoCl_2$-$CHCl_3$ systems.[2,3] Cabral et al.[3] have pointed out that 3-Me-py

is the weakest π-acceptor since the charge densities on the 2-, 4-, and 6-positions, on which charges from Co(II) are concentrated, increase through a 3-methyl substituent. Therefore, the smallest ΔH for the 3-Me-py complex is mainly due to the dative π-bonding from Co(II) to ligand 3-Me-py. However, the largest ΔH for the 4-Me-py complexes may not be interpreted only in terms of the dative π-bonding, since 4-Me-py is a weaker π-acceptor than py; nevertheless, ΔH is larger for the 4-Me-py complexes than for the py ones. In the $CoCl_2$-R-py systems, the dependence of ΔH on ligand R-py is not the same as that of the $CoBr_2$-R-py systems. Especially, ΔH in the $CoCl_2$-4-Me-py system seems to be comparatively small (Table 3).

Lastly, temperature effects for the 2-Me-py solution system are discussed. As stated above, the intensity of the T-band for $CoBr_2$ in 2-Me-py apparently decreases with increasing temperature (Fig. 5). A similar result has been observed for $CoCl_2$ (not shown). Even if the intensity was corrected for the thermal expansion coefficient (1.123×10^{-3} K^{-1} [24]), it decreases with increasing temperature (not shown). The temperature effect on broadening the T-band is found to be small; thus, the oscillator strength of the T-band may decrease slightly with increasing temperature. This fact is interesting from the view point of the temperature dependence of the oscillator strength of the T-band.

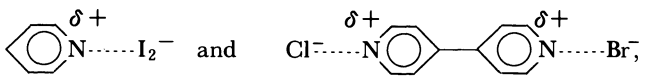
Assuming that only the tetrahedral complex $[CoX_2(2\text{-Me-py})_2]$ exists in the CoX_2-2-Me-py solutions at room temperature and atmospheric pressure, the molar absorption coefficient is estimated to be ε_{615}=537 $dm^3 mol^{-1} cm^{-1}$ for the chloro complex and ε_{650}=800 $dm^3 mol^{-1} cm^{-1}$ for the bromo complex. In the literature, the values of ε_{615} (693[16] and 610 $dm^3 mol^{-1} cm^{-1}$ [17]) and those of ε_{650} (853[16] and 832 $dm^3 mol^{-1} cm^{-1}$ [17]) have been reported; these values seem to be too large compared with those of this work. It is interesting that the inconsistency among the values of ε is large not for the bromo complex but for the chloro one. There are two possible explanations for this inconsistency. One is that no subtraction of the base lines for the T-bands was taken into account by Graddon and Watton[16] and by Libus et al.;[17] the other is that a partial dissociation of $[CoX_2(2\text{-Me-py})_2]$ probably occurs in the 2-Me-py solutions. This possible dissociation may be supported by the existence of both a weak band centered at about 510 nm and a weak, broad band ranging from ≈360 to ≈410 nm (Fig. 5).

The 510-nm band may be due to an ionic octahedral species of the type $[CoX_x(2\text{-Me-py})_{6-x}]^{2-x}$ [2,3] (x=0 or 1). According to a previous paper,[12] the band ranging from ≈360 to ≈410 nm may be assigned to a charge-transfer band arising in a contact pair of solvent molecule 2-Me-py with free ion X^-. $[CoX_x(2\text{-Me-py})_{6-x}]^{2-x}$ and free X^- may result from a dissociation of the tetrahedral complex $[CoX_2(2\text{-Me-py})_2]$.

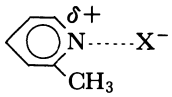
As Fig. 5 shows, the intensity of the CT band in the 2-Me-py system decreases with increasing temperature, which is contrary to that of the 3-Me-py system.[12] An explanation may be that in the 2-Me-py system the concentration of the free X^- ion decreases with increasing temperature, probably because of the formation of such an ionic tetrahedral species as $[CoX_3(2\text{-Me-py})]^-$ by a reaction between X^- and $[CoX_2(2\text{-Me-py})_2]$ at high temperatures.

The intensity of the CT band in the 2-Me-py system is less than that of the 3-Me-py system[12] at room temperature and the CT band is hardly observed in the py[10] and 4-Me-py systems. From these results, it is concluded that free ion X^- can be easily formed in solvents in the order 4-Me-py, py $\ll$ 2-Me-py $<$ 3-Me-py.

Referring to the literature[28,29] showing structures of the ion pairs as



the structure of the CT complex in the present study may be:



where X^- is a donor and nitrogen is an acceptor.

The author would like to express his sincere thanks to Professor Jiro Matsuda of Ritsumeikan University for valuable discussions, critical reading of the manuscript, and continuous encouragements. The author also wishes to thank Professor Ikuji Tsujikawa and Dr. Norimichi Kojima of Kyoto University for their encouragement. Thanks are due to Mr. Hajime Taguchi and Mr. Toshiro Nakada of Ritsumeikan University for their support during the experiment.

24) The thermal expansion coefficient of 4-Me-py, $1.038\times10^{-3}\,K^{-1}$, is evaluated from the slope of the least-square fitting straight line for the plots of the reciprocals of densities of 4-Me-py vs. temperatures. Those densities are given in "Beilsteins Handbuch der Organishen Chemie," ed. by Deutschen Chemischen Gesellschaft, Springer-Verlag, Berlin (1935), Hauptwerk Band XX, p. 240 and *ibid.*, ed. by Beilstein-Institut für Literatur der Organischen Chemie, Springer-Verlag, Berlin (1978), Ergänzungswerk III/IV, Band XX, p. 2734. By the same manner, the thermal expansion coefficients of the other amine bases are estimated as follows: $1.084\times10^{-3}\,K^{-1}$ for py, $0.875\times10^{-3}\,K^{-1}$ for 3-Me-py, and $1.123\times10^{-3}\,K^{-1}$ for 2-Me-py. In Refs. 10 and 12, the values of ΔH for the py and 3-Me-py systems (X=Cl, Br) have been obtained by using the approximate thermal expansion coefficient $1\times10^{-3}\,K^{-1}$. The values of ΔH estimated by using the above new coefficients are found to agree with those in the previous reports[10,12] within the experimental error.

(Received May 20, 1987)

Scandium(III) *p*-toluenesulfonate hexahydrate, as well as the isomorphous yttrium(III) and six lanthanoid(III) (Sm, Gd, Dy, Ho, Er, and Yb) *p*-toluenesulfonate enneahydrates, were synthesized and their structures were determined by the single-crystal X-ray diffraction technique. The scandium salt was monoclinic with the space group $P2_1/a$, $Z=4$ (the cell constants were $a=23.672(16)$, $b=15.792(6)$, $c=7.7543(12)$ Å, $\beta=92.86(3)°$, and the final R value was 0.059). The central metal atom is hexa-coordinated, being in an octahedral geometry, in which two unidentate sulfonate oxygen atoms (in cis-configuration) and four water oxygen atoms are ligated. The latter seven salts were also monoclinic with a space group of $P2_1/n$, and $Z=4$ (the cell constants of the holmium salt, for example, were $a=25.058(19)$, $b=7.476(2)$, $c=17.802(10)$ Å, $\beta=98.80(8)°$, and its final R value was 0.039). The central metal atom of these complexes are octa-coordinated, being in a square-antiprism geometry in which two unidentate sulfonate and six water oxygen atoms are ligated. In both types of complexes, no ligand bridgings were found, and one in three sulfonate ions was not coordinated to the metal atom. In the respective lanthanoid(III) complexes, M-O(sulfonato) bonds are shorter than the M-O(water) ones. The corresponding M-O bonds of the respective complexes decrease, almost proportional to the sum of the Shannon's ionic radii of the metal and oxygen, with the metal atomic numbers. Each M-O bond length of the yttrium(III) *p*-toluenesulfonate and 2-naphthalenesulfonate had the value expected from the corresponding bond lengths of the series of the respective isomorphous lanthanoid(III) salts, referring to its metal ionic radius.

Since only a few structural data concerning lanthanoid sulfonates have been published, the coordination behavior of such a hard base to a hard acid metal is very interesting. The structures of the lanthanoid 2-naphthalenesulfonates had already been elucidated,[1] but since the ligand is large, we should also examine the other arenesulfonates in order to reveal the common structure of the group of complexes. In the rare earth ethyl sulfates (La—Yb), all the coordination positions around the metal atom were occupied not by the sulfato but by the water oxygen atoms[2,3] On the other hand, in crystals of the lanthanoid(III) (Pr—Yb) 2-naphthalenesulfonates two in three anions as well as six water molecules act as unidentates. Since no bridging or chelating of the ligand was found, the coordination geometry around the metal atom is not so deformed as the carboxylato complexes.[4-8]

Recently, we could synthesize the scandium(III), yttrium(III), and some lanthanoid(III) (Sm through Yb) *p*-toluenesulfonates approximately by the same synthetic method. It is interesting to compare their structures with each other, especially those of the scandium and yttrium salts with the lanthanoid(III) ones.

We have relatively small numbers of structural data concerning the scandium(III) and yttrium(III) complexes. Regarding the scandium(III) carboxylates studied, the central metal atom was always hexa-coordinated and the high coordination number found in the yttrium or lanthanoid complexes were not recognized.[9,10] However, it was reported that tris(cyclopentadienyl)scandium and -lutetium have the same type chain structure, probably due to their similar atomic radii.[11] Therefore, the hexa-coordination of scandium is thought not to be always assured in all kinds of the complexes.

From the structural data, it was found that yttrium(III) formate,[12] acetate,[13] chloroacetate,[10] hexafluoroacetylacetonate,[14] and some acetylacetonates,[15,16] are isomorphous with the corresponding salts of lanthanoid(III). As the energy levels of the 4f orbitals in the yttrium(III) ion are thought to be too high to make any hybrid orbitals,[17] the orbitals are not likely used in the coordination bonds of its complexes. Although Cotton already wrote that 4f electrons hardly contribute to the formation of hybrid orbitals,[18] this fact can be more clearly proved if any isomorphous yttrium and lanthanoid complexes of the same ligand are found to always have the same geometrical environment around the respective metal atoms.

From this point of view, it is desirable to compare more structural data concerning their same ligand complexes, especially those which are obtained by the same synthetic technique and are isomorphous with each other.

The present study of the series of the rare earth *p*-

toluenesulfonates was aimed at investigating: 1) how the arenesulfonate ions are coordinated with the metal atoms, 2) if the scandium(III) and yttrium(III) salts have the same structures as those of the lanthanoid salts, and 3) how the M-O bond strength (which is related to the bond length observed) changes with the atomic number and with the metal ionic radius.

Therefore, we studied their crystal and molecular structures by the single-crystal X-ray diffraction technique. Their structures, bond lengths and angles were examined comparatively; especially their observed M-O bond lengths were compared with the standard values (the respective sums of the Shannon's ionic radii).[19]

The structures of the series of the rare-earth 2-naphthalenesulfonates,[1] including the newly obtained yttrium(III) and dysprosium(III) salts, have been examined comparatively, in order to clarify whether the relation between the observed M-O bond lengths and the sums of Shannon's ionic radii is the same as the *p*-toluenesulfonates.

a) The calculated values are shown in parentheses. b) HL=*p*-toluenesulfonic acid. c) Three in six water molecules of the original crystal $ScL_3{\cdot}6H_2O$ were lost by the drying process before the elemental analysis (lost water; Found 8.03%; Calcd 8.11%). d) HL'=2-naphthalenesulfonic acid.

Experimental

Syntheses of [Tetraaquabis(*p*-toluenesulfonato)scandium(III)] *p*-Toluenesulfonate Dihydrate. Into an aqueous solution of scandium(III) cholride (prepared by dissolving Sc_2O_3 (0.14 g, 1.0 mmol) into an excess of hydrochloric acid), excess of sodium hydroxide was added. Precipitated scandium(III) hydroxide was separated and dissolved in 10 cm^3 of water and *p*-toluenesulfonic acid hydrate (1.14 g, 6.0 mmol). The aqueous solution was left standing for several days until about two thirds of the water was evaporated off. Crystals of the title complex were deposited and were used for an X-ray structure analysis. Yield: 0.78 g (59%). Elemental analyses

e, f) See footnotes of Table 2. g) Their R values with inverse chirality were 0.069 and 0.059 respectively.

revealed that a sample dried for 24h in a vacuum desiccator over silica gel lost three water molecules per one metal atom. The results of the elemental analyses are shown in Table 1.

Syntheses of [Hexaaquabis(*p*-toluenesulfonato)yttrium-(III)] *p*-Toluenesulfonate Trihydrate and the Isomorphous. Lanthanoid(III) (Sm, Gd, Dy, Ho, Er, and Yb) Salts. An aqueous solution of the yttrium(III) salt was obtained almost in the same way as for the scandium(III) salt, starting with 0.23 g (1.0 mmol) of yttrium(III) oxide (Y_2O_3) and the acid hydrate (1.14 g, 6 mmol). It was left standing for several days in open air at room temperature until about four fifths of the water was removed. Crystals of the yttrium(III) complex were depositied. Yield: 1.12 g (72%). Isomorphous lanthanoid(III) (Sm, Gd, Dy, Ho, Er, Yb) salts were also obtained by an analogous method; their yields were between 70 and 80%.

All of the obtained salts did not show a mass loss beyond the experimental error after being left standing for two days in a vacuum silica gel desiccator at ambient temperature. However, when they were kept for several months under the conditions, some part of water was lost especially in the case of the samarium(III), and to a smaller extent, in the case of the gadolinium(III) salt. When these crystals were dipped into methanol, ethanol, or 1- or 2-propanol medium, crystals of the samarium salt were destroyed immediately, and those of the gadolinium salt after a few minutes. Althouth the heavier lanthanoid salts did not decompose soon, they also lost water while being kept in the medium longer. When all of these salts, after being kept for a long time in alcohol, were dried in a vacuum silica gel desiccator, dehydrated salts were obtained. The stability of these hydrated crystals probably increases depending on the atomic number of the metal. Analyses of these salts are shown in Table 1.

Attempts to obtain a lighter isomorphous lanthanoid(III) (La—Nd) *p*-toluenesulfonates by the same synthetic method were not successful; their salts in the triclinic system, which effloresce very rapidly, were obtained alternatively.

Syntheses of [Hexaaquabis(2-naphthalenesulfonato)yttrium(III)] 2-Naphthalenesulfonate Trihydrate. The synthetic technique for isomorphous lanthanoid(III) complexes previously reported[1] was used, starting with yttrium(III) chloride ($YCl_3\cdot 6H_2O$) (0.30 g, 1.0 mmol) and 2-naphthalenesulfonic acid (0.70 g, 3.4 mmol). Yield: 0.45 g (52%). Their analyses are shown in Table 1.

Single Crystal X-Ray Structure Analysis. The crystal and molecular structures of the ten titled complex crystals were examined by the single-crystal X-ray diffraction method. Their crystallographic data, experimental conditions for obtaining intensity data, and their final R values calculated after applying anisotropic thermal parameters to all non-hydrogen atoms are shown in Tables 2 and 3.

During the intensity data collection, the crystals of samarium(III) and gadolinium(III) complexes were destroyed through irradiation by X-rays in open air. Consequently, the crystals of the samarium and gadolinium salts used for the X-ray diffraction study were sealed into borosilicate glass capillaries. Since the decomposition rate decreases rapidly, depending on the atomic number of the metal, practically no trouble was found regarding measurements of the heavier lanthanoid complexes.

The reflections were collected on a Rigaku AFC-6A automated four-circle X-ray diffractometer with graphite-monochromated Mo $K\alpha$ (λ=0.71073 Å) radiation, with a scan speed of 4° (θ) min^{-1}. The ω-2θ scan technique was used for scandium *p*-toluensulfonate and both of the 2-naphthalenesulfonates, while the ω-scan method was applied for the other *p*-toluenesulfonates. The intensities were corrected for Lorentz and polarization factors, but not for absorption and extinction.

Structure Determination. The structure of the scandium(III) and yttrium(III) *p*-toluenesulfonates were solved by the heavy-atom method. The positions of the metal and sulfur atoms were, respectively, deduced from three dimensional Patterson maps. The positions of the other atoms were succesively located by Fourier syntheses. Their positional and thermal parameters were repeatedly refined by the block-diagonal least-squares method. In the end, all non-hydrogen atoms were found.

The structures of the isomorphous lanthanoid(III) *p*-toluenesulfonates were refined by starting with the parameters of the isomorphous yttrium complex. The structures of yttrium(III) and dysprosium(III) 2-naphthalenesulfonates were obtained starting with the final parameters of the isomorphous erbium(III) salt, $[Er(C_{10}H_7SO_3)_2(H_2O)_6](C_{10}H_7SO_3)\cdot 3H_2O$, and refined as usual.[1] In these cases, the positions of the naphthalene-ring hydrogen atoms were calculated assuming the C-H bond lengths to be 1.08 Å and their B_{iso}'s to be 6.0 Å^2. The parameters of the hydrogen atoms were fixed during the refinement. Since their crystals have no center of symmetry, refinements using the inverse chirality were also carried out; the one giving a lower R value was adopted for each complex. Both of them were found to have the same chirality as the erbium salt. All calculations were carried out on a HITAC M-682H appara-

tus at the Computer Center of the University of Tokyo using a local version of the UNICS program.[20] The atomic scattering factors were taken from Ref. 21.

Other Measurements. Their infrared spectra were obtained by a JASCO A-202 grating infrared spectrophotometer using liquid paraffin and hexachloro-1,3-butadiene mull. Simultaneous thermogravimetric (TG) and differential thermal analyses (DTA) were carried out with a Rigaku Denki "Thermoflex" M-8075 using samples weighing about 10 mg each, at a heating rate of 10 °C min^{-1} in air, α-alumina as the reference.

Results and Discussion

The final atomic parameters and the equivalent isotropic temperature factors of the scandium(III), yttrium(III), and lanthanoids(III) (Sm, Gd, Dy, Ho, Er, Yb) *p*-toluenesulfonates, as well as those of the yttrium(III) and dysprosium(III) 2-naphthalenesulfonates are shown in Table 4. Their selected bond lengths and bond angles are tabulated in Tables 5, 6, and 7.[22] A perspective drawings of the scandium(III) and yttrium(III) *p*-toluenesulfonates around their central metals, together with the numbering scheme, are shown in Figs. 1 and 2. The crystal packing diagrams of the scandium(III) and yttrium(III) *p*-toluenesulfonates, together with the nomination of the toluene rings, are shown in Figs. 3 and 4 respectively.

In the scandium(III) *p*-toluenesulfonate, the central metal atom is hexa-coordinated and is in an octahedral geometry, where two unidentate sulfonato oxygen

atoms are ligated in the cis-configuration; the other four coordinating positions are occupied by water oxygen atoms.

Both of the Sc-O (sulfonato) (2.044 Å, on the average (hereafter, shown by av.)) are shorter than the Sc-O (water) (2.117 Å av.), and the average of all the Sc-O bond lengths is 2.092 Å; this is approximately the same as the sum of the Shannon's ionic radii of Sc (Valence (Val)=3+, Coordination number (CN)=6) and O (Val=2−, CN=2), 2.10 Å.[19] The angle of Sc-O(11)-S(1) (147.2(2)°) is about the same as any M-O-S angles of lanthanoid *p*-toluenesulfonates and 2-naphthalenesulfonates,[1] but the other angle Sc-O(21)-S(2) (175.6(2)°) is much larger. This is probably due to a steric hindrance of the ligand coordinated at the cis-position. The third sulfonate ion is not coordinated to the metal atom, although it is bridged by hydrogen bondings to the coordinated water oxygen atoms. All three S-O bond lengths of the non-coordinated anion are not much different from each other (1.445, 1.452, and 1.462 Å). While in the coordinated anions, the S-O bond lengths of the ligated oxygen atoms (1.485 Å av.) are longer than the other two to the non-ligated oxygen atoms (1.431 Å av.). However, the average of all three S-O bond lengths of the coordinated and non-coordinated ions are not much different from each other (1.453 and 1.449 Å, respectively).

In the crystal, the metal atoms are approximately on the (200) planes. The hydrophobic layers of the tolyl groups of the ligands intercalate between respective pairs of hydrophilic metal complex planes. No ligand bridgings have been found between any neighboring

h) The equivalent isotropic temperature factors were computed using the following expression: $B_{eq}=4/3(B_{11}a^2+B_{22}b^2+B_{33}c^2+B_{13}ac\cos\beta)$. The B_{ij}'s are defined by $T=\exp[-(h^2B_{11}+k^2B_{22}+l^2B_{33}+2klB_{23}+2hkB_{12}+2hlB_{13}]$.

metal complexes, though they are bridged by hydrogen bondings via interposed crystalline water molecules and free anions. In the c-axis direction, hydrogen bond bridgings are found between any pairs of side-by-side metal complexes; however, in the b-axis direction, the respective pairs of the neighboring metal complexes are bridged or non-bridged alternately. Therefore, the hydrogen bond network in the crystal is extended like a belt in the c-axis direction.

As shown in Fig. 3, both tolyl groups of the ligands coordinated to the same metal atom are in the same side hydrophobic layer: Their methyl groups are

extended toward the same direction.

All toluene rings of the ligands are laid approximately perpendicular to the bc-plane, and A^i, B, C, as well as A, C^i, B^i, planes (i=0.5−*x*, 0.5+*y*, 1−*z*) are accumulated approximately in parallel, respectively: The dihedral angles between the ab-plane and the both group planes are about −30° and +30°, respectively.[22]

In yttrium(III) *p*-toluenesulfonate and, accordingly, in the isomorphous lanthanoid(III) salts as well the central metal atom is octa-coordinated, being in a square-antiprism geometry in which the oxygen atoms of the unidentate *p*-toluenesulfonate ions take positions on the different squares while keeping the maximum separation from each other. The general feature of the coordination geometry around the metal atom resembles that of the lanthanoid(III) 2-naphthalenesulfonates.[1]

Table 5. Selected Bond Lengths and Bond Angles of Scandium(III) *p*-Toluenesulfonate Hexahydrate

Bond length (*l*/Å)			
Sc-O(11)	2.067(4)	Sc-O(21)	2.021(4)
Sc-O(W1)	2.132(4)	Sc-O(W2)	2.119(4)
Sc-O(W3)	2.097(4)	Sc-O(W4)	2.118(4)
S(1)-O(11)	1.487(4)	S(1)-O(12)	1.457(4)

S(3)-O(33)	1.452(4)		
Bond angle (*φ*/°)			
Sc-O(11)-S(1)	147.2(2)	Sc-O(21)-S(2)	175.6(2)

The Y-O (sulfonato) bond lengths (2.326 Å av.) are shorter than the Y-O (water) (2.361 Å). The average of the all Y-O bond lengths is 2.352 Å, which is a little shorter than the sum of the Shannon's ionic radii, 2.369 Å.[19] The Y-O-S angles are 144.8 and 144.9°. These values are not much different from the corresponding ones of the yttrium and lanthanoid(III) 2-naphthalenesulfonates. As in the case of the scandium salt, the bond from the sulfur to the ligating oxygen atoms (1.467 Å av.) are longer than the bonds to the non-ligating oxygen atoms (1.442 Å av.), while three S-O bonds of the non-coordinated sulfonate ion are not much different from each other (1.453, 1.445, and 1.449 Å). As shown in Table 6, the same bond length relations are also found in the respective lanthanoid(III) salts.

The metal complex cores are located approximately on the planes parallel to (100), which cross the a-axis at 1/4 and 3/4. The metal complexes are connected with each other by two-dimensional hydrogen bonds, as shown schematically in Fig. 5. Each pair of the neighboring hydrophilic layers of the complex cores is intercalated by the hydrophobic layer of the tolyl groups of the anions. As shown in Fig. 4, the arrangement of the tolyl groups in the crystal is different from that in the scandium complex. Both of the toluene rings of the coordinating ligands are in the hydrophobic layers on both sides of the metal atoms; their methyl groups are extended toward the opposite directions from each other.

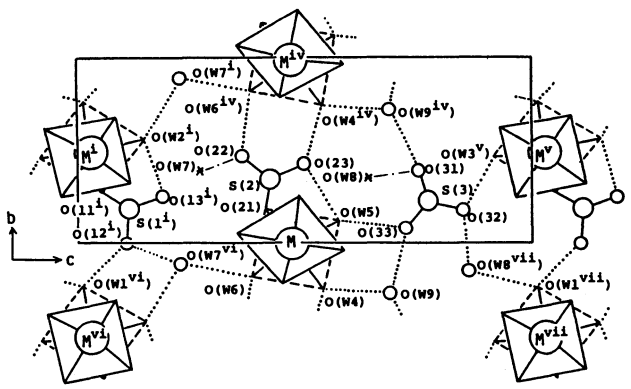

Fig. 5. Schematic presentation of the bridgings between the metal(III) complex molecules of yttrium(III) or lanthanoid(III) (Sm, Gd, Dy, Ho, Er, Yb) p-toluenesulfonate enneahydrates. As four two-fold screw axes are perpendicular to the ac-plane (crossing the plane at; 1/4, 0, 1/4; 1/4, 0, 3/4; 3/4, 0, 1/4; and 3/4, 0, 3/4), the same type of the linkage network exists also in the upper plane. Key to the symmetry operations: i, 0.5−x, 0.5+y, 0.5−z; ii, 1−x, 1−y, 1−z; iv, x, 1+y, z; v, 0.5−x, 0.5+y, 1.5−z; vi, 0.5−x, −0.5+y, 0.5−z; vii, 0.5−x, −0.5+y, 1.5−z.

The toluene rings of the anions are not perpendicular to the bc-plane, nor parallel with each other, and the dihedral angles between the bc-plane, and the A[i], B, C, planes are about 75, 79, and 84°, respectively.[22]

Generally, in the complexes of 3d-metals, the hard-base ligands such as the sulfonates cannot make strong coordination bonds, and the M-O bonds are usually longer than those by the common ligands.[23]

Table 8. Dihedral Angles between the Planes in the Square-Antiprism Geometry around Metal Atoms of Yttrium(III) and Lanthanoid(III) (Sm, Gd, Dy, Ho, Er, Yb) p-Toluenesulfonate Enneahydrates (θ/°)

M=	a—b[m]	c—d[m]
Y	1.78	44.34
Sm	1.74	44.64
Gd	1.87	44.29
Dy	1.70	44.53
Ho	1.42	44.51
Er	1.62	44.70
Yb	1.50	44.59

m) Respective least squares planes, a, b, c, and d, include atoms written as follows: a, O(11), O(W3), O(W1), O(W2); b, O(21), O(W5), O(W4), O(W6); c, O(11), M, O(W1); d, O(21), M, O(W4). The numbering of the atoms is the same as Fig. 3.

On the other hand, in these rare earth p-toluenesulfonates as well as in the 2-naphthalenesulfonates, the M-O (sulfonato) bond lengths are shorter than the standard M-O bond longths, the sum of the Shannon's ionic radii.[19] In cases of the other lanthanoid(III) complexes, their carboxylates, for example, have the M-O (carboxylato) bond lengths, which are almost the same as the respective sums of the Shannon's ionic radii.[4–10,12,13,24] Although in some lanthanoid(III) β-diketonates, the M-O (ligand) bond lengths are shorter than the respective sums,[25–27] it is rather due to the chelating effect of the ligand.

Since the title complexes have only unidentate ligands, sulfonato ions and water molecules, the square-antiprism geometry around the central metal atom is not much deformed from the ideal shape, as shown in Table 8. On the contrary, in carboxylato complexes, which have many chelating and bridging ligands, the geometry is much deformed. This is an expected result from the structural consideration by Kepert.[28,29]

As shown in Table 2, in the series of the isomorphous lanthanoid(III) p-toluenesulfonates, the cell-dimensions as well as the cell volume decrease, and the crystal density increases with the atomic number of the central metal atom. However, the size and shapes of the hydrocarbon part of the ligands stay approximately the same.

From a comparison of the atomic parameters of the corresponding atoms of the respective isomorphous complexes, those of the oxygen atom (sulfonato and water) and, to a smaller extent, those of the sulfur atoms change with the metal atomic number. However, the arene-carbon atoms also move to some extent, which may be caused by the larger standard deviations of their parameters. The largest observed deviations of

atomic parameters in the series of complexes are: the *x*-coordinate of O(12) (from 0.1497(2) (Sm) to 0.1533(2) (Yb)); the *y*-coordinate of O(W4) (from −0.2664(6) (Sm) to −0.2563(6) (Yb)); the *z*-coordinate of O(W2) (from 0.3469(3) (Sm) to 0.3528(3) (Yb)). All of these values change with the atomic number of the central metal atom.

Thus, the change of the packing in the unit cell due to a decrease in the metal ionic size occurs mainly around the coordination sphere. Consequently, it is important to clarify the relation between the observed M-O lengths and the respective standard value (now the sum of the Shannon's ionic radii[19] was adopted for the purpose) of the series of the isomorphous lanthanoid(III) complexes, which are shown graphically in Fig. 6.

In this figure, lines 1 and 2 show the average M-O (sulfonato) and M-O (water) bond-lengths of the complexes, respectively, while lines 3 to 6 are examples of the M-O bond lengths to the individual oxygen atoms. Line 7 is a reference line which shows the sum of the Shannon's ionic radii.

All of the observed M-O values do not deviate much from the respective lines (1—6), although the points of lines 3—6 are distributed over the wider range than those of lines 1 and 2.

All M-O bond lengths of the yttrium complex were found to be situated not far from the respective corresponding lines if the sum of its Shannon's ionic radii (2.37 Å) was taken as their abscissa value.

Although the same relation was found between the observed M-O bond lengths and the sums of the Shannon's ionic radii in the series of the yttrium and lanthanoid 2-naphthalenesulfonates, more detailed results were not obtained owing to the larger standard deviations of their final atomic parameters.

From these results, not only the carboxylates or β-diketonates, but also the arenesulfonates of yttrium were found to have the same coordination geometry and coordination number of the central metal atom as the corresponding salts of lanthanoids, especially which have approximately the same ionic radii.

Although scandium is also a member of the same group element of the periodic table, since its tervalent ionic radius is much smaller than those of yttrium or lanthanoids, it takes a different coordination number.

As shown in the former section, at ambient temperature, enneahydrated *p*-toluenesulfonates of samarium and gadolinium lost their water more easily. To clarify this dehydration process, we have examined simultaneous TG and DTA measurements of all the synthesized *p*-toluenesulfonates. Curves of the scandium and the gadolinium salts are shown in Fig. 7, as the examples, and the results of all the salts are tabu-

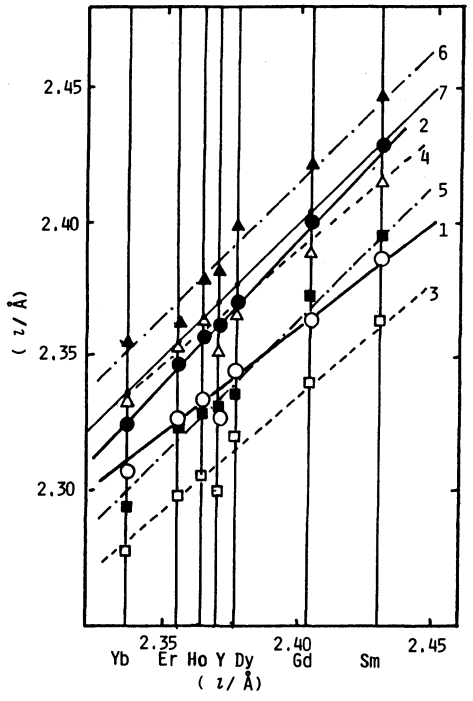

Fig. 6. The relation between the calculated (abscissa) and the observed (ordinate) M-O bond lengths of the yttrium and lanthanoids (Sm—Yb) *p*-toluenesulfonate enneahydrates. 1, —○—, the average of the M-O(sulfonato); 2, —●—, the average of the M-O(water); 3, –□–, M-O(11); 4, –△–, M-O(21); 5, –■–, M-O(W4), 6, –▲–, M-O(W3), 7, —●—, sum of the Shannon's ionic radii (calculated value).[22]

Second mass loss (t/°C)[n]		105	107	109	108	104	110	103
Lost water at first step (n/mol)[o]	6.0	7.3	7.4	7.5	7.6	7.6	7.7	7.8
Lost water at second step (n/mol)[o]		1.7	1.6	1.5	1.4	1.4	1.3	1.2
First peak of DTA (t/°C)[p]	73	70	77	84	85	85	86	86
Second peak of DTA (t/°C)[p]	(98)	127	128	127	126	128	128	126

n) The temperature where each TG curve is going down was read (the starting point of each mass loss). o) The mol numbers of the lost water at respective steps were calculated from the TG curves. p) The temperatures of respective endothermic peaks of the DTA curves.

lated in Table 9.

From the TG curves, it was found that the water molecules of the scandium salt were removed in one step, while those of the gadolinium through ytterbium as well as the yttrium complexes in two steps. On their DTA curves, all complexes show two endothermic peaks, the first big one and the second small one; both of them seem to correspond to the respective two steps of the mass loss of the TG curve, except for the scandium salt, which also shows a small second peak at a much lower temperature. The general feature of the respective TG and DTA curves of the isomorphous lanthanoid (Sm—Yb) complexes are approximately the same, though there are some continuous variations depending on the increase of the central metal atomic number:

i) All the hydrated water molecules in the crystals were lost in two steps: the ratio of the first step mass loss to the second one increases. (from 7.3(Sm) to 7.8(Yb) molecules of water).

ii) The temperature of the first endothermic peak of the DTA curve is elevated (from 70 (Sm) to 86 (Yb) (t/°C).

iii) The observed corresponding values of the yttrium complex took positions approximately between those of the dysprosium and holmium salts, while the metal ionic radius of yttrium was between those of the latter two metals.

Although we could clearly recognize that water in the crystals could be removed more easily from complexes of the lighter lanthanoid(III) complexes than those of the heavier ones at ambient temperature, the respective TG and DTA curves were not much different from each other.

As the coordination number of lanthanoid(III) is always high (commonly 8 or 9 except when the ligand is very large[30]) it does not decreased even when the hydrated water molecules are removed from the crystal. The sulfonate anions must move and act as multidentates forming more M-O bonds in place of the removed water oxygen atoms. From their unit cell size, as well as from their density, we can imagine that the anion can move more easily in samarium and gadolinium complexes, since there is more free space in the unit cell. Moreover, since we could not obtain isomorphous members of neodymium or lighter lanthanoid salts when the same synthetic process was applied, the crystal structures of the light lanthanoid elements may not be so stable as the heavier metal salts. However, the energy barrier to keep the hydrated water molecules in the respective positions is probably not high in all of these crystals, although they are effective in the heavier metal complexes at ambient temperature.

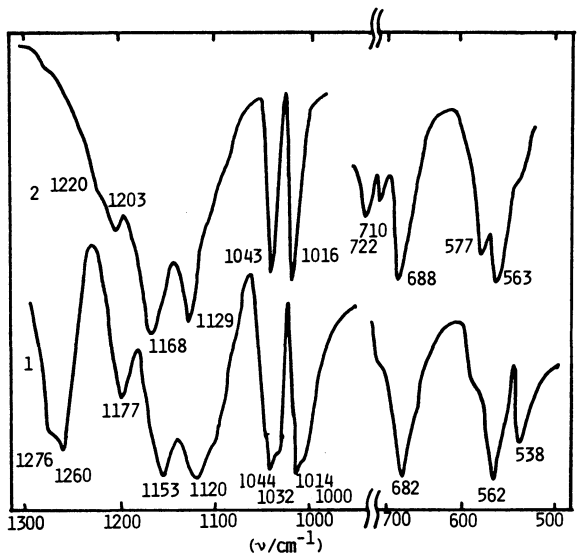

Fig. 8. Infrared spectra of 1, scandium(III) and 2, yttrium(III) *p*-toluenesulfonates, $ScL_3 \cdot 6H_2O$, and $YL_3 \cdot 9H_2O$ (HL=*p*-toluenesulfonic acid).

From their thermal analyses, it was shown that, when the temperature is elevated, all water molecules of even the heavier metal salts obtain sufficient kinetic energy to jump over the barrier and to move in the crystal easily. The dehydration rates of all the member salts are much more accerelated than those at room temperature, and are not much different from each other.

The infrared spectra of the scandium, yttrium, and lanthanoid (Sm, Gd, Dy, Ho, Er, Yb) *p*-toluenesulfonates were examined; the spectra of the former two in the 1100—1300 cm^{-1} as well as 500—700 cm^{-1} regions are shown in Fig. 8, where the characteristic bands of the sulfonato group are expected to appear.

The scandium salt, which is in a hexa-coordination geometry, gave an infrared spectrum that is a little different from those of the other salts, while the isomorphous lanthanoid as well as yttrium salts almost gave the same pattern spectra in these regions. Therefore, there are almost no differences between the bonding character of the sulfonato ions in the series of the latter complexes.

The authors wish to thank the Shin-Etsu Chemical Ind. Co., Ltd., for presenting us with the highly pure rare earth oxides.

(Received June 18, 1987)

The pH titration curves of λ-MnO_2 showed apparently dibasic acid character toward Li^+ ions, but a monobasic acid character toward Na^+, K^+, Rb^+, and Cs^+ ions. The adsorptive capacities of alkali metal ions increased in the order; K^+, Rb^+, $Cs^+ < Na^+ \ll Li^+$ at pH 10. Overall equilibrium constants were calculated by a simplified Gaines-Thomas equation from the titration curves based on the ion-exchange mechanism. Thermodynamic data were derived for the system of (0.1-M LiCl+LiOH)(1 M=1 mol dm^{-3}) at different temperatures. Effects of ionic strength and adsorption temperature on the lithium ion adsorptivity were studied using (LiCl+LiOH) and (KCl+LiOH) solutions.

Ion-sieve type manganese oxides show excellent selectivities for certain ions or group of ions.[1-7] They are prepared by a crystallization of manganese hydroxide containing metal ions, followed by a topotactic extraction of the metal ions with mineral acid. Their adsorptive properties depend on the kind of metal ions introduced as precursors into the manganese hydroxide.[2,6] When lithium and magnesium ions were used as introducing ions, the manganese oxides obtained show a remarkably high selectivity for lithium ions.[6,7] Their lithium-selective properties are closely related to the formation of such spinel-type materials as $LiMn_2O_4$ and $MgMn_2O_4$ during thermal crystallization while being prepared.

Recently, Hunter prepared spinel-type manganese oxide (λ-MnO_2) by extracting lithium from pure $LiMn_2O_4$ with acid.[8] Because of its uniform character, λ-MnO_2 is very suitable as a model compound for a fundamental study of the ion-sieve effect for metal ions extracted from the aqueous phase. In a previous paper, its adsorptive properties for various metal ions showed a remarkably high selectivity for lithium ions in a range above pH 2.5.[9] The metal-ion uptake at pH 10 reached about 5 meq·g^{-1} for lithium ions but less than 0.2 meq·g^{-1} for potassium and cesium ions. The distribution coefficients (K_d's) of metal ions at pH 4 were in the order $Na^+ < K^+ < Rb^+ < Cs^+ \ll Li^+$ for alkali metal-, $Mg^{2+} < Ca^{2+} < Sr^{2+} < Ba^{2+}$ for alkaline earth metal-, and $Ni^{2+} < Zn^{2+} < Co^{2+} < Cu^{2+}$ for transition metal-ions. These results are readily explained if we recognize that the tetrahedral vacant sites in λ-MnO_2 are too narrow for metal ions other than lithium to enter. The only species which can enter these sites are H^+ and dehydrated Li^+ ions.

The present paper describes a pH titration study on λ-MnO_2 for alkali metal ions. The selectivity constants and overall thermodynamic constant were evaluated from the titration data based on the ion-exchange model. Acid-base properties have been investigated for different types of manganese oxides from electrochemical[10,11] and geochemical[12-14] interests and for the fundamental study of the adsorption phenomena.[15,16]

Experimental

Ion-Exchange Material and Characterization. The λ-MnO_2 used was the same as that described in a preceding paper.[8] It was prepared by the acid treatment of $LiMn_2O_4$ with a 1-M HNO_3 solution. The lithium content of the acid-treated sample was 0.12 meq·g^{-1}, indicating that more than 97% of the lithium was extracted from the $LiMn_2O_4$ by the acid treatment. A powdered X-ray diffraction analysis showed λ-MnO_2 of a spinel type structure with an 0.800-nm lattice constant on a cubic unit cell.

pH Titration Curve. A weighed amount (0.100 g) of the λ-MnO_2 was immersed into a mixed solution (10 cm^3) of (MCl+MOH) (M=Li, Na, K, Rb, Cs) in varying ratios with intermittent shaking at 25 °C. The concentration of MCl was adjusted to 0.1 M. After shaking for 3 weeks, the pH of the supernatant solution was determined in a decarbonated atmosphere. The kinetic study showed that three weeks were sufficient to attain a constant pH value. The metal ion concentration in the supernatant solution was determined by atomic absorption spectrometry. The metal ion uptake by λ-MnO_2 was evaluated from the difference between the initial and equilibrium concentrations of the metal ion in the solution or from determining metal ions after dissolving metal ion-adsorbed λ-MnO_2 with a mixed solution of concentrated HNO_3 and HCl. The chloride ion uptake was determined by ion chromatography after dissolving the λ-MnO_2 with a mixed solution of H_2O_2 and H_2SO_4.

In the case of lithium ion adsorption, the effects of ionic strength and adsorption temperature were examined in (KCl+LiOH) and (LiCl+LiOH) systems in addition to the above titration.

Apparatus. X-Ray diffraction analysis was carried out with a Rigaku Denki X-ray diffractometer (model Rad II) using Ni filtered Cu $K\alpha$ radiation(graphite monochrometer). A Perkin-Elmer atomic absorption spectrophotometer (model 403) was employed for atomic absorption spectrometry and a Horiba M8s pH meter for pH measurement. A Dionex Ion Chromatograph apparatus (model 10) was used for ion chromatography.

Reagents. All the chemicals were of an analytical grade from Wako Pure Chemical Ind. Ltd., except for RbCl, RbOH, and CsOH which were obtained from Merck Ltd. These were used without further purification.

Results and Discussion

pH Titration Curves. The pH titration curves and pH dependences of metal ion uptakes are shown in Fig. 1. A remarkable difference was obtained between a (LiCl+LiOH) system and the other metal salt systems on the pH titration curve. The pH titration curve in the (LiCl+LiOH) system (Fig. 1, top right) showed a dibasic acid charactor. The apparent capacity of Li^+ was found to be about 5 meq·g^{-1} on the pH titration curve. The supernatant solutions at pH>8 had a slightly purplish color due to the presence of a small amount of Mn(VII) ions. Their concentration was less than 5×10^{-4} M by atomic absorption spectrometry. Smaller differences than the Li-system were observed between the pH titration curves for the other systems and for the blank experiment. A small apparent capacity of 0.2 meq·g^{-1} was obtained even on the system of (NaCl+NaOH). The supernatant solutions were colorless over the pH ranges studied.

The apparent capacities determined by metal ion uptakes were nearly equal to those obtained by the differences between the blank run and each titration curve (Fig. 1(B)). This suggests that the metal ion adsorption proceeds by an ion-exchange mechanism. The apparent adsorptive capacity increased in the order: Na, K, Rb, Cs≪Li at pH values below 7. The affinity order changed to K, Rb, Cs<Na≪Li above pH 7, probably due to the large steric effect for large unhydrated cations (K, Rb, Cs) at higher pH. The chloride ion uptakes were found to be less than 0.01 meq·g^{-1} over the pH range studied. The affinity orders in the present study showed large differences from those on other types of manganese oxides. For example, cryptomelane-type hydrous manganese(IV) oxide(CRYMO) shows the affinity orders; Li< Na<Cs<Rb<K at pH 2 and Cs<Rb<Na<Li<K at pH 10,[16] and the layered hydrous manganese oxide ($H_4Mn_9O_{18}\cdot7H_2O$) Li<Na<K at pH<4 and K< Na<Li at pH>5.[5]

The difference in the affinity order between λ-MnO_2 and CRYMO can well be understood based on the difference in crystal structure. Cryptomelane-type manganese oxide has [2×2] tunnels of edge-shared MnO_6 octahedra.[17] Tsuji and Abe have pointed out that these [2×2] tunnels are very suitable to fix the metal ions with an effective ionic radius of 0.14 nm (K^+, Rb^+, Ba^{2+}).[4] Our result agrees in showing that the manganese oxides with [2×2] tunnels have high selectivities for Rb^+ and K^+ ions.[6] The λ-MnO_2 in H^+ form can be derived from the spinel structure of $LiMn_2O_4$.[18] The cubic $LiMn_2O_4$ spinel (lattice parameter a_0) contains eight formula units and has its close-packed array of

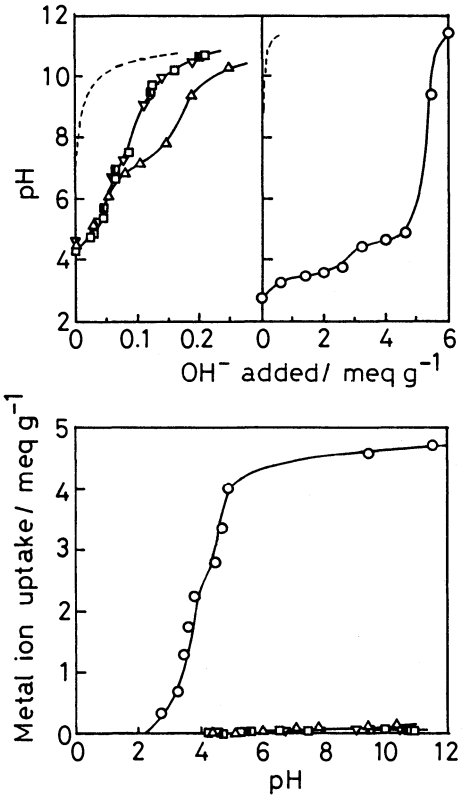

Fig. 1. pH titration curves of λ-MnO_2 by various bases and the pH dependences of metal ion uptake. λ-MnO_2: 0.100 g, soln: (0.1-M MCl+MOH) (M=Li(○), Na(△), K(□), Rb(▽), and Cs(◧)), total vol. of soln: 10 cm^3, temp: 25 °C. The dotted lines describe blank titrations.

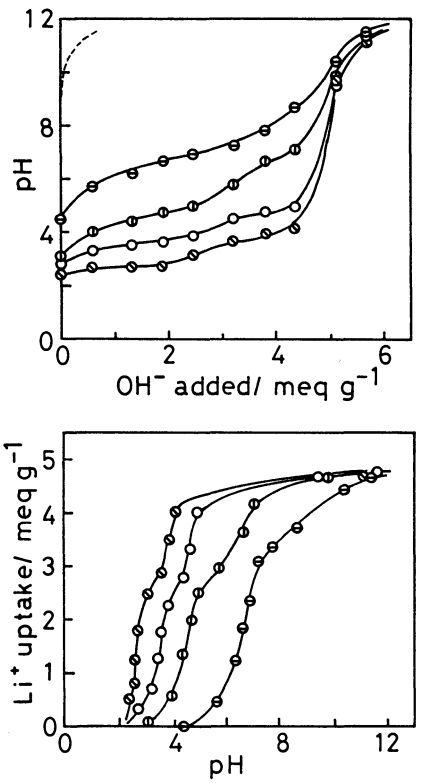

Fig. 2. pH titration curves of λ-MnO_2 toward lithium ions and the pH dependences of lithium ion uptakes. λ-MnO_2: 0.100 g, soln: (LiCl+LiOH) (concn of LiCl: 0 M(⊖), 0.01 M(Φ), 0.1 M(○), 1 M(⊗)), total vol. of soln: 10 cm^3, temp: 25 °C.

