The microdisk electrode makes the kinetic effect most distinctive of the ultramicroelectrodes currently employed. This intriguing feature encouraged derivation of analytical equations for stationary voltammograms complicated by the electrode kinetics at the microdisk electrode.[9] According to the theory,[9] the voltammogram can be transformed into a linear curve through a modified log-plot, of which slope and intercept provide kinetic parameters. In order to apply the modified log-plot to experimental curves, it is required to confirm the establishment of the steady state, to establish a method of residual current elimination or correction and to determine consistently the radius of the electrode and diffusion coefficients. In the paper, we construct platinum ultramicrodisk electrodes by anodic electropolishing[19,20] and measure stationary voltammograms for oxidation of Fe^{2+} and $[Fe(CN)_6]^{4-}$. From these curves, we evaluate the kinetic parameters by use of the modified log-plot, aiming at verification of the theory.

Experimental

Microdisk Electrodes. Two kinds of microdisk electrodes were constructed, one being ca. 7.5 μm in radius and the other being less than 1 μm. A platinum wire 7.5 μm in radius and 2 mm in length (Tanaka Noble Metal Ltd., Tokyo) was connected electrically to a copper wire with mercury contact. It was sealed with soft glass. The surface of the electrode was polished with 1200 mesh carbon powder on a glass plate until the disk-shaped electrode was exposed. It was polished with 0.05 μm alumina powder, followed by ultrasonication in distilled water for 5 minutes. A view of the exposed electrode through a SEM was a well-defined disk rather than a deformed circle.

An ultramicro filament with a radius less than 1 μm was constructed by anodic electropolishing of a platinum wire 32.5 μm in radius, according to a technique described previously.[19,20] The polished filament tapered off to a top. It was dipped into fused soft glass in a small furnace at 320 °C to yield a surface coating of soft glass with a few μm in thickness. This coating ensures high quality of the sealing. The coated filament was cured with epoxy resin (Quetol 812, Nisshin EM, Tokyo) and kept at 60 °C for 24 h. The epoxied block was cut with a diamond knife (Diatome) mounted with an ultramicrotome (Porter-BLUM Model MT2-B). It was difficult to discern quality of a circle through a SEM photograph. The shape was assumed to be a disk for the data analysis. Prior to each electrochemical msasurement, the electrode surface was renewed by the cutting; polished with 0.05 μm alumina powder, dipped into concentrated nitric acid for 2 min and rinsed with distilled water.

Electrochemical Measurements. Since Faradaic currents were as small as 10 nA, a two-electrode system was employed for current measurements, in which a saturated calomel electrode (SCE) was served as a counter electrode. Currents were measured with a high speed current amplifier (Keithley Model 427) in an electrically sealed box. An electrochemical cell was thermostated at 25 °C in a water bath. Before mea-

surements, the solution was deaerated with nitrogen gas for 20 min. All chemicals were of analytical grade.

Results and Discussion

We used oxidation of $[Fe(CN)_6]^{4-}$ and Fe^{2+} as a model reaction associated with electrode kinetics because these two species have well investigated electrochemically. Figure 1 shows three examples of background-corrected voltammograms for oxidation of $[Fe(CN)_6]^{4-}$ (Flg. 1A) and Fe^{2+} (Figs. 1B and 1C) at the potential sweep rate of 10 mV s^{-1}. Residual currents were almost a straight line, of which slope was ca. 0.8 nA V^{-1} for curves in Figs. 1A and 1B and 0.05 nA V^{-1} in Fig. 1C. Since they traced the same path at the forward and the reverse potential scan, they do not result from a capacitive factor. Thus, these electrodes are successful in excluding fully the capacitive current which frequently degrades voltammograms at microdisk electrodes. Hysteresis of the voltammogram was slight but sometimes detectable (in Fig. 1C). The current at the reverse scan was always smaller than the forward one. Two reasons for the hysteresis can be considered: One is unreached steady state and the other is deterioration of the electrode surface during electrolysis. We examined theoretically the extent of the unreached steady state through use of a geometrical parameter, $p=(nFa^2v/RTD)^{1/2}$, in linear sweep voltammetry, where a is a radius of the disk electrode, v the potential sweep rate, n the number of electrons transferred, F the faraday constant, R the gas constant, T the temperature, and D the diffusion coefficient.[21] Values of p were less than 0.21 for $a \leqq 7.5$ μm at $n=1$, $v=10$ mV s^{-1} and $D=0.5\times10^{-5}$ cm^2 s^{-1}, suggesting that the deviation from the steady-state current would be less than 3%[21] if the voltammogram were reversible. Thus the hysteresis is ascribed to deterioration of the electrode. When hysteresis was observed, voltammograms only at the forward scan were employed for the following data analysis.

