Thiocyanate ion is capable of bonding through either the hard nitrogen or soft sulfur end with Lewis acids depending on hardness and softness of the Lewis acids. Among thiocyanato complexes of d^{10} metal(II) ions, N-bonding was found in the $[Zn(NCS)_4]^{2-}$ complex that contains a relatively hard zinc(II) ion, while S-bonding was observed in the $[Hg(SCN)_4]^{2-}$ complex of soft mercury(II) ion.[2-4] For cadmium(II) ion, its hardness is weaker than that of zinc(II) ion and its softness is also less than that of mercury(II) ion, thiocyanate ions bind through two N and two S ends to form $[Cd(NCS)_2(SCN)_2]^{2-}$ in water.[2] Furthermore, the coordination of thiocyanate ions in lower complexes has been suggested to be $[Cd(NCS)]^+$ (N-bonding), $[Cd(NCS)(SCN)]$ (N- and S-bondings), and $[Cd(NCS)_2(SCN)]^-$ (two N- and one S-bondings) in water.[1] The result implies that the apparent hard and soft characters of cadmium(II) ion changes in the course of the stepwise complexation with thiocyanate ions. It is thus expected that the binding energies to cadmium(II) ion of the hard N and soft S ends of the SCN^- ion are very close to each other in water. In such a case, solvation of thiocyanate ion might also play an essential role for determining the N- or S-bonding of the ion to cadmium(II) ion.

We therefore aimed at investigating the formation and structure of cadmium(II) thiocyanato complexes in aprotic solvents with different solvating abilities. In this work we report the complexation between cadmium(II) and thiocyanate ions in *N,N*-dimethylformamide (DMF) studied by calorimetry. Raman spectra of cadmium(II) thiocyanate solutions were measured to elucidate the bonding types of SCN^- ion to cadmium(II) ion within the thiocyanato complexes.

Experimental

Reagents. All chemicals used were of reagent grade. Cadmium(II) perchlorate DMF solvate was prepared by dissolving $Cd(ClO_4)_2 \cdot 6H_2O$ crystals in DMF and then by recrystallizing it three times from DMF. The DMF solvate thus obtained is finally recrystallized from acetone and washed with ether. The cadmium(II) perchlorate DMF solvate thus obtained was dried at about 40 °C in a vacuum oven for several days and kept in a desiccator over P_2O_5. The value of x in the $Cd(ClO_4)_2 \cdot x$dmf was found to be 6 from the analysis of the metal concentration by EDTA titration. Tetraethylammonium perchlorate was recrystallized once from water and dried in a vacuum oven at 100 °C. Ammonium perchlorate of reagent grade was dried at 100 °C. Tetraethylammonium thiocyanate and ammonium thiocyanate of reagent grade were used without further purification and dried in vacuum in a desiccator over P_2O_5. *N,N*-Dimethylformamide was dried for several weeks over Molecular Sieve 4A 1/16 and then distilled at 25 °C under reduced pressure and stored over molecular sieve in a dark bottle with a P_2O_5 drying-tube.

Measurements. Calorimetric measurements were carried out in a room thermostated at (25±0.2) °C.[1] Test solutions contained either 0.4 mol dm^{-3} $(C_2H_5)_4NClO_4$ or 1 mol dm^{-3} NH_4ClO_4 as a constant ionic medium. A cadmium(II) perchlorate solution (50 cm^3) was placed in a stainless steel vessel, the inside wall of which was coated with Teflon. The vessel was inserted into an aluminium block thermostated at (25.0±0.0001) °C in an air-bath. The vessel was filled with dry nitrogen gas and isolated from moisture with a P_2O_5 drying-tube. A $Cd(ClO_4)_2$ solution in the vessel was then titrated with a 0.4 mol dm^{-3} $(C_2H_5)_4NSCN$ or a 1 mol dm^{-3} NH_4SCN DMF solution by using an autoburet (APB-118, Kyoto Electronics). Heats of complexation at each titration point were measured with a certainty of ±0.02 J and were corrected for heat of dilution of the titrant. The heat of dilution had been determined by separate experiments by titrating a 0.4 mol dm^{-3} $(C_2H_5)_4NClO_4$ (or 1 mol dm^{-3} NH_4ClO_4) DMF solution with a 0.4 mol dm^{-3} $(C_2H_5)_4NSCN$ (or 1 mol dm^{-3} NH_4SCN) DMF solution. The heat of dilution observed in this measurement was found to be very small. Calorimetric measurements were carried out by using a fully automatic on-line system developed in our

laboratory.

Raman spectra of cadmium(II) thiocyanate solutions were measured with a JRS-400T Raman spectrometer (JEOL) using 514.5 nm line of an NEC GLG argon ion laser in a room at 25 °C. The composition of solutions for the Raman spectroscopic measurements is listed in Table 1.

Data Analysis. A heat q_i measured at the ith titration point is represented by Eq. 1 using overall formation constants β_n and overall enthalpies $\Delta H^\circ_{\beta n}$ of formation of the $[CdX_n]^{(2-n)+}$ complexes.

$$q_i = -(V_i \sum \beta_n \Delta H^\circ_{\beta n} m_i x_i^n - V_{i-1} \sum \beta_n \Delta H^\circ_{\beta n} m_{i-1} x_{i-1}^n), \quad (1)$$

where V denotes the volume of a test solution, and m and x stand for the concentrations of free cadmium(II) and thiocyanate ions, respectively, which are related to their total concentrations C_M and C_X according to the mass-balance equations:

$$C_{M,i} = \sum \beta_n m_i x_i^n + m_i, \quad (2)$$

$$C_{X,i} = \sum n\beta_n m_i x_i^n + x_i. \quad (3)$$

The formation constants and enthalpies were simultaneously determined by minimizing the error-square sum, $U=\sum(q_{i,obsd}-q_{i,calcd})^2$ by using a non-linear least-squares program.

Results and Discussion

Calorimetric titration curves for the complexation of cadmium(II) with thiocyanate ions obtained in the $(C_2H_5)_4NClO_4$ DMF solution are depicted in Fig. 1, in which the values $-q/(\delta v C_{X,tit})$ are plotted against C_X/C_M, where q, δv, $C_{X,tit}$, C_X, and C_M denote the heat evolved and the volume of an aliquot of the titrant added at each titration point, the concentration of $(C_2H_5)_4NSCN$ in the titrant solution, and the total concentrations of SCN^- and Cd^{2+} ions in the test solution, respectively. The calorimetric data were analyzed by assuming the formation of various sets of mononuclear cadmium(II) thiocyanato complexes. Among various sets examined, the set (1—4) assuming the formation of $[CdX]^+$, $[CdX_2]$, $[CdX_3]^-$, and $[CdX_4]^{2-}$ (X=SCN), and the set (1,2,4) eliminating

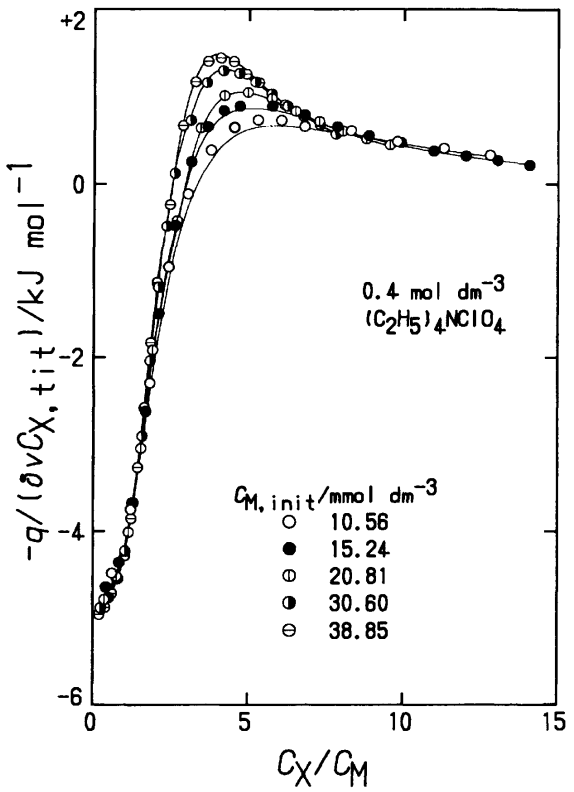

Fig. 1. Calorimetric titration curves of cadmium(II) thiocyanate DMF solutions containing 0.4 mol dm^{-3} $(C_2H_5)_4NClO_4$ at 25 °C. Concentrations of cadmium(II) ions, $C_{M,init}$/mmol dm^{-3}, in initial test solutions are given. The solid lines show the curves calculated by using the constants of the set (1—4) in the $(C_2H_5)_4NClO_4$ ionic medium in Table 2.

$[CdX_3]^-$ from the set (1—4) gave relatively small Hamilton R factors. The results for these sets are listed in Table 2. Other sets gave significantly large R values. Since both $\log \beta_3$ and $\Delta H^\circ_{\beta 3}$ values were obtained with small standard deviations and they laid within the reasonable range, we concluded that the $[CdX_3]^-$ can not be eliminated, and thus the set (1—4) is the best choice for describing the complexation of cadmium(II) with thiocyanate ions in DMF. In fact, as seen in Fig. 1, the solid lines calculated by using the constants for the set (1—4) in Table 2 well reproduce the experimental points over the whole range of C_X/C_M.

The titration curves obtained in the NH_4ClO_4 DMF solution are shown in Figs. 2 and 3. The data were analyzed by a similar way to that employed for data in the $(C_2H_5)_4NClO_4$ solution. In the NH_4ClO_4 solution, among various sets examined, the sets (1—4) and (1,2,3) gave relatively small R factors as shown in Table 2. Since the R value of the set (1—4) is appreciably smaller than that of the set (1,2,3), we adopted the parameters of the set (1—4) as the final choice.

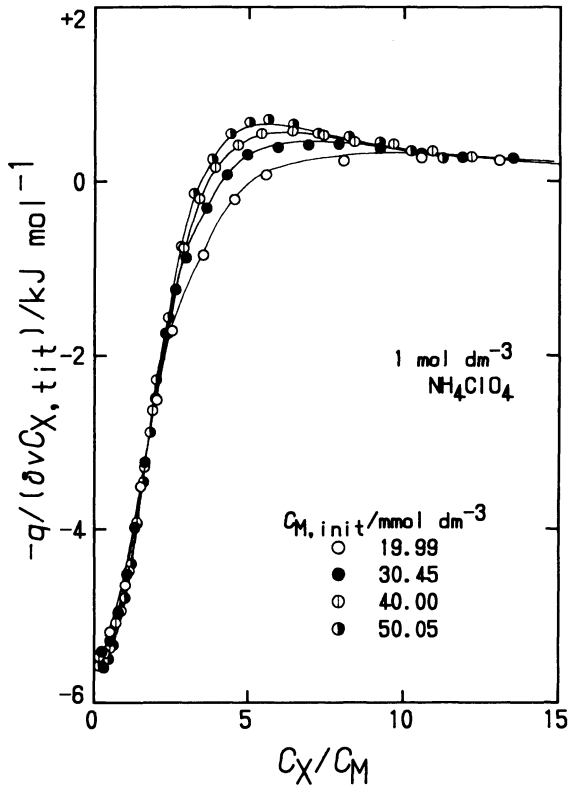

Fig. 2. Calorimetric titration curves of cadmium(II) thiocyanate DMF solutions containing 1 mol dm^{-3} NH_4ClO_4 at 25 °C. Concentrations of cadmium(II) ions, $C_{M,init}$/mmol dm^{-3}, in initial test solutions are given. The solid lines show the curves calculated by using the constants of the set (1—4) in the NH_4ClO_4 ionic medium in Table 2.

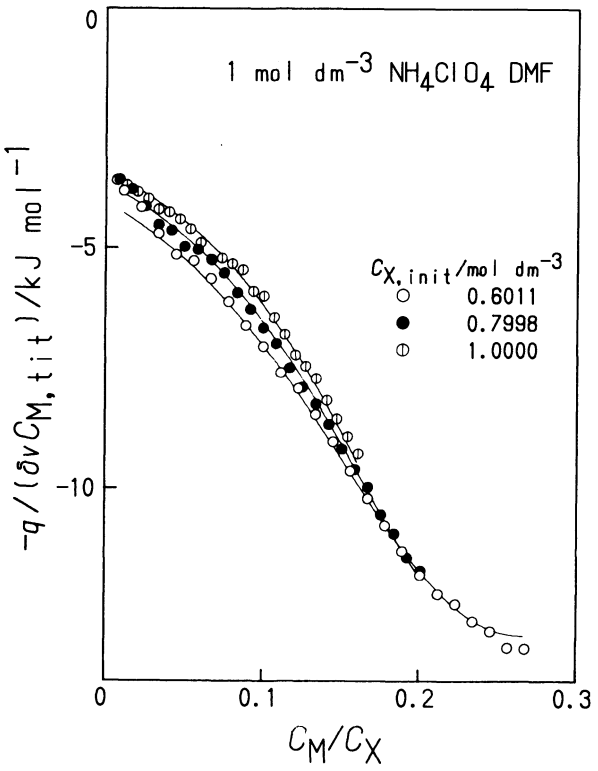

Fig. 3. Calorimetric back titration curves of cadmium(II) thiocyanate DMF solutions containing 1 mol dm^{-3} NH_4ClO_4 at 25 °C. Concentrations of cobalt(II) ions, $C_{X,init}$/mmol dm^{-3}, in initial test solutions are given. The solid lines show the curves calculated by using the constants of the set (1—4) in the NH_4ClO_4 ionic medium in Table 2.

plexes in these $(C_2H_5)_4NClO_4$ and NH_4ClO_4 DMF solutions in shown in Fig. 4, which is calculated by using the formation constants for the sets (1—4) in Table 2. It is demonstrated that the complexation is more favorable in 0.4 mol dm^{-3} $(C_2H_5)_4NClO_4$ than in 1 mol dm^{-3} NH_4ClO_4 ionic medium. A similar result has been obtained also in the copper(II) bromide system in DMF,[5] where it is suggested that bromide ion forms appreciably ion pairs with NH_4^+ ion, while the ion pair formation of bromide ion with $(C_5H_5)_4N^+$ ions is practically negligible.

Raman Spectra of the Cadmium(II) Thiocyanate Solutions. Raman spectra for the C-S stretching vibrations are shown in Fig. 5. The observed Raman bands were assigned to each complex by taking into

account the distribution of the cadmium(II) thiocyanato complexes in the NH_4ClO_4 solution in Fig. 4.

The C-S stretching vibrational band of free SCN^- ion appears at ca. 755 cm^{-1} in DMF. It is known that the band shifts toward higher and lower frequencies when SCN^- ion binds to a metal ion with the N and S ends, respectively.[6-11] Solutions A and B show a sole band at 795 cm^{-1}, which involve the mono- and di(thiocyanato)cadmium(II) complexes, respectively, as the main species. This shift for the C-S stretching band toward a higher frequency from 755 to 795 cm^{-1} evidently indicates that the SCN^- ions bind with the N end to cadmium(II) ion to yield the $[Cd(NCS)]^+$ and $[Cd(NCS)_2]$ complexes. For solution C are observed a band at 795 cm^{-1}, indicative of the Cd-NCS linkage, and a broad one ranging 730—760 cm^{-1}, showing the alternative Cd-SCN bonding, i.e., the tri(thiocyanato)-cadmate(II) complex may involve the Cd-SCN linkage suggesting the $[Cd(NCS)_2(SCN)]^-$ coordination. Solution D containing predominantly the tetra-(thiocyanato)cadmate(II) complex shows the 795 cm^{-1} band and a weak shoulder at 735 cm^{-1}, indicating that the complex involves both Cd-NCS and Cd-SCN linkages. According to the X-ray diffraction measurement,[12] the four-coordinate tetrahedral $[Cd(NCS)_3(SCN)]^{2-}$ complex with three Cd-N and one Cd-S arrangements is elucidated.

On the other hand, Raman spectra for the C-N stretching vibration of SCN^- ion show a sole band for all the cadmium(II) thiocyanate solutions examined. No significant shift of the band is observed with the successive complexation. Therefore, it was hard to conclude the binding mode of SCN^- ion to cadmium(II) ion from the C-N stretching vibrational band.

The Coordination Structure Change. In DMF cadmium(II) ion is present as the hexa-solvate $[Cd(dmf)_6]^{2+}$ complex according to the X-ray diffraction measurement.[12] The formation of the four-coordinate $[Cd(NCS)_3(SCN)]^{2-}$ complex thus indicates that the coordination structure changes from octahedral to tetrahedral at a certain step of the complexation between cadmium(II) and thiocyanate ions.

Stepwise thermodynamic quantities of formation of the cadmium(II) thiocyanato complexes in DMF are summarized in Table 3. In any solution examined, the ΔS_4° value is large and positive, even larger than the ΔS_n° (n=1,2,3) values. This result is in contrast to that obtained in the cadmium(II)-halide systems,[13] in which the tri(halogeno)cadmate(II) complexes have a tetrahedral coordination. Such a relatively large and positive ΔS_4° value, together with a relatively large and positive ΔH_4° value for breaking metal-solvent bonds, observed in the cadmium(II) thiocyanate system

Table 3. The Stepwise Formation Constants, $\log(K_n/\text{mol}^{-1}\,\text{dm}^3)$, Enthalpies, $\Delta H_n^\circ/\text{kJ mol}^{-1}$, and Entropies, $\Delta S_n^\circ/\text{J K}^{-1}\,\text{mol}^{-1}$, for the Cadmium(II)-$SCN^-$ System in *N,N*-Dimethylformamide at 25 °C

$\Delta S_{\beta_4}^\circ$[d]	−64	178	118

a) Ref. 1, the concentration of ionic medium is 3 mol dm^{-3}. b) 0.4 mol dm^{-3}. c) 1 mol dm^{-3}. d) For the overall reaction, $Cd^{2+}+4X^-=[CdX_4]^{2-}$ (X=SCN).

suggests that an extensive liberation of DMF molecules occurs at the fourth step, i.e., the tri(thiocyanato)cadmate(II) complex is octahedral, and the coordination structure changes from octahedral to tetrahedral at the formation of the tetra(thiocyanato)-cadmate(II) one.[14]

In water it was indicated that the corresponding coordination structure change occurs at the formation of the tri(thiocyanato)cadmate(II) complex.[1] Consequently, we note that the change in coordination about cadmium(II) ion from octahedral to tetrahedral takes place at the latter step of the complexation in DMF than that in water in the cadmium(II) thiocyanate system. A similar result has been found for the cadmium(II) halide systems in water and in DMSO,[15] in which the coordination changes from octahedral to tetrahedral at the second step in water, while at the third one in DMSO.

The Binding Mode Difference of Thiocyanate Ion in Water and in DMF. It is suggested in a previous section that a six-coordination for $[Cd(NCS)]^+$, $[Cd(NCS)_2]$, and $[Cd(NCS)_2(SCN)]^-$, and a four-coordination for $[Cd(NCS)_3(SCN)]^{2-}$ occur in DMF. It is noted that a six-coordination for $[Cd(NCS)]^+$ and $[Cd(NCS)(SCN)]$, and a four-coordination for $[Cd(NCS)_2(SCN)]^-$ and $[Cd(NCS)_2(SCN)_2]^{2-}$ are concluded in water.[1,2] These results imply that the apparent hard and soft characters of cadmium(II) ion changes with the stepwise complexation of thiocyanate ions. Furthermore, it is indicated that solvent properties are also responsible for determining the N- or S-bonding of an SCN^- ion to cadmium(II) ion.

Thiocyanate ion binds to cadmium(II) ion through the N end at the first step in both water and DMF, giving a slightly more negative ΔH_1° value in water than that in DMF. At the second step thiocyanate ion ligates to the metal(II) ion through the S end in water, while through the N end in DMF. The difference in the N- or S-bonding of SCN^- ion reflects on the ΔH_2° values. As seen in Table 3 the ΔH_2° value is less negative than the ΔH_1° value in DMF, while the reverse in the case in water. The binding of a soft S atom of SCN^- ion to cadmium(II) ion leads to remarkable exothermicity in water as compared with that of a hard N atom in DMF.

Solvation of SCN^- ion in aprotic DMF solvent may be very different from that in protic water, especially at the hydrogen-bonding N atom site. When the enthalpies are compared, despite the fact that cadmium(II) ion is more strongly solvated by ca. −63 kJ mol^{-1} in a strong donor solvent DMF than in water,[16] the ΔH_1° value for the formation of $[Cd(NCS)]^+$ in the former solvent is only slightly less negative than that in the latter. For the corresponding ΔH_1° values for the halogeno complexes,[13] even more negative value in DMF than that in water is in fact observed for chloride ion that is strongly hydrogen-bonded, i.e., strongly solvated in water. The ΔH_1° value is slightly less negative for bromide ion like thiocyanate ion, and much less negative for iodide ion in DMF than in water.[17,18] It is thus shown that thiocyanate ion is also hydrogen-bonded at the N atom site in water, although the interaction with water molecules is not so strong as in the case of chloride ion.

Cadmium(II) ion may behave as a harder ion in aprotic DMF solvent than in protic water.[15] In fact, the stability of $[CdX]^+$ increases in the sequence Cl<Br<I in water,[17,18] i.e. the decreasing order of the hydrogen-bonding abilities of halide ions, while the sequence is reversed in DMF[12] and also in DMSO.[19] Thiocyanate ion forms hydrogen bonds, especially at

the N atom site, with water molecules but not with DMF. On the other hand, solvation of SCN^- ion at the soft and large S atom site may be weak in both solvents, or even weaker in water than in DMF.[20] Therefore, the reactivity at the N atom site of SCN^- ion may be enhanced in DMF over water. Consequently, thiocyanate ion may favorably bind with cadmium(II) ion through the N end in DMF, while through the S end in water. It is thus reasonably expected that the $[Cd(NCS)_2]$ and $[Cd(NCS)_3(SCN)]^{2-}$ complexes are formed in DMF, while the [Cd(NCS)-(SCN)] and $[Cd(NCS)_2(SCN)_2]^{2-}$ ones in water.[1]

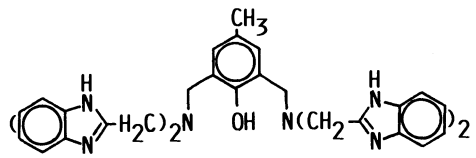
(Received July 2, 1988)

Two types of dinuclear high-spin mixed valence iron(II,III) complexes, $[Fe_2(L\text{-}Bzim)(RCOO)_2](BF_4)_2\cdot nH_2O$ (RCOO=CH_3COO (**1**) or C_6H_5COO (**2**)), and $[Fe_2(L\text{-}Bzim)(C_6H_5COO)_2(OH)]BF_4\cdot H_2O$ (**3**), and dinuclear high-spin iron(III,III) complexes, $[Fe_2(L\text{-}Bzim)(CH_3COO)_2](ClO_4)_3\cdot 3.5H_2O$ (**4**) and $[Fe_2(L\text{-}py)(C_6H_5COO)_2](ClO_4)_3\cdot CH_3CN\cdot H_2O$ (**5**) were prepared, where L-Bzim is 2,6-bis[bis(2-benzimidazolylmethyl)aminomethyl]-4-methylphenolate(1−) and L-py is 2,6-bis[bis(2-pyridylmethyl)aminomethyl]-4-methylphenolate(1−). Mössbauer spectra of the mixed valence complexes revealed that they involve high-spin iron(II) and (III) ions in equimolar amount. Their ESR spectra exhibited a signal at g_{av}=1.7 near liquid helium temperature characteristic of an antiferromagnetically spin coupled high-spin iron(II,III) dimer. Magnetic susceptibility measurements over the temperature range 80—300 K revealed that weak antiferromagnetic spin-exchange interactions are present between iron(II) and iron(III) ions ($J\approx-5$ cm^{-1}). The complexes showed an intervalence absorption band in the near infrared region, indicating that they belong to class II mixed valence type on the classification of Robin and Day. Cyclic voltammogram of **3** in acetonitrile showed two sets of reversible redox couples at 0.00 and 0.66 V vs. SCE, which are assigned to the redox reactions of Fe(II,III)/Fe(II,II) and Fe(III,III)/Fe(II,III), respectively. The complexes **4** and **5** exhibited weak antiferromagnetic interaction (J=−9—−12 cm^{-1}). ESR spectra of **4** and **5** showed a significant temperature dependence.

Dinuclear mixed valence iron(II,III) centers have been found to exist in some iron proteins such as pink uteroferrin,[1-5] the reduced form of bovine spleen acid phosphatase,[1,2,6] and semi-methemerythrin.[7-9] Those iron proteins were characterized mainly by ESR spectroscopy. They exhibit an ESR signal at $g<2.0$, which was interpreted in terms of antiferromagnetic exchange interaction between high-spin iron(II) and high-spin iron(III) ions.

In the previous studies,[10,11] we reported preparation of the first examples of dinuclear high-spin iron(II, III) complexes with the dinucleating ligand 2,6-bis-[bis(2-benzimidazolylmethyl)aminomethyl]-4-methylphenolate(1−)=L-Bzim or 2,6-bis[bis(2-pyridylmethyl)-aminomethyl]-4-methylphenolate(1−)=L-py (Fig. 1). The L-py complexes were characterized by various spectroscopies such as ESR and Mössbauer. Recently Brovik and Que determined the crystal structure of $[Fe_2(L\text{-}py)(C_2H_5COO)_2](BPh_4)_2\cdot CH_3COCH_3$, where two irons are triply bridged by phenolato and two carboxylato groups.[12] It is interesting to investigate how the ligand environment influences physicochemical properties of mixed valence iron(II,III) complexes. As an extension of our current work on the mixed valence iron(II,III) complexes with various dinucleating ligands, we report here details of physicochemical properties of the iron(II,III) and (III,III) complexes with L-Bzim in comparison with those of the L-py complexes. Recently such dinuclear mixed valence complexes with three bridging ligands (two carboxylate ions and oxide or phenolate ion) have been reported by two groups.[13,14]



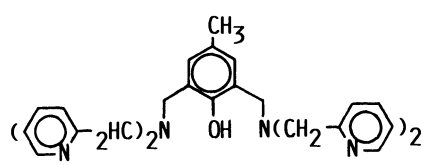


Fig. 1. Dinucleating ligands (HL-Bzim): 2,6-bis[bis(2-benzimidazolylmethyl)aminomethyl]-4-methylphenol and (HL-py): 2,6-bis[bis(2-pyridylmethyl)aminomethyl]-4-methylphenol.

Experimental

Materials. HL-Bzim and HL-py were prepared as previously described.[15,16] $Fe(BF_4)_2\cdot 6H_2O$ was prepared by the know method.[17] The other chemicals were of reagent grade.

Preparation of Iron(II,III) Complexes. $[Fe_2(L\text{-}Bzim)(RCOO)_2](BF_4)_2\cdot nH_2O$ (RCOO=CH_3COO (**1**) or C_6H_5COO (**2**)): A solution of $Fe(BF_4)_2\cdot 6H_2O$ (2 mmol) in 20 cm^3 of ethanol was added with stirring to a solution of HL-Bzim (1 mmol), RCOOH (2 mmol), and triethylamine (1 mmol) in 20 cm^3 of ethanol under N_2. The resulting pale brown solution was exposed to air to form dark brown solution,

which was allowed to stand for a few hours at room temperature to give greenish brown crystals. They were filtered off, washed with ethanol and ether, and dried in vacuo. The complexes were recrystallized from acetonitrile-diethyl ether.

$[Fe_2(L\text{-}Bzim)(C_6H_5COO)_2(OH)]BF_4\cdot H_2O$ (3): A solution of $Fe(BF_4)_2\cdot 6H_2O$ (2 mmol) in 20 cm^3 of ethanol was added to an ethanol solution (20 cm^3) of HL-Bzim (1 mmol), C_6H_5COOH (1 mmol), and triethylamine (3 mmol) with stirring. The solution was exposed to air at 10 °C. The color changed to violet instantaneously. The violet solution was allowed to stand for several hours to give violet crystals, which were filtered off, washed with ethanol and ether, and dried in vacuo.

Preparation of Iron(III,III) Complexes. $[Fe_2(L\text{-}Bzim)(CH_3COO)_2](ClO_4)_3\cdot 3.5H_2O$ (4): A solution of $Fe(ClO_4)_3\cdot 9H_2O$ (2 mmol) in 30 cm^3 of ethanol was mixed with a solution of HL-Bzim (1 mmol) and CH_3COONH_4 (2 mmol) in 20 cm^3 of ethanol with stirring. The resulting reddish brown solution was allowed to stand for several hours to give reddish brown crystals, which were collected by filtration, washed with ethanol and ether, and dried in vacuo.

$[Fe_2(L\text{-}py)(C_6H_5COO)_2](ClO_4)_3\cdot CH_3CN\cdot H_2O$ (5): A solution of $Fe(ClO_4)_3\cdot 9H_2O$ (2 mmol) in 20 cm^3 of acetonitrile was added to a solution of HL-Bzim (1 mmol), C_6H_5COOH (2 mmol), and triethylamine (2 mmol) in 30 cm^3 of ethanol. The resulting dark green solution was allowed to stand overnight to give dark green crystals, which were collected by filtration, washed with ethanol and ether, and dried in vacuo.

Analyses of iron(II) and iron(III) ions in the mixed valence complexes were carried out by the same method as that described in the literature.[11] The results are given in Table 1.

Measurements. The electronic spectra were measured on a Jasco UVIDEC 505 UV/VIS recording digital spectrophotometer and a Hitachi U-3400 spectrophotometer. Infrared spectra were obtained by the KBr-disk and Nujol mull methods with a Jasco A-3 infrared spectrophotometer. Magnetic susceptibilities were measured with a Shimadzu torsion magnetometer MB-2 which was calibrated with $Hg[Co(NCS)_4]$. Diamagnetic correction was made by using Pascal's constants.[18] Cyclic voltammograms were obtained with a Hokuto Denko HA-301 Potentiostat/Galvanostat and a Hokuto Denko HB-104 Function Generator in a cell containing a glassy carbon working electrode, a platinum-coil auxiliary electrode, and a saturated calomel electrode as reference electrode. Acetonitrile was used as the solvent and tetrabutylammonium perchlorate as the supporting electrolyte. Ferrocene was added for an internal check of redox potential and reversibility. $E_{1/2}$ of ferrocene was 0.39 V (vs. SCE) with a peak-to-peak separation (ΔE=70 mV). Mössbauer spectra were measured at 77 K against a $^{57}Co(Pt)$ source moving in a mode of constant acceleration. Velocity calibration was carried out by the resonance lines of metallic iron, and isomer shifts were given relative to iron metal at room temperature. The spectra of the mixed valence complexes were analyzed with a least square fitting program of Lorenztian functions into two sets of quadrupole doublets, each of which was fitted with an equal line width and intensity. ESR spectra were measured on a JEOL JES-FE2XG ESR spectrometer (X-band microwave unit, 100 KHz field modulation) equipped with an Air Product LTD-3-110 liquid helium transfer system. The microwave frequency was monitored with a Takeda Riken TR5212 microwave counter, and the resonance magnetic field values of the signals were measured with an NMR field meter (ECHO Electronics Co., Ltd.).

Results and Discussion

Characterization of Complexes. Chemical analyses of iron(II) and iron(III) ions in the complexes **1**, **2**, and **3** revealed that the complexes contain iron(II) and iron(III) ions in equimolar ratio. Mössbauer spectra also support the chemical analyses (vide infra). The molar conductivity of **1** in acetonitrile is 227 Ω^{-1} cm^2 mol^{-1}, characteristic of an 1:2 electrolyte. From the dinucleating nature of L-Bzim and the elemental analyses as well as the molar conductivities, the complexes **1** and **2** are formulated as $[Fe_2(L\text{-}Bzim)(RCOO)_2](BF_4)_2\cdot nH_2O$ (RCOO=CH_3COO or C_6H_5COO). Recently Jameson et al. determined the crystal structure of $[Fe_2(L\text{-}Bzim)(C_6H_5COO)_2](BF_4)_2\cdot 2[CF_3SO_3HN(C_2H_5)_3]$ where two iron ions are triply bridged by phenolato and two benzoato bridges in syn-syn configuration.[19] Such triply bridging structure has been found for similar mixed valence iron(II, III) and manganese(II, III) complexes.[12,20,21]

The complex **3** was also isolated by treating the complex **2** with one equivalent of triethylamine; the addition of base to the acetonitrile–ethanol (1:1) solution of **2** resulted in an instantaneous color change from brown to reddish violet. When diethyl ether was

Table 1. Analytical Data of the Complexes

No.	Complex	Found (Calcd) (%)				
		C	H	N	Fe(II)	Fe(III)
1	$[Fe_2(L\text{-}Bzim)(CH_3COO)_2](BF_4)_2\cdot 2H_2O$	47.67 (48.03)	3.96 (4.21)	12.44 (12.45)	4.9 (4.97)	5.1 (4.97)
2	$[Fe_2(L\text{-}Bzim)(C_6H_5COO)_2](BF_4)_2\cdot 3H_2O$	51.87 (52.12)	4.12 (4.21)	11.12 (11.05)	4.2 (4.41)	4.4 (4.41)
3	$[Fe_2(L\text{-}Bzim)(C_6H_5COO)_2(OH)]BF_4\cdot H_2O$	56.52 (56.87)	4.20 (4.34)	11.93 (12.06)	4.7 (4.81)	5.0 (4.81)
4	$[Fe_2(L\text{-}Bzim)(CH_3COO)_2](ClO_4)_3\cdot 3.5H_2O$	42.23 (42.33)	3.74 (3.95)	11.17 (11.09)		9.0 (8.87)
5	$[Fe_2(L\text{-}py)(C_6H_5COO)_2](ClO_4)_3\cdot CH_3CN\cdot H_2O$	47.48 (47.42)	4.14 (3.90)	7.76 (7.90)		8.9 (9.00)

added to this solution under an inert atmosphere, violet crystals were obtained. Thus basic conditions are necessary for the formation of **3**. The conductivity measurement in DMF (66 Ω^{-1} cm^2 mol^{-1}) revealed that the complex is an 1:1 electrolyte. From the above results, it seems reasonable that the complex contains hydroxide ion and is formulated as $[Fe_2(Bzim)(C_6H_5COO)_2(OH)]BF_4 \cdot H_2O$. At the present stage, however, the structure of **3** is not clear. The iron(III,III) complexes **4** and **5** also seem to have a triply bridging unit consisting of phenolato and two carboxylato bridges.

Magnetism. The effective magnetic moments of the mixed valence complexes **1**, **2**, and **3** at room temerature are all 7.7 B.M./Fe_2 and those of the iron(III,III) complexes **4** and **5** are 5.1 and 4.8 B.M./Fe, respectively. These values indicate that all the iron(II) and (III) ions are in high-spin state. Magnetic susceptivilities of the complexes were analyzed by the usual spin-spin interaction model based on exchange Hamiltonian $\mathscr{H}=-2JS_1 \cdot S_2$. The molar susceptibilities (χ_A) of spin coupling dimers, (S_1=2, S_2=5/2), and (S_1=5/2, S_2=5/2) are given in Eqs. 1 and 2, respectively.

$$\chi_A = \frac{N\beta^2 g^2}{4kT} \cdot \frac{x^{24} + 10x^{21} + 35x^{16} + 84x^9 + 165}{x^{24} + 2x^{21} + 3x^{16} + 4x^9 + 5} \quad (1)$$

$$\chi_A = \frac{2N\beta^2 g^2(1-P)}{kT} \cdot \frac{x^{28} + 5x^{24} + 14x^{18} + 30x^{10} + 55}{x^{30} + 3x^{28} + 5x^{24} + 7x^{18} + 9x^{10} + 11} + \frac{4.34P}{T} \quad (2)$$

where $x=\exp(-J/kT)$, the symbols have usual meanings, and temperature independent paramagnetisms ($N\alpha$) are assumed to be zero. The magnetic susceptibilities of the iron(II,III) and iron(III,III) complexes were interpreted in terms of the above equations with the parameters listed in Table 2 (Fig. 2). These results indicate that high-spin iron(II) and iron(III) ions in the iron(II, III) complexes are weakly antiferromagnetically coupled to yield an S=1/2 spin ground state. The iron (III, III) complexes also exhibit weak antiferromagnetic exchange interacrion to yield an S=0 spin ground state. Analogous mixed valence dinuclear iron(II,III) and manganese(II,III) complexes with phenolato and two carboxylato bridges show comparable magnitude of antiferromagnetic interaction (J=−3——8 cm^{-1}).[11,20,21] Thus phenolato and carboxylato bridges seem to provide weak antiferromagnetic interaction for all the iron and manganese dinuclear systems, regardless of homoval-ent or mixed valent system.

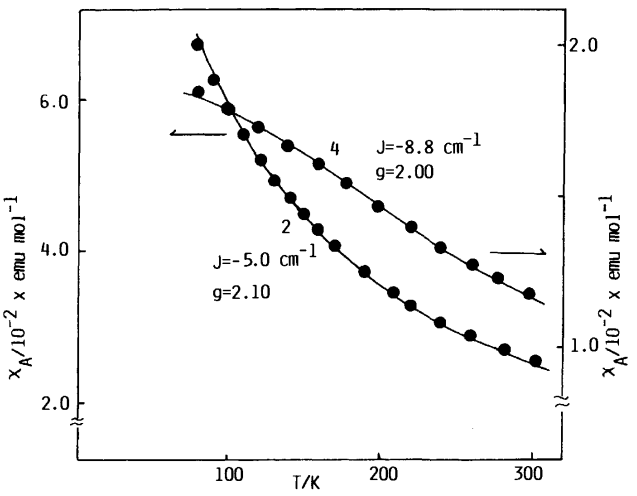

Fig. 2. Temperature dependence of magnetic susceptibilities of $[Fe_2(L\text{-}Bzim)(C_6H_5COO)_2](BF_4)_2 \cdot 3H_2O$ (**2**) and $[Fe_2(L\text{-}Bzim)(CH_3COO)_2](ClO_4)_3 \cdot 3.5H_2O$ (**4**).

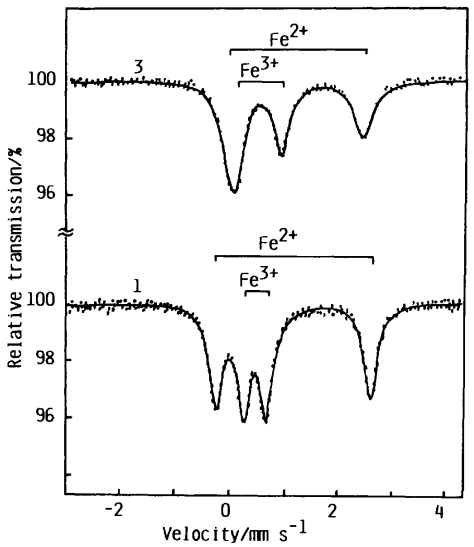

Fig. 3. Mössbauer spectra of $[Fe_2(L\text{-}Bzim)(CH_3COO)_2](BF_4)_2 \cdot 2H_2O$ (**1**), and $[Fe_2(L\text{-}Bzim)(C_6H_5COO)_2(OH)]BF_4 \cdot H_2O$ (**3**) at 77 K.

a) All data in mm s^{-1} except for A(Fe(III)/Fe(II)). b) Isomer shift, δ, relative to iron metal. c) Ratios of areas of Fe(III) to Fe(II). d) This work. e) Ref. 11.

Mössbauer Spectra. Mössbauer spectra of **2** and **3** are given in Fig. 3 and their parameters are listed in Table 3. The presence of iron(II) and iron(III) ions in equimolar ratio in mixed valence complexes is evidenced by the fact that the ratios of area of two sets of quadrupole doublets are nearly unity (Table 3). This fact agrees with the results of the chemical analyses. The quadrupole splitting ΔE and isomer shift δ in mm s^{-1} of the mixed valence complexes are 2.15—2.81 and 1.18—1.29 for iron(II) moieties, and 0.40—0.96 and 0.56—0.61 for iron(III) moieties, respectively. The former quadrupole splitting and isomer shift fall in the range of those of the high spin iron(II) complexes and the latters in the range of iron(III) complexes, respectively.[22] Although the structure of **1** and **2** seem to be almost identical, the quadrupole splittings of the iron(II) and iron(III) moieties in **1** and **2** significantly differ from each other. The iron(II) moiety of **1** exhibits a larger ΔE (2.81) than that of **2** (2.15), whereas the iron(III) moiety of **2** exhibits a larger ΔE (0.96) than that of **1** (0.40). A larger quadrupole splitting reflects a larger electric field gradient at the nucleus, suggesting a lower symmetry of ligand field; i.e., the distortion from octahedron in iron(II) moiety of **1** is larger than that of **2**, but this relation is reversed for iron(III) moieties. The quadrupole splittings of iron(II) and iron(III) moieties in the acetato and benzoato complexes with L-py are 2.42 and 2.06, and 0.51 and 0.47 mm s^{-1}, respectively, suggesting that structural difference between acetato and benzoato complexes with L-py is smaller than that between the L-Bzim complexes and a distortion from octahedron in the L-Bzim complexes is larger than that in L-py complexes. For further discussion, structural details are necessary.

ESR Spectra. All the ESR spectra of the mixed valence complexes in frozen glass of acetonitrile solution as well as in the polycrystalline phase (Fig. 4) show a broad signal at $g\approx 1.7$ at 12 K, indicative of the existence of dinuclear high-spin iron(II,III) mixed valence center where iron(II) and (III) ions are antiferromagnetically coupled to yield a spin ground state of $S=1/2$. The $g\approx 1.7$ signals are observable only near liguid helium temperature and almost disappear above 30 K. Such a spectral behavior is very similar to those of the mixed valence iron proteins such as semimethemerythrin[8] and the L-py complexes,[11] although the signal of the present complexes is very broad as compared with those of the iron proteins. All the frozen solution spectra exhibit a sharp signal at $g\approx 4.3$ attributable to a mononuclear rhombic high-spin iron(III) complex present as impurity formed by slight decomposition in solution. In fact, the spectrum of **3** in polycrystalline phase has no such signal at $g\approx 4.3$. It should be noted that in all the present mixed valence complexes there is a broad signal at $g\approx 5$—6 which is absent in the iron proteins and the L-py complexes.[11] As illustrated in Fig. 4a, b, and c, the $g\approx 5$—6 signals also show a temperature dependence which is similar to that at $g\approx 1.7$. The signals at $g\approx 5$—6 may be ascribed to the complex in $S=3/2$ spin state. The mixed valence manganese(II, III) complexes also have such a broad signal at $g\approx 4$.[20,21]

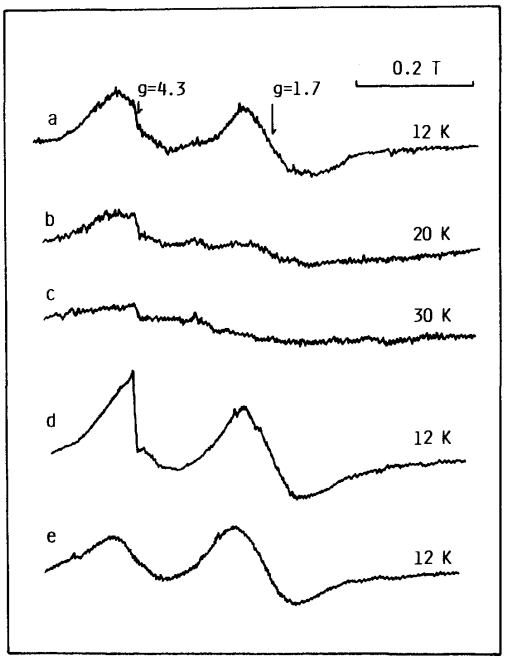

Fig. 4. ESR spectra of $[Fe_2(L\text{-}Bzim)(C_6H_5COO)_2](BF_4)_2\cdot 3H_2O$ (**2**) at 12 K (a), 20 K (b), and 30 K (c) in acetonitrile, and $[Fe_2(L\text{-}Bzim)(C_6H_5COO)_2(OH)]BF_4\cdot H_2O$ (**3**) at 12 K (d) in acetonitrile and at 12 K (e) in polycrystalline phase.

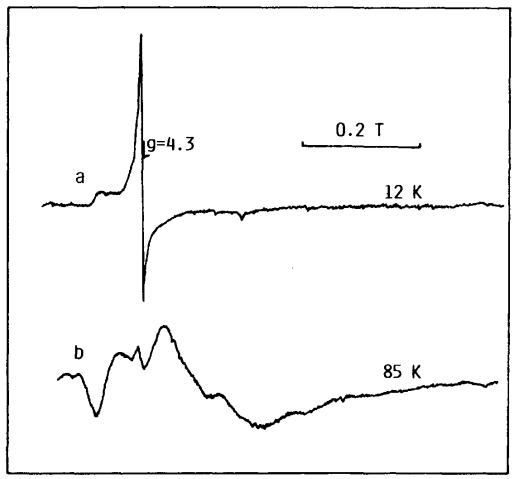

Fig. 5. ESR spectra of $[Fe_2(L\text{-}py)(C_6H_5COO)_2](ClO_4)_3\cdot CH_3CN\cdot H_2O$ (**5**) at 12 K (a) and at 85 K (b) in acetonitrile.

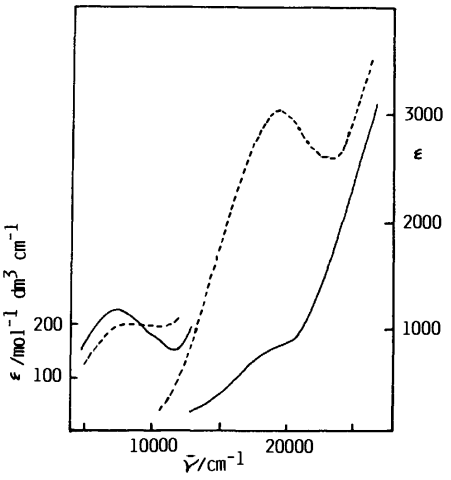

Fig. 6. Electronic spectra of $[Fe_2(L\text{-}Bzim)(C_6H_5COO)_2](BF_4)_2\cdot 3H_2O$ (**2**) (——) and $[Fe_2(L\text{-}Bzim)(C_6H_5COO)_2(OH)]BF_4\cdot H_2O$ (**3**) (------) in acetonitrile under nitrogen atmosphere.

The ESR spectrum of **5** is illustrated in Fig. 5. A significant temperature dependence is observed in the spectra. The spectral behavior of **4** is very similar to that of **5**. They have six spin states of S=0, 1, 2, 3, 4, and 5, in which an S=0 state is the lowest. The spectrum at 12 K exhibits an intense signal at $g\approx 4.3$ and weaker one at higher g values which are attributable to mononuclear iron(III) impurity. Since at 12 K, the population in the ESR active states (S=1, 2, 3, 4, and 5) is about 14%, which was estimated on the basis of Boltzmann distribution by using $J=-12$ cm^{-1}, the signals would be expected to be very weak. On the other hand, at 85 K the population of those states becomes larger (S=0: 19%, S=1: 38%, S=2: 28%, S=3: 11%, S=4: 3%, S=5: 1%) and signals would be expected. In fact, several broad and complicated signals are observed at 85 K (Fig. 5). Such complex spectra were also reported for dinuclear complexes.[23,24)]

Electronic Spectra. The electronic spectra of the mixed valence complexes exhibit an absorption band in the near infrared region (ε=200 mol^{-1} dm^3 cm^{-1}/Fe_2) in acetonitrile (Fig. 6 and Table 4), whereas no such band is observed in this region for the iron(III, III) complexes. The analogous iron(II, III) complexes with L-py also have a near infrared band. Such bands can be assigned to the intervalence transition (IT) of the type $[Fe^{2+}\text{-}Fe^{3+}]\xrightarrow{h\nu}[Fe^{3+}\text{-}Fe^{2+}]^*$. All the complexes have an IT band with a shoulder at higher energy side, while the L-py complexes exhibit only a single IT band. The presence of shoulder may reflect a splitting of t_{2g} orbitals of iron(III) moiety resulting from a lower ligand field symmerty.

All the mixed valence complexes have a charge-transfer transition (CT) from bridging phenolato group to iron(III) moiety in the visible region. The molar extinction coefficients of the CT bands in **1** and **2** are ca. 900 mol^{-1} dm^3 cm^{-1}, whereas that of **3** is 3200 mol^{-1} dm^3 cm^{-1}. The CT band of the iron(III, III) complex **4** showed a remarkable solvent effect (Table 4); the CT band appeared at 21740 cm^{-1} (ε=4120 mol^{-1} dm^3 cm^{-1}) in acetonitrile, and at 19800 cm^{-1} (ε=2060 mol^{-1} dm^3 cm^{-1}) in DMF. Thus such significant energy and intensity variations of the CT band may reflect some structural change in the phenolato bridge.

Ainscough et al.[25)] and Pyrz et al.[26)] pointed out that for mononuclear iron(III)-phenolate complexes the energy of CT band of phenolate moiety to iron(III) ion is sensitive to the donor strength of the other ligands

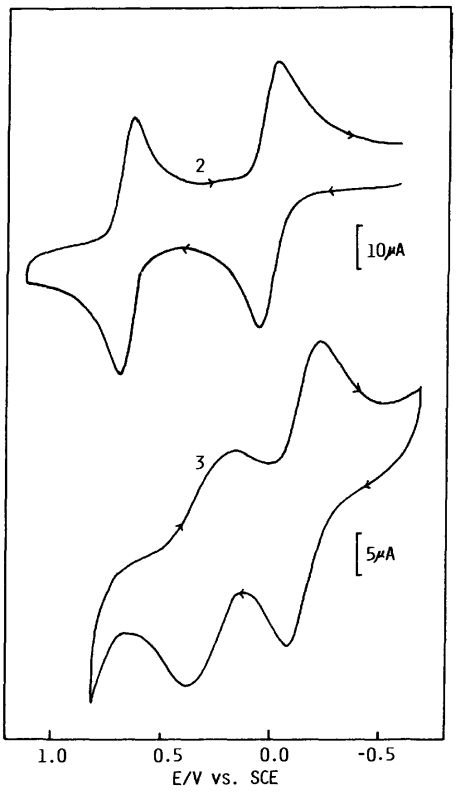

Fig. 7. Cyclic voltammograms of $[Fe_2(L\text{-}Bzim)(C_6H_5COO)_2](BF_4)_2\cdot 3H_2O$ (**2**) and $[Fe_2(L\text{-}Bzim)(C_6H_5COO)_2(OH)]BF_4\cdot H_2O$ (**3**) in 0.1 mol dm^3 tetrabutylammonium perchlorate in acetonitrile at a glassy carbon electrode at a scan rate of 100 mV s^{-1}.

coordinated and the redox potential of the complex; i.e., the donor strength of the other ligands becomes stronger, the more negative the redox potential and the higher the energy of the charge-transfer transition. The present iron(II, III) and (III, III) complexes have a charge-transfer band at higher energy region than the corresponding L-py complexes and the redox potentials of the L-Bzim complexes are more negative than those of the L-py complexes (vide infra). This observation implies that the benzimidazolyl group of L-Bzim is a stronger donor than the pyridyl group of L-py.

Cyclic Voltammogram. Figure 7 illustrates the cyclic voltammograms of **2** and **3** in acetonitrile (Table 5). The complex **2** shows two reversible redox couples at +0.00 and +0.66 V vs. SCE, which correspond to the redox reactions of Fe(II,III)/Fe(II,II) and Fe(III, III)/Fe(II,III). A similar CV was observed for **1**. The redox potentials of **1** and **2** are more negative by 50—120 mV than those of the corresponding L-py complexes. Such negative shifts are consistent with the shift of the CT band energies of the L-Bzim and L-py complexes. The CV of **3** also exhibits two redox couples at ca. −0.16 and +0.28 V vs. SCE, although the reversibility is poor as compared with those of **1** and **2**. Introduction of hydroxide ion seems to cause a poor reversibility and negative shift. A similar situation was obseved for the L-py complexes.[11]

Comproportionation constants of **1** and **2** in the following equilibrium are 5—2×10^{11}, indicating that the mixed valence

$$Fe(II, II) + Fe(III, III) \rightleftharpoons 2Fe(II, III)$$

complexes are significantly stabilized. Thus, the present ligand system (L-Bzim and two carboxylato) also provides favorable coordination sites toward M^{2+} and M^{3+} ions to form a mixed valence complex as the L-py ligand system (L-py and two carboxylate ions) does.

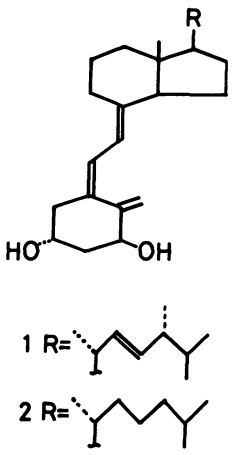
A Convenient Synthesis of 1α-Hydroxyvitamin D_2

Yoji TACHIBANA
Central Research Laboratory, Nisshin Flour Milling, Co., Ltd.,
Tsurugaoka, Ooimachi, Iruma-gun, Saitama 354
(Received February 20, 1988)

The enol acetylation of ergosta-1,4,6,22-tetraen-3-one (**4**) by treatment with isopropenyl acetate under acidic condition gave 3-acetoxy-1,3,5,7,22-ergostapentaene (**5**). The reduction of **5** with calcium borohydride afforded ergosta-1,5,7,22-tetraen-3β-ol (**6**). The *t*-butyldimethylsilyl ether derivatives (**8**) of the Diels–Alder cyclo adduct (**7**) derived from **6** and 4-phenyl-3*H*-1,2,4-triazole-3,5-dione was oxidized with *m*-CPBA to the diepoxide adduct (**9**). The 1α,2α-epoxide of the diepoxy alcohol (**10**) obtained after the removal of the silyl group of **9** was selectively reduced with $LiAlH_4$ to yield the 22,23-epoxy-1α,3β-diol (**11**) and **11** was subsequently converted to the corresponding diacetate (**12**). The deoxygenation of the 22,23-epoxide of **12** with a combination of sodium iodide and trifluoroacetic anhydride gave the 1α-acetoxyergosteryl acetate (**13**). Irradiation of **13** with a high-pressure mercury lamp followed by thermal isomerization, saponification, purification on silica gel and crystallization gave 1α-hydroxyvitamin D_2 (**1**) as colorless crystals.

It is reported that 1α-hydroxyvitamin D_2 (**1**)[1] is about ten times less toxic than 1α-hydroxyvitamin D_3 (**2**),[2] and yet appears to be almost equally potent in vitamin D activity.[3] This suggests that **1** might represent a therapeutically superior compound. DeLuca et al. reported the synthesis of **1** by the irradiation of 1α-acetoxyergosteryl acetate (**13**) followed by the thermal isomerization and saponification. However, concerning the synthesis of **13**, their preparative process utilizing ergost-5-en-3β-ol as a key intermediate generally gave a poor yield of **13** due to the side reactions involving the formation of a considerable amount of the 4,6-diene isomer.[4]



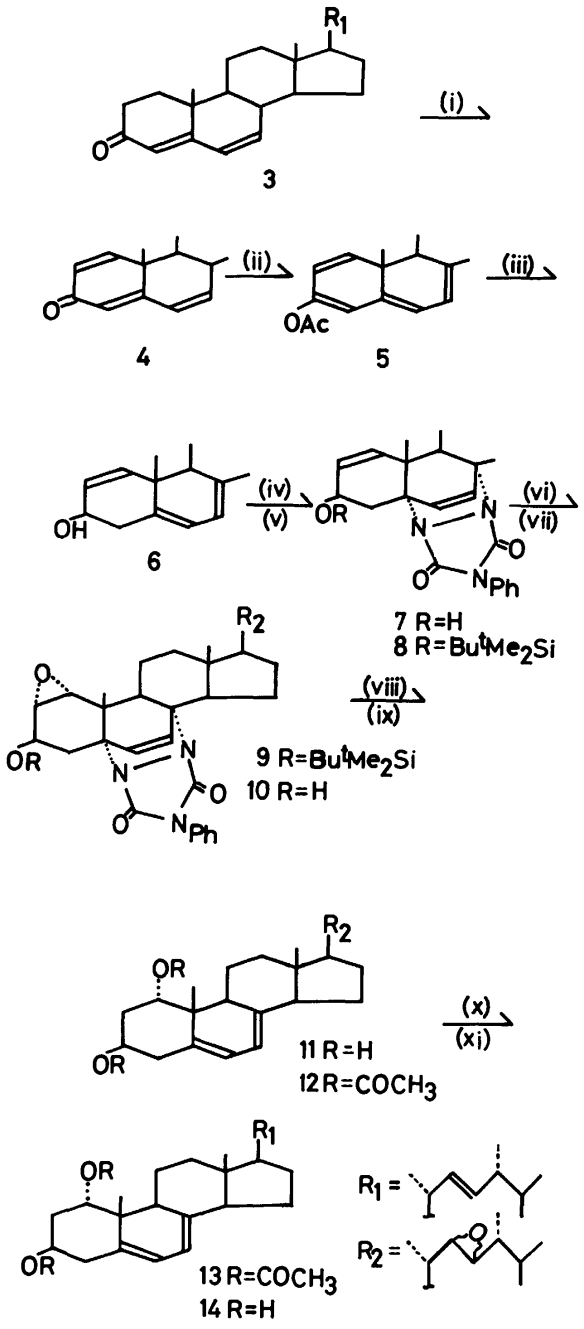
Thus, it is desirable to obtain **13** in higher yiled for the preparation of **1**. We have reported the conversion of cholesta-1,4,6-trien-3-one to cholesta-5,7-diene-1α,3β-diol via 3-acetoxy-1,3,5,7-cholestatetraene as a key intermediate.[5] This procedure seemed to be applicable to the synthesis of **13**. In the present paper, an alternative convenient method for the preparation of 1α-acetoxyergosteryl acetate (**13**) and its conversion to 1α-hydroxyvitamin D_2 (**1**) are described.

Ergosta-4,6,22-trien-3-one (**3**)[6] was dehydrogenated to ergosta-1,4,6,22-tetraen-3-one (**4**) by the modified method of Pelć et al.[7] Treatment of the 4,6,22-trienone (**3**) with 2,3-dichloro-5,6-dicyano-*p*-benzoquinone (DDQ) in the presence of a catalytic amount of 5-sulfosalicylic acid gave the tetraenone (**4**) in a fairly good yield. The tetraenone (**4**) was converted to 3-acetoxy-1,3,5,7,22-ergostapentaene (**5**) by the enol acetylation in the presence of a combination of isopropenyl acetate and *p*-toluenesulfonic acid. Longer time is required to complete this enol acetylation compared with that of cholesta-1,4,6-trien-3-one.[5] The pentaenyl acetate (**5**) was subsequently reduced with calcium borohydride[8] to yield ergosta-1,5,7,22-tetraen-3β-ol (**6**) in good yield.

After the 5,7-diene of **6** was protected with 4-phenyl-3*H*-1,2,4-triazole-3,5-dione[9] as a Diels–Alder adduct (**7**), the hydroxyl group was protected by conversion to *t*-butyldimethylsilyl derivative (**8**) for performing the selective α-epoxidation of the double bond (C-1).[10] In the next stage, the reactivity of the oxidizing reagent to the two different double bond (C-1 and C-22) was examined. When an equimolar amount of *m*-chloroperbenzoic acid (*m*-CPBA) was allowed to react with **8**, the ^1H NMR spectrum of the product showed that the signals due to the double bond at C-22 disappeared completely, indicating the double bond at C-22 was epoxidized selectively. Therefore, we planned to regenerate the double bond by removal of the epoxide after the hydroxyl group was introduced at the α position of C-1.

Theatment of **8** with excess *m*-CPBA afforded the diepoxide derivative (**9**) as diastereomeric mixtures with respect to the 22,23-epoxide, showing two spots on thin-layer chromatography.[11] On the other hand, the orientation of the 1,2-epoxide was confirmed as α-configuration by comparison of the ^1H NMR spectra of the compounds **9** and **10** (described later) with those of corresponding established 1α,2α-epoxide derivatives obtained from cholesterol.[8,10] Removal of the silyl group of **9** by treatment with tetrabutylammonium fluoride tetrahydrofuran solution gave the diepoxy

alcohol (**10**). The resulting **10** was reduced with excess $LiAlH_4$ to yield 22,23-epoxy diol (**11**). Crump et al. reported the reduction of the 22,23-epoxide of ergostery acetate protected with 4-phenyl-3*H*-1,2,4-triazole-3,5-dione ($LiAlH_4$ in tetrahydrofuran-ether, reflux for 3 days).[12] However, the 22,23-epoxide of **11** was not reduced under the conditions employed here (in tetrahydrofuran, reflux for 1 h).[13] The epoxy diol (**11**) was treated with pyridine–acetyl chloride to afford the corresponding diacetate (**12**). After trying several deoxygenating reagents,[14] we found that a combination of sodium iodide and trifluoroacetic anhydride[15] successfully deoxygenated the 22,23-epoxide of **12** to yield the desired 1α-acetoxyergosteryl acetate (**13**). The deoxygenation should be carried out at relatively low temperature (0—5 °C) to avoid side reactions involving the formation of the cis isomer. The *E* stereochemistry of the regenerated double bond (C-22) in **13** was supported by the ^1H NMR spectrum, where the coupling pattern of the olefinic protons at the side chain was in quite agreement with that of 1α-acetoxyergosteryl acetate obtained by the method described in the literature.[1] The diacetate (**13**) was hydrolyzed upon treatment with ethanolic potassium hydroxide to give the corresponding diol (**14**).



Scheme 1. (i) DDQ-5-sulfosalicylic acid. (ii) Isopropenyl acetate-*p*-TsOH. (iii) $Ca(BH_4)_2$, 0 °C in MeOH-EtOH. (iv) 4-Phenyl-3*H*-1,2,4-triazole-3,5-dione. (v) Bu^tMe_2SiCl-imidazole, 35 °C in DMF. (vi) *m*-CPBA. (vii) Bu_4NF, 5 °C in THF. (viii) $LiAlH_4$-THF. (ix) CH_3COCl-pyridine. (x) NaI-$(CF_3CO)_2O$, 5 °C in THF-acetonitrile. (xi) KOH-EtOH.

The irradiation of the diacetate (**13**) with high-pressure mercury lamp using aq. 1.2% KNO_3 solution as a filter followed by the thermal isomerization of precalciferol to calciferol and the subsequent saponification afforded the crude 1α-hydroxyvitamin D_2 (**1**). Purification by column chromatography on silica gel and crystallization gave **1** as colorless crystals.

Since 1α-acetoxyergosteryl acetate (**13**) is obtainable readily from ergosterol as described above, the present study provides an efficient method for the preparation of 1α-hydroxyvitamin D_2 (**1**).

Experimental

Melting points are uncorrected. UV spectra were taken on a Hitachi 320 spectrometer. ^1H NMR spectra were recorded in $CDCl_3$ on a JEOL JNF-FX200 spectrometer with TMS as an internal standard. Mass spectra were measured on a Hitachi M-80 mass spectrometer. Optical rotations were determined with a JASCO DIP-4 polarimeter. Solvents were removed under reduced pressure.

Ergosta-1,4,6,22-tetraen-3-one (4). A mixture of ergosta-4,6,22-trien-3-one (**3**) (65 g, 165.0 mmol), DDQ (65 g, 286.3 mmol) and 5-sulfosalicylic acid (12 g, 47.2 mmol) in dioxane (500 ml) was heated under reflux for 3 h. The solution was filtered to remove the hydroquinone formed and the filtrate was concentrated to dryness. The mixture was extracted with ethyl acetate. The extract was washed with aq. 10% KOH solution and brine, dried over sodium sulfate and evaporated. The residue was chromatographed on silica gel. Elution with ethyl acetate-hexane (1/9, v/v) gave crude tetraenone (**4**) (45 g), which was crystallized from acetone to afford pale yellow needles. 35 g (54%): mp 112—114 °C (lit,[6] 104—106 °C).

3-Acetoxy-1,3,5,7,22-ergostapentaene (5). A mixture of **4** (10 g, 25.5 mmol), *p*-toluenesulfonic acid (10 g, 52.6 mmol), and isopropenyl acetate (100 ml, 900.0 mmol) in butyl acetate (100 ml) was allowed to reflux for 16 h. The mixture solution was washed with water, aq. $NaHCO_3$ solution and brine, dried over sodium sulfate and evaporated. The residue was crystallized from acetone to give the pentaene (**5**) as yellow needles. 7.6 g (69%): mp 154—156 °C; λ_{max} 252 nm

(ε=9200, EtOH); *m/z* 434 (M^+); ^1H NMR δ 5.64—5.98 (m, 5H, H-1, H-2, H-4, H-6, H-7), 5.21 (m, 2H, H-22, H-23), 2.20 (s, 3H, $COCH_3$). Found: C, 82.53; H, 9.87%. Calcd for $C_{30}H_{42}O_2$: C, 82.88; H, 9.76%; $[\alpha]_D^{25}$ −508° (*c* 0.2, $CHCl_3$).

Ergosta-1,5,7,22-tetraen-3β-ol (6). The ether solution (100 ml) of the pentaene (**5**) (10 g, 23.0 mmol) was added dropwise at −10 °C to a stirred solution of calcium borohydride in ethanol-methanol (calcium chloride (30 g, 333.3 mmol) in methanol (300 ml) and sodium borohydride (15 g, 405.4 mmol) in ethanol (150 ml)). The mixture was stirred at 0 °C for 3 h and at room temperature overnight. After addition of 50% acetic acid to dissolve the resulted precipitates, the product was extracted with ethyl acetate. The extract was washed with water, aq. $NaHCO_3$ solution, brine and dried over sodium sulfate. The ethyl acetate was evaporated to dryness and the residue was chromatographed on silica gel. The product, which was eluted with hexane-ethyl acetate (4/1, v/v) was crystallized from acetone to give the tetraene (**6**). 7.7 g (85%): mp 156—157 °C; λ_{max} 282 nm (ε=11000, EtOH); *m/z* 394 (M^+); ^1H NMR δ=5.47—5.78 (m, 4H, H-1, H-2, H-6, H-7), 5.21 (m, 2H, H-22, H-23), 4.31 (1H, m, H-3). Found: C, 85.06; H, 10.71%. Calcd for $C_{28}H_{42}O$: C, 85.19; H, 10.75%.

The Diels-Alder Adduct of Ergosta-1,5,7,22-tetraen-3β-ol (7). The tetraenol (**6**) (9.6 g, 24.4 mmol) was dissolved in ethyl acetate (100 ml). To the solution, 4-phenyl-3*H*-1,2,4-triazole-3,5-dione (4.8 g, 27.4 mmol) was added by portion until a faint pink color persisted. The solvent was removed and the residue was purified by silica-gel column chromatography (eluted with chloroform) to give the adduct (**7**). 12.5 g (90%): mp 170—171 °C (crystallized from methanol); *m/z* 394 (M^+−175); ^1H NMR δ=7.40 (5H, m, C_6H_5), 6.44, 6.26 (2H, AB q, *J*=8 Hz, H-6, H-7), 6.04 (2H, m, H-1, H-2), 5.20 (2H, m, H-22, H-23), 5.06 (1H, m, H-3). Found: C, 75.74; H, 8.34; N, 7.29%. Calcd for $C_{36}H_{47}N_3O_3$: C, 75.87; H, 8.33; N, 7.37%.

The 3β-*O*-(*t*-Butyldimethylsilyl) Derivative (8) of the Diels-Alder Adduct (7). To the solution of the Diels-Alder adduct (**7**) (8.4 g, 14.8 mmol) in *N,N*-dimethylformamide (20 ml), *t*-butyldimethylsilyl chloride (3.6 g, 23.8 mmol) and imidazole (3.6 g, 52.9 mmol) was added. The mixture solution was warmed at 35° for 1 h and extracted with ether. The ether solution was washed with brine, dried over sodium sulfate and evaporated. The residue was crystallized from methanol-ether to give the silyl derivative (**8**). 9.1 g (90%): mp 186—188 °C; ^1H NMR δ=7.40 (5H, m, C_6H_5), 6.44, 6.26 (2H, AB q, *J*=8 Hz, H-6, H-7), 5.69 (2H, m, H-1, H-2), 5.18 (2H, m, H-22, H-23), 4.99 (1H, m, H-3). Found: C, 73.71; H, 9.07; N, 6.15%. Calcd for $C_{42}H_{61}N_3O_3Si$: C, 73.73; H, 9.01; N, 6.14%.

1α,2α:22,23-Diepoxide Derivative (9). The silyl derivative of the Diels-Alder adduct (**8**) (7.5 g, 10.7 mmol) was dissolved in chloroform (100 ml) and *m*-chloroperbenzoic acid (*m*-CPBA) (7.5 g, 43.5 mmol) was added. After the mixture was stirred at room temperature for 24 h, the solution was washed with sodium carbonate and brine, dried over sodium sulfate and evaporated to give the diepoxide (**9**). 7.1 g (90%): mp 194—195 °C (crystallized from methanol); *m/z* 541 (M^+−175); ^1H NMR δ=7.45 (5H, m, C_6H_5), 6.42, 6.20 (2H, AB q, *J*=8 Hz, H-6, H-7), 4.94 (1H, m, H-3), 3.17—3.34 (2H, m, H-1, H-2). Found: C, 70.34; H, 8.61; N, 5.85%. Calcd for $C_{42}H_{61}N_3O_5Si$: C, 70.43; H, 8.60; N, 5.87%.

22,23-Epoxy-ergosta-5,7-diene-1α,3β-diol (11). A tetrahydrofuran solution (50 ml) of the crude **9** (5.6 g, 7.8 mmol) and 1 M (1 M=1 mol dm^{-3}) tetrabutylammonium fluoride tetrahydrofuran solution (12 ml) was allowed to react at 5 °C for 16 h. The mixture was extracted with ethyl acetate, washed with brine and dried over sodium sulfate. Evaporation to dryness left a residue, which was chromatographed on silica gel with chloroform as eluent to afford the diepoxy alcohol **10** as oil. 3.7 g (79%): *m/z* 427 (M^+−175); ^1H NMR δ=7.45 (5H, m, C_6H_5), 6.43, 6.21 (2H, AB q, *J*=8 Hz, H-6, H-7), 5.04 (1H, m, H-3), 3.27 (2H, m, H-1, H-2).

To the tetrahydrofuran solution (400 ml) of $LiAlH_4$ (8.1 g, 213.7 mmol), **10** (2.7 g, 4.5 mmol) in tetrahydrofuran (150 ml) was added dropwise. The mixture was heated under reflux for 1 h. After decomposition of the excess $LiAlH_4$ by addition of water, dil. hydrochloric acid was added to give a clear solution. The solution was extracted with ethyl acetate, washed with aq. $NaHCO_3$ solution and brine, and dried over sodium sulfate. Chromatography on silica gel of the crude oil obtained after evaporation of ethyl acetate (eluted with chloroform-ethyl acetate) (4/1, v/v) yielded the epoxy diol (**11**). 1.2 g (63%): mp 155—157 °C (crystallized from acetone); *m/z* 428 (M^+); λ_{max} 282 nm (ε=10900, EtOH); ^1H NMR δ=5.70, 5.38 (2H, m, H-6, H-7), 4.05 (1H, m, H-3), 3.73 (1H, bs, H-1). Found: C, 78.11; H, 10.31%. Calcd for $C_{28}H_{44}O_3$: C, 78.44; H, 10.37%.

1α-Acetoxyergosteryl Acetate (13). The epoxy diol (**11**) (2.0 g, 4.7 mmol) was treated with pyridine (5 ml)-acetyl chloride (1 ml, 14.0 mmol) at room temperature for 2 h. The mixture was extracted with hexane, washed with dil. hydrochloric acid and brine, and dried over sodium sulfate. Chromatography on silica gel (eluted with hexane) gave the epoxy diacetate (**12**) as oil. 1.9 g (81%): *m/z* 512 (M^+); ^1H NMR δ=5.67, 5.39 (2H, m, H-6, H-7), 4.99 (2H, m, H-1, H-3), 2.09, 2.03 (6H, s, $COCH_3$).

Trifluoroacetic anhydride (1.5 ml, 10.6 mmol) was added to the solution of sodium iodide (6.0 g, 40.0 mmol) in 30 ml of acetonitrile-tetrahydrofuran (1/1, v/v). The mixture was stirred at room temperature for 30 min. After the solution was cooled to 0 °C, the epoxy diacetate (**12**) (900 mg, 1.8 mmol) in 10 ml of acetonitrile-tetrahydrofuran (1/1, v/v) was added dropwise. The mixture solution was kept at 5 °C for 48 h. The reaction mixture was extracted with hexane, washed with 5% sodium hydrogensulfite and brine, and dried over sodium sulfate. The residue after evaporation of the solvent was purified by column chromatography on silica gel (eluted with hexane-ethyl acetate, 95/5, v/v) to afford the crude **13**, which was crystallized from ethanol to yield the diacetate as colorless crystals. 350 mg (40%): mp 129—130 °C; *m/z* 496 (M^+); λ_{max} 282 nm (ε=10800, EtOH); ^1H NMR δ=5.68, 5.40 (2H, m, H-6, H-7), 5.19 (2H, m, H-22, H-23), 5.01 (2H, m, H-1, H-3), 2.08, 2.03 (6H, s, $COCH_3$). Found: C, 77.14; H, 9.78%. Calcd for $C_{32}H_{48}O_4$: C, 77.36; H, 9.76%.

The diacetate (**13**) (300 mg, 0.6 mmol) was treated with ethanolic potassium hydroxide (KOH 150 mg, EtOH 10 ml) under reflux for 10 min. The mixture was extracted with ether and washed with brine. Evaporation of the solvent followed by the crystallization from ethanol yielded the diol (**14**) as colorless crystals. 210 mg (84%): mp 197—198 °C; λ_{max} 282 nm (ε=11000, EtOH); *m/z* 412 (M^+); ^1H NMR δ=5.74,

5.37 (2H, m, H-6, H-7), 5.19 (2H, m, H-22, H-23), 4.07 (1H, m, H-3), 3.78 (1H, bs, H-1). Found: C, 80.92; H, 10.72%. Calcd for $C_{28}H_{44}O_2$: C, 81.48; H, 10.77%.

1α-Hydroxyvitamin D_2 (1). The ether solution of the diacetate (**13**) (200 mg, 0.4 mmol) was irradiated at room temperature for 2 min (high pressure mercury lamp, Ushio UM-452; aq. 1.2% KNO_3 solution as filter). After the ether was removed, the resulted residue was dissolved in ethanol (10 ml) and the solution heated under reflux for 1 h. To the solution, 1 M ethanolic potassium hydroxide solution (2 ml) was added and the mixture refluxed for a further 10 min. The solution was extracted with ether, washed with brine, and dried over sodium sulfate. Column chromatography on silica gel after evaporation of ether (eluted with chloroform–ethyl acetate, 9/1, v/v) afforded the crude hydroxyvitamin D_2 (**1**). Crystallization from hexane–ethyl acetate gave **1** as colorless crystals. 28 mg (17%): mp 136—138 °C (lit,[16] 138—140 °C); λ_{max} 265 nm (ε=18500, EtOH); $[\alpha]_D^{25}$ +47.5° (*c* 0.5, EtOH).

Rotational Isomerism in Fluorene Derivatives. XIII.[1] Conformational Equilibria of 9-(2-Methylaminophenyl)-fluorene and the Effect of Acid on It

Akiko NISHIDA, Makoto TAKESHITA, Shizuo FUJISAKI, and Shoji KAJIGAESHI*
Department of Industrial Chemistry, Faculty of Engineering,
Yamaguchi University, Tokiwadai, Ube 755
(Received March 18, 1988)

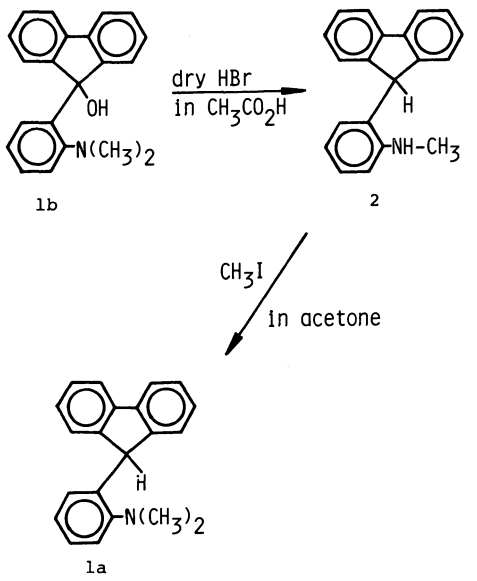
The compound 9-(2-methylaminophenyl)fluorene (**2**) was obtained by treatment of 9-(2-dimethylaminophenyl)-9-fluorenol (**1b**) with dry hydrogen bromide in acetic acid. The conformational equilibrium (*ap*⇄*sp*) of **2** was investigated on the basis of dynamic ^{1}H NMR spectra in $CDCl_3$. The stabilization of the *ap*-form could be ascribed to an N–H···π interaction between the methylamino group and the fluorene ring. The effect of trifluoroacetic acid on the equilibrium of **2** is also discussed.

Recently, we have investigated the conformational equilibria of 9-substituted 9-(2-dimethylaminophenyl)-fluorenes (**1**) on the basis of D NMR spectra. We also discussed the effect of trifluoroacetic acid on 9-(2-dimethylaminophenyl)fluorene (**1a**). In that case, we recognized the presence of N–H···π interaction in the *ap*-trifluoroacetate.[2] In the present paper, we wish to report on the preparation of 9-(2-methylaminophenyl)-fluorene (**2**) and on the conformational equilibrium of **2**, which essentially has an N–H group in the molecule. We also discuss the effect of trifluoroacetic acid on the equilibrium of **2**.

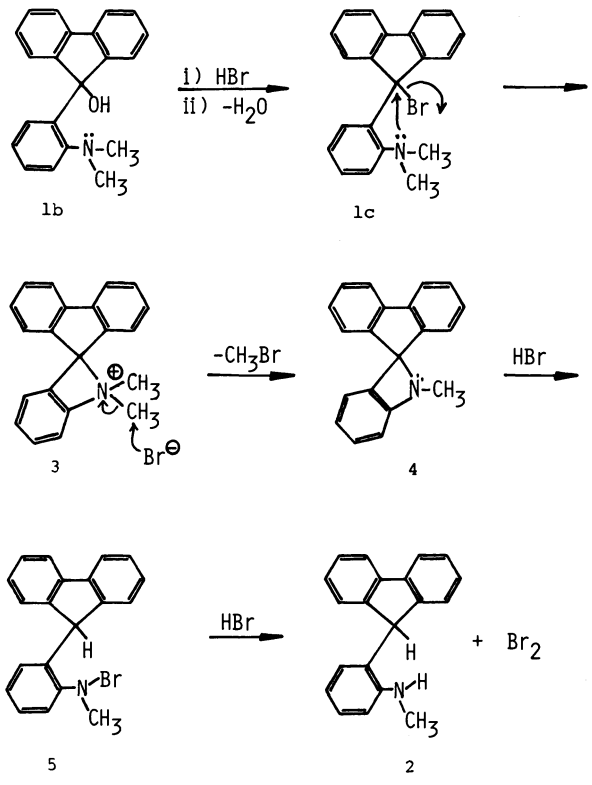
Results and Discussion

Preparation of 9-(2-Methylaminophenyl)fluorene (2). The reaction of 9-fluorenone with 2-dimethylaminophenylmagnesium bromide in dry ether-benzene gave 9-(2-dimethylaminophenyl)-9-fluorenol[2] (**1b**). Bubbling hydrogen bromide into a solution of **1b** in acetic acid unexpectedly afforded **2** in satisfactory yield (75%). In this case, the expected product, 9-bromo-9-(2-dimethylaminophenyl)fluorene (**1c**), was not obtained at all. The structure of **2** could be confirmed by elementary analysis and from its ^{1}H NMR and IR spectra. Furthermore, **2** could be converted into **1a** by treatment with methyl iodide in acetone at room temperature for a week, followed by treatment with aqueous sodium hydroxide.

It is interesting to form **2** by the reaction of **1b** with hydrogen bromide. The following mechanism has been suggested to account for the formation of **2** from **1b** with the aid of hydrogen bromide (Scheme 2). Actually, we confirmed the production of bromine by the usual test using iodo-starch paper. Elimination of methyl bromide from the four membered ring ammonium salt (**3**) to give four membered ring amine (**4**) is inferred from analogy with the von Braun



Scheme 1.



Scheme 2.

reaction,[3] in which a tertiary amine eliminates alkyl bromide to give a disubstituted cyanamide by means of cyanogen bromide. An *N*-bromoamine derivative (**5**) should be derived from **4** with hydrogen bromide owing to the release of the unstable four membered ring system.

On the other hand, the reaction of 9-(4-dimethylaminophenyl)-9-fluorenol (**6**) with hydrogen bromide in acetic acid and subsequent treatment of sodium hydroxide produced **6** instead of 9-(4-methylaminophenyl)fluorene (**7**). The result supported the above reaction mechanism which includes the four membered ring system.

Conformational Equilibria of 2 in Chloroform. Usually, in 9-(2-substituted phenyl)fluorene derivatives, two rotamers (*ap* and *sp*) were identified by their NMR spectra because of their high barriers to rotation about the C(9)–C(Ar) bond. The conformational equilibria *ap*⇄*sp* of these compounds are mainly controlled by intramolecular steric effects, nonbonding intramolecular interaction (attraction or repulsion), and solvent effects. The isomerization of **2** by rotation about the C(9)–C(Ar) bond is shown in Fig. 1.

As shown in Table 1, the two CH_3 signals were observed at δ 2.22 and 2.98 as broad singlets at room temperature, respectively. The dynamic NMR spectra of the methyl protons at various temperatures from 60 to −30 °C are shown in Fig. 2. The signal for the methyl group appeared as a sharp singlet at 60 °C, and this signal gradually split into two broad singlets with lowering of the temperature. Finally, the methyl signal showed one singlet (δ 3.00) and one doublet (δ 2.20, J=5 Hz) (1:2.1) at −30 °C. The former corresponded to the methyl proton of the *sp*-form; the latter corresponded to that of the *ap*-form. Two amino protons (N–H) were observed as a broad singlet at δ 4.36 (*sp*-form) and a broad quartet at δ 2.42 (*ap*-form) at −30 °C.

Since the amino protons easily exchange with one another, if the rate of the exchange is faster than the time scale of NMR, no coupling of the amino proton with the vicinal proton should occur. Therefore, in the case of the *sp*-form of **2**, both the methyl and amino protons are observed as singlets. For the other *ap*-form, the methyl and amino protons couple with one another; that is, the rate of the exchange of the amino proton is found to be slower than the NMR time scale.

Iwamura et al.[4] already proposed the presence of the N–H···π internal hydrogen bonding in the *ap*-form of 9-(2-aminophenyl)fluorene (**8**) to stabilize this form (the ratio; *ap*/*sp*=4/1 at −51 °C). Similarly,for compound **2**, we can show that N–H···π interaction exists between the methylamino group and the fluorene ring. This stabilizes the *ap*-form (*ap*/*sp*=2.1/1 at −30 °C) (Fig. 3). Thus, the methyl signal of **2**-*ap*

a) J=5 Hz. b) J=7 Hz.

should be observed as a doublet.

The IR spectrum of **2** in 0.1 mol l^{-1} solution of carbon tetrachloride exhibited an N–H streching frequency at 3435 cm^{-1}. This value did not alter on dilution with the solvent down to 0.02 mol l^{-1} concentration. According to this phenomenon, we can not detect the presence of the N–H···π hydrogen bonding in **2**, because intermolecular hydrogen bonding due to an N–H group is usually not influenced with respect to variation of its concentration.[5] The reference compound **7**, which was obtained from the reaction of 9-(4-dimethylaminophenyl)-fluorene (**9**) with cyanogen bromide, showed corresponding absorption at the same 3435 cm^{-1} in 0.05 mol l^{-1} solution of carbon tetrachloride.

Iwamura et al. observed the frequencies of the N–H stretching in **8** and 9-(4-aminophenyl)fluorene (**10**), and proposed that the low frequency shift of the symmetric NH vibration in **8** relative to the para isomer **10** indicates the presence of N–H···π hydrogen bonding in **8**.[4] However, Ōki et al. have recently examined the N–H streching frequencies of 9-(2-amino-1-naphthyl)fluorene (*ap*- and *sp*-) (**11**) and 9-(2-methylamino-1-naphthyl)fluorene (*ap*- and *sp*-) (**12**). They have confirmed that the N–H···π interactions in **11**-*ap* and **12**-*ap* have little affected on the N–H stretching frequencies because the frequencies are almost the same in both the *ap*- and *sp*-rotamers.[6] Thus, unfortunately, the N–H···π interaction in **2**-*ap* had not been confirmed from its IR spectral behavior because **2** and **7** give the same N–H stretching frequencies.

DNMR spectra of **2** were measured in $CDCl_3$ containing D_2O. The *ap*-methyl signal was observed as a singlet peak because the vicinal N–H proton exchanges rapidly with D^+ (Fig. 4). By line-shape analyses of the methyl signal in the DNMR spectra,[7] the activation free energies ($\Delta G^{\ddagger}$) of internal rotation (*ap*⇄*sp*) of **2** in $CDCl_3$–D_2O were obtained as 15.5 and 15.9 kcal mol^{-1} for the *sp*→*ap* and *ap*→*sp* processes, respectively. As compared with the $\Delta G^{\ddagger}$ values in **1a** ($\Delta G^{\ddagger}_{sp\to ap}$=15.5, $\Delta G^{\ddagger}_{ap\to sp}$=13.8 kcal mol^{-1}; 1 cal=4.184 J), it turned out that the ground state of **2**-*d*-*ap* is considerably stabilized.

Variation of Conformational Equilibria of 2 by Adding Trifluoroacetic Acid in the Chloroform Solution. As shown above, it is recognized that compound **2** maintains an equilibrium *ap*/*sp*=2.1/1 in chloroform at −10 °C. When trifluoroacetic acid was added dropwise to the solution of **2** in chlorofrm, the ^1H NMR signal of the methylamino group gradually changed in an interesting manner as shown in Fig. 5.

Compound **2** reacts with trifluoroacetic acid and gives a salt ammonium trifluoroacetate. In the process shown in Fig. 5, we can explain the variation of the methyl signal on adding trifluoroacetic acid as follows. (1) In the case of [CF_3COOH]≦[**2**]: By protonation of the methylamino group, the *sp*-methyl signal (singlet) gradually develops with shift to lower field, while the *ap*-methyl signal (doublet) changes into a singlet and gradually sinks with shift to higher

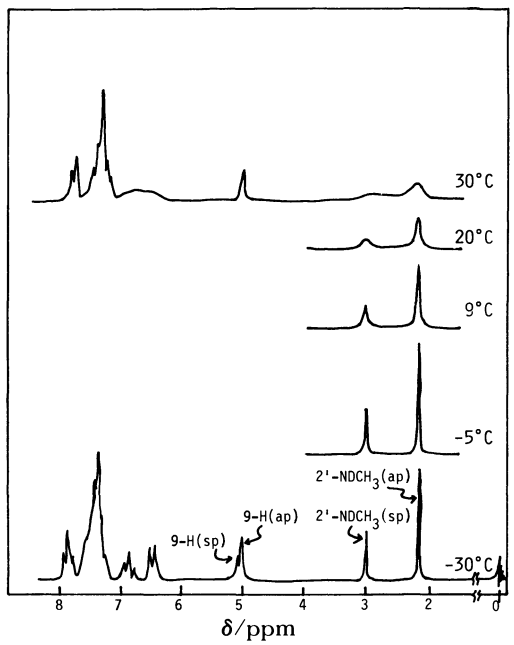

Fig. 4. Temperature-dependent spectra of **2** in $CDCl_3$–D_2O.

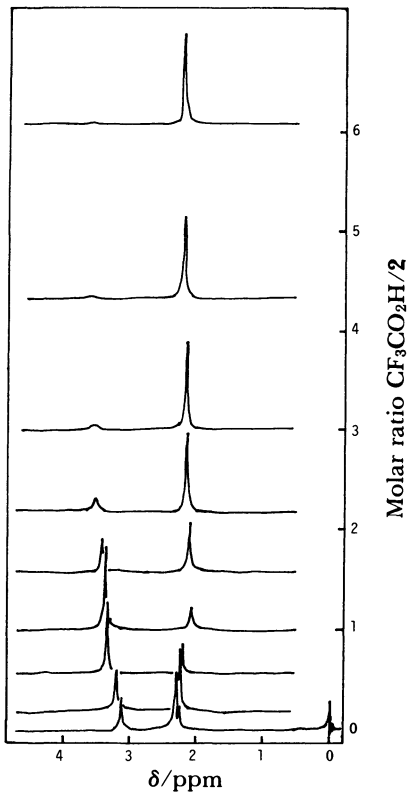

Fig. 5. ^1H NMR spectra of **2** and **2**–CF_3CO_2H salt at −10 °C.

field. That is, in the resulting ammonium trifluoroacetate the *sp*-form is more stable than the *ap*-form, contrary to the case of the free amine **2**. It is presumed that the trifluoroacetate ion acts as a medium to reduce the distance between the methylammonium group and the 9-proton (Fig. 6). This suggested bridging effect of the trifluoroacetate ion will make the *ap*⇄*sp* equilibrium incline predominantly to the *sp*-form. (2) In the case of [CF_3COOH]> [**2**]: The *sp* signal gradually shrinks with convergence to about δ 3.6, and the *ap* signal gradually enhances with convergence to about δ 2.2. That is, when excess equivalent of the acid is added, the trifluoroacetate ion associates with excess trifluoroacetic acid and loses its bridging effect between the methylammonium group and the 9-proton. In fact, with addition of methanol (or dimethylsulfoxide) to the solution of **2** in excess amount of acid, the *ap* signal, which had considerably developed, almost disappeared. In this case, the acid is associated with added methanol and its concentration is essentially diluted. Thus, it can be postulated that by increasing the concentration of the acid, the N–H···π interaction between the methylammonium group and the fluorene ring in the *ap*-salt predominates over the bridging effect of the trifluoroacetate ion in the *sp*-salt. In this way the *ap*-salt may be stabilized. Furthermore, in the case of [CF_3COOH]⩾[**2**], the *sp* signal almost disappears and the sharp *ap* signal (about δ 2.2) is observed. Accordingly, the N–H···π interaction makes the equilibria *ap*⇄*sp* incline to the *ap*-form, exclusively. However in any case, both the *ap*- and *sp*-methyl signals are probably observed together as weighted average of those of **2** and **2**-salt.

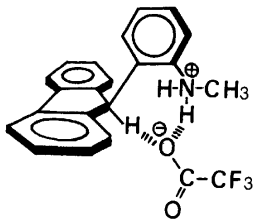

Fig. 6. A bridging effect of trifluoroacetate ion in **2**-*sp*-salt.

In this system, we can recognize a conformational equilibrium of **2** owing to the restricted rotation about the C(9)–C(Ar) bond, and both acid-base equilibria owing to the protonation of each conformer of **2** with trifluoroacetic acid, and additionally a conformational equilibrium exists between the two **2**-salts. Thus, at least the four equilibria described above participate in this system. The first and last equilibria can be determined by the relative stability of the two rotamers (*ap*- and *sp*-) in **2** and **2**-salt, respectively. Also the acid-base equilibria are governed by the concentration

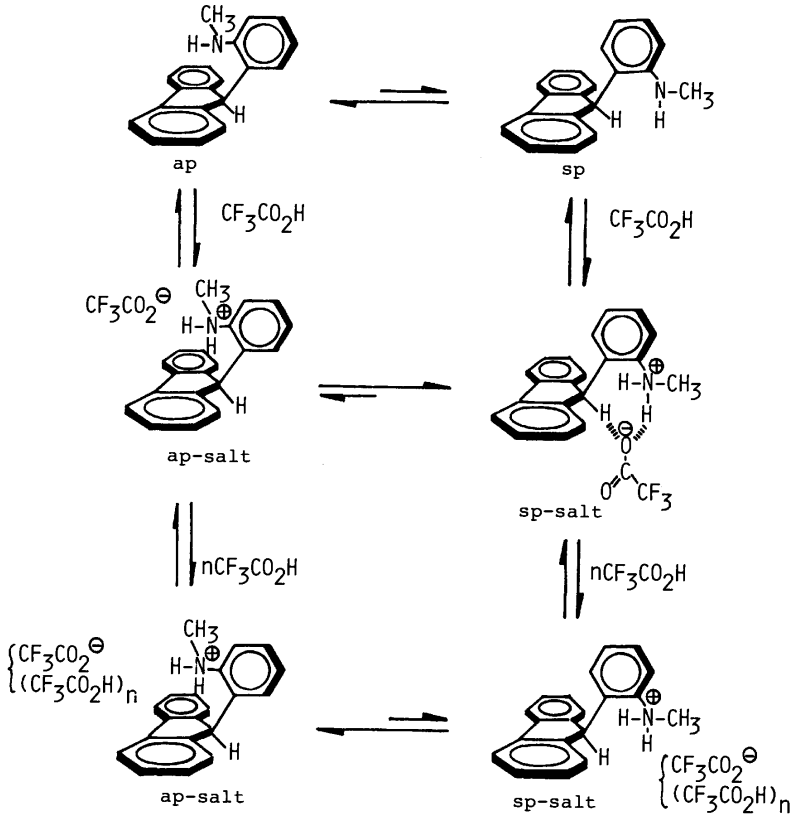

Fig. 7. Isomerization processes for **2** (*ap* and *sp*) and their trifluoroacetate salts.

of trifluoroacetic acid because the quantity of **2** is held constant. However, we consider that the stability of the rotamer may be independent of the rate of proton exchange between the acid and base.

We now show the above-mentioned interconversion for the conformers of the free amine **2** and its salt in Fig. 7.

Experimental

^{1}H NMR spectra were recorded on a JEOL-MH-100 spectrometer with a JEOL model JES-VT-3 variable temperature controller. The chemical shifts are expressed in ppm, with tetramethylsilane as an internal standard. Dynamic NMR spectra were analized by using a modified version of the computer program DNMR 3. The IR spectra were measured on a JASCO IRA-1 spectrometer solutions in carbon tetrachloride. Melting points are uncorrected.

9-(2-Methylaminophenyl)fluorene (2). To a solution of 9-(2-dimethylaminophenyl)-9-fluorenol (**1b**) (0.2 g, 0.7 mmol) in acetic acid (5 ml) was bubbled hydrogen bromide gas generated for 1 h. The mixture was concentrated, alkalized by sodium hydroxide solution, and extracted with benzene. The benzene solution was dried with magnesium sulfate, and concentrated in vacuo to obtain the residue which was recrystallized from acetone to give **2** as colorless needles; yield: 0.14 g (75%); mp 121—122 °C. IR (CCl_4): 3420 cm^{-1} (NH). Found: C, 88.38; H, 6.13; N, 5.05%. Calcd for $C_{20}H_{17}N$: C, 88.52; H, 6.32; N, 5.16%.

^{1}H NMR data of **2** in $CDCl_3$ at 25 and −30 °C were shown in Table 1.

9-(4-Dimethylaminophenyl)-9-fluorenol (6). A solution of fluorenone (1.8 g, 0.01 mol) in dry THF was added to the Grignard reagent prepared from magnesium turnings (0.4 g, 0.017 mol) and *p*-bromo-*N*,*N*-dimethylaniline (3 g, 0.015 mol). The mixture was refluxed for 1 h. After cooling, the solution was poured into dil. hydrochloric acid, alkalized by sodium hydroxide solution and extracted with benzene. The benzene solution was dried with magnesium sulfate, distilled off in vacuo, leaving a residue which was recrystallized from benzene to give **6** as colorless prisms; yield 2.0 g (66%); mp 157—158 °C. ^{1}H NMR ($CDCl_3$) δ=2.52 (1H, s, OH), 2.89 (6H, s, $2CH_3$), 6.68 (2H, d, J=8 Hz, 3′,5′-H), 7.16—7.73 (11H, m, 2′,6′-H and fluorenyl protons). Found: C, 83.99; H, 6.18; N, 4.41%. Calcd for $C_{21}H_{19}NO$: C, 83.69; H, 6.36; N, 4.65%.

9-(4-Dimethylaminophenyl)fluorene (9). Hydriodic acid (57%, 6.0 g, 50 mmol) was added to a solution of **6** (1.2 g, 4 mmol) in acetic acid (30 ml), and refluxed for 1.5 h. The reaction mixture was concentrated in vacuo to obtain a residue which was treated by sodium bisulfite, alkalized by sodium hydroxide solution, and extracted with benzene. The benzene solution was dried with magnesium sulfate and evaporated in vacuo to give **9** yield: 0.8 g (70%); colorless needles; mp 155—156 °C (from benzene-hexane (1:2)). ^{1}H NMR ($CDCl_3$) δ=2.92 (6H, s, $2CH_3$), 5.02 (1H, s, 9-H), 6.72 (2H, d, J=8 Hz, 3′, 5′-H), 7.06 (2H, d, J=8 Hz, 2′, 6′-H), 7.28—7.96 (8H, m, fluorenyl protons). Found: C, 88.72; H, 6.56; N, 4.68%. Calcd for $C_{21}H_{19}N$: C, 88.38; H, 6.71; N, 4.91%.

9-(4-Methylaminophenyl)fluorene (7). A solution of **9** (0.3 g, 1.05 mmol) and cyanogen bromide (0.3 g, 3.2 mmol) in acetone(5 ml) was refluxed for 16 h, and concentrated at atmospheric pressure to obtain a residue, which was extracted with dry ether. The ether filtrate was extracted with 15% hydrochloric acid solution and washed with water. The ether solution was dried with magnesium sulfate and concentrated in vacuo. The crude product (9[4-(*N*-cyano-*N*-methylamino)phenyl]fluorene (0.2 g)) was refluxed continuously in 20% hydrochloric acid solution for 6 h. The reaction mixture was alkalized by sodium hydroxide solution, extracted with benzene, dried with magnesium sulfate. The solution was evaporated in vacuo, leaving a residue which was column-chromatographed on alumina using benzene as an eluent to give **7**; yield: 0.06 g (22%); colorless needles; mp 126—127 °C. IR (CCl_4): 3420 cm^{-1} (NH). ^{1}H NMR ($CDCl_3$) δ=2.83 (3H, s, CH_3), 3.52 (1H, br. s, NH), 5.06 (1H, s, 9-H), 6.60 (2H, d, J=8 Hz, 3′,5′-H), 7.02 (2H, d, J=8 Hz, 2′,6′-H), 7.20—8.0 (8H, m, fluorenyl protons). Found: C, 88.40; H, 6.29; N, 5.07%. Calcd for $C_{20}H_{17}N$: C, 88.52; H, 6.32; N, 5.16%.

***N*-Methylation of 2.** To a solution of **2** (0.22 g, 0.8 mmol) was added methyl iodide (0.22 g, 1.6 mmol) and the mixture was allowed to stand for a week at room temperature. The reaction mixture was concentrated, alkalized by sodium hydroxide solution, and extracted with benzene. The benzene solution was dried with magnesium sulfate and the solvent distilled off in vacuo to give **1a**; yield: 0.14 g (60%); colorless crystals; mp 121—122 °C (from methanol–benzene). ^{1}H NMR ($CDCl_3$) δ=2.86 (6H, br.s, $2CH_3$), 5.86 (1H, br. s, 9-H), 6.34 (1H, d, 6′-H), 6.92—7.70 (11H, m, aromatic protons).

The authors wish to thank Professor Masashi Tashiro, Institute of Advanced Material Study, Kyushu University, for the elemental analyses, and are grateful for the financial support of this work by Research Grant-in-Aid from the Ministry of Education, Science and Culture (No. 60470023).

†Department of Chemistry, College of Science, Rikkyo University, Nishi-ikebukuro, Tokyo 171
(Received March 22, 1988)

Four cyclotetradecapeptides related to gramicidin S, *cyclo*(-Val-Orn-Leu-Leu-D-Phe-Pro-Leu-)$_2$ (14-peptide-**1**), *cyclo*(-Val-Orn-Leu-D-Leu-D-Phe-Pro-Leu-)$_2$ (14-peptide-**2**), *cyclo*(-Val-Orn-Leu-Leu-D-Phe-Pro-D-Leu-)$_2$ (14-peptide-**3**), *cyclo*(-Val-Orn-Leu-D-Leu-D-Phe-Pro-D-Leu-)$_2$ (14-peptide-**4**), were prepared in order to investigate the contribution of the ring size and the amino acid sequences around the Pro residue to the antibiotic activity and conformation. The CD spectra of these synthetic peptides in ethanol solutions were different from each other, indicating that they possess various conformations in ethanol solutions. 14-Peptides-**1**, -**2**, and -**3** showed 1/4—1/8 of the antibiotic activity of gramicidin S against the gram-positive microorganisms tested, whereas 14-peptide-**4** showed no activity. A clear relationship between CD spectra and the antibiotic activity of these synthetic peptides could not be found.

Gramicidin S-1 (GS)[1] is an antibiotic cyclodecapeptide, *cyclo*(-Val-Orn-Leu-D-Phe-Pro-)$_2$,[2] with a rigid β-pleated sheet conformation.[3] From numerous investigations of the relationship between the structure and the antibiotic activity of this antibiotic, it has been proposed that the D-Phe-Pro-Val sequence in the β-turn part is essential for its antibiotic activity.[4,5] On the other hand, we found during studies of an antibiotic cyclododecapeptide, gratisin (GR),[6] that *cyclo*(-Val-Orn-Leu-D-Phe-Pro-D-Tyr-)$_2$, *cyclo*(-Val-Orn-Leu-D-Phe-D-Tyr-Pro-)$_2$, and *cyclo*(-Val-Orn-Leu-Pro-D-Phe-D-Phe-)$_2$ possess a strong activity, although their sequences in the β-turn part are different from each other.[7] These results suggest that the presence of an amino acid residue, D-Tyr or D-Phe,

	1 2 3 4 5 6 7
14-peptide-1	cyclo(-Val-Orn-Leu-Leu-D-Phe-Pro-Leu-)$_2$
14-peptide-2	cyclo(-Val-Orn-Leu-D-Leu-D-Phe-Pro-Leu-)$_2$
14-peptide-3	cyclo(-Val-Orn-Leu-Leu-D-Phe-Pro-D-Leu-)$_2$
14-peptide-4	cyclo(-Val-Orn-Leu-D-Leu-D-Phe-Pro-D-Leu-)$_2$

Fig. 1. Primary structures of synthetic cyclotetradecapeptides.

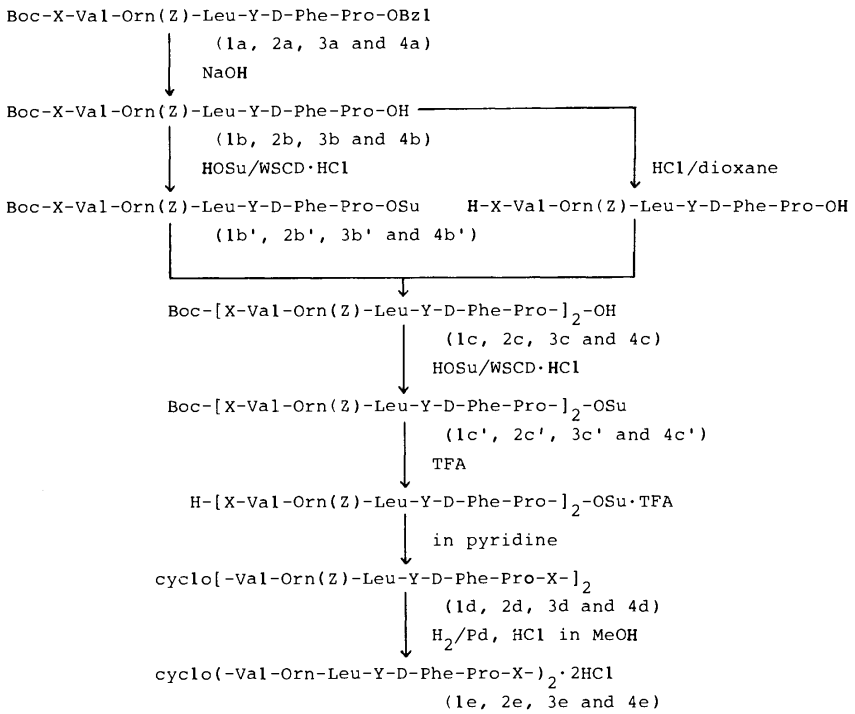

Fig. 2. Synthesis of cyclotetradecapeptides.
[X=Leu, Y=Leu (14-peptide-**1**), X=Leu, Y=D-Leu (14-peptide-**2**), X=D-Leu, Y=Leu (14-peptide-**3**), X=D-Leu Y=D-Leu (14-peptide-**4**)].

in gratisin peptides makes it possible for them to adopt a suitable conformation for antibiotic activity, regardless of the position of the Pro residue. Thus, it is of interest to study the structure–activity relationship of a cyclic peptide with a larger ring size than those of GS and GR. The configuration and the hydrophobic side chain of the amino acid residues around the D-Phe–Pro sequence are known to play an important role in stabilizing the β-turn formed by the D-Phe–Pro sequence.[4,7] In order to further investigate the contribution of the ring size and the amino acid sequence around the β-turn to the secondary structure and the antibiotic activity, we synthesized four cyclotetradecapeptides (Fig. 1) containing, respectively, partial sequences: Leu–D-Phe–Pro–Leu, D-Leu–D-Phe–Pro–Leu, Leu–D-Phe–Pro–D-Leu, and D-

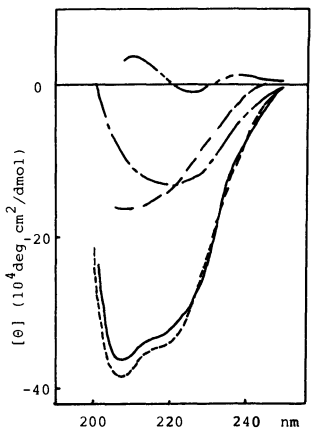

Fig. 3. CD spectra of synthetic cyclotetradecapeptides and GS in ethanol.
14-Peptide-**1** ——, 14-peptide-**2** — —, 14-peptide-**3** —·—, 14-peptide-**4** —···—, and GS ------.

Leu-D-Phe-Pro-D-Leu. The Leu residue was chosen as an amino acid residue having a hydrophobic side chain for an enlargement of the ring size.

These peptides were synthesized by conventional methods, as shown in Fig. 2. The yields, physical properties and analytical data regarding intermediary products are summarized in Table 1. The homogeneity of 14-peptide **1**—**4** was confirmed by means of thin-layer chromatography (TLC), amino acid analysis, high-performance liquid chromatography (HPLC), elemental analysis, and fast atom bombardment (FAB) or secondary ion (SI) mass spectrometry (Table 2).

The CD spectra of these synthetic peptides and GS in ethanol solutions are shown in Fig. 3. The spectral shapes of 14-peptide-**1**, -**2**, -**3**, and -**4** differ from each other, indicating that their peptides have different conformations in ethanol solutions. Recently, in CD spectroscopic studies of GS and GR, we reported that the CD spectra of their synthetic isomers could be classified into four groups, and that the isomers belonging to each group possess analogous partial sequences around the Pro residues.[5,7] 14-Peptide-**1**, having a D-Phe-Pro-Leu sequence, showed a similar CD curve to that of GS and GR-peptides having a D-Phe-Pro-X (X=Val or Tyr) sequence at the β-turn part, although the number of ring members of this peptide is different from that of GS or GR, and its ellipticity is almost the same as that of GS. This result indicates that 14-peptide-**1** possesses a conformation similar to that of GS in an ethanol solution, and that the amino acid sequence at the β-turn part makes a large contribution to the conformation. On the other hand, 14-peptides-**2**, -**3**, and -**4** showed CD spectra different from GS analogs and GR-peptides possessing Phe-Pro-D-X or D-Phe-Pro-D-X (X=Val or Tyr). These results suggest that it might be impossible to evaluate the contribution of the conformation around the Pro residue to the CD spectra of these 14-peptides by comparing their CD curves.

The antibiotic activity of these synthetic peptides against several microorganisms is summarized in Table 3. 14-Peptide-**1**, having a D-Phe-Pro-Leu sequence, showed 1/4—1/8 of the activity of GS against the gram-positive microorganisms tested. Recently, we reported that a GR-peptide having a D-Phe-Pro-Tyr sequence at the β-turn part possessed 1/4—1/16 of the activity of GS, and that its CD spectrum is similar to that of GS.[7] Supposing that the mode of action of these peptides having a -D-Phe-Pro- sequence at the β-turn part is the same as that of GS, the present results indicate that the ring size of a molecule is important in order to exhibit a strong and characteristic antibiotic activity, though it is not essential to exhibit activity. 14-Peptide-**2** and -**3** showed almost the same activity as that of 14-peptide-**1** toward gram-postive microorganisms, although their

Table 3. Antibiotic Activity of 14-Peptides-**1**—**4** and GS[a)]

Test organisms	GS	**1**	**2**	**3**	**4**
Staph. aureus MS353 C36 C	3.13	25	25	12.5	>50
Strept. pyogenes N.Y. 5	3.13	12.5	12.5	12.5	>50
Corynebact. diphtheriae P.W. 8	1.56	12.5	12.5	25	>50
Bac. subtilis ATCC 6633	3.13	12.5	25	25	>50
E. coli NIHJ-JC2	>100	>50	>100	>50	>50

a) Minimum inhibitory concentration ($\mu g\,ml^{-1}$) was determined by an agar dilution method with 10^6 organisms per milliliter.

sequences at the β-turn part are different from each other. Similar results were obtained in studies of peptides related to GR.[7] These results indicate that, for exhibiting activity, the amino acid sequence at the β-turn part is not limited to a D-Phe-Pro-Val sequence, which is of GS. On the other hand, 14-peptide-**4** showed no activity. This result indicates that Leu residues at positions 7 and 7′ in 14-peptide-**2**, or at positions 4 and 4′ in 14-peptide-**3**, could not be substituted by D-Leu residues without affecting the activities.

Experimental

All melting points are uncorrected. The CD spectra were obtained by use of a JASCO spectropolarimeter, model J-500, using a 0.5-mm quartz cell at room temperature. The CD spectroscopy of GS and four cyclotetradecapeptides were carried out with ethanol solutions of their dihydrochlorides at a concentration of 1.5—2.0×10^{-4} M (1 M=1 mol dm^{-3}). The molecular weights of these synthetic peptides were determined by FAB mass spectrometry using a JEOL JMS-D-300 mass spectrometer and SI mass spectrometry using a HITACHI M-80. Amino acid analyses were carried out by a Hitachi 835 amino acid analyzer, after hydrolysis of the peptides in 6 M HCl at 110 °C for 24 h. HPLC was performed by an ODS column (ϕ 4.6×250 mm) using MeOH-5% aq $NaClO_4$(5:1) as an elution solvent. TLC was performed on Merck silica-gel F_{254} plates with the following solvent systems (v/v): R_f^1, $CHCl_3$-MeOH (9:1); R_f^2, $CHCl_3$-MeOH-AcOH (95:5:3); R_f^3, *n*-BuOH-AcOH-H_2O (4:1:1); R_f^4, *n*-BuOH-pyridine-AcOH-H_2O (4:1:1:2). The yields of **1a**, **2a**, **3a**, and **4a** were calculated on the basis of the amount of Pro-OBzl as a starting material.

Boc-Leu-Val-Orn(Z)-Leu-Leu-D-Phe-Pro-OBzl (1a). HCl·Pro-OBzl (1.70 g, 7 mmol) was dissolved in $CHCl_3$ (30 ml); the solution was then washed with 5% Na_2CO_3 and water under cooling in an ice bath. To this solution were added Boc-D-Phe (1.85 g, 7 mmol), HOBt (1.08 g, 8 mmol) and WSCD·HCl (1.33 g, 7 mmol) at 0 °C. This solution was stirred for 1 h at 0 °C and 2 h at room temperature. The reaction mixture was washed successively with 5% citric acid, water, and 5% Na_2CO_3 and water; the solvent was then evaporated in vacuo. The residue was dissolved in 4 M HCl/dioxane (20 ml) at 0 °C. After stirring for 30 min at room temperature, the solution was concentrated in vacuo. The residue was dissolved in $CHCl_3$ (30 ml); the solution was then washed with 5% Na_2CO_3 and water under cooling in an ice bath. To this solution were added Boc-Leu(1.68 g, 7 mmol), HOBt (1.08 g, 8 mmol) and WSCD·HCl (1.33 g, 7 mmol) at 0 °C. The same procedure as described above was repeated for this reaction mixture. Further, Boc-Leu, Boc-Orn(Z), Boc-Val, Boc-Leu were successively coupled by the same method. All reactions were followed by TLC on a silica-gel plate. The crude protected heptapeptide obtained from the final reaction mixture was purified by reprecipitation from AcOEt-ether; overall yield, 3.73 g (47% from Pro-OBzl).

Compounds **2a**, **3a**, and **4a** were prepared in a similar manner. Compounds **2a** and **4a** were purified by chromatography on a silica-gel column (ϕ 1.2×40 cm) using a solvent system of $CHCl_3$-MeOH (50:1) and reprecipitation from AcOEt-ether.

Boc-Leu-Val-Orn(Z)-Leu-Leu-D-Phe-Pro-OH (1b). To a solution of **1a** (3.00 g, 2.63 mmol) in MeOH (20 ml) and dioxane (10 ml), 1 M NaOH (5.3 ml) was added. The solution was stirred for 10 h at room temperature. 5% citric acid (100 ml) was added to the reaction mixture. The resulting solid was collected by filtration, washed with water and dried. The product was recrystallized from MeOH-ether-hexane; yield 2.42 g (88%).

Compounds **2b**, **3b**, and **4b** were prepared in a similar manner.

Boc-[Leu-Val-Orn(Z)-Leu-Leu-D-Phe-Pro-]$_2$-OH (1c). To a solution of **1b** (1.05 g, 1.0 mmol) in DMF (10 ml) were added HOSu (0.23 g, 2.0 mmol) and WSCD·HCl (0.38 g, 2.0 mmol) at 0 °C, and then the mixture was stirred for 5 h at room temperature. After the solution was evaporated, water was added to the residue. The resulting solid, Boc-Leu-Val-Orn(Z)-Leu-Leu-D-Phe-Pro-OSu (**1b′**), was collected by filtration, washed with water and then dried. Another crop of **1b** (1.05 g, 1.0 mmol) was dissolved in 4 M HCl/dioxane (10 ml) at 0 °C. After stirring a room temperature for 30 min, the solution was concentrated in vacuo. To a solution of H-Leu-Val-Orn(Z)-Leu-Leu-D-Phe-Pro-OH (prepared as mentioned above) and TEA (0.28 ml, 2.00 mmol) in DMF (15 ml) at 0 °C was added **1b′** derived from **1b**. The mixture was left to stand for 2 h at 0 °C and overnight at room temperature. The solution was evaporated; then 5% citric acid was added to the residue. The resulting solid was collected by filtration, washed with water and then dried. The product was recrystallized from MeOH-ether-hexane; yield, 1.64 g (83%).

Compounds **2c**, **3c**, and **4c** were prepared in a similar manner.

***cyclo*[-Val-Orn(Z)-Leu-Leu-D-Phe-Pro-Leu-]$_2$ (1d).** Compound **1c** (0.80 g, 0.40 mmol) was converted into the *N*-hydroxysuccinimide ester (**1c′**) by the method described for **1c**. It was then dissolved in TFA (10 ml) at 0 °C. The mixture was stirred for 40 min at room temperature and then concentrated in vacuo. The residue, the trifluoroacetate of

the tetradecapeptide active ester, was triturated with ether and collected by filtration and dissolved in DMF (10 ml). The solution was poured, dropwise, into pyridine (350 ml) at 45 °C. After stirring for 3 h at 45 °C, the solution was concentrated. The addition of water to the residue afforded precipitates, which were filtered and washed with water. The purification of this compound was performed by chromatography on a silica-gel column (ϕ 1×20 cm) using a solvent system of $CHCl_3$–MeOH (50:1), followed by reprecipitation from MeOH–ether; yield, 0.41 g (55%).

Compounds **2d**, **3d**, and **4d** were prepared in a similar manner.

***cyclo*(-Val-Orn-Leu-Leu-D-Phe-Pro-Leu-)$_2$·2 HCl (1e).** Compound **1d** (121 mg, 0.065 mmol) was dissolved in 90% aq MeOH (15 ml) and dioxane (10 ml); then, 1 M HCl (0.15 ml) was added to the solution. This mixture was hydrogenolyzed in the presence of palladium black for 15 h. After removing the catalyst, the filtrate was concentrated in vacuo. The product was purified by gel filtration on a Sephadex LH-20 column (ϕ 1.2×120 cm) using MeOH as a solvent, and by reprecipitation from MeOH–ether; yield, 92 mg (85%).

Compounds **2e**, **3e**, and **4e** were prepared in a similar manner. However, in **2e**, the gel-filtration procedure was not required.

We are grateful to the staff of the Research Laboratories of Toyo Jozo Co. for elemental analyses, microbiological assays and the measurement of FAB mass spectra, and also to Professor Makoto Suzuki, Meijo University for the SIMS measurements.

Se-Aryl Alkane- or Arenecarboselenothioates: Synthesis and Some Reactions[1)]

Shinzi KATO,* Eiji YASUI, Kiyomitsu TERASHIMA, Hideharu ISHIHARA, and Toshiaki MURAI

Department of Chemistry, Faculty of Engineering, Gifu University, 1-1 Yanagido, Gifu 501-11

(Received March 30, 1988)

A series of *Se*-aryl carboselenothioates **3** (RCSSeAr, R=alkyl, aryl) were synthesized and characterized from the reaction of bis(thioacyl) sulfides **1** with sodium areneselenolates. The thionselenolesters **3** are stable (liquid or crystals) both thermally and to moisture. Reactions of **3** with aliphatic primary and secondary amines gave the corresponding ammonium carbodithioates **8** together with diphenyl diselenide **7**. In contrast, treatment with aromatic amines or sodium alcoholates afforded the corresponding thioamides or *O*-alkyl or *O*-aryl thionesters in good yields. The oxidation of **3** with *m*-chloroperbenzoic acid gave the corresponding sulfides **12** [RCS(O)SeAr] and acyl arylseleno sulfides **13** [RCOSSeAr] which are formed by a rearrangement of the ArSe group to the thiocarbonyl sulfur atom.

In the past decades, a number of esters of carboselenoic and carbotelluroic acids (RCOER', E=Se, Te) have been prepared and their physical and chemical properties have been revealed.[2)] In contrast, the chemistry of carboselenothioic acid esters **3** (RCSSeR')[3)] (hereafter cited as thionselenolesters) have virtually not been studied, because of their synthetic difficulty, though they are interesting compounds synthetically and spectroscopically. In earlier studies, we succeeded in isolating bis(thioacyl) sulfides **1**[4)] and demonstrated that they are very useful for the thioacylation of amines, alcoholates, and thiolates.[5)] We now wish to report on the synthesis of a series of thionselenolesters **3** from the reaction of bis(thioacyl) sulfides **1** with sodium areneselenolates and their various reactions.

Results and Discussion

For the synthesis of thionselenolesters **3**, the reaction conditions (using bis[4-methyl(thiobenzoyl)] sulfide **1i** and sodium benzeneselenolate) have been preliminary investigated in detail. As a result, the reaction conditions of bis(thioacyl) sulfides with a large excess of sodium areneselenolate at 0 °C for 1 h seemed to be preferable. For example, when a dichloromethane solution of the sulfide **1i** was added to three equivalents of sodium benzeneselenolate in ethanol at 0 °C, the color of the mixture quickly changed from dark green to reddish pink. After the usual work-up of the reaction mixture, a chromatographic separation on silica gel afforded 73% of *Se*-

of attempts to prepare a sterically hindered 2,4,6-trimethylphenyl derivative **3l** failed. In order to make a comparison with the above mentioned method, the following two synthetic methods were also examined: a) Reaction of thioacyl chloride with sodium benzeneselenolate (Method B) and b) with (phenylseleno)-trimethylsilane (Method C) (Eq. 2). As shown in

$$\underset{\mathbf{4}}{RC(=S)Cl} + \underset{\mathbf{2}}{C_6H_5SeNa} \xrightarrow[\text{Method B}]{0\,^\circ C,\ 30\ min,\ CH_2Cl_2} \underset{\mathbf{3}}{}$$

$$\underset{\mathbf{4}}{} + \underset{\mathbf{5}}{C_6H_5SeSi(CH_3)_3} \xrightarrow[\text{Method C}]{40\,^\circ C,\ 30\ min,\ CH_2Cl_2} \underset{\mathbf{3}}{} \quad (2)$$

Table 1, the former method led to analogous yields of **3**, while the later to low yields, because of the unexpected low reactivity of (phenylseleno)trimethylsilane.[7] It is noted that both methods are limited to the synthesis of aromatic derivatives (**3**, R=aromatic), because of a synthetic difficulty involving aliphatic thioacyl chlorides.[8]

The structures of the obtained thionselenolesters **3** were determined on the basis of mass, IR, UV/Vis, and ^1H and ^{13}C NMR spectroscopic data, and the results of microanalysis. The stretching frequencies, n–π^* transitions, and ^{13}C NMR spectra of the thiocarbonyl group of **3** are summarized in Table 2.

The thionselenolesters **3** are colored compounds: aliphatic derivatives (R=aliphatic) are yellow to orange and aromatic ones (R=aromatic) are red to reddish pink. They are stable both thermally and to moisture. They did not change at room temperaure for one week and can be storred in the refrigerator (0 °C) for over 3 years.

Spectra. It is known that νC=S bands of dithiocarboxylic acid esters appear in the region 1100—1200 cm^{-1} for the aliphatic derivatives and 1200—1250 cm^{-1} for the aromatic ones. As listed in Table 2, the characteristic thiocarbonyl stretching frequencies of **3** were observed in the 1220—1250 cm^{-1} region for the aliphatic derivatives and the 1000—1200 and/or 840—900 cm^{-1} regions for the aromatic derivatives. In the electron spectra of **3**, two characteristic absorption maxima were observed at 300—320 nm (π–π^*) and 480—495 nm (n–π^*,[10] C=S group) for the aliphatic derivatives and 530—540 nm (n–π^*,[10] C=S group) for the aromatic ones. The π–π^* and n–π^* transitions of the C=S group of *O*-phenyl 4-methylbenzenecarbothioate **11c**, phenyl 4-methylbenzenecarbodithioate **18**, and *Se*-phenyl 4-methylbenzenecarboselenothioate **3i** in both cyclohexane and ethanol are collected in Table 3. In going from E=*O*, to *S*, and *Se*, both absorption maxima shift to a longer-wavelength region. This is the first example of a bathochromic effect regarding the π–π^* and n–π^* transitions by an

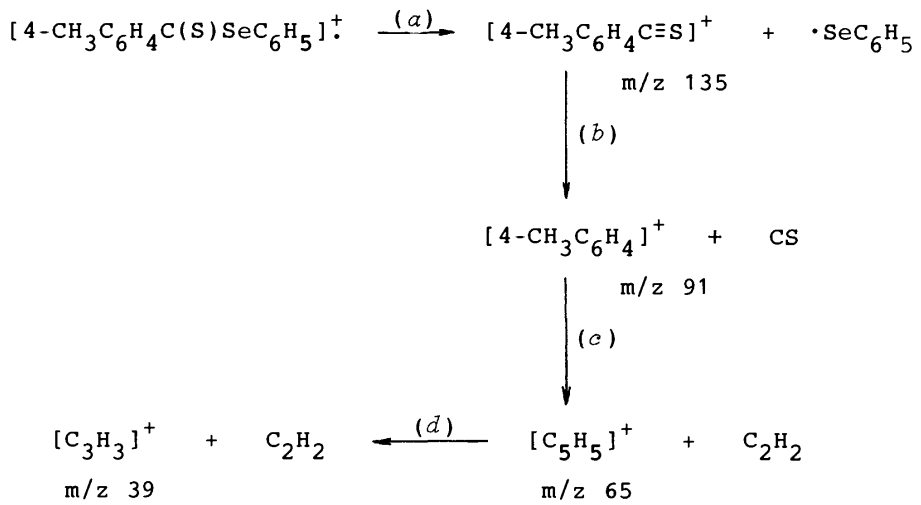

Scheme 1.

adjacent chalcogen element. In ^{13}C NMR spectra, ^{13}C=S values appear at δ 240—246 for the aliphatic derivatives and at 229—233 for the aromatic derivatives, respectively. As shown in Table 3, lower-field shifts of the thiocarbonyl carbon of the thion- **11c**, dithio- **18**, and thionselenolesters **3i** were observed in going from E=*O*, to *S*, and *Se*. Analogous lower shifts of the carbonyl carbon were observed for chalcogeno esters (RCOER′, E=*O*, *S*, *Se*, *Te*).[2]

It is well-known that *S*-alkyl benzenecarbothioates undergo a rearrangement of the alkyl group to the carbonyl oxygen atom, while the alkyl group of *O*-alkyl benzenecarbothioates migrates to the thiocarbonyl sulfur atom.[11-14] The obtained thionselenolesters **3** all afforded molecular ions. The fragment ions and the relative intensity of the 4-methyl derivative **3i** together with those of the corresponding thion- **11c** and dithioester **18** are shown in Table 4. As shown in the table, the cleavage pattern of the thionselenolester is substantially similar to those of the corresponding thion- and dithioesters.[15] Thus, the base peak is [4-CH$_3$C$_6$H$_4$C≡S]$^+$ peak at *m/z* 135 and the second highest one is the [C$_7$H$_7$]$^+$ peak at *m/z* 91; other significant peaks are those of the [C$_5$H$_5$]$^+$, [C$_6$H$_5$]$^+$, [C$_4$H$_3$]$^+$, [C$_3$H$_3$]$^+$, and [C$_6$H$_5$Se]$^+$, ions at *m/z* 65, 77, 51, 39, and 157, respectively. The most important successive frag-

mentations are (*a*)→(*b*)→(*c*), and→(*d*) (Scheme 1). In addition to these peaks, two characteristic peaks at *m/z* 183 and 109 can be observed corresponding to $[CH_3C_6H_4C{\equiv}Se]^+$ and $[C_6H_5S]^+$, respectively. This fact suggests a possible rearrangement of the phenyl group to the thiocarbonyl sulfur atom, followed by a fragmentation ion (**I**), though no metastable peaks corresponding to the fragmentation from the ion (**I**) could be observed (Scheme 2). Such a migration of the phenyl group bonded to a Se atom to the thiocarbonyl sulfur atom is the first example.

Reactions: In general, thion-[16] and dithioesters[17,18] react with primary and secondary amines to give the corresponding thioamides. In order to clarify the reactivity of the thionselenolester **3i**, several reactions with nucleophiles, such as amines and alcoholates, and oxidation by *m*-chloroperbenzoic acid were carried out using the 4-methyl derivative **3i** as the model thionselenolester. In Table 5, the reaction conditions of **3i** with primary and secondary amines and the products are summarized. At room temperature, **3i** does not react with an aromatic amine, such as aniline, though the reaction does occur under reflux in hexane to afford the corresponding thioanilide **6a** and diphenyl diselenide **7** in 68 and 99%, respectively. In contrast, the reaction with aliphatic amines, such as cyclohexylamine, diethylamine, and piperidine, occurrs at room temperature to give the corresponding ammonium salts **8** in 30—40% yields together with diselenide **7** and a dark-brown oil. No formation of the expected thioamides was observed.[18] In these reactions, the yields of diphenyl diselenide were quantitative. Over 60% the sulfur in the used **3i** was recovered as a dithio salt **8**, while the recovery of the $CH_3C_6H_4$ moiety was less than 45%. In order to elucidate the formation mechanism of **8**, a number of attempts to analyze the dark-brown oily substances have been undertaken. However, at the present stage, no appropriate explanation has been found regarding the formation of the ammonium dithiocarboxyates **8**.

The reaction with hydrazine at room temperature readily proceeded to give the corresponding thiohydrazide **6b**. When the reaction was carried out under reflux in ethanol, however, 1,3,4-thiadiazole **9** was obtained in a good yield. In addition, a reaction with thiosemicarbazide under the same conditions yielded 3,4-dihydro-2*H*-1,3,4-triazole-2-thione (**10**) in an almost quantitative yield. Presumably, **9** and **10** would be formed via the corresponding thioamide **6b** or **6c**, respectively. The same products **9** and **10** were obtained in reactions using the corresponding dithioesters **18**.

The thionselenolesters **3** do not react with methanol and ethanol at room temperature and even under refluxing conditions. However **3i** readily reacted with alkali metal alcoholates at room temperature to give the corresponding thionesters **11** in good yields (Eq. 5, Table 6). The formation of those thionesters seemed to proceed more smoothly than in cases using the corresponding phenyl arenecarbodithioates.[19]

The oxidation of dithioesters with peroxy acid provides a route to (alkyl- or arylthio)-, (alkyl- or arylsulfinyl)-, and (alkyl- or arylsulfonyl)sulfines.[20] The thionselenolesters **3i** upon treatment with peroxy acids are expected to produce the corresponding sulfines. In fact, the treatment of *Se*-phenyl 4-methylbenzenecarboselenothioate **3i** with one equivalent of *m*-chloroperbenzoic acid (mCPBA) in ether at 0 °C gave a 34% yield of a mixture of two isomeric phenylseleno(4-methylphenyl)sulfines (**12i** and **12'i**). No formation of the expected phenyl selenenyl (PhSeO–CSO–$C_6H_4CH_3$-4) and phenylselenonylsulfines (PhSeO$_2$–CSO–$C_6H_4CH_3$-4) were observed. Instead, phenylseleno 4-methylbenzoyl sulfides (**13i**), bis(4-methylbenzoyl) disulfide (**14**, R=4-$CH_3C_6H_4$), and diphenyl diselenide (**7**) were obtained in 11, 3, and 14% yields, respectively. Similarly, the oxidation of the aliphatic thionselenolesters, **3d** and **3e** afforded the corresponding sulfines as a mixture of the trans- (**12d**, **12e**) and cis-isomer (**12'd**, **12'e**), phenylseleno acyl sulfides **13d**, **13e**,[1] and diphenyl diselenide **7** in analogous yields.[21] The trans- **12** and cis-isomer **12'** were separated by thin-layer chromatography. The structures of the products, **12**, **13**, **14**, were established on the basis of the IR, ^1H and ^{13}C NMR, and mass spectra, and/or by comparisons of the spectra with those of authentic samples. In addition, the conformation of the trans- **12e** and cis-isomer **12'e** were deduced by the ^1H NMR spectra. For example, the methine and methylene protons of the trans- **12e** were shifted down field, compared with those of the cis-isomers **12'd** and **12'e**, respectively. In addition, the ortho-protons on the 4-methylbenzene ring of the trans-isomer **12i** showed a broad multiplet without

any downfield shift, while those of the cis-isomer **12′i** showed a singlet.[22)] Presumably, one of the reasons for such downfield shifts of the methine and methylene protons seems to be due to a deshielding action of the sulfinyl group.[23)] It is noted that the methine, methyl, and sulfine carbons of the *trans*-isopropyl(phenylseleno)sulfine **12d** were shifted upfield compared with those of the cis-isomer **12′i**. Similar upfield shifts of trans-isomer were observed for the ^{13}C NMR spectra of butyl(phenylseleno)sulfine, **12e** and **12′e**.

For the formation of phenylseleno acyl sulfides **13**, the possibility via the sulfine **12** and then 2-

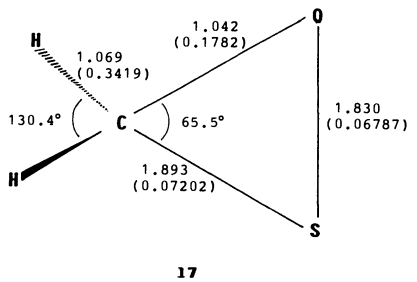

Fig. 1. Optimized geometry, bond lengths in Å, angles in deg. and bond populations in parentheses from 3-21G level MO calculations.

phenylseleno-3-alkyl (or aryl) oxathiirane **15** as intermediates can be considered (Scheme 3). However, after stirring trans- **12** or cis-isomer **12″** in dichloromethane at 20 °C for 2 h, no conversion between the trans- **12** and cis-isomers **12′** was observed. This result suggests that the possibility of a formation roue of **13** via the sulfine **12**, can be ruled out. In order to obtain additional information regarding the formation of the sulfine **12** via the oxathiirane **15**, an ab initio molecular orbital study was carried out by employing oxathiirane **17** as a model. The optimized molecular geometries[24)] of **17** were calculated by ab initio MO calculations at the 3-21G level using on energy-gradient method. As illustrated in Fig. 1, the bond population between sulfur and oxygen was smaller

than those of the carbon–oxygen and carbon–sulfur bonds. Thus, the S–O bond of the oxathiirane ring is weaker than the C–O and C–S bonds. Most probably, phenylseleno acyl sulfide **13** is formed by a migration of the phenylseleno group of the opening intermediate **16**.

Experimental

The melting points were obtained by using a Yanagimoto micromelting point apparatus and are uncorrected. The IR spectra were measured on a JASCO grating IR spectrophotometer (IR-G and A-302). The UV/Vis spectra were taken from a Hitachi 124 and 330 spectrometer. The ^{1}H and ^{13}C NMR spectra were recorded on Hitachi R-24 (60 MHz), R-22 (90 MHz), and JEOL JNM GX-270 (270 MHz) with tetramethylsilane as an internal standard.

The mass spectra were taken from a Hitachi RMU-6M mass spectrometer (70 eV, 180—190 °C). High-resolution mass spectroscopy was taken by a Shimazu high-resolution mass spectrometer (GCMS 9020-DF/PAC-1100). Elemental analyses were carried out by Elemental Analyses Center of Kyoto University and Alfred Bernhardt Analytical Laboratory, Engelskirhen (Germany).

Materials: Bis(thioacyl) sulfides,[4] piperidinium carbodithioates,[25] thioacyl chlorides,[26] phenylselenotrimethylsilanes,[27] diphenyl-,[27] bis(4-methylphenyl)-,[28] and bis(4-chlorophenyl) diselenides,[29] were prepared according to methods described in the literature. Sodium areneselenolates were prepared by a treatment of the corresponding diaryl diselenides with sodium borohydride, respectively.[30] Aniline, cyclohexylamine, diethylamine, and piperidine were dried by refluxing with potassium hydroxide, and distilled before use. Hydrazine hydrate, thiosemicarbazide, and *m*-chloroperbenzoic acid (80%) were of commercial grade and were used without further purification. The solvents were dried by the use of sodium metal or calcium chloride. Column chromatography was performed on Wako Gel 200.

The preparation methods of *Se*-phenyl 2-propane- (**3d**) and 4-methylbenzenecarboselenothioate (**3i**) (as typical procedures) are described in detail. All manipulations are carried out under nitrogen.

***Se*-Phenyl Methanecarboselenothioate (3a):** In a manner similar to the synthesis of **3d**, the reaction of bis[methyl(thiocarbonyl)] sulfide (**1a**, 3 mmol) in hexane (20 ml), freshly prepared from ethanedithioic acid (533 mg, 6 mmol) and dicyclohexylcarbodiimide (619 mg, 3 mmol), with a solution of sodium benzeneselenolate (3 mmol) in dichloromethane/methanol (3:1, 20 ml) at −60 °C for 30 min, followed by silica-gel column chromatography (hexane) and then bulb-to-bulb distillation yielded 170 mg (26%) of **3a** as orange liquid: bp 85 °C/1.5 Torr. IR (neat), 3047, 1582, 1480, 1442, 1359, 1208, 1195 (C=S), 1092, 1070, 1021, 1001, 831 (C=S) 737, 688, 494, and 468 cm^{-1}. UV/Vis (hexane) 258, 328, and 492 nm. ^{1}H NMR ($CDCl_3$) δ=2.84 (3H, s, CH_3), and 7.4—7.6 (5H, m, Ar). ^{13}C NMR ($CDCl_3$) δ=42.3 (CH_3), and 240.1 (C=S). MS (70 eV) *m/z* (rel intensity), 216 (M^+; 12), 157 ($C_6H_5Se^+$, 24), and 59 (CH_3CS^+, 100). Found: *m/z* 215.9503. Calcd for C_8H_8SSe: M, 215.9512.

***Se*-Phenyl Ethanecarboselenothioate (3b):** In a manner similar to the synthesis of **3d**, the reaction of bis[ethyl(thiocarbonyl)] sulfide (**1b**) (3 mmol) in hexane (20 ml), freshly prepared from propane dithioic acid (637 mg, 6 mmol) and dicyclohexylcarbodiimide (619 mg, 3 mmol), with a solution of sodium benzeneselenolate (3 mmol) in a mixed solvent of dichloromethane/methanol (3:1, 20 ml) at −10 °C for 30 min, followed by silica-gel column chromatography (hexane) and then bulb-to-bulb distillation yielded 353 mg (51%) of **3b** as orange liquid: bp 114 °C/3.5 Torr. IR (neat), 3025, 2950, 2290, 1577, 1480, 1441, 1280, 1191 (C=S), 1067, 1022, 1002, 968, 860 (C=S), 744, 691, and 471 cm^{-1}. UV/Vis (hexane) 258, 328, and 486 nm. ^{1}H NMR ($CDCl_3$) δ=1.35 (3H, t, CH_3), 3.04 (2H, q, CH_2), and 7.3—7.6 (5H, m, Ar). ^{13}C NMR ($CDCl_3$) δ=15.0 (CH_3), 47.1 (CH_2), and 246.4 (C=S). MS (70 eV) *m/z* (rel intensity), 230 (M^+; 5), 157 ($C_6H_5Se^+$, 5), and 73 ($C_2H_5CS^+$, 100). Found: *m/z* 229.9661. Calcd for $C_9H_{10}SSe$: M, 229.9668.

***Se*-Phenyl 1-Propanecarboselenothioate (3c):** In a manner similar to the synthesis of **3d**, bis[propyl(thiocarbonyl)] sulfide (**1c**) (3 mmol) in hexane (20 ml), freshly prepared from butanedithioic acid (721 mg, 6 mmol) and dicyclohexylcarbodiimide (619 mg, 3 mmol), was added to a solution of sodium benzeneselenolate (3 mmol) in a mixed solvent of dichloromethane/methanol (3:1, 20 ml) at 0 °C for 30 min, followed by silica-gel column chromatography and then bulb-to-bulb distillation yielded 496 mg (68%) of **3c** as orange liquid: bp 127 °C/3.5 Torr. IR (neat) 3025, 2980, 2950, 2880, 1580, 1478, 1460, 1440, 1380, 1240, 1184 (C=S), 1063, 1020, 1000, 922, 832 (C=S), 737, 687, and 468 cm^{-1}; UV/Vis (hexane) 258, 330, and 486 nm. ^{1}H NMR ($CDCl_3$) δ=0.99 (3H, t, CH_3), 1.88 (2H, m, CH_2), 3.04 (2H, t, CH_2), and 7.34—7.57 (5H, m, Ar). ^{13}C NMR ($CDCl_3$) δ=13.0 (CH_3), 23.7 (CH_2), 55.6 (CH_2), and 244.4 (C=S). MS (70 eV) *m/z* (rel intensity), 244 (M^+; 12), 157 ($C_6H_5Se^+$, 12), and 87 ($C_3H_7CS^+$, 100). Found: *m/z* 243.9836. Calcd for $C_{10}H_{12}SSe$: M, 243.9825.

***Se*-Phenyl 2-Propanecarboselenothioate (3d):** A solution of bis[isopropyl(thiocarbonyl)] sulfide (**1d**, 3 mmol) in hexane (20 ml), freshly prepared by a reaction of 2-methylpropanedithioic acid (721 mg, 6 mmol) with dicyclohexylcarbodiimide (619 mg, 3 mmol) in hexane (20 ml) at −70 °C for 30 min, was added to a solution of freshly prepared sodium benzeneselenolate (3 mmol) in a mixed solvent of dichloromethane/methanol (3:1, 20 ml) at 0 °C. The reaction mixture was then stirred at this temperature for 30 min. The color of the solution quickly changed from violet to orange. Hexane (15 ml) was added; the mixture was then washed with water (3×50 ml), followed by drying with anhydrous sodium sulfate. The solvent was evaporated in vacuo. The residue was chromatographed on silica gel [hexane/dichloromethane (9:1)]; then, a bulb-to-bulb distillation of the resulting orange eluent yielded 560 mg (77%) of **3d** as orange liquid: bp 111 °C/3.0 Torr. IR (neat) 3045, 3000, 2950, 2900, 1581, 1480, 1441, 1384, 1210 (C=S), 1160, 1067, 1031, 1021, 1001, 905, 815, 738, 688, and 470 cm^{-1}. UV/Vis (hexane) 258, 328, and 493 nm. ^{1}H NMR ($CDCl_3$) δ=1.36 (6H, d, CH_3), 3.59 (1H, m, CH), and 7.41—7.53 (5H, m, Ar). ^{13}C NMR ($CDCl_3$) δ=23.9, 50.8, and 242.2 (C=S). MS (70 eV) *m/z* (rel intensity), 244 (M^+; 12), 157 ($C_6H_5Se^+$, 42), and 87 (i-$C_3H_7CS^+$, 100). Found: *m/z* 243.9825. Calcd for $C_{10}H_{12}SSe$: M, 243.9825.

***Se*-Phenyl 1-Butanecarbothioselenoate (3e):** In a manner similar to the synthesis of **3d**, bis[butyl(thiocarbonyl)] sulfide (**1e**, 3 mmol) in hexane (20 ml), freshly prepared from pentanedithioic acid (806 mg, 6 mmol) and dicyclohexylcarbodiimide (619 mg, 3 mmol), was added to a solution of

sodium benzeneselenolate (3 mmol) in a mixed solvent of dichloromethane/methanol (3:1, 20 ml) at 0 °C for 30 min, followed by silica-gel column chromatography (hexane) and then bulb-to-bulb distillation of the resulting orange eluent yielded 460 mg (60%) of **3e** as orange liquid: bp 132 °C/3.5 Torr. IR (neat) 3050, 2970, 2950, 2580, 1580, 1478, 1440, 1380, 1300, 1220, 1180 (C=S), 1091, 1064, 1021, 1000, 867, 732, 688, and 468 cm^{-1}. UV/Vis (hexane) 258, 330, and 486 nm. ^1H NMR ($CDCl_3$) δ=0.91 (3H, t, CH_3), 1.39 (2H, m, CH_2), 1.82 (2H, m, CH_2), 3.06 (2H, t, CH_2), and 7.34—7.54 (5H, m, Ar). ^{13}C NMR ($CDCl_3$) δ=13.6, 21.6, 32.7, 53.5, and 244.3 (C=S). MS (70 eV) *m/z* (rel intensity), 258 (M^+; 10), 156 ($C_6H_5Se^+$, 50), and 101 (n-$C_4H_9CS^+$, 100). Found: *m/z* 257.9987. Calcd for $C_{11}H_{14}SSe$: M, 257.9987.

***Se*-Phenyl 1-Pentanecarboselenothioate (3f):** In a manner similar to the synthesis of **3d**, bis[1-pentyl(thiocarbonyl)] sulfide (**1f**, 3 mmol) in hexane (20 ml), freshly prepared from 1-hexanedithioic acid (890 mg, 6 mmol) and dicyclohexylcarbodiimide (619 mg, 3 mmol), was added to a solution of sodium benzeneselenolate (3 mmol) in dichloromethane/methanol (3:1, 20 ml) at 0 °C for 30 min, followed by silica-gel column chromatography [hexane/carbon tetrachloride (2:1)] and then bulb-to-bulb distillation yielded 560 mg (69%) of **3f** as orange liquid: bp 152 °C/3.5 Torr. IR (neat) 3027, 2990, 2950, 2880, 1578, 1475, 1460, 1448, 1376, 1210 (C=S), 1070, 1061, 1019, 999, 878, 821, 730, 681, and 464 cm^{-1}. UV/Vis (hexane) 258, 332, and 486 nm. ^1H NMR ($CDCl_3$) δ=0.90 (3H, t, CH_3), 1.33 (4H, m, CH_2), 1.84 (2H, m, CH_2), 3.06 (2H, t, CH_2), and 7.33—7.57 (5H, m, Ar). ^{13}C NMR ($CDCl_3$) δ=13.9 (CH_3), 22.3 (CH_2), 30.7 (CH_2), 30.9 (CH_2), 54.1 (CH_2), and 245.4 (C=S). MS (70 eV) *m/z* (rel intensity), 272 (M^+; trace), 157 ($C_6H_5Se^+$, 32), and 115 (n-$C_5H_{11}CS^+$, 100). Found: *m/z* 272.0147. Calcd for $C_{12}H_{16}SSe$: M, 272.0138.

***Se*-Phenyl Cyclohexanecarbothioselenoate (3g):** In a manner similar to the synthesis of **3d**, bis[cyclohexyl(thiocarbonyl)] sulfide (**1g**) (3 mmol) in hexane (20 ml), freshly prepared from cyclohexanecarbodithioic acid (962 mg, 6 mmol) and dicyclohexylcarbodiimide (619 mg, 3 mmol), was added to a solution of sodium benzeneselenolate (3 mmol) in dichloromethane/methanol (3:1, 20 ml) at 0 °C for 30 min. Silica-gel column chromatography [hexane/dichloromethane (3:1)] and then bulb-to-bulb distillation of the resulting orange eluent yielded 705 mg (83%) of **3g** as orange liquid: bp 119 °C/1.0 Torr. IR (neat) 3030, 2950, 2880, 1583, 1478, 1450, 1440, 1241, 1190 (C=S), 1131, 1066, 1020, 1001, 990, 919, 888, 860, 845, 780, 736, 687, and 470 cm^{-1}. UV/Vis (hexane) 261, 331, and 488 nm. ^1H NMR ($CDCl_3$) δ=1.15—2.03 (10H, m, CH_2), 3.25 (1H, tt, CH), and 7.4—7.6 (5H, m, Ar). ^{13}C NMR ($CDCl_3$) δ=25.5, 26.0, 34.6, 61.9, and 250.2 (C=S). MS (70 eV) *m/z* (rel intensity), 284 (M^+; 9), 157 ($C_6H_5Se^+$, 5) 127 (*cyclo*-$C_6H_{11}CS^+$, 100), and 83 (*cyclo*-$C_6H_{11}^+$, 51). Found: *m/z* 284.0133. Calcd for $C_{13}H_{16}SSe$: M, 284.0138.

***Se*-Phenyl Benzenecarboselenothioate (3h) (Method A):** In a manner similar to synthesis Method A of **3i**, the reaction of bis(thiobenzoyl) sulfide (**1h**, 3 mmol) in hexane (50 ml) with sodium benzeneselenolate (3 mmol), followed by silica-gel column chromatography [hexane/dichloromethane (5:1)], yielded 122 mg (44%) of chemically pure **3h** as violet crystals: mp 44—46 °C. IR (neat) 3120, 3100, 1595, 1582, 1578, 1480, 1444, 1318, 1245 (C=S), 1186, 1160, 1109, 1086, 1045, 1022, 1003, 836, 759, 738, 685, 622, 611, 560, and 471 cm^{-1}. UV/Vis (hexane) 302 (4.18), and 542 (1.92) nm. ^1H NMR ($CDCl_3$) δ=7.0—8.0 (10H, m, Ar). ^{13}C NMR ($CDCl_3$) δ=126.3—146.6 (Ar), and 232.2 (C=S). MS (70 eV) *m/z* (rel intensity), 278 (M^+; 3), 121 ($C_6H_5CS^+$, 100), and 77 ($C_6H_5^+$, 5). Found: *m/z* 277.9668. Calcd for $C_{13}H_{10}SSe$: M, 277.9668.

Method B: In a manner similar to synthesis Method B of **3i**, the reaction of thiobenzoyl chloride (**4a**, 386 mg, 2 mmol) with sodium benzeneselenolate (2 mmol), followed by silica-gel column chromatography [hexane/dichloromethane (5:1)], yielded 330 mg (60%) of **3h**.

Method C: In a manner similar to synthesis Method C of **3i**, the treatment of thiobenzoyl chloride (**4a**, 156 mg, 1 mmol) with (phenylseleno) trimethylsilane (229 mg, 1 mmol) in hexane (15 ml) at 20 °C for 1 h, followed by silica-gel column chromatography [hexane/dichloromethane (5:1)], yielded 33 mg (12%) of **3h** and 119 mg (76%) of diphenyl diselenide.

***Se*-Phenyl 4-Methylbenzenecarboselenothioate (3i) (Method A):** A solution of bis[4-methyl(thiobenzoyl)] sulfide (**1i**, 302 mg, 1 mmol) in dichloromethane (3 ml) was added to sodium benzeneselenolate (1 mmol) in a mixed solvent of dichloromethane and methanol (2:1, 15 ml) at 0 °C; the reaction mixture was then stirred at this temperature for 30 min. The color of the reaction mixture quickly changed from dark green to red. Dichloromethane (20 ml) was added; the mixture was then washed with water (3×30 ml), followed by drying with anhydrous sodium sulfate. After the solvent had been evaporated in vacuo, the residue was chromatographed on silica-gel column [hexane/dichloromethane (5:1)] to yield 213 mg (73%) of **3i** as reddish-pink crystals: mp 83—84 °C. IR (KBr) 1600, 1475, 1440, 1309, 1250 (C=S), 1181, 1045, 1020, 1010, 848, 817, 767, 732, 684, 630, 554, 471, and 458 cm^{-1}. UV/Vis (hexane) 265 (3.83), 315 (4.23), and 541 (1.97) nm. ^1H NMR ($CDCl_3$) δ=2.30 (3H, s, CH_3) and 7.22—7.93 (9H, m, Ar). ^{13}C NMR ($CDCl_3$) δ=21.6 (CH_3), 126.7—144.5 (Ar), and 231.8 (C=S). MS (70 eV) *m/z* (rel intensity), 292 (M^+; 12), 135 (4-$CH_3C_6H_4CS^+$, 100), and 91 (4-$CH_3C_6H_4^+$, 64). Found: C, 57.82; H, 4.49; S, 11.13; Se, 27.26%. Calcd for $C_{14}H_{12}SSe$: C, 57.57; H, 4.42; S, 10.99; Se, 27.03%.

Method B: A solution of 4-methyl(thiobenzoyl) chloride (**4b**, 341 mg, 2 mmol) in benzene (3 ml) was added to sodium benzeneselenolate (2 mmol) in a mixed solvent of benzene/methanol (1:1, 10 ml) at 0 °C; the mixture was stirred at this temperature for 30 min. Dichloromethane (50 ml) was added; the mixture was then washed with water (3×30 ml), followed by drying over anhydrous sodium sulfate. The solvent was evaporated using a rotary evaporator. The residue was chromatographed on a silica-gel column [hexane/dichloromethane (5:1)] to yield 330 mg (60%) of **3i**.

Method C: A solution of 4-methyl(thiobenzoyl) chloride (**4b**, 171 mg, 1 mmol) in hexane (3 ml) was added to (phenylseleno)trimethylsilane (229 mg, 1 mmol) in hexane (15 ml); the mixture was then stirred at 20 °C for 1 h. The solvent was evaporated in vacuo and the residue chromatographed on silica gel [hexane/dichloromethane (5:1)] the second red eluent)] to yield 34 mg (12%) of **3i** and 127 mg (81%) of diphenyl diselenide.

***Se*-(4-Methylphenyl) 4-Methylbenzenecarboselenothioate (3j) (Method A):** In a manner similar to synthesis Method A of **3i**, the reaction of sodium 4-methylbenzeneselenolate (1 mmol) in 15 ml of dichloromethane/methanol (2:1) with bis[4-methyl(thiobenzoyl)] sulfide (**1i**, 302 mg, 1 mmol) in

dichloromethane (5 ml) yielded 247 mg (81%) of **3j** as reddish-pink crystals: mp 118—120 °C. IR (KBr) 2920, 1595, 1485, 1305, 1250 (C=S), 1235, 1208, 1176, 1040, 1036, 1008, 890, 811, 800, 757, 629, 552, 485, and 467 cm^{-1}. UV/Vis (CH_2Cl_2) 226 (4.45), 258 (4.02), 323 (4.34), and 528 (2.05) nm. ^1H NMR ($CDCl_3$) δ=2.17 (3H, s, CH_3ArSe), 2.38 (3H, s, CH_3ArCS), and 7.2—8.0 (8H, m, Ar). ^{13}C NMR ($CDCl_3$) δ=21.5 (CH_3), 21.6 (CH_3), 126.6—144.5 (Ar), and 232.4 (C=S). MS (70 eV) *m/z* (rel intensity), 306 (M^+; 3), 171 ($CH_3C_6H_4Se^+$, <1), 135 ($CH_3C_6H_4CS^+$, 100), and 91 ($CH_3C_6H_4^+$, 3). Found: C, 59.11; H, 4.49%. Calcd for $C_{15}H_{14}SSe$: C, 59.01; H, 4.62%.

***Se*-(4-Chlorophenyl) 4-Methylbenzenecarboselenothioate (3k) (Method A):** In a manner similar to synthesis Method A of **3i**, the reaction of 4-chlorobenzeneselenolate (1 mmol) in 15 ml of dichloromethane/methanol (2:1) with bis[4-methyl(thiobenzoyl)] sulfide (**1i**, 302 mg, 1 mmol) in dichloromethane (5 ml) yielded 229 mg (70%) of **3k** as reddish pink needles: mp 96—97 °C. IR (KBr) 2980, 1594, 1468, 1384, 1306, 1253, 1223, 1177, 1086, 1036, 1005, 850, 839, 812, 760, 721, 621, 550, 490, 478, and 448 cm^{-1}. UV/Vis (hexane) 227 (4.61), 269 (4.11), 316 (4.48), and 540 (1.99) nm. ^1H NMR ($CDCl_3$) δ=2.38 (3H, s, CH_3), and 7.2—8.0 (8H, m, Ar). ^{13}C NMR ($CDCl_3$) δ=21.6 (CH_3), 126.7—144.2 (Ar), and 230.7 (C=S). MS (70 eV) *m/z* (rel intensity), 326 (M^+; 2), 191 ($ClC_6H_4Se^+$, <1), 135 ($CH_3C_6H_4CS^+$, 100), and 91 ($CH_3C_6H_4^+$, 5). Found: C, 51.63; H, 3.32%. Calcd for $C_{14}H_{11}SSeCl$: C, 51.62; H, 3.40%.

Attempt to Synthesize *Se*-Phenyl 2,4,6-Trimethylbenzenecarboselenothioate (3l) (Method A): A dichloromethane solution (5 ml) of bis[2,4,6-trimethyl(thiobenzoyl) sulfide (**1l**, 359 mg, 1 mmol) was added to a solution of freshly prepared sodium benzeneselenolate (1 mmol) in dichloromethane/methanol (1:1); the reaction mixture was then stirred at 0 °C for 30 min. After the usual work-up of the reaction mixture, the resulting residue was chromatographed on a silica-gel column [hexane/dichloromethane (10:1)] to give 150 mg (96%) of diphenyl diselenide **7** and 183 mg (51%) of the starting sulfide **1l**.

***Se*-Phenyl 4-Methoxybenzenecarboselenothioate (3m) (Method A):** In a manner similar to synthesis Method A of **3i**, the reaction of sodium benzeneselenolate (1 mmol) in dichloromethane/methanol(1:1) with bis[4-methoxy(thiobenzoyl)] sulfide (**1j** 334 mg, 1 mmol) in dichloromethane (3 ml) yielded 155 mg (51%) of **3m** as reddish-pink crystals: mp 63—65 °C. IR (KBr) 1595, 1568, 1501, 1440, 1310, 1259, 1240 (C=S), 1186, 1174, 1034, 1020, 845, 830, 737, 688, 627, 570, and 553 cm^{-1}. UV/Vis (hexane) 240 (4.05), 264 (3.77), 339 (4.38), and 538 (2.09) nm. ^1H NMR ($CDCl_3$) δ=3.85 (3H, s, CH_3O), and 6.9—8.1 (9H, m, Ar). ^{13}C NMR ($CDCl_3$) δ=55.6 (CH_3O), 113.7—163.9 (Ar), and 229.5 (C=S). MS (70 eV) *m/z* (rel intensity), 308 (M^+; 2), 151 ($4\text{-}CH_3OC_6H_4\text{-}CS^+$, 100), and 107 ($4\text{-}CH_3OC_6H_4^+$, 5). Found: C, 54.40; H, 4.33%. Calcd for $C_{14}H_{12}OSSe$: C, 54.58; H, 4.19%.

Method B: In a manner similar to synthesis Method B of **3i**, treatment of 4-methoxy(thiobenzoyl) chloride (**4c**, 374 mg, 2 mmol) in benzene (3 ml) with sodium benzeneselenolate (2 mmol) in a mixed solvent (1:1, 10 ml) at 0 °C for 30 min, followed by silica-gel column chromatography [hexane/dichloromethane (10:1)] yielded 188 mg (31%) of **3m**.

Method C: In a manner similar to synthesis Method C of **3i**, the reaction of 4-methoxy(thiobenzoyl) chloride (**4c**, 187 mg, 1 mmol) with phenylselenotrimethylsilane (229 mg, 1 mmol) in hexane (18 ml) at 0 °C for 1 h, followed by silica-gel column chromatograpy [hexane/dichloromethane (10:1)], gave 129 mg (82%) of diphenyl diselenide (**7**).

***Se*-Phenyl 4-Chlorobenzenecarboselenothioate (3n) (Method A):** In a manner similar to synthesis Method A of **3i**, the reaction of sodium benzeneselenolate (1 mmol) in a mixed solvent of dichloromethane/methanol (3:1, 20 ml) with bis[4-chloro(thiobenzoyl)] sulfide (**1i**, 1.1 mmol) in hexane (50 ml) at 0 °C for 30 min, followed by column chromatography on silica gel [hexane/dichloromethane (10:1)] yielded 244 mg (78%) of **3n** as reddish-pink crystals: mp 87—88 °C. IR (KBr) 1580, 1479, 1448, 1396, 1298, 1238 (C=S), 1173, 1090, 1041, 1018, 1009, 891, 822, 731, 691, 681, 621, 550, 490, 420, and 400 cm^{-1}. UV/Vis (hexane) 230sh (4.12), 312 (4.17), and 542 (1.92) nm. ^1H NMR ($CDCl_3$) δ=7.0—7.8 (9H, m, Ar). ^{13}C NMR ($CDCl_3$) δ=127.8—145.1 (Ar) and 230.5 (C=S). MS (70 eV) *m/z* (rel intensity), 312 (M^+; 8), 155 ($4\text{-}ClC_6H_4CS^+$, 100), and 111 ($4\text{-}ClC_6H_4^+$, 5). Found: C, 50.37; H, 3.09%. Calcd for $C_{13}H_9SSeCl$: C, 50.10; H, 2.96%.

Method B: In a manner similar to synthesis Method B of **3i**, treatment of 4-chloro(thiobenzoyl) chloride (**4d**, 382 mg, 2 mmol) in benzene (3 ml) with sodium benzeneselenolate (2 mmol) in a mixed solvent of benzene/methanol (1:1, 10 ml) at 0 °C for 30 min, followed by silica-gel column chromatography [hexane/dichloromethane (5:2)] yielded 500 mg (80%) of **3n**.

Method C: In a manner similar to synthesis Method C of **3g**, the reaction of 4-chloro(thiobenzoyl) chloride (**4d**, 191 mg, 1 mmol) with phenylselenotrimethylsilane (229 mg, 1 mmol) in 20 °C for 1 h, followed by silica-gel column chromatography [hexane/dichloromethane (10:1)] yielded 115 mg (37%) of **3n** and 62 mg (32%) of diphenyl diselenide (**7**).

For the reaction of thionselenolester **3** with amine, sodium alcoholates, typical procedures are described. The products were confirmed by comparisons of the melting point and IR or NMR spectra with those of authentic sample.

Reaction with Aniline: Aniline (93 mg, 1 mmol) was added to a solution of *Se*-phenyl 4-methylbenzenecarboselenothioate (**3i**, 291 mg, 1 mmol) in hexane (30 ml); the reaction mixture was then refluxed for 24 h. Filtration of the resulting precipitates gave 154 mg (68%) of 4-methylthiobenzanilide **6a**. The solvent was evaporated by a rotary evaporator then the residue was chromatographed on a silica-gel column (hexane), giving 152 mg (98%) of diphenyl diselenide (**7**).

Reaction with Cyclohexylamine: To a suspension of **3i** (291 mg, 1 mmol) in hexane (30 ml) was added cyclohexylamine (97 mg, 1 mmol). The reaction mixture was then stirred at 20 °C for 5 h. Filtration of the resulting red precipitates gave 96 mg (41%) of cyclohexylammonium 4-methylbenzenecarbodithioate (**8a**) as red crystals. Evaporation of the filtrate by a rotary evaporator, followed by a chromatographic separation of the resulting residue on silica gel (hexane), gave 140 mg (90%) of diphenyl diselenide (**7**).

Reaction with Diethylamine: The reaction of **3i** (291 mg, 1 mmol) with diethylamine (73 mg, 1 mmol) in hexane (30 ml) at 18 °C for 2 h, followed by silica-gel column chromatography (hexane), yielded 107 mg (44%) of diethylammonium 4-methylbenzenecarbodithioate (**8b**) as red crystals and 147 mg (94%) of **7**.

Reaction with Piperidine: The reaction of **3i** (291 mg, 1 mmol) with piperidine (85 mg, 1 mmol) in hexane (30 ml) at 20 °C for 30 min, followed by silica-gel column chroma-

tograph (hexane), yielded 78 mg (31%) of piperidinium 4-methylbenzenecarbodithioate (**8c**) as red crystals and 151 mg (97%) of **7**.

Reaction with Hydrazine: (Conditions A): A solution of hydrazine hydrate (80%, 63 mg, 1 mmol) in hexane (5 ml) was added dropwise to *Se*-phenyl 4-methylbenzenecarboselenothioate (**3i**, 291 mg, 1 mmol) in hexane (40 ml); the mixture was then stirred at 18 °C for 1 h. Filtration of the resulting precipitates gave 48 mg (29%) of 4-methylbenzenecarbothionohydrazide (**6b**) as slightly yellow crystals. After evaporating the filtrate, the residue was chromatographed on silica-gel column [hexane/dichloromethane (5:1)] to give 151 mg (96%) of **7**.

6b: Mp 115—125 °C. IR (KBr) 3200, 1590, 1519, 1492, 1410, 1365, 1312, 1287, 1240, 1220, 1180, 1021, 1001, 937, 821, 719, 671, 629, and 612 cm^{-1}. ^1H NMR ($CDCl_3$) δ=2.38 (3H, s, CH_3), 4.99 (2H, br, NH_2), 7.1—7.7 (4H, m, Ar), and 8.74 (1H, br, NH). MS (70 eV) *m/z* (rel intensity), 166 (M^+; 26), 135 (4-$CH_3C_6H_4CS^+$, 96), 91 (4-$CH_3C_6H_4^+$, 100), and 65 ($C_5H_5^+$, 45).

(Conditions B): Hydrazine hydrate (80%, 63 mg, 1 mmol) and **3i** (291 mg, 1 mmol) was stirred in ethanol (40 ml) at 18 °C for 1 h. The solvent was removed by a rotary evaporator; then, hexane (30 ml) was added. Filtration of the precipitates yielded 130 mg (78%) of 4-methylbenzenecarboselenohydrazide (**6b**). Evaporation of the filtrate, followed by silica-gel column chromatography [hexane/dichloromethane (5:1)], gave 150 mg (96%) of **7**.

Reaction with Sodium Methanolate: A solution of sodium methanolate (27 mg, 0.5 mmol) in methanol (10 ml) was added dropwise to a solution of *Se*-phenyl 4-methylbenzenecarboselenothioate (**3i**, 146 mg, 0.5 mmol) in ether (10 ml). The reaction mixture was stirred at ca. 20 °C for 2 h. The solvent was evaporated and ether (20 ml) was added. The resulting precipitates (C_6H_5SeNa) was filtered, followed by acidlysis with 1 mol dm^{-3} HCl (5 ml) and by extraction with hexane (50 ml). Evaporation of the extract under reduced pressure gave 70 mg (90%) of diphenyl diselenide. The filtrate (ether soluble part) was concentrated to ca. 1 ml, followed by silica-gel column chromatography [hexane/dichloromethane (5:1)],to give 71 mg (86%) of *O*-methyl 4-methylbenzenecarbothioate (**11a**).

Reaction with Sodium Ethanolate: Similarly, the reaction of **3i** (146 mg, 0.5 mmol) with sodium ethanolate (34 mg, 0.5 mmol) in ethanol (10 ml) yielded 82 mg (91%) of *O*-ethyl 4-methylbenzenecarbothioate (**11b**) and 72 mg (95%) of **7**.

Reaction with Sodium Phenolate: The reaction of **3i** (146 mg, 0.5 mmol) with sodium phenolate (146 mg, 0.5 mmol) in ether at 20 °C for 24 h yielded 91 mg (79%) of *O*-phenyl 4-methylbenzenecarbothioate (**11c**) and 68 mg (90%) of **7**.

Reaction of *Se*-Phenyl 2-Propanecarboselenothioate (3d) with *m*-Chloroperbenzoic acid: A solution of *m*-chloroperbenzoic acid (217 mg, 1 mmol) in ether (10 ml) was added to *Se*-phenyl 2-propanecarboselenothioate (**3d**, 243 mg, 1 mmol) in the same solvent (30 ml); the mixture was then stirred at 0 °C for 90 min. The reaction mixture was washed with saturated aqueous sodium hydrogen carbonate (50 ml) and then water (3×50 ml), followed by drying using anhydrous sodium sulfate. After evaporating the solvent by a rotary evaporator, the residue was separated by thin-layer chromatography [hexane/dichloromethane (5:1)] to yield 50 mg (35%) of diphenyl diselenide (**7**, R_f=0.76), 52 mg (19%) of 2-methylpropionyl phenylseleno sulfide (**13d**, R_f=0.51) as slightly yellow oil, 34 mg (13%) of *trans*-isopropyl(phenylseleno)sulfine(**12d**, R_f=0.22) as yellow oil, and 33 mg (13%) of *cis*-isopropyl(phenylseleno)sulfine (**12'd**, R_f=0.11) as slightly yellow oil.

12'd: IR (neat) 3080, 3000, 2950, 1573, 1471, 1460, 1452, 1437, 1380, 1358, 1190, 1140, 1050, 1019, 998, 930, 738, and 687 cm^{-1}. ^1H NMR ($CDCl_3$) δ=1.08 (6H, d, CH_3), 4.07 (1H, m, CH), and 7.3—7.7 (5H, m, Ar). ^{13}C NMR ($CDCl_3$) δ=20.9 (CH_3), 32.5 (CH), 128.8—132.9 (Ar), and 197.9 (C=S=O). MS (70 eV) *m/z* (rel intensity), 260 (M^+; <1), 87 ($C_3H_7CS^+$, 62), 71 (*i*-$C_3H_7CO^+$, 100), and 43 (*i*-$C_3H_7^+$, 46).

12'd: IR (neat) 3080, 3000, 2950, 1573, 1471, 1460, 1452, 1437, 1205, 1190, 1140, 1070, 1050, 1019, 998, 930, 738, and 687 cm^{-1}. ^1H NMR ($CDCl_3$) δ=1.18 (6H, d, CH_3), 2.77 (1H, m, CH), and 7.3—7.8 (5H, m, Ar). ^{13}C NMR ($CDCl_3$) δ=23.3 (CH_3), 33.7 (CH), 125.2 (Ar), and 205.8 (C=S=O). MS (70 eV) *m/z* (rel intensity), 260 (M^+; 5), 87 (*i*-$C_3H_7CS^+$, 100), 71 (*i*-$C_3H_7CO^+$, 22), and 43 (*i*-$C_3H_7^+$, 18).

13d: IR (Neat) 2980, 2940, 1710 (C=O), 1570, 1470, 1451, 1433, 1087, 1015, 947, 845, 730, and 681 cm^{-1}. ^1H NMR ($CDCl_3$) δ=1.24 (6H, d, CH_3), 3.02 (1H, sept, CH), and 7.2—7.8 (5H, m, Ar). MS (70 eV) *m/z* (rel intensity), 260 (M^+; <1), 157 ($C_6H_5Se^+$, 21), 87 (*i*-$C_3H_7CS^+$, 5), 71 (*i*-$C_3H_7CO^+$, 100), and 43 (*i*-$C_3H_7^+$, 43).

Reaction of *Se*-Phenyl 1-Butanecarboselenothioate (3e) with *m*-Chloroperbenzoic Acid: In a manner similar to the reaction of **3d**, the reaction of *Se*-phenyl 1-butanecarboselenothioate (**3e**, 257 mg, 1 mmol) with *m*-chloroperbenzoic acid (217 mg, 1 mmol) at 0 °C for 90 min, followed by dry silica-gel column chromatography [hexane/dichloromethane (5:1)], yielded 20 mg (28%) of pentanoyl phenylseleno sulfide† (**13e**, the first eluent), as slightly yellow oil 89 mg (32%) of *trans*-1-butyl(phenylseleno)sulfine (**12e** the second eluent) as yellow oil, and 58 mg (21%) of *cis*-butyl(phenylseleno)sulfine (**12'e** the third eluent) as yellow oil.

12e: IR (neat) 3060, 2950, 2870, 1573, 1470, 1460, 1455, 1434, 1420, 1180, 1076, 1017, 998, 970, 733, and 684 cm^{-1}. ^1H NMR ($CDCl_3$) δ=0.87 (3H, t, CH_3), 1.28—1.81 (4H, m, CH_2), 2.94 (2H, t, CH_2), and 7.2—7.6 (5H, m, Ar). ^{13}C NMR ($CDCl_3$) δ=13.6 (CH_3), 21.9 (CH_2), 29.9 (CH_2), 32.1 (CH_2CSO), 128.8—136.9 (Ar), and 191.8 (C=S=O). MS (70 eV) *m/z* (rel intensity), 274 (M^+; 15), 181 ($C_4H_9CSSe^+$, 11), 117 ($C_4H_9CSO^+$, 9), 101 ($C_4H_9CS^+$, 100), 85 ($C_4H_9CO^+$, 28), and 57 ($C_4H_9^+$, 36).

12'e: IR (neat) 3060, 2950, 2870, 1573, 1479, 1460, 1455, 1434, 1420, 1375, 1300, 1228, 1160, 1138, 1070, 1017, 998, 970, 733, and 684 cm^{-1}. ^1H NMR ($CDCl_3$) δ=0.69 (3H, t, CH_3), 1.1—1.6 (4H, m, CH_2), 2.47 (2H, t, CH_2), and 7.3—7.7 (5H, m, Ar). ^{13}C NMR ($CDCl_3$) δ=13.2 (CH_3), 21.6 (CH_2), 29.9 (CH_2), 31.7 (CH_2CSO), 124.1—136.9 (Ar), and 197.2 (C=S=O). † Containing below 2% of diphenyl diselenide.

Reaction of *Se*-Phenyl 4-Methylbenzenecarboselenothioate (3i) with *m*-Chloroperbenzoic Acid: A solution of *m*-chloroperbenzoic acid (216 mg, 1 mmol) in ether (20 ml) was added to a solution of *Se*-phenyl 4-methylbenzenecarboselenothioate (**3i**, 291 mg, 1 mmol) in the same solvent (30 ml); the mixture was then stirred at 0 °C for 90 min. The reaction mixture was washed with saturated aqueous sodium hydrogen carbonate (50 ml) and then with water (3×50 ml), followed by drying with anhydrous sodium sulfate. The solvent was evaporated by a rotary evaporator. The residue was chromatographed on silica gel [hexane/dichloromethane (2:1)] to give a first eluent (orange), a second (pink), and third eluent (yellow). The repeated chromatographic separation of the first eluent [hexane/dichloromethane (20:1)] gave 22 mg (14%) of diphenyl diselenide (**7**). Similarly, a chromatographic separation of the second eluent [hexane/dichloromethane (5:1)] gave 34 mg (11%) of phenylseleno 4-methyl(thiobenzoyl) sulfide (**13i**) as slightly yellow crystals 9 mg (3%) of bis[4-methyl(thiobenzoyl)] disulfide (**14**). Thin-layer chromatography [20 cm×20 cm, hexane/dichloromethane (2:1)] of the third eluent gave 81 mg (26%) of *trans*-4-methylphenyl(phenylseleno) sulfine (**12i**, R_f=0.39) as yellow oil and 25 mg (8%) of *cis*-4-methylphenyl(phenylseleno) sulfine (**12'i**, R_f=0.07) as yellow oil.

12i: IR (neat) 3050, 1601, 1571, 1480, 1438, 1276, 1183, 1100, 1017, 995, 810, 740, 690, 618, 542, 471, 438, and 410 cm^{-1}. ^1H NMR ($CDCl_3$) δ=2.25 (3H, s, CH_3) and 6.9—7.5 (9H, m, Ar). ^{13}C NMR ($CDCl_3$) δ=21.7 (CH_3), 128.8—142.9 (Ar), and 178.5 (C=S=O). MS (70 eV) *m/z* (rel intensity), 308 (M^+; 7), 215 (4-$CH_3C_6H_4CSSe^+$, 79), 135 (4-$CH_3C_6H_4CS^+$, 100), 119 (4-$CH_3C_6H_4CO^+$, 28), and 91 (4-$CH_3C_6H_4^+$, 9).

12'i: IR (neat) 3050, 1601, 1571, 1480, 1438, 1276, 1201, 1183, 1170, 1100, 1017, 995, 810, 740, 690, 618, 542, 471, 438, and 410 cm^{-1}. ^1H NMR ($CDCl_3$) δ=2.35 (3H, s, CH_3), and 7.0—8.3 (9H, m, Ar). ^{13}C NMR ($CDCl_3$) δ=21.3 (CH_3), 126.1—141.1 (Ar), and 194.1 (C=S=O). MS (70 eV) *m/z* (rel intensity), 308 (M^+; 8), 215 (4-$CH_3C_6H_4CSSe^+$, 83), 135 (4-CH_3CS^+, 100), 119 (4-$CH_3C_6H_4CO^+$, 29), and 91 ($CH_3C_6H_4^+$, 23).

13i: Mp 86—88 °C (lit,[3] 86—88 °C). ^1H NMR ($CDCl_3$) δ=2.38 (3H, s, CH_3) and 6.9—8.1 (9H, m, Ar). IR (KBr) 1660 cm^{-1}.

14: Mp 117—119 °C. IR (KBr) 1693 cm^{-1}. UV/Vis (*cyclo*-C_6H_{12}) 250sh, 265 (4.55), and 267sh nm

We wish to thank Professor Satoshi Inagaki of Gifu University for his helpful suggestions to regarding the ab initio molecular orbital calculation.

Synthesis of Branched-Chain Oligosaccharides in Sarsasaponins by Dehydrative Glycosylation

Shinkiti KOTO,* Naohiko MORISHIMA,[1] Masaharu UCHINO, Misa FUKUDA, Masayo YAMAZAKI, and Shonosuke ZEN
School of Pharmaceutical Sciences, Kitasato University, Shirokane, Minato-ku, Tokyo 108
(Received April 12, 1988)

The branched-chain oligosaccharides, 6-*O*-(β-D-glucopyranosyl)-4-*O*-(α-L-rhamnopyranosyl)-D-glucopyranose, and 2,6-di-*O*-(β-D-glucopyranosyl)-4-*O*-(α-L-rhamnopyranosyl)-D-glucopyranose, which compose sarsasaponins, as well as the structurally related 2-*O*-(β-D-glucopyranosyl)-4-*O*-(α-L-rhamnopyranosyl)-D-glucopyranose were synthesized stepwise via dehydrative glycosylation by a ternary mixture of *p*-nitrobenzenesulfonyl chloride, silver triflate, and triethylamine.

The dehydrative condensation of a protected monosaccharide, in which a reducing hydroxyl group and one of the nonreducing hydroxyl groups are unprotected, proceeds slowly, even under forced conditions, and its selectivity is generally poor.[2] The starting material used in such glycosylation is an anomeric mixture which may undergo self-condensation to give a nonreducing disaccharide. Because of these deficiencies, oligosaccharides with a fine structure have never been attempted using dehydrative glycosylation. Glycosylation of this kind, however, has an attractive feature in that it uses glycosyl donors with much longer shelf-lives compared to those of such hydrolyzable donors[3] as glycosyl halides and their equivalents. Studies of dehydrative glycosylation[4] have indicated that a ternary mixture of *p*-nitrobenzenesulfonyl chloride (NsCl), silver triflate (AgOTf), and triethylamine (Et_3N) (NST mixture) performs cross-condensation between 2,3,4,6-tetra-*O*-benzyl-D-glucopyranose (**1**) and various alcohols.[5] The reaction proceeds with moderate efficiencies and its selectivity depends on the type of donors,[6–9] reactivity of acceptors,[5,10] as well as the nature of any additives.[11] This report deals with the synthesis of bifurcated *O*-β-D-glucopyranosyl-(1→2)-*O*-[α-L-rhamnopyranosyl-(1→4)]-D-glucopyranose (**2**) and *O*-β-D-glucopyranosyl-(1→6)-*O*-[α-L-rhamnopyranosyl-(1→4)]-D-glucopyranose (**3**) as well as of trifurcated *O*-β-D-glucopyranosyl-(1→2)-*O*-[β-D-glucopyranosyl-(1→6)]-O-[α-L-rhamnopyranosyl-(1→4)]-D-glucopyranose (**4**),[12] while showing a practical limitation of glycosylation with an NST mixture.[5] The tetrasaccharide **4** composes the antibiotic saponins, parillin and sarsaparilloside from *Radix sarsaparillae*,[13] whereas the trisaccharide **2** might possibly constitute avenacoside A from the leaves and seeds of *Avena sativa*,[14] and another trisaccharide **3** is contained in a harb saponin, saikosaponin-*c* from the root of *Bupleurum falcatum* L.[15]

Synthesis of the Trisaccharide 2. The acceptor **5** for the synthesis of **2** was prepared from a known acetal **6**.[16] A controlled allylation of **6** with allyl bromide and sodium hydride gave 2-*O*-allyl ether **7** (54%) and an isomer **8** (11%). The structure of **7** was confirmed by measuring the ^1H NMR of its 3-acetate. Benzylation of **7** and a subsequent hydrolysis gave the diol **9**, which was subjected to controlled benzylation with benzyl chloride and sodium hydride to afford the desired **5** (55%) and the isomer **10** (11%).

Condensation of 2,3,4-tri-*O*-benzyl-L-rhamnopyranose[17] (**11**) and methyl 2,3,6-tri-*O*-benzyl-β-D-glucopyranoside[11] (**12**) using the NST mixture was first examined. The use of a 1.5 molar amount of the donor **11** produced a cross-condensate **13** (72% from **12**) and a self-condensate **14** (36% from **11**). The configuration of the interglycoside linkage was confirmed by measuring a $^1J_{CH}$[18] (170 Hz) for the signal (δ 98.4) of the anomeric carbon of the rhamnosyl residue in **13** and that in the corresponding debenzylated compound **15** (δ 102.3, 170 Hz). Rhamnosylation of **16**[16] with **11** was similarly carried out in order to furnish the disaccharide derivative **17** (68% from **16**) and **14** (36% from **11**). The anomeric carbon of the α-rhamnosyl residue of **17** appeared at δ 98.2 again with a $^1J_{CH}$ of 170 Hz (Table 1), whereas the corresponding proton gave a characteristic doublet (δ 5.07) with a small splitting (1.8 Hz). Thus, rhamnosylation with **11** of the 4-OH group was stereoselective but was apt to let the self-condensation of the donor undergo, differing from the case of glucosylation with **1**.[11] The acceptor **5** was then similarly condensed with **11** to give the

condensate **18** (81%). The anomeric carbon of the α-rhamnosyl moiety resonated at δ 98.2 with a $^1J_{CH}$ of 169 Hz. Deallylation of **18** with a rhodium complex and a subsequent hydrolysis[9] afforded the disaccharide acceptor **19**.

The 2-OH group of the simple acceptor **20**, which was readily prepared from **9**, was glucosylated with a 1.3 molar amount of **1** and the NST mixture to give the sophorose derivative **22** (38%) and a kojibiose derivative **21** (29%). The chemical shift of the anomeric proton (δ 5.20) and the anomeric carbon (δ 98.9) of the reducing end of **22** showed characteristic downfield shifts caused by a substitution by the tetra-*O*-benzylglucosyl residue at the 2-OH group in **20** (Table 1). Thus, glucosylation with **1** of the 2-OH group was marginally selective for the β-anomer.[10] Then, a similar glucosylation was applied to **19** to afford the desired trisaccharide derivative **24** (41%) and

a) The values in parentheses are those for $^1J_{CH}$(Hz). b) MR=methyl α-L-rhamunopyranoside (Ref. 22). c) S=sophorose (Ref. 20). d) MS=methyl β-sophoroside: the values are those in C_5D_5N (Ref. 21) subtracted by 1.0 arbitrarily. e) G=gentiobiose (Ref. 20).

the α-isomer **23** (29%). The new anomeric carbon resonated at δ 103.2 with a $^1J_{CH}$ of 162 Hz, indicating the β-configuration. The chemical shifts of the anomeric protons and carbons of **24** correspond well with those of the relevant disaccharide derivatives, **17** and **22** (Table 1).

A hydrogenolytic debenzylation of **24** furnished the trisaccharide **2**, the ^{13}C NMR spectrum of which was consistent with the proposed structure (Table 2); the assignment was tentatively carried out based on the spectra of sophorose,[20] methyl sophoroside,[21] methyl α-L-rhamnopyranoside,[22] and **15**.

Synthesis of the Trisaccharide 3. The synthesis was started from the known acceptor **25**.[16] The first glycosylation of **25** with **1** in the presence of the NST mixture afforded the gentiobiose derivative **27** (64%) and the isomaltose derivative **26** (21%). The new anomeric carbon of **27** appeared at δ 103.8, indicating the β-configuration. The glucosylation of the acceptor **28**[23] with **1** also gave the gentiobiose derivative **30**[24,25] (75%) and the α-isomer **29** (22%). Deallylation of **27** gave **31**, which was then subjected to the α-rhamnosylation with **11**. In this case, however, the 4-OH group of **31** was so unreactive to the activated **11**, due to the presence of the tetra-*O*-benzylglucosyloxyl group at the C-6 position, that a significant amount (18%) of the *p*-nitrobenzenesulfonate of **31** was formed expectedly,[26] indicating a practical limitation of the rhamnosylation with **11** and the NST mixture. Nevertheless, the desired trisaccharide derivative **32** was produced in a 36% yield with complete selectivity. The anomeric carbon of the α-rhamnosyl moiety in **32** appeared at δ 97.8 with a $^1J_{CH}$ of 168 Hz; the chemical shifts of the anomeric protons and carbons nicely correspond with those of the relevant disaccharide derivatives, **17** and **30** (Table 1).

Hydrogenolysis of **32** afforded the trisaccharide **3**, the ^{13}C NMR spectrum of which was tentatively assigned based on the spectra of gentiobiose[20] and **15** and was consistent with the proposed structure (Table 2).

Synthesis of the Tetrasaccharide 4. The key

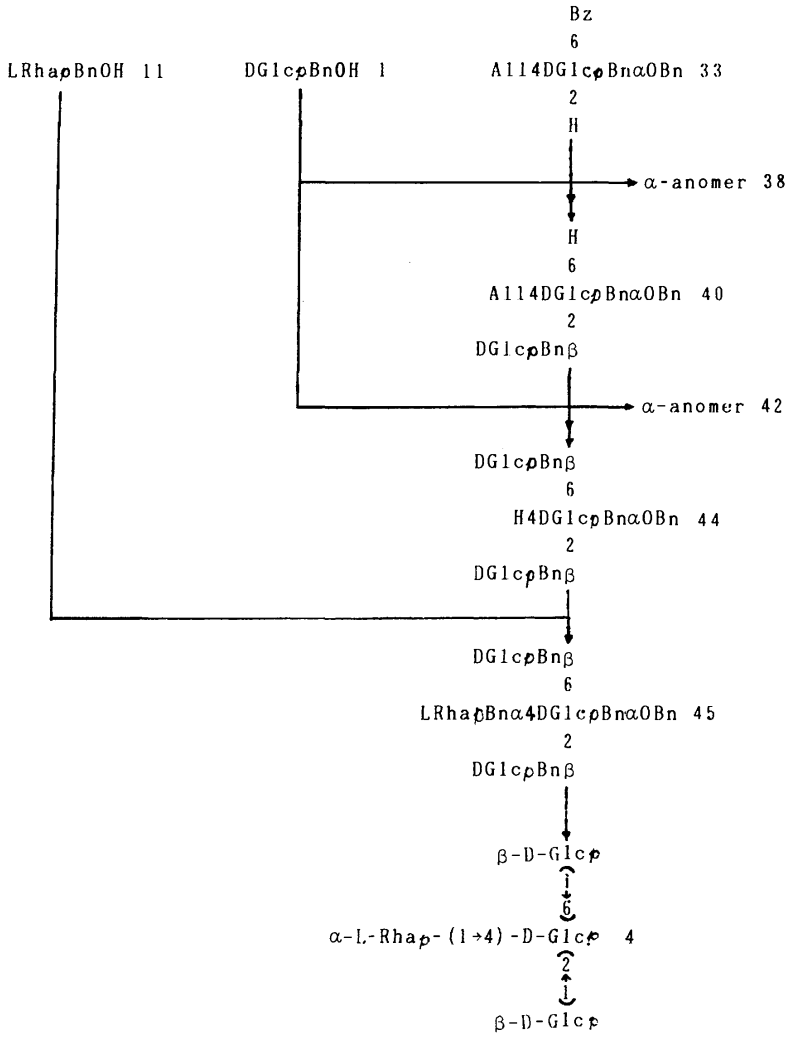

Fig. 1. Synthetic diagram[24] for the tetrasaccharide **4** (All=-$CH_2CH{=}CH_2$, Bn=CH_2Ph, Bz=-COPh).

acceptor **33** was prepared from the dityrityl ether **34**.[27] Brief heating of **34** in allyl bromide in the presence of a limited amount of sodium hydride, followed by forced benzylation by hot benzyl chloride and excess potassium hydroxide, and a subsequent detritylation with trifluoroacetic acid in methanolic chloroform gave the 4-*O*-allyl derivative **35** (79%) and the isomer **36** (9%). A bulky trityloxyl group at the C-2 position in **34** well diminished the reactivity of the neighboring 3-OH group. The structure of **35** was confirmed by converting it into the known **16**.[16] A mild benzoylation of **35** with benzoyl chloride in pyridine gave the desired acceptor **33** (52%) and the isomer **37** (12%). The H-2 of the 6-benzoate **33** resonates at δ 3.53, whereas that of the 2-benzoate **37** was so deshielded that it gave a signal at δ 4.90.

The first glucosylation of **33** with **1** and the NST mixture gave the desired product **39** (45%) and the α-isomer **38** (39%). As described above, a significant formation of the α-glucosides was also observed in glucosylation with **1** for the 2-OH group of **19** and **20**. The anomeric carbon of the nonreducing β-glucosyl residue of **39** appeared at δ 103.6. Debenzoylation of **39** gave the acceptor **40**. This was successively benzylated and deallylated to give another acceptor **41**. Rhamnosylation of **41** with **11** and the NST mixture provided the trisaccharide derivative **24** described above. Thus, the structure of **33** was strictly confirmed.

The second glucosylation of the 6-OH group of **40**

with **1** and the NST mixture furnished the desired **43** (68%) and the α-anomer **42** (31%). The anomeric carbon of the newly introduced β-glucosyl moiety of **43** appeared at δ 104.0. Deallylation of **43** smoothly gave the trisaccharide acceptor **44**.

The final rhamnosylation of **44** with **11** and the NST mixture afforded the fully benzylated tetrasaccharide **45** in a 37% yield, as the sole cross-condensate. The anomeric carbon of the α-rhamnosyl moiety appeared at δ 98.5 with a $^1J_{CH}$ of 173 Hz. All the anomeric carbons and protons of **45** are well correlated with those of the component trisaccharide derivative **24** and **32** (Table 1).

A catalytic hydrogenolysis of **45** gave the trifurcated tetrasaccharide **4**, the ^{13}C NMR spectrum of which was consistent with the proposed structure (Table 2). The assignment was tentatively carried out based on the spectra of sophorose,[20] gentiobiose,[20] **15**, **2**, and **3**.

Thus, the work described may illustrate the scope and limitations for the synthesis of complex oligosaccharides using the dehydrative glycosylation with an NST mixture.[5]

Experimental

The solvent systems for chromatography on a silica-gel column (gradient elution) and TLC were toluene-2-butanone (TB), hexane-ethyl acetate (HE), hexane-acetone (HA), IPE†-ethyl acetate (IE), and chloroform-methanol (CM) systems. The glycosylation with the NST mixture and the accompanying processing were performed as described earlier.[5,6,10] Sodium hydride in an oil suspension (60% of NaH by wt) was used without pre-washing. Hydrogenolytic debenzylation was carried out using a Parr-3911 hydrogenation apparatus under 340 kPa of H_2 at room temp. A concentration of the solution was carried out under reduced pressure. The NMR spectra were recorded with a Varian XL-400 spectrometer at 400 MHz for ^1H and at 100.6 MHz for ^{13}C or with a Varian VXR-300 spectrometer at 300 MHz for ^1H and at 75.5 MHz for ^{13}C; the chemical shifts of ^1H NMR are relative to the satelite peak of $CDCl_3$ at δ 7.26 in $CDCl_3$ and the peak of DOH at δ 4.70 in D_2O and those for ^{13}C NMR are to the central peak of $CDCl_3$ at δ 77.0 in $CDCl_3$ and the peak of 1,4-dioxane at δ 67.4 in D_2O. A routine measurement of the NMR spectra was carried out with a Varian EM-390 spectrometer at 90 MHz for ^1H and with a JEOL-PS-100 spectrometer linked to a JEOL-EC-100 computer at 25.2 MHz for ^{13}C; the chemical shifts are relative to the peak of internal TMS at δ 0.0 in $CDCl_3$ and that of external TMS at δ 0.0 in D_2O. For other items, refer to previous reports,[5,10,11] unless otherwise described.

Benzyl 2-*O*- and 3-*O*-Allyl-4,6-*O*-benzylidene-α-D-glucopyranosides (7 and 8). A mixture of **6**[16] (1.00 g), NaH in an oil suspension (144 mg) and allyl bromide (12 ml) was stirred for 3 h at 80 °C. The mixture was diluted with toluene and washed with cold H_2O. The organic layer was concentrated and chromatographed (IE system) to give the diallyl ether (0.11 g, 9%), **7** (0.60 g, 54%), mp 153—154 °C (from IPE), $[\alpha]_D^{20}$ +138° (*c* 0.7, $CHCl_3$), ^1H NMR ($CDCl_3$, 90 MHz) δ=3.42 (1H, dd, $J_{1,2}$=3.6 Hz, $J_{2,3}$=9.3 Hz, H-2), 5.01 (1H, d, H-1), 5.53 (1H, s, benzylidene), 5.7—6.2 (1H, m, allyl), ^{13}C NMR ($CDCl_3$, 75 MHz) δ=62.4 (C-5), 69.0 (C-6), 79.4 (C-2), 81.3 (C-4), 95.8 (C-1), 102.0 (benzylidene), 118.0, 134.4 (allyl), and **8** (0.12 g, 11%), mp 95—97 °C (from hexane), $[\alpha]_D^{20}$ +83° (*c* 2.8, $CHCl_3$), ^1H NMR ($CDCl_3$, 90 MHz) δ=5.01 (1H, d, $J_{1,2}$=3.0 Hz, H-1), 5.51 (1H, s, benzylidene), 5.7—6.2 (1H, m, allyl), ^{13}C NMR ($CDCl_3$, 75 MHz) δ=62.9 (C-5), 68.9 (C-6), 78.6 (C-4), 81.9 (C-3), 98.3 (C-1), 101.2 (benzylidene), 117.2, 135.0 (allyl).

Found: **7**, C, 68.91; H, 6.55%. **8**, C, 68.89; H, 6.51%. Calcd for $C_{23}H_{26}O_6$: C, 69.33; H, 6.58%.

A sample of **7** was acetylated with acetic anhydride and pyridine, followed by chromatography (HA system) to give the homogeneous acetate, ^1H NMR (CCl_4, 90 MHz) δ=2.02 (3H, s, Ac), 3.42 (1H, dd, $J_{1,2}$=3.6 Hz, $J_{2,3}$=9.6 Hz, H-2), 3.43 (1H, dd, $J_{3,4}$=9.6 Hz, $J_{4,5}$=9.0 Hz, H-4), 4.88 (1H, d, H-1), 5.36 (1H, s, benzylidene), 5.47 (1H, t, H-3) indicating that Ac is at the O-3 of **7**.

Benzyl 2-*O*-Allyl-3-*O*-benzyl-α-D-glucopyranoside (9). A mixture of **7** (0.55 g), crushed KOH (0.3 g), and $PhCH_2Cl$ (2.8 ml) was stirred for 1 h at 125 °C. The mixture was diluted with toluene and washed with cold H_2O. The organic layer was concentrated at 95 °C and then heated in aq AcOH (80%, 16 ml) for 1 h at 95 °C. The mixture was concentrated and chromatographed (TB system) to give **9** (0.52 g, 94%), mp 78—80 °C (from IPE), $[\alpha]_D^{20}$ +94° (*c* 2.1, $CHCl_3$), ^{13}C NMR ($CDCl_3$, 75 MHz) δ=62.3 (C-6), 79.7 (C-2), 81.2 (C-3), 95.5 (C-1), 117.5, 134.6 (allyl).

Found: C, 68.71; H, 6.93%. Calcd for $C_{23}H_{28}O_6$: C, 68.98; H, 7.05%.

Benzyl 2-*O*-Allyl-3,6- and -3,4-di-*O*-benzyl-α-D-glucopyranosides (5 and 10). A mixture of **9** (294 mg), NaH in an oil suspension (40 mg) and $PhCH_2Cl$ (2.9 ml) was stirred for 2 h at 110 °C. The mixture was processed and chromatographed (TB system) to give a fully benzylated product (49 mg, 11%), **5** (198 mg, 55%), $[\alpha]_D^{20}$ +79° (*c* 2.7, $CHCl_3$), ^{13}C NMR ($CDCl_3$, 75 MHz) δ=79.5 (C-2), 81.4 (C-3), 95.4 (C-1), 117.4, 134.6 (allyl), and **10** (38 mg, 11%), mp 55—56 °C, $[\alpha]_D^{20}$ +86° (*c* 5.8, $CHCl_3$), ^{13}C NMR ($CDCl_3$, 75 MHz) δ=61.7 (C-6), 77.4 (C-4), 79.9 (C-2), 81.8 (C-3), 95.5 (C-1), 117.4, 134.7 (allyl).

Found: **5**, C, 73.07; H, 6.93%. **10**, C, 73.77; H, 6.92%. Calcd for $C_{30}H_{34}O_6$: C, 73.45; H, 6.99%.

A sample of **5** was acetylated with acetic anhydride and pyridine, followed by chromatography (HA system) to afford the homogeneous acetate, ^1H NMR (CCl_4, 90 MHz) δ=1.71 (3H, s, Ac), 3.38 (1H, dd, $J_{1,2}$=3.6 Hz, $J_{2,3}$=9.3 Hz, H-2), 3.83 (1H, t, $J_{3,4}$=9.3 Hz), 4.83 (1H, d, H-1), 4.87 (1H, dd, $J_{4,5}$=9.6 Hz) indicating the presence of Ac at the O-4 or **5**.

Methyl *O*-(2,3,4-Tri-*O*-benzyl-α-L-rhamnopyranosyl)-(1→4)-2,3,6-tri-*O*-benzyl-β-D-glucopyranoside (13) and *O*-(2,3,4-Tri-*O*-benzyl-α-L-rhamnopyranosyl)-(1→1)-2,3,4-tri-*O*-benzyl-α-L-rhamnopyranoside (14). The acceptor **12**[11] (30.0 mg) was condensed with **11**[17] (42.1 mg) in the presence of NsCl (43.0 mg), AgOTf (Aldrich, 49.8 mg), and Et_3N (27.1 μl) in CH_2Cl_2 (0.4 ml), followed by chromatography (TB system) to give **14** (15.2 mg, 36% from **11**), $[\alpha]_D^{20}$ −74° (*c* 0.9, $CHCl_3$), ^{13}C NMR ($CDCl_3$, 25 MHz) δ=18.0 (C-6), 68.8 (C-5), 93.7 (C-1), and **13** (41.2 mg, 72% from **12**), $[\alpha]_D^{20}$ −23° (*c* 2, $CHCl_3$), ^{13}C NMR ($CDCl_3$, 25 MHz) δ=17.8 (C-6′), 56.8 (MeO), 98.4 ($^1J_{CH}$=170 Hz, C-1′), 104.9 ($^1J_{CH}$=156 Hz, C-1).

13, Found: C, 74.94; H, 6.73%. Calcd for $C_{55}H_{60}O_{10}$: C, 74.98; H, 6.86%.

† IPE=diisopropyl ether.

14, Found: C, 76.00; H, 6.88%. Calcd for $C_{54}H_{58}O_9$: C, 76.21; H, 6.87%.

Methyl *O*-α-L-Rhamnopyranosyl-(1→4)-β-D-glucopyranoside (15). Hydrogenolysis of **13** (76.5 mg) over Pd on C (10%, 50 mg) in AcOH (6 ml) containing H_2O (50 μl) overnight, followed by chromatography (CM system), gave a hygroscopic foam of **15** (17.3 mg, 59%), $[\alpha]_D^{20}$ −58° (*c* 1.2, H_2O), ^1H NMR (D_2O, 90 MHz) δ=1.28 (3H, d, $J_{5',6'}$=6.0 Hz, H-6'), 3.57 (3H, s, MeO), 4.39 (1H, d, $J_{1,2}$=7.8 Hz, H-1), 4.87 (1H, d, $J_{1',2'}$=1.8 Hz, H-1').

Found: C, 45.64; H, 7.16%. Calcd for $C_{13}H_{24}O_{10}$: C, 45.88; H, 7.11%.

Benzyl *O*-(2,3,4-Tri-*O*-benzyl-α-L-rhamnopyranosyl)-(1→4)-2,3,6-tri-*O*-benzyl-α-D-glucopyranoside (17). Rhamnosylation of **16**[16] (45.8 mg) with **11** (55.2 mg), NsCl (54.6 mg), AgOTf (65.4 mg), and Et_3N (35.5 μl) in CH_2Cl_2 (0.3 ml), followed by chromatography (TB system), furnished **14** (19.7 mg, 36% from **11**) and then **17** (55.4 mg, 68% from **16**), $[\alpha]_D^{20}$ +16° (*c* 1.9, $CHCl_3$).

Found: C, 76.28; H, 6.55%. Calcd for $C_{61}H_{64}O_{10}$: C, 76.54; H, 6.74%.

Benzyl *O*-(2,3,4-Tri-*O*-benzyl-α-L-rhamnopyranosyl)-(1→4)-2-*O*-allyl-3,6-di-*O*-benzyl-α-D-glucopyranoside (18). The acceptor **5** (260.7 mg) was treated with **11** (346.4 mg) in the presence of NsCl (353.5 mg), AgOTf (410.2 mg), and Et_3N (224.0 μl) in CH_2Cl_2 (2 ml). Chromatography (TB system) gave **14** (55.7 mg, 16% from **11**) and then **18** (388.8 mg, 81% from **5**), $[\alpha]_D^{20}$ +32° (*c* 1.3, $CHCl_3$), ^{13}C NMR ($CDCl_3$, 100 MHz) δ=18.0 (C-6'), 95.1 ($^1J_{CH}$=168 Hz, C-1), 98.2 ($^1J_{CH}$=169 Hz, C-1'), 117.6, 134.7 (allyl).

Found: C, 75.29; H, 6.93%. Calcd for $C_{57}H_{64}O_{11}$: C, 75.47; H, 6.89%.

Benzyl *O*-(2,3,4-Tri-*O*-benzyl-α-L-rhamnopyranosyl)-(1→4)-3,6-di-*O*-benzyl-α-D-glucopyranoside (19). A mixture of **18** (346.1 mg), TRC†† (Aldrich, 30 mg) and EBW†† (7.7 ml) was refluxed overnight. The mixture was concentrated and then heated in acetone (6 ml) containing aq HCl (3.5%, 60 μl) for 1 h at 45 °C. Chromatography (HE system) gave **19** (277.9 mg, 85%), $[\alpha]_D^{20}$ +32° (*c* 1.7, $CHCl_3$), ^{13}C NMR ($CDCl_3$, 100 MHz) δ=17.8 (C-6'), 97.6 ($^1J_{CH}$=168 Hz, C-1), 98.2 ($^1J_{CH}$=170 Hz, C-1').

Found: C, 74.85; H, 6.63%. Calcd for $C_{54}H_{58}O_{10}$: C, 74.80; H, 6.74%.

Benzyl 3,4,6-Tri-*O*-benzyl-α-D-glucopyranoside (20). A mixture of **9** (0.44 g), crushed KOH (0.74 g), and $PhCH_2Cl$ (5.3 ml) was stirred for 2 h at 125 °C. After processing, chromatography (HE system) gave the product, which was then refluxed in EBW (4 ml) in the presence of TRC (20 mg) overnight. After concentration, the residue was heated in acetone (4 ml) containing aq HCl (3.5%, 40 μl) for 1 h at 45 °C. Chromatography (HE system) furnished **20** (0.27 g, 45%), $[\alpha]_D^{20}$ +105° (*c* 1.8, $CHCl_3$) ^{13}C NMR ($CDCl_3$, 75 MHz) δ=68.4 (C-6). 69.8 (C-5), 70.7 (C-2), 73.1, 73.5, 75.0, 75.4 (benzyl), 77.4 (C-4), 83.5 (C-3), 97.9 (C-1).

Found: C, 75.60; H, 6.66%. Calcd for $C_{34}H_{36}O_6$: C, 75.53; H, 6.71%.

Benzyl *O*-(2,3,4,6-Tetra-*O*-benzyl-α- and β-D-glucopyranosyl)-(1→2)-3,4,6-tri-*O*-benzyl-α-D-glucopyranosides (21 and 22). The acceptor **20** (53.5 mg) was glucosylated with **1** (Pfânstiehl, 69.5 mg), NsCl (37.3 mg), AgOTf (43.3 mg), and Et_3N (23.5 μl) in CH_2Cl_2 (0.5 ml), followed by chromatography (TB system), gave **22** (40.1 mg, 38%), $[\alpha]_D^{20}$ +48° (*c* 0.9, $CHCl_3$), and then **21** (30.5 mg, 29%), $[\alpha]_D^{20}$ +79° (*c* 1.9, $CHCl_3$), ^1H NMR ($CDCl_3$, 400 MHz) δ=5.09 (1H, d, $J_{1',2'}$=3.6 Hz, H-1'), 5.24 (1H, d, $J_{1,2}$=3.5 Hz, H-1), ^{13}C NMR ($CDCl_3$, 100 MHz) δ=94.0 (C-1'), 95.0 (C-1).

Found: **21**, C, 76.76; H, 6.73%. **22**, C, 76.53; H, 6.62%. Calcd for $C_{68}H_{70}O_{11}$: C, 76.81; H, 6.64%.

Benzyl *O*-(2,3,4,6-Tetra-*O*-benzyl-α- and β-D-glucopyranosyl)-(1→2)-*O*-[(2,3,4-tri-*O*-benzyl-α-L-rhamnopyranosyl)-(1→4)]-3,6-di-*O*-benzyl-α-D-glucopyranosides (23 and 24). (i) The acceptor **19** (48.4 mg) was glucosylated with **1** (39.2 mg) in the presence of NsCl (24.8 mg), AgOTf (28.8 mg), and Et_3N (15.6 mg) in CH_2Cl_2 (0.4 ml), followed by chromatography (TB system), gave **24** (32.1 mg, 41%), $[\alpha]_D^{20}$ +20° (*c* 1.2, $CHCl_3$), and **23** (22.6 mg, 29%), $[\alpha]_D^{20}$ +48° (*c* 0.7, $CHCl_3$), ^{13}C NMR ($CDCl_3$, 100 MHz) δ=94.1 (C-1'), 94.9 (C-1), 98.3 (C-1'').

Found: **23**, C, 76.19; H, 6.64%. **24**, C, 76.27; H, 6.82%. Calcd for $C_{88}H_{92}O_{15}$: C, 76.06; H, 6.67%.

(ii) Rhamnosylation of **41** (see below, 38.9 mg) with **11** (26.0 mg), NsCl (26.6 mg), AgOTf (30.9 mg), and Et_3N (14.7 μl) in CH_2Cl_2 (0.4 ml), followed by chromatography (TB system), gave **14** (5.8 mg, 15%) and **24** (21.1 mg, 38%), the ^{13}C NMR spectrum of which was identical with that of **24** described above.

***O*-β-D-Glucopyranosyl-(1→2)-*O*-[α-L-rhamnopyranosyl-(1→4)]-D-glucopyranose (2).** Hydrogenolysis of **24** (58.8 mg) over Pd on C (10%, 36 mg) in AcOH (6 ml) containing H_2O (50 μl) overnight, followed by chromatography (CM system), afforded a hygroscopic foam of **2** (17.0 mg, 82%), $[\alpha]_D^{20}$ +1.4° (*c* 1.2, H_2O), ^1H NMR (D_2O, 300 MHz) δ=4.53 (0.7H, d, $J_{1',2'}$=7.5 Hz, H-1'α), 4.60 (0.3H, d, $J_{1,2}$=7.6 Hz, H-1β), 4.75 (1H, d, $J_{1'',2''}$=1.5 Hz, H-1''), 5.32 (0.7H, d, $J_{1,2}$=4.0 Hz, H-1α).

Found: C, 44.54; H, 6.98%. Calcd for $C_{18}H_{32}O_{15}$: C, 44.26; H, 6.60%.

Benzyl *O*-(2,3,4,6-Tetra-*O*-benzyl-α- and β-D-glucopyranosyl)-(1→6)-4-*O*-allyl-2,3-di-*O*-benzyl-α-D-glucopyranosides (26 and 27). The acceptor **25**[16] (50.0 mg) was condensed with **1** (60.0 mg) in the presence of NsCl (34.0 mg), AgOTf (39.5 mg), and Et_3N (21.4 μl) in CH_2Cl_2 (0.6 ml), followed by chromatography (TB system), gave **26** (22.2 mg, 21%), $[\alpha]_D^{20}$ +76° (*c* 1.3, $CHCl_3$), ^{13}C NMR ($CDCl_3$, 75 MHz) δ=94.5 (C-1), 97.3 (C-1'), 116.8, 135.0 (allyl), and **27** (65.8 mg, 64%), $[\alpha]_D^{20}$ +51° (*c* 1.1, $CHCl_3$), ^{13}C NMR ($CDCl_3$, 75 MHz) δ=95.2 (C-1), 103.8 (C-1'), 116.6, 134.8 (allyl).

Found: **26**, C, 76.12; H, 6.89%. **27**, C, 75.97; H, 6.83%. Calcd for $C_{64}H_{68}O_{11}$: C, 75.87; H, 6.76%.

Benzyl *O*-(2,3,4,6-Tetra-*O*-benzyl-α- and β-D-glucopyranosyl)-(1→6)-2,3,4-tri-*O*-benzyl-α-D-glucopyranosides (29 and 30). Condensation of **28**[23] (54.0 mg) with **1** (70.2 mg) in the presence of NsCl (37.7 mg), AgOTf (43.7 mg), and Et_3N (23.7 μl) in CH_2Cl_2 (0.54 ml), followed by chromatography (TB system), gave **29** (23.3 mg, 22%), mp 106—107 °C, $[\alpha]_D^{20}$ +79° (*c* 1.7, $CHCl_3$) [lit,[24] mp 102—105 °C, $[\alpha]_D^{20}$ +64° (*c* 0.6, $CHCl_3$)], ^{13}C NMR ($CDCl_3$, 75 MHz) δ=94.6 (C-1), 97.3 (C-1'), and **30** (79.2 mg, 75%), mp 132—134 °C, $[\alpha]_D^{20}$ +41° (*c* 0.7, $CHCl_3$) [lit, mp 128—130 °C,[24] 133—134 °C,[25] $[\alpha]_D^{20}$ +39° (*c* 0.4, $CHCl_3$),[24] +17.1° (*c* 1, $CHCl_3$)[25]].

Found: **29**, C, 76.53; H, 6.63%. **30**, C, 76.53; H, 6.54%.

†† TRC=tris(triphenylphosphine)rhodium(I) chloride and EBW is the mixture of EtOH, benzene, and H_2O (7:3:1, v/v) (Ref. 19).

Calcd for $C_{68}H_{70}O_{11}$: C, 76.81; H, 6.64%.

Benzyl *O*-(2,3,4,6-Tetra-*O*-benzyl-β-D-glucopyranosyl)-(1→6)-2,3-di-*O*-benzyl-α-D-glucopyranoside (31). A mixture of **27** (73.5 mg), TRC (20 mg), and EBW (4 ml) was refluxed overnight. After concentration, the residue was heated in acetone (2 ml) containing aq HCl (3.5%, 50 μl) for 1 h at 45 °C. Chromatography (HE system) gave **31** (43.6 mg, 62%), mp 128—129 °C, $[\alpha]_D^{20}$ +35° (*c* 0.7, $CHCl_3$), ^{13}C NMR ($CDCl_3$, 25 MHz) δ=95.6 (C-1), 103.9 (C-1′).

Found: C, 75.18; H, 6.67%. Calcd for $C_{61}H_{64}O_{11}$: C, 75.29; H, 6.63%.

Benzyl *O*-(2,3,4,6-Tetra-*O*-benzyl-β-D-glucopyranosyl)-(1→6)-*O*-[(2,3,4-tri-*O*-benzyl-α-L-rhamnopyranosyl)-(1→4)]-2,3-di-*O*-benzyl-α-D-glucopyranoside (32). Rhamnosylation of **31** (54.4 mg) with **11** (36.5 mg) in the presence of NsCl (27.3 mg), AgOTf (43.2 mg), and Et_3N (23.5 μl) in CH_2Cl_2 (0.4 ml), followed by chromatography (TB system), gave **14** (16.0 mg, 45% from **11**), the *p*-nitrobenzenesulfonate of **31** (12.0 mg, 18% from **31**), $[\alpha]_D^{20}$ +31° (*c* 1.3, $CHCl_3$), ^{13}C NMR ($CDCl_3$, 75 MHz) δ=94.5 (C-1), 103.7 (C-1′), 123.8, 125.8, 142.3, 149.9 (*p*-nitrobenzenesulfonyl) [Found: C, 69.64; H, 5.81; N, 1.28%. Calcd for $C_{67}H_{67}NO_{15}S$: C, 69.47; H, 5.83; N, 1.21%], and then **32** (27.7 mg, 36% from **31**), $[\alpha]_D^{20}$ +17 (*c* 1.7, $CHCl_3$).

Found: C, 75.64; H, 6.54%. Calcd for $C_{88}H_{92}O_{15}$: C, 76.06; H, 6.67%.

***O*-β-D-Glucopyranosyl-(1→6)-*O*-[α-L-rhamnopyranosyl-(1→4)]-D-glucopyranose (3).** Hydrogenolysis of **32** (77.6 mg) over Pd on C (10%, 50 mg) in AcOH (6 ml) containing H_2O (50 μl) for 2 d, followed by chromatography (CM system), gave a hygroscopic glass of **3** (15.4 mg, 56%), $[\alpha]_D^{20}$ −5.1° (*c* 1.1, H_2O), ^1H NMR (D_2O, 300 MHz) δ=4.35 (0.4H, d, $J_{1'',2''}$=8.0 Hz, H-1″α), 4.37 (0.6H, $J_{1'',2''}$=8.0 Hz, H-1″β), 4.54 (0.6H, $J_{1,2}$=8.0 Hz, H-1β), 4.80 (1H, s, H-1′), 5.11 (0.4H, $J_{1,2}$=4.0 Hz, H-1α).

Found: C, 43.98; H, 6.98%. Calcd for $C_{18}H_{32}O_{15}$: C, 44.26; H, 6.60%.

Benzyl 4-*O*-Allyl-3-*O*-benzyl- and 3-*O*-Allyl-4-*O*-benzyl-α-D-glucopyranosides (35 and 36). A mixture of **34**[27] (6.09 g), NaH in an oil suspension (0.49 g) and allyl bromide (30.7 ml) was stirred for 4 h at 60 °C. After removing some insoluble matter by filtration, the solution was evaporated to dryness. The residue was vigorously stirred in $PhCH_2Cl$ (160 ml) containing crushed KOH (60 g) for 6 h at 120 °C. After filtration and evaporation at 95 °C, the residue was refluxed in a mixture of MeOH (20 ml), $CHCl_3$ (30 ml), and trifluoroacetic acid (Tokyo Kasei, 5 ml) for 1.5 h. After Et_3N (11 ml) being added, evaporation and chromatography (TB system) gave **35** (2.56 g, 79%), mp 81—82 °C (from hexane containing IPE), $[\alpha]_D^{20}$ +131° (*c* 1.0, $CHCl_3$), ^{13}C NMR ($CDCl_3$, 75 MHz) δ=61.7 (C-6), 69.9 (C-5), 71.3 (C-2), 77.2 (C-4), 83.0 (C-3), 97.8 (C-1), 117.3, 134.5 (allyl), 136.8, 138.6 (benzyl), and **36** (0.28 g, 9%), mp 94.5—95.5 °C (from IPE), $[\alpha]_D^{20}$ +105° (*c* 0.3, $CHCl_3$), ^{13}C NMR ($CDCl_3$, 75 MHz) 61.7 (C-6), 69.9 (C-5), 71.3 (C-2), 77.2 (C-4), 82.8 (C-3), 97.8 (C-1), 116.8, 135.1 (allyl), 136.8, 137.8 (benzyl).

Found: **35**, C, 68.84; H, 7.01%. **36**, C, 68.75; H, 7.03%. Calcd for $C_{23}H_{28}O_6$: C; 68.98, H; 7.05%.

A sample (28.2 mg) of **35** was treated in DMF (0.6 ml) with NaH in an oil suspension (17 mg) and $PhCH_2Br$ (52 μl) at room temp for 1 h. Processing followed by chromatography (HE system) gave a product which was refluxed overnight in EBW (4 ml) containing TRC (8 ml). After concentration, the residue was heated in acetone (4 ml) containing aq HCl (3.5%, 40 μl) for 1 h at 45 °C. Chromatography (HE system) gave **16** (19.4 mg, 51%), which was identified with a sample prepared following the known method.[16]

Benzyl 4-*O*-Allyl-6- and -2-*O*-benzoyl-3-*O*-benzyl-α-D-glucopyranosides (33 and 37). To a solution of **35** (2.71 g) in pyridine (13.5 ml) was added PhCOCl (0.79 ml) portionwise at −10 °C. The mixture was then stirred overnight at 0 °C. Processing and chromatography (TB system) gave the dibenzoate (0.77 g, 19%), **33** (1.79 g, 52%), $[\alpha]_D^{20}$ +105° (*c* 1.0, $CHCl_3$), ^1H NMR (CCl_4, 90 MHz) δ=3.53 (1H, dd, $J_{1,2}$=4 Hz, $J_{2,3}$=10 Hz, H-2), 4.82 (1H, d, H-1), and **37** (0.40 g, 12%), $[\alpha]_D^{20}$ +174° (*c* 3.1, $CHCl_3$) ^1H NMR (CCl_4, 90 MHz) 4.06 (1H, dd, $J_{2,3}$=10 Hz, $J_{3,4}$=9 Hz, H-3), 4.90 (1H, dd, $J_{1,2}$=4 Hz, H-2), 5.12 (1H, d, H-1).

Found: **33**, C, 71.11; H, 6.32%. **37**, C, 71.01; H, 6.32%. Calcd for $C_{30}H_{32}O_7$: C, 71.41; H, 6.39%.

Benzyl *O*-(2,3,4,6-Tetra-*O*-benzyl-α- and β-D-glucopyranosyl)-(1→2)-4-*O*-allyl-6-*O*-benzoyl-3-*O*-benzyl-α-D-glucopyranosides (38 and 39). The acceptor **33** (1.749 g) was glucosylated with **1** (2.44 g) in the presence of NsCl (1.31 g), AgOTf (1.52 g), and Et_3N (0.82 ml) in CH_2Cl_2 (18 ml), followed by chromatography (TB system), gave **39** (1.6 g, 45%), $[\alpha]_D^{20}$ +56° (*c* 5.4, $CHCl_3$), ^{13}C NMR ($CDCl_3$, 25 MHz) δ=98.9 (C-1), 103.6 (C-1′), 117.6, 134.6 (allyl), 166.0 (C=O), and **38** (1.37 g, 39%), $[\alpha]_D^{20}$ +93° (*c* 2.3, $CHCl_3$), ^{13}C NMR ($CDCl_3$, 25 MHz) δ=94.5 (C-1′), 95.2 (C-1), 117.6, 133.3 (allyl), 166.6 (C=O).

Found: **38**, C, 74.79; H, 6.67%. **39**, C, 74.57; H, 6.54%. Calcd for $C_{64}H_{66}O_{12}$: C, 74.83; H, 6.48%.

Benzyl *O*-(2,3,4,6-Tetra-*O*-benzyl-β-D-glucopyranosyl)-(1→2)-4-*O*-allyl-3-*O*-benzyl-α-D-glucopyranoside (40). A mixture of **39** (1.53 g), MeOH (20 ml), and 1,4-dioxane (7.5 ml) was treated with dil methanolic NaOMe (7.5%, 7.5 ml) for 6.5 h at room temp. After AcOH was added, evaporation and chromatography (TB system) gave **40** (1.19 g, 87%), $[\alpha]_D^{20}$ +67° (*c* 0.6, $CHCl_3$), ^{13}C NMR ($CDCl_3$, 25 MHz) δ=99.1 (C-1), 103.6 (C-1′), 117.3, 134.9 (allyl).

Found: C, 74.13; H, 6.91%. Calcd for $C_{57}H_{62}O_{11}$: C, 74.17; H, 6.77%.

Benzyl *O*-(2,3,4,6-Tetra-*O*-benzyl-β-D-glucopyranosyl)-(1→2)-3,6-di-*O*-benzyl-α-D-glucopyranoside (41). A mixture of **40** (199.5 mg), NaH in oil suspension (41 mg), and DMF (1.5 ml) was stirred for 0.5 h at −5 °C. After $PhCH_2Br$ (0.13 ml) was added, the mixture was stirred for 1 h at room temp. Quenching with MeOH, processing, and subsequent chromatography (HE system) gave the product, which was then refluxed in EBW (4 ml) containing TRC (30 mg). After evaporation, the residue was heated in acetone (2 ml) containing aq HCl (3.5%, 30 μl) for 1 h at 45 °C. Chromatography (HE system) afforded **41** (80.1 mg, 40%), $[\alpha]_D^{20}$ +45° (*c* 1.3, $CHCl_3$), ^{13}C NMR ($CDCl_3$, 100 MHz) δ=99.0 (C-1), 103.5 (C-1′).

Found: C, 75.02; H, 6.72%. Calcd for $C_{61}H_{64}O_{11}$: C, 75.29; H, 6.63%.

Benzyl *O*-(2,3,4,6-Tetra-*O*-benzyl-β-D-glucopyranosyl)-(1→2)-*O*-[(2,3,4,6-tetra-*O*-benzyl-α- and -β-D-glucopyranosyl)-(1→6)]-4-*O*-allyl-3-*O*-benzyl-α-D-glucopyranosides (42 and 43). The acceptor **40** (1.19 g) was glucosylated with **1** (0.91 g), NsCl (0.49 g), AgOTf (0.57 g), and Et_3N (0.31 ml) in CH_2Cl_2 (7.0 ml), followed by chromatography (TB system) to afford

42 (0.58 g, 31%), $[\alpha]_D^{20}$ +69° (*c* 1.7, $CHCl_3$), ^{13}C NMR ($CDCl_3$, 25 MHz) δ=97.5 (C-1″), 98.6 (C-1), 103.6 (C-1′), 117.0, 135.2 (allyl), and **43** (1.26 g, 68%), $[\alpha]_D^{20}$ +43° (*c* 2.6, $CHCl_3$), ^{13}C NMR ($CDCl_3$, 25 MHz) δ=98.9 (C-1), 103.6 (C-1′), 104.0 (C-1″), 116.7, 135.0 (allyl).

Found: **42**, C, 75.34; H, 6.50%. **43**, C, 75.52; H, 6.52%. Calcd for $C_{91}H_{96}O_{16}$: C, 75.60; H, 6.69%.

Benzyl *O*-(2,3,4,6-Tetra-*O*-benzyl-β-D-glucopyranosyl)-(1→2)-*O*-[(2,3,4,6-tetra-*O*-benzyl-β-D-glucopyranosyl)-(1→6)]-3-*O*-benzyl-α-D-glucopyranoside (44). A mixture of **43** (1.04 g), TRC (0.20 g), and EBW (33 ml) was refluxed for 3 h. After evaporation, the residue was refluxed in acetone (50 ml) containing aq HCl (3.5%, 2 ml) for 0.5 h. Chromatography (TB system) furnished **44** (0.82 g, 81%), $[\alpha]_D^{20}$ +34° (*c* 1.1, $CHCl_3$), ^{13}C NMR ($CDCl_3$, 25 MHz) δ=99.2 (C-1), 103.8 (2C, C-1′ and C-1″).

Found: C, 75.28; H, 6.55%. Calcd for $C_{88}H_{92}O_{16}$: C, 75.19; H, 6.60%.

Benzyl *O*-(2,3,4,6-Tetra-*O*-benzyl-β-D-glucopyranosyl)-(1→2)-*O*-[(2,3,4,6-tetra-*O*-benzyl-β-D-glucopyranosyl)-(1→6)]-*O*-[(2,3,4-tri-*O*-benzyl-α-L-rhamnopyranosyl)-(1→4)]-3-*O*-benzyl-α-D-glucopyranoside (45). Rhamnosylation of **44** (735 mg) with **11** (431 mg) in the presence of NsCl (348 mg), AgOTf (404 mg), and Et_3N (219 μl) in CH_2Cl_2 (2.8 ml) and subsequent chromatography (TB system) gave, after the elution of **14** and the *p*-nitrobenzenesulfonate of **44**, ^{13}C NMR ($CDCl_3$, 25 MHz) δ=98.4 (C-1), 103.3 (C-1′), 104.0 (C-1″), 124.2, 126.3, 142.6, 150.2 (*p*-nitrobenzenesulfonyl), the sole cross-condensate **45** (352 mg, 37%), $[\alpha]_D^{20}$ +19° (*c* 1.3, $CHCl_3$).

Found: C, 75.63; H, 6.68%. Calcd for $C_{115}H_{120}O_{20}$: C, 75.80; H, 6.64%.

***O*-β-D-Glucopyranosyl-(1→2)-*O*-[β-D-glucopyranosyl-(1→6)]-*O*-[α-L-rhamnopyranosyl-(1→4)]-D-glucopyranose (4).** Hydrogenolysis of **45** (75 mg) over Pd on C (10%, 75 mg) in AcOH (6 ml) containing H_2O (50 μl) for 3 d, followed by chromatography (CM system), afforded **4** (11.5 mg, 43%), mp 179—180 °C (decomp), $[\alpha]_D^{20}$ −16° (*c* 0.3, H_2O), ^1H NMR (D_2O, 300 MHz) δ=4.35 (0.7H, d, $J_{1''',2'''}$=8.0 Hz, H-1‴α), 4.37 (0.3H, d, $J_{1''',2'''}$=8.0 Hz, H-1‴β), 4.52 (0.7H, d, $J_{1',2'}$=8.0 Hz, H-1′α), 4.60 (0.3H, d, $J_{1,2}$=8.0 Hz, H-1β), 4.80 (1H, d, $J_{1'',2''}$= 1.5 Hz, H-1″), 5.31 (0.7H, d, $J_{1,2}$=4.0 Hz, H-1α).

Found: C, 44.04; H, 6.65%. Calcd for $C_{24}H_{42}O_{20}$: C, 44.31; H, 6.51%.

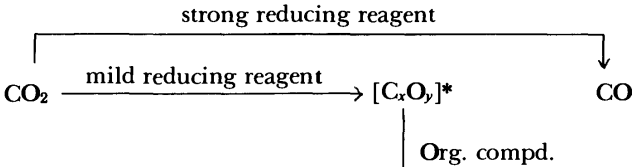
Reduction of Sulfur Dioxide and Carbon Dioxide with Benzoin Carbanion. Oxygen Transfer from Products Formed by the Reduction of Sulfur Dioxide to 7,7,8,8-Tetracyanoquinodimethane

Fuminori Akiyama
Chemical Research Institute of Nonaqueous Solutions, Tohoku University, Sendai 980
(Received April 28, 1988)

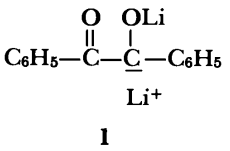
A reaction of sulfur dioxide (SO_2) with benzoin carbanion (the lithium salt of benzoin dianion, **1**) in tetrahydrofuran (THF) gave a mixture of benzil (**2**) and benzoin (**3**) in yields of 83 and 17%, respectively, irrespective of the reaction temperature between −78 and 25 °C. The reaction of carbon dioxide (CO_2) with **1** in THF gave a mixture of **2** and **3** accompanied by the formation of a small amount of lithium benzoate (**4**). The proportion of **2** in a mixture of **2** and **3** formed in the reaction of CO_2 with **1** were 49, 30, and 20% at −78, −22, and 25 °C, respectively. The reaction of SO_2 with **1** in the presence of 7,7,8,8-tetracyanoquinodimethane (TCNQ) gave oligomers of TCNQ with a yield of 60%, in which some parts of the cyano groups were transformed to carboxylato groups.

From the view point of the use of resources it is important to investigate the reaction of sulfur dioxide (SO_2) or carbon dioxide (CO_2) with organic compounds. Especially, reductions of CO_2 or SO_2 have been extensively investigated for many years. It has been reported that a reduction of SO_2 with hydrogen sulfide,[1] methane,[2] carbon,[3] carbon monoxide[4] gave elemental sulfur. A reduction of CO_2 in the presence of various catalysts have been reported to give formic acid,[5] methanol,[6] or methane.[7] Electrochemical or photoelectrochemical reduction of CO_2 has also been investigated.[8] In these reactions SO_2 or CO_2 is converted to compounds having relatively low reactivity, such as carbon monoxide, formic acid, methanol, or elemental sulfur. If a reduction of SO_2 or CO_2 is conducted using mild reducing reagents, there is a possibility that unstable oxides, which are very reactive, may be formed. If we can use the high reactivity of these unstable oxides effectively, there is a possibility that we can fruitfully utilize SO_2 or CO_2. An outline of this concept for the reduction of SO_2 was shown in a previous paper.[9] That for the reduction of CO_2 is shown in Scheme 1.

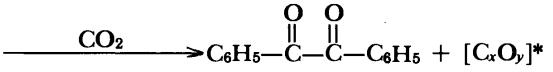
Various types of sulfur oxides are known.[10] Unstable sulfur monoxide has been known.[11] There might be other unstable sulfur oxides which have not been reported. Recently, unstable carbon oxides such as $C_2O_2^+$,[12] $C_2O_2^-$,[13] C_2O,[14] and C_3O[15] have been reported. In a previous paper the reduction of SO_2 with a mild reducing reagent, benzoin carbanion (the lithium salt of benzoin dianion, **1**), was reported to give unstable sulfur oxides which gave sulfur atoms to cyclopentadiene to form oligomers having sulfide linkages.[9] Although **1** has not been used as a reducing reagent in synthetic organic chemistry, it was found in a previous paper[9] that **1** reduced SO_2. In the present report it will be described that CO_2 is also reduced with **1**. The reaction scheme of a reduction of SO_2 with **1** was shown in the previous paper.[9] That for the reduction of CO_2 with **1** is shown as follows:



Scheme 1.



1



In addition to this result it will be described that the reduction products of SO_2 with **1** have sufficient reactivity to give an oxygen atom to 7,7,8,8-tetracyanoquinodimethane (TCNQ) and that the reduction products of CO_2 with **1** do not have sufficient reactivity to react with TCNQ.

Results and Discussion

Reaction of Benzoin Carbanion 1 with SO_2 (System A) or CO_2 (System B). Reactions of **1** with SO_2 or CO_2 were carried out in tetrahydrofuran (THF) at three reaction temperatures −78, −22, and 25 °C. The products were divided into water-soluble and -insoluble portions. Proportions of benzil (**2**) and benzoin (**3**) (the ratio of **2** to **3**) were measured from the NMR spectra of the water-insoluble portion and the yield of lithium benzoate (**4**) was measured from the NMR spectra of materials in the water-soluble portion (see Experimental).

In system A there was no **4** in the water-soluble portion and there were no organic compounds other than **2**, **3**, trace amounts of benzoic acid, and a small

Table 1. Products and Yields in the Reaction of Benzoin Carbanion 1 with SO_2 or CO_2 in THF

Reaction	Temp °C	Proportion (%)[a] of benzil and benzoin Benzil (2) / Benzoin (3)	Yield (%)[b] Lithium benzoate (4)	Benzoic acid
SO_2[c]	25 −22 −78	83 / 17	0	Trace
CO_2[d]	25	20 / 80[e]	4[f]	0
	−22	30 / 70[e]	10[f]	0
	−78	49 / 51[e]	18[f]	0

a) Proportions mean the ratio of **2** to **3**. b) 0.5 mol of product ×100/mol of **3** used. c) Proportion in the system A means actual yield.[16] Since several runs at three reaction temperature gave products having almost same proportions of **2** and **3**, the average value of the proportions was calculated. Although the yield of **2** in system A was reported to be 85% in the previous paper,[9] several times of reinvestigation showed that 83% was correct value. d) Actual yield of **2** or **3** can be calculated by multiplying proportion of them with (100−yield of **4**)/100.[17] e) Average values of three runs at each temperature are shown. f) Average values of two runs at each temperature are shown.

amount of the reaction products of SO_2 with diisopropylamine in the water-insoluble portion,[16] proportion of **2** and **3** being shown in Table 1.

Since in system B a small amount of **4** was formed and was found in the water-soluble portion, its yields were measured at three reaction temperature (Table 1). The proportions of **2** and **3** in the water-insoluble portion were measured (Table 1).[17]

Since one might suppose that a small amount of the oxygen contained in CO_2 or SO_2 or in the reaction vessel as an impurity plays an important role in the production of benzil, a reaction of **1** with air was undertaken at −22 °C in order to show that the reaction product of **1** with air was mainly **4**. Therefore, such a possibility can be excluded.

The possibility that oxygen of **4** comes from the oxygen contained as an impurity in the reaction vessel can be excluded for the following reasons. The facts that system A does not give **4** and scarcely gives benzoic acid and that the purity of CO_2 is more than 99 vol% exclude the existence of oxygen in system B. The fact that the yields of **2** and **4** increase as the reaction temperature decreases suggests that these two compounds are oxidation products of **1** with CO_2.

In system B, the lower was the reaction temperature, the higher was the yield of **2**. An increase in the yield of the oxidation product of **1** with a decreasing reaction temperature is, presumably, concerned with a change in the solvation of reaction intermediate (adduct of **1** with SO_2 or CO_2). Szwarc et al. have suggested that a decrease in the temperature facilitates the formation of a solvent-separated ion pair by the solvation of an ion pair.[18] If in system A the intermediate is well solvated and a change in temperature does not have any effect on the solvation, the yield of **2** is expected not to be affected by a change in the reaction temperature. If in system B the intermediate is poorly solvated at room temperature and the solvation of the intermediate is facilitated as the temperature decreases, the yield of **2** is expected to be affected by a change in the reaction temperature. The well-solvated structure of the intermediate presumably has a higher probability of an oxidation-reduction reaction than a poorly solvated one.

It was confirmed by means of TLC and gel-permeation chromatography of the products that elemental sulfur was not formed in system A. It was also confirmed by means of GLC or NMR analyses that carbon monoxide or formic acid was not formed in system B. These facts indicate the possibility that unstable oxides are formed in system A or B. Several attempts for their isolation were unsuccessful, presumably because of their instabilities.

In order to check the reactivities of the unstable oxides or intermediate formed in a reaction of SO_2 or CO_2 with **1**, the reaction of **1** with a mixture of TCNQ with an excess amount of SO_2 or CO_2 was carried out.

Reaction of Benzoin Carbanion 1 with a Mixture of TCNQ and SO_2 (System C) or CO_2 (System D). An experiment in which air or nitrogen was used in place of SO_2 or CO_2 was also carried out. The reaction products were mainly salt (LiTCNQ) and oligomers of TCNQ. The IR spectrum of the salt (KTCNQ, see Experimental) is well coincident with that of the authentic sample prepared by the method of Melby[19] and other workers.[20] Yields of the salt are shown in Table 2. Low yields of KTCNQ in the reaction in the presence of air or nitrogen are presumably attributed to hydrolysis of LiTCNQ or KTCNQ during the separation procedure (contact with saturated aqueous KCl solution) because of the strong basicity of the products.[21] The highest yield of KTCNQ was obtained in system D, as is shown in Table 2.

Oligomers of TCNQ formed in the reactions were separated; their yields are shown in Table 2. The yield of the oligomer of TCNQ was obtained in system C. The IR spectra of these oligomers obtained by four sorts of reactions were similar. The IR absorptions at 1587 and 1360 cm^{-1} for the oligomers indicate the presence of carboxylato groups.[22] The IR absorption

Table 2. Yields of the Oligomers of TCNQ and KTCNQ Obtained by the Reaction of Benzoin Carbanion **1** with a Mixture of TCNQ and SO_2, CO_2, Air, or Nitrogen at −22°C in THF

Reaction	Yield (%) of the oligomer of TCNQ[a)]	Yield (%) of KTCNQ[b)]
SO_2	60	31
CO_2	7	74
Air	13	7
Nitrogen	7	5

a) Yields were calculated as 100×wt of oligomer/wt of TCNQ used.[30] b) LiTCNQ formed was converted to KTCNQ (see work-up procedure in Experimental). Yields were calculated as 100×mol of KTCNQ/mol of TCNQ used.

of a COO^- symmetric stretching vibration at a relatively low frequency, such as 1360 cm^{-1}, has been reported for formates[23] or metal salts of amino acids.[24] The absence of IR absorption of 1540 and 860 cm^{-1}, which are seen in a spectrum of TCNQ, indicates that all of the TCNQ used were consumed. Two ^{13}C NMR signals at δ 160 and 170 in ^{13}C NMR of the oligomers indicate the presence of carboxylato groups. Steric crowding of the groups in the oligomers presumably brings about a slight upfield shift of the carboxylato group compared to the value reported in the literature (δ 170—185).[25] The difference in the chemical shift of these two signals is presumably attributed to different structures to which the carboxylato groups are attached. Elemental analyses of the oligomer obtained in system C indicated that N/C (ratio of N and C content) was 0.29, which was less than 0.39 (the calculated value for TCNQ). This fact indicates that the formation of the carboxylato group brought about the removal of a nitrogen atom from the oligomer of TCNQ. The molecular weight of these oligomers (calibrated to the molecular weight of standard polystyrene) was between 800—200 judged from the analyses by means of gel-permeation chromatography.

These above-stated facts show that in system C TCNQ was converted to low molecular weight oligomers of TCNQ in which some of the CN groups are transformed to a carboxylato group in considerable yield. One might suppose that the oxygen of the carboxylato group in this oligomer of TCNQ comes about from the moisture or oxygen contained in the reaction vessel as an impurity. However, the fact that only system C gave an oligomer having a carboxylato group in high yield and that other reactions carried out using CO_2, air or nitrogen by almost the same procedure as system C, did not give the oligomer so much supports the conclusion that the oxygen of the carboxylato group of the oligomer obtained in the former reaction comes about from the reduction products of SO_2. The formation of the oligomer of TCNQ in a yield of around 10% (see Table 2) is presumably concerned with the hydrolyses of TCNQ by the moisture contained in the reaction vessel as an impurity or hydrolysis during the work-up procedure by moisture in the atmosphere. Therefore, it can be concluded that the oxygen of the carboxylato group in a small amount of the oligomer obtained in system D does not come from the reduction products of CO_2.

The fact that the oligomer of TCNQ, having a carboxylato group, is formed in system C presumably indicates that an oxygen atom transfers from the formed unstable sulfur oxides to TCNQ. Previously, unstable sulfur oxides were trapped (see previous paper) and IR spectra were shown (see Fig. 4 in that paper).[9] Although one might suppose that water is possibly formed by a reduction of SO_2 with **1** and it hydrolyzes the CN groups of TCNQ to form a carboxylato group, the fact that system D, in which the reduction of CO_2 with **1** also possibly gives water, slightly gives a carboxylato group suggests the possibility that a carboxylato group is formed by an oxygen transfer from the formed unstable oxides. In order to show that the formation of oligomer in 60% yield in system C can not be attributed to a hydrolysis of the CN group by the formed water, a control experiment was carried out.[26] Since water formed, even if the reduction gives water in system C, is far less than the water added in the control experiment, it can be considered that 60% yield of the oligomer is too high to be attributed to hydrolyses by a small amount of the formed water.

The sulfur-transfer reaction in the previous paper gave an oligomer of cyclopentadiene which contained almost 20 wt% of sulfur.[9] On the other hand, the oligomer of TCNQ obtained in system C was found to have only less than 1 wt% of sulfur. It is not yet clear why TCNQ does not accept sulfur so much but accept oxygen atoms from the formed unstable sulfur oxides.

The reaction of unstable sulfur oxides or carbon oxides formed in system A or B with various reagents are now being investigated.

Experimental

General Procedures. The IR spectra were measured using a JEOL Fourier transform IR spectrophotometer. The ^1H NMR spectra were recorded on a JEOL Fourier transform NMR spectrometer operating at 89.55 MHz and a JNM-PMX 60SI NMR spectrometer operating at 60 MHz. The ^{13}C NMR spectra were recorded on a JEOL Fourier transform NMR spectrometer operating at 22.50 MHz. Thin-layer chromatography separations were carried out on silica

gel (Merk Art. 5717). Sulfur dioxide was distilled over phosphorous pentaoxide prior to use. Tetrahydrofuran was distilled over $LiAlH_4$ under a nitrogen atmosphere immediately prior to use. Diisopropylamine was distilled and dried over molecular sieves. Reagent-grade TCNQ was recrystalized from ethyl acetate prior to use. All other chemicals were of reagent grade and were obtained from commercial sources. In all reactions in the present report two-necked round-bottomed flask, one neck of which was capped with a serum cap and the other neck of which was installed with a delivery tube for SO_2, CO_2, air, or nitrogen, was used.

Reaction of Benzoin Carbanion 1 with SO_2 (System A) or CO_2 (System B). Since it has been reported that two sites of benzoin are converted to anion,[27] slight excess amount of lithium diisopropylamide (LDA) compared to 2 equivalent of benzoin was used to form **1**. To a THF solution of **1**, formed using 3 mmol of benzoin with the same procedure as that described in a previous paper,[9] 9 mmol of SO_2 or a large excess amount of CO_2 was bubbled as gas through a delivery tube. During the introduction of SO_2 or CO_2 into the reaction solution, the solution changed in color from orange-red to dark red (almost black), and then to yellow. In the case of the reaction of CO_2, the introduction of CO_2 was continued for at least 30 minutes after the reaction mixture changed in color to yellow. After the completion of the introduction of SO_2 or CO_2, THF was evaporated to give a yellow residue. The residue was washed with water several times in order to separate the products into a water-soluble portion and a water-insoluble organic portion. From the water-insoluble organic portion **2** and **3** were separated by means of preparative TLC using chloroform as an eluent; their structures were confirmed by comparisons of their IR and NMR spectra with those of authentic samples. For quantitative analyses the water-insoluble organic products were dissolved in $CDCl_3$ and their ^1H NMR were taken to give a ratio of **2** to **3** from signals of methine (δ 6.06) and aromatic protons (δ 7.17—8.17). Since benzoic acid was not formed in system B and was formed in only trace amount in system A, **2** and **3** are the only components derived from **1** in the water-insoluble portion (the proportions are shown in Table 1). The water-soluble portion was evaporated to give a white residue. This residue was treated several times with silica-gel column chromatography using water as an eluent to give pure **4**, the structure of which was confirmed by a comparison of their IR and NMR spectra with authentic samples. For quantitative analyses hexamethyldisiloxane was added to the white residue and its ^1H NMR spectra were taken in CD_3OD in order to measure the ratio of CH_3 protons of hexamethyldisiloxane (δ 0.07) and aromatic protons (δ 7.2—7.4 and 7.8—8.0) of **4**.

Reaction of Benzoin Carbanion 1 with a Mixture of TCNQ and SO_2 (System C). To 3 mmol of TCNQ in a nitrogen-containing two-necked 200 ml round-bottomed flask, 120 ml of absolute THF was added using a syringe and stirred for 30 minutes at room temperature under nitrogen atmosphere to obtain a homogeneous solution. This mixture was cooled to −22°C and 20 mmol of SO_2 was intriduced through delivery tube to this mixture. To this mixture THF solution of 3 mmol of **1**, which was prepared in other 100 ml two necked round-bottomed flask, was added dropewise through a serum cap using a syringe at −22 °C.

Work-up Procedure for the Reactions of the Systems C, D, E, and F. THF was evaporated from the reaction solutions to give residues. Each residue was treated with two different separation procedures in order to isolate metal-TCNQ salt and the oligomer of TCNQ.

One separation procedure is that for the separation of the metal-TCNQ salt. Since LiTCNQ has been known to be a little soluble in water and organic solvents (about 1%[19]), LiTCNQ was converted to KTCNQ, which was reported to be practically insoluble in water or organic solvents, in order to separate the metal-TCNQ salt from the reaction mixture. In this separation procedure 50 ml of saturated aqueous potassium chloride and 100 ml of ethyl acetate was added to the residue. The resulting mixture was shaken and filtered to give a purple powder, followed by washing it with water several times and then with ethyl acetate several times. The obtained powder was dried and elemental analyses were undertaken to show it to be KTCNQ (Found: C, 59.25; H, 1.66; N, 22.33; K, 16.25%. Calcd for $C_{12}H_4N_4K$: C, 59.24, H, 1.66; N, 23.02, K, 16.07%). Since there is no method for the purification of this salt (other than washing), a little discrepancy between the observed and calculated N contents is unavoidable. Analyses of potassium were undertaken using sodium tetraphenylborate.

In another separation procedure the residue was extracted with ethyl acetate several times and the extracts were treated with preparative TLC using ethyl acetate as an eluent to give oligomers of TCNQ. **2** and **3** were located in the range of a larger R_f value than 0.75. The oligomer of TCNQ obtained in system C or D were located in a TLC plate in the range of R_f=0.05—0.60 or R_f=0.03—0.08, respectively. The oligomers obtained in systems E and F were located in the range R_f=0.03—0.27. The obtained oligomers of TCNQ were colored dark brown. In the latter cases there was a trace amount of blue powder, which were located in the TLC plate in the range R_f=0.35—0.68, which showed an IR spectra different from those of the oligomer shown in Table 2. Since the amount of this blue powder was less than those located in R_f=0.03—0.27, this powder was not characterized and was not included in the oligomer shown in Table 2.

Reaction of Benzoin Carbanion 1 with a Mixture of TCNQ and CO_2 (System D). To a homogeneous mixture of 3 mmol of TCNQ and 120 ml of absolute THF in a nitrogen-containing two-necked 200 ml round-bottomed flask, CO_2, which was passed through an drying reagent, was introduced through a delivery tube for 30 minutes at −22 °C (during the introduction of CO_2 a part of CO_2 escapes from a needle which is attached to a serum cap). A 3-mmol THF solution of **1**, which was prepared in other 100 ml two-necked round-bottomed flask, was added dropwise to the THF solution of TCNQ, which was saturated with CO_2. During the addition of **1** CO_2 was continued to be introduced through a delivery tube. To our knowledge the solubility of CO_2 in THF has not been reported. However, the solubility of CO_2 in dichloromethane,[28] cyclohexane,[29] or dimethyl sulfoxide[29] at above room temperature has been reported. Since the solubilities in these solvents are not so much different form each other, the solubility of CO_2 in THF can be assumed to be not so much different from the solublities in these three solvents. Since we can assume that a decrease in the temperature from room temperature to −22°C brings about at least a two-fold increase in the solubility of CO_2 (on

the basis of the data in those literatures),[28,29] we can assume that the contained CO_2 is at least 9 times greater than TCNQ in the reaction mixture.

Reaction of Benzoin Carbanion 1 with TCNQ in the Presence of Air (System E). Almost the same reaction procedure that for system D was adopted, except for the use of air, which was passed through a 10% KOH aqueous solution in order to remove the CO_2 contained in air and drying reagent, in place of CO_2.

Reaction of Benzoin Carbanion 1 with TCNQ in the presence of Nitrogen Atmosphere (System F). Almost the same reaction procedure as that used in system D was adopted, except for the use of nitrogen, which was passed through a drying reagent, in place of CO_2.

21) In the system E or F ethyl acetate solution obtained from work-up procedure for separation of KTCNQ (contact with aqueous KCl solution) contained larger amount of oligomer of TCNQ (30% yield, compare with the yields in Table 2) than those obtained by the separation procedure of oligomer (TLC procedure without contact with water).

22) Oligomer contained in the ethyl acetate solution obtained from the separation procedure of KTCNQ in the systems E and F (see Ref. 21) also showed IR spectra having absorptions at 1587 and 1360 cm^{-1}. The fact that contact of the products with aqueous KCl solution gave oligomer having IR absorptions at 1587 and 1360 cm^{-1} supports conclusion that these absorptions can be attributed to carboxylato group.

26) After 13 ml of 1 mol dm^{-3} aqueous hydrochloric acid solution, amount of which was enough to neutralize the basic material, was added to the reaction solution of the system F carried out using 3 mmol of benzoin, the whole solution was evaporated and extracted with ethyl acetate. The oligomer of TCNQ was separated from this extract by means of TLC to show that the yield of oligomer was 30%.

27) H. G. Heine, *Liebigs Ann. Chem.*, **735**, 56 (1970).

28) F. H. Vonderheiden and J. W. Eldrige, *J. Chem. Eng. Data*, **8**, 20 (1963).

29) J. H. Dymond, *J. Phys. Chem.*, **71**, 1829 (1967).

30) IR spectra of the oligomers obtained in the system D, E, and F showed contamination of small amount of LiTCNQ in the oligomer separated with TLC. Therefore, actual yields of the oligomers in these three cases are a little lower than those shown in Table 2. Since solubility of LiTCNQ in ethyl acetate is relatively small and Rf of LiTCNQ is very low, contamination of LiTCNQ in the oligomer obtained in the system C can be neglected.

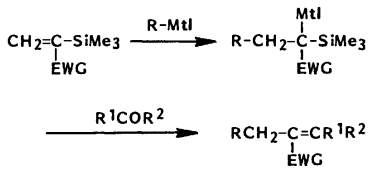
(Received April 30, 1988)

Reaction of organolithiums with a 1-(trimethylsilyl)ethenyl sulfide produces 1,2-bis(trimethylsilyl)-cyclopropanes, while use of 1-silylethenyl sulfides bearing a bulkier silyl moiety results in exclusive formation of the corresponding Michael adduct anions which are then quenched with aldehydes to give vinyl sulfides. On the contrary, a 1-(trimethylsilyl)ethenyl sulfoxide undergoes smooth Michael addition with a variety of organometallics and the resulting carbanion intermediates can be quenched with aldehydes to produce vinyl sulfoxides. Scope and limitations of these sequential reactions are discussed.

Development of a step-saving procedure for the sequence including several reaction steps is important from a standpoint of efficiency and simplification of synthetic route. Especially attractive is a one-flask procedure in which more than two steps of carbon–carbon bond forming processes are involved.

In a previous communication,[1] we reported the Michael addition–Peterson olefination sequence of methyl 2-(trimethylsilyl)acrylate (Eq. 1, EWG=COOMe). Thereafter we have been continuing our research program aiming at a wide extension of this consecutive reaction to other systems using electrophilic olefins such as 1-silylethenyl sulfides,[2] sulfoxides,[2] and ketones.



(1)

Meantime Ager reported Michael additions of phenyl 1-silylethenyl sulfide with organolithiums followed by alkylations or Peterson olefinations.[3,4] His two reports stimulated us to present our own results obtained in a similar research using the same 1-silylethenyl sulfide, its derivatives, and a silylethenyl sulfoxide. As discussed below, our results differ from the Ager's ones in some points.

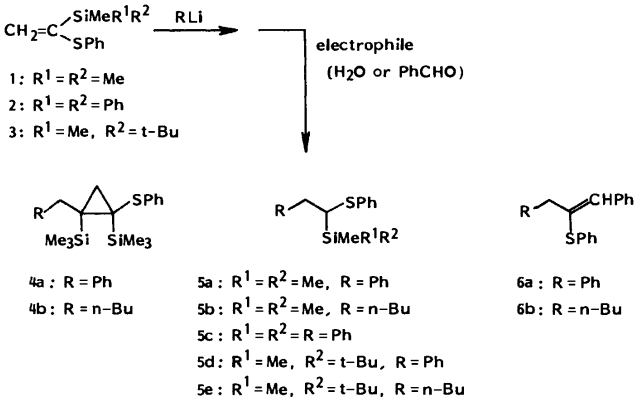
The Michael addition of 1-silyl-1-alkenyl sulfides was first reported by Seebach who briefly investigated the Michael addition–Peterson olefination sequence of a 1-silylethenyl sulfide.[5] Later this reaction was applied to a synthetic approach of sulfines[6] and 1-silylalkyl sulfides.[7] Although yields of the Michael addition step were unsatisfactory at the early stage of these investigations, they were improved by slow addition of a diluted solution of the Michael acceptors to excess nucleophiles.[7]

Compared with the relatively many reaction examples on 1-silyl-1-alkenyl sulfides, the corresponding sulfoxides and sulfones[6] with higher oxidation levels have been rarely utilized in the related reaction sequence. As 1-silylalkyl sulfoxides are labile compounds[6] so as to undergo sila-Pummerer rearrangement under mild conditions, the Michael addition to 1-silyl-1-alkenyl sulfoxides must be useful as a new method of generating 1-silyl-1-sulfinyl carbanions.[8]

The present article describes the scope and limitation of the Michael addition–Peterson olefination sequence of 1-silylethenyl sulfides and sulfoxide.

Results and Discussion

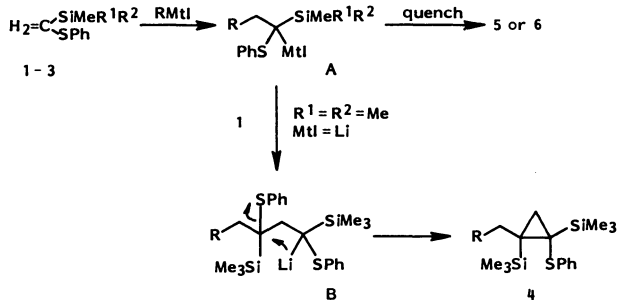
Michael Reactions of 1-Silylethenyl Sulfides. In the first place, the reactivity of phenyl 1-(trimethylsilyl)ethenyl sulfide (**1**) in Michael additions was examined by use of nucleophiles such as phenyllithium and phenylmagnesium bromide; the resulting anionic adduct was quenched with water. Although silane **1** was recovered quantitatively in the reaction with the Grignard reagent, phenyllithium underwent a smooth addition in diethyl ether or tetrahydrofuran (THF) in the presence of *N,N,N′,N′*-tetramethyl-1,2-ethanediamine (TMEDA) to afford **4a** as a single product (Scheme 1). The product **4a** which consisted of two stereoisomers in a 4.3:1 ratio was assigned not to be the expected 1-silylalkyl sulfide **5a** but 1-benzyl-2-phenylthio-1,2-bis(trimethylsilyl)cyclopropane (**4a**) on



Scheme 1.

the basis of spectral data. The maximum yield of **4a** reached 88% when the reaction was carried out in THF (Table 1, Entry 2). Nevertheless the formation of neither **4a** nor related compounds was reported in the previous works accomplished by Ager[3,4,7] and others.[5,6]

As shown in Scheme 2, phenyllithium adds to the β-carbon of vinylsilane **1** to provide carbanion intermediate **A** (R=Ph, R^1=R^2=Me, Mtl=Li). Exclusive formation of cyclopropane **4a** indicates that the resulting carbanion **A**, stabilized by both silyl and phenylthio moieties, is much more nucleophilic than the starting phenyllithium. Thus relatively rapid addition of **A** to **1** leads to bisadduct **B** (R=Ph) followed by internal nucleophilic substitution into **4a**. A related cyclopropanation has been recently demonstrated by Cohen who carried out the reactions of vinylsilane **1** with 1-(phenylthio)allyllithiums.[9] Use of two equivalents of phenyllithium also gave cyclopropane **4a** as a sole product (Table 1, Entry 3). Even when **1** was slowly added to excess phenyllithium (2 equiv) in a period of 1 h, **4a** was the major



Scheme 2.

product (62%); the 1:1 adduct **5a** was obtained only in 17% yield (Entry 4).

Use of butyllithium instead of phenyllithium in the Michael addition of **1** in diethyl ether and subsequent hydrolytic quench furnished a 1:1 mixture of cyclopropane **4b** and the expected Michael adduct **5b** (Scheme 1 and Table 1, Entry 6). They can be separated from each other by column chromatography. On the other hand, both the same reaction in THF (Entry 7) and the reaction using a catalytic amount of copper(I) chloride (Entry 8) in diethyl ether produced only cyclopropane **4b**.

Though quench of the carbanion intermediates **A** (R^1=R^2=Me, Mtl=Li) with benzaldehyde gave the expected phenyl vinyl sulfides **6a, b** as a 1:1 mixture of *E*- and *Z*-isomers, their yields remained unsatisfactory because of the competitive formation of undesired cyclopropanes **4a, b** (Entries 5 and 10). According to the reaction pathway shown in Scheme 2, Michael acceptors bearing a bulkier silyl moiety, e.g. *t*-butyldimethylsilyl or methyldiphenylsilyl, would effectively suppress the cyclopropanation.

1-(Methyldiphenylsilyl)ethenyl phenyl sulfide (**2**) and 1-(*t*-butyldimethylsilyl)ethenyl phenyl sulfide (**3**), prepared by treating 1-(phenylthio)ethenyllithium with the corresponding silyl chlorides, reacted with phenyl- or butyllithium under similar reaction conditions to afford the Michael adducts **5a—c** after hydrolytic quench, or vinyl phenyl sulfides **6a,b** after treatment with benzaldehyde (Scheme 1 and Table 1, Entries 11—15). No cyclopropanes were even detected as expected, but water-quenched adducts **5c** and **5e** were accompanied instead (Entries 12 and 15).

Structures of phenyl vinyl sulfides **6a,b** were based on the ^{1}H and ^{13}C chemical shifts (**6a**: CH_2C=: 3.46 (*Z*), 3.79 (*E*) and 44.29 (*Z*), 37.23 (*E*); =CHPh: 6.75 (*Z*), 6.81

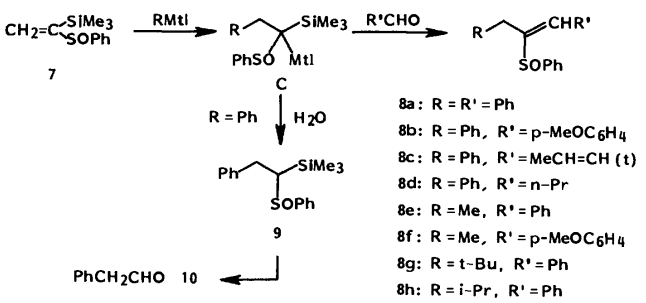
Donor molecules effectively employable in the Michael reactions of 1-silylethenyl sulfide **1** are quite limited to some organolithiums. Thus Grignard reagents and lithium enolates of esters, amides, and ketones are all ineffective.[10]

A Michael Addition-Peterson Olefination Sequence of a 1-Silylethenyl Sulfoxide. 1-Silylethenyl sulfoxides must be better Michael acceptors than 1-silylethenyl sulfides because of their higher capability of stabilizing the α-anionic center by a sulfinyl moiety. Accordingly were investigated Michael additions of phenyl 1-(trimethylsilyl)ethenyl sulfoxide (**7**) which was prepared by oxidation of **1** with *m*-chloroperbenzoic acid (MCPBA).

Treatment of **7** with TMEDA and phenyllithium (both 1 equiv) in THF at −78 °C for 1 h followed by hydrolytic quench gave a mixture of 2-phenyl-1-phenylsulfinyl-1-(trimethylsilyl)ethane (**9**) and phenylacetaldehyde (**10**) whose separation from each other was unsuccessful because of their lability (Scheme 3). No formation of cyclopropane derivatives was observed. As the relative ratio of **10** was gradually increased with liberation of benzenethiol when this mixture was allowed to stand at room temperature, aldehyde **10** was presumably formed from **9** via sila-Pummerer rearrangement,[11] not from the Michael adduct anion **C** (R=Ph).

Under similar reaction conditions, the anion **C** (R=Ph) was generated and then quenched with benzaldehyde to give the expected 1-alkenyl sulfoxide **8a** as a single stereoisomer in 71% yield based on **7** (Scheme 3, Table 2, Entry 1). Although the stereostructure of **8a** could not be determined only on the basis of spectral data, its assignment as *E*-isomer was accomplished by a chemical conversion. Thus **8a** was quantitatively deoxygenated into *E*-isomer of **6a** on treatment with trifluoroacetic anhydride, sodium iodide, and triethylamine.[12]



Scheme 3.

Methyllithium as a Michael donor (Entries 8 and 9) and aromatic, α,β-unsaturated, and aliphatic aldehydes as carbonyl quenchers (Entries 6 and 7) can be employed effectively. Grignard reagents (Entries 2 and 10), a lithium cuprate (Entry 3), and magnesium cuprates (Entries 4 and 11) are also reactive albeit yields of the Michael addition steps are relatively low.

As shown in Table 2 Peterson olefinations of the silyl- and sulfinyl-stabilized intermediates **C** (Mtl=Li) derived from **7** were highly *E*-selective (Entries 1—7, 10, and 11) except for the cases where a sterically small Michael donor such as methyllithium was employed in the initial Michael additions (Entries 8 and 9). This high *E*-selectivity makes a striking contrast to the aforementioned nonstereoselective Peterson condensations of the intermediates **A** (R^1=R^2=Me, Mtl=Li) derived from **1** and also contrast to the poor

a) All reactions were carried out in dry THF under nitrogen. b) One equimolar amount of an aldehyde was used. c) Yield of isolated products. d) In the presence of TMEDA (1.5 equiv). e) Determined by ^{13}C NMR. f) Determined by ^1H NMR. g) Three diastereomers are involved (^{13}C NMR).

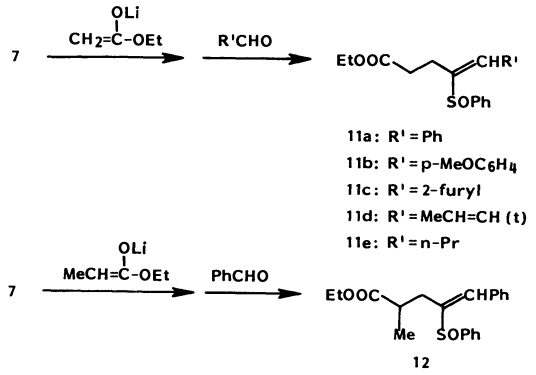
stereoselectivity observed in the Peterson reactions of the lithium anions derived from phenyl trimethylsilylmethyl sulfoxide.[8] Such high stereoselectivity will be discussed below.

1-Silylethenyl sulfoxide **7** also showed a high reactivity toward lithium enolates of esters. For example, the lithium enolate of ethyl acetate underwent a smooth Michael addition to **7** at −78 °C in 20 min and the resulting adduct anion was quenched with a variety of aldehydes to give vinyl sulfoxides **11a—e**, *E*-isomers as major products (Scheme 4 and Table 2, Entries 12—16). The *E*-selectivity is absolutely exclusive unless the Michael additions with a lithium enolate are followed by the Peterson olefinations with aromatic aldehydes (Entries 12—14).

Though in a low yield, a similar product **12** was obtained in the reaction of the lithium enolate of ethyl propanoate with **7** and benzaldehyde (Entry 17).

The stereoselectivity observed above is interpreted in Fig. 1. The sterically more favored intermediate adduct **D**[13] would be predominantly formed in the Michael addition step. Two chair transition states **E** and **F** are possible[14] where the bulky phenyl and silyl moieties always occupy equatorial positions. As Peterson olefination of the resulting adducts must occur, under the employed conditions, through cis-elimination of a silanol,[15] the carbonyl adducts formed via **E** and **F** should selectively lead to *E*- and *Z*-isomers, respectively, of **8**, **11**, and **12**. In the approach **F** there are two gausche interactions between R′–RCH_2 and R′–Me_3Si, whereas axial R′ in the approach **E** causes a less critical 1,3-diaxial interaction. This is the major reason for the selective or exclusive formation of *E*-olefins.

When R is small in size (R=Me), the gauche interaction between RCH_2 and R′ is relatively reduced. On the other hand the gauche repulsion is partly cancelled by an attractive interaction between the aromatic plane and the ester moiety when R is CH_2COOEt and R′ is aryl or hetero aryl (approach **G**). In these cases, relative stability of approach **F** is increased to lead to the decrease of *E*-selectivity.



Scheme 4.

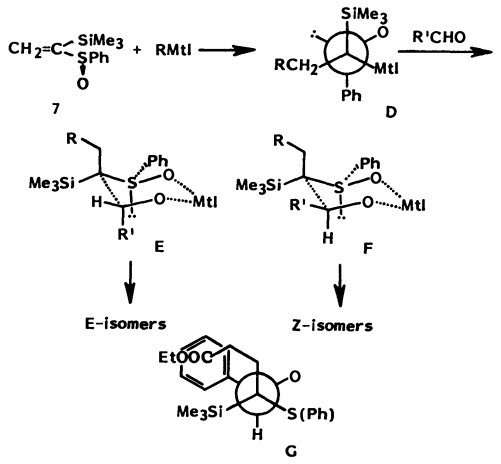


Fig. 1. Stereoselectivity in the Michael/Peterson sequences of 1-silylethenyl sulfoxide **7**.

Experimental

General. Melting points were determined on a Yanagimoto melting point apparatus and are uncorrected. IR spectra were taken with a JASCO IRA-1 or a JASCO A-702 spectrometer. ^1H NMR spectra were recorded on a Hitachi R-40 (90 MHz), a JEOL FX-100 (100 MHz), or a JEOL GSX-270 instrument (270 MHz), and ^{13}C NMR on a JEOL FX-100 (25.05 MHz) or a JEOL GSX-270 spectrometer (67.94 MHz). Chemical shifts are expressed in parts per million downfield from tetramethylsilane as an internal standard. Mass spectra were measured with a JEOL-O1SG-2 spectrometer at 70 eV of ionization energy. GC-mass spectra as well as high-resolution mass spectra were obtained on the same instrument. Elemental analyses were performed on a Hitachi 026 CHN analyzer. Thin-layer chromatography (TLC) was accomplished on 0.2 mm precoated plates of silica gel 60 F-254 (Merck) or of aluminum oxide 60 F-254 type-E (Merck). Visualization was made with ultraviolet light (254 and 365 nm), iodine, molybdophosphoric acid (5% in ethanol), or *p*-anisaldehyde (5% in ethanol containing 5% of sulfuric acid). For preparative column chromatography, Wakogel C-200, C-300 (Wako), and Silicagel 60 (Merck) were employed. Flash chromatography was carried out on an EYELA EF-10 apparatus using a column (20×180 mm) packed with Silicagel 60 (Merck, size: 0.04—0.063 mm). preparative high performance liquid chromatography (HPLC) was performed on a Kusano KHLC-201 apparatus with a UV-detector Uvilog-III using a column (22×300 mm) packed with silica gel (Wakogel LC-50H). Gas liquid chromatography (GLC) was accomplished on a Yanaco G-2800 gas chromatograph (Yanagimoto) with an ionization flame detector using a glass column (SE-30, 3×2000 mm) or a glass capillary column (Silicone GE, SE-30, 0.25×50000 mm). Micro vacuum distillation was carried out on a Sibata GTO-250R Kugelrohr distilling apparatus. Solvents were evaporated with a Tokyo Rikakikai rotary evaporator type-V at about 50 °C unless otherwise stated.

Materials. Phenyl 1-(trimethylsilyl)ethenyl sulfide (**1**) was prepared by reaction of 1-lithioethenyl phenyl sulfide with chlorotrimethylsilane.[7] Lithium diphenylcuprate,

magnesium bromide diphenylcuprate, and magnesium bromide diisopropylcuprate were in situ prepared from two equivalents of the corresponding organometallics and copper(I) iodide. The lithium enolates of ethyl acetate and propanoate were in situ prepared from equimolar amounts of lithium diisopropylamide (LDA) and the corresponding esters. Tetrahydrofuran (THF) or diethyl ether was distilled from lithium aluminum hydride or sodium metal, respectively, immediately before use. Diisopropylamine was distilled from sodium hydride.

Phenyl 1-(Methyldiphenylsilyl)ethenyl Sulfide (2): To a freshly prepared solution of LDA (66 mmol) in hexane was added dropwise, at −78 °C under nitrogen, phenyl vinyl sulfide (9 g, 66 mmol) in dry THF (40 ml) in a period of 15 min. After stirring for 1 h, chloro(methyl)diphenylsilane (15.5 g, 66 mmol) was slowly added. The resulting mixture was stirred at −78 °C for 30 min and then at 0 °C for additional 30 min, poured into saturated aqueous sodium chloride (30 ml), and extracted with dichloromethane (35 ml×2). The combined extracts were dried over magnesium sulfate and evaporated in vacuo. The residue was chromatographed over silica gel with hexane-ethyl acetate (20:1 v/v) to give **2** (16.8 g, 77%): Colorless liquid; bp 215—220 °C/27 Pa; IR (neat) 1420, 1240, 1100, 875, and 695 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.73 (3H, s, SiMe), 5.40, 5.47 (each 1H, s, $=CH_2$), and 7.1—7.7 (15H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=−3.88 (q, SiMe), 124.01 (t, $=CH_2$), 127.95, 128.42, 129.30, 129.77, 132.07, 134.89, 135.24, and 144.72; MS *m/z* (rel intensity, %) 332 (M^+, 22), 241 (13), 213 (10), 198 (20), 197 (base peak), 195 (17), 181 (17), 165 (13), 151 (13), 145 (16), 119 (14), 109 (12), 105 (43), 93 (11), 91 (38), and 77 (28). Found: C, 75.95; H, 6.13%. Calcd for $C_{21}H_{20}SSi$: C, 75.85; H, 6.06%.

1-(*t*-Butyldimethylsilyl)ethenyl Phenyl Sulfide (3). A similar procedure using LDA (66 mmol), phenyl vinyl sulfide (9 g, 66mmol) in THF (40 ml), and *t*-butylchlorodimethylsilane (9.9 g, 66 mmol) gave **3** (7.2 g, 61%) after vacuum distillation of the crude product: Colorless liquid; bp 73—76 °C/19 Pa; IR (neat) 1250 and 825 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.18 (6H, s, $SiMe_2$), 0.98 (9H, s, *t*-Bu), 5.17, 5.41 (each 1H, s, $=CH_2$), and 7.2—7.5 (5H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=−5.88 (q, $SiMe_2$), 17.00 (s, *t*-Bu), 26.83 (q, *t*-Bu), 120.30 (t, $=CH_2$), 128.41, 129.36 (each d), 132.18, 135.13 (each s), and 145.83 (s); MS *m/z* (rel intensity, %) 250 (M^+, 10), 193 (43), 177 (12), 168 (14), 167 (base peak),151 (48), 91 (24), 82 (16), 76 (23), and 75 (17).

General Procedure for the Michael Addition/Water Quench Sequence of Vinyl Sulfides 1—3 Leading to 4a,b and 5a—e. As a typical procedure, the reaction of phenyllithium with **1** is described (Entry 1 in Table 1): To a solution of *N,N,N′,N′*-tetramethyl-1,2-ethanediamine (TMEDA, 0.116 g, 1 mmol) in dry diethyl ether (3 ml) was added phenyllithium (or butyllithium) at 0 °C under nitrogen. After vinylsilane **1** (0.208 g, 1 mmol) in diethyl ether (10 ml) was added in a period of 1 h, the mixture was stirred for additional 1 h. It was poured into saturated aqueous ammonium chloride and extracted with diethyl ether (30 ml×2). The combined extracts were dried over magnesium sulfate and evaporated in vacuo. The residue was subjected to column chromatography over silica gel by using hexane to give **4a** (0.125 g, 65%). Other reactions were carried out under the reaction conditions listed in Table 1 and the results are summarized in the same table.

4a (a 4.3:1 mixture of two stereoisomers (^1H NMR)): Colorless liquid; IR (neat) 1250 and 839 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.02, 0.09, 0.14, 0.21 (18H, each s, 4.3:1:4.3:1, $SiMe_3$), 1.4—1.6 (2H, m, ring CH_2), 2.98, 3.29 (2H, each s, $PhCH_2$), and 7.0—7.3 (10H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=0.54, 1.22 (each q, $SiMe_3$), 21.97, 24.46 (each s, ring C), 25.39 (t, ring CH_2), 39.55, 39.99 (each t, 4.3:1, $PhCH_2$), 124.32, 124.61, 125.59, 125.88, 126.66, 127.34, 127.93, 128.32, 128.80 (each d, Ph), 139.65, 140.77, and 141.89 (each s, 4.4:4.2:1, Ph); MS *m/z* (rel intensity, %) 384 (M^+, 32), 218 (21), 167 (12), 135 (15), 129 (19), 128 (15), 110 (17), 109 (17), 91 (11), and 73 (base peak). Found; C, 68.68; H, 8.45%. Calcd for $C_{22}H_{32}SSi_2$: C, 68.68; H, 8.38%.

4b (a 2.2:1 mixture of two stereoisomers (^1H NMR)): Colorless liquid; IR (neat) 1250 and 839 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.08, 0.11, 0.18 (18H, each s, 2.2:3.2:1, $SiMe_3$), 0.89 (3H, t, J=6.0 Hz, n-C_5H_{11}), 1.0—1.8 (10H, m, n-C_5H_{11}), and 6.9—7.3 (10H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=1.00, 1.12, 1.29, 1.88 (each q, 2.6:1.2:2.0:1, $SiMe_3$), 14.35 (q, n-C_5H_{11}), 21.83, 22.83 (1:2.6), 23.41, 26.88 (1:3.1), 23.71, 24.47 (1:2.6), 29.36, 29.88 (2.5:1), 32.41, 32.65 (1:2.1) 34.13, 35.35 (1:2.6), 124.36, 124.65, 126.72, 127.36, 128.48 (each d, Ph), 140.30, and 140.66 (each s, 2.5:1, Ph); MS *m/z* (rel intensity, %), 364 (M^+, 11), 73 (base peak), 44 (16), and 42 (12). Found: C, 65.67; H, 9.95%. Calcd for $C_{20}H_{30}SSi_2$: C, 65.87; H, 9.93%.

5a: Colorless liquid; IR (neat) 1250 and 841 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.16 (9H, s, $SiMe_3$), 2.7—3.1 (3H, CH_2 and CH), and 7.0—7.4 (10H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=−2.22 (q, $SiMe_3$), 36.76 (d, CH), 38.14 (t, CH_2), 125.84, 126.17, 128.13, 128.62, 129.23, 129.97 (each d, Ph), 137.62, and 140.76 (each s, Ph); MS *m/z* (rel intensity, %) 286 (M^+, 17), 195 (20), 167 (45), 135 (44), 109 (21), 91 (40), 77 (21) 73 (base peak), and 65 (22). HRMS Found: *m/z* 286.1199. Calcd for $C_{17}H_{22}SiS$: M, 286.1210.

5b: Colorless liquid; IR (neat) 1250, 858, and 837 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.12 (9H, s, $SiMe_3$), 0.83 (3H, t, J=5.0 Hz, n-C_5H_{11}), 1.0—1.9 (8H, m, n-C_5H_{11}), 2.45 (1H, dd, J=5.0 and 6.0 Hz, CH), and 7.0—7.5 (5H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=−1.88(q, $SiMe_3$), 14.18 (q, n-C_5H_{11}), 22.65, 28.18, 31.94, 32.12 (each t, n-C_5H_{11}), 34.65 (d, CH), 125.89, 129.01, 129.77 (each d, Ph), and 138.89 (s, Ph); MS *m/z* (rel intensity, %) 266 (M^+, 23), 183 (10), 182 (66), 167 (28), 151 (12), 135 (11), 123 (13), 109 (12), 91 (14), and 73 (base peak). Found: C, 67.39; H, 9.83%. Calcd for $C_{15}H_{26}SSi$: C, 67.60; H, 9.83%.

5c: Yellow liquid; IR (neat) 1425, 1250, and 1110 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.00 (3H, s, SiMe), 2.0—2.7 (3H, m, CH_2 and CH), and 6.0—7.2 (20H, m, Ph); ^{13}C NMR δ=−5.03 (q, SiMe), 36.67 (d, CH), 38.48 (t, CH_2), 126.12, 126.22, 128.02, 128.12, 128.56, 129.54, 129.69, 130.56, 135.20, 137.79, and 140.57; MS *m/z* (rel intensity, %) 410 (M^+, 36), 241 (22), 197 (base peak), and 91 (22). Found: C, 79.03; H, 6.45%. Calcd for $C_{27}H_{26}SiS$: C, 78.97; H, 6.38%.

5d: Colorless liquid; IR (neat) 1250 and 820 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.04, 0.08 (each 3H, $SiMe_2$), 1.00 (9H, *t*-Bu), 2.7—3.3 (3H, m, CH_2 and CH), and 7.0—7.1 (10H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=−6.41, −5.76 (each q, $SiMe_2$), 17.88 (s, *t*-Bu), 27.59 (q, *t*-Bu), 35.18 (d, CH), 39.36 (t, CH_2), 125.71, 126.18, 128.18, 128.60, 129.36, 129.71 (each d, Ph), 138.30, and 141.13 (each s, Ph); MS *m/z* (rel intensity, %) 328 (M^+, 2), 167 (46), 151 (24),135 (51), 109 (31), 91 (56), 73 (base peak), 65 (33), 57 (58), and 41 (34). Found: C, 73.29; H, 8.68%. Calcd for $C_{20}H_{28}SiS$: C, 73.11; H 8.59%.

5e: Pale yellow liquid; IR (neat) 1250 and 830 cm^{-1}; ^1H NMR ($CDCl_3$) δ=−0.04, 0.00 (each 3H, s, $SiMe_2$), 0.7—1.6 (11H, m, n-C_5H_{11}), 0.86 (9H, s, t-Bu), 2.52 (1H, dd, J=6.6 and 4.4 Hz, CH), and 6.9—7.3 (5H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=−6.00 ($SiMe_2$), 14.01 (n-C_5H_{11}), 17.68, 27.93 (t-Bu), 22.49, 27.93, 31.89, 31.92, 32.68 (n-C_5H_{11} and CH), 125.53, 128.68 129.20, and 138.73 (Ph); MS m/z (rel intensity, %) 308 (M^+, 5), 251 (20), 167 (base peak), and 73 (43). HRMS Found: m/z 308.2006. Calcd for $C_{18}H_{32}SiS$: M, 308.2018.

General Procedure for the Michael Addition/Peterson Olefination Sequence of Vinyl Sulfides 1—3 Leading to 6. The reaction of **1** with phenyllithium and benzaldehyde is described as a typical example (Entry 5 in Table 1): To a solution of TMEDA (0.232 g, 2 mmol) in dry diethyl ether (10 ml) was added phenyllithium (2 mmole) at 0 °C under nitrogen. After vinylsilane **1** (0.208 g, 1 mmol) in diethyl ether (10 ml) was added in a period of 1 h, the mixture was stirred for additional 1 h. Benzaldehyde (0.212 g, 2 mmol) in diethyl ether (2 ml) was added and stirring was continued for 1 h. The mixture was poured into saturated aqueous ammonium chloride and extracted with diethyl ether (30 ml×2). The combined extracts were dried over magnesium sulfate and evaporated in vacuo. The residue was chromatographed over silica gel with hexane-ethyl acetate (50:1 v/v) to give **6a** (0.064 g, 21% $E:Z$=1:1) and then **4a** (0.141 g, 73%). Other reactions were carried out under the reaction conditions listed in Table 1 and the results are shown in the same table.

6a (a 1:1 mixture of E- and Z-isomers (^1H NMR)): Pale yellow liquid; IR (neat) 2854 cm^{-1}; ^1H NMR ($CDCl_3$) δ=3.46, 3.79 (2H, each s, CH_2), 6.75, 6.81 (1H, each s, =CH), and 7.0—7.9 (15H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=37.23, 44.29 (each t, CH_2), 126.37, 126.46, 127.02, 127.15, 127.35, 127.68, 127.89, 128.02, 128.25, 128.29, 128.46, 128.56, 128.91, 129.05, 129.12, 129.24, 129.28, 129.69, 131.59, 132.29, 132.75, 133.50, 133.85, 134.80, 135.07, 135.16, 136.48, 136.77, 137.14, 138.50, and 138.89; MS m/z (rel intensity, %) 302 (M^+, 21), 192 (36), 191 (27), 178 (32), 165 (38), 115 (94), 109 (65), 91 (base peak), 89 (24), 78(34), 77 (38), and 65 (79). HRMS Found: m/z 302.1123. Calcd for $C_{21}H_{18}S$: M, 302.1128.

Pure (E)-**6a** was obtained by deoxygenation of (E)-**8a** with trifluoroacetic anhydride-sodium iodide-triethylamine: Pale yellow plates (hexane); mp 80—81 °C; IR (KBr) 1630, 1628, 1600, 800, 790, 780 748 and 731 cm^{-1}; ^1H NMR ($CDCl_3$) δ=3.82 (2H, s, CH_2C=), 6.85 (2H, s, =CH), and 7.1—7.6 (15H, m, Ph).

6b (a 1:1 mixture of E- and Z-isomers (^1H NMR)): Pale yellow liquid; IR (neat) 2858 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.83 (3H, t, J=6.0 Hz, n-C_5H_{11}), 1.1—1.9 (6H, m, n-C_5H_{11}), 2.1—2.5 (2H, m, n-C_5H_{11}), 6.60, 6.76 (1H, s, =CH), and 7.1—7.6 (10H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=13.95, 13.99, 22.35, 22.42, 28.49, 28.57, 31.06, 31.49, 31.60, 38.26 (n-C_5H_{11}), 126.62, 126.75, 127.11, 127.30, 127.56, 127.96, 128.30, 128.39, 128.82, 129.07, 129.21, 130.95, 132.11, 134.26, 134.42, 136.05, 136.77, 137.17, and 139.82 (Ph); MS m/z (rel intensity, %) 282 (M^+, 44), 226 (27), 135 (43), 117 (37), 116 (47), 115 (base peak), 91 (66), and 42 (35). HRMS Found: m/z 282.1435. Calcd for $C_{19}H_{22}S$: M, 282.1430.

Phenyl 1-(Trimethylsilyl)ethenyl Sulfoxide (7):[16] To a solution of sulfide **1** (6 g, 29 mmol) in dichloromethane (60 ml) was added dropwise 3-chloroperbenzoic acid (MCPBA, 6.7 g, 29.1 mmol in dichloromethane (100 ml)) in a period of 30 min. The mixture was stirred at room temperature for 30 min, poured into saturated aqueous sodium hydrogensulfite (100 ml) and extracted with dichloromethane (60 ml×3). The combined extracts were washed with saturated sodium hydrogencarbonate, dried over magnesium sulfate, and evaporated in vacuo. The residue was chromatographed over silica gel by using hexane-ethyl acetate (10:1 v/v) to give **7** (6.16 g, 95%): Colorless liquid; IR (neat) 1240, 1040, and 840 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.05 (9H, s, $SiMe_3$), 6.19, 6.77 (each 1H, s, =CH_2), and 7.5—7.6 (5H, m, Ph);^{13}C NMR ($CDCl_3$) δ=−1.21 (q, $SiMe_3$), 126.63, 129.15, 129.24 (each d, Ph), 131.53 (t, =CH_2), 143.67 (s, Ph), and 157.22 (s, =C); MS m/z (rel intensity, %) 224 (M^+, 27), 167 (89), 126 (89), 77 (19), 75 (11), 73 (base peak), and 45 (12). HRMS Found: m/z 224.0683. Calcd for $C_{11}H_{16}OSiS$: M, 224.0690.

General Procedure for the Michael Addition/Peterson Olefination Sequence of Vinyl Sulfoxide 7 Leading to 8a—h, 11a—e, and 12. As a typical procedure, the reaction of **2** with phenyllithium and benzaldehyde is described (Entry 1 in Table 2): To a solution of TMEDA (0.174 g, 1.5 mmol) in dry THF (3 ml) was added phenyllithium (1.5 mmol) at −78 °C under nitrogen. After 30 min, vinyl sulfoxide **7** (0.224 g, 1 mmol) in THF (1 ml) was added in a period of 5 min and the mixture was stirred for 1 h. Benzaldehyde (0.16 g, 1.5 mmol) in THF (1 ml) was added and stirring was continued at the same temperature for 1 h. The mixture was poured into saturated aqueous ammonium chloride and extracted with diethyl ether (30 ml×2). The combined extracts were dried over magnesium sulfate and evaporated in vacuo. The residue was chromatographed over silica gel by using hexane-diethyl ether (20:1 v/v) to give **8a** (0.216 g, 71%) as a single isomer. Other reactions were carried out under the reaction conditions listed in Table 2. The results are also summarized in the same table.

8a: Colorless needles (hexane); mp 98—99 °C; IR (KBr) 1050 cm^{-1}; ^1H NMR ($CDCl_3$) δ=3.46, 3.82 (each 1H, d, J_{gem}=16.5 Hz, CH_2C=), and 6.9—7.7 (16H, Ph and =CH); ^{13}C NMR ($CDCl_3$) δ=31.40 (t, CH_2C=), 125.78 (d, =CH), 129.24, 131.49, 132.81 (each d, Ph), 134.27, 136.62, 142.58 (each s, Ph), and 143.84 (s, =C); MS m/z (rel intensity, %) 318 (M^+, 2), 184 (43), 183 (78), 105 (base peak), 79 (24), 78 (31), and 77 (56). Found: C, 79.40; H, 5.94%. Calcd for $C_{21}H_{18}OS$: C, 79.21; H, 5.70%.

The sulfoxide **8a** was converted into (E)-**6a** by the following procedure: To a solution of **8a** (0.244 g, 0.76 mmol) in acetone (5 ml) were added sodium iodide (0.3 g, 2 mmol) and triethylamine (0.25 ml, 2 mmol). After cooled to 0 °C, trifluoroacetic anhydride (0.3 ml, 2 mmol) was slowly added. The mixture was stirred at the same temperature for 10 min and evaporated in vacuo. The residue was treated with water and extracted with diethyl ether (30 ml×3). The combined extracts were washed with diluted aqueous sodium thiosulfate and dried over magnesium sulfate. Evaporation of the ether in vacuo provided (E)-**6** (0.227 g, 98%).

8b: Colorless prisms (hexane); mp 91—93 °C; IR (KBr) 1040 cm^{-1}; ^1H NMR ($CDCl_3$) δ=3.51, 3.98 (each 1H, d, J_{gem}=17.3 Hz,CH_2C=), 3.75 (3H, s, p-OMe), 6.8—6.9 (2H, m, Ar), and 6.9—7.7 (13H, m, Ar and =CH); ^{13}C NMR ($CDCl_3$) δ=31.30 (t, CH_2C=), 55.42 (q, OMe), 114.36 (d, Ar), 125.77 (d, =CH), 126.54, 127.07, 128.35, 128.36, 129.24, 131.13, 131.36 (each d, Ar), 133.13, 136.95, 141.48 (each s, Ar), 143.31 (s, =C), and 160.36 (s, Ar); MS m/z (rel intensity, %), 348 (M^+, 5), 223

(61), 222 (base peak), 207 (31), 178 (24), 116 (32), and 91 (47). Found: C, 76.01; H, 5.71%. Calcd for $C_{22}H_{20}O_2S$: C, 75.83; H, 5.78%.

8c: Pale yellow liquid; IR (neat) 1040 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.82 (3H, d, J=5.1 Hz, Me), 3.33, 3.67 (each 1H, d, J_{gem}=15.3 Hz, CH_2C=), 6.14 (1H, dq, J=15.0 and 5.1 Hz, MeCH=), 6.24 (1H, dd, J=15.0 and 10.6 Hz, =CH), and 6.9—7.7 (11H, m, Ar and =CH); ^{13}C NMR ($CDCl_3$) δ=18.36 (q, Me), 29.88 (t, CH_2C=), 124.95 (d, =CH), 125.34, 125.93, 127.98, 128.07, 128.71, 130.61 (each d, Ph), 133.40, 137.84 (each d, =CH), 137.59, 140.87 (each s, Ph), and 142.83 (s, =C); MS m/z (rel intensity, %) 282 (M^+, 16), 157 (29), 142 (25), 141 (43), 129 (43), 128 (37), 126 (19), 125 (19), 116 (61), 97 (27), 91 (base peak), 78 (80), 77 (80), and 65 (44). Found: C, 76.40; H, 6.57%. Calcd for $C_{18}H_{18}OS$: C, 76.56; H, 6.42%.

8d: Colorless liquid; IR (neat) 1040 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.80 (3H, t, J=7.0 Hz, n-Pr), 1.2—1.8, 1.9—2.4 (each 2H, m, n-Pr), 3.15, 3.52 (each 1H, d, J_{gem}=15.6 Hz, CH_2C=), 6.57 (1H, t, J=6.0 Hz, =CH), and 6.8—7.6 (10H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=13.38 (q, n-Pr), 21.53, 29.78 (each t, n-Pr), 30.18 (t, CH_2C=), 124.95, 125.98, 128.17, 128.80, 130.66, 137.20 (each d, Ph and =CH), 137.59, 142.77 (each s, Ph), and 143.55 (s, =C); MS m/z (rel intensity, %) 284 (M^+, 23), 159 (base peak), 130 (28), 126 (86), 117 (89), 115 (32), 91 (98), 89 (72), 78 (23), 77 (21), 71 (67), and 56 (41). HRMS Found: m/z 284.1231. Calcd for $C_{18}H_{20}OS$: M, 284.1234.

8e (a 1.7:1 mixture of E- and Z-isomers (^{13}C NMR)): Pale yellow liquid; IR (neat) 1040 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.90 (1/2.7×3H, t, J=7.6 Hz, Et (Z)), 1.05 (1.7/2.7×3H, t, J=7.6 Hz, Et (E)), 1.8—2.8 (2H, m, Et), 7.00 (1/2.7H, br s, =CH (Z)), and 7.2—7.8 (10H+1.7/2.7H, m, Ph and =CH (E)); ^{13}C NMR ($CDCl_3$) δ=12.87, 13.10 (each q, Et), 18.84, 19.01 (each t, Et),124.26, 125.43, 126.72, 126.90, 128.18, 128.30, 128.41, 128.65, 128.99, 129.12, 129.47, 130.17, 131.10, 134.56, 135.08, 142.98 (s, Ph), 143.98 (s, Ph), 147.60, and 148.25 (each s, =C); MS m/z (rel intensity, %) 256 (M^+, 5), 131 (42), 116 (32), 115 (56), 91 (base peak) 79 (62), 78 (34), 77 (90), and 52 (61). Found: C, 74.75; H, 6.37%. Calcd for $C_{16}H_{16}OS$: C, 74.96; H, 6.29%.

8f (a 2.3:1 mixture of E- and Z-isomers (^{13}C NMR)): Pale yellow liquid; IR (neat) 1040 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.89 (1/3.3×3H, t, J=7.0 Hz, Et (Z)), 0.97 (2.3/3.3×3H, t, J=7.0 Hz, Et (E)), 2.38 (1/3.3×2H, q, J=7.0 Hz, Et (Z)), 2.40 (2.3/3.3×2H, t, J=7.0 Hz, Et (E)), 3.80 (3H, s, p-OMe), 6.7—7.0 (2H, m, Ar), 7.24 (1/3.3H, s, =CH (Z)), and 7.3—7.8 (8H+2.3/3.3H, m, Ar and =CH (E)); ^{13}C NMR ($CDCl_3$) δ=13.09 (q, Et), 18.65 (t, Et), 55.37 (q, OMe), 114.16, 114.40 (each d, Ar), 124.61, 125.63 (each d, =CH), 127.25, 128.71, 129.30, 130.37, 131.00, 131.15, 131.34, 131.69, 135.20, 143.75, 145.36, and 160.16 (s, Ar); MS m/z (rel intensity, %) 286 (M^+, 9), 161 (77), 145 (44), 125 (47), 121 (43), 117 (32), 103 (37), 97 (33), 91(58), 78 (44), and 77 (base peak). Found: C, 71.03; H, 6.16%. Calcd for $C_{17}H_{18}O_2S$: C, 71.30; H, 6.33%.

8g: Colorless prisms (hexane); mp 115—116 °C; IR (KBr) 1040 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.86 (9H, s, t-Bu), 1.58, 2.85 (each 1H, d, J_{gem}=14.7 Hz, CH_2C=), 7.3—7.4 (5H, m, Ph), 7.4—7.5 (3H, m, Ph), and 7.7—7.8 (3H, m, Ph and =CH); ^{13}C NMR ($CDCl_3$) δ=30.40 (t-Bu), 33.51 (t-Bu), 39.18 (CH_2C=), 126.63, 127.82, 128.51, 128.97, 129.36, 129.87, 131.64, 135.88, 143.74, and 144.32 (=C); MS m/z (rel intensity, %) 298 (M^+, 1), 131 (22), 126 (23), 125 (27), 117 (21), 116 (51), 115 (base peak), 91 (31), 78 (33), and 77 (29). Found: C, 76.30; H, 7.46%. Calcd for $C_{19}H_{22}OS$: C, 76.47; H, 7.43%.

8h: Colorless liquid; IR (neat) 1050 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.82, 0.85 (each 3H, d, J=6.6Hz, i-Pr), 1.8—2.0 (2H, m, i-Pr and one of CH_2C=) 2.48 (1H, dd, J=14.3 and 6.6 Hz, the other of CH_2C=), 7.3—7.4 (5H, m, Ph), 7.4—7.5 (4H, m, Ph and =CH), and 7.6—7.7 (2H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=22.15, 22.69 (each i-Pr), 27.07 (i-Pr), 35.12 (CH_2C=), 125.99, 128.16, 128.59, 129.05, 129.27, 130.28, 131.37, 135.06, 143.34 (Ph and =CH), and 145.39 (=C); MS m/z (rel intensity, %) 284 (M^+, 8), 117 (25), 115 (29), 108 (78), 107 (59), 103 (21), 91 (61), 79 (base peak), 78 (22), 77 (65), and 51 (37). Found: C, 75.92; H, 7.30%. Calcd for $C_{18}H_{20}OS$: C, 76.02; H, 7.09%.

11a (a 1.8:1 mixture of E- and Z-isomers (^1H NMR)): Pale yellow liquid; IR (neat) 1730 and 1040 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.16 (1/2.8×3H, t, J=7.2 Hz, OEt (E)), 1.17 (1.8/2.8×3H, t, J=7.2 Hz, OEt (Z)), 2.0—2.8 (4H, m, CH_2CH_2), 4.19 (1/2.8×2H, q, J=7.2 Hz, OEt (Z)), 4.25 (1.8/2.8×2H, q, J=7.2 Hz, OEt (E)), 7.02 (1/2.8H, br s, =CH (Z)), and 7.2—7.8 (10H+1.8/2.8H, m, Ph and =CH (E)); ^{13}C NMR ($CDCl_3$) δ=14.06 (q, OEt), 20.88, 32.65 (each t, CH_2CH_2 (E)), 22.65, 33.83 (each t, CH_2CH_2 (Z)), 60.48, 60.59 (each t, OEt), 124.42, 125.54 (each d, =CH), 128.72, 129.01, 129.13, 129.42, 129.71, 130.60, 131.42, 132.89, 134.30, 137.19, 143.07 (s), 144.95, 145.42 (each s, =C), 172.07, and 172.42 (each s, COOEt); MS m/z (rel intensity, %) 312 (M^+ −16, 4), 283 (2), 223 (37), 203 (38), 149 (base peak), 110 (50), 109 (42), 84 (30), 76 (38), 73 (31), and 43 (43). Found: C, 69.45; H, 6.16%. Calcd for $C_{19}H_{20}O_3S$: C, 69.49; H, 6.14%.

11b (a 2:1 mixture of E- and Z-isomers (^{13}C NMR)): Pale yellow liquid; IR (neat) 1730 and 1040 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.20 (3H, t, J=7.0 Hz, OEt), 2.0—2.8 (4H, m, CH_2CH_2), 3.80 (3H, s, p-OMe), 4.06 (2H, q, J=7.0 Hz, OEt), 6.7—7.0 (2H, m, Ar), 7.00 (1/3H, s, =CH (Z)), and 7.2—7.8 (7H+2/3H, m, Ar and =CH (E)); ^{13}C NMR ($CDCl_3$) δ=14.18 (q, OEt), 20.88, 32.71 (each t, CH_2CH_2, (E)), 23.00, 34.12 (each t, CH_2CH_2 (Z)), 55.42 (q, OMe), 60.71 (t, OEt), 114.24, 114.60 (each d, Ar), 124.60, 125.54, 126.89, 129.42, 130.60, 131.07, 131.30, 142.36, 143.42 (s, =C), 160.25 (s, Ar), 172.42, and 174.66 (each s, COOEt); MS m/z (rel intensity, %) 342 (M^+ −16, 5), 313 (12), 233 (base peak), 204 (28), 203 (42), 191 (38), 163 (61), 161 (23), 159 (22), 145 (52), 116 (25), and 77 (22). Found: C, 66.91; H, 6.27%. Calcd for $C_{20}H_{22}O_4S$: C, 67.02; H, 6.19%.

11c (a 2:1 mixture of E- and Z-isomers (^{13}C NMR)): Yellow liquid; IR (neat) 1730 and 1040 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.18 (2/3×3H, t, J=7.0 Hz, OEt (E)), 1.20 (1/3×3H, t, J=7.0 Hz, OEt (Z)), 2.0—3.0 (4H, m, CH_2CH_2), 4.04 (2/3×2H, q, J=7.0 Hz, OEt (E)), 4.08 (1/3×2H, q, J=7.0 Hz, OEt (Z)), 6.0—6.7 (2H, m, Ar), 7.16 (1/3H, br s, =CH), and 7.3—7.8 (6H, m, Ar); ^{13}C NMR ($CDCl_3$) δ=14.24 (q, OEt), 21.77, 33.41 (each t, CH_2CH_2 (E)), 22.12, 34.06 (each t, CH_2CH_2 (Z)) 60.65 (t, OEt), 114.36, 119.54 (each d), 124.24, 125.83 (each d), 141.60, 142.50 (s, =C), 144.48 (d), and 172.60 (s, COOEt); MS m/z (rel intensity, %) 273 (M^+ −45, 4), 193 (42), 164 (30), 125 (19), 123 (70), 109 (20), 107 (67), 91 (base peak), 78 (56), 77 (63), and 65 (49). Found: C, 63.90; H, 5.70%. Calcd for $C_{17}H_{18}O_4S$: C, 64.13; H, 5.70%.

11d: Pale yellow liquid; IR (neat) 1725 and 1040 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.22 (3H, t, J=7.0 Hz, OEt), 1.88 (3H, dd, J=6.6 and 1.1 Hz, Me), 2.0—2.6 (4H, m, CH_2CH_2), 4.07 (2H, q, J=7.0 Hz, OEt), 6.15 (1H, dq, J=15.0 and 6.6 Hz,

MeCH=), 6.29 (1H, ddd, J=15.0, 6.6, and 1.1 Hz, =CH), and 7.1—7.7 (6H, m, Ph and =CH); ^{13}C NMR ($CDCl_3$) δ=14.80 (q, OEt), 18.77 (q, Me), 29.36, 34.00 (each t, CH_2CH_2), 60.59 (t, OEt), 125.24, 129.36 (each d, =CH), 131.19, 134.13, 138.54 (each d), 141.24 (s), 143.48 (s, =C), and 172.31 (s, COOEt); MS m/z (rel intensity, %) 247 (M^+ −45, 17), 167 (57), 97 (base peak), 95 (50), 93 (42), 91 (35), 78 (58), and 77 (37). Found: C, 65.72; H, 6.99%. Calcd for $C_{16}H_{20}O_3S$: C, 65.73; H, 6.89%.

Facile Formations of *o*- and *p*-Tropoquinone Mono- and Bisacetals by Anodic Oxidations of 2,3-, 2,5-, 2,7-, and 4,5-Dimethoxytropones[1)]

Akira MORI, Tadahiko KUBOTA,† and Hitoshi TAKESHITA*

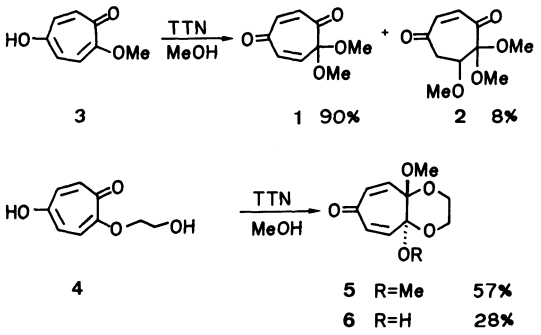
(Received May 9, 1988)

o- and *p*-Tropoquinone mono- and bisacetals (tetramethoxycycloheptadienones) were prepared from 2,3-, 2,5-, 2,7-, and 4,5-dimethoxytropones by means of anodic oxidations in practical yields. Cerium(IV) salt oxidations of dimethoxytropones afforded a mixture of products i.e., a hydrolysis product and/or a methanol adduct of tropoquinone bisacetals. By treating with sulfuric acid in a mixture of acetic acid and acetic anhydride, 4,4,7,7- and 2,2,7,7-tetramethoxycycloheptadienones gave the Thiele-type reaction products with a high positional selectivity. Similarly, 2-bromo-7-methoxytropone was anodically oxidized to 4,4,7,7-tetramethoxycycloheptadienone and its 2-bromo derivative. The mechanism of the reaction is also discussed in detail.

The facile acetal formation of *p*-tropoquinone (3,6-cycloheptadiene-1,2,5-trione) in methanol and the hydrate formation of *o*-tropoquinone (4,6-cycloheptadiene-1,2,3-trione) in water are well-known and repulsive dipole–dipole interactions of 1,2-dione and 1,2,3-trione moieties are attributable for the phenomena.[2,3)] Recently, we prepared tropoquinone acetals, which are useful for further transformations, toward functionalized troponoids: i.e., a) the 2,3-dichloro-5,6-dicyano-*p*-benzoquinone (DDQ) oxidation of the ketol, derived from tropone via a photosensitized oxidation, an acetalization, and a bond cleavage of the endoperoxide with triethylamine[4)] and b) DDQ,[5)] thallium(III) nitrate (TTN),[6)] and cerium(IV) ammonium nitrate (CAN)[7)] oxidations of 2-alkoxy-5-hydroxytropones. We have now developed an improved preparation of bisacetals by the anodic oxidation of 2,3-, 2,5-, 2,7-, and 4,5-dimethoxytropones. This anodic oxidation was also applicable to tropone, 2-methoxytropone, and 2-bromo-7-methoxytropone.