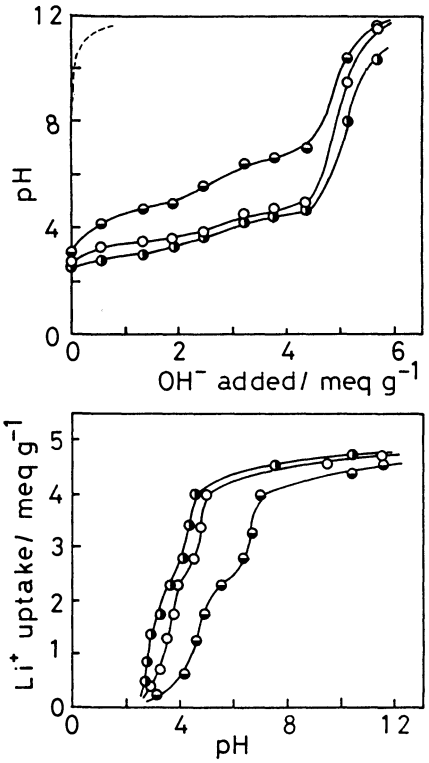

Fig. 3. pH titration curves in (0.1-M LiCl+LiOH) solution and the pH dependences of lithium ion uptakes. The experimental conditions are the same as those in Fig. 2 except for adsorption temperature. Temp: 10°C(◒), 25°C(○), 40°C(◑).

oxygens located at the 32e positions of the space group $Fd3m(O_h^7)$.[19] The Mn^{3+} and Mn^{4+} ions occupy half the octahedral sites, and the Li^+ ions an eighth of the tetrahedral sites. The acid treatment of $LiMn_2O_4$ causes the removal of nearly all of the lithium from the tetrahedral sites while maintaining a spinel structure.[8] Therefore, λ-MnO_2 has a structure that is related to spinel but with vacant tetrahedral sites. Since the size of the vacant sites is markedly smaller than the width of the [2×2] tunnels, it is reasonable to consider that the vacant sites are too narrow to hold the alkali metal ions except lithium even in a dehydrated state. Therefore, the pH titration curves for Na^+, K^+, Rb^+, and Cs^+ ions suggests that the ion-exchange reactions proceed only at the surface of the λ-MnO_2 particles.

The pH Titration Curves in (LiCl+LiOH) Solutions. Figure 2 illustrates the pH titration curves in (LiCl+LiOH) solutions with different LiCl concetrations. The pH titration curve shifts to lower pH range with increasing LiCl concentration. Figure 3 showed that the titration curve shifted to lower pH range with increasing adsorption temperature in the system of the (0.1-M LiCl+LiOH). The maximum lithium ion uptake can be estimated to be 4.75 meq · g^{-1} from Figs. 2 and 3, which is somewhat smaller than the value that is expected from the chemical formula of $LiMn_2O_4$ (5.7 meq · g^{-1}).

The previous paper indicated that the lattice constant (a_0) of the spinel structure increased by adsorption of lithium ions.[9] A similar tendency was also observed in the present study. The a_0 value calculated from the d_{111} peak of the X-ray diffraction pattern is plotted against $\overline{X}_{Li}$ ($\overline{X}_{Li}$ in Fig. 4: Equivalent fraction of lithium ions in λ-MnO_2=lithium ion uptake/ maximum lithium ion uptake). There was a difference in a_0 vs. $\overline{X}_{Li}$ curves between $\overline{X}_{Li}<0.5$ and $\overline{X}_{Li}>0.5$. The curve was sigmoidal at $\overline{X}_{Li}<0.5$ with steep slope around $\overline{X}_{Li}=0.25$. The a_0 value increased gradualy with increasing $\overline{X}_{Li}$ in a range of $\overline{X}_{Li}>0.5$. The lithium ion uptake vs. pH curves (Fig. 2) showed a pH rise at the boundary of the two curves ($\overline{X}_{Li}=0.5$). These results suggest that the mode of the insertion reaction of lithium ions differed slightly between $\overline{X}_{Li}<0.5$ and $\overline{X}_{Li}>0.5$. The presence of a stable $Li_{0.5}Mn_2O_4$ species has been observed in the case of the electrochemical removal of lithium from $LiMn_2O_4$; the removal of lithium proceeds easily to $Li_{0.5}Mn_2O_4$ but further electrochemical extraction becomes more difficult.[19]

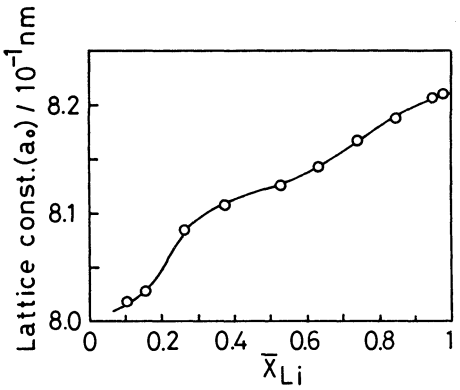

Fig. 4. Lattice constant of spinel structure as a function of $\overline{X}_{Li}$. Ion-exchanged λ-MnO_2 are obtained from (1-M LiCl+LiOH) solution at 25°C.

The pH Titration Curves in (KCl+LiOH) Solutions. Figure 5 illustrates pH titration curves in (KCl+LiOH) solutions with different KCl concentrations. The pH titration curve and the lithium ion uptake curve were scarcely influenced by the addition of KCl in a range below pH 7. This indicates that the sites for lithium ion adsorption are very specific and are scarcely influenced by the presence of potassium ions. In the range above pH 7, the pH titration curve showed a tendency to shift to lower pH values by the addition of KCl, and the lithium ion uptake to increase. The increase of the lithium ion uptake may not be due to a Li^+-K^+ exchange, because the lithium ion uptake decreases with KCl concentration in the case of competing exchange between lithium and potassium ions. The pH titration curves suggest that the λ-MnO_2 has negative charge at pH>5. Therefore, both the decrease of the pH value and the increase of the lithium ion uptake may be due to a decrease of the negative potential at the surface of λ-MnO_2 by the addition of KCl. The decrease of pH with increasing

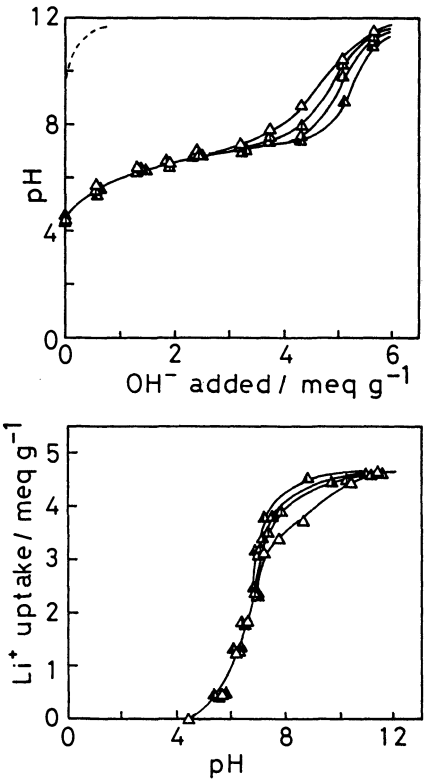

Fig. 5. pH titration curves in (KCl+LiOH) solutions and the pH dependences of lithium ion uptakes. The experimental conditions are the same as those in Fig. 2 except for KCl concentration. KCl concn: 0 M(△), 0.03 M(▲), 0.1 M(▲), and 1 M(▲).

salt concentration usually occurs in aqueous phase for negatively charged metal oxides owing to a decrease of the surface negative charge.[14,20]

Analysis Based on the Model of Ion-Exchange Reaction. The pH titration data can be analyzed on the basis of the ion-exchange mechanism as follows,

$$\bar{H}^+ + M^+ \rightleftarrows \bar{M}^+ + H^+ \quad (1)$$

where bar refers to H^+ or M^+ in λ-MnO_2 and M^+ is monovalent alkali metal ions. The equilibrium constant, K, of the above reaction is defined as,

$$K=[a_H(\bar{f}_M\bar{X}_M)]/[a_M(\bar{f}_H\bar{X}_H)]=K_C(\bar{f}_M/\bar{f}_H) \quad (2)$$

where a_H and a_M are activities of protons and metal ions in solution, respectively, $\bar{X}_H$ and $\bar{X}_M$ are the equivalent fractions of H^+ and M^+ in the λ-MnO_2, respectively, and $\bar{f}_H$ and $\bar{f}_M$ are the activity coefficients of H^+ and M^+ in the λ-MnO_2 phase, respectively. K_c is the selectivity constant including the activity coefficient of the metal ions in solution. It can be evaluated from the pH titration data as follows,

$$pK_C=-\log K_C = -\log[(a_H\bar{X}_M)/(a_M\bar{X}_H)] = pH-\log[\bar{X}_M/(1-\bar{X}_M)]+\log a_M. \quad (3)$$

In the case of a uni-univalent ion-exchange system, the contribution of the activity coefficient term in aqueous solution does not deviate seriously even over a temperature range from 283 to 313 K. Therefore, Eq. 3 can be related to the concentration term of metal ions (C_M) of Eq. 4,

$$pK_C \doteqdot pH-\log[\bar{X}_M/(1-\bar{X}_M)]+\log C_M. \quad (4)$$

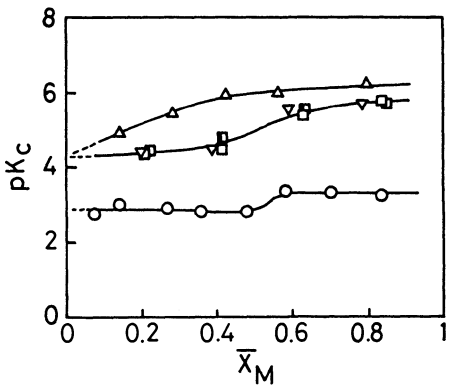

Fig. 6. pK_c vs. $\bar{X}_M$ plots calculated from Fig. 1. The symbols are the same as those in Fig. 1.

The K value and standard free energy change ($\Delta G°$) can be evaluated by using the simplified treatment of the Gaines-Thomas equation, assuming that the change of water content in the exchanger and the entrance of anion from the solution phase are negligible,[21]

$$pK = -\log K = \int_0^1 pK_C\, d\bar{X}_M \quad (5)$$

$$\Delta G° = (2.303\,RT)\,pK \quad (6)$$

pK_c vs. $\bar{X}_M$ Plots. Figure 6 illustrates a plot of pK_c vs. $\bar{X}_M$ in (MCl+MOH) system using Eq. 4. The maximum uptakes ($\bar{X}_M$ =1) of the metal ions were estimated as 4.75 meq·g^{-1} for Li^+, 0.18 meq·g^{-1} for Na^+, and 0.10 meq·g^{-1} for K^+, Rb^+, and Cs^+, respectively. The pK_c value was nearly constant (2.9) for Li^+/H^+ exchanges in the range below $\bar{X}_{Li}<0.5$ while it increased to 3.4 at $\bar{X}_{Li}>0.5$. This indicates the presence of two types of adsorption sites with slightly different affinities for lithium ions. The pK_c values showed a tendency to increase with increasing $\bar{X}_M$ for the other M^+/H^+ exchanges, probably due to an increase of negative surface charge with $\bar{X}_M$. The selectivity constant at $\bar{X}_M=0$ (pK_0) could be estimated by extrapolating pK_c value to $\bar{X}_M=0$ (Table 1).

Figure 7 illustrates the pK_c vs. $\bar{X}_{Li}$ plots in (LiCl+LiOH) and (KCl+LiOH) solutions. The pK_0 values were nearly equal (2.9—3.2) regardless of the salt species and salt concentration (Table 1). In the range above $\bar{X}_{Li}>0.5$, the pK_c value showed a tendency to decrease with increasing salt concentration. Since the decrease of pK_c in the (KCl+LiOH) system corresponds to the decrease of the pH with KCl concentration, the decrease may be partly due to the decrease of surface negative potential by the addition of neutral salt.

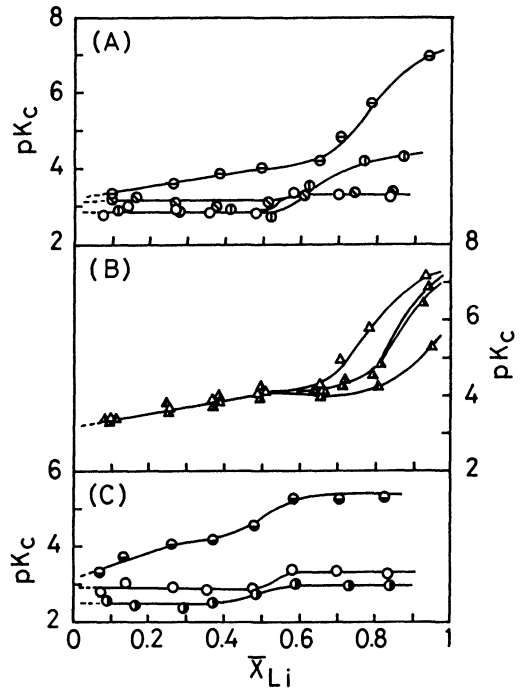

Fig. 7. pK_c vs. $\bar{X}_{Li}$ plots. Figures 8(A), 8(B), and 8(C) are calculated from Figs. 2, 5, and 3, respectively. The symbols are the same as those in the corresponding figures.

Table 1. Values of pK_0, pK, and $\Delta G°$ for λ-MnO_2

System	Concentration of added salt / mol dm^{-3}	T / °C	pK_0	pK	$\Delta G°$ / 10^3J mol^{-1}
LiCl+LiOH	0	25	3.23	4.53	25.9
	0.01	25	2.96	3.40	19.4
	0.1	25	2.91	3.13	17.9
	0.1	10	3.08	4.64	26.5
	0.1	40	2.58	2.74	16.4
	1	25	3.11	3.24	18.5
KCl+LiOH	0.03	25		4.33	24.7
	0.1	25	3.23	4.29	24.5
	1	25		4.01	22.8
NaCl+NaOH	0.1	25	4.2	5.8	33
KCl+KOH	0.1	25	4.2	5.1	29
RbCl+RbOH	0.1	25	4.2	5.1	29
CsCl+CsOH	0.1	25	4.2	5.1	29

Calculation of Equilibrium Constant. The pK values calculated using Eq. 5 and the $\Delta G°$ values are given in Table 1. The $\Delta G°$ value for Li^+/H^+ exchange showed tendencies to decrease with salt concentration and to decrease with adsorption temperature. The standard enthalpy and entropy changes ($\Delta H°$ and $\Delta S°$) at 298 K could be evaluated from the temperature dependence of $\Delta G°$ by the usual method. The $\Delta H°$ value, estimated with least square method, was 120 kJ per mole of lithium and a corresponding $\Delta S°$ 300 J K^{-1} mol^{-1}. Both of the $\Delta H°$ and $\Delta S°$ values were positive and were larger than those of Li^+/H^+ exchanges on another type of inorganic ion exchangers.[22,23] The positive $\Delta G°$ values may possibly arise from the increase of the volume of the unit cell and of water transfer to the aqueous solution from the exchanger with increasing adsorption of lithium ions at the tetrahedral vacant sites. Further study may be needed to determine the alternative contribution for $\Delta S°$ in this system.

Synthesis of the Cyclohexylammonium Form of α-Zirconium Phosphate and Its Application to Nickel(II) Ion Exchange[1)]

Yoshitsugu HASEGAWA,* Kaname SASAKI, and Hiroe TANAKA
Department of Industrial Chemistry, Faculty of Technology, Tokyo University of Agriculture and Technology, Nakamachi, Koganei, Tokyo 184
(Received June 22, 1987)

The uptake of cyclohexylamine with α-zirconium phosphate was studied by means of the pH-titration method. Cyclohexylamine was loaded up to 75% of the ion-exchange capacity of α-zirconium phosphate. Chemical analysis, thermal analysis, infrared spectroscopy, and X-ray diffractometry were used to characterize the product obtained at the final step of pH titration, which was referred to as the cyclohexylammonium form. The chemical composition can be presented as $Zr(C_6H_{11}NH_3)_{1.5}(H)_{0.5}(PO_4)_2 \cdot H_2O$. The interlayer distance of the exchanger expanded to 18.4 Å upon the uptake of cyclohexylamine. The cyclohexylammonium ion was exchanged easily with the nickel(II) ion in a solution.

α-Zirconium phosphate, having a layered structure, has been investigated not only as an inorganic ion exchanger but also as the host of an intercalate.[2)] Generally, the intercalate obtained has a larger interlayer distance than that of α-zirconium phosphate, and it can be expected to show a specific reaction toward a large cation.

Primary alkylamines, such as methyl- and ethylamine, have also been studied, and the relationship between the alkyl-chain length and the interlayer distance of the product has been discussed.[3)] Clearfield and Tindwa have found that the butylamine intercalate of α-zirconium phosphate can be ion-exchanged with a large cation.[4)] Recently, the electric conductivity was measured by using the intercalation compounds of α-zirconium phosphate with propylamine.[5)] Among the compounds with a ring system, benzylamine has been studied, but the details of the work have not been published.[2)]

Since cyclohexylamine is more strongly basic in an aqueous solution than is ammonia,[6)] the ion-exchange reaction can be expected to proceed easily. In this work cyclohexylamine is selected as an intercalant (guest) and the uptake of the amine was investigated by means of the pH-titration method. The cyclohexylammonium form of α-zirconium phosphate (ZP-Cy) obtained was then used in nickel(II) ion exchange.

Experimental

Reagents. The α-zirconium phosphate was prepared according to the literature.[6)] Reagent-grade cyclohexylamine (Wako Pure Chemical Industries, Ltd.; guaranteed) was used without further purification. Reagent-grade nickel(II) dichloride hexahydrate (Koso Chemical Co., Ltd.) was also used.

pH Titration. A weighed amount of α-zirconium phosphate was equilibrated with a mixture of 0.1 mol dm^{-3} cyclohexylamine and its hydrochloride solution. The composition of the solution was adjusted so that the total amount of the cyclohexylammonium ion was always equal to 0.1 mol dm^{-3} while the ratio of cyclohexylamine to its chloride was varied in the range from 1 to 0. The mixture was shaken continuously at 25 °C for a specified period of time, and then the pH value of the supernatant was measured on a pH meter.

A slight excess of cyclohexylamine to the ion-exchange capacity of α-zirconium phosphate was added to a weighed amount of the exchanger, and the mixture was shaken at 25 °C for 48 h. Then, the solid was separated with centrifugation and dried at room temperature in air. The product thus obtained is referred to as ZP-Cy (the cyclohexylammonium form of zirconium phosphate).

Nickel(II) Ion Exchange. The ion exchange was carried out by the batch method. The nickel(II) ion was exchanged by adding a weighed amount of ZP-Cy to a solution of 0.03 mol dm^{-3} nickel chloride. The amount of nickel was equal to 150% of the total ion-exchange capacity of the α-zirconium phosphate. The mixture was shaken continuously at 25°C for 48 h. After the reaction, the solid was separated from the solution and then washed with distilled water until it was free from chloride ions. The nickel-ion content in a solution was determined by an EDTA titration using PAN (1-(2-pyridylazo)-2-naphthol) as an indicator.

Analytical Procedure. The change in the crystal structure was studied by means of X-ray diffractometry using Ni-filtered Cu $K\alpha$ radiation (λ=1.542 Å)(Rigaku Geigerflex RAD-2B). Thermogravimetric (TG) and differential thermal analysis (DTA) data were obtained on a Shimadzu thermal analyzer at the heating rate of 10 °C min^{-1} in static air. The infrared (IR) spectra were measured on a A-302 spectrophotometer (Japan Specroscopic Co., Ltd.).

The chemical composition of the nickel form was analyzed according to the method in the literature.[8)] In this work, zirconium was separated as an mandelate and then ignited to zirconium oxide and weighed. The carbon, hydrogen, and nitrogen contents of ZP-Cy and the nickel form were determined by means of elemental analysis.

Results and Discussion

To determine the equilibration time, the pH value in the solution was measured after a given period of time by adding cyclohexylamine of 4.5 meq g^{-1} α-zirconium phosphate to the samples. Since equilibrium was attained within 12 h, the reaction time of 48 h was chosen.

Figure 1 shows the titration curve of α-zirconium

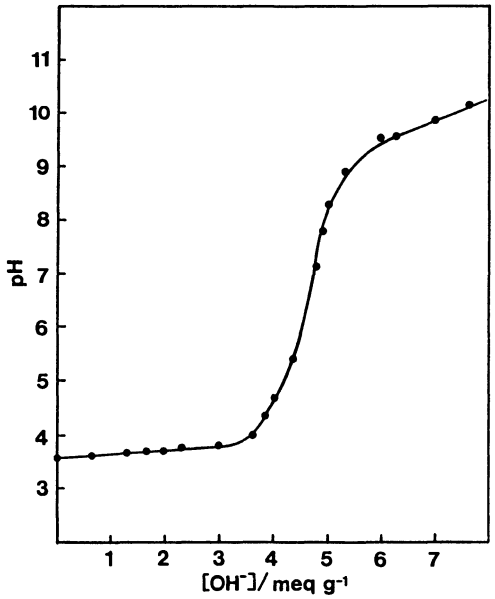

Fig. 1. pH titration curve.

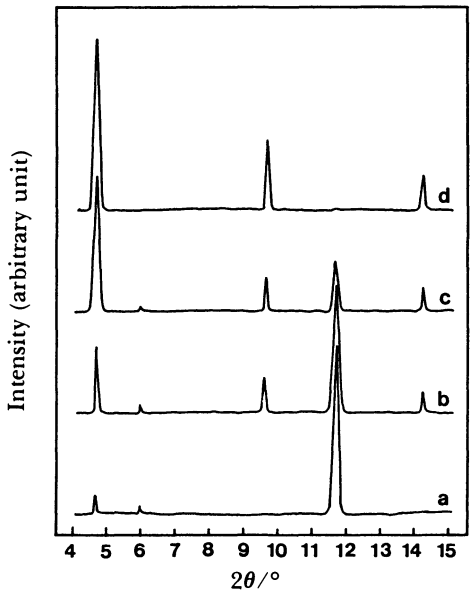

Fig. 2. Schematic diagram of X-ray powder diffraction at the lowest angle region. The percentage of ion exchange: a 15; b 30; c 45; d 60%.

phosphate with cyclohexylamine. Cyclohexylamine was taken up at a low pH value. The end point corresponded to 75% of the total ion-exchange capacity of α-zirconium phosphate.

Figure 2 shows the change in the crystal structure of the exchanger. Since α-zirconium phosphate has a layered structure, the change in the interlayer distance can be observed at the lowest angle region of the X-ray diffractogram. At the beginning of the ion-exchange reaction, only the α-zirconium phosphate phase (α-phase) was present. Between the loading from 10 to 55% of the total ion-exchange capacity of the exchanger, two phases, Phase I (interlayer distance

18.4 Å) and the α-phase, were present. The ratio of Phase I to α-phase increased with an increase in the exchange process. In the region of 60—75% of the loading, however, only phase I was present.

It is possible for cyclohexylamine to form two conformations, chair and boat. Since the chair conformation is more stable than the boat one,[10] it can be assumed that the cyclohexylamine is present as the chair conformation between the layers. While the bond length of C-C and the ∠CCC bond angle are 1.54 Å and 111° respectively in the molecule of cyclohexane, the length and the angle are 1.53 Å and 114° in the butane molecule.[11] If the angle and the distnce of the bond between the carbon and amino groups are almost identical in the butylamine and cyclohexylamine molecules, the lengths of the two molecules can be estimeted to be equal. Since the interlayer distance is equal to 19.0 Å in the butylamine intercalate of α-zirconium phosphate[12] and equal to 18.4 Å in the cyclohexylamine ones, the above assumption is reasonable. The estimation also suggests that the orientation of cyclohexylamine is similar to that of butylamine between the layers of zirconium phosphate. The sizes of benzylamine and cyclohexylamine can also be estimated based on the molecular sizes of cyclohexane and toluene. In consideration of the size of the amino group, the length of cyclohexylamine is calculated to be 8.7 Å, and that of benzylamine, to be 9.3 Å. Hence, the interlayer distance of the cyclohexylamine intercalates is comparable with that of the benzylamine form, having the interlayer spacing of 19.2 Å.[2]

The solid phases formed in the exchange process tend to lose hydrated water(s). After the solid has been exposed to room air on a sample holder, the X-ray diffractogram was different from that recorded under wet conditions. For example, the solid obtained at a 45% loading showed three peaks—at 18.4 Å (2θ=4.79°), 17.8 Å (2θ=4.96°), and 14.7 Å (2θ=5.96°)— after a short exposure. Table 1 shows the intensities of the peaks obtained after drying at room temperature. The intensity of the peak at 14.7 Å reached a maximum at about

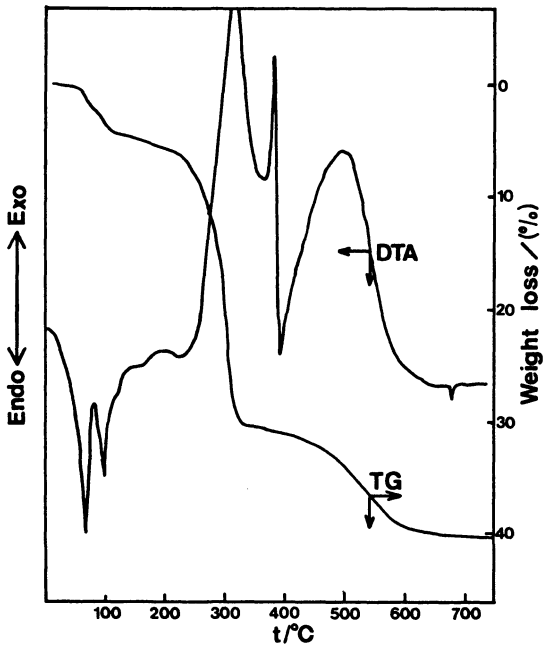

Fig. 3. Thermoanalytical curves.

a 20% loading. The intensity of the 17.8 Å peak increased up to a 60% loading. No change in the interlayer distance was observed above the 60% loading. These facts indicate that the hydrated water(s) play(s) an important role in expanding and maintaining the interlayer distance of the exchanger and that, at higher loadings, cyclohexylamine itself acts as a "pillar." Also, it is suggested that, when the intercalate compound with the amine lose hydrated water(s), the orientation of cyclohexylamine must change in the solid.

Characterization of ZP-Cy. The interplanar spacings (d-values) of ZP-Cy are shown in Table 2. The interlayer distance was comparable with those of the butylamine and benzylamine intercalate of α-zirconium phosphate described above.

Figure 3 shows the TG and DTA curves of ZP-Cy. The decomposition took place in three steps. In the first, the dehydration ocurred. In the temperature region of 200—300 °C, a weight loss and exothermic

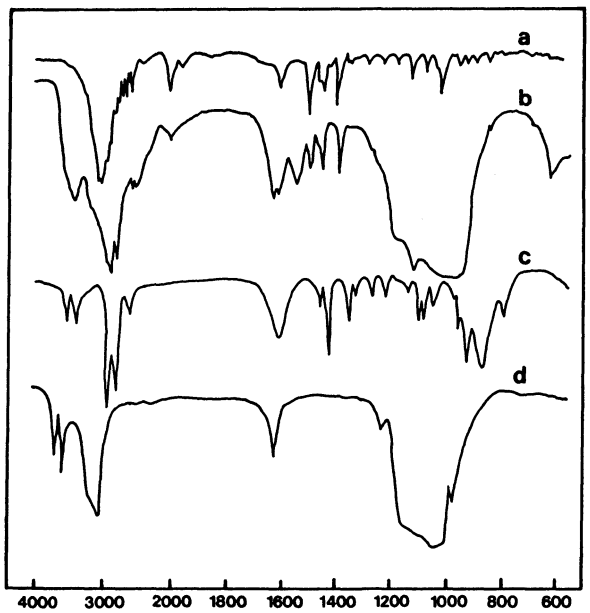

Fig. 4. Infrared spectrum of a cyclohexylamine hydrochloride, b ZP-Cy, c cyclohexylamine, and d α-zirconium phosphate.

peaks were observed. The weight loss was, however, smaller than that to be expected from the chemical formula (see below). These facts indicate that, in this step, the cyclohexylamine was evolved, decomposed, and oxidized partially on the surface of a platinum pan, and that a small amount of a residue (presumably carbon) was formed. The decomposition temperature was higher than that observed for the ammonium form, reflecting the basicity of cyclohexylamine.[13] In the temperature region of 400—500 °C, a weight loss was observed caused by the dehydration associated with the condensation of $(HPO_4)_2$ to P_2O_7. The reaction was supposed to be endothermic, but an exothermic peak appeared. This was caused by the oxidation of the residue formed at the second step, since the weight loss was larger than that to be expected from the chemical formula.

The IR spectra of ZP-Cy and related compounds are shown in Fig. 4. It is clear that the spectrum of ZP-Cy was almost identical with that of cyclohexylammonium chloride in the region of 1800—3500 cm^{-1}. Especially, the absorption was found at 2000 cm^{-1} only for the hydrochloride and ZP-Cy. This absorption is assigned to the group of NH_3^+. The absorption due to -OH stretching was present near 3500 cm^{-1} in the spectrum of ZP-Cy. These facts indicate that the cyclohexylamine was present as the cyclohexylammonium ion between the layers and that the unexchanged protons appear as $-HPO_4$, similarly to the situation in α-zirconium phosphate.

The contents of carbon, hydrogen, and nitrogen were as follows: Found: C, 24.0: H, 5.3: N, 4.3%. Calcd

for $Zr(C_6H_{11}NH_3)_{1.5}(H)_{0.5}(PO_4)_2 \cdot H_2O$: C, 24.0; H, 5.3; N, 4.3%.

It is concluded that α-zirconium phosphate uptakes cyclohexylamine up to 75% of the total ion-exchange capacity and that the cyclohexylamine is present as the cyclohexylammonium ion between the layers.

Nickel(II) Ion Exchange. The determination of nickel(II) showed that all the cyclohexylammonium ions in ZP-Cy were exchanged with Ni(II) in a solution. This also indicates that the cyclohexylamines are present as quartarnary ammonium ions between the layers of zirconium phosphate. The ion-exchange reaction did not proceed further, even if the solid phase after the first ion exchange was immersed in a nickel (II) solution. Thus, the nickel(II) in a solution can be exchanged easily only with the cyclohexylammonium ion in the solid. The product was pale green. The X-ray diffraction pattern of the product agreed well with that reported for $ZrNi(PO_4)_2 \cdot 4H_2O$. The chemical composition was as follows: Zr, 23.6; Ni, 11.6; PO_4, 47.5; H, 1.8: ignition loss, 17.4%. Calcd for $ZrNi_{0.75}H_{0.5}(PO_4)_2 \cdot 3.5H_2O$: Zr, 23.5; Ni, 11.3; PO_4, 48.9; ignition loss, 17.4%. The contents of carbon and nitrogen were within the background limit indicated by the elemental analysis.

The authors wish to express their thanks to Professor Isao Tomita, Ochanomizu University, for the measurement of the thermal analysis.

Oxygen Evolution by Means of Water Oxidation Catalyzed by Mononuclear Ruthenium-Ammine Complexes

Masao KANEKO,* Ramasamy RAMARAJ, and Akira KIRA
Solar Energy Science Research Group, The Institute of Physical and Chemical Research, Wako, Saitama 351-01
(Received August 3, 1987)

Water oxidation was achieved catalytically by the use of mononuclear ruthenium-ammine complexes and using Ce(IV) as an oxidant. Cyclic voltammetric studies of the mononuclear ruthenium-ammine complexes $[Ru(NH_3)_5Cl]^{2+}$ and $[Ru(NH_3)_5(H_2O)]^{3+}$, have been carried out using Basal Plane Pyrolytic Graphite (BPG) coated with poly(*p*-styrenesulfonate), Nafion, or Kaolin clay. The electrochemical properties of these ruthenium-ammine complexes show that they can be used as two-electron oxidants for water oxidation. It has also been found that these complexes oxidize water to evolve oxygen in the presence of excess Ce(IV) under homogeneous as well as heterogeneous conditions. The oxygen evolution by means of water oxidation was confirmed by using the $H_2{}^{18}O$ isotope in the reaction medium. The water oxidation process was found to be dependent on the ionic strength of the medium. Higher acidic conditions gave higher O_2 yields. Heterogeneous catalysis with the Ru complex adsorbed in Kaolin clay was as effective as the homogeneous one. The water oxidation reaction catalyzed by ruthenium-ammine complexes was also discussed.

The oxidation of water to molecular oxygen is of great importance as a means of converting light energy into chemical energy, because, among the possible methods of solar energy storage, its conversion into the energy of chemical fuels seems to be one of the most promising.[1,2] In order to realize such light-to-chemical energy conversion systems, the use of water as an electron donor, i.e., water oxidation, is a crucial point, as in the photosynthesis in nature. Oxygen evolution is significantly more difficult to accomplish than hydrogen evolution because four electrons must be transferred in the reaction (Eq. 1):

$$2H_2O \rightarrow O_2 + 4H^+ + 4e^- \quad (1)$$

The photogeneration of oxygen from water is an essential part of green-plant photosynthesis, where the oxygen evolves as a result of water photooxidation in the active center of the photosystem II, with the participation of Mn ions.[3] However, the mechanism of Mn catalytic action is still unclear. The difficulty of creating such models lies in the need to couple the four-electron oxidation of water (Eq. 1) with the one-electron chemistry of the photoredox process.[4] Several types of oxygen evolving catalysts have been identified,[5] but these catalysts are far from ideal, and there are many problems associated with their use in model photochemical systems.[4-8] In recent reports,[9-13] it has been shown that the soluble polynuclear metal complexes work as homogeneous[9-11] as well as heterogeneous catalysts[12-14a] to oxidize water to oxygen.

Recently, Collin and Sauvage[15] have prepared several complexes of ruthenium(II) which contain two molecules of sterically hindering diimine as ligands; they have studied the catalytic activity of the complexes toward water oxidation. None of these complexes display catalytic activity for oxygen formation from water in the presence of excess cerium(IV). Based on their observations, they concluded that a multimetallic system is required to achieve water oxidation to oxygen. Until now it has seemed quite rational to think that only the polynuclear complexes are candidates for the water oxidation because the reaction is a four-electron process. However, the present authors have found, for the first time, that mononuclear ruthenium-ammine complexes catalyze oxygen evolution by means of water oxidation in the homogeneous[14b] as well as in the heterogeneous state; they wish to report their findings in this paper.

Experimental

$[Ru(NH_3)_5Cl]^{2+}$ (Aldrich Chemicals) was used as received, while $[Ru(NH_3)_5(H_2O)]^{3+}$ was prepared by modifying the reported procedure.[16] A hot solution of silver trifluoroacetate, prepared by dissolving 0.079 g of Ag_2O in a 4 ml aqueous solution of 2 M trifluoroacetic acid (1 M=1 mol dm^{-3}), was added to 0.1 g of $[Ru(NH_3)_5Cl]^{2+}$. The AgCl precipitate was digested by heating and stirring for several minutes. The AgCl precipitate was then removed by filtration, and the solution was cooled to room temperature. The pH of the solution was adjusted to about pH 3 by the drop-by-drop addition of 3 M NaOH. The solid $[Ru(NH_3)_5(H_2O)]^{3+}$ complex was isolated by adding solid NH_4PF_6 (about 0.5 g) to the solution, which was then filtered and washed with ethanol and finally with ether. The Kaolin clay (Nakarai Chemicals) was used in this investigation without further treatment. Kaolin clay with the $[Ru(NH_3)_5(H_2O)]^{3+}$ catalyst adsorbed was prepared by mixing the known amounts of the clay and the catalyst in deionized water. The mixture was stirred until complete adsorption was noticed. The clay was filtered after adsorption, washed with deionized water, and dried in air. The adsorbed complex was not desorbed upon dipping into fresh water.

Cyclic voltammograms were run using a Function Generator HB-104 model and a Potentiostat/Galvanostat HA-301 model of Hokuto Denko, Ltd. A basal plane pyrolytic graphite (BPG) electrode coated with poly(*p*-styrenesulfonate), Nafion, or Kaolin clay was used as the working electrode; platinum wire, as the counter electrode, and a Saturated Calomel Electrode (SCE), as the reference electrode. The supporting electrolyte was 0.5 M H_2SO_4.

A water oxidation experiment was carried out under an argon atmosphere by mixing the mononuclear ruthenium-ammine complex and excess ammonium cerium(IV) nitrate.[10,13] The gas evolved by the reaction was analyzed by the use of the Gas Chromatogram (Shimadzu GC 4C, 1.5-m column of Molecular Sieve 5A and an argon carrier). The amount of O_2 evolved was corrected by subtracting the amount of O_2 coming from the dissolved air. The water oxidation was confirmed by using $H_2{}^{18}O$ in the reaction medium, and a Quadrupole Mass Spectrometer from the Ulvac Corporation (MSQ-150A) was used to analyze the gas evolved.

Results and Discussion

The solution chemistry of ruthenium ammine complexes has been studied extensively.[17] These complexes are widely used as quenchers[18] for the excited state of $[Ru(bpy)_3]^{2+}$. The electrochemical behavior of the ruthenium-ammine complexes has also been investigated;[19] however, attention has not been focused on the redox chemistry involving the higher oxidation states, e.g., Ru(IV) and Ru(V).

Cyclic voltammograms obtained for $[Ru(NH_3)_5Cl]^{2+}$ and $[Ru(NH_3)_5(H_2O)]^{3+}$ are given in Fig. 1. When the uncoated BPG was used to record the cyclic voltammograms in the potential region from 0.5 to 1.5 V vs. SCE, a large catalytic current attributable to the electrochemical water oxidation was observed. However, a better cyclic voltammogram was obtained when the BPG was modified with poly(*p*-styrenesulfonate), Nafion, or Kaolin clay.

For both the ruthenium-ammine complexes, the $[Ru(NH_3)_5Cl]^{2+/+}$ and $[Ru(NH_3)_5(H_2O)]^{3+/2+}$ couples were observed in the potential region from −0.5 to 0.3 V vs. SCE (Fig. 1). Figure 1 shows that there are two oxidative peaks in the potential region from 0.5 to 1.5 V vs. SCE, peaks which are reversible in the reductive scan for the $[Ru(NH_3)_5Cl]^{2+}$ and $[Ru(NH_3)_5(H_2O)]^{3+}$ complexes. However, the reductive waves were not clear because of the larger catalytic current caused by water oxidation.

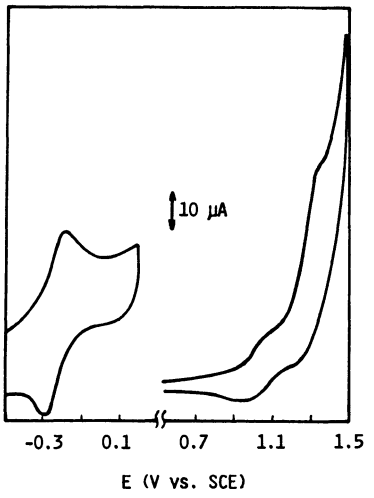

Fig. 1. Cyclic voltammogram of $[Ru(NH_3)_5Cl]^{2+}$ in 0.1 M H_2SO_4 at Nafion coated BPG at a scan rate of 50 mV s^{-1}.

The $[Ru(NH_3)_5Cl]^{2+/+}$ couple appears at −0.25 V vs. SCE. The other two peaks in the potential region from 0.5 to 1.5 V vs. SCE indicate the formation of $[Ru^{V}(NH_3)_5Cl]^{4+}$ by a series of one-electron oxidation of $[Ru^{III}(NH_3)_5Cl]^{2+}$ (Eq. 2). Similar results were observed for the $[Ru(NH_3)_5(H_2O)]^{3+}$ complex. However, the peak potentials are slightly shifted to less positive values than those for the $[Ru(NH_3)_5Cl]^{2+}$ complex. It has already been reported[19] that the formal potentials of the $[Ru(NH_3)_5Cl]^{2+/+}$ and $[Ru(NH_3)_5(H_2O)]^{3+/2+}$ couples are almost the same. Based on the present results, the various redox processes occurring in the chloropentammine ruthenium complex may be said to be as given in Eq. 2:

$$[Ru^{II}(NH_3)_5Cl]^{+} \underset{+e^-}{\overset{-e^-}{\rightleftharpoons}} [Ru^{III}(NH_3)_5Cl]^{2+} \underset{+e^-}{\overset{-e^-}{\rightleftharpoons}} \quad (-0.25\ \text{V}, \quad 1.06\ \text{V})$$

$$[Ru^{IV}(NH_3)_5Cl]^{3+} \underset{+e^-}{\overset{-e^-}{\rightleftharpoons}} [Ru^{V}(NH_3)_5Cl]^{4+} \quad (1.28\ \text{V}) \qquad (2)$$

For both the complexes, fairly large peak separations (100 mV) were observed. They may be caused by the rapid reduction of the higher-oxidation-state ruthenium by water or by the polymer coating rather than by electrochemical reduction. Such processes have already been observed in our own earlier works[10,11] with dinuclear ruthenium complexes. It has also been reported that the $[Ru(NH_3)_5Cl]^{+}$ complex undergoes rapid aquation with a rate constant of 4.7 s^{-1} (Eq. 3), which corresponds to a half-life of 0.15 s:[20]

$$[Ru(NH_3)_5Cl]^{+} + H_2O \rightarrow [Ru(NH_3)_5(H_2O)]^{2+} + Cl^{-} \qquad (3)$$

The monomeric ruthenium complexes easily form higher-oxidation-state Ru(V) complexes upon chemical oxidation, and the redox potentials of the ruthenium complexes show that they can be used as oxidants for water oxidation. These monomeric ruthenium complexes can act as two-electron oxidants and, therefore, might be able to bring about the four-electron oxidation of water to oxygen only on the surface of a suitable catalyst. However, oxygen evolution was observed visibly in a homogeneous solution upon the addition of excess Ce(IV) to the monomeric ruthenium complexes, without the addition of any external oxygen evolution catalyst. Gas bubbles were observed in solution soon after the addition of excess Ce(IV), and the chromatographic results (Fig. 2) show that the gas evolved is oxygen. Water oxidation was confirmed by mass spectrometry using water containing $H_2{}^{18}O$ isotopes. Oxygen was confirmed by the peaks at m/z=32, 34, and 36, which correspond to $^{16}O_2$, $^{18}O^{16}O$, and $^{18}O_2$ respectively. Both the gas-chromatograph and mass-spectral data clearly showed that oxygen is

evolved by the water oxidation. The experimental results of the homogeneous catalysis of water oxidation by monomeric ruthenium complexes were treated with great caution because the decomposition product of the compounds is often ruthenium oxide, which is catalytically active for water oxidation.[21,22] The Ru complex was stable in water, even in the presence of excess Ce(IV), as was confirmed by visible spectroscopy. Gas bubbles were observed immediately after Ce(IV) had been added to the complex solution. These results indicate that the Ru complex itself is active in the catalysis.

The amount of oxygen evolved in 90 minutes with different Ru : Ce(IV) ratios (molar ratio) under homogeneous conditions are given in Table 1. When the Ru: Ce(IV) (molar ratio) was changed from 1 : 50 to 1 : 300, the oxygen evolution increased with the increase in the Ce(IV) concentration. The results shown in Table 1 indicate that the monomeric ruthenium complex works as a catalyst in the water oxidation process. Table 2 shows that when the ruthenium complex concentration is decreased from 6.7×10^{-4} to 2.01×10^{-4} M the oxygen evolution is increased 2.6 times. However, Table 3 shows that the increase in the ionic strength leads to the decrease in the oxygen evolution. The four-electron oxidation of water must be realized through the interaction of two intermediate mononuclear ruthenium complexes. Such interaction would be hindered by increasing the ionic strength. It is clear that the effect of the concentration change on

water oxidation shown in Table 2 is attributable to the ionic strength effect. The change in the concentration of the ruthenium complex did not have any important effect on the water oxidation process under a constant ionic strength (Table 4).

The effect of acid on the water-oxidation process was also studied; the data are given in Table 5. When the HNO_3 concentration was increased to 0.2 M, an increase in the oxygen evolution with the HNO_3 concentration was observed. In an acidic solution, $[Ru(NH_3)_5Cl]^{2+}$ readily undergoes aquation accompanied by the formation of the water-substituted pentammine ruthenium complex; the higher rate of oxygen evolution can be explained on the basis that the water molecule in the coordination sphere is involved in the water oxidation process. When $[(bpy)_2(H_2O)RuORu(H_2O)(bpy)_2]^{4+}$ was used as the catalyst for water oxidation,[9,23] it was explained that the water ligands in the dinuclear ruthenium complex take part in the water oxidation reaction.

As catalysts for water oxidation, the $[Ru(NH_3)_5(H_2O)]^{3+}$ complex was used in a homogeneous state, and the Kaolin clay-adsorbed complex, in a heterogeneous state. The amount of oxygen evolved in 90 minutes with different concentration of Ce(IV), using the homogeneous as well as the heterogeneous state $[Ru(NH_3)_5(H_2O)]^{3+}$ in water oxidation, are given in Table 6. The effect of the concentration of the complex adsorbed in the clay in the heterogeneous catalysis was also studied; the results are given in Table 7. A comparison of the results of Table 6 (homogeneous system) and Table 2 will show that the $[Ru(NH_3)(H_2O)]^{3+}$ is a better catalyst than the chloropentammineruthenium complex. One reason for the better catalytic activity of the aquapentammine complex can be the fact that the water molecules in the coordination sphere are involved in the water oxidation process, as has been explained before. It should also be noted that the $[Ru(NH_3)_5(H_2O)]^{4+/5+}$ couple is less positive than the chloropentammine complex and that the Ce(IV) will more readily oxidize the water complex than the chloro complex, thus producing the higher-oxidation-state ruthenium complex. From the electrochemical data, it is clear that the ruthenium-ammine complexes can act as a two-electron oxidants for water oxidation. In order to evolve one molecule of oxygen by water oxidation, two molecules of a ruthenium complex are needed. The addition of excess Ce(IV) to a solution of a mononuclear ruthenium-ammine complex should lead to the oxidation of the complex to give Ru(V) complex; then, the two molecules of the Ru(V) complex will oxidize water to oxygen.

When $[Ru(NH_3)_5Cl]^{2+}$ is used as a catalyst for water oxidation, the water will coordinate at first to the $[Ru^{V}(NH_3)_5Cl]^{4+}$ higher-oxidation-state complex, and then the two molecules of the water-coordinated intermediate should lead to oxygen evolution. Such a seven coordination in the intermediate step has been suggested for the Ru(IV) and Ru(III) complexes (d^4 and d^5 ions) in the oxidation-reduction reactions of monomeric ruthenium-ammine complexes.[24,25] It is probable that the Cl^- ligand will be oxidized by the Ru(V) metal center or by the Ce(IV), which will lead to the formation of the water substituted ruthenium complex. Considering that the coordinated water molecule is involved in the water-oxidation reaction, as has been reported for the dinuclear ruthenium complex,[7,19] the following reaction scheme is proposed to explain the oxygen evolution by the monomeric ruthenium-ammine complex. Two molecules of the water coordinated monomeric Ru(V) complex would lead to the formation of a peroxo-bridged dinuclear ruthenium complex, Ru-O-O-Ru, and then the intermediate would release one molecule of oxygen. Such a peroxo-bridged ruthenium intermediate complex is not known; however, the oxo-bridged dinuclear

ruthenium complex, $[(NH_3)_5RuORu(NH_3)_5]^{4+}$, is known.[26]

Porter[27] suggested that manganese(IV) complexes of porphyrin might oxidize water and that this water-oxidation reaction might be expected to occur via an intermediate oxygen bridged dinuclear complex. So far, the generation of oxygen with such systems has remained ambiguous, and there are no substantiated reports in which a metalloporphyrin has been used to oxidize water to oxygen. The oxygen evolution in the photosystem II is expected to occur via oxygen-bridged dinuclear species.[3,28] Recently, the formation of an O-O bond as an intermediate has been proposed to explain the oxygen evolution by water oxidation using multimetal complex systems,[9,10,13,23] which would support the above mentioned intermediate formation.