Radii of the two kinds of microdisk electrodes were evaluated from measurements of the stationary diffusion-controlled limiting current, I_d, for oxidation of 5 mmol dm^{-3} $[Mo(CN)_8]^{4-}$ in 0.5 mol dm^{-3} Na_2SO_4 through the following equation:[22]

$$I_d=4nFc^*Da \qquad (1)$$

where c^* is the bulk concentration of the electroactive species. It was assumed that $D=4.6\times10^{-6}$ cm^2 s^{-1} for $[Mo(CN)_8]^{4-}$.[19] The calculated value of the radius of the large electrode was identical with a nominal value; 7.5 μm. The evaluated radius of the electropolished electrode was 0.70 μm.

We attempted to evaluate the radii from the limiting currents in Fig. 1 by use of $D=4.7\times10^{-6}$ cm^2 s^{-1} for Fe^{2+}[23] and $D=6.32\times10^{-6}$ cm^2 s^{-1} for $[Fe(CN)_6]^{4-}$.[24] The radii were 7.5 and 7.1 μm, respectively, for curves in Figs. 1A ($[Fe(CN)_6]^{4-}$) and 1B (Fe^{2+}). The former is in good agreement with both the nominal value and

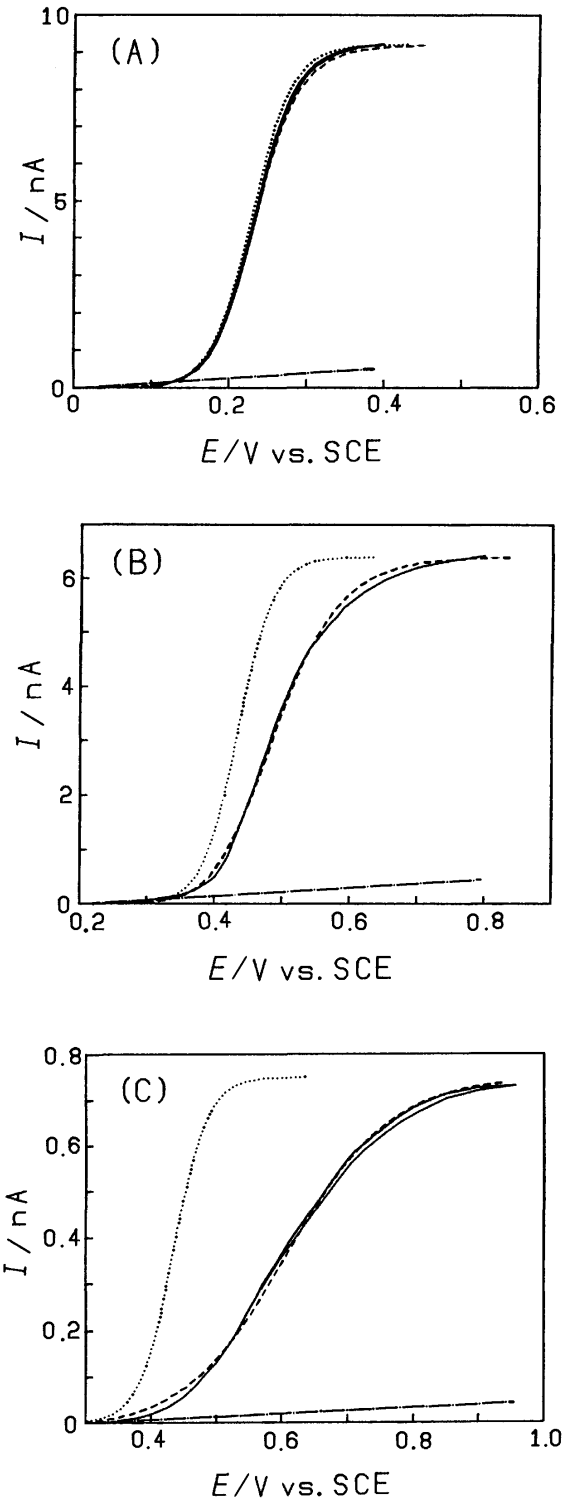

Fig. 1. Cyclic voltammogram (——) for 5 mmol dm^{-3} $[Fe(CN)_6]^{4-}$ in 1 mol dm^{-3} HCl solution at the electrode of $a=7.5$ μm (Fig. 1A), that (——) for 5 mmol dm^{-3} Fe^{2+} in 1 mol dm^{-3} H_2SO_4 solution at the electrode of $a=7.5$ μm (Fig. 1B) and that (——) for 5 mmol dm^{-3} Fe^{2+} in 1 mol dm^{-3} H_2SO_4 solution at the electrode of $a=0.88$ μm (Fig. 1C) when measure at $v=10$ mV s^{-1}. Curves (-·-·-) are residual currents. Dashed curves are simulated waves calculated from Eq. 5 at kinetic parameters evaluated from the modified log-plot. Reversible voltammograms might be expressed by dotted curves.

the value evaluated from the current of $[Mo(CN)_8]^{4-}$. Slight discrepancy for the latter may be due to an incomplete plateau of the limiting current. An expedient of satisfying Eq. 1 so as to make no influence on the log-plot is to determine the diffusion coefficient of Fe^{2+} specific to this electrochemical system. The value of D thus determined is 4.4×10^{-6} cm^2s^{-1}. This value will be used for D of Fe^{2+} in the discussion below. On the other hand, the radius evaluated from the limiting current in Fig. 1C by use of the above value of D was 0.88 μm, which was larger than 0.70 