Scheme 1.

Results and Disccusion

2,5-Disubstituted Tropones. We have already shown that 7,7-dimethoxycyclohepta-2,5-diene-1,4-dione (**1**) can be prepared in good yield together with its methanol adduct (**2**) by the TTN-oxidation of 5-hydroxy-2-methoxytropone (**3**) in methanol.[6)] Similarly, 2-(2-hydroxyethoxy)-5-hydroxytropone (**4**) gave two bisacetals **5** and **6** in good combined yields.[6)] However, it is desirable to develop a selective formation of either of the two. Thus, when **3** was anodically oxidized in a singel-cell apparatus without accurate potential control in anhydrous methanol with lithium perchlorate, a single product **1** was obtained in 62% yield. In parallel, **4** gave **6** in 75% yield. Consequently, anodic oxidation is a practical method to obtain a single product selectively.

Table 1. Anodic and CAN Oxidations of Troponoids

Substrate	Anodic Oxidation	CAN Oxidation
3	1 62%	not tried
4	6 75%	not tried
 7	 8 97%	1 15% 2 77%
 9	 + 11* 10 57% 7%	 12 59%
 13	 14 94%	14 6%
 15	8 +  23% 16 67%	not reacted

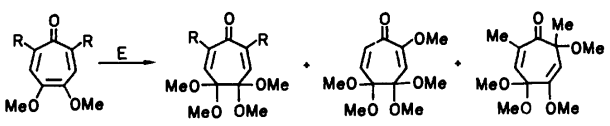
*11 = 
A similar electrolysis of 2,5-dimethoxytropone (**7**) also gave a single product (**8**) in quantitative yield. Its ^{1}H NMR spectrum showed two sets of an *AB*-quartet around δ 5.8—6.4, suggesting the structure to be 4,4,7,7-tetramethoxy-2,5-cycloheptadien-1-one. Again, the CAN-oxidation of **7** gave **1** and **2** in 15 and 77% yields. The difference in product distributions might depend on the reaction conditions, i.e., hydrolysis and Michael addition reactions must follow in an acidic medium under CAN-oxidation conditions, while the bisacetal **8** was stable under neutral electrolysis conditions.

2,3-Disubstituted Tropones. The electrode oxidation of 2,3-dimethoxytropone (**9**)[8] gave two products **10** and **11** in 57 and 7% yields: the major product **10** was deduced to be 6,6,7,7-tetramethoxy-2,4-cycloheptadien-1-one from its ^{1}H NMR spectrum, showing four methoxyl and four olefinic proton signals. The by-product **11**, four methoxyl signals and two olefinic and three aliphatic proton signals, was suggested to be 4,4,4′,4′,5,5,5′,5′-octamethoxy-[bi-2-cyclohepten-1-yl]-6,6′-dione. The CAN-oxidation of **9** gave the symmetrical monoacetal **12** in 59% yield. Its structure was determined by spectral data.

2,7-Disubstituted Tropones. The anodic oxidation of 2,7-dimethoxytropone (**13**)[8] gave a single product **14** in 94%, whose NMR spectrum suggested it to be 2,2,7,7-tetramethoxy-3,5-cycloheptadien-1-one. On the other hand, **13** was slightly reactive to the CAN-oxidation to give **14** in only 6% yield with 9% conversion.

In the case of 2-bromo-7-methoxytropone (**15**), the CAN-oxidation gave no identifiable product at all. However, electrolysis afforded two products: one was **8** in 23% and the other, its relatively unstable bromo derivative **16**, in 67%. The oxidation occurred selectively at C-4, the para position to the methoxyl group and the bromine atom was removed to give **8** during electrolysis.

4,5-Dimethoxytropones. The anodic oxidation of 4,5-dimethoxytropone (**17**)[9] gave 4,4,5,5-tetramethoxy-2,6-cycloheptadien-1-one (**18**) in 41% and its methanol adduct **19** in 10% yields. The structure of **19** was unambiguously ascertained from the spectral data. The position of the methoxyl group in **19** was elucidated to be at C-2 from a consideration of the ^{13}C chemical shifts[10] i.e., C-2 at δ 152.6 and C-3 at δ 109.3 together with an absence of a long-range coupling between a singlet at δ 5.37 and a doublet at δ 6.13.



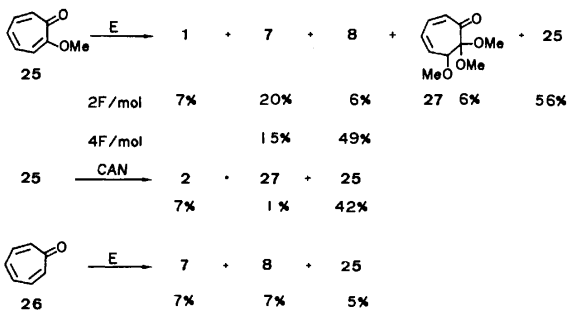
Scheme 2.

Therefore, the structure of **19** was determined to be 2,4,4,5,5-pentamethoxy-2,6-cycloheptadien-1-one.

Electrolysis of 4,5-dimethoxy-2,7-dimethyltropone (**20**)[5] gave 4,4,5,5-tetramethoxy-2,7-dimethyl-2,6-cycloheptadien-1-one (**21**) in 77% and its methanol adduct **22** in 8%. The structure of **22** was deduced from the ^{1}H chemical shifts of methyl signals at δ 1.37 and 1.92. No further transformation under anodic oxidation conditions occurred from **22** because of the presence of the methyl group, being different from the case of **19**.

Moreover, the oxidation of 4,5-dimethoxy-2,7-dipropyltropone (**23**) gave a single product **24** in 97%. The structure of **24** was determined to be 4,4,5,5-tetramethoxy-2,7-dipropyl-2,6-cycloheptadien-1-one from the same spectral criteria as **18** and **21**.

Other Troponoids. Since a further oxidation, **18** to **19**, took place in the anodic oxidation of **17**, other tropones, 2-methoxytropone (**25**) and tropone (**26**), should be examined: 2-Methoxytropone gave four products (**1**; 7%, **7**; 20%, **8**; 6%, and **27**; 6%) with a recovery of **25** in 56% after the consumption of 2 F mol^{-1} of electricity. By passing 4 F mol^{-1} of electricity, yields of **8** and **7** increased to 49 and 15%, respectively. Three (**1**, **7**, and **8**) of them were identical with authentic samples. The structure of a new product, **27**, was identified as 6,7,7-trimethoxy-2,4-cycloheptadien-1-one on the basis of the doublet methine proton at δ 4.09 and the carbonyl absorption at 1685 cm^{-1}. On the other hand, the CAN-oxidation of **25** afforded **2** in 7% and **27** in 1% yields. Tropone gave **7**, **8**, and **25** in 7, 7, and 5% yields, respectively.

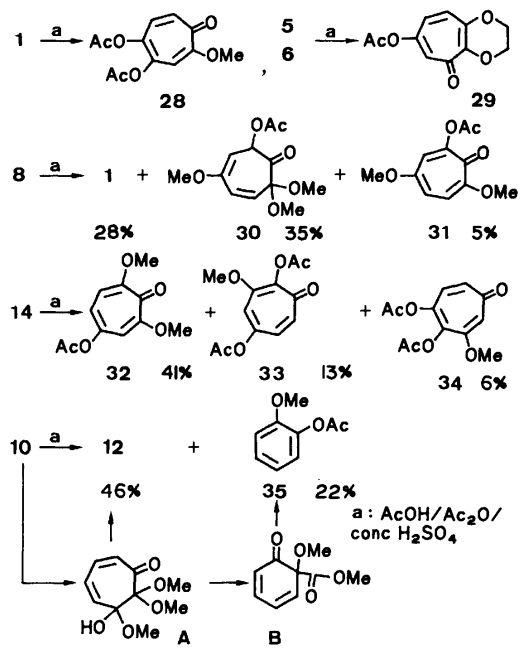


Scheme 3.

Thus, anodic oxidations of tropone and 2-methoxytropone were less satisfactory. Although the yields of products were not always high, a one-step formation of methoxylated troponoids is of practical value.

Thiele-Type Reactions of Bisacetals. As has been seen in CAN-oxidations of **7** and **25** and in anodic oxidations of **17** and **20**, methanol added to the C=O conjugated C=C double bond. It has been shown[6] that Thiele-type reactions of acetal **1** and bisacetals **5** and **6**, respectively, gave 4,5-diacetoxy-2-methoxytropone (**28**) and 6-acetoxy-2,3-(ethylenedioxy)tropone (**29**) with a high positional selectivity. The treatment of **8** with a 1 : 1-mixture of acetic acid and acetic anhydride with a catalytic amount of concd sulfuric acid gave three

products (**1**; 28%, **30**; 35%, **31**; 5%). The structures of **30** and **31** were determined by the spectral data. Since **31** showed a carbonyl carbon at δ 168.4 in the ^{13}C NMR spectrum, an acetotropy, which is common in 2-acetoxytropones,[11] is operative in **31**. Additionally, the decoupled ^1H NMR spectrum disclosed a long-range coupled ABX_3 system. Therefore, **31**, was 2-acetoxy-4,7-dimethoxytropone.



Scheme 4.

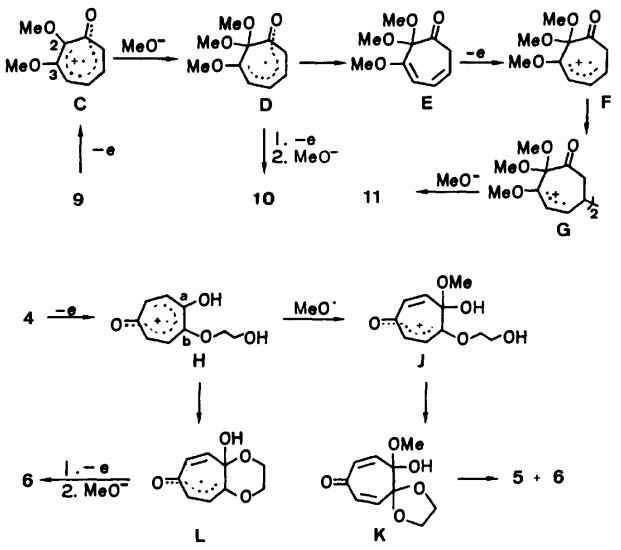
The ^1H NMR of the major product, **30**, showed an acetoxyl and three methoxyl signals together with three olefinic proton signals and a doublet methine proton signal at δ 5.65 (J=8.2 Hz). Taking the IR carbonyl absorption (1690 cm^{-1}) into account, the structure of **30** was assigned to be 2-acetoxy-4,7,7-trimethoxy-3,5-cycloheptadien-1-one.

Next, **14** furnished three troponoids (**32**; 41%, **33**; 13%, **34**; 6%) by a treatment under Thiele-type reaction conditions. All ^1H NMR spectral splittings of these compounds were suggested to be 5,7-disubstituted tropolone derivatives; i.e., two of three olefinic protons vicinally coupled (J=10.3—12.8 Hz) and the third proton appeared as a doublet with a small coupling constant (J≈2.5 Hz). From the presence of an acetoxyl and two methoxyl signals, the structure of **32** was deduced to be 4-acetoxy-2,7-dimethoxytropone. As **33** and **34** showed a methoxyl and two acetoxyl signals, the structures of **33** and **34** were 2,5-diacetoxy-3-methoxytropone[12] (J=10.3 Hz) and 4,5-diacetoxy-3-methoxytropone (J=12.8 Hz), respectively. On the contrary, **10** afforded only the hydrolysis product **12** in 46% and 2-acetoxyanisole (**35**) in 22% yields, but no Thiele-type product.

The formation of **35** from **10** could be explained in terms of a hydrolysis of one of the methoxyl groups at C-6 to give **A**, followed by a ring contraction and a decarbonylation via a six-membered dienone **B**.

Mechanistic Consideration of the Anodic Oxidation. According to mechanistic studies for anisoles[13] and 1,4-dimethoxybenzenes described in literature,[14] a sequence involving a methoxyl radical attack to the aryl radical cations (EECC sequence) in methanolic potassium hydroxide has been proposed. Under conditions without methoxide ion, the nucleophilic attack of methanol to anodically formed radical cations was predominant to give cations; further oxidation and methoxylation followed (ECEC sequence).

Since the present anodic oxidations of troponoids were performed in the presence of lithium perchlorate, methoxyl radicals would hardly exist under the reaction conditions. Therefore, the ECEC mechanism to **10** was assumed as shown in Scheme 5. An attack of a methoxide ion to the radical cation **C** occurred to give **D** at C-2 since the resultant radical could be more stabilized than the alternative from a C-3 attack of a methoxide ion in **C**. Further electrolysis and methoxylation should give **10**. The mechanism for the dimeric product **11** could be explained in terms of an intermediary formation of **E** from **D**. Successive oxidation, dimerization, and methoxylation gave product **11**. An attempted electrolysis of **10** gave no **11**. Additionally, the ECEC mechanism was also favored in the oxidation of **4**. If an EECC mechanism was operative, the attack of a methoxyl radical to **H** would be more preferable at C-a to give **J** than at C-b bacause of the steric hindrance. From **J**, a mixture of acetals **5** and **6** should be obtained via **K**. On the other hand, an internal attack of the hydroxyethoxy group in **H** led to radical **L**, which was further oxidized and a methoxylation followed to give **6**. Thus, an ECEC mechanism was favored.



Scheme 5.

Next, for the formation of **8**, from **15**, a reduction process might be involved, since the reactions were

Table 2. Results of Controlled Anodic Oxidation of **15**

Electricity	Ratio of component				
F mol^{-1}	**15**	**36**	**16**	**8**	**37**
2.4	17	5	1	0	0
3.2	15	6	2	Trace	0
4.1	6	2	6	6	Trace
5.0	4	1	9	6	Trace
5.9	2	Trace	9	5	Trace
6.8	2	0	9	5	Trace
7.7	1.5	0	9	5.5	0.5

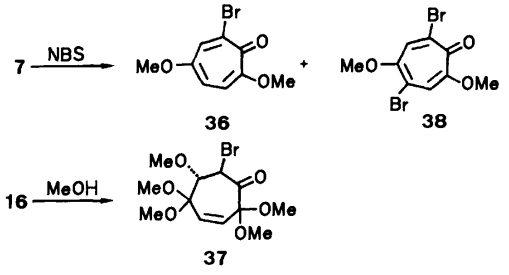
12.3	0	0	4	4	3
			(16)	(22)	(17)

Numbers in parentheses are yields isolated.

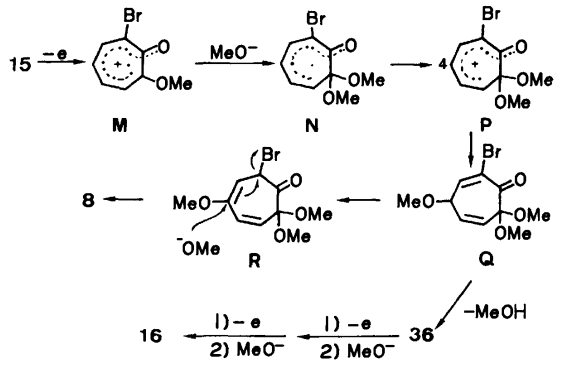
conducted in an undivided cell. In order to make the point clear, we investigated the reaction of **15** in some detail. When the reaction was traced by the ^{1}H NMR spectrum of the whole reaction mixture every hour, product distributions were obtained, as summarized in Table 2. After 3 h, a new product **36** was formed. After 5 h, the amount of **36** decreased with increasing amounts of **8** and **16**. Finally, another new product **37** was produced while **15** and **36** were consumed. Compound **36** was identical with the authentic 2-bromo-4,7-dimethoxytropone, which was prepared from the reaction of *N*-bromosuccinimide and **7** together with the dibromo derivative **38**.[15] Compound **37** was a methanol adduct of **16** from the spectral data.



Scheme 6.

An attempted oxidation of **16** gave only **37** but no **8** at all. The formation of **37** required no electricity since **37** was formed simply by standing in a methanol solution of **16**. On the other hand, an anodic oxidation of **36** gave **16** in quantitative yield.

Taking these evidences into account, the mechanism shown in Scheme 7 can be proposed. Compound **15** was electrolyzed to the cation radical **M**, where the attack of methanol, further oxidation, and methoxylation occurred to give **Q**. A subsequent elimination of methanol from **Q** led to **36**, which was again oxidized and methoxylated to **16**. On the other hand, a prototropy occurred from **Q** to **R** and a subsequent addition-elimination process led to give **8**. An exclusive attack of a methoxide ion to C-4 of **P** could be explained by a steric hindrance from the bromine and dimethyl acetal groups.



Scheme 7.

Conclusion

As has been described, the oxidation of twelve troponoids proceeded in practical yields. Interestingly, an electrode oxidation and a CAN-oxidation were complementary to some extent with each other. For instance, **13** having shown a better result regarding electrode oxidation, was inert to CAN-oxidation. Its conversion to **14** after 4.5 h was only 7%.

The reactivities of bisacetals to Thiele-type reactions were quite different and the site of the reaction with the acetate anion was selective in each case.

Experimental

The elemental analyses were performed by Miss S. Hirashima, of Institute of Advanced Material Study, Kyushu University. NMR spectra were measured by a JEOL 270H spectrometer in a $CDCl_3$ solution (unless otherwise specified); chemical shifts are expressed in the unit δ. Mass spectra were measured with a JEOL 01SG -2 spectrometer. IR spectra were taken as KBr disks or as a liquid film inserted between NaCl plates using a Jasco IR-A 102 spectrometer. UV spectra were measured by a Hitachi U-3200 spectrophotometer.

Anodic Oxidation of 5-Hydroxy-2-methoxytropone (3). An anhydrous MeOH solution (90 cm^3) of **3** (51.4 mg) and $LiClO_4$ (41 mg) was electrolyzed in an undivided cell fitted with a circular Pt-gauze (10 mm in diameter×20 mm in height) anode and a Pt cathode under a constant current (10 mA). After 2.2 F mol^{-1} of electricity were passed at room temperature under an N_2 atmosphere, the solvent was evaporated in vacuo. The residue was diluted with water and extracted with $CHCl_3$. The solvent was evaporated and the residue was chromatographed on a silica-gel column to give 37.9 mg (62%) of **1**: a pale-yellow oil, which was identical with the authentic sample.[6]

Anodic Oxidation of 5-Hydroxy-2-(2-hydroxyethoxy)-tropone (4). An anhydrous MeOH solution (90 cm^3) of **4** (100 mg) and $LiClO_4$ (40 mg) was oxidized anodically to give 87.7 mg (75%) of **6**: colorless crystals, mp 123—124 °C, which was identical with the authentic sample.[6]

Anodic Oxidation of 2,5-Dimethoxytropone (7). An anhydrous MeOH solution (80 cm^3) of **7** (101.6 mg) and $LiClO_4$ (44 mg) was electrolyzed (2 F mol^{-1}) to give 135 mg (97%) of **8**: a colorless oil; ^1H NMR δ=3.29 (6H, s), 3.30 (6H, s), 5.82 (1H, d, J=12.5 Hz), 6.01 (1H, d, J=12.5 Hz), 6.09 (1H, dd, J=12.5, 2.0 Hz), and 6.34 (1H, dd, J=12.5, 2.0 Hz); ^{13}C NMR δ=49.7 (2C), 50.4 (2C), 98.5, 101.9, 127.4, 131.2, 135.9, 139.8, and 193.0; IR 1705, 1460, 1440, 1390, 1300, and 1210 cm^{-1}; UV (MeOH) 202 (ε 6000), 229 (sh 2900), and 336 nm (140).

Found: C, 57.62; H, 7.12%. Calcd for $C_{11}H_{16}O_5$: C, 57.88; H, 7.07%.

CAN-Oxidation of 7. An anhydrous MeOH solution (1.5 cm^3) of **7** (60 mg) and CAN (396 mg) was stirred at 0 °C and the mixture was kept at room temperature for 4.5 h with stirring. Silica-gel chromatography of the mixture afforded 9.7 mg (15%) of **1** and 59.4 mg (77%) of **2**: a colorless oil. The latter was identical with the authentic sample.[6]

Anodic Oxidation of 2,3-Dimethoxytropone (9). An anhydrous MeOH solution (100 cm^3) of **9** (122 mg) and $LiClO_4$ (104 mg) was electrolyzed (2.8 F mol^{-1}) to give 95.4 mg (57%) of **10** and 11.6 mg (7%) of **11**.

10: Colorless crystals, mp 107—108 °C; ^1H NMR δ=3.36 (6H, br s), 3.42 (6H, s), 5.86 (1H, dd, J=12.0, 1.0 Hz), 6.06 (2H, m), and 6.40 (1H, ddd, J=12.0, 6.0, 2.0 Hz); ^{13}C NMR δ=51.3 (2C), 52.9 (2C), 101.2, 103.5, 126.2, 128.1, 133.4, 137.9, and 194.5; IR 1670, 1420, 1140, and 1120—980 cm^{-1}; UV (MeOH) 201 (ε 3800), 231 (2400), and 293 nm (4700).

Found: C, 57.99; H, 6.88%. Calcd for $C_{11}H_{16}O_5$: C, 57.88; H, 7.07%.

11: Colorless crystals, mp 150—152 °C; ^1H NMR δ=2.26 (2H, d, J=11.0 Hz), 2.62 (2H, m), 2.96 (2H, t, J=11.0 Hz), 3.17 (6H, s), 3.35 (6H, s), 3.38 (6H, s), 3.47 (6H, s), 5.73 (2H, dd, J=11.7, 2.2 Hz), and 5.93 (2H, dd, J=11.7, 3.7 Hz); ^{13}C NMR δ=39.1 (2C), 44.8 (2C), 50.6 (2C), 51.1 (2C), 51.2 (2C), 51.5 (2C), 101.6 (2C), 106.2 (2C), 132.1 (2C), 134.3 (2C), and 202.7 (2C); IR 1720, 1440, 1170, and 1100 cm^{-1}; UV (MeOH) 297 nm (ε 130).

Found: C, 56.49; H, 7.39%. Calcd for $C_{22}H_{34}O_{10}\cdot 1/2H_2O$: C, 56.53; H, 7.49%.

CAN-Oxidation of 9. An anhydrous MeOH solution (2 cm^3) of **9** (31.6 mg) was treated with CAN (115 mg) to give 20.3 mg (59%) of **12** and 11.3 mg of unreacted **9**.

12: Pale-yellow crystals, mp 69—70 °C; ^1H NMR δ=3.38 (6H, s), 6.0—6.1 (2H, m), and 6.5—6.6 (2H, m); ^{13}C NMR δ=52.7 (2C), 104.6, 129.5 (2C), 133.0 (2C), and 195.1 (2C); IR 1700, 1450, 1420, and 1220 cm^{-1}; UV (MeOH) 313 nm (ε 3500).

Found: C, 59.42; H, 5.61%. Calcd for $C_9H_{10}O_4$: C, 59.33; H, 5.53%.

Anodic Oxidation of 2,7-Dimethoxytropone (13). An anhydrous MeOH solution (50 cm^3) of **13** (48.2 mg) and $LiClO_4$ (54 mg) was electrolyzed (3.1 F mol^{-1}) to give 62.1 mg (94%) of **14**: a colorless oil; ^1H NMR δ=3.26 (12H, s), 5.5—5.7 (2H, m), and 6.1—6.3 (2H, m); ^{13}C NMR δ=50.5 (4C), 101.0 (2C), 127.4 (2C), 130.2 (2C), and 192.5; IR 1740, 1175, 1140, 1080, and 1050 cm^{-1}; UV (MeOH) 206 (ε 7600) and 259.6 nm (2900).

Found: C, 57.74; H, 7.07%. Calcd for $C_{11}H_{16}O_5$: C, 57.88; H, 7.07%.

CAN-Oxidation of 13. a) An anhydrous MeOH solution (2 cm^3) of **13** (43.4 mg) was oxidized with CAN (145 mg) to give 3.4 mg (6%) of **14** and 39.3 mg of unreacted **13**.

b) An anhydrous MeOH solution (4 cm^3) of **13** (12.1 mg) was oxidized with CAN (130 mg) to give a complex mixture.

Anodic Oxidation of 2-Bromo-7-methoxytropone (15). a) An anhydrous MeOH solution (50 cm^3) of **15** (98 mg) and $LiClO_4$ (57 mg) was electrolyzed (8.1 F mol^{-1}) to give 23.6 mg (23%) of **8** and 94.7 mg (67%) of **16**: a pale-yellow oil; ^1H NMR δ=3.24 (6H, s), 3.27 (6H, s), 5.82 (1H, d, J=12.0 Hz), 6.07 (1H, dd, J=12.0, 2.0 Hz), and 6.84 (1H, d, J=2.0 Hz); ^{13}C NMR δ=49.8 (2C), 50.6 (2C), 99.4, 101.0, 121.2, 131.0, 135.5, 140.1, and 188.3; IR 1720, 1620, 1460—1440, 1380, and 1100—1020 cm^{-1}.

Found: m/z 306.0074 and 308.0041. Calcd for $C_{11}H_{15}O_5Br$: M, 306.0101 and 308.0081.

b) An anhydrous MeOH solution (50 cm^3) of **15** (98 mg) and $LiClO_4$ (58 mg) was electrolyzed. Every 1 cm^3 of the mixture was taken out, evaporated, and filtered by a silica cartridge (Sep-pak) in order to monitor by ^1H NMR spectroscopy. After 3 h, the work-up gave the crude **36**, whose ^1H NMR spectrum was identical with that of an authentic sample. After 11 h, the whole mixture was evaporated and the residue was chromatographed to give 19.3 mg (16%) of **16**, 19.2 mg (22%) of **8**, and 22 mg (17%) of **37**: pale-yellow crystals, mp 76—78 °C; ^1H NMR δ=3.08 (3H, s), 3.13 (3H, s), 3.29 (3H, s), 3.38 (3H, s), 3.67 (3H, s), 3.95 (1H, d, J=6.2 Hz), 4.80 (1H, d, J=6.2 Hz), 5.86 (1H, d, J=11.8 Hz), and 6.01 (1H, d, J=11.8 Hz); ^{13}C NMR δ=48.9, 49.1, 49.6, 50.3, 54.8, 60.0, 87.5, 97.8, 101.0, 130.0, 133.5, and 188.3; IR 1750, 1460, and 1390 cm^{-1}; UV (MeOH) 201.8 (ε 2600) and 290 nm (170).

Found: C, 42.31; H, 5.57%. Calcd for $C_{12}H_{19}O_6Br$: C, 42.49; H, 5.65%.

NBS-Bromination of 2,5-Dimethoxytropone (7). Preparation of 2-Bromo-4,7-dimethoxytropone (36). A CCl_4 solution (4 cm^3) of **7** (222 mg) and NBS (248 mg) was refluxed for 2 h. After cooling the mixture to room temperature, the precipitate was filtered. The solvent was evaporated and the residue was chromatographed on a silica-gel column to give 38 mg (12%) of **36**, 28 mg (6%) of **38**, and 90 mg of recovered **7**.

36: Pale-yellow crystals, mp 146—147 °C; ^1H NMR δ=3.78 (3H, s), 3.88 (3H, s), 6.43 (1H, dd, J=11.0, 3.0 Hz), 6.79 (1H, d, J=11.0 Hz), and 8.07 (1H, d, J=3.0 Hz); ^{13}C NMR δ=55.9, 56.6, 108.3, 113.7, 135.9, 138.5, 156.6, 157.3, and 173.6; IR 1580, 1495, 1390, 1340, 1245, 1210, 1185, and 1120 cm^{-1}.

Found: C, 43.86; H, 3.76%. Calcd for $C_9H_9O_3Br$: C, 44.11; H, 3.70%.

38: Pale-yellow crystals, mp 139—142 °C (lit,[15] mp 140—142 °C).

Anodic Oxidation of 36. An anhydrous MeOH solution (50 cm^3) of **36** (30 mg) and $LiClO_4$ (51 mg) was electrolyzed (5.6 F mol^{-1}) to give 37 mg (99%) of **16**, which was identical with the authentic sample.

CAN-Oxidation of 15. An anhydrous MeOH solution (2 cm^3) of **15** (59 mg) was treated with CAN (301 mg). The starting material was completely recovered.

Anodic Oxidation of 4,5-Dimethoxytropone (17). An anhydrous MeOH solution (40 cm^3) of **17** (53 mg) and $LiClO_4$ (54 mg) was electrolyzed (5.2 F mol^{-1}) to give 29.6 mg (41%) of **18** and 8.5 mg (10%) of **19**.

18: A colorless oil; ^1H NMR δ=3.31 (6H, br s), 3.48 (6H, br s), 6.10 (2H, dm, J=12.5 Hz), and 6.42 (2H, dm, J=12.5 Hz); ^{13}C NMR δ=50.4 (2C, br), 51.7 (2C, br), 102.2 (2C), 131.0 (2C), 141.2 (2C), and 190.8; IR 1665, 1620, 1460,

and 1390 cm^{-1}; UV (MeOH) 209 nm (ε 9000).

Found: C, 57.83; H, 6.90%. Calcd for $C_{11}H_{16}O_5$: C, 57.88; H, 7.07%.

19: A colorless oil; ^1H NMR δ=3.30 (6H, br s), 3.51 (6H, br s), 3.67 (3H, s), 5.37 (1H, s), 6.13 (1H, d, J=12.6 Hz), and 6.41 (1H, d, J=12.6 Hz); ^{13}C NMR δ=50.4 (2C, br), 51.6 (2C, br), 55.4, 101.6, 103.3, 109.3, 130.0, 140.7, 152.6, and 186.4; IR 1720, 1670, 1640, and 1460 cm^{-1}.

Found: m/z 258.1103. Calcd for $C_{12}H_{18}O_5$: M, 258.1108.

Anodic Oxidation of 4,5-Dimethoxy-2,7-dimethyltropone (20). An anhydrous MeOH solution (120 cm^3) of **20** (186 mg) and $LiClO_4$ (116 mg) was electrolyzed (3.7 F mol^{-1}) to give 188 mg (77%) of **21** and 20.3 mg (8%) of **22**.

21: Colorless crystals, mp 98—100 °C; ^1H NMR δ=1.93 (6H, d, J=1.4 Hz), 3.27 (6H, br s), 3.45 (6H, br s), and 6.14 (2H, d, J=1.4 Hz); ^{13}C NMR δ=20.4 (2C), 50.2 (2C, br), 51.5 (2C, br), 102.0 (2C), 134.1 (2C), 138.1 (2C), and 194.9; IR 1635, 1440, and 1385 cm^{-1}; UV (MeOH) 240 nm (ε 6400).

Found: C, 60.80; H, 7.92%. Calcd for $C_{13}H_{20}O_5$: C, 60.92; H, 7.87%.

22: A colorless oil; ^1H NMR δ=1.37 (3H, s), 1.92 (3H, d, J=1.4 Hz), 3.15 (3H, s), 3.26 (3H, s), 3.28 (3H, s), 3.63 (3H, s), 4.46 (1H, s), and 6.06 (1H, d, J=1.4 Hz); ^{13}C NMR δ=19.3, 25.8, 49.6, 50.3, 52.4, 55.1, 81.9, 99.6, 101.3, 134.8, 139.2, 158.6, and 203.8; IR 1710, 1650, 1450, and 1350 cm^{-1}.

Found: m/z 256.1307. Calcd for $C_{13}H_{20}O_5$: M, 256.1308.

Anodic Oxidation of 4,5-Dimethoxy-2,7-dipropyltropone (23). An anhydrous MeOH solution (50 cm^3) of **23** (26 mg) and $LiClO_4$ (52 mg) was electrolyzed (6.7 F mol^{-1}) to give 31.6 mg (97%) of **24**: a colorless oil; ^1H NMR δ=0.90 (6H, t, J=7.3 Hz), 1.41 (4H, m), 2.29 (4H, m), 3.25 (6H, br s), 3.45 (6H, br s), and 6.01 (1H, t, J=1.1 Hz); ^{13}C NMR δ=13.6 (2C), 21.8 (2C), 36.0 (2C), 50.4 (2C, br), 51.4 (2C, br), 102.1 (2C), 133.1 (2C), 143.0 (2C), and 196.3; IR 1670, 1650, 1460, 1430, 1380, and 1360 cm^{-1}; UV (MeOH) 243 nm (ε 6300).

Found: C, 65.27; H, 8.91%. Calcd for $C_{17}H_{28}O_5$: C, 65.36; H, 9.03%.

Anodic Oxidation of 2-Methoxytropone (25). a) An anhydrous MeOH solution (50 cm^3) of **25** (427.4 mg) and $LiClO_4$ (53 mg) was electrolyzed (2.0 F mol^{-1}) to give 103.5 mg (20%) of **7**, 44.5 mg (6%) of **8**, 37.5 mg (7%) of **1**, 37 mg (6%) of **27**, and 237.8 mg of unreacted **25**.

27: A pale-yellow oil; ^1H NMR δ=3.28 (3H, s), 3.40 (3H, s), 3.41 (3H, s), 4.09 (1H, d, J=6.0 Hz), 5.90 (1H, d, J=12.0 Hz), 6.10 (1H, dd, J=11.5, 6.5 Hz), 6.33 (1H, ddd, J=11.5, 6.0, 1.0 Hz), and 6.48 (1H, ddd, J=12.0, 6.5, 1.0 Hz); ^{13}C NMR δ=51.2, 51.4, 58.7, 76.8, 102.0, 127.4, 127.5, 134.3, 135.0, and 195.0; IR 1685, 1595, 1450, and 1425 cm^{-1}.

Found: m/z 198.0890. Calcd for $C_{10}H_{14}O_4$: M, 198.0859.

b) An anhydrous MeOH solution (65 cm^3) of **25** (101 mg) and $LiClO_4$ (40 mg) was electrolyzed (4.0 F mol^{-1}) to give 18.4 mg (15%) of **7** and 82.5 mg (49%) of **8**.

CAN-Oxidation of 25. An anhydrous MeOH solution (2 cm^3) of **25** (48 mg) was treated with CAN (437 mg) to give 5.6 mg (7%) of **2**, 1 mg (1%) of **27**, and 20 mg of unreacted **25**.

Anodic Oxidation of Tropone (26). An anhydrous MeOH solution (50 cm^3) of **26** (84 mg) and $LiClO_4$ (58 mg) was electrolyzed (2.5 F mol^{-1}) to give 5.3 mg (5%) of **25**, 9.8 mg (7%) of **7**, 11.8 mg (7%) of **8**, and 40 mg of unreacted **26**.

Thiele-Type Reaction of 8. A 1:1-mixture (3 cm^3) of AcOH and Ac_2O, and **8** (177.5 mg) was stirred with a catalytic amount of concd H_2SO_4 at room temperature for 2 h. The mixture was diluted with water and extracted with $CHCl_3$. The solvent was evaporated in vacuo and the residue was chromatographed on a silica-gel column to give 39.5 mg (28%) of **1**, 67 mg (35%) of **30**, and 8.7 mg (5%) of **31**.

30: A pale-yellow oil; ^1H NMR δ=2.01 (3H, s), 3.25 (3H, s), 3.37 (3H, s), 3.60 (3H, s), 5.25 (1H, dd J=8.2, 2.2 Hz), 5.65 (1H, d, J=8.2 Hz), 5.98 (1H, d, J=13.2 Hz), and 6.41 (1H, dd, J=13.2, 2.2 Hz); ^{13}C NMR δ=21.0, 49.9, 52.0, 54.9, 69.4, 97.5, 100.4, 126.7, 136.4, 156.6, 169.9, and 193.2; IR 1750, 1690, 1650, 1405, 1370, and 1230 cm^{-1}.

Found: m/z 256.0945. Calcd for $C_{12}H_{16}O_6$: M, 256.0945.

31: Colorless crystals, mp 131—133 °C; ^1H NMR δ=2.37 (3H, s), 3.78 (3H, s), 3.89 (3H, s), 6.65 (1H, dd, J=12.1, 2.9 Hz), 6.84 (1H, d, J=2.9 Hz), and 6.90 (1H, d, J=12.1 Hz); ^{13}C NMR δ=20.7, 55.8, 57.4, 120.0, 120.4 (2C), 156.9, 160.6, and 168.4 (3C); IR 1770, 1590, 1510, 1460, 1250, and 1170 cm^{-1}.

Found: m/z 224.0684. Calcd for $C_{11}H_{12}O_5$: M, 224.0684.

Thiele-Type Reaction of 10. A 1:1-mixture of AcOH and Ac_2O (1 cm^3) of **10** (97 mg) was stirred in the presence with a catalytic amount of concd H_2SO_4 to give 35.9 mg (46%) of **12** and 15.5 mg (22%) of **35**. The latter was identical with an authentic sample.

Thiele-Type Reaction of 14. A 1:1-mixture of AcOH and Ac_2O (0.4 cm^3) and **14** (31.6 mg) was stirred with a catalytic amount of concd H_2SO_4 to give 12.6 mg (41%) of **32**, 4.5 mg (13%) of **33**, and 2.1 mg (6%) of **34**.

32: A pale-yellow oil; ^1H NMR δ=2.32 (3H, s), 3.93 (6H, s), 6.62 (1H, d, J=2.6 Hz), 6.65 (1H, dd, J=10.3, 2.6 Hz), and 6.80 (1H, d, J=10.3 Hz); ^{13}C NMR δ=21.1, 56.6 (2C), 111.6, 112.2, 117.3, 147.8, 160.6, 161.2, 169.5, and 173.1; IR 1760, 1595, 1500, 1450, 1380, and 1360 cm^{-1}.

Found: m/z 224.0685. Calcd for $C_{11}H_{12}O_5$: M, 224.0685.

33: A colorless oil; ^1H NMR δ=2.33 (3H, s), 2.36 (3H, s), 3.94 (3H, s), 6.59 (1H, d, J=2.2 Hz), 6.62 (1H, dd, J=10.3, 2.2 Hz), and 7.24 (1H, d, J=10.3 Hz); ^{13}C NMR δ=20.6, 21.1, 56.7, 111.3, 116.4, 127.1, 152.9, 163.9, 168.4 (2C), and 168.8 (2C); IR 1785, 1600, 1500, and 1370 cm^{-1}.

Found: m/z 252.0631. Calcd for $C_{12}H_{12}O_6$: M, 252.0631.

34: A colorless oil; ^1H NMR δ=2.29 (6H, s), 3.80 (3H, s), 6.51 (1H, d, J=2.2 Hz), 6.78 (1H, d, J=12.8 Hz), and 6.91 (1H, dd, J=12.8, 2.2 Hz).

Found: m/z 252.0633. Calcd for $C_{12}H_{12}O_6$: M, 252.0631.

The authors thank Mr. Seishi Kasai for his experimental assistance and the Ministry of Education, Science and Culture for financial support, a Grant-in-Aid for Scientific Research given to A. M. (No. 60470025).

12) Due to the 1,9-sigmatropy generally operative in 2-acetoxytropones,[11b] the first priority for the numberings of carbons should be given to the acetoxyl group adjacent to the C-1 carbonyl (like the hydroxyl in tropolones). Then, **33** should be designated as 2,5-diacetoxy-3-methoxytropone, regardless of its tautomeric contribution.

The first generation of a new sulfur-functionalized nitrile oxide 1,3-dipole, (phenylthio)acetonitrile oxide, is presented. Its cycloadditions to a variety of olefins and acetylenes lead to 3-(phenylthiomethyl)-2-isoxazolines and -oxazoles, the formers being selectively deprotonated at the carbon substituted by the sulfur moiety. The resulting sulfur-stabilized carbanions react with aldehydes, esteric Michael acceptors, and alkyl halides to enable the introduction of a carbon substituent to the side chain on 3-position. Raney Ni reduction of these 2-isoxazolines gives β,β'-dihydroxy ketones and β-hydroxy ketones.

A phosphorus-functionalized nitrile oxide, (diethoxyphosphinyl)acetonitrile oxide, was first prepared in our laboratory[1] and its synthetic versatility is now gradually established.[2-4] Advantages of the phosphorus-functionalized nitrile oxide in organic synthesis are that 1) its cycloadditions to olefins or acetylenes regioselectively lead to 3-(phosphinylmethyl)-2-isoxazolines or -oxazoles bearing a variety of substituents at the 5-position, 2) these heterocycles can be converted into 3-[1-(diethoxyphosphinyl)alkyl], 3-(1-alkenyl), and 3-acyl derivatives via the phosphorus-stabilized carbanions, 3) the phosphorus moiety of the cycloadducts can survive intact on their reductive cleavage of the nitrogen–oxygen bond with Raney Ni to afford 4-hydroxy-2-oxoalkylphosphonates which undergo Horner–Emmons olefinations under mild conditions.

A sulfur-functionalized nitrile oxide, (phenylthio)-acetonitrile oxide, is an additional example for the family of α-functionalized nitrile oxides. Its synthetic applications would be characterized by its cycloadditions with olefins or acetylenes leading to 3-(phenylthio)-substituted 2-isoxazolines or isoxazoles and the generation of sulfur-stabilized carbanions followed by the subsequent reactions with electrophiles. The most characteristic advantage would be that reductive cleavage of the nitrogen–oxygen bond and elimination of the sulfur moiety can be carried out in one step.[5]

The present paper presents the first preparation of a sulfur-functionalized nitrile oxide, (phenylthio)acetonitrile oxide, and its synthetic application.

Results and Discussion

Generation of (Phenylthio)acetonitrile Oxide. Two routes were examined for the generation of (phenylthio)acetonitrile oxide (**3**). One consists of the direct oxidation of (phenylthio)acetaldehyde oxime (**2**) with sodium hypochlorite–triethylamine in dichloromethane (Scheme 1). As oxime **2** (syn:anti=4:5 by ^{1}H NNR; 91% from **1**) can be readily prepared in quantities and in a good yield from commercially available bromoacetaldehyde diethyl acetal via (phenylthio)acetaldehyde diethyl acetal (**1**, 95% based on the starting acetal), the rather low yield oxidation step of **2** into **3** is enough compensated. The nitrile oxide **3** is trapped, as soon as it is generated, in a 1,3-dipolar cycloaddition with an olefinic dipolarophile. This will be mentioned below.

The other route involves the Mukaiyama reaction[6] using 2-phenylthio-1-nitroethane (**5**). A mixture of the nitro compound **5** and phenyl isocyanate was heated in benzene in the presence of triethylamine and an olefin. The strating **5** is available from 2-nitroethanol via 1-bromo-2-nitroethane (**4**), however this preparation involves the use of rather expensive and difficult-to-handle 2-nitroethanol and the poor yield of **4**.[7]

The bromination of oxime **3** with *N*-bromosuccinimide (NBS)[8] or the chlorination with *N*-chlorosuccinimide (NCS) followed by the dehydrohalogenation with triethylamine failed to generate nitrile oxide **3**.

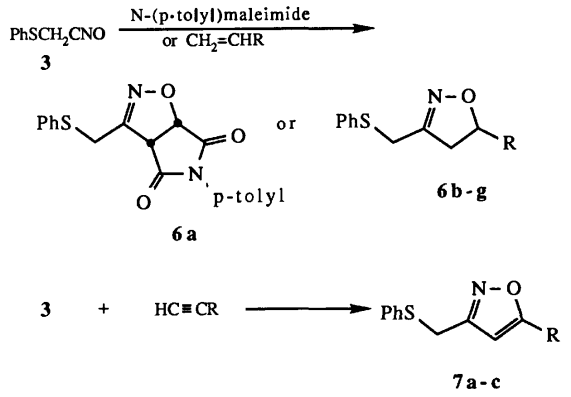
Scheme 1.

Cycloadditions of (Phenylthio)acetonitrile Oxide to Olefins and Acetylenes. Efficiency in the generation of (phenylthio)acetonitrile oxide (**3**) from the above two precursors, oxime **2** and nitro compound **5**, was evaluated in the trapping reactions of **3** with olefinic dipolarophiles. An equimolar mixture of oxime **2** and *N*-(*p*-tolyl)maleimide in dichloromethane was treated with 5% aqueous sodium hypochlorite (3 equiv) and a catalytic amount of triethylamine in benzene at room temperature for 4 h. After chromatographic purification, the expected 2-isoxazoline **6a** was obtained in 65% yield based on **2** (Scheme 2 and Table 1, Entry 1).



Scheme 2.

The generation step of nitrile oxide **3** from oxime **2** was, first of all, optimized in its cycloaddition reaction with *N*-(*p*-tolyl)maleimide as a highly reactive dipolarophile. Employment of a phase-transfer catalyst (Entry 6) did not improve the yield of **6a**; replacement of aqueous hypochlorite with the sodium hypochlorite supported on Celite 545[9] failed to generate nitrile oxide **3** (Entry 7). The use of 3 equivalents of aqueous sodium hypochlorite at room temperature (Entry 5) gave the best yield of **6a** (compare with Entries 1—3 and 8—10).

Trapping experiments of nitrile oxide **3** with other olefinic dipolarophiles were performed under the conditions which gave the best yield of **6a** (Table 1, Entry 5). Nitrile oxide **3** could be regioselectively trapped with electron-deficient olefins, 1-alkenes, and electron-rich olefins to produce 5-substituted 3-(phenylthiomethyl)-2-isoxazolines **6b—g** (Scheme 2 and Table 2, Entries 2, 4, 6—8, and 10). Similar

Table 1. Generation of (Phenylthio)acetonitrile Oxide **3** from Oxime **2** and Its Trapping with *N*-(*p*-Tolyl)maleimide Leading to **6a**

Entry	NaOCl (equiv)[a]	Condition[b]	Yield/%[c]

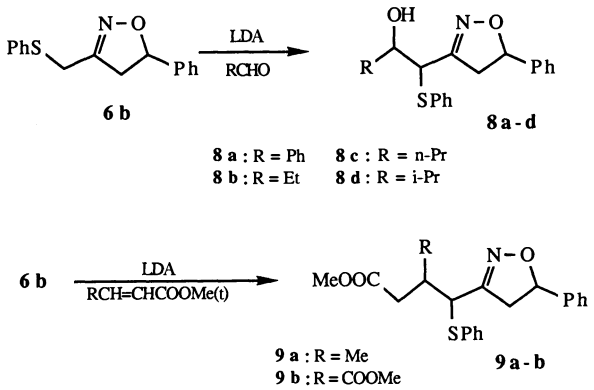
a) A: NaOCl (3 equiv)-NEt_3 (0.1 equiv) in dichloromethane; B: PhNCO (2 equiv)-NEt_3 (cat.) in benzene; C: NaOCl (2.5 equiv)-NEt_3 (0.25 equiv) in dichloromethane. b) Yield of isolated product based on **2** or **5**.

cycloadditions to electron-deficient acetylenes and 1-alkynes gave isoxazoles **7a—c** as single regioisomers, albeit in low yields (Scheme 2 and Table 2, Entries 11—13).

The relatively low yield formation of **6** and **7** mentioned above is apparently due to the poor efficiency in the generation step of **3** from **2** since the same nitrile oxide **3** undergoes a high-yield cycloaddition (90%) to styrene when generated by the dehydration of **5** with phenyl isocyanate (Table 2, Entry 3). In all the attempted cases the generation of **3** from **5** is much more effective than the generation from **2** (Entries 3, 5, 9, and 14).

Reactions of the Carbanions of 3-(Phenylthiomethyl)-2-isoxazolines with Electrophiles. The phenylthio functionality of 2-isoxazolines **6** would permit the selective deprotonation at the position adjacent to the sulfur moiety rather than 4-position.[10] Accordingly the styrene adduct **6b** as an example was deprotonated with lithium diisopropylamide (LDA) and the resulting anion was captured with aromatic and aliphatic aldehydes. Thus excellent yields of adducts **8a—d** were obtained as mixtures of diastereomers when the anions were treated with three equivalents of aldehydes (Scheme 3 and Table 3, Entries 1—4).



Scheme 3.

Although Michael additions of the carbanion derived from **6b** with methyl crotonate as an acceptor did not take place at −78 °C in THF, the presence of hexamethylphosphoric triamide (HMPA, 1.2 equiv) highly accelerated the addition reaction. Thus the Michael adducts **9a,b** were produced, as mixtures of diastereomers, in the reactions with methyl crotonate and dimethyl fumarate (Scheme 3 and Table 3, Entries 5,6). Use of 3-buten-2-one as a Michael acceptor led to a mixture of complex products with the 53% recovery of **6b**. Presumably the olefin acceptor underwent a base-catalyzed polymerization under the above basic conditions.

The carbanion of 2-isoxazoline **6b** was similarly alkylated at −78 °C in the presence of HMPA (Scheme 4 and Table 3). Not only alkyl iodides (Entries 7,8) but also alkyl bromides could be employed as well (Entries 9—11). Especially methylation, benzylation, and allylation were effective. On the other hand, the carbanion derived from methyl 2-isoxazoline-5-carboxylate **6c** could not be smoothly alkylated with methyl iodide, the starting **11** being partly recovered (44%). Accordingly the ester **6c** was first hydrolyzed quantitatively by aqueous lithium hydroxide in *t*-

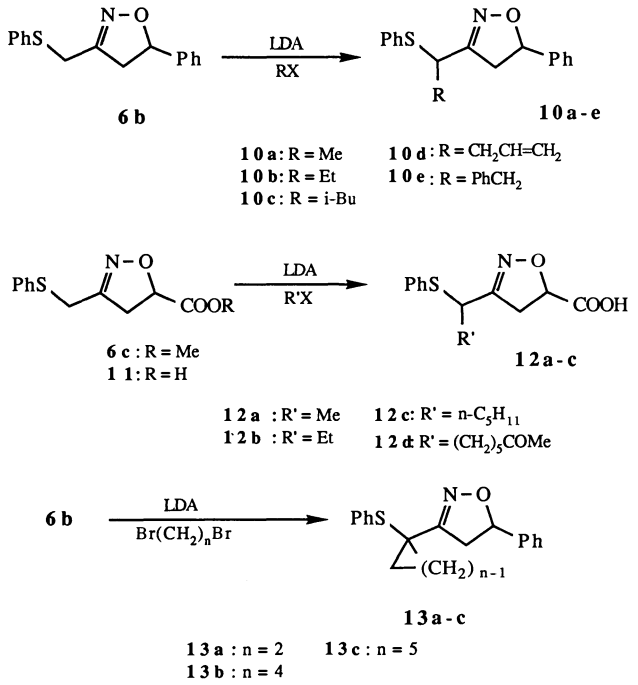
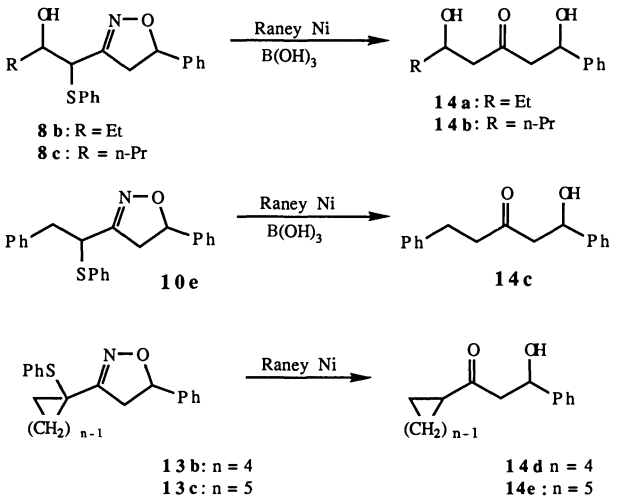
a) A—D: The carbanion of **6b** was generated by treating with LDA (1.2 equiv) in THF at −78 °C. After an electrophile was added, the reaction was continued at −78 °C in the absence (Condition A) or presence of HMPA (B: 1.2 equiv; C: 5.7 equiv; D: 11.5 equiv). E: The carbanion of **6b** or **11** was generated by treating with LDA (2.2—2.4 equiv) in THF at −78 °C. After an electrophile and HMPA (11.5 equiv) were added, the reaction was continued at −78 °C. b) Yield of isolated products. c) Recovered **6b**: 27%. d) Recovered **6b**: 40%. e) Recovered **11**: 30%. f) Recovered **11**: 34%. g) Recovered **11**: 17%. h) Recovered **6b**: 41%.



Scheme 4.



Scheme 5.

butyl alcohol and the resulting acid **11** was used for alkylation. The acid **11** was converted into the dianion with a little excess than two equivalents of LDA and then alkylations with several alkyl halides were performed to give moderate to good yields of alkylated acids **12a—d** (Entries 12—15). In the alkylation with 7-iodo-2-heptanone ethylene acetal, the dioxolane protecting group was cleaved on the usual acidic work up to give **12d**.

Alkylations of **6b** with 1,2-dibromoethane, 1,4-dibromobutane, and 1,5-dibromopentane in the presence of more than two equivalents of LDA produced 3-[1-(phenylthio)cycloalkyl]-2-isoxazolines **13a—c** (Entries 16—19).

Raney Ni Reduction of 2-Isoxazolines Leading to β-Hydroxy Ketones. It was anticipated that the sulfur moiety of 3-[1-(phenylthio)alkyl]-2-isoxazolines would be concurrently removed on the reductive cleavage of the nitrogen–oxygen bond with Raney Ni.[5] This desulfurization must be particularly important in the synthetic applications of sulfur-functionalized nitrile oxide **3** since the sulfur functionality can serve as a side chain-activating group through a sequence of deprotonation and reactions with nucleophiles.

Aldehyde adducts **8b,c** were treated with Raney Ni in aqueous ethanol in the presence of boric acid to give β,β′-dihydroxy ketones **14a,b** as mixtures of two diastereomers of desulfurized products, respectively (Scheme 5). Alkylated 2-isoxazolines **10e** and **13b,c** were similarly reduced to produce the corresponding β-hydroxy ketones **14c—e**.

Although sulfur-functionalized nitrile oxides are quite rare,[11] organic synthesis using 3-sulfinyl-2-isoxazolines has been recently reported.[5] These isoxazolines could be prepared in an optically pure form by treatment of 3-lithiomethyl-2-isoxazolines with a chiral sulfinate after separation of two diastereomers. Though the cycloadducts of our nitrile oxide **3** are synthetically equivalent to these precedents, one advantage is that a variety of functionalities can be introduced at the 5-position of 2-isoxazoline ring by use of **3**.[12]

Experimental

General. Melting points were determined on a Yanagimoto melting point apparatus and are uncorrected. IR spectra were taken with a JASCO IRA-1 or a JASCO A-702 spectrometer. ^{1}H NMR spectra were recorded on a Hitachi R-40 (90 MHz), a JEOL FX-100 (100 MHz), or a JEOL GSX-270 (270 MHz) instrument and ^{13}C NMR on a JEOL FX-100 (25.05 MHz) or a GSX-270 spectrometer (67.94 MH). Chemical shifts are expressed in parts per million downfield from tetramethylsilane as an internal standard. Mass spectra were measured with a JEOL-01SG-2 spectrometer at 70 eV of ionization energy. High-resolution mass spectra were obtained on the same instrument. Elemental analyses were performed on a Hitachi 026 CHN analyzer. Thin-layer chromatography (TLC) was accomplished on 0.2 mm precoated plates of silica gel 60 F-254 (Merck). Visualization was made with ultraviolet light (254 and 365 nm), iodine, molybdophosphoric acid (5% in ethanol), or *p*-anisaldehyde (5% in ethanol containing 5% of sulfuric acid). For preparative column chromatography, Wakogel C-200, C-300 (Wako), and Silicagel 60 (Merck) were employed.

(Phenylthio)acetaldehyde Diethyl Acetal (1). To a solution of sodium ethoxide (20.4 g, 0.30 mol) in dry ethanol (90 ml) was added thiophenol (33.0 g, 0.30 mol). After the mixture was stirred at room temperature for 0.5 h, bromoacetaldehyde diethyl acetal (68.43 g, 0.33 mol) was added in a period of 1.5 h. The mixture was stirred for 22 h, poured into water (80 ml), and extracted with diethyl ether (100 ml×2). The combined extracts were dried over magnesium sulfate and evaporated in vacuo. The residue

was subjected to vacuum distillation to give **1** (64.95 g, 95%): Colorless liquid; bp 103—104 °C/106 Pa; ^{1}H NMR ($CDCl_3$) δ=1.18 (6H, t, J=7.0 Hz, Me), 3.13 (2H, d, J=5.4 Hz, SCH_2), 3.32—3.81 (4H, m, OEt), 4.61 (1H, t, J=5.4 Hz, CH), and 7.06—7.42 (5H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=15.24 (q, Me), 37.53 (t, SCH_2), 62.24 (t, OEt), 102.01 (d, CH), 126.24, 129.07, 129.54 (each d), and 136.72 (s); MS m/z (rel intensity, %) 226 (M^+, 5), 135 (47), 123 (58), 109 (35), 103 (59), 77 (Ph, 34), 75 (66), 65 (30), 51 (35), 47 (base peak), 45 (63), 43 (24), and 39 (21). Found: C, 63.63; H, 7.94%. Calcd for $C_{12}H_{18}O_2S$: C, 63.68, H, 8.02%.

(Phenylthio)acetaldehyde Oxime (2). To a solution of acetal **1** (10.0 g, 44.25 mmol) in ethanol (60 ml) was added aqueous hydroxylamine hydrochloride (3.38 g, 48.67 mmol in 30 ml of water). This mixture was stirred at 50 °C for 5 h and the ethanol was evaporated in vacuo. From the resulting aqueous solution products were extracted with dichloromethane (30 ml×2). The combined extracts were dried over magnesium sulfate and evaporated in vacuo. The residue was chromatographed over silica gel with hexane-ethyl acetate (5:1 v/v) to give oxime **2** (6.69 g, 91%) as a 4:5 mixture of syn and anti isomers: Pale yellow viscous oil; IR (neat) 3000 and 1570 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=3.53 (1H, d, J=6.5 Hz, one of SCH_2), 3.75 (1H, d, J=5.8 Hz, the other of SCH_2), 6.74 (4/9H, t, J=5.8 Hz, CH (syn)), 7.08—7.50 (6H, m, Ph and CH (anti)), and 8.90 (1H, br s, OH); ^{13}C NMR ($CDCl_3$) δ=26.95 (t, SCH_2 (syn)), 32.88 (t, SCH_2 (anti)), 126.72, 127.19, 129.18, 129.42, 130.77 (each d), 134.30, 135.01 (each s), 148.01, and 148.66 (each d); MS m/z (rel intensity, %) 167 (M^+, 21), 123 (49), 110 (71), 109 (base peak), 104 (21), 77 (54), 69 (50), 66 (24), 65 (86), 63 (22), 51 (91), 50 (41), 45 (85), and 39 (77). HRMS Found: m/z 167.0404. Calcd for C_8H_9NOS: M, 167.0399.

General Procedure for the Generation of Nitrile Oxide 3 from Oxime 2 and Its Cycloadditions with Olefins Leading to 6a—g. To a solution of oxime **2** (0.167 g, 1 mmol) and an olefin (1 to 5 mmol) in dichloromethane (20 ml) was added slowly an aqueous solution of soduim hypochlorite (5%, 4.47 g, 3 mmol) and triethylamine (0.01 g, 0.1 mmol). The mixture was stirred at room temperature for 4 to 5 h, poured into ice water (30 ml), and extracted with dichloromethane (20 ml×2). The combined extracts were dried over magnesium sulfate and evaporated in vacuo. The residue was chromatographed over silica gel by using hexane-ethyl acetate as an eluent to give cycloadduct **6**. The ratios of hexane-ethyl acetate employed are as follows: **6a**, **6c**, **6d**: 4:1 v/v; **6b**: 20:1 v/v; **6e**: 1:1 v/v; **6f**: 10:1 v/v; **6g**: 6:1 v/v. Yields of **6**, molar amounts of the olefin used, and reaction times are summarized in Table 2.

6a: Colorless needles (ethyl acetate-hexane); mp 129—130 °C; IR (KBr) 1700 and 1570 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=2.34 (3H, s, Me), 3.75 (1H, d, J=14.5 Hz, one of SCH_2), 4.63 (1H, d, J=14.5 Hz, the other of SCH_2), 5.29 (1H, d, J=9.5 Hz, 4-H), 5.29 (1H, d, J=9.5 H, 5-H), and 7.00—7.44 (9H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=21.24 (q, Me), 29.30 (t, SCH_2), 54.89 (d, 4-C), 79.59 (d, 5-C), 126.07, 127.77, 128.30, 129.54, 130.13, 130.78 (each d), 133.66, 139.60 (each s), 152.01 (s, 3-C), 170.30, and 171.48 (each s, C=O); MS m/z (rel intensity, %) 352 (M^+, 81), 187 (26), 162 (22), 146 (24), 133 (56), 132 (45), 130 (24), 109 (base peak), 104 (39), 91 (51), 78 (33), 77 (58), 69 (20), 65 (68), 52 (50), 51 (50), 45 (47), and 39 (34). Found: C, 64.66; H, 4.67; N, 8.12%. Calcd for $C_{19}H_{16}N_2O_3S$: C, 64.76; H, 4.58; N, 7.95%.

6b: Yellow oil; IR (neat) 1580 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=2.94 (1H, dd, J=8.3 and 17.0 Hz, one of 4-H), 3.37 (1H, dd, J=11.0 and 17.0 Hz, the other of 4-H), 3.67 (1H, d, J=14.7 Hz, one of SCH_2), 3.87 (1H, d, J=14.7 Hz, the other of SCH_2), 5.45 (1H, dd, J=8.3 and 11.0 Hz, 5-H), and 7.02—7.38 (10H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=30.76 (t, SCH_2), 43.55 (t, 4-C), 82.32 (d, 5-C), 125.88, 127.15, 128.17, 129.24, 130.33 (each d), 134.18, 141.02 (each s), and 155.83 (s, 3-C); MS m/z (rel intensity, %) 269 (M^+, 4), 125 (74), 109 (21), 97 (35), 76 (base peak), 51 (63), and 50 (25). HRMS Found: m/z 269.0875. Calcd for $C_{16}H_{15}NOS$: M, 269.0874.

6c: Yellow oil; IR (neat) 1740 and 1585 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=3.28 (2H, d, J=9.0 Hz, 4-H), 3.67 (3H, s, Me of COOMe), 3.77 (2H, s, SCH_2), 4.92 (1H, t, J=9.0 Hz, 5-H), and 7.13—7.40 (5H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=30.47 (t, SCH_2), 39.53 (t, 4-C), 52.71 (q, COOMe), 77.77 (d, 5-C), 127.36, 129.30, 130.42 (each d), 134.13 (s), 155.71 (s, 3-C), and 170.66 (s, C=O); MS m/z (rel intensity, %) 251 (M^+, 20), 123 (46), 109 (68), 77 (34), 69 (23), 65 (50), 59 (base peak), 54 (23), 51 (47), 44 (57), and 38 (36). HRMS Found: m/z 251.0617. Calcd for $C_{12}H_{13}NO_3S$: M, 251.0615.

6d: Yellow oil; IR (neat) 1720 and 580 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.04 (3H, s, Me), 3.18 (1H, d, J=11.0 Hz, one of 4-H), 3.20 (1H, d, J=7.2 Hz, the other of 4-H), 3.66 (1H, d, J=16.0 Hz, one of SCH_2), 3.84 (1H, d, J=16.0 Hz, the other of SCH_2), 4.75 (1H, dd, J=11.0 and 7.2 Hz, 5-H), and 7.12—7.39 (5H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=25.94 (q, Me), 30.47 (t, SCH_2), 37.94 (t, 4-C), 84.06 (d, 5-C), 127.42, 129.30, 130.60 (each d), 133.83 (s), 156.01 (s, 3-C), and 207.66 (s, C=O); MS m/z (rel intensity, %) 235 (M^+, 11), 123 (67), 109 (32), 77 (27), 65 (27), 51 (28), 45 (33), 43 (base peak), and 39 (20). HRMS Found: m/z 235.0665. Calcd for $C_{12}H_{13}NO_2S$: M, 235.0666.

6e: Yellow viscous oil; ^{1}H NMR ($CDCl_3$) δ=2.37 (1H, d, J=6.0 Hz, one of CH_2CN), 2.39 (1H, d, J=5.5 Hz, the other of CH_2CN), 2.84 (1H, dd, J=6.0 and 17.2 Hz, one of 4-H), 3.23 (1H, dd, J=10.0 and 17.4 Hz, the other of 4-H), 3.72 (1H, d, J=17.2 Hz, one of SCH_2), 3.86 (1H, ddd, J=6.0, 6.0, and 5.5 Hz, 5-H), and 7.14—7.43 (5H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=23.18 (t, CH_2CN), 30.53 (t, SCH_2), 40.47 (t, 4-C), 75.54 (d, 5-C), 116.36 (s, CN), 127.54, 129.48, 130.54 (each d), 133.95 (s), and 156.12 (s, 3-C); MS m/z (rel intensity, %) 232 (M^+, base peak), 164 (21), 163 (35), 162 (25), 130 (40), 123 (44), 109 (78), 77 (30), 65 (46), 54 (38), 51 (29), 45 (37), and 39 (28). HRMS Found: m/z 232.0666. Calcd for $C_{12}H_{12}N_2OS$: M, 232.0669.

6f: Colorless needles (ethyl acetate-hexane); mp 32—33 °C; IR (KBr) 1575 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.85 (3H, t, J=6.0 Hz, Me), 1.02—1.68 (8H, m, CH_2 of n-C_5H_{11}), 2.61 (1H, dd, J=8.2 and 7.0 Hz, one of 4-H), 3.02 (1H, dd, J=10.1 and 17.0 Hz, the other of 4-H), 3.67 (1H, d, J=14.5 Hz, one of SCH_2), 3.85 (1H, d, J=14.5 Hz, the other of SCH_2), 4.28—4.65 (1H, m, 5-H), and 7.10—7.42 (5H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=14.00 (q, Me), 22.47, 24.94, 31.00, 31.59, 35.00 (each t, CH_2 of n-C_5H_{11}), 40.41 (t, 4-C), 81.36 (d, 5-C), 127.01, 129.24, 130.07 (each d), 134.66 (s), and 155.71 (s, 3-C); MS m/z (rel intensity, %) 263 (M^+, 72), 192 (base peak), 130 (21), 123 (51), 110 (29), 109 (42), 77 (45), 64 (22), 56 (21), 55 (29), 44 (29), 40 (36), and 38 (20). Found: C, 68.35; H, 7.95; N, 5.24%. Calcd for $C_{15}H_{21}NOS$: C, 68.40; H, 8.04; N, 5.32%.

6g: Yellow oil; IR (neat) 1740 and 1580 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.96 (3H, s, Me), 2.96 (1H, dd, J=1.5 and 18.0 Hz, one of 4-H), 3.26 (1H, dd, J=6.2 and 18.0 Hz, the other of 4-H), 3.81 (2H, s, SCH_2), 6.55 (1H, dd, J=1.5 and 6.2 Hz, 5-H), and 7.14—7.43 (5H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=20.94

(q, Me), 30.59 (t, SCH_2), 41.83 (t, 4-C), 95.83 (d, 5-C), 127.60, 129.36, 130.83 (each d), 133.83 (s), 156.89 (s, 3-C), and 169.72 (s, C=O); MS *m/z* (rel intensity, %) 251 (M^+, 43), 163 (28), 123 (29), 109 (25), 45 (22), and 43 (base peak). HRMS Found: *m/z* 251.0610. Calcd for $C_{12}H_{13}NO_3S$: M, 251.0615.

General Procedure for the Cycloadditions of Nitrile Oxide 3 Generated from Oxime 2 with Acetylenes Leading to 7a—c. To a solution of oxime **2** (0.334 g, 2 mmol) and acetylene (3 mmol to 4 mmol) in dichloromethane (15 ml) was added slowly an aqueous solution of sodium hypochlorite (5%, 7.45 g, 5 mmol) and triethylamine (0.051 g, 0.5 mmol). The mixture was stirred at 50 °C for 4 h, poured into water (15 ml), and extracted with dichloromethane (20 ml×2). The combined extracts were dried over magnesium sulfate and evaporated in vacuo. The residue was chromatographed over silica gel by using hexane–ethyl acetate to give cycloadduct **7**. The ratios of hexane–ethyl acetate employed as eluents are as follows: **7a**: 50:1 v/v; **7b**: 2:1 v/v **7c**: 100:1 v/v. Yields of **7**, molar amounts of the acetylene used, and reaction times are summarized in Table 2.

7a: Colorless needles (diethyl ether–hexane); mp 39—40 °C; ^{1}H NMR ($CDCl_3$) δ=3.87 (3H, s, Me), 4.10 (2H, s, SCH_2), 6.86 (1H, s, 4-H), and 7.12—7.40 (5H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=29.00 (t, SCH_2), 52.89 (q, Me), 109.42 (d, 4-C), 127.48, 129.19, 130.48 (each d), 134.13 (s), 157.25 (s, C=O), 160.54 (s, 3-C), and 162.42 (s, 5-C); MS *m/z* (rel intensity, %) 249 (M^+, 60), 190 (base peak), 162 (22), 144 (34), 125 (26), 123 (52), 110 (22), 109 (80), 77 (69), 65 (38), 51 (50), 45 (59), and 39 (27). Found: C, 58.05; H, 4.76; N, 5.72%. Calcd for $C_{12}H_{11}NO_3S$: C, 57.82; H, 4.45; N, 5.62%.

7b: Yellow oil; ^{1}H NMR ($CDCl_3$) δ=3.58 (1H, br s, OH), 4.00 (2H, s, SCH_2), 4.56 (2H, s, CH_2OH), 6.14 (1H, s, 4-H), and 7.06—7.36 (5H, m, Ph) ^{13}C NMR ($CDCl_3$) δ=28.91 (t, SCH_2), 56.15 (t, CH_2OH), 101.76 (d, 4-C), 127.05, 129.24, 129.98 (each d), 134.77 (s), 161.57 (s, 3-C), and 172.41 (s, 5-C); MS *m/z* (rel intensity, %) 221 (M^+, 17), 190 (39), 162 (29), 144 (26), 130 (22), 123 (64), 109 (base peak), 77 (59), 69 (35), 65 (64), 53 (25), 52 (23), 51 (77), 50 (25), 45 (88), 39 (66), and 31 (69). HRMS Found: *m/z* 221.0508. Calcd for $C_{11}H_{11}NO_2S$: M, 221.0509.

7c: Pale yellow needles (diethyl ether–hexane); mp 47—48 °C; ^{1}H NMR ($CDCl_3$) δ=4.03 (2H, s, SCH_2), 4.47 (2H, s, CH_2Cl), 6.21 (1H, s, 4-H), and 7.10—7.39 (5H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=29.10 (t, SCH_2), 34.47 (t, CH_2Cl), 103.71 (d, 4-C), 127.29, 129.34, 130.27 (each d), 134.66 (s), 161.96 (s, 3-C), and 168.06 (s, 5-C); MS *m/z* (rel intensity, %) 241 (M^+ +2, 16), 239 (M^+, 37), 206 (20), 198 (27), 190 (33), 162 (39), 149 (26), 145 (20), 142 (28), 123 (31), 110 (21), 109 (base peak), 76 (68), 65 (37), 45 (37), 43 (25), and 39 (27). Found: C, 55.21; H, 4.34; N, 5.74%. Calcd for $C_{11}H_{10}NOSCl$: C, 55.11; H, 4.20; N, 5.84%.

General Procedure for the Cycloadditions of Nitrile Oxide 3 Generated from 2-Phenylthio-1-nitroethane 5. To a solution of the nitro compound **5** (1.5 g, 8.2 mmol) and triethylamine (0.10 g, 1.0 mmol) in dry benzene (5 ml) was added the solution of an olefin (16.4 mmol) and phenyl isocyanate (1.95 g, 6.4 mmol). The mixture was stirred at room temperature for 1 h, and then refluxed for 4 h. The insoluble material (*N,N'*-diphenylurea) was filtered off, and the filtrate was evaporated in vacuo. The residue was chromatographed over silica gel with hexane–ethyl acetate to give cycloadduct **6** or **7**. The ratios of hexane–ethyl acetate employed are as follows: **6b**, **6f**, **7c**: 20:1 v/v; **6c**: 4:1 v/v. Yields of **6** or **7**, molar amounts of the olefin or acetylene used, and reaction times are summarized in Table 2.

General Procedure for the Addition Reactions of 2-Isoxazoline 6b with Aldehydes Leading to 8a—d. To a solution of diisopropylamine (0.242 g, 2.4 mmol) in dry THF (25 ml) was added butyllithium (15% in hexane, 1.5 ml, 2.4 mol) at −78 °C under nitrogen. After 5 min, a solution of 2- isoxazoline **6b** (0.538 g, 2 mmol) in dry THF (15 ml) was added. After 0.5 h at −78 °C, an aldehyde (6 mmol) was added. The mixture was stirred at the same temperature for 1 h, poured into saturated aqueous ammonium chloride (50 ml), and extracted with dichloromethane (40 ml×2). The combined extracts were dried over magnesium sulfate and evaporated in vacuo. The residue was chromatographed over silica gel by using hexane–ethyl acetate (10:1 v/v) as an eluent to give adduct **8**. All the adducts **8** were mixtures of more than three diastereomers (^{13}C NMR). The results are summarized in Table 3.

8a: Yellow viscous oil; IR (neat) 3400 and 1575 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=2.64—3.50 (2H, m, 4-H), 3.70 (1H, br s, OH), 4.20—4.44 (1H, m, SCH), 4.81—5.08 (1H, m, CHOH), 5.11—5.44 (1H, m, 5-H), and 6.82—7.42 (15H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=43.30 (t, 4-C), 55.12, 55.36 (each d, SCH), 74.01, 74.42 (each d, CHOH), 81.89 (d, 5-C), 125.89, 126.54, 126.89, 127.07, 127.89, 128.13, 128.36, 128.54, 128.65, 129.24, 132.25, 132.54, (each d), 133.30, 133.48, 140.13, 140.60, 140.77 (each s), 157.01, 157.25, and 157.36 (each s, 3-C); MS *m/z* (rel intensity, %) 269 (M^+ −PhCHO), and 105 (22). Satisfactory elemental analysis was not available because of its instability.

8b: Yellow oil; IR (neat) 3400 and 1580 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.81—1.08 (3H, m, Me), 1.40—1.80 (2H, m, CH_2), 2.80—3.64 (3H, m, 4-H and OH), 3.64—3.96 (1H, m, CHOH), 3.96—4.26 (1H, m, SCH), 5.27—5.57 (1H, m, 5-H), and 6.94—7.47 (10H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=9.94 (q, Me), 27.59, 27.88, 28.18 (each t, CH_2), 43.00, 43.36 (each t, 4-C), 51.42, 51.77, 53.24, 53.47 (each d, SCH_2), 72.95, 73.12, 73.53, 73.65 (each d, CHOH), 125.95, 126.13, 127.71, 127.83, 128.25, 129.30, 132.07, 132.25 (each d), 133.19, 133.42, 133.71, 140.95, 141.07 (each s), 157.77, 157.89, and 158.19 (each s, 3-C); MS *m/z* (rel intensity, %) 327 (M^+, 5), 269 (base peak), and 77 (22). HRMS Found: *m/z* 327.1288. Calcd for $C_{19}H_{21}N_2OS$: M, 327.1292.

8c: Yellow oil; IR (neat) 3400 and 1580 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.91 (3H, t, *J*=7.0 Hz, Me), 2.15—2.77 (4H, m, CH_2), 2.80—3.64 (3H, m, 4-H, CHOH), 3.76—4.22 (2H, m, SCH and OH), 5.30—5.58 (1H, m, 5-H), and 6.95—7.47 (10H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=13.88 (q, Me), 18.88 (t, CH_2), 36.71, 37.00, 37.36, (each t, CH_2), 43.12, 43.24, 43.47 (each t, 4-C), 51.89, 52.18, 53.77, 54.00 (each d, SCH), 71.42, 71.59, 72.06 (each d, CHOH), 82.01 (d, 5-C), 125.95, 127.89, 128.25, 128.77, 129.36, 132.25 (each d), 133.13, 133.54, 133.71 (each s), 140.95, 141.07 (each s), 157.30, 157.72, 157.95, and 158.06 (each s, 3-C); MS *m/z* (rel intensity, %) 341 (M^+, 7), 269 (base peak), 126 (45), 111 (31), 110 (22), 78 (27), 77 (39), 51 (22), and 43 (30). HRMS Found: *m/z* 341.1447. Calcd for $C_{20}H_{23}NO_2S$: M, 341.1448.

8d: Yellow oil; IR (neat) 3400 and 1580 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.99 (6H, d, *J*=6.8 Hz, Me), 1.77—2.08 (1H, m, CH), 2.65 (1H, br s, OH), 2.90—3.77 (3H, m, 4-H, CHOH), 4.20—4.41 (1H, m, SCH), 5.47 (1H, dd, *J*=8.2 and 10.8 Hz, 5-H), and 6.97—7.44 (10H, m, Ph); ^{13}C NMR ($CDCl_3$)

δ=16.41, 17.24, 19.41, 19.94 (each q, Me), 31.36 (d, CH), 42.94, 43.30 (each t, 4-C), 49.94, 51.95 (each d, SCH), 76.48, 77.18 (each d, CHOH), 82.06 (d, 5-C), 126.01, 127.89, 128.18, 128.77, 129.36, 132.30 (each d), 133.07, 133.30, 141.13 (each s), 157.25, and 157.83 (each s, 3-C); MS *m/z* (rel intensity, %) 341 (M^+, 5), 269 (base peak), 126 (27), 111 (23), 77 (23), and 43 (23). HRMS Found: *m/z* 341.1444. Calcd for $C_{20}H_{23}NO_2S$: M, 341.1446.

General Procedure for the Michael Additions of 2-Isoxazoline 6b Leading to 9a,b. To a solution of diisopropylamine (0.121 g, 1.2 mmol) in dry THF (10 ml) was added butyllithium (15% in hexane, 0.75 ml, 1.20 mol) at −78 °C under nitrogen. After a solution of 2-isoxazoline **6b** (0.269 g, 1 mmol) in dry THF (10 ml) was added, stirring was continued at −78 °C for 0.5 h. An α,β-unsaturated ester (1.2 mmol) and HMPA (0.215 g, 1.2 mmol) were added. The mixture was stirred at the same temperature for 2 h, poured into saturated aqueous ammonium chloride (30 ml), and extracted with dichloromethane (40 ml×2). The combined extracts were dried over magnesium sulfate and evaporated in vacuo. The residue was chromatographed over silica gel by using the following eluent to give adduct **9**: **9a**: hexane-ethyl acetate (6:1 v/v); **9b**: chloroform. All the adducts **9** were mixtures of more than two diastereomers. The results are summarized in Table 3.

9a: Yellow oil; ^{1}H NMR ($CDCl_3$) δ=1.04—1.33 (3H, m, Me), 2.06—2.66 (3H, m, CH and CH_2), 2.72—3.81 (2H, m, 4-H), 3.51, 3.57 (3H, each s, CO_2Me), 3.94—4.18 (1H, m, SCH), 5.22—5.55 (1H, m, 5-H), and 6.80—7.46 (10H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=18.12 (q, Me), 32.41 (t), 38.71, 39.24 (each d, SCH), 42.12 (t, 4-C), 51.36, 51.47 (each q, CO_2Me), 81.77 (d, 5-C), 125.71, 127.36, 127.89, 128.48, 129.07, 130.01, 131.71 (each d), 133.36, 133.77, 140.60, 140.95 (each s), 157.42, 157.95 (each s, 3-C), 172.25, and 172.36 (each s, C=O); MS *m/z* (rel intensity, %) 369 (M^+, base peak), 260 (67), 228 (73), 129 (23), 115 (27), 113 (30), 109 (45), 105 (25), 104 (33), 103 (30), 91 (39), 78 (20), 77 (50), 65 (29), 55 (22), 51 (22), 38 (20), and 25 (21). HRMS Found: *m/z* 369.1400. Calcd for $C_{21}H_{23}NO_3S$: M, 369.1399.

9b: Yellow oil; ^{1}H NMR ($CDCl_3$) δ=2.53—3.79 (11H, m, 4-H, CH_2, CH, and CO_2Me), 4.16—4.44 (1H, m, SCH), 5.32—5.62 (1H, m, 5-H), and 6.94—7.47 (10H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=34.47 (t), 42.71, 43.30, 43.94, 47.94 (each d, SCH), 51.95, 52.36 (each q, CO_2Me), 82.30 (d, 5-C), 125.89, 128.30, 128.77, 129.42, 132.54, 132.83 (each d), 133.01, 140.77, 140.60 (each s), 156.18, 156.36 (each s, 3-C), 171.71, 171.89, 172.31, and 172.54 (each s, C=O); MS *m/z* (rel intensity, %) 413 (M^+, 37), 272 (29), 168 (22), 155 (21), 153 (20), 147 (28), 141 (29), 129 (23), 128 (43), 116 (20), 115 (42), 110 (21), 109 (base peak), 105 (36), 104 (49), 103 (33), 51 (43), and 40 (34). HRMS Found: *m/z* 413.1296. Calcd for $C_{22}H_{23}NO_5S$: M, 413.1296.

General Procedure for the Alkylations of 2-Isoxazoline 6b Leading to 10a—e. To a solution of diisopropylamine (0.121 g, 1.2 mmol) in dry THF (10 ml) was added butyllithium (15% in hexane, 0.75 ml, 1.2 mol) at −78 °C under nitrogen. A solution of 2-isoxazoline **6b** (0.269 g, 1 mmol) in dry THF (10 ml) was added. After stirring was continued for 0.5 h at −78 °C, an alkyl halide (1.2 to 3 mmol) and HMPA (1.2 mmol to 11.5 mmol) were added. The mixture was stirred at −78 °C for 2 h, poured into saturated aqueous ammonium chloride (30 ml), and extracted with dichloromethane (40 ml×2). The combined extracts were dried over magnesium sulfate and evaporated in vacuo. The residue was chromatographed over silica gel by using hexane-ethyl acetate as an eluent to give **10**. The ratios of hexane-ethyl acetate employed are as follows: **10a**: 6:1 v/v; **10b**, **10c**, and **10e**: 15:1 v/v; **10d**: 10:1 v/v. These adducts **10** were all mixtures of two diastereomers. The results are summarized in Table 3.

10a: Pale yellow oil; ^{1}H NMR ($CDCl_3$) δ=1.46, 1.47 (3H, each d, each J=7.0 Hz, Me), 2.95 (H, dd, J_{4-5}=8.5 and J=16.7 Hz, one of 4-H), 3.37 (1H, dd, J_{4-5}=11.0 and J=16.7 Hz, the other of 4-H), 4.14, 4.28 (1H, each q, J=7.0 Hz, SCH), 5.25—5.54 (1H, m, 5-H), and 6.87—7.40 (10H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=18.12, 18.35 (each q, Me), 40.00, 40.41 (each d, SCH), 41.30, 41.94 (each t, 4-C), 81.89, 82.06 (each d, 5-C), 125.83, 127.66, 127.83, 128.01, 128.18, 128.65, 129.13, 132.07, 132.30 (each d), 133.42, 140.95, 141.24 (each s), 159.01, and 159.42 (each s, 3-C); MS *m/z* (rel intensity, %) 283 (M^+, 63), 174 (base peak), 156 (34), 131 (44), 129 (71), 128 (31), 126 (20), 115 (20), 110 (34), 109 (43), 104 (28), 103 (32), 91 (28), and 77 (27). HRMS Found: *m/z* 283.0980. Calcd for $C_{17}H_{17}NOS$: M, 283.1030.

10b: Pale yellow oil; ^{1}H NMR ($CDCl_3$) δ=0.95, 1.02 (3H, each t, J=7.5 Hz, Me), 1.53—1.89 (2H, m, CH_2), 2.48—3.56 (2H, m, 4-H), 3.98, 4.08 (1H, each t, J=7.0 Hz, SCH), 5.37 (1/2H, dd, J_{5-4}=8.2 and 11.0 Hz, 5-H), 5.41 (1/2H, dd, J_{5-4}=8.0 and 11.0 Hz, 5-H), and 6.83—7.44 (10H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=11.82, 11.94 (each q, Me), 25.18, 25.35 (each t, CH_2), 41.06, 41.59 (each t, 4-C), 46.71, 47.12 (each d, SCH), 81.59 (d, 5-H), 125.60, 127.24, 127.42, 127.83, 127.95, 128.48, 128.60, 128.95, 131.66 (each d), 133.42, 133.60, 140.95, 141.13 (each s), 157.89, and 158.30 (each s,3-C); MS *m/z* (rel intensity, %) 297 (M^+, 4), 109 (base peak), and 77 (56). HRMS Found: *m/z* 297.1180. Calcd for $C_{18}H_{19}NOS$: M, 297.1186.

MS *m/z* (rel intensity, %) 325 (M^+, 22), 269 (38), 218 (27), 216 (base peak), 109 (32), 44 (43), 42 (35), and 40 (30). HRMS Found: *m/z* 325.1506. Calcd for $C_{20}H_{23}NOS$: M, 325.1499.

10d: Colorless prisms (diethyl ether); mp 110—111 °C; ^{1}H NMR ($CDCl_3$) δ=2.96 (1H, dd, J_{4-5}= 8.5 and J=17.0 Hz, one of 4-H), 3.34 (1H, dd, J_{4-5}= 10.8 and J=17.0 Hz, the other of 4-H), 3.10 (2H, d, J=8.0 Hz, CH_2), 4.41, 4.47 (1H, each t, J=8.0 Hz, SCH), 5.37 (1H, dd, J_{5-4}= 8.5 and 10.8 Hz, 5-H), and 6.84—7.38 (15H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=38.43, 38.57 (each t, CH_2), 41.80, 42.09 (each t, 4-C), 46.73, 46.87 (each d, SCH), 81.98 (d, 5-C), 125.93, 127.20, 127.73, 128.12, 128.76, 129.20, 132.23 (each d), 133.30, 137.50, 141.02 (each s), and 157.66 (s, 3-C); MS *m/z* (rel intensity, %) 359 (M^+, 7), 109 (22), 91 (base peak), 77 (39), 65 (32), 51 (22), and 39 (21). Found: C, 76.70; H, 5.83; N, 4.05%. Calcd for $C_{23}H_{21}NOS$: C, 76.85, H, 5.89; N, 3.90%.

10e: Pale yellow oil; ^{1}H NMR ($CDCl_3$) δ=2.34—2.62 (2H,

m, CH_2), 2.72—3.56 (2H, m, 4-H), 4.17, 4.24 (1H, each t, J=8.0 Hz, SCH), 4.84—6.01 (4H, m, 5-H, CH_2=CH), and 6.83—7.20 (10H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=36.24, 36.41 (each t), 41.41, 41.94 (each t, 4-C), 44.77, 45.12 (each d, SCH), 81.89, 82.01 (each d, 5-C), 118.18 (t,=CH_2), 125.83, 127.66, 127.83, 128.07, 128.65, 129.19, 132.13 (each d), 133.13 (s), 133.95 (d, =CH), 141.01, 141.13 (each s), 157.72, and 158.13 (each s, 3-C); MS m/z (rel intensity, %) 309 (M^+, 4), 129 (29), 128 (46), 115 (32), 109 (base peak), 105 (30), 104 (28), 103 (24), 91 (44), 77 (36), 76 (86), 69 (22), 65 (63), 53 (23), 51 (51), 41 (35), and 39 (49). HRMS Found: m/z 309.1179. Calcd for $C_{19}H_{19}NOS$: M, 309.1186.

Hydrolysis of 2-Isoxazoline-5-carboxylate 6c into 2-Isoxazoline-5-carboxylic Acid 11. To a solution of 2-isoxazoline **6a** (1 g, 4 mmol) in aqueous 2-methyl-2-propanol (50%, 20 ml) was added lithium hydroxide (monohydrate, 0.18 g, 4.2 mmol). The mixture was stirred at room temperature for 1 h, poured into water (20 ml), and washed with diethyl ether (20 ml). The pH of the aqueous layer was adjusted below 5 with 1 M hydrochloric acid, and the resulting water layer was extracted with dichloromethane (40 ml). The extract was dried over magnesium sulfate and evaporated in vacuo to give 2-isoxazoline-5-carboxylic acid **11** (0.92 g, 97%): Pale yellow solid; mp 72—73 °C; IR (KBr) 3000 and 1700 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=3.28 (1H, d, J_{4-5}=8.5 Hz, one of 4-H), 3.29 (1H, d, J_{4-5}=9.5 Hz, the other of 4-H), 3.73 (2H, s, SCH_2), 4.92 (1H, dd, J_{5-4}=8.5 and 9.5 Hz, 5-H), 7.01—7.38 (5H, m, Ph), and 9.19 (1H, s, CO_2H); ^{13}C NMR ($CDCl_3$) δ=30.47 (t, SCH_2), 39.83 (t, 4-C), 77.30 (d, 5-C), 127.66, 129.48, 130.83 (each d), 133.83 (s), 156.54 (s, 3-C), and 174.01 (s, C=O); MS m/z (rel intensity, %) 237 (M^+, 21), 192 (28), 164 (26), 130 (38), 123 (93), 109 (base peak), 76 (49), 69 (27), 65 (61), 54 (27), 51 (59), 50 (20), 45 (96), and 39 (46). Found: C, 55.46; H, 4.72; N, 5.86%. Calcd for $C_{11}H_{11}NO_3S$: C, 55.68; H, 4.67; N, 5.90%.

General Procedure for the Alkylations of 2-Isoxazoline-5-carboxylic Acid 11 Leading to 12a—c. To a solution of diisopropylamine (0.222 g, 2.2 mmol) in dry THF was added butyllithium (15% in hexane, 1.38 ml, 2.2 mmol) at −78°C under nitrogen. A solution of 2-isoxazoline **11** (0.237 g, 1 mmol) in dry THF (5 ml) was added. After 0.5 h at −78 °C, an alkyl iodide (1.2—2 mmol) and HMPA (2 ml, 11.5 mmol) were added, and the mixture was stirred for the time shown in Table 3. Saturated aqueous ammonium chloride (30 ml) was added, the mixture was acidified to pH 5 by adding 1 M hydrochloric acid, and extracted with dichloromethane (30 ml×2). The combined extracts were dried over magnesium sulfate and evaporated in vacuo. The residue was chromatographed over silica gel by using hexane–ethyl acetate containing acetic acid as an eluent to give **12**: The ratios of hexane–ethyl acetate–acetic acid employed are as follows: **12a**: 10:10:1 v/v **12b**: 50:10:3 v/v; **12c**: 15:5:1 v/v. All the alkylated 2-isoxazoline-5-carboxylic acids **12** were mixtures of two diastereomers. The results are summarized in Table 3.

12a: Yellow viscous oil; IR (neat) 2920, 1730, and 1580 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.48 (3H, d, J=7.0 Hz, Me), 3.35 (1H, d, J_{4-5}=8,6 Hz, one of 4-H), 3.37 (1H, d, J_{4-5}=9.0 Hz, the other of 4-H), 4.15 (1H, q, J=7.0 Hz, SCH), 4.91 (1/2H, t, J_{5-4}=8.6 Hz, 5-H), 4.96 (1/2H, J_{5-4}=9.0 Hz, 5-H), 7.12—7.44 (5H, m, Ph), and 8.32 (1H, br s, CO_2H); ^{13}C NMR ($CDCl_3$) δ=17.97, 18.36 (each q, Me), 38.04 (t, 4-C), 39.84, 40.48 (each d, SCH), 77.05 (d, 5-C), 128.22, 128.41, 129.34, (each d), 132.66 (s), 160.10 (s, 3-C), 173.83, and 173.97 (each s, C=O); MS m/z (rel intensity, %) 251 (M^+, 7), 177 (28), 150 (25), 111 (base peak), 110 (55), 66 (30), 43 (30), 41 (22), 39 (29), and 32 (21), HRMS Found: m/z 251.0605. Calcd for $C_{12}H_{13}NO_3S$: M, 251.0613.

12b: Pale yellow viscous oil; IR (neat) 3000, 1730, and 1580 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.02, 1.04 (3H, each t, J=7.2 Hz, Me), 1.61—1.99 (2H, m, CH_2), 3.21—3.45 (2H, m, 4-H), 3.99 (1/2H, dd, J_{5-4}=7.0 and 10.5 Hz, 5-H), 4.98 (1/2H, dd, J_{5-4}=6.6 and 10.8 Hz, 5-H), 7.09—7.43 (5H, m, Ph), and 9.81 (1H, br s, CO_2H); ^{13}C NMR ($CDCl_3$) δ=12.00 (q, Me), 25.24, 25.65 (each t, CH_2), 37.71, 37.83, (each t, 4-C), 46.65, 47.42 (each d, SCH), 76.83, 77.01 (d, 5-C), 127.89, 128.25, 129.30, 132.07, 132.95 (each d), 133.19 (s), 159.18, 159.36 (each s, 3-C), and 174.48 (s, C=O); MS m/z (rel intensity, %) 265 (M^+, 31), 156 (34), 110 (58), 109 (39), 65 (20), and 41 (base peak). 12c: Pale yellow oil; IR (neat) 3000, 1730, and 1580 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.89 (3H, t, J=7.0 Hz, Me), 1.09—1.94 (8H, m, CH_2), 3.04—3.63 (2H, m, 4-H), 3.95—4.22 (1H, m, SCH), 4.77—5.09 (1H, m, 5-H), 7.08—7.44 (5H, m, Ph), and 10.24 (1H, br s, CO_2H); ^{13}C NMR ($CDCl_3$) δ=13.94 (q, Me), 22.35, 27.00, 31.24, 31.77, 32.12 (each t, CH_2), 37.71 (t, 4-C), 44.94, 45.71 (each d, SCH), 76.83, 77.01 (each d, 5-C), 127.89, 128.25, 129.30, 132.07, 132.95 (each d), 133.24 (s, 1-C of Ph), 159.48 (s, 3-C), and 174.60 (s, C=O); MS m/z (rel intensity, %) 307 (M^+, 17), 198 (45), 135 (24), 123 (30), 110 (59), 109 (86), 91 (21), 77 (27), 65 (43), 56 (95), 52 (22), 46 (24), 42 (31), 41 (base peak), and 39 (47). HRMS Found: m/z 307.1242. Calcd for $C_{16}H_{21}NO_3S$: M, 307.1241.

Alkylation of 2-Isoxazoline-5-carboxylic Acid 11 with 7-Iodo-2-heptanone Ethylene Acetal Leading to 12d. To a solution of LDA prepared from diisopropylamine (0.355 g, 3.51 mmol) and butyllithium (15% in hexane, 2.2 ml, 3.51 mmol) in dry THF (21 ml) was added 2-isoxazoline-5-carboxylic acid **11** (0.379 g, 1.67 mmol) in dry THF (12 ml) at −78 °C under nitrogen. After 0.5 h, 7-iodo-2-heptanone ethylene acetal (0.951 g, 3.35 mmol) and HMPA (3.3 ml, 19.0 mmol) were added. The mixture was stirred at −78 °C for 48 h and poured into saturated aqueous ammonium chloride (50 ml). After acidified to pH 1 by adding diluted sulfuric acid (10%), the mixture was extracted with dichloromethane (50 ml×3). The combined dichloromethane extracts were washed with water, dried over magnesium sulfate, and evaporated in vacuo. The residue was chromatographed over silica gel with hexane–ethyl acetate–acetic acid (10:10:1 v/v) to give isoxazoline **12d** (0.202 g, 35%) and **11** (0.067 g, 17%).

12d: Pale yellow viscous oil; ^{1}H NMR ($CDCl_3$) δ=1.19—2.00 (8H, m, CH_2), 2.12 (3H, s, Me), 2.44 (2H, t, J=6.8 Hz, CH_2CO), 3.10—3.64 (2H, m, 4-H), 4.06 (1H, t, J=7.5 Hz, SCH), 4.84—5.14 (1H, m, 5-H), 7.16—7.30 (5H, m, Ph), and 8.62 (1H, s, CO_2H); MS m/z (rel intensity, %) 349 (M^+, 19), 137 (21), 123 (23), 110 (46), 109 (36), and 52 (base peak). HRMS Found: m/z 349.1321. Calcd for $C_{18}H_{23}O_4NS$: M, 349.1346.

General Procedure for the Dialkylations of 2-Isoxazoline 6b Leading to 13a—c. To a solution of diisopropylamine (0.242 g, 2.4 mmol) in dry THF (10 ml) was added butyllithium (15% in hexane, 1.5 ml, 2.4 mol) at −78 °C under nitrogen. A solution of 2-isoxazoline **6b** (0.269 g, 1 mmol) in dry THF (10 ml) was added at −78 °C. After

0.5 h, an α,ω-dibromoalkane (2 to 4 mmol) and HMPA (2 ml, 11.5 mmol) were added. The mixture was stirred at −78 °C for 2 h, poured into saturated aqueous ammonium chloride (30 ml), and extracted with dichloromethane (40 ml×2). The combined extracts were dried over magnesium sulfate and evaporated in vacuo. The residue was subjected to column chromatography over silica gel by using hexane-ethyl acetate as an eluent to give **13**. The ratios of hexane-ethyl acetate employed are as follows: **13a** and **13c**: 10:1 v/v; **13b**: 15:1 v/v. The results are summarized in Table 3.

13a: Pale yellow oil; ^{1}H NMR ($CDCl_3$) δ=1.16—1.43, 1.45—1.69 (4H, m, CH_2CH_2), 3.06 (1H, dd, $J_{4\text{-}5}$=8.0 and J=17.5 Hz, one of 4-H), 3.49 (1H, dd, $J_{4\text{-}5}$=10.8 and J=17.5 Hz, the other of 4-H), 5.47 (1H, dd, $J_{5\text{-}4}$=8.0 and 10.8 Hz, 5-H), and 6.83—7.52 (10H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=17.24, 17.63 (each t), 21.97 (s, q-C), 44.48 (t, 4-C), 82.86 (d, 5-C), 125.83, 125.98, 126.12, 127.68, 128.17, 128.76, 129.15, 129.34, 132.81 (each d), 136.18, 141.06 (each s), and 160.88 (s, 3-C); MS m/z (rel intensity, %) 295 (M^+, 89), 278 (49), 218 (47), 189 (28), 188 (72), 169 (29), 168 (64), 156 (37), 149 (22), 147 (23), 141 (27), 128 (37), 117 (24), 116 (22), 115 (60), 110 (45), 109 (base peak), 105 (39), 104 (41), 103 (29), 91 (58), 78 (31), 77 (90), 69 (23), 65 (54), 51 (50), 45 (21), 43 (39), and 39 (33). HRMS Found: m/z 295.1027. Calcd for $C_{18}H_{17}NOS$: M, 295.1030.

13b: Pale yellow oil; ^{1}H NMR ($CDCl_3$) δ=1.44—2.24 (8H, m, CH_2), 3.12 (1H, dd, $J_{4\text{-}5}$=8.5 and J=16.7 Hz, one of 4-H), 3.54 (1H, dd, $J_{4\text{-}5}$=10.8 and J=16.7 Hz, the other of 4-H), 5.51 (1H, dd, $J_{5\text{-}4}$=8.5 and 10.8 Hz, 5-H), and 6.94—7.38 (10H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=23.41, 36.65, 36.88 (each t, CH_2), 43.41 (t, 4-C), 58.12 (s, q-C), 82.18 (d, 5-C), 125.77, 128.01, 128.72, 128.89, 134.60 (each d), 132.72, 141.24 (each s), and 161.25 (s, 3-C); MS m/z (rel intensity, %) 323 (M^+, 6), and 214 (base peak). HRMS Found: m/z 323.1345. Calcd for $C_{20}H_{21}NOS$: M, 323.1345.

13c: Pale yellow oil; ^{1}H NMR ($CDCl_3$) δ−1.17—2.12(10H, m, CH_2), 3.10 (1H, dd, $J_{4\text{-}5}$=8.5 and J=16.5 Hz, one of 4-H), 3.53 (1H, dd, $J_{4\text{-}5}$=11.0 and J=16.5 Hz, the other of 4-H), 5.51 (1H, dd, $J_{5\text{-}4}$=8.5 and 11.0 Hz, 5-H), and 7.21—7.27 (10H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=22.65, 25.47, 35.00, (each t, CH_2), 42.47 (t, 4-C), 52.53 (s, q-C), 81.77 (d, 5-C), 125.89, 128.06, 128.77, 129.18, 136.54 (each d), 130.65, 141.30 (each s), and 160.54 (s, 3-C); MS m/z (rel intensity, %) 337 (M^+, 2), 228 (78), 115 (23), 110 (22), 109 (base peak), 104 (28), 91 (36), 81 (30), 79 (28), 78 (27), 77 (57), 65 (54), 53 (21), 51 (34), 41 (33), and 39 (44). HRMS Found: m/z 337.1512. Calcd for $C_{21}H_{23}NOS$: M, 337.1491.

General Procedure for the Raney Ni Hydrogenolysis of 2-Isoxazolines 8, 10, and 13 Leading to 14. To a solution of 2-isoxazoline **8**, **10**, or **13** (0.809 mmol) in aqueous ethanol (17%, 9.8 ml) were added boric acid (0.25 g, 4.045 mmol) and Raney Ni (W-2, 0.4 ml, 0.8 ml suspension in ethanol). Air in the reaction flask was replaced with hydrogen gas by repeated (5 times) evacuation and flushing with hydrogen. The mixture was stirred under hydrogen at room temperature. Insoluble materials were removed off by filtration through Celite 545. To the filtrate was added water (100 ml) and the organic layer was extracted with dichloromethane (100 ml×3). The combined extracts were dried over magnesium sulfate and evaporated in vacuo to give **14**. Reaction times, yields of **14**, and purification methods are as follows: **14a**: 16 h, 97%, silica-gel chromatography with hexane-diethyl ether (3:2 v/v) **14b**: 13 h, 76%, silica-gel chromatography with hexane-diethyl ether (2:1 v/v); **14c**: 18.5 h, 56%, silica-gel chromatography with dichloroethane; **14d**: 14.5 h, 91%, silica-gel chromatography with hexane-diethyl ether (3:1 v/v); **14e**: 16 h, 91%, silica-gel chromatography with hexane-diethyl ether (3:1 v/v).

14a: (a 1:1 mixture of two diastereomers (by ^{13}C NMR)): Colorless viscous oil; IR (neat) 3400 and 1700 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.95 (3H, t, J=7.0 Hz, Et), 1.27—1.68 (2H, m, Et), 2.50—3.10 (4H, m, $COCH_2$), 3.98 (2H, m, OH), 5.16 (2H, dd, J=4.0 and 9.0 Hz, CHOH), and 7.16—7.40 (5H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=9.79 (Me), 29.52, 29.56 (Et), 49.93, 49.99, 52.11, 52.37, ($COCH_2$), 68.93, 69.16, 69.83, 69.99 (CHOH), 125.65, 127.67, 128.53, 143.02, 143.06, 211.27 (CO), and 211.44 (CO); MS m/z (rel intensity, %) 232 (M^+, 64), 149 (base peak), 107 (81), 104 (32), 83 (50), 79 (39), 77 (37), 55 (37), and 41 (25). HRMS Found: m/z 222.1255. Calcd for $C_{13}H_{18}O_3$: M, 222.1255.

14b: (a 1:1 mixture of two diastereomers (by ^{13}C NMR)): Pale yellow viscous oil; IR (neat) 3400 and 1700 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.76—1.02 (3H, m, n-Pr), 1.12—1.70 (4H, m, n-Pr), 2.31—3.07 (4H, m, $COCH_2$), 4.00 (2H, br s, OH), 5.02—5.22 (2H, m, CHOH), and 7.12—7.40 (5H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=13.86 (Me), 18.48 (CH_2), 38.72 (CH_2), 50.12, 51.12, 52.06, 52.35 ($COCH_2$), 67.15, 67.33, 69.55, 69.72 (CHOH), 125.54, 127.35, 128.23, 143.21, 210.72 (CO), and 210.90 (CO); MS m/z (rel intensity, %) 236 (M^+, 16), 162 (23), 120 (64), 107 (base peak), 106 (25), 105 (85), 104 (35), 78 (45), 76 (38), 73 (20), 58 (33), 55 (34), and 42 (42). HRMS Found: m/z 236.1414. Calcd for $C_{14}H_{20}O_3$: M, 236.1411.

14c: Colorless viscous oil; IR (neat) 3440 and 1720 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=2.52—3.06 (6H, m, CH_2), 3.26 (1H, br s, OH), 5.14 (1H, dd, J=5.0 and 7.5 Hz, CHOH), and 7.04—7.40 (10H, m, Ph); MS m/z (rel intensity, %) 254 (M^+, 23), 236 (53), 229 (39), 149 (20), 145 (21), 135 (23), 131 (22), 121 (44), 107 (65), 105 (80), 104 (99), 91 (base peak), 79 (56), and 77 (53). Found: C, 80.07; H, 7.12%. Calcd for $C_{17}H_{18}O_2$: C, 80.28; H, 7.13%.

14d: Pale yellow viscous oil; IR (neat) 3440 and 1700 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.40—1.92 (8H, m, cyclopentyl), 2.65—3.03 (3H, m, $CHCOCH_2$), 3.56 (1H, br s, OH), 5.09 (1H, dd, J=5.0 and 7.0 Hz, CHOH), and 7.12—7.38 (5H, m, Ph); MS m/z (rel intensity, %) 218 (M^+, 13), 149 (33), 107 (65), 105 (23), 104 (40), 103 (22), 79 (base peak), 78 (29), 77 (98), 71 (22), 69 (69), 51 (33), 43 (25), 41 (87), and 39 (42). HRMS Found: m/z 218.1303. Calcd for $C_{14}H_{18}O_2$: M, 218.1306.

14e: Colorless viscous oil; IR (neat) 3440 and 1700 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.04—2.00 (10H, m, cyclohexyl) 2.12—2.50 (1H, m, cyclohexyl), 2.76 (1H, dd, J=17.0 and 5.5 Hz, one of $COCH_2$), 2.92 (1H, dd, J=17.0 and 7.0 Hz, the other of $COCH_2$), 3.60 (1H, br s, OH), 5.11 (1H, dd, J=7.0 and 5.5 Hz, CHOH), and 7.18—7.40 (5H, m, Ph); MS m/z (rel intensity, %) 222 (M^+, 20), 204 (30), 120 (58), 107 (base peak), 106 (26), 105 (70), 104 (25), 79 (58), 78 (26), 77 (51), 59 (32), 58 (38), and 43 (45). HRMS Found: m/z 232.1464. Calcd for $C_{15}H_{20}O_2$: M, 232.1462.

The present work was financially supported in part by a Grant-in-Aid for Scientific Research (No. 61470095) from the Ministry of Education, Science and Culture.

Interaction of Poly[*N*-(3-aminopropyl)glycine] and Its Derivatives with Lipid Membrane

Yoshiko YAGI, Shunsaku KIMURA, and Yukio IMANISHI*
Department of Polymer Chemistry, Kyoto University,
Yoshida Honmachi, Sakyo-ku, Kyoto 606
(Received November 14, 1987)

Poly[*N*-(3-aminopropyl)glycine] (PolyNAPGly, **5**) and its derivatives were synthesized as model peptides of the membrane-bound enzymes, and investigated on their interactions with lipid membrane. PolyNAPGly (**5**) was shown to be distributed to dipalmitoylphosphatidyl choline bilayer membrane without destruction of the vesicle structure. Dodecyl groups were introduced to the side chains of PolyNAPGly (**5**), and found to facilitate binding of the polymer to lipid membrane. However, the introduction of the excess amount of hydrophobic groups to PolyNAPGly (**5**) caused the formation of polymer micelles, and the addition of such polymers to lipid vesicles destroyed the membrane structure. The derivative of PolyNAPGly (**5**) (n=35) bearing one or two dodecyl groups and some N^{ε}-benzyloxycarbonylhistidyl groups was found to be bound tightly to lipid membrane without destruction of the membrane structure. The addition of these polypeptides to vesicles decreased the membrane fluidity.

The significance of the membrane-bound enzymes in cell physiology is well recognized. For example, in the case of signal transduction through cell membrane, binding of a hormone to its receptor on the cell membrane induces the activation of phospholipase C to break down phosphatidylinositol to yield diacylglyceride, which is known to trigger the activation of protein kinase C in the presence of Ca^{2+} ion. The well-known protein kinase C is a cytosolic enzyme, but associated with lipid membrane in cooperation with Ca^{2+} and diacylglycerol.[1] Under these conditions, it is activated for phosphorylation of proteins, which is the key step for the regulation of the protein function.[2] Another instance of membrane-bound enzyme in relation to the signal transduction is the hormone-sensitive adenylate cyclase, activated by binding of a hormone to the receptor through GTP-binding protein.[3] These functions of membrane-bound enzymes must be deeply dependent on the nature of membrane environments.[4]

Peptide hormones have also been shown to interact specifically with lipid membrane, and their physiological activities have been discussed in terms of their conformation and orientation in lipid membrane. For example, Kaiser and Kezdy have succeeded in synthesizing biologically active peptides which possess a sequence designed to take a specific secondary structure.[5] Furthermore, Schwyzer has shown that the mode of interaction of opioid peptides with lipid membrane can be correlated with the receptor subtype selection.[6] These reports emphasize the significance of amphiphilic structures of peptides in their interactions with lipid membrane. In the present investigation, we aimed at the elucidation of fundamental aspects of interactions between enzymes and lipid membrane using enzyme-model polypeptides.

Various kinds of polymer models of enzymes have been investigated in a homogeneous solution. Kiefer et al. synthesized branched poly(ethyleneimine)s containing nucleophilic catalytic and hydrophobic groups, and observed that they efficiently hydrolyzed hydrophobic esters.[7] The flexibility of polymer structures was suggested as one of the key factors of catalytic efficacy. Overberger and his coworkers have reported on efficient solvolytic activity of poly(*N*-vinylimidazole) and copolymers.[8] However, application of such polymers to a membrane system has not been reported, probably because they were not distributed well to lipid membrane or because they collapsed membrane structures.

The interactions of cationic polymers with lipid membrane has been studied on poly(lysine).[9,10] Poly(lysine) did not interact with a neutral lipid membrane, but was distributed into a negatively charged membrane due to electrostatic and hydrophobic interactions. The solution conformation and the chirality of the polypeptide affect the mechanism of the interactions.

We chose poly[*N*-(3-aminopropyl)glycine] (PolyNAPGly) as a starting polypeptide and its derivatives were prepared by the reaction of amino groups in side chains. These polymers are characterized by flexible chains for the *N*-substituted amide linkages: lack of amide protons to form a hydrogen bond and cis/trans isomerization around the amide bond.[11] This flexibility would be favorable for the polymers to be partitioned into lipid membrane and to function as a catalyst by a conformational adjustment at membrane surface.

N^{ε}-Benzyloxycarbonylhistidyl (ZHis) and dodecyl groups were introduced into the polymers as a nucleophilic catalytic moiety and as an anchor to lipid membrane, respectively, and the interactions of these polymers with lipid membrane were investigated. Perturbation of lipid membrane is represented by the change in membrane fluidity and by the leakage of carboxyfluorescein (CF) entrapped in the vesicle. Perturbation is discriminated from destruction of vesicle structure.

Experimental

Synthesis. Synthetic scheme of the polymer is shown in Fig. 1.

***N*-(3-Aminopropyl)glycine (1)**: Bromoacetic acid (3.5 g) in ethanol was added dropwise to 1,3-propanediamine (18.5 g) in ethanol. After refluxing for 72 h, ethanol was evaporated, and 5 M NaOH (25 ml; 1 M=1 mol dm^{-3}) was added and evaporated. The water addition/evaporation was repeated, and the residue was dissolved in ether/water, and evaporated. The obtained oil was used for the next step without further purifications.

***N*-Benzyloxycarbonyl-*N*-[3-(benzyloxycarbonylamino)-propyl]glycine (2)**: Benzyloxycarbonyl chloride (0.1 M) was added to 2.5 M NaOH aqueous solution (40 ml) of *N*-(3-aminopropyl)glycine at 0 °C under a vigorous stirring. After stirring for 24 h at room temperature, the aqueous phase was washed with ether and acidified with HCl, and extracted with ethyl acetate. The ethyl acetate solution was washed with water and dried over Na_2SO_4. After eluting on silica gel with chloroform/methanol/acetic acid (95/5/3 v/v) as an eluant, the oil was crystallized from ether/ethanol, yield 4.2 g (42%); mp 96—98 °C. Found: C, 62.88 ; H, 6.07; N, 7.09%. Calcd for $C_{21}H_{24}N_2O_6$: C, 62.99; H, 6.04; N, 6.96%.

Poly[*N*-[3-(benzyloxycarbonylamino)propyl]glycine] (4): Compound **2** (8.5 g) was reacted with thionyl chloride (10 ml) at 60 °C for 20 min. The solution was added into hexane (200 ml). The obtained white precipitate was recrystallized from benzene, yield 3.4 g (56%); mp 86—87 °C. The purified *N*-carboxy anhydride (NCA) (**3**) was polymerized in dichloromethane (40 ml) using hexylamine as an initiator (25.9 mg). After 70 h, the solution was added into ether (200 ml) to precipitate the product. The obtained polymer was reprecipitated from acetone. The degree of polymerization of the polymer was estimated to be 35 by vapor-pressure osmometry.

Poly[*N*-(3-aminopropyl)glycine] (PolyNAPGly) (5): Compound **4** (0.5 g) in acetic acid (20 ml) was treated with 3 M HBr/acetic acid (2 ml) at room temperature for 1 h. The solution was added into ether to precipitate the product. The white solid obtained was purified by dialysis (Spectrapore 1000, Ieda Inc.), yield 106 mg (30%).

Poly[*N*-[3-(dodecylamino)propyl]glycine] (Poly(C_{12})$_n$-NAPGly) (6,7): PolyNAPGly(**5**) (0.1 g) in dimethyl sulfoxide (2 ml) was reacted with dodecyl iodide (15.2 mg, in the case of n=1) in the presence of lutidine (1 ml) under a nitrogen atmosphere at 60 °C for 60 h. The solution was added to acetic acid/ether (1/4 v/v), and the obtained solid was purified by dialysis, yield 24 mg (25%). It was shown by NMR measurement that dodecyl groups were introduced on 2.8% of amino groups in the polymer.

Poly[*N*-[3-[[N^{α}-(benzyloxycarbonyl)histidyl]amino]propyl]-glycine] (PolyZHis$_n$NAPGly) (8,9): A solution of PolyNAPGly (50 mg) in dimethyl sulfoxide (2 ml) was reacted overnight with $N^{\alpha,im}$-bis(benzyloxycarbonyl)histidine *p*-nitrophenyl ester (15.8 mg, in the case of n=4) in the presence of triethylamine (100 ml) under a nitrogen atmosphere at 30 °C. Then the solution was added to ether (100 ml). The obtained oil was dissolved in *N*,*N*-dimethylformamide (2 ml), and pH was adjusted to 9 with 2 M NaOH. After standing for 30 min for deblocking the protected imidazolyl group, the solution was acidified by acetic acid, and added to ether. The obtained polymer was purified by dialysis, yield 12.5 mg (20%). Histidyl groups were introduced on 12.5% of total amino groups in the polymer.

Preparation of Small Unilamellar Vesicles (SUV). The lipid dispersion in a buffer (2-[4-(2-hydroxyethyl-1-piperazyl]ethanesulfonic acid (HEPES) (pH 7.2) or tris(hydroxymethyl)aminomethane (Tris) (pH 9.0) (10 mM), NaCl (0.1 M), and EDTA (0.1 mM)) was sonicated under a nitrogen atmosphere above the phase transition temperature for 20 min using a probe type of ultrasonic disruptor (TOMY SEIKO Co., Ltd., Japan) at the power of range 3, and ultracentrifuged at 100000 g to remove aggregates other than small unilamellar vesicles[12] and any titanium from the probe.[13] Vesicles, in which CF was trapped, were prepared according to the method reported by Barbet et al.[12]

Lipid concentration was determined by the method reported by Raheja et al.[14]

Measurements. Fluorescence measurements were carried out on a Hitachi MPF-4 fluorescence spectrophotometer. Fluorescence depolarization was measured by a modified MPF-4 apparatus installed with a fixed polarizer at the monitor side and a rotating polarizer at the excitation side which is driven by a stepping motor to 0° or 90° with respect to another polarizer. A depolarizer was set in front of the polarizer at the excitation side. At each position of the rotating polarizer, four data points were measured, processed by microcomputer, and averaged out. One polarization value was obtained at every 30 s. Excitation wavelengths of 8-anilino-1-naphthalenesulfonoic acid (ANS), 1,6-diphenyl-1,3,5-hexatriene (DPH), and CF were 380, 360, and 490 nm, respectively.

The concentration of polymer is represented in terms of the peptide residue unit.

Results

Derivatives of PolyNAPGly (5). PolyNAPGly (**5**) derivatives carrying one and two dodecyl groups in a polymer chain are represented as PolyC_{12}-NAPGly(**6**) and Poly(C_{12})$_2$-NAPGly (**7**), respectively. Other derivatives are PolyZHis$_4$-NAPGly (**8**), PolyZHis$_5$-NAPGly (**9**), and PolyC_{12}ZHis$_3$-NAPGly (**10**), which contain in a polymer chain four ZHis groups, five ZHis groups, and one dodecyl and three ZHis groups, respectively (Fig. 1). These derivatives were purified by dialysis to eliminate contamination by low molecular weight compounds.

CF Leakage from Vesicles by Polymer Addition. CF leakage from vesicles induced by the addition of the polymers represents perturbation to the membrane structure.[12] Figure 2 shows the time course of the CF leakage from dipalmitoylphosphatidyl choline (DPPC) vesicles induced by the addition of the polymers above the phase transition temperature of DPPC membranes. The addition of PolyNAPGly (**5**) and PolyZHis$_5$-NAPGly (**9**) did not increase the leakage so much, but the addition of Poly(C_{12})$_2$-NAPGly (**7**) and PolyC_{12}-ZHis$_3$-NAPGly (**10**) increased the CF leakage. Therefore, the polymers are tightly bound to the lipid

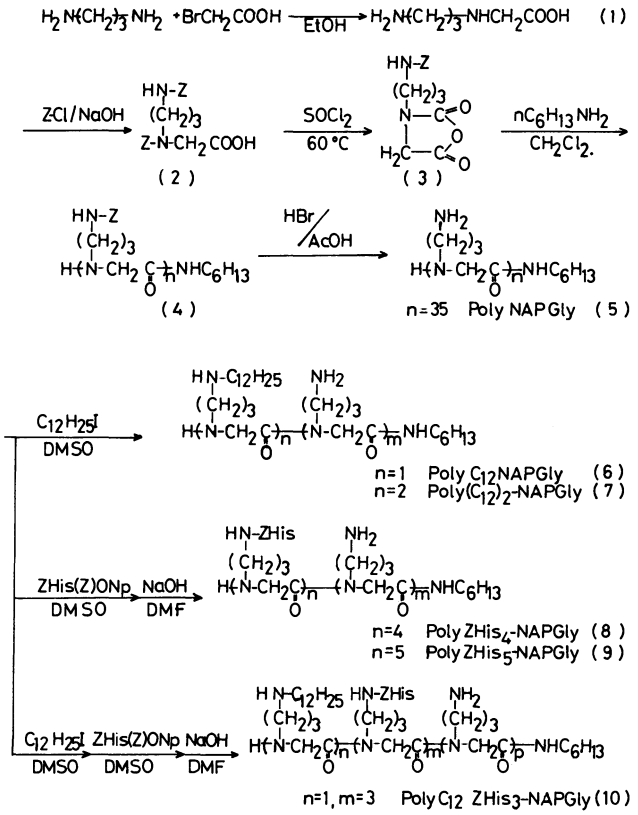

Fig. 1. Synthetic scheme of PolyNAPGly and its derivatives.

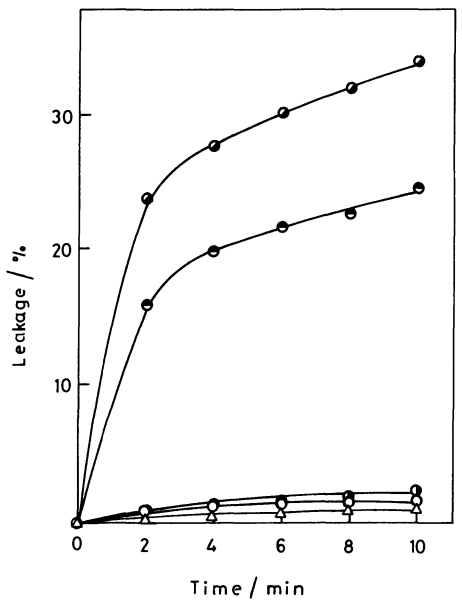

Fig. 2. Time course of CF leakage from DPPC vesicles by the addition of polymers at 46°C and at pH 9.0. DPPC lipid, 17 μM; polymer, 3.2 μM. △, Buffer; ○, PolyNAPGly (**5**); ◓, Poly(C_{12})$_2$-NAPGly (**7**); ◑, PolyZHis$_5$-NAPGly (**9**); ◕, Poly-C_{12}ZHis$_3$-NAPGly (**10**).

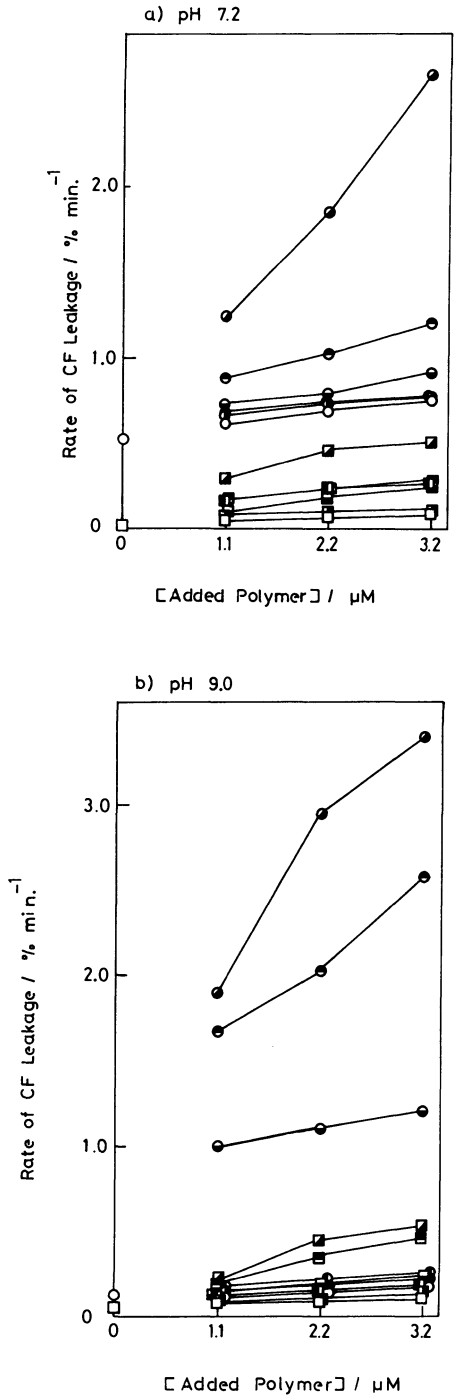

Fig. 3. The dependence of CF leakage from DPPC vesicles on the concentration of added polymers. The rate of CF leakage was determined at 10 min after the polymer addition. membrane by the action of the dodecyl groups as anchoring groups.

Dependence of CF Leakage on pH, Temperature, and Amount of Added Polymer. The rate of CF leakage from DPPC vesicles was determined at 10 min after the polymer addition. Figure 3 shows the rates of CF leakage at different pH values, temperatures, and concentrations of added polymers. The rate of CF leakage at pH 9.0 was larger than that at pH 7.2, while it is considered that distribution to and permeation across lipid membrane of CF are more difficult at pH 9.0 than at pH 7.2 because of its pK_a values of 4.5 and 6.3.[12] The rate of CF leakage was small at 33 °C, which is lower than the phase transition temperature. However, it was enhanced at 46 °C, which is higher than the phase transition temperature. The higher the hydrophobicity of the polymer is, the more the CF leakage was enhanced. In the case of less hydrophobic polymer, the CF leakage was not increased so much with increasing concentration of added polymers. This indicates weak interactions of these polymers with bilayer membranes and a small number of binding sites in the lipid membranes for these polymers. On the other hand, the CF leakage induced by the addition of Poly(C_{12})$_2$-NAPGly (**7**) and PolyC_{12}-ZHis$_3$-NAPGly (**10**) increased with an increase in the concentration of added polymers, indicating a strong binding of these polymers to the membrane.

The Change in Membrane Fluidity upon the Polymer Addition. The change in membrane fluidity induced by the addition of a polymer was investigated by measuring fluorescence depolarization of ANS and DPH in the membrane (Fig. 4). The fluorescent probes, ANS and DPH, reflect the fluidity of the surface region and the hydrophobic domain of lipid membrane, respectively. Figure 5 shows the relative change in fluorescent polarization induced by the polymer addition. It was found that the addition of every polymer increases the polarization, that is, it decreases the membrane fluidity. Poly(C_{12})$_2$-NAPGly (**7**) and PolyC_{12}ZHis$_3$-NAPGly (**10**) were shown to effectively decrease the membrane fluidity below the phase transition temperature.

Discussion

Dissolution of the polymers into lipid bilayer membrane without a serious destruction of the membrane structure is indispensable for polymers to be a model compound of membrane-bound enzymes. PolyNAPGly (**5**) was expected to satisfy the conditions as follows. i) A propyl group should act as an anchor group for the polypeptide to be bound to membrane. ii) The backbone of the polypeptide is flexible due to *N*-substituted amide bonds, hence the polypeptide easily fits to the membrane surface. iii) PolyNAPGly (**5**) is difficult to go deeply into the membrane, because it is positively charged at the neutral pH and the lack of amide protons makes carbonyl groups unshielded from solvents. Taking these points into consideration, it is suggested that the polypeptides tend to be incorporated into the membrane surface compartment.

The synthetic polymers are soluble in water. The molecular structures of these polymers are composed of hydrophilic and hydrophobic regions. However, they were designed not to form a polymer micelle by avoiding the introduction of hydrophobic substituents excessively to the polymer. The absence of micelle formation was confirmed by a hydrophobic fluorescent probe, ANS.[15,16] The derivatives neither enhanced nor shifted the emission from ANS in aqueous solution. This indicates the absence of hydrophobic environment imposed on ANS by micelle formation. An extensive introduction of hydrophobic groups to PolyNAPGly (**5**) makes it a polymer micelle, which is an unfavorable structure to collapse the vesicles. For instance, the polymer bearing nine ZHis groups in a chain enhanced the emission intensity of ANS in solution, indicating the formation of polymer micelle. The addition of this polymer to CF-trapped vesicles induced a complete leakage of CF immediately after polymer addition, indicating the destruction of vesicle structures. Such polymers were not used in the present investigation. After all, the amount of dodecyl and ZHis substituents in a polymer chain should be less than two and five, respectively, in order for the

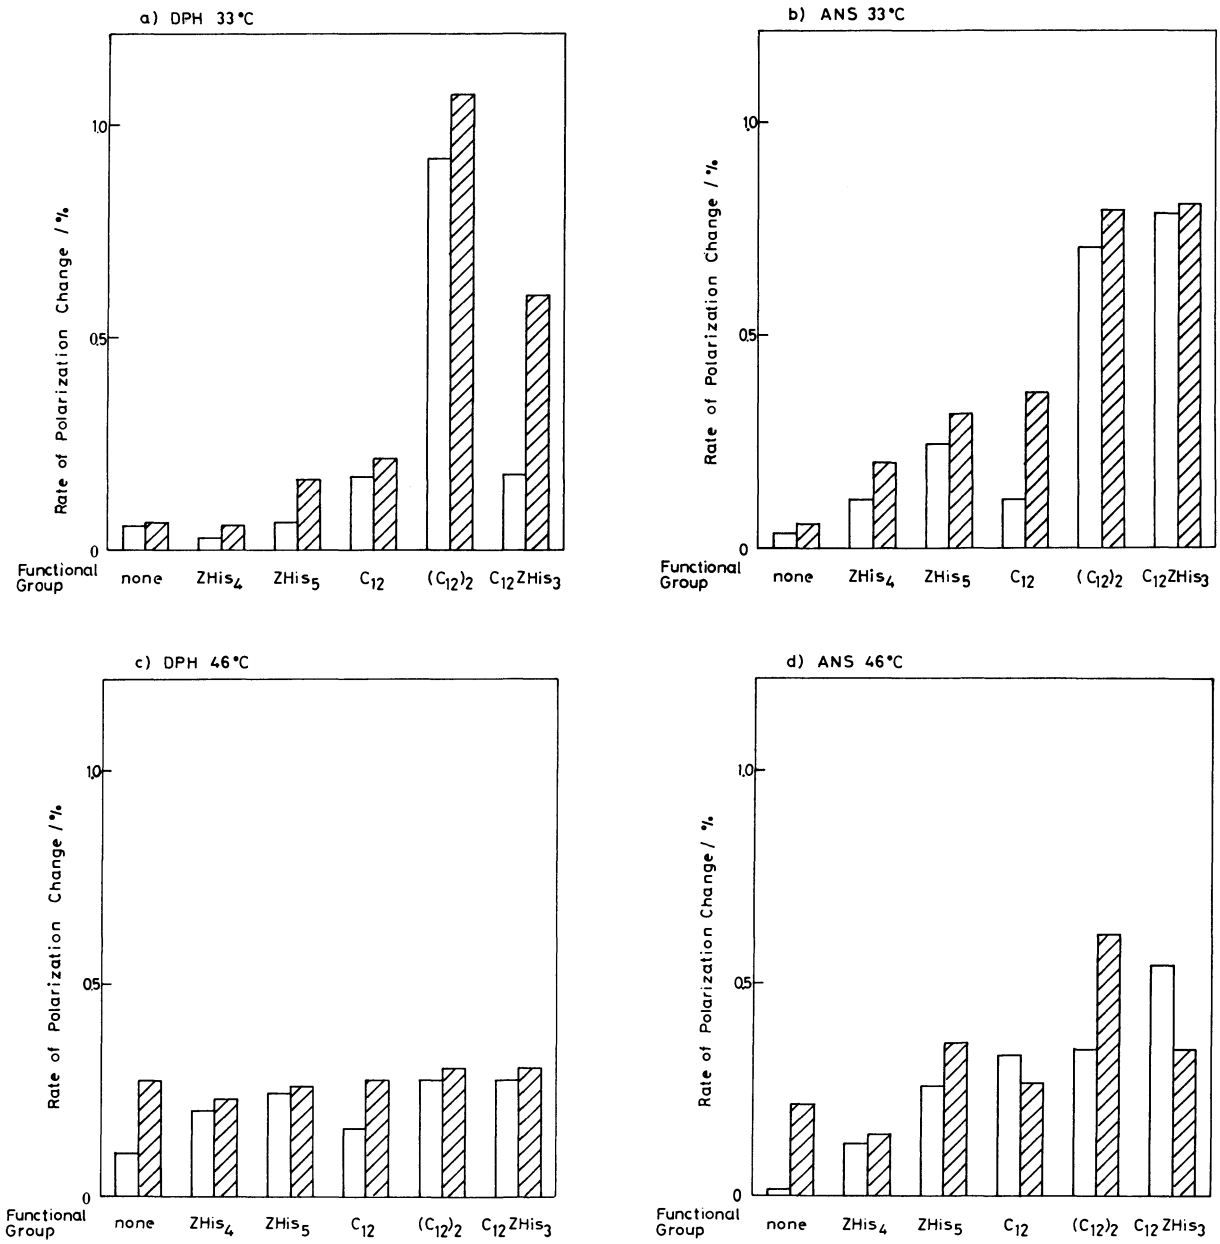

Fig. 5. The relative change in fluorescence polarization of DPH and ANS in DPPC vesicles induced by the addition of polymers. The relative change in fluoresence polarization is represented by $(P-P_0)/P_0$, where P designates the average polarization value at 5 min after the addition of polymer (20 μM), and P_0 means the polarization value in the absence of polymer. The temperature and used fluorescent probe are indicated at the top of each figure. The observed P_0 values are a) 0.285 (pH 7.2) and 0.275 (pH 9.0), b) 0.163 (pH 7.2 and 9.0), c) 0.096 (pH 7.2) and 0.091 (pH 9.0), and d) 0.098 (pH 7.2) and 0.095 (pH 9.0).
□, pH 7.2; ▨, pH 9.0.

derivatives of PolyNAPGly(**5**) to interact with lipid membrane without a serious damage of the membrane structure.

In the presence of DPPC vesicles, the addition of PolyNAPGly (**5**) changed the polarization of ANS in the lipid membrane. The varied polarizations of ANS should be attributed to the fluidity change of the membrane on interaction of PolyNAPGly (**5**) with the lipid membrane. While, CF leakage from DPPC vesicles was not influenced so much by the addition of PolyNAPGly (**5**), indicating the absence of the serious damage of the lipid membrane. These observations strongly support that PolyNAPGly (**5**) is a suitable polymer for the investigation of membrane-bound enzymes.

The effect of substituents of the polymer on binding to the membrane was investigated. The introduction of ZHis groups to PolyNAPGly (**5**) did not affect its

interaction with lipid membrane so much. However, the incorporation of dodecyl groups enhanced the binding to membrane (Fig. 2). Since PolyC$_{12}$ZHis$_3$-NAPGly (**10**) disturbed the membrane structure more extensively than PolyZHis$_4$-NAPGly (**8**), the dodecyl group of PolyC$_{12}$ZHis$_3$-NAPGly (**10**) should enhance the binding of the polymer to membrane (Fig. 3). Therefore, dodecyl group is effective in anchoring water-soluble compounds to lipid membrane. This result is consistent with that reported by Sunamoto, who succeeded in coating lipid vesicles with polysaccharide carrying a few hydrophobic alkyl chains.[17]

Cationic charges on the amino groups of the polymer also influence the affinity of the polymer with lipid membrane. Figure 3 shows that the effect of polymer addition on the CF leakage is larger at pH 9.0 than at pH 7.2. At pH 9.0 positive charges on the polymer are less than those at pH 7.2. Therefore, the polymer is bound to the neutral membrane at pH 9.0 more favorably than at pH 7.2. CF leakage did not reach 100% under the conditions in which several polymer molecules per one vesicle were added, indicating that the polymers do not completely destroy the vesicle structure. The time course of the CF leakage is biphasic (Fig. 2). One is just after the polymer addition, which is a transient state accompanied by the insertion of the polymer molecules into the membrane. The following slow leakage of CF should be attributed to a disordering of the membrane structure occurring after the complete incorporation of the polymers into the membrane.

The phase transition temperature of DPPC vesicles was raised by about 1 °C on addition of PolyNAPGly, PolyZHis$_4$-NAPGly (**8**), PolyC$_{12}$-NAPGly (**6**), or PolyC$_{12}$ZHis$_3$-NAPGly (**10**). This was detected by investigating the temperature dependence of fluorescence intensity of ANS according to the method by Mayer et al. (data not shown).[16] This observation also indicates that the polymers are absorbed on the membrane surface and slightly decreased the mobility of lipid molecules.

This effect of the polymers on the membrane fluidity was more prominent below the phase transition temperature. Based on the polarization of DPH, fluidity of the hydrophobic domain of a lipid membrane was almost independent of the nature of added polymers above the phase transition temperature, indicating that these polymers do not have serious effects on the structure of hydrophobic domain of a lipid membrane. However, below the phase transition temperature, effects of polymers on the fluidity of the hydrophobic domain of a lipid membrane were strongly dependent on the nature of polymers (Fig. 5). Especially, Poly(C$_{12}$)$_2$-NAPGly (**7**) and PolyC$_{12}$ZHis$_3$-NAPGly (**10**) perturbed markedly the structure of hydrophobic domain of lipid membrane. Dufourcq and his coworkers have reported that interactions of melittin, which is an amphiphilic polypeptide toxin, with phosphatidyl choline bilayers are stronger above the phase transition temperature than those below it.[18] However, it might be inferred that amphiphilic compounds tend to be bound more tightly to gel-state membrane than to liquid-crystalline membrane. Since the complex formed between amphiphilic compounds and lipid molecules should be highly ordered, the binding should accompany a large entropy loss. The entropy loss upon binding might be smaller for gel-state membrane than for liquid-crystalline membrane, leading to a larger loss of free energy upon binding to gel-state membrane than to liquid-crystalline membrane. For example, it has been reported that glucagon is bound tightly to gel-state membrane.[19,20] The present polymers behaved similarly to glucagon in the interaction with lipid membranes.

It should be noted that binding of polymer to lipid membrane decreased the membrane fluidity. Decrease in membrane fluidity by Ca^{2+} has been observed and attributed to the dehydration of head groups of lipid molecules by Ca^{2+} binding.[21] The decrease in membrane fluidity on the polymer addition might be explained by the same reason—that is, the ammonium and carbonyl groups of the polymer are bound to the polar groups of lipid molecules to dehydrate the membrane surface.[22]

To conclude, water-soluble polymers can be bound to lipid membrane by introducing hydrophobic groups as anchoring groups. The membrane affinity is adjustable by the number and the properties of the hydrophobic group. These points are very essential in the simulation of membrane-bound enzymes, since they affect sensitively physical properties of membrane, such as membrane fluidity and packing of lipid molecules.

Footprint Catalysis. I. A New Method for Designing "Tailor-Made" Catalysts with Substrate Specificity: Silica (Alumina) Catalysts for Butanolysis of Benzoic Anhydride

Kensaku MORIHARA,* Sachiyo KURIHARA, and Junko SUZUKI
Department of Chemistry, Faculty of Science, Nara Women's University, Kitauoyanishi-machi, Nara 630
(Received March 22, 1988)

The design of tailor-made specific catalysts for a given organic reaction was investigated. Dibenzamide or *N*-benzoylbenzenesulfonamide, transition state analogs of benzoic anhydride on transacylation, was found to act as a template upon aluminium ion-doped silica gel and to imprint specific adsorption sites, "footprints," on the surface. The footprints were particular Lewis acid sites with a complementary structure to the template. They demonstrated an enzyme-like specific catalytic function on the butanolysis of benzoic anhydride through their specific affinities for substrate molecules in the transition state.

Several kinds of enzyme-simulating catalysts consisting of a binding site and catalytic functional group(s) have been extensively investigated, and fair success has been reported.[1-4] However, there remain some problems,[5] and their catalytic features might seem, to date, somewhat unlike those of real enzymes. This is mainly because the present synthetic means encounters much difficulty in preparing so highly organized catalytic sites as those of natural enzymes and, consequently, the catalytic sites of such enzyme mimics cannot effectively used the non-covalent binding energy of E–S complexes to lower the activation energy barrier to a reaction as do the active sites of natural enzymes in their activities.[6-8]

Another approach to enzyme mimics, however, might be possible if the competitive inhibition mechanism for enzymes by transition state analogs, proposed by Wolfenden,[9] is applicable to designing enzyme-like catalytic sites. According to this mechanism, transition state analogs are specifically adsorbed on the active sites of enzymes much more tightly than the substrates themselves. Since these strong bonding in E–I complexes are similar in kind to those in E–S complexes, such a large bonding energy in E–I complexes can be applicable to the design of catalysts. If adsorption sites of any kind are available that possess complementary structures to the transition state analogs and, thereby, have a specific affinity for them, the sites might show a catalytic function when they bind the substrate molecules of the reaction. This is because the sites might misuse their specific affinity for the substrate molecules in a transition state to stabilize them and to lower the activation energy barrier of the reaction, which is, say, a reversed application of the inhibition mechanism by transition state analogs[9] to catalysis.

Such specific adsorption sites can be prepared on the surfaces of appropriate materials by rather easy imprinting procedures using chemically stable transition state analogs as template molecules. Thus, how to design a specific catalyst for a given reaction becomes directly how to design a specific adsorbent for a transition state analog of the substrate for the reaction. One of the present authors has found a method for imprinting specific adsorption sites for Methyl Red on the surface of silica(alumina) gels,[10,11] by a similar procedure as that described by Dickey.[12] These adsorption sites, regarded as "footprints" of Methyl Red, possess a Lewis acidic nature, keeping a complementary structure to the template molecules. This leads to a possibility of their use as an acid catalyst with substrate specificity.

The present paper reports that the "footprints" could be marked on the surface of commercially available silica gel by surface modification using aluminium ions and transition state analogs, e.g., dibenzamide or *N*-benzoylbenzenesulfonamide†, and that the "footprints" revealed unusual and specific catalytic behaviors on butanolysis of benzoic anhydride.

Experimental

Materials and Apparatus. All materials, if not specified, were of guaranteed grade of Nacalai Tesque Co. Ltd., and were used without further purification.

Silica gel; Merck Kieselgel 60, art. no. 7754, particle size 0.06—0.20 mm, mesh 70—230.

Dibenzamide (Bz-NH-Bz); prepared from benzonitrile.[13] Mp 145 °C (lit, 148 °); (Found: C, 74.81; H, 4.88; N, 6.18%).

N-Benzoylbenzenesulfonamide (Ph-SO_2-NH-Bz); prepared by usual pyridine-assisted benzoylation of benzenesulfonamide. Mp 148 °C (lit, 147 °C); (Found: C, 59.51; H, 4.26; N, 5.37%).

Dibenzoylmethane; recrystallized from petroleum benzine. Mp 74.5 °C (lit, 77.5—78 °C).

Benzoic anhydride; recrystallized from benzene-petroleum benzine. Mp 42 °C (lit, 42 °C).

Phthalic anhydride; recrystallized from benzene. Mp 130 °C (lit, 138.8 °C).

† In the strict sence, this compound is not a true transition state analog, but a tetrahedral intermediate analog as shown in Scheme 1. Its action on catalysis, however, nearly the same as a transition state analog according to Hammond rule.

Acetone; purified by distillation after refluxing with potassium permanganate.

1-Butanol; purified by distillation.

Benzene; purified by distillation over sodium metal.

Acetonitrile; purified by distillation after drying with calcium sulfate, and phosphorus pentoxide.

Anhydrous barium perchlorate; obtained by dehydration of barium perchlorate (3—4 H_2O) at 140 °C in vacuo.

pH-meter; Toa Electronics Ltd. HM-5B with a glass electrode GC-125.

Preparation of Catalysts. Kieselgel (100 g) was refluxed with concd hydrochloric acid for 4 h to release free surface silanol groups according to Fritz et al. and King et al.[14,15] The gel was throughly washed with water and, successively, with dil. aqueous ammonia till pH of supernatant reached 6.0—7.0. The gel was collected by filtration and pressed on filter papers. The "wet" gel, thus obtained, (equivalent to 10 g of dry weight), was added to 0.2 mol·l^{-1} aluminium chloride aqueous solution (50 cm^3) and the pH of the supernatant was adjusted to 7.0—8.0 with dil. aqueous ammonia. The mixture was then allowed to stand for one or two days. The precipitated aluminium hydroxide was removed off by decantation, and the silica(alumina) gel was washed three times with dil. hydrochloric acid (pH 4.0). To this gel, was added dibenzamide (450 mg) (or *N*-benzoylbenzenesulfonamide) in aqueous ammonia (40 cm^3) or in a minimum amount of acetone in order to dissolve the templates immediately. The supernatant was acidified to pH 4.0 quickly, and the mixture was allowed to stand for one or two days with an occasional pH adjustment. The gel was collected by filtration, and added to dil. hydrochloric acid (50 cm^3, pH 4.0) for washing, and collected by filtration and again washed on filter paper with the same hydrochloric acid. It was then air-dried at room temperature for 2—5 days to reach constant weight. The dried gel was subjected to methanol extraction by the use of a Soxhlet extractor untill no more absorbance at 243 nm could be observed. After extraction, the gel was quickly transfered into a desiccator over calcium chloride and dried under atmospheric pressure for one day and then under reduced pressure (25 mHg[††]) for a further one or two days. Finally, it was dried at 120—140 °C under reduced pressure (3 mHg) to give a sample ("imprinted") silica(alumina) gel catalyst preparation. A blank gel catalyst which omitted aluminium ions and templates, and a control gel catalyst which omitted only templates were prepared, respectively, by quite the same procedure as the sample gel catalyst preparation (always in parallel). All final gel preparations were carefully stored in tightly stoppered vinials for protection against moisture. The gel catalysts, inactivated by moisture, could be re-activated by repeated azeotropic dehydration with 2-propanol (20 cm^3) and benzene (80 cm^3) for 1 h.

Acidic Properties of Gel Catalysts. An acid strength determination was carried out by a method of Benesi with Hammett indicators,[16] and Lewis acid site detection was made with phenolphthalein according to a method of Pines and Haag.[17]

Kinetic Measurements. The reaction conditions for the butanolysis of benzoic anhydride was the same as that of phthalic anhydride described by Tarama et al.[18] To a mixture of benzene (70 cm^3) and 1-butanol (30 cm^3), was added a weighed amount of catalysts; the mixture was equilibrated at 55 °C for 1 h. In inhibition studies, an inhibitor was added 40 min later, and the mixture was kept at 55 °C for a further 20 min. Under vigorous stirring with a magnetic stirrer, an exactly weighed quantity of benzoic anhydride (2.262 g) was added to the mixture in order to initiate the reaction. Aliquots of 5 cm^3 were taken out at proper intervals in order to analyze the benzoic acid formed by the method of Greenhow,[19] as follows. To acetonitrile (10 cm^3) containing anhydrous barium perchlorate (0.225 g), was added an aliquot of the reaction mixture; the resulting solution was subjected to potentiometric titration with a 0.01 M[†††]-tripropylamine acetone solution using a glass electrode. Time courses of the butanolyses were practically linear up to 120 min and V_{obs}s were obtained from the slope. $V=V_{obs}-V_{uncat}$, where V_{uncat} was V_{obs} of catalyst amount extrapolated to zero. Kinetic parameters, K_ms and V_{max}s, were obtained from the usual Lineweaver-Burk plots, and activation parameters were calculated from the V_{max} values obtained at 50 °C, 55 °C, and 62 °C, respectively, where $\ln V_{max}$ vs. T^{-1} plots were finely linear (Fig. 3). Since the catalysts varied in activity by preparation lots and were very susceptible to moisture during storage, the kinetic parameters of catalysts of the same lots and of the same determination were always compared for a meaningful discussion of the catalytic behaviors of the gels.

Results

Table 1 demonstrates the acidic properties of gels, and the catalytic activities observed thereof. The purple coloration of sample (imprinted) gels by phenolphthalein for Lewis acid sites was immediately lost by an addition of the original template molecules. Table 2 shows that inactivated catalysts by moisture were regenerated by azeotropic dehydration. Figure 1 (A, B, C) displays typical Lineweaver-Burk plots for the catalytic butanolysis by the sample (imprinted) catalysts and the control catalyst, suggesting that the catalyzed reaction follows Michaelis-Menten kinetics with respect to the benzoic anhydride concentration in the range of 0.5—5.5 M of 1-butanol. Figure 2 shows that the initial velocity is nearly linear with respect to 1-butanol concentration below 0.8 M and, thereafter, leveled off. The rate of the catalyzed reaction can be expressed as follows:

$$\text{rate} = \frac{V_{max}[\text{benzoic anhydride}][\text{1-butanol}]}{K_m + [\text{benzoic anhydride}]} \quad (1)$$

In Table 3, are shown the kinetic parameters, and in Table 4, the activation parameters calculated from data shown in Table 3 and Fig. 3. In Figs. 4 and 5 are shown competitive inhibition plots by the original templates, and in Fig. 6, those plots by dibenzoylmethane, for sample (imprinted) gels-catalyzed butanolysis, respectively. The inhibition constants, K_is, are

†† 1 mmHg≈133.322 Pa.

††† 1 M=1 mol dm^{-3}.

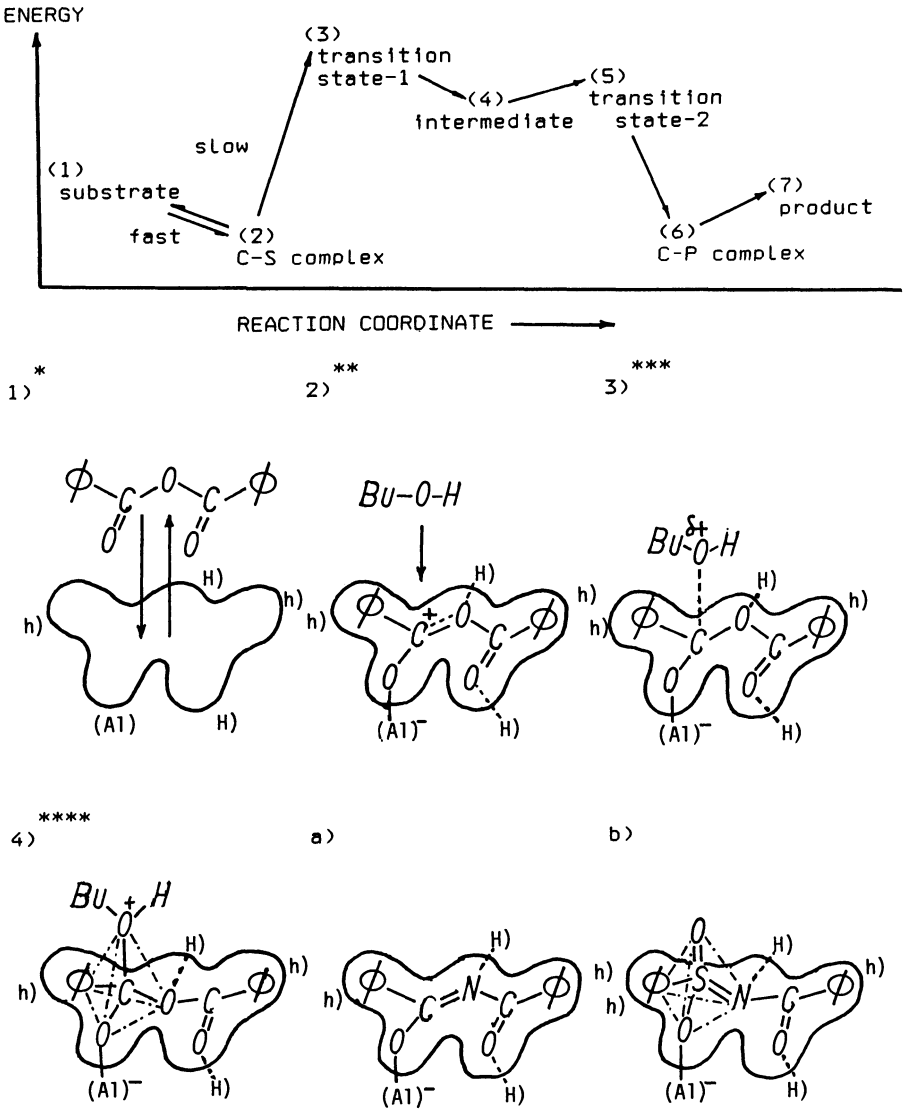
shown in Table 5. No competitive inhibition by the templates (Bz–NH–Bz, Ph–SO_2–NH–Bz, 2.24×10^{-3} M) was observed on Lineweaver-Burk plots (not shown) for the control gel-catalyzed butanolysis. Lineweaver-Burk plots (not shown) for the sample (imprinted) gels and the control gel-catalyzed butanolyses of phthalic anhydride are almost identical, and the kinetic parameters are shown in Table 6.

Discussion

The butanolysis of benzoic anhydride, a water-free esterification, was selected as a catalysis assay system because water was known to be poison for silica alumina catalysts, and benzoic anhydride was preferable to phthalic anhydride because its related derivatives for further studies were more easily available.

The linear relationship between the amounts of the sample (imprinted) and the control catalysts and the increase in reaction rates comfirms that the butanolyses are catalyzed reactions.

As shown in Table 1, the catalytic activities of the sample (imprinted) gel and the control gel are evidently caused by Lewis acid sites on the silica



Scheme 1. Speculated catalytic mechanism for butanolysis of benzoic anhydride upon a footprint catalytic site.

(alumina) gels, since both the blank gel lacking all kinds of acid sites and the "not dried" gels possessing acid sits, but lacking Lewis acid sites, are fully inactive. Furthermore, Lewis acid sites, not Brønsted acid sites, are assured to participate in the catalysis on the "imprinted" catalytic sites for following reasons: 1) Only such catalyst preparation as are positive (purple) to phenolphthalein for Lewis acid sites and lose immediately the purple collor upon the addition of templates showed the characteristic catalytic behaviors of "imprinted" catalytic sites, as mentioned below. 2) The catalytic activities were strongly affected by a Lewis base, such as water. 3) Dibenzoylmethane showed a competitive inhibition effect (Fig. 6) which could bind only onto Lewis acid sites through its enol-form but not to Brønsted acid sites.

The rate law of Eq. 1 for the butanolysis suggests that the reaction proceeds through a Rideal-Eley mechanism in which benzoic anhydride molecules initially adsorb onto the catalytic sites to activate carbonyl groups for the rate-limitting nucleophilic attack of 1-butanol in solution, as shown in Scheme 1.

As shown in Table 3, the K_m values of "imprinted" catalytic sites of the sample gels are clearly smaller than those of the corresponding control catalysts. Repeated the preparation of catalysts demonstrated that these difference in K_ms were reproducible: The K_ms observed on several sample (imprinted) catalysts laid between 0.13—0.28 M, and those of control catalysts laid between 1.25—2.31 M. Such differences in the K_ms indicate that the "imprinted" catalytic sites of the sample gels always possess about a 10-times stronger affinity ($1/K_m$) for benzoic anhydride than those of the control gels. An exact comparison of the substrate specificity (V_{max}/K_m) of the catalytic sites between the two catalysts is impossible, since amounts of the catalytic sites are unkown here. However, the number of "imprinted" catalytic sites of a sample catalyst is assumed to be nearly same, or less than those of the corresponding control catalyst, since the two catalyst have been prepared in parallel from the same aluminium ion-doped silica gel preparation. Therefore, the "imprinted" catalytic sites of sample catalysts

--○--: [I]=0, --●--: [I]=2×10^{-4} M, --⊙--: [I]=3×10^{-4} M.

The "imprinted" catalytic sites can also be characterized by the activation parameters, shown in Table 4. There is a distinct difference in the E_a values between the "imprinted" and the "native" catalytic sites, which confirms that the former are more effective catalytic sites, and supports the idea that an increase in the specificity of the former are caused by not only binding steps (K_m), but also by catalytic steps (V_{max}). The difference in ΔS^* values suggests that substrate molecules in transition states on the "imprinted" catalytic sites are assumed to be more firmly restricted than on the "native" catalytic sites of the control gel.

The other characteristic of the "imprinted" catalytic sites are their unusual behaviors toward the inhibitory effect by the template molecules. As shown in Figs. 4 and 5, markedly strong competitive inhibitions have been observed in catalysis on the "imprinted" catalytic sites by action of the templates used for imprinting, where the ratio of K_m/K_i is 2765 in one case. On the other hand, absolutely no inhibition by the templates has been found on Lineweaver-Burk plots (not shown) for a catalyzed reaction on "native" catalytic sites.

Furthermore, butanolysis with another substrate, phthalic anhydride,[18] was examined in order to characterize the "imprinted" catalytic sites. No difference in Lineweaver-Burk plots (not shown) was observed between the "imprinted" and the "native" catalytic sites. As can be seen from the kinetic parameters in Table 6, the "imprinted" catalytic sites show no particular affinity for phthalic anhydride at all and simply serve as usual acidic catalytic sites.

These unusual behaviors of the "imprinted" catalytic sites cannot be attributed merely to their acidic nature, since no difference in the acidic character was detected between the two catalysts, as shown in Table 1. Therefore, it is necessary to assume the presence of particular adsorption sites of Lewis acidic nature like "footprints" of the templates used for imprinting, as illustrated in Scheme 1. The following speculation is probable regarding the formation and molecular recognition capability of the "footprints".

Isomorphic substitutions of surface silicate by aluminate can form potential Lewis acid sites which coordinate to the conjugate bases of template molecules to yield surface acid-base complexes. Among some models of Lewis acid sites of silica alumina gels reported thus far, the model proposed by Tamele[20] is the most favorable in this case, since the "imprinted" catalytic sites have been formed by surface modification in mild conditions.

The acid-base complexes must make maximal interaction, such as hydrogen bonding and hydrophobic bonding, etc., with surrounding silicates throughout a continual and reversible rearrangement being subjected to thermodynamic control, which gives rise to most energetically stable surface complexes. A subsequent repeated extraction with hot methanol forces the removal of template molecules from stable acid-base complexes; the resulting decomposition of the complexes leaves energetically unstable particular sites, "footprints", on the surface with "complementarity" toward the templates. The term "complementarity" has dual meaning, i.e., "geometric" and "electronic".[21] The latter affords the footprints "electronic strain", a situation of high energy, postulated by Blow and Steiz[21] for the active sites of enzymes. The "electronic strain" arises from an unpaired lone-pair acceptor (Lewis acid), unpaired hydrogen bond donor(s) and/or acceptor(s), and so on toward even weaker forces, as can be seen in Scheme 1. This may provide a driving force for the molecular recognition capability to the footprints. This must be an origin of the enzyme-like "specific" Lewis acid catalysis on "footprint" catalytic sites.

Since the net structure of bulk silica gel must remain unchanged and shrinking never occurs during drying, unlike Dickey's silica gel,[12] the destruction of a surface structure can be prevented and a reproducible preparation of catalytic sites can be possible.

The "footprint" catalysis reported here has unprecedented features, such as substrate specificities, turnover capability, and easy and "tailor-made" preparability, etc., which are of greater advantage than any other stoichiometric synthetic reactions using template effects on surfaces of synthetic polymers recently reported,[22] and further studies on the "footprint" catalysis are in progress.

The authors are indebted to Professor Yujiro Imanaga for his interest throughout this work and also to Ms. Naoko Matzumoto and Ms. Kazue Kobayashi for help in parts of the experiments.

Footprint Catalysis. II. Molecular Recognition of Footprint Catalytic Sites

Kensaku MORIHARA,* Emiko NISHIHATA, Mari KOJIMA, and Sayoko MIYAKE
Department of Chemistry, Faculty of Science, Nara Women's University,
Kitauoyanishi-machi, Nara 630
(Received March 22, 1988)

In order to investigate the molecular recognition capability of "footprint" catalytic sites, the affinities of nine "footprint" catalysts for eleven competitive inhibitors, closely related to template molecules, were estimated through the competitive inhibition constants, K_i. An examination of the affinity revealed that the recognition by "footprint" catalytic sites was so highly specific that it could recognize not only the whole, but also the partial, structures of the bound molecules.

Our preceding paper of this series[1] reported that a new imprinting procedure for aluminium ion-doped silica gel by the action of a transition state analog (i.e., dibenzamide or *N*-benzoylbenzenesulfonamide) as a template formed unprecedented "imprinted" Lewis acid sites ("footprints") with a structure complementary to the template used, and that the "footprints" showed enzyme-like specific catalytic behavior regarding the butanolysis of benzoic anhydride.

The unique specific catalysis by the footprints has been assumed to arise from the molecular recognition capability of the "imprinted" catalytic sites through their "complementarity"[1] (or "electronic strain"[2]) to the molecule of transition state analog used.

The present paper describes a further investigation regarding the molecular recognition capability of the "imprinted" catalytic sites in order to prove the assumptive "complementarity"[1] and to obtain fundamental data necessary for designing tailor-made catalysts with substrate specificity by this imprinting method.

Since both substrate specificity in catalysis and susceptibility to competitive inhibitors originate from the same "complementarity" of the footprints, an examination of the suceptibility ($=K_i$) was carried out, before any investigation of the substrate specificity.

Nine "imprinted" catalysts were prepared by the imprinting method using nine different templates which were closely related to dibenzamide or *N*-benzoylbenzenesulfonamide, respectively. They were subjected to a "cross" inhibition study, in which all catalytic sites were crosswise affected by several competitive inhibitors, including the original template, in order to estimate the binding affinity ($1/K_i$) between the catalytic sites and the inhibitors.

The magnitude of the recognition capability of the catalytic sites was defined as $-dG\{=RT\ln(1/K_i)\}$. An examination of the observed $-dG$ values proved that the recognition by the footprints were so highly specific and exact that the catalytic sites could recognize not only whole bound molecules but also even partial structures of the molecules.

Experimental

Materials. Template molecules and related compounds (**1**—**15**) were prepared by the usual pyridine-assisted acylation of benzamide, benzenesulfonamide, and their para-substituted derivatives with benzoyl chloride, *p*-toluoyl chloride, and acetic anhydride, and characterized by mp, IR (JASCO IRA-1), NMR (HITACHI R-600, 60 MHz), and elemental analysis, if necessary. Other materials were the commercial products of guaranteed grade from Nacalai Tesque Co. Ltd., which were used without further purification, if not specified.

N-Benzoylbenzenesulfonamide (**1**); mp 148 °C (lit, 147 °C).

Dibenzamide (**2**); mp 145.5—148 °C (lit, 148 °C); (Found; C, 74.81; H, 4.88; N, 6.14%).

N-Acetylbenzamide (**3**); mp 116—117 °C (lit, 115 °C); (Found; C, 66.25; H, 5.52; N, 8.58%).

N-Benzoyl-*p*-toluenensulfonamide (**4**); mp 145 °C (lit, 147—150 °C).

N-(*p*-Toluoyl)-*p*-toluenesulfonamide (**5**); mp 138—139 °C; IR(Nujol) 3300 (N–H), 1700 (C=O), 1345 and 1175 cm^{-1} (SO_2); ^1H NMR ($CDCl_3$) δ=8.18—6.87 (m, 8H, ArH), 2.36 (s, 3H, CH_3–), and 2.29 (s, 3H, CH_3–); (Found; C, 61.98; H, 5.20; N, 4.78%).

N-Acetylbenzenesulfonamide (**6**); mp 125—126 °C; IR (Nujol) 1690 (C=O), 1360 and 1165 cm^{-1} (SO_2); ^1H NMR ($CDCl_3$) δ=9.47 (s, 1H, NH), 8.40—7.35 (m, 5H, ArH), and 2.05 (s, 3H, CH_3–); (Found; C, 48.38; H, 4.57; N, 7.00%).

N-Benzoyl-4-(decanoylamino)benzenesulfonamide (**7**); mp 211 °C; IR (Nujol) 3285, 3200 (N–H), 1720, 1695 (C=O), 1340 and 1180 cm^{-1} (SO_2); ^1H NMR($CDCl_3$) δ=7.26 (m, 9H, ArH), 1.90 (s, 2H, $-CH_2-CO-$) and 0.98 (s, 3H, CH_3–); (Found; C, 63.89; H, 7.01; N, 6.66%).

N-Benzoyl-4-(acetamido)benzenesulfonamide (**8**); mp 257—260 °C; IR (Nujol) 3300 (N–H), 1655 (C=O), 1535 (amide II), 1320 and 1170 cm^{-1} (SO_2); ^1H NMR ($CDCl_3$) δ=7.22 (m, 9H, ArH) and 1.47 (s, 3H, CH_3–).

4-(Decanoylamino)benzenesulfonamide (**9**); prepared by chlorosulfonation and succesive amination of decananilide; mp 207—209 °C; IR (Nujol) 3265 (N–H), 1685 (C=O), 1535 (amide II), 1320 and 1155 cm^{-1} (SO_2); ^1H NMR($CDCl_3$) δ=7.24 (m, 4H, ArH), 1.95 (s, 2H, $-CH_2-CO-$), 1.51 (m, 14H, $-CH_2-$), and 0.96 (s, 3H, CH_3–); (Found; C, 59.11; H; 8.00; N, 8.62%).

4-(Acetamido)benzenesulfonamide (**10**); mp 219.5 °C (lit, 219 °C).

N-Acetyl-4-(decanoylamino)benzenesulfonamide (**11**); mp

165 °C; IR(Nujol) 3340, 3290 (N-H), 1730, 1690 (C=O), 1520 (amide II), 1320, 1160 cm^{-1} (SO_2); ^1H NMR ($CDCl_3$) δ=8.1—7.1 (m, 6H, ArH), 2.01 (s, 2H, $-CH_2-CO-$), 1.49 (s, 14H, $-CH_2-$) and 1.21 (S, 6H, CH_3-); (Found; C, 58.77; H, 7.72; N, 7.71%).

N-Acetyl-4-(acetamido)benzenesulfonamide (**12**); mp 251°C; IR(Nujol) 3330(N-H), 1705, 1680(C=O), 1550 (amide II), 1320 and 1170 cm^{-1} (SO_2); ^1H NMR ($CDCl_3$) δ=7.24 (m, 4H, ArH), and 1.52 (s, 6H, CH_3-); (Found; 46.79; H, 4.64; N, 11.00%).

N-Benzoyl-4-(methanesulfonamido)benzenesulfonamide (**13**); mp 264—267 °C; IR (Nujol) 3190 (N-H), 1690 (C=O), 1350, 1330, 1170, and 1140 cm^{-1} (SO_2); ^1H NMR (DMSO-d_6) δ=7.50 (m, 9H, ArH) and 3.22 (s, 3H, CH_3-SO_2-); (Found; C, 47.49; H, 3.83; N, 8.04%).

4-(Methanesulfonamido)benzenesulfonamide (**14**); prepared by methanesulfonylation of sulfanilamide; mp 184—187 °C; IR (Nujol) 3400, 3310, 3260 (N-H), 1625, 1350 and 1170 cm^{-1} (SO_2); ^1H NMR (DMSO-d_6) δ=7.6 (m, 4H, ArH) and 3.19 (s, 3H, CH_3-SO_2-); (Found; C, 33.73; H, 3.93; N, 11.10%).

Diacetamide **15**; prepared from acetamide according to a method described in the literature.[2] Mp 75—76 °C (lit, 77.5—78 °C).

Dibenzoylmethane **16**; recrystallized from ethanol. mp 74.5 °C (lit, 77.5—78 °C).

Catalysts. The preparation procedures and acid sites characterizations of catalysts were the same as those described in the preceding paper, except for the use of different compounds as templates.

Kinetic Measurement. The reaction conditions and procedures were the same as those reported in the preceding paper, i.e., 1-butanolysis of benzoic anhydride at 55 °C in 1-butanol–benzene mixture (30:70 v/v), and the kinetic parameters, V_{max}, K_m, and K_i were obtained as usual from Lineweaver–Burk plots.

Reslts and Discussion

All the butanolyses obeyed Michaelis–Menten kinetics with respect to the concentration of benzoic anhydride; the kinetic parameters for catalized reactions are shown in Table 1. Some typical competitive inhibition plots are shown in Figs. 1—5. A coincidence of the intercepts on the $1/V$ axis were observed in all Lineweaver–Burk plots in the presence of different inhibitors (Figs. 2—5), which confirmed that all the different inhibitors were bound onto the same catalytic sites. Therefore, the affinities of a catalytic site for different inhibitors can be estimated and significantly compared with each other. The affinity, molecular recognition, by the catalytic sites is

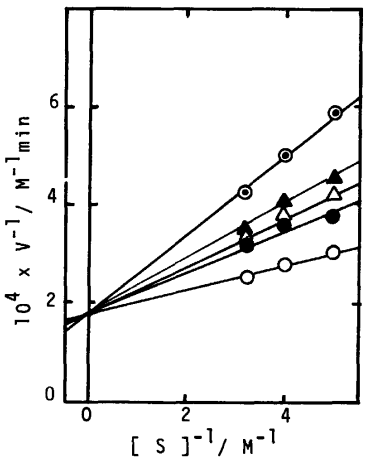

Fig. 3. Competitive inhibition of footprint catalyst {7} by **1**, **7**, **9**, and **11**.
Catalyst {7} (K_m 0.13 M), 700 mg; [I]=5.0×10^{-4} M; ⊙: by **7**, K_i=2.05×10^{-4} M (−dG=23.0 kJ), ▲: by **9**, K_i=3.56×10^{-4} M (21.8 kJ), △: by **11**, K_i=4.53×10^{-4} M (20.9 kJ), ●: by **1**, K_i=5.59×10^{-4} M (20.5 kJ), O: no inhibitor.

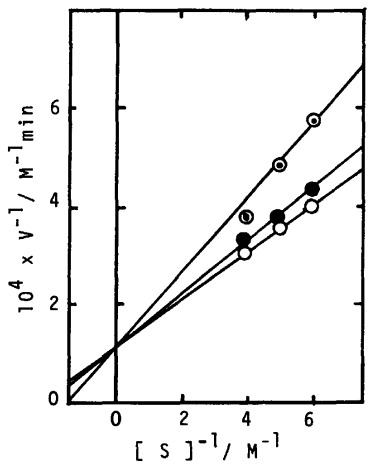

Fig. 4. Competitive inhibition of footprint catalyst {9} by **1** and **9**.
Catalyst {9} (K_m 0.35 M), 700 mg; [I]=3.0×10^{-4} M; ⊙: by **9**, K_i=4.32×10^{-4} M (−dG=21.3 kJ), ●: by **1**, K_i=2.77×10^{-3} M (15.9 kJ), O: no inhibitor.

expressed by the negative value of the free-energy change on binding; $-dG=RT\ln(1/K_i)$, where K_i is a competitive inhibition constant.

As can be seen in Table 2, each catalytic site reveals the maximum affinity(specified by *) for its original template (the template used in imprinting process.) as an inhibitor without exception. This fact strongly suggests that the molecular recognition capability of the footprints must be closely related to its formation process, and that the it must arise from a "complementarity" to its original template. Since molecular recognition is based on the "complementarity",[1] ("electronic strain"),[2] the magnitude of the affinity for a bound molecule greatly depends upon the resemblance in shapes and structures between the original template of the footprint and the inhibitors, e.g., footprint {1}* clearly differentiates **1** from **3**, **4**, **5**, **6**, and **15** by more than 14.7 kJ (=23.9−9.2 kJ; dG for **3**), whereas it hardly differentiates **1** from the structurally resembling **2** by only 1.3 kJ (=23.9−22.6 kJ), and similar feature is also seen on footprint {2} and {3}. Footprints show less affinity for molecules and/or groups that are too small to fit into the "complementary" structures, e.g., footprint {2} prefers **2** to **3** by 14 kJ, and exclude molecules and/or group that are too large to fit the structures, e.g., footprint {1} excludes **4** and **5** by about 20 kJ.

* Footprint{N} represents the footprint imprinted by template **N**.

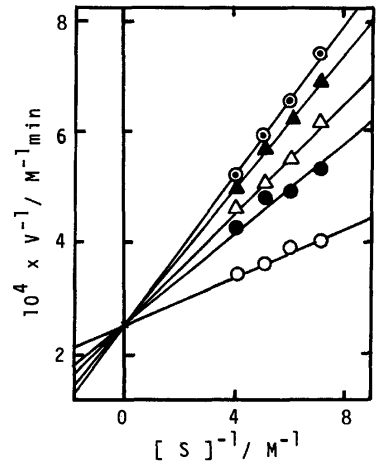

Fig. 5. Competitive inhibition of footprint catalyst {13} by **1**, **8**, **13**, and **14**.
Catalyst {13} (K_m 0.08 M), 300 mg; [I]=5.0×10^{-4} M; ⊙: by **13**, K_i=2.29×10^{-4}M (−dG=23.0 kJ), ▲: by **14**, K_i=2.68×10^{-4} M (22.6 kJ), △: by **8**, K_i=3.68×10^{-4} M (21.8 kJ), ●: by **1**, K_i=5.59×10^{-4} M (20.5 kJ), O: no inhibitor.

It should be noted that the magnitude of differentiation by the "imprinted" catalytic sites mentioned above is sufficiently large to be comparable to those by the "built-in" receptor sites of macrocycles, considering that 18-crown-6 differentiates K^+ from Na^+ by 10.15 kJ,† and dibenzo-18-crown-6 does so by 3.66 kJ† in methanol at 25 °C.

Furthermore, an examination of the data in Table 2 proves that the affinity for whole molecules(dG_w) can be expressed as the sum of those for partial structures(dG_p s) of the binders(inhibitors and templates); $dG_w=\sum dG_p$, as shown in Scheme 1. Assuming that the footprint {7} consists of three subsites (**X**, **Y**, **Z**) (**X** is situated for the *p*-substituent moiety, **Y** for the benzenesulfonamide moiety, and **Z** for the *N*-acyl

subsite **X**;	$-dG_p$ of subsite **X**{N}* toward **I**-**K**; {N} = {I}	{J}	{K}
I; *p*-(CH_3-CO-NH-)	2.5		1.2
J; *p*-(C_9H_{19}-CO-NH-)		2.5	
K; *p*-(CH_3-SO_2-NH-)			2.5

* Subsite **Y**{N} represents the subsite **Y** of the footprint imprinted by template **N**.

dG_y values (19.3—20.1 kJ) are much higher than the dG_z values (0.4–1.2 kJ) and the dG_x value (2.5 kJ), which indicates that only one Lewis acid site has been formed and located at subsite **Y** (in each case).

Footprints {**7**}, and {**8**} differentiate acetyl groups of inhibitors **11** and **12** from th benzoyl groups of inhibitors **7** and **8**, respectively, with a negative partial affinity (−0.9, −1.3 kJ). This reveals that an enforced binding occurs to give an intramolecular strain to the bound molecule since the catalytic sites are rigid.

The partial affinities of footprints can be estimated from the data given in Table 2 and shown in Table 4. In the estimation process, the average value of dG_z (1.0 kJ) of footprints {**7**} and {**8**} was used as a starting standard value under the assumption of a priority order for subsite **Y**, *N*-acetyl > -C_6H_4-SO_2-NH- > *N*-benzoyl, because all the inhibitors in Table 2 are ambiguous in action mode during the imprintig and the binding(inhibition) processes. Such a priority order is therefore necessary to define their action mode in the inhibition. Only the above order has offered reasonable estimates agreeable to the observed values shown in the Table 2. The true calculated values (** in Table 2) obtained from the partial footprint affinity (Table 4) agree reasonably well with the practically reliable observed values (> ca. 5 kJ). This finding confirms that the assumption that $dG_w = \sum dG_p$ is reasonable, i.e., the molecular recognition of the footprints can govern even the partial structures of the bound molecules. It also shows that the data given in Table 3 are reliable as a whole.

Though the values given in Tables 2 and 4 have been obtained only from the present catalyst preparations and the reaction system employed in the present work, the whole feature might not change so very much in other reaction systems.

Since the specific affinities and intramolecular strain effects would be essential in enzymatic catalysis,[5] the data for the partial affinities and strains shown in Tables 2 and 3 might be applicable to the design of tailor-made enzyme-simulated catalysts with any substrate specificities. Various attempts are now in progress.

The Photochemistry of Steroidal 6-Membered Cyclic α-Nitro Ketones[1)]

Hiroshi SUGINOME,* Yoshitaka KUROKAWA, and Kazuhiko ORITO
Organic Synthesis Division, Department of Chemical Process Engineering,
Faculty of Engineering, Hokkaido University, Sapporo 060
(Received April 25, 1988)

The results of the photolysis of five steroidal 6-membered cyclic α-nitro ketones in ethanol are described. Irradiation with a Pyrex-filtered light of 2-nitro-5α-cholestan-3-one in ethanol, which exists exclusively in the enol form in the solvent, resulted in a new photorearrangement and gave 5α-cholestane-2,3-dione 3-oxime with the accompanying formation of the corresponding α-diketone. We propose a path involving a nitro–nitrite rearrangement for this anomalous formation of 5α-cholestane-2,3-dione 3-oxime. However, similar irradiation of 4,4-dimethyl-2-nitro-5α-choloestan-3-one, which exists exclusively as the enol form in ethanol, and 3-nitro-5α-cholestan-2-one, which is in an 1:1 equilibrium mixture of keto and enol forms in ethanol, gave the corresponding α-hydroxyimino ketone and α-diketone respectively. Irradiation of 4β-nitro-5β-cholestan-3-one and 6α-nitro-5α-cholestan-7-one, both of which exist as the keto form in ethanol, gave similarly the corresponding α-hydroxyimino ketone respectively, but without the accompanying formation of α-diketone. The α-hydroxyimino ketones from the above four 6-membered cyclic α-nitro ketones arise through the hydrogen abstraction by the n,π* excited nitro group of the keto forms of the α-nitro ketones followed by the elimination of the element of water, while α-diketones are formed via the nitro–nitrite rearrangement of the excited nitro group of the enol forms.

In connection with our studies of nitrite photolysis[2)] and of photoinduced nitro–nitrite rearrangement,[3)] we have been interested, too, in the photochemistry of cyclic α-nitro ketones.

In this paper, we report the photochemistry of five steroidal 6-membered cyclic α-nitro ketones, three of which exist in solution predominantly in their enol form. The photochemistry of cyclic α-nitro ketones which in solution exist in their keto forms has been reported by Reid and Tucker, who found that 2-nitrocycloheptanone and α-nitro camphor rearrange to give cyclic *N*-hydroxy imides and α-hydroxyimino ketones on irradiation in solution.[4)]

Results

Preparations and Structures of the α-Nitro Ketones. Five steroidal 6-membered cyclic α-nitro ketones, 2-nitro-5α-cholestan-3-one (**3**)[5,6)] 4,4-dimethyl-2-nitro-5α-cholestan-3-one (**4**), 3-nitro-5α-cholestan-2-one (**11**), 4β-nitro-5β-cholestan-3-one (**13**), and 6α-nitro-5α-cholestan-7-one (**17**),[6)] chosen for the present study, were prepared by mononitration of the corresponding steroidal ketones with alkyl nitrate and bases.[7,8)]

We found that nitration of 5α-cholestan-3-one (**1**) under the conditions reported by previous investigators [butyl nitrate (3.35 mol) and potassium *t*-butoxide (5.78 mol) in *t*-butyl alcohol at 17—20 °C][5)] led to the substantial formation of α,ω-dinitro secosteroid; this arose from the hydrolytic cleavage of the dipotassium salt of α,α′-dinitro ketone.[9)] The formation of α,ω-dinitro secosteroid as a by-product in the nitration of ketone **1** with an excess of ethyl nitrate and potassium *t*-butoxide in THF at −40—0 °C has also been reported by Meakins and his colleagues.[6)] We found that the formation of the α,ω-dinitro secosteroid that is formed by the hydrolysis of the dipotassium salt of 2,4-dinitro-5α-cholestan-3-one can be avoided; no α,ω-dinitro secosteroids or ω-nitro carboxylic esters[7)] that arise from cleavage reactions were found in the products when a lesser amount of a base was used [propyl nitrate (2.9 mol) and potassium *t*-butoxide (2.6 mol)].

All five steroidal 2-nitro ketones are crystalline compounds. The IR spectra of 2-nitro-5α-cholestan-3-one (**3**) in Nujol exhibited strong bands at 1616 and 1513 cm^{-1} due to the carbon–carbon double bond and a conjugated nitro group. There were also very weak bands at 1746 and 1561 cm^{-1} owing to the carbonyl and a nonconjugated nitro group. 2-Nitro-5α-cholestan-3-one (**3**) seems therefore to exist almost exclusively as its enol form in the mulled state although a small portion exists as the keto form.[10)]

The absence of any bands due to the presence of non-conjugated 2-nitro ketone indicates that 4,4-dimethyl-2-nitro-5α-cholestane (**4**) in the mulled state exists exclusively in its enol form. The IR spectrum of 3-nitro-5α-cholestan-2-one (**11**) in Nujol exhibited two bands at 1619 and 1509 cm^{-1} due to the conjugated nitro group, and two bands at 1735 and 1562 cm^{-1} due to the carbonyl and nonconjugated nitro groups. It is clear that this nitro ketone in the mulled state exists as an equilibrium mixture of the keto and enol forms. On the other hand, the IR spectra of 4β-nitro-5β-cholestan-3-one (**13**) and 6α-nitro-5α-cholestan-7-one (**17**) indicated that these ketones in the mulled state exist almost exclusively in their keto form (Table 1).

The ^1H NMR spectra of 2-nitro-5α-cholestan-3-one (**3**) and its 4,4-dimethyl derivative (**4**) in $CDCl_3$ indicated that these 2-nitro ketones in the solution exist entirely as their enol form (see Experimental). It thus becomes apparent that these 2-nitro ketones in a more polar protic solvents such as the ethanol used in the present photolysis exist exclusively in their enol form.

In contrast to the behavior of these 2-nitro ketones,

Table 1. Infrared Absorptions of Cyclic α-Nitro Ketones[a]

α-Nitro ketone	Absorptions of functional groups (cm^{-1})	
	HO-C=C-NO_2	O=C-CH-NO_2
3	1513 and 1616	1561[b] and 1746[b]
4	1513 and 1605	—
11	1509 and 1619	1562 and 1735
13	—	1558 and 1714
17	—	1558 and 1728

a) In Nujol mull. b) A very weak band.

the ^{1}H NMR spectrum of 3-nitro-5α-cholestan-2-one (**11**) in $CDCl_3$ exhibited the presence of signals assignable to the 3α-H of its keto form (see Experimental) and indicated that it exists in an equilibrium with the enol form in $CDCl_3$. The ^{1}H NMR spectrum of **11** in methanol exhibited a singlet at δ 0.69 and a doublet of a doublet at δ 5.60 (J=7.2 and 11.9 Hz); these were assignable to the 18-H and the 3α-H of its keto form respectively; there was also a singlet at δ 0.71, assignable to the 18-H of its enol form. The ratio of the keto and enol forms in methanol estimated by their signal area was 45.5:54.5.

The ^{1}H NMR spectra of 4β-nitro-5β-cholestan-3-one (**13**) and 6α-nitro-5α-cholestan-7-one (**17**)[6] in $CDCl_3$ indicated that in solution they exist exclusively in their keto forms.

The aliphatic nitro group is known to exhibit two absorption bands, one in 210 nm and another in the 270—280 nm region.[11] The band at the lower wavelengths with a low intensity is due to the n→π* transition while the 210 nm band is due to the π→π* transition.[12-14] The α,β-unsaturated nitro compounds, on the other hand, are known to show absorption maxima with high intensity; these are assignable to the π→π* transitions, in the region 220—250 nm.[11-14]

The absorption maxima and the intensities of the UV spectra of the above five α-nitro ketones in three solvents are summarized in Table 2. The spectral data are in agreement with the conclusion on the keto-enol equilibria deduced by the ^{1}H NMR spectroscopy. 2-Nitro-5α-cholestan-3-one **3** and its 4,4-dimethyl derivative **4** in ethanol exhibited intense absorption maxima due to the π→π* transitions of a conjugated nitro group at 343 and 337 nm. The displacement of the absorption maxima to the longer wavelengths, when compared with the absorption maxima of the corresponding nitro olefins, is attributable to the effects of the additional hydroxyl group in the chromophore.

The nitro ketones **3** and **4** also exhibited intense absorption maxima at 310 and 315 nm in hexane respectively although their intensities were reduced in hexane in the case of **3** presumably owing to the presence of a greater amount of the keto form in the nonpolar solvent. 3-Nitro-5α-cholestan-2-one (**11**) exhibited weaker absorption maxima at 330 nm in ethanol and at 312 nm in hexane, assignable to the π→π* transitions. The decreased intensities are apparently due to the greater extent of the keto form. As expected, the intensities of absorptions due to the enol forms of the above three α-nitro ketones enhanced in ethanol containing sodium ethoxide where these α-nitro ketones exist exclusively in their enol forms.

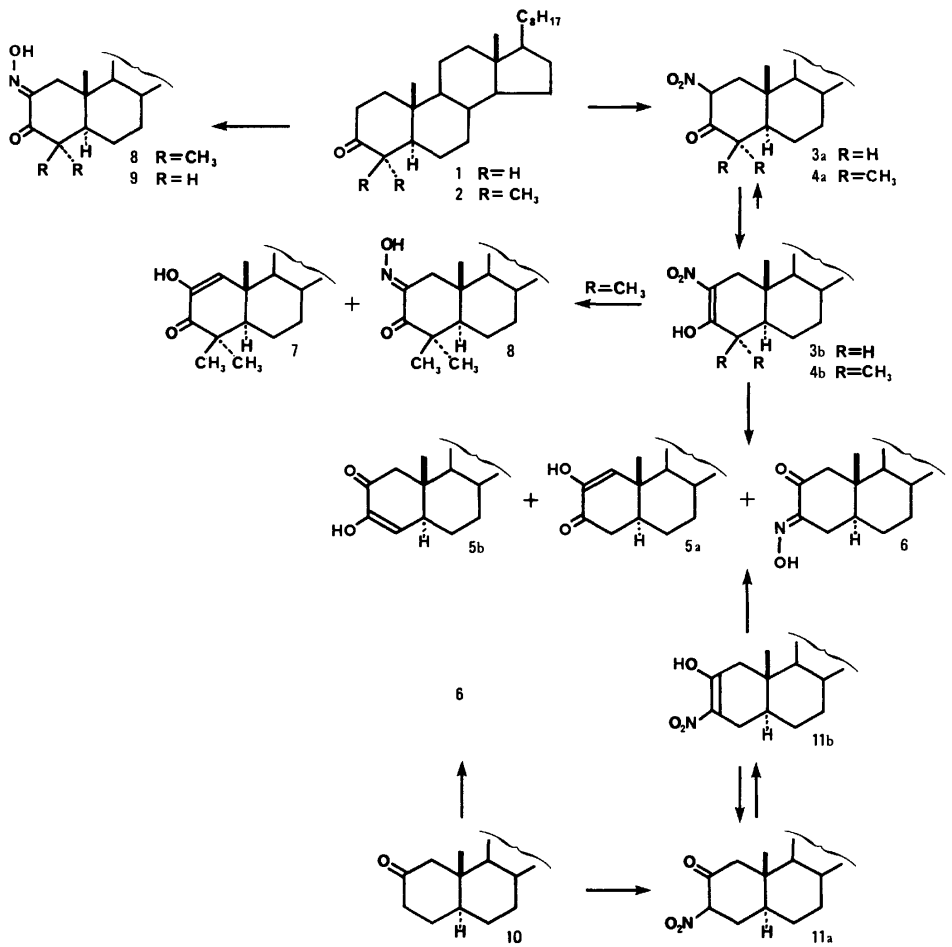
Table 2. UV Spectra of 6-Membered Cyclic α-Nitro Ketones

	λ_{max}/nm (ε)		
	EtOH	Hexane	EtOH-NaOEt
3	343 (14800)	310 (8900)	338 (13800)
4	337 (12300)	315 (10400)	330 (18400)
11	330 (5100)	312 (7700)	338 (14900)
13	345 (60) 284 (110)	270—330 (ca. 400)	342 (450) 235 (9800)
17	239 (1550) 291 (220)	226 (1890) 274 (160)	235 (6500)

6α-Nitro-5α-cholestan-7-one (**17**), on the other hand, exhibited broad weak absorption at 274 nm in hexane. The absorption maximum is assignable to the n→π* transition of the nitro- and/or the carbonyl groups on the basis of a bathochromic shift of the band in ethanol as well as its intensity. This α-nitro ketone **17** was found to be hardly enolizable at room temperature since no appreciable change of the UV spectrum was observed when it was taken in ethanol containing sodium ethoxide.

4β-Nitro-5β-cholestan-3-one (**13**) in hexane exhibited broad and weak absorption maxima from 270 to 330 nm attributable to the n→π* transitions of the nitro and/or the carbonyl group of the keto form as well as the band attributable to the π→π* transition of the conjugated nitro group of the enol form which is present in a trace amount.

Photochemistry of Cyclic α-Nitro Ketones. (a) 2-Nitro-5α-cholestan-3-one (3) (Scheme 1). Photolysis of **3** in ethanol with a Hanovia 450-W high pressure Hg arc through Pyrex for 2.5 h in an atmosphere of nitrogen gave a product mixture from which a crystalline mixture of diosphenols, (22.5%) 2-hydroxy-5α-cholest-1-en-3-one (**5a**) and its isomer **5b**,[15-21] as well as a ketonic product **6** (11.6%) were isolated by means of preparative TLC (Scheme 1). No other pure



Scheme 1.

products were isolated. Recrystallization of the mixture of diosphenols from ethanol gave a mixture of **5a** and **5b**. The ratio of **5a** and **5b** determined before and after recrystallization by ^{1}H NMR spectroscopy was approximately 1:1.

High resolution mass spectrometry indicated that the ketonic product **6** has the molecular formula $C_{27}H_{45}NO_2$. The IR spectrum exhibited a series of bands assignable to a hydroxyimino and an unstrained carbonyl group. The ^{1}H NMR spectrum of **6** exhibited two one-proton doublets at δ 2.77 and 2.09 (J=17.58 Hz) and a doublet of a doublet centered at δ 2.99 (J=19.42 and 5.5 Hz). These spectral results suggested that the structure of **6** was either 5α-cholestane-2,3-dione 2-oxime (**8**)[6,16,22,23] or 5α-cholestane-2,3-dione 3-oxime (**6**). The structure of **6** was determined to be the latter by a direct comparison between oximes **6** and **8** prepared by means of nitrosation of 5α-cholestan-2-one and 5α-cholestan-3-one. The oxime **6** obtained by the photolysis was identical with the oxime prepared by the nitrosation of 5α-cholestan-2-one and differed from the oxime prepared by the nitrosation of 5α-cholestan-3-one. The signals at δ 2.77, 2.09, and 2.99 in the ^{1}H NMR of **6** were then assignable to the 1α-H, 1β-H, and 4α-H respectively. The considerable downfield shift of the signal due to the 4α-H is attributable to the deshielding by the hydroxyl group of the hydroxyimino function and indicates that the hydroxyl of the hydroxyimino group was oriented anti to the 2-carbonyl group.[24] The ^{1}H NMR spectrum of **8** exhibited two doublets at δ 1.93 and 3.22 assignable to the 1α-H and 1β-H. The considerable downfield shift of the signal due to the 1β-H is similarly attributable to the deshielding by the hydroxyimino group, which is oriented anti to the carbonyl group.

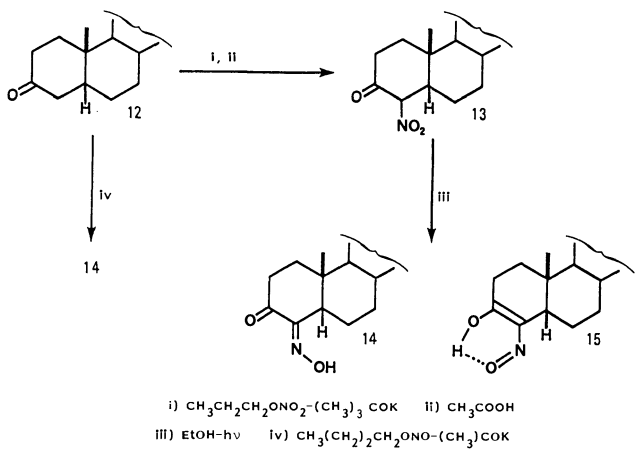
(b) Photolysis of 4,4-Dimethyl-2-nitro-5α-cholestan-3-one (4) (Scheme 1). Photolysis of 4,4-dimethyl derivative **4** was then undertaken. The photolysis of **4** in ethanol for 1 h under the same conditions as for the photolysis of **3b** led to a 76% conversion of the oxime and gave a mixture of the products. Preparative TLC of the products gave a diosphenol, 4,4-dimethyl-2-hydroxy-5α-cholest-1-en-3-one (**7**),[25,26] and ketonic product **8** in 22% and 11.6% yields. The structure of **8** was deduced by means of spectroscopy (see Experimental). High resolution mass spectrometry indicated that the ketonic product **8** had the molecular

formula $C_{29}H_{49}NO_2$. The IR spectrum exhibited bands assignable to a hydroxyimino and an unstrained carbonyl group. The ^1H NMR spectrum indicated two doublets at δ 2.17 and 3.03 (J=18.7 Hz). These spectral results suggested that the structure of the product was 4,4-dimethyl-5α-cholestane-2,3-dione 2-oxime (**8**).[27] This assumed structure was confirmed by a direct comparison with the specimen obtained by the synthesis. The signals at δ 2.81 and 3.02 in the ^1H NMR spectrum are assignable to the 1α-H and 1β-H respectively. Thanks to a considerable shift of the signal of the 1β-H to the low field in comparison with the signal of the 1α-H, it was confirmed that the hydroxyl group in the hydroxyimino group is again oriented anti to the carbonyl group.

(c) Photolysis of 3-Nitro-5α-cholestan-2-one (11). Photolysis of nitro ketone **11** in ethanol with a Eikosha 500-W high pressure Hg arc through a Pyrex for 3 h in an atmosphere of nitrogen resulted in a 93% conversion of the nitro ketone and gave a mixture of products from which we obtained a poor yield of the diosphenols, 5α-cholestane-2,3-dione (**5a** and **5b**)(4%) produced by the photolysis of nitro ketone **3** and a ketonic product **6** (18%). The product **6** had the molecular formula $C_{27}H_{45}NO_2$ and was identical in every respects with 5α-cholestane-2,3-dione 3-oxime (**6**) obtained by the photolysis of 2-nitro-5α-cholestan-3-one (**3**).

(d) Photolysis of 4β-Nitro-5β-cholestan-3-one (13) (Scheme 2). As we have said, nitro ketone **13** exists as its keto form in ethanol while nitro ketones, **3**, **4**, and **11** exist mostly as their enol froms **3b**, **4b**, and **11b** in the solvent. It is, therefore, of considerable interest to know how the difference in the tautomeric nature of the nitro ketones is reflected in the products of their photolysis.

The photolysis of nitro ketones **13** in ethanol for 3 h under the conditions described above resulted in a 51% conversion of the substrate and gave a mixture cf products which was subjected to column chromatography

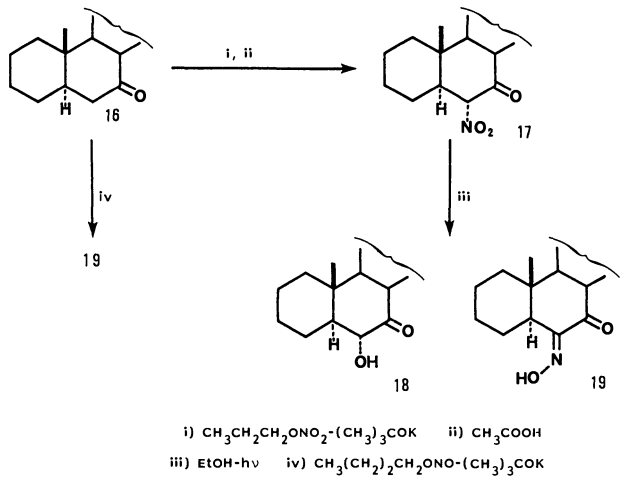


Scheme 2.

to give two crystalline products **14** and **15**. The compound **14** had the molecular formula $C_{27}H_{45}NO_2$ (high resolution mass spectrometry). The IR spectrum exhibited bands at 3340, 1693, and 1571 cm^{-1} assignable to a hydroxyimino group conjugated with a carbonyl group. This result, together with the ^1H NMR spectrum, indicated that it was 5β-cholestane-3,4-dione 4-oxime (**14**). The structure was confirmed by a direct comparison with oxime **14** which was prepared by nitrosation of 5β-cholestan-3-one **12**.

The ^1H NMR spectrum of **14** exhibited a doublet of a doublet at δ 2.93 (1H) with J=5.5 and 2.9 Hz assignable to the angular 5β-H. The observed displacement of this signal to the low field indicates that the 5β-H is deshielded by the hydroxyl of the hydroxyimino function which is oriented anti to the carbonyl group. High resolution mass spectrometry of compouhd **15** indicated that compound **15** is an isomer of α-hydroxyimino ketone **14**. The product had a double melting point and the higher melting point was nearly in agreement with that exhibited by α-hydroxyimino ketone **14**. IR spectrum exhibited a broad band at 3330 cm^{-1} due to a hydrogen-bonded hydroxyl group but no band due to a carbonyl group. Instead, there was a weak band at 1650 cm^{-1} due to a C=C bond in the IR spectrum. These results together with its ^1H NMR spectrum indicated that compound **15** was 4-nitroso-5β-cholest-3-en-3-ol. The assigned structure was then confirmed by isomerizing **15** to the oxime **14**. The nitroso steroid **15** was heated up to 140 °C and recrystallization of the melt gave a specimen which was identical with α-hydroxyimino ketone **14**. So far the nitroso-monomer has rarely been isolated. The nitroso-monomer **15** in this case may perhaps be isolated as a result of stabilization by an intramolecular hydrogen bond between the hydroxyl group and the nitroso oxygen. The mixture of the products of the photolysis was carefully examined by means of TLC but no cyclic α-diketones and cyclic imides were found.

(e) Photolysis of 6α-Nitro-5α-cholestan-7-one (17)[6] (Scheme 3). Nitro ketone **17** is again in a keto form in ethanol as in the case of nitro ketone **13**. Photolysis of nitro ketone **17** in ethanol for 7 h under the conditions as mentioned above, resulted in a 59% conversion and gave a complex mixture of the products. Two crystalline products **18** and **19** were isolated in 13 and 12% yields from the products by means of preparative TLC. The molecular formulae of **18** and **19** were determined to be $C_{27}H_{46}O_2$ and $C_{27}H_{45}NO_2$ by means of high-resolution mass spectrometry. The structure of product **18** was confirmed to be 6α-hydroxy-5α-cholestan-7-one on the basis of their IR and ^1H NMR spectra (see Experimental). The structure of product **19** was also deduced to be 5α-cholestane-6,7-dione 6-oxime on the basis of the IR, ^1H NMR, and mass



Scheme 3.

spectra (see Experimental) and this was finally confirmed by its preparation by nitrosation of 5α-cholestan-7-one (**16**). The ^1H NMR spectrum of **19** exhibited a doublet of a doublet at δ 2.17 (J=11.6 and 2.9 Hz) assignable to the 5α-H and a triplet at δ 2.48 (J=10.8 Hz) assignable to the 8β-H. It should be noted that although the hydroxyl group of the hydroxyimino function is almost certainly oriented anti to the carbonyl group, the 5α-proton is not deshielded to the same extent as 5β-proton of 5β-cholestane-3,4-dione 4-oxime. An inspection of the molecular model indicates that the orientation of the hydroxyl group is unable to deshield the axial 5α-proton. In the ^1H NMR spectrum of **19**, there was another one-proton multiplet centered at δ 2.28 assignable to the 4α-H which is likely to be deshielded by the hydroxyl group.

Discussion

A wide variety of photochemical transformations of aromatic, α,β-unsaturated, and aliphatic nitro compounds have been reported. The subject was first reviewed in 1969[14] and has recently been updated.[28]

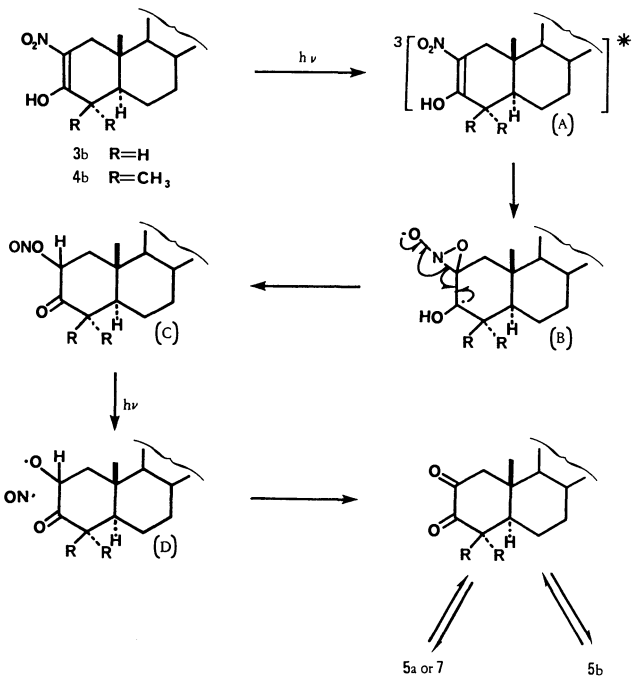
Although the photochemistry of some cyclic α-nitro ketones which exist in their keto form in solution has been investigated by Reid and Tucker,[4] no investigation has been carried out on the photochemistry of cyclic α-nitro ketones which in solution exist predominantly as their enol forms. The cyclic α-nitro ketones which exist as their enol forms are regarded as substituted α,β-unsaturated nitro compounds.

Chapman and his colleagues were the first to report the photochemical transformation of 2-nitro-1-phenylpropane into 1-hydroxyimino-1-phenyl-2-propanone via nitro–nitrite rearrangement.[29] Analogous photorearrangements to hydroxyimino ketones via the Chapman rearrangement have since been reported of several acyclic nitroalkenes, β-bromo-β-nitrostyrene,[30] *cis*-α,4-dinitrostilbene,[31] 1-aryl-2-nitro-1-propenes,[32] 1-(2-pyridyl)- and 1-(3-pyridyl)-2-nitro-1-alkenes,[33] and simple aliphatic nitroalkenes.[34] Intramolecular cycloaddition followed by a carbon–carbon double bond cleavage has been reported[31,32] to compete with the nitro–nitrite rearrangements in some of the above nitroalkenes.

The analogous photochemical formation of α-hydroxyimino ketones with the accompanying formation of cyclic ketones and enones via nitro–nitrite rearrangements have been observed for 6-membered cyclic nitroalkenes.[34,35] Another variation of the reported photochemistry of nitroalkenes is a photoinduced deconjugation which takes place when intramolecular abstraction of γ-hydrogen is possible.[34]

Our experiments have shown that the common products of the photolysis of the 6-membered cyclic α-nitro ketones which exist as their enol forms in protic solvents are cyclic α-diketones and cyclic α-hydroxyimino ketones. It should be noted that no cyclic imides, which have been found in the products of the photolysis of 2-nitrocycloheptanones and α-nitrocamphor,[4] were found in the products of the present photolysis.

The formation of α-diketones **5** and **7** from **3b**, **4b**, and **11b** is analogous to the formation of cyclic ketones in the photolysis of cyclic nitroalkenes. The pathway to these α-diketones involving the nitro–nitrite rearrangement is outlined in Scheme 4. Thus, excited 6-membered cyclic α-nitro ketones (**A**) rearrange to the corresponding cyclic α-hydroxy ketone nitrites (**C**) through oxaziridine intermediate (**B**). Disproportionation or the scission of a hydrogen atom of the alkoxyl



Scheme 4.

radical (**D**) generated from the nitrite (**C**) affords cyclic α-diketones such as **5a**, **5b**, or **7**.

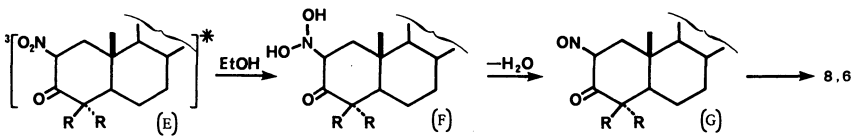
On the other hand, the path of the formation of cyclic α-hydroxyimino ketones from the excited cyclic α-nitro ketones (**4a**→**8**, **11a**→**6**) is outlined in Scheme 5. As outlined, these cyclic α-hydroxyimino ketones are simply derived through the isomerization of α-nitroso ketone (**G**) which can be formed from the intermediate (**F**) generated by the hydrogen abstraction from the solvent by the n,π* triplet excited nitro group[36–39] of the keto form (e.g., **E**) or the enol forms (e.g., **A**).

It is very likely, however, that α-hydroxyimino ketone **6** or **8** from α-nitro ketone **4** or **11** is formed from their keto form since α-hydroxyimino ketone **14** is obtained in the photolysis of α-nitro ketone **13** which exists exclusively in the keto form in ethanol.

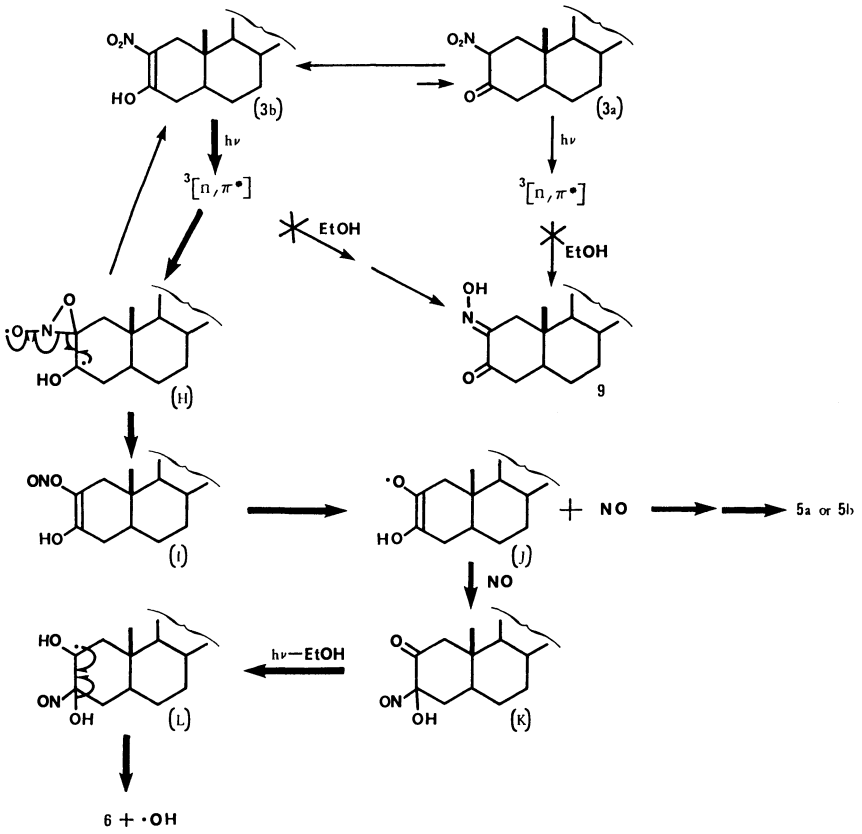
An anomalous result in the present experiments, however, is the formation of 5α-cholestane-2,3-dione 3-oxime (**6**) in the photolysis of 2-nitro-5α-cholestan-3-one (**3a**).

One of the probable geneses of the anomalous formation of α-hydroxyimino ketones **6** from 2-nitro-5α-cholestan-3-one **3** is outlined in Scheme 6. Thus, irradiation of 2-nitro-5α-cholestan-3-one (**3**) generates the n,π* triplet from which the nitrite (**I**) is formed by the Chapman rearrangement.[28–35] The combination of nitrogen monoxide with the C-3 of the enoloxyl radical (**J**) generated from the nitrite may give a nitroso ketone (**K**). The hydrogen abstraction by the excited nitroso ketone (**K**) then may give α-hydroxyimino ketone **6** through the removal of a hydroxyl radical from a ketyl radical (**L**). The competing process from the n,π* triplet, a hydrogen abstraction from the solvent, leading to the formation of α-hydroxyimino ketone **8** is unlikely to be as efficient as the Chapman rearrangement.

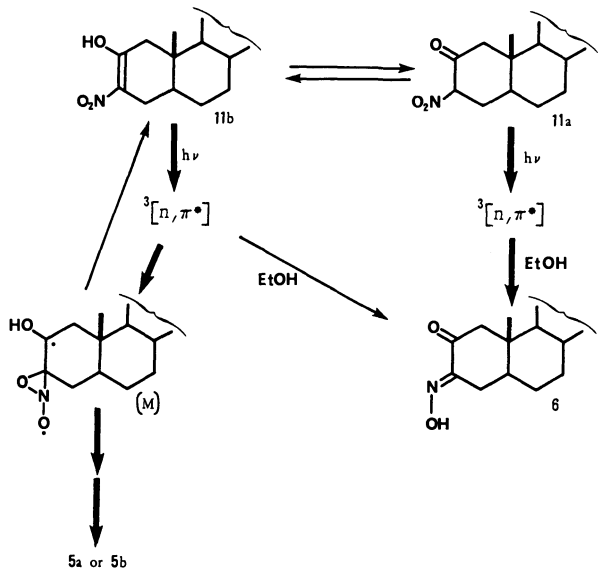
No α-hydroxyimino ketones based on the pathway involving the Chapman rearrangement outlined in Scheme 6 were formed in the photolysis of 3-nitro-5α-cholestan-2-one (**11**) and 4,4-dimethyl-2-nitro-5α-cholestan-3-one (**4**) even though photolysis resulted in the



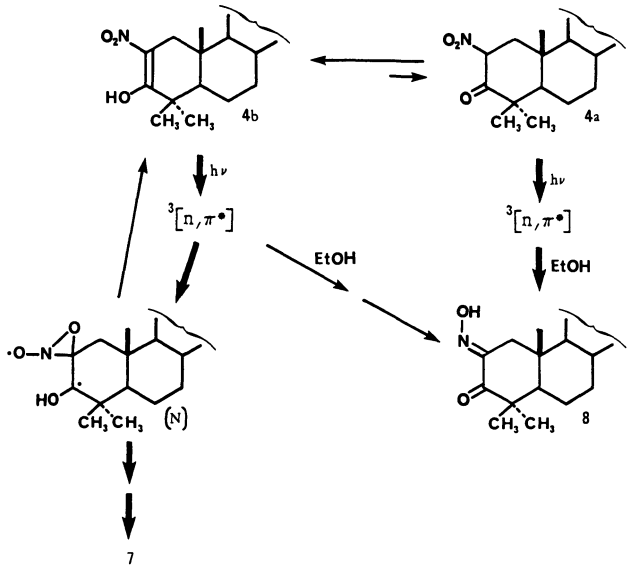
Scheme 5.



Scheme 6.



Scheme 7.



Scheme 8.

formation of diketones **5** or **7**, which involves the nitro–nitrite rearrangement as outlined in Schemes 7 and 8. The absence of α-hydroxyimino ketone **9** in the photolysis of nitro ketone **11** based on the mechanism outlined in Scheme 6 is attributable to steric inhibition of the combination of nitrogen monoxide with the C-2 of the intermediate by the 10β-methyl group. The absence of 4,4-dimethyl-5α-cholestane-2,3-dione 3-oxime in the photolysis of nitro ketone **4** is similarly attributable to the steric inhibition of the combination of nitrogen monoxide with the C-3 of the intermediate such as (**J**) (Scheme 6) by the C-4 *gem*-dimethyl group.

There are precedents for the formation of α-hydroxyimino ketones **14** and **19** in the photolysis of α-nitro ketones **13** and **17**, which exist in their keto forms.[4] These products are apparently formed by the elimination of the element of water from the intermediate formed from the hydrogen abstraction from the solvent by the n,π* excited nitro group. The unprecedented isolation of the unstable nitroso intermediate **15** in the photolysis of α-nitro ketone **13** is of interest in connection with this pathway.

The α-hydroxy ketone **18** is likely to be generated from the corresponding nitrite. The nitrite in this case may be formed either through the Chapman rearrangement of the enol form, which exists in a trace amount, or through the dissociation–recombination mechanism[3] of the nitro group of the keto form.[40]

Experimental

Mp's were recorded with a Yanagimoto micro mp apparatus. IR spectra were determined for Nujol mulls with a Hitachi Model 285 infrared spectrophotometer or a JASCO IR 810 infrared spectrophotometer unless otherwise indicated. ^{1}H NMR spectra were determined with a JEOL PS 200 high resolution FT-NMR spectrometer (200 MHz) or a JEOL JNM-FX 270 spectrometer (270 MHz) (solvent, $CDCl_3$; $SiMe_4$ as an internal standard) (Faculty of Pharmaceutical Sciences of this University). TLC was carried out on a Merck Kiesel gel 60-PF_{254}. The high and low resolution mass spectra were determined with a JEOL JMS-D-300 spectrometer (70 eV) (Faculty of Pharmaceutical Sciences of this University). Elemental analyses were performed by the staff of the analytical laboratory of Faculty of Pharmaceutical Sciences.

2-Nitro-5α-cholestan-3-one (2-Nitro-5α-cholest-2-en-3-ol) (3). 5α-Cholestan-3-one (**1**) (2 g 5.18 mmol) was dissolved in *t*-butyl alcohol (50 ml) containing potassium *t*-butoxide (1.5 g, 13.4 mmol). To this solution at 22 °C propyl nitrate (1.5 ml, 15 mmol) was added and the solution was stirred for 2 h at room temperature. The solution was then poured into iced water (200 ml). A yellow-colored potassium salt of α-nitro compound **3** (2.512 g) was collected by filtration. The potassium salt was dissolved in glacial acetic acid (100 ml) by heating. The solution was cooled to room temperature and water was added to the solution to yield colorless crystals of 2-nitro-5α-cholestan-3-one (**3**) (2.157 g, 96.6%), mp 117—125 °C. This nitro ketone was recrystallized from ethanol to yield analytical specimen (1.487 g, 66.6%), mp 132—135 °C (lit,[5] mp 135—136 °C). IR (Nujol) 1616 (C=C), 1513 (conjugated NO_2) 1746, (very weak band, C=O), and 1561 cm^{-1} (very weak bond non-conjugated NO_2); ^{1}H NMR (100 MHz) δ=0.67 (3H, s, 18-H), 0.83 (3H, s, 19-H), and 2.70 (1H, *J*=15.9 Hz, 1-H); MS, *m/z* (rel intensity) 431 (M^+, 83.8%), 227 (64.8, M^+—D-ring) 276 (89.7), 95 (64.0), 81 (65.4), 69 (61.8), 57 (67.4), 55 (94.4), and 43 (100).

4,4-Dimethyl-2-nitro-5α-cholestan-3-one (4). 4,4-Dimethyl-5α-cholestan-3-one (**2**) (5 g) was dissolved in *t*-butyl alcohol (185 ml) containing potassium *t*-butoxide (7.5 g). To this solution, propyl nitrate (5.15 ml) was added and the solution was stirred for 3 h 45 min at room temperature. The solution was then poured into iced water (700 ml). A yellow-colored potassium salt of α-nitro compound (7.4 g) was collected by filtration. The potassium salt was dissolved in glacial acetic acid (200 ml), and water was slowly added to

the solution to yield colorless crystals of 4,4-dimethyl-2-nitro-5α-cholestan-3-one (**4**) (4.2 g, 75.6%). This nitro ketone was recrystallized from hexane to yield an analytical specimen (3.0 g, 54%), mp 123—127 °C. Found: C, 75.74; H, 10.95; N, 2.95%. Calcd for $C_{29}H_{49}NO_3$; C, 75.77; H, 10.74; N, 3.05%. IR (Nujol) 1605 (C=C), 1513 (conjugated NO_2), and 1297 cm^{-1}; ^1H NMR (270 MHz) δ=0.66 (3H, s, 18-H), 0.88 (3H, s, 19-H), 1.30 and 1.32 (each 3H, each s, 4-Me), 2.05 and 2.80 (each 1H, each d, J=15.38 Hz, 1α-H and 1β-H). MS, m/z (rel intensity) 459 (M^+, 100%), 441 (15.3), 412 (M^+-HNO_2, 15.0), 403 (29.2), 315 (58.0), 304 (59.6), 95 (80.8), 81 (70.7), 69 (70.7), 55 (74.1), and 43 (79.1).

3-Nitro-5α-cholestan-2-one (11). 5α-Cholestan-2-one (**10**) (1.5 g) was dissolved in THF (50 ml) containing potassium t-butoxide (1.4 g). To this solution, isopentyl nitrate (2 g) in THF (3 ml) was added over the course of 20 min, while being cooled with Dry Ice–methanol. After the solution was stirred for 40 min at room temperature, the solution was neutralized by the addition of glacial acetic acid. The solution was then poured into water (250 ml) and the solution was extracted with dichloromethane. Combined organic layers were worked up by the usual method. The crude oily nitro ketone (1.786 g) was recrystallized from ethanol to yield crystals of nitro ketone **11** (1.372 g. 81.7%), mp 117—120 °C, ^1H NMR (270 MHz) δ=0.67 (3H, s, 18-H), 0.85 (3H, s, 19-H), 5.28 (0.37H, dd, J=12.9 and 6.9 Hz, 3β-H of the keto form **11b**) and 13.8 (0.63H, s, OH); IR (Nujol) 1735 (C=O), 1619 (C=C), 1562 (non-conjugated NO_2), 1509 cm^{-1} (conjugated NO_2); MS (70 eV), m/z (rel intensity) 431 (M^+, 91.4%), 416 (6.9), 291 (11.3), 276 (M^+—D-ring, 100), 262 (27.9), and 55 (43.3). Found: C, 74.99; H, 10.45; N, 3.09%. Calcd for $C_{27}H_{45}NO_3$: C, 75.13; H. 10.50; N, 3.25%.

4β-Nitro-5β-cholestan-3-one (13). 5β-Cholestan-3-one (**12**) (500 mg, 1.30 mmol) was dissolved in t-butyl alcohol (10 ml) containing potassium t-butoxide (200 mg, 1.79 mmol). To this solution at 22 °C, propyl nitrate (0.15 ml, 1.5 mmol) was added and the solution was stirred for 2.5 h at room temperature. The solution was then poured into iced water (70 ml). Glacial acetic acid was added to this aqueous pale yellow solution of the potassium salt of α-nitro ketone until pH 3. The solution was stirred for 30 min and extracted with dichloromethane. The organic layer was washed with water and dried over anhydrous Na_2SO_4. The workup in the usual way gave an oil (546 mg). This oily 4β-nitro-5β-cholestan-3-one (**13**) crystallized upon the addition of ethanol. (123 mg, 22%), mp 157—160 °C. The filtrate contained the starting 3-ketone and 2,4-dinitro ketone. Found: C, 75.02; H, 10.39; N, 3.27%. Calcd for $C_{27}H_{45}NO_3$: C, 75.13; H, 10.51; N, 3.25%. IR (Nujol) 1714 (C=O), 1558 cm^{-1} (NO_2); ^1H NMR (200 MHz) δ=0.69 (3H, s, 18-H), 1.13 (3H, s, 19-H), and 5.67 (1H, d, J=12.7 Hz, 4α-H); MS, m/z (rel intensity) 431 (M^+, 34.8%), 385 (M^+-NO_2, 30.7), 276 (22.3), 231 (30.7), 229 (37.2), 140 (38.8), 95 (72.4), 81 (75.1), 69 (69.7), 55 (100), and 43 (84.1).

6α-Nitro-5α-cholestan-7-one (17). The α-nitro ketone **17** was prepared according to the procedure reported by Meakins et al.[6] Yield was 34%. Mp 143—144 °C (lit,[6] mp 137—139 °C). IR (Nujol) 1728 (C=O) and 1558 cm^{-1} (non-conjugated NO_2).

Photolysis of 2-Nitro-5α-cholestan-3-one (3). 2-Nitro-5α-cholestan-3-one (**3**) (300 mg, 10.7 mmol) in absolute ethanol (450 ml) was irradiated with a Pyrex-filtered light (Hanovia 450-W high pressure Hg arc) for 1.5 h in an atmosphere of dry nitrogen. The removal of the solvent under a reduced pressure gave an oily residue (341 mg) which was subjected to preparative TLC with benzene to yield two fractions. The more mobile oily fraction (63 mg, 22.5%) was 5α-cholestane-2,3-dione (**5**). Its NMR spectrum indicated that it was a 1:1 mixture of two isomeric enols **5a** and **5b**. Recrystallization of the mixture with ethanol gave a crystalline mixture of 2-hydroxy-5α-cholest-1-en-3-one (**5a**) and its isomer **5b** in a 1 to 1 ratio. Mp 119—155 °C (lit,[21] mp of pure enol **5a**, 163—167 °C). ^1H NMR δ=0.56 (s, 18-H of **5b**), 0.68 (s, 18-H of **5a**), 5.70 (d, J=2.6Hz, 4-H of **5b**), 5.68 (s, OH of **5a** and **5b**), 6.38 (s, 1H of **5a**). The polar fraction (190 ml) was subjected to preparative TLC with a 3:1 benzene–ethyl acetate to yield 5α-cholestan-2,3-dione 3-oxime (**6**) (34 mg, 11.6%). An analytical specimen was obtained by recrystallization with ethanol. Mp 196—198 °C. IR (Nujol) 3628, 3445, and 3228 (OH), 1708, and 1687 (C=O), 1608 and 1585 (C=N), 1272, 1031, and 985 cm^{-1}; ^1H NMR (270 MHz), δ=0.66 (3H, s, 18-H), 0.85 (3H, s, 19-H), 2.77 (1H, d, J=17.6 Hz, 1β-H), 2.09 (1H, d, J=17.2 Hz, 1α-H), and 2.99 (1H, dd, J=19.4 and 5.5 Hz, 4α-H); EIMS (rel intensity) 415 (M^+, 100%), 400 (6.3), 399 (6.3), 398 (9.5), 261 (28.3), 260 (55.6), and 43 (95.8). Found: m/z 415.3480. Calcd for $C_{27}H_{45}NO_2$: M, 415.3450.

Synthesis of 5α-Cholestan-2,3-dione 3-Oxime (6). To a solution of the ketone (100 mg) in t-butyl alcohol (10 ml) containing potassium t-butoxide (35 ml), butyl nitrite (0.035 ml) was added and the solution was stirred for 30 min at room temperature. The solution was then poured into iced water. After aq. 2 M hydrochloric acid (1 M=1 mol dm^{-3}) had been added, the solution was extracted with diethyl ether. The combined organic layers were washed with water and dried over anhydrous sodium sulfate. The usual workup of the solution gave an oily product (193 mg) which was subjected to preparative TLC with a 2:1 benzene–ethyl acetate to give a crude oxime (83 mg, 77%). Recrystallizations from ethyl acetate–methanol gave pure oxime **6**, (54 mg), mp 196—198 °C. This oxime was identical with oxime **6** obtained from the photolysis of nitro ketone **3**.

Synthesis of 5α-Cholestane-2,3-dione 2-Oxime (9),[6,16,22,23] This hydroxyimino ketone **9** was prepared according to the procedure reported by Chadwick et al.[6] Butyl nitrite was used instead of pentyl nitrite. The oxime which was recrystallized from THF melted at 271—274 °C. (lit, mp 240—242 °C;[6] 203—205 °C;[16] 268—270 °C[22,23]). IR (Nujol) 3136 (OH), 1718 (C=O), 1619 (C=N), 1294, 975, and 817 cm^{-1}; MS, m/z (rel intensity) 415 (M^+, 79.8%), 398 [$(M-OH)^+$, 100], 384 (27.9), 314 (20.7), 260 (76.3), 244 (27.1), 216 (22.3), 136 (36.3), 121 (39.1), 107 (37.0), 95 (55.8), 81 (55.1), 69 (52.4), 55 (73.8), and 43 (66.7%); ^1H NMR (270 MHz) δ=0.67 (3H, s, 18-H), 0.85 (3H, s, 19-H), 1.93 (1H, d, J=18.0 Hz, 1α-H), 2.44 (1H, dd, J=5.5 and 18.9 Hz, 4-H), and 3.22 (1H, d, J=18.0 Hz, 1β-H).

Photolysis of 4,4-Dimethyl-2-nitro-5α-cholestan-3-one (4). 2-Nitro steroid (**4**) (350 mg, 0.76 mmol) in absolute ethanol (350 ml) was flashed with nitrogen and was irradiated with a Pyrex-filtered light (Eikosha 500-W high pressure Hg arc) for 1 h in an atmosphere of dry nitrogen. The removal of the solvent under a reduced pressure gave an oily residue (352 mg) which was subjected to preparative TLC with chloroform to yield three fractions. The most mobile fraction (83 mg, 24%) was the starting material (**4**). The second mobile fraction (54 mg, 21.6%) was 4,4-dimethyl-2-hydroxy-5α-cholest-1-en-3-one (**7**) which was recrystallized

from ethanol-water to yield crystals, mp 165—169 °C (lit, mp 165—167 °C,[25] 168 °C[26]). IR (Nujol) 3442, 3412 (OH), 1668, and 1652 cm^{-1} (C=C and C=O of diosphenol); EIMS, *m/z* (rel intensity) 428 (M^+, 67.2%), 425 [$(M-Me)^+$, 25.4]. 400 [$(M-CO)^+$, 16.3], 385 (14.9), 341 (13.1), 315 (37.1), 300 (37.5), 247 (22.8), 166 (28.8), 81 (54.6), 69 (55.1), 55 (64.5), and 43 (100); ^1H NMR (270 MHz) δ=0.68 (3H, s, 18-H), 1.11 (3H, s, 19-H), 1.13 (3H, s, 4β-Me), 1.91 (3H, s, 4α-Me), 5.99 (1H, s, OH), and 6.40 (1H, s, 1-H). The most polar fraction (33 mg, 12.7%) was 4,4-dimethyl-5α-cholestane-2,3-dione 2-oxime (**8**)[27] which was recrystallized from ethanol-water. Mp 202—205 °C (lit,[27] mp 197—198 °C). IR (Nujol), 3270 (OH), 1705 (C=O), 1612 (C=N), 962, and 759 cm^{-1}; ^1H NMR (270 MHz) δ=0.66 (3H, s, 18-Me), 0.85 (3H, s, 19-Me), 1.12 (3H, s, 4β-Me), 1.17 (3H, s, 4α-Me), 2.17 (1H, d, J=18.7 Hz, 1α-H), and 3.03 (1H, d J=18.7 Hz, 1β-H).

Synthesis of 4,4-Dimethyl-5α-cholestane-2,3-dione 2-Oxime (8). This oxime was prepared according to the procedure reported by French workers.[27] Mp 202—205 °C (lit,[27] mp 197—198 °C). This hydroxyimino ketone was identical with the specimen obtained by the photolysis of 4,4-dimethyl-2-nitro-5α-cholestan-3-one.

Photolysis of 3-Nitro-5α-cholestan-2-one (11). 3-Nitro-5α-cholestan-2-one (**11**) (300 mg, 0.7 mmol) in ethanol (300 ml) was irradiated with a Pyrex-filtered light (Eikosha 500-W high pressure Hg arc) for 3 h in an atmosphere of a nitrogen. A workup of the irradiated solution as in the case of 2-nitro steroid **3b** gave an oily residue (323 mg) which was subjected to preparative TLC with dichloromethane to yield three fractions. The most mobile fraction (22 mg, 7.5%) was the starting material **11b**. The second mobile fraction (11 mg, 4.2%) was a mixture of α-diketones **5a** and **5b** and it was recrystallized from methanol-water to yield a mixture of α-diketones **5a** and **5b** mp 116—158 °C. The most polar fraction (47 mg, 17.7%) was 5α-cholestane-2,3-dione 3-oxime (**6**) which was recrystallized from methanol-water. Mp 196—198 °C. This oxime was identical with the specimen obtained by the photolysis of 2-nitro-5α-cholestan-3-one (**3a**).

Photolysis of 4β-Nitro-5β-cholestan-3-one (13). Nitro steroid **13** (300 mg, 0.7 mmol) in absolute ethanol (400 ml) in a quartz vessel was irradiated with a low pressure Hg arc in a Rayonet chamber reactor for 3 h in an atmosphere of dry nitrogen. The removal of the solvent under reduced pressure gave an oily residue (330 mg) which was subjected to the separation by means of column chromatography (silica gel). Elution with benzene gave the starting nitro steroid (148 mg) and then nitroso steroid **15** (37 mg, 25.2%). The latter was recrystallized from ethanol to yield a specimen for analysis, mp 113—119 °C and 167—174 °C. IR (Nujol) 1650 (C=C), 1528 and 1000 cm^{-1}; ^1H NMR (200 MHz) δ=0.67 (3H, s, 18-H), 1.14 (3H, s, 19-H); EIMS *m/z* (rel intensity) 415 (M^+, 14.2%), 398 [$(M-OH)^+$, 43.1], 356 (21.9), 140 (39.7), and 124 (100). Found: *m/z* 415.3457. Calcd for $C_{27}H_{45}NO_2$: M, 415.3450. Elution with a 99:1 diethyl ether-methanol gave a crude α-keto oxime **14** (74 mg, 50.4%) which was subjected to preparative TLC with a 97:3 dichloromethane-methanol to yield 30 mg of α-keto oxime **14**. It was recrystallized from ethanol to yield an analytical specimen, mp 186—188 °C. IR (Nujol) 3340 (OH), 1693 (C=O), and 1571 cm^{-1} (C=N); ^1H NMR (270 MHz), δ=0.66 (3H, s, 18-H) and 1.09 (3H, s, 19-H), 2.93 (1H, dd, J=5.5 and 2.9 Hz, 5β-H), and 2.47 (2H, m, 2-H);MS, *m/z* (rel intensity) 415 (M^+, 9.4%), 398 [$(M-OH)^+$, 33.0], 356 (24.5), 276 (14.0), 260 (100), 160 (6.5), 128 (31.2), 124 (86.8), 109 (31.4), 95 (38.5), 81 (41.6), 69 (40.5), 55 (52.0), and 41 (44.7); Found: *m/z* 415.3440. Calcd for $C_{27}H_{45}NO_2$: M, 415.3448.

Synthesis of 5α-Cholestane-3,4-dione 4-Oxime (14). To 5β-cholestan-3-one (100 mg) in *t*-butyl alcohol (10 mg) containing potassium *t*-butoxide (35 ml), butyl nitrite (0.035 ml) was added. The solution was stirred for half an hour at room temperature and poured into iced water. After aq. 2 M hydrochloric acid had been added, the aq. solution was extracted with diethyl ether. The combined ethereal extracts were washed with water and dried over anhydrous sodium sulfate. The usual work-up of the solution gave an oily hydroxyimino ketone (141 mg). This crude product was subjected to preparative TLC with a 2:1 benzene-ethyl acetate to give a crude oxime (66 mg, 66%). The specimen for analysis (27 mg) was obtained by recrystallizing from methanol-water. It was identical with oxime **14** obtained by the photolysis of 4β-nitro-5β-cholestan-3-one (**13**). Mp 186—188 °C.

Photolysis of 6α-Nitro-5α-cholestan-7-one (17). 6α-Nitro-5α-cholestan-7-one (**17**)(300 mg, 0.7 mmol) in ethanol (300 ml) was irradiated with a Pyrex-filtered light (Eikosha 500-W high pressure Hg arc) for 7 h in an atmosphere of a nitrogen. Evaporation of the solvent under a reduced pressure gave an oily residue (315 mg) which was subjected to preparative TLC with dichloromethane to yield three fractions. The most mobile fraction (122 mg, 40.6%) was the starting material. The second mobile fraction (27 mg, 13.2%) was 6α-hydroxy-5α-cholestan-7-one (**18**). The ketone **18** was recrystallized from ethanol-water to yield the specimen for analysis. Mp 123—128 °C. IR (Nujol) 3468 (OH) and 1705 cm^{-1} (C=O); ^1H NMR (270 MHz) δ=0.67 (3H, s, 18-H) 1.11 (3H, s, 19-H), 2.44 (1H, br. t, J=11.7 Hz, 8β-H), 3.15 (1H, d, J=4.5 Hz, OH), and 3.86 (1H, ddd, J=11.82, 4.5 and 1.1 Hz, 6β-H); ($CDCl_3$-D_2O) δ=3.86 (1H, dd, J=11.72 and 1.1 Hz, 6β-H); MS *m/z* (rel intensity) 402 (M^+, 100%), 384 [$(M-H_2O)^+$, 23], 271 (13.4), 257 (13.5), 247 (16.3), 231 (15.7), 194 (24.9), 125 (45.9), 109 (37.8), 95 (47.3), 81 (52), 55 (60.6), and 43 (55.8); Found: *m/z* 402.3517. Calcd for $C_{27}H_{46}O_2$: M, 402.3498.

The most polar fraction (25 mg, 12.2%) was 5α-cholestane-6,7-dione 6-oxime (**19**) and this was recrystallized from methanol-water to give an analytical specimen. Mp 155—158 °C. IR (Nujol) 3292 cm^{-1} (OH), 1717 (C=O), and 1673 (w, C≡N): ^1H NMR (270 MHz) δ=0.67 (3H, s, 18-H), 0.98 (3H, s, 19-H), 2.17 (1H, dd, J=11.72 and 2.94 Hz, 5α-H), 2.49 (1H, t, J=11.0 Hz, 8β-H) and 8.76 (1H, s, NOH); MS *m/z* (rel intensity) 415 (M^+, 43.6%), 398 [$(OH)^+$, 43.0%)], 370 (73.0), 344 (100), 95 (90.4), 81 (68.3), 69 (84.5); Found: *m/z* 415.3443; Calcd for $C_{23}H_{45}NO_2$: M, 415.3449.

As in the case of the photoreaction of nitro ketone **13** the absence of cyclic α-diketone and cyclic imides in the products was confirmed by means of TLC and a color reaction ($FeCl_3$-water).

Synthesis of 5α-Cholestane-6,7-dione 6-Oxime (19). To 5α-cholestan-7-one (500 mg) in *t*-butyl alcohol (20 ml) containing potassium *t*-butoxide (500 mg), butyl nitrite (1.8 ml) was added. The solution was stirred for 12 h at room temperature and poured into iced water. After aq. 2 M-hydrochloric acid had been added the aq. solution was extracted with diethyl ether, washed with water and dried over anhydrous sodium sulfate. The usual workup gave an

oily oxime (647 mg) which was subjected to preparative TLC to give a crude keto oxime **19** (97 mg). The oxime was recrystallized from methanol to give the specimen for analysis (40 mg). Mp 155—158 °C. This oxime was identical in every respect with the specimen obtained by the photolysis of nitro ketone **17**.

(Received May 17, 1988)

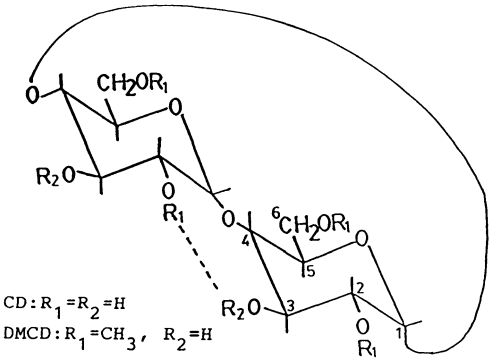
Intramolecular hydrogen bonding of α-, β-, and γ-cyclodextrins, and α- and β-dimethyl cyclodextrins has been investigated in dimethyl sulfoxide-d_6 by ^{1}H NMR spectroscopy. The temperature dependence of ^{1}H chemical shifts of secondary hydroxyl protons of cyclodextrins and dimethyl cyclodextrins reveals the existence of the intramolecular hydrogen bond. The strength of hydrogen bond becomes stronger as the ring size becomes smaller and by methylation. The intramolecular hydrogen bond in which the OH(3) is proton donor is preferred in α-cyclodextrin as well as in α- and β-dimethyl cyclodextrins. The orientation of secondary hydroxyl groups was estimated with the Karplus-type equation and the orientation is found to be suitable for making intramolecular hydrogen bond.

Cyclodextrins (CDs) are cyclic oligosaccharides consisting of six or more D-glucose units, which are connected by α-1,4-glucosidic linkages.[1] α-, β-, and γ-CDs are typical CDs composed of 6, 7, and 8 glucose units, respectively. Since CDs can accommodate guest molecules of suitable size in their cavities in both solid and solution states,[1–5] they have been paid great attention in various fields. The CD molecules have been modified chemically in attempts to improve properties such as the solubility and the complexation ability.[2,4,6–9] 2,6-Di-*O*-methyl-α- and β-CDs (α- and β-DMCDs, respectively) are typical examples of such modified CDs and they not only have higher solubility to both water and organic solvents but also appear to have significantly enhanced abilities of complexation and improved chiral recognition upon the inclusion processes.[2,10,11]

Hydrogen bonding is one of important interactions involved in determining the three-dimensional structures of biopolymers such as proteins, nucleic acids, and carbohydrates. The hydrogen bonds in these systems can be located by crystal structure analysis, especially by the neutron diffraction study which can directly prove the location of hydrogen atoms in the crystal lattice.[12,13] In solution state, on the contrary, it is not always easy to detect directly hydrogen-bond formation. Nuclear magnetic resonance spectroscopy (NMR) is one of potential physicochemical techniques which can provide the information about the hydrogen bonding in solution. Chemical shift or coupling constant, and temperature dependence of chemical shift, deuterium exchange and/or isotope effect, have been effectively used to study the hydrogen bonds, and in some case, to distinguish between the inter- and the intramolecular hydrogen bonds.[15–19]

X-Ray[20–24] and neutron diffraction[12,13] studies have shown that in solid state round but slightly conical form of CD macrocyclic ring structure is stabilized by the intramolecular hydrogen bonds between OH(2) and OH(3) groups of the adjacent glucose units. The existence of intramolecular hydrogen bonds of both O(3)–H···O(2) and O(3)···H–O(2) types in solid state have been suggested for α- and β-CDs. In DMCDs the formation of O(3)–H···O(2) type hydrogen bonds has also been suggested.[23,25]

There have been many attempts to determine the driving forces for complexation processes of CD and to make use of CDs inclusion ability in various field. Since CD inclusion complexation usually occurs in solution, the determination of CD conformation in solution could give some information on the complexation mechanism of CD inclusion complexes. The intramolecular hydrogen bond might play an important role for stabilizing the structure of CD macrocycle in solution. In the present work, the hydrogen bonding properties of CDs and DMCDs in DMSO-d_6 solution and orientation of their hydroxyl group were studied by the temperature dependence of chemical shifts and coupling constants of hydroxyl protons.



Experimental

α-, β-, and γ-CDs were generous gifts from Nihon Shokuhin Kako Co. Ltd. and methyl α-D-glucoside (MG) was purchased from Nakarai Chemicals and were dried in vacua at 120 °C before use to remove most of the hydrated water. α-DMCD was purchased from Toshin Chemical Co., and was used after recrystallization from water. β-DMCD

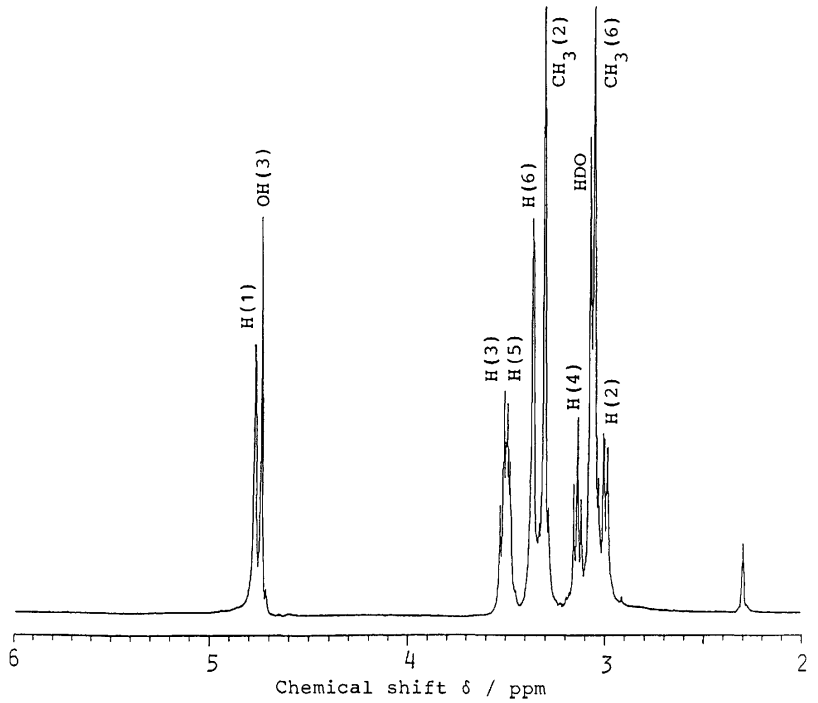


Fig. 1. The 500 MHz ^{1}H NMR spectrum of β-DMCD in DMSO-d_6 solution at 35 °C.

was obtained from Toshin Chemical Co., and was purified using the procedures reported by Koizumi et al.[26] The NMR solvent, deuterated dimethyl sulfoxide (DMSO-d_6), was purchased from Merck Co.

500 MHz ^{1}H NMR spectra were recorded on a JEOL GX-500 spectrometer in DMSO-d_6 at several temperatures from 25 to 75 °C. Concentration of all samples is 0.02 M (1 M= 1 mol dm^{-3}). Chemical shifts are given in parts per million (ppm) down field from tetramethylsilane (TMS). Digital resolution of the spectra is 0.0006 ppm (0.3 Hz).

Results and Discussion

Chemical Shift of Hydroxyl Proton Resonances in CDs. In Fig. 1 is shown the 500 MHz ^{1}H NMR spectrum of β-DMCD at 35 °C. In a previous paper,[27] we have assigned ^{1}H NMR spectra of some CDs and permethylated CDs by means of two-dimensional NMR techniques. ^{1}H NMR chemical shifts and coupling constants of hydroxyl groups and H(1) of α-, β-, and γ-CDs, and α- and β-DMCDs and MG in DMSO-d_6 at 35 °C are listed in Table 1. The resonances of the secondary hydroxyl protons of α-, β-, and γ-CDs (δ 5.2—5.6), and that of β-DMCD (δ 4.70) appear at lower field than those of the primary hydroxyl protons (δ 4.2—4.4) and the hydroxyl protons of MG (δ 4.1—4.6). These results suggest that the secondary hydroxyl groups form intramolecular hydrogen bond in α-, β-, and γ-CDs and β-DMCD. When the hydrogen bond is formed, polarization like $O^{\delta-}\cdots H^{\delta+}\text{-}O^{\delta-}$ along the hydrogen bond net work is enhanced and the proton participating in hydrogen bond becomes more positive in its electronic character. Therefore, such proton is deshielded compared to the proton that is not concerned with the hydrogen bond, i.e. its signal shifts to lower field. The resonance of secondary hydroxyl proton of α-DMCD appears at δ 4.45, which is clearly at higher field than the chemical shifts of other secondary proton resonances of CDs. But ^{1}H chemical shift data alone are not sufficient, and another supporting data are necessary to conclude that the intramolecular hydrogen bond is present in CDs and DMCDs (see below).

Table 1. Chemical Shifts[a] of H(1) and Hydroxyl Protons of Some CDs, DMCDs and MG in DMSO-d_6 at 35 °C

	H(1)	OH(2)	OH(3)	OH(6)	OH(4)
α-CD	4.60	5.32	5.26	4.28	
β-CD	4.68	5.52	5.48	4.26	
γ-CD	4.74	5.53	5.57	4.32	
α-DMCD	4.77		4.45		
β-DMCD	4.77		4.70		
MG	4.32	4.41	4.46	4.12	4.58

a) Chemical shifts are expressed in ppm from TMS.

Temperature Dependence of Hydroxyl Proton Chemical Shifts. Figure 2 shows the chemical shift changes of hydroxyl proton resonances of α-CD over the temperature range examined. Although the chemical shift of H(1) changes little with temperature, those of hydroxyl protons shift to higher field almost linearly with the increase of temperature (Fig. 3). Similar results are found for β- and γ-CDs, α- and

β-DMCDs, and MG.

For dilute solutions of CDs, DMCDs, and MG in DMSO-d_6, the following equilibrium of hydrogen bonding is present.

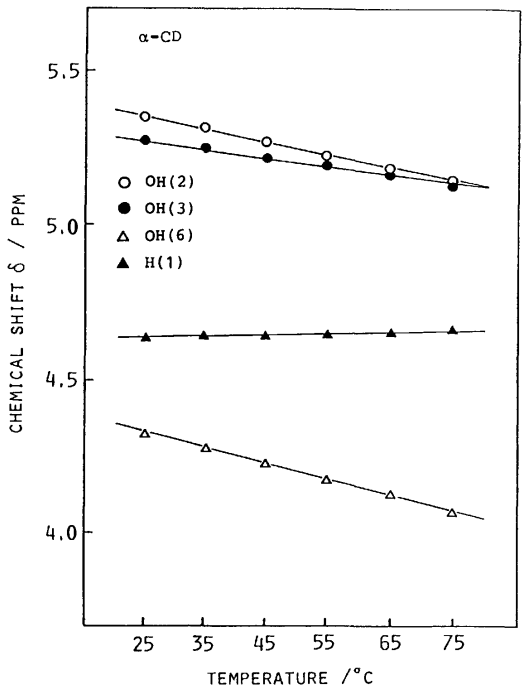

Fig. 2. Temperature dependence of the chemical shift of the hydroxyl and anomeric protons in α-CD.

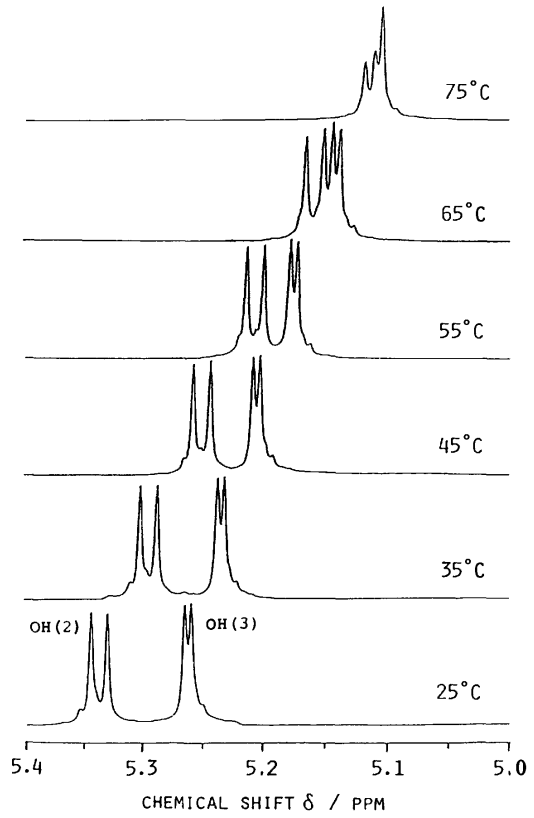

Fig. 3. The 500 MHz ^{1}H NMR spectrum of the secondary protons of α-CD at indicated temperature.

$$-OH\cdots HO- \rightleftarrows -OH\cdots O{=}S(CD_3)_2$$

The observed upfield shift of hydroxyl proton resonances with increase of temperature is attributed to decrease in the strength of the solvent-solute association. The smaller value of temperature coefficient of the chemical shift ($d\delta/dT$) means that the above equilibrium more prefers to lie to the left side i.e. hydroxyl groups preferentially form the intramolecular hydrogen bonds. The temperature dependent chemical shifts of hydroxyl protons of α-, β-, and γ-CDs and MG show that the $d\delta/dT$ values of all OH(6) proton signals are large and are nearly equal with each other (Fig. 4-A, Table 2). This observation suggests that all OH(6) protons are exposed to solvent DMSO-d_6 in a similar fashion. Since MG can't form intramolecular hydrogen bond, hydrogens of OH(6) of CDs do not participate in intramolecular hydrogen bonding. On the other hand, the $d\delta/dT$ values for OH(2) and OH(3) of CDs and DMCDs are significantly smaller than those of MG (Figs. 4-B and 4-C, respectively). This suggests that the secondary hydroxyl groups of α-, β-, and γ-CDs, and α- and β-DMCD prefer to form intramolecular hydrogen bond between OH(2) (in the case of DMCD, methoxy group) and OH(3) of the adjacent glucose units rather than to form a hydrogen bond with DMSO-d_6. The $d\delta/dT$ values for both OH(2) (α-, β-, and γ-CDs) and OH(3) increase in the following order: α-DMCD≒β-DMCD<α-CD<β-CD<γ-CD, indicating that the strength of the intramolecular hydrogen bond in DMSO-d_6 is in the following order: γ-CD<β-CD<α-CD<β-DMCD≒α-DMCD. The strength becomes weaker according to increase the ring size except α- and β-DMCDs. The macrocycle size of γ-CD might be

Fig. 4. Temperature dependence of the chemical shifts of the hydroxyl protons of α-, β-, and γ-CDs, and α- and β-DMCDs and MG; (A) OH(6), (B) OH(2), (C) OH(3). The ordinate refers to the magnitude of the upfield shift relative to the chemical shift observed at 25 °C.

too large to form the tight intramolecular hydrogen bond, and so its macrocyclic ring might be flexible. The ring size could be an important factor to form the strong intramolecular hydrogen bond.

Harata[22] has found from the X-ray study that in the hydrated crystal state the OH(2)···OH(3′) distance of adjacent glucose units is in order of α-CD>β-CD>γ-CD, indicating that the OH(2)···OH(3′) intramolecular hydrated crystal state the OH(2)···OH(3′) distance of adjacent glucose units is in order of α-CD>β-CD>γ-CD, indicating that the OH(2)···OH(3′) intramolecular remarkably distorted and two intramolecular hydrogen bonds are disrupted because of the sharp inclination of one glucose unit.[20,24] This can make weak the intramolecular hydrogen bond of α-CD. In solution, the flexibility of α-CD macrocyclic ring is sufficiently high to compensate for the disruption of intramolecular hydrogen bond. On occasion of crystallization, CDs may take energetically stable conformations, which are not necessarily suitable to form a strong hydrogen bond. Thus, it is concluded that not all of the results for the solids necessarily correspond with those for solution. For solutions, the role of solvent molecules must be considered also. The methylation of OH(2) groups are found to lead the formation of stronger intramolecular hydrogen bond. This point will be discussed in a following section.

Type of Intramolecular Hydrogen Bond. Three different modes (Fig. 5) are possible for the intramolecular hydrogen bonds of CD in DMSO-d_6, i.e. in types 1 and 2, OH(2) and OH(3) groups are main proton donors of the intramolecular hydrogen bond, respectively, and in type 3 (flip-flop type) the rapid exchange is assumed to occur between type 1 and type 2. St-Jacques et al.[17] have reported from the analysis of coupling constant $^3J_{HOCH}$ that α- and β-CDs form type 2 intramolecular hydrogen bond and Christofides et al.[18,19] have also reported from the studies of ^2H isotope effect on ^1H and ^{13}C chemical shifts that α- and β-CDs form type 2 hydrogen bond, but there is no description about the difference between α- and β-CDs. For DMCDs the type of intramolecular hydrogen bond to be considered is only type 4, because there is only one type of secondary hydroxyl group in each glucose constituent. To identify the type of

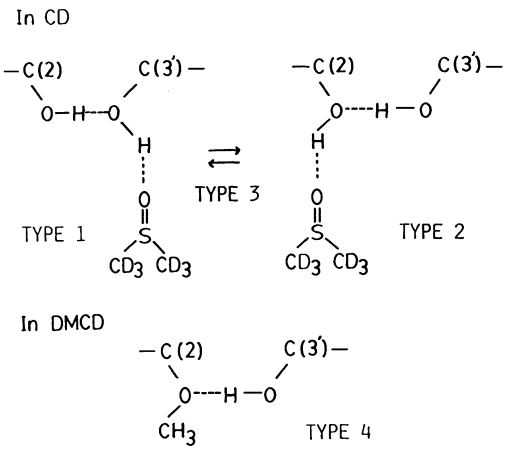

Fig. 5. The schematic representation of the intramolecular hydrogen bonds in CDs and DMCDs.

intramolecular hydrogen bond, we have tried to measure deuterium exchange rates of CD hydroxyl protons upon an addition of small amounts of deuterium oxide. If the hydrogen bond is type 1 or 2, ^1H–^2H exchange rate of hydrogen-donating hydroxyl group is slower than that of free hydroxyl group. But, ^1H–^2H exchange rate could not be estimated, since it was too rapid as compared to the NMR time scale. Then, the type of intramolecular hydrogen bond is identified based on R values (Table 2), defined as follows,

$$R = \frac{d_j^i \delta/dT}{d_j^{MG}\delta/dT}$$

where $d_j^i\delta/dT$ and $d_j^{MG}\delta/dT$ indicate the temperature coefficients of chemical shifts of j-th hydroxyl group of CD and MG, respectively, and superscript i and subscript j are,

i = α-, β-, and γ-CDs, and α- and β-DMCDs
j = OH(2), OH(3), and OH(6).

A hydroxyl group with R value of 1 is considered to be forming the intermolecular hydrogen bond with DMSO-d_6 in a similar way as that of MG. The R value smaller than 1 means that a hydroxyl group prefers to form the intramolecular hydrogen bond. The R values for the OH(6) groups of all CDs are nearly equal to 1, indicating they form the intermolecular hydrogen bond with DMSO-d_6. The OH(3) groups of α- and β-DMCDs have the smallest R values of 0.25 and 0.26, which are strongly supporting the conclusion obtained from the $d\delta/dT$ values that α- and β-DMCDs form the strongest intramolecular hydrogen bond. In α-CD the R value for the OH(3) groups (0.41) is much smaller than that for the OH(2) groups (0.60). So the OH(3) group is considered to be a dominant proton donor (type 2) for the intramolecular hydrogen bond between it and the OH(2) group of the adjacent glucose unit. Similar tendency is also observed for β-CD, though the absolute R values for OH(2) and OH(3) become larger. Thus in β-CD the type 2 intramolecular hydrogen bond is dominant, but the type 3 intramolecular hydrogen bond and the intermolecular hydrogen bond with solvent DMSO-d_6 are also formed more frequently than in α-CD. In γ-CD the R value for OH(2) is nearly equal to that for OH(3) and both are relatively large, although they are clearly less than 1. So the preferred intramolecular hydrogen bond in γ-CD is type 3, and the extent of hydrogen bond with DMSO-d_6 is not negligibly small. Therefore the character of intramolecular hydrogen bond is found to change from type 2 to type 3 with increasing the ring size of CD. The ring size of CD is considered to be an important factor determining not only the strength but also the type of the intramolecular hydrogen bond.

Orientation of Secondary Hydroxyl Groups. The values of vicinal coupling constants $^3J_{HOCH}$ for OH(2) and OH(3) groups of α-, β-, and γ-CDs didn't change within experimental error over the temperature ranged from 25 to 75 °C. This result indicates that the orientation of hydroxyl group is independent of the temperature range examined here, because the $^3J_{HOCH}$ value can be related to the dihedral angle Φ around the HO–CH bond through the Karplus type equation;[28]

$$^3J_{HOCH} = 10.4\cos^2\Phi - 1.5\cos\Phi + 0.2. \quad (1)$$

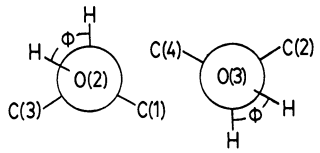
The values of coupling constants for the secondary hydroxyl groups and the estimated dihedral angles Φ are listed in Table 3. Some sets of values of dihedral angles Φ for α-, β-, and γ-CDs appear to be reasonable for making an intramolecular hydrogen bond. From the CPK molecular model study, in the case of combination of $\Phi_{OH(2)}$ and $\Phi_{OH(3)}$ values both of which are positive, formation of the intramolecular hydrogen bond between adjacent glucose units is impossible.

It is noteworthy that the $^3J_{HOCH}$ values for OH(2) of α-, β-, and γ-CDs are almost the same with that of MG, while those for OH(3) of all CDs are quite different from that of MG. This result implies that significant conformational change occurs not at OH(2) but at OH(3) group by cyclization. Needless to say that MG is monosaccharide, so it does not form the intramolecular hydrogen bond like CDs. Thus, such conformational change of the secondary hydroxyl groups of CDs might be attributed to the formation of the intramolecular hydrogen bond. The change of orientation of OH(3) group implies again that OH(3) is a major proton donor of the hydrogen bond, i.e., the predominant type of the hydrogen bond in all CDs is type 2. For these cases, the negative values of $\Phi_{OH(3)}$ are adequate for α- and β-CDs. The OH(3) group is directed to opposite direction of OH(2′) of the adjacent glucose unit, when $\Phi_{OH(3)}$ value is positive.

Table 3. The Observed Vicinal Coupling Constants $^3J_{HCOH}$ and the Calculated Dihedral Angles of Secondary Hydroxyl Groups of Some CDs in DMSO-d_6 at 35°C

	OH(2)			OH(3)		
	J/Hz	Φ/deg[a]		J/Hz	Φ/deg[a]	
α-CD	7.0	±27.9,	±137.7	2.8	±54.7,	±115.7
β-CD	6.7	±30.0,	±136.1	2.5	±56.8,	±113.8
γ-CD	7.0	±27.9,	±137.7	2.5	±56.8,	±113.8
α-DMCD				ca. 0.0	ca. ±85.9	
β-DMCD				ca. 0.0	ca. ±85.9	
MG	6.6	±30.7,	±135.7	5.1	±40.3,	±135.7

a) Φ's were computed based on the following Karplus type equation,
$^3J_{HCOH} = 10.4\cos^2\Phi - 1.5\cos\Phi + 0.2$.



For β-DMCD we can not determine the exact value of coupling constant $^3J_{HOCH}$, since the splitting of the OH(3) resonance is too small even at 500 MHz. If $^3J_{HOCH}$ value for OH(3) of β-DMCD is assumed to be 0.0 Hz, the dihedral angles estimated from Eq. 1 are ±85°. When the type 4 hydrogen bond is formed, the value of +85° is ruled out. Making CPK model with the value of −85°, the distance between OH(3′) and O(2) is found to become the shortest. This results corresponds well with small temperature coefficient of OH(3) proton chemical shift, indicating the formation of very strong intramolecular hydrogen bond in β-DMCD. It is also found from the CPK model study that the rim of β-DMCD made by the secondary hydroxyl and the methoxyl groups is slightly wider than that of β-CD made by the secondary hydroxyl groups. For 2,3,6-tri-*O*-methyl-β-CD with no intramolecular hydrogen bond, some conformational changes around the glucosidic linkage have been detected from ^{13}C NMR study,[27] but for β-DMCD any obvious changes have not been detected. The secondary hydroxyl groups of β-DMCD form the intramolecular hydrogen-bond network which maintains the stable macrocyclic structure in DMSO-d_6. For α-DMCD we can not also determine the exact value of coupling constant $^3J_{HOCH}$, because the line width of the secondary hydroxyl proton is too large in this system. The value of the coupling constant of α-DMCD is expected to be the same order as that of β-DMCD. In such case, the distance between OH(3′) and O(2) of α-DMCD becomes nearly the same as that of β-DMCD. Hence it is reasonably expected that the strength of the intramolecular hydrogen bond of α-DMCD is about the same as that of β-DMCD. This expectation is also derived from the values of $d\delta/dT$ and R.

Conclusion

In α-, β-, and γ-CDs and α- and β-DMCDs the intramolecular hydrogen bond is formed between OH(2) and OH(3′) groups of adjacent glucose units in DMSO-d_6. The strength of the intramolecular hydrogen bond of CDs in DMSO-d_6 is in the following order: α-DMCD≒β-DMCD>α-CD>β-CD>γ-CD, and this order is opposite to that found in solid. For solutions, the role of solvent molecules must be considered. α- and β-CDs prefer to form the intramolecular hydrogen bond in which OH(3) is the donor of proton. The intramolecular hydrogen bond plays an important role to maintain the stable macrocyclic structure of CDs and DMCDs investigated here.

Stereoselective Total Synthesis of (±)-Labdane-8α,15-diol and (±)-Eperuane-8β,15-diol[1]

Hiroshi HIROTA,* Toshio NAKAMURA, Takahiko TSUYUKI, and Takeyoshi TAKAHASHI†
Department of Chemistry, Faculty of Science, The University of Tokyo,
Hongo, Bunkyo-ku, Tokyo 113
(Received May 17, 1988)

(±)-Labdane-8α,15-diol and (±)-eperuane-8β,15-diol, diastereomeric diterpenes to each other, were prepared separately and stereoselectively, via a common 7-membered lactone from the known tricyclic keto alcohol.

A large number of diterpenoids possessing a labdane skeleton (**1**) occur in nature[2] and labdanolic acid (**2**) and eperuic acid (**3**) are two of the representative labdane-type diterpenoids. These acids are antipodal except for the asymmetric center at C-13 position, which was assigned to be the same (*S*)-configuration. Stereochemical assignment at C-13 position has been difficult on most of labdane-type compounds,[3] and therefore X-ray structure analysis of a derivative of labdanolic acid has been applied to establish the C-13 configuration.[4]

Concerning the synthetic works, Barltrop et al. have reported the total synthesis of methyl labdanolate (**4**) and its 13-epimer corresponding to an enantiomer of methyl eperuate (**5**), but their synthesis included non-stereoselective formation of the C-13 methyl group by hydrogenation at the final stage.[5] In this paper, we wish to report the stereoselective total synthesis of (±)-labdane-8α,15-diol (**6**) and (±)-eperuane-8β,15-diol (**7**) from a common key intermediate ((±)-**8**).

Our fundamental synthetic strategies were based on the following considerations. i) Alkylation at the α-position of the lactone carbonyl group of **8** via an enolate ion would proceed stereoselectively from the sterically less-hindered α-side. ii) If a methyl group was introduced from the α-side at this position and then one carbon-unit was homologated at the lactone carbonyl carbon, (±)-labdane-8α,15-diol (**6**) would be afforded unambiguously. iii) On the other hand, if some C_2-unit equivalent was introduced from the α-side at this position and then the lactone carbonyl carbon was converted into a methyl group, (±)-eperuane-8β,15-diol (**7**) could be obtained stereoselectively.

Preparation of the Tricyclic Lactone ((±)-8). The racemic α,β-unsaturated ketone (**9**), which could be obtained easily via the known procedure,[6] was treated with 3.5 equivalent moles of lithium in liquid ammonia, and the resulting alkoxy enolate was trapped with methyl iodide[7] to afford a methylated keto alcohol (**10**) quantitatively. The carbonyl group of **10** was removed by Huang-Minlon reduction to give unsaturated alcohol (**11**) in 95% yield. Hydrogenation of **11** over platinum catalyst afforded a saturated alcohol (**12**) in 98% yield. Jones oxidation of the alcohol (**12**) gave the corresponding ketone (**13**) quantitatively. The ketone (**13**) was treated with perbenzoic acid[8] to afford a single lactone (**8**), the Baeyer-Villiger oxidation product, in 61% yield.

Thus, (±)-**8** was obtained from the known ketone (**9**) via a five-step reaction sequence in 57% overall yield.

Synthesis of (±)-Labdane-8α,15-diol (6). The lactone (**8**) was treated with lithium diisopropylamide (LDA) followed by methyl iodide to afford a 13α-methylated lactone (**14**) in 72% yield. Since no peak due to the stereoisomeric compound could be detected in the ^{13}C NMR spectrum of the reaction product, it was concluded that the stereoselective methylation had

occurred from the sterically less-hindered α-side of the enolate. Lithium aluminium hydride reduction of this lactone (**14**) gave the corresponding diol (**15**) quantitatively.

The C_1-unit homologation at the hydroxymethyl group of **15** was attempted by Wittig reaction. Pyridinium chlorochromate oxidation of the diol (**15**) gave an aldehyde (**16**) in 46% yield, which was treated with methylenetriphenylphosphorane and hydroboration was followed. A mixture of (±)-labdane-8α,15-diol (**6**) and (±)-eperuane-8β,15-diol (**7**) was obtained in a ratio of ca. 2:1 in 65% yield. This means that the isomerization at C-13 position would take place under the Wittig reaction conditions. Hence, the transformation of hydroxyl group into cyano group was next examined to synthesize **6** without isomerization at the C-13 position.

The diol (**15**) was treated with *p*-toluenesulfonyl chloride at 0 °C to afford a monotosylate (**17**) in 87% yield. On treatment with sodium cyanide,[9] **17** afforded a cyanide (**18**) in 93% yield, which was hydrolyzed with sodium hydroxide in the presence of aqueous hydrogen peroxide[10] to give (±)-labdanolic acid (**2**) stereoselec-

a) Shift values were obtained from the ^{13}C NMR charts of authentic samples which were sent from Profs. E. L. Ghisalberti and P. R. Jefferies. Eperuane-8β,15-diol (**7**) was a natural compound and other samples (**4** and **5**) were derived from natural ones.

tively in 75% yield. This acid (**2**) was converted into (±)-methyl labdanolate (**4**) and then into (±)-labdane-8α,15-diol (**6**) via known procedures.[11]

The ^{13}C and ^{1}H NMR spectral data of synthetic **4** and **6** were completely identical with those of natural methyl labdanolate[5,12-15] and labdane-8α,15-diol[12,14,16,17] (see Table 1 for the comparison of ^{13}C NMR spectral data). Thus (±)-labdane-8α,15-diol (**6**) was synthesized stereoselectively from the lactone (**8**) by a seven-step reaction sequence in 43% overall yield.

Synthesis of (±)-Eperuane-8β,15-diol (7). As mentioned before, it is necessary to introduce a C_2-unit equivalent at the α-position of lactone carbonyl group of **8** to build up the side chain of **7**. Ethylene oxide being turned out to be ineffective,[18] the introduction of C_2-unit equivalent was achieved by allylation followed by ozonolysis. The lactone (**8**) was treated with LDA followed by allyl bromide to afford the 13α-allylated lactone (**19**) in 62% yield. No stereoisomer could be detected by ^{13}C NMR spectrum examination of the reaction product. This result indicates that allylation exclusively occurred from the sterically less-hindered α-side of the enolate. On reduction with lithium aluminium hydride, this lactone (**19**) gave the corresponding diol (**20**) in 97% yield, which was monotosylated with *p*-toluenesulfonyl chloride. The reaction product was then reduced with lithium aluminium hydride to afford an alcohol (**21**) in 80% yield, which was treated with ozone. A reductive treatment with sodium borohydride[19] was followed to give (±)-eperuane-8β,15-diol (**7**) in 82% yield. This diol (**7**) was transformed into (±)-eperuic acid (**3**) and methyl eperuate (**5**) by known procedures.[20]

The ^{13}C and ^{1}H NMR spectral data of synthetic **5** and **7** were completely identical with those of natural methyl eperuate[5,12,13,20] and eperuane-8β,15-diol,[12,20] respectively (see Table 1 for ^{13}C NMR spectral data).

Thus, (±)-eperuane-8β,15-diol (**7**) was synthesized stereoselectively by five step reactions in 39% overall yield from the same intermediate (**8**) as that used for a preparation of **6**.

Experimental

General Procedures. All melting points were measured on a Mel-temp capillary melting point apparatus (Laboratory Devices) and uncorrected. Infrared (IR) spectra were measured on a Hitachi 260-30 spectrometer. Proton nuclear magnetic resonance (^{1}H NMR) spectra were taken using a Varian EM-390 and a JEOL FX-90Q (both 90 MHz) spectrometers at ambident temperature. ^{13}C NMR spectra were measured on a JEOL FX-90Q (22.5 MHz) spectrometer. Chloroform-*d* was used as the NMR solvent unless otherwise mentioned. Chemical shifts were expressed in δ (ppm) downfield from tetramethylsilane as an internal standard and coupling constants in Hz. Mass spectra (MS) were run on a JEOL JMS-D300 mass spectrometer operating at 70 eV. Thin-layer chromatography (TLC) was carried out on Kieselgel 60 GF_{254} coated in 0.25 mm thickness. Wakogel C-200 (Wako) was used for silica-gel column chromatography.

(±)-8β-Hydroxy-1,1,4aβ,8aβ-tetramethyl-3,4,4a,6,7,8,8a,9,10,10aα-decahydro-2(1*H*)-phenanthrenone (10). In a three-necked flask, lithium metal (570 mg) and liquid ammonia (150 ml) were placed at −78 °C and stirred for 10 min under a nitrogen atmosphere. A tetrahydrofuran (THF; 70 ml) solution of keto alcohol (**9**; 6.00 g) was added to the mixture and stirred at a refluxing temperature of ammonia for 1 h. At −78 °C methyl iodide (12 ml) was added to the mixture, and the whole was again stirred at a refluxing temperature of ammonia for 2 h. After removal of ammonia at room temperature, the reaction mixture was neutralized with about 2 M hydrochloric acid (1 M=1 mol dm^{-3}) and was extracted with chloroform four times. The combined chloroform extract was washed with saturated brine, and was dried over sodium sulfate. Removal of the solvent afforded keto alcohol (**10**; 6.37 g; quantitative yield) as white crystals (from acetone), mp 139.5—142.5 °C; IR (KBr) 3400 and 1710 cm^{-1}; ^{1}H NMR δ=1.08(6H, s), 1.17 (3H, s), 1.28 (3H, s), 3.41 (1H, dd, *J*=8.5 and 7 Hz), and 5.33 (1H, t, *J*=4 Hz); MS *m/z* (%) 276 (M^+, 37), 258 (100), and 232 (82); Found: *m/z* 276.2099. Calcd for $C_{18}H_{28}O_2$: M, 276.2090.

(±)-4bβ,8,8,10aβ-Tetramethyl-1,2,3,4b,5,6,7,8,8aα,9,10,10a-dodecahydro-1β-phenanthrenol (11). To a suspension of keto alcohol (**10**; 3.70 g) in diethylene glycol (64 ml) were added 80% hydrazine hydrate (7 ml) and potassium hydroxide (9.1 g). After the mixture was heated for 2 h at 170 °C (bath temperature) about 10 ml of the solvent was distilled off and the mixture was heated for 1 h at 230 °C. Water (70 ml) and 6 M hydrochloric acid (70 ml) were added, and the mixture was extracted with benzene. The usual work-up yielded the reduction product (**11**; 3.34 g) in 95% yield as white crystals (from benzene), mp 153.5—155 °C; IR (KBr) 3300 cm^{-1}; ^{1}H NMR δ=0.87 (6H, s), 1.13 (6H, s), 3.41 (1H, dd, *J*=8.5 and 7 Hz), and 5.27 (1H, t, *J*=4 Hz); MS *m/z* (%) 262 (M^+, 21), 244 (61), 203 (75), and 106 (100); Found: C, 82.57; H, 11.61%; and *m/z* 262.2291. Calcd for $C_{18}H_{30}O$: C, 82.38; H, 11.52%; and M, 262.2298.

(±)-4bβ,8,8,10aβ-Tetramethyl-4aα*H*,8aα*H*-tetradecahydro-1β-phenanthrenol (12). A catalytic amount of platinum oxide was added to a solution of **11** (1.91 g) in acetic acid (60 ml) and the mixture was stirred under a hydrogen atmosphere at room temperature for 2.5 d. The reaction was monitored as follows; a small portion of the reaction mixture was treated with *m*-chloroperbenzoic acid. Only starting material (**11**), if present, was transformed into an epoxide, which could be differentiated from **12** by TLC examination. Filtration and evaporation afforded an alcohol (**12**; 1.89 g) in 98% yield as white crystals (from benzene), mp 179—182 °C; IR (KBr) 3300 cm^{-1}; ^{1}H NMR δ=0.81(3H, s), 0.86 (6H, s), 0.88 (3H, s), and 3.12 (1H, dd, *J*=10 and 5 Hz); MS *m/z* (%) 264 (M^+, 41), 249 (26), and 191 (100); Found: *m/z* 264.2452. Calcd for $C_{18}H_{32}O$: M, 264.2455.

(±)-4bβ,8,8,10aβ-Tetramethyl-3,4,4aα,4b,5,6,7,8,8aα,9,10,10a-dodecahydro-1(2*H*)-phenanthrenone (13). Jones reagent (5 ml) was added to a solution of the saturated alcohol (**12**; 3.47 g) in acetone (450 ml) at 0 °C , and the mixture was stirred for 30 min at the same temperature. To the mixture, a saturated aqueous solution (ca. 100 ml) of sodium sulfite was added, and then acetone was removed under reduced pressure. The reaction product was extracted with benzene

three times and dried over sodium sulfate. The benzene solution was passed through a small amount of Florisil, and the solvent was evaporated to afford ketone (**13**; 3.44 g) quantitatively, as white crystals (from ether), mp 102.5—103 °C; IR (KBr) 1710 cm^{-1}. ^1H NMR δ=0.83 (3H, s), 0.87 (3H, s), 0.95 (3H, s), and 1.14 (3H, s); MS *m/z* (%) 262 (M^+, 78), 247 (43), and 191 (100); Found: C, 82.06; H, 11.82%; and *m/z* 262.2304. Calcd for $C_{18}H_{30}O$: C, 82.38; H, 11.52%; and M, 262.2298.

(±)-5aβ,8,8,11aβ-Tetramethyl-7aαH,11bαH-tetradecahydronaphth[2,1-*b*]oxepin-4-one (8). Perbenzoic acid (9.7 g) was added to a solution of the saturated ketone (**13**; 6.20 g) in chloroform (90 ml), and the mixture was stirred at room temperature for 2 d under dark. A saturated aqueous solution (20 ml) of sodium hydrogensulfite was added to the reaction mixture, and the chloroform layer was separated, washed three times with a saturated aqueous solution of sodium hydrogencarbonate, and dried over sodium sulfate. Purification by silica-gel column chromatography (0.6% acetone in benzene) afforded 7-membered lactone (**8**; 4.00 g) in 61% yield, as white crystals (from benzene), mp 100.5—102.5 °C; IR (KBr) 1705 cm^{-1}; ^1H NMR δ=0.83 (6H, s), 0.90 (3H, s), and 1.51 (3H, s); MS *m/z* (%) 278 (M^+, 42), 263 (72), and 137 (100); Found: C, 77.81; H, 11.18%; and *m/z* 278.2238. Calcd for $C_{18}H_{30}O_2$: C, 77.65; H, 10.86%; and M, 278.2247.

(±)-3α,5aβ,8,8,11aβ-Pentamethyl-7aαH,11bαH-tetradecahydronaphth[2,1-*b*]oxepin-4-one (14). Under an argon atmosphere, a hexane solution of butyllithium (1.6 M; 5.7 ml) and diisopropylamine (1.7 ml) were added successively to THF (80 ml) at −78 °C. The mixture was stirred for 20 min at room temperature and then kept to −78 °C, to which a THF (50 ml) solution of the lactone (**8**; 1.89 g) was added. After stirring for 30 min at −78 °C and addition of methyl iodide (0.90 ml), the whole mixture was stirred at room temperature for 2 h and then a mixture of 14% aqueous solution of ammonium chloride and a small amount of sodium sulfite was added. The reaction product was extracted with ether three times, worked up as the usual manner, and separated by silica-gel column chromatography (0.3% acetone in benzene) to afford methylated lactone (**14**; 1.42 g) in 72% yield as white crystals, mp 125.5—127 °C; IR (KBr) 1715 cm^{-1}; ^1H NMR δ=0.81 (6H, s), 0.90 (3H, s), 1.17 (3H, d, *J*=7 Hz), 1.15 (3H, s); ^{13}C NMR δ=15.1, 18.8, 18.8, 19.7, 21.8, 22.9, 24.4, 32.9, 33.4, 33.6, 38.8, 39.9, 40.3, 41.6, 43.7, 55.6, 57.9, 85.5, and 177.4; MS *m/z* (%) 292 (M^+, 34), 277 (56), and 137 (100); Found: *m/z* 292.2390. Calcd for $C_{19}H_{32}O_2$: M, 292.2404.

(±)-1β-[(3*S*)-4-Hydroxy-3-methylbutyl]-2β,5,5,8aβ-tetramethyl-4aαH-decahydro-2α-naphthalenol (15). Under an argon atmosphere, lithium aluminium hydride (140 ml) was added to a solution of the methylated lactone (**14**; 1.40 g) in ether (5 ml), and the mixture was stirred at 0 °C for 30 min. The reaction was stopped by addition of a small amount of water and the mixture was filtered. The filtrate, after addition of water (50 ml), was extracted with ether three times, and the ethereal layer was dried over magnesium sulfate and successively evaporated to give diol **15** (1.42 g) quantitatively as white crystals, mp 114—115 °C; IR (KBr) 3350 cm^{-1}; ^1H NMR δ=0.80 (6H, s), 0.88 (3H, s), 0.91 (3H, d, *J*=6 Hz), 1.15 (3H, s), and 3.46 (2H, br t, *J*=5 Hz); MS *m/z* (%) 296 (M^+, 8), 278 (21), 263 (25), and 69 (100); Found: *m/z* 296.2714. Calcd for $C_{19}H_{36}O_2$: M, 296.2717.

(±)-1β-[(3*S*)-3-Methyl-4-oxobutyl]-2β,5,5,8aβ-tetramethyl-4aαH-decahydro-2α-naphthalenol (16). A solution of diol **15** (300 mg) in dichloromethane (20 ml) was added to a solution of pyridinium chlorochromate (1.04 g) in dichloromethane (70 ml) and the mixture was stirred at room temperature for 40 min. A saturated aqueous solution (100 ml) of sodium hydrogencarbonate together with a small amount of sodium sulfite was added. After filtration with Celite under reduced pressure, the reaction mixture was extracted three times with chloroform, dried over magnesium sulfate, and separated by a silica-gel column chromatography (1% acetone in benzene). Pure hydroxy aldehyde **16** (140 mg) was obtained in 46% yield as a colorless oil; IR (neat) 3450 and 1720 cm^{-1}; ^1H NMR δ=0.78 (6H, s), 0.86 (3H, s), 1.08 (3H, d, *J*=9 Hz), 1.13 (3H, s), 2.33 (1H, br sextet, *J*=6 Hz), and 9.57 (1H, d, *J*=2 Hz); MS *m/z* (%) 294 (M^+, 7), 276 (28), and 109 (100); Found: *m/z* 294.2541. Calcd for $C_{19}H_{34}O_2$: M, 294.2560.

Preparation of a Mixture of (±)-Labdane-8α,15-diol (6) and (±)-Eperuane-8β,15-diol (7) from the Hydroxy Aldehyde (16). Under a nitrogen atmosphere, a solution of methyltriphenylphosphonium iodide (426 mg) in THF (25 ml) was added to a hexane solution of butyllithium (1.6 M; 0.7 ml) at 0 °C, and the mixture was stirred at room temperature for 1.5 h. A solution of the hydroxy aldehyde **16** (140 mg) in THF (10 ml) was added to the mixture, and was refluxed for 18 h. Addition of a saturated aqueous solution (30 ml) of ammonium chloride followed by evaporation of THF gave a residue, which was extracted with hexane three times and dried over magnesium sulfate. Separation by column chromatography on silica gel (0.5% acetone in benzene) afforded a diastereomeric mixture of the Wittig reaction product (60 mg) as an oil; IR (neat) 3450 and 1635 cm^{-1}; ^1H NMR δ=0.77 (6H, s), 0.85 (3H, s), 0.97 (3H, d, *J*=6 Hz), 1.11 (3H, s), 4.88 (1H, br d, *J*=11 Hz), 4.92 (1H, br d, *J*=17 Hz), and 5.63 (1H, ddd, *J*=17, 11, and 4 Hz); MS *m/z* (%) 292 (M^+, 19), 274 (10), and 69 (100); Found: *m/z* 292.2776. Calcd for $C_{20}H_{36}O$: M, 292.2768. To a solution of the diastereomeric mixture (60 mg) in THF (7 ml) was added a THF solution of diborane (0.4 M; 1 ml) at 0 °C under nitrogen atmosphere, and the mixture was stirred at room temperature for 1.5 h. Water (1 ml), 3 M aqueous solution of sodium hydroxide (1 ml), and 30% aqueous solution of hydrogen peroxide (1 ml) were successively added, and the mixture was stirred at 40 °C for 1.5 h, and then extracted with ether three times. The ethereal layer was dried over magnesium sulfate and purified by silica-gel column chromatography (5% acetone in benzene) to afford 27 mg of labdane-8α,15-diol (**6**; 42% yield) and 14.5 mg of eperuane-8β,15-diol (**7**; 23% yield), both as crystalline compounds. Physical and spectral data of these diols (**6** and **7**) were completely identical with those synthesized from separate routes mentioned below.

(±)-1β-[(3*S*)-3-Methyl-4-(*p*-tolylsulfonyl)butyl]-2β,5,5,8aβ-tetramethyl-4aαH-decahydro-2α-naphthalenol (17). The diol (**15**; 191 mg) and *p*-toluenesulfonyl chloride (300 mg) were dissolved into pyridine (6 ml), and the mixture was stirred at 0 °C for 12 h. After addition of water and 2 M hydrochloric acid, the reaction product was extracted. The ethereal extract was worked up as usual and subjected to separation by Florisil column chromatography to afford monotosylate (**17**; 254 mg; 87% yield) as white crystals (from ether), mp 97—98.5 °C; IR (KBr) 3600—3400, 1360, and 1180 cm^{-1}; ^1H NMR δ=0.75 (3H, s), 0.78 (3H, s), 0.86 (3H, s),

0.89 (3H, d, J=6 Hz), 1.06 (3H, s), 2.43 (3H, s), 3.80 (2H, d, J=6 Hz), 7.27 (2H, d, J=8 Hz), and 7.71 (2H, d, J=8 Hz); MS m/z (%) 450 (M^+, 6), 432 (59), 417 (42), and 191 (100); Found: m/z 450.2788. Calcd for $C_{26}H_{42}O_4S$: M, 450.2803.

(±)-1β-[(3*S*)-4-Cyano-3-methylbutyl]-2β,5,5,8aβ-tetramethyl-4aα*H*-decahydro-2α-naphthalenol (18). The monotosylate (**17**; 226 mg) and sodium cyanide (260 mg) were added to a mixture of tributylamine (0.2 ml) and water (1 ml), and the whole mixture was refluxed with vigorous stirring for 6 h. The reaction product was extracted with ether and worked up as usual. Column chromatography on Florisil afforded nitrile (**18**; 142 mg; 93% yield) as white crystals (from ether–hexane), mp 51—52 °C; IR (KBr) 3600—3400, 2250, and 940 cm^{-1}; ^1H NMR (CCl_4) δ=0.79 (6H, s), 0.85 (3H, s), 1.07 (3H, d, J=7 Hz), 1.09 (3H, s), and 2.26 (2H, m); MS m/z (%) 305 (M^+, 5), 290 (4), 287 (3), 272 (7), and 71 (100); Found: m/z 305.2689. Calcd for $C_{20}H_{35}NO$: M, 305.2717.

(±)-Labdanolic Acid (2). A mixture of the nitrile **18** (49 mg), sodium hydroxide (500 mg), ethanol (5 ml), and 30% aqueous hydrogen peroxide (5 ml) was stirred at ca. 70 °C for about 30 min until the evolution of oxygen ceased. Then the mixture was refluxed for 7.5 h. After addition of an aqueous solution of sodium sulfite, evaporation of ethanol, and then addition of 2 M hydrochloric acid, the reaction product was extracted with ether. The ethereal layer was washed with a saturated brine, dried over sodium sulfate and evaporated to give a crude reaction mixture, which was separated by silica-gel column chromatography. From the ether eluant, 39 mg (75% yield) of labdanolic acid (**2**) was obtained as white crystals (from hexane–ether), mp 150.5—152 °C; IR (KBr) 3400, 1705, and 1690 cm^{-1}; ^1H NMR δ=0.80 (6H, s), 0.87 (3H, s), 0.98 (3H, d, J=6.5 Hz), 1.15 (3H, s), and 2.27 (2H, m); MS m/z (%) 324 (M^+, 45), 306 (45), 291 (43), and 69 (100); Found: m/z 324.2671. Calcd for $C_{20}H_{36}O_3$: M, 324.2665.

(±)-Methyl Labdanolate (4). To an ethereal solution of labdanolic acid (**2**; 34 mg) was added an ethereal solution of diazomethane (about three equivalent moles), and the mixture was stood for 5 h at room temperature. Removal of ether afforded the corresponding methyl ester **4** quantitatively as an oil; IR (neat) 3500 and 1740 cm^{-1}; ^1H NMR δ=0.80 (6H, s), 0.86 (3H, s), 0.95 (3H, d, J=6.5 Hz), 1.15 (3H, s), 2.25 (2H, m), and 3.64 (3H, s); ^{13}C NMR (Table 1); MS m/z (%) 338 (M^+, 13), 320 (8), 305 (8), 144 (60), and 69 (100); Found: m/z 338.2802. Calcd for $C_{21}H_{38}O_3$: M, 338.2819.

(±)-Labdane-8α,15-diol (6). To a solution of methyl labdanolate (**4**; 31.5 mg) in THF (10 ml) was added lithium aluminium hydride (20 mg), and the mixture was stirred at room temperature for 1 h. After addition of 2 M hydrochloric acid, the reaction mixture was extracted with ether. The ethereal layer was worked up in the usual manner and separated by silica-gel column chromatography. Pure labdane-8α,15-diol (**6**; 28.5 mg) was obtained in 99% yield as white crystals (from chloroform–hexane), mp 111.5—112.5 °C; IR (KBr) 3350 cm^{-1}; ^1H NMR δ=0.79 (6H, s), 0.87 (3H, s), 0.90 (3H, d, J=6.5 Hz), 1.14 (3H, s), and 3.66 (2H, t, J=6 Hz); ^{13}C NMR (Table 1); MS m/z (%) 310 (M^+, 3), 292 (17), 277 (20), and 69 (100); Found: m/z 310.2856. Calcd for $C_{20}H_{38}O_2$: M, 310.2873.

(±)-5aβ,8,8,11aβ-Tetramethyl-3α-(2-propenyl)-7aα*H*, 11bα*H*-tetradecahydronaphth[2,1-*b*]oxepin-4-one (19). Under an argon atmosphere, a hexane solution of butyllithium (1.6 M; 6.3 ml) and diisopropylamine (1.75 ml) were added successively to THF (70 ml) at −78 °C. The mixture was stirred for 20 min at room temperature and then kept at −78 °C. A solution of the lactone (**8**; 2.10 g) in THF (60 ml) was added to the mixture and the stirring was continued for 30 min at −78 °C. Then a mixture of allyl bromide (1.7 g) and THF (5 ml) was added, and the whole mixture was stirred at room temperature for 2 h. The reaction mixture was subjected to the same work-up as that for **14** and separated on silica-gel column chromatography (0.3% acetone in benzene), and the allylated lactone **19** (1.49 g) was obtained in 62% yield as white crystals (from benzene), mp 78.5—79.5 °C; IR (KBr) 1720 and 1650 cm^{-1}; ^1H NMR δ=0.77 (6H, s), 0.85 (3H, s), 1.48 (3H, s), 5.00 (1H, br d, J=11 Hz), 5.03 (1H, br d, J=15 Hz), and 5.63 (1H, ddt, J=15, 11, and 5 Hz); ^{13}C NMR δ=15.0, 18.7, 19.6, 21.7, 22.9, 24.3, 29.6, 33.3, 33.5, 36.7, 38.7, 39.8, 41.5, 43.6, 45.1, 55.5, 57.9, 85.7, 116.8, 136.3, and 176.2; MS m/z (%) 318 (M^+, 18), 303 (39), and 191 (100); Found: m/z 318.2546. Calcd for $C_{21}H_{34}O_2$: M, 318.2560.

(±)-1β-[(3*R*)-3-Hydroxymethyl-5-hexenyl]-2β,5,5,8aβ-tetramethyl-4aα*H*-decahydro-2α-naphthalenol (20). Under an argon atmosphere, lithium aluminium hydride (160 mg) was added to a solution of the allylated lactone (**19**; 1.40 g) in ether (7 ml), and the mixture was stirred at 0 °C for 30 min. The same work-up as that for **15** was followed to afford diol **20** (1.38 g) in 97% yield as white crystals, mp 109—110 °C; IR (KBr) 3350 and 1640 cm^{-1}; ^1H NMR δ=0.79 (6H, s), 0.86 (3H, s), 1.14 (3H, s),2.09 (2H, br t, J=7 Hz), 3.47 (1H, dd, J=11 and 3 Hz), 3.65 (1H, dd, J=11 and 3 Hz), 4.96 (1H, br d, J=11 Hz), 5.02 (1H, br d, J=16 Hz), and 5.80 (1H, ddt, J=16, 11, and 7 Hz); MS m/z (%) 332 (M^+, 4), 304 (9), 289 (16), and 95 (100); Found: C, 78.10; H, 11.95%; m/z 322.2867. Calcd for $C_{21}H_{38}O_2$: C, 78.20; H, 11.87%; M, 322.2873.

(±)-1β-[(3*R*)-3-Methyl-5-hexenyl]-2β,5,5,8aβ-tetramethyl-4aα*H*-decahydro-2α-naphthalenol (21). Under an argon atmosphere, *p*-toluenesulfonyl chloride (1.60 g) was added to a solution of the diol **20** (1.30 g) in pyridine (50 ml) at 0 °C, and the mixture was stirred at room temperature for 10 h. The reaction mixture was subjected to the same work-up as that for **17**, and separated by silica-gel column chromatography (0.7% acetone in benzene) to afford monotosylate (1.80 g) as an oil. To a solution of this crude monotosylate, without further purification, in ether (60 ml) was added lithium aluminium hydride (1.20 g), and the mixture was refluxed for 7 h under an argon atmosphere. The reaction was completely stopped by addition of water, and the mixture was filtered under reduced pressure. The filtrate was extracted with ether three times, and the ethereal extract was worked up as usual to yield olefinic alcohol **21** (1.00 g) in 80% yield as white crystals, mp 47—47.5 °C; IR (KBr) 3350 and 1640 cm^{-1}; ^1H NMR δ=0.78 (6H, s), 0.86 (3H, s), 0.89 (3H, d, J=6.5 Hz), 1.15 (3H, s), 4.97 (1H, br d, J=10 Hz), 4.99 (1H, br d, J=17 Hz), and 5.78 (1H, ddt, J=17, 10, and 7 Hz); MS m/z (%) 306 (M^+, 15), 288 (12), 273 (16), and 69 (100); Found: C, 82.25; H, 12.78%; m/z 306.2927. Calcd for $C_{21}H_{38}O$: C, 82.29; H, 12.49%; M, 306.2924.

(±)-Eperuane-8β,15-diol (7). To a solution of the olefin alcohol **21** (935 mg) in chloroform (45 ml) was introduced ozone (8%; 0.015 mol h^{-1}) at −20 °C for 1.5 h with stirring. Sodium borohydride (935 mg) in a 50% ethanol aqueous solution (80 ml) was added at 0 °C, and the whole mixture was stirred at 50 °C for 1 h, and then at room temperature for 5 h. After neutralization with 10% sulfuric acid, the reaction product was extracted with chloroform three times and the

organic layer was worked up as usual. Evaporation followed by silica-gel column chromatography (5% acetone in benzene) afforded eperuane-8β,15-diol (**7**; 773 mg) in 82% yield as white crystals (from benzene), mp 126—128 °C; IR (KBr) 3300 cm^{-1}; ^1H NMR δ=0.79 (6H, s), 0.87 (3H, s), 0.91 (3H, d, J=7.5 Hz), 1.15 (3H, s), 3.68 (2H, td, J=6 and 1.5 Hz); ^{13}C NMR (Table 1); MS m/z (%) 310 (M^+, 11), 292 (8), 277 (9), and 69 (100); Found: C, 75.16; H, 12.44%. Calcd for $C_{20}H_{38}O_2 \cdot 1/2\,H_2O$: C, 75.18; H, 12.30%; Found: m/z 310.2893. Calcd for $C_{20}H_{38}O_2$: M, 310.2873.

The authors wish to thank Professors E. L. Ghisalberti and P. R. Jefferies, Department of Organic Chemistry, the University of Western Australia for the kind sending of the ^1H and ^{13}C NMR spectral charts of optically active methyl labdanolate (**4**), methyl eperuate (**5**), and eperuane-8β,15-diol (**7**).

A Highly Chemoselective Reduction of Conjugated Nitro Olefins with Hantzsch Ester in the Presence of Silica Gel

Masayuki FUJII
Department of Industrial Chemistry, Faculty of Engineering, Kinki University in Kyushu, 11-6 Kaya-no-mori, Iizuka, Fukuoka 820
(Received May 19, 1988)

An effective system to reduce conjugated nitro olefins into the corresponding nitroalkanes is described. The system composed of Hantzsch ester (HEH) and silica gel in benzene exerts high yield and excellent chemoselectivity under almost neutral conditions. Facile applications of the system to the syntheses of natural products are also described.

The importance of aliphatic nitro compounds has remarkably increased in synthetic organic chemistry.[1] They are very useful tools for carbon–carbon bond formation because the strongly electron-withdrawing property of nitro group makes it possible to generate an α-carbanion adjacent to the group and to react with various electrophiles under mild reaction conditions. Moreover, nitro group itself can be converted into other functions such as carbonyl,[2] amino,[3] oxime,[4] hydrogen,[5] and so on. Namely the preparation[6] and reaction[7] of conjugated nitro olefins have been studied extensively and the compounds of this class have been widely accepted as intermediates to nitroalkanes via reductive hydrogenation.[8–12] Although a number of reducing reagents to convert a nitro olefin into the corresponding nitroalkane have been reported, there still remain several problems to be improved. For example, catalytic hydrogenation also reduces non-conjugated carbon–carbon double bonds,[9] and sodium borohydride cannot be employed for the reduction of compounds with a carbonyl function.[10]

On the other hand, reduction with NAD(P)H or its analogs received a wide interest in the recent decade. Particularly, the discussion on the mechanism of reduction has involved a lot of researchers not only in organic chemistry but also physical, analytical, and biochemistries.[13] It is suspected that 1,4-dihydropyridine derivatives might be characterized as a remarkable reducing reagent because the compounds in this category have too low potentials to reduce most of various functional groups, which, in turn, may exert interesting selectivity (chemo-, regio-, stereo-, or some other), especially for substrates with a variety of functional groups, under certain reaction conditions. However, unfortunately, studies on 1,4-dihydropyridine derivatives as tools in synthetic chemistry have enjoyed little attention and only few reports have been published concerning to this subject.[14,15] Namely, we found that silica gel catalyzes the reduction of certain functional groups while others remain unaffected.[14,16,17]

As a part of our research to find a selective organic reaction, it was elucidated that 3,5-bis(ethoxycarbonyl)-2,6-dimethyl-1,4-dihydropyridine (Hantzsch ester, HEH) is indeed a useful reagent to reduce certain functional groups selectively. In this report, the author wishes to describe a convenient method for the reduction of nitro olefins with HEH, in the presence of silica gel, with high chemoselectivity and in high yield under mild reaction conditions.[18]

Experimental

Instruments. ^{1}H NMR spectra were measured at 100 MHz with a JOEL JUN-FX 100 Fourier transform NMR spectrometer and at 400 MHz with a JOEL GX400 Fourier transform NMR spectrometer. IR spectra were recorded on a Hitachi EPI-S2 infrared spectrometer. Elemental analyses were performed with a Yanaco MT-3 elemental analyzer. Gas chromatographic data were recorded on a Yanaco G-1800 gas chromatograph (OV 330). GC mass data were recorded on a Hitachi M-80A GC Mass analyzer.

Materials. Hantzsch ester (HEH) and its 4,4-dideuteriated analog (HEH-4,4-d_2) were prepared as reported in a previous paper.[19] The deuterium content in HEH-4,4-d_2 was confirmed to be 98% by 400 MHz ^{1}H NMR analysis. Solvents were freshly distilled before the use. Silica gel (Nakarai Silica Gel 60, 35—70 mesh) was dried in an oven at 80 °C for a few days.

Preparation of Nitro Olefins. 1-Nitro-4-methyl-1-pentene (1a): A mixture of 8.6 g of 3-methylbutanal, 9.2 g of nitromethane, and 2.0 g of triethylamine was stirred at room temperature for 17 h, then quenched by addition of 50 ml of 2 M (1 M=1 mol·dm^{-3}) hydrochloric acid. The resulting solution was washed with water (2×50 ml) and 50 ml of brine, and dried on anhydrous sodium sulfate. After removal of the solvent, the residue was purified by a column chromatography on silica gel with benzene eluent to give 11.4 g (78%) of 1-nitro-4-methyl-2-pentanol. The β-nitro alcohol was then added into a mixture of 16 g of acetic anhydride and 18.4 g of pyridine and the solution was stirred at room temperature for 2 h. The reaction mixture was poured into 50 ml of 2 M hydrochloric acid and extracted with ether (3×30 ml). The organic layer was washed with water (3×30 ml) and brine (1×30 ml) and then dried on anhydrous sodium sulfate. After removal of the solvent the residue was purified by column chromatography on silica gel with hexane–benzene (1:1) as an eluent to give 14.4 g (98%) of the acetate. 14.4 g of the acetate was dissolved in 100 ml of benzene and the resulting solution was refluxed with 32 g of sodium carbonate for 5 h. The reaction mixture was filtered and the filtrate was washed with water (2×50 ml)

and brine (1×50 ml). The organic layer was dried and the solvent was evaporated under reduced pressure. Distillation of the residue with a Kugelrohr distillator gave 5.7 g (58%) of **1a**: bp 100 °C (2.7×10^3 Pa). ^{1}H NMR ($CDCl_3$) δ=0.98 (d, 6H, J=6 Hz), 1.65—2.04 (m, 1H), 2.18 (t, 2H, J=6 Hz), 6.95 (d, 1H, J=14 Hz) and 7.25 (dt, 1H, J=14, 6 Hz). IR (neat) 3000 (m), 1655 (s), 1530, and 1383 cm^{-1} (s).

Other nitro olefins except **1i** were prepared with the same method as described for **1a**.

1-Nitro-1-nonene (1b): Yield 43%. ^{1}H NMR ($CDCl_3$) δ=0.88 (t, 3H, J=6 Hz), 1.20—1.63 (m, 10H), 2.26 (q, 2H, J=6 Hz), 6.94 (d, 1H, J=14 Hz), and 7.25 (dt, 1H, J=14, 6 Hz). IR (neat) 3000 (m), 1656 (m), 1532, and 1357 cm^{-1} (s).

Methyl 4-Nitro-4-heptenoate (1c): Yield 67%. ^{1}H NMR ($CDCl_3$) δ=1.14 (t, 3H, J=7 Hz), 2.16—2.48 (m, 2H), 2.78—3.01 (m, 4H), 3.68 (s, 3H), and 7.06 (t, 1H, J=7 Hz). IR (neat) 3000 (m), 1750 (s), 1644(m), 1530, and 1375 cm^{-1} (s).

5-Nitro-5-octen-2-one (1d): Yield 51%. ^{1}H NMR ($CDCl_3$) δ=1.13(t, 3H, J=7 Hz), 2.16—2.48 (m, 2H), 2.63—2.96 (m, 4H), and 7.11 (t, 1H, J=7 Hz). IR (neat) 3000 (m), 1725 (s), 1644 (m), 1530, and 1370 cm^{-1} (s).

3,6-Dimethyl-9-nitro-2,8-undecadiene (1e): Yield 60%. Bp 80—90 °C (9.3×10 Pa) (by Kugelrohr distillation). ^{1}H NMR ($CDCl_3$) δ=0.95 (d, 3H, J=6 Hz), 1.10 (t, 3H, J=7 Hz), 1.07—1.44 (m, 3H), 1.60 (s, 3H), 1.68 (s, 3H), 1.91—2.27 (m, 4H), 2.61 (q, 2H, J=7 Hz), 5.07 (m, 1H), and 7.06 (t, 1H, J=8 Hz). IR (neat) 3000 (m), 1670 (m), 1527, and 1380 cm^{-1} (s).

4,8-Dimethyl-1-nitro-1,7-nonadiene (1f): Yield 63%. Bp 100—120 °C (3.3×10 Pa) (by Kugelrohr distillation). ^{1}H NMR ($CDCl_3$) δ=0.95 (d, 3H, J=6 Hz), 1.10—1.44 (m, 3H), 1.60 (m, 3H), 1.68 (m, 3H), 1.93—2.44 (m, 4H), 5.07 (m, 1H), 6.95 (d, 1H, J=14 Hz), and 7.25 (dt, 1H, J=14, 8 Hz). IR (neat) 3000 (m), 1650 (m), 1530, and 1380 cm^{-1} (s).

β-Nitrostyrene (1j): Yield 60%. Mp 58 °C. ^{1}H NMR ($CDCl_3$) δ=7.36—7.50 (m, 5H), 7.53 (d, 1H, J=14 Hz), and 7.96 (d, 1H, J=14 Hz). IR (Nujol) 3000 (m), 1630 (m), 1515, and 1385 cm^{-1} (s).