The authors are thankful to the Grant-in-Aid (No. 62612002) for Scientific Resesarch on Priority Area of "Macromolecular Complex" from the Ministry of Education, Science and Culture.

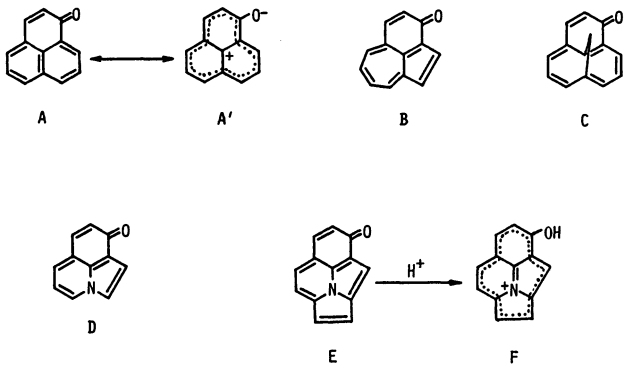
(Received May 14, 1987)

3-Phenyl-4*H*-benzo[*hi*]pyrrolo[2,1,5-*cd*]indolizin-4-one (**5**) was prepared by saponification accompanied by the decarboxylation of the corresponding 1,2-bis(methoxycarbonyl) derivative, which was obtained by the DDQ oxidation of 5,6-dihydro one. Investigations concerning its spectral data and MO calculations revealed interesting electronic features for **5**, e.g., i) a highly polarized structure in the ground state, ii) the exsistence of a peripheral [12]annulene system in acidic media, and iii) a significant stabilization of the excited state by protonation.

Much attention has been paid to the chemistry of 1*H*-phenalen-1-one (**A**) owing to its unusual properties, e.g., high basicity, high dipole moment, low-frequency shift of carbonyl absorption, and so on. These properties have been ascribed to an important contribution of an ionic structure (**A'**) to the resonance hybrid.[2)] From synthetic and physicochemical viewpoints, much effort has been made to prepare the iso π-electronic analogs of **A**, e.g., 3*H*-benz[*cd*]azulen-3-one (**B**)[3)] and 2,14-dihydrotricyclo[7,3,2,$0^{5,13}$]tetradeca-1,3,5,7,9,11-hexaen-2-one (**C**).[4)] Their interesting properties have been elucidated during the last two decades.



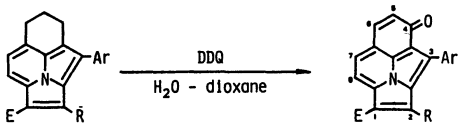
A more recent report[5)] on the synthesis and properties of 9*H*-pyrrolo[3,2,1-*ij*]quinolin-9-one (**D**) stimulated us to investigate 4*H*-benzo[*hi*]pyrrolo[2,1,5-*cd*]indolizin-4-one (**E**), which involves a peripheral 10 π-electronic [3.2.2]cyclazine system instead of the indolizine nuclei of **D**. Therein, the [12]annulene system **F**, perturbed by an internal azomethinium ion, would be provided by the protonation of **E**.

In a preliminary paper,[6)] we communicated a facile preparation of the derivatives of **E** and a few of their interesting electronic features. In the present paper, details concerning the syntheses of 3-aryl-4*H*-benzo[*hi*]pyrrolo[2,1,5-*cd*]indolizin-4-ones are described; also, their properties are discussed on the basis of spectral evidence and molecular orbital (MO) calculations.

Results and Discussion

Synthesis. According to the reported method for the introduction of a carbonyl function into the α-methylene moiety in azulene,[7)] 5,6-dihydro-1-methoxycarbonyl- and 5,6-dihydro-1,2-bis(methoxycarbonyl)-3-aryl-4*H*-benzo[*hi*]pyrrolo[2,1,5-*cd*]-indolizinenes (**1**) were oxidized with 2,3-dichloro-5,6-dicyano-*p*-benzoquinone (DDQ) (4 mol equiv.) in 10% aqueous dioxane to give selectively 4*H*-benzo-[*hi*]pyrrolo[2,1,5-*cd*]indolizin-4-one derivatives (**2**) (Scheme 1). The structures of **2** were confirmed on the basis of analytical data and spectral evidence. These results and spectral data for **2** are summarized in Tables 3 and 4, respectively.

For this regioselective oxidation leading to **2**, we proposed a reaction pathway which initiates a CT complex formation between DDQ and aryl groups at the 3-position of **1** (Fig. 1). This was supported by the following results; at an earlier stage of the reaction, a dark-green solution was observed, which was in accordance with CT complex formation.[8)] The progress of



a: Ar=C_6H_5, R=H; b: Ar=C_6H_5, R=E; b-d_5: Ar=C_6D_5, R=E; c: Ar=C_6H_4-OMe(*p*), R=E; d: Ar=C_6H_4-Br(*p*), R=E; e: Ar=4-Biphenyl, R=E; f: 2-Naphthyl, R=E.

Scheme 1.

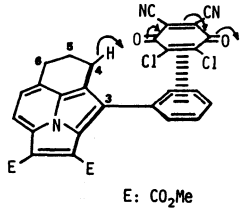


Fig. 1. CT complex formation between the phenyl group of **1a** and DDQ.

the oxidation was dependent upon the facility of the CT complex formation, which was also ascribed to the electron density of the aromatic ring at the 3-position.[9]

In order to prepare the 3-phenyl-4*H*-benzo[*hi*]-pyrrolo[2,1,5-*cd*]indolizin-4-one (**5**), the corresponding 5,6-dihydro derivative **3** was treated with 1.5 mol equiv. of DDQ to give 5,6-dihydro-3-phenyl-4*H*-benzo[*hi*]pyrrolo[2,1,5-*cd*]indolizin-4-one (**4**) in 42% yield. A similar treatment with 4.0 mol equiv. of DDQ gave the desired **5** and **4** in 33 and 16% yields, respectively. However, a successive oxidation of **4** to **5** was considerably sensitive to the reaction conditions employed; therefore, another synthetic approach to **5** was surveyed.

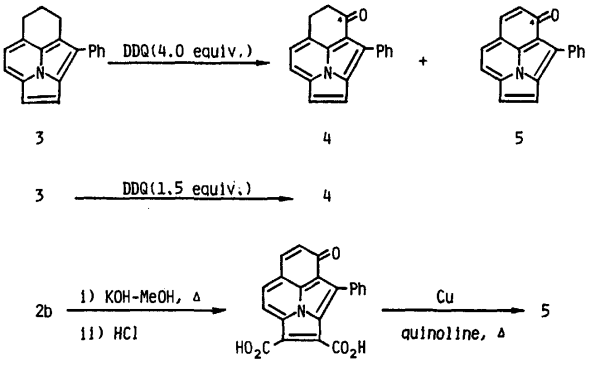
The saponification of **2b** with methanolic potassium hydroxide followed by acidification gave the corresponding dicarboxylic acid, which was decarboxylated in refluxing quinoline in the presence of copper dust to afford **5**. Similarly, the 3-pentadeuteriophenyl derivative **5**-d_5 was obtained from **2b**-d_5 (Scheme 2).

MO Calculations. In an attempt to obtain a better understanding of the properties of **5**, MO calculations using the MNDOA method[10] for the parent compound **E** were performed. All of its bond lengths and valence angles were reinvestigated using the structure optimization program therein (see Experimental section).

The results of these calculations indicate that there is no significant departure from planarity of molecule **E**. Among these results, the bond lengths and atomic charges for **E** are presented in Fig. 2. These suggest that the enone moiety attached to the peri position of [3.2.2]cyclazine nuclei is electron-withdrawing and that a considerable negative charge is located at the carbonyl oxygen atom. Consequently, the carbonyl group is highly polarized and the dipole moment was calculated to be 4.26 D, which is comparable to that of tropone.[11]

IR Spectra. The lower-frequency shift of 44 cm^{-1} for the carbonyl absorption was caused by a conversion of the 5,6-dihydro derivative **4** (1650 cm^{-1}) into fully conjugated **5** (1606 cm^{-1}). The carbonyl absorptions at the 4-position for **2** were also observed at 1624—1592 cm^{-1}, which were somewhat lower than those of the other systems: **A**, **B**, and **D**.[2,3,5] These results indicate that the carbonyl groups of **2** and **5** are highly polarized and that the ionic structure **E′** is important to the resonance hybrid in the ground state of **E** (Scheme 3).

^{13}C NMR Spectra. A full assignment of the ^{13}C NMR spectrum for **5** was accomplished by a comparison with the spectra for **2a**, **2b**, **2c**, and **5**-d_5 using several decoupling techniques (see Experimental section). The chemical shifts are presented in Fig. 3; these values for the benzopyrroloindolizinone moiety of **5** corresponded to the atomic charges of the 4*H*-



Scheme 2.

benzo[*hi*]pyrrolo[2,1,5-*cd*]indolizin-4-one system (**E**) calculated by MNDOA (Fig. 2). This implies that the results from the MNDOA calculations for **E** are useful for a qualitative discussion of the electronic features for **2** and **5**.

^{1}H NMR Spectra. The assignment and discussion concerning the cyclazine ring protons of **5** were achieved by an analysis of the spectrum of the pentadeuteriophenyl derivative **5**-d_5. The chemical shifts[12] and coupling constants of **3**-d_5 and **5**-d_5 are tabulated in Table 1. Therein, the introduction of the enone moiety into [3.2.2]cyclazine caused a small upperfield shift for all protons other than 7-H. The spectral data for **5**-d_5 in deuteriochloroform ($CDCl_3$) and in trifluoroacetic acid-d_1 (CF_3CO_2D) are summarized in Table 2. The positive charge resulting from the protonation caused relatively small downfield shifts for the protons (Δδ: within −0.6); interestingly, a small upfield shift was observed for 2-H in CF_3CO_2D in comparison with that in $CDCl_3$. The differences among the coupling constants became smaller in CF_3CO_2D, which implied that the bond-alternation of the peripheral π-system was weakened by the protonation.

As is well-known, the protonation of other iso π-electronic systems caused considerable downfield shifts of all the ring protons, i.e., Δδ=−0.7—−1.8 for 1*H*-phenalen-1-one,[13] Δδ=0.0—−1.3 for 7,9-dimethyl-3*H*-benz[*cd*]azulen-3-one,[3b] and Δδ=−0.4—−0.9[14] for 2-ethoxycarbonyl-7-phenyl-9*H*-pyrrolo[3,2,1-*ij*]quinolin-9-one. On the other hand, 5*H*-cyclopenta[*cd*]-phenalen-5-one, a [13]annulenone perturbed by an internal vinyl π-system, exhibited both small up and downfield shifts for the ring protons on protonation (Δδ=−0.3—0.3), for which the existence of the paramagnetic ring current arising from the peripheral 12 π-electronic system has been proposed.[15]

The results in the present work are probably attributable to the ring current due to the peripheral [12]-annulene system, which is cross-linked by an azomethinium ion.

Electronic Spectra. The electronic spectra of **3**, **4**, and **5** are shown in Fig. 4. These reveal that the introduction of an enone moiety into the [3.2.2]cyclazine system causes a significant change in π-electronic features of the parent system. The solvent dependency of the spectra of **5** was also investigated. The spectra in chloroform, methanol, and methanol-sulfuric acid (100/1) do not show any solvent effect.[16]

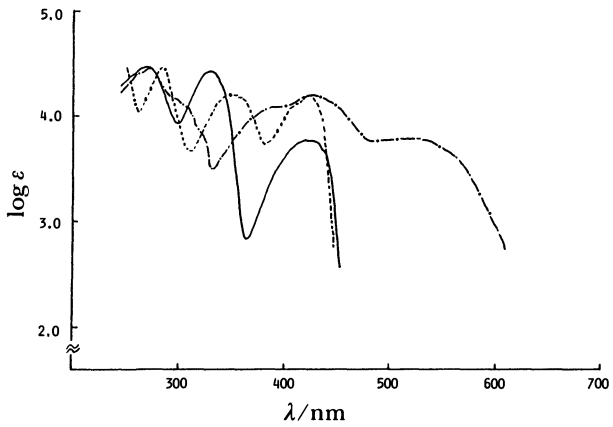

Fig. 4. Electronic spectra of **3** (——), **4** (----), and **5** (-·-·-) in $CHCl_3$.

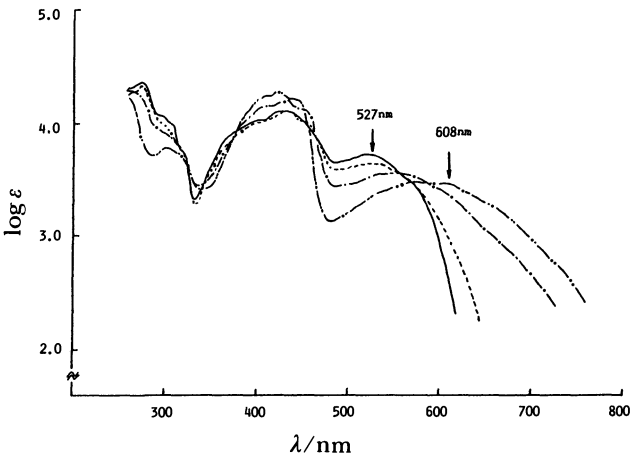

Fig. 5. Change of the electronic spectra of **5** with acid concentrations: (——) in $CHCl_3$; (----) in $CHCl_3$–CF_3COOH=100/1; (-·-·-) in 50/1; (-···-) in 3/2.

However, when the protonation of carbonyl oxygen atom of **5** was complete,[17] the absorption maximum due to the first electronic transition was shifted to a longer wavelength, and the spectra were changed as the acid concentrations decreased (Fig. 5). The longer wavelength shift by the protonation of **5** did not depend on the concentrations of substrate **5** in the range 8.0×10^{-7} to 3.6×10^{-6} M (1M=1 mol dm^{-3}). The addition of *p*-dimethoxybenzene or 1,4-dimethoxynaphthalene caused no changes of the spectra in acidic media. Also, the 1,2-bis(methoxycarbonyl) derivative

2a showed the same behavior under acidic conditions as those of **5**.

From these results, we suggest that the shift was not due to an intermolecular interaction, e.g., a CT complex formation between **5** and its protonated species, but due to inherent changes in the electronic system of **5** by protonation.[18]

On the other hand, the spectra of phenalenones[2] or 3*H*-benz[*cd*]azulen-3-one[3b] in acidic media exhibited considerable hypsochromic shifts, which were ascribed to a stabilization of their ground states. Accordingly, the present results indicate that protonation onto the carbonyl oxygen atom of **5** results in a more significant stabilization of its excited state, rather than of its ground state.

In order to confirm this point, MO calculations for **F**, the protonated species of **E**, were attempted. The HOMO and LUMO energy levels of **F** were calculated to be −8.52 and −3.98 eV, respectively. This means that a very small instabilization of the HOMO and a large stabilization of the LUMO are caused by the protonation, in comparison with those of **E** (HOMO: −8.62 eV; LUMO: −1.54 eV). Also, as shown in Fig. 6, the positive charge caused by the protonation was delocalized over the peripheral system of **F**, and the peripheral bond lengths were averaged, indicating the bond alternations of the π-system were less significant.

In conclusion, 4*H*-benzo[*hi*]pyrrolo[2,1,5-*cd*]-indolizin-4-one (**E**) has the following characteristic properties: i) a highly-polarized structure in the ground state and ii) a significant stabilization of the LUMO of **E** by protonation, which is considerably different from its π-electronic analogs, such as 1*H*-phenalen-1-one (**A**), 3*H*-benz[*cd*]azulen-3-one (**B**), and 9*H*-pyrrolo[3,2,1-*ij*]quinolin-9-one (**D**).

Experimental

General. All melting points are uncorrected. The IR spectra were measured on a JASCO IRA-1 spectrometer. The ^{1}H NMR spectra were obtained on JEOL FX-200 and/or JMN-MH-100 spectrometers and ^{13}CNMR spectra were recorded on a JEOL FX-200 spectrometer at 50.1 MHz. Chemical shifts are expressed in parts per million (ppm) downfield from tetramethylsilane. The mass spectra were determined with a JEOL JMS-D spectrometer at 75 eV using a direct inlet method. The electronic spectra were taken by a Hitachi 220 spectrophotometer. The elemental analyses were performed on a Hitachi 026 CHN analyzer. Most of the reactions were monitored by thin-layer chromatography (Silica gel 60F-254, Merck). The visualization was made with ultraviolet light (254 and 365 nm). Wakogel C-200 and C-300 (Wako Pure Chemical Industries LTD) and Aluminium Oxide 90 (Merck) were used for preparative column chromatography.

The unknown starting materials **1a**, **1c**, **1d**, **1e**, and **1f** were prepared from reactions of the corresponding benzo[*hi*]indolizines and acetylenes in a similar manner to the reported method.[19]

Oxidation of 1 with DDQ to 2. General Procedure: To a 10% aqueous dioxane solution (30 mL) of **1a** (500 mg, 1.59 mmol), DDQ (1.44 g, 6.36 mmol) was added portionwise at room temperature; the reaction mixture was heated under reflux for 6 h. The resultant hydroquinone was filtered off and the filtrate was evaporated to dryness. The residue was subjected to a short column chromatography (alumina-chloroform) in order to remove any unreacted DDQ. The chloroform elution was collected and concentrated to give a residue. The residue was chromatographed on silica gel to afford **2a** (359 mg, 69%) as a chloroform eluent.

2a: Red needles (ethanol); mp 274—275 °C. Found: C, 76.87; H, 4.15; N, 4.56%. Calcd for $C_{21}H_{13}NO_3$: C, 77.05; H, 4.00; N. 4.28%.

A similar oxidation of **1b—f** gave the corresponding 4*H*-benzo[*hi*]pyrrolo[2,1,5-*cd*]indolizin-4-one derivatives **2b—2f**.

2b: Red needles (ethanol); mp 189—190 °C. Found: C, 71.42; H, 4.09; N, 3.43%. Calcd for $C_{23}H_{15}NO_5$: C, 71.68; H, 3.92; N, 3.64%.

2c: Red needles (ethanol); mp 225—226 °C. Found: C, 69.16; H, 4.17; N, 3.35%. Calcd for $C_{24}H_{17}NO_6$: C, 69.39; H, 4.13; N, 3.37%.

2d: Deep red needles (ethanol); mp 227—229 °C. Found: C, 59.44; H, 3.18; N, 3.24%. Calcd for $C_{23}H_{14}BrNO_5$: C, 59.44; H, 3.18; N, 3.24%.

2e: Red needles (ethanol); mp 256—258 °C. Found: C, 75.56; H, 4.21; N, 3.28%. Calcd for $C_{29}H_{19}NO_5$: C, 75.48; H, 4.15; N, 3.04%.

2f: Deep red needles (ethanol); mp 219—220 °C. Found: C, 74.64; H, 4.11; N, 3.44%. Calcd for $C_{27}H_{17}NO_5$: C, 74.47; H, 3.93; N, 3.22%.

These results and the spectral data for **2** are presented in Tables 3 and 4, respectively.

Oxidation of 3 with DDQ to 4 and 5. A mixture of **3** (265 mg, 1.03 mmol) and DDQ (350 mg, 1.54 mmol) in 10% aqueous dioxane (10 mL) was stirred at room temperature for 18 h. After similar procedures as mentioned above, **4** was obtained in 42% yield. Also, the oxidation of **3** with DDQ (4.0 mol equiv.) in 10% aqueous dioxane under reflux for 12

Preparation of 5 from 2b. Compound **2b** (570 mg, 1.48 mmol) was heated under reflux in 5% methanolic potassium hydroxide (30 mL) for 12 h and the methanol was removed to give a residue. The residue was made acidic with concd hydrochloric acid. The resultant diacid was filtered, dried, and subjected to the next decarboxylation without further purification. A solution of the diacid in quinoline (30 mL) was refluxed for 0.5 h in the presence of copper dust (100 mg). The copper dust was filtered off and the filtrate was evaporated to give a residue. The residue was dissolved in benzene (50 mL) and washed with 0.5 M hydrochloric acid (50 mL×3) in order to completely remove the quinoline. The organic layer was collected, dried and evaporated to dryness. The residue was subjected to a chromatography on alumina to afford **5** (74% from **2b**) as a chloroform eluent.

Similarly, the pentadeuteriophenyl derivative **5**-d_5 was obtained from **2b**-d_5 in 80% yield.

MO Calculations. The calculations were carried out by using the ACOS system 1000 computer in the Computation Center of Osaka University. For an optimization of the

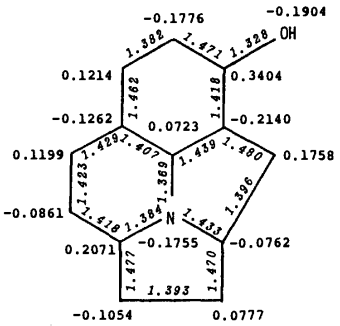

Fig. 6. Net atomic charge and atomic distance (Å) of **F** by MNDOA.

structure, the initial structure was taken as follows: for the geometries of the cyclazine moiety of **E**, the X-ray analytical data for 1,4-dibromopyrrolo[2,1,5-*cd*]indolizine[20] were used. Those of the enone part were estimated by using the molecular models fused by the above cyclazine system. The distance of the C=O bond was taken from that of acrylaldehyde (1.23 Å). A structure optimization was performed for the bond length and valence and dihedral angles of all the atoms of **E**, except for the hydrogen atoms. Among the results, the net atomic charge and bond length for **E** are demonstrated in Fig. 2. A structure optimization for the 3-phenyl derivative **5** was also performed. For the geometries of the benzopyrroloindolizinone moiety and of the phenyl one of **5**, the data for **E** obtained above and for biphenyl were taken, respectively. An optimization was performed for the C-C bond length and the dihedral angle between the mother nuclei and the phenyl one. The results showed that the dihedral angle was calculated to be 76.7°. This showed that the π-electronic system of the phenyl ring had little effect on the mother nuclei.

The structural optimization for **F**, the protonated species of **E**, was performed using the attained geometries for **E** as an

initial structure. The net atomic charge and bond length for **F** are presented in Fig. 6.

^{13}C NMR Spectra. On the basis of the ^{1}H NMR spectral data, assignments for the ^{13}C signals were made by using the nuclear Overhauser effect (NOE) and complete decoupling (COM), non-decoupling (NON), proton selective decoupling (SEL), and/or low-power selective proton decoupling techniques (LPSEL).[21]

It seemed to be difficult to directly assign the ^{13}C signals of **5**, since its ^{1}H signals were superimposed on each other; therefore, the relationships between the ^{1}H and ^{13}C signals were obscure. Thus, first the assignment for **2b** was attempted; the SEL technique for the ring protons accomplished the assignment for C-5, -6, -7, and -8, and the quartery C-3a, -6a, and -6b were confirmed by using LPSEL measurements. The assignments for C-1 and -2 were accomplished through comparisons with those of the 1-methoxycarbonyl derivative **2a**; also, the phenyl carbons (C-2′, -3′, and -4′) were assigned by the comparisons with those of the 3-(*p*-methoxyphenyl) derivative **2c**. On the basis of the above results for **2b**, the assignment for **5** was attained, except for the signals at δ=131.6, 132.2, and 133.2 due to C-2a, -8a, and -1′. The replacement of the phenyl group of **5** by pentadeuteriophenyl one, **5**-d_5, resulted in changes of the coupling patterns of the signal due to C-1′: the carbon signal at δ=133.2 (NON: t) for **5** was changed to a singlet (δ=132.9) for **5**-d_5, and, therefore, assigned to be C-1′. The LPSEL technique irradiating the 7-H (δ=7.57) of **5**-d_5 caused a simplification of the signal patterns at δ=132.3, and the signal at δ=132.2 of **5** was assignable to be C-8a. Consequently, the signal at δ=131.8 of **5** was deduced to be C-2a.

These assignments for **5** and **2b** are summarized in Table 5.

The authors wish to thank Professor Masashi Tashiro, Research Institute of Industrial Science, Kyushu University, for the elemental analyses. The author (M. N.) is grateful to the Ministry of Education, Science and Calture for financial support through a Grand-in-Aid for Scientific Research (No 59750691).

14) These values were obtained after the addition of a few drops of CF_3CO_2D to the $CDCl_3$ solution.[5] Probably, the protonation onto the carbonyl oxygen atom at 9-position was incomplete at the point, and more downfield shift would be expected in CF_3CO_2D.

15) I. Murata, K. Yamamoto, T. Hirotsu, and M. Morioka, *Tetrahedron Lett.*, **1972**, 331.

16) The electronic spectrum in cyclohexane was somewhat different from those in these solvents. The absorption maxima were shifted wholly to shorter wavelength (ca. 10 nm), and fine structures were observed over the ranges of 480—570 nm.

17) No significant changes of its electronic spectra were observed at higher acid concentrations than $CHCl_3$-CF_3CO_2H (8/1). On the contrary, the downfield shifts of the ring protons on the ^1H NMR spectra were observed up to the acid concentration of $CDCl_3$-CF_3CO_2D (2/3).

18) Similar behaviors on the electronic spectra were found in 6*H*-benzo[*hi*]pyrrolo[2,1,5-*cd*]indolizin-6-one system, a regio-isomer of **E**. Those results would be published elsewhere.

New Ferroelectric Liquid Crystal Materials: (+)-4-(2-Methylbutoxycarbonyl)-phenyl 4-(5-Alkyl-1,3-dioxan-2-yl)benzoate

Yuichiro HARAMOTO,* Katumasa KAWASHIMA, and Hiroyoshi KAMOGAWA
Department of Applied Chemistry, Yamanashi University, Takeda 4, Kofu 400
(Received May 30, 1987)

(+)-4-(2-Methylbutoxycarbonyl)phenyl 4-(5-alkyl-1,3-dioxan-2-yl)benzoate (**12**), (+)-4-(2-methylbutoxy)-phenyl 4-(5-alkyl-1,3-dioxan-2-yl)benzoate (**11**) and the corresponding 1,3-oxathiane (**13**, **14**) and 1,3-dithiane compounds (**15**, **16**) were synthesized. The mesomorphic behaviors of these compounds were measured. Compounds **12** exhibited the ferroelectric liquid-crystal behavior (R=*n*-$C_{11}H_{23}$: −4 SmC* 94 °C), while the corresponding 1,3-oxathiane (**13**, **14**) and 1,3-dithiane compounds (**15**, **16**) did not exhibit such behavior. Therefore, 1,3-dioxane compounds are more favorable for transition of SmA to SmC* than the 1,3-oxathiane or 1,3-dithiane analogs.

2,5-Disubstituted 1,3-dioxanes, 1,3-oxathianes, and 1,3-dithianes were synthesized recently as new types of nematic liquid crystal materials.[1-10] With increasing interests in liquid-crystal displays using ferroelectric liquid crystals, various ferroelectric liquid crystal compounds have been synthesized: the basic structure of optically active liquid-crystal compounds with a 1,3-dioxane, a 1,3-oxathiane, and a 1,3-dithiane ring have been synthesized.[11,12] In a previous letter,[12] we reported new ferroelectric liquid-crystal compounds with a 1,3-dioxane ring. This paper deals with the synthesis and the mesomorphic behavior of these compounds in detail.

Results and Discussion

(+)-4-(2-Methylbutoxy)phenyl 4-(5-alkyl-1,3-dioxan-2-yl)benzoate (**11**), (+)-4-(2-methylbutoxycarbonyl)phenyl 4-(5-alkyl-1,3-dioxan-2-yl)benzoate (**12**) and the corresponding oxathianes (**13**, **14**) and dithianes (**15**, **16**) were synthesized via the following route.

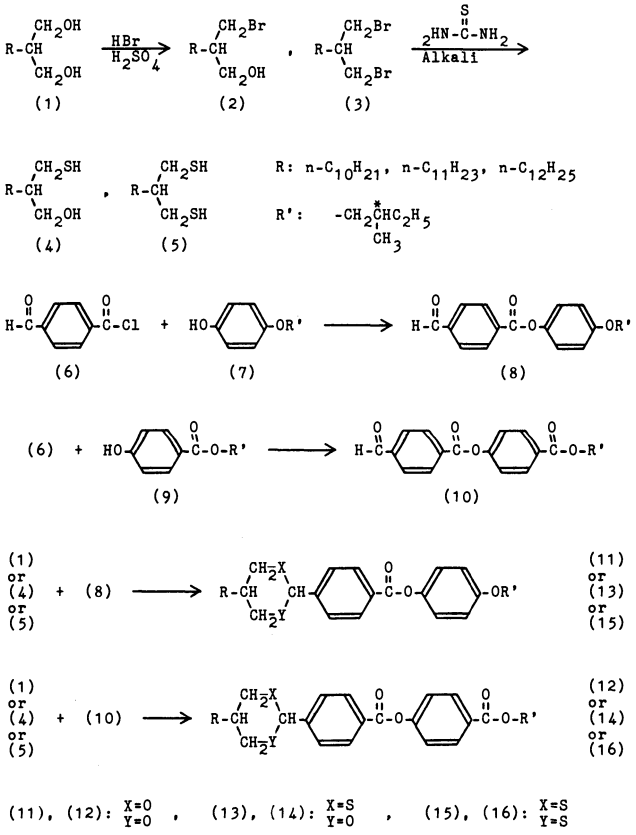

Fig. 1.

In step **1**→**2**, **3**, the reaction temperature of bromination was kept within the range 80 to 85 °C in order to obtain compounds **2** and **3** at nearly equal yields. In the conversion of **2**, **3** into **4**, **5** respectively, a mixture of compounds **2** and **3** was used. The mixture of compounds **4** and **5**, thus obtained, was separated by column chromatography. Compound **4** was eluted in an ether fraction and **5** in a hexane fraction. Compound **7** was synthesized by the monoetherification of hydroquinone.

Compound **9** was obtained by the esterification of *p*-hydroxybenzoic acid with (+)-2-methyl-1-butanol in the presence of an acid catalyst using a Dean-Stark trap. A two-day reaction is necessary to obtain a sufficient yield.

In steps **6**,**7**→**8** and **6**,**9**→**10**, 1,8-diazabicyclo[5.4.0]-undec-7-ene (DBU) was used as a base. Both compounds **8** and **10** were extracted with hexane.

Compounds **11**—**15**, and **16** were synthesized by ring-formation reactions of compounds **1**, **4**, and **5** with aldehydes (**8**, **10**), respectively. The products, **11**—**16**, were purified by column chromatography and recrystallized from hexane. The trans isomers of **11**, **13**, **15**, **16** were isolated by means of TLC (hexane: ether=5:2) of the cis and trans mixtures. In the ^{1}H NMR data of the 1,3-dioxane, 1,3-oxathiane, and 1,3-dithiane compounds, C-2 proton signals of the 1,3-dioxane, 1,3-oxathiane, and 1,3-dithiane rings for the trans and cis isomers are separated by about 0.05 ppm. For example, the C-2 proton of the trans isomers absorbs at δ=5.50 (compound **12-1**), 5.75 (**14-1**), and 5.20 (**16-1**) but that of the corresponding cis isomer absorbs at δ=5.55 (**12-1**), 5.80 (**14-1**), and 5.15 (**16-1**), respectively.

a) C: crystal; S: smectic; I: isotropic.

Measurements of the mesomorphic ranges and assignments of the mesophases were carried out by means of a micro melting point apparatus equipped with polarizers and a differential scanning calorimeter (DSC).

To determine the type of smectic phase, the observed smectic phases were compared with color photographs found in the literature.[13,14] Mesomorphic ranges of the synthesized compounds are given in Table 1. SmA, SmB, and SmC* mean smectic A, smectic B, and chiral smectic C phase, respectively.

Though SmC* of compounds **12** can be driven in homogenious cells (d=2 μm, applied voltage=20 V), other smectic phases can not. Therefore, compounds **12** are ferroelectric liquid-crystal compounds and others are not.

The 1,3-oxathiane and 1,3-dithiane compounds which correspond to compounds **12** did not exhibit a SmC* liquid-crystal phase. This must imply that 1,3-dioxane compounds are more favorable for the transition of SmA to SmC* than the corresponding 1,3-oxathiane or 1,3-dithiane compounds.

Though compounds **12** exhibit an SmC* phase, compounds **11** do not. The difference in these two compounds lies in the number of the carbonyl group. Therefore, a carbonyl group having a dipole moment in a vertical direction to the molecular axis must contribute to the transition from SmA to SmC*.

The transition temperatures of SmA to isotropic ($T_{S\text{-}I}$) for 1,3-oxathiane compounds are lower than those for the corresponding 1,3-dioxanes and 1,3-dithianes. In a smectic liquid crystal, the temperature of the isotropic to smectic transition ($T_{S\text{-}I}$) is affected by two factors: the molecular width and interactions of side substituens.[15] The 1,3-oxathiane compounds are bent at the 1,3-oxathiane ring, caused by a difference in the atomic size between sulfur and oxygen. Therefore, the width of 1,3-oxathiane compounds is wider than that of the corresponding 1,3-dioxane or 1,3-dithiane compounds. This must make $T_{S\text{-}I}$ for 1,3-oxathiane compounds lower than those for the corresponding 1,3-dioxane or 1,3-dithiane compounds.

The transition temperatures of SmA to isotropic ($T_{S\text{-}I}$) for compounds A are nearly equal to those for the corresponding compounds B. This difference in the terminal group hardly affects the thermal stability of smectic phase.

Textures of SmA and SmB are focal-conic fan texture.

At the transition temperatures of the SmA to SmB phase, pronounced transition bars appeared on the surface of the focal-conic fan texture. Textures of

SmC* are broken focal-conic fan texture.

Several properties as a ferroelectric liquid crystal compound were measured for compound **12-3**; the strength of the spontanious polarization=1.3 $nC\,cm^{-2}$ (85 °C), helical pich length=14.3 μm (85 °C), the response of the optical transmission=61 μs (85 °C, 20 V), tilt angle=13.5° (85 °C).

Though the strength of the spontanious polarization of compound **12-3** is smaller than that of (S)-2-methylbutyl *p*-(*p*-decyloxybenzylideneamino)cinnamate (DOBAMBC),[16] the helical pitch length of this compounds is longer than that of DOBAMBC.

The most remerkable feature of these new ferroelectric liquid crystal compounds is that, with the appearance of the supercooling state, they exhibit the ferroelectric liquid crystal behavior over a very wide range, including ordinary room temperature (**12-1**: 14 SmC* 93, **12-2**: −4 SmC* 94, **12-3**: 30 SmC* 95).

$\Delta H_{C\text{-}S}$ of compounds **11-3**, **12-3**, **13-3**, **14-3**, **15-3**, and **16-3** are 25.0, 34.1, 29.5, 19.5, 18.7, and 16.8 $kJ\,mol^{-1}$, respectively.

These values are somewhat smaller than those of other common liquid crystal materials.[17]

The $\Delta H_{S\text{-}I}$ of these compounds are 6.0, 5.8, 6.7, 6.5, 3.0, and 5.2 $kJ\,mol^{-1}$, respectively. Nearly the same values have been obtained for other common smectic liquid crystal compounds.[18]

Experimental

IR, ^{1}H NMR, and mass spectra were obtained with a Hitachi 215 spectrophotometer, a JNM-PMX 60 spectrometer, and a Hitachi M-80B spectrometer, respectively. Elemental analyses were carried out with a Perkin-Elmer 250 instrument. Transition temperatures and mesomorphic phases were determined by means of both a Mitamura Riken micro melting-point apparatus equipped with polarizers and a Rigaku Denki DSC CN8059L1, CN8208A2. The rate of cooling was fixed to 1 $°C\,min^{-1}$.

Mixtures of 2-alkyl-3-bromo-1-propanol (**2**) and 2-alkyl-1,3-dibromopropane (**3**) were prepared previously.[11]

2-Alkyl-3-mercapto-1-propanol (4) and 2-Alkyl-1,3-propanedithiol (5). The same procedure as that in the previous paper[11] was used. Compounds **4** were colorless transparent liquid and **5** were yellow transparent liquid.

IR ($CHCl_3$): Compounds **4**; 3600 (OH), 2800—3000 (alkyl) cm^{-1}. Compounds **5**; 2800—3000 (alkyl) cm^{-1}.

^{1}H NMR ($CDCl_3$): Compounds **4**; δ=0.6—2.0 (m, R-CH, SH), 2.5—2.8 (m, 2H, CH_2S), 3.4—4.0 (m, 3H, CH_2OH), Compounds **5**: δ=0.6—2.0 (m, R-CH, SH), 2.5—2.9 (m, 4H, CH_2S).

(+)-4-(2-Methylbutoxy)phenol(7). The Williamson synthesis was applied to hydroquinone and (+)-2-methylbutyl bromide. As the diether was produced as a side product, the crude product was purified by column chromatography. Compound **7** was eluted with benzene and the diether with hexane. Transparent liquid was obtained in a 30—40% yields.

IR ($CHCl_3$) 3600 (OH), 2800—3000 (alkyl), 1600 (Ar), 1260 (ether) cm^{-1}.

^{1}H NMR ($CDCl_3$) δ=0.6—2.3 (m, 9H, $OCH_2C_4\underline{H}_9$), 3.8 (d, 2H, OCH_2), 5.9 (s, 1H, OH), 6.8 (s, 4H, ArH).

(+)-2-Methylbutyl *p*-Hydroxybenzoate (9). A solution of *p*-hydroxybenzoic acid (0.1 mol) and 2-methylbutanol (0.1 mol) and *p*-toluenesulfonic acid (0.3 g) in anhyd. toluene (100 ml) was refluxed for 48 h with a Dean-Stark trap fitted. Then toluene was removed on a rotary evaporator. The residue was dissolved in diethyl ether (300 ml), washed with 5% aq. $NaHCO_3$ (200 ml), dried over anhyd. Na_2SO_4, and evaporated in vacuo.

Transparent liquid was obtained in a 85—90% yields.

IR ($CHCl_3$) 3600 (OH), 2800—3000 (alkyl), 1715 (C=O), 1600 (Ar) cm^{-1}.

^{1}H NMR ($CDCl_3$) δ=0.7—2.2 (m, 9H, $OCH_2C_4\underline{H}_9$), 4.2 (d, 2H, OCH_2), 7.5 (q, 4H, ArH), 8.5 (s, 1H, OH).

(+)-4-(2-Methylbutoxy)phenyl 4-Formylbenzoate (8). To a solution of compound **7** (0.03 mol), and 1,8-diazabicyclo-[5.4.0]undec-7-ene (0.03 mol) in anhyd. *N*,*N*-dimethylformamide (30 ml) was added compound **6** (0.03 mol) in a nitrogen atmosphere, followed by stirring at 40 °C for 18 h. The solution was poured into ice water and extracted twice with ether (each 200 ml). The extract was washed with cold 2% aq. HCl, dried over anhyd. Na_2SO_4, and evaporated in vacuo at 40 °C. The residue was extracted with hexane, and concentrated under reduced pressure. Light yellow liquid was obtained in a 50—55% yields.

IR ($CHCl_3$) 2800—3000 (alkyl), 1740, 1680 (C=O), 1600 (Ar), 1260 (ether) cm^{-1}.

^{1}H NMR ($CDCl_3$) δ=0.7—2.2 (m, 9H, $OCH_2C_4\underline{H}_9$), 3.75 (d, 2H, OCH_2), 6.7—8.5 (m, 8H, ArH), 10.05 (s, 1H, CHO).

(+)-4-(2-Methylbutoxycarbonyl)phenyl 4-Formylbenzoate (10). The same procedure as that for compound **8** was used for preparation of compounds **6** and **9**. Light yellow liquid was obtained in 50—60% yields.

IR ($CHCl_3$) 2800—3000 (alkyl), 1680—1740 (C=O), 1600 (Ar) cm^{-1}.

^{1}H NMR ($CDCl_3$) δ=0.6—2.2 (m, 9H, $OCH_2C_4\underline{H}_9$), 4.2 (d, 2H, OCH_2), 7.2—8.5 (m, 8H, ArH), 10.2 (s, 1H, CHO).

(+)-4-(2-Methylbutoxy)phenyl 4-(5-Alkyl-1,3-dioxan-2-yl)-benzoate (11). To a solution of compound **1** (0.004 mol) and compound **8** (0.004 mol) in anhyd. $CHCl_3$ (200 ml) cooled in an ice bath were added $BF_3\cdot(C_2H_5)_2O$ (0.5 g) and Molecular Sieves (3A, 1/15; 3 g). The mixture was stirred at 0—5 °C for 8 h and then at 20—25 °C for 16 h. The solution was washed with 10% aq. $NaHCO_3$ (400 ml), dried over anhyd. Na_2SO_4, and concentrated under reduced pressure at 40 °C. The crude product was purified by column chromatography and recrystallizations from hexane, then separetive TLC was used to remove cis isomer.

Mechanism of the Carboxylation of Cyclohexanone with Carbon Dioxide Catalyzed by 1,8-Diazabicyclo[5.4.0]undec-7-ene

Hisakazu MORI
Kyoritsu College of Pharmacy, Shibakoen, Minato-ku, Tokyo 105
(Received June 13, 1987)

The dependence of the rate of carboxylation upon the concentration of the reactant was investigated in dimethyl sulfoxide. The reaction rate depended upon the concentration of cyclohexanone and 1,8-diazabicyclo[5.4.0]undec-7-ene(DBU) in the first order, respectively. The reaction also followed first-order kinetics regarding the CO_2 pressure in the range 50—400 Torr. From these reaction characteristics, it is suggested that carboxylation proceeds via a reaction between CO_2 dissolved in dimethyl sulfoxide and the anion of cyclohexanone, rather than between the CO_2 adduct with DBU and cyclohexanone. The results of carboxylation by the CO_2 adduct with DBU and by CO_2 dissolved in dimethyl sulfoxide also support the above conclusion. The formation of the cyclohexanone anion by a reaction of cyclohexanone with DBU was verified by the UV spectrum of a solution of concentrated DBU and cyclohexanone.

A number of carbon dioxide fixation reactions catalyzed by a base is known in organic chemistry. In these reactions, compounds containing active methylene are transformed to carboxylic acids. The bases used as the

$$RH + CO_2 + B^- \rightarrow RCO_2^- + BH$$

catalyst are classified into two groups. One of them contains metal oxides such as sodium[1] or potassium[2,3] phenoxide or magnesium methoxide.[4] Another group includes nitrogen bases. Strong bases such as 1,8-diazabicyclo[5.4.0]undec-7-ene(DBU)[5] or tetramethylguanidine[6] are used in the absence of metal ions, and weak bases such as triethylamine[7] and 2-imidazolidinone[8] are used in the presence of metal ions.

We have investigated carboxylation using potassium phenoxide (PhOK).[2,3] With regard to the mechanism of this reaction, it was suggested[3] that the CO_2 complex with PhOK served as the CO_2 source of the carboxylate. We are now interested in the catalysis of nitrogen bases. Among nitrogen bases, DBU has been extensively studied by Haruki et al.[9] and was established as an effective carboxylating agent in synthetic chemistry. In a preliminary experiment, we found that the carboxylation of cyclohexanone using this base in dimethyl sulfoxide (DMSO) gives 2-oxocyclohexanecarboxylic acid in a homogeneous reaction system. We therefore selected this reaction system as a typical carboxylation by a nitrogen base, and studied it from a mechanistic view point. Iwatani et al.[10] studied this system under a high pressure of CO_2. In the present paper, the kinetics of carboxylation with CO_2 under a pressure lower than atmospheric are reported, and a reaction mechanism under this condition is proposed.

Experimental

Material and Glassware. DBU was dried with NaOH for several days at room temperature and distilled under nitrogen at a reduced pressure prior to use. Cyclohexanone was distilled under atmospheric pressure. DMSO was refluxed with CaH_2 for about 3 h, and distilled under a reduced nitrogen pressure. Well-dried glassware was used for the uptake of CO_2 by DBU and for carboxylation.

The Uptake of CO_2 by DBU. The uptake of CO_2 by DBU was investigated with a 0.2-M (1 M=1 mol dm^{-3}) DMSO solution at 20 °C in the vacuum system described in a previous paper.[3] The amount of CO_2 taken up by DBU was calculated by subtracting the amount dissolved in DMSO from the total amount taken up by the DMSO solution of DBU.

Carboxylation of Cyclohexanone with DBU and CO_2. CO_2 at atmospheric pressure was passed through a DMSO solution of DBU for 1 h at 20 °C. Then, cyclohexanone was added to this solution. A portion of the mixture was withdrawn at predetermined intervals, acidified with diluted HCl, and extracted with ether. The ethereal layer was dried with anhydrous sodium sulfate and treated with diazomethane. The methyl ester of the carboxylic acid was determined by means of gas chromatography. In a study of the dependence of the reaction rate upon the concentration of DBU, varying amounts of DBU in the ranges of 5—40 mmol and 10 mmol of cyclohexanone were used with 100 cm^3 of DMSO. Similarly, to study the dependence upon the concentration of cyclohexanone, 10 mmol of DBU and 5—40 mmol of cyclohexanone were used. In a study regarding the dependence upon the CO_2 pressure, mixtures of N_2 and CO_2 in varying ratios were used. The amounts of DBU and cyclohexanone used in this experiment were 20 and 10 mmol, respectively, with 100 cm^3 of DMSO.

Spectral Measurement. Infrared (IR) spectra were measured with a Hitachi EPI-G3 spectrophotometer, and electronic spectra, with a Hitachi 100-50 spectrophotometer.

Results and Discussion

Regarding carboxylation with PhOK, we suggested[3] that CO_2 complexed with PhOK plays the role of a CO_2 source. Accordingly, we first investigated the reaction between DBU and CO_2 in DMSO. After CO_2 was passed through a DMSO solution of DBU, a new absorption was observed at 1642 cm^{-1} in the IR spectrum. This fact indicates that CO_2 forms an adduct with DBU. In Fig. 1 is shown the uptake of CO_2 by

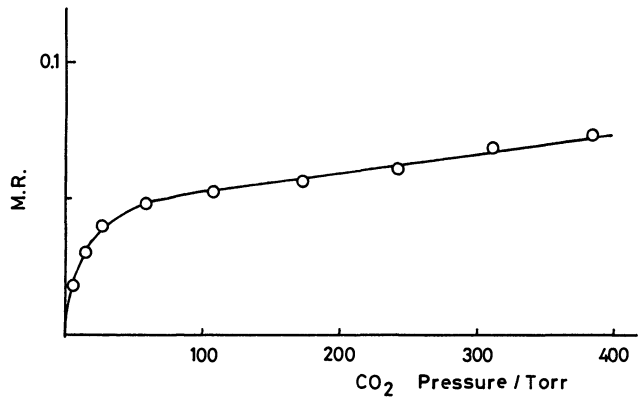

Fig. 1. The uptake of CO_2 by DBU at 20°C under various CO_2 pressure (0.2 M DMSO solution).

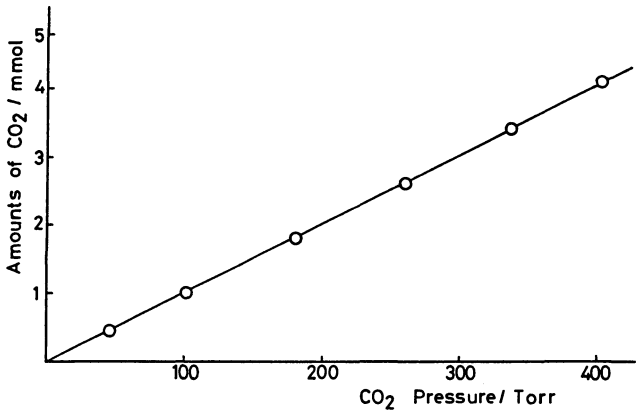

Fig. 2. The solubility of CO_2 in 50 cm^3 of DMSO at various CO_2 pressure at 20°C.