μm evaluated for $[Mo(CN)_8]^{4-}$. Such difference was frequently observed when the electrode surface was renewed by cutting at each measurement. The discrepancy may not be ascribed to difference in electroactive species but may be attributed to poor reproducibility of the renewal. Thus, for the analysis of a voltammetric waveform, it is desirable to use a radius determined from a limiting current at each renewed electrode.

According to the theory of the stationary voltammogram involving electrode kinetics at microdisk electrodes, the current-potential curves for the quasi-reversible and the totally irreversible waves are expressed by the following modified log-plot:[9]

$$E=E^*-2.3\frac{RT}{(1-\alpha)nF}\log\frac{[1-(I/I_d)\{1+\exp(-nF(E-E^{\circ\prime})/RT)\}]^{1.11}}{I/I_d} \quad (2)$$

with

$$E^*=E^{\circ\prime}-2.3[RT/\{(1-\alpha)nF\}]\log[(\pi/4)k^{\circ\prime}a/D] \quad (3)$$

where the Butler-Volmer equation has been used for the kinetic equation. Here I is the current at electrode potential E, α the cathodic transfer coefficient, $k^{\circ\prime}$ is the formal electrode reaction rate constant, and $E^{\circ\prime}$ the formal potential. On the other hand, the reversible wave can simply be expressed by

$$E=E^{\circ\prime}+2.3(RT/nF)\log[I/(I_d-I)] \quad (4)$$

We temporarily assume that the voltammograms in Fig. 1 are reversible. The conventional log-plots given by Eq. 4 are shown in Fig. 2. Plot A for $[Fe(CN)_6]^{4-}$ falls on a straight line of which inverse slope is 62 mV. The half-wave potential is shifted positively by 3 mV from the middle value (0.230 V vs. SCE) of the anodic and the cathodic peak potential measured at a platinum disk electrode 2 mm in diameter. Thus the reaction is very close to the reversible one although there appears slight kinetic effects. On the other hand; plots B and C for Fe^{2+} are curved and half-wave potentials are positively shifted by 55 and 171 mV, respectively, from the middle value (0.435 V vs. SCE) of the anodic and the cathodic peak potential measured at the large electrode. Thus the oxidation of Fe^{2+} belongs to the totally irreversible group. The difference in the radius is obviously responsible for the difference in the partic-