***o*-Methoxy-β-nitrostyrene (1k):** Yield 78%. Mp 81.5—82 °C. ^{1}H NMR ($CDCl_3$) δ=3.91 (s, 3H), 6.90—7.05 (m, 2H), 7.35—7.52 (m, 2H), 7.80 (d, 2H, J=14 Hz), and 8.06 (d, 2H, J=14 Hz). IR (Nujol) 3000 (m), 1628 (m), 1538, and 1375 cm^{-1} (s).

***p*-Methoxy-β-nitrostyrene (1l):** Yield 74%. Mp 85.5—86.5 °C. ^{1}H NMR ($CDCl_3$) δ=3.85 (s, 3H), 6.85—7.00 (m, 2H), 7.41—7.56 (m, 2H), 7.48 (d, 1H, J=14 Hz), and 7.95 (d, 1H, J=14 Hz). IR (Nujol) 3000 (m), 1608 (m), 1608 (m), 1513, and 1375 cm^{-1} (s).

β-Methyl-β-nitrostyrene (1m): Yield 82%. Mp 64 °C. ^{1}H NMR ($CDCl_3$) δ=2.42 (s. 3H), 7.39 (m, 5H), and 8.02 (m, 1H). IR (Nujol) 3000 (m), 1650 (m), 1530, and 1378 cm^{-1} (s).

***p*-Methoxy-β-methyl-β-nitrostyrene (1n):** Yield 50%. Mp 46.5—47 °C. ^{1}H NMR ($CDCl_3$) δ=2.45 (s, 3H), 3.84 (s, 3H), 6.86—7.01 (m, 2H), 7.31—7.44 (m, 2H), and 8.02 (m, 1H). IR (Nujol) 3000 (m), 1605(m), 1515, and 1380 (s).

2-(2-Furyl)-1-nitroethene (1o): Yield 32%. Mp 72 °C. ^{1}H NMR ($CDCl_3$) δ=6.51—6.58 (m, 1H), 6.84—6.88 (m, 2H), 7.49 (d, 1H, 14 Hz), and 7.69 (d, 1H, J=14 Hz). IR (Nujol) 3000 (m), 1635 (m), 1500, and 1375 cm^{-1} (s).

2-(2-Thienyl)-1-nitroethene (1p): Yield 66%. Mp 79—80 °C. ^{1}H NMR ($CDCl_3$) δ=7.07—7.16 (m, 1H), 7.21—7.56 (m, 2H), 7.43 (d, 1H, J=13 Hz), and 8.12 (d, 1H, J=13 Hz). IR (Nujol) 3000 (m), 1622(m), 1525, and 1380 cm^{-1} (s).

Ethyl 3-Methyl-2-nitro-2-butenoate (1g): A mixture of 7.6 ml of 90% fuming nitric acid and 1.1 ml of water was cooled to 0 °C, and 2.56 g of ethyl 3-methyl-2-butenoate was added to this mixture over 1.25 h with vigorous stirring. The solution was stirred for 1.5 h at 0 °C and 1 h at room temperature, and then poured onto 50 ml of crushed ice and extracted three times with 30 ml of chloroform. The extracts were combined and washed three times with 50 ml of water, six times with 30 ml of saturated aqueous sodium hydrogencarbonate and twice with 30 ml of brine, dried over anhydrous sodium sulfate, and concentrated under reduced pressure. The residual oil was distilled to give 3.14 g (91%) of **1i** as colorless oil. Bp 87.5 °C (3.1×10^2 Pa). ^{1}H NMR ($CDCl_3$) δ=1.29 (t, 3H, J=7 Hz), 1.97 (s, 3H), 2.25 (s, 3H), and 4.27 (q, 2H, J=7 Hz). IR (neat) 3000 (m), 1725 (s), 1650 (m), 1540, and 1375 cm^{-1} (s).

2-Methyl-2-(2-nitroethenyl)cyclohexanone (**1h**) and 1-(2-nitroethenyl)cyclohexanecarbaldehyde (**1i**) were supplied by Prof. K. Fuji of Institute for Chemical Research, Kyoto University.

Reduction of Nitro Olefins. 1-Nitro-4-methylpentane (2a): In a 30 ml round-bottom flask equipped with a magnetic stirrer and a reflux condenser were placed 258 mg (2.0 mmol) of **1a**, 560 mg (2.2 mmol) of HEH, 2.0 g of silica gel (Nakarai Silica Gel 60, 35—70 mesh), and 10 ml of anhydrous benzene. The reaction mixture was heated to reflux for 30 minutes under an argon atmosphere. The reaction mixture was cooled to room temperature, filtered, and the precipitate was washed with 30 ml of benzene. The combined organic solution was concentrated under reduced pressure and the residue was subjected to column chromatography on silica gel with hexane–benzene (1 : 1) as an eluent. As a pure product, 202 mg (78%) of **2a** was obtained. ^{1}H NMR ($CDCl_3$) δ=0.91 (d, 6H, J=6 Hz), 1.14—1.36 (m, 2H), 1.42—1.74 (m, 1H), 1.86—2.08 (m, 2H), and 4.34 (t, 2H, J=7 Hz). IR (neat) 3000 (m), 1555, and 1390 cm^{-1} (s).

Reductions of the other nitro olefins were carrried out following the general procedure described above.

1-Nitrononane (2b): Yield 91%. ^{1}H NMR ($CDCl_3$) δ=0.88 (t, 3H, J=6 Hz), 1.20—1.40 (m, 12H), 2.00 (m, 2H), and 4.36 (t, 2H, J= 7 Hz). IR (neat) 3000 (m), 1558, and 1385 cm^{-1} (s).

Methyl 4-Nitroheptanoate (2c): Yield 87%. ^{1}H NMR ($CDCl_3$) δ=0.95 (t, 3H, J=6 Hz), 1.20—1.53 (m, 2H), 2.00—2.46 (m, 6H), 3.70(s, 3H), and 4.42—4.69 (m, 1H). IR (neat) 3000 (m), 1743 (s), 1550, and 1380 cm^{-1} (s).

5-Nitro-2-octanone (2d): Yield 86%. ^{1}H NMR ($CDCl_3$) δ=0.95 (t, 3H, J=6 Hz), 1.20—1.53 (m, 6H), 2.08 (s, 3H), and 4.44—4.71 (m, 1H). IR (neat) 3000 (m), 1715 (s), 1550, and 1370 cm^{-1} (s).

3,6-Dimethyl-9-nitro-2-undecene (2e): Yield 88%. ^{1}H NMR ($CDCl_3$) δ=0.87 (d, 3H, J=6 Hz), 0.95 (t, 3H, J=7 Hz), 1.08—1.48 (m, 6H), 1.59 (s, 3H), 1.75—2.08 (m, 5H), 4.21—4.48 (m, 1H), and 4.97—5.16 (m, 1H). IR (neat) 3000 (m), 1560, and 1380 cm^{-1} (s).

2,6-Dimethyl-9-nitro-2-nonene (2f): Yield 83%. ^{1}H NMR ($CDCl_3$) δ=0.91, (d, 3H, J=6 Hz), 1.12—1.44 (m, 5H), 1.60 (s, 3H), 1.68 (s, 3H), 1.97 (q, 2H, J=7 Hz), 2.03 (t, 2H, J=7 Hz), 4.35 (t, 2H, J=7 Hz), and 4.98—5.16 (m, 1H). IR (neat) 3000 (m), 1563, and 1390 cm^{-1} (s).

Ethyl 3-Methyl-2-nitrobutanoate (2g): Yield 71%. ^{1}H

NMR ($CDCl_3$) δ=1.13 (d, 6H, J=7 Hz), 1.35 (t, 3H, J=7 Hz), 2.47—2.96 (m, 1H, J=7 Hz), 4.34 (q, 2H, J=7 Hz), and 5.93 (d, 1H, J=8 Hz). IR (neat) 3000 (m), 1760 (s), 1570, and 1380 cm^{-1} (s).

2-Methyl-2-(2-nitroethyl)cyclohexan-1-one (2h): Yield 90%. ^1H NMR ($CDCl_3$) δ=1.20 (s, 3H), 1.68—1.90 (m, 6H), 2.04—2.46 (m, 4H), and 4.43 (t, 2H, J=7 Hz). IR (neat) 3000 (m), 1715 (s), 1560, and 1390 cm^{-1} (s).

1-(2-Nitroethyl)cyclohexanecarbaldehyde (2i): Yield 45%. ^1H NMR ($CDCl_3$) δ=1.27—1.98 (m, 10H), 2.22 (t, 2H, J=7 Hz), 4.32 (t, 2H, J=8 Hz), and 9.23 (s, 1H). IR (neat): 3000 (m), 1710 (s), 1561, and 1390 cm^{-1} (s).

(2-Nitroethyl)benzene (2j): Yield 84%. ^1H NMR ($CDCl_3$) δ=3.30 (t, 2H, J=7 Hz), 4.58 (t, 2H, J=7 Hz), and 7.11—7.33 (m, 5H). IR (neat) 3000 (m), 1530, and 1380 cm^{-1} (s).

1-Methoxy-2-(2-nitroethyl)benzene (2k): Yield 84%. ^1H NMR ($CDCl_3$) δ=3.31 (t, 2H, J=7 Hz), 3.81 (s, 3H), 4.59 (t, 2H, J=7 Hz), and 6.81—7.35 (m, 4H). IR (neat) 3000 (m), 1556, and 1383 cm^{-1} (s).

1-Methoxy-4-(2-nitroethyl)benzene (2l): Yield 65%. ^1H NMR ($CDCl_3$) δ=3.27 (t, 2H, J=7 Hz), 3.91 (s, 3H), 4.58 (t, 2H, J=7 Hz), and 6.80—7.17 (m, 4H). IR (neat) 3000 (m), 1550, and 1380 cm^{-1} (s).

2-Nitropropylbenzene (2m): Yield 87%. ^1H NMR ($CDCl_3$) δ=1.51 (d, 3H, J=6 Hz), 2.86—3.40 (m, 2H), 4.57—4.92 (m, 1H), and 7.07—7.30 (m, 5H). IR (neat) 3000 (m), 1550, and 1390 cm^{-1} (s).

1-Methoxy-4-(2-nitropropyl)benzene (2n): Yield 100%. ^1H NMR ($CDCl_3$) δ=1.50 (d, 3H, J=6 Hz), 2.80—3.32 (m, 2H), 3.74 (s, 3H), 4.52—4.87 (m, 1H), and 6.74—7.08 (m, 4H). IR (neat) 3000 (m), 1545, and 1385 cm^{-1} (s).

2-(2-Furyl)-1-nitroethane (2o): Yield 62%. ^1H NMR ($CDCl_3$) δ=3.34 (t, 2H, J=7 Hz), 4.62 (t, 2H, J=7 Hz), 6.08—6.14 (m, 1H), 6.26—6.32 (m, 1H), and 7.30—7.33 (m, 1H). IR (neat) 3000 (m), 1555, and 1380 cm^{-1} (s)

2-(2-Thienyl)-1-nitroethane (2p): Yield 83%. ^1H NMR ($CDCl_3$) δ=3.49 (t, 2H, J=7 Hz), 4.57 (t, 2H, J=7 Hz), 6.02—6.95 (m, 2H), and 7.03—7.18 (m, 1H). IR (neat) 3000 (m), 1550, and 1382 cm^{-1} (s).

Reduction of 1j with HEH-4,4-d_2: A mixture of 75 mg (0.5 mmol) of **1j**, 280 mg (1.1 mmol) of HEH-4,4-d_2 (98% purity in deuterium) and 500 mg of silica gel in 5 ml of anhydrous benzene was refluxed for 30 minutes under a nitrogen atmosphere. The reaction mixture was worked up as described above giving 71 mg (93%) of **2j**-d_1. The analysis of the 400 MHz ^1H NMR spectrum revealed that the deuterium was incorporated into the 2-position of **2j** quantitatively.

400 MHz ^1H NMR ($CDCl_3$) δ=3.24 (tt, 1H, J=2, 8 Hz), 4.53 (d, 2H, J=8 Hz), 7.19—7.35 (m, 5H). GC-MS: m/z 152 (M^+).

Synthesis of 3,7,11-Trimethyl-1-dodecanol (8). The nitro olefin, **4**, was prepared starting from 7.8 g of 3,7-dimethyloctanal (**3**) and 6.1 g of nitromethane in 81% yield following the procedure described above for **1a**.

^1H NMR ($CDCl_3$), δ=0.83 (d, 6H, J=7 Hz), 0.90 (d, 3H, J=7 Hz), 1.03—1.78 (m, 8H), 2.23 (t, 2H, J=6 Hz), 6.93 (d, 1H, J=14 Hz), and 7.22 (dt, 1H, J=14, 6 Hz). IR (neat) 3000 (m), 1663 (m), 1530, and 1350 cm^{-1} (s).

Reduction of 1.99 g of **4** with 2.80 g of HEH and 10 g of silica gel was carried out as described for **1a** to give 1.95 g (97%) of 4,8-dimethyl-1-nitrononane (**5**).

^1H NMR ($CDCl_3$) δ=0.86 (d, 6H, J=7 Hz), 0.88 (d, 3H, J=7 Hz), 1.03—1.56 (m, 10H), 1.83—2.12 (m, 2H), and 4.33 (t, 2H, J=6 Hz). IR (neat) 2950 (m), 1576, and 1380 cm^{-1} (s). Found: C, 65.89; H, 11.34; N, 6.88%. Calcd for $C_{11}H_{23}NO_2$: C, 65.61; H, 11.52; N, 6.96%.

A mixture of 1.0 g of **5**, 0.57 g of ethyl crotonate, 0.8 g of DBU and 5 ml of DMF was stirred at room temperature for 20 h. The reaction mixture was worked up as an usual way to give 0.87 g (55%) of ethyl 3,7,11-trimethyl-4-nitrododecanoate (**6**).

^1H NMR ($CDCl_3$) δ=0.82 (d, 9H, J=7 Hz), 0.95—2.51 (m, 21H), 4.05—4.18 (m, 2H), and 4.32—4.49 (m, 1H). IR (neat) 3000 (m), 1750 (s), 1575, and 1380 cm^{-1} (s). Found: C, 65.08; H, 10.53; N, 4.37%. Calcd for $C_{17}H_{33}NO_4$: C, 64.71; H, 10.55; N, 4.44%.

A mixture of 630 mg (2.0 mmol) of **6**, 700 mg (2.4 mmol) of tributyltin hydride, and 100 mg (0.6 mmol) of AIBN in 5 ml of benzene was heated to reflux for 5 h. The reaction mixture was chromatographed on silica gel using benzene/hexane (1/1) as an eluent to give 351 mg (65%) of ethyl 3,7,11-trimethyldodecanoate (**7**).

^1H NMR ($CDCl_3$) δ=0.82 (d, 6H, J=7 Hz), 0.86 (d, 6H, J=7 Hz), 0.95—1.61 (m, 11H), 2.24 (d, 2H, J=6 Hz), and 4.12 (q, 2H, J=6 Hz). IR (neat) 3000 (m) and 1745 cm^{-1} (s). Found: C, 75.86; H, 12.55%. Calcd for $C_{17}H_{34}O_2$: C, 75.48; H, 12.68%.

The ester **7** was reduced with $LiAlH_4$ in ether at 0 °C to give the aimed alcohol **8** in 90% yield.

^1H NMR ($CDCl_3$) δ=1.78—1.88 (m, 12H), 1.95—1.62 (m, 17H), 3.20 (bs, 1H), and 3.58 (t, 2H, J=6 Hz). IR (neat) 3580 (s), and 2975 cm^{-1}.

Synthesis of Dendrolasin: To a solution of 6.1 g of nitromethane and 9.6 g of 3-furancarbaldehyde (**9**) in 100 ml of ethanol was added 10 ml of 10 M KOH over 30 minutes at 0 °C with vigorous stirring. The reaction mixture was stirred for 30 minutes and poured onto 100 ml of ice water. The precipitate was filtered and recrystallized from hot ethanol to give 12.0 g (86%) of 1-(3-furyl)-2-nitroethene (**10**) as yellow needles. Mp 68—70 °C.

^1H NMR ($CDCl_3$) δ=6.60 (dd, 1H, J=6, 1 Hz), 6.93 (d, 1H, J=6 Hz), 7.54 (d, 1H, J=14 Hz), 7.60 (m, 1H), and 7.79 (d, 1H, J=14 Hz). IR (KBr) 3010 (m), 1640 (m), 1500, and 1375 cm^{-1} (s).

A mixture of 1.39 g of **10**, 3.08 g of HEH, 10.0 g of silica gel and 50 ml of benzene was heated to reflux under a nitrogen atmosphere for 30 minutes. Silica gel was filtered off and the filtrate was chromatographed on silica gel using benzene as an eluent to give 1.33 g (94%) of 1-(3-furyl)-2-nitroethane (**11**) as yellowish oil.

^1H NMR ($CDCl_3$) δ=3.34 (t, 2H, J=7 Hz), 4.62 (t, 2H, J=7 Hz), 6.13 (m, 1H), 6.31 (m, 1H), and 7.35 (m, 1H). IR (neat) 3000 (s), 1550, and 1375 cm^{-1} (s).

To a solution of 705 mg (5 mmol) of **11** and 700 mg of 2,6-dimethyl-5-heptenal in 10 ml of toluene was added 132 mg (1.5 mmol) of *N*,*N*-dimethylethylenediamine. The mixture was heated to reflux for 24 h. The reaction mixture was diluted with 20 ml of 2 M hydrochrolic acid and extracted with ethyl acetate. The extract was condensed and chromatographed on silica gel to give two isomeric products, 46% of **12** and 25% of **13**. The nitro olefin **13** was easily isomerized into allylic nitro compound **12** in quantitative yield by refluxing it in benzene in the presence of 0.1 equivalent amount of triethylamine for 5 h.

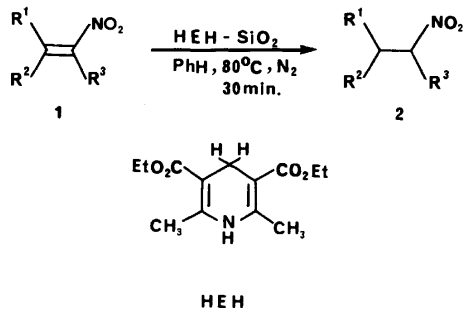
^{1}H NMR ($CDCl_3$) δ=1.61 (s, 6H), 1.86 (s, 3H), 2.20—2.61 (m, 5H), 5.08 (q, 1H, J=7 Hz), 5.23—5.64 (m, 2H), 6.31 (s, 1H), 7.21 (s, 1H), and 7.41 (t, 1H, J=2 Hz). IR (neat) 2950 (s), 1625 (m), 1560, and 1375 cm^{-1} (m).

A mixture of 526 mg (2.0 mmol) of **12**, 1.75 g (6.0 mmol) of tributyltin hydride 98 mg of AIBN, and 10 ml of benzene was refluxed for 5 h and then washed with water and brine. The solution was condensed under reduced pressure and chromatographed on silica gel using benzene as an eluent to give 187 mg (43%) of dendrolasin (**14**).

^{1}H NMR ($CDCl_3$) δ=1.59 (s, 6H), 1.85 (s, 3H), 2.23—2.58 (m, 8H), 5.18—5.43 (m, 2H), 6.30 (s, 1H), 7.22 (s, 1H), and 7.36 (t, 1H, J=2 Hz). IR (neat) 2950 (s), and 1620 cm^{-1} (m). GC-Ms m/z 218 (M^+).

Results and Discussion

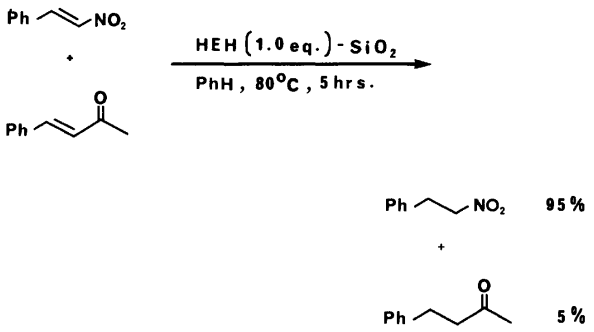
Reduction of Nitro Olefins: It was reported that silica gel activates HEH in benzene effectively and α,β-unsaturated carbonyl compounds are reduced with this system in satisfactory yields and with high chemo- and regioselectivities.[20] The reduction of carbon-carbon double bonds in α,β-conjugated nitro olefins also proceeds with the same reducing system; as shown in Scheme 1, a mixture of a nitro olefin, 1.1 equivalent amount of HEH, and silica gel in refluxing benzene



Scheme 1.

affords the corresponding nitroalkane quite smoothly. The results are summerized in Table 1. Both aromatic and aliphatic nitro olefins are reduced in excellent to good yields. It is worth while to note that the carbon-carbon double bonds in nitro olefins that bear carbonyl functional groups can be reduced with the present system without affecting any influence on the carbonyl functions.

The carbon-carbon double bond in an α,β-unsaturated ketone is a function which is reduced with the HEH–silica gel system. However, when an α,β-unsaturated carbonyl compound was subjected to the reduction competitively with an equivalent amount of nitro olefin, 95% of the latter was reduced after 5 h whereas 95% of the former was found unreacted (Scheme 2).



Scheme 2.

When 3,5-bis(ethoxycarbonyl)-2,6-dimethyl-1,4-dihydropyridine-4,4-d_2 (HEH-4,4-d_2) was subjected to the reduction of β-nitrostyrene and 1-nitro-2-phenylethane produced was analyzed on 400 MHz ^{1}H NMR spectrometer, it was found that more than 98% of the deuterium was incorporated into the 2-position, which indicates that the hydrogen on the 4-position of HEH migrates onto the substrate without exchanging with hydrogens in the solvent.

The reduction of nitro olefin is accompanied by the formation of dimeric products.[10] No dimer was detected, however, in the products from the present reduction system. In previous papers of the series, it was reported that silica gel plays not only a role of a Lewis acid catalyst to activate HEH but also a role of a proton donner with the silanol group on its surface.[17] Here again, it seems reasonable to expect that a carbanion formed from the substrate nitro olefin by accepting a (net) hydride from HEH is immediately protonated on the surface of silica gel to afford a stable product.

Although stereoselective reduction has not been examined yet, the author believes that the present reduction system can provide a versatile method in organic synthesis with its high yield, excellent chemoselectivity, and facility of the procedure, and the method has been applied to the syntheses of natural products as will be described in the following section.

Syntheses of Natural Product. Synthesis of 3,7,11-Trimethyl-1-dodecanol: A sesquiterpene alcohol, 3,7,11-trimethyl-1-dodecanol (**8**), has been widely accepted as a key intermediate in the synthesis of α-Tocopherol (Vitamin E).[21] The present reduction system can usefully be applied to the synthesis of this alcohol. The whole reaction scheme is shown in Scheme 3.

3,7-Dimethyloctanal (**3**) was condensed with nitromethane to give a β-nitro alcohol in the presence of triethylamine as a catalyst. The nitro alcohol was then converted into conjugated nitro olefin, **4**, via acetylation and elimination of acetic acid. The nitro olefin **4** was reduced with 1.1 equivalent amount of HEH into the corresponding nitroalkane **5** in 97% yield. Michael-type addition of **5** to ethyl crotonate in the presence of DBU[22] gave the γ-nitro ester **6**, which was subjected to the reaction with tributyltin hydride and AIBN as a free radical initiator, to substitute the

nitro group by a hydrogen.[5] The resulting ester **7** was converted into the alcohol **8** by the reduction with lithium aluminum hydride in 90% yield. The overall yield of **8** based on the aldehyde **3** was 24%.

Synthesis of Dendrolasin: A furanoterpenoid, dendrolasin (**14**) was isolated from *Lasius (Dendrolasius) fuliginosus*, an ant, as an alarm pheromone[23] and synthesized by several groups.[24] It is found that the application of the present reduction system provides a very short (4 steps, 25% overall yield) process for **14** as shown in Scheme 4.

Condensation of furan-3-carbaldehyde (**9**) with nitromethane in 10 M KOH–MeOH gave 1-(3-furyl)-2-nitroethene (**10**) in 86% yield. The nitro olefin **10** was reduced into the corresponding saturated nitro compound **11** in 94% yield, which was condensed with 2,6-dimethyl-5-heptenal in the presence of *N,N*-dimethylethylenediamine under reflux in toluene[25] to yield the allylic nitro compound **12** (46% yield) together with the conjugated nitro olefin **13** (25% yield). The latter can be isomerized into the former quantitatively under reflux in benzene with triethylamine. Substitution of the nitro group in **13** by a hydrogen can be achieved in 43% yield by treating **13** with tributyltin hydride in the presence of AIBN to give dendrolasin (**14**).

The author deeply thanks Prof. Atsuyoshi Ohno and Dr. Kaoru Nakamura of Institute for Chemical Reseach, Kyoto University, and Prof. Tetsuo Aida of Kinki University in Kyushu for their helpful discussion.

A Convenient Method for the Preparation of Secondary Propargylic Ethers. The Reactions of Acetals with 1-Trimethylsilyl-1-alkynes Promoted by the Combined Use of Catalytic Amounts of Tin(IV) Chloride and Zinc Chloride

Masaji HAYASHI,* Atsuro INUBUSHI, and Teruaki MUKAIYAMA
Department of Applied Chemistry, Faculty of Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162
(Received May 20, 1988)

In the coexistence of catalytic amounts of $SnCl_4$ and $ZnCl_2$, acetals undergo a coupling with 1-trimethylsilylalkynes to give secondary propargylic ethers in good yields. Similarly, propargylic ethers are directly produced from aldehydes by the treatment with alkoxytrimethylsilanes and 1-trimethylsilylalkynes under the same conditions. This catalyst system also efficiently promotes aldol reaction of silyl enol ethers with acetals or aldehydes, and the Michael reaction of silyl enol ethers with α,β-unsaturated ketones.

Over the years there have been a large body of efforts directed to the construction of carbon skeleton by employment of various kinds of silyl carbon nucleophiles, and those to develop catalysts which efficiently promote the coupling with electrophiles have been extensively studied.[1] Recently, various carbon–carbon bond forming reactions[2] were shown to be achieved by the use of a catalytic amount of Lewis acids such as trityl salts developed by us[2b] for example, and it becomes apparent that a stoichiometric amount of Lewis acid, such as $TiCl_4$ or $SnCl_4$,[3] is not necessarily required in these types of acid-promoted reactions of carbonyl compounds with silyl nucleophiles. During our continuing work on the development of efficient promotors, a convenient carbon–carbon bond forming reaction was developed by the combined use of catalytic amounts of various neutral molecules and weakly acidic Lewis acids such as TrCl–$SnCl_2$, TMSCl–$SnCl_2$.[4] Thus divalent tin is able to accept halogen ion from the above mentioned active organic halide or silyl halide to generate cationic species (Tr^+, TMS^+-like cation etc.). In an extension of this concept, we considered that higher capability of $SnCl_2$ could accept halogen ion from the other Lewis acid such as $TiCl_4$ to generate $TiCl_3^+$–$SnCl_3^-$, or by the combination of Lewis acids such as $ZnCl_2$–$SnCl_4$ to generate $ZnCl^+$–$SnCl_5^-$, and that such species should be applicable for the activation of electrophiles, as promotors, in various reactions with moderately reactive silyl nucleophiles.

We screened further more effective combination of various Lewis acids and it was found that the combined use of $SnCl_4$ and $ZnCl_2$ is quite efficient for a coupling reaction of acetals with 1-trimethylsilyl-1-alkynes, as we have briefly reported in a preliminary communication.[5] We now describe in full the results of our investigation on the above coupling reaction using this new catalyst system and further the application to aldol and the Michael reactions.

Results and Discussion

Ethynylation (1). The reaction of 1-trimethylsilyl-1-alkynes with acetals generally requires an equimolar amount or a large exess of Lewis acids, such as $TiCl_4$,[6] and it was also shown that the above mentioned reaction was hardly promoted by a catalytic amount of Lewis acid. In the first place, we examined the reaction of 3-phenylpropanal dimethyl acetal (**2**) with (trimethylsilylethynyl)benzene (**1**) in the presence of 10 mol% each of two metal salts (A and B), as shown in Table 1. The reactions were carried out as follows: A suspension of 10 mol% each of catalysts A and B in CH_2Cl_2, was stirred for 30 min at room temperature. After cooling to 0 °C, **2** was added, followed by the addition of **1** at the same temperature, and the reaction mixture was stirred at 0 °C. Usual workup of the

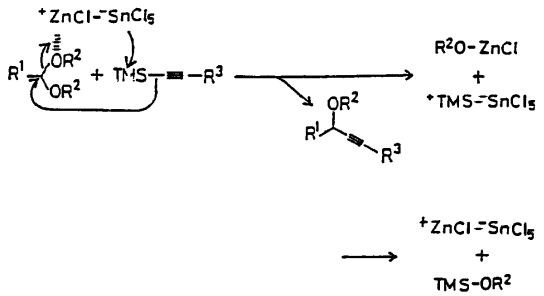
reaction mixture afforded 1,5-diphenyl-3-methoxy-1-pentyne (**3**).

Conventionally employed promotors, such as TrCl-$SnCl_2$ or TMSCl-$SnCl_2$[4] were not effective in the above mentioned reaction (Entries 1 and 2). The results indicate that these catalysts are insufficient to activate the acetal to produce the coupling product with **1**. Now, from the point of view that $SnCl_2$ is a potential metal salt to accept halogen ion from organic halide or silyl halide, it was assumed that more active cationic species than Tr^+-$SnCl_3^-$ or TMS^+-$SnCl_3^-$ should be generated by the combined use of strong Lewis acids ($TiCl_4$, $SnCl_4$, etc.) and weak Lewis acids ($SnCl_2$, $ZnCl_2$, etc.). As the result, in almost cases the reactions proceeded effectively to afford the desired product (**3**) in high yields (Entries 3—11). The combination of $SnCl_4$ and $ZnCl_2$ gave the best result concerning the yield of **3**. The mechanism of the reformation of $SnCl_4$-$ZnCl_2$ catalyst system could be explained as follows; In $ZnCl^+$-$SnCl_5^-$-like species initially generated,[7] $ZnCl^+$ activates oxygen atom of the acetal and at the same time $SnCl_5^-$ attacks silicon atom of the 1-trimethylsilyl-1-alkyne to activate the acetylene by way of forming TMS^+-$SnCl_5^-$-like species, which is in turn transformed into TMS-OR^2 and the original catalytic species. In the case of the combined use of $TiCl_4$ and $SnCl_2$, initially $TiCl_3^+$-$SnCl_3^-$-like species will be generated.



In the case of using $SnCl_2$, the yields of **3** were influenced by the co-catalyst, that is, the yields depended on the strength of Lewis acidity of co-catalyst (Entries 4—7). On the other hand, by the use of $ZnCl_2$ instead of $SnCl_2$, the yields of **3** did not consist with the Lewis acidity[7] of the co-catalyst (Entries 9 and 10). As shown in Entries 3,4,8 and 10,11, the substituents of tin(II) or zinc(II) salts remarkably influenced on the turn-over of the catalyst. It is assumed that Sn(II) with more electronegative atom can accept halogen ion from co-catalyst such as $TiCl_4$ to generate $TiCl_3^+$, and that Zn(II) with more electronegative atom as Cl can generate stronger cationic species as $ZnCl^+$, and consequently the oxygen atom of the acetal group would be activated more effectively. In the case of SnF_2, the yield was not so high because of its insolubility to the solvent.

The combination of Zn(II)-Sn(IV) proved better than those of Sn(II)-Sn(IV), Zn(II)-Ti(IV), Sn(II)-Ti(IV) in the present reaction. However, these tendencies can not be explained by considering solely the Lewis acid strength of $SnCl_4$ and $TiCl_4$,[7] and it may be pointed out that the difference of the affinities of central metal as Ti, Si, and Zn toward oxygen atom reflects on the regeneration step of the catalysts. By the use of 20 mol% of $SnCl_4$ as catalyst in the absence of other co-catalyst (Entyl 15), the same reaction resulted in the formation of **3** in a moderate yield.

Next, we examied the optimum reaction conditions by using the above reaction as a model, and the results are summarized in Table 2. As shown in the Table, the coupling reaction proceeded effectively in CH_2Cl_2 at 0 °C in the coexistence of 10 mol% each of $SnCl_4$ and $ZnCl_2$. It should be noted that the ratio of $SnCl_4/ZnCl_2$ influences the yield of **3**, assuming that the unbalance of the amounts of $SnCl_4$ and $ZnCl_2$ should give rise to decrease in the population of a key species $ZnCl^+$-$SnCl_5^-$.

Then we examined the coupling reaction of various 1-trimethylsilyl-1-alkynes (**5**) with dimethyl acetals (**4**) in the presence of catalytic amounts of $SnCl_4$-$ZnCl_2$ as shown in Table 3, and the corresponding secondary propargylic ethers (**6**) were obtained in good yields. In the case of the reaction of aromatic or conjugated aldehyde dimethyl acetal (Entries 1,10,11), the side reactions forming a dipropargyl derivative (for example, **7** or **8**) took place because of the high reactivities of benzyl or allyl cations. Concerning the effect of acetals, the yield of propargylic ethers indicates a

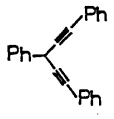
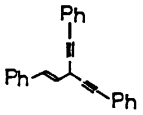
a) Reaction was carried out in CH_2Cl_2 at room temperature in the coexistence of 10 mol% each of $SnCl_4$ and $ZnCl_2$. b) Isolated yield. c) 20 mol% each of $SnCl_4$ and $ZnCl_2$ was used.

tendency to decrease as R^2 substituent becomes more bulky (Entry 12), and cyclic acetals such as 1,3-dioxolane did not react with 1-trimethylsilyl-1-alkynes under the above condition. When benzyl acetal was used as a substrate, unknown side reactions accompanied. The reaction of α-substituted aldehyde dimethyl acetal with **5** was very slow to afford **6** in poor yield (Entry 6). In addition, under the above conditions, silylalkynes having bulky substituents on the silicon atom, such as (triphenylsilylethynyl)benzene, did not react with acetals.



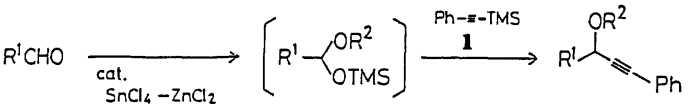
7



8

Ethynylation (2). From the synthetic point of view, it is more desirable to prepare the above-mentioned propargylic ethers directly from the corresponding aldehydes. On the basis of such consideration, the reaction of in situ formed hemiacetal-type compounds (**9**) with **5** was examined. As shown in Table 4, in the coexistence of 20 mol% each of $SnCl_4$ and $ZnCl_2$, adducts **9** were initially formed from alkoxytrimethylsilanes and aldehydes, and **9** in turn reacted with **5** to form the desired secondary propargylic ethers **6**. In the case of benzyloxytrimethylsilane, the yield was not so high (Entry 1) and unknown side reactions accompanied as same as the above mentioned reaction.

Allylation of Propargylic Ethers. It was reported that allyl ethers reacts with silyl nucleophiles, such as allylsilane[8] or silyl enol ethers,[9] in the presence of a catalytic amount of $TrClO_4$ to result in the formation



9 6

Table 4. Synthesis of Secondary Propargylic from Aldehydes[a]

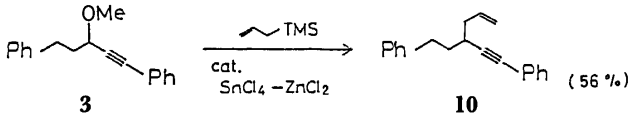
a) Reaction was carried out in CH_2Cl_2 at −78 °C for 4 h, then at room temperature for 6 h in the coexistence of 20 mol% each of $SnCl_4$ and $ZnCl_2$. b) Isolated yield. Yields are based on aldehydes. c) *S*-configuration.

of a new carbon skeleton having tertiary carbon. These facts and the above-mentioned side reaction to form bis propargyl compounds **7** or **8** suggested us to develop a convenient method for the two carbon-carbon bond formations by one-pot procedure, that is, the secondary propargylic ethers thus obtained had a potentiality to couple with the second nucleophile such as allylsilane. Expectedly, **3** smoothly reacted with allyltrimethylsilane at 0 °C in the coexistance of 20 mol% each of $SnCl_4$ and $ZnCl_2$ to afford the 1,5-enyne compound (**10**) in 56% yield. And **10** was also

obtained according to the above-mentioned methods from acetal (**1**) (in 29% yield), from 3-phenylpropanal (in 60% yield) by one-pot procedure.



3 **10**

Aldol Reaction. This new catalyst system ($SnCl_4$-$ZnCl_2$) also promoted the aldol reaction of silyl enol ethers and aldehydes or acetals smoothly and some experimental results are shown in Table 5. The ratios of anti/syn (threo/erythro) adducts are slightly different from those in the cases of using other promotors, such as $TrClO_4$,[1] TrCl-$SnCl_2$, or TMSCl-$SnCl_2$.[4]

The Michael Reaction. Tin(IV) chloride and zinc chloride catalyst system also promoted the Michael reaction of silyl enol ethers with α,β-unsaturated ketones as shown in Table 6. The uk (anti) adducts[4] were obtained preferentially similar to the reactions using other promotors (Tr^+ or TMS^+-like cation). These diastereoselectivities are almost the same as consistent with those of Tr^+ or TMS^+-like cation-promoted Michael reactions.

Allylation of Aldehydes. Under the acidic condition, allyltrimethylsilane generally reacts with aldehyde to give a complicated product mixture by the occurrence of further reactions, which contains the reaction of hemiacetal (**11**) formed by the addition of initially formed silyl alkoxide to the starting aldehyde followed by the addition of the allyltrimethylsilane. In contrast, by using the present catalyst system, the desired homoallyl alcohols were obtained in good yields as shown below.

Table 5. Aldol Reaction of Aldehydes or Dimethyl Acetals with Trimethylsilyl Enol Ethers

It is concluded that the catalytic use of equimolar amounts of $SnCl_4$ and $ZnCl_2$ effectively promotes the reaction of 1-trimethylsilyl-1-alkynes with acetals, and also secondary propargylic ethers thus obtained are converted into 1,5-enyne compounds by the further reaction with allyltrimethylsilane in the same flask. The present cationic promotors based on the combination of two metal salts will open many synthetic and theoritical possibilities in carbon-carbon bond forming reactions.

Experimental

The IR spectra were determined on Hitachi Model 260-30 spectrometer. The ^1H NMR spectra were recorded with a Hitachi R-24B, a Varian EM-390, and a JEOL GX-400 spectrometers in $CDCl_3$ with trimethylsilane as an internal standard. The mass spectra were taken on a JEOL JMS-D300. Diethyl ether was freshly distilled from sodium benzophenone ketyl. Dichloromethane was distilled from CaH_2 and stored over Molecular Sieve. Purification of products was performed by column chromatography on silica gel (Wakogel C-200, C-300 or Merck, Art. 9385 Kieselgel 60, 230—400 mesh), preparative TLC on silica gel (Wakogel B-5F).

1-Trimethylsilyl-1-alkynes **1a—g** were prepared by trimethylsilylation of the corresponding lithium acetylide (butyllithium and alkynes), and purified by distillation or column chromatography on silica gel. Dimethyl acetals **2a—h** were prepared by transacetalization of the corresponding aldehydes with trimethyl orthoformate in the presence of *p*-TsOH·H_2O.

Preparation of Propargylic Ethers (6). (Table 3) A typical reaction procedure is described for 3-phenylpropanal dimethyl acetal with (trimethylsilylethynyl)benzene (Entry 2): a CH_2Cl_2 (4 ml) suspension of $SnCl_4$ (0.11 mmol) and $ZnCl_2$ (0.11 mmol) was stirred for 30 min at room temperature, to which were added succeccively (trimethylsilylethynyl)benzene (1.0 mmol) in CH_2Cl_2 (3 ml) and 3-phenylpropanal dimethyl acetal (1.5 mmol) in CH_2Cl_2. The reaction mixture was stirred for 3.5 h at the same temperature, then quenched with aqueous solution of sodium hydrogencarbonate. The organic materials were extracted with CH_2Cl_2, and the combined extracts were dried over $MgSO_4$. After evaporation of the solvent, the residue was purified by preparative TLC (silica gel) to afford 1,5-diphenyl-3-methoxy-1-pentyne (**1a**) (0.85 mmol, 85%). IR (neat) 2835, 2240, 1610, 1500 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.87—2.30 (m, 2H), 2.72—2.97 (m, 2H), 3.45 (s, 3H), 4.11 (t, J=6 Hz, 1H), 6.95—7.60 (m, 10H); MS m/z 250 (M^+). Found: C, 86.29; H, 7.26%. Calcd for $C_{18}H_{18}O$: C, 86.36; H, 7.25%.

Other analysis data are presented: 1,3-Diphenyl-3-methoxy-1-propyne (Entry 1). IR (neat) 2815, 2215, 1600, 1490 cm^{-1}; ^1H NMR ($CDCl_3$) δ=3.47 (s, 3H), 5.27 (s, 1H), 7.2—7.6 (9m, 10H); MS, m/z 222 (M^+).

6-Phenyl-4-methoxy-1-hexyne (Entry 3). IR (neat) 2825, 2235, 1610, 1500; ^1H NMR ($CDCl_3$) δ=1.84 (d, 3H, J=1.8 Hz), 1.75—2.20 (m, 2H), 2.53—2.97 (m, 2H), 3.53 (s, 3H), 3.63—4.08 (m, 1H), 7.17 (s, 5H); MS, m/z 188 (M^+).

3-Methoxy-1-phenyl-1-decyne (Entry 4). IR (neat) 2815, 2220, 1600, 1495 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.63—1.73 (m, 11H), 1.73—2.46 (m, 4H), 3.38 (s, 3H), 3.55—4.16 (m, 1H), 7.18 (s, 5H); MS, m/z 244 (M^+). Found: C, 83.61; H, 9.95%. Calcd for $C_{17}H_{24}O$: C, 83.55; H, 9.90%.

1,5-Diphenyl-3-benzyloxy-1-pentyne (Entry 5). IR (neat) 2225, 1610, 1495, 1270, 1040 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.93—2.40 (m, 2H), 2.58—3.06 (m, 2H), 4.28 (dd, 1H, J=6.5, 6.5 Hz), 4.28 (d, 2H, J=11 Hz), 6.85—7.27 (m, 15H); MS, m/z 326 (M^+). Found: C, 88.45; H, 6.78%. Calcd for $C_{24}H_{22}O$: C, 88.31; H, 6.79%.

1,4-Diphenyl-3-methoxy-1-pentyne (Entry 6). ^1H NMR ($CDCl_3$) δ=1.43 (d, 2H, J=7 Hz), 2.83—3.35 (m, 1H), 3.42 (s, 1H), 4.22 (dd, 1H, J=7 Hz, 6.7 Hz), 7.26 (s, 5H); MS, m/z 250 (M^+).

1-Phenyl-3-methoxy-1-undecyne (Entry 7). IR (neat) 1600, 1490 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.67—2.07 (m, 17H), 4.50 (s, 3), 4.15 (t, 1H), 7.1—7.6 (m, 5H); MS, m/z 258 (M^+).

4-Methoxy-1-hexadecyne (Entry 8). IR (neat) 2235 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.67—1.99 (m, 17H), 3.36 (s, 3H), 3.72—4.05 (m, 1H) MS, m/z 196 (M^+).

8-Methoxy-1-hexadecyne (Entry 9). ^1H NMR ($CDCl_3$) δ=1.56—1.93 (m, 26H), 1.97—2.38 (m, 2H), 3.35 (s, 3H), 3.68—4.03 (m, 1H); MS, m/z 252 (M^+).

1,5-Diphenyl-3-methoxy-1-penten-4-yne (Entry 10). IR (neat) 2815, 1675 (m), 1595, 1490, 960 cm^{-1}; ^1H NMR ($CDCl_3$) δ=3.32, 3.43 (s, 3H), 4.74 (d, 1.5H, J=5.5 Hz), 5.25 (d, 1.5 H, J=9.5 Hz), 5.72—6.27 (m, 2H), 7.1—7.25 (m, 10) (cis, trans mixture).

3-Methoxy-1-phenyl-4-hexen-1-yne (Entry 11). IR (neat) 2815, 2195, 1590, 1490, 960 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.26 (d, 3H, J=6.5 Hz), 3.28 (s, 3H), 4.78 (t, 1H, J=6.5 Hz), 5.65—6.32 (m, 2H), 7.17—7.56 (m, 5H); MS, m/z 186 (M^+).

3-Ethoxy-1-phenyl-1-butyne (Entry 12). IR (neat) 2210, 1600, 1490 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.15 (t, 3H, J=6.6 Hz), 1.35 (d, 3H, J=7.5 Hz), 3.23—4.10 (m, 2H), 4.34 (q, 1H, J=6.6 Hz), 7.09—7.58 (m, 5H); MS, m/z 174 (M^+). Found: C, 82.58; H, 8.08%. Calcd for $C_{12}H_{14}O$: C, 82.72; H, 8.10%.

Preparation of Propargylic Ether (6). (Table 4). A typical reaction procedure is described for 3-phenylpropanal with methoxytrimethylsilane and (trimethylsilylethynyl)-benzene (Entry 2): a CH_2Cl_2 (4 ml) suspension of $SnCl_4$ (0.2 mmol) and $ZnCl_2$ (0.2 mmol) was stirred for 30 min at room temperature, to which were added successively methoxytrimethylsilane (1.6 mmol) in CH_2Cl_2 (2 ml) and

3-phenylpropanal (1.0 mmol) in CH_2Cl_2 (2 ml) at −78 °C and stirred for 4 h, then warmed to room temperature, a solution of (trimethylsilylethynyl)benzene (1.5 mmol) in CH_2Cl_2 (2 ml) was added to the reaction mixture and stirred for 6 h at the same temperature. After quenching with aqueous solution of sodium hydrogencarbonate, the solution was extracted with CH_2Cl_2. The extracts were dried over $MgSO_4$ and condensed in vacuo. Purification by preparative TLC on silica gel (hexane:ether 1:1, v/v) afforded 1,5-diphenyl-3-methoxy-1-pentyne (0.78 mmol, 78%).

Other spectral data presented: 1,5-Diphenyl-3-ethoxy-1-pentyne (Entry 3), IR (neat) 2200, 1600, 1490 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.22 (t, 3H, J=7.5 Hz), 1.91—2.32 (m, 2H), 2.70—3.03 (m, 2H), 3.27—4.03 (m, 1H), 4.17 (q, 2H, J=7.5 Hz), 7.0—7.5 (m, 10H); MS, m/z 246 (M^+). Found: C, 86.50; H, 7.71%. Calcd for $C_{19}H_{20}O$: C, 86.32; H, 7.63%.

4-Methoxy-2-decyne (Entry 4). IR (neat) 2830, 2210, 1605, 1495 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.73—2.35 (m, 13H), 3.42 (s, 3H), 3.92—4.21 (m, 1H), 7.07—7.53 (m, 5H); MS, m/z 230 (M^+).

1,5-Diphenyl-3-(1-phenylethoxy)-1-pentyne (Entry 5). ^1H NMR ($CDCl_3$) δ=1.27, 1.43 (d, 3H, J=6.5 Hz), 1.80—2.28 (m, 2H), 2.57—3.03 (m, 2H), 4.03 (q, 1H, J=6.5 Hz), 4.1—5.0 (m, 1H), 6.90—7.47 (m, 10H); MS, m/z 340 (M^+).

Preparation of 1,5-Diphenyl-3-methoxy-1-pentene (Cis-Isomer): 1,5-Diphenyl-3-methoxy-1-pentyne (1 mmol) was dissolved in AcOEt (5 ml) and hydrogenated with Lindler catalyst (50 mg) and quinoline (30 mg) at 1 atm. The catalyst was removed by filtration and the solvent was condensed in vacuo. Then the residue was purified by preparative TLC on silica gel to afford 1,5-diphenyl-3-methoxy-1-pentene (0.89 mmol, 89%). IR (neat) 2810, 1600, 1490, 1405 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.63—2.07 (m, 2H), 2.55—2.90 (m, 2H), 3.11 (s, 3H), 3.82—4.27 (m, 1H), 5.50 (dd, 1H, J=12 Hz, 8.5 Hz), 6.52 (d, 1H, J=12 Hz), 6.77—7.40 (m, 10H); MS, m/z 252 (M^+). Found: C, 85.90; H, 7.97%. Calcd for $C_{18}H_{20}O$: C, 85.67; H, 7.99%.

Allylation of Propargylic Ethers: A CH_2Cl_2 suspension of $SnCl_4$ (0.4 mmol) and $ZnCl_2$ (0.4 mmol) was stirred for 30 min at room temperature, to which were added successively methoxytrimethylsilane (1.5 mmol) in CH_2Cl_2 (2 ml) and 3-phenylpropanal (1.0 mmol) in CH_2Cl_2 (2 ml) at 0 °C, and stirred for 4 h. Then to the reaction mixture was added (trimethylsilylethynyl)benzene (1.5 mmol) in CH_2Cl_2 (2 ml) at the same temperature and stirred for 6 h. After warming to room temperature allyltrimethylsilane (5 mmol) in CH_2Cl_2 (3 ml) was added and stirred for 15 h at the same temperature. Usual workup and purification by preparative TLC on silica gel afforded 1-phenyl-3-(2-phenylethyl)-5-hexen-1-yne (0.6 mmol, 60%). IR (neat) 1640, 1595, 1485, 910 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.58—3.03 (m, 3H), 4.90—5.29 (m, 2H), 5.57—6.34 (m, 1H), 7.05—7.66 (m, 10H); MS, m/z 260 (M^+).

Aldol Reaction and the Michael Reaction: Representative procedure is described for the reaction of silyl enol ether of propiophenone and benzaldehyde; a CH_2Cl_2 (4 ml) suspension of $SnCl_4$ (0.1 mmol) and $ZnCl_2$ (0.1 mmol) was stirred for 30 min at room temperature, to which was added a CH_2Cl_2 solution (2 ml) of silyl enol ether of propiophenone (1.1 mmol) and a CH_2Cl_2 (2 ml) solution of benzaldehyde (1.0 mmol) successively at −78 °C. The reaction mixture was further stirred for 2 h at this temperature, and the reaction quenched with satd. $NaHCO_3$ solution. The organic materials were extracted with CH_2Cl_2 twice, and the combined extracts were washed with brine and dried over Na_2SO_4. After evaporation of the solvent, the crude product was purified by silica gel thin layer chromatography to give the product in 99% yield.

Allylation of Aldehydes: A typical procedure is described for the reaction of 3-phenylpropnal with allyltrimethylsilane; a CH_2Cl_2 (4 ml) suspension of $SnCl_4$ (0.1 mmol) and $ZnCl_2$ (0.1 mmol) was stirred for 30 min at room temperature, to which was added allyltrimethylsilane (1.2 mmol) in CH_2Cl_2 (2 ml) and benzaldehyde (1.0 mmol) in CH_2Cl_2 (2 ml) successively at 0 °C. The reaction mixture was further stirred for 2 h at this temperature. Usual workup and purification by preparative TLC on silica gel afforded the product in 74% yield.

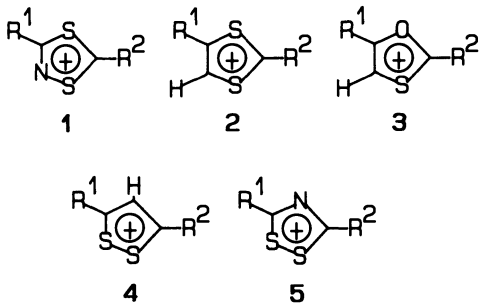
Reaction of 1,4,2-Dithiazolium Salts with Amino Compounds

Katsumi YONEMOTO* and Isao SHIBUYA*
National Chemical Laboratory for Industry, Tsukuba, Ibaraki 305
(Received June 10, 1988)

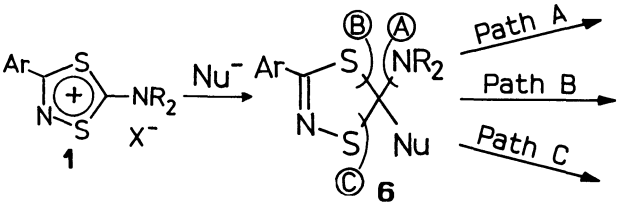
Systematic studies on the behavior of 1,4,2-dithiazolium cations (**1**) toward various amino compounds (ammonia, aliphatic and aromatic amines, hydrazine, semicarbazide, thiosemicarbazide derivatives, etc.) were performed. The reaction pathway could be classified into three types depending on possible three fission modes of the initially-formed adduct. The main products were 5-imino-1,4,2-dithiazole, thiourea, and 1,3,4-thiadiazole derivatives, through the three different pathways, respectively. In order to clarify the factors controlling the reaction courses, the reactions of **1** with *p*-substituted aniline derivatives were carried out under systematically varying conditions. The strength of bases and the polarity of solvents had clear influence on the reactivity. The reaction mechanism is also discussed.

Chemistry of five-membered heteroaromatic cations, which are stabilized by 6 π-electron system satisfying Hückel's rule, has been extensively studied and reviewed. These cations have attracted much attention to their reactivity as potentially versatile intermediates for a wide range of heterocyclic compounds involving sulfur and/or nitrogen atoms. In particular, the reactivity of 1,3-dithiolium (**2**)[1] or 1,3-oxathiolium cations (**3**)[2] toward nucleophiles such as active methylene and amino compounds has been the subject of detailed investigations. Convenient synthetic methods for 1,2-dithiolium (**4**)[3] and 1,2,4-dithiazolium cations (**5**)[4] and their reactions with a number of active methylene compounds have been also reported. On the other hand, chemistry of 1,4,2-dithiazolium cations (**1**), aza-analogues of **2** as well as isomeric ring system of **5**, has not been fully explored. The synthesis of **1** was recently established by Paton,[5] Sammes,[6] and the authors.[7] Some reactions of **1** with nucleophiles were also attempted.[5,6b] However, no systematic study on the reactivity of **1** has been reported. In our continued investigation on the chemistry of 1,4,2-dithiazolium cations (**1**), we have examined systematically the behavior of **1** toward various amino compounds.



Results and Discussion

The reaction of **1** with amino compounds took place by initial attack of the terminal nitrogen of nucleophiles at the C-5 position of cations **1**, leading to the intermediate adducts (**6**) (Scheme 1), analogously to the case for **2** or **3**. However, the subsequent



Scheme 1.

pathway from this stage was unique and can be classified into the following three types depending on possible three fission modes (A, B, and C in Scheme 1).

Path A: Proton abstraction by base followed by liberation of dialkylamino group to give 5-imino-1,4,2-dithiazole derivatives.

Path B: Loss of proton results in, in turn, the C–S bond cleavage to afford an open-chain intermediate, which then undergoes either recyclization or decomposition leading to final products.

Path C: Spontaneous fragmentation of dithiazole ring to form thiourea derivatives together with nitrile and sulfur.

The reaction conditions, products (classified according to these three pathways), and their yields are summarized in Table 1.

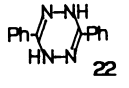
a) Isolated yield. b) Conversion yield based on **1b**. c) 3,6-Diphenyl-1,4-dihydro-1,2,4,5-tetrazine **22** was also obtained in 3% yield. d) Thiobenzamide **15** was formed via Path B (Entries 8—12): 27% (Entry 8), 18% (Entry 9), 30% (Entry 10), 55% (Entry 11), 84% (Entry 12).



22

ing 3-phenyl-5-substituted imino-1,4,2-dithiazoles (**7**—**11**) (via Path A) was observed. In the case of Entry 5, extrusion of sulfur from sulfenamide moiety simultaneously proceeded. On the other hand, the reaction of **1** with *N*-unsubstituted sulfenamides such as *S*-dimethylthiocarbamoyl substituted sulfenamide did not give this type of compounds, but afforded 1,4,2,5-dithiadiazine derivatives, arising from ring expansion on nitrogen atom.[8]

The reaction of **1a** with cyclohexylamine (Entry 6) and *S,S*-diphenylsulfilimine (Entry 7) gave *N*-cyclohexyl-*N'*,*N'*-dimethylthiourea (**12**) and *N*-(dimethylthiocarbamoyl)-*S,S*-diphenylsulfilimine (**13**), respectively, together with benzonitrile and sulfur via Path C (Scheme 2).

On treatment with a large excess of aqueous ammonia (Entry 8), **1a** yielded not only *N,N*-dimethylthiourea (**16**) (via Path C) but 5-dimethylamino-3-phenyl-1,2,4-thiadiazole (**14**) and thiobenzamide (**15**) (both via Path B). The formation of **14** and **15** can be rationalized as follows. The initially-formed adduct **6a** (Scheme 3) opens the ring (via Path B) to form the second intermediate **17**, which then undergoes either ring closure reaction accomplished by elimination of H_2S or decomposition reaction, to give final products **14** and **15**, respectively. Furthermore, when treated with *N,N*-dimethylhydrazine (Entry 9), **1a** gave three types of products, i.e., dithiazole derivative (**18**) (via Path A), thiobenzamide (**15**) (via Path B), and thiourea derivative (**19**) (via Path C).

In the case of an excess of hydrazine hydrate (Entry 10), the reaction with **1b** gave an unexpected product 2,5-bis(diethylamino)-1,3,4-thiadiazole (**20**) togther with thiobenzamide (**15**). A mechanistic interpretation for the formation of **20** is shown in Scheme 4. The intermediate adduct by the reaction of **1b** with NH_2NH_2 undergoes ring scission to provide *N,N*-diethylthiosemicarbazide (**21**) (via Path C), which then reacts with another molecule of **1b** as a nucleophile to afford the alternative adduct **6b** followed by ring opening (via Path B) and ring closure reaction with liberation of **15** and sulfur to give the final product **20**. The reason why **1b** reacts exclusively with **21** even in the presence of an excess of hydrazine hydrate seems to be as follows. **1b** is almost insoluble in water and the reaction of **1b** with hydrazine proceeds slowly. Thus, the crystalline **1b** reacts preferentially with oily **21** free from water in contrast with NH_2NH_2 in aqueous solution. The concomitant formation of 3,6-diphenyl-1,4-dihydro-1,2,4,5-tetrazine (**22**) in 3% yield seems to result from a side reaction of PhCN with NH_2NH_2. In order to confirm this latter pathway, the reaction of **1b** with **21** (Entry 11) was carried out in the presence of triethylamine in aqueous solution. The reaction also gave **20** in a good yield.

A similar reaction was observed with thiobenzoylhydrazine (Entry 12) in the presence of Et_3N to give

a) ppm from internal TMS. b) In DMSO-d_6.

2-diethylamino-5-phenyl-1,3,4-thiadiazole (**23**) in a good yield via the same pathway (Path B) mentioned above. On the other hand, on treatment with its oxa-analogue, benzoylhydrazine, **1a** gave only a product **9** in the absence of base (via Path A) (Entry 3), whereas, in the presence of Et_3N (Entry 13), **1a** afforded 4-benzoyl-1,1-dimethylthiosemicarbazide (**24**) (via Path C).

From the above results, the basicity of reaction solution as well as the nature of nucleophiles seem to be important factors determining the reaction modes. In order to get additional information on the factors controlling the three reaction courses, we selected the combination of **1a—g** with *p*-substituted anilines to examine the reaction under various conditions (Table 3).

First of all, to explore the effects of base strength, the reaction of **1a** with *p*-toluidine was examined in the presence of four different bases and in the absence of base. It was found that the formation of *N,N*-dimethyl-*N'*-(*p*-tolyl)thiourea (**26e**) (via Path C) predominates in comparison with that of 5-(*p*-tolyl)imino-3-phenyl-1,4,2-dithiazole (**25e**) (via Path A) with increasing value of pK_a (Entries 14—18); the ratio between the two products varies widely. Toluidine itself (pK_a 5.09) can act as a base, although its basicity is lower than that of pyridine. A similar trend was evident in the reaction of **1b** with *p*-toluidine (Entries 19—21). Furthermore, even when triphenylphosphine was used instead of amine base, **26** was produced selectively (Entries 22, 23).

These results can be interpreted as follows. Attack

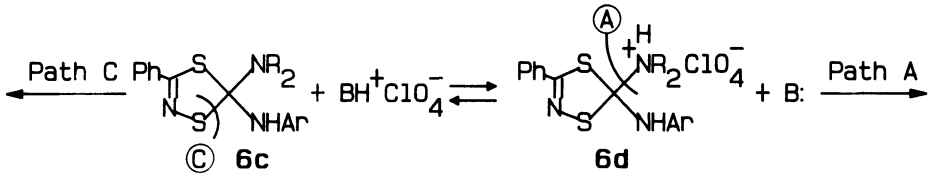
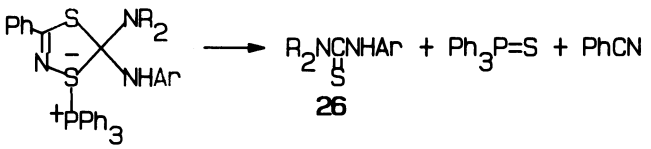


Scheme 5.



Scheme 6.

of *p*-toluidine on the C-5 position of **1** leads to intermediate **6c** which is in equilibrium with **6d** as shown in Scheme 5. The equilibrium is shifted toward **6c** in the presence of a stronger base by effective trapping of perchloric acid, and hence fragmentation of **6c** proceeds preferentially to afford **26** (via Path C). On the other hand, in the presence of a weaker base, considerable contribution of **6d** leads to the pre-

ferential liberation of dialkylamino group to give **25** (via Path A). In the case of phosphine, nucleophilic attack by Ph_3P on the sulfur atom (1- or 4-position) of adduct **6c** promotes the sulfur extrusion resulting in the preferential formation of **26**; triphenylphosphine sulfide was also formed as expected.

In order to examine the influence of substituents in 1,4,2-dithiazolium cations (**1**), the reactions of **1a—g**, bearing different aryl groups at the C-3 position (Entries 24—27) and different di-substituted amino groups at the C-5 position (Entries 28—31), with *p*-toluidine in the presence of γ-picoline were carried out. The yields and the ratio of products **25** and **26** depend mainly on the substituents at the C-5 position which is the reaction center, but almost negligible dependence upon those at C-3 was found. According to the rationalization mentioned above, the equilibrium should be shifted toward **6d** (Scheme 5) with high basicity of the di-substituted amino groups at C-5. Therefore, the formation of **25** should be favored. However, the fact obtained stands in contrast to this expected result. It may be attributable to an extra factor: a liberating secondary amine from **6d**, in turn, acts as a base. The increasing order of basicity of the corresponding secondary amines is known as follows: $Et_2NH \approx Me_2NH > O(C_2H_4)_2NH > PhMeNH$.[9] Thus, in the case where the liberating amine has relatively strong basicity (e.g. Me_2NH and Et_2NH), the yield of **26** somewhat increased.

When the reaction was carried out in four different solvents (Entries 32—35), the selectivity proved to be clearly solvent-dependent, where the ratio of **25** to **26** decreased linearly with increase in dielectric constant (ε_γ). It could be postulated that adduct **6** tends to cleave in polar solvents, probably because the transition state in the ring scission reaction has some

polar character and scission energy is reduced in polar media.

Finally, the reactions of **1** with aniline derivatives bearing different substituents X (MeO, Me, and Cl) at the para-position were examined (Entries 36—38). However, the substituents X showed little effect on both the yields and the ratio of **25** to **26**. For definite interpretation on the factors which favor Path B, further detailed information will be needed.

In summary, the reactivity of 1,4,2-dithiazolium cations (**1**) proved to be partly similar to that of 1,3-dithiolium cations (**2**)[1] or 1,3-oxathiolium cations (**3**)[2] (Path A and a part of Path B), but partly different from that of all of other five-membered heteroaromatic cations[1-4] (Path C and a part of Path B). The reaction of **1** with various active methylene compounds has currently been studied; the results will be reported in a separate paper.

Experimental

All the melting points were uncorrected. The ^{1}H NMR spectra were recorded on a Hitachi R-40, in $CDCl_3$, using TMS as an internal standard. The IR spectra were measured on a JASCO A-302 spectrometer using KBr disks. The low-resolution mass spectra were taken on Hewlett Packard 5995A spectrometer by electron impact ionizing technique at 70 eV.

1,4,2-Dithiazolium salts (**1**),[7] *S*-benzoylsulfenamide,[10] *N,N*-diethylthiocarbazide (**21**),[11] and thiobenzoylhydrazine[12] were prepared according to the procedures in the literatures. Other reagents were commercially available and used without any purification.

Reaction of 1a, b with Amino Compounds; General Procedure. 1,4,2-Dithiazolium perchlorates **1a,b** (1 mmol) were added to stirred solutions (6 ml) of amino compounds (2 mmol), except for aqueous ammonia (28%) (4 ml) (Entry 8) and hydrazine monohydrate (80%) (0.2ml) (Entry 10). In the case of using base, the combination of **1** (1 mmol), amino compounds (1 mmol), and triethylamine (1 mmol) was adopted (Entries 11—13). Other reaction conditions were listed in Table 1. After the solvent was removed in vacuo, the residue was purified by column chromatography on silica gel and recrystallization from appropriate solvents listed in Table 3. The yields of products are presented in Table 1 and their characterization data are shown in Table 3. On the other hand, **7**,[5] **13**,[13] **14**,[14] and **16**[15] were identified by direct comparison with each authentic sample.

Reaction of 1a—g with *p*-Substituted Aniline Derivatives. 1,4,2-Dithiazolium perchlorates (**1a—g**) (1 mmol) were added to stirred solutions (4 ml) of the aniline derivatives (1.1 mmol) in the presence of base (1.1 mmol). The reaction mixture was stirred for 6 h at room temperature. The crude products were extracted with dichloromethane (20 ml×2) after addition of 2% hydrochloric acid. The two products **25** and **26** were isolated by preparative TLC. Their mps and spectral data are shown in Tables 4 and 5. The elemental analyses of **25e** and **26e** are shown below. Identification of other **25** and **26**'s was based only on spectral data.

25e: Found: C, 63.18; H, 4.21; N, 9.75%. Calcd for $C_{15}H_{12}N_2S_2$: C, 63.35; H, 4.25; N, 9.85%.

26e: Found: C, 61.71; H, 7.28; N, 14.37%. Calcd for $C_{10}H_{14}N_2S$: C, 61.82; H, 7.26; N, 14.42%.

Highly Regio- and Stereoselective Ring-Opening Reaction of γ-Alkenyl-γ-butyrolactones with Allylsilanes in the Presence of Trimethyloxonium Salt Leading to Methyl 4,8-Alkadienoates

Masatoshi KAWASHIMA and Tamotsu FUJISAWA*
Chemistry Department of Resources, Mie University, Tsu, Mie 514
(Received June 29, 1988)

The reaction of γ-alkenyl-γ-butyrolactones with allylic trimethylsilanes in the presence of trimethyloxonium tetrafluoroborate proceeded regio- and stereoselectively with an allylic rearrangement of the substrate to afford methyl (*E*)-4,8-alkadienoates in high yields. On the other hand, the ring opening of 4-hexen-6-olide afforded exclusively methyl (*Z*)-4,8-alkadienoates in high yields. The synthetic utility of the reaction was demonstrated by the short step synthesis of β-sinensal and β-farnesene.

Alkadienoic acids possessing 1,5-diene structure such as 2,6-, 3,7-, and 4,8-alkadienoic acids are incorporated in terpenoid carboxylic acids and many synthetic methods have been developed. For example, the Claisen rearrangement of 2-alkenoic acid allylic esters via trimethylsilylketene acetals produces 3-carboxy-1,5-diene derivatives, which are subsequently converted into 2,6-alkadienoic acids by the Cope rearrangement.[1] Palladium-catalyzed carbonylation accompanying allylic rearrangement of 3-hydroxy-1,6-diene derivatives gives 3,7-alkadienoic acids.[2] The Claisen rearrangement of 3-acetoxy-1,6-heptadiene via *t*-butyldimethylsilylketene acetal gives 4,8-nonadienoic acid.[3] In these synthetic methods, there is no example which satisfies both convenience of the operative procedure and the stereoselectivity of the carbon–carbon double bond. In our laboratory, the ring opening of ω-alkenyllactones such as β-alkenyl-β-propiolactone, γ-vinyl-γ-butyrolactone, and δ-vinyl-δ-valero lactone with organocopper reagents were developed and utilized for the synthesis of the various kinds of alkenoic acids.[4] Alkadienoic acids such as 3,7- ,4,8-, and 5,9-alkadienoic acids were prepared by this method using diallylcuprate, however, the product yields are not so high and the predomination of *E*-configuration of the carbon-carbon double bond is not perfect. The reason may be due to the lack of thermal stability of the cuprate and formation of copper π-allyl complex.[5] The yield and the stereoselectivity of the carbon-carbon double bond of 4,8-nonadienoic acid obtained by the ring opening of γ-vinyl-γ-butyrolactone are the lowest among these alkadienoic acids and not adequate for the further utilization of the acid. Therefore to develop more stereoselective synthetic method of 4,8-alkadienoic acids or their esters, allylsilane, which is thermally stable compound, was noticed for the nucleophile as the source of allyl group toward the ring opening of γ-vinyl-γ-butyrolactone. The present paper describes details on the regio- and stereoselective reaction of γ-alkenyl-γ-butyrolactones and the analogous lactone, 4-hexen-6-olide, with allylsilanes in the presence of trimethyloxonium tetrafluoroborate to afford methyl (4*E*)- and (4*Z*)-4,8-alkadienoates in high yields, respectively.[6]

The reactions of allylsilane with acetal,[7] aldehyde,[8] enone,[9] and so on,[10] are achieved in the presence of the activator of the electrophile such as Lewis acids because of the low nucleophilicity of allylsilane. Therefore, the reactions of γ-vinyl-γ-butyrolactone (**1**) with allyltrimethylsilane were carried out in the presence of catalytic or equimolar amount of Lewis acid such as $TiCl_4$, $SnCl_4$, $AlCl_3$, $Me_3SiOSO_2CF_3$, and Me_3SiI, however, the desired allylation of the lactone did not proceed to result in a recovery of the starting material **1**. When the Meerwein reagent, triethyloxonium tetrafluoroborate, which was known as the ethylating agent of the oxygen atom of γ-butyrolactone,[11] was used as the activator of the lactone **1**, the reaction of **1** with allylsilane proceeded in CH_2Cl_2 at room temperature to afford ethyl 4,8-nonadienoate (**2**) in 49% yield accompanying with many complex products formed by the over alkylation of the initial product **2**. Since the side reaction seemed to be attributed to the high reactivity of triethyloxonium salt, trimethyloxonium tetrafluoroborate was used instead of triethyloxonium salt resulting in remarkable increase of the yield of the corresponding methyl ester, methyl 4,8-nonadienoate (**3a**) (100%) in spite of heterogeneous reaction. The product showed the regioselective attack of allylsilane to the terminal vinyl carbon of the lactone **1** without accompanying the attack to the γ-carbon. The present result of the allylic rearrangement of the electrophile in the reaction of allylic silanes has been rarely reported.[12] Moreover the exclusive *E*-configuration of the newly formed carbon-carbon double bond of the ester **3a** was confirmed by NMR, IR spectra, and GLPC analysis in

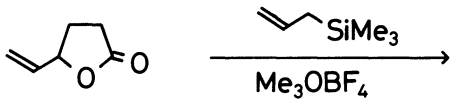
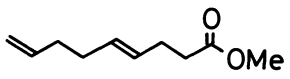
a) The molar ratio of lactone, oxonium salt, and allylsilane is 1:2:3. b) No reaction proceeded.

comparison with those of methyl ester of 4,8-nonadienoic acid obtained by the reaction of **1** with diallylcuprate.[4] The reaction did not proceed at all in nonpolar solvent such as benzene. When nitromethane was used as the co-solvent of dichloromethane to dissolve the oxonium salt, the yield of the methyl ester **3a** was remarkably decreased. The reactions in



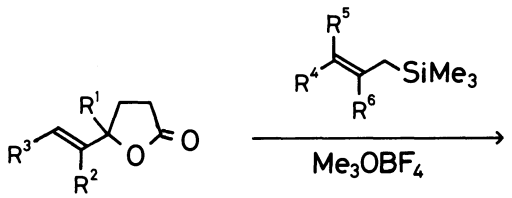
1

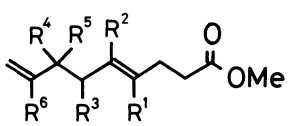


3a

refluxing CH_2Cl_2 and $CHCl_3$ decreased the yields to 83% and 72%, respectively, although the reaction time was markedly shortened to about a tenth. These representative results are summarized in Table 1.

Wide applicability of this ring opening of γ-vinyl-γ-butyrolactones was elucidated by the reaction of various γ-alkenyl-γ-butyrolactones with allylic silanes. In the reactions of allyltrimethylsilane with methyl substituted γ-vinyl-γ-butyrolactones such as





3

γ-isopropenyl- and γ-(1-propenyl)-γ-butyrolactones, the ring opening of both lactones afforded the corresponding methyl 4,8-alkadienoates **3b,c** with

Table 2. Ring Opening of γ-Alkenyl-γ-butyrolactones[a]

Lactone	Allylsilane	Product	Yield/%
		**3a** 	100
		**3b** 	85
		**3c** 	81
		**3d** 	90
		**3e**	93

a) All reactions were performed at room temperature for 94 h in CH_2Cl_2. The molar ratio of lactone, oxonium salt, and allylsilane is 1:2:3.

methyl group at 5- and 6-positions in high ylelds (81% and 85%, respectively). The reaction of γ-methyl-γ-vinyl-γ-butyrolactone gave the corresponding ester **3d** with methyl group at 4-position in 74% yield. The ring opening of γ-vinyl-γ-butyrolactone with substituted allylsilanes such as (2-methyl-2-propenyl)-trimethylsilane, (3-methyl-2-butenyl)trimethylsilane, and 2-(trimethylsilylmethyl)-1,3-butadiene also proceeded regio- and stereoselectively to afford the corresponding methyl 4,8-alkadienoates **3e—g** with substituent at 7- and 8-positions. In a recent report on the ring opening of 2-vinyltetrahydrofuran with allylsilanes, the regioselectivity is affected by the substituent on the allylsilane.[12a] In the present ring opening of γ-alkenyl-γ-butyrolactones, no formation of regioisomer produced by the attack of allylsilane to the γ-carbon of γ-alkenyl-γ-butyrolactones could be confirmed. Moreover, IR spectra and GLPC analyses of

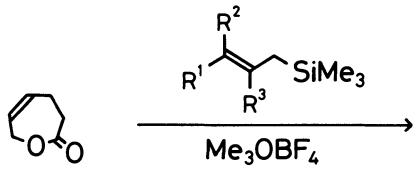
Table 3. Ring Opening of 4-Hexen-6-olide[a)]

Allylsilane		Product	Yield/%
	5a		87
	5b		84
	5c		86
	5d		60

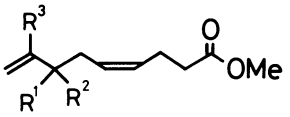
a) All reactions were performed at room temperature for 94 h in CH_2Cl_2. The molar ratio of lactone, oxonium salt, and allylsilane is 1:2:3.

the products showed exclusive *E*-configuration of the newly formed carbon–carbon double bond on 4-position of the esters. These results are summarized in Table 2.

4-Hexen-6-olide (**4**) is also a kind of allylic esters similar to γ-alkenyl-γ-butyrolactones. It is significant to investigate whether allylic rearrangement of the lactone **4** in reaction of **4** with allylic silane in the presence of trimethyloxonium tetrafluoroborate arises or not. Reaction with allyltrimethylsilane was carried out under the same conditions for the ring opening of **1**, in CH_2Cl_2 at room temperature to give a single product. Surprisingly, the product was methyl 4,8-nonadienoate, without accompanying a trace amount of methyl 4-vinyl-6-heptenoate. Moreover the carbon–carbon double bond at 4-position of the obtained ester retained completely the *Z*-configuration of 4-hexen-6-olide. This is noticeable result compared with the ring opening of 4-hexen-6-olide with organocuprate to give a mixture of (*E*)- and (*Z*)-4-alkenoic acids (S_N2 product) and 4-vinylalkanoic acid (S_N2' product).[13)] Oxonium salt-promoted reaction of **4** with other methyl-substituted allylsilanes proceeded with high regio- and stereoselectivity to afford methyl (4*Z*)-4,8-alkadienoate **5**. The results are summarized in Table 3. Thus perfect S_N2' reaction in the ring opening of γ-alkenyl-γ-butyrolactones and perfect S_N2 reaction in that of 4-hexen-6-olide provide both geometrically pure (4*E*)- and (4*Z*)-4,8-alkadienoates.

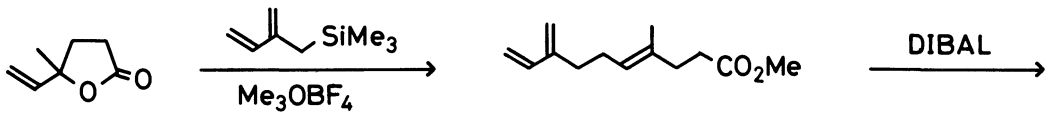


4

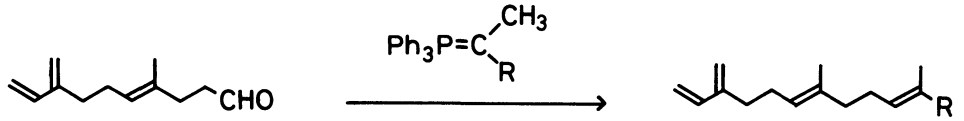


5

The applicability of the present stereoselective synthetic method of methyl 4,8-alkadienoate is demonstrated in a short step synthesis of β-sinensal **6**, an important constituent of the odor and taste of Chinese orange oil (*Citrus sinensus* L.)[14)] and β-farnesene **7**, natural aphid alarm pheromone. Methyl 4-methyl-8-methylene-4,9-decadienoate (**3h**), obtained in a yield of 65% by the reaction of γ-methyl-γ-vinyl-γ-butyrolactone with 2-(trimethylsilylmethyl)-



3h



8

R = CHO 6

R = CH_3 7

1,3-butadiene, was reduced by diisobutylaluminum hydride in THF–toluene to give 4-methyl-8-methylene-4,9-decadienal (**8**) in 83% yield. The Wittig reaction of the aldehyde **8** with (α-formylethylidene)-triphenylphosphorane and with isopropylidenetriphenylphosphorane afforded the desired *trans,trans*-β-sinensal **6** and *trans*-β-farnesene **7** in 82% and 54% yields, respectively.

The present ring opening reaction of γ-alkenyl-γ-butyrolactone and 4-hexen-6-olide with allylsilanes in the presence of trimethyloxonium tetrafluoroborate involves several characteristic features as follows: (1) Both isomers of (*E*)- and (*Z*)-4,8-alkadienoic acid methyl esters are obtained in high yields, respectively, by selecting the starting lactone, either γ-alkenyl-γ-butyrolactone or 4-hexen-6-olide. (2) High regio- and stereoselectivity is easily achieved at room temperature. (3) The operative procedure is extremely simple.

Experimental

General. Boiling points were measured at the pressure indicated and are uncorrected. Infrared spectra were recorded on a Hitachi EPI-G2 spectrometer. ^{1}H NMR spectra were recorded on a Varian A-60 spectrometer and on a Jeol JNM-PMX60SI spectrometer and are reported in parts per million (δ) from TMS. Samples were dissolved in CCl_4 containing TMS as an internal standard. Preparative thin-layer chromatography (TLC) was performed on 20×20 cm glass plates coated with 1.5 mm of silica gel (Wakogel B-5F). All reactions were run under a positive pressure of dry argon. Reactions requiring anhydrous conditions were performed in a flame-dried glassware that was cooled under argon. Anhydrous solvents were transferred by an oven-dried syringe. Solvents were distilled before use: Dichloromethane was distilled from phosphorus pentaoxide.

Materials. γ-Vinyl-, γ-isopropenyl-, and γ-(1-propenyl)-γ-butyrolactones were prepared according to the published method.[16] γ-Methyl-γ-vinyl-γ-butyrolactone[17] and 4-hexen-6-olide[13] were prepared by the reported method. Trimethyl-[18] and triethyloxonium tetrafluoroborates[19] were prepared by the published method. Allyltrimethylsilane, (3-methyl-2-butenyl)trimethylsilane, and 2-(trimethylsilylmethyl)-1,3-butadiene were purchased from Petrarch Systems Inc. (2-Methyl-2-propenyl)trimethylsilane was prepared by the reported procedure.[20]

Procedure for the Reaction of γ-Alkenyl-γ-butyrolactones with Allylsilanes in the Presence of Trimethyloxonium Tetrafluoroborate. In a typical experiment, a flask equipped with a magnetic stirring bar and septum was charged 592 mg (4.00 mmol) of Me_3OBF_4. After flushing with dry argon, a solution of 686 mg (6.00 mmol) of allyltrimethylsilane in CH_2Cl_2 (6 ml) was added to the flask at room temperature. Then a solution of 224 mg (2.00mmol) of γ-vinyl-γ-butyrolactone in CH_2Cl_2 (6 ml) was added and the reaction mixture was stirred at the same temperature for 94 h. The reaction was quenched with 10 ml of saturated $NaHCO_3$. The organic layer was separated and aqueous layer was extracted with CH_2Cl_2. The combined organic layer was washed with brine, dried with anhydrous $MgSO_4$, and concentrated. The residue was purified by TLC (hexane:CH_2Cl_2=2:1) to afford 336 mg (2.00 mmol) (100%) of methyl 4,8-nonadienoate (**3a**). R_f=0.5; ^{1}H NMR δ=2.07 (br d, *J*=3 Hz, 4H), 2.27 (br s, 4H), 3.55 (s, 3H), 4.70—5.95 (m, 5H); IR (neat) 1740, 1000, 970, 910 cm^{-1}; Anal. ($C_{10}H_{16}O_2$) C, H.

In the same manner as above, all other ring opening reactions of γ-alkenyl-γ-butyrolactones and 4-hexen-6-olide were performed.

Methyl (*Z*)-8-Methyl-4,8-nonadienoate (5b): R_f=0.5; ^{1}H NMR δ=1.72 (s, 3H), 2.07 (br s, 4H), 2.27 (br s, 4H), 3.57 (s, 3H), 4.60 (br s, 2H), 5.20—5.50 (m, 2H); IR (neat) 1740, 890 cm^{-1}; Anal. ($C_{11}H_{18}O_2$) C, H.

Methyl (*Z*)-7,7-Dimethyl-4,8-nonadienoate (5c): R_f=0.5; ^{1}H NMR δ=0.95 (s, 6H), 1.83—2.17 (m, 2H), 2.28 (br s, 4H), 3.57 (s, 3H), 4.57—6.03 (m, 5H); IR (neat) 1740, 990, 910 cm^{-1}; Anal. ($C_{12}H_{20}O_2$) C, H.

Methyl (*Z*)-8-Methylene-4,9-decadienoate (5d): R_f=0.5; ^{1}H NMR δ=2.20 (br s, 4H), 2.27 (br s, 4H), 3.57 (s, 3H), 4.83—5.57 (m, 6H), 6.30 (dd, *J*=18 Hz, 11 Hz, 1H); IR (neat) 1740, 990, 890 cm^{-1}; Anal. ($C_{12}H_{18}O_2$) C, H.

Methyl (*E*)-4-Methyl-8-methylene-4,9-decadienoate (3h).[21] In the same manner as above, **3h** was prepared in a yield of 65% by the reaction of γ-methyl-γ-vinyl-γ-butyrolactone 131 mg (1.04 mmol) with (trimethylsilylmethyl)-1,3-butadiene 438 mg (3.12 mmol) in the presence of trimethyloxonium tetrafluoroborate 154 mg (1.04 mmol) in CH_2Cl_2 10 ml at room temperature for 71 h. R_f=0.5; IR (neat) 1740, 990, 890, 850 cm^{-1}.

(*E*)-4-Methyl-8-methylene-4,9-decadienal (8).[22] Under an argon atmosphere, to a solution of **3h** 140 mg (0.676 mmol) in THF 2 ml, was added dropwise a toluene solution of 1 M (1 M=1 mol dm^{-3}) diisobutylaluminum hydride 0.7 ml (0.7 mmol) at −78 °C. After the mixture was stirred at the same

temperature for 2.7 h, the reaction was quenched by the addition of 10 ml of saturated aqueous NH_4Cl solution. Organic layer was separated and aqueous layer was extracted with twice of 10 ml of ether. The combined organic layer was washed with brine, dried with anhydrous $MgSO_4$, and concentrated. The residual crude product was purified by preparative TLC (hexane:Et_2O=2:1, R_f=0.7) to afford 100 mg (0.561 mmol) of **8**.

β-Sinensal (6).[22] According to the published procedure,[22] **6** was prepared by the Wittig reaction of **8** with (α-formylethylidene)triphenylphosphoran in refluxing benzene.

β-Farnesene (7).[23] Under an argon atmosphere, to a solution of isopropylidenetriphenylphosphorane, prepared from isopropyltriphenylphosphonium bromide 1.40 g (3.64 mmol) and 1.59 M butyllithium 2.40 ml (3.82 mmol) in ether (10 ml) at room temperature for 3 h, a solution of **8** (324 mg, 1.82 mmol) in ether (2 ml) was added at the same temperature. After the mixture was stirred at room temperature for 3 h, precipitated phosphine oxide was removed by filtration. The filtrate was concentrated to give an oil. The crude product was purified by preparative TLC (Hexane, R_f=0.8) to afford 200 mg (0.979 mmol) of **7**.

We thank Mr. Shogo Ando for his invaluable assistance in the experimental work.

Multinuclear NMR and the Rotational Barriers about the C-N Bonds of Several, *N,N*-Disubstituted Arenecarboxamides

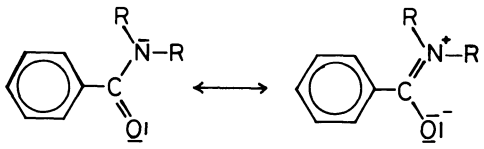
Hiroko SUEZAWA,* Kin-ya TSUCHIYA, Eiji TAHARA, and Minoru HIROTA
Department of Synthetic Chemistry, Division of Material Science and Engineering,
Faculty of Engineering, Yokohama National University,
Hodogaya-ku, Yokohama 240
(Received July 6, 1988)

The ^{15}N, ^{17}O, and ^{13}C NMR spectra of substituted *N,N*-dimethyl- and *N,N*-dibenzylbenzamides and *N,N*-dimethylnaphthamides were measured and correlated with the height of their rotational barriers. The ^{15}N and ^{17}O chemical shifts of the amides were shown to be controlled predominantly by the extent of the contribution of the polar mesomeric structure (**II**) and, especially in the case of ^{15}N, could be used to estimate the rotational barrier.

In recent decades, dynamic nuclear magnetic resonance spectroscopy has supplied much useful information on the exchange and the dynamic behaviors of molecules. Amides and related nitrogen compounds were investigated most extensively by this method partly because their NMR spectra show the coalescence phenomena at temperatures near ambient.[1-7]

Rotational barrier about the C–N bond of the amide is directly related to the partial double bond character of the bond and often used to examine the electronic properties of amides, such as the effect of conjugation, the effect of the electronegativity of the substituent on the acyl carbon, etc. For instance, the rotational barriers about the C–N bond of unsaturated and aromatic amides have been shown to be affected very sensitively by the conjugative properties of their hydrocarbon moieties with the carbonyl group. The fact is reflected in the rotational barriers of *N,N*-dimethylacrylamide (69.8 kJ mol^{-1})[1] and *N,N*-dimethylbenzamide (64.9 kJ mol^{-1})[2] which are considerably lower than that of *N,N*-dimethylformamide (87.4 kJ mol^{-1}).[3] The partial double bond character of the C–N bond is usually assumed to be originated from the polar mesomeric structure (**II**) bearing a positive charge on the nitrogen and a negative charge on the carbonyl oxygen; the higher C–N bond order should be expected when the contribution of the canonical structure **II** becomes more predominant. Hence, the pi-electron densities on the nitrogen and the oxygen atoms should be correlated with the height of the rotational barrier.

Very extensive studies on the ^{1}H and ^{13}C chemical shifts of aromatic compounds revealed the fact that the chemical shift could be correlated linearly with the electron density of the carbon atom derived from MO calculations for the series of aromatic compounds having closely related structures.[8-10] It has thus become a well-known fact that the electron density should be correlated linearly with the chemical shift of the respective nucleus in a manner to induce a shift towards a higher field by the increase in the electron density. As to ^{15}N chemical shifts, this fact was substantiated by Mason.[11] Carbonyl ^{17}O chemical shifts of many acyl derivatives were also measured and correlated with the electron densities by Delseth and coworkers.[12]



(I) (II)

For this reason, the increase in the rotational barrier should cause the down-field shift of ^{15}N signal and the up-field shift of ^{17}O signal. From this point of view, the ^{13}C, ^{15}N, and ^{17}O chemical shifts were measured with several arenecarboxamides and correlated with their rotational barriers, or their activation free energies of internal rotation, about the C–N bonds.

Results and Discussion

Carbonyl and *N*-methyl carbons, amide nitrogen, and carbonyl oxygen are expected to be affected most significantly by the change in the partial double bond character of the amide moiety. Hence, the NMR spectra were reported only with the nuclei concerned (viz., ^{13}C of carbonyl and *N*-methyl, ^{15}N of amide, and ^{17}O of carbonyl) in several solvents; the chemical shifts are given in Table 1. The table also includes the rotational barriers of the amides reported previously by the present authors.[13,14] In order to examine the correlation with the rotational barrier, the chemical shifts were plotted as ordinate and the rotational barriers as abscissa; the results are given in Figs. 1 and 2 for the ^{15}N chemical shift and in Fig. 3 for the ^{17}O chemical shift. Throughout this paper chemical shifts were expressed by the conventional δ-scale, which assigns a positive value to the region more deshielded than the standard. Here the chemical shifts (δ/ppm) were correlated linearly with the height of the rotational barrier ($\Delta G^{\ddagger}$/kJ mol^{-1}) by the following equation:

a*,c*	P	8	0.204	91.83	0.77
a*,c*	D	4	0.446	80.13	0.86
a*,c*	M	6	0.116	105.90	0.51

a) *n*; number of plotted data, *k*; slope of the regression line, *m*; intercept of the regression line, *r*; correlation coefficient. b) The amides are classified as follows: a; **1—7**, b; **14—17**, **19**, and **20**, c; **21**, **22**, and **26—28**, a*; **8—13**, c*; **23—25**. a* and c* are *o*-hydroxylated amides. c) C; $CDCl_3$, P; C_5D_5N, D; CD_3SOCD_3, M; CD_3OD.

$$\delta = k\Delta G^* + m$$

The best fit slope (k) and the intercept (m) values for the plot were calculated by the least squares calculations and given in Table 2. In order to show the limit of reliability of the plot explicitly, the correlation coefficient (r) was given in the same table.

The plotted data of *o*-hydroxy derivatives constitute a group clearly distinguishable from those of other amides lacking *o*-hydroxyl group in the chemical shift vs. rotational barrier diagram of both ^{15}N and ^{17}O series. Besides the presence of the *o*-hydroxyl group, the important factors affecting the chemical shifts are (i) the polar and the conjugative properties of the substituents and (ii) the nature of the solvent. However, the influence induced by these factors were sometimes obscured because the rotational barriers are also perturbed by the similar factors in a manner proportional to the effect on the chemical shift.

In order to make the discussion more straightfor-

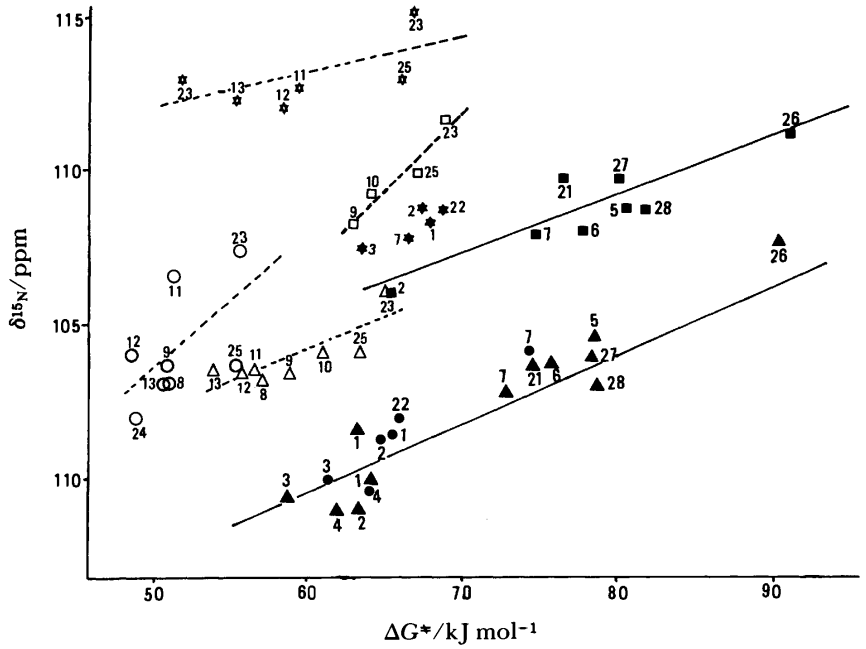

Fig. 1. The ^{15}N chemical shift (δ_{15N}) vs. the height of the rotational barrier[14] ($\Delta G^{\ddagger}$) plots of *N,N*-dimethylbenzamides (a) and *N,N*-dimethylnaphthamides (c) in various solvents [chloroform-*d* (●), pyridine-d_5 (▲), dimethyl-d_6 sulfoxide (■), and methanol-d_4 (★)]. The amides bearing *o*-hydroxyl group are shown by open marks; those without *o*-hydroxyl group shown by filled marks.

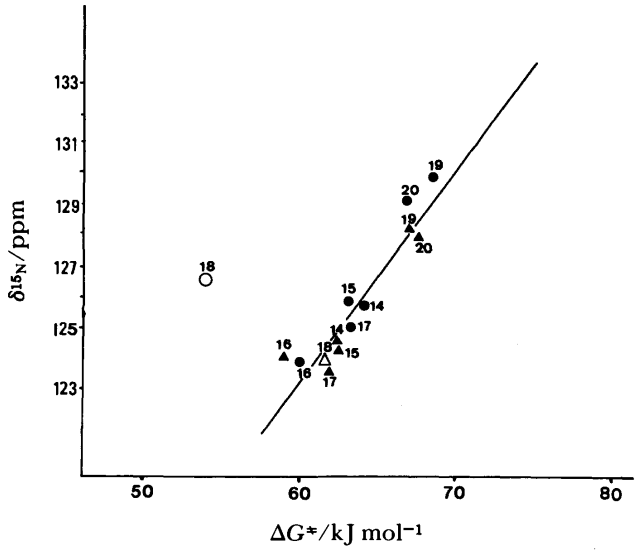

Fig. 2. The ^{15}N chemical shift (δ_{15N}) vs. the height of the rotational barrier[14] ($\Delta G^{\ddagger}$) plots of *N,N*-dibenzylbenzamides (b) in various solvents. The points have the same meaning as in Fig. 1.

ward, the amides employed in this work were classified on the basis of their structural feature into three groups; namely, (a) *N,N*-dimethylbenzamides **1—13**, (b) *N,N*-dibenzylbenzamides **14—20**, and (c) *N,N*-dimethylnaphthamides **21—28**. As the chemical shift was perturbed considerably by the solvent, the chemical shift data in each solvent were correlated individually with the rotational barriers in the same solvent; the difference in the solvent was also discussed. In several cases, the plots in several different solvents were combined in the statistical treatment. Except for the *o*-hydroxy derivatives, good to excellent correlations were obtained. Since these factors affect each nucleus of the atoms comprising the $CONR_2$ moiety in a different way, their chemical shift vs. rotational barrier correlations will be discussed individually.

The Correlation of ^{15}N Chemical Shifts with the Rotational Barriers. As expected, the ^{15}N chemical shift vs. rotational barrier plots in various solvents were shown to have positive slopes, which means that the chemical shift moves towards down-field as the height of the rotational barrier increases. The trend is in line with the rotational barrier vs. ^{15}N chemical shift plots for a series of *m*- and *p*-substituted benzamides reported by Randall and coworkers.[15] Since the ^{15}N chemical shifts were perturbed most predominantly by the nature of the substituent on the nitrogen atom, the *N,N*-dibenzyl derivatives (b) resonate at far lower fields than the *N,N*-dimethyl derivatives (a) and (c), constituting a group of plotted points in the upper half of Fig. 1. The down-field shift might be caused by either or both of the electronic and the magnetic anisotropy effects.

The effects on the ^{15}N chemical shift of the

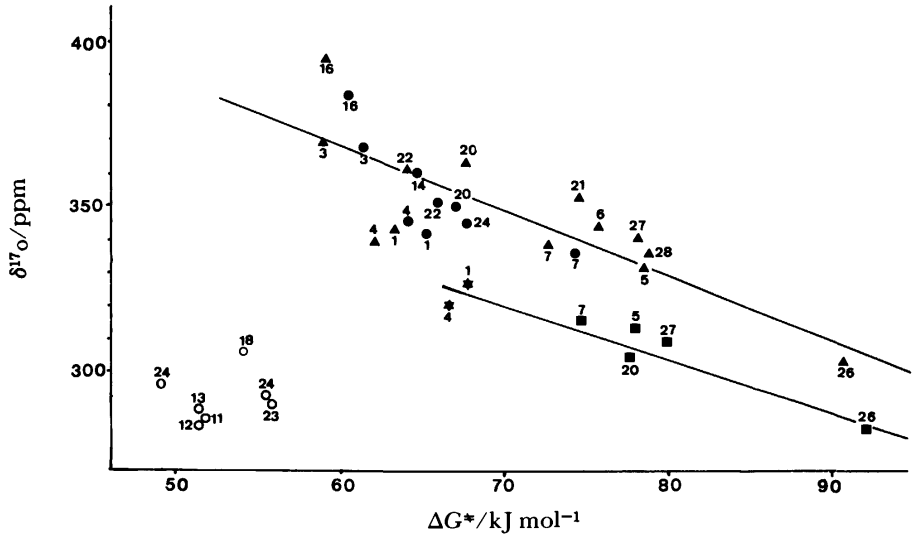

Fig. 3. The ^{17}O chemical shift (δ_{17O}) vs. the height of the rotational barrier[14] (ΔG^*) plots of the three series of the *N,N*-dialkylarenecarboxamides (a, b, and c) in various solvents. The points have the same meaning as in Fig. 1.

structural changes and of the substituent(s) in the aromatic part of the molecule do not seem to cause apparently observable deviation from the combined regression lines for the series of *N,N*-dimethylbenzamide (a) and -naphthamide (c) except for *o*-hydroxy derivatives (Fig. 1). This implies that the direct through-space effects, such as anisotropy and steric effects, due to the structural change far apart from the ^{15}N nucleus do not induce a serious deviation of the ^{15}N chemical shifts of these amides.

If we assume (i) that the chemical shift should be controlled exclusively by the electron density on the nitrogen atom throughout these two series of *N,N*-dimethyl derivatives [(a) and (c)], and (ii) that the solvent effect is merely electrostatic,[16] both the increase in the rotational barrier and the down-field shift should be originated by the increase in the contribution of the polar mesomeric structure (**II**), which causes the descreening of the nitrogen nucleus. Therefore, the chemical shift vs. rotational barrier plot should merge into a single regression line irrespective of the solvent used. This situation may be realized approximately when the solvent is less polar as in the cases of chloroform and pyridine solutions. Thus, the plots in these two solvents constitute a group, giving a regression line with r=0.90. However, the correlation is better with the regression lines drawn by use of the data in the two solvent independently (r=0.94 for the $CDCl_3$ solutions and r=0.914 for the C_5D_5N solutions). The solvent effect becomes more evident in dimethyl sulfoxide and methanol.

In cases of the *o*-hydroxy derivatives (**8—13**, **18**, and **23—25**), the plots deviate strikingly from those for the amides lacking *o*-hydroxyl group. However, the chemical shift vs. rotational barrier plots still hold positive slopes analogous to the other series of amides investigated; the plots showed clearly that the ^{15}N chemical shift is controlled by the contribution of polar mesomeric structure (**II**) even in this series of amides. The regression lines separately drawn for the plot of the *o*-hydroxy amides occupy considerably upward positions in Fig. 1 in comparison with the corresponding lines for the amides lacking *o*-hydroxyl group; which means that the nitrogen is more deshielded than estimated by the screening of the nucleus probably due to the strong neighbor anisotropy effect of the hydrogen-bonded chelate ring.

The Correlation of ^{17}O Chemical Shifts with the Rotational Barriers. The ^{17}O chemical shift vs. rotational barrier plots are given in Fig. 3. As rationalized by the increased contribution of the polar mesomeric structure **II** which increases the negative charge on the oxygen, the regression lines for the plots have negative slopes (negative k values). In sharp contrast to the large separation between the plots of ^{15}N chemical shifts, the plotted points of ^{17}O chemical shifts for the *N,N*-dimethyl amides [(a) and (c)] and those for the *N,N*-dibenzyl amides (b) constitute a rather scattered but single group in Fig. 3. The fact suggest that the effect of *N*-substituent is attenuated significantly on the carbonyl oxygen.

The direct through-space effect caused by the *o*-substituent (and peri-substituent) becomes more important in the ^{17}O chemical shift, which may cause irregular fluctuation of the chemical shift and decreased the reliability of the correlation (lowering of r value).

The chelate ring formation by intramolecular

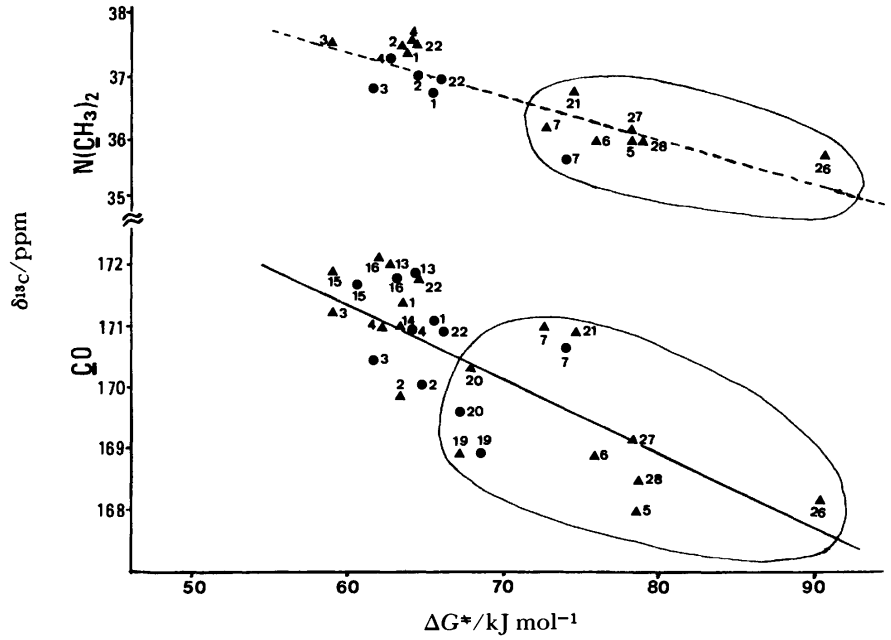

Fig. 4. The ^{13}C chemical shift (δ_{13C}) vs. the height of the rotational barrier[14] (ΔG^*) plots of the three series of the *N,N*-dialkylarenecarboxamides (a, b, and c) in chloroform-*d* and pyridine-d_5. The points have the same meaning as in Fig. 1.

hydrogen bonding with the *o*-hydroxyl group causes a considerable up-field shift of carbonyl ^{17}O chemical shift. This tendency is in accord with the reported chemical shifts of salicylaldehyde and methyl salicylate.[17]

The Correlation of ^{13}C Chemical Shifts with the Rotational Barrier. The ^{13}C chemical shifts of the *N*-methyl and the carbonyl carbons were also measured and given together in Table 1 and correlated with the rotational barriers in Fig. 4. It is remarkable that the ^{13}C chemical shift of the *N*-methyl carbon would move apparently towards high field as the rotational barrier increases, since this trend is just opposite to the direction of the shift observed with ^{15}N which moves down-field during the similar change. The methyl ^{13}C chemical shift can be expected to move in the same direction as the ^{15}N if the inductive effect which decreases the carbon electron density alone is assumed to operate. Thus we need an explanation for this apparently contradictory behavior of the carbon chemical shift.

The *N*-methyl ^{13}C chemical shift is generally rather insensitive to the structural modification of the aromatic part and also to the nature of the solvent; populating in a narrow range of the chemical shift. The range became far narrower when the amides were classified in reference to the presence of the ortho substituent. Thus, the *o*-unsubstituted amides resonate within the range 36.8—37.6 ppm and most of the *o*-substituted amides (but void of *o*-hydroxyl group) in the range 35.7—36.2 ppm.

If we adopt the geometries estimated by Baumstark and co-workers,[18] one of the *N*-methyl groups of *N,N*-dimethyl-1-naphthamide (**21**) should be subjected to the strong diamagnetic anisotropy effect from the aromatic ring. If we assume that the *o*-substituted amide takes a conformation similar to **21** due to the steric hindrance caused by the ortho-substituent, this conclusion is effective to all ortho-substituted amides. In contrast, the methyl group does not seem to be exposed to diamagnetic magnetic field induced by the aromatic ring in the cases of the *o*-unsubstituted amides. When we examined the ^{13}C chemical shift vs. rotational barrier plot closely, superficial negative slope is suspected to arise from the fact that the plotted points for the *o*-substituted amides (encircled points in Fig. 4) lie in the right bottom part of the diagram. This comes, of course, from the anisotropy effect just described. The explanation could be extended to the *o*-hydroxy amides whose methyl carbons resonate at lower fields and which are assumed to become more planar due to chelate ring formation.

The ^{13}C chemical shifts of *p*-substituted *N,N*-dimethylbenzamides were correlated with σ_p and also with Dewar's F constants by Jones and Wilkins.[19] Analogously, the carbonyl ^{13}C chemical shifts of **5—13** could be interpreted by the somewhat exaggerated electronic effect caused by the ortho-substituent, or by the combined substituent effect in the cases of polysubstituted derivatives, operating in a through-bond manner.

Solvent Effect on the ^{15}N and ^{17}O Chemical

a) $\Delta\delta=\delta_{solv}-\delta_{CDCl_3}$.

Shifts. The solvent induced shifts with reference to the chemical shifts in chloroform-*d* solutions are given in Table 3. At a glance of the whole data, they seemed to be in line with a very simple and straightforward interpretation that the polarity of the solvent favors the contribution of the dipolar mesomeric structure **II**.

However, the whole of the solvent induced shift could not be attributed merely to the dielectric nature of the solvents, since the rotational barrier vs. chemical shift plots were solvent dependent giving a different regression line for each solvent. Moreover, the down-field shift of the ^{15}N chemical shift and the up-field shift of the ^{17}O chemical shift becomes more predominant in the following order of the solvent: benzene<pyridine<chloroform<DMSO<methanol. Pyridine is exceptional when the solvent effect is compared in reference to the dielectric nature of the solvent, inducing an up-field shift of ^{15}N signal and a down-field shift of ^{17}O signal. Similar irregularity was observed with the rotational barrier of the same amides reported in our previous paper.[14] This trend of the solvent effect is in accord with the order of the hydrogen-donating ability[20] (in forming hydrogen bonds) of the C–H or OH group in the solvent molecule. Association by forming hydrogen bonds is a specific solvent–solute interaction which requires the access of the solvent molecule with an appropriate orientation from a specified direction. In this situation, the solvent molecule, usually anisotropic, should induce an anisotropic field around the amide molecule. Thus the observed solvent dependency of the regression lines is explicable by the hydrogen-bond-like interaction between the solvent and the solute molecules.

In conclusion, both the rotational barrier and the ^{15}N and ^{17}O chemical shifts can be assumed to be controlled by the same origin, the extent of the mesomeric contribution of the canonical structure **II**, or the C–N bond order and the electron densities on the nitrogen and oxygen atoms, when their measurements were carried out in the same solvent. The correlation is excellent with the rotational barrier vs. ^{15}N chemical shift plot for the dimethylamides lacking *o*-hydroxyl group. Consequently, ^{15}N chemical shifts of the amides should be a probe of the heights of their rotational barriers.

Experimental

N,N-Dimethyl- and *N,N*-dibenzylarenecarboxamides were prepared as usual by the reaction of the corresponding aroyl chlorides with dimethyl- and dibenzylamines, respectively.

^{15}N, ^{17}O, and ^{13}C NMR spectra were recorded on a JEOL FX-90Q spectrometer using 10-mm probe. In order to obtain strong signals from ^{15}N and ^{17}O nuclei of natural abundance, the samples for the measurements were prepared by dissolving as concentrated as possible, ca. 500 mg of the amide in ca. 1.5 ml of the solvent. Chloroform-*d*, methanol-d_4, pyridine-d_5, dimethyl-d_6 sulfoxide (DMSO-d_6), and benzene-d_6 were used as solvents throughout this work. The multi-nuclear measurements were carried out under the following conditions:

Nucleus	^{15}N	^{17}O	^{13}C
Resonance frequency (MHz)	9.04	12.10	22.50
Pulse length (μs)	18(45°)	20(90°)	12(45°)
Delay	3 s	100 ms	2 s
Number of data points	8K	1K	8K
Spectral width (Hz)	3000	10000	5000
Accuracy (Hz)	0.7 (0.08 ppm)	10 (0.8 ppm)	1.2 (0.05 ppm)
Number of scans	ca. 10000	ca. 100000	ca. 500
Reference	liq. NH_3 external	H_2O external	TMS internal

The authors wish to express their hearty thanks to Professor Masatsune Kainosho, Tokyo Metropolitan University, for his valuable advice throughout this work. The ^{15}N experiments were set forth by his suggestion to which we are especially grateful. This research is partly supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture.

ESR Studies of Copper(II) Ion Doped in Single Crystal of Benzo-15-crown-5 Complex

Yong Li, Kunihiko Tajima, Kazuhiko Ishizu,* and Nagao Azuma†
Department of Chemistry, Faculty of Science, Ehime University, Matsuyama 790
†Faculty of General Education, Ehime University, Matsuyama 790
(Received February 6, 1988)

Angular-dependent ESR measurements were carried out at 77 K for ^{65}Cu(II) ions doped in a single crystal of benzo-15-crown-5 (B15C5) magnesium complex. Not only the allowed resonance lines of copper(II) ions, but also the forbidden lines arising from a nuclear quadrupole interaction were observed. Based on an analysis of the single crystal ESR spectra, the spin Hamiltonian containing the quadrupole term was determined for a B15C5–^{65}Cu(II) complex having a $3d_{z^2}$ ground state in a B15C5–Mg(II) solid matrix.

Regarding previous work, we have reported ESR studies on copper(II) complexes with 15-crown-5 (15C5) derivatives in solution,[1] where the benzo-15-crown-5–copper(II) complexes (B15C5–Cu(II)) revealed the characteristic ESR g-anisotropies ($g_Z < g_X, g_Y$) which are typical of the copper(II) ion with a $3d_{z^2}$ ground-state doublet. In the ESR spectra measured in solution, however, the full Hamiltonian involving the nuclear quadrupole interaction could not be determined.

In the present paper, we report on the ESR spectra observed at 77 K for a B15C5–^{65}Cu(II) complex doped in a diamagnetic single crystal composed of a benzo-15-crown-5–Mg(II) complex. The copper(II) complex also exhibited the inverse g-values ($g_Z < g_X, g_Y$) featured by the $3d_{z^2}$ ground state. In addition, strong lines due to a forbidden transition of the copper(II), ascribed to a quadrupole interaction, were successfully observed for the $3d_{z^2}$ ground state. An analysis of the angular-dependent ESR spectra determined the magnitude of the nuclear quadrupole interaction, which would be affected by a strong axial perturbation in the present complex.

Experimental

B15C5 was prepared according to Pedersen's method.[2] $Mg(ClO_4)_2 \cdot 6H_2O$ and 60%-$HClO_4$ were purchased.

In order to obtain a B15C5–Mg(II) single crystal doped with copper(II), $^{65}CuSO_4 \cdot 5H_2O$ was added to a 0.5 mol dm^{-3} 60%-$HClO_4$ solution of B15C5 and $Mg(ClO_4)_2 \cdot 6H_2O$ mixed in an equivalent molar ratio, in which the ^{65}Cu(II) concentration was controlled to be 1% of the total Mg(II) concentration. The mixture was left standing for one week, after which yellow single crystals were obtained.

A doped single crystal was mounted on the plane of a goniometer rod with silicone grease. The single crystal ESR spectra were recorded at 77 K. Figure 1 (a) illustrates the relation between the magnetic field $\boldsymbol{H}$ and the coordinate systems used. The coordinate systems, (*0-xyz*) and (*0-123*), represent those fixed to the goniometer and to the single crystal, respectively. By appropriate intervals in the ϕ angle, the crystal was rotated around the z-axis (Fig. 1(a)) with α=2.8° and 18.2° being adopted. The direction of the magnetic field $\boldsymbol{H}$ is taken in the x-y plane. Figure 1 (b) shows the arrangement of the (*0-123*) coordinate system in the single crystal with its dimensions.

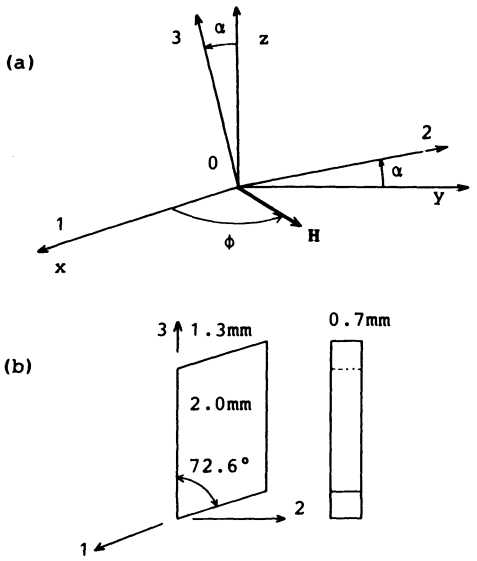

Fig. 1. (a) Coordinate systems adopted in the ESR measurement. The systems (*0-xyz*) and (*0-123*) were fixed to the goniometer and to the crystal, respectively. The crystal is mounted on the y-z plane, with keeping the axis *1* parallel to the x axis, and α is the angle between the axes *3* and z. The crystal is rotated around the z axis, so the magnetic field $\boldsymbol{H}$ is also rotated in the x-y plane by ϕ angle. (b) The arrangement of the (*0-123*) coordinate system in the single crystal with its dimension.

The ESR measurements were carried out on a JEOL-FX-2XG X-band ESR spectrometer operating with a 100-kHz magnetic-field modulation. The positions of the resonance lines were determined by taking Li-TCNQ (g=2.0025) as a standard. The magnetic fields were calibrated based on the hyperfine splitting of Mn(II) in powdered MgO (8.69 mT).

Results and Discussion

Figure 2 (a) shows the powder ESR spectrum observed at room temperature. The spectrum revealed a typical g-anisotropy, $g_Z < g_X, g_Y$, which was similar to that of a B15C5–copper(II) complex also having a $3d_{z^2}$

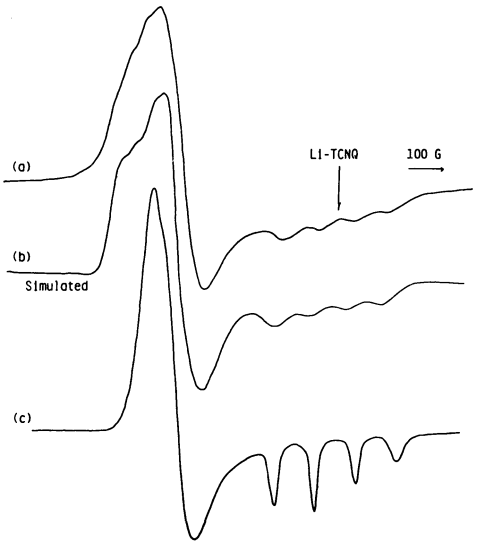

Fig. 2. Powder ESR spectrum of ^{65}Cu(II) doped in the crystal of B15C5-Mg(II) complex, measured at room temperature (a) and its simulation (b). Spectrum (c) was obtained from the B15C5-^{65}Cu(II) complex in 60%-$HClO_4$ aqueous solution at 77 K.

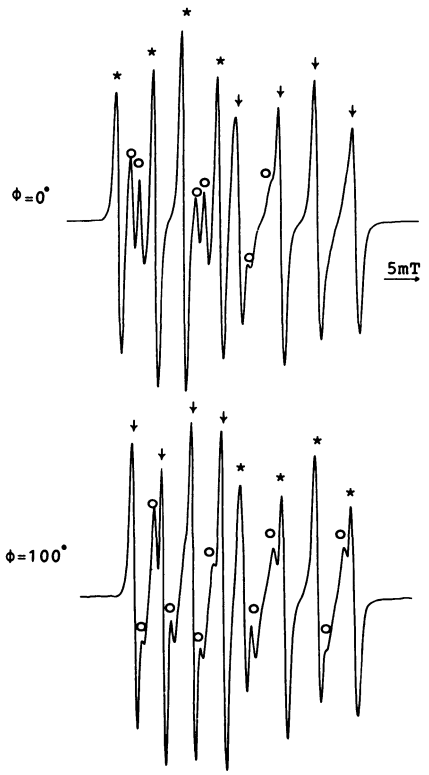

Fig. 3. ESR spectra of ^{65}Cu(II) doped in the single crystal of B15C5-Mg(II) complex. The temperature of the sample was 77 K and the α angle was 2.8°. The definition of the α and ϕ angles are given in Fig. 1. Asterisk and arrow indicate the allowed hyperfine splittings of the sites 1 and 2, respectively. The other spectral lines with open circle are due to the forbidden transitions.

ground state in solution (Fig. 2(c)).

Figures 3 and 4 show the angular-dependent ESR spectra of the ^{65}Cu(II) doped in a single crystal. The eight lines marked with asterisks and arrows have been assigned to the allowed transitions in two magnetically unequivalent copper sites. The other lines are ascribed to the forbidden transition ($\Delta M_I=\pm 1$). However, the range of the rotation angle (ϕ), in which one could observe each of those forbidden lines, has been very small. This is because the hindrance by the much stronger eight allowed lines and the overlapping between the forbidden transition lines themselves are inevitable. Therefore, an analysis of the angular variation of the forbidden lines has been almost impossible. We therefore confined our spectral analysis to only the allowed lines. In a usual case, the forbidden transition of copper(II) ion can not be detected in the X-band ESR spectra, because of its small transition probability. Thus, information concerning the quadrupole coupling is usually obtained from the Q-band ESR spectra for a single crystal.[3] Here, it is quite noteworthy that the forbidden lines were observed, even in the X-band spectra. This indicates that the probability of a forbidden transition is large enough to allow a clear detection in the observed ESR hyperfine structures.

In addition, it has been widely accepted that forbidden hyperfine lines are enhanced in intensity and that their resonant field positions are affected by a combination of the nuclear Zeeman interaction and nuclear quadrupole interaction.[3] If the magnitudes of the two terms are about the same and sufficiently enough for the detection of a forbidden transition, one can expect three pairs of forbidden transition lines to occur in middle of the respective allowed ^{65}Cu(II) hyperfine splittings; that is, the low-, medium-, and high-field pairs of forbidden transitions should be detected at a medium magnetic field, between those of four hyperfine lines of the copper(II) ion. The intensity of the medium-field pair is affected by the nuclear Zeeman term. On the other hand, the nuclear quadrupole term, as well as the nuclear Zeeman term, contribute to the intensity of the low- and high-field pairs, which results in the asymmetry of the observed forbidden hyperfine structure. In the present case, however, the line intensity for each of the low- and high-field pairs is nearly the same, while the intensity for the medium-field pair is greatly reduced in comparison with those of the low- and high-field pairs, as can be seen in Figs. 3 and 4. The contribution of the nuclear quadrupole term to the intensity of the low- and high-field pairs is calculated as to be the same. Therefore, it is suggested that the forbidden transitions mainly arise from a nuclear quadrupole interaction, and that the contribution to the line intensity from the nuclear quadrupole term is rather larger than that from the nuclear Zeeman term in this

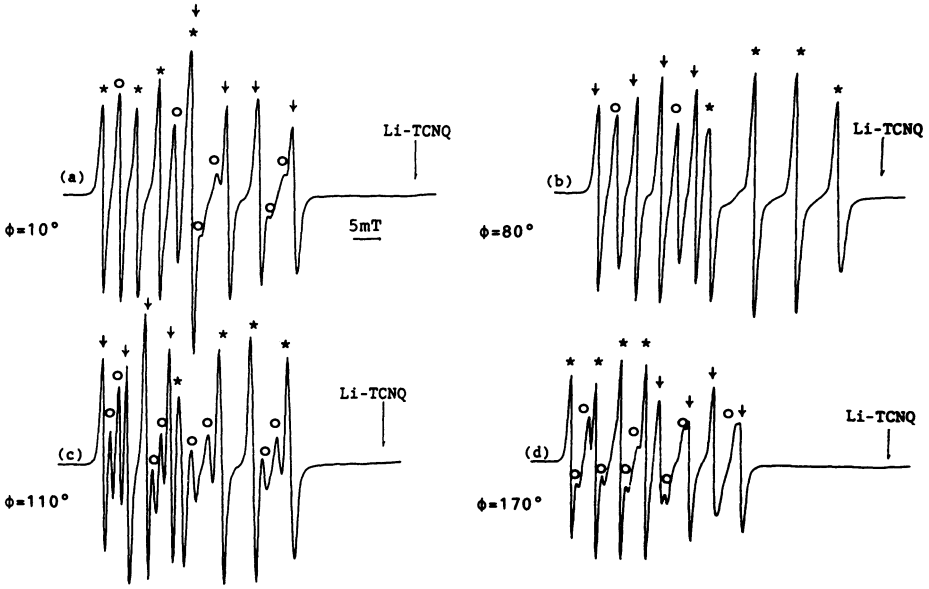

Fig. 4. The angular dependent forbidden ESR spectra of ^{65}Cu(II) doped in the single crystal of B15C5-Mg(II) complex, which are labeled with open circle. The symbols and the condition in the experiment are the same as those in Fig. 3, except for α=18.2°.

case.

By taking account of the view described above, an analysis of the single-crystal ESR spectra was performed based on the spin Hamiltonian given by

$$\mathscr{H} = \beta \boldsymbol{H}\boldsymbol{S}\cdot\boldsymbol{g}\cdot\boldsymbol{h} + \boldsymbol{I}\cdot\boldsymbol{A}\cdot\boldsymbol{S} + \boldsymbol{I}\cdot\boldsymbol{Q}\cdot\boldsymbol{I},$$

where $\boldsymbol{h}$ is a unit vector along the external magnetic field and the other symbols refer to the usual conventions. Within the limits of a high-field approximation, a general solution to the second order has been derived by Iwasaki[4] for the Hamiltonian in an arbitrary coordinate system without making any assumption that the $\boldsymbol{g}$, $\boldsymbol{A}$, and $\boldsymbol{Q}$ tensors are coaxial. According to the general solution, a computer analysis was carried out for the angular variation of the single crystal ESR spectra.

Figure 5 shows the angular variation of the allowed hyperfine lines of ^{65}Cu(II) doped in a single-crystal of B15C5-Mg(II). The open and solid circles indicate the observed line positions of the two copper sites. The spin Hamiltonian parameters estimated from the single-crystal ESR study are listed in Table 1. The solid lines in Fig. 5 represent the angular variations calculated based on the spin Hamiltonian parameters.

As shown in Fig. 5, the measured values agree well with the calculated values. At some ϕ angles, the high-field and low-field spacings of the ^{65}Cu(II) hyperfine splittings are not equal to the medium-field spacing. This has also been realized by means of the quadrupole interaction, since the second-order perturbation due to this interaction shifts the respective positions of the four lines.

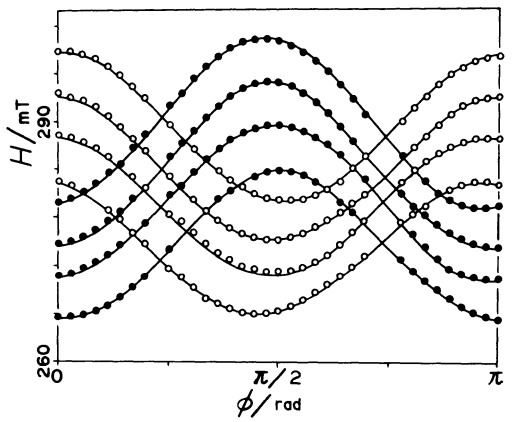

Fig. 5. The angular variation of the allowed hyperfine line positions of ^{65}Cu(II) doped in the single crystal of B15C5-Mg(II) complex at α=2.8°. The solid and open circles are of the sites 1 and 2, respectively. The solid lines are the reproduction calculated with the parameters in Table 1.

The simulated powder ESR spectrum based on the same parameters is close to the observed spectrum, as shown in Figs. 2 (a) and (b). This fact confirmed that the copper(II) ion was doped in the single crystal in the form of a B15C5-copper(II) complex. The spin Hamiltonian parameters of the two sites are in agreement within the error limit. Therefore, the two copper(II) sites are in the same ligand field environ-

ment.

The angles between the estimated principal axes of the g and A tensors, and those of g and Q tensors, are listed in Table 2. Those values are varied from 3.2° to 16.4° and the simple mean value is 9.7°. In order to determine whether these values are significant or not, the error limit required in the direction cosines is less than 2%. However, the accuracy in the present meurements is not considered enough to do so.

The marked nuclear quadrupole interaction can be attributed to the considerable perturbing effect of the axial ligands on the copper(II) ion with a $3d_{z^2}$ ground state in a B15C5–Cu(II) complex,[1,5] since a strong axial ligation results in a large molecular electric field gradient which interacts with the nuclear electric quadrupole.

In the present paper, the relation between the principal axes of the g, A, and Q tensors and the crystallographic axes of the single crystal is not discussed, since X-ray structural analysis of the host crystal has not yet been performed.

ESR measurements were carried out at the Advanced Instrumentation Center for Chemical Analysis of this University. The calculations were performed at the Computer Center of this University.

Bistability and Oscillations in the Bromate-Bromide-Cerium(III) System in Continuous-Flow Stirred Tank Reactor. A Simulation Using a New Set of Rate Constants of the FKN Scheme

Yoshihiro SASAKI
Institute for Chemical Research, Kyoto University, Uji, Kyoto 611
(Received June 7, 1988)

The bahavior of a bromate-bromide-cerium(III) system in a continuous-flow stirred tank reactor was simulated within the framework of the FKN reaction scheme and a new set of rate constants prepared by Field and Försterling. The characteristic properties such as bistability, hysteresis and minimal oscillations could be reproduced. In order to understand bistability in this system, the dynamic behavior of a four-variable model was examined by means of a two-variable approximation.

The bromate-bromide-cerium(III) system in a sulfuric acid medium in a continuous-flow stirred tank reactor (CSTR) can possess either one or two steady states or an oscillatory state.[1-4] The bistable system exists in either of the two steady states under the same set of constraints. When the system is perturbed, it relaxes to either of the two steady states, depending on the magnitude and direction of the perturbation. When the constraints are slowly changed, the system moves via a hysteresis loop between the two steady states. While the system does not contain organic substrates, it can exhibit minimal oscillations under certain conditions.

The reaction behavior of the system has been reproduced successfully through the FKN reaction scheme.[2,4-9] However, it was confirmed that several rate constants in the FKN scheme are inconsistent with some kinetic studies.[10-12] Therefore, Field and Försterling prepared a new set of rate constants (FF set of rate constants) on the basis of the recent results.[13] The FF values are similar to the Tyson's "Lo" values.[9,14] However, Bar-Eli and Ronkin found that the "Lo" values do not reproduce experiment very well, compared with the FKN values.[9] Therefore, we may become interested in a computation using the FF values. In this study, the bistability and oscillations of the bromate-bromide-cerium(III) system in a CSTR were re-investigated by means of a simulation method.

Calculations

The FKN reaction scheme can be described as follows:

$$Br^- + HOBr + H^+ \rightleftharpoons Br_2 + H_2O \quad (1)$$

$$Br^- + HBrO_2 + H^+ \rightleftharpoons 2HOBr \quad (2)$$

$$Br^- + BrO_3^- + 2H^+ \rightleftharpoons HOBr + HBrO_2 \quad (3)$$

$$2HBrO_2 \rightleftharpoons HOBr + BrO_3^- + H^+ \quad (4)$$

$$HBrO_2 + BrO_3^- + H^+ \rightleftharpoons 2BrO_2\cdot + H_2O \quad (5)$$

$$Ce(III) + BrO_2\cdot + H^+ \rightleftharpoons Ce(IV) + HBrO_2 \quad (6)$$

$$Ce(IV) + BrO_2\cdot + H_2O \rightleftharpoons Ce(III) + BrO_3^- + 2H^+ \quad (7)$$

1 M=1 mol dm^{-3}.

This scheme has been used in order to explain the oxidation of cerium(III) by bromate in a sulfuric acid solution.[13,15,16] The new set of rate constants at 20 °C prepared by Field and Försterling is shown in Table 1.[13] When the oxidation reaction is carried out in a CSTR, the term, $k_0(C_{0i}-C_i)$, is added to the rate equations generated from Reactions 1—6, where C_i and C_{0i} are the concentrations of species i in the solution and in the feed flow, respectively. k_0 is the ratio between the flow rate, dV/dt, and the volume of the reaction vessel. The external parameters, or constraints, for the reaction system are $[BrO_3^-]_0$, $[Br^-]_0$, $[Ce(III)]_0$, $[H^+]_0$, k_0, and the temperature.[2] Therefore, the states of the system are dependent on the constraints.

In this study, the seven-variable rate equations were employed because the value of $[H^+]_0$ was assumed to be large. The calculation of the steady states was performed by Newton's method. The temporal evolution of the system was obtained by using Gear's algorithm.[17] The stability of the steady states was surveyed by means of linearized stability analysis.[18]

Results and Discussion

Figure 1 shows the relationship between $[Br^-]_0$ and the concentration of bromide in the steady states, $[Br^-]_{ss}$, when $[H^+]_0=1.5$ mol dm^{-3}, $[Ce(III)]_0=1.5\times10^{-4}$ mol dm^{-3} and $k_0=0.004$ s^{-1}. The state of the reaction system depended on the concentration of bromate in the feed flow. That is, when $[BrO_3^-]_0\leq6\times10^{-5}$ mol dm^{-3}, the system existed in ssI, which was characterized by a relatively high $[Br^-]_{ss}$ and a low $[Ce(IV)]_{ss}$.

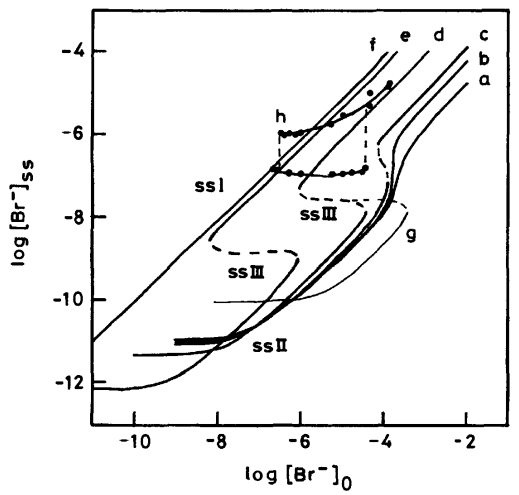

Fig. 1. Relationship between $[Br^-]_0$ and $[Br^-]_{ss}$. $[Ce(III)]_0=1.5\times10^{-4}$ M, $[H^+]_0=1.5$ M, and $k_0=0.004$ s^{-1}. $[BrO_3^-]_0$ (M) a: 0.1, b: 0.032, c: 0.016, d: 0.002, e: 2×10^{-4}, f: 5×10^{-5}. g: calculated according to the four-variable model under the same conditions in d. h: experimental results at 25°C under the same conditions in d.[2]

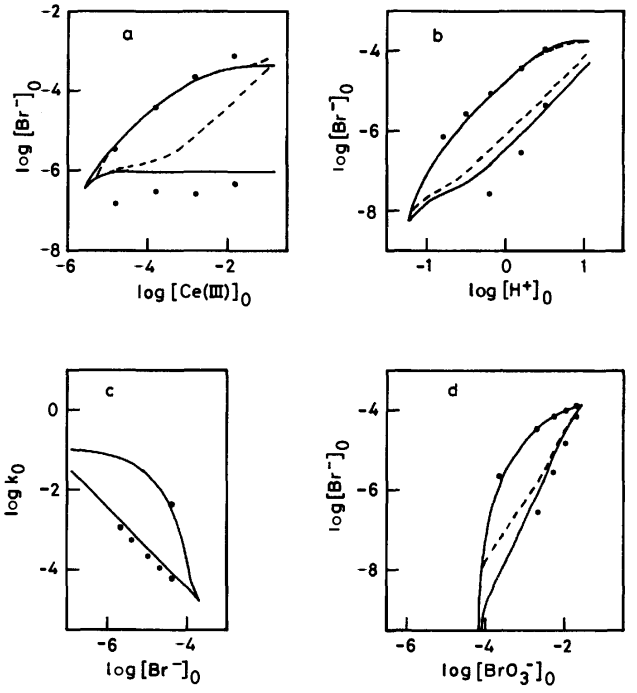

Fig. 2. Hysteresis limits. Solid lines: calculated, points: experimental (25°C),[2] dashed lines: calculated when $k_{-7}=0.001$ M^{-3} s^{-1}. Subspaces and fixed constraints a: $[Ce(III)]_0$-$[Br^-]_0$, $[BrO_3^-]_0=0.002$ M, $[H^+]_0=1.5$ M, $k_0=0.004$ s^{-1}; b: $[H^+]_0$-$[Br^-]_0$, $[BrO_3^-]_0=0.002$ M, $[Ce(III)]_0=1.5\times10^{-4}$ M, $k_0=0.004$ s^{-1}; c: $[Br^-]_0$-k_0, $[BrO_3^-]_0=0.002$ M, $[Ce(III)]_0=1.5\times10^{-4}$ M, $[H^+]_0=1.5$ M; d: $[BrO_3^-]_0$-$[Br^-]_0$, $[Ce(III)]_0=1.5\times10^{-4}$ M, $[H^+]_0=1.5$ M, $k_0=0.004$ s^{-1}.

When $[BrO_3^-]_0\geq0.032$ mol dm^{-3}, the steady state of the system varied smoothly from ssI to ssII (low concentration of bromide and high concentration of cerium(IV)) with a decrease of $[Br^-]_0$. On the other hand, when 7.5×10^{-5} mol $dm^{-3}\leq[BrO_3^-]_0\leq2.2\times10^{-2}$ mol dm^{-3}, the system could possess three steady states (ssI, ssII, and ssIII) under the same set of $[BrO_3^-]_0$ and $[Br^-]_0$. The steady states (ssI and ssII) were stable and had all the negative eigen-values (nodes). The steady state (ssIII) was unstable and had one positive and the other negative eigenvalues (saddle point). These results mean that we can not attain ssIII experimentally and that the system exists in either ssI or ssII. Also, if $[Br^-]_0$ is continually changed to a sligtly different value, the system in one steady state suddenly moves to the other steady state at a critical value of $[Br^-]_0$. Thus, we obtain a hysteresis loop. The calculated curve, d, was not consistent with the experimental results at 25 °C due to Geiseler and Bar-Eli[2] in the region of low bromide-concentration. The inconsistency may be attributed to a difficulty involving the determination of bromide in the region by means of a bromide-sensitive electrode.[19] However, the dynamical behavior, such as bistability and hysteresis, could be reproduced successfully.

Figure 2 shows the calculated hysteresis limits together with the experimental results due to Geiseler and Bal-Eli.[2] The bistable region of the system lays in a five-dimensional space of $[BrO_3^-]_0$, $[Ce(III)]_0$, $[H^+]_0$, $[Br^-]_0$, and k_0. Four of 10 two-dimensional subspaces were examined in this study. In the figure, the system existed in ssII below the lower lines and in ssI above the upper lines, respectively. In the intermediate region, the two steady states coexisted. All of the upper lines were consistent with the experimental data. However, the lower lines deviated slightly from the experimental data. The reason for the deviation is not apparent at present.

The bromate-bromide-cerium(III) system which we studied possessed a small oscillation region in the neighborhood of the bistable domain. Figure 3 shows the oscillation region projected on the $[BrO_3^-]_0$-$[Br^-]_0$ subspace, where a represents an oscillation domain having one unstable steady state ($Re(\lambda)>0$) and b denotes a bistable region. In regions c and d, there were three steady states (one saddle point, one stable node and one unstable steady state ($Re(\lambda)>0$)). The system then settled in a stable node after a long time. However, in the domain where c and d were piled up, three unstable states were obtained and the system exhibited one limit cycle. In the other region of Fig. 3, one stable steady state existed. The region, a, calculated here seems to reproduce the experimental oscillation region at 25 °C, e, due to Bar-Eli and Geiseler in location, size and shape.[4] The oscillation preiod and the ratio, $[Br^-]_{max}/[Br^-]_{min}$, calculated are shown in Table 2. At high $[BrO_3^-]_0$ and $[Br^-]_0$, the amplitude and the period were comparably small and at low $[BrO_3^-]_0$ and $[Br^-]_0$, comparably large. A similar trend was obtained experimentally.[4] The

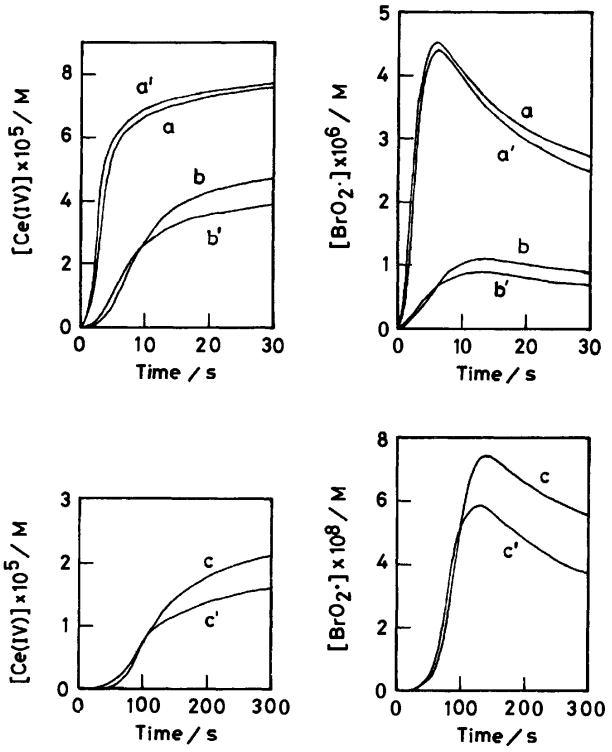

Fig. 4. Simulations of [Ce(IV)] and $[BrO_2\cdot]$ in the oxidation reaction of Ce(III) with bromate in 1 M sulfuric acid solution. $[H^+]_{initial}$=1 M, $[Ce(III)]_{initial}$= 10^{-4} M. $[BrO_3^-]_{initial}$ (M) a: 1, b: 0.1, c: 0.002. The prime represents the experiment due to Field and Försterling.[13]

magnitudes of the oscillation period and the amplitude were also consistent with the experiment (the oscillation period: 156—493 s and the amplitude: 1.6—15).

The FF set of rate constants, prepared on the basis of recent kinetic data, reproduces the reaction behavior of the bromate-bromide-cerium(III) system well, as is shown in Figs. 1—3. In the calculation, the contribution of Reaction 7 is not taken into account due to Field and Försterling, who assumed that a small quantity of bromide remaining as an impurity in bromate is a trigger for the oxidation of Ce(III) by bromate in a sulfuric acid medium. It is reported that the induced period varies in the oxidation of Ce(III) (3×10^{-4} mol dm^{-3}) by 0.001 mol dm^{-3} of bromate,[20] which may support the assumption by Field and Försterling.

However, Reaction 7 is a conceivable trigger for the oxidation of Ce(III) by bromate. Therefore, in order to examine the contribution of Reaction 7, we simulated the observed [Ce(IV)] and $[BrO_2\cdot]$ during the overall reaction of Ce(III) with bromate and the hysteresis limits by taking account of the reaction. The unknown value of k_{-7} was estimated by trial and k_7 was obtained according to the relationship, $k_5k_6k_{-7}=k_{-5}k_{-6}k_7$. Figure 4 shows the calculated concentrations of Ce(IV) and $BrO_2\cdot$ when k_{-7}=0.001 mol^{-3} dm^9 s^{-1}. The calculated curves in Fig. 4 were consistent with the experimental results due to Field and Försterling.[13] The hysteresis limits calculated when k_{-7}=0.001 mol^{-3} dm^9 s^{-1} are shown in Figs. 2a, b, and d. Reaction 7 influenced mainly the lower lines, especially in the regions of relatively large $[Ce(III)]_0$ and small $[BrO_3^-]_0$. Figures 2a, b, and d suggest that the contribution of Reaction 7 to the behavior of the bromate-bromide-cerium(III) system in a CSTR is not so large.

As is described above, a bromate-bromide-cerium-(III) system kept far from thermodynamic equilibrium can possess two steady states under the same set of

constraints. The behavior is based on the autocatalytic formation of $HBrO_2$ by Reactions 5 and 6, and based on competition between Reactions 2 and 5. However, because this explanation is not sufficient to understand the properties of the system, we examined the dynamical behavior of a four-variable model composed of Reactions 1—4 and 8.

$$BrO_3^- + HBrO_2 + 2Ce(III) + 3H^+ \longrightarrow$$

$$2HBrO_2 + 2Ce(IV) + H_2O \quad (8)$$

Reaction 8 is obtained when the backward reactions in Reactions 5 and 6 are neglected. In this model, Reaction 5 is assumed to be rate determining in the autocatalytic reaction. Such a condition can be realized when $[Ce(III)]_0$ is very large. Thus, the rate of Reaction 8 is yielded as follows:

$$v_8 = k_5[H^+]_0[BrO_3^-][HBrO_2] \quad (9)$$

Because the bromate–bromide–cerium(III) system studied here contains a large excess of bromate, $[BrO_3^-]$ is substantially equal to $[BrO_3^-]_0$ and the backward reactions in Reactions 2 and 4 can be neglected. The state of the model system depends on four constraints, $[H^+]_0$, $[BrO_3^-]_0$, $[Br^-]_0$, and k_0.

The rate equations generated from the four-variable model are written as follows:

$$d[Br_2]/dt = k_1[H^+]_0[Br^-][HOBr] - (k_0 + k_{-1})[Br_2] \quad (10)$$

$$d[HBrO_2]/dt = k_3[H^+]_0^2[BrO_3^-]_0[Br^-] - k_{-3}[HOBr][HBrO_2] - k_2[H^+]_0[Br^-][HBrO_2] + k_5[H^+]_0[BrO_3^-]_0[HBrO_2] - 2k_4[HBrO_2]^2 - k_0[HBrO_2] \quad (11)$$

$$d[HOBr]/dt = k_3[H^+]_0^2[BrO_3^-]_0[Br^-] - k_{-3}[HOBr][HBrO_2] + k_{-1}[Br_2] - k_1[H^+]_0[Br^-][HOBr] + 2k_2[H^+]_0[Br^-][HBrO_2] + k_4[HBrO_2]^2 - k_0[HOBr] \quad (12)$$

$$d[Br^-]/dt = k_{-3}[HOBr][HBrO_2] - k_3[H^+]_0^2[BrO_3^-]_0[Br^-] - k_1[H^+]_0[Br^-][HOBr] + k_{-1}[Br_2] - k_2[H^+]_0[Br^-][HBrO_2] + k_0([Br^-]_0 - [Br^-]) \quad (13)$$

The curve, g, in Fig. 1 shows the relationship between $[Br^-]_0$ and $[Br^-]_{ss}$ calculated by using Eqs. 10—13 when $[BrO_3^-]_0=0.002$ mol dm^{-3}, $[H^+]_0=1.5$ mol dm^{-3}, and $k_0=0.004$ s^{-1}. The curve suggests that the four-variable model is essentially equal to the FKN reaction scheme. In order to reduce the number of independent variables to two, we adopt the approximation that $d[Br_2]/dt=0$ and $d[HBrO_2]/dt=0$ at all times according to Bar-Eli and Noyes.[21] Thus, we can obtain the following equations:

$$[Br_2] = (k_1[H^+]_0/(k_0 + k_{-1}))[Br^-][HOBr] \quad (14)$$

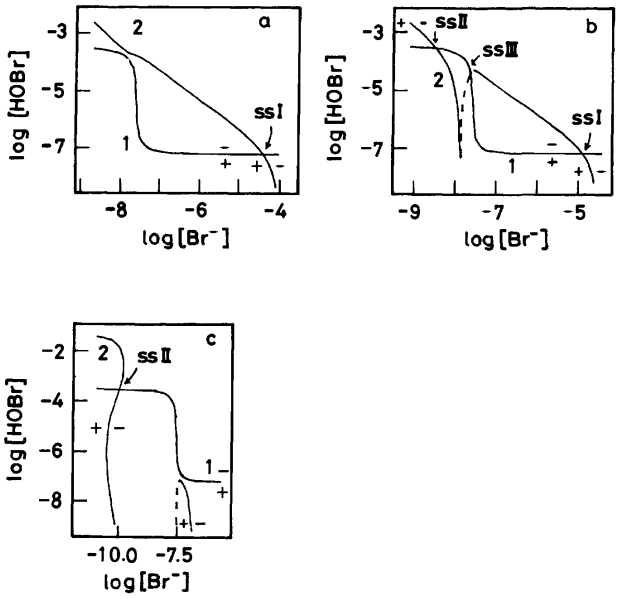

Fig. 5. Nullclines of the four-variable model. $[BrO_3^-]_0=0.002$ M, $[H^+]_0=1.5$ M, and $k_0=0.004$ s^{-1}. $[Br^-]_0$ a: 5×10^{-4} M, b: 1.55×10^{-4} M, c: 7×10^{-7} M. 1: $d[HOBr]/dt=0$, 2: $d[Br^-]/dt=0$. +: $d[HOBr]/dt>0$ or $d[Br^-]/dt>0$, −: $d[HOBr]/dt<0$ or $d[Br^-]/dt<0$.

$$[HOBr] = (k_3[H^+]_0^2[BrO_3^-]_0[Br^-] - k_2[H^+]_0[Br^-][HBrO_2] + k_5[H^+]_0[BrO_3^-]_0[HBrO_2] - k_0[HBrO_2] - 2k_4[HBrO_2]^2)/(k_{-3}[HBrO_2]) \quad (15)$$

A domain of $[HBrO_2]$ where $[HBrO_2]>0$ and $[HOBr]>0$, is defined from Eq. 15. We can depict the trajectory of the model system by using Eqs. 12—15.

Figure 5 shows the dependency of the HOBr and Br^- nullclines on $[Br^-]_0$ when $[BrO_3^-]_0=0.002$ mol dm^{-3}, $[H^+]_0=1.5$ mol dm^{-3} and $k_0=0.004$ s^{-1}. In Fig. 5b ($[Br^-]_0=1.55\times10^{-4}$ mol dm^{-3}), there are three intersections, i.e., three steady states (two stable nodes and one saddle point). Because the Br^- nullcline has an S-shape, interesting circumstances occur. In the left side of the Br^- nullcline, $d[Br^-]/dt>0$ and a state of the model system in the region varies temporally to the right. A state in the right side of the Br^- nullcline moves to the left for a similar reason. Therefore, the solid lines in the Br^- nullcline are stable because a state of the model system moves temporally toward the solid lines. On the other hand, the dashed line is unstable because a state of the model system temporally goes away from the dashed line. Thus, the middle intersection corresponds to an unstable steady state (saddle point) and the intersections of both sides to stable steady states (stable nodes). There is a separatrix through the saddle point, which separates the basins of attraction associated with the nodes. When the model system in a steady state is perturbed to pass the separatrix, the system relaxes to the other

steady state. On the other hand, Figs. 5a and c correspond to the case that the system has one stable steady state. Figures 5a—c suggest that at a critical value of $[Br^-]_0$, the nullclines yield one intersection and one point of contact and that at the $[Br^-]_0$, the model system jumps to the other steady state.

The four-variable model gives dynamical information on bistability in the bromate–bromide–cerium-(III) system, but the oscillatory state in the model system has not yet been found at present.

(Received March 28, 1988)

The conductances of bis(2,4-pentanedionato)(diamine)cobalt(III) perchlorates, $[Co(acac)_2(diamine)]ClO_4$ (where acac: 2,4-pentanedionato; diamine: en (ethylenediamine) and *N,N,N',N'*-tmen (*N,N,N',N'*-tetramethylethylenediamine)) in methanol (MeOH), ethanol (EtOH), 2-propanol (*i*-PrOH), methyl ethyl ketone (MEK), and methyl isobutyl ketone (MIBK) and of bis(β-diketonato)(ethylenediamine)cobalt(III) perchlorates, $[Co(\beta\text{-dik})_2(en)]ClO_4$ (where β-dik: acacBr (3-bromo-2,4-pentanedionato) and $acacNO_2$ (3-nitro-2,4-pentanedionato)) in EtOH, acetone (Me_2CO), and MEK were measured at 25 °C. $[Co(acac)_2(en)]ClO_4$ in the alcohols was found to be more dissociated than $[Co(acac)_2(N,N,N'N'\text{-tmen})]ClO_4$. This behavior was explained as being due to the strong solvation of $[Co(acac)_2(en)]^+$ by the alcohols. $[Co(acac)_2(N,N,N',N'\text{-tmen})]^+$ seems to be solvated in ketones rather than alcohols. The sequence of the ionic association constant for $[Co(\beta\text{-dik})_2(en)]ClO_4$, acac<acacBr<$acacNO_2$, could be interpreted in terms of an enhanced polarity of the cations with the electron-withdrawing groups.

In order to understand the solute-solvent interactions characteristic of metal-chelate ions, we have measured the conductances of 17 metal-chelate electrolytes, bis(β-diketonato)(diamine)cobalt(III) complexes, $[Co(\beta\text{-dik})_2(diamine)]X$ (X^-=ClO_4^-, I^-, and Br^-) in organic solvents at 25 °C.[1-5] From the obtained conductance parameters (the limiting conductance, Λ_0, the Walden product of the cations, $\lambda_0^+ \cdot \eta$, and the ionic association constant, K_a), we have clarified the effects of the following factors on the mobility of the chelate cations and ionic association: (a) interactions between NH protons of diamine in the cations and solvent dipole;[1,2] (b) solvation of the ligands in the cations through hydrogen bonding;[3] (c) *N*-methylation of the ligand ethylenediamine in the cations[1-3] and the relative acidity of the residual NH protons;[4] and (d) polar substituents such as the nitro group in the ligand β-diketonato.[5]

However, factors (b) and (d) have been examined only in 1-propanol (*n*-PrOH) and acetone (Me_2CO), and nitrobenzene ($PhNO_2$), respectively. In this study, in order to obtain more information on their factors, the conductances of $[Co(\beta\text{-dik})_2(diamine)]ClO_4$ were measured in several alcohols and ketones. The obtained results are discussed in detail regarding the difference in solvation of the chelate cations by alcohols and ketones as well as the polarity of the chelate cations.

Experimental

(a) $[Co(\beta\text{-dik})_2(diamine)]ClO_4$ was prepared and purified as described previously.[1,5] Tetraethylammonium perchlorate (Et_4NClO_4, commercial product) was purified by two recrystallizations. The purity of all products was checked by chemical analyses of C, H, and N. Methanol (MeOH) and ethanol (EtOH) were refluxed for 3 days over magnesium methoxide and magnesium ethoxide, respectively, and fractionally distilled. 1-Propanol (*n*-PrOH) and 2-propanol (*i*-PrOH) were refluxed over calcium oxide for 2 days and fractionally distilled. Acetone (Me_2CO), methyl ethyl ketone (MEK), and methyl isobutyl ketone (MIBK) were refluxed over Drierite after dehydration and fractionally distilled. The distillation was performed under a flow of N_2 gas.

(b) The procedure for the conductance measurements and other measurements (viscosity and density) were described previously.[1] The dielectric constant (ε) and viscosity (η in mPa s) of the solvents for an analysis were as follows: for MeOH ε=32.62,[6] η=0.5460; for EtOH ε=24.33,[7] η=1.082; for *n*-PrOH ε=20.45,[7] η=1.948; for *i*-PrOH ε=19.41,[8] η=2.078; for Me_2CO ε=20.56,[9] η=0.3052; for MEK ε=18.01,[10] η=0.3803; for MIBK ε=12.8,[11] η=0.5478.

Results

The conductances Λ(S cm^2 mol^{-1}) at six to nine concentrations, C(mol dm^{-3}) of $[Co(\beta\text{-dik})_2(diamine)]ClO_4$ and Et_4NClO_4 covering the range from 4.2×10^{-3} to 10^{-5} mol dm^{-3} in the alcohols and the ketones were measured at 25 °C.[12] The data were analyzed by the Fuoss-Hsia equation with $E=E_1\Lambda_0-2E_2$ in the form,[13]

$$\Lambda = \Lambda_0 - SC^{1/2}\gamma^{1/2} + EC\gamma\log C\gamma + J_1(d)C\gamma - J_2(d)C^{3/2}\gamma^{3/2} - K_aC\gamma f_\pm^2\Lambda, \quad (1)$$

where Λ_0 and K_a refer to the limiting conductance and the ionic association constant, respectively, and the other symbols have their usual meanings. The procedure for fitting in terms of Λ_0, K_a, and the distance parameter d has been described previously.[1]

The obtained conductance parameters are given in Tables 1 and 2 for the alcohols and the ketones,

a) and b) are the same as in Table 1. c) Ref. 3.

respectively, together with those in 1-propanol (*n*-PrOH) and acetone (Me_2CO). The limiting conductances (λ_0^+/S cm² mol⁻¹) and Walden products ($\lambda_0^+ \cdot \eta$/S cm² mol⁻¹ 10⁻¹ Pa s) of the chelate cations are given in Table 3, together with those in *n*-PrOH, Me_2CO, nitrobenzene ($PhNO_2$), and 1,2-dichloroethane (1,2-DCE) for comparison. The data were obtained from the limiting conductances of the perchlorate ion, λ_0^- (ClO_4^-): in MeOH, 70.94;[6] in EtOH, 32.04;[7] in *i*-PrOH, 15.24;[8] in Me_2CO, 118.35;[9] in MEK, 93.0;[10] in MIBK, $\lambda_0^- \cdot \eta = 0.34$.[14]

Discussion

(1) Solvation and Association of $[Co(acac)_2(diamine)]ClO_4$. (a) Ionic Mobility: Figure 1 shows the Walden products ($\lambda_0^+ \cdot \eta$) for $[Co(acac)_2(en)]^+$ and $[Co(acac)_2(N,N,N',N'\text{-tmen})]^+$ in each solvent. It is clear that $\lambda_0^+ \cdot \eta$ for $[Co(acac)_2(en)]^+$ is much smaller than that for $[Co(acac)_2(N,N,N',N'\text{-tmen})]^+$ except for the result in 1,2-DCE, although the size of $[Co(acac)_2(en)]^+$ is smaller than $[Co(acac)_2(N,N,N',N'\text{-tmen})]^+$

with four *N*-methyl groups.[15] The difference in $\lambda_0^+ \cdot \eta$ is larger in the alcohols than in the other solvents.

These are in opposition to the results for tetraalkylammonium ion (R_4N^+), for which $\lambda_0^+ \cdot \eta$ decreases with increasing the ionic size in the order $Et_4N^+ < Pr_4N^+ < Bu_4N^+ < (i\text{-Am})_3BuN^+$ in each solvent, as is hydrodynamically expected.[1,6–10,16]

It is considered that there exist three main factors for solute-solvent interactions of [Co(acac)$_2$(diamine)]$^+$: (1) Lewis acid-base interaction ; (2) an ion-dipole interaction; and (3) van der Waals interactions. Table 4 gives the solvent properties: (1-a) donor number (DN),[17] (1-b) acceptor number (AN);[17] (2) dipole moment (μ);[11] (3) solubility parameter (δ).[18] These parameters correspond to the above factors (1—3), respectively.

The alcohols have both basic (oxygen atom) and acidic (OH proton) parts for which the corresponding parameters are DN and AN, respectively (Table 4).

Table 4. Solvent Parameters

Solvent	DN[a]	AN[b]	μ[c]	δ[d]
MeOH	19	41.3	1.70	14.5

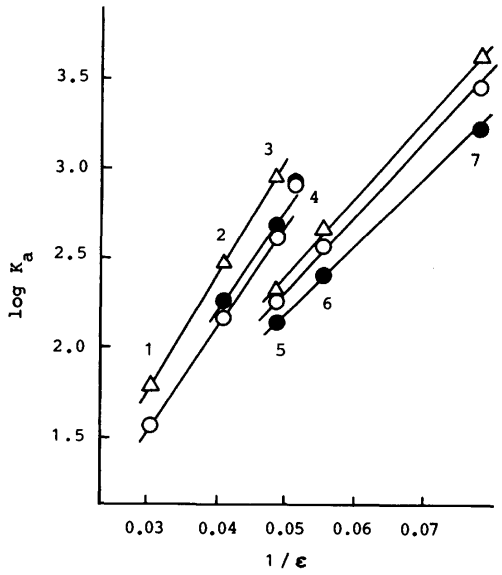

Fig. 2. Plots of log K_a with $1/\varepsilon$ for O, $[Co(acac)_2(en)]ClO_4$; ●, $[Co(acac)_2(N,N,N',N'\text{-tmen})]ClO_4$; and △, Et_4NClO_4.
Alcohols: 1, MeOH; 2, EtOH; 3, *n*-PrOH;[3] 4, *i*-PrOH. Ketones: 5, Me_2CO;[3] 6, MEK; 7, MIBK.

Thus, they can solvate the NH protons of the ligand en and the oxygen atoms of the ligand acac in $[Co(acac)_2(en)]^+$. A molecular model for the solvation of $[Co(acac)_2(en)]^+$ by one alcohol molecule is possible without crowding. This acid-base interaction contributes to a lower mobility in the alcohols than in the ketones. The effect of an ion-dipole interaction (factor 2) in the alcohols is small due to their lower dipole moments. This was confirmed from the result in 1,2-DCE with low polarity, in which the mobility of $[Co(acac)_2(en)]^+$ was comparable to that of $[Co(acac)_2(N,N,N',N'\text{-tmen})]^+$.[1]

The ketones have a basic (CO group) part and act as a hydrogen bonding donor for the NH protons in $[Co(acac)_2(en)]^+$ (factor 1-a). This solvation may result in a lower mobility. However, since the μ values of the ketones are smaller than that of $PhNO_2$ which strongly solvates the NH protons by an ion-dipole interaction,[1] factor 2 is not so effective.

Further, it is noteworthy that the Walden products for $[Co(acac)_2(N,N,N',N'\text{-tmen})]^+$ in the ketones are much smaller than in the alcohols, as is shown in Table 3. On the other hand, for Bu_4N^+ there is no appreciable change with solvents: $\lambda_0^+ \cdot \eta$ is 0.212,[6] 0.213,[7] 0.209,[7] and 0.211[8] for MeOH, EtOH, *n*-PrOH, and *i*-PrOH, and 0.201[9] and 0.199[10] for Me_2CO and MEK, respectively.

Since $[Co(acac)_2(N,N,N',N'\text{-tmen})]^+$ has no NH protons, another factor should be considered regarding the decreased mobility in the ketones. Van der Waals forces between $[Co(acac)_2(N,N,N',N'\text{-tmen})]^+$ and the ketones/alcohols may be operative compared to $[Co(acac)_2(en)]^+$, because the charge of Co(III) is shielded by the bulky ligands, *N,N,N',N'*-tmen and acac. The solubility parameter, δ is an indication for the van der Waals interactions. Although δ values of charged species are not available, δ values of $[Co(acac)_3]$ (9.72, 10.12, and 10.7)[19] are more close to those of the ketones than the alcohols (Table 4), suggesting that the ketone molecules solvate more strongly $[Co(acac)_2(N,N,N',N'\text{-tmen})]^+$. Furthermore, the fact that the chelate electrolyte is more soluble in the ketones than the alcohols supports the above view. Another factor may be dipole (ion)–dipole (solvent) interactions, because of the polarity of this cation, in addition to ion-dipole (solvent) interactions. These effects are also larger for ketones with high polarity.

(b) Ionic Association: Figure 2 shows that the variation of K_a with $1/\varepsilon$ for $[Co(acac)_2(diamine)]ClO_4$ and Et_4NClO_4. With good approximations, straight lines are obtained for all electrolytes, as is expected from the coulombic theory of ionic association,[20]

$$\log K_a = e^2 / akT \cdot 1/\varepsilon + \log K_a^\circ, \qquad (2)$$

where a is the contact distance between the cation and the anion, k is the Boltzman constant and T is the absolute temperature. K_a° contains the contribution to the association for all factors, except for the long-range coulombic interaction.

Two trends are shown: (i) Each electrolyte is more associated in the alcohols than the ketones at the same dielectric constant and (ii) the slope of log K_a vs. $1/\varepsilon$ is a little larger in the alcohols than the ketones. Trend (i) has been observed for tetraalkylammonium per-

chlorates:[7-9] The larger association constant in the alcohols could be explained in terms of (1) diminution in dielectric constant in the vicinity of an ion pair and (2) a multiple-step association process with solvation and desolvation of ClO_4^- by the alcohol molecules. The increasing effect of K_a due to this multiple-step association process[8,9] increases in the order MeOH< EtOH<*n*-PrOH<*i*-PrOH, which may be responsible for trend (ii).

The different pattern of K_a for [Co(acac)$_2$(diamine)]-ClO$_4$ was observed. In the ketones, K_a for [Co(acac)$_2$-(en)]ClO$_4$ is larger than that for [Co(acac)$_2$(*N*,*N*,*N'*,*N'*-tmen)]ClO$_4$. In the alcohols, on the other hand, the reverse trend is observed although the difference in K_a is small. Since [Co(acac)$_2$(*N*,*N*,*N'*,*N'*-tmen)]$^+$ has a large molal volume compared to [Co(acac)$_2$(en)]$^+$, its cation charge may be more shielded. Therefore, K_a for [Co(acac)$_2$(*N*,*N*,*N'*,*N'*-tmen)]ClO$_4$ should be smaller than that for [Co(acac)$_2$(en)]ClO$_4$, though this is not the case in alcohols.

An explanation is based on the strong solvation of [Co(acac)$_2$(en)]$^+$ by the alcohols: solvation of the NH protons (en) by the oxygen atom of alcohols and of the oxygen atoms (acac) by the OH proton of the alcohols through hydrogen bonding, as is discussed in the preceding section. This leads to the formation of strongly solvated cation and the cation may be behave as a distinct entity which has a larger molal volume compared to [Co(acac)$_2$(*N*,*N*,*N'*,*N'*-tmen)]$^+$. However, the steric structure of the chelate cation would not be affected, even if the alcohols solvate the cation firmly. This has been confirmed from a result which showed that the absorption spectra of $^1A_{1g}$–$^1T_{1g}$ have no appreciable change with solvents.[15] In the ketones, the NH protons in [Co(acac)$_2$(en)]$^+$ are solvated by the oxygen atom of the CO group. However, since they have no acidic part for solvation of the acac in [Co(acac)$_2$(en)]$^+$, the solvation may not be so effective compared to that by the alcohols.

The K_a values in *i*-PrOH are larger than those expected from the line of the plots of the primary alcohols, showing weaker solvation by *i*-PrOH, which may result from its lower acidity or steric hindrance.

(2) Solvation and Association of [Co(β-dik)$_2$(en)]-ClO$_4$: The coordinated acac in this type of metal-chelate cations is of pseudo aromatic character with a ring current[21] and has a electron-mediating ability. Therefore, it is expected that the introduction of the electron-withdrawing substituents, Br and NO_2 at the C-3 position of the acac in [Co(acac)$_2$(en)]$^+$ increases the relative acidity of the NH protons of the ligand en through the pseudo aromatic chelate ring, although these are far from the substituents. This is justified from the result that the rate of H-D exchange of the NH protons in a deuterium oxide/dimethyl-d_6-sulfoxide mixture (weight ratio 1:3.9) by ^{1}H NMR measurement increase in the sequence acac<acacBr<

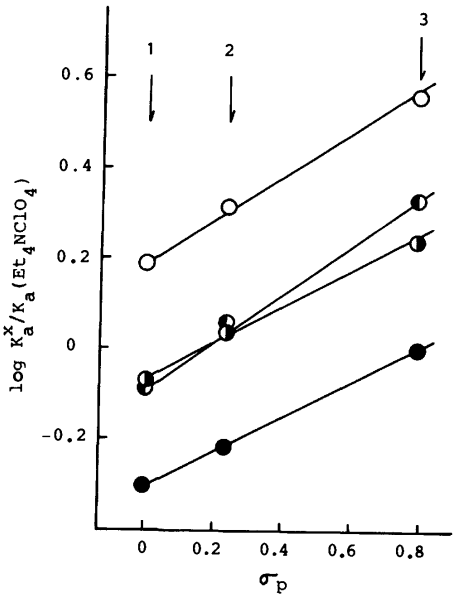

Fig. 3. Hammett's relationship for the ratio of K_a for [Co(β-dik)$_2$(en)]ClO$_4$ to Et$_4$NClO$_4$.
β-dik: 1, acac; 2, acacBr; 3, acacNO_2. Organic solvents: ●, EtOH; ◑, Me_2CO; ◐, MEK; ○, $PhNO_2$.[1,5]

acacNO_2,[5] in accordance with Hammett's σ_p values of electron-withdrawing tendency of the substituents.

Figure 3 shows a plot of the ratio of K_a for [Co(β-dik)$_2$(en)]ClO$_4$ to Et$_4$NClO$_4$ vs. Hammett's σ_p value. Since the Et$_4$N$^+$ ion has no specific site for solvation or ion pair formation in each solvent, the change in the ratio of K_a may suggest specific interactions of the chelate electrolytes. The trends indicated in Fig. 3 show two characteristics: (i) The ratio of K_a for [Co(acac)$_2$(en)]ClO$_4$ to Et$_4$NClO$_4$ increases in the order EtOH<MEK≈Me_2CO<$PhNO_2$, and (ii) the ratio increases in the same order [Co(acac)$_2$(en)]ClO$_4$< [Co(acacBr)$_2$(en)]ClO$_4$<[Co(acacNO_2)$_2$(en)]ClO$_4$ as the rate of H-D exchange. Furthermore, a linear relationship with a similar slope is obtained for all the solvent systems.

For [Co(acac)$_2$(en)]ClO$_4$, a solvent-separated ion pair is formed in the alcohols and ketones and the solvation of the cation by the alcohols is much stronger. On the other hand, a contact ion pair between the NH protons and ClO_4^- is formed in $PhNO_2$ by a partial exclusion of nitrobenzene molecules, leading to a larger K_a value.[1] These correspond to the order of the ratio of K_a for [Co(acac)$_2$(en)]ClO$_4$ to Et$_4$NClO$_4$, EtOH<MEK≈Me_2-CO<$PhNO_2$.

For the introduction of substituents, Br and NO_2, the two effects on the increase in K_a should be considered: (1) The increase in the relative acidity of the NH protons in the ligand en, leading to a stronger interaction between the NH protons and ClO_4^- and (2) the increase in the polarity of the chelate cations,

leading to a stronger cation–anion interaction. At the same time, the two effects also enhance the solvation of the cations, leading to a decrease in K_a. The increased solvation of the cations is supported by the fact that the introduction of Br and NO_2 largely decreases the mobility of the cations in the order acac>acacBr> acacNO_2 (Table 3). In practice, however, since K_a values are increased by the introduction of Br and NO_2, the decreasing effect of solvation on K_a is overcome by the increasing effects, (1) and (2). In EtOH, since the $[Co(acac)_2(en)]^+$ cation is strongly solvated, the increase in K_a by the introduction of Br and NO_2 is attributed to effect (2). In Me_2CO and MEK, a solvent-separated ion pair is similarly formed, although the solvation is not so effective compared to that in EtOH. Thus, it seems that the contribution of effect (1) is small and that of effect (2) is large. In $PhNO_2$, where a contact ion pair between the NH protons and ClO_4^- is formed, the contribution of both effects (1) and (2) is considered. However, in view of the fact that the slope for $PhNO_2$ is similar to that for EtOH (Fig. 3), it is likely that effect (2) is predominant.

The Potentiometric Detection of Complex Formation between IgG and anti-IgG Using a Chemically Modified Tantalum Electrode

Toshihiko TANAKA,† (the late) Naoto YAMAMOTO, and Hiroshi TSUBOMURA*
Faculty of Engineering Science, Osaka University,

(Received April 2, 1988)

Tantalum electrodes were chemically modified with anti-IgG to detect IgG (immunoglobulin G) or with IgG to detect anti-IgG by using cyanuric bromide. Changes in the potential as a result of the antigen-antibody reaction can be explained by a simple first-order kinetics equation, while the polarity of the changes at various pH's can be explained in terms of the charge transfer between anti-IgG and IgG in a way similar to that shown in previous reports for the case of Ti electrodes. The surface modification was confirmed by Auger Electron Spectroscopy (AES).

Many kinds of electrochemical methods have been investigated in order to detect biological substances.[1-7] Among them, the potentiometric detection method using chemically modified electrodes,[4-7] developed in our laboratory, is unique in that the responses depend directly on the complex formation on the electrode surface, and so quantitative detection can be achieved without using any enzymes which produce H_2O_2, NH_4^+ , or other electrochemically active species. For example, antigen (hCG) was detected[4-6] by the use of a titanium electrode chemically modified with antibody (anti-hCG) without being marked by any reactive chemicals like peroxidase. In a similar way, other immunological substances, enzymes (e.g., trypsin), or enzyme inhibitor (e.g., aprotinin) were detected by the use of modified titanium or tungsten electrodes.[6,7]

The stability in the potential of these chemically modified electrodes critically influences the detection limits, reliability, accuracy, and precision of the potentiometric determination. In a recent attempt, we coated a tungsten electrode with a plasma polymerized film prior to the chemical modification in order to improve its electrochemical stability.[7] Tantalum/tantalum oxide electrodes were foumd by Lerner et al.[8] to be stable as implanted stimulating electrodes.

In this paper, a tantalum electrode chemically modified with an antibody (anti-human IgG-Fc, momoclonal) and an antigen (human IgG) were investigated to determine their possible use as a potentiometric sensors for an antigen (human IgG) and an antibody (anti-human IgG) respectively. The kinetic properties and the pH effects on the response of the tantalum electrodes were also investigated for the further elucidation of the potential change.

Electron spectroscopic analysis techniques such as X-ray photoelectron spectroscopy (XPS), Auger electron spectroscopy (AES), and electron energy-loss spectroscopy (ELS) are efficient for analyzing the surfaces of chemically modified electrodes. The surfaces of graphite, tin oxide, and indium oxide electrodes chemically modified with hydroxymethylferrocene (HMF) or 1,1′-bis(hydroxymethyl)ferrocene (BHMF) by using cyanuric chloride were investigated by means of XPS by Yacynych and Lin.[9,10] In this report, the chemical modification of a tantalum surface by using cyanuric bromide was monitored by AES.

Experimental

Material. Lyophilized IgG from human serum (98% pure) was obtained from the Green Cross Co. The anti-human IgG-Fc, monoclonal antibody, and lyophilized bovine serum albumin (BSA) were obtained from Wako Pure Chemical Industries Ltd. Tantalum sheets, 0.1 mm thick and 99.9% pure, for the surface investigations, and a tantalum rod 4 mm in diameter (99.95% pure) for use as an electrode were obtained from the Japan Lamp Industrial Co., Ltd.

Preparation of Tantalum Electrodes. Figure 1 shows the structure of a typical tantalum electrode for the potentiometric measurement; it consists of a tantalum tip 4 mm in diameter, a tantalum rod 2 mm in diameter and 40 mm in length, a stainless steel nut, and a chlorotrifluroethylene (CTFE) pipe. The tantalum tip was washed by ultrasonifi-

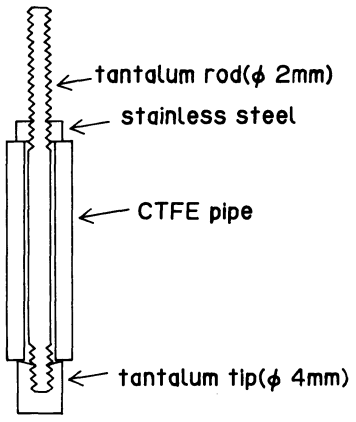

Fig. 1. The structure of a tantalum electrode.

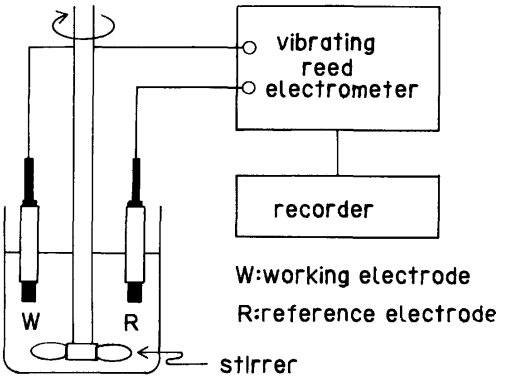

Fig. 2. A schematic illustration of the apparatus for the potentiometric measurement.

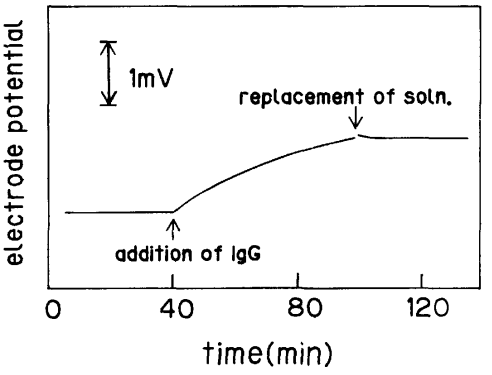

Fig. 3. The potential change of an anti-IgG-Fc electrode caused by addition of human IgG(2.5×10^{-8} M) in veronal buffer (pH 8.6).

cation in 2 M hydrochloric acid (1 M=1 mol dm^{-3}), a 2 M sodium hydroxide solution, acetone, and then in purified water, each for 10 min. Then the tip was treated with a ca. 500 V low-frequency plasma discharge in a vacuum chamber for 20 min under an oxygen atmosphere of 0.15 Torr (1 Torr≈133.322 Pa) before chemical modification.

Chemical Modification. The chemical modification of the tantalum electrode surface was performed by a method similar to that of March et al.[11] The tip was chemically activated in a stirred aqueous solution containing 1.2 M sodium carbonate, 0.5 M cyanogen bromide, and 1 M acetonitrile. Then, the tip was immersed in a borate buffer solution (pH 8.1) containing a 0.02 wt% anti-human IgG-Fc monoclonal antibody for 90 min to form an anti-IgG-Fc electrode. A human IgG electrode was made similarly in a buffer solution containing 0.02 wt% human IgG instead of anti-human IgG-Fc. A BSA electrode, used as the reference, was similarly made in a buffer containing 0.02 wt% BSA instead of human IgG. At the end of the chemical modification, all the electrodes were immersed in a borate buffer solution (pH 8.1) containing 0.7 M urea for 30 min in order to block the unreacted part of the electrode surface.

Potentiometric Measurement. The potential between the working and reference electrodes were measured by using a vibrating reed electrometer, TR8411, of the Takeda Riken Industry Co., Ltd. The experimental set-up is shown schematically in Fig. 2. The solution in the measuring vessel is a 15 ml veronal buffer solution (pH 8.6, 0.05 M) kept at 30°C and stirred constantly. The pH effect was measured in Britton Robinson buffers[12] whose ionic strength was adjusted to 0.1 by diluting with water,[13] although it is known from our previous work that the ionic strength of a solution scarcely affects the electrode response.

Surface Analysis. The structure of the tantalum surfaces at each step of the chemical modification were investigated by AES using a PhiModel 10-155 cyrindrical mirror analyzer (CMA) at an electron-beam voltage of 3.0 keV and with a current of 10^{-6} A. The differential spectra were obtained by a 6 V modulation. Tantalum sheets (13 mm×13 mm) were treated in the same manner as with the anti-human IgG-Fc electrodes and were then used as specimens for the surface analysis.

Results and Discussion

Potentiometric Measurement. Compared with the titanium electrode used in our previous work, the tantalum electrode is electrochemically more stable, and the time necessary for stabilizing the electrode potentioal for the tantalum electrode became about one tenth of that for the titanium electrodes.

As is shown in Fig. 3, the potential of an anti-human IgG-Fc electrode changes irreversibly to the positive upon the addition of human IgG to the veronal buffer solution at pH 8.6. The potential did not, however, change after the replacement of the sample solution with a fresh buffer solution. In an irreversible case, the complex-formation on the surface is expressed as follows:[4-6]

$$A_{fixed} + B \xrightarrow{k} C \qquad (1)$$

where A_{fixed} is an immobilized antibody on the surface; B, an antigen in solution; C, the complex formed on the surface, and k, the rate constant. On the assumption that the potentiometric response of the electrode, $U(t)$, is proportional to the surface concentration of C, [C], $U(t)$ is expressed as follows:

$$U(t) = U_m [1 - \exp(-k[B]_0 t)] \qquad (2)$$

where $[B]_0$ is the initial concentration of [B], t is the reaction time after the addition of B, and U_m is the response to be realized when all surface fixed anti-IgG molecules are complexed. In this equation, [B] is assumed to keep the initial value $[B]_0$, because the quantity of B in the solution is much larger than that of A_{fixed}. The obtained potential changes from Fig. 3 fit in well with Eq. 2, and by treating the data, $k=3.8\times10^4$ ($M^{-1}\,s^{-1}$) and $U_m=1.3$ mV (pH 8.6, 30°C) are derived. The k value is of the same order of magnitude as the $k=1.6\times10^4$ ($M^{-1}\,s^{-1}$) previously obtained for a titanium anti-hCG electrode to hCG.

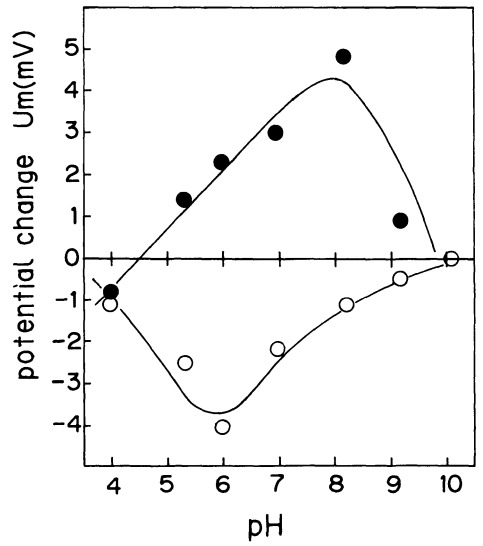

Fig. 4. The response of anti-IgG and IgG electrodes at various pH. ●: an anti-IgG electrode by an addition of IgG. ○: an IgG electrode by an addition of anti-IgG.

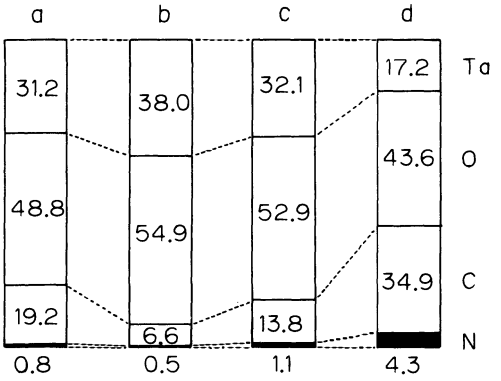

Fig. 5. The atomic concentration(%) of a tantalum surface measured by AES for each step of chemical modification. (a) After washing, (b) after O_2 plasma treatment, (c) after CNBr treatment, (d) after immersing in antibody soln.

The k values for reactions between various sets of antigens and antibodies, as determined by Karush, lie between 2×10^5 (M^{-1} s^{-1}) and 4.8×10^8 (M^{-1} s^{-1}).[14] Our present values are appreciably smaller than Karush's, like those obtained in our previous work.[4-6]

The antigen-antibody complex formed on the tantalum electrode can be dissociated by immersing it in a 2 M $MgCl_2$ stirred aqueous solution containing 1 M urea for 20—30 min. After this has been done, the anti-IgG electrode again shows a response to the antigen. Thus, the electrode could be used 7 to 8 times, although the response gradually became small; the potential could be restored by immersion in a fresh buffer. This degradation indicates a denaturation of the antibody by urea. In the case of IgG electrodes, the potential change upon the addition of anti-IgG-Fc is of almost the same order of magnitude as in the case of the anti-IgG-Fc electrode upon the addition of IgG except that the direction is negative.

pH Effect. The U_m values for the anti-IgG electrode in the reaction with IgG were determined from the data of the potential shift and Eq. 2 at various pH's. The U_m values thus obtained are always positive, from pH=5 to 9.2 (Fig. 4). The negative value at pH4 might have been caused by the partial denaturation of the protein, and so this value can be omitted. On the other hand, for the IgG electrode, the U_m value is always negative, from pH=4 to pH=9.2, with the minimum at pH=6. These results (shown in Fig. 4) indicate that the direction of the potential shift in the anti-IgG electrode is generally the opposite of that in the IgG electrode. As can be seen from Eq. 2, the U_m value is independent of the kinetics of the reaction or the binding energy between the proteins. It should be dependent on (1) the electrical dipole moment or the charge polarization between the antigen and antibody and (2) the coverage of the protein chemically attached to the electrode surface, because the change of the surface potential is linearly dependent on the electrical double layer at the interface, that is, the polarization per unit of surface area. Therefore, the results shown in Fig. 4 indicate that the direction of the electrical polarization between complexed protein molecules is independent of the pH. This implies that the polarization is mainly caused by a weak chemical bonding (a sort of charge transfer complexation or hydrogen bonding) between antigen and antibody. If, on the other hand, we assume that the potential shift is caused by the net charge of the protein molecule to be detected, its direction must be reversed at its isoelectric point (pH=5.8—7.3). The results in Fig. 4 clearly show this is not the case.

Surface Analysis. Figure 5 shows the relative atomic concentrations of the electrode surface at the successive steps of the chemical modification, calculated from the AES peak to peak heights for Ta(174 eV), C(273 eV), N(384 eV), and O(510 eV).[15] As the surface concentrations of N and C decrease from (a) to (b), one can see that organic contaminations are taken away by O_2 plasma treatment. The increase in the concentrations of N and C from (b) to (c) shows the attachment of an organic group such as imidocarbonate by BrCN. The incerase in the concentrations of N and C from (c) to (d) shows the attachment of a significant amount of anti-IgG to the surface. These results confirm each of the steps of the chemical treatment and support the idea that the result obtained from the potentiometric measurement is really caused by the specific complexing of immuno-proteins.

In conclusion, the specific detection of immunoactive proteins , IgG or anti-IgG, can be performed by the use of a tantalum electrode modified with the

antibody or antigen. The steps of the protein immobilization of the tantalum surface have been confirmed by AES.

Transesterification Reaction of Tetraethoxysilane and Butyl Alcohols

Isao HASEGAWA and Sumio SAKKA*,†
Division of Molecular Engineering, Graduate School of Engineering, Kyoto University, Sakyo-Ku, Kyoto, Kyoto-Fu 606
†Institute for Chemical Research, Kyoto University, Uji, Kyoto-Fu 611
(Received June 14, 1988)

Tetraethoxysilane was treated with Amberlyst 15 cation-exchange resin in the presence of butyl alcohols. On treating the mixture of tetraethoxysilane and 1-butanol, the transesterification took place in which butoxyl groups were substituted for ethoxyl groups in tetraethoxysilane. The degree of the transesterification depended on the molar ratio of tetraethoxysilane to 1-butanol of the mixture. The distribution of alkoxysilane species present in the tetraethoxysilane–1-butanol solution was compared with the tetrabutoxysilane–ethanol solution, and it was found that the degree of the transesterification depended on the ratio of numbers of alkyl groups in tetraalkoxysilane and alcohol used. The time required for equilibrium in the distribution of alkoxysilane species in the solution was different with the variety of butyl alcohols used, suggesting the presence of steric effect of butyl alcohols on this reaction.

Tetraethoxysilane ($Si(OC_2H_5)_4$, abbreviated to TEOS) has been widely used for syntheses of silica-based materials as starting material for silica, especially for the synthesis of silica glass by the sol–gel method.[1] For the preparation of silica gels, the mixture of TEOS, alcohol as solvent, water for the hydrolysis and catalyst, such as hydrochloric acid, is usually used. In the course of hydrolysis and polymerization of TEOS, it is reported that transesterification, in which alcohols used displace ethoxyl groups in TEOS to produce ethanols, occurs.[2,3]

The purpose of this study is to investigate the transesterification reaction between TEOS and different isomers of butyl alcohols by using Amberlyst 15 cation-exchange resin. Since no water is used in this study, polymerization reaction caused by the hydrolysis of TEOS can be suppressed to a low percentage.

Amberlyst 15 is a powerful proton donor which acts for the cleavage of siloxane bond in the similar way to trichloroacetic acid and concentrated sulfuric acid.[4] This cation-exchange resin has been used for the post-treatment of trimethylsilylation of silicates, since incompletely trimethylsilylated derivatives with a silanol group or alkoxyl groups are formed in the crude products.[5–7] The trimethylsilylation reaction is completed by treating the crude products in the excess of hexamethyldisiloxane with Amberlyst 15. It is also reported that partially trimethylsilylated derivatives from tetraalkoxysilanes or alkyltriethoxysilanes are produced by treating them with Amberlyst 15 in the presence of hexamethyldisiloxane.[8,9]

Experimental

Materials. Tetraethoxysilane, tetrabutoxysilane ($Si(OC_4H_9)_4$, TBOS), 1-butanol (Bu^nOH), 2-butanol (Bu^sOH), 2-methyl-1-propanol (Bu^iOH), 2-methyl-2-propanol (Bu^tOH), and ethanol (EtOH) were of reagent grade. Amberlyst 15 cation-exchange resin was used after heating in an oven of 80 °C and cooling in a desiccator, as suggested by Garzó et al.[10]

Preparation of Solutions. TEOS was added to 1-butanol so that the mixed solutions might have various mixing molar ratio. The mixing molar ratio of alcohol (ROH) to tetraalkoxysilane (TAOS) is expressed as the ROH/TAOS ratio in this study. After stirring 20 cm^3 of the mixture for 5 min for homogenization of the solution, 0.5 g of Amberlyst 15 was added. After the vessel of the solution was sealed up, the solution was kept standing in an oven of 40 °C. In this way, the solutions with the Bu^nOH/TEOS ratios from 1.0 to 10.0 were prepared.

In order to estimate the degree of polymerization of TEOS which occurs as a side reaction, the TEOS–EtOH solutions whose EtOH/TEOS ratios ranged from 1.0 to 10.0 were prepared by mixing TEOS and ethanol. Quantity of the monomeric species after Amberlyst treatment can be estimated as the residual ratio of TEOS, since only the compounds with ethoxyl groups are present in this system even when the transesterification reaction occurs.

For comparison of the distribution of ester-exchanged derivatives in the TEOS–Bu^nOH solutions, the TBOS–EtOH solutions with the EtOH/TBOS ratios from 1.0 to 8.0 were prepared in the same way as described above by using TBOS and ethanol.

Moreover, for investigating the effect of the structure of butyl alcohols on the transesterification reaction, TEOS–Bu^iOH, TEOS–Bu^sOH, TEOS–Bu^tOH solutions at the BuOH/TEOS ratio of 4.0 were also prepared in the same way.

Analytical Procedure. All the solutions were analyzed with a Shimadzu GC-12A gas chromatograph equipped with a hydrogen flame ionization detector and a CLH-702 split sample injector for capillary gas chromatography. The analytical conditions were the same as those described in the previous paper.[8] Each peak on the gas chromatograms was identified with a JEOL JMS-DX 300 gas chromatograph-mass spectrometer in the same analytical conditions described previously.[9]

Quantitative analysis was performed on TEOS and TBOS by using tetradecane as an internal standard. Since standard samples of other compounds formed could not be obtained, however, the distribution of each alkoxysilane species in the solutions was expressed in terms of the peak area ratio.

Results and Discussion

Gas Chromatography. Figure 1 shows the gas chromatograms of (a) the TEOS-Bu^{n}OH solution without Amberlyst treatment, (b) the TEOS-EtOH solution with Amberlyst treatment and (c) the TEOS-Bu^{n}OH solution with Amberlyst treatment. These solutions were kept standing in an oven of 40 °C for 120 h and the ROH/TEOS ratios of the solutions are all 4.0. When Amberlyst 15 is not added, only the peak of TEOS, which is the starting material, is detected, indicating that no transesterification reaction occurs. When Amberlyst 15 is added, however, other peaks than TEOS appear, as seen in Fig. 1 (b) and (c). These peaks were identified by conducting combined gas chromatograph-mass spectrometry and the assignments of the peaks on Fig. 1 (a)—(c) are summarized in Table 1.

In this table, it is seen that polymerization of TEOS occurs by treating the TEOS-EtOH solution with Amberlyst 15, as hexaethoxydisiloxane ($Si_2O_7(C_2H_5)_6$) and octaethoxytrisiloxane ($Si_3O_{10}(C_2H_5)_8$) were detected. The peaks corresponding to other compounds than TEOS on the gas chromatogram shown in Fig. 1 (c) are assigned to partially or fully ester-exchanged products formed from TEOS and those from hexaethoxydisiloxane. This fact indicates that the transesterification reaction occurs by treating the mixture of TEOS and Bu^{n}OH with Amberlyst 15, although the polymerization occurs slightly at the same time.

Polymerization of TEOS by Amberlyst Treatment. Figure 2 shows the variation in the distribution of alkoxysilane species and the residual ratio of TEOS in the TEOS-EtOH solutions with the EtOH/TEOS ratio after treating with Amberlyst 15 at 40 °C for 120 h. With the increase of the EtOH/TEOS ratio, TEOS decreases, and the dimer ($Si_2O_7(C_2H_5)_6$) and trimer ($Si_3O_{10}(C_2H_5)_8$) increase, and the residual ratio of TEOS is only 66% at the EtOH/TEOS ratio of 10.0, suggesting that the polymerization as a side reaction

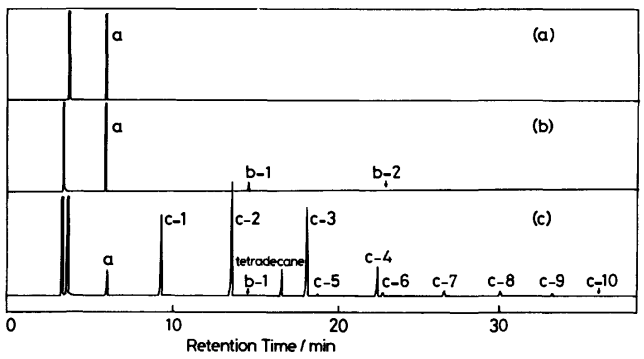

Fig. 1. Gas chromatograms of alkoxysilane species present in (a) the TEOS-Bu^{n}OH solution without Amberlyst treatment, (b) the TEOS-EtOH solution, and (c) the TEOS-Bu^{n}OH solution with Amberlyst treatment after keeping the solutions standing in an oven of 40 °C. The ROH/TEOS ratios of the solutions are all 4.0.

Table 1. Identification of Peaks on the Gas Chromatograms Shown in Fig. 1(a)—(c)

Peak	Retention time/min	Formula	Molecular weight
a	5.6	$SiO_4(C_2H_5)_4$	208
b-1	14.4	$Si_2O_7(C_2H_5)_6$	342
b-2	23.3	$Si_3O_{10}(C_2H_5)_8$	428
c-1	9.0	$SiO_4(C_2H_5)_3(C_4H_9)$	236
c-2	13.4	$SiO_4(C_2H_5)_2(C_4H_9)_2$	264
c-3	18.1	$SiO_4(C_2H_5)(C_4H_9)_3$	292
c-4	22.5	$SiO_4(C_4H_9)_4$	320
c-5	18.7	$Si_2O_7(C_2H_5)_5(C_4H_9)$	370
c-6	22.8	$Si_2O_7(C_2H_5)_4(C_4H_9)_2$	398
c-7	26.6	$Si_2O_7(C_2H_5)_3(C_4H_9)_3$	426
c-8	30.1	$Si_2O_7(C_2H_5)_2(C_4H_9)_4$	454
c-9	33.3	$Si_2O_7(C_2H_5)(C_4H_9)_5$	482
c-10	36.2	$Si_2O_7(C_4H_9)_6$	510

proceeds by this treatment.

It was reported that the recovery of the monomeric silicate species was only 0.3% after soaking the TEOS-EtOH-water-hydrochloric acid solution at the TEOS:EtOH:water:hydrochloric acid molar ratio of 1:7:2:0.01 in a water bath of 40 °C.[11] Although the residual ratio of TEOS is fairly low in the solutions at higher EtOH/TEOS ratios as is shown in Fig. 2, the value is much higher than the recovery of monomeric silicate species in the TEOS-EtOH-water-hydrochloric acid system, that is, water containing system after only 10 h of soaking at 40 °C. This fact suggests that polymerization of TEOS in the present study is fairly suppressed because of the absence of water. Therefore, it is thought that the ester-exchange reaction in TAOS-ROH solutions can be investigated with the Amberlyst treatment.

Transesterification of TEOS with 1-Butanol. Figure 3 shows the variation in the distribution of each alkoxysilane species present in the TEOS-Bu^{n}OH solutions with the Bu^{n}OH/TEOS ratio after Amberlyst treatment at 40 °C for 120 h and the recoveries of TEOS and TBOS at each Bu^{n}OH/TEOS ratio are shown in Fig. 4. The degree of transesterification varies with the Bu^{n}OH/TEOS ratio, increasing with increasing Bu^{n}OH/TEOS ratio. At the Bu^{n}OH/TEOS ratio of 20.0, 35.5% of TEOS added to the solution changes to TBOS after the treatment. It seems that there are optimum conditions for the formations of species with different ester-exchanged ratios. The optimum conditions for the formation of $Si(OEt)_3(OBu^n)$, $Si(OEt)_2(OBu^n)_2$, and $Si(OEt)(OBu^n)_3$ can be determined as the ratios of 2.0, 4.0, and 8.0, respectively, from Fig. 3.

Figure 3 also indicates that there may be no linear relationship on the optimum Bu^{n}OH/TEOS ratio for obtaining a species with a specific degree of transesterification as a main product. It appears, however, that larger amounts of Bu^{n}OH against TEOS are required to change $Si(OEt)_2(OBu^n)_2$ to $Si(OEt)(OBu^n)_3$ than to change $Si(OEt)_3(OBu^n)$ to $Si(OEt)_2(OBu^n)_2$. Actually, even when the solution with the Bu^{n}OH/TEOS ratio of 80.0 is treated in the same manner, the change of TEOS to TBOS is not complete. The peak area ratio of $Si(OBu^n)_4$ is 66.9 %, that of $Si(OEt)(OBu^n)_3$ is 9.5% and that of $Si(OEt)_2(OBu^n)_2$ is 2.2%, while $Si(OEt)_4$ and $Si(OEt)_3(OBu^n)$ are hardly confirmed on the chromatogram. This fact suggests that the transesterification reaction does not occur at a constant rate on relative steps and larger amounts of Bu^{n}OH to TEOS are required to form the species with higher degrees of transesterification.

Transesterification of TBOS with Ethanol. Figure 5 shows the variation in the distribution of each species present in the TBOS-EtOH solutions with the EtOH/TBOS ratio after Amberlyst treatment at 40 °C

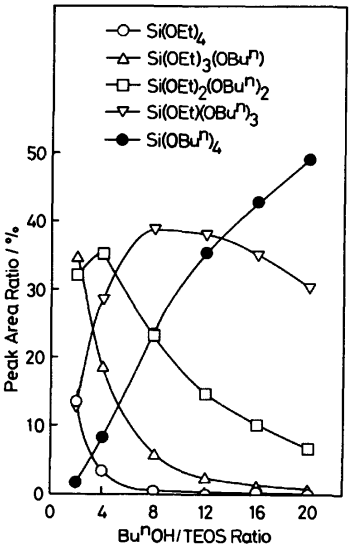

Fig. 3. Variation in the distribution of alkoxysilane species in the TEOS-Bu^{n}OH solutions with the Bu^{n}OH/TEOS ratio after Amberlyst treatment at 40 °C for 120 h.

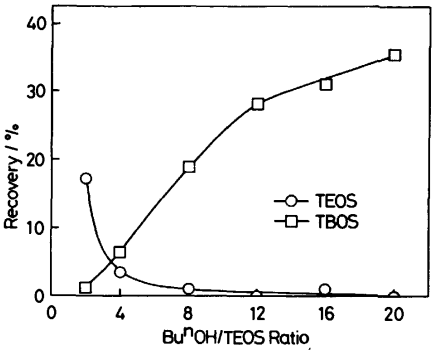

Fig. 4. Variation in the recoveries of TEOS and TBOS in the TEOS-Bu^{n}OH solutions with the Bu^{n}OH/TEOS ratio after Amberlyst treatment at 40 °C for 120 h.

for 120 h. With the increase of this ratio, the degree of substitution of ethoxyl group for butoxyl increases. Compared with the distribution in TEOS-Bu^{n}OH solutions shown in Fig. 3, peak area ratios of each alkoxysilane species at the EtOH/TBOS ratios of 1.0, 2.0, 4.0, and 8.0 show almost the same values as those at the Bu^{n}OH/TEOS ratios of 16.0, 8.0, 4.0, and 2.0, respectively. This fact means that the distribution of alkoxysilane species after Amberlyst treatment depends on the ratio of number of alkyl group in TAOS and that in ROH used, since the ratio of $-C_2H_5/-C_4H_9$ (the ratio of number of ethyl group to that of butyl group) both at the EtOH/TBOS ratio of 1.0 and the Bu^{n}OH/TEOS ratio of 16.0 is 0.25 and the ratio of $-C_2H_5/-C_4H_9$ both at the EtOH/TBOS ratio of 8.0 and the Bu^{n}OH/TEOS ratio of 2.0 is 2.0.

Effect of Treatment Time. Figure 6 shows the

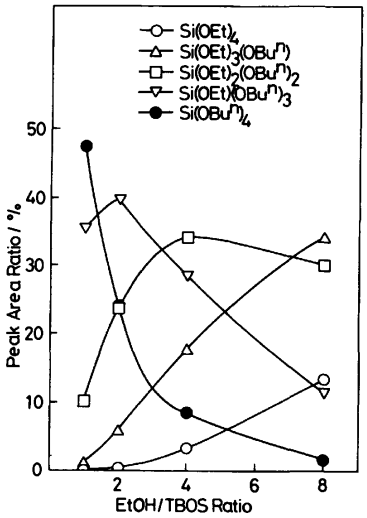

Fig. 5. Variation in the distribution of alkoxysilane species in the TBOS-EtOH solutions with the EtOH/TBOS ratio after Amberlyst treatment at 40 °C for 120 h.

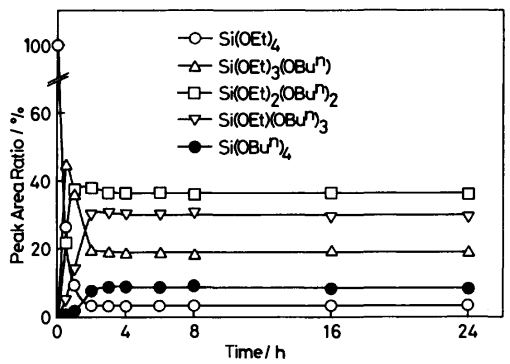

Fig. 6. Variation in the distribution of alkoxysilane species in the TEOS-Bu^{n}OH solution at the Bu^{n}OH/TEOS ratio of 4.0 with time of Amberlyst treatment at 40 °C.

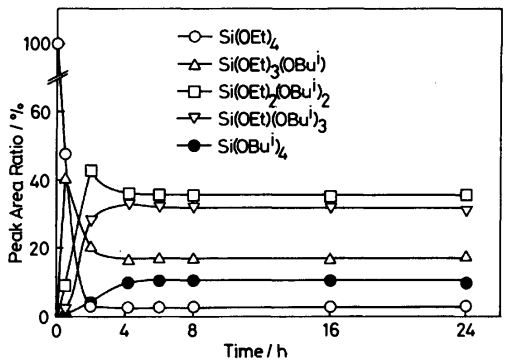

Fig. 7. Variation in the distribution of alkoxysilane species in the TEOS-Bu^{i}OH solution at the Bu^{i}OH/TEOS ratio of 4.0 with time of Amberlyst treatment at 40 °C.

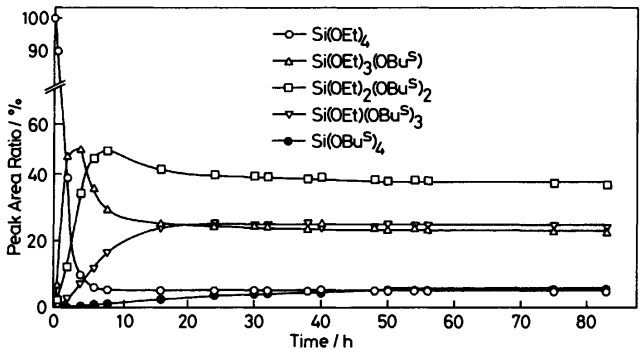

Fig. 8. Variation in the distribution of alkoxysilane species in the TEOS-Bu^{s}OH solution at the Bu^{s}OH/TEOS ratio of 4.0 with time of Amberlyst treatment at 40 °C.

variation in the distribution of alkoxysilane species in the TEOS-Bu^{n}OH solution at the Bu^{n}OH/TEOS ratio of 4.0 with time of Amberlyst treatment at 40 °C. In this figure, it is seen that the distribution of each alkoxysilane species does not vary and the equilibrium on the distribution is established on and after 2 h, indicating that the transesterification reaction between TEOS and Bu^{n}OH proceeds very rapidly.

Effect of the Structure of Butyl Alcohols. Variations in the distribution of alkoxysilane species with time of Amberlyst treatment at 40 °C in the TEOS-Bu^{i}OH and the TEOS-Bu^{s}OH solutions both at the BuOH/TEOS ratio of 4.0 are shown in Figs. 7 and 8, respectively. It is seen that the equilibrium on the transesterification is achieved in 6 h in the TEOS-Bu^{i}OH solution and in 50 h in the TEOS-Bu^{s}OH solution. The times for attaining the equilibrium in the TEOS-Bu^{i}OH and TEOS-Bu^{s}OH solutions are longer than that in the TEOS-Bu^{n}OH solution and the time is shorter in the TEOS-Bu^{i}OH system than in the TEOS-Bu^{s}OH system. It is considered that these differences are attributed to the steric effect of butyl alcohols on this transesterification reaction, and the time for the equilibrium seems to be shorter when the number of branching of alkyl group in a butyl alcohol is less and the number of C-C bond at the carbon atom to which a hydroxyl group attaches in a butyl alcohol is less.

When the TEOS-Bu^{t}OH solution at the Bu^{t}OH/TEOS ratio of 4.0 is treated with Amberlyst 15, however, the peak of TEOS become smaller with the treatment time and is hardly seen on the gas chromatogram after keeping the solution standing in an oven of 40 °C for 84 h. Then the solution gels after ca. 20 days. This suggests that the main reaction in this system is polymerization of TEOS. Typical gas chromatogram of the TEOS-Bu^{t}OH solution is shown in Fig. 9. By identifying the peaks on Fig. 9 with combined gas chromatograph-mass spectrometry, the peak a is assigned to $Si(OC_2H_5)_3(OH)$ (M, 180), which hardly appears in the other systems, and

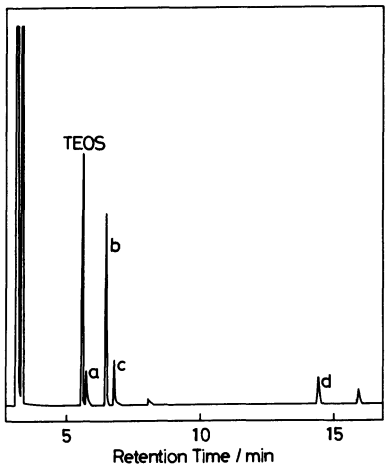

Fig. 9. Gas chromatogram of the TEOS-Bu^{t}OH solution at the Bu^{t}OH/TEOS ratio of 4.0 after Amberlyst treatment at 40 °C for 16 h.

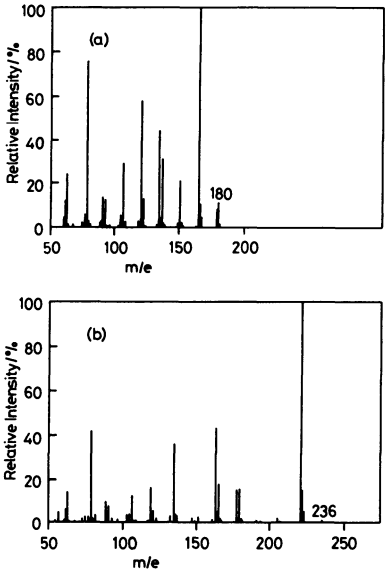

Fig. 10. 70-eV mass spectra of (a) Si(OEt)$_3$(OH) and (b) Si(OEt)$_3$(OBu^t) corresponding to peaks a and b in Fig. 9.

the peak b is assigned to Si(OC$_2$H$_5$)$_3$(OBu^t) (M, 236). The mass spectra of these compounds are shown in Fig. 10 (a) and (b), respectively. The peak c is assigned to Si(OC$_2$H$_5$)$_2$(OBu^t)(OH) and the peak d is assigned to Si$_2$O$_7$(C$_2$H$_5$)$_6$. It is considered that the polymerization rather than the transesterification occurs in this system because of the presence of the species with a reactive silanol group.

General Reaction Mechanism. The results described above suggest that the fundamental reaction of the transesterification in the present study may proceed as follows;

$$\text{A-H} + \text{Si(OR}^1\text{)}_4 \longrightarrow \text{A-Si(OR}^1\text{)}_3 + \text{R}^1\text{OH} \quad (1)$$

(A-H: Amberlyst-H)

$$\text{A-Si(OR}^1\text{)}_3 + \text{R}^2\text{OH} \longrightarrow \text{A-H} + \text{Si(OR}^1\text{)}_3\text{(OR}^2\text{)} \quad (2)$$

The ester-exchange reaction would proceed to the degree which is determined by the ROH/TAOS ratio.

The differences in the time for establishing the equilibrium in the TEOS-Bu^{n}OH, TEOS-Bu^{t}OH, and TEOS-Bu^{s}OH systems may be attributed to the steric effect of butyl alcohols. It is supposed that the differences arise in Reaction (2). In Reaction (2), butyl alcohol molecules present in the solution and EtOH formed by Reaction (1) would react with A-Si(OR)$_3$ competitively. In the final stage, however, the quantity of a butyl alcohol in the solution is expected to determine the degree of transesterification, since the main products in these three systems are Si(OEt)$_2$-(OBu)$_2$ in spite of the variety of butyl alcohols.

The presence of alkoxydisiloxane and alkoxytrisiloxane species, as is seen in Fig. 1 (b) and (c), and the occurrence of gelation in the TEOS-Bu^{t}OH solution indicate that polymerization of TEOS occurs together with the transesterification. The following polymerization reactions are assumed.

$$\text{A-H} + \text{Si(OR)}_4 \longrightarrow \text{A-R} + \text{Si(OR)}_3\text{(OH)} \quad (3)$$

$$\text{Si(OR)}_3\text{(OH)} + \text{Si(OR)}_4 \longrightarrow (\text{RO})_3\text{Si-O-Si(OR)}_3 + \text{ROH} \quad (4)$$

$$\text{Si(OR)}_3\text{(OH)} + \text{A-Si(OR)}_3 \longrightarrow (\text{RO})_3\text{Si-O-Si(OR)}_3 + \text{A-H} \quad (5)$$

$$\text{Si(OR)}_3\text{(OH)} + \text{Si(OR)}_3\text{(OH)} \longrightarrow (\text{RO})_3\text{Si-O-Si(OR)}_3 + \text{H}_2\text{O} \quad (6)$$

The occurrence of gelation in the TEOS-Bu^{t}OH solution may be explained by the presence of the species with a reactive silanol group formed by Reaction (3), which may lead to the polymerization.

Conclusion

Transesterification reaction took place when the mixture of TEOS and a butyl alcohol was treated with Amberlyst 15 cation-exchange resin except for Bu^{t}OH. A slight degree of polymerization of TEOS also took place as a side reaction. The degree of transesterification of TEOS depended mainly on the ratio of mixing of TEOS and a butyl alcohol, indicating that alkoxysilane species with a specific ester-exchanged ratio can be obtained as the main product in a solution by choosing the optimum ratio of mixing of TAOS and ROH. Additionally, the distribution of alkoxysilane species with different degrees of transesterification in a solution was governed by the ratio of numbers of alkyl groups in TAOS and ROH used, regardless of the kinds of TAOS and ROH used as starting materials. The kind of butyl alcohols also affected the time for attaining the equilibrium of transesterification reaction. When Bu^{t}OH was used as

a butyl alcohol, polymerization of TEOS was more dominant than the transesterification, which led to the gelation of the solution.

Structural Study of Na_2O-TeO_2 Glasses by Mössbauer Spectroscopy and Differential Thermal Analysis

Tetsuaki NISHIDA,* Setsuko SARUWATARI, and Yoshimasa TAKASHIMA
Department of Chemistry, Faculty of Science, Kyushu University 33,
Hakozaki, Higashiku, Fukuoka 812
(Received June 22, 1988)

A Mössbauer spectrum of $x$$Na_2O$·$(95-x)$$TeO_2$·$5Fe_2O_3$ glasses ($0 \leqq x \leqq 35$) consists of a paramagnetic quadrupole doublet peak with an isomer shift of 0.39 ± 0.01 mm s^{-1} with respect to metallic iron. Quadrupole splitting of the doublet peak changes gradually from 0.76 to 0.60 mm s^{-1} when Na_2O content is changed from 0 to 35 mol% at 5 mol% intervals. These results suggest that Fe^{3+} ions are present at substitutional sites of Te^{4+} ions constituting distorted TeO_4 trigonal bipyramids. Each of the distorted TeO_4 trigonal bipyramids has an oxygen vacancy and a lone electron pair at one of the equatorial sites. Decreased quadrupole splitting is ascribed to an increased symmetry of FeO_4 (and also TeO_4) trigonal bipyramids, due to a formation of nonbridging oxygen atoms followed by a gradual change of the glass matrix from a two-(β-TeO_2) or three-(α-TeO_2) dimensional network structure to a lower dimensional network structure. These structural changes are also deduced from a composition dependency of glass transition temperatures (T_g), which decrease continuously from 318 to 232 °C with increasing Na_2O content.

It is known that tellurite (TeO_2-based) glasses have some excellent physical properties such as low glass transition temperature (T_g), high refractive index, high dielectric constant, high thermal expansion coefficient, and high transmission in the IR region.[1-5] Structural study of tellurite glasses has been performed by several researchers by means of X-ray diffraction,[6-8] IR,[8-11] neutron diffraction,[12-16] and Mössbauer spectroscopy.[11,17-19] Local structure of TeO_2 glass was first studied by Brady,[6] who indicated that TeO_2 glass is composed of distorted TeO_6 octahedra. On the other hand, an X-ray diffraction study of V_2O_5-TeO_2 glasses performed by Dimitriev and Dimitrov[7] showed that coordination number of Te^{4+} ion changes from 4 to 3 when V_2O_5 is incorporated into TeO_2 matrix. An X-ray diffraction and IR absorption study of alkali tellurite glasses was performed by Dimitriev et al.,[8] who elucidated that alkali tellurite glasses are composed of TeO_4 groups. An IR study of binary alkali or alkaline earth tellurite glasses was performed by Mochida et al.,[9] who elucidated that these tellurite glasses have a layer structure composed of distorted TeO_4 trigonal bipyramids having a lone electron pair at one of the equatorial sites (in the xy plane). Each Te^{4+} ion has an oxygen vacancy at one of the equatorial sites.[9] The IR results obtained by Mochida et al.[9] were supported by Dimitriev et al.,[10] who showed that an introduction of MoO_3 into TeO_2 matrix results in a structural change from TeO_4 trigonal bipyramids to TeO_3 trigonal pyramids, similarly to the structural change of V_2O_5-TeO_2 glasses.[7] Neutron diffraction studies revealed that tellurite glasses are composed of distorted TeO_4 trigonal bipyramids.[12-16] Neov et al. proposed that tellurite glasses are composed of TeO_4 tetrahedra.[13] A neutron diffraction study performed by Neov et al.[14] revealed that TeO_4 trigonal bipyramids, constituting the glass matrix of tellurite glasses, gradually change into TeO_3 trigonal pyramids when P_2O_5 is incorporated into TeO_2 matrix. This structural change is similar to that of V_2O_5-TeO_2[7] and MoO_3-TeO_2[10] glasses described above. Structural change of V_2O_5-TeO_2 glasses was also observed by Johnson et al.[16] by using a neutron diffraction method. Mössbauer studies on the structure of tellurite glasses were performed by Binczycka et al.[17] and Bahgat et al.[11,18,19] Some of the Mössbauer studies[17,18] suggested that iron is present as octahedral Fe^{3+} ions in tellurite glasses, in spite that both the isomer shift (<0.40 mm s^{-1} with respect to metallic iron) and the quadrupole splitting (0.6—0.9 mm s^{-1}) indicated the coordination number smaller than 6. On the other hand, Mössbauer studies performed by Bahgat et al.[11,19] lead to a conclusion that Fe^{3+} ions are present at tetrahedral environments in strontium tellurite and several rare earth tellurite glasses. This conclusion[11,19] was drawn because the Mössbauer parameters of Fe^{3+} ions in these tellurite glasses were almost comparable to those of tetrahedral Fe^{3+} ions obtained for several oxide glasses. In Ref. 19, it was concluded that an increased SrO content results in an increased number of nonbridging oxygen atoms in FeO_4 and TeO_4 tetrahedra.

Present Mössbauer study of a series of Na_2O-TeO_2 glasses containing a small amount (5 mol%) of Fe_2O_3 was carried out in order to elucidate the short-range (local) and also middle- or long-range structures of tellurite glasses, e.g., a steric configuration around the iron (and also tellurium) atom and a structural change caused by alkali oxide (Na_2O) which was incorporated into TeO_2 matrix. DTA measurements of the Na_2O-TeO_2 glasses containing 5 mol% Fe_2O_3 were also performed in parallel, because glass transition temperature (T_g) is known to be sensitive to a change in the coordination number of network-forming atoms and to a formation of nonbridging oxygen,[20-24] chlorine,[25] and fluorine[26] atoms followed by a depolymerization of the network structure.

Experimental

A series of xNa$_2$O·(95−x)TeO$_2$·5Fe$_2$O$_3$ glasses were prepared by fusing individual mixtures (1 g) of commercially available Na$_2$CO$_3$, TeO$_2$, and Fe$_2$O$_3$, of guaranteed reagent grade. Each of the mixtures, in which x was changed at 5 intervals, was fused at 750 °C for 1 h in air by using an electric muffle furnace. After the fusion, each melt in a platinum crucible was immediately quenched with ice-cold water. Transparent and light brown glasses were obtained in a compositional region $0 \leqq x \leqq 35$. Mössbauer and DTA measurements were performed on pulverized tellurite glasses. Mössbauer measurements were performed by a constant acceleration method at room temperature, by using a proportional counter and a multichannel (1024-channel) analyzer. Cobalt-57 (10 mCi) diffused into a palladium foil was used as a Mössbauer source. As a standard material for the isomer shift, a piece of metallic iron foil enriched with iron-57 was used. The iron foil was also used for calibrating the velocity of Mössbauer spectrometer. Each Mössbauer spectrum was analyzed into a quadrupole doublet by a least-squares method. DTA measurements of tellurite glasses were performed in the temperature range between room temperature and 600 °C, with a heating rate of 5 °C min^{-1}. Powder of α-Al$_2$O$_3$ was used as a standard material in the DTA measurements.

Results and Discussion

A Mössbauer spectrum of 20Na$_2$O·75TeO$_2$·5Fe$_2$O$_3$ glass is shown in Fig. 1, which indicates a characteristic doublet peak due to paramagnetic Fe^{3+} ions of high spin state.[27,28] Since the absorption is symmetric, each Mössbauer spectrum is analyzed into a quadrupole doublet peak having equal linewidth and equal intensity. All the Mössbauer parameters of Na$_2$O–TeO$_2$–Fe$_2$O$_3$ glasses are shown in Figs. 2 and 3. Figure 2a indicates that isomer shift is independent of the composition, showing a constant value of 0.39±0.01 mm s^{-1}. Comparing the present results with recent Mössbauer results of alkali borate,[25,29–32] alkali borosilicate,[32–34] and other glasses cited in review articles,[35–37] we can deduce that Fe^{3+} ions are four-fold coordinated in Na$_2$O–TeO$_2$ glasses, and that they are not octahedrally coordinated as in several phosphate glasses.[38–41] In the Mössbauer spectra of tetrahedrally coordinated Fe^{3+} ions, isomer shifts were located in a range of 0.22—0.38 mm s^{-1} with respect to metallic iron.[25,29–37] These experimental results obtained so far indicate that isomer shift of Fe^{3+} ions is less than 0.40 mm s^{-1} when they are four-fold coordinated. The experimental error of isomer shift is estimated to be ±0.01 mm s^{-1}. On the other hand, Mössbauer spectra of Fe^{3+} ions in several phosphate glasses[38–41] indicate that isomer shift is more than 0.42 mm s^{-1} when they are octahedrally coordinated with oxygen atoms. These results suggest that a boundary of isomer shift lies at about 0.40 mm s^{-1} for four-fold and six-fold coordinated Fe^{3+} ions with oxygen atoms.[42] Therefore, the isomer shift of

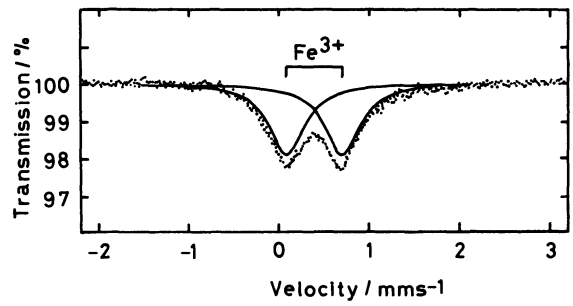

Fig. 1. Mössbauer spectrum of 20Na$_2$O·75TeO$_2$·5Fe$_2$O$_3$ glass measured at room temperature.

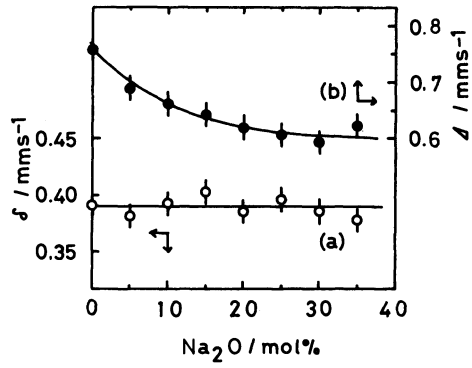

Fig. 2. Composition dependencies of (a) isomer shift (δ) and (b) quadrupole splitting (Δ) of Fe^{3+} ions in xNa$_2$O·(95−x)TeO$_2$·5Fe$_2$O$_3$ glasses.

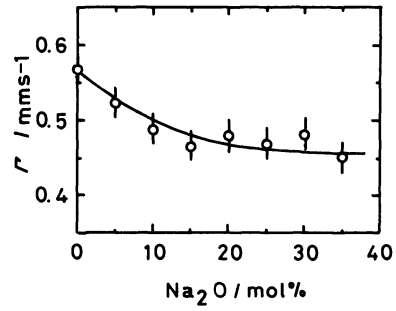

Fig. 3. Composition dependency of linewidth (Γ) of Fe^{3+} ions in xNa$_2$O·(95−x)TeO$_2$·5Fe$_2$O$_3$ glasses.

0.39±0.01 mm s^{-1} (Fig. 2a) will suggest four-fold coordinated Fe^{3+} ions (of high spin state). The relatively large isomer shift values (0.39±0.01 mm s^{-1}) suggest that s-electron density at iron nucleus is lower than that of tetrahedral Fe^{3+} ions observed in several oxide glasses.[25,29–37] Earlier Mössbauer results on tellurite glasses obtained by Binczycka et al.[17] and Bahgat et al.,[18] suggesting that Fe^{3+} ions are octahedrally present in tellurite glasses, are unlikely because the isomer shift values were less than 0.40 mm s^{-1} with respect to metallic iron. It should be noted that recent IR[9,10] and neutron diffraction[12–16] studies propose a presence of distorted

TeO_4 trigonal bipyramids having an oxygen vacancy and a lone electron pair at one of the equatorial sites. Taking into account these IR and neutron diffraction results,[9,10,12–16] we can tentatively conclude that the present Mössbauer results (isomer shift) suggest distorted FeO_4 trigonal bipyramids having an oxygen vacancy at one of the equatorial sites. Apart from Te^{4+} ions, Fe^{3+} ions will not have a lone electron pair at the equatorial sites. They will form sp^3d hybrid orbital, similarly to the Te^{4+} ions constituting TeO_4 trigonal bipyramids.

From the electronic point of view, the four-fold coordinated FeO_4 trigonal bipyramid having one oxygen vacancy is equivalent to an FeO_4 tetrahedron without oxygen vacancy. The almost constant and large isomer shift values located around 0.39 mm s^{-1} (Fig. 2a), irrespective of the composition, may be concerned with the oxygen vacancy at one of the equatorial sites in FeO_4 trigonal bipyramids. A part of negative charge on the Fe^{3+} ion will be attracted to the oxygen vacancy. As a result, 4s-electron density at the iron nucleus will be decreased. This will cause a relatively large isomer shift values. Also, the larger isomer shift values will be concerned with lower s-electron density in an sp^3d hybrid orbital, because a contribution of s-orbital to the sp^3d hybrid orbital is lower as compared with sp^3 hybrid orbital. The Fe^{3+} ions attached to oxygen vacancies will be less sensitive to a change of electron densities at iron nucleus. In several vanadate glasses,[20,21,42,43] a drastic change of glass matrix was observed from VO_5 tetragonal pyramids to VO_4 tetrahedra when alkali or alkaline earth oxide was incorporated into V_2O_5 matrix. This structural change corresponds to an orbital change in the V^{5+} or V^{4+} (and also Fe^{3+}) ions from sp^3d to sp^3 hybrid orbital. From the relatively large and constant isomer shift values (0.39 ± 0.01 mm s^{-1}) observed in tellurite glasses, we can deduce the presence of oxygen vacancies at neighboring sites of Fe^{3+} ions in FeO_4 trigonal bipyramids and also sp^3d hybrid orbital in the Fe^{3+} ions. This will be discussed later in connection with a formation of nonbridging oxygen atoms.

Continuous decrease in the quadrupole splitting shown in Fig. 2b suggests that a symmetry of FeO_4 (and also TeO_4) trigonal bipyramids increases with increasing Na_2O content. In the case of high-spin Fe^{3+} ions, an electric field gradient brought about by neighboring atoms (q_{lat}) primarily causes the quadrupole interaction. Similar decrease in the quadrupole splitting of Fe^{3+} ions was observed in several alkali borate[25,29–32] and alkali borosilicate[32–34] glasses, where the decrease was ascribed to a formation of nonbridging oxygen and chlorine atoms in BO_4, SiO_4, and BO_3Cl tetrahedra. Decrease in the quadrupole splitting of Fe^{3+} ions has also been observed in alkali vanadate[20,21,42] glasses, from which we could know a formation of nonbridging oxygen atoms in VO_4 tetrahedra and a depolymerization of the layer structure originally composed of VO_5 tetragonal pyramids. The experimental error of quadrupole splitting is estimated to be ±0.02 mm s^{-1}. Quadrupole splitting of Fe^{3+} ions octahedrally coordinated with oxygen atoms (e.g. 0.3—0.6 mm s^{-1}) is usually smaller than that of tetrahedrally coordinated Fe^{3+} ions (e.g. 0.6—0.9 mm s^{-1}), owing to a higher symmetry of the former. It should be noted that a change of middle- or long-range structure, as well as a change of short-range structure, is sometimes reflected in the quadrupole splitting of Fe^{3+} ions. Therefore, the continuous decrease in quadrupole splitting (Fig. 2b) is ascribed to a formation of nonbridging oxygen atoms in distorted FeO_4 (and also TeO_4) trigonal bipyramids having an oxygen vacancy at one of the equatorial sites. Furthermore, a lone electron pair will be present in the sp^3d hybrid orbital of Te^{4+} ion constituting a TeO_4 trigonal bipyramid. An introduction of alkali oxide (Na_2O) into TeO_2 matrix will result in a depolymerization of original α-TeO_2[10,13,14] or β-TeO_2[9,16] type structure, composed of distorted TeO_4 trigonal bipyramids having a lone electron pair at one of the equatorial sites. Comparing Fig. 2a with Fig. 2b, we can know that quadrupole splitting (Δ) is more sensitive to the structural change than isomer shift (δ). Similar phenomenon was observed in a crystallization study of several borate and borosilicate glasses.[32]

Figure 3 indicates that a formation of nonbridging oxygen atoms and a depolymerization of the glass matrix are reflected in the linewidth. It is generally known that linewidth of the absorption peak due to iron in glasses is greater than about 0.4 mm s^{-1}. This is a characteristic feature of the absorption for amorphous materials. Each linewidth shown in Fig. 3 is in a range of 0.46—0.57 mm s^{-1}. A continuous decrease in linewidth (Fig. 3) suggests that bond length and bond angle between Fe^{3+} (and also Te^{4+}) ions and neighboring oxygen atoms become more uniform when nonbridging oxygen atoms are formed in FeO_4 (and also TeO_4) trigonal bipyramids. Figure 3 demonstrates that linewidth decreases by adding Na_2O into TeO_2 matrix and becomes almost constant (about 0.46 mm s^{-1}) when Na_2O content is higher than about 20 mol%. This indicates that a distinct structural change occurs in tellurite glasses of low alkali oxide content. The composition dependency is in good agreement with that of quadrupole splitting described above.

Glass transition temperatures (T_g) of tellurite glasses obtained from DTA measurements are plotted in Fig. 4. Each DTA curve of Na_2O–TeO_2 glasses containing 5 mol% Fe_2O_3 shows a broad endothermic peak due to glass transition and exothermic peaks due to crystallization. Recent DTA studies on the structure of several glasses revealed that T_g is closely concerned with a change in the coordination number of network-

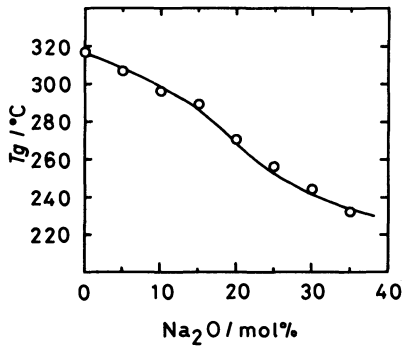

Fig. 4. Composition dependency of glass transition temperature (T_g) of xNaO·(95−x)TeO$_2$·5Fe$_2$O$_3$ glasses.

forming atoms and with a formation of nonbridging oxygen or halogen atoms.[20–26,42–44] The latter structural change causes a depolymerization of network structure. T_g shows a distinct increase/decrease with increasing/decreasing coordination number of network-forming atoms, because the coordination number is responsible for the degree of bridging in the glass matrix. Also, a formation of nonbridging oxygen atoms is deduced from a decrease in T_g.[20–24,42–44] Therefore, a continuous decrease in T_g ranging from 318 to 232 °C (Fig. 4) is ascribed to an increased fraction of less distorted TeO_4 and FeO_4 trigonal bipyramids having nonbridging oxygen atoms. At the same time, it is concluded that a middle- or long-range structural change occurs from the original three-dimensional network (α-TeO_2) structure or two-dimensional layer (β-TeO_2) structure to a lower dimensional network structure, i.e., one-dimensional chain structure. This structural change is similar to that of alkali vanadate (K_2O–V_2O_5,[20] Na_2O–V_2O_5,[21] and Li_2O–V_2O_5[42]) glasses. In alkali vanadate glasses,[20,21,42] a simultaneous decrease in T_g and quadrupole splitting (of the Fe^{3+} ions) was ascribed to a structural change from a two-dimensional layer structure composed of VO_5 tetragonal pyramids to a one-dimensional chain structure composed of VO_4 tetrahedra which have nonbridging oxygen atoms.

A simultaneous decrease in T_g and quadrupole splitting (of Fe^{3+} or Sn^{4+} ions) has been observed when nonbridging oxygen atoms are formed in GeO_4 and GaO_4 tetrahedra constituting alkali (K_2O-) germanate[24] and gallate[44] glasses, respectively. Concordant composition dependencies of T_g and quadrupole splitting, observed in several vanadate,[20,21,42,43] germanate,[24] gallate,[44] and tellurite glasses, suggest that a structural information obtained from Mössbauer measurements is representative of the whole glass matrix. Mössbauer atoms will be homogeneously distributed in the glass matrix either at the substitutional sites of the individual network-forming ions (e.g. V^{5+}, V^{4+}, Ga^{3+}, and Te^{4+}) or at the interstitial sites in the glass matrix (e.g. phosphate glasses), depending on the type of glass matrix. From the constant isomer shifts described above (Fig. 2a), it is speculated that nonbridging oxygen atoms will be preferentially formed at axial oxygen sites. The longer interatomic distance and resultant weaker covalent bond between Fe^{3+} (and also Te^{4+}) ions and oxygen atoms at axial sites will bring about little effect on the s-electron density and therefore on the isomer shift.

It is concluded that Fe^{3+} ions are present at substitutional sites of the Te^{4+} ions constituting TeO_4 trigonal bipyramids. Each of the TeO_4 trigonal bipyramids has an oxygen vacancy and a lone electron pair at one of the equatorial sites. An Fe^{3+} ion in the FeO_4 trigonal bipyramid does not have a lone electron pair. It is also concluded that an introduction of Na_2O into TeO_2 matrix results in a change of the glass matrix from an original three-dimensional network (α-TeO_2) or a two-dimensional layer (β-TeO_2) structure to a lower dimensional network structure, i.e., a chain structure composed of less distorted TeO_4 trigonal bipyramids which have nonbridging oxygen atoms.

The authors are grateful to Prof. Toshinobu Yoko of Kyoto University for his useful comments and discussion. One of the authors (TN) is indebted to Yoshida Science Foundation and Kazuchika Ohkura Memorial Foundation for a financial support.

Redox-Linked Protonation of $[Fe_4X_4(YR)_4]^{2-}$ (X,Y=S and Se; R=*n*-$C_{12}H_{25}$ and C_6H_4-*p*-*t*-Bu) in Aqueous Solutions

Masami NAKAMOTO,† Koji TANAKA,* and Toshio TANAKA*
Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamada-oka, Suita, Osaka 565
†Osaka Municipal Technical Research Institute, Morinomiya, Joto-ku, Osaka 536
(Received June 25, 1988)

A series of $[Fe_4X_4(YR)_4]^{2-}$ (X,Y=S and Se; R=*n*-$C_{12}H_{25}$ and C_6H_4-*p*-*t*-Bu) were prepared as *n*-Bu_4N^+ salts. In aqueous Triton X-100 micellar solutions, only the reduced forms of $[Fe_4X_4(YR)_4]^{2-}$ (X,Y=S and Se; R=*n*-$C_{12}H_{25}$ and C_6H_4-*p*-*t*-Bu) undergo protonation reactions at the sulfur or selenium atom of the Fe_4X_4 (X=S and Se) core to exist as an equilibrium mixture of the protonated and unprotonated clusters. On the other hand, not only the oxidized but also the reduced forms of $[Fe_4X_4(YC_6H_4$-*p*-*t*-$Bu)_4]^{2-}$ (X,Y=S and Se) undergo protonation reactions in aqueous poly[2-(dimethylamino)hexanamide] (PDACA) solutions. The pK_{ox} values of $[Fe_4X_4(YC_6H_4$-*p*-*t*-$Bu)_4]^{2-}$ (X,Y=S and Se) vary depending on the terminal thiolate and selenolate ligands; 5.9 for Y=S and 6.8 for Y=Se, whereas the pK_{red} values of $[Fe_4X_4(YC_6H_4$-*p*-*t*-$Bu)_4]^{3-}$ are controlled by the core sulfur and selenium; 8.8 for X=S and 7.3 for X=Se. Such characteristic pK_{ox} and pK_{red} values suggest that the protonation takes place at the terminal sulfur or selenium atom of the oxidized clusters $[Fe_4X_4(YC_6H_4$-*p*-*t*-$Bu)_4]^{2-}$ (X,Y=S and Se), while it occurs at the sulfur or selenium atom of the Fe_4X_4 core of the reduced clusters $[Fe_4X_4(YC_6H_4$-*p*-*t*-$Bu)_4]^{3-}$ (X,Y=S and Se).

Iron-sulfur proteins containing Fe_4S_4 cores function as electron transfer catalysts in various biological redox reactions, such as photosynthesis,[1] nitrate reduction,[2] dinitrogen fixation,[3] and so on. As models of active sites of iron-sulfur proteins, the various iron-sulfur clusters with thiolate ligands have been synthesized.[4-9] The electrochemistry of those clusters[10-16] has elucidated that synthetic water soluble Fe_4S_4 clusters in aqueous solutions exhibit more positive redox potentials than water insoluble Fe_4S_4 clusters in organic solvents.[10,12,17] The redox potentials of the former, however, are still more negative than those of 4-Fe and 8-Fe ferredoxins (−0.52 to −0.73 V vs. SCE around pH 7.0) in water.[18] Such negative redox potentials of synthetic Fe_4S_4 clusters may be associated with the absence of hydrogen bondings formed between amide hydrogen of the peptide chain and sulfur of the Fe_4S_4 core and/or of the terminal cysteine residue ligated on the iron atoms in 4-Fe ferredoxins.[19-21] In accordance with this, the redox potential of $[Fe_4S_4(SCH_2CH_2CO_2)_4]^{6-}$ in water in the presence of bovine serum albumin or bovine insulin is 170—220 mV more positive than that of the cluster in water.[17] Recently, we have demonstrated that a Fe_4S_4 cluster $[Fe_4S_4(SC_6H_4$-*p*-*n*-$C_8H_{17})_4]^{2-}$ undergoes a redox-linked protonation in an aqueous micellar solution, and the protonated and unprotonated clusters exist as an equilibrium mixture below pH 10.[22] Such a redox-linked protonation of $[Fe_4X_4(Y$-*n*-$C_{12}H_{25})_4]^{2-}$ (X, Y=S and Se) has briefly been communicated to take place at the sulfur atom of the Fe_4S_4 core rather than the terminal thiolate sulfur on the basis of the electrochemical study in aqueous micellar solutions.[23] This paper describes the protonation behaviors of a series of $[Fe_4X_4(YC_6H_4$-*p*-*t*-$Bu)_4]^{2-}$ (**I**) as well as $[Fe_4X_4(Y$-*n*-$C_{12}H_{25})_4]^{2-}$ (**II**) (X, Y=S and Se) in aqueous micellar and poly[2-(dimethylamino)hexanamide] (PDACA) solutions in more detail.

(X, Y=S and Se)

Experimental

General Procedure and Materials. All manipulations were carried out under N_2 atmosphere. Solvents used for preparations and physical measurements were purified by distillations over dehydration chemicals; magnesium methoxide for MeOH, calcium hydride for MeCN, and calcium oxide for DMF. Commercially available guaranteed reagent grades of 1-dodecanethiol and *p*-*t*-butylbenzenethiol were used without purification. 1-Dodecaneselenol was obtained by the reaction of 1-bromododecane with selenourea supplied by Shinko Chemical Co., Ltd. in EtOH by the similar manner to the preparation of 1-dodecanethiol.[24] *p*-*t*-Butylbenzeneselenol,[25] $[n\text{-}Bu_4N]_2[Fe_4S_4(S\text{-}t\text{-}Bu)_4]$,[4] and $[n\text{-}Bu_4N]_2[Fe_4Se_4(S\text{-}t\text{-}Bu)_4]$[26] were prepared according to the literature. Poly[2-(dimethylamino)hexanamide] (PDACA) supplied by Toray Co., Ltd. was purified by dialysis.

Preparation of $[n\text{-}Bu_4N]_2[Fe_4S_4(SR)_4]$ (R=*n*-$C_{12}H_{25}$ and C_6H_4-*p*-*t*-Bu). To a MeOH (100 cm³) solution containing MeONa (2.43 g, 45 mmol) and 1-dodecanethiol or *p*-*t*-butylbenzenethiol (45 mmol) was added a filtered MeOH (50 cm³) solution of $FeCl_3$ (2.5 g, 15 mmol), and a MeOH (50 cm³) solution containing MeONa (0.81 g, 15 mmol) and

NaSH (0.84 g, 30 mmol) successively. After stirred for 24 h, the resulting black solution was filtered. To the filtrate was added slowly *n*-Bu_4NBr (4.0 g, 12 mmol) in MeOH (50 cm^3) to give a black precipitate of $[n\text{-}Bu_4N]_2[Fe_4S_4(SR)_4]$, which was collected by filtration and recrystallized from MeCN, 47% for R=*n*-$C_{12}H_{25}$ and 51% for R=C_6H_4-*p*-*t*-Bu. Found for $[n\text{-}Bu_4N]_2[Fe_4S_4(S\text{-}n\text{-}C_{12}H_{25})_4]$: C, 58.37; H, 10.37; N, 1.68%. Calcd for $C_{80}H_{172}Fe_4N_2S_8$: C, 58.51; H, 10.56; N, 1.71%. Found for $[n\text{-}Bu_4N]_2[Fe_4S_4(SC_6H_4\text{-}p\text{-}t\text{-}Bu)_4]$: C, 57.76; H, 8.28; N, 1.45%. Calcd for $C_{72}H_{124}Fe_4N_2S_8$: C, 57.74; H, 8.35; N, 1.87%.

Preparation of $[n\text{-}Bu_4N]_2[Fe_4S_4(SeR)_4]$ (R=*n*-$C_{12}H_{25}$ and C_6H_4-*p*-*t*-Bu). The selenolate ligated cluster $[n\text{-}Bu_4N]_2[Fe_4S_4(SeR)_4]$ (R=*n*-$C_{12}H_{25}$ and C_6H_4-*p*-*t*-Bu) was prepared by the ligand substitution reaction[27] of $[Fe_4S_4(S\text{-}t\text{-}Bu)_4]^{2-}$ with selenol as follows; a DMF (80 cm^3) solution containing $[n\text{-}Bu_4N]_2[Fe_4S_4(S\text{-}t\text{-}Bu)_4]$ (1.0 g, 0.84 mmol) and 1-dodecaneselenol (2.0 g, 8.0 mmol) or *p*-*t*-butylbenzeneselenol (1.8 g, 8.4 mmol) was stirred at 50 °C for 7 h, during which time N_2 gas was bubbled into the solution every 5 min to remove *t*-BuSH from the solution. The resulting solution was evaporated to dryness under reduced pressure. The residual solid was recrystallized from MeCN to give black crystals, 50% for R=*n*-$C_{12}H_{25}$ and 61% for R=C_6H_4-*p*-*t*-Bu. Found for $[n\text{-}Bu_4N]_2[Fe_4S_4(Se\text{-}n\text{-}C_{12}H_{25})_4]$: C, 52.07; H, 9.37; N, 1.62%. Calcd for $C_{80}H_{172}Fe_4N_2S_4Se_4$: C, 52.51; H, 9.48; N, 1.53%. Found for $[n\text{-}Bu_4N]_2[Fe_4S_4(SeC_6H_4\text{-}p\text{-}t\text{-}Bu)_4]$: C, 51.63; H, 7.44; N, 1.66%. Calcd for $C_{72}H_{124}Fe_4N_2S_4Se_4$: C, 51.31; H, 7.42; N, 1.66%.

Preparation of $[n\text{-}Bu_4N]_2[Fe_4Se_4(SR)_4]$ (R=*n*-$C_{12}H_{25}$ and C_6H_4-*p*-*t*-Bu). To a MeOH (20 cm^3) solution containing MeOLi (0.76 g, 20 mmol) and 1-dodecanethiol or *p*-*t*-butylbenzenethiol (20 mmol) was added a filtered MeOH (20 cm^3) solution of $FeCl_3$ (0.82 g, 5.0 mmol) in 10 min, followed by the addition of selenium powder (0.40 g, 5.0 mmol) rapidly. After stirred for 24 h, the resulting solution was filtered. To the filtrate was added slowly *n*-Bu_4NBr (1.2 g, 3.8 mmol) in MeOH (15 cm^3) to give a precipitate, which was collected by filtration, washed with MeOH, and dried in vacuo. The resulting powder was recrystallized from MeCN to give black crystals, 48% for R=*n*-$C_{12}H_{25}$ and 51% for R=C_6H_4-*p*-*t*-Bu. Found for $[n\text{-}Bu_4N]_2[Fe_4Se_4(S\text{-}n\text{-}C_{12}H_{25})_4]$: C, 52.14; H, 9.54; N, 1.50%. Calcd for $C_{80}H_{172}Fe_4N_2S_4Se_4$:C, 52.51; H, 9.48; N, 1.53%. Found for $[n\text{-}Bu_4N]_2[Fe_4Se_4(SC_6H_4\text{-}p\text{-}t\text{-}Bu)_4]$: C, 51.52; H, 7.43; N, 1.34%. Calcd for $C_{72}H_{124}Fe_4N_2S_4Se_4$: C, 51.31; H, 7.42; N, 1.66%.

Preparation of $[n\text{-}Bu_4N]_2[Fe_4Se_4(SeR)_4]$ (R=*n*-$C_{12}H_{25}$ and C_6H_4-*p*-*t*-Bu). A DMF (80 cm^3) solution containing $[n\text{-}Bu_4N]_2[Fe_4Se_4(S\text{-}t\text{-}Bu)_4]$ (1.16 g, 0.84 mmol) and 1-dodecaneselenol (2.1 g, 8.4 mmol) or *p*-*t*-butylbenzeneselenol (1.8 g, 8.4 mmol) was stirred at 50 °C for 7 h, during which time N_2 gas was bubbled into the solution. The resulting solution was evaporated to dryness under reduced pressure. The residual solid was recrystallized from MeCN to give black crystals, 45% for R=*n*-$C_{12}H_{25}$ and 67% for R=C_6H_4-*p*-*t*-Bu. Found for $[n\text{-}Bu_4N]_2[Fe_4Se_4(Se\text{-}n\text{-}C_{12}H_{25})_4]$: C, 47.39; H, 8.76; N, 1.18%. Calcd for $C_{80}H_{172}Fe_4N_2Se_8$: C, 47.63; H, 8.59; N, 1.39%. Found for $[n\text{-}Bu_4N]_2[Fe_4Se_4(SeC_6H_4\text{-}p\text{-}t\text{-}Bu)_4]$: C, 46.59; H, 6.69; N, 1.54%. Calcd for $C_{72}H_{124}Fe_4N_2Se_8$: C, 46.17; H, 6.67; N, 1.50%.

Preparation of Aqueous Micellar Solutions. A DMF (1.0 cm^3) solution of the cluster (12 μmol) was added to a stirred aqueous solution (25 cm^3, pH 5—10) containing NaOH-H_3PO_4 (0.1 mol dm^{-3}) and either Triton X-100 (0.025—0.5 mol dm^{-3}) or poly[2-(dimethylamino)hexanamide] (PDACA) (0.1 g). Dark brown aqueous Triton X-100 micellar or PDACA solutions thus prepared was used after filtration.

Physical Measurements. Cyclic voltammetry measurements were performed with a Hokuto Denko HA-501 potentiostat/galvanostat using a glassy carbon electrode in DMF or with a hanging mercury drop electrode (HMDE) in aqueous micellar solutions, respectively. As supporting electrolytes were used *n*-Bu_4NClO_4 in DMF and H_3PO_4-NaOH in aqueous solutions. A saturated calomel electrode (SCE) was used as a reference.

Results and Discussion

Redox Behaviors of $[Fe_4X_4(YR)_4]^{2-}$ (X, Y=S and Se; R=*n*-$C_{12}H_{25}$ and C_6H_4-*p*-*t*-Bu) in Aqueous Triton X-100 Micellar Solutions. Cyclic voltammograms of the present clusters show reversible $[Fe_4X_4(YR)_4]^{2-/3-}$ redox couples in the range $E_{1/2}$=−0.94 to −1.37 V vs. SCE in DMF (Table 1), where $E_{1/2}$ is approximated by the average of the cathodic and anodic peak potentials. As typical examples, the cyclic voltammograms of $[Fe_4S_4(S\text{-}n\text{-}C_{12}H_{25})_4]^{2-}$ and $[Fe_4S_4(SC_6H_4\text{-}p\text{-}t\text{-}Bu)_4]^{2-}$ are depicted in Fig. 1a and 1c. The redox potentials of synthetic Fe_4S_4 clusters as well as ferredoxins are affected significantly by the change of a medium.[10,18] The redox behaviors of synthetic Fe_4S_4 clusters in

water, therefore, seem to be very important in connection with those of 4-Fe and 8-Fe ferredoxins. However, the fact that Fe_4S_4 clusters with alkanethiolate ligands such as $[Fe_4S_4(S\text{-}t\text{-}Bu)_4]^{2-}$ and $[Fe_4S_4(SCH_2CH_2CO_2)_4]^{6-}$ are subject to hydrolysis reactions in an aqueous medium[28] makes it difficult to study on the redox behaviors of synthetic Fe_4S_4 clusters in water. In order to protect the present clusters $[Fe_4X_4(YR)_4]^{2-}$ (X, Y=S and Se; R=n-$C_{12}H_{25}$ and C_6H_4-p-t-Bu) from such a hydrolysis reaction, those clusters are solubilized in an aqueous Triton X-100 micellar solution. The high stability of those clusters in this medium was confirmed by their electronic absorption spectra showing no appreciable change for 4 h under N_2. It has been reported that various surfactants strongly adsorb on solid electrodes such as glassy carbon and platinum plates and almost completely inhibit a direct electron transfer between those electrodes and the electrochemically active species in aqueous micellar solutions.[29] On the other hand, cyclic voltammograms of $[Fe_4S_4(SC_6H_4\text{-}p\text{-}n\text{-}C_8H_{17})_4]^{2-}$ solubilized in aqueous micellar and vesicle solutions have been obtained successfully[22,30] by taking advantage of a strong affinity of sulfur for an Hg electrode.[31] In accordance with this, the cyclic voltammograms of $[Fe_4S_4(S\text{-}n\text{-}C_{12}H_{25})_4]^{2-}$ and $[Fe_4S_4(SC_6H_4\text{-}p\text{-}t\text{-}Bu)_4]^{2-}$ by the use of a hanging mercury drop electrode (HMDE) clearly show the (2−/3−) redox couple at $E_{1/2}$=−0.59 and −0.55 V vs. SCE, respectively, in aqueous Triton X-100 micellar solution at pH 7.0 (Fig. 1b and 1d). A large cathodic peak current compared with anodic one

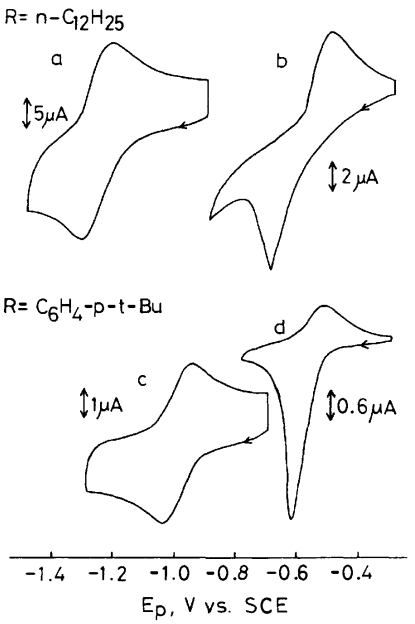

Fig. 1. Cyclic voltammograms of $[Fe_4S_4(SR)_4]^{2-}$ with a glassy carbon electrode in DMF (a, c) and with a hanging mercury drop electrode in aqueous Triton X-100 micellar solutions at pH 7.0 (b, d); scan rate 0.2 V s^{-1}.

of the $[Fe_4S_4(SR)_4]^{2-/3-}$ (R=n-$C_{12}H_{25}$ and C_6H_4-p-t-Bu) redox couple (Fig. 1b and 1d) suggests that adsorption of the oxidized cluster $[Fe_4S_4(SR)_4]^{2-}$ is stronger than that of the reduced species $[Fe_4S_4(SR)_4]^{3-}$ (R=n-$C_{12}H_{25}$ and C_6H_4-p-t-Bu) on the surface of an HMDE.[22,29,30] It has been shown that the adsorption of $[Fe_4S_4(SC_6H_4\text{-}p\text{-}n\text{-}C_8H_{17})_4]^{2-}$ on an Hg electrode causes the $E_{1/2}$ value of the cluster to shift cathodically by 80 mV compared with that of the free species in solutions.[30] Based on this fact, the $E_{1/2}$ values of $[Fe_4X_4(YR)_4]^{2-/3-}$ couple (X, Y=S and Se; R=n-$C_{12}H_{25}$ and C_6H_4-p-t-Bu) in aqueous Triton X-100 micellar solutions at pH 7.0 are considered to be shifted anodically by at least 150—780 mV compared with those in DMF and fall in the range −0.55 to −0.91 V vs. SCE at pH 7.0 (Table 1), which are compared to the redox potentials of 4-Fe (−0.52 to −0.67 V vs. SCE) and 8-Fe ferredoxins (−0.65 to −0.73 V vs. SCE) in water.[18] Thus, the redox potentials of Fe_4X_4 (X=S and Se) clusters are affected significantly by the extrinsic effect of the medium used.

Although the concentration of Triton X-100 (0.025—0.5 mol dm^{-3}) hardly influences the redox potentials of the present clusters, proton concentrations gave a significant effect on the redox potentials. Figure 2 shows the plots of the $E_{1/2}$ values of the present clusters vs. pH of aqueous Triton X-100 micellar solutions at 20 °C. The $E_{1/2}$ values of the $[Fe_4S_4(Y\text{-}n\text{-}C_{12}H_{25})_4]^{2-/3-}$ (Y=S (○) and Se (●) in Fig. 2a) and $[Fe_4Se_4(Y\text{-}n\text{-}C_{12}H_{25})_4]^{2-/3-}$ (Y=S (△) and Se (▲) in Fig. 2a) couples are shifted by about −55 mV/pH in the pH lower than ca. 9.0 and 7.7, respectively, while they remain constant in the pH higher than those values. Similarly, $[Fe_4S_4(YC_6H_4\text{-}p\text{-}t\text{-}Bu)_4]^{2-}$ (Y=S (○) and Se (●) in Fig. 2b) and $[Fe_4Se_4(YC_6H_4\text{-}p\text{-}t\text{-}Bu)_4]^{2-}$ (Y=S (△) and Se (▲) in Fig. 2b) display the same shifts of $E_{1/2}$ in the pH lower than ca. 8.5 and 7.3, respectively, and the $E_{1/2}$ values are constant in the pH higher than those values. The pH dependence of $E_{1/2}$ values (ca. −55.0 mV/pH) for the present clusters indicates that the redox-linked protonation of the clusters takes place and the resulting protonated cluster exists as an equilibrium mixture with unprotonated one. The electron density of $[Fe_4X_4(YR)_4]^{3-}$ (X, Y=S, Se; R=n-$C_{12}H_{25}$, C_6H_4-p-t-Bu) is apparently larger than that of $[Fe_4X_4(YR)_4]^{2-}$. The turning point of each plot in Fig. 2a and 2b, therefore, corresponds to the pK_a value of the reduced forms of the clusters, which is classified into four groups: ca. 9.0, 7.7, 8.5, and 7.3 for the $[Fe_4S_4(Y\text{-}n\text{-}C_{12}H_{25})_4]^{3-}$, $[Fe_4Se_4(Y\text{-}n\text{-}C_{12}H_{25})_4]^{3-}$, $[Fe_4S_4(YC_6H_4\text{-}p\text{-}t\text{-}Bu)_4]^{3-}$, and $[Fe_4Se_4(YC_6H_4\text{-}p\text{-}t\text{-}Bu)_4]^{3-}$ (Y=S and Se), respectively (Table 1). Thus, the pK_a values of the $[Fe_4X_4(YR)_4]^{3-}$ (X, Y=S and Se; R=n-$C_{12}H_{25}$ and C_6H_4-p-t-Bu) are controlled by the difference of the Fe_4S_4 and Fe_4Se_4 cores rather than that of the terminal sulfur and selenium atoms of the Y-n-$C_{12}H_{25}$ or YC_6H_4-p-t-Bu moiety. This result

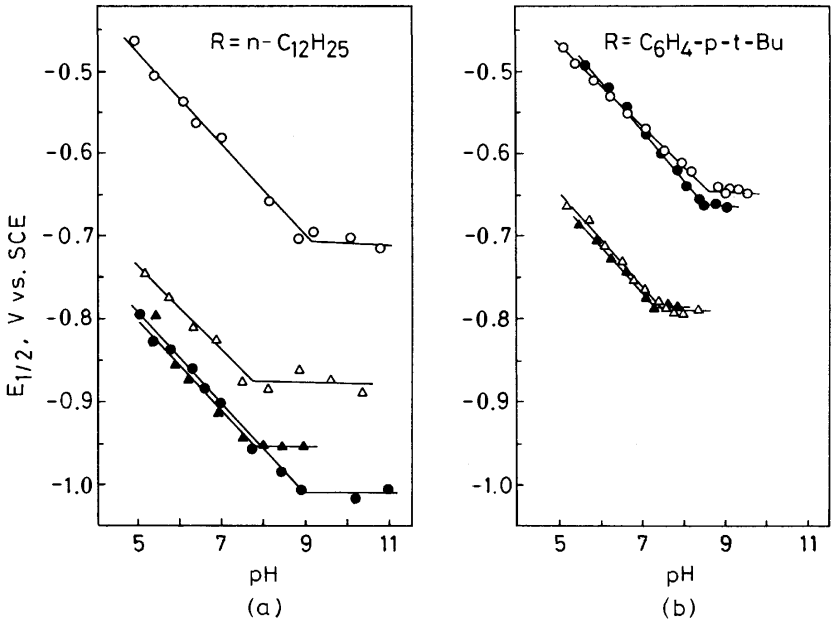

Fig. 2. Plots of the $E_{1/2}$ values of the $[Fe_4X_4(YR)_4]^{2-/3-}$ (R=n-$C_{12}H_{25}$ (a) and C_6H_4-p-t-Bu (b)) redox couples vs. pH in aqueous Triton X-100 micellar solutions at 20°C; X,Y=S,S (○); S,Se (●); Se,S (△); Se,Se (▲).

suggests that the present redox-linked protonation takes place at the sulfur or selenium atom of the Fe_4X_4 core (X=S and Se) of $[Fe_4X_4(YR)_4]^{3-}$ (X, Y=S and Se; R=n-$C_{12}H_{25}$ and C_6H_4-p-t-Bu).

Redox Behaviors of $[Fe_4X_3(YC_6H_4$-p-t-Bu$)_4]^{2-}$ (X, Y=S and Se) in an Aqueous Poly[2-(dimethylamino)-hexanamide] (PDACA) Solution. The preceding discussion reveals that the protonation of $[Fe_4X_4(YR)_4]^{3-}$ (X, Y=S and Se; R=n-$C_{12}H_{25}$ and C_6H_4-p-t-Bu) in aqueous Triton X-100 micellar solutions takes place at the sulfur or selenium atom of the Fe_4X_4 (X=S and Se) core. The hydrophobic sphere of a nonionic Triton X-100 micelle is, however, apparently different from the environments formed by polypeptide chains of 4-Fe ferredoxins, which may be stabilized by hydrogen bondings between amide protons of peptide chains and terminal and/or core sulfur atoms. In order to introduce amide groups around the Fe_4S_4 core in a model system, poly[2-(dimethylamino)hexanamide] (PDACA) involving both amide and amino groups in the polymer chains was employed for solubilizing the clusters in aqueous solutions. The

PDACA: $-(-NHCH_2CH_2CH_2CH_2CHCO-)_n$ with $N(CH_3)_2$ on the CH

electronic absorption spectrum of $[Fe_4S_4(S$-n-$C_{12}H_{25})_4]^{2-}$ in an aqueous PDACA solution (pH 7.0), however, showed a decrease of the absorption maximum at 420 nm with a half-life $t_{1/2}=1.3\times10^3$ s at 20 °C, suggesting that $[Fe_4S_4(S$-n-$C_{12}H_{25})_4]^{2-}$ slowly undergoes a hydrolysis reaction in this medium. On the other hand, the cluster in the Triton X-100 micellar solution exhibited no spectral change for 4 h under N_2. Such a difference may result from a strong hydrophobicity of Triton X-100 micelle compared with an aqueous PDACA solution. The hydrolysis of $[Fe_4S_4(S$-n-$C_{12}H_{25})_4]^{2-}$ in an aqueous PDACA solution may result in a dissociation of the terminal ligand, which is adsorbed strongly on an HMDE.[31] In fact, the cyclic voltammogram of $[Fe_4S_4(S$-n-$C_{12}H_{25})_4]^{2-}$ in an aqueous PDACA solution at pH 7.0 showed a pair of cathodic and anodic waves at $E_{pc}=-0.63$ V and $E_{pa}=-0.56$ V vs. SCE, respectively, which are consistent not only with the peak potentials but also with the appearance of those of S-n-$C_{12}H_{25}^-$ (n-Bu_4N^+ salt) in the same medium. Similarly, the redox waves due to S-n-$C_{12}H_{25}^-$ or Se-n-$C_{12}H_{25}^-$ were observed in the cyclic voltammograms of other three clusters in aqueous PDACA solutions. Thus, the 1-dodecanethiolate and -selenolate ligated clusters $[Fe_4X_4(Y$-n-$C_{12}H_{25})_4]^{2-}$ (X, Y=S and Se) undergo the ligand dissociation in aqueous PDACA solutions.

In contrast to the lability of $[Fe_4X_4(Y$-n-$C_{12}H_{25})_4]^{2-}$ in aqueous PDACA solution, $[Fe_4X_4(YC_6H_4$-p-t-Bu$)_4]^{2-}$ (X, Y=S and Se) is fairly stable in this medium, since the electronic absorption spectra of the latter except for $[Fe_4Se_4(SeC_6H_4$-p-t-Bu$)_4]^{2-}$ [32] in an aqueous PDACA solution (pH 7.0) were almost unchanged for 6 h. In fact, $[Fe_4X_4(YC_6H_4$-p-t-Bu$)_4]^{2-}$ (X, Y=S and Se) in aqueous PDACA solution at pH 7.0 exhibit each redox couple arising from the cluster ($E_{1/2}=-0.57$ for

X, Y=S, S; −0.56 for X, Y=S, Se; −0.79 for X, Y=Se, S; −0.77 V vs. SCE for X, Y=Se, Se), and the redox couple neither of SC_6H_4-*p*-*t*-Bu$^-$ (E_{pc}=−0.70 and E_{pa}=−0.60 V) nor of SeC_6H_4-*p*-*t*-Bu$^-$ (E_{pc}=−1.01 and E_{pa}=−0.89 V vs. SCE) was observed, indicating that $[Fe_4X_4(YC_6H_4\text{-}p\text{-}t\text{-}Bu)_4]^{2-}$ (X, Y=S and Se) undergoes one-electron redox reaction in aqueous PDACA solution without dissociation of the YC_6H_4-*p*-*t*-Bu$^-$ ligand at pH 7.0. Moreover, the cyclic voltammograms of those clusters obtained even after applying the electrode potential at −1.00 V vs. SCE for 5 min exhibited only the redox waves of those clusters. The electrochemical study on the clusters in aqueous PDACA solutions, therefore, is restricted to $[Fe_4X_4(YC_6H_4\text{-}p\text{-}t\text{-}Bu)_4]^{2-}$ (X, Y=S and Se) in the present study.

The $E_{1/2}$ values of the $[Fe_4X_4(YC_6H_4\text{-}p\text{-}t\text{-}Bu)_4]^{2-/3-}$ redox couples at various pH are depicted in Fig. 3, which reveals that all the $E_{1/2}$ values for X, Y=S and Se are shifted cathodically in linear fashion with increasing the pH value in the intermediate pH range,

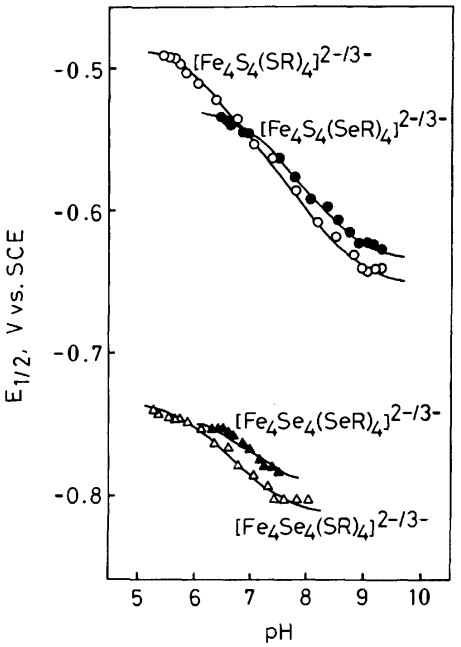

Fig. 3. Plots of the $E_{1/2}$ values of the $[Fe_4X_4(YR)_4]^{2-/3-}$ (R=C_6H_4-*p*-*t*-Bu) redox couples in aqueous PDACA solutions vs. pH at 10°C; X,Y=S,S (○); S,Se (●); Se,S (△); Se,Se (▲).

being similar to those in aqueous Triton X-100 micellar solutions, while the values are likely to show a tendency to level off from each linear relation not only in alkaline but also in acidic sides.[33] Such characteristic pH dependence of the $E_{1/2}$ value may be interpreted in terms of protonation/deprotonation equilibria of the oxidized clusters $[Fe_4X_4(YC_6H_4\text{-}p\text{-}t\text{-}Bu)_4]^{2-}$ as well as of the reduced species $[Fe_4X_4(YC_6H_4\text{-}p\text{-}t\text{-}Bu)_4]^{3-}$ (X, Y=S and Se) in aqueous PDACA solutions, as shown in Scheme 1, where K_{ox} and K_{red} are the acid dissociation constants of the protonated species $[Fe_4X_4(YR)_4H]^-$ and $[Fe_4X_4(YR)_4H]^{2-}$ (X, Y=S and Se; R=C_6H_4-*p*-*t*-Bu), respectively, as expressed by Eqs. 1 and 2, and

$$K_{ox} = \frac{[[Fe_4X_4(YR)_4]^{2-}][H^+]}{[[Fe_4X_4(YR)_4H]^-]} \quad (1)$$

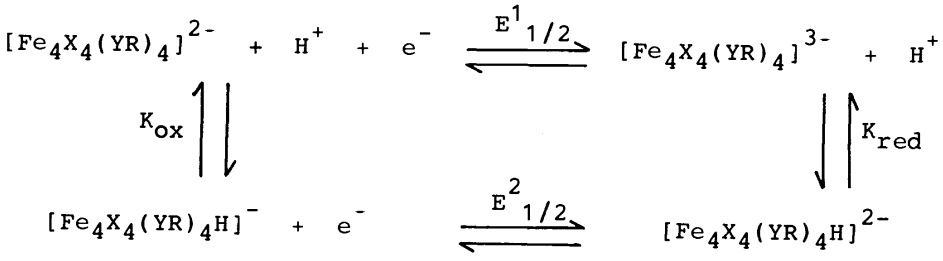
$$K_{red} = \frac{[[Fe_4X_4(YR)_4]^{3-}][H^+]}{[[Fe_4X_4(YR)_4H]^{2-}]} \quad (2)$$

$E^1_{1/2}$ and $E^2_{1/2}$ are the half-wave potentials of the redox couples of unprotonated and protonated species, respectively. The half-wave potential $E_{1/2}$ for the overall electrode reaction, therefore, can be written as Eq. 3 or 4,[34,35] where R, T, and F are the gas constant,

$$E_{1/2} = E^1_{1/2} + \frac{RT}{F}\ln\frac{K_{ox}(K_{red} + [H^+])}{K_{red}(K_{ox} + [H^+])} \quad (3)$$

$$E_{1/2} = E^2_{1/2} + \frac{RT}{F}\ln\frac{K_{red} + [H^+]}{K_{ox} + [H^+]} \quad (4)$$

temperature, and the Faraday constant, respectively. An anodic shift of $E_{1/2}$ values with increasing the proton concentration (Fig. 3) suggests that the K_{ox} value is larger than the K_{red} value (Eq. 3). Therefore, $E_{1/2}$ approaches to $E^1_{1/2}$ (Eq. 3) and $E^2_{1/2}$ (Eq. 4) under the proton concentrations being $[H^+] \ll K_{red}$ (Eq. 3) and $[H^+] \gg K_{ox}$ (Eq. 4), respectively. Thus, the redox potential $E_{1/2}$ of $[Fe_4X_4(YC_6H_4\text{-}p\text{-}t\text{-}Bu)_4]^{2-/3-}$ (X, Y=S and Se) in aqueous PDACA solution may be leveled off both in acidic and in alkaline regions (Fig. 3). Computer simulation curves of the $E_{1/2}$ value using Eq. 3 or 4 with the pK_{red}, pK_{ox}, and $E^1_{1/2}$ or $E^2_{1/2}$ values listed in Table 2 give reasonable agreement with the observed $E_{1/2}$ values of those clusters,[36] as shown by solid lines in Fig. 3.



Scheme 1. R=C_6H_4-*p*-*t*-Bu.

Table 2. pK Values of the Oxidized and Reduced Clusters in Aqueous PDACA Solution

Cluster	pK_{ox}	pK_{red}[a]	$E^1_{1/2}$[b]	$E^2_{1/2}$[b]
$[Fe_4S_4(SC_6H_4$-p-t-$Bu)_4]^{2-}$	5.85	8.80	−0.650	−0.484
$[Fe_4S_4(SeC_6H_4$-p-t-$Bu)_4]^{2-}$	6.90	8.80	−0.632	−0.526
$[Fe_4Se_4(SC_6H_4$-p-t-$Bu)_4]^{2-}$	5.85	7.30	−0.811	−0.732
$[Fe_4Se_4(SeC_6H_4$-p-t-$Bu)_4]^{2-}$	6.70	7.30	−0.795	−0.744

a) Values for the 3− species. b) Values for the 2−/3− couple.

The pK_{red} values of $[Fe_4X_4(YC_6H_4$-p-t-$Bu)_4]^{3-}$ (Table 2) obtained from the simulation are devided into two groups; 8.8 for X=S and 7.3 for X=Se, where Y=S and Se. The close similarity of the pK_{red} values of the clusters with Fe_4S_4 and Fe_4Se_4 cores in an aqueous PDACA solution to the pK_a values of those in an aqueous Triton X-100 micellar solution also supports the view that the pK_a values in Triton X-100 micellar solutions are associated with the proton dissociation constants of the reduced species of the clusters. Thus, the protonation of the reduced clusters takes place at the sulfur or selenium of the Fe_4X_4 core (X=S and Se) both in aqueous Triton X-100 micellar and in aqueous PDACA solutions. On the other hand, the pK_{ox} values of $[Fe_4X_4(YC_6H_4$-p-t-$Bu)_4]^{2-}$ (Table 2) are devided into two group; 5.85 for $[Fe_4X_4(SC_6H_4$-p-t-$Bu)_4]^{2-}$ and 6.8±0.1 for $[Fe_4X_4(SeC_6H_4$-p-t-$Bu)_4]^{2-}$ (X=S and Se). This behavior indicates that pK_{ox} values are controlled by the terminal sulfur and selenium atoms in contrast to pK_{red} which depends on the core sulfur or selenium atom. Thus, the protonation of the oxidized clusters $[Fe_4X_4(YC_6H_4$-p-t-$Bu)_4]^{2-}$ (X, Y=S and Se) takes place at the terminal sulfur or selenium atoms in aqueous PDACA solutions. These results lead us to the conclusion that the basicities of the terminal sulfur and selenium in the oxidized clusters may be stronger than those of the core sulfur and selenium atoms, while in the reduced cluster, the basicities may be opposite; the core sulfur and selenium atoms stronger than the terminal those atoms.

32) The electronic absorption spectrum of $[Fe_4Se_4(SeC_6H_4\text{-}p\text{-}t\text{-}Bu)_4]^{2-}$ in aqueous PDACA showed the 76% decrease of the absorptivity of the CT band at 490 nm for 6 h.

33) The cyclic voltammogram of $[Fe_4X_4(YC_6H_4\text{-}p\text{-}t\text{-}Bu)_4]^{2-}$ (X, Y=S and Se) exhibits only a (2−/3−) redox couple in the intermediate pH range (Fig. 3). When pH is higher than ca. 7.3 or 8.8 and lower than ca. 5.9 or 6.8, however, a new redox couple due to free $YC_6H_4\text{-}p\text{-}t\text{-}Bu^-$ (Y=S and Se) appeared besides a redox couple of the clusters, suggesting the partial dissociation of $YC_6H_4\text{-}p\text{-}t\text{-}Bu^-$ (Y=S and Se) in the pH range higher than ca. 7.3 or 8.8 and lower than ca. 5.9 or 6.8 in the PDACA solution.

36) The $E_{1/2}$ value of the $[Fe_4Se_4(SeC_6H_4\text{-}p\text{-}t\text{-}Bu)_4]^{2-/3-}$ couple observed in acid and alkaline regions is slightly deviated from computer simulation curves of the $E_{1/2}$ value, which may be due to the instability of the Fe_4Se_4 cluster with selenolate ligands, as described elsewhere.[9,32]

Ion-Solvent Interaction of Amino Acids. The Role of the "Zwitterionic" and the "Ionic" Forms in the Modification of Water Structure over the Temperature Range 25—45 °C

Moni Mohan Bhattacharyya and Mihir Sengupta*
Department of Chemistry, University College of Science, Calcutta 700 009, India
(Received October 2, 1987)

Viscosities and densities of aqueous glycine, glycinium chloride, sodium glycinate, betaine, betainium chloride [$(CH_3)_3\overset{+}{N}CH_2COOH \cdot Cl^-$], and tetramethylammonium bromide solutions have been measured at 25, 30, and 40 °C over the concentration range 0.01 to 0.1 M. The sequence of the viscosity B-coefficient values obtained is in the order: $B_{anion} > B_{cation} > B_{zwitterion}$ for the glycine and betaine systems. The comparatively higher structure promoting behavior of the anion has been discussed in terms of the charge delocalization effect. Apparent molal volumes at infinite dilution have also been calculated, and the ratio B/ϕ_v° furnishes important information about the nature of solvation around the ion. The present study indicates that in the betaine molecule, the opposing nature of ion-water interaction at the two charge centers renders the system neither a "structure maker" nor a "breaker" in aqueous solution.

In an earlier communication[1] viscosity studies on amino acids at different pH's in presence of free acids and alkalis, and at different temperatures have been reported. It was found that the viscosity data of amino acids in the acidic and basic solutions used could not be processed properly using the Jones-Dole equation[2]

$$\eta/\eta_0 = 1 + A\sqrt{c} + Bc, \quad (1)$$

as unreasonable negative A coefficient values, together with B-values with large standard deviations, were obtained. Instead, the use of the following equation, generally obeyed by uncharged molecules and neutral (zwitterionic) amino acids,[3] viz.

$$\eta/\eta_0 = 1 + Bc \quad (2)$$

was found to be more satisfactory. The B-coefficient values obtained from the above two equations are of course not the same, and in fact significant differences were observed.[3]

For a dilute solution of spherical particles, the Einstein equation[4] $\eta/\eta_0 = 1 + 2.5\theta$, ($\theta$=solute volume fraction) when combined with Eq. 2 gives the hydrodynamic volume per mole (V_h) of the (solute) particles, which tend to rotate in the fluid streamlines:

$$B = 2.5\, V_h \times 10^{-3} \quad (3)$$

For ellipsoidal particles at low concentrations a more general expression for V_h may also be derived:[5]

$$B = k\, V_h \times 10^{-3} \quad (4)$$

where k is a shape factor, being equal to 2.5 for spherical molecules. Since the apparent molal volume at infinite dilution: ϕ_v° ($=\overline{V}^\circ$) and V_h are approximately equal, the magnitude of the ratio B/ϕ_v° is expected to offer valuable information about the nature of interaction of solute molecules with the solvent.

Both neutral glycine and tetramethylammonium ion are the lowest members in the respective series of compounds, and also are well-known structure breakers[3,6] in aqueous solutions due to the presence of peripheral charge. It is interesting to investigate how these moieties, when conjoined in the form of a single molecule (e.g., in betaine) interact with the solvent water. The study of betaine and its homologues is also important in view of the current interest[7] in the potential utilization of their surfactant properties for tertiary oil recovery. Further, the purpose of the present work is also to investigate the comparative applicability of the Jones-Dole equation (Eq. 1) or Eq. 2, using amino acid salts in water only, instead of in acids or alkalis as done earlier,[1] and also the effects of the "zwitterionic" and the "ionic" form surface charges on the solvent water while either keeping unaltered, or else altering suitably, the size of the solute molecule.

With these objects in view, we have measured the viscosities of solutions of glycine, glycinium chloride, sodium glycinate, tetramethylammonium bromide, betaine, and betainium chloride, at three different temperatures over the range 25—40 °C. For betaine solutions measurements were also made at two other temperatures (35 and 45 °C). The density measurements enable the calculation of the apparent molal volumes directly, which further enables us to study the ion-solvent interactions from the complementary view points of viscosity and apparent molal volume.

Experimental

Glycine used was medicinal grade (E. Merck) and was purified as described earlier.[1] Sodium glycinate and glycinium chloride were prepared by mixing equivalent amounts of glycine and the corresponding alkali or acid as required. Betaine was obtained from betaine monohydrate (Fluka, Purum) by dissolving in hot absolute ethanol and precipitating white anhydrous betaine by adding anhydrous ether;[5] it was dried in vacuo at 100 °C, and stored in a desiccator under a reduced pressure. Betainium chloride (B.D.H.) was purified by precipitating from a saturated aqueous solution with ethyl alcohol.[8] It was dried at 110 °C for a few hours and stored in a desiccator. Tetramethylam-

Tetramethylammonium bromide			

monium bromide was purified as described earlier.[9] All the amino acids and their salts were dried at 100 °C for about two hours before being dissolved in redistilled water (from an all Pyrex still), and the solutions were prepared and dilutions made on molal basis.

Details of the method of viscosity measurement have been described earlier.[1] The densities were measured in a 30 cm^3 Sprengel type bicapillary pycnometer, fitted with ground glass caps, and are precise to $\pm10^{-5}$ g cm^{-3} (bouyancy corrections not made). A constant temperature bath, controlled to within ±0.005 °C was used. The literature values[10] of the density of water used in the calculations were 0.99707, 0.99568, 0.99406, 0.99220, and 0.99024 g cm^{-3} at 25, 30, 35, 40, and 45 °C, respectively. The viscosity and density data at different concentrations and at different temperatures are recorded in Table 1.

Calculations and Results. For the computerised least squares analysis of the viscosity data of glycine and betaine Eq. 2 was used, whereas for the salt forms of the amino acids both Eqs. 1 and 2 were tried. In the case of the salts, the acceptable positive values of the intercepts as also B-values with comparatively smaller standard deviations obtained, showed the better applicability of the Jones-Dole equation (Eq. 1) rather than Eq. 2 in contrast to the earlier finding.[1] The B and A-values thus obtained, at different temperatures, are recorded in Table 2 (together with the s.d. of fit only).

The apparent molal volumes were calculated from the density data by the use of the usual equation $\phi_v=\frac{1}{m}[(1000+mM_2)/\rho_m-(1000/\rho_o)]$; the values at infinite dilution for the salts were obtained from a least-squares fit of the Redlich-Meyer equation[11]

$$\phi_v - S_v\sqrt{c} = \phi_v^\circ + hC \qquad (5)$$

where h is an empirical constant, and S_v the Debye-Hückel limiting slope, the different values of which at the different temperatures were taken from literature.[11] The "hydrolysis effect" corrections[12] for the ϕ_v values have been made, but

Table 3. ϕ_v° Values ($cm^3 mol^{-1}$) at Different Temperature

System	25 °C	30 °C	35 °C	40 °C	45 °C

System	40 °C B_{ion} / kg mol^{-1}	40 °C $\phi_{v(ion)}^\circ$ / cm^3 mol^{-1}	B/ϕ_v°
Glycinium chloride	0.145	44	3.3
Sodium glycinate	0.235		
Betaine hydrochloride	0.221	101	2.2
Tetramethylammonium bromide		87	
Betaine			2.2
Glycine			3.4

the correction for the "dissociation effect" was found to be negligibly small (<1 $cm^3 mol^{-1}$).[12] The ϕ_v values for the neutral amino acids were analyzed according to the equation:

$$\phi_v = \phi_v^\circ + aC \quad (6)$$

where a is an empirical constant. The ϕ_v° values for all the systems mentioned are shown in Table 3. Both B and ϕ_v° values for the salts of amino acids have been further reduced to the corresponding ionic values, and then the ratio B/ϕ_v° for the ions calculated for different temperatures; these are incorporated in Table 4.

Discussion

A comparison of the B-value of glycine at 25 °C (0.132)† with literature data shows that our value is slightly lower than that reported by Devine and Lowe[3] (0.143) and Mason and Kampmeyer[13] (0.142), but is close to that reported by Tsangaris and Martin[8] and Tyrrell and Kennerly[5] when these values are extrapolated to 25 °C. Our earlier found value for glycine at 40 °C also agreed well with that reported by Tsangaris and Martin.[8] Both the latter two groups of workers reported B-values for betaine which are significantly different from each other, the present value at 25 °C (0.226) is close to the extrapolated value (0.224) for the same system reported by Tyrrell and Kennerley.[5] The B-value of tetramethylammonium bromide at 25 °C agrees with that reported by Kay et al.[14] Tsangaris and Martin's reported B-value for glycinium chloride at 40 °C (0.15)[8] agrees satisfactorily with ours (0.152), but their own calculated B-value for betainium chloride at 16 °C (−0.06) from the data procured from other sources seems to be in error, and thus largely disagrees with the present value (0.236 at 25 °C).

The ϕ_v° value for betaine at 25 °C (100) is consistent with the value reported by Tyrrell and Kennerley[5] at 20 °C (98.4 $cm^3 mol^{-1}$). Our ϕ_v° values for glycinium chloride and sodium glycinate at 25 °C (66 and 40 cm^3 respectively) are slightly lower than those reported by Shahidi[12] for the same systems (67.22 and 42.81 respectively).

The earlier found better suitability of Eq. 2 (valid for uncharged species in solution) for reproducing the concentration variation of the viscosity of amino acids in acidic or alkaline medium was suprising, because amino acids are known to be present in such solutions rather as salts. The said experimental observation was also apparently justified on the basis of theoretical calculations according to the Fuoss–Onsager theory[15] of mixed electrolyte solutions, which showed that the

† All B values expressed in kg mol^{-1} units.

net electrostatic contribution part: $(A_{mix}-A_{HCl\ or\ NaOH})\sqrt{I}$ out of the total relative viscosity value, was negligibly small, thereby apparently rendering redundant the applicability of the Jones–Dole equation (Eq. 1). In the present more comprehensive investigation where purely aqueous solutions of salts of different amino acids of varying cationic and anionic sizes were taken, the experimental results at all the temperatures have convincingly shown the better applicability of Eq. 1 rather.

The observed sequence of *B*-coefficient values for the present systems is: $B_{anion}>B_{cation}>B_{zwitterion}$, which was also obtained by Tsangaris and Martin[8] for the glycine system. However, for the betaine system, they reported a different sequence, i.e., $B_{zwitterion}>B_{cation}$, which is quite at variance with the observation in the present case. As mentioned, their reported negative value for betainium chloride at 16 °C appears unacceptable.

The ionisation of glycine is as follows:

$$^{+}NH_3CH_2COOH \underset{}{\overset{+H^+}{\rightleftharpoons}} {}^{+}NH_3CH_2COO^- \overset{+OH^-}{\rightleftharpoons} NH_2CH_2COO^- + H_2O$$

The different *B*-values obtained for the three different ionic species, having almost identical sizes and structures, indicate substantially different types of solvent–solute interactions, due entirely to the varying nature of charge on the three molecules. The high *B* value of the glycinate anion clearly points to extra structure promotion by this ion. This type of structure enhancement was also observed by Laurence and Wolfenden[16] for the acetate anion (B_{HAc}=0.117 and B_{Ac^-}=0.245). The glycinate ion being essentially the amino acetate ion, the exactly similar observation here is quite in order. The fact that the acetate anion is stabilized by the extremely effective delocalization of charge between the two canonical structures of identical energy involved, accounts for the extra order produced by this ion, compared to the zwitterion or acetic acid. By contrast, for the glycinium cation any such delocalization effect would be much less effective because it would first involve a separation of charge in the COOH group; this is seen reflected in the lower value of *B*-coefficient for this cation.††

The simultaneous presence of the two charge centers in the zwitterion makes it a unique system, as is seen from the abrupt reduction of *B*-coefficient value compared to either of the two ionic forms. An exactly similar situation arises also in the case of the $\overline{V}^\circ$ values of the dipolar ions. In the zwitterionic glycine system, the electron-withdrawing inductive effect[19] of the NH_3^+ from the acetate anion largely reduces the availability of the negative charge at the other end, thereby resulting in a net reduction of both the *B*-coefficient and $\overline{V}^\circ$ values.

The temperature coefficient of the *B*-value of glycine is positive, while that for both glycinate and glycinium ions are negative, thus indicating the latter two to be net structure makers in water, over the temperature range investigated. Both the ions are therefore solvated to some extent, and definitely have their primary solvation sheath.

In the context of the above discussion, the betaine system appears to be very interesting. The betaine molecule is obtained by substituting the three hydrogen atoms of the charged nitrogen atom by methyl groups, the result of which is faithfully reflected in the higher *B*-coefficient value (Einstein volume effect). The comparatively slightly higher value of *B*-coefficient of the betaine cation ($(CH_3)_3\overset{+}{N}CH_2COOH$) as compared to that for betaine itself, may be due to the same reason as mentioned earlier in the case of the glycinium cation.

The temperature coefficient of the *B*-value of betaine better reflects its structural interaction with the solvent than does the *B*-coefficient value itself. The *B* value remains almost unchanged over the temperature range (25—45 °C) investigated; this was also observed by Tyrrell and Kennerley over the range 5—20 °C (whose results are consistent with ours). By introducing three methyl groups at the charged nitrogen atom of the glycine molecule, this part of the betaine molecule virtually becomes a tetramethylammonium moiety. It therefore appears that in betaine, the extent of structure breaking by the "tetramethyl" moiety and structure making by the acetate moiety within the molecule are evenly balanced, therefore rendering the betaine molecule neither a "maker" nor a "breaker" in the solvent at all the temperatures.

The temperature coefficient of betaine cation is also negative, making it a structure maker like the glycinium cation. In both these molecular ions, the localized positive charge facilitates the separation of proton on the other end through the inductive effect, and therefore, not as much available at the periphery of the molecule as in the tetramethylammonium ion, thus causing it to behave like a structure maker.

The B/ϕ_v° values are important indicators[5] as to whether a particular solute is solvated or unsolvated, since a value between 0 and 2.5 points to unsolvated species, and any higher value to solvated ones. Based upon this criterion, the tetramethylammonium and betaine systems fall in the "unsolvated" category, whereas the glycinium, glycinate, and glycine are well

†† Nightingale[17] also explained the higher *B*-value of the iodate ion in comparison to that of the periodate ion, as due to the more effective delocalization of charge by the oxygen atoms in the former, thus permitting more extensive interaction with the solvent. Were localization of charge the more effective solvent puller (than the charge-delocalization effect) for such larger molecular ions, as observed by Gurney,[18] glycinium cation or periodate ion would give rise to higher *B*-values.

within the "solvated" class having definite primary solvation sheaths. Tyrrell and Kennerley[5] also observed similar interaction with the solvent for the glycine, tetramethylammonium, and betaine systems. The high value of B/ϕ_v°, together with the very low value of ϕ_v° for the glycinate anion, clearly indicates that this system interacts much more strongly with the solvent molecules, as compared to either the glycine or glycinium systems.

The betaine cation seems to have a primary solvation sheath, as is also evident from the negative temperature dependence of B/ϕ_v° value. The peculiar behavior of betaine is also reflected in the value of B/ϕ_v° and its temperature invariance. The fact that the ϕ_v values of betaine decrease with concentration at all temperatures is another point of departure from the common trend shown by amino acids. This type of concentration dependence was also noted by Tyrrell and Kennerley[5] for the same system, and by Wen and Saito[20] for the larger tetraalkylammonium bromide system. The explanation furnished for the latter was that when the cosphere of the bromide ion interacts with that of the tetraalkylammonium cation, there results a negative contribution to the partial molal volume. It is highly probable that in the betaine system a similar interaction between the hydration spheres of the tetramethylammonium and the "acetate" moieties takes place, resulting in a diminution of apparent molal volumes.

Extraction-Spectrophotometric Determination of Pd(II) with 4-(3,5-Dichloro-2-pyridylazo)-1,3-diaminobenzene and Trichloroacetate. I

C. A. Fontán,* (the late) C. B. Marone, and R. Olsina
Departamento de Química Analítica "Dr. Carlos B. Marone"
Universidad Nacional de San Luis, Argentina
(Received April 11, 1987)

In acid acqueous ethanol solutions Pd(II) reacts with 4-(3,5-dichloro-2-pyridylazo)-1,3-diaminobenzene (3,5-Cl2PADAB=L) making up three colored complex species. The three complexes have a 1:1 metal-ligand molar ratio and they differ from each other only in their protonation degree. In solutions with H_2SO_4 or $HClO_4$ concentrations higher than 10 or 8 M, respectively, the complex species is yellow, and in less acid solutions (pH 0.80 to 2 M H_2SO_4 or pH 0.8 to 3 M $HClO_4$ range) it changes in a reversible way to a violet color while its intensity increases (molar absorptivity 8.2×10^4 $dm^3\,mol^{-1}\,cm^{-1}$ at 588 nm and 5.2×10^4 $dm^3\,mol^{-1}\,cm^{-1}$ at 545 nm). The red purple complex formed in the pH range 3—4 are insoluble in 10% (v/v) ethanol-water solutions. The complex species were given the formulation $PdH_nL^{(n+2)+}$ ($n>1$) ($H_2SO_4>10$ M, or $HClO_4>8$ M), $PdHL^{3+}$ (pH 0.8 to 2 M H_2SO_4 or pH 0.8 to 3 M $HClO_4$ range) and PdL^{2+} (pH 3—4), and the existence of one or another depends exclusively upon the acidity of the reaction medium. In 10% (v/v) ethanol-water solutions acidified with H_2SO_4 or $HClO_4$, only the last two species are extracted into benzene as $PdL^{2+}\cdot(TCA^-)_2$ and $PdHL^{3+}(TCA^-)_3$ (TCA^-=trichloroacetate) ion-associations. The composition of the complexes formed in aqueous solutions was estimated by the composition of the ion-association complexes transferred to the organic phase.

4-2(-Pyridylazo)-1,3-diaminobenzene (PADAB), 5-(2-pyridylazo)-2,4-diaminotoluene (PADAT) and its halogen-substituted compounds constitute a relatively new type of *o*-amino azo analytical reagents. All of them react chromatically only with a few metallic ions (Co(II), Pd(II), Zn(II), Cu(II), Au(III), Fe(II), Fe(III), Ni(II), and Ag(I)). Several of them have been used for the spectrophotometric determination of Co(II)[1–6] and Pd(II).[7–13] Cobalt(II) reacts with these reagents to form CoL_2 complexes (pH range 3—11) which are changed into other deeply colored monoprotonated and diprotonated complexes by the addition of hydrochloric or other mineral acids. The CoL_2 complexes,[3] or their ion-association species formed with a suitable organic base, can be extracted into an organic solvent.[3,14]

In the course of a systematic investigation on the reaction between one of these pyridylazo reagents, 3,5-Cl2PADAB, and Pd(II),[12] and on the extraction of the complexes formed, we have found that the behavior of the Pd(II)–3,5-Cl2PADAB complexes resembles those of Co(II).

As we have not found detailed information about the reaction between Pd(II) and this type of reagents, this work is devoted to elucidate the mechanisms of formation of the Pd(II)–3,5-Cl2PADAB complexes and their extraction as ion-association species formed with trichloroacetate.

Bearing in mind that in the search of new sensitive and selective chromogenic reagents, a full knowledge of the reactions involved in the formation and extraction of metallic complexes yields important information, which can be used as the basis for the development of new spectrophotometric methods.

Experimental

Apparatus. pH was measured on a digital Orion Mod. 701-A pH-meter provided with a glass/Ag–AgCl combination electrode. Both absorbance measurements and spectral recordings were carried out on a Varian Mod. 634-UV spectrometer equipped with 10-mm glass cells.

For the extractions, 100×35 mm "Pyrex"-type glass tubes with polyethylene stoppers were used. Equilibrations were carried out by mechanical shaking of the tubes with longitudinal desplacements of 35—40 mm and a rate of 300 fluctuations per minute. Temperature was kept at 20±0.5 °C.

Reagents. 3,5-Cl2PADAB Solutions: The synthesis of the reagent was described earlier.[12] A 1×10^{-3} M solution (1 M=1 mol dm^{-3}) was prepared in 96% pure ethanol by using a purified and solid reagent. Other solutions having the concentration required for each particular test were prepared by means of dilutions, with the same solvent, of that solution.

Pd(II) Standard Solution (5×10^{-3} M). $Pd(NO_3)_2\cdot2H_2O$ (0.2665 g) was dissolved in 50 cm^3 of (4+6) H_2SO_4. The solution was heated to guarantee complete dissolution. Once cold, it was put in a volumetric flask and distilled water was added up to 200 cm^3. The effective concentration of the metal was complexometrically determined.[15] More diluted solutions were daily prepared from the previous one. Pd(II) solutions remain unaltered during 5 days if kept in glass vessels.

Trichloroacetic Acid (HTCA) Solution. The acid solution (500 cm^3, 5 M) was prepared from the solid drug. The exact content of the trichloroacetic acid was alkalimetrically determined on aliquot portions of the previous solution.[16]

General Procedures. Color Development. Aliquots of conveniently diluted Pd(II) solutions were diluted with distilled water up to about 15 cm^3. Acidity was adjusted to the value required for each test by adding concentrated

H_2SO_4 or $HClO_4$. When the medium acidity corresponded to the pH values higher than 0, the concentration of Na_2SO_4 or $NaClO_4$ was kept at 1 or 2 M, respectively. In these cases the pH of the solutions was adjusted at the required values by the addition of the diluted solution of H_2SO_4, $HClO_4$, or NaOH. The solutions were transferred to 25 cm^3 volumetric flasks, and 2.5 cm^3 of the ethanolic solution of the reagent were added. The absorbance of the solutions, as well as the absorption spectra of the solutes dissolved in them, were recorded when the color of each test reached its maximum insensity and remained, at least for ten minutes, unchanged.

Extractions. The complexation reactions were promoted on Pd(II) solutions (10—15 cm^3), put in extractions tubes and conditioned in the above-described way. The total initial HTCA concentration was kept constant at 1 M in all tests. Once the complexation was finished, a volume of pure benzene equal to that of the aqueous solution contained in the tubes was added, and the whole was mechanically shaken from 40min to 1 h. Then the organic phases were transferred to 25 cm^3 dried volumetric flask. The aqueous phases were washed twice, each time with 3 cm^3 portions of pure benzene, and the washing liquids were put together with the bulk of each benzenic extract, adding, in the end, benzene until completing 25 cm^3. After reaching the equilibrium, the pH of the aqueous phases was potentiometrically measured. The percentage of palladium extracted was spectrophotometrically determined by using 3,5-Cl2PADAB as chromogenic reagent.

Results and Discussion

In a previous paper,[12] we showed that in aqueous ethanol solutions Pd(II) reacts slowly with 3,5-Cl2PADAB in a wide range of concentrations of H_2SO_4 or $HClO_4$. The spectra of the palladium(II) chelates were measured for the 10% (v/v) ethanol-water solutions containing various concentrations of the components at different acidity conditions.

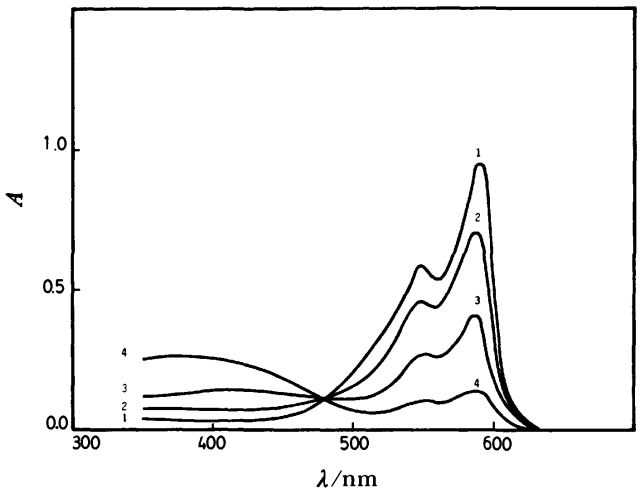

Fig. 1. Absorption spectra of Pd(II)-3,5-Cl2PADAB complexes in aqueous ethanol acid solution with 1.20×10^{-5} M reagent. Sulfuric acid concentration: (1) 2 M; (2) 7 M; (3) 8.30 M; (4) 9.80 M. Ethanol 10% (v/v).

Figures 1 and 2 show the absorption spectra of a mixture containing an excess of Pd(II) compared with 3,5-Cl2PADAB. The wavelength of maximum absorbance and intensities at the maxima (Table 1) remained without changes for mixtures containing a 10 mole

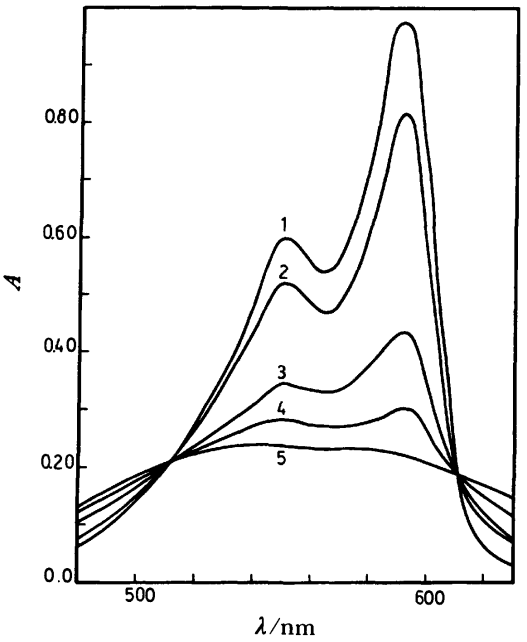

Fig. 2. Absorption spectra of Pd(II)-3,5-Cl2PADAB complexes in aqueous ethanol acid solution. Reagent, Pd(II) and ethanol concentrations as for Fig. 1. pH: (1) 1.00; (2) 1.70; (3) 2.30; (4) 2.80; (5) 3.20.

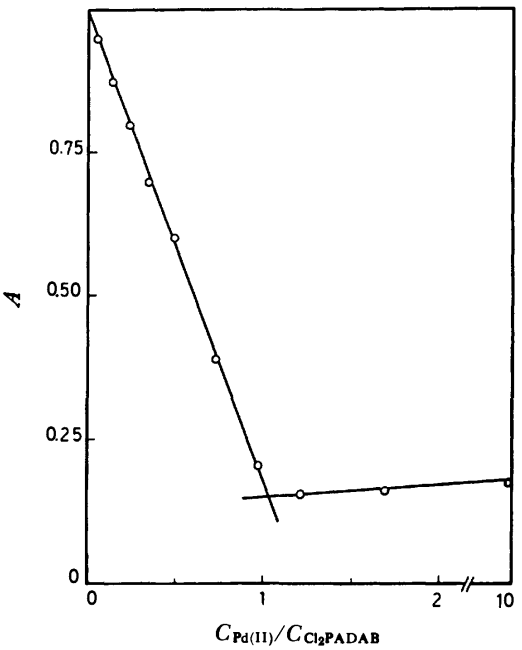

Fig. 3. Saturation curve of Pd(II)-3,5-Cl2PADAB complex in aqueous solution. 3,5-Cl2PADAB concentration was kept constant=3.50×10^{-5} M; Pd(II)= variable; 10% (v/v) ethanol; pH=3; λ=430 nm; water as blank.

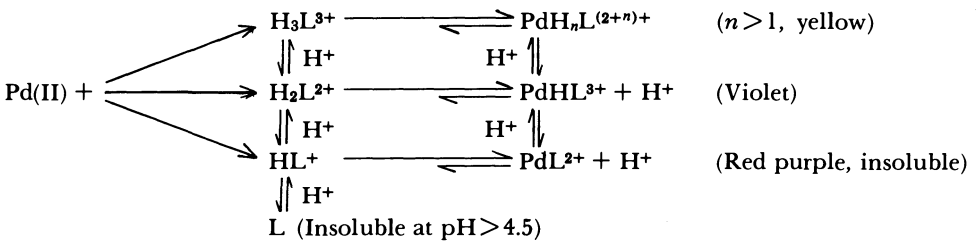
excess of reagent. In these cases, the spectra were scanned with similar 3,5-Cl2PADAB solutions as reference because the mixtures showed a strong absorption due to of the great concentration of 3,5-Cl2PADAB.

As is evident from the comparison of the spectra in Figs. 1 and 2, two Pd(II)–3,5-Cl2PADAB complexes exist in aqueous ethanol, depending only on the acidity. The color of the complex formed in H_2SO_4>10 M solutions is yellow, similar to the reagent at this acidity, while the solutions containing the complex formed in the acidity range from pH 1 to 2 M H_2SO_4 or from pH 1 to 3 M $HClO_4$ showed a violet color. An insoluble red purple complex was precipitated in less acidic media (pH 3—4), starting from pH 1. Anyone of these comlexes was generated either by promoting the chelation reaction at the suitable acidity, or by conveniently adjusting the acidity of media of the solution containing any of them.