DBU in DMSO under various CO_2 pressures. The amount of CO_2 taken up by DBU was obtained by subtracting the amount of CO_2 dissolved in DMSO (Fig. 2, slope=2.05×10^{-4} mmol $Torr^{-1}$ cm^{-3}, 1 Torr= 133.322 Pa) from that dissolved in the DMSO solution of DBU. The ordinate indicates the M.R.: that is, the molar ratio of CO_2 adduct to the total amount of DBU. The value of M.R. was less than 0.1, even at a CO_2 pressure of about 400 Torr. On the contrary, the uptake by PhOK was extensive and the M.R. value amounted to more than 0.5 at 10 Torr.[3]

In Fig. 3, the time courses of the carboxylation with varying amounts of DBU are shown. The yields of carboxylate were calculated on the basis of the amount of cyclohexanone initially added (10 mmol). The yield of carboxylate increased almost linearly with the reaction time. The initial rates of carboxylate formation were calculated from the results. A plot of the initial rates of carboxylate formation against the initial concentration of DBU gave a straight line with a slope of 1.71 ± 0.07 (% min^{-1} M^{-1}). Thus, it was shown that the rate of carboxylation depended upon the concentration of DBU in the first order.

The dependence of the reaction rate upon the concentration of cyclohexanone was also studied. In this

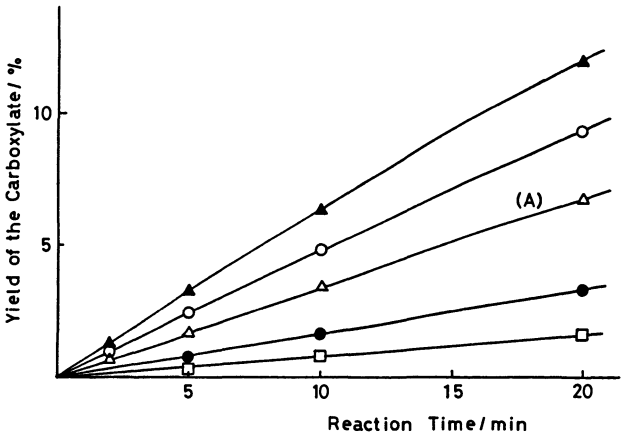

Fig. 3. The carboxylation with various amounts of DBU. —□—, 5 mmol; —●—, 10 mmol; —△—, 20 mmol; —○—, 30 mmol; —▲—, 40 mmol.

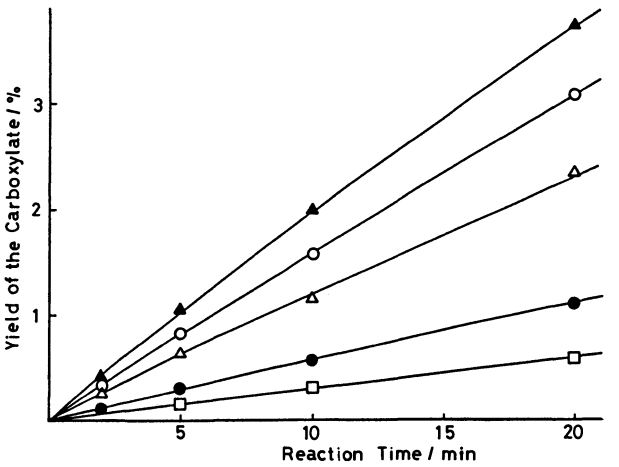

Fig. 4. The carboxylation with various CO_2 pressure. —□—, 47.5 Torr; —●—, 95 Torr; —△—, 190 Torr; —○—, 285 Torr; —▲—, 380 Torr.

case, the yield of carboxylate was calculated on the basis of the amount of DBU initially added. The rate of the carboxylation increased almost linearly with the increase in the concentration of cyclohexanone, with a slope of 1.67 ± 0.15 (% min^{-1} M^{-1}). Thus, the relationship between the reaction rate and the concentration of cyclohexanone showed a first-order dependence; the obtained slope was almost the same magnitude as that obtained in the study of the dependence upon the concentration of DBU. Thus, the slopes give a pseudo second-order rate constant of about 1.7 (% min^{-1} M^{-1}).

In Fig. 4, the time courses of carboxylation under various CO_2 pressures are shown. The yield of the carboxylate increased almost linearly with the reaction time. The initial rates of the carboxylate formation were obtained from the results. A plot of the initial rate against the CO_2 pressure gave a curve with a slight deviation from a straight line (Fig. 5).

With respect to carboxylation, two species can be considered as the possible CO_2 source of the carboxylate. They are the CO_2 adduct with DBU and CO_2

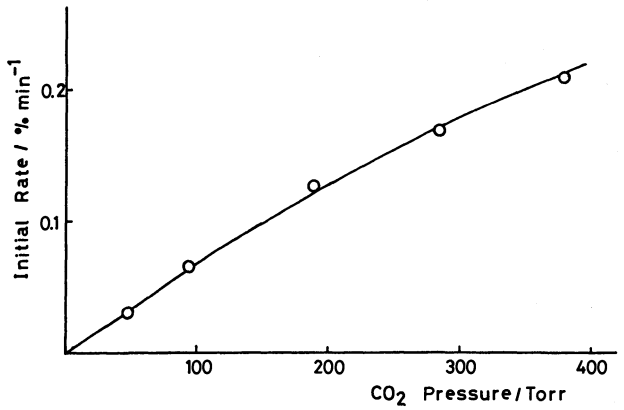

Fig. 5. The relationship between the initial rate of the carboxylation and CO_2 pressure.

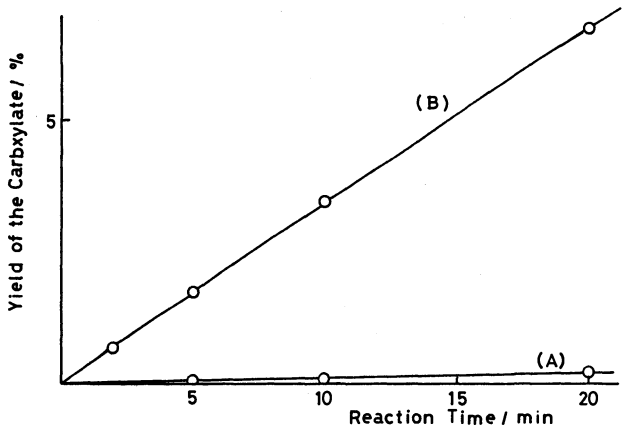

Fig. 6. The time courses of the carboxylation. (A) in the case of using CO_2 adduct with DBU, (B) in the case of using CO_2 dissolved in DMSO.

dissolved in DMSO. We now discuss the reaction mechanisms corresponding to the respective CO_2 species. The mechanism including CO_2 adduct with DBU is shown below, as is proposed by Iwatani et al.[10] Here,

$$\text{(A)} \quad \begin{cases} \text{DBU} + CO_2 \rightarrow \text{DBU} \cdot CO_2 & (1) \\ \text{DBU} \cdot CO_2 + \text{ChH} \rightarrow \text{ChCO}_2^- \cdot \text{DBUH}^+ & (2) \end{cases}$$

ChH designates cyclohexanone. In this mechanism, a CO_2 transfer occurs from the adduct to cyclohexanone to form the carboxylate (step (2)). Since the DMSO solution of DBU was preequilibrated with CO_2, step (1) might be in equilibrium. In such a case, the concentration of the adduct can be expressed by

$$c = aPK/(1+PK), \quad (3)$$

where P is the pressure of CO_2, K is the equilibrium constant of step (1), and a is the total concentration of DBU. This equation indicates that the concentration of the adduct increases proportionately with the initial concentration of DBU under a constant CO_2 pressure. In the carboxylation reaction, cyclohexanone was added to a CO_2 saturated DMSO solution of DBU. Therefore, the initial rate of carboxylation would be that of step (2). The rate of step (2) would show a first-order dependence upon the concentrations of both cyclohexanone and the adduct and, consequently, upon the concentration of DBU (as shown in Eq. 3). Experimental results were in accordance with the above discussion. The dependency of the rate upon the CO_2 pressure was assumed to be analogous to the curve shown in Fig. 1, since this curve indicates the dependence of the concentration of the adduct upon the CO_2 pressure. However, the experimental results (Fig. 5) were not in agreement with this assumption.

Another possible mechanism (B) is shown below:

$$\text{(B)} \quad \begin{cases} \text{ChH} + \text{DBU} \rightarrow \text{Ch}^- \cdot \text{DBUH}^+ & (4) \\ \text{Ch}^- \cdot \text{DBUH}^+ + CO_2 \rightarrow \text{ChCO}_2^- \cdot \text{DBUH}^+ & (5) \end{cases}$$

Cyclohexanone anion (Ch^-) is formed by the reaction between cyclohexanone and DBU (step (4)) and reacts with CO_2 dissolved in DMSO to form the carboxylate (step (5)). If step (5) was the rate-limiting step, the reaction rate would depend upon the respective concentrations of the anion and CO_2 to the first order. Cyclohexanone is a very weak acid (pK_a=16.9[11]), and DBU is a strong base with a pK_a of 11.5.[12] Thus, a small amount of cyclohexanone anion might be formed in step (4), and during the initial stage of carboxylation, the amount of formed cyclohexanone anion would be proportional to the amounts of the respective substrates. Though a part of DBU forms the adduct with CO_2 (as indicated in Eq. 3), the resultant concentration of DBU increases along with an increase in the initial concentration of DBU. Thus, the rate of carboxylation would show a first-order dependence upon the initial concentrations of both DBU and cyclohexanone. As shown in Fig. 2, the solubility of CO_2 in DMSO increased linearly in accordance with the increase in CO_2 pressure. Therefore, the rate of the reaction would increase linearly with an increase in the CO_2 pressure. Experimental results described previously seem to be consistent with this mechanism (B).

As discussed above, it is suggested that carboxylation proceeds via the reaction mechanism (B) rather than mechanism (A). In order to obtain further support for this mechanism, we studied carboxylation using only one CO_2 species. In the absence of the solvent, DBU (neat) was reacted with CO_2 at atmospheric pressure. It absorbed CO_2 in the molar ratio of 0.08. The carboxylation reaction was carried out with this mixture of the adduct and unreacted DBU.[13] The time course of the reaction is shown in Fig. 6 (curve (A)). A separate experiment[14] showed that CO_2 was scarcely transferred from the adduct to the solvent. If carboxylation proceeded via reaction mechanism (A), the initial rate of carboxylation with this adduct sample should have been the same as that of carboxylation for the case[15] in which atmospheric CO_2 was passed

through about a 0.2-M DMSO solution of DBU (Fig. 3 curve (A)). However, the initial rate of the former was considerably smaller than that of the latter (in the ratio of about 1 : 30). This result shows that the contribution of the adduct to the carboxylation was very small. As shown in Fig. 1, the concentration of the adduct, the low active species, increases with an increase in the CO_2 pressure, reducing the concentration of DBU. Thus, with respect to the curve shown in Fig. 5, the deviation from a straight line could be ascribed to the reduced amount of DBU at the starting point of carboxylation with the increased CO_2 pressure.

Carboxylation using CO_2 dissolved in DMSO was also carried out.[16] The time course of this carboxylation is given in Fig. 6 (curve (B)). This curve for carboxylate formation is very similar to that shown in Fig. 3 (curve (A)). It can therefore be pointed out that CO_2 dissolved in DMSO plays an important role in carboxylation by DBU.

The reaction between DBU and cyclohexanone was studied spectrophotometrically. Figure 7 shows the electronic absorption spectrum of a DMSO solution containing both 1 M DBU and 1 M cyclohexanone (spectrum (A)), which was measured with a 1-M DMSO solution of DBU as a reference. Since cyclohexanone does not have an absorption in this region of the spectrum, a new absorption with a maximum between 360 and 370 nm can be ascribed to the formation of the cyclohexanone anion. The spectrum of potassium salt of cyclohexanone (enolate)[17] in DMSO has a maximum at 362 nm (spectrum (B)). The results confirmed the reaction between cyclohexanone and DBU to form the cyclohexanone anion (step (4)).

The experimental results described above support the idea that carboxylation catalyzed by DBU proceeds via reaction mechanism (B). On the contrary, Iwatani et al. suggested[10] mechanism (A) for carboxylation under a higher CO_2 pressure and higher concentrations of DBU and cyclohexanone than ours. However, upon inspecting their data, it seems that mechanism (B) could not always be excluded as a possible mechanism. A further investigation may be necessary before the results of the two groups can be understood with consistency, considering the difference in the reaction conditions.

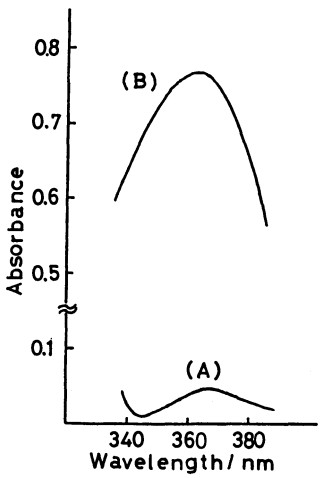

Fig. 7. Electronic absorption spectra. (A) DMSO solution containing both 1 M DBU and 1 M cyclohexanone, (B) DMSO solution of potassium salts of cyclohexanone.

Anyhow, the results obtained in our present work strongly suggest that the reaction proceeds mainly via reaction mechanism (B). This mechanism is in contrast with that of carboxylation catalyzed by PhOK, in which the CO_2 source of the carboxylate was considered to be CO_2 complexed with PhOK.[3] In the two reactions, the rate of the latter is, generally, much larger than that of the former, especially at a low CO_2 pressure. The dependence of the rate upon the CO_2 pressure is fairly different among the two reactions. It is noted that PhOK binds with CO_2 more strongly than DBU, in spite of its low pK_a (pK_a of phenol is 10.0). The formation of CO_2 species other than $CO_2 \cdot$ PhOK is suggested (data are not shown). Thus, the difference of the reactivity in carboxylation between PhOK and DBU may result from the unique reactivity of PhOK toward CO_2.

The author is very grateful to Professor Yoshikazu Matsushima (Kyoritsu College of Pharmacy) for helpful discussion.

13) Twenty mmol of DBU(neat) was reacted with CO_2 of atmospheric pressure for 1 h, absorbing 1.6 mmol of CO_2

(gravimetrically determined). This sample was dissolved in 100 cm^3 of DMSO and reacted with 10 mmol of cyclohexanone.

14) The variation of the concentration of CO_2 adduct with DBU was observed in the IR spectra after the sample was dissolved in DMSO. The relative intensity of the absorption at 1642 cm^{-1} to that at 1610 cm^{-1} due to DBU was followed for 1 h. And no marked variation of the relative intensity was observed. It was also shown, by comparison with the spectrum of the DBU solution (in DMSO) which was saturated with CO_2 of atmospheric pressure, that most parts of the dissolved adduct retained the form of adduct in solution.

15) With respect to this solution, it was estimated by the gravimetric method that 100 cm^3 of DMSO dissolves 15.0 mmol of CO_2 and 20 mmol of DBU uptakes 1.8 mmol of CO_2, respectively.

16) CO_2 of atmospheric pressure was passed through the solution containing 100 cm^3 of DMSO and 10 mmol of cyclohexanone for 1 h. Then 20 mmol of DBU was added. In connection with this carboxylation reaction, the experiment as shown below was carried out. DBU was added to the CO_2 saturated DMSO solution and the IR spectrum of the solution was measured. The spectrum showed that only a small portion of CO_2 was present in the adduct form in the solution.

17) Potassium salt of cyclohexanone was prepared in THF by the reaction of cyclohexanone with potassium hydride (Ref. 18), and this solution was diluted with DMSO.

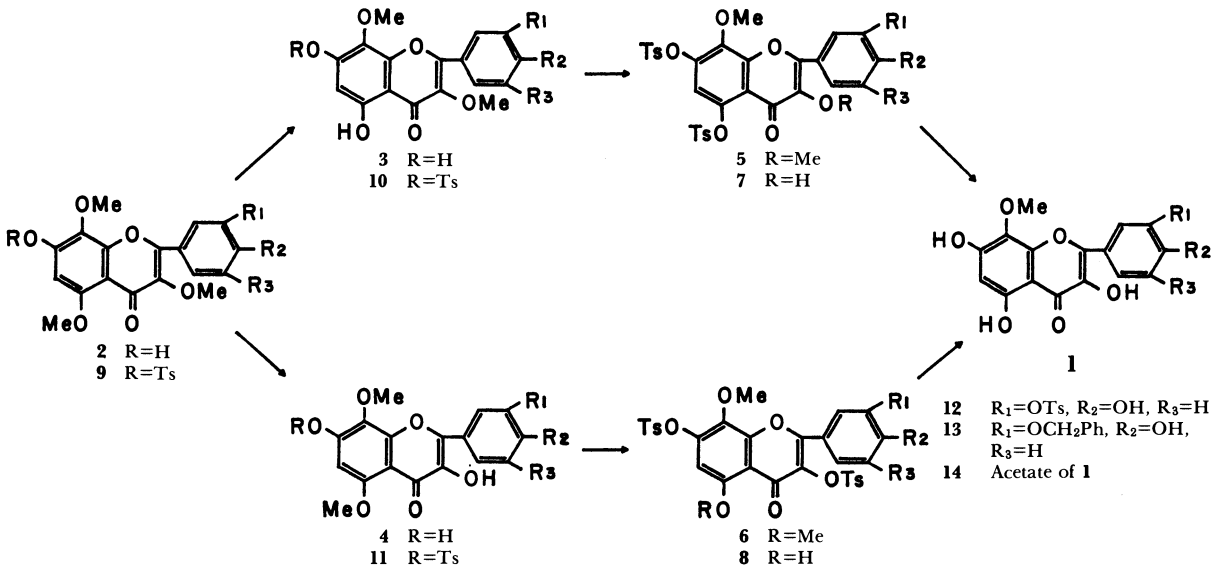
Studies of the Selective *O*-Alkylation and Dealkylation of Flavonoids. XI. A New Convenient Method for Synthesizing 3,5,7-Trihydroxy-8-methoxyflavones from 7-Hydroxy-3,5,8-trimethoxyflavones[1)]

Tokunaru HORIE,* Masao TSUKAYAMA, Yasuhiko KAWAMURA, Masamichi SENO, and Shigeo YAMAMOTO
Department of Applied Chemistry, Faculty of Engineering, Tokushima University, Minamijosanjima-cho, Tokushima 770
(Received July 4, 1987)

The 3- or 5-methoxyl group in the ditosylates of 5,7-dihydroxy-3,4′,8-trimethoxy- and 3,7-dihydroxy-4′,5,8-trimethoxyflavones was quantitatively demethylated with anhydrous aluminum bromide in acetonitrile to give the corresponding monohydroxyflavones, which were easily hydrolyzed into 3,5,7-trihydroxy-4′,8-dimethoxyflavone. On the basis of the results, the following convenient method for synthesizing 3,5,7-trihydroxy-8-methoxyflavones from 7-hydroxy-3,5,8-trimethoxyflavones was established. 7-Hydroxy-3,5,8-trimethoxyflavones or their tosylates were demethylated with 5% w/v anhydrous aluminum bromide in acetonitrile to give a mixture of the corresponding 3- and 5-hydroxyflavones. The mixture was tosylated and the resultant mixture was demethylated under the same conditions. The demethylated products were hydrolyzed with anhydrous potassium carbonate in methanol to give the desired 3,5,7-trihydroxy-8-methoxyflavones in high yields.

Generally, the selective cleavage of the 5-methoxyl group in flavones with free 3-hydroxyl and 8-methoxyl groups is not possible and the syntheses of 3,5,7-trihydroxy-8-methoxyflavones (**1**) from 7-hydroxy-3,5,8-trimethoxyflavones (**2**) by the selective demethylation have not also been successful.[2)] Therefore, the 3,5,7-trihydroxyflavones have been synthesized by the four following routes which bypassed the difficulty of the selective demethylation, albeit in low yields: (1) oxidative demethylation of the dibenzyl ether of 3,7-dihydroxy-5,8-dimethoxyflavones (**4**),[3)] (2) partial *O*-alkylation and dealkylation of 3,5,7,8-tetrahydroxyflavones,[4)] (3) Allan-Robinson reaction of ω-benzoyloxy-2,4,6-trihydroxy-3-methoxyacetophenone,[5)] and (4) nuclear oxidation of 3,7-bis(benzyloxy)-5-hydroxyflavones.[6)]

In previous papers, we reported that the demethylation of 7-hydroxy-3,5,8-trimethoxyflavones (**2**) with anhydrous aluminum bromide in acetonitrile afforded quantitatively a mixture of 5,7-dihydroxy-3,8-dimethoxyflavones (**3**) and 3,7-dihydroxy-5,8-dimethoxyflavones (**4**),[1)] and that 3-hydroxy-5,7,8-trimethoxyflavones were demethylated to 3,5-dihydroxy-7,8-dimethoxyflavones via the corresponding sulfonates.[7)] The results show that 3,5,7-trihydroxyflavones (**1**) are easily synthesized from **2** when the respective 3- and 5-methoxyl groups in tosylates of **3** and **4** are selectively cleaved and the tosyloxyl groups



Scheme 1.

are easily hydrolyzed. Therefore, we studied the selective demethylation of ditosylates (**5a** and **6a**) of 5,7-dihydroxy-3,4′,8-trimethoxyflavone (**3a**) and 3,7-dihydroxy-4′,5,8-trimethoxyflavone (**4a**) and the hydrolysis of the resultant 3- and 5-hydroxyflavones, and consequently established a convenient method for synthesizing 3,5,7-trihydroxy-8-methoxyflavones (**1**) from 7-hydroxy-3,5,8-trimethoxyflavones (**2**). In this paper, we report on a general method for synthesizing **1** and their characterization.

Results and Discussion

Selective Demethylation of 5,7-Dihydroxy-3,4′,8-trimethoxyflavone (3a) and 3,7-Dihydroxy-4′,5,8-trimethoxyflavone (4a). The outline of the demethylation of the dihydroxyflavones **3a** and **4a** to **1a** was as follows. The 3-methoxyl group of the ditosylate **5a**, which was easily synthesized from **3a** by the tosylation, was selectively cleaved with 5% w/v anhydrous aluminum bromide in acetonitrile to give quantitatively 3-hydroxy-4′,8-dimethoxy-5,7-bis(tosyloxy)flavone (**7a**). The tosyloxyl groups in **7a** were smoothly hydrolyzed with potassium carbonate in methanol and the desired 3,5,7-trihydroxy-4′,8-dimethoxyflavone (**1a**) was easily obtained. On the other hand, the 3-hydroxyflavone **4a** was also demethylated to **1a** under similar conditions via the corresponding ditosylates **6a** and **8a**. All of the reactions proceeded quantitatively and no side reaction products were detected by TLC. The results show that **1a** was easily synthesized by the demethylation of 7-hydroxy-3,4′,5,8-tetramethoxyflavone (**2a**) as shown in Scheme 1.

A Method for Synthesizing 3,5,7-Trihydroxy-8-methoxyflavones (1). The demethylation of **2a** with anhydrous aluminum bromide in acetonitrile gave quantitatively a mixture of **3a** and **4a**.[1] The condensation of the mixture with *p*-toluenesulfonyl chloride in the presence of potassium carbonate afforded a mixture of tosylates **5a** and **6a**. The mixture of tosylates was selectively demethylated with anhydrous aluminum bromide in acetonitrile to give the monohydroxyflavones **7a** and **8a**, which were hydrolyzed to the desired **1a** with anhydrous potassium carbonate in methanol under nitrogen atmosphere. The overall yield of **1a** was 72%. The flavones **1b** and **1c** with no hydroxyl groups on the B ring were easily synthesized from the corresponding 7-hydroxyflavones **2b** and **2c** by this method.

On the other hand, the tosylates **9l** and **9m** of hydroxyflavones **2e** and **2g** as starting materials were used for syntheses of the 3,5,7-trihydroxyflavones **1e** and **1g** with hydroxyl groups on the B ring, since the selective demethylation of flavones with no hydroxyl group proceeded more smoothly than that of flavones with hydroxyl groups.[1,8] 3,4′,5,7-Tetrahydroxy-3′,8-dimethoxyflavone (**1e**) was easily synthesized from the tosylate **9l**. The tosylate **9m** of **2g** was also demethylated under similar conditions to give a mixture of two monohydroxyflavones **10m** and **11m**. The mixture was converted into a mixture of 3-hydroxy-8-methoxy-3′,4′,5,7-tetrakis(tosyloxy)flavone (**7m**) and 5-hydroxy-8-methoxy-3,3′,4′,7-tetrakis(tosyloxy)flavone (**8m**) by tosylation and subsequent demethylation. However, these tosylates were not easily hydrolyzed with potassium carbonate in methanol, and a mixture (ca. 1/1) of **1g** and its 3′-tosylate **12** was obtained in the hydrolysis for 10 h.

The results show that the 3-, 4′-, 5-, and 7-tosyloxyl groups which are associated with the carbonyl group in the flavone skeleton are easily hydrolyzed under mild conditions, but that hydrolysis of the tosyloxyl groups at the other positions is difficult. It is desired that the alkaline hydrolysis is carried out under as mild conditions as possible in the flavone synthesis, since the stability of flavones in alkaline media generally decreases with increasing the number of hydroxyl groups. Therefore, an alternative method for the protection of the hydroxyl groups on the B ring was studied in order to establish a general method for synthesizing 3,5,7-trihydroxy-8-methoxyflavones (**1**).

A General Method for Synthesizing 3,5,7-Trihydroxy-8-methoxyflavones (1) from 7-Hydroxy-3,5,8-trimethoxyflavones (2). In the demethylation, a benzyl group seems to be the most suitable protecting group of the hydroxyl groups when the 3- or 5-methoxyl group in the 3,5-dimethoxyflavone derivatives with benzyloxyl groups on the B ring is selectively cleaved without the cleavage of benzyloxyl groups. However, the demethylation of the 5-methoxyl group in the 5,7,8-trioxygenated flavones by anhydrous aluminum chloride in acetonitrile is generally more difficult than that in 5,6,7-trioxygenated flavones, and that the 5-methoxyl group in 8-hydroxy-5,7-dimethoxyflavones with benzyloxyl groups on the B ring is not demethylated selectively with anhydrous aluminum chloride because of the simultaneous cleavage of the benzyloxyl groups.[1,9] On the other hand, anhydrous aluminum bromide as a demethylating reagent can be expected to be much more selective than aluminum chloride.[7,10] Therefore, the demethylation of tosylates **9i** and **9k** of **2i** and **2k** was examined. The 3- or 5-methoxyl group in the tosylate **9i** with a benzyloxyl group on the B ring was selectively cleaved with 5% w/v anhydrous aluminum bromide in acetonitrile for 1 h at room temperature without debenzylation to give a mixture of the two monohydroxyflavones **10i** and **11i**, which was easily converted into **1i** via the corresponding tosylates by the demethylation and hydrolysis. The tosylate **9k** with two adjacent benzyloxyl groups on the B ring was also selectively demethylated under similar conditions, but a little amount of debenzylated products were detected by TLC. And the mixture of the tosylates of the demethylated products was converted into **1k** and a little

Table 3. UV Spectral Data for 3,5,7-Trihydroxy-8-methoxyflavones (**1**, **12**, and **13**) and Ditosylates of **1a** (**7a** and **8a**)[a)]

a) sh, shoulder; i, inflection point.

and **8a** show the presence of two tosyloxyl groups and the UV spectra exhibit the characteristic properties for 3- or 5-hydroxyflavones, suggesting that the structure of **7a** and **8a** are the 5,7- and 3,7-ditosylates of **1a**, respectively (Tables 1 and 3).

The properties of five of the synthesized flavones **1** agreed with those of the flavones **1a**,[3] **1d**,[6] **1e**,[5] **1g**,[4] and **1i**[5] which had been synthesized by the alternative routes, respectively. Also, the flavones **1a**—g afforded the corresponding acetates **14a**—g by the acetylation with acetic anhydride-pyridine. The ^{1}H NMR data for these flavones are shown in Tables 1 and 2. Signals of C_6-protons in **1** (in DMSO-d_6) are in the range of δ 6.23 to 6.28 and those in the acetates **14** (in $CDCl_3$) of **1** shift paramagnetically into the range of δ 6.75 to 6.82. The signals of C_6-protons in 5,7-

dihydroxy-3,8-dimethoxyflavones (**3**) and their acetates are appeared in a similar range,[1] respectively. The chemical shifts of the aromatic protons on the B ring are affected by the 3-hydroxyl or acetoxyl groups; these signals were similar to those in 3,7-dihydroxy-5,8-dimethoxyflavones (**4**) and their acetates.[1]

In the UV spectral data for **1**, Bands I and II are seen at 375 to 385 and 260 to 275 nm, respectively (Table 3). These Bands I shift bathochromically about 60 nm by the addition of aluminum chloride, but the bathochromic shift of Bands II is not observed. On the other hand, Bands I and II in all 3,5,7-trihydroxy-8-methoxyflavones shift bathochromically upon the addition of sodium acetate and the characteristic shift attributed to the 4′-hydroxyl group could not be found. These properties in the UV spectra are useful for a distinction from the other flavones, such as 3,5-dihydroxy-7,8-dimethoxyflavones,[7] but are shown to be applicable for the assignment of 4′-hydroxyl group in 3,5,7-trihydroxy-8-methoxyflavones in contrast to that in 5,7,8-trioxygenated flavones with no hydroxyl group at the 3-position.[9]

The ^{1}H NMR spectrum for **12** shows the presence of a methoxyl and a tosyloxyl group, suggesting that the structure is a monotosylate of **1g**. In a comparison of the ^{1}H NMR spectra for **1g** and **12**, the aromatic protons at 2′- and 6′-positions in **12** are more largely influenced by the tosyloxyl group than that at the 5′-position; both signals appeared at δ 8.00. The results show that the structure of **12** is the 3′-*O*-tosylate of **1g**. The ^{1}H NMR spectrum for **13** shows the presence of a benzyl group and the UV spectral data are similar to those for **12**, suggesting that the structure of **13** is the 3′-*O*-benzyl ether of **1g**.

Identification of a Natural Flavone (1f). During the survey of the flavonoids in the *Primulaceae*, Harborne proposed originally that the structure of Primula F 3A, which was isolated from an acid hydrolysate of several yellow-flowered Primula species, was a methyl ether of quercetagetin.[11] The author later revised its structure: Primula F 3A could be the as yet unknown 8,4′-dimethyl ether of gossypetin; however, further studies are required.[12] The UV spectral data for the flavone are essentially identical with those for the synthetic flavone (**1f**) and it shows that the proposed structure is correct. However, a direct comparison between the natural and synthetic flavones is required for a more accurate determination of the structure since the UV spectral data for the 3,5,7-trihydroxyflavones having 3,3′,4′,5,7,8-hexaoxygenated structure are similar to each other (Table 3).

Conclusion

The method for synthesizing 3,5,7-trihydroxy-8-methoxyflavones consists of the following three fundamental reactions which proceed quantitatively:

1. The 3- or 5-methoxyl group in 7-hydroxy-3,5,8-trimethoxyflavones (**2**) and their tosylates (**9**) was selectively cleaved with 5% w/v anhydrous aluminum bromide in acetonitrile at room temperature for 1—2 h to give a mixture of the corresponding 3- and 5-hydroxyflavones, and the benzyloxyl groups on the B ring were hardly cleaved under the conditions.
2. The respective 3- and 5-methoxyl groups in the 3-methoxy-5-tosyloxy- and 5-methoxy-3-tosyloxyflavone derivatives were also cleaved selectively under similar conditions.
3. The tosyloxyl groups at the 3-, 4′-, 5-, and 7-positions which are associated with the carbonyl group in the flavone skeleton, are hydrolyzed under mild conditions such as potassium carbonate in methanol.

It seems that the reactions can not be attributed to the characteristic properties for 3,5,7,8-tetraoxygenated flavones. Therefore, the method would be widely applied to the syntheses of 3,5-dihydroxyflavone derivatives.

Experimental

All melting points were determined in glass capillaries and are uncorrected. ^{1}H NMR spectra were recorded on a Hitachi R-24 spectrometer (60 MHz), using tetramethylsilane as an internal standard, and chemical shifts were given in δ values. UV spectra were recorded on a Hitachi 124 spectrometer. Thin-layer chromatography was carried out with silica-gel plates (Merck, Kiesel gel 60 F_{254}) using chloroform–ethyl acetate as an eluent. Elemental analyses were performed with a Yanaco CHN corder model MT-2.

7-Hydroxy-3,5,8-trimethoxyflavones (2). Flavones **2** were synthesized from 2,4-dihydroxy-3,6,ω-trimethoxyacetophenone by the Allan-Robinson reaction according to the method described in a previous paper.[1] 4′-Benzyloxy-7-hydroxy-3,5,8-trimethoxyflavone (**2h**): mp 238—240 °C (from ethyl acetate); (lit,[13] mp 240—242 °C); yield 55%. 3′-Benzyloxy-7-hydroxy-3,4′,5,8-tetramethoxyflavone (**2j**): mp 214—216 °C (from methanol); (lit,[14] mp 215—217 °C); yield 52%.

3-Hydroxy-4′,8-dimethoxy-5,7-bis(tosyloxy)flavone (7a). The flavone **5a** (85 mg) was dissolved in a solution of 5% w/v anhydrous aluminum bromide in acetonitrile (10 cm^3) and allowed to stand for 2 h. The mixture was poured into 2% hydrochloric acid and heated at 70—80 °C for 20 min and diluted with water. After the mixture was concentrated under reduced pressure, the crystals separated as yellow needles were collected, washed with water and dried to give **7a**: mp 173—174 °C; yield 80 mg (96%). Found: C, 58.15; H, 3.89%. Calcd for $C_{31}H_{26}O_{11}S_2$: C, 58.31; H, 4.08%.

5-Hydroxy-4′,8-dimethoxy-3,7-bis(tosyloxy)flavone (8a). The flavone **6a** (85 mg) was demethylated and treated under the same conditions as described above to give **8a** as pale yellow plates: mp 173—174 °C; yield 77 mg (93%). Found: C, 58.10; H, 3.89%. Calcd for $C_{31}H_{26}O_{11}S_2$: C, 58.31; H, 4.08%.

3,5,7-Trihydroxy-4′,8-dimethoxyflavone (1a). A mixture of **7a** (70 mg) and anhydrous potassium carbonate (0.5 g) in methanol (25 cm^3) was refluxed with stirring for 2 h. The mixture was acidified with diluted hydrochloric acid; then the methanol was evaporated under reduced pressure. The

separated crystals were recrystallized from aq methanol to give **1a** as yellow needles, yield 30 mg (83%). The flavone **1a** was also synthesized from **8a** (60 mg) by the hydrolysis described above, yield 25 mg (80%).

3,5,8-Trimethoxy-7-tosyloxyflavones 9a—c and 9h—k. A mixture of 7-hydroxy-3,5,8-trimethoxyflavone (**2**) with no hydroxyl groups on the B ring (1 mmol), *p*-toluenesulfonyl chloride (285 mg; 1.5 mmol), and anhydrous potassium carbonate (1.5—2 g; 8—11 mmol) in acetone (30—50 cm^3) was refluxed with stirring until the starting material disappeared (2—3 h). The cooled reaction mixture was poured into diluted hydrochloric acid and then concentrated under reduced pressure. The separated precipitate was collected, washed with water and a little amount of ether, and then recrystallized to give **9** as colorless prisms or needles. The results are shown in Table 4.

3,4′,8-Trimethoxy-5,7-bis(tosyloxy)flavone (5a), 4′,5,8-Trimethoxy-3,7-bis(tosyloxy)flavone (6a), and 3,3′,5,8-Tetramethoxy-4′,7-bis(tosyloxy)flavone (9l). A mixture of the flavone[1] (**3a**, **4a**, or **2e**) (0.3 mmol), *p*-toluenesulfonyl chloride (190 mg; 1 mmol), and anhydrous potassium carbonate (1.5 g; 10 mmol) in acetone (20—30 cm^3) was refluxed with stirring for 3—5 h. The reaction mixture was treated by the method described above to give the ditosylate as colorless needles or prisms (Table 4).

3,5,8-Trimethoxy-3′,4′,7-tris(tosyloxy)flavone (9m). The flavone **2g** (180 mg) was tosylated with *p*-toluenesulfonyl chloride (450 mg), and anhydrous potassium carbonate (2 g) in acetone to give **9k** as colorless needles (Table 4).

A General Method for Synthesizing 3,5,7-Trihydroxy-8-methoxyflavones (1) from 3,5,8-Trimethoxy-7-tosyloxyflavones (9). The flavone **9** (1 mmol) was dissolved in a solution of 5% w/v anhydrous aluminum bromide in acetonitrile (25—30 cm^3; 4.5—5.5 mmol) and the solution is allowed to stand at room temperature (25—28 °C) for 2 h. The reaction times in the demethylation of the flavones **1h—k** with benzyloxyl groups on the B ring were reduced to 1 h. The reaction mixture was poured into 2% hydrochloric acid

Table 4. 3,5,8-Trimethoxy-7-tosyloxyflavones (**9**) and 5,7- and 3,7-Ditosyloxyflavones (**5a** and **6a**)

(50—60 cm^3), heated at 70—80 °C for 15—30 min, and diluted with water. After the solvent was evaporated under reduced pressure, the separated yellow crystals were collected, washed with water, and dried to give a mixture of **10** and **11**.

The mixture was refluxed with *p*-toluenesulfonyl chloride (285 mg; 1.5 mmol) and anhydrous potassium carbonate (2 g; 11 mmol) in acetone (40—50 cm^3) with stirring until the hydroxyflavones disappeared (3—6 h). The mixture was poured into diluted hydrochloric acid and the solvent was evaporated under reduced pressure. The separated precipitate was collected, washed with water and dried to give a mixture of **5** and **6**.

However, the precipitate obtained from the flavone **1h—k** with benzyloxyl groups on the B ring was extracted with ethyl acetate, and the extract was washed with water and then concentrated to give a mixture of **5** and **6**. The mixture was contaminated with a small amount of *p*-toluenesulfonyl chloride; however, the following demethylation was not affected by the chloride.

The mixture of **5** and **6** was demethylated with 5% w/v anhydrous aluminum bromide in acetonitrile under the same conditions as described in the demethylation of **9**. The demethylated product was extracted with ethyl acetate, and the extract was washed with water and then concentrated to give a mixture of **7** and **8**. To the mixture, methanol (40—50 cm^3) and anhydrous potassium carbonate (3—4 g; 21—28 mmol) were added. The mixture was refluxed with stirring under nitrogen atmosphere for 2—3 h, and then poured into diluted hydrochloric acid. The methanol was evaporated under reduced pressure and the separated yellow crystals were collected to give a crude product **1**. All products except for **12** and **13** were purified by recrystallization to give **1** as yellow needles. The flavone **13** was obtained from the mother liquor of **1k** by silica-gel chromatography with chloroform.

Only the mixture of **7m** and **8m** was hydrolyzed for 10 h under conditions similar to that described above, and the products were separated by the preparative HPLC, using a column (20×600 mm) packed with Hitachi gel #3019 and methanol as an eluent, to give **1g** and **12**. The results are shown in Table 5.

3,5-Dihydroxyflavones (**1a**, **1b**, and **1c**) were also synthesized from the corresponding 7-hydroxyflavones **2a**, **2b**, and **2c** by a method similar to that described above.

3,5,7-Trihydroxy-8-methoxyflavones (1d—g) with Hydroxyl Groups on the B Ring. The benzyloxyflavones **1h—k** (200 mg) were hydrogenated over palladium on charcoal (10%; 100 mg) in ethyl acetate-methanol (1/2 volume ratio; 300 cm^3) until the uptake of hydrogen ceased. After the catalyst was filtered off, the filtrate was evaporated and the residue was recrystallized to give **1** as yellow needles (Table 5).

Acetates (14a—g) of 1. The flavone **1** (40 mg) was dissolved in acetic anhydride (0.4 cm^3)-pyridine (0.04 cm^3), and allowed to stand at room temperature for 1 day and then treated with water to give **14** as colorless needles. The results are shown in Table 6.

Reaction of Benzeneseleninyl Chloride with Olefins in the Presence of a Lewis Acid. A Novel One Step Vinylic Chlorination

Nobumasa KAMIGATA,* Takeshi SATOH, and Masato YOSHIDA
Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Fukazawa, Setagaya-ku, Tokyo 158
(Received July 9, 1987)

In the presence of aluminum chloride benzeneseleninyl chloride was found to be an excellent vinylic chlorinating reagent of olefins under mild conditions. However, such olefins as styrene, *trans*-stilbene, and *trans*-1-phenylpropene afforded dichloro adducts under similar conditions. A plausible reaction mechanism involving positive chlorine intermediate is proposed.

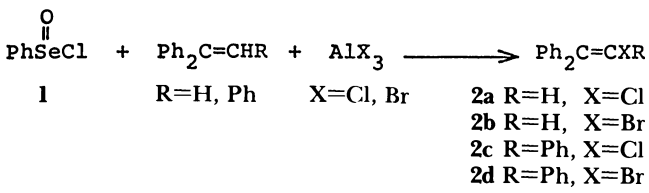
In recent years organic selenium reagents have become a very powerful tool in organic synthesis.[1] Of particular importance is the following discovery: a) Epoxides are converted into olefins by treatment with triphenylphosphine selenide in the presence of an acid,[2] b) selenoxides prepared by oxidation of selenides undergo clean syn elimination of selenenic acid to form olefins at or below room temperature,[3] c) epoxides are converted into allylic alcohols by ring opening with benzeneselenolate ion followed by selenoxide fragmentation and the intermediate β-hydroxy alkyl selenides are transformed into olefin,[4] d) selenium metal catalyze the reaction of amines and alcohols with carbon monoxide to give ureas and carbonates, respectively,[5] e) olefins are converted into ally alcohols by treatment with selenium dioxide,[6] and f) semicarbazones are transformed into 1,2,3-selenadiazoles by treatment with selenium dioxide which collapse at high temperatures to produce acetylenes.[7]

Benzeneseleninyl chloride (**1**) was first prepared by Ayrey et al. by the reaction of benzeneselenenyl chloride with ozone and is known to be highly hygroscopic and hydrolyzed to benzeneseleninic acid.[8] So far, little effort has been made to employ compound **1** as a synthetic tool; however, a few papers were found (reported by Czarny and Sosnovsky) in which aminodiphenylmethane and benzylamine were oxidized by **1** to give benzophenone and benzyl cyanide, respectively.[9,11] We found that a reaction of compound **1** with olefins in the presence of a Lewis acid gives chloro-substituted olefins at olefinic carbon. The results are described in this paper, and the mechanism is discussed.

Results and Discussion

The reaction of benzeneseleninyl chloride (**1**) with 1,1-diphenylethylene was carried out in dichloromethane in the presence of a Lewis acid at room temperature. When aluminum chloride was employed as a catalyst, the reaction occurred very smoothly and after stirring for 2 h at room temperature, 2-chloro-1,1-diphenylethylene (**2a**) was formed in 94% yield. However, such Lewis acids as iron(III) chloride and zinc chloride afforded the chlorinated compounds **2a** under similar conditions in 68 and 26% yield, respectively. The reaction proceeded very slowly when the reaction was carried out in the absence of a Lewis acid, and 2-chloro-1,1-diphenylethylene was obtained in 60% yield after 142 h at 40 °C.

When aluminum bromide was used as the catalyst instead of aluminum chloride in the reaction of **1** with 1,1-diphenylethylene, 2-bromo-1,1-diphenylethylene (**2b**) was obtained in 84% yield after stirring at room temperature for 1 h. The reaction of **1** with triphenylethylene in the presence of aluminum chloride and aluminum bromide under similar conditions afforded chlorotriphenylethylene (**2c**) and bromotriphenylethylene (**2d**) in quantitative yield, respectively. The results are summarized in Table 1.



The present reaction seems to be an excellent halogenating method since a direct vinylic halogenation of olefins is hitherto unknown. A possible reaction mechanism shown in Scheme 1 accounts for these novel one-step vinylic chlorinations of olefins with **1**.

The aluminum catalyst abstracts chloride ion from benzeneseleninyl chloride to give benzeneseleninyl cation species **3** and aluminum tetrachloride anion species, as is known for the acylium ion intermediate in the Friedel-Crafts acylation of acyl chloride with aluminum chloride. The electrophilic addition of **3** to olefin affords cyclic selenoxonium ion intermediate **4a**, which is attacked by a chloride ion to give a ring-

Table 1. Reaction of Benzeneseleninyl Chloride with Vinyl-Substituted Arenes at Room Temperature

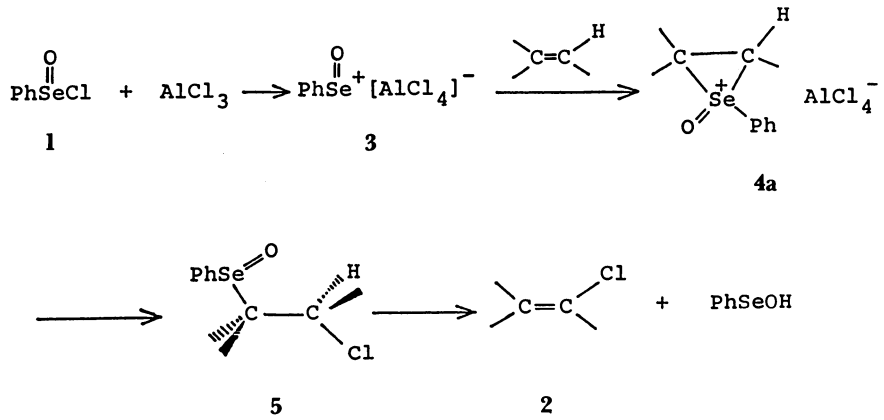
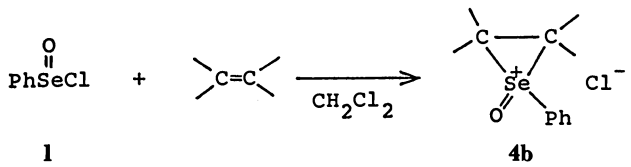
a) The reaction was carried out at 40 °C.

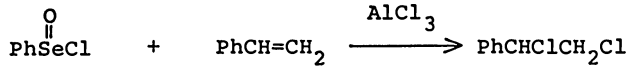


Scheme 1.

opening adduct **5**. The following syn-elimination of benzeneselenenic acid from **5** gives the final vinylic chlorination product **2**. The syn-elimination of benzeneseleninyl group with β-hydrogen is well-known and this method has been given much attention for the synthesis of olefins.[3] The reason why the reaction of **1** with 1,1-diphenylethylene in the absence of aluminum chloride is slow can be best accounted for by the fact that direct electrophilic reaction of **1** to the olefin forming cyclic selenoxonium intermediate **4b** is slow: meanwhile, the benzeneseleninyl cation species **3** reacts with olefin very smoothly.



The reaction of **1** with phenyl-substituted ethylenes such as styrene, *trans*-stilbene, and *trans*-1-phenylpropene was carried out in the presence of aluminum chloride. In the reaction of **1** with styrene, styrene dichloride was isolated in 48% yield, and no formation of chloro-substituted styrene obtainable from substitution at olefinic hydrogen was observed.



In the reaction of **1** with stilbene, *dl*- and *meso*-1,2-dichloro-1,2-diphenylethane **6a**, **6b** were isolated in 21 and 31% yield, respectively.

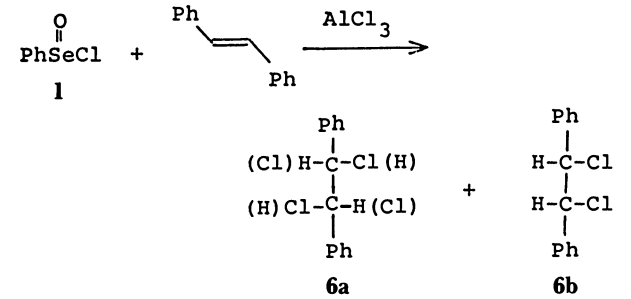


Table 2. α-Chlorination of α,β-Unsaturated Carbonyl Compounds **7** with Benzeneseleninyl Chloride Catalyzed by $AlCl_3$ at 40 °C

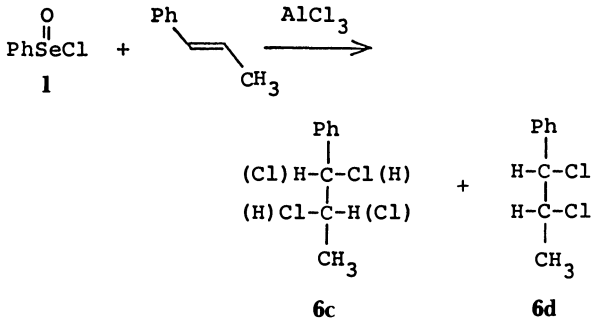
	Compound **7**			Reaction time/h	Product	Yield/%
	R_1	R_2	R_3			
7a	Me	H	H	2	**8a**	77
7b	Ph	H	H	55	**8b**	61
7c	Ph	Ph	H	71	**8c**	45
7d	Ph	H	Me	18	**8d**	50
7e	Ph	H	Ph	78	**8e**	30
7f	H	H	OEt	26	**8f**	70
7g	H	H	OBu^n	22	**8g**	46
7h	Me	H	OMe	23	**8h**	96
7i	Me	H	OEt	23	**8i**	88
7j	Ph	H	OMe	30	**8j**[a]	11
7k	Ph	H	OEt	26	**8k**[b]	17

a) The mixture of *threo*- and *erythro*-methy 2,3-dichloro-3-phenyl propionate was isolated in 33% yield together with **8j**. b) The mixture of *threo*- and *erythro*-ethyl 2,3-dichloro-3-phenyl propionate was isolated in 48% yield together with **8k**.

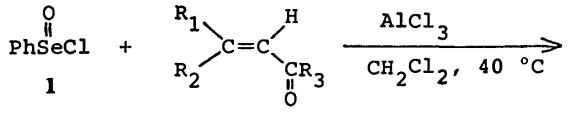
Similarly, in the reaction of *trans*-1-phenylpropene, *threo*- and *erythro*-1,2-dichloro-1-phenylpropane **6c**, **d** were obtained in 38 and 23% yield, respectively.

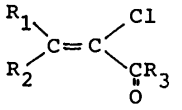


Against our expectations, the reaction of **1** with these phenyl-substituted ethylenes did not afford chloro-substituted arenes but formed dichloro adducts. It is difficult to explain these addition products by a reaction mechanism involving the cyclic selenoxonium ion intermediate shown in Scheme 1.

The reaction of **1** with α,β-unsaturated carbonyl

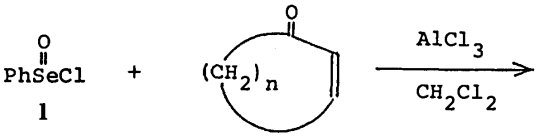
compounds in the presence of aluminum chloride was carried out at 40 °C. The chloro-substituted products at α-hydrogen were obtained in moderate to high yield. The structure of the products was determined by IR, ^{1}H NMR, ^{13}C NMR, and mass spectra (see experimental section). The results are summarized in Table 2.



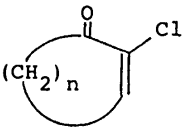


In the case of the reaction of **1** with methyl and ethyl cinnamate, dichloro adducts *threo*- and *erythro*-2,3-dichloro-3-phenylpropionic acid methyl ester (33%) and *threo*- and *erythro*-2,3-dichloro-3-phenylpropionic acid ethyl ester (48%) were formed together with chloro-substituted products **8j** and **8k**, respectively. The results mean that the addition and substitution occurr competitively.

The reaction of **1** with 2-cyclopenten-1-one (**9a**) in the presence of aluminum chloride at room temperature afforded 2-chloro-2-cyclopenten-1-one (**10a**) in 47% yield. Similarly, 2-cyclohexen-1-one (**9b**) and 2-cycloheptenone-1-one (**9c**) were chlorinated by **1** in the presence of aluminum chloride to give corresponding 2-chlorocycloalkenones **10b** and **10c** in moderate to good yield. 1,4-Benzoquinone was also chlorinated by **1** under similar conditions to give 2-chloro-1,4-benzoquinone (**10d**) in 44% yield. However, no chloro-



9a n=2
9b n=3
9c n=4



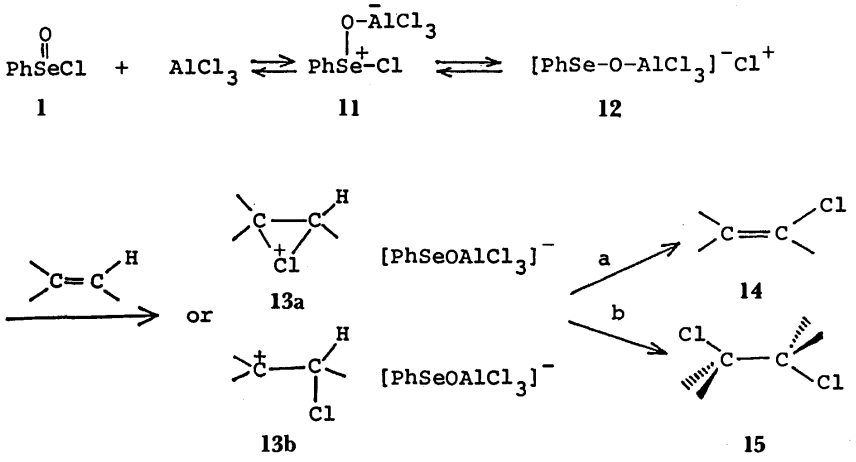
substituted product was obtained in the reaction of **1** with 1,4-naphthoquinone catalyzed by aluminum chloride under various reaction conditions. The results are summarized in Table 3.

Table 3. α-Chlorination of Cyclic α,β-Unsaturated Ketones

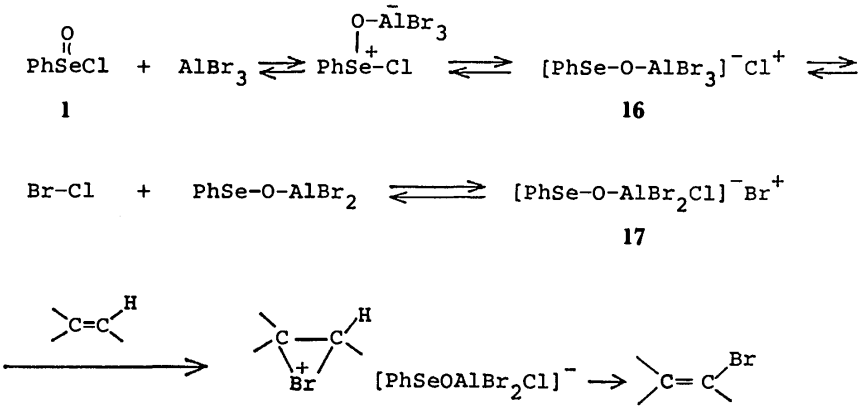
Ketone	Reaction temp/°C	Reaction time/h	Product	Yield/%
9a	Room temp	48	**10a**	47
9b	0	9	**10b**	41
9c	0	7	**10c**	56
1,4-Benzoquinone	40	22	**10d**	44

The results in the Tables 1, 2, and 3 show that the reaction of benzeneseleninyl chloride (**1**) with olefins catalyzed by aluminum chloride provides chloro-substituted compounds at vinyl position in one step in good yield; therefore, **1** can be regarded as an excellent vinylic chlorinating reagent and a new synthetic tool for chlorination.

The reaction mechanism shown in Scheme 1 can explain the vinylic chlorination products but can not



Scheme 2.



Scheme 3.

easily explain the dichloro-addition products observed in the reaction of **1** with such olefins as styrene, *trans*-1-phenylpropene, and *trans*-stilbene. An alternative mechanism shown in Scheme 2 interprets both the chloro-substituted products at the vinyl position and the dichloro-adducts from the common reactive intermediate.

Aluminum chloride does not abstract the chloride ion but reacts with the oxygen atom of the benzeneseleninyl chloride to form the intermediate **11** which easily converts to chloronium trichloro(phenylselenooxy)aluminate (**12**). The following electrophilic reaction of the chloronium ion with olefin gives either a chloronium ion **13a** or a carbocation intermediate **13b**. If the chloride ion of the trichloro(phenylselenooxy)aluminate species attacks the hydrogen atom of intermediate **13** (path a), chloro-substituted vinyl products **14** are obtained. On the other hand, when a chloride ion of the trichloro(phenylselenooxy)aluminate species attacks the carbon atom of intermediate **13a** or the carbocation intermediate **13b** (path b), dichloro adducts are obtained. The reaction of path a will occur in the following cases: a) the substituents of the olefin are a bulky group, b) the β-hydrogen of the cation intermediate **13a** or **13b** is relatively acidic. Case a) was observed in such olefins as 1,1-diphenylethylene and triphenylethylene, and case b) was observed in α,β-unsaturated carbonyl compounds. Such olefins as styrene, *trans*-1-phenylpropene, and *trans*-stilbene formed dichloro adducts since these olefins do not conform to these two cases.

When aluminum bromide was employed instead of aluminum chloride in the reaction of **1** with 1,1-diphenylethylene, 2-bromo-1,1-diphenylethylene was obtained in 84% yield, and no formation of 2-chloro-1,1-diphenylethylene was observed. This means that chloronium tribromo(phenylselenooxy)aluminate (**16**), formed by the reaction of **1** with aluminum bromide, transforms rapidly to bromonium dibromochloro-(phenylselenooxy)aluminate(**17**). The following electrophilic reaction of the bromonium ion with olefin gives the bromo-substituted products as shown in Scheme 3.

To justify the mechanism shown in Scheme 2, ^{77}Se NMR studies were carried out. The ^{77}Se NMR signal of benzeneseleninyl chloride in dichloromethane appeared at 850 ppm, shifted to 670 ppm when equimolar ammounts of aluminum chloride were added to a solution of **1** in dichloromethane (diphenyl diselenide was employed as the internal standard). The results suggest that the $PhSe^{+}[AlCl_4]^{-}$ species (**3**) is not formed by the addition of aluminum chloride to **1** (as shown in Scheme 1), since one can expect a down-field shift more than 850 ppm about such a benzeneseleninyl cation species **3** from diphenyl diselenide. Thus, we believe that the observation of the 180 ppm up-field shift can be attributed to the formation of chloronium trichloro(phenylselenooxy)aluminate intermediate (**12**).

Experimental

Measurement. Melting points and boiling points were uncorrected. The infrared absorption spectra were determined on a Hitachi Model 260-10 spectrometer with samples as either neat liquid or KBr disks. The proton magnetic resonance spectra were recorded at 60 MHz by using a JEOL JNM-PMX 60 SI spectrometer with Me_4Si as an internal standard in $CDCl_3$. The ^{13}C and ^{77}Se NMR spectra were recorded by using a JEOL JNM-FX 90Q spectrometer with Me_4Si and PhSeSePh as an internal standard, respectively. Gas chromatography was performed by using a Hitachi 163 and 263-30 gas chromatograph using SE 30 (10%), 1 m column. The gel-permeation chromatography was performed by using a JAI Model LC-08 liquid chromatograph with a JAIGEL-1H column (20×600 mm×2) using chloroform as an eluent. Mass spectra were determined with a JEOL JMX-DX 300 mass spectrometer with a JEOL JMA 5000 Mass Data System at an ionizing voltage of 20—70 eV.

Materials. Benzeneselenenyl chloride of Nakarai Chemicals was distilled prior to use; bp 82 °C/3 mmHg† (120 °C/20 mmHg).[10] Benzeneseleninyl chloride (**1**) was prepared by ozonization of benzeneselenenyl chloride with stirring in dry dichloromethane at −70 °C until the orange-red color faded

† 1 mmHg=133.322 Pa.

to a light yellow[8,11] by introducing ozone prepared by a Nippon Ozone Model 0-3-2 ozonizer. The prepared benzeneseleninyl chloride was used in reactions with olefins in situ since the compound is extremely hygroscopic and care must be taken to avoid moisture.

General Procedure for the Reaction of Benzeneseleninyl Chloride with Olefins. To a stirred solution containing 2.0 mmol of benzeneseleninyl chloride (**1**) in 20 cm^3 of dichloromethane under nitrogen bubbling in an ice bath was added 2 mmol of an olefin and 2 mmol of a Lewis acid. The mixture was stirred for an adequate time (until **1** has almost consumed by TLC analysis) at 0 °C or room temperature. Water (30 cm^3) was added to the reaction mixture, and the organic layer was separated and dried over anhydrous magnesium sulfate. The reaction products were isolated by gel-permeation chromatograph, and the structure was identified on the basis of their spectroscopic data.

2-Chloro-1,1-diphenylethylene (2a): Bp 118 °C/0.5 mmHg (298 °C);[12] IR (neat) 3070, 1600, 1500, 1445, 830, 755, and 695 cm^{-1}; ^1H NMR ($CDCl_3$) δ=6.57 (1H, s), 7.21 (5H, s), and 7.33 (5H, s); MS m/z 214 (^{35}Cl, M^+).

2-Bromo-1,1-diphenylethylene (2b): Bp 125—126 °C/1 mmHg (175—176 °C/11.5 mmHg);[13] IR (neat) 3065, 1590, 1500, 1445, 1220, 1075, 765, 740, and 695 cm^{-1}; ^1H NMR ($CDCl_3$) δ=6.70 (1H, s), 7.18 (5H, s), and 7.30 (5H, s); MS, m/z 258 (^{79}Br, M^+).

Chlorotriphenylethylene (2c): Mp 116—117 °C (117 °C);[14] IR (KBr) 3060, 1600, 1495, 1445, 750, and 695 cm^{-1}; ^1H NMR ($CDCl_3$) δ=6.81—7.47 (15H, m); MS m/z 290 (^{35}Cl, M^+).

1,2-Dichloro-1-phenylethane:[15] IR (neat) 3000, 1485, 1445, 1195, 1075, 940, 920, and 695 cm^{-1}; ^1H NMR ($CDCl_3$) δ=3.89 (2H, d, J=7.6 Hz), 4.95 (1H, t, J=7.6 Hz), and 7.29 (5H, s); MS m/z 174 (^{35}Cl, M^+).

***dl*-1,2-Dichloro-1,2-diphenylethane (6a):** Mp 93 °C (93 °C);[16] IR (KBr) 3070, 1490, 1450, 1230, 1205, 1070, 775, 745, and 700 cm^{-1}; ^1H NMR ($CDCl_3$) δ=5.18 (2H, s) and 7.09—7.28 (10H, m); MS m/z 250 (^{35}Cl, M^+).

***meso*-1,2-Dichloro-1,2-diphenylethane (6b):** Mp 190 °C (191 °C);[16] IR (KBr) 3010, 1490, 1440, 1225, 1175, 1065, 805, 760, and 685 cm^{-1}; ^1H NMR ($CDCl_3$) δ=5.17 (2H, s) and 7.36 (10H, s); MS m/z 250 (M^+).

2-Chloro-2-butenal (8a): Bp 147—148 °C (147—150 °C);[17] IR (neat) 1695 and 1175 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.06 (3H, d, J=6.6 Hz), 6.93 (1H, q, J=6.6 Hz), and 9.27 (1H, s); MS m/z 104 (^{35}Cl, M^+).

2-Chloro-3-phenylpropenal (8b): Bp 90—91 °C/1 mmHg (132—134 °C/8 mmHg);[17] IR (neat) 1685 and 1295 cm^{-1}; ^1H NMR ($CDCl_3$) δ=7.36—8.09 (6H, m) and 9.41 (1H, s); MS m/z 166 (^{35}Cl, M^+).

2-Chloro-3,3-diphenylpropenal (8c): Mp 117—119 °C; IR (KBr) 1685 and 1150 cm^{-1}. ^1H NMR ($CDCl_3$) δ=7.01—7.30 (10H, m) and 9.34 (1H, s); MS m/z 242 (^{35}Cl, M^+); Found: m/z 242.0492. Calcd for $C_{15}H_{11}OCl$: M, 242.0498.

3-Chloro-4-phenyl-3-buten-2-one (8d): IR (neat) 1695 and 1210 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.52 (3H, s) and 7.23—7.92 (6H, m); MS m/z 180 (^{35}Cl, M^+); Found: m/z 180.0346. Calcd for $C_{10}H_9OCl$: M, 180.0342.

2-Chloro-1,3-diphenyl-2-propen-1-one (8e): IR (neat) 1660 and 1250 cm^{-1}; ^1H NMR ($CDCl_3$) δ=7.27—7.91 (11H, m); ^{13}C NMR ($CDCl_3$) δ=128.39, 128.56, 129.48, 129.86, 130.34, 130.56, 132.46, 132.94, 136.84, 139.34, and 191.07; MS m/z 242 (^{35}Cl, M^+); Found: m/z 242.0497. Calcd for $C_{15}H_{11}OCl$: M, 242.0498.

Ethyl 2-Chloropropenoate (8f): IR (neat) 1745 and 1275 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.33 (3H, t, J=7.2 Hz), 4.28 (2H, q, J=7.2 Hz), 5.92 (1H, d, J=2.0 Hz), and 6.45 (1H, t, J=2.0 Hz); MS m/z 134 (^{35}Cl, M^+); Found: m/z 134.0139. Calcd for $C_5H_7O_2Cl$: M, 134.0134.

Butyl 2-Chloropropenoate (8g): IR (neat) 1745 and 1280 cm^{-1}. ^1H NMR ($CDCl_3$) δ=0.80—2.00 (7H, m), 4.20 (2H, t, J=7.2 Hz), 5.94 (1H, d, J=2.0 Hz), and 6.44 (1H, d, J=2.0 Hz); MS m/z 162 (^{35}Cl, M^+); Found: m/z 162.0452. Calcd for $C_7H_{11}O_2Cl$: M, 162.0447.

Methyl 2-Chloro-2-butenoate (8h): Bp 160—161 °C (161 °C);[18] IR (neat) 1745 and 1275 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.94 (3H, d, J=7.0 Hz), 3.78 (3H, s), and 7.10 (1H, q, J=7.0 Hz); MS m/z 134 (^{35}Cl, M^+).

Ethyl 2-Chloro-2-butenoate (8i): Bp 175—176 °C (176 °C);[18] IR (neat) 1725 and 1265 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.33 (3H, t, J=7.2 Hz), 1.94 (3H, d, J=7.2 Hz), 4.24 (2H, q, J=7.8 Hz), and 7.07 (1H, q, J=7.2 Hz); ^{13}C NMR ($CDCl_3$) δ=14.09, 14.91, 61.98, 125.96, 137.07, and 162.36; MS m/z 148 (^{35}Cl, M^+).

Methyl 2-Chloro-3-phenylpropenoate (8j): Mp 32—33 °C (33.0—33.5 °C);[19] IR (neat) 1730 and 1270 cm^{-1}; ^1H NMR ($CDCl_3$) δ=3.90 (3H, s) and 7.19—7.62 (6H, m); ^{13}C NMR ($CDCl_3$) δ=53.37, 121.84, 128.56, 130.24, 130.67, 132.95, 137.23, and 163.94; MS m/z 196 (^{35}Cl, M^+).

Ethyl 2-Chloro-3-phenylpropenoate (8k): Bp 104—105 °C/1 mmHg (209 °C/75 mmHg);[20] IR (neat) 1735 and 1265 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.36 (3H, t, J=7.4 Hz), 4.32 (2H, q, J=7.4 Hz), and 7.17—8.16 (6H, m); ^{13}C NMR ($CDCl_3$) δ=14.26, 62.58, 122.28, 128.51, 130.13, 130.62, 133.00, 136.90, and 163.39; MS m/z 210 (^{35}Cl, M^+).

Methyl *threo*-2,3-Dichloro-3-phenylpropionate:[21] ^1H NMR ($CDCl_3$) δ=3.57 (3H, s), 4.61 (1H, d, J=8.4 Hz), 5.42 (1H, d, J=8.4 Hz), and 7.33 (5H, s); MS m/z 232 (^{35}Cl, M^+).

Methyl *erythro*-2,3-Dichloro-3-phenylpropionate:[21] IR (KBr) 1750 and 1210 cm^{-1}; ^1H NMR ($CDCl_3$) δ=3.84 (3H, s), 4.54 (1H, d, J=10.8 Hz), 5.13 (1H, d, J=10.8 Hz), and 7.33 (5H, s); MS m/z 232 (^{35}Cl, M^+).

Ethyl *threo*-2,3-Dichloro-3-phenylpropionate:[21] ^1H NMR ($CDCl_3$) δ=1.06 (3H, t, J=7.4 Hz), 4.02 (2H, q, J=7.4 Hz), 4.63 (1H, d, J=8.6 Hz), 5.27 (1H, d, J=8.6 Hz), and 7.35 (5H, s); MS, m/z 246 (^{35}Cl, M^+).

Ethyl *erythro*-2,3-Dichloro-3-phenylpropionate:[21] IR (neat) 1750 and 1275 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.32 (3H, t, J=7.4 Hz), 4.28 (2H, q, J=7.4 Hz), 4.56 (1H, d, J=10.4 Hz), 5.17 (1H, d, J=10.4 Hz), and 7.31 (5H, s); MS m/z 246 (^{35}Cl, M^+).

2-Chloro-2-cyclopenten-1-one (10a): IR (neat) 1730 and 1300 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.35—2.86 (4H, m) and 7.51 (1H, t, J=2.8 Hz); MS, m/z 116 (^{35}Cl, M^+); Found: m/z 116.0032. Calcd for C_5H_5OCl: M, 116.0029.

2-Chloro-2-cyclohexen-2-one (10b): Mp 70—72 °C (70 °C);[22] IR (KBr) 1680 and 1320 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.78—2.75 (6H, m) and 7.07 (1H, t, J=4.8 Hz); MS, m/z 130 (^{35}Cl, M^+); Found: m/z 130.0192. Calcd for C_6H_7OCl: M, 130.0185.

2-Chloro-2-cyclohepten-1-one (10c): IR (neat) 1690 and 1350 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.34—2.91 (8H, m) and 6.95 (1H, t, J=6.8 Hz); MS m/z 144 (^{35}Cl, M^+); Found: m/z 144.0338. Calcd for C_7H_9OCl: M, 144.0342.

2-Chloro-1,4-benzoquinone (10d): Mp 55—56 °C (57 °C);[23] IR (KBr) 1655 and 1285 cm^{-1}; ^1H NMR ($CDCl_3$) δ=6.79 (2H, s) and 6.95 (1H, s); MS m/z 142 (^{35}Cl, M^+).

^{77}Se NMR Studies. A solution containing 1.92 g (10 mmol) of benzeneselenenyl chloride in 20 cm^3 of dry dichloromethane was ozonized at −50 °C. A part of the solution containing benzeneseleninyl chloride (**1**) was transferred to a NMR tube, and the ^{77}Se NMR spectrum was determined. The ^{77}Se NMR signal was observed at 850 ppm from diphenyl diselenide as the internal standard. Then, to a solution of benzeneseleninyl chloride prepared by the same manner described above was added 1.33 g (10 mmol) of aluminum chloride, and the mixture was stirred for 10 min at −50 °C. A part of the solution was transferred to a NMR tube, and the ^{77}Se NMR was determined. The ^{77}Se NMR signal was observed at 670 ppm from diphenyl diselenide as the internal standard.

2-(Trifluoromethylsulfonyloxy)pyridine as a Reagent for the Ketone Synthesis from Carboxylic Acids and Aromatic Hydrocarbons

Takashi KEUMI,* Kiichiro YOSHIMURA, Masakazu SHIMADA, and Hidehiko KITAJIMA
Department of Applied Chemistry, Faculty of Engineering, Fukui University, Bunkyo, Fukui 910
(Received July 11, 1987)

A new reagent 2-(trifluoromethylsulfonyloxy)pyridine (**TFOP**) was prepared by the reaction of sodium salt of 2-pyridinol with trifluoromethylsulfonyl chloride in dioxane. The compound **TFOP** in trifluoroacetic acid has been found to intermolecularly dehydrate from benzoic acid and aromatic hydrocarbons to give the corresponding benzophenones in high yield. It was further elucidated, in the reaction of fluorene, that a variety of carboxylic acids can be used as the acyl precursor for the aromatic ketone synthesis in conjunction with the **TFOP/TFA** system. This acylation procedure has been applied to the synthesis of 2-acylthiophenes, which are hard to prepare in a satisfactory yield by the classical Friedel-Crafts reaction using aluminum chloride as the catalyst.

Acylation is one of the most important reaction in organic synthesis. Although various procedures for the acylation of hetero atoms of amines or alcohols, and for that of aliphatic carbons are available, only a few routes of acylation of aromatic carbons are known.[1] Among them, the Friedel-Crafts reaction using aluminum chloride as a catalyst is the most useful means.[2] However, we have encountered some inconveniences in the use of aluminum chloride as the catalyst. The acylation generally requires molar amounts of a catalyst which is a hygroscopic solid and forms complexes with the products. A consequent work-up is needed to decompose these complexes, and the catalyst is usually non-recoverable. A large amount of hydrochloric acid evolves during the reaction and during the hydrolysis of the complexes. In addition, the catalyst sometimes induces undesirable side reactions. For example, an acylation of thiophene with acid chloride and aluminum chloride is accompanied by a polymerization of the substrate.[3]

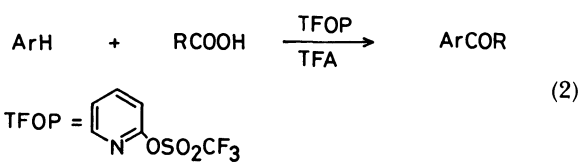
Recently, some procedures capable of acylating aromatic hydrocarbons without the use of the classical catalyst have been developed.[4-13] Above all the report by Effenberger that a carboxylic trifluoromethylsulfonic anhydride (I) has an ability to acylate aromatic hydrocarbons is very interesting.[4]

We have previously reported that an acyl group of 2-acyloxypyridines undergoes transacylation catalyzed by trifluoroacetic acid (**TFA**) to aromatic hydrocarbons existing in the solution to give aromatic ketones (Eq. 1).[8]

(1)

Analogously, the "transsulfonylation" could be expected to occur from 2-(trifluoromethylsulfonyloxy)pyridine (**TFOP**) to carboxylic acid in a **TFA** solution to give the mixed anhydride **I**, which is a good acylating agent of aromatic hydrocarbons.

In the present paper, we will report on the synthesis of **TFOP** and its application to a condensation reaction between carboxylic acids and aromatic hydrocarbons to give aromatic ketones.[14]

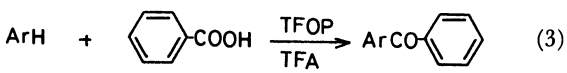


(2)

Results and Discussion

A new reagent, **TFOP**, was prepared by a reaction of the sodium salt of 2-pyridinol with trifluoromethylsulfonyl chloride in dioxane. The compound is a relatively stable and colorless liquid. Its physical data are shown in the experimental section.

The utility of **TFOP** as a dehydrating reagent between carboxylic acid and aromatic hydrocarbon to give aromatic ketones was investigated. First, a reaction involving some kinds of aromatic hydrocarbons with benzoic acid in the presence of **TFOP** has been carried out in **TFA** solution (Eq. 3). For example, durene was heated with benzoic acid and **TFOP** in a molar ratio of 1 : 1.1 : 1.1, respectively, in **TFA** under reflux for 5 h to give 2,3,5,6-tetramethylbenzophenone in a quantitative yield. In a similar procedure, reactions of some other aromatic hydrocarbons with benzoic acid were carried out. The results are summarized in Table 1. Dimethoxybenzenes, tri- and tetramethylbenzenes, anisoles, dibenzofuran, and diphenyl ether reacted with benzoic acid in the presence of **TFOP** in **TFA** to give the corresponding benzophenone derivatives in satisfactory yields. Alternatively, benzene, biphenyl, and *p*-xylene were not benzoylated by this method.



(3)

The validity of the **TFOP/TFA** system as a reagent leading carboxylic acids and aromatic hydrocarbons to

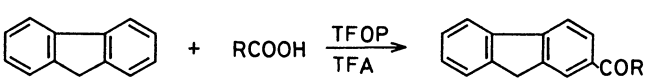
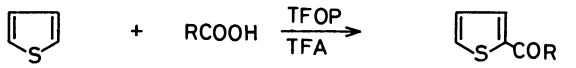
a) All the reactions were carried out under reflux of a solution of fluorene (6 mmol), carboxylic acid (7 mmol), and TFOP (7 mmol) in TFA (5 mL) for 5 h. b) The products were identified by the mixed melting point test with authentic samples previously reported in Ref. 9. c) Heterogeneous reaction due to the low solubility of *p*-nitrobenzoic acid in boiling TFA.

ketones was further investigated in a reaction of fluorene with a variety of carboxylic acids (Eq. 4). Reactions were also carried out in a manner similar to that described for the benzoylation of durene. The results are summarized in Table 2. Except for *p*-nitrobenzoic acid, aliphatic and aromatic carboxylic acids gave the corresponding 2-acylfluorenes in good isolated yields. Particularly, aliphatic carboxylic acids and benzoic acids, having an electron-donating group, resulted in a high yield of 2-acylfluorenes.



(4)

The combination of carboxylic acid with the **TFOP/TFA** system was applied to the acylation of thiophene (Eq. 5). A mixture of thiophene, *p*-chlorobenzoic acid, and **TFOP** was heated in **TFA** under reflux for 4 h to yield 2-(*p*-chlorobenzoyl)-thiophene in a quantitative yield. Other acylthiophenes were also obtained by the reaction of thiophene with **TFOP** and carboxylic acids in satisfactory yields. The results are given in Table 3.



(5)

Thus, **TFOP** has been shown to serve as a condensation reagent between a variety of carboxylic acids and aromatic hydrocarbons to give aromatic ketones.

The classical catalyst aluminum chloride is not so suitable for an acylation of thiophene by Friedel-Crafts method since the catalyst partly induces a polymerization of thiophene. Although some improved procedures using less weak acids such as BF_3/MeOH complex,[24] $SnCl_4$,[3] 85% H_3PO_4,[21] or solid super acid Nafion-H,[12] and so on, have been used, the yields of acylthiophenes are still not very satisfactory. The

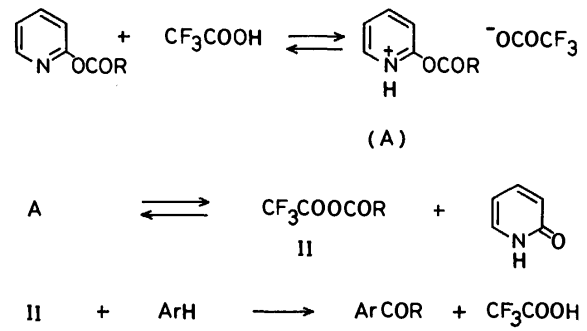
method described here directly gives the 2-acylthiophenes from carboxylic acid and thiophene in a quite high yield.

In light of the reaction mechanism, the effect of **TFA** on the ketone yields was investigated in the benzoylation of thiophene with benzoic acid and **TFOP** in a solvent. The results are shown in Table 4. As can be seen, the acylation reaction dose not occur without the addition of **TFA**. The reaction requires at least two equivalents of **TFA** to **TFOP** to result in a satisfactory yield of the ketone. An inert solvent with a relatively high boiling point, 1,2-dichloroethane, seems to be recommendable as a co-solvent for a ketone synthesis by the carboxylic acid/**TFOP**/**TFA** system.

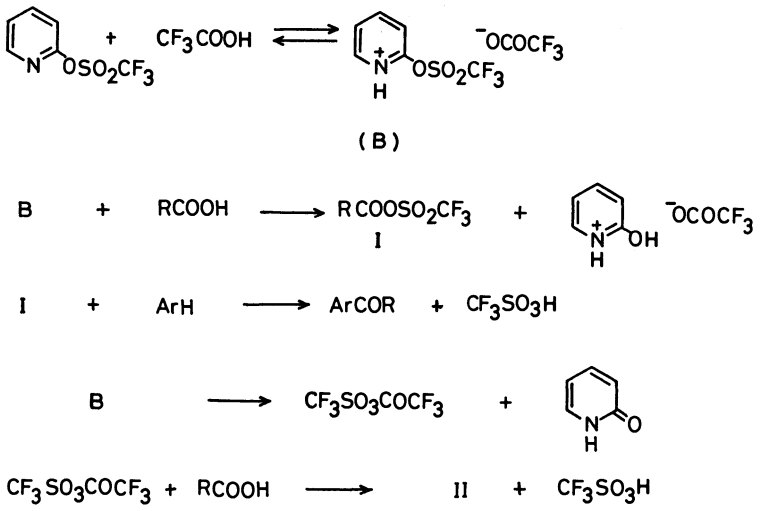
If the acylation reaction proceeds via a cationic acyl species which attacks an aromatic nucleus in the rate-determining step, as in a usual Friedel-Crafts reaction, the ketone yields should increase with an electron-withdrawing group in the acylating species.[25] On the contrary the yields of 2-acylfluorenes by the substituted benzoic acid/**TFOP**/**TFA** system have resulted in a decrease with an electron-withdrawing group in the benzoic acid (entries 5 and 10 in Table 2). Hence, a direct electrophilic attack on the aromatic nucleus by the cationic acyl carbon dose not seem to be involved in the rate-determining step.

We have previously reported that the 2-acyloxypyridine/**TFA** system acylates fluorene to give 2-acylfluorene, in which a mechanism proceeding via the formation of pyridinium salt **A** followed by acyl trifluoroacetate (**II**) playing a role as the real acylating entities was assumed (shown in Scheme 1).[8] The substituent effects on acylation of fluorene by the substituted benzoic acids/**TFOP**/**TFA** system is similar to the trend observed in the acylation by the 2-acyloxypyridine/**TFA** system.



Scheme 1.

Effenberger had reported that the mixed anhydride **I** prepared from carboxylic acid chloride and silver trifluoromethylsulfonate can acylate an aromatic hydrocarbon. Here also, it can be considered that these kinds of mixed anhydrides could be formed via the activated pyridinium salt **B** in the course of the reaction. Thus, the transsulfonylation of the salt **B** to carboxylic acid would take place to give the anhydride **I**, and/or the salt **B** would generate the very reactive trifluoroacetic trifluoromethylsulfonic anhydride which reacts with carboxylic acid to give the mixed anhydride **II**. Either **I** or **II**, or both of them, seem to work as an acylating agent of aromatic compounds, as shown in Scheme 2. The formation of mixed anhydrides **I** and **II** might be involved in the rate-controlling step regarding the reaction. A significant substituent effect in the substi-



Scheme 2.

tuted benzoic acids, however, has not been observed in the acylation of thiophene which is more reactive than fluorene. Consequently, a cleavage of the carbon-oxygen bond between the acyl group and trifluoromethylsulfonate or trifluoroacetate, respectively, in **I** or **II** would be involved in the transition state, so that the yield of 2-acylfluorenes would be lower in the reaction with the benzoic acids containing an electron-withdrawing group, since the bond in such anhydrides is difficult to break.

In conclusion, we have now established that **TFOP** is useful as a reagent for a condensation between carboxylic acid and aromatic hydrocarbon to give aromatic ketones. Our method seems to have the following superior points. The ketones can be directly obtained by a reaction of aromatic compound with an equivalent mole of carboxylic acid in quite high yield. This system can acylate thiophene to give 2-acylthiophenes free from contamination by polymerization products. Trifluoroacetic acid is now popular and it has a moderate boiling point to make it easy to recover from the reaction mixture by distillation. If necessary, we can use 1,2-dichloroethane as the co-solvent to reduce a quantity of **TFA**. The reaction products can be easily separated by washing the mixture with water after distilling off **TFA**. Trifluoromethylsulfonic acid dissolved in the washing aqueous solution can be recoverd quantitatively as the barium salt.

Experimental

Materials and Measurements. All the acylated products were identified by comparing their physical data with those of authentic samples synthesized by classical Friedel-Crafts reactions, or by IR, ^{1}H NMR, and elemental analysis. Melting points are uncorrected. The IR spectra were recorded on a Hitachi EPI-S2 model infrared spectrophotometer. ^{1}H NMR spectra were recorded on a JEOL-FX 270 FT-NMR spectrometer in chloroform-*d* solution with tetramethylsilane internal standard. GLC analysis was carried out on a Hitachi GC Model 163 gas chromatograph equipped with a hydrogen flame ionization detector and a stainless steel column (length 3 m, i.d. 3 mm) packed with 3% Dexil 300 GC on Chromosorb W.

Preparation of TFOP. To a solution of 2-hydroxypyridine (14.07 g, 0.148 mol) in dry dioxane (100 mL), a suspension of sodium hydride (3.55 g, 0.148 mol) in dioxane (20 mL) was added with stirring at 40 °C over 15 min. Then, a solution of trifluoromethylsulfonyl chloride (25.0 g, 0.148 mol) in dry tetrahydrofuran (20 mL) was added slowly to the mixture with stirring over 1 h. After stirring at room temperature for 2 h, the reaction mixture was filtered, and the solvent of filtrate was evaporated under reduced pressure. The residue was distilled under reduced pressure to give **TFOP** (22 g, 65% yield); bp 108 °C/25 mmHg,† 105 °C/22 mmHg, 95 °C/19 mmHg; IR (neat) 1600, 1430, 1260, 1175, and 890 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=8.41 (dd, 1H, J=0.5 and 2 Hz), 7.92 (dt, 1H, J=0.72 and 3Hz), 7.38—7.43 (m, 1H), and 7.24 (d, 1H, J=7 Hz); MS *m/z* (rel intensity, %) 227 (M^+, 70), 163 (10), 135 (100), and 113 (20). Found: C, 31.65; H, 2.00; N, 6.18%. Calcd for $C_6H_4NO_3SF_3$: C, 31.72; H, 1.77; N, 5.17%.

Benzoylation of Durene. To a mixture of benzoic acid (7 mmol) and **TFOP** (7 mmol) in **TFA** (5 mL), durene (6 mmol) was added. After the mixture was heated under reflux for 5 h, it was poured into ice-water, and the resulting precipitate was filtered and washed with water and a dilute alkali solution to give the crude product of 2,3,5,6-tetramethylbenzophenone (mp 119 °C, 99% yield). Recrystallization of the crude product from methanol gave a product of mp 119—120 °C (85% yield).

***p*-Chlorobenzoylation of Fluorene.** To a mixture of fluorene (6 mmol), *p*-chlorobenzoic acid (7 mmol), and **TFOP** (7 mmol), **TFA** (5 mL) was added and the mixture was heated under reflux for 5 h. Then, after evaporating **TFA** under reduced pressure, unreacted fluorene was distilled off with steam to give 2-(*p*-chlorobenzoyl)fluorene as the residue (mp 172—176 °C, 81% yield). Recrystallization of the product from ethanol gave a product of mp 177—179 °C.

***o*-Methylbenzoylation of Thiophene.** To a mixture of thiophene (6 mmol), *o*-methylbenzoic acid (7 mmol), and

† 1 mmHg=133.322 Pa.

TFOP (7 mmol), **TFA** (5 mL) was added and the mixture was heated under reflux for 4 h. Then, the reaction mixture was poured into ice-water and was extracted by ether. The organic layer was washed with water, alkali, and water, and was dried over anhydrous sodium sulfate. After evaporation of the solvent, crude 2-(*o*-methylbenzoyl)thiophene was obtained as the oily product (95% yield). The distillation of the oil under reduced pressure gave a product of bp 145—147 °C/5 mmHg (85% yield); IR (Neat) 1637, 1410, 1305, 1276, 850, and 735 cm^{-1}; ^1H NMR ($CDCl_3$) δ=7.70 (d, 1H, J=2 Hz), 7.36—7.66 (m, 5H), 7.13—7.16 (m, 1H), and 2.42 (s, 3H, Me). Found: C, 71.21; H, 4.94%. Calcd for $C_{12}H_{10}OS$: C, 71.26; H, 4.98%.

By a similar procedure, the following 2-acylthiophenes were prepared.

2-(*m*-Methylbenzoyl)thiophene: 93% yield; bp 219—220 °C/25 mmHg; IR (neat) 1632, 1410, 1290, 1210, 775, and 730 cm^{-1}; ^1H NMR ($CDCl_3$) δ=7.70—7.72 (m, 4H), 7.29—7.42 (m, 2H), 7.08—7.25 (m, 1H), and 2.38 (s, 3H, Me). Found: C, 71.42; H, 4.99%. Calcd for $C_{12}H_{10}OS$: C, 71.26; H, 4.98%.

2-(*m*-Methoxybenzoyl)thiophene: 92% yield; bp 146—148 °C/3 mmHg; IR (neat) 1635, 1410, 1285, 890, and 730 cm^{-1}; ^1H NMR($CDCl_3$) δ=7.65—7.71 (m, 2H), 7.38—7.45 (m, 3H), 7.10—7.16 (m, 2H), and 3.85 (s, 3H, OMe). Found: C, 66.09; H, 4.58%. Calcd for $C_{12}H_{10}O_2S$: C, 66.03; H, 4.62%.

2-(*m*-Chlorobenzoyl)thiophene: 93% yield; Mp 62—64 °C (from hexane); IR (KBr) 1635, 1400. 1290, 890, and 730 cm^{-1}; ^1H NMR ($CDCl_3$) δ=7.41—7.83 (m, 6H) and 7.16—7.20 (m, 1H). Found: C, 9.49; H, 3.22%. Calcd for $C_{11}H_7OSCl$: C, 59.33; H, 3.17%.

2-(*p*-Fluorobenzoyl)thiophene: 99% yield; Mp 95—96 °C (from 60% EtOH); IR (KBr) 1630, 1412, 1295, 850, and 720 cm^{-1}; ^1H NMR ($CDCl_3$) δ=7.89—7.94 (m, 2H), 7.63—7.75 (m, 2H), and 7.15—7.25 (m, 3H). Found: C, 63.89; H, 3.21%. Calcd for $C_{11}H_7OSF$: C, 64.06; H, 3.42%.

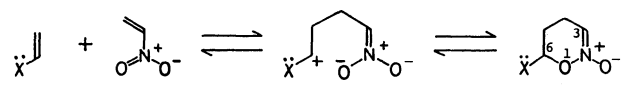
(Received July 28, 1987)

An electron-deficient nitro olefin, methyl α,*p*-dinitrocinnamate, reacts with vinyl ethers to give cyclic nitronic esters, which are stable as compared with those produced by reactions of nitro olefins with enamines. Stability of the cyclic nitronate depends on the properties of the substituents at 4- and 6-positions of the ring. The adducts undergo fragmentation by a catalytic amount of base to β,γ-unsaturated α-hydroxyimino esters.

A cyclic nitronic ester, 5,6-dihydro-4*H*-1,2-oxazine 2-oxide, has been known as an interesting intermediate which can be converted into nitroalkylated enamines,[1] 1,4-diones,[2] and so forth[3] via easy heterolytic cleavage of the O(1)-C(6) bond. Such cyclic compounds are easily obtainable by reactions of simple nitro olefins with enamines,[1] silyl enol ethers,[2] enolate anions,[4] or cyclohexene,[5] although little has been clarified on the chemical properties of them except for the O(1)-C(6) bond cleavage owing to their thermal and hydrolytic instability. In order to investigate further reactivities of the dihydrooxazine *N*-oxide, we wished to prepare stable cyclo adducts by reaction of nitro olefins with vinyl ethers. The dihydrooxazine *N*-oxide might be stable if the carbocation formed by the bond cleavage of the compound would be unstable (Scheme 1) or, in other words, if the substituent X in Scheme 1 would be less electron-donating. Direct reaction of simple nitro olefins with vinyl ethers failed, however, to give adducts because of low nucleophilicity of the latters. Another strategy to prepare the stable cycloadduct may be usage of highly electrophilic nitro olefins. We report here cycloaddition of an electron-deficient nitro olefin, methyl α,*p*-dinitrocinnamate (**1**), with vinyl ethers, and some properties of the cycloadducts.



Scheme 1.

Results and Discussion

Reaction of **1** with ethyl vinyl ether in DMF at room temperature gave a diastereomeric mixture **2** of two cycloadducts in 92% yield. The ^{1}H NMR spectra of the isomers **2a** and **2b** reveal that they have cyclic structures rather than the alternative linear ones, methyl 5-ethoxy-2-nitro-3-(*p*-nitrophenyl)-2-, 3-, or 4-pentenoates. The ratio of the isomers **2a** and **2b** was about 4 : 1 regardless of the configurations of the nitro olefin. The results are consistent with the mechanism of the step wise cyclization shown in Scheme 1. The small coupling constants (ca. 3.5 Hz) between 6-H and 5- or 5′-H of both isomers show that the 6-ethoxyl group is in an axial position of a pseudo chair ring. The configuration may be rationalized by the strong anomeric effect of the ring.[6] A difference between the spectra of **2a** and **2b** lies in the coupling patterns of 4-H ($J_{4,5}$ and $J_{4,5'}$=3.5 Hz and 8.7 Hz for **2a**; $J_{4,5}$ and $J_{4,5'}$=8.7 Hz and 9.1 Hz for **2b**). This difference may arise from different configurations of the aryl group at C(4) of the ring. The aryl group of **2a** is in a pseudoaxial position, while that of **2b** is in a pseudoequatorial one. Another difference is observed in the ester stretching band (1705 cm^{-1} for **2a**; 1745 cm^{-1} for **2b**). The higher frequency of the carbonyl band of **2b** may be interpreted in terms of restricted conjugation between the ester and the nitronic ester groups due to steric repulsion between the ester and the aryl groups (Fig. 1). From these results the structures of **2a** and **2b** were assigned to *cis*- and *trans*-6-ethoxy-3-methoxycarbonyl-4-(*p*-nitrophenyl)-5,6-dihydro-4*H*-1,2-oxazine 2-oxide, respectively (Fig. 1).

Other substituted vinyl ethers also reacted with **1** at higher temperatures to give the similar cyclic adducts **3**—**6** (Eq. 1 and Table 1). These substituted vinyl ethers did not reacted at room temperature because of the bulkiness of the reagents. The ^{1}H NMR and IR spectra of the adducts show that they are also a mixture of diastereomers, although details of their stereochemistry are not clear yet.

Fig. 1. Structures of the adducts **2a** and **2b**. (Ar=$C_6H_4NO_2$-*p*)

Table 1. Cycloaddition of Methyl α,*p*-Dinitrocinnamate (**1**) with Vinyl Ethers

Vinyl ether	Reaction conditions		Product	Decomp temp/°C	Yield/%
	Temp./°C	Time/h			
Ethyl vinyl ether	r.t.	24	**2**	124—127	92
2,3-Dihydrofuran	60	12	**3**	148—153	80
3,4-Dihydro-2*H*-pyran	60	12	**4**	140—143	30
1-Methoxycyclopentene	50	12	**5**	141—144	84
1-Methoxycyclohexene	50	12	**6**	174—175	72

When **1** was reacted with 1-morpholinocyclohexene at 0 °C in benzene, an unstable adduct, which was assumed to be a dihydrooxazine *N*-oxide derivative, was precipitated. It spontaneously decomposed into the Michael adduct in benzene solution as well as other cyclic adducts of nitro olefins with enamines.[1] On the contrary, the adducts **2—6** were very stable even at 100 °C. This fact indicates that the stability of the dihydrooxazine *N*-oxide structure depends on the electronic properties of the substituents at C(6) as expected.

Reactions of methyl α-nitrocinnamate (**7**) or less electrophilic nitro olefins such as methyl β-methoxy-α-nitroacrylate or β,*p*-dinitrostyrene, with ethyl vinyl ether did not give the corresponding 1 : 1 cycloadducts even at higher temperatures. On the other hand, treatment of **7** with ethyl vinyl ether in the presence of acrylonitrile at 70 °C in DMF gave an 1 : 1 : 1 adduct **8** in 57% yield (Eq. 2). The role of the acrylonitrile is to trap an unstable dihydrooxazine *N*-oxide by 1,3-dipolar addition, because **2a** also reacted with acrylonitrile even in the presence of ethyl vinyl ether to give the corresponding 1 : 1 : 1 adduct **9** (Eq. 3). In the absence of acrylonitrile, the reaction of **2a** with ethyl vinyl ether gave an 1 : 2 adduct **10** at 70 °C in DMF. These reactions are consistent with the reactivity of nitronic esters as an electron-rich 1,3-dipole.[7] The 1 : 1 cycloadduct of **7** with ethyl vinyl ether (see Eq. 2) could not be isolated in contrast with the stable nitronate **2**. The fact implies that the stability of the dihydrooxazine *N*-oxide seems to be affected by the C(4)-substituent as well as the C(6)-one.