The Composition of the Complex and the Mechanism of Complex Formation. Earlier studies[12] have shown that the Pd(II): 3,5-Cl2PADAB ratio of the violet complex is 1:1. In spite of its low solubility in aqueous ethanol solutions, the composition of the complex prevailing in the pH range 3—4 was spectrophotometrically obtained by means of absorbance variations, measured at the reagent maximum absorption wavelength (420 nm), of the pH 3 solutions containing constant concentration of 3,5-Cl2PADAB and varied proportions of Pd(II) (Fig. 3). The molar ratio obtained was also 1:1. Because of its low molar absorptivity, no further studies were carried out on the yellow complex, but it is likely to have contain the same molar ratio as the others. Similar situations have been indicated by Shibata et al. with respect to the Co(II)–5-Cl2PADAB[3] and Co(II)–3,5-Cl2PADAT[6] complexes. In agreement with the above considerations, the spectral changes observed when the acidity of the Pd(II)–3,5-Cl2PADAB complex solutions was varied were due to protonation or acid dissociation of these complexes, rather than to a cange in the Pd(II):reagent molar ratio. Furthermore, knowing that the Pd(II) complex formed depends on the acidity of the reaction media and that in the pH 4 to 18 M H_2SO_4 or pH 4 to 10 M $HClO_4$ range three species of 3,5-Cl2PADAB,[12] H_3L^{3+}, H_2L^{2+}, and HL^+ are involved in its acid-base behavior, it can be assumed that the reaction between Pd(II) and 3,5-Cl2PADAB is described by the following equilibria:



The above scheme is in good agreement with the experimental facts observed. In order to prove, at least partially, the validity of the above equilibria, the number of protons released in the reaction as

$$PdHL^{3+} \rightleftharpoons PdL^{2+} + H^+ \quad (1)$$

was spectrophotometrically examined for solutions containing excess of Pd(II). Studies in solutions showed that the $PdH_nL^{(2+n)+}$ and $PdHL^{3+}$ acid dissociation equilibria are sufficiently separated, so that they can be treated independently. If the acid dissociation constant for Eq. 1 is given by Eq. 2

$$K_a^{PdHL^{3+}} = [PdL^{2+}][H^+]/[PdHL^{3+}] \quad (2)$$

the dependence of $\log\{[PdL^{2+}]/[PdHL^{3+}]\}$ is written as

$$pK_a^{PdHL^{3+}} = \log\{(A - A_{PdHL^{3+}})/(A_{PdL^{2+}} - A)\} + pH \quad (3)$$

were A is the total absorbance of the solutions at a specified pH, and $A_{PdHL^{3+}}$ and $A_{PdL^{2+}}$ are the absorbance of solutions containing only the protonated complex and the soluble fraction of the non-protonated complex, respectively. The plot $\log\{(A-A_{PdHL^{3+}})/(A_{PdL^{2+}}-A)\}$ against pH gave a straight line with a slope of unity, value that is in good agreement with the supposition of Eq. 1. The $pK_a^{PdHL^{3+}}$=2 was calculated from the pH at which $\log\{(A-A_{PdHL^{3+}})/(A_{PdL^{2+}}-A)\}$ equals zero.

General Study of Extractable Pd(II)-3,5-Cl2PADAB-TCA^- Ion-Association Complexes. Considering that only positively charged Pd(II)–3,5-Cl2PADAB complexes can be formed, the extraction of such chelates can be carried out in the presence of suitable organic bases which form extractable ion-association complexes. In this sense, the best results were obtained for the trichloroacetate–benzene system. Pd(II) is quantitatively extracted into benzene in the presence of 3,5-Cl2PADAB, ethanol and high concentrations of trichloroacetate anion (TCA^-) within the acidity range from pH 4 to 2 M H_2SO_4 or from pH 4 to 1 M $HClO_4$ (Fig. 4). In strongly acidic solutions (pH 1 to 2 M H_2SO_4 or pH 1 to 1 M $HClO_4$ range), only a violet ion association complex is extracted into benzene.

Comparing the absorption spectra of this compound in benzene with those of the Pd(II)-3,5-Cl2PADAB complexes formed in aqueous solutions with the same mineral acid concentration, and in the presence or absence of trichloroacetate (Table 1) showed that the violet complex extracted was that stated as $PdHL^{3+}$. Although some Pd(II) complexes were formed in aqueous solutions of H_2SO_4 (C>10 M), they were not extracted into benzene, probably because under such conditions the HTCA dissociation is repressed to such

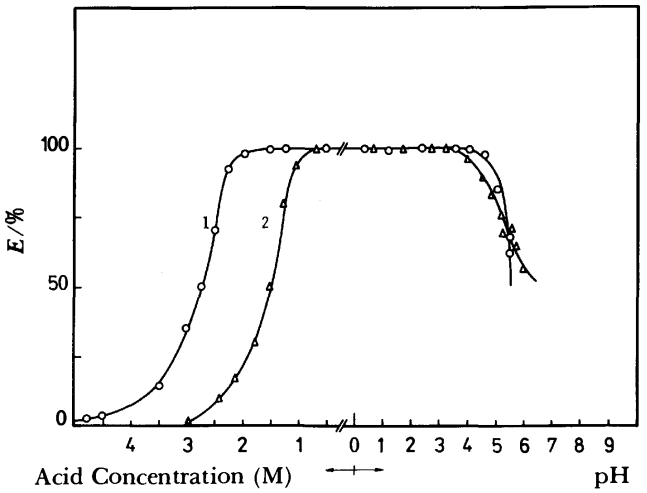


Fig. 4. Effect of pH or mineral acid concentration on extraction of the Pd(II)-3,5-Cl2PADAB-TCA^- system. Extractions from aqueous 10% (v/v) ethanol solutions with 1.80×10^{-5} M Pd(II), 1.20×10^{-4} M 3,5-Cl2PADAB and 1 M HTCA. Curves: (1) H_2SO_4; (2) $HClO_4$. $V_o=V_w$. an extent that practically no free anion occurs.

When the pH of the aqueous phases was increased from 1 to 4, the extraction was accompanied by a change in the absorption spectra of the extracts (Fig. 5), which is reversible with the acidity variations of the aqueous phases. In the pH range 3—4, only a red purple ion-association complex is extracted. This compound, and the reagent excess at pH 3—4, are not greatly soluble in benzene or in ethanol-benzene mixtures. In Table 1 are summarized the wavelength of maximum absorption and the molar absorptivities of the two ion-associations extracted.

The 1:1 Pd(II):3,5-Cl2PADAB molar ratio of the colored ion-association complexes in the organic phases were corroborated at 2 M H_2SO_4 by the molar ratio and slope-ratio methods, and at pH 3 by the molar ratio method (Fig. 6). The total Pd(II)-3,5-Cl2PADAB-TCA^- composition was also spectrophotometrically studied. The knowledge of the number of trichloroacetate anion molecules associated to each of the complexes extracted confirmed their charge and, consequently, the $PdHL^{3+}$ and PdL^{2+} composition postulated in aqueous solutions. The expression applied to establish the total (Pd(II)-3,5-Cl2PADAB)-TCA^- composition was derived as follows.

In some additional experiments on the extraction into organic solvents, it was established that Pd(II)-3,5-Cl2PADAB complexes are not extracted in the presence of the anions sulfate, perchlorate, nitrate, or chloride. They were extracted only in the presence of trichloroacetate anion. Therefore, it was concluded that this is the anion that takes part in the formulation of the extracted compound, and not any other. Bearing this in mind, as well as the 1:1 Pd(II):3,5-Cl2PADAB composition observed during complex formation and extraction, a general quantitative description of the complex extraction must consider the following ion-association reaction and distribution equilibria:

$$PdH_nL^{s+} + s\,TCA^- \rightleftharpoons PdH_nL^{s+}\cdot(TCA^-)_s \quad (4)$$

$$PdH_nL^{s+}\cdot(TCA^-)_s \rightleftharpoons (PdH_nL^{s+}\cdot(TCA^-)_s)_{org} \quad (5)$$

were the subscript org refers to the benzene phase, and the absence of a subscript indicates the aqueous phase. The ion-association formation constant and the distribution constant are given by:

$$K_{ass} = [PdH_nL^{s+}\cdot(TCA^-)_s]/\{[PdH_nL^{s+}][TCA^-]^s\}, \quad (6)$$

$$K_D^{ass} = [PdH_nL^{s+}\cdot(TCA^-)_s]_{org}/[PdH_nL^{s+}\cdot(TCA^-)_s]. \quad (7)$$

The extraction constant of ion-association is given by:

$$K_{ex} = K_D^{ass}\cdot K_{ass} = [PdH_nL^{s+}\cdot(TCA^-)_s]_{org}/\{[PdH_nL^{s+}][TCA^-]^s\} \quad (8)$$

Introducing the HTCA acid association constant (K_a^{HTCA}) and distribution constant (K_D^{HTCA}) in material balance for HTCA after extraction, and taking into account that $C_{Pd(II)} \ll\ll C_{HTCA}$, it can be shown that

$$[TCA^-] = C_{HTCA}/\{1 + [H^+]/(K_a^{HTCA} + K_D^{HTCA}\cdot[H^+]/K_a^{HTCA})\} \quad (9)$$

At constant proton concentration and salt content, Eq. 9 becomes:

$$[TCA^-] = C_{HTCA}/cte \quad (10)$$

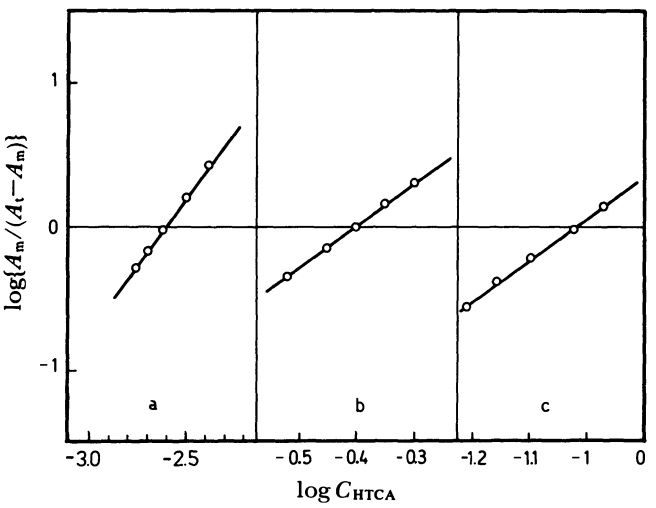

Fig. 7. $\log\{A_m/(A_t-A_m)\}$ vs. log C_{HTCA} curves for the Pd(II)-3,5-Cl2PADAB-TCA^- system. See text.

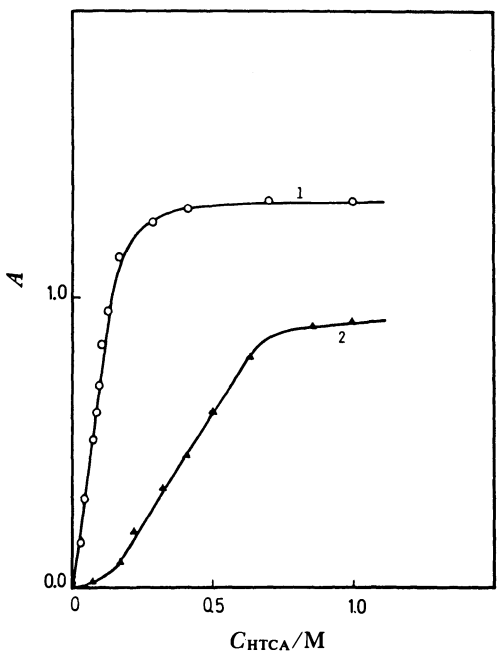

Fig. 8. Absorbance of Pd(II)-3,5-Cl2PADAB-TCA^- compounds in benzene vs. HTCA concentration in the aqueous phases. Concentrations present in the aqueous phases (10 cm^3): 3.90×10^{-5} M Pd(II), 10% ethanol, (1) 4.00×10^{-4} M 3,5-Cl2PADAB, 1 M H_2SO_4, λ_{max}=600 nm; (2) pH 1.50 (H_2SO_4), 5.90×10^{-5} M 3,5-Cl2PADAB, λ_{max}=600 nm. Benzene as blank. Organic extracts (10 cm^3) diluted to 25 cm^3 with pure benzene after equilibration.

Introducing Eq. 10 in Eq. 8, rearranging and taking logarithm, the Eq. 8 takes the form:

$$\log[\mathrm{PdH}_n\mathrm{L}^{s+}\cdot(\mathrm{TCA}^-)_s]_{org}/[\mathrm{PdH}_n\mathrm{L}^{s+}] = \log K^*_{ex} + s\log C_{HTCA} \quad (11)$$

where K^*_{ex} is the extraction constant based on total initial HTCA concentration in the aqueous phase:

$$K^*_{ex} = K_{ex}\cdot \mathrm{cte}^s \quad (12)$$

where cte is defined by Eqs. 9 and 10.

For any C_{HTCA}, the ratio $[\mathrm{PdH}_n\mathrm{L}^{s+}\cdot(\mathrm{TCA}^-)_s]_{org}/[\mathrm{PdH}_n\mathrm{L}^{2+}]$ could be calculated from absorbance of $\mathrm{PdH}_n\mathrm{L}^{s+}\cdot(\mathrm{TCA}^-)_s$ in benzene vs. C_{HTCA} curves. In this case, this ratio becomes equal to $A_m/(A_t-A_m)$, where A_t is the absorbance of extracts for the C_{HTCA} at which the extraction is quantitative, and A_m is the absorbance of extracts for any C_{HTCA} lower than the suitable for the quantitative extraction. Thus, the concentration of $\mathrm{PdH}_n\mathrm{L}^{s+}$ remaining in the aqueous phase will be A_t-A_m; Eq. 11, then, becomes,

$$\log\{A_m/(A_t - A_m)\} = \log K^*_{ex} + s\cdot\log C_{HTCA} \quad (13)$$

Eq. 13 indicates that the plot of $\log\{A_m/(A_t-A_m)\}$ against $\log C_{HTCA}$ should give a straight line with a slope of s, that is the number of trichloroacetate anion associated to the complex. Figure 7c shows this plot for A_t and A_m values taken from the absorbance (600 nm) vs. C_{HTCA} curve (Fig. 8 curve 1) obtained at 1 M H_2SO_4. The straight line has a slope of 3. Carrying out the extractions at pH 3—4, the value s calculated was not completely reliable owing to the very great absorbance even of a slight reagent excess, that disturbed seriously the absorbance measurements.

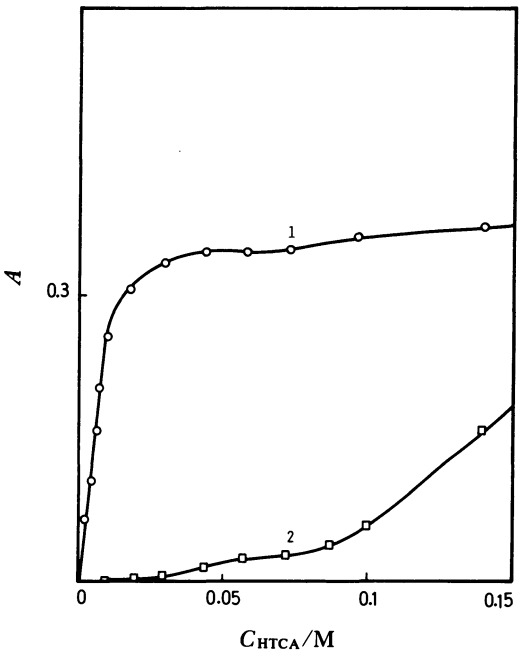

Fig. 9. Absorbance of Pd(II)-3,5-Cl2PADAB-TCA$^-$ ion-association compound in benzene vs. HTCA concentration in the aqueous phases. Amounts present in the aqueous phases (10 cm^3) 3.90×10^{-5} M Pd(II); 5.90×10^{-5} M 3,5-Cl2PADAB; 10% ethanol; pH 1.50. (1) λ_{max}=545 nm; (2) λ_{max}=600 nm. Benzene as blank. Organic extracts diluted to 25 cm^3 with pure benzene after equilibrations.

The complex-to-TCA$^-$ molar ratio of the red purple ion-association was established carrying out extractions at pH 1.5 in solutions containing a 1.5-fold molar excess of 3,5-Cl2PADAB with respect to Pd(II), and reading the absorbance against pure benzene. At pH 1.5 both complexes are formed and exracted. However, in the C_{HTCA} range from "0" to 0.07 M practically only the red purple ion-association complex is extracted (Fig. 9), while for C_{HTCA} higher than 0.07 M both ion-association complexes are simultaneous extracted. In the latter case, the absorbance measures at 600 nm were not disturbed by the presence of the red purple ion-association complex in the extracts (Fig. 8, curve 2).

According to what has been said above, it can be shown that, carrying out the extractions at pH 1.5 within the appropriate C_{HTCA} range and reading the absorbance of extracts at the suitable wavelength, Eq. 13 can be applied to establishing simultaneously the composition of the two ion-association complexes.

Figures 7a and 7b show the results obtained by applying Eq. 13 when the extractions were carried out in the C_{HTCA} ranges from "0" to 0.07 M and from 0.07 M to 1 M, respectively.

In the first case, the slope value of the straight line is 2, and in the second, such value is 3. This values agree with the essential electroneutrality of the extracted compound, assuming that the Pd(II) chelates have the composition PdL^{2+} and PdHL^{3+}, as suggested.

For the purpose of analytical applications, because of its very high molar absorptivity (600 nm) in benzene, the $\mathrm{PdHL}^{3+}\cdot(\mathrm{TCA}^-)_3$ ion-association complex is the most important.

Extraction-Spectrophotometric Determination of Pd(II) with 4-(3,5-Dichloro-2-pyridylazo)-1,3-diaminobenzene and Trichloroacetate. II

C. A. Fontán,* (the late) C. B. Marone, and R. Olsina
Departamento de Química Analítica "Dr. Carlos B. Marone"
Universidad Nacional de San Luis, Argentina
(Received April 11, 1987)

The influence of different variables affecting the extraction of Pd(II) with 4-(3,5-dichloro-2-pyridylazo)-1,3-diaminobenzene (3,5-Cl2PADAB) and trichloroacetate are described. The complexation reaction between palladium(II) and 3,5-Cl2PADAB, in 1 M trichloroacetic acid aqueous solutions containing ethanol (10% v/v) and an acidity range from pH near 1 to 2 M H_2SO_4 is completed 10 min after having mixed the reagents. Under these experimental conditions, Pd(II) is extracted into benzene as an colored ion-association compound with trichloroacetate. At 600 nm, Beer's law is fulfilled up to a Pd(II) concentration of 2.16 ppm, being the most appropriate concentrations for the metal spectrometry those ranging from 0.24 to 2.12 ppm. The apparent molar absorptivity is 8.60×10^4 dm^3 mol^{-1} cm^{-1}, and the method's sensitivity (Sandell) of 0.00123 μg Pd(II)·cm^{-2}. The assayed procedures for suppressing the most serious interferences produced by Au(III) and Hg(II) are specified, and the procedure for increasing the tolerance as to Ag(I), Cu(II), Co(II), Cr(III)-(IV), Ir(III)-(IV), Os(VIII), and Ru(III)-(VIII) are described.

In previous papers[1,2] we showed that Pd(II) reacts with 4-(3,5-dichloro-2-pyridylazo)-1,3-diaminobenzene (3,5-Cl2PADAB=L) in an acidity range from pH 4 to 2 M† H_2SO_4 (or from pH 4 to 3 M $HClO_4$) to form three complexes having an equal metal-to-reagent molar ratio (1:1) though different Pd(II)-to-H^+ ratio.

These complexes were assigned as the formulas of $PdH_nL^{(2+n)+}$ ($n>1$), $PdHL^{3+}$, and PdL^{2+}. They are related to each other by means of reversible acid-base equilibria, and the formation of one species or another depends on the acidity of the reaction medium.

The complex species $PdHL^{3+}$ and PdL^{2+} are quantitatively extracted into benzene in the form of ion-association compounds formed with trichloroacetate (TCA^-) under different acidity conditions.[2] Pd(II) is extracted as $PdHL^{3+}\cdot(TCA^-)_3$ in the acidity range from pH near 1 to 2 M H_2SO_4, while in less acid aqueous ethanol phase (pH range 3—4) it is quantitatively extracted as $PdL^{2+}\cdot(TCA^-)_2$. The high molar absorptivity of the ion-association compound $PdHL^{3+}\cdot(TCA^-)_3$ dissolved in benzene, as well as its suitable solubility in this solvent, accounted for carrying-out a study focused on establishing the most appropriate experimental conditions for the separation and spectrophotometric determination of palladium(II).

This is the aim of this work, as well as to describe the procedures assayed in order to avoid the interference of some metallic ions, and eliminate or, at least, reduce to allowable values their concentrations in solutions containing together with Pd(II), in those particular cases in which they are found at higher proportions than the tolerated by the proposed procedure.

† 1 M=1 mol dm^{-3}.

Experimental

Apparatus. A Varian 634 UV model spectrophotometer was used for recording spectra and individual absorbance measurements, with 10-mm path-length glass or quartz cells. The pH was measured on an Orion pH-meter model 701 A, equipped with a glass/Ag-AgCl combination electrode.

Reagents. 3,5-Cl2PADAB Solutions: The reagent was synthesized as previously described.[1] Ethanol solution (0.025% (w/v) of the pure material was generally used. When necessary, other solutions with the required concentration were prepared either by diluting the previous solutions with the same solvent, or by direct weighing of the reagent.

5×10^{-3} M Pd(II) Solution: Distilled water (50 ml) and concentrated sulfuric acid (2 ml) were added to 0.2664 g of $Pd(NO_3)_2\cdot2H_2O$ contained in a 150 ml precipitation flask. The whole was softly heated until complete dissolution of the salt. Once cooled, the resulting solution was transferred to a 200 ml volumetric flask and then the volume made up to the mark with distilled water. The metal's actual concentration was complexometrically determined.[3] This solution, stored in a glass vessel, keeps its concentrations unchanged for 5 days. More diluted solutions of Pd(II) were daily prepared from the previous one.

Trichloroacetic Acid Standardized Solution: An approximately 5 M solution (500 cm^3) of the acid was prepared from the solid reagent. The exact content of trichloroacetic acid was alkalimetrically determined on portions of the previous solutions.[4] All other reagents used were of analytical grade.

General Procedures. The trichloroacetate anion was added in the aqueous phases as trichloroacetic acid standardized solution, and the 3,5-Cl2PADAB reagent as an ethanol solution. For the extraction, the solutions were mechanically shaken in 100 mm long.×35 mm diameter "Pyrex-type" glass tubes with polyethylene stoppers. The temperature was kept at 20±0.5 °C. The percentage of palladium(II) extracted was calculated by determining both the amount of metallic ion transferred to the organic phase and that remaining in the aqueous phase after the

equilibrium is reached, using a spectrophotometric procedure that employes 3,5-Cl2PADAB.[1] When dealing with the extraction of single ion-association compound, the %E was evaluated by means of the absorbance measurements of its organic extracts at the maximum absorption wavelength of the spectral curve of that compound. To do this, it was necessary to previously determine the value of its molar absorptivity under the experimental conditions of the quantitative extraction of Pd(II).

Recommended Procedure for the Extraction-Spectrophotometric Determination of Palladium(II). In an extraction tube, put 2 cm^3 of acid solution of the sample containing no more than 27 ppm of Pd(II), 5 cm^3 of 2 M HTCA solution, 0.5—1 cm^3 of 96% H_2SO_4, 1 cm^3 of 0.025% ethanol solution of the reagent, and make volume up to 10 cm^3 with distilled water. Let it stand for 15 minutes and then, add 10 cm^3 of pure benzene. Shake the whole mechanically during 15 minutes. Allow the phases to separe, and then decant the organic layer into a 25 cm^3 dry volumetric flask. Wash the aqueous phase twice with 3 cm^3 portion of pure benzene; mix the washing liquids together with the bulk of the organic extract and, afterwards dilute up to the mark with pure benzene. If the so-obtained solution shows any turbidity, centrifuge before carrying out the absorbance measurement at 600 nm against a reagent blank. Calculate the palladium concentration from a calibration curve obtained by operating in the same way.

Results and Discussion

Although 3,5-Cl2PADAB is soluble in benzene, no less than a 45 min agitation period was required for the quantitative extraction of Pd(II) when the reagent dissolved in benzene was used. This is because, on the one hand, the complexation reaction needs at least 10 min to become complete and, on the other, the reagent is only slightly transferred to the aqueous phase under the experimental conditions exacted for the quantitative extraction of the metallic ion. This latter fact contributes to reduce the rate of the complexation reaction in the aqueous phase. Thus, in order to reduce the time interval employed in the extraction, the reagent has to be added as the ethanol solution to the aqueous phase. Once the Pd(II)–3,5-Cl2PADAB complexation reaction is over, the complex formed can be extracted into benzene in a second stage.

For the extraction of Pd(II) with 3,5-Cl2PADAB and trichloroacetate other organic solvents immiscible with water, such as higher alcohols, esters, ethers, chloroform, carbon tetrachloride, etc., were tested, but benzene was selected due to the greater stability of the extracted solute dissolved in this solvent.

Influence of the Trichloroacetic Acid and Ethanol Concentrations. The extraction was studied up to 2 M HTCA concentration. Different minimum concentrations of the organic acid was required for extracting the PHL^{3+} mixed-complex and the excess of the reagent (Fig. 1). 1 M was the optimum concentration of HTCA which ensures complete extraction of both complex and reagent excess. With higher values the percentage extraction did not drop although strongly emulsified extracts were obtained. Ethanol was necessarily added in the aqueous phases together with the reagent. In 1 M HTCA with 1—2 M H_2SO_4 solutions, both the percentage extraction and color stability of the organic extracts do not change significantly up to 15% (v/v) ethanol concentration; whereas contents greather than the previous one disminish the extraction yield. Ethanol also stabilizes the extract color. The absorbance remains virtually unchanged for at least 10 h in its presence, but for only 20 min in its absence.

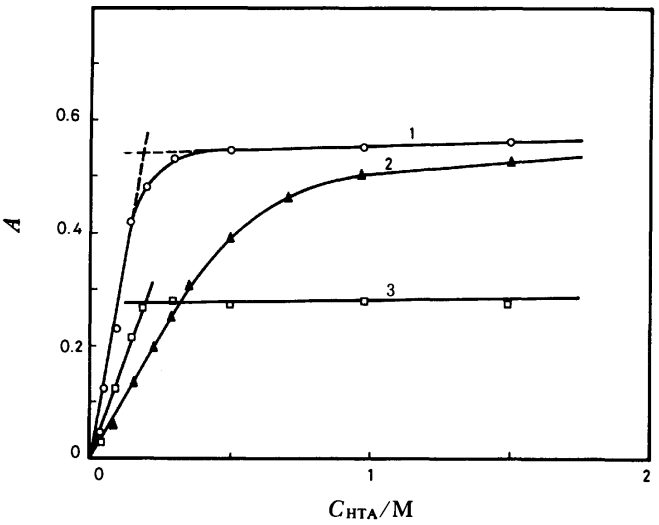

Fig. 1. Influence of total trichloroacetic acid concentration in the aqueous phase on benzene extraction of $PdHL^{3+}\cdot(TCA^-)_3$ ion-association compound. Concentrations in the aqueous phases: (1) and (2) 1.60×10^{-5} M Pd(II); 9.00×10^{-5} M 3,5-Cl2PADAB. (3) 4.60×10^{-5} M 3,5-Cl2PADAB. (1), (2), and (3) HTCA=variable; 1 M H_2SO_4; 10% ethanol. (1) λ_{max}= 600 nm, (2) λ_{max}=555 nm, (3) λ_{max}=440 nm. V_o= V_w=10 ml. Organic extracts diluted to 25 cm^3 with pure benzene after equilibrations. Time of full color development of $HLPd^{3+}$ complex=period of equilibration=45 min. Absorbance measures vs. (1) and (2) reagents, (3) water.

Still under the best experimental conditions, ethanol and HTCA were partially extracted by benzene, changing in this way the initial phase volumes. A strong scattering of absorbance measures was observed with phase volume changes. To increase reproducibility, a dilution step of the benzene extracts to a final fixed volume was included after extraction.

Periods of Color Development and Equilibration. In 1—2 M H_2SO_4 solutions with 1 M HTCA and 10% ethanol, Pd(II)–3,5-Cl2PADAB reaction was completed about 10 min after reagent addition. Being the complexation over, a few seconds' equilibration were required for the quantitative extraction. In practice, however, it was necessary to prolong both periods (color development and equilibration) to 15 min in

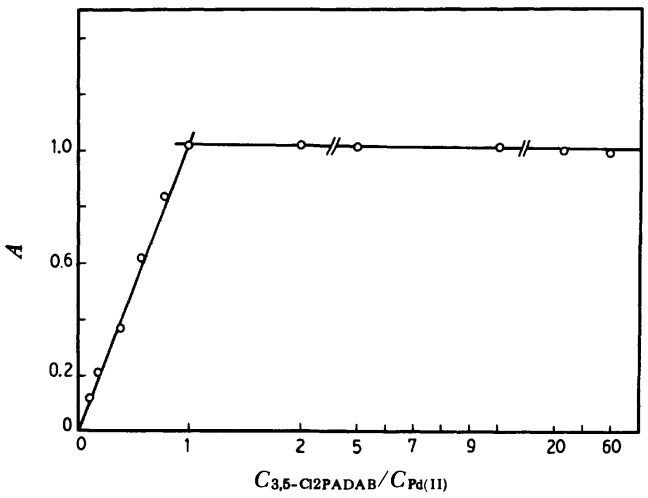

Fig. 2. Effect of 3,5-Cl2PADAB concentration on benzene extraction of $PdHL^{3+}\cdot(TCA^-)_3$ ion-association complex. Saturation curve. Concentrations in the aqueous phases: 3.00×10^{-5} M Pd(II); 3,5-Cl2PADAB=variable; HTCA 1 M; 1 M H_2SO_4; 10% ethanol. λ_{max}=600 nm. Reagent blank. Time of full color development=period of equilibration= 15 min. $V_o=V_w$=10 ml. Organic extracts diluted to 25 cm^3 with pure benzene after equilibrations.

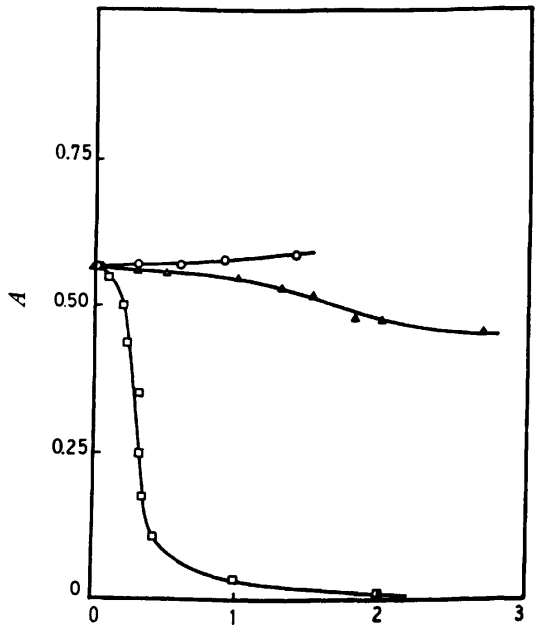

Fig. 3. Effect of aqueous salts on benzene extraction of the $PdHL^{3+}\cdot(TCA^-)_3$ association complex. Concentrations in the aqueous phases (10 cm^3): 1.60×10^{-5} M Pd(II); 1.60×10^{-4} M 3,5-Cl2PADAB; 1 M HTCA; 1 M H_2SO_4; 10% ethanol. (1) Na_2SO_4 (2) $NaClO_4$; (3) NaCl. λ_{max}=600 nm. Reagent blank. Organic extracts (10 cm^3) diluted to 25 cm^3 with pure benzene after equilibrations.

order not to obtain strongly emulsified benzene extracts.

Effect of Reagent Concentration. All other factors being kept constant, the reagent concentration was varied. It was found that a slight excess of reagent sufficed to extract completely the complex and to reach the maximum benzene extracts absorbance. Although this last magnitude remained unaltered for high 3,5-Cl2PADAB-to-Pd(II) ratios (Fig. 2), large amounts of reagent are not convenient because the absorption of reagent blanks becomes too high. Accordingly, 1 cm^3 of 0.025% (w/v) 3,5-Cl2PADAB solution every 10 cm^3 of aqueous phase is specified in the procedure. Figure 2 also shows that the extracted complex has high stability.

Influence of Foreign Salts. The influence of the salt content in the aqueous phases on the absorbance of the benzene extracts was studied by extracting Pd(II) in solutions where the H_2SO_4, 3,5-Cl2PADAB, HTCA, and ethanol concentrations were kept constant, and at the most convenient values. In separate test, different concentrations of sodium salts of sulfuric, perchloric, and hydrochloric acids were assayed. Figure 3 shows the results obtained. Chloride ions decrease the extraction yield and therefore, HCl cannot be recommended for dissolution of samples. Na_2SO_4 or $NaClO_4$ concentrations lower than 1 M influence significantly neither on the absorbance of benzene extracts of $PdHL^{3+}\cdot(TCA^-)_3$ nor on the yield of the extraction. For $NaClO_4$ concentrations higher than 1 M, the yield of the extraction diminishes due to the occlusion of Pd(II) and $PdHL^{3+}$ by the $NaClO_4$ crystals, precipited by the addition of the ethanolic solution of the reagent.

Beer's Law. Sensitivity. Under the experimental conditions described in the recommended procedure for the extraction-spectrophotometric determination of Pd(II), Beer's law is fulfilled up to a concentration of 2.16 ppm of Pd(II) in the organic extracts. The method's sensitivity, estimated according to Sandell's criterion, is 0.00123 μg of Pd(II) cm^{-2} for $\log(I_o/I_t)$= 0.001, and the apparent molar absorptivity of the ion-association compound extracted happened to be 8.6×10^4 $dm^3\,mol^{-1}\,cm^{-1}$ (s=900; $CL_{\alpha=0.05}^{85360-86640}$), at 600 nm. The reproducibility of the method, expressed by the percentual relative standard deviation, which was calculated on the basis of 20 determinations, is 0.59—0.39 depending on the metallic ion concentration.[5] The color of the diluted organic extracts is stable at least during 10 h.

Effect of Foreign Ions. The influence of foreign ions on the determination of Pd(II) by applying the proposed method, was studied for 18 cations that may generally appear with palladium in an analytical system, as well as for some common anions and masking agents. The criterion for interference was a change of ±3% in the absorbance for 2 ppm of palladium. Table 1 shows the results obtained. The greatest limitations are brought by Au(III). The interference of Au(III), when it is found in concen-

trations lower than 7 ppm, was avoided reducing it to metal by adding a few mg of solid $FeSO_4$, $NaNO_2$, Na_3AsO_3, or oxalic acid to its aqueous solutions and allowing the system to stand for 15 min before adding the reagent and HTCA. In higher concentrations, it was quantitatively extracted by means of Yoe and Overholser's technique[1,6] without change in the palladium concentration. Hg(II) interference could be controlled neither by masking nor by reducing it to metal; prior separation proved to be the only way of avoiding its interference. For that purpose, and in order to expand the method's applications to samples containing large amounts of Cr(III)-(VI), Os(IV)-(VIII), Ru(III)-(VIII), Cu(II), Co(II), Ir(III)-(IV), or Ag(I), several separative procedures were assayed. Volatilization[7,8] in hot concentrate H_2SO_4 or $HClO_4$ solutions proved to be the most efficient and practical method to separate mercury, chromium, osmium, and ruthenium. By combining the previous extraction of Pd(II) that uses acetylacetone dissolved in benzene[9] with the procedure suggested in this work, was the most convenient way for the Pd(II) determination in solutions containing high proportions of Cu(II), Co(II), Ir(III)-(IV), or Ag(I).

Volatilization Procedure. (i) Place 2—20 cm^3 of sample solution containing up to 50 μg of Pd(II) in an extraction tube. Add 10 cm^3 of 94—96% sulfuric acid and 10—15 drops of 72% $HClO_4$ and fume in hot plate until decoloration of the solution or reduction of the volume up to 5 cm^3. (ii) On reaching this stage, add carefully 20 cm^3 of a mixture solution of concentrate HCl and $HClO_4$ (1:8), drop by drop, and keep on heating. During the operation, stop adding the acid mixture whenever the sample color becomes greenish-grey, and keep on adding when it turns red-orange. (iii) Being the solution decolorized, go on heating until almost dried. Let it cool and then continue with the recommended procedure for Pd(II) determination.

If the sample had a great amount of chromium (up to 5.000 ppm) it was volatilized as chromyl chloride through the applications of steps (i) and (ii). But if only osmium and ruthenium occur (up to 6.000 ppm each), the steps to follow were just (i) and (iii). This procedure also enabled the removal of Hg(II) (as $HgCl_2$) up to 1.000 ppm by replacing in step (ii) the acid mixture by 30 cm^3 of 37% HCl.

Procedure Using Acetylacetone Dissolved in Benzene. Into an extraction tube place 20 cm^3 of solution containing between 10 and 100 μg of Pd(II). Adjust the pH to 0.5—0.8 with $HClO_4$ or NaOH solution. Next, add 20 cm^3 of benzenic 0.02% (v/v) acetylacetone solution and shake the tube for 30 min. Allow the phases to separate, and then shake 10 cm^3 of the benzene extract during 30 min with equal volume of an aqueous solution containing 1 M H_2SO_4, 1 M HTCA, 9×10^{-5} M 3,5-Cl2PADAB, and 10% ethanol. Afterwards, transfer the extract, by now colored, to a 25 cm^3 volumetric flask and dilute to the mark with pure benzene. Measure the absorbance of the benzene solution at 600 nm against a blank obtained in the same manner as described for the tests. Calculate the concentration of palladium from a calibration curve obtained under identical conditions.

Applications. The effectiveness of the one-step extraction procedure described in this paper, was evaluated by carrying out Pd(II) determinations on six synthetic solutions prepared from pure solutions of their components. Tables 2 and 3 outlines the compositions of the solutions and the results obtained. Sample No. 2 in Table 2 simulated, both in its compositions and in the component contents, the dissolution of a sample of a concentrate mineral of native platinum. A final stage of sample decomposition was simulated by repeated treatment (2—3 times) of the synthetic solution aliquots with portions of concentrate HCl-HNO_3 (3:1) mixture. Next, in order to eliminate completely osmium and virtual traces of chloride ions, these sample portions were heated until

Conformational Dependence of Mass Spectral Fragmentation of Pinane Derivatives

Tse-Lok Ho†
SCM Organic Chemicals Division, P.O.Box 389, Jacksonville, FL 32201, U.S.A.
(Received September 18, 1987)

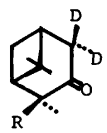
The major fragmentation pathway for pinane derivatives on electron impact involves cleavage of the cyclobutane bond which is part of a boat-cyclohexane. This trend is followed by ketones, alcohols, and hydrocarbons of the same skeleton.

Stereochemical correlation of mass spectrometric fragmentations has been investigated by many chemists.[1] While the majority of the reported data is concerned with the differences arising from configuration variation of functional groups, the effects of molecular conformations on the fragmentation pathways remain a subject of great interest but insufficient inquiry. The reason for this apparent lack of activity in the area is two fold: general consensus indicates that highly energetic species are generated in the mass spectrometer and the decomposition of these species must be accompanied by the destruction of conformational integrity of the original molecules; more importantly, adequate conformational isomers are difficult to identify.

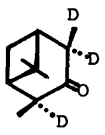
We are convinced that the electron impact-induced fragmentation of a molecule must be biased by conformational factors. For studying this possibility we chose the diastereoisomeric 3-pinanones, i.e., pinocamphone (*trans*-3-pinanone (**1**)) and isopinocamphone (*cis*-3-pinanone (**2**)). They are a pair of stable compounds which can be regarded as closest to being conformationally isomeric.[2] Thus, if we ignore the methylene bridge of the bicyclic structure, pinocamphone is reduced to 2,4,4-trimethylcyclohexanone in a flattened chair form, whereas isopinocamphone, that a flattened boat.

(1)

(2)



(1-d_3) R=D
(1-d_2) R=H



(2-d_3)

Since both ketones contain an equatorial α-methyl group, there is only a conformational difference between the two with respect to the cyclohexanone moiety. As ionization in the mass spectrometer of such ketones is commonly localized at the carbonyl group, factors affecting their fragmentation pathways other than the conformations must be the same. The pairwise comparison of the principal peaks in their mass spectra should then provide clues to the conformational influence on the fragmentation of the 3-pinanones.

In the electron impact mass spectra of the 3-pinanones the relative intensities of ions *m/z* 83 and 55 are reversed (see Figs. 1 and 2). The *m/z* 83 ion is stronger and *m/z* 55 ion is weaker in the spectrum of **1**, and the opposite is true for that of **2**. These results are clear-cut and reproducible under GC-MS conditions. With the help of high resolution mass analysis and by examination of the corresponding deuterated ketones, Schemes 1 and 2 can be postulated to account for the differences.

The rationale is supported by spectral analysis of pinocamphone-2,4,4-d_3 (**1**-d_3), pinocamphone-4,4-d_2 (**1**-d_2), and isopinocamphone-2,4,4-d_3 (**2**-d_3). The following mass shifts were observed: with the trideuterated ketones— *m/z* 83→84, 69→71, 55→56, and 41→43. Furthermore, the negligible 55→56 shift in the spectrum of **1**-d_2 and the much lower intensity of *m/z* 84 in the same spectrum confirm the assignment of the ion structure.

While these ions are actually doublets, invariably the hydrocarbon species are in much higher abundance, therefore there is no possibility of misinterpreting the trends. The ratios of the hydrocarbon ions to acylium ions for **1** are 10.63 for *m/z* 83, 8.28 for *m/z* 69, 64.91 for *m/z* 55, and those for **2** are 4.74 (*m/z* 83), 10.85 (*m/z* 69), 29.33 (*m/z* 55) as determined by high resolution scans.

It appears then the α-cleavage at the C(2)-C(3) bond of the ketones is rapidly followed by a rupture of the four-membered ring, with the latter fragmentation displaying a remarkable degree of selectivity. It may be concluded that the cyclobutane bond which also constitutes a part of the boat-shaped cyclohexanone, and the one subtended by it, break preferentially. This process, but not the alternative mode of cleavage,

† Present address: The NutraSweet Co., 601 Kensington Rd., Mt. Prospect, IL 60056, U.S.A.

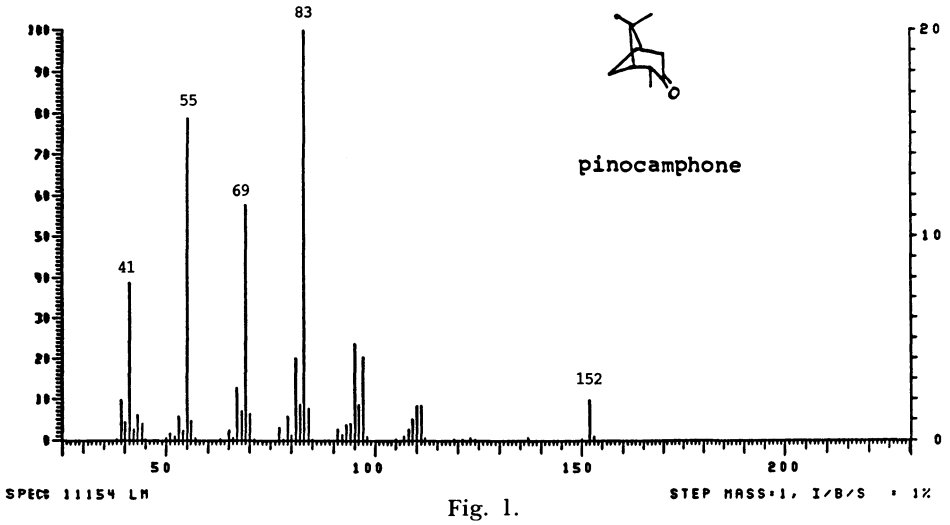


Fig. 1.

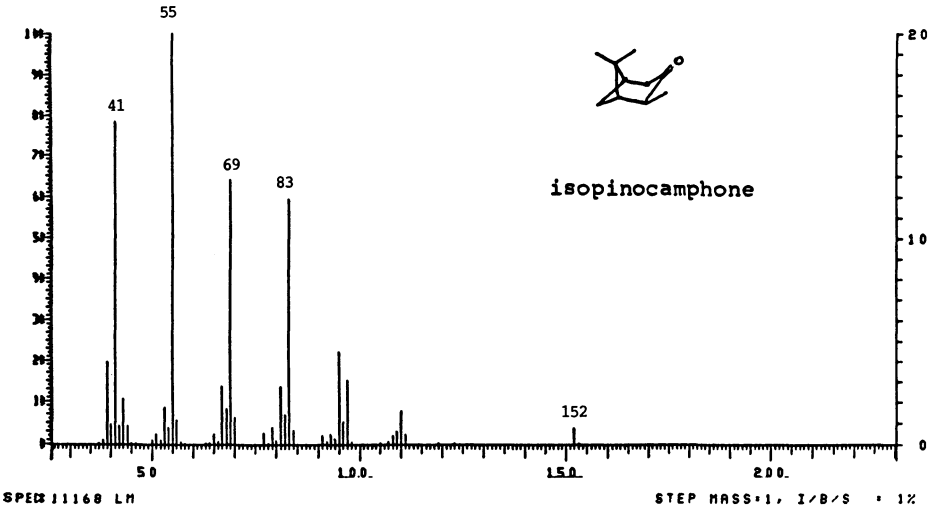

Fig. 2.

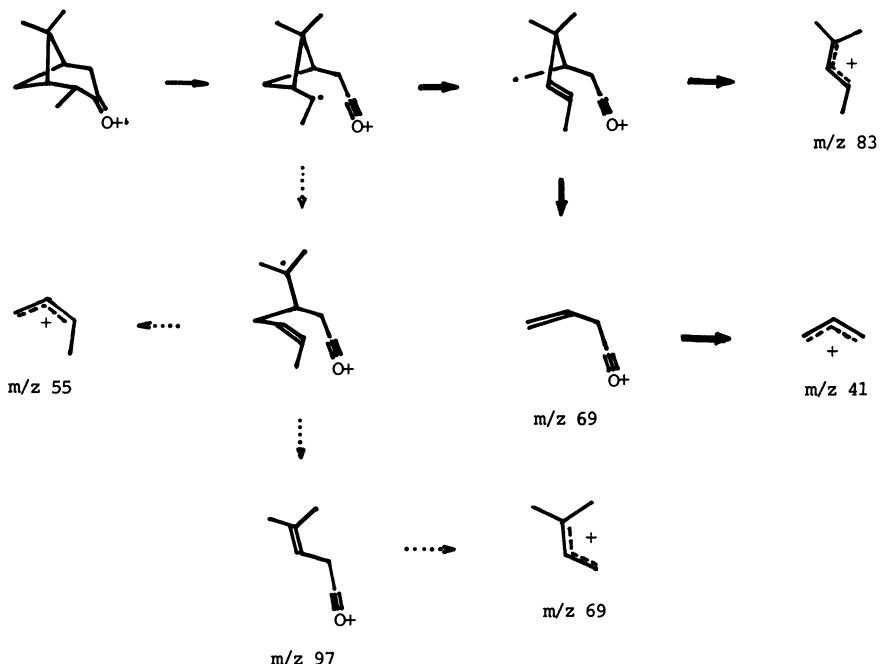
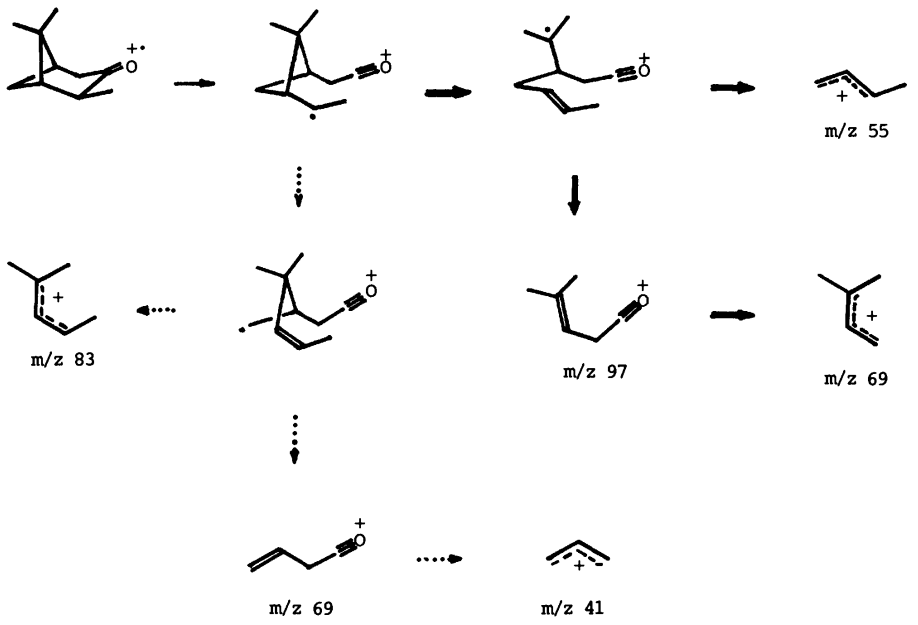


Scheme 1.



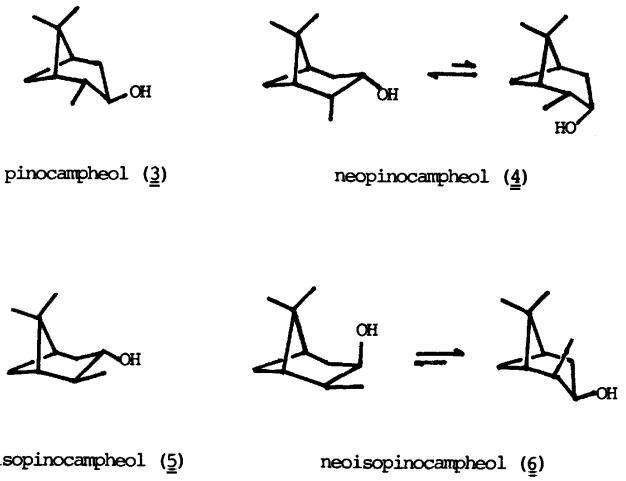
Scheme 2.

relieves a larger portion of the inherent strain of the molecule.

While the strain relief must play a contributory role in the selective fragmentation, the more important factor may be related to the Principle of Least Motion. Newman projections along the C(2)-C(1) bond of the ketones clearly show a smaller dihedral angle subtended by C(3) and C(7) than that subtended by C(3) and C(6) in pinocamphone (**1**) and a larger dihedral angle in isopinocamphone (**2**). Cyclobutane cleavage of the 2,3-seco radical ion is favored at the bond nearly parallel to the original C(2)-C(3) bond for easier development of a double bond involving the empty orbital $C(2)^+$ or radical $C(2)^{\cdot}$. This preference for bond cleavage finds analogy in the E2 elimination which is least favored when the departing groups are close to being orthogonal and becomes progressively more favorable as the dihedral angle narrowed or widened, maximizing at 0° or 180°.

Perhaps it should be emphasized that the fragmentation of the 2,3-seco radical ions is instantaneous such that their intermediacy is unnecessary. In other words, acyclic species could have been generated more or less directly. This transiency explains the maintenance of the original conformations and their influence on the fragmentation pathways.

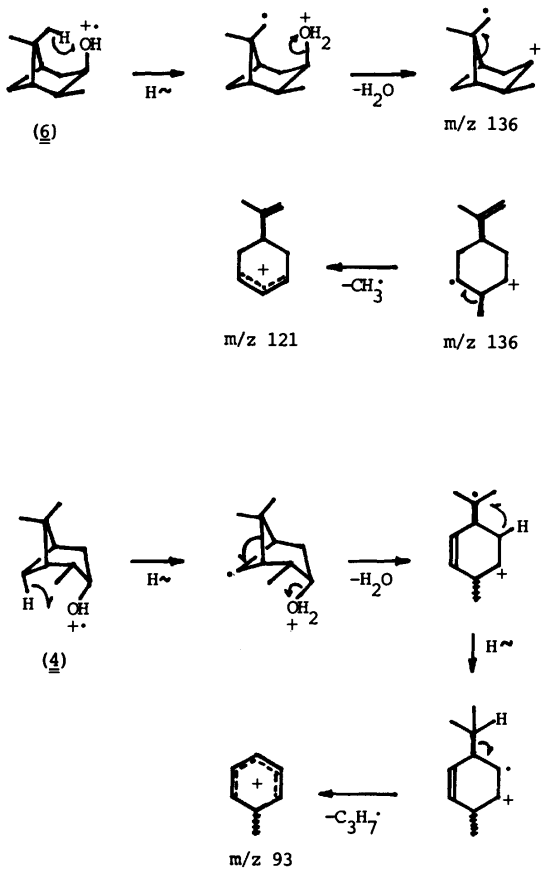
It may be interesting to speculate also that molecular conformations have subtle effects on the initial cleavage sites. Undoubtedly the more highly substituted C(2)-C(3) bond is the preferred locale of fragmentation, but this mode is not to the exclusion of the C(3)-C(4) bond fission, as evinced by the appearance of $C_5H_7O^+$ and $C_3H_3O^+$ ions. An increased percentage of the C(3)-C(4) bond cleavage in **2** relative to that in **1** is apparent from examination of the $C_nH_{2n-1}^+/C_nH_mO^+$ ratio of the twin peaks at *m/z* 83 and 55.



The four stereoisomeric 3-pinanols[3] also exhibit discernible intensity variations in a number of fragments. The members of the neo alcohols, each being capable of assuming a conformation in which the hydroxyl group is axially oriented and juxtaposed to a remote hydrogen atom, give rise to more abundant ($M-H_2O$) and ($M-H_2O-CH_3$) peaks— *m/z* 136: neopinocampheol (**4**) 6%, neoisopinocampheol (**6**) 5%, pinocampheol (**3**) 3%, isopinocampheol (**5**) 2%; *m/z* 121: **4** 9%, **6** 14%, **3** 0.5%, **5** 1%. On the other hand, the normal/iso compounds, having equatorial hydroxyl groups, display considerably stronger ions at *m/z* 43: **3** 85%, **5** 82%, **4** 40%, **6** 46%. Based on the conformations of the four alcohols (Fig. 3) the more

facile dehydration and the tandem demethylation of the neo alcohols becomes clear (Scheme 3).

The *m/z* 55 fragment is the base peak of pinocampheol **3**. In the spectra of the other isomers this fragment is approximately half as intense. The appearance of *m/z* 56 as the major peak in the cluster of the surrounding region in the mass spectrum of the 2,4,4-trideuterated alcohols suggests its main component as a crotyl cation composing of a carbon segment of C(7,1,2,10) (Scheme 4).

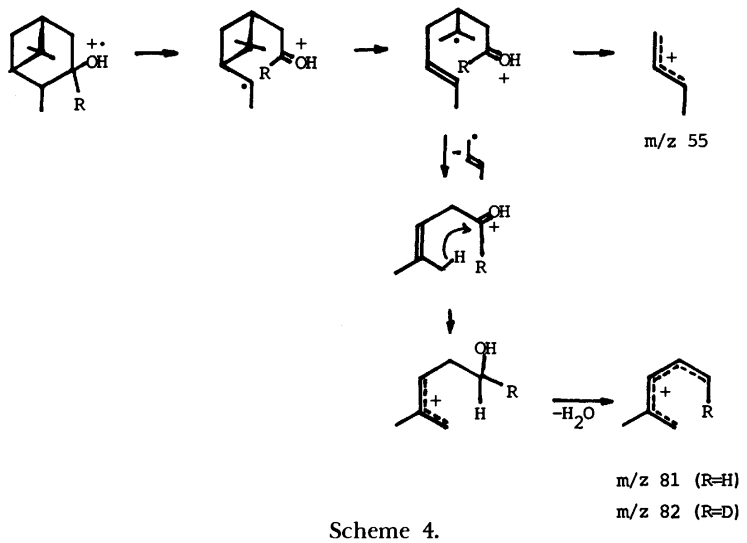


Scheme 3.

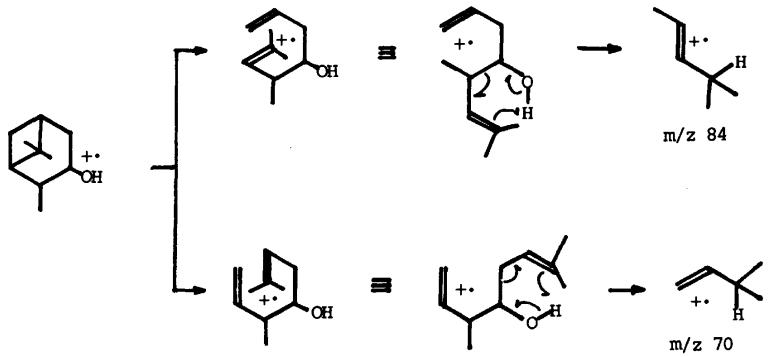
The most noticeable peak shift in the spectra of the 3-deuterio alcohols is *m/z* 81→82, in addition to the (M−H_2O) and (M−H_2O−CH_3) ions. Thus the *m/z* 81 ion could arise from the same seco species by losing a crotyl radical, and subsequent dehydration.

It is likely that *m/z* 84 and 70 are interrelated. Both peaks are derivable from the molecular ions via analogous processes albeit involving scission of different bonds. The relative intensities of *m/z* 84 are in the descending order of **4>3≈6>5**, whereas those of *m/z* 70 are **5≈6>3>4**. The trends are most satisfactorily explained by Scheme 5 in which a preferential ring fission involving C(1)-C(7) and C(5)-C(6) bonds when the compound contains a chair-like trimethylcyclohexane and cleavage at C(1)-C(6) and C(5)-C(7) bonds when the trimethylcyclohexane moiety is forced into a boat-like conformation is indicated. Assignment of the fragment is also consistent with the observed mass shifts of *m/z* 70→72 and 84→85 in the 2,4,4-trideuterio alcohols. Mass shift is absent with regard to these two ions in the 3-deuterio alcohols.

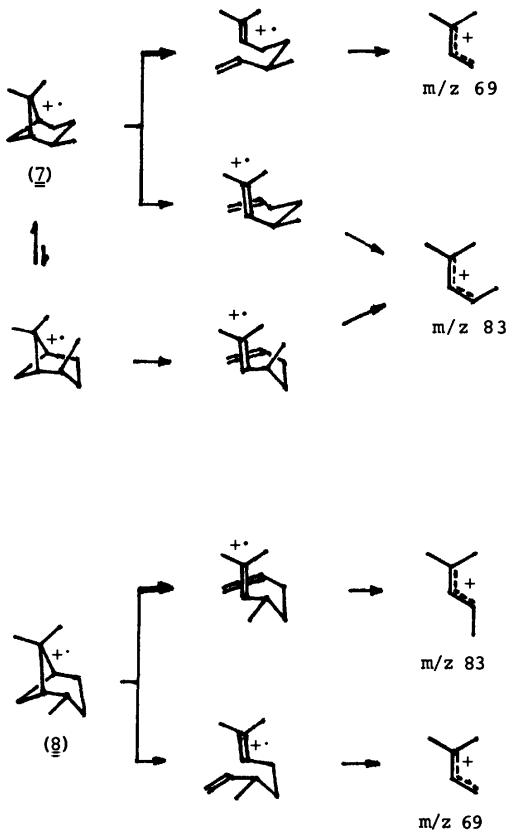
The major direction of cyclobutane ring cleavage for the alcohols follows the two ketones. Remarkably, even the parent hydrocarbons *cis*-pinane (**7**) and *trans*-pinane (**8**) manifest parallel intensity differences in the relevant peaks. While we observed approximately equal intensity of the *m/z* 83 and 69 ions for **7** at ca. 54%, the corresponding peaks registered at 63% and 48%, respectively, in **8**. The coincidental balance of the fragmentation pathways for *cis*-pinane may be actually due to further conformational modification or flattening of the boat-shaped trimethylcyclohexane ring as flagpole interaction between the axial hydrogen at C(3) and the syn-methyl group at C(6) is rather severe. Scheme 6 showing two extreme conformational isomers is only presented for the sake of clarity. It should also be stated that the seco ions indicated



Scheme 4.



Scheme 5.



Scheme 6.

in Schemes 5 and 6 could be generated in a stepwise manner instead of a synchronous process.

The recognizable differences in the mass fragmentation of pinane derivatives are hardly fortuitous. As the only dissimilarity among members of the three series of compounds is in their conformations, it seems that the fragmentation pathways are indeed affected to a large extent by those factors.

The origin of the conformational preferences of the compounds discussed above can be traced to the secondary methyl group. It appears that this group has an additional effect in causing the cyclobutane bond nearest to dihedrally orthogonal to it to undergo rupture preferentially. The destabilization of that cyclobutane bond and/or slight stabilization of the antiperiplanar counterpart may be expected on the basis of an electronic transmission which is operated in the three-bond spin-spin coupling (Karplus relationship).

Experimental

All known compounds were prepared according to literature methods.[3] Deuteration of **1** and **2** were carried out in a mixture of dioxane and deuterium oxide in the presence of sodium methoxide at room temperature. The alcohols were obtained by reduction of the ketones with either sodium borohydride or lithium aluminum deuteride.

Mass spectra were measured in a Finnigan MAT 112 mass spectrometer connected to a Perkin Elmer Sigma gas chromatograph which was equipped with a DX-4 column (30 m×0.246 mm) and temperature-programmed at 4 °C min^{-1} from 60 to 250 °C using helium as carrier gas.

The author is greatly indebted to Dr. A. F. Thomas (Firmenich Cie.) for his criticisms and help, Sonya Sapp for her expert operation of the GC-MS system.

Kinetics of Reduction of Silver(II) by Sodium Tetrahydroborate

Manash DASGUPTA and Mahendra K. MAHANTI*
Department of Chemistry, North-Eastern Hill University, Shillong 793003, India
(Received September 28, 1987)

The kinetics of reduction of silver(II) by sodium tetrahydroborate in aqueous acidic solution has been investigated. The reaction was observed to proceed in two steps, namely, (a) the formation of the intermediate Ag^{I} and (b) the subsequent conversion of Ag^{I} to Ag^{0}. The activation parameters for the two steps have been separately calculated. The intermediate Ag^{I} species, and the final products, were characterized by chemical and spectral methods. A plausible mechanism for the reduction of Ag^{II} ions has been proposed.

The mechanism of oxidation by Ag^{II} has been the subject of several investigations in which organic[1] and inorganic[2] substrates have been used. The Ag^{II}/Ag^{I} couple has a high reduction potential of +2.00 V in 1.0 M $HClO_4$ (1 M=1 mol dm^{-3}).[3] Silver(II) reacts rapidly even with substrates that exhibit sluggish behavior towards other commonly employed reagents. The kinetics of oxidation of Fe^{2+}, Mn^{2+}, Co^{2+}, Ce^{3+}, and V^{4+} by Ag^{II} revealed a wide range of reduction potentials and self-exchange rates.[4] Many oxidation reactions such as the oxidation of Hg^{I} by Ce^{4+} ions,[5] the peroxydisulfate oxidations of Ce^{III}, Cr^{III}, V^{IV}, and N_2H_4,[6] and of oxalate,[7] are all catalyzed by Ag^{+} ions, and the kinetics have been visualized as proceeding via the initial oxidation of Ag^{I} to Ag^{II}, which then undergoes reduction by the substrate. The reactions of the tetrahydroborate ion with transition metal compounds usually result either in a reduction of metal to a lower oxidation state and possibly the formation of a hydride compound, or the formation of a tetrahydroborate or a diborane derivative.[8,9] Sodium tetrahydroborate in water or methanol solution was found to be an effective reducing agent for the conversion of aldehydes and ketones to the corresponding alcohols.[10,11] In an earlier paper, we had reported our results on the kinetics of reduction of hexacyanoferrate(III) by sodium tetrahydroborate.[12] In continuation of our work on the kinetics of reduction of transition metal ions by sodium tetrahydroborate, we report here the kinetic features of the reduction of silver(II) by sodium tetrahydroborate in aqueous acidic medium, at constant ionic strength, under a nitrogen atmosphere. A plausible mechanistic pathway for the reduction reaction has been suggested.

Experimental

Materials, Methods, and Stoichiometry. Sodium tetrahydroborate (Loba Chemical Co.) was kept under vacuum. Tetrakis(pyridine)silver(II) peroxodisulfate, $[Ag(py)_4]S_2O_8$, was prepared by the standard procedure,[13] and was used as the source of Ag(II). Perchloric acid and sodium perchlorate were of E. Merck products. All solutions were prepared in dark-colored flasks in order to prevent exposure of Ag^{II} solutions to light.

Solutions of sodium tetrahydroborate were prepared in water. Since sodium tetrahydroborate undergoes hydrolysis in aqueous medium,[12] all the solutions used for the kinetic runs were prepared by dissolving 2.5 times more of $NaBH_4$ than what was theoretically necessary. Solutions of Ag^{II} were prepared in $HClO_4$ and $NaClO_4$ to maintain a constant ionic strength. It has been shown that Ag(II) can undergo disproportionation according to:[14,15]

$$2\,Ag^{II} \rightleftharpoons Ag^{I} + Ag^{III}$$

Hence, an excess of Ag^{I} solution (0.10 M) was added to prevent disproportionation of Ag^{II}. The two solutions were separately thermostated at 15 °C for 1 h under nitrogen, and then mixed in equal volumes by syringing into the spectrophotometric cell (UV-26, Beckman). The progress of the reaction was monitored at 375 nm by observing:

(i) An increase in the optical density due to the reduction of the Ag^{II} to the Ag^{I} species. This solution does not contain any Ag^{II} ion at the end of this reaction.

(ii) The subsequent decrease in the optical density at 375 nm (due to the reduction of the Ag^{I} to the Ag^{0} species).

The pH of the reaction mixture was checked periodically during the course of the reaction (Control Dynamics, digital model), and found to remain constant. Since the grey-colored Ag^{0} species was formed as the final reaction product, care was taken to ensure that the reaction mixture remained homogeneous for the duration of the kinetic runs. It was observed that there was no precipitation during the course of the kinetic runs.

The stoichiometry of the reaction was determined in the following manner: reaction mixtures containing $NaBH_4$ and an excess of Ag^{II} were allowed to react at 15 °C for 24 h under nitrogen, and then analyzed, spectrophotometrically at 375 nm for the Ag^{II} which was left. The results gave a ratio of substrate to reductant according to the equation:

$$2\,BH_4^- + 8\,Ag^{2+} + 6\,H_2O \longrightarrow 8\,Ag^{0} + 2\,B(OH)_3 + 14\,H^+.$$

Analysis of the Ag(I) Intermediate. Two milliliters of the reaction mixture were withdrawn within 1 min of the initiation of the reaction, and spectrally analyzed over a range of wavelengths from 300 nm to 900 nm. The dark colored species[16] was found to absorb at 375 nm, which was due to the presence of the Ag^{I} intermediate species. In an earlier investigation, it was shown that Ag^{II} was reduced to an Ag^{I} species.[17]

Product Analysis. A solution of $NaBH_4$ (2×10^{-5} M) in 100 ml of water, was mixed with a solution containing the

Ag^{II} complex (2×10^{-5} M) in $HClO_4$, and excess of Ag^{I} solution (ionic strength adjusted to 0.05 M by the addition of $NaClO_4$), and the reaction mixture allowed to stand at 15 °C for 24 h under nitrogen. Greyish colored particles were precipitated along with a thin layer of shining silver mirror formed on the walls of the reaction vessel. The reaction mixture was filtered. The precipitate was washed with distilled water, tested for the complete removal of Ag^{+} ions, and then dried. The filtrate was analyzed for the presence of borate, as described earlier.[12]

The precipitate (0.5187 g) was taken, and converted to AgCl by the standard method,[18] and gravimetrically estimated as AgCl. The weight of AgCl was 0.6682 g, which corresponded to 0.5029 g of silver. This value compared favorably, within the limits of experimental error, with the theoretical percentage of silver present in the final product (theoretically, 100%; experimentally obtained by this method, 96.9%). This confirmed that the silver was present in the final product as Ag^{0}.

Results and Discussion

Kinetics Results. The rates of the reactions (the formation of Ag^{I} from Ag^{II} and the subsequent conversion of Ag^{I} to Ag^{0} species) were dependent on the first powers of the concentrations of each of the reactants (Table 1). The two rate constants have been separated, and individually calculated as k_1 (conversion of the Ag^{II} to the Ag^{I} species) and k_2 (conversion of the Ag^{I} to the Ag^{0} species). Plots of k_1 and k_2, respectively, versus a twenty-five fold range of concentration of BH_4^- ions, gave a straight line passing through the origin, indicating that the rate of the reaction was dependent on the first power of the concentration of BH_4^- ions. At constant BH_4^- concentration (large excess), the first-order rate constants (k_1 and k_2, respectively) did not change with changing Ag^{2+} ion concentrations (twenty-fold range), which indicated a first order dependence on the Ag^{2+} ion concentration (Table 1).

The reaction was studied at varying pH (Table 1). The logarithm of the rate of disappearance of Ag^{2+} ion divided by the tetrahydroborate ion concentration, was plotted against pH. The plot was linear, indicating a first order dependence of the rate of the reaction on the hydrogen ion concentration.

The reaction was influenced by changes in the temperature (Table 1), and the activation parameters have been evaluated and shown in Table 2. It has been suggested[14] that in the exchange of Ag^{I} with Ag^{II}, the

a) 20°C; b) 25°C; c) 30°C; d) 35°C (all temperature corrections were ±0.1°C). All values of rate constants were the average of three experiments, agreement being ±3%.

Table 2. Activation Parameters

Parameter	$Ag^{II} \longrightarrow Ag^{I}$	$Ag^{I} \longrightarrow Ag^{0}$
E	28±2 kJ mol^{-1}	43±2 kJ mol^{-1}
A	2×10^2 s^{-1}	5×10^4 s^{-1}
ΔH^{*}	25±2 kJ mol^{-1}	40±2 kJ mol^{-1}
ΔS^{*}	−208±4 J K^{-1} mol^{-1}	−166±4 J K^{-1} mol^{-1}

rate law was consistent with a disproportionation mechanism

$$2Ag^{II} \rightleftharpoons Ag^{I} + Ag^{III}$$

the rate of exchange being equal to the rate of the disproportionation reaction at equilibrium. This would necessarily imply that the rate constant for the reverse reaction (the reaction between the Ag^{I} and the Ag^{III} species) must be quite large. In the present investigation, since excess Ag^{I} has been added to the initial Ag^{II} solution, one might envisage the suppression of the disproportionation reaction involving the formation of the Ag^{III} species. This would enable the facile conversion of Ag^{II} to Ag^{I} which has been reflected in the activation parameters (Table 2) for the first step of the reaction. The conversion of Ag^{I} to Ag^{0} has been observed in this investigation.

Variations in the ionic strength of the medium using $NaClO_4$ (range of ionic strength 0.01 to 0.075 mol l^{-1}), did not affect the rate of the reaction.

Under the present experimental conditions, the rate law could be expressed as:

$$\text{Rate} = -\frac{d[\text{Ag(II)}]}{dt} = k_{obs}[\text{Ag(II)}][BH_4^-][H^+]$$

where k_{obs} corresponds to the composite rate constant for the reaction, which has been separated into the individual rate constants, k_1 and k_2 (Table 1).

Mechanism. Since the rate of the reaction was dependent on the concentrations of each of the reactants, the first step of the reaction could be represented as:

$$BH_4^- + H^+ \longrightarrow H^+BH_4^-. \quad (1)$$

The redox steps following Eq. 1 would involve the reaction of Ag^{II} with the tetrahydroborate species. There is evidence from the hydrolysis of diborane[19] that intermediates of partially hydrolyzed boron hydride compounds do exist, and that these intermediates differ in their reducing capacities. In the present investigation, the intermediate boron compounds could not be isolated, although the reactions of diborane with ice and with the "bound water" in silica gel do indeed suggest the existence of intermediate boron compounds.[19]

Molecular hydrogen reacts homogeneously with a number of metal ions in solution, reducing them to a lower oxidation state. For example, the mechanism of reduction of Cu^{2+} to Cu^{+} has been shown to be [20,21]

$$Cu^{2+} + H_2 \rightleftharpoons CuH^+ + H^+$$

$$CuH^+ + Cu^{2+} \longrightarrow 2Cu^+ + H^+,$$

the intermediate CuH^+ being stabilized by covalent bonding.

The reactions of Hg^{2+}, Hg_2^{2+}, and MnO_4^- with molecular hydrogen had indicated that hydrogen behaved as a two-equivalent reductant. Thus, the mechanism for the reduction of Hg^{2+} to Hg_2^{2+} was suggested to be:[22]

$$Hg^{2+} + H_2 \longrightarrow Hg^0 + 2H^+$$

$$Hg^0 + Hg^{2+} \xrightarrow{\text{fast}} Hg_2^{2+}.$$

In the reactions with Hg_2^{2+} and MnO_4^-, the rate-determining step appeared to be a two-equivalent reduction, leading to the formation of Hg_2^0 and Mn^{V}, respectively, as intermediates.

It has been earlier reported that acidic solutions of Ag^{2+} ions have been reduced to metallic silver by a variety of reducing agents.[23–28] Aqueous solutions of $AgClO_4$ were reduced by hydrogen to the metal,[29] a homolytic cleavage of hydrogen being suggested as follows:

$$2Ag^+ + H_2 \longrightarrow 2AgH^+$$

$$2AgH^+ + \text{Substrate} \longrightarrow \text{Products} + 2Ag^+.$$

At lower concentrations of Ag^+, a heterolytic splitting of H_2 was proposed:[30]

$$Ag^+ + H_2 \longrightarrow AgH + H^+$$

$$AgH + Ag^+ \longrightarrow \text{Intermediate} \xrightarrow{\text{Substrate}} \text{Products}.$$

The effect of complex formation with ligands other than water was studied by following the reduction of silver complexes by hydrogen to the metal,[31] and the rate data indicated a heterolytic cleavage of hydrogen. The reduction of silver–amine complexes to metallic silver by hydrogen was investigated in an attempt to correlate reactivity with ligand properties,[32] thus:

$$[Ag(NR_3)_2]^+ + H_2 \longrightarrow Ag + 2R_3NH^+.$$

The kinetic results of the present investigation would suggest a stepwise reduction of Ag^{2+} ions by sodium tetrahydroborate. In the first instance, the Ag^{2+} ion would be reduced to Ag^{I}, which in turn, is converted to Ag^{0}.

In the present investigation, the reaction sequence could be represented as follows:

$$H^+ + BH_4^- \longrightarrow H^+BH_4^-$$

$$H^+BH_4^- \longrightarrow \frac{1}{2}B_2H_6 + H_2$$

$$4H_2 + 8Ag^{2+} \longrightarrow 8Ag^+ + 8H^+$$

$$8Ag^+ + BH_4^- + 3H_2O \longrightarrow 8Ag^0 + B(OH)_3 + 7H^+$$

$$\frac{1}{2}B_2H_6 + 3H_2O \longrightarrow B(OH)_3 + 3H_2.$$

The overall stoichiometric reaction is:

$$2BH_4^- + 8Ag^{2+} + 6H_2O \longrightarrow 8Ag^0 + 2B(OH)_3 + 14H^+$$

The intermediate formation of the Ag(I) species, and also the formation of Ag^0 as the final product, have

been confirmed by spectral and chemical methods, in the present investigation.

Visible Light Assisted Heterogeneous Catalysis. Decomposition of Peroxomonosulfate over Doped and Undoped WO_3 Dispersions in Aqueous Medium

Pichai MARUTHAMUTHU,* Muthupandian ASHOKKUMAR, and Lakshmanan VENKATASUBRAMANIAN
Department of Energy, University of Madras, A.C. College Campus, Madras 600025, India
(Received December 7, 1987)

Aqueous suspension of RuO_2-loaded WO_3 powder on illumination with light of $\lambda \geqslant 410$ nm was found to decompose peroxomonosulfate (PMS, HSO_5^-) efficiently. The rate and other kinetic parameters indicated that the decomposition process followed Langmuir kinetics; at low concentrations of HSO_5^- ($0.54—2.06\times10^{-3}$ mol dm^{-3}) the reaction obeyed a first-order kinetics and at higher concentrations, ($[HSO_5^-]>3.00\times10^{-3}$ mol dm^{-3}) the rate became independent of $[HSO_5^-]$. The effects of pH and the molar percentage of the dopant on the rates were also investigated. Small amount of doping by RuO_2 (2.5 molar percentage) was found to increase the photocatalytic decomposition of HSO_5^- whereas the higher amount of doping decreased the rate. Added 2-propanol to the system was found to increase the rate of decomposition of peroxomonosulfate. The proposed mechanism of the decomposition of PMS involves the reactions of the photogenerated valence band holes and the conduction band electrons of WO_3, by radiation of wavelength $\geqslant 410$ nm, in presence and absence of 2-propanol. The rate constants and quantum yields have also been evaluated. The photocatalytic decomposition of peroxomonosulfate is one of the few examples of a unimolecular reaction catalyzed by both the photogenerated holes (h^+_{vb}) and electrons (e^-_{cb}).

The photocatalytic and photosynthetic reactions involving homogeneous and heterogeneous catalyses have recently attracted much attention because of their possible applications in solar energy conversion processes.[1] Particular interest has been focussed on the generation of hydrogen from water using semiconductors[2] and radiations of wavelength matching the sunlight. Recent works involve the simplified conventional photoelectrochemical cell with the use of semiconductor dispersions to carry out photocatalytic[3] and photosynthetic[4] reactions. These dispersed particles consist of single semiconductor alone or metallized semiconductor.[5,6] It has also been shown that a combination of redox systems with metal catalysts is indispensable for the efficient transfer of photon-induced conduction band electrons and valence band holes for redox reactions as well as protection of semiconductors against photocorrosion.[7,8] Since the photons absorbed in a thin layer close to the semiconductor–electrolyte interface alone are responsible for the chemical process, a large surface area of the active catalyst is desirable. This is best provided by catalysts in the form of powders and colloids. Although the area of illuminated surfaces is almost independent of the total surface area, as the size of the particle is decreased the density of the catalyst in the form of powder or colloid in the area of illumination gets increased and hence the catalytic efficiency will also be increased. Krasnovskii and Brin[9] have investigated the photocatalytic oxygen evolution reaction using WO_3 as a photocatalyst and Fe^{3+} as the electron acceptors. Darwent and Mills[10] have investigated the effect of RuO_2-loaded on WO_3 on oxygen evolution from water using Fe^{3+} as an electron acceptor. Recently Gratzel and coworkers[11] have reported the reactions of WO_3-coated electrodes and Nozik et al. have explored the electron-transfer reactions with WO_3 colloids.[12]

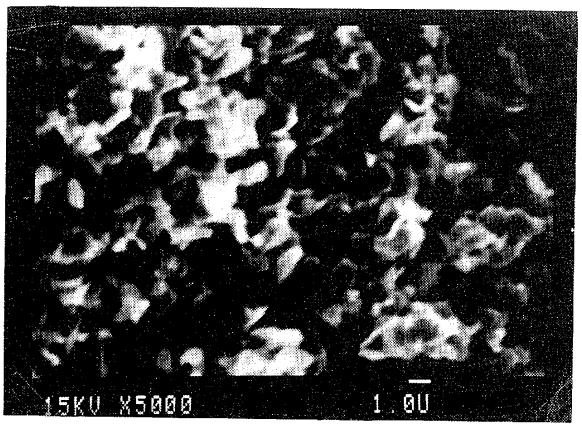
In this article we report the photocatalytic decomposition reactions of an inorganic peroxide namely peroxomonosulfate, $HOOSO_3^-$ (PMS) in aqueous suspension of WO_3 powder with radiation of wavelength $\geqslant 410$ nm. During the decomposition of PMS by the e^-_{cb} and h^+_{vb} of WO_3, oxidation of water to oxygen was also observed. Hence PMS may be considered as a sacrificial agent for the production of oxygen from water. PMS itself is an oxidizing agent ($E^\circ=1.82$ V) similar to peroxodisulfate and undergoes radiolytic and photolytic reactions.[13,14] It does not undergo photochemical decomposition unless the wavelength used is $\leqslant 260$ nm. However, in presence of WO_3 powder, with and without RuO_2 loading, efficient decomposition of PMS is observed on illumination with light of $\lambda \geqslant 410$ nm. The effects of (i) pH, (ii) catalyst amount, (iii) percentage doping of RuO_2, and (iv) 2-propanol on the heterogeneous photocatalytic decomposition of PMS are discussed. The significance of this investigation is that the substrate chosen (PMS) itself is an oxidant, but capable of simultaneously scavenging the e^-_{cb} and h^+_{vb} formed by band-gap irradiation of WO_3. The reaction is also a typical example for visible light induced catalytic decomposition of PMS which otherwise happens by UV irradiation.

Experimental

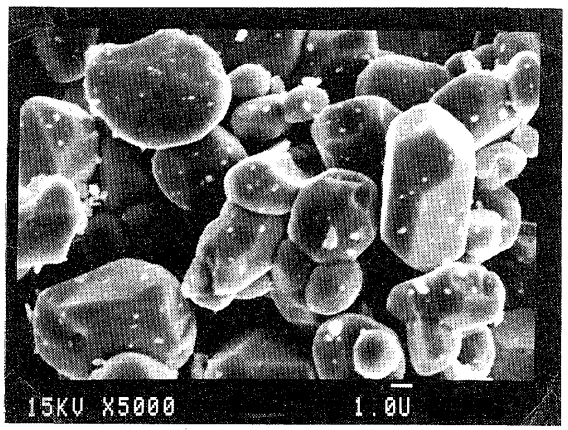
WO_3 used was from Fluka (>99.99%). RuO_2 loading was done using the technique described by Gratzel and coworkers[15] by dissolving calculated amount of $RuCl_3\cdot H_2O$ in water and mixing thoroughly with WO_3. The slurry was dried and heated in a muffle furnace in argon atmosphere at 800—900 °C for 4 h. Diffuse reflection measurements were

taken using Beckman Quartz Spectrophotometer (Model-DU: Serial 92906) at room temperature in the wavelength region 350—700 nm. Scanning Electron Microscope pictures (Fig. 1) were taken with JEOL JSM-35 CF Model. The particle sizes varied from 1—10 μm. An interesting observation in SEM pictures is that the doping increases the crystallinity of WO_3 semiconductor powders.

The surface areas of the catalysts were determined by BET method and found to be 1.0 to 1.5 m^2g^{-1}. PMS was from E.I. du Pont de Nemours & Co., USA, in the form of triple salt ($2KHSO_5 \cdot KHSO_4 \cdot K_2SO_4$) and was used as such. Other chemicals used were of the purest research grade available. Photocatalytic reactions were carried out in a rectangular all quartz reactor. Prior to irradiation, WO_3 dispersions were freed from dissolved oxygen by purging with purified Argon. A high pressure Mercury lamp (250 watt, Applied Photophysics, London) in combination with suitable cut-off filters emitting the light of $\lambda \geqslant 410$ nm was used as the light source. The intensity of the incident radiation, I_0, determined by trisoxalatoferrate(III) actinometry[16] was 6.91×10^{-8} Eins s^{-1}. The emission spectrum of the mercury lamp shows that the emitted light above 410 nm has the maximum intensity (ca. 99%) only at λ=436 nm. The IR radiations were removed using a water jacket. The change in the concentration of PMS with time was estimated iodometrically as reported in literature.[13] Unless otherwise mentioned, all the reactions were carried out with 25 mg of the 2.5% RuO_2/WO_3 photocatalyst in 35 ml of the reaction mixture.



(A)



(B)

Fig. 1. SEM photographs of (A) unloaded WO_3 (sintered at 800—900 °C) and (B) 2.5% RuO_2/WO_3 (sintered at 800—900 °C).

Quantum yields (Φ) of the photocatalytic reactions were determined using the relation,

$$\Phi = \frac{\text{Rate of decomposition of PMS}}{[\,(I_0 \times \text{Absorbance of the catalyst at } \lambda = 436\,\text{nm})/100\,]} \qquad \text{(a)}$$

which has been derived from the basic definition,

$$\Phi = \frac{\text{Number of moles decomposed per unit time}}{\text{Number of Einsteins absorbed per unit time}}$$

In this study the number of moles decomposed per unit time is nothing but the rate of decomposition of PMS. From the diffuse reflection spectra it has been found that the catalyst powder absorbs only a fraction of the total incident radiation at λ=436 nm. Hence number of Einstein absorbed per unit time from the total incident radiation (I_0) has been calculated using the expression written in the denominator of the relation (a). Also the absorbances of undoped and 2.5% RuO_2 doped WO_3 are found to be 70% and 87% of the incident radiations respectively. Oxygen evolution was identified using TL's Digital Oxygen Analyser Model DP 2M.

Results and Discussion

About 90% of PMS was decomposed in about three hours of illumination of an aqueous slurry containing PMS ($0.54—2.06 \times 10^{-3}$ mol dm^{-3}) and RuO_2/WO_3 (25 mg). No dissolution of WO_3 was observed even after six hours of continuous irradiation. Blank experiments were also conducted under the similar conditions without the photocatalyst and there was no decomposition of PMS observed even after four hours of prolonged irradiation.

Effect of Initial Concentrations of PMS. At low concentrations of PMS, the initial rate (r_0) of decomposition of PMS, $-d[PMS]/dt$ was found to increase with increase in the initial concentrations but at higher concentrations, the rate became independent of $[PMS]_0$. The plots of r_0 vs. $[PMS]_0$ exhibited a curvature, characteristic of saturable surface and the rates are described by a simple Langmuir form,

$$r_0 = \frac{kK[PMS]_0}{1 + K[PMS]_0} \qquad (1)$$

where k is the proportionality constant and K is the equilibrium constant. The first order rate constant k_1 can be calculated from k using the relation, $k_1 = k/[PMS]_0$. These observations are conveniently demonstrated by the linearity of the plot of $1/r_0$ vs. $1/[PMS]_0$ (Fig. 2) as given by the relation,

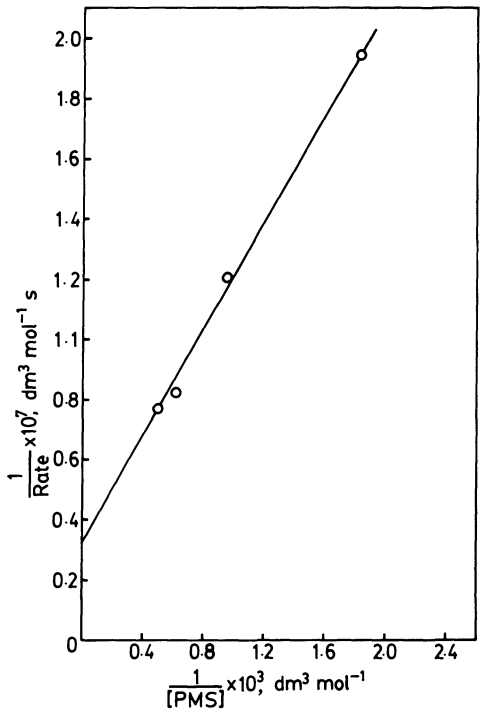


Fig. 2. Evaluation of k and K.

$$\frac{1}{\text{rate}_0} = \frac{1}{kK[\text{PMS}]_0} + \frac{1}{K} \quad . \tag{2}$$

From the slope and intercept of the above plot, the values of k and K were evaluated as 3.19×10^{-7} mol dm^{-3} s^{-1} and 3.52×10^2 dm^3 mol^{-1} respectively. At lower concentrations of PMS, Eq. 1 is reduced to

$$\text{rate}_0 = kK[\text{PMS}]_0 \tag{3}$$

and the overall reaction obeyed a first-order kinetics (assuming the surface to be truly Langmurian).

Effect of pH. The photocatalytic decomposition of PMS over RuO_2-doped WO_3 powders at different pH (1.0—5.0), at constant $[PMS]_0$ (1.00×10^{-3} mol dm^{-3}) as well as catalyst amount (25 mg) exhibited a maximum rate at pH=3.0 (Fig. 3) with a sharp decrease above and below this pH. Since the pK_a values of PMS ($pK_1<0$ and $pK_2=9.4$)[17] are not within the pH of the reaction slurry, the rate profile with pH may be due to the energetics of the conduction band and valence band edges with respect to the redox potential of PMS ($E^\circ=1.82$ V).[18] Photocatalysis implies an excess charge carrier transfer between the catalyst and reactant across the interface. The efficiency of the catalytic process is determined by the contribution of this transfer to the total excess charge carrier decay. This charge transfer between WO_3 and PMS is probably much favored at pH=3 as evidenced by the kinetic data.

Effect of Catalyst Amount. The photocatalytic effect of RuO_2/WO_3 powders is proved by its successful cleavage of PMS. The reactivity of the catalyst is maintained even after its successive participation in the photodecomposition reaction of PMS. The nonphotocorrosive nature of this catalyst is seen by the absence of tungsten ions in the reaction solution even after six hours of prolonged irradiation. Increase in the amount of catalyst is found to increase the rate of decomposition of PMS at constant $[PMS]_0$ (1.00×10^{-3} mol dm^{-3}). The calculated rates for different catalyst amounts at constant $[PMS]_0$ are given in Table 1.

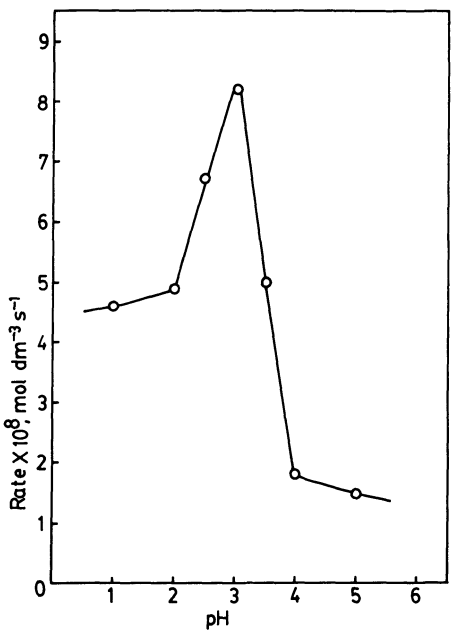

Fig. 3. Effect of pH.

Table 1. Effect of Catalyst Amount

Catalyst amount/mg	Rate$\times10^7$/mol dm^{-3} s^{-1}
15	0.44
25	0.82
35	1.20
45	1.29

Effect of RuO_2 Loading. Doping at different molar percentages (1.0%—12.5%) of RuO_2 shows that upto 2.5% loading of RuO_2 on WO_3 increases PMS decomposition beyond which there is a decrease. Although RuO_2 is a well-known catalyst for oxygen evolution[19] it has been widely employed as a good catalyst for hydrogen evolution.[20] Sakata and coworkers[19] have examined the catalytic properties of RuO_2 on n-type semiconductors under illumination for both oxygen and hydrogen evolution from water. In the present investigation, the rates of decomposition of PMS for 1.0 and 2.5% RuO_2/WO_3 photocatalysts are more than that for undoped WO_3 and the rates decrease beyond this percentage (Table 2). This might be due to the nature of deposition of RuO_2 on WO_3 surface. RuO_2 is deposited very finely (Fig. 1B)

Table 2. Effect of RuO_2-Loading

Molar percentage of RuO_2 loading	Rate$\times 10^8$/mol dm^{-3} s^{-1}
Undoped WO_3	3.00
1.0	5.95
2.5	8.23
5.0	3.26
7.5	2.50
10.0	1.82
12.5	1.56

on the WO_3 surface. With increasing amount of RuO_2, the density of deposition is increased. For this kind of deposition, RuO_2 particles on WO_3 surface would be expected to function as recombination centers since the distance between the particles becomes shorter than the distance at which the image force to both electron and hole is effective. The other reason would be that the photoejected electrons are also consumed for the reduction of RuO_2 prior to PMS reduction.

Reaction Pathway. It has been shown by Krasnovskii[9] that the aqueous dispersions of WO_3 illuminated by visible light produce oxygen as a result of the reaction of the valence band holes (h^+_{vb}) with water,

$$4h^+_{vb} + 2H_2O \longrightarrow O_2 + 4H^+. \quad (4)$$

It is also proved by Gratzel and co-workers[11a] that valence band hole of WO_3 is capable of oxidizing SO_4^{2-} to $SO_4^{\cdot-}$. Hence it is probable that PMS is also attacked by h^+_{vb} eventhough PMS is a powerful oxidizing agent ($E°$=1.82 V).[18] Moreover, it is well established that electrons (e^-_{aq}) react with PMS almost at a diffusion controlled rate.[14a] Hence, it is not surprising that both h^+_{vb} and e^-_{cb} react with PMS. This type of reactivity of PMS, as an electrophile as well as nucleophile, has already been observed by us[21] in visible light induced photochemical reactions of PMS with excited state $[Ru(bpy)_3]^{2+}$. While the conduction band electrons generate $SO_4^{\cdot-}$ and/or ·OH, the valence band holes are capable of removing the hydrogen atom from $HOOSO_3^-$ forming $SO_5^{\cdot-}$. These radicals and radical ions should favor the evolution of oxygen appreciably than the water oxidation by h^+_{vb} alone. Considering these reactions, we propose the following mechanism (Fig. 4):

$$WO_3 \xrightarrow[\lambda \geqslant 410\,nm]{h\nu} h^+_{vb} + e^-_{cb} \quad (5)$$

$$[HSO_5^-] + WO_3 \longrightarrow [HSO_5^-]_{ad.}\,WO_3 \quad (6)$$

$$[HSO_5^-]_{ad.} + e^-_{cb} \longrightarrow \begin{cases} SO_4^{\cdot-} + OH^- & (7a) \\ SO_4^{2-} + \dot{O}H & (7b) \end{cases}$$

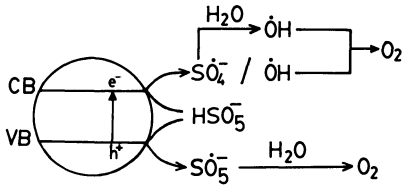

Fig. 4. Schematic representation of PMS decomposition by WO_3 particle.

$$HSO_5^- + SO_4^{\cdot-} \longrightarrow SO_5^{\cdot-} + HSO_4^- \quad (8)$$

$$SO_4^{\cdot-} + H_2O \longrightarrow SO_4^{2-} + H^+ + \dot{O}H \quad (9)$$

$$HSO_5^- + \dot{O}H \longrightarrow SO_5^{\cdot-} + H_2O \quad (10)$$

$$2\dot{O}H \longrightarrow 1/2O_2 + H_2O \quad (11)$$

$$[HSO_5^-]_{ad.} + h^+_{vb} \longrightarrow SO_5^{\cdot-} + H^+ \quad (12)$$

$$2SO_5^{\cdot-} \xrightarrow{H_2O} 2HSO_4^- + O_2 \quad (13)$$

The reaction of the electron with PMS occurs in two ways, Reactions 7a and 7b. The formation of $SO_5^{\cdot-}$, $SO_4^{\cdot-}$, and ·OH as radical products from PMS were identified by optical pulse radiolysis[14a] and in-situ-photolysis ESR investigation using spin-trapping agents[22] such as fumaric and maleic acids.

The overall reaction for the decomposition of PMS by illuminated WO_3 could be written as

$$HSO_5^- \xrightarrow[\lambda \geqslant 410\,nm]{WO_3,\ h\nu} 1/2\,O_2 + SO_4^{2-} + H^+.$$

The quantum yields (Φ) determined, as explained previously, for the undoped and 2.5% RuO_2 doped WO_3 were 0.62 and 1.36 respectively. Since both the photogenerated e^-_{cb} and h^+_{vb} are capable of decomposing PMS, the expected quantum yield is 2. The low value observed in our experiments might be due to (i) all the photons hitting the surface of the reaction vessel are not absorbed by the semiconductor slurry (ii) electron–hole recombination and (iii) recombination of $SO_4^{\cdot-}$ and ·OH to form PMS.

Effect of 2-Propanol. Addition of 2-propanol is found to increase the rate of decomposition of PMS. The reaction was investigated by photolysing aqueous slurry containing various concentrations of 2-propanol (0.25—1.00 mol dm^{-3}) with a constant $[PMS]_0$ (1.00×10^{-3} mol dm^{-3}) and catalyst amount (25 mg). The rate of decomposition of PMS increased with increase in [2-PrOH]. The enhanced decomposition of PMS in the presence of 2-propanol is due to the additional Reactions 14 and 15 along with Reactions 8—13.

$$(CH_3)_2CHOH + h^+_{vb}, SO_4^{\dot{-}}, \dot{O}H \longrightarrow (CH_3)_2\dot{C}OH \quad (14)$$

$$(CH_3)_2\dot{C}OH + HSO_5^- \longrightarrow (CH_3)_2C{=}O + SO_4^{\dot{-}} + H_2O \quad (15)$$

In the presence of 2-propanol (0.50 mol dm^{-3}) the Φ values are 2.21 and 2.71 for undoped and 2.5% RuO_2 doped WO_3 respectively. The comparatively high Φ values observed here could be due to the reaction of $SO_4^{\dot{-}}$ and $\dot{O}H$ with 2-propanol instead of recombination and also due to the reduction of PMS by the alcohol radical formed (Eqs. 14 and 15).

It may be concluded that peroxomonosulfate which is photochemically active at $\lambda \leqslant 260$ nm is found to be decomposed in the presence of WO_3, doped and undoped with RuO_2, by visible radiation. The presence of 2-propanol further enhanced the decomposition of PMS.

The authors are indebted to Dr. K. I. Vasu, Director and his fellow Scientists, of Central Electrochemical Research Institute, Karaikudi, India for their assistance in taking diffuse reflection spectra and SEM photographs. One of the authors (M. Ashokkumar) acknowledges the financial support (as fellowship) from the University Grants Commission, New Delhi, India.

Studies on Metal Chelates of 8-Hydroxy-5-quinolyl Ketone Oxime, *O*-Carbamoyl and *O*-Thiocarbamoyl Derivatives as Bactericides

Z. H. KHALIL, A. A. ABDEL-HAFEZ, A. S. YANNI,* and A. M. MOHARAM
Chemistry and Botany Departments, Faculty of Science, Assiut University, Egypt
(Received February 29, 1988)

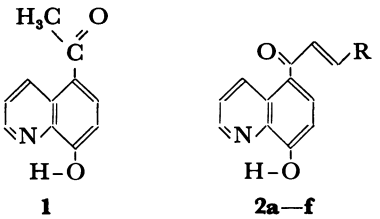
The reaction of 5-acetyl-8-quinolinol (**1**) and corresponding chalcone derivatives **2a—f** with hydroxylamine hydrochloride in boiling pyridine gave the corresponding oximes **3** and **4a—f** respectively in almost quantitative yields. Further interaction of **3** and **4a—e** with phenyl isocyanate and/or thiocyanate the corresponding carbamate and/or thiocarbamate (**5a,b**) and (**6a—e**, **7a—e**) were achieved. Metal chelates of **1**, **3**, and **4e,f** with bivalent metal cations like Fe(II), Cu(II), and Zn(II) have been synthesized and characterized by elemental and IR-spectral analysis. The synthesized compounds were biologically screened to study the structure activity relationship, (SAR) and the effect of complexation and type of metal cation on the potency of the more biologically active compounds.

The biological activity of oximes, carbamates, and thiocarbamates is of interest. Acetophenone *O*-methylcarbamoyl oxime and esters of dithiocarbamic acids, have clearly been established as insecticides,[1] leading anthelmintic[2-4] and herbicidal[5] agents. It has been observed recently that some drugs have increased activity when administered as metal complexes more so their metal chelates.[6,7]

In this work SAR has been done to evaluate the bactericidal activity of the oxime, carbamate, thiocarbamate derived from 5-acetyl-8-quinolinol and/or its chalcone derivatives. Effect of complexation and type of metal cation on the potency of the more effective compounds was considered.

Results and Discussion

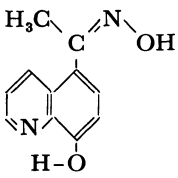
Interaction of **1** and the chalones **2a—f** with hydroxylamine hydrochloride gave the corresponding oximes **3** and **4a—f** respectively.



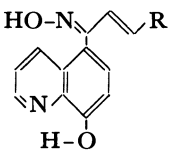
1

2a—f

a, R = C_6H_5
b, R = *p*-$CH_3OC_6H_4$
c, R = *p*-ClC_6H_4
d, R =
e, R = *n*-C_3H_7
f, R = *n*-C_6H_{13}



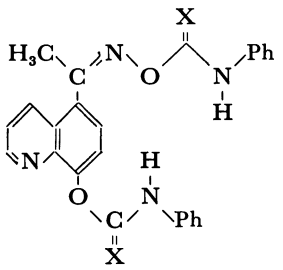
3



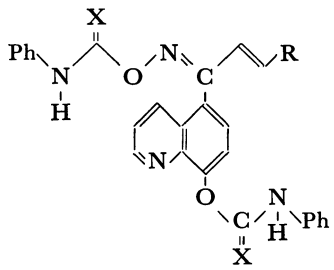
4a—f

The IR spectra of compound **3** and **4a—f** showed a broad band at 3200—2800 cm^{-1} characteristic to the oxime hydroxyl group in addition to ν C=N at 1600 cm^{-1} with the lack of ν C=O group. The NMR (DMSO) of compound **3** revealed signals at δ 2.3 (s, 1H, OH), 2.8—3.2 (s, 3H, CH_3), and 6.75—7.4 (m, 5H, aromatic), the proton of Q-OH was appeared at δ 7.2 confusing with the aromatic protons.

Phenyl isocyanate and phenyl isothiocyanate react readily with the oximes **3** and **4a—e** in boiling dry benzene in presence of triethylamine to afford the corresponding carbamates and thiocarbamates **5a,b**; **6a—e** and **7a—e** in good yields.



5a, X=O
b, X=S

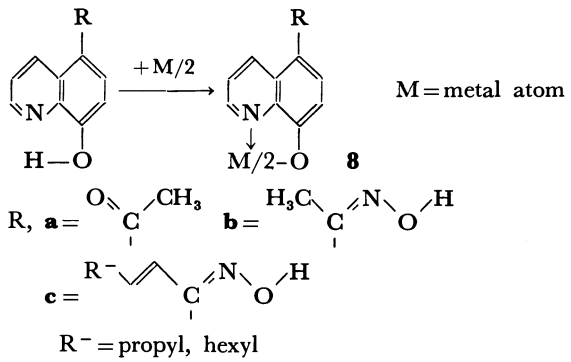


6a—e, X=O
7a—e, X=S

The structure of the carbamates **6a—e** and thiocarbamates **7a—e** was assigned on both analytical and spectral data. The IR spectra of carbamates showed the lack of (ν OH) and presence of (ν NH) as a single band in the 3200 cm^{-1} region and (ν C=O) in the region 1700 cm^{-1}. The NMR (DMSO) spectra of **5b** showed signals at δ 3.25 (s, 3H, CH_3), 7.5—8.5 (m, 10H, aromatics), and 8.7 (s, 1H, NH); **6b** δ 2.8 (s, 3H, CH_3), 6.5—7.0 (m, 15H, aromatics), and 8.2 (s, 1H, NH).

Interaction of compounds **1**, **3**, **4e,f** with the appropriate amounts of metal salt solution gave the corresponding complex. The IR spectra showed a broad distinct band at 3200—3100 cm^{-1} in the ligands were found due to hydrogen bonding.[8,9] On this basis the intramolecular hydrogen bonded chelate structures (-O-H-N-) have been proposed for the ligands. A critical examination of the spectra of metal chelates indicates that the bands at 3100 cm^{-1} present in the ligands is shifted to higher values (3600—3300 cm^{-1}) in the chelates. Thus on metal chelate formation, the bands between 3600—3300 cm^{-1} which appear in all chelates are not present in the original ligands.[10,11] The disappearance of hydrogen-bonded -OH in the

ligands and its reappearance in the metal chelates are suggestive of O–M–N bond formation, where M is a metal atom. The bands of medium intensity around 1600 cm^{-1} in the spectra of ligands due to (ν C=N–) is shifted to lower values with weak intensity in the spectra of chelates. It is due to M←N bond formation. The bands between 1600—1490 cm^{-1} are due to aromatic rings. The overall study and the analytical data show that the ligands form chelates of the type ML_2 where L=ligand. The reaction may be written as follows:



The structure of the metal chelate is in good agreement with previous work.[12,13]

Screening for Antimicrobial Activity: The bacteriostatic properties of the oxime, carbamates, and metal chelate complexes were studied by the usual cupplate agar diffusion technique[12] against some selected Gram positive: *Bacillus cereus, Staphylococcus aureus,* and *Micrococcus luteus*; and Gram negative bacteria: *Serratia* sp., *E. coli,* and *Pseudomonas aeruginosa.*

A final concentration of 100 ppm of the tested compounds in ethylene glycol was used.

5-[1-(Hydroxyimino)ethyl]-8-quinolinol (**3**) is effective only against the tested Gram positive bacteria. Substituting the methyl group by a styryl Ph–CH=CH (**4a**) abolishes its potency, while further substitution by an electron releasing or activating group at the phenyl neucleus (**4b,c**) restore this activity towards *Bacillus cereus* and *Staph. aureus.* The same observation was noticed also on using furfurylidene instead of benzylidene Ph–CH= derivative (**4d**). On the other hand, substitution by a 1-pentenyl or 1-octenyl group (**4e** and **f**) enhances similarly the bactericidal activity and is also extends towards other tested *Gram negative* bacteria.

Converting the oxime **3** to its carbamate **5a** or thiocarbamate derivative **5b** removes its activity while the carbamate or thiocarbamate **6** or **7** have no effect on *micrococcus luteus,* and their activity either abolishes or have no changes on the other *Gram positive* bacterial species. It is worthy to mention that the thiocarbamate is less effective than the carbamate derivative (cf. **6e**, **7e**).

Metal chelation of the more effective bactericidal compounds **3**, **4e,f** with bivalent metal cations e.g. Cu^{2+}, Zn^{2+}, Fe^{2+} has different effect depending on the type of substituent at the 5-position within 8-quinolinol nucleus and the type of metal cation. Complexing with zinc increases largely its potency towards both *Gram positive* and *Gram negative* bacteria and is not significantly affected by the type of substitution at the 5-position of 8-quinolinol while complexing with Cu has different effect depending on the type of 5-substituent. The larger effect was noticed on increasing the alkyl side chain length within the 5-substituent relative to unsubstituted 5-acetyloxime, cf. $[\mathbf{3}]_2Cu$, $[\mathbf{4e}]_2Cu$, and $[\mathbf{4f}]_2Cu$; and 5-[1-(hydroxyimino)ethyl] complex $[\mathbf{3}]_2Cu$ is less effective than its precursor 5-acetyl $[\mathbf{1}]_2Cu$. On the other hand complexing with Fe^{3+} has different effect. It decreases sharply or abolishes the potency after complexation especially on enlarging alkyl side chain with the 5-substituent, (cf. $[\mathbf{4e}]_2Fe$, $[\mathbf{4f}]_2Fe$).

Conclusion

5-Acetyl-8-quinolinol is more effective as bactericides than its oxime, while the chalcone oxime derivatives **4a—f** have variable effect depending on the type of the substituent R. Conversion of the oxime to carbamate or thiocarbamate decreases or abolishes this activity and the carbamates are more effective than corresponding thiocarbamates.

On complexation of the ligands it increases and extends the activity towards *Gram negative* bacteria depending on the type of metal cation used. The more effective complexes are those containing Zn metal independing on the 5-substituent which is not the case of Cu.

Experimental

All the melting points are uncorrected. IR spectra were recorded on a Perkin-Elemer infrared 137B spectrophotometer. NMR spectra in DMSO were measured on a Varian, 90 MHz. The time allowed for the completion of the reaction and the purity of the prepared compounds were monitored by TLC.

Reaction of 5-Acetyl-8-quinolinol (1) and Its Chalcone Derivatives 2a—f with Hydroxylamine Hydrochloride: A solution of 5-acetyl-8-quinolinol (**1**) and/or corresponding chalcones **2a—f** (0.01 mol) and hydroxylamine hydrochloride (0.015 mol) in dry pyridine[14] (20 ml) was heated under reflux for 3 h. The reaction mixture was poured onto crushed ice and the precipitated solid was filtered off and crystallized from the suitable solvent to give the corresponding oximes **3** and **4a—f** respectively. The results are given in Table 1.

Reaction of Oximes 3 and 4a—f with Phenyl Isocyanate and Phenyl Isothiocyanate: A solution of the oximes **3**, **4a—e** (0.01 mol), phenyl isocyanate or phenyl isothiocyanate (0.01 mol) in dry benzene 25 ml containing triethylamine (0.5 ml) was heated under reflux for 4 h. The

Terpenoids. XI.[1] Mayurone Oxide

Shizuo NAGAHAMA,* Takafumi FUCHINOUE, and Masato TAZAKI
The Kumamoto Institute of Technology, Ikeda 4-22-1, Kumamoto 860
(Received April 30, 1988)

Synopsis. Epoxidation of mayurone **7** gave mayurone oxide **21** in good yield. Grignard methylation of **21** gave epoxy alcohols, **17** and **22**. Thujopsadiene monoepoxide **23** was synthesized from **21** by Wittig reaction. Oxide **21** and **23** were found in the autoxidation product of **1**. Oxide **21** was found in the autoxidation product of **2**, **3**, and **6**.

Oxidation of thujopsene **1** under various conditions[1-3] generally gave a complicated mixture including mayurone **7**.[4] Our current concern is the full characterization of the complicated mixture in order to determine the reaction mechanism and to control the reaction specific to a chiral thujopsane derivative bearing versatile functionalities. During the time consuming separation and isolation of the minor products from permanganate oxidation of **1**, some epoxy ring containing products are indicated as well as **5**[3] and **17**[1] isolated earlier.

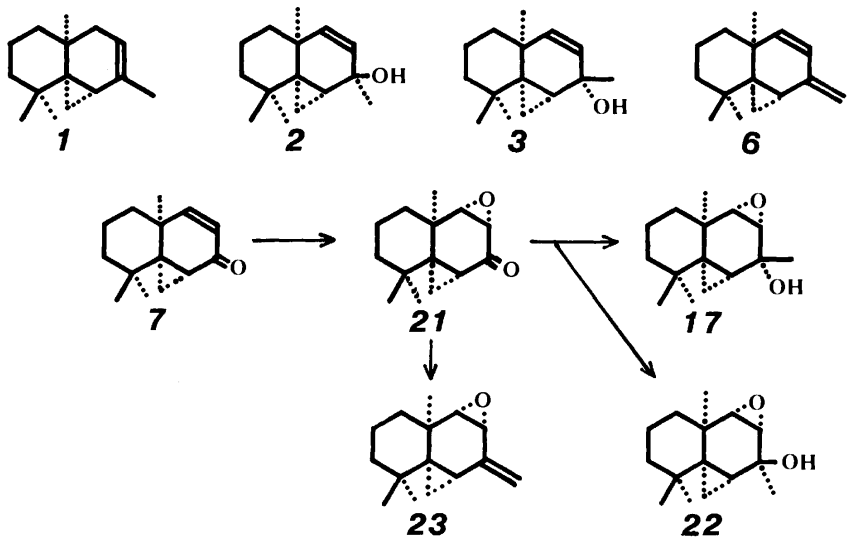
Direct epoxidation of **1** failed under various conditions,[5] but an epoxidation of mayurone **7** gave a new oxide **21** in high yield. The compound **21** was a useful intermediate to synthesize some standard samples of epoxy-ring-containing thujopsanes for the characterization of minor products in the oxidation products of **1**.

Results and Discussion

Mayurone **7** gave only an epoxide in high yield upon treatment with alkaline hydrogen peroxide in aqueous methanol. The epoxidation is highly diastereoselective, i.e., no epimeric epoxide was found in the products by GLC and ^{1}H NMR analyses. The ^{1}H NMR of the epoxide showed two vicinal protons on an epoxy ring, one of which showed a long-range coupling constant of 1.6 Hz. The configuration of the epoxy ring was further established as the structure **21** by correlation to a known epoxide **17**[1] as described below. A Grignard methylation of **21** at low temperature occurred at the carbonyl group, giving a mixture of two epoxy alcohols. They were separated by silica-gel chromatography to about an 8:1 product ratio. Since the minor product was identical with **17**,[1] α-configuration of the epoxy ring in **21** was established. The major epoxy alcohol mp 80 °C was assigned as structure **22**. Interestingly, the stereoselectivity in the methylation is reversed on going from mayurone[3] **7** to its epoxide **21**, due to a subtle difference in steric hindrance around the carbonyl groups.

Reaction of **21** with triphenylphosphonium methylide gave a new thujopsane derivative **23**, assigned by IR and ^{1}H NMR spectra.

Since our major interest was the full characterization of the complicated mixture from **1** by permanganate oxidation in anhydrous acetone,[3] reanalysis by GLC of the mixture was attempted briefly. The result suggested the presence of the new compounds **21** and **23**, but their direct formation by permanganate oxidation is unlikely. Rather they were considered to have arisen from secondary autoxidation of the major components in the product, i.e., **1** (unreacted), **2**, **3**, and **6**,[3] during the time consuming separations. Therefore the autoxidation was examined on these components separately. Mayurone oxide **21** and thujopsadiene 8α,9-epoxide **23** were found in the products of the autoxidation of **1**. Mayurone oxide **21** was also found in the autoxidation products of thujopsadiene **6** and 9-thujopsen-8-ols **2** and **3** besides **7**. These results show that the complex mixture from permanganate oxidation of **1** is partly due to the autoxidation of the primary products.



Experimental

Mayurone oxide 21 from Mayurone 7: Mayurone 74 mg was added to a mixture of 30% H_2O_2 (0.15 ml), 6 M-NaOH (0.024 ml; 1 M=1 mol dm^{-3}) and methanol (1.0 ml) and the mixture was stirred for 1 h at room temperature. After the addition of water (50 ml) and sat. NaCl (20 ml), the mixture was extracted with ether-hexane (2:1). Evaporation of the solvent gave **21** 79 mg as the sole product. **21**: mp 93.5—94.5 °C (from methanol). IR (KBr) 3020, 2950, 1680, 1488, 1465, 1446, 1390, 1380, 1366, 1290, 1247, 1172, 1040, 1018, 980, 965, 945, 912, 868, 840, 828, 780, 770, 650, and 446 cm^{-1}. ^1H NMR ($CDCl_3$) δ=0.57 (3H, s), 1.10 (3H, s), 1.53 (3H, s), 3.04 (1H, d, J=4.0 Hz), 3.25 (1H, dd, J=4.0 and 1.6 Hz), and 0.64—2.18 (9H, m).

Grignard Methylation of 21: Mayurone oxide **21** (0.50 g) in dry THF (10 ml) was cooled to −70 °C. Methylmagnesium iodide (1.37 M, 1.66 ml) was added under an argon atmosphere and stirred for 1 h at −70 °C. The reaction mixture was hydrolyzed with aqueous ammonium acetate solution at −50 °C, extracted with ether-hexane (1:1), and dried over sodium sulfate. The solvent was evaporated and the residue was chromatographed on a silica-gel column. Hexane-CH_2Cl_2 (8:2 to 7:3) eluted unchanged **21** (0.25 g). Hexane-CH_2Cl_2 (1:1) and CH_2Cl_2 eluted **22** (228 mg) and ether-CH_2Cl_2 (1:19) eluted **17** (27.5 mg) mp 106 °C, identified by IR and ^1H NMR.[1] **22**: mp 78—80 °C. IR (KBr) 3470, 3380 (OH), 3100, 2950, 2930, 1480, 1370, 1128, 1090, 1050, 965, 938, 908, 858, 822, 812, 801, 742, 606, and 503 cm^{-1}. ^1H NMR ($CDCl_3$) δ=0.26 (1H, dd, J=10.1 and 4.3 Hz), 0.55 (3H, s), 0.89 (1H, dd, J=5.6 and 4.3 Hz), 1.02 (3H, s), 1.33 (3H, s), 1.46 (3H, s), 2.66 (1H, d, J=3.8 Hz), and 2.93 (1H, dd, J=3.8 and 2.0 Hz).

Thujopsadiene Monoepoxide 23 from Mayurone Oxide 21: To a suspension of methyltriphenylphosphonium bromide, 200 mg (0.56 mmol) in 5 ml of tetrahydrofuran, 0.28 ml of 1.55 M butyl lithium in hexane was added at −40 °C. After stirring the mixture for 30 min, 100 mg of mayurone oxide **21**, 0.46 mmol was added at room temperature and the mixture was refluxed for 4 h. Four ml of aqueous sodium chloride solution was added and the organic layer was separated. GLC analysis of the layer showed **23**, 39%, **21**, 11%, triphenylphosphine oxide 39% and unidentifiable products 11%. The products were chromatographed on silica gel. Hexane-CH_2Cl_2 eluted 47 mg of **23**. Oil, IR (neat) 3080, 3050, 3000, 2850, 1633 (CH_2=C), 1460, 1385, 1370, 1253, 1170, 1043, 945, 903, 878, 863, 832, 805, 762, and 682 cm^{-1}. ^1H NMR ($CDCl_3$) δ=0.58 (3H, s), 1.04 (3H, s), 1.38 (3H, s), 2.77 (1H, d, J=4 Hz), 3.41 (1H, dd, J=4 and 1.5 Hz), and 5.16 (2H, broad s).

Compounds 21 and 23 in Autoxidation Products of 1: In the autoxidation products of thujopsene (23.8 g) reported previously,[1] a fraction (265 mg, 1.1%, 90% pure by GC) just after the elution of dimeric peroxide **16** was found to be **23** by comparison of the IR. The crude mayurone fraction was combined and rechromatographed on SiO_2 gel affording **21** (28 mg, 0.1%) preceeding the mayurone fraction, identified by IR.

Compound 21 from Allylic Alcohol 2: A sample of alcohol **2** (93% pure) was autoxidized on standing for 6 months. Gas chromatography showed **6**, 6%, **2**, 21%, **7**, 33%, and **21**, 14%.

Compound 21 from Allylic Alcohol 3: Alcohol **3** 0.50 g was autoxidized on standing for more than 6 months. Gas chromatography showed **6**, 52%, **3**, 2%, **7**, 23%, and **21**, 10%. Alumina and silica gel chromatography gave 0.02 g of **21**, identified by IR.

Compound 21 from Thujopsadiene 6: Thujopsadiene **6** was synthesized from mayurone and methylmagnesium iodide. The diene **6**, 2.88 g was autoxidized on standing for more than 6 months. Gas chromatography showed **6**, 53%, **7**, 32%, and **21**, 6%. Silica-gel chromatography gave 0.05 g of **21**, identified by IR.

Selective Nuclear Halogenation of Polymethylbenzenes with Alumina-Supported Copper(II) Halides

Mitsuo KODOMARI,* Hiroaki SATOH, and Suehiko YOSHITOMI
Department of Industrial Chemistry, Shibaura Institute of Technology, Shibaura, Minato-ku, Tokyo 108
(Received May 19, 1988)

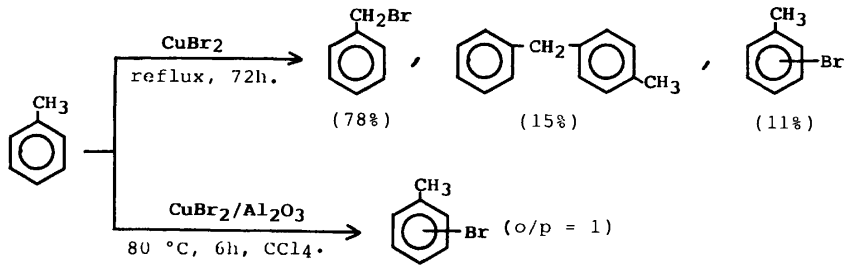
Synopsis. The halogenation of polymethylbenzenes with alumina-supported copper(II) halides under heterogeneous conditions in nonpolar solvents gave nuclear-halogenated compounds selectively in high yields; no side-chain-halogenated compounds were formed.

Although copper(II) halides have been used to halogenate aromatic hydrocarbons under heterogenous conditions in nonpolar solvents,[1] aromatic hydrocarbons with ionization potential (IP) higher than approximately 7.55 eV are entirely unreactive toward chlorination with copper(II) chloride.[2] For example, chlorination of naphthalene (IP=8.10[3]) or phenanthrene (IP=8.03[3]) does not occur, even under reflux, with copper(II) chloride in high-boiling solvents, such as chlorobenzene and nitrobenzene.[1,4] Previously, we reported that copper(II) halides can be activated remarkably by supporting onto neutral alumina,[5] and polycyclic aromatic hydrocarbons or alkoxybenzenes are halogenated selectively to give corresponding halides by use of copper(II) halides supported onto neutral alumina.[6,7] In reactions of alkylbenzenes with metal halides, side-chain-halogenation and polymerization in addition to nuclear-halogenation occur.[8] In contrast, we found that similar reactions with alumina-supported copper(II) halides gave selectively nuclear-halogenated products in high yields. In this paper, we report on a convenient method of selective nuclear halogenation of polymethylbenzenes with alumina-supported copper(II) halides.

Results and Discussion

The halogenation of polymethylbenzenes with alumina-supported copper(II) halides in nonpolar solvents in which copper(II) halides were not soluble, occurred as a heterogeneous reaction on the surface and gave only nuclear-halogenated compounds in high yields; no side-chain-halogenated compounds were obtained. The reaction of copper(II) bromide with mesitylene in carbon tetrachloride at reflux yielded no detectable products after 5 h. In contrast, in a similar reaction using alumina-supported copper(II) bromide, bromomesitylene in 97% yield from a reaction run at 50 °C for 1 h and dibromomesitylene in 99% yield from the reaction run at 80 °C for 5 h were obtained. The results of chlorination and bromination of polymethylbenzenes are summarized in Tables 1 and 2. The reactivity of polymethylbenzenes toward copper(II) halides increased with increasing the number of methyl groups. For instance, bromination of toluene in carbon tetrachloride did not proceed at reflux, even though pentamethylbenzene was brominated at 30 °C to give bromopentamethylbenzene quantitatively. Toluene and copper(II) bromide reacted at reflux for 72 h to give benzyl bromide as the main product. In a similar reaction with alumina-supported copper(II) bromide, bromotoluene (*o*/*p*=1) was obtained in good yield and no side-chain-brominated compounds were detected.

The reaction of alkylbenzene with copper(II) bromide is critically influenced by the presence of water in small quantities.[9] With toluene, nuclear bromination predominates in a rigorously anhydrous system. When small amounts of water are added, phenyl(*p*-tolyl)methane is the main product, in addition to benzyl bromide. In contrast, in a reaction with alumina-supported copper(II) bromide in the presence of water in small quantities, only nuclear bromination occurred and no products resulting from side-chain-bromination were formed. It seems that alumina not only activates copper(II) halides but also acts as a dehydrating agent in this system. Copper(II) chloride was less reactive than copper(II) bromide toward the polymethylbenzenes. The chlorination of the polymethylbenzenes required more severe conditions than that of bromination. The chlorination of xylene did not occur under the same conditions, even though the bromination proceeded at 80 °C in carbon tetrachloride. With polymethylbenzenes containing more than three methyl groups. The corresponding nuclear-monochlorinated compounds were obtained selectively in high yield. A reaction of pentamethylbenzene, even at 80 °C for 5 h gave chloropentamethylbenzene in 98% yield (isolated).



Scheme 1.

Table 1. Bromination of Polymethylbenzenes with $CuBr_2/Al_2O_3$[a]

Polymethylbenzene	Reaction temp/°C	Reaction time/h	Product	Yield/%[b]
a Methyl-	80	6	2- and 4-Br	85[c]
b 1,3-Dimethyl-	80	2	4-Br	98(85)
c 1,2,3-Trimethyl-	80	1	4-Br	97(87)
d 1,3,5-Trimethyl-	50	1	2-Br	97(86)
	80	5	2,4-Br	99(97)
e 1,2,3,5-Tetramethyl-	50	1	4-Br	92(90)
	80	5	4,6-Br	99(98)
f 1,2,3,4,5-Pentamethyl-	30	1	6-Br	(99)

a) All the reaction was carried out in carbon tetrachloride. The molar ratio of CuBr/polymethylbenzene was 5. b) Determined by GLC; figures in parentheses show the yield of isolated product. c) $o/p=1$.

Table 2. Chlorination of Polymethylbenzenes with $CuCl_2/Al_2O_3$[a]

Polymethylbenzene	Reaction temp/°C	Reaction time/h	Product	Yield/%[b]
c	110	4	4-Cl	95(80)
d	110	5	2-Cl	90(78)
e	130	3	4-Cl	91(82)
f	80[c]	5	6-Cl	(98)

a) Reactions were carried out in chlorobenzene. The molar ratio of $CuCl_2$/polymethylbenzene was 5. b) Determined by GLC; figures in parentheses show the yield of isolated product. c) The reaction was carried out in carbon tetrachloride.

The advantages of this procedure are simple workups, mild reaction conditions and higher selectivities. Products can be isolated by simple filtration and solvent evaporation, and no extraction steps are required.

Experimental

Preparation of Copper(II) Bromide Supported on Alumina: To a solution of copper(II) bromide (10 g) in distilled water (30 ml) was added neutral alumina (20 g, Woelm N-Super 1) at room temperature. The water was evaporated by using a rotary evaporator at 80 °C under reduced pressure. The resulting reagent was then dried under vacuum (4 Torr; 1 Torr≈133.322 Pa) at 100 °C for 15 h. The preparation of alumina-supported copper(II) chloride was similar to that described above.

4-Bromo-*m*-xylene: General Procedure for Bromination of Polymethylbenzenes. A mixture of *m*-xylene (2.4 g, 22.6 mmol), alumina-supported copper(II) bromide (50.5 g), and carbon tetrachloride (60 ml) was placed in a 100 ml round-bottom flask and stirred with a Teflon-coated magetic stirring bar at 80 °C for 1 h. The products mixture was filtered, and the spent and unused reagent were washed with carbon tetrachloride (30 ml). The solvent was evaporated from the combined filtrate under reduced pressure, and the residue was distilled under vacuum to give 3.6 g (86%) of 4-bromo-*m*-xylene. Bp 89—91 °C/14 Torr (lit,[10] 203 °C). The ^1H NMR and IR spectra was identical with those of an authentic sample.

6-Chloro-1,2,3,4,5-Pentamethylbenzene: General Procedure for Chlorination of Polymethylbenzenes. A mixture of pentamethylbenzene (2.0 g, 13.5 mmol), alumina-supported copper(II) chloride (28 g) and carbon tetrachloride (40 ml) was stirred at 80 °C for 5 h. The product mixture was filtered, and the spent and unused reagents were washed with carbon tetrachloride (30 ml). Evaporation of the solvent from the combined filtrate under reduced pressure yielded 2.42 g (98%) of 6-chloro-1,2,3,4,5-pentamethylbenzene as a white solid having mp 152—153 °C (lit,[11] mp 154.5—155 °C). The ^1H NMR and IR spectra was identical with those of an authentic sample.

Normal Pressure Double Carbonylation of Aryl Halides Using Cobalt(II) Chloride in the Presence of either Sodium Sulfide or Sodium Borohydride

Kenji ITOH, Masahiro MIURA,* and Masakatsu NOMURA
Department of Applied Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka 565
(Received May 27, 1988)

Synopsis. Tetracarbonylcobaltate ion generated by a treatment of cobalt(II) chloride with either sodium sulfide or sodium borohydride under a normal pressure of carbon monoxide was capable of catalyzing carbonylation of aryl halides in the presence of calcium hydroxide and methyl iodide to give arylglyoxylic acids in good selectivity.

Several effective methods for cobalt-catalyzed carbonylation of aryl halides to produce the corresponding carboxylic acids, α-keto carboxylic acids, and alkyl aryl ketones have recently been developed, using either tetracarbonylcobaltate ion $Co(CO)_4^-$ under photostimulation[1,2] or alkyltetracarbonylcobalt complexes $RCo(CO)_4$.[3,4] In the latter case, we reported that the product distribution is a marked function of the solvent system employed.[4] These reactions smoothly proceed in the presence of an appropriate base under extremely mild conditions. The catalytically active species are usually prepared in situ from somewhat air-sensitive octacarbonyldicobalt $Co_2(CO)_8$. Simple inorganic cobalt salts have also been successfully used as the catalyst precursors;[5-7] however only the monocarboxylic acids were isolated.

As part of our study, we have undertaken the synthesis of the α-keto carboxylic acids using cobalt salts in order to provide a convenient route to the acids.[8] We observed that the tetracarbonylcobaltate ion prepared by a treatment of cobalt chloride with either sodium sulfide in water[9] or sodium borohydride in dioxane[10] can catalyze the carbonylation of aryl halides (**1**) at room temperature under a normal pressure of carbon monoxide to give the corresponding α-keto acids (**2**) in good selectivity along with the glycolic acids (**3**) and the mono acids (**4**) (Eq. 1 and Table 1).[11]

$$\mathrm{ArX} \xrightarrow[\mathrm{Na_2S\ or\ NaBH_4\ /Ca(OH)_2}]{\mathrm{CO/CoCl_2/MeI}} \mathrm{ArCOCOOH} + \mathrm{ArCH(OH)COOH} + \mathrm{ArCOOH} \quad (1)$$

6	**1a** (5)	Na_2S	B	90	89	3	6
7	**1a** (10)	Na_2S	B	53	89	4	7
8	**1a** (10)	Na_2S	B[f]	31	88	7	2
9	**1a** (10)	Na_2S	B[g]	31	82	3	10
10	**1a** (5)[h]	Na_2S	B	11	20	17	60
11	**1b** (5)	Na_2S	A	42	53[i]	4	5
12	**1b** (5)	$NaBH_4$	A	40	57[i]	2	8
13	**1b** (5)	Na_2S	B	74	48[i]	2	8
14	**1c** (5)	Na_2S	A	61	62[i]	3	5
15	**1c** (5)	$NaBH_4$	A	48	68[i]	3	5
16	**1c** (5)	Na_2S	B	78	64[i]	3	13

a) The reaction was carried out using $CoCl_2$ (0.5 mmol), Na_2S (0.25 mmol) or $NaBH_4$ (1 mmol), $Ca(OH)_2$ (35 mmol), and methyl iodide (25 mmol) at 20 °C for 20 h. b) A: Dioxane–H_2O (3:1, v/v). B: 2-Propanol–H_2O (1:1, v/v). c) Yield based on the halide consumed was determined by GLC after trimethylsilylation with *N,O*-bis(trimethylsilyl)acetamide or methylation with diazomethane. d) Reaction for 40 h. e) $Co_2(CO)_8$ (0.25 mmol). f) 2-Propanol–H_2O (3:1, v/v). g) 2-Propanol–H_2O (1:2, v/v). h) Reaction at 60 °C. i) The keto acid was obtained as a mixture of the acid and the condensated product with pyruvic acid. The value indicates that after hydrolysis of the product mixture with NaOH.[3,4]

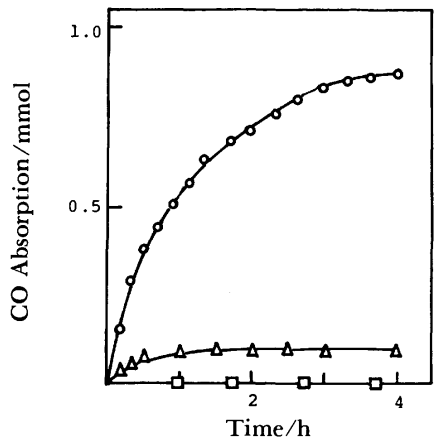

Fig. 1. CO Absorption in the treatment of $CoCl_2$ (0.5 mmol) with sulfur-containing compounds in the presence of $Ca(OH)_2$ (35 mmol): Na_2S (0.25 mmol) ○, $NaSCH_3$ (0.5 mmol) △, and $C_2H_5OCS_2K$ (0.5 mmol) □.

When cobalt chloride (0.5 mmol) was treated with sodium sulfide (0.25 mmol) in the presence of calcium hydroxide in water at 20 °C under carbon monoxide (1 atm) for 4 h, about 0.9 mmol of carbon monoxide was consumed (Fig. 1). The IR spectrum of the solution showed a single characteristic peak for $Co(CO)_4^-$ at 1913 cm^{-1} in the region 1700 to 2000 cm^{-1}. The addition of **1** (5 or 10 mmol) in dioxane, together with methyl iodide to the solution, gave **2** along with **3** and **4**. The formation of aryl methyl ketone was not detected in each reaction. The conversion of **1** and the selectivity of **2** were comparable with those using $Co_2(CO)_8$ (0.25 mmol) (Runs 1 and 5). Cobalt sulfide could not be used in place of $CoCl_2$–Na_2S, suggesting that the sulfide does not participate in the formation of the active species. While sodium methanethiolate, which is an efficient reagent for the preparation of nickel(0) carbonyl derivatives from nickel chloride,[12] could also be used in place of sodium sulfide, it was considerably less effective than the sulfide (Run 3 and Fig. 1). Potassium ethylxanthogenate and sodium diethyldithiocarbamate were ineffective.

As an alternative catalyst system for the carbonylation, $CoCl_2/NaBH_4/Ca(OH)_2$ could also be successfully used (Runs 4, 12, and 15). In this case, the cobaltate ion was prepared within 1.5 h (see Experimental).

It is noteworthy that, in the reaction in 2-propanol-water (1 : 1, v/v), a remarkably higher conversion of **1**, accompanied by a little decrease of the selectivity of **2**, was observed (Runs 6, 13, and 16). This is in contrast with the reactions in dioxane–water (1 : 1) and ethanol–water (1 : 1) in which the mono acids **4** were the major products.[4] The conversion of **1**, however, decreased as a result of changes in the 2-propanol–water ratio from 1 : 1 to both 3 : 1 and 1 : 2 (Runs 8 and 9).

In conclusion, the double carbonylation reaction of aryl halides to give arylglyoxylic acids was conveniently carried out using only simple reagents which are inexpensive and easily handled.

Experimental

Generation of Tetracarbonylcobaltate Ion. (a) To a flask containing cobalt chloride (0.5 mmol), sodium sulfide nonahydrate (0.25 mmol), and calcium hydroxide (35 mmol) was added water (10 cm^3). The mixture was stirred for 4 h at room temperature under carbon monoxide (1 atm). (b) A mixture of cobalt chloride (0.5 mmol) and sodium borohydride (1 mmol) in dioxane (10 cm^3) was stirred at 20 °C for 1 h, while bubbling carbon monoxide. Then, water (5 cm^3) and calcium hydroxide (35 mmol) were added and stirred for a further 20 min.

Carbonylation of Aryl Halides 1 and the Product Analysis. The methods were essentially the same as those described previously.[4]

The present work was partly supported by a Grant-in-Aid for Scientific Research No. 62750783 from the Ministry of Education, Science and Culture.

(Received June 7, 1988)

Synopsis. A linear correlation of the Hammett relationship was obtained for a catalytic reduction of substituted benzaldehydes with 2-propanol with hydrous zirconium oxide. The reaction constant ρ was 1.35, indicating that the electronic effect on the reaction is larger than that on the standard one.

In a previous paper, we reported that the reduction of aldehydes and ketones with 2-propanol proceeds efficiently in the presence of hydrous zirconium oxide.[1,2] All the conjugated ketones, as well as sterically hindered ones, could be substantially reduced by this method. The reduction of conjugated, as well as sterically hindered ketones, took a long time. The reduction of ketones with chloride substituted at the α-position was faster. There results suggested that both steric and electronic factors affect the reaction. The Hammett relationship is a useful method for an interpretation of the reaction mechanism, since it indicates the relative electronic effect quantitatively.[3]

In this paper, we report on the relative electronic effect on the reduction by use of the reaction constant (ρ), which was obtained by the Hammett relationship.

Experimental

Catalyst and Materials. Hydrous zirconium oxide was prepared in the manner described in a previous paper.[2] The calcination of the catalyst was performed at 300 °C for 5 h. Commercial reagents were used for the reaction without further purification.

Reduction and Analysis. In a 10 cm^3 round-bottom flask equipped with a reflux condenser, 1 mmol of aldehyde, 0.1 mmol of a hydrocarbon as an internal standard, 2 cm^3 of 2-propanol, and 0.1 g of hydrous zirconium oxide were placed. The reaction mixture was immersed in an oil bath which was kept at 78±0.1 °C, and 0.1—0.2 μl samples were removed at appropriate time intervals and analyzed by gas chromatography (capilary column PEG 20M 30m).

Results and Discussion

The reduction of substituted benzaldehydes proceeded efficiently to give the corresponding alcohols. No by-products were detected. Exceptionally, *p*-hydroxybenzaldehyde and *p*-(dimethylamino)benzaldehyde were mainly converted to *p*-hydroxybenzyl isopropyl ether and *p*-(dimethylamino)benzyl isopropyl ether, respectively. In all cases, a linear correlation between the natural logarithm of the concentration of aldehyde and reaction time was obtained. It indicated that the reaction rate is of pseudo-first-order in the aldehyde concentration,[2] and the rate constants, k, were calculated from the slope of the line, and are listed in Table 1.

The Hammett relationship for the reduction is illustrated in Fig. 1, and shows ln k/k_0, where k_0 is the rate constant for the reduction of benzaldehyde, plotted against σ, where σ is the substituent constant.[4] A linear correlation was obtained, except for the cases of *p*-hydroxybenzaldehyde and *p*-(dimethylamino)-benzaldehyde. This result suggests that a linear free

energy relationship exists in the reduction, and that the electronic effect can be directly evaluated.

The reaction constant, ρ, which was obtained from the slope of the line, reflects the sensitivity of the reaction rate to the electronic effect. The value of ρ was 1.35, which indicates that the electronic effect on the reduction was larger than that on the standard reaction (the esterification of substituted benzoic acids).[4]

The reduction of aldehyde with 2-propanol was believed to proceed via the attack on the carbonyl by the hydride from 2-propanol. From this it follows that the electronic deficient aldehyde was reduced faster. This interpretation is supported by the results for the Hammett relationship.

In the case of the reduction of *p*-hydroxybenzaldehyde and *p*-(dimethylamino)benzaldehyde, the rates were too slow and the products were mainly ethers. This is because the affinity of the hydroxyl or dimethylamino group to hydrous zirconium oxide is stronger than that of the carbonyl group.

The Synthesis and Characterization of Manganese(III) Complexes with the General Formula of $[Mn(X)(L)]^{n+}$ (n=0, 1) (X=Cl^-, N_3^-, Pyridine, *N*-Methylimidazole, L=*N*,*N*′-[(Methylimino)bis(trimethylene)]-bis[salicylideneaminate]: The X-Ray Crystal Structure of $[Mn(N\text{-MeIm})(L)][BPh_4]$

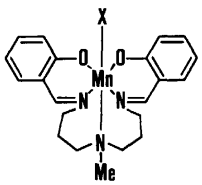
Synopsis. A series of manganese(III) complexes with the general formula of $[Mn(X)(L)]^{n+}$ (n=0, 1) have been prepared and characterized, where X=Cl^-, N_3^-, pyridine, *N*-methylimidazole, and L=quinquedentate Schiff base ligand *N*,*N*′-[(methylimino)bis(trimethylene)]bis[salicylideneaminate]. The X-ray analysis of $[Mn(N\text{-MeIm})(L)][BPh_4]$ confirmed that the coordination geometry of the manganese(III) ion is a tetragonal bipyramid in which two axial positions are occupied by a central amine nitrogen atom N(3) and an imidazole nitrogen atom N(4), with elongated bond distances of Mn–N(3)=2.388(6) Å and Mn–N(4)=2.251(6) Å.

Recently we have reported on imidazolate-bridged iron(III)–copper(II) and manganese(III)–copper(II) binuclear complexes.[1] As for the iron(III) and the manganese(III) component complexes of their binuclear complexes, complexes with a quinquedentate ligand *N*,*N*′-[methylimino)bis(trimethylene)]bis[salicylideneaminate], $[Fe(L)][BPh_4]$ and $[Mn(L)][BPh_4]$, were employed, because they can provide a coordination site by expanding coordination number. We have already reported on iron(III) complexes with the ligand and found that the iron(III) complexes with $[Fe(X)(L)]^{n+}$ (n=0, 1) constitute a family of spin-equilibrium complexes.[2,3] In this study, a series of manganese(III) complexes $[Mn(X)(L)]^{n+}$ (n=0, 1) (see the drawing) have been prepared and characterized.



Experimental

Syntheses. Ligand $[H_2L]$. The quinquedentate ligand was prepared by mixing salicylaldehyde (40 mmol) and bis(3-aminopropyl)amine (20 mmol) in 100 cm^3 of methanol. This ligand solution was subsequently used for the preparation of the manganese(III) complexes.

$[Mn(Cl^-)(L)]\cdot 1.5CH_3OH$. To a solution of $[H_2L]$ (20 mmol) in 100 cm^3 of methanol was added a solution of manganese(III) acetate dihydrate (20 mmol) in 30 cm^3 of methanol. The mixture was then stirred at room temperature for 10 min. The resulting solution was gently warmed under stirring for 30 min. To the mixture was added LiCl (50 mmol). The dark green needle crystals thus precipitated were collected by suction filtration and dried.

$[Mn(L)][BPh_4]\cdot 2CH_3OH$. To a solution of $[H_2L]$ (10 mmol) in 50 cm^3 of methanol was added a solution of manganese(III) acetate dihydrate (10 mmol) in 30 cm^3 of methanol. The mixture was then stirred at room temperature for 30 min. To the mixture was added a solution of sodium tetraphenylborate (15 mmol) in 30 cm^3 of methanol. The resulting solution was gently warmed on a water bath for 20 min and then cooled to room temperature. After several hours, black needle crystals thus precipitated were collected by filtration and dried.

$[Mn(N_3^-)(L)]\cdot 0.5H_2O$. To a solution of $[Mn(Cl^-)(L)]$ $2CH_3OH$ (1 mmol) in 30 cm^3 of methanol was added sodium azide (1.5 mmol) in a minimum amount of water. The solution was then gently warmed on a water bath for 10 min and filtered. The filtrate was cooled to room temperature. After several hours, the black crystals thus precipitated were collected by filtration and dried.

$[Mn(X)(L)][BPh_4]$ (X=Py, *N*-MeIm). To a solution of $[Mn(L)][BPh_4]$ in 30 cm^3 of methanol was added pyridine or *N*-methylimidazole (ca. 1.5 times by mole ratio). The solution was then warmed on a water bath for 10 min and then filtered. The filtrate was cooled to room temperature. After several hours, the black crystals thus precipitated were collected and dried.

Physical Measurements. The elemental analyses were performed by Mr. Shinichi Miyazaki at the Technical Service Center of Kumamoto University. The melting points were measured on a Yanagimoto micro melting point apparatus and were uncorrected. The electrical conductivity measurements were carried out on a Denki Kagaku Keiki AOC-10 digital conductometer on ca. 10^{-3} mol dm^{-3} acetonitrile solutions. The infrared spectra were recorded on KBr discs with a JASCO A-702 spectrophotometer. The magnetic susceptibilities were obtained by the Faraday method at room temperature using a Cahn 2000 electric balance. The susceptibilities were corrected for the diamagnetism of component atoms by the use of Pascal's constants. The molar effective magnetic moment was calculated by means of this equation $\mu_{eff}=2.828\sqrt{\chi_A T}$.

X-Ray Diffraction Study of $[Mn(N\text{-MeIm})(L)][BPh_4]$. The diffraction data were obtained on a Rigaku AFC-5 four-circle diffractometer at the Faculty of Science, Kyushu University, using graphite-monochromatized Mo $K\alpha$ radiation at 20±1 °C. Data concerning the conditions for crystallographic data collection and structure refinement is as follows: Formula=$MnO_2N_5C_{49}BH_{51}$, F.W.=807.7, triclinic, space group=$P\bar{1}$, a=11.680(5) Å, b=16.617(4) Å, c=11.649(4) Å, α=104.30(4)°, β=99.81(2)°, γ=93.26(2)°, V=2147.2 $Å^3$, D_{calcd}=1.249 g cm^{-3} (Z=2), D_{measd}=1.22 g cm^{-3} (by the floatation method in an aqueous KI solution), crystal dimension 0.4×0.3×0.3 mm,

Calcd values are in parentheses.

μ(Mo $K\alpha$)10.2 cm^{-1}, scan mode θ-2θ, scan speed 6° min^{-1}, scan width (1.1+0.5 tanθ)°, 2θ range 2.5—48°, octant collected h, $\pm k$, $\pm l$, no. of unique reflections data used 3960, R=6.48%, R_w=6.60%.

The intensity data were corrected for the Lorentz-polarization effect but not for the absorption. The structure was solved by the heavy atom method and refined by the block-diagonal least-squares method, in which weight w=1 was adopted for all the reflections. The hydrogen atoms were included in the structure factor calculations, but not refined. The calculations were carried out by the use of UNICS III computer program system[4] on a FACOM M 780 computer at the Computer Center of Kyushu University. The final positional parameters are given in Table 1.

Results and Discussion

The elemental analytical data, melting points, molar electrical conductivities, and effective magnetic moments at room temperature are given in Table 2. Either complex, [Mn(Cl^-)(L)] or [Mn(L)][BPh_4]2CH_3-OH, can be used as the starting compound for the synthesis of other complexes by using a way similar to that used for iron(III) complexes.[2,3] The chloro ion of [Mn(Cl^-)(L)] is easily substituted by N_3^- ion to

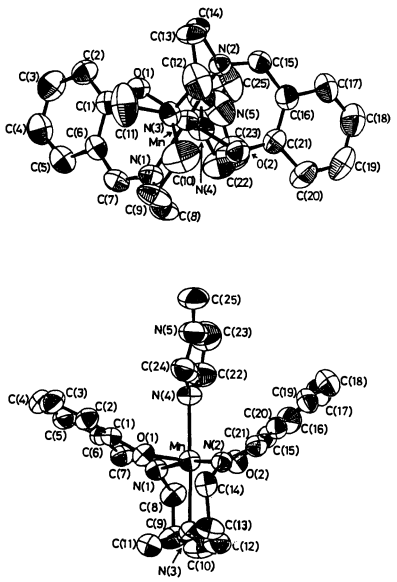

Fig. 1. Perspective drawing of the cation [Mn(*N*-MeIm)(L)]$^+$ with the atom numbering scheme.

produce the azide complex. The molar electrical conductances of the complexes [Mn(Cl^-)(L)] and [Mn(N_3^-)(L)] are not zero. This indicates that the unidentate ligands, such as Cl^- and N_3^-, are partially dissociated in the acetonitrile solutions. The electrical conductances of [Mn(L)][BPh_4], [Mn(*N*-MeIm)(L)]-[BPh_4], and [Mn(Py)(L)][BPh_4] are consistent with that of the 1:1 electrolyte. The effective magnetic moments of all the complexes indicate that the manganese(III) ions are in high-spin state (S=2).

Structural Description of [Mn(*N*-MeIm)(L)][BPh_4].[5] A perspective drawing of the [Mn(*N*-MeIm)(L)]$^+$ cation with the atom numbering scheme is shown in Fig. 1. The bond distances and angles are given in tables which are deposited as supplementary data.[5] The manganese(III) ion assumes a tetragonal bipyramidal coordination geometry, where the equatorial plane comprises N_2O_2 donors of two salicylideneamine moieties and where the two axial positions are occupied by the central amine nitrogen of L and a nitrogen of *N*-methylimidazole. The two salicylideneaminate moieties construct a shallow cave, in which the *N*-MeIm ligand is positioned. The geometry is similar to that of the analogous iron(III) complex [Fe(4-Mepy)(L)]$^+$.[2] A drastic difference between the iron(III) and manganese(III) complexes is found in the metal-axial ligand bond distances. The bond distances between the manganese(III) ion and the axial ligands are elongated, as in Mn–N(3)=2.388(6) Å and Mn–N(4)=2.251(6) Å, while the corresponding distances of the iron(III) analogue are 2.035(6) Å and 2.010(6) Å.[2]

Racemization of Optically Active Cysteine via Formation of 2,2-Dimethyl-4-thiazolidinecarboxylic Acid

Tadashi SHIRAIWA,* Kazuo KATAOKA, Shinji SAKATA, and Hidemoto KUROKAWA
Faculty of Engineering, Kansai University,
Yamate-cho, Suita, Osaka 564
(Received April 9, 1988)

Synopsis. Optically active cysteine (Cys) was racemized via formation of (*RS*)-2,2-dimethyl-4-thiazolidinecarboxylic acid ((*RS*)-DMT) by refluxing in the presence of acetone in 10-fold molar amount in acetic acid. The formed (*RS*)-DMT was hydrolyzed by adding water to the reaction mixture to give (*RS*)-Cys in 95—97% yield.

(*R*)-Cysteine (abbreviated as (*R*)-Cys), a useful material for medicines, food additives, and cosmetics, has been obtained mainly from hair. Such acquisition of (*R*)-Cys from natural products is apt to be unstationary. (*S*)-Cys, a useful material for antibiotics, is difficult to obtain from natural products. An efficient synthesis of (*RS*)-Cys has been reported, [1,2] and (*R*)- and (*S*)-Cys can be obtained by an optical resolution using preferential crystallization.[3-5] (*R*)-Cys has been demanded in large amounts, but (*S*)-Cys is not in so large an amount. Therefore, a practical method for the racemization of optically active Cys must also be established to use the preferential crystallization procedure for industrial purposes.

Optically active amino acids are racemized in the presence of aldehydes in several organic acids, such as formic acid and acetic acid, and the racemization rate is largest in acetic acid.[6] However, Cys forms 4-thiazolidinecarboxylic acid derivatives by reacting with aldehydes or ketones.[7-9] Of these derivatives, 2,2-dimethyl-4-thiazolidinecarboxylic acid (DMT) is obtained by reacting Cys with acetone and easily hydrolyzed in water to regenerate Cys.[8,9] Threfore, the racemization of optically active Cys via formation of (*RS*)-DMT was tried in the presence of acetone in acetic acid.

Experimental

Materials (*R*)-Cysteine hydrochloride monohydrate was purchased from Wako Pure Chemicals Ind. and recrystallized from water. An aqueous solution of the hydrochloride was adjusted with concentrated aqueous ammonia to pH 6 to obtain (*R*)-Cys: $[\alpha]_D^{20}$ +6.49° (*c* 4.04, 5 mol dm^{-3} HCl) (lit,[10] $[\alpha]_D^{25}$ +6.5° (*c* 2, 5 mol dm^{-3} HCl)). (*S*)-Cys ($[\alpha]_D^{20}$ −6.52° (*c* 3.99, 5 mol dm^{-3} HCl)) was obtained by optical resolution using the preferential crystallization of (*RS*)-4-thiazolidinecarboxylic acid[4] or (*RS*)-cysteine salt of 4-ethylbenzenesulfonic acid.[5]

Racemization. A mixture of 0.0200 mol (2.42 g) of (*R*)- or (*S*)-Cys and 0.200 mol (11.6 g) of acetone in 30 cm^3 of acetic acid was refluxed (approximately 93 °C) for 1—2.5 h. After adding 10 cm^3 of water to the mixture, the solution was dried under reduced pressure at 45 °C and the residue was redissolved in 10 cm^3 of water. The solution was dried under reduced pressure at 45 °C. The suspension of the residue in 50 cm^3 of methanol was stirred for 30 min at room temperature. (*RS*)-Cys was collected by filtration, washed with methanol, and dried; the (*RS*)-Cys showed no optical rotation in water or 5 mol dm^{-3} hydrochloric acid having mp 222—225 °C (decomp). The ^{1}H NMR spectrum of the obtained (*RS*)-Cys in deuterium oxide was recorded on a JEOL JNM-PMX 60 NMR spectrometer, with no methyl protons indicated.

Synthesis of (*R*)-2,2-Dimethyl-4-thiazolidinecarboxylic Acid. A mixture of 0.0200 mol of (*R*)-Cys and 0.0400 mol of acetone in 30 cm^3 of acetic acid was stirred at 30 °C for 0.5 h. After evaporating the mixture to 5 cm^3 at 45 °C, 50 cm^3 of diethyl ether was added to the solution and the suspension was stirred for 4 h at room temperature. The formed (*R*)-DMT was collected by filtration and washed thoroughly with diethyl ether. Found: C, 44.53; H, 6.84; N, 8.55% (Calcd for $C_6H_{11}NO_2S$: C, 44.70; H, 6.88; N, 8.69%); yield 2.52 g (78.2%); mp 144—145 °C (lit,[8] 138—140 °C); $[\alpha]_D^{20}$ −188° (*c* 0.102, acetone) (lit,[8] $[\alpha]_D^{22}$ −183° (acetone)), $[\alpha]_D^{20}$ −144° (*c* 0.503, methanol).

Rate Constant of Racemization. A mixture of 0.0200 mol of (*R*)-Cys and 30 cm^3 of acetic acid was heated at 60, 70, 80, or 90 °C. After adding 0.100, 0.200, or 0.400 mol of acetone to the mixture, the resulting solution was stirred at each temperature; (*R*)-Cys was dissolved completely by stirring for several minutes. One cm^3 portions of the solution were pipetted out at appropriate time intervals and diluted rapidly to 10 cm^3 with acetic acid. The optical rotation at 589 nm was measured with a Union Giken PM-101 digital polarimeter equipped with a quartz cell of 0.50 dm path length. The rate constant of racemization (k_R/h) was calculated by the least-squares method from

$$\ln \alpha_0 / \alpha_t = k_R t, \quad (1)$$

where α_t is the optical rotation at time t h and α_0 that extrapolated to zero time. The half-life period ($t_{1/2}$/h) was calculated on the basis of k_R values obtained by Eq. 1.

The racemization rate for (*R*)-DMT was similarly measured at 90 °C by using 0.0200 mol of (*R*)-DMT and 0.180 mol of acetone.

Results and Discussion

Formation and Hydrolysis of (*R*)-2,2-Dimethyl-4-thiazolidinecarboxylic Acid. (*R*)-DMT was obtained in 78.2% yield by reacting 0.0200 mol of (*R*)-Cys with 0.0400 mol of acetone in acetic acid at 30 °C for 0.5 h, as described in the experimental section. In this reaction, (*R*)-Cys was completely dissolved by stirring for 20 min, and the resulting solution showed a negative optical rotation. If (*R*)-Cys is merely dissolved and (*R*)-DMT does not form, the solution should show a positive optical rotation since (*R*)-Cys has $[\alpha]_D$ +13.0° (acetic acid)[12] and (*R*)-DMT $[\alpha]_D^{20}$ −109° (*c* 0.103, acetic acid). This result indicates that (*R*)-DMT forms rapidly with dissolution of (*R*)-Cys. Optically active amino acids and their derivatives are racemized in the presence of aldehydes or ketones.[6,11]

The (*R*)-DMT obtained under the above conditions is optically pure because the specific rotation (−188 °) in acetone agrees closely with the reported value (−183 °).[8]

After stirring the above reaction mixture for 0.5 h at 30 °C followed by adding water, a drying of the solution gave (*R*)-Cys($[\alpha]_D^{20}$ +6.50 ° (*c* 3.97, 5 mol dm^{-3} HCl)) as the residue in 89.1% (2.16 g) recovery.

The above result indicates that (*R*)-DMT is formed rapidly by reacting (*R*)-Cys with acetone in acetic acid and is easily hydrolyzed by adding water to regenerate (*R*)-Cys.

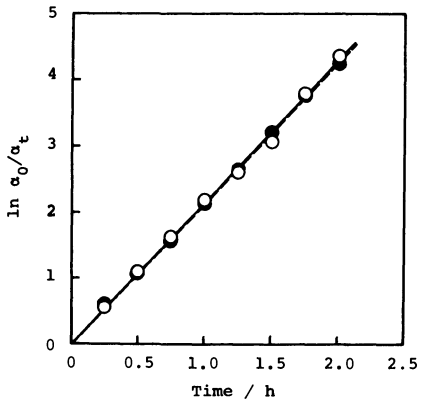

Fig. 1. First-order reaction for racemization.
Conditions: (*R*)-Cysteine ((*R*)-Cys) or (*R*)-2,2-dimethyl-4-thiazolidinecarboxylic acid ((*R*)-DMT) 0.0200 mol; acetic acid 30 cm^3; temperature 90 °C. —○—: (*R*)-Cys; acetone 0.200 mol. --●--: (*R*)-DMT; acetone 0.180 mol. α_0: Optical rotation extrapolated to zero time. α_t: Optical rotation at time *t* h.

Racemization of (*R*)-2,2-Dimethyl-4-thiazolidinecarboxylic Acid. (*R*)-Cys (0.0200 mol) was also reacted similarly with 0.200 mol of acetone at 50 °C for 1 h to give (*R*)-DMT in 85.9% (2.77 g) yield. The obtained (*R*)-DMT seemed to be partially racemized: $[\alpha]_D^{20}$ −139 ° (*c* 0.494, methanol); 96.5% optical purity. This result indicates that the formed (*R*)-DMT is racemized by increasing the amount of acetone and heating.

The optical rotation (α_t) of (*R*)-DMT or (*R*)-Cys was measured at 90 °C in the presence of acetone in 9- or 10-fold molar amount in acetic acid at 15 min intervals, as described in the experimental section. These racemizations can be regarded as first-order reactions because linear relationships are found between ln α_0/α_t and time *t*, as shown in Fig. 1. The rate constant (2.14 h^{-1}) for (*R*)-Cys agrees well with that (2.13 h^{-1}) for (*R*)-DMT. These results indicate that the rate-determining step is the racemization of (*R*)-DMT.

The rate constant for the racemization (k_R/h^{-1}) was measured at 60, 70, 80, or 90 °C. Acetone was used in 0.100, 0.200, and 0.400 mol for 0.0200 mol of (*R*)-Cys, the corresponding k_R's being represented as $k_{R(0.1)}$, $k_{R(0.2)}$, and $k_{R(0.4)}$, respectively. The k_R values and half-life periods ($t_{1/2}$/h) are listed in Table 1 for which the correlation coefficients between ln α_0/α_t and time *t* are over 0.99.

The $k_{R(0.2)}$ value (0.820 h^{-1}) at 80 °C is approximately equal to $k_{R(0.4)}$ (0.838 h^{-1}), though the $k_{R(0.1)}$ value (0.675 h^{-1}) is smaller than these values. Therefore, this racemization does not require acetone more than 10 times the molar amount of (*R*)-Cys. The dependence of $k_{R(0.2)}$ on temperature is given in the range 60—90 °C by

$$\ln k_{R(0.2)} = -12951 / T + 36.44, \quad (2)$$

Table 1. Rate Constant and Half-Life Period for Racemization[a]

Conditions		Rate constant	Half-life period
Temperature	Acetone	h^{-1}	h
°C	mol		
60	0.200	0.089	7.80
70	0.200	0.258	2.68
80	0.100	0.675	1.03
80	0.200	0.820	0.85
80	0.400	0.838	0.83
90	0.200	2.14	0.32

a) (*R*)-Cysteine (0.0200 mol) and acetone were stirred in 30 cm^3 of acetic acid.

Table 2. Racemization of Optically Active Cysteine[a]

Configuration of optically active Cys	Racemization period	Yield of (*RS*)-Cys
	h	g [%[b]]
(*R*)	1.0	2.32 [95.7]
(*R*)	1.5	2.33 [96.0]
(*R*)	2.0	2.34 [96.7]
(*S*)	2.0	2.35 [96.9]
(*S*)	2.5	2.35 [96.9]

a) Cys: Cysteine. Conditions: (*R*)- or (*S*)-Cys 0.0200 mol; acetone 0.200 mol; acetic acid 30 cm^3; temperature approximately 93 °C. b) The yield was calculated on the basis of the amount of (*R*)- or (S)-Cys used by reaction.

where T/K is temperature, and the correlation coefficient has been found to be 0.999. The $k_{R(0.2)}$ value at 50 °C was calculated to be 0.0262 h^{-1} from Eq. 2, which value suggests that the (*R*)-DMT obtained from the reaction at 50 °C for 1 h has 97.4% optical purity. The calculated optical purity agrees well with that (96.5%) of the obtained (*R*)-DMT.

Racemization of Optically Active Cysteine. Based on the above results, (*R*)- or (*S*)-Cys was racemized in the presence of acetone in 10-fold molar amount under reflux (approximately 93 °C). The results are listed in Table 2.

The k_R and $t_{1/2}$ values at 93 °C were calculated from Eq. 2 to be 2.90 h^{-1} and 0.24 h, respectively. These values suggest that 99.7% of optically active Cys is racemized by reacting for 2 h. As seen in Table 2, the racemization is almost complete in reaction for 2 h, and (*RS*)-Cys is obtained in high yield (97%).

(Received May 25, 1988)

Synopsis. Asymmetric induction during the aminolysis of 5(4*H*)-oxazolones from *N*-benzoyl amino acids was investigated using a series of amino acid esters as amine nucleophiles. The reaction of the oxazolone from *N*-benzoyl-DL-*t*-leucine with methyl L-prolinate was found to produce the diastereomeric D–L isomer, almost specifically, under appropriate conditions.

The formation of a chirally labile 5(4*H*)-oxazolone has been regarded as one of the main causes of racemization during segment coupling in peptide synthesis.[1] When a racemic oxazolone is allowed to react with an optically active amino acid ester, the peptide product is usually not a 1:1 mixture of diastereomers because of the occurrence of asymmetric induction. However, such asymmetric induction, reported first by Weygand et al.,[2] has not hitherto been explicitly taken into account in the problem of racemization during the segment coupling of two chiral residues.[3] Recently, Benoiton et al.[4] have studied the solvent and temperature effects on asymmetric induction during the aminolysis of the oxazolones from Bz-DL-Leu[5] and Z-Gly-DL-Leu with N^{ε}-Z-L-lysine esters, and have showed that the diastereomeric D–L isomer is formed in excess in a non-polar solvent (dichloromethane or THF) and the L–L isomer is formed in excess in a polar solvent (DMF), the proportion of the L–L isomer increasing with decreasing temperature. On the contrary, in the aminolysis of the pseudooxazolones from *N*-trifluoroacetyl amino acids in THF, it has been reported that the L–L isomer is formed in excess when the esters of amino acids (except proline, as mentioned below) are used as amine nucleophiles.[2b,6] These results indicate that the direction of asymmetric induction depends not only on the solvents but also on the nature of the reactants. It is difficult to draw general conclusions concerning the direction and the extent of asymmetric induction, because relevant experimental data have so far been very limited. This is partly due to the restriction of the methods for the analysis of peptide diastereomers.

We have recently found that diastereomeric pairs of a variety of *N*-acyl dipeptide esters can be separated well by reversed phase high performance liquid chromatography (RP-HPLC).[7] Taking advantage of this procedure we set about to conduct a further study on asymmetric induction in peptide synthesis from the viewpoint of the substituent, solvent, and temperature effects. During the course of this investigation we found a reaction system which generates the largest degree of induction reported to date.

We first investigated asymmetric induction during the aminolysis of the oxazolone from Bz-DL-Val with a series of L-amino acid esters both in a representative non-polar solvent, dichloromethane, and in a representative polar solvent, DMF. As shown in Table 1, even in DMF it is only when L-alanine methyl ester was used as an amine nucleophile that the L–L isomer

was formed in excess, while the D-L isomer was the predominant one in other cases. This was also the case with the aminolysis of the oxazolone from Bz-DL-Leu. When the solvent was changed from DMF to dichloromethane, the proportion of the D-L isomer increased in most cases, though there was observed one exception where L-isoleucine methyl ester was used as an amine nucleophile.

Amine nucleophiles had a profound effect on asymmetric induction. The most prominent was the fact that the proportion of the D-L isomer was exceedingly large both in dichloromethane and in DMF when L-proline methyl ester was used as an amine nucleophile. In the aminolysis of 2-trifluoromethyl-5(2*H*)-oxazolones, it has been reported that when an L-proline ester is used as an amine nucleophile, the direction of asymmetric induction is reversed, that is, the D-L isomer is formed predominantly in this case, in contrast to the cases using other L-amino acid esters which generate the L-L isomer in excess.[6] The direction of asymmetric induction during the aminolysis of 2-phenyl-5(4*H*)-oxazolones with proline methyl ester, however, was the same as that caused by the other amino acid esters as amine nucleophiles.

Next, using the proline ester as an amine nucleophile, we examined the aminolysis of the oxazolone derived from *t*-leucine (2-amino-3,3-dimethylbutanoic acid, Tle),[8] an unusual amino acid with a bulkier side chain than valine, in expectation of the generation of a higher degree of asymmetric induction. Thus, the oxazolone from Bz-DL-Tle was allowed to react with L-proline methyl ester in a variety of solvents at different temperatures (50 to −20 °C). The results are summarized in Table 2. Under all the conditions examined the D-L isomer was formed in excess to a large extent (≥70% D-L isomer), as expected. The effect of the solvent was extremely significant. Thus, the proportion of the D-L isomer was smallest in DMF and became largest in aromatic hydrocarbons. A similar effect of aromatic hydrocarbons was observed in the aminolysis (24 h at 0 °C) of other oxazolones with L-proline methyl ester as follows: the percentage of D-Val-L-Pro formed in the aminolysis of the oxazolone from Bz-DL-Val, 66 (DMF), 87 (toluene), 88 (*m*-xylene), 89 (*o*-xylene); percentage of D-aIle-L-Pro formed in the aminolysis of the oxazolone from Bz-DL-Ile, 79 (DMF), 92 (toluene), 92 (*m*-xylene), 92 (*o*-xylene). The effect of the temperature was also profound, especially in less apolar solvents. A lower temperature favored the formation of the D-L isomer in the present case. As a result of both the solvent and the temperature effects, the D-L isomer was formed almost specifically (97% D-L isomer) in the aminolysis of the oxazolone from Bz-DL-Tle in toluene or xylenes at −20 °C. This is the largest degree of asymmetric induction during the aminolysis of the oxazolones reported to date,[9] and makes a unique example of nearly exclusive formation of one epimer via the kinetic resolution of stereochemically labile enantiomers by a chiral reagent.

Experimental

Optical rotations were measured with a JASCO DIP-4 polarimeter. TLC and preparative TLC were performed on Merck Kieselgel $60F_{254}$ and Kieselgel GF_{254} (Type 60), respectively. The liquid chromatograph employed was a Shimadzu LC-3A instrument, equipped with a Shimadzu SPD-2A variable wavelength UV monitor and a Shimadzu Chromatopac C-R1A data processor. A prepacked ODS column (Cosmosil $5C_{18}$) consisted of a stainless-steel tube, 4.6 mm I.D. and 150 mm long. Bz-DL-Val-OH, Bz-DL-Leu-OH, Bz-DL-Ile-OH, and Bz-DL-Tle-OH[8b] were obtained as described by Greenstein and Winitz.[10] They were converted to 5(4*H*)-oxazolones using DCC or EDC·HCl according to methods described in the literature.[11,12]

HPLC Separation of the Diastereomers of *N*-Benzoyl Dipeptide Methyl Esters. Bz-DL-Val-OH (0.15 mmol) was coupled with H-L-AA-OMe·HCl (or TosOH) (where AA denotes the amino acid residues listed in Table 3) (0.15 mmol) in CH_2Cl_2 (2 ml) at 0 °C in the presence of TEA (0.14 mmol) by the DCC method. The neutral fraction was separated from the reaction mixture as usual. This fraction was submitted to a separation of the diastereomers by RP-HPLC under the conditions shown in Table 3. On the other hand, authentic samples to identify the L-L isomer on the chromatogram were prepared as follows: H-L-Val-L-AA-OMe·HCl (prepared via the coupling of Z-L-Val-OH (1 mmol) with H-L-AA-OMe·HCl (or TosOH) (1 mmol) in the presence of TEA (1 mmol) by means of EDC·HCl (1 mmol) and the subsequent debenzyloxycarbonylation by hydrogenation in the presence of 5% Pd-C and concd HCl) was dissolved in $CHCl_3$ (12 ml) and treated with benzoyl chloride (1.5 mmol) in the presence of TEA (2.2 mmol) for several hours. The neutral fraction was separated from the reaction mixture as usual. The capacity factors ($k'=(t_R-t_0)/t_0$, where t_R=retention time and t_0=void time) and the separation factors ($\alpha=k'_{D-L}/k'_{L-L}$) are listed in Table 3. The diastereomers of Bz-D/L-Val-L-AA-OMe for AA=Ser, Thr, Asp(OMe), Asn, Glu(OMe), Gln, Trp, and His could not be separated ($\alpha=1$) under any conditions examined.

Samples of a diastereomer mixture (L-L isomer + D-L isomer) and the corresponding L-L isomer for Bz-Leu-AA-OMe were prepared in the same manner as mentioned above.

D: mobile phase, 45% MeOH aq; flow rate, 0.8 ml min^{-1}; column temp; 50°C. c) In this case, $\alpha=k'_{L-L}/k'_{D-L}$.

Their HPLC data are also listed in Table 3. The diastereomers of Bz-D/L-Leu-L-AA-OMe for AA=Thr, Asp(OMe), Asn, Glu(OMe), Gln, and Trp could not be separated under any of the conditions examined.

Samples of a diastereomer mixture, L-Ile-L-Pro + D-aIle-L-Pro, and the corresponding L-L isomer were prepared in the same manner as mentioned above: k' for D-aIle-L-Pro was 3.67 and k' for L-Ile-L-Pro 4.30, and α=1.17 under the conditions B in the footnote b of Table 3.

Bz-L-Tle-L-Pro-OMe and Bz-D-Tle-L-Pro-OMe. These were obtained through a treatment of H-L(or D)-Tle-L-Pro-OMe·HCl (prepared in the same manner as described above for the valyl peptide derivatives) with benzoyl chloride in the presence of *N,N*-diisopropylethylamine in $CHCl_3$. L-L Isomer: syrup, purified by preparative TLC on silica gel with $CHCl_3$-EtOAc (9:1); $[\alpha]_D^{25}$ −70.5° (*c* 1.5, MeOH); Anal. ($C_{19}H_{26}N_2O_4$) C, H, N. D-L Isomer: mp 123—124°C (uncorrected) (EtOAc-petroleum ether); $[\alpha]_D^{22}$ −26.1° (*c* 1.0, MeOH); Anal. ($C_{19}H_{26}N_2O_4$) C, H, N. HPLC k'_{L-L}=5.20, k'_{D-L}=4.58, and α=1.14 (t_0=ca. 3.3 min) under the following conditions: mobile phase, 50% MeOH aq; flow rate, 1.0 ml min^{-1}; column temperature, 30°C; detection, 254 nm; sensitivity range, 0.02 absorbance units full scale (a.u.f.s.).

Aminolysis of 5(4*H*)-Oxazolones with L-Amino Acid Methyl Esters. A 5(4*H*)-oxazolone (0.15 mmol) and H-L-AA-OMe·HCl (or TosOH) (where AA denotes the amino acid residues listed in Table 1) (0.15 mmol) were dissolved (or suspended) in 1.5 ml of solvent, and the mixture was placed into a thermostatted bath (−20°C, 0°C, 5°C, 30°C, or 50°C). After 15 min, a solution of TEA (0.15 mmol) in 0.5 ml of the solvent was added and the reaction mixture was stirred for 24 h at the set temperature. After an addition of EtOAc (20 ml), the organic layer was separated, washed with 5% HCl, water, sat. $NaHCO_3$, and water, and dried over Na_2SO_4. One part of the residue obtained by the evaporation of the solvent was dissolved in MeOH and submitted to HPLC analysis. The results are summarized in Tables 1 and 2.

Decalino-14-crown-4. New Type of Lithium Ion Selective Ionophore

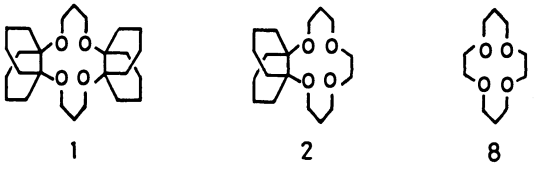
Department of Applied Fine Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka 565
(Received June 24, 1988)

Synopsis. A new type of crown ether, decalino-14-crown-4, has been synthesized and found to be a highly selective and effective ionophore for lithium ion.

Recently, lithium has become increasingly important not only in the wide area of the synthetic and industrial chemistry but also in the field of the atomic fusion as a vital raw material for tritium.[1] From the viewpoint of supplying for its great demand, much attention has been paid even to the concentration of lithium from the sea water. But the extration of lithium ion from the aqueous phase has been very difficult because of the strong hydration of water molecules around the cation. Only a few reports have been so far presented on the extraction or transport of lithium ion. Bartsch et al. reported that 14-crown-4 derivative bearing carboxyphenyl group as an additional binding site exhibited good lithium/sodium ion selectivity in competitive extraction.[2] Takagi,[3] Sasaki,[4] Shono,[5] and their co-workers independently reported that crown ethers with phenolic group as an additional binding site showed the excellent lithium/sodium ion selectivity in extraction of alkali metal ions.

On the other hand, as an extension of a decalin wall strategy for the design of new host molecules with high guest-selectivity,[6] we have previously reported that the cylindrical crown ether, didecalino-14-crown-4† (**1**), with no additional binding site exhibits highly effective extractabilty for lithium ion due to the embedding effect of decalin wall, by which the coordinated lithium ion was buried deep in lipophilic cylinder and was protected from the hydration of water molecules.[7] Althogh the crown ether **1** was an excellent **extractant** for lithium ion, it is not expected to be a selective and effective **ionophore** for lithium ion, because of the low efficiency of decomplexation process suppressed by the embedding effect of the decalin walls.

We now design a new type of lithium ion selective ionophore, decalino-14-crown-4 (**2**), containing one decalin subunit. This molecule is expected to satisfy the indispensable conditions as a selective ionophore: i) the appropriate balance between complexation and decomplexation abilities with the cation and ii) high lipophilicity required for efficient recycle of ionophore. In this paper, we wish to report on the synthesis of **2** and the effect of incorporated decalin subunits on lithium ion transport.

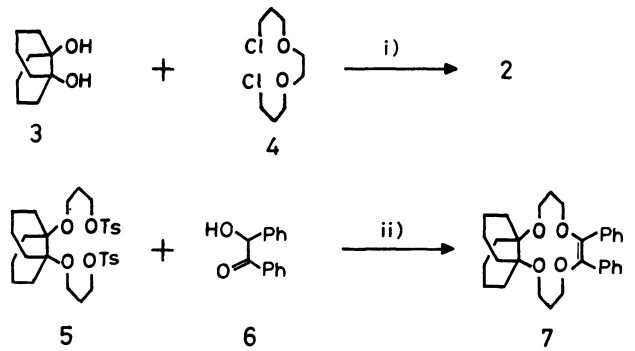


1 2 8

† Ortho-fused cyclic compound is tentatively named "decalino" for decahydronaphtho[4a, 8a].

Results and Discussion

The target ionophore **2** was synthesized by the similar procedure described by Liotta et al.[8] Reaction of 4a,8a-decalindiol (**3**) with 1,10-dichloro-4,7-dioxadecane (**4**) in dimethyl sulfoxide (DMSO) with NaOH as a base at 110 °C gave **2** as crystals (mp 69—70 °C), as shown in Scheme 1. As a reference compound, stilbene-incorporated decalino-18-crown-6, 7,8-dipheyl-2,6,9,13-tetraoxatricyclo[12.4.4.0^{1,14}]docos-7-ene (**7**), was designed. In this molecule, the stilbene unit is expected to have high lipophilicity as well as the decalin subunit. But, there is a marked difference in influence on the structure of crown ether ring between two subunits. Namely, two vinyl oxygen atoms bonding to the stilbene subunit must be fixed on the same plane, in contrast with gauche conformation of two oxygen atoms bonding to the decalin subunit or flexible conformation of them bonding to the ethane subunit. Crown ether **7** was synthesized by the method similar to that described by Merz[9a] and Inoue et al.[9b] Namely, reaction of 4a,8a,-bis[3-(tosyloxy)propoxy]-decalin (**5**) and benzoin with aqueous NaOH under phase-transfer conditions produced **7** in 22% yield as crystals (mp 154—155 °C).



i) NaOH, $LiClO_4$ ii) NaOH, Bu_4NBr

Scheme 1.

Prior to the transport experiment of alkali metal ions, solvent extraction was carried out in water/dichloromethane system[7] in order to know the complexation ability of the ionophore **2** toward some alkali metal ions. The results are listed in Table 1. The data in Table 1 clearly show that ionophore **2** has both excellent extractability for lithium ion (81%) and prominent Li^+/Na^+ selectivity (Li^+/Na^+=16), as

compared with **1** ($Li^+/Na^+=5$) and the reference compounds, **7** ($Li^+/Na^+=4$) and 14-crown-4 (**8**) ($Li^+/Na^+=11$). In addition, ionophore **2** could hardly extract K^+, Rb^+, and Cs^+. The selectivity order of **2** is $Li^+ \gg Na^+ > K^+ \simeq Rb^+ \simeq Cs^+$, indicating that ionophore **2** would be an efficient and selective ionophore for lithium ion. These high extractability of **1** and **2** is ascribed to the embedding effect of decalin wall by which the coordinated lithium ion is buried deep in the lipophilic atmosphere and is protected from hydration by excluding water molecules out of its coordination sphere. The difference of Li^+ and Na^+ extractability by using **1** and **2** is explained as follows: In the case of **1** having two decalin subunits, the embedding effect is expected to be very strong. Accordingly, ionophore **1** extracts Na^+ which is somewhat larger than the cavity size of **1**, not to mention Li^+ being suitable for its cavity. In the case of **2** having one decalin subunit, the embedding effect is not so strong as compared with in the case of **1**. Therefore, ionophore **2** extracts only Li^+ effectively being suitable for its cavity, while does not Na^+ being somewhat larger than its cavity.

Next, the competitive alkali metal ion transport was executed at 25 °C in a double glass cell where two aqueous phases were separated by the chloroform membrane containing the ionophore. Figure 1a illustrates the plots for competitive transport of Li^+ by using **2**, **7**, or **8** and in which those for other alkali metal ions are omitted from a graph for clarification.[10] As expected, the target ionophore **2** turned out to be an effective ionophore for Li^+ as compared with the reference compounds **7** and **8** (Fig. 1a). The rate of Li^+ transport by using **2** is about ten-fold faster than those by using **7** and **8**. Figure 1b illustrates the results of competitive transport of alkali metal ions by using **2**. The ionophore **2** did not transport K^+, Rb^+, and Cs^+ at all. The most outstanding in Fig. 1b is the high Li^+/Na^+ selectivity of **2**. Significantly, the Li^+/Na^+ selectivity, although not very accurate because of the slow transport of Na^+, was determined to be 20 (calculated from the ratio of the average flux during 24 h). As a result, a new type of ionophore **2** having one decalin subunit without additional binding site is proved to be a highly lithium ion selective and effective ionophore.

Further studies on the separation of isotopes ($^6Li^+$ and $^7Li^+$) by the decalino-14-crown-4 derivatives are now in progress.

Experimental

All melting points were uncorrected. IR spectra were recorded on a Hitachi 260-10 spectrometer. Mass spectra were recorded on a Hitachi RMU-6E spectrometer at 70 eV ionization energy. ^1H NMR spectra were measured on a JEOL JNM-PS 100 spectrometer in $CDCl_3$ solution using Me_4Si as an internal standard. ^{13}C NMR spectrum was measured on a JEOL JNM-FX-60 spectrometer in $CDCl_3$ solution. Electronic spectra were taken with a Hitachi 356 spectrophotometer. Flame photometric analyses were performed on a Nippon Jarrell Ash AA-8500 Mark II spectrophotometer.

Materials. Benzoin and dimethyl sulfoxide (DMSO) were purchased from Wako Pure Chemical Industries.

Synthesis. 1,10-Dichloro-4,7-dioxadecane (**4**) was prepared from 4,7-dioxadecane-1,10-diol[5] by chlorination as an oil: IR (neat) 1120 cm^{-1}; MS *m/z* (rel intensity) 214 (M^+), 151 (4), 122 (24), 108 (72), 41 (100); ^1H NMR (CCl_4) δ=1.95 (q, *J*=6 Hz, 4H), 3.4—3.7 (m, 12H). Found: C, 44.62; H, 7.55; Cl, 32.75%. Calcd for $C_8H_{16}Cl_2O_4$: C, 44.67; H, 7.50; Cl, 32.96%. 4a,8a-Bis[3-(tosyloxy)propoxy]decalin (**5**) was prepared from 4a,8a-bis(3-hydroxypropoxy)decalin by usual method and was used without further purification. 4a,8a-Bis(3-hydroxypropoxy)decalin was prepared from 4a,8a-decalindiol (**3**) by reaction with allyl bromide followed by hydroboration-oxidation: IR (neat) 3400, 1080 cm^{-1}; MS *m/z* (rel intensity) 286 (M^+), 211 (8), 136 (100); ^1H NMR (CCl_4) δ=1.0—2.1 (m, 20H), 3.3—4.2 (m, 10H). Found: C, 65.93; H, 10.55%. Calcd for $C_{16}H_{30}O_4 \cdot 0.3\ (H_2O)$; C, 65.86; H, 10.56%.

Decalino-14-crown-4 (2). A mixture of 4.5 g (0.11 mol) of NaOH and 12 g (0.11 mol) of $LiClO_4$ in 80 ml of DMSO was brought to 100 °C slowly and stirred for 20 min. After being cooled to room temperature, 8.2 g (48 mmol) of diol **3** was added. To this mixture was added dropwise a solution of 5.1 g (24 mmol) of dichloride **4** in 5 ml of DMSO over 2 h. The mixture was stirred at 110 °C for 24 h and then another 5.2 g (24 mmol) of **4** in 5 ml of DMSO was added dropwise over 2 h. The mixture was stirred for 12 h at 110 °C and cooled to room temperature. To this mixture was added 400 ml of water and the resulting solution was extracted with dichloromethane. The organic phase was dried over $MgSO_4$ and the solvent was evaporated in vacuo. The residure was

chromatographed on silica gel (ether/light petroleum=5/95) to afford 100 mg (1%) of **2**: mp 69—70 °C (recrystallized from light petroleum); IR (KBr) 1120 cm^{-1}; MS *m/z* (rel intensity) 312 (M^+), 178 (6), 136 (100); ^1H NMR δ=1.0—1.9 (m, 20H), 3.0—4.0 (m, 12H, s at 3.69); ^{13}C NMR δ=20.7 (t, 2C), 23.4 (t, 2C), 30.4 (t, 2C), 31.3 (t, 4C), 56.7 (t, 2C), 67.6 (t, 2C), 71.3 (t, 2C), 78.0 (s, 2C). Found: C, 69.01; H, 10.35%. Calcd for $C_{18}H_{32}O_4$: C, 69.20; H, 10.32%.

7,8-Diphenyl-2,6,9,13-tetraoxatricyclo[12.4.4.0^{1,14}]docos-7-ene (7). A mixture of 10.9 g (18 mmol) of ditosylate **5** and 3.9 g (18 mmol) of benzoin in 130 ml of benzene was stirred mechanically for 1 h at 40 °C. After being cooled, 98 mg (0.47 mmol) of tetrabutylammonium bromide was added. To this mixture was added 20 ml of 50% NaOH. After continuous stirring for 40 h at 70 °C, the mixture was cooled to room temperature, washed with 100 ml of water and the organic phase was separated. The aqueous phase was extracted with dichloromethane and the combined organic phase was dried over $MgSO_4$. The solvent was removed by evaporation and the residue was chromatographed on silica gel (ether/light petroleum=3/97) to give 1.89 g (22%) of **7**: mp 154—155 °C (recrystallized from light petroleum); IR (KBr) 3050, 1590, 1100 cm^{-1}; MS *m/z* (rel intensity) 462 (M^+), 252 (65), 147 (100); ^1H NMR δ=1.2—2.1 (m, 20H), 3.4—4.2 (m, 8H), 7.0—7.4 (m, 10H). Found: C, 77.84; H, 8.33%. Calcd for $C_{30}H_{38}O_4$:, C, 77.89; H, 8.28%.

Extraction. Extraction of alkali metal picrates by crown ethers into dichloromethane was preformed by the method described previously.[7]

Transport. Competitive transport of alkali metal ions through chloroform membrane containing ionophore was performed at 25.0±0.1°C using a double glass cell (diameters: inner 2.6 cm and outer 5.0 cm) where two aqueous phases were separated by chloroform membrane containing ionophore. Membrane: ionophore (1.5×10^{-4} M; 1 M=1 mol dm^{-3}) in 60.0 ml of chloroform; source phase: LiOH, NaOH, KOH, RbOH, and CsOH (each 1.0×10^{-2} M) and picric acid (6.0×10^{-3} M) in 15.0 ml of deionized water; recieving phase: 20.0 ml of deionized water. Metal ion concentrations were determined by flame photometry.

We are grateful to Professor Toshiyuki Shono and Dr. Keiichi Kimura for their helpful discussion and advice.

A Determination Method of Absolute Configuration

Fumio TODA,* Koji MORI, and Atsushi SATŌ
Department of Industrial Chemistry, Faculty of Engineering,
Ehime University, Matsuyama 790
(Received June 29, 1988)

Synopsis. A determination method of absolute configuration of sulfoxides, amines, and aminoalcohols by measuring their ^{1}H NMR spectra in the presence of optically active 2,2′-dihydroxy-1,1′-binaphthyl and 1,6-di(*o*-chlorophenyl)-1,6-diphenyl-2,4-hexadiyne-1,6-diol, was reported.

There are mainly three determination methods of absolute configuration of chiral compounds, CD- and X-ray analyses and chemical conversion to a configurationally known compound. However, each method has own problem. We report a simple method of determining the absolute configuration by a combination of host–guest complexation and ^{1}H NMR spectra measurement. Previously, it was reported that optically active 2,2′-dihydroxy-1,1′-binaphthyl (**1**) and 1,6-di(*o*-chlorophenyl)-1,6-diphenylhexa-2,4-diyne-1,6-diol (**2**) form complex with a wide variety of organic compounds not only in the solid state[1] but also in solution,[2] and these host compounds can be used as chiral shift reagents.[2]

We recently found that the direction and magnitude of shifts of the proton signals of the complex depend on the difference of absolute configuration of the host and guest compounds, and that the phenomena are applicable to determining the absolute configuration of the guest compounds. Although a similar determination method of the absolute configuration of sulfinate esters[3] and γ-lactones[4,5] by using optically active 1-phenyl- (**3a**), 1-(1-naphthyl)- (**3b**), and 1-(9-anthryl)-2,2,2-trifluoroethanol (**3c**) has been known, application of this method to sulfoxides, amines, and aminoalcohols has not been reported.

Experimental

General. All the ^{1}H NMR spectra were measured in $CDCl_3$ by JEOL-PMX 60 Spectrometer. All the host (**1** and **2**) and the guest compounds (**4**—**18**) were prepared according to the reported method in the literature cited.[1]

Results and Discussion

For example, the methyl signal (δ 2.717) of racemic methyl phenyl sulfoxide (**4**) is split into two signals at δ 2.654 and 2.667 in the presence of an equimolar amount of (*S*)-(−)-**1** (**1a**) (Table 1). The optically pure (*R*)-(+)- and (*S*)-(−)-**4**[6] show the former and the latter signals, respectively, under the same conditions. In the case of other alkyl aryl sulfoxides, **6**[7] and **7**,[8] the methyl signals of (*S*)-(−)-enantiomers are also in higher field than those of (*R*)-(+)-ones (Table 1). (*S*)-(+)-Enantiomer of butyl methyl sulfoxide (**7**)[9] showed its methyl signal at higher field than did (*R*)-(−)-one. Although the configuration of other dialkyl sulfoxides **8**—**10** has not been determined, their (+)-enantiomers which show the methyl signal at higher field probably have (*S*)-configuration. This assignment is probably correct because (+)-enantiomers of many alkyl methyl sulfoxides such as ethyl methyl,[9] methyl propyl, isopropyl methyl,[10,11] isobutyl methyl,[11] and *t*-butyl methyl sulfoxides[9] have been reported to have (*S*)-configuration. In the case of dialkyl sulfoxides, however, more than two molar amounts of **1a** are necessary for a splitting of the methyl signal (Table 1).

In the case of amines, **11**,[12] **12**,[13] **13**,[14] and **14**, the methyl signals of their (*R*)-enantiomers appeared at higher field than did those of (*S*)-ones in the presence of **1a** (Table 1). However, the methine signal of **15**[15] or **16** appeared at higher field when the configuration is (*S*). Although the methine signals of **12** (δ 4.117) and **13** (4.217) were not split by **1a**, these were split to δ 3.801 and 3.843, and 4.040 and 4.067, respectively, in the presence of (*R*,*R*)-(−)-**2** (**2a**), and the signal of (*S*)-enantiomers appeared at higher field. Methyl signals of aminoalcohols **17**[16] and **18**[17] were also split by **1a**, and those of (*S*)-enantiomers appeared at higher field (Table 1). These data clearly show again the presence of a correlation between the manner of shift in

a) All the spectra were measured at a concentration of guest compound 0.02 g in 1 ml $CDCl_3$. When the signal is multiplet, chemical shift value at a center of the signal is indicated.

^{1}H NMR spectra and absolute configuration. Using the relation, absolute configuration of amines and aminoalcohols can be determined.

Of course, the two signals at higher and lower fields take turn when **1b** and **2b** are used instead of **1a** and **2a**, respectively.

The regular correlation between the configuration and the manner of shift of signal is probably due to the shielding effect in the complex of the components (Fig. 1). For example, **1a** forms complexes with (*S*)-**4** (**19**) and with (*R*)-**4** (**20**). In **19**, the methyl is shielded by the naphthyl group of **1a** and its signal appears at higher field than that of **20** (Fig. 1).

In all complexes, hydrogen bond may play an important role as is shown in Fig. 1. Since amines and aminoalcohols form relatively stronger hydrogen bond with **1a** than do dialkyl sulfoxide, smaller amount of **1a** is probably enough for the splitting of the former's signal. Nevertheless, the complex formation in solution does not always support the formation of crystalline inclusion complex. For example, **4**, **5**, and **7** form crystalline complex with **1**, and these are effectively resolved.[1)] However, **6**, **8**, **9**, and **10** do not form complex with **1**. Contrarily, **7**—**10** form complex with **2** and these are resolved.[1)] Although **11** forms complex with **2** and is efficiently resolved,[18)] **12**—**18** do not from comlex with **2**. Nevertheless, **17** and **18** form complex with **1** and are resolved.[19)]

(Received January 16, 1988)

Polarized ATR spectra have been measured for the dye layers adsorbed on stacked, thin glass plates. For the adsorbed Crystal Violet (CV) layer, the metachromasy band in the || polarized ATR spectrum is blue-shifted and intensified in comparison with that in the ⊥ polarized ATR spectrum. This is in marked contrast to the observation for the adsorbed Methylene Blue (MB) layer that the || polarized ATR spectrum is similar in shape and position to the ⊥ polarized ATR spectrum. The blue shift and the enhancement of the metachromasy band in the || polarized ATR spectrum for the adsorbed CV layer is ascribed to an optical property characteristic of the adsorbed CV layer; the adsorbed CV layer exhibits an extra electronic transition band located at the high-energy side of the metachromasy band and polarized normal to the glass plane. Two possible explanations for the occurrence of this extra band are presented.

A conventional measurement of the absorption spectrum of molecules adsorbed on a glass surface using a polarized light with normal incidence allows only a two-dimensional detection of the optical anisotropy in the glass plane. In contrast, the polarized ATR (attenuated total reflection) method enables observations of the three-dimensional optical anisotropy of the adsorbed layer, including the anisotropy in the direction of the thickness.[1] Wilks and Hirschfeld proposed a method for obtaining the ATR spectra by employing a stack of thin internal-reflection plates, the sample material being sandwiched between the plates.[2] This method is ideal for liquids contained between the plates by capillary action. In the present study we measured the polarized ATR spectra in the visible region for adsorbed dye layers using a stack of thin glass plates whose surfaces adsorbed dye molecules.

Experimental

Commercial Crystal Violet (CV) and Methylene Blue (MB) were used without further purification. A borosilicate glass plate (55×9.5×0.16 mm) was thoroughly washed by successive sonications in isopropyl alcohol, hot distilled water, concd nitric acid and hot distilled water and finally by steam washing with distilled water. Sixty sheets of the glass plates, thus cleaned, were placed in a holder appropriate for preventing stacking, and dipped in CV or MB aqueous solution for several hours. These glass plates which adsorbed CV or MB were, after rinsing several times with distilled water, placed in a plastic cell filled with distilled water, as illustrated in Fig. 1a. The polarized ATR spectrum for this sample cell was measured using a Shimadzu UV-360 spectrophotometer equipped with a Rochon-type polarizer made of synthetic quartz (Karl Lambrecht Corp.). The optical arrangement is shown in Fig. 1b. Ordinary rays from a Rochon-type polarizer are almost perfectly plane-polarized and the plane of their electric field vector can be rotated by rotating the polarizer. The || and ⊥ polarized light thus obtained, the vibrating electric field vectors of which are parallel and perpendicular, respectively, to the plane of incidence, as defined in Fig. 1a, are introduced into the side of the stack of thin glass plates with an angle of incidence of θ, defined in Fig.

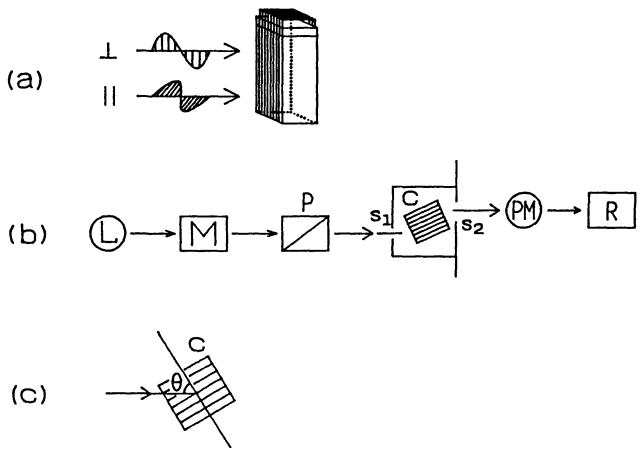

Fig. 1. Optical arrangement.
(a): definitions of the || and ⊥ polarized lights. (b): optical path for the measurement of the polarized ATR spectrum. L: tungsten lamp, M: monochromator(prism+grating), P: Rochon-type polarizer, S_1 and S_2: slit, C: cell containing a stack of thin glass plates, PM: photomultiplier, R: recorder. (c): definition of the angle of incidence (θ).

1c. Part of the incident light is scattered from the side surface of the glass plates, and a major part of the light entering the glass plates propagates within each plate, being totally reflected if θ is larger than the critical angle (θ_c=61° for the light passing from the glass layer to the water layer); the number of total reflections is about 20 for θ=70° and about 10 for θ=80°. In the case of these multiple total reflections, the || (⊥) polarized light remains || (⊥) polarized and the evanescent wave penetrates into the adsorbed dye layer; thus, the so-called || (⊥) polarized ATR spectrum for the adsorbed dye layer can be obtained. A correct, undistorted ATR spectrum can be obtained only when θ is well above θ_c.[3] To compensate for the effect of light scattering from the glass surface and so forth, we used a reference cell which was identical with the sample cell, except that glass plates with no adsorbed dye layer were employed. As shown in Fig. 1b, we cut extraordinary rays from the Rochon-type polarizer by entrance slit S_1 in order to avoid their disturbance on the ATR spectra, and admitted totally reflected ordinary rays

only to the detector by exit slit S_2, which was shifted in position from the entrance slit, S_1.

Results

Unpolarized and Polarized ATR Spectra of the Adsorbed CV Layer. It is well-known that an aqueous solution of CV shows a metachromasy band in the visible region, with a shape and location which depends on the CV concentration, as shown in Fig. 2.[4] With increasing CV concentration, the monomer band at 590 nm is weakened and a metachromasy band appears at 535 nm with an enhanced intensity.

We first confirmed that a reference cell containing 60 glass plates and filled with water gives no characteristic band and that the amount of the light loss is constant over the whole wavelength region examined, i.e., the absorbance of the reference cell was wavelength-independent, irrespective of the light polarization and θ. Figure 3 shows the unpolarized ATR spectra for the adsorbed CV layer with several values of θ. As θ decreased, the metachromasy band at 526 nm was intensified to a greater degree than the monomer band at 590 nm. A correct, undistorted ATR spectrum giving a spectral pattern similar to the ordinary transmission spectrum was obtained when $70° \leqq \theta \leqq 80°$ ($\theta_c < \theta$).

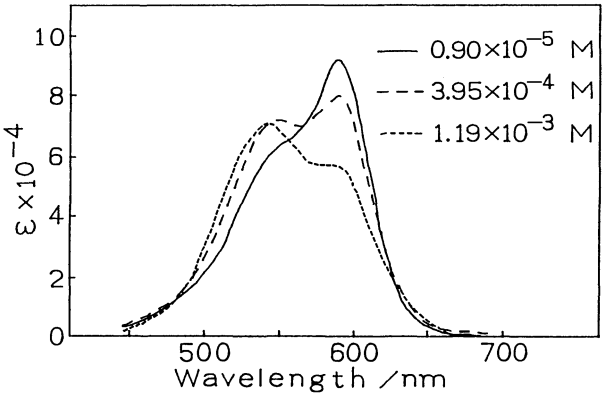

Fig. 2. Absorption spectra for the CV aqueous solutions of various concentrations.

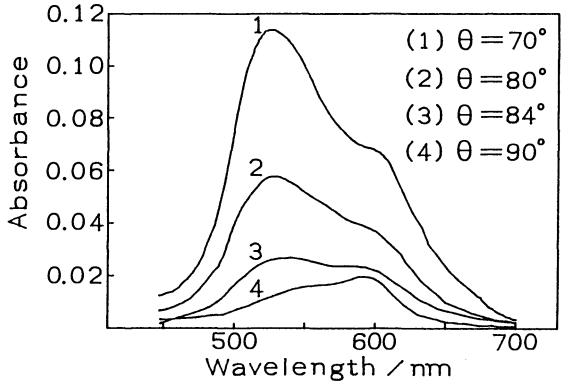

Fig. 3. Unpolarized ATR spectra for the adsorbed CV layer with several values of θ.

Figure 4 shows the changes in absorbance at the band peak of the CV layer with respect to the adsorption time. According to the curve for $\theta=0°$ (normal incidence), the absorbance increased with increasing adsorption time. This means that the adsorption of CV molecules on the glass surface is not completed, even after 300 hours. In contrast to the curve for $\theta=0°$, the absorbance is almost saturated in the curve for $\theta=70°$. This may reflect some aspects characteristic of the ATR spectrum, i.e., the inapplicability of Lambert's law due to the attenuation or the finite penetration depth of the evanescent wave.

In Fig. 5 the unpolarized ATR spectrum for $\theta=70°$ is compared with the unpolarized transmission spectrum measured with $\theta=0°$ (normal incidence). On going from $\theta=70°$ to $\theta=0°$, the absorbance increased as a whole; this seems to agree with the trend shown in Fig. 3. However, it should be emphasized that the peak position of the metachromasy band for $\theta=70°$, 526 nm, is different from that for $\theta=0°$, 535 nm. The spectrum for $\theta=0°$ in Fig. 5 agrees with that for a highly concentrated aqueous solution of CV regarding peak position

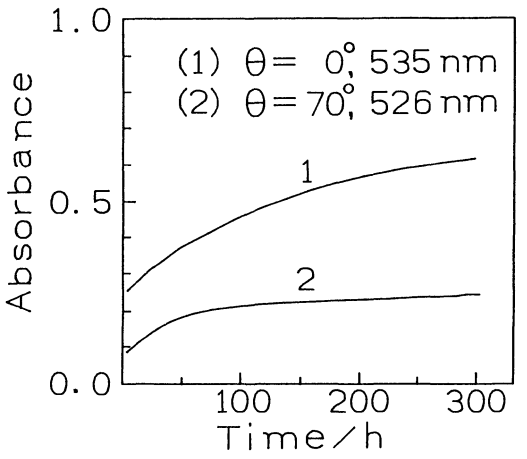

Fig. 4. Changes in the absorbance at the band peak of the adsorbed CV layer for $\theta=0°$ and 70° with respect to the adsorption time.

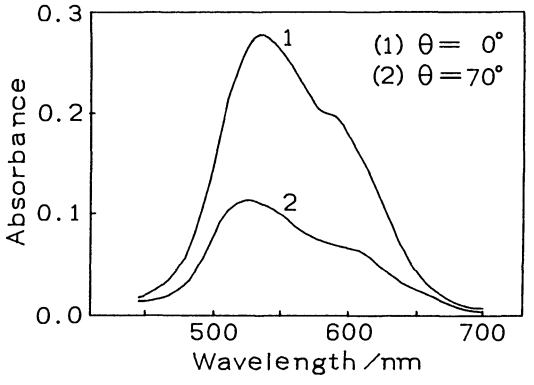

Fig. 5. Comparison of the unpolarized ATR spectrum of the adsorbed CV layer for $\theta=70°$ with the unpolarized transmission spectrum for $\theta=0°$.

and shape.

The polarized transmission and ATR spectra measured for the adsorbed CV layer are summarized in Fig. 6. The essential coincidence of the || and ⊥ polarized transmission spectra (θ=0°, Fig. 6a) implies that the adsorbed CV layer is optically isotropic within the surface plane of the glass plate. However, differences in the peak positions and absorbances are observed between the || and ⊥ spectra for θ=70° and 80° (Figs. 6b and 6c). The differences are especially pronounced for θ=70°. The ⊥ polarized ATR spectrum for θ=70° (Fig. 6b) is nearly identical to the transmission spectrum (θ=0°, Fig. 6a), except for the band intensity (about twice), whereas the metachromasy band of the || polarized ATR spectrum for θ=70° in Fig. 6b is largely blue-shifted in comparison with that of the ⊥ spectrum. This blue shift may be related to the origin of the difference in the peak positions observed in the unpolarized ATR and transmission spectra shown in Fig. 5. This blue shift is further enhanced with an increasing amount of adsorbed CV, as inferred from Fig. 6d.

Unpolalized and Polarized ATR Spectra of the Adsorbed MB Layer. Like CV, MB shows a metachromasy band at the high-energy side of the monomer band in higher MB concentrations.[5] In order to check whether the behavior of this ATR spectra is similar to that of the adsorbed CV layer, we measured the unpolarized and polarized ATR spectra of the adsorbed MB layer. The unpolarized ATR spectrum of the adsorbed MB layer measured with θ=70° is compared in Fig. 7 with the unpolarized transmission spectrum measured with θ=0° (normal incidence). In contrast to the unpolarized ATR and transmission spectra of the adsorved CV layer shown in Fig. 5, the two spectra are quite similar and there is no difference in the peak positions. Figure 8 shows the polarized ATR spectra of the adsorbed MB layer for θ=70°; the || and ⊥ polarized ATR spectra are similar in shape, and the peak positions are coincident. This is, again, in marked contrast to the case of the adsorbed CV layer given in Fig. 6b or 6d.

Discussion

For bulk materials or thick films, it is well-known that the || and ⊥ ATR spectra are both red-shifted and that the longer-wavelength bands are relatively more intense in comparison with the ordinary transmission spectrum measured with normal incidence (θ=0°)[6] by the following factors: (a) an anomalous dispersion in the refractive index, n,[7,8] and (b) a wavelength dependence of the penetration depth of the evanescent wave.[9]

From the viewpoint of the general trend of the || and ⊥ ATR spectra for bulk materials, the most remarkable features of the present observations are the differences in the polarized ATR spectra for the adsorbed CV (Fig. 6b) and the MB (Fig. 8) layers. As shown in Fig. 6b (CV), the metachromasy band of || (520 nm) is blue-shifted from that of ⊥ (535 nm) and the intensity ratio of the metachromasy band to the monomer band for || is larger than that for ⊥. In contrast, the main feature of Fig. 8 (MB) is that the peak position of || coincides with that of ⊥ and that the intensity ratio in question for || is essentially equal to that for ⊥. This feature of Fig. 8 excludes the possible influence of the

above-mentioned two factors that cause a deviation of the polarized ATR spectra from the transmission spectrum. This leads to the following conclusions: (1) The influence of non-total reflection[7] due to the anomalous dispersion in n of an adsorbed dye layer is negligible for $\theta=70°$ in the case of the adsorbed MB layer, i.e., the dispersion in n of the adsorbed MB layer is not sufficiently large, even in the wavelength region of the absorption band, to influence the band location and intensity. (2) The evanescent wave penetrates the adsorbed MB layer perfectly, invalidating the wavelength dependence of the penetration depth of the evanescent wave. The former is in accordance with the known fact that the polarized and unpolarized ATR spectra of a thin film resemble its transmission spectrum unless there is a very strong dispersion in n,[10] as is the case for the adsorbed MB layer, which is considered to be a very thin film. The latter is also in accordance with the observation that the thickness of the adsorbed MB layer is estimated to be at most two or three molecular layers, if we assume that the molecular planes of MB are parallel to the surface of the glass plate. On the other hand, the penetration depth of the evanescent wave for visible light is several hundred Å; that is, the evanescent wave can penetrate into about one hundred molecular layers of the adsorbed MB.

As pointed out in the Results section, the $\perp$ ATR spectrum for CV in Fig. 6b is considered to be equivalent to the transmission spectrum for CV in Fig. 6a measured with normal incidence. Therefore, the above-mentioned spectral features of the $\parallel$ ATR spectra for the adsorbed CV layer concerning the location and intensity, in comparison with that of the $\perp$ ATR spectra, are in marked contrast to those of the ATR spectra for bulk materials. This difference can be explained as follows: If there is a very strong dispersion in n of the thin film, the absorption maxima for the $\parallel$ and $\perp$ polarizations may not occur at the same wavelength; that is, the band for $\parallel$ polarization is displaced to a shorter wavelength relative to the band for $\perp$ polarization.[10] If this is the case, the results in Fig. 6b could be explained as being due to a strong dispersion in n of the adsorbed CV layer. However, the following reasons can be used to eliminate this possibility. First, the magnitude of the molecular extinction coefficient (ε) in the visible region for CV (ε=70000—92000) is comparable to that for MB (ε=60000—85000). Second, the actual absorbance, i.e., the thickness of the adsorbed dye layer is also similar for CV and MB. Third, the degree to which the two bands in the visible region are overlapped is essentially the same for CV and MB, implying that there is no significant difference between CV and MB in the overlapping effect[8] of the two anomalous dispersion curves in n. It must be recalled here that the peak for the $\parallel$ ATR spectrum of CV adsorbed on an absorbing gold film electrode was blue-shifted from that of CV adsorbed on a transparent glass.[11] That is, the presence of an extra absorption due to the gold film can cause a shift in the $\parallel$ ATR spectrum of the adsorbed dye layer to a shorter wavelength. In conformity with this observation, we may conclude that the blue shift and the enhancement of the metachromasy band of the $\parallel$ ATR spectra in Fig. 6b reflect an optical property characteristic of the adsorbed CV layer. We, thus, propose that the adsorbed CV layer exhibits an extra electronic transition band which is located at the high-energy side of the metachromasy band and is polarized normal to the glass plane. This extra electronic transition band can be detected only in the $\parallel$ ATR spectrum, not in the $\perp$ ATR spectrum nor in the transmission spectrum observed with $\theta=0°$. We obtained this extra electronic transition band as a difference spectrum between the $\parallel$ and $\perp$ ATR spectra, as shown in Fig. 6c by the ($\parallel-\perp$) curve.

There are two possible explanations for the occurrence of this extra electronic transition band under the assumption that CV molecules are adsorbed with their molecular planes parallel to the glass plane. First, CV has a nonplanar structure which gives rise to an out-of-plane polarized component of the electronic transition; it may, in turn, give rise to an extra electronic transition band polarized normal to the glass plane, under the present assumption. Second, the adsorption process gives an electronic perturbation to each CV molecule in the adsorbed CV layer to a different degree, being dependent on the distance from the glass plane, which may induce an intermolecular charge-transfer band with a nonvanishing intensity. In this charge-transfer band, the charge transfer occurs in the direction (z) perpendicular to the glass plane; the transition moment should also be in the same direction.

We now give an explanation for the spectra shown in Fig. 3. With a decrease in θ for $90°>\theta>\theta_c$, the electric field amplitude of the $\parallel$ polarized evanescent wave ($E_\parallel$) increases to a larger degree than that of the $\perp$ polarized evanescent wave ($E_\perp$), although both $E_\parallel$ and $E_\perp$ increase.[12] Among the electric field components of the evanescent wave that contribute to $E_\parallel$, especially the E_z component polarized perpendicularly to the glass surface increases in amplitude very sharply with a decrease in θ for $90°>\theta>70°$.[12] In conformity with this variation, the ATR spectrum for the extra electronic transition band, polarized perpendicularly to the glass surface and detected by the E_z component of unpolarized natural light, should increase in intensity with a decerase in θ for $90°>\theta>70°$. The above change yields, along with an enhancement of the entire ATR band, an increase in the intensity of the metachromasy ATR band to a greater degree than the monomer ATR band with a decrease in θ. There is, of course, the influence of an increasing number of total reflections with a decrease in θ for $90°>\theta>70°$, which should also cause an enhancement of the entire ATR band.

The authors wish to express their thanks to

Professor Kozo Kuchitsu, Nagaoka University of Technology, for his critical reading of the manuscript.

The Charge Carried by a Layer Formed by an Aggregation of Polyelectrolytes in a Solution Containing a Salt

Tetsuo KANEKO
Kogane Kazusa-cho 16-1, Matsudo-shi, Chiba-ken 270
(Received February 22, 1988)

A layer formed by the aggregation of polyelectrolyte molecules is charged according to the ionic dissociation of the layer in a simple salt solution. The charge carried by the layer is estimated on a basis of solutions of the Poisson-Boltzmann equation. It has been found that this charge is independent of the concentration, n_s, of a salt, in spite of the permanence of the layer to counter ions when the density, n_g, of charged groups in the polyelectrolyte molecules is much higher than the concentration n_s. As the result, the charge may be given as a function of three parameters (temperature, density n_g, and thickness of the layer) except for n_s. Moreover, it has been found that the distribution of counter ions within the layer and their distribution in the vicinity of the layer may be independent of n_s and that these distributions of counter ions may agree with that in a salt-free solution.

An electric field is formed around a polyelectrolyte molecule in an aqueous solution because of the ionic dissociation of the polyelectrolyte molecule. This formed electric field restricts the diffusion of counter ions due to thermal motion and a repulsive force between the counter ions. In general, it is known that the charge density of a polyion in a solution may be independent of the concentration of a salt.[1]

Guéron and Weisbuch noted, on a basis of calculations using the Poisson-Boltzmann equation, that counter ions exist with quite high densities in the immediate vicinity of the surface of highly charged polyelectrolyte molecules.[2] Moreover, they found that the distribution of counter ions in the vicinity of these polyelectrolyte molecules is insensitive to the concentration, n_s, of a salt, as has been noted by Stigter,[3] and that this distribution is not strongly dependent on the shapes of the polyelectrolyte molecules.[2]

Plates, cylinders, and spheres, the surfaces of which hold constant surface-charge densities, were introduced as models of polyelctrolytes in order to ascertain these properties of counter-ion distributions.[2] In the layer-model system of a polyelectrolyte solution,[4] layers formed by the aggregations of polyelectrolyte molecules were immersed in a solvent instead of plates, which hold a constant surface-charge density. This layer model was capable of giving a quantitative estimation of the charged characteristics of a polyion in a salt-free solution. Counter ions in the layer-model system distribute continuously from the inside of the layers of polyelectrolytes to the outside of the layers, since the layers are permeable to counter ions. The purpose of this investigation was to show that the charge carried by such layers of polyelectrolytes may be independent of the salt concentration. If a salt is added to a layer-model system, it is doubtful whether the charge of the layers would be influenced by the salt, owing to an effect related to the permeance of the layers which may not occur on charged surfaces of constant surface-charge density. If the layer model is capable of having a nature found in the relation between the charge density of polyion and the concentration of a salt (as described above), the charge of the polyelectrolyte layers should not be affected by a salt added to a layer-model system.

Engström and Wennerström used the Gouy-Chapman solution in order to estimate the density of counter ions in the immediate vicinity of charged plates which maintain a constant surface-charge density and which immerse in a simple salt solution; they showed that this density of cunter ions is independent of the concentration of a salt, and that it agrees with the counter-ion density in a salt-free solution.[5] Similarly, by using the Gouy-Chapman solution in this study it has been shown that the distribution of counter ions in the vicinity of the surface of the layers may be independent of n_s under the condition that any effect dependent on the distance between the layers can be ignored. Also, this counter-ion distribution may agree with that in a salt-free solution. In accordance with the above condition, the layer-model system described in this paper is composed of one layer of polyelectrolytes immersed in a simple salt solution. It is shown here that any charge carried by the layer can be independent of n_s.

In addition, the charged circumstance of the layer can be represented as the total charge contained in an imaginary cylinder. This imaginary cylinder is perpendicular to the surface of the layer and has a unit cross section. Also, the both ends of the imaginary cylinder are at the center of the layer and on the surface of the layer, respectively. A system composed of a layer can be an electric equivalent to a system composed of a charged plate of a conductor substituted for the layer, if the charge per unit area on the surface of the plate is equal to the total charge in an imaginary cylinder as is described above. On the basis of this situation, the total charge in the imaginary cylinder was regarded as being the surface-charge density on a polyelectrolyte layer in a previous paper,[4] although this surface-charge density was imaginary. The charged circumstance of the layer differs, in fact, from the charged circumstance of the dielectric in an electric field in which the dielectric induces a charge on its surface and

from the charged circumstance of a charged conductor in which a charge accumulates on its surface. In this paper, the total charge in the imaginary cylinder will be called the layer-charge density (LCD), in order to avoid any confusion between these charged circumstances.

Model

Structure of a Layer Model. The layer-model system used in order to estimate the charged characteristics of polyions in a salt-free solution consisted of many layers formed by aggregations of polyelectrolyte molecules and arranged in a solvent.[4] When these layers are immersed in a simple salt solution, it is difficult to estimate the charge carried by the layers (i.e., LCD), the distribution of counter ions, etc., by considering any effect dependent on the distance between the layers and by solving the Poisson-Boltzmann equation. In this paper, a certain condition, which corresponds to the dilute concentration of polyelectrolytes, is assumed in order to avoide this difficulty, i.e., it is assumed that the electrostatic interaction between layers of polyelectrolytes is negligible. The estimations of the LCD, of the electric field, and of the counter-ion distribution under this condition are the objects of this investigation. Consequently, the layer-model system used in this paper consists of one layer of polyelectrolytes (Fig. 1); this layer is immersed in a simple salt solution. The thickness of the layer is Δx and the density of the charged groups packed in the layer is n_g. The concentration of a salt in the solution, in which the layer is immersed, is n_s. In addition, even in the layer-model system which is salt-free, though the distance between neighboring layers of polyelectrolytes is of the order 10^2 Å, the electrostatic interaction between the layers hardly affects the LCD in the system when this LCD is of the order 10^{-2} C·m^{-2}.[4]

Electrostatic Potential. Though it is assumed that the absolute value of the charge of a counter ion is the same as that of a co-ion, the electrostatic potential ψ in the layer-model system (as is shown in Fig. 1) can be described by the following Poisson-Boltzmann equation: within a layer of polyelectolytes ($-\Delta x/2 < x < \Delta x/2$) it is

$$\frac{d^2\psi_1}{dx^2} = -\frac{1}{\varepsilon}\{-z'en_g - zen_s \exp[ze\psi_1/kT] + zen_s \exp[-ze\psi_1/kT]\}, \quad (1)$$

while outside the layer ($\Delta x/2 \leqq x$) it is

$$\frac{d^2\psi_2}{dx^2} = \frac{2zen_s}{\varepsilon} \sinh[ze\psi_2/kT]. \quad (2)$$

In the above, ε is the dielectric constant of a solvent, $-z'e$ is the charge of a charged group, ze is the charge of a counter ion, $-ze$ is the charge of a co-ion, k is Boltzmann's constant, and T is the absolute temperature. In addition, it is assumed that the dielectric constant within the layer is the same as that of a solvent.

For boundary conditions

$$\psi_1\left(\frac{\Delta x}{2}\right) = \psi_2\left(\frac{\Delta x}{2}\right) \text{ and } -\varepsilon \frac{d\psi_1}{dx}\Big|_{x=\Delta x/2} = -\sigma,$$

the approximate solution of Eq. 1 can be obtained as follows:[4,6]

$$\begin{aligned}\psi_1(x) = &-\frac{kT}{ze} \cdot \operatorname{arcsinh} f \\ &+ \frac{kT}{2ze} \cdot \left\{\sqrt{2}\,\Lambda\sigma + \frac{ze\psi_2(\Delta x/2)}{kT} + \operatorname{arcsinh} f\right\} \cdot \exp\left[-\mu\left(\frac{\Delta x}{2} - x\right)\right] \\ &+ \frac{kT}{2ze} \cdot \left\{-\sqrt{2}\,\Lambda\sigma + \frac{ze\psi_2(\Delta x/2)}{kT} + \operatorname{arcsinh} f\right\} \cdot \exp\left[\mu\left(\frac{\Delta x}{2} - x\right)\right], \end{aligned} \quad (3)$$

where $\Lambda^2 \equiv z/(2z'kT\varepsilon n_g)$, $\mu^2 \equiv zz'e^2n_g/(\varepsilon kT)$, and $f \equiv z'n_g/(2zn_s)$. Also, $-\sigma$ is the layer-charge density (LCD). By considering the continuity of the electric field in the layer, it can be described as

$$-\sigma = \int_0^{\Delta x/2} \{-z'en_g - 2zen_s \sinh[ze\psi_1/kT]\}\, dx.$$

On the other hand, the Gouy-Chapman solution given for the following boundary conditions is used as a solution of Eq. 2:

$$\psi_2(\infty) = 0, \quad -\varepsilon \frac{d\psi_2}{dx}\Big|_{x=\infty} = 0, \quad -\varepsilon \frac{d\psi_2}{dx}\Big|_{x=\Delta x/2} = -\sigma.$$

The Formulation of the LCD. A formula which represents the LCD, $-\sigma$, in a simple salt solution can be formed by substituting the Gouy-Chapman solution into $\psi_2(\Delta x/2)$ in Eq. 3 and by considering the following condition in conectin with the continuity of the electric field $-\varepsilon\, d\psi_1/dx$ in the layer:

$$-\varepsilon \frac{d\psi_1}{dx}\Big|_{x=0} = 0. \quad (4)$$

As a result, the obtained formula is

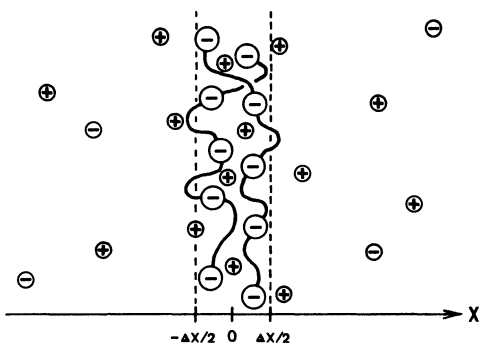

Fig. 1. A layer model. Charged groups, counter ions, and co-ions are represented by ~(−)~, (+), and (−), respectively.

$$\Delta\sigma\cdot\left[\ln\left\{\left(\sqrt{\frac{1}{4}+\left(\frac{zn_s}{z'n_g}\right)^2}+\frac{1}{2}\right)^{-1/2}\cdot\left(\sqrt{\frac{1}{4}\Delta^2\sigma^2+\frac{zn_s}{z'n_g}}+\frac{1}{2}\Delta\sigma\right)\right\}\right]^{-1}=-\sqrt{2}\tanh\left[\mu\frac{\Delta x}{2}\right]. \quad (5)$$

Thus, the LCD is given by Eq. 5 as a function of four parameters (T, n_g, n_s, Δx).

If the existance of co-ions in the layer can be ignored, the $-zen_s\cdot\exp[ze\psi_1/kT]$ term disappears in Eq. 1 and, as a result, the $(zn_s/z'n_g)^2$ term disappears in Eq. 5. Moreover, if the existance of co-ions on the surface of the layer can be ignored, the $zn_s/z'n_g$ term also disappears in Eq. 5. It has been suggested that, if co-ions can be sufficiently excluded in the vicinity of the layer, the LCD may be independent of n_s.

In addition, an approximation to Eq. 5 can be given when $zn_s/z'n_g$ is small. It is possible that the $zn_s/z'n_g$ ratio is sufficiently small, because the value of n_g is of the order of 10^{28} m^{-3},[4] if a polyacrylate molecule is considered as an example. For a small $zn_s/z'n_g$ ratio, the magnitude of $\Delta\sigma$, in accordance with the sign of the right-hand side of Eq. 5, must satisfy $\Delta\sigma<1$. In accordance with the magnitude of this right-hand side, $\Delta\sigma$ can be close to 1. By considering this magnitude of $\Delta\sigma$ and the sign of $\Delta\sigma$, the following approximation for $-\sigma$ is found when $zn_s/z'n_g$ is sufficiently small:

$$-\sigma=-\sigma_0+\Delta\sigma(n_s), \quad (6)$$

where $-\sigma_0$ is the LCD in a salt-free solution[4] and it is

$$-\sigma_0=-\frac{Y}{2\Delta}\{(2+Y)-\sqrt{Y(Y+4)}\},$$

In Eq. 6, $\Delta\sigma(n_s)$ is defined as

$$\Delta\sigma(n_s)\equiv\frac{2kT\varepsilon}{\sigma_0}\sqrt{\frac{Y}{Y+4}}\cdot n_s.$$

In the above formulae, Y is defined as

$$Y\equiv 2\sqrt{2}\tanh[\mu\Delta x/2].$$

Results and Discussion

Layer-Charge Density (LCD). LCD in a simple salt solution can be given as a function of four parameters (T, n_g, n_s, Δx). It can be shown, however, that this LCD becomes a function of three parameters (T, n_g, Δx) if the $zn_s/z'n_g$ ratio is sufficiently small.

When $zn_s/z'n_g$ is small, Eq. 6 becomes an approximation of Eq. 5, and the relationship between $-\sigma$ and n_s can be well understood in Eq. 6. For the conditions used in order to estimate the charge density of polyion in a salt-free, dilute solution of a polyelectrolyte (the T, n_g and Δx parameters are 298 K, 1.7×10^{28} m^{-3}, and 3 Å, respectively, and both z and z' are 1),[4] the $\Delta\sigma(n_s)/\sigma_0$ ratio is of the order of 10^{-2} if n_s is 10^{-1} mol·dm^{-3}. This ratio is much smaller than 1. Thus, the second term in the right-hand side of Eq. 6 reduces, when $zn_s/z'n_g$ is small. As is shown in Fig. 2, the LCD $-\sigma$ may become independent of n_s, even though the layer is permeable to counter ions. Moreover, this LCD, which is independent of n_s, may agree with that in a salt-free solution, as can be seen from Eq. 6. In addition, if n_g is small, $-\sigma$ is liable to be influenced by n_s, as can be seen in Fig. 2.

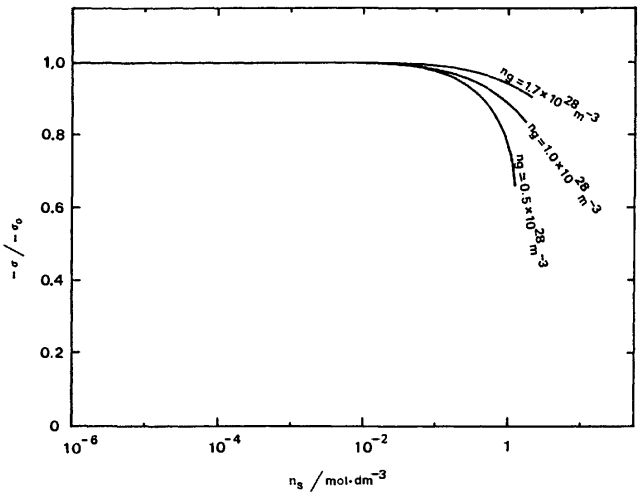

Fig. 2. The dependence of $-\sigma/\sigma_0$ on n_s at 298 K on the basis Eq. 6. The $-\sigma/\sigma_0$ ratio is values calculated for Δx=3 Å.

On the other hand, when the distribution of co-ions within the layer and in the vicinity of the layer can be ignored, the $zn_s/z'n_g$ and $(zn_s/z'n_g)^2$ terms disappear in Eq. 5; then, LCD agrees with that in a salt-free solution. This result shows that when $z'n_g$ is much larger than zn_s, co-ions are sufficiently excluded within the layer and in the vicinity of the layer.

Ultimately, it is inferred that the independence of the charge density of polyions from the concentration of a salt occurs owing to the quite high density of charged groups contained in the polyions (then, co-ions are sufficiently excluded in the vicinity of the polyions).

Electric Field. The electric field, $-\varepsilon d\psi/dx$, on the surface of the layer is proportional to $-\sigma$. Since $-\sigma$ for the small value of $zn_s/z'n_g$ is independent of n_s, for such a value of $zn_s/z'n_g$ the electric field on the surface is independent of n_s. Moreover, it can be shown that the electric field in the vicinity of the layer is insensitive to n_s if n_s is sufficiently small. The electric field in the vicinity of the layer is given by

$$-\varepsilon\frac{d\psi_2}{dx}=\varepsilon E_0+\varepsilon E(n_s), \quad (7)$$

where εE_0 is the electric field occurring in a salt-free solution[4] and it is

$$\varepsilon E_0=\frac{-\sigma_0}{1-\frac{\Delta\sigma_0}{\sqrt{2}}\cdot\mu\left(\frac{\Delta x}{2}-x\right)}$$

In Eq. 7, $\varepsilon E(n_s)$ is defined as

$$\varepsilon E(n_s) \equiv \varepsilon E_0 \cdot \left[- \frac{\Delta\sigma/\sigma_0}{1 - \frac{\Delta\sigma_0}{\sqrt{2}}\mu\left(\frac{\Delta x}{2} - x\right)} \right.$$

$$+ \frac{\sqrt{2}}{f\Delta\sigma_0} \cdot \frac{\mu\left(\frac{\Delta x}{2} - x\right)}{\left\{1 - \frac{\Delta\sigma_0}{\sqrt{2}}\mu\left(\frac{\Delta x}{2} - x\right)\right\}^2} \cdot \left\{1 - \sqrt{2}\Delta\sigma_0\mu\left(\frac{\Delta x}{2} - x\right)\right.$$

$$\left. \left. + \frac{1}{3}\left(\sqrt{2}\Delta\sigma_0\mu\left(\frac{\Delta x}{2} - x\right)\right)^2 - \frac{1}{24}\left(\sqrt{2}\Delta\sigma_0\mu\left(\frac{\Delta x}{2} - x\right)\right)^3 \right\} \right].$$

In the Guoy-Chapman solution, the coefficient κ defined as

$$\kappa^2 \equiv \frac{2z^2e^2n_s}{\varepsilon kT},$$

is contained. Equation 7 is obtained by considering n_s and $\kappa\cdot(\Delta x/2 - x)$ to be small and by approximating $-\varepsilon d\psi/dx$ given by the Gouy-Chapman solution. The ratio of the second term to the first term in the right-hand side of Eq. 7, $|E(n_s)/E_0|$, is much smaller than 1 in the vicinity of the layer, as is found from the dependence of $\{E_0+E(n_s)\}/E_0$ on x in Fig. 3. As a result, it is found that the electric field in the vicinity of the layer may be independent of n_s, and that it may agree with the electric field in a salt-free solution. Moreover, the dependence of $\{E_0+E(n_s)\}/E_0$ on x in Fig. 3 suggests that the extent of the electric field insensitive to n_s expands more if n_s decreases more.

In addition, the electric field within the layer is given by the following formula obtained by using Eq. 3 and by considering Eq. 4:

$$-\varepsilon\frac{d\psi_1}{dx} = -\frac{\sigma}{2}\left\{\left(1 + \frac{2\sqrt{2}}{Y}\right)\cdot\exp\left[-\mu\left(\frac{\Delta x}{2} - x\right)\right]\right.$$

$$\left. + \left(1 - \frac{2\sqrt{2}}{Y}\right)\cdot\exp\left[\mu\left(\frac{\Delta x}{2} - x\right)\right]\right\}.$$

As is noted by this formula, the dependence of this electric field on n_s is the same as the dependence of $-\sigma$ on n_s. If $zn_s/z'n_g$ is sufficiently small, $-\varepsilon d\psi_1/dx$ may be independent of n_s and may agree with the electric field in a salt-free solution (as can be noted according to Ref. 4).

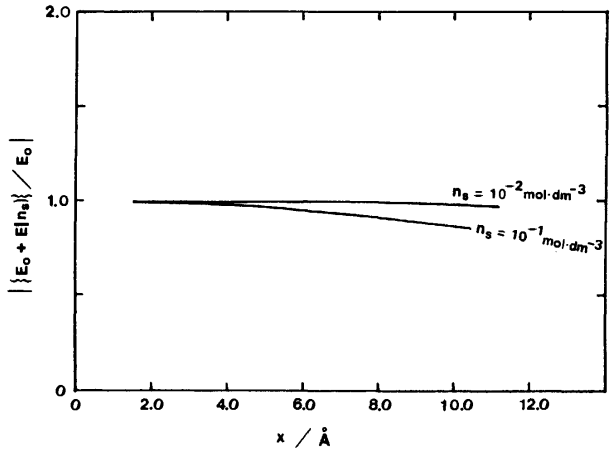

Fig. 3. The dependence of $\{E+E(n_s)\}/E_0$ on x at 298 K on the basis of Eq. 7. The $\{E+E(n_s)\}/E_0$ ratio is values calculated for n_g=1.7×10^{28} m^{-3} and Δx=3 Å.

The Distribution of Counter Ions. The property of the electric field in the vicinity of the layer suggests that the distribution of ions in the vicinity of the layer is insensitive to n_s and that the extent of the ion-distribution insensitive to n_s expands in accordance with a reduction in n_s. The relationship between the counter-ion distribution and n_s in the vicinity of the layer may be represented by

$$n_2(x) = n_0(x) + n_0(x)\cdot\left[- \frac{2\Delta\sigma/\sigma_0}{1 - \frac{\Delta\sigma_0}{\sqrt{2}}\mu\left(\frac{\Delta x}{2} - x\right)} \right.$$

$$+ \frac{2}{f\Delta^2\sigma_0^2}\cdot\frac{1}{\left\{1 - \frac{\Delta\sigma_0}{\sqrt{2}}\mu\left(\frac{\Delta x}{2} - x\right)\right\}^2}\cdot\left\{1 - \sqrt{2}\Delta\sigma_0\mu\left(\frac{\Delta x}{2} - x\right)\right.$$

$$+ \frac{1}{2}\left(\sqrt{2}\Delta\sigma_0\mu\left(\frac{\Delta x}{2} - x\right)\right)^2 - \frac{1}{6}\left(\sqrt{2}\Delta\sigma_0\mu\left(\frac{\Delta x}{2} - x\right)\right)^3$$

$$\left. \left. + \frac{1}{48}\left(\sqrt{2}\Delta\sigma_0\mu\left(\frac{\Delta x}{2} - x\right)\right)^4 \right\} \right], \quad (8)$$

where $n_2(x)$ is the density of counter ions, and $n_0(x)$ is the density of counter ions in a salt-free solution,[4] i.e.:

$$n_0(x) = \frac{{\sigma_0}^2}{2kT\varepsilon\left\{1 - \frac{\Delta\sigma_0}{\sqrt{2}}\cdot\mu\left(\frac{\Delta x}{2} - x\right)\right\}^2}.$$

In addition, Eq. 8 is obtained by considering n_s and $\kappa\cdot(\Delta x/2 - x)$ to be small and by approximating the counter-ion density given by the Gouy-Chapman solution. It is noted in Fig. 4 (depicted in accordance with Eq. 8) that the density of counter ions in the vicinity of the layer, $n_2(x)$, may be insensitive to n_s if n_s is less than 0.1 mol·dm^{-3} ($zn_s/z'n_g$ is less than 10^{-2}). The insensitivity of $n_2(x)$ to n_s is similar to the property of the counter-ion distribution in the vicinity of the charged surfaces of plates, cylinders, and spheres.[2,3] The behavior of $n_2(x)$ (Fig. 4) suggests that the extent of the distribution of counter ions insensitive to n_s expands in accordance with a reduction in n_s. Furthermore, when n_s is so small that the second term in the right-hand side of Eq. 8 can be ignored, the density $n_2(x)$ may agree with the counter-ion density in a salt-free solution. This result is similar to that regarding the charged-plates model of Engström and Wennerström.[5]

On the other hand, the density of co-ions in the vicinity of the layer is given by

$$n_s^2/n_2(x).$$

This formula does not include terms independent of n_s. The formula shows that the density of co-ions is quite small when $zn_s/z'n_g \ll 1$ is satisfied. As a result, the co-ion distribution in the vicinity of the layer may be ignored, although this distribution depends on n_s. Therefore, it is deduced that the insensitivity of the electric field to n_s is attributable to only the property of the counter-ion distribution in the vicinity of the layer.

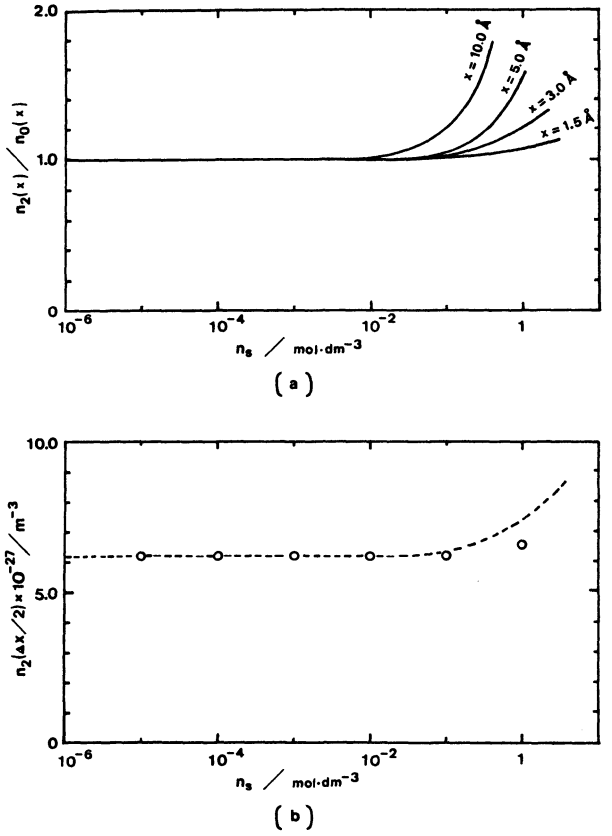

Fig. 4. The dependence of $n_2(x)$ on n_s at 298K on the basis of Eq. 8. The $n_2(x)/n_0(x)$ ratio is values calculated for n_g=1.7×1.0^{28} m^{-3} and Δx=3 Å. The circles represent the $n_2(\Delta x/2)$ counter-ion density on the surface of the layer. The broken line represents the counter-ion density in the immediate vicinity of a charged plate and its surfaces hold a constant surface-charge density 0.190 C·m^{-2} (which equals to a value given by the layer model under the above condition when n_s=0).

In addition, in Fig. 4 the behavior of counter-ion distribution in the immediate vicinity of a charged plate, which holds a constant surface-charge density (0.190 C·m^{-2}), agrees well with the behavior of n_2 $(\Delta x/2)$ (which is n_2 (x) on the surface of the layer) depicted by the circles. The insensitivity of the LCD to n_s is reconfirmed by means of an agreement between these circles and the broken line in Fig. 4.

The density of counter ions within the layer, n_1 (x), is given by using Eq. 3 and by considering Eq. 4; it is represented as

$$n_1(x)=\frac{z'n_g}{z}\cdot\left(\sqrt{\frac{1}{4}+\left(\frac{zn_s}{z'n_g}\right)^2}+\frac{1}{2}\right)\cdot\exp\left[-\frac{\Delta\sigma}{\sqrt{2}}\left\{\left(1+\frac{2\sqrt{2}}{Y}\right)\cdot\exp\left[-\mu\left(\frac{\Delta x}{2}-x\right)\right]-\left(1-\frac{2\sqrt{2}}{Y}\right)\cdot\exp\left[\mu\left(\frac{\Delta x}{2}-x\right)\right]\right\}\right].$$

The density n_1 (x) described by this formula may be as insensitive as n_2 (x), expressed by Eq. 8, if $zn_s/z'n_g$ is sufficiently small. Under the condition that satisfies $zn_s/z'n_g \ll 1$, the density n_1 (x) may agree with the counter-ion density in a salt-free solution (as can be noted according to Ref. 4). Ultimately, it is found that the counter-ion distribution within the layer and in the vicinity of the layer may agree with that in a salt-free solution not only when n_s is zero, but also when it is small.

Conclusion

The LCD in a layer model system containing a salt is given as a function of three parameters (T, n_g, Δx) when $zn_s/z'n_g$ is sufficiently small, even though a layer of polyelectrolytes is immersed in a simple salt solution. Thus, in spite of the permeance of the layer to counter ions, it has been determined that the LCD in this system may be quite insensitive to n_s, though the system satisfies $zn_s/z'n_g \ll 1$. It may be inferred that the independence of the polyion-charge density from the concentration of a salt is attributable to the much higher density of charged groups than the concentratin of the salt. In addition, under the condition that the existance of co-ions in the layer can not be ignored (i.e., $zn_s/z'n_g$ is not small) the LCD in the layer model system may depend on four parameters (T, n_g, n_s, Δx).

The independence of the LCD from n_s in the layer model system is attributable to the insensitivity of counter-ion distribution to n_s. When $zn_s/z'n_g$ is small, the counter-ion distribution in the vicinity of the layer may become quite insensitive to n_s. This result indicates an insensitivity similar to that found from the behavior of the counter-ion distribution in the vicinity of the charged surfaces of the plates, of the cylinders, and of the spheres which hold a constant surface-charge density. Moreover, it has been found that a counter-ion distribution which shows a behavior independent of n_s may agree with the counter-ion distribution in a salt-free solution. If a polyelectrolyte molecule satisfies $zn_s/z'n_g \ll 1$, it is inferred that the cunter-ion distribution in the vicinity of its polyion may be identified with that in a salt-free solution, although n_s is not zero.

Application of the SPE Method to Organic Electrochemistry. IX. Reaction Profiles of an Iron Redox Couple Incorporated into Pt-Nafion with Ascorbic Acid

Zempachi OGUMI,* Toshiyuki MIZOE, and Zen-ichiro TAKEHARA
Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606
(Received March 16, 1988)

Fe^{3+} has been incorporated into Pt-Nafion. The behavior of Fe^{3+} as a mediator was examined in detail in a system comprising the oxidation of L-ascorbic acid (AA) to dehydroascorbic acid (AD). The diffusion of AA in Nafion is slower than that of Fe^{3+}. The concentration profiles of Fe^{3+} and AA in Pt-Nafion have been clarified and a reaction of the mediator with AA took place within a very narrow zone close to the surface. The averaged diffusion coefficients of Fe^{3+} and AA are 1.5×10^{-7} $cm^2 s^{-1}$ and 4.7×10^{-8} $cm^2 s^{-1}$, respectively.

The present authors have investigated the application of the SPE method to organic electrochemistry[1,2] using Nafion as an SPE material. The use of a mediator system in electroorganic syntheses gives some advantages, such as a higher reaction selectivity, easier separation, higher reactivity etc. It was clarified in a previous paper[3] by the present authors that an iron redox couple incorporated into Pt-Nafion acted as a mediator for the oxidation of L-ascorbic acid, AA, to dehydroascorbic acid, AD. In this work, the reaction of Fe^{3+} with AA and their concentration profiles in Pt-Nafion were both examined in detail.

Two configurations are possible in the use of SPE composite electrodes, as described in a previous paper.[3] In configuration a, in Fig. 3 in Ref. 3, substrates are introduced into the working electrode compartment. In configuration b of the same figure, substrates are introduced into the counter electrode compartment. The former configuration is more useful for enhancing the reaction rate. On the other hand, it is easier in the latter configuration to investigate concentration profiles in a composite electrode, since the contribution from any direct electrode reaction of the substrates is suppressed. The latter configuration (b) is focused upon here.

Pt-Nafion has, inherently, the structure of a Nafion-coated electrode. Many workers have investigated Nafion-coated electrodes prepared by the casting of a Nafion solution,[4-6] owing to their potential applications to such electrochemical devices as sensors and electrochromic displays. The concentration profiles on polymer-coated-electrodes have been extensively investigated by Saveant and co-workers[7,8] as well as others. Polymer-coated electrodes were mainly prepared by using a solution casting method including Nafion-coating. Solution-cast films are thin and it is not easy to characterize their structure well. In some cases, the structure of a solution-cast film is different from that of a thicker membrane prepared by a conventional method. For example, a Nafion film cast from its solution, without an adequate following curing treatment, is different from the characteristic ionomer structure of Nafion. In the case of Pt-Nafion, the coating layer is thick (100—300 μm) and its structure is well characterized.[9] Utilizing these advantages, concentration profiles and a reaction zone inside the Nafion which coated a porous Pt electrode were investigated. The obtained results present a clearer typical model of the concentration distribution on Nafion-coated electrodes. These are useful in giving higher functions to SPE composite electrodes regarding their applications to organic electrochemistry.

Experimental

Chemicals. Commercially available chemicals of reagent grade were used without further purification.

Pt-Nafion Composite Electrodes. Nafion 125 and Nafion 120 were used as SPE materials. These two Nafions are different only in their thickness, and are nominally 125 and 250 μm (5 and 10 mil) thick. After standard boiling water treatments, platinum was deposited on one side of the Nafion by a method previously described.[3] An iron redox couple was incorporated into Pt-Nafion by a previously described method.[3]

Electrolysis Cell. The electrolysis cell was composed of two compartments, a working electrode compartment (w.e.c. 15 cm^3) and a counter electrode compartment (c.e.c. 14.5 cm^3), which were divided by Pt-Nafion. Argon was filled in w.e.c. and an aqueous sulfuric acid solution (in most cases 0.025 mol dm^{-3}) without or with AA (in most cases 0.15 mol dm^{-3}) in c.e.c. The cell was thermostated at 25 °C.

Electrochemical Measurements. Chronopotentiometry, chronoamperometry, and steady state current measurements were adopted in order to obtain information on the concentration profiles of Fe^{3+} and AA. The apparent effective surface area of composite electrodes was 3.1 cm^2.

Results

The Concentration of Fe^{3+} inside Pt-Nafion. By a method similar to that used before,[3] the exchange selectivity of Nafion for Fe^{3+} was investigated. The concentration of Fe^{3+} in Pt-Nafion equilibrated with an Fe^{3+}solution of concentration higher than 0.3 mol dm^{-3} was 0.31 mol dm^{-3}-whole-wet-resin. Fe^{3+} is exchanged with other cations in the solution when it is soaked in an electrolyte solution free from Fe^{3+} until the concentration distribution reaches an equilibrium state between the contacting solution and Pt-Nafion. Therefore, after the electrolytic cell was set up and

filled with a sulfuric acid solution in c.e.c. (14.5 cm^3), the concentration of Fe^{3+} inside Pt-Nafion decreased to 0.29 and 0.12 mol dm^{-3}-whole-wet-resin (Nafion 125) for 0.050 and 0.10 mol dm^{-3} in c.e.c., respectively.

The Thickness of Pt-Nafion. Swelling changes the volume of Nafion, resulting in a change in its thickness. The degree of swelling is known to be dependent on its pretreatment conditions. After the standard boiling water treatment, the thickness of Nafion 125 and 120 was measured using a micrometer. The averaged values were 139 and 284 μm, respectively, which approximately agreed with values 143 and 289 μm calculated using an empirical equation[9] of swelling while assuming an isotropic expansion by swelling.

Diffusion of Fe^{3+}. Chronopotentiometry measurements gave $i\tau^{1/2}$ of 29.6 mA $s^{1/2}$ on Pt-Nafion containing Fe^{3+} and contacting with 0.05 mol dm^{-3} H_2SO_4. Substituting 0.29 mol dm^{-3} for the concentration of Fe^{3+}, the Sand equation,[10] Eq. 1, gave the diffusion coefficient of Fe^{3+} in Pt-Nafion, and $D_{Fe}=1.5\times10^{-7}$ $cm^2\,s^{-1}$ was obtained.

$$I\tau^{1/2}=nFAcD^{1/2}\pi^{1/2}/2 \quad (1)$$

This value is reasonable, compared with the value for Na^+, $D_{Na}=9.44\times10^{-7}$ $cm^2\,s^{-1}$, measured by a tracer method for Nafion 120.[11]

The constant current for a reduction of Fe^{3+} on Pt-Nafion contacting 0.5 mol dm^{-3} $Fe_2(SO_4)_3$ was measured under mass-transfer limiting conditions using Nafion 125 and Nafion 120 at 200 mV vs. Ag/AgCl. Assuming that the diffusion layer thickness is equal to the Nafion thickness (139 and 284 μm, respectively), a calculation using Eq. 2 and c=0.31 mol dm^{-3} gave $D_{Fe}=1.4\times10^{-7}$ $cm^3\,s^{-1}$.

$$I=nFADc/d \quad (2)$$

After equilibrating Fe-type Pt-Nafion with 0.05 mol dm^{-3} H_2SO_4, the electrode potential was stepped from 700 mV (vs. Ag/AgCl) to 200 mV, where Fe^{3+} was reduced to Fe^{2+} under mass-transfer limiting conditions. As plotted in Fig.1, in the range of small t the transient current decreased linearly with $t^{1/2}$, and in the range of larger t the current remained constant. Using the Cottrell Eq. 3,[12] and substituting c=0.29 mol dm^{-3}, $D_{Fe}=1.8\times10^{-7}$ $cm^2\,s^{-1}$ was obtained.

$$I=nFAcD^{1/2}/\pi^{1/2}t^{1/2} \quad (3)$$

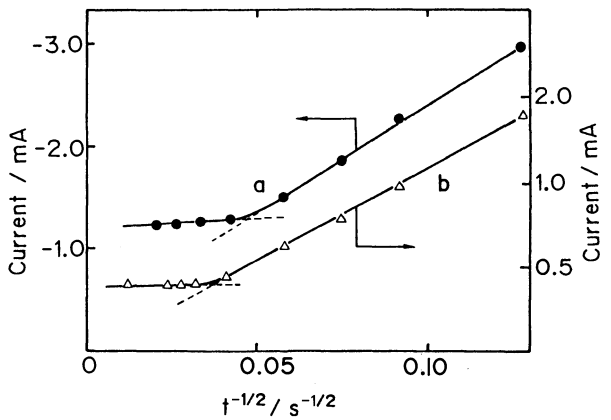

Fig. 1. Cottrell plots of the reduction of Fe^{3+} (a) and oxidation of L-ascorbic acid (b) on Pt-Nafion 125.
Fe^{3+}: 0.75—0.20V, 0.2 M Fe^{3+} and 25 mM H_2SO_4 in c.e.c.
AA: 0.25—0.75V, 0.15 M AA, 25 mM H_2SO_4 in c.e.c.

The diffusion layer thickness increased with the time after the potential stepping; a model involving semiinfinite diffusion was no longer valid after the time that the surface of Nafion began to significantly affect the diffusion of Fe^{3+}. On the other hand, at a longer time, the reduction was controlled by the mass transfer, which was limited by the linear diffusion through the Nafion layer of Pt-Nafion under steady state conditions. This situation leads to a constant current as shown in the figure. The intersecting point of two linear lines gives the time when the thickness of the diffusion layer becomes equal to the thickness of the Nafion. Using $d=(\pi Dt)^{1/2}$ and $t^{-1/2}=0.05$ $s^{-1/2}$ (at the intersecting point), a calculation gave the thickness of 143 μm, which agreed fairly well with the directly measured value, 139 μm.

Diffusion of AA. Since AA is known to be oxidized on a Pt electrode, the diffusion coefficient of AA in Pt-Nafion was measured by electrochemical methods. Chronoamperometry measurements were carried out by stepping a potential of Pt-Nafion without any incorporation of iron ions from 250 to 750 mV, at which all AA reaching the electrode surface on Pt-Nafion through the Nafion layer was sufficiently quickly oxidized to dehydroascorbic acid. As shown in Fig. 1, the transient current decreased proportionally to $t^{-1/2}$ for a shorter time. A slope of i-$t^{-1/2}$ gives the diffusion coefficient using the Cottrell equation, Eq. 3, if the concentration of AA inside the Pt-Nafion c_{At} is known. As discussed below, a concentration in a solution contacting Pt-Nafion can be adopted as the value in Pt-Nafion within an error of less than 10%. Under this situation, the Cottrell equation, Eq. 3, leads to the diffusion coefficient of AA in Pt-Nafion, $D_{AA}=4.4\times10^{-8}$ $cm^2\,s^{-1}$. By a treatment similar to that in the chronopotentiometry of Fe^{3+}, the intersecting point of a Cottrell plot with a steady state current (which corresponds to the diffusion limiting current through the Nafion 125 layer on Pt-Nafion) gave a thickness of 127 μm. The value is about 10% less than the measured value for Nafion 125 (139 μm). The diffusion current of AA through the Nafion layer on Pt-Nafion at 750 mV was proportional to the concentration of AA in the contacting solution. The diffusion current using Nafion 125 was two-times larger than that with Nafion 120, as expected from the difference in the diffusion flux through two membranes of different thickness.

Discussion

The concentration profiles of AA and Fe^{3+} inside Pt-Nafion is discussed. The reaction of AA, with Fe^{3+}, in an aqueous solution is described as follows.[13]

$$-dc_{At}/dt = kc_{At}[Fe^{3+}] \quad (4)$$

c_{At}; total concentration of ascorbic acid AA dissociates to AA^- and AA^{2-} in an aqueous solution. Neglecting the second dissociation, AA^{2-} since it makes a very small contribution,[13] Eq. 4 can be rewritten

$$-dc_{At}/dt = k_1[AA^0][Fe^{3+}] + k_2[AA^-][Fe^{3+}]. \quad (5)$$

Using the dissociation constant, K_1,

$$-dc_{At}/dt = (k_1 + k_2K_1/[H^+])[AA^0][Fe^{3+}]. \quad (6)$$

The rate constants, k_1 and k_2, and the dissociation constant, K_1, were obtained previously:[13]

$$k_1 = 1.6\times10^2\ mol^{-1}\,dm^3\,s^{-1},$$
$$k_2 = 6.4\times10^3\ mol^{-1}\,dm^3\,s^{-1},$$

and

$$K_1 = 9.2\times10^{-5}\ mol\,dm^{-3}.$$

Since Fe^{2+} is generated inside Pt-Nafion by a reaction of Fe^{3+} with AA, the cation is demanded in Nafion in order to satisfy the requirements of electroneutrality there. In this system, H^+ produced by the oxidation of AA satisfies this requirement. Further, as discussed previously, not all counter ions of Nafion are changed to Fe^{3+}, but some H^+ coexists in the Nafion as a counter ion. For these reasons, the concentration of H^+ at the reaction site in Pt-Nafion is higher than 0.29 mol dm^{-3} under the situation that the reaction between AA and Fe^{3+} takes place. This consideration allows one to neglect the second term in the parenthesis of Eq. 6, namely to neglect the contribution from the reaction of dissociated ascorbic acid. Equation 6 simplifies as follows:

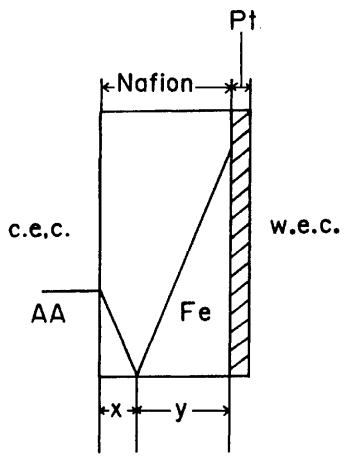

Fig. 2. A simplified model of the concentration profile of indirect oxidation of AA by Fe(3+/2+) redox couple inside the Pt-Nafion. x: diffusion layer thickness of AA, y: diffusion layer thickness of Fe^{3+}.

$$-dc_{At}/dt = k_1[AA^0][Fe^{3+}]. \quad (7)$$

Assuming the simple model shown in Fig. 2, the concentration profiles of AA and Fe^{3+} were calculated using this equation. In this model it was assumed that a reaction is completed at the surface where AA and Fe^{3+} meet. Saveant and co-workers have extensively investigated the concentration profiles on polymer-coated electrodes.[7,8] The rate constants and diffusion coefficients of electroactive species and substrates through both a coating layer and a solution should be taken into consideration as factors which affect the concentration profiles in the coating layer. In the present treatment, the diffusion through a solution contacting Pt-Nafion is neglected because a much slower diffusion through the coating layer is expected. Yeager et al. investigated the mass transport of Na^+ through Nafion and through a depletion layer formed on the surface of Nafion.[14] Their result that the thickness of the depletion layer was as thin as 15 μm, supports the expectation that the mass transfer is predominantly controlled by the diffusion through Nafion. The reaction rate is also considered to be very fast, compared with the rate of mass transfer.

Some specific partition has been observed for many species at the interface between an ion-exchange membrane and the solution.[15] Therefore, the concentration of AA inside Pt-Nafion might be different from that in the solution. As discussed above, all ascorbic acid exists in its neutral form in Pt-Nafion. At the intersecting point in Fig. 1, the current obtained by a chronoamperometry measurement must be equal to the steady state current, though the former value can be estimated by extrapolation. Using Eqs. 2 and 3,

$$I_s = nFAlc_{At}/\pi t_l. \quad (8)$$

Substituting the values into I_s, n, F, A, l, and t_l in Eq. 8, c_{At} becomes 0.16 mol dm^{-3}, which is close to 0.15 mol dm^{-3}, the concentration in the contacting solution. From the above discussion it is concluded that the above assumption, that c_{At} is equal to the concentration of the contacting solution within the experimental error in the concentration range examined here, is acceptable and that there exists neither a specific affinity nor a repulsion between Nafion and ascorbic acid in the present system, though a strong affinity was often reported between organic substances and ion exchange membranes.

In the model of Fig. 2, the followings are applicable:

$$x + y = 0.0139, \quad (9)$$

$$J_{Fe} = 2J_{AA}, \quad (10)$$

$$\text{The flux of AA, } J_{AA} = D_{AA}c_{At}/x, \quad (11)$$

and

$$\text{The flux of } Fe^{3+},\ J_{Fe} = D_{Fe}c_{Fe}/y, \quad (12)$$

From the above equations,

$$y = D_{Fe}c_{Fe}\times0.0139/(2D_{AA}c_{At} + D_{Fe}c_{Fe}). \quad (13)$$

The calculated values of y are plotted as a function of c_{At} in Fig. 3. Using the values for y and Eq. 2, the oxidation current of AA was calculated and is described in Fig. 4 (open circle, solid line) together with the experimental results (triangle and black circle). The experimental values are smaller than the calculated values. The difference can partly be ascribed to the exclusion of Fe^{3+} by H^+ formed by the oxidation of AA from the membrane.

In the above treatment, it was assumed that the reaction between AA and Fe^{3+} proceeded instantaneously at the surface where two species met. The concept of a reaction zone was introduced in order to examine whether the model of instantaneous reaction between Fe^{3+} and AA is valid or not. The model shown in Fig. 5 describes the reaction zone. The concentration of reactants is assumed to be uniform inside the zone (thickness; d) and equal to each other (c_{av}).

$$dc/dt = k_1 c_{av}^2 \qquad (14)$$

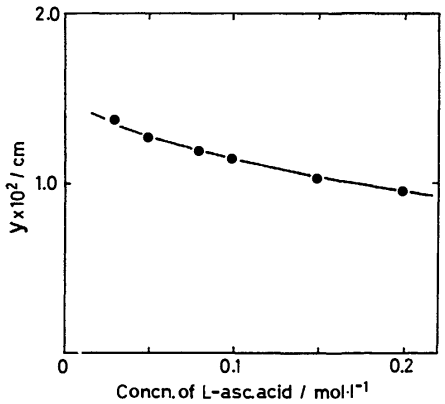

Fig. 3. The dependence of the thickness of diffusion layer for AA (y) on the concentration of AA in c.e.c. on Pt-Nafion 125 incorporated with Fe(3+/2+) redox couple (x+y=139 μm).

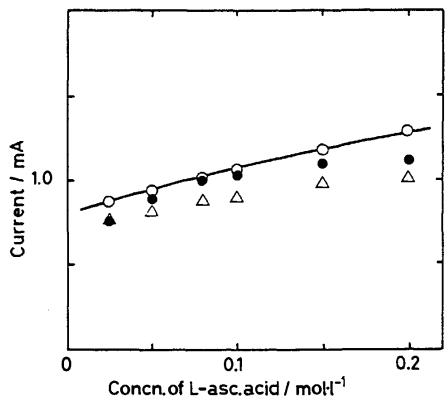

Fig. 4. Dependencies of oxidation current of AA on the concentration of AA in c.e.c. using Pt-Nafion 125 incorporated with Fe(3+/2+) redox couple. Solid line: values calculated using y in Fig. 3 and D_{Fe} and D_{AA}.
△: Run 1, ●:Run 2.

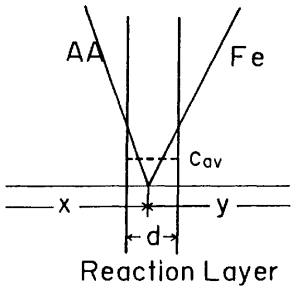

Fig. 5. A reaction layer model of indirect oxidation of AA on Pt-Nafion incorporated with Fe(3+/2+) redox couple.
d: reaction layer thickness, x: diffusion layer thickness of AA, y: diffusion layer thickness of Fe^{3+}, c_{av}: average concentration of AA and Fe^{3+}.

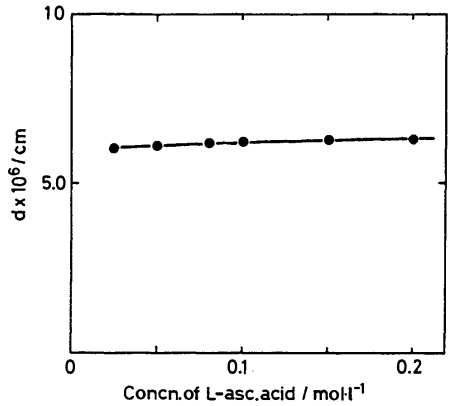

Fig. .6. The dependence of the reaction layer thickness (d in Fig. 5) on the concentration of AA in c.e.c. on Pt-Nafion 125 incorporated with Fe(3+/2+) redox couple.

Under a steady state,

$$k_1 c_{av}^2 \times d/1000 = D_{AA} c_{At}/x. \qquad (15)$$

A numerical calculation gave d, which is plotted in Fig. 6 as a function of c_{At}. As shown in the figure, the thickness is about 6 μm, about 4% of the Nafion thickness. This results reveals that the model of Fig. 2 is valid.

From the above discussion, it is shown that the rate of a mediated reaction is mainly controlled by the slow diffusion of AA and takes place within a narrow zone very close to the Nafion surface facing against c.e.c. Configuration a in Fig. 3 of Ref. 3, where substrates are contained in w.e.c., will make the diffusion pass of Fe^{3+} shorter and will remarkably enhance the reaction rate, though a direct reaction of substrates on the electrode bound on Nafion must proceed rapidly in this configuration.

Conclusion

Pt-Nafion incorporated with iron ions gave an example of a polymer coated electrodes containing redox mediators. Details of the concentration profiles

of the reactants in the coating polymer, Nafion, were examined. A Fe^{2+}/Fe^{3+} redox couple incorporated into Pt-Nafion worked as a mediator in the oxidation of ascorbic acid. The diffusion of Fe^{3+} and AA was rate-determining, and the diffusion of the latter was slower. The mediation reaction proceeded in the very narrow zone, quite close to the Nafion surface. The averaged diffusion coefficients in Nafion, D_{Fe} and D_{AA}, were 1.5×10^{-7} cm^2 s^{-1} and 4.7×10^{-8} $cm^2 s^{-1}$, respectively. Ascorbic acid did not show any specific affinity to Nafion.

SPE composite electrodes were functionalized by the incorporation of mediator systems into SPE materials. This modification is expected to enhance its activity and reaction selectivities in its application to organic electrochemistry, sensors, etc. Configurations in which substrates are contained in the w.e.c. will enhance the activity of SPE composites electrodes incorporated with mediators.

A Novel Approach to the Enumeration of Reaction Types by Counting Reaction-Center Graphs Which Appear as the Substructures of Imaginary Transition Structures

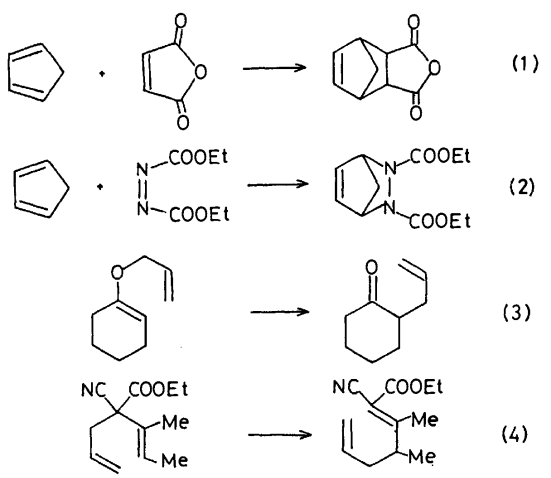
Shinsaku FUJITA
Research Laboratories, Ashigara, Fuji Photo Film Co., Ltd., Minami-Ashigara, Kanagawa 250-01
(Received March 30, 1988)

A novel method of enumerating reaction types is presented. The reaction types are formulated as reaction-center graphs (RCGs) that are derived from a parent basic reaction graph (BRG) or from a parent reaction graph (RG) by the substitution of various atoms on the vertices and/or by the attachment of single, double, or triple par-bonds to the edges. The counting of the isomeric RCGs is solved by applying Pólya's theorem to the derivation of a cycle index, in which different variables are introduced to the different orbits of the permutation group of a parent BRG (or RG). Various atom-figure and bond-figure inventories are described in order to count the isomers of RCGs. The numbers of the RCGs are given in the form of the coefficients of a generating function called an RCG-counting polynomial series.

The collection of reaction types as a knowledge database is necessary for the construction of a computer system dealing with organic reactions.[1-12] The reaction data should be classified clearly and consistently in order to keep the database manageable. A well-defined classification of reaction types is also of fundamental importance for the purpose of retrieving organic reactions[13] as well as for the intention of providing organic chemistry with a more logical and systematic format.[14]

The classification of reaction types necessitates their enumeration, since the expanse of the information regarding them must be preestimated.[15] In addition, the enumeration implies the generation of new organic reactions that fundamentally supports a system of synthetic design.[2c]

The systematic enumeration of reaction types has been achieved only to a limited extent. This stems from the fact that an individual organic reaction is represented by a conventional reaction diagram which contains substrates and products combined with an arrow, as shown in Scheme 1.[16,17j] The conventional enumeration of reaction types thereby requires a multiple comparison among the molecules contained in both sides of the respective diagrams. The treatment of such dual representations is cumbersom and may lead to an overlooking of various possibilities and/or to duplicated counting.



Scheme 1.

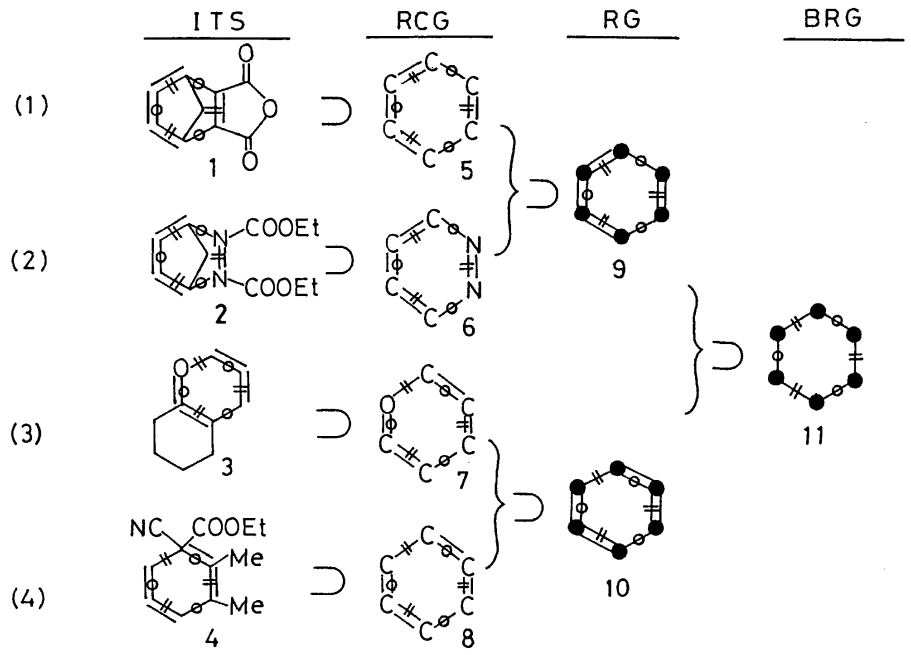
In previous papers,[17] we have proposed the concept of imaginary transition structures (ITS) which afford unitary representations of individual organic reactions. As a result, the manipulation of reaction data is transformed to that of ITSs as a kind of structural formulas. An abstraction of the reaction types is thereby accomplished by finding appropriate subgraphs or substructures of ITSs. Among the useful subgraphs, imaginary rings (ITS rings),[17a,i] reaction-center graphs (RCG),[17a] reaction graphs (RG),[17b,c,f,g] and three- or four-nodal subgraphs[17d,k] are especially effective for characterizing organic reactions.

By a formulation based on the ITSs, an enumeration of the reaction types is transformed into the counting of the subgraphs. In this connection, we have enumerated reaction graphs (RG) to afford a generic classification of reaction types.[17b,c,f,g] As a continuation of this work, the present report deals with a general method for counting reaction types and, especially, with an enumeration of the RC graphs (RCG) which provide us with more detailed information concerning reaction types than the reaction graphs do.

Formulation and Methods

Unique Representations of Reaction Types. Scheme 2 summarizes the formulation of the reaction types discussed in this paper. These ITSs and the related substructures correspond to the diagrams shown in Scheme 1. Although the respective concepts have been reported in the previous papers,[17a,b] they should be restated and extended with the purpose of being applied to the present problem of enumeration.

The *imaginary transition structure (ITS)* of a given reaction contains the participating atoms (C, H, N, O, etc.) and three kinds of bonds (in- (⊖), out- (⧺), and par-bonds (—)), which bonds correspond to the structural changes during the reaction.[17a]



Scheme 2.

A *reaction-center graph (RCG)* is defined as a substructure or a subgraph of a given ITS, in which all reaction centers and imaginary bonds between them are collected.[17b] For example, the RCGs (**5**—**8**) are extracted from the corresponding ITSs (**1**—**4**), as shown in Scheme 2. The RCGs (**5** and **6**) represent generic reaction types, both of which are called *Diels-Alder reactions.* They are discriminated from each other in the light of node values (i.e., C_6 and C_4N_2). The Claisen and Cope rearrangements are represented by the RCGs (**7** and **8**), which are the substructures of the ITSs (**3** and **4**) respectively. The RCGs (**7** and **8**) differ from each other in their node values (i.e. C_5O vs. C_6).

A *reaction graph (RG)* is a more abstract substructure that disregards the node values of an RC graph.[17b] The RCGs (**5** and **6**) give the same RG (**9**), which coresponds to a generic class of the Diels-Alder reactions. The RCGs (**7** and **8**) afford another reaction graph (**10**) that represents a [3,3]sigmatropic rearrangement.

A *basic reaction graph (BRG)* is defined as a substructure that contains reaction centers without node values and has in- and out-bonds but no par-bonds on the edges.[17b] The BRG indicates an electron-shift pattern, which is a descriptor of a broad class of organic reactions. A common basic reaction graph (**11**) is obtained from the RGs (**9** and **10**) by deleting all of the par-bonds therefrom (Scheme 2).

A *reaction pair* consists of two graphs (ITSs, RCGs, RGs, or BRGs) interchangeable by an operation which exchanges all in-bonds and out-bonds with each other (*transformation to reverse reaction*: TRR). For example, the TRR operation on RG (**9**) affords the RG of the corresponding reverse reaction, i.e., retro-Diels-Alder reaction. We call a reaction pair of RG level *an RG pair,* and distinguish it from an RCG pair that is a reaction pair of the RCG level.

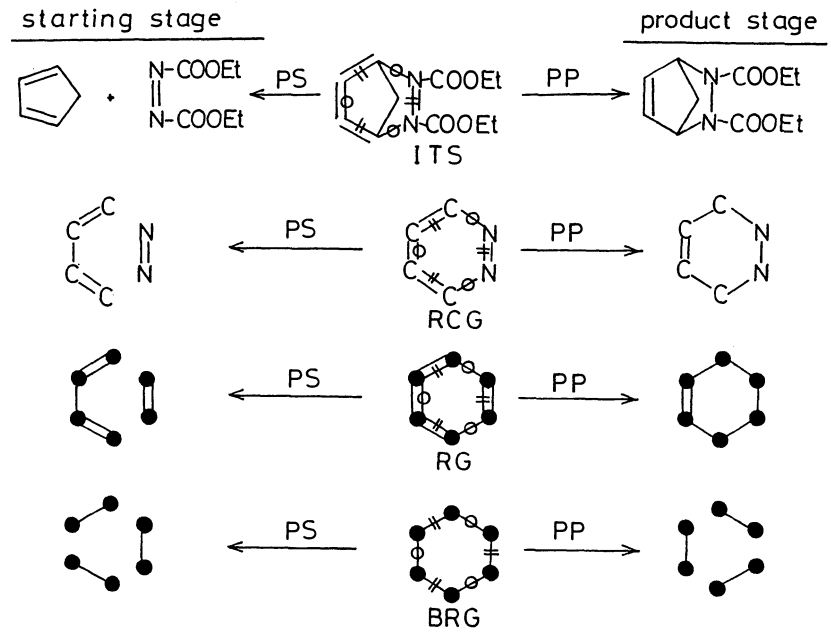
A *self reaction pair* is a special case of a reaction pair, the graph of which is invariant on the TRR operation. For example, RCG **8** and RG **10** are self-reaction pairs in the respective levels.

Scheme 2 indicates a hierarchical classification of organic reactions in terms of the ITS approach. It should be emphasized that the levels of the hierarchy, i.e., RCG, RG, and BRG, give explicit representations to the respective generic reaction types.

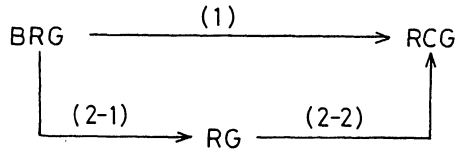
In order to avoid any unfamiliarity with the ITS approach, we introduce *projections to starting stage (PS)* and *to product stage (PP)* that derive conventional diagrams or general schemes from the corresponding ITS, RCG, RG, and BRG (Scheme 3). The PS operation involves a deletion of in-bonds (or taking up par- and out-bonds), and the PP operation involves a deletion of out-bonds (or the taking-up of par- and in-bonds).

Formulation of the Enumeration Problem of Reaction Types. In the light of the formulation described above, our subject to enumerate reaction types is now regarded as the counting of RCGs, RGs, and BRGs. In the present paper, we will discuss two approaches to the enumeration of RCGs (Scheme 4).

The first approach is a one-step method (Scheme 4(1)). An RC graph (RCG) is, thus, considered as being a derivative of a parent BRG that is attached by l_1 single par-bonds (—) and/or l_2 double par-bonds (=) on its edges and is substituted by an appropriate number of atoms on its vertices (nodes). The RCGs (**5**, **6**, **7**, and **8**) are derivatives based on BRG **11** in this sense.



Scheme 3.



Scheme 4.

An alternative approach consists of two steps (2-1 and 2-2 of Scheme 4). In the first step (2-1), a reaction graph (RG) is considered to be a derivative of a basic reaction graph (BRG) that is substituted by l_1 single par-bonds and/or l_2 double par-bonds on its edges. For example, the RGs (**9** and **10**) are isomers that contain 4 single par-bonds but differ from one another in their manner of substitution (Scheme 2). Several RGs have been enumerated in this line and reported in previous papers.[17b,c,f,g] The present paper affords a more general treatment regarding this step than the previous reports. The 2nd step (2-2) concerns an RCG as the derivative of a parent RG that is substituted by an appropriate number of atoms on its vertices.[18] For example, the RCGs (**5** and **6**) are derivatives that have C_6 and C_4N_2, respectively, on the vertices of the RG (**9**). Similarly, the RCGs (**7** and **8**) are derivatives having C_5O and C_6, respectively, on the vertices of the RG (**10**).

One-Step Enumeration. In the one-step approach, an appropriate BRG is selected as a parent graph. Let **G** be the group of symmetry (order g) of the parent BRG, there being p vertices (nodes) at which atoms can be substituted and being q edges to which par-bonds can be attached. Let **H** (degree: $p+q$ and order: g) be a permutation group isomorphic to **G**. Let h_C be the number of the permutations in **H** which have a cycle structure of the type:

$$C=[i_1+j_1, i_2+j_2, \cdots, i_r+j_r, \cdots],$$

wherein i_r cycles of length r are concerned with a substitution to the vertices and j_r cycles or length r are with respect to the edges; they satisfy the following relationships:

$$1i_1+2j_2+\cdots+pi_p=p$$
$$1j_1+2j_2+\cdots+qi_q=q$$

Since the edges and vertices obviously are not interchangeable by **H** (in other words, the two construct different classes or orbits), the cycle index of **H** is obtained by restating Pólya's theorem[19] in an applicable form to our cases:

$$Z(\mathbf{H})=(1/g)\sum_C h_C(s_1^{i_1}s_2^{i_2}\cdots s_p^{i_p})(t_1^{j_1}t_2^{j_2}\cdots t_q^{j_q}), \quad (1)$$

where the summation is taken over all different types (C) of partitions (Appendix 1).

Then, let s_r be an atom-figure inventory that indicates the manner of atom constitution (an atom figure). Also let t_r be a bond-figure inventory that shows the mode of par-bond substitution (a bond-figure). They are defined as shown in the following equations:

$$s_r=1+u_1^r+u_2^r+u_3^r+\cdots \quad (2)$$
$$t_r=1+x_1^r+x_2^r. \quad (3)$$

By introducing s_r (Eq. 2) and t_r (Eq. 3) into the cycle index (Eq. 1), we obtain an RCG-counting polynomial series (Eq. 4) in the form of a generating function:

$$G(u_1, u_2, \cdots x_1, x_2)=Z(\mathbf{H}, 1+u_1+u_2+\cdots, 1+x_1+x_2)$$
$$=\sum A(k_1k_2\cdots l_1l_2)(u_1^{k_1}u_2^{k_2}\cdots)(x_1^{l_1}x_2^{l_2}). \quad (4)$$

The coefficient $A(k_1k_2\cdots l_1l_2)$ of $(u_1^{k_1}u_2^{k_2}\cdots)(x_1^{l_1}x_2^{l_2})$ gives the number of RC graphs when k_1 atoms of the first kind, k_2 of the second kind and so on are introduced to the vertices of the parent BRG, and l_1 of sin-

gle par-bonds and l_2 of double par-bonds are attached to the edges of the BRG. It should be noted that the two kinds of figure-counting series, which we call an *atom-figure inventory* and a *bond-figure one*, can take various forms according to the objects of enumeration. Although they are obviously equivalent from a mathematical point of view, the discrimination between them is convenient in chemical usage. This point will be exemplified in the following discussions.

The cycle index (Eq. 1) can be further generalized so as to be applicable to a case in which the vertices and/or edges subdivided to two or more intransitive orbits in a permutation group (Appendix 1).

An RCG pair-counting polynomial series $P(u_1, u_2, \cdots, x_1, x_2)$ can be obtained in a similar manner, except that the group of the parent BRG is replaced by that of a structure in which the difference between in- and out-bonds is disregarded.[20] The explicit forms for specific cases are listed in the discussions below.

Two-Step Enumeration. This approach contains two successive steps of enumeration (Scheme 4(2-1) and (2-2)). Suppose that a parent BRG has p edges belonging to one orbit and q edges to another different orbit of a permutation group **H** (degree: $p+q$ and order: g) and that the p edges can be attached by single par-bonds and that the q edges can be attached by single or double par-bonds. Variables t_{ar} and t_{br} are assigned to the respective orbits. The mathematical framework described above is thereby applicable to this case and, hence, the corresponding cycle index can be represented as

$$Z(\mathbf{H}) = (1/g)\sum_C h_C(t_{a1}{}^{i_1}t_{a2}{}^{i_2}\cdots t_{ap}{}^{i_p})(t_{b1}{}^{j_1}t_{b2}{}^{j_2}\cdots t_{bq}{}^{j_q}), \quad (5)$$

wherein the other characters have the same meanings as stated above.

In order to obtain an RG-counting polynomial series, suppose that t_{ar} is a bond-figure inventory of the first orbit (a) and t_{br} is another bond-figure inventory of the second orbit (b):

$$t_{ar} = 1 + x_1{}^r \quad (6)$$

$$t_{br} = 1 + x_1{}^r + x_2{}^r \quad (7)$$

We obtain the polynomial $G_b(x_1, x_2)$ (Eq. 8) for counting RGs by introducing t_{ar} (Eq. 6) and t_{br} (Eq. 7) into the cycle index (Eq. 6):

$$G_b(x_1, x_2) = Z(\mathbf{H}, 1 + x_1, 1 + x_1 + x_2) = \sum B(l_1 l_2) x_1{}^{l_1} x_2{}^{l_2} \quad (8)$$

The coefficient $B(l_1 l_2)$ of $x_1{}^{l_1}x_2{}^{l_2}$ gives the number of RGs in which l_1 of single par-bonds and l_2 of double par-bonds are attached to the edges of the parent BRG.

In the second step of the two-step method, we select an appropriate parent RG that has been derived at the first step described above. Suppose that p and q vertices of a parent RG belong to the two different orbits of a permutation group **H** (degree: $p+q$ and order: g), respectively. The p of the vertices of the first orbit can be substituted by n_1 kinds of atoms. On the other hand, q of the vertices of the second orbit can be substituted by n_2 kinds of atoms. Two different variables, S_{ar} and s_{br}, are assigned to the respective orbits. We then obtain the following cycle index:

$$Z(\mathbf{H}) = (1/g)\sum_C h_C(s_{a1}{}^{i_1}s_{a2}{}^{i_2}\cdots s_{ap}{}^{i_p})(s_{b1}{}^{j_1}s_{b2}{}^{j_2}\cdots s_{bq}{}^{j_q}), \quad (9)$$

wherein the other characters have the same meanings as stated above.

Let s_{ar} and s_{br} be the respective atom-figure inventories for orbits a and b and be defined as

$$s_{ar} = 1 + u_1{}^r + \cdots + u_{n1}{}^r \quad (10)$$

and

$$s_{br} = 1 + u_1{}^r + \cdots + u_{n2}{}^r \quad (11)$$

These equations are introduced to the cycle index (Eq. 9), which is, in turn, expanded into a generating function. An RCG-counting polynomial series $G_a(u_1, u_2, \cdots)$ is thus obtained:

$$G_a(u_1, u_2, \cdots) = Z(\mathbf{H}, 1 + u_1 + \cdots + u_{n1}, 1 + u_1 + \cdots + u_{n2}) = \sum C(k_1 k_2 \cdots)\,(u_1{}^{k_1}u_2{}^{k_2}\cdots). \quad (12)$$

The coefficient $C(k_1 k_2 \cdots)$ of the term $u_1{}^{k_1}u_2{}^{k_2}\cdots$ gives the number of RC graphs in which k_1 atoms of a first kind, k_2 of a second kind and so on are introduced to the vertices of the parent RG.

Results and Discussion

Enumeration of RC Graphs Based on a Parent Basic Reaction Graph. Examples of the One-Step Method. Table 1 summarizes representative BRGs selected as parent graphs and the corresponding cycle indices for the counting of RCGs and/or RCG pairs. These results have been obtained by applying Eq. 1 to the respective cases in accord with their permutation groups. The number of RCGs in each case is obtained where variables s_r and t_r of the cycle index collected in Table 1 are substituted by the figure-counting series (Eqs. 2 and 3).

To exemplify the derivation of cycle indices and of RCG-counting polynomial series, we examine the counting of isomers of hexagonal reaction graphs (Table 2).[21] Suppose that a parent BRG (**11**) is substituted by l_1 single par-bonds on its edges and attached by k_1 nitrogen atoms and k_2 oxygen atoms (and $6-k_1-k_2$ of implicit carbon or other atoms) on its vertices. The vertices of **11** are numbered as 1, 2, ··· 6 and the edges are designated as a, b, ··· f.

The symmetry of **11** is $\mathbf{D}_3$ (order 6). Hence, the permutation corresponding to each symmetry operation is obtained, as shown in Table 2, which permutation is represented by the product of cycles, e.g.,

$$C_{2(1)} \sim \begin{pmatrix} 1 & 2 & 3 & 4 & 5 & 6 & a & b & c & d & e & f \\ 2 & 1 & 6 & 5 & 4 & 3 & a & f & e & d & c & b \end{pmatrix} = (1\ 2)\,(3\ 6)\,(4\ 5)\,(a)\,(d)\,(b\ f)\,(c\ e).$$

Table 1. Parent Basic Reaction Graphs and Cycle Indices for the One-Step Enumeration[a)]

BRG	Symmetry	Cycle indes[b,c)]	Eq.
 12	D_2	G: $(1/4)(s_1^4t_1^4+2s_2^2t_1^2t_2+s_2^2t_2^2)$	13

a) The cycle indices are obtained by applying Eq. 1 to the respective BRGs. b) A variable s_r is assigned to the cycle of length r which is concerned with a permutation of the vertices. On the other hand, a variable t_r is with respect to a permutation of the edges. c) G: a cycle index for counting RCGs. P: a cycle index for counting RCG pairs.

Table 2. A Permutation Group Based on a Parent BRG (**11**)

Parent BRG: 
11 (D_3)

Symmetry operation	Permutation	Variable[a)] assigned
I	(1)(2)(3)(4)(5)(6) (a)(b)(c)(d)(e)(f)	$s_1^6t_1^6$
$C_{2(1)}$	(1 2)(3 6)(4 5) (a)(d)(b f)(c e)	$s_2^3t_1^2t_2^2$
$C_{2(2)}$	(1 6)(2 5)(3 4) (c)(f)(a e)(b d)	
$C_{2(3)}$	(1 4)(2 3)(5 6) (b)(e)(a c)(d f)	
C_3	(1 5 3)(2 6 4) (a e c)(b f d)	$s_3^2t_3^2$
C_3^2	(1 3 5)(2 4 6) (a c e)(b d f)	

a) A variable is assigned to each permutation in acord with the cycle structure wherein s_r and t_r are concerned with vertices and edges, respectively. Strictly speaking, this example has three orbits, i.e., (1,2,···6), (a,c,e), and (b,d,f). However, the same variable t_r can be assigned to the latter two orbits without losing generality.

Let us consider a permutation group of degree 12 (=6+6) that is isomorphic to the symmetry of the parent BRG. Obviously, the set of the six vertices and that of the six edges construct different orbits. In other words, the six vertices and six edges are not interchanged with each other by any permutation collected in Table 2. Hence, we introduce different variables, s_r and t_r, to the respective orbits. The assigned variables collected in Table 2 are derived from the cycle structures of the permutations. Upon collecting these assigned variables over all the permutations, we found that the corresponding cycle index (Eq. 15 of Table 1) is a specific case of Eq. 1. Therefore, the variables of Eq. 15 are replaced by atom-figure and bond-figure inventories:

$$s_r = 1 + u^r + v^r \tag{22}$$

and

$$t_r = 1 + x^r. \tag{23}$$

As a result, the following equation is derived as a

generating function called an RCG-counting polynomial series:

$$G(u, v, x)=(1/6)\ \{(1+u+v)^6(1+x)^6+ 3(1+u^2+v^2)^3(1+x)^2(1+x^2)^2+ 2(1+u^3+v^3)^2(1+x^2)^2\}. \quad (24)$$

Since the parent BRG (**11**) is a self-reaction pair, the set of isomers counted by Eq. 24 contains one or more self-reaction pairs. The next problem is the counting of reaction pairs. The corresponding parent graph (**14**) has $\mathbf{D}_6$ symmetry (order 12) and affords the cycle index (Eq. 16) as collected in Table 1. Then, an RCG pair-counting polynomial $P(u, v, x)$ (Eq. 25) is derived by the introduction of Eqs. 22 and 23 into Eq. 16:

$$P(u, v, x) =(1/12)\ \{(1+u+v)^6(1+x)^6+(1+u^2+v^2)^3(1+x^2)^3+ 3(1+u+v)^2(1+u^2+v^2)^2(1+x^2)^3+ 3(1+u^2+v^2)^3(1+x)^2(1+x^2)^2+ 2(1+u^3+v^3)^2(1+x^3)^2+ 2(1+u^6+v^6)(1+x^6)\}. \quad (25)$$

The expansion of Eq. 24 gives a polynomial series in which the coefficient of the term $u^{k_1}v^{k_2}x^l$ indicates the number or isomers derived from the parent BRG (**11**) with l single par-bonds on the edges along with k_1 of nitrogen and k_2 of oxygen atoms. Similarly, an expansion of Eq. 25 affords a polynomial series, the coefficients of which show the numbers of the corresponding RCG pairs. The coefficients derived from Eqs. 24 and 25 are found in Table 3.

Table 3. Enumeration of Reaction Types Based on BRG (**11**)[a]

k_1k_2	Number of RCGs (RCG pairs)			
	l=0 or 6	l=1 or 5	l=2 or 4	l=3

a) The numbers of RCGs with k_1 or nitrogens, k_2 of oxygens and one single par-bond are obtained as the coefficients of $u^{k_1}v^{k_2}x^l$ in Eq. 24. The numbers in the parentheses indicate the number of RCG pairs which are obtained by the expansion or Eq. 25.

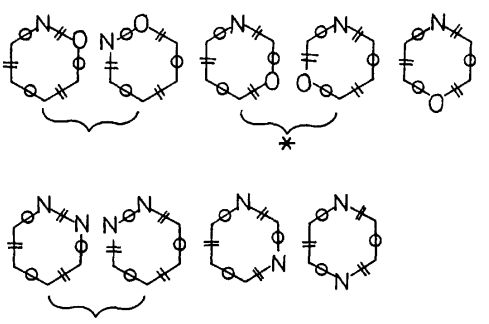
The results of Table 3 have been obtained by a mathematical treatment and, hence, affords a good probe to test the validity of manual enumeration. From this point of view, let us examine several examples derived from the parent BRG (**11**). Table 4 collects isomers with one nitrogen and one oxygen and no par-bonds ($k_1=k_2=1$, $l=0$) as well as isomers with two nitrogen ($k_1=2$, $k_2=l=0$).[22] Each couple of the RCGs linked with a brace (Table 4) is a reaction pair. An isolated one is a self reaction pair. The number of NO isomers is 5; this number is obtained as the coefficient of the term uv ($=u^1v^1x^0$) of Eq. 24 (Table 3, $k_1=k_2=1$, $l=0$). The number of RCG pairs is 3, which is obtained from Eq. 25 (the data in parentheses of Table 3 at $k_1=k_2=1$, $l=0$). The latter N_2 case affords 4 for RCGs and 3 for RCG pairs as the respective coefficients of the term u^2 ($=u^2v^0x^0$) in Eqs. 24 and 25 (Table 3). The results shown in Table 4 are, thus, confirmed by the values of Table 3.

A comparison between the NO and N_2 substitutions (Table 4) reveals that the RCG pair of the former NO case (marked by an asterisk) is degenerated to a self RCG pair in the latter N_2 case. This fact reflects the symmetries of the RCGs, which determine the values of the coefficients.

Table 5 shows the case of $k_1=k_2=l=1$. The number of isomers of RC graphs is 30 and that of RCG pairs is 15, which are in accord with the results obtained from the generating functions (Table 3).

It must be emphasized that *the number of reaction types is given in the form of the coefficient of a generating function such as Eq. 24 but not as a result of manual enumeration.* Therefore, the present method

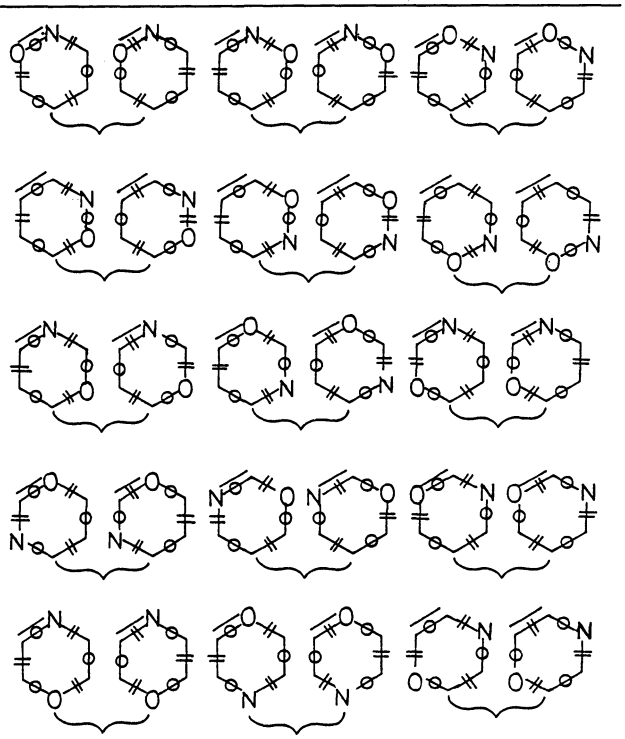
Table 4. Isomeric RCGs with NO or N_2 on the Vertices but No Par-Bonds on the Edges[a]



a) Each couple of RCGs linked with a brace is a reaction pair. An isolated RCG is a self-reaction pair. The number of RCGs and that of RCG pairs are obtained as the coefficients of the respective generating functions (Eqs. 24 and 25). These numbers are listed in Table 3 ($k_1=k_2=1$, $l=0$; and $k_1=2$, $k_2=l=0$).

affords an assurance of the validity to a computer program for the enumeration of reaction types or for generating new reactions.

Table 5. Isomeric RCGs Substituted by One Nitrogen and One Oxygen on the Vertices and by One Single Par-Bond on the Edge[a)]



a) Each couple or RCGs linked with a brace is a reaction pair. The number of RCGs and that of RCG pairs are obtained as the coefficients of $u^1v^1l^1$ of Eqs. 24 and 25, respectively (Table 3, $k_1=k_2=l=1$).

Enumeration of RC Graphs Based on a Parent Reaction Graph. The 2nd Step of the Two-Step Method. The number of isomers obtained in the last section contains that of several RCGs in which the valency of the atoms exceeds chemically reasonable values. Hence, a more specific treatment than that mentioned above is necessary in order to avoid counting chemically unreasonable isomers. This approach starts from an appropriate reaction graph (RG) in place of the BRG described above.

Table 6 summarizes parent RGs of the hexagonal class having 0 to 6 single par-bonds along with the respective cycle indices for counting RCGs and/or RCG pairs. The two parent RGs in alignment are a reaction pair with one another (e.g. **23** and **24**). Contrarily, the RG coupled with a broken-lined graph is a self-reaction pair (e.g. **11** followed by **14**). The two cases are slightly different in a practical treatment, although the results are obtained by applying Eq. 9 to each of the parent RGs in a similar manner. In the former case, the number of RCGs derived from a parent RG is equal to the value based on the corresponding reverse RG. Hence, the number of RCG pairs is always half of the total number of RCGs, based on the RG and the reverse RG as parents. On the other hand, the latter case requires a separate treatment of counting the RCG pairs, since the parent RG is a self-reaction pair.

To exemplify the method of enumeration, let us work out the RG (**9**) as a parent and count the isomers having k_1 nitrogen and k_2 oxygen atoms. The six vertices, whose numbering is shown, are divided into three classes by the corresponding permutation group ($\mathbf{C}_2$), i.e., 1, 2; 3, 4; and 5, 6 (Table 7). The cycle index for **9** (Eq. 39) is obtained, as collected in Table 6, when we

a) The cycle indices are obtained by applying Eq. 9 to the respective RGs. A variable s_{ar} is assigned to the cycle of length r which is concerned with a permutation of the restricted vertices (■). A variable s_{br} is with respect to a permutation of the unmarked vertices. b) G: a cycle index for counting RCGs. P: a cycle index for counting RCG pairs.

Table 7. Permutation Group Based on a Parent RG (**9**)

Parent RG: 
9 (C_2)

Symmetry operation	Permutation	Variable[a] assigned
I	(1)(2) (3)(4) (5)(6)	$s_{a1}^2 s_{b1}^4$
C_2	(1 2) (3 4) (5 6)	$s_{a2} s_{b2}^2$

a) The vertices, 1 and 2, are distinguished from the others because of limitation of valency. The variable s_{br} is given to the former vertices (marked by ■). The other vertices are assigned to s_{br}.

give a variable s_{ar} to the first class and s_{br} to the 2nd and 3rd classes. This treatment stems from the facts that vertices 1 and 2 (marked by boldface squares) are unable to be substituted by oxygen atoms due to a valency limitation and that the substituents on vertices 3 to 6 can be selected freely from a set of nitrogen, oxygen, and implicit carbon atoms.

We then introduce two kinds of atom-figure inventories:

$$s_{ar} = 1 + u^r \tag{45}$$

and

$$s_{br} = 1 + u^r + v^r, \tag{46}$$

the first of which is used for a substitution only by nitrogen atoms and the 2nd of which is used for a substitution by nitrogen and oxygen atoms. The variables of Eq. 39 are substituted by Eqs. 45 and 46 to afford an RCG-counting polynomial series (Eq. 47):

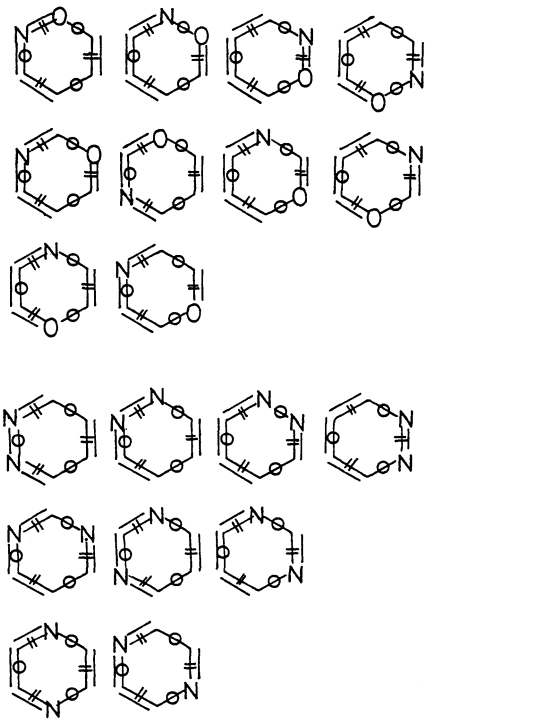
$$G(u, v) = (1/2)\{(1+u)^2(1+u+v)^4 + (1+u^2)(1+u^2+v^2)^2\}. \tag{47}$$

The expanded equation from Eq. 47 is a generating function in which the coefficient of $u^{k_1}v^{k_2}$ is the number of isomers with k_1 nitrogen and k_2 oxygen atoms.

Table 8 shows isomers in which one nitrogen and one oxygen atom substitute the vertices of the parent RG (**9**). The number of isomers collected is 10, the number of which is equal to the coefficient of the term u^1v^1 of Eq. 47. Table 8 also contains isomers having two nitrogen substituents on the RG (**9**). This list contains the isomers of the RCG (**6**) shown in Scheme 2. The number of N_2 isomers is 9, which is, again, confirmed by a comparison with the coefficient of u^2v^0 in Eq. 47.

The parent RG (**9**) is not a self-reaction pair and the TRR operation affords RG (**38**) of the reverse reaction (the retro Diels-Alder reaction). The enumeration of isomers based on RG (**38**) gives the same results as those of RG (**9**).

Table 8. Isomeric RCGs Derived by NO and N_2 Substitution on the Parent RG (**9**)[a]



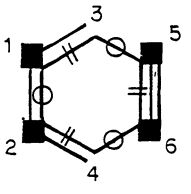
a) The numbers of RCGs are obtained as the coefficients of uv for NO substitution (Table 9, **9**, $k_1=k_2=1$) and of u^2 for N_2 substitution (Table 9, **9**, $k_1=2$, $k_2=0$). See Appendix 2.

The Diels-Alder type addition of a triple bond is represented by the RG (**45**) that also has three classes of vertices (1, 2; 3, 4; and 5, 6). Since vertices 1, 2, 5, and 6 are unable to have oxygen substituents, the cycle index (Eq. 48) is different from Eq. 39.

$$Z(\mathbf{C}_2) = (1/2)(s_{a1}^4 s_{b1}^2 + s_{a2}^2 s_{b2}) \tag{48}$$

By applying Eqs. 45 and 46 to Eq. 48, we obtain the following RCG-counting polynomial series (Eq. 49):

$$G(u, v) = (1/2)\{(1+u)^4(1+u+v)^2 + (1+u^2)^2(1+u^2+v^2)\}. \tag{49}$$



45 (C_2)

Let us next consider a case in which a parent RG is a self-reaction pair. The representative example is the RG (**10**) that has $\mathbf{C}_2$ symmetry (Table 6). The six vertices are divided into three orbits. The vertices of the first orbit (marked by heavy squares) can take only C and N as a substituent because of a valency limitation.

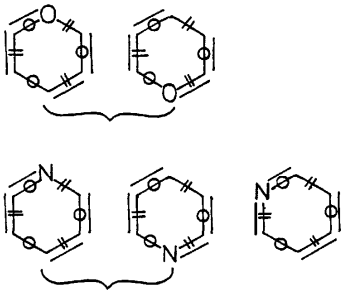
a) The coefficients of $u^{k1}v^{k2}$ indicate the numbers of isomeric RCG with k_1 of nitrogens and k_2 of oxygens on each of parent RG. These values are obtained by introducing Eqs. 45 and 46 to each of the cycle indices (Table 4). b) Obtained by the expansion of Eq. 47.

The other vertices are capable of taking a C, N, or O substituent. The cycle index for the parent RG (**10**) is obtained, as shown in Table 6 (Eq. 37), when we introduce a variable s_{ar} to the first orbit and s_{br} to the 2nd and 3rd orbits. In order to obtain an RCG-counting polynomial series, two kinds of atom-figure inventories (Eqs. 45 and 46) are introduced into the cycle index (Eq. 37). The result of the expansion of this polynomial is listed in Table 9.

Since the parent RG (**10**) is a self-reaction pair, the resulting set of isomers contains one or more self RCG pairs. The next problem is counting the RCG pairs. A parent graph (**37**) for counting RCG pairs is obtained by equalizing the in- and out-bonds of RG (**10**). This graph has $\mathbf{D}_2$ symmetry. The six vertices are divided into two orbits by this symmetry. We then obtain the cycle index of Eq. 38 (Table 6), in which two variables (s_{ar} and s_{br}) are assigned to the orbits in accord with their limitation (maked by ■). The expansion of this polynomial gives a generating function that affords the number of RCG pairs with k_1 of oxygen and k_2 of nitrogen atoms as the coefficient of $u^{k_1}v^{k_2}$. The results are listed also in Table 9.