Methanolysis of **2a** and **2b** under acidic conditions gave the same product, methyl 5,5-dimethoxy-2-nitro-3-(*p*-nitrophenyl)pentanoate as a result of the common O(1)-C(6) bond cleavage.[1-4]

Treatment of **2a** by a catalytic amount of sodium hydroxide in DMSO-d_6 at room temperature gave ethyl formate and methyl 2-hydroxyimino-3-(*p*-nitrophenyl)-3-butenoate (**11**), immediately and quantitatively. Ammonia was a less efficient catalyst because of poor yield of **11**. Bulky triethylamine did not give any products even at a reflux temperature of THF. On the other hand, the stereoisomer **2b** gave neither **11** nor **8** under the corresponding reaction conditions. These results may be attributed to the steric hinderance around the nitronic ester moiety of **2b** as mentioned above. Although the adducts **2—6** are mixtures of diastereomers, they also gave the fragmentation products **11—15** in good to moderate yields by treatment with sodium methoxide (Eq. 4 and Table 2). The formation of the products **12** and **13** may proceed via easy hydrolysis of the initially formed formate given in Eq. 4. On the basis of these results, the rate-determinig step of the fragmentation may be deprotonation of 4-H of the ring. Such a reaction of the 5,6-dihydro-4*H*-1,2-oxazine 2-oxides has not been known yet, while the similar fragmentation of some related compounds, 5-thia analogues[8] or N-alkyl salts[9] of 5,6-dihydro-4*H*-1,2-oxazine have been reported. Most of the reported reactions of the dihydrooxazine *N*-oxides with strong bases also proceed via the O(1)-C(6) bond cleavage.[1a,4] Stability of the O(1)-C(6) bond may be one of the important factors of this fragmentation.

Table 2. Fragmentation of 6-Alkoxy-5,6-dihydro-4*H*-1,2-oxazine 2-Oxides by Sodium Methoxide

Substrate	Product	R^1	Mp θ_m/°C	Yield/%
2	**11**	H	149.5—151.5	82
3	**12**	$(CH_2)_2OH$[a)]	140.5—144.5	25
4	**13**	$(CH_2)_3OH$[a)]	96.5—98.5	80
5	**14**	$(CH_2)_3CO_2Me$	98.5—99.0	78
6	**15**	$(CH_2)_4CO_2Me$	Oil	64

a) The isolated products were given by hydrolysis of the initial products [R^1=$[(CH_2)_nOCOH]$ under the reaction conditions.

Reduction of **2a** and **2b** by triethyl phosphite gave the corresponding isomers of 2-deoxygenated products, **16a** and **16b**, respectively. Treatment of **16a** with a catalytic amount of sodium methoxide in THF gave the other isomer **16b** in 42% yield probably via deprotonation of 4-H of the ring. However the similar fragmentation of **16b** shown by Eq. 4 did not occur at all. Reported transformations of other 5,6-dihydro-4*H*-1,2-oxazines[10] are also quite different from this fragmentation. Consequently the *N*-oxide function of the adducts must play a significant role in the fragmentation.

The present fragmentation is a unique reaction of stable 5,6-dihydro-4*H*-1,2-oxazine 2-oxides.

Experimental

The infrared spectra were measured in nujol by means of a Hitachi 260-10 spectrophotometer and the ^{1}H NMR spectra were taken on a Hitachi R-20B spectrometer.

Methyl α,*p*-Dinitrocinnamate (1). This nitro olefin was prepared by the method of Dornow[11] in 72% yield (E : Z=3 : 4 by ^{1}H NMR). Fractional recrystallization from CCl_4 gave each isomer. E Isomer: Pale yellow needles; mp 135—138 °C. ^{1}H NMR ($CDCl_3$) δ=3.96 (s, 3H), 7.69 (d, 2H, *J*=8.9 Hz), 8.12 (s, 1H), 8.31 (d, 2H, *J*=8.9 Hz). IR: 1740 cm^{-1} (C=O), 1520, 1350 cm^{-1} (NO_2). Found: C, 47.57; H, 3.21; N, 10.98%. Calcd for $C_{10}H_8H_2O_6$: C, 47.62; H, 3.20; N, 11.11%. Z Isomer: Pale yellow needles; mp 125—130 °C. ^{1}H NMR ($CDCl_3$) δ=3.97 (s, 3H), 7.60 (d, 2H, *J*=8.6 Hz), 7.63 (s, 1H), 8.28 (d, 2H, *J*=8.6 Hz). IR: 1720 cm^{-1} (C=O), 1550, 1535, 1340 cm^{-1} (NO_2). Found: C, 47.50; H, 3.14; N, 11.13%. Calcd for $C_{10}H_8N_2O_6$: C, 47.62; H, 3.20; N, 11.11%.

Reaction of 1 with Ethyl Vinyl Ether. A solution of 2.52 g (10 mmol) of **1** and 3.60 g (50 mmol) of ethyl vinyl ether in 20 ml of DMF was allowed to stand for 1 d. After the solvent was removed in vacuo the residual solid was recrystallized from benzene-hexane to give 2.98 g (92%) of a diastereomeric mixture (**2a** : **2b**=4 : 1) of 6-ethoxy-3-methoxycarbonyl-4-(*p*-nitrophenyl)-5,6-dihydro-4*H*-1,2-oxazine 2-oxide (**2**). Fractional recrystallization of **2** from benzene-hexane gave each isomer.

2a (cis isomer): Colorless prisms; mp 124—126 °C (decomp). ^{1}H NMR ($CDCl_3$) δ=1.18 (t, 3H, *J*=7.1 Hz), 2.26 (td, 1H, *J*=3.5 Hz and 14.3 Hz), 2.65 (ddd, 1H, *J*=3.5 Hz, 8.7 Hz, and 14.3 Hz), 3.70 (s, 3H), 3.8 (m, 2H), 4.50 (dd, 1H, *J*=3.5 Hz and 8.7 Hz), 5.48 (t, 1H, *J*=3.5 Hz), 7.46 (d, 2H, *J*=8.8 Hz), 8.16 (d, 2H, *J*=8.8 Hz). IR: 1705 cm^{-1} (C=O), 1595 cm^{-1} (C=N), 1520, 1345 cm^{-1} (NO_2). Found: C, 51.78; H, 4.93; N, 8.57%. Calcd for $C_{14}H_{16}N_2O_7$: C, 51.85; H, 4.97; N, 8.64%.

2b (trans isomer): Colorless prisms; mp 137—139 °C (decomp). ^{1}H NMR ($CDCl_3$) δ=1.29 (t, 3H, *J*=7.0 Hz), 2.34 (dd, 1H, *J*=9.1 Hz and 3.9 Hz), 2.40 (dd, 1H, *J*=8.7 Hz and 3.0 Hz), 3.70 (s, 3H), 3.77 (qd, 1H, *J*=7.0 Hz and 9.7 Hz), 4.07 (qd, 1H, *J*=7.0 Hz and 9.7 Hz), 4.54 (dd, 1H, *J*=8.7 Hz and 9.1 Hz), 5.50 (dd, 1H, *J*=3.0 Hz and 3.7 Hz), 7.44 (d, 2H, *J*=8.4 Hz), 8.20 (d, 2H, *J*=8.4 Hz). IR: 1745 cm^{-1} (C=O), 1590 cm^{-1} (C=N), 1520, 1350 cm^{-1} (NO_2). Found: C, 51.72; H, 4.95; N, 8.64%. Calcd for $C_{14}H_{16}N_2O_7$: C, 51.85; H, 4.97; N, 8.64%.

Reaction of 1 with 2,3-Dihydrofuran. A solution of 2,3-dihydrofuran (2.90 g, 41.4 mmol) and **1** (1.34 g, 5.3 mmol) in 6 ml of DMF was heated at 60 °C for 12 h. After removal of the solvent, residual solid was recrystallized from benzene-hexane to give 1.37 g (80%) of a diastereomeric mixture of **3** [mp 148—153 °C (decomp), IR: 1730 and 1700 cm^{-1}]. Recrystallization of **3** from ether gave one of the isomers **3b**; colorless prisms; mp 150—154 °C (decomp). ^{1}H NMR ($CDCl_3$) δ=1.8—2.7 (m, 2H), 3.1—3.6 (m, 1H), 3.91 (s, 3H), 3.9—4.3 (m, 2H), 4.63 (m, 1H), 5.94 (d, 1H, *J*=7.0 Hz), 7.50 (d, 2H, *J*=8.5 Hz), 8.20 (d, 2H, *J*=8.5 Hz). IR: 1730 cm^{-1} (C=O), 1580 cm^{-1} (C=N), 1520, 1355 cm^{-1} (NO_2). Found: C, 52.50; H, 4.40; N, 8.40%. Calcd for $C_{14}H_{14}N_2O_7$: C, 52.17; H, 4.38; N, 8.69%.

Reactionof 1 with 3,4-Dihydro-2*H*-pyran. A solution of 2.77 g (11 mmol) of **1** and 4.62 g (55 mmol) of dihydropyran in 5 ml of DMF was heated at 60 °C for 12 h. After removal of the solvent in vacuo, residual oil was column-chromatographed on solica gel. The first eluent (chloroform-benzene 1 : 1) gave 0.83 g (30%) of the recovered nitro olefin. The second eluent (chloroform-acetone 20 : 1) gave 1.11 g (30%) of a diastereomeric mixture of the adduct **4** [mp 140—143 °C (decomp), IR: 1730, 1710, 1695 cm^{-1}]. Recrystallization of **4** from benzene-hexane gave an isomer **4a**; colorless powder; mp 142—145 °C (decomp). ^{1}H NMR ($CDCl_3$) δ=1.4—1.8 (m, 4H), 2.2—2.7 (m, 1H), 3.63 (s, 3H), 3.7—4.1 (m, 2H), 4.74 (d, 1H, *J*=8.4 Hz), 5.85 (m, 1H), 7.31 (d, 2H, *J*=8.7 Hz), 8.19 (d, 2H, *J*=8.7 Hz). IR: 1690 cm^{-1} (C=O), 1580 cm^{-1} (C=N), 1515, 1360, 1345 cm^{-1} (NO_2). Found: C, 53.33; H, 4.82; N, 8.43%. Calcd for $C_{15}H_{16}N_2O_7$: C, 53.57; H, 4.80; N, 8.33%.

Reaction of 1 with 1-Methoxycyclopentene. A solution of 2.52 g (10 mmol) of **1** and 5.90 g (50 mmol) of 1-methoxycyclopentene in 10 ml of DMF was heated at 50 °C

for 12 h. After removal of the solvent in vacuo, the residue was recrystallized from benzene-hexane to give 2.93 g (83%) of the adduct **5**. Colorless needles; mp 141—144 °C (decomp). ^{1}H NMR ($CDCl_3$) δ=1.4—2.6 (m, 7H), 3.49 (s, 3H), 3.63 (s, 3H), 4.06 (d, 1H, J=4.5 Hz), 7.43 (d, 2H, J=8.8 Hz), 8.16 (d, 2H, J=8.8 Hz). IR: 1740, 1725 cm^{-1} (C=O), 1595 cm^{-1} (C=N), 1515, 1350 cm^{-1} (NO_2). Found: C, 54.91; H, 5.14; N, 7.95%. Calcd for $C_{16}H_{18}N_2O_7$: C, 54.85; H, 5.17; N, 7.99%. Similarly the adduct **6** was obtained from a reaction of **1** with 1-methoxycyclohexene. Colorless prisms; mp 174—175 °C (decomp). ^{1}H NMR ($CDCl_3$) δ=1.2—2.5 (m, 9H), 3.33 (s, 3H), 3.71 (s, 3H), 4.10 (s, 1H), 7.38 (d, 2H, J=9.0 Hz), 8.15 (d, 2H, J=9.0 Hz). IR: 1735 cm^{-1} (C=O), 1585 cm^{-1} (C=N), 1520, 1345 cm^{-1} (NO_2). Found: C, 56.15; H, 5.49; N, 7.55%. Calcd for $C_{17}H_{20}N_2O_7$: C, 56.04; H, 5.53; N, 7.69%.

Reaction of Methyl α-Nitrocinnamate (7) with Ethyl Vinyl Ether and Acrylonitrile. A solution of 0.41 g (2 mmol) of **7**, 0.32 g (6 mmol) of acrylonitrile, and 0.72 g (10 mmol) of ethyl vinyl ether in 5 ml of DMF was heated at 70 °C for 3 h. After removal of the solvent, residual oil was crystallized from benzene-hexane to give 0.38 g (57%) of 8-cyano-3-ethoxy-6-methoxycarbonyl-5-phenyl-2,9-dioxa-1-azabicyclo[4.3.0]nonane (**8**). Colorless needles; mp 165—174 °C. ^{1}H NMR ($CDCl_3$) δ=1.31 (t, 3H, J=7.0 Hz), 2.2 (ddd, 1H, J=13.0 Hz, 6.6 Hz, and 2.9 Hz), 2.5—4.2 (m, 6H), 3.42 (s, 3H), 5.02 (dd, 1H, J=7.7 Hz and 6.6 Hz), 5.31 (dd, 1H, J=10.2 Hz and 4.3 Hz), 7.0—7.4 (m, 5H). IR: 1740 cm^{-1} (C=O). Found: C, 61.13; H, 6.15; N, 8.40%. Calcd for $C_{17}H_{20}N_2O_5$: C, 61.43; H, 6.07: N, 8.43%.

Similarly, by a reaction of **2a** with acrylonitrile in the presence of ethyl vinyl ether, 8-cyano-3-ethoxy-6-methoxycarbonyl-5-(*p*-nitrophenyl)-2,9-dioxa-1-azabicyclo-[4.3.0]nonane (**9**) was obtained in 87% yield. Colorless powder; mp 210—218 °C. ^{1}H NMR (DMSO-d_6) δ=1.22 (t, 3H, J=7.2 Hz), 2.0—4.0 (m, 7H), 3.36 (s, 3H), 5.07 (t, 1H, J=7.3 Hz), 5.65 (dd, 1H, J=9.8 Hz and 4.7 Hz), 7.51 (d, 2H, J=8.9 Hz), 8.19 (d, 2H, J=8.9 Hz). IR: 1735 cm^{-1} (C=O), 1520, 1510, 1350, 1345 cm^{-1} (NO_2). Found: C, 54.30; H, 5.12; N, 11.03%. Calcd for $C_{17}H_{19}N_3O_7$: C, 54.11; H, 5.08; N, 11.14%.

Reaction of 2a with Ethyl Vinyl Ether. A solution of 0.65 g (2 mmol) of **2a** and 0.72 g (10 mmol) of ethyl vinyl ether in 5 ml of DMF was heated at 60 °C for 5 h. After removal of the solvent, residue was recrystallized from benzene-hexane to give 0.66 g (83%) of 3,8-diethoxy-6-methoxycarbonyl-5-(*p*-nitrophenyl)-2,9-dioxa-1-azabicyclo[4.3.0]nonane (**10**). Colorless needles; mp 174—175 °C. ^{1}H NMR ($CDCl_3$) δ=1.11 (t, 3H, J=7.0 Hz), 1.32 (t, 3H, J=7.0 Hz), 2.0—2.4 (m, 9H), 3.37 (s, 3H), 4.98 (t, 1H, J=7.0 Hz), 5.80 (d, 1H, J=6.0 Hz), 7.36 (d, 2H, J=8.6 Hz), 8.18 (d, 2H, J=8.6 Hz). IR: 1740 cm^{-1} (C=O), 1515, 1350 cm^{-1} (NO_2). Found: C, 54.33; H, 6.09; N, 7.01%. Calcd for $C_{18}H_{24}N_2O_8$: C, 54.55; H, 6.10; N, 7.10%.

Reaction of 1 with 1-Morpholinocyclohexene. To a solution of 1.66 g (6.6 mmol) of **1** in 60 ml of benzene, 1.10 g (6.6 mmol) of 1-morpholinocyclohexene in 10 ml of benzene was added at 0 °C. After 2 h, 0.55 g (20%) of colorless precipitate was obtained which was assumed to be a cyclo adduct. Decomp 80—81.5 °C. IR: 1730 cm^{-1} (C=O), 1565, 1520, 1345 cm^{-1} (NO_2). Residual benzene layer was crystallized from benzene-hexane to give 1.65 g (60%) of a mixture (1 : 1) of two diastereomers of methyl 3-(2-morpholino-2-cyclohexenyl)-2-nitro-3-(*p*-nitrophenyl)propanoate. Yellow powder; mp 120—124.5 °C. ^{1}H NMR ($CDCl_3$) δ=1.1—3.2 (m, 11H), 3.55 (s, 3H, ester methyl protons of one isomer), 3.80 (s, 3H, ester methyl protons of another isomer), 3.6—3.9 (m, 4H), 4.3 (m, 1H), 4.98 (t, 1H, J=3.9 Hz, an olefin proton of enamine), 5.86 (d, 1H, J=8.8 Hz, 2-H of one isomer), 6.02 (d, 1H, J=9.7 Hz, 2-H of another isomer), 7.44 (d, 2H, J=8.9 Hz, one isomer), 7.46 (d, 2H, J=8.9 Hz, another isomer), 8.11 (d, 2H, J=8.9 Hz). IR: 1745 cm^{-1} (C=O), 1650 cm^{-1} (C=C-N). Found: C, 57.28; H, 5.99: N, 9.87%. Calcd for $C_{20}H_{25}N_3O_7$: C, 57.27; H, 6.01; N, 10.02%.

Methanolysis of 2 by Acid Catalyst. A solution of 0.975 g (3 mmol) of **2a** and 0.057 g (0.3 mmol) of *p*-toluenesulfonic acid in 30 ml of dry methanol was refluxed for 4 h. After removal of the solvent, residual oil was dissolved in chloroform, washed with water, and dried over sodium sulfate. The crude product was recrystallized by benzene-hexane to give 0.72 g (70%) of one of the diastereomers of methyl 5,5-dimethoxy-2-nitro-3-(*p*-nitrophenyl)pentanoate. Colorless plates; mp 94—98 °C. ^{1}H NMR ($CDCl_3$) δ=1.9—2.3 (m, 2H), 3.22 (s, 3H), 3.26 (s, 3H), 3.89 (s, 3H), 3.7—4.2 (m, 2H), 5.47 (d, 1H, J=10.0 Hz), 7.51 (d, 2H, J=8.7 Hz), 8.24 (d, 2H, J=8.7 Hz). IR: 1760 cm^{-1} (C=O), 1565, 1520, 1350 cm^{-1} (NO_2). Found: C, 49.35; H, 5.29; N, 8.16%. Calcd for $C_{14}H_{18}N_2O_8$: C, 49.12; H, 5.30; N, 8.18%. The similar treatment of **2b** gave the same product in 67% yield.

Fragmentation of the Adduct 2 by Sodium Methoxide. To a solution of 0.65 g (2 mmol) of **2** in 30 ml of THF at −15 °C, 1 ml (0.35 mmol) of sodium methoxide in methanol solution was added. The solution turned to red and was allowed to stand at room temperature for 30 min. An equimolar amount of hydrogen chloride (methanol solution, 0.8 mol dm^{-3}) was added to the solution and the solvent was removed under reduced pressure. The residue was dissolved in chloroform, washed with water, and dried over magnesium sulfate. After removal of the solvent, residual solid was recrystallized from benzene-hexane to give 0.41 g (82%) of methyl 2-hydroxyimino-3-(*p*-nitrophenyl)-3-butenoate (**11**). Colorless prisms; mp 149.5—151.5 °C. ^{1}H NMR ($CDCl_3$) δ=3.85 (s, 3H), 5.59 (s, 1H), 5.68 (s, 1H), 7.46 (d, 2H, J=8.7 Hz), 8.13 (d, 2H, J=8.7 Hz), 8.54 (s, 1H). IR: 3320 cm^{-1} (O-H), 3120, 3090 cm^{-1} (vinyl C-H), 1730 cm^{-1} (C=O), 1510, 1345 cm^{-1} (NO_2). Found: C, 53.03; H, 4.07; N, 11.07%. Calcd for $C_{11}H_{10}N_2O_5$: C, 52.80; H, 4.03; N, 11.20%.

The similar treatment of the adducts **3**—**6** gave the oximes **12**—**15**, which were purified by column chromatography on silica gel. Acetone-chloroform elutes were recrystallized from benzene-hexane.

Methyl 6-Hydroxy-2-hydroxyimino-3-(*p*-nitrophenyl)-3-hexenoate (12): Colorless needles; mp 140.5—144.5 °C. ^{1}H NMR ($CDCl_3$) δ=2.4—2.8 (m, 3H), 3.69 (s, 3H), 3.7—4.0 (m, 2H), 6.41 (t, 1H, J=7.3 Hz), 7.51 (d, 2H, J=9.0 Hz), 8.21 (d, 2H, J=9.0 Hz), 11.6 (broad s, 1H). IR: 3250 cm^{-1} (O-H), 1740 cm^{-1} (C=O), 1510, 1350 cm^{-1} (NO_2). Found: C, 53.40; H, 4.87; N, 9.55%. Calcd for $C_{13}H_{14}N_2O_6$: C, 53.06; H, 4.80; N, 9.52%.

Methyl 7-Hydroxy-2-hydroxyimino-3-(*p*-nitrophenyl)-3-heptenoate (13): Colorless prisms; mp 96.5—98.5 °C. ^{1}H NMR ($CDCl_3$) A mixture of two configurational isomers A and B (A : B=3 : 2). A: δ=1.4—3.0 (m, 5H), 3.4—3.8 (m, 2H), 3.91 (s, 3H), 6.01 (t, 1H, J=7.7 Hz), 7.25 (d, 2H, J=8.7 Hz), 8.21 (d, 2H, J=8.7 Hz), 8.61 (s, 1H). B: δ=1.4—3.0 (m, 5H), 3.4—3.8 (m, 2H), 3.70 (s, 3H), 6.28 (t, 1H, J=8.0 Hz), 7.49 (d, 2H, J=8.7 Hz), 8.19 (d, 2H, J=8.7 Hz), 11.49 (s, 1H). IR: 3480, 3170 cm^{-1} (O-H), 1740, 1730 cm^{-1} (C=O), 1515,

1350 cm^{-1} (NO_2). Found: C, 54.79; H, 5.26; N, 9.12%. Calcd for $C_{14}H_{16}N_2O_6$: C, 54.54; H, 5.23; N, 9.09%.

Dimethyl 2-Hydroxyimino-3-(*p*-nitrophenyl)-3-octenedioate (14): Colorless prisms; mp 98.5—99 °C. ^1H NMR ($CDCl_3$) δ=1.5—2.5 (m, 6H), 3.59 (s, 3H), 3.88 (s, 3H), 5.95 (t, 1H, J=8.2 Hz), 7.31 (d, 2H, J=8.6 Hz), 8.20 (s, 1H), 8.22 (d, 2H, J=8.6 Hz). IR: 3300 cm^{-1} (O-H), 1735 cm^{-1} (C=O), 1520, 1350 cm^{-1} (NO_2). Found: C, 54.97; H, 5.23; N, 8.01%. Calcd for $C_{16}H_{18}N_2O_7$: C, 54.85; H, 5.17; N, 7.99%.

Dimethyl 2-Hydroxyimino-3-(*p*-nitrophenyl)-3-nonenedioate (15): Colorless oil. ^1H NMR ($CDCl_3$) δ=1.4—1.8 (m, 4H), 2.2—2.5 (m, 4H), 3.68 (s, 3H), 3.76 (s, 3H), 6.33 (t, 1H, J=7.5 Hz), 7.49 (d, 2H, J=9.1 Hz), 8.16 (d, 2H, J=9.1 Hz), 10.76 (s, 1H). IR: 3350 cm^{-1} (O-H), 1735 cm^{-1} (C=O), 1520, 1345 cm^{-1} (NO_2). Mass spectra: m/z 364 (M^+).

Reduction of 2 with Triethyl Phosphite. A solution of 0.65 g (2 mmol) of **2a** and 0.46 g (3 mmol) of triethyl phosphite in 10 ml of xylene was heated at 95 °C for 7.5 h under a nitrogen atmosphere. After removal of the solvent in vacuo, residue was recrystallized from benzene-hexane to give 0.47 g (76%) of *cis*-6-ethoxy-3-methoxycarbonyl-4-(*p*-nitrophenyl)-5,6-dihydro-4*H*-1,2-oxazine (**16a**): Colorless prisms; mp 91—92.5 °C. ^1H NMR ($CDCl_3$) δ=1.07 (t, 3H, J=7.0 Hz), 2.2—2.5 (m, 2H), 3.3—4.0 (m, 2H), 3.80 (s, 3H), 4.08 (dd, 1H, J=6.7 Hz and 4.0 Hz), 5.23 (t, 1H, J=3.2 Hz), 7.36 (d, 2H, J=9.1 Hz), 8.14 (d, 2H, J=9.1 Hz). IR: 1730 cm^{-1} (C=O), 1520, 1345 cm^{-1} (NO_2). Found: C, 54.44; H, 5.22; N, 8.97%. Calcd for $C_{14}H_{16}N_2O_6$: C, 54.54; H, 5.23; N, 9.09%.

Similarly, **16b** (trans isomer) was obtained by a reaction of **2b** with triethyl phosphite in 61% yield. Colorless powder; mp 101—103 °C. ^1H NMR ($CDCl_3$) δ=1.25 (t, 3H, J=6.9 Hz), 2.04 (ddd, 1H, J=13.6 Hz, 11.4 Hz, and 2.6 Hz), 2.38 (ddd, 1H, J=13.6 Hz, 7.8 Hz, and 2.6 Hz), 3.3—4.2 (m, 2H), 3.70 (s, 3H), 4.13 (dd, 1H, J=11.4 Hz and 7.8 Hz), 5.24 (t, 1H, J=2.6 Hz), 7.36 (d, 2H, J=9.0 Hz), 8.20 (d, 2H, J=9.0 Hz). IR: 1745 cm^{-1} (C=O), 1515, 1350 cm^{-1} (NO_2). Found: C, 54.33; H, 5.33; N, 8.89%. Calcd for $C_{14}H_{16}N_2O_6$: C, 54.54; H, 5.23; N, 9.09%.

Isomerization of 16a to 16b. Treatment of **16a** with sodium methoxide under the similar conditions of the fragmentation of **2a** with sodium methoxide gave **16b** in 42% yield.

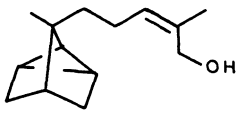
The Asymmetric Diels-Alder Cycloaddition Using Ethyl (−)-(*Z*)-(*R*)$_S$-2-Methyl-3-(*p*-tolylsulfinyl)propenoate: Application to an Enantioselective Synthesis of (+)-*epi*-β-Santalene

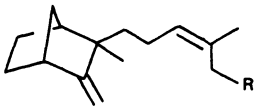
Yoshitsugu ARAI, Masatoshi YAMAMOTO, and Toru KOIZUMI*
Faculty of Pharmaceutical Sciences, Toyama Medical and Pharmaceutical University, Sugitani 2630, Toyama 930-01
(Received July 31, 1987)

The Diels-Alder reaction of ethyl (−)-(*Z*)-(*R*)$_S$-2-methyl-3-(*p*-tolylsulfinyl)propenoate (**6**)[1] with cyclopentadiene gave the cycloadducts **7**, **8**, and **9** in a high diastereoselective manner. The cycloadduct **7** was transformed into the acetal (−)-**25**. The racemic **25** was used as an intermediate in the synthesis of (±)-β-santalol. Thus, the chiral acetal (−)-**25** should provide a route to (−)-β-santalol. The cycloadduct **8** was converted into (+)-*epi*-β-santalene in 11 steps.

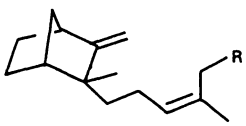
East Indian sandalwood oil was obtained from the tree, *Santalum album* L., growing in the forest of Mysore, India.[2] The oil is prized for its woody sweet and very long-lasting odor. Recently, it was pointed[3] that the orfactory character was responsible mainly for two major components of the essential oil, (+)-α-santalol (**1**), and (−)-β-santalol (**2**). Of course, many of the minor components, e.g., (−)-β-santalene (**3**), (+)-*epi*-β-santalene (**4**), and (+)-*epi*-β-santalol (**5**) are also considered to contribute the perfume character. The structural relationship and absolute configuration of these sesquiterpenes were established by Money and co-workers.[4] Since the appearence of the pioneering work of Corey,[5] Brieger,[6] and Money,[7] a number of



1



2 R = OH
3 R = H

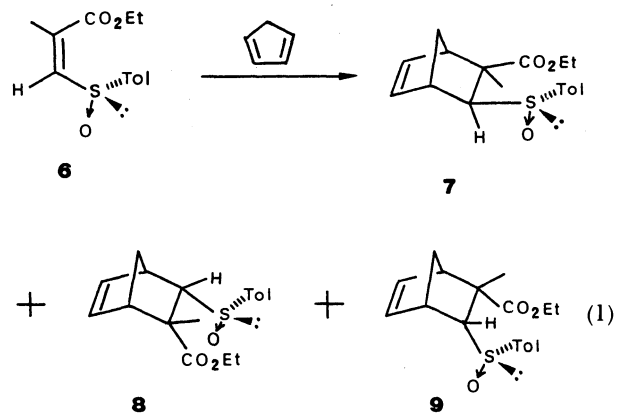


4 R = H
5 R = OH

syntheses of the santalols and santalenes have come on the scene.[8] However, there have been only two reports on the chiral synthesis of these sesquiterpenes: an elegant synthesis of (−)-**3** by Oppolzer[9] and a novel synthesis of some sesquiterpenes by Money.[4] Especially, the Oppolzer's synthesis involved an asymmetric Diels-Alder cycloaddition as a crucial step.

In the past few years, an asymmetric Diels-Alder reaction employing α,β-unsaturated sulfoxides has received a great deal of attention.[10] Because of the high diastereodifferentiation, the interpretation of the stereochemical course of the cycloadditions has been recently reported by Hehre from theoretical interest.[11] However, there have been few reports on the application to natural product synthesis, based upon the strategy of the asymmetric cycloaddition using chiral sulfoxides.[12]

As part of our investigation in this area, we reported that the Diels-Alder cycloaddition of the sulfoxides **6** and cyclopentadiene gave the cycloadducts **7**, **8**, and **9**



(1)

(ratio 32:66:2) in 92% combined yield. The diastereomeric excesses of the exo and endo adducts were proved to be 100 and 94% by HPLC analysis, respectively.[13] The absolute configuration of **7** was determined by chemical correlation. Although the absolute stereochemistry of the endo diastereomers was not clarified, we pointed out that the structure of **8** should be shown as depicted in Eq. 1, based upon our proposal of the steric course in the cycloaddition.

Since chirons[14] **7**—**9** derived from **6** possess functionalized bicyclo[2.2.1]heptane systems, the bicyclic sesquiterpenes such as **2** and **4** seemed to be attractive as a synthetic target molecule. In a preliminary communication,[15] we have described the use of the chirons **7** and **8** for the chiral synthesis of the bicyclic sesquiterpenes. In this paper we report in details these results.

Results and Discussion

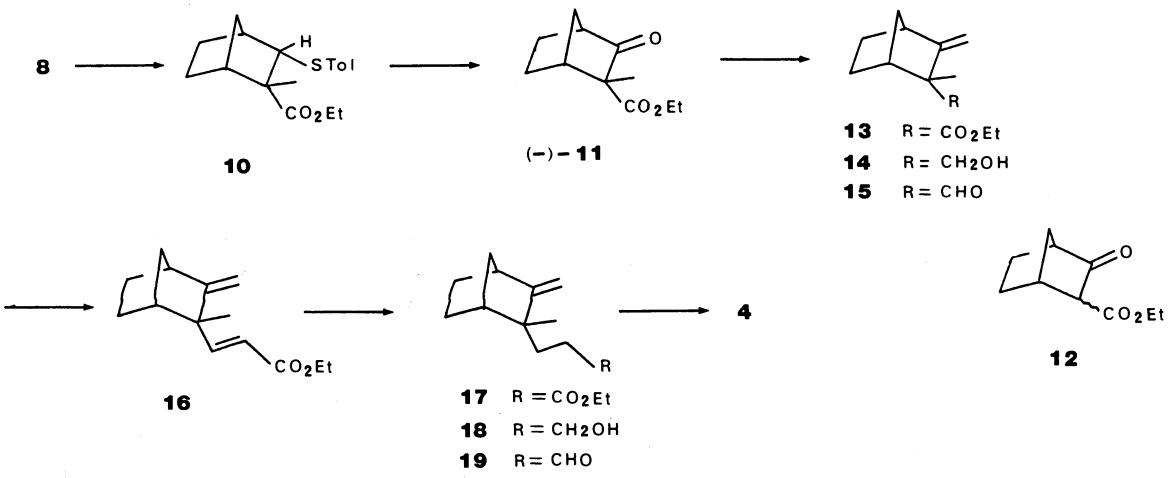
Synthesis of (+)-*epi*-β-Santalene. At the outset, we undertook the transformation of the sulfinyl group in

8 into the carbonyl function (Scheme 1). Hydrogenation of **8** ($[\alpha]_D^{19}$ −4.8°) over Pd on carbon followed by reduction of the sulfinyl group gave the sulfide **10** ($[\alpha]_D^{26}$ −7.32°) in 92% yield. Transformation of **10** into the keto ester (−)-**11** ($[\alpha]_D^{26}$ −7.15°) proceeded smoothly by chlorination with *N*-chlorosuccinimide (NCS) and subsequent oxidative hydrolysis,[16] in 85% yield. The stereostructure of (−)-**11** was ascertained by the following experiment. (±)-Norcamphor was ethoxycarbonylated with ethyl cyanoformate[17] under kinetically controlled conditions affording ester (±)-**12** whose enolate was stereoselectively methylated on the less hindered exo face of the ester to give (±)-**11**. The spectral and gas chromatographic characteristics were identical with those of (−)-**11** derived from **8**. The enantiomeric excess of (−)-**11** was proved to be no less than 97% by ^{1}H NMR examination in the presence of Eu(hfc)$_3$.

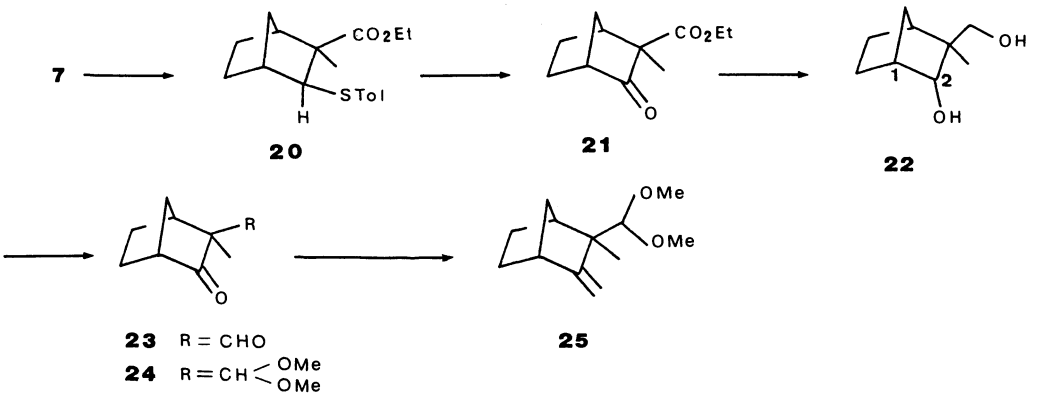
The next stage was set for the introduction of the terminal olefin in (−)-**11**. Reaction of (−)-**11** with a Wittig type reagent (methylenetriphenylphosphorane or the carbanion generated from diethyl methylphosphonate) did not produce the desired product **13**. In order to introduce the terminal olefin at a later stage, we tried to protect the keto group in (−)-**11**. Several attempts under a variety of conditions were unsuccessful, probably due to the steric hindrance. Finally, methylenation of the hindered carbonyl in (−)-**11** was best carried out by the Nozaki's method[18] (CH_2Br_2/Zn/$TiCl_4$) to produce **13** ($[\alpha]_D^{29}$ −46.3°) in 40% yield.[19]

The procedure adopted for converting the ester group in **13** into the requisite 4-methyl-3-pentenyl side chain is as follows. Reduction of **13** with diisobutylaluminium hydride (DIBAL, 2 equiv) gave the alcohol **14** ($[\alpha]_D^{26}$ + 96.2°) in quantitative yield. Pyridinium chlorochromate (PCC) oxidation[20] of **14** yielded the unstable aldehyde **15** (90%), $[\alpha]_D^{18}$ +17.1°, which was subjected to the Emmons-Horner condensation (triethyl phosphonoacetate, *n*-BuLi) giving the unsaturated ester **16** (96%), $[\alpha]_D^{26}$ −136°, as a single *E*-isomer. Reaction of **16** with Li-NH_3 gave the alcohol **18** in low yields. Good yields of **18** were obtained by the following operations. Hydrosilylation of **16** with triethylsilane in the presence of Wilkinson catalyst ($(Ph_3P)_3RhCl$) followed by ethanolysis provided the ester **17**, $[\alpha]_D^{25}$ +25.8°, in quantitative yield.[21] The spectroscopic data were consistent with those reported previously by Christenson and Willis in their synthesis of racemic **4**,[8b] According to the procedure of Christenson,[22] **17** was converted into (+)-*epi*-β-santalene by a 3-step sequence in 51% overall yield; reduction (DIBAL), PCC oxidation, and Wittig reaction. The spectral data (NMR, IR) were identical with those of an authentic sample kindly supplied by Dr. P. Christenson and the optical rotation ($[\alpha]_D^{27}$ +26.4°) was in good agreement with that reported in the literature ($[\alpha]_D^{27}$ +26.9°).[4]

Synthesis of the Intermediate (−)-25 of (−)-β-Santalol. In a manner similar to the first step of the synthesis of (+)-**4** the exo sulfoxide **7** was converted into the keto ester **21**, $[\alpha]_D^{25}$ −93.7° (Scheme 2). The structure of **21** was confirmed by direct comparison with that independently obtained by ethoxycarbonylation of (±)-3-methylnorcamphor.[23] Because the methylenation of the hindered keto group in **21** had been proved to be difficult, we chose the transformation of the ester group. The ester **21** was reduced with lithium aluminium hydride (LAH) to give the diol **22** (63%), $[\alpha]_D^{25}$ −8.5°, as a single isomer. The coupling constant ($J_{1,2}$=4 Hz) of the NMR spectrum showed that the C-2 hydroxyl group was located in the endo configuration. Swern oxidation[24] of **22** afforded the unstable keto aldehyde **23** (96%), and the aldehydic group was then selectively acetalized[25] with trimethyl orthoformate in the presence of cerium trichloride giving the acetal (−)-**24** (72%), $[\alpha]_D^{24}$ −62.6°. The enantiomeric excess (ee) of (−)-**24** was proved to be >97% as judged by NMR spectroscopy using Eu(hfc)$_3$. The exocyclic methylene group was introduced by the Nozaki's method to give (−)-**25** , $[\alpha]_D^{24}$ −119°, in 30%



Scheme 1.



Scheme 2.

yield. Since the absolute configuration of a chiron **7** have been determined,[13] the absolute stereochemistry of (−)-**25** should be deduced as depicted in Scheme 2. Racemic **25** was employed as an intermediate in the synthesis of (±)-**2** by the BASF group.[26] Having chiral acetal (−)-**25** in hand, it will be possible to transform the intermediate into (−)-**2**.

In conclusion, the chiron **7** was converted into a key intermediate in the synthesis of (−)-β-santalol. The chiron **8** was transformed into (+)-*epi*-β-santalene in enantiomerically pure form. Therefore, the absolute stereochemistry of the cycloadduct **8** was proved to be depicted in this paper. Based on our proposal[13] in the cycloaddition of a chiral sulfoxide, it was found that absolute stereostructure of the adducts could be predictable. And, we believe that the chirons would serve as the chiral intermediates for the synthesis of other natural products by transformation of the functionality such as the olefin, sulfinyl group and ethoxycarbonyl groups.

Experimental

The melting points and boiling points are uncorrected. ^{1}H NMR spectra were determined on a JEOL PMX-60, a Varian XL-200 or a JEOL GX-270 spectrometer. IR spectra were recorded on a JASCO A-102. Mass determinations were obtained on a JEOL D-200 spectrometer. Optical rotations were taken with a JASCO DIP-140 digital polarimeter. Gas chromatography was carried out on a Shimadzu GC-4A instrument with a column packed with 10% SE-30.

All experiments were carried out under a slight positive pressure of argon. Column chromatography was performed with Nakarai Chemicals 70—230 mesh silica gel. Wako's precoated thin-layer silica $PF70_{254}$ plates were used for monitoring the reactions. MPLC (medium-pressure chromatography) was performed with a Michael-Miller column (Ace Glass Co.) packed with 230—400 mesh silica gel (Nakarai Chemicals). Analytical high performance liquid chromatography (HPLC) was carried out on a Waters Associates chromatograph by using a μ-Polasil column and monitoring at 254 nm. Peak areas were measured with a Shimadzu (Chromatopac C-R3A) integrator. Evaporation of the solvents was performed by a rotary evaporator below 15 °C.

Ethyl (−)-(*Z*)-(*R*)$_s$-2-Methyl-3-(*p*-tolylsufinyl)propenoate (6). To a stirred solution of diethyl *p*-tolylsulfinylmethylphosphonate[13] (4.74 g, 16.3 mmol), $[\alpha]_D^{24}$ +96.3° (*c* 1.3, $CHCl_3$) in dry THF (50 ml) was added dropwise 1.56 M (1 M=1 mol dm^{-3}) *n*-BuLi in hexane (21 ml, 32.8 mmol) at −80 °C over a period of 9 min. After stirring at the same temperature for 30 min freshly distilled ethyl pyruvate (3.5 ml, 31.9 mmol) in dry THF (20 ml) was added dropwise for 10 min. After an additional 10 min the orange-colored mixture was quenched with 3% hydrochloric acid to become slightly acidic. The solvent was removed by a rotary evaporator and the aqueous solution was extracted with $CHCl_3$ (3×100 ml). The extracts were washed with water (3×100 ml), dil. $NaHCO_3$ aq (2×100 ml), sat. brine (100 ml) and dried ($MgSO_4$). After evaporation of the solvent the crude oil was purified by MPLC (hexane-ethyl acetate 7:3). Initial fractions contained pure (*E*)-**6** (1.033 g, 25%). Late fractions gave pure (*Z*)-**6** (1.222 g, 33%). (*E*)-**6**: bp 125—130 °C/0.1 mmHg (1 mmHg=133.322 Pa); $[\alpha]_D^{25}$ −78.9° (*c* 1.26, $CHCl_3$); IR (neat) 1730, 1630, 1050 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.28 (t, *J*=7 Hz, 3H), 2.30 (d, *J*=2 Hz, 3H), 2.45 (s, 3H), 4.22 (q, *J*=7 Hz, 2H), 7.18 (m, 1H), 7.33, 7.58 (ABq, *J*=8 Hz, 2×2H). Found: C, 61.76; H, 6.24%. Calcd for $C_{13}H_{16}O_3S$: C, 61.87; H, 6.40%; MS *m/z* 253 (M^+ +1), 236, 204, 159. (*Z*)-**6**: bp 130—135 °C/0.1 mmHg; $[\alpha]_D^{24}$ −390.8° (*c* 1.18, $CHCl_3$); IR (neat) 1720, 1660, 1600, 1090 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.36 (t, *J*=7 Hz, 3H), 2.03 (d, *J*=2 Hz, 3H), 2.40 (s, 3H), 4.33 (q, *J*=7 Hz, 2H), 6.50 (m, 1H), 7.28, 7.72 (ABq, *J*=8 Hz, 2×2H). Found: C, 61.8; H, 6.2%. Calcd for $C_{13}H_{16}O_3S$: C, 61.87; H, 6.40%; MS *m/z* 253 (M^+ +1), 236, 204, 159.

If the reaction conditions (−80 °C) are not maintained throughout, partial racemization occurs, resulting in low optically active (*E*)- and (*Z*)-**6**.

As indicated in the preliminary communication,[13] a Emmons-Horner condensation using NaH as a base gave the (*E*)- and (*Z*)-**6** in 23 and 10% yields, respectively. A variety of conditions were explored to optimize the yields. Finally, it was found that the reaction conducted by the use of *n*-BuLi as a base, at low temperature, gave slight satisfactory yields of (*Z*)-**6** (33%) and (*E*)-**6** (25%).

Diels-Alder Reaction of (*Z*)-6 and Cyclopentadiene. A mixture of freshly distilled cyclopentadiene (240 ml, 2.9 mol) and (*Z*)-**6** (22.13 g, 87.8 mmol, $[\alpha]_D^{26}$ −337° (*c* 1.0, $CHCl_3$)) was heated at 90 °C for 5 h in a pressure bottle tightly sealed with a stainless steel cap. Unreacted cyclopentadiene was removed under reduced pressure to give crude material, which was filtered by a silica-gel column (6×40 cm) in hexane. Elution with the solvent gave dicyclopentadiene. Elu-

tion was continued with ethyl acetate giving a mixture of **7**—**9** and recovered **6**. The HPLC analysis (hexane-ethyl acetate 1 : 1) of the crude product showed a mixture of 32 : 66 : 2 (**7** : **8** : **9**). Thus, the diastereomeric excesses of exo and endo sulfoxides were determined to be 100% and 94%, respectively. The crude mixture was chromatographed on silica gel (MPLC, 350 g) with hexane-ethyl acetate (1 : 3) to afford (*Z*)-**6** (1.084 g). Elution with ethyl acetate gave **7** (8.772 g, 31%), **8** (16.011 g, 57%), and **9** (0.848 g, 3%).

Ethyl (+)-(*R*)$_S$-(1*R*,4*S*)-*endo*-2-Methyl-*exo*-3-(*p*-tolylsulfinyl)bicyclo[2.2.1]hept-5-ene-*exo*-2-carboxylate (7). mp 91 °C (hexane); $[\alpha]_D^{24}$ +60.2° (*c* 0.72, $CHCl_3$); IR (KBr) 1725, 1600, 1040 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.17 (s, 3H), 1.33 (t, *J*=7 Hz, 3H), 1.57 (br d, *J*=9 Hz, 1H), 2.23 (d, *J*=9 Hz, 1H), 2.25 (d, *J*=3 Hz, 1H), 2.45 (s, 3H), 3.1 (br s, 1H), 3.2 (br s, 1H), 4.24 (q, *J*=7 Hz, 2H), 6.12 (br s, 2H), 7.20, 7.47 (ABq, *J*=9 Hz, 2×2H). Found: C, 67.92; H, 6.94%. Calcd for $C_{18}H_{22}O_3S$: C, 67.88; H, 6.98%; MS *m*/*z* 319 (M^+ +1), 273, 179.

Ethyl (−)-(*R*)$_S$-(1*S*,4*S*)-*exo*-2-Methyl-*endo*-3-(*p*-tolylsulfinyl)bicyclo[2.2.1]hept-5-en-*endo*-2-carboxylate (8). mp 85—86 °C (hexane); $[\alpha]_D^{19}$ −4.82° (*c* 0.65, $CHCl_3$); IR (KBr) 1730, 1600, 1030 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.12 (*J*=8 Hz, 3H), 1.12 (s, 3H), 1.54 (s, 2H), 2.30 (s, 3H), 2.83 (s, 1H), 3.10 (d, *J*=4 Hz, 1H), 3.40 (s, 1H), 4.00 (m, 2H), 6.18 (dd, *J*=6, 3 Hz, 1H), 6.47 (dd, *J*=6, 3 Hz, 1H), 7.20, 7.70 (ABq, *J*=8 Hz, 2×2H). Ethyl (−)-(1*R*,4*S*)-*exo*-2-Methyl-*endo*-3-(*p*-tolylthio)-bicyclo[2.2.1]heptane-*endo*-2-carboxylate (10). A mixture of **8** (3.59 g, 11.3 mmol) and 10% Pd on carbon (495 mg) in ethanol (45 ml) was evacuated, flushed with hydrogen and stirred vigorously under hydrogen atmosphere at room temperature for 7 h. The mixture was filtered through a short pad of Celite and the filter pad was washed with warm ethanol (4×25 ml). Solvent evaporation gave the dihydro sulfoxide (3.61 g, 100%). mp 67 °C (hexane); $[\alpha]_D^{26}$ −104.6° (*c* 1.01, $CHCl_3$); IR (melt) 1730, 1600 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.77 (s, 3H), 1.27 (t, *J*=7 Hz, 3H), 1.3—1.7 (m, 6H), 2.2 (br, 1H), 2.40 (s, 3H), 2.6 (m, 1H), 3.0 (br, 1H), 4.13 (q, *J*=7 Hz, 2H), 7.20, 7.67 (ABq, *J*=8 Hz, 2×2H). Found: C, 67.40; H, 7.53%. Calcd for $C_{18}H_{24}O_3S$: C, 67.47; H, 7.55%; MS *m*/*z* 321 (M^+ +1), 181, 153.

To a solution of the sufoxide obtained above (3.396 g, 10.6 mmol) in ethanol (30 ml) was added dropwise ca. 25% aq. $TiCl_3$ solution (8 ml, 13 mmol) at room temperature. The reaction mixture was stirred for 1 h and diluted with water (50 ml). Most of the ethanol was evaporated and the aqueous layer was extracted with ether (5×50 ml). Evaporation and purification by distillation afforded pure sulfide **10** (2.952 g, 92%). bp 110—113 °C/0.2 mmHg; $[\alpha]_D^{26}$ −7.32° (*c* 1.09, $CHCl_3$); IR (neat) 1725, 1500 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.2—1.8 (m, 6H), 1.30 (t, *J*=7 Hz, 3H), 1.38 (s, 3H), 2.2 (br s, 2H), 2.32 (s, 3H), 3.00 (dd, *J*=4, 2 Hz, 1H), 4.17 (q, *J*=7 Hz, 2H), 7.00, 7.27 (ABq, *J*=8 Hz, 2×2H). Exact mass Found: *m*/*z* 304.1462. Calcd for $C_{18}H_{24}O_2S$: M, 304.1497; MS *m*/*z* 304 (M^+), 236, 153, 91.

Ethyl (−)-(1*S*,4*R*)-*exo*-2-Methyl-3-oxobicyclo[2.2.1]-heptane-*endo*-2-carboxylate ((−)-11). A mixture of sulfide **10** (216 mg, 0.7 mmol) and NCS (513 mg, 3.8 mmol) in CCl_4 (6 ml) was refluxed for 30 min. The reaction mixture was filtered and the filtrate was concentrated to dryness. Without further purification the crude product was successively treated with $CuCl_2 \cdot 2H_2O$ (309 mg, 2 mmol), CuO (247 mg, 3.1 mmol), acetone (10 ml) and water (1 ml) to reflux for 20 min. The reaction mixture was then filtered through a short pad of Celite and the filtrate was concentrated. The residue was partitioned with ether (2×30 ml) and water (10 ml). The combined ether portions were washed with sat. brine, dried ($MgSO_4$) and concentrated. The crude product was purified by silica-gel chromatography(benzene and then ether) to give **11** (119 mg, 85%). A prolonged heating resulted in gradual decomposition of the product. **11**: bp 114—118 °C/7 mmHg; $[\alpha]_D^{26}$ −7.15° (*c* 1.55, $CHCl_3$); IR (neat) 1750, 1720 cm^{-1}; ^1H NMR (CCl_4) δ=1.0—2.0 (m, 6H), 1.27 (t, *J*=8 Hz, 3H), 1.27 (s, 3H), 2.53 (br, 2H), 4.13 (q, *J*=8 Hz, 2H). Exact mass Found: *m*/*z* 196.110. Calcd for $C_{11}H_{16}O_3$: M, 196.110. In the NMR spectrum of (±)-**11**, the two enantiotopic tertiary methyl hydrogens resonate at 3.17 and 3.28 ppm due to (+)- and (−)-enantiomer, respectively, by adding a chiral shift reagent, tris[3-(heptafluoropropylhydroxymethylene)-*d*-camphorato]europium(III) (Eu(hfc)$_3$). No such separation was observable under the same conditions (0.28 equiv used) in the spectrum of (−)-**11** derived from **10**.

Ethyl (−)-(1*R*,4*S*)-*exo*-2-Methyl-3-methylenebicyclo[2.2.1]-heptane-*endo*-2-carboxylate (13). A suspension of activated zinc dust (2.124 g, 32.5 mmol) and dibromomethane (1.2 ml, 17.1 mmol) in dry THF (10 ml) was treated with 1 M $TiCl_4$ solution in CH_2Cl_2 (3.8 ml, 3.8 mmol) at room temperature. Instantaneous reaction occurred under evolution of heat and the color changed to dark brown. After 20 min **11** (730 mg, 3.72 mmol) in dry THF (10 ml) was added by a syringe for 15 min. The suspension was stirred for 21 h at room temperature. The reaction mixture was diluted with ether (20 ml) and poured into 5% hydrochloric acid (15 ml). The aqueous layer was extracted with ether (5×20 ml). The extracts were washed with brine, dried ($MgSO_4$) and concentrated. Purification by chromatography on silica gel gave **13** (288 mg, 40%). bp 76—81 °C/13 mmHg; $[\alpha]_D^{29}$ −46.3° (*c* 0.75, $CHCl_3$); IR (neat) 1735, 1718, 1260, 1250 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.27 (t, *J*=7 Hz, 3H), 1.33 (s, 3H), 1.1—1.8 (m, 6H), 2.33 (br s, 1H), 2.73 (br s, 1H), 4.17 (q, *J*=7 Hz, 2H), 4.83 (s, 1H), 5.03 (s, 1H). Exact mass Found: *m*/*z* 194.1303. Calcd for $C_{12}H_{18}O_2$: M, 194.1306; MS *m*/*z* 194 (M^+), 149, 121, 93; R_f 0.44 (benzene).

(+)-(1*R*,4*S*)-*exo*-2-Methyl-3-methylenebicyclo[2.2.1]-heptane-*endo*-2-methanol (14). Diisobutylaluminium hydride (1 M in hexane, 3 ml, 3 mmol) was added slowly to a solution of **13** (288 mg, 1.48 mmol) in dry ether (5 ml) at −78 °C. The mixture was stirred for 1 h at that temperature and diluted with 5% hydrochloric acid (5 ml). The clear solution was extracted with ether (5×10 ml) and the extracts were washed with sat. brine and dried ($MgSO_4$). Evaporation gave **14** (226 mg, 100%) as an oil, which crystallized. bp 117—121 °C/63 mmHg; mp 74—79 °C (pentane); $[\alpha]_D^{24}$ +96.2° (*c* 0.85, $CHCl_3$); IR (neat) 3380, 1645 cm^{-1}; ^1H NMR

($CDCl_3$) δ=1.12 (s, 3H), 1.0—2.0 (m, 6H), 2.13 (br s, 1H), 2.72 (br s, 1H), 3.50 (s, 2H), 4.47 (s, 1H), 4.80 (s, 1H). Found: C, 79.01; H, 10.41%. Calcd for $C_{10}H_{16}O$: C, 78.90; H, 10.59%; MS *m/z* 152 (M^+), 121, 79; R_f 0.1 (benzene).

(+)-(1*R*,4*S*)-*exo*-2-Methyl-3-methylenebicyclo[2.2.1]-heptane-*endo*-2-carbaldehyde (15). A mixture of PCC (1.084 g, 5.03 mmol), **14** (226 mg, 1.48 mmol) and Molecular Sieves 4A (822 mg) in dry CH_2Cl_2 (5 ml) was stirred vigorously for 30 min. The mixture was diluted with ether (15 ml) and the ether layer was filtered through a short pad of Florisil. This work-up was repeated three times and the filtrates were concentrated to give the aldehyde **15** (158 mg, 90%). bp 113—117 °C/80 mmHg; $[\alpha]_D^{28}$ +17.1° (*c* 1.46, $CHCl_3$) ; IR (neat) 1715, 880 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.13 (s, 3H), 1.0—2.0 (m, 6H), 2.30 (br s, 1H), 2.83 (br s, 1H), 4.60 (s, 1H), 5.03 (s, 1H), 9.60 (s, 1H). Exact mass Found: *m/z* 150.1007. Calcd for $C_{16}H_{14}O$: M, 150.1043; MS *m/z* 150 (M^+), 149, 113, 57; R_f 0.52 (benzene).

(*E*)-Ethyl (−)-(1*R*,4*S*)-3-[*exo*-2-Methyl-3-methylene-bicyclo[2.2.1]hept-*endo*-2-yl]-2-propenoate (16). To a solution of triethyl phosphonoacetate (0.6 ml, 3.02 mmol) in dry THF (3 ml) was added 1.62 M *n*-BuLi in hexane (1.8 ml, 2.92 mmol) at −78 °C. After 45 min the reaction mixture was added to a stirred solution of **15** (158 mg, 1.05 mmol) in dry THF (2 ml) by a cannula. The mixture was stirred at that temperature for 30 min. Diluted hydrochloric acid was poured into the mixture and the aqueous layer was extracted with ether (5×10 ml). The combined extracts were washed with brine, dried ($MgSO_4$) and concentrated. The crude oil was purified by chromatography (ether/pentane 1 : 4) to give **16** (223 mg, 96%). bp 116—121 °C/15 mmHg; $[\alpha]_D^{28}$ −132.5° (*c* 1.12, $CHCl_3$); IR (neat) 1719, 1642, 1280, 1170 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.17 (s, 3H), 1.30 (t, *J*=7 Hz, 2H), 1.0—2.0 (m, 6H), 2.10 (br s, 1H), 2.77 (br s, 1H), 4.18 (q, *J*=7 Hz, 2H), 4.52 (s, 1H), 4.97 (s, 1H), 5.92 (d, *J*=16 Hz, 1H), 6.93 (d, *J*=16 Hz, 1H). Exact mass Found: *m/z* 220.1487. Calcd for $C_{14}H_{20}O_2$: M, 220.1462; MS *m/z* 220 (M^+), 191, 147, 91; R_f 0.50 (benzene).

Ethyl (+)-(1*R*,4*S*)-3-[*exo*-2-Methyl-3-methylenebicyclo-[2.2.1]hept-*endo*-2-yl]propanoate (17). A mixture of **16** (281 mg, 1.28 mmol), triethylsilane (0.3 ml, 1.9 mmol) and a catalytic amounts of tris (triphenylphosphine) chlororhodium was heated at 90 °C for 20 min. After cooling, ethanol (0.5 ml) was added to the mixture. The mixture was concentrated and the crude oil was chromatographed (ether-pentane 1 : 5) to give **17** (283 mg, 100%). bp 140—144 °C/15 mmHg; $[\alpha]_D^{26}$ +25.8° (*c* 2.45, $CHCl_3$); IR (neat) 1738 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.00 (s, 3H), 1.27 (t, *J*=7 Hz, 3H), 1.0—2.6 (m, 11H), 2.70 (br s, 1H), 4.16 (q, *J*=7 Hz, 2H), 4.53 (s, 1H), 4.78 (s, 1H). (−)-(1*S*,4*R*)-*endo*-2-Hydroxy-*exo*-3-methylbicyclo[2.2.1]heptane-*endo*-2-methanol (22). A solution of keto ester **21** (2.328 g, 12 mmol) in dry Et_2O (10 ml) was added to a suspension of $LiAlH_4$ (1.163 g) in dry Et_2O (30 ml) at 0 °C. The mixture was stirred for 3 h at room temperature. The excess of reagent was destroyed by addition of a minimal amount of H_2O. The mixture was filtered and the filtrate was concentrated under vacuum. Purification by crystallization from *i*-Pr_2O afforded diol **22** (1.282 g, 69%). mp 108—110 °C; $[\alpha]_D^{25}$ −8.55° (*c* 0.52, $CHCl_3$); IR (KBr) 3320, 2975, 1470, 1355 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.92 (s, 3H), 1.0—2.0 (m, 7H), 2.32 (br, 1H), 2.55 (br, 2H, OH), 3.35 (s, 2H), 3.75 (d, *J*=4 Hz, 1H). Found: C, 69.43; H, 10.23%. Calcd for $C_9H_{16}O_2$: C, 69.19; H, 10.32%; MS *m/z* 138 (M^+ −18), 123, 107, 95, 69, 67.

(−)-(1*S*,4*R*)-*endo*-2-Methyl-3-oxobicyclo[2.2.1]heptane-*exo*-2-carbaldehyde (23). To a solution of CH_2Cl_2 (25 ml) and oxalyl dichloride (0.07 ml, 0.8 mmol) was added dropwise DMSO (0.12 ml, 1.7 mmol) in CH_2Cl_2 (0.5 ml) at −50—60 °C. The mixture was stirred for 3 min and the diol **22** (107 mg, 0.69 mmol) in CH_2Cl_2 (1 ml) was added dropwise over a period of 5 min. The reaction mixture was stirred for an additional 20 min. Triethylamine (4.5 ml, 32 mmol) was added and the mixture was stirred for 20 min. After diluting with H_2O (10 ml) the aqueous layer was extracted with CH_2Cl_2 (3×15 ml). The combined extracts were washed with dil HCl, sat. brine, dried ($MgSO_4$) and concentrated. Purification of the oily product by distillation gave keto aldehyde **23** (100 mg, 96%). bp 65—75 °C/6 mmHg; $[\alpha]_D^{24}$ −329.1° (*c* 0.43, $CHCl_3$); IR (neat) 2720, 1750, 1710 cm^{-1}; ^1H NMR (CCl_4) δ=1.20 (s, 3H), 1.3—2.1 (m, 6H), 2.57 (br, 1H), 2.83 (br, 1H), 9.36 (s, 1H). Found: C, 68.77; H, 8.03%. Calcd for $C_9H_{12}O_2$: C, 71.02; H, 7.95%. Exact mass Found: *m/z* 152.0841. Calcd for $C_9H_{12}O_2$: M, 152.0837; MS *m/z* 152 (M^+), 124, 109, 95, 67.

(−)-(1*S*,4*R*)-*endo*-2-Methyl-3-oxobicyclo[2.2.1]heptane-*exo*-2-carbaldehyde Dimethyl Acetal (24). Keto aldehyde **23** was dissolved in a 0.2 M methanolic solution of $CeCl_3 \cdot 7H_2O$ (1.5 ml, 0.3 mmol) and trimethyl orthoformate (0.166 ml, 1.5 mmol) was added to the solution. The reaction mixture was allowed to stand for 3 days at room temperature. After addition of sat. $NaHCO_3$ (3 ml), the mixture was extracted with Et_2O (3×15 ml) and the extracts were concentrated. Purification by distillation afforded acetal **24** (43 mg, 72%, purity >86% from vpc). An analytical sample was obtained by redistillation. bp 65—75 °C/3 mmHg; $[\alpha]_D^{24}$ −62.6° (*c* 0.71, $CHCl_3$); IR (neat) 1740, 1445, 1110, 1065 cm^{-1}; ^1H NMR (CCl_4) δ=0.95 (s, 3H), 1.12—1.87 (m, 6H), 2.37 (br, 1H), 2.62 (br, 1H), 3.32 (s, 3H), 3.38 (s, 3H), 4.12 (s, 3H). Found: C, 66.49; H, 9.24%. Calcd for $C_{11}H_{18}O_3$: C, 66.64; H, 9.15%; MS *m/z* 198 (M^+), 167, 139, 107, 75, 67.

In the ^1H NMR, racemic **24** (prepared from (±)-**21**) was resolved to a pair of singlets due to the tertiary methyl at 2.97 and 3.10 ppm using a chiral shift reagent Eu(hfc)$_3$ (1.67 equiv used). The acetal (−)-**24** showed the tertiary methyl signal at 2.97 ppm. The peak of the corresponding enantiomer was hardly observed within the limit of detection.

(−)-(1*S*,4*R*)-*endo*-2-Methyl-3-methylenebicyclo[2.2.1]heptane-*exo*-2-carbaldehyde Dimethyl Acetal (25). A suspension of activated Zn (129 mg, 2 mg atom) and CH_2Br_2 (0.04 ml, 0.57 mmol) in dry THF (0.5 ml) was treated with 1 M $TiCl_4$ in CH_2Cl_2 (0.4 ml, 0.4 mmol) at room temperature. During the reaction the color changed to dark brown. After 15 min, keto acetal **24** (72 mg, 0.36 mmol) in dry THF (0.5 ml) was added dropwise over a period of 15 min via a syringe. The mixture was stirred for 21 h at ambient temperature. The reaction mixture was partitioned with CH_2Cl_2 (5 ml) and sat. $NaHCO_3$ (5 ml). The aqueous layer was extracted with CH_2Cl_2 (3×10 ml). The combined extracts were concentrated to dryness. Purification by chromatography (pentane) afforded acetal **25** (43 mg, 60%, 51% purity from vpc). An analytical sample was obtained by a Kugelrohr distillation. bp 120—125 °C/42 mmHg; $[\alpha]_D^{24}$ −119.3° (*c* 0.91, $CHCl_3$); IR (neat) 1655, 1450, 1190, 1110, 1070, 985, 890 cm^{-1}; ^1H NMR ($CDCl_3$, 270 MHz) δ=1.08 (s, 3H), 1.0—1.9 (m, 6H), 2.32 (br, 1H), 2.69 (br, 1H), 3.49 (s, 3H), 3.48 (s, 3H), 4.01 (s, 1H), 4.73 (s, 1H), 4.84 (s,1H). Found: C, 70.40; H, 10.00%. Calcd for $C_{12}H_{20}O_2$: C, 73.43; H, 10.27%; MS *m/z* 167 (M^+ −29), 149, 93, 75.

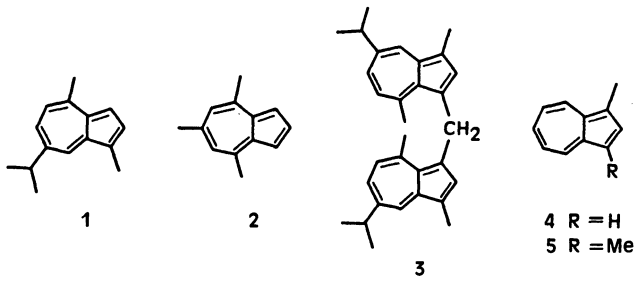
††Tokyo Research Laboratories, Takasago Corporation, 5-36-31 Kamata, Ohta-ku, Tokyo 144
(Received August 17, 1987)

Autoxidation of guaiazulene was examined in detail under the following conditions: in a highly diluted DMF solution, in DMF in the presence of acid or base (at 80—100 °C), and as solid state under sunlight or in the dark (at 25—50 °C). In all cases a wide variety of products were obtained (33 separable compounds altogether), and a comparable study on the distribution of the products under the various reaction conditions was made to establish more precise reaction pathways for the formation of these interesting compounds.

In the past few years we have undertaken a detailed study on various azulenes in *N,N*-dimethylformamide (DMF) or hexamethylphosphoric triamide: e.g., guaiazulene (**1**),[2)] 4,6,8-trimethylazulene (**2**),[2b,3)] 3,3′-methylenebisguaiazulene (**3**),[4)] 1-methyl- and 1,3-dimethylazulene (**4**,**5**)[5)] as well as azulene itself.[6)] As a result, these azulenes gave a wide variety of products possessing interesting structures through such several types of reactions as oxidative dimerization, oxidation of side chains, azulenequinone formation, intermolecular one-carbon transfer reactions, and rearrangements to naphthalenoid, benzenoid, and 1*H*-inden-1-one derivatives. The product distribution of these oxidation and coupling reactions was found to heavily depend upon the type of the starting azulenes employed, although the facility of the radical attack of oxygen (or various other free radical species) on the C-1 and C-3 position of the azulene nucleus mostly exceeded that on various positions of the seven-membered ring, as in the cases of many other electrophilic reactions of azulenes.[7)]



1 2 3 4 R = H 5 R = Me

We now wish to report in this paper the detailed study on autoxidation of guaiazulene (**1**) as a solid (at 25—50 °C) and in a DMF solution in the presence of base or acid (at 80—100 °C). This study was conducted to compare the mode of the oxidation under different reaction conditions to establish a further general aspect of the reaction mechanism of oxidation of azulenes by taking **1** as a representative, model compound.

Results and Discussion

Autoxidation of Guaiazulene (1). The oxidation was conducted under the conditions summarized in Table 1: namely, *A* (expt ii), in a much more dilute DMF solution than the previous experiment;[2)] *B* (expt iii), in a DMF solution in the presence of 1,4-diazabicyclo[2.2.2]octane (Dabco/DMF); *C* (expt iv), in a DMF solution in the presence of dilute sulfuric acid (H_2SO_4/DMF); *D* (expt v), as a solid under sunlight; *E* (expt vi) as a solid in a laboratory; *F* (expt vii), as a solid protected from light. The experiments in DMF solutions were carried out in a manner similar to that described previously[2)] by allowing finely bubbling oxygen to pass into a solution of the substrate **1** in DMF at 100 °C and the reaction was monitored by the use of the reversed phase high-pressured liquid chromatography (HPLC) or silica-gel TLC. The solid oxidation was conducted by impregnating **1** on a filter paper and allowing it to stand under the conditions shown in Table 1. The time-dependent HPLC diagrams of the expts ii—vii are shown in Fig. 1. Then, the reaction products were separated into each component by using chromatography, when about a half of the starting material was consumed. The products thus obtained as pure components [33 altogether besides the recovered starting material **1** (**1A**$_1$)] are referred to as Compounds **1A**—**S** according to the same

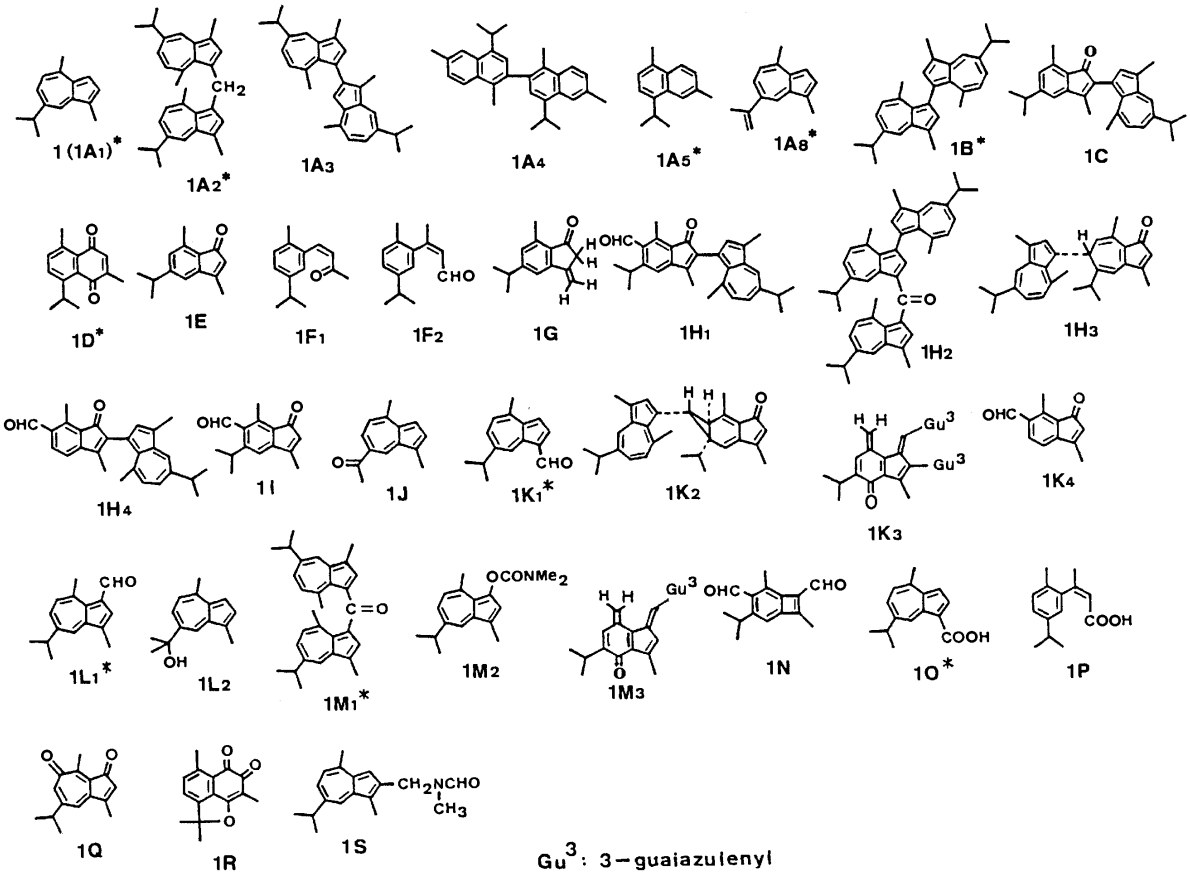

Chart 1. Structures of the autoxidation products from **1**; *previously known compounds.

definition employed in the previous study.[2-6]

In Chart 1 are summarized structures of these products which were established by spectroscopy and chromatography by taking into account the parameters established earlier[2-6] for similar compounds as will be explained below. Among these products, the followings were isolated for the first time in the present study: **1A**$_8$,[8] **1H**$_3$, **1H**$_4$, **1K**$_2$, **1K**$_3$, **1K**$_4$, **1L**$_2$, and **1M**$_3$; other products were identified as all known compounds.[9] The theoretical yields of these isolated products and of an unidentified resinous polar product of rather high molecular weights are summarized in Table 2.

Compounds **1A**$_8$ and **1M**$_3$ were shown to have compositions of $C_{15}H_{16}$ and $C_{15}H_{18}O$ by MS. Thus structures of 7-isopropenyl-[8] and 7-(1-hydroxy-1-methylethyl)-1,4-dimethylazulene were respectively assigned to these minor products by the careful comparison of the ^{1}H NMR spectral data (see the Experimental section) with those of the starting material **1**.

Compounds **1K**$_4$ and **1H**$_4$ showed similar UV and IR spectra to those[2] of **1I** and **1H**$_1$, respectively. The ^{1}H NMR spectra of **1K**$_4$ and **1H**$_4$ also closely resembled those[2] of **1I** and **1H**$_1$, respectively, except for the absence of 5-isopropyl group in **1K**$_4$ and **1H**$_4$. Therefore, the structures without the 5-isopropyl group were assigned to these newly isolated products and were confirmed by MS. Compound **1K**$_4$ appears to gradually dimerize on setting aside at 25 °C (after ca. 7 d).[10]

Compounds **1H**$_3$ and **1K**$_2$ (both $C_{30}H_{34}O$ by MS) were shown by ^{1}H NMR to be dimeric guaiazulenes having a 3-guaiazulenyl moiety ($C_{15}H_{17}$) attached to different nuclei that both consisted of $C_{15}H_{17}O$ containing a carbonyl group (1685—1680 cm^{-1}). By the careful analysis of the parameters of the ^{1}H NMR of these compounds as well as their reactivities (see below), structures of 6-(3-guaiazulenyl)-1(6*H*)-guaiazulenone (**1H**$_3$) and its norcaradiene isomer **1K**$_2$ were assigned to these products. When either of these compounds was kept in oxygen-free cyclohexane, a noticeable equilibrium was observed between them; the equilibrium ratio was 20/80 for **1H**$_3$/**1K**$_2$ at 25 °C. The reasons for the equilibrium in favor of **1K**$_2$ are assumed to be not only electronic and steric effects of the substituents on the cyclopropane ring but also the non-cyclopentadienone structure of the fused five-membered ring.[11] It is the first example, to the best of our knowledge, among carbocyclic compounds that both norcaradiene and cycloheptatriene forms have been separated as pure compounds and an equilibrium has been confirmed between them.[12]

Compounds **1M**$_3$ and **1K**$_3$ were found by MS to have dimeric ($C_{30}H_{32}O$) and trimeric ($C_{45}H_{48}O$) compositions, respectively. The ^{1}H NMR, UV, and IR spectra of both compounds showed the presence of a 3-guaiazulenyl group and a common non-azulenic nucleus containing a conjugated carbonyl; **1K**$_3$ contained another 3-guaiazulenyl group attached to the above nucleus. Combination of these spectral data led to 1-[(3-guaiazulenyl)methylene]-5-isopropyl-3-methyl-7-methylene-4,7-dihydro-4(1*H*)-indenone and its 2-(3-guaiazulenyl) derivative as the most likely structures

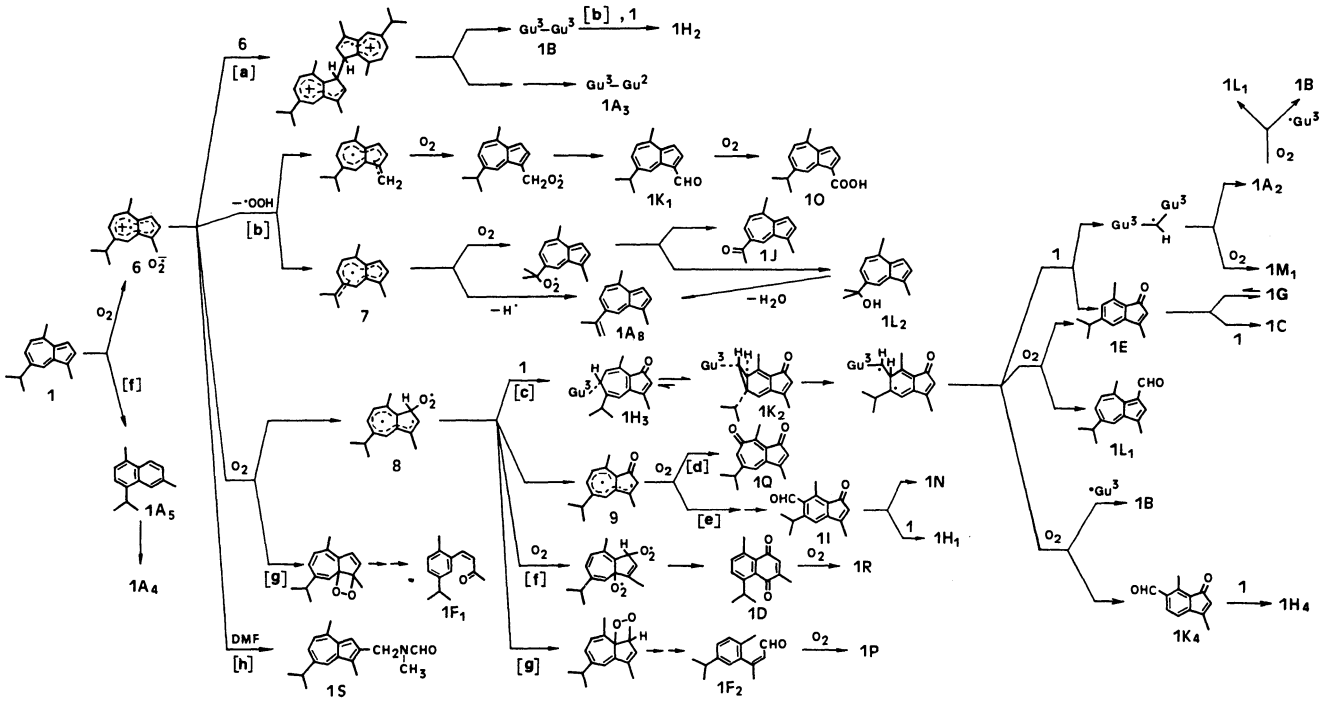
a) The yield of each product is based on the consumed **1** (see Table 1); *, Although the compound was detected by the HPLC and TLC checking during the oxidation, it was not isolable after the work-up owing to decomposition; —, the compound was not detected. b) [a]. Oxidative dimerization; [b], side-chain oxidation; [c], one-carbon-transfer reaction; [d], 1,7-azulenequinone formation; [e], rearrangement to indenone derivatives; [f], rearrangement to naphthalenoids; [g], rearrangement to benzenoids; [h], condensation with solvent. c) Expts i—vii correspond those in Table 1. d) Polar resinous substance.



Scheme 1. Possible reaction pathways for the autoxidation products from **1**.

for $\mathbf{1M_3}$ and $\mathbf{1K_3}$, respectively;[13] the assignments for the NMR parameters are given in the Experimental section.

Possible Reaction Pathways for the Formation of Autoxidation Products of 1 and a Comparative Study of the Product Distribution. Autoxidation of **1** under various different conditions has resulted in the simultaneous formation of many kinds of complex products by competitive processes as was observed earlier.[2] In order to grasp an overall view of the autoxidation of **1** and other azulenes, an attempt will now be made here to consider the various reaction pathways as a whole and the product distribution under these different conditions. The possible reaction pathways are summarized in Scheme 1, although many of these intermediates in the Scheme have been presented previously.[2]

By attack of oxygen, guaiazulene (**1**) is considered to initially form an electron-transfer complex **6**, which in turn leads to the formation of various products mainly through the following six kinds of reaction pathways [a]—[g] as illustrated in Scheme 1. The yields of the products shown in Table 2 are grouped together by the reaction pathway and the total yield of each pathway is also given in the Table. Although the figures of these yields do not necessarily reflect the ease of the corresponding reaction pathway, they are listed for a comparative study of the product distribution and the reaction pathways under various conditions as will be explained below.

[a] Oxidative Dimerization: It is characteristic that this type of reaction does not take place in dilute DMF or Dabco/DMF. Dimerization of **6** thus appears to be retarded by the presence of the base. Under other conditions, the 3,3′-dimer **1B** is always obtained as one of the main products in the oxidation, whereas 2,3′-dimer $\mathbf{1A_3}$ is formed in a much smaller quantity.

[b] Side-Chain Oxidation: Under all conditions employed in the present study, the methyl group at C-1 of the azulene nucleus is preferentially oxidized, giving the aldehyde $\mathbf{1K_1}$ as one of the main products. Of particular, it is noted that the yield of this type of compound considerably increases in the case of the solid oxidation in the dark and in Dabco/DMF, under which conditions other reactions are presumed to be relatively suppressed due to the facile decomposition (by Dabco) of the secondarily formed various peroxide intermediates.

Compared with the oxidation of 1-methyl group, the α-hydrogen of the isopropyl group at C-7 of **1** is not readily oxidized in all cases on the evidence of the extremely low yields of the 7-acetyl derivative **1J**. In the present study minor quantities of compounds $\mathbf{1A_8}$ and $\mathbf{1L_2}$ which are apparently derived through the same reaction pathways as **1J** (via **7**, see Scheme 1) have been obtained as well.

Also newly isolated in the present study are small quantities of compounds $\mathbf{1M_3}$ and $\mathbf{1K_3}$. The former is most likely formed by further oxidation[4] of $\mathbf{1A_2}$ accompanied by rearrangement, and the latter ($\mathbf{1K_3}$) is derived by condendation of $\mathbf{1M_3}$ with another molecule of **1**. This indicates that the side chain at C-4 is also susceptible, to a small extent, to the autoxidation of **1** as solid or in H_2SO_4-DMF. Under all conditions examined in the present study, the side chain oxidation as a whole is apparently one of the main reactions in the autoxidation of **1**, by taking into consideration

the total yield of the reaction products of this type.

[c] Intermolecular One-Carbon-Transfer Reaction: This reaction path has been established by the following additional, experimental facts[1] as illustracted in Scheme 1: *1)* 6-(3-guaiazulenyl)-1(6*H*)-guaiazulenone (**1H**$_3$) was isolated and confirmed to become in an equilibrium with the norcaradiene isomer **1K**$_2$; *2)* in the presence of one equivalent of **1**, **1K**$_2$ afforded 3,3′-methylenebisguaiazulene (**1A**$_2$) and 5-isopropyl-3,7-dimethyl-1*H*-inden-1-one (**1E**) under nitrogen at 100 °C in DMF; *3)* on exposure to air, however, **1K**$_2$ yielded 3-formylguaiazulene (**1L**$_1$) and **1E** at 25 °C. It has become evident presently that in the presence of oxygen **1K**$_2$ and **1** afford **1B** as well as **1K**$_4$ and **1H**$_4$, an elimination of the 5-isopropyl group being accompanied in the last to compounds. Compound **1A**$_2$ has also been confirmed to yield **1B** and **1L** in the presence of air. The most likely intermediates and the reaction pathways of these transformation are shown in Scheme 1.

It is a characteristic feature that only a very small quantity of **1A**$_2$ was obtained by the autoxidation of solid **1** and in dilute DMF or Dabco/DMF, whereas **1A**$_2$ was isolated as a main product in a concentrated DMF solution and in H_2SO_4/DMF. In particular, the presence of Dabco suppresses the reaction path [c] considerably as a whole. It is also notable in the present study that the presence of dilute sulfuric acid in DMF resulted in the formation of **1K**$_2$ in as high as 4% yield, although the role of acid on the reaction mechanism is still under investigation.

[d] 1,7-Guaiazulenequinone (1Q) Formation: As for the reaction path for **1Q**, diradical **8** and then 3-oxoguaiazulenyl radical **9** shown in Scheme 1 were presumed[2] as possible intermediates. It should be noticed that the solid autoxidation at 25—30 °C in the dark and the oxidation in Dabco/DMF produce **1Q** in as high as 19 and 10% yield, respectively (see Table 2). This would be mainly due to the stability of **1Q** under the above reaction conditions compared with others, although the exact role of Dabco in this case has also remained to be clarified. However, the present result is of significance in view of exploitation of a convenient synthetic scheme for azulenequinones, which are currently drawing increasing interest in the potential utility of the physicochemical properties and biological activity.[14]

[e] Rearrangement to 6-formyl-1*H*-inden-1-one (1I) and its Derivatives: This type of reaction takes place under all reaction conditions examined, yielding **1I** and its 2-(3-guaiazulenyl) derivative **1H**$_1$ illustrated in Scheme 1. The solid oxidation of **1** in the dark gives the highest total yield of the products via path [e].

[f] Rearrangement to Naphthalenoids: These compounds have been presumed[2] to be derived through the pathways shown as path [f] in Scheme 1. It has become apparent by the present experiment that no skeletal rearrangement of this type takes place in Dabco/DMF and as a solid, the reason for which is not certain at this stage.

[g] Rearrangement to Benzenoids: Although in relatively small quantities, these compounds have been found to be always produced under all conditions. However, this reaction path (Scheme 1) can be regarded as a minor one.

[h] Condensation with Solvent DMF: It has become apparent in the present study that the product **1S** of this type considerably increases in a dilute DMF solution and in the presence of Dabco/DMF.

The polar resinous substances (R_f=0 on TLC) appears to relatively decrease in the autoxidation of **1** in Dabco/DMF and as solid state in the dark, under which conditions various oligomerization and polymerization reactions seem to be suppressed.

Autoxidation of guaiazulene and the product distributions under various conditions have been closely examined. As a result, complex reaction pathways of the autoxidation of a representative, naturally occurring azulene **1** have been made clarified to a considerable extent. Such information in turn gives important suggestion for the elucidation of exact mechanism of the oxidation of azulenes using various other oxidizing reagents.[15]

Experimental

Melting points were determined with a Yanagimoto MP-S3 instrument and are uncorrected. Column chromatography was performed with Wako C-300 silica gel. TLC was conducted on plates precoated with silica gel 60F-254 (0.25 mm, Merck) by using 15:85 AcOEt–hexane as eluant. HPLC was carried out with Hitachi gel #3011 packed in a Pyrex column (ϕ 5 mm, 500 mm length) with 1 : 9 hexane–MeOH as solvent.

UV and IR (in MeOH and $CHCl_3$, respectively, unless otherwise specified) spectra were taken on a Hitachi 323 spectrophotometer and a Nihonbunko IR-A-202 Grating spectrometer, respectively. NMR spectra were recorded in $CDCl_3$ (unless otherwise stated) with a JEOL-FX200 cryospectrometer (200-MHz for ^{1}H and 50-MHz for ^{13}C) at 27 °C. Chemical shifts are reported as δ values in parts per million rel to tetramethylsilane (δ 0.0) as the internal standard. The assignments of all signals were made by employing a first-order analysis with the aid of decoupling technique and the parameters were confirmed by a computer-assisted simulation analysis. Mass spectra were taken on a JEOL JMS-HX100 (with a JEOL JMA-DA5000 mass data system) high-resolution instrument and are given in terms of m/z (rel intensity) compared with the base peak.

Oxidation of Guaiazulene (1) in DMF. A. In Dilute DMF Solution (expt ii): A soln of **1**[16] (0.020 g) in freshly distilled HMPA (20 g) was placed in a Pyrex flask (ϕ 18 mm, 600 mm height) and subjected to autoxidation by allowing finely bubbling oxygen to pass through the soln (from the bottom of the flask) for 24h at 100 ±5 °C. Time-dependent HPLC diagrams of this reaction are given in Fig. 1. After cooling, the mixture was diluted with water (200 cm^3) and extracted with ether (4×50 cm^3). The combined organic layers were washed with water, dried (Na_2SO_4), and evaporated in vacuo,

giving a brown oil. This oil was preliminarily separated into five fractions by means of preparetive HPLC with Hitachi gel #3019 (100 g) using methanol as eluant. Then each fraction was carefully separated by silica-gel column or thin layer with AcOEt-hexane; when necessary, this chromatographic procedure was repeated. Thus, the 22 products were obtained as pure substances (**1A—S**), besides the recovered starting material **1** (**1A**$_1$: 13.2 mg (66%); R_f=0.95) and polar resinous substances [1.5 mg, 22.2% (w/w), R_f=0.0]. The yield of each product based on the consumed starting material (6.8 mg) is summarized in Table 2.

B. In the Presence of Dabco (expt iii): The same oxidation procedures as those shown above (expt ii) were employed. Thus, a solution of **1** (1.00 g) dissolved in DMF (20 g) containing Dabco (0.28 g, 0.5 mole equiv.) was oxidized at 85±5 °C for 6 d, and the yield of each product is summarized in Table 2; 70% of the starting material **1** was recovered.

C. In the Presence of Sulfuric Acid (expt iv): Similarly, a solution of **1** (1.00 g) in DMF (20 g) containing 0.5 M sulfuric acid (5 cm^3) was oxidized, and the yield of each product is summarized in Table 2.

Oxidation of Solid Guaiazulene (1). A. Under Sunlight (expt v): Solid **1** (0.10 g) dissolved in hexane (0.5 cm^3) was homogeneously impregnated into a filter paper (70×50 mm, 0.27 mm thickness), which was hanged on a wire in a Pyrex beaker (500 cm^3) covered with a thin layer of cotton and allowed to stand at 40—50 °C for 8.5 d under the sunlight. After the same work-up, the yield of each product isolated is summarized in Table 2.

B. In a Laboratory (expt vi): **1** (0.10 g) was similarly oxidized on exposure to air in an ordinary laboratory room (without protection from light) at 25—35 °C for 134 d, and the yield of each product is summarized in Table 2.

C. Under the Protection from Light (expt vii): **1** (0.10 g) was similarly oxidized in a dark room at 25—35 °C for 127 d; the time-dependent HPLC diagrams are shown in Fig. 1. The yield of each product is summarized in Table 2.

7-Isopropenyl-1,4-dimethylazulene (Lactarazulene,[8] 1A$_8$). Blue prisms: mp 22 °C (Ref. 8, 20—22 °C); R_f 0.95; UV λ_{max} nm (log ε) 243 (4.53), 290 (4.58), 354sh (4.08), 368 (4.11), 374sh (4.10), 604 (2.94), 630sh (2.93), and 650sh (2.92); MS m/z 196 (M$^+$; 100), 181 (49), 165 (56), and 28 (54); ^{1}H NMR δ=2.27 (3H, brs, CH$_3$-C-7), 2.66 (3H, s, Me-1), 2.83 (3H, s, Me-4), 5.15 (1H, dq, J=1.0 Hz, (*E*)-HC=C-7), 5.27 (1H, brs, (*Z*)-HC=C-7), 6.97 (1H, d, $J_{5,6}$=11.0 Hz, H-5), 7.23 (1H, d, $J_{2,3}$=4.0 Hz, H-3), 7.57 (1H, dd, $J_{6,8}$=2.0 Hz, H-6), 7.59 (1H, d, H-2), and 8.36 (1H, d, H-8); (Found: m/z 196.1281).

6-(3-Guaiazulenyl)-1(6*H*)-guaiazulenone (1H$_3$). Dark blue prisms: mp 137 °C (from hexane); R_f 0.64; UV λ_{max} (hexane) nm (log ε) 225sh (4.19), 249 (4.29), 290 (4.31), 307sh (4.20), 340sh (3.94), 355 (3.98), 373 (3.96), 624 (3.03), and 650sh (2.99); MS m/z 410 (M$^+$; 100), 395 (28), 367 (45), and 198 (66); IR 1685 cm^{-1} (C=O); ^{1}H NMR δ=1.08, 1.12 (3H each, d, J=7.0 Hz, *i*-Pr-5), 1.34 (6H, d, J=7.0 Hz, *i*-Pr-7′), 2.02 (3H, s, Me-4′), 2.26 (3H, d, $J_{2,Me}$=1.5 Hz, Me-3), 2.54 (1H, sept, HC-5), 2.67 (3H, s, Me-1′), 2.68 (3H, brs, Me-8), 3.01 (1H, sept, HC-7′), 4.66 (1H, d, $J_{6,7}$=6.0 Hz,H-6), 5.86 (1H, brd, H-7), 5.92 (1H, brq, H-2), 6.45 (1H, s, H-4), 6.79 (1H, d, $J_{5',6'}$=11.0 Hz, H-5′), 7.23 (1H, dd, $J_{6',8'}$=2.0 Hz, H-6′), 7.76 (1H, s, H-2′), and 8.09 (1H, d, H-8′), (DMSO-d_6) 1.07, 1.09 (3H each, d, J=7.0 Hz, *i*-Pr-5), 1.29 (6H, d, J=7.0 Hz, *i*-Pr-7′), 1.90 (3H, s, Me-4′), 2.26 (3H, d, $J_{2,Me}$=1.5 Hz, Me-3), 2.36 (3H, d, $J_{7,Me}$=1.5 Hz, Me-8), 2.63 (3H, s, Me-1′), 3.00 (1H, sept, HC-7′), 4.57 (1H, d, $J_{6,7}$=6.0 Hz, H-6), 5.89 (1H, dq, H-7), 5.95 (1H, qd, $J_{2,4}$≃0.3 Hz, H-2), 6.56 (1H, d, H-4), 6.83 (1H, d, $J_{5',6'}$=11.0 Hz, H-5′), 7.30 (1H, dd, $J_{6',8'}$=2.0 Hz, H-6′), 7.81 (1H, s, H-2′), and 8.05 (1H, d, H-8′).

Found: m/z 410.2620. Calcd for $C_{30}H_{34}O$: M, 410.2609.