Table 10 lists the isomers of $k_1=0$, $k_2=1$ (O substitution) and of $k_1=1$, $k_2=0$ (N substitution). The number of RCGs in the former case is 2 and that of RCG pairs is 1. These values are equal to the coefficients of the term u^0v^1 listed in Table 9. On making a substitution of one nitrogen, we obtain 3 isomers of RCG and 2

Table 10. Isomeric RCGs with O and N Substitution on the Parent RG (**10**)[a,b]



a) The number of the O isomers is the coefficient of v (Table 9, **10**, $k_1=0$, $k_2=1$). The number of RCG pairs is shown also in Table 9 (**37**, $k_1=0$, $k_2=1$). b) The number of the N isomers is the coefficient of u (Table 9, **10**, $k_1=1$, $k_2=0$). The number of RCG pairs is found Table 9 (**37**, $k_1=1$, $k_2=0$). See Appendix 2.

RCG pairs. These numbers are the same values as the coefficients of u^1v^0 collected in Table 9.

Table 9 also lists the other results that are obtained by applying atom-figure inventories (Eqs. 45 and 46) to the cycle indices shown in Table 6. When a parent RG is a self-reaction pair, the isomers, therefrom, contain one or more self-RCG pairs. In this case, Table 9 indicates the results of counting RCG-pairs as well as those of counting RCGs.[23]

In this section, we have dealt only with parent RGs of the hexagonal class. The method discussed, however, is applicable to the other types of parent RGs which are derived from the respective parent BRGs given in Table 1. Although the detailed results are abbreviated, full lists of the latter cases would be of essential importance for didactic and taxonomic purposes.

Enumeration of RGs Based on a Fused BRG. Improved Examples of the First Step of the Two-Step Method. In a previous paper,[17g] we reported an enumeration of RGs in which they are considered to be the isomers of basic reaction graphs given in Table 11. The previous treatment has not differenciated the fused bonds from the other pericyclic bonds. In light of the extension described in this paper, this subject can be discussed in a more detailed fashion.

Suppose that the fused positions can be attached only by a single par-bond and other pericyclic edges can be substituted by a singe or double par-bond. This formulation allows Eq. 5 to be applied to the various parent BRGs given in Table 11, in which the corresponding cycle indices are listed. Upon making the substitution $t_{ar}=1+x^r$ and $t_{br}=1+x^r+y^r$ and collecting like powers of xy, the coefficients of term $x^{l_1}y^{l_2}$ are obtained in order to indicate the number of isomers with l_1 single par-bonds and l_2 double par-bonds.

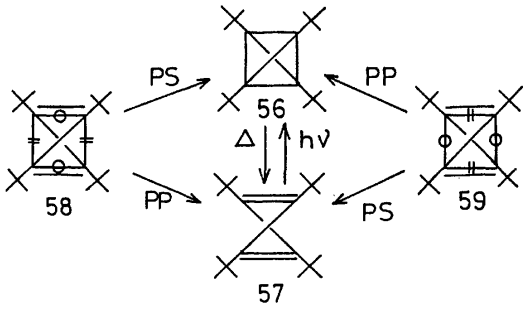
Enumeration of RGs with Cross-Bonds. Extended Examples of the First Step of the Two-Step Method. The above-mentioned treatment presumes that only in-bonds and out-bonds on edges are the positions of substitution. However, a more general enumeration is sometimes desirable. For example, tetra-*t*-butyltetrahedrane (**56**) and tetra-*t*-butylcyclobutadiene (**57**) have been reported to be interconvertible (Scheme 5).[24] The ITSs (**58** and **59**) represent these reactions. The corresponding reaction graphs (RGs) contain cross-bonds. The final problem discussed in this article is counting this type of reaction graph.

We select a basic reaction graph (**60**) as a parent, which has 4 usual edges and 2 phantom edges (cross-

Table 11. Fused BRG as Parent Graphs and Their Cycle Indices[a]

Fused BRG	Symmetry	Cycle index[b]	Eq.
 46  47	D_2	G: $(1/4)(t_{a1}t_{b1}^6+2t_{a1}t_{b2}^3+t_{a1}t_{b1}^2t_{b2}^2)$	50
 48  49	D_2	G: $(1/4)(t_{a1}t_{b1}^{10}+2t_{a1}t_{b2}^5+t_{a1}t_{b1}^2t_{b2}^4)$	51
 50  51	D_2	G: $(1/4)(t_{a1}t_{b1}^8+3t_{a1}t_{b2}^4)$	52
 52	C_2	G: $(1/2)(t_{a1}^2t_{b1}^4+t_{a1}^2t_{b2}^2)$	53
 53	D_2	P: $(1/4)(t_{a1}^2t_{b1}^4+2t_{a2}t_{b2}^2+t_{a1}^2t_{b2}^2)$	54
 54	C_2	G: $(1/2)(t_{a1}^2t_{b1}^8+t_{a1}^2t_{b2}^4)$	55
55	D_2	P: $(1/4)(t_{a1}^2t_{b1}^8+2t_{a2}t_{b2}^4+t_{a1}^2t_{b2}^4)$	56

a) The cycle indices are obtained by applying Eq. 5 to the respective BRGs. b) A variable t_{ar} is respect to the fused edges, whereas t_{br} is assigned to the pericyclic edges.

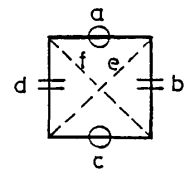


Scheme 5.

linkages of broken lines) as the positions of substitution (Table 12). The consideration of phantom edges is a new matter, compared with the previous enumeration.[17b] When the six edges are marked as above, the 4 permutations of $\mathbf{D}_2$ group (degree 6) are easily obtained (Table 12). The edges are divided into three orbits, i.e., a, c; b, d; and e, f. The edges of the first and 2nd orbits are unable to have a triple par-bond (≡) as a substituent. On the other hand, the phantom edges of the 3rd orbit can be attached by either single, double or triple par-bond. Hence, we introduce a variable t_{ar} to the former and another variable t_{br} to the latter orbits. We thereby obtain a cycle index (Eq. 57), as shown in Table 13.

Table 12. Permutation Group Based on a Parent BRG (**60**)[a]

Parent BRG:



60 (D_2)

Symmetry operation	Permutation	Variable assigned[b]
I	(a)(c) (b)(d) (e)(f)	$t_{a1}^4 t_{b1}^2$
$C_{2(1)}$	(a)(c) (b d) (e f)	$t_{a1}^2 t_{a2} t_{b2}$
$C_{2(2)}$	(a c) (b)(d) (e f)	$t_{a1}^2 t_{a2} t_{b2}$
$C_{2(3)}$	(a c) (b d) (e)(f)	$t_{a2}^2 t_{b1}^2$

a) A broken line indicates a phontom edge which can be substituted by a single, double, or triple par-bond. b) The pericyclic edges have a variable t_{ar}. A variable t_{br} is respect to the phontom edges.

In order to obtain an RG-counting polynomial series $G(x, y, z)$, the variables of Eq. 57 are substituted by the following two kinds of bond-figure inventories:

$$t_{ar} = 1 + x^r + y^r \tag{61}$$

and

$$t_{br} = 1 + x^r + y^r + z^r, \tag{62}$$

wherein t_{ar} is used for a substitution by a single or double par-bond and t_{br} for a substitution by a single, double, or triple par-bond. The expansion of the polynomial affords the following generating function for the counting of RGs:

$$\begin{aligned} G(x, y, z) &= (1 + 3x + 3y + 6x^2 + 9xy + 6y^2 + 8x^3 + 18x^2y + 18xy^2 + \\ &\quad 8y^3 + 6x^4 + 18x^3y + 27x^2y^2 + 18xy^3 + 6y^4 + \cdots) + \\ &\quad z(1 + 3x + 3y + 6x^2 + 10xy + 6y^2 + \cdots) + \\ &\quad z^2(1 + 2x + 2y + 3x^2 + 4xy + 3y^2 + \cdots). \end{aligned} \tag{63}$$

The coefficient of $x^{l_1}y^{l_2}z^{l_3}$ of Eq. 63 is the number of RGs having l_1 single, l_2 double, and l_3 triple par-bonds on the edges.

Table 14 collects RGs of $l_1=3$, $l_2=l_3=0$ as an example. The number of the isomeric RGs is 6, which number is the coefficient of the term $x^3y^0y^0$ of the Eq. 63. Table 14 also shows isomeric RGs of $l_1=4$, $l_2=l_3=0$, the number of which is found as the coefficient of $x^4y^0z^0$ of Eq. 63. The two RGs connected with a brace construct a reaction pair and the isolated ones are self reaction pairs, respectively. The number of reaction pairs can be obtained by using the cycle index (Eq. 58) and the bond-figure inventories (Eqs. 61 and 62).

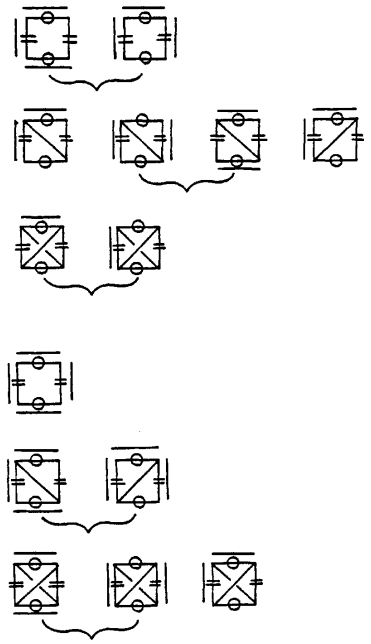
The BRG (**9**) has 9 additional phantom edges in light of the approach taken in this section. Hence we obtain the cycle index (Eq. 59) shown in Table 13. The degree and order of the permutation group obtained are 15 and 6, respectively. The cycle index (Eq. 60) for counting the corresponding reaction pairs

Table 13. Parent BRGs with Phantom Edges and Their Cycle Indices[a]

BRG	Symmetry	Cycle index[b,c]	Eq.
60	$\mathbf{D}_2$	G: $(1/4)(t_{a1}^2t_{b1}^2+2t_{a1}^2t_{a2}t_{b2}+t_{a2}^2t_{b1}^2)$	57
	$\mathbf{D}_4$	P: $(1/8)(t_{a1}^4t_{b1}^2+2t_{a1}^2t_{a2}t_{b2}+3t_{a2}^2t_{b1}^2+2t_{a4}t_{a2})$	58
61	$\mathbf{D}_3$	G: $(1/6)(t_{a1}^6t_{b1}^9+3t_{a1}^2t_{a2}^2t_{b1}t_{b2}^4+2t_{a3}^2t_{b3}^3)$	59
	$\mathbf{D}_6$	P: $(1/12)(t_{a1}^6t_{b1}^9+3t_{a1}^2t_{a2}^2t_{b1}t_{a2}^4+2t_{a3}^2t_{b3}^2+3t_{a2}^3t_{b1}^3t_{b2}^3+t_{a2}^3t_{b1}^3t_{b2}^3+2t_{a6}t_{b3}t_{b6})$	60

a) The cycle indices are obtained by applying Eq. 5 to the respective BRGs having phantom edges. b) A variable t_{ar} is assigned to the pericyclic edges. The phantom edges have a variable t_{br} assigned. c) G; a cycle index for counting RGs. P: a cycle index counting RG pairs.

Table 14. Isomeric RGs with Cross-Bonds[a)]



a) Out- and in-bonds are presumed to take pericyclic positions and thus the cross-bonds always consist of par-bonds. This table contains only two types of isomers, i.e. $l_1=3$, $l_2=l_3=0$, and $l_1=4$, $l_2=l_3=0$.

is also found in Table 13. When we introduced bond-figure inventories (Eqs. 61 and 62) to these cycle indices, we obtain generating functions for counting RGs and RG pairs, respectively, of hexagonal class.

Conclusion

We have formulated an enumeration of reaction types as a counting of reaction graphs (RG) and of reaction-center graphs (RCG). The problem has been solved by applying Pólya's theorem in which different variables are introduced to different intransitive orbits of the graph in order to afford a cycle index. Various atom-figure inventories and bond-figure inventories are described for counting the isomers of RG and of RCG. Since the number of isomeric RCGs (or RGs) is obtained by such a mathematical equation as a generating function, the present approach affords a versatile probe for testifying the manual enumeration of reaction types.

Appendix 1

This appendix is dovoted to a derivation of a generating function which enumerates the number of equivalence classes of configurations under the conditions of the present article.

1. Let **D** be a domain which consists of $p+q$ elements called *positions*. Let **H** (order $|\mathbf{H}|$) be a permutation group which acts on a domain **D**. Suppose that **D** is partitioned by **H** into two orbits:

$$\mathbf{D}_1=\{d_{11}, d_{12}, \cdots d_{1p}\} \text{ and } \mathbf{D}_2=\{d_{21}, d_{22}, \cdots d_{2q}\}.$$

Let **X** be a codomain which contains m elements called *figures*:

$$\mathbf{X}=\{X_1, X_2, \cdots X_m\}.$$

Let f_α and f_β be two functions from the domain **D** to the codomain **X**, i.e., f_α: $\mathbf{D}\rightarrow\mathbf{X}$ and f_β: $\mathbf{D}\rightarrow\mathbf{X}$, wherein the functions are called *configurations*.

Definition 1. (binary relation). A relationship between f_α and f_β is defined as a binary relation ($f_\alpha \sim f_\beta$), if the following equation is fulfilled for $^{\exists}H$ ($\in\mathbf{H}$):

$$f_\alpha(d)=f_\beta(H(d)) \quad \text{for } {}^{\forall}d\in\mathbf{D}.$$

Theorem 1. (The proof is abbreviated). The binary relation defined above is an equivalence relation. Therefore, the set of the functions are partitioned into equivalence classes by this relation.

2. We use the terms and notations defined in Definition 1. This section deals with the weight of a function (configuration).

Defenition 2. (the weight of a function). Suppose that two types of weights, $w_1(X_r)$ and $w_2(X_r)$ are assigned to each element (X_r) of the codomain **X**. We then define the weight $W(f)$ for each function (f: $\mathbf{D}\rightarrow X$) as follows:

$$W(f)=\prod_{d\in\mathbf{D}_1} w_1(f(d)) \prod_{d\in\mathbf{D}_2} w_2(f(d)).$$

Theorem 2. Let f_α: $\mathbf{D}\rightarrow\mathbf{X}$ and f_β: $\mathbf{D}\rightarrow\mathbf{X}$ be equivalent. Then,

$$W(f_\alpha)=W(f_\beta).$$

Proof. Since $f_\alpha\sim f_\beta$, an appropriate H ($\in\mathbf{H}$) is present which satisfies the follwing relationship:

$$f_\alpha(d)=f_\beta(H(d)) \text{ for } {}^{\forall}d\in\mathbf{D}.$$

Then,

$$W(f_\alpha)=\prod_{d\in\mathbf{D}_1} w_1(f_\alpha(d)) \prod_{d\in\mathbf{D}_2} w_2(f_\alpha(d))$$
$$=\prod_{d\in\mathbf{D}_1} w_1(f_\beta(H(d))) \prod_{d\in\mathbf{D}_2} w_2(f_\beta(H(d))). \quad \text{(a)}$$

Because of Definition 2,

$$W(f_\beta)=\prod_{d\in\mathbf{D}_1} w_1(f_\beta(d)) \prod_{d\in\mathbf{D}_2} w_2(f_\beta(d)). \quad \text{(b)}$$

A comparison of the right-hand side of (a) with that of (b) shows their equality, since a set of $H(d)$'s is the same as that of d's, except for the sequence. Hence, $W(f_\alpha)=W(f_\beta)$.

It should be noted that the converse of Theorem 2 is not always true: two functions (configurations) having the same weight do not always belong to the same equivalence class. Therefore, our goal is to obtain the number of equivalence classes having the same weight in the form of a generating function based on $W(f)$.

3. Let $\mathbf{F}_\mu$ is a set of functions (f: $\mathbf{D}\rightarrow\mathbf{X}$), all of which have the same weight $W_\mu(f)$. Let H be a permutation of **H** on **D**. This section shows that there is a permutation group on $\mathbf{F}_\mu$ onto which **H** is homomorphic.

Theorem 3. A function $H^{(\mu)}$: $\mathbf{F}_\mu\rightarrow\mathbf{F}_\mu$ is defined in accord with H as follows:

$$H^{(\mu)}(f(d))=f(H(d)) \text{ for } {}^{\forall}d\in\mathbf{D} \text{ and } {}^{\forall}f\in\mathbf{F}_\mu.$$

Then,

(1) The function $H^{(\mu)}$ is a permutation on the set of $\mathbf{F}_\mu$.

(2) The mapping of $\mathbf{H}$ onto $\mathbf{H}^{(\mu)}$ defined above is homomorphic, wherein $\mathbf{H}^{(\mu)}$ is the set of all $H^{(\mu)}$.

Proof. (1) Suppose that both f_α and f_β of $\mathbf{F}_\mu$ ($f_\alpha \neq f_\beta$) are mapped by $H^{(\mu)}$ to the same function, i.e.,

$$H^{(\mu)}(f_\alpha(d)) = H^{(\mu)}(f_\beta(d)) \text{ for } {}^\forall d \in \mathbf{D}.$$

Because of the above definition,

$$H^{(\mu)}(f_\alpha(d)) = f_\alpha(H(d)) \text{ and } H^{(\mu)}(f_\beta(d)) = f_\beta(H(d)).$$

Hence, $f_\alpha(H(d)) = f_\beta(H(d))$. This equation indicates that $f_\alpha = f_\beta$. This is contrary to the presumption. Thererore, ${}^\forall f_\alpha$ ($\in \mathbf{F}_\mu$) is transformed by $H^{(\mu)}$ into a function different from itself. This fact shows that $H^{(\mu)}$ is a permutation on the set of $\mathbf{F}_\mu$.

(2) Let $H_\delta^{(\mu)}$ and $H_\varepsilon^{(\mu)}$ be the permutations on $\mathbf{F}_\mu$. They correspond to H_δ and H_ε ($\in \mathbf{H}$), respectively. Then the following equations are obtained in the light of the definition:

$$H_\delta^{(\mu)}(f(d)) = f(H_\delta(d)) \tag{a}$$

and

$$H_\varepsilon^{(\mu)}(f(d)) = f(H_\varepsilon(d)). \tag{b}$$

Since $\mathbf{H}$ is a permutation group,

$$H_{\varepsilon\delta} = H_\varepsilon H_\delta. \tag{c}$$

Let $H_{\varepsilon\delta}^{(\mu)}$ correspond to $H_{\varepsilon\delta}$ ($\in \mathbf{H}$). Then,

$$H_{\varepsilon\delta}^{(\mu)}(f(d)) = f(H_{\varepsilon\delta}(d)) \overset{c}{=} f(H_\varepsilon H_\delta(d)) = f(H_\varepsilon(H_\delta(d)) \overset{b}{=} H_\varepsilon^{(\mu)}(f(H_\delta(d))) \overset{a}{=} H_\varepsilon^{(\mu)} H_\delta^{(\mu)}(f(d)).$$

That is, $H_{\varepsilon\delta}^{(\mu)} = H_\varepsilon^{(\mu)} H_\delta^{(\mu)}$, which indicates that the mapping of $\mathbf{H}$ onto $\mathbf{H}^{(\mu)}$ is homomorphic.

This theorem shows that $\mathbf{H}^{(\mu)} = \{H^{(\mu)}\}$ is a permutation group on $\mathbf{F}_\mu$ onto which the original permutation group $\mathbf{H}$ on $\mathbf{D}$ is homomorphic.

4. According to Definition 1, the domain $\mathbf{D}$ is partitioned by $\mathbf{H}$ into two orbits $\mathbf{D}_1$ and $\mathbf{D}_2$. Suppose that H ($\in \mathbf{H}$) has the following cycle structure:

$[i_1, i_2, \cdots i_p]$ for a permutation of $\mathbf{D}_1$ part, and
$[j_1, j_2, \cdots j_q]$ for a permutation of $\mathbf{D}_2$ part, wherein
$i_1 + 2i_2 + \cdots + pi_p = p$ and
$j_1 + 2j_2 + \cdots + qj_q = q$.

The function f: $\mathbf{D} \to \mathbf{X}$, which has a weight defined in Definition 2, affords a configuration in which the orbit $\mathbf{D}_1$ has p_1 X_1, p_2 X_2, $\cdots$, and $p_m X_m$ on its positions and the orbit $\mathbf{D}_2$ has q_1 X_1, q_2 X_2, $\cdots$, and q_m X_m on its positions, wherein

$$p_1 + p_2 + \cdots + p_m = p \text{ and}$$
$$q_1 + q_2 + \cdots + q_m = q.$$

Then, the weight of the function $W(f)$ is obtained by Definition 2:

$$W(f) = [w_1(X_1)^{p_1} w_1(X_2)^{p_2} \cdots w_1(X_m)^{p_m}] \cdot [w_2(X_1)^{q_1} w_2(X_2)^{q_2} \cdots w_2(X_m)^{q_m}].$$

Let $A_{p_1, \cdots p_m, q_1, \cdots q_m}$ be the total number of such functions (configurations) which are invariant on a permutation (H) of $\mathbf{H}$ and has $W(f)$ as the weight. Let $B_{p_1, \cdots p_m, q_1, \cdots q_m}$ be the total number of different classes of configurations which have the same weight $W(f)$. To begin with, let us examine the total number of functions.

Theorem 4. A generating function for counting $A_{p_1, \cdots p_m, q_1, \cdots q_m}$ is represented by:

$$\sum A_{p_1, \cdots p_m, q_1, \cdots q_m} [w_1(X_1)^{p_1} \cdots w_1(X_m)^{p_m}] \cdot [w_2(X_1)^{q_1} \cdots w_2(X_m)^{q_m}] = (s_1^{i_1} s_2^{i_2} \cdots s_p^{i_p})(t_1^{j_1} t_2^{j_2} \cdots t_q^{j_q}),$$

wherein $s_r = w_1(X_1)^r + w_1(X_2)^r + \cdots + w_1(X_m)^r$ and
$t_r = w_2(X_1)^r + w_2(X_2)^r + \cdots + w_2(X_m)^r$.

The summation is taken over all the partitions of p ($p_1 + p_2 + \cdots + p_m = p$) and of q ($q_1 + q_2 + \cdots + q_m = q$).

Proof. Let π_1 is a cycle of length r_1 which is involved in H ($\in \mathbf{H}$) and is concerned with the permutation of $\mathbf{D}_1$. Let π_2 be a cycle of length r_2 which is contained in H ($\in \mathbf{H}$) and is concerned with $\mathbf{D}_2$. When a function (configuration) is invariant on the permutation H, it is also invariant on the operations by π_1 and π_2. Then, the r_1 positions of $\mathbf{D}_1$ concerning with π_1 should have r_1 of the same figures, i.e., $r_1 X_1$ or $r_1 X_2 \cdots$ or $r_1 X_m$. Similarly, the r_2 positions of $\mathbf{D}_2$ should have $r_2 X_1$ or $r_2 X_2 \cdots$ or $r_2 X_m$. Hence, the corresponding generating function are represented by:

$$s_{r_1} = \sum_{k=1}^{m} w_1(X_k)^{r_1} \text{ and}$$

$$t_{r_2} = \sum_{k=1}^{m} w_2(X_k)^{r_2}$$

The same kinds of generating functions are obtained for all of the cycles involved in the permutation H. Therefore, a generating function for counting $A_{p_1, \cdots p_m, q_1, \cdots q_m}$ is obtained as follows:

$$\sum A_{p_1, \cdots p_m, q_1, \cdots q_m} [w_1(X_1)^{p_1} \cdots w_1(X_m)^{p_m}] \cdot [w_2(X_1)^{q_1} \cdots w_2(X_m)^{q_m}] = (s_1^{i_1} s_2^{i_2} \cdots s_p^{i_p})(t_1^{j_1} t_2^{j_2} \cdots t_q^{j_q}) = \prod_{r=1}^{p} (\sum_{k=1}^{m} w_1(X_k)^r)^{i_r} \cdot \prod_{r=1}^{p} (\sum_{k=1}^{m} w_2(X_k)^r)^{j_r},$$

which is in accord with the cycle structure of H. When this polynomial is expanded, we obtained a generating function.

We call such summations as s_r and t_r figure inventories.

5. Let us work out H ($\in \mathbf{H}$) which has been defined in Section 4. We introduced a formal variable s_r which corresponds to a cycle of length r of $\mathbf{D}_1$ part. Similarly, a variable t_r is concerned with a cycle of lengh r of $\mathbf{D}_2$ part. We then obtain the following product for H:

$$(s_1^{i_1} s_2^{i_2} \cdots s_p^{i_p})(t_1^{j_1} t_2^{j_2} \cdots t_q^{j_q}).$$

Since the same kind of products can be obtained for all the permutation of $\mathbf{H}$, these products are summed over $\mathbf{H}$.

Definition 3. (cycle index). The following equation is defined as a *cycle index* for $\mathbf{H}$:

$$Z(\mathbf{H}) = \frac{1}{|\mathbf{H}|} \sum_{H \in \mathbf{H}} (s_1^{i_1} s_2^{i_2} \cdots s_p^{i_p})(t_1^{j_1} t_2^{j_2} \cdots t_q^{j_q}).$$

6. We used the terms and notations described in Section 4. The purpose of this section is to derive a generating function of $B_{p_1, \cdots p_m, q_1, \cdots q_m}$.

Theorem 5. A generating function of counting $B_{p_1, \cdots p_m, q_1, \cdots q_m}$ which concerns with the total number of equivalence classes is represented by:

$$\sum B_{p_1, \cdots p_m, q_1, \cdots q_m} [w_1(X_1)^{p_1} \cdots w_1(X_m)^{p_m}] \cdot [w_2(X_1)^{q_1} \cdots w_2(X_m)^{q_m}] = Z(\mathbf{H}; \sum_{k=1}^{m} w_1(X_k)^r, \sum_{k=1}^{m} w_2(X_k)^r),$$

wherein the right-hand side indicates that the two terms denoted by the summations should be introduced to s_r and t_r of $Z(\mathbf{H})$ (Definition 3), respectively. The summation of the left-hand side is taken over all the partitions of p ($p_1+p_2+\cdots+p_m=p$) and of q ($q_1+q_2+\cdots+q_m=q$).

Proof. Let $\mathbf{F}_\mu$ be a set of functions which have the same weight

$$W_\mu=[w_1(X_1)^{p_1}\cdots w_1(X_m)^{p_m}]\cdot[w_2(X_1)^{q_1}\cdots w_2(X_m)^{q_m}]. \quad \text{(a)}$$

Let δ_μ be the number of equivalent classes contained in $\mathbf{F}_\mu$. Then, a generating function for counting equivalence cases is obviously as follows:

$$\sum_\mu \delta_\mu W_\mu .$$

Since $\mathbf{H}_\mu$ is homomorphic to $\mathbf{H}$ (Theroem 3), the number δ_μ is obtained by Burnside's lemma:[19c]

$$\delta_\mu = \frac{1}{|\mathbf{H}|}\sum_{H\in\mathbf{H}} \psi(H^{(\mu)}).$$

wherein $\psi(H^{(\mu)})$ is the number of invariant functions (configurations) of $\mathbf{F}_\mu$ on the operation of $H^{(\mu)}$. Since this lemma is true for all μ,

$$\sum_\mu \delta_\mu W_\mu = \sum_\mu \left(\frac{1}{|\mathbf{H}|}\sum_{H\in\mathbf{H}} \psi(H^{(\mu)})\right) W_\mu$$

$$= \frac{1}{|\mathbf{H}|}\sum_{H\in\mathbf{H}}\sum_\mu \psi(H^{(\mu)})W_\mu . \quad \text{(b)}$$

Because of the definition of $\psi(H^{(\mu)})$ and W_μ, the term

$$\sum_\mu \psi(H^{(\mu)})W_\mu$$

indicates the total number of functions invariant on the permutation H which corresponds to each $H^{(\mu)}$. The term is thus equal to the equation proved in Theorem 4. Therefore,

$$\sum_\mu \psi(H^{(\mu)})W_\mu$$

$$=\sum A_{p_1,\cdots p_m,q_1,\cdots q_m}[w_1(X_1)^{p_1}\cdots w_1(X_m)^{p_m}]\cdot[w_2(X_1)^{q_1}\cdots w_2(X_m)^{q_m}]$$

$$= (s_1^{i_1}s_2^{i_2}\cdots s_p^{i_p})(t_1^{j_1}t_2^{j_2}\cdots t_q^{j_q}), \quad \text{(c)}$$

wherein the summation of the second equation is taken over all the partitions of p ($p_1+p_2+\cdots+p_m=p$) and of q ($q_1+q_2+\cdots+q_m=q$); and the variables s_r and t_r of the 3rd equation are represented by:

$$s_r = \sum_{k=1}^{m} w_1(X_k)^r$$

and

$$t_r = \sum_{k=1}^{m} w_2(X_k)^r.$$

Since Eq. (c) can be established for each H corresponding to $H^{(\mu)}$, the following equation is obtained by the substitution of Eq. (b) by Eq. (c):

$$\sum_\mu \delta_\mu W_\mu = \frac{1}{|\mathbf{H}|}\sum_{H\in\mathbf{H}}(s_1^{i_1}s_2^{i_2}\cdots s_p^{i_p})(t_1^{j_1}t_2^{j_2}\cdots t_q^{j_q})$$

$$= Z(\mathbf{H}; \sum_{k=1}^{m} w_1(X_k)^r , \sum_{k=1}^{m} w_2(X_k)^r),$$

wherein the latter relationship comes from Definition 3. Since

$$\sum_\mu \delta_\mu W_\mu =$$

$$\sum B_{p_1,\cdots p_m,q_1,\cdots q_m}[w_1(X_1)^{p_1}\cdots w_1(X_m)^{p_m}]\cdot[w_2(X_1)^{q_1}\cdots w_2(X_m)^{q_m}],$$

we obtain the relationship to be proved.

7. The weights $w_j(X_k)$ (k=1, 2, ···, m) for $\mathbf{D}_j$ are determined in accord with the restrictive conditions, which are concerned with bond multiplicity (or complex bond number) or the valency of atoms in the present chemical application. The following examples show the effectiveness of Theorem 5.

Example 1. (the derivation of Eq. 4 of the text). The present domain **D** consists of edges and nodes which construct two different orbits on the operation of **H**. Then, Eq. 1 of the text is easily obtained in the light of Definition 3. The codomain **X** contains atom-figures (A, B, C, ···) and bond-figures (ϕ, −, =), i,e.,

$$\mathbf{X}=\{\text{A, B, C, }\cdots;\ \phi, -, =\},$$

wherein the symbol (ϕ) indicates no substitution of bonds on the edges, and the symbols, − and =, denote single and double par-bonds, respectively. Then the weights of them are given as follows:

$$w_1(\text{A})=1,\quad w_1(\text{B})=u_1,\ w_1(\text{C})=u_2,\ \cdots;$$
$$w_1(\phi)=0,\ w_1(-)=0,\ w_1(=)=0 \text{ and}$$
$$w_2(\text{A})=0,\quad w_2(\text{B})=0,\ w_2(\text{C})=0,\ \cdots;$$
$$w_2(\phi)=1,\ w_2(-)=x_1,\ w_2(=)=x_2.$$

Hence, Eqs. 2 and 3 of the text are obtained easily:

$$s_r = \sum_{k=1}^{m} w_1(X_k)^r = 1+u_1^r+u_2^r+\cdots \quad (2)$$

and

$$t_r = \sum_{k=1}^{3} w_2(X_k)^r = 1+x_1^r+x_2^r. \quad (3)$$

Equation 4 is then derived by means of Theorem 5.

Example 2. (the derivation of Eq. 8 of the text). Equation 5 of the text is obtained easily by Definition 3. The codomain **X** contains bond-figures:

$$\mathbf{X}=\{\phi, -, =\}.$$

The weights of them are given as follows:

$$w_1(\phi)=1,\ w_1(-)=x_1,\ w_1(=)=0 \text{ and}$$
$$w_2(\phi)=1,\ w_2(-)=x_1,\ w_2(=)=x_2.$$

Hence, two type of bond-figure inventories are easily obtained:

$$s_r = \sum_{k=1}^{3} w_1(X_k)^r = 1+x_1^r \quad (6)$$

and

$$t_r = \sum_{k=1}^{3} w_2(X_k)^r = 1+x_1^r+x_2^r. \quad (7)$$

In the text, s_r and t_r are denoted as t_{ar} and t_{br}, respectively. Theorem 5 gives Eq. 8 in this case.

8. Theorem 5 can be easily extended to the case in which the domain **D** has three or more orbits. All the proofs described above hold the generality in the extended case. Such extended items are given below:

Domain: $\mathbf{D}=(\mathbf{D}_j)$ for j=1, 2, ··· n.

Orbits of the domain:

$\mathbf{D}_j=\{d_{jk}\}$ for $k=1, 2, \cdots|\mathbf{D}_j|$, $j=1, 2, \cdots n$.
Codomain: $\mathbf{X}=\{X_k\}$ for $k=1, 2, \cdots m$.
Function (Configuration): f: $\mathbf{D}\rightarrow\mathbf{X}$.
Weight of a function (conriguration):

$$W(f) = \prod_{j=1}^{n} \left(\prod_{d\in\mathbf{D}} w_j(f(d)) \right).$$

Cycle structure of **H**:

$$[i_{jk}]\ (k=1 \text{ to } |\mathbf{D}_j|) \text{ for } \mathbf{D}_j\ (j=1 \text{ to } n),$$

wherein

$$\sum_{k=1}^{|\mathbf{D}_j|} k i_{jk} = |\mathbf{D}_j| \quad (j=1, 2, \cdots n).$$

Cycle index of **H**:

$$Z(\mathbf{H}) = \frac{1}{|\mathbf{H}|} \sum_{H\in\mathbf{H}} \left(\prod_{j=1}^{n} \left(\prod_{r=1}^{|\mathbf{D}_j|} s_{jr}^{i_{jr}} \right) \right).$$

Counting polynomial:

$$\sum_{(p_{jk})} B_{(p_{jk})} \left(\prod_{j=1}^{n} \left(\prod_{k=1}^{m} w_j (X_k)^{p_{jk}} \right) \right)$$

$$= Z\left(\mathbf{H}, \sum_{k=1}^{m} w_j (X_k)^r \text{ (for all } j)\right).$$

The summation concerned with (p_{jk}) is taken over all partitions of $|\mathbf{D}_j|$ represented by:

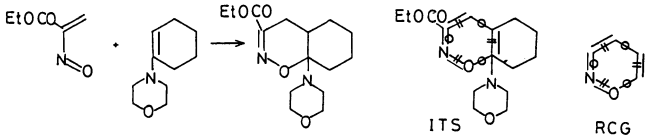
$$\sum_{k=1}^{m} p_{jk} = |\mathbf{D}_j| \text{ for } j = 1, 2, \cdots |\mathbf{D}_j|.$$

Appendix 2

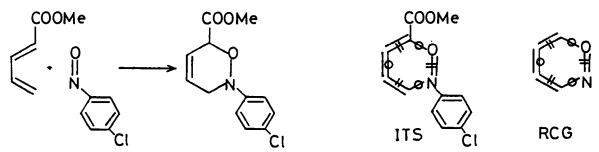
This appendix collects several reactions reported in the literature in order to exemplify the RC graphs of Tables 8 and 10. The examples have been taken from D. L. Boger, *Tetrahedron*, **39**, 2869 (1983); S. B. Needleman and M. C. C. Kuo, *Chem. Rev.*, **62**, 405 (1962); and some original articles. This list contains imaginary transition structures and RC graphs along with conventional reaction diagrams.

The RC graphs which do not appear in this list, but in Table 10, provide us with useful suggestions that would help in the development of new reactions. For example, the

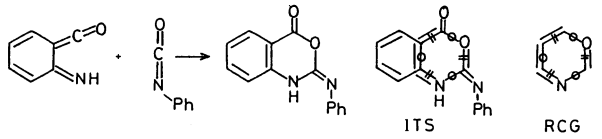
(1-1) Cycloaddition of a vinylnitroso compound with an enamine. (T. L. Gilchrist, D. A. Lingham, and T. G. Roberts, *J. Chem. Soc., Chem. Commun.*, **1979**, 1089).



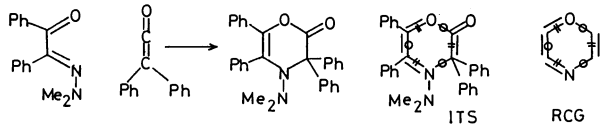
(1-2) Cycloadition of a diene with a nitroso compound. (G. Kreeze and J. Firl, *Tetrahedron Lett.*, **1965**, 1163).



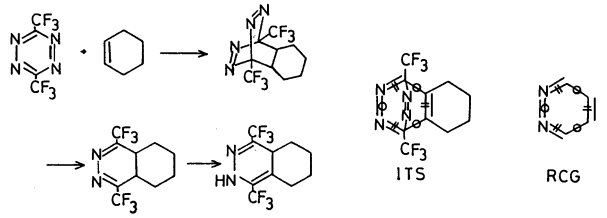
(1-3) Cycloaddition of a reactive *o*-quinone methide ketene with phenyl isocyanate. (H. Herlinger, *Angew. Chem.*, **76**, 437 (1964)).



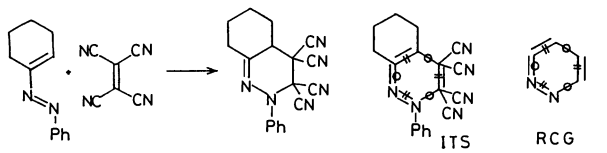
(1-4) Cycloaddition of a hydrazone with diphenylketene. (R. Gommper, *Angew. Chem., Int. Ed. Engl.*, **8**, 312 (1969)).



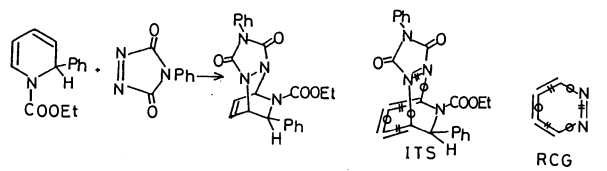
(1-5) The reaction of a 1,2,4,5-tetrazine with cyclohexene. (M. G. Barlow, R. N. Haszeldine, and J. A. Pickett, *J. Chem. Soc., Perkin Trans. 1*, **1978**, 378).



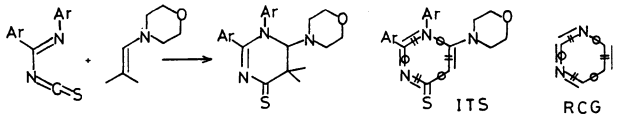
(1-6) Cycloaddition of 1-phenylazocyclohexene with a dienophile. (L. Caglioli, G. Rosini, P. Tundo, and A. Vigevari, *Tetrahedron Lett.*, **1970**, 2349).



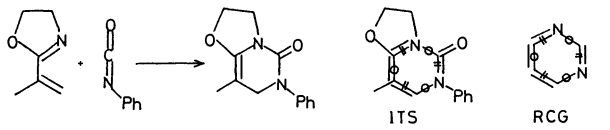
(1-7) Cycloaddition of *N*-ethoxycarbonyl-1,2-dihydropyridine with 4-phenyl-4*H*-1,2,4,-triazole-3,5-dione. (E. E. Knaus, F. M. Pasutto, C. S. Giam, and E. A. Swinyard, *J. Heterocycl. Chem.*, **13**, 481 (1976)).



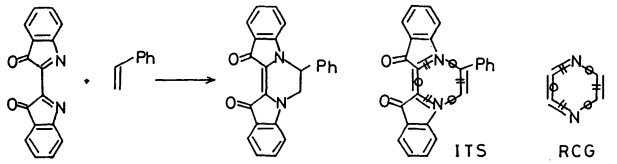
(1-8) The reaction of an imidoyl isothiocyanate with an enamine. (H. M. Blatter and H. Lukaszewski, *J. Org. Chem.*, **31**, 722 (1966)).



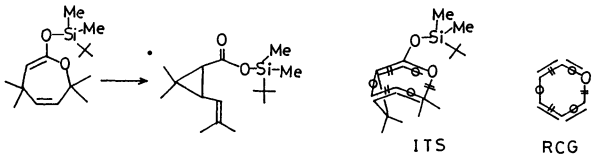
(1-9) Cycloaddition of 2-isopropenyl-2-oxazoline with phenylisocyanate. (A. E. Seelinger, W. Diepers, R. Feinauer, R. Nehring, W. Thier, and H. Hellmann, *Angew. Chem., Int. Ed. Engl.*, **5**, 875 (1966)).



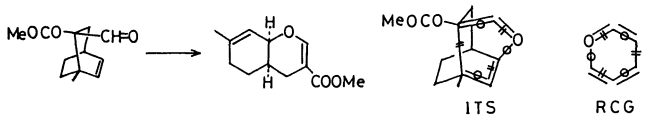
(1-10) Cycloaddition of dehydroindigo with an olefin. (R. Pummerer and E. Stieglitz, *Ber.*, **75**, 1072 (1942)).



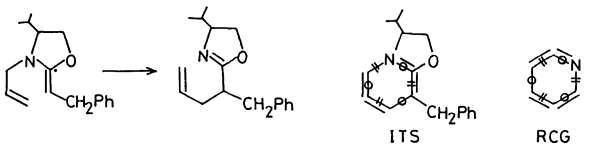
(2-1) The alicyclic Claisen rearrangement. (R. L. Funk and J. D. Munger, Jr., *J. Org. Chem.*, **50**, 707 (1985); A. G. Cameron and D. W. Knight *Tetrahedron Lett.*, **26**, 3503 (1985)).



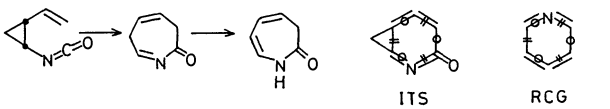
(2-2) The retro-Claisen rearrangement. (R. K. Boeckman, C. J. Flann, and K. M. Poss, *J. Am. Chem. Soc.*, **107**, 4359 (1985)).



(2-3) The Claisen rearrangement of a ketene *N*-allyl-*N*,*O*-acetal. (H. Hope and M. D. Yanuck, *J. Am. Chem. Soc.*, **107**, 443 (1985)).



(2-4) The rearrangement of a cyclopropane derivative. (E. Vogel and R. Erb, *Angew. Chem.*, **74**, 76 (1962)).



Claisen rearrangement (2-1) and the retro one (2-2) have already been investigated. Although the N-analog of the Claisen rearrangement is a known reaction (2-3), a retro-rearrangement has never been reported, to the best of our knowledge.

20) For the examples of reaction pairs, see Ref. 17b.

21) For the treatment in which only edges are considered in the same parent BRG, see Ref. 17b.

22) The equivalent problem has been dealt with previously by a difrerent approach,[3a] but the result is different from ours.

23) Hendrickson's manual enumeration of reaction types (Table 1 of Ref. 3a) corresponds to the cases of k_1=0—3, k_2=0—3 collected in Table 9. His enumeration is limited only to that of RCG pairs in the present sense. Although his approach has introduced a σ-shell as a novel concept to solve the problem, a manual enumeration tends to overlook several possible reaction types. In fact, his list (Table 1) contains different values from the results of our work at B=0, NO, C_4Z_2(O); B=2 (O), O, C_3Z_3(V); B=2 (P), N_2O and NO_2(V); B=3 (Δ), N and O, C_4Z_2 (O); B=3 (Δ), NO C_4Z_2 (M); and B=3 (Δ), N and O, C_3Z_3 (L). As a result, the total number of reaction types listed in Table 1 (Ref. 3a) is 957, although the corresponding number of RCG pairs in our result (Table 9) is calculated to be 964.

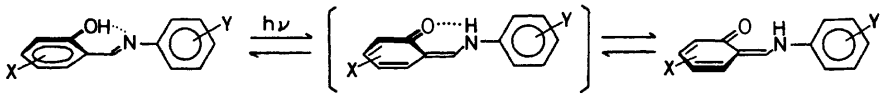
Structure and Optical Properties of a Thermochromic Schiff Base. Thermally Induced Intramolecular Proton Transfer in the *N,N'*-Bis(salicylidene)-*p*-phenylenediamine Crystals

Naomi HOSHINO,† Tamotsu INABE,* Tadaoki MITANI, and Yusei MARUYAMA*
Institute for Molecular Science, Myodaiji, Okazaki 444
(Received April 9, 1988)

A thermochromic derivative of salicylideneaniline, *N,N'*-bis(salicylidene)-*p*-phenylenediamine (BSP), has been prepared and subjected to structural and optical studies in the crystalline state. An X-ray crystallographic analysis has shown that the molecules are planar and are stacked in a parallel fashion to form one-dimensional columns. The interplanar spacing has been found to be quite short, suggesting the existence of an intermolecular charge-transfer interaction. The molecule contains fairly short O-H ··· N hydrogen bonds, the strength of which is manifested in an OH stretching absorption band in the infrared region, showing considerable broadening and a low-frequency shift. The BSP crystals are remarkably thermochromic, and visible absorption and emission spectral changes with temperature have been interpreted in terms of an intramolecular proton transfer from the hydroxyl oxygen to imine nitrogen through the O-H ··· N hydrogen bond. The emission spectra have also been examined under high pressures.

N-Salicylideneaniline and its derivatives have long been known to show photochromism in the solid state,[1] and a number of studies have revealed that the chromism is produced by intramolecular proton transfer associated with a change in the π-electron configuration and, subsequently, in a molecular conformation (Scheme 1; the nonplanar moleoule undergoes the geometric isomerization, i.e., cis-trans isomerization, following the proton transfer reaction[2]). On the other hand, crystals of some other salicylideneaniline derivatives are thermochromic.[3] This chromism is also due to a change in the π-electron configuration induced by a proton transfer (Scheme 2). In this case, the proton transfer can occur in the ground state. On the basis of comparative structural studies on photochromic and thermochromic salicylideneaniline derivatives, Bregman et al. have concluded that the significant difference lies in the manner of molecular packing in the lattice.[4,5] Namely, photochromic salicylideneanilines are packed rather loosely in the crystal, in which nonplanar molecules may undergo some conformational changes, while thermochromic salicylideneanilines are planar and packed tightly to form one-dimensional columns. It should be noted that this planar structure makes it possible for the proton to transfer through the hydrogen bond in the ground state with a small energy requirement. The title compound is also one of the thermochromic derivatives of salicylideneaniline.

The thermochromic salicylideneanilines, which have attracted less attention, have proved to be interesting to us in that they may be a candidate to construct a novel type of conductive organic material in which the proton motion is essentially correlated to the electron conduction. Particularly favorable features are (1) the proton transfer inevitably involves a π-electron con-



Scheme 1.

N,N'-bis(salicylidene)-p-phenylenediamine
(BSP)

† Present address: Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060.

figurational change, (2) two interconvertible molecules which have different energy levels are thermally distributed, (3) the planar conjugated systems are stacked one-dimensionally, and (4) the π-electron system can be easily extended by chemical modification. When conduction electrons are introduced into these systems, which seems possible because of the one-dimensional stacking nature and the ease of extension of the conjugated system, one would expect that the proton motion would couple to the conduction electron motion. Consequently the proton transfer could operate as a kind of "phonon." Apparently this "phonon" is quite different from the normal variety since the mass of proton is extremely light compared with the whole mass of the molecule. The possibility of this type of "electron-phonon coupling" has never been examined experimentally.

Bearing in mind a subsequent extension to systems furnished with conduction electrons, this study has been initiated by investigating the basic nature of proton transfer of the title compound. Little has been reported on the thermochromism, even for such a simple derivative of salicylideneaniline. In this paper are described the crystal and molecular structures and the single crystal optical properties of the *N,N'*-bis(salicylidene)-*p*-phenylenediamine (BSP). Especially noted is that in the infrared region the OH stretching absorption band was clearly observed for the first time for salicylideneaniline analogues by using a single crystal.

Experimental

Materials. A conventional synthetic method for Schiff base compounds was applied for the preparation of BSP. A methanolic solution containing *p*-phenylenediamine and salicylaldehyde at 1 : 2 molar ratio was refluxed for a couple of hours. Orange microcrystals formed upon cooling, which were then recrystallized from benzene. Slow evaporation of the solvent resulted in the formation of orange platelets of 1×1.5×0.03 mm^3 size. The preparation of the deuterated analogue, BSP-d_2, was carried out by refluxing 40 mg of the above product in a mixture of 10 ml of methanol-d_1 and 10 ml of benzene-d_6 for 25 hours. Slow evaporation of the solvent under an argon flow over a period of one week yielded orange platelets typically of 1×1×0.02 mm^3 size. Mass spectral analysis confirmed completion (>90%) of the deuteration reaction.

Optical Measurements. Single-crystal infrared absorption spectra were measured using an assembled optical system that consisted of a JASCO infrared radiation source, a JASCO CT-25C monochromator, an SBRC HgCdTe detector, and a PAR Model 124A lock-in amplifier. Visible absorption spectra were obtained with a similar system comprising a halogen-gas-filled tungsten incandescent lamp, an ISA Jobin Yvon Type HR1000 monochromator, and a HAMAMATSU R376 photomultiplier. Emission spectra were recorded using the same optical components, except that the light source was replaced by a sample crystal which was irradiated with an argon laser (457.9 nm, 50 mW). The Air-Products HELI-TRAN cryostat was used for variable-temperature measurements. The flat (100) face of the crystals was irradiated with incident light throughout the optical measurements. Emission spectra under high pressures were obtained using a diamond anvil cell with an 0.50-mm aperture. Pressures were monitored by the shift of the ruby R_1 fluorescence line using the linear pressure scale (+0.365 Å $kbar^{-1}$).

X-Ray Measurements. An automated RIGAKU AFC-5R diffractometer with graphite monochromatized Mo $K\alpha$ radiation was used for data collection. Twenty-five reflections with $20°<2\theta<30°$ were used to determine the lattice parameters. Crystal data; monoclinic, space group $P2_1/c$, a=14.643(3), b=4.573(1), c=12.224(3) Å, β=112.04(1)°, V=758.8 (3) $Å^3$, Z=2, and D_c=1.385 g cm^{-3}. The intensity data was collected in the region of $2\theta<60°$ in θ-2θ mode at scan rate of 6° min^{-1}; three standard reflections, −1 −1 5, 6 1 −2, and 2 −1 4, were monitored every 100 reflections. Then, 1428 independent reflections with $|F_o|>3\sigma(F_o)$ were used for structure analysis. The structure solution was obtained by a direct method with MULTAN-71 in the UNICS III[6] computer program system at IMS. An anisotropic block-diagonal least-squares refinement for non-hydrogen atoms and isotropic refinement for hydrogen atoms gave the final R value (weighting scheme, $1/w=\sigma^2+(0.015\,|F_o|)^2$), R=0.059, for the 1428 reflections.

Results and Discussion

Molecular and Crystal Structures. The atomic parameters obtained by the X-ray structure analysis are listed in Table 1,[6] and the molecular geometry is illustrated in Fig. 1. The molecule is located on the center of inversion so that half of molecule is crystallographically independent. Attention was focused first on the equilibrium position of the proton. As revealed by the optical measurements (vide infra), the proton-transferred state of BSP is populated to some extent at

Table 1. Atomic Parameters for BSP

Atom	x	y	z	B_{eq}[a]
O	0.7933(1)	−0.2668(4)	0.1408(1)	4.2
N	0.8640(1)	−0.5744(3)	0.0111(1)	2.4

a) Thermal parameters of the non-hydrogen atoms are given by the equivalent isotropic temperature factors ($Å^2$).

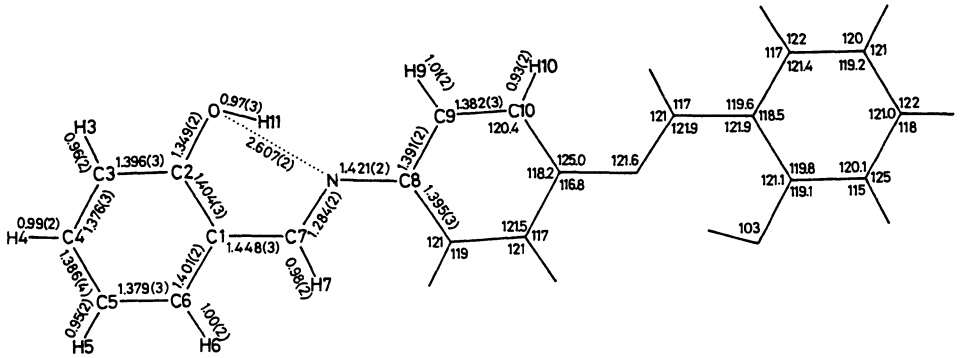

Fig. 1. Bond lengths (Å) and bond angles (degree, standard diviations are 1° for the angles including bond with hydrogen and 0.2° for the other angles).

room temperature. The bond length between O and H11 atoms is still normal as an ordinary hydroxyl group, although the H11 atom has a relatively large thermal parameter (see Table 1).[7] The distance between O and N atoms, which are intramolecularly hydrogen bonded, is 2.607(2) Å and is comparable to those observed for the thermochromic *N*-5-chlorosalicylideneaniline (2.584 Å)[4,8] and the photochromic 2-chloro-*N*-salicylideneaniline (2.609 Å).[8] It is notable that the C3–C4 and C5–C6 bond lengths are considerably shortened. This is a characteristic feature observed among most of the thermochromic salicylideneanilines.[4,8,9] As shown schematically in Scheme 2, the phenol moiety is converted into the *o*-quinoid structure upon proton transfer and the shortening of C3–C4 and C5–C6 bonds should reflect the resonance contribution from the quinoid structure. Such a quinoid contribution is not observed in 2-chloro-*N*-salicylideneaniline, which is photochromic.[8] A reduction in the bond length was also observed for the C2–O bond (1.349 Å), compared with 2-chloro-*N*-salicylideneaniline (1.365 Å); this is due to a contribution from the C2=O quinoid structure.

The dihedral angle between the central and terminal benzene rings is only 2.9° and the molecule is practically planar; the deviation from the mean plane, consisting of three benzene rings, is less than 0.06 Å for nonhydrogen atoms. The crystal structure is shown in Fig. 2. The planar molecules are stacked one-dimensionally along the *b*-axis with an interplanar distance of 3.29 Å. This value appears to be small compared with aromatic hydrocarbons and also with other thermochromic salicylideneanilines, e.g. 3.4 Å for *N*-5-chlorosalicylideneaniline,[8] 3.50 Å for *N*-salicylidene-2-aminopyridine and 3-methyl-*N*-(3-methoxysalicylidene)-2-aminopyridine,[9] 3.42 Å for *N*-(5-bromosalicylidene)-2-aminopyridine,[9] and 3.43 Å for 5-chloro-*N*-(5-methoxysalicylidene)-2-aminopyridine.[9] There must be some intermolecular interaction in BSP; the most probable is that due to charge transfer. It should be recalled that the molecular structure after the proton transfer consists of the *o*-benzoquinone and the aromatic amine moieties. The

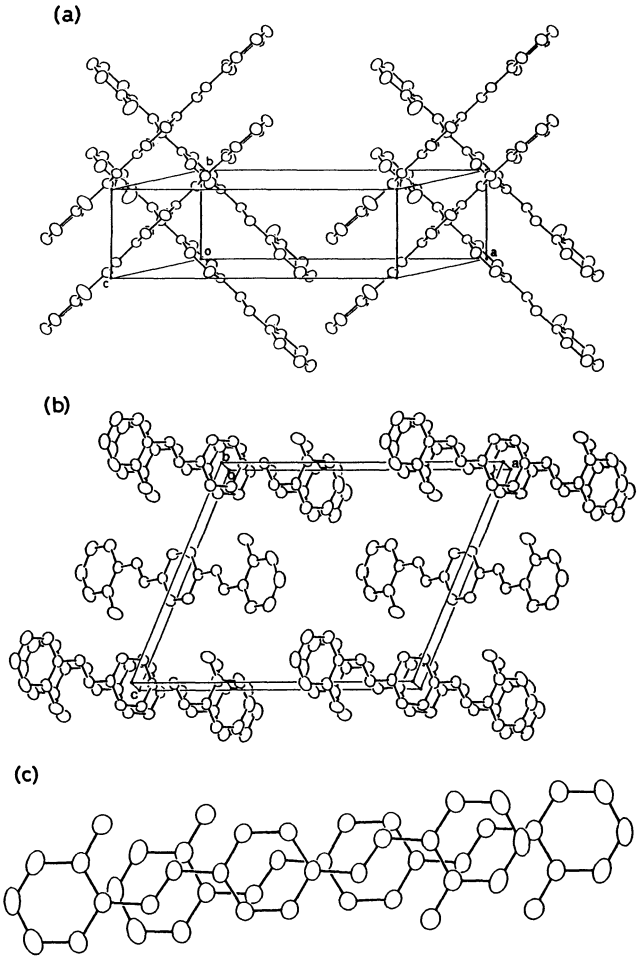

Fig. 2. Crystal structure of BSP (a), (b), and molecular overlap (c).

former is a particularly well-known electron acceptor. Thus, the molecule contains both acceptor and donor portions and the proton transferred species can be an intramolecular charge-transfer compound. The optical studies by Cohen et al.[10] revealed that the thermochromic electronic transition is polarized along the long axis in the molecular plane. Since the intermolecular charge-transfer interaction in their system is not so strong, it is likely that the intramolecular

charge-transfer absorption mainly occurs. In the case of BSP one donor portion carries two acceptor portions. By considering the packing arrangement, a more effective donor-acceptor overlap is seen in BSP (Fig. 2(c)). It should also be noted that the effective overlap between the azomethine groups and the benzene rings may produce intermolecular charge-transfer interactions in the stack of enol form molecules. The contribution from these charge-transfer interactions may lead to a contraction of the interplanar spacing. In order to generate a conduction electron system, the existence of intermolecular interactions in solids is essential. Attempts have been made to extend the system to those which have a stronger charge-transfer interaction; the results will be published elsewhere.[11]

Vibrational Spectra of BSP. The short O···N distance indicated by the crystal structure should be advantageous for the intramolecular proton transfer and an optical study in the infrared spectral region was made in order to obtain information on the vibrational states. Although a few infrared spectroscopic studies of salicylideneanilines to investigate the proton transferring behavior have so far been reported,[12-14] none of the reports has mentioned the OH stretching mode. The infrared measurements with solution,[12] polycrystalline thin film,[14] or KBr disc[12,13] specimens are apparently not adequate for detecting this particular mode. Preliminary experiments using a conventional Nujol mull also faced the same difficulty. However, in this study the OH stretching band was clearly observed for the first time when the spectra were taken using a single crystal specimen. The spectra, thus obtained, are shown in Fig. 3. A broad absorption centered at 2620 cm^{-1} (half width, $\nu_{1/2}$, ca. 550 cm^{-1}) with some subband structure is assigned to the OH stretching mode. A deuteration experiment clearly confirmed this assignment; the absorption band shifts to 2050 cm^{-1} on deuteration, as shown in Fig. 3, with the isotopic frequency ratio ν_{OH}/ν_{OD} of 1.28. The band observed at around 3040 cm^{-1}, which does not shift by deuteration, is assignable to the ν_{CH} band. Changes are also observed in the range below 1600 cm^{-1} upon deuteration. Another pronounced change on deuteration is the disappearance of the band at 1200 cm^{-1}, which is reasonably assigned to the OH in-plane bending mode. The band at 1370 cm^{-1}, which is not influenced by deuteration, can be assigned to the C-O stretching mode. A bunch of bands between 1500 and 1650 cm^{-1} which are slightly affected by deuteration, are assigned to the overlapping bands of the aromatic ring vibration and the C=N stretching. Further assignments have not been attempted.

The broadening and low-frequency shift of this OH stretching absorption band, compared with the free OH group, are characteristic of fairly strongly hydrogen-bonded hydroxyl groups. Novak established a relationship between ν_{OH} frequency and O···O distances for a number of systems involving linear O-H···O hydrogen bonds.[15] Decreasing the O···O distance results in decreasing ν_{OH} and the dependence of the O···O distance on ν_{OH} varies with the hydrogen-bond strength. On the other hand, Wood et al. conducted an IR spectroscopic study on β-diketones and found that the prediction of O···O distances (2.6—2.7 Å) from ν_{OH}, γ_{OH}, and their isotopic frequency ratios based on the Novak's relationship did not coincide with the observed distances (2.42—2.55 Å).[16] These authors suggested that the discrepancy comes from a bent configuration of the O-H···O bond in β-diketones. In the case of BSP, the O-H···N bond is indeed non-linear (O-H···N angle, ca. 155°). However, the observed frequency, 2620 cm^{-1}, predicts the O···N distance as 2.6—2.7 Å on the basis of Novak's relationship (taking into account the larger van der

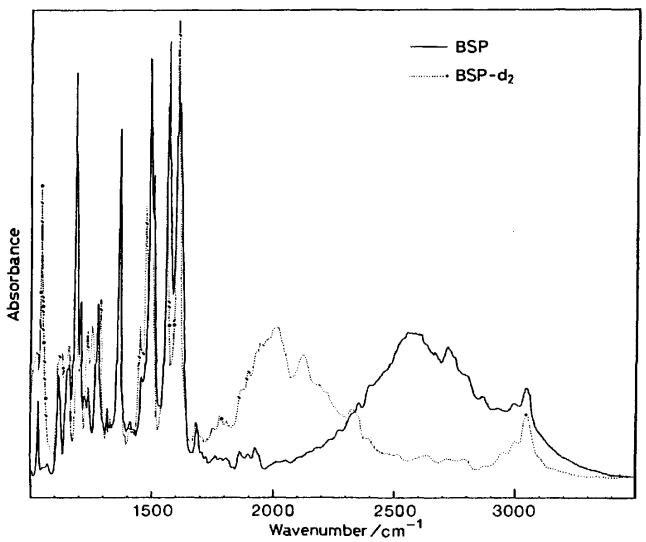

Fig. 3. Single-crystal infrared spectra for BSP and BSP-d_2 recorded at room temperature.

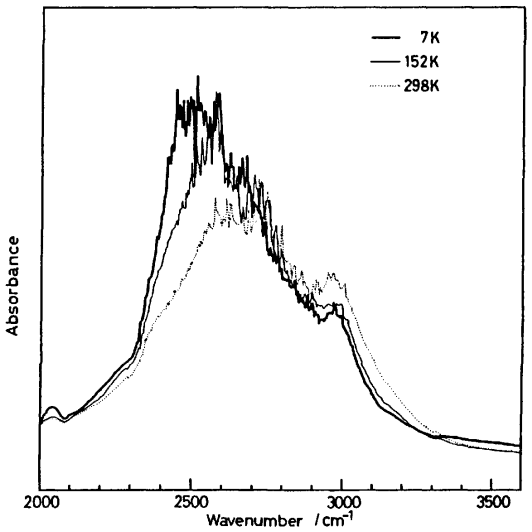

Fig. 4. Single-crystal infrared spectral change of the ν_{OH} band with temperature. The hump near 3000 cm^{-1} is the ν_{CH} band.

Waals radius of nitrogen), which is in good agreement with the observed distance, 2.607 Å. The structural situation of the present system lies between the above two cases of linear and bent hydrogen bond configurations. However, it is found that the small deviation from the linear hydrogen bond configuration does not influence the ν_{OH} frequency.

As shown in the following section, the BSP crystal exhibits an electronic absorption spectral change with a temperature in accord with the π-electron structural change induced by a proton transfer from the hydroxyl oxygen to the imine nitrogen. This self-isomerization process is believed to have some effect on the OH stretching band. In order to investigate this effect, the temperature dependence of the infrared spectra has been measured (Fig. 4). At low temperatures the population of proton-transferred species can be ignored and the crystal is regarded to contain only a single component with all protons bound to the oxygen atoms. At the lowest temperature, the band is still broad ($\nu_{1/2}$ 460 cm^{-1}) and asymmetric. Factors affecting the ν_{OH} band profile may include anharmonic coupling between the ν_{OH} and ν_{OH-N} modes, Fermi resonances between ν_{OH} and combinations or overtones involving δ_{OH} and γ_{OH} modes, and an anharmonicity in the ν_{OH} mode itself. Other factors specific to the solid state, such as Davidov coupling and structural disorder, cannot be ignored.[17] In the case of BSP the primary factor which causes the band to be broad seems to be the anharmonic coupling between the ν_{OH} and ν_{OH-N} modes. Far-infrared spectra[18] have also been measured in order to search for the ν_{OH-N} frequency and, indeed, the spectrum observed at 8 K has exhibited a single peak at 240 cm^{-1}, which can be assigned to the ν_{OH-N} mode. Other peaks in the spectrum are located below 100 cm^{-1}. Then the broad ν_{OH} band observed at 7 K can be fitted to the progression of several bands separated by 240 cm^{-1} (Fig. 5). It can be seen that each of the bands is still broad, suggesting the additional anharmonic coupling with lower-energy phonon modes and/or anharmonicity in the ν_{OH} mode itself.

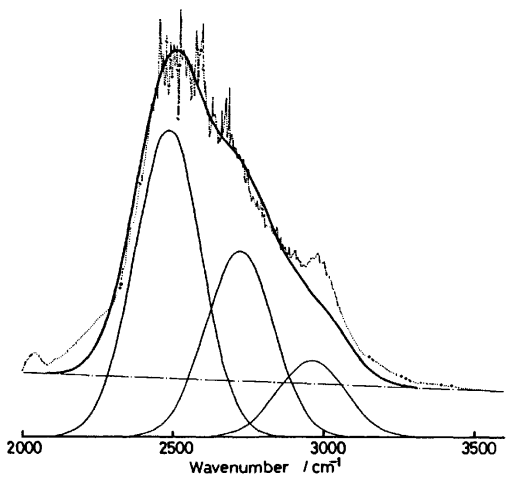

Fig. 5. Simulated infrared band profile as a progression of Gaussian bands equally separated by 240 cm^{-1} (solid line) and the observed OH stretching band at 7 K (dotted line).

With increasing temperature the intensity of the low-energy side of the band decreases, while the high-energy side changes slightly in the opposite way. Below 80 K the ν_{OH} band shows almost no change (for clarity the band observed at 72 K is not presented in Fig. 4). These changes parallel the visible spectral changes (vide infra). The ν_{OH} band profile at 298 K is not satisfactorily explained merely by the progression of bands due to the coupling with the ν_{OH-N} mode, which is observed at 230 cm^{-1} at 323 K in the far-infrared spectra. This must be a consequence, at least partly, of the proton transfer. In the simplest case the two tautomers are distributed statistically as observed in NQR measurements of salicylideneanilines.[19] In the ^{14}N NQR spectra of thermochromic salicylideneanilines, growth of a pair of new absorption peaks which corresponds to the thermally induced species has been observed by increasing temperature, as the original pair of peaks diminishes. Thus, the two chemical species are separable on an NQR time scale. However, the time scale is several orders greater in the infrared experiment. If the dynamic or resonance effect is to be considered, the band profile should not be thought of as a simple superimposition of two components. Furthermore, if the chemical species are interacting with each other in the crystal, which is very likely, the situation becomes more complicated. In any case the band profile cannot be considered as being due to a simple local mode and more information on dynamic and microscopic aspects is required to understand the situation completely.

Electronic Absorption and Emission Spectra of BSP. Crystals of BSP are an orange color at room temperature and turn yellow upon cooling in liquid nitrogen. This thermochromic change was followed spectrophotometrically over a wide temperature range (4—293 K); the results are given in Fig. 6. At the lowest temperature an absorption edge is observed rising sharply around 2.8 eV and tailing down to 2.4 eV; the former is assigned to the π-π^* transition in the enol form. The latter tail has some structure; the slope changes in two regions, 2.42—2.61 and 2.61—2.80 eV. The width of both ranges is 0.19 eV. We feel that this tailing is due to the non-Franck-Condon type absorption and that the appearance of two different slopes is due to the coupling with the CN or CO stretching mode. Up to 80 K practically no temperature effect on the spectra was observed, which agrees well with the observation of the temperature dependence of the ν_{OH} band profile as mentioned in the previous section.

As the temperature rises above 80 K, the absorption band at 2.4 eV grows in and at room temperature this band shows its edge at 2.26 eV. With this band assigned to the keto isomer, the energy difference

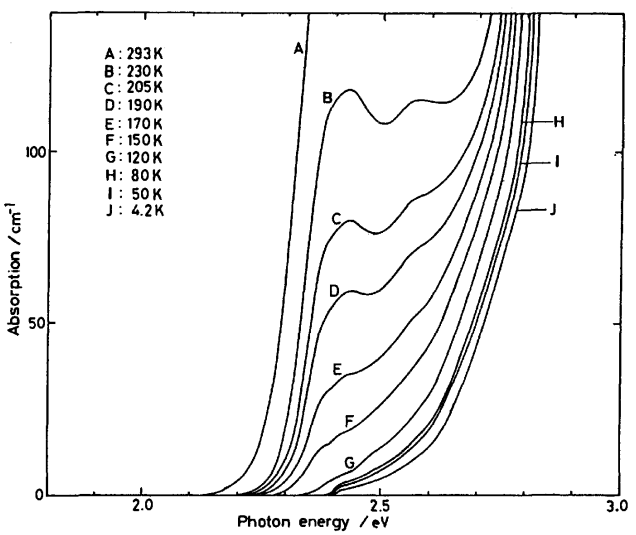

Fig. 6. Single crystal absorption spectral changes with temperature for BSP.

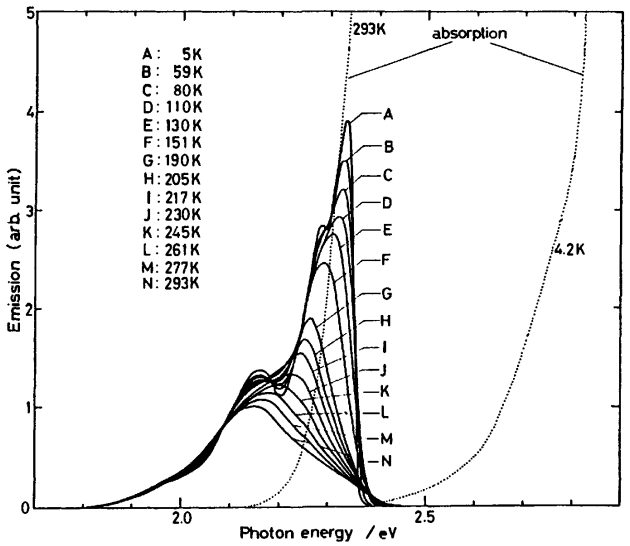

Fig. 7. Single crystal emission spectral changes with temperature for BSP.

between the two tautomers in Scheme 2 is evaluated to be ca. 0.1 eV, which is comparable to that observed for *N*-5-chlorosalicylideneaniline (0.08 eV).[3] The electronic absorption spectral change with temperature indicates that a substantial amount of the proton-transferred species is present at room temperature. The relative population of the enol and keto species has been estimated to be about 50 : 1 at room temperature by assuming that the system is followed by the Boltzmann-type distribution. It is noticed that the absorption band of the keto isomer shows some vibrational structure with an energy difference of ca. 0.14 eV and a shoulder near the absorption edge.

An observation of emission spectra, shown in Fig. 7, gives support for the above explanation of the thermochromism as caused by the proton transfer. It should be noted that the emission spectrum A at 2.33 eV recorded at 5 K shows a large Stokes shift (ca. 0.4 eV) from the corresponding absorption. This is one of the characteristic features of the proton-transfer reactions in salicylideneaniline derivatives.[2] It can be seen that the emission band has some fine structure; humps appear at around 2.33, 2.29, 2.15, 1.97 eV. The separation between the first and the second peaks is small, and this detailed structure could be assigned to the ν_{OH-N} vibrational fine structure. The energy differences between the first and the third and between the third and the fourth are equally 0.18 eV. This energy may correspond to the CN or CO stretching mode. It may be noticed that this fine structure well corresponds to the structure observed in the thermochromic band. The energy of 0.14 eV, which is the energy difference between the second and the third peaks of emission at 5 K, is exactly the energy difference between the two peaks observed in the thermochromic band. The small energy difference between the first and the second peaks of the emission may correspond to that between the shoulder and the first peak of the thermochromic band. Consequently, the emission band can be regarded as a mirror image of the thermochromic band. Cohen and Flavian studied the emission and absorption spectra of several thermochromic salicylideneanilines including BSP in the solid state,[20] and they concluded that the emission is due to deactivation from the same excited state to the same ground state as those involved in the thermochromic absorption. Our results are clearly consistent with their interpretation. Especially, low-temperature emission experiments have confirmed the origin of the largely shifted emission band. The emission gradually diminishes at elevated temperatures, the fine structure becoming less noticeable. At room temperature a broadened emission centered around 2.15 eV remains (spectrum N). The temperature dependence of the emission spectra is better explained by reabsorption by the thermally induced species as discussed in Ref. 19, since the emission intensity changes only at the high energy side where the absorption grows with increasing temperature. The reabsorption effect on the emission band is also reflected in spectral difference between the emissions from different crystal faces; when the (100) face is irradiated, a shoulder-like band observed at 2.25 eV on the higher-energy side in the emission from the flat (100) face is absent in the emission from the lateral (001) face, which reflects the longer penetration depth of this emitted light in this direction.

Since our interest lies in the extent of intermolecular interaction, we examined the pressure effect on the optical properties. Drickamer et al. extensively used high pressures to investigate intra- and intermolecular interactions in molecular crystals.[21] They also examined the pressure effect on the electronic spectra of several thermochromic derivatives of salicylideneani-

line both in the crystalline state[22] and in solid dispersions.[23] According to these authors, thermochromic crystals of *N*-5-bromosalicylideneaniline, for instance, exhibit piezochromic absorption in the visible region, which shifts to lower energy and intensifies with increasing pressure in compensation for the original ultraviolet absorption band. They identified this piezochromic peak as the thermochromic peak under atmospheric pressure, thus describing the pressure effect as a driving force for the proton-transfer equilibrium towards the keto form.

In the case of BSP, the shift in the absorption edge with pressure was also observed. However, the magnitude (0.17 eV by 33 kbar) was larger than that observed for the systems studied by Hockert and Drickamer (less than 0.1 eV by 30 kbar for the absorption peak). On the other hand, the emission spectral changes with pressure for BSP (Fig. 8) indicate only a small maximum shift to lower energy. This is in contrast to the finding of the above-mentioned authors that the energy difference between the piezochromic band and the emission band for *N*-5-bromosalicylideneaniline remains fairly constant over a wider pressure range. It is also noticed that the pressure dependence of the emission intensity of BSP is different from that of other derivatives studied by Hockert and Drickamer[23] and by ourselves;[11] the pressure dependence of the intensity cannot be fitted by a single exponential function in the case of BSP. Thus, the apparent emission spectral changes can only be qualitatively accounted for by an increase in the probability of quenching due to the level crossing resulting from the change of potential surface and/or increase of the reabsorption accompanied by the red shift of absorption. At any rate, the distinctive behavior of BSP must be associated with the existence of a stronger intermolecular interaction in this compound.

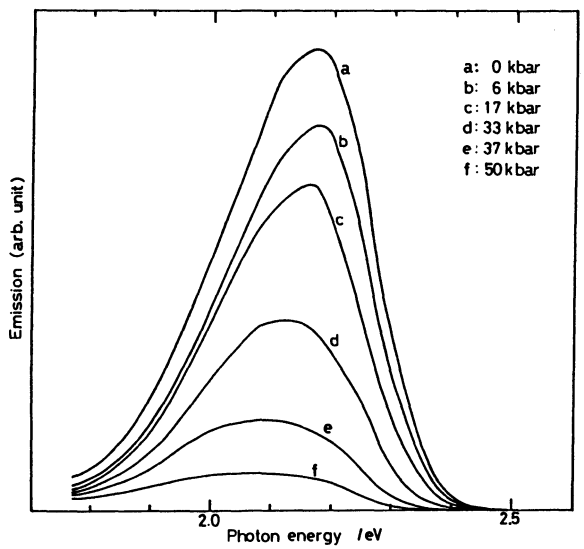

Fig. 8. Single crystal emission spectral changes with pressure for BSP.

Summary

Thermochromic BSP single crystals have been studied both structurally and optically. From the structural study it has been found that the interplanar distance is shorter than in other thermochromic salicylideneanilines, while retaining the normal one-dimensional packing of molecules. Since the keto form of the BSP molecule consists of donor and acceptor portions, it is suggested that the charge-transfer interaction operates in the crystalline state as an intermolecular interaction. The infrared spectroscopic study clearly demonstrates the presence of OH stretching absorption for the first time among the salicylideneanilines and is interpreted in the regime of strong hydrogen bonds. The effect of the thermal proton transfer on the proton vibrational spectra has not been characterized, but additional information on microscopic or dynamic aspects will facilitate the understanding.

The visible absorption and emission spectra are basically understandable in terms of the ground state and the excited-state proton transfer, respectively, as for other salicylideneanilines previously studied. We would like to point out, however, that unconventional interpretations are possible for some detailed aspects noted in this study. Firstly, the absorption band has a long low-energy tail at temperatures below ca. 80 K where thermochromic absorption is not highly visible. Secondly, the emission band edge coincides the edge of this absorption tail edge at 2.4 eV, where the thermochromic absorption also shows up. With regard to the low-energy absorption tail, it is possible that quantum mixing of enol and keto ground states due to proton tunneling results in a significant amount of the population in the latter, even at low temperatures. Another possibility is that this weak absorption is due to non-Frank-Condon type transitions from the enol ground state to the keto excited state cannot be ruled out. This would mean that the optical electronic excitation simultaneously causes the proton transfer, and implies that the excited state of this system has a potential surface close to a single minimum well. Another interesting feature observed in the absorption and emission spectra of BSP is that all spectra related to the proton transfer have phonon structures due to the coupling with the vibrational modes involved in the skeleton of the hydrogen-bonded chelate ring. This becomes particularly important when the coupling between the electronic properties of solids and proton transfer is to be considered. Further studies on extended systems which are designed to introduce the stronger intermolecular charge-transfer interaction are being made, and preliminary results indicate that the equilibrium position of hydrogen atoms is fairly sensitive to the electronic state of the system. Systematic studies of the structure and optical properties of extended systems should help clarify the nature of the

proton transfer and, especially, its coupling with the electronic state.

We are grateful to Dr. Yoshiki Wada for his assistance in optical measurements. This work was partly supported by Scientific Research Grants-in-Aid No. 6155027 from the Ministry of Education, Science and Culture.

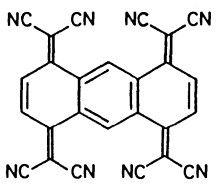
Charge Transfer Complexes Based on the Twin-TCNQ-Type Acceptor 11,11,12,12,13,13,14,14-Octacyano-1,4:5,8-anthradiquinotetramethane (OCNAQ)

Tamotsu INABE,* Tsutomu MITSUHASHI,† and Yusei MARUYAMA*
Institute for Molecular Science, Myodaiji, Okazaki 444
†Department of Chemistry, Faculty of Science, The University of Tokyo, Bunkyo-ku, Tokyo 113
(Received May 13, 1988)

Charge transfer complexes of OCNAQ with pyrene, PT (phenothiazine), TMTTF (tetramethyltetrathiafulvalene), TTT (5,6:11,12-bis(epidithio)naphthacene), and TTF (tetrathiafulvalene) have been prepared. The pyrene and PT complexes are electrically insulating and the ground state is neutral. In most of the other complexes OCNAQ is fully charged. One of the TTT complexes, $(TTT)_2$OCNAQ(DMF), where DMF is *N,N*-dimethylformamide, has been found to show metallic conductivity. A structural study has revealed that short S···N contacts exist between TTT and OCNAQ, in addition to one-dimensional TTT stacks. This transverse interaction has been demonstrated by the small anisotropy of the conductivity. The 2:1 TTF complex is also metallic down to 43 K, at which point a metal-to-insulator transition occurs. A structure analysis and thermoelectric power data suggest that the charge conduction in this crystal takes place not only through the TTF stacks but also through a two-dimensional network of the OCNAQ molecules.

Recently, a synthesis and characterization of the title compound OCNAQ (systematic name: 1,4,5,8-tetrakis(dicyanomethylene)anthracene), a twin-TCNQ-type acceptor, has been reported.[1,2] From its molecular structure it is expected that the on-site Coulomb repulsion should be reduced compared with TCNQ. In fact, a cyclic voltammogram shows that the first and second redox waves are closely located.[1,2] Furthermore, the monovalent tetraethylammonium salt $Et_4N \cdot$ OCNAQ exhibits a rather high conductivity[2] as a simple salt. The molecular shape of OCNAQ is nonplanar due to a steric interaction between the cyano groups. The nonplanarity is not advantageous for high electrical conduction through the molecular stacks, since insufficient overlapping between the molecules in a stack causes a small transfer integral and, consequently, a partial reduction state cannot be sufficiently stabilized. Actually, the approaches to obtain any fractionally reduced OCNAQ salts with closed-shell cationic species have so far failed, and only monoanionic and dianionic OCNAQ salts have been obtained.



OCNAQ

As a next step toward achieving higher conductivity based on OCNAQ, complexes with various donor molecules, instead of closed-shell cationic species, have been investigated, and the metallic properties of $(TTT)_2$OCNAQ(DMF) have recently been reported.[3] In this compound OCNAQ interacts transversely with the TTT stacks. In this paper the preparation, structures, and charge transport properties of the OCNAQ complexes with pyrene, PT, TMTTF, TTT, and TTF are described. Among them, one of the TTF complexes has been found to be metallic, in which the OCNAQ molecules form a two-dimensional network. A twin-type molecular structure may be responsible for this stacking nature.

TTF

Experimental

Materials. OCNAQ was synthesized by the same method reported previously.[2] DMF used as a solvent was dried with Molecular Sieve 4A and distilled under reduced pressure. Acetonitrile was dried before distillation with P_2O_5 and repeated with K_2CO_3. 1,2-Dichlorobenzene was used without purification. All donors were purified by recrystallization or sublimation.

Pyrene-OCNAQ: Slow cooling of a hot acetonitrile solution containing pyrene and OCNAQ with a molar ratio of 3:1 yielded black needle-like crystals. Solvent inclusion was found by elemental analysis. Found: C, 78.48; H, 2.79; N, 18.57%. Calcd for $C_{44}H_{19}N_9$ (pyrene·OCNAQ(CH_3CN)): C, 78.45; H, 2.84; N, 18.70%.

PT-OCNAQ: The complex was prepared by slow cooling of a hot acetonitrile solution, including PT and OCNAQ, with a molar ratio of 4:1. The precipitate was found to be a mixture of two kinds of crystals; one is a black needle-like crystal and another is a brown plate-like crystal. One polymorph is PT·OCNAQ(CH_3CN) and the other is PT·OCNAQ. Found: C, 72.06; H, 2.46; N, 20.21%. Calcd

for 2:3 weight fraction of PT·OCNAQ and PT·OCNAQ-(CH_3CN): C, 71.98; H, 2.59; N, 20.53%.

TMTTF-OCNAQ: A powdered material was prepared by mixing TMTTF in hot acetonitrile and OCNAQ in the same solvent with a molar ratio of 2:1. The elemental analysis indicated the 1:1 stoichiometry. Found: C, 62.48; H, 2.68; N, 16.30%. Calcd for $C_{36}H_{18}N_8S_4$: C, 62.59; H, 2.63; N, 16.21%. The same material was obtained in a fine needle-like shape by conventional electrocrystallization using Et_4N·OCNAQ as a supporting electrolyte.

TTT-OCNAQ: Slow cooling of a hot 1,2-dichlorobenzene solution containing TTT and OCNAQ with a molar ratio of 1:1 gave black plate-like crystals. An elemental analysis shows that the composition is $(TTT)_3(OCNAQ)_2$-(dichlorobenzene)$_2$, abbreviated TTT-OCNAQ(I). Found: C, 64.26; H, 1.85; N, 10.40; S, 17.21%. Calcd for $C_{94}H_{44}Cl_4N_{16}S_{12}$: C, 64.06; H, 2.19, N, 10.13; S, 17.40%.

When the complex was prepared electrochemically in DMF, the obtained crystal was found to contain DMF molecules. The composition confirmed by an X-ray structure analysis was $(TTT)_2$OCNAQ(DMF), abbreviated TTT-OCNAQ(II).

TTF-OCNAQ: The complexes were prepared by the following three methods: (1) mixing of the TTF and OCNAQ solutions, and (2) mixing of the $(TTF)_3(BF_4)_2$ and Et_4N·OCNAQ solutions, (3) electrocrystallization. Acetonitril was used as a solvent. Microcrystals were obtained by the first and second methods. An elemental analysis of these materials always showed a slight deviation from the 1:1 stoichiometry, i.e., an excess content of TTF.[1] This small deviation is due to the coexistence of a 1:1 phase and a donor-rich phase. In fact, the stoichiometry of the minor product obtained by the third method was found to be 2:1 by X-ray structure analysis. The correspondence of the major products in all methods was confirmed by optical and electrical measurements. Hereafter, the 1:1 complex is abbreviated TTF-OCNAQ(I) and the 2:1 complex TTF-OCNAQ(II).

Measurements. Infrared spectra were taken by a HITACHI 295 spectrometer by using a Nujol mull specimen. Electrical conductivity measurements were carried out by a conventional four-probe or two-probe method. Thermoelectric power measurements were performed by a method similar to that reported by Chaikin and Kwak.[4]

X-Ray Structure Analyses. The computer program system used was UNICSIII[5] run on a HITACHI M680 at IMS.**

TTT-OCNAQ(II): A black plate-like crystal having approximate dimensions of 0.40×0.15×0.05 mm^3 was used for the crystallographic study. Diffraction data were collected at room temperature using an automated RIGAKU AFC-5R fourcircle diffractometer with graphite monochromatized Mo $K\alpha$ radiation. Fifty reflections with $20°<\theta<30°$ were used to determine the lattice parameters. Crystal data; chemical formula $C_{65}H_{29}N_9OS_8$, formula weight M=1208.51, triclinic, space group $P\bar{1}$, a=11.522(2), b=16.406(3), c=7.942(1) Å, α=94.23(2), β=95.13(2), γ=116.51(1)°, V=1327.0(4) Å^3, Z=1, D_c=1.51 g cm^{-3}, and μ=3.77 cm^{-1}. The intensity data were collected in the region $2\theta<60°$ in the θ-2θ mode at a scan rate of 6° min^{-1}. 3716 independent reflections with $|F_o|>3\sigma(F_o)$ were used for a structure analysis. The structure was solved by the Patterson method. An anisotropic block-diagonal least-squares refinement for non-hydrogen atoms with isotropic hydrogen atoms gave a final R value of 0.063.

TTF-OCNAQ(III): A black plate-like crystal having approximate dimensions of 0.33×0.15×0.05 mm^3 was used for the crystallographic study. The data collection and structure analysis were performed using the same procedure as TTT-OCNAQ(II), except for the diffractometer (RIGAKU AFC-5) and scan rate (3° min^{-1}). Crystal data; chemical formula $C_{38}H_{14}N_8S_8$, formula weight M=839.04, triclinic, space group $P\bar{1}$, a=6.702(6), b=19.302(8), c=7.239(5) Å, α=86.69(5), β=109.22(8), γ=93.64(6)°, V=882(1) Å^3, Z=1, D_c=1.58 g cm^{-3} and μ=5.29 cm^{-1} The intensiy data were collected in the region $2\theta<50°$; 1126 independent reflections with $|F_o|>3\sigma(F_o)$ were used for a structure analysis. The final R value was 0.061.

Results and Discussion

Infrared Spectra. Chapell et al. showed that the reduction state of TCNQ could be estimated from the frequency of the C≡N stretching mode.[6] For OCNAQ, a similar dependence of the frequency of the C≡N stretching mode on the reduction state is expected, since the same type LUMO as TCNQ was obtained by calculation.[2] Figure 1 shows the C≡N stretching bands for OCNAQ, Et_4N·OCNAQ, and $(Et_4N)_2$-OCNAQ. The frequency is 2214, 2186, and 2170 cm^{-1}, respectively; thus, a similar charge dependence of the frequency can be obtained. However, the frequency

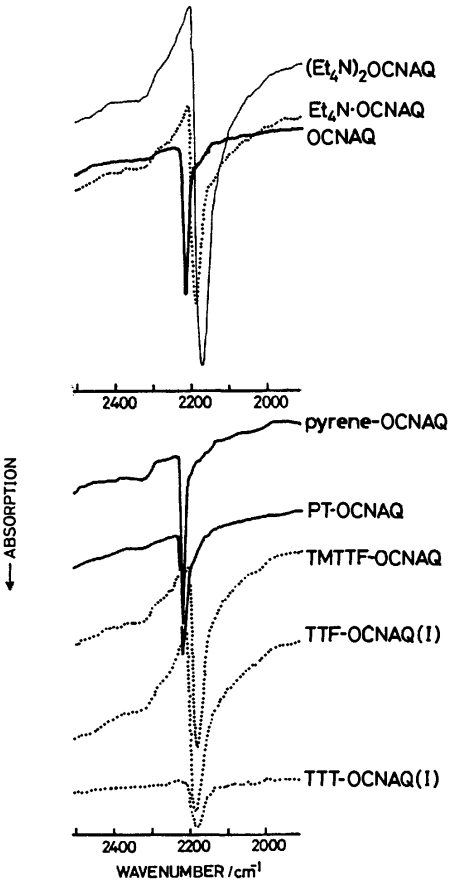

Fig. 1. Infrared spectra of OCNAQ and the OCNAQ complexes.

shift by charge is not as large as that of TCNQ (frequency shift $\Delta\nu$ for TCNQ→TCNQ$^-$, 44 cm^{-1}; $\Delta\nu$ for OCNAQ→OCNAQ$^-$, 28 cm^{-1}). This seems to arise from the main characteristics of OCNAQ, namely a twin-TCNQ-type nature. Indeed, the shift from OCNAQ to OCNAQ^{2-} amounts to 44 cm^{-1}, which is exactly the same as that from TCNQ to TCNQ$^-$.

The C≡N stretching bands in the infrared spectra for pyrene-OCNAQ, PT-OCNAQ, TMTTF-OCNAQ, TTF-OCNAQ(I), and TTT-OCNAQ(I) are also shown in Fig. 1. Owing to an electronic transition, which extends in this region in TTT-OCNAQ(II), the infrared spectrum did not provide any useful information about the ionicity of this compound. Data for TTF-OCNAQ(II) are also absent, because the sample amount was insufficient to examine the infrared spectrum. From the position of the C≡N stretching mode a neutral nature was found for the pyrene and PT complexes. Since the ionization potentials of pyrene and PT are relatively high compared with the other donor molecules, a neutral nature for the ground state is reasonable. In the other complexes the OCNAQ molecules are fully ionized, and the electronic structures are represented as (TMTTF$^+$)(OCNAQ$^-$), (TTF$^+$)-(OCNAQ$^-$) for TTF-OCNAQ(I), and $(TTT_3)^{2+}$-$(OCNAQ^-)_2$(dichlorobenzene)$_2$ for TTT-OCNAQ(I).

Crystal Structure. TTT-OCNAQ(II): The molecular structures of TTT and OCNAQ in this compound, obtained by X-ray analysis, are shown in Fig. 2 and the atomic parameters are listed in Table 1.[7] The TTT molecule is essentially planar (deviations from the mean plane are less than 0.15 Å for non-hydrogen atoms). On the other hand, the OCNAQ molecule is largely deformed from the planar structure. The deformation pattern is the same as that observed in

$Et_4N \cdot OCNAQ$,[2] namely the TCNQ nuclei are distorted into boat forms and the two TCNQ boats are linked by two methylidine groups upside-down with each other.

Since the electronic structure cannot be determined by the infrared spectra, the bond lengths of the molecules were carefully examined by X-ray structure analysis in order to elucidate the charge on the molecules. The mean dimensions of TTT are listed in Table 2 along with data for TTT^0, TTT$^{1/2+}$ (TTT_2I_3), and TTT$^+$ ($TTT(TCNQ)_2$). Major structural differences between TTT^0 and TTT$^{1/2+}$ appear in the bond lengths of A, B, E, and F in Table 2, whereas those between TTT$^{1/2+}$ and TTT$^+$ appear in bond C. By a comparison with these data it is favorable to assign the TTT molecule in TTT-OCNAQ(II) to TTT$^{1/2+}$. The same kind of information can be obtained from the molecular structure of OCNAQ, of which bond

a) Averaged values.

lengths are listed in Table 3. Unfortunately, the structure of neutral OCNAQ has not been obtained. However, the molecular dimensions of $OCNAQ^-$ and $OCNAQ^{2-}$ are known[2] and are listed in Table 3. The differences between $OCNAQ^-$ and $OCNAQ^{2-}$ appear in the C=C bond length between dicyanomethylene and the ring carbon (e and i in Table 3). Judging from these bond lengths the charge of OCNAQ in TTT-OCNAQ(II) has been assigned as −1. This assignment is consistent with the charge of TTT, and the electronic structure of this compound is represented as $(TTT)_2^+OCNAQ^-(DMF)$.

The crystal structure is shown in Fig. 3. The TTT molecules form one-dimensional columns along the *c*-axis, while the OCNAQ molecules overlap only partly with each other. The DMF molecule is positionally disordered, i.e., one DMF molecule can occupy two positions which are related to each other by an inversion center. Molecular overlapping patterns between the TTT molecules in the stack and between the OCNAQ molecules are shown in Fig. 4. The interplanar and short interatomic distances between the molecules are listed in Table 4. There are

two kinds of interplanar spacings between the TTT molecules. Spacing between A and B (3.26 Å; d_2 in Fig. 3) is shorter than that between B and A′ (3.38 Å; d_1 in Fig. 3) by 0.12 Å. The molecular overlapping pattern between A and B is the same as that observed in TTT_2I_3,[8] and there are short contacts between sulfur atoms (3.506(3) Å). On the other hand the molecular overlapping between B and A′ is not the same as the pattern reported so far, and there are no effective S ··· S contacts (>3.9 Å). Consequently, TTT is weakly dimerized between A and B in the stack. As can be seen from Fig. 4(c), the overlap between the OCNAQ molecules is only partial; therefore, the interaction is supposed to be weak. The shortest contact between the OCNAQ molecules (3.33(1) Å) are actually larger than those observed in $Et_4N \cdot$OCNAQ (3.05(1) and 3.14(1) Å).[2] Interestingly, a rather strong interaction of OCNAQ exists in the direction toward the donor molecules. As shown in Fig. 3, two nitrogen atoms of OCNAQ strongly interact with the sulfur atoms of TTT. The distances of d_3 (3.084(9) Å) and d_4 (3.252(7) Å) are less than the sum of the van der Waals radii, 3.35 Å. Consequently, the interactions between the molecules in this system are rather two-dimensional.

TTF-OCNAQ(II): The molecular structures of TTF and OCNAQ in this compound are shown in Fig. 5, and the atomic parameters are listed in Table 5.[7] The TTF molecule is perfectly planar (deviations from the mean plane are less than 0.05 Å for the non-hydrogen atoms). The structure of OCNAQ is practically the same as that in TTT-OCNAQ(II). As listed in Table 3 the bond lengths of OCNAQ are close to the values observed for $OCNAQ^-$. The mean dimensions of TTF (Table 6) are closer to those observed in TTF-TCNQ, in which the oxidation state of TTF is +0.59, than those of TTF^0. Therefore, the electronic structure of this complex is supposed to be near $(TTF)_2^+OCNAQ^-$, although there remains some ambiguity (vide infra).

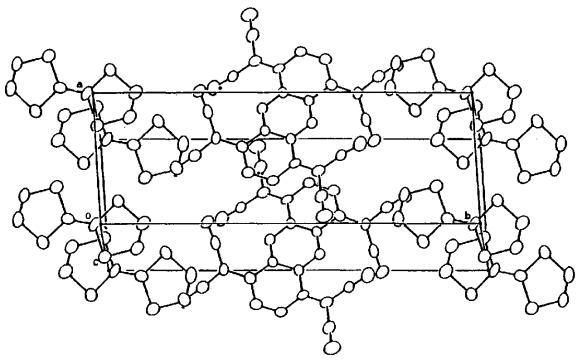

Fig. 6. Crystal structure of TTF-OCNAQ(II).

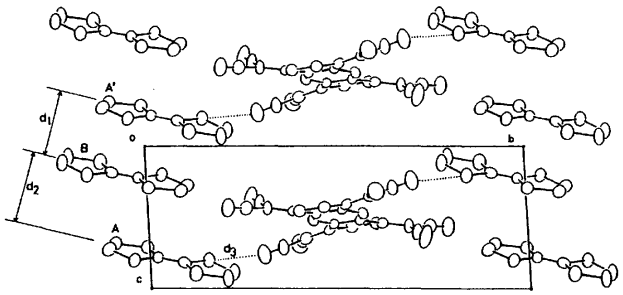

Fig. 7. Donor and acceptor arrangement in TTF-OCNAQ(II) in the (100) plane.

The crystal structure is shown in Figs. 6 and 7. The TTF molecule forms one-dimensional columns along the *c*-axis, and there are no effective intermolecular contacts between the columns. Molecular overlapping patterns between the TTF molecules and between the OCNAQ molecules are shown in Figs. 8 and 9, respectively, and the interplanar and interatomic distances are listed in Table 7. The overlapping pattern between the TTF molecules of B and A′ is similar to that of TTF-TCNQ,[12] in which the intermolecular S ··· S distances are rather large (>3.70 Å). On the other hand, in the overlapping pattern between A and B there is a shorter S ··· S contact (S4 ··· S4; 3.671(5) Å). However, this distance is still longer than those observed for the eclipsed-type stacking of TTF in $TTF \cdot X_y$ (3.55—3.60 Å; where X=Cl, Br, I, and etc.).[13]

In contrast with the case of TTT-OCNAQ(II), efficient stacking of OCNAQ in TTF-OCNAQ(II) can be seen from Fig. 6. There are two kinds of overlapping

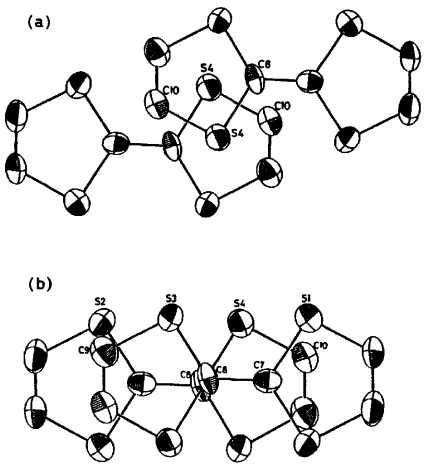

Fig. 8. Molecular overlapping between the TTF molecules; between A and B (a), and between B and A′ (b) in Fig. 7.

patterns and one OCNAQ moleoule interacts with four OCNAQ molecules (Fig. 9). The interplanar distances listed in Table 7 are the distances between the mean planes, calculated for the anthracene framework. Although one of the interplanar distances is large (3.82 Å vs. 3.30 Å), the cyano groups, which are largely deviated from the plane, make the interatomic distances short (e.g., 3.345(17) Å for C17 ··· C23). Therefore, the OCNAQ molecules effectively form a two-dimensional network in the (010) plane. In similarity to the TTT-OCNAQ(II) system, an extra interaction between nitrogen atoms of OCNAQ and a sulfur atom

of TTF exists. However, the distance, 3.292(11) Å, is not as short as those observed in TTT-OCNAQ(II).

Charge Transport. The electrical resistivities of the OCNAQ complexes are shown in Fig. 10, except for pyrene-OCNAQ and PT-OCNAQ, which are electrically insulating. The data shown in Fig. 10 were obtained along the long axis of the crystal.

TMTTF-OCNAQ and TTF-OCNAQ(I): As revealed by the infrared spectra, TMTTF-OCNAQ and TTF-OCNAQ(I) are simple salts. The temperature dependence of the resistivities shows a semiconducting behavior with activation energies of 0.14 eV for TMTTF-OCNAQ and 0.15 eV for TTF-OCNAQ-(I). The resistivities at room temperature, 10^2—10^3 Ω cm, are rather small compared with those of usual simple radical salts. This supposedly reflects the main effect produced by the twin-type structure, i.e., a reduced on-site Coulomb repulsion. Indeed, the resistivity at room temperature of $Et_4N \cdot OCNAQ$ is of the same order (2.5×10^3 Ω cm).[2)]

The thermoelectric power (TEP) data are shown in Fig. 11. For a simple salt the energy gap is usually related to the on-site Coulomb repulsion. In these systems the on-site Coulomb repulsion of a donor molecule is much larger than that of OCNAQ, and the charge transport of these systems should be largely governed by OCNAQ. The observed large negative values are consistent with electron conduction through OCNAQ.

TTT-OCNAQ(I): Since the electronic structure of this complex is $(TTT_3)^{+2}(OCNAQ^-)_2$(dichlorobenzene)$_2$, the TTT molecule is formally charged by +2/3. Thus, the resistivity of this compound is expected to be lower than those of simple salts. In fact the resistivity is lower compared with TMTTF-OCNAQ and TTF-OCNAQ(I), although the temperature dependence is semiconducting (Fig. 10). The TEP data shown in Fig. 11 are consistent with TTT based hole conduction. In this compound OCNAQ simply acts as a

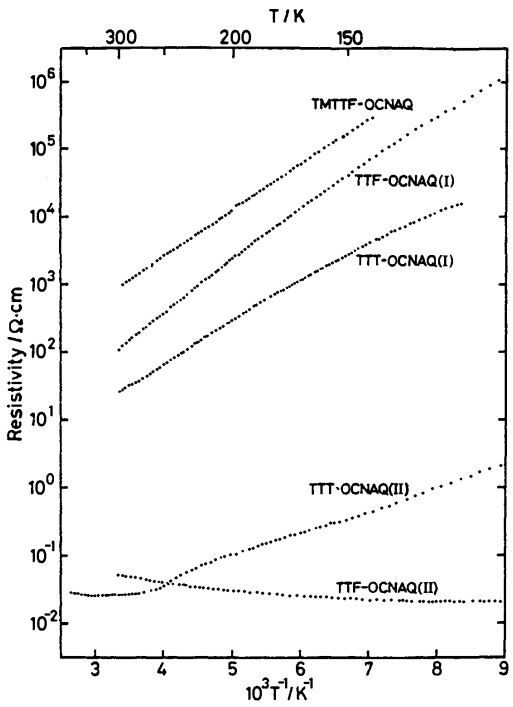

Fig. 10. Electrical resistivities of the OCNAQ complexes.

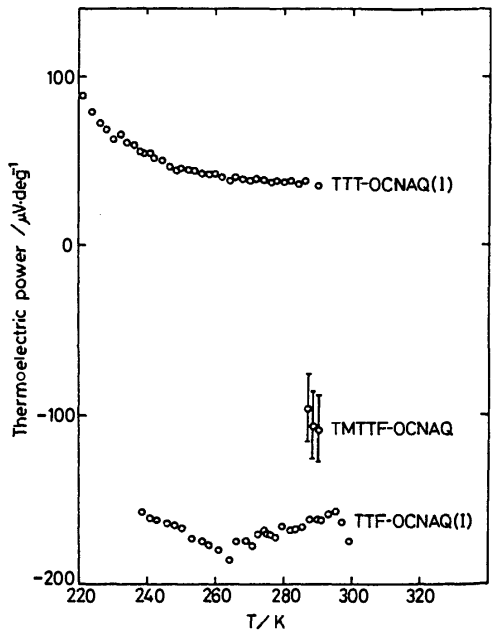

Fig. 11. Thermoelectric power of the OCNAQ complexes.

counterion, and makes no contribution to the charge transport.

TTT-OCNAQ(II): This compound shows a weak metallic behavior down to 250 K, at which point the material turns to the semiconducting state with an activation energy of 0.05 eV. As suggested by the structure analysis, there is a transverse interaction between the TTT columns through the OCNAQ molecules. In order to see this structural peculiarity the conduction was measured not only along the TTT stacking direction but also in the direction corresponding to the transverse interaction. The results are shown in Fig. 12. The anisotropy of the conduction, $\rho(\perp c)/\rho(/\!/c)$, was found to be 30. This value is the smallest among the TTT complexes so far reported.

The TEP measurements were also carried out for both directions, and the results are shown in Fig. 13. The TEP is linearly correlated to the temperature in both directions above 250 K, which corresponds to the metallic state of this compound observed by the conduction measurements. The positive slope suggests that the major charge carrier is a hole in the TTT stacks. However, the TEP crosses zero in the metallic region and becomes negative below the anomaly at 250 K. This behavior is not a typical one of low-dimensional radical cation salt-type conductors, such as D_2X, where D is a donor and X is a counterion, in which the conduction occurs only through the donor stacks. In such compounds the TEP usually decreases towards zero in the metallic region. The deviation from the typical behavior in TTT-OCNAQ(II) is, thus, caused by the structural peculiarity of this compound, i.e., the existence of a transverse interaction between the TTT columns through OCNAQ. When the interaction between the TTT molecules in the stack is large, the total interaction between the donor and acceptor molecules in the system is nearly two-dimensional in the ($\bar{1}10$) plane. However, even at room temperature the TTT molecules are not stacked uniformly, and are weakly dimerized between molecules A and B in Fig. 3. If the dimerization of TTT becomes more developed with decreasing temperature, an energy gap is opened along the stacking direction. However, the interaction along the [112] direction, which corresponds to the $(TTT)_2\cdots OCNAQ\cdots (TTT)_2$ chain, will remain. The charge transport along this chain below 250 K is supposed to be governed by OCNAQ, since the sign of TEP is changed. The additional anomaly at 140 K, which is detectable in the resistivity data, may be related to this chain.

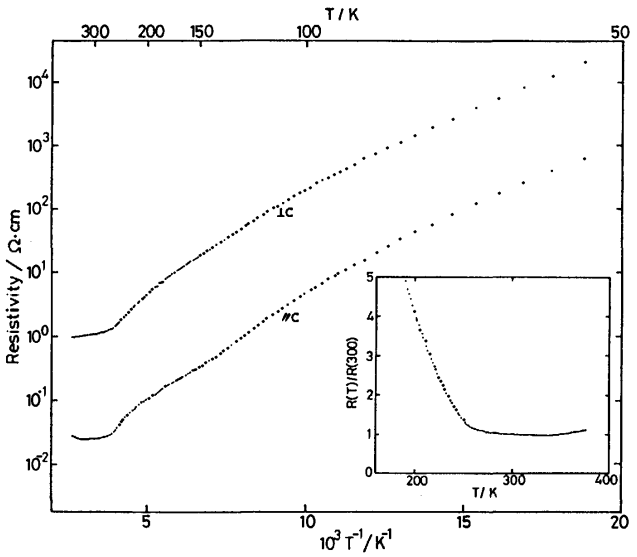

Fig. 12. Electrical resistivities of TTT-OCNAQ(II).

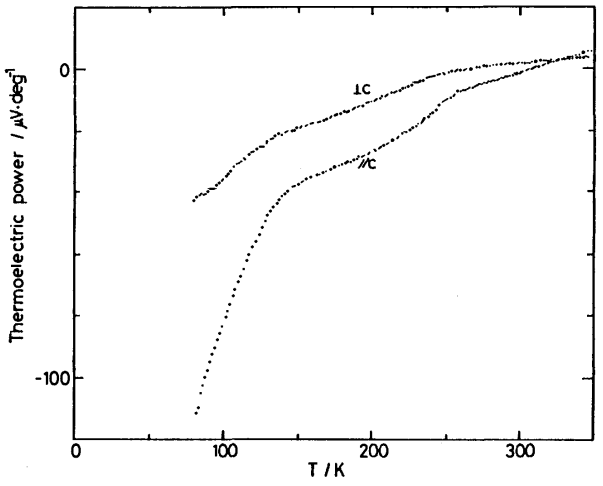

Fig. 13. Thermoelectric power of TTT-OCNAQ(II).

The structure of this compound has some similarities to HMTSF-TCNQ,[14] where HMTSF is bis(trimethylene)tetraselenafulvalene, in which short Se···N contacts between the donor and acceptor molecules exist. The anisotropy of conduction of this material is also 30. The most remarkable characteristic of this material is that the metallic state is stabilized at very low temperature. Comparing this system to TTT-OCNAQ(II), two structural differences can be noted. First, the interaction between the acceptor molecules: in HMTSF-TCNQ a rather strong interaction between the TCNQ molecules exists, while in TTT-OCNAQ(II) the interaction between the OCNAQ molecules is quite weak. Secondly, the pattern of the interaction between the donor and acceptor molecules is different. In HMTSF-TCNQ all the nitrogen atoms of TCNQ interact with all the selenium atoms of HMTSF so that a uniform stacking of the donor (acceptor) is maintained by the transverse interaction with the neighboring acceptor (donor) stacks. On the other hand, in TTT-OCNAQ(II) only two of the eight nitrogen atoms of OCNAQ interact with two of the four sulfur atoms of TTT. This type of transverse interaction is not sufficient to prevent the deformation of the donor stack. These structural differences may cause the difference in the physical properties.

TTF-OCNAQ(II): The temperature dependence of the conductivity is shown in Fig. 14. The conduc-

tivity increases with decreasing temperature down to ca. 90 K then gradually decreases; at 43 K, where the conductivity is still as high as that observed at room temperature, a sharp drop occurs. The temperature dependence of the TEP is shown in Fig. 15. The TEP decreases linearly down to 90 K, and then starts to increase. If this anomaly is due to a metal-to-insulator transition, this upturn is assumed to be caused by a gap formation of the donor stack. However, the TEP below 90 K does not fit a simple activation behavior. Furthermore, for simple hole conduction the zero crossing at 160 K cannot be explained. The TEP rather increases linearly towards zero. This means that the charge transport is metallic and that the major charge carrier is an electron in this region. As discussed in the structure analysis, a crystal of this material consists of TTF and OCNAQ stacks. Thus, the major route of conduction is the TTF stacks above 90 K; it changes to OCNAQ stacks in the region between 43 and 90 K. The material is essentially in a semimetal state. The anomaly at 43 K is assumed to be a normal metal-to-insulator transition.

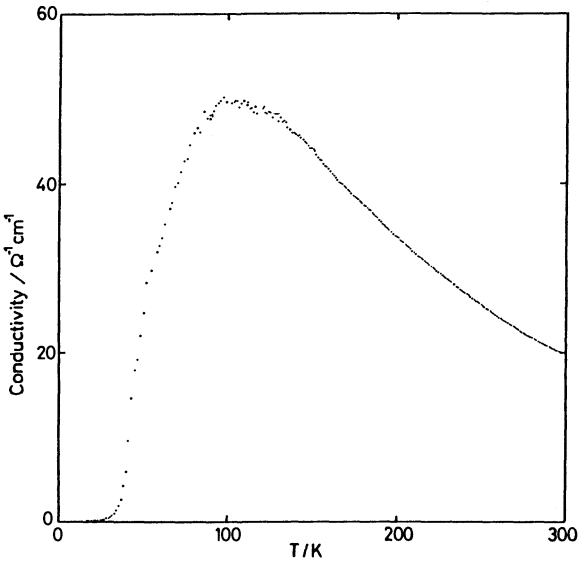

Fig. 14. Electrical conductivity of TTF-OCNAQ(II).

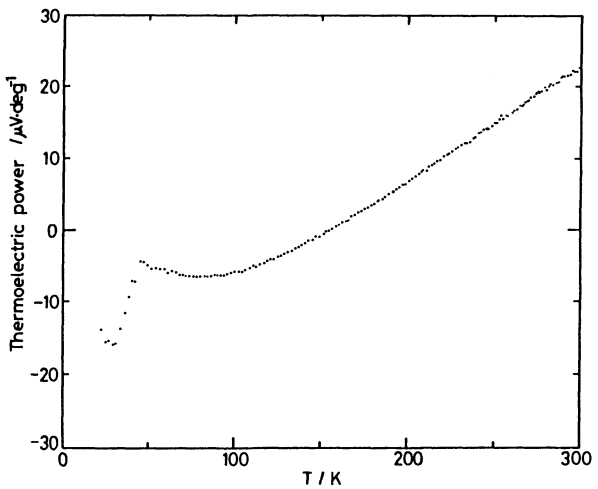

Fig. 15. Thermoelectric power of TTF-OCNAQ(II).

It is noteworthy that conduction through the OCNAQ stacks is realized in this system. This fact suggests that the reduction state of OCNAQ is slightly deviated from an integral value. Such a fractional charge is stabilized only if considerable electron transfer interaction between molecules exists. Although the OCNAQ molecule is not planar, the existence of an intermolecular interaction between the OCNAQ molecules is indicated by an X-ray structure analysis, and the charge transport properties of this material strongly suggests that the interaction is sufficient enough to stabilize the metallic character of the OCNAQ stacks.

Remarks

In the present paper various aspects of OCNAQ are reported. The reduced on-site Coulomb repulsion is manifested in the electrical properties of simple salts. In TTT-OCNAQ(II) a unique transverse interaction through OCNAQ molecules has been found. In TTF-OCNAQ(II) the metallic character of OCNAQ stacks has been observed. Of further interest is the stacking pattern of the OCNAQ molecules in TTF-OCNAQ-(II), in which one OCNAQ undergoes interactions with four OCNAQ molecules. Therefore, this interaction is completely two-dimensional. This stacking pattern is the type expected for a molecule having a twin-type structure. Unfortunately, in this system the stabilization of the metallic state at low temperatures is not realized, since the transfer integral is not sufficiently large to maintain the metallic nature at low temperatures, due to the nonplanarity of the molecule. However, it should be pointed out that one promising approach to design two-dimensional systems is to use such twin-type donor or acceptor molecules.

We are grateful to Dr. Takehiko Mori and Mr. Kenichi Imaeda for helpful discussions and assistance in measurements.

A Molecular Orbital Study of Cyclodextrin Inclusion Complexes. I. The Calculation of the Dipole Moments of α-Cyclodextrin-Aromatic Guest Complexes

Masaki KITAGAWA, Hajime HOSHI, Minoru SAKURAI,* Yoshio INOUE, and Riichirô CHÛJÔ
Department of Biomolecular Engineering, Tokyo Institute of Technology,
12-1 O-okayama 2-chome, Meguro-ku, Tokyo 152
(Received May 9, 1988)

The dipole moments of α-cyclodextrin(α-CD)-aromatic guest systems have been calculated by means of the CNDO/2 molecular orbital (MO) method in order to investigate the role of electrostatic interaction in the stabilization of the inclusion complexes. It is found that α-CD has a remarkably large dipole moment which amounts to 13.5 D and is directed from its secondary hydroxyl side (the wider rim) towards the primary hydroxyl side (the narrower rim). The dipole moments of the guests, benzene derivatives, run antiparallel to that of α-CD in the complexed state. The MO total energy of the α-CD-guest supermolecular complexes shows that these antiparallel-orientations are energitically more favorable than the reversed one. It is concluded that the electrostatic interaction, mainly dipole-dipole interaction, between the α-CD and the guest molecules plays an essential role in determining the guest orientation. On the basis of these results, it is deduced that during complexation the CD molecule undergoes appreciable amount of conformational change, suggesting that the "induced-fit" mechanism is operating when the guest molecule is admitted into the host cavity.

Cyclodextrin (cycloamylose, CD) is a cyclic oligosaccharide composed of at least six α-1,4-linked D-glucose residues. CD has an intramolecular cavity and forms inclusion complexes with a variety of guest molecules. Much attention has been paid to this property of CD, since CD catalyzes various organic reactions via the formation of host-guest complexes in a way similar to that of enzymes. The mechanism of complex formation must be elucidated for a better understanding of the catalytic behavior of CD. A variety of physicochemical models for CD-guest interactions has been proposed.[1-4] Usually, the driving forces for complexation are attributed to the following interactions: van der Waals interaction,[5-9] hydrogen bonding,[10,11] hydrophobic interaction,[12] release of high-energy cavity water,[13,14] release of macrocyclic ring strain,[15,16] and effects of solvent-surface tension.[17] In spite of much effort, there is no general agreement as to the main force stabilizing the inclusion complexes at present.

From the standpoint of intermolecular interaction theory,[18] long-range types of interaction, especially electrostatic interaction, should be primarily important for stabilizing such non-covalent types of molecular complexes. However, there have been no explicit studies on electrostatic properties of CD, e.g., its dipole moment or electronic distribution. Recently, the importance of the dipole-dipole interaction between CD and guest molecules has been pointed out on the basis of NMR measurements of α-CD-aromatic guest complexes.[19,20] Therefore it is of mechanistic interest to study more extensively and directly the CD-guest inclusion phenomena. Quantum-chemical approaches may be suitable for this purpose. We have already confirmed that the CNDO calculation provides valuable information on the geometry of CD-guest complexes.[21,22]

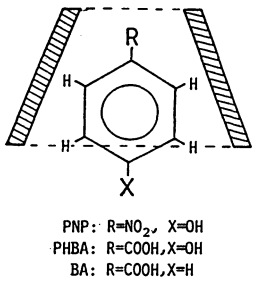
In this paper we calculate the dipole moments of α-CD (composed of six glucose units) and some guest molecules in their complexed states using the CNDO/2 molecular orbital (MO) method. Here *p*-nitrophenol (PNP), *p*-hydroxybenzoic acid (PHBA), benzoic acid (BA), and water are selected as guest molecules because the α-CD inclusion complexes with them have been extensively studied in both solution and crystal.[19-26] On the basis of the calculated results, we discuss the role of dipole-dipole interaction, the leading term of electrostatic interaction, in stabilizing the inclusion complexes. It is suggested that α-CD has a large dipole moment and the dipole-dipole interaction plays a key role in determining the guest-orientation in each complex. Finally, the mechanism of the inclusion process is discussed. The preliminary results have been already reported.[27]

Methods

The dipole moments of the host and guest molecules were calculated using the CNDO/2 method.[28] Each molecular geometry was derived from the X-ray data for the corresponding inclusion complexes: α-CD-water,[25] α-CD-PNP,[26] and α-CD-PHBA.[26] Figure 1 schematically shows the geometries of α-CD-PNP and α-CD-PHBA complexes determined by the X-ray method. The dipole moments of the host α-CD and guest molecules were calculated separately. The three geometries of α-CD derived from these X-ray data are different from each other. The standard geometrical values by Pople and Beveridge[28] were used for BA molecule because of the lack of the crystalline data by X-ray diffraction.

For the α-CD-PNP complex, the dipole moments of the six glucose residues constructing the α-CD molecule were also estimated separately. Here, the C1 and C4 positions of each glucose residue were terminated by the substitution of hydroxyl groups and the geometry of the residual part remains to be identical with that of the X-ray data.

The MO total energies of the α-CD-PNP and -PHBA supermolecuar complexes were obtained for two modes of



PNP: R=NO_2, X=OH
PHBA: R=COOH, X=OH
BA: R=COOH, X=H

Fig. 1. Schematic representation of the inclusion complex between α-CD and some benzene derivatives. The α-CD has a bucket-like cavity; the diameter on the wider-rim side is 8.8 Å and that on the narrower-rim side is 5.6 Å. Due to the bulkiness of the substituents, the orientational freedom of the guest molecule in the cavity is restrained. Usually, two modes of orientations are descriminated according to which substituent is inserted into the cavity. Here the experimentally determined-orientation is shown for each α-CD-guest complex.

guest-orientations (see Fig. 1): i) the nitro or carboxyl group is included in the α-CD cavity, and ii) the phenolic hydroxyl group is in the α-CD cavity. The former corresponds to the X-ray structure. The geometry of the latter was determined on the assumption that the position of the benzene ring relative to the CD-cavity is kept constant against the inversion of the guest-orientation.

Results and Discussion

Dipole Moment of Host and Guest Molecules. The values of dipole moments for the host molecules are shown in Table 1, together with those for the guest molecules. It is apparent that the host α-CD in all the complexes has a remarkably large dipole moment. The direction of the α-CD dipole moment in each complex runs from the side of the secondary hydroxyl groups to the side of the primary hydroxyl groups of α-CD, although it is not exactly parallel to the apparent cavity axis of α-CD.

It has been confirmed that for a variety of small molecules the values of dipole moments based on the CNDO/2 method are in fairly good agreement with the observed data.[1] However, the dipole momens of the α-CDs are too large in comparison with those of ordinary standard molecules. Thus in order to support the above finding, we again attempted to calculate the dipole moment of the α-CDs by means of the MM2 molecular mechanics method.[29] In this method molecular dipole moments are estimated as the sum of bond dipoles, and the accuracy of the computation would not appreciably depend on the size of molecules. As a result the dipole moment of α-CD in the α-CD-PNP complex is evaluated to be 12.4 D,[30] which is sufficiently close to the CNDO-value (13.5 D).

Moreover, the dipole moments of the glucose residues constructing α-CD were calculated in order to investigate the origin of the large dipole moment of α-CD. For the α-CD-PNP complex, the respective glucose units have diverse values of the dipole moments from 1.8 to 5.1 D, as shown in Table 2. According to the X-ray data for this complex,[26] there are some conformational diffrences among these six residues, which should be responsible for the diversity of the dipole moments. Here we could not find explicit correlations between structural parameters and the magnitudes of dipole moments obtained. The dipole moment averaged over all the residues amounts to 3.4 D. The sum of the contributions from all the residues is not less than the apparent dipole moment of the parent molecule. Therefore it is reasonable that the α-CD molecule has the large dipole moment as shown in Table 1.[31]

Table 1. The Dipole Moments of the Host α-CD and the Guests in Their Inclusion Complexes

Guest	Magnitude/D		Direction[a]/degree			
	host	guest	θ	ϕ	ψ	ω
PNP	13.5	5.0	31	19	22	152
PHBA	10.7	2.3	32	41	9	116
BA[b]	—	1.5	—	44	—	—
$(H_2O)_2$	9.5	1.1	80	—	—	138

a) The definitions of θ, ϕ, and ψ are given in Fig. 2. ω indicates the angle between the dipole moment vectors of the host and the guest. Its value was derived from θ, ϕ, and ψ. b) X-Ray data are unavailable.

Table 2. The Dipole Moments of Glucose Residues of α-CD

Glucose No.[a]	Dipole moment/D
1	1.8
2	5.1
3	4.4
4	4.1
5	2.3
6	2.6

a) Each No. of glucose units corresponds to that found in Ref. 13.

The angle ω between the two dipole moment vectors of the host and the guest was derived from the three tilting angles θ, ϕ, and ψ described in Fig. 2. The results (the last column of Table 1) show that in the complexed state the dipole moment of the guest is nearly antiparallel to that of the hosts. The guest orientations in these complexes are schematically shown in Fig. 1. It has been found that the orientations of the guests in aqueous solution[8,15,16] are the same as those in the crystalline state for the α-CD-PNP and the α-CD-PHBA complexes.

For the α-CD-BA complex, it is difficult to estimate the angle ω, since its crystalline structure has not been published. It has been found that the carboxyl-side of BA is located in the α-CD cavity in solution,[17] as also shown in Fig. 1. The calculated dipole moment of BA runs from the carboxyl group to its para position. As in the previous cases, the two dipole moments of the

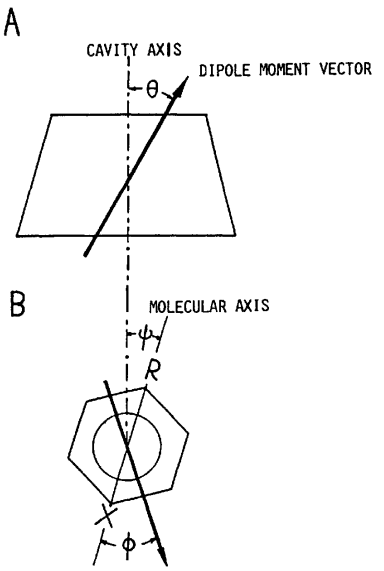


Fig. 2. Definition of the direction in the dipole moment vectors of α-CD and the guest molecules. **A.** The dipole moment of α-CD runs from the wider-rim side to the narrower-rim one. Its direction is defined as the tilting angle θ against the cavity (pseudo-six fold) axis. The angle θ varies dramatically and depends on the type of guest molecule included with concomitant variations in the magnitude of dipole moment. This suggests the conformational change in the macrocyclic ring. **B.** The direction in the dipole moment of the guest molecule is defined as the tilting angle ϕ against its molecular axis. In the crystalline state, the axis is tilted by $\psi°$ against the cavity axis. The angle ψ is estimated from the X-ray data for each complex. Thus, the angle ω between the dipole moment vectors of α-CD and the guest can be derived from θ, ϕ, and ψ. In the complexed state, the dipole moment of the guest is nearly antiparallel to that of the host. The numerical values for the angles defined here are summarized in Table 1.

host and the guest again run antiparallel each other.

Therefore, the antiparallel relationship between the host- and guest-dipole moments holds for all the α-CD complexes studied here, which suggests that electrostatic interaction, chiefly dipole-dipole interaction, is a main contributor stabilizing their complex and thus determines the guest-orientation.

Total Energy of the α-CD-PNP Complex. The MO total energies of the α-CD-guest supermolecular complexes are summarized in Table 3. The total energy of the α-CD-PNP complex with experimentally determined geometry, in which the nitrophenyl group is included in the cavity, is 45 kJ mol^{-1} lower than the sum of the host's and guest's total energies, while that of the complex with the reversed guest-orientation, namely, in the case that the hydroxyphenyl group is in the cavity, is 96 kJ mol^{-1} higher than the sum. Thus, the former orientation is 141 kJ mol^{-1} more stable than the latter. That is, the complex state, in which the nitrophenyl group is included in the cavity, is more stable than the isolated state of

Table 3. The Energy Difference of α-CD-PNP and α-CD-PHBA Complexes for Two Modes of the Guest Orientation

	Energy difference[a]/kJ mol^{-1}	
	PNP	PHBA
Complex[b]	−45	−31
Complex[c]	96	−13

a) Energy difference is calculated from the equation, $E=E_{complex}-E_{host}-E_{guest}$, where $E_{complex}$, E_{host}, and E_{guest} are the total energies for the complex, the host, and the guest, respectively. b) The nitrophenyl and carboxylphenyl groups are located in the α-CD cavity for α-CD-PNP and α-CD-PHBA complexes, respectively. c) The hydroxylphenyl group is located in the cavity.

the two partners, and than the complex state for the reversed guest-orientation. Similarly, in the case of the CD-PHBA complex the experimentally-determined orientation is again more stable. These results imply that the guest-orientations are determined by the electronic interactions, including electrostatic interactions, between the host and the guest molecules.

According to the X-ray data for these complexes, the nitro or carboxyl group is located in the vicinity of the primary hydroxyl groups of CD, but is not hydrogen-bonded with them. Thus, in both cases hydrogen bonding is a less important factor for stabilizing the complexes. However, the polar groups of the guests participate in other hydrogen-bonding networks. The phenolic hydroxyl group protrudes from the CD-cavity, and forms the hydrogen bond with the oxygen atom of the neighboring CD in crystal. Similarly, this group could be hydrogen-bonded with solvent molecules in solution. The effects of such hydrogen bonds, formed with molecules other than the host, on the stabilization of the complexes may be nonnegligible. However, they are not main factors determining the guest-orientation, because for the reversed guest-orientation similar hydrogen-bonding networks in which the newly protruded groups participate are also possible.

On the basis of molecular mechanics calculation, Tabushi et al.[8] have shown that van der Waals interaction is a major contributor for stabilizing α-CD-aromatic guest complexes, and supported the idea that the specificity of substrate binding by CD is mainly related to the extent of host-guest fitting. Mastui[7] has determined the geometry of the some α-CD-guest complexes using Hill's potential,[32] which is an emprical equation evaluating van der Waals interaction. Accoding to his results for the α-CD-PNP complex, the stabilization energy due to van der Waals interaction is 52.26 kJ mol^{-1} for experimentaly determined guest-orientation, and 41.17 kJ mol^{-1} for the reverse guest-orientation. The former is comparable to the stabilization energy estimated from the MO total energy (Table 3). As shown in Table 3, the interaction energy based on the CNDO calculations dramatically

changes depending on the guest-orientation. The energy-difference (141 kJ mol^{-1}) between the two orientations is fairly large compared with that from Mastui's data (11 kJ mol^{-1}).[1] In other words, the van der Waals (dispersion) interactions are less important for determining the guest-orientation than the electronic interaction.

The Formation-Mechanism of α-CD Inclusion Complexes with Aromatic Guests. When two water molecules are included in the α-CD cavity (α-CD-water complex), the dipole moment vector of α-CD considerably deviates from the cavity axis; the θ value in Fig. 2 A is 80°. This finding reflects the fact that the macrocyclic ring of α-CD including two water molecules is highly distorted, as is indicated by Manor and Saenger.[25] On the other hand, in both the α-CD-PNP and α-CD-PHBA complexes, the macrocyclic ring shows a slightly distorted hexagon,[26] corresponding to the smaller tilting angle (θ=30°) of the dipole moment vector.

It is apparent from Table 1 that the values of dipole moment of α-CD in the α-CD-PNP and α-CD-PHBA complexes are larger than that for the α-CD-water complex. Namely, when α-CD accommodates the aromatic guest instead of the two water molecules, its dipole moment becomes larger. Here it is convenient to introduce the induced dipole moment defined as the difference in the dipole moments (magnitudes) between in the α-CD-water and in the α-CD-aromatic guest complexes. The induced dipole moments are evaluated to be 4.0 and 1.2 D for α-CD for the inclusion of PNP and PHBA, respectively. The larger the dipole moment of the guest is, the larger is the induced dipole moment of the α-CD. As described above, the guest-dependence of dipole moment should be related to the conformational changes of the host molecule. Therefore, this finding suggests that on complexation the α-CD molecule undergoes the appreciable extent of conformational changes to strengthen the dipole-dipole interaction with the guest molecules.

If a guest molecule approaches a CD cavity in solution so that its dipole moment would run antiparallel to that of the CD after complexation, the dipole-dipole interaction should produce an energy barrier for complexation and makes it rather difficult to penetrate the guest into the α-CD cavity. This difficulty could be partially removed if the α-CD molecule changes its conformation depending on its relative position to the guest molecules. As described above, the skeleton of α-CD is flexible enough to respond to the perturbation from guest molecules. Thus during the release of included waters and the subsequent inclusion of the guest, the macrocyclic ring of α-CD may take another conformation[34] giving a smaller dipole moment. It is then possible that the conformational change causes the energy barrier to be lower, and thus a guest molecule penetrates into the α-CD cavity more easily. After complexation, α-CD again changes its conformation so that it would make its dipole moment larger to form a more stable complex. The flexibility of the CD macrocycle in aqueous solution has been confirmed by the measurements of ^{13}C spin-lattice relaxation time.[35,36]

More extensive study on the electronic structure of α-CD is required to confirm the above model about the complexation process. At present stage other factors driving the complexation should not be excluded. A thermodynamic study[37] on CD-apolar guest complexation has shown the importance of hydrophobic interaction (apolar binding), which originates from the breakdown of the structural water molecules around an apolar guest. According to this report, a favorable entropy change due to hydrophobic interaction is largely responsible when a guest molecule approaches a CD-cavity from their isolated state. On the other hand, after inclusion of the guest the complex can be stabilized by other factors providing favorable enthalpy change. It is, therefore, natural to say that owing to the hydrophobicity of the aromatic ring PNP is driven into the α-CD cavity with the aid of the hydrophobic interaction. Once the guest is trapped into the α-CD cavity, the complex is predominantly stabilized in terms of the dipole-dipole interaction as is described above.

In conclusion, α-CD has a remarkably large dipole moment so that the host-guest electrostatic interaction can determine a guest orientation in the complexed state. The dipole moment of α-CD varies depending on the type of guest molecule, which reflects the conformational change of the macrocyclic ring of α-CD. On the basis of these results, we conclude that the "induced-fit" mechanism effectively operates on α-CD-guest complex formation and the conformational change of α-CD is caused by the dipole-dipole interaction between the host and the guest molecules. The CD molecule serves a highly electrically anisotropic medium to the guest molecules. The term like a "hydrophobic pocket" is insufficient to describe the character of CD-cavity. We are currently investigating whether these results are applicable to other types of guest molecules like aliphatic compounds.

31) The feature of the electronic distribution in α-CD can be seen from its electrostatic potential maps. Recently we have found that the side of the secondary hydroxyl groups of the CD has positive potentials, while the side of the primary hydroxyl groups does negative ones. Therefore, a very large separation of charges is caused along the CD-cavity axis, resulting in the large dipole moment. This preliminary result has been already accepted for publication (M. Sakurai et al., *Chem. Lett.*, **1988**, 895).

33) The geometry for the reversed guest-orientation used here does not necessarily correspond to the energitically optimized one. Thus our calculation should underestimate the stabilization energy for this case. However it is known that the position of the aromatic ring in the cavity, namely the depth of inclusion, is almost independent of the type of substituent (see Ref. 26). It seems that the main conclusions obtained here are no problem.

(Received May 19, 1988)

Several model compounds of poly(thiotrimethylene), including one to four thiotrimethylene units, were studied by means of a molecular mechanics method. The geometric and statistical weight parameters were directly derived from the results of molecular mechanics calculations concerning several conformers of these model compounds. Although the first-order interactions of poly(thiotrimethylene) were significantly larger than those of poly(oxyalkylenes), the second-order interactions of this polymer were much smaller. The "gauche effect" by sulfur atoms seemed to be mainly caused by small second-order interactions. By means of the model, compounds including more than three repeating units, the calculated configuration-dependent properties were in better agreement with the experimental ones than that calculated earlier. The better agreement was obtained by varying some of the geometric parameters. Compounds including more than three repeating units of the polymer were available as model compounds. Since this was also true in poly(oxyalkylenes), it was found that a combination of the methods of molecular and statistical mechanics was sufficiently effective to investigate the configurational properties of poly(thiotrimethylene).

Poly(thioalkylenes) have been investigated[1-8] with regard to their configurational properties in comparison with the analogous poly(oxyalkylenes),[9-13] because of their similarity in structure. In the case of poly(oxyalkylenes), it has been shown that the gauche conformations, which are associated with the O-CH_2 interactions, are much preferred to the trans state. This anomalous gauche preference is called the "oxygen gauche effect." Earlier semiempirical calculations[9] of the conformational energies for the model compounds of poly(oxyalkylenes) could not succeed in providing proper interpretations of such anomalous gauche preference, although structural studies in crystal[14,15] or vibrational spectroscopic studies[16] have been well established. In previous studies,[10-13] we undertook the first attempts to combine the molecular mechanics method[17] with the calculations involving statistical mechanics. When the lone-pair electrons on an oxygen atom were taken into consideration, molecular mechanics calculations on the model compounds of poly(oxyalkylenes) prevailed to estimate the proper amount of the gauche oxygen effect. The configuration-dependent properties of poly(oxyalkylenes), which were calculated by means of the rotational isomeric states approximations directly obtained from the results of molecular mechanics on the model compounds, were in fairly good agreement with the experimental ones.

In analogy to the poly(oxyalkylenes), it was found that poly(thioalkylenes) had a similar gauche effect,[1-8] although it was different in amount. Similarly, in poly(oxyalkylenes), earlier conformational energy calculations[6-8] of the model compounds of poly(thioalkylenes) also could not provide proper interpretations of the rotational isomeric states approximations. Moreover, molecular mechanics, which provided successful interpretations of the rotational states approximations for the model compounds of poly(oxyalkylenes), had as yet never been applied to the model compounds of poly(thioalkylenes) for such approximations, except regarding the conformational and packing stability in crystal[18] or the vibrational spectra analysis using the group coordinate force field.[19-21] Poly(thioalkylenes), which included one or two methylene groups in their repeating units, had not been experimentally investigated with regard to the configuration-dependent properties, because of their high melting points and poor solubility in solvents. The simplest poly(thioalkylenes), whose configuration-dependent properties have been experimentally observed, is poly(thiotrimethylene).[8] Therefore, in this study, molecular mechanics were applied to the model compounds of poly(thiotrimethylene), which have various chain lengths. By means of these results, the configuration-dependent properties of this polymer could be estimated. The calculated values were compared with the experimentally observed ones. Then, the most suitable length of the model compound of poly(thiotrimethylene) could be determined. Here, the propriety of the application of the molecular mechanics to the poly(thioalkylenes) is also discussed.

Theoretical

Molecular Mechanics Calculation. Molecular mechanics[17] (or force field method) is a method that allows calculations of the structure and energy of a molecule by means of several potential functions (bending, stretching, torsional, van der Waals, electrostatic, their cross terms) and their experimentally derived parameters. Then the energy is minimized. In recent years, molecular mechanics has become one of the most popular methods, occupying a significant position in the field of computer chemistry, called "applied theoretical chemistry".[22] Although many force fields have been suggested, each force field has a different object to simulate a molecule. The force

fields of Scheraga[23] or Kallman[24] shows fine performances for calculations of the molecular structure of polypeptide or nucleic acids. That of Lifson/Warshel[25,26] has proven to be highly efficient for calculations of the packing of molecules in a crystal, and that of Tadokoro[27] or Williams[28] aim at estimations of crystalline structures. Matsuura et al.[18,19] developed a group coordinate force field, which had been initiated by Shimanouchi et al.,[29] and proved to be suitable for treating the vibrations of molecules. For the general force fields aimed at hydrocarbons, Schleyer's,[30] Boyd's,[31] and Allinger's[32] are very famous. Among them, Allinger's force field is available for a wide range of the problems concerning organic chemistry, since the parameters of hydrocarbons and those of various heteroatoms are made courteously. The use of this method has spread remarkably around world. In this study, the force field of Allinger[32] was selected, because of this remarkably wide spread usage and the reliability of parameters for heteroatoms. Another positive point is that a satisfactory estimation of the rotational isomeric states of poly(oxyalkylenes) had been obtained by the previous force field of Allinger, i.e. MMI;[17,33] therefore, the calculated results of poly(thioalkylenes) can be directly compared with the previous results of poly(oxyalkylenes). More recently, since computer programs for molecular mechanics, which can run on a microcomputer, have become available,[33] molecular mechanics has become easier to use. In this study we used a molecular mechanics program which was reported in 1977 by Allinger et al. (MM2[32]). This program could execute under MS-DOS[34] and be transformed so as to be able to run on a PC-9801 microcomputer.[35]

Considering structural symmetry, and for the purpose of deriving the geometric and statistical weight parameters in order to calculate the configuration-dependent properties of poly(thiotrimethylene), the following model compounds, including one to four thiotrimethylene units $CH_2CH_2CH_2S$ with terminal methyl or ethyl groups, were studied; i.e. 2,6-dithiaheptane (**4T**) $CH_3SCH_2CH_2CH_2SCH_3$, 3,7-dithianonane (**6T**) $CH_3CH_2SCH_2CH_2CH_2SCH_2CH_3$, 2,6,10-trithiaundecane (**8T**) $CH_3S\text{-}(CH_2CH_2CH_2S\text{-})_2\text{-}CH_3$, 3,7,11-trithiatridecane (**10T**) $CH_3CH_2S\text{-}(CH_2CH_2CH_2S)_2CH_2CH_3$, 2,6,10,14-tetrathiapentadecane (**12T**) $CH_3S(CH_2CH_2CH_2S)_3CH_3$, 2,6,10,14,18-pentathianonadecane (**16T**) $CH_3S(CH_2CH_2CH_2S)_4\text{-}CH_3$. The numbers with **T** in parentheses denote the number of skeletal bonds whose rotations experience a first-order interaction between CH_2 and CH_2, or CH_2 and S atoms; these abbreviations are used here instead of the full names of model compounds. Regarding these model compounds, the all-trans conformer, the conformers including one gauche state and those including consecutive two gauche states, were calculated by molecular mechanics. In molecular mechanics, the effect of any solvent was taken into account by considering the solvent as an isotropic continuum having a macroscopic dielectric constant. Under such conditions, the rotational states of molecules have a preference for gauche states as the polarity of solvents increases. The configuration-dependent properties of this polymer, which were to be compared with the results of molecular mechanics, were obtained in a nonpolar solvent, i.e. benzene.[8] Moreover, the configuration-dependent properties of the polymer were studied under an unperturbed state; therefore, no additional treatment was made regarding the effect of a solvent.

Results and Discussion

Results of Molecular Mechanics Calculations on the Model Compounds of Poly(thiotrimethylene). As the model compounds of poly(thiotrimethylene), the six compounds described in the previous section were used in molecular mechanics calculations, in which the dipole-dipole interactions with common atoms were taken into consideration. The calculated energy differences between corresponding an all-trans conformer and several conformers of each model compound are listed in Table 1.

With respect to compound **4T**, the all-trans conformer has the lowest energy and a TTTG conformer with a rotational state of CC-SC is gauche, has secondly low energy. Concerning the derivation of the statistical-weight parameters of poly(thiotrimethylene), **4T** is too short to derive all of the parameters (eight kinds of parameters are needed, although only six are obtained from **4T**).

The **6T** is the smallest model compound of poly(thiotrimethylene), which can be used to derive all of the eight statistical-weight parameters required for a calculation of the configuration-dependent properties of the polymer. The all-trans conformer of **6T** also has the lowest energy; a TTTTGT conformer with a rotational state of CC-SC is gauche, has the second lowest energy.

Throughout the calculated results of all the model compounds, the gauche state about CC-SC is lower in energy than that about SC-CC. In poly(oxytrimethylene), the gauche state about the central bond in the sequence CC-CO has been found to be lower in energy than that in the sequence CC-OC. This is caused by the fact that a C-O bond (1.407 Å) is considerably shorter than a C-C bond; therefore, the van der Waals interactions of a gauche in CC-OC become larger than those in CC-CO and is caused by the large electrostatic attractions of a gauche in CC-CO. On the contrary, the gauche of poly(thiotrimethylene) in CC-SC has been found to be lower in energy than that in CC-CS. The preference of the former is mainly due to stabilizations by van der Waals and torsional interactions owing to the long bond length of C-S, i.e. $l_{C\text{-}S}$=1.815 Å. These contributions to the steric energy are larger

than those from electrostatic interactions in these conformers.

A similar tendency was also found in a report by Tai et al.[18] Their conformational analysis of the crystal states of poly(oxytrimethylene) showed that the molecular chain, consisting of the sequence $C\overset{O}{\overset{\diagdown}{\tau_1}}\ \tau_2 C \tau_3\ \overset{C}{\overset{\diagdown}{\tau_4}}C$, was stable when the C-O bonds were trans and the C-C bonds were gauche, namely $(T_2G_2)_2$ helix ($\tau_1=\tau_2\simeq180°$ and $\tau_3=\tau_3\simeq60°$). It emphasized the preference of GG of the $O\diagdown C\diagup C\diagdown C\diagup O$ bond and coincided with our previous results. The same report also showed that the conformations in the crystal states of poly(thiotrimethylene) about the molecular chain consisted of the sequence $C\diagdown S\diagup C\diagdown C\diagup C$. It showed that the lowest energy conformation was the $(G_2T_2)_2$-type helix, though it has not yet been observed. The next lowest energy conformation was the G_4-type of

the actual existence. The following low-energy conformations were T_4 planar zigzag and a $(T_2G_2)_2$ helix. It demonstrated that the conformer which contained the two consecutive gauche in the bond sequence C\C/S\C/C was the most stable. This result is coincident with the present study, though details are somewhat different because of the premises of the molecular state, namely in the crystal state and in a dilute solution. More recently, Matsuura et al.[20] studied the vibrational spectra of the model compound of poly(thiotrimethylene), $CH_3S(CH_2)_3SCH_3$, by a normal coordinate calculation. This study had helped to clarify that the terminal GT+ and GG+ conformations, namely gauche about the CH_3S-CH_2 axis, were more stable than the TT+ and TG+ conformations, namely trans about the same axis (in the liquid state). Our results are contrary to these owing to a different assumption concerning the molecular state (in crystal or liquid against in gaseous or isolated molecule in some solvent). The propriety of our results were examined in terms of the configuration-dependent properties, which are discussed in following sections.

In the case of model compounds which are longer than **6T**, conformers with rotational states of CC-S-CC in the central positions are two consecutive gauche of the same sign ($G^{\pm}G^{\pm}$), are the lowest in energy among the respective conformers; for example, TTTGGTTT of **8T**, TTTTGGTTTT of **10T**, TTTTTTTGGTTT of **12T**, TTTTTTTTTTTGGTTT and TTTTTTTGGTTTTTTT of **16T**. Because these conformers which include two consecutive gauche of same signs, form a helical structure, the steric repulsions between bulky terminal groups are greatly reduced. Therefore, the van der Waals, torsional and electrostatic interaction energies of these conformers are much smaller than those of others. Contrary to this, the conformers which include two successive gauche about CC-S-CC in the terminal position are not so stable; i.e. TTTTGG of **6T** or TTTTTTTTGG of **10T**. It seems that the helix formation with the terminal part of these conformers does not cause a large reduction in the energy since one of the terminal groups is much larger than the previously mentioned conformers. The conformers containing two successive gauche of the opposite signs about CC-S-CC ($G^{\pm}G^{\mp}$) are also lower in energy than other consecutive gauche of the opposite signs with some exceptions.

Geometric and Statistical Weight Parameters of Poly(thiotrimethylene). From the results of molecular mechanics calculations on the model compounds of poly(thiotrimethylene), the geometric parameters obtained by Boltzmann averaged values over each conformer in Table 1 are shown in Table 2. In any case, the bond lengths are stretched and the bond angles are widened from those in a state of equilibrium, i.e. $l_{C\text{-}S}$=1.815 Å, $l_{C\text{-}C}$=1.523 Å, ∠CSC=96.3°, ∠SCC=109.0°, ∠CCC=109.5°. The bond angle of CSC is especially widened. In this study, the dihedral angles are defined as zero when the rotational state of a skeleton is in an ideal trans state. It is clear from Table 2 that the amount of twisting from the original trans position is small; on the other hand, those from gauche are somewhat large. The differences of the geometric parameters among the model compounds are slight.

The statistical-weight parameters of poly(thiotrimethylene) are constructed by two kinds of first-order interactions and six kinds of second-order interactions (Fig. 1). The skeleton of a repeating unit of poly(thiotrimethylene) consists of four kinds of bonds; each bond is distinguished by an alphabetic notation. Namely, σ and σ' are defined for a first-order interaction due to a rotation around the C-C (*b* and *c*) and C-S (*a* and *d*) bond, respectively. When the gauche sequence of the same sign, $G^{\pm}G^{\pm}$, are consecutive, the second-order interaction parameter ϕ is defined for *bc*, ϕ' for *ab* and *cd*, ϕ'' for *da*. For the consecutive gauche sequence of opposite sign, $G^{\pm}G^{\mp}$, ω with a corresponding number of primes are defined in the same way as ϕ.

For each model compound, the conformers listed in

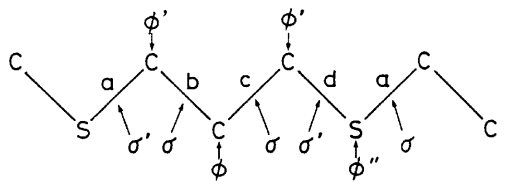

Fig. 1. Alphabetical notation of the skeletal bond and the statistical weight parameters of poly(thiotrimethylene).

Table 1 and include the same first- or second-order interactions are averaged: for example, $E_\sigma+E_{\sigma'}+E_{\phi'}=$ 1.063 kJ mol^{-1} is obtained from TTTTTTGG and TTTTGGTT of **8T**, etc.; then, the obtained simultaneous equations containing eight variables are solved.[10] The obtained statistical-weight parameters are listed in Table 3. Figure 2 shows the variation of E_σ and E_ϕ with no or one prime, and E_ϕ with two primes against the chain length of the model compounds. From Table 3 and Fig. 2, it is clear that the averaged values of first-order interactions, E_σ and $E_{\sigma'}$, assume minima in **8T**; these values increase gradually. This may be caused by a progressive increase of the steric repulsions between bulky substituents when the sole gauche happens to appear in the inner position of the chains. The second-order interaction parameters, E_ϕ, $E_{\phi'}$, and $E_{\phi''}$, decrease with an increase in the chain length with some vibrations. Comparing the first-order interaction energies of poly(oxytrimethylene), i.e. $E_\sigma=-1.67$, $E_{\sigma'}=3.26$ kJ mol^{-1},[13] they are significantly different from those of poly(thiotrimethylene). Even the sequence of E_σ and $E_{\sigma'}$, is reverse. This is due to the same reason mentioned in the previous section. These results show the characteristic fact that the "sulfur gauche effect" is significantly different from the "oxygen gauche effect." The "oxygen gauche effect" causes gauche states about the central bond of CC-CO to be much lower in energy than trans. Compared with this, the "gauche effect" by a sulfur atom seems to be diminished. The second-order interaction energies of poly(oxytrimethylene), i.e. $E_\phi=1.09$, $E_{\phi'}=-0.63$, $E_{\phi''}=0.46$, $E_\omega=9.87$, $E_{\omega'}=6.65$, and $E_{\omega''}=3.22$ kJ mol^{-1},[13] are also different from those of poly(thiotrimethylene). The second-order interaction energies for $G^\pm G^\pm$ of poly(thiotrimethylene), i.e. E_ϕ, $E_{\phi'}$, and $E_{\phi''}$, are all smaller and almost all have negative values. The small values of the second-order interaction energies are caused by the long bond length of C-S, and the stabilization by the helical structure formation (as mentioned before). These small second-order interaction energies are regarded as a metamorphosed "gauche effect." Namely, although an isolate gauche of poly(thiotrimethylene) is unstable, the conformers which include consecutive gauche states lower the conformation energy. These results are strongly supported by the fact that the crystalline-state configuration of poly(thiotrimethylene) has been reported to be $[G^\pm G^\pm G^\pm G^\pm]$.[36]

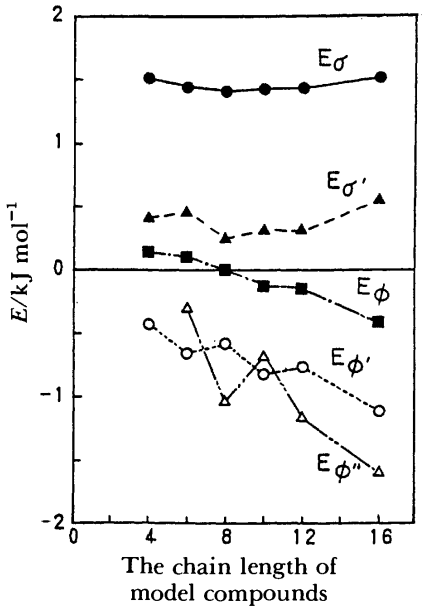

Fig. 2. The variation of statistical weight parameters plotted against the chain length of model compounds of poly(thiotrimethylene).

Unperturbed Dimensions and Dipole Moment. The characteristic ratios, dipole moment ratios and their temperature coefficients, which are calculated by means of the geometric and statistical weight parameters listed in Tables 2 and 3, are plotted in Figs. 3 and 4 against the chain length of the model compounds. Figure 3 shows the unperturbed dimension and its temperature coefficient of poly(thiotrimethylene) with infinite chain length; i.e. more than 500 in degree of polymerization. Figure 4 shows the dipole moment ratio and its temperature coefficient. The characteristic ratio takes a minimum at **8T**, then increases until **12T** and remains on the same level at **16T**. Although its temperature coefficient also takes a minimum at **8T** and shows a similar tendency, its variation with the chain length is larger than that of the characteristic ratio. Because these configuration-dependent properties have not been observed experimentally, the quality of the calculated results could not be ascertained. The

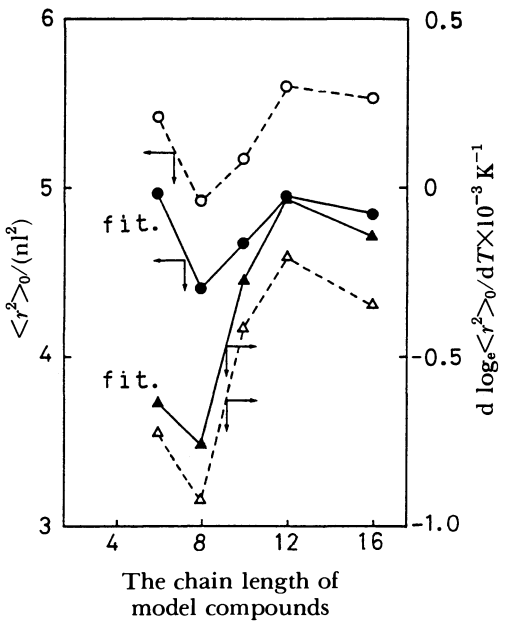

Fig. 3. The dependence of the characteristic ratio and its temperature coefficient of poly(thiotrimethylene) on the chain length of model compounds. Filled circles and filled triangles denote the results after fitting procedure, see text.

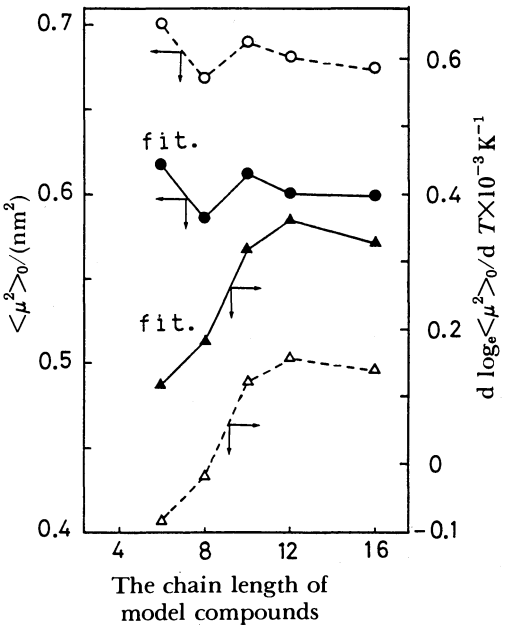

Fig. 4. The dependence of the dipole moment ratio and its temperature coefficient of poly(thiotrimethylene) on the chain length of model compounds. Filled circles and filled triangles denote the results after fitting procedure, see text.

dipole moment ratio becomes minimum at **8T** and increases at **10T**, then slightly decreases with an increase in the chain length to **16T**. Although its temperature coefficient increases from **6T** to **12T**, and remains on the same level at **16T**, the differences between the model compounds from **10T** to **16T** are small. From the variation of configuration-dependent properties with the chain length of model compounds, because these values become almost same at more than **10T** or **12T** and near to observed values, such sizes of molecules seem to be appropriate to the model compound of poly(thiotrimethylene).

In earlier calculations, Guzman et al.[8] obtained $\langle\mu^2\rangle_0/(\mathrm{nm}^2)=0.691$ and $d\log_e(\langle\mu^2\rangle_0)/dT=-0.08\times10^{-3}$ K^{-1} by means of a three-state approximation and $\langle\mu^2\rangle_0/(\mathrm{nm}^2)=0.63$, $d\log_e(\langle\mu^2\rangle_0)/dT=-0.2\times10^{-3}$ K^{-1} by means of a five-state approximation. Although the dipole moment ratio $\langle\mu^2\rangle_0/(\mathrm{nm}^2)$ calculated by means of the five-state approximation is closer to the observed value, i.e. $\langle\mu^2\rangle_0/(\mathrm{nm}^2)=0.598$ (at 20 °C), than that calculated by their three-state approximation, the temperature dependence of the dipole moment by five-state is more different from the observed value ($d\log_e(\langle\mu^2\rangle_0)/dT=1.2\times10^{-3}$ K^{-1}) than that by their three-state. Their first-order interaction energies are $E_\sigma=0.38$ and $E_{\sigma'}=0.46$ kJ mol^{-1}, which had been derived by Welsh et al.[2] They had concluded that all of the skeletal bonds of poly(thiotrimethylene) should have gauche and trans states of essentially the same energy (within 0.4 kJ mol^{-1}); therefore, this molecule may be an interesting approximation to the "freely-rotating" chain used as a highly idealized reference state in configurational analysis.[2] If this polymer is regarded as an ideal "freely-rotating" chain, the temperature coefficients of square moments should be almost zero because of an equal probability of rotational states about the skeletal bonds. The observed temperature coefficient of the dipole moment is, however, too large to regard this polymer as such a chain. Thus, the discrepancy between the observed and their calculated temperature coefficients (almost zero in their three-state approximation) are large.

In contrast to these results, the values of the dipole moment ratio calculated in this study lies between the value calculated by the earlier three-state approximation and that by the five-state calculation. These calculated ratios agree better than that of the previous three-state. The temperature coefficients calculated by the earlier three- and five-state approximations are different, even in the sign. On the other hand, the calculated values in this study become close to the observed one. Considering that the dipole moments are not experimentally observed in the exact unperturbed state, and comparing the results obtained in this study with those obtained by an earlier three- or five-state approximation, the calculations in this study give much more satisfactory results.

As a trial, the geometric parameters obtained from the model compound **8T** were changed while seeking a parameter set which gives a better agreement with the experimentally observed configuration-dependent properties. The bond angles and the dihedral angles of trans and gauche are changed alone or in combination with them by ±5° or ±10° from the original angles

of Table 2, respectively. When the bond angle of CCS decrease by 5° and the torsional angles of CC-SC with both trans and gauche increase by 10°, the best agreement is obtained. Likewise by adding 5° to the bond angle of CCS and 10° to the torsional angles of the trans and gauche of CC-SC, the dipole moment ratios and the temperature coefficients of each model compound calculated by the new geometric parameters and are also shown in Fig. 4. The characteristic ratio and its temperature coefficient are shown in Fig. 3. The calculated values using revised geometric parameters are denoted by *"fit."* in Figs. 3 and 4. Although the general tendencies are similar to those obtained by unchanged geometric parameters, the characteristic ratios and dipole moment ratios become small and their temperature coefficients become large. Using the parameters obtained from the model compounds which are longer than **12T**, the calculated dipole moment ratios, i.e. $\langle\mu^2\rangle_0/(nm^2)=0.612$ at **10T**, 0.600 at **12T** and 0.599 at **16T**, are in fairly good agreement with the observed value of 0.598 at 20 °C and 0.608 at 30 °C. Although the temperature coefficients of the dipole moment, $d\log_e\langle\mu^2\rangle_0/dT=0.32\times10^{-3}K^{-1}$ at **10T**, 0.36×10^{-3} K^{-1} at **12T**, and 0.33×10^{-3} K^{-1} at **16T** are even smaller than the experimentally obtained value of 1.2×10^{-3} K^{-1}, they are much larger and closer to the experimental value than that previously calculated. It is noteworthy that the statistical weight parameters are left unchanged throughout this rough fitting procedure. In this case, the model compounds of **10T** to **16T** also seems to be suitable; especially the model compound of **12T** gives the best results. The model compound of **10T** includes two thiotrimethylene units with terminal ethyl groups. Model compounds **12T** and **16T** include, respectively, three and four repeating units with terminal methyl groups. Therefore, model compounds of the polymer containing more than three repeating units are available. When model compounds containing two repeating units are used, the larger terminal groups are recommended. From these discussions, it is found that the parameters directly derived from the results of molecular mechanics calculations on the model compounds lead to a good agreement between experimental and calculated configuration-dependent properties. Also, a better agreement is obtained by varying the geometric parameters to fit the calculated configuration-dependent properties to the experimental values. Then, a method combining molecular and statistical mechanics is successful for poly(thioalkylenes), just as is the case for poly(oxyalkylenes).

(Received June 20, 1988)

The effective electron-electron interaction in the high polymers of polyacene carbon skeleton is investigated. The appearance of various phases in this system depends on associated parameters characterizing the electron-electron interactions near the Fermi level. The main purpose of this work is to estimate these parameters under the random phase approximation and to presume whether this polymer may or may not be superconductor at room temperature.

In studies of the high temperature superconductivity, many one- or two-dimensional models have been proposed and the probability of it was discussed.[1,2] We also studied, in our previous reports,[3,4] various phases of polyacene, especially its superconducting phase, which is quasi-one-dimensional system. We have stressed that a characteristic band structure near the Fermi surface of the present system leads to preferable properties to usual one-dimensional models in some points. For example, the gap and the transition temperature are proportional to the exponential of coupling constants in the BCS model for metal:[5]

$$\Delta = \omega_D \exp\left(\frac{-1}{\nu_F |g|}\right), \tag{1}$$

$$T_c = \omega_D \frac{\gamma}{\pi} \exp\left(\frac{-1}{\nu_F |g|}\right). \tag{2}$$

These are due to the linear dispersion of band structure near the Fermi surface. On the other hand, the quadratic dispersion of band structure in polyacene yields,[4]

$$\Delta = \frac{K^2}{4\pi^2 t} \lambda^2, \tag{3}$$

$$T_c = \frac{Z^2}{4t} \lambda^2, \tag{4}$$

where t is the transfer integral between adjacent sites, λ the characteristic parameter responsible for the phase transition (see Eq. 22), K and Z being the positive numerical factors of order 1 (the precise form is given in Ref. 4). The relations, (3) and (4) suggest that polyacene has a more extended region of superconducting phase than that in metal.

We have applied g-ology to our system, which parametrizes the interaction matrix elements near the Fermi momentum ($k=\pi$). In the present work, we estimate the g value numerically and wish to determine the phases of polyacene. In the BCS theory the superconducting phase occurs for negative g value, arising from the electron-phonon interaction. If the latter be replaced by any electronic process, even in the BCS superconductor, the Debye frequency in Eq. 2 is replaced by the associated electronic frequency, so that the critical temperature would be expected to be ten or hundred times larger. To make this be realized, we consider the system composed of the side chains attached to the both sides of polyacene skeleton (Fig 1). This is nothing but the idea proposed by Little.[8]

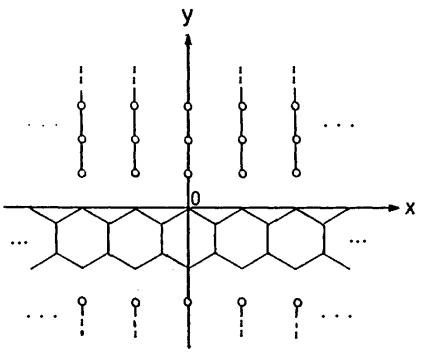

Fig. 1. Polyacene with side chains.

Single Particle States of Polyacene

We consider the transfer integral t between only the adjacent sites. In the case without bond alternation, the Hamiltonian is

$$H_0 = t\sum_n (a_{n1}^+ a_{n2} + a_{n2}^+ a_{n3} + a_{n4}^+ a_{n3} + \text{h.c.}) + t\sum_n (a_{n+1,1}^+ a_{n2} + a_{n+1,4}^+ a_{n3} + \text{h.c.}). \tag{5}$$

Here a_{nr}^+ (a_{nr}) is the creation (annihilation) operator of an electron at r-site of n-th unit cell (see Fig. 2). Because of the periodic property of polymer, the Born

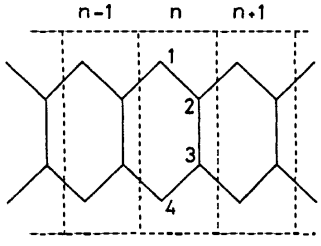

Fig. 2. Polyacene skeleton with the site and cell numbers.

von-Karman condition leads to

$$H_0 = t\sum_k \{(1+e^{-ik})\,(a_{k1}^+ a_{k2} + a_{k4}^+ a_{k3}) + a_{k2}^+ a_{k3} + \text{h.c.}\}, \tag{6}$$

where, for example, a_{ki} is the Fourier transform of a_{ni}:

$$a_{ki} = \sum_n e^{-ikn}\, a_{ni}. \tag{7}$$

The spectrum is composed of four bands given by

$$\begin{aligned}
\varepsilon_{c'}(k) &= \frac{-t}{2}\{1 + s(k)\}\ , \\
\varepsilon_{c}(k) &= \frac{t}{2}\{1 - s(k)\}\ , \\
\varepsilon_{v}(k) &= \frac{-t}{2}\{1 - s(k)\}\ , \\
\varepsilon_{v'}(k) &= \frac{t}{2}\{1 + s(k)\}\ ,
\end{aligned} \tag{8}$$

with

$$s(k) = \sqrt{9 + 8\cos k}\ , \tag{9}$$

and LCAO coefficients for atomic sites are

$$\|U_{rb}(k)\| = \begin{bmatrix} N_{c'} & N_c & N_v & N_{v'} \\ -N_{c'}\varepsilon_{c'}/\tilde{t}_k & -N_c\varepsilon_c/\tilde{t}_k & -N_v\varepsilon_v/\tilde{t}_k & -N_{v'}\varepsilon_{v'}/\tilde{t}_k \\ N_{c'}\varepsilon_{c'}/\tilde{t}_k & -N_c\varepsilon_c/\tilde{t}_k & N_v\varepsilon_v/\tilde{t}_k & -N_{v'}\varepsilon_{v'}/\tilde{t}_k \\ -N_{c'} & N_c & -N_v & N_{v'} \end{bmatrix}, \tag{10}$$

where

$$N_b^2 = \frac{|\tilde{t}_k|^2}{2[|\tilde{t}_k|^2 + \varepsilon_b^2]}\ ,\quad \tilde{t}_k^{-1} = \frac{e^{ik/2}}{2t\cos(k/2)}\ . \tag{11}$$

In the above the column refers to the site, while the row to the level.

Instability

The interaction Hamiltonian H_{int} is written as

$$H_{\text{int}} = \frac{1}{4}\sum_{ijkl}\sum_{\alpha\beta\gamma\delta} \Gamma_{\alpha\beta\gamma\delta}^{ijkl}\, a_{i\alpha}^+ a_{j\beta}^+ a_{k\gamma} a_{l\delta}, \tag{12}$$

where Γ is the bare vertex part:

$$\Gamma_{\alpha\beta\gamma\delta}^{ijkl} = \langle i_\alpha j_\beta | k_\gamma l_\delta\rangle \delta_{\alpha\delta}\delta_{\beta\gamma} - \langle i_\alpha j_\beta | l_\delta k_\gamma\rangle \delta_{\alpha\gamma}\delta_{\beta\delta}, \tag{13}$$

with

$$\langle i_\alpha j_\beta\, | k_\beta l_\alpha\rangle = \int d r_1\, d r_2 \phi_{i\alpha}^*(r_1)\phi_{j\beta}^*(r_2) V(r_1, r_2)\phi_{k\beta}(r_2)\phi_{l\alpha}(r_1)\,. \tag{13a}$$

In order to consider the phase transition, we take into account only of v (the highest valence) and c (the lowest conduction) bands. Thus we obtain

$$\begin{aligned}
H_{int} = \frac{1}{4}\sum_{p_1p_2p_3p_4} \delta(p_1+p_2, p_3+p_4)[&\Gamma_{\alpha\beta\gamma\delta}^{vvvv} a_{vp_1\alpha}^+ a_{vp_2\beta}^+ a_{vp_3\gamma} a_{vp_4\delta} \\
&+ \Gamma_{\alpha\beta\gamma\delta}^{vvcc} a_{vp_1\alpha}^+ a_{vp_2\beta}^+ a_{cp_3\gamma} a_{cp_4\delta} \\
&+ 2\Gamma_{\alpha\beta\gamma\delta}^{vcvc} a_{vp_1\alpha}^+ a_{cp_2\beta}^+ a_{vp_3\gamma} a_{cp_4\delta} + (v\leftrightarrow c)].
\end{aligned} \tag{14}$$

Γ's are given by

$$\begin{aligned}
\Gamma_{\alpha\beta\gamma\delta}^{vvvv} &= \Gamma_{\alpha\beta\gamma\delta}^{cccc} = g_1(\delta_{\alpha\delta}\delta_{\beta\gamma} - \delta_{\alpha\gamma}\delta_{\beta\delta}), \\
\Gamma_{\alpha\beta\gamma\delta}^{vvcc} &= \Gamma_{\alpha\beta\gamma\delta}^{ccvv} = g_2(\delta_{\alpha\delta}\delta_{\beta\gamma} - \delta_{\alpha\gamma}\delta_{\beta\delta}), \\
\Gamma_{\alpha\beta\gamma\delta}^{vcvc} &= \Gamma_{\alpha\beta\gamma\delta}^{cvcv} = g_3\delta_{\alpha\delta}\delta_{\beta\gamma} - g_4\delta_{\alpha\gamma}\delta_{\beta\delta},
\end{aligned} \tag{15}$$

with

$$\begin{aligned}
g_1 &= \langle vv|vv\rangle = \langle cc|cc\rangle, \\
g_2 &= \langle vv|cc\rangle = \langle cc|vv\rangle, \\
g_3 &= \langle vc|vc\rangle = \langle cv|cv\rangle, \\
g_4 &= \langle vc|cv\rangle = \langle cv|vc\rangle.
\end{aligned} \tag{16}$$

Since two-body collisions near the Fermi surface play an important role, we have, in the above, constant matrix elements at the Fermi surface. For example, g_1 is given by

$$g_1 = \int d r_1 d r_2 \phi_{vk_F}^*(r_1)\phi_{vk_F}^*(r_2) V(r_1, r_2)\phi_{vk_F}(r_2)\phi_{vk_F}(r_1)\,, \tag{17}$$

where ϕ_{vk_F} is a single-particle wave function for the valence band at the Fermi surface. As will be seen in the following, electrons near Fermi level localize almost at the 1- or 4-site. Therefore it is expected that electrons passing along edges of skeleton are strongly influenced by the polarized side chains around the spine (see Fig. 1). When $k=k_F=\pi$, Eq. 10 leads for ϕ_{vk} and ϕ_{ck} to

$$\begin{aligned}
\phi_{vk} &= 2^{-1/2}(\chi_{k1} - \chi_{k4}), \\
\phi_{ck} &= 2^{-1/2}(\chi_{k1} + \chi_{k4}),
\end{aligned} \tag{18}$$

where χ_{k1} is the Fourier transform of the Wanier function at site-1 of n-th cell. Namely,

$$\begin{aligned}
\phi_{vk} &= (2L)^{-1/2}\sum_n (x_{n1} - x_{n4})\, e^{ikn}, \\
\phi_{ck} &= (2L)^{-1/2}\sum_n (x_{n1} + x_{n4})\, e^{ikn}.
\end{aligned} \tag{19}$$

Moreover we neglect all differential overlaps. As a result, Eq. 17 turns out to be

$$\begin{aligned}
g_1 &= \frac{1}{(2L)^2}\int d r_1 d r_2 \sum_{m,n} V(r_1, r_2) \\
&\quad \times [\,|x_{m1}(r_1)|^2 + |x_{m4}(r_1)|^2\,][\,|x_{n1}(r_2)|^2 + |x_{n4}(r_2)|^2\,] \\
&= \frac{1}{(2L)^2}\sum_{m,n}(V_{m1,n1} + V_{m1,n4} + V_{m4,n1} + V_{m4,n4})\,.
\end{aligned} \tag{20}$$

Each matrix element depends on the difference, $m-n$, so that we give

$$\begin{aligned}
g_1 &= \frac{1}{2L}\sum_n (V_{01,n1} + V_{01,n4}), \\
g_2 &= \frac{1}{2L}\sum_n (V_{01,n1} - V_{01,n4}), \\
g_3 &= \frac{1}{2L}\sum_n (V_{01,n1} - V_{01,n4}), \\
g_4 &= \frac{1}{2L}\sum_n (V_{01,n1} + V_{01,n4}).
\end{aligned} \tag{21}$$

Let us denote that[4]

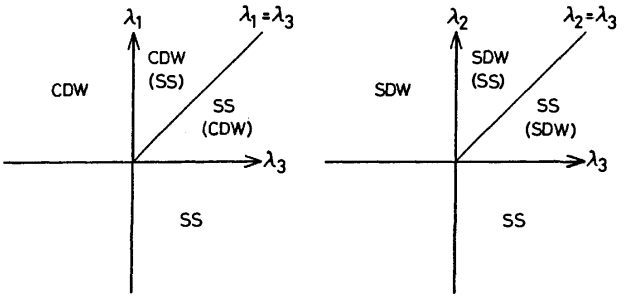

Fig. 3. Phase diagrams for polyacene.

$$\lambda_1 = -g_2 - 2g_3 + g_4,$$
$$\lambda_2 = g_2 + g_4,$$
$$\lambda_3 = -g_1 - g_2. \tag{22}$$

In the previous paper,[4] we have derived the phase diagram versus λ_1, λ_2, and λ_3 on the basis of simple mean field theory as shown in Fig. 3. Positive values of them correspond to appearance of CDW, SDW, and the singlet superconductivity (SS) phases, respectively. The figure suggests that the most possible ordered phase has the largest positive value of λ. Although the theory neglects the interference between various singular channels, we tentatively apply this result to the discussion about the model proposed by Little. In the following sections we calculate these parameters numerically.

Effective Interaction

The screening effect for the electron-electron interaction in the spine near the Fermi surface by electrons in the spine and in the polarized side chains is treated by the perturbation method as shown in Fig. 4. The double wavy line describes the effective interaction, $\tilde{V}_{\text{eff}}$, and the sigle wavy line the bare interation, V_{bare}. For V_{bare}, we adopt the Nishimoto-Mataga potential:

$$V_{\text{bare}} = \frac{14.40}{R_{rs}(n) + 1.33}\ (\text{eV}), \tag{23}$$

where $R_{rs}(n)$ is the distance from r-site of 0-th cell to s-site of n-th cell (in the unit of Å). The calculations were carried out using the following units: the bond length of benzene, 1.4 Å, for distances and the absolute value of the transfer integral, 2.5 eV, for energies. The shaded part of Fig. 4 displays the proper polarization part which includes various processes. We approximate it by the first two diagrams as shown in Fig. 4.

The Dyson equation for $\tilde{V}_{\text{eff}}$ is an integral equation in the coordinate space and is difficult to solve, but is easily manipulated in the momentum space. We take the Fourier transform of $V_{0r,ns} = V_{rs}(n)$ as

$$V_{rs}(n) = \frac{1}{L}\sum_k e^{ikn} v_{rs}(k) \tag{24}$$

and its inverse transform is

$$v_{rs}(k) = \sum_{n=-N}^{N} e^{-ikn} V_{rs}(n). \tag{25}$$

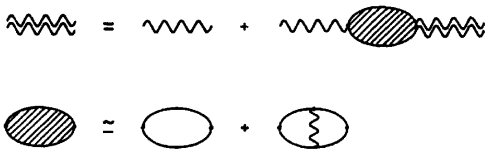

Fig. 4. The Dyson equation for electron-electron interaction and the approximation for the polarization part.

Thus the effective interaction is written in k pace as

$$\tilde{v}(k) = [1 - v(k)\Pi(k)]^{-1} v(k), \tag{26}$$

where $\tilde{v}$ and v are the effective and bare potentials, respectively. Note that each term is a matrix with respect to the atomic sites in the unit cell. We divide this into two parts, P and Q. The former refers to the spine and the latter to the side chain. Then Eq. 26 becomes[6]

$$\begin{bmatrix} \tilde{v}_{PP} & \tilde{v}_{PQ} \\ \tilde{v}_{QP} & \tilde{v}_{QQ} \end{bmatrix} = \left\{1 - \begin{bmatrix} v_{PP} & v_{PQ} \\ v_{QP} & v_{QQ} \end{bmatrix} \begin{bmatrix} \Pi_{PP} & \Pi_{PQ} \\ \Pi_{QP} & \Pi_{QQ} \end{bmatrix}\right\}^{-1} \begin{bmatrix} v_{PP} & v_{PQ} \\ v_{QP} & v_{QQ} \end{bmatrix}. \tag{27}$$

In order to proceed further, we assume $\Pi_{PQ} = \Pi_{QP} = 0$, which implies that the charge transfer between the spine and the side chain is neglected, i.e., there is a single bond between them. Thus we get

$$\tilde{v}_{PP} = [1 - v_{PP}\Pi_{PP} - v_{QP}\Pi_{QQ}(1 - v_{QQ}\Pi_{QQ})^{-1} v_{QP}\Pi_{PP}]^{-1} \times [v_{PP} + v_{PQ}\Pi_{QQ}(1 - v_{QQ}\Pi_{QQ})^{-1} v_{QP}]. \tag{28}$$

If we restrict ourselves to retain the first order term with respect to Π_{QQ}, we get

$$\tilde{v}_{\text{Little}} = (1 - v_{PP}\Pi_{PP})^{-1} v_{PP} + v_{PQ}\Pi_{QQ}v_{QP}, \tag{29}$$

which is the Little's approximation.[6]

If we employ the random phase approximation for the proper polarization part, Π, which is given by the ring diagram in Fig. 4 and denoted by Π^0, it follows that

$$\Pi^0_{sr}(k, \omega) = 2\int \frac{d\nu}{2\pi i} \frac{1}{L}\sum_q G_{sr}(k+q, \omega+\nu) G_{rs}(q, \nu). \tag{30}$$

Using the representation diagonalizing the Hamiltonian (5) and carrying out the integration, we can get

$$\Pi^0_{sr}(k, \omega) = \frac{4}{L}\sum_q \sum_b^{un} \sum_{b'}^{occ} \frac{\langle s|b, k+q\rangle\langle b, k+q|r\rangle\langle r|b', q\rangle\langle b', q|s\rangle}{\omega - \varepsilon_b(k+q) + \varepsilon_{b'}(q)}. \tag{31}$$

In the above, we consider the symmetry property of each band to the Fermi surface. In carrying out the summation with respect to q we make a small cut-off around the Fermi momentum, because electrons in this small region are responsible for the instabilities associated with phase transitions.

In order to improve the random phase approximation for the polarization part, we take into accout the oyster diagram, the second one in the right hand side

of Fig. 4. This involves four Green's functions in the integral the calculation of which requires enormous machine time. Then we are obliged to use an approximation in which the bare electron-electron interaction is restricted only to the one-center type. Thus we get

$$\Pi^1_{sr}(k) = \frac{-1}{2}\sum_t \Pi^0_{st}(k)\, v_{tt}(k)\, \Pi^0_{tr}(k)\,. \qquad (32)$$

It is said that this approximation amounts to 70—80% of the full contribution.[8]

In the following, we use the static approximation, as with $\omega=0$ in Eq. 31.

Side Chain

Since, in the present case, the polarization of the side chain plays a role of the phonon part in the ususal superconductor, it is crucial to choose a suitable side chain. We proceed our consideration along the Salem's idea.[9]

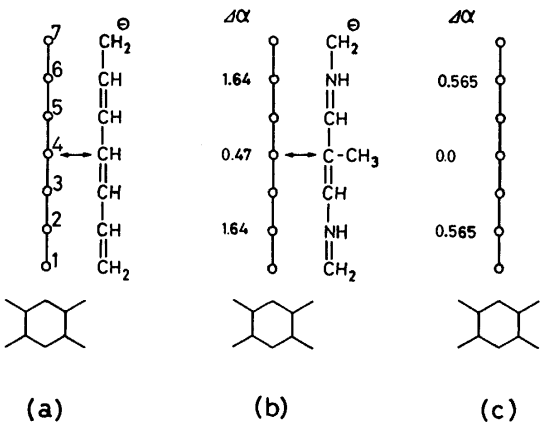

Fig. 5. Side chains. $\delta\alpha_s$ is given in the unit t. (a) Unoptimized, (b) optimized by Salem, and (c) optimized perturbatively.

As the simplest case, we take a dye molecule which is, as shown in Fig. 5a, a conjugated hydrocarbon with eight π-electrons and seven atomic sites. In this molecule, the polarization spreads all over the molecule, so that it is not so effective to reduce the electron-electron interaction on the spine. In order to make it efficient, one can introduce some substituents. Due to the well known symmetry properties of the alternant hydrocarbon, the nonbonding molecular orbital, say the 4-th one in this case, has vanishing amplitude on the even-numbered sites (called the unstarred sites). Even if we put substituents on these sites, this orbital is not affected. Therefore we can design these substituents so that the transition amplitude to the next higher level, which is expected to be most effective for polarization, shall be considerably small except for the both molecular ends.

Following this idea, Salem has obtained the one shown in Fig. 5b, exactly in the frame-work of the Hückel theory. Note that this is not unrealistic from the experimental view-points.

What mentioned above is well understood by the elementary perturbation theory, too.[7] A small perturbation at s-th site, $\delta\alpha_s$ changes the amplitude, $\langle r|i\rangle$ to $\langle r|\tilde{i}\rangle$ as

$$\langle r|\tilde{i}\rangle = \langle r|i\rangle + \sum_{j,s} \frac{\langle r|j\rangle\langle j|s\rangle\delta\alpha_s\langle s|i\rangle}{\varepsilon_i - \varepsilon_j}\,, \qquad (33)$$

where r refers to the site except the two ends, s to unstarred one and i to the lowest vacant level. The optimizing condition for the substituents is found by putting the left hand side of Eq. 33 equal to zero. The coditions obtained by the perturbation analysis are more general but less accurate than the Salem's ones. $\delta\alpha_4=0$ at the beginning, then we obtain a result given in Fig. 5c.

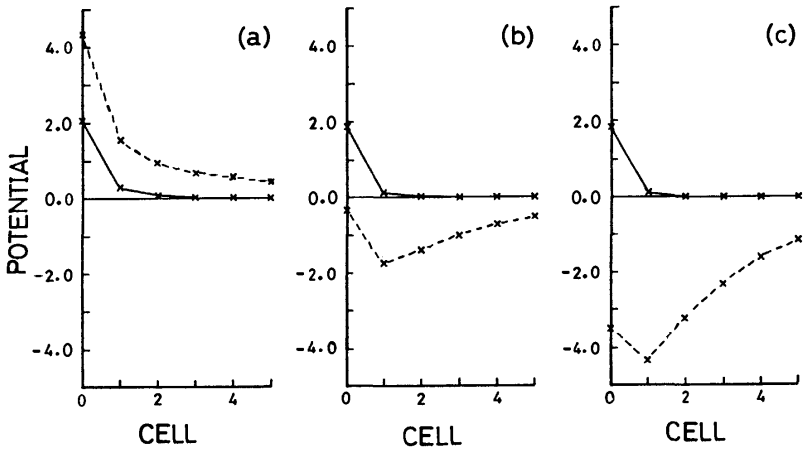

Fig. 6. The screened potential for various cases. (a) Only the spine. Dotted line is for the bare interaction and the solid line for the screened one. (b) The spine with unoptimized side chains. (c) The spine with optimized side chains by Salem. In the cases of (b) and (c), the dotted lines refer to the Little's approximation, and the solid ones to ours. For all cases, the cut-off is 0.01.

Results and Discussion

We should like to mention a little about the numerical procedures. Our final object is to get the coupling constants g_1—g_4. Since these (see Eq. 21) are the components with $k=0$ in the momentum representation, we can get them as the simple sums of coupling constants in the space representation, of course, the latters being renormalized. Suppose that we use two hundred cells in the practical calculation. Since each cell contains four atomic sites, the procedure for getting the screening effect becomes a problem of 800×800 matrix manipulation. This is considerably tedious. In the momentum space, one needs 200 4×4 matrix manipulations. In order to evaluate each term in the right hand side of Eq. 21, the inverse-Fourier transform is used.

The values of $V_{1,1}(n)$ thus obtained are shown in Fig. 6. In Fig. 6a, the screened potential (the solid line) decays very fast and becomes almost zero at the next neighbor cell. This result contrasts with that obtained by Schug et al.[10] They calculated the screened potential for $C_{57}H_{59}$ molecule only within the random phase approximation and obtained the potential which is screened in short-range region but is enhanced in long range region. This shows that for the screening effect in conjugated molecules the Π^1 effect is impotant as well as the Π^0 one. The Little's approximation (dotted lines in Figs. 6b and c) tells us that the side chain works very well to get attractive interactions, while in our higher approximation (solid lines) the potential is not attractive. The modification for the side chain does not affect the behavior qualitatively.

The above trends are shown in more detail in Table 1. It is noted that results are almost independent of cut-off parameters. In the table, every case has two lines, the upper is carried out by including Π^0 only, while the lower by including Π^0 and Π^1. The Π^1 effect is not so significant. Look at the final group. Little's approximation suggests the spine be superconducting at 900 K or higher. But our more elaborate calculation denies his conclusion. As to the side chain effect, the first order effect which is described by the Little's approximation for the polarization part in the side chain gives a considerable effect to the spine, but the higher order effects which are something like the back flows, cancel the first order effect.

We have made several trials for the shape of the side chains, e.g., some networks of the above mentioned side chains, which are constructed by introducing appropriate transfers between them. However, everything has been in vain to make the potential attractive.

Finally, our result is shown in Table 2 for the case of the spine with unoptimized side chains (other models also give qulitatively the same results.). Present result predicts that the SS state is not likely since $\lambda_3<0$ and the SDW state is more favorable than the CDW state since $\lambda_2>\lambda_1$.

Table 2. The Coupling Parameters

g_1	g_2	g_3	g_4	λ_1	λ_2	λ_3
0.059	0.004	0.004	0.059	0.046	0.063	−0.063

These are calculated for the case of the spine with unoptimized side chains. For the treatment of the side chain polarization, of course, ours is adopted. The cut-off parameter is 0.010.

Table 1. Possibility of Superconducting State

(Received June 20, 1988)

The electron-electron interaction which is crucial in determining whether new phases will arise or not in polyacene is investigated by means of the renormalization group. This approach is valuable to effectively include, from the view-point of the group theory, the higher order diagrams not taken into account in the random phase approximation of the previous work. It is found that there is a range of coupling constants where the singlet superconducting phase without simultaneous CDW ordering can be expected.

In the previous papers,[1] we have treated the electron-electron interactions in polyacene from the view-point of the random phase approximation. The system under consideration is, concretely speaking, composed of the one-dimensional polyacene skeleton (called spine) with suitable side chains. These are composed of, for instance, the dye molecules with several carbon atoms and several π-electrons.

The mechanism of phase change in our case is manipulated in terms of the highest valence band (v) and the lowest conduction band (c). The electron-electron interactions in these bands are treated to be screened as follows. We must consider two sources of screening. One is due to the excitation from the lower valence bands to the higher conduction bands inside the spine. The other is due to the excitation in the side chain. The former plays a role to reduce the long range Coulomb repulsion to a short range potential, while the latter produces attractive interaction in the spine. We assume that these two mechanisms of screening can be treated independently. In order to make the superconductivity advantageous, we attempt to optimize the side chain composition in the following manner. Replacing the carbon in the side chain by nitrogen, or replacing hydrogen by a suitable substituent group, we can make the transition amplitude between the highest occupied and lowest vacant orbitals as large as possible. This procedure leads possibly to the largest attractive interaction in the spine as expected.

Thus we might conclude that the superconducting phase be possible in this system, though an anxiety that other phases of CDW or SDW ordering overwhelm the superconducting phase remains.

As is mentioned above, the screening effect inside the spine is independent of that of the side chain, so that interference between them is disregarded. This last phenomenon seems to work unfavorably for the screening. One of the traditional approaches relies on the random phase approximation. It adopts only the ring diagrams, treating that various processes of scattering channels independently. In order to make up for these imperfections, we employ the method of renormalization group,[2,3] as one of the exellent techniques to consider the interfering channels self consistently.

This method will be, in a considerably detail, explained in Appendix and expressed in a form suitable for the present problem. Here we outline the result, which is enough to proceed with the following analysis.

The Dyson equation is invariant under a multiple renormalization of Green's function and coupling parameter (see Eq. A.3). Due to this invariance a complicated scaling procedure leads to a concept of the invariant coupling satisfying a functional equation,

$$\tilde{g}_i(y, u, g)=\tilde{g}_i(y/t, u/t, \tilde{g}(t, u, g)), \tag{1}$$

where y and u are parameters with the dimension of energy, and g is the set of original couplings, $\{g_i\}$. In order to provide practical facilities, Eq. 1 is translated to a differential equation,

$$y\frac{\partial}{\partial y}\tilde{g}_i(y,u,g)=\frac{\partial}{\partial \xi}\tilde{g}_i(\xi, u/y, \tilde{g}(t,u,g))|_{\xi=1}. \tag{2}$$

To solve the above equation, we begin with estimating the right-hand side of Eq. 2 by means of the perturbation theory. Then, if $\tilde{g}_i$ is obtained as a solution of Eq. 2, it must satisfy the group theoretical condition of the renormalization group. We can convince that through this procedure the renormalized coupling parameters are improved better than in the simple random phase approximation. These in turn provide various response functions within the same renormalization scheme.

$$y\frac{\partial}{\partial y}\ln \Lambda(y,u,g)=\frac{\partial}{\partial \xi}\ln \Lambda(\xi, u/y, \tilde{g}(y,u,g))|_{\xi=1}, \tag{3}$$

where Λ is the external vertex.

Invariant Coupling, Application to the Case of Polyacene

Preliminarily, we observe the singular behaviour of the perturbation series in the case of polyacetylene and compare it with that of polyacene, which plays an important role in discussing the ground state of the

systems. As is well known,[4,5] the terms in the perturbation series which become divergently large as the temperature is lowered are, in the case of polyacetylene:

$$\begin{aligned}&\text{I.}\quad g\ln(T/D),\ \{g\ln(T/D)\}^2,\ \cdots,\ \{g\ln(T/D)\}^n,\ \cdots,\\ &\text{II.}\quad g^2\ln(T/D),\ g\{g\ln(T/D)\}^2,\ \cdots,\\ &\text{III.}\quad g^3\ln(T/D),\ g^2\{g\ln(T/D)\}^2,\ \cdots,\\ &\cdots\cdots,\end{aligned}\tag{4}$$

where D is the band width of the conducting π-electrons. The series I is the most divergent terms, II and III, $\cdots$ being the next and further lower divergent terms. Similar behaviours of the perturbation series are well-known in another field of physics, e.g., in the case of the Kondo effect[6,7] and QED.[2] If we take into account only the most divergent series (I), the summation of series diverges at the mean-field critical temperature, T_c. If we do the next divergent series (II), the sum diverges only at the temperature of absolute zero.[5] This aspect is consistent with the theorem of absence of any phase change in a purely one-dimensional system at a finite temperature.

In the case of polyacene, however, the divergent series are not logarithmic but are classified as[1]

$$\begin{aligned}&\text{I.}\quad g(T/t)^{-1/2},\ \cdots,\ \{g(T/t)^{-1/2}\}^n,\ \cdots,\\ &\text{II.}\quad g^2(T/t)^{-1/2},\ \cdots,\ g\{g(T/t)^{-1/2}\}^n,\ \cdots,\\ &\cdots\cdots.\end{aligned}\tag{5}$$

The divergent character of this series are governed by the power law thus stronger than in the case of polyacetylene. The perturbation calculation based on the above classification becomes less accurate than the logarithmic problem. However, the renormalization group theory is still a convenient method to improve the perturbation method and obtain a qualitatively correct result.

It is noted that the most divergent series arises only in the correction of the vertex function, Γ. Zeroth order vertices are given by,[1]

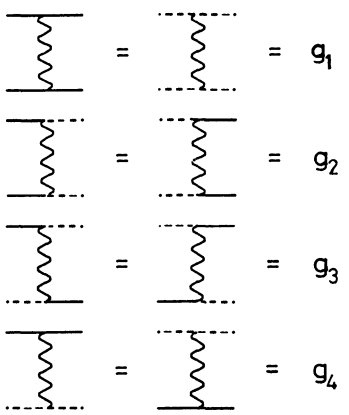

Fig. 1. Various electron–electron scattering amplitudes. The solid line represents the v-state, the dotted line the c-state and the wavy line the electron–electron interaction.

$$\begin{aligned}\Gamma^{(0)vvvv}_{\alpha\beta\gamma\delta}&=g_1(\delta_{\alpha\delta}\delta_{\beta\gamma}-\delta_{\alpha\gamma}\delta_{\beta\delta}),\\ \Gamma^{(0)vvcc}_{\alpha\beta\gamma\delta}&=g_2(\delta_{\alpha\delta}\delta_{\beta\gamma}-\delta_{\alpha\gamma}\delta_{\beta\delta}),\\ \Gamma^{(0)vcvc}_{\alpha\beta\gamma\delta}&=2(g_3\delta_{\alpha\delta}\delta_{\beta\gamma}-g_4\delta_{\alpha\gamma}\delta_{\beta\delta}),\end{aligned}\tag{6}$$

where v and c denote valence and conduction bands lying closest to the Fermi surface, respectively. α—δ are spin indices. The electron-electron interactions g_1—g_4 are shown schematically in Fig. 1.

The complete vertex function, Γ is defined in terms of the two-particle Green's function as

$$\begin{aligned}&G^{II}_{\alpha\beta\gamma\delta}(x_1,x_2,x_3,x_4)\\ &=-<T\psi_\alpha(x_1)\psi_\beta(x_2)\psi^+_\gamma(x_3)\psi^+_\delta(x_4)S>_{conn}\\ &=G_{\alpha\gamma}(x_1,x_3)G_{\beta\delta}(x_2,x_4)-G_{\alpha\delta}(x_1,x_4)G_{\beta\gamma}(x_2,x_3)\\ &\quad+\int dx_{1'}-dx_{4'}\sum_{\alpha'\beta'\gamma'\delta'}G_{\alpha\alpha'}(x_1,x_{1'})G_{\beta\beta'}(x_2,x_{2'})\\ &\quad\times\Gamma_{\alpha'\beta'\gamma'\delta'}(x_{1'},x_{2'},x_{3'},x_{4'})G_{\gamma'\gamma}(x_{3'},x_3)G_{\delta'\delta}(x_{4'},x_4),\end{aligned}\tag{7}$$

where $G_{\alpha\alpha'}$ is the electron propagator and

$$G_{\alpha\alpha'}=\delta_{\alpha\alpha'}G.\tag{8}$$

As the lowest order correction, the renormalized Γ involves the contributions described by (a)—(j) in Fig. 2. Here we present in detail, as an example, a derivation of (a) type correction in Fig. 2: Consider the second order term in the expansion of S in Eq. 7, and take the constructions which give the diagram of Fig. 2(a). Then, we have

$$\begin{aligned}&\delta G^{II}(p_1,p_2,p_3,p_4)\\ &=-\frac{1}{2}\left(-\frac{1}{4}\right)^2\int dt'dt'\Gamma^{(0)vvvv}_{\alpha'\beta'\gamma'\delta'}\Gamma^{(0)vvvv}_{\alpha''\beta''\gamma''\delta''}\\ &\quad\times<Ta_{vp_1\alpha}(t_1)a_{vp_2\beta}(t_2)\\ &\quad\times a^+_{vp_1'\alpha'}(t')a^+_{vp_2'\beta'}(t')a_{vp_3'\gamma'}(t')a_{vp_4'\delta'}(t')\\ &\quad\times a^+_{vp_1''\alpha''}(t'')a^+_{vp_2''\beta''}(t'')a_{vp_3''\gamma''}(t'')a_{vp_4''\delta''}(t'')\\ &\quad\times a^+_{vp_3\gamma}(t_3)a^+_{vp_4\delta}(t_4)>\end{aligned}\tag{9}$$

$$\begin{aligned}&=\frac{1}{2}\int dt'dt''\Gamma^{(0)vvvv}_{\alpha\beta\gamma'\delta'}\Gamma^{(0)vvvv}_{\alpha'\beta'\gamma\delta}\delta_{\alpha'\gamma'}\delta_{\beta'\delta'}\\ &\quad\times G_{vq_1}(t'-t'')G_{vq_2}(t'-t'')\\ &\quad\times G_{vp_1}(t_1-t')G_{vp_2}(t_2-t')G_{vp_3}(t''-t_3)G_{vp_4}(t''-t_4).\end{aligned}\tag{9a}$$

In Eq. 9, the summation with respect to primed variables are implied. The unprimed momentum variables are subjected to the condition of the conservation. In order to get Eq. 9a four procedures (i)—(iv) are needed. (i) Two annihilation operators representing incoming lines are combined with the succeeding creation operators to yield propagators. (ii) The last four propagators yield propagators similarly. These four propagators expressed in the last line of Eq. 9a correspond to the external four lines in Fig. 2(a). (iii) The two propagators with momenta, q_1 and q_2 are constructed from the remaining four operators (The summation with respect to q_1 and q_2 is also omitted for simplicity.). (iv)

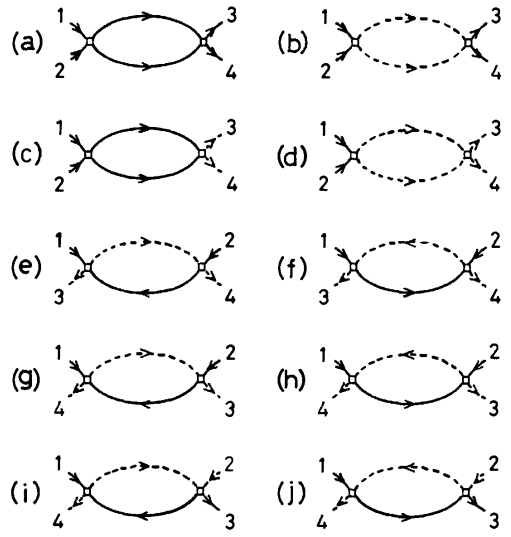

Fig. 2. Various second order corrections to Γ.

The equivalent terms are counted in following manner. The procedures (i)—(iii) are doubly possible, and further we can exchange wholly the singly primed terms for the doubly primed terms. These four procedures result in yielding sixteen equivalent terms. If we insert, in the integrand, $\delta(t_{2'}-t_{1'})$ together with an integration with respect to $t_{2'}$, we can arrange Eq. 9a in the form of Eq. 7, obtaining

$$\Gamma^{vvvv}_{\alpha\beta\gamma\delta}(a) = \frac{1}{2} T\sum G_v(q_1)G_v(q_2)\Gamma^{(0)vvvv}_{\alpha\beta\alpha'\beta'}\Gamma^{(0)vvvv}_{\alpha'\beta'\gamma\delta}$$
$$= -(\delta_{\alpha\delta}\delta_{\beta\gamma}-\delta_{\alpha\gamma}\delta_{\beta\delta})g_1^2\Pi^{vv} \tag{10a}$$

where, for example, q_1 denotes both frequency and momentum in short.

Other contributions denoted by Fig. 2 (b)—(j) are given in the following:

$$\Gamma^{vvvv}_{\alpha\beta\gamma\delta}(\mathrm{b}) = \frac{1}{2} T\sum G_c(q_1)G_c(q_2)\Gamma^{(0)vvcc}_{\alpha\beta\alpha'\beta'}\Gamma^{(0)cc\,vv}_{\alpha'\beta'\gamma\delta}$$
$$= -(\delta_{\alpha\delta}\delta_{\beta\gamma}-\delta_{\alpha\gamma}\delta_{\beta\delta})g_2^2\Pi^{vv}, \tag{10b}$$

$$\Gamma^{vvcc}_{\alpha\beta\gamma\delta}(\mathrm{c}) = \frac{1}{2} T\sum G_v(q_1)G_v(q_2)\Gamma^{(0)vvvv}_{\alpha\beta\alpha'\beta'}\Gamma^{(0)vvcc}_{\alpha'\beta'\gamma\delta}$$
$$= -(\delta_{\alpha\delta}\delta_{\beta\gamma}-\delta_{\alpha\gamma}\delta_{\beta\delta})g_1g_2\Pi^{vv}, \tag{10c}$$

$$\Gamma^{vvcc}_{\alpha\beta\gamma\delta}(\mathrm{d}) = \frac{1}{2} T\sum G_c(q_1)G_c(q_2)\Gamma^{(0)vvcc}_{\alpha\beta\alpha'\beta'}\Gamma^{(0)vvvv}_{\alpha'\beta'\gamma\delta}$$
$$= -(\delta_{\alpha\delta}\delta_{\beta\gamma}-\delta_{\alpha\gamma}\delta_{\beta\delta})g_1g_2\Pi^{vv}, \tag{10d}$$

$$\Gamma^{vvcc}_{\alpha\beta\gamma\delta}(\mathrm{e}) = \frac{1}{2} T\sum G_c(q_1)G_v(q_2)\Gamma^{(0)vvcc}_{\alpha\gamma'\gamma\beta'}\Gamma^{(0)vcvc}_{\beta\beta'\gamma'\delta}$$
$$= -\frac{1}{2}\{g_2g_3\delta_{\alpha\gamma}\delta_{\beta\delta}+g_2g_4(\delta_{\alpha\delta}\delta_{\beta\gamma}-\delta_{\alpha\gamma}\delta_{\beta\delta})\}\Pi^{vc}, \tag{10e}$$

$$\Gamma^{vvcc}_{\alpha\beta\gamma\delta}(\mathrm{f}) = \Gamma^{vvcc}_{\alpha\beta\gamma\delta}(\mathrm{e}), \tag{10f}$$

$$\Gamma^{vvcc}_{\alpha\beta\gamma\delta}(\mathrm{g}) = \frac{1}{2} T\sum G_c(q_1)G_v(q_2)\Gamma^{(0)vvcc}_{\alpha\gamma'\delta\beta'}\Gamma^{(0)vcvc}_{\beta\beta'\gamma'\gamma}$$
$$= \frac{1}{2}\{g_2g_3\delta_{\alpha\delta}\delta_{\beta\gamma}-g_2g_4(\delta_{\alpha\delta}\delta_{\beta\gamma}-\delta_{\alpha\gamma}\delta_{\beta\delta})\}\Pi^{vc}, \tag{10g}$$

$$\Gamma^{vvcc}_{\alpha\beta\gamma\delta}(\mathrm{h}) = \Gamma^{vvcc}_{\alpha\beta\gamma\delta}(\mathrm{g}), \tag{10h}$$

$$\Gamma^{vcvc}_{\alpha\beta\gamma\delta}(\mathrm{i}) = T\sum G_v(q_1)G_c(q_2)\Gamma^{(0)vvcc}_{\alpha\beta'\alpha'\delta}\Gamma^{(0)vvcc}_{\alpha'\beta\gamma\beta'}$$
$$= g_2^2\delta_{\alpha\gamma}\delta_{\beta\delta}\Pi^{vc}, \tag{10i}$$

$$\Gamma^{vcvc}_{\alpha\beta\gamma\delta}(\mathrm{j}) = T\sum G_c(q_1)G_v(q_2)\Gamma^{(0)vcvc}_{\alpha\beta'\alpha'\delta}\Gamma^{(0)vcvc}_{\alpha'\beta\gamma\beta'}$$
$$= \{2g_3(g_3-g_4)\delta_{\alpha\delta}\delta_{\beta\gamma}+g_4^2\delta_{\alpha\gamma}\delta_{\beta\delta}\}\Pi^{vc}, \tag{10j}$$

It can be shown that Γ's given in the above equations depend not only on frequency and momentum of the external line but also on temperature in general. But if every momentum and frequency concerned are much smaller than temperature, Γ's are allowed to be functions only of temperature. We are concerned with this special case in the following analysis. Whence

$$\Pi^{vv} = -\Pi^{vc} \equiv L(T) \tag{11}$$

with

$$L(T) = \frac{Z}{2(tT)^{1/2}} - \frac{1}{2\pi t p_c}, \tag{12}$$

where

$$Z = \frac{1}{(2\pi)^{1/2}}\int_0^\infty \frac{dx}{x^{1/2}\cosh^2 x}. \tag{13}$$

In Eq. 12, p_c is the cut off momentum which is smaller than the Fermi momentum (namely $tp_c \fallingdotseq t$). If temperature is smaller than any of the other variables, T in Eqs. 11 and 12 must be understood as the largest of them. At $T \fallingdotseq t$, we can see

$$L(T) \fallingdotseq 0. \tag{14}$$

Contrariwise, we should in advance adjust p_c so that Eq. 14 is held. As the contribution from the region, $|p|>p_c$, is nonsingular, we can start with the initial coupling parameter g.

Thus we can express the coupling terms, corresponding to those in Eq. 6, as

$$\Gamma^{vvvv}_{\alpha\beta\gamma\delta} = g_1\Gamma_1(\delta_{\alpha\beta}\delta_{\beta\gamma}-\delta_{\alpha\gamma}\delta_{\beta\delta}),$$
$$\Gamma^{vvcc}_{\alpha\beta\gamma\delta} = g_2\Gamma_2(\delta_{\alpha\beta}\delta_{\beta\gamma}-\delta_{\alpha\gamma}\delta_{\beta\delta}),$$
$$\Gamma^{vcvc}_{\alpha\beta\gamma\delta} = g_3\Gamma_3\delta_{\alpha\delta}\delta_{\beta\gamma}-g_4\Gamma_4\delta_{\alpha\gamma}\delta_{\beta\delta}. \tag{15}$$

In Table 1, we have tabulated the contributions of Fig. 2(a)—(j).

For the sake of convenience, we express every g_i in unit of the transfer integral t:

$$g_i/t \to g_i. \tag{16}$$

Then we have

$$L(T) \to \frac{Z}{2}\sqrt{t/T} - \frac{1}{2\pi}\sqrt{t/D} \tag{17}$$

$L(T)$ vanishes at $T=t$ as required by Eq. 14. The condition leads to

$$D = t/(\pi Z)^2. \tag{18}$$

If we remember $D=tp_c^2$, the above requirement determines the cut-off parameter p_c. For the later conven-

Table 1. Coupling Terms Versus Diagrams

$g\Gamma$	Diagram	Contribution	Total
$g_1\Gamma_1$	(a)	$-g_1^2L(T)$	$-(g_1^2+g_2^2)L(T)$
	(b)	$-g_2^2L(T)$	
$g_2\Gamma_2$	(c)	$-g_1g_2L(T)$	$g_2(-2g_1-g_3+2g_4)L(T)$
	(d)	$-g_1g_2L(T)$	
	(e)	$-g_2(g_3-2g_4)L(T)$	
	(f)		
	(g)		
	(h)		
$g_3\Gamma_3$	(j)	$-2g_3(g_3-g_4)L(T)$	$-2g_3(g_3-g_4)L(T)$
$g_4\Gamma_4$	(i)	$g_2^2L(T)$	$(g_2^2+g_4^2)L(T)$
	(j)	$g_4^2L(T)$	

ience, it is better to introduce a parameter κ to rewrite Eq. 17 as

$$L(T)=\frac{1}{2\pi}\{\sqrt{t/(\kappa T)}-\sqrt{t/D}\}, \tag{19}$$

with

$$L(t)=0. \tag{20}$$

Now we try to get the invariant coupling $\tilde{g}_i$. As long as we work within the most divergent approximation, the Green's functions are not renormalized (d=1 in Eq. A.4). But the electron-electron interaction should be:

$$\bar{g}_i=g_i\Gamma_i(y, u, g) \tag{21}$$

where, as mentioned in the previous section,

$$y=T/\lambda,\ u=t/\lambda. \tag{22}$$

As to g_1, consulting Table 1, we have

$$\bar{g}_1=g_1-(g_1^2+g_2^2)L(y, u, g) \tag{23}$$

with

$$L(y, u, g)=\frac{1}{2\pi}\{\sqrt{u/(\kappa y)}-\sqrt{u/u'}\}, \tag{24}$$

where

$$u'=D/\lambda. \tag{25}$$

Thus we have an explicit expression for the differential equation of the renormalization group, Eq. 2. Its right-hand side is

$$\begin{aligned}&\frac{\partial}{\partial\xi}\tilde{g}_1(\xi, u/y, \tilde{g}(y, u, g))\\&=\frac{\partial}{\partial\xi}[\tilde{g}_1-(\tilde{g}_1^2+\tilde{g}_2^2)\frac{1}{2\pi}\{\sqrt{(u/y)/(\kappa\xi)}-\sqrt{u/u'}\}]|_{\xi=1}\\&=\frac{1}{4\pi}\sqrt{u/(\kappa y)}\,(\tilde{g}_1^2+\tilde{g}_2^2).\end{aligned} \tag{26}$$

Then Eq. 2 becomes

$$y\frac{\partial}{\partial y}\tilde{g}_1=\frac{1}{4\pi}\sqrt{u/(\kappa y)}\,(\tilde{g}_1^2+\tilde{g}_2^2). \tag{27}$$

Transforming the variable as

$$\frac{1}{2\pi}\sqrt{u/(\kappa y)}=x, \tag{28}$$

we can rewrite Eq. 27 as

$$\frac{\partial}{\partial x}\tilde{g}_1=-(\tilde{g}_1^2+\tilde{g}_2^2). \tag{29}$$

Similar procedures are applicable to $\tilde{g}_2$—$\tilde{g}_4$ to lead to

$$\frac{\partial}{\partial x}\tilde{g}_2=\tilde{g}_2(-2\tilde{g}_1-\tilde{g}_3+2\tilde{g}_4), \tag{30}$$

$$\frac{\partial}{\partial x}\tilde{g}_3=-2\tilde{g}_3(\tilde{g}_3-\tilde{g}_4), \tag{31}$$

$$\frac{\partial}{\partial x}\tilde{g}_4=\tilde{g}_2^2+\tilde{g}_4^2 \tag{32}$$

Instabily in Polyacene, Renormalization of the External Vertex

The external vertices in the case of polyacene are corrected, up to the first order of H_{int}, as[1]

$$\begin{aligned}&\Lambda_1=1+(-g_2-2g_3+g_4)L(T),\\&\Lambda_2=1+(g_2+g_4)L(T),\\&\Lambda_3=1-(g_1+g_2)L(T),\end{aligned} \tag{33}$$

where Λ_1 refers to CDW, Λ_2 to SDW, and Λ_3 to the singlet superconductivity (SS). If we use Eq. 33 for Λ_i of the right-hand side of Eq. 3, it follows that within the most divergent approximation

$$\Lambda_1(\xi, u/y, \tilde{g}(y, u, g))=1+(-\tilde{g}_2-2\tilde{g}_3+\tilde{g}_4)L(\xi, u/y), \tag{34}$$

and from Eq. 24

$$L(\xi, u/y)=\frac{1}{2\pi}\{\sqrt{u/(\kappa y)}-\sqrt{u/u'}\}. \tag{35}$$

Since we have set L as Eq. 14, it is seen that

$$L(1, u/y)=0, \tag{36}$$

or from Eq. 35

$$L(1, u/y)=\frac{1}{2\pi}\{\sqrt{u/(\kappa y)}-\sqrt{u/u'}\}. \tag{37}$$

Thus Eq. 3 becomes

$$y\frac{\partial}{\partial y}\ln\Lambda_1=\frac{1}{4\pi}\sqrt{u/(\kappa y)}\,(\tilde{g}_2+2\tilde{g}_3-\tilde{g}_4). \tag{38}$$

Changing the variables as in Eq. 28, we get

$$\frac{\partial}{\partial x}\ln\Lambda_1=-\tilde{g}_2-2\tilde{g}_3+\tilde{g}_4. \tag{39}$$

In a similar way, we have

$$\frac{\partial}{\partial x}\ln\Lambda_2=\tilde{g}_2+\tilde{g}_4, \tag{40}$$

$$\frac{\partial}{\partial x}\ln\Lambda_3=-\tilde{g}_1-\tilde{g}_2. \tag{41}$$

Relations obtained in Eqs. 29—32 and in Eqs. 39—41 are the same as those obtained by Kimura and Mishima[8] by means of the parquet diagram sum.

Finally we should like to add a few comments about approximations employed in the present treatment. The typical higher order corrections not taken into

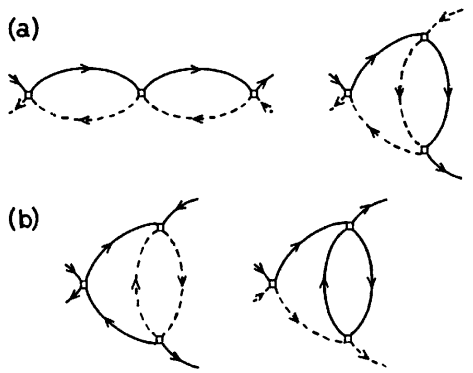

Fig. 3. Typical higher order corrections to Γ.

consideration can be expressed diagrammatically as shown in Figs. 3(a) and (b). The diagrams in Fig. 3(a) involve Π^{vc} twice (called overlap divergence), but those in Fig. 3(b) only once. Therefore, their contributions are proportional to $g^3L^2(T)$ in the former and are proportional to $g^3L(T)$ in the latter. If we use these diagrams to evaluate the right-hand side of Eq. 1, we obtain (with some constants, a and b)

$$\frac{\partial}{\partial\xi}\{\cdots + a\tilde{g}^3L^2(\xi, u/y, g) + b\tilde{g}^3L(\xi, u/y, g)\}|_{\xi=1}$$
$$= 2a\tilde{g}^3L(1, n/y, g)\frac{\partial}{\partial\xi}L(\xi, u/y, g)|_{\xi=1}$$
$$+ b\tilde{g}^3\frac{\partial}{\partial\xi}L(\xi, u/y, g)|_{\xi=1}. \tag{42}$$

Here we use Eq. 36 to get

$$\text{Eq. 42} = b\tilde{g}^3\frac{\partial}{\partial\xi}L(\xi, u/y, g)|_{\xi=1}. \tag{43}$$

Namely, the terms of overlap divergence, g^nL^m ($m\geqq 2$) have no effect on the renormalization equation (Eq. 1). These have been implicitly taken into account when the elementary divergent term ($\propto L$) is input as an initial term.

Next, we examine the approximation arising from the condition that the cut-off parameter p_c is set so that the relation (36) is held. The polarization part is expressed more exactly as

$$\Pi^{vv} = \int_{-\pi}^{\pi}\frac{dq}{2\pi}\frac{1}{2\varepsilon_q^v}\tanh\frac{\varepsilon_q^v}{2T}$$
$$\equiv L(T) + L'(T), \tag{44}$$

where

$$L(T) = \int_{-p_c}^{p_c}\frac{dq}{2\pi}\frac{1}{2\varepsilon_q^0}\tanh\frac{\varepsilon_q^0}{2T} \tag{45}$$

with

$$\varepsilon_p^0(\doteqdot\varepsilon_p^v) = tp^2, \tag{46}$$

and the residual part, L' is analyzed as

$$L'(T) = \int_{-\pi}^{\pi}\frac{dq}{2\pi}\frac{1}{2\varepsilon_q^v}\tanh\frac{\varepsilon_q^v}{2T} - \int_{-p_c}^{p_c}\frac{dq}{2\pi}\frac{1}{2\varepsilon_q^0}\tanh\frac{\varepsilon_q^0}{2T}$$
$$= \int_{-p_c}^{p_c}\frac{dq}{2\pi}\left(\frac{1}{2\varepsilon_q^v}\tanh\frac{\varepsilon_q^v}{2T} - \frac{1}{2\varepsilon_q^0}\tanh\frac{\varepsilon_q^0}{2T}\right)$$
$$+ 2\int_{p_c}^{\pi}\frac{dq}{2\pi}\frac{1}{2\varepsilon_q^v}\tanh\frac{\varepsilon_q^v}{2T}. \tag{47}$$

We can see that from the above expression, L' is regular and a slowly varying function with respect to T. Therefore, since it might be possible for us to choose g, at the beginning, so as to include the effect from L', Π in Eq. 44 is well approximated only by $L(T)$.

Solutions of Renormalization Equation

Our basic equations to look for the low-temperature phases are Eqs. 29—32 for g_i's, and Eqs. 39—41 for Λ_i's.

First, we observe that the equations are invariant under the transformations

$$\tilde{g}_i\to\lambda\tilde{g}_i,\ x\to x/\lambda, \tag{48}$$

where λ is an arbitrary constant.

The initial condition for $\tilde{g}_i$'s and Λ_i's is given at temperature $T=t$

$$\tilde{g}_i = g_i, \text{ and } \Lambda_i = 1, \tag{49}$$

according to Eq. 14. Because of the transformation property, Eq. 48, any solution for a given set of the values of g_i can be scaled into the solutions for another set of initial values λg_i.

We can obtain an analytic solution for Eqs. 29—32 only for the special case of $g_2=0$.

$$\tilde{g}_1 = \frac{1}{x + g_1^{-1}},$$
$$\tilde{g}_2 = 0,$$
$$\tilde{g}_3 = \frac{\tilde{g}_4^2}{2\tilde{g}_4 - Cg_4},$$
$$\tilde{g}_4 = \frac{-1}{x - g_4^{-1}}, \tag{50}$$

where

$$C = 2 - \frac{g_4}{g_3}. \tag{51}$$

Substituting the above into Eqs. 39—41, we obtain

$$\Lambda_1 = \frac{1}{Cg_3x + 1},$$
$$\Lambda_2 = \frac{-1}{g_4x - 1},$$
$$\Lambda_3 = \frac{1}{g_1x + 1}. \tag{52}$$

The phase diagrams corresponding to the case are shown in Figs. 4(a) and (b).

For the case of $g_2\neq 0$, the renormalization equations must be solved numerically. The resulting phase diagrams are shown in Figs. 4(c)—(i).

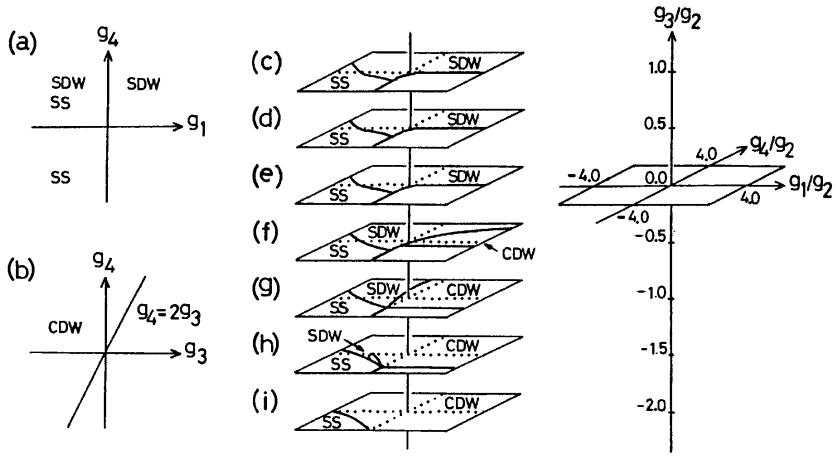

Fig. 4. Phase diagrams for various sets of g_j. (a) and (b): Those for the case of $g_2=0$. (c)—(i): Those for $g_2\neq 0$, and g_3/g_2 is 1.0, 0.5, 0.0, −0.5, −1.0, −1.5, and −2.0, respectively. The coordinate axis for them is shown on their right.

Conclusion

We have discussed the phase diagrams of the polyacene molecules in the framework of renormalization group theory within the most divergent approximation. Under this approximation the instability of the normal electronic state appears at a finite temperature.

Here, we must add some arguments for the justification of the present method. One may take a skeptical view about the validitiy of our results, considering that the renormalization group method is applicable only to a logarithmic singularity but not to a power low case. Indeed, the applications of this method thus far worked out have been fully successful for logarithmic problems.[2-5] However, we stress that the procedure to obtain the fundamental renormalization group equations is not grounded on or restricted within the logarithmic behaviour of the perturbation series, as reviewed in Appendix at some length. In the present problem, the singular terms in the perturbation series for the coupling constants are of the form

$$\tilde{g}=g+Ag^2L+Bg^3L^2+Cg^3L+\cdots, \tag{53}$$

where L is given by Eq. 19 and A, B, and C are constants. In our present analysis, we have taken only the second term of the right hand side of Eq. 53. The next order perturbation will give the third and fourth terms. The third B-term belongs to the most singular class, but does not contribute to the renormalization group equation due to the condition, Eq. 20. The effect has been included in the resultant solutions of that equation. Therefore, an overcounting of divergent diagrams does not occur. The situation is the same as in the logarithmic case. Thus the present results are justifiable within the most divergent approximation. A practical difficulty will arise to obtain the less divergent series, the C and further terms. As discussed in Ref. 1, the next divergent terms would lower the transition temperature to the absolute zero and shift the phase boundary to some extent. The correct estimation of these higher order terms is hard to manipulate because of the stronger singularity in the present problem than the logarithmic case.

The most divergent approximation gives correctly the behaviour of the dominant instabilities in the temperature region higher than the mean field transition temperatre. As for the phase diagram the present results are considered to be reliable at least qualitatively. In usual one-dimensional metals, it was found that superconductivity and CDW tend to appear simultaneously for the negative backward scattering. In the present case, however, the result shows that there is a wide range where nagative constants lead to only the superconductivity phase. In this respect the present system is expected to be more suitable to design for superconductivity.

In conclusion, the electron-electron interaction can lead to various type of ordered phases in the ground state. Such a variety of ordered phases has been observed in recent experiments about conducting organic materials such as TTF-TCNQ and BEDT-TTF where the states of superconductivity, CDW and SDW are mutually correlated and competing. Our result sheds some light on these phenomena. In this connection, we note the overlapping or adjacent appearance of superconducting and SDW states in our phase diagram, which has been discussed as the paramagnon effect in usual texts. By using the renormalization group method within g-ology, we can predict what kind of phase occurs for given interaction parameters. In the present paper, we have considered the interaction constants on the spine as parameters, which are influenced by various complex effects such as the screening by the σ-electron on the spine of polyacene and possibly, the interaction through the side-chain which may be synthesized with various

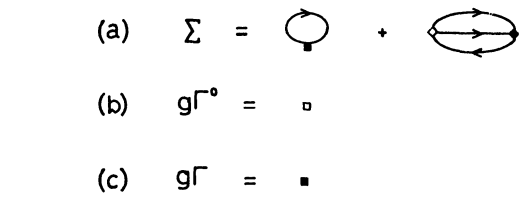

Fig. 5. Diagrammatic expressions for the self-energy and vertices. (a) Self-energy. (b) Bare vertex. (c) Full vertex.

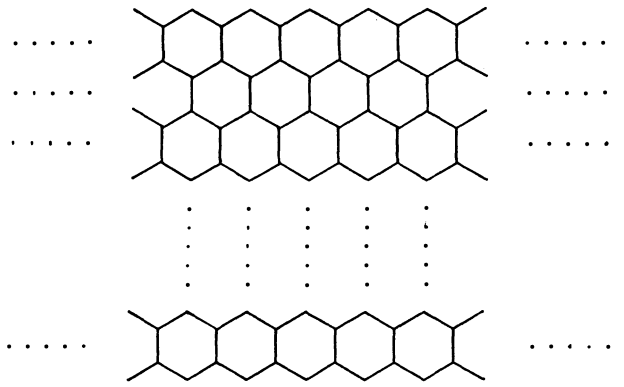

Fig. 6. Polyacene carbone skeleton.

designs. Therefore we can hope to get any phases in the ground state, if side-chains are suitably modified. The problem to analyze the effective interactions including a screening effect and an excitonic processes was discussed in our separate paper.[9]

As pointed earlier,[1,10] the π-electron energy spectrum is similar for polymers with a bridged array of an arbitrary number of polyacene skeletons (Fig. 6), i.e., the conduction- and valence bands are degenerate (or almost degenerate) at the points $k=\pm\pi$. The present theory applies equally to such a system. In the limit of an infinite number of such skeletons, however, the polymer tends to be system with a planar carbon lattice. Even in this two-dimensional lattice the degeneracy of two bands remains, but the one dimensional van Hove singularity as treated here disappears, so that $T^{-1/2}$ singularity will be weakened to the one of ln T. For the latter case many of the qualitative features of the present results remain unaltered. The detailed analysis will be reported elsewhere.

Appendix. Renormalization Group

In this appendix we reformulate the renormalization equations used in the text in a form suitable for the present analysis.[2,3] The Dyson equation for the Green's function G is written symbolically as

$$G=G^0+G^0\Sigma G, \tag{A. 1}$$

which is a matrix notation, and G^0 is for one without interaction. The self-energy part, Σ is

$$\Sigma=g\Gamma G+g\Gamma^0GGGg\Gamma, \tag{A. 2}$$

and it can be expressed diagrammatically as shown in Fig. 5(a), where we extract the coupling g from the vertex part, say, the bare vertex, $g\Gamma^0$ and the full vertex, $g\Gamma$ corresponds to Figs. 5(b) and (c), respectively.

Relations (A. 1) and (A. 2) are invariant under the multiple renormalization such as

$$G \to \frac{1}{Z_1}G, \quad G^0 \to \frac{1}{Z_1}G^0,$$

$$\Gamma_i \to \frac{1}{Z_{i,2}}\Gamma_i, \quad \Gamma_i^0 \to \frac{1}{Z_{i,2}}\Gamma_i^0,$$

$$g_i \to Z_1^2 Z_{i,2} g_i, \tag{A.3}$$

where the index i refers to the i-th element.

The Green's function G is formally written as

$$G(p) = \frac{d(p)}{\varepsilon - \varepsilon_p}, \tag{A.4}$$

for which the transformation (A. 3) is interpreted in such manner,

$$d(T/\lambda_2,\ t/\lambda_2, g_{\lambda_2}) = \frac{1}{Z_1} d(T/\lambda_1, t/\lambda_1, g_{\lambda_1}). \tag{A.5}$$

Strictly speaking, G and Γ depend on quantities with the dimension of energy, i.e., on ε, ε_p, T (temperature) and t (transfer integral). However, we note explicitly only T and t.

We are allowed to set, without loss of generality, as

$$d(1,\ t/\lambda,\ g_\lambda)=1. \tag{A. 6}$$

Then, putting $T=\lambda_2$ in Eq. A. 5, we get

$$Z_1=d(\lambda_2/\lambda_1,\ t/\lambda_1,\ g_{\lambda_1}), \tag{A. 7}$$

and similarly

$$\Gamma_i(T/\lambda_2, t/\lambda_2, g_{\lambda_2}) = \frac{1}{Z_{i,2}}\Gamma_i(T/\lambda_1, t/\lambda_1, g_{\lambda_1}). \tag{A.8}$$

Putting $T=\lambda_2$ in Eq. A. 8, we obtain

$$Z_{i,2} = \frac{\Gamma_i(\lambda_2/\lambda_1, t/\lambda_1, g_{\lambda_1})}{\Gamma_i(1, t/\lambda_2, g_{\lambda_2})}. \tag{A.9}$$

Relations (A. 7) and (A. 9) enable us to lead

$$g_{i,\lambda_2} = g_{i,\lambda_1} d^2(\lambda_2/\lambda_1, t/\lambda_1, g_{\lambda_1}) \frac{\Gamma_i(\lambda_2/\lambda_1, t/\lambda_1, g_{\lambda_1})}{\Gamma_i(1, t/\lambda_2, g_{\lambda_2})}. \tag{A.10}$$

What we want to prove is invariant character of the right-hand side of Eq. A. 10 under a scale transformation. To this end, inserting Eq. A. 7 into Eq. A. 5, and also Eq. A. 8 into Eq. A. 9, we obtain

$$d(T/\lambda_2,\ t/\lambda_2,\ g_{\lambda_2}) = \frac{d(T/\lambda_1, t/\lambda_1, g_{\lambda_1})}{d(\lambda_2/\lambda_1, t/\lambda_1, g_{\lambda_1})}, \tag{A.11}$$

$$\frac{\Gamma_i(T/\lambda_2, t/\lambda_2, g_{\lambda_2})}{\Gamma_i(1, t/\lambda_2,\ g_{\lambda_2})} = \frac{\Gamma_i(T/\lambda_1, t/\lambda_1, g_{\lambda_1})}{\Gamma_i(\lambda_2/\lambda_1, t/\lambda_1, g_{\lambda_1})}. \tag{A.12}$$

Here we put

$$\Gamma_i(1, t/\lambda, g_\lambda)=1. \tag{A. 13}$$

This assumption is not always necessary, but will be met in practical cases. From Eqs. A. 11 and A. 12, we obtain

$$d^2(T/\lambda_2,\ t/\lambda_2,\ g_{\lambda_2})\,\Gamma_i(T/\lambda_2,\ t/\lambda_2,\ g_{\lambda_2}) \times d^2(\lambda_2/\lambda_1,\ t/\lambda_1,\ g_{\lambda_1})\,\Gamma_i(\lambda_2/\lambda_1,\ t/\lambda_1,\ g_{\lambda_1}) g_{i,\lambda_1} = g_{i,\lambda_1} d^2(T/\lambda_1,\ t/\lambda_1,\ g_{\lambda_1})\Gamma_i(T/\lambda_1,\ t/\lambda_1,\ g_{\lambda_1}). \tag{A. 14}$$

If we use Eq. A. 10 in the left-hand side of Eq. A. 14, we have

$$g_{i,\lambda_2}d^2(T/\lambda_2, t/\lambda_2, g_{\lambda_2})\Gamma_i(T/\lambda_2, t/\lambda_2, g_{\lambda_2}) = g_{i,\lambda_1}d^2(T/\lambda_1, t/\lambda_1, g_{\lambda_1})\Gamma_i(T/\lambda_1, t/\lambda_1, g_{\lambda_1}). \quad \text{(A. 15)}$$

This relation is nothing but the invariant character which we have intended to show. We call the above quantity the *invariant coupling*:

$$\bar{g}_i(T/\lambda, t/\lambda, g_\lambda) = d^2(T/\lambda, t/\lambda, g_\lambda)\Gamma_i(T/\lambda, t/\lambda, g_\lambda)g_{i,\lambda}. \quad \text{(A. 16)}$$

Now introducing new variables:

$$y = T/\lambda_1, \quad u = t/\lambda_1, \quad t = \lambda_2/\lambda_1, \quad \text{(A. 17)}$$

we get from Eq. A. 15,

$$\begin{aligned}\bar{g}_i(y, u, g) &= d^2(y, u, g)\Gamma_i(y, u, g)g_i \\ &= d^2(y/t, u/t, g_{\lambda_2})\Gamma_i(y/t, u/t, g_{\lambda_2})g_{i,\lambda_2}, \quad \text{(A. 18)}\end{aligned}$$

where we put

$$g_{\lambda_1} = g. \quad \text{(A. 19)}$$

Since we can rewrite g_{i,λ_2} in Eq. A. 18, by the use of Eq. A. 10, as

$$\begin{aligned}g_{i,\lambda_2} &= g_i d^2(t, u, g)\Gamma_i(t, u, g) \\ &= \bar{g}_i(t, u, g), \quad \text{(A. 20)}\end{aligned}$$

substituting this into Eq. A. 18, we can obtain

$$\bar{g}_i(y, u, g) = d^2(y/t, u/t, \tilde{g}(t, u, g))\Gamma_i(y/t, u/t, \tilde{g}(t, u, g)) \times \tilde{g}_i(t, u, g). \quad \text{(A. 21)}$$

Observing Eq. A. 16, we can rewrite the above as

$$\bar{g}_i(y, u, g) = \bar{g}_i(y/t, u/t, \tilde{g}_i(t, u, g)). \quad \text{(A. 22)}$$

This is a really beautiful functional equation.

In view of a practical use, a form of differential equation is preferable: Differentiating Eq. A. 22 with respect to y, followed by putting $t=y$, we obtain

$$y\frac{\partial}{\partial y}\tilde{g}_i(y,u,g) = \frac{\partial}{\partial \xi}\tilde{g}_i(\xi, u/y, \tilde{g}(y,u,g))\,|_{\xi=1} \quad \text{(A.23)}$$

with the boundary condition, Eq. A. 19. In order to get $\bar{g}_i$ through Eq. A. 23, we begin with calculating $\tilde{g}$ in the right-hand side by the perturbation method. Then solving the differential equation Eq. A. 23, we get $\bar{g}_i$ being improved to be invariant under the operations of the renormalization group.

Another differential equation satisfying $\tilde{g}_i$ is obtained by differentiating Eq. A. 22 with respect to t, followed by putting $t=1$:

$$\left\{y\frac{\partial}{\partial y} + u\frac{\partial}{\partial u} - \sum_j \frac{\partial \tilde{g}_j(t,u,g)}{\partial t}|_{t=1}\frac{\partial}{\partial g_j}\right\}\tilde{g}_i(y,u,g) = 0\,. \quad \text{(A.24)}$$

Similar treatments are possible for d and Γ. From Eqs. A. 11, A. 12, and A. 13 we obtain

$$d(y, u, g) = d(y/t, u/t, \tilde{g}(t, u, g))d(t, u, g) \quad \text{(A. 25)}$$

and

$$\Gamma_i d(y, u, g) = \Gamma_i(y/t, u/t, \tilde{g}(t, u, g))\Gamma_i(t, u, g). \quad \text{(A. 26)}$$

If we differentiate logarithms of both side of Eq. A. 26 with respect to t, and then put $t=y$, the results are

$$y\frac{\partial}{\partial y}\ln d(y,u,g) = \frac{\partial}{\partial \xi}\ln d(\xi, u/y, \tilde{g}(y,u,g))\,|_{\xi=1} \quad \text{(A.27)}$$

and

$$y\frac{\partial}{\partial y}\ln \Gamma_i(y,u,g) = \frac{\partial}{\partial \xi}\ln \Gamma_i(\xi, u/y, \tilde{g}(y,u,g))\,|_{\xi=1}\,. \quad \text{(A.28)}$$

An entirely analogous analysis will be done for the external vertices. These will be transformed, together with ones in Eq. A. 3, as

$$\Lambda_i \to \frac{1}{Z_{i,3}}\Lambda_i\,, \quad \text{(A.29)}$$

which is interpreted as a scale transformation:

$$\Lambda_i(T/\lambda_2, t/\lambda_2, g_{\lambda_2}) = \frac{1}{Z_{i,3}}\Lambda_i(T/\lambda_1, t/\lambda_1, g_{\lambda_1})\,. \quad \text{(A.30)}$$

In the same way as in Eq. A. 13, we assume

$$\Lambda_i(1, t/\lambda, g_\lambda) = 1. \quad \text{(A. 31)}$$

If we put $T=\lambda_2$ in Eq. A. 30, and use Eq. A. 31, it follows that

$$Z_{i,3} = \Lambda_i(\lambda_2/\lambda_1, t/\lambda_1, g_{\lambda_1}). \quad \text{(A. 32)}$$

Substituting this in Eq. A. 30, we obtain

$$\Lambda_i(T/\lambda_1, t/\lambda_1, g_{\lambda_1}) = \Lambda_i(T/\lambda_2, t/\lambda_2, g_{\lambda_2})\Lambda_i(\lambda_2/\lambda_1, t/\lambda_1, g_{\lambda_1}). \quad \text{(A. 33)}$$

By the use of Eqs. A. 17, A. 19, and A. 20, we can rewrite Eq. A. 33 as

$$\Lambda_i(y, u, g) = \Lambda_i(y/t, u/t, \tilde{g}(t, u, g))\Lambda_i(t, u, g). \quad \text{(A. 34)}$$

If we differentiate this with respect to y and put $t=y$, we obtain the result similar to Eqs. A. 27 and A. 28,

$$y\frac{\partial}{\partial y}\ln \Lambda_i(y, u, g) = \frac{\partial}{\partial \xi}\ln \Lambda_i(\xi, u/y, \tilde{g}(y,u,g))\,|_{\xi=1}\,. \quad \text{(A.35)}$$

We can easily realize the transformation characters given by Eqs. A. 3 and A. 29 by use of the perturbation expansions of the correponding quantities.

ESR Studies of Solvent and Pressure Effects on Spin Exchange of Nitroxide Radicals in Solution

Yoshimi SUEISHI,* Norio NISHIMURA, Koichi HIRATA,† and Keiji KUWATA†
Department of Chemistry, Faculty of Science, Okayama University, Okayama 700
†Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560
(Received April 12, 1988)

The rate constants of spin exchange for 2,2,6,6-tetramethyl-4-oxo-1-piperidinyloxyl (Tanone) in various solvents at high pressures were estimated from the line-broadening in ESR spectra. The rate constants of the spin exchange were in the range of 10^9—10^{10} M^{-1} s^{-1} and were compared with the calculated ones on the basis of the Smoluchowski-Stokes-Einstein equation. A significant disagreement between them was observed as the solvent viscosity decreased. The activation volumes estimated from the pressure dependence of the rate constant for the spin exchange were slightly smaller than those for diffusive processes. These findings suggest that the rate process for the spin exchange is virtually a diffusion-controlled one. An interpretation of activation volumes for diffusive process of spin exchange is given.

Recently, the usefulness of the examination of kinetic pressure effects has become recognized in mechanistic studies on the chemical reactions taking place near the diffusion-controlled limit. In particular, such studies have been made actively in the field of photochemistry. Interesting reports on the dynamic measurements of transient fluorescence for some exciplex-formation systems have been put forward,[1-3] and the mechanism of the exciplex-formation reaction has been explained in terms of diffusion-controlled encounters. The physical meaning of the activation volume which is formally obtained from the pressure dependence on the diffusion-controlled rate constants, however, has not yet been well established.

The rate constants of the spin exchange can be easily estimated from the line-broadening of ESR-spectra of radicals.[4] The spin exchange reaction can be regarded as a simplified model of a complex chemical reaction. Up to the present, few ESR studies at high pressures have been done, mainly due to the technical difficulty.

Plachy and Schaafsma[5] used a vessel containing a microwave helix and the field-modulation coils for the measurement of ESR signals at high pressures, and such a vessel can withstand pressures of several thousand atmospheres. It, however, is unsuitable for ESR measurements in polar solvents. Böddeker et al.[6] designed a high-pressure glass cell which could be pressurized to 405 bar.

In the present report, a study on the spin exchange reaction in the solvents of various polarities was carried out at various pressures using a newly designed high-pressure cell for ESR measurements. From the pressure dependence on the rate constant of the spin exchange the activation volumes were estimated, and the results were discussed on the basis of the volume change associated with diffusive processes.

Experimental

Materials. 2,2,6,6-Tetramethyl-4-oxo-1-piperidinyloxyl (Tanone) was purchased from Wako Pure Chemicals, and used without further purification. Toluene, acetone, 2-propanol, methanol, and nitrobenzene are of guaranteed grade and were purified in the usual manner.

High-Pressure ESR Cell. The high-pressure vessel, which is made of copper-beryllium alloy and equipped with a stop valve, is shown in Fig. 1. The sample cell for ESR measurements was composed of a Pyrex glass capillary and its top was bound to the high-pressure vessel by epoxy resin. The glass parts, which were hand-made in our laboratory, were sealed at an open end, annealed, and washed with the 5% aqueous hydrogen fluoride solution at room temperature. In preliminary tests, the cell was designed to be repeatedly pressurized up to 588 bar, however, it was broken at 883 bar as an example (1 bar=0.1 MPa).

Procedures. Pressures were generated by means of a plunger pump, and the pressure was measured by a Haise Bourdon gauge. The sample solution was purged by bubbling nitrogen for ca. 30 min and charged into the pressure cell under a nitrogen atmosphere. After a required pressure

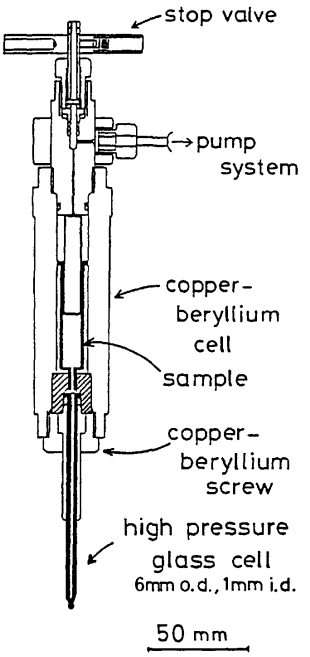

Fig. 1. High pressure cell for use in standard ESR spectrometer.

was established the stop valve was closed, and the pressure vessel separated from the pump system and placed in the ESR cavity.

ESR measurements were performed using a home-made X-band spectrometer with a 100-kHz field modulation. The peak-to-peak width of the central component of the hyperfine structure of the nitroxide radical was measured. The accuracy of the linewidth thus obtained was ±1.5%.

Results

Spin Exchange at High Pressures. The second-order rate constant k_e for the spin exchange process has been estimated easily from the dependence of line-broadening on the concentration of radicals.[4]

$$k_e = A(\Delta H - \Delta H_0)/C, \quad (1)$$

where ΔH_0/mT and ΔH/mT are linewidths in the absence and presence of spin exchange, respectively. C is a radical concentration. A is a constant and its value for the spin exchange of nitroxide radicals has been given to be 2.28×10^8 mT^{-1} s^{-1}.[4] The linear relationships between the linewidths ΔH and the concentrations of the Tanone radical in toluene at different pressures are shown in Fig. 2. This linear relationship shows that the spin exchange makes the major contribution to line-broadening in the concentration range from 10^{-3} to 10^{-2} M (1M=1 mol dm^{-3}) at high pressures as well as at 1 bar. Thus the rate constants k_e for the spin exchange of the Tanone radicals could be estimated by Eq. 1 in various solvents and those values are listed in Table 1.

In Fig. 3, the rate constants of the spin exchange are plotted against the applied pressures. Each plot is seen to be almost linear in the pressure range up to 588 bar. It is noted that the slope is positive in water due to the viscosity decrease with increase of pressure in this pressure range at 288 K (Table 1).

The second-order rate constant of the diffusive processes is given by the Smoluchowski expression,[7] namely

$$k_{diff} = 4\pi aD = (8000\,RT)(3\eta)^{-1}/M^{-1}\,s^{-1}, \quad (2)$$

where a is the sum of the radii of the diffusive molecules, D is the sum of the Stokes-Einstein diffusion

Water	288	1.40	4.57	1.91±0.10	1.35	4.74	2.21±0.07

a) The viscosities for toluene, 2-propanol, and methanol were estimated from the data at 30 and 75 °C according to $\ln\eta = A + B/T$, and the viscosity of water at 15 °C was estimated from the data at 0, 10.3, and 30 °C. The viscosity of nitrobenzene is the data at 30 °C. b) At 441 bar.

coefficients, and η/Pa·s is the viscosity coefficient of the medium. By this equation and using available data[8] for viscosity, k_{diff}-values were estimated and are given in Table 1.

Discussion

Spin Exchange of Tanone Radicals. As seen in Table 1, the rate constants k_e for the spin exchange in various solvents almost reach the diffusion-controlled limit k_{diff}. As far as our data are concerned, no correlation between the k_e-value and the dielectric constant ε of solvent is observed. This could be accepted when we recall that Tanone is not a polar species. The rate of the spin exchange, however, is invariably retarded by the increase in the solvent viscosity, as predicted by Eq. 2. The rate constant is plotted as a function of inverse viscosity in Fig. 4, where two remarkable features are seen. One is that k_e deviates more and more from that predicted for the diffusive process (Eq. 2) as the solvent viscosity decreases. Another is that the plots of k_e against inverse viscosity seem to fall roughly on a same curve irrespective of solvent, temperature, and pressure. These findings strongly indicate that the spin exchange is controlled by the diffusive processes. At a solvent viscosity $\eta>0.3$ mPa·s the discrepancy between the rate constants of the diffusion collisions calculated according to Eq. 2 and those obtained from the spin exchange amounts to about two-fold, which may be attributed to the discrepancy between the measured diffusion coefficient D[9,10] and the calculated one. At low viscosity $\eta<0.3$ mPa·s the large deviation may be due to transition into the region of weak exchange[4] as well as above.

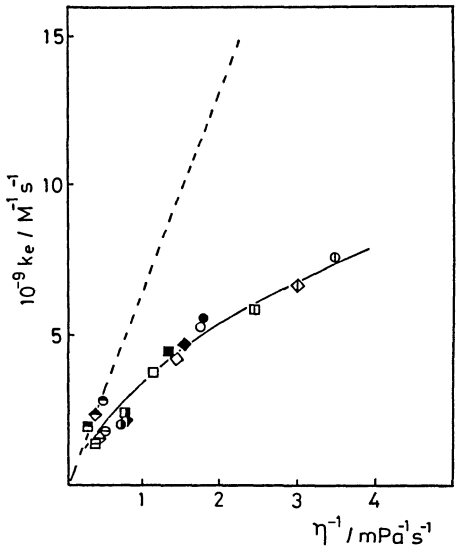

Fig. 4. Plots of k_e against η^{-1} in various solvents, and at various temperatures and pressures; ○ at 1 bar, ◇ at 288 bar, □ at 588 bar. Dashed line; calculated from Eq. 2. The key is shown in Fig. 3.

Comparison of $\Delta V^{\neq}_{obs}$ with $\Delta V^{\neq}_{diff}$. The solid lines in Fig. 3 represent the following linear regression equation.

$$\ln k_e = ap + b \tag{3}$$

The activation volumes $\Delta V^{\neq}_{obs}$ at 1 bar were estimated as

$$RT(\partial \ln k_e/\partial p)_T = aRT = -\Delta V^{\neq}_{obs} + \Delta n^{\neq} \kappa_T RT \tag{4}$$

where $\Delta V^{\neq}_{obs}$ is the partial molar volume change that occurs when a molecule passes from an initial state into a transition state, $\Delta n^{\neq}$ (=−1 in the present case) is the difference in number of species between the activated and initial states, and κ_T is the isothermal compressibility of the solvent. The values of $\kappa_T RT$ at 1 bar were calculated from available data.[8] The values of $\Delta V^{\neq}_{obs}$ are given in the third column of Table 2. The apparent activation volume for this process $\Delta V^{\neq}_{diff}$ can be calculated by

$$RT(\partial \ln k_{diff}/\partial p)_T = -RT(\partial \ln \eta/\partial p)_T = -\Delta V^{\neq}_{diff} - \kappa_T RT \tag{5}$$

The calculated values $\Delta V^{\neq}_{obs}$ are given in the fourth column of Table 2.

It is interesting to examine how $\Delta V^{\neq}_{obs}$ relates to $\Delta V^{\neq}_{diff}$. The observed activation volumes $\Delta V^{\neq}_{obs}$ were in the range from −7.6 to 15.4 $cm^3\ mol^{-1}$ and no systematic solvent dependency was observed (Table 2). On the other hand, the values of $\Delta V^{\neq}_{obs} - \Delta V^{\neq}_{diff}$ in Table 2 are small and all negative. The present values of $\Delta V^{\neq}_{obs} - \Delta V^{\neq}_{diff}$ seem to be classified with regard to viscosity of solvent and difference in solvation; $\Delta V^{\neq}_{obs} - \Delta V^{\neq}_{diff} \approx 0$ $cm^3\ mol^{-1}$ in aprotic solvents, −4.6 $cm^3\ mol^{-1}$ in acetone, a solvent of low viscosity, and ca.−4 $cm^3\ mol^{-1}$ in protic solvents. $\Delta V^{\neq}_{obs}$ in aprotic solvents (toluene and nitrobenzene) are almost equal to $\Delta V^{\neq}_{diff}$, indicating that the spin exchange in such solvents is governed by diffusion of the Tanone radicals. The relatively large difference between $\Delta V^{\neq}_{obs}$ and $\Delta V^{\neq}_{diff}$ was found in protic solvents (methanol, 2-propanol, and water). When we examined the relationship between $\Delta V^{\neq}_{obs}$ and $\Delta V^{\neq}_{diff}$ in protic solvents, a plot of $\Delta V^{\neq}_{obs}$ against $\Delta V^{\neq}_{diff}$ was found to be almost linear; a slope of 1.0±0.1 and intercept of −4.2±1.1. For reactions governed by a diffusive process, the slope and intercept are expected to be ca. 1 and ca. 0, respectively. An appar-

Table 2. Activation Volumes ($cm^3\ mol^{-1}$) for Spin Exchange of Tanone Radicals in Various Solvents

Solvent	T/K	$\Delta V^{\neq}_{obs}$	$\Delta V^{\neq}_{diff}$	$\Delta V^{\neq}_{obs} - \Delta V^{\neq}_{diff}$
Toluene	296	13.7±0.9	14.2	−0.5
Nitrobenzene	293	13.3±0.7	14.1	−0.8
Acetone	303	7.7±0.4	12.3	−4.6
2-Propanol	298	15.4±0.9	19.5	−4.1
Methanol	298	6.7±1.1	8.8	−2.1
Water	288	−7.6±0.4	−2.5	−5.1

ent disagreement between the intercept obtained in protic solvents and that expected for the diffusion-controlled reactions was found and this finding may be ascribed to specific solvation of alcohols to nitroxide radicals. In fact, the observations of large hyperfine coupling constants and g-values of nitroxide radical in protic solvents compared with those in aprotic solvents have been reported.[11] The present value (-4.6 cm^3 mol^{-1}) in acetone is probably to be attributed to weak exchange.[4]

Value of the Activation Volume for Diffusive Processes. Although $\Delta V^{\neq}_{\text{diff}}$ is formally obtainted from the pressure dependence of viscosity (Eq. 2), no clear-cut interpretation of its physical meanings has been put forward so far. In this section, we would like to try to explain the physical meanings of the activation volume of the diffusion process and to estimate its value.

According to the theory of rate processes,[12] the flow of a molecule in the liquid phase can be treated as a rate process. The jump of a molecule from its equilibrium site to the neighboring site is described as a passage over a potential energy surface. The number of times that a molecule passes over the barrier per second is given by

$$k=(kT/h)(q^{\neq}/q)\exp(-\varepsilon_0/kT), \tag{6}$$

where q's are the partition functions and the other notations have their usual meanings. If the passage is to occur, the generation of a hole is necessary, and the excavation of such a hole requires the expenditure of energy. According to this model,[12] the potential energy ε_0 can approximately be related to the viscosity coefficient η of the medium such as

$$\eta=(hL/V)(q/q^{\neq})\exp(\varepsilon_0/kT), \tag{7}$$

where L is the Avogadro number and V the partial molar volume of the molecule. Combining Eq. 6 with Eq. 7, k is given by

$$k=(RT/V)/\eta. \tag{8}$$

Thus the number of passages over the barrier is inversely proportional to η. If we tentatively set $\eta=10^{-3}$/Pa·s (the order of viscosities for most solvents under ordinary conditions), $V=10^{-4}$/m^3 mol^{-1}, and $RT=2.5\times10^3$/J mol^{-1}, then we have $k=2.5\times10^{10}$/s^{-1}, in a reasonable order of magnitude.

It follows from Eq. 8 that

$$RT(\partial \ln\eta/\partial p)_T=\kappa_T RT+\Delta V^{\neq}_{\text{diff}} \tag{9}$$

This is formally the same as Eq. 5. Thus the process for a particle to move from the initial state to the activated state is deduced to require two kinds of energies. The first term comes from the kinetic energy even for a point particle. On the theoretical basis, this term has been predicted[13,14] and has been verified recently.[15] For most liquids, $\kappa_T RT$ is an order of a few cm^3 mol^{-1}.

The second term is considered to be associated with the work to generate a hole as stated above. The volume of this hole is predicted to be a fraction of the molecular volume of the solvent.[12] This could be justified as follows: Let λ be the distance between two equilibrium positions in the direction of motion. The potential energy barrier is assumed to be symmetric. The distance between the initial and the activated state position is $\lambda/2$, thus the ratio of the volume of the molecule to that of the hole may be ca. 8 ($=\lambda^3/(\lambda/2)^3$). Therefore, the predicted $\Delta V^{\neq}_{\text{diff}}$-value is an order of 12—25 cm^3 mol^{-1} since the partial molar volume of most solvents are between 100 and 200 cm^3 mol^{-1}. This is in agreement with available data for $\Delta V^{\neq}_{\text{diff}}$ estimated from the pressure dependence of the viscosity.[2,3] It is noted that the reported $\Delta V^{\neq}_{\text{diff}}$-values are almost independent of the size of the diffusing molecules. For instance, the $\Delta V^{\neq}_{\text{diff}}$-values for the termination constants of free radical polymerization of vinyl monomers are between 13 and 21 cm^3 mol^{-1}.[16] In this case only work to make a hole for the terminal radical segment to move need be necessary.

Concluding Remarks

We estimated the rate constant for the spin exchange reaction of Tanone at high pressures by means of linewidth measurement. The rate was well correlated to the applied pressure. By comparing the rate constant and the activation volume with those for diffusive processes, the conclusion that the rate of the spin exchange is virtually governed by a diffusive process is given. An interpretation for the activation volume associated with the diffusive process is also given.

Potentiometric Studies on Sulfato Complex of Aluminium(III) in Aqueous Solution at Elevated Temperatures

Yoshiyuki MATSUSHIMA, Akio MATSUNAGA, Kazuhiro SAKAI, and Akitsugu OKUWAKI*
Department of Molecular Chemistry and Engineering, Faculty of Engineering, Tohoku University, Sendai 980
(Received April 1, 1988)

Equilibria in aluminium sulfate solutions with a 1 mol kg^{-1} KCl medium and low pH range have been investigated by means of acidity measurements with a hydrogen ion concentration cell from 25 to 125 °C. The results were treated with a nonlinear least squares computer program to analyze the equilibrium constants for aluminium complexes by using a single parameter type of Debye-Hückel equation. The log(K/mol^{-1} kg) values of the formation constant for the reaction, $Al^{3+}+SO_4^{2-} \rightleftarrows [AlSO_4]^+$ varied from 3.35 at 25 °C to 5.34 at 125 °C and were formulated as a function of temperature. The standard enthalpy and entropy of the complex formation computed from the variation of the formation constant with temperature are presented over the experimental temperature range. The species $[Al(SO_4)_2]^-$ was not detected under the present conditions.

Sulfate ion affects the hydrolysis and the precipitation of polyvalent metal ions considerably through complex formation at elevated temperatures and much evidence has been reported for the interaction of sulfate ion with metal ions such as aluminium(III)[1] and iron(III).[2]

Izatt et al. have reported a large number of formation constants for sulfato complexes at 25 °C as determined by calorimetry.[3] Those values become greater with the charge of metal ion.

However, those data are very limited even at moderate temperatures because the hydrolysis of metal ions is too complicated to allow satisfactory analysis of the equilibrium in the solution. Nikolaeva has measured the formation constants of sulfato complexes of bivalent metal ions up to 90 °C by the conductometric method.[4] With regards to tervalent metal ions, only Matijević et al. have investigated sulfato complexes of iron(III)[5] and aluminium(III)[6] ions up to 100 °C with respect to the preparation of monodispersed particles of the hydrous oxides of the metal ions.

At elevated temperatures, Marshall et al. studied the formation of $[MgSO_4]$[7] and $[CaSO_4]$[8] by solubility measurements.

Akitt and his co-workers have studied the complex formation in aqueous aluminium sulfate solution by aluminium-27 NMR spectroscopy.[9] The spectrum of aluminium sulfate solution contains two resonances, one due to the hexa-aqua cation and the other due to the inner sphere sulfato complex. This result showed direct evidence of the existence of sulfato complex of aluminium ion. Unfortunately, an increase in the temperature caused broadening of the two signals and prevented accurate measurements. In a previous study,[10] we have evaluated the second dissociation constant of sulfuric acid up to 200 °C using a hydrogen-ion concentration cell with a view to determining the formation constants for sulfato complexes of multivalent metal ions such as Al^{3+} and Fe^{3+}, because those values are especially important for quantitative analysis of the precipitation of nickel sulfide from the sulfate solutions and the removal of Fe^{3+} from the sulfate solutions at elevated temperatures.

The present study has been undertaken to determine the formation constant for sulfato complexes of aluminium ion in aluminium sulfate solutions using the hydrogen-ion concentration cell at elevated temperatures. It is favorable to study aluminium ion since the solubility of aluminium sulfate is relatively high even at elevated temperatures and aluminium hydrolysis products have been extensively studied.[11]

Experimental

Materials: All aluminium solutions were prepared by dissolving reagent grade aluminium chloride in dilute hydrochloric acid to suppress the hydrolysis of aluminium ion. The total concentration of aluminium ions was determined by back titration of an excess of EDTA with a standard Zn^{2+} solution. The total equivalent cation concentration was determined by using ion exchange resin Amberlite IR-120B(H) in the hydrogen form, followed by titration of the eluate with a 0.1 M (M=mol dm^{-3}) NaOH solution. A stock solution of a 0.1 M HCl was prepared from analytical grade hydrochloric acid diluted with doubly distilled water. Reagent grade KCl and K_2SO_4 were used without further purification. Ultrapure H_2 (99.99999%) was used.

Potentiometric Apparatus and Procedures: The hydrogen ion concentration cell is shown in Fig. 1. The apparatus and the procedure were first developed by Le Peintre[12] and later, Mesmer[13] and MacDonald[14] made similar measurements with some modifications. It consists of a titanium autoclave housing an outer glass beaker and an inner PTFE cup containing matched hydrogen electrodes. These two compartments were connected through the fluid phase by a porous PTFE disk,[10] and vapor space was interconnected via a 0.7 mm pin hole which allowed rapid pressure equilibration of hydrogen gas, yet was small enough to minimize the distillation of hydrochloric acid. The reversible hydrogen electrodes consisting of pure platinum were insulated from the autoclave body and were lightly platinized by electrolysis in a dilute solution of hexachloroplatinic acid before use. A porous PTFE disk (pore size, 0.2 μm; thickness 1 mm), which replaced air in the pores with a saturated KCl solution, was employed for the liquid junction. The treatment of the porous PTFE has been described previously.[10]

The cell representation is:

$$\mathrm{Pt},\ \mathrm{H_2}\ \left|\begin{array}{ll}\mathrm{AlCl_3} & (m_1)\\ \mathrm{HCl} & (m_2)\\ \mathrm{K_2SO_4} & (m_3)\\ \mathrm{KCl} & (m_5=1)\end{array}\right\|\left|\begin{array}{ll}\mathrm{HCl} & (m_4=0.001)\\ \mathrm{KCl} & (m_5=1)\end{array}\right|\ \mathrm{H_2},\ \mathrm{Pt} \qquad \text{(I)}$$

where m represents molality. The right hand (inner cup) of the cell (I) contains the reference electrode. Solution compositions in the test solutions are listed in Table 1. In order to suppress hydrolysis of aluminium ion, the test solutions were acidified (pH<3). The concentration of hydrochloric acid in the reference solution was 0.001 mol kg^{-1}. To minimize the liquid junction potential and to keep the ionic strength constant, KCl was added as a supporting electrolyte in both solutions (1 mol kg^{-1}).

After assembly the gas in the cell was exchanged by alternatively pressurizing it with hydrogen gas to 1.0 MPa and by venting it to an atmospheric pressure five times. Finally, the cell was pressurized to about 0.5 MPa with the hydrogen.

The entire autoclave was immersed in an oil bath. Potentials were measured successively from 25 to 125 °C at 25 °C intervals with a digital voltmeter and were recorded after they had reached a stable value within 0.1 mV for a few minutes.

1 mol kg^{-1} KCl as a supporting electrolyte.

Results and Discussion

The results of the potentiometric measurements are summarized in Table 2.

The potentials E (V) for the cell (I) are given by the expression:

$$E=(RT/F)\ln(a_{H^+,t}/a_{H^+,r})+E_j \qquad (1)$$

where a_{H^+} represents the activity of hydrogen ion and subscripts t and r denote the test and reference solutions, respectively. The second term in Eq. 1 represents the liquid junction potential, which can be estimated using the Henderson equation:[13]

$$E_j=-\sum D_i(m_{i,t}-m_{i,r}) \qquad (2)$$

$$D_i=(RT/F)(|Z_i|/Z_i)\lambda_i/\sum(|Z_i|\bar{m}_i\lambda_i) \qquad (3)$$

where $\bar{m}_i$ denotes the average concentration of species i in the two compartments, Z_i is the ionic charge, and λ_i is the limiting equivalent conductance of the i th ion. Values of λ_i have been reported by Quist and Marshall,[15] but that of Al^{3+} was calculated from the Stokes's law:

$$\lambda_i=0.820|z_i|r_s\eta \qquad (4)$$

where r_s is the "Stokes radius" taken as 3.95 Å for aluminium(III) ion[16] and η is the viscosity of water. Since the molal ratio of supporting electrolyte to total aluminium was large, the liquid junction term in Eq. 1 rarely exceeded 1 mV.

It has been recognized that the activity coefficients for uni- and bivalent[17–19] ionic species are expressed

sufficiently to 1 molal 1-1 electrolyte solutions by the single parameter type of Debye-Hückel equation and to 5 molal solutions by the extended Debye-Hückel equation. Although those of the highly charged ions can be estimated only very poorly, Lietzke and Stoughton,[20] and Marshall and Slusher[21] have proved the efficacy of applying the equation to the extent of tervalent ion in the solubility measurement of lanthanum sulfate and samarium sulfate, respectively. Therefore, we used a Debye-Hückel equation to calculate the activity coefficients for ionic species at elevated temperatures:

$$\log \gamma_i = -Z_i{}^2 S\sqrt{I}/(1+A\sqrt{I}) \quad (5)$$

where I is the ionic strength and, S is the Debye-Hückel limiting slope given by:

$$S = 1.824\times10^6\, \rho^{1/2}/(\varepsilon T)^{3/2}\ (\mathrm{kg}^{1/2}\,\mathrm{mol}^{-1/2}) \quad (6)$$

Dielectric constant of water ε is available up to 640 K by Akerlof and Oshry[22] and ρ is the density of water. The adjustable parameter A was experimentally determined from the solubility measurements of various sulfates,[17-19] i.e. A varies from 1.5 at 25 °C to 1.6 at 125 °C.

The principal equilibrium reactions governing the thermodynamic behavior of aluminium sulfate solution at elevated temperatures are assumed to be:

$$Al^{3+} + SO_4^{2-} \rightleftharpoons [AlSO_4]^+ \quad (7)$$

$$2Al^{3+} + 2H_2O \rightleftharpoons [Al_2(OH)_2]^{4+} + 2H^+ \quad (8)$$

$$HSO_4^- \rightleftharpoons H^+ + SO_4^{2-} \quad (9)$$

$$K^+ + SO_4^{2-} \rightleftharpoons KSO_4^- \quad (10)$$

Aluminium ion is extensively hydrolyzed at elevated temperatures and produces various hydroxo complexes.[23] Under the present conditions we assume only one hydrolyzed product, $[Al_2(OH)_2]^{4+}$, reported by MacDonald et al., because the present experimental conditions of hydrothermal hydrolysis (pH, ionic strength, and aluminium concentration) were similar to their ones.

Equilibrium constants for above reactions are expressed as follows:

$$K_f = a_{[AlSO_4]^+}/a_{Al^{3+}}\, a_{SO_4^{2-}} \quad (11)$$

$$= (\gamma_{[AlSO_4]^+}/\gamma_{Al^{3+}}\, \gamma_{SO_4^{2-}})(m_{[AlSO_4]^+}/m_{Al^{3+}}\, m_{SO_4^{2-}}) \quad (11')$$

$$K_h = a_{[Al_2(OH)_2]^{4+}} a_{H^+}^2/a_{Al^{3+}}^2 \quad (12)$$

$$= (\gamma_{[Al_2(OH)_2]^{4+}}\gamma_{H^+}^2/\gamma_{Al^{3+}}^2)(m_{[Al_2(OH)_2]^{4+}} m_{H^+}^2/m_{Al^{3+}}^2) \quad (12')$$

$$K_2 = a_{H^+} a_{SO_4^{2-}}/a_{HSO_4^-} \quad (13)$$

$$= (\gamma_{H^+}\gamma_{SO_4^{2-}}/\gamma_{HSO_4^-})(m_{H^+} m_{SO_4^{2-}}/m_{HSO_4^-}) \quad (13')$$

$$K_k = a_{KSO_4^-}/a_{K^+}\, a_{SO_4^{2-}} \quad (14)$$

$$= (\gamma_{KSO_4^-}/\gamma_{K^+}\gamma_{SO_4^{2-}})(m_{KSO_4^-}/m_{K^+} m_{SO_4^{2-}}) \quad (14')$$

The values of K_2 and K_k were determined previously at temperatures up to 200 °C.[10]

Total analytical concentrations of Al^{3+}, H^+, K^+, and SO_4^{2-} ions are given by:

$$m_{Al^{3+}} + m_{[AlSO_4]^+} + 2m_{[Al_2(OH)_2]^{4+}} = m_1 \quad (15)$$

$$m_{H^+} + m_{HSO_4^-} - 2m_{[Al_2(OH)_2]^{4+}} = m_2 \quad (16)$$

$$m_{K^+} + m_{KSO_4^-} = 2m_3 + m_5 \quad (17)$$

$$m_{[AlSO_4]^+} + m_{HSO_4^-} + m_{KSO_4^-} + m_{SO_4^{2-}} = m_3 \quad (18)$$

And the ionic charge balance in the solution is:

$$3m_{Al^{3+}} + m_{[AlSO_4]^+} + 4m_{[Al_2(OH)_2]^{4+}} + m_{H^+} + m_{K^+} = 2m_{SO_4^{2-}} + m_{HSO_4^-} + m_{KSO_4^-} + m_{Cl^-} \quad (19)$$

If a, h, and s are taken as the Al^{3+}, H^+, and SO_4^{2-} concentrations, the solution of Eqs. 11—19 can be obtained by the following simultaneous equations:

$$a + h + \gamma^{12}K_f as + \gamma^4 hs/K_2 - m_1 - m_2 = 0 \quad (20)$$

$$s + \gamma^{12}K_f as + \gamma^4 hs/K_2 + \gamma^4 K_k(1+2m_3)s/(1+\gamma^4 K_k s) - m_2 = 0 \quad (21)$$

$$h + 3a + \gamma^{12}K_f as + 4K_h a^2/h^2 - (1+3m_1+m_2) - \gamma^4 hs/K_2 - 2s + (1+2m_3)(1-\gamma^4 K_k s)/(1+\gamma^4 K_k s) = 0 \quad (22)$$

The computer program employed to carry out the calculation of K_f and K_h was described below. First, a preliminary value of ionic strength was assumed and was substituted into Eq. 5 to yield the activity coefficients. The concentrations of each ionic species was determined by simultaneous solution of Eqs. 20—22 by the Newton-Raphson method. The ionic strength of the solutions was calculated from the concentrations of each kind of ions and determined by the method of successive approximations. Thus, the activity of hydrogen ion, a_{H^+}, was determined and combined with Eq. 1, and the calculated value of potential was obtained. Then the experimental data were treated with a nonlinear least squares method to analyze the most appropriate set of K_f and K_k, i.e., to minimize the summation of the square difference of observed and calculated values of the potential. The computations were carried out for each system from 25 to 125 °C at 25 °C intervals. The formation constants of aluminium sulfate obtained by the above procedure are presented in Table 3 and illustrated in Fig. 2. Their change with temperature shows that the association of aluminium ion and sulfate ion increases strongly with temperature. Potentials measured at temperatures higher than 125 °C increased gradually, presumably due to the hydrolysis of aluminium ion, followed by precipitation. Therefore it was difficult to deter-

a) Ref. 3.

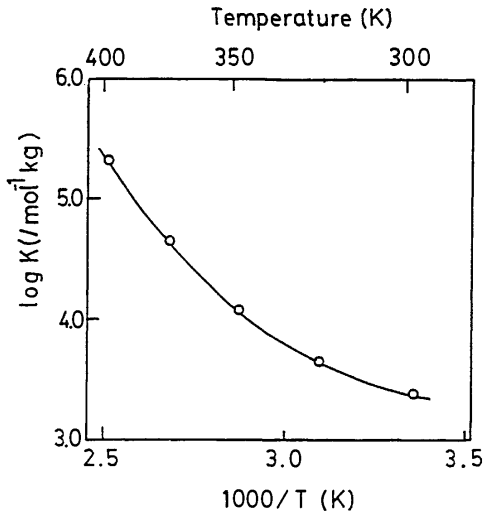

Fig. 2. The formation constant of $AlSO_4^+$ from 25 °C to 125 °C.

mine the association constant of the $[AlSO_4]^+$ ion pair at temperatures above 125 °C. The X-ray diffraction patterns of the precipitate showed that the major constituent was alunite, $KAl_3(SO_4)_2(OH)_6$. Lines assignable to aluminium oxides, hydroxides, and oxychlorides were not observed.

Essentially, the equilibrium constant obtained by the e.m.f. measurements is a sum of the equilibrium constants for the inner-sphere complex, $[Al(SO_4)(OH_2)_{6-x}]^+$ and the outer-sphere one, $[Al(OH_2)_6(SO_4)]^+$. These constants were determined by the pressure jump method up to 40 °C[25] and the inner-sphere complex occupies 17% at 25 °C. The NMR measurements of aluminium sulfate solutions show that the ratio of the inner-sphere complex to the outer one increases with an increase in temperature.[9]

Although the disulfato complex, $[Al(SO_4)_2]^-$, has been reported by other authors[3,6,26] we could not find evidence of its existence. It is supposed that the experimental conditions of both low pH level and small ratio of $[SO_4^{2-}]/[Al^{3+}]$ are unfavorable to the formation of the disulfato complex. If we take into account the precipitation of alunite above 125 °C, it seems that the disulfato or hydroxodisulfato complex may be formed at higher temperatures because aluminium ion in the crystal of alunite is hexa-coordinated with two oxygen atoms of SO_4^{2-} ions and four OH^- ions.[27]

From the formation constant obtained in this work, it is possible to compute the composition of the aluminium sulfate solutions. Some examples are shown in Table 4. As has been pointed out by Akitt et al.,[9] HCl suppresses the formation of $[AlSO_4]^+$, due to the formation of HSO_4^- over the pH range examined at all temperatures.

On the assumption of the linear dependency of ΔC_p° over the temperature range of 25 to 125 °C, the present values of the formation constant were fitted by a method of least squares to yield the four-parameter

Table 4. Molalities of Various Species Present in a Solution Containing 0.020 m in $AlCl_3$ and 0.032 m in K_2SO_4, and 0.032 m in HCl at Various Temperatures

Species	Temperature		
	298 K	348 K	398 K
Al^{3+}	1.78×10^{-2}	1.61×10^{-2}	1.08×10^{-2}
$AlSO_4^+$	2.19×10^{-3}	3.87×10^{-3}	8.32×10^{-3}
$Al_2(OH)_2^{4+}$	—	—	4.53×10^{-4}
SO_4^{2-}	1.80×10^{-2}	1.14×10^{-2}	4.54×10^{-3}
HSO_4^-	6.51×10^{-3}	1.33×10^{-2}	1.77×10^{-2}
KSO_4^-	5.26×10^{-3}	3.44×10^{-3}	1.46×10^{-3}
H^+	2.55×10^{-2}	1.87×10^{-2}	1.52×10^{-2}

1 m=1 mol kg^{-1}.

equation as a function of temperature (K):

$$\log(K_f/\text{mol}^{-1}\,\text{kg}) = -765.90 + 290.1611\log(T/\text{K}) + 26255/(T/\text{K}) - 0.1234(T/\text{K}) \quad (23)$$

From the treatment of Eq. 23, thermodynamic functions for the standard Gibbs energy (ΔG°), enthalpy (ΔH°), and entropy (ΔS°) were obtained from 25 to 125 °C. The values are given in Table 3. At 25 °C the values ΔG°, ΔH°, and ΔS° in this table were compared reasonably with those of Izatt et al.[3]

Another equation for $\log K_f$ was obtained by assuming that ΔC_p° varied as quadratic function of temperature. This equation is given as follows:

$$\log(K_f/\text{mol}^{-1}\,\text{kg}) = -14847.75 + 6358.721\log(T/\text{K}) + 328608/(T/\text{K}) - 7.75167(T/\text{K}) + 3.66574\times10^{-3}(T/\text{K})^2 \quad (24)$$

The thermodynamic quantities derived from Eq. 24 at 25 °C showed unreasonably low values. Therefore, the four-parameter equation (Eq. 23) is believed to yield a better description of the present equilibrium from 25 to 125 °C.

Because all of the test solutions were fairly acidic (pH<3), hydrolysis of Al^{3+} ion at moderate temperatures was suppressed, and consequently, the formation constant for the hydrolyzed product, $[Al_2(OH)_2]^{4+}$, was ill-defined. The hydrolysis occurred with an increase in temperature, and $\log(K_h/\text{mol}\,\text{kg}^{-1}) = -3.0$ was determined for the formation of $[Al_2(OH)_2]^{4+}$ at 125 °C.

We wish to thank Sumitomo Electric Industries, Ltd. for supplying the porous PTFE disks.

^{81}Br NQR and ^{119}Sn Mössbauer Study for $MSnBr_3$ (M=Cs and CH_3NH_3)

Koji YAMADA,* Sayuri NOSE, Takako UMEHARA, Tsutomu OKUDA, and Sumio ICHIBA
Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Naka-ku, Hiroshima 730
(Received April 8, 1988)

Successive phase transitions were observed for $CsSnBr_3$ and $CH_3NH_3SnBr_3$ by means of ^{81}Br NQR and DTA. These compounds are isomorphous with each other and have typical cubic perovskite structures at room temperature. However, with decreasing temperature both compounds showed successive phase transitions and complex ^{81}Br NQR spectra at 77 K. In the case of $CH_3NH_3SnBr_3$, both ^{81}Br NQR and ^{119}Sn Mössbauer spectra changed markedly with decreasing temperature from those at room temperature. These findings suggested a large distortion of the $SnBr_6$ octahedron from the regular one and were interpreted on the basis of the three-center-four-electron bond model. In relation to these structural changes, a broad-line ^{1}H NMR experiment on $CH_3NH_3SnBr_3$ was also observed in order to determine the effect of the dynamic properties of the cation.

Trihalostannate anions, SnX_3^- (X=Cl, Br, and I), in the solid state still provide us with interesting problems, since the anion changes its structure variously with the replacement of the counter cation. Furthermore, drastic changes of the ^{81}Br NQR spectra accompanied by phase transitions have been reported with decreasing temperature.[1] The structural variety of the SnX_3^- anion has been understood on the basis of the stereochemical activity (or nonactivity) of the nonbonding pair of s-electrons.[2] In the series of our NQR and Mössbauer studies on SnX_3^- anions, however, the structural variety and phase transitions have been disscused on the basis of the hypervalent character of the central metal.[3] In other words, the trans Br-Sn-Br bond is described as a three-center-four-electron (3c-4e) bond.[4] This bond changes continuously from a symmetric X-Sn-X to an asymmetric X-Sn···X, as has been observed for the trans Br-Sb-Br bond in $(C_5H_5NH)SbBr_4$.[5] In this model an inter anionic interaction, such as X-Sn···X, can also be regarded as an extremely asymmetric case of the 3c-4e bond. According to the crystal structures containing SnX_3^- anions, the tin atom forms regular or distorted octahedron with six nearest-neighbor halogens. Therefore, four structural models shown in Fig. 1 can be systematically understandable in terms of whether the trans X-Sn-X bond is a symmetric or asymmetric in each of the three orthogonal directions.[1] The appearance of models (B), (C), and (D) can be interpreted as being a result of a displacement of the central metal in the three different directions shown in model (A). The model (A) structure has been reported for $CsSnBr_3$,[6,7] model (B) for $KSnF_3\cdot(1/2)H_2O$,[8] model (C) for $CsSnI_3$[9] and $(NH_4)SnBr_3\cdot H_2O$,[1,10] and model (D) for $CsSnCl_3$.[11] In our previous paper model (C) anions in $MSnBr_3\cdot H_2O$ (M=K and NH_4) changed their structure with decreasing temperature toward model (D), at which the ^{81}Br NQR frequencies assigned to the basal plane increased enormously.[1]

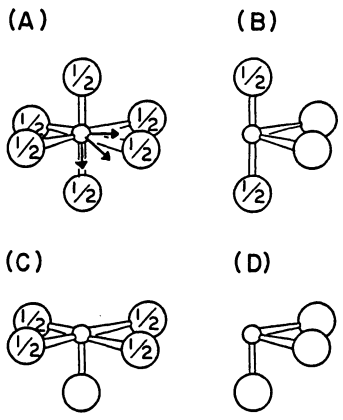

Fig. 1. Structural models for SnX_3^- anion on the basis of octahedral environment around the Sn.

In this paper the structural phase transitions for $CsSnBr_3$ and $CH_3NH_3SnBr_3$ were studied by means of ^{81}Br NQR, DTA, ^{119}Sn Mössbauer effect, and ^{1}H NMR. Especially in the $CH_3NH_3^+$ analogue, the tin environment changed from a regular octahedron at room temperature to a markedly distorted one at 77 K, as was expected from the 3c-4e bond. Furthermore, an interesting problem is the relationship between the 3c-4e bond model and the semimetallic conductivity of the perovskite structure. For the Cs analogue, both experimental and theoretical studies concerning the electric structure have been reported.[12]

Experimental

$CH_3NH_3SnBr_3$ was crystallized as red crystals from ethanol containing stoichiometric amounts of $SnBr_2$ and CH_3NH_3Br. This compound is unstable in air, especially if there exists a trace of hydrobromic acid. $CsSnBr_3$ was obtained from a melt using a Bridgman furnace. These two compounds were identified to be isomorphous with each other at room temperature using powder X-ray diffraction. The cell constants of the cubic perovskite were determined to be a=5.808 and 5.901 Å for Cs and CH_3NH_3 salts, respectively. The former lattice constant agreed well with the value reported previously, a=5.804 Å.[6]

^{79,81}Br NQR was detected with a pulsed spectrometer and was assigned using the quadrupole moment ratio, $Q(^{79}Br)/Q(^{81}Br)$=1.1971. At low temperature, owing to their large line width (ca. 100 KHz), only spin echo signals could be detected using 90°—180° pulses. ^{119}Sn Mössbauer spectra were recorded by means of a constant acceleration type spec-

trometer, using $Ca^{119m}SnO_3$ as a gamma-ray source. The velocity was calibrated with Sn and $BaSnO_3$.

Results and Discussion

^{81}Br NQR and DTA. Figure 2 shows the temperature dependence of the ^{81}Br NQR frequency for $CsSnBr_3$. The phase transition temperatures were determined to be 290±1 and 85±2 K, the former agreeing well with the value reported previously by Scaife et al.[13] Both transitions were accompanied by a continuous temperature dependence of the NQR frequency and no thermal hysteresis, characteristics of a second-order transition. A preliminary experiment concerning the NQR spin-lattice relaxation times also showed a character of the second-order type phase transition; steep minima in the T_1 vs. temperature curve near the phase-transition temperatures. The intermediate phase II has two NQR lines with intensity ratio 2:1, from the highest, suggesting a tetragonally distortion of the perovskite. As Fig. 3 shows, however, the spectra at 77 K is complicated. At least seven ^{81}Br lines could be detected separately, though the exact number of nonequivalent Br sites could not be determined due to the broad linewidth. However, the distortion of the $SnBr_6$ octahedra from a regular form is considered to be only slight because of the small splitting of the NQR frequencies. This was also supported by the ^{119}Sn Mössbauer spectrum, which had no quadrupole splitting (as described later).

Figure 4 shows the temperature dependence of the ^{81}Br NQR frequency for $CH_3NH_3SnBr_3$. One ^{81}Br NQR line was observed near 66 MHz at room temperature, as was expected from the cubic perovskite structure. This NQR signal disappeared at 232 K with decreasing temperature and six new lines appeared at about 180 K, as shown in Fig. 4. Because of the wide distribution of the spectra at 77 K, one part of the ^{79,81}Br NQR spec-

Compounds	Frequency/MHz	
	77 K	296 K
$CsSnBr_3$	65.72, 65.13, 64.90, 64.65 64.39, 63.18, 62.92	62.970
$CH_3NH_3SnBr_3$	74.95, 72.83, 71.93 67.15, 65.85, 61.85	65.766

a) Estimated errors ±0.05 and ±0.005 MHz at 77 and 296 K, respectively.

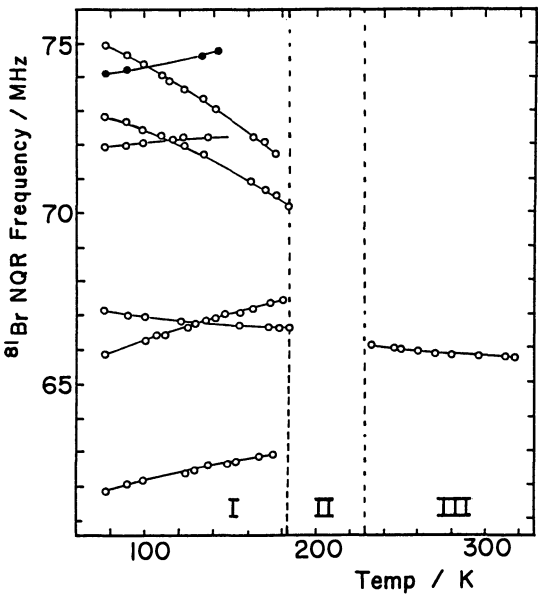

Fig. 4. Temperature dependence of the ^{81}Br NQR frequencies for $CH_3NH_3SnBr_3$. A part of the ^{79}Br NQR line was also observed in the same frequency range because of the wide distribution of the spectrum. Dotted lines show the averaged phase transition temperatures determined by the DTA.

tra overlapped with each other, as shown in Fig. 4. The DTA measurements for this compound are shown in Fig. 5 in the temperature range 160—280 K. Two large peaks corresponding to solid-solid phase transitions appeared with several degrees of hysteresis. Between these two peaks a very small one appeared, though it could not be confirmed by the NQR because of there being no signal in this intermediate phase. Therefore, at least three phases (I, II, and III) exist between 300 and 77 K. Associated with the phase transition between II↔III, the color changed drastically from red to yellow, suggesting a significant structural change. In relation to these successive phase transitions, it is particularly interesting that the splitting of the NQR frequency at 77 K is considerably larger for $CH_3NH_3SnBr_3$ than that expected from the crystal field effect. That is, the highest frequency, about 75 MHz, is comparable to that of a discrete pyramidal $SnBr_3^-$ anion having model (D);[1] the lowest one, about 62 MHz, is lower than that of a room-temperature perovskite structure having model (A). These findings suggest that there are at least two different $SnBr_3^-$ anions having distorted $SnBr_6$ octahedra (such as model (B), (C), or (D)) in the phase I.

Recently, in the course of this study, similar structural phase transitions from model (A) to (D) were reported for a series of $CsGeX_3$ (X=Cl, Br, and I)[14] in which the GeX_3^- anions have the same valence electron configuration as that of SnX_3^-. The high-temperature phase of these compounds belongs to a cubic perovskite, so that the trans Br-Ge-Br bond is symmetric. In the low-temperature phase, however, the Ge atom in the halogen octahedral is considerably displaced from the center of the octahedra along the three-fold axis and the octahedra becomes distorted rhombohedrally. Hence, three trans X-Ge-X bonds become asymmetric X-Ge··· X and the anion can also be regarded as an isolated anion. These structural changes are expected for a main-group element having a valence state with an s-electron lone pair, such as Sn(II), Ge(II), As(III), Sb(III), and Te(IV). The nuclear quadruple resonance of halogens is a useful technique for this problem and drastic NQR frequency shifts have been observed for $MSnBr_3 \cdot H_2O$[1] and $(C_5H_5NH)SbBr_4$.[5]

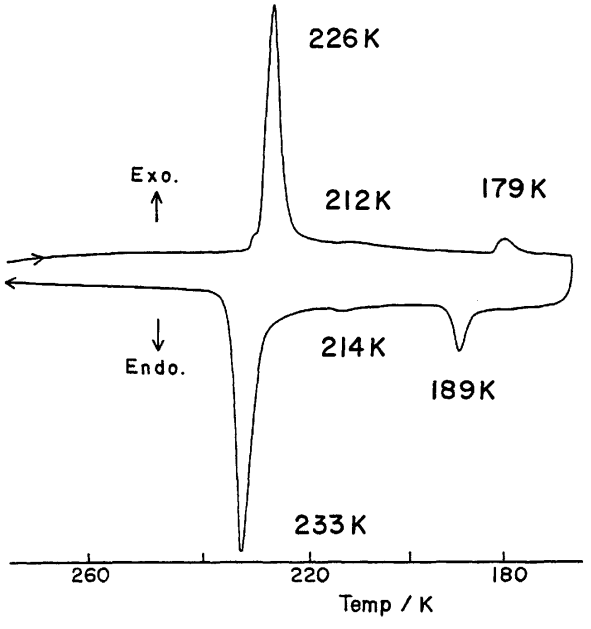

Fig. 5. DTA curve for $CH_3NH_3SnBr_3$ in the temperature range 280—160 K. The transition temperatures, which were determined at the peak positions, show several degrees of hysteresis.

The ^{119}Sn Mössbauer Effect for the $MSnBr_3$ (M=Cs and CH_3NH_3). ^{119}Sn Mössbauer spectra at 93 K are shown in Fig. 6. A quadrupole splitting appears only for $CH_3NH_3SnBr_3$, as was expected from the ^{81}Br NQR. On the other hand, the spectra at 293 K are very weak single Lorentzian, having ca. 1% relative absorption. ^{119}Sn Mössbauer parameters at 293 and 93 K are summarized in Table 2. It is particularly significant that not only the quadrupole splitting but also the isomer shift changed drastically only for the $CH_3NH_3^+$ analog with decreasing temperature. These results suggest that the symmetry at the Sn site lowered and the s-electron density decreased accompanied by structural phase transitions. This large change of the Mössbauer parameters is reasonable if some structural change

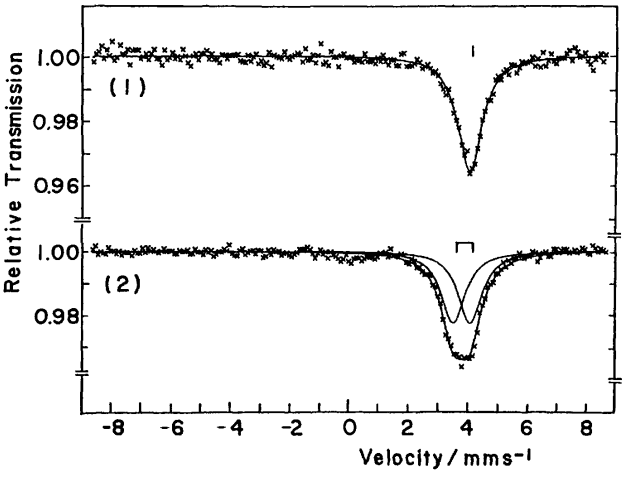

Fig. 6. ^{119}Sn Mössbauer spectra for $CsSnBr_3$ (1) and $CH_3NH_3SnBr_3$ (2) at 93 K.

Table 2. ^{119}Sn Mössbauer Parameters for $MSnBr_3$ (M=Cs and CH_3NH_3)[a]

Compound	Temp / K	I.S. / mm s^{-1}	Q.S. / mm s^{-1}	Line width / mm s^{-1}
$CsSnBr_3$	293	4.00	0	0.84
	93	4.01	0	0.91
	80[b]	3.98	0	0.84
$CH_3NH_3SnBr_3$	293	3.98	0	1.05
	93	3.81	0.54	0.99

a) Estimated error ±0.03 m s^{-1}. b) Ref. 23.

from model (A) to (D) or (B) takes place. In the case of model (A), the tin atom forms symmetric 3c-4e bonds in three orthogonal directions, so that there is no s-orbital hybridization to the bonds. On the other hand, in the model (D) or (B) structure, the bond angle of the $SnBr_3^-$ anion (Br-Sn-Br) becomes slightly larger than 90 degrees and, hence, a hybridization of the s-orbital to the p-orbitals takes place.[15] Thus, the smaller isomer shifts at 93 K than 293 K can be attributed to a decrease in the s-electron density due to a hybridization of the s-orbital to the pure p-orbital bonding.

^{1}H NMR for $CH_3NH_3SnBr_3$. In order to examine the relationship between these phase transitions and the dynamical property of the cation, the ^{1}H NMR was observed as a function of temperature (Fig. 7). The calculated second moments in phases I and III were almost constant and were 8±0.5 and 0.5±0.1 G^2(1G= 10^{-4} T), respectively. According to the previous ^{1}H NMR studies containing the same cation, the second moment of about 7—8 G^2 corresponds to the reorientational motion of the cation around its C_3 axis.[16-19] The second moment of about 0.5 G^2 corresponds to an interionic contribution, indicating that an overall rotation of the cation takes place at a rate higher than ca. $10^5\,s^{-1}$. These phase transitions take place at almost the same temperature at which the 2nd moment changed stepwise. These results suggest that the phase transitions are largely affected by the dynamical properties of the $CH_3NH_3^+$ cation. Many structural phase transitions containing the $CH_3NH_3^+$ cation have been reported, partly because of a change in the effective volume and partly because of a breakdown of the hydrogen-bonding networks.[20-22] In this case, it is particularly noteworthy that the structure and the bonding of the anion are also affected associated with these phase transitions due to the nature of the 3c-4e bond.

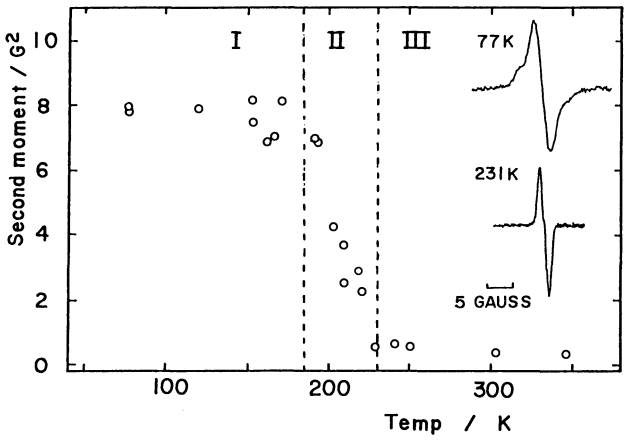

Fig. 7. Temperature dependence of the ^{1}H NMR second moment for $CH_3NH_3SnBr_3$.

Study of Polarographic Anodic Wave in the Presence of Sulfate Ions by a Numerical Method

Kenji KIKUCHI* and Teisuke MURAYAMA†
Shiga Prefectural Junior College, Hikone, Shiga 522
†Department of Applied Chemistry, Faculty of Engineering, Shizuoka University, Johoku, Hamamatsu 432
(Received April 27, 1988)

A polarographic anodic wave in the presence of sulfate ions increases with any increase in the concentration of sulfate ions, contrary to the expectation based on a free dissolution of electrode mercury. It does not show any diffusion current plateau. The precipitation of mercury(I) sulfate, the product of an electrode reaction, does not take place within a dropping time. An analysis using a new numerical method previously reported proved that the wave is caused by the formation of a mercury(I) complex, $[Hg_2(SO_4)]$, with a stability constant of 150 $mol^{-1}\,dm^3$.

Kolthoff and Miller reported that an anodic process involving the electrooxidation of mercury appeared as a free dissolution wave in a solution of 0.1 mol dm^{-3} potassium nitrate, since nitrate ions do not depolarize a mercury electrode.[1)]

When sulfate ions are added into the solution, the anodic wave is expected to remain unchanged as long as the concentration of the mercury(I) sulfate produced is below its solubility. This means that the current-potential curve should be written as

$$E=E^0+(RT/2F)\ln \bar{i}. \quad (1)$$

In the above, E is the electrode potential of the dropping mercury electrode, E^0 the standard electrode potential, $\bar{i}$ the average current, and F is the Faraday constant. Equation 1 says that the anodic current is independent of the concentration of sulfate ions. This is not the case, however. The anodic current any increases with increase in the concentration of sulfate ions, as shown in Fig. 1. This fact contradicts Eq. 1.

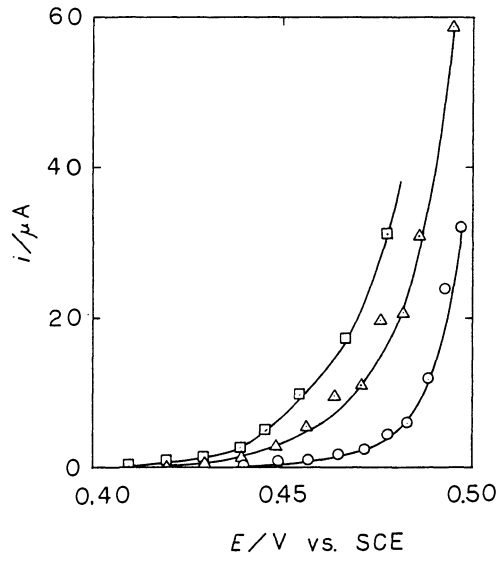

Fig. 1. Effect of the concentration of sulfate ions on the anodic current in a solution of pH 1.93. Concentration of a sodium sulfate, ○; 2 mmol dm^{-3}, △; 10 mmol dm^{-3}, □; 20 mmol dm^{-3}.

Figure 1 also shows that the anodic current does not attain the diffusion current plateau as expected for the anodic current with precipitate formation, of which a treatment was described in a previous paper.[2)]

The purpose of this paper is to clarify processes involving the anodic wave in the presence of sulfate ions by applying a numerical method which was developed in previous reports.[2,3)]

Theory

In the anodic process, mercury is dissolved into solution as a mercury(I) ion; a mercury(I) ion reacts with a sulfate ion to produce a mercury(I) sulfate complex. When the concentration of the complex exceeds its solubility, precipitate particles of mercury(I) sulfate appear in the solution. The sequence of the reactions can be written as follows:

$$2Hg \rightleftharpoons Hg_2^{2+} + 2e^- \quad (2)$$

$$HSO_4^- \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} H^+ + SO_4^{2-} \quad (3)$$

$$Hg_2^{2+} + SO_4^{2-} \underset{k_{-3}}{\overset{k_3}{\rightleftharpoons}} Hg_2SO_4 \quad (4)$$

$$Hg_2SO_4 \underset{k_{-4}}{\overset{k_4}{\rightleftharpoons}} \text{precipitate} \quad (5)$$

In the above, k_2, k_{-2}, k_3, k_{-3}, k_4, and k_{-4} are the rate constants of Reactions 3—5. The rate of dissolution of precipitate particles in Reaction 5 is nil in the absence of a precipitate.

An analysis of the anodic current is carried out with using two alternative assumptions.

(1) The first assumption is that the mercury(I) sulfate precipitate particles are produced when the concentration of a mercury(I) sulfate complex exceeds its solubility.

When precipitate particles exist in a volume element or the concentration of the complex exceeds its solubility in it, the simultaneous equations governing the concentrations of species in the sequence of Reactions 2—5 are

$$\frac{\partial C_A}{\partial t} = D_A\left(\frac{\partial^2 C_A}{\partial r^2}\right) + \left(\frac{2}{r}D_A - u\right)\frac{\partial C_A}{\partial r} - k_3 C_A C_B + k_{-3} C_C, \quad (6)$$

$$\frac{\partial C_B}{\partial t} = D_B\left(\frac{\partial^2 C_B}{\partial r^2}\right) + \left(\frac{2}{r}D_B - u\right)\frac{\partial C_B}{\partial r} + k_2 C_D - k_{-2} C_H C_B - k_3 C_A C_B + k_{-3} C_C \ , \quad (7)$$

$$\frac{\partial C_C}{\partial t} = D_C\left(\frac{\partial^2 C_C}{\partial r^2}\right) + \left(\frac{2}{r}D_C - u\right)\frac{\partial C_C}{\partial r} + k_3 C_A C_B - k_{-3} C_C - k_4 C_C + k_{-4} \ , \quad (8)$$

$$\frac{\partial C_D}{\partial t} = D_D\left(\frac{\partial^2 C_D}{\partial r^2}\right) + \left(\frac{2}{r}D_D - u\right)\frac{\partial C_D}{\partial r} - k_2 C_D + k_{-2} C_H C_B \ , \quad (9)$$

and

$$\frac{\partial C_P}{\partial t} = -u\frac{\partial C_P}{\partial r} + k_4 C_C - k_{-4} \ . \quad (10)$$

In the above

$$u = m/(4\pi\rho r^2), \quad (11)$$

where C_h is the concentration of species h, r the distance from the center of the electrode mercury drop, m the flow rate of mercury, and ρ the density of mercury. As for the subscript, A denotes the mercury(I) ion, B the sulfate ion, C the mercury(I) sulfate complex, D the hydrogen sulfate ion, and P the mercury(I) sulfate precipitate.

When the precipitate particles do not exist in a volume element, or the concentration of the complex is below its solubility, partial derivatives in Eq. 10 become zero. This results in the relation $k_4 C_C = k_{-4}$. Using this relation, Eqs. 6—9 become

$$\frac{\partial C_A}{\partial t} = D_A\left(\frac{\partial^2 C_A}{\partial r^2}\right) + \left(\frac{2}{r}D_A - u\right)\frac{\partial C_A}{\partial r} - k_3 C_A C_B + k_{-3} C_C \quad (12)$$

$$\frac{\partial C_B}{\partial t} = D_B\left(\frac{\partial^2 C_B}{\partial r^2}\right) + \left(\frac{2}{r}D_B - u\right)\frac{\partial C_B}{\partial r} + k_2 C_D - k_{-2} C_H C_B - k_3 C_A C_B + k_{-3} C_C \ , \quad (13)$$

$$\frac{\partial C_C}{\partial t} = D_C\left(\frac{\partial^2 C_C}{\partial r^2}\right) + \left(\frac{2}{r}D_C - u\right)\frac{\partial C_C}{\partial r} + k_3 C_A C_B - k_{-3} C_C \ , \quad (14)$$

and

$$\frac{\partial C_D}{\partial t} = D_D\left(\frac{\partial^2 C_D}{\partial r^2}\right) + \left(\frac{2}{r}D_D - u\right)\frac{\partial C_D}{\partial r} - k_2 C_D + k_{-2} C_H C_B . \quad (15)$$

The initial conditions are

$$C_A = 0,\ C_B = C^*_B,\ C_C = 0,\ C_D = C^*_D,\ C_P = 0 \ (t = 0,\ r = a), \quad (16)$$

and the boundary conditions are

$$C_A = C_{A0} = \exp\{2F(E - E^0)/RT\}/\gamma_A,\ (\partial C_B/\partial r)_{r=a} = 0,\ (\partial C_C/\partial r)_{r=a} = 0,\ (\partial C_D/\partial r)_{r=a} = 0 \ (t > 0,\ r = a) \quad (17)$$

$$C_A = 0,\ C_B = C^*_B,\ C_C = 0,\ C_D = C^*_D \text{ and } C_P = 0 \ (t > 0,\ r = \infty). \quad (18)$$

In the above, C_{A0} is the concentration of mercury(I) ions at the surface of the mercury electrode and γ_A is the activity coefficient of mercury(I) ions.

The relation between the concentration of hydrogen sulfate and sulfate ions is expressed by

$$C_F = C_D + C_B$$

and

$$(C_H + K_{a2})C_B/K_{a2} = (C_H + K_{a2})C_D/C_H. \quad (19)$$

In the above, C_H is the concentration of hydrogen ions, and K_{a2} the dissociation constant of the hydrogen sulfate ion. Equations 6—9 and 12—15 can be rewritten using Eq. 19. The following equations are derived from Eqs. 6—9 and 12—15:

$$\frac{\partial C_A}{\partial t} = D_A\left(\frac{\partial^2 C_A}{\partial r^2}\right) + \left(\frac{2}{r}D_A - u\right)\frac{\partial C_A}{\partial r} - \frac{k_3 C_A C_F K_{a2}}{C_H + K_{a2}} + k_{-3} C_C, \quad (20)$$

$$\frac{\partial C_F}{\partial t} = D_F\left(\frac{\partial^2 C_F}{\partial r^2}\right) + \left(\frac{2}{r}D_F - u\right)\frac{\partial C_F}{\partial r} - \frac{k_3 C_A C_F K_{a2}}{C_H + K_{a2}} + k_{-3} C_C \ , \quad (21)$$

$$\frac{\partial C_C}{\partial t} = D_C\left(\frac{\partial^2 C_C}{\partial r^2}\right) + \left(\frac{2}{r}D_C - u\right)\frac{\partial C_C}{\partial r} + \frac{k_3 C_A C_F K_{a2}}{C_H + K_{a2}} - k_{-3} C_C - k_4 C_C + k_{-4} \ , \quad (22)$$

and

$$\frac{\partial C_C}{\partial t} = D_C\left(\frac{\partial^2 C_C}{\partial r^2}\right) + \left(\frac{2}{r}D_C - u\right)\frac{\partial C_C}{\partial r} + \frac{k_3 C_A C_F K_{a2}}{C_H + K_{a2}} - k_{-3} C_C \quad (23)$$

The initial conditions are transformed as

$$C_A = 0,\ C_F = C^*_F,\ C_C = 0,\ C_P = 0 \ (t = 0,\ r = a). \quad (24)$$

The boundary conditions are

$$C_A = C_{A0},\ (\partial C_F/\partial r)_{r=a} = 0,\ (\partial C_C/\partial r)_{r=a} = 0 \ (t > 0,\ r = a) \quad (25)$$

$$C_A = 0,\ C_F = C^*_F,\ C_C = 0,\ C_P = 0 \ (t > 0,\ r = \infty). \quad (26)$$

The instantaneous current, i, is given by

$$i = 2FD_A S(\partial C_A/\partial r)_{r=a}, \quad (27)$$

where S is the surface area of the electrode mercury drop.