2-(3-Guaiazulenyl)-3,7-dimethyl-1-oxo-1*H*-indene-6-carbaldehyde (1H$_4$). Dark red-violet prisms: mp 145 °C (from hexane); R_f 0.64; UV λ_{max} nm (log ε) 248 (4.15), 291 (4.15), 305sh (4.10), 351 (3.81), 368 (3.79), 384sh (3.73), and 526 (3.53); MS m/z 382 (M$^+$; 100) and 367 (23); IR 1700 and 1680 cm^{-1} (C=O); ^{1}H NMR δ=1.38 (6H, d, J=7.0Hz, *i*-Pr-7′), 2.38 (3H, s, Me-3), 2.64 (3H, s, Me-1′), 2.65 (6H, s, Me-7.4′), 3.08 (1H, sept, HC-7′), 6.96 (1H, d, $J_{5',6'}$=11.0 Hz, H-5′), 7.10 (1H, d, $J_{4,5}$=8.0 Hz, H-4), 7.38 (1H, dd, $J_{6',8'}$=2.0 Hz, H-6′), 7.39 (1H, s, H-2′), 7.82 (1H, d, H-5), 8.16 (1H, d, H-8′), and 10.63 (1H, s, OHC-6); ^{13}C NMR δ=197.27, 189.50, 151.43, 148.68, 145.70, 142.49, 141.15, 140.21, 139.63, 138.93, 135.78, 135.31, 133.79, 132.21, 131.16, 129.47, 128.07, 127.72, 125.03, 115.63, 37.96, 25.81, 24.70, 18.45, 17.81, and 12.96.

Found: m/z 382.1897. Calcd for $C_{27}H_{26}O_2$: M, 382.1933.

The Norcaradiene Isomer of 1H$_3$: 1-(3-Guaiazulenyl)-6a-isopropyl-2,5-dimethyl-1,1a,3,6a-tetrahydrocyclopropa[*f*]-inden-3-one (1K$_2$). Dark green prisms: mp 155 °C (from hexane); R_f 0.49; UV λ_{max} (hexane) nm (log ε) 228sh (4.18), 247 (4.27), 251 (4.28), 289 (4.25), 305sh (4.17), 364 (400), 385 (4.02), 638 (2.81), and 670sh (2.77); MS m/z 410 (M$^+$; 100), 395 (27), 367 (53), and 198 (78); IR 1680 cm^{-1} (C=O); ^{1}H NMR* δ=0.79, 0.87 (3H each, d, J=7.0 Hz, *i*-Pr-5), 1.11 (1H, sept, HC-5), 1.34 (6H, d, J=7.0 Hz, *i*-Pr-7′), 2.22 (3H, d, $J_{2,Me}$=1.5 Hz, Me-3), 2.46 (1H, d, $J_{6,7}$=5.5 Hz, H-7), 2.55 (1H, d, H-6), 2.58 (3H, s, Me-8), 2.63 (3H, s, Me-1′), 2.90 (3H, s, Me-4′), 3.01 (1H, sept, HC-7′), 6.08 (1H, q, H-2), 6.36 (1H, s, H-4), 6.84 (1H, d, $J_{5',6'}$=11.0 Hz, H-5′), 7.26 (1H, dd, $J_{6',8'}$=2.0 Hz, H-6′), 7.48 (1H, s, H-2′), and 8.05 (1H, d, H-8′), * the numbering of **1K$_2$** for the assignment of the NMR spectrum corresponds to that of **1H$_3$** for the purpose of comparison.

(Received August 21, 1987)

Anion radical salts of bis[1,2,5]thiadiazolotetracyanoquinodimethan (BTDA) containing forty kinds of alkylammonium ions were prepared whose molar ratios are unique for each cation and changed from 1 : 1 (**2A**—**2L**) to 2 : 3 (**2M**—**2Z**), 1 : 2 (**2a**—**2m**), and 2 : 5 (**2n**) with elongation of the side chains. The electrical conductivities of the salts are largely affected by the molar ratio and the spatial requirement of cations (ρ_{RT} 3.1 Ω cm for **2a** and 4.2×10^6 Ω cm for **2L**), and some of the salts exhibit high electrical conductivities (ρ_{RT} 3.1—8.3 Ω cm for **2a**—**2e**) with small anisotropy ($\rho_{//}$ 1.7 Ω cm, $\rho_{\perp}$ 21.6 Ω cm for a single crystal of **2g**). Three salts (**2A**, **2M**, and **2g**) showed semiconducting temperature dependence of electrical conductivity with the activation energies of 0.12—0.20 eV. The X-ray study of three kinds of the salts (**2A**, **2g**, and **2m**) revealed that two-dimensional networks are formed by S-N≡C interactions (3.12—3.33 Å) of BTDA anion radicals. The crystals of **2A** and **2g** showing higher conductivities consist of two-dimensionally expanded "ribbon" networks accompanied with equally spaced columnar stackings while molecules are pairing to form dyads in **2m** which exhibits lower conductivity.

Bis[1,2,5]thiadiazolotetracyanoquinodimethan (BTDA, **1**) which forms highly conductive charge-transfer complexes with some donors[1] is a new type of electron acceptor designed in anticipation of the possible interheteroatom interactions as well as the decreased Coulomb repulsion by the annelation of thiadiazole rings. Recently **1** has been revealed to form a two-dimensional "sheet-like" network by strong transverse interactions of S-N≡C in the crystal.[2] In connection with the importance of such interactions[3] in the superconducting $(TMTSF)_2X$ and $(BEDT\text{-}TTF)_2X$ salts,[4] it is extremely intriguing to examine the anion radical salts of **1** in which two-dimensional networks are also expected to be formed. We report here the electrical properties and crystal structures of BTDA anion radical salts containing simple ammonium ions, from which the two-dimensional character of these salts and the relationship between the properties and crsytal structures are discussed.

Results

Preparation of Anion Radical Salts. Most of the anion radical salts were prepared by reaction of BTDA **1** with corresponding alkylammonium iodides[5] in acetonitrile and some were prepared by reaction of **1** with free amines followed by the hydrogen abstraction of aminium cation radicals.[5] These salts were obtained as black powder or microcrystals and the molar ratios were determined on the basis of elemental analyses. They are summarized in Table 1 along with the decomposion points and CN stretching frequencies. Interestingly, the molar ratios of the salts were unique for the kind of ammonium ions as shown in Table 1. Attempts to obtain the 1 : 1 salts which correspond to the complex salts **2M**, **2T**, **2a**, **2i**, and **2m** by metathesis of $Li^+(BTDA)^-$ with corresponding ammonium iodides in acetonitrile were unsuccessful. In addition, treatment of the 1 : 1 salts **2A**, **2G**, and **2K** with another equivalent of BTDA in acetonitrile did not give the 1 : 2 salts but only starting 1 : 1 salts were recovered. This result is in sharp contrast to the case of 7,7,8,8-tetracyanoquinodimethan (TCNQ)[5] whose 1 : 1 salts give the corresponding 1 : 2 salts by treatment with another equivalent of TCNQ. On the other hand, the molar ratios of $BTDA^-$ salts seem to depend on the size and shape of the cations, and gradually change from 1 : 1 to 2 : 3, 1 : 2, and 2 : 5 with elongation of the side chain of ammonium ions. Thus, ethyltrimethylammonium ion forms 1 : 1 salt **2A**, while diethyldimethyl one forms 2 : 3 salt **2T** and triethylmethyl one forms 1 : 2 salt **2f**.

Electrical Conductivities of Anion Radical Salts. Electrical resistivities measured on the compaction samples with a two-probe method are shown in Table 1. Some of the complex salts (**2a**—**2e**) exhibit high electrical conductivities because the partial charge-transfer state[6] is easy to be achieved in these complex salts. It should be noted here that ethyltrimethylammonium 1 : 1 salt **2A** in which the complete charge transfer occurs shows fairy good conductivity (ρ 82 Ω cm). Unfortunately, easy twinning of the crystals prevented the measurements of electrical conductivity on single crystals for many cations. However, we succeeded in preparing three kinds of single crystals (**2A**, triethylammonium 2 : 3 salt **2M**, and methyltributylammonium 1 : 2 salt **2g**) which afford the following electrical resistivities (ρ) and activation energies (E_a): **2A**, ρ 33 Ω cm (E_a 0.198 eV); **2M**, ρ 1.3 Ω cm (E_a 0.124 eV); **2g**, $\rho_{//}$ 1.7 Ω cm (E_a 0.14 eV) along the c axis in the crystal, $\rho_{\perp}$ 21.6 Ω cm along the a axis in the crystal. These single crystal conductivities are rather lower

a) Measured on compaction pellets by two-probe method at room temperature. b) Containing one molar of H_2O.

than expected from those for the compaction samples because 50- to 1000-fold conductivity is expected in usual pseudo one-dimensional organic solids.[7] The anisotropy of the conductivity is very small for the salt **2g** (1:13:140—700[8] along the c, a, and b axes in the crystal), which clearly shows the two-dimensional electrical character of this salt.

Crystal Structure of Ethyltrimethylammonium 1:1 Salt (2A). Three views of the crystal structure of **2A** are shown in Figs. 1—3. The crystal of **2A** consists of segregated layers of anion radicals and cations. The BTDA anion radicals form a two-dimensional "ribbon" network along the c axis (Fig. 1) and stack in a "zigzag" fashion along the b axis (Fig. 2). The cations are packed in the cavity of the alternately stacked anion radicals to separate the planar networks. It should be noted that this stacking motif is quite similar to those found isostructurally in the $(TMTSF)_2X$ salts.[9] According to the crystallographic requirement that the molecules must lie on the mirror planes, the completely planar BTDA anion radicals are structurally equivalent and equally spaced. The molecular overlapping is a familiar "ring-double bond" type[10] (Fig. 4) and the stacking distance of 3.24 Å (b/2) is short enough to be compared with those for the conductive TCNQ complexes (3.17—3.26 Å).[11] The nota-

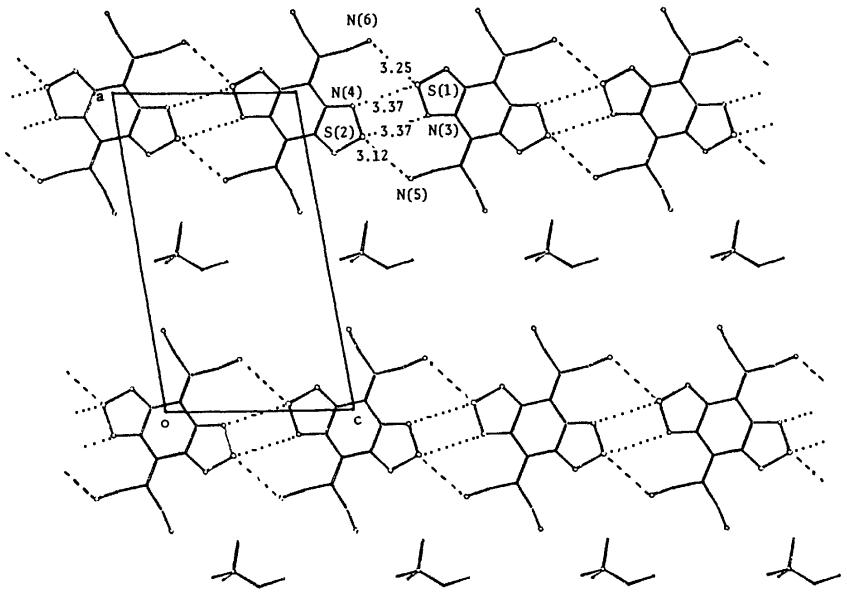

Fig. 1. "Ribbon" network of $BTDA^{-}$ in **2A**. S(1)-N(6)≡C(10) [3.25 Å] and S(2)-N(5)≡C(9) [3.12 Å] interactions are indicated by broken lines. Thiadiazole linkages of S(1)-N(4) [3.37 Å] and S(2)-N(3) [3.37 Å] are also indicated by dotted line.

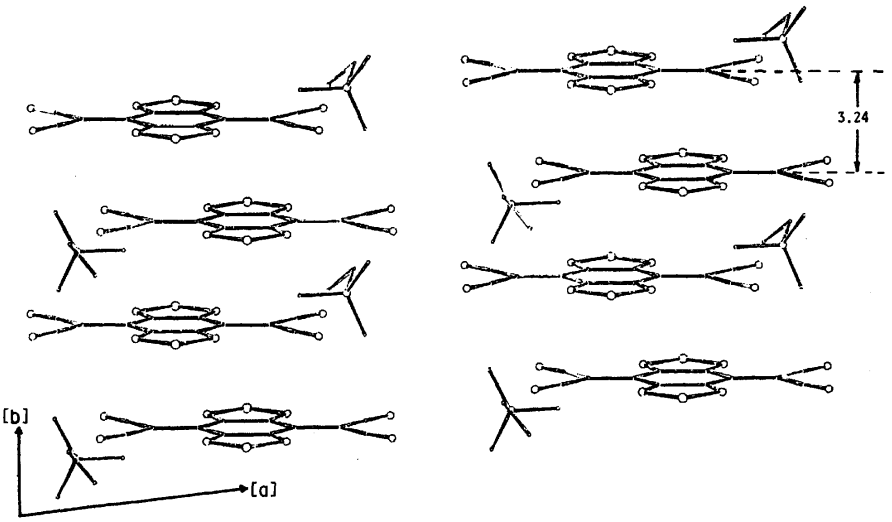

Fig. 2. "Zigzag" stacking in **2A** (tilted 10°). The ammonium N atoms locate on the same plane with the molecular plane of $BTDA^{-}$. Only one-sided mirror images are shown for the disordered ammonium ions.

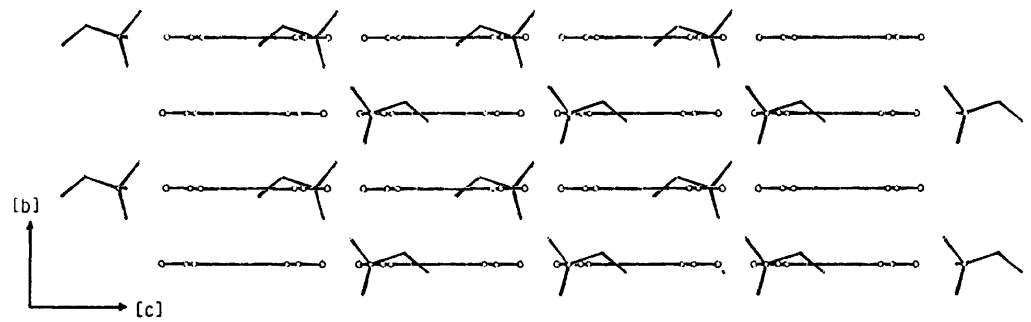

Fig. 3. Coplanar "ribbon" network in **2A** (side view). The interplanar distance is 3.24 Å. Only one-sided mirror images are shown for the disordered ammonium ions.

ble feature of this crystal is the two-dimensional "ribbon" network formed by two short S-N≡C interactions (3.12 and 3.25 Å) together with the thiadiazole linkages (3.37 Å) (Fig. 1). This network is also formed restrictedly in coplanar (Fig. 3), indicating the charge delocalization through the side-by-side network. The appearance of S-N linkage of fused rings, which does not exist in the crystal of neutral **1**,[2] is one of indications that the thiadiazole N atoms possess enhanced negative charge by delocalization since the S-N interaction between thiadiazole rings is caused by the polarized sulfur nitrogen bond.[12] The more definite indications appear in the molecular structure of $BTDA^{\cdot-}$ shown in Table 2 in which those of **1** and $TCNQ^{\cdot-}$[13] are also shown for comparisons. It should be pointed out that the dicyanomethylene C=C bond becomes shorter than that of $TCNQ^{\cdot-}$ (1.390 Å vs. 1.420 Å) and the thiadiazole C=N bond length is longer than that of **1** (1.346 Å vs. 1.330 Å).

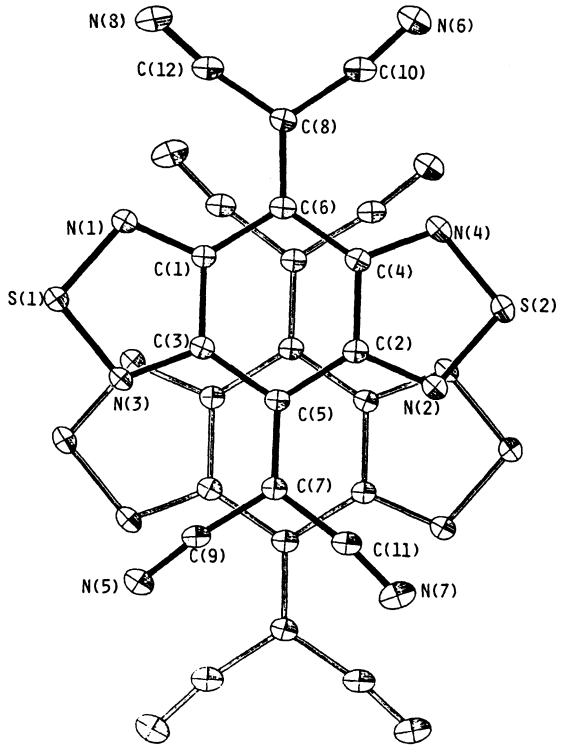

Fig. 4. "Ring-double bond" type overlapping in **2A**. Selected bond lengths: S(1)-N(1) 1.615(4), S(1)-N(3) 1.610(4), S(2)-N(2) 1.624(4), S(2)-N(4) 1.605(4), N(1)-C(1) 1.348(6), N(2)-C(2) 1.347(5), N(3)-C(3) 1.345(5), N(4)-C(4) 1.345(6), N(5)-C(9) 1.142(6), N(6)-C(10) 1.146(7), N(7)-C(11) 1.138(7), N(8)-C(12) 1.137(7), C(1)-C(3) 1.442(6), C(1)-C(6) 1.444(6), C(2)-C(4) 1.443(6), C(2)-C(5) 1.439(6), C(3)-C(5) 1.431(6), C(4)-C(6) 1.433(6), C(5)-C(7) 1.394(6), C(6)-C(8) 1.385(6), C(7)-C(9) 1.427(6), C(7)-C(11) 1.423(6), C(8)-C(10) 1.434(7), C(8)-C(12) 1.432(7) Å.

Crystal Structure of Methyltributylammonium 1:2 Salt (2g). Because of the positional disorder of the ammonium ions, the unit cell contains $Z=0.5$ for the formula of $MeBu_3N^+(BTDA)^{\cdot-}_2$. BTDA anion radicals are related by a center of symmetry at the origin of the unit cell. Similarly to the case of **2A**, the strong transverse interactions of S-N≡C (3.27 and 3.30 Å) connect the anion radicals to form a linear "ribbon" network along the a axis. The positionally disordered cations are packed between the "ribbon" networks along the b axis. An important difference from **2A** is that the networks are not coplanar but corrugated resulting in the formation of a three-dimensional "honeycomb" structure as shown in Fig. 5. Furthermore, the mode of stacking is a uniform type (not a zigzag type) in which BTDA anion radicals are structurally equivalent and equally spaced with the short interplanar distance of 3.24 Å (Fig. 6) and the "ring-double bond" type overlapping (Fig. 7). BTDA molecule possesses an almost planar conformation although the deviations of cyano groups from the molecular plane cause a slight twisting of the exo methylene double bond (1.6°). The bond lengths of dicyanomethylene C=C bond (1.379 Å) and thiadiazole C=N bond (1.340 Å) are intermediate between those in neutral **1** and those in 1 : 1 salt **2A** (Table 2), which reflect the fact that only a half of the negative charge is located on a BTDA molecule in 1 : 2 salt **2g**.

Crystal Structure of Tetraethylammonium 1:2 Salt (2m). Three views of crystal structure are shown in

Table 2. Comparison of Bond Lengths[a] (Å) in BTDA Molecule

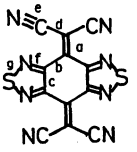

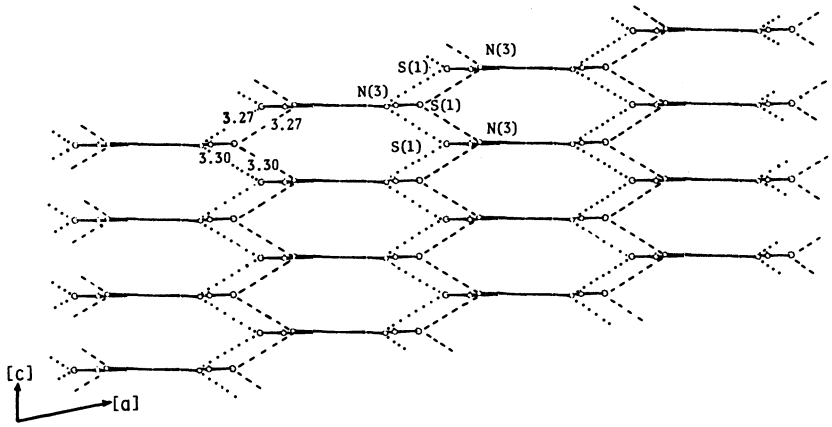

Fig. 5. "Honeycomb" network in **2g** (side view perpendicular to the molecular plane of BTDA). S(1)-N(3)≡C(5) [3.27 and 3.30 Å] interactions are indicated by broken lines. The interplanar distance is 3.24 Å. Disordered ammonium ions are not included for ease.

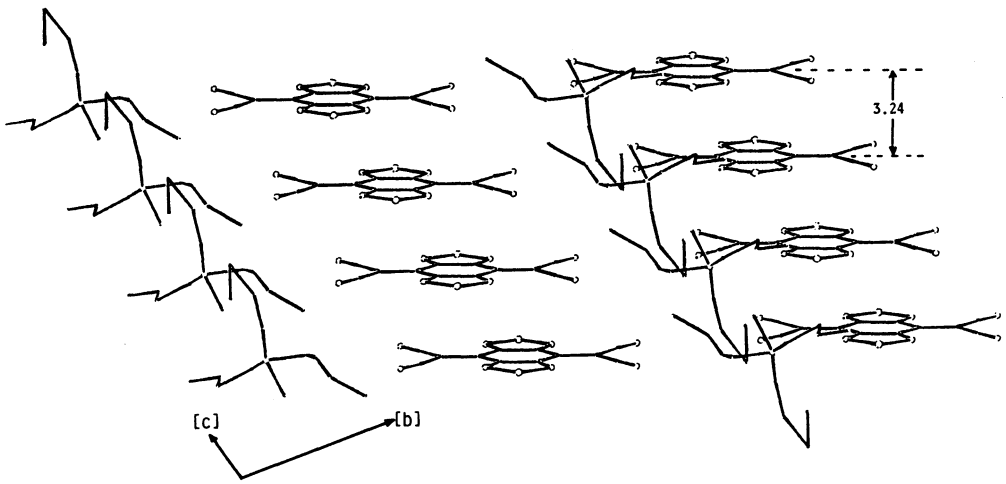

Fig. 6. Uniform segregated stacking in **2g** (tilted 10°). Ammonium ions are disordered along the stacking c axis (multiplicity 0.5), and also related by a center of symmetry which are not shown for ease.

Figs. 8—10. Because of $Z=2$ for the space group $P\bar{1}$, two different kinds of BTDA molecules exsist in the crystal (abbreviated as BTDA-1 and BTDA-2). Each molecule forms columnar stacks along the c axis in which molecules are not equally spaced but pairing to form dyads (Fig. 8). The interplanar distances are 3.17 and 3.39 Å for BTDA-1, and 3.26 and 3.41 Å for BTDA-2, respectively. Although each molecule forms corrugated "ribbon" networks along the a axis like **2g** (Figs. 9 and 10), these networks can not form the "honeycomb" because of the dyad formation as well as the ununiform overlapping patterns. That is, the molecular overlappings are "ring-double bond" type in the dyads for both BTDA-1 and BTDA-2, but molecules are slipped in parallel in the overlapping between the dyads (Figs. 11 and 12). Although both molecules are almost planar, slight twisting of dicyanomethylene C=C bond (2.8° and 1.4°) are observed for BTDA-2. Comparisons of molecular structure of BTDA-1 and BTDA-2 with those of neutral **1** and 1 : 1 salt **2A** indicate that BTDA-2 possesses the larger amount of negative charge than BTDA-1 (Table 2). For example, bond f for BTDA-2 is elongated [C(205)=C(207), 1.392 Å] which is nearly the same value with that for 1 : 1 salt **2A** [C(5)=C(7), 1.394 Å]. This charge distribution also affects the molecular packing. The cationic center of ammonium N atom is located on the same plane with the molecular plane of BTDA-2 (Fig. 10), while the molecular plane of BTDA-1 is shifted vertically (Fig. 9).

Discussion

The annelation of 1,2,5-thiadiazole rings to the TCNQ skeleton results in two significant differences from TCNQ itself. One of them is the two-dimensional electrical property and crystal structure formed by the strong interheteroatom interactions of

S-N≡C and the other is the decreased on-site Coulomb repulsion in the reduction form of **1**. The former is the most important characteristic of **1** since none of the organic electron acceptor have shown such a two-dimensional network so far.[14] The crystal structures described here are different from each other, indicating that the patterns of interactions are variable according to the spatial requirements of counter cations. This fact shows that the molecular interaction of BTDA is not only strong but also flexible. However, some common features are observed, which are the "ribbon" network and face-to-face columnar stacking. The "ribbon" is coplanar in **2A** and corrugated in **2g** and **2m**. The stacking pattern of **2A** is equally spaced "zig-zag" type like $(TMTSF)_2X$ salts and that of **2g** is equally spaced uniform type like TTF·TCNQ complex,[15] while molecules are dimerized in **2m** which is often observed in anion radical salts with low electrical conductivities. The fact that molar ratios of the salts are unique for each cation seems to be related with these networks since the ratios are gradually changed from 1:1 to 2:5 as the cations get larger. Cyclic ammonium ions tend to give 1:1 salts compared with corresponding acyclic cations as seen in a comparison of **2L** and **2J** with **2T** and **2S**. This fact also indicates that the spatial conditions play an important role in determining the molar ratios. This behavior is explained by considering that the cations locate between BTDA molecules which are connected in two directions of "ribbon" and stacking. Therefore, the larger the cation is, the more repeated units of "ribbon" and stacking are needed since the distances of the transverse S-N≡C interaction and the face-to-face overlapping are in some definite range of 3.12—3.33 and 3.17—3.41 Å, respectively. Once the molar ratio is determined with keeping this range of distances for a certain cation, the shape of the cation affects the mode of stacking and the "ribbon" network which reflect its electrical conductivity. These common features of the crystal structures make some difficulty in obtaining single crystals since disorder or twinning is very easy to occur in the direction where BTDA and cations are aligned alternately (the a axis for **2A**, the b axis for **2g** and **2m**). Whether the semiconducting properties of three salts (**2A**, **2M**, and **2g**) described here are attributed to this easy twinning or not is still ambiguous.

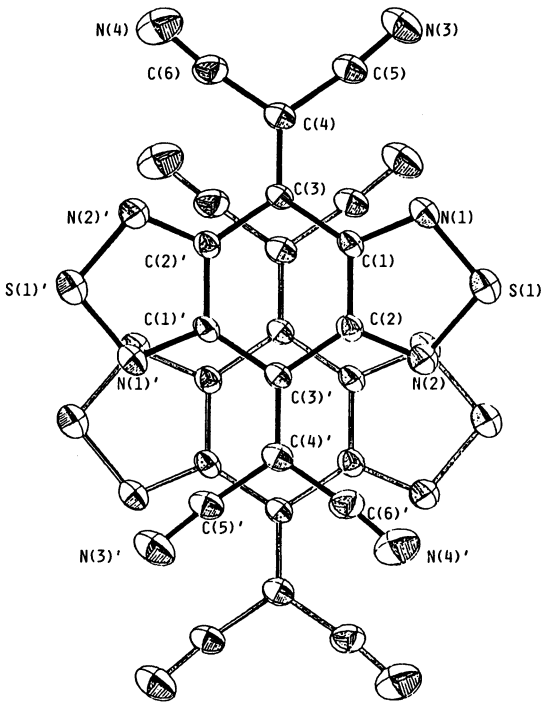

Fig. 7. "Ring-double bond" type overlapping in **2g**. Selected bond lengths: S(1)-N(1) 1.611(6), S(1)-N(2) 1.613(6), N(1)-C(1) 1.339(8), N(2)-C(2) 1.340(8), N(3)-C(5) 1.128(10), N(4)-C(6) 1.125(11), C(1)-C(2) 1.422(8), C(1)-C(3) 1.447(8), C(2)-C(3) 1.450(8), C(3)-C(4) 1.379(8), C(4)-C(5) 1.424(9), C(4)-C(6) 1.420(10) Å.

The second point is the decreased Coulomb repulsion in the reduction form of BTDA. This is first suggested by measuring the reduction potentials of **1**. The cyclic voltammogram of **1** shows four reversible reduction waves with the half wave potentials of −0.02, −0.49, −1.21, and −1.76 V vs. SCE.[1a,16] The

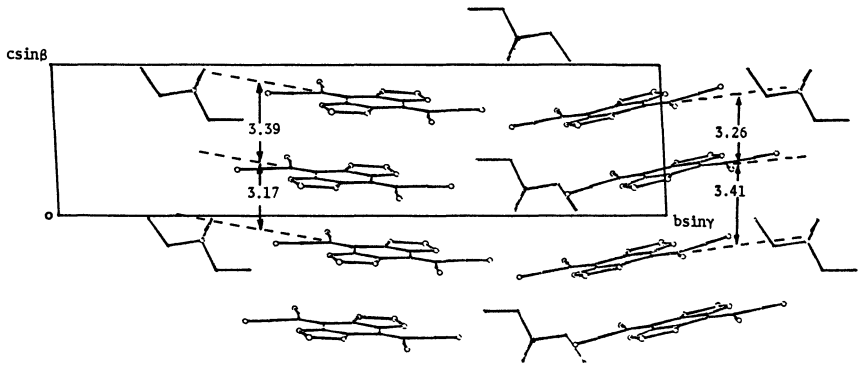

Fig. 8. Dimeric segregated columns in **2m** viewed along the a axis. The interplanar distances are 3.17 and 3.39 Å for BTDA-1 (left) and 3.26 and 3.41 Å for BTDA-2 (right), respectively.

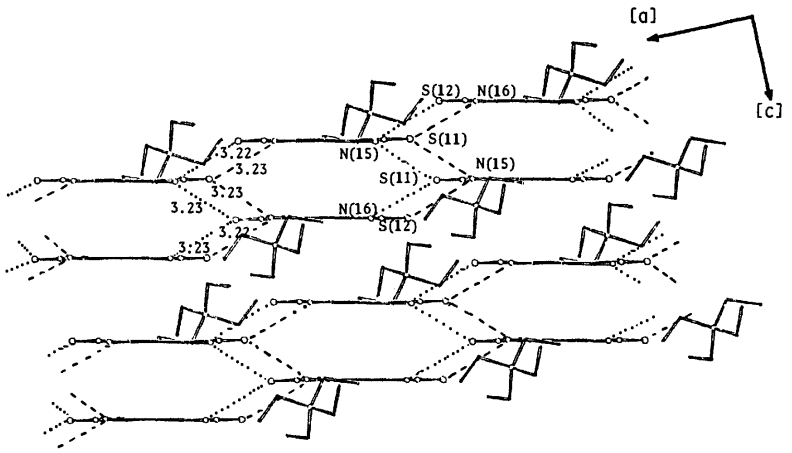

Fig. 9. Dimerized "ribbon" network of BTDA-1 in **2m** (side view). S(11)-N(15)≡C(109) [3.23 Å], S(11)-N(16)≡C(110) [3.23 Å], and S(12)-N(15)≡C(109) [3.22 Å] are indicated by broken lines.

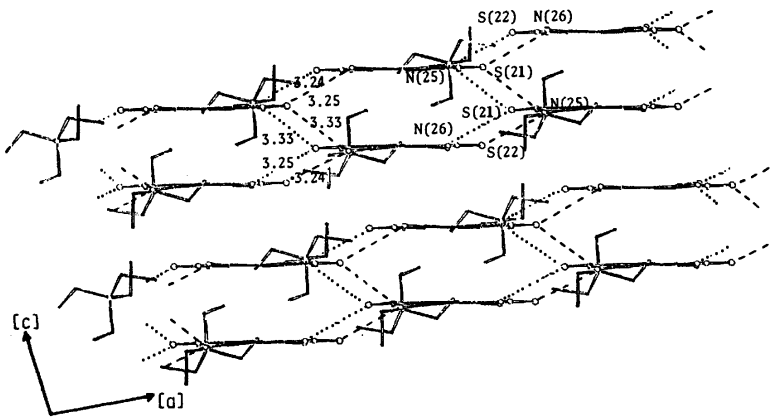

Fig. 10. Dimerized "ribbon" network of BTDA-2 in **2m** (side view). S(21)-N(25)≡C(209) [3.33 Å], S(21)-N(26)≡C(210) [3.25 Å], and S(22)-N(25)≡C(209) [3.24 Å] are indicated by broken lines.

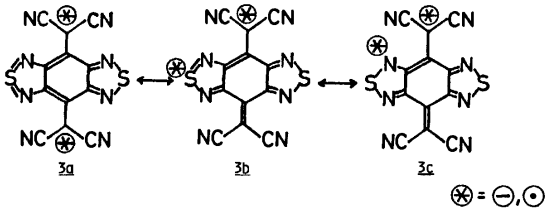
semiquinone formation constant (K_{sem}) calculated using these values is 8.10 while that of TCNQ is 9.31. This contraction is attributed to the decreased Coulomb repulsion of $\mathbf{1}^{\cdot-}$ compared with $TCNQ^{\cdot-}$. This is also suggested by the fact that the dianion of BTDA is easily isolated as stable sodium salts[17] while the dianion of TCNQ is unstable and isolated only when special metal complex ions were used.[18] In this study, the comparisons of the molecular geometry in BTDA molecule show that the negative charge is delocalized to the fused thiadiazole rings. That is, the C=N double bond of thiadiazole (bond f in Table 2) is elongated by adding the negative charge on a BTDA molecule (1.330 Å in BTDA°, 1.340 Å in $BTDA^{1/2\cdot-}$ and 1.346 Å in $BTDA^{\cdot-}$), which is rationalized by considering the contribution of the structures **3b** and **3c** (Scheme 1) for the anion radical of BTDA **1**. The fact that 1 : 1 salt **2A** which is completely charge transferred exhibits higher electrical conductivity than usual Mott insulators[19] may be attributed to this decreased Coulomb repulsion of $\mathbf{1}^{\cdot-}$.



Scheme 1.

Conclusion

This study has revealed the novel properties of $BTDA^{\cdot-}$ which can construct the segregated columnar stacks with the face-to-face overlapping (uniform type or zigzag type) as well as the "ribbon" networks (coplanar or corrugated) by strong transverse interactions.[20] The modes of overlapping and transverse interactions in $BTDA^{\cdot-}$ are strongly affected by the spatial requirements of the cations, while these interactions also define the molar ratios of the salts since the ratios were unique for the cations. Although all of

three anion radical salts examined here were semiconductors with the activation energies of 0.12—0.20 eV, BTDA and analogous compounds[21] containing higher chalcogen atoms instead of sulfur atoms are promising electron acceptors to afford organic metals whose metallic states are stabilized by the novel two-dimensional structures as described here.

Experimental

General. IR spectra were measured in KBr disks on a Shimadzu IR-435 spectrometer with a DR-1 data recorder. The ν_{CN} values were determined as the minima of the transmittances measured by every 0.5 cm^{-1} using the ν_{max} of 1944 and 1871 cm^{-1} of the polystyrene film as standard. All the melting points are uncorrected. Electrical resistivities were measured by a conventional two-probe method for compaction samples at room temperature, and by a four-probe method for single crystals using the gold wire and gold paste for the connection.

Materials. Anion radical salts **2A—2n** were prepared by reaction of BTDA (0.4 mmol) with the corresponding ammonium iodides (3—5 equivalents) in boiling acetonitrile (30 ml) except for the case of **2C**, **2N**, **2O**, **2P**, and **2Q** in which free amines (1 equivalent) were used instead of the iodides. The salts showed correct elemental analyses for C, H, and N (±0.4%) without purification. Single crystals of **2A** and **2M** were prepared by electrochemical reduction (5—10 μA) of BTDA (10^{-3} mol dm^{-3}) containing $Me_3NEt^+MeSO_4^-$ or $Et_3NH^+BF_4^-$ as supporting electrolyte (10^{-1} mol dm^{-3}) in acetonitrile. Single crystals of **2g** were obtained when a hot acetonitrile solution of **1** and the iodide was cooled slowly, and those for **2m** were prepared by recrystallization from acetonitrile.

Structural Analysis of Ethyltrimethylammonium 1 : 1 Salt (2A). A needle-like crystal with dimensions of 0.08×0.30×0.15 mm^3 along the a, b, and c axes was used for the X-ray study. Crystal data are as follows: a=15.854(1), b=6.482(1), c=9.141(1) Å, β=100.07(1)°, V=924.9(2) $Å^3$, $P2_1/m$, Z=2, D_{calcd}=1.47 g cm^{-3}. A total of 1979 independent reflections was collected with graphite monochromated Cu $K\alpha$ radiation (λ=1.5418 Å) up to 2θ=128° using a Rigaku automated four circle diffractometer (AFC-6). The structure was solved by the direct method and refined by the block-diagonal least-squares method. Refinement was converged successfully for the space group $P2_1/m$ rather than the non-centrosymmetric $P2_1$. Therefore, the molecules are restricted in the way that all the atoms of BTDA molecule are located on the mirror planes of y=1/4 and y=3/4. The cations are disordered in the way that methylene C atoms are separated largely in two mirror images while others are slightly shifted. Most of hydrogen atoms are located by the difference

Fourier map, which are included in the refinement together with the others calculated. The final R value is 0.049 for 1596 reflections with $|F_o|>1.5\sigma|F_o|$. The final atomic coordinates are given in Table 3.

Structural Analysis of Methyltributylammonium 1:2 Salt (2g). An almost twinning plate-like crystal with the dimensions of 0.10×0.30×0.30 mm^3 was used for the data collection on a Rigaku automated four circle diffractometer (AFC-5R) with rotating anode using graphite monochromated Mo $K\alpha$ radiation (λ=0.71069 Å). A total of 2850 reflections within 2θ=60° was collected. Although the Weissenberg photograph shows the disorder or twinning along the b and c axis, the most primitive cell was chosen for the structual determination. Thus obtained crystal data are as follows: a=8.943(2), b=14.756(3), c=3.991(1) Å, α=92.31(2), β=93.64(2), γ=110.27(2)°, V=492.0(2) Å^3, $P\bar{1}$, Z=0.5, D_{calcd}=1.42 g cm^{-3}. The structure was solved by the direct method and the parameters of BTDA molecule were obtained. After the block-diagonal least-squares refinement for these atoms with anisotropic temperature factors, the remaining atoms of ammonium ion were searched by the difference Fourier syntheses. By supposing the doubled unit cell along the stacking c axis, the positions of ammonium ions were proved to be disordered along this axis.[22] Furthermore, the N atom of the ammonium ion does not locate the center of symmetry, indicating that the cation is also orientationally disordered. Although these disordering made some difficulty, the atoms of the cation were successively picked up from the difference Fourier map. The final R value including these atoms is 0.097 for 1972 reflections with $|F_o|>3\sigma|F_o|$, and hydrogen atoms are not included in the refinement. The final atomic coordinates are given in Table 4.

Structural Analysis of Tetraethylammonium 1:2 Salt (2m). A needle-like crystal with dimensions of 0.15×0.15×0.25 mm^3 was used for the data collection. Crystal data are as follows: a=8.959(1), b=27.442(3), c=6.924(1) Å, α=92.78(1), β=97.24(1), γ=100.74(1)°, V=1654.6(4) Å^3, $P\bar{1}$, Z=2, D_{calcd}=1.55 g cm^{-3}. A total of 7199 reflections within 2θ=52° was collected on a Rigaku automated four circle diffractometer (AFC-5) using graphite monochromated Mo $K\alpha$ radiation (λ=0.71069 Å). The structure was solved by the direct method by supposing the space group to be noncentrosymmetric $P1$, and four kinds of BTDA molecules appeard in the Fourier map. These atoms were refined by the block-diagonal least-squares method followed by the difference Fourier syntheses from which the positions of two ammonium ions were determined. After refinement with isotropic temperature factors, two pairs of BTDA molecules and two ammonium ions were related by a center of symmetry indicating the space group to be centrosymmetric $P\bar{1}$ rather than $P1$. After transformation to the space group $P\bar{1}$ and successive refinement with anisotropic temperature factors, all the hydrogen atoms were located on the difference Fourier map. These are included in the refinement to give the final R value of 0.071 for the 3577 reflections with $|F_o|>3\sigma|F_o|$. The final atomic coordinates are given in Table 5.

For these three crystals, RANTAN 81 program[23] with some modification was used in the direct method. The atomic scattering factors from the International Tables for X-Ray Crystallography[24] were used. All the computation were carried out by an ACOS 1000 computer at Tohoku University using the applied library program of UNICS III system.[25]

Table of analytical values of anion radical salts **2A—2n**; listings of positional and thermal parameters, bond lengths and angles, and structural factors for **2A**, **2g**, and **2m** are kept at the Chemical Society of Japan (Document No. 8777).

NAD(P)$^+$-NAD(P)H Models. 65. Photochemical Reductive Desulfonylation of β-Keto Sulfones with Hantzsch Ester

Masayuki Fujii,† Kaoru Nakamura, Hideyuki Mekata, Shinzaburo Oka, and Atsuyoshi Ohno*

A new procedure for the reductive desulfonylation of β-keto sulfones is described. The reaction proceeds under a photochemical conditions with the Hantzsch ester in pyridine in the presence of ruthenium(II). Various functional groups are unaffected under the reaction conditions. Application of the procedure to the syntheses of certain natural products is also described.

NAD(P)H and its model compounds have been widely studied from the viewpoint of mimeses of biochemical transformations. As a consequence, it has been succeeded in reducing certain activated carbonyl compounds with excellent stereospecificity.

However, on the other hand, little attention has been paid to apply dihydropyridine derivatives as reductants in organic synthesis, and the functional groups susceptible to the reduction with the model compounds are limited. Since the reactivity of NAD(P)H or its analogs is quite low, biological systems employ appropriate enzymes as catalysts for the transformations. Therefore, it is reasonable to expect that a dihydropyridine derivative may be an interesting reductant in organic reactions if an appropriate catalyst is found. Along this idea, we have studied to extend the scope and limitation of the reduction with dihydropyridine derivatives. The use of a dihydropyridine derivative as an organic reductant introduces interesting specificities into organic reactions. For example, α,β-unsaturated aldehydes and ketones are reduced into the corresponding saturated aldehydes and ketones with the Hantzsch ester (HEH) in the presence of silica gel, whereas α,β-unsaturated esters and nitriles are not affected at all. We recently found that desulfonylation of β-keto sulfone undergoes with HEH in the presence of ruthenium(II) without influencing many other functional groups. Since the α-position of β-keto sulfone is highly susceptible to the attack by an electrophile, β-keto sulfones are hopeful candidate as building blocks for organic syntheses, and we studied the scope of this desulfonylation.[4] In this paper, we would like to describe the details of the reaction and its application to the syntheses of natural products.

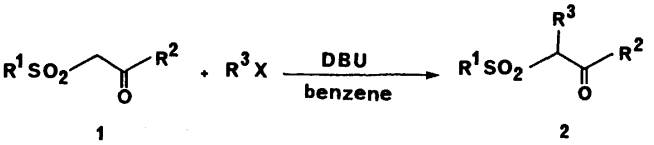
Results and Discussion

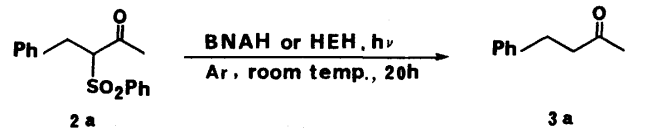
Alkylation. Alkylation of active methylene compounds has been studied extensively and many improved procedures have been reported.[5] Among these, it was found that the use of alkyl halide in benzene at room temperature in the presence of 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) is the best method for mono-alkylation of β-keto sulfones.[6] The results are summarized in Table 1.



1 2

(1)

Desulfonylation. It is reported that α-nitro sulfones can be desulfonylated by *N*-benzyl-1,4-dihydronicotinamide (BNAH) in DMF into the corresponding nitro compounds.[7] We have proposed that the reduction with a dihydropyridine derivative is initiated by an electron transfer from the reductant to the substrate.[8] Although a strongly electron-defficient substrate such as an α-nitro sulfone may be reduced without a catalyst, the electron defficiency of a β-keto sulfone is not sufficient enough to undergo the desulfonylation spontaneously. Photo-irradiation is a method to activate a dihydropyridine derivative[9] and we first examined the efficiency of BNAH-DMF/*hν* system for the reduction of 4-phenyl-3-phenylsulfonyl-2-butanone (**2a**). However, the yield from this system was found to be quite low as shown in Table 2.



2a 3a

(2)

After several attempts, it was found that BNAH is sensitive to the photo-irradiation and self-decomposition proceeds rapidly. Therefore, HEH, which is less sensitive to the photodecomposition, is superior to BNAH for the purpose. Finally, we came to a conclu-

Table 1. Alkylation of β-Keto Sulfones[a)]

Reactant/g	Halide/g	Product/g	Yield/%
1-Phenylsulfonyl-2-propanone **1a** (1.98)	Benzyl bromide (1.71)	4-Phenyl-3-phenylsulfonyl-2-butanone **2a** (1.83)	64
1-Phenylsulfonyl-2-propanone **1a** (1.98)	Hexyl iodide (2.12)	3-Phenylsulfonyl-2-nonanone **2b** (2.43)	86
1-Phenylsulfonyl-2-propanone **1a** (1.52)	Cinnamyl bromide (1.68)	3-Phenylsulfonyl-6-phenyl-5-hexen-2-one **2c** (2.04)	65
Phenylsulfonylmethyl phenyl ketone **1b** (2.60)	Allyl bromide (1.21)	1-Phenyl-2-phenylsulfonyl-4-penten-1-one **2d** (2.19)	73
Methyl phenylsulfonylacetate **1c** (1.26)	Benzyl bromide (1.80)	Methyl 3-phenyl-2-phenylsulfonylpropionate **2f** (1.92)	62
Phenylsulfonylacetonitrile **1d** (2.14)	Benzyl bromide (1.71)	3-Phenyl-2-phenylsulfonylpropionate **2g** (2.79)	69[b)]
p-Nitrophenylsulfonylacetone **1e** (1.56)	Benzyl bromide (1.48)	3-*p*-Nitrophenylsulfonyl-4-phenyl-2-butanone **2h** (1.72)	89

a) Solvent; benzene (50 ml). Base; DBU (1.52 g). b) Solvent; benzene (20 ml). Base; DBU (0.66 g).

Table 2. Photo-Reduction of 4-Phenyl-3-phenylsulfonyl-2-butanone (**2a**)

Reducing agent[a)]	$h\nu$[b)]	Catalyst[c)]	Solvent	Yield/%[d)]
BNAH	None	None	DMF	0
BNAH	A	None	DMF	13
BNAH	B	None	DMF	5
BNAH	A	None	CH_3CN	17
BNAH	A	+	DMF	14
BNAH	A	+	Pyridine	2
HEH	B	+	Pyridine	13
HEH	A	+	DMF	Trace
HEH	A	+	CH_3CN	2
HEH	A	+	Pyridine	68
HEH	B	+	Pyridine	97
HEH[e)]	B	+	Pyridine	59
HEH[f)]	B	+	Pyridine	83

a) Three equivalent amounts were used unless otherwise indicated. b) A: 600 W high-pressure mercury lamp with a Pyrex filter. B: USHIO HALOGEN LAMP JCD (100 V-650 W). c) 1% mol of $RuCl_2(bpy)_3$ was used. d) Determined on VPC (OV 330, 1 m, 130 °C). e) 1.5 equivalent amounts. f) 2.0 equivalent amounts.

sion that the use of 3 equivalent amounts of HEH in pyridine in the presence of 1% mole of $RuCl_2(bpy)_3$, as a photosensitizer, with irradiation of visible light under an inert atmosphere affords the best result as listed in Table 2. The procedure was applied to the desulfonylation from various β-keto sulfones as summarized in Table 3. Interestingly, while a sulfonyl group at the α-position to the keto group can be substituted by a hydrogen in food to excellent yields under the present reaction conditions, those at the α-positions of an ester and a cyano group are not affected at all.