The following parameters are used to simplify the description of the simultaneous equations:

$$y_A = C_A/C^*_F,\ y_F = C_F/C^*_F,\ y_C = C_C/C^*_F,\ y_P = C_P/C^*_F,\ y_H = C_H/C^*_F,\ d_A = D_A/D_F,\ d_F = D_F/D_F,\ d_C = D_C/D_F,\ x = (r - a)/L,\ s = 1 - 1/\{1 + (r - a)H/L\},\ T = D_F t/L^2,\ U = Lur^2/D_F a^2 \text{ and } K^*_{a2} = K_{a2}/C^*_F. \quad (28)$$

An introduction of the above parameters into Eq. 20 results in

$$\frac{\partial y_A}{\partial T} = d_A H^2(1 - s)^4\frac{\partial^2 y_A}{\partial s^2} + \left\{\frac{2d_A}{x + a/L} + \frac{x(x + 2a/L)}{(x + a/L)^2}U - 2d_A H(1 - s)\right\}H(1 - s)^2\frac{\partial y_A}{\partial s} - \frac{L^2 C^*_F k_3 y_A y_F K^*_{a2}}{D_F(y_H + K^*_{a2})} + k_{-3} y_C L^2/D_F \ . \quad (29)$$

The space and time coordinates are expressed as

$$s_i = i\Delta s,\ T_j = j\Delta T,\ x_i = i\Delta s/H(1+i\Delta s)$$

and

$$y_A(s,\ t) = y_A(s_i,\ T_j) = y_{A,i,j}. \tag{30}$$

The reaction rate constants are replaced by following parameters:

$$k^*_3 = \Delta TL^2C^*_F K^*_{a2}k_3/D_F(y_H + K^*_{a2}),$$
$$k^*_{-3} = \Delta TL^2k_{-3}/D_F,\ k^*_4 = \Delta TL^2k_4/D_F,$$

and

$$k^*_{-4} = \Delta TL^2k_{-4}/D_FC^*_F. \tag{31}$$

The centered space difference method and the forward time method are used for converting the diffusion equations, except for one involving the concentration of precipitate particles.[3]

By using a method reported by Morihara and Cheng,[4] the chemical kinetics term involving the concentration of mercury(I) sulfate complex can be reformulated as

$$k^*_3(y_{A,i,j+1}y_{F,i,j+1} + y_{A,i,j}y_{F,i,j})/2 = k^*_3(y_{A,i,j+1}y_{F,i,j} + y_{A,i,j}y_{F,i,j+1})/2. \tag{32}$$

The introduction of Eqs. 30, 31, and 32 to Eq. 29 gives the following equations:

$$(E_{A,i} + k^*_3y_{F,i,j}/2)y_{A,i,j+1} = F_{A,i,j+1}y_{A,i+1,j+1} + G_{A,i,j+1}y_{A,i-1,j+1} + D_{A,i,j} - k^*_3y_{F,i,j+1}y_{A,i,j}/2 + k^*_{-3}(y_{C,i,j+1} + y_{C,i,j})/2, \tag{33}$$

$$E_{A,i} = 1 + \Delta TH(1-s_i)^4/(\Delta s)^2, \tag{34}$$

$$F_{A,i,j+1} = \Delta TH(1-s_i)^2\{d_AH(1-s_i)^2/\Delta s + d_A/(x_i+a_{j+1}/L) + x_i(x_i+2a_{j+1}/L)U_{j+1}/2(x_i+a_{j+1}/L)^2 - d_AH(1-s_i)\}/2\Delta s, \tag{35}$$

$$G_{A,i,j+1} = \Delta TH(1-s_i)^2\{d_AH(1-s_i)^2/\Delta s - d_A/(x_i+a_{j+1}/L) - x_i(x_i+2a_{j+1}/L)U_{j+1}/2(x_i+a_{j+1}/L)^2 + d_AH(1-s_i)\}/2\Delta s, \tag{36}$$

and

$$D_{A,i,j} = F_{A,i,j+1}y_{A,i+1,j} + G_{A,i,j+1}y_{A,i-1,j} + \{1-\Delta Td_AH^2(1-s_i)^4/\Delta s^2\}y_{A,i,j}. \tag{37}$$

In much the same way, Eq. 22 is transformed as

$$(E_{F,i} + k^*_3y_{A,i,j}/2)y_{F,i,j+1} = F_{F,i,j+1}y_{F,i+1,j+1} + G_{F,i,j+1}y_{F,i-1,j+1} + D_{F,i,j} - k^*_3y_{A,i,j+1}y_{F,i,j}/2 + k^*_{-3}(y_{C,i,j+1} + y_{C,i,j})/2. \tag{38}$$

The following equations are derived from Eqs. 22 and 23:

$$\{E_{C,i} - (k^*_{-3} - k^*_4)/2\}y_{C,i,j+1} = F_{C,i,j+1}y_{C,i+1,j+1} + G_{C,i,j+1}y_{C,i-1,j+1} + D_{C,i,j} - k^*_3(y_{A,i,j+1}y_{F,i,j}/2 + y_{A,i,j}y_{F,i,j+1})/2 + (k^*_{-3} - k^*_4)y_{C,i,j}/2, \tag{39}$$

and

$$(E_{C,i} - k^*_{-3}/2)y_{C,i,j+1} = F_{C,i,j+1}y_{C,i+1,j+1} + G_{C,i,j+1}y_{C,i-1,j+1} + D_{C,i,j} - k^*_3(y_{A,i,j+1}y_{F,i,j}/2 + y_{A,i,j}y_{F,i,j+1})/2 + k^*_{-3}y_{C,i,j}/2. \tag{40}$$

The backward space difference method must be used in order to obtain the difference equations of Eq. 10 for a precipitate, as was done in a previous study.[2] Equation 10 is transformed as follows. For i=1, the difference equation is expressed with concentrations at nodes (1, j), (2, j), (3, j), (4, j), (1, j+1), (2, j+1), (3, j+1), and (4, j+1).

$$(1+11M_{P,1,j+1})y_{P,1,j+1} = M_{P,1,j+1}(18y_{P,2,j+1} - 9y_{P,3,j+1} + 2y_{P,4,j+1}) + M_{P,1,j+1}(-11y_{P,1,j} + 18y_{P,2,j} - 9y_{P,3,j} + 2y_{P,4,j}) + y_{P,1,j} + k^*_4(y_{C,1,j+1} + y_{C,1,j})/2 - k^*_{-4} \tag{41}$$

For $1<i<99$, the difference equation is expressed with concentrations at nodes (i−1, j), (i, j), (i+1, j), (i+2, j), (i−1, j+1), (i, j+1), (i+1, j+1), and (i+2, j+1).

$$(1+3M_{P,i,j+1})y_{P,i,j+1} = M_{P,i,j+1}(-2y_{P,i-1,j+1} + 6y_{P,i+1,j+1} - y_{P,i+2,j+1}) + M_{P,i,j+1}(-2y_{P,i-1,j} - 3y_{P,i,j} + 6y_{P,i+1,j} - y_{P,i+2,j}) + y_{P,i,j} + k^*_4(y_{C,i,j+1} + y_{C,i,j})/2 - k^*_{-4} \tag{42}$$

For a node with i=99, only an outer node is a node with i=100. Therefore, the backward space difference method is not applicable for a transformation; thus, the forward space difference method is used for this purpose. The difference equation is expressed with the concentrations at nodes (97, j), (98, j), (99, j), (100, j), (97, j+1), (98, j+1), (99, j+1), and (100, j+1).

$$(1-3M_{P,99,j+1})y_{P,99,j+1} = M_{P,99,j+1}(y_{P,97,j+1} - 6y_{P,98,j+1} + 2y_{P,100,j+1}) + M_{P,99,j+1}(y_{P,97,j} - 6y_{P,98,j} + 3y_{P,99,j} + 2y_{P,100,j}) + y_{P,99,j} + k^*_4(y_{C,99,j+1} + y_{C,99,j})/2 - k^*_{-4} \tag{43}$$

$$M_{P,i,j+1} = \Delta TH(1-s_i)^2U_{j+1}x_i(x_i+2a_{j+1}/L)/6\Delta s(x_i+a_{j+1}/L)^2 \tag{44}$$

The derived expression of the boundary condition in Eq. 25 can be rewritten with concentrations at nodes (0, j), (1, j), (2, j), (3, j), (0, j+1), (1, j+1), (2, j+1), and (3, j+1) by a previously reported procedure:[2]

$$y_{F,0,j+1} = (18y_{F,1,j+1} - 9y_{F,2,j+1} + 2y_{F,3,j+1})/11 \tag{45}$$

$$y_{C,0,j+1} = (18y_{C,1,j+1} - 9y_{C,2,j+1} + 2y_{C,3,j+1})/11 \tag{46}$$

Values of $y_{A,i,j+1}$, $y_{C,i,j+1}$, and $y_{F,i,j+1}$ are calculated by using Eqs. 33, 38, 40, 45, and 46 when precipitate particles do not exist in a volume element; these and the value of $y_{P,i,j+1}$ are calculated by using Eqs. 33, 39, 41, 42, 43, 45, and 46 when precipitate particles exist in a volume element.

(2) The second alternative assumption consists of two parts. The first part is that the concentration of the mercury(I) sulfate complex is negligible compared with the concentrations of the mercury(I) and sulfate

ions. A corollary to this is that derivatives in Eqs. 8 and 14 are zero. The second part is that the reaction rates of Reactions 4 and 5 are so large that reactions attains equilibrium within the dropping time. This latter condition is usually assumed for an analysis of a wave involving a precipitation reaction.

When precipitate particles exist in a volume element, Eq. 47 can be derived from Eq. 8:

$$C_C=(k_3C_AC_B+k_{-4})/(k_{-3}+k_4) \tag{47}$$

By the introduction of Eq. 47 to Eqs. 6, 7, 9, and 10, the following equations are obtained:

$$\frac{\partial C_A}{\partial t}=D_A\left(\frac{\partial^2 C_A}{\partial r^2}\right)+\left(\frac{2}{r}D_A-u\right)\frac{\partial C_A}{\partial r}-\frac{k_3k_4C_AC_B-k_{-3}k_{-4}}{k_{-3}+k_4}, \tag{48}$$

$$\frac{\partial C_B}{\partial t}=D_B\left(\frac{\partial^2 C_B}{\partial r^2}\right)+\left(\frac{2}{r}D_B-u\right)\frac{\partial C_B}{\partial r}+k_2C_D-k_{-2}C_HC_B-\frac{k_3k_4C_AC_B-k_{-3}k_{-4}}{k_{-3}+k_4}, \tag{49}$$

$$\frac{\partial C_D}{\partial t}=D_D\left(\frac{\partial^2 C_D}{\partial r^2}\right)+\left(\frac{2}{r}D_D-u\right)\frac{\partial C_D}{\partial r}-k_2C_D+k_{-2}C_HC_B, \tag{50}$$

and

$$\frac{\partial C_P}{\partial t}=-u\frac{\partial C_P}{\partial r}+\frac{k_3k_4C_AC_B-k_{-3}k_{-4}}{k_{-3}+k_4}. \tag{51}$$

The solubility product is related to the reaction rate constants by

$$K_{sp}=C_AC_B=k_{-3}k_{-4}/k_3k_4. \tag{52}$$

When precipitate particles do not exist in a volume element, the simultaneous equations governing the concentration of species involving Reactions 2 and 3 are given as

$$\frac{\partial C_A}{\partial t}=D_A\left(\frac{\partial^2 C_A}{\partial r^2}\right)+\left(\frac{2}{r}D_A-u\right)\frac{\partial C_A}{\partial r}, \tag{53}$$

$$\frac{\partial C_B}{\partial t}=D_B\left(\frac{\partial^2 C_B}{\partial r^2}\right)+\left(\frac{2}{r}D_B-u\right)\frac{\partial C_B}{\partial r}+k_2C_D-k_{-2}C_HC_B, \tag{54}$$

and

$$\frac{\partial C_D}{\partial t}=D_D\left(\frac{\partial^2 C_D}{\partial r^2}\right)+\left(\frac{2}{r}D_D-u\right)\frac{\partial C_D}{\partial r}-k_2C_D+k_{-2}C_HC_B. \tag{55}$$

Equations 48—51 and 53—55 are rewritten by use of Eq. 19:

$$\frac{\partial C_A}{\partial t}=D_A\left(\frac{\partial^2 C_A}{\partial r^2}\right)+\left(\frac{2}{r}D_A-u\right)\frac{\partial C_A}{\partial r}-\frac{k_3k_4C_AC_FK_{a2}}{(k_{-3}+k_4)(C_H+K_{a2})}+\frac{k_{-3}k_{-4}}{k_{-3}+k_4}, \tag{56}$$

$$\frac{\partial C_F}{\partial t}=D_F\left(\frac{\partial^2 C_F}{\partial r^2}\right)+\left(\frac{2}{r}D_F-u\right)\frac{\partial C_F}{\partial r}-\frac{k_3k_4C_AC_FK_{a2}}{(k_{-3}+k_4)(C_H+K_{a2})}+\frac{k_{-3}k_{-4}}{k_{-3}+k_4}, \tag{57}$$

$$\frac{\partial C_P}{\partial t}=-u\frac{\partial C_P}{\partial r}+\frac{k_3k_4C_AC_FK_{a2}}{(k_{-3}+k_4)(C_H+K_{a2})}-\frac{k_{-3}k_{-4}}{k_{-3}+k_4}, \tag{58}$$

$$\frac{\partial C_A}{\partial t}=D_A\left(\frac{\partial^2 C_A}{\partial r^2}\right)+\left(\frac{2}{r}D_A-u\right)\frac{\partial C_A}{\partial r}, \tag{59}$$

and

$$\frac{\partial C_F}{\partial t}=D_F\left(\frac{\partial^2 C_F}{\partial r^2}\right)+\left(\frac{2}{r}D_F-u\right)\frac{\partial C_F}{\partial r}. \tag{60}$$

In much the same way as Eq. 20 was transformed to a difference equation, Eqs. 56, 57, 58, and 60 can be transformed as follows:

$$\{E_{A,i}+k^*_3k^*_4y_{F,i,j}/2(k^*_{-3}+k^*_4)\}y_{A,i,j+1}=F_{A,i,j+1}y_{A,i+1,j+1}+G_{A,i,j+1}y_{A,i-1,j+1}+D_{A,i,j}-k^*_3k^*_4y_{A,i,j}y_{F,i,j+1}/2(k^*_{-3}+k^*_4)+k^*_{-3}k^*_{-4}/(k^*_{-3}+k^*_4), \tag{61}$$

$$\{E_{F,i}+k^*_3k^*_4y_{A,i,j}/2(k^*_{-3}+k^*_4)\}y_{F,i,j+1}=F_{F,i,j+1}y_{F,i+1,j+1}+G_{F,i,j+1}y_{F,i-1,j+1}+D_{F,i,j}-k^*_3k^*_4y_{A,i,j+1}y_{F,i,j}/2(k^*_{-3}+k^*_4)+k^*_{-3}k^*_{-4}/(k^*_{-3}+k^*_4), \tag{62}$$

$$E_{A,i}y_{A,i,j+1}=F_{A,i,j+1}y_{A,i+1,j+1}+G_{A,i,j+1}y_{A,i-1,j+1}+D_{A,i,j}, \tag{63}$$

and

$$E_{F,i}y_{F,i,j+1}=F_{F,i,j+1}y_{F,i+1,j+1}+G_{F,i,j+1}y_{F,i-1,j+1}+D_{F,i,j}. \tag{64}$$

The following equation is derived from Eq. 58 by the same procedure as applied Eq. 10:

$i=1$

$$(1+11M_{P,1,j+1})y_{P,1,j+1}=M_{P,1,j+1}(18y_{P,2,j+1}-9y_{P,3,j+1}+2y_{P,4,j+1})+M_{P,1,j+1}(-11y_{P,1,j}+18y_{P,2,j}-9y_{P,3,j}+2y_{P,4,j})+y_{P,1,j}+k^*_3k^*_4(y_{A,1,j+1}y_{F,1,j}+y_{A,1,j}y_{F,1,j+1})/2(k^*_{-3}+k^*_4)-k^*_{-3}k^*_{-4}/(k^*_{-3}+k^*_4), \tag{65}$$

$1<i<99$

$$(1+3M_{P,i,j+1})y_{P,i,j+1}=M_{P,i,j+1}(-2y_{P,i-1,j+1}+6y_{P,i+1,j+1}-y_{P,i+2,j+1})+M_{P,i,j+1}(-2y_{P,i-1,j}-3y_{P,i,j}+6y_{P,i+1,j}-y_{P,i+1,j})+y_{P,i,j}+k^*_3k^*_4(y_{A,i,j+1}y_{F,i,j}+y_{A,i,j}y_{F,i,j+1})/2(k^*_{-3}+k^*_4)-k^*_{-3}k^*_{-4}/(k^*_{-3}+k^*_4), \tag{66}$$

and

$i=99$

$$(1-3M_{P,99,j+1})y_{P,99,j+1}=M_{P,99,j+1}(y_{P,97,j+1}-6y_{P,98,j+1}+2y_{P,100,j+1})+M_{P,99,j+1}(y_{P,97,j}-6y_{P,98,j}+3y_{P,99,j}+2y_{P,100,j})+y_{P,99,j}+k^*_3k^*_4(y_{A,99,j+1}y_{F,99,j}+y_{A,99,j}y_{F,99,j+1})/2(k^*_{-3}+k^*_4)-k^*_{-3}k^*_{-4}/(k^*_{-3}+k^*_4), \tag{67}$$

When precipitate particles exist in a volume element, the values of $y_{A,i,j+1}$, $y_{F,i,j+1}$ and $y_{P,i,j+1}$ are calculated from Eqs. 45, 46, 61, 62, 65, and 66. When the precipitate particles do not exist in a volume ele-

ment, the values of $y_{A,i,j+1}$ and $y_{F,i,j+1}$ are calculated from Eqs. 45, 46, 63, and 64.

The observed corrected anodic current is obtained by subtracting the anodic current in the absence of sulfate ions from one in the presence of a sulfate ion. A numerical method to calculate an anodic current of mercury in the absence of sulfate ion will now be described.

The differential equation governing the concentration of the mercury(I) ion is given as

$$\frac{\partial C_A}{\partial t} = D_A\left(\frac{\partial^2 C_A}{\partial r^2}\right) + \left(\frac{2}{r}D_A - u\right)\frac{\partial C_A}{\partial r}. \quad (68)$$

The initial condition is

$$C_A = 0 \qquad (t=0, r=a). \quad (69)$$

The boundary conditions are

$$C_{A0} = C_{A0} \qquad (t=0, r=a), \text{ and} \quad (70)$$

$$C_A = 0 \qquad (t>0, r=\infty). \quad (71)$$

The difference equation form of Eq. 68 is

$$E_{A,i}y_{A,i,j+1} = F_{A,i,j+1}y_{A,i+1,j+1} + G_{A,i,j+1}y_{A,i,j+1} + D_{A,i,j}. \quad (72)$$

The instantaneous anodic current in the absence of a sulfate ion, i_r, is given by

$$i_r = 2FD_AS(\partial C_A/\partial_r)_{r=a}. \quad (73)$$

The corrected anodic current, i_C, is obtained by

$$i_C = i - i_r. \quad (74)$$

The corrected current is the current mainly caused by either a complex formation reaction or a precipitation reaction.

Experimental

The chemicals used were of reagent grade. The concentration of sodium sulfate in the stock solution was calculated from a weighed amount of anhydrous sodium sulfate after drying 150 °C for 2 h. The concentration of hydrogen ions in the test solution was controlled with sodium carbonate and perchloric acid. The ionic strength of the solution was also adjusted to 0.1 mol dm^{-3}.

Measurements were carried out using a Hokuto Denko Model HA-104 Potentio-Galvanostat in conjunction with the three-electrode method. Precautions were taken in order to prevent any permeation of both chloride and potassium ions from the salt bridges.

The electric resistance of the test solution in the electrolytic system was determined from the free dissolution wave of electrode mercury. The method used was as follows. The value of the resistance was assumed and the electrode potential (E) was corrected by subtracting the iR drop. The corrected electrode potential was plotted against log i. Such a plot does not necessarily produce a straight line. When the assumed value of the resistance is incorrect, the plot is curved. In this case, plotting is repeated with a slightly different value of resistance. This procedure was repeated until the plotting produced a straight line. When plotting produces a straight line, the value of resistance used is the correct value of the resistance of the circuit. This procedure gave 200 Ω for the corrected value of the resistance. The value of the slope of the straight line, ranging from 32.5 mV/unit to 33.0 mV/unit,[1] agrees with the value reported by Kolthoff and Miller. All potentials reported in this paper were corrected for the iR drop and all polarographic currents were corrected for the residual current.

The dropping mercury electrode used had the following characteristics (in 0.1 mol dm^{-3} sodium perchlorate at zero applied potential vs. SCE, and at a mercury head of 80.0 cm): a flow rate of mercury (m) of 1.86 mg s^{-1}, a drop time (t) of 3.20 s, and a capillary constant ($m^{2/3}t^{1/6}$) of 1.846 mg$^{2/3}$ s$^{-1/2}$.

Results and Discussion

The anodic current in a solution of sulfate ion was examined by our numerical method.

The value of the diffusion coefficient of the mercury(I) ion was chosen so as to give the smallest difference between the calculated diffusion currents and the observed ones.[3] This procedure gave a value of 0.847×10^{-5} cm^2 s^{-1}. A value of 1.08×10^{-5} cm^2 s^{-1} for a sulfate ion was taken from Ref. 5. The value of the diffusion coefficient of a mercury(I) complex is assumed to be equal to that for mercury(I) ion. Values of pK_{a2} and K_{sp} used are 1.99 and 7.4×10^{-7} mol^2 dm^{-6}.[6,7]

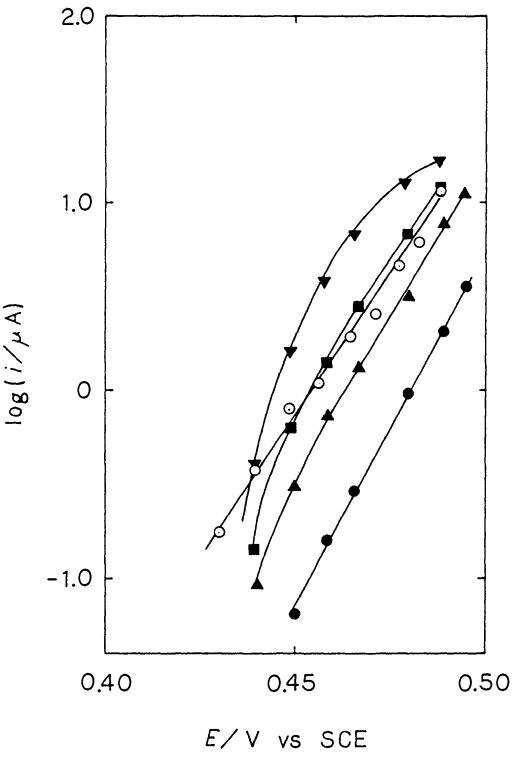

Fig. 2. Effect of the dissolution rate constant on the logarithmic plot in a solution of 2×10^{-3} mol dm^{-3} sodium sulfate and pH 1.93. Computation was carried out using the second alternative assumption. The value of K_{sp} is 0.25×10^{-7} mol^{2}dm^{-6}. ○; observed. Precipitation reaction rate constant (mol^{-1}dm^3 s^{-1}), ●; 10, ▲; 50, ■; 100, ▼; 300.

At first, the anodic current was analyzed using the second assumption, that the concentration of mercury-(I) sulfate complex is negligible compared with the concentrations of mercury(I) and sulfate ions. The observed anodic current does not show any diffusion current plateau. It was shown in a previous report[2] that a diffusion current plateau is observed in the case of a large precipitation rate, even with a large value of K_{sp}. Hence, the absence of a plateau indicates that the rate of Reaction 5 is not so large.

Figure 2 shows the effect of the precipitation reaction rate k_4 on the plots of log i against E, constructed from observed and computed polarograms. The anodic current increased with an increase in the value of k_4. For a value of 100 mol^{-1} dm^3 s^{-1} for k_4, the difference between the calculated and observed current at 0.47 V vs. SCE is smallest compared with other values. However, this value is not sufficiently large to give a plateau.

Figure 3 shows plots of log i against E, constructed from observed and computed polarograms. The observed polarograms give straight lines, of which slope is 30—32 mV/unit. The calculated points approach to the observed points with a decrease in K_{sp}. A fair agreement between the calculated and observed points was obtained with a value of K_{sp} which was smaller than 1/50 of the accepted value.[7] This shows that the second assumption is in contradiction with the observed polarograms.

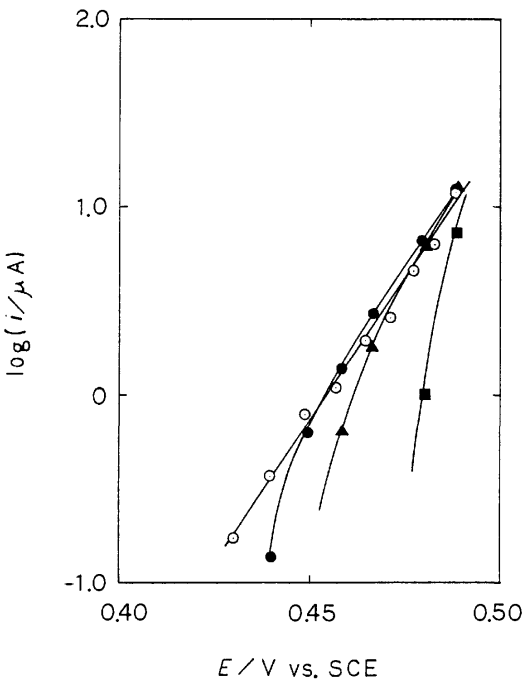

Fig. 3. Logarithmic plots of the anodic current in the solution of 2×10^{-3} mol dm^{-3} sodium sulfate and pH 1.93. Computation was carried out using the second assumption. The value of precipitation reaction rate is 100 mol^{-1} dm^3 s^{-1}. O; observed data. The value of K_{sp} ($mol^2 dm^{-6}$), ●; 0.25×10^{-7}, ▲; 0.93×10^{-7}, 7.40×10^{-7}.

Table 1. The Time Necessary for Appearance of Precipitate Particles after Mixing of Solution of Mercury(I) and Sulfate Ions. The Appearance was Observed Visually

$[Hg_2^{2+}][SO_4^{2-}]$ / 1×10^{-5} mol^2 dm^{-6}	$[Hg_2^{2+}][SO_4^{2-}]/K_{sp}$	Time / min
1.5	2.54	150
3.0	5.08	20
4.5	7.62	1
7.5	12.7	0.5
15.0	25.4	0.5

The solutions of sulfate ion in pH 1.93 are mixed with a solution of 8.03 mM mercury(I) ion in pH 1.93.

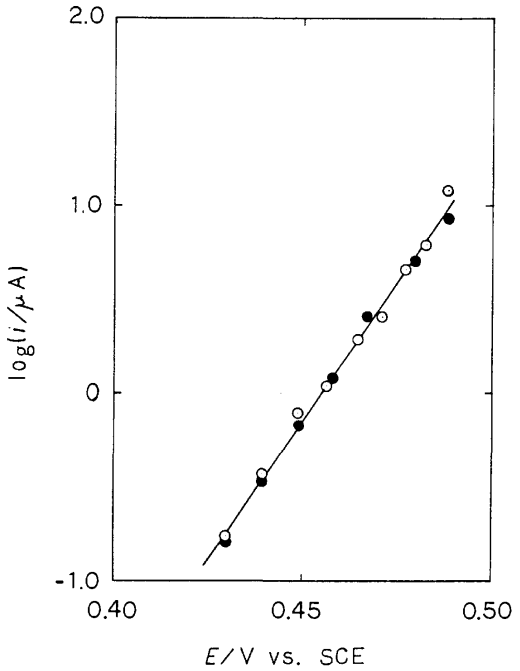

Fig. 4. Logarithmic plots of the anodic current in the solution of 2×10^{-3} mol dm^{-3} soddium sulfate and pH 1.93. Computation was carried out using the first assumptions.
O; observed data, ●; calculated data.

Table 1 shows the time necessary for the appearance of precipitate particles after mixing of solutions of mercury(I) and sulfate ions. The appearance was observed visually. It has been found that the time necessary for the appearance of precipitate particles is too large compared with the dropping time. This means that the values of k_4 and k_{-4} are nearly equal to zero.

Figure 4 shows the anodic current computed by using the first assumption that the mercury(I) sulfate precipitate is produced when the concentration of the mercury(I) sulfate complex exceeds its solubility. The calculated anodic currents are in fair agreement with the observed values. Calculated points were computed with a value of 150 $mol^{-1}dm^3$ for the equilibrium constant of Reaction 4.

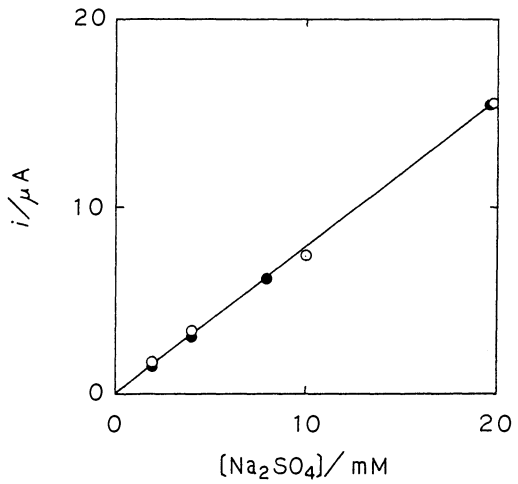

Fig. 5. Effect of the concentration of sodium sulfate on the anodic current at 0.46 V vs. SCE in the solution of pH 1.93. O; observed data, ●; calculated data.

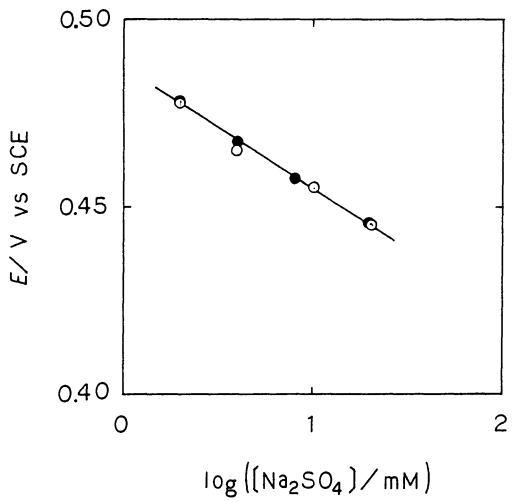

Fig. 6. Effect of the concentration of sodium sulfate on the electrode potential with the value of 5 μA for anodic current in the solution of pH 1.93. O ; observed data, ●; calculated data.

Figure 5 shows the relation between the concentration of the sulfate ions and the anodic current at 0.46 V vs. SCE. It shows that the observed currents agree well with calculated values, and that both are proportional to the concentration of sulfate ions.

Figure 6 shows the relation between the concentration of sulfate ions and the electrode potential where the anodic current is 5 μA. The calculated values agree well with the observed ones.

From the above discussion, it is certain that the anodic current is caused by the formation of a mercury(I) sulfate complex and that the precipitation reaction is slow and negligible within the dropping time.

Conclusion

An anodic wave in the presence of sulfate ions has been studied by a new numerical method. It was found that the value of the anodic current increases with an increase in the concentration of sulfate ions, and that the current is caused by the formation reaction of a mercury(I) sulfate complex. It has been confirmed by a numerical method that the precipitation reaction of mercury(I) sulfate does not take place within a dropping time. The value of the stability constant of a mercury(I) sulfate complex has been determined to be 150 $mol^{-1} dm^3$.

Intercalation of a Triethylenetetraminated Cyclodextrin by Na-, Ca-, Zn-, and Cu-Montmorillonites

Tsuyoshi KIJIMA,* Hiromoto NAKAZAWA, and Michiko KOBAYASHI
National Institute for Research in Inorganic Materials, Tsukuba-City, Ibaraki 305
(Received June 3, 1988)

The uptake of mono[6-[(8-amino-3,6-diazaoctyl)amino]-6-deoxy]-β-cyclodextrin (CDtrien) by Na-, Ca-, Zn-, and Cu-montmorillonites has been examined at 25 °C. All of the minerals form only one intercalated phase in which the CDtrien molecules are arranged as a bilayer with their cavity axes perpendicular to the silicate layers. The modes of intercalation for Na- and Ca-montmorillonites are explained differently by an ion exchange of the interlayer Na^+ ions with the divalent cationic forms of CDtrien and by the formation of CDtrien$(H_2O)_2$-Ca complexes, respectively. The intercalation by Zn- and Cu-montmorillonites proceeds by complexation at low uptakes and by the combined modes of ion exchange and complexation at higher loadings.

Inclusion phenomena have aroused increasing interest in the field of organic and inorganic chemistry, but little attention has been paid to the complexation of two or more kinds of host components. Recently, we have prepared several intercalates of layered montmorillonites and zirconium phosphate with α-, β-, and γ-cyclodextrins and their derivatives containing methoxyl or 2-aminoethylamino (en) substituents.[1-5] Some models have been proposed for the arrangement of intercalated cyclodextrin molecules in the interlayer space of the layered crystals. It was also suggested that a family of cyclodextrin intercalates may be useful as artificial enzymes, solid supports in gas or liquid chromatography and as micro-encapsulating agents of unstable substances. In order to develop these functional possibilities, further studies would be required for similar intercalates with cyclodextrin derivatives having longer chain or polyfunctional substituents. Cyclodextrins functionalized with polyamines interact with such metal ions as Cu^{2+} or Zn^{2+} in aqueous solution and the resultant cyclodextrin-metal complexes act as a metal enzyme model endowed with specific metal-substrate binding interaction.[6] If similar complexes are formed in the interlayer space of Cu- or Zn-monlmorillonite, any intercalation effect may be added to their catalytic properties.

We have, thus, attempted to prepare the intercalates of montmorillonite with mono[6-[(8-amino-3,6-diazaoctyl)amino]-6-deoxy]-β-cyclodextrin (CDtrien). This paper reports on the intercatation behavior of CDtrien for Na-, Ca-, Zn-, and Cu-montmorillonites.

Experimental

The Na-, Ca-, Zn-, and Cu-montmorillonite samples used were the same as those used in the preceding studies.[2-5] CDtrien was prepared by a manner similar to that reported for mono[6-(2-aminoethylamino)-6-deoxy]-β-cyclodextrin (CDen).[1,5] β-CD was tosylated with 0.5 equivalent of *p*-toluenesulfonyl chloride in dry pyridine at 5 °C for 2 days. The resulting mono[6-*O*-(*p*-toluenesulfonyl)]-β-CD (CDts) was dissolved in water and recrystallized. The CDts was reacted with triethylenetetramine (trien) at 70 °C for 5 h under nitrogen atmosphere. The crude product was purified by chromatography, using a carboxymethylcellulose column with 0.1 mol dm^{-3} ammonium hydrogencarbonate as an eluent, followed by repeated evaporation of the elute in the presence of a small amount of ammonia, and CDtrien was obtained in a 17% yield based on CDts. The montmorillonite sample was soaked in an aqueous solution containing various amounts of CDtrien at 25 °C for 10 days, centrifuged, fully washed with water, and air-dried at 40 °C.

Results

The uplakes of CDtrien for Na-, Ca-, Zn-, and Cu-montmorillonites are plotted against the amount of CDtrien added in Fig. 1, along with the amount of metal ion released into solution in the intercalation process. Figure 2 shows the variation of the CDtrien concentration and pH of the equilibrated solution in the uptake process.

The interlayer spacings of the dried forms of the resulting complexes were determined from the 001

reflections in the X-ray diffraction patterns. The results are shown in Fig. 3, where the Δ values on the right ordinate indicate the thickness of the intercalated layer obtained by subtracting the thickness of the silicate layers, 9.5 Å, from the observed spacings. At a level of 0.3 mmol CDtrien added per gram of each clay, a phase with a Δ value of 14.2—14.7 Å appeared and coexisted with a small amount of its parent host phase. At a level of 1.5 mmol g^{-1}, the solid was totally converted to a single phase with a Δ value of 16.9 Å for the Na-complex and 16.1 Å for the others, and the uplake level of CDtrien became almost constant.

Table 1 summarizes the interlayer spacing and composition of intercalates of Na-, Ca-, Zn-, and Cu-montmorillonites with CDtrien at its full loadings. Our previous study[2] revealed that the content of releasable metal ions in Na-riched montmorillonite was comparable to that of interlayer cations compensating the negative charge of the silicate layers, while the Cu-exchanged mineral possesses two types of copper ions, one held as interlayer ions and one adsorbed as any neutralized species on the external surface of crystals. It was also conceivably possible that the cupric ions in the latter mineral are assigned to $[CuOH]^+$ ions as well as Cu^{2+}. This assignment, however, was inconsistent with the data for the amount of cupric ion desorbed in the intercalation of CDen by the Cu-exchanged mineral. Ca- and Zn-montmorillonites also contained releasable metal ions in some amount exceeding that of interlayer cations.[5] The excess amount of these divalent metal ions also probably exists as any neutralized species with low solubilities. The initial amounts of the interlayer cationic and the neutralized forms of metal ions in montmorillonites are thus evaluated and listed in Table 1 as v_{1i}° and v_{1e}°, respectively. In Tables 1 and 2, the sub- and superscripts are 1=releasable metal ion, 2=CDtrien, i=interlayer, e=external, °=initial, d=desorbed, and r=remaining.

Discussion

CDtrien Uptake Mechanism. As can be seen in Fig. 1, the uptake of CDtrien for Na-montmorillonite is

Table 1. Characterization of Intercalates of Na-, Ca-, Zn-, and Cu-Monmorillonites with CDtrien at Its Full Loadings

Interlayer metal ion	Interlayer spacing/Å	Δ Value/Å	Amount of CDtrien/mmol g^{-1} clay[a] v_2	Amount of releasable metal ion/mmol g^{-1} clay[a]				
				Initial			Desorbed	Remaining
				total v_1°	int[b] v_{1i}°	ext[b] v_{1e}°	v_1^{d}	v_1^{r}

accompanied by the release of Na^+ ions of about twice the CDtrien uptake or more in molar amount on the entire range of CDtrien added. On the other hand, the Ca^{2+} release for Ca-montmorillonite is kept at a level as low as 0.02 mmol g^{-1}. The release of Zn^{2+} or Cu^{2+} ions from Zn- and Cu-analogues at low addition levels of CDtrien remains at an extremely low value, but increases remarkably with any further addition of CDtrien. The pK_{a_i} (i=1—4) values for trien are 3.32, 6.67, 9.20, and 9.92,[7] which are likely to be close to those for CDtrien. The uptake reaction for Na-montmorillonite takes place in the pH range of 9.5—10.1, while that for the others occurs below 9. In these two pH ranges the molecules of CDtrien would exist predominantly as CD-$NH(CH_2)_2NH(CH_2)_2NH(CH_2)_2$-$NH_2$(CDtrien) and CD-$NH(CH_2)_2NH(CH_2)_2$ $H(CH_2)_2$-NH_3^+ (CDtrienH$^+$) and as CDtrienH$^+$ and CD-$NH_2^+(CH_2)_2NH(CH_2)_2NH(CH_2)_2NH_3^+$ (CDtrien2H$^+$), respectively. The CDtrien uptake data are, thus, explained as follows: Na-montmorillonite takes up CDtrien by a two-step reaction. In the first step one mole of CDtrien is taken up as monovalent cation CDtrienH$^+$ by ion exchange with one mole of Na^+ ions. This ion exchange would be followed by the protonation of the CDtrienH$^+$ into CDtrien2H$^+$ in the interlayer medium, with an accompanying release of Na^+ and OH^- ions. On the other hand, Ca-montmorillonite intercalates neutral CDtrien molecules to form complexes with intercayer Ca^{2+} ions over the entire range of CDtrien added. Zn- and Cu-analogues also form similar complexes allow addition levels. The intercalation of CDtrien by Zn- and Cu-montmorillonites with an accompanying release of interlayer metal ion could be interpreted in terms of the combined modes of complexation and an ion exchange of Zn^{2+} or Cu^{2+}/CDtrien2H$^+$.

According to previous studies,[2,5] the neutral species on the external surface of Cu-monlmorillonite are feasibly desorbed in a CDen solution of low concentration, while those for Ca- and Zn-montmorillonites remain undissolved, even at high concentration. The dissolution of the neutral copper(II) species are probably caused by the high stability of a CDen-Cu^{2+} complex in solution. The stability constant of $10^{10.7}$ $mol^{-1}dm^3$ for a 1 : 1 CDen-Cu^{2+} complex in solution is comparable to $10^{10.72}$ for a 1 : 1 en-Cu^{2+} complex.[8] Therefore, the stability constants of 1 : 1 CDtrien-Cu^{2+} and 1 : 1 CDtrien-Zn^{2+} complexes would be as high as close to $10^{20.4}$ for trien-Cu^{2+} and $10^{12.1}$ for trien-Zn^{2+},[9] respectively. This leads us to predict that the extremely high stability of CDtrien-Cu^{2+} and CDtrien-Zn^{2+} complexes would cause not only a dissolution of the copper(II) and zinc species adsorbed on the external surface of montmorillonite crystals, but also the succeeding desorption of interlayer Cu^{2+} and Zn^{2+} ions by an ion exchange with ionized CDtrien. The amount of interlayer metal ion desorbed in the intercalation process, v_{1i}^d, can be estimated by $v_{1i}^d = v_1^d - v_{1e}^\circ$ for the case of $v_1^d > v_{1e}^\circ$. Results are listed in Table 2. The v_{1i}^d data give an expected value for the amount of the ionized form of CDtrien taken up by ion exchange. The v_2 value of 0.34 mmol g^{-1} for the sodium complex is close to an expected value of 0.385 mmol g^{-1} for the ion exchange of two moles of interlayer Na^+ ion with one mole of divalent cation CDtrien2H$^+$. Furthermore, the observed value of 0.42 mmol g^{-1} of CDtrien intercalated by Zn-montmorillonite is more than the 0.32 mmol expected for the interlayer ion exchange of Zn^{2+}/CDtrien2H$^+$ and much less than 0.64 CDtrien mmol g^{-1} expected for that of Zn^{2+}/CDtrienH$^+$. This fact indicates that CDtrien acts as a divaent cation CDtrien2H$^+$ for ion exchanges with interlayer Zn^{2+} ions in montmorillonite crystals. A similar mechanism would also be applicable to Cu-montmorillonite. These considerations enabe us to evaluate the amounts of both neutral and ionized forms of intercalated CDtrien (Table 2).

Arrangement of Intercalated CDtrien. The interlayer thickness (Δ value) of the CDtrien-montmorillonite complex is independent of the interlayer metal ions, except for the sodium complex: the Δ value of the sodium complex is also only slightly larger than that of the others. The Δ value of 16.1 Å for the calcium, zinc, and copper(II) complexes is in good agreement with twice the 8.0 Å for the van der Waals thickness of torus-shaped parent molecule. This suggests that the CDtrien molecules would be arranged as a bilayer with their cavity axes perpendicular to the silicate layers and with trien groups alternatively pointing up- and downward. The lateral packing of the CDtrien mole-

Table 2. Parameters for the Full Uptakes of CDtrien by Na-, Ca-, Zn-, and Cu-Montmorillonites

Interlayer metal ion	Amount of interlayer metal ion released/mmol g^{-1} v_{1i}^d	Amount of CDtrien/mmol g^{-1}[a]			ξ/Å[b]	Mode of intercalation[c]
		Total	Neutral form	Divalent cationic form		
Na	0.77	0.34	0 (0)	0.34(100)	5.1	E
Ca	0	0.33	0.33(100)	0 (0)	5.3	C

cules in the interlayer may be drawn by the following estimation. If we assume that CDtrien molecules, each 15.4 Å in diameter, are hexagonally packed at a distance of $15.4+\xi$ in Å (center to center), the effective area per molecule is given by $(\sqrt{3}/2)(15.4+\xi)^2$ in Å^2. As the surface area of one face of the unit cell of montmorillonite is estimated as being 46 Å^2,[10] the CDtrien content, v_2, is represented by $v_2=2\times46/\{(\sqrt{3}/2)(15.4+\xi)^2w_0\}$, where w_0 is the unit-cell weight of the host montmorillonite. The ξ values evaluated using the v_2 data are listed in Table 2. Referring to the structural characteristics of well-known complexes of Ca, Zn, and Cu(II),[11] the interlayer Ca^{2+}, Zn^{2+}, and Cu^{2+} ions in the CDtrien intercalates are likely to form coordination groups $[Ca(trien)(H_2O)_2]^{2+}$, $[Zn(trien)]^{2+}$, and $[Cu(trien)]^{2+}$ which are octahedral, tetrahedral and square planar in the atomic configuration, respectively, as illustrated in Fig. 4(a). Thus, models are proposed for the packing of CDtrien moecules in the interlayer space of montmorillonite, as exemplified for the copper complex in Fig. 4(b). The order of the CDtrien content in the resulting complexes is Ca~Na<Zn~Cu. This may be tentatively explained as follows. The relation of Ca<Cu is probably due to the octahedral coordination group $[Ca(trien)(H_2O)_2]^{2+}$ in the calcium complex being more voluminous than the planar $[Cu(trien)]^{2+}$ in the copper one. The v_2 value for the sodium complex is as small as that for the calcium one, suggesting that, in the sodium complex, the trien groups in divalent cationic forms woud largely attract water molecules which would results in the loose packing of CDtrien molecules. Although three quarters of the CDtrien molecules in the zinc complex exist in the same form as in the sodium complex, the CDtrien content in the former is close to that in the copper complex. A possible explanation of this may be that the uptake of CDtrien by Zn-monlmorillonite occurs initially by complexation, followed by the release of Zn^{2+} ion induced by the ionization of the trien group in the interlayer space.

Previously, we reported the CDen intercalates of Cu- and Zn-montmorillonites in which the CDen molecules form a bilayer with a thicknesses of 23.9 or 25.2 Å. The bilayered structure was attributed to a dimerization of pairs of 1:1 $CDen(H_2O)_2$-Cu^{2+} or CDen-$(H_2O)_2$-Zn^{2+} complexes with a tail-to-tail arrangement in the interlayer space. The present observations, on the other hand, indicated that the molecules of CDtrien are also placed as a bilayer, but that the bilayered molecules are in contact with each other in

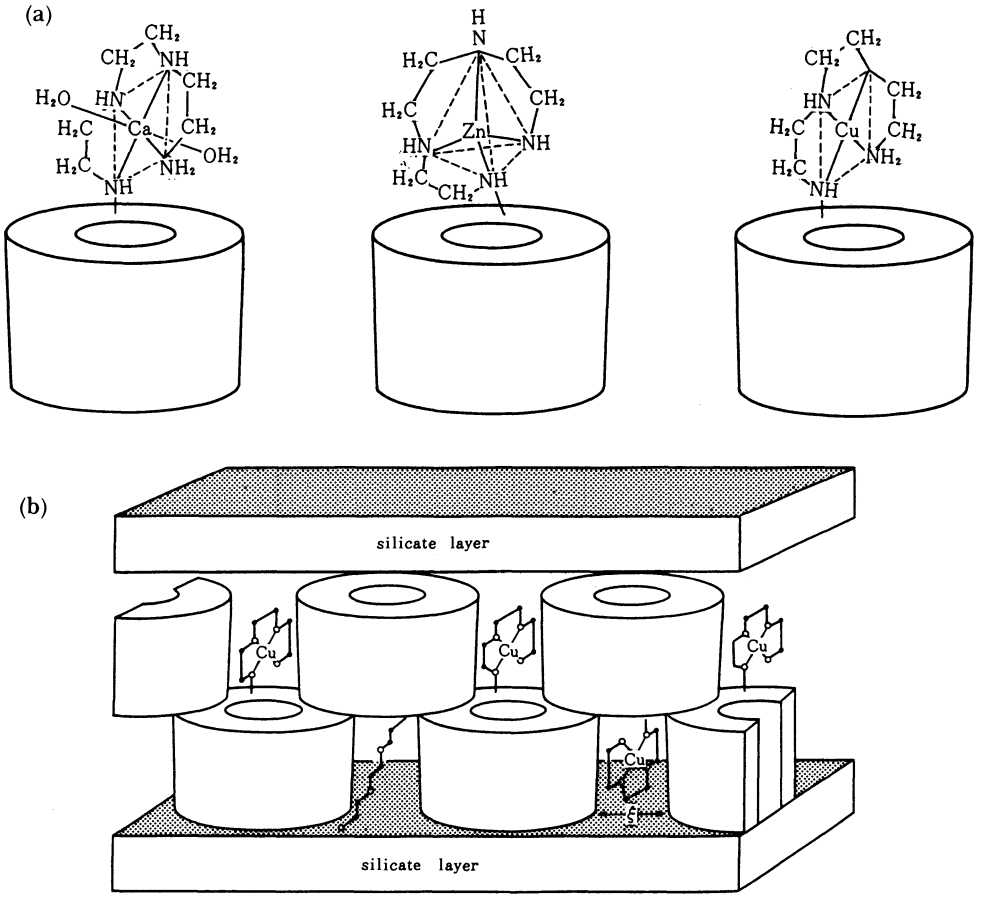

Fig. 4. Models proposed for (a) the atomic configuration of $CDtrien(H_2O)_2$-Ca^{2+}, CDtrien-Zn^{2+}, and CDtrien-Cu^{2+} complexes in montmorillonite and (b) the packing of CDtrien molecules in the interlayer space of Cu-montmorillonite. ●, C; ○, N.

the van der Waals distance. The distinct difference between the thicknesses of the cyclodextrin layers may be explained by referring to Fig. 4: Cu^{2+} or Zn^{2+} ions make a complex with the tail of CDtrien or CDen, as shown in Fig. 4(a). In the present case, the tails and the bodies of CDtrien-Cu^{2+} or CDtrien-Zn^{2+} complexes are arranged in an interfingered manner, as shown in Fig. 4(b), while they are faced and dimeraized in the previous case of CDen. The dimerization in the CDen intercalates is essentially due to a hydrogen bond by which one of the two water molecules associated with one CDen molecule is linked to one of the seven primary hydroxyl groups in the other CDen molecule faced.

The authors wish to thank Dr. Haruo Ohashi and Dr. Yu Komatsu for their helpful discussions.

Resonance Raman Spectroscopic Studies of Electrogenerated Cation Radicals by Column-Electrolytic Continuous-Flow Method

Munetaka Oyama, Koichi Nozaki, Hiroyuki Hatano, and Satoshi Okazaki*
Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto 606
(Received June 22, 1988)

For the measurement of resonance Raman (RR) spectra of electrogenerated cation radicals in solution, a column-electrolytic continuous-flow method has been developed. This method has the advantage that the concentration of cation radicals can be easily varied by controlling the applied current. The RR spectra of the thianthrene cation radical ($TH^{+\cdot}$) have been successfully observed. The structure of $TH^{+\cdot}$ is discussed, based on the assignment of the RR band. The RR spectra of the oxidized solutions of three aromatic amines have also been measured. These spectra were assigned not due to those of cation radicals but to those of dimer cation radicals produced in the consecutive reactions.

The resonance effect in Raman spectroscopy has permitted analysis of structural and electronic changes in transient intermediates of organic compounds. These changes in many ion radicals have been studied using this technique. In most of these studies, radical anions and cations were generated by chemical and/or photochemical methods.[1-10]

In the field of electrochemistry, surface enhancement Raman scattering (SERS) and/or surface enhancement resonance Raman scattering (SERRS) have been studied extensively. A potential modulation Raman spectroscopy (PMRS) is also useful for in situ observation of electrode/electrolyte interface.[11,12] With this technique, the change in spectra of surface species with potential was obtained. In these cases, the subjects were restricted to adsorbed species on the electrode surface and/or species near electrodes. To investigate the structure of electrogenerated intermediates in dynamic state, e.g. on their chemical reactions, it is also necessary to observe their Raman spectra in bulk solution. There have been few studies, however, on electrochemically generated ion radicals in solution using resonance Raman spectroscopy (RRS).[13]

In the resonance Raman (RR) measurement of solutions by using a conventional Raman spectrophotometer with 90° scattering geometry, there are two major experimental problems as follows: (1) The concentration of a substrate must be adjusted to optimum condition.[14] (2) Decomposition and thermal absorption of the substrate by excitation laser light must be avoided. As to substrate concentration, it must be high enough to permit the RR spectrum observation. As the concentration increases, however, loss of excitation light and/or scattering light due to the absorption of a substrate also increases. So the concentration of a substrate must be adjusted carefully to the optimum range for RR measurement.

We have therefore developed a column-electrolytic continuous-flow system for Raman spectroscopy to obtain the RR spectra of electrochemically generated ion radicals in homogeneous solutions. The column electrolysis flow-cell and related techniques developed by the author (S.O.)[15,16] has been widely utilized in the preparation of organic ion radicals for their ESR,[17,18] or stopped-flow spectroscopic studies.[19,20] With this technique, it becomes easy to generate ion radicals at high concentration and vary their concentration by controlling the electrolysis current and flow rate. The second problem, decomposition and thermal absorption, can be avoided using the flow system. Thus, this method will provide the vibrational information of electrogenerated intermediates in bulk solution without any influence of the electrode conditions, such as electrode materials, pretreatments, adsorption phenomena, etc.

The present paper first describes the measurement of the resonance Raman spectra of the thianthrene (TH) cation radical ($TH^{+\cdot}$) by using this method. $TH^{+\cdot}$, one of the most stable cation radicals in acetonitrile (AN), has been the subject of a number of electrochemical studies. Recently, Jørgensen clarified its structure as being very similar to the parent molecule via ab initio MO calculation;[21] the present study also shed some light on the structure.

Also measured were the RR spectra of the oxidized AN solutions of aromatic amines such as triphenylamine (TPA), *N*-methyl-*N*-phenylaniline (MPA), and *N*,*N*-dimethylaniline (DMA). In these cases, the cation radicals of aromatic amines are unstable and dimerize rapidly. Thus we obtained the RR spectra not of monomer cation radicals but dimer cation radicals. The observed RR spectra in the flow system are discussed in connection with the absorption spectra and their consecutive reactions.

Experimental

Apparatus and Method. Visible absorption spectra were measured by a Unisoku USP-500 spectrophotometer equipped with a multichannel photodiode array detector. Raman spectra were recorded on a JEOL 400 D Raman spectrophotometer with an argon ion laser excitation source. A Toho Giken 2020 galvanostat was used for constant current electrolysis.

The outline of a column-electrolytic continuous-flow cell for Raman spectroscopy is shown in Fig. 1. The solution containing the parent molecules and supporting electrolyte

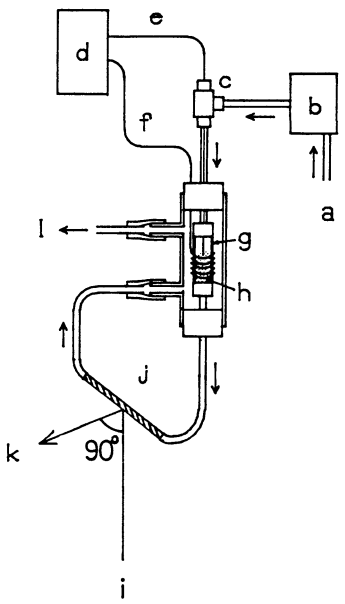

Fig. 1. Outline of the column-electrolytic continuous-flow cell for Raman spectroscopy. (a) reservoir, (b) peristaltic pump, (c) T-joint, (d) galvanostat, (e) Pt-lead to working electrode, (f) Pt-lead to counter electrode, (g) porous glass diaphragm tube, (h) carbon wool working electrode, (i) laser source, (j) capillary cell, (k) detector, (l) drain.

was sent to the column-electrolytic cell by a peristaltic pump at a constant flow rate. Acetonitrile (AN) solvent was used to acquire the RR spectra of electrogenerated cation radicals because: (1) Cation radicals are rather stable in AN. (2) AN shows relatively fewer Raman peaks than other aprotic solvents. The supporting electrolyte used was tetraethylammonium perchlorate (TEAP). The column-electrolytic cell consisted of a carbon wool working electrode which was tightly filled in a porous glass diaphragm tube (i.d. 4 mm, 3 cm length), with a platinum wire (0.3 mm) counter electrode wound outside the tube. The parent molecules were electrooxidized in the course of passing through the cell. The electrolyzed solution was then sent to a capillary cell, where the Raman spectrum was observed. The excitation light was focused from below to the capillary and the scattering light was collected at a 90° angle to the excitation light beam. The solution was then sent to the outer chamber of the cell, to serve as counter electrolyte solution and was then drained.

During measurement of a Raman spectrum, the solution flowed at a constant rate and the parent molecules were electrooxidized by constant current electrolysis. The concentration of electrogenerated cation radicals could be easily adjusted by controlling the electrolysis current and/or the sample flow rate. If the lifetime of a cation radical is sufficiently long to make the concentration decay negligible, concentration at the capillary cell can be estimated as follows:

For a simple one-electron oxidation process, the concentration of the electrogenerated cation radical, c, is given by Eq. 1,

$$c/\text{mol dm}^{-3} = \frac{\text{i/A}}{(F/\text{C mol}^{-1})\,(\text{v/dm}^3\,\text{s}^{-1})} \qquad (1)$$

or Eq. 2 using practical units.

$$c/\text{mol dm}^{-3} = 6.22 \times 10^{-4}\ \frac{i/\text{mA}}{v/\text{ml min}^{-1}} \qquad (2)$$

Where i, i are electrolysis current, v, v are the flow rate, and F is the Faraday constant.

Reagents. Thianthrene (Tokyo Kasei GR grade), triphenylamine, *N*-methyl-*N*-phenylaniline, and *N*,*N*-dimethylaniline (Nacalai tesque GR grade) were used without further purification. AN was twice distilled over P_2O_5. The supporting electrolyte, TEAP, was prepared by adding tetraethylammonium bromide to the aqueous solution of sodium perchlorate, recrystallizing it four times from water and drying over P_2O_5 in vacuo at 80 °C overnight before use.

The sample solutions used were 2.5 mM (1 M=1 mol dm^{-3}) TH with 0.05 M TEAP in AN and 10 mM aromatic amines with 0.1 M TEAP in AN.

Results and Discussion

Acquisition of RR Spectra of TH$^{+\cdot}$. Without the electrolysis current, the Raman spectra show only some peaks due to AN solvent, as shown in Fig. 2a, over all excitation wavelengths of the Ar^+ laser (between 457.9 and 514.5 nm). The Raman peaks of TH in AN were not observed, because (1) TH has no absorption in the region between 457.9 and 514.5 nm and (2) its concentration (2.5 mM) was too low for normal Raman measurement.

Under applied electrolysis current, by contrast, several additional Raman peaks appeared, as shown in Figs. 2b—g. These peaks were identified as the resonance Raman peaks of electrogenerated TH$^{+\cdot}$, based on

Fig. 2. Raman spectra without electrolysis current (a) and resonance Raman spectra of TH$^{+\cdot}$ (b—g) recorded between 300 and 1600 cm^{-1} using (b) 457.9, (c) 476.5, (d) 488.0, (e) 496.5, (f) 501.7, and (g) 514.5 nm excitation. Electrolysis current: 1.5 mA; flow rate: 1.1 ml min^{-1}. Solvent bands are marked with S.

the facts that (1) these peaks were observed only when the electrolysis current was applied, (2) the electrooxidized solution of TH has absorption in the Ar^+ excitation range as shown in Fig. 3; arrows indicate wavelengths of various excitation lines of the Ar^+ laser used, and (3) the absorption spectrum in Fig. 3 is in good agreement with the reported spectrum of $TH^{+\cdot}$.[22] Figures 2b—g show the effect of excitation laser wavelengths on the resonance Raman spectra of $TH^{+\cdot}$. The concentration of $TH^{+\cdot}$ was kept constant in all measurements by controlling the applied current and flow rate as the same.

Raman intensity was proportional to the excitation light intensity and the four powers of an absolute wavenumber of the peak. In the case of resonance Raman spectroscopy, excitation and scattering light were decreased by the absorption of the species. Thus, in considering the excitation profiles, we normalized the Raman peak intensities using the AN band at 920 cm^{-1}. Figure 4 shows the excitation profiles of resonance Raman peaks of $TH^{+\cdot}$. The relative intensities of all Raman bands in Fig. 4 depend on the wavelengths of the excitation laser lines and exhibit the same profile as the absorption spectrum of $TH^{+\cdot}$. This also indicates that these observed peaks are the RR peaks of $TH^{+\cdot}$.

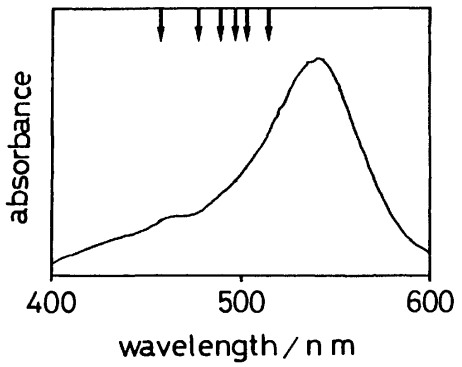

Fig. 3. Visible absorption spectrum of oxidized solution of TH. Arrows show laser lines used.

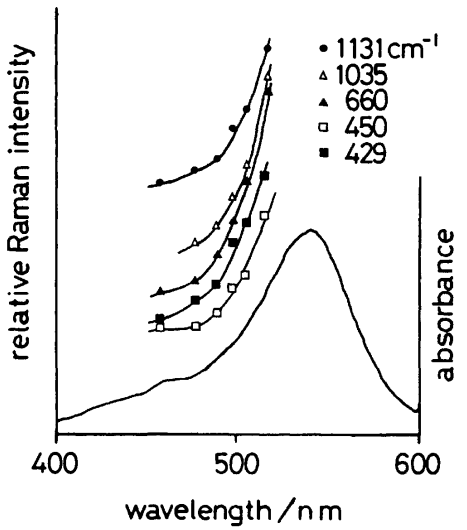

Fig. 4. Visible absorption spectrum of $TH^{+\cdot}$ and excitation profiles of resonance Raman bands, calculated using AN band at 920 cm^{-1} as internal standard.

Control of the $TH^{+\cdot}$ Concentration. Resonance Raman spectra of $TH^{+\cdot}$ were observed under various applied currents and flow rates. Table 1 summarizes the relative intensities of these $TH^{+\cdot}$ bands, normalized with the AN band at 920 cm^{-1}. The concentration of $TH^{+\cdot}$ at each run was calculated using Eq. 2. It was found that the normalized peak intensity is roughly proportional to the molar concentration of $TH^{+\cdot}$.

Figure 5 shows the effect of the electrolysis current (i.e. the concentration of $TH^{+\cdot}$) on absolute Raman intensities. In this figure, the Raman peak of AN at 381 cm^{-1} (a) and the RR peak of $TH^{+\cdot}$ at 429 cm^{-1} (b), under various applied currents at the same flow rate are shown. If there is no loss of light due to absorption by the substrate, the Raman peak of AN should have a constant intensity, while that of $TH^{+\cdot}$ should increase. The result showed, however, that the intensity of the AN band decreased and that of $TH^{+\cdot}$ band did not increase uniformly with increasing electrolysis current, owing to the absorption of the increasing $TH^{+\cdot}$. Thus, the higher concentration is not necessarily the better conditions for measurement, because the scattered light is absorbed to a great extent by the substrate itself in the 90° scattering geometry measurement.

Table 1. Relative Raman Intensities of $TH^{+\cdot}$ under Various Applied Currents and Flow Rates

Current	Flow rate	$[TH^{+\cdot}]$	Relative intensity					
			Raman sifts of $TH^{+\cdot}/cm^{-1}$

Excitation wavelength: 497.5 nm.

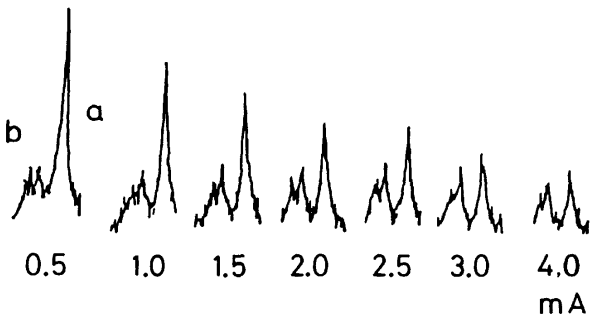

Fig. 5. Changes in intensities of AN solvent 381 cm^{-1} band (a) and $TH^{+\cdot}$ 429 cm^{-1} band (b) by applied currents. Flow rate: 1.7 ml min^{-1}; excitation wavelength: 514.5 nm.

With the electrolysis current of 4.0 mA, the RR peak of $TH^{+\cdot}$ and the Raman peak of AN became rather weak owing to the light loss due to $TH^{+\cdot}$ absorption. As a result, applied current range of 2.5 to 3.0 mA (i.e. the concentration of $TH^{+\cdot}$ was from 0.92 to 1.1 mM) was preferable for obtaining RR spectra of $TH^{+\cdot}$ with high peak intensity. Thus, it was concluded that the optimal concentration of $TH^{+\cdot}$ for the RR measurement was ca. 1.0 mM in this experiment.

Though the flow rate employed in this study was slower than 2.5 ml min^{-1} for the observation of RR spectra of very stable $TH^{+\cdot}$, faster flow-rates, up to 10 ml min^{-1}, can be applied for the acquisition of RR spectra of less short-lived species.

Comparison between the RR Spectrum of $TH^{+\cdot}$ and the Raman Spectrum of TH. The RR spectrum of $TH^{+\cdot}$ in AN (a) and the Raman spectrum of solid TH (b) are shown in Fig. 6. The Raman spectrum of TH powder was observed by the conventional procedure with a capillary cell. Vibrational modes were assigned using the reported Raman spectra of analogous molecules such as phenothiazine,[23] its cation radical,[6] and 5,10-dihydrophenazine cation radical.[8] The results are summarized in Table 2. In the case of $TH^{+\cdot}$, only nine bands were observed in this study. It seems only the most enhanced Raman bands are observed because of self-absorption.

In considering the structural difference between TH and $TH^{+\cdot}$, the significant feature is the change in its dihedral angle (θ in Fig. 7). The structure of TH has been the subject in the fields of X-ray diffraction[24] and electron diffraction.[25] It was revealed that the molecule has a folded C_{2v} conformation with a dihedral angle of 131°. Whereas, as for the structure of $TH^{+\cdot}$, it has been recently clarified by ab initio MO calculation that $TH^{+\cdot}$ is very similar in structure to TH.[21]

Hester et al. analyzed the change in dihedral angles between the phenothiazine derivatives and their cation radicals by comparing their Raman spectra.[6] In the case of phenothiazine, its dihedral angle changes in the cation radical from that of the parent molecule. This change in dihedral angle is thought to appear as the remarkable shifts in the Raman bands of the C-S-C and C-N-C skeletal deformation bands.

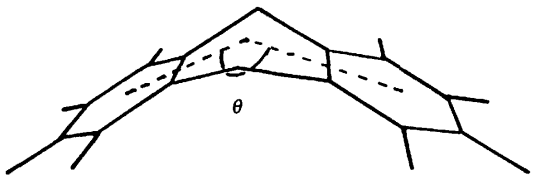

Fig. 7. Structure of $TH^{+\cdot}$. θ: dihedral angle.

In the present study, the C-S-C skeletal deformation band is assumed to correspond with the shift from 419 cm^{-1} in TH to 429 cm^{-1} in $TH^{+\cdot}$. This value is rather smaller than that of phenothiazine. It is therefore surmised that the dihedral angle of $TH^{+\cdot}$ is almost the same as that of TH, as the MO calculations predicted that the structure of $TH^{+\cdot}$ would be very similar to that of TH. However, comparison was made between TH in solid state and $TH^{+\cdot}$ in solution, since the Raman spectrum of TH could not be observed in AN owing to its poor solubility therein (10 mM). So the frequency shifts of Raman bands on dissolution of TH in AN could not be estimated. Moreover, in the short wavenumber range, the Raman spectra in the solution cannot be observed so clearly as in the solid. At present, there are still some experimental difficulties for further discussion as to the structural change in $TH^{+\cdot}$, i.e. the AN peak at 380 cm^{-1} interferes with observa-

tion of the RR spectrum of $TH^{+\cdot}$. Further investigations using other methods are needed for assessing the structural change of TH to $TH^{+\cdot}$.

RR Spectra of the Oxidized Solutions of Aromatic Amines. The RR spectra of electrooxidized solutions of the three aromatic amines TPA, MPA, and DMA were also observed by this method. Table 3 summarizes their RR shifts. For the assignment of those spectra, the reactivities of their cation radicals must be considered; that is because they dimerize rapidly and produce dimer cation radicals and/or dimer dications.

For example, on anodic oxidation of TPA, the reaction proceeds under the following schemes.[26] Here, TPB denotes *N,N,N′,N′*-tetraphenylbenzidine.

$$TPA - e^- \rightarrow TPA^{+\cdot} \quad (3)$$
$$2TPA^{+\cdot} \rightarrow TPB + 2H^+ \quad (4)$$
$$TPB - e^- \rightarrow TPB^{+\cdot} \quad (5)$$
$$TPB^{+\cdot} - e^- \rightarrow TPB^{2+} \quad (6)$$

Hinoue et al. observed in situ absorption spectra in the course of their reactions by means of internal reflection spectroscopy with an optically transparent electrode.[27]

Though the absorption spectra of $TPA^{+\cdot}$ and $TPB^{+\cdot}$ could be observed, $DMA^{+\cdot}$ seemed to be so unstable and to dimerize so rapidly (within 1 ms) that the detectable species was *N,N,N′,N′*-tetramethylbenzidine (TMB) cation radical ($TMB^{+\cdot}$) or dication (TMB^{2+}).

Hester et al. obtained the RR spectrum of $TMB^{+\cdot}$ by the photoionization of TMB in a glassy ethanol matrix at 77 K (Table 3 d).[9] The obtained RR spectrum in the oxidized solution of DMA showed quite similar results in comparison with the RR spectrum of $TMB^{+\cdot}$ (Table 3 c). Furthermore, as previously reported,[28] the Raman spectrum of dimer dication differs from that of the cation radical. In the case of dianions, the Raman spectra also differed from those of anion radicals.[1] Therefore, the observed RR spectrum of the oxidized solution of DMA was assigned to $TMB^{+\cdot}$ This indicates the possibility of identifying intermediates in the course of electrochemical reactions by comparison with results from other methods.

The RR spectra of the oxidized solutions of MPA and TPA were also observed (see Table 3 a,b). In the case of MPA, the RR spectrum was assigned to *N,N′*-dimethyl-*N,N′*-diphenylbenzidine cation radical ($MPB^{+\cdot}$), considering its stability and the result of DMA. As $TPA^{+\cdot}$ is much more stable than $MPA^{+\cdot}$, $TPA^{+\cdot}$ and dimer cation radicals ($TPB^{+\cdot}$) were assumed to coexist in the capillary cell where the RR spectra were observed. The time resolved visible absorption spectra of the oxidized TPA solution were observed by column-electrolytic stopped-flow spectroscopy,[19,20] where the electrogenerated intermediate was sent rapidly to the optical flow cell and the absorption spectra at every 50 ms were observed by a multichannel photodiode array detector. The results are shown in Fig. 8, in which the decreasing peak at 651 nm was assigned to $TPA^{+\cdot}$ and the increasing peak at 464 nm was that of $TPB^{+\cdot}$. The absorption spectrum of the electrooxidized solution also indicated that $TPA^{+\cdot}$ and $TPB^{+\cdot}$ were present in the flowing solution. Though there were two species, on the basis

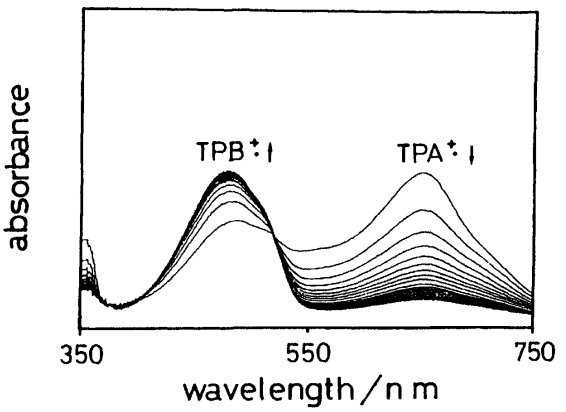

Fig. 8. Time-resolved visible absorption spectra of oxidized solution of TPA by column-electrolytic stopped-flow method.
Observation interval: 50 ms.

of the excitation wavelength (488.0 nm) the observed RR spectrum was assigned not to $TPA^{+\cdot}$ but to $TPB^{+\cdot}$. As well, the observed Raman shift of inter-ring C-C stretching band at 1324 cm^{-1} indicated that the source species is the dimer cation radical.

Though the excitation laser lines were restricted to the range between 457.9 and 514.5 nm in this study, it is very interesting that the RR spectrum of short-lived $TPA^{+\cdot}$ can be observed separately from $TPB^{+\cdot}$ using the excitation lines around 650 nm. This indicates the possibility of selective observation of the RR spectra of substances coexisting in the solution.

In conclusion, the RR spectra of electrogenerated cation radicals have been successfully measured using this method. The great feature of this method is the ease of controlling the concentration of the species, which makes the method a powerful tool for the resonance Raman study of electrogenerated intermediates in a free state, apart from electrodes.

The authors express their gratitude to Prof. Kazuhiro Maruyama for providing the Raman spectrophotometer. This work was supported in part by a Grant-in-Aid for Scientific Research, No 63470029 from the Ministry of Education, Science and Culture.

Kinetic Study on the Reaction of *p*-Nitrophenyl Acetate with 6-Substituted 2,4-Diamino-1,3,5-triazines

Takeo KONAKAHARA,* Koji KISHIMOTO, Hiroyuki SATO, Yasushi TAKAGI, and Kenji SATO
Department of Industrial and Engineering Chemistry, Faculty of Science and Technology, Science University of Tokyo, Noda, Chiba 278
(Received March 2, 1988)

The reactions of *p*-nitrophenyl acetate (**1**) with six 6-substituted 2,4-diamino-1,3,5-triazines, (**2a—2f**), were kinetically investigated in aqueous DMSO or in water at 30 °C. It was found that the reaction rate R could be expressed according to the equation $R=(k_0+k_N[\mathbf{2}])[\mathbf{1}]$, and that Brönsted-type plots for the k_N-reaction give a straight line with a slope (β) of 1.05. The solvent deuterium isotope effect was not observed in this reaction [$k_N(H)/k_N(D)=1.0—1.15$]. Furthermore, the isolated reaction product was 2-acetylamino-4-amino-6-methyl-1,3,5-triazine (**4c**), which was formed by a nucleophilic attack of **2c** to **1**. From these results, the mechanism for this nucleophilic reaction is discussed.

The structure-reactivity relationship in acyl transfer reactions has been investigated by many workers.[1] Among these reactions, nucleophilic reactions of tertiary amines, pyridines, or imidazoles are especially useful in the preparation of acylated compounds[2,3] and in the catalytic hydrolyses of esters.[1] Furthermore, nucleophilic catalyses of secondary or primary amines in acyl transfer reactions are important as a model of enzymatic reactions.[1] It is therefore worthwhile studying the reaction of an ambident nucleophile, such as a 2-aminopolyazine, with carbonyl compounds. It has been reported that 2-aminopyridines[4] or 2-aminopolyazines, such as 2-aminopyrimidines[5] and 2-amino-1,3,5-triazines,[6,7] react with formaldehyde to give 2-(hydroxymethylamino)pyridines or 2-(hydroxymethylamino)polyazines. In addition, 2-aminopyridines and/or 2-aminopyrimidines react with picryl chloride and/or fluoride to give 2-picrylamino derivatives by initial formation and subsequent rearrangement of 1-picryl-2-imino-1,2-dihydro derivatives.[8,9] That is to say, the reacting site in the initial step of this reaction is not the amino-nitrogen atom, but the ring-nitrogen atom of this ambident nucleophile. Since we have been investigating kinetics for the reaction of 2,4,6-triamino-1,3,5-triazine (melamine) with formaldehyde,[10] it is very interesting for us to determine the actual nucleophilic site of this ambident nucleophile.

In this paper, we wish to report on the reaction of *p*-nitrophenyl acetate (**1**) with 6-substituted 2,4-diamino-1,3,5-triazines (**2a—2f**) in aqueous DMSO or water, as an extension of our above-mentioned study or in connection with an investigation regarding the model of enzymatic reactions. The reaction was kinetically investigated by the aid of Brönsted-type plots, the solvent deuterium isotope effect, and product analyses by HPLC.

Results and Discussion

Kinetics. When *p*-nitrophenyl acetate (**1**) was treated with the 1,3,5-triazines (**2a—2f**) in the presence of phosphate buffers at 30 °C in aqueous DMSO [DMSO : water=3 : 7 (v/v)] or in water, *p*-nitrophenol was generated according to the reaction rate R expressed by Eqs. 1 and 2,

$$R=k_{obsd}[\mathbf{1}] \quad (1)$$

$$k_{obsd}=k_0+k_N[\mathbf{2}] \quad (2)$$

where k_0 is a rate constant for a reaction in the absence of **2** in the buffered media, and k_N is a rate constant for a nucleophilic attack of the 1,3,5-triazines (**2**) to the ester (**1**) (described later). The second-order rate constants (k_N) for the reaction were obtained as slopes of plots of $[\mathbf{2}]_0$ against the observed pseudo first-order rate constants, k_{obsd} (Table 1), at constant pH, buffer concentration, and ionic strength (Eq. 2). Typical examples of the plots are shown in Fig. 1; the k_N values, thus obtained, were not affected by the pH in the medium. Therefore, the mean values are shown in Table 2 together with each pK_a of the conjugate acid of **2**.

Mechanism. The rate constants for the formation of *p*-nitrophenol catalyzed by both water (the spontaneous formation) and phosphate buffers are included in the k_0 term. Since the rate constant k_{obsd} is proportional to the concentration of the 1,3,5-triazine (**2**), as shown in Eq. 2, the following three mechanisms, expressed by Schemes 1—3, are conceivable, where HA and A$^-$ are the acid and base components of the phosphate buffer.

The rate laws of all these three mechanisms are given by Eq. 2. Generally, the solvent isotope effects, k_H/k_D, for the first mechanism shown in Scheme 1 is in the range 2 to 4 when a proton is being transferred in the transition state.[11] However, the observed $k_N(H)/k_N(D)$ values for the reactions of **1** with **2a**, **2c**, and **2e** are 1.0—1.15 in aqueous DMSO or in water (Table 3). Therefore, the first mechanism (Scheme 1) would be ruled out; it is expected that the 1,3,5-triazine (**2**)

Table 1. Experimental Conditions for the Determination of the Rate Constants, k_{obsd}, for the Reaction of *p*-Nitrophenyl Acetate (**1**) with the 1,3,5-Triazine (**2a—2f**) in Aqueous DMSO in the Presence of Phosphate Buffers at 30 °C, Ionic Strength of 0.3 (KCl)[a]

a) DMSO: H_2O=3:7 (v/v). b) The value of the conjugate acid of **2** was determined by a titrimetric method in aqueous DMSO at 30 °C and ionic strength of 0.3 with KCl. c) The pH's in the medium did not affect on the k_N values, and the error shown is standard deviation of the slope, by least-squares analysis, for the plots of Eq. 2.

nucleophilically attacks the carbonyl carbon of *p*-nitrophenyl acetate (**1**) to form the acetylated compound[12] through a tetrahedral intermediate, as shown in Scheme 2 or 3, like a reaction of 2,4-dinitrophenyl acetate with pyridine,[13] or a reaction of **1** with imidazoles.[14]

In order to determine the reacting site of this ambident nucleophile **2**, the log k_N's for the reactions of the six 1,3,5-triazines (**2a—2f**) in aqueous DMSO were plotted against the pK_a's of their conjugate acids (the Brönsted-type plots). A good linear relationship (the slope, β=1.05) was obtained (Fig. 2). The deviation of **2e** from the line is suggestive that the 1-N atom is the actual nucleophilic site in the reaction of **2e**, because the deviation must result from a steric hindrance by the relatively bulky isopropoxy group adjacent to the 1-N atom[15,16] (Scheme 2). When the log k_N values were statistically corrected, **2b** also showed a large negative deviation from a line like **2e**. This deviation of **2b** and **2e** from statistically corrected Brönsted-type plots is not explicable by the third mechanism (Scheme 3), in which the substituent X does not sterically hinder a carbonyl attack of the amino group. Furthermore, the 1,3,5-triazine **2** is not protonated at the amino group but at the ring-nitrogen,[16] and the basicity or electron density (nucleophilicity) of the amino-nitrogen is extremely diminished by the electron-withdrawing 1,3,5-triazine ring[17] compared

a) pD="meter pH"+0.40 (see Ref. 30). b) DMSO: H_2O (or D_2O)=3 : 7 (v/v).

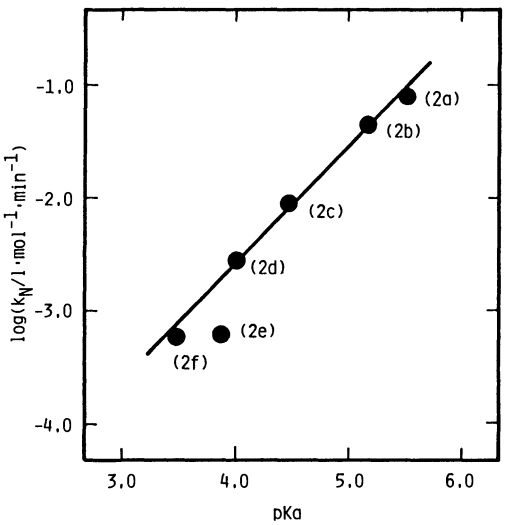

Fig. 2. The Brönsted-type plots for the reaction of *p*-nitrophenyl acetate (**1**, 5×10^{-5} mol·l^{-1}) with the 6-substituted 2,4-diamino-1,3,5-triazines (**2a—2f**) in the presence of phosphate buffers (pH 8.7) in aqueous DMSO at 30 °C and ionic strength of 0.3 (KCl); the slope β=1.05 and correlation coefficient r=0.99. When the k_N values were corrected by statistical factors in order to explain the third mechanism in Scheme 3, **2b** showed a large negative deviation from a line like **2e**.

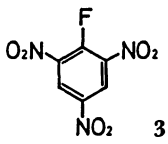
with the amides[18] or urea (pK_b=13.8).[19] This low nucleophilicity of the amino-nitrogen of **2** was demonstrated by lack of reactivity of **2c** against picryl fluoride (**3**), as described later. From these results, it is



3

inferred that the reaction proceeds through an initially formed unstable acetyl adduct (**6**). In other words, the second mechanism (Scheme 2) is more probable as the main reaction in our system than the third (Scheme 3).

The slope (β=1.05) of the Brönsted-type plots (Fig. 2) is nearly equal to those for aminolysis reactions of activated carbonyl compounds[13] such as 2,4-dinitrophenyl acetate (β=0.85) and methyl chloroformate (β=0.93). If the result of Castro and Freudenberg[13] is applicable to our system, the 1,3,5-triazine leaves more

easily from the tetrahedral intermediate than the *p*-nitrophenoxy group ($k_{-1} \gg k_2$); that is, the second step (the k_2-reaction) would be rate determining in Scheme 2.

We now give another conceivable mechanism (the fourth mechanism). It has been reported by Okano and Ogata[20] that the hydroxymethylation of melamine (**2b**) with formaldehyde in the presence of a basic catalyst takes place by a consecutive mechanism, including a carbonyl attack by a conjugate base of **2b**, which is generated from **2b** by the action of a basic catalyst. However, an analogous mechanism for the reaction of **2** with **1** (the fourth mechanism) would also be ruled out[17] because the amino-hydrogen of **2** (pK_a of **2b**, 36)[17] is not acidic enough to be abstructed by the basic component of the buffer (hydrogenphosphate, pK_a of the conjugate acid,[21] 7.63).

Reaction of *p*-Nitrophenyl Acetate (1) or Picryl Fluoride (3) with 2,4-Diamino-6-methyl-1,3,5-triazine (2c). In order to determine the structure of the product in the reaction of the ester (**1**) with the 1,3,5-triazine (**2**), **1** or **3** was treated with one of the 1,3,5-triazines, **2c**, in dry DMSO, which was employed as a solvent instead of aqueous DMSO to minimize the hydrolysis of **1** or **3** and to increase the solubility of **2c** in the medium.

First, 2,4-diamino-6-methyl-1,3,5-triazine (**2c**) was heated with *p*-nitrophenyl acetate (**1**) in dry DMSO at 100 °C for 17.5 h to afford 2-acetylamino-4-amino-6-methyl-1,3,5-triazine (**4c**) in 60% yield as colorless crystals. The formation of this compound **4c** looks strange in comparison with the result from the Brönsted-type plots (Fig. 2), which supports the second mechanism illustrated in Scheme 2. This discrepancy may be interpreted by the hypothesis that the 1,3,5-triazine (**2**) attacks the ester (**1**) to afford, ultimately, the acetylamino derivative (**4**) by initial formation and subsequent fast rearrangement of 3-acetyl-4-amino-2-imino-2,3-dihydro-1,3,5-triazine derivatives (**6**) or the corresponding 1-acetyl derivatives[16] (Scheme 4). In fact, it has been reported that 2-aminopyridines analogously react with picryl chloride or **3**.[8,9] Accordingly, the 1,3,5-triazine (**2c**) was treated with **3** in dry DMSO at 80 °C. However, neither the corresponding 3-picryl product nor the 2-picrylamino-6-methyl-1,3,5-triazine obtained, and most of the unreacted **2c** was recovered as the picrate. This result indicates that the sterically crowded ring-nitrogen of **2c** is not able to attack the 1-C atom of **3**, which is more crowded than the carbonyl carbon of **1**, and that the acetylation of **2** with **1** must proceed through the pathway illustrated in Schemes 2 and 4.

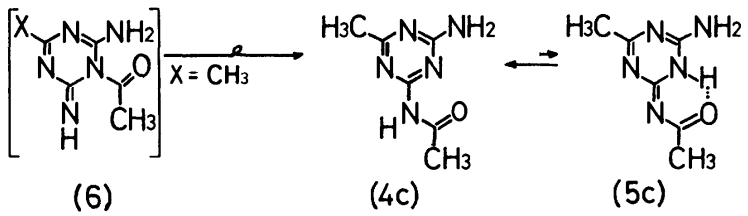
The acetylated product **4c** was considerably stable under the kinetic conditions in this study, and it was identical with the product in the kinetic runs (by HPLC).

The structure of **4c** was determined by its spectroscopic data. The MS of **4c** showed a molecular ion (M^+) peak at m/z 167 (molecular weight of **4c**; $C_6H_9N_5O$= 167.18), and the IR spectrum, measured in a KBr disk, suggested that the acetylated product was a tautomeric mixture of **4c** and **5c** (Scheme 4). That is to say, absorption bands assignable to the acetylamino form (**4c**) were observed at 3300 (ν_{NH} of the secondary amide), 1680 ($\nu_{C=O}$, amide I band), 1540 (amide II band), 1315 (amide III band), and 815 cm^{-1} (medium, 1,3,5-triazine ring) in addition to those of acetylimino form **5c** at 3230 (ν_{NH} of the ring), 1615 ($\nu_{C=N}$), 1375 (δ_{NH} of the ring), and 760 cm^{-1} (very weak, 2,3-dihydro-1,3,5-triazine ring).[22] Analogous tautomerization was observed in 2,4-diamino-6-cyanoamino-1,3,5-triazine.[22] However, the equilibrium would lie to the left (as discussed below regarding to UV and ^1H and ^{13}C NMR spectra).

Compound **6** is not expected to have a UV absorption maximum in the wavelength region 220 to 280 nm,[23,24] whereas product **4c** shows absorption maxima at 223, 260, and 326 nm. The ^1H NMR spectrum of **4c** consists of two methyl protons (δ 2.4 and 2.7) and the NH protons of NH_2 (δ 7.7) and NH groups (δ 7.1), and ^{13}C NMR of **4c** in acetic acid exhibited a signal at δ 166.9 for the ring-carbon 2-C which was attached to the acetylamino group. This low-field shift of 2-C, compared with 4-C (δ 163.1), must result from the acetyl group. If the structure of the acetylated product is **6**, the ring-carbons would resonate at a higher magnetic field than δ 163.1. Signals assignable to the tautomeric isomer (**5c**) were not observed in the spectrum.

Experimental

All melting and boiling points are uncorrected. The UV spectra were recorded on a JASCO UVIDEC-505 spectrophotometer, and the IR spectra on a Hitachi model 260-50 spectrophotometer. The ^1H NMR spectra were recorded with a JEOL PMX-60SI spectrometer for solutions in DMSO-d_6 or



Scheme 4.

CF_3COOH, and ^{13}C and ^{19}F NMR spectra with a JEOL FX-90Q spectrometer in acetic acid. The chemical shifts are reported in δ (internal standard Me_4Si or $CFCl_3$). The MS were determined with a Hitachi M-80 double-focusing mass spectrometer at 70 eV. The pH was measured with a Toa model HM-5ES pH meter. The analytical HPLC determination was carried out with a JASCO TWINCLE apparatus equipped with a UV detector.

Materials. Commercially available 2,4,6-triamino-1,3,5-triazine (**2b**) and 2,4-diamino-6-methyl-1,3,5-triazine (**2c**) were recrystallized from water. 2,4-Diamino-1,3,5-triazine (**2d**) was kindly presented by Dr. E. Ichikawa (Tokyo Institute of Technology) and recrystallized from water, mp 322.3—324.0 °C (lit,[25] 329 °C). The other 6-substituted 2,4-diamino-1,3,5-triazines, (**2a**, **e**, and f), were prepared by methods in literature,[26,27] and recrystallized from water, **2a**; mp 310—312 °C (lit,[28] 307—308 °C), **2e**; mp 168.5—169.5 °C (lit,[27] 172 °C), **2f**; mp 237—238 °C (lit, [27] 229—230 °C). All the 1,3,5-triazines, (**2a—2f**), were dried at 50 °C for one day, and then at room temperature for three days under reduced pressure (5 mmHg; 1 mmHg=133.322 Pa) after recrystallization. ^1H NMR (DMSO-d_6) **2a**, δ=5.97 (4H, s, NH_2), 3.02 (6H, s, CH_3); **2b**, 6.02 (s, NH_2); **2c**, 6.45 (4H, s, NH_2), 1.88 (3H, s, CH_3); **2d**, 6.61 (4H, s, NH_2), 7.91 (1H, s, H); **2e**, 6.63 (4H, s, NH_2), 5.28 (1H, se, J=7 Hz, CH), 1.43 (6H, d, J=7 Hz, CH_3); **2f**, 6.62 (4H, s, NH_2), 3.73 (3H, s, CH_3); ^{13}C NMR (CH_3COOH) **2c**, δ=173.5 (CH_3-C-ring), 164.0 (C-NH_2), 21.7 (CH_3). Picryl fluoride (**3**) was also prepared by a method in literature[29] and recrystallized from carbon tetrachloride. Yield 60—70%, mp 122—123 °C (lit,[29] 122—123 °C). ^1H NMR ($CDCl_3$) δ=8.95 (d, J=5.6 Hz); ^{19}F NMR (84.31 MHz, $CDCl_3$) δ=−116.36 (t, J=5.49 Hz).

Kinetics. Rates of the reaction of **1** with **2a—2f** were followed on a spectrophotometer equipped with an isothermal cell holder (30±0.2 °C) and 1-cm cells by observing the appearance of *p*-nitrophenolate at 408 [in aqueous DMSO, DMSO : H_2O=3 : 7 (v/v)] or 400 nm (in water). The reaction was initiated by stirring the buffer solution with a Teflon rod, on which 30 μl of a stock solution (5.05×10^{-3} mol·l^{-1}) of **1** in DMSO (or in acetonitrile for the reaction in water) was put with a Gilmont micrometer buret. The buffer solution (KH_2PO_4/Na_2HPO_4, [Na_2HPO_4]=1.25×10^{-2} mol·l^{-1}) contained the 1,3,5-triazine (**2**), and the ionic strength was maintained at 0.3 with potassium chloride. The final concentration of acetonitrile, which was introduced with solutions of **2**, in the reaction mixture did not exceed 1%. The initial rate, R_0, was proportional to $[\mathbf{1}]_0$ at constant $[\mathbf{2}]_0$ (5×10^{-5} mol·l^{-1}) and pH (8.7), and a slope of $\log R_0$ vs. $\log[\mathbf{1}]_0$ plots is 1.0. Furthermore, (R_0-R_{00}) was proportional to $[\mathbf{2}]_0$ at constant $[\mathbf{1}]_0$ (5×10^{-5} mol·l^{-1}) and pH (8.7), and a slope of $\log(R_0-R_{00})$ vs. $\log[\mathbf{2}]_0$ plots was also 1.0, where R_{00} is the initial rate in the absence of **2**.

The observed pseudo first-order rate constants, k_{obsd}, were calculated from the spectrometric data by the use of the usual first-order equation (correlation coefficient r is larger than 0.999 for each run), and are summarized in Table 1 along with the reaction conditions. The concentration of (**1**), 5×10^{-5} mol·l^{-1}, was ordinarily used to determine the rate constants k_N by using Eq. 2. The reaction product in the kinetic run of **2c** was found to be identical to the acetylamino derivative **4c** by means of HPLC [column, 4.6×250 mm, Finepak Sil C_{18}, 5 μm; eluent, 0.02 mol·l^{-1} K_2HPO_4/NaH_2PO_4 buffer (pH 6.8) in 10% (v/v) aqueous MeOH; flow rate, 0.5 ml·min^{-1}; detection, 260 nm; retention time of **2c** and **4c**, 23.5 and 25.6 min].

Solvent isotope effect experiments were performed in DMSO-D_2O for **2a**, **2c**, and **2e** and in D_2O for **2c** in the presence of the deuterated phosphate buffers under a nitrogen atmosphere (over a more restricted pD range). The results are summarized in Table 3. The pD values were calculated by adding 0.4 unit to the pH value obtained by using a conventional pH meter.[30]

Reaction of *p*-Nitrophenyl Acetate (1) with 2,4-Diamino-6-methyl-1,3,5-triazine (2c); Preparation of 2-Acetylamino-4-amino-6-methyl-1,3,5-triazine (4c). The 1,3,5-triazine (**2c**) (1.25 g, 0.01 mol) and **1** (3.6 g, 0.02 mol) were heated in dry DMSO (20 ml) at 100 °C for 17.5 h. After cooling, the reaction mixture was poured into 200 ml of water containing crashed ice to afford a crystalline product, which was washed with carbon tetrachloride to give the pure product **4c** in 60% yield. Its homogeneity was established by HPLC (conditions are shown above). Mp 271.0—272.5 °C; UV(EtOH) λ_{max} 223 (ε 2800), 260 (5500), and 326 nm (850); IR(KBr) 3300, 3230, 3140, 1690, 1680, 1615, 1540, 1375, 1315, 815, and 760 cm^{-1}; ^1H NMR(CF_3COOH) δ=7.7 (2H, b, NH_2), 7.1 (1H, b, NH), 2.7 (3H, s, $COCH_3$), 2.4 (3H, s, ring-CH_3); ^{13}C NMR (CH_3COOH) δ=176.6 (CO), 173.1 (CH_3-C-ring), 166.9 (N=C-NH-Ac), 163.1 (C-NH_2), 25.2 (CH_3CO), 22.9 (CH_3-ring); MS m/z (rel intensity in %) 169 (2), 168 (8), 167 (M^+, 80), 139 (19), 126 (10), 125 (M − CH_2=C=O, 97), 110 (13), 98 (42), 85 (11), 84 (27), 83 (22), 68 (24), 43 (100), 42 (59).

Found: C, 42.83; H, 5.37; N, 41.61%. Calcd for $C_6H_9N_5O$: C, 43.11; H, 5.43; N, 41.90%.

Reaction of 2c with Picryl Fluoride (3). A mixture of **2c** (1.25 g, 0.01 mol) and **3** (4.6 g, 0.02 mol) was heated in dry DMSO at 80 °C for 48 h. After cooling, the reaction mixture was poured into 200 ml of water containing crashed ice to afford the corresponding crude picrate (99.6% yield), which was recrystallized from tetrahydrofuran (73% yield, Found: C, 34.23; H, 2.92; N, 31.04%), and it was identical to an authentic sample. Mp 277—278 °C (decomp., browned at 259—260 °C; lit,[31] 275 °C). UV(EtOH) λ_{max} 250 (sh), 360 (ε 1400), 410 nm (sh); IR (KBr) 3430, 3340, 3260, 3120, 1700, 1645, 1625, 1600, 1570, 1545, 1360, 1325, and 790 cm^{-1}; MS m/z (rel intensity in %) 229 [27, 228.9962 (+0.9 mu, $C_6H_3N_3O_7$)], 125 [100, 125.0698 (−0.2 mu, $C_4H_7N_5$)], 62 (10), 42 (28).

Stability of 4c. A solution of the compound **4c** (5×10^{-3} mol·l^{-1}) in aqueous DMSO was maintained at 30 °C under the same conditions used in the kinetic runs. Aliquots were periodically removed, and the amount of unreacted **4c** was determined by HPLC (conditions are shown above). After 1 h, compound **4c** was still unchanged but 5—10% of **4c** was decomposed after 2 h.

We are indebted to Mr. Yuichi Sugiura for his assistance in the experimental work and to Dr. Eiichi Ichikawa (Tokyo Institute of Technology) for his kind gift of 2,4-diamino-1,3,5-triazine (**2d**).

Rotamer Populations and Molecular Structure of 9-Isobutyl-1,4-dimethoxytriptycene: Further Evidence for the Presence of CH_3···O Hydrogen Bond

(Received March 18, 1988)

^{1}H NMR spectra of the title compound at low temperatures show the presence of the *sc* conformer as a major constituent: $\Delta H°=0.9\pm0.3$ kcal mol^{-1}, $\Delta S°=5\pm2$ cal mol^{-1} for the $sc \rightleftarrows ap$ equilibrium. The line shape analysis of the spectra at various temperatures afforded the following activation parameters for the internal rotation about the C_9-$C_{i\text{-}Bu}$ bond: $\Delta H^*=8.8\pm0.3$ kcal mol^{-1}, $\Delta S^*=-5.0\pm1.2$ cal mol^{-1} K^{-1} for the $ap \rightarrow sc$ process. X-Ray crystallography of the compound revealed that the molecule exists as *sc* conformers in the crystal. One of the methyl groups of the isobutyl group that directs inward relative to the triptycene skeleton, is placed very closely to the 1-methoxy-oxygen to indicate the presence of the CH_3···O hydrogen bond. Implications of other structural parameters are also discussed.

While we have reported that the presence of CH_3··· O hydrogen bond can be detected as the population ratios of rotamers in appropriately substituted triptycenes, the population of the *sc* isomer has never overwhelmed that of the *ap* isomer, although the former is stabilized by the presence of the hydrogen bond.[1,2] The results have been attributed to the weakness of the hydrogen bond that competes with other repulsive forces like van der Waals repulsion in determining the population ratios. Indeed, it has been pointed out that the ρ value in the Hammett plot of the population ratios against the substituent constants for the series of 9-(aryloxymethyl)-1,4-dimethyltriptycenes is unusually small, -0.114,[1] for the interaction involving an atom that is directly attached to the aromatic ring.[3]

This reluctance of showing the electronic effect of the substituent on the rotamer populations is attributed to the steric effect that destabilizes the *sc* form of 1,9-disubstituted triptycenes, although that form is stabilized by the hydrogen bond. Although the β atom in the 9-substituent is close enough to the unsubstituted peri-positions of the triptycene skeleton, when it takes the *ap* position relative to the 1-substituent, the distance is still larger than that between the 1-substituent and the β atom of the 9-substituent when it takes the *sc* position. The situation is clear when one considers the cases in which no strong interactions between the 1- and 9-substituents are expected. 1-Substituted 9-isopropyltriptycenes are known to exist exclusively as the *sc* isomer except for the 1-fluoro derivative.[4] So are 9-allyl-1,4-dimethyltriptycene,[5] 9-(formylmethyl)-1,4-dimethyltriptycene,[5] and 9-(2-acetoxyethyl)-1,2,3,4-tetrachlorotriptycene.[6]

We have been interested in manifesting the overwhelming population of *sc* isomers due to the weak interactions. To this end, it is necessary to lessen the difference in the steric situations of the *sc* and *ap* conformers of the 1,9-disubstituted triptycenes relative to the cases cited. This must be accomplished by destabilizing the *ap* form, while the ground state of the *sc* form is destabilized little, by a modification of the molecule. As one of the candidates of this technique, introduction of a substituent in the β position of the 9-substituent has been tried for the following reasons. Introduction of a methyl group to an *o*-position of the benzyl-phenyl group in 9-benzyltriptycenes raises the ground state energy, if the methyl group directs inward, and the molecule resides in the conformation only for a short time.[7] This idea led to the finding that the molecular gears with two- and three-toothed wheels[8] and two three-toothed wheels[9] could be made. Although the β-carbon in the substituent in the former is sp^2-hybridized, that in the latter is sp^3-hybridized. There is a good reason to expect that the introduction of a substituent there manifests the desired effect.

Following these considerations, we decided to prepare 9-isobutyl-1,4-dimethoxytriptycene (**1**). There are two rotational axes in the 9-substituent of this molecule: C_9-C_α and C_α-C_β. Although there is limited freedom of rotation in the C_9-C_α bond if we consider only stable conformations, namely *ap* and $\pm sc$ only, there are varieties of conformations we must take into account about the C_α-C_β axis.

If the molecule takes the *ap* conformation about the C_α-C_β axis (Fig. 1a), the steric interactions between the peri-CH groups and the isopropyl-methyl groups are too severe to allow the conformation to exist. If the molecule takes the *sc* conformation about the same axis (Fig. 1b), one of the isopropyl-methyl groups is still too close to the peri-CH group to be stable. If this conformation is to exist, it may be necessary to rotate this part slightly so that the repulsive interactions concerned become smaller.

If the molecule has to take a conformation twisted slightly from the normal staggerred form, it will also be possible to take a conformation that is twisted

† Present address: Department of Chemistry, Faculty of Science, Okayama University of Science, Ridaicho, Okayama 700.

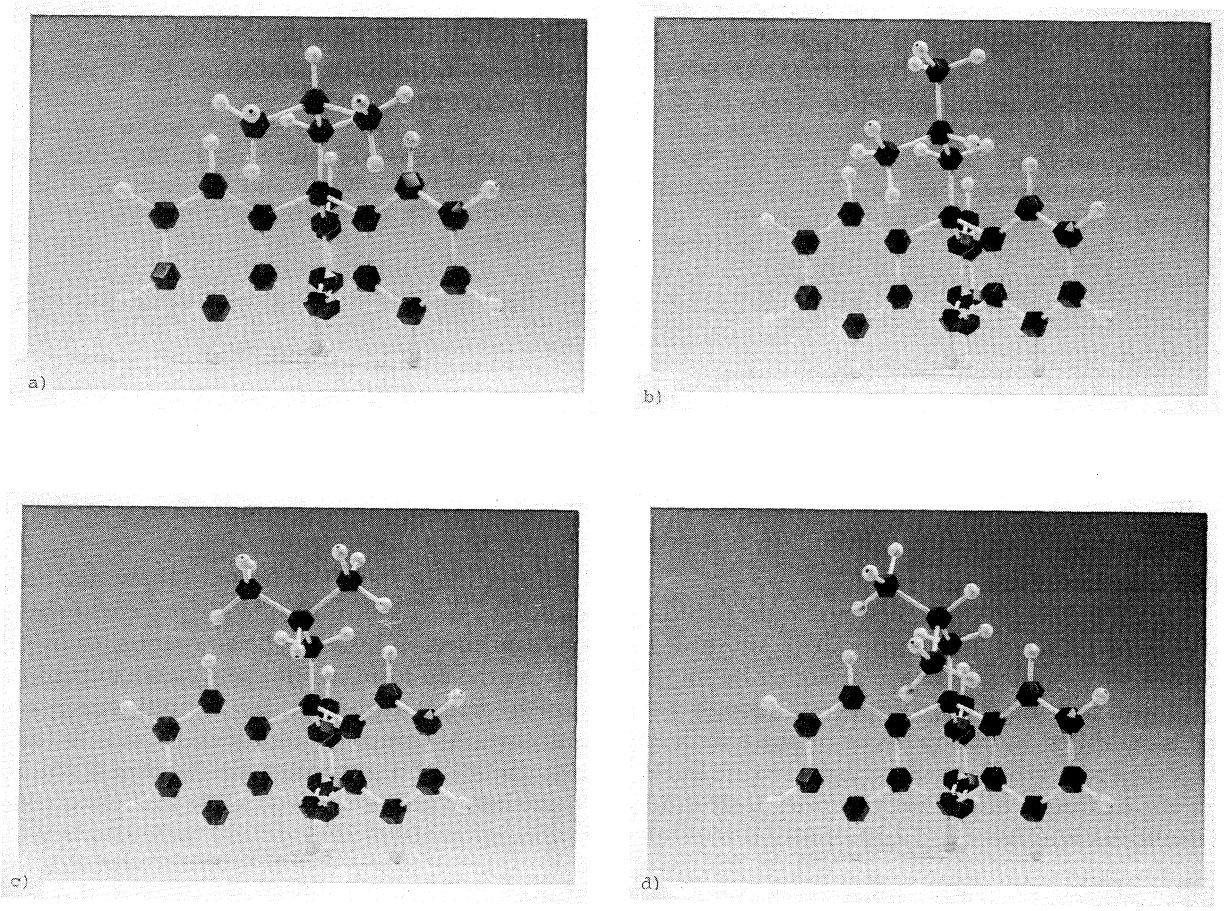

Fig 1. Some extreme conformations of 9-isobutyltriptycene: for clarity, two methoxyl groups at 1 and 4 positions are removed. a) *ap* conformation, b) $+sc$ conformation, c) *sp* conformation, d) $+ac$ conformation.

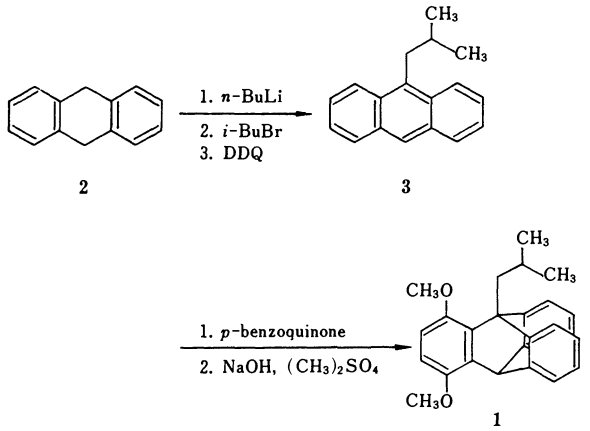
slightly from the eclipsed conformations. The *sp* conformation (Fig. 1c) may be stabilized by rotating the isopropyl group to some extent about the C_α-C_β bond, because the strain due to eclipsing is eased by doing so. However, this twisting causes another strain between the isopropyl-methyl group and the peri-CH group. It is unlikely that the molecule takes a conformation that is close to the *sp*. In the $\pm 120°$ conformations (Fig. 1d), the repulsive interactions between the two benzeno bridges and the isopropyl-methyl group, which is directing inward relative to the triptycene skeleton, will be minimal. However, the molecule has to avoid the eclipsing interactions of the groups concerned. Although this twisting about the isopropyl-to-methylene bond in the isobutyl group necessarily increases the steric repulsions between the benzeno bridge and the inside-methyl group, these interactions might not be so severe as are expected from the molecular models, because, in the molecular structures of 9-(prim. alkyl)triptycenes, it is known that the dihedral angles made by the two benzeno bridges which flank the β-atom of the substituent is larger than the normal one.[5,10]

In the conformation which is $\pm sc$ about the C_9-C_α bond and is a little twisted from the $\pm 120°$ form about the C_α-C_β bond in 9-isobutyl-1,4-dimethoxytriptycene, the $CH_3 \cdots O$ hydrogen bond is possible, while the $CH \cdots O$ hydrogen bond may have to be between the β-CH and the methoxy-oxygen in the conformation which is $\pm sc$ about the C_9-C_α and is a little twisted from the $\mp 120°$ form about the C_α-C_β bond, if one considers the steric effects caused by the methyl groups by proximating one of them to the 1-methoxy-oxygen. Therefore, if the molecule takes this type of conformation, at the equilibrium between the rotamers, the *sc* conformation may be favored relative to the *ap* owing to the presence of the $CH_3 \cdots O$ hydrogen bond, because the steric effect given by the inward-methyl group will be severe not only in the *sc* conformation but also in the *ap*.

It is not possible to decide which of the two possible conformations discussed above, nearly $\pm sc$ and nearly $\pm ac$ conformations about the C_α-C_β bond, is more stable from the molecular models. In order to find the experimental results, the synthesis of 9-isobutyl-1,4-dimethoxytriptycene (**1**) was undertaken in the following way. Deprotonation of 9,10-dihydroanthracene (**2**) with butyllithium followed by alkylation with iso-

butyl bromide afforded 9-isobutyl-9,10-dihydroanthracene, of which dehydrogenation with 2,3-dichloro-5,6-dicyano-*p*-benzoquinone afforded 9-isobutylanthracene (**3**). The reaction of **3** with *p*-benzoquinone in the presence of boron trifluoride afforded a Diels-Alder adduct which was treated with aqueous sodium hydroxide and dimethyl sulfate to give the desired compound (**1**).



2 3 1

In accordance with the expectation, the barrier to rotation in compound **1** about the C_9-C_α bond is lowered considerably, as evidenced by the fact that the ^{1}H NMR spectrum of the compound in chloroform-*d* did not show decoalescence of any signals, although broadened, at the lowest temperature attainable for the solvent at 270 MHz: The barrier to rotation about the C_9-C_α bond in 1-substituted 9-(prim. alkyl)triptycenes is normally 12—16 kcal mol^{-1} (1 cal=4.184 J) and decoalescence of various signals is complete at about -20 °C.[11-13]

We thus measured the ^{1}H NMR spectra of compound **1** in CD_2Cl_2-CS_2 at 400 MHz. At this magnetic field, the rotation about the C_9-C_α bond was negligibly slow at or below -90 °C. The population ratios were determined at these temperatures and the differences in standard enthalpy and entropy were obtained. The results are shown in Table 1.

Assignment of the signals to *ap* and *sc* conformers was accomplished by finding that, in the 400 MHz ^{1}H NMR spectra at low temperatures, an AB quartet and a singlet,[14] each of which showed further coupling with the methine proton, were separated. In those spectra, the two-proton signals due to the aromatic protons of the dimethoxybenzeno bridge appeared as AB quartets; one at the lower field showed a larger chemical shift difference than that at the higher magnetic field, indicating that the signals at the lower field should be ascribed to the *sc* isomer. The intensity ratios of the proton signals due to the aromatic ring and the α-methylene of the 9-substitutent agreed satisfactorily. Due to the overlaps, however, the determination of the populations was made with the use of the isopropyl-methyl signals.

Table 1. Population Ratios of Rotameric 9-Isobutyl-1,4-dimethoxytriptycene and Differences in Standard Enthalpy and Entropy of the Rotamers in 1 : 1 CD_2Cl_2-CS_2 for the $sc \rightleftarrows ap$ Equilibrium

Temp/°C	−110.6	−100.5	−95.5	−90.5	−85.4
ap/*sc*	0.33	0.37	0.41	0.43	0.48

$\Delta H°$=0.87±0.28 kcal mol^{-1}
$\Delta S°$=4.5±1.6 cal mol^{-1} K^{-1}

Clearly the majority is the *sc* conformation at or below -85 °C. The population of the *sc* form is more than the statistical one and suggests the presence of a kind of stabilizing effects in that form, because no apparent destabilization of the *ap* form is expected. According to the discussion (vide supra), this effect is very likely to be the $CH_3\cdots O$ hydrogen bond. Of another interest is that the preference of the *sc* form over the *ap* diminishes when the temperature is raised: although the low correlation coefficient, 0.984, in the statistical treatment of the equilibrium constants precludes the detailed discussion of the difference in standard entropy, it is tempting to consider that the entropy increases in the process *sc*-**1**→*ap*-**1**, as it appears in the numerical value. This is consistent with the idea that the $CH_3\cdots O$ hydrogen bond reduces the freedom of rotation of the methyl group concerned.

The chemical shift differences between the protons due to isopropyl-methyls are interesting. Whereas that due to the *ap* form gives a simple doublet, the chemical shift differences for the diastereotopic methyl groups in the *sc* form is very large. As is already discussed, there are two conformations of the isobutyl in each rotamer about the C_α-C_β bond. If the rotation of the isopropyl group is slow on the NMR time scale, the chemical shift differences between the two methyl-protons should be large even in the *ap* form because of the anisotropy effect of the benzene ring. The simple doublet signal for these two methyls in the *ap* means that the rotation is fast on the NMR time scale. It is tempting to consider that the large chemical shift difference between the methyl-protons in the *sc* form means that one of the conformers is stabilized relative to the other to make the life-time long, because otherwise the chemical shift differences may be reduced due to the fact that the inside-methyl group in one form is outside in another.

Total line shape analysis of the isopropyl-methyl proton signals was performed with the use of DNMR3 program.[15] Here the rotation of the isobutyl group, in which the isopropyl group passes over the 1-methoxyl group, is assumed not taking place because of the large chemical shift difference between the two methyl signals of the *sc* form: if this rotation takes place, the inside methyl group exchanges the site with the outer methyl even in the absence of rotation about the C_α-C_β bond. The results are shown in Table 2. The low barrier to rotation in compound **1** is clearly derived by

the relatively unstable ground state. The same reason may apply for the lower barrier to rotation in 9-benzyl-1,4-dimethoxytriptycene[11] than those in 9-ethyl-1,4-dimethoxytriptycene[12] and 9,10-bis(chloromethyl)-triptycene.[13]

The results presented here are all in accordance with the presence of the $CH_3 \cdots O$ hydrogen bond in the *sc* form of compound **1**. However, the results do neither guarantee that the real conformation about the isobutyl group is nearly 120°, nor tell which of the two isopropyl-methyl groups forms the $CH_3 \cdots O$ hydrogen bond with the 1-methoxy-oxygen atom. In order to get further into insight, we decided to perform X-ray crystallographic study of the molecular structure of **1**.

The atomic coordinates, selected bond distances, selected bond angles, selected torsion angles, selected nonbonding distances, and deviations of carbon atoms comprising three benzene rings from the mean plane of the rings are compiled in Tables 3—8, respectively. An ORTEP diagram is shown in Fig. 2 together with numbering of atoms and designation of rings.

The crystallography clearly shows that the molecules are packed in the crystals as *sc* forms. This is quite fortunate, because the molecular structural parameters give information about the $CH_3 \cdots O$ hydrogen bond, but is quite unusual. We have shown that a compound which exhibits the presence of *ap* conformation only gives crystals of *ap* conformation,[5]

and that even a compound which exists solely as *sc* conformation in solution gives crystals which contain both *ap* and *sc* conformations.[10] We believe the reasons for this phenomenon that compound **1** crystallizes in the *sc* form should include the factor that the *sc* form is more stable than the *ap*.

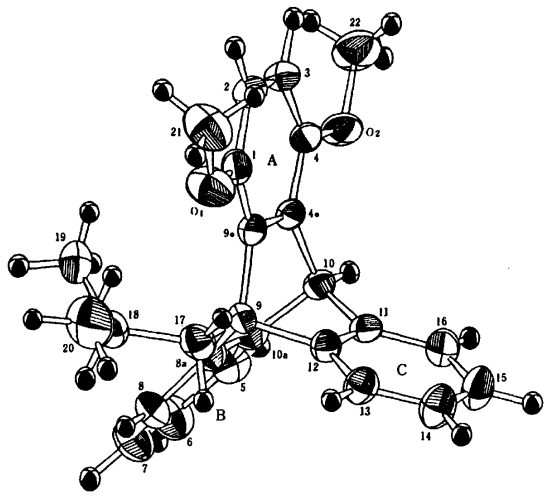

Fig. 2. An ORTEP diagram of 9-isobutyl-1,4-dimethoxytriptycene with numberings of atoms and designation of rings.

As all the data suggest, the structure around the C(10), that is the opposite side of the 9-substituent in the triptycene skeleton, is nearly normal, whereas abnormal are the atomic positions comprising the 9-substituent and the peri-positions which are close to the 9-substituent. We can point out some of the common features of 9-substituted triptycenes[5,10] which are also seen in this compound. The bonds connecting the C(9) and the benzene rings are long, especially long being that between C(9) and the aromatic ring which carries two methoxyl groups. The pyramid made by C(8a), C(9a), C(12), and C(9) has very small C-C-C apex angles at C(9) and correspondingly the angles C(17)-C(9)-C(n), where C(n) is the carbon atom of the aromatic rings, are large. These features are derived to relieve the steric strain formed by the 1- and 9-substituents.

One of the methyl groups in the 9-substituent directs inward relative to the triptycene skeleton, as was expected from the model study, and the eclipsing strain is relieved by rotating 26.5° from the eclipsing position. To accommodate the inward-directing methyl group, the C(8a)-C(9)-C(9a) angle is widened considerably relative to other apex angles and the torsion angles consisting this notch, i.e. C(8)-C(8a)-C(9)-C(9a) and C(8a)-C(9)-C(9a)-C(1), are very large. These are reflected in the dihedral angles made by two average planes of the benzene rings: A and B 132.7°, A and C 112.3°, B and C 114.9°. The difference in the torsion angles involving the same notch is due to the twisting of the benzene rings at the peri-carbons: the peri-carbons flanking the 9-substituent are dislocated from the average plane of the benzene rings away from the substituent, whereas another peri-carbon, C(13), is closely in the average plane of the benzene ring. This situation is clearly seen by the torsion angles involving the axes of bridge carbons of the benzeno moiety.

Whereas the torsion angle, C(10)-C(11)-C(12)-C(13), is very close to 180°, those that involve the peri-carbons flanking the 9-substituent, C(10)-C(4a)-C(9a)-C(1) and C(8)-C(8a)-C(10a)-C(10), are much smaller than 180°. The corresponding torsion angles about the bridge carbon-carbon axis involving the C(9) and the peri-carbon that is in the opposite side of the triptycene skeleton relative to the 9-substituent are again very close to 180°.

Deformation of the benzene rings in the molecule deserves special mention. As are shown in Table 8, while ring C is practically planar and ring B is slightly distorted, deviations of atoms comprising ring A from the average plane are rather large. The situation of ring A is more distinct if one takes deviations of atoms from the mean plane formed by atoms C(3), C(4), C(4a), and C(9a): these atoms comprise a fairly good plane, the atomic shifts being less than 0.003 Å, though that does not mean that these atoms are located normally because, whereas C(9) is in this plane, C(10) is out of this plane by 0.142 Å. C(1) is out of this plane away from the 9-substituent by 0.144 Å and so is C(2) by 0.106 Å. These deformations must be due to the severe steric interactions of the methyl group in the 9-substituent and the atoms of the ring concerned.

The torsion angle at the C_α-C_β axis of the 9-substituent indicates that the substituent is tilted toward the benzene ring which does not carry the methoxyl groups. This is considered to avoid the steric interactions between the 1-methoxyl group and the 9-substituent. The C_α-C_β bond in the substituent is unusually long as an sp^3-sp^3 carbon bond and the bond angle C(9)-C(17)-C(18) is very large. These should be the results of relieving the strain caused by the inside-methyl group and the benzeno bridges that form the notch.

The inside-methyl group is very close to the 1-methoxy-oxygen, the distance being 3.017 Å, well within the sum of the van der Waals radii of the groups concerned. Of course, this distance alone cannot be taken as evidence for the presence of the $CH_3 \cdots O$ hydrogen bond, because the intramolecular nonbonding distance can be very small,[17] especially in congested molecules. However, if one compares the distances, C(19)-O(1) and C(20)-O(1), there is a significant difference between them. This may well support the presence of the $CH_3 \cdots O$ hydrogen bond.

There is another interesting feature in the molecular structure of **1**. That is the 1-methoxyl group is twisted to make the methoxy-methyl group out of the plane of the average benzene ring. Since anisole and related compounds are believed to be stable at a planar structure[18] and the 4-methoxyl group in **1** is indeed in the plane of the benzene ring, there must be a reason for this nonplanar conformation of the 1-methoxyl group. We should tentatively like to attribute this structure to being favorable for forming the $CH_3 \cdots O$ hydrogen bond. If the 1-methoxy-oxygen is sp^2-hybridized, both the direction of the orbital of the oxygen lone pair, of which ionization potential is minimum, and the high ionization potential of the electrons in the orbital, of which axis is parallel to the p-orbitals of the benzene ring, are not favorable for the hydrogen bond. Thus although energetically unfavorable from the view point of conjugation with the benzene ring, the 1-methoxyl group rotates to a small extent about the C(1)-O(1) bond to make the $CH_3 \cdots O$ interaction favorable.

The structure around the methoxy-oxygen is of interest in another point. That is, the C(1)-O(1) bond is bent out of the average plane of ring A and the O(1) atom is shifted from the C(3)-C(4)-C(4a)-C(9a) plane by 0.359 Å away from the 9-substituent. The reason for this deformation is not clear at present, but we believe both the steric and $CH_3 \cdots O$ hydrogen-bond effects are responsible for this unusual structure.

In conclusion, all the data presented in this paper suggest that there is $CH_3 \cdots O$ hydrogen bond in compound **1** both in solution and in the solid state. The technique of introducing a substituent to the β-position of the 9-substituent to lessen the steric energy gap between the *sc* and the *ap* forms may find other uses in manifestation of weak molecular interactions.

Experimental

Material. The sythesis of the compound was carried out as follows.

9-Isobutylanthracene (3). To a solution of 5.4 g (30 mmol) of 9,10-dihydroanthracene (**2**) in 75 mL of tetrahydrofuran, was slowly added 13.5 mL (32 mmol) of butyllithium in hexane at ca. −45 °C under a nitrogen atmosphere. Stirring was continued for further 30 min and then the solution was added to 3.6 mL (33 mmol) of isobutyl bromide in 10 mL of tetrahydrofuran at −30 °C under a nitrogen atmosphere. The mixture was allowed to warm up and then stirred overnight at room temperature. The mixture was treated with water and extracted with benzene. After evaporation of the solvent, the residue was taken up in 30 mL of benzene and heated at 40—60 °C for 1 h with 6.81 g (30 mmol) of 2,3-dichloro-5,6-dicyano-*p*-benzoquinone. The precipitate was filtered off and the solvent was evaporated from the filtrate. The residue was submitted to chromatography on silica gel (hexane eluent) to afford 2.79 g (40%) of the desired product, mp 66—67 °C (lit,[19] mp 57 °C). ^{1}H NMR ($CDCl_3$) δ=0.98 (6H, d, J=6.3 Hz), 2.19 (1H, nonet, J=6.3 Hz), 3.47 (2H, J=6.3 Hz), 7.3—7.8 (9H, m).

9-Isopropyl-1,4-dimethoxytriptycene (1). A solution of 980 mg (4.2 mmol) of 9-isobutylanthracene and 710 mg (6.6 mmol) of *p*-benzoquinone in 7.5 mL of ether was mixed with 1.1 mL of boron trifluoride-etherate and the mixture was stirred for 1 h under a nitrogen atmosphere at room temperature. The produced precipitate was collected by filtration to yield 970 mg of a Diels-Alder adduct. The adduct (670 mg or 2.0 mmol) was dissolved in 22 mL of dioxane and treated with aqueous sodium hydroxide and dimethyl sulfate by adding them alternatively in small portions. In total, 2.0 g of sodium hydroxide (500 mmol) in 20 mL of water and 7.0 mL (75 mmol) of dimethyl sulfate were used. The precipi-

tate was collected and submitted to chromatography on silica gel (5:1 hexane-dichloromethane eluent) to afford 260 mg (36%) of **1**, mp 188.5—189.5 °C. Found: C, 84.30; H, 7.08%. Calcd for $C_{26}H_{26}O_2$: C, 84.29; H, 7.07%. ^{1}H NMR ($CDCl_3$, 270 MHz, room temperature): δ=1.19 (6H, d, J=6.6 Hz), 2.76 (1H, m), 3.31 (2H, d, J=7.7 Hz), 3.70 (3H, s), 3.78 (3H, s), 5.83 (1H, s), 6.45 and 6.49 (2H, ABq, J=9.0 Hz), 6.98 (4H, m), 7.38 (2H, m), 7.59 (2H, m). ^{1}H NMR (CD_2Cl_2-CS_2, δ, 400 MHz, −100 °C): *ap*-form 1.20 (6H, d, J=6.6 Hz), 2.49 (1H, m), 3.36 (2H, d, J=6.6 Hz), 3.68 (3H, s), 3.75 (3H, s), 5.77 (1H, s), 6.41 (2H, br s), 6.87 (2H, t, J=7.1 Hz), 6.97 (2H, t, J=7.5 Hz), 7.25 (2H, d, J=7.3 Hz), 7.60 (2H, m); *sc*-form 0.80 (3H, d, J=6.6 Hz), 1.28 (3H, d, J=6.6 Hz), 2.87 (1H, m), 3.00 and 3.32 (2H, AB of ABX, J=14.3 and 8.8 Hz), 3.70 (3H, s), 3.80 (3H, s), 5.79 (1H, s), 6.52 and 6.57 (2H, ABq, J=9.2 Hz), 7.06 (4H, m), 7.33 (1H, d, J=7.3 Hz), 7.41 (2H, m), 7.73 (1H, d, J=7.0 Hz).

NMR Spectroscopy at Low Temperatures. Compound **1** was dissolved in 1:1 (v/v) carbon disulfide and dichloromethane-d_2 to make up a 19 mmol L^{-1} solution. The spectra at various temperatures were obtained with a JEOL GX400 spectrometer, the temperature being calibrated with a thermocouple. The populations, chemical shift differences, and the coupling constants were checked at 4 temperatures in the slow exchange limit. For the determination of the populations of rotamers, the signals due to the isopropyl-methyl protons were used for the following reasons. Although there was an overlap of the signal due to the α-methylene protons of the 9-substituent in the *ap* form with the lower signal of the two due to the α-CH_2 (AB) protons of the *sc* form, clearly the signals due to the *sc* form were more intense than that due to the *ap* at −100 °C and the assignment of the signals due to the isopropyl-methyl protons was possible by comparing the intensities of the two. The signals due to the isopropyl-methyl protons were found to give more accurate populations than those due to the α-CH_2 protons. The spectra were simulated with the use of the signals due to the isopropyl-methyl protons by the DNMR3 program.[15]

Logarithms of the popultaiton ratios shown in Table 1, when plotted gainst $1/T$(K), afforded the difference in standard enthalpy and entropy, which were used to estimate the populations of the rotamers at temperatures where the change in the line shapes was observed. The coupling constants were constant in the temperature range examined, whereas the chemical shift differences changed linearly with temperature. A straight line was drawn by the least squares method to correlate the chemical shift difference ($\Delta\nu$/Hz) with temperature (t/ °C). The following equations were obtained, where A is the chemical shift at a lower magnetic field than the counterpart B of the AB protons and C denotes the chemical shift of the protons due to the *ap* form: $\Delta\nu_{AC}$=−0.21110t+13.63 Hz, $\Delta\nu_{AB}$=−8.287t+109.70 Hz. These lines were used for the calculation of the chemical shift differences at a given temperature. The chemical shift of the X proton was used as observed at low temperatures. T_2 was estimated as 0.10 s from the line width due to other protons and this value was used throughout the line shape simulation. It was assumed that the observed process was $A_3B_3X \rightleftarrows C_6X \rightleftarrows B_3A_3X$, the direct exchange $A_3B_3X \rightleftarrows B_3A_3X$ being negligibly slow, and could be approximated by $ABX \rightleftarrows C_2X \rightleftarrows BAX$.

X-Ray Crystallography. Crystals were grown from a tetrahydrofuran-hexane solution. The colorless crystal with dimensions 0.6×0.6×0.2 mm was mounted on a Rigaku AFC-5R four-circle diffractometer and the intensity data were collected using Mo$K\alpha$ radiation (λ=0.71073 Å). The ω-2θ scan technique was employed at a scan rate of 4° min^{-1} in ω, and the scan range was calculated by 1.2°+0.5° tanθ. A total of 6644 independent reflections within the 2θ<60° were measured, and 3364 reflections with $|F_o| \geq 3\sigma|F_o|$ were regarded as observed reflections and used for the structure determination and refinement.

The crystal data are as follows: $C_{26}H_{26}O_2$, F.W.=370.47, monoclinic, space group $P2_1/a$, a=15.803(3), b=8.276(1), c=15.706(3) Å, β=101.02(2)°, V=2016.2 Å^3, Z=4, D_c=1.22 g cm^{-3}, μ=0.816 cm^{-1}. The structure was solved by direct methods (MULTAN 78) and refined by the block-diagonal least-squares technique with anisotropic thermal parameters for non-hydrogen atoms and isotropic for hydrogens. All the hydrogen atoms were located on a difference map but their positional parameters were not refined. The atomic scattering factors were taken from International Tables for X-Ray Crystallography.[20] The weighting scheme $w=[\sigma_c^2+(0.03F_o^2)]^{-1}$ was employed. The final R and R_w values were 4.93 and 6.08%, respectively.

All the calculations were carried out on a HITAC M-200H computer with crystallographic computation program systems, MULTAN and UNICS III, filed at the Computer Center of the Institute for Molecular Science. The complete F_o−F_c data are deposited as Document No. 8838 at the Office of the Editor of the Bulletin of the Chemical Society of Japan.

The ^{1}H NMR spectra at 400 MHz were obtained at the JEOL laboratory. We wish to thank for the assistance and the permission of the use of the spectrometer.

Reactivities of Stable Rotamers. XXIII. Some Addition Reactions toward the Vinyl Group in 9-(2-Vinyl-1-naphthyl)-fluorene Rotamers[1)]

Michinori Ōki,*,† Jiro Tsukahara, Yoriko Sonoda, Kazuhiro Moriyama, and Nobuo Nakamura
Department of Chemistry, Faculty of Science, The University of Tokyo, Bunkyo-ku, Tokyo 113
(Received March 18, 1988)

Addition reactions to the vinyl group of the *ap* and the *sp* rotamers of 9-(2-vinyl-1-naphthyl)fluorene were carried out. Whereas action of sulfuric acid on the *sp* rotamer caused a cyclization reaction, the *ap* isomer was recovered under the conditions. While addition of bromine afforded normal products for both the isomers, reaction of chlorine afforded chlorine-substituted products (chloro olefins) in addition to the normal adduct, the formation of the former being predominant, in the *sp* form. The slightly enhanced reactivity of the *sp* form relative to the *ap* in bromination together with the formation of the chloro olefin and the behavior of the *sp* form in the treatment with sulfuric acid are attributed to the stabilization of the intermediates by the π-participation of the fluorene ring. Other addition reactions, epoxidation, hydrogenation, hydroboration, osmium tetraoxide oxidation, chlorination with (dichloroiodo)benzene, and diimide reduction, which are believed to proceed through a cyclic transition state, have also been studied to show that the rates of the reactions of one isomer are not much different from those of another. Spectroscopic data suggest that the conformation of the vinylnaphthalene portion in both isomers are similar. Little difference in the reaction rates of the two rotamers are attributed to the possible transition state conformation which may not be affected by the steric hindrance of the fluorene ring.

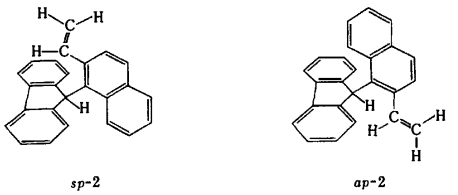
In previous papers of this series, we have pointed out that, in 9-(2-substituted 1-naphthyl)fluorene derivatives (**1**), reactions which occur over the fluorene ring with bulky transition states can be much slower than those which occur in the remote sites from the fluorene moiety.[2,3)] Thus the reactions that occur in the X group of the *ap* conformer (*ap*-**1**) are much

ap-1 *sp*-1

(if X precedes C_{8a} of naphthalene in the sequence rule)

slower than those occurring in the X of the *sp* conformer (*sp*-**1**), the k_{sp}/k_{ap} values exceeding 30 in some cases.

Based on these generallizations, we see that addition reactions of 9-(2-formyl-1-naphthyl)fluorenes (**1**: X= CHO) are on the border line, because the following relative rates, k_{sp}/k_{ap}, are obtained: sodium tetrahydroborate reduction 7.6, oxime formation 3.7, addition of Gringard reagents ca. 1.8.[2)] In view of these results, it will be worthwhile to examine some other reactions that would give similar situations in the transition states of reactions to that of the aldehyde. Since a vinyl group has a similar bulkiness with a formyl group as far as we consider the CH= group that should give important steric interactions with the fluorene moiety, 9-(2-vinyl-1-naphthyl)fluorene (**2**) is a good model to further the understanding of the steric effects in some reactions of this type of compounds. In addition, various types of addition reactions to an olefin which proceed with cyclic and consequently bulky transition states are known. This paper discusses the results of some addition reactions of **2**.



sp-2 *ap*-2

Rotational Barriers and Equilibrium Constant. In order to avoid complexity arising from isomerization of one rotamer to another, it is desirable to run reactions under conditions that do not permit contamination of one isomer by another produced by isomerization. Thus at the outset of the investigation we undertook the measurement of the rates of isomerization of these isomers. *ap*-**2** in toluene-d_8 exhibited the equilibrium constant (*sp*/*ap*) of 0.47 and the rate constant of isomerization of 8.48×10^{-6} s^{-1} at 80 °C. Similarly, the *sp* isomer gave the following results: *ap*/*sp* 2.1, *k*(isomerization) 1.95×10^{-5} s^{-1}. These results agree quite well. The free energy ef activation for rotation is 28.9 kcal mol^{-1} (1 cal=4.184 J) for the *ap*→*sp* process, and is 28.4 kcal mol^{-1} for the *sp*→*ap* process at 80 °C.

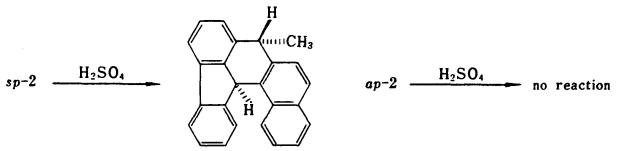
The barriers to rotation in these olefins are appreciably higher than those in the aldehyde (**1**: X=CHO), 26.8 kcal mol^{-1} at 80 °C.[2)] The equilibrium constant, 2.1, is significantly larger than the corresponding value, 1.5, for the aldehyde.[2)] The difference cannot be attributed to the difference in the ground state conformations, because both the aldehyde[4)] and the olefins (**2**), for which evidence is described in Experimental section, are coplanar with the naphthalene nucleus.

We attribute the difference in the equilibrium con-

† Present address: Department of Chemistry, Faculty of Science, Okayama University of Science, Ridaicho, Okayama 700.

stants between the aldehyde (**1**: X=CHO) and the olefin (**2**) to the difference in the solvents, hexachlorobutadiene for the aldehyde and toluene-d_8 for the olefin.

Addition Reactions of Cationic Species. Treatment of *sp*-**2** with concentrated sulfuric acid afforded *trans*-8-methyl-8,14c-dihydrodibenz[*a*,*l*]aceanthrylene (**3**) smoothly which was identical with the authentic specimen reported in a previous paper.[5] The result unambiguously shows that the benzylic cation formed by addition of a proton to the vinyl group can attack the aromatic ring of the fluorene moiety if the conformation of the starting olefin is *sp*. By contrast, we recovered *ap*-**2** after the same treatment for 60 days. Thus it is extremely difficult to get a cyclized product from a cation produced in the benzylic position of *ap*-**2**, as reported for another case of dehydration reaction of *sp*-9-[2-(1-hydroxyethyl)-1-naphthyl]fluorene.[6]



3

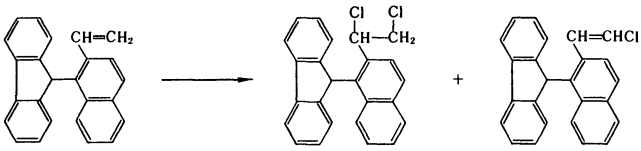
Addition of bromine to the olefinic bond is usually assumed to proceed through a bridged bromonium ion because of the stereospecificity of the reaction.[7] However, the stereospecificity is lost in the addition of bromine to *cis*- and *trans*-1-propenylbenzene.[8] Since the compounds we are concerned here are styrene derivatives, the reaction might be assumed to follow the path where an open-chain cation intervenes. If the intermediate is distinctly a cation, then we might expect to obtain a cyclized product from *sp*-**2** as was the case for the sulfuric acid treatment.

In the actual reaction, no anomaly was observed not only for *ap*-**2** but also for *sp*-**2**: normal addition reaction products (**4**) were obtained. This would mean that the cationic species formed during the reaction is not a naked cation but is stabilized by the participation of the bromine atom beta to the cationic center. The nonstereospecificity of the bromine addition[8] is not inconsistent with this interpretation but would mean that, due to the weak participation of the bromine atom, the bond between the cationic center and the bromine atom breaks and reforms rapidly under the conditions, when stereochemistry is reversed. This result is consistent with the finding that, in the addition reaction of bromine to 1-propenylbenzene, partial stereoselectivity is observed.[8,9]

The relative rate (k_{ap}/k_{sp}) of the bromine addition was 0.80 in carbon tetrachloride. It is rather surprising to note that the reaction which occurs at a crowded site is faster than that in a less crowded site. It is especially so when we compare the results with those of addition reactions to the formyl group: although the relative rates vary from reaction to reaction, the reactions that occur in a less crowded site are always faster than those in a crowded site.[2] We wish to attribute this apparently anomalous relative rate to the participation of the π-system of the fluorene ring. Namely the cationic species formed by addition of a cationic bromine is partly stabilized by the π-participation. In agreement with this interpretation, we found that the same reaction in acetonitrile prefers the *ap*-olefin, although the degree of the preference is rather small, k_{ap}/k_{sp}=1.2. It has been found that solvation shell around the cationic species formed over the fluorene ring is completed by involving the participation of the fluorene ring.[6] Thus, if the solvent molecules are good nucleophiles, the cation formed from *ap*-**2** must be more stable than that from *sp*-**2**, because the solvation shell is completed by solvent molecules alone in the *ap*-**2** case.

2 4

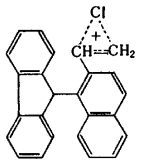
The reactions of the olefin (**2**) with chlorine were rather surprising: while the *ap*-form afforded the chlorine-addition product (**5**), as the normal olefin, in addition to a small amount of an unidentified material, the ratio of the addition product (**5**) to a chlorine-substitution product (**6**) was 1.0 : 1.4 in the case of *sp*-**2**. Compound **6** is not the secondary product from **5**, because the formation ratio, **5**/**6**, at the later stage of the reaction was the same with that at the earlier stage and **6** was not converted practically to **5** under the reaction conditions in a separate experiment.



2 5 6

The mechanism of the formation of **6** is assumed to be that the intervening cation (**7**) which is stabilized, though weak, by the participation of the chlorine atom in the β-position suffers from deprotonation more preferably than the attack of the chloride ion at the α-position. The preferred formation of **6** in the case of *sp*-**2** must be derived from the facts that the vinyl group is situated in the sterically more hindered site and that the ionic character of the intervening **7** is more significant than that of the *ap*-form because of the π-participation. It might be argued that the chloronium ion is possible only in aliphatic β-chloro carbocations and not for the benzylic cation.[10] In the addition of chlorine to an olefinic bond in compounds of styrene type, open-chain β-chloro cations which form ion-pairs are postulated.[11] However, the postulate cannot accommodate the difference in the reactivities

of the rotamers observed here. We prefer, therefore, that the chlorine participation is significant in this case, though the C-Cl bond may break and form rapidly because the participation is weak. The formation of the chloro-olefin which is also observed in other cases is attributed to deprotonation from either the weakly chloro-participated **7** or transitionally formed open-chain cation.



7

Addition Reactions with Cyclic Transition States. Relative rates (k_{ap}/k_{sp}) are given in Scheme 1 for various addition reactions of which transition states are cyclic, together with some related reactions.

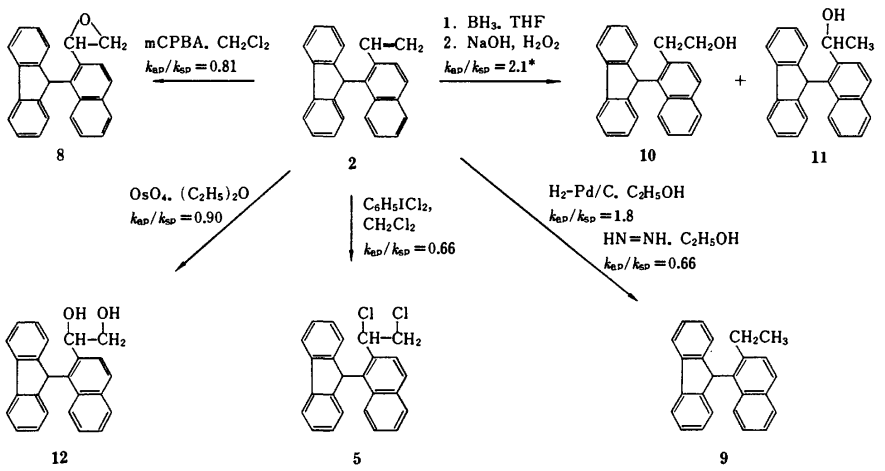
Epoxidation of olefins with peroxycarboxylic acids is known to proceed stereospecifically.[12] Even *cis*-stilbene gives a stereospecific addition product, *cis*-2,3-diphenyloxirane.[13] Thus in the formation of epoxides, the transition state may be unequivocally assumed to be a three-membered cycle. Both *ap*-**2** and *sp*-**2** reacted smoothly with *m*-chloroperbenzoic acid to give epoxides (**8**). The relative rate was very close to unity but the reaction of *sp*-**2** was significantly favored over that of *ap*-**2**.

Four-membered cyclic transition states are assumed for catalytic hydrogenation[14] and addition of borane.[15] Hydrogenation of *ap*-**2** and *sp*-**2** over palladium on carbon proceeded smoothly to afford *ap*- and *sp*-9-(2-ethyl-1-naphthyl)fluorene (**9**), respectively. The relative rate was ca. 2. Addition of borane to *sp*-**2** in tetrahydrofuran, followed by oxidation with alkaline hydrogen peroxide, afforded 9-[2-(2-hydroxyethyl)-1-naphthyl]fluorene (**10**) and 9-[2-(1-hydroxyethyl)-1-naphthyl]fluorene (**11**) in 7:3 ratio, whereas *ap*-**2** afforded the corresponding **10** and **11** in 5:2 ratio. This poor regioselectivity in the borane addition was also reported in the literature for the case of styrene.[15,16] Strictly speaking, therefore, we observed two reactions, which differ in the rate constants, to make the comparison of the reactivities of the rotamers very difficult. However, since the product ratios due to the regiochemically different additions in both rotamers are not far from each other and the rates of the additions to the two olefinic substrates are comparable, we may compare the reactivity of the rotamers, as a rule of thumb, by taking the rates of decrease in the amount of the starting materials, *sp*-**2** and *ap*-**2**. These results are shown in Scheme 1. This reaction is the one among those examined in this work, that shows the highest reactivity of the *ap*-isomer relative to the *sp*. Although we tried to add 9-borabicyclo[3.3.1]nonane, which should give distinct steric effects,[17] to the olefin, isomers failed to give products.

Cis-addition, though not exclusive, of chlorine to olefins was first established by Barton and Miller[18] when (dichloroiodo)benzene was used. Although this addition reaction has a complicated nature,[19] it will be worthwhile to try the reaction as an example of a five-membered cyclic transition state. The reaction of (dichloroiodo)benzene with *ap*-**2** and *sp*-**2** proceeded smoothly to give the corresponding dichlorides (**5**). The relative rate was 0.66. Although this reaction can involve ionic, radical, and cyclic intermediates (or transition state), details are not known. However, the results suggest that the mechanism of the reaction of **2** with this reagent is different from the addition reaction of chlorine, because the product ratios were different.

A five-membered cyclic transition state is also expected for the oxidation of the olefin with osmium tetraoxide.[20] Addition of the reagent gave the corresponding diols (**12**). The relative rate was 0.90.

Diimide addition to olefins is also stereospecific and



Scheme 1. Reactions of *ap*- and *sp*-9-(2-vinyl-1-naphthyl)fluorene rotamers, products, and relative reactivities (k_{ap}/k_{sp}).
* For k_{ap}/k_{sp} here, see the text.

a six-membered cyclic transition state is involved.[21] Since the isomerization of the rotamers of **2** can occur under the alkaline conditions, we used the method of generation of diimide under neutral conditions.[22] The reduction of **2** took place smoothly to afford 9-(2-ethyl-1-naphthyl)fluorene (**9**). The relative reactivity is less than unity to mean that the vinyl group over the fluorene ring is more vulnerable to the reaction.

Summarizing these results, we notice that the rates of addition reactions of various reagents to the olefinic bond of compound **2** do not differ to a large extent from the *ap* to the *sp* rotamer, even though we selected various space-demanding reactions with cyclic transition states from a three membered to a six-membered ring.

Although the ground state conformations of the vinylnaphthalene moieties are planar, the rotamers cannot react in the conformations as such, because the bulky transition state must be taken that should strongly interfere with the fluorene ring in the *sp* rotamer. Therefore, a strong possibility is that the vinyl group rotates from the naphthalene plane to permit the access of the reagent. This rotation will occur in both conformers, *ap*-**2** and *sp*-**2**, because the reactions of *ap*-**2**, especially those which are not electron-demanding, must be faster than those of *sp*-**2**, to an extent that is determined by the energy required for the rotation, if *ap*-**2** reacts in the planar conformation. Though the electron density in the vinyl group should increase by taking the nonplanar structure, this effect on the reaction rate may be neglected.

If the vinyl group takes the nonplanar conformation invoked above, in the transition state of addition reactions where the benzylic carbon must approach the sp^3-hybridized geometry, the hydrogen on the benzylic carbon will direct toward the fluorene moiety to make the steric interaction energy minimum. We conclude therefore, that in this kind of transition state conformations the steric hindrance is minimum and the transition state energy is by and large the same for the two rotamers to make the relative reaction rates close to unity.

Close examination of the results in Scheme 1 reveals that in nonpolar solvent the reactions in which electron-demanding reagents are used tend to give smaller values of k_{ap}/k_{sp} than unity except for hydroboration. Although we should not overlook solvent effects, it is tempting to consider that the π-participation from the fluorene system is accelerating the reactions of *sp*-**2**.

Borane will not be an adding species as such: it should be accompanied by solvent molecule(s) because of its high Lewis acidity. This steric effect may be the reason why borane gives a k_{ap}/k_{sp} value of more than one. We do not have a good explanation for the results of diimide reduction at present. Probably the solvent effect is important because we used strongly polar and hydrogen-bonding ethanol as a solvent.

Coming back to the situation of addition reactions to the aldehyde (**1**: X=CHO), we now believe that, since the steric situation of it is very close to the olefin (**2**), the k_{sp}/k_{ap} value which is close to unity is normal. Those reactions which give large k_{sp}/k_{ap} values for the aldehyde may involve factors of solvation.

Experimental

^{1}H NMR spectra were recorded on either a Varian EM390 spectrometer which operates at 90 MHz or a JEOL GX270 machine which operates at 270 MHz. Melting points are not corrected.

Infrared Spectra. They were recorded on a Hitachi IR-260-30 spectrophotometer with a thalium(I) chloride cell of 0.1 mm path length. The solutions were prepared by dissolving the sample in carbon tetrachloride to make up 1.04 mol L^{-1} solutions for both isomers. Both isomers exhibited absorptions due to C=C stretching at the identical wavenumber, 1620 cm^{-1}.

Ultraviolet Absorption Spectra. They were recorded on a Hitachi-UV-340 spectrophotometer with a silica cell of 1.0 cm in length. Samples were dissolved in methanol and the concentrations of **2** were ca. 1×10^{-5} mol L^{-1} for the short wavelength region (<300 nm) and ca. 6×10^{-4} mol L^{-1} for the long wavelength region (>300 nm). The spectrum of 2-vinylnaphthalene was recorded for only the long wavelength region with 7.79×10^{-4} mol L^{-1} concentration in methanol because absorptions at the shorter wavelength region have been reported.[23] The following absorption maxima were recorded (wavelength in nm and log ε parentheses given):

sp-**2**:[5] 249 (4.59), 293 (4.09), 303 (4.09), 328 (sh), 346 (1.86).
ap-**2**:[5] 242 (4.65), 267 (sh), 280 (sh), 290 (4.19), 302 (4.17), 320 (sh), 344 (1.69).
2-vinylnaphthalene: 323 (2.69), 331 (2.41), 340 (2.50).

***trans*-8-Methyl-8,14c-dihydrodibenz[*a,l*]aceanthrylene (3).** A solution of 1.0 g of *sp*-**2** in 10 mL of 1,2-dimethoxyethane was mixed with a mixture of 30 mL of 1,2-dimethoxyethane and 30 mL of concentrated sulfuric acid and stirred overnight at room temperature. The mixture was poured into water and extracted with ether. The ethereal extract was washed with aqueous sodium hydrogencarbonate and dried over magnesium sulfate. The solvent was evaporated and the residue was chromatographed on silica gel (hexane eluent) to afford the cyclic compund (**3**), mp 173.0—174.0 °C, in 90% yield. The compound was identical with that previously reported.[5]

9-[2-(1,2-Dibromoethyl)-1-naphthyl]fluorene (4). A solution of 1.0 g (3.1 mmol) of the *ap*-olefin in 150 mL of carbon tetrachloride was mixed with 510 mg (3.2 mmol) of bromine in 50 mL of carbon tetrachloride, by adding the latter gradually at 0 °C. The solvent was evaporated after 30 min and the residue was chromatographed through a short column of silica gel. The *sp*-dibromide was obtained in 1.4 g (93%) yield, mp 173.0—174.0 °C. Found: C, 62.64; H, 3.80; Br, 33.83%. Calcd for $C_{25}H_{18}Br_2$: C, 62.77; H, 3.80; Br, 33.43%. ^{1}H NMR ($CDCl_3$) δ=4.1—4.6 (2H, m), 5.81 (1H, s), 6.0—6.3 (1H, m), 6.4—8.0 (14H, m).

Similarly the *sp*-olefin gave *ap*-dibromide, mp 137.5—138.5 °C. Found: C, 62.69; H, 3.67; Br, 33.71%. Calcd for $C_{25}H_{18}Br_2$: C, 62.77; H, 3.80; Br, 33.43%. ^{1}H NMR ($CDCl_3$) δ=3.2—3.5 (2H, m), 4.0—4.3 (1H, m), 6.17 (1H, s), 7.0—8.0

(13H, m), 8.4—8.6 (1H, m).

Reaction of Olefin 2 with Chlorine. A solution of 50 mg (0.16 mmol) of the olefin (**2**) in 50 mL of carbon tetrachloride was mixed with 8.3 mL of ca. 20 mmol L^{-1} solution of chlorine in carbon tetrachloride at 0 °C and the mixture was stirred for 3.5 h at the temperature. From the reaction mixture, the solvent and other volatile materials were evaporated and the residue was chromatographed on silica gel with 5 : 1 hexane-dichloromethane as an eluent.

ap-**2** afforded the dichloride (*sp*-**5**), mp 150—151 °C, and a small amount of an unidentified by-product. Found: C, 77.41; H, 4.76; Cl, 17.92%. Calcd for $C_{20}H_{18}Cl_2$: C, 77.13; H, 4.66; Cl, 18.21%. ^{1}H NMR ($CDCl_3$) δ=4.25—4.42 (2H, m), 5.83 (1H, s), 5.96—6.06 (1H, m), 6.46—8.00 (14H, m).

sp-**2** afforded the dichloride (*ap*-**5**) and the olefin (*sp*-**6**) in 1.0 : 1.4 ratio. *ap*-**5** was identical with the product obtained from the reaction of *sp*-**2** with (dichloroiodo)benzene which is described later but decomposed on standing to give *sp*-**2** and *sp*-**6**. The olefin originally contained ca. 11 : 1 trans and cis olefins as judged by ^{1}H NMR spectra and gave trans-olefin (*sp-trans*-**6**) on recrystallization from ethanol, mp 134.0—135.0 °C. Found: C, 85.25; H, 5.03%. Calcd for $C_{25}H_{17}Cl$: C, 85.10; H, 4.86%. ^{1}H NMR ($CDCl_3$) δ=5.68 (1H, d, J=14 Hz), 5.90 (1H, d, J=14 Hz), 6.14 (1H, s), 7.11—7.98 (13H, m), 8.53—8.60 (1H, m). The following ^{1}H NMR data ($CDCl_3$, δ) for the *cis*-chloro olefin (*sp-cis*-**6**) were collected: 5.38 (1H, d, J=9 Hz), 5.46 (1H, d, J=9 Hz), 6.12 (1H, s), 7.11—7.98 (13H, m), 8.53—8.60 (1H, m).

9-[2-(1,2-Epoxyethyl)-1-naphthyl]fluorene (8). To a solution of 150 mg (0.47 mmol) of the *ap*-olefin (**2**) in 30 mL of chloroform, was added 110.0 mg (0.64 mmol) of *m*-chloroperbenzoic acid which had been washed with a buffer solution of pH 7.6 to remove any acidic materials.[24] The mixture was stirred for a week at room temperature and the mixture was directly submitted to chromatography on silica gel with 1 : 1 hexane-dichloromethane eluent to give 95% *sp*-epoxy compound. The compound was purified by recrystallization from benzene-hexane, mp 144.0—145.0 °C. Found: C, 89.55; H, 5.16%. Calcd for $C_{25}H_{18}O$: C, 89.79; H, 5.43%. ^{1}H NMR ($CDCl_3$) δ=2.95—3.32 (2H, m), 4.55—4.60 (1H, m), 5.90 (1H, s), 6.40—8.00 (14H, m).

Similar treatment of the *sp*-olefin with stirring for 22 h afforded 70% *ap*-epoxy compound (*ap*-**8**), mp 134.0—135.0 °C, after recrystallization from benzene-hexane. Found: C, 89.67; H, 5.14%. Calcd for $C_{25}H_{18}O$: C, 89.79; H, 5.43%. ^{1}H NMR ($CDCl_3$) δ=1.83—1.95 (2H, m), 2.64—2.68 (1H, m), 6.17 (1H, s), 7.05—8.05 (13H, m), 8.46—8.55 (1H, m). The yield was not improved after stirring for 7 d: unreacted material was detected.

Hydroboration of 2. A solution of 100 mg (0.31 mmol) of *ap*-**2** in 40 mL of tetrahydrofuran, which was freshly distilled from lithium tetrahydridoaluminate, was mixed with 1.4 mL of 1 mol L^{-1} solution of borane in tetrahydrofuran and the mixture was stirred for 2.5 h under a nitrogen atmosphere. To the reaction mixture diluted with 50 mL of tetrahydrofuran, were added 1.5 mL of 30% hydrogen peroxide and 1.5 mL of 3 mol L^{-1} aqueous sodium hydroxide and the whole was stirred for 1.5 h under a nitrogen atmosphere. The mixture was poured into water and extracted with ether. The ether layer was dried over magnesium sulfate and the solvent was evaporated. Chromatography of the residue on silica gel under medium pressure, with 1 : 4 hexane-ether eluent, afforded 1.0 : 2.5 *sp*-1-ol (**11**) and *ap*-2-ol(**10**). The former was identical with that reported[2,5] and the latter was recrystallized from dichloromethane-pentane, mp 110.0—111.5 °C. High resolution MS: m/z 336.1553. Calcd for $C_{25}H_{20}O$: M, 336.1515. ^{1}H NMR ($CDCl_3$) δ=3.44 (2H, t, J=9 Hz), 4.13 (2H, t, J=9 Hz), 5.77 (1H, s), 6.40—7.98 (14H, m). The OH proton was not detected.

Similarly the *sp*-olefin gave 42% *sp*-2-ol (**10**) and 18% *ap*-1-ol (**11**), which was identical with authentic specimen.[2,5]

sp-2-Ol (**10**), mp 115.5—117.5 °C. Found: C, 89.16; H, 6.23%. Calcd for $C_{25}H_{20}O$: C, 89.25; H, 5.99%. ^{1}H NMR ($CDCl_3$) δ=1.91 (2H, t, J=7 Hz), 3.00 (2H, t, J=7 Hz), 6.15 (1H, s), 7.0—8.0 (13H, m), 8.4—8.6 (1H, m). The OH proton was not detected.

9-(2-Ethyl-1-naphthyl)fluorene (9). a) Catalytic Hydrogenation of 2. A solution of 60 mg of the *sp*-olefin in 80 mL of ethanol was added to 10 mg of 5% palladium on carbon, which was activated by shaking with hydrogen and 20 mL of ethanol, and the whole was stirred under a hydrogen atmosphere. The hydrogen absorption was completed after 20 h. The product was recrystallized from ethanol, mp 118.8—119.5 °C. The yield was 99%. Found: C, 93.46; H, 6.11%. Calcd for $C_{25}H_{20}$: C, 93.71; H, 6.29%. ^{1}H NMR ($CDCl_3$) δ=0.48 (3H, t, J=7 Hz), 1.65 (2H, q, J=7 Hz), 6.15 (1H, s), 7.12—7.97 (13H, m), 8.52 (1H, m).

Similarly *ap*-**9**, mp 107.5—108.0 °C, was obtained in 99% yield. Found: C, 93.41; H, 6.19%. Calcd for $C_{25}H_{20}$: C, 93.71; H, 6.29%. ^{1}H NMR ($CDCl_3$) δ=1.40 (3H, t, J=8 Hz), 3.10 (2H, q, J=8 Hz), 5.69 (1H, s), 6.35—7.92 (14H, m).

b) Diimide Reduction of 2. A solution of 100 mg (0.31 mmol) of *sp*-**2** in 100 mL of ethanol was mixed with 0.5 mL (8.6 mmol) of hydrazine hydrate and 1 drop of 1% aqueous copper(II) sulfate. To the mixture was slowly added 2.0 mL (17 mmol) of 30% aqueous hydrogen peroxide with ice-cooling. After 30 min, the mixture was poured into water and extracted with ether. The ethereal extract was dried over magnesium sulfate and the solvent was evaporated to give 95% *sp*-**9** which was identical with the compound obtained above.

Similarly *ap*-**2** afforded *ap*-**9**, identical with the compound described above, in almost quantitative yield.

Reaction of (Dichloroiodo)benzene with 2. To a solution of 40 mg (0.12 mmol) of *ap*-**2** in 35 mL of dichloromethane was added 35 mg (0.12 mmol) of (dichloroiodo)benzene[25] and the mixture was stirred for 23 h at room temperature. The solvent and the volatile materials were removed by distillation in vacuo and the residue was recrystallized from hexane to give *sp*-**5** in almost quantitative yield.

Similarly, the reaction of *sp*-**2** with (dichloroiodo)benzene afforded *ap*-**5**, mp 90—95 °C (decomp). This compound decomposed on attempted recrystallization from pentane to yield *sp*-**2** and *sp*-**6**, though it was stable at 0 °C. It also decomposed slowly at room temperature even in the solid state on standing. The yield was ca. 80%. High resolution MS: m/z 388.0742 and 390.0701. Calcd for $C_{25}H_{16}{}^{35}Cl_2$ and $C_{25}H_{16}{}^{35}Cl^{37}Cl$: M, 388.0784 and 390.0754. ^{1}H NMR ($CDCl_3$) δ=3.05—3.40 (2H, m), 4.04—4.12 (1H, m), 6.22 (1H, s), 7.08—8.02 (13H, m), 8.52—8.64 (1H, m).

Reaction of 2 with Osmium Tetraoxide. To a solution of 70 mg (0.22 mmol) of **2** in 50 mL of ether, was added a solution of ca. 60 mg (0.24 mmol) of osmium tetraoxide in 4.0 mL of ether under an argon atmosphere and the whole was stirred for 24 h at room temperature. To the solution was added 2.5 g of sodium hydrogensulfite, 10 mL of water

and 10 mL of ethanol and the mixture was heated at 60 °C with stirring for 24 h. The mixture was poured into water and the ether layer was separated. The aqueous layer was extracted with ether and the combined extracts were dried over magnesium sulfate. The solvent was evaporated to give the diol (**12**) in ca. 70% yields. The following ^{1}H NMR data were collected ($CDCl_3$, δ). *sp*-**12**: 3.91—4.15 (2H, m), 5.63—5.72 (1H, m), 5.79 (1H, s), 6.40—8.02 (14H, m). The OH protons were not detected. *ap*-**12**: 2.60—3.24 (2H, m), 3.70—3.80 (1H, m), 6.20 (1H, s), 7.13—8.01 (13H, m), 8.52—8.59 (1H, m).

These diols were characterized by converting them to acetonides through treatment of the diols with acetone and *p*-toluenesulfonic acid.

***sp*-Diol Acetonide:** Mp 151.5—152.0 °C, after recrystallization from hexane. High resolution MS: *m/z* 392.1741. Calcd for $C_{28}H_{24}O_2$: M, 392.1775. ^{1}H NMR ($CDCl_3$) δ=1.54 (3H, s), 1.67 (3H, s), 3.96—4.58 (2H, m), 5.64 (1H, s), 5.90—5.96 (1H, m), 6.41—7.95 (14H, m).

***ap*-Diol Acetonide:** oil. High resolution MS: *m/z* 392.1739. Calcd for $C_{28}H_{24}O_2$: M, 392.1775. ^{1}H NMR ($CDCl_3$) δ=0.80 (3H, s), 1.37 (3H, s), 2.56—3.07 (2H, m), 4.07—4.12 (1H, m), 6.18 (1H, s), 7.04—7.97 (13H, m), 8.53—8.56 (1H, m).

Competitive Addition Reactions. Two rotational isomers (10 mg each or 0.03 mmol) of **2** were dissolved in an appropriate solvent with a small amount of fluorene which served as a reference. The appropriate reagent (0.03 mmol or less) in an appropriate solvent was added to the solution and the decrease in the amount of each rotamer was recorded with the use of either integration of ^{1}H NMR signals or calibration curves for the amounts of the olefins drawn by using the UV absorption at 254 nm which was used for the detection in HPLC. The reaction conditions were similar to those described above for the individual rotamers except for the addition of bromine and chlorine, when a dilute solution (ca. 0.1 mmol L^{-1}) of the halogen in carbon tetrachloride was added to the solution of **2**. The results given in Scheme 1 are averages of 2—3 runs which were terminated before 50% completion of the reactions.

Determination of Barriers to Rotation in 9-(2-Vinyl-1-naphthyl)fluorene (2). A solution of 40 mg of the *ap* isomer in 0.5 mL of toluene-d_8 was sealed in an NMR tube. The tube was immersed in a boiling benzene bath. The rotation was quenched by cooling rapidly with an ice-water bath at a given time and the isomer ratio was determined by ^{1}H NMR spectroscopy. The equilibrium constant was obtained by heating the sample tube as above for 48 h. The isomer ratio did not change after heating for further 12 h. The data were treated by assuming a first order reversible reaction.

The *sp*-isomer was treated similarly. It gave the same equilibrium constant that was obtained form the *ap* isomer.

Reactivities of Stable Rotamers. XXIV. Formation of Isomeric Ketones by Cyclization of Rotameric 3-Methyl-3-(1,2,3,4-tetrahalo-9-triptycyl)butanoyl Chloride and Barriers to Isomerization of the Ketones[1)]

Michinori Ōki,*,† Toshihiro Tanuma, Yasuhiro Tanaka, and Gaku Yamamoto

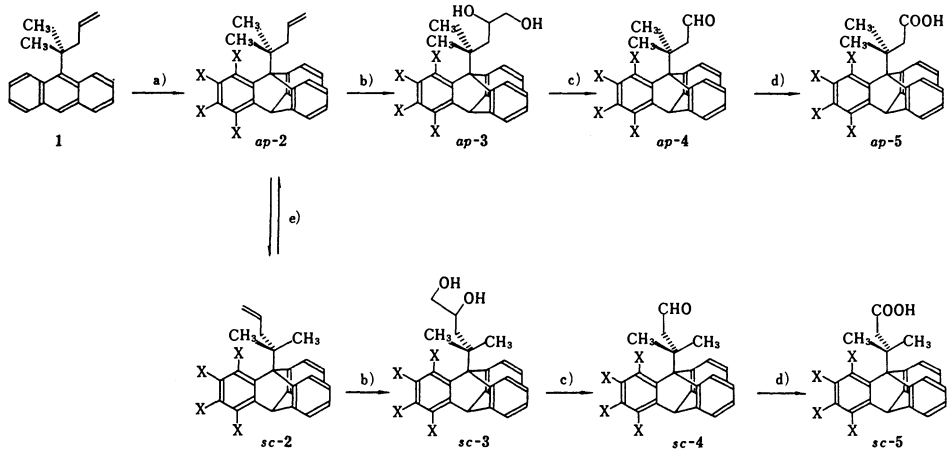
(Received March 29, 1988)

Rotational isomers of 3-methyl-3-(1,2,3,4-tetrahalo-9-triptycyl)butanoic acid, where the halo is either fluoro or chloro have been prepared. Cyclization of their acid chlorides afforded *ap*- and *sc*-ketones from *ap*- and *sc*-isomers, respectively. The barriers to isomerization were 29.9 and 26.8 kcal mol^{-1} at 363 K, for the fluoro and the chloro ketones, respectively, for the $ap \rightarrow \pm sc$ process. The equilibrium constants (*sc*/*ap*) at 363 K were 2.34 and 18.5 for the fluoro and the chloro compounds respectively. The barriers to isomerization and the relative stabilities of the isomeric ketones were discussed based on the MMP2(NONPLANAR) calculation results and the steric congestion in the ground state.

While we have reported interesting differences in reactivities of 3-(1,4-disubstituted 9-triptycyl)-3-methylbutanoyl chloride rotamers, when they were treated with Lewis acids, and isomerization kinetics of the ketones obtained from the respective rotamers,[2)] it is hoped to increase the number of data to discuss the general trends in reactivities, equilibrium constants, and barriers to isomerization. We thus prepared 3-methyl-3-(1,2,3,4-tetrahalo-9-triptycyl)butanoic acid rotamers, and then examined their reactivities, the barriers to isomerization of the ketones derived from them, and the equilibrium constants of the ketones. This paper reports and discusses results of such investigations.

The 3-methyl-3-(1,2,3,4-tetrahalo-9-triptycyl)butanoic acid rotamers (**5**) were prepared in the following ways. Addition of tetrahalobenzyne to 9-(1,1-dimethyl-3-butenyl)anthracene (**1**)[2)] afforded a mixture of rotamers of 9-(1,1-dimethyl-3-butenyl)-1,2,3,4-tetrahalotriptycene (**2**) which contained *ap*-rotamers predominantly. The mixture was heated in boiling 1-chloronaphthalene to enrich *sc*-isomers by isomerization and the resulted mixture of rotamers was separated by chromatography on silver nitrate-impregnated silica gel. The olefins were oxidized with trimethylamine oxide in the presence of osmium tetraoxide[3)] to produce the corresponding diols (**3**) which were further oxidized with periodic acid to afford the aldehydes (**4**).[4)] The aldehydes were finally oxidized with potassium permanganate to produce the desired carboxylic acids (**5**).

The individual rotamers of the carboxylic acids were converted to the corresponding acid chlorides (**6**) by the treatment with oxalyl dichloride, and the acid chlorides were treated with titanium(IV) chloride to produce the ketones (**7**). As expected, due to the low



Scheme 1. Synthetic routes to 3-methyl-3-(1,2,3,4-tetrahalo-9-triptycyl)butanoic acid rotamers: a series X=F, b series X=Cl. a) Tetrahalobenzyne, b) OsO_4-$(CH_3)_3NO$, c) HIO_4, e) heating and chromatography on SiO_2–$AgNO_3$. Only one of the *sc*-forms is shown.

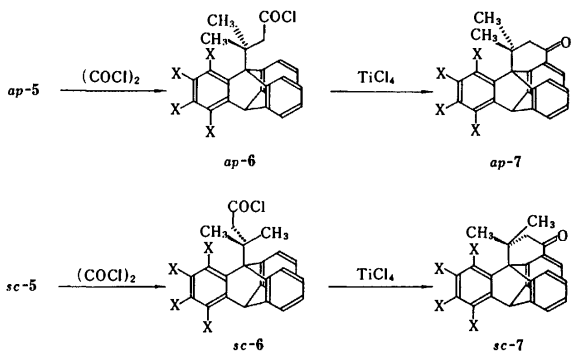
† Present address: Department of Chemistry, Faculty of Science, Okayama University of Science, Ridaicho, Okayama 700.

electron density at the 1-position of these compounds (**6**), no ipso attack by the intervening acylium cation was apparent. The corresponding ketones (**7**) were the exclusive products: even the *sc*-isomers afforded **7** only, though in other instances *sc*-isomers gave products of different types.

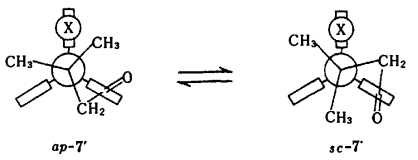
Although the difference in the reactivities of the rotamers of the chloro compound (**6b**) was not apparent, we noticed a difference in the fluoro compound (**6a**): whereas the reaction of **6b** with titanium(IV) chloride in benzene for 3 hours at room temperature afforded the corresponding cyclic ketones (**7**) of both isomers in good yields, the same treatment of *sc*-**6a** for 4 hours gave back some unreacted compound which was recovered as *sc*-**5a** in addition to the ketone (**7**) (31 and 58% yields, respectively). The incomplete reaction of *sc*-**6a** under the conditions was not due to the hydrolysis of *sc*-**6a** to *sc*-**5a** but slowness of the cyclization reaction. This was checked in two ways. Firstly, ^{1}H NMR spectra did not show any signals due to the hyrolyzed product in the reaction mixture. Secondly, treatment of (*sc*-**6a**) for 6 hours gave the ketones as sole products and no acid *sc*-**5a** was recovered.

It may be argued that the formation of a cation in the vicinity of the fluoro substituent was slow because, in cases where a chloronium or fluoronium ion of a three-membered ring could be formed in competition, only the former was formed.[6,7] However, we believe the results are better interpreted by considering the fact that there are two benzene rings in the *ap*-form (*ap*-**6a**) to react with the acylium ion, whereas there is only one such ring in *sc*-**6a**, because *ap*-**6a** gave 10% recovered acid after 2 hour treatment. The slow reaction in both isomers in **6a** relative to **6b** may be attributed to the stronger electron-withdrawing effect of the fluorine atom than the chlorine.

Ketones, *ap*-**7′** and *sc*-**7′**, obtained from *ap*-**6** and *sc*-**6**, respectively, were different compounds and could be isomerized with each other on heating. The barriers to the isomerization and the equilibrium constants between the isomers are listed in Tables 1 and 2, for the fluoro and the chloro compounds, respectively. The interesting trends seen in these tables are that the isomerization is easier in the chloro compound than in the fluoro compound and the equilibrium constant (*sc*/*ap*) is larger in the chloro compound than in the fluoro compound.



Scheme 2. Formation of isomeric ketones from rotamers of **5**.



Scheme 3. Isomerization of the ketones (**7**).

In order to see the effects of the 1-substituent on the barriers to isomerization and on the equilibrium constants, the data are summarized in Table 3 together with those of 8,11-dimethyl and 8,11-dimethoxy compounds (**8**). Generally speaking, the bulkier the 1-substituent, the lower the barrier to isomerization and the larger the equilibrium constant. This means that the ground state energy is more effectively raised than the transition state energy for isomerization by introducing a bulky substituent at the 11-position. It is especially so for the *ap*-ketones. The trend observed in the barriers to isomerization is parallel to that observed in 1,2,3,4-tetra- or 1,4-disubstituted 9-(1,1-dimethyl-2-phenylethyl)triptycenes (**9**),[8] open-chain analogs of the ketones.

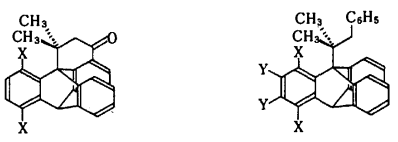

Table 3. Comparison of Free Energies of Activation for Isomerization, $ap \rightarrow sc$, and Equilibrium Constants of Ketones in Toluene-d_8 at 90 °C

Compound	1-Substituent	$\Delta G^{\ddagger}_{363}$ / kcal mol^{-1}	K(sc/ap)	Reference
8b	CH_3	26.0	17.2	2
7b	Cl	27.0	18.5	This work
8a	CH_3O	29.4	6.0	2
7a	F	29.8	2.29	This work

Table 4. Steric Energies and Dissected Energies of Ketones as Calculated by MMP2(NONPLANAR) Method

Conformation		**7a**		**7b**	
		ap	*sc*	*ap*	*sc*
Steric energy		36.375	35.584	49.337	47.896
Compression		3.463	3.358	5.291	5.489
Bending		12.363	12.446	14.138	15.432
Stretch-Bend		0.040	0.024	0.128	0.143
van der Waals	a)	21.574	21.596	27.186	27.677
	b)	−2.600	−2.737	−1.938	−0.763

Dipole		10.561	10.588	9.192	9.234

a) 1,4 energy. b) Others.

Since single crystals of these compounds have not been obtained yet, we performed molecular mechanics MMP2(NONPLANAR) calculations, in order to get further into insight. The results are shown in Table 4. This program seems to yield more realistic results than MM2 or MMP2 programs, of which results were previously reported.[2,9] As were the cases previously reported, the total energies indicate that *sc*-**7** is always more stable than *ap*-**7** and the main difference in the total energies is attributed to the difference in the torsion terms: *ap*-**7** suffers from severer torsion than the *sc* form and the difference is larger in the case of a bulky 11-substituent than in the case of a less bulky substituent.

Although the reliability of the MM2 calculation results for this kind of highly congested molecules might be argued, we believe, as discussed in the previous paper,[2] that the results are supported by the following ^{1}H NMR data. Namely, there is a methyl group, of which protons give a ^{1}H NMR signal at a considerably high magnetic field, in each of the isomers of **7a** and **7b**. These signals show coupling with a small coupling constant to indicate that there is a long range coupling with a proton. MMP2-(NONPLANAR) calculations show that the −*sc*-methyl in *ap*-**7′** and the *ap*-methyl in *sc*-**7′** are located in the shielding zone of the distorted benzene ring. The *ap*-methyl in *sc*-**7′** suffers from additional shielding of the carbonyl moiety. These methyl groups are exactly antiperiplanar with one of the methylene protons, thus forming a W-letter skeleton that is favorable for the long range coupling.[10]

The spin-couplings between the 1-fluorine and the methyl-protons in *ap*- and *sc*-**7a** are also consistent with the calculated structures. The *ap*-methyl-protons in *sc*-**7′** fail to show coupling with the fluorine but there is a distinct coupling observed with the methylene proton. The distance between the +*sc*-methyl and 1-F in *sc*-**7′** and that between the +*sc*-methyl and 1-F in *ap*-**7′**, 2.73 and 2.71 Å, respectively, are almost the same in agreement with almost the same F-H coupling constants, 7.9 and 8.1 Hz, respectively, for the former and the latter. The distance between the −*sc*-methyl and the 1-F in *ap*-**7′** is much longer than that between the +*sc*-methyl and the 1-F in *ap*-**7′**, 2.99 and 2.71 Å, respectively, justifying the observed coupling constants of 2.6 Hz for the former and 8.1 Hz for the latter. These distances between the methyls and the 1-F would not have been expected from the molecular models.

Experimental

^{1}H NMR spectra were recorded with a JEOL GX-270 spectrometer and infrared spectra with a Hitachi IR-260-30 spectrometer. Freshly distilled benzene was used for the Friedel-Crafts reaction. Others were of commerical origin.

1,2,3,4-Tetrafluoro-9-(1,1-dimethyl-3-butenyl)triptycene (2a). To a solution of 9.92 g (49.1 mmol) of chloropentafluorobenzene in 100 mL of dry ether, cooled with Dry Ice-acetone, was added slowly 32.6 mL (49.1 mmol) of butyllithium in hexane under a nitrogen atmosphere and the mixture was stirred at that temperature for 6 h. To this mixture was added 2.55 g (9.81 mmol) of 9-(1,1-dimethyl-3-butenyl)anthracene (**1**)[2] in 10 mL of ether from a syringe. The whole was stirred for 2 h at −78 °C, for 2 h at 0 °C, and then for 60 h at 13 °C. The reaction was completed by heating under reflux for 2 h and the mixture was washed with dilute hydrochloric acid and then with water. The ether layer was dried over magnesium sulfate and the solvent was evaporated. Chromatography of the residue on silica gel (hexane eluent) afforded a mixture of *ap*-**2a** and *sc*-**2a**, which was contaminated with a 1,4-adduct of the benzyne to the anthracene. The ratio of *ap*-**2a**, *sc*-**2a**, and the 1,4-adduct was 7 : 3 : 1.

The mixture, which weighed 2.5 g at this stage, was dissolved in a small amount of 1-chloronaphthalene and heated under reflux for 50 h under a nitrogen atmosphere. Rough chromatography of the product on silica gel (hexane eluent) afforded a mixture which contained *ap*-**2a** and *sc*-**2a** in 1 : 2 ratio. The mixture was separated by chromatography on silica gel impregnated ca. 10% silver nitrate with the use of 5 : 1 hexane-dichloromethane as an eluent. The order of elution was *sc*-**2a**, *ap*-**2a**, and the 1,4-adduct.

***ap*-2a**, mp 163—164 °C, yield, 3.6%. It was recrystallized from hexane. Found: C, 76.54; H, 5.00%. Calcd for $C_{26}H_{20}F_4$: C, 76.46; H, 4.94%. ^{1}H NMR ($CDCl_3$) δ=2.00 (6H, d, J=8.9 Hz), 3.29 (2H, d, J=7.1 Hz), 5.20—5.36 (2H, m), 5.69 (1H, d. J=1.0 Hz), 6.18—6.37 (1H, m), 7.00—7.12 (4H, m), 7.38—7.48 (2H, m), 7.81—7.90 (2H, m).

***sc*-2a**, caramel, yield 6.7%. ^{1}H NMR ($CDCl_3$) δ=1.93 (3H, d, J=8.1 Hz), 2.05 (3H, s), 3.01 (1H, dd, J=14.5 and 7.2 Hz), 3.31 (1H, dd, J=14.5 and 6.8 Hz), 5.20—5.36 (2H, m), 5.69 (1H, d, J=1.0 Hz), 6.15—6.35 (1H, m), 6.99—7.12 (4H, m), 7.36—7.48 (2H, m), 7.79—7.95 (2H, m).

1,2,3,4-Tetrachloro-9-(1,1-dimethyl-3-butenyl)triptycene (2b). This compound was prepared similarly as described above for the tetrafluoro compound (**2a**) from **1** and hexachlorobenzene, except the followings. The lithiation of hexachlorobenzene was carried out at −30 °C and the generation of the benzyne by stirring for 5—6 h with gradual raise of temperature to −10 °C and then stirring overnight in an ice-bath, during which time the temperature was allowed to rise to room temperautre. A product which contained *ap*-**2b**, *sc*-**2b**, and a 1,4-adduct in 7 : 3 : 5 ratio was obtained in ca. 20% yield. The *ap*-olefin could be isolated by recrystallization of the mixture from hexane-dichloromethane. The separation of the *sc*-isomer from others was carried out by chromatography on SiO_2-$AgNO_3$, after isomerization by heating a 1-chloronaphthalene solution for 20 h, which gave a ca. 1 : 1 *ap*-**2b** and *sc*-**2b** mixture.

ap-**2b**, mp 230.5—231.0 °C. Found: C, 65.99: H, 4.10; Cl, 29.85%. Calcd for $C_{26}H_{20}Cl_4$: C, 65.85; H, 4.25; Cl, 29.90%. ^{1}H NMR ($CDCl_3$) δ=2.29 (6H, s), 3.24 (2H, d, J=7 Hz), 5.22—5.28 (2H, m), 6.07 (1H, s), 6.17—6.32 (1H, m), 7.03—7.11 (4H, m), 7.44—7.47 (2H, m), 7.92—7.95 (2H, m).

sc-**2b**, caramel. ^{1}H NMR ($CDCl_3$) δ=2.60 (3H, s), 2.18 (3H, s), 3.49 (1H, dd, J=15.2 and 6.2 Hz), 3.65 (1H, dd, J=15.2 and 8.1 Hz), 5.26—5.32 (2H, m), 6.09 (1H, s), 6.19—6.34 (1H, m), 7.03—7.11 (4H, m), 7.42—7.48 (2H, m), 7.93—7.98 (1H, m), 8.02—8.05 (1H, m).

***ap*-4-Methyl-4-(1,2,3,4-tetrafluoro-9-triptycyl)-1,2-pentanediol (3a).** To a solution of 251 mg (0.615 mmol) of the olefin (**2a**) in 50 mL of *t*-butyl alcohol, were added 3.76 g (33.8 mmol) of trimethylamine oxide dihydrate, 2 mL of pyridine, and 15 mL of water. To the solution under an argon atmosphere, was added ca. 20 mg of osmium tetraoxide in 1 mL of *t*-butyl alcohol, and the whole was heated for 24 h. The mixture was treated with 20 mL of 20% aqueous sodium hydrogensulfite and then most of *t*-butyl alcohol was evaporated. The residue was extracted with dichloromethane or ether and the extract was washed with saturated aqueous sodium chloride and dilute hydrochloric acid. Evaporation of the solvent afforded the desired product as caramel, which was used directly for the next reaction. The following ^{1}H NMR data ($CDCl_3$, δ) were recorded: 2.03 (3H, d, J=8.1 Hz), 2.13 (3H, d, J=8.8 Hz), 2.66 (1H, dd, J=15.1 and 2.7 Hz), 2.89 (1H, dd, J=15.1 and 7.5 Hz), 3.59 (1H, t, J=8.0 Hz), 4.27 (1H, dd, J=8.0 and 6.0 Hz), 4.63—4.79 (1H, m), 5.69 (1H, br s), 7.02—7.11 (4H, m), 7.39—7.47 (2H, m), 7.69—7.76 (1H, m), 8.03—8.09 (1H, m).

The *sc*-diol (*sc*-**3a**) was prepared similarly and used for the next reaction. The crude product contained two diastereomers due to the presence of a new chiral center in addition to the chirality of being the *sc* form. Due to the complexity of the ^{1}H NMR spectra, only the signals due to methyl protons were recorded ($CDCl_3$, δ): 2.02 (3H, d, J=7.0 Hz), 2.11 (3H, d, J=7.7 Hz), 2.12 (3H, s), 2.24 (3H, s). The formation ratio of the two isomers was 4 : 3.

***ap*-4-Methyl-4-(1,2,3,4-tetrachloro-9-triptycyl)-1,2-pentanediol (3b).** This compound was prepared similarly as above. ^{1}H NMR ($CDCl_3$) δ=2.34 (3H, s), 2.48 (3H, s), 2.63—2.73 (1H, m), 3.45—3.54 (1H, m), 3.68—3.77 (1H, m), 4.33—4.47 (1H, m), 6.07 (1H, s), 7.03—7.10 (4H, m), 7.43—7.46 (2H, m), 7.75—7.79 (1H, m), 8.06—8.10 (1H, m). In addition, a very broad peak at δ 2.1—2.6 was observed.

***sc*-Diol (*sc*-3b).** ^{1}H NMR ($CDCl_3$, δ): *sc*-**3b**(I), 2.20 (3H, s) and 2.25 (3H, s); *sc*-**3b**(II), 2.08 (3H, s) and 2.38 (3H, s). The ratio of *sc*-**3b**(I) and *sc*-**3b**(II) was 4 : 3.

***ap*-3-Methyl-3-(1,2,3,4-tetrafluoro-9-triptycyl)butanal (4a).** The product obtained by the dihydroxylation described above was dissolved in 10 mL of tetrahydrofuran and stirred with 0.46 g (2.0 mmol) of periodic acid dihydrate in 3 mL of water for 3 h at room temperature. The mixture was diluted with 100 mL of water and extracted with dichloromethane. Evaporation of the solvent afforded a crude product which was used directly for the next reaction. The following ^{1}H NMR data ($CDCl_3$, δ) were recorded: 2.22 (6H, d, J=9.2 Hz), 3.66 (2H, d, J=2.2 Hz), 5.70 (1H, d, J=1.0 Hz), 7.04—7.13 (4H, m), 7.42—7.49 (2H, m), 7.75—7.83 (2H, m), 10.23 (1H, t, J=2.6 Hz).

sc-**4a**. ^{1}H NMR ($CDCl_3$) δ=2.19 (3H, d, J=7.9 Hz), 2.25 (3H, d, J=0.7 Hz), 3.47 (1H, br dd, J=16.5 Hz), 3.63 (1H, br dt, J=16.5 and 2.9 Hz), 5.70 (1H, d, J=1.3 Hz), 7.02—7.11 (4H, m), 7.38—7.48 (2H, m), 7.73—7.84 (2H, m), 10.22 (1H, t, J=2.1 Hz).

***ap*-3-Methyl-3-(1,2,3,4-tetrachloro-9-triptycyl)butanal (4b).** This compound was prepared similar as above. ^{1}H NMR ($CDCl_3$) δ=2.49 (6H, s), 3.64 (2H, d, J=2.0 Hz), 6.08 (1H, s), 7.04—7.11 (4H, m), 7.45—7.49 (2H, m), 7.84—7.88 (2H, m), 10.16 (1H, t, J=2.0 Hz).

sc-**4b**. ^{1}H NMR ($CDCl_3$) δ=2.28 (3H, s), 2.42 (3H, s) 3.72 (1H, dd, J=17.0 and 1.8 Hz), 4.16 (1H, dd, J=17.0 and 2.9 Hz), 6.10 (1H, s), 7.07—7.10 (4H, m), 7.44—7.49 (2H, m), 7.83—7.92 (2H, m), 10.20 (1H, dd, J=2.9 and 1.8 Hz).

***ap*-3-Methyl-3-(1,2,3,4-tetrafluoro-9-triptycyl)butanoic Acid (5a).** The aldehyde (*ap*-**4a**) obtained above was dissolved in 22 mL of acetone and stirred for 2 h with 0.29 g (1.8 mmol) of potassium permanganate in 5 mL of water and a small amount of sodium hydrogencarbonate at room temperature. The mixture was acidified with dilute sulfuric acid and the excess of the permanganate was destroyed with 20% aqueous sodium hydrogensulfite. The mixture was extracted with dichloromethane and the solvent was evaporated. The residue was purified by preparative TLC on silica gel (11 : 1 dichloromethane-ether eluent). An analytical sample was obtained by recrystallization of the product from tetrahydrofuran-pentane, mp 282—284 °C (decomp). The yield was 68% based on the olefin (*ap*-**2a**). Found: C, 70.20; H, 4.07%. Calcd for $C_{25}H_{18}F_4O_2$: C, 70.42; H, 4.25%. ^{1}H NMR ($CDCl_3$) δ=2.21 (6H, d, J=8.4 Hz), 3.62 (2H, s), 5.71 (1H, br s), 7.05—7.17 (4H, m), 7.41—7.50 (2H, m), 7.80-7.95 (2H, m), 10.4—11.1 (1H, br s).

sc-**5a**, mp 285—287 °C (decomp), was prepared similarly from the corresponding aldehyde and purified by recrystallization from dichloromethane-hexane. The yield was 67% based on the olefin (*sc*-**2a**). Found: C, 70.14; H, 4.37%. Calcd for $C_{25}H_{18}F_4O_2$: C, 70.42; H, 4.25%. ^{1}H NMR ($CDCl_3$) δ=2.20 (3H, d, J=8.1 Hz), 2.25 (3H, s), 3.46 (1H, dd, J=15.3 and 2.0 Hz), 3.70 (1H, d, J=15.3 Hz), 5.71 (1H, br s), 7.02—7.17 (4H, m), 7.37—7.50 (2H, m), 7.77—7.88 (1H, m), 7.88—7.98 (1H, m), 10.8—11.8 (1H, br s).

***ap*-3-Methyl-3-(1,2,3,4-tetrachloro-9-triptycyl)butanoic Acid (5b).** This compound was prepared similarly as above, the yield being 70% based on the olefin (*ap*-**2b**), and purified by recrystallization from dichloromethane-hexane. The melting point was 254—256 °C (decomp). This compound failed to give correct analytical data but the corresponding methyl ester did. ^{1}H NMR ($CDCl_3$) δ=3.49 (6H, s), 3.60 (2H, s), 6.09 (1H, s), 7.09—7.13 (4H, m), 7.46—7.50 (2H, m), 7.92—7.97 (2H, m).

The methyl ester, mp 209—211 °C. Found: C, 61.75; H, 4.11; Cl, 28.08%. Calcd for $C_{26}H_{20}Cl_4O_2$: C, 61.69; H, 3.98; Cl, 28.01%. ^{1}H NMR ($CDCl_3$) δ=2.44 (6H, s), 3.51 (2H, s), 3.82 (3H, s), 6.08 (1H, s), 7.08—7.13 (4H, m), 7.43—7.50 (2H, m), 7.91—7.95 (1H, m), 8.01—8.05 (1H, m).

***sc*-5b**, mp 286—287 °C (decomp), was similarly prepared in 65% yield based on the olefin (*sc*-**2b**) and purified by recrystallization from dichloromethane-hexane. This compound failed to give correct analytical data but the methyl ester did. ^{1}H NMR ($CDCl_3$) δ=2.24 (3H, s), 2.46 (3H, s), 3.84 and 4.22 (2H, ABq, J=15 Hz), 6.10 (1H, s), 7.07—7.13 (4H, m), 7.43—7.50 (2H, m), 7.91—7.95 (1H, m), 8.01—8.05 (1H, m).

The methyl ester, mp 206—208 °C. Found: C, 61.49; H, 4.28; Cl, 27.98%. Calcd for $C_{26}H_{20}Cl_4O_2$: C, 61.69; H, 3.98; Cl, 28.01%. ^{1}H NMR ($CDCl_3$) δ=2.15 (3H, s), 2.40 (3H, s), 3.84 (3H, s), 3.76 and 4.14 (2H, ABq, J=15.2 Hz), 6.08 (1H, s), 7.06—7.11 (4H, m), 7.42—7.48 (2H, m), 7.90—7.93 (1H, m), 8.03—8.06 (1H, m).

Intramolecular Friedel-Crafts Reaction of the Acid Chloride (6) Derived from 5. The typical reaction is described with the use of *ap*-**5a**. To a solution of 52 mg (0.12 mmol) of *ap*-**5a** in 10 mL of benzene was added 0.1 mL (1.2 mmol) of oxalyl dichloride under a nitrogen atmosphere and the whole was stirred for 4 h at room temperature. The excess of oxalyl dichloride and the solvent were removed in vacuo. The residue showed the following signals in ^{1}H NMR ($CDCl_3$, δ): 2.20 (6H, d, J=9.2 Hz), 4.26 (2H, s), 5.71 (1H, br s), 7.04—7.16 (4H, m), 7.41—7.51 (2H, m). 7.72—7.81 (2H, m). The residue was taken up in 10 mL of benzene and was mixed with 0.2 mL (1.8 mmol) of titanium(IV) chloride. The mixture was stirred for 3 h at room temperature and then treated with water. The organic layer was separated and the aqueous layer was extracted with dichloromethane. The combined organic layers were dried over magnesium sulfate and the solvent was evaporated. The residue was purified by preparative TLC on silica gel (dichloromethane eluent) to give 78% *ap*-8,9,10,11-tetrafluoro-1,1-dimethyl-1,2-dihydro-7*H*-7,11b-*o*-benzeno-3*H*-benz[*dl*]anthracen-3-one (**7a**). The pure sample, mp 176—177 °C, was obtained by recrystallization from hexane. Found: C, 73.62; H, 3.99%. Calcd for $C_{25}H_{16}F_4O$: C, 73.53; H, 3.95%. ^{1}H NMR ($CDCl_3$) δ=1.63 (3H, dd, J=2.6 and 1.4 Hz), 2.03 (3H, d, J=8.1 Hz), 2.78 (1H, d, J=15 Hz), 3.36 (1H, dd, J=15 and 1.4 Hz), 5.76 (1H, d, J=1.5 Hz), 6.95—7.11 (2H, m), 7.15—7.29 (1H, m), 7.33—7.41 (1H, m), 7.58—7.72 (1H, m), 7.77—7.85 (1H, m). IR (Nujol mull): 1695 cm^{-1}. The same treatment for 2 h gave 65% *ap*-**7a** and 10% recovered *ap*-**5a**.

The following ^{1}H NMR data ($CDCl_3$, δ) of *sc*-**6a** were recorded: 2.17 (3H, d, J=8.6 Hz), 2.25 (3H, s), 4.06 (1H, dd, J=18.1 and 4.3 Hz), 4.34 (1H, d, J=18.1 Hz), 5.71 (1H, br d, J=1.3 Hz), 7.01—7.16 (4H, m), 7.38—7.52 (2H, m), 7.70—7.81 (2H, m).

***sc*-7a**, mp 196—197 °C was similarly prepared from the acid chloride (*sc*-**6a**) and purified by recrystallization from hexane. However, the reaction of the acid chloride was slow in this case: after 4 h stirring at room temperature, the ketone was obtained in 58% yield, whereas 31% acid *sc*-**5a** was recovered. When the reaction was continued for 6 h, the ketone was obtained in 87% yield and no acid was recovered. Found: C, 73.78; H, 4.24%. Calcd for $C_{25}H_{16}F_4O$: C, 73.53; H, 3.95%. ^{1}H NMR ($CDCl_3$) δ=1.68 (3H, d, J=1.3 Hz), 2.06 (3H, d, J=7.9 Hz), 2.75 (1H, d, J=15.8 Hz), 3.55 (1H, br d, J=15.8 Hz), 5.81 (1H, d, J=1.3 Hz), 7.13—7.25 (3H, m), 7.50—7.57 (1H, m), 7.58—7.64 (1H, m), 7.67—7.74 (1H, m), 7.86—7.93 (1H, m). IR (Nujol mull): 1690 cm^{-1}.

ap-8,9,10,11-Tetrachloro-1,1-dimethyl-1,2-dihydro-7*H*-7,11b-*o*-benzeno-3*H*-benz[*dl*]anthracen-3-one (**7b**), mp 257—259 °C, when recrystallized from dichloromethane-hexane, was similarly obtained from the corresponding tetrachloro acid (*ap*-**5b**) in 70% yield. Since this compound failed to give the correct analytical data, high resolution mass spectrum was recorded. Found: m/z 471.9970, 473.9988, 475.9924, and 477.9817. Calcd for $C_{25}H_{16}{}^{35}Cl_4O$, $C_{25}H_{16}{}^{35}Cl_3{}^{37}ClO$, $C_{25}H_{16}{}^{35}Cl_2{}^{37}Cl_2O$, and $C_{25}H_{16}{}^{35}Cl^{37}Cl_3O$: 471.9955, 473.9926, 475.9897, and 477.9865. The intensity ratios of the signals agreed with those expected from the natural abundances of ^{35}Cl and ^{37}Cl. ^{1}H NMR ($CDCl_3$) δ=1.83 (3H, d, J=1.5 Hz), 2.34 (3H, s), 2.78 (1H, d, J=15 Hz), 3.31 (1H, dd, J=15 and 1.5 Hz), 6.09 (1H, s), 7.00—7.12 (2H, m), 7.18—7.23 (1H, m), 7.38—7.41 (1H, m), 7.63—7.66 (1H, m), 7.67—7.71 (1H, m), 7.87—7.90 (1H, m). IR (KBr disc): 1690 cm^{-1}.

***sc*-7b**, mp 258—260 °C, was similarly prepared from the corresponding acid (*sc*-**5b**) in 70% yield. Recrystallization of the compound from dichloromethane-hexane afforded the analytical sample. Found: C, 63.36; H, 3.51; Cl, 29.61%. Calcd for $C_{25}H_{16}Cl_4O$: C, 63.32; H, 3.40; Cl, 29.90%. ^{1}H NMR ($CDCl_3$) δ=1.64 (3H, d, J=1.5 Hz), 2.31 (3H, s), 2.78 (1H, d, J=16 Hz), 4.20 (1H, dd. J=16 and 1.5 Hz), 6.14 (1H, s), 7.15—7.23 (3H, m), 7.53—7.56 (1H, m), 7.63—7.66 (1H, m), 7.74—7.77 (1H, m), 7.90—7.93 (1H, m). IR (KBr disc): 1690 cm^{-1}.

Kinetics of Isomerization of Ketones (7). The *ap*-ketone was dissolved in toluene-d_8 to make up a ca. 20 mmol L^{-1} solution. The sample solution was placed in a thermostatted bath, except for one case where a boiling benzene bath was used. The rates of isomerization were followed by the change in intensities of ^{1}H NMR signals due to the methyl protons or the 7-proton. The data were treated by assuming the reversible first order reactions. The rate constants thus obtained were put into the Eyring equation to produce kinetic parameters.

Comparison of the Kinetic and Thermodynamic Parameters. The parameters shown in Table 3 were obtained by extrapolation of the thermodynamic and kinetic parameters obtained in the temperature ranges other than the given temperature. The thermodynamic parameters may include large errors, especially for those which give large K values.

Molecular Mechanics Calculations. Molecular mechanics calculations were performed using the MMP2(82) program[11] at the Computer Center of the University of Tokyo, assuming a "nonplanar" π-system for each compound. As the force field does not contain parameters for halogen atoms attached to an sp^2 carbon atom, several necessary parameters were added. The equilibrium bond length (Å) and stretching force constant (md Å^{-1}) for C(sp^2)-X were assumed to be 1.715 and 2.66, respectively, when X=Cl, and 1.330 and 5.10, respectively, when X=F. The equilibrium bond angle (deg) and bending force constant (md Å rad^{-2}) were 120.0 and 0.40, when X=Cl, for C(sp^2)-C(sp^2)-X, and 120.0 and 0.65, respectively, for X=F. Torsional constants, V_1 and V_2, of −0.93, and 9.0 kcal mol^{-1}, respectively, for X-C(sp^2)-R, where R is any atom, were used. The out-of-plane bending parameter of 0.05 md Å rad^{-1} was used for both the cases where X=Cl and F.

Synthesis of Fluorescent Amino Acids and Peptides with 2-Aminopyridine at the Carboxyl or Amino Terminus

Tomohiro MEGA,* Yasuki HAMAZUME, and Tokuji IKENAKA
Department of Chemistry, Osaka University College of Science, Toyonaka, Osaka 560
(Received April 16, 1988)

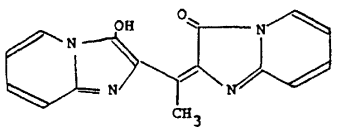
N-(2-Pyridyl) derivatives of glycine (**1**), DL-alanine (**2**), DL-valine (**3**), and DL-norleucine (**4**) were synthesized as fluorescence labeled amino acids. These amino acids were used for the synthesis of N-terminal fluorescence-labeled peptides. *N*-(2-Pyridyl)-1,2-ethanediamine (**7**) was synthesized and used for the C-terminal labeling of amino acids and peptides. With these amino acid derivatives, some peptides labeled with 2-aminopyridine were synthesized and their spectroscopic characteristics were examined.

Fluorescent labeling of the reducing ends of sugars with 2-aminopyridine has become a useful method in the structure analyses of the sugar moiety of glycoconjugates.[1] This is because of the stability of the 2-pyridylamino group against acid, alkaline, and other reagents, and also the facility both for the detection and purification of 2-pyridylaminosugars during electrophoresis or in several chromatographies including HPLC, owing to its positive charge in acidic conditions or the hydrophobic nature in alkaline conditions. Fluorescence-labeled sugars has been used as substrates for some carbohydrases[2] and glycosyltransferases.[3] This labeling can be employed in the preparation of fluorescent amino acids and peptides that can be used as substrates for enzymes participating in the post-translational modification of the proteins or peptides. Labelling of the N-terminus, C-terminus, or both termini of a peptide may protect the molecule against exopeptidase digestion and serve as the fluorescence marker for the compound. No peptide with 2-aminopyridine has been synthesized. This prompts us to synthesize the *N*-2-pyridylamino peptides. *N*-(2-Pyridyl)glycine (**1**), the sole amino acid reported as a 2-pyridylamino derivative, seemed to be a suitable compound for use in the synthesis of N-terminal and C-terminal fluorescence-labeled peptides, but it was found not to be suitable for the labeling of the C-terminus of peptides because of the low reactivity of its imino group to acylation and because acylation causes the loss of its fluorescence. We then selected *N*-(2-pyridyl)-1,2-ethane diamine (**7**) as a reagent for C-terminal fluorescence-labeling of amino acids and peptides, and found **1** is synthesized by the reduction of *N*-(2-pyridylamino)acetaldehyde oxime with $LiAlH_4$. Here, we develop a new easy route for the preparation of **7**, synthesize some fluorescent peptides with **7** at the C-terminal together with peptides with **1** or **2** at their N-terminal, and examine their fluorescent and UV spectra at different pH's.

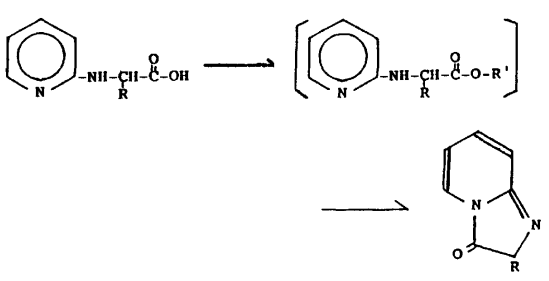
Results and Discussion

Four methods have been reported for the synthesis of **1**.[4] We synthesized **1** from formaldehyde via its nitrile by the method of Ohta and Masaki.[4b] This method could be applied to the synthesis of other *N*-(2-pyridyl) derivatives of DL-alanine (**2**), DL-valine (**3**), and DL-norleucine (**4**) using acetaldehyde, isobutyraldehyde, and valeraldehyde as the starting material, respectively. These four *N*-(2-pyridyl) α-amino acids can be used similarly for the syntheses of N-terminal fluorescence-labeled peptides. Here, the synthesis of some peptides starting from **1** and **2** and the characteristics of the peptides were examined.

Blocking the imino group of **1** or **2** by a benzyloxycarbonyl or *t*-butoxycarbonyl group was unsuccessful. *N*-Acetylation of **1** by acetic anhydride in pyridine gave a green by-product, which was not identified, but seemed to be mesomethyloxonol, because **1** is reported to give a green dye with the structure shown below when treated with hot acetic anhydride.[5]



Accordingly, the coupling of **1** to amino acids or peptides was done without blocking the imino group in chloroform with dicyclohexylcarbodiimide (DCC) or in water with water soluble carbodiimide (WSC). When peptide synthesis was carried out in chloroform or methylene dichloride, powdered **1** was used because of the low solubility of **1** in the solvents. The reaction solution of **1** became greenish in a few minutes, and the color increased to dark green or dark purple depending upon the pH of the solution. The yield of the desired peptide was about 50—60% on several conditions and did not exceed 70%. The synthesis of active esters of **1** was unsuccessful, because the active ester may be unstable and convert to 1,3a-diazaindan-3-one.[5]



The coupling reaction with **2** proceeded like that with **1**, but the reaction solution turned yellow, because of the formation of unknown by-products.

N-(2-Pyridyl)-1,2-ethanediamine (**7**) has been synthesized from *N*-(2-pyridylamino)acetaldehyde oxime by reduction with $LiAlH_4$.[4a] We found that **7** could be prepared by heating a mixture of 2-chloropyridine and ethylenediamine in a good yield.

Coupling of **7** to carboxyl components proceeded with a good yield in the presence of DCC or WSC without formation of the colored by-products. The 2-pyridylamino derivatives were usually soluble in water at acidic pH and in organic solvents at alkaline pH. These characteristics were sometimes useful and sometimes disadvantageous in the purification of the product. As a whole, the synthesis of 2-pyridylamino peptides was more troublesome than the normal peptide synthesis.

Since the spectroscopic characteristics of *N*-2-pyridyl amino acids or peptides have not been reported, the effect of pH on the UV and fluorescence spectra of these compounds was examined first. Figures 2-A and 2-B present the emission and excitation spectra of **1** at different pH's. The figures show that the fluorescence intensity of **1** is influenced strongly by pH, but the maximum wavelengths for excitation and emission are not influenced. Figure 2-C shows the emission spectra of the four compounds **1**, **2**, **5**, and **7** under the same conditions. The fluorescence intensity decreased in the order of **5**>**7**>**1**>**2**. Compound **2** seems not to be very useful for the synthesis of fluorescent peptides because of its low fluorescence intensity. But the peptide produced from **2** had the normal fluorescence intensity (as shown in Fig. 3-B).

Figure 3 shows the pH dependence of the fluorescence intensities of nine compounds. The fluorescence intensities of these compounds were lowest at around pH 5, and high at around pH 10—11, becoming very low above pH 12. These characteristics were common to all of the 2-pyridylamino derivatives examined. The fluorescence intensities of the *N*-2-pyridylamino acids **2** (Fig. 3-B), **3** (Fig. 3-C), and **4** (data not shown) were weaker than those of the other 2-pyridylamino compounds, but gradually increased when **2** and **3**

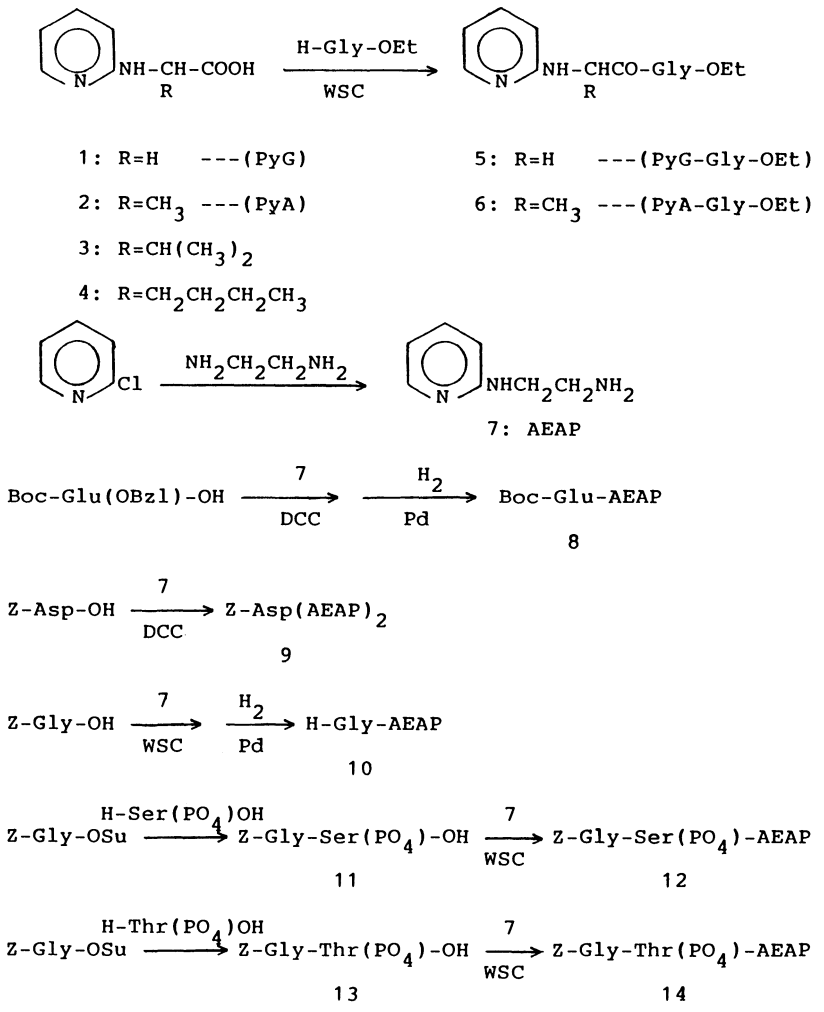


Fig. 1. Structures and syntheses of several fluorescent amino acids and peptides labeled with 2-aminopyridine.

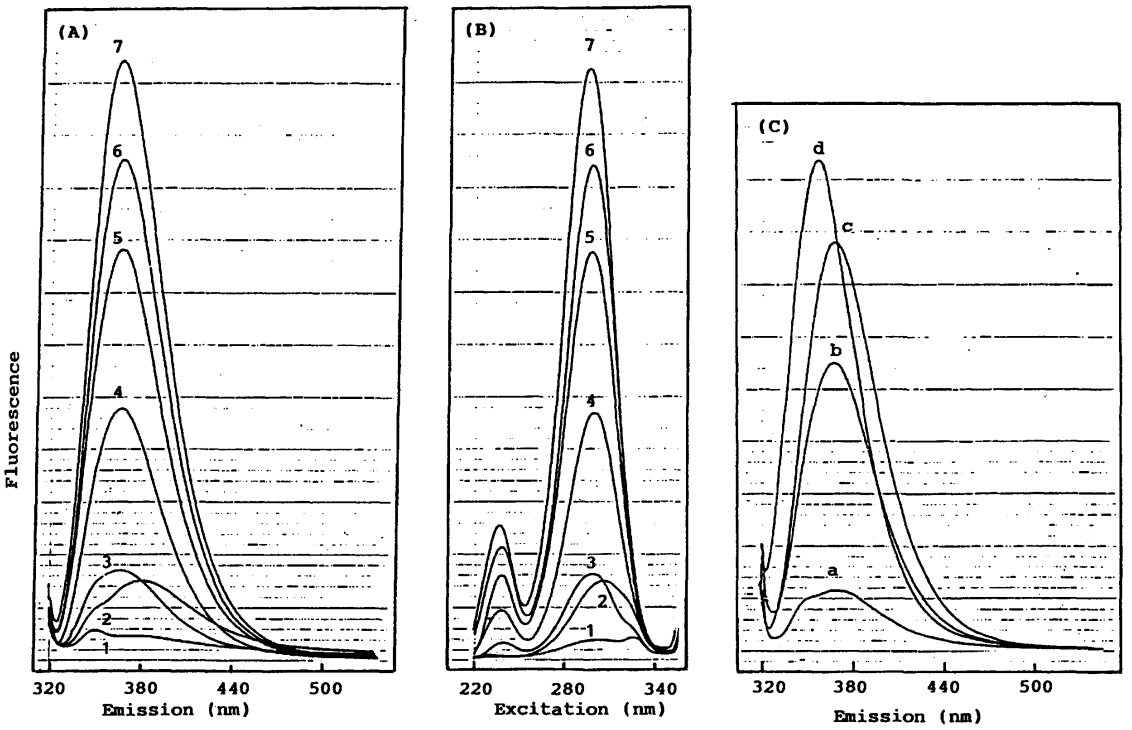

Fig. 2. (A) Emission spectra of **1** in different buffers.
Fluorescence was measured at the excitation wavelength of 304 nm and at the concentration of 2.4 μM. Solvents used were: 1, pH 5 (acetate); 2, 0.1 M HCl; 3, pH 6 (acetate); 4, 0.1 M NaOH; 5, pH 7 (acetate); 6, pH 8 (borate); 7, pH 10 (borate).
(B) Excitation spectra of **1** at the emission wavelength of 375 nm in different solvents. Solvents used were the same as those in A.
(C) Emission spectra of some 2-pyridylamino derivatives measured in borate buffer, pH 10, at the excitaton wavelength of 304 nm and at the concentration of 1.2 μM. Compounds were as follows: a, *N*-(2-pyridyl)-DL-alanine; b, *N*-(2-pyridyl)glycine; c, *N*-(2-pyridyl)-1,2-ethanediamine, and d, PyG-Gly-OEt.

were kept acidic.

The fluorescent intensities of N-terminal-labeled peptides (**5** and **6**) were higher than those of the component amino acids **1** or **2** (Fig. 3-A or 3-B). Fluorescence intensities of the C-terminal-labeled amino acids **8** (Fig. 3-E) and **10** (Fig. 3-D) were higher than those of N-terminal-labeled derivatives.

Figure 4 shows the absorption spectra of **1** in 0.1 M HCl (1 M=1 mol dm^{-3}), 0.1 M NaOH, and acetate buffer, pH 5. Compound **1** had two maxima around 240 and 306 nm. The absorbance at 306 nm in acidic pH was higher than in alkaline pH. The absorption maxima and molar extinction coefficients of compounds **2** and **3** in either 0.1 M HCl or 0.1 M NaOH were almost the same as those of **1** (Table 1). Compounds **6**, **7**, and **8** also had similar UV absorption spectra.

These spectroscopic characteristics were convenient for the detection of the 2-pyridylamino derivatives by TLC and HPLC.

Compound PyG-Gly-OEt (**5**), DL-PyA-Gly-OEt (**6**), Boc-Glu-AEAP (**8**), and Z-Asp(AEAP)$_2$ (**9**) were synthesized to test the coupling reaction and to use as starting materials for the synthesis of many fluorescent peptides. We also synthesized fluorescent phosphopeptides Z-Gly-Ser(PO_4)-AEAP and Z-Gly-Thr(PO_4)-AEAP to study the β-elimination reaction of phosphoserine and phosphothreonine peptides and as substrates for phosphatases. In the coupling of Z-Gly-Ser(PO_4)-OH (**11**) and **7** with WSC, one main product (peak c) appeared (Fig. 5), it was found to be **12**, Z-Gly-Ser(PO_4)-AEAP. Peaks a and b were **7** and **11**, respectively. This shows that *N*-blocked phosphoserine or phosphothreonine could be used as an acid component without blocking the phosphate. The reaction was completed in 2 h and the product (peak c) was isolated using HPLC.

In a study of hen riboflavin-binding protein (RBP), we have found that RBP in hen blood, the precursor of RBP in egg yolk, was 11 or 13 amino acid residues longer than the protein in egg yolk.[6] It is likely that the C-terminal part is removed by protease(s) in the oocyte membrane during the incorporation of RBP from the blood to the oocyte (egg yolk). To search for a specific protease that modifies the C-terminal of the protein, a fluorescent peptide (**15**), PyG-Gln-Lys-Lys-Leu-Leu-Lys-Phe-Glu-βAla having a similar amino acid sequence to that of the C-terminal part was

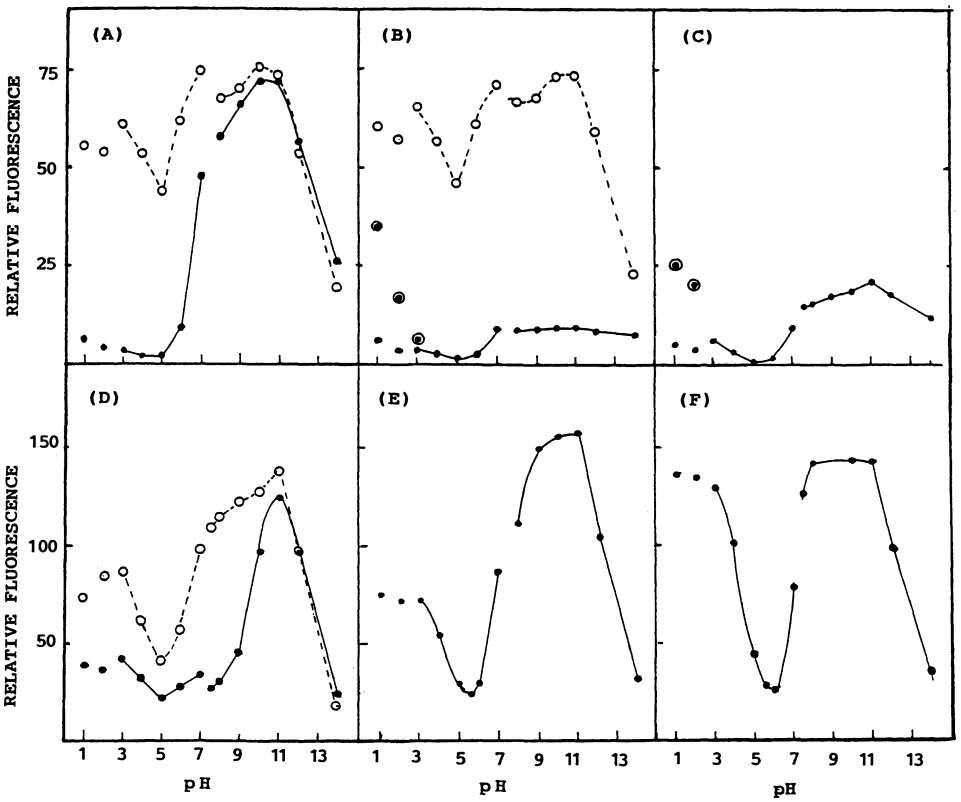

Fig. 3. Relationship of fluorescence and pH for some 2-pyridylamino derivatives at the concentration of 1.2 μM.
(A), **1** (●) and **5** (○); (B), **2** (●) and **6** (○); (C), **4**; (D),**7** (●) and **10** (○); (E), **8** and (F), **9**. The marks (○) in (B) and (C) were the values after 24 h. The excitation wavelength was 304 nm and the emission wavelength was 375 nm. Solvents were: pH 1, 0.1 M HCl; pH 2, 0.02% TFA; pH 3—7, 0.1 M acetate buffer; pH 7.5—12, 0.1 M borate buffer; pH 13, 0.1 M NaOH.

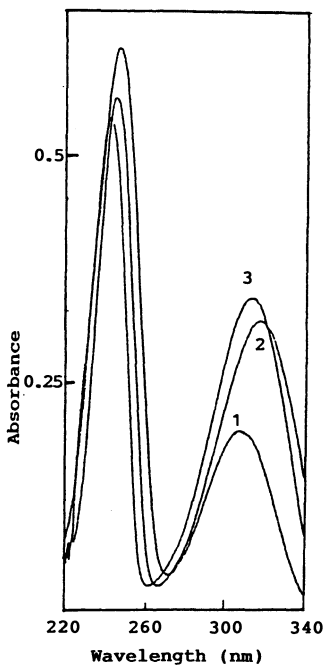

Fig. 4. Absorption spectra of **1** in 0.1 M NaOH (1), 0.1 M acetate buffer (pH 5) (2), and 0.1 M HCl (3) at the concentration of 50 μM.

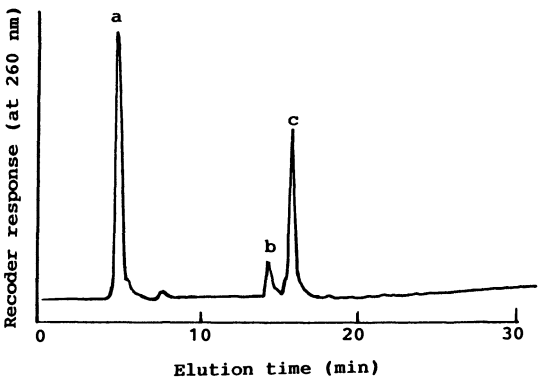

Fig. 5. HPLC of the reaction mixture of **11** and **7** with WSC. Peaks a, b, and c were **7**, **11**, and **12**. Elution was with an exponential gradient of CH_3CN from 0% to 50% in 0.05% TFA, and the starting volume was 50 ml. Column, ODS-120 T (7×250 mm); flow rate, 3 ml min^{-1}.

synthesized. The synthesis of **15** was performed by the solid phase peptide synthesis. In the coupling of **1** with peptides on the resin, the reaction was performed in the CH_2Cl_2 with the suspension of **1** because of its low solubility in the solvent. The reaction solution

	NaOH	301	3600	239	12200

a) The value is at its maximum wavelength. b) Sodium acetate.

colored dark purple and the resin was stained with the same color. In spite of the strong staining of the resin and using the suspension of **1**, the yield of the coupling was fairly good.

Since fluorescence labeled peptides with 2-aminopyridine can be synthesized by the usual method or with reagents as described above, the labeled peptides are expected to work as useful compounds for the analyses of some enzymes or some reactions owing to its unique spectroscopic characteristics.

Experimental

General. Melting points were measured on a Yanagimoto melting point apparatus and were uncorrected. ^1H NMR spectra were recorded on a Varian XL-100 (100 MHz) or a JEOL FX-90 (90 MHz) spectrometer with Me_4Si as an internal standard, unless otherwise stated.

TLC was done on silica-gel plates (Merck Kieselgel 60 F254). The solvent system was *n*-BuOH-AcOH-H_2O (4 : 1 : 1) unless otherwise stated. HPLC conditions were as follows: column, TSK ODS-120T (7×250 mm); flow rate, 3 ml min^{-1}; detection of pyridylamino compounds at 310 nm or of benzyloxycarbonyl compounds at 260 nm; elution systems; (1), exponential or linear gradient of 0.05% TFA and 50% CH_3CN-0.05% TFA; (2) several isocratic conditions. Fluorescence was measured by a Hitachi spectrophotometer 650-10S.

N-(2-Pyridyl)glycine (**1**) and 2-(2-pyridylamino)propionitrile were synthesized by the method of Ohta and Masaki.[4b]

***N*-(2-Pyridyl)-DL-alanine (2):** A solution of 2-(2-pyridylamino) propionitrile (7 g) in 6 M HCl (100 ml) was refluxed for 5 h and concentrated. Crystals (NH_4Cl) that appeared were filtered off and washed with ethanol. The washings and filtrate were combined and concentrated. The crystals that appeared were filtered off. The filtrate was applied to a Dowex 50 H^+ column (2×12 cm). Compound **2** was eluted with 0.2 M ammonium acetate as a yellow fraction. The solution was concentrated and **2** was crystallized with ethanol; yield 4.7 g (59%); mp 153 °C; pale yellow needles; ^1H NMR (D_2O) δ=1.48 (3H, d, CH_3), 4.0—4.2 (1H, q, CH), 6.8—7.0 (2H, m, pyridine), 7.7—8.0 (2H, m, pyridine). Found: C, 57.82; H, 6.07; N, 16.86%. Calcd for $C_8H_{10}O_2N_2$: C, 57.73; H, 6.10; N, 16.65%.

***N*-(2-Pyridyl)-DL-alanine (2):** A solution of 2-(2-pyridylamino) propionitrile (7 g) in 6 M HCl (100 ml) was refluxed for 5 h and concentrated. Crystals (NH_4Cl) that appeared were filtered off and washed with ethanol. The washings and filtrate were combined and concentrated. The crystals that appeared were filtered off. The filtrate was applied to a Dowex 50 H^+ column (2×12 cm). Compound **2** was eluted with 0.2 M ammonium acetate as a yellow fraction. The solution was concentrated and **2** was crystallized with ethanol; yield 4.7 g (59%); mp 153 °C; pale yellow needles; ^1H NMR (D_2O) δ=1.48 (3H, d, CH_3), 4.0—4.2 (1H, q, CH), 6.8—7.0 (2H, m, pyridine), 7.7—8.0 (2H, m, pyridine). Found: C, 57.82; H, 6.07; N, 16.86%. Calcd for $C_8H_{10}O_2N_2$: C, 57.73; H, 6.10; N, 16.65%.

***N*-(2-Pyridyl)-DL-alaline Hydrochloride:** Mp 160—161 °C. Found: C, 47.42; H, 5.47; N, 13.83; Cl, 17.50%. Calcd for $C_8H_{10}O_2N_2HCl$: C, 47.27; H, 5.46; N, 13.69; Cl, 17.48%.

***N*-(2-Pyridyl)-DL-valine Hydrochloride (3):** Isobutyraldehyde (7.2 g) was mixed with an aqueous solution of $NaHSO_3$ (10 g in 10 ml H_2O) and warmed (60—70 °C) for 0.5 h. 2-Aminopyridine (9.4 g) was added and warmed 0.5 h more. Finally NaCN (7.6 g in 16 ml of water) was added and the mixture was heated under continuous stirring in a boiling water bath for 6 h. The dark brown product of the nitrile (α-(2-pyridylamino)isovaleronitrile) was extracted with 40 ml of chloroform five times, and the organic layer dried over $MgSO_4$ and concentrated. The nitrile was directly hydrolyzed in 6 M HCl (400 ml) under reflux for 6 h. The hydrolysate was concentrated to remove NH_4Cl as crystals and filtered. The filtrate was neutralized with 4 M NaOH, washed with chloroform, and evaporated. The residue was dissolved in water, acidified with 6 M HCl, and concentrated. The crystals that appeared (NaCl) were removed by filtration and washed with acetone. The filtrate and washings were combined and concentrated, giving the desired product in crystalline form. The product was recrystallized from water: Yield, 7.2 g (62%); mp 151—152 °C; ^1H NMR (D_2O) δ=1.7 (6H, d, 2×CH_3), 2.28—2.62 (1H, m, CH), 4.39 (1H, d, CH), 6.9—7.2 (2H, m, pyridine), 7.8—8.1 (2H, m, pyridine). Found: C, 51.94; H, 6.53; N, 12.14%. Calcd for $C_{10}H_{14}N_2O_2HCl$: C, 52.06; H, 6.55; N, 12.14%.

***N*-(2-Pyridyl)-DL-norleucine Hydrochloride (4):** Compound **4** was synthesized similarly as **3** from valeraldehyde. Mp 132—134 °C; ^1H NMR (D_2O) δ=0.9 (3H, t, CH_3), 4.4—5.6 (1H, m, CH), 6.9—7.2 (2H, m, pyridine), 7.8—8.2 (2H, m, pyridine). Found: C, 53.91; H, 6.96; N, 11.42%. Calcd for $C_{11}H_{16}N_2O_2HCl$: C, 53.99; H, 7.00; N, 11.45%.

PyG-Gly-OEt (5): To a solution of **1** (1.9 g), glycine ethyl ester hydrochloride (2.8 g), triethylamine (2 ml) in $CHCl_3$ (80 ml) and DMF (20 ml), and WSC (2.1 g) were added. The mixture was stirred for 2 days at room temperature. The dark green reaction mixture was diluted with 0.1 M HCl, washed with $CHCl_3$ twice and neutralized with triethylamine to pH 7.5. The product was extracted 4 time with $CHCl_3$. The extracts were combined, dried over $MgSO_4$, and concentrated, giving crystalline **5**. The crystals were washed with ethyl acetate. The yield was 1.4 g (61%). Recrystallization was done with ethanol: mp 121.5—122 °C.

^{1}H NMR ($CDCl_3$) δ=1.2—1.34 (3H, t, CH_3), 5.47 (1H, br, NH), 6.4—6.8 (2H, m, pyridine), 7.4—7.6 (1H, m, pyridine), 8.08—8.16 (1H, m, pyridine). Found: C, 55.65; H, 6.38; N, 17.76%. Calcd for $C_{11}H_{15}N_3O_3$: C, 55.69; H, 6.37; N, 17.71%.

DL-PyA-Gly-OEt: WSC (21 mg) was added to a cooled mixture of **2** (17 mg), glycine ethyl ester hydrochloride (28 mg), triethylamine (15 μl), DMF (0.1 ml), and $CHCl_3$ (0.9 ml). The mixture was stirred for 3 h at room temperature. Product **6** was isolated by HPLC with a C_{18}-column. The peak around 7 min on isocratic elution with 25% acetonitrile- 0.01 M NH_4OAc buffer (pH 5.6) was collected, concentrated, and crystallized with ethanol: Yield, 12 mg (48%), mp 109—110 °C. ^{1}H NMR ($CDCl_3$) δ=1.24 (3H, t, $CH_2C\underline{H}_3$), 1.51 (3H, d, $CHC\underline{H}_3$), 5.8 (1H, br, NH), 6.4—6.72 (2H, m, pyridine), 7.3—7.6 (1H, m, pyridine), and 8.08—8.16 (1H, m, pyridine). Found: C, 57.47; H, 6.82; N, 16.78%. Calcd for $C_{12}H_{17}N_3O_3$: C, 57.36; H, 6.82; N, 16.72%.

***N*-(2-Pyridyl)-1,2-ethanediamine Dihydrochloride (7):** A mixture of 1,2-ethanediamine (100 ml) and 2-chloropyridine (10 g) was refluxed for 8 h and concentrated to remove as much of the unreacted 1,2-ethanediamine as possible under reduced pressure. Then 2 M NaOH (40 ml) was added to the residue and the product extracted 8 times with 50 ml of $CHCl_3$ each time. The extracts were evaporated under reduced pressure. Hydrochloric acid was added to the residue and concentrated to crystallize **7**. Recrystallization from a mixture of water and ethanol after charcoal treatment gave **7** as faintly yellow needles: yield 11 g (62%); mp 215—216 °C; ^{1}H NMR (D_2O) δ=3.35 (2H, t, CH_2), 3.79 (2H, t, CH_2), 6.9—7.2 (2H, m, pyridine), and 7.8—8.1 (2H, m, pyridine). Found: C, 39.04; H, 6.22; N, 19.95%. Calcd for $C_7H_{11}N_3$, 2HCl : C, 40.02; H, 6.24; N, 20.00%.

Boc-Glu(OBzl)-AEAP: A solution of Boc-Glu(OBzl)-OH (1.6 g, 5 mmol) in chloroform (20 ml) was mixed with a solution of **7** (1.0 g) in 20 ml of chloroform and 0.7 ml of triethylamine. DCC (1.0 g) was added to the cooled upper solution. After 3 h, the reaction mixture was filtered and evaporated. Ethyl acetate (40 ml) was added to the residue and insoluble materials were removed by filtration. The filtrate was washed twice with 2.5% Na_2CO_3 and then with water, dried over Na_2SO_4, and concentrated to a syrup. The yield was about 80% from the absorbance at 310 nm, the purity was confirmed by TLC (*n*-BuOH-AcOH-H_2O, 4 : 1 : 1) and the compound was used for the next step without further purification.

Boc-Glu-AEAP Acetate (8): The *O*-benzyl group of Boc-Glu(OBzl)-AEAP was removed by hydrogenation over Pd-black in methanol-acetic acid (10 : 1). After filtration and evaporation of the reaction solution, the product was crystallized as acetate from methanol-ethyl acetate: mp 136—137 °C. Found: C, 53.15; H, 7.04; N, 13.14%. Calcd for $C_{19}H_{30}N_4O_7$: C, 53.51; H, 7.09; N, 13.14%.

Z-Asp(AEAP)$_2$ (9): Z-Asp (0.62 g, 2.3 mmol), **7** (1.0 g, 5 mmol), and triethylamine (0.8 ml) were dissolved in a mixture of 5 ml of H_2O and 10 ml of dioxane. WSC (1.1 g, 5.5 mmol) was added to the mixture at 0 °C. After 2 h, the reaction mixture was evaporated; the residue was dissolved in 0.1 M HCl and washed three times with chloroform. After the addition of a sat. $NaHCO_3$ solution to the aqueous layer, the product was extracted twice with $CHCl_3$. The chloroform layer was dried over $MgSO_4$ and concentrated. Compound **9** was crystallized by the addition of ethyl acetate; yield, 0.7 g (60%); mp 103—104 °C; ^{1}H NMR ($CDCl_3$) δ= 2.57—2.72 (2H, m, CH_2), 3.36 (8H, s, 2×CH_2-CH_2), 4.4—4.6 (1H, m, CH), 5.02 (2H, s, $C\underline{H}_2$Ph), 5.5 (2H, br, NH), 6.3—6.7 (4H, m, pyridine), 7.3 (5H, s, Ph), 7.3—7.32 (2H, m, pyridine), 7.5 (1H, s, NH), 7.7 (1H, s, NH), and 7.9—7.96 (2H, m, pyridine). Found: C, 61.22; H, 6.11; N, 19.30%. Calcd for $C_{26}H_{31}N_7O_4$: C, 61.77; H, 6.18; N, 19.39%.

Gly-AEAP (10): WSC (192 mg) was added to a cooled solution of Z-Gly (209 mg), **7** (210 mg), triethylamine (150 μl), chloroform (18 ml), and DMF (2 ml) and stirred for 3 h at room temperature. The product was extracted with 0.1 M HCl, and washed with chloroform. Saturated $NaHCO_3$ was added, and the mixture was extracted with chloroform. The organic layer was concentrated and hydrogenated over Pd-black in 0.1 M HCl to give **10**. Compound **10** was crystallized with ethanol: yield 163 mg (61%); mp 190—192 °C; ^{1}H NMR (D_2O) δ=3.62 (4H, s, CH_2-CH_2), 3.89 (2H, s, CH_2), 6.9—7.2 (2H, m, pyridine), and 7.8—8.1 (2H, m, pyridine). Found: C, 37.78; H, 6.45; N, 19.67%. Calcd for $C_9H_{14}N_4O$, 2HCl, H_2O: C, 37.91; H, 6.36; N, 19.65%.

Z-Gly-Ser(P)OH (11): A solution of Z-Gly-OSu (400 mg) in 2 ml of dioxane was added with stirring to the phosphoserine solution (200 mg) in 4 ml of water and 2 ml of dioxane, the pH of which had been adjusted to 8.5. The mixture was stirred at room temperature for 8 h and concentrated under reduced pressure. The residue was dissolved in water, washed with ethyl acetate three times, and applied to HPLC to purify **11**. Compound **11** was eluted around 13 min, concentrated, and crystallized with chloroform: 246 mg (58%); mp 164—165 °C. ^{1}H NMR (D_2O) δ=3.80 (2H, s, NCH_2), 4.1—4.3 (2H, m, CH_2OP), 5.0 (2H, s, CH_2-O), and 7.26 (5H, s, Ph). Found: C, 41.38; H, 4.43; N, 7.39%. Calcd for $C_{13}H_{17}N_2O_9P$: C, 41.49; H, 4.56; N, 7.44%.

Z-Gly-Thr(P)OH (13): Compound **13** was synthesized in a similar way to **11** with 90 mg (0.45 mmol) of phosphothreonine and 300 mg (0.98 mmol) of Z-Gly-OSu. Compound **13** could not be obtained as a crystal even after purification by HPLC: Yield, 143 mg (78%); ^{1}H NMR (D_2O) δ=1.06 (3H, d, CH_3), 3.74 (2H, s, $NHC\underline{H}_2CO$), 4.42—4.56 (1H, m, CHOP), 4.86 (2H, s, $C\underline{H}_2$Ph), 7.12 (5H, m, Ph).

Z-Gly-Ser(P)-AEAP (12): To a solution of **11** (19.6 mg) and **7** (20.6 mg) in water (0.5 ml), the pH of which had been adjusted to 6, WSC (9.5 mg) was added. The reaction was monitored by the use of HPLC (Fig. 5) to confirm the production of **12** (elution time, 15.5 min). The reaction was completed in 2 h and **12** was isolated by HPLC: Yield, 18 mg (62%); ^{1}H NMR (D_2O) δ=3.48 (4H, s, 2×CH_2), 3.91 (2H, s, NCHCO), 4.4—4.2 (1H, m, CHOP), 5.12 (2H, s, CH_2Ph), 6.28—7.06 (2H, m, pyridine), 7.37 (5H, s, Ph), and 7.76—8.0 (2H, m, pyridine).

Z-Gly-Thr(P)-AEAP (14): Compound **14** was synthesized in a similar way to **12**. The elution time of **14** on HPLC was 15.6 min: Yield, 66%; ^{1}H NMR (D_2O) δ=1.26 (3H, d, CH_3), 3.45 (4H, s, 2×CH_2), 3.92 (2H, s, NCH_2CO), 5.21 (2H, s, $C\underline{H}_2$Ph), 6.8—7.06 (2H, m, pyridine), 7.38 (5H, s, Ph), and 7.7—8.0 (2H, m, pyridine).

PyG-Gln-Lys-Lys-Leu-Leu-Lys-Phe-Glu-βAla (15): Compound **15** was synthesized by the solid phase peptide synthesis.[7] Boc-β-alanine (5 mmol) was coupled to 10 g of chloromethylated polystyrene resin (Peptide Institute, Inc.) according to the method of Gisin[8] and obtained a β-alanyl resin (0.25 mmol g^{-1}). Three fold of Boc-amino acid (26 mmol) was coupled to the resin (3.5 g) stepwise with DCC. The coupling reaction was repeated in the introduction of

Boc-Phe-DCAA and Boc-Gln. In the introduction of *N*-(2-pyridyl)glycine, **1** was powdered in a mortar because of its low solubility in methylene dichloride.

Peptide **15** was purified by HPLC after HF treatment (0 °C, 1 h). The yield was about 55% from the β-alanyl resine. The structure of **15** was confirmed by FAB-mass,[9] (Found: *m/z* 1238.8. Calcd for the structure: M, 1238) and also by amino acid analysis of the peptide. The amino acid composition of **15** was $Glu_{2.1}$ $Leu_{2.0}$ $Phe_{1.0}$ $Lys_{3.0}$ β-$Ala_{1.2}$. PyG could not be analyzed under ordinary analysis conditions.

The authors are grateful to Prof. Yasutsugu Shimonishi, Dr. Toshifumi Takao, and Mr. Hiroyuki Watanabe, Institute for Protein Research, Osaka University, for technical help in the solid phase peptide synthesis and for the FAB-MS measurements.

Reactions of Wittig Reagents with Episulfides or Elemental Sulfur

Kentaro OKUMA,* Yuji TACHIBANA, Jun-ichi SAKATA, Takashi KOMIYA, Isao KANEKO, Yasuo KOMIYA, Yusuke YAMASAKI, Shin-ichi YAMAMOTO, and Hiroshi OHTA
Department of Chemistry, Faculty of Science, Fukuoka University, Jonan-ku, Fukuoka 814-01
(Received April 25, 1988)

The reactions of Wittig reagents with episulfides gave symmetrical olefins and triphenylphosphine sulfide in moderate yields. The same olefins were obtained by reactions of Wittig reagents with elemental sulfur. These reactions might proceed through thiocarbonyl intermediates, the existence of which was confirmed by Diels-Alder reactions with dienes.

The Wittig reaction has been widely adopted for the synthesis of olefins.[1] During the past decade, several authors have reported on the reactions of Wittig reagents (**1**) with epoxides to afford cyclopropane derivatives.[2] Corey and Kang also reported that the reaction of the methylenetriphenylphosphorane anion with epoxides, followed by the addition of carbonyl compounds, gave 2-hydroxy olefin derivatives.[3] One of the methods for the synthesis of thioketones is the reaction of phosphonium ylides with elemental sulfur.[4] In a previous communication, we reported that the reactions of stable Wittig reagents with episulfides (**2**) afforded olefins (**3**) via thiocarbonyl intermediates in moderate yields.[5] Recently, we also found that the reaction of Wittig reagents with elemental selenium gave the corresponding olefins via selenocarbonyl intermediates.[6] This consideration, in turn, prompted us to investigate the possibility of the formation of **3** and thioaldehydes (**4**) by reactions of elemental sulfur with Wittig reagents. In this paper, we would like to report that the reaction of **1** with **2** or elemental sulfur produced **3** via thioaldehyde intermediates.

Results and Discussion

We first tried the reaction of **1** with **2**. A treatment of carbomethoxymethylenetriphenylphosphorane (**1a**) with styrene sulfide (**2a**) in toluene afforded styrene, dimethyl fumarate (**3a**), dimethyl maleate (**3a'**), and triphenylphosphine sulfide (**5**) in 20, 42.5, 9.5, and 74% yields, respectively. It took 2 days of refluxing to complete this reaction. We then carried out this reaction in refluxing benzene as a solvent. However, the yields of the products were lowered less than half, even after refluxing for 8 days. As shown in Table 1, other dialkyl fumarates and maleates were prepared in a similar manner.

Benzylidenetriphenylphosphorane (**1f**) was thermally decomposed at temperatures over 240 °C to give symmetrical olefins via carbene intermediates.[7] In this case, the reaction might proceed through similar carbene intermediates, as shown in Scheme 2. However, the thermolysis of **1a** in refluxing toluene without episulfide did not afford the olefins, but only the recovered starting materials, even after refluxing for 8 days. This result showed that the above-mentioned mechanism was not correct.

It is well-known that the reaction of benzhydrylidenetriphenylphosphorane with elemental sulfur affords thiobenzophenone, which changes to tetraphenylethylene upon heating at temperatures over 200 °C.[4a] Fluorenylidenetriphenylphosphorane was also found to react with sulfur to give thiofluore-

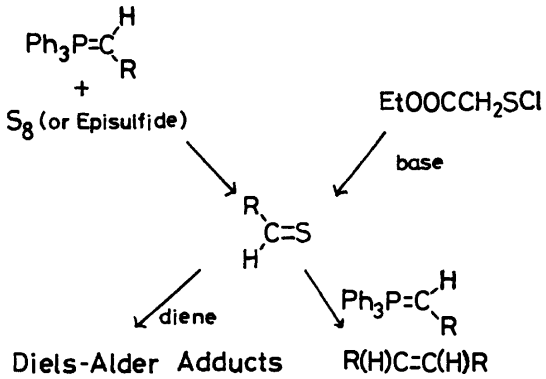

Scheme 7.

none.[4b] Tokunaga and coworkers reported that the reaction of **1f** with sulfur afforded cyclic pentasulfide and a very small amount of stilbene.[8] We therefore tried a reaction of **1** with sulfur in refluxing toluene. A treatment of **1a** with elemental sulfur gave **3a**, **3a'**, and **5** in 63, 13, and 79% yields, respectively. The reaction was faster than that of **2**. As shown in Table 2, olefins **3** and **5** were obtained in good yields. Mägerlein and Meyer reported the same reaction in the case of **1f** in refluxing toluene.[9] They also found that only *trans*-stilbene was obtained in this reaction. These results suggested that a reaction of **1** with **2** or sulfur might proceed through thioaldehyde intermediates. The ylide carbanion attacks episulfide sulfur or sulfur to give the corresponding **4**. The resulting thioaldehyde **4** further reacts with the phosphonium ylide to afford olefins via a Wittig-like reaction. Recently, Kirby and coworkers reported the generation of **4b** by the reaction of ethoxycarbonylmethanesulfenyl chloride (**6**) with triethylamine.[10a] To confirm this mechanism, we tried a similar reaction by using **6**, triethylamine, and **1b**. As shown in Scheme 5, the corresponding **3** and **5** were obtained in good yields (75%, trans/cis=4.5). Compounds **4** were recently prepared by several groups: photolysis of phenacyl sulfide derivatives;[11] reaction of sulfenylchlorides with bases;[10a] reaction of Bunte salts with bases;[12] thermolysis of thiolsulfinates;[13,14] catalytic base abstraction of trimethylsilyl derivatives.[15] While most of thioaldehydes were trapped by dienes, Okazaki and coworkers isolated aromatic and aliphatic thioaldehydes.[16] To confirm the formation of **4** in our case, we carried out a Diels-Alder reaction. A treatment of **1** and elemental sulfur (or styrene sulfide) resulted in the formation of thioaldehydes, which further reacted with dienes to give the corresponding adducts (**7** and **8**) in moderate yields. This result provides another possibility to produce **4**.

In summary, the reaction of **1** with **2** gave symmetrical **3** and **5** in moderate yields. Similarly, the reaction of **1** with elemental sulfur afforded symmetrical **3** and **5** in good yields. Both reactions might proceed through thioaldehyde intermediates, the existence of which was confirmed by a Diels-Alder reaction. We also confirmed that the reaction of thioaldehydes with Wittig reagents gave the corresponding olefins.

Experimental

General Methods. Melting points are uncorrected. NMR spectra were obtained by using JEOL PMX-60 and FX-90Q spectrometers. IR spectra were recorded on a Hitachi IR-345 spectrometer.

Materials. Compounds **1** were prepared by a method mentioned in the literature.[1,3] Compounds **2** were prepared by reactions of epoxides with KSCN or thiourea.[17] Cyclopentadiene was obtained from dicyclopentadiene by distillation. 2,3-Dimethyl-1,3-butadiene was obtained from Aldrich Chem. and used without further purification. Authentic alkyl maleates or fumarates were purchased from Wako Pure Chemicals.

Reaction of 1a with 2a in Benzene. To a solution of **2a** (0.68 g, 5.0 mmol) in benzene (30 ml) was added **1a** (1.67 g, 5.0 mmol) in one portion. After refluxing for eight days, the reaction mixture was evaporated and extracted three times with hexane (30 ml×3). The residue was a mixture (1.19 g) of **1a** (50%) and **5** (24%, yields were determined by its NMR spectrum). The combined extracts were subjected to column chromatography (silica gel). Five components were obtained: styrene (0.05 g, 0.5 mmol) was eluted first (eluant, hexane). A complex mixture of unidentified products (0.03 g) was obtained second (eluant, 80% hexane-dichloromethane). A mixture of dimethyl fumarate and dimethyl maleate (0.05 g, 0.35 mmol, 14%, yields were determined by its NMR spectrum) was further eluted (eluant, 50% hexane-

dichloromethane). A small amount of **5** (0.05 g, 0.17 mmol, 3%) was eluted last (eluant, dichloromethane).

Other reactions were carried out in a similar manner.

Reaction of 1a with Elemental Sulfur. To a solution of **1a** (3.34 g, 10 mmol) in toluene (100 ml) was added a suspension of sulfur (0.38 g, 12 mmol) in toluene (15 ml). After refluxing for 3 h, the solvent was evaporated from the reaction mixture and the remaining oil was extracted three times with hexane (50 ml×3). The residue was mainly triphenylphosphine sulfide, which was purified by recrystallization with benzene-hexane (2.32 g, 7.9 mmol, 79%). The combined extracts were evaporated and chromatographed over silica gel by elution with hexane-dichloromethane (2:1) to give a mixture of dimethyl fumarate and dimethyl maleate in 76% yields (0.51 g, 3.8 mmol, 5:1 ratio by NMR).

Other reactions were carried out in a similar manner.

Reaction of Wittig Reagent with Thioaldehyde (4b) Derived from 6. To a suspension of *N*-chlorosuccinimide (0.93 g, 7.0 mmol) in toluene (20 ml) was added dropwise a solution of ethyl thioglycolate (0.72 g, 6.0 mmol) in toluene (10 ml) at room temperature. After stirring for 2 h, the reaction mixture was filtered to give a yellow solution of the corresponding sulfenyl chloride. This solution was added dropwise to a refluxing solution of **1b** (1.74 g, 5.0 mmol) and triethylamine (0.71 g, 7.0 mmol) in toluene (20 ml). After refluxing for 3 h, the reaction mixture was washed with water (20 ml×3), dried over $MgSO_4$, and evaporated to give pale brown oil which was extracted with pentane (20 ml× 3). The combined extract was evaporated to give a crude mixture of olefins (0.54 g, 3.75 mmol, 75% trans/cis=4.5 by NMR). The resulting oil was chromatographed over silica gel by elution with hexane-dichloromethne (5:1) to give a mixture of diethyl maleate and diethyl fumarate (0.37 g, 2.6 mmol, 52%).

Reaction of Wittig Reagent with Styrene Sulfide in the Presence of 2,3-Dimethylbutadiene. To a solution of **1a** (1.68 g, 5.0 mmol) and 2,3-dimethyl-1,3-butadiene (2 ml, 20 mmol) in toluene (30 ml) was added a solution of styrene sulfide (2.04 g, 15 mmol) in toluene (15 ml). After refluxing for 30 h, the resulting mixture was evaporated to give pale brown oily crystals, which were chromatographed over silica gel by elution of hexane-dichloromethane (1:1) to give adduct **7a** (0.36 g, 1.9 mmol, 38%). ^{1}H NMR ($CDCl_3$) δ=1.73 (6H, s, Me), 2.33—2.47 (2H, br.), 2.98—3.27 (2H, br.), 3.67 (1H, t, J=6.3 Hz), 3.77 (3H, s, Me).

Reactions of 1a with Sulfur in the Presence of Diene. To a solution of **1a** (1.68 g, 5.0 mmol) and 2,3-dimethyl-1,3-butadiene (2 ml, 20 mmol) in toluene (40 ml) was added elemental sulfur (0.64 g, 20 mmol). After refluxing for 20 h, the resulting mixture was evaporated to give reddish-brown oily crystals. This mixture was extracted with methanol (30 ml×2). The combined extracts were evaporated to give a reddish-brown oil, which was chromatographed over silica gel by elution with hexane-dichloromethane (3:1) to give adduct **7a** (0.52 g, 2.8 mmol, 56%). Other reactions were carried out in a similar manner. **8a**; 0.54 g (3.2 mmol, 64%). ^{1}H NMR ($CDCl_3$) (Endo) δ=1.66 (br s, CH_2), 3.65 (s, Me), 3.75 (br s, CH), 4.18 (br, CH), 4.44 (d, CH, J=3.9 Hz), 5.73 (dd,=CH, J=3.3 and 5.1 Hz), 6.49 (dd, =CH, J=3.0 and 5.1 Hz); (Exo) δ=1.84 (br s, CH_2), 3.29 (s, CH), 3.54 (br, CH), 3.86 (s, Me), 4.07 (br, CH), 5.91 (dd, =CH, J=3.2 and 6.2 Hz), 6.36 (dd, =CH, J=3.2 and 4.8 Hz). **7b**; 0.49 g, (2.45 mmol, 49%). ^{1}H NMR ($CDCl_3$) δ=1.27 (t, Me, J=7.5 Hz), 1.74 (s, Me), 2.46 (br, CH_2), 3.06 (br, CH_2), 3.62 (t, CH, J=6.0 Hz), 4.19 (q, CH_2, J=7.5 Hz). **8b**; 0.92 g (4.2 mmol, 84%). ^{1}H NMR ($CDCl_3$) (Endo) δ=1.22 (t, Me, J=7.0 Hz), 1.65 (m, CH_2), 3.75 (br, CH), 4.07 (br s, CH), 4.12 (q, CH_2, J=7.0 Hz), 4.42 (d, CH, J=3.6 Hz), 5.70 (dd, =CH, J=5.4 and 2.6 Hz), 6.45 (dd, =CH, J=3.0 and 5.4 Hz). Oxidation of Coals in Liquid Phases. IX. Kinetics of the Base-Catalyzed Oxidation of Acetate Ion by Oxygen at Elevated Temperatures

Takayoshi WAKABAYASHI† and Akitsugu OKUWAKI*
Department of Molecular Chemistry and Engineering, Faculty of Engineering, Tohoku University, Sendai 980
(Received March 26, 1988)

The kinetics of the oxidation of the acetate ion by oxygen have been studied to clarify the mechanism of the formation of oxalate from coal in concentrated alkaline solutions at elevated temperatures. The rate for the oxidation in a nickel reactor in the presence of 3 g of iron powder was expressed as $-dm_{Ac}/dt=k' m_{Ac}m_{OH}{}^2P_{O_2}$, where k' is the apparent rate constant, m_{Ac} is the molality of acetate ion, m_{OH} is molality of the hydroxide ion, and P_{O_2} is the partial pressure of oxygen. This result indicates that the oxidation of the acetate ion proceeds according to a base-catalyzed mechanism. The activation energy was 160 kJ mol^{-1}. In addition, the rate of oxidation was affected by the coexistence of the metal powder and the oxidation activity in the order Cu > Ni > Co > Mn ≒ Fe > Cr. The catalytic effect of metal oxides on the rate is discussed.

Oxalate ion is formed with a 30—50% yield of carbon in the oxidation of coal by oxygen in concentrated NaOH solutions at 498—523 K.[1,2] The yield of oxalate ion increases with increasing concentration of NaOH. Essentially, the oxidation of coal may take place via a base-catalyzed oxidation mechanism, since similar yields of oxalate have been obtained in the oxidation of various model compounds such as phenols and carboxylates including acetate.[3]

In spite of the importance of this reaction mechanism for increasing the yield of oxalate from coal, the mechanism of the oxidation of carbonaceous materials under alkaline conditions has not been investigated kinetically in detail. In the present work, kinetic studies have been carried out to clarify the mechanism of the formation of oxalate and to improve the yield of oxalate from coal using acetate ion as the simplest model compound. This is one of the important intermediates in the oxidation of coal in alkaline solutions.

Experimental

A beaker made of nickel or carbon steel was set in a 1 dm^3 SUS 316 autoclave; the stirrer and sampling tube were of the same material as the beaker. Water (550 g), sodium acetate (0.08 mol kg^{-1} H_2O), NaOH, and Na_2CO_3, and metal powder (under 100 mesh), were put into the autoclave, and the amount of Na_2CO_3 was adjusted to coincide with the ionic strength of a 5 molal NaOH solution. The NaOH and Na_2CO_3 concentrations (molal) were 2, 0.253; 3, 0.171; and 4, 0.083; respectively. After replacement of air with N_2 three times, the autoclave was heated to a temperature 20 K below the reaction temperature. The sample solution was withdrawn immediately after oxygen was introduced during stirring at 500—800 rpm (reaction time of 0). The temperature rapidly rose on pressurization of oxygen, reaching the final reaction temperature in 15 min. A sample solution (8—15 cm^3) was then withdrawn at 30-min intervals. The volume of each sample was calculated from its weight and the density of the solution corresponding to the same NaOH concentration. The concentrations of acetate and oxalate ions were determined by ion chromatography after sodium/hydrogen ion exchange.

† Present address: Sumitomo Electric Corp., Itami 664.

Results and Discussion

Oxalate and carbonate ions are formed by the oxidation of acetate ion in the reaction, and the ratio of oxalate to carbonate has been found to vary extensively with the reactor materials. We have not succeeded in finding any corrosion-resistant material under such corrosive conditions and have been obliged to use stainless steels or nickel as the reactor material. Even these metals were corroded considerably to form metal oxides during the reaction time under the present conditions, and the resulting metal oxides affected the rate of the oxidation and the selectivity. The selectivity of the oxalate ion was highest in the presence of iron powder using the nickel beaker.[4]

Catalytic Effect of Various Metals Contained in Stainless Steels. The following preliminary experiments have been carried out to elucidate the significance of adding iron powder.

Activity of Metals: The first order plots of the concentration of acetate ion in the reaction with 3 g of various metal powders in the nickel beaker are shown in Fig. 1. The rate of oxidation of the acetate ion was approximately proportional to the acetate ion concentration and nearly the same in the presence of Cr, Mn, and Fe, all of which have standard electrode potentials lower than that of Ni. On the other hand, the rate of oxidation was accelerated slightly in the presence of Ni the standard electrode potential of which is higher than those of Cr, Mn, and Fe. The first order plots shifted gradually upward with reaction time as was observed in the absence of Ni. Cobalt only slightly affected the rate of oxidation. Copper, the standard electrode potential of which is higher than that of Ni, promoted the reaction remarkably. These results indicate that Cr, Mn, and Fe inhibit the effect of nickel on the reaction rate which was used as the reactor material whereas Cu promotes the reaction. This is an interesting phenomenon suggesting the promotion of the oxidation of coal by the addition of copper oxide.

●: Fe, ○: Ni.

This effect has been confirmed for the oxidation of lignite.[5]

Effect of Reactor Material: Figure 2 demonstrates the first order plots of concentration of acetate ion in nickel and carbon steel reactors without metal powder. The initial rate of oxidation in the steel reactor was obviously greater than that in the nickel reactor. The reason is that in the case of the steel reactor the temperature of the solution rose rapidly up to 540 K, 17 K higher than the reaction temperature of 523 K due to the heat of extreme oxidation of the steel, and it took 30 min until the temperature decreased to 523 K. After the temperature rise had settled, the rate of oxidation

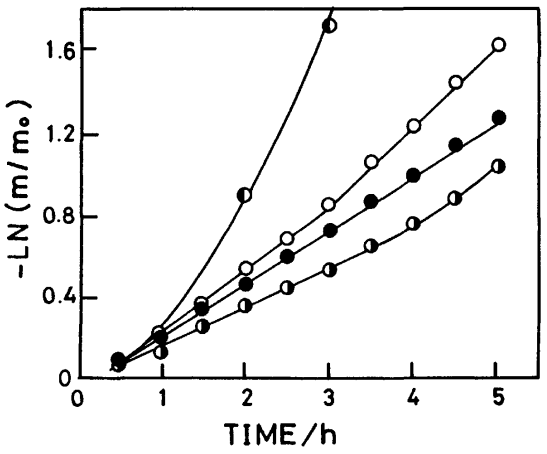

Fig. 3. Effect of Fe powder and Fe_2O_3 on the rate of oxidation in a Ni reactor at 523 K and P_{O_2} 5 MPa.
◑: Fe 1 g, ●: Fe 3 g, ○: Fe_2O_3 4.3 g, ◐: none .

in the steel reactor approached that in the nickel reactor and the two became approximately equal between 1.5 and 3 h. A large amount of Fe_2O_3, haematite, was produced by corrosion of the steel.

Effect of the Amount of Iron Powder on the Reaction in the Nickel Reactor: Figure 3 shows the effects of the amount of iron powder and reagent haematite on the rate of oxidation. Only 1g of iron powder retarded the oxidation of acetate ion in the nickel reactor, but the rate of oxidation was slightly increased in the presence of 3 g of iron powder. This indicates that 1 g of iron powder is enough to control the activity of the nickel reactor. On the other hand, excessive Fe_2O_3 formed by the oxidation of an additional 3 g of iron powder begins to promote the oxidation of the acetate ion. The fact that the rate of oxidation in the steel reactor was approximately equal to that in the nickel reactor under the steady state, supports the hypothesis that Fe_2O_3 promotes the oxidation as oxides of nickel. Namely, the role of iron powder in the nickel reactor seems to change from that of depressor to that of catalyst when increasing amounts of iron powder are added.

The rate of the oxidation of acetate ion with the addition of haematite corresponding to 3 g of iron powder was apparently greater than that with the addition of 3 g of iron powder. This result also supports the hypothesis that excessive Fe_2O_3 accelerates oxidation, since in this case, a large amount of haematite is present from the beginning of the oxidation. This is different from the case of the oxidation with iron powder where Fe_2O_3 is produced gradually with increase in the reaction time. In addition, the first order plot shifted gradually upward compared to that of the iron powder. Thus, iron powder is required to maintain the linearity of the first order plot. With an addition of 1 g of iron powder, however, the first order plot shifted upward during the course of the reaction as shown in Fig. 3. This shows that the oxidation of

acetate ion had begun to be accelerated due to complete consumption of the metallic iron. Consequently, 3 g of iron powder is necessary to maintain the linearity of the first order plot at least for 6 h. Under such reaction conditions, the effects of various parameters on the rate of oxidation of the acetate ion can easily be observed. It is especially important to elucidate the dependency of the rate of the oxidation of the acetate ion on the hydroxide ion concentration to confirm if the oxidation of acetate ion proceeds by a base-catalyzed mechanism. Thus, the kinetic study was just carried out in the presence of 3 g of iron powder in the nickel reactor.

The Rate Equation of the Oxidation of Acetate Ion with 3 g of Iron Powder. The effects of NaOH concentration, partial pressure of oxygen, and temperature have been measured; this system is written below as Ni(Fe).

Effect of NaOH Concentration: Figure 4 shows the first order plots of the concentration of the acetate ion with varying NaOH concentration. It shows that the reaction is first order with respect to acetate ion. The reason why the first order plots do not pass through the origin is that the initial temperature was lower than the reaction temperature in the steady state. The hydroxide ion concentration was calculated using the pK_b (1.07 at 523 K[6]) and an extended Debye-Hückel equation as set forth below since NaOH does not dissociate completely at elevated temperatures.

The following reactions can be assumed at $t=0$:

$$NaOH \overset{K_b}{\rightleftharpoons} Na^+ + OH^- \quad (1)$$

$$NaAc \longrightarrow Na^+ + Ac^- \quad (2)$$

$$Na_2CO_3 \longrightarrow 2Na^+ + CO_3^{2-} \quad (3)$$

$$K_b = a_{Na}a_{OH}/a_{NaOH} \quad (4)$$

a: activity of the corresponding species

The dissociation constant of NaOH, K_b, can be expressed by the molalities of the sodium ion, m_{Na}, the acetate ion, m_{Ac}, the carbonate ion, m_c, the total NaOH, m_o, the undissociated NaOH, m_{NaOH}, and the hydroxide ion, m_{OH}, the degree of dissociation of NaOH, α, and the activity coefficient for monovalent ion, γ, respectively.

$$K_b = \gamma^2 m_{Na} m_{OH}/m_{NaOH} \quad (5)$$

$$= \gamma^2\alpha\,(m_{Ac}+\alpha m_o+2m_c)/(1-\alpha) \quad (5')$$

The ionic strength, I, is given by Eq. 6. Activity coefficients

$$I = m_{Ac}+\alpha m_o+2m_c \quad (6)$$

are expressed by Eq. 7 in the measurement of the solubility of $CaSO_4$ up to 623 K and 5 molal NaCl solutions.[7]

$$\log\gamma = -Z_i^2 S I^{1/2}/(1+A_k I^{1/2}) \quad (7)$$

Z_i: charge of ion i, S: limiting slope of the Debye-Hückel Eq. (0.9785 at 523 K),[8] A_k: 1.74 at 523 K.[7]

The hydroxide ion concentration (αm_o) was obtained by calculating the degree of dissociation in each condition using Eqs. 5′—7.

The relationship between the apparent rate constant and calculated hydroxide ion concentration is shown in Fig. 5. The rate of oxidation of the acetate ion was approximately proportional to the second order in hydroxide ion concentration.

Effect of Partial Pressure of Oxygen: Figure 6 shows the effect of the partial pressure of oxygen on the apparent rate of oxidation. The rate of oxidation was proportional to the partial pressure of oxygen.

Effect of Temperature: The activation energy of the oxidation obtained from the Arrhenius plot of the

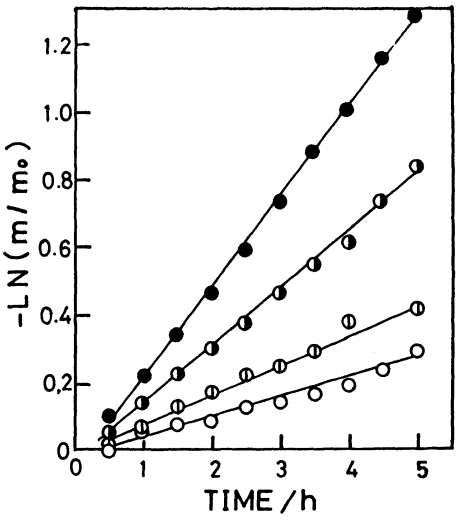

Fig. 4. Effect of NaOH concentration on the rate of oxidation in Ni(Fe) at 523 K and P_{O_2} 5 MPa.

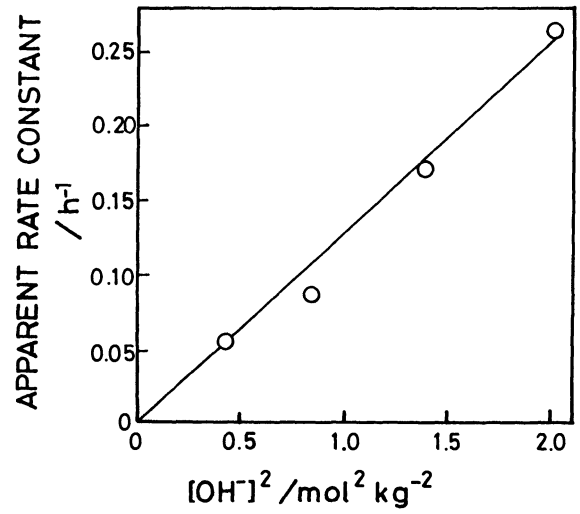

Fig. 5. Relationship between the apparent rate constant and hydroxide ion concentration in Ni(Fe) at 523 K and P_{O_2} 5 MPa.

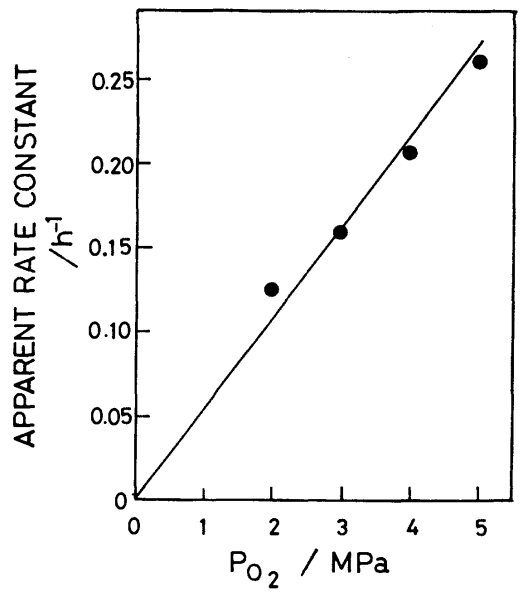

Fig. 6. Effect of partial pressure of oxygen on the rate of oxidation in Ni(Fe) at 523 K and 5 mol kg^{-1} H_2O.

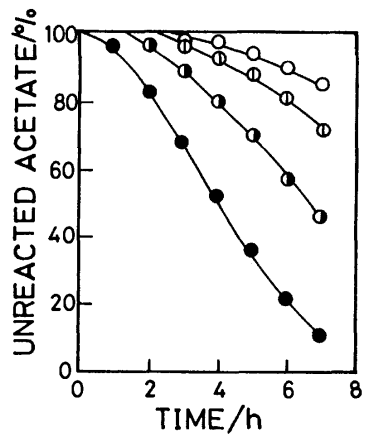

Fig. 7. Effect of NaOH concentration on the rate of oxidation in Ni(R) at 503 K and P_{O_2} 5 M Pa. NaOH concn (mol kg^{-1} H_2O) ○: 2.00, ⊕: 3.00, ◑: 4.00, ●: 5.00.

apparent rate constants at 503, 513, and 523 K was 160 kJ mol^{-1}. This value clearly shows that the rate-determining step is a chemical reaction process.

Rate Equation of the Oxidation: Finally from the above results, the rate of the oxidation of the acetate ion in the presence of 3 g of iron powder in the nickel reactor can be expressed by Eq. 8.

$$-dm_{Ac}/dt = k' m_{Ac} m_{OH}^2 P_{O_2} \quad (8)$$

k': the apparent rate constant, m_{Ac}: molality of the acetate ion, the m_{OH}: molality of the hydroxide ion, P_{O_2}: partial pressure of oxygen.

Oxidation of Acetate Ion without Iron Powder. This system is written as Ni(R) below.

Effect of NaOH Concentration: The first order relationship was not obtained at 523 K, since the rate of the oxidation increased exponentially with the reaction time in the beginning. This tendency is more evident at 503 K as is shown in Fig. 7. This may indicate that some oxide of nickel is involved in the rate-determining step of the reaction and that its amount increases exponentially with the reaction time, since the acetate ion concentration changes slightly in the beginning.

Effect of Partial Pressure of Oxygen: In this case, the effect appeared only in the beginning, and the rate of the oxidation became constant independent of the pressure of oxygen as is shown in Fig. 8. This may indicate that the amount of the oxide of nickel formed is little affected by the partial pressure of the oxygen.

Effect of Initial Concentration of Sodium Acetate: In the case of Ni(Fe), naturally, the initial concentration did not affect the rate of oxidation as it was first order with respect to the acetate ion concentration. However, the rate of oxidation of the acetate ion in Ni(R) at 503 K became constant after 2 h and was proportional to the initial concentration of the acetate ion as is shown in Fig. 9.

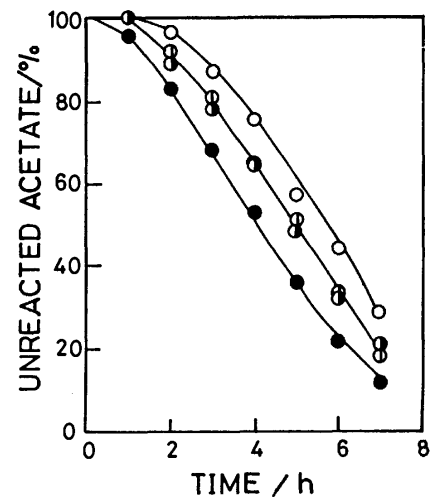

Fig. 8. Effect of partial pressure of oxygen on the rate of oxidation in Ni(R) at 503 K and 5 mol NaOH/kg H_2O. P_{O_2}(MPa) ○: 2.0, ⊕: 3.0, ◑: 4.0, ●: 5.0.

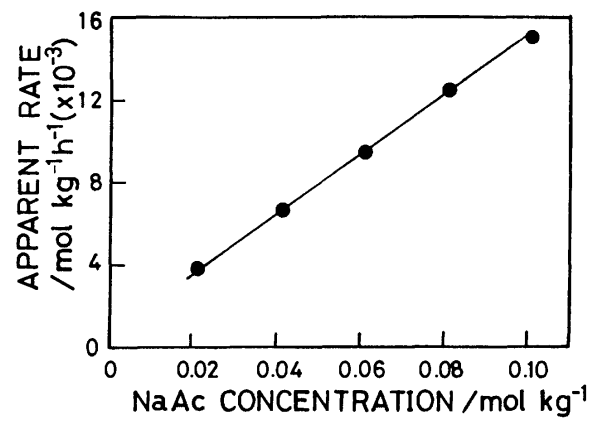

Fig. 9. Effect of initial concentration of acetate ion on the apparent rate constant in Ni(R) at 503 K and P_{O_2} 5 MPa.

The difference in the cases of Ni(Fe) and Ni(R) is discussed in the following mechanism.

Mechanism of the Oxidation of Acetate Ion. Base and Metal Oxide-Catalyzed Oxidation Mechanism: It is thought that this oxidation reaction involves a base-catalyzed oxidation mechanism[9] as follows:

$$XCH_3 + OH^- \overset{K}{\rightleftharpoons} XCH_2^- + H_2O \ (X=COO^-) \quad (9)$$

$$XCH_2^- + O_2 \xrightarrow[(MeO)]{k} XCH_2\cdot + O_2^- \quad (10)$$

$$XCH_2\cdot + O_2 \longrightarrow XCH_2OO\cdot \quad (11)$$

$$XCH_2OO\cdot + XCH_2^- \longrightarrow XCH_2OO^- + XCH_2\cdot \quad (12)$$

$$XCH_2OO\cdot + O_2^- \longrightarrow XCH_2OO^- + O_2 \quad (13)$$

K: equilibrium constant, k: rate constant, MeO: metal oxide

The peroxoanion formed from the oxidation of the carbanion, XCH_2OO^-, is easily oxidized further to oxalate ion.

In Ni(Fe), acetate and hydroxide ions increase the concentration of the carbanion, which is a reactant in the rate-determining step, according to the first order dependence of its formation on the concentrations of acetate and hydroxide ions, as shown by Eq. 9. We may assume Henry's law for the solubility of oxygen in the solutions at constant NaOH concentration and temperature. Thus, the concentration of oxygen should be proportional to its partial pressure. In this case, however, the reaction mechanism seems to be a base-catalyzed oxidation reaction involving the iron oxide catalyst as shown in Eq. 10. There are two results supporting this. Firstly, the rate of the oxidation is proportional to the second order in the concentration of hydroxide ion. This seems to indicate that the rate of formation of a catalyst, the iron oxide, is proportional to the concentration of the hydroxide ion. Although such measurements have not been carried out in the present work or found in the literature, in the anodic oxidation of iron in a 1 mol kg^{-1} LiOH solution at 473 K, oxoanions of iron are formed by the reaction of iron and hydroxide ion.[10] Secondly, the rate of oxidation increased with increasing amount of iron powder as shown in Fig. 3. This means that the soluble species of iron can not be the major oxidizing species, since the solubilities of iron oxides in alkaline solutions are very low[11] and the reaction solutions should be saturated with iron ion even with the addition of 1 g of iron powder. Consequently, the oxidation of acetate ion in Ni(Fe) proceeds on the surface of the iron oxide due to a base-catalyzed and iron oxide-catalyzed oxidation mechanism as shown in Eq. 10.

The mechanism in Ni(R) should be similar to that in the above-mentioned case. A distinct difference is that the rate of reaction in Ni(R) increased exponentially with the reaction time in the initial stage; it then became constant as is shown in Figs. 7 and 8. The rate of reaction is proportional with respect to the initial acetate ion concentration as is shown in Fig. 9. These results may be boldly explained as follows. The amount of nickel oxide formed by corrosion of the reactor material increases exponentially with the reaction time. By analogy with the mechanism of the oxidation of acetate ion in Ni(Fe), the rate in Ni(R) should also be proportional to the products of the concentration of the carbanion and amount of nickel oxide. If the concentration of the carbanion decreases exponentially with the reaction time and both rates compensate each other, the rate of oxidation of the acetate ion becomes constant and is approximately proportional to the initial concentration of acetate ion.

Figure 10 shows the effect of the amount of nickel powder on the oxidation of acetate ion in Ni(R) at 503 K. The rate of the oxidation increases with increasing amounts of nickel. Clearly, these results support the hypothesis that the nickel oxide formed by the corrosion acts as a catalyst since nickel powder is easily oxidized under the reaction conditions. It seems that the hydroxide ion concentration accelerates mainly the formation of the catalyst compared to the amount of nickel powder or partial pressure of oxygen.

The Valency of Nickel in the Oxides Formed in Ni(R): When the Ni(R) run has finished, a greenish white precipitate and a small amount of a black substance are suspended in the solution. Two peaks were observed in the ESCA spectra of the precipitate at 857.8 and 856.4 eV for Ni $2p_{3/2}$ which may correspond to 856.2 and 855.2 eV for reagent Ni_2O_3, respectively. This indicates that Ni^{3+} is contained in the precipitates. There are many types of oxide of nickel having excess oxygen.[12] Only NiO, however, was identified in the precipitates by XRD. According to the

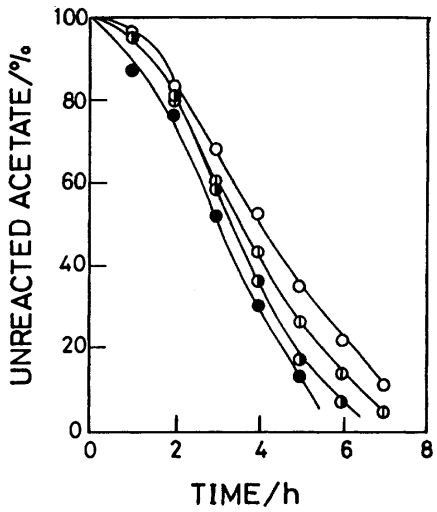

Fig. 10. Effect of amount of Ni powder on the oxidation in Ni(R) at 503 K and P_{O_2} 5 MPa. Amount of Ni(g) ○: 0, ◑: 2, ◑: 4, ●: 6.

potential-pH diagram of a Ni-water system at 523 K,[13-16] even Ni_2O_3 can be formed under the reaction conditions, at a calculated pH of 10.8 (2 mol kg^{-1}) −11.2 (5 mol kg^{-1}) and P_{O_2} 5 MPa. However, in Ni(R), Ni^{3+} probably is not the catalyst but the reactant which directly oxidizes the carbanion, since the partial pressure of oxygen only slightly affected the rate of oxidation as is shown in Fig. 8, in contrast to the case for Ni(Fe) shown in Fig. 6.

Retardation Mechanism of the Oxidation in Ni(Fe): This mechanism can be reasonably explained by the action of metals or Fe_2O_3 added on Ni^{3+} formed by the corrosion of the nickel reactor. There are two factors which cause this phenomenon. One is an electrochemical effect and the other is a mechanical effect.

The former occurs when a metal whose electrode potential is lower than that of nickel is present in the solution as is shown in Fig. 1. According to the mechanism of oxidation in Ni(R), this effect brings about protection of the formation of Ni^{3+} because of the cathodic polarization of the nickel surface covered by iron powder in alkaline solutions or the reduction of Ni^{3+} by iron powder and FeO as shown in Eqs. 14 and 15.

$$2Ni^{3+} + Fe + 6OH^- \longrightarrow 2NiO + FeO + 3H_2O \quad (14)$$

$$2Ni^{3+} + 2FeO + 6OH^- \longrightarrow 2NiO + Fe_2O_3 + 3H_2O \quad (15)$$

The retardation seems to take place without adherence of oxides since it was recognized in Ni(Cr) in which soluble chromate was formed instead of Cr_2O_3. The sole suspension of haematite in the oxidation with the carbon steel reactor does not seem to retard the rate as shown in Fig. 3. In the case of Ni(Fe_2O_3), however, retardation was also observed. This may be caused by the nickel surface being covered with haematite since the electrochemical effect can not take place in this case. Actually, haematite adhered tightly to every part of the nickel reactor in contact with the solution and could not be removed easily by brushing. Consequently, haematite adhering to the nickel surface inhibits the formation of Ni^{3+} by preventing the nickel surface from coming in contact with the solution. Haematite, however, seems not to control the formation of Ni^{3+} completely as it can not reduce Ni^{3+} like iron does. Thus, Ni^{3+}, which forms gradually, accelerates the rate of oxidation.

Copper accelerated the oxidation and this mechanism should be further studied.

Conclusion

In the kinetics of the oxidation of acetate ion by oxygen in strong alkaline solutions at elevated temperatures, the following results have been obtained. In the case of Ni(Fe), the first order plots of acetate ion concentration remain approximately linear while metallic iron remains in the solution. This is realized by the inhibition of the formation of Ni^{3+} by the metallic iron. The rate equation of the oxidation in Ni(Fe) can be expressed as follows: $-dm_{Ac}/dt = k' m_{Ac} m_{OH}^2 P_{O_2}$ where k' is the apparent rate constant. This equation shows quantitatively that the oxidation of acetate ion in alkaline solutions proceeds by a base-catalyzed mechanism. The activation energy is 160 kJ mol^{-1}. In the case of Ni(R), the Ni^{3+} species formed by the oxidation of the nickel reactor was thought to be the reactant which oxidizes the carbanion and increases with the reaction time. In the presence of metal powder, the rate of oxidation in a nickel reactor is in the following order: Cu>Ni>Co>Mn≒Fe>Cr. The effect of metals on the oxidation is also discussed.

(Received May 6, 1988)

The effects of some metal ions on the amination and arylation of 5,8-quinolinedione (**1**) and on the amine displacement of 6-piperidino-5,8-quinolinedione have been investigated. The reaction of **1** with various amines in chloroform or ethanol was specifically promoted by Ni(II) ions to give selectively the corresponding 6-(substituted amino)-5,8-quinolinediones. With *N,N*-dialkylanilines in acetic acid the reaction was strongly promoted by Cu(II) ions to give exclusively 6-arylated products, 6-[*p*-(dialkylamino)phenyl]-5,8-quinolinediones. The metal chelate complex was proposed as an activated intermediate.

It is generally known that the reactivities and electronic structures of organic ligands are affected by coordination to metal ions. In recent papers, we have reported novel direct alkylaminations of various α-substituted anthraquinones in the presence of metal ions.[1] The formation of a metal chelate complex, in which the α-substituent and the neighboring oxygen atom of the quinone carbonyl group coordinate to the metal ion, was proposed to increase the electrophilicity of the anthraquinone nucleus and to facilitate the ocurrence of direct alkylamination.

A strong activation effect induced by metal chelate formation has also been found in the reactions of various amines with 5,8-quinolinedione (**1**), giving 6-aminated and 6-arylated products selectively.[2] In this paper, we report on details of the effect of metal ions on the reaction of 5,8-quinolinediones with various amines. The spectral features for metal chelate formation upon the addition of the metal salts to solutions of substituted 5,8-quinolinediones were also investigated.

Results and Discussion

Amine Displacement of 6-Piperidino-5,8-quinolinedione (2) Catalyzed by Metal Ions. The reaction of 6-piperidino-5,8-quinolinedione (**2**) with butylamine was found to be catalyzed by some metal ions. As shown in Table 1, the reaction of **2** with butylamine gave 6-butylamino-5,8-quinolinedione (**4**); the amine exchange reaction proceeded at 30 °C in the presence of metal salts (Runs 2—7), but did not proceed at all in the absence of metal salt (Run 1). The catalytic activity of metal chlorides was found to be in the following order: Ni(II)≫Cu(II)>Co(II)>Al(III), Ce(III). The activity of Ni(II) ion was particularly superior to those of other metal ions. In the presence of 0.1 mole ratio of nickel(II) chloride, an 83% yield of **4** was obtained after 2.5 h (Run 5). Copper(II) chloride was less active than nickel(II) chloride; however, the yield of **4** was greatly improved and the reaction proceeded more rapidly with an increase in the amount of catalyst (Runs 2 and 3). Though the displacement of the piperidino group of **2** by butylamine proceeded smoothly in the presence of Ni(II) ions, an amine exchange reaction was not observed when 7-piperidino-5,8-quinolinedione (**3**) and 2-piperidino-1,4-naphthoquinone (**19**) were used instead of **2**, and the starting materials (**3** and **19**) were recovered.

Figure 1 shows the spectral changes observed upon an addition of nickel(II) chloride to a chloroform (10 vol% DMF) solutions of **2**. In the case of **2** the absorption maximum around 470 nm, due to a free ligand, was shifted to a longer wavelength with an increase in the absorption intensity. The maximum and constant absorbance were obtained over the range of the mole ratio of [Ni(II)]/[**2**]=0.8—2.0. We tested other metal

ions (Cu(II) and Co(II)) and observed similar spectral changes. Table 2 summarizes the values of the bathochromic shift, $\Delta\lambda_{max}=\lambda'_{max}$ (complex)$-\lambda_{max}$ (free ligand), and the relative ratio of the absorption intensity, $RA_{max}=A'_{max}$ (complex)$/A_{max}$ (free ligand), calculated on the basis of spectral data. The values of $\Delta\lambda_{max}$ and RA_{max} for the metal ions are compatible with the order of catalytic activity in the amine exchange reaction. In Fig. 2, continuous-variation plots at [**2**]+[Metal(II)]=2.50×10^{-4} mol dm^{-3} are illustrated. The wavelengths (≈500 nm) at the absorption maxima of the metal complexes were employed. Figure 2 clearly shows that maxima appear at [**2**]/([**2**]+[Metal(II)])= 0.67, supporting the formation of 2:1 (Compound (**2**): Metal(II)) chelate complexes.

On the other hand, the spectral changes of compound **3** were fairly smaller than those of **2**, and the pattern of the changes was quite different from that observed in Fig. 1. Furthermore, in the case of **19** the absorption spectrum was not affected at all by the addition of nickel(II) salt. These results suggest that the formation of a metal chelate (**20**), in which the 1-nitrogen atom and the oxygen atom of the 8-carbonyl group of **2** coordinate to the metal ion, probably increases the electrophilicity of the 6-carbon atom and facilitates a nucleophilic substitution of the 6-piperidino group by butylamine. However, the formation of a similar metal chelate of **3** could not facilitate the displacement of the 7-piperidino group, probably because the electron density of the 7-carbon atom is not affected so much by metal chelate formation.

Regioselective 6-Amination of 5,8-Quinolinedione

(1) Catalyzed by Nickel(II) Ion. From the results of the catalytic action of metal ions in the amine exchange reaction of **2**, it is expected that nickel(II) ions can well catalyze the amination of **1** and the amino group would be preferentially introduced onto the 6-position of **1**. Therefore, we examined the reaction of **1** with various amines in the presence of nickel(II) chloride under atmospheric oxygen. The reaction of **1** with aromatic amines is already known to produce a mixture of 6- and 7-arylaminated products;[3,4] however, a reaction with aliphatic amines has not yet been reported. As shown in Table 3, in the absence of metal salt the reactions gave isomeric mixtures of the products, 6- and 7-amino derivatives of **1** (Runs 8, 10, 12, and 15). However, in the presence of nickel(II) chloride the regioselective and the regiospecific 6-amination of **1** were achieved in reactions with the aliphatic and primary aromatic amines, respectively (Runs 9, 11 and 13, 16, 17, 19). The reaction was considerably affected by the amounts of nickel(II) chloride, especially when strong electron-donating amino groups were introduced, more than a half molar ratio of the metal salt to **1** was needed. This suggests that the metal ion is preferentially combined with the aminated product rather than with **1** and that, consequently, the catalytic action of the metal ion is prohibited. When the reaction was conducted under anaerobic conditions, the amination was suppressed considerably (Runs 13 and 14). Atmospheric oxygen plays an important role as an oxidizing agent for the completion of the amination of **1**; the adducts formed by a Michael-type addition of amines to **1** can be dehydrogenated by both the unchanged **1** and atmospheric oxygen to give aminated products. The electrophilicity of 6-position of **1** would be so strongly increased by the formation of nickel(II) chelate that the 6-amination of **1** can proceed even in a reaction with *p*-nitroaniline (Runs 18 and 19). From the results described above, the mechanism of the regioselective 6-amination of **1** was proposed, as shown in Scheme 1.

Regioselective 6-Arylation of 5,8-Quinolinedione (1) with *N*-Alkyl- and *N,N*-Dialkylanilines Promoted by Metal Ions. Griffiths et al. found that the reaction of 1,4-naphthoquinone with *N,N*-dialkylarylamines in acetic acid gave 2-[*p*-(dialkylamino)aryl]-1,4-naphthoquinones in 10—66% yields.[5)] As the structure of **1** is analogous to that of 1,4-naphthoquinone, **1** was expected to undergo the arylation by the reaction with *N,N*-dialkylarylamines. Hence, we examined the effects of metal ions on the reaction of **1** with some *N,N*-dialkyl- and *N*-alkylanilines in organic solvents. As shown in Table 4, in the absence of metal salt, the reaction of **1** with *N,N*-dimethylaniline in acetic acid proceeded slowly to give a mixture of 6- and 7-[*p*-(dimethylamino)phenyl]-5,8-quinolinediones (**12** and **13**) in low yields (Run 20). However, the reaction was strongly promoted by some metal ions and gave exclusively the 6-arylated products (Runs 24—29). Metal acetates were arranged in the order of activity as follows: Cu(II)>Ni(II)>Co(II)>Zn(II)≫Ce(III). The activity of Cu(II) ion was particularly superior to those of other metal ions in the arylation. The reaction was also drastically affected by the kind of solvent. The arylation hardly proceeded when ethanol, chloroform, or pyridine was used instead of acetic acid (Runs 21—23). In these solvents, **1** and *N,N*-dimethylaniline immediately formed a reddish purpule charge-transfer complex having an absorption maximum at ca. 510 nm, which was hardly affected by prolonged reaction time. On the contrary, in acetic acid the two reagents hardly form a charge-transfer complex, and gradually reacts to give arylated products. Similar solvent effects were also observed in the arylation of 1,4-naphthoquinone.[5)]

With *N*-alkylanilines, the reaction was also affected by the kind of solvent and metal salt. Pratt has already reported that the reaction of **1** with *N*-methylaniline in an alcohol solution gave a mixture of 6- and 7-(*N*-methylanilino)-5,8-quinolinediones in low yields, but in the presence of cerium(III) chloride the 6-amino isomer (**17**) was obtained exclusively in satisfactory yield.[3c)] In our case of using copper(II) acetate in acetic acid, however, the corresponding reaction gave the 6-arylated product,6-[*p*-(methylamino)phenyl]-5,8-quinolinedione (**15**), together with the 6-aminated product (**17**): the ratio of the yields was abuot 1 : 5 (Run 31). However, in a reaction with *N*-butylaniline the yield of the 6-arylated product (**16**) was higher than that of the corresponding 6-aminated product (**18**): the ratio was about 4 : 3 (Run 32). These results reveal that in a reaction of **1** with *N*-alkylanilines in acetic acid the regioselective 6-arylation competes with the 6-amination, and that the former proceeds predominantly along with an increase in the size of the alkyl residue of *N*-alkylaniline. The nucleophilic attack of the nitrogen atom of *N*-butylaniline would cause a considerable steric crowding in the transient state. The 6-arylation was presumably initiated by a nucleophilic attack of para-position of the benzene ring of the arylamine onto the electron deficient 6-position of **1** complexed with the metal ion, giving the 1,4-adduct and was completed by a subsequent oxidation of the adduct as the similar mechanism shown in Scheme 1.

Experimental

Measurements. All the melting points are uncorrected. The visible spectra were measured using a Hitachi 220A spectrometer. The ^1H NMR spectra were taken on a JEOL Model MH-100 spectrometer with TMS as the internal standard. The elemental analyses were measured on a Yanaco CHN recoder MT-2. Thin-layer chromatography was performed on silica gel (Merk Kieselgel 60) and the resulting chromatograms were measured on a chromatoscanner (Shimadzu CS-900).

Materials. 5,8-Quinolinedione (**1**) was prepared according to a procedure described in the literature.[6)] All of the metal chlorides and the metal acetates were reagent-grade and were used without further purification. All of the metal

perchlorate hexahydrates were prepared according to methods described in the literature.[7] The amines and the solvents were purified by ordinary methods.[8]

Reaction of 2 with Butylamine. The general procedure was as follows. To a solution of **2** (0.5 g, 2.06 mmol) and metal chloride (0—2.06 mmol) in 15 ml of pyridine was added 5 ml of butylamine dropwise with stirring at 30 °C. The reaction was monitored by TLC analysis. (silica gel/ethyl acetate); **2**: R_f=0.25, **4**: R_f=0.35. After the reaction, the solvent was removed under reduced pressure. To the residue was added a cold 1% hydrochloric acid solution; the product was then extracted with chloroform. The chloroform layer was washed with water, dried (Na_2SO_4), and then concentrated. The crude products were separated by column chromatography (silica gel: Wakogel C-300) using ethyl acetate as an eluent. The yields are summarized in Table 1.

Reaction of 1 with Various Amines. The general procedure was as follows. A solution of **1** (1 g, 6.28 mmol) in 100 ml of 95% ethanol was added to a solution of the amine (18.8 mmol) and $NiCl_2$ (0—6.28 mmol) in 50 ml of 95% ethanol with stirring in an open flask at 30 °C. The reaction was monitored by TLC analysis. After the reaction, the solvent was removed under reduced pressure. A cold 1% hydrochloric acid solution was added to the residue in order to decompose the nickel chelate complex of the aminated 5,8-quinolinediones. The aminated products were extracted with chloroform from an acidic solution containing a fine dispersed precipitate. The extraction was repeated several times. After the combined chloroform extracts had been washed with water, dried (Na_2SO_4), and concentrated, the crude products were separated by column chromatography (silica gel: Wakogel C-300) using ethyl acetate and/or chloroform as eluents. The yields are summarized in Table 3.

Reaction of 1 with *N*-Alkyl- and *N,N*-Dialkylanilines. A solution of **1** (1 g, 6.28 mmol) in 80 ml of acetic acid was slowly added to a solution of the *N*-substituted aniline (18.84 mmol) and metal salt (6.28 mmol) in 20 ml of acetic acid with stirring in an open flask at 30 °C. The reaction was monitored by TLC analysis. After the starting material **1** was consumed, the products were extracted with chloroform from the reaction solution. The extraction was repeated several times. After the combined chloroform extracts were washed with saturated sodium carbonate aqueous solution, washed further with water, dried (Na_2SO_4) and then concentrated in vacuo. The crude products were separated by column chromatography (silica gel: Wakogel C-300) using chloroform or ethyl acetate as eluents. The yields are summarized in Table 4.

Characterization and Identification of Products. Some properties of the compounds (**2**,[9] **10**,[3c] and **17**[3c]), were already known; these were identified by data described in the literature, together with the following additional data.

6-Piperidino-5,8-quinolinedione (2): mp 147—148 °C (lit,[9] 146—148 °C). λ_{max} (benzene) 462 nm (ε 3600). ^{1}H NMR ($CDCl_3$) δ=1.6—1.9 (6H, m, $(CH_2)_3$), 3.4—3.7 (4H, m, N-CH_2×2), 6.16 (1H, s, H^7), 7.54 (1H, dd, H^3), 8.30 (1H, dd, H^4), 8.95 (1H, dd, H^2). Found: C, 69.42; H, 6.09; N, 11.48%. Calcd for $C_{14}H_{14}N_2O_2$: C, 69.41; H, 5.82; N, 11.56%.

7-Piperidino-5,8-quinolinedione (3): mp 93—95 °C. λ_{max} (benzene) 465 nm (ε 3400). ^{1}H NMR ($CDCl_3$) δ=1.6—1.9 (6H, m, $(CH_2)_3$), 3.4—3.7 (4H, m, N-CH_2×2), 6.01 (1H, s, H^6), 7.55 (1H, dd, H^3), 8.33 (1H, dd, H^4), 8.86 (1H, dd, H^2). Found: C, 69.18; H, 6.03; N, 11.46%. Calcd for $C_{14}H_{14}N_2O_2$: C, 69.41; H, 5.82; N, 11.56%.

6-Butylamino-5,8-quinolinedione (4): mp 148—150 °C. λ_{max} (benzene) 446 nm (ε 3450). ^{1}H NMR ($CDCl_3$) δ=0.98 (3H, t, CH_3), 1.1—1.9 (4H, m, $(CH_2)_2$), 3.21 (2H, q, NH-CH_2), 5.86 (1H, b, NH), 5.90 (1H, s, H^7), 7.53 (1H, dd, H^3), 8.34 (1H, dd, H^4), 8.97 (1H, dd, H^2). Found: C, 68.17; H, 6.42; N, 12.19%. Calcd for $C_{13}H_{14}N_2O_2$: C, 67.81; H, 6.13; N, 12.17%.

7-Butylamino-5,8-quinolinedione (5): mp 139—141 °C. λ_{max} (benzene) 447 nm (ε 3100). ^{1}H NMR ($CDCl_3$) δ=0.98 (3H, t, CH_3), 1.1—1.9 (4H, m, $(CH_2)_2$), 3.22 (2H, q, NH-CH_2), 5.76 (1H, s, H^6), 6.10 (1H, b, NH), 7.63 (1H, dd, H^3), 8.43 (1H, dd, H^4), 8.89 (1H, dd, H^2). (Received May 9, 1988)

The reaction of 1-(disubstituted amino)-2,3-diphenylcyclopropenium salt with phenyl- and alkylmagnesium halides afforded, regioselectively, 1-aminocyclopropenes in good yields. The reactions of these 1-aminocyclopropenes were studied under acidic and nonacidic conditions to yield regioselective ring-opening products (C_2-C_3 and C_1-C_3 bond fissions of the cyclopropene) associated with the carbenium ions and carbene intermediates, respectively.

The chemistry of cyclopropene derivatives has attracted considerable interest due to the high strain energy associated with the unsaturated three-membered ring. A number of studies on the photochemical and thermal ring-opening reactions of cyclopropenes have appeared in recent years.[1-3] In a continuation of our studies on the cyclopropenes substituted with heteroatom groups, we have shown, for example, that a facile ring opening of 1-(methylthio)-2,3,3-triphenylcyclopropene via vinylcarbene intermediate at 50 °C, while 3-(methylthio)-1,2,3-triphenylcyclopropene is stable under similar reaction conditions (Scheme 1).[2a]

Here, we report on the preparation and regioselective acid-catalyzed and thermal ring-opening reactions of 1-aminocyclopropenes.

1-Aminocyclopropenium tetrafluoroborates **1a—e** were prepared in moderate-to-good yields by the reaction of diphenylcyclopropenone with triethyloxonium tetrafluoroborate, followed by treatments with secondary amines.[4-6] To a solution of phenylmagnesium bromide **2a** in tetrahydrofuran (THF) at room temperature was added 1-(diphenylamino)-2,3-diphenylcyclopropenium tetrafluoroborate **1a** in one portion; the mixture was stirred, giving a clean solution. After 10 min the resulting solution was poured on ice water and extracted with ether to give 1-(diphenylamino)-2,3,3-triphenylcyclopropene (**3a**) in a 92% yield. The structure **3a** was unambigously evident from its IR (1820 cm^{-1}) and ^{13}C NMR (s at δ=41.3 of sp^3 carbon of

C_3) spectra and comparisons of the data with those of the isomer 3-diphenylamino-1,2,3-triphenylcyclopropene (**6a**) prepared from triphenylcyclopropenium perchlorate[5] with diphenylamine (Scheme 3). None of the isomer **6a** was found in the Grignard reaction mixtures, indicating a regioselective nucleophilic attack of Grignard reagent **2a** to **1a**.

The reaction of **1a** with methyl-, ethyl-, and isopropylmagnesium halides **2b—d** yielded cyclopropenes **3b—d** in good yields. In contrast, the reactions of **2a** and the salt **1b—e** yielded two types of products, depending on the reaction conditions employed. Although the reaction of **1b** with **2a** in ether afforded 2-morpholinoindene **4e** in low yield, the use of THF as the reaction medium raised the yield of **4e** up to 41%, together with 1-morpholinoindene **5e**. The reaction at 60 °C afforded **5e**, exclusively, in moderate yield. Similar results were observed for the reaction of **1c—e** with **2a** (Table 1). Attempts to isolate cyclopropenes **3e—h** at low temperature, or direct isolation from the Grignard mixture without aqueous workup, failed, yielding 2-aminoindenes **4e—h** as sole reaction products. These results seem to indicate that the cyclopropenes substituted with relatively basic amino groups undergo a facile ring opening.

The cyclopropenes **3a—d** are relatively stable at room temperature in crystalline form. However, in a chloroform solution at room temperature **3a** afforded **4a** quantitatively, and upon refluxing in benzene for 5 h **5a** in 79% yield. The effect of hydrochloric acid formed from chloroform on the ring opening via the C_2–C_3 bond fission was proven by the conversion of **3a** to **4a** in benzene upon the addition of a small amount of concd HCl, trifluoroacetic acid, or even Lewis acids (Table 2).

Upon heating at reflux in methanol **3a** gave a mixture of aminal **9** and acetal **10** (failed to separate), both of which were converted to aldehyde **11**.[8] The formations of **9** and **10** are supposed to proceed by an insertion of a vinylcarbene to the OH bond of methanol,[2a] followed by methanolysis to yield **10**. A treatment of **3a** in methanol in the presence of acetic acid yielded only **4a** in a good yield.

The structures of indenes **4a** and **5a** were confirmed on the basis of their spectroscopic data as well as converting to 2-indanone **7** and 1*H*-inden-1-one **8**[7] by

hydrolysis or oxidation (Scheme 4). Similar spectra were obtained for all indenes **4** and **5**.

These two types of ring openings were also observed for cyclopropenes **3b—d** substituted with alkyl groups (Scheme 5 and Table 3). Although an addition of trifluoroacetic acid to solutions of **3b** and **3c** in benzene accelerated the ring opening to yield tarry mixtures, treatments of **3b** and **3c** in chloroform at room temperature yielded butadienes **12** in good yields. The isomer **3d** gave a resinous material under similar conditions. In contrast, upon heating in benzene at reflux **3b—d** afforded a mixture of 1-aminoindene **5** and butadiene derivative **14**. Aminobutadienes **12** and **14** were converted to the carbonyl derivatives, **13** and **15**, respectively, by acidic hydrolyses and their structures were confirmed. Ultraviolet irradiation of **15** gave a new set of ^{1}H NMR absorption corresponding to the stereo-

Scheme 5.

isomer of **15**. A shielding effect of the phenyl groups and NOE studies revealed the stereochemistry of **15** to be the *Z*-form.

These results indicate that two routes are possible for the ring opening of 1-amino-substituted cyclopropenes **3**, involving either a carbenium ion or carbene intermediates (Scheme 4). The protonation of **3a** and the fission of the C_2-C_3 bond via a well-known thermally allowed disrotatory ring opening might give a vinylcarbenium ion **A** stabilized by the neighbouring amino group,[9] followed by cyclization[10] to yield **4a**. The higher reactivity of **3e—h** (not isolated), whose amino groups are stronger bases than that of **3a**, seems to furnish intermediate **A**. Another process is the scission of the C_1-C_3 bond of **3a** to give the vinylcarbene intermediate **B**. Stabilization of the carbene by the contiguous amino group might facilitate the ring opening,[11] since tetraphenylcyclopropene rearranges at temperatures over 200 °C,[12] isomer **6** was recovered unchanged upon prolonged heating in refluxing benzene. Thus, the selection of the reaction conditions controls the regioselective ring opening of 1-aminocyclopropenes **3**. The facile ring opening found for phenylcyclopropenes (**3**: R=Ph), rather than alkylcyclopropenes **3b—d**, could be explained in terms of the resonance stabilization of intermediates **A** and **B** by the phenyl group.

Experimental

General. Melting points were uncorrected. The ^{13}C NMR spectra were recorded either on a JEOL JMN FX-60 spectrometer (15.04 MHz) or JEOL JNM FX-90Q (22.49 MHz) and ^1H NMR spectra on a Hitachi R-24B (60 MHz). The IR spectra were recorded on a JASCO A-3 spectrometer.

Preparation of 1-Amino-2,3-diphenylcyclopropenium Tetrafluoroborates (1). The salts **1** were prepared by a known method.[4-6]

The Reaction of 1 with Grignard Reagents 2. General Procedure. To a solution of phenylmagnesium bromide **2a** (3 mmol) in THF (20 cm^3) was added **1a** (1 mmol) in one portion; the mixture was stirred at room temperature for 10 min to yield a clear solution. The resulting solution was poured into cold water containing 1% of KH_2PO_4 and extracted with an appropriate solvent. The extract was dried over sodium carbonate, condensed in vacuo, and recrystallization from 2-propanol afforded the cyclopropene **3a** (extraction by ether or benzene) or 2-diphenylaminoindene **4a** (extraction by chloroform). Upon refluxing for 1 h, the Grignard reaction mixture yielded 1-diphenylaminoindene **5a** after a similar treatment as mentioned above. **3a**: mp 145—147 °C; IR (KBr) 1820 cm^{-1}; ^1H NMR ($CDCl_3$) δ=6.7—7.5 (m, 25H, 5Ph). ^{13}C NMR ($CDCl_3$) δ=41.7(s), 88.8(s), 120.4(s), 123.8(d), 124.7(d), 125.5(d), 125.9(d), 127.9(d), 128.3(d),128.4(d), 128.5(d), 128.7(d), 129.2(d), 144.2(s), and 145.1(s). Ring-Opening Reactions of 3. Cyclopropene **3a** was treated under various reaction conditions while checking the mixture by TLC at suitable time intervals. The usual treatment of the reaction mixture afforded crystalline products **4a** or **5a**. Reactions in methanol afforded resinous mass. The ^1H NMR spectra of the products indicated the presence of aminal **9** and acetal **10**. Attempts to separate these products by fractional crystallization, TLC, and CC failed. The hydrolysis of the crude mixture by aqueous hydrochloride (3 mol dm^{-3}) yielded 2,3,3-triphenylpropenal **11**: mp 176—178 °C (lit,[8] mp 175 °C); ^1H NMR ($CDCl_3$) 6.8—7.6 (m, 15H, 3Ph) and 9.65 (s, 1H, CHO); MS m/z 284(M^+).

Cyclopropenes **3b, c** were treated as follows.

(i) A solution of **3** (1 mmol) in chloroform (5 cm^3) was allowed to stay at room temperature. After the reaction, the crude product was chromatographed over silica gel or recrystallized. The results are given in Table 3. **12a**: oil; IR (KBr) 1600 cm^{-1}; ^1H NMR ($CDCl_3$) δ=5.19 (s, 1H, CH), 5.50 (s, 1H, CH), 6.40 (s, 1H, CH), and 6.7—7.5 (m, 20H, Arom). ^{13}C NMR ($CDCl_3$) δ=117.9(t), 120.9(d), 121.1, 121.6, 122.8, 125.2, 127.0, 127.3(d), 127.5(d), 127.8(d), 128.1(d), 128.5(d), 128.8(d), 129.2, 135.1(s), 141.1(s), 143.2(s), 145.3(s), and 148.1(s). Acidic hydrolyses of **12** afforded vinyl ketones **13** in quantitative yields. **13a**: oil; IR(neat) 1690 cm^{-1}; ^1H NMR ($CDCl_3$) δ=3.95 (s, 2H, CH_2), 5.80 (s, 1H, =CH), 6.05 (s, 1H, =CH), 6.6—8.0 (m, 10H, 2Ph). Found: C, 86.33; H, 6.32%; M^+, 222. Calcd for $C_{16}H_{14}O$: C, 86.45; H, 6.35%; M, 222. **13b**: oil; IR (neat) 1680 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.65 (d, J=7 Hz, 3H, Me), 3.80 (s, 2H, CH_2), and 6.7—7.6 (m, 10H, 2Ph). Found: C, 86.36; H, 6.89%; M^+, 236. Calcd for $C_{17}H_{16}O$: C, 86.40; H, 6.82%; M, 236.

(ii) A solution of **3** (1 mmol) in benzene (10 cm^3) was heated at reflux until the disappearance of the absorption at around 1800 cm^{-1} in IR spectrum. Evaporation of the solvent under reduced pressure and trituration with cold ethanol afforded crystalline 1-aminoindene **5** and oily 1-aminobutadiene **14**. The former product was recrystallized from ethanol. The latter oil was hydrolyzed with aqueous hydrochloric acid (3 mol dm^{-3}) at room temperature for one day. The chloroform extract gave crystalline aldehyde **15** from ethanol. The results are collected in Table 3. **14c**: mp 103—105 °C; IR (KBr) 1590 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.75 (s, 3H, Me), 2.08 (s, 3H, Me), 6.40 (s, 1H, CH), and 6.5—7.5 (m, 20H, 4Ph). ^{13}C NMR ($CDCl_3$) δ=22.5(q), 23.1(q), 122.3(d), 122.4(d), 125.7(d), 125.9(d), 127.0(d), 127.6(d), 128.4(d), 128.7(d), 129.6(d), 130.4(s), 132.3(s), 132.4(d), 137.2(s), 138.1(s), 142.4(s), and 145.9(s). Found: C, 89.54; H, 6.75; N, 3.71%; M^+, 401. Calcd for $C_{30}H_{27}N$: C, 89.78; H, 6.73; N, 3.49%; M, 401. **15a**: mp 128—130 °C; IR (KBr) 1660 cm^{-1};

^{1}H NMR ($CDCl_3$) 2.18 (s, 3H, Me), 7.0—7.7 (m, 10H, 2Ph), and 9.61 (s, 1H, CHO). Found: *m/z* 222.1039. Calcd for $C_{16}H_{14}O$: M, 222.1045. **15b**: mp 105—106 °C; IR (KBr) 1660 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.90 (t, *J*=7 Hz, 3H, Me), 2.51 (q, *J*=7Hz, 2H, CH_2), 7.0—7.6 (m, 10H, 2Ph), and 9.58 (1H, s, CHO). ^{13}C NMR ($CDCl_3$) δ=12.7(q), 30.2(t), 127.6(d), 128.3 (d), 128.7(d), 129.2(d), 129.7(d), 135.3(s), 137.8(s), 139.9(s), 165.0(s), and 193.2(s). Found: *m/z* 236.1181. Calcd for $C_{17}H_{16}O$: M, 236.1202.

Irradiation of **15a** in benzene with a high-pressure mercury lamp for 8 h gave an equilibrium mixture of two isomers (6:5). New signals ($CDCl_3$) were 2.57 (s, 3H, Me) and 10.35 (s, 1H, CHO). Similarly **15b** gave 1.18 (t, *J*=7 Hz, 3H, Me), 3.09 (q, *J*=7Hz, 2H, CH_2), and 10.37 (s, 1H, CHO) in 7:5.

Preparation of 3-Amino-1,2,3-triphenylcyclopropenes (6). A mixture of triphenylcyclopropenium perchlorate (2 mmol) and secondary amine (6 mmol) in benzene (30 cm^3) was stirred at room temperature for 2 h. In the reaction of diphenylamine 2 mmol of triethylamine was added. The product was recrystallized from benzene-petroleum ether. **6a** in 15% yield: mp 218—220 °C; IR (Nujol) 1810 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=6.5—8.2 (m, 25H, 5Ph). ^{13}C NMR (C_6D_6) δ=53.0(s), 118.0(s), 121.9(d), 123.5(d), 126.1(d), 128.1(d), 128.3(d), 128.5(s), 129.1(d), and 146.9(s). Found: C, 91.23; H, 5.79; N, 2.97%; M^+, 435. Calcd for $C_{33}H_{25}N$: C, 91.03; H, 5.75; N, 3.22%; M, 435. **6b** in 56% yield: mp 150—151 °C; IR (KBr) 1810 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=2.5—2.8 (m, 4H, CH_2NCH_2), 3.6—3.9 (m, 4H, CH_2OCH_2), and 7.1—7.9 (m, 15H, 3Ph). ^{13}C NMR ($CDCl_3$) δ=50.9(t), 54.4(s), 67.3(t), 119.5(s), 126.0(d), 127.2(d), 128.3(d), 128.9(d), 129.2(s), 129.8(d), and 144.1(s). Found: C, 85.26; H, 6.54; N, 3.99%; M^+, 353. Calcd for $C_{25}H_{23}NO$: C, 84.99; H, 6.52; N, 3.97%; M, 353. **6c**: in 65% yield: mp 128—130 °C; IR (KBr) 1800 cm^{-1}; ^{1}H NMR ($CDCl_3$) 1.3—1.9 (m, 6H, $(CH_2)_3$), 2.4—2.7 (m, 4H, CH_2NCH_2), and 7.0—7.8 (m, 15H, 3Ph). ^{13}C NMR ($CDCl_3$) δ=24.7(t), 26.8(t), 51.8(t), 54.9(s), 119.5(s), 125.8(d), 127.2(d), 128.3(d), 128.6(d), 128.9(d), 129.6(s), 129.8(d), and 145.0(s). Found: C, 88.59; H, 7.15; N, 3.82%; M^+, 351. Calcd for $C_{26}H_{25}N$: C, 88.89; H, 7.12; N, 3.99%; M, 351.

(Received June 8, 1988)

2,3-Diphenyl-, 2-methyl-3-phenyl-, and 2-methyl-3-(4-methylphenyl)cyclopropenone oxime hydrochlorides (**3**) were prepared in good yields from the corresponding cyclopropenones and hydroxylamine hydrochloride in methanol. The salts **3** reacted with alkyl and aryl isocyanates in the presence of triethylamine to afford 1:2 addition products 4,6-diazaspiro[2.3]hexenones in moderate yields. In contrast, acetone, acetophenone, and cyclohexanone oximes reacted with twice excess of methyl isocyanates to give linear 1:2 addition products and benzophenone oxime yielded only 1:1 addition product.

The physical and chemical properties of cyclopropenones, cyclopropenium ions, and triafulvenes have been of great interest and are currently being investigated[1] as microcyclic aromatics. In a continuation of our studies on the chemistry of cyclopropenium salts possesing heteroatom substituents[2] we have found an easy route for the preparation of cyclopropenone oximes; however, their chemical properties have not yet been well-explored.

Several studies have been repored on the reaction of diphenylcyclopropenone (**1a**) with hydroxylamine. Breslow[3] has shown that a reaction of **1a** with hydroxylamine hydrochloride **2** in aqueous ethanol yields deoxybenzoin oxime and diphenylisoxazolone. Kitahara[4] has obtained diphenylcyclopropenone oxime (**4a**) as colorless needles from **1a** and **2** in methanol, followed by treating with aqueous sodium hydrogencarbonate. On the other hand, Eicher has prepared 1-hydroxyamino-2,3-diphenylcyclopropenium tetrafluoroborate (**3a** as BF_4 salt) from 1-ethoxy-2,3-diphenylcyclopropenium salt and hydroxylamine.[5] However, only the reaction of **4a** with secondary amines has been shown.[6]

2,3-Diphenyl-, 2-methyl-3-phenyl-, and 2-methyl-3-(4-methylphenyl)cyclopropenone (**1a—c**) reacted easily with hydroxylamine hydrochloride **2** in methanol at room temperature for one day. The hydrochloride **3a** precipitated from the reaction mixture and the salts **3b, c** were obtained as a dichloromethane soluble products. The salts **3a—c** were colorless and stable at room temperature. Upon treating with aqueous sodium hydrogen carbonate or triethylamine yielded free diphenylcyclopropenone oxime **4a** as yellow needles in quantitative yield which were stable for a long-time storage at room temperature. However, the free oximes **4b, c** turned brown and decomposed at room temperature within one hour while giving a resinous mass. The structures of **3a—c** and **4a** were confirmed by IR, ^1H and ^{13}C NMR and mass spectroscopic studies. The NMR spectra ($CDCl_3$+CF_3CO_2H, 10:1) of **3b, c**, as shown in Table 1, revealed the presence of two isomers, corresponding to *E*- and *Z*-form, in nearly

Table 1. Yields and Physical Properties of Cyclopropenone Oxime Derivatives **3** and **4**

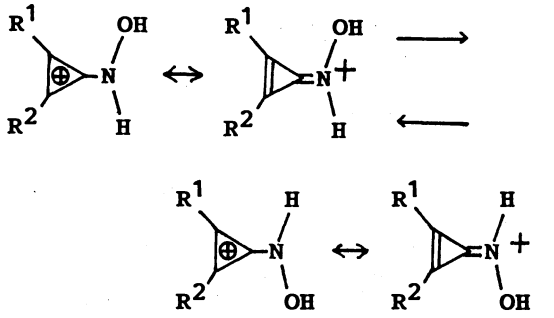
a) In a mixture of $CDCl_3$ and CF_3CO_2H (10:1). b) Yield from **3a**. c) Lit,[5] mp 116—116.5 °C. d) Insoluble in $CDCl_3$, methanol-d_4, or CD_2Cl_2.

equal amounts.



An equimolar reaction of **3a** with methyl isocyanate **5a** in the presence of triethylamine at room temperature gave 4-methyl-6-methylcarbamoyloxy-1,2-diphenyl-4,6-diazaspiro[2.3]hex-1-en-5-one (**6aa**) in a 40% yield. The use of twice excess moles of **5a** yielded **6aa** in a 75% yield. The structure of **6aa** was assigned from its ^{1}H and $^{13}CNMR$, and mass spectroscopic studies and chemical transformations. Thus, upon treating with potassium methoxide in methanol **6aa** afforded 3,3-diaminocyclopropene **7** in a 61% yield. An acidic hydrolysis of **7** gave **1a**, indicating the presence of the cyclopropene ring in **6aa** and **7** (Schemes 2 and 3). A similar treatment of **3a** at room temperature or **3b** at a lower temperature with two moles of **5** yielded spiro compounds **6** in moderate yields, as listed in Table 2. No 1 : 1 addition product could be isolated by us.

It has been well-known that aldoximes and ketoximes react with isocyanates **5** to yield carbamates.[7] To check these results the reaction of ketoximes **8** and **5a** was studied in the presence of triethylamine. The reactions of acetone oxime **8a** with **5a** in 1 : 1 and 1 : 2 molar ratios afforded carbamate-type products **9a** and **10a**, respectively, in moderate yields. Similarly, acetophenone oxime **8b** and cyclohexanone oxime **8d**

yielded the open-chain 1 : 2 addition products **10b, d**. However, the bulky benzophenone oxime **8c** gave no 1 : 2 addition product under similar reaction conditions (Scheme 4 and Table 2). None of the cyclic product was obtained from reactions of these oxime **8** with **5a**.

Although the isolation of (carbamoyloxyimino)cyclopropene **A**, a 1 : 1 addition product, failed, the intermediacy of **A** was clear from the final product **6**. The reaction of the highly polarized form **B** with **5** would be faster than that of **4** with **5**. Although it has been shown that some C=N derivatives react with **5** to afford the 1 : 1 cycloaddition products, 1,3-diazetidines,[6-8] to our knowledge no spiro derivatives, like **6**, have been reported. The marked difference in the products between **6** from **3** and **10** from **9** can be explained in terms of the polarization of imino nitrogens of oximes **B** and **9**. The highly polarized imino nitrogen of **B** facilitate the formation of **6**, while such activation was not observed for **9**.

Experimental

General. Melting points were uncorrected. The ^{13}C NMR spectra were recorded either on a JEOL JMN FX-60 spectrometer (15.04 MHz) or JEOL JNM FX-90Q (22.49 MHz) and ^1H NMR spectra on a Hitachi R-24B (60 MHz). The IR spectra were recorded on a JASCO A-3 spectrometer.

Preparation of 1-Hydroxyamino-2,3-diphenylcyclopropenium Chloride 3a and 4a. A solution of diphenylcyclopropenone **1a** (5.26 g, 25 mmol) and hydroxylamine

hydrochloride **2** (5.30 g, 76 mmol) in 30 cm^3 of methanol was allowed to stay at room temperature for a day. The precipitated salt **3a** was collected and washed with a small amount of cold methanol and dried under reduced pressure. The salt **3a** was treated with aqueous sodium hydrogencarbonate and extracted with dichloromethane. The extract was dried over sodium carbonate, condensed in vacuo, and recrystallization from methanol yielded diphenylcyclopropenone oxime **4a**. The physical properties are shown in Table 1.

Preparations of 3b and 3c. A solution of **1b** or **1c** (10 mmol) and **2** (10.5 mmol) in methanol (6 cm^3) was reacted at room temperature for one day. The solvent was removed in vacuo and the dichloromethane soluble product was separated. Trituration of the dichloromethane soluble mass with benzene afforded pure cyclopropenone oxime hydrochloride **3b** or **3c** (Table 1).

The Reaction of 3 with Isocyanates 5. A General Procedure. A mixture of **3** (2 mmol), **5** (2 mmol), and triethylamine (4 mmol) in dichloromethane (15 cm^3) was stirred well at appropriate temperature. The resulting solution was poured into cold water and an organic layer was separated. The extract was dried over sodium carbonate, condensed in vacuo, and recrystallized from ether-petroleum ether to give the spiro derivative **6**. **6aa**: mp 135—137 °C; IR (KBr) 3430, 1780, and 1720 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.59 (s, 3H, CNMe), 2.85 (d, J=6 Hz, 3H, NHMe), 6.13 (bs, 1H, NH), and 7.2—7.9 (m, 10H, 2Ph); ^{13}C NMR ($CDCl_3$) δ=26.5(q), 26.6(q), 65.7(s), 118.4(s), 125.9(s), 128.9(d), 129.9(d), 130.4(d), 155.4(s), and 160.0(s). The reactivities of 1-buten-3-yne derivatives toward hydroformylation were studied using a rhodium catalyst. Unexpectedly, cyclopentenone derivatives were obtained in moderate yields together with formyl-substituted dienes and unsaturated lactones. This reaction offers a new method for the catalytic synthesis of cyclopentenones. A mechanism for the cyclic carbonylation of enynes is also discussed.

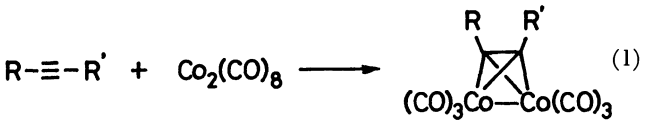
The transition-metal-catalyzed carbonylation of unsaturated compounds with carbon monoxide is one of the most important reactions in synthetic organic chemistry, and a number of reports have appeared so far.[1]

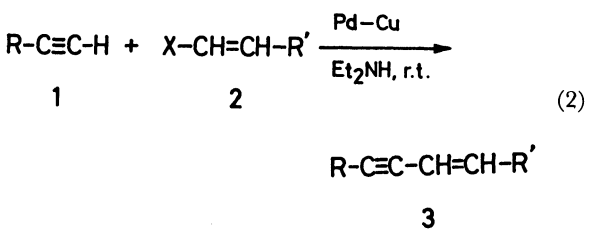
Using synthetic gas (H_2/CO), olefins are effectively carbonylated by the catalysis of such transition metal complexes as Co and Rh to yield the hydroformylated products (oxo process).[2] Although this method is applicable to a variety of olefins such as alkenes, acrylates, and dienes, the reports dealing with the hydroformylation of acetylenes are few. It is known that acetylenes show lower reactivities than olefins toward cobalt-catalyzed hydroformylation. This may be attributed to the formation of a stable cobalt-acetylene complex[3] (Eq. 1) resisting hydroformylation



(1)

under usual reaction conditions.[4] Under drastic conditions, i.e., higher reaction temperature and higher CO pressure, acetylenes are converted mainly to saturated aldehydes in analogy with the case of hydroformylation of olefins.[5]

Thus, we attempted to compare the reactivity of carbon-carbon triple bonds with that of double bonds toward hydroformylation. Enynes, R-C≡C-CH=CH-R′, are a suitable candidate for this purpose because they have carbon-carbon triple molecular bonds and double bonds. Moreover, a variety of their derivatives can be conveniently prepared from the palladium-catalyzed reaction (Eq. 2) which we reported previously.[6] Then, we have examined the

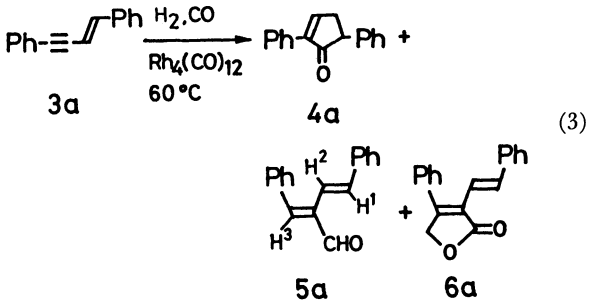


(2)

reactivity of the enynes toward rhodium-catalyzed hydroformylation, and found that the triple bonds are much more reactive than the double bonds and, unexpectedly, the cyclic enones are obtained in moderate yields which might be derived from the hydrocarbonylation of the acetylene group along with the participation of the olefinic part.[7] Here, we wish to report on the results in detail as well as the reaction mechanism.

Results and Discussion

Reactions of 1,4-Diphenyl-1-buten-3-yne (3a) under Hydroformylation Conditions. Enyne **3a** was reacted with carbon monoxide and hydrogen in the presence of a catalytic amount of $Rh_4(CO)_{12}$ at 60 °C. The reaction mixture was concentrated in vacuo and chromatographed on silica. Gradient elution by hexane-benzene gave three carbonylated products, **4a**, **5a**, and

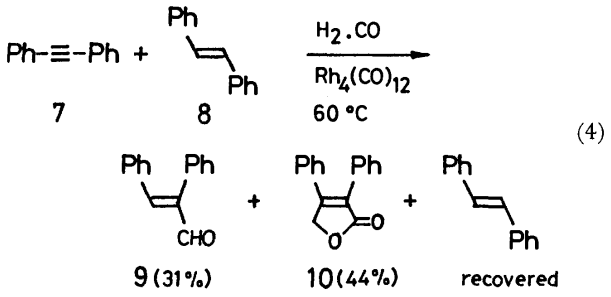


(3)

6a, together with a small amount of the recovered starting material (Eq. 3). One of them was identified as an unexpected cyclocarbonylation product, cyclopentenone **4a**, and others were a normal monoformylated compound **5a** and lactone **6a**. The structure of **4a** was determined by ^{1}H NMR, which showed a characteristic AMX pattern in the aliphatic region and a double-doublet at δ 7.96 (olefinic proton). The parent ion peak at m/z 234 in the mass spectrum and the CO stretching band at 1700 cm^{-1} in the IR spectrum are also consistent with the assigned structure of **4a**. The major product **5a** showed a CO stretch at 1695 cm^{-1} in the IR spectrum and a ^{1}H NMR signal at δ 9.65 (s),

indicating that this compound is α,β-unsaturated aldehyde. To confirm the structure, **5a** was led to 2,4-dinitrophenylhydrazone, which showed ^{1}H NMR signals at δ 7.07 (s) and 7.15 (d, J=16.5 Hz) attributable to H^3 and H^1, respectively. Product **6a** showed a parent ion peak at m/z 262 in the mass spectrum, indicating that two molecules of carbon monoxide and one molecule of hydrogen were introduced to the starting material. The IR spectrum exhibited ν_{CO} at 1760 cm^{-1} and the ^{1}H NMR spectrum signals appeared at δ 5.05 (s, 2H), 7.02 (d, 1H, J=16.3 Hz), and 8.98 (d, 1H, J=16.3 Hz). These spectral data indicate that **6a** has an unsaturated lactone ring and a trans-olefinic part; the structure was then defined as that shown in Eq. 3.

Cyclopentenone derivative **4a** is derived from the hydrocarbonylation of the acetylene group along with a participation of the olefinic part. On the other hand, formyl-substituted diene **5a** and lactone **6a** are formed by the carbonylation of just the acetylene group of **3a**; the olefinic moiety remains intact. This implies that the acetylenic part in the conjugated enynes is more reactive than the olefinic part under the hydroformylation conditions. This idea is also supported by a competitive reaction between diphenylacetylene (**7**) and



(4)

diphenylethylene (**8**), which gave only the carbonylated product derived from diphenylacetylene, whereas diphenylethylene was recovered, as shown in Eq. 4.

In order to investigate the effect of the partial pressure of carbon monoxide and hydrogen on the product distribution, **3a** was reacted at 60 °C under the conditions shown in Table 1. In these experiments, the total pressure was kept constant at 200 atm and the ratio of carbon monoxide to hydrogen was varied as shown in Table 1. The conversion and the product distribution are plotted against the partial pressure (Fig. 1). As can be seen from Fig. 1, the conversion of **3a** increases with the partial pressure of hydrogen. The selectivities for both **4a** and **5a** have a maximum point around a pressure of H_2/CO=1. Thus, the pressure dependence of the selectivity is commonly observed in hydroformylation reactions.[2] On the other hand, the selectivity of **6a** is almost constant to the H_2/CO ratio. This fact implies that the catalytic cycle producing compounds, **4a** and **5a**, would be different from that of **6a**, which will be discussed later.

In order to obtain further information on the reac-

Table 1. Partial Pressure Dependence of the Reactivity of **3a**[a)]

100	100	91	23	32	9
120	80	97	19	22	23

a) Reaction conditions: **3a**, 4.85 mmol; $Rh_4(CO)_{12}$, 0.027 mmol; benzene, 10 ml; 60 °C; 6 h. b) Isolated yields based on **3a** consumed.

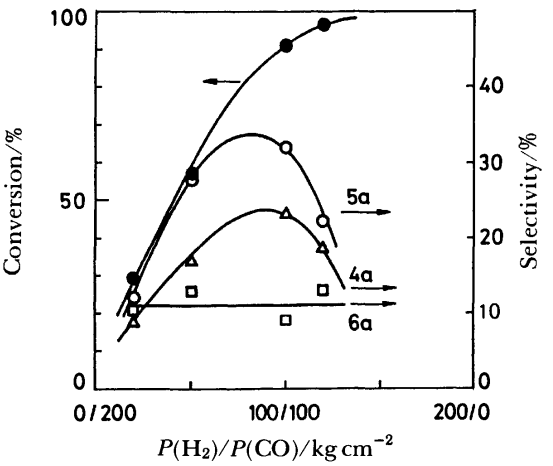

Fig. 1. Partial pressure dependence of conversion (●) and selectivity of **4a** (△), **5a** (○), and **6a** (□).

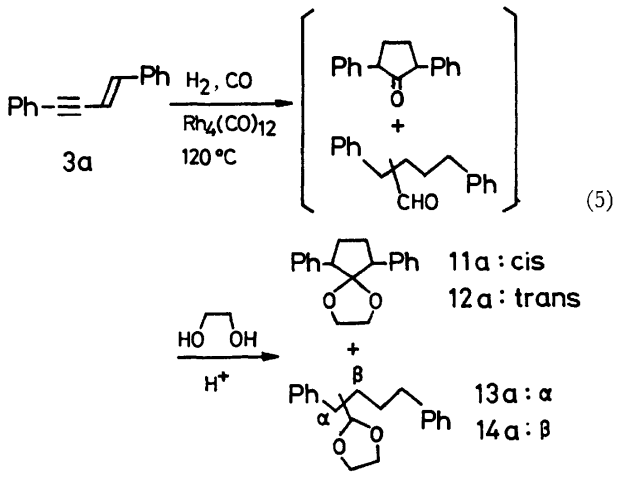
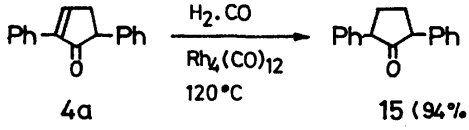
tion, the reaction temperature was increased to 120 °C. A direct isolation of the carbonylated products was so difficult in this case that the reaction mixture was first led to the stable acetals by treating with ethylene glycol in the presence of a catalytic amount of *p*-toluenesulfonic acid. Then, the resultant products were separated by silica column chromatography, giving four acetals **11a**—**14a** (Eq. 5). Thus, in this reaction at



(5)

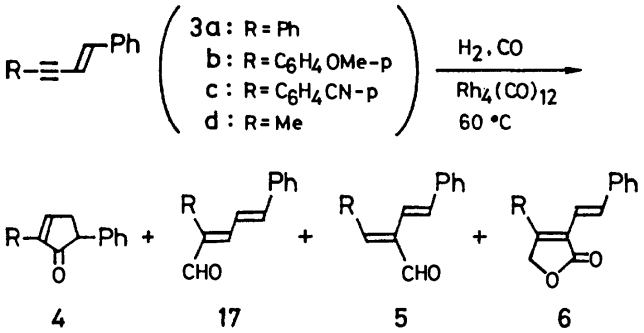
120 °C, saturated cyclic ketone and aldehyde were formed, meaning that **4a** and **5a** once formed would be hydrogenated at a higher temperature under the

hydroformylation conditions to give saturated aldehydes and kotones. In fact, **4a** was hydrogenated at 120 °C and gave 2,5-diphenylcyclopentanone (**15**) in an almost quantitative yield.



4a 15 (94%) (6)

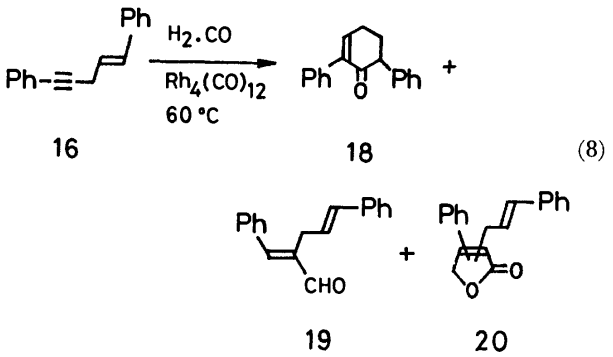
Reaction of Enynes other than 3a under the Hydroformylation Conditions. In order to examine the scope of the present reaction and to obtain information about the reaction mechanism, the hydroformylation of conjugated enynes **3b**, **3c**, and **3d**, and a nonconjugated enyne **16** was also carried out. The results are summerized in Table 2.



(7)

Of the enynes having aryl substituents at the acetylenic part (**3a**, **3b**, and **3c**), the reactivity increases with increasing the electron density of the acetylenic part: **3c**<**3a**<**3b**. But this electronic effect is not clearly reflected by the product distribution.[8] The methyl-substituted enyne **3d** showed a lower reactivity than the aryl substituted enynes and gave a different result: that not cyclopentenone derivative **4d** but (*E*,*E*)-α-formyldiene **17d** was formed with 19% selectivity. It is noteworthy that the latter **17** was not found among the products from the hydroformylation-yielding cyclopentenones. This phenomenon is discussed later.

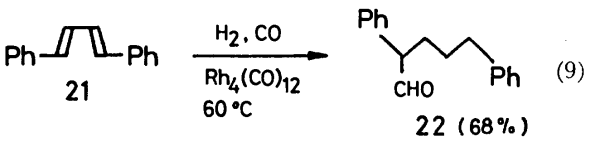
On the other hand, a nonconjugated enyne, 1,5-diphenyl-1-penten-3-yne (**16**), showed a similar reactivity to that of the conjugated ones toward hydroformylation, giving cyclohexenone **18**, 2-formyl-1,4-alkadiene **19**, and lactone **20** in 40, 11, and 18% selectivity, respectively (Eq. 8). This result indicates that the formation of cyclic enones does not require the conjugation of unsaturated bonds.



(8)

There are some examples[9–11] of carbonylations of enynes to afford cyclopentenones using cobalt carbonyl. The carbonylation of titana- or zirconacyclopentene complexes, obtained from the reaction of enynes with an equimolar amount of dichlorotitanium or zirconium complexes, also affords cyclopentenones in good yields.[12] With respect to these reactions, all of which being the stoichiometric syntheses from enynes, our method may be characterized in terms of the "catalytic" synthesis of cyclopentenones from the conjugated enynes, though the selectivity is not so high at the present stage.

Reaction Mechanism. First of all, in order to determine whether the formation of cyclic products is characteristic to the enynes, 1,4-diphenyl-1,3-butadiene (**21**), having the same carbon skeleton as enyne **3a**, was reacted under the same conditions as adopted for **3a**. At 60 °C, **21** gave only an α-monoformylated product **22** with 68% selectivity; no cyclization product was formed (Eq. 9). This suggests that the cyclization of



(9)

enynes does not pass through butadiene derivatives which might be formed under the conditions if the addition of hydrogen to the acetylenic part of enynes occurs during the first step. Thus, it should be emphasized that the cyclopentenone derivatives are formed directly from the conjugated enynes by the catalysis of the rhodium complex under the hydroformylation conditions.

As described above, the acetylenic part of enynes is thought to be more reactive than the olefinic one toward the rhodium-catalyzed hydroformylation based on judging the structure of the products. Therefore, the first attack of the rhodium carbonyl hydride species H-[Rh], presumably $HRh(CO)_3$, to the enynes may

Table 2. Conversion and Product Distribution for the Reaction of 3[a]

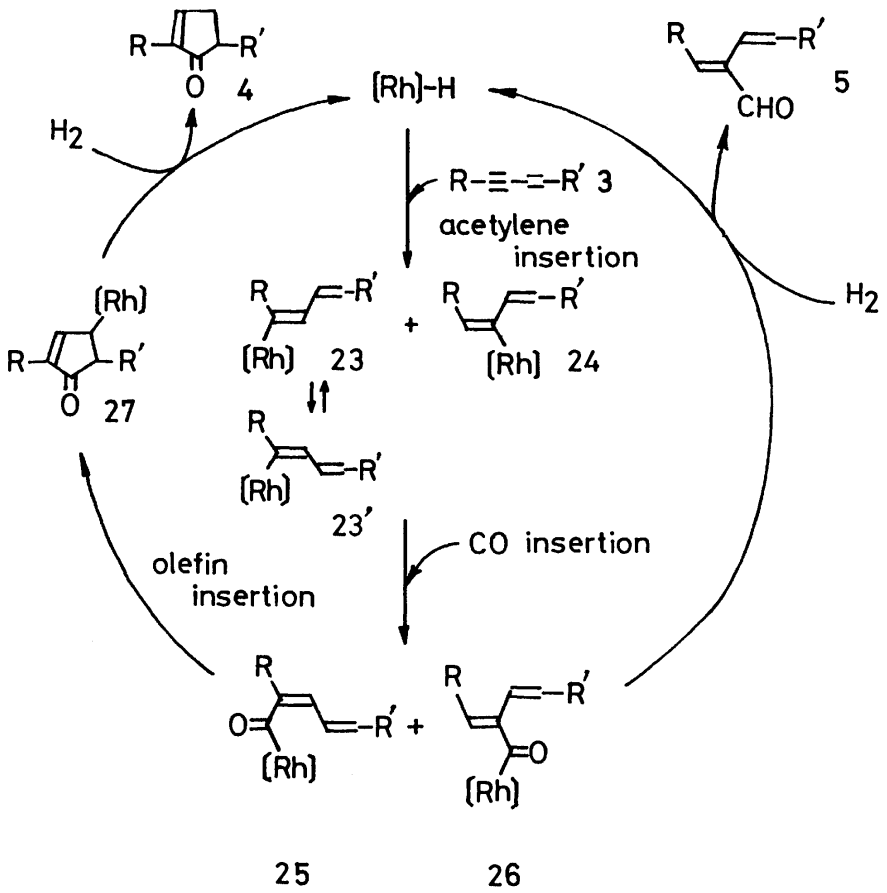
a) Reaction conditions: **3**, 4.85 mmol; $Rh_4(CO)_{12}$, 0.027 mmol; benzene, 10 ml; H_2, 100 atm; CO, 100 atm; 60 °C; 6 h. b) Isolated yields based on **3** consumed.



Scheme 1. Proposed reaction mechanism.

occur at the acetylenic part. On the basis of this assumption, a reaction mechanism giving **4** and **5** is proposed in Scheme 1.

The first step may be an insertion of the acetylenic part of the enyne to the Rh-H bond, which gives two η^1-diene intermediates, **23** and **24**, depending on the direction of Rh-H addition to the triple bond. They undergo a CO insertion during the next step, forming an isomeric pair of η^1-acyl intermediates, **25** and **26**. α-Acyl intermediate **25** would cyclize to give **27** by an intramolecular insertion of the olefinic part into the Rh-C bond, followed by a cleavage of the Rh-C bond by hydrogen or H-[Rh] to give cyclopentenone derivative **4**. On the other hand, since β-acyl intermediate **26** wouldn't be able to cyclize, due to the steric factor, it gives β-formyl diene **5** via the direct cleavage of **26** by the action of either H-[Rh] or hydrogen. Under the severer reaction conditions, these unsaturated products would suffer hydrogenation to give saturated products.

The formation of other products may be understood by the following reaction path. Thus, α-formyldiene **17**, which was obtained from the reaction of methyl substituted enyne **3d**, may be formed through intermediate **23** having (*E*,*E*)-diene structure. Whereas, cyclocarbonylation passing through **27** may require (*Z*,*E*)-diene structure **23'**. This suggests the isomerization of (*E*,*E*)-dienyl rhodium intermediate **23** to (*Z*,*E*)-isomer **23'**. Interchanges between (*Z*)- and (*E*)-alkenyl isomers have been reported concerning transition metal-alkenyls such as iron[13] and nickel[14] complexes. On the other hand, a reaction at 120 °C gave both cyclopentanone and saturated aldehyde **13a** (isolated as acetal), which was formed by hydrogenation of α-formyldiene, implying that the olefin insertion step of **25** may compete with the cleavage of the Rh-C bond by either H-[Rh] or hydrogen.

The mechanism yielding unsaturated lactone **6** is not clear at present. But it may be sure that the first step of the lactone formation would not involve an insertion of the acetylenic part to H-[Rh]. The unsaturated lactone ring is constructed by a carbon-carbon triple bond with two molecules of carbon monoxide and one molecule of hydrogen, and the carbon monoxide formally adds to the triple bond in cis-fashion. There are some reports on the formation of lactones from the transition metal-catalyzed carbonylation of acetylenes in alcoholic media.[15]

In the course of our study on the carbonylation of the enynes, we also found that the acetylenes give, selectively, unsaturated lactones under water gas shift conditions.[16] This suggests that the formation of **6** under hydroformylation conditions may be closely related to the presence of a small amount of water in the reaction mixture.

Experimental

General Methods. High-pressure work was carried out by using a stainless-steel autoclave.

Rhodium carbonyl, $Rh_4(CO)_{12}$, was prepared by methods described in the literature.[17] Solvents were distilled before use. The reagents were purified by either distillation or recrystallization.

Melting points were determined by Yanagimoto micro melting point apparatus and are uncorrected. Infrared spectra were recorded on a Hitachi 295 infrared spectrophotometer. Nuclear magnetic resonance spectra were run on a JEOL JNR-PMX 60SI or a Bruker AM-360. Chemical shifts are expressed in parts per million downfield from internal standard, tetramethylsilane. Mass spectra were obtained with JEOL JMS 06. Elemental analyses were performed by the Material Analysis Center, I. S. I. R., Osaka University.

Preparation of Enynes. Conjugated enynes were prepared by a reported method[6] and the preparation of new enynes, **3b** and **3c**, are described below. Non-conjugated enyne **16** was prepared by the reaction of (*E*)-1-phenyl-3-bromopropane with copper(I)-phenylacetylide in the presence of LiBr.[18]

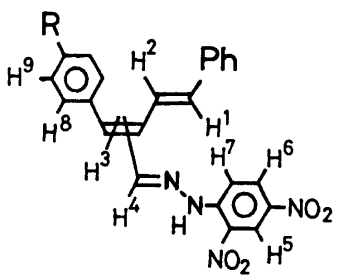
4-(4-Methoxyphenyl)-1-phenyl-1-buten-3-yne (3b). A solution of (4-methoxyphenyl)acetylene (2.0 g, 15.1 mmol), (*E*)-β-bromostyrene (2.8 g, 15.1 mmol), in diethylamine (30 ml) was placed in a 100 ml two-necked round-bottom flask. To the solution were added $PdCl_2(PPh_3)_2$ (35 mg) and CuI (10 mg). Then, the reaction mixture was stirred at room temperature under N_2 for 24 h. The precipitated $Et_2NH \cdot HBr$ was filtered off and washed several times with Et_2NH. The filtrate and the washing were combined and evaporated to dryness. The pale-yellow solid, thus obtained, was dissolved in a small amount of benzene and passed through a short alumina column to remove the catalyst. Elution with benzene gave a crude product, which was recrystallized from EtOH to yield 2.76 g (78%) of **3b**.

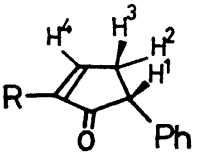
3b: Colorless fine needles from EtOH, mp 94—95 °C; ^{1}H NMR (360 MHz, $CDCl_3$) δ=3.81 (s, 3H, CH_3), 6.38 (d, 1H, PhCH=C<u>H</u>, *J*=16.2 Hz), 6.86 (bd, 2H, *o*-H to OCH_3, *J*=8.7 Hz), 6.99 (d, 1H, PhC<u>H</u>=CH, *J*=6.2 Hz), 7.2—7.5 (m, 9H, arom); IR (Nujol) 2190 cm^{-1}; Found: C, 86.89; H, 5.78%. Calcd for $C_{17}H_{14}O$: C, 87.15; H, 6.02%.

4-(4-Cyanophenyl)-1-phenyl-1-buten-3-yne (3c) was prepared similarly from the reaction of (4-cyanophenyl)acetylene with (*E*)-β-bromostyrene in 78% yield.

3c: Colorless needles from EtOH, mp 127—129 °C; ^{1}H NMR (360 MHz, $CDCl_3$) δ=6.37 (d, 1H, PhCH=C<u>H</u>, *J*=16.2 Hz), 7.10 (d, 1H, PhC<u>H</u>=CH, *J*=16.2 Hz), 7.3—7.45 (m, 5H, Ph), 7.5—7.62 (m, 4H, C_6H_4-CN, AA'BB'); IR (Nujol) 3230, 2210, 2095 cm^{-1}; Found: C, 89.28; H, 5.07; N, 6.10%. Calcd for $C_{17}H_{11}N$: C, 89.06; H, 4.84; N, 6.11%.

Reaction of Enynes. For an assignment of the spectra, the protons of cyclopentenones and 2,4-dinitrophenylhydrazone are numbered as shown below.





Reaction of 1,4-Diphenyl-1-buten-3-yne (3a) at 60 °C. A solution of **3a** (1.0 g, 4.9 mmol) and $Rh_4(CO)_{12}$ (20 mg, 0.027 mmol) in benzene (10 ml) was put into a 20 ml glass ampule, which was placed in a 100 ml stainless-steel autoclave. The autoclave was charged with 100 atm of carbon monoxide and 100 atm of hydrogen, and then shaken for 6 h at 60 °C. After cooling to room temperature, the reaction mixture was poured onto silica gel (2 g) and evaporated to dryness. It was then placed at the top of a column containing 30 g of silica gel. Gradient elution with hexane-benzene gave three carbonylated products, **4a** (23%), **5a** (32%), and **6a** (9%) together with a small amount of the starting material (90 mg; 91% conversion).

4a: Colorless columns from hexane, mp 75—76 °C; ^{1}H NMR (360 MHz, $CDCl_3$) δ=2.83 (ddd, 1H, H^2, J_{12}=2.8 Hz, J_{24}=2.8 Hz, J_{23}=19.8 Hz), 3.26 (ddd, 1H, H^3, J_{23}=19.8 Hz, J_{13}=7.1 Hz, J_{34}=3.0 Hz), 3.77 (dd, 1H, H^1, J_{12}=2.8 Hz, J_{13}=7.1 Hz), 7.1—7.6 (m, 10H, arom), 7.96 (dd, 1H, H^4, J_{24}=2.8 Hz, J_{34}=3.0 Hz); IR (Nujol) 1700 cm^{-1}; MS, *m/z* 234 (M^+); Found: C, 87.29; H, 5.74%. Calcd for $C_{17}H_{14}O$: C, 87.15; H, 6.02%.

5a: Pale-yellow viscous oil; IR (neat) 1695 cm^{-1}. This was led to 2,4-dinitrophenylhydrazone, **5a-(2,4-D)**, and purified by recrystallization.

5a-(2,4-D): Dark-brown crystals from benzene, mp 221—223 °C; ^{1}H NMR (360 MHz, $CDCl_3$) δ=7.07 (s, 1H, H^3), 7.15 (d, 1H, H^1, J_{12}=16.5 Hz), 7.3—7.5 (m, 11H, H^2 and Ph), 7.98 (d, 1H, H^5, J_{56}=9.6 Hz), 8.06 (s, 1H, H^4), 8.35 (dd, 1H, H^6, J_{67}=2.5 Hz, J_{56}=9.6 Hz), 9.17 (d, 1H, H^7, J_{67}=2.5 Hz), 11.32 (s, 1H, NH); IR (Nujol) 3280 1625, 1590, 1515, 1340, 1305, 745, 690 cm^{-1}; MS, *m/z* 414 (M^+); Found: C, 66.86; H, 4.10; N, 13.47%. Calcd for $C_{23}H_{18}N_4O_4$: C, 66.66; H, 4.38; N, 13.52%.

6a: Pale-yellow crystals from hexane-benzene, mp 114—115 °C; ^{1}H NMR (360 MHz, $CDCl_3$) δ=5.05 (s, 2H, CH_2), 7.02 (d, 1H, PhCH=C<u>H</u>, *J*=16.3 Hz), 7.25—7.5 (m, 10H, arom), 7.99 (d, 1H, PhC<u>H</u>=CH); IR (Nujol) 1760 cm^{-1}; MS, *m/z* 262 (M^+); Found: C, 82.13; H, 5.42%. Calcd for $C_{18}H_{14}O_2$: C, 82 42; H, 5.38%.

Reaction of 1,4-Diphenyl-1-buten-3-yne (3a) at 120 °C. In a similar manner to the procedure adopted for the reaction at 60 °C, **3a** was reacted with carbon monoxide and hydrogen in the presence of a catalytic amount of $Rh_4(CO)_{12}$ at 120 °C for 4 h. The reaction mixture was then placed into a 100 ml flask fitted with a Soxhlet extraction apparatus which was filled with Molecular Sieves 3A. To the solution were added ethylene glycol (0.30 g) and a catalytic amount of *p*-toluenesulfonic acid with an additional 20 ml of benzene. Then, azeotropic dehydration was continued under nitrogen for 4 h. The solution was cooled to room temperature, poured onto silica gel (3 g) and evaporated to dryness. It was then placed at the top of a column containing 30 g of silica gel. Gradient elution with hexane-benzene gave four acetals, in the order of increasing polarity, **11a** (8%), **12a** (7%), **14a** (26%), and **13a** (12%). **11a** and **12a** were further purified by recrystallization and **13a** and **14a** by microdistillation.

11a: Colorless columns from hexane, mp 106—107 °C; ^{1}H NMR (360 MHz, $CDCl_3$) δ=2.0—2.3 (m, 4H, C-CH_2-CH_2-C, A_2B_2), 2.96 (t, 2H, O-CH_2CH_2-O, *J*=6.3 Hz), 3.19 (t, 2H, O-CH_2CH_2-O, *J*=6.3 Hz), 3.42 (bt, 2H, PhC<u>H</u>, *J*=7.0 Hz), 7.2—7.4 (m, 10H, arom); IR (Nujol) 1600, 1200, 1055, 750, 700 cm^{-1}; MS, *m/z* 280 (M^+); Found: C, 81.63; H, 6.90%.

Calcd for $C_{19}H_{20}O_2$: C, 81.40; H, 7.19%.

12a: Colorless needles from hexane, mp 90.5—91.5 °C; ^{1}H NMR (360 MHz, $CDCl_3$) δ=2.06 (m, 2H, C-C$\underline{H}_2$CH$_2$-C), 2.20 (m, 2H, C-CH$_2$C$\underline{H}_2$-C), 2.96 (m, 2H, O-C$\underline{H}$H′), 3.28 (bt, 2H, PhC$\underline{H}$, J=10 Hz), 3.55 (m, 2H, O-CH$\underline{H}$′), 7.2—7.5 (m, 10H, arom); IR (Nujol) 1600, 1180, 1065, 960, 755, 700 cm^{-1}; MS, m/z 280 (M$^+$); Found: C, 81.36; H, 6.92%. Calcd for $C_{19}H_{20}O_2$: C, 81.40; H, 7.19%.

13a: Colorless oil; ^{1}H NMR (360 MHz, $CDCl_3$) δ=1.4—2.0 (m, 4H, PhCH$_2$C$\underline{H}_2$C$\underline{H}_2$-), 2.5—2.7 (m, 2H, PhC$\underline{H}_2$-), 2.83 (dt, 1H, C$\underline{H}$Ph, J=10.8, 4.5 Hz), 3.82 (m, 2H, OC$\underline{H}_2$C$\underline{H}_2$O), 4.98 (d, 1H, OCHO, J=4.5 Hz), 7.0—7.3 (m, 10H, arom); IR (neat) 1600, 1130, 1080, 1050, 1030, 740, 700 cm^{-1}; MS, m/z 282 (M$^+$); Found: C, 80.74; H, 6.88%. Calcd for $C_{19}H_{22}O_2$: C, 80.82; H, 6.78%.

14a: Colorless oil; ^{1}H NMR (360 MHz, $CDCl_3$) δ=1.6—2.1 (m, 3H, PhCH$_2$C$\underline{H}$C$\underline{H}_2$-), 2.6—3.0 (m, 4H, PhC$\underline{H}_2$CH), 3.85, 3.97 (m, 4H, OCH$_2$CH$_2$O), 4.82 (d, 1H, OCHO, J=3.5 Hz), 7.1—7.4 (m, 10H, arom); IR (neat) 1605, 1140, 1080, 1035, 750, 700 cm^{-1}; MS, m/z 282 (M$^+$); Found C, 80.80; H, 6.88%. Calcd for $C_{19}H_{22}O_2$: C, 80.82; H, 6.78%.

Reaction of 4-(4-Methoxyphenyl)-1-phenyl-1-buten-3-yne (3b). 3b was reacted at 60 °C in a similar manner to the procedure for the reaction of **3a**. The products were separated by column chromatography on silica to give three carbonylated products, **4b** (15%), **5b** (20%), and **6b** (12%).

4b: Colorless needles from hexane-benzene, mp 134—136 °C; ^{1}H NMR (360 MHz, $CDCl_3$) δ=2.80 (ddd, 1H, H^2, J_{12}=2.8 Hz, J_{24}=2.8 Hz, J_{23}=19.8 Hz), 3.24 (ddd, 1H, H^3, J_{13}=7.1 Hz, J_{23}=19.8 Hz, J_{34}=3.2 Hz), 3.74 (dd, 1H, H^1, J_{12}=2.4 Hz, J_{13}=7.1 Hz), 3.81 (s, 3H, -CH$_3$), 6.92 (d, 2H, H^6, J=8.7 Hz), 7.15—7.35 (m, 5H, -Ph), 7.73 (d, 2H, H^5, J=8.7 Hz), 7.87 (dd, 1H, H^4, J_{24}=2.8 Hz, J_{34}=3.0 Hz); IR (Nujol) 1700 cm^{-1}; MS, m/z 264 (M$^+$); Found: C, 82.04; H, 5.83%. Calcd for $C_{18}H_{16}O_2$: C, 81.79; H, 6.10%.

5b: Pale-yellow viscous oil; IR (neat) 1695 cm^{-1}. **5b** was led to 2,4-dinitrophenylhydrazone, **5b-(2,4-D)**, and purified by recrystallization.

5b-(2,4-D): Red crystals from benzene, mp 201—204 °C; ^{1}H NMR (360 MHz, $CDCl_3$) δ=3.87 (s, 3H, O-CH$_3$), 6.96 (d, 2H, H^9, J_{89}=8.8 Hz), 7.01 (s, 1H, H^3), 7.14 (d, 1H, H^1, J=16.5 Hz), 7.3—7.5 (m, 8H, -Ph, H^2, and H^8), 7.98 (d, 1H, H^7, J_{67}=9.5 Hz), 8.03 (s, 1H, H^4), 8.34 (dd, 1H, H^6, J_{56}=9.2 Hz, J_{67}=2.3 Hz), 9.17 (d, 1H, H^5, J_{56}=2.3 Hz), 11.3 (bs, 1H, NH); IR (Nujol) 3280, 1615, 1590, 1330, 1305, 1260, 1175, 1130, 755, 735 cm^{-1}; MS, m/z 444 (M$^+$); Found: C, 64.60; H, 4.33; N, 12.42%. Calcd for $C_{24}H_{20}N_4O_5$: C, 64.86; H, 4.54; N, 12.61%.

6b: Pale-yellow crystals from hexane-benzene, mp 123—125 °C; ^{1}H NMR (360 MHz, $CDCl_3$) δ=3.89 (s, 3H, O-CH$_3$), 5.07 (s, 2H, CH$_2$), 7.03 (m, 3H, Ph-CH=C$\underline{H}$ and 2H), 7.2—7.5 (m, 7H, arom), 7.95 (d, 1H, Ph-C$\underline{H}$=CH, J=16.2 Hz); IR (Nujol) 1745 cm^{-1}; MS, m/z 292 (M$^+$); Found: C, 78.05; H, 5.48%. Calcd for $C_{19}H_{16}O_3$: C, 78.06; H, 5.52%.

Reaction of 4-(4-Cyanophenyl)-1-phenyl-1-buten-3-yne (3c). 3c was reacted at 60 °C in a similar manner to the procedure for the reaction of **3a**. The products were separated by column chromatography on silica to give three carbonylated compounds **4c** (17%), **5c** (23%), and **6c** (6%) together with a small amount of the starting material (conversion: 70%).

4c: Pale yellow crystals from hexane-benzene, mp 134—136 °C; ^{1}H NMR (360 MHz, $CDCl_3$) δ=2.81 (m, 1H, H^3), 3.27 (m, 1H, H^2), 3.77 (dd, 1H, H^1, J=7.2, 2.5 Hz), 7.2—7.5 (m, 5H, Ph), 7.6—8.0 (m, 5H, H^4, H^5, and H^6); IR (Nujol) 2220, 1705 cm^{-1}; MS, m/z 259 (M$^+$); Found: C, 82.68; H, 4.73; N, 5.26%. Calcd for $C_{18}H_{13}NO$: C, 83.38; H, 5.05; N, 5.40%.

5c: Pale-yellow viscous oil, IR (neat) 1695 cm^{-1}. **5c** was led to the 2,4-dinitrophenylhydrazone, **5c-(2,4-D)**, and purified by recrystallization.

5c-(2,4-D): Dark-brown powder, mp 233—235 °C; ^{1}H NMR (360 MHz, $CDCl_3$) δ=7.03 (s, 1H, H^3), 7.35—7.5 (m, 6H, -Ph and H^2), 7.58 (d, 2H, H^8, J_{89}=8.4 Hz), 7.70 (d, 2H, H^9, J_{89}=8.4 Hz), 7.98 (d, 1H, H^7, J_{67}=9.6 Hz), 8.05 (s, 1H, H^4), 8.39 (dd, 1H, H^6, J_{67}=9.6 Hz, J_{56}=2.4 Hz), 9.18 (d, 1H, H^5, J_{56}=2.4 Hz), 11.35 (bs, 1H, NH); IR (Nujol) 3280, 2220, 1615, 1330, 1305, 1280, 1140, 1075, 740, 715 cm^{-1}; MS, m/z 439 (M$^+$); Found: C, 65.61; H, 3.98; N, 15.70%. Calcd for $C_{24}H_{17}N_5O_4$: C, 65.60; H, 3.90; N, 15.94%.

6c: Pale-yellow viscous oil; ^{1}H NMR (360 MHz, $CDCl_3$) δ=5.09 (s, 2H, CH$_2$), 6.93 (d, 1H, Ph-CH=C$\underline{H}$, J=16 Hz), 7.2—7.5 (m, 5H, -Ph), 7.61 (m, 2H, o-H to C=C), 7.82 (m, 2H, o-H to CN), 7.92 (d, 1H, Ph-C$\underline{H}$=CH, J=16 Hz); IR (neat) 1765 cm^{-1}; MS, m/z 287 (M$^+$).

Reaction of 1-Phenyl-1-penten-3-yne (3d). 3d was reacted at 60 °C in a similar manner to the procedure for the reaction of **3a**. The products were separated by column chromatography on silica gel to give three carbonylated compounds, **5d** (17%), **17** (19%), and **6d** (20%) together with the unreacted starting material (conversion: 49%).

5d: Pale-yellow viscous oil. **5d** was led to the 2,4-dinitrophenylhydrazone, **5d-(2,4-D)**, and purified by recrystallization.

5d-(2,4-D): Orange powder from benzene, mp 191—193 °C; ^{1}H NMR (360 MHz, $CDCl_3$) δ=2.12 (d, 3H, CH$_3$), 6.25 (q, 1H, H^3, J=7.2 Hz), 7.02 (d, 1H, H^1, J_{12}=16.5 Hz), 7.27 (d, 1H, H^2, J_{12}=16.5 Hz), 7.3—7.53 (m, 5H, Ph), 7.86 (s, 1H, H^4), 7.93 (d, 1H, H^7, J_{67}=9.6 Hz), 8.33 (dd 1H, H^6, J_{56}=2.5 Hz, J_{67}=9.8 Hz), 9.16 (d, 1H, H^5), 11.17 (s, 1H, N); IR (Nujol) 3270, 1620, 1590, 1330, 1305, 1260, 1215, 1115, 755, 745 cm^{-1}; MS, m/z 352 (M$^+$); Found: C, 61.40; H, 4.48; N, 15.65%. Calcd for $C_{18}H_{16}N_4O_4$: C, 61.36; H, 4.58; N, 15.90%.

17: Pale-yellow solid. **17** was led to the 2,4-dinitrophenylhydrazone, **17-(2,4-D)**, and purified by recrystallization.

17-(2,4-D): Dark-red crystals from benzene, mp 232—234 °C; ^{1}H NMR (360 MHz, $CDCl_3$) δ=2.20 (s, 3H, CH$_3$), 6.62 (bd, 1H, H^3, J=10.3, 1 Hz), 6.80 (d, 1H, H^1, J=15.5 Hz), 7.23 (dd, 1H, H^2, J=10.5, 15.4 Hz), 7.3—7.5 (m, 5H, Ph), 7.82 (s, 1H, H^4), 7.99 (d, 1H, H^7, J_{67}=9.6 Hz), 8.33 (dd, 1H, H^6, J_{67}=9.6 Hz), 9.15 (d, 1H, H^5), 11.26 (s, 1H, NH); IR (Nujol) 3280, 1620, 1590, 1330, 1300, 1265, 1205, 1135, 1075, 970, 745 cm^{-1}; MS, m/z 352 (M$^+$); Found: C, 61.02; H, 4.29; N, 15.91%. Calcd for $C_{18}H_{16}N_4O_4$: C, 61.36; H, 4.58; N, 15.90%.

6d: Colorless crystals from hexane-benzene, mp 132.5—133.5 °C; ^{1}H NMR (360 MHz, $CDCl_3$) δ=2.20 (s, 3H, CH$_3$), 4.71 (s, 2H, CH$_2$), 6.79 (d, 1H, C$\underline{H}$=CH-Ph, J=16.3 Hz), 7.2—7.5 (m, 5H, Ph), 7.77 (d, 1H, CH=C$\underline{H}$-Ph, J=16.3 Hz); IR (Nujol) 1750 cm^{-1}; MS, m/z 200 (M$^+$); Found: C, 77.54; H, 6.00%. Calcd for $C_{13}H_{12}O_2$: C, 77.98; H, 6.04%.

Reaction of 1,5-Diphenyl-1-penten-4-yne (16). 16 was reacted at 60 °C in a similar manner to the procedure for the reaction of **3a**. The products were isolated by column chromatography on silica gel to give carbonylated compounds, **18** (40%), **19** (11%), and **20** (18%) together with the unreacted starting material (conversion: 45%).

18: Colorless crystals from hexane, mp 72—74 °C; ^{1}H NMR (360 MHz, $CDCl_3$) δ=2.0—2.2 (m, 1H, Ph-CH-CHH′), 2.5—2.7 (m, 1H, Ph-CH-CHH′), 2.9—3.1 (m, 1H, =CH-CHH′), 3.1—3.2 (m, 1H, =CH-CHH′), 3.61 (dd, 1H, Ph-CH, J=9.7, 10 Hz), 7.2—7.6 (m, 11H, Ph and C=CH); IR (Nujol) 1725 cm^{-1}; MS, m/z 248 (M^+); Found: C, 87.21; H, 6.80%. Calcd for $C_{18}H_{16}O$: C, 87.06; H, 6.49%.

19: Pale-yellow viscous oil; IR (neat) 1685 cm^{-1}. **19** was led to 2,4-dinitrophenylhydrazone, **19-(2,4-D)**, and purified by recrystallization.

19-(2,4-D): Orange-red powder from benzene, mp 218—220 °C; ^{1}H NMR (360 MHz, $CDCl_3$) δ=3.65 (bd, 2H, CH_2, J=5.5 Hz), 6.46 (dt, 1H, H^2, J=5.2, 16 Hz), 6.54 (d, 1H, H^1, J=16 Hz), 7.03 (s, 1H, H^3), 7.2—7.5 (m, 10H, Ph), 7.95 (s, 1H, H^4), 7.95 (d, 1H, H^7, J_{67}=9.5 Hz) 8.29 (dd, 1H, H^6, J_{67}=9.5 Hz, J_{56}=2.3 Hz), 9.14 (d, 1H, H^5), 11.27 (s, 1H, NH); IR (Nujol) 3280, 1610, 1325, 1120, 1085, 750 cm^{-1}; MS, m/z 428 (M^+); Found: C, 67.27; H, 4.64; N, 12.90%. Calcd for $C_{24}H_{22}N_4O_4$: C, 67.28; H, 4.71; N, 13.08%.

20 was a mixture of two isomeric lactones and unable to separate each of the isomers by column chromatography.

20: Pale-yellow viscous oil; ^{1}H NMR (360 MHz, $CDCl_3$) δ=3.43 and 3.49 (d/d, 2H/2H, =C-CH_2-C= for two isomers, J=6.1 Hz/6.7 Hz), 4.85 and 5.09 (s/s, 2H/2H, O-CH_2 for two isomers), 6.18 and 6.32 (dt/dt, 1H/1H, Ph-CH=CH for two isomers, J=15.8, 6.7 Hz/J=15.9, 6.1 Hz), 6.47 and 6.50 (d/d, 1H/1H, Ph-CH for two isomers, J=15.8 Hz/J=15.8 Hz), 7.2—7.6 (m/m, 10H/10H, Ph for two isomers); IR (Nujol) 1770 cm^{-1}; MS, m/z 276 (M^+).

Reaction of 1,4-Diphenyl-1,3-butadiene (21) at 60 °C. 21 (1.0 g, 4.85 mmol) was reacted at 60 °C in a similar manner to the procedure for the reaction of **3a**. After a reaction for 6 h, the reaction mixture was poured to silica gel (1.5 g) and concentrated to dryness. Then, the silica gel was put onto the top of a column containing 20 g of silica gel. Elution by hexane-benzene gave 0.54 g of unreacted **21** (conversion: 46%) and 0.36 g (68% based on **21** consumed) of monoformylated product, **22**.

22: Colorless oil; ^{1}H NMR (60 MHz, $CDCl_3$) δ=1.1—2.1 (m, 4H, Ph-CH_2-(CH_2)$_2$), 2.55 (t, 2H, Ph-CH_2, J=7 Hz), 3.45 (dt, 1H, Ph-CH, J=7, 1 Hz), 7.1—7.5 (m, 10H, Ph), 9.55 (d, 1H, CHO, J=1 Hz); IR (neat) 1735 cm^{-1}. The structure of **22** was also supported by a comparison with the hydrated product of acetal **13a**.

Competitive Reaction between Diphenylacetylene (7) and *trans*-Stilbene (8). An equimolar mixture of **7** (0.86 g, 4.85 mmol) and **8** (0.87 g, 4.85 mmol) was reacted at 60 °C in a similar manner to the procedure for the reaction of **3a**. After a reaction for 6 h, the reaction mixture was evaporated to dryness and chromatographed on silica gel, giving two carbonylated products **9** and **10** in 31 and 44% yields, respectively, which were derived from **7**, while **8** was recovered almost quantatively.

Reaction of Cyclopentenone (4a) at 120 °C. 4a (210 mg) was treated at 120 °C in a similar manner to the procedure for the reaction of **3a**. After a reaction for 4 h, the reaction mixture was passed through a short column of alumina and the eluent was evaporated to dryness, affording 200 mg (94%) of cyclopentanone **15a**.

15a:[19] Colorless crystals from hexane, mp 75—80 °C; *^{1}H NMR (60 MHz, $CDCl_3$) δ=1.9—2.7 (m, 4H, -CH_2-CH_2-),* 3.5 (m, 2H, CH), 7.2—7.5 (m, 10H, Ph); IR (Nujol) 1775 cm^{-1}; MS, m/z 236 (M^+).

The authors wish to express their thanks to Drs. Hiroshi Yamazaki and Pangbu Hong, the Institute of Physical and Chemical Research, for their helpful discussions. We also wish to thank Mr. Osamu Nakanishi, Sekisui Chemical Co. Ltd., for his continuous encouragement. We are grateful to The Material Analysis Center, I. S. I. R., Osaka University, for spectral measurement and microanalysis.

Synthesis and Absolute Configuration of the Acetalic Lignan (+)-Phrymarolin I

Fumito ISHIBASHI and Eiji TANIGUCHI*
Department of Agricultural Chemistry, Faculty of Agriculture, Kyushu University, 6-10-1 Hakozaki, Higashi-ku, Fukuoka 812
(Received June 24, 1988)

The natural (+)-phrymarolin I was stereoselectively synthesized and its absolute configuration was unequivocally determined as being (1*S*,2*S*,5*R*,6*S*)-1-acetoxy-2-(2-methoxy-4,5-methylenedioxyphenoxy)-6-(2-methoxy-4,5-methylenedioxyphenyl)-3,7-dioxabicyclo[3.3.0]octane.

The unique lignans of *Phryma leptostachya* L., phrymarolin I and II, are the first examples of naturally occurring 1,2-dioxygenated 3,7-dioxabicyclo-[3.3.0]octanes.[1] Recently, their congeners, including desacetylphrymarolin III and higher insecticidal sesquilignans,[2] were isolated from the same plant. Concerning the development of new pesticides, we are interested in their absolute configurations and syntheses.

A structure involving the relative configuration of phrymarolin I (**1a**) was proposed on the basis of chemical and spectroscopic information.[1] A total synthesis and a consequent establishment of the whole stereochemistry of (+)-phrymarolin I have recently been communicated.[3] Full details of this work will be described herein.

The strategy for the synthesis is basically the same as that for the syntheses of racemic phrymarolin II and its stereoisomers[4] (Fig. 1); the 1-hydroxy-6-aryl-2-aryloxy-3,7-dioxabicyclo[3.3.0]octane skeleton (**1a**) was constructed from β-vinyl-γ-butyrolactone, 2-methoxy-4,5-methylenedioxybenzaldehyde and 2-methoxy-4,5-methylenedioxyphenol. However, we found that cadmium carbonate-catalyzed condensation[5] of the chloride (**2**) with 2-methoxy-4,5-methylenedioxyphenol (**4**), not as well as sesamol, only gave the undesirable 2α-epimer (**1b**) in low yield (14%). A synthesis of 2β-epimer was achieved by extending the stereocontrolled glycosylation method, developed by Mukaiyama et al., using glycosyl fluoride and tin(II) chloride.[6] The new method improved 2β-isomer production and prevented an epimerization at the C-6 position.

The chiral starting substance, (*S*)-(+)-β-vinyl-γ-butyrolactone, was prepared from its racemate[7] by optical resolution, as shown in Fig. 2. Aminolysis of (±)-**5** with (*S*)-(−)-α-methylbenzylamine in the presence of trimethylaluminium[8] in dichloromethane gave an oily mixture of the hydroxy amides (**7a** and **7b**) in 56% combined yield. The diastereomers were separated by repeated liquid chromatography on silica gel with 3 vol% isopropyl alcohol in benzene as the eluent. Purely isolated **7a** was subjected to alkaline hydrolysis followed by lactonization with an azeotropic removal of the water to afford (+)-**5** in 58% yield. In the same manner as mentioned above, another diastereomer (**7b**) was converted to (−)-**5** in 64% yield. The absolute stereochemistry of the two enantiomeric lactones was unknown at this stage. Hydrogenation of the lactone [(+)-**5**], followed by reduction with lithium aluminium hydride gave the enantiomer, (*R*)-(+)-**8**, $[\alpha]_D$ +14.3° ($CHCl_3$), whereas another lactone [(−)-**5**] led to the opposite enantiomer, (*S*)-(−)-**8**, $[\alpha]_D$ −13.0° ($CHCl_3$). Their absolute configurations were assigned by a comparison of their optical rotations with that of

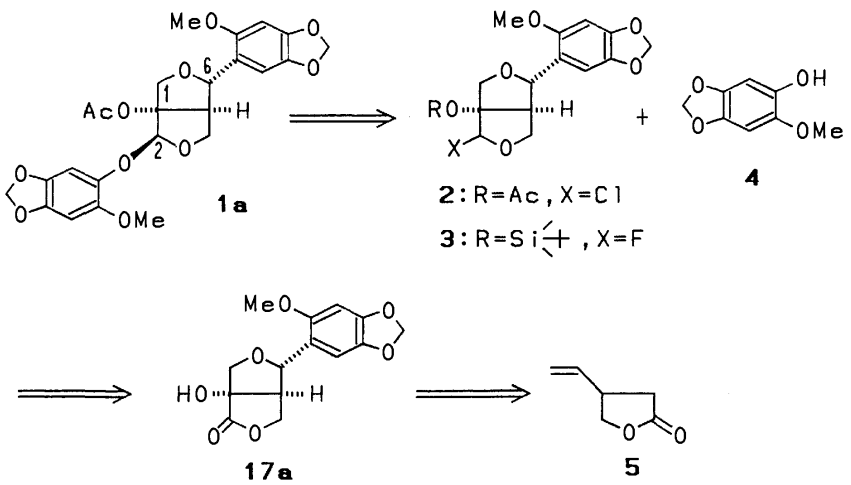

Fig. 1.

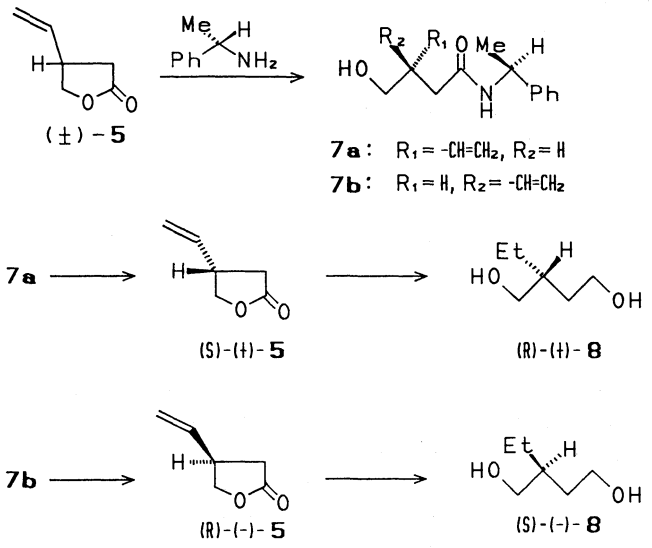

Fig. 2.

the diol (*R*)-(+)-**8** of which configuration was known, $[\alpha]_D$ +7.7° (neat).[9] The stereochemistries of (+)-**5** and (−)-**5** were defined as an (*S*)- and (*R*)-configuration, respectively.

The addition of the lithium enolate of (*S*)-(+)-**5** generated by lithium diisopropylamide (LDA) to 2-methoxy-4,5-methylenedioxybenzaldehyde (**6**) in tetrahydrofuran at −75 °C afforded the erythro and threo aldols (**9**) in 98% yield in the ratio of 65/35 (based on NMR), respectively. Due to the steric repulsion of the vinyl moiety of **5**, the reaction was supposed to be favorable to the (2*R*, 3*S*)-*trans* isomers. Without separation, the mixture was silylated with *t*-butyldimethylsilyl triflate[10] in the presence of 2,6-lutidine in dichloromethane at −30 °C (92% yield), and the silylated lactone was reduced with lithium aluminium hydride in a mixture of ether and tetrahydrofuran (2 : 1) at −10 °C to give the diol (**11**) in 82% yield. The terminal olefin of **11** was oxidized to the carbonyl function by successive oxidation with a catalytic amount of osmium tetraoxide and *N*-methylmorpholine *N*-oxide[11] in a

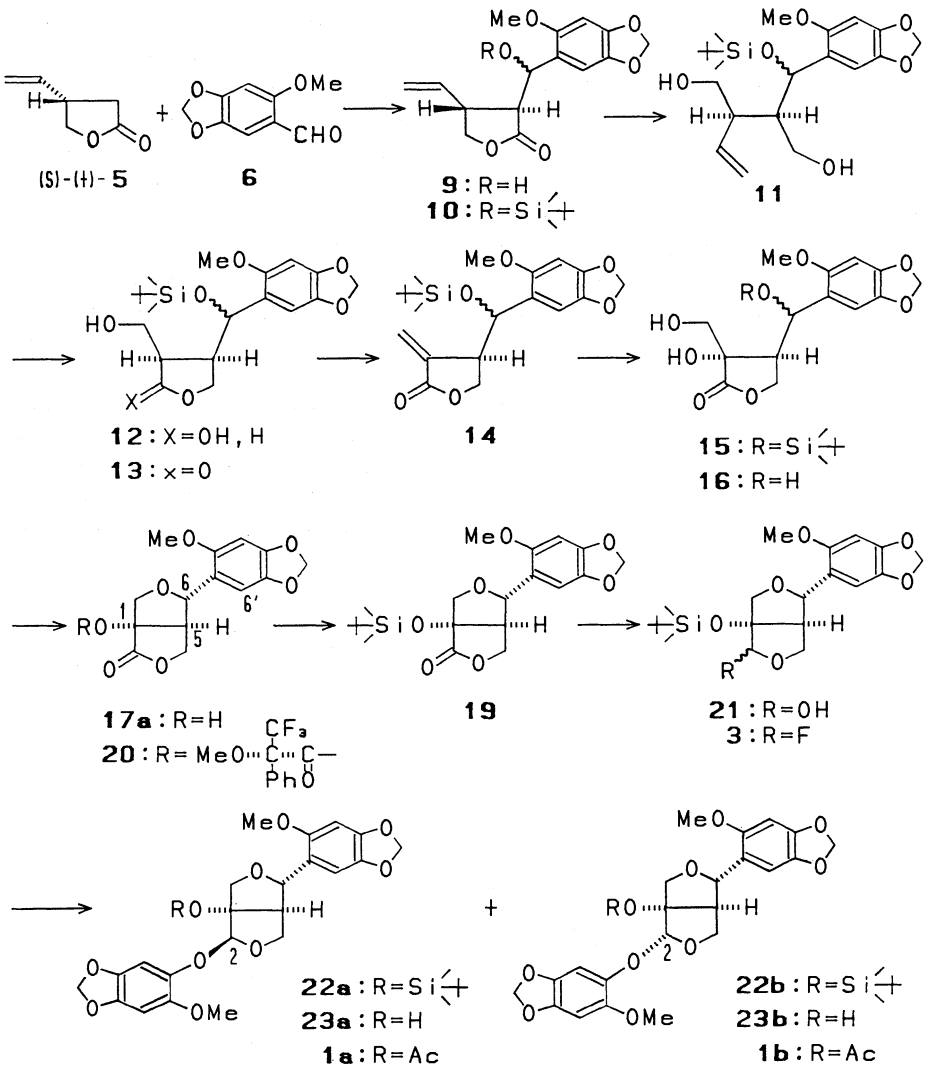

Fig. 3.

mixture of acetone, *t*-butyl alcohol and water at room temperature, followed by sodium periodate in a mixture of ethyl acetate and water. The lactol (**12**) was oxidized to the lactone (**13**) with silver carbonate on Celite in refluxing benzene in 91% overall yield from **11**. After sulfonylation of the primary hydroxyl group in **13** with mesyl chloride, the unstable mesylate was immediately treated with 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) in benzene at room temperature to furnish the methylene lactone (**14**) in 87% yield. Dihydroxylation with catalytic osmium tetraoxide and *N*-methylmorpholine *N*-oxide[11] in a mixture of acetone, *t*-butyl alcohol and water quantitatively gave the 2α-diol (**15**) in high stereoselectivity, resulting from an exclusive attack of the reagent to the less hindered α-face of the molecule.

After removing the *t*-butyldimethylsilyl group with tetrabutylammonium fluoride in tetrahydrofuran at 0 °C, the resulting triol (**16**) was subjected to dehydrative cyclization with a catalytic amount of 10-camphorsulfonic acid (CSA) in dichloromethane at room temperature to afford the key intermediate (**17a**) in 59% yield, along with a 10% recovery of **15**.

It should be noted that both erythro and threo isomers of **16** afforded **17a** (6α) as the sole product via the thermodynamically preferable common transition state (**18a**), since the alternative transition state (**18b**), leading to **17b** (6β), was destabilized by the 1,3-diaxial interaction between the aromatic ring and the C-4 methylene group (Fig. 4). Under strongly acidic conditions, e.g., with diethyl ether-boron trifluoride (1/1) in dichloromethane or hydrogen chloride in tetrahydrofuran, the cyclization gave a mixture of **17a** and **17b**, probably due to the isomerization of **17a** under the conditions.

After recrystallizing **17a** from a mixture of benzene and diisopropyl ether, the lactone alcohol, $[\alpha]_D$ +67.3° ($CHCl_3$), was derivatized to the ester of α-methoxy-α-(trifluoromethyl)phenylacetic acid (MTPA) according to Mosher et al.[12] The ^{1}H NMR spectrum of the (*S*)-(−)-MTPA ester was measured at 400 MHz; the aromatic proton (6′-H) of the (1*S*, 5*R*, 6*S*)-(*S*)-ester resonated at a higher field (6.73 ppm) than that of the diastereomeric (1*R*, 5*S*, 6*R*)-(S)-ester (6.97 ppm), indicating the optical purity (96% e.e.).

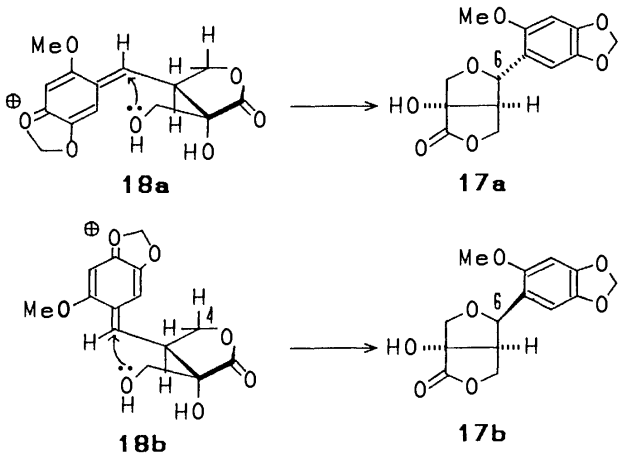

Fig. 4.

The crude sample of (+)-**17a** was treated with *t*-butyldimethylsilyl triflate and 2,6-lutidine[10] in dichloromethane (85% yield), and the resulting silyl ether (**19**) was reduced to the lactol (**21**) in 98% yield with diisobutylaluminium hydride (DIBAL) in toluene at −75 °C. The lactol was fluorinated in 92% yield with 2-fluoro-1-methylpyridinium tosylate and triethylamine[6] in dichloromethane, and the unstable fluoride (**3**) was immediately reacted with 2-methoxy-4,5-methylenedioxyphenol (**4**)[13] in the presence of tin(II) chloride, trityl perchlorate[6] and 4A Molecular Sieves in ether at 0 °C. A mixture of 2β-/2α-isomer, **22a** and **22b**, was obtained in 50% combined yield (**22a**/**22b**= 33/67, based on NMR). Desilylation of the mixture with tetrabutylammonium fluoride in tetrahydrofuran and separation of the products by preparative TLC on silica gel furnished (+)-**23a** and (−)-**23b** in 11 and 29% yields from **3**, respectively (Fig. 3). The optical purity of (+)-**23a** was estimated to be 85% e.e. on the basis of the 400 MHz ^{1}H NMR spectrum of its (*S*)-(−)-MTPA ester.

The rather low optical yield may have resulted from contamination due to the unseparated diastereomer, (2*S*, 3*S*)-*cis*-**9**, produced by the aldol condensation of the benzaldehyde and vinylbutyrolactone during the first step of the synthesis. The (2*S*, 3*S*)-*cis* isomer should give the enantiomeric intermediate, (1*S*, 5*S*, 6*R*)-**17a** and (1*R*, 2*R*, 5*S*, 6*R*)-(−)-phrymarolin I in the following reactions.

Finally, the target molecule (1*S*, 2*S*, 5*R*, 6*S*)-**1a**, $[\alpha]_D$ +106.9° (dioxane), was obtained by acetylation of (+)-**23a** in acetic anhydride containing a small excess of 4-(dimethylamino)pyridine (DMAP). The optical rotation of natural **1a** was $[\alpha]_D$ +131.3° (dioxane). Although the synthesized (+)-**1a** was optically impure, the present synthesis unambiguously established the (1*S*, 2*S*, 5*R*, 6*S*)-configuration of the natural and dextrorotatory phrymarolin I.

Experimental

All melting points and boiling points are uncorrected. IR spectra were determined on a Shimadzu IR-420 spectrophotometer. Unless stated otherwise, ^{1}H NMR spectra were measured in $CDCl_3$ on a JEOL FX-100 spectrometer. Mass spectra were performed by an ESCO FMD-05A spectrometer at 70 ev. Optical rotations were determined on a Union Giken PM-101 polarimeter.

Gravity column chromatography and medium-pressure liquid chromatography were performed with Merck silica gel 60 (70—230 mesh ASTM) and Merck LiChroprep Si 60 (40—63 μm), respectively. TLC was performed on precoated silica-gel plates 60 F_{254} (0.25 mm or 0.5 mm thickness) supplied by E. Merck. Anhydrous sodium sulfate was used for drying solutions.

Optical Resolution of β-Vinyl-γ-butyrolactone. To a solution of (*S*)-(−)-α-methylbenzylamine (10.82 g, 89.2 mmol) in dry CH_2Cl_2 (300 ml) was added a 1 mol dm^{-3} solution of Et_3Al in hexane (90.0 ml, 90.0 mmol). After 30 min, (±)-**5** (10.00 g, 89.2 mmol) was added. The mixture was heated under reflux for 5 h and then poured into a mixture of 2 mol dm^{-3} aqueous HCl and crushed ice. The CH_2Cl_2 layer was separated, washed with water, dried, and concentrated in vacuo. The crude product was purified by medium-pressure liquid chromatography on silica gel eluted with 3 vol% *i*-PrOH in EtOAc to give **7a** (5.38 g, 23.1 mmol) and **7b** (6.37 g, 27.3 mmol) in 56% combined yield. **7a**: mp 97—99 °C; $[\alpha]_D^{14}$ −100.0° (*c* 2.3, $CHCl_3$). **7b**: A viscous oil; $[\alpha]_D^{14}$ −78.2° (*c* 2.2, $CHCl_3$).

A solution of **7a** (5.25 g, 22.5 mmol) in 1 mol dm^{-3} KOH in ethylene glycol (35 ml) was heated at 175 °C under an atmosphere of nitrogen for 10 h. The mixture was then cooled to room temperature, acidified with 2 mol dm^{-3} aqueous HCl (20 ml), diluted with brine, and extracted three times with EtOAc. The organic extracts were combined, dried, and concentrated in vacuo. The crude product was dissolved in benzene (50 ml) and a catalytic amount of *p*-TsOH was added. The resulting solution was heated under reflux with a concominant removal of water. After the mixture had been cooled to room temperature and concentrated in vacuo, the oily residue was chromatographed on silica gel. Elution with hexane–ether (1 : 1) gave crude (+)-**5**, which was distilled using micro Kugelrohr to afford pure (*S*)-(+)-**5** (1.39 g, 58%) as a colorless oil: bp 170 °C (bath)/2666 Pa; $[\alpha]_D^{19}$ +4.9° (*c* 4.3, EtOH). In the same manner as above, the amide (**7b**) gave (*R*)-(−)-**5** in 64% yield: $[\alpha]_D^{22}$ −5.2° (*c* 2.3, EtOH).

A Mixture of (3*R*,4*S*)-4-Ethenyl-3-[(1*R*/*S*)-1-hydroxy-1-(2-methoxy-4,5-methylenedioxyphenyl)methyl]dihydro-2(3*H*)-furanones (9). To a solution of LDA [prepared from butyllithium (15 wt% in hexane, 5.90 ml, 9.5 mmol) and diisopropylamine (1.33 ml, 9.5 mmol) at −10 °C for 15 min in dry THF (30 ml)] was added as drops a solution of (*S*)-(+)-**5** (1.00 g, 8.9 mmol) in dry THF (5 ml) at −75 °C under an atmosphere of dry argon. After 30 min, a solution of 2-methoxy-4,5-methylenedioxybenzaldehyde (1.76 g, 9.8 mmol) in dry THF (20 ml) was added as drops. After 3 h at −75 °C, the reaction was quenched by 10 wt% aqueous NH_4Cl. The solution was then allowed to warm up to room temperature and was extracted twice with ether. The combined organic layers were washed with 5 wt% aqueous $NaHCO_3$ and brine, dried, and evaporated. The crude product was chromatographed on silica gel eluted with EtOAc–benzene (1 : 9) to afford the diastereomeric aldols (**9**) (2.52 g, 8.63 mmol, 97%) as a slightly yellow viscous oil: IR ($CHCl_3$) 1040, 1150, 1185, 1483, 1760, and 3350 cm^{-1}; MS *m*/*z* 292 (M^+), 181, 166, 165, 151, 123, 95, and 53. Found: C, 61.51; H, 5.60%. Calcd for $C_{15}H_{16}O_6$: C, 61.64; H, 5.52%.

A Mixture of (3*R*,4*S*)-3-[(1*R*/*S*)-1-[(*t*-Butyldimethylsilyl)oxy]-1-(2-methoxy-4,5-methylenedioxyphenyl)methyl]-4-ethenyldihydro-2(3*H*)-furanones (10). A solution of *t*-$BuMe_2SiOTf$ (3.0 ml, 12.9 mmol) in dry CH_2Cl_2 (7 ml) was added as drops to a solution of **9** (2.52 g, 8.63 mmol) and 2,6-lutidine (2.0 ml, 17.3 mmol) in the same solvent (30 ml) at −30 °C under an atmosphere of dry argon. After 40 min at that temperature, the mixture was poured into 5 wt% aqueous $NaHCO_3$. The organic layer was separated and the aqueous layer was extracted with ether (75 ml). The combined organic layers were washed successively with 10 wt% aqueous $Cu(NO_3)_2$ and brine, dried, and evaporated. The oily residue was chromatographed on silica gel eluted with hexane–EtOAc (3 : 1) to give the silyl ether (**10**, 3.22 g, 7.93 mmol, 92%) as a mixture of diastereomers. A part of the mixture was separated by medium-pressure liquid chromatography on silica gel with EtOAc–benzene (1 : 19) as the eluant. *erythro*-**10**: A viscous oil; ^{1}H NMR δ=−0.09 (3H, s), 0.12 (3H, s), 0.93 (9H, s), 2.68 (1H, dd, *J*=3 and 8 Hz), 3.06 (1H, m), 3.73 (3H, s), 3.81 (1H, dd, *J*=8 and 9 Hz), 4.21 (1H, dd, *J*=8 and 9 Hz), 5.00—5.30 (3H, m), 5.52—5.84 (1H, m), 5.89 (2H, dd, *J*=3 and 1 Hz), 6.42 (1H, s), and 7.07 (1H, s); IR ($CHCl_3$) 830, 1040, 1150, 1185, 1481, 1762, and 2940 cm^{-1}; MS *m*/*z* 406 (M^+), 350, 349, 295, 169, and 75. *threo*-**10**: White crystals (mp 98—101 °C); ^{1}H NMR δ=−0.06 (3H, s), 0.12 (3H, s), 0.93 (9H, s), 2.81 (1H, dd, *J*=3 and 8 Hz), 3.10—3.48 (1H, m), 3.76 (3H, s), 3.88 (1H, dd, *J*=8 and 9 Hz), 4.38 (1H, t, *J*=8 Hz), 4.52—4.82 (2H, m), 5.12—5.44 (1H, m), 5.65 (1H, d, *J*=2 Hz), 5.89 (2H, q, *J*=1 Hz), 6.44 (1H, s), and 6.93 (1H, s). Found: C, 61.99; H, 7.48%. Calcd for $C_{21}H_{30}O_6Si$: C, 62.04; H, 7.44%.

A Mixture of (2*R*,3*R*)-2-[(1*R*/S)-1-[(*t*-Butyldimethylsilyl)oxy]-1-(2-methoxy-4,5-methylenedioxyphenyl)methyl]-3-vinyl-1,4-butanediols (11). A solution of **10** (3.22 g, 7.93 mmol) in dry THF (25 ml) was added as drops to a stirred slurry of lithium aluminium hydride (0.33 g, 8.68 mmol) in dry ether (50 ml) at −10 °C under an atmosphere of dry argon. After 30 min at −10 °C, the excess reagent was decomposed carefully by the addition of EtOAc followed by 10 wt% aqueous citric acid (100 ml). The organic layer was separated and the aqueous layer was extracted with EtOAc. The two organic extracts were combined, washed with 5 wt% aqueous $NaHCO_3$, dried, and concentrated in vacuo. The oily residue was chromatographed on silica gel eluted with hexane–EtOAc (1 : 1) to give **11** (2.66 g, 6.49 mmol, 82%) as a colorless viscous oil: IR ($CHCl_3$) 835, 1040, 1050, 1070, 1185, 1255, 1462, 1480, 2930, and 3350 cm^{-1}; MS *m*/*z* 295 (M^+ −$SiMe_2Bu$-*t*), 278, 180, 179, 165, 163, 134, and 75. Found: C, 61.30; H, 8.36%. Calcd for $C_{21}H_{34}O_6Si$: C, 61.43; H, 8.34%.

A Mixture of (3*R*,4*R*)-3-Hydroxymethyl-4-[(1*R*/*S*)-1-[(*t*-butyldimethylsilyl)oxy]-1-(2-methoxy-4,5-methylenedioxyphenyl)methyl]dihydro-2(3*H*)-furanones (13). A solution of **11** (2.66 g, 6.49 mmol), *N*-methylmorpholine *N*-oxide monohydrate (0.96 g, 7.10 mmol) and 2 wt% aqueous OsO_4 (1 ml) in a mixture of acetone (30 ml), *t*-BuOH (7 ml), and water (7 ml) was allowed to stand at room temperature under an atmosphere of argon for 15 h. Celite and aqueous $NaHSO_3$ (0.9 g/15 ml) were added and the mixture was filtered. The residue was washed well with acetone, and the filtrate was concentrated in vacuo. The oily residue was taken up in EtOAc and washed with brine.

To the EtOAc extract was added a solution of $NaIO_4$ (1.40 g, 6.55 mmol) in water (100 ml). The resulting two phases were vigorously stirred at room temperature for 3 h. The organic layer was separated and the aqueous layer was extracted with EtOAc. The combined organic layers were dried, and concentrated in vacuo to leave practically pure **12** as a viscous oil, which was used for the next step without further purification.

A mixture of **12** and silver carbonate on Celite (10.0 g, containing ca. 10 mmol of the silver salt) in benzene (75 ml) was heated under reflux for 45 min. After cooling to room temperature, the mixture was filtered through a pad of Celite with more of benzene. After removing the solvent, the oily

residue was chromatographed on silica gel eluted with hexane-EtOAc (1 : 1) to give **13** (2.43 g, 5.93 mmol, 91%) as a viscous oil: IR ($CHCl_3$) 835, 1005, 1040, 1150, 1170, 1185, 1260, 1465, 1482, 1760, 2850, and 3500 cm^{-1}; MS *m/z* 335 (M^+ −Bu-*t*), 295, 278, 268, 259, 208, 165, and 75. Found: C, 58.49; H, 7.36%. Calcd for $C_{20}H_{30}O_7Si$: C, 58.51; H, 7.37%.

A Mixture of (4*R*)-4-[(1*R*/*S*)-1-[(*t*-Butyldimethylsilyl)oxy]-1-(2-methoxy-4,5-methylenedioxyphenyl)methyl]-3-methylenedihydro-2(3*H*)-furanones (14). Methanesulfonyl chloride (0.69 ml, 8.90 mmol) was added to a solution of **13** (2.43 g, 5.93 mmol) and Et_3N (1.65 ml, 11.86 mmol) in dry benzene (50 ml) at ca. 5 °C. The mixture was stirred at room temperature for 4 h before the addition of DBU (1.35 g, 8.90 mmol). After 30 min, the mixture was washed with water and the aqueous layer was extracted with EtOAc. The two organic layers were combined, washed successively with 10 wt% aqueous citric acid and 5 wt% aqueous $NaHCO_3$, and dried. After removing the solvent, the oily residue was chromatographed on silica gel eluted with hexane-EtOAc (4 : 1) to afford **14** (2.02 g, 5.15 mmol, 87%) as a viscous oil: IR ($CHCl_3$) 1040, 1100, 1185, 1480, and 1755 cm^{-1}. Found: C, 61.14; H, 7.18%. Calcd for $C_{20}H_{28}O_6Si$: C, 61.20; H, 7.19%.

A Mixture of (3*S*,4*R*)-4-[(1*S*/*R*)-1-[(*t*-Butyldimethylsilyl)oxy]-1-(2-methoxy-4,5-methylenedioxyphenyl)methyl]-3-hydroxy-3-(hydroxymethyl)dihydro-2(3*H*)-furanones (15). A solution of **14** (2.02 g, 5.15 mmol), *N*-methylmorpholine *N*-oxide monohydrate (0.80 g, 5.92 mmol) and 2 wt% aqueous OsO_4 (1 ml) in a mixture of acetone (30 ml), *t*-BuOH (7 ml) and water (7 ml) was allowed to stand at room temperature under an atmosphere of argon for 12 h. Celite and aqueous $NaHSO_3$ (1.0 g/20 ml) were then added and the mixture was filtered through a pad of Celite. The residue was washed well with acetone, and the filtrate was concentrated in vacuo. The oily residue was taken up in EtOAc and washed with brine. The extract was dried, concentrated in vacuo, and chromatographed on silica gel eluted with hexane-EtOAc (1 : 2) to give **15** (2.12 g, 4.98 mmol, 97%) as a gummy oil: IR ($CHCl_3$) 835, 1040, 1070, 1100, 1150, 1185, 1480, 1600, 1770, and 3350 cm^{-1}; MS *m/z* 369 (M^+−Bu-*t*), 295, 294, 277, 191, 181, 180, 165, 161, 133, and 75. Found: C, 56.41; H, 7.09%. Calcd for $C_{20}H_{30}O_8Si$: C, 56.31; H, 7.09%.

(1*S*,5*R*,6*S*)-(+)-1-Hydroxy-6-(2-methoxy-4,5-methylenedioxyphenyl)-3,7-dioxabicyclo[3.3.0]octan-2-one (17a). A 1 mol dm^{-3} solution of *n*-Bu_4NF in THF (6.00 ml, 6.00 mmol) was added to a solution of **15** (2.12 g, 4.98 mmol) in dry THF (20 ml) at 0 °C. After 2 h at 0 °C the mixture was poured into 10 wt% aqueous NH_4Cl and extracted twice with EtOAc. The extracts were combined, dried, concentrated in vacuo, and chromatographed on silica gel eluted with EtOAc to give **16** as a gummy oil. Found: C, 53.74; H, 5.30%. Calcd for $C_{14}H_{16}O_8$: C, 53.85; H, 5.16%.

The triol **16** was dissolved in dry CH_2Cl_2 (50 ml) containing a catalytic amount of 10-camphorsulfonic acid. The solution was stirred at room temperature for 3 h before being quenched with a few drops of Et_3N. After removing the solvent, the oily residue was chromatographed on silica gel eluted with hexane-EtOAc (1 : 1) to afford **17a** (0.86 g, 2.93 mmol, 59%) as white crystals. An analytically pure sample was obtained by recrystallization from *i*-Pr_2O-benzene: mp 136—137.5 °C; $[\alpha]_D^{25}$ +67.3° (*c* 2.02, $CHCl_3$); ^1H NMR (acetone-d_6) δ=2.84 (1H, s), 2.93 (1H, dt, *J*=8 and 5 Hz), 3.81 (3H, s), 4.11 (2H, s), 4.38 (1H, dd, *J*=5 and 10 Hz), 4.63 (1H, dd, *J*=8 and 10 Hz), 5.07 (1H, d, *J*=5 Hz), 5.92 (2H, s), 6.67 (1H, s), and 6.97 (1H, s); IR ($CHCl_3$) 1040, 1115, 1160, 1187, 1481, 1774, and 3400 cm^{-1}; MS *m/z* 294 (M^+), 277, 180, 165, and 133. Found: C, 57.06; H, 4.81%. Calcd for $C_{14}H_{14}O_7$: C, 57.14; H, 4.80%.

(1*S*,5*R*,6*S*)-1-[(*t*-Butyldimethylsilyl)oxy]-6-(2-methoxy-4,5-methylenedioxyphenyl)-3,7-dioxabicyclo[3.3.0]octan-2-one (19). A solution of *t*-$BuMe_2SiOTf$ (0.70 ml, 2.30 mmol) in dry CH_2Cl_2 (2 ml) was added as drops to a solution of (+)-**17a** (0.48 g, 1.63 mmol) and 2,6-lutidine (0.57 ml, 4.89 mmol) in the same solvent (10 ml) at −10 °C under an atmosphere of dry argon. The reaction mixture was gradually warmed up to room temperature and kept at this temperature for 18 h. The mixture was then diluted with ether (30 ml) and washed successively with 5 wt% aqueous $NaHCO_3$, 20 wt% aqueous $Cu(NO_3)_2$, brine, and again 5 wt% aqueous $NaHCO_3$. The ethereal extract was dried, concentrated in vacuo, and chromatographed on silica gel eluted with hexane-EtOAc (4 : 1) to give **19** (0.57 g, 1.39 mmol, 85%) as a colorless oil: ^1H NMR δ=0.04 (3H, s), 0.17 (3H, s), 0.81 (9H, s), 2.92 (1H, m), 3.76 (3H, s), 4.08 (1H, d, *J*=10 Hz), 4.21 (1H, d, *J*=10 Hz), 4.33 (1H, dd, *J*=5 and 10 Hz), 4.57 (1H, dd, *J*=8 and 10 Hz), 5.05 (1H, d, *J*=5 Hz), 5.90 (2H, s), 6.49 (1H, s), and 6.97 (1H, s); IR ($CHCl_3$) 843, 1043, 1160, 1195, 1487, 1780, and 2960 cm^{-1}; MS *m/z* 408 (M^+), 352, 351, 181, 165, 127 (base), and 75. Found: C, 58.73; H, 6.90%. Calcd for $C_{20}H_{28}O_7Si$: C, 58.80; H, 6.91%.

A Mixture of (1*S*,2*R*/*S*,5*R*,6*S*)-1-[(*t*-Butyldimethylsilyl)oxy]-2-hydroxy-6-(2-methoxy-4,5-methylenedioxyphenyl)-3,7-dioxabicyclo[3.3.0]octanes (21). A 1 mol dm^{-3} solution of DIBAL in toluene (1.60 ml, 1.60 mmol) was added as drops to a solution of **19** (566 mg, 1.39 mmol) in dry toluene (12 ml) at −70 °C under an atmosphere of dry argon. After 1 h at −75 °C, the mixture was diluted with ether and washed successively with 1 mol dm^{-3} aqueous HCl and 5 wt% aqueous $NaHCO_3$. The ethereal extract was dried, concentrated in vacuo, and chromatographed on silica gel eluted with hexane-EtOAc (2 : 1) to give **21** (567 mg, 1.38 mmol, 99%) as a viscous oil: ^1H NMR δ=0.04—0.28 (6H, s×4), 0.84—0.96 (9H, s×2), 2.28—2.68 (1H, m), 3.48—4.32 (5H, m), 3.75 (3H, s), 4.68—4.98 (1H, d×2, *J*=7 and 8 Hz), 5.02—5.24 (1H, d×2, *J*=6 and 8 Hz), 5.91 (2H, s), 6.49 (1H, s), and 6.94—7.06 (1H, s×2); IR ($CHCl_3$), 840, 910, 1045, 1190, 1260, 1487, 2970, and 3150—3650 cm^{-1}; MS *m/z* 410 (M^+), 394, 353, 191, 173, 165 (base), 161, and 75. Found: C, 58.70; H, 6.85%. Calcd for $C_{20}H_{30}O_7Si$: C, 58.51; H, 7.37%.

A Mixture of (1*S*,2*R*/*S*,5*R*,6*S*)-1-[(*t*-Butyldimethylsilyl)oxy]-2-fluoro-6-(2-methoxy-4,5-methylenedioxyphenyl)-3,7-dioxabicyclo[3.3.0]octanes (3). A solution of **21** (146 mg, 0.36 mmol), 2-fluoro-1-methylpyridinium tosylate (150 mg, 0.54 mmol) and Et_3N (0.10 ml, 0.72 mmol) in dry CH_2Cl_2 (3 ml) was stirred at room temperature for 50 min. The mixture was then concentrated in vacuo and the residue was chromatographed on silica gel. Elution with hexane-EtOAc (3 : 1) afforded **3** (134 mg, 0.33 mmol, 92%) as a viscous oil: ^1H NMR δ=0.10 (6H, s), 0.84—0.88 (9H, s×2), 2.36—2.90 (1H, m), 3.48—4.48 (4H, m), 3.74 (3H, s), 4.74—5.06 (1H, d×2, *J*=7 Hz each), 5.06—5.90 (1H, d×2, *J*=64 Hz each), 5.90 (2H, s), 6.47 (1H, s), and 7.00—7.06 (1H, s×2); IR ($CHCl_3$) 838, 1035, 1042, 1105, 1145, 1160, 1190, 1260, 1485, and 2950 cm^{-1}; MS *m/z* 412 (M^+), 355 (base), 191, 175, 165, and 75.

(1*S*,2*S*,5*R*,6*S*)-(+)-1-Hydroxy-2-(2-methoxy-4,5-methylenedioxyphenoxy)-6-(2-methoxy-4,5-methylenedioxyphenyl)-3,7-dioxabicyclo[3.3.0]octane and Its (1*S*,2*R*,5*R*,6*S*)-Isomer [23a (Desacetyl Phrymarolin I) and 23b]. A mixture of

the fluoride **3** (130 mg, 0.32 mmol), 2-methoxy-4,5-methylenedioxyphenol (62 mg, 0.38 mmol), $TrClO_4$ (0.13 g, 0.38 mmol), $SnCl_2$ (0.12 g, 0.64 mmol) and pulverized 4A Molecular Sieve in dry ether (10 ml) was stirred at 0—5 °C for 2.5 h. After the reaction had been quenched by 0.5 mol dm^{-3} aqueous NaOH, the resulting mixture was filtered through a pad of Celite with the aid of ether. The ethereal layer was separated, washed with 0.5 mol dm^{-3} NaOH, dried, and concentrated in vacuo. The crude product was purified by preparative TLC on silica gel developed with benzene-EtOAc (19:1) to give a mixture of **22a** and **22b** (88 mg, 0.16 mmol, 50%).

The crude product was dissolved in dry THF (2 ml) and a 1 mol dm^{-3} solution of n-Bu_4NF in THF (0.35 ml, 0.35 mmol) was added. After 1.5 h at room temperature, the mixture was diluted with CH_2Cl_2, washed with 10 wt% aqueous NH_4Cl, dried, and concentrated in vacuo. The crude product was purified by preparative TLC on silica gel developed with 20 vol% EtOAc in benzene to give **23a** (15.5 mg, 0.034 mmol, 21%) and **23b** (41.6 mg, 0.093 mmol, 58%). **(1*S*,2*S*,5*R*,6*S*)-23a:** mp 133—134 °C (lit. mp 133—134 °C); $[\alpha]_D^{23}$ +128.6° (*c* 0.49, $CHCl_3$); ^1H NMR δ=2.57 (1H, m), 3.72 (1H, d, *J*=10 Hz), 3.74 (3H, s), 3.75 (3H, s), 3.70—3.90 (1H, br), 4.06 (1H, dd, *J*=3 and 10 Hz), 4.31 (1H, d, *J*=10 Hz), 4.40 (1H, dd, *J*=7 and 10 Hz), 4.91 (1H, d, *J*=6 Hz), 5.16 (1H, s), 5.88 (2H, s), 5.89 (2H, s), 6.48 (1H, s), 6.53 (1H, s), 6.76 (1H, s), and 7.12 (1H, s); IR ($CHCl_3$) 1040, 1070, 1165, 1185, 1485, 1503, 2900, and 3150—3650 cm^{-1}; MS *m/z* 446 (M^+), 278, 181, 180, 168 (base), 165, and 153. **(1*S*,2*R*,5*R*,6*S*)-23b:** $[\alpha]_D^{24}$ −38.1° (*c* 1.39, $CHCl_3$); ^1H NMR δ=2.64 (1H, q, *J*=7 Hz), 2.80—3.20 (1H, br), 3.74 (3H, s), 3.78 (3H, s), 4.05 (1H, d, *J*=11 Hz), 4.18 (2H, d, *J*=7 Hz), 4.53 (1H, d, *J*=11 Hz), 5.02 (1H, d, *J*=7 Hz), 5.30 (1H, s), 5.87 (2H, s), 5.89 (2H, s), 6.47 (1H, s), 6.54 (1H, s), 6.74 (1H, s), and 7.05 (1H, s); IR ($CHCl_3$), 865, 940, 1005, 1040, 1162, 1185, 1430, 1483, 1502, 2900, and 3150—3650 cm^{-1}; MS *m/z* 446 (M^+), 278, 181, 180, 168 (base), 165, and 153.

(1*S*,2*S*,5*R*,6*S*)-(+)-1-Acetoxy-2-(2-methoxy-4,5-methylenedioxyphenoxy)-6-(2-methoxy-4,5-methylenedioxyphenyl)-3,7-dioxabicyclo[3.3.0]octane [la (Phrymarolin I)]. A mixture of **23a** and a catalytic amount of DMAP in Ac_2O (ca. 1 ml) was allowed to stand at room temperature for 12 h before being poured onto crushed ice. After the ice had melted, the precipitated solids were collected and dissolved in EtOAc. The extract was washed successively with 1 mol dm^{-3} aqueous HCl and 5 wt% aqueous $NaHCO_3$, dried, and concentrated in vacuo. The crude product was purified by preparative TLC on silica gel developed with benzene-EtOAc (9:1) to give **1a** as white crystals: mp 155—157 °C (lit. mp 155—157 °C); $[\alpha]_D^{25}$ +106.9° (*c* 0.11, dioxane); ^1H NMR δ=2.12 (3H, s), 2.88 (1H, m), 3.73 (3H, s), 3.75 (3H, s), 3.80 (1H, d, *J*=11 Hz), 4.03 (1H, dd, *J*=2 and 9 Hz), 4.49 (1H, dd, *J*=7 and 9 Hz), 4.60 (1H, d, *J*=11 Hz), 4.87 (1H, d, *J*=7 Hz), 5.66 (1H, s), 5.86 (2H, s), 5.91 (2H, s), 6.51 (2H, s), 6.82 (1H, s), and 7.03 (1H, s).

This work was partially supported by a a Grant-in-Aid for Research No. 59470113 from Ministry of Education, Science and Culture.

Preparation and Properties of Inclusion Compounds of η^3-Allylpalladium Complexes with Cyclodextrins

Akira HARADA,* Mizutomo TAKEUCHI, and Shigetoshi TAKAHASHI*
The Institute of Scientific and Industrial Research, Osaka University, Ibaraki, Osaka 567
(Received June 27, 1988)

Inclusion compounds of di-μ-chloro-bis(η-allyl)dipalladium and its analogues with cyclodextrins (CDs; α-CD, β-CD, and γ-CD) were prepared. One-to-one inclusion compounds were obtained in high yields by the treatment of β- and γ-cyclodextrin with di-μ-chloro-bis(η-allyl)dipalladium and its analogues. The formation of inclusion compounds is selective. β-CD formed inclusion compounds with di-μ-chloro-bis[1-3-η-(2-methylallyl)]dipalladium in high yield, but it did not form any inclusion compounds with di-μ-chloro-bis(1-3-η-2-butenyl)dipalladium. γ-CD formed inclusion compounds with all the η^3-allylpalladium complexes tested in high yields. α-CD did not form inclusion compounds with any η^3-allylpalladium complexes tested. The thermogravimetric measurements show that η^3-allylpalladium complexes are stabilized when they are included in the CD cavity. The inclusion compounds were characterized by ^{1}H NMR, IR, UV, and circular dichroism spectra.

Organotransition metal complexes have been extensively used as homogeneous catalysts in organic reactions and much effort has been paid to improve their activity and selectivity.[1] Meanwhile, cyclodextrins (CDs) have been studied as a model of enzyme for selective catalysts. Therefore to combine the function of organometallic complexes and that of cyclodextrins, we tried to prepare the inclusion compounds of organometallic complexes with cyclodextrins. There are a large number of reports on the inclusion compounds of organic molecules with cyclodextrins.[2,3] In marked contrast, there are only a few reports on the inclusion compounds of organometallic complexes with cyclodextrins.[4,5] We previously reported the preparation and properties of inclusion compounds of ferrocene and its analogues with cyclodextrins as an example of cyclodextrin inclusion compounds of organometallic complexes.[6-9] These observations prompted us to examine the interaction of CD with η^3-allylpalladium complexes which are frequently used in a variety of organic syntheses. Moreover, recently much attention has been devoted to the preparation and properties of inclusion compounds of more than one metal center because of their importance of the cooperative effects.[10] Now we found that β- and γ-cyclodextrin form inclusion compounds with some η^3-allylpalladium complexes and that the formation of the inclusion compounds is selective. In a previous letter,[11] we reported briefly on the preparation of inclusion compounds of π-allyl palladium complexes. We describe here the preparation and properties of inclusion compounds of di-μ-chloro-bis-(η-allyl)dipalladium, $[(\eta\text{-allyl})PdCl]_2$, and its analogues with cyclodextrins in detail and discuss the binding mode. These inclusion compounds are the first inclusion compounds accommodating dinuclear species in a single cavity of CD. We also found that allylpalladium complexes are stabilized when they are included in the CD cavity.

Results and Discussion

Preparation of Inclusion Compounds. Di-μ-chloro-bis(η-allyl)dipalladium, $[(\eta\text{-}C_3H_5)PdCl]_2$, and its analogues are almost insoluble in water. So a co-crystallization method from aqueous solutions, which is usually used to obtain inclusion compounds with water-soluble compounds, cannot be used in this case. We tried to prepare the inclusion compounds by direct addition of fine crystals of π-allylpalladium complexes into a saturated aqueous solution of cyclodextrin at 35 °C. The product precipitated was washed thoroughly with water to remove remaining CD, and dried in vacuo. Unincluded metal complexes were removed by washing with chloroform. During this process, the included guest was not liberated from the CD cavity.

The inclusion compounds are characterized by elemental analysis and their IR, UV, and ^{1}H NMR spectra. Stoichiometries were determined by elemental analysis, including atomic absorption analysis of the metal contents, and from their ^{1}H NMR and UV spectra. All the inclusion compounds obtained in this work were stoichiometric one-to-one complexes. β-CD and γ-CD formed 1 : 1 inclusion compounds even if they were treated with two molar excess of η^3-allylpalladium complexes. This result indicates that the interaction between cyclodextrin and η^3-allylpalladium complexes is a real inclusion phenomenon. Table 1 shows the results on the preparation of inclusion compounds of η^3-allylpalladium complexes with CD. β-CD and γ-CD formed 1 : 1 inclusion compounds with allylpalladium complexes, regardless of the molar ratio of the host to guest in the reaction. γ-CD formed 1 : 1 inclusion compounds with all the η^3-allylpalladium complexes tested in high yields. The inclusion compounds of $[(\eta\text{-allyl})PdCl]_2$ and $[(\eta\text{-allyl})PdBr]_2$ with γ-CD were obtained in quantitative yields. β-CD formed 1 : 1 inclusion compounds with

a) Calculated from cyclodextrin.

[1-3-η-(2-methylallyl)PdCl]$_2$ in high yield, but it did not form inclusion compounds with [(1-3-η-2-butenyl)PdCl]$_2$ complex. β-CD also formed 1 : 1 inclusion compounds with the chloro- and bromo-bridged complexes in moderate yields but not with the iodo-bridged complex. The yields of the inclusion compounds decreased in the order Cl>Br$\gg$I. β-CD is apparently able to discriminate not only the position of the substituents on the π-allyl ligands but the size of the bridging halogens. α-CD did not form inclusion compounds with any η^3-allylpalladium complexes tested. It is reasonable because the examination of CPK models shows that these allylpalladium complexes are too large to fit in the α-CD cavity.

Properties of Inclusion Compounds. η^3-Allylpalladium complexes are stabilized thermally by the formation of the inclusion compounds with cyclodextrin. Di-μ-chloro-bis(η-allyl)-dipalladium, for example, did not decompose on heating at 170 °C in vacuo when it was included in cyclodextrin. At this temperature the unincluded η^3-allylpalladium complex decomposes to give allyl chloride and palladium metal. Figure 1 shows the results on the thermogravimetric analysis of the inclusion compounds of di-μ-chloro-bis(η-allyl)dipalladium with β-cyclodextrin under nitrogen atmosphere, together with that of the mixture of β-CD and the allylpalladium complex, and that of the free allylpalladium complex. η^3-Allylpalladium complex starts to decompose at 145 °C and shows about 42% weight loss by 190 °C. This weight loss corresponds to 2 moles of allylchloride. In the case of the inclusion compounds there is no significant change until 190 °C except for the weight loss due to the dehydration. Rapid weight loss was observed around 200 °C, probably due to the decomposition of the guest molecule (liberation of allyl ligands). In the case of the mixture the allylpalladium complex decomposes at 145 °C. The decomposition point of π-allylpalladium rose about 50 °C by the formation of inclusion compounds. This is the first observation that metal complex is stabilized by the formation of inclusion compounds with cyclodextrin. γ-CD did not show such a stabilizing effect. On the other hand the decomposition point of β-CD was lowered by the presence of palladium complexes. Uncomplexed β-CD melts and decomposes at about 300 °C, but β-CD

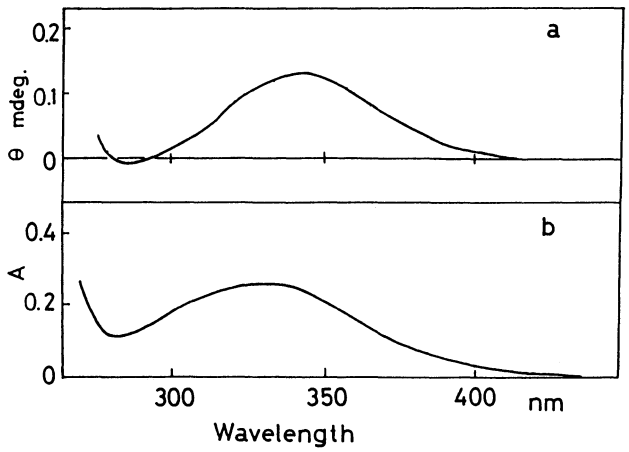

Fig. 2. Circular dichroism spectrum (a) and absorption spectrum (b) of [(η-allyl)PdCl]$_2$ in the presence of β-CD in ethylene glycol at 25 °C. [cyclodextrin] =[(η-allyl)PdCl]$_2$=10^{-3} mol dm^{-3}.

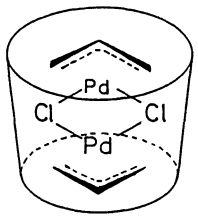

Fig. 3. Proposed structure of the inclusion compound of [(η-allyl)PdCl]$_2$ with β-cyclodextrin.

in the inclusion compound starts to decompose around 200 °C. β-CD also decomposes around 200 °C in the presence of palladium complexes.

The inclusion compounds are insoluble in usual organic solvents such as benzene, hexane, chloroform, and so on. They are soluble in ethylene glycol, dimethyl sulfoxide, and *N,N*-dimethylformamide, and slightly soluble in water. However, the inclusion compounds have been found to dissociate in dimethyl sulfoxide or in *N,N*-dimethylformamide. The inclusion behavior was observed in ethylene glycol solution.

Figure 2 shows the absorption spectra and circular dichroism spectra of [(η-allyl)PdCl]$_2$ in the presence of β-CD in ethylene glycol solution. β-CD causes a positive Cotton effect at about 345 nm with a small negative Cotton effect around shorter wavelength. γ-CD showed no effects. These results indicate that [(η-allyl)PdCl]$_2$ is included in the β-CD cavity with a fixed orientation and are in accordance with those of the inclusion compounds of β-CD–ferrocene and β-CD–arene chromium complexes, which show both positive Cotton effects in the longer wavelength region. This result indicates that π-allylpalldium complexes are included in β-CD cavity with a "perpendicular" manner as shown in Fig. 3 in a similar fashion to those of the ferrocene complex and arene chromium complexes.[7]

According to CPK molecular models, chloro-bridged allylpalladium complexes appear to fit well into the β-CD cavity, whereas bromo-bridged and iodo-bridged complexes are too large to fit in the β-CD cavity. 2-Methyl derivative is symmetric and more compact than 1-methyl derivative. So 2-methyl derivative fits well in the β-CD cavity, but 1-methyl derivative is not able to fit the cavity. Proposed structure for the β-CD–di-μ-chloro-bis(η-allyl)dipalladium is shown in Fig. 3, which could account for the selective inclusion in terms of the steric factor of both the allylic ligands and bridging halogens.

Another feature of these inclusion compounds is their stoichiometry. The inclusion compounds of di-μ-chloro-bis(cyclooctadiene)dirhodium(I) with β-cyclodextrin, which have a similar molecular structure to π-allylpalladium chloride, show 2 : 1 (CD : guest) stoichiometry,[12] whereas the inclusion compounds of π-allylpalladium complexes show 1 : 1 stoichiometry. This result can be interpreted in terms of the bulkiness of the ligands of the metal complexes. Cyclooctadienyl ligand is large enough to fill a single β-CD cavity, whereas π-allyl ligands are too small to fill the cavity which can accommodate the whole molecule of the complex resulting in one to one inclusion compounds. Consequently, the inclusion compounds contain two palladium metals in a single cavity. These inclusion compounds are the first example of those accommodating dinuclear species in a single cyclodextrin ring.

Experimental

All the manipulations were performed under an atmosphere of nitrogen.

Materials. Cyclodextrins (α-CD, β-CD, and γ-CD) were obtained from Hayashibara Biochemical Laboratories Inc. Their purities were checked by elemental analysis and optical rotation. η^3-Allylpalladium complexes were prepared according to the methods described in the literature.[13]

The inclusion compound of di-μ-chloro-bis(η-allyl)dipalladium with β-CD was prepared by adding finely ground crystals of di-μ-chloro-bis(η-allyl)dipalladium complex (0.344 g, 0.95 mmol) to an aqueous solution of β-CD ($10H_2O$ adduct, 0.658 g, 0.50 mmol) at 35 °C with stirring. The product was washed with water to remove remaining CD,

Table 2. Analytical Data of Inclusion Compounds

and dried in vacuum. Nonincluded (η^3-allyl)palladium complex was removed by washing the residue with chloroform. The product was recrystallized from water or aqueous ethanol to give pale yellow crystals. For β-CD ($10H_2O$-dichlorobis(allyl)dipalladium complex: mp 200—205 °C (decomp).

The other inclusion compounds were prepared in a similar way and their analytical data are summarized in Table 2.

Instrumentation. Infrared spectra were taken on a Hitachi 295 spectrometer and UV spectra were recorded on a Shimadzu UV-202 spectrophotometer. ^{1}H NMR spectra were run on a JEOL FX100 spectrometer. Circular dichroism spectra were recorded on a JASCO J-205 spectropolarimeter. Thermogravimetric analysis was made using a Shimadzu thermal analyzer DT-30. Atomic absorption analysis was made using a Shimadzu A-610S atomic absorption/flame spectrophotometer.

The Use of Silica Gel-Supported Ionenes as Reagents and Catalysts for Several Substitution Reactions in Toluene[1)]

(Received July 1, 1988)

Several ionene bromides were used as reagents for the displacement of decyl methanesulfonate into 1-bromodecane. They were very reactive when adsorbed by silica gel. The enhanced activities of the ionenes were hardly dependent on their structures and molecular weights but decreased gradually with increasing the amount of ionene adsorbed by silica gel. Ionene chlorides exhibited a similar enhancement of reactivity when adsorbed by silica gel. However, unlike the ionenes, a large increase in activity due to adsorption was not observed with pendant-type polycations such as poly(4-vinylpyridinium bromide) and poly[(4-vinylbenzyl)tributylammonium chloride]. The silica gel-supported ionenes also exhibited excellent catalytic activities for solid-liquid-solid triphase substitution reactions, particularly for the reactions between 1-bromodecane and such inorganic salts as consisted of relatively hard-basic nucleophilic anions.

It is well-known that lipophilic quaternary ammonium salts are not only good nucleophilic reagents in nonpolar media but also excellent phase-transfer catalysts.[2)] In order to simplify salt recovery and product isolation, the salts have been covalently attached as a pendant group, either to the matrix of swellable cross-linked polymer or to the surface of porous inorganic materials.[3-6)] To those insoluble materials, the salts have been introduced usually at random, which leads to an ambiguous distribution of active sites and an unavoidable assumption about the microenvironment around the active sites. Furthermore, immobilization of the salts gives rise, in most cases, to the reduction of overall activities of the salts, which has been explained in terms of diffusional limitation.[5)]

On the other hand, few reports except two studies[7,8)] have been concerned with reaction and catalysis of the quaternary salts which are adsorbed by inorganic materials. If the quaternary salts are lipophilic, however, this reaction system is likely of little value because the salts are in dynamic equilibrium between adsorbed and desorbed states.[7)] This equilibrium makes it difficult to evaluate the influence of adsorbent unless the adsorption induces a drastic change in activities of the salts. The equilibrium also makes it difficult to accomplish a complete recovery of the salts.

Ionenes are a specific kind of polycations having a definite chemical structure in which quaternary ammonium groups are spaced regularly along the polymer backbone.[9)] Generally, they are quite hydrophilic and easily soluble in water but most of them are neither soluble nor swellable in nonpolar organic solvents. This nature of the ionenes has restricted their use only to aqueous reaction systems. Thus, we have successfully utilized them as catalysts for aqueous interionic reactions[10)] and as flocculants of aqueous kaolin suspension.[11)]

This work demonstrates the applicability of some hydrophilic ionenes, which are shown in Fig. 1(a)—(d), to excellent reagents and catalysts of various substitution reactions in toluene under the conditions where the ionenes are deposited on the surface of silica gel or other inorganic supports. The method is quite simple. After silica gel and a methanol solution of the ionenes (x—y, X) were mixed and equilibrated, the mixture was evaporated to dryness. The obtained silica gel–ionenes complexes (x—y, X/silica gel) were used as reagents of the liquid-solid biphase reactions (Eq. 1) or as catalysts for the solid-liquid-solid triphase catalytic reactions (Eq. 2).

$$n\text{-}C_{10}H_{21}OMs + x\text{-}y,\ X/\text{silica gel} \longrightarrow n\text{-}C_{10}H_{21}X + x\text{-}y,\ OMs/\text{silica gel} \quad (1)$$
$$X = Cl \text{ or } Br,\ OMs = CH_3SO_3$$

$$n\text{-}C_{10}H_{21}X + KY(\text{solid}) \xrightarrow{x\text{-}y,\ Br/\text{silica gel}} n\text{-}C_{10}H_{21}Y + KX(\text{solid}) \quad (2)$$
$$X = OMs \text{ or } Br,\ Y = I,\ CN,\ Br,\ OPh,\ \text{or } OAc$$

The rate enhancement through adsorption has been examined for the ionenes as well as some pendant-type polycations as shown in Fig. 1(e)—(g).

Experimental

Materials. Commercial α,ω-alkanediamines and piperazine were converted to the corresponding α,ω-bis(dimethylamino)alkanes and N,N'-dimethylpiperazine using formalin–formic acid. α,ω-Dihaloalkanes and α,α'-dichloro-p-xylene were purchased and distilled.

Ionene polymers (x—y, X) were prepared from the reaction of the N-methylated diamines with the equimolar dihalides under the conditions previously reported.[11)] 2-Hydroxy-3-ionene chloride, 3-OH, Cl was prepared according to the literature.[12)] The intrinsic viscosities of the ionenes were measured. The data are summarized as follows: x-y, X, $[\eta]/\text{dl g}^{-1}$ (25 °C, aq 0.4 mol dm^{-3} KBr unless otherwise stated); 2-5, Br, 0.12; 3-3, Br, 0.07; 3-4, Br(I), 0.22; 3-4, Br(II), 0.15; 3-4, Br(III), 0.10; 3-6, Br, 0.15; 4-4, Br, 0.05; 6-2, Br,

†† Present address: Tokyo Kasei University, Kaga, Itabashi-ku, Tokyo 173.

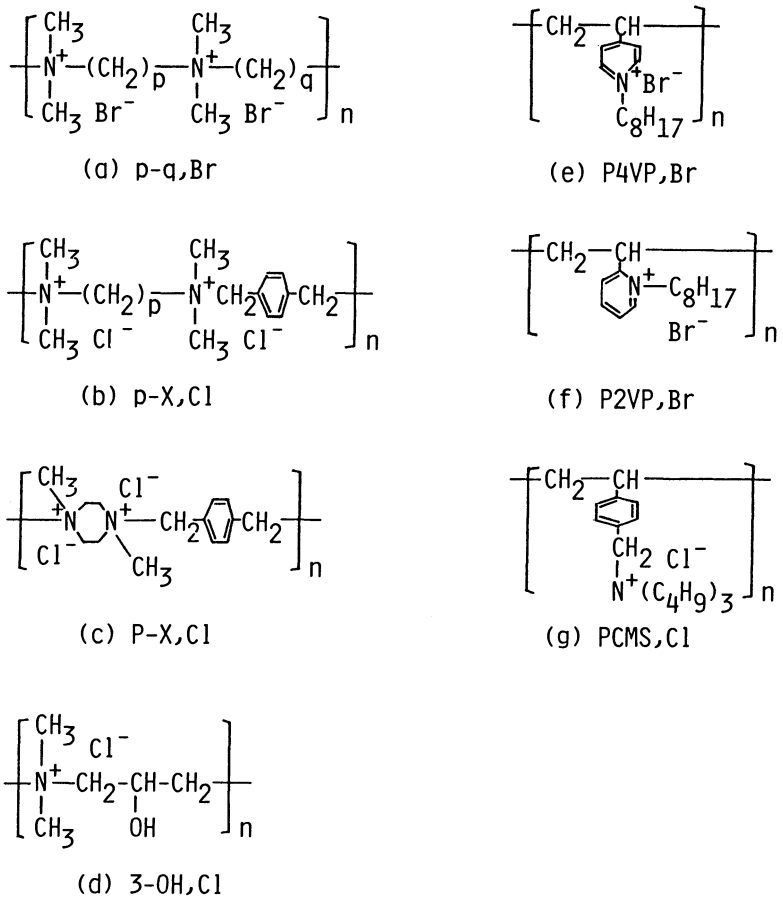

Fig. 1. Ionenes and pendant-type polycations used.

0.09; 6-6, Br, 0.19; 2-X, Cl, 0.18 (0.3 mol dm^{-3} KBr); 3-X, Cl, 0.21; 6-X, Cl, 0.23 (0.3 mol dm^{-3} KBr); P-X, Cl, 0.18 (0.2 mol dm^{-3} KBr); 3-OH, Cl, 0.08. The viscosity-molecular weight relationships for ionenes are available only for 3-4, Br and 6-6, Br.[13] The molecular weights of 3-4, Br(I), 3-4, Br(II), 3-4, Br(III), and 6-6, Br were 40000, 27000, 15000, and 20000, respectively.

Freshly distilled 2- and 4-vinylpyridines were polymerized and then quaternized by 1-bromooctane,[14] to give P2VP, Br and P4VP, Br. Poly[4-(chloromethyl)styrene] was prepared by suspension polymerization of distilled 4-(chloromethyl)-styrene using benzoyl peroxide for 7 h at 80 °C and was purified to remove insoluble crosslinked resins through several reprecipitations using dioxane-methanol. The linear poly[4-(chloromethyl)styrene] was reacted with tributylamine in *N*,*N*-dimethylformamide [14 d, 50 °C] to give the corresponding ammonio-attaching polystyrene, PCMS, Cl. The molecular weight and the degree of quaternization of P2VP, Br, P4VP, Br, and PCMS, Cl were measured according to the literature:[14] Polycation, molecular weight, degree of quaternization; P2VP, Br, 450000, 37.4%; P4VP, Br, 74000, 79.7%; PCMS, Cl, —, 60.0%.

Silica gel (Wakogel C-200, 100—200 mesh), activated alumina (Wako, abt. 200 mesh), neutral alumina (Wako, W-200), and activated carbon powder (Wako, —200 mesh) were dried in vacuo prior to use [3 h, 110 °C]. Molecular Sieves (Wako, 4A 1/16) was ground to a powder and was dried prior to use. The specific surface area of the inorganic supports was measured on Yanagimoto Surface Area Analyzer GSA-10.

Potassium phenoxide, prepared from neutralization of phenol with aqueous potassium hydroxide, and all other commercial solid inorganic reagents were also dried [3 h, 110 °C in vacuo]. Decyl methanesulfonate (abbreviated as decyl mesylate hereinafter) was prepared by the reaction of 1-decanol with methanesulfonyl chloride,[15] and was purified by vacuum distillation.

Silica Gel-Supported Ionenes. A given amount of the pre-dried silica gel was added in one portion to a stirred solution of an ionene in 30 ml of methanol or ethanol. The mixture was stirred for 1 h at room temperature. The solvent was then evaporated and the resulting ionene-silica gel complex (abbreviated as complex hereinafter) was dried in vacuo at 110 °C for 3 h. Other supported polycations were also prepared by the same procedure. Ion content, the ammonium content per gram of the complex, was adjusted to be 0.25 mmol g^{-1} unless stated otherwise. For comparison with the ionenes, potassium bromide and sodium chloride were also supported on silica gel in a manner similar to the literature.[16]

Ionene Halide as a Reagent for Nucleophilic Substitution Reactions. A 25 ml culture tube with a Teflon-lined screw cap was charged with 0.073 mmol of ionene supported or nonsupported plus 1.0 ml of toluene containing pentadecane as an internal standard. The tube was placed in an oil bath maintained at 90 °C and the mixture was stirred for 20 min with a Teflon-coated magnetic stirring bar, followed by injection of 0.073 mmol of decyl mesylate via a syringe.

The disappearance of the mesylate and the appearance of 1-halodecane in the toluene phase were followed by GLC (Hitachi 163 Gas Chromatograph).

Ionene Halides as Solid-Liquid-Solid Triphase Catalysts. To a 25 ml culture tube with a Teflon-lined screw cap was added 5 mmol of solid reagent salt (KBr, NaI, NaCN, KOPh, or KOAc), 0.05 mmol of a polycation supported or nonsupported, and 4.0 ml of toluene containing pentadecane as an internal standard. The mixture was stirred for 1 h at 90 °C, followed by injection of decyl mesylate (0.8 mmol) or 1-bromodecane (0.7 mmol). The substrates and the products were quantitatively analyzed by GLC.

Results and Discussion

Ionene Halide as a Reagent. Nonsupported ionene bromides were all insoluble in toluene. They were very slow to react with the eqimolar amount of decyl mesylate. The results of typical ionene bromides are shown in Fig. 2. The reactions did not follow second-order kinetics. Even after several days, the substantial parts of the bromides were found to remain unreacted.

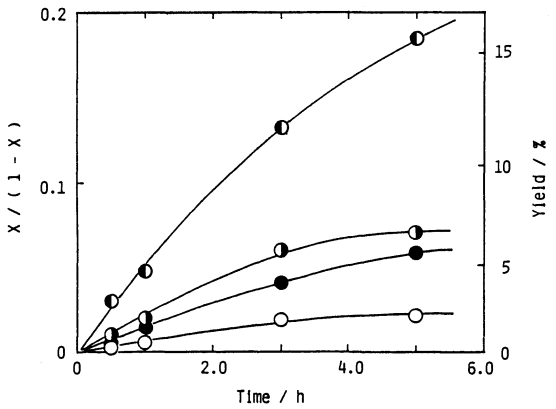

Fig. 2. Reaction of nonsupported ionene bromides with decyl mesylate.

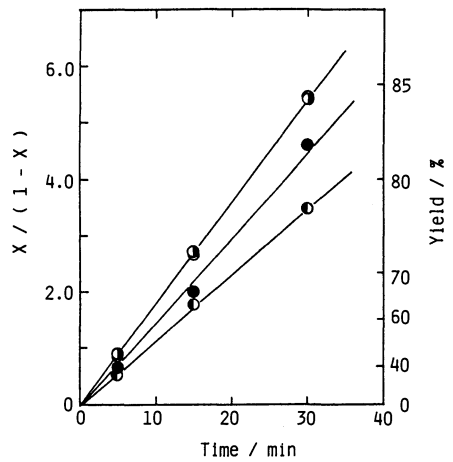

Fig. 3. Reaction of silica gel-supported ionene bromides with decyl mesylate.
●, 3-3, Br; ○, 3-4, Br(I); ◑, 4-4, Br; ◐, 6-6, Br.

When the ionene bromides were supported on silica gel, however, the rates of the substitution were dramatically increased as shown in Fig. 3. The reactions were completed in a few hours. A plot of $x/(1-x)$ vs. reaction time was almost linear for all the supported ionenes, indicating that the reactions were of second order, that is, first order with respect to both decyl mesylate and ammonium bromide. This also indicates that all the ammonium bromides of one ionene have an equal reactivity. The desorption of the ionenes during the reactions was neglected because the weight loss of 3-4, Br complex was not observed after the complex was soaked in toluene for 1 h at 90 °C, separated by filtration, and dried in vacuo. The second-order rate constants calculated from the slopes of the plots are in the narrow range of 2.7×10^{-3} to 4.3×10^{-3} mol^{-1} dm^3 s^{-1}, which are comparable to the reported data for organic-soluble quaternary onium salts.[17] Despite of a polar nature of silica gel surface, the high reactivities observed for the adsorbed ionenes are striking. The results of silica gel-supported and nonsupported ionene bromides are summarized in Table 1 together with the results of P4VP, Br, P2VP, Br, and KBr. It should be noted again that the reactivity of silica gel-supported ionene bromides was hardly dependent on the ionene structure and that the reactivity was much higher than that of nonsupported ionene bromides.

These results clearly indicate that, being adsorbed on silica gel, the ionenes allow decyl mesylate to diffuse easily to active sites and provide an increased number of the active sites. Ionene bromides are crystalline polymers.[9] They have crystalline regions under the nonsupported state. The ammonium bromides in the crystalline region are likely difficult to react. It is therefore assumed that the difference in reactivity of the nonsupported ionenes is attributable partly to the difference in the morphological structure aside from the influence of the powder size.

Table 1. Substitutions of Decyl Mesylate into 1-Bromodecane Using Nonsupported and Silica Gel-Supported Ionene Bromides[a]

Ionene bromide	Yield/%	
	Nonsupported	Supported
2-5, Br	1.4	94.4
3-3, Br	4.0	97.0
3-4, Br(I)	1.7	97.9
3-6, Br	0.1	99.2
4-4, Br	5.6	98.0
6-2, Br	2.2	96.1
6-6, Br	11.9	95.9
P4VP, Br	64.2	86.0
P2VP, Br	3.5	44.2
KBr	1.0[b]	28.9[b]

a) Reactions were carried out in toluene at 90 °C for 3 h: n-$C_{10}H_{21}OMs$, 0.0734 mmol; ammonium bromide, 0.0734 mmol; toluene, 1.0 ml. b) Yield after 20 h.

The adsorption to silica gel possibly induces the destruction of the crystalline region and also weakens the electrostatic interaction among the ammonium bromide ion pairs, so that the formation of aggregates of the ion pairs becomes difficult.

As shown in Fig. 4 (solid line), silica gel-supported 3-4, Br gave an identical reactivity irrespective of molecular weight of the ionene. This fact and the equal reactivity of the ammonium bromides in one ionene strongly suggest uniform and monolayer coverage of ionene over the silica gel surface. The result shown in Fig. 5 supports the validity of the assumption. At low levels of loading on silica gel, 3-4, Br exhibited a constant reactivity. But, beyond 0.5 mmol g^{-1} of ion content, the reactivity of the 3-4, Br complex decreased with increasing loading. The specific surface area of the silica gel was ca. 270 $m^2 g^{-1}$ obtained from BET measurement. Since the maximum cross section per mmol of ammonium unit, estimated from CPK model, is ca. 200 m^2 when 3-4, Br molecule is fully extended, it seems reasonable to assume monolayer adsorption in the case of low ion content.

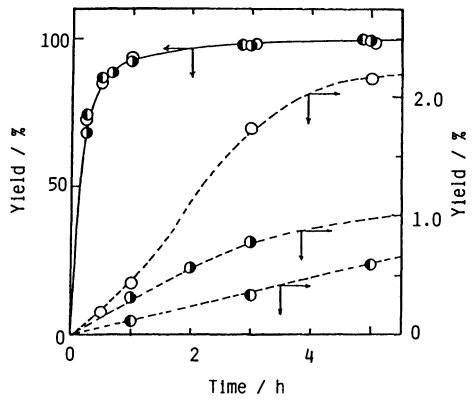

Fig. 4. Effect of molecular weight on the activities of nonsupported and silica gel-supported 3-4, Br toward decyl mesylate.
○, 40000; ◐, 27000; ◑, 15000.——,supported. ----,nonsupported.

P4VP, Br was relatively active without any carrier, whereas P2VP, Br was as poorly active as ionene bromides (Table 1). P4VP, Br swells well in toluene. The high reactivity and swellability imply the absence of the extensive aggregation among the ion pairs of P4VP, Br. Therefore, an increase in activity due to adsorption was not significant for P4VP, Br, while P2VP, Br exhibited a moderate improvement. It is noted that, under the adsorbed state, these pendant-type polycations are not so reactive as ionene bromides. This implies either the relatively weak interaction of the pendant ammonio groups with the silica gel surface or the presence of a dynamic equilibrium of the ammonio groups between adsorbed and desorbed states to form a sort of looped structure of the polymer chains over the silica gel surface. The looped structure is often assumed in the case of the adsorptions of linear polyelectrolytes from aqueous solutions.[18]

As mentioned above, the state of adsorption may be a primary factor to determine the effectiveness of this reaction system. An additional factor to influence the reaction rate is the local concentration of decyl mesylate. Since 0.3 g of uncoated silica gel adsorbs 54% of decyl mesylate from the reaction mixture, decyl mesylate is undoubtly concentrated around the active sites, whereas the adsorption of the product, 1-bromodecane, is as small as 1%.

Figure 6 shows the effect of carriers upon the reactivity of 6-6, Br supported on them. The yield of 1-bromodecane increased in the order of silica gel>activated carbon>Molecular Sieves 4A>activated alumina. This order did not correlate to an ability of carrier to adsorb decyl mesylate from the reaction mixture; silica gel (54%)>activated alumina (34%)>active carbon (8%)>Molecular Sieves 4A (6%). These facts suggest that the interaction between support surface and ammonium bromides is important and that silica gel may attract preferentially ammonium ions to make bromide counter ions somewhat free from the electrostatic restraint of the ammonium ions.

NaCl	0.0[b)]	16.0[b)]

a) Reactions were carried out in toluene at 90 °C for 3 h: n-$C_{10}H_{21}OMs$, 0.0734 mmol; ammonium chloride, 0.0734 mmol; toluene, 1.0 ml. b) Yield after 20 h.

Contrary to expectation,[7,16,19)] alumina was not only ineffective in this system but also promotive of the hydrolysis of both decyl mesylate and 1-bromodecane. The hydrolysis takes place possibly due to the presence of an irremovable water adsorbed by the alumina. The use of neutral alumina instead of activated alumina brought about any improvement neither on reaction rate nor on product composition. Active carbon also gave the hydrolysis product, 1-decanol, as a by-product, whose yield had reached ca. 25% when the mesylate completely disappeared.

Similarly, ionene chlorides were found to be much more reactive toward decyl mesylate when they were supported on silica gel. The results are summarized in Table 2 together with the results of PCMS, Cl, and NaCl. The reaction rates enhanced by adsorption were very similar for all ionene chrolides, while the rates of nonsupported ionenes differed from each other. PCMS, Cl, which contains pendant ammonio groups, is active without any carrier probably due to its high swellability. Its adsorption onto silica gel, therefore, did not induce a significant increase in activity. This tendency was quite similar to that of P4VP, Br.

Silica Gel-Supported Ionenes as Solid-Liquid-Solid Triphase Catalysts. Silica gel-supported ionenes were found to enhance some substitution reactions between liquid substrates and solid inorganic reagents. Figure 7 shows the results of the reaction between decyl mesylate and potassium bromide. The reaction hardly proceeded either in the absence of catalysts or even in the presence of nonsupported 3-4, Br. The two rates were almost identical. This indicates that the nonsupported 3-4, Br has no catalytic activity.

However silica gel-supported 3-4, Br largely accelerated the reaction. Although uncoated silica gel also promoted the reaction, it was less catalytically active than the 3-4, Br complex. This is consistent with the result that, as reagents, the supported 3-4, Br was much more reactive than the supported KBr (Table 1). Contrary to the lack of catalytic activity of the nonsupported 3-4, Br, the supported 3-4, Br contributes substantially to the rate enhancement. The contribution of the supported 3-4, Br tends to be amplified with decreasing ion content of the complex (Fig. 7).

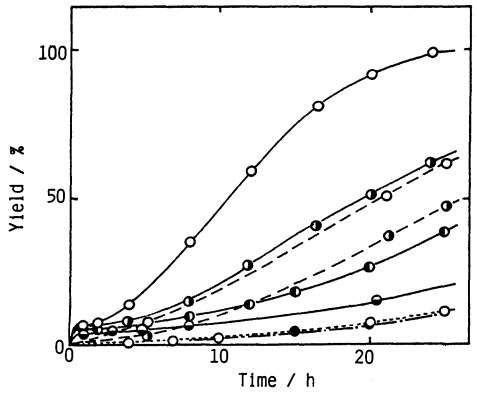

Fig. 7. Catalytic effects of silica gel and 3-4, Br on the solid-liquid-solid triphase reactions between decyl mesylate and potassium bromide.

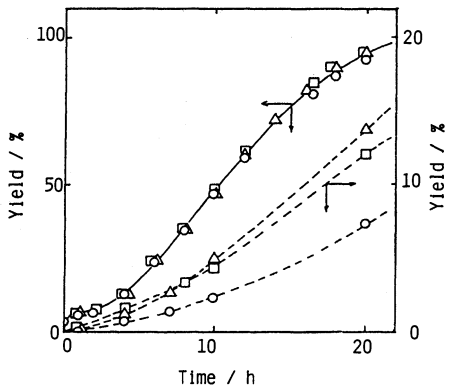

Fig. 8. Solid-liquid-solid triphase catalytic reaction between decyl mesylate and potassium bromide.
○, 3-4, Br; △, 4-4, Br; □, 6-6, Br. ——, supported; ---, nonsupported.

Figure 8 shows the effect of ionene structure on the catalysis. Unlike 3-4, Br, nonsupported 6-6, Br and 4-4, Br, which had relatively high reactivities toward decyl mesylate (Table 1), had minimal catalytic activities. When adsorbed on silica gel, every ionene afforded much higher catalytic efficiency. The enhanced rates were very similar from one ionene to another.

A specific feature of the catalysis of the complexes is the large reaction rates at the initial stage, which is hardly observed either for uncoated silica gel or for nonsupported ionenes. The amount of 1-bromodecane formed within the first one hour approximately corresponded to that of ammonium bromides of the ionene added (Figs. 7 and 8). After the initial stage of the rapid reaction, a rather slow increase in the yield was observed and the time-yield curve presents somewhat autocatalytic feature. These phenomena can be

Table 3. Solid-Liquid-Solid Triphase Reactions Catalyzed by Silica Gel and Silica Gel-Supported 3-4, Br[a)]

	KOPh	0	17	48
	KOAc	0	9	35

a) Reactions were carried out in toluene at 90 °C for 25 h: n-$C_{10}H_{21}OMs$, 0.81 mmol ; n-$C_{10}H_{21}Br$, 0.72 mmol; solid reagents, 5.0 mmol; silica gel, 0.2 g. b) Ion content, 0.25 mmol g^{-1}; complex weight, 0.2 g. c) Yield after 1.0 h. d) Yield after 15 min.

accounted for in terms of high reactivity of active sites and slow regeneration of the active sites. Namely, the adsorbed ammonium salts in the form of bromide, which are the active sites in this system, can react immediately with decyl mesylate but ion exchange, which restores the ionene to the original bromide form, is slow compared to the chemical reaction. A clear account has not been given of the mechanism of this sort of ion exchange. There are many possible ways in which the counter ions of the ammonio groups are displaced: exchange by direct contact with the solid KBr, indirect exchange via contact with silica gel-adsorbed KBr, exchange by the trace amounts of KBr salt dissolved in the organic phase, and exchange by the KBr salt dissolved in the minimal amounts of irremovable water. Some discussion on this matter will be done later in this paper.

Table 3 shows the results of other substitution reactions catalyzed by the 3-4, Br complex. Generally, in S_N2 reactions, mesylate is a good leaving group compared to bromide. Hence decyl mesylate underwent rather facile substitutions, particularly with sodium iodide and with potassium phenoxide even in the absence of any catalyst. It was found, however, that the catalytic efficiencies of the complex as well as the uncoated silica gel had no relation to the substrate reactivity, but the efficiencies were determined by the combination of leaving group and attacking nucleophile.

Neither the complex nor the uncoated silica gel facilitated the displacements of decyl mesylate attacked by soft-basic ions, such as iodide and cyanide. In contrast, the displacements of the mesylate by hard-basic ions, acetate and phenoxide, were enhanced both by the complex and by the uncoated silica gel. The catalysis of the complex in these reactions, however, has nothing to do with the supported ionene because the catalytic efficiency of the complex coincides with that of the uncoated silica gel. Interestingly, it is only with bromide ion, a medium-basic nucleophile, that the substitution of decyl mesylate was really catalyzed by the ionene adsorbed on silica gel.

When bromide was a leaving group, the distinct catalytic action of the 3-4, Br complex was observed except for the reaction with sodium cyanide (Table 3), while the nonsupported 3-4, Br hardly catalyzed either reaction. The complex was catalytically more active than the uncoated silica gel, indicating that the adsorbed ionene played a key role in the catalysis. Furthermore, the reaction of 1-bromodecane was fast with hard acetate or phenoxide rather than with soft iodide, though the rates were considerably leveled among these reactions compared to the reactions of decyl mesylate. This fact is consistent with the observations that acetate[8)] and phenoxide[20)] are relatively reactive under anhydrous phase-transfer conditions.

On the basis of all the results, the catalysis of the complex may be summarized as follows. Silica gel undoubtly assists the catalysis through activating the ammonium salts of the ionene. However, the overall rates of the catalytic reactions were controlled by ion-exchange process. Taking into consideration that the uncoated silica gel accelerates the substitutions with hard-basic nucleophiles, silica gel likely facilitates the ion exchange rather selectively of hard-basic anions.

Asymmetric Hydrocyanation of Aldehydes Using Chiral Titanium Reagents

Hiroyuki MINAMIKAWA, Satoshi HAYAKAWA, Tohru YAMADA, Nobuharu IWASAWA, and Koichi NARASAKA*
Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113
(Received July 30, 1988)

Two highly enantioselective methods for hydrocyanation of aldehydes were developed by using chiral alkoxytitanium reagents. Treatment of benzaldehyde with cyanotrimethylsilane in the presence of a chiral alkoxytitanium affords mandelonitrile in good chemical and optical yields. By the use of the chiral cyanotitanium reagent generated in situ from the chiral alkoxytitanium and cyanotrimethylsilane, aliphatic aldehydes are converted into the corresponding cyanohydrins in a highly enantioselective manner.

Asymmetric synthesis of cyanohydrins is an important process in organic synthesis, because cyanohydrins can be easily converted into a variety of valuable synthetic intermediates such as α-hydroxy carboxylic acids, α-hydroxy ketones, and β-amino alcohols. Since the first report by Bredig and Fiske who discovered that chiral mandelonitrile can be obtained by the quinine-catalyzed reaction of hydrogen cyanide and benzaldehyde,[1] a great progress has been made in the asymmetric synthesis of cyanohydrins, and recently several efficient methods have been reported to prepare cyanohydrins in high optical purity. For example, optically active cyanohydrins are obtained with good selectivity by diastereoselective reactions of cyanating reagents with chiral acetals.[2] However, the chiral auxiliaries are destroyed in the process of removing them from the products and not recovered. In the enantioselective reactions using chiral catalysts, such as boryl compounds,[3] D-oxynitrilase,[4] and synthetic peptides,[5] the optical purities of the resulting cyanohydrins are not sufficient except in the case of the preparation of mandelonitrile derivatives.

We reported an enantioselective Diels-Alder reaction by the use of the chiral alkoxytitanium-Molecular Sieves (MS) 4A system.[6] As another utility of this chiral titanium reagent, we examined the asymmetric hydrocyanation of aldehydes.[7]

Firstly, we examined the reaction of 3-phenylpropanal and cyanotrimethylsilane using the chiral alkoxytitanium generated in situ by mixing dichlorodiisopropoxytitanium(IV) and the chiral 1,4-diol, (2*R*,3*R*)-2,3-*O*-(1-phenylethylidene)-1,1,4,4-tetraphenyl-1,2,3,4-butanetetrol (**1**). When 3-phenylpropanal was treated with cyanotrimethylsilane in the presence of the chiral titanium reagent in toluene at −65 °C, the reaction proceeded slowly. On the other hand, by the addition of MS 4A to this solution, the reaction was found to proceed smoothly at the same temperature. Thus, powdered MS 4A were added at room temperature to a toluene solution of dichlorodiisopropoxytitanium(IV), and the chiral diol **1**, then 3-phenylpropanal and excess amounts of cyanotrimethylsilane were added at −65 °C to afford 2-hydroxy-4-phenylbutanenitrile (**3a**, 89% yield, 74% ee). The asymmetric hydrocyanation of 3-phenylpropanal was also investigated in various solvents such as cumene (55% yield, 60% ee, at −65 °C), mesitylene (70% yield, 60% ee, at −45 °C), dichloromethane (23% yield, 72% ee, at −65 °C), acetonitrile (77% yield, 36% ee, at −45 °C), diethyl ether (42% yield, 0% ee, at −65 °C) and tetrahydrofuran (72% yield, 0% ee, at −65 °C): Among them, high enantioselectivity was achieved when the aromatic solvents or dichloromethane was used, but the enantioselectivity decreased when the solvents having

good donor property such as acetonitrile, diethyl ether, and tetrahydrofuran were employed.

It was also found that cyanotrimethylsilane gave the best chemical and optical yields among various cyanating reagents examined: The reaction did not proceed even at room temperature when potassium cyanide with 18-crown-6 or t-butyl isocyanide was employed, and low chiral induction was observed when cyanotributyltin(IV) (52% yield, 0% ee, at −78 °C) or cyanodiethylaluminium (81% yield, 7% ee, at −78 °C) was used as a cyanating reagent. Therefore, the asymmetric hydrocyanation of various aldehydes with cyanotrimethylsilane was examined in toluene at −65 °C (Scheme 1), and the results are summarized in Table 1.

As shown in Table 1, these aldehydes smoothly react with cyanotrimethylsilane to give the optically active cyanohydrins in good optical yield (68—96% ee). Especially, benzaldehyde is converted into (*R*)-mandelonitrile in high optical purity (Entry 5, 96% ee).

When we tried the reaction of 3-phenylpropanal with cyanotrimethylsilane in the presence of a 25% molar amount of the chiral titanium reagent, the chemical yield of the cyanohydrin **3a** was 26%. Furthermore, in every case, no trimethylsilyl ether of a cyanohydrin was detected after the treatment of the reaction mixture with pH 7 phosphate buffer. These results show that cyanohydrins are generated not as silyl ethers but as titanium ethers **2**. The following experiments were carried out in order to examine whether the optically active cyanohydrins were obtained thermodynamically or kinetically. When 3-phenylpropanal was treated with cyanotrimethylsilane in the presence of the chiral titanium reagent and MS 4A at room temperature for 12 h and then the reaction mixture was stirred at −65 °C for 1 d, the optical purity of the resulting cyanohydrin was low (ca. 10% ee). Almost the same level of chiral induction (10% ee) was observed when the above reaction was performed at room temperature for 12 h. These results indicate that the cyanohydrin obtained by the present procedure is not a thermodynamic product but a kinetic product.

In order to get informations on the reaction mechanism, NMR spectrum of cyanotrimethylsilane and the titanium reagent was measured. The ^1H NMR spectrum of the mixture of cyanotrimethylsilane and the chiral alkoxytitanium prepared in situ by mixing the chiral diol **1** and dichlorodiisopropoxytitanium(IV) in toluene-d_8 at −65 °C shows a singlet peak at δ=−0.09 which corresponds to cyanotrimethylsilane, and no absorption is observed at δ=0.20 which corresponds to chlorotrimethylsilane irrespective of the presence or absence of MS 4A. This observation seems to suggest that in the reaction at low temperature the chiral alkoxytitanium reagent activates an aldehyde as a Lewis acid and the activated aldehyde reacts with cyanotrimethylsilane to afford a cyanohydrin. On the other hand, when the mixture of the chiral alkoxytitanium and cyanotrimethylsilane is slowly warmed up to room temperature, the ^1H NMR spectrum indicates the decreasing of the absorption at δ=−0.09 and the appearance of a singlet peak at δ=0.20. This phenomenon is explained by assuming that the ligand-exchange reaction occurs between the chiral alkoxytitanium and cyanotrimethylsilane at room temperature,

a) Reaction temperature is −65 °C.

resulting in the formation of cyanotitanium species and chlorotrimethylsilane. Integration of the peak at δ=0.20 was attributed to 2 molar amounts of chlorotrimethylsilane, that is, titanium dicyanide species **4** might be generated by the addition of excess (5 molar) amounts of cyanotrimethylsilane (Scheme 2). We were interested in utilizing this chiral cyanotitanium species **4** as a chiral cyanating reagent of aldehydes (Scheme 3). Thus, to a toluene solution of dichlorodiisopropoxytitanium(IV) was added the chiral diol **1** and then cyanotrimethylsilane at 1 hour intervals at room temperature to generate the chiral cyanotitanium reagent. Then 3-phenylpropanal was added at −78 °C and the mixture was further stirred for 20 h. Work-up of the reaction mixture afforded 2-hydroxy-4-phenylbutanenitrile (**3a**) in 88% yield and the optical purity rose up to 91% ee as compared with the result of the previous procedure (74% ee).

The same reactions using various aldehydes were examined in toluene at −78 °C and the results are summarized in Table 2. According to this procedure, the optical purity of aromatic cyanohydrins (Entries 2 and 6) are not sufficiently high, but aliphatic cyanohydrins are prepared in good yield with high optical purity (>85% ee, Entries 3, 4, and 5). The absolute configurations of (+)-2-hydroxy-3-phenylpropanenitrile (**3b**), (+)-mandelonitrile (**3e**), and (+)-2-hydroxyundecanenitrile (**3f**) obtained by employing the (2*R*, 3*R*)-diol **1** were determined to be *R* by the comparison of their rotations with those of the literature.[8] As for (+)-2-hydroxydecanenitrile (**3c**) and (+)-2-hydroxy-11-dodecenenitrile (**3g**), there is no literature concerning the absolute configuration. However, from the analogy that straight-chain aliphatic cyanohydrins such as (*S*)-2-hydroxyhexanenitrile, (*S*)-2-hydroxyheptanenitrile, (*S*)-2-hydroxyoctanenitrile and (*S*)-2-hydroxyundecanenitrile have (−)-rotation,[8] they are assumed to have *R* absolute configuration. Exceptionally 2-hydroxy-4-phenylbutanenitrile (**3a**) was obtained with the opposite (−)-rotation, but the absolute configuration was determined to be *R* after the hydrolysis to the known 2-hydroxy-4-phenylbutanoic acid.[9] These results indicate that cyanide attacks the *si*-face of aldehydes when the (2*R*,3*R*)-diol **1** is employed as a chiral auxiliary.

In conclusion, the optically active cyanohydrins can be obtained not only from aromatic aldehydes but also from aliphatic aldehydes in high optical yields by applying either method. The both enantiomers of cyanohydrins can be prepared in high optical purity since each enantiomer of the chiral 1,4-diol **1** is readily prepared from the commercially available (*R*)- and (*S*)-tartaric acids.

Experimental

General. (a) Spectrometers: IR spectra were measured with a Hitachi Model 260-30 spectrophotometer. ^{1}H NMR spectra were recorded with Hitachi R-24B, JEOL FX90Q and Varian EM390 spectrometers. ^{19}F NMR spectra were taken by using a Varian EM390 spectrometer. High-mass spectra were recorded with a JEOL JMS-D300 mass spectrometer operating at 70 eV. The optical rotations were measured with a JASCO DIP-181 digital polarimeter. (b) Chromatography: Column chromatography was conducted under silica gel (E. Merck, 7734, 70—230 mesh). Preparative TLC was carried out on silica gel (Wakogel B-5F). HPLC was performed using a Waters RESOLVE C_{18} (86016) column. (c) Solvents and Reagents: Toluene was distilled and dried over MS 4A. Dichloromethane was distilled from P_2O_5 then from CaH_2, and was dried over MS 4A. Diethyl ether and tetrahydrofuran were freshly distilled from sodium benzophenone ketyl. Acetonitrile was distilled from P_2O_5, and further distilled from CaH_2, and dried over MS 4A. Mesitylene was distilled and dried over MS 4A. Cumene was distilled from $LiAlH_4$. Dichlorodiisopropoxytitanium(IV) was prepared from titanium(IV) chloride and tetraisopropoxytitanium(IV) according to the literature.[10] Aldehydes

were distilled prior to use. Cyanotrimethylsilane was purified by distillation.

Preparation of (2*R*,3*R*)-2,3-*O*-(1-Phenylethylidene)-1,1,4,4-tetraphenyl-1,2,3,4-butanetetrol (1). Dimethyl (2*R*,3*R*)-2,3-*O*-(1-Phenylethylidene)tartrate. To a benzene solution of dimethyl (2*R*,3*R*)-tartrate (10.7 g, 60 mmol) and acetophenone dimethyl acetal (10.6 g, 60 mmol) was added a catalytic amount of *p*-toluenesulfonic acid, and the mixture was heated to reflux to remove liberated methanol azeotropically with occasional addition of benzene until the boiling point reached 80.5 °C. The mixture was washed with sat. aq. $NaHCO_3$ and then with brine and dried over Na_2SO_4. The solvent was removed under reduced pressure and the residual oil was purified by column chromatography (8:1 hexane/diethyl ether) to afford the product, which was further purified by distillation to give the pure product (10.7 g, 63% yield). Bp 132 °C/0.30 mmHg (1 mmHg≈133.322 Pa); ^1H NMR ($CDCl_3$) δ=1.58 (s, 3H), 3.30 (s, 3H), 3.64 (s, 3H), 4.65 (s, 2H), and 7.0—7.7 (m, 5H); IR (neat) 1740 cm^{-1}; $[\alpha]_D$ +11° (*c* 2.6, CH_2Cl_2).

(2*R*,3*R*)-2,3-*O*-(1-Phenylethylidene)-1,1,4,4-tetraphenyl-1,2,3,4-butanetetrol (1). To a tetrahydrofuran (50 ml) solution of phenylmagnesium bromide (25.0 mmol) was added a tetrahydrofuran (10 ml) solution of dimethyl (2*R*,3*R*)-2,3-*O*-(1-phenylethylidene)tartrate (1.4 g, 5.0 mmol) at 0 °C. After stirring for 4 h at room temperature, the reaction was quenched with sat. aq. NH_4Cl solution. Organic materials were extracted with ethyl acetate, and the combined extracts were washed with brine, and dried over Na_2SO_4. The solvent was removed under reduced pressure and the residue was purified by column chromatography (9:1 hexane/diethyl ether) to afford white amorphous solid. This solid was dissolved in a small amount of hexane, and 2-propanol was added with stirring to afford white crystals. These crystals were recrystallized from 1:1 mixture of hexane and 2-propanol. The crystals thus obtained were a complex of **1** and 2-propanol, and 2-propanol was removed azeotropically with benzene 3 times to afford **1** as white amorphous solid (1.6 g, 60% yield). ^1H NMR ($CDCl_3$) δ=1.30 (s, 3H), 2.32 (s, 1H), 2.45 (s, 1H), 5.04 (d, 1H, *J*=6.0 Hz), 5.08 (d, 1H, *J*=6.0 Hz), and 6.8—7.6 (m, 25H); IR(KBr) 3300, 1490, 1445, and 695 cm^{-1}; $[\alpha]_D^{23}$ +82.9° (*c* 1.3, $CHCl_3$). The elemental analysis was performed after the conversion to the corresponding bis(trimethylsilyl) ether: Found: C, 74.68; H, 7.12%. Calcd for $C_{42}H_{48}O_4Si_2$: C, 74.96; H, 7.19%.

Cyanohydrins: General Procedure for Hydrocyanation of Aldehydes (Method A, Table 1). All reactions were carried out under argon atmosphere. To a toluene (1 ml) solution of dichlorodiisopropoxytitanium(IV) (119 mg, 0.5 mmol) was added a toluene (2 ml) solution of the chiral diol **1** (291 mg, 0.55 mmol) at room temperature. After 1 h, powdered MS 4A (65 mg, heated at 200—300 °C in vacuo prior to use) were added to this solution. Then a toluene (1 ml) solution of aldehyde (0.5 mmol), and a toluene (1 ml) solution of cyanotrimethylsilane (250 mg, 2.5 mmol) were added at −65 °C. After stirring for 0.5—2 d at this temperature, the reaction was quenched with pH 7 phosphate buffer, and the resulting mixture was filtered through Celite. Organic materials were extracted with ethyl acetate, and the combined extracts were washed with brine, and dried over Na_2SO_4. The solvent was removed under reduced pressure and the residue was purified by preparative TLC (hexane/diethyl ether) to afford the corresponding cyanohydrin. The optical purity was assayed by HPLC (40:1 hexane/ethyl acetate) or by ^{19}F NMR analysis of the corresponding (*R*)-(+)-3,3,3-trifluoro-2-methoxy-2-phenylpropionate (MTPA).[11]

General Procedure for Hydrocyanation of Aldehydes Using the Chiral Cyanotitanium(IV) Species (Method B, Table 2). To a toluene (1 ml) solution of dichlorodiisopropoxytitanium(IV) (119 mg, 0.5 mmol) was added a toluene (1 ml) solution of the chiral diol **1** (291 mg, 0.55 mmol) at room temperature. After 1 h, a toluene (1 ml) solution of cyanotrimethylsilane (250 mg, 2.5 mmol) was added at room temperature, and after 1 h, a toluene (1 ml) solution of aldehyde (0.5 mmol) was added at −78 °C. After stirring for 12—122 h at this temperature, the reaction was quenched with pH 7 phosphate buffer, and the resulting cyanohydrin was isolated by the same procedure described above.

2-Hydroxy-4-phenylbutanenitrile (3a). ^1H NMR ($CDCl_3$) δ=1.8—2.2 (m, 2H), 2.6—2.9 (m, 2H), 3.7—4.0 (br, 1H), 4.3 (t, 1H), and 7.1 (s, 5H); IR(CCl_4) 3440, 2930, 1600, 1500, 1450, and 1070 cm^{-1}; $[\alpha]_D^{22}$ −6.79° (*c* 2.04, $CHCl_3$, 89% ee). HRMS Found: *m/z* 161.0873. Calcd for $C_{10}H_{11}NO$: M, 161.0841.

2-Hydroxy-3-phenylpropanenitrile (3b). ^1H NMR ($CDCl_3$) δ=2.9—3.1 (m, 3H), 4.4—4.7 (m, 1H), and 7.3 (s, 5H); IR (CH_2Cl_2) 3430, 3020, 2920, 1600, 1480, and 1050 cm^{-1}; $[\alpha]_D^{26}$ +8.3° (*c* 1.10, $CHCl_3$, 65% ee), lit, $[\alpha]_D^{25}$ −0.5° ($CHCl_3$, 1% ee, (*S*)-form major).[8] HRMS Found: *m/z* 147.0654. Calcd for C_9H_9NO: M, 147.0685.

2-Hydroxydecanenitrile (3c). ^1H NMR (CCl_4) δ=0.8—1.8 (m, 17H), 3.2—3.4 (m, 1H), and 4.3—4.5 (m, 1H); IR (CH_2Cl_2) 3590, 3420, 2940, 2870, 2300, and 1430 cm^{-1}; $[\alpha]_D^{25}$ +12.8° (*c* 2.52, $CHCl_3$, 93% ee).

2-Cyclohexyl-2-hydroxyacetonitrile (3d). ^1H NMR ($CDCl_3$) δ=1.2—1.8 (m, 11H), 3.2—3.5 (br, 1H), and 4.1—4.4 (br, 1H); IR($CHCl_3$) 3600, 3430, 2930, 2860, 1450, and 1040 cm^{-1}; $[\alpha]_D^{25}$ +5.45° (*c* 2.96, $CHCl_3$, 58% ee).

Mandelonitrile (3e). ^1H NMR spectra and IR spectra agreed with those of literatures. $[\alpha]_D^{21}$ +45.5° (*c* 3.53, $CHCl_3$, 96% ee), lit, $[\alpha]_D^{25}$ +43.5° (*c* 5, $CHCl_3$, 92.5% ee, (*R*)-form major).[2a]

2-Hydroxyundecanenitrile (3f). ^1H NMR ($CDCl_3$) δ= 0.8—1.2 (m, 19H), 3.2—3.6 (br, 1H), and 4.4 (t, 1H); IR (CH_2Cl_2) 3580, 3410, 2910, 2850, and 1450 cm^{-1}; $[\alpha]_D^{25}$ +7.9° (*c* 4.03, $CHCl_3$, 85% ee), lit, $[\alpha]_D^{25}$ −2.4° ($CHCl_3$, 16% ee, (*S*)-form major).[8]

2-Hydroxy-11-dodecenenitrile (3g). ^1H NMR ($CDCl_3$) δ= 1.2—2.1 (m, 16H), 3.4—3.6 (br, 1H), 4.4 (t, 1H), 4.8—5.1 (m, 2H), and 5.5—6.1 (m, 1H); IR(CCl_4) 3420, 2900, 2250, and 1640 cm^{-1}; $[\alpha]_D^{21}$ +10.5° (*c* 2.68, $CHCl_3$, 93% ee). HRMS Found: *m/z* 195.1592. Calcd for $C_{12}H_{21}NO$: M, 195.1624.

Hydrolysis of 3a. To **3a** (0.36 mmol, 77% ee, $[\alpha]_D^{23}$ −4.46° (*c* 8.40, $CHCl_3$)) was added 4 ml of concentrated hydrochloric acid. After refluxed for 4 h, 4 ml of water was added and organic materials were extracted with ethyl acetate. The combined extracts were washed with brine, and dried over Na_2SO_4. The solvent was removed under reduced pressure and the residue was recrystallized from benzene to afford white crystals of 2-hydroxy-4-phenylbutanoic acid (59 mg, 91% yield). ^1H NMR ($CDCl_3$) δ=1.7—2.4 (m, 2H), 2.8 (t, 2H), 4.2 (t, 1H), 5.2—6.2 (br, 2H), and 7.2 (s, 5H); IR(KBr) 3470, 2920, 1730, 1600, 1500, 1290, and 1240 cm^{-1}; $[\alpha]_D^{24}$ −6.03° (*c* 1.18, C_2H_5OH), lit, $[\alpha]_D$ −8.6° (*c* 1, C_2H_5OH, (*R*)-form).[9]

The Redox Reaction by Ferrocene Derivatives Introduced to a Crown Ether in a Liquid Membrane System

Eiichi Ozeki, Shunsaku Kimura, and Yukio Imanishi*
Department of Polymer Chemistry, Kyoto University, Yoshida Honmachi, Sakyo-ku, Kyoto 606
(Received December 26, 1987)

In an organic liquid membrane system, 4′-(ferrocenylcarbonylamino)benzo-18-crown-6 (FCC) dissolved in a dichloromethane membrane was found to reduce hexacyanoferrate(III) ions in the aqueous phase to hexacyanoferrate(II) ions at a rate dependent on the type of metal ion coexisting in the aqueous phase, and bound to the benzo-18-crown-6 unit of FCC.

Transport of electrons, protons, and metal ions across a biological membrane plays an essential role in the transduction of information through the biological membrane. It is known that the transport is mediated by various substances, and furthermore, the different transport systems are frequently coupled with each other.[1]

Recently, several kinds of crown ether derivatives including "antenna" compounds, which respond to light,[2,3] pH,[4,5] redox reagents,[6-8] and electrochemical potential,[9-12] have been synthesized and investigated for the facilitated capture and transport of cations.

In the present study, 4′-(ferrocenylcarbonylamino)-benzo-18-crown-6 (FCC), composed of a ferrocene and a crown ether unit, was synthesized. Ferrocene derivatives are known as electron carriers through a lipid and liquid organic membrane in the presence of lipophilic anions. A ferrocene unit possesses a positive charge in the oxidized state and is neutral in the reduced state.[13] 18-Crown-6 forms a complex with alkali metal ions, especially with a K^+ ion, and it is capable of transporting metal ions through an organic liquid membrane.[14,15]

We examined the redox reaction of FCC solubilized in an organic liquid membrane with a redox reagent dissolved in an aqueous phase containing metal ions. The purpose of the present study is to investigate if the redox reaction of the ferrocene unit of FCC is regulated by the binding of cation with the crown ether unit of FCC, and to examine the possibility of coupled electron and metal-ion transport across an organic liquid membrane.

Experimental

Synthesis. 4′-(Ferrocenylcarbonylamino)benzo-18-crown-6 was prepared according to the scheme shown in Fig. 1. Benzo-18-crown-6 was synthesized from catechol and pentaethylene glycol.[16] An amino group was introduced to the benzene ring of benzo-18-crown-6 by a nitration and reduction reaction.[17] Ferrocenecarbonyl chloride[18] was coupled with 4′-aminobenzo-18-crown-6 in a *N,N*-dimethylformamide (DMF) solution with stirring overnight. DMF was distilled off and the residue was dried under reduced pressure. The crude product obtained was purified by eluting through a silica-gel column (95% $CHCl_3$/5% CH_3OH). Found: C, 59.97; H, 6.27; N, 2.30%. Calcd for $C_{27}H_{33}NO_7Fe$: C, 60.15; H, 6.18; N, 2.60%.

1,1′-Dibutylferrocene (DBF) and dibenzo-18-crown-6 (DBC) were commercially available and used as reference mediators.

Measurement. The electron and cation transport were measured using a U-shaped tube.[19] The aqueous phase I (5 ml) was separated from aqueous phase II (5 ml) by an organic liquid membrane phase (20 ml) containing mediators.

The redox capability of FCC was examined by a two-phase system composed of dichloromethane/water. The aqueous phase (5 ml) contained 1 mM potassium hexacyanoferrate(III) and 54 mM metal chloride, and the dichloromethane phase (10 ml) contained 0.3 mM FCC.

The concentration of hexacyanoferrate(III) ions was determined by measuring the absorption at 420 nm.

The cyclic voltammogram of FCC was measured in an acetonitrile solution containing 0.1 M tetrabutylammonium-hexafluorophosphate.

Results and Discussion

The redox reaction by FCC dissolved in a dichloromethane membrane was examined by using a U-shaped tube system (Fig. 2). It was found that FCC did not extensively reduce hexacyanoferrate(III) ions in the aqueous phase I, before the addition of Na^+ ions. However, the concentration of hexacyanoferrate(III) ions decreased rapidly upon the addition of Na^+ ions to the aqueous phase I. The effect of metal ions on the

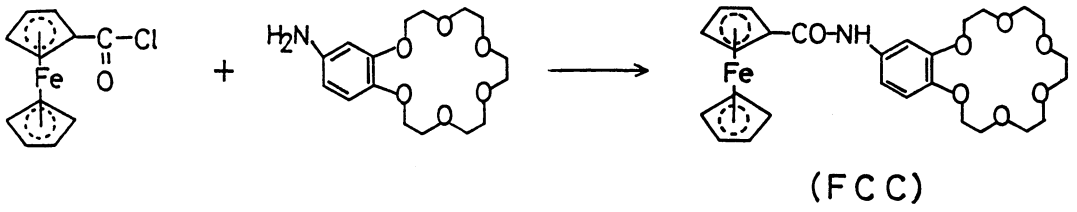

Fig. 1. Synthetic route of FCC.

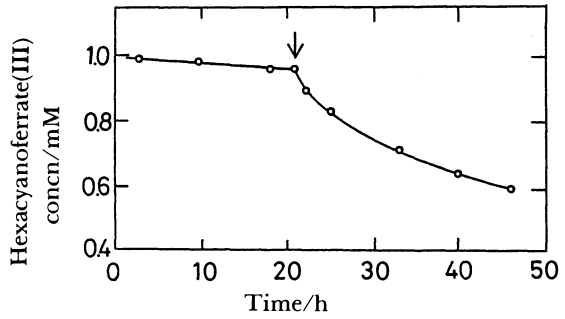

Fig. 2. Change in the concentration of hexacyanoferrate(III) ions against time in the aqueous phase I. Initial composition: aqueous phase I, 1 mM potassium hexacyanoferrate(III); aqueous phase II, 2.5 mM sodium ascorbate; organic phase M, 0.3 mM FCC in DCM. ↓: addition of 1 M NaCl.

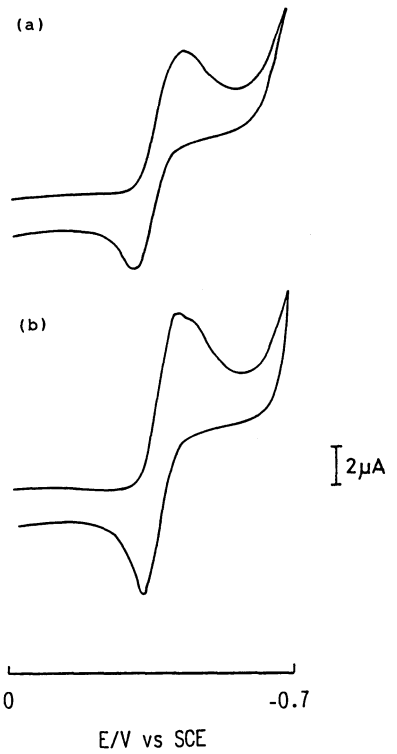

Fig. 3. Cyclic voltammograms in acetonitrile solution of FCC (a) in the absence and (b) in the presence of 1.0 equiv of $KClO_4$.

redox reaction of FCC was examined by a cyclic voltammogram (Fig. 3), and UV and NMR spectroscopies. In these measurements, no significant change was observed on the addition of a metal ion. It is therefore concluded that complexation of the crown ether unit of FCC with a metal ion does not change the redox potential or electron density of the ferrocene unit. Taken together, these experimental results show that the redox reaction by FCC is regulated by the complexation of the crown ether unit of FCC with a metal ion in the aqueous phase. However, the complexation process does not alter the redox potential of the ferrocene unit of FCC.

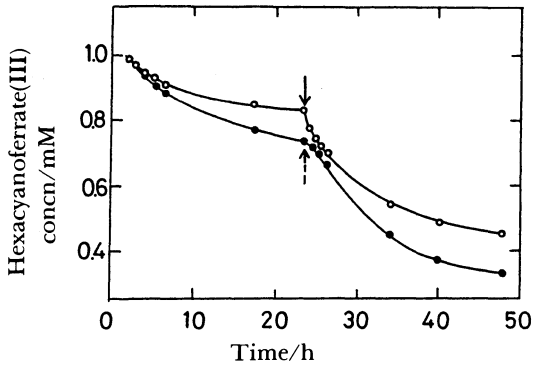

Fig. 4. Change in the concentration of hexacyanoferrate(III) ions against time in aqueous phases I (○) and II (●). Initial composition: aqueous phase I, 1 mM potassium hexacyanoferrate(III), 1 mM potassium hexacyanoferrate(II) and 54 mM $NaClO_4$; aqueous phase II, 1 mM potassium hexacyanoferrate(III), 1 mM potassium hexacyanoferrate(II) and 54 mM $KClO_4$; organic phase, 0.3 mM FCC in DCM .↓: addition of 540 mM NaCl, ↑: addition of 540 mM KCl.

When 1,2-dichloroethane (DCE) was used as an organic liquid membrane, the concentration of hexacyanoferrate(III) ions did not decrease. DCE and DCM have a similar dielectric constant, however, their solubilities in water are different (0.869 g of DCE and 2.0 g of DCM are soluble in 100 g of water).[20] Therefore, the state on the water/DCM boundary region must be different from that of water/DCE, indicating that the nature of the interface between the organic phase and aqueous phase should have a strong influence on the redox reaction by FCC.

An active electron transportation with DBF driven by the different concentration of lipophilic anions between the two aqueous phases has been reported by Sinbo et al.[21] In this study, FCC was examined as a mediator of the active electron transport against redox potential driven by the selective complexation with metal ions and/or the cation transport through an organic membrane. Aqueous phases containing the same concentrations of hexacyanoferrate(III) and hexacyanoferrate(II) ions were separated by a DCM membrane containing FCC. Na^+ ions were added to the aqueous phase I and K^+ ions to the a aqueous phase II. Figure 4 shows the change in the concentration of hexacyanoferrate(III) ions in the aqueous phases I and II. In both phases, concentration of hexacyanoferrate(III) ions decreased. The decrease in the concentration of hexacyanoferrate(III) ion in the aqueous phase II containing K^+ ions was larger than that in the aqueous phase I containing Na^+ ions. This indicates that FCC failed to transport electrons across the DCM membrane.

Reduction of hexacyanoferrate(III) ions by FCC in the DCM solution was examined using a two-phase system (DCM/water). It was found that FCC in the DCM solution reduced hexacyanoferrate(III) ions in

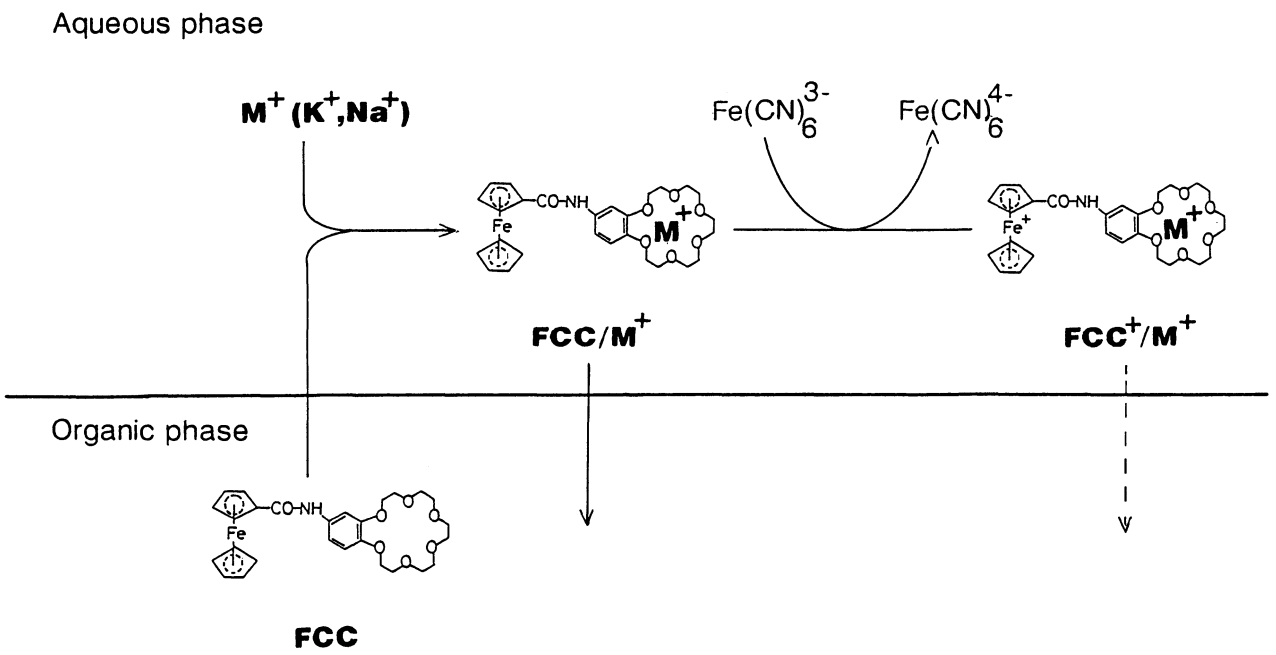

Fig. 5. The diagram of redox behavior of FCC in a liquid organic membrane system with a metal ion.

the aqueous phase containing a high concentration of either K^+ or Na^+ ions. The degree of the reduction of hexacyanoferrate(III) ions by FCC in the aqueous phase was 60% in the presence of K^+ ions, and 45% in the presence of Na^+ ions for 15 h after contacting both phases. These observations indicate that FCC reduces hexacyanoferrate(III) ions to hexacyanoferrate(II) ions in the presence of a metal ion, and that the extent of the reaction is controlled by the type of metal ion in the aqueous phase.

These experimental results can be explained by the mechanism shown in Fig. 5. The ferrocene unit of FCC in DCM solution can not be in contact with hexacyanoferrate(III) ions in the aqueous phase efficiently without metal ions. However, in the presence of metal ions, the ferrocene unit of FCC interacts with hexacyanoferrate(III) ions by complexation of the crown ether unit with a metal ion. FCC was shown to reduce hexacyanoferrate(III) ions more efficiently in the presence of a K^+ ion than in the presence of a Na^+ ion, because 18-crown-6 forms a complex with a K^+ ion more selectively than with a Na^+ ion. However the oxidized FCC (FCC^+) or its complex with a metal ion is so hydrophilic[22,23] that the molecule including an oxidized ferrocene unit can not diffuse freely across a DCM membrane even in the presence of lipophilic anions. This could be the reason for the failure of electron transport by FCC through an organic liquid membrane.

On the other hand, FCC was shown to transport 13.3 μmol of K^+ ions through DCM membrane in 12 h. This was determined by an atomic absorption method. However DBC transported 30.9 μmol of K^+ ions and DBF did not in the experiments using the U-shaped tube system (the aqueous phase I, 0.1 mM potassium hexacyanoferrate(III); the aqueous phase II, 0.1 mM sodium ascorbate and 300 mM KSCN; the DCM phase, 1 mM FCC, DBC, or DBF). This indicates that FCC can transport K^+ ions according to the concentration gradient of K^+ ions, when a metal ion does not exist in the aqueous phase I, in other words, the ferrocene unit of FCC is not oxidized by hexacyanoferrate(III) anions in the aqueous phase I.

Uphill transport of a picrate anion under a concentration gradient of K^+ ions across an organic liquid membrane has been examined using several mediators.[24] It is found that FCC showed an active transport of a picrate anion as in the case of a DBC mediator. This indicates that FCC, which is not oxidised, is active as an ionophore for K^+ ion in the presence of a picrate anion.

We thank Dr. Naoki Kamo, Hokkaido University, for his advice on the transport experiment.

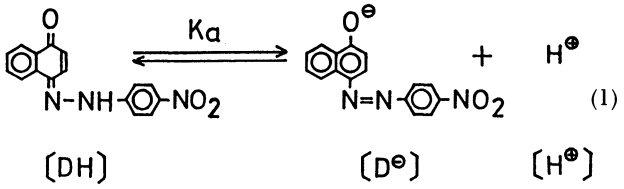
Studies on Coupling Reaction of 1-Naphthol. XI.[1] Effect of Additives on the Dissociation Equilibrium of 4-(4-Nitrophenylazo)-1-naphthol in Pyridine

Satoshi KISHIMOTO,* Tsuneo OKUSHI, and Tsuneaki HIRASHIMA
Osaka Municipal Technical Research Institute, Morinomiya, Joto-ku, Osaka-shi 536
(Received January 30, 1988)

The dissociation of 4-(4-nitrophenylazo)-1-naphthol (azo dye) in pyridine was found to be accelerated by the addition of small amounts of quaternary ammonium compounds, $R_4N^+X^-$. The apparent equilibrium constant of the azo dye was influenced enormously by the species of X^-, but was little affected by the structures of R. The effect increased as the X^- became more basic, $ClO_4^- < I^- < BF_4^- < Br^- < HSO_4^- < Cl^-$, in proportion to the ability of X^- to bind with protons formed by dissociated azo dye. The basicity of the X^-, pK_c, was correlated linearly with the variation of the equilibrium constant, owing to the addition of $R_4N^+X^-$, δpK_a. The dissociation of the azo dye in pyridine-water mixtures was also accelerated upon increasing the amount of water (0—10 vol%), correlating with an increase in the basicity of the solution.

The physical properties of azo dyestuffs (e.g., tone, color, crystal form) have been closely related with their dissociation as well as their tautomerism.

4-(4-Nitrophenylazo)-1-naphthol (azo dye) is particularly interesting as the basic structure of the azo compound. The undissociated form of the azo dye, fortunately, exists entirely as a hydrazone form in a solvent such as pyridine, as described in a previous paper.[2] Therefore, the dissociation of azo dye can be described by the equilibrium between the hydrazone form, DH, and the dissociated form, $D^\ominus$, as shown in Eq. 1.



(1)

In polar aprotic solvents, such as dimethyl sulfoxide and *N,N*-dimethylformamide, azo dye exists partly in the dissociated form.[2] In this paper we report that the dissociation of azo dye in pyridine is accelerated by the addition of small amounts of quaternary ammonium compounds, R_4NX. We also describe the relationship between the variation of the equilibrium constant, owing to the addition of R_4NX, and the basicity of the $X^\ominus$.

Experimental

Material. The azo dye, 4-(4-nitrophenylazo)-1-naphthol, was prepared according to a method described in the literature.[3]

Methods. The spectra of the azo dye were taken on a Shimadzu UV-240 spectrometer in a 1.6×10^{-5} M solution (1 M=1 mol dm^{-3}) with 10 mm cuvettes; Beer's law was shown to be obeyed this concentration. The variation of the equilibrium constant, owing to the addition of R_4NX, δpK_a, of azo dye, was estimated in the following way. The absorption maxima for DH and $D^\ominus$ in pyridine are 472 and 655 nm, respectively. If the molar extinction coefficients of DH (or $D^\ominus$) at 472 and 655 nm in pyridine are expressed by ε_{472}^{DH} and ε_{655}^{DH} (or $\varepsilon_{472}^{D^\ominus}$ and $\varepsilon_{655}^{D^\ominus}$), and the mole fractions of DH and $D^\ominus$ by y and x, respectively, then the ratios of the molar extinction coefficients at 472 and 655 nm ($\varepsilon_{472}/\varepsilon_{655}$) should be

$$\frac{\varepsilon_{472}}{\varepsilon_{655}} = \frac{x\varepsilon_{472}^{D^\ominus} + y\varepsilon_{472}^{DH}}{x\varepsilon_{655}^{D^\ominus} + y\varepsilon_{655}^{DH}} \quad (2)$$

Figure 1 shows that the ε_{655}^{DH} is almost zero;[2] therefore, Eq. 2 yields

$$\frac{y}{x} = \frac{\varepsilon_{655}^{D^\ominus}}{\varepsilon_{472}^{DH}} \times \left(\frac{\varepsilon_{472}}{\varepsilon_{655}} - \frac{\varepsilon_{472}^{D^\ominus}}{\varepsilon_{655}^{D^\ominus}}\right) . \quad (3)$$

The ratio $\varepsilon_{472}^{D^\ominus}/\varepsilon_{655}^{D^\ominus} = 2.8/80.3 = 0.035$ was determined by measurements in a pyridine solution saturated with sodium hydroxide; $2.23 (=(80.3-4.1)\times10^3/(36.9-2.8)\times10^3)$ for $\varepsilon_{655}^{D^\ominus}/\varepsilon_{472}^{DH}$ was evaluated by the ratio of the difference in the molar extinction coefficients at 655 and 472 nm between solutions of the azo dye in pyridine and pyridine saturated with sodium hydroxide. From these two ratios Eq. 3 yields

$$\frac{y}{x} = 2.23 \times \left(\frac{\varepsilon_{472}}{\varepsilon_{655}} - 0.035\right) . \quad (4)$$

From the y/x value, the proportions (%) and the concentrations ([DH] and [$D^\ominus$], mol l^{-1}) of DH and $D^\ominus$ can be calculated. When [$H^\oplus$] is equal to [$D^\ominus$] in the dissociation constant (pK_a) of Eq. 5 applied in the equilibrium of Eq. 1, the apparent dissociation constant (pK_a') in the individual solutions containing the quaternary ammonium salts can be represented by the form of Eq. 6, and the difference (δpK_a) between the pK_a and the pK_a' may be expressed as in Eq. 7.

$$pK_a = -\log \frac{[D^\ominus][H^\oplus]}{[DH]} \quad (5)$$

$$pK_a' = -\log \frac{[D^\ominus]^2}{[DH]} \quad (6)$$

$$\delta pK_a = pK_a - pK_a' \quad (7)$$

If the solution of the azo dye is free from the quaternary ammonium salts pK_a' is equal to pK_a.

The pK_a' values in a pyridine-water solution were also estimated by using the same method.

Results and Discussion

Figure 1 shows the electronic spectrum of the azo dye in pure pyridine or pyridine saturated with sodium hydroxide. The band of the undissociated form (hydrazone form, DH) appeared at 472 nm, and that of the dissociated form (phenolate ion, $D^{\ominus}$) at 655 nm.[2] In pyridine, the addition of quaternary ammonium salts (R_4NX) increased the proportion of $D^{\ominus}$, while that of DH decreased. These two bands gave a well-defined isosbestic point at about 520 nm.

Table 1 exhibits the percentage of DH and $D^{\ominus}$ calculated from y/x (Eq. 4), the pK_a' from Eq. 6 and the δpK_a from Eq. 7 together with the molar extinction coefficients (ε_{472} and ε_{655}) at 472 and 655 nm upon the addition of various concentrations of tetrabutylammonium chloride ($(n\text{-}C_4H_9)_4NCl$). Figure 2 exhibits the relation of the δpK_a to the concentration of $(n\text{-}C_4H_9)_4NCl$. The δpK_a increased with increasing concentration of $(n\text{-}C_4H_9)_4NCl$, with the most dramatic effects observed at lower concentrations. Table 2 shows the result for addition of various quaternary ammonium salts (R_4NX) in 8.0×10^{-5} M solution. In all cases the apparent dissociation constant pK_a' for the addition of R_4NX gave a smaller value than the true dissociation constant pK_a (=7.41). The difference (δpK_a) between pK_a and pK_a' was influenced enormously by the species of anion $X^{\ominus}$ in $R_4N^{\oplus}X^{\ominus}$, but was little affected by the structure of an alkyl group R. Table 3 exhibits the dissociation constant pK_{HX}[4] for the conjugated acid HX of the $X^{\ominus}$ together with the δpK_a, and a plot of δpK_a vs. pK_{HX} is shown in Fig. 3. It is apparent from Fig. 3 that δpK_a increases linearly with increasing basicity of $X^{\ominus}$. These results lead to the following

discussion. The proton $H^{\oplus}$ formed[5] by the dissociation of azo dye (Eq. 1) reacts with the $X^{\ominus}$ produced in Eq. 8 to give HX (Eq. 9). Therefore, the equilibrium of Eq. 1 is shifted to the right.

$$R_4NX \overset{K_c}{\rightleftharpoons} R_4N^{\oplus} + X^{\ominus} \quad (8)$$

$$HX \overset{K_{HX}}{\rightleftharpoons} H^{\oplus} + X^{\ominus} \quad (9)$$

The above hypothesis can be tested by using the three dissociation constants into Eqs. 1, 8, and 9. Since the pK_a in Eq. 1 is 7.41 ($K_a=3.89\times10^{-8}$), $[H^{\oplus}]$ is equal to 0.077×10^{-5} mol l^{-1} at a total concentration of the azo dye of 1.6×10^{-5} mol l^{-1}; $[X^{\ominus}]$ in Eq. 8 is estimated to be $(7.45—5.25)\times10^{-5}$ mol l^{-1} at an R_4NX concentration of 8×10^{-5} mol l^{-1} because the pK_c[6] is 3—4. Next, we consider the equilibrium of HX, by employing

$[H^{\oplus}]=0.077\times10^{-5}$ and $[X^{\ominus}]=(7.45—5.25)\times10^{-5}$ mol l^{-1} in Eq. 9. If the $X^{\ominus}$ is a strong base, [e.g., the conjugate base of a very weak acid such as HCl in pyridine ($pK_{HCl}=5.7$, $K_{HCl}=2.0\times10^{-6}$)], [HX] becomes $(0.075—0.074)\times10^{-5}$ mol l^{-1}, corresponding to 97—96% of $[H^{\oplus}]=0.077\times10^{-5}$ mol l^{-1}. Therefore, the equilibrium of Eq. 1 may be significantly shifted to the right. On the other hand, if the $X^{\ominus}$ is a weak base [e.g., the conjugate base of a strong acid such as $HClO_4$ in pyridine ($pK_{HClO_4}=3.3$, $K_{HClO_4}=5.0\times10^{-4}$)], [HX] becomes $(0.0100—0.0075)\times10^{-5}$ mol l^{-1}, corresponding to 13—10% of $[H^{\oplus}]$. This means that the equilibrium of Eq. 1 may be only slightly shifted to the right.

The dissociation of azo dye in pyridine is also accelerated by the addition of a large quantity of water. Figure 4 shows the relation of δpK_a to the content of water. The δpK_a for 1 (0.56), 2(1.1), 5(2.8), and 10 vol% (5.6 mol l^{-1}) of water is 0.34, 0.64, 1.28, and 1.75, respectively. This indicates that the hydroxy anion $OH^{\ominus}$ formed in Eq. 10 reacts with a proton $H^{\oplus}$ (in Eq. 1), as shown in Eq. 11, so that the dissociation described in Eq. 1 may be accelerated, and that the basicity in such a solvent system may increase with the water content.

The Chlorination of Vinyl Compounds in Alcohols

Kiyonori SHINODA* and Kensei YASUDA
Toyama National College of Technology, 13 Hongo, Toyama 939
(Received April 25, 1988)

Upon the chlorination of vinyl compounds in alcohols, the reaction products were composed of 2-alkoxy-1-chloro compound (A), 1-alkoxy-2-chloro compound (B) and vicinal dichloride (C). Various vinyl compounds were chlorinated in alcohols at 40 °C in order to elucidate the effect of their molecular structure on the product distribution. The A/(A+B) was inversely proportional to the relative rate of ordinary chlorination in carbon tetrachloride. The A/(A+B) for the chlorination of allyl chloride in methanol was little affected by the reaction conditions: (1) reaction temperature, (2) mole ratio, and (3) elapse of time. However, the A/(A+B) increased with increasing E_s value of the alkyl group of alcohol.

It has been well-known that vicinal dichloride is accompanied by solvent-incorporated products during chlorination in common protic solvents.[1-3] The addition of bromine to olefin in methanol also produces methoxybrominated products.[4,5] The chlorination of various olefins in the protic solvent has been reviewed in detail by de la Mare and Bolton.[6] The kinetic forms, environmental effects, structural effects on the rates of chlorination and products have been described. The solvent-incorporated products for the chlorination of vinyl compound in methanol are composed of 1-methoxy-2-chloro and 2-methoxy-1-chloro compounds. These compounds represent Markownikoff and anti-Markownikoff orientations, respectively.

However, little is known concerning the formation ratio of two solvent-incorporated products. Furthermore, there has been no report on a quantitative examination of the alkoxychlorination of vinyl compounds.

The chlorination of vinyl compounds in various alcohols was carried out in order to elucidate the effect of the molecular structure on alkoxychlorination.

Results and Discussion

The solvent-incorporated products for the chlorination of vinyl compounds in methanol are composed of 1-methoxy-2-chloro and 2-methoxy-1-chloro compounds. The formation ratio of a mixture of two methoxychlorides to dichloride was gradually decreased with the elapse of time in the chlorination of vinyl compounds in methanol. This was because the concentration of methanol decreased as the reaction proceeded. The product composition of the chlorination of allyl cyanide in methanol is illustrated in Table 1.

On the other hand, the proportion of two methoxy chlorides was, roughly, kept constant throughout the reaction. Nevertheless, the formation ratio of two methoxy chlorides was widely changed with the molecular structure of the substrate. The product ratios for the chlorination of various vinyl compounds in methanol at 40 °C are shown in Table 2, together with the rate ratios for chlorination in carbon tetrachloride.[7] Symbols A, B and C represent 2-methoxy-

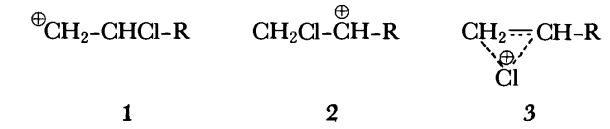
○: A/(A+B), ●: k/k_0.

1-chloro, 1-methoxy-2-chloro compounds and vicinal dichloride in the product composition, respectively. Two vinyl compounds were competitively chlorinated in carbon tetrachloride in the presence of oxygen at 30 °C. The value of the relative rate constant was caluculated according to a previously described method.[8] The k/k_0 is the relative rate constant with respect to the standard reaction (allyl chloride in this case). Figure 1 shows the effect of the molecular structure of a vinyl compound upon the formation ratio of two methoxy chlorides [A/(A+B)]. The logarithms of the relative rate constant for the chlorination of a vinyl compound in the presence of oxygen in carbon tetrachloride, as well as the formation ratio of two methoxy chlorides for the chlorination in methanol, are plotted against Taft's substituent constant (σ^*).[9] The data follow two straight lines, though opposite in sign. It is essential that k/k_0 be compared with A/(A+B) in order to consider the reaction mechanism of alkoxychlorination. The general nature of the first stage of attack by chlorine on an unsaturated molecule is established by the effect of the structure on the reaction rate.

As can be seen in Fig. 1, the rate of dark chlorination of a vinyl compound in the presence of oxygen in carbon tetrachloride was increased by the electron-releasing substituent group and decreased by the electron-withdrawing group. The reaction of chlorine with the vinyl compound (Q) in methanol might proceed according to the following mechanism:[2]

$$\mathrm{Q} + \mathrm{Cl_2} \longrightarrow \mathrm{QCl}^{\oplus} \xrightarrow{\mathrm{Cl}^{\ominus}} \mathrm{QCl\text{-}Cl}$$
$$\qquad\qquad\quad \xrightarrow{\mathrm{MeOH}} \mathrm{QCl\text{-}OMe} + \mathrm{H}^{\oplus} \qquad (1)$$

Fahey and Schubert,[1] using a stereochemical criterion, have shown that $QCl^{\oplus}$ may be either bridged or open, depending upon the stability of the open ion. It can be assumed that the intermediates formed in the rate-determining step for chlorination may alternatively be carbonium ion (**1**), carbonium ion (**2**) or bridged chloronium ion (**3**). In view of previous



1 **2** **3**

results,[7] the chlorine cation attacks on the carbon which carries an electron-withdrawing substituent to form the carbonium ion (**1**), whereas the substrate, having an electron-releasing group, converts into the carbonium ion (**2**). On the contrary, the bridged chloronium ion (**3**) is formed by the reaction of a chlorine cation with a vinyl compound having a moderate group, such as allyl chloride. While carbonium ion (**2**) is predominantly converted into B by a nucleophilic attack of methanol, carbonium ion (**1**) is transformed into A. It is reasonable to consider that A, B and C are produced by a competitive nucleophilic attack of methanol and a chloride ion to the bridged chloronium ion. That is to say, A/(A+B) is dependent on the carbocationic intermediate, which is controlled by the relative rate constant.

Since allyl chloride could be considered to have a moderate group, allyl chloride was chlorinated in order to investigate the effect of the reaction condition on the A/(A+B) and C/(A+B+C). While the relative rate of chlorination to alkoxychlorination C/(A+B+C) was increased with an increase in the concentration of allyl chloride in methanol, the A/(A+B) was little affected by the concentration of allyl chloride in methanol (Fig. 2) and the reaction temperature. A/(A+B) also remained approximately constant throughout the chlorination, despite the elapse of time. Neither photochemical chlorination under irradiation nor dark chlorination in the presence of oxygen could change A/(A+B). It could be assumed that the chlorination of a vinyl compound in methanol was an ionic reaction.

Since the nucleophilicity and steric hindrance of an alkyl group in a long or bulky chain alcohol were

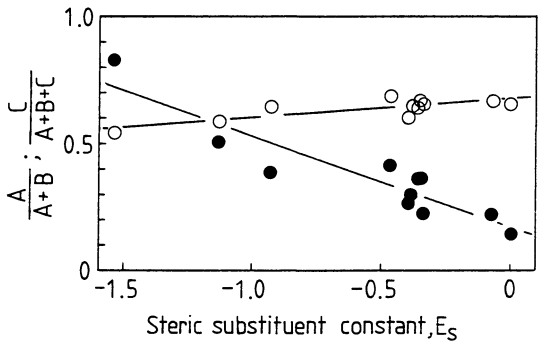

Fig. 3. The relations of A/(A+B) vs. E_s and C/(A+B+C) vs. E_s for the chlorination of allyl chloride in various alcohols at 40 °C.
○: A/(A+B), ●: C/(A+B+C).

compensated for by each other, the variation of A/(A+B) was over a narrow range, even through allyl chloride was chlorinated in several alcohols at 40 °C (Table 3).

The A/(A+B) value for the alkoxychlorination of allyl chloride in various alcohols slightly decreased in the following order:

i-$C_3H_7OH > C_2H_5OH > i$-$C_5H_{11}OH > CH_3OH >$
n-$C_6H_{13}OH > n$-$C_4H_9OH > i$-$C_4H_9OH > n$-$C_3H_7OH >$
n-$C_5H_{11}OH > s$-$C_4H_9OH > t$-C_4H_9OH.

The relations of A/(A+B) and E_s as well as of C/(A+B+C) and E_s are shown in Fig. 3. E_s on the abscissa indicates the steric substituent constants[10] for the alkyl group of alcohol. Since the C/(A+B+C) value increased with the elapse of time, C was obtained by extrapolating the experimental data back to the initial time. The increase in the C/(A+B+C) value with the elapse of time can be explained by using the same reason why the concentration of alcohol in a reaction solution decreases as the reaction proceeds.

It is clear that the rate of a nucleophilic attack on the intermediate was decreased with a long or bulky chain alcohol. On the other hand, the rate of the addition of chloride ion might remain unaltered. Therefore, the C/(A+B+C) value might be changed by the E_s value of the alkyl group of alcohol.

Experimental

Reagents. All the reagents used in this work were purchased from Tokyo Kasei Kogyo Co., except for the alcohols, which were obtained from Wako Pure Chemical Industries. They were not purified further. Chlorine and oxygen were fed from commercial cylinders and were passed through a sulfuric acid trap before use.

Chlorination of Vinyl Compound in Methanol. A 100 ml, flat, cylindrical semibatch Pyrex reactor thermostated at 40 °C was equipped with a Teflon magnetic stirring bar, a gas inlet tube and a reflux condenser. A mixture of 0.1 mol of vinyl compound and 50 ml of methanol was added to the reactor. Chlorine gas was fed into the reactor at the rate of 0.01 mol h^{-1}, until the reaction solution became a pale-yellow color. Chlorination products were analyzed by means of gas chromatography (Shimadzu GC-5A, SDC 550, PEG 6000).

Chlorination of Allyl Chloride in Methanol. Allyl chloride was chlorinated in methanol under various reaction conditions. The photochemical procedure and dark chlorination procedure in the presence of oxygen were similar to those used in the previous study.[7] Furthermore, 30 ml of methanol was mixed with allyl chloride at various volume ratios. The chlorination of this mixture was the same as the preceding techniques.

Chlorination of Allyl Chloride in Various Alcohols. The chlorination procedure was the same as that used in methanol. 30 ml of alcohol was mixed with 0.1 mol allyl chloride and the mixture was then placed in the reactor. The chlorination temperature was maintained at 40 °C. At regular intervals, 1 ml samples were taken from the reaction system and analyzed by gas chromatography.

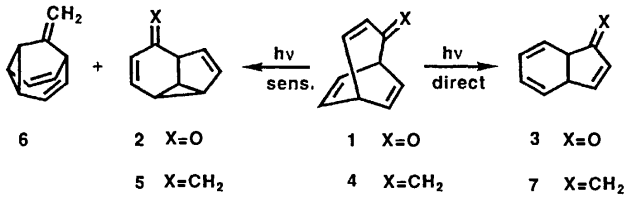
Synthetic Photochemistry. XLV.[1] Photoconversion of 2-Methylenehomobarrelenes to 9-Methylenebarbaralanes

Guan Rong TIAN,† Shigeru SUGIYAMA, Akira MORI, and Hitoshi TAKESHITA*
Institute of Advanced Material Study, 86, Kyushu University, Kasuga-koen, Kasuga, Fukuoka 816
(Received April 27, 1988)

The photolysis of 4-methoxycarbonyl-2-oxatricyclo[6.2.2.0^{1,5}]dodeca-4,6,9,11-tetraen-3-one derivatives yielded 9-methylenebarbaralanes along with 5-methylenetricyclo[4.3.0.0^{2,9}]nonadiene and 1-methyleneindan derivatives. From the benzophenone-sensitization experiments, 9-methylenebarbaralane and 5-methylenetricyclo[4.3.0.0^{2,9}]nonadiene were formed via a triplet excited state, but 1-methyleneindan was formed via a singlet excited state.

Previously, the benzophenone-sensitized irradiation of bicyclo[3.2.2]nona-3,6,8-trien-2-one (homobarrelenone) (**1**) was shown to give a tricyclic ketone (**2**),[2] while direct photolysis afforded the dihydroindenone (**3**).[3] Furthermore, the acetone-sensitized photolysis of 2-methylenehomobarrelene (**4**) resulted in two isomeric products (**5** and **6**) and the direct irradiation of **4** gave methylenedihydroindene (**7**)[4,5] via a concerted [1,3] vinyl shift. Recently, we prepared 2-methylenehomobarrelenes (**8**) from cyclohepta[*b*]furan-2-one derivatives and 2,3-bis(methoxycarbonyl)-7-oxanorbornadiene by a high-pressure cycloaddition-thermal cycloreversion procedure.[6] In this paper we describe the photochemical behaviors of these 2-methylenehomobarrelenes as well as the reaction mechanism.



Scheme 1.

Photolysis of 2-Methylenehomobarrelenes. Upon UV-light irradiation by means of a 400-W high-pressure mercury lamp through a Pyrex-glass filter, 4-methoxycarbonyl-2-oxatricyclo[6.2.2.0^{1,5}]dodeca-4,6,9,11-tetraen-3-one (**8a**) furnished three photoproducts (**9a—11a**) in 19, 15, and 25% yields. The structures of these photolysates were determined to be derivatives of a barbaralylidene (type I), a tricyclo[4.3.0.0^{2,9}]nonadiene (type II), and an indanylidene (type III) according to spectral evidence. When the photolysis of **8a** was monitored by ^{1}H NMR spectroscopy, a new set of signals appeared at δ 3.66 (1H, dd, J=11.4, 2.2 Hz), 4.06 (1H, ddq, J=11.4, 4.0, 2.6 Hz), 5.47 (1H, dd, J=6.0, 2.2 Hz), 5.50 (1H, dd, J=9.5, 4.0 Hz), 5.88 (1H, ddd, J=9.5, 6.0, 2.6 Hz), 7.06 (1H, dd, J=5.5, 2.6 Hz), and 7.43 (1H, dd, J=5.5, 2.6 Hz) together with the signals of **9a**, **10a**, and **11a**. These new signals disappeared after silica-gel chromatography. From this evidence, the intermediary product was assigned to be a dihydroindene derivative (**12a**) which isomerized to an indan derivative (**11a**) upon being worked up.

Similarly, the products obtained from 7-chloro-4-methoxycarbonyl-2-oxatricyclo[6.2.2.0^{1,5}]dodeca-4,6,9,11-tetraen-3-one (**8b**) and 7-methoxy-4-methoxycarbonyl-2-oxatricyclo[6.2.2.0^{1,5}]dodeca-4,6,9,11-tetraen-3-one (**8c**) were type I (**9b** and **9c**), type II (**10b** and **10c**), and type III (**11b** and **11c**).

Mechanistic Considerations. In order to determine

24	69	60	7	13	7	16	18	12
84	22	15	15	25	17	37	46	24

Photolysis conditions: A, 0.21 mol dm^{-3} of **8a** in $CDCl_3$. E, 0.21 mol dm^{-3} of **8a** and 0.24 mol dm^{-3} of benzophenone in $CDCl_3$.

the multiplicity of the excited state, reactions of **8a** with 1,3-pentadiene were traced by means of ^{1}H NMR spectroscopy. Distributions of photolysates, together with results of the photolyses in acetone and of the benzophenone-sensitized photolysis, are summerized in Tables 1—3 and Fig. 1.

As shown in Table 1, product distributions from **8a** were insensitive to the concentrations of 1,3-pentadiene, a triplet quencher. No quenching by 1,3-pentadiene indicates that a singlet state of **8a** can lead to photolysates. However, a triplet intermediate could not be ruled out, since the rate of the intramolecular rearrangements to photolysates could occur more rapidly than a diffusion controlled rate. Product distributions in acetone were almost similar to those in chloroform. The benzophenone-sensitized photolysis of **8a**, however, showed that the yields of **9a** and **10a** increased roughly twice and those of **11a** and **12a** decreased by roughly one half, with a small increasement of the consumption of **8a**. Therefore, **9a** and **10a** formed via a

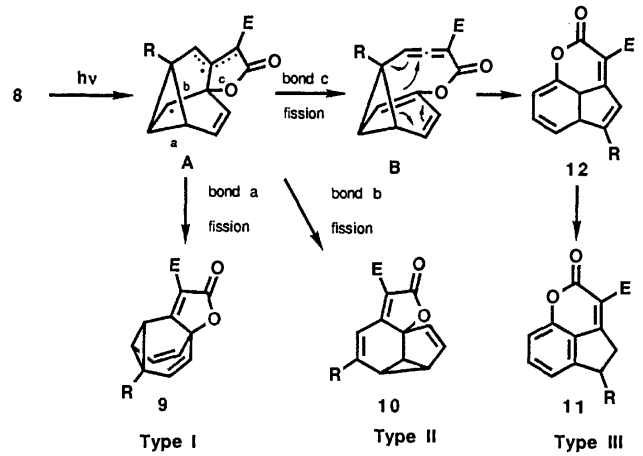

Scheme 3.

triplet excited state and **11a** and **12a** via a singlet excited state.

The formation of photolysates can be explained by di-π-methane rearrangements,[7] as shown in Scheme 3. Bond-a fission in a diradical **A** gave type-I products, while bond-b fission gave type-II products. On the other hand, bond-c fission led to a tricyclic allene derivative (**B**); further, an electrocyclic [4πs+2πa+2σs] path should give a dihydroindan derivative (**12**). Subsequent aromatization and a dehydrogenation of **12** gave type-III products.

These results are as same as those of the previously reported **4**[4,5] and **1**[2,3] in respect to not only the product distributions, but also the multiplicities of the concerned excited state.

Experimental

Elemental analyses were performed by Miss S. Hirashima, of Institute of Advanced Material Study, Kyushu University. The NMR spectra were measured by a JEOL 270 H Spectrometer in a $CDCl_3$ solution, unless otherwise specified, and the chemical shifts expressed were in δ unit. The mass spectra were measured with a JEOL 01SG-2 Spectrometer at 70 eV. The IR spectra were taken in a $CHCl_3$ solution using a Jasco IR-A 102 Spectrometer. The UV spectra were measured by a Hitachi U-3200 Spectrophotometer.

Irradiation of 8. A $CHCl_3$ solution (1 cm^3) of **8** (**8a**, 160 mg; **8b**, 250 mg; **8c**, 223 mg) was irradiated for 3 h with a 400-W high-pressure mercury lamp through a Pyrex filter and the reaction was monitored by ^1H NMR spectroscopy. The solvent was evaporated and the residue was purified by a silica-gel column and HPLC to give products (**9—11**) and the recovered **8** (**8a**, 45.5 mg; **8b**, 116 mg; **8c**, 58 mg).

Rechargeable Lithium Batteries Using Polypyrrole-Poly(styrenesulfonate) Composite as the Cathode-Active Material

Atsushi SHIMIZU,* Kazunori YAMATAKA, and Masashi KOHNO

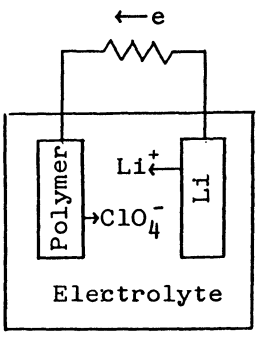
(Received May 20, 1988)

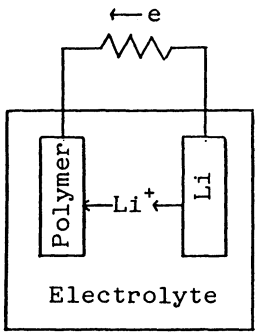
Polypyrrole-polyelectrolyte composite, obtained by electrochemical polymerization on a vapor-grown carbon fiber (VGCF) electrode, was used as a cathode-active material for a rechargeable lithium battery. Poly(styrensulfonate) ion was suitable as a dopant in terms of rechargeability of the battery. The VGCF, which has a fibrous structure, was effective as a current collector for the polymer electrode. The content of the dopant calculated by the molar ratio of sulfur and nitrogen was ca. 30%. The open-circuit voltage was 3.55 V at the time. A charge-discharge, accompanied by an Li^+ deinsertion-insertion of the composite, was observed. The charge-discharge mechanism is similar to that of inorganic cathode-active materials that show Li^+ intercalation. The battery was cycled stably beyond 30 times between 3.66 and 1.50 V at a constant current of 0.889 mA cm^{-2}. An experimental capacity of 57 Ah kg^{-1} was obtained at the largest value on the basis of the weight of the active material. There is a possibility of developing a light-weight rechargeable battery using the polypyrrole-poly(styrenesulfonate) composite.

A conductive polymer can be used as a cathode-active material for a lithium rechargeable battery.[1-11] A capacity has been reported of more than 100 Ah kg^{-1}, based on the weight of the active material.[2-4,8] The discharge mechanism of a battery using a p-type conductive polymer is shown in Scheme 1. The following problem, however, must be considered for a practical use of the batteries. For instance, 1.0 g of polypyrrole, which has 0.47 g of ClO_4^- (30% doping), needs ca. 5.2 g of propylene carbonate at a minimum to dissolve ClO_4^- at 1.0 mol dm^{-3}. A lot of solvent, which is 5 to 10 times the weight of the active material, is usually necessary to assemble a p-type conductive polymer into a lithium battery. The total weight of the battery will inevitably be heavy, even if the cathode-active material is light. This problem might be solved if an n-type conductive polymer was used, since it could accept Li^+ as the dopant and the electrolyte is only a path for Li^+. The discharge mechanism of a battery using an n-type conductive polymer is shown in Scheme 2. The n-type conductive polymers, however, are usually unstable.[12]

A polypyrrole-polyelectrolyte (PPY-PE) composite that has a charge-discharge property accompanied by Li^+ deinsertion-insertion, despite a p-type conductive polymer, has recently been reported.[13-15] There is a possibility to construct a light-weight rechargeable lithium battery when a PPY-PE composite is used as the cathode-active material. The performance of such a battery (Li|$LiClO_4$|PPY-PE) has been investigated in this study.



Scheme 1. Discharge mechanism of secondary battery using p-type polymer cathode.



Scheme 2. Discharge mechanism of secondary battery using n-type polymer cathode.

Experimental

Preparation of Polymer Cathode of Rechargeable Batteries. The cathode consisted of a polypyrrole-polyelectrolyte (PPY-PE) composite and a current collector, which is a piece of vapor-grown carbon fiber (VGCF) electrode or a platinum plate. The PPY-PE was prepared by electrochemical polymerization on the current collector from an aqueous solution containing polyanion and pyrrole monomer with a constant-current system (PAB-1A, Kikusui). Reactions were carried out at a constant current density in a 30 ml cell having a VGCF electrode or a Pt electrode, with a working of 15 mm×15 mm, and titanium mesh as the cathode. Pyrrole monomer was dissolved at 6 wt% in 10 wt% of sodium poly(styrenesulfonate) (NaPSS) or sodium poly(ethylenesulfonate) (NaPES) solutions prepared from concentrated solutions of NaPSS or NaPES (Aldrich Chemical). All PPY-PE electrodes were dried in a vacuum oven at 80 °C for 2 h and weighed. All reaction conditions are summarized in Table 1.

Table 1. Conditions of Polymerization Reactions

Run No.	Polymer	Current collector/mg	Reaction conditions			Weight of polymer /mg
			Current/mA	Time/h	Temp/°C	
1	PPY-PSS	Pt plate	0.05—1.0V[a]	5 min	r.t.	—
2	PPY-PSS	Pt plate	10	ca. 2	r.t.	33.9
3	PPY-PSS	VGCF[b] 10.3	10	ca. 3	r.t.	60.8
4		VGCF 33.5				
5	PPY-PSS	VGCF 10.2	10	4	r.t.	79.6

a) Polymerization potential vs. Ag/AgCl. b) VGCF electrode was not shaped into a square.

The VGCF electrode was prepared as follows. 0.05 g of VGCF (Asahi Chemical), which was 0.05—0.1 μm in diameter and 50 μm in length, was suspended in 100 ml of methanol. The suspension was unfolded onto filter paper, which was 35 mm in diameter, through vacuum filtration. After drying, the VGCF felt was cut to a size of 15 mm×20 mm. A platinum plate terminal was bound to the edge of the VGCF felt with a conductive binding agent (Electrodug 504, Acheson Japan). The VGCF electrode was washed with methanol and then with water to become hydrophilic before the polymerization reaction.

The Formation of the Cells and Evaluation of the Batteries. All cells have a PPY-PE cathode, a lithium anode, and a lithium reference electrode. The lithium anode was made by squashing lithium wire on an SUS net. The anode and the cathode were set up at a clearance of 10 mm, and the tip of the reference electrode was set up between the two electrodes in a cylindrical cell. The solvent was propylene carbonate containing 1.0 mol dm^{-3} of $LiClO_4$. This propylene carbonate (exclusive grade for batteries, Mitsubishi Uka) was stored with Molecular Sieves (4Å) and then used. The support electrolyte was dried in a vacuum oven at 50 °C for one day. The amount of solution was 60 ml. Argon gas was filled into the cell, which was made a vacuum in advance. All cells were galvanostatically cycled between two preset voltage limits by a charge-discharge system (HJ-201B, Hokuto Denko). The upper limit was 3.6 or 3.7 V, and the lower limit was 1.5 V.

The Pressing Electrode. Dried PPY-PSS-VGCF electrode was soaked in 6% of a poly(tetrafluoroethylene) dispersion prepared by diluting a 60% dispersion (Polyflon D-2, Daikin), and it was dried for 2 h in a vacuum oven at 80 °C. This material, which was 1 mm thick, was pressed at 50 kg cm^{-2}, and a 0.5 mm thick electrode was obtained.

Results and Discussion

A cyclicvoltamogram of PPY-PSS film on Pt plate (Run 1) showed good reversibility of the redox reaction in an aqueous solution containing 1 mol dm^{-3} of $LiClO_4$, as shown in Fig. 1. A three-volt grade of rechargeable battery was expected in combination with a lithium anode. A cell using a PPY-PSS film

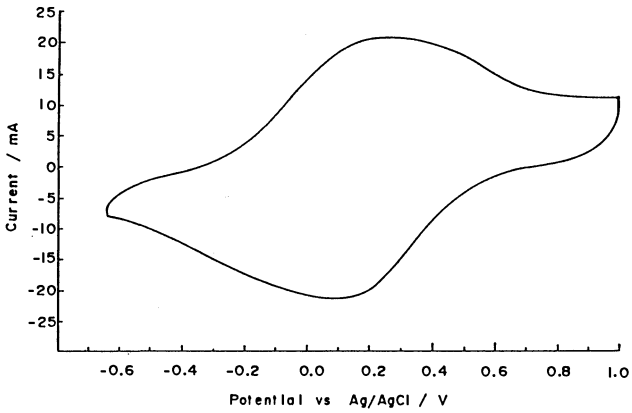

Fig. 1. Cyclic voltamogram of a PPY-PSS film on Pt plate (Run 1). Scan rate: 10 s V^{-1}. Counter electrode: Pt. Reference electrode: Ag/AgCl. Electrolyte: 1 mol dm^{-3} $LiClO_4$ in H_2O.

and a lithium anode was investigated in Run 2. Figure 2-A shows the charge-discharge cycles of this cell at a constant current of 1.0 mA (0.27 mA cm^{-2}). This cell initially showed a 2.80 V of open-circuit voltage, though the cell voltage decreased rapidly during discharge. The capacity was about 1 Ah kg^{-1}. The cause of this low performance was presumed to be the high internal resistance of the active material or the small amount of dopant in the active material. Elemental analysis showed that a SO_3 unit existed at a rate of 1/4—1/5 unit per polypyrrole unit. (Found: C, 55.7; H, 4.3; N, 8.2; S, 4.3%). If the charge had been able to be completely used, the capacity should have been 57 Ah kg^{-1}. It was presumed that an electrode having a fibrous structure, like VGCF felt, would reduce the resistance, since the dense morphology of PPY film probably caused the high Li^+ diffusion resistance.[13] The combination of PPY-PSS and VGCF in Run 3 improved the charge-discharge curve, as shown in Fig. 2-B, according to expectation. The cell had 3.55 V of open-circuit voltage and a flat charge-discharge curve.

The capacity was 42 Ah kg^{-1}, based on the polymer weight. The surface structure of PPY-PSS caused by VGCF surely improved the charge-discharge curve, since VGCF alone did not had a good charge-discharge curve as shown in Fig. 2-C (Run 4). Lithium insertion and deinsertion was confirmed as a result of an elemental analysis after 10 cycles of charge-discharge. (Charged state. Found: C, 58.4; H, 3.2; N, 8.9; S, 6.0; Li, 0.3%. Discharged state. Found: C, 57.0; H, 3.2; N, 8.3; S, 6.0; Li, 1.0%). An energy density of about 40 Ah kg^{-1} was calculated from the lithium content in the charged state. The experimental capacity was in good accordance with the calculated capacity. The cathode reaction is shown as follows:

$$(PPY)(PSS)^{-}\,Li^{+} \rightleftarrows (PPY)^{+}(PSS)^{-} + Li^{+} + e. \quad (1)$$

This mechanism is similar to that of inorganic cathode-active materials that show Li^{+} intercalation.[16,17] The mechanism is very important in terms of setting up a light-weight battery, since the solvent between two electrodes is only a path for lithium ions (Scheme 2) and does not have to exist in large quantities. The degradation of the inorganic active material is accelerated by an excessive discharge, since excessive lithium intercalation causes a destruction of the crystal structure of the active material.[18] The polymer material, which has the mechanism shown by Eq. 1, on the other hand, may have less degradation caused by an excessive discharge, since Li^{+} cannot insert beyond the limit determined by the content of the SO_3 unit.

The battery in Run 5 could be galvanostatically cycled stably over 30 times. The cycles were stopped due to considerable lithium dendrite. Figure 3-A shows the charge-discharge curve. The capacities were about 40 Ah kg^{-1} (including VGCF weight), and the coulombic efficiencies were 100% in each cycle, as shown in Fig. 4. A quick charge seemed possible, since the cell showed a very low overpotential of 0.1 V at the end of the charge. A low overpotential is an important performance factor for practical rechargeable batteries, since it restrains the degradation of both the electrolyte and active material. When the cell was charged under 4 mA (1.78 mA cm^{-2}) in Run 5, it was also cycled stably with 100% coulombic efficiencies and with 42 Ah kg^{-1} of capacity, as shown in Fig. 3-B. The capacities were almost constant under various different discharge currents in Run 6. The results are shown in Fig. 5. The highest capacity was 57 Ah kg^{-1} under 1.0 mA (0.44

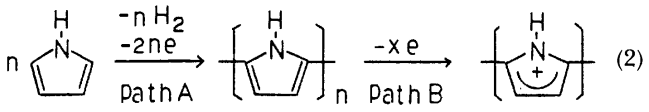
mA cm^{-2}) of discharge.

The polymerization current of PPY-PSS affected such performances of the cell as the initial cell voltage (just after setting up the cell), the capacity of the cell, the weight of the polymer, and the overpotential at the end of the charge. All results of Runs 6, 7, and 8 are summarized in Fig. 6. The polymerization and oxidation reaction proceeds as follows:

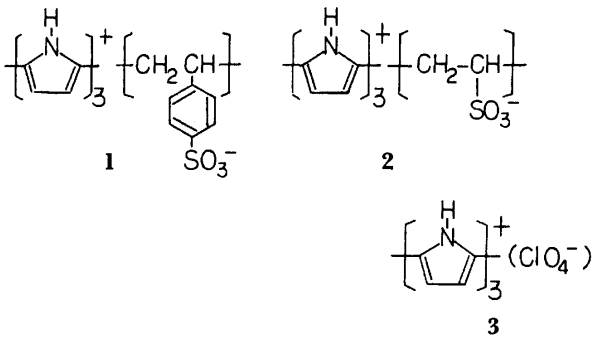


(2)

A large oxidation current probably encouraged path A oxidation, followed by a lack of the charged polymer by path B, from the fact that a large oxidation current caused a lower initial cell voltage just after setting up the cell, as well as a large amount of polymer. A small oxidation current probably made the dense structure of polymer followed by the large diffusion resistance of lithium ions, from the fact that a small oxidation current caused a high overpotential, and a small amount of polymer. The medium-range (10 mA) oxidation reaction probably resulted in the largest capacity of the cell, as a result of these facts.

The effects of temperature at polymerization on the capacities of cells were investigated in Runs 9—12. The charge-discharge properties of these cells are shown in Fig. 7. Polymerization at room temperature afforded the largest capacity.

How are the weight increase and volume increase of PPY-PE, itself, compared with polypyrrole such an incorporating monomer dopant as ClO_4^- ? When polypyrrole is doped with the poly(styrenesulfonate) ion, the poly(ethylenesulfonate) ion, and ClO_4^- at ca. 33.3%, unit structures per one electron are exhibited as follows:



The molecular weights of these units are 378, 302, 294.5, respectively. Although a light-weight unit is

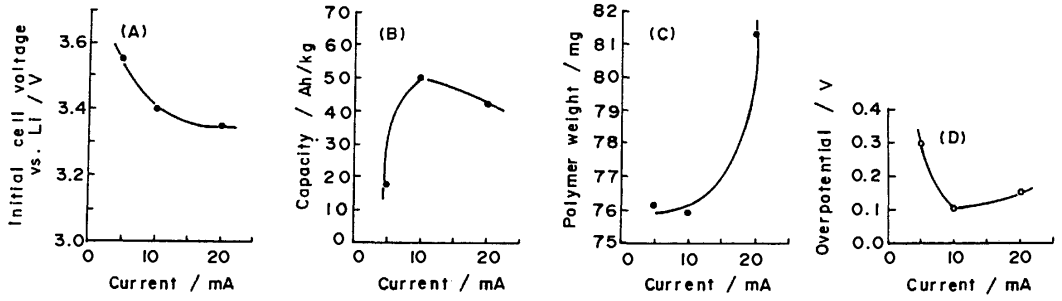

Fig. 6. Polymerization current effects on initial cell voltage, capacity, polymer weight, and overpotential.

desirable for a light-weight battery, a 28% weight excess of unit **1**, compared with unit **3**, is allowable, since the total weight of the battery is not determined only by the cathode active material. The volume of polypyrrole varies with the dopant, and it is not always in direct proportion to the dopant size. It was reported that polypyrrole film incorporating PSS^- had about half the thickness of polypyrrole film incorporating ClO_4^-.[15] This is a suitable performance factor for a compact battery.

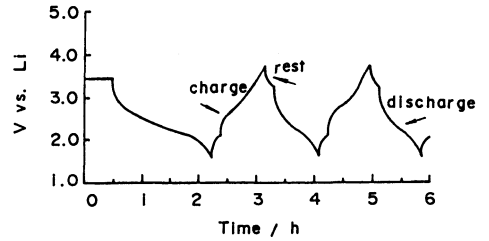

Fig. 8. Charge-discharge curve of PPY-PSS-VGCF cell. Charge current=2 mA. Discharge current=2 mA.

If poly(ethylenesulfonate) ions (**2**) had been capable of being used as a dopant, a very light, active material could have been obtained. However, the performance of the cell using poly(ethylenesulfonate) ions in Run 13 was not very good. Figure 8 shows the charge-discharge curve of the battery. The initial capacity was relatively large (43 Ah kg^{-1}), but the capacity could not be repeated by charging up to 3.7 V.

A pressed cathode was investigated in Run 14, since the capacity of a battery per unit volume is an important performance factor of a battery, as well as the capacity per unit weight. The result of the charge-discharge property is shown in Fig. 9. This approach was useful since the capacity rose to 40 Ah l^{-1} form 20 Ah l^{-1}. On the other hand, an overpotential at the end of the charge increased and the flatness of the curve became reduced. There is room for an improvement in the pressing technique, such as the kinds of binder and the intensities of pressure.

Figures 10-A,B,C, and D are SEM photographs of

the VGCF electrode and the PPY-PSS-VGCF electrode. Samples of the PPY-PSS-VGCF composite maintained a fibrous structure as well as the VGCF current collector. This structure must have encouraged the good charge-discharge property, compared with the PPY-PSS film. There were many fibrils of different diameters. Some were about 0.5 μm (Fig. 10-B), but some were about 5 μm (Fig. 10-D). The samples after pressing were slightly crushed and some fibrils were broken (Fig. 10-C). The lower charge-discharge property compared with the non-pressed sample may be due to this structure.

We conclude that the PPY-PSS-VGCF having a lithium insertion-deinsertion mechanism can be used for a light-weight secondary battery, and that the fibrous structure of PPY-PPS-VGCF is essential for a good performance of the battery. This polymer battery is characterized by a low overpotential at the end of the charge, a stable capacity independent of the charge-discharge current, and a 100% coulombic capacity. These are desirable for a practical secondary battery.

Kinetics of the Oxidation of [*N*-(2-Hydroxyethyl)ethylenediamine-*N*,*N*′,*N*′-triacetato]chromium(III) by Periodate

Ahmed A. ABDEL-KHALEK* and Mahmoud M. ELSEMONGY†
Chemistry Department, Faculty of Science, Cairo University, Beni-Suef City, Egypt
†Chemistry Department, Faculty of Education, Umm Al-Qura University, Al-Taif City, Shihar, Saudi Arabia
(Received November 19, 1987)

The kinetics of oxidation of $[Cr^{III}(H_2O)(TOH)]$, (TOH=*N*-(2-hydroxyethyl)ethylenediamine-*N*,*N*′,*N*′-triacetate) by periodate in aqueous solutions has been found to obey the following equation

$$\text{Rate} = \frac{k_2 K_6 [Cr^{III}]_T [I^{VII}]_T}{1 + [H^+]/K_5 + K_6 [I^{VII}]_T}$$

where k_2 is the rate constant for the electron-transfer process, K_5 is the equilibrium constant for dissociation of $[Cr^{III}(H_2O)(TOH)]$ to $[Cr^{III}(OH)(TOH)]^- + H^+$ and K_6 is the pre-equilibrium formation constant. The activation parameters are reported. It is proposed that electron transfer proceeds via an innersphere mechanism with the hydroxo ligand of the chromium(III) complex bridging the two reactants.

Metal complexes, which are relatively easily oxidized by IO_4^- in aqueous solution, seem to fall into one of two classes: (i) labile complexes[1-6] or (ii) inert complexes that can offer a bridging ligand.[7,8] The mechanism of oxidation of the labile complexes is believed to be of the innersphere type, and in several cases direct evidence in support of this mechanism has been presented.[2-6] Substitution into the inner coordination sphere of the IO_4^- ion, which is labile, is likely.[9] In case of oxidation of $[Cr^{III}(edta)(H_2O)]$ by periodate,[6] it was proposed that the oxidation may proceed via one- or two-electron transfer giving Cr(IV) or Cr(V), respectively, in the rate-determining step, followed by a fast step leading to Cr(VI). An innersphere process is also believed to be operating in the oxidation of inert complexes.[7,8] The unusual second-order dependence on $[Cr(H_2O)_6]^{3+}$ in the chromium(III)-periodate reaction seems to support an innersphere mechanism.[7] The two electron transfer step proposed for this reaction requires this mechanism,[10] where the hydroxo form, $[CrOH]^{2+}$, was considered to be the reactive chromium(III) species.

In particular we have chosen the edta analogues in that it can be supported that some properties of the respective complexes are influenced by the position and number of the functional groups. In this study the kinetics of oxidation of $[Cr^{III}(H_2O)(TOH)]$, where TOH is *N*-(2-hydroxyethyl)ethylenediaminetriacetate, is reported.

Experimental

Reagents. Reagent grade *N*-(2-hydroxyethyl)ethylenediamine-*N*,*N*′,*N*′-triacetic acid, sodium periodate, chromium(III) nitrate hexahydrate, sodium dihydrogenphosphate, sodium hydroxide, and sodium nitrate were used without further purification. Solution of $[Cr^{III}(H_2O)(TOH)]$ was prepared by the method of Wharton and Sykes.[11] Molar absorption coefficients of this complex were calculated on the basis of the chromium concentration which was determined spectrophotometrically as chromate.[12] At the range of pH 6.1—7.3 the species found in the solution have $\varepsilon_{394}=104$ and $\varepsilon_{575}=133$ M^{-1} cm^{-1} (M=mol dm^{-3}) as reported for $[Cr^{III}(OH)(TOH)]^-$.[11] A stock solution of periodate was made up by weight and wrapped with Al foil to avoid photochemical decomposition.[13] Sodium dihydrogenphosphate, sodium hydroxide, and sodium nitrate solutions were made up by weight. Buffer solutions were made up from sodium dihydrogenphosphate-sodium hydroxide mixtures.

Kinetic Measurements. A Unicam SP8000 spectrophotometer, equipped with a thermostated cell holder, was used to monitor the reaction. The reactants in buffer solutions in the two compartments of an intended flask, were thermostated for about 20 minutes. These were thoroughly mixed and quickly transferred to an absorption cell. The formation of the chromium(VI) was followed at a wavelength in the 350—372 nm range where the absorption is maximal at the pH of the reaction. Pseudo-first order conditions were maintained in all runs by using a large excess of periodate concentrations (more than 10-fold) over those of $[Cr^{III}(H_2O)(TOH)]$. The pH of the reaction was measured on a Radiometer digital pH meter model PHM62. The ionic strength was maintained constant by using the appropriate amounts of sodium nitrate solution.

Results and Discussion

The stoichiometry of the $[Cr^{III}(H_2O)(TOH)]$-IO_4^- reaction can be represented by Eq. 1

$$2\,Cr^{III} + 3\,I^{VII} \rightarrow 2\,Cr^{VI} + 3\,IO_3^- \quad (1)$$

where Cr^{III} and I^{VII} represent total chromium(III) and periodate, respectively. The concentration ratio of IO_4^- initially present to Cr^{VI} produced was found to be 1.50±0.04. The stoichiometry is also consistent with the observation that IO_3^- does not oxidize the chromium(III) complex over the pH range where the kinetics was investigated.

At all the chromium(III) complex concentrations used, in presence of vast excess of periodate, plots of $\ln(A_\infty - A_t)$ vs. time, where A_∞ and A_t are the absorbances at infinity and time t, respectively, were linear up to 85% of the reaction. The pseudo-first order rate con-

a) Unless otherwise stated $[Cr^{III}(H_2O)(TOH)]=1.0\times10^{-4}$ M. For b), c), and d), $[Cr^{III}(H_2O)(TOH)]$ was 2.0×10^{-5} M, 5×10^{-5} M, and 2.0×10^{-4} M respectively.

stant, k_{obs}, was calculated from the slopes of these plots by using a linear least-squares program.

The constancy of k_{obs}, over the complex concentration range $(5.0—20.0)\times10^{-4}$ M under the fixed experimental conditions, shown in Table 1, is in agreement with a first-order dependence on its concentration.

The variation of k_{obs} with periodate concentration, Table 1, exhibits rate saturation at high periodate. Plots of $1/k_{obs}$ versus $1/[IO_4^-]$ were found to be linear with a definite intercept as shown in Fig. 1. The dependence of k_{obs} on periodate concentration is thus described by

$$k_{obs} = \frac{a[IO_4^-]}{1+b[IO_4^-]} \quad (2)$$

or

$$1/k_{obs} = \frac{1}{a[IO_4^-]} + \frac{b}{a}. \quad (3)$$

The values of a and b were obtained from the slope and the intercept as (1.52±0.6) M^{-1} s^{-1} and (529±15) M^{-1}, respectively at 25 °C and pH=7.30.

The effect of hydrogen-ion concentration on the reaction rate was investigated over the pH range 6.10—7.30. Table 2 shows that the rate of reaction increases with increasing pH value.

Table 2. Effect of pH on k_{obs} (s^{-1}) at $[Cr^{III}(H_2O)(TOH)]=1.0\times10^{-4}$ M, I=0.5 M, and T=25 °C

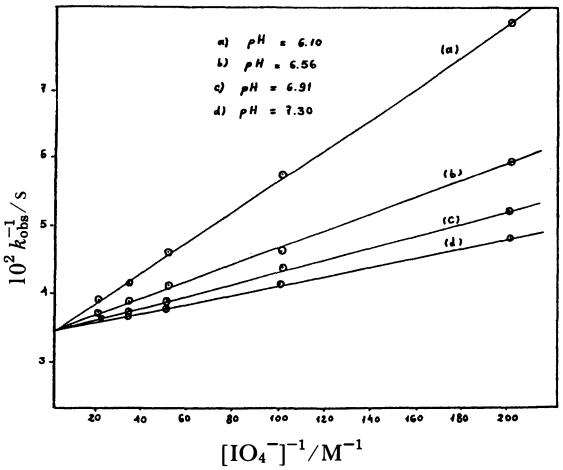

Fig. 1. Plots of k_{obs}^{-1} against $[IO_4^-]^{-1}$.

Bustin and Earley[14] reported that $[Cr^{III}(H_2O)(TOH)]$ undergoes the following equilibria

$$[Cr^{III}(H_2O)(TOH)] \rightleftarrows [Cr^{III}(OH)(TOH)]^- + H^+; K_1 \quad (4)$$

$$[Cr^{III}(OH)(TOH)]^- \rightleftarrows [Cr^{III}(OH)(TO)]^{2-} + H^+; K_2 \quad (5)$$

with K_1 and K_2 having values of 3.63×10^{-7} M and 1.58×10^{-10} M, respectively at 25 °C and I=0.1 M. It is clear from the value of K_2 that $[Cr^{III}(OH)(TO)]^{2-}$ was not present at the employed pH values at the present study. The species present at low pH has the ligand bound in a quinquedentate manner, with the 2-hydroxyethyl group uncoordinated.[14] The absence of an acid dissociation constant at pK_a ca. 3 precludes the presence of any uncomplexed-COO^- groups.[14]

From the reported equilibrium constants of aqueous periodate solutions, it may be concluded that, over the H^+ range used in this study, the periodate species likely to be present are IO_4^-, $H_4IO_6^-$, and $H_3IO_6^{2-}$ [15] which are in the equilibria

$$H_4IO_6^- \rightleftarrows H_3IO_6^{2-} + H^+; K_3 = 5\times10^{-6} \quad (6)$$

$$H_4IO_6^- \rightleftarrows IO_4^- + 2H_2O; K_4 = 40. \quad (7)$$

It is clear from the value of K_4 that IO_4^- is not predominant species (I^{VII} will be used to represent $H_4IO_6^-$ and $H_3IO_6^-$).

The experimental rate equation suggests that a fast equilibrium step precedes the slow intramolecular electron transfer step. A possible mechanism is described by Eqs. 8—12.

$$[Cr^{III}(H_2O)(TOH)] \rightleftarrows [Cr^{III}(OH)(TOH)]^- + H^+; K_5 \quad (8)$$

$$[Cr^{III}(OH)(TOH)]^- + I^{VII} \rightleftarrows [(TOH)Cr^{III}(OH)\text{-}I^{VII}]^-; K_6 \quad (9)$$

$$[(TOH)Cr^{III}(OH)\text{-}I^{VII}]^- \xrightarrow{k_2} Cr^V + IO_3^- + TOH^{3-} \quad (10)$$

$$Cr^V + I^{VII} \xrightarrow{fast} CrO_4^{2-} + I^{VI} \quad (11)$$

$$2\,I^{VI} \xrightarrow{fast} I^{VII} + IO_3^- \quad (12)$$

From the above mechanism, rate of the reaction is given by

$$\begin{aligned} \text{rate} &= k_2[(TOH)Cr^{III}(OH)\text{-}I^{VII}] \\ &= k_2K_6[Cr^{III}(OH)(TOH)^-][I^{VII}]. \end{aligned} \quad (13)$$

If $[Cr^{III}]_T$ represent the total concentrations of Cr^{III} species, then

$$\begin{aligned} [Cr^{III}]_T &= [Cr^{III}(OH)(TOH)^-][H^+]/K_5 \\ &+ [Cr^{III}(OH)(TOH)^-] + K_6[Cr^{III}(OH)(TOH)^-][I^{VII}]. \end{aligned} \quad (14)$$

Substitution for $[Cr^{III}(OH)(TOH)^-]$ from Eq. 14 into Eq. 13, gives

$$\text{rate} = k_2K_6[Cr^{III}]_T[I^{VII}]_T/1 + ([H^+]/K_5) + K_6[I^{VII}]_T \quad (15)$$

and

$$k_{obs} = k_2K_6[I^{VII}]_T/1 + ([H^+]/K_5) + K_6[I^{VII}]_T \quad (16)$$

which on rearrangement, gives

$$1/k_{obs} = K_5 + [H^+]/k_2K_5K_6[I^{VII}]_T + 1/k_2. \quad (17)$$

At constant $[H^+]$ Eq. 18 follows, in which A is a constant

$$1/k_{obs} = A/k_2K_5K_6[I^{VII}]_T + 1/k_2 \quad (18)$$

which is identical to the experimental results shown in Eq. 3, where $a = k_2K_5K_6/A$ and $b = K_5K_6/A$.

Values of k_2 and K_6, at the temperature used, calculated from these relationships, by substitution $K_5 = 3.63\times10^{-7}$ M, are listed in Table 3. The activation parameters obtained from a least-squares' fit to the transition state theory equation are $\Delta H^{\ddagger}_2 = 76.0\pm2.1$ kJ mol^{-1} and $\Delta S^{\ddagger}_2 = -38.7\pm7.1$ J K^{-1} mol^{-1}. The enthalpy of the pre-equilibrium reaction $\Delta H^{\circ}_6 = -32.1\pm1.7$ kJ mol^{-1} is obtained from the temperature variation of K_6. Negative $\Delta S^{\ddagger}$ for the redox reactions between reactants with charges of the same sign were claimed to be largely the result of the charge concentration on encounter complex formation, which causes substantial mutual ordering of the solvated water molecules.[16] Value of $\Delta H^{\ddagger}_6$ indicates that the formation of the precursor complex $[(TOH)Cr^{III}(OH)\text{-}I^{VII}]^-$, is an exothermic process as found in the reaction between $[Co^{II}(edta)^{2-}]$ and IO_4^-.[3] The intramolecular electron transfer step, is endothermic as indicated by the value of $\Delta H^{\ddagger}_2$.

Table 3. Values of k_2 and K_6 at Different Temperatures

T/°C	10^3k_2/s^{-1}	K_6/M^{-1}
20	1.50	751
25	2.95	596
30	4.31	503
35	7.30	414

The contributions of $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ to the rate constant seem to compensate each other. This fact suggests that the factors controlling $\Delta H^{\ddagger}$ must be closely related to those controlling $\Delta S^{\ddagger}$. Therefore, the solvation state of the encounter complex would be important in determining $\Delta H^{\ddagger}$.[16] Thus, the relatively small enthalpy of activation, $\Delta H^{\ddagger}_2$, can be explained in terms of the formation of more solvated complex $[(TOH)\text{-}Cr^{III}(OH)\text{-}I^{VII}]^-$.[17]

From Eq. 17 and Fig. 1, it follows that slopes of the plots can be represented by Eq. 19.

$$\text{slope} = [H^+]/k_2K_5K_6 + 1/k_2K_6 \quad (19)$$

It is obvious, from Eq. 19 that the slope is dependent on $[H^+]$. This plot is shown in Fig. 2 which indicates the validity of our proposed mechanism. Value of K_5 was calculated from Fig. 2, to be 2.70×10^{-7} M. This value is in good agreement with the reported[14] value of $K_5 = 3.63\times10^{-7}$ M at 25 °C. The equilibrium constant K_6 obtained from Eq. 19 and Fig. 2 is 571 M^{-1} which is in a good agreement ($K_6 = 596$ M^{-1}) with that obtained from Eq. 18 and Fig. 1 at 25 °C.

An innersphere mechanism is proposed for the oxidation of $[Cr^{III}(H_2O)(TOH)]^-$ by IO_4^- in which the $[Cr^{III}(OH)(TOH)]^-$ is bridged to IO_4^- through the hydroxo ligand because hydroxide on $[Cr^{III}(OH)\text{-}(TOH)]^-$ is a better bridging ligand than H_2O on $[Cr^{III}(H_2O)(TOH)]$. The assignment of an innersphere mechanism through the hydroxo bridge for this reaction seems to be supported by the following reasons: (i) Periodate ion is capable of acting as a ligand as evidenced from its coordination to copper(III)[18] and nickel(IV).[19] (ii) The hydroxo ligand is a firm ligand bridge. (iii) No reaction was observed at pH below 6.0 where the hydroxo species is not present. (iv) The inverse dependence of $[H^+]$ is usually ascribed to oxidation of the hydroxy species offering a very effective OH bridge in an innersphere process.[20]

The oxidation of $[Cr^{III}(H_2O)(TOH)]$ by IO_4^- may proceed via one- or two-electron transfer giving Cr^{IV} or

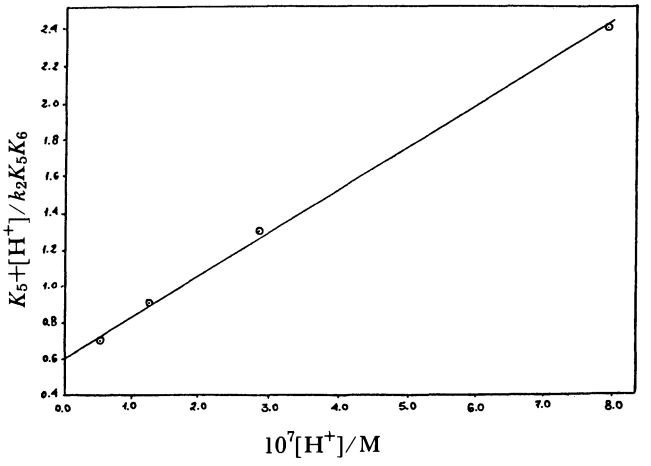

Fig. 2. Plots of $K_5+[H^+]/k_2K_5K_6$ vs. $[H^+]$.

Cr^{V}, respectively in the rate determining step. These may then followed by a fast step leading to Cr^{VI}. The fact that acrylonitrile was not polymerized seems to support two-electron transfer process.

In comparison with oxidation of $[Cr^{III}(edta)(H_2O)]$,[7] under the same conditions, the both hydroxy complexes, $[Cr^{III}(edta)(OH)]^{2-}$ and $[Cr^{III}(OH)(TOH)]^{-}$, are significantly more reactive than their conjugate acids. Value of k_2K_6 (k_2 is the intramolecular transfer rate constant and K_6 is the pre-equilibrium formation constant), for the oxidation of $[Cr^{III}(H_2O)(TOH)]$, is equal to 1.74 at 25 °C. This value is very close to the value of $k^{et}K_4$ (1.81±0.18) for the oxidation of $[Cr^{III}(edta)(H_2O)]$, where $k^{et}K_4$ corresponds to k_2K_6. It would be more informative to compare the intramolecular electron transfer rate constants. However, this is not possible because the value of k^{et} for the edta complex is not known.

It is a great pleasure to acknowledge Prof. Y. Sulfab, Chemistry Department, Faculty of Science, Kuwait University, for his useful ideas.

Efficiency of Azodyes in Retarding the Dissolution of Aluminium in Hydrochloric Acid

Abd El-Aziz El-Sayed FOUDA,*,† Hamed ABU-EL-NADER, Mahmoud Nor El-Din MOUSSA, and Ibrahim SHEHATA
Chemistry Department, Faculty of Science, Mansoura University, Mansoura, Egypt
(Received December 11, 1987)

The inhibition of the corrosion of aluminium in hydrochloric acid solution by some 4-(*m*-Substituted phenylazo)pyrazoles has been studied by three different techniques. The inhibitor efficiency calculated from the three techniques are in good agreement. The corrosion rate is a function of temperature, concentration, and nature of the inhibitor. The inhibitors appear to function through general adsorption following the Langmuir adsorption isotherm. Thermodynamic parameters for adsorption of inhibitors have been calculated and discussed.

The industrial importance of corrosion inhibitors is widespread, ranging from pickling to water-cooled systems. The selection of inhibitor for a given system depends on the corrosive medium, the nature of the metal, the magnitude of the charge at the metal-solution interface, and the cathodic reaction.[1] The study of adsorption of organic compounds at electrode-electrolyte interfaces is a subject with pronounced practical significance in view of its relevance to electrochemical energy conversion, electro-organic synthesis, and corrosion inhibition. The latter is most popular since such compounds effectively inhibit the corrosion process even when present in trace amounts.[2] It is known that inhibitor efficiency depends on the mode of adsorption of inhibitor molecule, electron density at the electroactive center[3] and the state of the surface.[4]

Aluminium is extensively used in various industrial operations and the study of its corrosion inhibition is of great importance. Oxygen- and nitrogen-containing organic compounds have been tried as corrosion inhibitors for metals.[2,5-7]

The aim of this article is to throw some light on the mechanism of inhibition of these bulky molecules on the corrosion of aluminium in hydrochloric acid.

Experimental

Thermometric Method. Chemicals used were of analytical grade and were used without further purifications. The solutions were made from freshly prepared twice distilled water. The procedure for the determination of metal dissolution rate by the thermometric method has been described previously,[8] the reaction tube being placed inside a vacuum flask to minimize heat losses. Aluminium strips measuring 100×10×1 mm were lightly abroaded with 2/0 and 3/0 emery paper, then degreased with alkaline solution ((15 g Na_2CO_3+ 15 g Na_3PO_4)·l^{-1}) and washed with running twice distilled water. The specimens were then dried between two filter papers. Each experiment was carried out with a new Al strip and 15 ml of the corroding solution, and repeated to ensure reproducibility of the results.

The reaction number (RN) is defined as $RN=(T_m-T_i)/t$ °C min^{-1}. T_m, T_i are the maximum and initial temperatures, respectively and t is the time in min, taken to reach T_m. All experiments were started at 25±0.1 °C (T_i). The percentage inhibition, I, is taken as:

$$\%I=(RN_{pure}-RN_{inh})\,100/RN_{pure} \quad (1)$$

Weight Loss Method. The test pieces measuring 20×20×1 mm were prepared as before, weighed, then immersed in 50 ml of the test solution at a temperature of 25±0.1 °C for a period of 15 min. They were then cleaned and washed with distilled water, dried and re-weighed.

$$\%\,I=\frac{\text{Wt. loss}_{pure}-\text{Wt. loss}_{inh}}{\text{Wt. loss}_{pure}}\times 100\,\% \quad (2)$$

Gasometeric Method. The reaction vessel and procedure for determining the rate of dissolution of aluminium in HCl were the same as described before.[9] The test pieces measuring 20×20×1 mm were prepared as before.

The efficiency of the inhibitors used can be evaluated as the percentage reduction in RR, viz.

$$\%\text{ Reduction in RR}=(R_{free}-R_{inh})\,100/R_{free} \quad (3)$$

where R_{free} and R_{inh} are rates of Al dissolution in the absence and presence of the additive, respectively, both measured at the same reaction time.

Results and Discussion

By following the temperature changes of the system in absence and presence of different concentrations of 4-(*m*-substituted phenylazo)pyrazoles, the temperature of the system was found to change slightly during the initial stages of the reaction (due to the originally formed oxide film). After a certain period which depended upon the concentration of the additives, the temperature rose to attain a maximum value. A representative temperature-time relationship obtained in presence of varying concentrations of compound **1** is shown in Fig. 1. The relationship between the reaction number (RN) of the system and the logarithm of the concentration (C) of compound **1** is indicated by the curve shown in Fig. 2. Curves having the same character are obtained with the other tested materials.

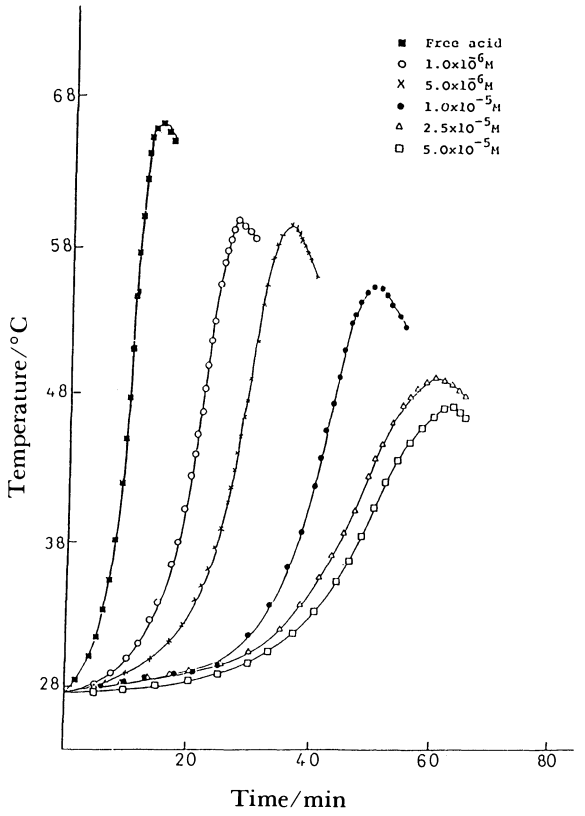

Fig. 1. Temperature-time curves obtained in the absence and presence of varying concentrations of compound **1**.

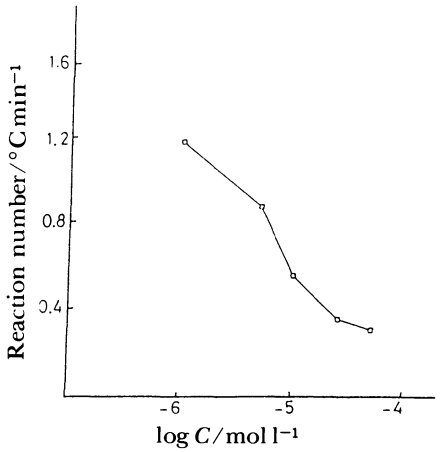

Fig. 2. Variation of the reaction number with the logarithm of concentration of compound **1**.

The reaction number-log C curves consist of an initial descending portion along which RN decreases slowly followed by a sharp descending portion to a certain limit of concentration. On further increase of the concentration of the additive, the values of RN decreases linearly with concentration and then become more or less constant. This behavior is explained on the basis of one-step adsorption process. The inhibiting action of tested compounds on Al dissolution is manifested by a decrease in T and an increase in the incubation period. The increase in the incubation period indicates that the additive acts in the acid solution as a strong cathodic inhibitors[10,11] and the lowering in T_m shows the strong adsorbability of the additive.[11]

The results obtained (Table 1) support the view that tested compounds have an inhibitive effect on the corrosion of Al in HCl. This apparent from the reduction of the values of RN of the metal by increasing the concentration of the additive. The percentage reduction in RN for all tested compounds are presented in Table 2.

Table 1. Efficiency of Corrosion Inhibition of 4-(*m*-Substituted phenylazo)pyrazoles as Determined by Percentage Reduction in Reaction Number in 2 M HCl

Concn of the additive in mol l^{-1}	% Reduction in RN			
	1	**2**	**3**	**4**
1.0×10^{-6}	55.3	50.8	36.0	33.0
2.5×10^{-6}	—	53.6	43.3	36.7
5.0×10^{-6}	67.0	63.4	51.3	48.0
1.0×10^{-5}	70.3	74.8	65.0	60.7
2.5×10^{-5}	86.8	81.2	72.7	68.5
5.0×10^{-5}	88.5	82.6	75.1	69.4

Table 2. Comparison between Efficiency of 4-(*m*-Substituted phenylazo)pyrazoles as Determined by Thermometric Weight Loss and Hydrogen Evolution Techniques in 2 M HCl at 10^{-5} M Inhibitors Concentration

Inhibitor	% Reduction in RN	% Inhibition	Reduction in RR
1	79.3	94.0	70.7
2	74.8	92.4	69.6
3	65.0	89.4	59.0
4	60.7	87.4	48.4

Figure 3 shows the volume of hydrogen evolved in $ml\,cm^{-2}$ vs. the reaction time of compound **1**. The slope of the curve at specified times gives the reaction rate in $1\,m^{-2}\,min^{-1}$. The percentage reduction in RR, after 60 min, for all the studied compounds are presented in Table 2.

Figure 4 represents the relation between the weight loss and time for compound **1**. The inhibition efficiences of the additives after 60 min are included in Table 2. In this table the 4-(*m*-substituted phenylazo)-pyrazoles examined are arranged in the order of decreasing inhibition efficiency. The same order is obtained from both the experimental methods employed.

According to Damaskin[12] the surface coverage (θ) can be determined as follows:

$$\theta = 1 - \frac{I}{I_0} \tag{4}$$

where I and I_0 are the current densities of the given potentials in electrolytes with and without inhibitor, respectively. But Rozenfeld[13] and Gardner[14] replace the current density by the capacitance of the double layer, dissolution rates, adsorption potential, or weight losses. Accordingly, it seemed promising to use U values instead of any of these variables. Equation 4 can thus be written as:

$$\theta = 1 - \frac{U_i}{U} \tag{5}$$

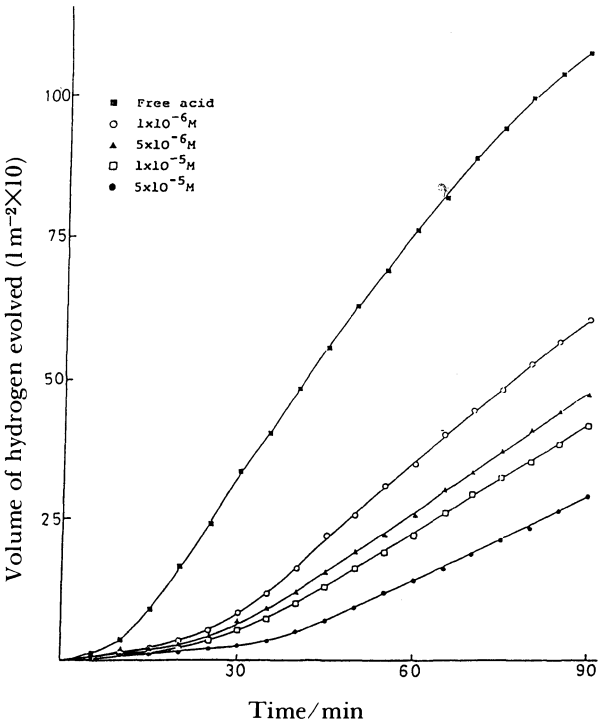

Fig. 3. Volume of hydrogen evolved-time curves obtained in the absence and presence of varying concentrations of compound **1**.

where U_i and U are corrosion rates in solution with and without inhibitor, respectively in case of weight loss method. It is available from the results of the present investigation to calculate the surface coverage, θ. The Langmiur adsorption isotherm may be written in the form:[15]

$$\log \frac{\theta}{1-\theta} = \log BC - G/2.303\,RT \tag{6}$$

where B is the adsorption equilibrium constant and G is the free energy of adsorption. Plotting $\log[\theta/(1-\theta)]$ against $\log C$ of compound **1** gives straight line, Fig. 5,

Table 3. Effect of Temperature on the % Reduction in RR in Presence of 10^{-5} M 4-(m-Substituted phenylazo)pyrazoles at 30 min

Temp/°C	1	2	3	4
25	83.5	82.4	78.8	55.1
35	76.0	66.8	60.4	58.5
40	67.0	59.7	57.2	53.3
45	50.0	45.1	41.2	36.0

indicating almost a general agreement with Langmiur adsorption isotherm.

To study the effect of temperature on the rate of hydrogen evolution, hydrogen evolved was determined in 2 M HCl (1 M=1 mol dm^{-3}) without (Fig. 6) and with 10^{-5} M (Fig. 7) from compound **1** at solution temperatures of 25, 35, 40, and 45 °C. It was observed from the results of Table 3 that the inhibitive efficiency of all tested compounds decreases with the rise in temperature from 25 to 45 °C. This indicates that these compounds are physically adsorbed on aluminium surface.

The values of energy of activation, E, were calculated from the slopes of the Arrhenius plots of $\log k$ vs. $1/T$, where k is the corrosion rate and T the absolute temperature (Fig. 8). The E values are given in Table 4. From Table 4 it is evident that the E values in presence of additives are significantly lower than in its absence. This indicates that the four compounds function as effective inhibitors. The almost similar values of E suggest that the inhibitors are similar in their mechanism of action and the order of efficiency may be related to the preexponential factor A by the equation:

$$\log k = \log A - E/RT \qquad (7)$$

This is further related to concentration, steric effects, metal surface characteristics etc.

For calculating the values of heat of adsorption of the various inhibitors, plots were drawn of log

Table 4. Thermodynamic Parameters for Adsorption of Inhibitors on to an Aluminium Surface in 2 M HCl Containing 10^{-5} M Inhibitors

Inhibitor	E	$-\Delta G^{\circ}_{ads}$	ΔS°_{ads}	$-Q$	Slope of
	kcal mol^{-1}	kcal mol^{-1}	cal K^{-1} mol^{-1}	kcal mol^{-1}	log[θ/(1−θ)]vs.(1/T)

4	14.1	10.3	51.6	5.1	1.1
3	17.8	10.4	50.4	4.6	1.0
2	15.5	10.6	49.5	4.2	0.9
1	17.4	10.8	47.1	3.2	0.7

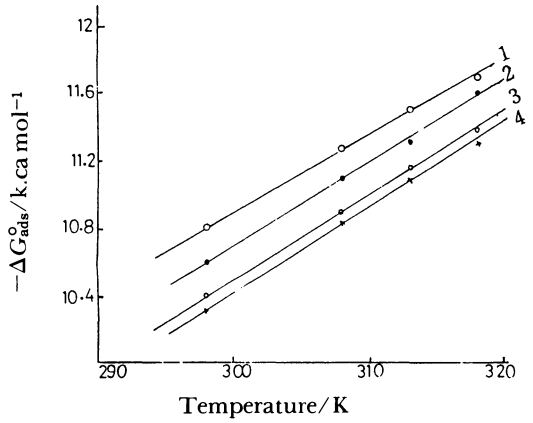

Fig. 9. Relation between $-\Delta G^{\circ}_{ads}$ and temperature for different 4-(m-substituted phenylazo)pyrazoles.

[θ/(1−θ)] vs. 1/T [θ=fraction of the surface covered by the inhibitor=1−μ_i/μ]. The Q values obtained from the slopes of these plots (ranging from 0.7—1.1) are given in Table 4. From the results it may be generalized that the more efficient inhibitor the less value of Q it has and vice versa.

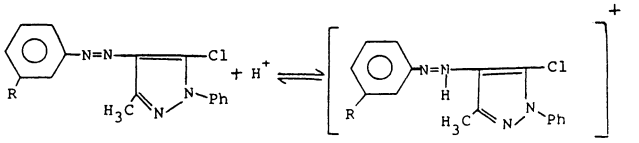
The values of free energy of adsorption ΔG°_{ads}, are given in Table 4 at 25 °C. The results show that compound **1** which gives maximum efficiency shows more negative free energy of adsorption indicating that it is strongly adsorbed on the metal surface. In general, the negative values of free energy of adsorption, ΔG°_{ads}, indicate the spontaneous adsorption of inhibitors on aluminium. Also the entropy of adsorption, ΔS°_{ads}, was calculated[16] from the slopes of Fig. 9 and its values are recorded in Table 4.

Effect of Chemical Constitution on Inhibition Efficiency. The order of decreased inhibition efficiency for 4-(m-substituted phenylazo)pyrazoles **1**, **2**, **3**, and **4** is: H>CH_3>Cl>OCH_3 as indicated by the results in Table 2. Differences in the inhibition efficiency for aluminium corrosion in 2 M HCl as indicated by the above orders probably do not originate from the pyrazole moiety of the molecule, but arise from the substituents in the phenylazo group. It is evident that the electrophilic character of these substituents plays a determining role in imparting inhibition efficiency. Therefore, increase in electron-withdrawing ability of substituents is expected to increase the positive charge on the protonated form (acid form) of the inhibitors

Table 5. Spectroscopic Data for 4-(m-Substituted phenylazo)pyrazoles

Compound	λ_{max}/nm	pK
1	334	12.2
2	336	6.4
3	360	5.8
4	334	5.3

which is adsorbed on the aluminium surface. In strong acid solutions at pH 0 the acid-base equilibrium of the azo inhibitors to consider is as follows:



R = H, CH_3, Cl, OCH_3

Moreover, the intensity of the azo bands decreases with increase in pH and isobestic points are observed in the absorption spectra at longer wavelength. This behavior refers to the presence of the acid-base equilibrium and indicates that the acid form is predominant at low pH values. Also pK values were determined spectrophotometrically by well-known procedure.[17] A large value points to the presence of the azo inhibitors more in the acid form. The results of spectrophotometric measurements are summarized in Table 5. The order of decrease of these pK values is: H>CH_3>Cl>OCH_3 which is similar to that of decreased inhibition efficiency.

Fouda[18] and Barradas[19] reported before that the increased protection efficiency for some derivatives of thiophene is due to the presence of electrophilic substituents. This phenomenon was accounted[20] for by the adsorption of the protonated form of the inhibitor species and hence a decrease in the electron density of the functional group leads to an effective increase in its positive charge. Consequently, adsorption is reinforced by electrostatic forces.

The electrophilic character of the substituents used is decreased in the order:[21] Cl>H>CH_3>OCH_3. This order runs parallel to the above mentioned observed sequence of decreased inhibition efficiency of the azo inhibitors (**1**—**4**) with exception of the Cl-substituted one (**3**) which could be accounted for by the operation of a mesomeric effect (+M) involving

electron pairs on Cl which acts in opposite direction to the −I effect and the overall mechanism constitutes electron release which reduces the positive charge on the protonated from of the azo inhibitor **3** in a greater extent than the methyl-substituted compound **2** and renders it less inhibitive. Also the increase in red shift for R=Cl over that for R=CH_3 supports the suggestion that +M effect operates in this case.

(Received July 27, 1987)

A comparative study of the behaviors of 1,1′-bis(selenocyanatomercurio)ferrocene (FBMS) with those of its thiocyanate analog (FBMT), has been made. Various physicochemical studies indicate that the Lewis acids and the adducts formed by FBMS are less stable than those of FBMT. The D_q values of FBMS adducts are higher, but the β values are lower. The matching constant values of FBMT complexes are higher than their corresponding FBMS complexes. The structures of Lewis acids and the adducts are similar in both the cases.

In our recent communication we have reported on the complexes of 1,1′-bis(thiocyanatomercurio)ferrocene (FBMT).[1] Since selenocyanate derivatives differ in their mode of bonding in certain cases,[2] a comparative study of the complexes of 1,1′-bis(selenocyanatomercurio)ferrocene (FBMS) was done.

Experimental

Material and Manipulation. Reagent grade solvents were purified before use. KSeCN was prepared and recrystallized by the method described elsewhere.[3] Nicotinamide (nia) and 2,2′-bipyridyl (bpy) were used from fresh bottle. 1,1′-Bis(selenocyanatomercurio)ferrocene (FBMS) was prepared as given below.

Preparation of FBMS. 11.5 g of ferrocene was dissolved in 65 ml of benzene. A suspension of 20 g of $Hg(OAc)_2$ in 250 ml of methanol was very slowly added to the solution of ferrocene through a dropping funnel with vigorous stirring. A clear dark brown solution was obtained. To this a solution of 6.5 g KSeCN in 10 ml of water was added with continuous stirring. A yellow precipitate was obtained, which was filtered on a Buchner funnel and washed with petroleum ether. This yellow compound was a mixture of (selenocyanatomercurio)ferrocene and FBMS. The former was removed by repeated extraction with hot 1,2-dichloroethane. FBMS left as insoluble yellow solid was dissolved in DMSO. To the solution a few drops of water were added, and it was left for a few days. Crystals of FBMS formed, were filtered, washed with the solvent and dried in vacuum.

Analytical Data. Mp 115 °C (decomp); Found: N, 6.74; Hg, 50.00; Se, 19.12%; Calcd for $C_{12}N_2H_8Se_2Hg_2Fe$: N, 7.04; Hg, 50.37; Se, 19.89%. IR (Nujol); ν(C-N) 2180(s), 2130(s), 2080 (sh); ν(C-Se) 765(s), 730(s), 680(m); δ(NCSe) 440(s), 420(s). IR(acetone): ν(C-N) 2130(s), 2070(s); ν(C-Se) 760(s), 740(s), 680(s), 660(m); δ(NCSe) 440(s), 510(s).

Preparation of Lewis Acids, $Fe(C_5H_4HgSeCN)_2M(NCS)_2$ [M=Ni(II), Co(II), and Zn(II)]. A calculated amount of FBMS was dissolved in a small quantity of DMSO and diluted to 200 ml of acetone. $M(NCS)_2$ was dissolved either in acetone or DMSO-acetone mixture. The solutions were mixed in 1 : 1 molar ratio and stirred for 24 h or until precipitate appeared. When the quantity of DMSO was too much, the precipitate was obtained by the addition of ethanol. The precipitate was filtered, washed with ethanol and dried in vacuum. The compounds thus obtained were recrystallized from acetone-ethanol mixture.

Preparation of Adducts, $Fe(C_5H_4HgSeCN)_2M(NCS)_2 \cdot L_x$ [M=Ni(II), Co(II), and Zn(II); x=2 when L is nia and one when bpy]. The adducts were prepared by two methods:

1. A suspension or solution of the Lewis acids was prepared in acetone-ethanol mixture and mixed with an ethanol solution of nicotinamide in 1 : 2 molar ratio or with bpy in 1 : 1 molar ratio and stirred for 24 h. In each case precipitate was formed, filtered, washed with ethonal, and dried in vacuum. The compounds were recrystallized from acetone-ethanol mixture.

2. $M(NCS)_2(nia)_2$ were first prepared by reaction of $M(NCS)_2$ with nicotinamide in 1 : 2 molar ratio in ethanol. Precipitate appeared in each case which was filtered, washed with ethanol and dried in vacuum. The complexes were recrystallized from acetone-ethanol mixture. $M(NCS)_2(nia)_2$ was dissolved in acetone and FBMS was dissolved in DMSO-acetone mixture. The solutions of $M(NCS)_2(nia)_2$ and FBMS were mixed in 1 : 1 molar ratio and stirred for 24 h. The precipitate formed was filtered, washed with ethanol and dried in vacuum. The compounds were recrystallized from acetone-ethanol mixture.

Analysis of the Complexes. Selenium was estimated as selenium metal, the other elements (Co, Ni, S, Hg) were analyzed as described.[1]

Physical Measurements. The molar conductance of the complexes were measured in DMSO using a Philips conductivity bridge model PR 9500. The magnetic susceptibility measurements were made at room temperature by Gouy's method using $CoHg(SCN)_4$ as standard. The diamagnetic corrections were made using Pascal's constants. Infrared spectra of the complexes were recorded as Nujol mulls on a Pye Unicam SP3-300 infrared spectrophotometer in the range 4000—200 cm^{-1}. The electronic spectra in DMSO (except FBMS·$Co(NCS)_2$) were recorded on a Cary-14 spectrophotometer. The spectra of FBMS·$Co(NCS)_2$ was recorded in solid phase adopting the procedure of Lee.[10]

Results and Discussion

Lewis Acids, $Fe(C_5H_4HgSeCN)_2M(NCS)_2$ [M= Ni(II), Co(II), and Zn(II)]. Like their SCN analogs[1] these Lewis acids are prepared by direct reaction of FBMS and $M(NCS)_2$. The positions of IR bands in the region of ν(CN), ν(CSe), and δ(NCSe) in FBMS·$Co(NCS)_2$ are basically similar to those of FBMT·$Co(NCS)_2$ except in the number of bands in the ν(CN), ν(CX), and δ(NCX) (X=S or Se) regions (cf. Table 2). This difference is due to the different local symmetries around Co(II), i.e. Td in the former C_{2v} in the latter.

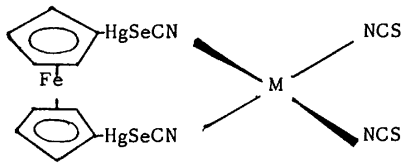
s=strong, sh=shoulder, b=broad, m=medium, w=weak; X=S or Se.

This increase of number of bands is due to the presence of ν(CN), ν(CS), ν(CSe), δ(NCS), and δ(NCSe) bands. The IR spectra show the presence of both bridged and terminal NCX groups (Table 1).

The magnetic moment values show close resemblance with the SCN analogs. The electronic spectral bands positions and the spectral parameters of FBMS·$Co(NCS)_2$ are presented in Table 2. Two intense bands (Fig. 5) observed in the region 15500 and 6000 cm^{-1} are assigned to $^4A_2 \rightarrow {}^4T_2(F)$ (ν_3) and $^4A_2 \rightarrow {}^4T_1(P)$ ($\nu 2$). These bands, D_q and magnetic moment values show that cobalt is in tetrahedral geometry. The compound is non-conducting but is dissociated significantly. The following structure (Fig. 1) can thus be proposed for the Lewis acids where M is Co(II), and also for Zn(II) which is very similar.

The electronic spectra of Lewis acid with Ni(II) show three bands in the region 28200, 16800, and 10010 cm^{-1} which are assigned to $^3A_{2g} \rightarrow {}^3T_{1g}$ (P) (ν_3), $^3A_{2g} \rightarrow {}^3T_{1g}$ (F) (ν_2), and $^3A_{2g} \rightarrow {}^3T_{2g}$ (F) (ν_1), respectively. Various spectral parameters have been calculated with the help of ν_2 and ν_3 bands using the secular equation



M = Co(II) and Zn(II)

Fig. 1.

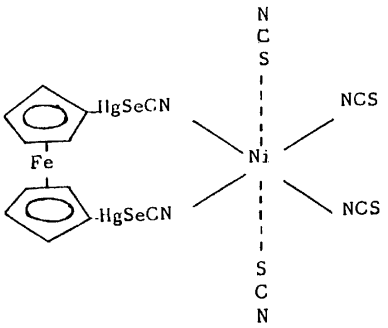


Fig. 2.

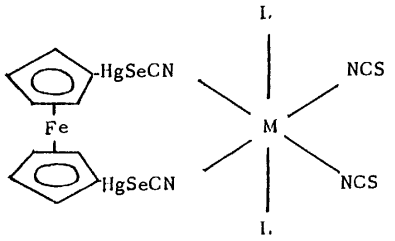

[M= Co(II), Ni(II) and Zn (II); L= nicotinamide (nia)]

[M= Co(II), Ni(II) and Zn (II); L= 2,2′-bipyridyl (bpy)]

Fig. 4.

of Tanabe and Sugano[4] and the results are included in Table 2. The electronic spectra and magnetic moment values for FBMS·Ni(NCS)$_2$ are indicative of octahedral coordination geometry around Ni(II), which is achieved by axial coordination from adjacent layer. On the basis of these results the structure in Fig. 2 can be proposed for it.

The D_q values of the FBMT Lewis acids are lower than those of FBMS Lewis acids. This indicates that FBMS exerts stronger ligand field than FBMT.[5] The B' value shows a decrease on changing from FBMT to FBMS indicating greater orbital overlap. The D_q, B', and β values of different series are presented in Table 2.

Adducts. Fe(C$_5$H$_4$HgSeCN)$_2$M(NCS)$_2$L$_x$ [M= Co(II), Ni(II), Zn(II); x=2 when L is nia and one when bpy]. In FBMS-M(NCS)$_2$ the coordination number of Co(II) and Zn(II) is four, against the maximum of six, hence they can be treated as Lewis acids. In case of the Ni(II) analogs the weak axial NCS ligands can easily be replaced by any strong base. Accordingly, when all the Lewis acids were treated with nicotinamide and 2,2′-bipyridyl, adducts of general formula FBMS·M(NCS)$_2$·L$_x$ were formed. The molar conductance values of these complexes in DMSO are in the range 40 to 63 cm^2 mho mol^{-1} (Table 1) showing that they are dissociated significantly.

IR spectra show that the positions of ν(CN), ν(CS), ν(CSe), δ(NCS), and δ(NCSe) bands of the Lewis acids are not significantly changed on adduct formation. The slight changes observed are due to, the change in stereochemistry around M. This reveals that the original structure of the Lewis acids is retained and only the coordination geometry of M changes on account of linkage of ligands. On adduct formation there is a slight change in ν(M-NCS) band in the case of Co and Zn. While, there is almost no change in ν(M-NCS) band in the case of Ni. The negative shifts in the case of Co and Zn are due to the change from tetrahedral geometry around M in the Lewis acids to octahedral in the adducts.[6,7] Such a change is not observed in Ni adduct because of the presence of octahedral configuration in the Lewis acids and the adducts as well. The electronic spectra of FBMS·Co(SCN)$_2$L$_x$ show the presence of three bands in the regions 19230—20800, 15870—17700, and 10450—10500 cm^{-1} which are assigned to $^4T_{1g}\rightarrow{}^4T_{1g}(P)$ (ν_3), $^4T_{1g}\rightarrow{}^4A_{2g}$ (ν_2), and $^4T_{1g}\rightarrow{}^4T_{2g}$ (ν_1) transitions respectively. The electronic spectra of Ni complexes show the presence of three bands in the regions 27850—28000, 16700—16950, and 9100—9500 cm^{-1} which are assigned just as in the case of the parent Lewis acid. The D_q values calculated from ν_2 and ν_3 are presented in Table 2. The structure as in Figs. 3 and 4 can be proposed for the adducts. Though a trans structure has been shown in Fig. 3, yet the possibility of cis structure is not ruled out.

Comparison with the Complexes of FBMT.

1. The Lewis acids and the adducts formed by FBMS are less stable than those formed by FBMT. The former complexes start decomposing after a month giving selenium metal.

2. Molar conductance values of FBMS complexes are slightly lower than those of FBMT analog, indicating that their dissociation in solution is less.

3. Complexes of FBMS are less soluble in DMSO than those of FBMT.

4. Three bands are present in ν(CN) region in the Lewis acids and adducts of FBMS series against two in FBMT analog. This is due to the difference in local symmetry around M.

5. The ν(M-NCSe) bands in the Lewis acid appear at lower frequency as compared with ν(M-NCS) band.

6. The D_q values of FBMS adducts are higher than their FBMT analogs. The β values show a decrease on changing from the latter to the former, indicating greater orbital overlap.

Quantitative Softness. The softness value of a metal ion has been denoted by $E_n^{\ddagger}$ and that of a base ion by $E_m^{\ddagger}$ and the difference between the two by $\Delta E_{nm}^{\ddagger}$.[8] The softness value of any metal in different compounds has been expressed by effective softness and denoted by $E_{n(eff)}^{\ddagger}$, similarly the softness of any atom in a neutral base such as nitrogen in nicotinamide and 2,2′-bipyridyl has been denoted by $E_{m(eff)}^{\ddagger}$ the difference between the two is denoted by $\Delta E_{nm(eff)}^{\ddagger}$. This is described as matching. A higher value of $\Delta E_{nm}^{\ddagger}$ indicates better matching. This can be represented by the following equation. The detail description of estimation of various softness parameters is given in Ref. 9.

$$\Delta E_{nm(eff)}^{\ddagger}\,(\text{Matching}) = |E_{n(eff)}^{\ddagger} - E_{m(eff)}^{\ddagger}| + \text{CFSE}$$

The $\Delta E_{nm}^{\ddagger}$ values in the Table 3 indicate that FBMT show better match with various $M(NCS)_2$ than FBMS. The effective softness of ligands and of M in the Lewis acids have also been calculated. The matching between the two has been derived and is presented in Table 4. A reference to Table 4 shows that 2,2′-

$Fe(C_5H_4HgSeCN)_2Zn(NCS)_2(nia)_2$	−4.13	13.86	9.73	—	9.73
$Fe(C_5H_4HgSeCN)_2Zn(NCS)_2(bpy)$	−4.13	24.08	15.82	—	15.82

bipyridyl forms more stable M-L bond than nicotinamide agreeing with the established fact. $\Delta E^{\ddagger}_{nm(eff)}$ values are highest when M=Ni(II) and lowest when M=Zn(II). The sequence with other M is as follows:

Nickel > Cobalt > Zinc.

On changing organomercury thiocyanate part of the Lewis acid with organomercury selenocyanate, the M becomes slightly more soft and accordingly $\Delta E^{\ddagger}_{nm}$ values also become lower. Thus the complexes of FBMT are more stable than those of FBMS.

Solvent and Reversed-Phase Extraction Chromatographic Separation of Niobium, Zirconium, and Hafnium with Aliquat 336

Nitya Ranjan Das* and Putul Chattopadhyay
Nuclear Chemistry Division, Saha Institute of Nuclear Physics, Sector-1, Block-'AF',
Bidhannagar, Calcutta-700 064, India
(Received December 10, 1987)

Aliquat 336 has been employed as an effective anionic extractant for the radiochemical separation of niobium, zirconium, and hafnium in mixtures using solvent extraction and reversed phase extraction chromatography (RPEC). In solvent extraction, niobium and zirconium are extracted with reagent solutions in the respective concentration ranges <0.001—0.04 mol dm^{-3} and 0.5 mol dm^{-3} leaving hafnium in the aqueous phase. In RPEC, niobium and zirconium are extracted by the reagent impregnated column and hafnium is completely eluted with water. Zirconium and niobium subsequently are eluted successively with 0.5 mol dm^{-3} HNO_3 and 1 mol dm^{-3} HF solutions. Distribution studies indicate that the extracted species for niobium and zirconium are respectively mono- and dinegative in charge. The extent of separation and the purity of the separated species were verified by means of gamma-ray spectrometry.

Zirconium and hafnium constitute the most important congeneric pair of elements in the periodic system and their similarity, both in the metallic state and in their compounds, is greater than that of any other homologous elements. It is not surprising that they invariably accompany each other in nature. With respect to elemental purity, their mutual separation has always been problem for analytical chemists. Moreover, in radiochemical separations of zirconium from hafnium, the presence of niobium must be taken into account since ^{95}Zr always occurs in equilibrium with its daughter isotope, ^{95}Nb.

Amongst the analytical procedures generally used in their separation study, solvent extraction[1-6] and reversed-phase extraction chromatography (RPEC) using various organic extractants[7,8] are found to be very effective. Survey of literature[9] reveals that the liquid exchangers, namely, the high-molecular-weight organonitrogenous compounds, in general, show very promising features in liquid-liquid extraction applications[10-13,14a] such as nuclear fuel processing and fission product recovery.[14b] Similarly, in RPEC[15-17] also, the column loaded with strong organic base is mainly devoted to the use of quaternary ammonium compounds as the stationary phase for various separation studies. In this regard, the quaternary ammonium salt, Aliquat 336 (tricaprylmethylammonium chloride), although displaying very high selectivity for different elements under specific experimental conditions as an anion exchanger involving solvent extraction as well as RPEC, it has not yet been fruitfully utilized for the individual separation of the concerned elements in a mixture.

With these facts in view, in the present study, attempts have been made to develop effective solvent extraction and RPEC procedures for tracer scale separation of the critical element pair, zirconium-hafnium, in admixture with niobium using the quaternary ammonium compound, Aliquat 336, as the liquid anion exchanger.

Experimental

Reagents. Aliquat 336 of molecular weight 404.17 was procured from Aldrich Chemical Co., Inc. USA. All other reagents used were of analytical grade. The carrier-free radioisotopes, ^{95}Zr (65d) and ^{95}Nb (35d) in hydrochloric acid solution and ^{181}Hf (44.6d) as HfO_2 of high specific activity were supplied by BARC, Trombay, India. HfO_2 powder was dissolved in the minimum quantity of a mixture of hydrofluoric and nitric acids and then diluted with water as required.

Solvent Extraction. Extractant stock solutions of desired concentrations were prepared by adding the necessary amount of Aliquat 336 to the nonpolar diluent cyclohexane, together with 3% (v/v) octanol as phase modifier. About 20 ml of the aqueous feed containing the mixture of the radiotracers, ^{95}Zr-^{95}Nb and ^{181}Hf ($<10^{-7}$ mol dm^{-3}) in acid medium were shaken with equal volumes of the extractant solution for ten minutes. Following separation, elements present in both phases were measured radiometrically. The optimal condition for complete separation of the tracers were such that niobium was first extracted from 9 mol dm^{-3} HCl solution with Aliquat 336 in cyclohexane in the concentration range <0.001—0.04 mol dm^{-3} leaving zirconium and hafnium in the aqueous phase. In the second stage, zirconium was separated from hafnium with 0.5 mol dm^{-3} extractant solution, whereby hafnium remained entirely in the aqueous phase.

RPEC. For the separation of the tracer mixture, the extraction column of hydrophobised kieselguhr impregnated with the exchanger, Aliquat 336, was prepared and preconditioned.[18,19] When the tracer species, i.e., ^{95}Zr-^{95}Nb and ^{181}Hf in dilute hydrochloric acid solution was loaded on the top of the column, hafnium emerged without being extracted by the reagent, whereas zirconium and niobium remained completely absorbed on the column. Subsequently, zirconium and niobium were successively separated by elution with nitric (0.5 mol dm^{-3}) and hydrofluoric (1 mol dm^{-3}) acids respectively. A flow rate of 10—12 drops per minute was maintained with the aid of a peristaltic pump. Radioactivity present in different fractions of the effluents was measured by means of a GM counter.

In both methods, the extraction or elution of each species

was first tested with individual tracers under identical experimental conditions.

Results and Discussion

Solvent extraction and RPEC procedures, though independent, appear to be inter-related in that they follow similar types of extraction mechanisms. In solvent extraction, elements which have a higher affinity for the extractant are easily extracted in the organic phase, leaving others in the aqueous phase. In the RPEC system, a mixture of metal ions is percolated through the column of inert material impregnated with an organic exchanger, and elements which are readily bound to the extractant molecules are extracted in the column by the extractant and subsequently eluted by means of suitable agents. Elements with low affinity for the reagent come out of the column by simple washing with water. Depending on experimental conditions, both procedures may thus be applied to the separation of the critical pair of elements, zirconium and hafnium in the presence of niobium.

Aliquat 336 is amphiphilic in nature, i.e., the molecule has a polar end and a long hydrophobic alkyl chain. The simultaneously hydrophobic-hydrophilic nature of the extractant is essential in maintaining both a high solubility in diluents with low dielectric constant and a high complexing power with respect to inorganic metal species. These reagents are accordingly characterized by high interfacial activity and enhanced extracting power. Reaction of the surface-active reagent with the metal ion takes place at the interface. The nonpolar alkyl groups surround the metal complex formed at the interface and solubilize it in the bulk organic phase. In this case the extractant and the extractant metal complex can undergo aggregation and disaggregation processes which can affect the distribution ratio value appreciably.

The higher efficiency of the quaternary salts is understandable for conditions under which the extraction mechanism is of the ion-association or ion-exchange type; in such instances, the charge of the metal anionic complexes in aqueous medium is balanced by salts which results in the formation of neutral species.[20]

Niobium and zirconium, unlike hafnium, tend to form negatively charged species in the acidic medium and are extracted to a different extent by Aliquat 336, depending upon the types of the acids and their acidities. In the present study, it was observed that the difference in the extent of extraction is especially pronounced in hydrochloric acid medium. It is also evident from Fig. 1 that the extent of extraction of zirconium along with its niobium daughter increases with increasing acid concentration, complete extraction occurring at 9 mol dm^{-3} HCl. However, hafnium has a lower tendency to form anionic complexes under these conditions, and remains unextracted by Aliquat 336 in the concentration region where niobium and zirconium are extracted. At higher acid concentrations viz., at about 10 mol dm^{-3} HCl, hafnium is extracted to a slight extent.

The concentration of the reagent is important, 0.5 mol dm^{-3} reagent solution extracting both niobium and zirconium completely from the aqueous solution and leaving hafnium in the aqueous phase. Niobium can be separated from the mixture with a lower concentration of the reagent. Extraction of niobium begins at <0.001 mol dm^{-3} reagent and is complete at 0.04 mol dm^{-3} reagent. Whereas the extraction of zirconium starts at about 0.05 mol dm^{-3} reagent, other conditions remaining same (Fig. 2).

It is evident from Fig. 3 that under conditions of RPEC, the extractional behavior of these elements corresponds closely to that of the solvent extraction. When the mixture is absorbed on the column impregnated with Aliquat 336, hafnium elutes quantitatively

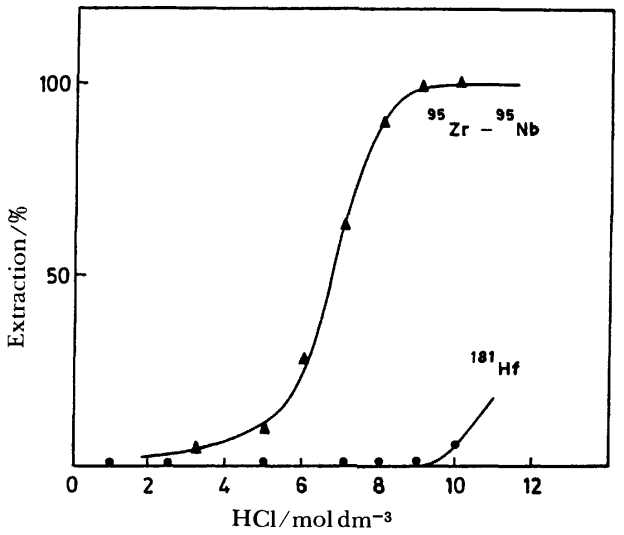

Fig. 1. Extraction dependence of ^{95}Zr–^{95}Nb and ^{181}Hf on HCl concentration using 0.5 mol dm^{-3} Aliquat 336 solution.

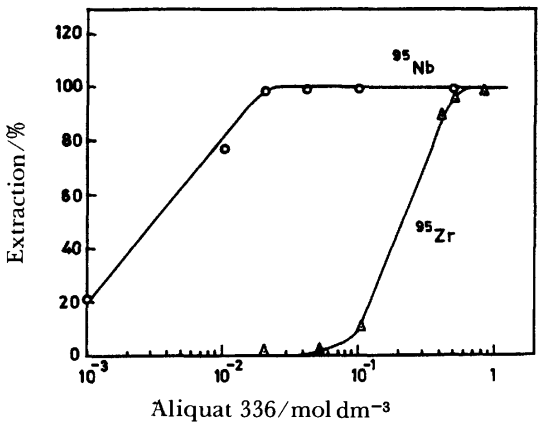

Fig. 2. Extraction dependence of ^{95}Nb and ^{95}Zr on Aliquat 336 concentration in 9 mol dm^{-3} HCl solution.

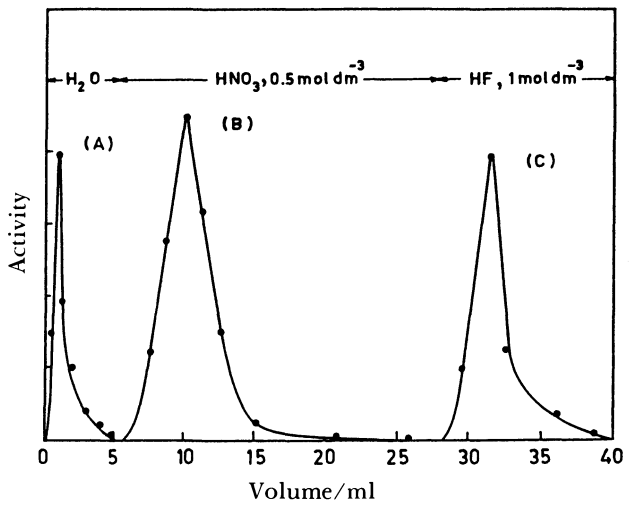

Fig. 3. Separation of ^{95}Zr, ^{95}Nb, and ^{181}Hf in the RPEC method (A) ^{181}Hf by water, (B) ^{95}Zr by 0.5 mol dm^{-3} HNO_3, and (C) ^{95}Nb by 1 mol dm^{-3} HF.

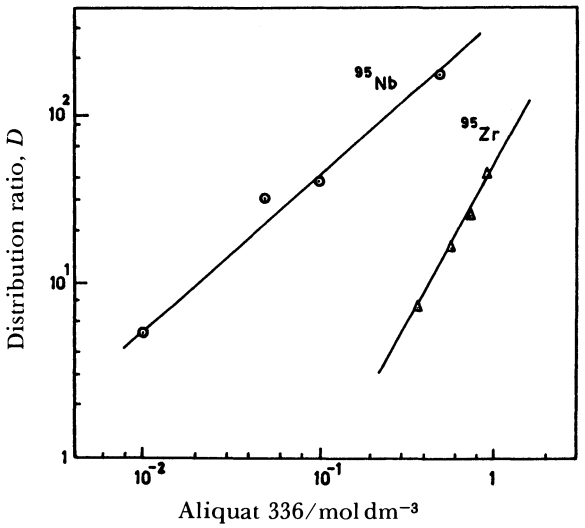

Fig. 4. Distribution ratio, D, of ^{95}Nb and ^{95}Zr as a function of Aliquat 336 concentration in 9 mol dm^{-3} HCl.

since it does not form anionic species in this case. Zirconium can be eluted with dilute nitric acid since it is bound by the reagent less firmly than niobium, which is finally eluted with dilute hydrofluoric acid.

Although both niobium and zirconium can form anionic species in aqueous medium, the difference in extraction of these species results from their competitive association with the bulky reagent cation. The preferential extraction of niobium with respect to zirconium may be attributed to the fact that the former primarily forms singly charged oxo- and hydroxychlorocomplexes such as $NbOCl_4^-$, $Nb(OH)_2Cl_4^-$,[21] etc., which are readily extracted by the reagent. Zirconium in aqueous solution generally forms dinegative species like $ZrCl_6^{2-}$ and hence it requires two molecules of the reagent to form a neutral complex. Moreover, it tends to form polymerized species[22,23] of the form $(ZrOCl_4)_n^{2-}$ resulting in an overall hindrance in its extraction.

This behavior is evident from the results shown in Fig. 4 for which the values of the distribution ratio for niobium and zirconium were measured at various concentrations of Aliquat 336 in the organic phase. For niobium, it is observed that D values increase with increasing extractant concentrations, and the slope of this increment is 1. It follows that niobium forms uninegative species in the aqueous phase, and is easily extracted into the organic phase. In the case of zirconium, however, the increment in D-values with the increase in concentration of Aliquat 336 is characterized by a slope of about 2, indicating that zirconium forms dinegative species in the aqueous phase. Hence, the mechanism of extraction of niobium and zirconium may be represented as

$$R_3R'\overset{+}{N}\,Cl^-_{org} + NbOCl_{4aq} \longrightarrow R_3R'N\,NbOCl_{4org} + Cl^-_{aq}$$

and

$$2R_3R'\overset{+}{N}\,Cl^-_{org} + ZrCl^{2-}_{6aq} \longrightarrow (R_3R'N)_2ZrCl_{6org} + 2Cl^-_{aq}$$

where,

R = capryl (C_8—C_{10}-alkyl) group,
R′ = methyl group.

The absence of any anionic species of hafnium as indicated by its extraction behavior towards the anionic extractant may be attributed to its electronic configuration. Hafnium ions are very weakly polarizing and as a result the formation of the complex compounds is very unusual.

The purity of the separated elements in both methods was monitored by gamma ray spectrometry at each stage of separation. The elements were identified by their characteristic gamma ray spectral lines using the following energies, 765.8 keV for ^{95}Nb, 724.0 and 756.6 keV for ^{95}Zr and 133.1, 345.7, and 482.2 keV for ^{181}Hf (Fig. 5).

In RPEC, kieselguhr was selected as a support because of its high resistance to nuclear radiation. This property is essential for radiochemical studies[24,25] of this kind. Moreover, kieselguhr is sufficiently porous, has a large capacity for absorbing the organic extractant with which it is impregnated and is chemically inert.

It is considered that the RPEC procedure is preferable to solvent extraction owing to its simplicity and selectivity. In liquid-liquid extraction, fresh portions of the reagent are repeatedly necessary, whereas in RPEC, the column can be impregnated with the reagent and used for several runs. In liquid-liquid extraction sometimes a phase modifier is required to prevent the formation of emulsions. But in RPEC, where the extractant is used as a stationary phase in the extraction columns the addition of the phase modifier is not required. Furthermore, the latter process is less time-consuming and results in a quantitative and

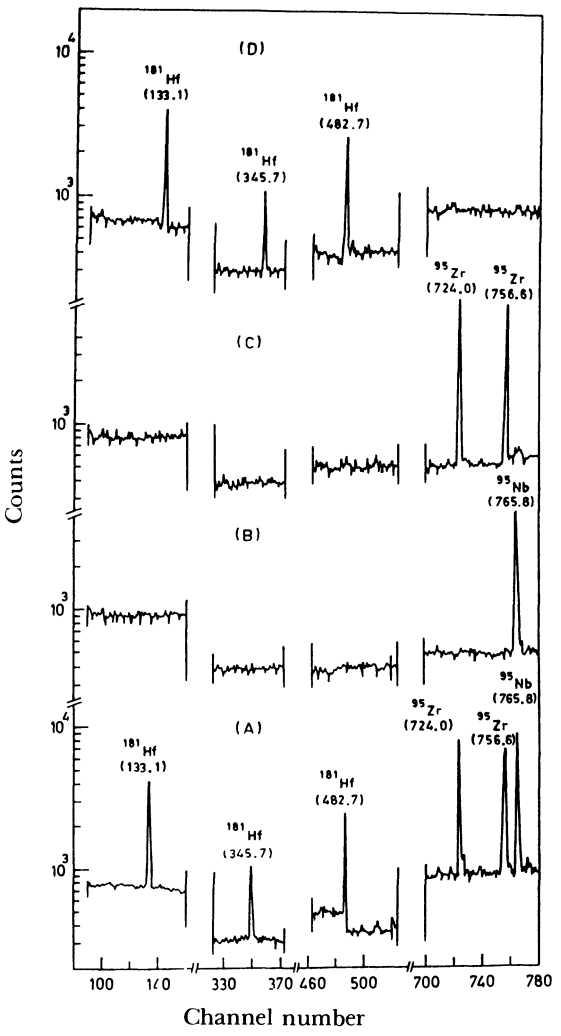

Fig. 5. Gamma spectra of ^{95}Nb, ^{95}Zr, and ^{181}Hf separated by solvent extraction. (A) Mixture of ^{95}Nb, ^{95}Zr, and ^{181}Hf before separation (B) ^{95}Nb separated in Aliquat 336 (0.02 mol dm^{-3}) (C) ^{95}Zr separated in Aliquat 336 (0.5 mol dm^{-3}) and (D) ^{181}Hf in aqueous phase.

clear-cut separation with minimal contamination.

Grateful acknowledgement is due to Professor S. N. Bhattacharyya, Head, Nuclear Chemistry Division, for his encouragement in the work.

Synthesis of γ-Butyrolactones, Quinoxalines, and Azauracils from 4-Aryl-2-oxobutanoic Acid Derivatives[1)]

G. H. Labib, M. Abdel Rahman, Y. El-Kilany, A. I. El-Massry, and E. S. H. El-Ashry*
Chemistry Department, Faculty of Science, Alexandria University, Alexandria, Egypt (A. R. E.)
(Received November 26, 1987)

4-Aralkyl-5-aryl-3-hydroxy-2(5*H*)-furanones (**2**) have been prepared from the corresponding 4-aryl-2-oxobutanoic acids (**1**). The anticipated products from the reaction of the furanones (**2**) with *o*-phenylenediamine (**3**) have not been isolated, but products resulting from the condensation followed by retro-aldol type of reaction are obtained and determined as 3-(2-arylethyl)-2(1*H*)-quinoxalinones (**4**). Compounds **4** could be readily obtained by the condensation of **3** with **1**. 4-Aryl-2-oxobutanoic acid thiosemicarbazones (**5**) have been cyclized to 5-(2-arylethyl)-6-azauracils (**6**).

Butyrolactones are one of the integral building blocks of many natural products.[2)] Moreover, they exhibit a wide range of biological activities.[3)] The antitumour properties of lignans and the identification of a butyrolactone, with *m*-hydroxybenzyl residues in the urine of certain mammals have attracted much interest in their physiological activities and consequently, in their synthesis.[4)] In the present report, as a continuation of our work[5)] on lactones and vitamin C, we have prepared a number of unsaturated γ-butyrolactones possessing aralkyl residues. Having the above aspects in mind, the prepared lactones are of potential value as precursors for the synthesis of biologically important functionalized lactones. Moreover, their conversion into heterocyclic compounds of potential chemotherapeutic interest, such as quinoxalines and azauracils, have been investigated.

Results and Discussion

The 4-aryl-2-oxobutanoic acids (**1**) were prepared by the reductive rearrangement of the corresponding 4-aryl-2-oxo-3-butenoic acids; the preparation[6)] of which was carried out by the condensation of pyruvic acid with aromatic aldehydes in alkaline medium followed by acidification.

The condensation of the keto acids **1** with aromatic aldehydes in a solution of acetic acid and in the presence of hydrogen chloride afforded the corresponding butyrolactones **2**. The structures of **2** were deduced from the mode of their preparation[6)] as well as from their spectral data (Table 1). They exist exclusively in the enolic form in the solid state. This conclusion was based on the absence of carbonyl absorption bands in their IR spectra, whereas they showed absorptions indicating the presence of lactone carbonyl and hydroxyl groups at 1740—1755 and 3210—3350 cm^{-1}, respectively. The ^1H NMR spectrum of **2g** in a solution of $CDCl_3$ showed a broad singlet at δ 6.0 due to the hydroxyl group. The singlet appearing at δ 5.45 was due to H-5 and agreed with the enolic structure, otherwise it would be splitted by a neighboring proton if it existed in the keto form. The methylene protons appeared as two doublets at δ 3.68 and 2.82 (J=16 Hz) indicating their nonequivalence. This may be attributed to the difference in orientation of the two protons with respect to the anisotropic effect of the aromatic residue on position 5.

The reaction of α-keto lactones such as dehydroascorbic acid and its analogues with *o*-phenylenediamine **3** has been investigated extensively[5,7)] in our laboratory. The reaction products were usually of the 2(1*H*)-quinoxalinone type resulting from a direct condensation accompanied by a lactone ring opening. However, the attempted condensation of the lactones **2** with **3** did not similarly afford the anticipated 2(1*H*)-quinoxalinones or even fused furoquinoxaline derivatives. The reaction products were assigned to be the structures **4**. This was apparent from the elemental analysis which indicated the loss of the elements Ar'CHO. The infrared spectra of **4** showed the presence of bands in the carbonyl frequency region at 1665 cm^{-1} indicating the presence of OCN groups, thus, rejecting the structure having the fused heterocyclic ring in agreement with a structure having a quinoxalinone ring. The ^1H NMR spectrum (DMSO-d_6) of **4**, showed a singlet of four-proton intensity at δ=3.10 due to the ethylene group and a singlet of one proton intensity at δ=12.37 due to NH. The aromatic protons appeared as a multiplet at δ=7.0—8.0. Conclusive evidence for the structure to be 3-aralkyl-2(1*H*)-quinoxalinone was provided by their unequivocal synthesis by the reaction of the corresponding 4-aryl-2-

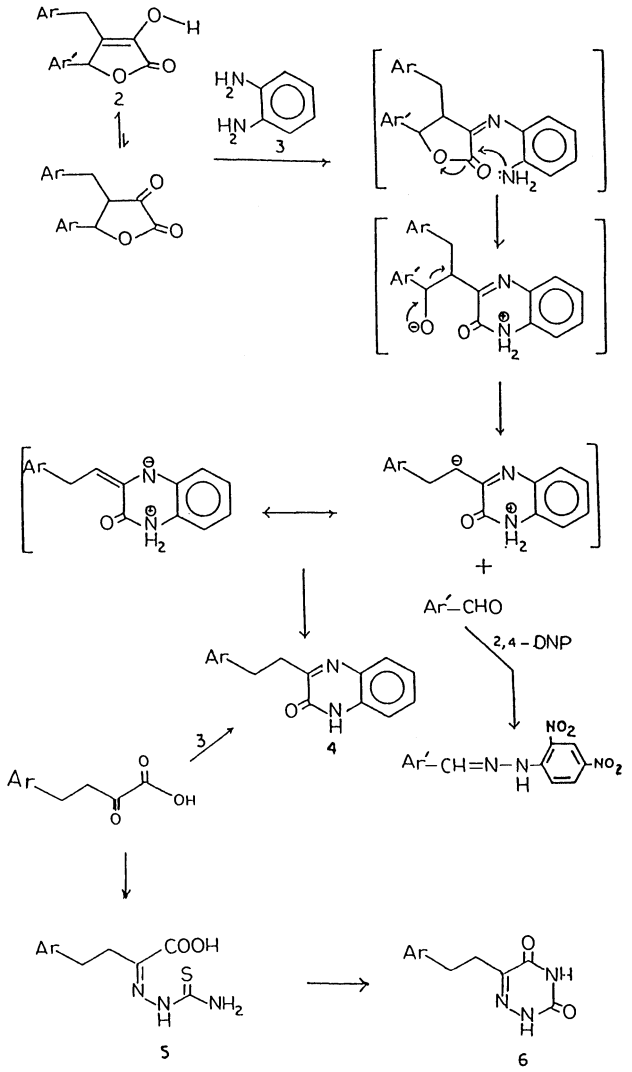

Scheme 2.

oxobutanoic acid **1** with *o*-phenylenediamine.

The formation of **4** from the lactone **2** may be explained as outlined in Scheme 2. The reaction may be started by a nucleophilic attack of the amino group on the α-carbonyl group in the keto form of **2** to give the Schiff base, which was not isolated, followed by the attack of the second amino group on the lactone carbonyl group which caused its ring opening. The final step of the reaction sequence is a retro-aldol condensation in which aldehyde is split off to give the product **4**. The generated aldehyde was trapped and isolated as its 2,4-dinitrophenylhydrazone.

When 4-aryl-2-oxobutanoic acids (**1**) were treated with thiosemicarbazide, they gave the corresponding thiosemicarbazones **5**, which upon boiling with methyl iodide in ethanol afforded colorless products whose elemental analyses and spectroscopic data agreed with the cyclized structures **6**. Their infrared spectra showed bands at 1685—1665 cm^{-1} due to the OCN groups and bands at 3240—3100 cm^{-1} due to NH groups. Their ^{1}H NMR spectra agreed with the assigned structures.

Experimental

Generals. Melting points were determined with Meltemp apparatus with a 76-mm immersion thermometer, and are uncorrected. Infrared spectra were recorded with a pye Unicam SP1025 spectrometer. ^{1}H NMR spectra were taken on a Varian EM-390 spectrometer. Chemical shifts are expressed in δ scale relative to tetramethylsilane as an internal standard. Elemental analyses were performed at Faculty of Science, Cairo University.

4-Aralkyl-5-aryl-3-hydroxy-2(5*H*)-furanone (2). A solution of **1** (5.6 mmol) and the aromatic aldehyde (5.6 mmol) in glacial acetic acid (6 ml) and 18% hydrochloric acid (6 ml) was heated on a water-bath for 4 h. The reaction mixture was poured onto crushed ice. The organic material was extracted with ether and the ether extract was washed with water, 5% sodium hydrogencarbonate solution to separate the unreacted acid, followed by 5% sodium hydroxide solution. The sodium hydroxide extract was cooled, acidified with cold concentrated hydrochloric acid and left overnight. The product was filtered, washed with water, dried, and recrystallized from the indicated solvent (Table 2).

The *p*-methylbenzaldehyde which splitted out from the reaction was trapped as *p*-methylbenzaldehyde 2,4-dinitrophenylhydrazone.

b) A solution of **1a** (0.78 g, 4.4 mmol), and *o*-phenylenediamine (0.47 g, 4.4 mmol) in ethanol (20 ml) was heated under reflux on a water-bath for 1 h, and the product (yield 0.3 g, 27%) was found to be identical with the one obtained by method a.

3-[2-(*p*-Chlorophenyl)ethyl]-2(1*H*)-quinoxalinone (4g). a) A solution of **2g** (0.6 g, 1.9 mmol), *o*-phenylenediamine (0.2 g, 1.9 mmol) and drops of acetic acid in ethanol (18 ml) was processed as above to give the title compound (yield 0.35 g, 65%) as pale yellow needles; mp 218—220 °C; ν_{max}^{KBr} 1665 (OCN) and 3140 (NH) cm^{-1}. ^{1}H NMR (DMSO-d_6): δ=3.10 (s, 4H, $2CH_2$), 7.33, 7.76 (m, d, 8H, Ar), 12.36 (s, 1H, NH is D_2O exchangeable).

Found: C, 67.3; H, 4.9; N, 9.8%. Calcd for $C_{16}H_{13}Cl\ N_2O$: C, 67.5; H, 4.6; N, 9.8%.

The *p*-methylbenzaldehyde which splitted out from the reaction was trapped as *p*-methylbenzaldehyde 2,4-dinitrophenylhydrazone.

b) A solution of 4-(*p*-chlorophenyl)-2-oxobutanoic acid (**1f**, 0.12 g, 0.6 mmol), and *o*-phenylenediamine (0.06 g, 0.6 mmol) in ethanol (10 ml) was processed as before to give a product (yield 0.1 g, 63%) identical with that obtained by method a.

4-(*p*-Methylphenyl)-2-oxobutanoic Acid Thiosemicarbazone (5c). A solution of **1c** (1.92 g, 10 mmol) and thiosemicarbazide (0.91 g, 10 mmol) in ethanol (50 ml) was heated under reflux on a water-bath for 1 h. The product was crystallized from water as colorless crystals; mp 174—175 °C; ν_{max}^{KBr} 1680 (COOH), 3200, 3280, 3440 (NH, NH_2, OH) cm^{-1}.

Found: C, 54.6; H, 5.9; N, 15.8%. Calcd. for $C_{12}H_{15}N_3O_2S$: C, 54.3; H, 5.7; N, 15.9%.

4-(*p*-Chlorophenyl)-2-oxobutanoic Acid Thiosemicarbazone (5f). A solution of **1f** (1.06 g, 5 mmol) and thiosemicarbazide (0.45 g, 5 mmol) in ethanol (25 ml) was processed as above to give the title compound (yield 0.8 g, 56%) as colorless crystals; mp 178—179 °C; ν_{max}^{KBr} 1687 (COOH), 3200, 3290, 3470 (NH, NH2, OH) cm^{-1}.

Found: C, 46.6; H, 4.3; N, 14.5%. Calcd for $C_{11}H_{12}ClN_3O_2S$: C, 46.2; H, 4.2; N, 14.7%.

5-[2-(*p*-Methylphenyl)ethyl]-6-azauracil (6c). A solution of **5c** (0.27 g, 1 mmol) in ethanol (5 ml) was treated with methyl iodide (0.15 ml) and the reaction mixture was heated under reflux on a water bath for 3 h. The product (yield 0.15 g, 65%) was crystallized from ethanol as colorless crystals; mp 207—208 °C; ν_{max}^{KBr} 1685 (OCN) and 3240 (NH) cm^{-1}. ^{1}H NMR (DMSO-d_6): δ=2.17 (s, 3H, CH_3), 2.67 (s, 4H, $2CH_2$), 6.90 (m, 4H, Ar), 11.80 (s, 2H, 2NH are D_2O exchangeable).

Found: C, 62.0; H, 5.6; N, 18.4%. Calcd for $C_{12}H_{13}N_3O_2$: C, 62.3; H, 5.6; N, 18.2%.

5-[2-(*p*-Chlorophenyl)ethyl]-6-azauracil (6f). A solution of **5f** (0.29 g, 1 mmol) in ethanol (10 ml) was treated with methyl iodide (0.15 ml) and the reaction mixture was processed as above to give the product (yield 0.17 g, 68%); mp 229—230 °C; ν_{max}^{KBr} 1665 (OCN) and 3100 (NH) cm^{-1}. ^{1}H NMR (DMSO-d_6): δ=2.81 (s, 4H, $2CH_2$), 7.22 (m, 4H, Ar), 11.93 (s, 2H, 2NH are D_2O exchangeable).

Found: C, 52.4; H, 4.0; N, 16.6%. Calcd. for $C_{11}H_{10}ClN_3O_2$: C, 52.5; H, 4.0; N, 16.7%.

α,β-Unsaturated Nitriles in Heterocyclic Synthesis. Novel Synthesis of Pyridines and Thieno[2,3-*b*]pyridine Derivatives

Galal E. H. ELGEMEIE,* Hassan A. ELFAHHAM,† and Hesham A. NABEY†
Chemistry Department, Faculty of Science, Bani Suef, Egypt
†Chemistry Department, Faculty of Science, Minia University, Minia, Egypt
(Received February 15, 1988)

Arylmethylenecyanothioacetamide reacts with ethyl acetoacetate and acetylacetone to give the corresponding 3-cyano-2(1*H*)-pyridinethione derivatives, which can be alkylated at sulfur atom and cyclized into the corresponding thieno[2,3-*b*]pyridine derivatives.

α,β-Unsaturated nitriles are versatile reagents that have been extensively utilized in heterocyclic synthesis.[1-3] We have previously reported several novel syntheses of azoles,[4] azines,[5] and azoloazines[6] utilizing α,β-unsaturated nitriles as starting components. In continuation of this work, we report here the results of our investigation into the utility of the readily obtainable arylmethylenecyanothioacetamide in heterocyclic synthesis. The investigation have resulted in the development of a novel procedure for the synthesis of pyridines and thieno[2,3-*b*]pyridine derivatives. The compounds obtained seem promising for further chemical transformations and for biological evaluation studies.

Thus, it has been found that benzylidencyanothioacetamide (**1a**) reacted with acetylacetone (**2a**) in boiling ethanol containing catalytic ammounts of piperidine to yield a product with the molecular formula $C_{15}H_{12}N_2OS$ (M^+ 268). Structure **4a** was considered for the product. ^1H NMR spectroscopy was used to confirm this structure for the product. Thus, ^1H NMR revealed two singlets at δ 1.90 and 2.55 assignable for two methyl groups, a broad band at δ 13.86 assignable to NH group, and a multiplet at δ 6.24—

7.00 assigned for aromatic protons (cf. Table 2). The formation of **4** from the reaction of **1** with **2** is assumed to proceed via Michael type addition of the methylene function in **2** to the activated double bond in **1** to yield acyclic Michael adducts **3** which then loses H_2O and cyclizes into the final isolable stable compounds **4**.

Subjecting the potassium salts of **4** to the action of alkylating agents such as methyl iodide afforded the corresponding *S*-alkyl derivatives **5**. The sturcture of **5** was inferred from analysis, MS and ^{1}H NMR. When using phenacyl bromide as alkylating agent, the *S*-alkylated derivative can not be isolated, but cyclized into thieno[2,3-*b*]pyridines **6**. The structure of **6a** could be established for the reaction product based on the absence of a CN absorption in the IR spectrum and on ^{1}H NMR which revealed two singlets at δ 2.00 and 2.26 assignable for two methyl groups, a broad band at δ 6.66 assignable to amino group, and a multiplet at δ 7.22—7.88 assigned for aromatic protons (cf. Table 2). The formation of **6** from reaction of **4** with phenacyl bromide constitutes a new synthesis of thieno[2,3-*b*]pyridine derivatives.

Experimental

All melting points are uncorrected. Analytical data were obtained from the Microanalytical Data Unit at Cairo University. The IR spectra were obtained on a Pye-Unicam SP-1000 spectrophotometer. ^{1}H NMR spectra were measured in DMSO or $CDCl_3$ on a Varian EM-360-60 MHz using TMS as internal standard and chemical shifts are expressed as δ ppm. Mass spectra were recorded on a Varian MAT 112 spectrometer.

Compounds **1a—d** were prepared following literature procedure.[7]

5-Substituted 4-Aryl-3-cyano-6-methyl-2(1*H*)-pyridinethione (4a—d). General Procedure: To a mixture of arylmethylenecyanothioacetamide **1** (0.01 mol) and acetylacetone **2a** or ethyl acetacetate **2b** (0.01 mol) in ethanol (50 ml), piperidine (a few drops) is added. The mixture is heated under reflux for 3 h, and then allowed to stand overnight. The resultant precipitate is isolated by suction and crystallized.

5-Substituted 4-Aryl-3-cyano-6-methyl-2-(methylthio)pyridines (5a—d). General Procedure. A mixture of **4** (0.01 mol), KOH powder (0.02 mol), and MeI (0.02 mol) in dry CH_2Cl_2 (50 ml) was stirred at room temperature for 3 h and then diluted with cold water (100 ml). The dichloromethane layer was washed several times with water, dried and then evaporated. The resulting solid product was collected by filteration and crystallized.

Thieno[2,3-*b*]pyridine Derivatives (6a—d). General Procedure: A mixture of **4** (0.01 mol), K_2CO_3 (0.02 mol), and phenacyl bromide (0.01 mol) in dry DMF (50 ml) was stirred at room temperature for 3 h and then diluted with cold water (50 ml). The resulting solid product was collected by filteration and crystallized.

Synthesis and Structure of the Diterpenoid Peucelinendiol

Joaquín R. Moran, Victoria Alcazar, and Manuel Grande*
Department of Organic Chemistry, F. C. Químicas, University of Salamanca, 37008 Salamanca, Spain
(Received March 19, 1988)

The synthesis of peucelinendiol has been carried out starting from geraniol, and using as a key intermediates the anion of phenylthiogeraniol and (−)-geraniol epoxide obtained by the Sharpless procedure. Its structure was stablished as (6*S*,7*R*)-7-hydroxymethyl-2,6,10,14-tetramethylpentadeca-2,9,13-trien-6-ol. Isopeucelinendiol, epipeucelinendiol, and epiisopeucelinendiol were also synthesized.

Some years ago we isolated from *Magydaris panacifolia* (Umbelliferae) a new diterpenoid named magydardiendiol,[1] for which the irregular isoprenoid structure **1** was recently proposed.[2] The structure of this diol seems to be the result of a head to head coupling of two monoterpene units, i.e. two geranyl units linked through C_1-C_2' and C_3-C_4'.

Although the head to head coupling is normal in the biogenesis of triterpenoids and carotenoids, it is quite unusual in the case of lower terpenoids. We have only found two more diterpenoids with a head to head skeleton, namely digeranyl[3] and peucelinendiol **2**.[4] Moreover the C_1-C_2' union between isoprenoid chains, quite uncommon, is also present for instance in lavandulol and in tetraterpenes like that one isolated from *Elodea canadensis*.[5]

We were interested in peucelinendiol, because it could be a biogenetic precursor of **1**, and the fact that neither the absolute nor the relative stereochemistry for **2** were given, encouraged us to accomplish the total asymmetric synthesis of peucelinendiol.

Peucelinendiol can be envisaged as the product from the attack of anion **A** on the epoxide **B**, both materials easily available from geraniol. The synthesis of each one of the two possible diastereomers for **2** can be done if the suitable cis or trans epoxide **B** is used as starting material.

The nucleophile **A** can be prepared as a magnesium derivative, a cuprate or a sulfur-stabilized anion. However the high nucleophilicity of stabilized sulfur anions allows to carry out the displacement reactions under very mild conditions and formation of secondary by-products (rearrangement, allylic attack, halohydrine formation···) is minimized. Also good yields are reported in the reaction of allylic sulfur-stabilized anions and epoxides.[6,7] We chose the geranyl phenyl sulfide **4**, as a synthetic equivalent of carbanion **A**.

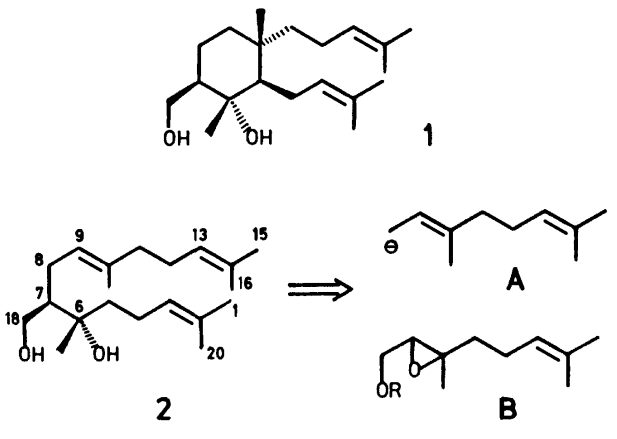

Chart 1.

Treatment of geraniol with 2,4-dinitro-1-fluorobenzene[8] yielded the aromatic ether **3**, which on reaction with potassium benzenethiolate gave the expected allylic sulfide **4** whose physical properties are in good agreement with those reported.[6]

It is known that the hydroxyl group in allylic alcohols can induce the selective epoxidation of the β,γ-double bond in the presence of other olefins. Furthermore, it is possible the asymmetric epoxidation of allylic alcohols with *t*-butyl hydroperoxide, (+)-diethyl tartrate and titanium(IV) isopropoxide.[9] We used this method to prepare the epoxidic substrate **B**. In our hands, the asymmetric epoxidation of geraniol proceeded smoothly to yield the optically active geranyl epoxide **5** in 80% e.e.

The free hydroxyl group of **5** is not compatible with the strong basic conditions needed to the coupling with the anion **A**, so that protection either with butyl vinyl ether, or with methyl isopropenyl ether was used, to give the respective acetal derivatives **6** or **7** in high yield.

Metallation of the allylic sulfide **4** (BuLi, DABCO/THF −25 °C), followed by addition of the protected alcohol epoxide **6** gave in a fast and clean reaction, after deprotection, a single mixture of the phenylthio isomers **8**.

Desulfuration of this material was accomplished either with Raney Ni, or with $Li/NH_3/Et_2NH$. In both cases mixtures of constitutional isomers **2** and **9** were obtained. Although the ratio **2**/**9** was higher when the desulfurization was carried out with $Li/NH_3/Et_2NH$, the product distribution was difficult to control. Chromatography on SiO_2 allowed us to separate both compounds. The physical constants of the diol with the three trisubstituted double bonds were in good agreement with the previously reported for peucelinendiol, and also the optical activity ($[\alpha]_D$+4.4°) was the expected for an 80% e.e. (reported $[\alpha]_D$+5.4°).[4]

According to the stereochemistry of the reactions

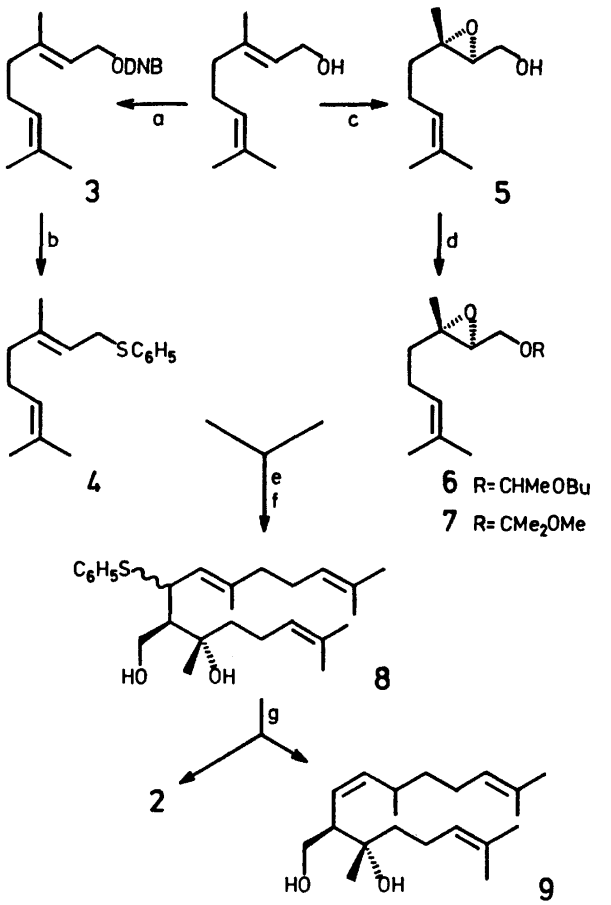

Chart 2.

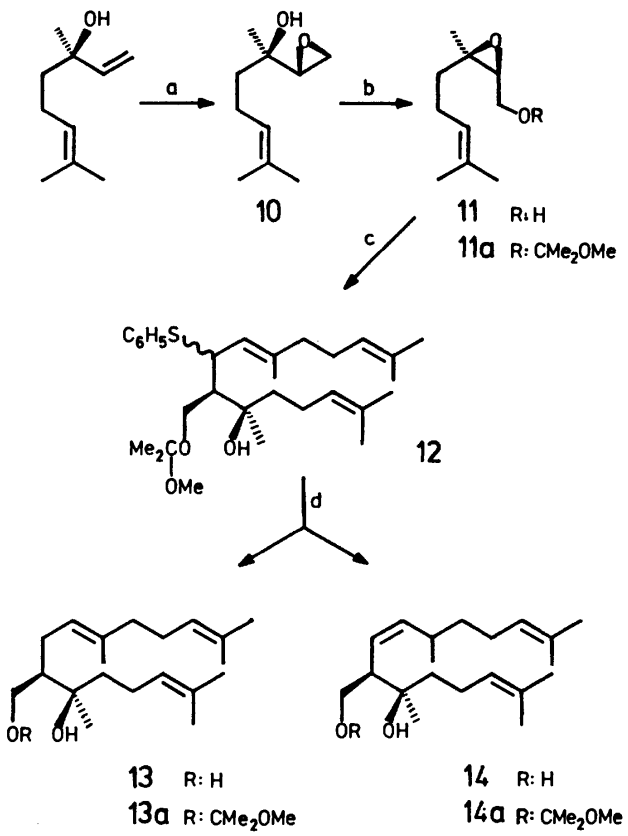

Chart 3.

a) *t*-BuOOH, $VO(acac)_2/C_6H_6$, b) KOH/H_2O, c) MeOCMe=CH_2/C_6H_6 (TsOH); BuLi, DABCO/THF −25°C; **4**, d) Li, NH_3/Et_2NH.

described, we consequently propose for compound **2** the absolute configuration 6*S*, 7*R*.

However to rule out definitively the alternative stereochemistry, we repeated the reaction with the isomeric epoxide **11**. The synthesis of this compound was accomplished starting from (−)-linalool, using *t*-butyl hydroperoxide and $VO(acac)_2$, to get the epoxidation product **10**. This material rearranged cleanly into the trisubstituted epoxide **11** when handled with aqueous KOH.[10] Protection of the hydroxyl group with methyl isopropenyl ether (**11a**), and reaction with the foregoing anion **4**, produced the expected epimeric mixture **12** which upon hydrolysis and desulfurization with $Li/NH_3/Et_2NH$ led to epipeucelinendiol **13** ($[\alpha]_D$−7.5°) and its isomer with the disubstituted double bond **14**.

Comparison of the ^{13}C NMR spectra, specially the signals at 5-C (39.8 vs. 41.6), 7-C (49.6 vs. 47.7), 11-C (38.3 vs. 39.9), and 19-C (26.4 vs. 23.4) of epipeucelinendiol and the already described peucelinendiol, led no doubt about their different structures. As a conclusion we propose the structure **2** for natural peucelinendiol.

Experimental

Optical rotations were measured on a polarimeter Perkin-Elmer 241. IR spectra were recorded on a Beckman Acculab II. NMR were recorded on a Bruker WP 200 SY (200 MHz ^1H, 50.3 MHz ^{13}C).

Protection of Geranyl Epoxide. The alcohol **5** (2.6 g), prepared as described in Ref. 9, was dissolved in ether (30 ml) and reacted with methyl isopropenyl ether or with butyl vinyl ether (5 ml) and a trace of TsOH. After 30 minutes at room temperature, ether and aqueous Na_2CO_3 (4%) were added, the organic layer was dried and the solvent removed in vacuo to yield a crude material (3.2 g) which was used without further purification.

8-Phenylthiopeucelinendiol (8). The sulfide **4** (1.5 g), prepared as described in Ref. 6 in THF (60 ml) and DABCO (750 mg) was cooled down to −20 °C. An excess of BuLi (5 ml, 1.6 M in hexane; 1 M=1 mol dm^{-3}) was then added. The reaction mixture turns then into orange. After 5 minutes, the epoxide **6** (or **7**) was slowly dropped, and the mixture was allowed to warm up to room temperature. Work up, hydrolysis (0.5 M HCl) and chromatography on SiO_2 (60 g, hexane/ether, 6:3) rendered 2.05 g (80%) of a 1:1 mixture of the epimeric hydroxy sulfides **8**. ^1H NMR ($CDCl_3$) δ=7.30 (10H, m), 5.25 (6H, m), 4.10 (6H, m), 1.62 (6H, s), 1.60 (6H, s), 1.56 (6H, s), 1.52 (6H, s), 1.34 (3H, s), 0.95 (3H, s).

Peucelinendiol (2) and Isopeucelinendiol (9). Desulfurization of the foregoing mixture was carried out as follows: over the stirred sulfide mixture (380 mg) in diethylamine (3 ml), was condensed NH_3 (30 ml). Li (100 mg) was added in small pieces and the blue solution was kept at reflux temperature for 30 minutes. MeOH was then dropped in until the blue color vanished and NH_3 was allowed to evaporate. Work up with ether and aqueous HCl (0.5 M) yielded a mixture (280 mg) of two compounds which could be separated on a SiO_2 column (60 g, hexane/ether, 7 : 3) affording 175 mg of peucelinendiol **2** ($[\alpha]_D$ +4.4° *c* 3, $CHCl_3$) and isopeucelinendiol **9** (60 mg), which showed the following physical data: $[\alpha]_D$ −11.0° (*c* 3.3, $CHCl_3$). IR (film) 3400, 2950, 1450, 1380, 1200, 1040, 990 cm^{-1}. ^1H NMR ($CDCl_3$) δ=5.37 (1H, dd *J*=15 and 7 Hz, 9-H), 5.07 (1H, dd, *J*=15 and 9 Hz, 8-H), 5.03 (2H, m, 3-H, 13-H), 3.78 (1H, dd, *J*=9 and 8 Hz, 18-H_A), 3.55 (1H, dd, *J*=9 and 6 Hz, 18-H_B), 2.35 (1H, m, 7-H), 1.60 (6H, s, 1-CH_3, 15-CH_3), 1.54 (3H, s, 16-CH_3), 1.50 (3H, s, 20-CH_3), 1.10 (3H, s, 19-CH_3), 0.89 (3H, d, *J*=7 Hz, 17-CH_3). ^{13}C NMR ($CDCl_3$) δ=140.9 (d, 8-C), 131.7 (s, 2-C), 131.2 (s, 14-C), 125.4 (d, 9-C), 124.6 (d, 3-C), 124.5 (d, 13-C), 75.4 (s, 6-C), 64.2 (t, 18-C), 52.8 (d, 7-C), 4.16 (t, 5-C), 37.1 (t, 11-C), 36.6 (d, 10-C), 25.8 (t, 12-C), 25.6 (q, 1-C, 15-C), 23.5 (q, 19-C), 21.7 (t, 4-C), 20.6 (q, 17-C), 17.6 (q, 16-C, 20-C).

8-(Phenylthio)epipeucelinendiol (12). The alcohol **11** (710 mg) prepared according to Ref. 10, in ether (5 ml) was protected by reacting it with 2 ml of 2-methoxy propene and a trace of pyridinium tosylate during 10 minutes. Work up with aqueous Na_2CO_3 (4%) and ether produced 750 mg of the epoxy acetal **11a** which was used without purification in the next reaction. The sulfide **4** (500 mg) and DABCO (200 mg) in THF (20 ml) at −20 °C were treated with BuLi in hexane (2 ml, 1.6 M). After 5 minutes the epoxy acetal **11a** (400 mg) in THF (10 ml) was added and the reaction was allowed to warm up to room temperature. Usual work up followed by chromatography on SiO_2 (50 g, hexane/ether, 95 : 5) afforded 650 mg of an epimeric sulfide mixture **12** which was further reacted by dissolving it in 6 ml of diethylamine and 50 ml of refluxing NH_3. Li (200 mg) was then added with strong stirring and the reaction mixture was allowed to stand for 30 minutes more. After this time MeOH was added until the blue color disappeared. Evaporation of the NH_3 and usual work up with aqueous HCl (0.5 M) and ether produced a mixture (420 mg) which could be resolved on a SiO_2 column (80 g, hexane/ether, 9 : 1) to yield epipeucelinendiol acetal **13a** (85 mg) and epiisopeucelinendiol acetal **14a** (210 mg).

Epipeucelinendiol Acetal 13a. Oily, $[\alpha]_D$ −11.0° (*c* 0.9, $CHCl_3$). IR (firm) 3400, 2950, 1460, 1380, 1220, 1090, 1050 cm^{-1}. ^1H NMR ($CDCl_3$) δ=5.10 (3H, m, 3-H, 9-H, 13-H), 3.55 (2H, m, 18-H), 3.16 (3H, s, OCH_3), 1.64 (6H, s, 1-CH_3, 15-CH_3), 1.57 (9H, s, 15-CH_3, 17-CH_3, 20-CH_3), 1.30 (3H, s, CH_3), 1.29 (3H, s, CH_3), 1.20 (3H, s, 19-CH_3). ^{13}C NMR ($CDCl_3$) δ=136.1 (s, 10-C), 131.3 (s, 2-C), 131.2 (s, 14-C), 124.9 (d, 3-C), 124.2 (d, 13-C), 123.5 (d, 9-C), 100.3 (s, O-C-O), 74.8 (s, 6-C), 61.1 (t, 18-C), 48.8 (q, OCH_3), 47.9 (d, 7-C), 39.8 (t, 5-C), 38.6 (t, 11-C), 26.7 (t, 8-C), 25.9 (q, 19-CH_3), 25.5 (q, 1-CH_3, 15-CH_3), 25.5 (t, 12-C), 24.3 (q, 2CH_3), 22.4 (t, 4-C), 17.5 (q, 16-CH_3, 20-CH_3), 16.2 (q, 17-CH_3).

Epipeucelinendiol (13). The acetal **13a** (110 mg) was hydrolyzed in MeOH (8 ml) with aqueous HCl (1 ml, 0.5 M) for ten minutes. Work up with aqueous Na_2CO_3 (4%), yielded 81 mg of the compound **13**. Colorless oil. $[\alpha]_D$ −7.5° (*c* 0.8, $CHCl_3$). IR (film) 3400, 2950, 1450, 1380, 1150, 1050, cm^{-1}. ^1H NMR ($CDCl_3$) δ=5.05 (3H, m, 3-H, 9-H, 13-H), 3.75 (2H, m, 18-H), 1.65 (6H, s, 1-CH_3, 15-CH_3), 1.58 (9H, s, 16-CH_3, 17-CH_3, 20-CH_3), 1.26 (3H, 19-CH_3). ^{13}C NMR ($CDCl_3$) δ=136.5 (s, 10-C), 131.8 (s, 2-C), 131.6 (s, 14-C), 124.5 (d, 13-C), 124.3 (d, 3-C), 123.3 (d, 9-C), 76.2 (s, 6-C), 63.1 (t, 18-C), 49.6 (d, 7-C), 39.8 (t, 5-C), 38.3 (t, 11-C), 26.7 (t, 8-C), 26.4 (q, 19-C), 25.6 (q, 1-C, 15-C), 25.3 (t, 12-C), 22.4 (t, 4-C), 17.6 (q, 16-C, 20-C), 16.1 (q, 17-C).

Epiisopeucelinendiol Acetal (14a). Oily, IR (film) 3400, 2950, 1450, 1380, 1200, 1090, 980 cm^{-1}. ^1H NMR ($CDCl_3$) δ=5.05 (2H, m, 3-H, 13-H), 3.55 (2H, m, 18-H), 3.16 (3H, s, OCH_3), 1.63 (6H, s, 1-CH_3, 15-CH_3), 1.57 (3H, s, 16-CH_3), 1.54 (3H, s, 20-CH_3), 1.30 (6H, s, 2 CH_3), 1.14 (3H, d, *J*=7 Hz, 17-CH_3). ^{13}C NMR ($CDCl_3$) δ=140.0 (d, 8-C), 131.1 (s, 2-C), 131.0 (s, 14-C), 126.4 (d, 9-C), 100.3 (s, O-C-O), 74.0 (s, 6-C), 63.0 (t, 18-C), 52.1 (q, OCH_3), 48.7 (d, 7-C), 38.8 (t, 5-C), 37.2 (t, 11-C), 36.7 (d, 10-C), 25.9 (t, 12-C), 25.6 (q, 19-C), 25.5 (q, 1-C, 15-C), 24.3 (q, 2 CH_3), 22.1 (t, 4-C), 20.7 (q, 17-C), 17.6 (q, 16-C, 20-C).

We wish to thank Mr. A. Zarzo, University of Alicante, for the synthesis of **4** and Dr. Cambronero, ACEDESA, El Palmar, Murcia (Spain) for samples of geraniol and (−)-linalool.

The Magnetic Properties of Copper(II) Alkanoate Adducts with Pyridine and Quinoline Analogues

Shuji EMORI,* Katsuko OHISHI, Hikari KURIHARA, and Yoneichiro MUTO
Department of Chemistry, Faculty of Science and Engineering, Saga University, Honjo-machi, Saga 840
(Received June 24, 1988)

Synopsis. Various copper(II) alkanoate adducts with pyridine and quinoline analogues have been prepared, and characterized by means of magnetic susceptibility and IR measurements. The effects of axial ligands on the magnetic moments are discussed on the basis of their basicities and steric requirements.

In most dinuclear copper(II) carboxylate adducts, the coordination geometry is essentially five-coordinate tetragonal pyramidal.[1-5] The addend donor occupies the apical site (axial position) and affects the strength of the spin-exchange coupling within the dinuclear complex.[2] For adducts with σ-donor ligands, which exhibit no steric hindrance to an axial coordination, the room-temperature magnetic moments (BM) can be expressed according to Eq. 1:

$$\mu_{eff} = -0.052(pK_a - 0.068pK_a' - 4.56) + \Delta\mu_\alpha + 1.38_5, \quad (1)$$

where pK_a and pK_a' are the acidities of the conjugate acids of alkanoate and axial ligands, respectively.[6] $\Delta\mu_\alpha$ is the correction term for the substitution in the methyl group of acetic acid (-0.05_8 and -0.07_0 for the series of mono- and disubstituted acetates, respectively), including corrections for the steric strain, field effect, and hyperconjugation.[6] On the other hand, for adducts with *N*-heteroaromatic (pyridine-type) donors, the magnetic moments are, more or less, lower than those of the adducts with alkyl-[6,7] and arylamines,[8] owing to a steric hindrance to their axial coordination.[9-11] In order to investigate these steric effects quantitatively, we prepared several copper(II) alkanoate adducts with pyridine (py), 3-chloropyridine (3-Clpy), 3-bromopyridine (3-Brpy), 3,5-dichloropyridine (3,5-Cl_2py), 3-ethylpyridine (3-Etpy), 4-methylpyridine (4-Mepy), pyrazine (pyz), quinoline (quin), 4-methylquinoline (4-Mequin), and quinoxaline (quix), and measured their magnetic susceptibilities at room temperature.

The adducts were obtained, except for the cyclohexanecarboxylates, by standard procedures,[12] and recrystallized from chloroform whenever possible. The cyclohexanecarboxylates were prepared in a similar way, using dioxane as a solvent.[13] The effective magnetic moments of these compounds (Table 1) were evaluated from the room-temperature magnetic susceptibilities, which were corrected for the diamagnetic contribution (χ_{dia}) using Pascal constants[14] and for temperature-independent paramagnetism ($N\alpha$) using the value of 60×10^{-6} emu mol^{-1} (1 emu$=4\pi\times10^{-6}$ m^3). Although a number of copper(II) alkanoate adducts with various pyridine-type donors have been already studied magnetically,[2,15-17] their magnetic moments were reevaluated in order to avoid any errors derived from differences in the standard samples used for susceptibility measurement and in the correction values for χ_{dia} and $N\alpha$. The IR spectra of the solid compounds show characteristic bands connected with unsymmetric and symmetric carboxyl stretching vibrations, the latter with a variable intensity.[18] The magnetic and IR spectral data indicate that the present compounds have a bridged dinuclear structure similar to that of copper(II) acetate monohydrate.[2]

Although a pyridine-type donor can function as a π-acceptor in some circumstances, it functions here almost entirely as a σ-donor base,[5] because X-ray crystallographic analyses indicate that a pyridine or quinoline analogues adopts a staggered orientation with respect to the planes of carboxylato groups.[1-5] By analogy with Eq. 1, the magnetic moments of the present adducts may be expressed as

$$\mu_{eff} = -0.052(pK_a - 0.068pK_a' - 4.56) + \Delta\mu_\alpha + \Delta\mu_{ST} + 1.38_5, \quad (2)$$

where the correction term $\Delta\mu_{ST}$ depends on the steric hindrance to an axial coordination; its value can be evaluated from the graphic interpolation shown in Fig. 1. In this series of axial ligands, the pK_a' value varies from -2.60 for 1/2quix to -2.10, 0.67, 0.72, 2.89, 3.16, 4.94, 5.23, 5.73, 5.89, and 6.04 for 1/2pyz, 3,5-Cl_2py, quix, 3-Brpy, 3-Clpy, quin, py, 4-Mequin, 3-Etpy, and 4-Mepy, respectively. To plot the points for the 1/2pyz and 1/2quix adducts, the first dissociation constants of pyrazine and quinoxaline are selected, since their

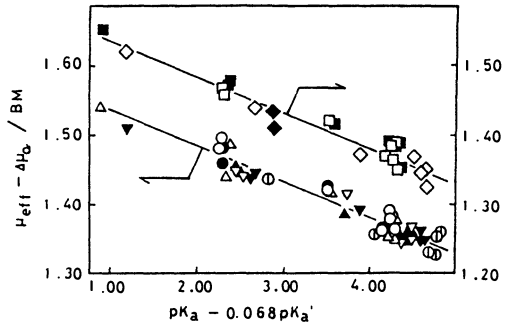

Fig. 1. The corrected magnetic moments at 20°C plotted against the acidities of the ligands for the copper(II) alkanoate adducts with 1/2quix (◆), 1/2pyz (Φ), 3,5-Cl_2py (▼), quix (◇), 3-Brpy (▽), 3-Clpy (▲), quin (■), py (△), 4-Mequin (□), 3-Etpy (●), and 4-Mepy (○).

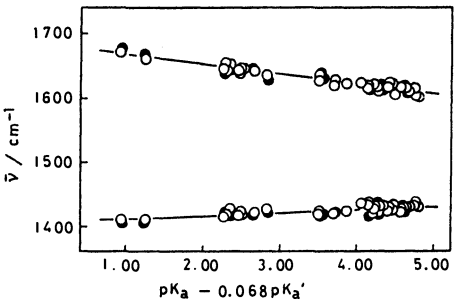

Fig. 2. The carboxyl stretching frequencies plotted against the acidities of the ligands for the copper(II) alkanoate adducts with pyridine analogues (○) and quinoline analogues (●).

second coordination abilities must be reduced by the first coordination on the other sites. The obtained slope of −0.052 BM is exactly the same as that shown in Eq. 2, indicating the validity of the equation, although we disregard interactions between different dinuclear complexes,[19] the presence of modifications,[2] and crystallographically independent dinuclear complexes,[1,4] and packing effects. The obtained values of $\Delta\mu_{ST}$ are -0.03_3 BM for the adducts with pyridine analogues (py, 3-Clpy, 3-Brpy, 3,5-Cl_2py, 3-Etpy, 4-Mepy, and pyz) and -0.03_4BM for those with quinoline analogues (quin, 4-Mequin, and quix), being almost the same with each other. This fact is consistent with the coincidence of the singlet-triplet separation values for the copper(II) acetate adducts with pyridine and quinoline,[20] and should be attributed to a similarity of the steric interferences hindering their axial coordination; a mutual repulsion between the adjacent Cu-O and N-C bonding electron pairs may be taken as such a steric hindrance.[21]

The correlation between the magnetic moments and the acidities of the parent carboxlic acids (Eq. 2) suggests that the magnitude of spin-exchange coupling is closely related to the nature of Cu-O bonds. It has been pointed out that, for carboxylate compounds with the same structure, the frequency shift of the carboxyl stretching vibrations can be used as a measure of the relative strengths of the metal-oxygen bonds.[22] Systematic shifts of the carboxyl frequencies against the acidities of the parent carboxylic acids (Fig. 2), which can also be demonstrated for the dimeric aliphatic[23] and arenecarboxylic asids,[24] indicate that an increase in the acidity of the parent carboxylic acid leads to a more asymmetric structure of the carboxyl group, thereby resulting in an increase in the frequency separation of the two carboxyl bands. The slopes and intercepts found here −15.0 and 1682 cm^{-1} for unsymmetric and +4.9 and 1407 cm^{-1} for symmetric vibrations. These slopes are almost the same with those found for the adducts with unhindered σ-donors ($\tilde{\nu}_{unsym}$=1692−15.1(pK_a−0.068pK_a'))[6] and for the dimeric arenecarboxylic acids ($\tilde{\nu}_{unsym}$=1760−14.7pK_a).[24] On the other hand, the difference in the values of the intercept between the adducts with unhindered σ-donors and the present adducts indicates the existence of a steric hindrance to the axial coordination of pyridine-type donors.

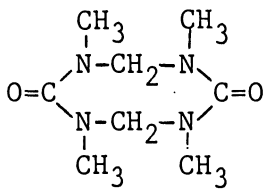
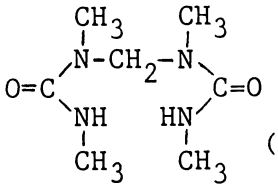
(Received March 26, 1988)

Synopsis. A new 1,3-dimethylurea-formaldehyde condensate, bis(1,3-dimethylureido)methane, was prepared and the molecular structure, as determined by X-ray analysis, and possible specific interaction to alkaline metal ions were compared with those of 1,3,5,7-tetramethyltetrahydro-1,3,5,7-tetrazocine-2,6(1*H*,3*H*)-dione. Although both structures are different from each other, their UV spectra in aqueous solution show that alkaline metal ions, Li^+ and Na^+, are caught by both of them.

In a previous paper,[1] 1,3,5,7-tetramethyltetrahydro-1,3,5,7-tetrazocine-2,6(1*H*, 3*H*)-dione (tetramethyldimethylenediurea: TMDMU) was reported to have a hole of 0.5—1.6 Å in the interior of the ring structure. When TMDMU was added to an aqueous solution of the lithium or sodium salt of phenol, a discernible shoulder at 225 nm characteristic to alkaline metal salts of phenol disappeared and the absorption spectrum in the UV region changed to that of phenol.[1]



(TMDMU)



(BDMUM)

A new 1,3-dimethylurea-formaldehyde condensation product, bis(1,3-dimethylureido)methane (BDMUM), was prepared and its molecular structure was determined by X-ray analysis. Possible specific interactions to alkaline metal ions in aqueous solution were compared with those of TMDMU.

Experimental

The Preparation of BDMUM. Ten grams of 1,3-dimethylurea were dissolved in 23.5 g of formalin and the pH of the solution was adjusted to 8.8 by successive additions of 20% NaOH aqueous solution. The reaction was carried out at 50 °C for 30 min. The reaction solution was evaporated to dryness under reduced pressure at 18—25 °C. A few ml of concd HCl was added as an acid catalyst to the desiccated residue in a large excess of MeOH. Keeping the temperature of the solution at 0—5 °C for 30 min, the reaction solution was neutralized with 20% NaOH aqueous solution at below −15 °C. After evaporation of the solvent, the methoxymethylated products were extracted with CH_2Cl_2, then with diethyl ether. After a viscous solution was evaporated under reduced pressure, the residue was distilled at 95—99 °C/1—2 Torr (1 Torr=133.322 Pa) to give 1-methoxymethyl-1,3-dimethylurea (yield 71%).

As an acid catalyst, 100 mg of *p*-toluenesulfonic acid was added to a mixture of 5 g of 1-methoxymethyl-1,3-dimethylurea and 3.3 g of 1,3-dimethylurea. The mixture was stirred for 30 min at 110 °C using an oil bath. Upon cooling, deposited white crystals were separated by filtration. Recrystallization from CH_2Cl_2 gave white rod-like crystals (Yield 82%), mp 145.0—146.2 °C. BDMUM was assigned by elemental analysis, ^1H and ^{13}C NMR and FD-MS spectrometry. ^1H and ^{13}C NMR spectra were measured in a $CDCl_3$, with TMS as the internal standard, at 90 MHz on a JEOL FX90Q instrument. Found: C, 44.57; H, 8.60; N, 29.72%: Calcd for $C_7H_{16}N_4O_2$: C, 44.68; H, 8.51; N, 29.79%: ^1H NMR, δ=6.32 (2H, q, J=4Hz, -NH-), 4.79 (2H, s, -CH_2-), 3.00 (6H, s, -CH_3), 2.78 (6H, d, J=4.5 Hz, -CH_3): ^{13}C NMR, δ=159.47 (>C=O), 63.07(-CH_2-), 34.90 (-CH_3), 27.50 (-CH_3): MS(FD); m/z=188(M^+).

X-Ray Analysis. A colorless single crystal with dimensions of ca. 0.1×0.2×0.2 mm^3 was mounted on a Rigaku AFC-6S diffractometer. The lattice parameters were determined by least-squares from 18 reflections in the 2θ range 20—30°. Systematic absences $0kl$ for k odd, $h0l$ for l odd, $hk0$ for h odd. Intensity data were measured by means of the ω-2θ scan mode (scan speed 4° min^{-1} in ω) up to 2θ of 45° by using graphite-monochromated Mo $K\alpha$ radiation (λ=0.7107 Å). A deterioration of the crystal was not observed during measurements. Lorentz and polarization corrections were made, but no correction was made for absorption. 1008 independent reflections with $|F_o|>3\sigma(|F_o|)$ were used for a structure determination.

Crystal data for $C_7H_{16}N_4O_2$: M.W.=188.23, orthorhombic, space group Pbca, a=14.350(5), b=12.115(4), c=12.015(5) Å; V=2089(1) $Å^3$: Z=8; D_m=1.199, D_c=1.197 $g\cdot cm^{-3}$; μ(Mo $K\alpha$)=0.9 cm^{-1}.

The structure of BDMUM was solved by a direct method (MULTAN78[2]). The positions of H atoms were determined

from a difference Fourier map. The structure was refined anisotropically for non-H atoms and isotropically for H atoms by a block-diagonal least-squares method. The final R was 0.087 and R_w was 0.082 (w=unit wt) (s=2.3), $(\Delta/\sigma)_{max}$ in final refinement cycle was 0.103 for non-H atoms, max. and min. $\Delta\rho$ in the final difference map were +0.3 and −0.4 e Å^{-3}. The atomic scattering factors were taken from Ref. 3. Calculations were carried out on a HITAC M-680H computer at the Computer Center of The University of Tokyo, using the local version of UNICS III.[4] The final atomic parameters are given in Table 1.[5] Bond lengths and angles are given in Table 2.

Results and Discussion

A view of the molecule with atomic numbering is shown in Fig. 1. O(1), C(2), N(1), and N(2) lie on a plane, which makes an angle of 98° with the other plane composed of O(2), C(6), N(3), and N(4). While two ureido groups are substantially on a plane in TMDMU, forming a ring with a hole of 0.5—1.6 Å, the BDMUM molecule has no such ring structure in the crystalline state. In spite of the difference in the molecular structures of TMDMU and BDMUM, a possible specific interaction with Li^+ or Na^+ was observed for both compounds. K^+, however, was apparently caught by BDMUM, but not by TMDMU. These facts suggest that BDMUM takes a similar structure to TMDMU by capturing alkaline metal ions in solutions, though the former is more flexible to catch metal ions than the latter. The possibility of interactions of metal ions with carbonyl anions can be ruled out. That is, the extent of resonance of the ureido groups in urea,[7] BDMUM, and TMDMU decreases in this order since the C=O bond lengths of these are 1.262, 1.241(8), and 1.250(8), and 1.216 Å respectively, and the C-N bond lengths adjacent to the carbonyl groups are 1.335 Å in urea, 1.342(9), 1.345(9), 1.364(9), and 1.377(9) Å in BDMUM, and 1.377 and 1.378 Å in TMDMU. Even though the differences in the C=O bond lengths are partly due to the presence and absence of the hydrogen bonds involving the C=O bonds (urea has 4, BDMUM has 1 and TMDMU has no hydrogen bonds), the conclusion described above can hold. None of the urea, bis(ureido)methane, and bis(1-methylureido)methane showed any effect on the UV spectra of the solutions of phenol-alkaline metal salts.[1] Thus, interactions between alkaline metal ions and BDMUM or TMDMU are possibly correlated to the localized electron densities of four nitrogen atoms donated by the methyl groups.

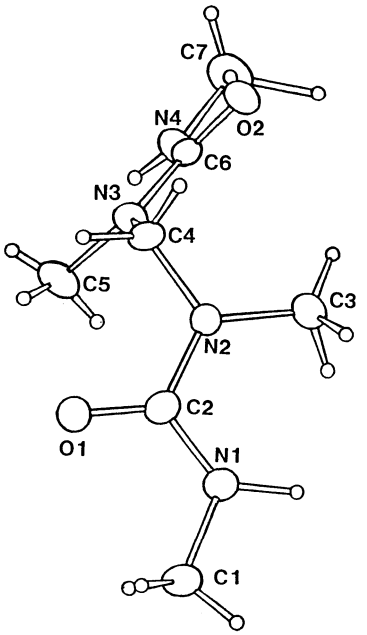

Fig. 1. The view of the molecule with atomic numbering.

The authors wish to express their hearty thanks to Prof. Hayao Kobayashi of Toho University, for his kind support in the data collection on Rigaku AFC-6S diffractometer at Toho Unversity and regarding computation.

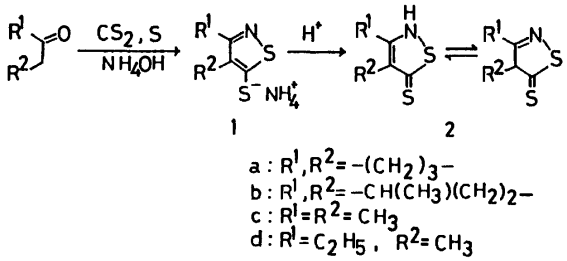
(Received May 11, 1988)

Synopsis. The reaction of the ammonium salts of 5(2*H*)-isothiazolethiones with *p*-bromophenacyl bromide, and methyl and phenyl isocyanates afforded 5-(*p*-bromophenacylthio)-, and 5-(carbamoylthio)isothiazoles. From phenyl isothiocyanate and hydrazine, 2,4-pyrimidinedithione, and 3*H*-pyrazole-3-thione derivatives were obtained, respectively.

Previously, we have reported on a new zwitterion, *N*-(1-ammoniocyclohexyl)-1,4,5,6-tetrahydro-2,1-benzisothiazole-3-thiolate, obtained through a reaction of cyclohexanone with carbon disulfide in the presence of aqueous ammonia and sulfur.[1] Under similar conditions, cyclopentanone gave 1,4,5,6-tetrahydro-3*H*-cyclopent[*c*]isothiazole-3-thione(**2a**),[1] which was the cyclo-oxidation product of 2-iminocyclopentanecarbodithioic acid.[2] Although many 5-substituted isothiazole derivatives have been reported, there are few 5(2*H*)- and 5(4*H*)-isothiazolethiones, and 5-alkylthioisothiazoles mentioned in the literature.[3] In this note, we wish to report on a new synthesis of 5-(*p*-bromophenacylthio)- (**3**), and 5-(carbamoylthio)isothiazoles (**4** and **5**) by a reaction of ammonium salts



Scheme 1.

1a—d with *p*-bromophenacyl bromide, and methyl and phenyl isocyanates.

Salts **1b—d** were obtained from 2-methylcyclopentanone, ethyl methyl ketone, and diethyl ketone, respectively, in lower yields in a similar manner as described for the preparation of **1a**.[1] A treatment of **1** with hydrochloric acid gave 5(2*H*)-isothiazolethiones **2**. Salts **1** reacted with *p*-bromophenacyl bromide to give 5-(*p*-bromophenacylthio)isothiazoles **3**, whereas it was difficult to obtain crystalline products by a reac-

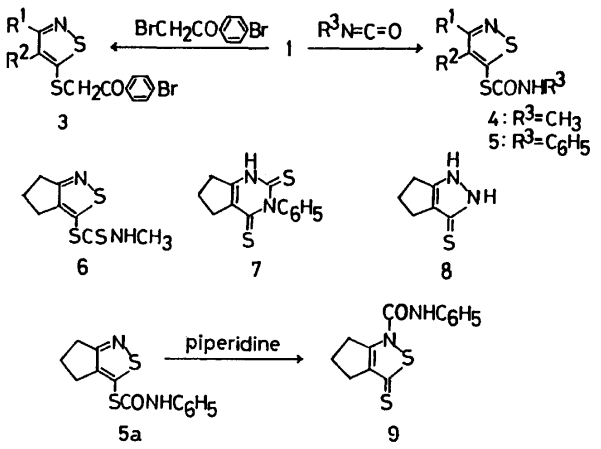

Scheme 2.

tion with methyl iodide.

Reaction of **1** with methyl and phenyl isocyanates gave the corresponding addition compounds, 5-(carbamoylthio)isothiazoles **4** and **5**. Although the expected adduct, 5-(thiocarbamoylthio)isothiazole **6**, was obtained from methyl isothiocyanate, the reaction of **1a** with phenyl isothiocyanate afforded a ring-expanded compound **7**. The structure of **7** was judged from the microanalysis, and mass (M^+ 260) and UV spectra (432 nm). Salt **1a** reacted with hydrazine hydrate to give the pyrazole derivative **8**, which we had previously prepared from 2-imino-[4] or 2-oxocyclopentanecarbodithioic acid.[5] Perhaps the mechanism of the reaction leading to **7** or **8** involves a replacement of either the sulfur atom of **1a** by a nitrogen atom of isothiocyanate or hydrazine. It is of interest that a treatment of **5a** with piperidine afforded isomer **9**. The UV spectrum of **9** showed a red shift due to the thione-type structure (Table 1). A rearrangement, however, did not occur in **5b—d**.

Experimental

The Ammonium Salts (1) and 5(2*H*)-Isothiazolethiones (2). General Procedure. A mixture of ketone (0.25 mol), carbon disulfide (38 g, 0.5 mol), aqueous ammonia (28%; 70 ml), and sulfur (10 g, 0.31 mol) was stirred for 6 h—2 days at 0 °C. The mixture was kept for 2—7 days at 0—4 °C. The solid product was collected, and washed with carbon disulfide and ether. The crude salt was dissolved in water; the solution was then filtered and saturated with ammonium chloride to give practically pure crystals for use in reactions. The yields and melting points (from ethanol-hexane) of the salts were: **1a**, 61%, 145—146 °C;[1] **1b**, 30%, 93—95 °C; **1c**, 6%, 158—159 °C (decomp); **1d**, 3%, 97—99 °C. The salt **1** was dissolved in water and acidified with dilute hydrochloric acid to give yellow crystals, 1,4,5,6-tetrahydro-3*H*-cyclopent-[*c*]isothiazole-3-thione (**2a**),[1] 6-methyl-1,4,5,6-tetrahydro-3*H*-cyclopent[*c*]isothiazole-3-thione (**2b**), or 3,4-dimethyl-5(2*H*)-isothiazole-5-thione (**2c**). Compound **2d**, an oil, was not analyzed.

3-(*p*-Bromophenacylthio)-5,6-dihydro-4*H*-cyclopent[*c*]isothiazole (3a) and 3-(*p*-Bromophenacylthio)-6-methyl-5,6-dihydro-4*H*-cyclopent[*c*]isothiazole (3b). To a solution of **1** (0.003 mol) in ethanol (3 ml) was added a solution of *p*-bromophenacyl bromide (1.3 g, 0.005 mol) in ethanol (2 ml) with stirring at room temperature. The solid product was collected, washed with ether, and recrystallized from ethanol.

3-(Methylcarbamoylthio)-5,6-dihydro-4*H*-cyclopent[*c*]isothiazole (4a), 6-Methyl-3-(methylcarbamoylthio)-5,6-dihydro-4*H*-cyclopent[*c*]isothiazole (4b), 3,4-Dimethyl-5-(methylcarbamoylthio)isothiazole (4c), and 3-Ethyl-4-methyl-5-(methylcarbamoylthio)isothiazole (4d). To a solution or suspension of **1** (0.002 mol) in ethanol (2 ml) was added an excess of methyl isocyanate (0.004—0.005 mol); the mixture was kept for 2 days at 4—20 °C. In the case of **4a** or **4b**, the mixture was warmed at 60 °C for 20 min, and then kept for 3 days at 4 °C. The solid product was collected, washed with carbon disulfide and ethanol, and recrystallized from ethanol.

3-(Phenylcarbamoylthio)-5,6-dihydro-4*H*-cyclopent[*c*]isothiazole (5a), 6-Methyl-3-(phenylcarbamoylthio)-5,6-dihydro-4*H*-cyclopent[*c*]isothiazole (5b), 3,4-Dimethyl-5-(phenylcarbamoylthio)isothiazole (5c), and 3-Ethyl-4-methyl-5-(phenylcarbamoylthio)isothiazole (5d). Compounds **5b—d** were prepared by the method used for **4c** and **4d**, and recrystallized from methanol. In the case of **5a**, **1a** (0.35 g, 0.002 mol) was dissolved in ethanol (3.5 ml) at 50 °C, and to the warm solution was added phenyl isocyanate (0.6 g, 0.005 mol). When a large excess of phenyl isocyante was used, needles of *N,N'*-diphenylurea (mp 238 °C) were obtained together with **5**.

3-(Methylthiocarbamoylthio)-5,6-dihydro-4*H*-cyclopent[*c*]-isothiazole (6). To a suspension of **1a** (0.5 g, 0.0029 mol) in ethanol (3 ml) were added methyl isothiocyanate (0.4 g, 0.0055 mol) and acetic acid (0.12 ml), and the mixture was warmed for 10 min at 60 °C. The solid product was collected and washed with ethanol and carbon disulfide.

3-Phenyl-6,7-dihydro-1*H*-cyclopentapyrimidine-2,4(3*H*, 5*H*)-dithione (7). A mixture of **1a** (0.5 g, 0.0029 mol) and phenyl isothiocyanate (0.8 g, 0.0059 mol) was kept for 4 days at room temperature. The solid product was collected, washed with ethanol and carbon disulfide, and recrystallized from methanol.

1,4,5,6-Tetrahydrocyclopenta[*c*]pyrazole-3(2*H*)-thione (8). To a suspension of **1a**(0.5 g, 0.0029 mol) in ethanol (3 ml) was added 80% hydrazine hydrate (0.5 g, 0.008 mol). The mixture was warmed for 3 min at 60 °C and cooled to room temperature. Acetic acid (1 ml) was then added dropwise, and the solid product was collected, washed with water and ethanol, and recrystallized from ethylene glycol; mp 230 °C (decomp). The IR spectrum was identical with that reported.[4,5]

1-(Phenylcarbamoyl)-1,4,5,6-tetrahydro-3*H*-cyclopent[*c*]isothiazole-3-thione (9). A mixture of **5a** (0.1 g, 0.00036 mol), ethanol (3 ml), and piperidine (0.04 ml) was warmed for 10 min at 60 °C and kept overnight at room temperature. The solid product was collected and recrystallized from ethanol-pyridine.

Resolution of Hosoya's Mystery?

Sven J. CYVIN
Division of Physical Chemistry, The University of Trondheim, N-7034, Trondheim-NTH, Norway
(Received December 26, 1987)

Synopsis. Three classes of polynomials for conjugated hydrocarbons are studied: characteristic polynomials (Hückel determinants) for cyclic polyenes, and combinatorial formulas for Kekulé structure counts of two classes of circulenes.

In the present communication three classes of polynomials are discussed, which all have relevance to molecular topology of conjugated hydrocarbons.

The characteristic polynomial of a conjugated system is very similar to the well-known Hückel determinant in the chemical context; see, e.g.[1] The simple Hückel molecular orbital theory is recognized as a part of molecular topology or graph theory.[2,3] In modern times these mathematical methods seem to penetrate into organic chemistry to a high degree.[4]

The two other classes of polynomials considered here describe the Kekulé structure counts (K) for classes of circulenes, which have counterparts in a new class of polycyclic aromatic hydrocarbons called cycloarenes.[5] Kekulene is a famous member of this class. The number K=200 for this molecule was probably given for the first time by Aihara.[6]

The present article is formulated as a comment on a remark by Hosoya,[7] who observed a coincidence between the forms of two polynomials, which are found in Table 1 under the designations $\phi_6(x)$ and $K_1(x, 6)$. In Hosoya's wording: "The reason for this mystic coincidence, however, is not known."[7] During the attempts to shed some light into this matter it was found that the coincidence is more far-reaching than the single example of Hosoya indicates.

The scope of the present work is, however, considerably broader than an attempt to resolve "Hosoya's mystery." It was aimed at a more general insight into the topological properties of circulene systems.

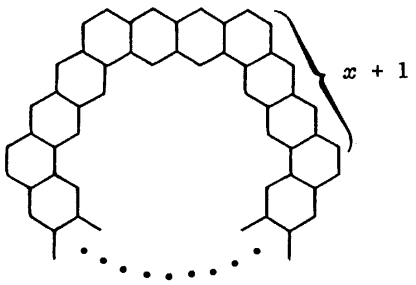

Fig. 1. Definition of a circulene. For N segments the number of hexagons is Nx.

Characteristic Polynomials. The class of characteristic polynomials for the cyclic polyacene systems (cyclopropenyl, cyclobutadiene, cyclopentadienyl, benzene,···) are considered and denoted $\phi_N(x)$ for N vertices (or N carbon atoms). An alternative to the well-known Hückel determinant is another standard formula, which reads

$$\phi_N(x)=\prod_k[x-2\cos(2k\pi/N)];$$
$$k=0, \pm1, \pm2, \cdots, \begin{cases} \pm(N-1)/2;\ N=3, 5, 7, \cdots \\ \pm(N-2)/2,\ N/2;\ N=4, 6, 8, \cdots. \end{cases} \quad (1)$$

Perhaps somewhat less known is the explicit formula

$$\phi_N(x)=2^{-N}[x+(x^2-4)^{1/2}]^N+2^{-N}[x-(x^2-4)^{1/2}]^N-2 \quad (2)$$

and the accompanying recurrence relation:

$$\phi_{N+3}=(x+1)(\phi_{N+2}-\phi_{N+1})+\phi_N \quad (3)$$

A special treatment of recurrence relations for characteristic (and other) polynomials is found in a paper of Hosoya and Ohkami,[8] which also may be consulted for some key references to this topic.

Cycloarenes with N Segments. Consider the class of circulenes consisting of N linear segments of x+1 hexagons each; see Fig. 1. The number of Kekulé structures is[9]

$$K_1(x, N)=2^{-N}[x+(x^2+4)^{1/2}]^N + 2^{-N}[x-(x^2+4)^{1/2}]^N+1+(-1)^N. \quad (4)$$

We find a striking similarity between Eqs. 2 and 4, which were derived from two apparently disconnected phenomena. The K formula for the class of circulenes considered by Hosoya,[7] and independently by others,[10,11] corresponds to N=6 in Eq. 4. The constant (x-independent) terms are somewhat elaborate. In the expanded polynomials (cf. Table 1) they manifest themselves in a repeating sequence (−2, 0, −2, −4) for $\phi_N(x)$ and (0, 4) for $K_1(x, N)$. Otherwise we find the same terms for a given N in the two polynomials, with the difference that they have alternating signs in ϕ, but

Table 1. Three Classes of Polynomials in Expanded Form for Some Values of N

N	$\phi_N(x)$	$K_1(x, N)$	$K_2(x, N)$
3	x^3-3x-2	x^3+3x	x^3-3x+2
4	x^4-4x^2	x^4+4x^2+4	x^4-4x^2+4
5	x^5-5x^3+5x-2	x^5+5x^3+5x	x^5-5x^3+5x+2
6	$x^6-6x^4+9x^2-4$	$x^6+6x^4+9x^2+4$	$x^6-6x^4+9x^2$
7	$x^7-7x^5+14x^3-7x-2$	$x^7+7x^5+14x^3+7x$	$x^7-7x^5+14x^3-7x+2$
8	$x^8-8x^6+20x^4-16x^2$	$x^8+8x^6+20x^4+16x^2+4$	$x^8-8x^6+20x^4-16x^2+4$

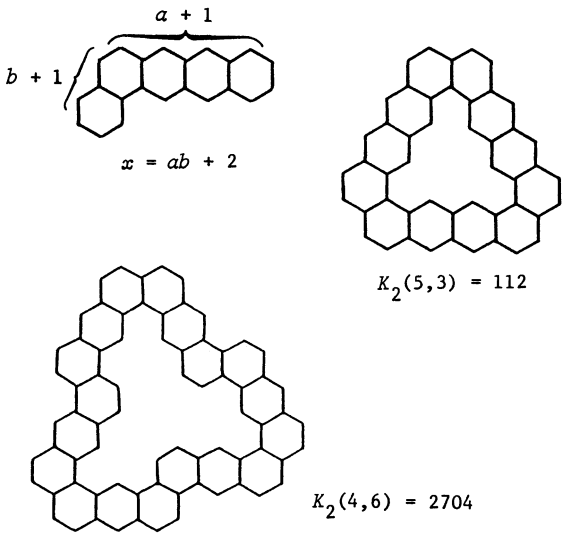

Fig. 2. Another class of circulenes. For N units the number of hexagons is $N(a+b)$. Two examples of complete systems are shown, and their K numbers are indicated.

are all positive in K_1. This feature is a consequence of the different signs in the square roots of Eqs. 2 and 4.

The function $K_1(x, N)$ may, as an alternative to Eq. 4, be expressed in terms of an $N \times N$ determinant as:

$$K_1(x, N)=(-1)^N \begin{vmatrix} -x & 1 & 0 & \cdots & 0 & 1 \\ -1 & -x & 1 & \cdots & 0 & 0 \\ 0 & -1 & -x & \cdots & 0 & 0 \\ \cdot & \cdot & \cdot & \cdots & \cdot & \cdot \\ 0 & 0 & 0 & \cdots & -x & 1 \\ -1 & 0 & 0 & \cdots & -1 & -x \end{vmatrix} \quad (5)$$

Cycloarenes with 2*N* Segments. We wish to show a modification of the system in Fig. 2 so that the K formula becomes a polynomial with alternating signs as in Eq. 2; it will in fact be identical with Eq. 2 apart from the constant term.

Consider a circulene with N units, each of them being a chain with two linear segments as shown in Fig. 2. The variable x, as determined by the two segments of one unit, is specified in the figure. An explicit equation for the K numbers was derived and reads

$$K_2(x, N)=2^{-N}[x+(x^2-4)^{1/2}]^N + 2^{-N}[x-(x^2-4)^{1/2}]^N+2. \quad (6)$$

It should be compared with Eq. 2. The sequence for constant terms of the polynomial $K_2(x, N)$ is (2, 4, 2, 0); cf. Table 1.

We give also a determinant formula for $K_2(x, N)$, which may be related to the characteristic polynomial of a Möbius ring.[12]

$$K_2(x, N)=(-1)^N \begin{vmatrix} -x & 1 & 0 & \cdots & 0 & -1 \\ 1 & -x & 1 & \cdots & 0 & 0 \\ 0 & 1 & -x & \cdots & 0 & 0 \\ \cdot & \cdot & \cdot & \cdots & \cdot & \cdot \\ 0 & 0 & 0 & \cdots & -x & 1 \\ -1 & 0 & 0 & \cdots & 1 & -x \end{vmatrix} \quad (7)$$

Conclusion

In the present note some similarities are pointed out for a class of characteristic polynomials and formulas for Kekulé structure counts of certain classes of circulenes. The results have bearings on a coincidence between the forms of two polynomials, viz. $\phi_6(x)$ and $K_1(x, 6)$, which Hosoya[7] observed and characterized as a mystery. The present work does not pretend to give a complete resolution, since it is still unknown, in a deeper sense, why these coincidences should appear.

Organophosphorus Analogues and Derivatives of the Natural L-Amino Carboxylic Acids and Peptides. IV.[1] A Phospha^{C}-Peptide Analogue of Plumbemycin A

Ivan A. NATCHEV
Research Centre Konstrukcionni Polymeri, 5-003 Gara Iskar, 1528 Sofia, Bulgaria
(Received October 3, 1987)

Synopsis. A condensation of 1,2-azaphosphorine **1** and the dipeptide **2** to the entirely protected phospha^{C}-tripeptide **3** was carried out by the DCC method. A high selectivity was achieved in the enzyme-catalyzed hydrolysis of the ethoxycarbonyl groups with alkaline mesintericopeptidase to **4** and of the peptide bond Ala-Asp with α-chymotrypsin to **5**, which in acid-catalyzed hydrolysis releases the norvaline **6**. Antitumor activity of the phospha^{C}-peptides **4** and **5** was found.

The tripeptide antibiotic Plumbemycin A was isolated from *Streptomices plumbeus* by Hirota and Sakai.[2,3] Its physiological activity was also studied.[4]

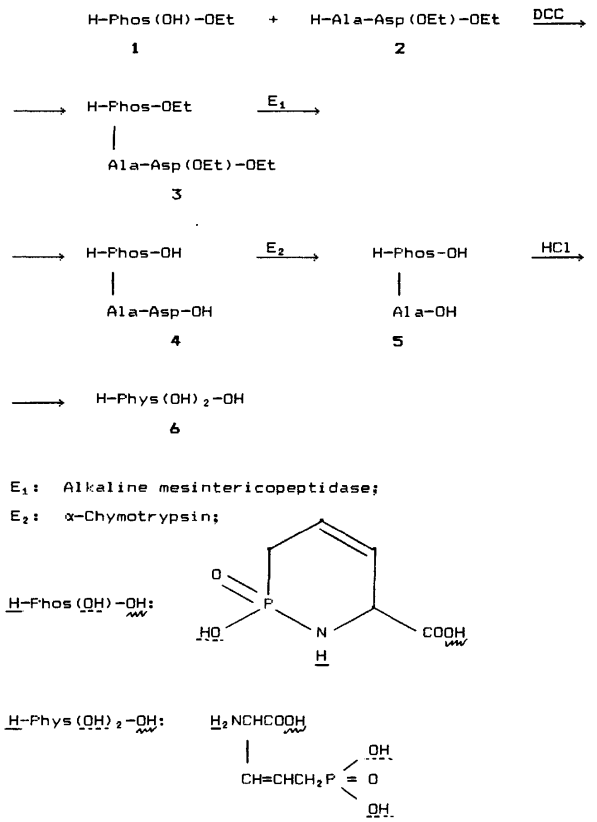
With a view to studying the relationship between the chemical structure and the physiological activity, in the present note the synthesis of phospha^{C}-peptide analogue of the above mentioned antibiotic is discussed.

Cyclic analogue of C-terminal-phosphonylated amino acid-3,4-didehydro-5-phosphono-L-norvaline= (*S*)-(6-ethoxycarbonyl-2-hydroxy-1,2,3,6-tetrahydro-1,2-azaphosphorine 2-oxide (**1**) recently synthesized (cf. later commun. of the same author) by us and the commercially available dipeptide H-Ala-Asp(OEt)-OEt (**2**) were chosen as starting substances. The condensation was carried out by DCC method. After the usual work-up of the reaction mixture, the fully protected phospha^{C}-tripeptide **3** was isolated with a yield of about 70%. At "mild" acid-catalyzed hydrolysis, the simultaneous hydrolytic cleavage of both PO-NH bonds (cyclic and exocyclic) was attained and the following products were obtained: 3,4-didehydro-5-phosphono-L-norvaline ethyl ester and the dipeptide H-Ala-Asp (OEt)-OEt (**2**) (see Scheme 1).

To ensure selective hydrolysis of the ethoxycarbonyl groups of the dipeptide **3** the alkaline mesintericopeptidase was used. Under the optimum conditions,[5] namely, 20 g substrate **3**, 5 mg enzyme in an aqueous buffer (500 ml, pH 7.8), stirring at 25 °C to a ninhydrin positive detection, the phospha^{C}-tripeptide **4** was isolated in about 90% yield.

The second enzyme we employed was α-chymotrypsin. Under the usual conditions (25 °C, pH 7.8) this enzyme enhances the hydrolysis of the peptide bond Ala-Asp selectively with no effect on the two PO-NH bonds. Thus, using 20 g substrate **4** and 5 mg enzyme α-chymotrypsin, the phospha^{C}-dipeptide **5** was isolated in about 70% yield. A "mild" acid hydrolysis (0.5 M HCl, 50 °C, 30 min) of the product **5** liberated the norvaline **6**.

The enzymes phosphodiesterase I and alkaline phosphatase did not exhibit enzyme-substrate interaction with the synthesized phospha^{C}-peptide analogues of Plumbemycin A.



Scheme 1.

Preliminary physiological tests with the phospha^{C}-tri- and dipeptides **4** and **5** have been carried out. When applied to an experimental tumor L1210 in mice in doses of 20 and 28 mg/kg per day for 5 consecutive days, the T/L (T/L% is the ratio of the mean survival time, expressed as a percentage of untreated controls) was 184% and 172% for the tripeptide **4** and for the dipeptide **5**, respectively. The insecticidal activity of the two peptides was also studied and it has been established that the tripeptide **5** is the stronger. It is of interest to point out the following observation: when the tripeptide **5**, Plumbemycin A, L-norvaline **6**, and its cyclic analogue (*S*)-1,2,3,6-tetrahydro-1,2-azaphosphorine-6-carboxylic acid were compared, it was found that the 1,2-azaphosphorine analogue had the highest insecticidal activity, whereas in the L-norvaline **6** and in Plumbemycin A, it was entirely missing.

Detailed investigations on the insecticidal activity are now under way and the results will be published soon.

Experimental

General. IR spectra, elemental analysis, mp, Mw, $[\alpha]_D^{22}$ on Perkin-Elmer instruments; ^{1}H NMR—JEOL 100 MHz and Brucker 250 MHz; Mass spectra—LKB 900 and Barian; reagents and solvents from "Aldrich," and "Merck"; α-chymotrypsin—from Pharmachim, Bulgaria; alkaline mesintericopeptidase—Inst. Org. Chem., Bulg. Acad. Sci.; TLC-silica gel film—molybdophosphate or ninhydrin detection.

***N*-[(*S*)-(6-Ethoxycarbonyl-1,2,3,6-tetrahydro-1,2-azaphosphorin-2-yl)]alanylaspartic Acid α,β-Diethyl Ester (3).** A mixture of 1,2-azaphosphorine (**1**) (20.52 g, 0.1 mol), the dipeptide (**2**) (26.03 g, 0.1 mol) and DCC (22.69 g, 0.11 mol) in dry ethyl acetate (300 ml) was stirred in a closed Erlenmeyer flask at room temperature for 24 h. After filtration, the reaction mixture was washed consecutively with water, 5% aqueous sodium carbonate, water, 0.5% hydrochloric acid, water, and then dried over anhydrous $MgSO_4$. After distillation under vacuum to dryness, the oily residue was taken into a silica-gel column and eluted with chloroform: methanol from 9 : 1 to 7 : 3 v/v. The product was dissolved in cold dry ethyl acetate (250 ml) and dry hexane was added until it becomes turbid. After rubbing to the flask walls with a glass stick and after a continuous stay in refrigerator at −5 °C, the product **3** was slowly crystallized.

Compound 3: Yield, 29.17 g (67.3%); mp 78—81 °C (EtOAc/*n*-C_6H_{14}); IR (KBr) cm^{-1}; 1755—1730, 1640, 1520, 1330—1300, 1200; R_f: 0.68 ($CHCl_3$: MeOH=9 : 1); $[\alpha]_D^{20}$ −46.4° (*c* 1, MeOH).

Found: C, 48.60; H, 6.86; N, 9.07%. Calcd for $C_{18}H_{30}N_3O_8P$: C, 48,32; H, 6.76; N, 9.39%. Mw, Found/Calcd, 443/447.427.

The substance is soluble in the usual organic solvents and insoluble in water. When **3** (4.47 g, 0.01 mol) was heated in 0.5 M HCl (25 ml) at 50 °C for 30 min, the products isolated were: H-Ala-Asp(OEt)-OEt (**2**) in a yield of 2.11 g (81.2%) and 3,4-didehydro-5-phosphono-L-norvaline ethyl ester: yield 1.58 g (77.7% as HCl salt); mp 210 °C (decomp); IR (KBr) cm^{-1}: 1750, 1550, 1240, 1010, 970; ^{1}H NMR (DMSO-d_6, δ, free basse) δ=1.26 (3H, t, $OCH_2C\underline{H}_3$), 2.75 (2H, dd, $J_{P\text{-}C\underline{H}_2}$=8.6 and 23 Hz), 4.03 (2H, q, $OC\underline{H}_2CH_3$), 4.80 (1H, d, *J*=8 Hz, CH), 5.65 (1H, m, C<u>H</u>=CH), 6.13 (1H, m, CH=C<u>H</u>CH_2), 10.4—10.8 (2H, br, s, PO_3H_2); MS-free base, *m/z*, Found/Calcd, 223 (18%)/223.166; R_f: 0.33 (*n*-BuOH : AcOH : H_2O=3 : 1 : 1); $[\alpha]_D^{20}$ −56.3° (*c* 1, 0.1 M NaOH).

Found: C, 32.71; H, 5.61; N, 5.42%. Calcd for $C_7H_{14}NO_5P \cdot HCl$: C, 32.38; H, 5.82; N, 5.40%.

***N*-[(*S*)-(6-Carboxyl-1,2,3,6-tetrahydro-1,2-azaphosphorin-2-yl)]alanylaspartic Acid (4).** A mixture of the tripeptide **3** (20 g, 0.04 mol) homogenized with 3—4 drops of "Tween-8-", and the enzyme alkaline mesintericopeptidase (5 mg) in an aqueous buffer [tris(hydroxymethyl)aminomethane-(Trisma^R), 500 ml, 0.05 M, pH 7.8 at 25 °C] was stirred until it gave a positive test on ninhydrin. After acidification (pH 6.5) and distillation under vacuum to dryness, the organic mass was extracted with boiling ethanol. After cooling, the product **4** was filtered.

Compound 4: Yield, 14.18 g (87.3%); mp 162—165 °C (EtOH); IR (KBr) cm^{-1}; 3860—2800, 1760, 1640, 1520, 1340, 1265, 970—840, 630; ^{1}H NMR (D_2O+Na_2CO_3) δ=1.52 (3H, d, *J*=8 Hz, $CHC\underline{H}_3$), 2.26 (2H, d, CH_2CO), 4.2—4.6 (3H, m, 3×CH), 2.72 (2H, m, PCH_2), 5.68 and 6.21 (2H, m, C<u>H</u>=C<u>H</u>), R_f: 0.56 (DMF: dioxane: $CHCl_3$=9 : 1 : 1); $[\alpha]_D^{20}$ 63.8° (*c* 0.1, 0.1 M NaOH).

Found: C, 40.00; H, 5.11; N, 11.38%. Calcd for $C_{12}H_{18}N_3O_8P$: C, 39,67; H, 4.99; N, 11.57%. Mw, Found/Calcd, 360/363.327.

The substance is highly soluble in DMF, DMSO, hexamethylphosphoric triamide, and water, less in dioxane and ethanol and is insoluble in chloroform, ether, and hexane. When **4** (3.60 g, 0.01 mol) was heated in 0.5 M HCl (25 ml) at 50 °C for 30 min, the following products were isolated: the dipeptide H-Ala-Asp-OH (1.70 g, 83.4%) and 3,4-didehydro-5-phosphono-L-norvaline (**6**): yield 1.52 g (78.3%) mp 188—190 °C (decomp) [for the D-form mp: 183—185 °C[1]]; IR (KBr) cm^{-1}: 1735, 1630, 1520, 1240, 1150 1040, 930, 860, 725, 630; ^{1}H NMR (D_2O+NaOD) δ=2.75 (2H, dd, $J_{P\text{-}CH_2}$=8.3 and 23 Hz), 4.03 (2H, q, $OC\underline{H}_2CH_3$), 4.81 (1H, d, *J*=8 Hz, CH), 5.66 (1H, m, C<u>H</u>=CH), 6.12 (1H, m, CH=C<u>H</u>CH_2) and five exchangeable protons NH_2, COOH, PO_3H_2; MS, *m/z*, Found/Calcd, 195/195.112; R_f: 0.33 (*n*-BuOH : Pyr : AcOH : H_2O=15 : 12 : 3 : 10) and 0.10 (*n*-BuOH : AcOH : H_2O=3 : 1 : 1); $[\alpha]_D^{20}$ −53.2° (*c* 1, H_2O).

Found: C, 30.53; H, 5.28; N, 7.06%. Calcd for $C_5H_{10}NO_5P \cdot HCl$: C, 30.78; H, 5.17; N, 7.18%.

***N*-[(*S*)-(6-Carboxyl-1,2,3,6-tetrahydro-1,2-azaphosphorin-2-yl)]alanine (5).** A mixture of the tripeptide **4** (20 g, 0.55 mol) and α-chymotrypsin (5 mg) in an aqueous buffer [tris-(hydroxymethyl)aminomethane(Trisma^R), 500 ml, 0.05 M, pH 7.8 at 25 °C] was stirred for 6 h. After acidification (pH 5.8) and vacuum distillation to dryness, the organic residue was extracted with boiling ethanol. After cooling, the product **5** was filtered.

Compound 5: Yield, 11.04 g (82.8%); mp approx. 200 °C (decomp); IR (KBr) cm^{-1}; 3800—3000, 1750—1725, 1360, 1280, 960, 840, 720, 630; ^{1}H NMR (D_2O+Na_2CO_3) δ=1.48 (3H, d, *J*=8 Hz, $CHC\underline{H}_3$), 4.18 and 4.42 (2H, m, 2×CH), 2.77 (2H, m, PCH_2), 5.72 and 6.33 (2H, m, C<u>H</u>=C<u>H</u>), and four exchangeable protons; MS, *m/z*: Found/Calcd, 248 (18%)/248.175; R_f: 0.68 (DMF: dioxane: $CHCl_3$=9 : 1 : 3); $[\alpha]_D^{20}$ −63.7° (*c* 1, H_2O).

Found: C, 38.66; H, 5.41; N, 11.36%. Calcd for $C_8H_{13}N_2O_8P$: C, 37,72; H, 5.28; N, 11.29%. Mw, Found/Calcd, 251/248.175.

The substance is very soluble in DMF, DMSO, hexamethylphosphoric triamide, comparatively in dioxane and ethanol and is insoluble in chloroform, ether and hexane. When **5** (2.51 g, 0.01 mol) was heated in 0.5 M HCl (25 ml) at 50 °C for 30 min, the product 3,4-didehydro-5-phosphono-L-norvaline (**6**) (1.74 g, 89.1%) was isolated and has spectral data identical with those obtained by based-hydrolysis of the peptide **4** (cf. the above section).

A Theoretical Study on Bromochlorination

Shinichi YAMABE* and Tsutomu MINATO†,††
Department of Chemistry, Nara University of Education, Takabatake-cho, Nara 630

(Received January 23, 1988)

Synopsis. The bromochlorination to ethylene is studied by ab initio MO calculations. The presence of the bridge ion is verified by a transition state (TS) search. The TS geometry is represented as an ion pair. Two mechanistic questions, orientation of Br-Cl and the anti Cl^- addition, are discussed in terms of the frontier-orbital theory.

Additions of bromine chloride (BrCl) in CCl_4 or CH_2Cl_2 have been investigated extensively.[1,2] The regioselectivity of the bromochlorination may be explained by the AD_E (electrophilic addition) mechanism, where a bridged bromonium ion intermediate is attacked by a chloride ion.[1] This scheme is based on the product analysis of 1-hexene in a nonpolar solvent (CCl_4) and a protic solvent (methanol).

n-BuCH=CH_2 + BrCl → n-BuCHCl-CH_2Br + Others (in CCl_4)

n-BuCH=CH_2 + BrCl → n-BuCH(OMe)-CH_2Br + Others (in MeOH)

Two mechanistic questions emerge.

(1) Why is no chloronium ion intermediate formed in the electrophilic attack of BrCl on a double bond?

(2) What is the driving force for anti addition of a nucleophile to a bridged bromonium ion in Fig. 1? In a cyclic intermediate, the cationic nature is retained in the bromine atom, and two carbon atoms are somewhat anionic (see Fig. 4).

To solve these problems, ab initio MO calculations were made with 3-21G and 3-21G(*) basis sets,[3] using the GAUSSIAN 82 program.[4]

MO Calculations of the BrCl Addition to Ethylene

In Fig. 2, two TS structures are shown. The two geometries are found to be similar. Bromide and chloride ions are remote from the cyclic chloronium and bromonium ions, respectively. It is noteworthy that

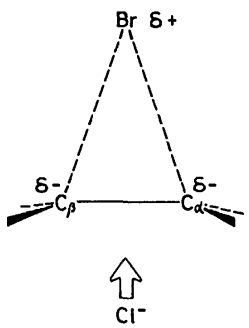

Fig. 1. Schematic presentation of the anti attack of Cl^- to the cyclic bromonium ion.

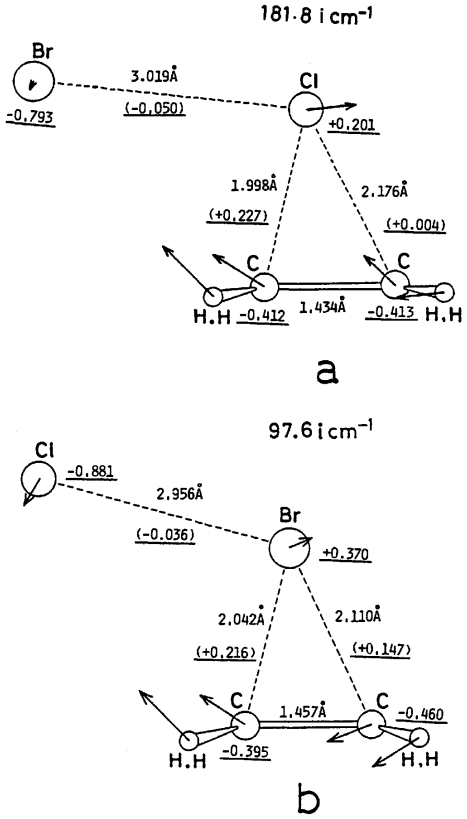

Fig. 2. Transition-state geometries of the bromochlorination to ethylene obtained with the 3-21G optimization. The imaginary-frequency vibrational mode showing the reaction path is sketched with arrows. The 3-21G(*)//3-21G total energies are −3095.12477 a.u. (a) and −3095.17221 a.u. (b). 1 a.u.=627.566 kcal mol^{-1}=2625.736 k J mol^{-1}.
The underlined numbers denote the 3-21G(*) atomic net charges (negative, anionic) and those in parentheses are atom-atom bond populations.

bridged halonium ions are almost formed at TS. The ion-pair formation is more complete in TS *b* ($Br^{+0.370}$ vs. $Cl^{-0.881}$) than in TS *a* ($Cl^{+0.201}$ vs. $Br^{-0.793}$). Also, there is a noticeable difference in the bonding nature between the C··· Br bonds and the C··· Cl bonds. While the C··· Br bonds have large bonding populations (+0.216 and +0.147), one of the C··· Cl bonds has a small bonding population (+0.004). These results of the electron population indicate that TS *b* is more favorable for the formation of a bridged intermediate plus an anion than TS *a*. In fact, the activation energy of TS *b* [=44.6 kcal mol^{-1} (1 cal mol^{-1}=4.184 J mol^{-1}), 3-21G(*)//3-21G relative to the energy of the C_{2v} π complex, C_2H_4 ··· BrCl] is much smaller than that of TS *a* [=71.9 kcal mol^{-1}]. Thus, the present calculation

†† Present address: Institute for Natural Science, Nara University, 1500 Misasagi-cho, Nara 631.

shows that a bromonium ion intermediate is formed in the bromochlorination.[1)]

The ease of the cyclic bromonium ion formation in the BrCl addition is explicable by the shape of the lowest unoccupied MO (LUMO) of Br-Cl. The ionization potential of the chlorine atom (=12. 976 eV) is larger than that of the bromine atom (=11.814 eV). The difference leads to the asymmetric orbital extension. The energy of the LUMO of BrCl is close to that of the Br atomic orbital, and the LUMO has a bromine $4p_\sigma$ character. Therefore. the electrophilicity is larger at the bromine site, and the charge transfer (CT) from the ethylene π MO to the LUMO is effective in $C_2H_4 \rightarrow$BrCl coordination as is shown in Fig. 3. Thus, the first question of the bromonium ion selectivity has been answered by the frontier orbital theory. [5)]

The Origin of the Anti Nucleophilic Addition

After the cyclic bromonium ion is formed, how is the anti addition of the chloride ion brought about? In Fig. 4, the optimized structure of the cyclic bromonium ion is shown. It is realized that the geometry is close to that at TS *b* in Fig. 2. The b_2 in-plane antisymmetric vibrational mode is also shown in Fig. 4 and it has the lowest value among the 15 (=3×7 atoms−6) harmonic frequencies. This mode indicates that the "b_2 spring" is the most fragile (C··· Br bond cleaved) against the external fluctuation (i.e., the Cl^- attack). When the C_{2v} geometry is deformed along the b_2 vibration, two low-lying vacant MO's mix with each other. The mixing leads to the lowering of the energy level of the LUMO and consequently to higher reactivity against the nucleophilic attack. The mixing also causes a change in the shape of the MO's as is shown in Fig. 5. The α carbon atom has the larger lobe of the LUMO and is ready to catch Cl^- in syn and anti directions (two bold empty arrows). The syn direction is apparently more favorable than the anti one, because there is a larger lobe of the LUMO along the C··· Br bond. However, a crucial factor of making the syn attack unfavorable is the nodal property of the LUMO. Although the magnitude of the spatial extension of the LUMO is larger at the syn site than the anti site, the presence of the distinct node prohibits the effective CT from the chloride ion. The anti attack is not prohibited by the nodal property of the LUMO and may cause the larger CT. Thus, the second question is answered. The anti attack shown by the lower arrow is initiated by the geometric distortion along the lowest-frequency vibration and the resultant MO mixing. The Cl^- orientation is determined not by the electrostatic force but by the shape of the frontier orbital, the LUMO. To prove this prediction, the partial geometric optimizations for syn and anti attacks were made with the $Cl^- \cdots C_\alpha$ distance fixed to 2.3 Å. The

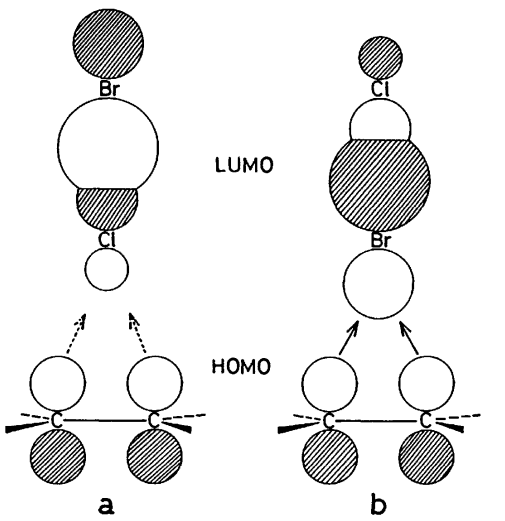

Fig. 3. $C_2H_4 \rightarrow$ClBr(a) and $C_2H_4 \rightarrow$BrCl(b) charge-transfer interactions.

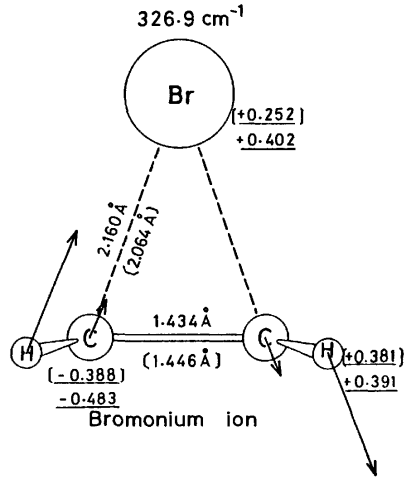

Fig. 4. The geometry of the bridged bromonium ion intermediate ($C_2H_4Br^+$) and the lowest-frequency vibrational mode. Numbers in brackets denote the 3-21G(*) optimized distances and the net charges. The C_{2v} geometry was also obtained by Poirier et al. with a somewhat different basis set.[6)] The 3-21(*)//3-21G total energy is −2637.57871 a.u.

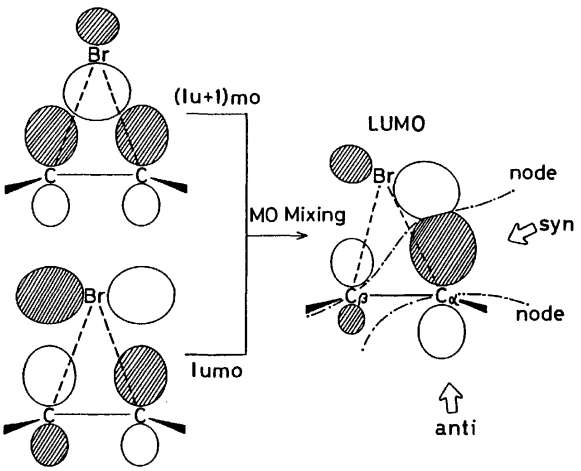

Fig. 5. The mixing of two low-lying vacant MO's, lumo and (lu+1)mo, to give LUMO through the geometric distortion along the harmonic vibration of the smallest frequency. LUMO and lumo are the lowest unoccupied MO's. The (lu+1)mo is the next lowest unoccupied one. Bold empty arrows indicate possible directions of the Cl^- attack.

distance is thought to correspond approximately to the transition state of the nucleophilic Cl^- addition. The anti attack is calculated to be 12.3 kcal mol^{-1} more stable (smaller activation-energy barrier) than the syn attack. This result supports the above prediction.

In Fig. 4, the 3-21G and 3-21G(*) bond distances are found to be similar. Therefore, the basis set dependence of the geometry seems not to be so significant as that of the electron distributions (underlined numbers), and the 3-21G(*)//3-21G calculation may be appropriate to the present discussion.

Concludig Remarks

In this work, an electrophilic addition of bromine chloride to ethylene is investigated theoretically. Two mechanistic questions are solved by the frontier orbital theory. The first is the orientation of Br-Cl toward the double bond of ethylene. The softer atom, bromine, gets the larger lobe in the LUMO and is directed to ethylene. Activation energies for two models of the BrCl approach are compared, and the predicted orientation is confirmed. Noteworthy is the TS geometry in Fig. 2(b), where the cyclic bromonium ion intermediate and the chloride ion are almost separated. The formation of the ion pair is found to be possible without the assistance of a polar solvent. The second question is concerned with the theoretical origin of the Cl^- anti addition. The nucleophilic attack becomes likely through the coupling of the fragle b_2 in-plane vibration and the MO mixing. In spite of the anionic nature of the ethylenic carbon atom, C_α, it accepts the Cl^- attack through the LUMO.

The authors thank the Institute for Molecular Science for the allotment of the CPU time of the HITAC S-810 computer.

Phospholipid Inverted Micellar Aggregate as an Ionophore in Liquid Membrane System

Kozue KAIBARA,* Keiko ITO, and Kenji MIYAKAWA†
Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812

(Received July 11, 1988)

Synopsis. Electrochemical, thermochemical, and light scattering investigations were performed on the 1-octanol liquid membrane systems containing dipalmitoyl-DL-phosphatidylcholine (DPPC) as an ionophore. It was suggested that DPPC molecules form inverted micellar aggregate in water saturated 1-octanol and that the membrane processes can be regulated by an endothermic phase transition of the DPPC multimolecular cation carrier.

Phospholipids, as an essential constituent of the biological systems, are important to assemble a bimolecular layer structure of the biomembrane. Bimolecular membrane structure of lipids observed in the artificial planar membrane or liposome has long been a useful model to investigate the biological membrane-related processes. On the other hand, it has been demonstrated that phospholipids dissolved in organic solvent with trace water content form inverted micellar aggregates.[1-5] There is interest in inverted micelles in these days as a mediator of the specific chemical reactions relating to a water pool trapped inside the micelle phase. In the present study, the ionophoretic capabilities of the inverted micellar aggregates of phospholipid in liquid membrane systems were investigated.

Experimental

Liquid membranes were prepared by dissolving dipalmitoyl-DL-phosphatidylcholine (DPPC), purchased from Sigma Chemical Co. and used without further purification, into 1-octanol saturated with water or 10^{-2} mol dm^{-3} aqueous NaCl solution by applying the ultrasonic irradiation above the main transition temperature of DPPC-water system. Three types of experiments, electrochemical, thermochemical, and photon correlation spectroscopic measurements, were carried out: (A) Transmembrane potentials and conductances were measured with varying temperature, 0—50 °C, in an immobilized liquid membrane-aqueous NaCl system to estimate the ion selectivity parameters. The immobilized liquid membrane systems consisted of solution phase I, where NaCl concentration was varied from 10^{-1} to 10^{-3} mol dm^{-3}, and phase II with a fixed NaCl concentration of 10^{-2} mol dm^{-3} separated a poly(tetrafluoroethylene) membrane filter (Fluoropore FP100, pore size: 1.00 μm, Sumitomo Electric Co.) impregnated with a 1-octanol solution of 10^{-2} mol dm^{-3} DPPC saturated with 10^{-2} mol dm^{-3} NaCl solution. (B) A differential scanning calorimeter (SSC/560U, Dainiseikosha Co.) was employed to observe thermal behavior of DPPC molecules using a 50 μl liquid membrane sample containing 1 mg DPPC sealed in a silver pan with a main scanning rate at 1 °C min^{-1}. (C) Laser light scattering equipments and measuring conditions were the same as used in the previous experiments.[6] The liquid membrane samples were illuminated by an argon laser operated in the TEM_{00} mode at 514.5 nm, at a power 100 mW. Providing that autocorrelation function, $C(t)$, in the heterodyne regime has a single exponential decay mode, the relaxation time, τ, was determined from a nonlinear least-squares fit to the relation as:

$$C(t)=A+B\exp(-t/\tau) \quad (1)$$

where A is the background part of $C(t)$ and B is a constant.

Results and Discussion

Figure 1 summarizes the experimental data and the estimated parameters as a function of temperature. The observed membrane potential data indicated that DPPC in the 1-octanol liquid membrane phase acts as a cation carrier with a transport number to Na^+, 0.82—0.92. The transport number to Na^+ increased with raising temperature and decreasing NaCl concentration in phase I. Systematic investigations by Green et al.[7-9] demonstrated that phospholipids function as an ionophore and, in some cases, ionophoretic capabilities are comparable to those of authentic antibiotic ionophores. Highly selective and specific biomembrane transport processes are considered nowadays to be determined by proteinic materials embedded in the phospholipid bilayers such as ionophoretic substances and transport enzymes. However, phospholipids still play some roles in the broad spectrum of biomembrane transport capabilities. In the context of a possible physiological significance of the ionophoretic activities of phospholipids, involvements to the energy coupling process were suggested.[7]

As can be seen in Fig. 1-A, the curve relating the membrane conductance, G_m, with temperature shows a change of gradient at around 18 °C. And, the curve relating the membrane permeabilities to Na^+ and Cl^-, P_{Na} and P_{Cl}, with temperature in Fig. 1-B shows a change of gradient as corresponding with the membrane conductance change as a function of temperature. P_{Na} and P_{Cl}, indicating the membrane permselectivities by referring to the permeating speed of respective ions, can be calculated from the membrane potential and conductance data based on the preceding membrane theory.[10,11] The membrane permeability ratio, P_{Cl}/P_{Na}, decreased slightly with raising temperature.

It is a well-known fact that the conductance of phospholipid bilayer membrane changes drastically at the temperature corresponding to the gel-liquid crystal phase transition temperature observed in phospholipid-water system. Differential scanning calorimetry (DSC) measurements on the DPPC-1-octanol liquid membrane were carried out to examine a phase behavior of DPPC molecule at around 18 °C where the temperature-dependent characteristics of membrane transport altered. Examples of the DSC thermogram of the DPPC-1-octanol liquid membrane fluid are

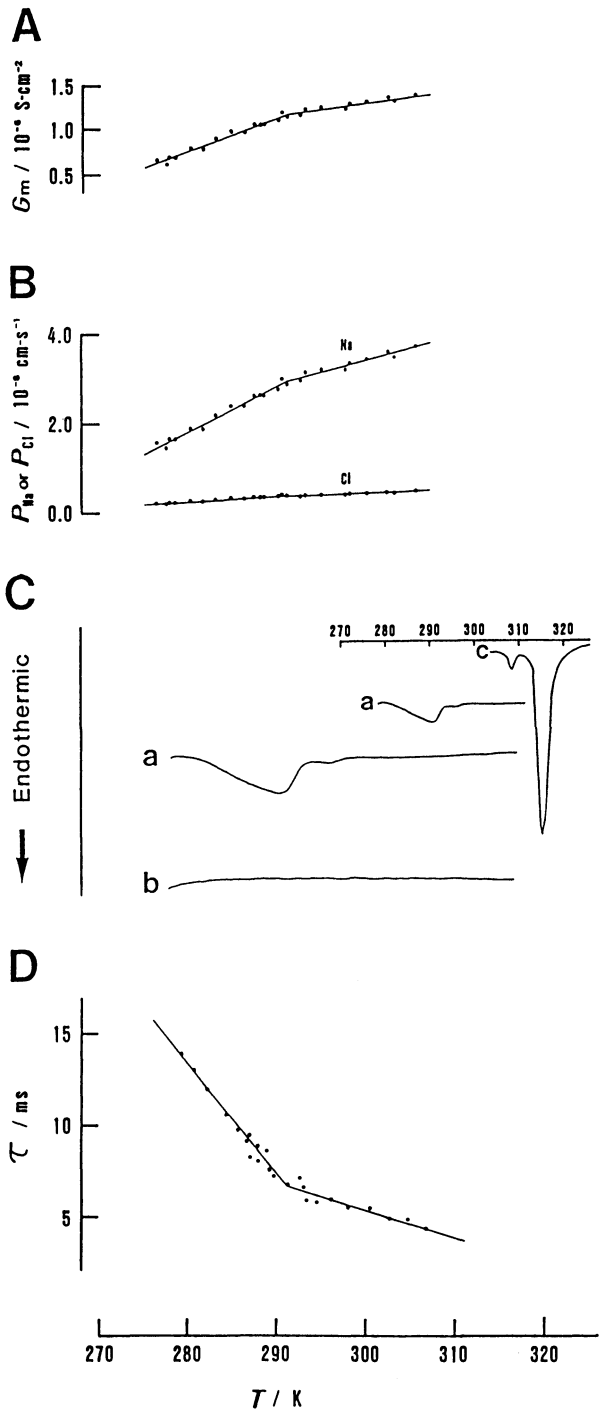

Fig. 1. Membrane conductance [A], membrane permeabilities to Na^+(●) and Cl^-(○) [B], DSC thermogram [C], and relaxation time obtained by the light scattering study [D] as a function of temperature. The membrane conductance and permeability values were obtained for 10^{-2} mol dm^{-3} NaCl(I)-10^{-2} mol dm^{-3} NaCl(II) system. In Fig. 1-C, thermograms a, b, and c were recorded for the systems in which DPPC dissolved in 1-octanol saturated with 10^{-2} mol dm^{-3} NaCl aqueous solution, in pure 1-octanol, and in 10^{-2} mol dm^{-3} NaCl aqueous solution, respectively. The scale of the upperright frame comparing the thermograms a and c is reduced to 1/2 of the original scale for the thermograms a and b.

shown in Fig. 1-C. As illustrated in the thermogram a, an endothermic peak was detected at around 18 °C in 1-octanol solution of DPPC saturated with water or aqueous NaCl solution. None of the detectable thermal changes were observed, on the contrary, in the pure 1-octanol solution of DPPC (thermogram b) and in the system without DPPC. Up to 80—90 °C, additional thermal changes were not observed in these systems. The peak height of the thermogram a is approximately 1/10 of that of the established endothermic changes for the gel-liquid crystal transition of DPPC-water system (compare the thermograms a and c). The thermograms a, b, and c were recorded from the samples containin 20 mg ml^{-1} DPPC dissolved into respective solvents. The present DSC results suggest that the changes in mode of the DPPC-mediated cation transport at critical temperature, 18 °C, are related in some way to endothermic phase transitions of DPPC in the liquid membrane phase.

It is also a common observation that addition of short-chain normal alkanols cause broadening of the thermal peak and lowering of the temperature for the endothermic gel-liquid crystal transition of phospholipid-water system.[12,13] These alterations in the endothermic behavior were suggested to be due to the penetrations of additives into the phospholipid bilayer structure. The present DPPC-1-octanol liquid membrane systems are different definitely in 1-octanol/water ratio from these phospholipid-excess water system with adding alcohols. It is expected, accordingly, in the present DPPC-1-octanol with trace water system (solubility of water in 1-octanol at 25 °C: ca. 3.5 wt%)[14] that the DPPC molecules form inverted micellar aggregates trapping a pool water phase. The formation of micelles in nonaqueous solvent is suggested to be affected by a trace amount of water existing in the solvent.[2,3] In the present system, appearance and peak height of the endothermic change illustrated in the DSC thermogram Fig. 1-C-a were quite sensitive to water content in the 1-octanol liquid membrane phase (unpublished observations).

To confirm the participations of DPPC inverted micellar aggregate in the cation transport across liquid membrane, the micelle formation was detected directly by means of the photon correlation spectroscopy. The mode of temperature dependences of the relaxation time constant obtained from the analyses of laser light scattering measurements on the DPPC-1-octanol membrane fluid samples saturated with water or aqueous NaCl solution is shown in Fig. 1-D. In case of the samples with pure 1-octanol as well as the samples without DPPC, none of the evidence indicating aggregate formations was obtained. The DPPC inverted micellar diameter at 18 °C can be estimated approximately at 0.1 μm, on the assumption of a formation of spherical aggregates. As illustrated in Fig. 1-D, the curve relating the relaxation time constant with temperature shows a distinct change of slope, and, accordingly, indicates an alteration of the temperature dependences of diffusion coefficient of the DPPC aggregate at around 18 °C. Possible mechanisms to decrease the diffusion coefficient of DPPC inverted micellar aggregate in lower temperature

region are increases in micellar diameter, changes in micellar shape, fusion of micellar aggregate, etc. It was reported that the inverted micellar size increases with decreasing solvent dielectric constant and with lowering temperature.[1,15] An increase in micellar diameter due to the fusion of DPPC aggregates is possible in relation to the decrease in water solubility into 1-octanol. Changes in the surface charge conditions of DPPC aggregates are also possible in addition to these mechanisms.

The present results, especially the DSC and light scattering investigations demonstrating the importance of trace water content in the present liquid membrane system, suggest that the DPPC molecules form inverted micellar aggregates and function as a multimolecular cation carrier across the liquid membrane phase. Cations are thought to be transported by means of the trapping into a pool water phase as well as of the binding to the phosphate charges on the inverted micellar surface. The multimolecular ion carrier is expected to serve more possibilities to regulate membrane transport processes than the usual unimolecular ion carrier as shown in the present results, in which the effects of temperature on membrane permeability to Na^+ are demonstrated based on the endothermic phase transition of the DPPC inverted micellar aggregates. A detailed description of the phase behavior of the DPPC-1-octanol-trace water system requires further careful experiments, since the contents of trace amount of water seem to play a critical role for the phase behavior and the contributions to the liquid membrane transport. These experiments are also required for more direct evidence indicating the existence of the DPPC inverted micellar aggregates in the liquid membrane phase. The phase behavior studies of phospholipid-water system with and without addition of organic substances have been carried out extensively. For better understanding of the biological importance of phospholipids, however, systematic investigations on the phase behavior of phospholipid-organic solvent with trace water system are required. In the context of an existence of trace amount of water within membrane phase, the liquid membrane systems containing inverted micellar aggregates as an ion carrier provide an interesting model system to analyze the ion transport mechanisms of highly hydrophobic fluorinated ion-exchange membrane,[16,17] of which technological importance in membrane utilizing process is recognized in these days.

The authors wish to thank Prof. Shoji Kaneshina of Tokushima University for facilities for the DSC measurements. The authors are grateful to the Ministry of Education, Science and Culture of Japan for a Grant-in-Aid for Scientific Research on Priority Areas and one of the authors (K.K.) is also grateful to the Kurata Foundation for the research grant support.

Crystal Structure of $K_4[H_2P_2Mo_5O_{21}]\cdot 2H_2O$

Tomoji OZEKI, Hikaru ICHIDA, Hiroshi MIYAMAE,† and Yukiyoshi SASAKI*
Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo 113
†Department of Chemistry, Faculty of Science, Josai University, Keyakidai, Sakado-shi 350-02
(Received April 16, 1988)

Synopsis. $K_4[H_2P_2Mo_5O_{21}]\cdot 2H_2O$ crystallizes in monoclinic system, $P2_1/a$ with a=13.648(4), b=15.591(7), c=10.889(4) Å, β=94.21(2)°, U=2311(1) Å^3, Z=4. It contains a discrete pentamolybdodiphosphite anion, $[H_2P_2Mo_5O_{21}]^{4-}$, which has, approximately, a C_{2v} symmetry. Its framework is the same as those found in the pentamolybdodiphosphate and the pentamolybdodiphosphonate anions. The P-O and Mo-O distances are 1.49—1.55 and 1.69—2.46 Å, respectively.

It has been known since early this century that trivalent phosphorus forms heteropolymolybdates.[1] Kwak et al.[2] reported the synthesis and characterization of a series of anions $[(RP)_2Mo_5O_{21}]^{4-}$, where R=H, CH_3, C_2H_5, C_6H_5, $C_2H_4NH_3^+$, and p-$CH_2C_6H_4NH_3^+$. Stalik and Quicksall[3] carried out X-ray structure analyses of complexes with R=CH_3 and $C_2H_4NH_3^+$. They have identical oxometalate structures as those of the pentamolybdodiphosphate anion[4] and its protonated species[5] containing pentavalent P atoms: $[(HOP)_n(OP)_{2-n}Mo_5O_{21}]^{(6-n)-}$ where n=0, 1, 2. We have investigated the crystal structure of $[(HP)_2Mo_5O_{21}]^{4-}$, which turned out to have the same framework as those of pentamolybdodiphosphate and pentamolybdodiphosphonate anions.

Experimental

Colorless tabular crystals of the title compound were obtained by mixing a K_2MoO_4 solution (3.0 g in 20 ml H_2O) and a H_3PO_3 solution (0.4 g in 10 ml H_2O), followed by the addition of 2.0 ml of acetic acid to adjust the pH to ca. 7. A single crystal (0.05×0.08×0.18 mm^3) was mounted on a RIGAKU AFC-5 diffractometer and intensity data were collected using graphite monochromatized Mo$K\alpha$ radiation (λ=0.71069 Å). The lattice parameters were obtained by least-squares from 40 reflections with 2θ ranging from 30° to 40°. Crystal data are as follows: $K_4[H_2P_2Mo_5O_{21}]\cdot 2H_2O$; Mr=1072.1; monoclinic; space group $P2_1/a$; a=13.648(4), b=15.591(7), c=10.889(4) Å, β=94.21(2)°, U=2311(1) Å^3; Z=4; $F(000)$=2024; D_x=3.08 g cm^{-3}; μ(Mo $K\alpha$)=3.53 mm^{-1}. A total of 7335 reflections ($2\theta\leqq 60°$) were collected by the ω-2θ scan method with the scan rate of 3° min^{-1} in ω. The ranges of the indices were $0\leqq h\leqq 19$, $0\leqq k\leqq 21$, $-15\leqq l\leqq 15$. Three standard reflections were monitored every 100 reflections. Their intensity variations were within ±3%. The intensity data were corrected for the Lorentz-polarization effect. Absorption correction was not applied. 3433 independent reflections with $|F_o|\geqq 3\sigma(|F_o|)$ and $|F_o|\geqq 8.0$ were used for a structure determination and refinement. The Weissenberg photograph of the $h0l$ layer showed some reflections with $h=2n+1$, breaking the extinction rule for the space group $P2_1/a$. However, most of them were not observed. Assuming the space group to be $P2_1$, the Patterson function was analysed to give the positions of ten Mo atoms, followed by Fourier syntheses which were used to locate the P and O atoms of the two independent $[H_2P_2Mo_5O_{21}]^{4-}$ anions. These positional parameters indicated that these two anions are related to each other by a center of symmetry; also, a full-matrix least-squares refinement showed a strong correlation between the parameters related by the center of symmetry. Therefore, the space group was assumed to be $P2_1/a$ and the atomic parameters of these atoms were refined. The difference Fourier map calculated at this stage showed the peaks assigned to the K atoms and O atoms of the water of crystallization. The heights of these peaks and the distances between them indicated that some of them are disordered. The appearance of $h0l$ reflections with $h=2n+1$ is due to the partial order of these groups. These groups tend to keep the 2_1 symmetry rather than the a-glide. The site occupancies of these disordered atoms were fixed to 0.5, and the average structure, based on the centric space group, was refined with

the block-diagonal least-squares method on F with anisotropic temperature factors for all atoms by using UNICSIII program system.[6] The final refinement converged at $R(=\sum||F_o|-|F_c||/\sum|F_o|)=0.072$, $wR(=[\sum w(|F_o|-|F_c|)^2/\sum w|F_o|^2]^{1/2})=0.092$ and $S(=[\sum w(|F_o|-|F_c|)^2/(m-n)^{1/2}])=1.55$. The weighting scheme employed was $w^{-1}=\sigma^2(|F_o|)+(0.03|F_o|)^2$. All of the calculations were carried out on HITAC M680-H computers at the Computer Centre of the University of Tokyo. The complex atomic scattering factors were taken from the International Tables for X-Ray Crystallography.[7] The H atoms, which are supposed to be attached to the P atoms, were not found by this X-ray analysis. The final atomic parameters are given in Table 1.[††] The notation of the O atoms in the anion is as follows: Ot for the terminal O atoms, Op for the O atoms shared by one P atom and one or two Mo atoms, and Ob for those shared by two Mo atoms, with appended numerals in the following parentheses representing the numbers of the Mo and/or P atoms to which they are bound.

Results and Discussion

Figure 1 shows an ORTEP[8] view of the $[H_2P_2Mo_5O_{21}]^{4-}$ anion with the Mo-O and P-O bond distances in it. The anion consists of five MoO_6 octahedra which form a ring. These octahedra are joined together by sharing edges, except at one contact (Mo(3)-Mo(4)), where they share only one corner. Two P atoms are attached to this ring, one above and the other below, each having three O atoms in common with the ring and forming a PO_3 trigonal pyramid. This anion nearly possesses a twofold rotation axis running through the Mo(1) and Ob(34) atoms.

The Mo-Mo, Mo-P, and P-P distances are listed in Table 2. The Mo-Mo distances for the edge shared octahedra are 3.360—3.397 Å (av. 3.39(2) Å while that for the corner shared octahedra is 3.716 Å. The deviations of the P-Mo distances are explained by the shifts of the Mo atoms from the least-squares plane calculated for the five Mo atoms which crosses the P(6)-P(7) vector with the angle of 86.8°. Mo(1) lies almost on the plane, Mo(3) and Mo(5) are displaced toward the same direction with P(6), and Mo(2) and Mo(4) to the opposite side, thus forming a skew conformation of the Mo_5 ring.

The O-P-O angles in the PO_3 pyramids are listed in Table 3. These angles agree well with those found in the simple salts containing HPO_3^{2-} anions.[9] The P-O distances for the Op atoms doubly shared by one P and one Mo atoms (Op(36) and Op(47)) are 1.49 and 1.51 Å, while they are 1.52—1.55 Å (av. 1.53(2) Å) for those triply shared by one P and two Mo atoms. However, the O-P-O angles are not affected by the differences of the coordination around the O atoms. In the penta-

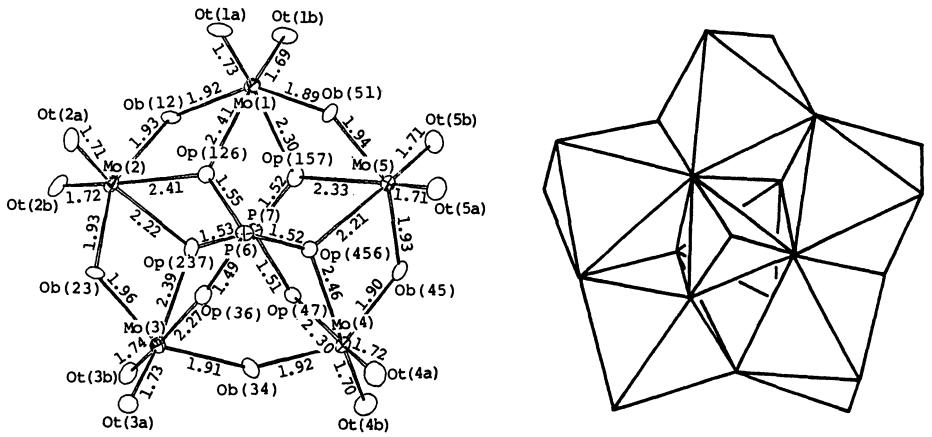

Fig. 1. The structure of the $[H_2P_2Mo_5O_{21}]^{4-}$ anion by the ORTEP[8] drawing and the polyhedra representation. The P-O and Mo-O distances are given in Å. Their e.s.d.'s are 0.02 Å for Mo(4)-Ot(4a) and 0.01 Å elsewhere. Thermal ellipsoids are scaled to enclose 30% probability level.

†† Lists of the structure factors and the anisotropic thermal parameters are deposited at the office of the Chemical Society of Japan as Document No. 8842.

molybdodiphosphonate anions, the P–O distances for doubly shared Op atoms are 1.52(1) Å, for triply shared Op atoms 1.54(1) Å, and the O–P–O angles are 111(1)°. This shows that the organic groups covalently bonded to the P atoms have only a little influence on the coordination of the PO_3 trigonal pyramids.

The MoO_6 octahedra are highly distorted in forming this polyanion. Each Mo atom is surrounded by six O atoms which are divided into three groups: two Ot's in the *cis* position relative to each other, two Op's each of which is in the *trans* position to an Ot atom. and two Ob's in the *trans* position to each other. The average Mo–O distances are 1.72(1), 2.38(8), and 1.92(2) Å, for Mo–Ot, Mo–Ob, and Mo–Ob, respectively. These values agree well with those of the pentamolybdodiphosphate and pentamolybdodiphosphonate anions.

Ferrocene-Mediated Enzyme Electrode for Glucose with the Use of Conducting Polymer Support

Fumio MIZUTANI* and Michihiko ASAI
Research Institute for Polymers and Textiles, 1-1-4 Higashi, Tsukuba, Ibaraki 305
(Received April 20, 1988)

Synopsis. An amperometric glucose-sensing electrode has been constructed by immobilizing glucose oxidase and fine particles of ferrocene in a photo-crosslinked poly(vinyl alcohol) layer. The magnitude of the response of the ferrocene-mediated electrode to glucose (0.5—50 mmol dm^{-3}) increases when polypyrrole, an electrically conducting polymer, is incorporated into the poly(vinyl alcohol) support.

Much effort has been directed at devising an amperometric electrode for glucose by combining immobilized glucose oxidase (GOD) with immobilized electroactive molecules that mediate the electron transfer between the enzyme and an electrode:[1-4]

$$\text{glucose} + \text{GOD/FAD} \rightarrow \text{gluconolactone} + \text{GOD/FADH}_2$$
$$\text{GOD/FADH}_2 + 2\text{M}^+ \rightarrow \text{GOD/FAD} + 2\text{M} + 2\text{H}^+$$
$$2\text{M} \rightarrow 2\text{M}^+ + 2\text{e (at the electrode)}$$

In this scheme, GOD/FAD and $GOD/FADH_2$ represent the oxidized and reduced forms of flavin adenine dinucleotide within GOD, respectively, and M^+/M, the mediator which is assumed to be a one-electron couple. One of the most convenient ways for preparing such a mediator-based glucose electrode is the use of a membrane-type polymer containing an immobilized GOD/mediator-couple. However, the rate of charge transport through the nonconducting layer is much lower than desired,[5] which seriously limits the application of the layer system.

The use of an electrically conducting polymer as the support seems to be a suitable approach, since the conducting support is expected to enhance the effectiveness of the mediator by providing a larger microscopic electrode surface area and a larger percentage of active centers than the case of nonconducting support being used.[6-9] We report here on the construction and preliminary testing of a ferrocene (bis(cyclopentadienyl)iron, abbreviated FcH)-mediated glucose electrode. Two kinds of polymer supports, an insulator and a conductor, were employed for the construction of the glucose electrode with the use of the GOD/FcH-couple; the current response to the substrate was examined in connection with the electrical conductivity of the support.

Experimental

A type-I layer, a poly(vinyl alcohol) (PVA)-based one, was prepared from a mixture of GOD (Sigma Chemical Co., Type X), FcH (Aldrich Chemical Co., ground to a powder with a diameter less than 1 μm), and a photo-crosslinkable PVA (generous gift from Dr. K. Ichimura of this Institute, 8 wt. % aqueous solution, pH 7), 1 : 3 : 30 by weight, according to a procedure similar to that described previously.[10-12] In the type-I layer, GOD was physically entrapped in the crosslinked PVA matrix and FcH was embedded in the matrix. The thickness of the prepared type-I layer was about 20 μm. A type-II layer, with a matrix comprising a polymer mixture of crosslinked PVA and polypyrrole (PPy), was prepared by incorporating PPy into the type-I layer. The incorporation of PPy was performed through the oxidative polymerization of pyrrole with $K_2S_2O_8$ as follows. The type-I layer was placed so as to be in contact with a monomer-containing solution from one side and an oxidant-containing solution from the other side (for 30 min at 25 °C):

aqueous solution containing 0.1 mol dm^{-3} pyrrole, 0.05 mol dm^{-3} $KClO_4$, and 0.1 mol dm^{-3} phosphate buffer (pH 7)/type I layer/aqueous solution containing 0.1 mol dm^{-3} $K_2S_2O_8$, 0.05 mol dm^{-3} $KClO_4$, and 0.1 mol dm^{-3} phosphate buffer (pH 7)

The type-II layer, thus prepared, was thoroughly washed with 0.1 mol dm^{-3} phosphate buffer (pH 7).

The type-I or -II layer was separately placed on a platinum disk electrode (diameter, 5 mm) and covered with a polyester mesh (diameter, 20 mm). The mesh was held in place with rubber rings so that the layer was directly in contact with the electrode surface. The test solution used was a phosphate buffer (0.1 mol dm^{-3}, pH 7, 30 °C), being saturated with argon, unless otherwise stated. A saturated calomel electrode (SCE) and a platinum wire were used as reference and auxiliary electrodes, respectively. All potentials given in the present paper were measured against an SCE. The layer-attached electrodes were stored in a phosphate buffer (0.1 mol dm^{-3}, pH 7) at 4 °C when not in use.

The GOD activities in the layers were measured by using the 4-aminoantipyrine/phenol/peroxidase color-generating system[13] at a glucose concentration of 0.1 mol dm^{-3}. The diffusion coefficients of glucose in the layers, D's, were determined by applying a method similar to that described elsewhere.[12] The electrical conductivities of the layers were measured by using a two-point probe method, after a thorough washing of the samples with distilled water and drying under a vacuum below 10^{-1} Pa.

Results and Discussion

The parameters measured for the type-I and -II layers are given in Table 1. As shown in Table 1, the incorporation of PPy into the PVA matrix brought about a slight decrease in the GOD activity and a little decrease in the D-value, but a remarkable increase in the electric conductivity, as expected. However, the

Table 1. Parameters Obtained for the Type I and II Layers

Type of layer	GOD activity in the layer	Diffusion coefficient of glucose, D	Electrical conductivity
	U cm^{-3}	cm^2 s^{-1}	s cm^{-1}
I	135	4×10^{-7}	$<10^{-8}$
II	125	1×10^{-7}	2×10^{-4}

conductivity of the type-II layer, 2×10^{-4} S cm^{-1}, was still lower than that of a PPy-containing polymer mixture obtained under appropriate conditions.[8,9,14-16] Further examinations for obtaining the PPy/PVA mixture with a higher conductivity are in progress.

Nevertheless, the increase in the conductivity of the support was effective for enhancing the electron transferability between the mediator and the electrode. Figure 1 shows cyclic voltammograms on the layer-attached electrodes for the immobilized redox system of ferricinium ion (FcH^+) and FcH. The electrode coated with the type-II layer exhibited much larger current peaks than that with the type-I layer.

It is expected that the enhanced electron transferability of the FcH^+/FcH system in the type-II layer results in an increased current response to glucose, compared with the case of the type-I layer. Figure 2 shows the response/time curves. The electrode potential, 0.25 V, was sufficient for the oxidation of FcH to form FcH^+ (Fig. 1). The electrode with the type-II layer gave a larger current response, as expected, than that with the type-I layer.

A few additional characteristics of the electrode with the type-II layer, as a glucose-sensing one, were then examined. Figure 3 shows calibration curves of the electrode obtained in argon-saturated and air-saturated solutions. The introduction of air into the test solution brought about a decrease in the current response by ca. 5% at all the glucose concentrations examined (0.5—50 mmol dm^{-3}). The decrease in the response is considered to be caused by interference with oxygen in the air: oxygen reacts with GOD/$FADH_2$ to form GOD/FAD and hydrogen peroxide, and the electrode potential was not sufficiently positive to reoxidize the hydrogen peroxide produced. However, in each solution, the electrode gave a linear current response in the range of 0.5—8 mmol dm^{-3} glucose and a discernible increase in the response with an increase in the glucose concentration above 8 mmol dm^{-3}. These results indicated that the electrode could be used for a determination of glucose in the high concentration range (e.g., blood glucose concentration range), even in an air-saturated buffer. Subsequent experiments were, therefore, performed in air-saturated buffers. The relative standard deviations were ca. 1.5 and 2.5% for 10 successive measurements of 4 and 15 mmol dm^{-3} of glucose, respectively. The long-term stability of the electrode was examined as follows: the determination of 4 mmol dm^{-3} glucose was carried out 10 times a day, every day for one month. The average value of the measurement on each day did not virtually change during this period.

Recently, another method involving the use of PPy for the construction of glucose-sensing electrodes has been reported: GOD was entrapped in a PPy layer on an electrode by the electrolytic polymerization of pyrrole in the presence of the enzyme.[17-19] The procedure for the preparation of the glucose electrode seems to be of particular interest due to its simplicity. However, the resulting GOD/PPy electrode, unfortunately, showed a rather poor stability.[17] The current response of the electrode to glucose diminished within a few days owing to the leaching of GOD out of the PPy

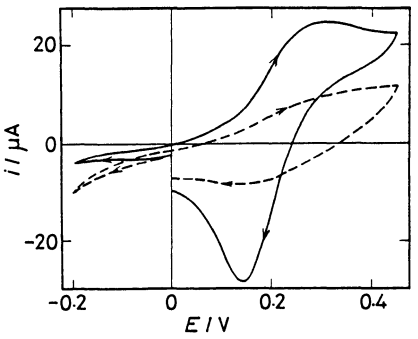

Fig. 1. Cyclic voltammograms on the electrode covered with the type-I layer (----) and with the type-II (——) layer. Potential sweep rate, 50 mV s^{-1}; solution, argon-saturated phosphate buffer (not containing glucose).

matrix and to the chemical and/or electrochemical decomposition of PPy during the measurement of hydrogen peroxide, the product of the GOD-catalyzed reaction in the absence of the non-physiological mediator such as FcH^+/FcH couple. On the other hand, the present electrode was essentially free from these problems, which resulted in the higher stability of the electrode, although the procedure for its construction was more complicated. The approach to obtain a glucose electrode having a high performance by a simpler process is in progress, with the use of the conducting support system.

†Department of Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya 464
(Received May 24, 1988)

Synopsis. The crystal structure of a 1:2 complex of bis(methylthio)dithiapyrene and tetrahydrobarreleno-TCNQ contained face-to-face packings of acceptor-donor-acceptor units which are isolated from each other. The IR spectrum, geometry, and absorption spectrum showed the neutral nature of this complex.

Recently, we reported the synthesis and properties of three-dimensionally modified tetracyanoquinodimethanes (TCNQ's). An interesting result was the formation of relatively highly conducting charge transfer (CT) complexes.[1] More recently, we have explored new donor molecules, such as 2,7-bis(methylthio)-1,6-dithiapyrene (MTDTPY) and 2,3:7,8-bis(ethylenedithio)-1,6-dithiapyrene (ETDTPY), which are classified into peri-condensed Weitz-type donors[2] having alkylthio substituents. MTDTPY produced metallic CT complexes with TCNQ, chloranil, and bromanil.[3] In this report, we present the crystal structure and some physical properties of the title 1:2 CT complex, which is composed of MTDTPY and one of the three-dimensionally modified TCNQ derivatives, tetrahydrobarreleno-TCNQ (THBTCNQ).

Experimental

Preparation of Single Crystals of MTDTPY-(THBTCNQ)$_2$ Complex. A solution of the donor and the acceptor in dichloromethane (ca. 0.02 M) was allowed to evaporate at room temperature. After several days, black prisms of MTDTPY-(THBTCNQ)$_2$ were grown: mp 202—204 °C. The stoichiometry was deduced from an X-ray analysis.

Crystal Structure Analysis. Crystal data: $C_{52}H_{36}S_4N_8$, FW =901.15, triclinic, space group $P\bar{1}$, a=14.589 (3), b= 15.4421 (3), c=7.367 (1) Å, α=93.32 (2), β=92.50 (2), γ=139.22 (1), V=1072.3 Å^3, d_{obs}=1.400 g cm^{-3}, d_{calc}=1.396 g cm^{-3}, Z=1. A prism-like crystal with dimensions of 0.5×0.5×0.3 mm was used for data collection on a Rigaku automated four-circle diffractometer (AFC-5) using graphite-monochromated Cu $K\alpha$ radiation (λ=1.5418 Å). 2θ-ω scan mode was employed ($2\theta_{max}$=126°). The structures were solved by the Monte-Carlo direct method[4] with a MULTAN-78[5] program system using 3061 non-zero unique reflections and refined on F^2 by a full-matrix least-squares program with absorption corrections made by an analytical method.[6] The donor molecule turned out to contain an orientational disorder. The occupancy ratio for disordered sulfur and carbon atoms of SC1 and SC2 was assumed to be 1:1. Anisotropic temperature factors were used for the refinement of non-H atoms. The final R value ($R=\sum||F_o|-|F_c||/\sum|F_o|$) is 0.057. Atomic scattering factors were taken from International Tables for X-ray Crystallography.[7] All calculations were made on FACOM M-382 computer at the computer center of Nagoya University. The complete F_o-F_c data and the temperature parameters are deposited as Document No. 8845 at the Office of the Editor of Bull. Chem. Soc. Jpn.

Results and Discussion

The atomic coordinates as well as the bond lengths and angles are listed in Tables 1—3, respectively. An ORTEP drawing of the molecular structures and numbering schemes are shown in Fig. 1. As shown in the crystal structures (Figs. 2 and 3), the donor (D) and the acceptor (A) form an ADA-type arrangement in which each donor molecule lies on an inversion center. The interplanar spacing between D and A is 3.5 Å. One of the C≡N bonds is tilted away from the quinodimethane moiety (Fig. 3): the deviation from the plane of the six-membered ring is 0.446 Å for C19 and 0.701 Å for N3. Methylthio groups also deviate from

the almost planar DTPY skeleton: 0.508 Å for C8. The molecular overlap mode is shown in Fig. 4. There are no shorter intermolecular distances between ADA units than the van der Waals contacts. In this sense, ADA units are isolated from each other.

This complex can be classified into a neutral complex, as inferred from the following evidence. The stretching frequency of the C≡N bonds for the complex appeared at 2219 cm^{-1}, which is almost the same as that of the neutral THBTCNQ, itself (2213 cm^{-1}).[1] From the bond-length-ratio procedure of Kistenmacher et al.,[8] the degree of CT was calculated to be 0.25 by using the average bond lengths of the assumed *mmm* molecular symmetry. Although such a calculation is too primitive to draw a precise ionicity, both the stretching frequency and the molecular geometry show the neutral nature of the complex.

The ionicity of CT complexes can be conveniently predicted from $\Delta E^{o,r}$ which denotes the difference between the oxidation potential of the donor and the reduction potential of the acceptor. The value of $\Delta E^{o,r}$ for MTDTPY and THBTCNQ is 0.23 eV, which falls within the range of neutral to partial-ionic complexes. Therefore, the neutral nature of the complex is consistent with such a prediction. $\Delta E^{o,r}$ exhibits a further utility when the CT transition energy is taken into account for discussion. Torrance et al. reported a simple V-shape correlation between the energy of the CT absorption band ($h\nu_{CT}$) and $\Delta E^{o,r}$ for mixed stacking complexes. In the electronic spectrum of this complex dispersed in KBr, a strong absorption band at 23900 cm^{-1} and a weak band at 5800 cm^{-1} are assignable to the molecular absorption band of both neutral THBTCNQ[1] and MTDTPY,[3] and a CT band

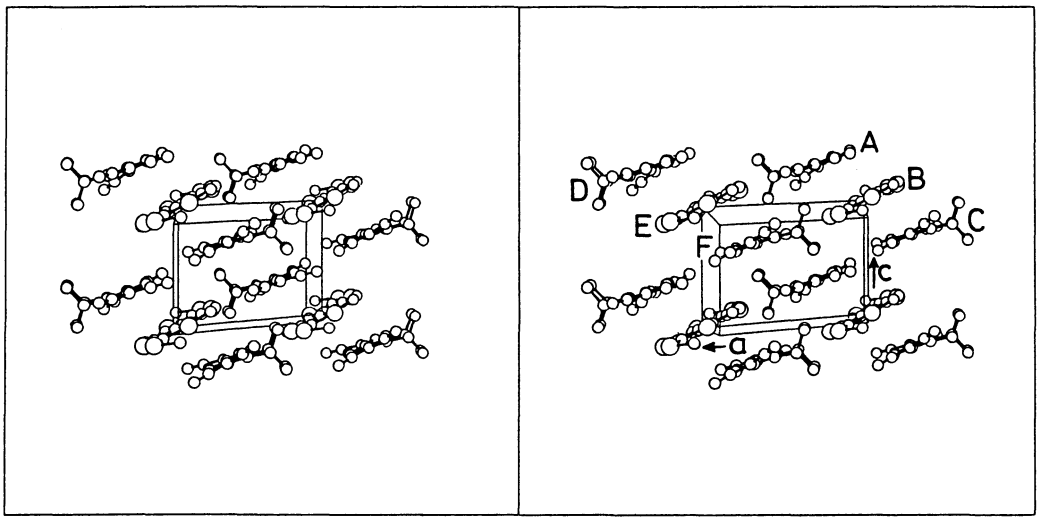

Fig. 3. Stereoview of the crystal packing viewed along the b axis.

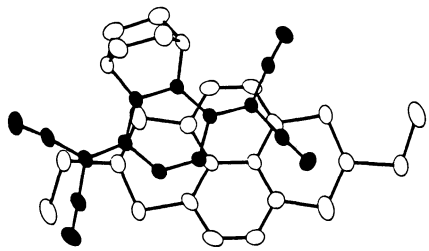

Fig. 4. The mode of molecular overlap between the donor and the acceptor.

between two component molecules, respectively. Although this complex cannot be classified into the usual mixed stacking complexes, it essentially contains a DA-type overlap mode. Therefore, we could estimate the CT transition energy for the complex by the empirical formula,[1,10] $h\nu_{CT,N}=\Delta E^{o,r}+0.5$ (eV), deduced from the V-shape correlation. The estimated value, 0.73 eV, is very close to the observed one, 0.72 eV (5800 cm^{-1}). Such a result suggests the potential applicability of the V-shape correlation to a wider range of CT complexes with DA-type overlap modes, although more data are needed to make this argument conclusive. However, such rough information regarding the electronic structure, which can be obtained readily from 1 mg of powdered sample, is especially valuable for chemists exploring new component molecules of organic conductors.

The Baeyer-Villiger Reaction of Polycyclic Aromatic Aldehydes: Preparation of Polycyclic Phenols

Koichi FUJISHIRO and Shuichi MITAMURA*
Chemicals Research Laboratory, R & D Laboratories-1, Nippon Steel Corporation, 1618 Ida, Nakahara-ku, Kawasaki 211
(Received May 10, 1988)

Synopsis. Baeyer-Villiger reactions of such polycyclic aromatic aldehydes as 2-dibenzofurancarbaldehyde with various peroxy compounds have been studied in detail, giving predominantly the corresponding phenols.

In contrast to simple benzenoid aromatics, only a little attention has been paid to such polycyclic aromatic compounds as naphthalene, dibenzofuran, anthracene and so on, though they have attractive attributes, i.e., their rigid ring skeletons and rich π-electron systems. We have been interested in the reaction characteristic of the polycyclic aromatic systems to provide a variety of useful derivatives. In this paper, we wish to report on the Baeyer-Villiger reaction (B-V reaction)[1] of polycyclic aromatic aldehydes yielding a series of polycyclic phenols.

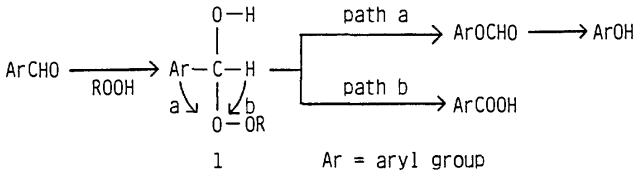
6		97	86	1
7		99	92	2

a) X is the conversion of the aldehyde.

Several kinds of polycyclic aromatic aldehydes[2] were allowed to react with *m*-chloroperbenzoic acid (MCPBA) in dry dichloromethane at room temperature under an argon atmosphere. The results are shown in Table 1. Polycyclic aromatic aldehydes gave the corresponding phenols predominantly, while benzaldehyde yielded a mixture of phenol and benzoic acid. This difference can be attributed to a difference in the electron-donative nature between the polycyclic aromatic ring and the benzene ring. The mechanism shown in Scheme 1 is generally proposed.[3] A peroxy compound (ROOH) attacks the carbonyl group of an aldehyde (ArCHO) to afford an intermediate **1**, followed by a migration of the aryl group, Ar, (path a) or the hydride, H, (path b). The relative migratory aptitude of Ar and H depends on their electron-donative nature, so that the more electron-donative polycyclic aromatic ring migrates predominantly to give the formate, which is transformed into the phenol, ArOH, by alkaline hydrolysis. Thus, this work presents a new synthetic method regarding polycyclic phenols.



Scheme 1.

Many kinds of peroxy compounds were examined as oxidants instead of MCPBA in this B-V reaction of 2-dibenzofurancarbaldehyde (**2**). Table 2 shows the results of a reaction of **2** with aqueous hydrogen peroxide (30 wt%) in the presence of various acids to yield 2-dibenzofuranol (**3**) and 2-dibenzofurancarboxylic acid (**4**). The reaction was strongly affected by the

a) The molar ratio of the peroxy compound to **2** is 1.2. b) The concentration of H_2SO_4 is 5 wt%.

acidity of the acid used. The reaction in formic acid gave **3** in high yield (81%, Run 10) and high selectivity, while the reaction in acetic acid proceeded slowly and gave **4** (47%, Run 8). When the reaction was carried out in trifluoroacetic acid, the yield of **3** was low (13%) and tarry materials were obtained (Run 11). Acid catalysts yield the conjugate acids of aldehydes and accelerate the nucleophilic additions of peroxides to the protonated carbonyl groups (Scheme 1).[3] The acidity of formic acid (pK_a=3.75 at 25 °C) is stronger than that of acetic acid (pK_a=4.76); thus, a reaction in formic acid gives **3** predominantly. In the case of trifluoroacetic acid (pK_a=0.23), its acidity is so strong that **2** and products would be further converted to tarry materials. When sulfuric acid (pK_a=1.99, Run 12) or chloroacetic acid (pK_a=2.87, Run13) was added to acetic acid solvent, the yield of **3** increased, while the addition of formic acid or sulfuric acid in methanol (Runs 15, 16) and acetone (Run 17) did not improve the yield of **3**.

Table 3 shows the results of a reaction of **2** with several kinds of peroxy compounds. The reaction of **2** with *t*-butyl hydroperoxide (*t*-BuOOH) in methanol-sulfuric acid (Run 19) proceeded more rapidly and gave **3** more dominantly than that in formic acid (Run 18). When *t*-butyl peracetate (Run 20) and 2,2-bis(*t*-butyldioxy)propane (Run 21) were used as oxidants, **3** was also obtained more than **4**. On the other hand, other peroxy compounds such as dibenzoyl peroxide (Run 22), potassium peroxodisulfate (Run 23) and peracetic acid (Run 24) gave **4** predominantly. These results indicate that the nature of the leaving group of the intermediate **1** may affect the relative migratory tendency of the aryl and the hydride groups.

To sum up, polycyclic phenols were obtained from the corresponding aldehydes under the system of MCPBA-CH_2Cl_2, H_2O_2-HCOOH, H_2O_2-CH_3COOH-$CH_2ClCOOH$ or *t*-BuOOH-CH_3OH-H_2SO_4. This reaction provides a new method for the preparation of polycyclic phenols.

Experimental

All melting points were measured by a Yanagimoto micro melting point apparatus and were uncorrected. NMR spectra were taken on a JEOL JMN-FX90 spectrometer. Mass spectra were obtained with a Shimadzu QP-1000 spectrometer. Gas chromatographs were obtained with a Shimadzu GC-9A. All aldehydes, except for **2**, were commercially available and purified by a column chromatography on silica gel with dichloromethane as the eluent. Solvents such as benzene and dichloromethane were dried on Molecular Sieves 3A. All peroxy compounds and acids, except for peracetic acid, were purchased commercially and were used without purification. Peracetic acid was prepared in situ by the reaction of acetic anhydride with aqueous hydrogen peroxide.[4]

Preparation of 2-Dibenzofurancarbaldehyde (2). To a solution of 21.4 g (127 mmol) of dibenzofuran in 40 cm^3 of dry benzene was added 38.3 g (287 mmol) of aluminum chloride and 1.2 g (12 mmol) of copper(I) chloride in a 200 cm^3 autoclave. It was filled with carbon monoxide until the pressure reached 4.9 MPa; the mixture was then stirred at 40 °C for 3 h maintaining the pressure at 4.9 MPa. The mixture was poured onto 500 g of ice to hydrolyze the complex of the product and aluminum chloride. The aqueous layer was removed; then, the organic layer was washed with 100 cm^3 of water and dried (magnesium sulfate). After evaporation in vacuo, the residue was purified by a column chromatography (silica gel, dichloromethane). The eluent was evaporated, and the residual solid was recrystallyzed from petroleum ether to afford 17.4 g of **2** (70% yield).

2-Dibenzofurancarbaldehyde (2): Mp 61—63 °C; ^1H NMR ($CDCl_3$) δ=7.1—7.4 (4H, m), 7.6—7.8 (2H, m), 8.09 (1H, d, J=2 Hz) and 9.90 (1H, s, CHO); ^{13}C NMR ($CDCl_3$) δ=111.71, 111.81, 120.75, 122.54, 123.14, 123.30, 124.71, 127.96, 128.66, 131.91, 156.62, 159.27, and 190.69; MS (70 eV) m/z (rel intensity) 196 (M^+; 90), 195 (100), 167 (30), and 139 (58); Found: C, 79.62; H, 4.08%; Calcd for $C_{13}H_8O_2$: C, 79.61; H, 4.08%.

B-V Reaction of 2 with MCPBA. To a solution of 392 mg (2 mmol) of **2** in 5 cm^3 of dry dichloromethane was added 414 mg (2.4 mmol) of MCPBA. The mixture was stirred at room temperature under an argon atmosphere for 20 h. An excessive amount of aqueous sodium thiosulfate solution was added to the reaction mixture and no remains of MCPBA were checked by potassium iodide-starch paper. After an addition of 10 cm^3 of 2 mol dm^{-3} NaOH and 10 cm^3 of methanol, the mixture was stirred for 0.5 h and neutralized to pH 7—8 with 1 mol dm^{-3} HCl and aqueous sodium hydrogencarbonate solution, then extracted with 30 cm^3 of dichloromethane. The amounts of **2** and **3** in the organic layer were determined by gas chromatography (200 °C, Fuloxylate-K, 3 mm×2 m) using dimethyl 2,6-naphthalenedicarboxylate as an internal standard. After the organic layer was evaporated, **3** was isolated from the residue by column chromatography (silica gel, dichloromethane) and recrystallization from ethanol.

2-Dibenzofuranol (3): Mp 136—137 °C; ^{1}H NMR ($CDCl_3$) δ=4.82 (1H, s, OH), 6.95 (1H, dd, J=9 Hz, 3 Hz), 7.1—7.7 (5H, m), and 7.90 (1H, dd, J=9 Hz, 2 Hz); MS (70 eV) m/z (rel intensity) 184 (M^+; 100), 155 (9), 128 (17), and 127 (10); Found: C, 78.07; H, 4.35%; Calcd for $C_{12}H_8O_2$: C, 78.28, H, 4.34%.

The aqueous layer, which contained **4**, was acidified with concentrated HCl and extracted with 30 cm^3 of ethyl acetate. A diazomethane-ether solution was added to the organic layer to convert **4** into the methyl ester; then, the amount of the methyl ester was measured by gas chromatography. The methyl ester was isolated by column chromatography (silica gel, dichloromethane).

Methyl 2-Dibenzofurancarboxylate: ^{1}H NMR ($CDCl_3$) δ=3.97 (3H, s), 7.3—7.7 (4H, m), 7.9—8.2 (3H, m), and 8.60 (1H, d, J=2Hz); MS (70 eV) m/z (rel intensity) 226 (M^+; 66), 195 (100), 167 (25), and 139 (31); Found: C, 74.30; H, 4.48%; Calcd for $C_{14}H_{10}O_3$: C, 74.33; H, 4.46%.

The products of the B-V reaction of other aldehydes (Table 1) were analyzed using the same method, except for the reaction of 9-anthracenecarbaldehyde. They were identified through a comparison of their respective retention times in gas chromatography and the mass spectra with those of commercially available chemicals. 9-Anthryl formate was isolated by column chromatography (silica gel, dichloromethane) without an alkaline hydrolysis of the reaction mixture.

9-Anthryl Formate: Mp 90—91 °C; ^{1}H NMR ($CDCl_3$) δ= 7.4—7.7 (4H, m), 7.9—8.2 (4H, m), 8.41 (1H, s), and 8.66 (1H, s); MS (70 eV) m/z (rel intensity) 222 (M^+; 20), 195 (16), 194 (100), 193 (18), 165 (75), and 163 (14); Found: C, 81.11; H, 4.66%; Calcd for $C_{15}H_{10}O_2$:C, 81.10; H, 4.50%.

(Received May 28, 1988)

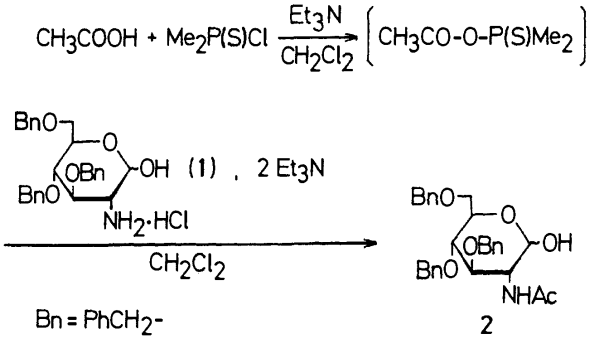
Synopsis. Dimethylphosphinothioic (Mpt) mixed anhydrides of carboxylic acids were found to be useful for *N*-acylation of 2-amino-2-deoxy-D-glucopyranose derivatives without protecting the hydroxyl functions. By this method, *N*-acylation of 2-amino-2-deoxy-D-glucopyranose hydrochloride in methanol was also found to be possible.

In recent years, *N*-acyl derivatives of amino sugars became interesting substances in biochemical studies. In order to study their structure-activity relationship etc., analogs of amino sugars which have various acyl group are desired. Symmetrical anhydrides are widely used for the *N*-acylation of amino sugars.[1,2] However, it seems difficult to introduce various acyl groups into the amino group without protecting the hydroxyl functions in sugars and acyl groups. For example, it was reported that 2-acetamido-3,4,6-tri-*O*-benzyl-2-deoxy-D-glucopyranose (**2**) was prepared by the deprotection of *O*-acetyl group from *N*,*O*-diacetate which was derived from 2-amino-3,4,6-tri-*O*-benzyl-2-deoxy-D-glucopyranose (**1**) and acetic anhydride.[2]

Recently, it has been reported that the dimethylphosphinothioic (Mpt) mixed anhydride method is useful for the synthesis of peptides containing hydroxyamino acids without protecting the hydroxyl functions.[3] In this paper, we wish to describe an efficient and general *N*-acylation of 2-amino-2-deoxy-D-glucopyranose derivatives by Mpt mixed anhydrides which were derived from the corresponding carboxylic acids and dimethylphosphinothioyl chloride (Mpt-Cl).[4]

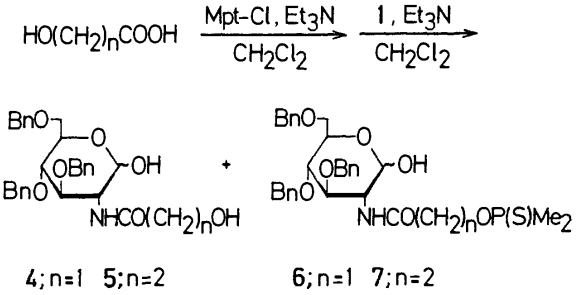
Results and Discussion

First, the reactivity of the Mpt mixed anhydride with hemiacetal hydroxyl group, which had not been previously reported, was investigated by the *N*-acylation of **1**. Mpt acetic anhydride was synthesized from Mpt-Cl and acetic acid in the presence of triethylamine in dichloromethane. It could be detected by silica-gel thin-layer chromatography (TLC). To this reaction mixture, compound **1** and 2 equiv of triethylamine were added and the resulting solution was stirred overnight at room temperature. The usual work-up gave the desired *N*-acetyl derivative (**2**) in quantitative yield. Similarly, the *N*-benzoyl derivative (**3**) was obtained in 86% yield. During these reactions no 1-*O*-acyl derivative could be detected by TLC.

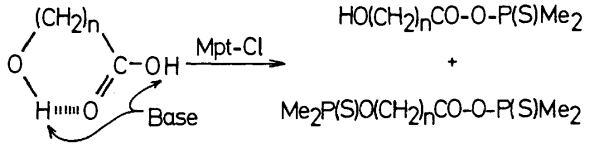


Next, we studied *N*-hydroxyacylation of **1** using Mpt mixed anhydrides according to a procedure similar to those described above. *N*-Hydroxyacyl amino sugars are found in complex carbohydrates, such as lipid A, *N*-glycoloyl neuraminic acid. Usually for the *N*-hydroxyacylation, *O*-protected acylation reagents were used.[5,6] However, by the Mpt mixed anhydride method *N*-hydroxyacylation without protecting the hydroxyl function in the acyl group was anticipated to occur.

In spite of the poor reactivity of Mpt-Cl with alcohol,[3] the mixture of the desired *N*-hydroxyacyl derivatives (**4**, **5**) and the corresponding *O*-dimethylphosphinothioyl derivatives (**6**, **7**) were obtained unexpectedly in the case of glycolic acid and 3-hydroxypropanoic acid in accord with following equation.



This side reaction suggested that Mpt-Cl might react with the hydroxyl group in carboxylic acid, which was activated by the formation of intramolecular hydrogen bond, to give two mixed anhydrides. In fact, these two mixed anhydrides could be detected by TLC. Therefore, we expected that this side reaction could be overcome if a polar solvent and a low nucleophilic base were used.



Based on this hypothesis, we studied the *N*-glycoloylation of **1**, and found *N*,*N*-diisopropylethylamine (DIEA) in tetrahydrofuran (THF) effective to promote selective *N*-acylation. On the other hand, we also found that the *N*-glycoloyl derivatives (**4**) could not be obtained in good yield by the reaction of gly-

Table 1. *N*-Glycoloylation of **1** by Mpt Mixed Anhydride

Base	Solvent	Yield/%	
		3	**5**

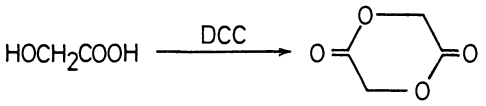
$HO(CH_2)_2CO$-	68
$HO(CH_2)_{15}CO$-	78

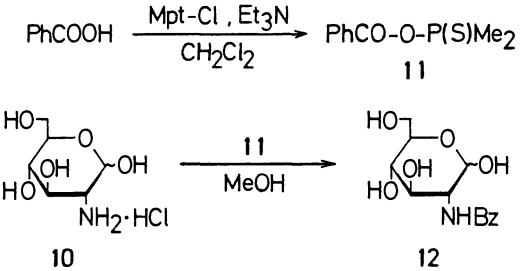
colic acid and **1** using dicyclohexylcarbodiimide (DCC). To clarify this point, we attempted the synthesis of the symmetrical anhydride of glycolic acid by DCC according to the literature[5] and found that 1,4-dioxane-2,5-dione (**8**) was obtained as the main product.



8

In a similar manner using Mpt mixed anhydrides, *N*-(3-hydroxypropanoyl) and *N*-(16-hydroxyhexadecanoyl) derivatives (**5**, **9**) were obtained in good yields. The results described above are summarized in Tables 1 and 2.

Finally, we applied this method to the *N*-benzoylation of 2-amino-2-deoxy-D-glucopyranose hydrochloride (**10**) in methanol. In order to simplify the reaction system the benzoyl Mpt mixed anhydride was purified by means of silica-gel flash-column chromatography to give colorless crystals **11** in 93% yield. The reaction of compound **10** and Mpt mixed anhydride **11** in the presence of various bases in methanol was tried. The desired 2-benzamido-2-deoxy-D-glucopyranose (**12**) was obtained in 76% yield as colorless crystals by using of DIEA. On the contrary, in the case of 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU), only benzoic acid was obtained. These results suggested that the nucleophilicity of the base might be an important factor for this reaction.



10 **12**

According to the present method, various *N*-acyl derivatives of 2-amino-2-deoxy-D-glucopyranose could be synthesized in good yields. It should be noted that the protection of the hydroxyl functions in acyl groups and sugars was not necessary and further, this *N*-acylation could be carried out in an alcoholic solvent, such as methanol.

Experimental

Mp's were uncorrected. Optical rotations were measured at 26—29 °C after being kept overnight at room temperature.

Typical Procedure for *N*-Acylation of 1. To a mixture of carboxylic acid (0.2 mmol) and 0.2 mmol of base (triethylamine or DIEA) in dichloromethane or THF (1 mL) was added a solution of Mpt-Cl (25.7 mg; 0.2 mmol) in the solvent (1 mL) under ice-cooling. After stirring for 30 min, the formation of Mpt mixed anhydride could be confirmed by TLC, then compound **1** (97.2 mg; 0.2 mmol) and the base (0.4 mmol) were added to it. The resulting mixture was stirred overnight at room temperature. Usual work-up followed by evaporation and preparative thin-layer chromatography gave the desired *N*-acyl derivatives in good yield.

2-Acetamido-3,4,6-tri-*O*-benzyl-2-deoxy-D-glucopyranose (2). 98.3 mg (100%): Mp 216—217 °C (lit; 216—219 °C);[7] $[\alpha]_D$ +67.2° (*c* 1.08, $CHCl_3$) (lit; +71.3° (*c* 1.08, $CHCl_3$)).[2]

2-Benzamido-3,4,6-tri-*O*-benzyl-2-deoxy-D-glucopyranose (3). 95.2 mg (86%): Mp 215—217 °C (lit; 215—217 °C);[8] $[\alpha]_D$ +80.8° (*c* 0.48, pyridine) (lit; +88.6° (*c* 0.48, pyridine)).[8]

3,4,6-Tri-*O*-benzyl-2-deoxy-2-glycoloylamino-D-glucopyranose (4). 84.8 mg (84%): Mp 204—206 °C; $[\alpha]_D$ 40.0° (*c* 0.4, 10% MeOH/$CHCl_3$). Found: C, 67.08; H, 6.46; N, 2.65%. Calcd for $C_{29}H_{33}NO_7 \cdot 1/2H_2O$: C, 67.43; H, 6.63; N, 2.71%.

3,4,6-Tri-*O*-benzyl-2-deoxy-2-(3-hydroxypropanoylamino)-D-glucopyranose (5). 70.0 mg (68%): Mp 191—194 °C; $[\alpha]_D$ +51.2 (*c* 1, $CHCl_3$). Found: C, 68.23; H, 6.70; N, 2.66%. Calcd for $C_{30}H_{35}NO_7 \cdot 1/2H_2O$: C, 67.91; H, 6.84; N, 2.64%.

3,4,6-Tri-*O*-benzyl-2-deoxy-2-(16-hydroxyhexadecanoylamino)-D-glucopyranose (9). 109.5 mg (78%): Amor.; $[\alpha]_D$ +20.0° (*c* 0.4, 20% $CHCl_3$/MeOH). Found: C, 72.14; H, 8.69; N, 2.08%. Calcd for $C_{43}H_{61}NO_7 \cdot 1/2H_2O$: C, 72.44; H, 8.77; N, 1.96%.

2-Benzamido-2-deoxy-D-glucopyranose (12). To the mixture of compound **10** (107.8 mg; 0.5 mmol) and DIEA (0.19 mL; 1.5 mmol) in methanol (4 mL) was added the solution of benzoic Mpt mixed anhydride (160.7 mg; 0.75 mmol) in 1 mL of methanol. After stirring overnight at room temperature, the methanol was evaporated in vacuo. The residue was dissoleved in water and adsorbed on Dia-ion HP-20. The resin was washed with water and eluted with methanol and evaporated. The residue was purified by preparative thin-layer chromatography using the chloroform-methanol-acetic acid (85 : 25 : 20) solvent system. The desired band was eluted with methanol and evaporated in vacuo. The residue was dissolved in methanol, placed in a Sephadex LH-20 column (2×100 cm), and eluted with methanol. The desired fractions were collected to yield **10** as colorless crystals (107.6 mg, 76%). Mp 198 °C (decomp) (lit; 198—200 °C);[9] $[\alpha]_D$ +29.2° (*c* 1, H_2O) (lit; +35.0° (*c* 2, H_2O)).[9] The similar procedure using 1 equiv of **11** in the presence of 2 equiv of Et_3N or DIEA gave **12** in 58, 62% yield, respectively. On the other hand, when 2 equiv of DBU was used only benzoic acid was recovered.

We are deeply indebted to Profs. Teruaki Mukaiyama and Hidefumi Hirai, the Science University of Tokyo, for their helpful discussions.

Preparation of Pyrroles Having Long Alkyl Chains from Nitroalkenes

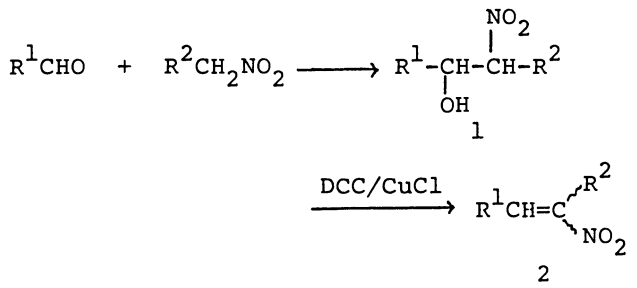
Noboru ONO* and Kazuhiro MARUYAMA
Department of Chemistry, Faculty of Science, Kyoto University, Kyoto 606
(Received June 16, 1988)

Synopsis. Pyrroles having long alkyl chains at the 3- and/or 4-positions are readily prepared by the reaction of ethyl isocyanoacetate with nitroalkenes having long alkyl chains.

As pyrroles having long alkyl chains at the 3- and/or 4-positions are important intermediates for the synthesis of lipophilic polypyrroles and porphyrins, synthesis of such pyrroles is becoming important in recent years.[1] Acylation of pyrroles followed by the reduction of the carbonyl group[2] or the Wittig type reaction of 3-formyl pyrroles followed by hydrogenation of the double bond has been used for the introduction of long chains at the 3-position.[3] However, they require tedious procedures and can not be applied to the synthesis of pyrroles having two long alkyl groups at the 3- and 4-positions. In connection with our study of porphyrin model systems, we need a more simple and effective method for the preparation of pyrroles having long alkyl chains. In this paper we wish to report the preparation of hitherto unfamiliar nitroalkenes having long alkyl chains and their conversion into the corresponding pyrroles by the reaction with isocyanides.[4]

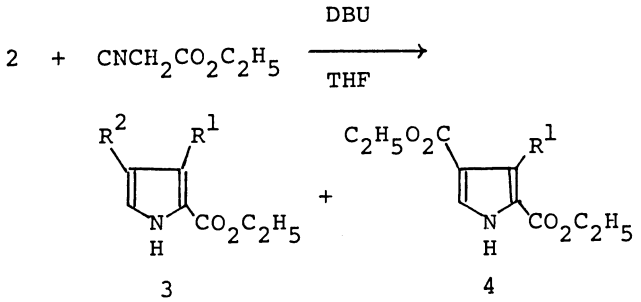
Results and Discussion

The requisite nitroalkenes were prepared by dehydration of the corresponding nitro alcohols (**1**) on treatment with dicyclohexylcarbodiimide (DCC) in the presence of copper(I) chlorid.[5] Nitro alcohols (**1**)



were prepared by the nitro aldol condensation of higher alkanals with higher nitroalkanes. A strong base such as 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) was required for this step.[6] Althogh many methods are available for the conversion of **1** into nitroalkenes (**2**)[7] the formation of nonconjugated nitroalkenes is a serious problem for higher nitroalkenes. In fact, the most widely used method consisted of methansulfonylation and the effecting elimination on treatment with a base[8] gave a mixture of **2** and the nonconjugated nitroalkenes whose ratio was about 7 : 3. Dehydration with DCC in the presence of copper(I) chloride gave **2** in good yields without formation of nonconjugated nitroalkenes. The results are summarized in Table 1.

Nitroalkenes **2** were converted into pyrroles on treatment with ethyl isocyanoacetate in the presence of a base.[4] The reaction was carried out by stirring a mixture of **2**, ethyl isocyanoacetate, and DBU in tetrahydrofuran (THF) at room temperature. 2-Ethoxycarbonyl-3,4-dialkylpyrroles (**3**) and 2,4-bis(ethoxycarbonyl)-3-alkylpyrroles (**4**) were obtained in 70—80% and 5—10% yields, respectively. They are readily separated by column chromatography (silica gel/benzene) to afford pure **3** and **4**. The results are summarized in Table 2. Formation of **4** has not been reported



in the literature,[4] but it is unavoidable in the preparation of pyrroles using nitroalkenes. The possible route for the formation of **3** and **4** is shown in Scheme 1. The intermediate **5** undergoes either cyclization to give **3** or elimination of the anion of nitro compounds to give **6** which reacts with ethyl isocyanoacrtate to give **4**.[9]

(a) The reaction was carried out by stirring amixture of **2** (10 mmol), ethyl isocyanoacetate (10 mmol), and DBU (10 mmol) in THF (20 ml). The separation of **3** was carried out by column chromatography (silica gel/benzene).

Thus, pyrroles having long alkyl chains are conveniently prepared from nitroalkenes. Pyrroles **3** are useful for the synthesis of lipophilic porphyrins.[1]

Experimental

Nitroalkanes were prepared by the reaction of the corresponding alkyl bromides with sodium nitrite in dimethyl sulfoxide,[10] or the Michael addition of nitrometane to methyl acrylate.[11] Aldehydes were used after distillation of commercially available materials. Ethyl isocyanoacetate was prepared according to the literature.[12]

Preparation of β-Nitro Alcohols. Method A: A mixture of nitroethane (8.3 g, 0.11 mol), heptanal (11.4 g, 0.10 mol), and DBU (0.15 g, 0.01 mol) in acetonitrile (10 ml) was stirred at room temperature for 24 h and then diluted with water (50 ml) containing 1 M HCl (10 ml; 1 M=1 mol dm^{-3}), and extracted with ethyl acetate. The extracts were washed with water and dried with anhydrous magnesium sulfate. The solvent was removed under reduced pressure, and the residue was distilled to give 2-nitro-3-nonanol (**1a**), 16 g (90%), bp 100—105 °C/1 mmHg (1 mmHg=133.32 Pa); lit.,[11] 110 °C/1.5 mmHg. 2-Nitro-3-dodecanol (**1b**): bp 110—115 °C/1 mmHg.

Method B: A mixture of 1-nitrooctane (3.2 g, 20 mmol), hexanal (2.0 g, 20 mmol), and DBU (0.45 g, 2 mmol) was stirred at room temperature for 24 h and then diluted with ethyl acetate (20 ml). The resulting solution was poured into 1 M HCl (100 ml) and extracted with ethyl acetate. The extracts were washed with water and the solvent was removed to give 7-nitro-6-tetradecanol (**1c**), which was pure enough to use for the next step; 4.9 g (98%).

Preparation of Nitroalkenes (2). A mixture of **1c** (3.68 g, 14.2 mmol), copper(I) chloride (34 mg, 3.4 mmol), and DCC (3.50 g, 17.1 mmol) in dioxane (40 ml) was stirred at room temperature for 48 h. The precipitated solid was removed by filtration and washed with hexane. The filtrate and washings were combined, and washed with 1 M HCl and water. The solvent was removed after drying with anhydrous magnesium sulfate. The residue was subjected to column chromatography (silica gel/ benzene-hexane) to give **2c**, 3.01 g (88%). ^{1}H NMR ($CDCl_3$) δ=0.87 (t, 6 H, J=7 Hz), 1.00—1.60 (m, 16 H), 1.64—1.98 (m, 2 H), 2.04—2.68 (m, 2 H), 5.63 (t, Z-CH=C), and 6.98 (t, E-CH=C). IR (neat) 1360, 1530, and 1670 cm^{-1}. Found: m/z 241.2064. Calcd for $C_{14}H_{27}NO_2$: M, 241.2042.

Following nitroalkenes were prepared by this procedure.

2a: ^{1}H NMR ($CDCl_3$) δ=0.90 (t, 3 H, J= 7 Hz), 1.10—1.70 (m, 8 H), 2.10 (s, 3 H), 2.28—2.45 (m, 2 H), 5.83 (t, Z-CH=C), and 7.07 (t, E-CH=C). IR (neat) 1360, 1530, and 1650 cm^{-1}. Found: m/z 171.1138. Calcd for $C_9H_{17}NO_2$: M, 171.1145.

2b: ^{1}H NMR ($CDCl_3$) δ=0.90 (t, 3 H, J= 7 Hz), 1.05—1.75 (m, 14 H), 2.08 (s, 3 H), 2.20—2.50 (m, 2 H), 5.83 (t, Z-CH=C), and 7.02 (t, E-CH=C). IR (neat) 1360, 1530, and 1650 cm^{-1}. Found: m/z 230.1932. Calcd for $C_{12}H_{23}NO_2$: M, 230.1934.

2f: ^{1}H NMR ($CDCl_3$) δ=0.89 (t, 3 H, J=7 Hz), 1.10—1.80 (m, 6 H), 2.12—2.82 (m, 4 H), 2.85 (q, 2 H, J=8 Hz), 3.64 (s, 3 H), 5.91 (t, Z-CH=C), and 7.13 (t, E-CH=C). IR (neat) 1360, 1530, 1650, and 1730 cm^{-1}. Found: m/z 229.1314. Calcd for $C_{11}H_{19}NO_4$: M, 229.1314.

Preparation of Pyrroles. Typical Procedure: A mixture of **2a** (1.71 g, 10 mmol), ethyl isocyanoacetate, and DBU (1.52 g, 10 mmol) in THF (20 ml) was stirred at room temperature for 15 h. The reaction mixture was poured into water (100 ml) containing 1 M HCl (10 ml) and extracted with ethyl acetate (3×50 ml). The extracts were washed with water and dried with anhydrous magnesium sulfate, The solvent was

removed under reduced pressure, and the reside was subjected to column chromatography (silica gel/benzene) to give **3a** (1.85 g, 78%) and **4a** (0.24 g, 8%). **3a**: mp 55—56 °C. IR (KBr) 3340 and 1680 cm^{-1}. ^1H NMR ($CDCl_3$) δ=0.95 (t, 3 H, J=7 Hz), 1.2—1.8 (m, 11 H), 2.02 (s, 3 H), 2.70 (q, 2 H, J=7 Hz), 4.25 (q, 2 H, J=7 Hz), 6.70 (d, 1 H, J=3 Hz), and 9.45 (br s, 1 H). Found: C, 70.76; H, 9.87; N, 5.93%. Calcd for $C_{14}H_{23}NO_2$: C, 70.84; H, 9.77; N, 5.90%. **4a**: oil. IR (neat) 3340, 1620, and 1680 cm^{-1}. ^1H NMR ($CDCl_3$) δ=0.95 (t, 3 H, J=7 Hz), 1.2—1.7 (m, 14 H), 3.10 (q, 2 H, J=7 Hz), 4.28 (q, 2 H, J=7 Hz), 4.35 (q, 2 H, J=7 Hz), 7.45 (d, 1 H, J=2 Hz), and 9.28 (br s, 1 H). Found: C, 65.14; H, 8.39; N, 4.68%. Calcd for $C_{16}H_{25}NO_4$: C, 65.06; H, 8.53; N, 4.74%. Following pyrroles were prepared by this procedure.

3b: Oil. IR (neat) 3340 and 1685 cm^{-1}. ^1H NMR ($CDCl_3$) δ=0.90 (t, 3 H, J=7 Hz), 1.1—1.8 (m, 17 H), 2.0 (s, 3 H), 2.69 (q, 2 H, J=7 Hz), 4.25 (q, 2 H, J=7 Hz), 6.68 (d, 1 H, J=3 Hz), and 9.40 (br s, 1 H). Found: C, 75.51; H, 10.78; N, 5.13%. Calcd for $C_{17}H_{29}NO_2$: C, 75.79; H, 10.85; N, 5.20%.

3c: Oil. IR (neat) 3340 and 1680 cm^{-1}. ^1H NMR ($CDCl_3$) δ=0.90 (t, 6 H, J=7 Hz), 1.1—1.8 (m, 19 H), 2.36 (q, 2 H, J=7 Hz), 2.70 (q, 2 H, J=7 Hz), 4.25 (d, 2 H, J=7 Hz), 6.66 (d, 1 H, J=3 Hz), and 9.20 (br s, 1 H). Found: C, 74.38; H, 10.78; N, 4.79%. Calcd for $C_{19}H_{33}NO_2$: C, 74.22; H, 10.82; N, 4.56%.

3d: Oil. IR (neat) 3320 and 1680 cm^{-1}. ^1H NMR ($CDCl_3$) δ=0.90 (t, 6 H, J=7 Hz), 1.1—1.8 (m, 23 H), 2.38 (q, 2 H, J=7 Hz), 2.70 (q, 2 H, J=7 Hz), 4.25 (q, 2 H, J=2 H), 6.62 (d, 1 H, J=3 Hz), and 8.98 (br s, 1 H). Found: C, 75.25; H, 11.28; N, 4.28%. Calcd for $C_{21}H_{37}NO_2$: C, 75.17; H, 11.12; N, 4.18%.

3e: Oil. IR (neat) 3320 and 1680 cm^{-1}. ^1H NMR ($CDCl_3$) δ=0.90 (t, 6 H, J=7 Hz), 1.1—1.8 (m, 27 H), 2.40 (q, 2 H, J=7 Hz), 2.72 (q, 2 H, J= 7 Hz), 4.26 (q, 2 H, J=7 Hz), 6.62 (d, 1 H, J=3 Hz), and 9.90 (br s, 1 H). Found: C, 75.89; H, 12.57; N, 3.74%. Calcd for $C_{23}H_{41}NO_2$: C, 75.98; H, 12.32; N, 3.85%.

3f: Oil. IR (neat) 1680, 1730, and 3340 cm^{-1}. ^1H NMR ($CDCl_3$) δ=0.97 (t, 3 H, J=7 Hz), 1.2—2.0 (m, 11 H), 2.64 (q, 2 H, J=7 Hz), 2.86 (q, 2 H, J=7 Hz), 3.64 (s, 3 H), 4.28 (q, 2 H, J=7 Hz), 6.78 (d, 1 H, J=3 Hz), and 9.90 (br s, 1 H). Found: C, 65.28; H, 8.38; N, 4.57%. Calcd for $C_{16}H_{25}NO_4$: C, 65.06; H, 8.53; N, 4.74%.

4b: Oil. IR (neat) 3340, 1640, and 1680 cm^{-1}. H NMR ($CDCl_3$) δ=0.95 (t, 3 H, J=7 Hz), 1.2—1.8 (m, 20 H), 3.12 (q, 2 H), J=7 Hz), 4.26 (q, 2 H, J=7 Hz), 4.36 (q, 2 H, J=7 Hz), 7.35 (d, 1 H, J= 2 Hz), and 9.26 (br s, 1 H). Found: C, 67.73; H, 9.12; N, 4.27%. Calcd for $C_{19}H_{31}NO_4$: C, 67.62; H, 9.26; N, 4.15%.

4c: Oil. IR (neat) 3340, 1640, and 1680 cm^{-1}. ^1H NMR ($CDCl_3$) δ=0.95 (t, 3 H, J=7 Hz), 1.2—1.8 (m, 12 H), 3.20 (q, 2 H, J=7 Hz), 4.25 (q, 2 H, J=7 Hz), 4.36 (q, 2 H, J=7 Hz), 7.40 (d, 1 H, J=2 Hz), and 9.30 (br s, 1 H). Found: C, 64.17; H, 8.13; N, 4.78%. Calcd for $C_{15}H_{23}NO_4$: C, 64.04; H, 8.24; N, 4.92%.

4d: Oil. IR (neat) 3340, 1640, and 1680 cm^{-1}. ^1H NMR ($CDCl_3$) δ= 0.95 (t, 3 H, J=7 Hz), 1.2—1.8 (m, 16 H), 3.12 (q, 2 H, J=7 Hz), 4.25 (q, 2 H, J=7 Hz), 4.36 (q, 2 H, J=7 Hz), 7.32 (d, 1 H, J= 2 Hz), and 9.25 (br s, 1 H). Found: C, 66.17; H, 8.89; N, 4.40%. Calcd for $C_{17}H_{27}NO_4$: C, 65.99; H, 8.80; N, 4.53%.

4e: Oil. IR (neat) 3340, and 1680 cm^{-1}. ^1H NMR ($CDCl_3$) δ=0.95 (t, 3 H, J=7 Hz), 1.2—1.8 (m, 18 H), 3.12 (q, 2 H, J=7 Hz), 4.25 (q, 2 H, J=7 Hz), 4.36 (q, 2 H, J=7 Hz), 7.37 (d, 1 H, J=2 Hz), and 9.25 (br s, 1 H). Found: C, 66.79; H, 9.23; N, 4.15%. Calcd for $C_{18}H_{29}NO_4$: C, 66.84; H, 9.04; N, 4.33%.

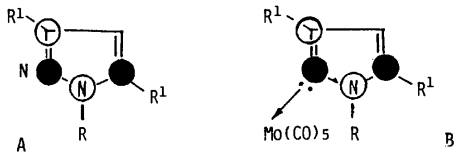
Hexacarbonylmolybdenum-Induced N-N Bond Cleavage of Pyrazoles. Conversion of 1-Acylpyrazoles to Pyrimidines

Makoto NITTA,* Tatsuo HAMAMATSU, and Hiroyuki MIYANO
Department of Chemistry, School of Science and Engineering, Waseda University, Shinjuku-ku, Tokyo 160
(Received June 17, 1988)

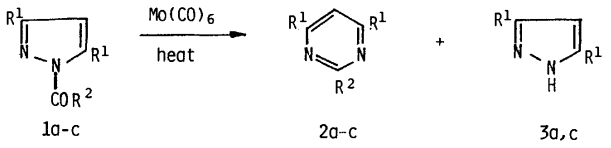
Synopsis. [$Mo(CO)_6$]-induced reactions of 1-acyl-3,5-disubstituted pyrazoles underwent N-N bond cleavage and subsequent cyclocondensation to give pyrimidines as well as deacylation to give 3,5-disubstituted pyrazoles. Under similar conditions, 1,3,5-trisubstituted pyrazoles, which have no electron-withdrawing substituent on N1, gave no product, except for the starting materials.

Previous studies in this series have included papers involving a system which formally contains a C=N-O group. The reaction of substituted 2-isoxazolines with [$Mo(CO)_6$], [$Fe_2(CO)_9$], or [$Fe(CO)_5$] under thermal conditions or photo-irradiations has been shown to undergo N-O and C4-C5 bond cleavages to give two fragments of aldehydes (or ketones) and complexed vinylnitrenes, which could collapse to ketones in a protic media.[1,2] Similarly substituted isoxazoles underwent a reductive cleavage of the N-O bond to give β-amino enones in good yields.[3] The *N*-complexed isoxazole has been isolated as a reasonable intermediate in the reaction.[3] The easy, metal-carbonyl prompted N-O bond cleavage has a strong resemblance to the photochemically induced N-O bond cleavage of isoxazoles to give oxoazirines.[4] The photochemical reaction of a pyrazole has also been known to undergo a possible N-N bond cleavage to give an imidazole.[5] In pyrazoles the nitrogen-nitrogen linkage appears to be antibonding in character



(LUMO shown as **A** in the Figure), and this seems to cause a possible photochemical N-N bond cleavage. Considering the pyrazoles *N*-complexed **B** to a [$Mo(CO)_5$] species, a possible delocalization of a π-d electron from the central metal to the π* (LUMO) of the pyrazole is expected to facilitate an N-N bond cleavage. This paper describes the [$Mo(CO)_6$]-induced N-N bond cleavage of 1-acetyl- and 1-benzoyl-3,5-disubstituted pyrazoles and a subsequent cyclocondensation to give 2,4,6-trisubstituted pyrimidines.

The thermal reaction of 1-acetyl-3,5-diphenyl-, 1-benzoyl-3,5-diphenyl-, and 1-benzoyl-3,5-dimethylpyrazoles (**1a—c**) with [$Mo(CO)_6$] in dry 1,2-dimethylbenzene underwent an N-N bond cleavage and a subsequent cyclocondensation to give pyrimidine derivatives **2a—c** as well as deacylation to give 3,5-disubstituted pyrazoles **3a, c** (Scheme 1). The detailed



a: R^1 = Ph; R^2 = Me, b: R^1 = R^2 = Ph, c: R^1 = Me; R^2 = Ph

Scheme 1.

reaction conditions and the yields of the products are summarized in Table 1 (Entries 1—3). Since compound **1a** underwent no reaction under heating in the absence of [$Mo(CO)_6$], [$Mo(CO)_6$] is indispensable for the formation of **2** and **3**. The structures of the pyrimidines **3a**,[6] **3b**,[7] and **3c**[6] were confirmed by comparisons of their physical data with those found in the literature. On the other hand, reactions proceeded slowly in dry toluene or acetonitrile in place of 1,2-dimethylbenzene, and gave pyrimidines **2a—c** as well as pyrazoles **3a,c**, in addition to the unreacted starting materials **1a—c** (Table 1, Entries 4—7). Compound **1c** does not seem to be labile, as compound with **1a,b**, in N-N cleavage reactions (Entries 3 and 7).

The formation of pyrimidines **2a—c** and pyrazoles **3a, c** can be explained as follows. Since [$Mo(CO)_6$] has been shown to give an *N*-complexed isoxazoles, the

Table 1. Experimental Results Obtained in the Reaction of **1a—c** with [$Mo(CO)_6$][a]

Entry	Pyrazole			Solvent	Product (yield/%)		Recovery (%)
	1	R^1	R^2		2	3	1

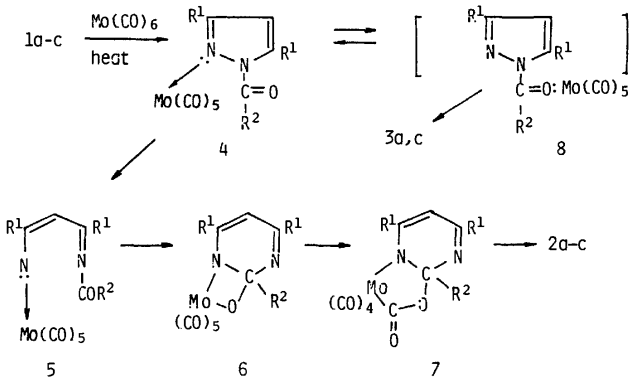
5	**1a**			CH_3CN	**2a** (9)	**3a** (60)	**1a** (10)
6[c]	**1b**			CH_3CH	**2b** (5)	**3a** (47)	**1b** (45)
7[c]	**1c**			CH_3CN	**2c** (0)	**3c** (82)	**1c** (15)

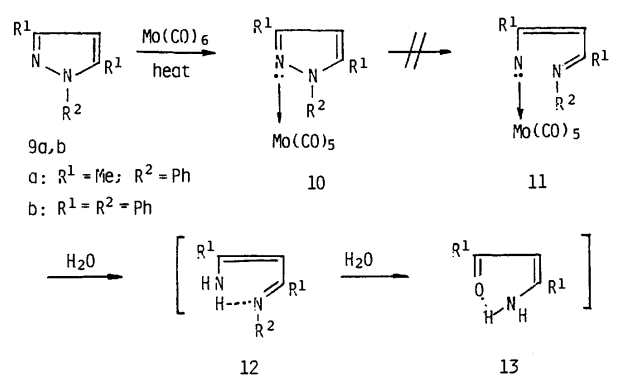
a) A molar equivalent amount of [$Mo(CO)_6$] was used, being heated under reflux for 24 h. b) DMB denotes 1,2-dimethylbenzene. c) Benzoic acid was isolated as ethyl benzoate albeit in low yields (ca. 1—12 %) (see Experimental).



Scheme 2.

initial step is a complexation of **1** to give **4**.[3] The following N-N bond cleavage of **4** gives complexed nitrene **5**. The intermediate **5** can cyclize to give **6**, a ligand migration of which is followed by decomplexation would give pyrimidines **2a—c**.[8] Although isolated yields of benzoic acid (Entries 2,3,6, and 7) were very low, pyrazoles **3a,c** presumably originate from the formally postulated complex **8**, which undergoes deacylation with contaminated water or under workup conditions. Even a reaction in a dry solvent can not eliminate the possibility of stray water. In a deacylation reaction, a molybdenum moiety seems to act as a Lewis acid. The carbonyl ligand of $[Mo(CO)_6]$ is easily substituted by acetonitrile,[3,9] several carbonyl ligands in each of the postulated complexes **4—8** are possibly exchanged with acetonitrile in the reactions of Entries 5—7. The formation of pyrazoles **3a, c** predominates over pyrimidines **2a—c**. This fact is suggestive of a high energy barrier of N-N bond cleavage, as compared to that of deacylation, and a possible existence of equilibrium between **4** and **8**. Although the N-N bond cleavage of **1a—c** was enhanced by $[Mo(CO)_6]$, the reaction seems to require a higher temperature, compared to that of isoxazoles.[3] This fact is ascribed to the large resonance energy of pyrazole, as compared to that of isoxazole.[10] Thus, the appreciable delocalization of a d electron from the central metal to the π^* (LUMO) of the pyrazole is actually suggested by the present reactions (figure).

Similarly, a reaction of 1-phenyl-3,5-dimethyl- and 1,3,5-triphenylpyrazoles (**9a, b**), both of which have no electron-withdrawing substituent at N1, was studied (Scheme 3). In this case, the expected vinylnitrene complex **11** can not collapse to pyrimidine. Thus, reactions expected N-N bond cleavage in moist solvents to give such products as **12** (and/or **13**) were carried out as in reactions of isoxazoles to give β-amino enones.[3] However, the reactions gave no product, except for the starting materials (see Experimental). This fact is suggestive of an enhanced resonance energy and a strong N-N bond of **9a, b**, compared to those of 1-acyl-substituted pyrazoles **1a—c**.



Scheme 3.

Experimental

The ^1H NMR spectra were recorded on a Hitachi R-24 spectrometer and the chemical shifts are given in ppm (δ) relative to the internal $SiMe_4$ standard. The desired compounds, 1-acylpyrazole derivatives **1a—c**, 1-phenyl-3,5-dimethylpyrazole (**9a**), and 1,3,5-triphenylpyrazole (**9b**), were prepared according to methods described in the literature.[11] All of the reactions were carried out under a dry nitrogen atmosphere.

General Procedure for the Reaction of Acylpyrazoles 1a—c with $[Mo(CO)_6]$ in 1,2-Dimethylbenzene. A solution of **1** (0.5 mmol) and $[Mo(CO)_6]$ (133 mg, 0.5 mmol) in 1,2-dimethylbenzene (5 cm^3) was refluxed for 24 h. After the solvent was evaporated, the residue was dissolved in chloroform (10 cm^3); it was then filtered through Celite to remove insoluble materials. After the filtrate was concentrated, the residue was separated by TLC on silica gel. In the reaction of **1a**, the first band (R_f 0.3) from the TLC plates developed by hexane-chloroform (1/3) gave pyrimidine **2**. The second band (R_f 0.1) gave **3a**. In reactions of **1b, c**, the first band (R_f 0.8 for **2b**; 0.6 for **2c**) from the TLC plates developed by hexane-AcOEt (6/1) gave pyrimidine **2b,c**. The second band (R_f 0.3 for **3b**; 0.2 for **3c**) gave a mixture containing **3b,c**. This mixture was heated in ethanol (5 cm^3) and H_2SO_4 (0.2 cm^3) for 3.5 h. After the usual workup, the pyrazole and ethyl benzoate (ca. 7%) were obtained. The yields of the products are summarized in Table 1. For **2a**: mp 91—92 °C (lit, mp 96—97 °C); ^1H NMR ($CDCl_3$) δ=2.83 (3H, s), 7.3—7.6 (6H, m), 7.79 (1H, s), 7.9—8.0 (4H, m).[6] For **2b**: mp 183—184 °C (lit, mp 183—184 °C); ^1H NMR ($CDCl_3$) δ=7.3—7.7 (9H, m), 7.98 (1H, s), 8.0—8.5 (4H, m), 8.5—8.9 (2H, m).[7] For **2c**: mp 74—78 °C (lit, mp 81—83 °C); ^1H NMR ($CDCl_3$) δ=2.62 (6H, s), 6.95 (1H, s), 7.3—7.7 (3H, m), 8.3—8.7 (2H, m).[6]

Thermal Reaction of 1-Acetyl-3,5-diphenylpyrazole 1a in 1,2-Dimethylbenzene. A solution of **1a** (131 mg, 0.5 mmol) in 1,2-dimethylbenzene (5 cm^3) was heated under reflux for 24 h. After the solvent was evaporated, the residue was purified by TLC on silica gel using hexane-AcOEt (5/1) as a developer to give **1a** (111 mg, 85%).

Reaction of 1-Acetyl-3,5-diphenylpyrazole 1a with $[Mo(CO)_6]$ in Toluene. A solution of **1a** (132 mg, 0.5 mmol) and $[Mo(CO)_6]$ (133 mg, 0.5 mmol) in dry toluene (5 cm^3) was heated under reflux for 24 h. After the solvent was evaporated, the residue was dissolved in dichloromethane (10 cm^3), and the solution was filtered through Celite to remove insoluble materials. The filtrate was concentrated and the resulting residue was separated by TLC on silica gel using hexane-chloroform (1/2) as a developer. The first band (R_f 0.6) from the TLC plates gave the starting material **1a**. The second band (R_f 0.2) gave the pyrimidine **2a**. The third band (R_f 0.1) gave the pyrazole **3a**. The yields are summarized in Table 1.

General Procedure for the Reaction of 1a—c with $[Mo(CO)_6]$ in Acetonitrile. A solution of **1** (1 mmol) and $[Mo(CO)_6]$ (266 mg, 1 mmol) in dry acetonitrile (5 cm^3) was

heated under reflux for 24 h. The acetonitrile was evaporated and the residue was dissolved in dichloromethane (10 cm^3). After the solution was filtered through Celite to remove insoluble materials, the filtrate was concentrated and the residue was separated by TLC on silica gel. In the reaction of **1a**, the first band (R_f 0.6) from the TLC plates developed by hexane-chloroform (1/3) gave **1a**. The second band (R_f 0.3) gave pyrimidine **2a**. The third band (R_f 0.1) gave pyrazole **3a**. In reactions of **1b, c**, the first band (R_f 0.6 for **1b**; 0.7 for **1c**) from the TLC plates developed by hexane-AcOEt (6/1) gave **1b, c**. The second band (R_f 0.3 for **2b**) gave pyrimidine **2b**. The third band (R_f 0.3 for **3b**; 0.2 for **3c**) gave a mixture containing **3b,c**. This mixture was then heated in ethanol (5 cm^3) and H_2SO_4 (0.2 cm^3) under reflux. The usual workup afforded pyrazole **2** and ethyl benzoate (ca. 1—12%).

General Procedure for the Reaction of Pyrazoles 9a, b with [Mo(CO)$_6$] in Moist Toluene and/or Acetonitrile. A solution of **9** (0.5 mmol) and [$Mo(CO)_6$] (133 mg, 0.5 mmol) in moist toluene (5 cm^3) and/or acetonitrile (5 cm^3) was heated under reflux for 24 h. After the reaction mixture was concentrated, the resulting residue was purified by TLC on silica gel using hexane-AcOEt (3/1) as a developer to give the starting material: **9a** (84% in acetonitrile); **9b** (96% in acetonitrile and 94% in toluene).

General Synthesis of 2-, 3-, and 4-Hydroxyalkylphosphonium Salts by the Reaction of Triphenylphosphine with Cyclic Ethers in the Presence of Strong Acids

Shin-ichi YAMAMOTO (formerly NAKAMURA), Kentaro OKUMA,* and Hiroshi OHTA
Department of Chemistry, Faculty of Science, Fukuoka University, Jonan-ku, Fukuoka 814-01
(Received June 20, 1988)

Synopsis. Cyclic ethers were efficiently converted to the corresponding hydroxyalkylphosphonium salts by the reaction with triphenylphosphine and trifluoromethanesulfonic or trifluoroacetic acid. The reaction of these salts with bases afforded the corresponding phosphonium inner salts which reacted with carbonyl compounds to give homoallylic alcohols.

2-Hydroxyalkylphosphonium salts (**1**) are an important class of compounds because of their use in the mechanistic investigation of the Wittig reaction and their versatile synthetic utility.[1] However, there are only a few reports regarding the synthesis of **1**.[2-4] While triphenylposphine (**2**) has been found to react with epoxides (**3**) to afford olefins via betaine intermediates,[5] there is, to our knowledge, no report on the synthesis of **1** from epoxides and triphenylphosphine. Recently, we reported the convenient synthesis of (hydroxyalkyl)dimethylsulfonium salts from cyclic ethers, acid, and dimethyl sulfide.[6] This result, in turn, prompted us to investigate the possibility of the synthesis of hydroxyalkylphosphonium salts. We report here a new general and convenient method for the preparation of **1**, 3- (**4**), and 4-hydroxyalkylphosphonium salts (**5**) by the reaction of **2** with **3**, oxetane (**6**), or tetrahydrofuran (**7**) in the presence of trifluoromethanesulfonic acid (**8a**) or trifluoroacetic acid (**8b**).

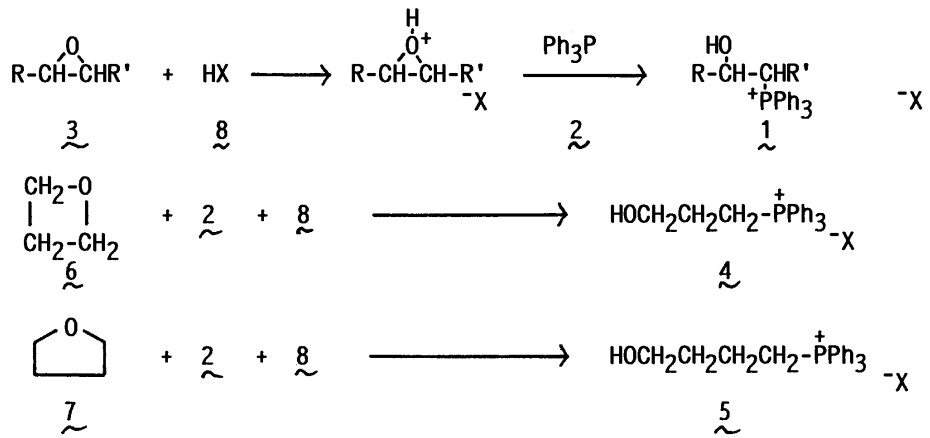
Results and Discussion

We first tried the reaction of epoxides with triphenylphosphine. Treatment of 1,2-epoxycyclohexane (**3a**) with **2** in the presence of **8a** afforded corresponding 2-hydroxycyclohexylphosphonium triflate (**1a**) in 65.0% yields. As shown in Table 1, phosphonium salts **1** were prepared in good yields. Previously, com-

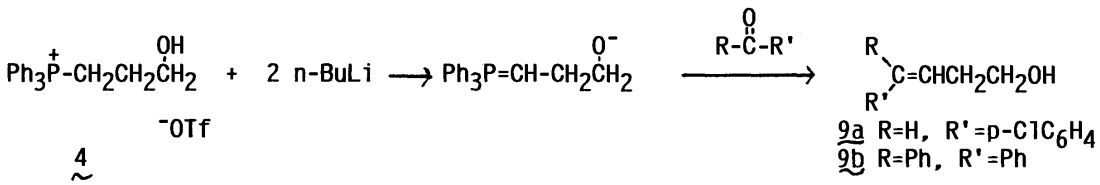
Table 1. Preparation of Hydroxyalkylphosphonium Salts

Cyclic ether	Acid		Phosphonium salt[a]	Anion	Yield/%	Mp/°C
1,2-Epoxycyclohexane	**8a**	**1a**		$^-$OTf	65.0	184—185
	8b	**1a′**		$^-$BPh$_4$	37.8[b]	219—220
2-Metyloxirane	**8a**	**1b**	$Ph_3\overset{+}{P}$-$CH_2CH(Me)OH$	$^-$BPh$_4$	78.0	172—173
	8b	**1b**			80.4	
2-Ethyloxirane	**8a**	**1c**	$Ph_3\overset{+}{P}$-$CH_2CH(Et)OH$	$^-$BPh$_4$	75.7	161—162
	8b	**1c**			69.5	
Oxetane	**8a**	**4**	$Ph_3\overset{+}{P}$-$CH_2CH_2CH_2OH$	$^-$BPh$_4$	90.0	178—179
	8b	**4′**		$^-$OCOCF$_3$	84.3	162—163
Tetrahydrofuran	**8a**	**5**	$Ph_3\overset{+}{P}$-$CH_2CH_2CH_2CH_2OH$	$^-$BPh$_4$	65.0	197—198

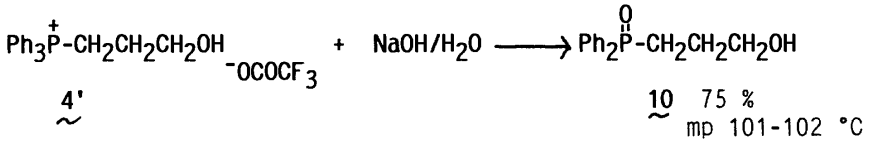
a) Since most of the products were oils, yields and elemental analyses were determined by their tetraphenylborates except **1a** and **4′**. When styrene oxide was used as epoxide, corresponding phosphonium salt could not be isolated. b) Triphenylphosphine was recovered in 34% yield



Scheme 1.



Scheme 2.



Scheme 3.

pounds **1** were obtained from the corresponding 2-hydroxyalkyl halides and triphenylphosphine,[2] by the reaction of the more nucleophilic 2,6-disubstituted triphenylphosphine with epoxides,[3] or by the reaction of phosphonium ylides with aldehydes followed by the addition of acids.[7] The reaction is stereospecific and regiospecific. The present method requires only one step and good yields were generally obtained.

Reactions of **2** with **3** have long been known to demand much more severe conditions. Products of these reactions in protic solvents are complex mixtures of triphenylphosphine oxide and alkenes formed directly from betaine or oxaphosphetane intermediates.[5] The present method will provide a much more precise mechanistic view of these reactions.

Corey and Yamamoto reported that the reaction of Wittig reagents with aldehydes gave the corresponding adducts at low temperature, which further reacted with a base to afford 2-phosphonio-1-alkanolates.[8] They also reported the reaction of phosphonium ylide anions with epoxides to give 3-phosphino-1-alkanolates.[9] Schlosser et al. and Maryanoff et al. also reported the stereoselective synthesis of alkenols from **1**.[10] The present method may be an alternative approach for the synthesis of the above alcohols. To confirm this possibility, we investigated the reaction of **4** with two equivalents of a base followed by the addition of carbonyl compounds. As expected, the corresponding homoallyl alcohols (**9a**, **b**) were obtained in good yields.

Recently, Warren and co-workers reported the stereoselective synthesis of homoallylic alcohols by the reactions of (hydroxyalkyl)diphenylphosphine oxide (**10**) with aldehydes.[11] So, we tried the preparation of **10** from **4**. As shown in Scheme 3, compound **10** was obtained in good yields.[12]

Within the current synthetic effort in organic chemistry, hydroxyalkylphosphonium salts play an important role in the total synthesis of many conventional natural products containing double bonds.[13] There is therefore a requirement for a simple preparative method for this key intermediate. This synthesis should afford many applications in olefin synthesis.

Experimental

General Methods. Melting points are uncorrected. ^{1}H NMR spectra were recorded on a JEOL JNM-90Q and a JEOL JNM-60 SI spectrometers with Me_4Si as the internal standard.

Synthesis of 1 and 4. General Procedure. To a solution of triphenylphosphine (**2**) (5 mmol) and a solution of corresponding acids (**8**) (5.2 mmol) in dichloromethane (10 mL) was added a solution of cyclic ether (**3**, **6**) (5.5 mmol) in dichloromethane (10 mL) at room temperature. After refluxing for 8 h, the reaction mixture was evaporated to give a pale yellow oil. The residue was washed with ether (20 mL) for several times to yield color less crystals. Recrystallization from dichloromethane-ether gave pure salts. **1a**: mp 184—185 °C. ^{1}H NMR ($CDCl_3$) δ=3.42 (1H, m, CH), 4.00 (1H, m, CH), 4,87 (1H, d, OH), 7.78 (15H, m, Ph). Calcd for $C_{25}H_{24}F_3O_4PS$: C, 59.05; H, 4.76%. Found: C, 59.05; H, 5.01%. **4'**: mp 162—163 °C. ^{1}H NMR ($CDCl_3$) δ=1.83 (2H, m, CH_2), 3.53 (2H, m, CH_2), 3.78 (2H, t, CH_2), 5.64 (1H, br, OH) 7.76 (15H, d, Ph). Calcd for $C_{23}H_{22}F_3O_3P$: C, 63.59; H, 5.10%. Found: C, 63.98; H, 4.80%.

Other salts were obtained as colorless oils. These compounds were converted to their tetraphenylborates for elemental analysis: To a solution of the resulting oil in acetone (5 mL) was added a solution of sodium tetraphenylborate (5.20 mmol) in acetone (5 mL). Colorless crystals of tertaphenylborates were precipitated by addition of ether (50 mL). Recrystallization from dichloromethane gave pure tetraphenylborate salts. **1a'**: mp 219—220 °C. ^{1}H NMR (DMSO-d_6) δ=3.52 (1H, m, CH), 4.76 (1H, m, CH), 5.12 (1H, br, OH), 7.66 (15H, m, Ph). Calcd for $C_{48}H_{46}BOP$: C, 84.70; H, 6.81%. Found: C, 84.90; H, 6.96%. **1b**: mp 172—173 °C. ^{1}H NMR (DMSO-d_6) δ=0.95 (3H, t, CH_3), 3.95 (3H, m, CH-CH_2), 4.70 (1H, d, OH), 7.73 (15H, m, Ph). Calcd for $C_{43}H_{42}BOP$: C, 84.37; H, 6.61%. Found: C, 84.74; H, 6.36%. **1c**: mp 161—162 °C. ^{1}H NMR (DMSO-d_6) δ=0.92 (3H, q, CH_3), 1.59 (2H, m, CH_2), 3.68 (3H, m, CH-CH_2), 5.32 (1H, br, OH), 7.72 (15H, m, Ph). Calcd for $C_{44}H_{44}BOP$: C, 84.40; H, 6.77%. Found: C, 84.78; H, 6.48%. **4**: mp 178—179 °C. ^{1}H NMR (DMSO-d_6) δ=1.64 (2H, m, CH_2), 3.51 (2H, t, CH_2), 3.72 (1H, br, OH), 7.72 (15H, m, Ph). Calcd for $C_{43}H_{42}BOP$: C, 84.37; H, 6.61%. Found: C, 84.26; H, 6.81%.

Synthesis of 5. To a solution of triphenylphosphine (**2**) (1.32 g, 5.03 mmol) in THF (10 mL) was added trifluoromethanesulfonic acid (**8a**) (0.787 g, 5.25 mmol) at room temperature. After refluxing for 8 h, reaction mixture was evaporated to give a pale yellow oil. A solution of sodium tetraphenylborate (1.80 g, 5.25 mmol) in acetone (5 mL) was added to a solution of this oil in acetone (5 mL). When ether (50 mL) was added to the mixture, colorless crystals were precipitated. Recrystallization from dichloromethane gave pure phosphonium salts (2.20 g, 65.0%). Mp 197—198 °C. ^{1}H NMR δ=1.59 (4H, m, CH_2-CH_2), 3.18 (2H, m, CH_2), 3.39

(2H, m, CH_2), 4.46 (1H, br, OH), 7.74 (15H, d, Ph). Calcd for $C_{46}H_{44}BOP$: C, 84.40; H, 6.77%. Found: C, 84.29; H, 6.87%.

Synthesis of 9. To a suspension of **4** (2.35 g, 5.00 mmol) in THF (15 mL) was added a solution of two equimolar amounts of butyllithium in THF (5 mL) at −78 °C. After stirring for 1 h, a solution of *p*-chlorobenzaldehyde (0.744 g, 5.29 mmol) or benzophenone (1.00 g, 5.47 mmol) in THF (10 mL) was added to the mixture at 0 °C. After stirring for 10 h at 30 °C, water (5 mL) was added to the mixture and the solvent was evaporated. Aq. NH_4Cl was added to neutralize the mixture. The aqueous mixture was extracted with dichloromethane (25 mL×2). The combined extracts were dried over $MgSO_4$ and evaporated to give a pale yellow oil. The resulting residue was extracted with hexane (20 mL×3). The combined extracts were evaporated to give a yellow oil. The corresponding homoallyl alcohol **9** was isolated from this oil by column chromatography on silica gel by elution with dichloromethane. **9a** was obtained as a mixture of *E*- and *Z*-isomers. Yield 74% (0.673 g). ^{1}H NMR ($CDCl_3$) δ=2.47 (2H, q, CH_2), 3.74 (2H, t, CH_2), 4.63 (1H, br, OH), 5.97—6.53 (2H, m, CH=CH), 7.25 (4H, s Ph). M^+_{found}=182.0497, $C_{11}H_{11}OCl$ (^{35}Cl) requires 182.0498. **9b**: Yield 56% (0.627 g). ^{1}H NMR ($CDCl_3$) δ=2.39 (2H, q, CH_2), 3.50 (2H, t, CH_2), 3.71 (1H, br, OH), 6.12 (1H, t, CH), 7.21 (10H, s, PH). M^+_{found}=224.1181, $C_{16}H_{16}O$ requires 224.1201.

Synthesis of 10. A suspension of **4'** (1.30 g, 3.00 mmol) in 30% aqueous NaOH (20 mL) was refluxed for 3 h. The reaction mixture was extracted with 20 mL of dichloromethane for three times. The combined extracts was dried over $MgSO_4$ and evaporated to give yellow oil. When the yellow oil was washed with ether (20 mL×3), the crystals were obtained. Recrystallization from ethyl acetate gave pure crystals (0.585 g, 2.25 mmol, 75%). Mp 101—102 °C. ^{1}H NMR ($CDCl_3$) δ=1.85 (2H, m, CH_2), 2.36 (2H, m, CH_2), 3.68 (2H, q, CH_2), 4.38 (1H, t, OH), 7.48 (10H, m, Ph). Calcd for $C_{15}H_{17}O_2P$: C, 69.22; H, 6.58%. Found: C, 69.14; H, 7.07%.

This work was partly supported by the Central Research Institute of Fukuoka University. We are grateful to Dr. Haruo Matsuyama at Tokyo Metropolitan University for the high-resolution mass spectroscopic analysis.

Withacoagin, a New Withanolide from *Withania coagulans* Roots

Partha NEOGI, Masao KAWAI, Yasuo BUTSUGAN,* Yuji MORI,† and Makoto SUZUKI†
Department of Applied Chemistry, Nagoya Institute of Technology, Showa-ku, Nagoya 466
†Faculty of Pharmacy, Meijo University, Tenpaku-ku, Nagoya 468
(Received July 14, 1988)

Synopsis. The structure of withacoagin, a new withanolide isolated from *Withania coagulans*, has been elucidated as (20*R*,22*R*)-5α,20-dihydroxy-1-oxowitha-2,6,24-trienolide by spectral analysis and chemical transformation to a known compound. This is the second report of a Δ^6-withanolide. Isolation of three known compounds, (20*R*,22*R*)-6α,7α-epoxy-5α,20-dihydroxy-1-oxowitha-2,24-dienolide, (20*S*, 22*R*)-6α,7α-epoxy-5α-hydroxy-1-oxowitha-2,24-dienolide, and withaferin A, are also reported.

Withanolides[1] are a group of ergostanolides, generally having a δ-lactone in the side chain and a 2-en-1-one system in the A ring. These are exclusive to the family *Solanaceae*[2-6] and withaferin A,[1] the first withanolide, was isolated from *Withania somnifera* L. Dun. Withanolides are interesting because they show antitumorous[2,5] antibacterial,[7] antiinflammatory,[8] and immunosupressive[9] activities.

W. coagulans Dunal, which grows widely in India and West Pakistan, is used in the Indian indigenous system of medicine[10] and fruits of the plant have milk coagulating properties.[11] In addition to a biogenetically important precursor of withanolides,[12] four withanolides from the roots,[13] two from the leaves,[14] and two from the fruits[12,15] of this plant were reported. Here we will describe the isolation from the roots of *W. coagulans* and the structure elucidation of a new withanolide (**1**), named withacoagin, as well as the isolation and characterization of three known withanolides.

Dried roots of *W. coagulans* were defatted with hexane and extracted with methanol. The extract was subjected to silica gel column chromatography and the major component **2** was characterized as the known (20*R*,22*R*)-6α,7α-epoxy-5α,20-dihydroxy-1-oxowitha-2,24-dienolide[13a] by ^{1}H and ^{13}C NMR spectra (Tables 1 and 2).

Withacoagin (**1**), also isolated from the methanol extract as colorless crystals (mp 230—232 °C), showed a molecular peak at *m/z* 454. The M^+-H_2O peak in the high-resolution mass spectrum established its molecular formula as $C_{28}H_{38}O_5$. The IR spectrum showed

a) Superscripts a1, a2, and a3 refer to interchangeable data. b) Assignments are based on Ref. 23.

absorption bands for hydroxyl (3435 cm^{-1}), cyclohexenone (1672 cm^{-1}), and α,β-unsaturated δ-lactone (1716 cm^{-1}). The ultraviolet spectrum showed absorption maximum at 225 nm (ε 12000) characteristic of summation of absorptions of the conjugated enone and the conjugated δ-lactone chromophores[16] which are commonly present in withanolides. The fragment ion peaks at m/z 169 and 125 in its mass spectrum suggested that **1** is a 20-hydroxywithanolide.[17]

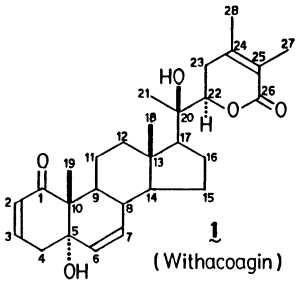
The ^1H NMR spectrum of **1** showed three singlets at δ 0.95, 1.20, and 1.32 which were assigned to C(18)-, C(19)-, and C(21)-methyl groups, respectively. The chemical shift of the deshielded C(21)-methyl singlet and the appearance of the C(22)-methine signal (δ 4.21) as a double doublet (J=13.3 and 3.5 Hz) also supported the presence of an OH group at C(20)-position. The two vinylic methyl singlets at δ 1.89 and 1.95 were assigned to the methyl groups attached to the conjugated lactone group in the side chain. The ^1H signals assignable to the hydrogens at C(18), C(21), C(22), C(27), and C(28) of **1** resembled closely to those of **2** as shown in Table 1, which suggested the identity of substitution pattern of the D ring and the side chain in **1** and **2**. Dependence of the chemical shifts of the methyl peaks upon the stereochemistry of the hydroxyl group at C(20) was already documented.[18]

The α- and β-hydrogen signals of the conjugated enone system at the A ring were observed at δ 5.89 (dd, J=10.0 and 2.4 Hz) and 6.58 (ddd, J=10.0, 5.2, and 2.2 Hz), respectively. The allylic methylene signals at δ 2.36 (dd, J=19.0 and 5.2 Hz) and 2.63 (dt, J=19.0 and 2.3 Hz) indicated that C(4) is unsubstituted and that C(5) bears no hydrogen atom. Thus, hydroxyl group can be located at the C(5)-position. Unlike the common withanolides it showed an additional set of mutually coupled olefinic proton signals at δ 5.57 (dd, J=9.9 and 2.7 Hz) and 5.73 (dd, J=9.9 and 1.7 Hz) indicating the presence of a cis-disubstituted double bond. The cis-double bond can be located either at C(6)-C(7), at C(11)-C(12), or at C(15)-C(16) position. The comparison of ^{13}C NMR spectral data of **1** and **2** given in Table 2 revealed their close resemblance except the resonances assignable to C(6) and C(7). Thus, the Δ^6-structure has been assigned to **1**. All of the 28 carbon resonance signals of **1** are consistent with the 5,20-dihydroxy-Δ^6-withanolide structure.

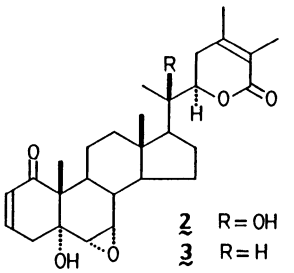
Stereochemistry of **1** was studied by the CD spectrum measured in methanol solution. A negative Cotton effect ([θ] −5200) at 333 nm observed for **1** revealed the trans juncture of the A/B ring moiety,[19] and a positive Cotton effect ([θ] +7000) at 250 nm suggested the R-configuration at C(22).[20]

Withacoagin (**1**) has been found to differ from **2** only at the moiety of C(6) and C(7), i.e., while a double bond is present in the former, the latter possesses an α-epoxide group in the corresponding position. So a chemical transformation of **1** to **2** was then attempted to prove the structure of **1**. Epoxidation of **1** with m-choloroperbenzoic acid yielded an epoxide which was identical in all respects with the naturally occuring **2**. Thus, structure of **1** was established unambiguously as (20R,22R)-5α,20-dihydroxy-1-oxowitha-2,6,24-trienolide. This compound constitutes the second example of a Δ^6-withanolide.[17]

The third compound (**3**) isolated from the roots, mp 254—255 °C, was found to be isomeric with **1** and showed close resemblance in spectral properties to its congener **2**. Detailed analysis of the ^1H and ^{13}C NMR spectral data revealed that **3** is a 20-dehydroxy analog of **2**. The compound **3**, namely (20S,22R)-6α,7α-epoxy-5α-hydroxy-1-oxowitha-2,24-dienolide, is known as lycium substance B, isolated earlier from *Lycium chinense* and *Datura* species,[21,22] but this is the first report of the isolation of **3** from a *Withania*



1 (Withacoagin)



2 R=OH
3 R=H

species. The study of ^{13}C NMR spectra with DEPT method indicated that the assignments of C(10) and C(17) resonances in the original paper[21a] should be interchanged as shown in Table 2.

In addition to the three withanolides **1**, **2**, and **3** described above, withaferin A was also isolated, though only in minor quantity, from the extracts of *W. coagulans* and was characterized by ^1H NMR spectroscopy.

Withanolides are significant for displaying antitumour activity. Withacoagin (**1**), compound **2**, and lycium substance B (**3**) were studied for their cytotoxicity against HeLa cells. All the three compounds, however, did not show significant antitumour activity, i.e., inhibitory concentrations of **1**, **2**, and **3** to the proliferation of HeLa cells were 84, 87, and >100 $\mu g\,ml^{-1}$, respectively. While these impotent withanolides contain a 5α-hydroxyl and/or a 6α,7α-epoxy group, the cytotoxic withanolides possess a 5α,6β-epoxy group.[2,5] In the case of physalins, cytotoxic steroids from *Physalis* plants having highly oxygenated ergostane skeleton, it was proposed that α-hydroxyl and α-epoxy groups at ring A or ring B markedly decrease the cytotoxicity and that β-hydroxyl and β-epoxy groups increase or do not affect the activity.[24]

Experimental

Melting points are uncorrected. Optical rotation was measured using a JASCO DIP-4 digital polarimeter. IR

spectra were recorded as KBr discs on a JASCO IRA-1 spectrometer and FT-IR on a JEOL JIR-100 instrument using a diffuse reflectance accessory. NMR spectra were run on a JEOL JNM-GX 400 spectrometer at 400 MHz for ^{1}H NMR and at 100 MHz for ^{13}C NMR with $CDCl_3$ solutions. UV, CD, and mass spectra were measured on HITACHI 124, JASCO J-40C, and HITACHI M 2000 spectrometers, respectively. Column chromatography was performed using SiO_2 (Merck, Silicagel 60, 7734). Precoated SiO_2 plates (Merck, Silica Gel 60 F_{254}) were used for TLC analysis and R_f values with $CHCl_3$-MeOH (19 : 1) system are given.

Plant Material. The roots of *W. coagulans* Dunal were purchased from United Chemicals and Allied Products, Calcutta, India and a specimen sample is being preserved.

Isolation. The air-dried roots (3.0 kg) were powdered, defatted with hexane, and extracted twice with cold MeOH. The MeOH extract was chromatographed over SiO_2 and the column was eluted with hexane-AcOEt (1 : 0, 3 : 1, 1 : 1, 1 : 2, and 0 : 1). The eluates with hexane-AcOEt (1 : 1 and 1 : 2) were pooled together and subjected to repeated chromatography using $CHCl_3$-MeOH as eluent to yield **1** (62 mg), **2** (650 mg), **3** (40 mg), and withaferin A (43 mg).

Withacoagin (1). Colorless needles from $CHCl_3$; mp 230—232 °C; R_f 0.29; $[\alpha]_D^{24}$ +114° (*c* 0.19, $CHCl_3$); IR (KBr) 3435, 1716, and 1672 cm^{-1}; UV (MeOH) 225 nm (ε 12000); MS (70 eV) *m/z* (rel intensity) 454 (M+; 0.2), 436 (M^+-H_2O; 5), 421 (2), 311 (57), 269 (15), 171 (25), 169 (16), 148 (16), 134 (18), 125 (100), 85 (15), and 69 (12); CD (MeOH) $[\theta]_{333}$ −5200, $[\theta]_{268}$ 0, and $[\theta]_{251}$ +7000. Found: *m/z* 436.2576. Calcd for $C_{28}H_{36}O_4$: M−H_2O, 436.2611.

Compound 2. Colorless needles from $CHCl_3$; mp 282—285 °C (decomp) (lit,[13] mp 282—284 °C); R_f 0.36.

Compound 3. Colorless plates from $CHCl_3$; mp 252—254 °C (lit,[21b] mp 260—65 °C); R_f 0.55.

Withaferin A. Colorless needles from $CHCl_3$; mp 241—243 °C (lit,[1] mp 243—245 °C); R_f 0.35.

Epoxidation of 1. To a solution of **1** (10 mg) in $CHCl_3$ was added *m*-chloroperbenzoic acid (10 mg) and stirred at room temperature for 26 h. Usual workup and SiO_2 column chromatography ($CHCl_3$) yielded a solid (7.6 mg), which crystallized from $CHCl_3$ as fine needles, mp 286—289 °C; FT-IR (KBr) 3456, 3429, 1716, 1683, 1373, and 1344 cm^{-1}. The FT-IR spectrum of this epoxide was found to be indistinguishable with that of **2**.

The authors are grateful to Mr. Jun'ichi Ohya of Pharmaceuticals Laboratory, Mitsubishi Chemical Industries Ltd. for the assay of cytotoxic activity and to Instrument Center, Nagoya Institute of Technology for mass spectra and FT-IR measurements.

Synopsis. Difluorotricarbonylmolybdenum $MoF_2(CO)_3$ has been synthesized by selective fluorination of molybdenum carbonyl by xenon difluoride in perfluoro solvents as well as in anhydrous hydrogen fluoride. The titled compound was isolated as an orange yellow solid and its composition was established by elemental analysis. It decomposes very slowly at room temperature, but on heating at 100 °C it decomposes completely to yield molybdenum carbonyl, molybdenum fluoride oxide and molybdenum fluoride. The compound was structurally characterized using IR, mass spectral, and X-ray powder diffraction analysis.

Sharp in 1960 reported[1] the preparation of dicarbonyl octafluoro platinum $PtF_8(CO)_2$ and dicarbonyl trifluoro rhodium $RhF_3(CO)_2$, though the existence of these compounds is still considered to be doubtful. Haig[2] later proved that dicarbonyl octafluoro platinum was nothing but dibromo dicarbonyl platinum. O'Donnell and Phillips[3] reported the isolation of $MoF_4(CO)_4$ from the reaction mixture of molybdenum hexacarbonyl and molybdenum hexafluoride in Kel-F system. The product obtained by Donnell and Phillips,[3] was however, contaminated with molybdenum tetrafluoride oxide and unreacted molybdenum carbonyl as well molybdenum pentafluoride. The same authors[4] also studied the fluorination of rhenium carbonyl by rhenium fluoride and have isolated a compound which was formulated to be $ReF_3(CO)_3$. Bruce and coworkers[5] have made a systematic study of the reaction of rhenium carbonyl with rhenium hexafluoride in anhydrous hydrogen fluoride and have isolated two types of products: orange presin and green platelets in very high yield. O'Donnell and Phillips[6] later modified their version and have reported the formation of $ReF(CO)_5$ from the reaction between rhenium carbonyl and rhenium hexafluoride; further reaction of $ReF(CO)_5$ with XeF_2, they asserted yielded $ReF_3(CO)_3$. One of the authors (SNM) attempted the selective fluorination of rhenium carbonyl by xenon difluoride in perfluoro solvents and had isolated a complex having the composition $3[ReF_2(CO)_3]\cdot ReF_5$. Similar interesting results were obtained when iridium system was studied. In view of this we have tried to prepare difluorotricarbonyl molybdenum; isolation and structural characterization of this compound are reported in this paper.

Experimental

Reaction of Molybdenum Carbonyl and Xenon Difluoride in Inert Solvent Genetron/Perfluoro Hydrocarbons Like PP-3 (Perfluoro-1,3-dimethylcyclohexane) and PP-9 (Perfluoro-1-methyldecaline). The apparatus used is shown in Fig. 1. Hexacarbonyl molybdenum (0.360 g) was transferred to the reaction flask and it was connected to the vacuum line and evacuated. The glass vacuum line was evacuated to exclude moisture and air. Perfluoro hydrocarbons or genetron was condensed in the reaction flask by the help of Taps T_1, T_2, T_3. All the taps were closed and the delicate glass seal of xenon difluoride tube was broken by dropping nickel balls through a magnet and xenon difluoride was condensed in the reaction flasks maintained at liquid oxygen temperature. The reaction was exothermic and resulted in the isolation of orange solid. Excess solvent was then distilled out and the

Fig. 2. Metal vacuum line with Kel-F reaction vessel.

system was pumped for overnight to remove unreacted xenon difluoride and other volatile contaminant. The reaction vessel was then disconnected from the line by sealing off its narrow end and immediately transferred to the inert box (yield 63%). Found: Mo, 43.6; C, 15.8; F, 18.4%. Calcd for $MoC_3O_3F_2$: Mo, 44.5; C, 16.3; F, 17.2%.

Reaction of Molybdenum Carbonyl and Xenon Difluoride in Stoichiometric Ratio 1:2 in Anhydrous Hydrogen Fluoride in Metal Vacuum Line. The reaction was carried out in assembly shown in the Fig 2. Both Kel-F tubes were first seasoned with hydrogen fluoride overnight. One of the tubes was removed from the line and placed in the dry box. A weighed amount of molybdenum carbonyl (0.4 g) was then transferred to the tube and the tube was connected to the vacuum line and evacuated. Anhydrous hydrogen difluoride (0.5 g) was condensed in another Kel-F tube which already had xenon difluoride. Both the tubes were then connected by opening the values in between them so that xenon difluoride hydrogen fluoride mixture slowly gets condensed in the tube containing molybdenum carbonyl. This assembly was left as such overnight. An orange crystalline solid separated out from the resulting orange solution. The solvent was then removed with the isolation of more and more solid. The product was purified by repeated washing with anhydrous hydrogen fluoride in the vacuum line. Found: Mo, 44.0; F, 18.0%. Calcd for $MoC_3O_3F_2$: Mo, 44.5; F, 17.2%.

Purification of Carbonyl Fluoro Molybdenum. Tricarbonyl difluoro molybdenum was taken in quartz tube B in the inert box and the assembly was evacuated by attaching it to the vacuum line. Tungsten hexafluoride was condensed at tube B by cooling it at liquid air temperature. After collecting sufficient amount of WF_6 the tube B was warmed up to the room temperature and left for two hours. The whole assembly was then rotated by 180° so that insoluble carbonyl fluoro molybdenum remained in the tube B while soluble fluorides of molybdenum collected in the tube A. Excess WF_6 was pumped back to the storage tube and the product in the tube B was dried in vacuo and characterized by analysis and IR.

Molybdenum in this complex was estimated by fusing with NaOH and Na_2O_2 mixture followed by precipitating metal gravimetrically as 8-hydroxy quinolinate. Fluorine in this compound was estimated by Seels' method.

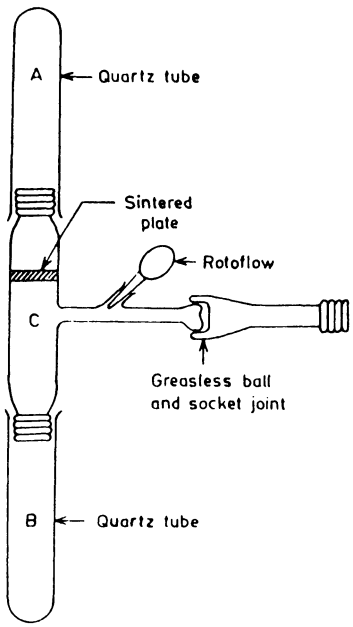

Fig. 3. Assembly used for the purification of cabonyl fluoride.

The molecular weight of carbonylfluoromolybdenum was determined in anhydrous hydrogen fluoride cryoscopically; this revealed a molecular complexity of around 4, thus indicating the molecules to be a tetramer, having the composition $[MoF_2(CO)_3]_4$.

Results and Discussion

O'Donnell and Phillips claimed to have isolated a polymeric dicarbonyltrifluoromolybdenum(III)[6] from the reaction mixture of molybdenum hexafluoride and hexacarbonyl molybdenum(0) in Kel-F apparatus. However, an attempt made by Edward and coworkers[8] to study the same reaction in glass apparatus resulted in the formation of fluorides of molybdenum and with

no evidence for the formation of any other compounds. O'Donell's samples were invariably contaminated with molybdenum pentafluoride and molybdenum tetrafluoride oxide.

Holloway and Szary[9] have made a systematic study of molybdenum carbonyl molydbenum pentafluoride system in genetron and in anhydrous hydrogen fluoride in the stoichiometric ratio of 1 : 1. They have observed that the reaction was slow in genetron but faster in anhydrous hydrogen fluoride. The product showed carbonyl stretching at 2145 (s) and 2060 (s) cm^{-1}. This compound was neither molybdenum pentafluoride nor carbonylfluoro complex, which is generally formed in xenon difluoride reaction. The resulting product was identical with the one isolated by O'Donnell; however, Holloway and Szary have proposed the following formulation for the resulting compound:

$[Mo(CO)_6]^+[MoF_6]$ or $[Mo(CO)_6]^+[Mo_2F_{11}]$ or $[Mo(CO)_5]^+[Mo_3F_{16}]$ or $[Mo(CO)_4F_2][Mo_2F_{11}]$

Elemental analyses of the products obtained in our reactions established the stoichiometry unequivocally as $Mo(CO)_3F_2$. The bands observed in the region 2200—1900 cm^{-1} in the infrared spectrum of carbonylfluoromolybdenum are typical of terminal carbonyl ligands [ν_{CO} at 2125(s), 2085(s), 2035(s), 1980(s), 1950(s)]. Since the carbonyl fluoride contains highly electronegative fluorine as substituent, it is not surprising that the carbonyl frequencies are also observed at higher wavenumber than the parent carbonyl complex. A comparison of the infrared spectra of the carbonylhalogeno complexes of molybdenum [$MoCl_2(CO)_3$ ν_{CO} at 2100(s), 2050(s), 1980(s), 1956(s), and $MoBr_2(CO)_3$ ν_{CO} at 2098(s), 2080(s), 2007(s), 1958(s)] confirm that these shift to lower wavenumber as the substituent changes from fluorine to bromine.

The Mo-F stretching frequencies were observed at 660 (w), 620 (w), 600 (w), and 560 (w) cm^{-1} indicating terminal and bridging fluoride ligands.

In the tricarbonyldifluoromolybdenum, the metal has d^4 configuration, which is quite susceptible to Jahn Teller distortion to one of the lower states, which will destroy the electronic degeneracy. When the distortion energy is comparable to the energy of the relevant vibration mode, no static distortion will be observed; however, certain abnormalities in the electronic spectra are expected as a result of electronic coupling.

The mass spectrum of tricarbonyl difluoromolybdenum indicated the presence of some fragments with dimeric units such as $[MoF_2(CO)_2]^+$, $[MoF_2(CO)_3]^+$, and $[MoF_4(CO)_4]^+$ along with several monomeric units, suggesting the molecular complexity to be more than two.

Our efforts to grow single crystals suitable for a detailed X-ray diffraction study were met with no success. However, a decent powder pattern of the substance could be recorded with Ni filtered Cu $K\alpha$ radiation. The analysis of this photograph showed that though the compound gives a pattern similar to that of tricarbonyl difluororuthenium, for which a detailed X-ray study has been carried out by Peacock et al.,[10] the intensities differ somewhat. The powder pattern could be indexed on an orthorhombic cell of dimensions a=11.221, b=10.742, and c=9.384 Å. The density calculated on the basis of 8 formula units per unit cell is 2.560 g cm^{-1}. The study on the ruthenium[10] compound also indicated that it exists as a tetrameric unit with fluorides in cis arrangement and in bridging positions.

A mechanistic study on the structural arrangement can be attempted on the following lines. The formation of 'cis' isomer from hexacarbonyl complex and fluorine can be tentatively explained by assuming simultaneous attack of hexacarbonyl complex by two atoms of the fluorine molecule. The alternate possibility of heterocyclic cleavage of fluorine molecule to give the nucleophilic fluorine would result in the preliminary introduction of the 'first fluorine'; entry of the second fluorine in the cis position would certainly be statistically favored and most probably electronically favoured too in view of the strong 'trans' effect of the carbon monoxide ligand.

One of the authors (S.N.M.) is extremely grateful to Prof. R. D. Peacock of Leicester University for providing a Senior Research Fellowship (1970—72) and his keen interest in this field.

Synthesis, Characterization, and the Thermal Decomposition of Copper(II) Bis(oxalato)cuprate(II) Dihydrate

Nidhuban Deb, Pradip K. Gogoi, and Narendra N. Dass*
Department of Chemistry, Dibrugarh University, Dibrugarh 786004 (Assam), India
(Received January 14, 1988)

Synopsis. Copper(II) bis(oxalato)cuprate(II) dihydrate, $Cu[Cu(C_2O_4)_2]\cdot 2H_2O$, has been synthesized and characterized by elemental analysis, magnetic moment measurement, and IR, electronic and ESR spectral studies. The low value of magnetic moment (1.57 B.M.) from spin-only value is indicative of the antiferromagnetic spin pairing between two paramagnetic copper(II) ions. The ESR spectrum of the powder showed a single signal with a g value of 2.1. The thermal decomposition in air and nitrogen media was investigated by TG, DTG, and DSC. Some of the decomposition products were identified by spectral, analytical and X-ray powder diffraction studies.

There has been a considerable interest in the study of oxalato complexes of transition metals[1-10] and much of the work have been periodically reviewed.[11] Binuclear complexes of Cu(II) with oxygen donor ligands involving metal-metal bonding have been reported.[12-16] However, studies on the compounds of the type $M[M(C_2O_4)_n]\cdot xH_2O$, [where M=same metal] are still rare.[17] The synthesis of copper(II) bis(oxalato)-cuprate(II) dihydrate, has not been reported so far. Here we are reporting the synthesis and characterization of copper(II) bis(oxalato)cuprate(II) dihydrate, $Cu[Cu(C_2O_4)_2]\cdot 2H_2O$. The thermal decomposition was also investigated and a tentative mechanism of thermal decomposition has been proposed.

Experimental

Materials. Copper(II) hydroxide, prepared from copper(II) chloride was made free from chloride. It was dissolved in glacial acetic acid and the mixture was heated on a steam bath. A light blue compound was precipitated by dropwise addition of a saturated solution of oxalic acid in glacial acetic acid. The compound was filtered off and purified by standard procedure.[17] The compound was insoluble in common organic solvents, however, decomposes in presence of acid or alkali. The water content was determined thermogravimetrically, while copper content was determined iodometrically. The percentages of carbon and hydrogen were estimated with Thomas CH analyzer. Found: C, 14.42; H, 1.13; Cu, 37.62; H_2O, 10.56%. Calcd for $C_4H_4O_{10}Cu_2$: C, 14.17; H, 1.19; Cu, 37.48; H_2O, 10.61%.

Measurements. IR spectra of the gases evolved were recorded by the reported method[17] and those of the complex and the intermediates were recorded on a Perkin-Elmer 781 spectrophotometer in CsI as well as in Nujol. The low frequency IR spectrum (600—100 cm^{-1}) of the complex was obtained using a Polytec FIR-30 instrument. Diffuse reflectance spectrum was recorded with a Shimadzu UV-240 spectrophotometer using $BaSO_4$ as the reference material. ESR spectrum at liquid nitrogen temperature was obtained on a Varian E-line century series ESR spectrometer with TCNE as marker. The magnetic moment of the complex was measured as described earlier.[17] The thermogravimetric (TG) and derivative thermogravimetric (DTG) curves were obtained in the range from room temperature to 800 °C with a Perkin-Elmer thermal analyzer at a heating rate of 10 °C min^{-1}. Differential scanning calorimetric (DSC) screen was performed using a Mettler TA 3000. The experiment was carried out in air purged at a rate of 30 cm^3 min^{-1} with a heating rate of 10 °C min^{-1}. X-Ray powder diffraction patterns of the decomposition products were taken using Cu $K\alpha$ radiation. The time of exposure was 4 h. The residues were identified by direct comparison with photograph of standard materials. For decomposition the complex was heated in a tube as described earlier.[17]

Results and Discussion

Spectral and Magnetic Studies. The room temperature magnetic moment of the compound was 1.57 B.M. The considerable lowering on μ_{eff} from the spin-only value may be attributed to extreme distortion or partial quenching of the spin moment of the copper ions[18] or may be due to the presence of intramolecular exchange interaction between adjacent copper atoms.[19] In the ESR spectrum of the powdered compound at liquid nitrogen temperature, a strong signal with a g value of 2.1 was obtained. From the above results a binuclear configuration of the compound with antiferromagnetic spin pairing between two paramagnetic copper(II) ions could be suggested.[12,20] Further, the electronic spectrum of the solid sample (Fig. 1) showed bands around 13260 sh, 15500, 20200, 33100, and 40800 cm^{-1}, of which the bands around 13000—20000 cm^{-1} are d-d transitions. The shoulder at 13260 cm^{-1} and the band at 15500 cm^{-1} are tentatively assigned to $\delta\rightarrow\sigma(d_{x^2-y^2}\rightarrow d_{z^2})$ and $\delta\rightarrow\pi$ or $\delta'[d_{x^2-y^2}\rightarrow d_{zx}, d_{yz}, \text{or } d_{xy}]$ respectively.[16] The intense bands observed at higher frequencies are L→M or M→L charge transfer, of which the band at 33100 cm^{-1} could be possibly due to transition involving the Cu-Cu bond.[21] The two

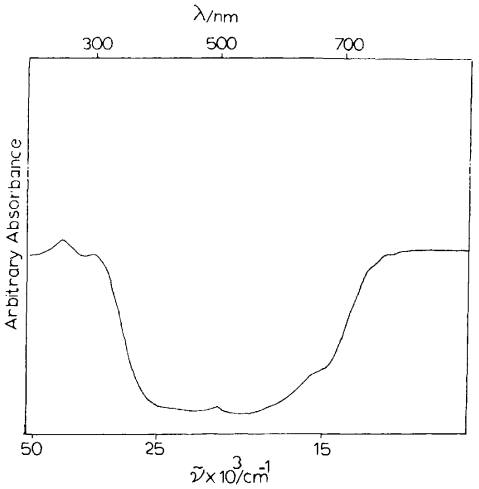

Fig. 1. Reflectance spectrum of $Cu[Cu(C_2O_4)_2]\cdot 2H_2O$.

copper atoms may be linked by either a δ bond (by lateral overlap of two $d_{x^2-y^2}$ orbitals with their lobes parallel) or σ bond due to end to end on overlap of d_{z^2} orbitals. In view of the g value of 2.1 and on the basis of valance bond and molecular orbital arguments[12,16] the nature of the Cu-Cu covalent bond is likely to be δ-type. The chelating character of the oxalato group was identified by IR spectroscopy[22] as shown in Table 1. In the farinfrared region a sharp peak at 188 cm^{-1} is due to Cu-Cu stretching vibrations[23] which further substantiated the presence of metal-metal bond.

TG, DTG, and DSC Studies. In the TG plot of the complex in nitrogen and air media (Fig. 2) the respective weight losses of 5.2% (at 292 °C) and 5% (at 298 °C) indicated the removal of one molecule of water. The calculated mass loss for this is 5.3%. Removal of this water at high temperature is suggestive of coordination with the metal ion with possible hydrogen bonding with the chelated oxalato group. Beyond 292 °C in nitrogen a steep slope up to 322 °C with a weight loss (Found 56.79%; Calcd 57.80%) indicated the formation of a mixture of Cu and CuO. The formation of a mixture of Cu and CuC_2O_4 as an unstable intermediate cannot be ruled out as CuC_2O_4 decomposes immediately to CuO at about 310 °C.[1,8] Corresponding to this overall decomposition a sharp peak ranging between 246—322 °C with a ΔT_{max} of 309 °C was obtained in DTG curve. The activation energy and order of reaction of the overall decomposition stage were computed on the basis of the Freeman and Carroll's equation[24] and were found to be 348.14 kJ mol^{-1} and 1.5 respectively. The rise in the TG curve beyond 322 °C and stabilization around 483 °C with a net gain of weight by 3.79% and overall weight loss (Found 53%; Calcd 53.08%) indicated the formation of a probable stable compound like 2CuO. The gain in weight may be due to the presence of carbon formed during disproportionation of some CO(g) to C and CO_2(g), due to catalytic activity of CuO.[25] The reduction of some amount of CuO to elementary copper by CO(g) cannot be ruled out.[7] In air medium beyond 298 °C a steep slope up to 310 °C in TG curve with a weight loss 84.75% apparently indicated the formation of metallic copper. This was confirmed as the positions and number of lines in the X-ray diffraction powder photograph exactly coincide with that obtained from pure copper wire. The activation energy and order of decomposition were calculated to be 503.63 kJ mol^{-1} and 1 (unity) respectively. In the DSC curve recorded in air (Fig. 3), the presence of two overlapping exotherm indicated that the complex decomposes via two stages. The first exotherm at 260.3—312 °C with a ΔT_{max} of 295.7 °C with activation energy and enthalpy change 252.79±10.38 and 155.09 kJ mol^{-1} respectively. The second exotherm at 312—329 °C with a ΔT_{max} of 323.4 °C with respective activation energy and enthalpy change 412.51±16.64 and 99.17 kJ mol^{-1}. The intermediate compound formed corresponding to first exotherm could not be identified by the temperature arrest technique as it was immediately decomposed to subsequent product and is suggestive of the removal of coordinated water molecule. The weight loss (Found 53%; Calcd 53.08%) after complete decomposition indicated the compound to be 2CuO. The residue gave an analysis, Cu, 80.15% compared to the calculated value of 79.88%. The X-ray

Table 1. Selected Bands in the Infrared Spectrum of the Complex $Cu[Cu(C_2O_4)_2]\cdot 2H_2O$

IR band/cm^{-1}	Assignment
3200—3660b	ν_{sy}(O-H)+ν_{asy}(O-H)
1610s	δ_{sy}(H-O-H)
1500—1750b	ν_{asy}(C=O)
ca. 1390m	ν(C-O) and/or ν(C-C)
ca. 1350s, ca.1305s, and ca. 1265m	ν(C-O) and/or δ(O-C=O)
810s	ν(Cu-O) and/or δ(O-C=O)

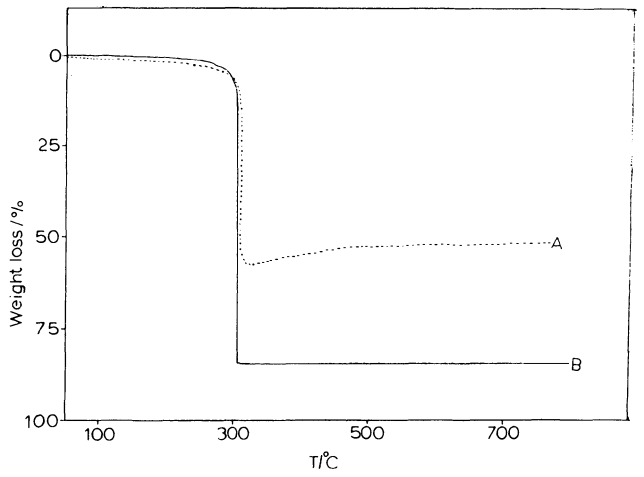

Fig. 2. A: TG curve of $Cu[Cu(C_2O_4)_2]\cdot 2H_2O$ in a flowing nitrogen atmosphere. B: TG curve of $Cu[Cu(C_2O_4)_2]\cdot 2H_2O$ in a flowing air atmosphere.

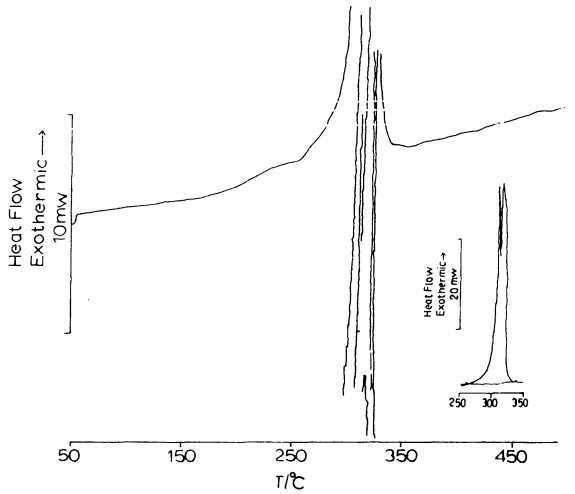

Fig. 3. DSC curve of $Cu[Cu(C_2O_4)_2]\cdot 2H_2O$ in a flowing air atmosphere.

powder diffraction photograph is similar to that of pure CuO which confirmed the black residue to be 2CuO. In the farinfrared absorption spectrum of the residue the presence of band around 600, 540, 410, and 310 (strong) cm^{-1} further substantiated the compound to be 2CuO.[26] In comparison with TG in air discussed above, the corresponding weight loss in DSC is 53% instead of 84.75% and apparently this could be due to the escape of CO(g) through the pan hole before reducing CuO. X-Ray powder diffraction analysis of the product obtained on heating beyond 310 °C in a closed vessel suggested the reduction of CuO to metallic copper.[27] The infrared spectral analysis[22] of the gaseous products confirmed the evaluation of both carbon monoxide and carbon dioxide.

On the basis of above results the following thermal decomposition processes in nitrogen medium may be suggested.

$$Cu[Cu(C_2O_4)_2]\cdot 2H_2O \xrightarrow{\text{ca. } 292\,^\circ C} Cu[Cu(C_2O_4)_2]\cdot H_2O$$

$$+ H_2O(v) \xrightarrow{322\,^\circ C} Cu + CuO + H_2O(v) + CO_2(g)$$

$$+ CO(g) \xrightarrow{\text{ca. } 483\,^\circ C} 2CuO \text{ (stable)}.$$

We thank the RSIC, CDRI, Lucknow for C, H analysis and IR spectra, RSIC, IIT, Madras for low frequency IR spectra, RSIC, IIT, Bombay for the ESR spectra, RSIC, Nagpur University for TG and DTG and Dr. S. K. Datta of Forensic Science Laboratory, Gauhati, Assam for DSC.

Organophosphorus Analogues and Derivatives of the Natural L-Amino Carboxylic Acids and Peptides. V.[1] Synthesis of Analogues of Plumbemycin A

Ivan A. NATCHEV
Research Centre Konstrukcionni Polymeri, 5-003 Gara Iskar, 1528 Sofia, Bulgaria
(Received October 3, 1987)

Synopsis. Analogues of antibiotic Plumbemycin A were synthesized by an exchange of D-norvaline residue with 1,2,3,6-tetrahydro-1,2-azaphosphorine and by coupling of alanylaspartic acid with N-terminal norvaline. The protecting groups were released by highly selective enzyme hydrolysis.

With a view to studying the relationship between the structure and the physiological activity, we wish to report some of the chemical modifications of the tripeptide antibiotic Plumbemycin A.[2,3]

As a starting substance for the first modification, we have selected (*R*)-2-ethoxy-1,2,3,6-tetrahydro-1,2-azaphosphorine-6-carboxylic acid 2-oxide (**1**) [H-Phos(OEt)-OH] recently synthesized by us. The condensation with H-Ala-Asp(OEt)-OEt (**2**)[4] was carried out by the usual DCC method for peptide synthesis to give H-D-Phos(OEt)-Ala-Asp(OEt)-OEt in a yield of 72—75%.

As the tetrahydro-1,2-azaphosphorine ring is very unstable under the conditions of both base- and acid-catalyzed hydrolysis, we have chosen the method[5] of enzyme-catalyzed hydrolysis of substrates containing organophosphorus groups.

It was found that the enzyme phosphodiesterase I hydrolyzes only the ethoxyphosphinylidene group of **3** to give the corresponding free cyclic derivative **4** quantitatively.

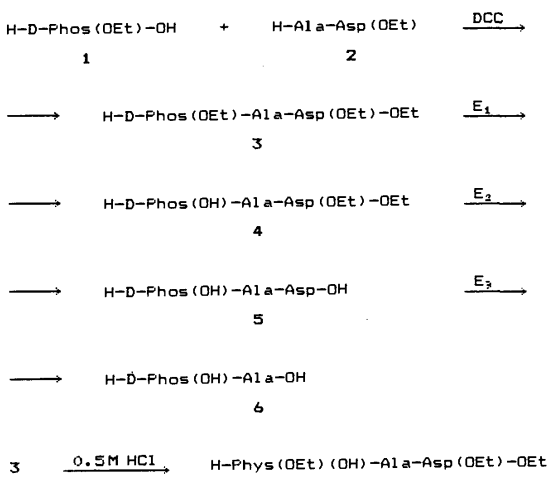
The hydrolysis of the *O*-protected groups of **4** can not be carried out by conventional methods of base- or acid-hydrolysis,because the 1,2-azaphosphorine ring is easily hydrolyzed in the bond PO-NH. The ester hydrolysis of **4** with alkaline mesintericopeptidase was applied successfully to give the corresponding free tripeptide **5**.

When the treatment of **5** with α-chymotrypsin is carried out, only the hydrolysis of the peptide bond in Ala-Asp sequence took place to give H-D-Phos(OH)-Ala-OH (**6**) (see Scheme 1) due to the D-tetrahydro-1,2-azaphosphorine ring. It is worthwhile noting that the catalytic activity of phosphodiesterase I is quite independent on the optical form of 2-ethoxy-1,2,3,6-tetrahydro-1,2-azaphosphorine 2-oxide.

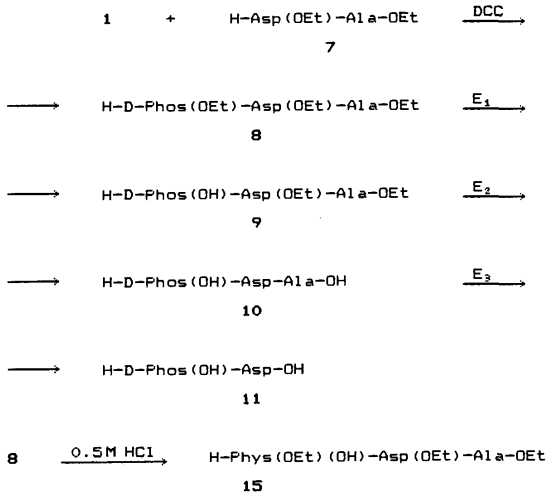
An analogous scheme was applied for the synthesis of the other possible modified peptide with C-terminal Ala residue. The condensation of **1** with H-Asp(OEt)-Ala-OEt (**7**)[6] was carried out by the DCC method described above to give the expected tripeptide **8** obtained in ca. 75% yield. The subsequent enzyme-catalyzed hydrolysis of the ethoxyphosphinylidene group of **8** with phosphodiesterase I was similarly worked up under the above conditions to give the corresponding tripeptide **9**. The two ethylesters of **9** were hydrolyzed with alkaline mesintericopeptidase to give the free tripeptide **10**.

Following Scheme 1, we subjected **10** to a treatment similar to that employed for α-chymotripsin. As was expected, enzyme-substrate interaction took place to give H-D-Phos(OH)-Asp-OH (**11**) in about 90% yield (Scheme 2).

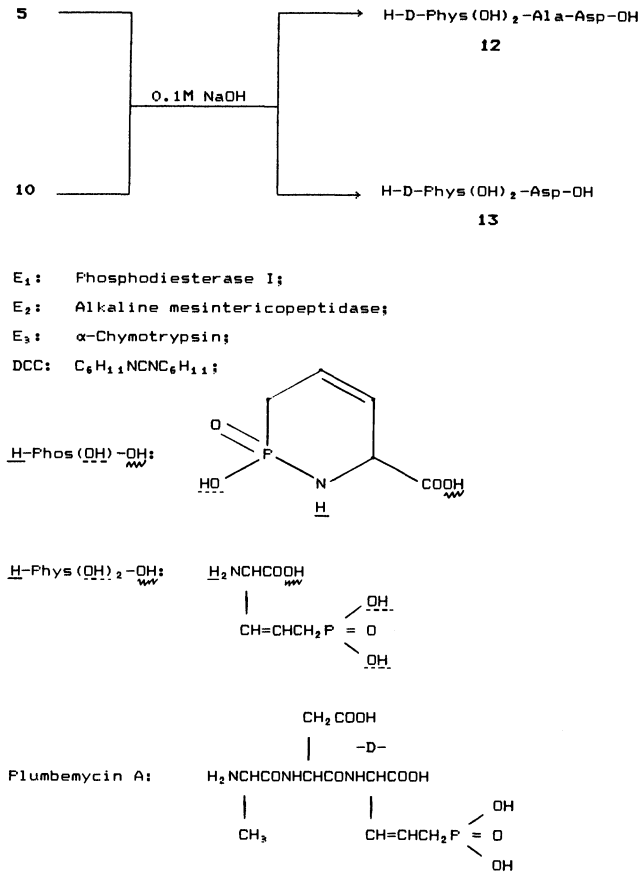
The marked difference in the case of hydrolysis of the peptide bond on the one hand and the 1,2,3,6-tetrahydro-1,2-azaphosphorine ring on the ether makes it possible to be "soft" base-catalyzed hydrolysis and to obtain Plumbemycin A analogues, which L-amino acids were arranged each other. However, heating **5** and **10** in 0.1 M NaOH (1 M=1 mol dm^{-3}), the



Scheme 1.



Scheme 2.



Scheme 3.

H-D-Phys(OH)$_2$-Ala-Asp-OH (**12**) and H-D-Phys-(OH)$_2$-Asp-OH (**13**) were obtained in about 90% yields, respectively (Scheme 3).

The facile hydrolysis of PO-NH bond also occured when compounds **3** and **8** were treated with dilute hydrochloric aicd. As a result, the protected tripeptides **14** and **15**, in which ethoxyl groups remain unchanged, were obtained in about 80% yields in both cases.

Preliminary tests for physiological activity point to some interesting problems with structure changes of the studied compounds. Thus, the modified tripeptides **5** and **10** were found to have a more pronounced bactericidal activity than Plumbemycin A, whereas that of three tripeptides **12**, **13**, and Plumbemycin A is almost the same. The modified aspertic acid **11** was proved to possess the highest bactericidal activity, while that of the modified alanine **6** is much weaker, though still better pronounced than that of Plumbemycin A. A detailed study of the discussed activities is now under way and will be published separately.

Experimental

General. IR spectra, elemental analysis, mp, HPLC, and $[\alpha]_D^{20}$ were measured with Perkin-Elmer instruments; TLC-molybdophosphate acid or ninhydrin detection; enzymes and buffers from "Signa."

H-D-Phos(OEt)-Ala-Asp(OEt)-OEt (3) and H-D-Phos-(OEt)-Asp(OEt)-Ala-OEt (8). A mixture of **1** (20.52 g, 0.12 mol) and dipeptides **2** (26.03 g, 0.10 mol) or **7** (22.70 g, 0.11 mol) and DCC (22.70 g, 0.11 mol) in dry ethyl acetate (250 ml) was stirred at room temperature for 12 h. After filtration, the filtrate is washed consecutively with 5% aqueous sodium carbonate, water, 5% hydrochloric acid, water, and finally dried over anhydrous $MgSO_4$ and distilled. The oily residue was purified on a silica-gel column using a mixture of chloroform and methanol (9:1). After evaporation under vacuum the residue was dissolved in dry ethyl acetate (200 ml) and cooled to −5 °C and then hexane was added until the mixture became turbid. The mixture was left overnight in refrigerator and products precipitated were collected.

Compound 3: Yield, 32.71 g (73.1%); mp 73—75 °C (EtOAc/*n*-C_6H_{14}); R_f: 0.76 (DMF:$CHCl_3$:MeOH=2:8:1); $[\alpha]_D^{20}$ 78.3° (*c* 1, MeOH).

Found: C, 48.66; H, 6.52; N, 9.38%. Calcd for $C_{18}H_{30}N_3O_9P$: C, 48.31; H, 6.76; N, 9.39%.

Compound 8: Yield, 34.14 g (76.3%); mp 98—101 °C (EtOAc/*n*-C_6H_{14}); R_f: 0.80 (DMF:$CHCl_3$:MeOH=2:8:1); $[\alpha]_D^{20}$ 79.1° (*c* 1, MeOH).

Found: C, 48.11; H, 6.93; N, 9.61%. Calcd for $C_{18}H_{30}N_3O_8P$: C, 48.31; H, 6.76; N, 9.39%.

H-Phys(OEt)(OH)-Ala-Asp(OEt)-OEt (14) and H-D-Phys(OEt)(OH)-Asp(OEt)-Ala-OEt (15). A suspension of **3** or **8** (4.47 g, 0.01 mol) in 0.5 M HCl (50 ml) was heated with stirring at 45 °C for 30 min. A homogeneous solution obtained was cooled and neutralized with 1% aqueous sodium carbonate. After extraction with ethyl acetate (3×20 ml) the combined organic extracts were dried over anhydrous $MgSO_4$ and distilled under vacuum to dryness. The residue was dissolved in chilled ethyl acetate (25 ml) and hexane was added until it became turbid. After standing overnight in refrigerator, the tripeptides **14** and **15** were collected, respectively.

Compound 14: Yield, 4.13 g (88.7%); mp 102—104 °C (EtOAc/*n*-C_6H_{14}); R_f: 0.81 (DMF:$CHCl_3$:MeOH=2:1:3); $[\alpha]_D^{20}$ 69.7° (*c* 1, MeOH).

Found: C, 46.31; H, 7.11; N, 8.77%. Calcd for $C_{18}H_{32}N_3O_9P$: C, 46.45; H, 6.93; N, 9.03%.

Compound 15: Yield, 3.83 g (76.3%); mp 111—114 °C (EtOAc/*n*-C_6H_{14}); R_f: 0.80 (DMF:$CHCl_3$:MeOH=2:1:3); $[\alpha]_D^{20}$ 77.7° (*c* 1, MeOH).

Found: C, 46.66; H, 6.76; N, 9.17%. Calcd for $C_{18}H_{32}N_3O_9P$: C, 46.45; H, 6.93; N, 9.03%.

Enzyme-Catalyzed Hydrolysis of 3 and 8. A mixture of the corresponding substrates **3** and **8** (each 20 g), phosphodiesterase I (5 mg or 10—15 mg in case that it is spread on a polymer carrier) in aqueous buffer (500 ml, pH 8.8) was stirred at 37 °C for 6 h. After removal of the enzyme acidification and concentration, the reaction mixture is extracted with diisopropyl ether (3×50 ml). The organic extracts collected are dried over anhydrous $MgSO_4$ and distilled to dryness. The residue was dissolved in dry ethyl acetate (200 ml) and hexane was added until the solution became turbid. After overnight in refrigerator, the products **4** and **9** were filtered.

***N*-[(*R*)-(2-Hydroxy-1,2,3,6-tetrahydro-1,2-azaphosphorin-6-yl)carbonyl]alanylaspartic Acid α,β-Diethyl Ester (4):** Yield, 15.27 g (81.6%); mp 92—94 °C (EtOAc/*n*-C_6H_{14}); IR (KBr) cm^{-1}: 2840—2320, 1760—1735, 1640, 1550, 1250, 1100, 930, 810, 720, 630; R_f: 0.61 (DMF:$CHCl_3$:MeOH=2:8:1); $[\alpha]_D^{20}$ 80.4° (*c* 1, MeOH).

Organophosphorus Analogues and Derivatives of the Natural L-Amino Carboxylic Acids and Peptides. VI.[1] A Phospha^C-Peptide Analogue of Plumbemycin A

Ivan A. NATCHEV
Research Centre Konstrukcionni Polymeri, 5-003 Gara Iskar, 1528 Sofia, Bulgaria
(Received October 3, 1987)

Synopsis. A phospha^C-peptide of Plumbemycin A has been studied. Condensation of *N*-trifluoroacetyl-3,4-didehydro-5-(ethoxyhydroxyphosphinyl)norvaline (**1**) and L-analyl-L-aspartic acid diethyl ester (**2**) is carried out by the DCC method to give the entirely protected phospha^C-tripeptide (**3**). Conditions for the enzyme-catalyzed hydrolysis of the ester groups with alkaline mesintericopeptidase, phosphodiesterase I, and α-chymotrypsin and the removal of the trifluoroacetyl group with an aqueous ammonia solution has been achieved.

Phospha^C-peptides (the CO-NH group is exchanged for PO-NH) were first synthesized by Imoto et al.[2] and Martell et al.[3] The protected phospha^C-peptide [[(benzyloxycarbonyl)amino]methylphosphinyl]phenylalanine[4] has been synthesized and studied as inhibitor of enzyme carboxypeptidase. A. Yamauchi et al.[5] synthesized *N*-[(2-aminoethyl)ethoxyphosphinyl]glycine ethyl ester. This compound is a phospha^C-peptide, in which a hydroxyl group in the phosphoryl group is protected as an ester. The major problem in the synthesis of "pure" phospha^C-peptides (without protected groups) is its highly sensitive nature upon hydrolysis to even mild acids and bases.[3] Campbell et al.,[6] recommend for removal of two *O*-ethyl groups in diethyl phosphonate ($-PO(OEt)_2 \rightarrow -PO_3H_2$) to use HBr/AcOH or to carry out treatment of $-PO(OSiMe_3)_2$, which are more readily hydrolyzable with Me_3SiBr. The last possibility was explored by Issleib et al.[7] to obtain "pure" phospha^C-peptides. Our attempts to apply these methods to the synthesis of phospha^C-peptides analogues of Plumbemycin were unsuccessful due to the rather sensitive olefinic bond of 3,4-didehydronorvaline. Our studies directed toward the synthesis of methylphosphoryl analogue of Plumbemycin A,[8] methylphosphoryl- and phosphono analogues of gluthathion[9,10] and phospha^C-peptide analogue of Bialaphos (SF-1923)[11] showed as a most promising method for the synthesis of "pure" phospha^C-peptides, the one developed in our laboratory[12] which makes possible the use of highly selective enzymes to catalyze the hydrolysis of the blocking groups.

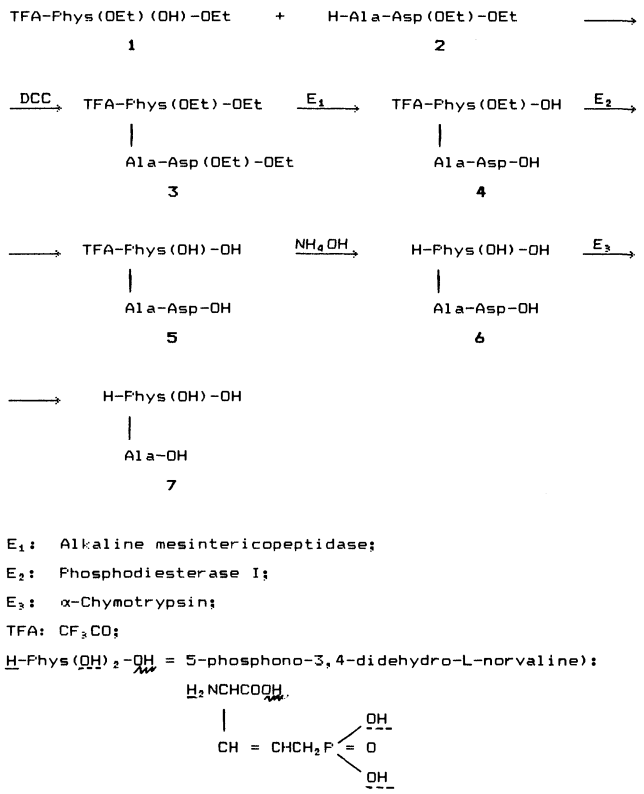
The condensation of *N*-trifluoroacetyl-3,4-didehydro-5-(ethoxyhydroxyphosphinyl)norvaline ethyl ester (**1**) synthesized by us (cf. later communication from the same author) and L-alanyl-L-aspartic acid diethyl ester (**2**) was carried out by the DCC method. When we used *N*-TFA-3,4-didehydro-5-phosphono-L-norvaline ethyl ester free phosphono groups, extra products were obtained and the yield of the protected phospha^C-peptide **3** was much lower.

A mixture of molar equivalent amounts of components **1** and **2** and a 10% excess of DCC in dry ethyl acetate at room temperature was stirred for 12 h and after the usual work-up, the phospha^C-tripeptide **3** was isolated in about 70% yield.

An attempt at the base- or acid-catalyzed hydrolysis of the ethoxycarbonyl groups of **3** afforded the hydrolytic decomposition of PO-NH.

When the enzyme alkaline mesintericopeptidase was applied under the most favorable conditions established by us [20 g substrate **3**, 6—7 mg enzyme in aqueous buffer (500 ml, pH 7.8), stirring at 25 °C to a ninhydrin-positive detection], selective hydrolysis of the ethoxycarbonyl groups proceeded to give the *N*- and *P*-protected phospha^C-tripeptide **4**.

The enzyme phosphodiesterase I, free or spread on a polymer carrier, contributed to the hydrolysis of the ethoxyphosphonyl group to afford phospha^C-tripeptide acid *N*-trifluoroacetyl **5**, which was isolated in almost quantitative yield. Naturally, the previously established amount of 5 mg phosphodiesterase I for 20 g substrate can be varied, but the enzyme/substrate ratio must be within the prescribed limits. The experimental technique was much simplified when the enzyme was spread on a polymer carrier. In that case 10—15



Scheme 1.

mg enzyme was used for 20 g of the substrate and continuous stirring of the reaction mixture was necessary. The enzyme spread on a polymer carrier can be used at least in twelve consecutive experiments without losing its activity towards the standard substrate bis(4-nitrophenyl) hydrogenphosphate.

It is of interest to note that none of the substrates with PO-NH bond studied in our laboratory underwent hydrolytic cleavage of PO-NH bonds with phosphodiesterase I.

On the other hand alkaline phosphatase with closely related activity has a catalytic effect towards neither ethoxyphosphinyl, nor aminophosphinyl groups.

The main problem in the synthesis of "pure" phospha^{C}-peptide analogue of Plumbemycin A is the removal of the *N*-protective group. Unfortunately, positive results were not obtained for the samples studied here. Thus, the test for selective hydrolysis of *N*-acetyl group with the proteolytic enzymes resulted in decomposition of the peptide bond Ala-Asp. The catalytic hydrogenation, the treatment with HBr/AcOH or the base- or acid-catalyzed hydrolysis of other *N*-protective groups were also unsuitable due to lability of the PO-NH group and the olefinic bond. The optimum conditions were found by using the *N*-trifluoroacetyl protective group, which could be removed in about 45% yield with aqueous ammonia-dioxane solution (pH 10) at 30—40 °C for 1 h to afford phospha^{C}-peptide analogue **6** of Plumbemycin A.

Base-catalyzed hydrolysis of **6** liberates, 3,4-didehydro-5-phosphono-L-norvaline[12] and the dipeptide alanyl-aspartic acid.

Under the optimum conditions[12] [20 g substrate **6**, 5 mg α-chymotrypsin in an aqueous buffer medium (500 ml, pH 7.8), stirring at 25 °C for 6 h] the dipeptide **7** was isolated in about 85% yield.

Studies of the physiological activity of the newly snythesized phospha^{C}-peptides **6** and **7** are under way and will be published in due course.

Experimental

General. IR spectra, elemental analysis, mp, Mw, HPLC, $[\alpha]_D^{22}$ on Perkin-Elmer instruments; reagents and solvents from "Fluka", "Aldrich", and "Merck"; phosphodiesterase I-"Sigma"; α-chymotrypsin—Pharmachim, Bulgaria; alkaline mesintericopeptidase—Inst. Org. Chem., Bulg. Acad. Sci.; TLC—silica-gel film "Merck"-molibdophosphate or ninhydrin detection.

Synthesis of the *N*-[(*S*)-(4-Ethoxycarbonyl-4-trifluoroacetamido-2-butenyl)ethoxyphosphinyl]alanylaspartic Acid α,β-Diethyl Ester (3). A mixture of *N*-trifluoroacetyl-1-L-3,4-didehydro-(*S*)-(ethoxyhydroxyphosphinyl)norvaline ethyl ester **1** (34.72 g, 0.1 mol), alanylaspartic acid diethyl ester **2** (26.03 g 0.1 mol) and DCC (22.69 g, 0.11 mol) in dry ethyl acetate (300 ml) is stirred at room temperature for 12 h. After filtration, the reaction mixture is washed consecutively with water, 5% aqueous sodium carbonate solution, water, 5% hydrochloric acid, water, and dried over anhydrous $MgSO_4$, and concentrated under vacuum to dryness. The light yellow viscous oil is loaded on a silica-gel column, which is eluted with chloroform : methanol (9 : 1).

Compound 3: Yield, 41.38 g (70.2%); mp 73—75 °C (after a continuous stay of the obtained oil in EtOAc/*n*-C_6H_{14} at −5 °C in refrigerator); IR (KBr) cm^{-1}: 1750—1720, 1670—1620, 1550, 1310, 1210, 1000, 960, 855, 730, 635; R_f: 0.75 ($CHCl_3$: MeOH=9 : 1); $[\alpha]_D^{20}$ −96.3° (*c* 1, MeOH).

Found: C, 44.61; H, 6.11; N, 6.96%. Calcd for $C_{22}H_{35}F_3N_3O_{10}P$: C, 44.82; H, 5.98; N, 7.13%. Mw, Found/Calcd, 587/589.503.

The substance is soluble in most organic solvents and is insoluble in water. Heating of **3** (5.88 g, 0.01 mol) in 0.2 M HCl (25 ml) (1M=1 mol dm^{-3}) at 50 °C for 30 min gives the starting norvaline (**1**) (2.99 g, 86.3%) and the dipeptide (**2**) (1.93 g, 73.4%).

***N*-[(*S*)-(4-Carboxy-4-trifluoroacetamido-2-butenyl)ethoxyphosphinyl]alanylaspartic Acid (4).** A mixture of the tripeptide **3** (20 g, 0.034 mol), alkaline mesintericopeptidase (8 mg), 3—4 drops of "Tween-80" (beforehand homogenized with **3** in 200 ml of water) in an aqueous buffer (500 ml, pH 7.8) is stirred at 25 °C to a ninhydrin-positive detection. After acidification (pH 6.5) and evaporation to dryness, the amorphous residue is extracted with boiling ethanol. After cooling, the tripeptide **4** is filtered.

Compound 4: Yield, 15.19 g (88.6%); mp 182—186 °C (EtOH); IR (KBr) cm^{-1}: 3750—2840, 1760, 1640, 1520, 1370, 1250, 1100—940, 870, 630; R_f: 0.62 (*n*-BuOH: 25% NH_3aq= 6 : 1); $[\alpha]_D^{20}$ −83.6° (*c* 0.1, 0.1 M NaOH);

Found: C, 44.61; H, 6.11; N, 6.96%. Calcd for $C_{22}H_{35}F_3N_3O_{10}P$: C, 44.82; H, 5.98; N, 7.13%. Mw, Found/Calcd, 587/589.503.

***N*-[(*S*)-(4-Carboxy-4-trifluoroacetamido-2-butenyl)hydroxyphosphinyl]alanylaspartic Acid (5).** A mixture of the tripeptide **4** (20 g, 0.039 mol) and phosphodiesterase I (5 mg or 10—15 mg, if spread on a polymer carrier) is stirred at 37 °C for 6 h. After removal of the enzyme by ultrafiltration or centrifugation (in case the enzyme is spread on a polymer carrier), the reaction mixture is acidified (pH 6.0) and evaporated under vacuum to dryness. The amorphous residue is extracted with boiling ethanol and after cooling, the product **5** is filtered.

Compound 5: Yield, 18.38 g, (97.3%); mp about 200 °C (decomp); IR (KBr) cm^{-1}: 3480—2860, 2840—2460, 1760, 1640, 1520, 1320, 1250, 980—840, 630; R_f: 0.39 (*n*-BuOH: 25% NH_3aq=6 : 1); $[\alpha]_D^{20}$ −83.6° (*c* 0.1, 0.1 M NaOH).

Found: C, 35.46; H, 3.88; N, 8.91%. Calcd for $C_{14}H_{19}F_3N_3O_{10}P$: C, 35.27; H, 4.01; H, 8.80%. Mw, Found/Calcd, 481/477.287.

***N*-[(*S*)-(4-Carboxy-4-amino-2-butenyl)hydroxyphosphinyl]-alanylaspartic Acid (6).** A solution of the tripeptide **5** (23.86 g, 0.05 mol) in a mixture of dioxane: 25%. aq. ammonia (150 ml, pH 10.0) is heated at 35—40 °C for 1 h. After evaporation under vacuum to dryness and additon of 200 ml of water, the solution is once again evaporated under vacuum. The product **6** is isolated by fractional crystallization.

Compound 6: Yield, 9.38 g (49.2%); mp 163—165 °C (decomp); IR (KBr) cm^{-1}: 3480—2860, 2460—2120, 1750—1720, 1640, 1520, 1310, 1200; R_f: 0.66 (DMF : $CHCl_3$: MeOH= 9 : 2 : 3); $[\alpha]_D^{20}$ −93.3° (*c* 0.1, 0.1 M NaOH).

Found: C, 38.01; H, 5.11; N, 10.93%. Calcd for $C_{12}H_{20}N_3O_9P$: C, 37.80; H, 5.29; N, 11.02%. Mw, Found/Calcd, 380/381.279.

The substance is quite soluble in DMF, DMSO, hexamethylphosphoric triamide, less in dioxane, and is insoluble in ethanol, ethyl acetate, ether, chloroform, and hexane. When **6** (3.81 g, 0.01 mol) is heated in 0.1 M NaOH (20 ml) at 50 °C for 30 min, the dipeptide H-Ala-Asp-OH (1.74 g, 85.3%) and 3,4-didehydro-5-phosphono-L-norvaline is isolated: yield 1.48 g (76.1%); mp 188—190 °C (decomp) [for the D-form 183—185 °C (decomp)];[12] IR (KBr) cm^{-1}: 1735, 1630, 1520, 1240, 1150, 1040, 930, 860, 775, 630; ^1H NMR (D_2O+NaOD, δ, ppm): 2.75 (2H, dd, $J_{P\text{-}CH_2}$=8.3, and 23 Hz), 4.81 (1H, d, *J*=9 Hz), 5.66 (1H, m, C<u>H</u>C<u>H</u>), 6.12 (1H, m, CH=C<u>H</u>CH_2)

and five exchangeable protons NH_2, COOH, PO_3H_2; R_f: 0.24 (*n*-BuOH : Pyr : AcOH : H_2O=15 : 12 : 3 : 10) and 0.10 (*n*-BuOH : AcOH : H_2O=3 : 1 : 1); $[\alpha]_D^{20}$ −53.2° (*c* 1, H_2O).

Found: C, 30.87; H, 4.93; N, 7.33%. Calcd for $C_5H_{10}NO_5P$: C, 30.78; H, 5.17; N, 7.18%. Mw, Found/Calcd, 197/195.112.

***N*-[(*S*)-(4-Carboxy-4-amino-2-butenyl)hydroxyphosphinyl]-alanine (7).** A mixture of the tripeptide **6** (20 g, 0.071 mol) and α-chymotrypsin (5 mg) in an aqueous buffer (500 ml, pH 7.8) is stirred at 25 °C for 6 h. After acidification and evaporation under vacuum to dryness, the amorphous residue is extracted with hot dioxane. After cooling, the dipeptide **7** is filtered.

Compound 7: Yield, 12.01 g (86.1%); mp about 200 °C (decomp); IR (KBr) cm^{-1}: 3450—2920, 2840—2460, 1750, 1640, 1520, 1320, 980—740, 635; R_f: 0.62 (*n*-BuOH : AcOH : H_2O=9 : 1 : 1); $[\alpha]_D^{20}$ −63.4° (*c* 0.1, 0.1 M NaOH).

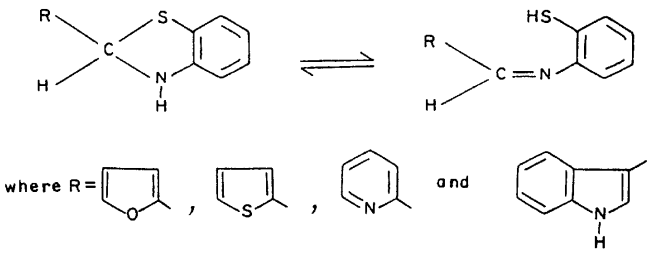
Spectral and Biological Studies on Organotin(IV) Complexes of Heterocyclic Benzothiazolines

Kiran SINGH, Ranvir SINGH, and Jagdish Prasad TANDON*
Department of Chemistry, University of Rajasthan, Jaipur-302004, India
(Received January 25, 1988)

Synopsis. The monobasic bidentate benzothiazolines, which were produced by the reaction of 2-mercaptoaniline and the heterocyclic aldehydes e.g., 2-furaldehyde, 2-thiophenecarbaldehyde, 2-pyridinecarbaldehyde, and 3-indolecarbaldehyde, have reacted with dialkyltin dichloride to give colored compounds. These compounds were characterized on the basis of elemental analyses, molar conductance, molecular weight determination, electronic and infrared spectral studies. Multinuclear NMR(^{1}H, ^{13}C, and ^{119}Sn) data suggest trigonal bipyramidal and octahedral geometries for the resulting $Me_2Sn\widehat{Cl(NS)}$ and $Me_2Sn(\widehat{NS})_2$ type complexes where $\widehat{NS}$ indicates benzothiazoline ligand, respectively. The fungitoxicity of 2-(2-thienyl)benzothiazoline and its complexes has been evaluated on pathogenic fungi.

During the recent years, much interest has been shown in the synthesis of metal chelates with sulfur containing ligands due to their different biological applications.[1,2] It has, however, been reported that on complexation[3,4] the activity of sulfur-containing ligands increases still further. Our continuing interest in the synthesis of biologically active complexes have led us to prepare and study the structures as well as other features of organotin complexes of heterocyclic benzothiazolines. The equilibrium forms of the ligands used during these investigations are shown below:



Experimental

Chemicals and solvents used were dried and purified by standard methods and moisture was excluded from the glass apparatus using $CaCl_2$ guard tubes. The ligands were prepared as reported in our earlier publication.[5]

Preparation of Complexes. To a weighed amount of dimethyltin dichloride in ca. 30 cm^3 of dry methanol in 100 cm^3 R.B. flask, was added the calculated amount of sodium salt of the ligand in 1 : 1 and 1 : 2 molar ratios. The mixture was heated under reflux for about 6 hours and the precipitate of sodium chloride so formed was filtered off. The solvent was removed and the product dried in vacuo. It was repeatedly washed with dry cyclohexane and again dried in vacuo. The physical properties and analytical data of these complexes are recorded in Table 1.

^{1}H NMR spectra were recorded on a JEOL FX 90Q spectrometer in DMSO-d_6 at 89.55 MHz, and ^{13}C and ^{119}Sn NMR spectra in methanol at 22.49 MHz and 33.35 MHz, respectively. Other methods of analyses and physical measurements are same as reported earlier.[5,6]

Results and Discussion

The reactions of dimethyltin dichloride with benzothiazolines (abbrev. to $\widehat{NS}$) in 1 : 1 and 1 : 2 molar ratios proceed as follows:

$$Me_2SnCl_2 + \widehat{NS}Na \xrightarrow[1:1]{MeOH} Me_2SnCl(\widehat{NS}) + NaCl$$

$$Me_2SnCl_2 + \widehat{NS}Na \xrightarrow[1:2]{MeOH} Me_2SnCl(\widehat{NS})_2 + NaCl$$

All the newly synthesized complexes are colored solids and soluble in most of the common organic solvents. The low values of molar conductance (15—20 ohm^{-1} cm^2 mol^{-1}) in anhydrous *N,N*-dimethylformamide show them to be nonelectrolytic in nature. The molecular weight determinations show them to be monomeric.

The electronic spectra of the ligands consist of two bands around 250 nm and 315 nm characteristic of benzothiazolines.[8] These bands arise out of θ-θ^* and π-π^* benzenoid[8] transitions and which remain almost unchanged in all the tin complexes. However, an additional band is also observed in the region 390—410 nm due to n-π^* electronic transitions of the azomethine[8] and which indicates rearrangement of the ligands to the imine on complexation.

In the IR spectra of the ligands strong bands in the regions 3370—3200 cm^{-1} and 1670—1705 cm^{-1} due to NH stretching and deformation vibrations, respectively are observed. The absence of ν(SH) at 2500—2600 cm^{-1} and ν(C=N) at 1600—1650 cm^{-1} is indicative of the benzothiazolines.[9] In complexes, the bands due to NH vibrations are not observed and this indicates the chelation of nitrogen with the tin atom. A new band at ca. 1600 cm^{-1} in the spectra of complexes due to ν(C=N) vibrations suggests that the complexes are metal-Schiff base derivatives as the benzothiazoline ring rearranges to give the Schiff base derivatives in the presence of metal ion.[8] Several new bands in the spectra of tin complexes[6] in the regions 390—450, 325±20, and 280±15 cm^{-1} may be assigned to ν Sn←N, ν Sn-S, and ν Sn-Cl respectively, and this lends further support to the proposed coordication in these complexes.

^{1}H NMR spectral studies further support the bonding pattern as discussed above. The N-H proton signals at δ 4.20 (2-furyl-BztH) and δ 4.36 (2-thienyl-BztH) in the spectra of benzothiazolines disappear in the corresponding tin complexes. The azomethine proton signal shifts down field in the spectra of complexes due to the formation of a coordinate linkage

	123.72	121.90	120.87	121.22	125.85	153.32	126.75	126.31	126.32	126.42	127.82	140.23	16.85

Table 3. Fungicidal Screening Data of Ligand and Its Complexes

Compound	Average percentage inhibition after 96 h: Organism Helminthosporium gramineum concn used 0.01%	0.1%	Organism Rhizopus oryzae concn used 0.01%	0.1%	Organism Aspergillus concn used 0.01%	0.1%
2-Thienyl-BztH	37	41	34	46	41	53
Me_2SnCl(2-thienyl-Bzt)	58	68	65	85	70	84
Me_2Sn(2-thienyl-Bzt)$_2$	56	71	60	79	63	85

between nitrogen and tin atoms. The protons of the methyl groups appear at δ 1.12, 1.34, 1.08, and 1.33 in the tin complexes.

^{13}C NMR spectra of 2-(2-pyridyl)benzothiazoline and its 1 : 1 and 1 : 2 tin complexes were also recorded (Table 2). The considerable shifts in the positions of carbons of the tin complexes marked by (6) and (12) attached to N and S, respectively, clearly indicate that

the nitrogen and sulfur of the mercapto group participate in complexation reaction as discussed earlier.

The compound Me_2SnCl(2-pyridyl-Bzt) gives a signal at −147 ppm in the ^{119}Sn NMR indicative of five-coordination around the tin atom as it is in agreement with the previously reported values.[10]

On the basis of the foregoing discussions, trigonal bipyramidal and octahedral geometries around the tin atom have been proposed in 1:1 and 1:2 tin complexes, respectively.

Evaluation of the Antifungal Activity. Helminthosporium gramineum, Rhizopus oryzae and Aspergillus flavus were employed to check the antifungal activity of the benzothiazoline and its 1:1 and 1:2 complexes. The results of the antifungal activity given in Table 3 show that Me_2Sn(2-thienyl-Bzt)$_2$ shows almost complete inhibition in higher concentration. As compared to 2-(2-thienyl)benzothiazoline, Me_2SnCl(2-thienyl-Bzt) and Me_2Sn(2-thienyl-Bzt)$_2$ exhibit greater fungitoxicity against all the fungi. The fungitoxicity of ligand and its complexes decreases on lowering the concentration. The increased fungitoxicity of the complexes as compared to the ligand may be due to chelation as the polarity of the metal ion in the complexes which reduces considerably due to the partial sharing of its positive charge with the donor groups and possible π-electron delocalization over the whole chelate ring system. This in turn increases the hydrophobic character of the metal favoring its permeation through the lipoid layers of the fungal membranes.[11]

Studies in the Extraction of Metals with 3-Phenyl-4-acetyl-5-isoxazolone

A. JYOTHI and G. N. RAO*
Chemistry Department, Indian Institute of Technology, Hauzkhas, New Delhi-110016, India
(Received February 22, 1988)

Synopsis. Extraction of manganese(II), iron(II), cobalt(II), nickel(II), copper(II), zinc(II), and cadmium(II) from aqueous solution with 3-phenyl-4-acetyl-5-isoxazolone (HPAI) in 4-methyl-2-pentanone (MIBK) has been studied and the extraction constants have been calculated for all the systems except cadmium(II). Separation factors have been calculated for the separation of metals.

In the extraction of metals, β-diketones such as thenoyltrifluoroacetone (HTTA)[1] are extensively used. Acylpyrazolones have been proved promising reagents for the extraction of metals from acidic media.[2-8] In our previous paper,[9] we have reported the extraction of iron(II), manganese(II), cobalt(II), nickel(II), zinc(II), cadmium(II), and lead(II) with 3-phenyl-4-benzoyl-5-isoxazolone (HPBI), a new chelating ligand in which the β-diketone moiety is fused to a heterocyclic ring. In continuation of this work, 3-phenyl-4-acetyl-5-isoxazolone (HPAI) has been used to evaluate the potential of this reagent for the extraction of metals. Solid complexes of these metals with HPAI have also been isolated and studied.[10] In common with other β-diketones (like acylpyrazolones) HPAI exists in keto and enol forms (Fig. 1). It has been confirmed by the presence of an enolic peak at δ 12 relative to TMS in the ^{1}H NMR spectrum of ligand HPAI. The present paper deals with the extraction of iron(II), manganese(II), cobalt(II), nickel(II), copper(II), zinc(II), and cadmium(II) into MIBK and the effectiveness of the ligand HPAI in the separation of metals. 4-Methyl-2-pentanone was used as solvent as it is commonly employed in atomic absorption studies and the ligand was soluble to a greater extent in this solvent than other solvents like toluene or chloroform.

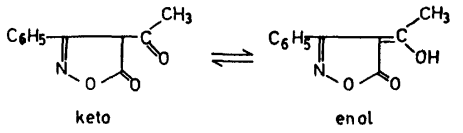

Fig. 1. The enolic and keto forms of the 3-phenyl-4-acetyl-5-isoxazolone.

Experimental

Reagents. Ethyl benzoylacetate (Fluka), acetic anhydride (Merck), sodium acetate (Merck), and hydroxylamine hydrochloride (Sarabhai) were used for the preparation of ligand. MIBK (BDH) was used as solvent for the extraction. The pH of the aqueous phase was maintained by using mixtures of potassium chloride and hydrochloric acid for pH 1—3, sodium acetate-acetic acid for pH 4—6, acetic acid-ammonia for pH 6—8 and ammonium chloride-ammonia for pH 8—10. A constant ionic strengths of 0.1 mol dm^{-3} was maintained by using potassium nitrate solution. Stock solutions were prepared by using AR grade chemicals.

Preparation of the Ligand. The ligand 3-phenyl-4-acetyl-5-isoxazolone (HPAI) was prepared by using 3-phenyl-5-isoxazolone and acetic anhydride in the presence of sodium acetate as described by Korte and Storiko.[11] Mp 140±2 °C, Calcd for $C_{11}H_9O_3N$: C, 65.02; H, 4.43; N, 6.89%. Found: C, 64.86; H, 4.48; N, 6.95%. The UV spectrum of the ligand in 95% ethanol showed two absorption maxima at 285 and 232 nm.

Extraction Procedure. Ten ml of the aqueous solution containing an aliquot of metal solution, five ml of the buffer solution and one ml of 1 mol dm^{-3} KNO_3 solution was equilibrated with ten ml of organic phase containing the required amount of the ligand in a stoppered bottle. The mixture was shaken on a mechanical shaker for one hour at 25±1 °C. After equilibration, the aqueous phase was separated from the organic layer and its pH was measured by using an expanded scale pH meter (ECIL India). The concentration of metal ion was monitored using atomic absorption spectrophotometer. A Pye-Unicam SP-191 unit with air-acetylene burner and the required hollow cathode lamps was utilized in this study. Distribution coefficient K_d (defined as the total concentration of metal in organic phase divided over the total concentration of metal in aqueous phase) was calculated.

Results and Discussion

The extraction curves of each element as a function of pH of the aqueous solution are shown in Fig. 2. Quantitative extraction of iron(II) was observed in the pH range 1.5 to 8.0. Above pH 8.0, the extraction registered a sharp drop and at pH 9.5 iron(II) showed only 90% extraction. Nickel(II) and cobalt(II) were extracted quantitatively from pH 3.0 to 9.0. Between

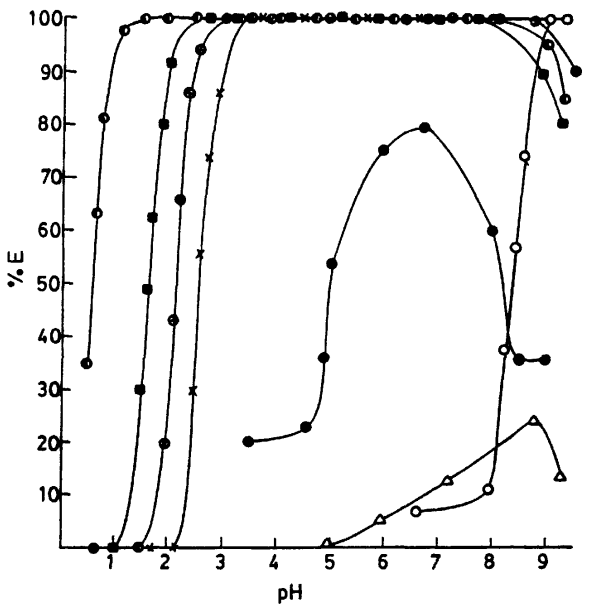

Fig. 2. Plot of %E vs. pH. ○=Mn(II); ◐=Fe(II); ■=Cu(II); ⊗=Ni(II); ×=Co(II); ●=Zn(II); △=Cd(II); HPAI 0.01 mol dm^{-3} in MIBK.

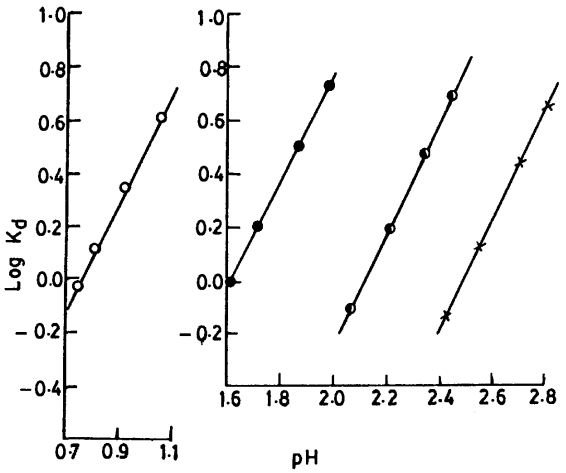

Fig. 3. Plots of log K_d vs. pH. ○=Fe(II); ●=Cu(II); ◐=Ni(II); ×=Co(II); HPAI 0.01 mol dm^{-3} in MIBK.

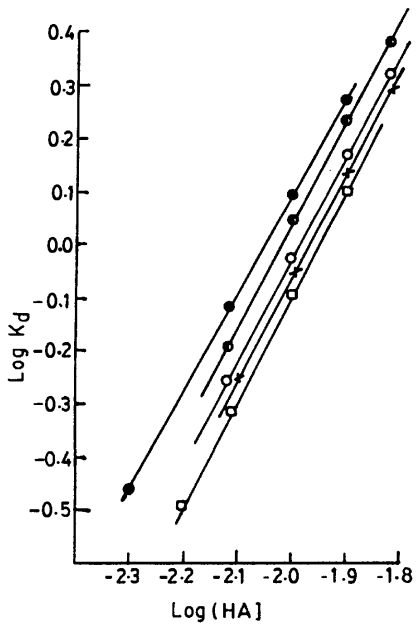

Fig. 4. Plot of log K_d vs. log[HA]. ○=Mn(II) (pH 8.4); ●=Zn(II) (pH 5.0); ×=Cu(II) (pH 1.55); ◐=Fe(II) (pH 0.75); □=Ni(II) (pH 2.05).

pH 9.0 and 9.5 the % extraction dropped to 90%. The extraction of copper(II) was quantitative in the pH range 2.5 to 8.0, then the extraction decreased at higher pH values and at pH 9.0 only 80% of copper(II) was extracted. Maximum extraction of zinc(II) (80%) was observed over the pH range 6.0 to 7.0, then the extraction decreased at higher pH up to 9.0, where only 35% zinc(II) was extracted. Figure 2 shows a sharp rise in the extraction of manganese(II) from pH 8.0 and the quantitative extraction of manganese(II) into the organic phase was observed at pH 9.0. Below pH 6.0 no appreciable quantity of manganese(II) was extracted. Maximum extraction shown by cadmium-(II) was only 25% at a pH of 8.8.

In order to understand the extraction behavior in more detail, log of distribution coefficient K_d was plotted against pH and log of ligand concentration at fixed ligand concentration and pH respectively (Figs. 3 and 4). The plots were linear with a slope of ca. 2 indicating the release of two H^+ ions and involvement of two molecules of ligand (HPAI) during the extraction process. It can be inferred from these results that the main equilibrium involved in the extraction process is

$$M^{2+} + 2HPAI_{(org)} \rightleftharpoons M(PAI)_{2(org)} + 2H^+ \quad (1)$$

where, PAI=anion of 3-phenyl-4-acetyl-5-isoxazolone.

The extraction constant values (log K_{ex}) in Eq. 1 were calculated for manganese(II), iron(II), nickel(II), cobalt(II), copper(II), and zinc(II) systems and are given in Table 1. The $pH_{1/2}$ values (pH at which 50% of the metal ion is extracted) for the extracted metals are compared with those of the corresponding systems using thenoyltrifluoroacetone (HTTA) (Table 1). It is evident from the table that the extraction of copper(II), iron(II), cobalt(II), nickel(II), and zinc(II) occurs in the acidic medium as in HTTA. Manganese(II) is extracted from slightly acidic medium with HTTA, whereas with HPAI it is extracted from rather alkaline medium. In case of cadmium(II), quantitative extraction is accomplished from the alkaline medium with HTTA,[12] in contrast to its partial extraction (25%) with HPAI at higher pH values.

The possibility of utilizing this reagent HPAI for the separation of metals has been investigated by calculating the separation factor S which is the ratio of the distribution coefficients of the elements to be separated.[16] A separation in which not more than 1% of one element is coextracted will be obtained if $S \geqslant 10^4$ and the product of distribution coefficients is unity. The separation factors calculated are given in Table 2. It can be concluded from the table that the reagent

Table 1. Extraction Data of Some Metals Using 0.01 mol dm^{-3} HPAI in MIBK

Metal	$pH_{1/2}$(50% extraction)	log K_{ex}	$pH_{1/2}$, 0.15 mol dm^{-3} HTTA in benzene[a]
Mn(II)	8.4	−12.63	6.05
Fe(II)	0.6	+ 2.57	—
Co(II)	2.6	− 1.10	4.1
Ni(II)	2.1	− 0.51	5.0
Cu(II)	1.6	+ 0.75	1.34
Zn(II)	5.0	− 5.89	5.10
Cd(II)	Only 25% extraction	—	8.0

a) Refs. 12—15.

Table 2. Separation Factors for the Separation of Metals Using 0.01 mol dm^{-3} HPAI in MIBK

Metals to be separated	Separation factor	Metals to be separated	Separation factor
Fe(II)-Mn(II)	1.5×10^{15}	Mn(II)-Cu(II)	2.3×10^{13}
Fe(II)-Co(II)	4.6×10^{3}	Mn(II)-Zn(II)	5.4×10^{6}
Fe(II)-Ni(II)	1.2×10^{3}	Co(II)-Ni(II)	4
Fe(II)-Cu(II)	66	Co(II)-Cu(II)	70
Fe(II)-Zn(II)	2.8×10^{8}	Co(II)-Zn(II)	6.1×10^{4}
Mn(II)-Co(II)	3.3×10^{11}	Ni(II)-Cu(II)	18
Mn(II)-Ni(II)	1.3×10^{12}	Cu(II)-Zn(II)	4.3×10^{6}

HPAI would be useful for the separation of manganese(II), and zinc(II) from the other metals reported here. In conclusion, like HTTA and acylpyrazolones, these acylisoxazolones represent a new group of versatile chelating agents with great potential in solvent extraction.

The authors wish to thank CSIR (India) for financial support.