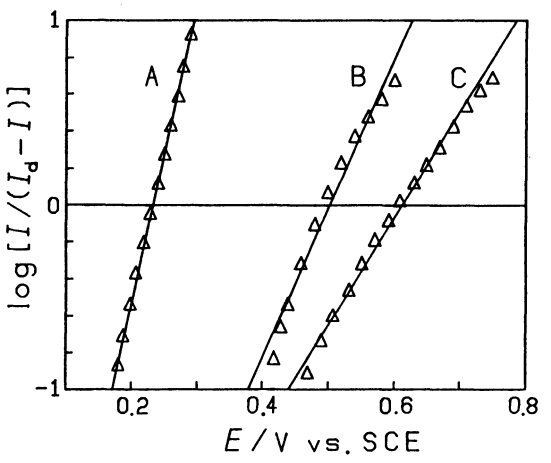

Fig. 2. Conventional log-plots for stationary voltammograms of (A) $[Fe(CN)_6]^{4-}$ at the electrode of a=7.5 μm, (B) Fe^{2+} at a=7.5 μm and (C) Fe^{2+} at a=0.88 μm. These three plots correspond to voltammograms in Fig. 1.

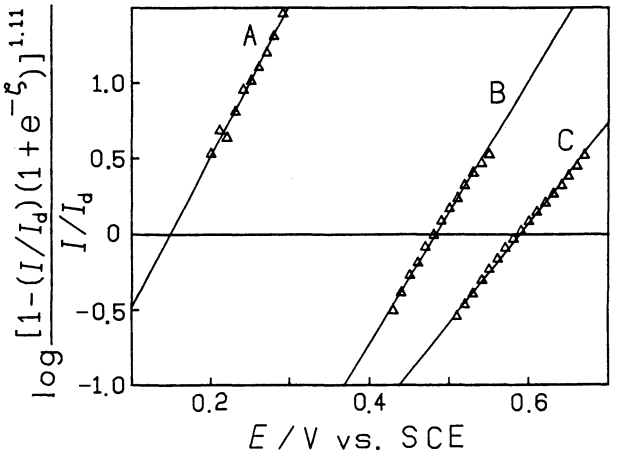

Fig. 3. Modified log-plots for voltammograms in Fig. 1. Plots A, B, and C correspond to waves in Fig. 1.

ipation of electrode kinetics. From the empirical concept on the electrode kinetics, logarithm of the reduced rate constant, $k^{\circ\prime}a/D$, has linear relation with $(1-\alpha)(nFE/RT)$. Thus the difference in the half-wave potential may be equivalent to $[RT/\{(1-\alpha)nF\}]\ln(a_B/a_C)$, where a_B and a_C are radii of electrodes for curves B and C, respectively. The difference in the measured half-wave potential was 0.116 V while the differences calculated from $\ln(a_B/a_C)$ were 0.110 and 0.117 V for α=0.5 and α=0.53, respectively. Agreement is good for reasonable values of α, demonstrating that miniaturizing electrodes causes the potential shift by the amount of $[RT/\{(1-\alpha)nF\}]\ln(a_0/a)$, where a_0 is the reference radius of a microdisk electrode.

It is possible to evaluate $k^{\circ\prime}$ and α from the modified log-plot through Eqs. 2 and 3. In Fig. 3, values of E are plotted against the logarithmic term involving Eq. 2 for the three voltammograms. Although plots B and C are slightly curved, the points fall on a straight line.

Equation 2 shows that the slope of the plot is $2.3RT/\{(1-\alpha)nF\}$, from which α can be evaluated. The slope was evaluated by the method of linear least squares. Values of α are 0.48 and 0.65 for plots B and C, respectively. The literature value is 0.58.[25] The intercept with the E-axis gives E^*, which determines $k^{o\prime}$ through Eq. 1 at known values of $E^{o\prime}$, α, and D. Values of $k^{o\prime}$ thus obtained are 3.0×10^{-3} (α=0.48, $D=4.4\times10^{-6}$ cm^2 s^{-1}, a=7.5 μm) and 6.5×10^{-3} cm s^{-1} (α=0.65, $D=4.4\times10^{-6}$ cm^2 s^{-1}, a=0.88 μm) for plots B and C, respectively. The discrepancy of $k^{o\prime}$ is ascribed to the difference in α because it has been demonstrated in the above that the difference in the half-wave potential was equivalent quantitatively to $\ln(k^{o\prime}a/D)$ at a common value of α. The difference in α may result in edge effects other than those due to diffusion, e.g., activation at the edge, selective adsorption at the edge, and deformation of the disk form of the electrode. If we take a common value of α to be 0.55 retaining values of E^*, values of $k^{o\prime}$ become common, being 3×10^{-3} cm s^{-1}.

Plot A in Fig. 3 falls on a straight line although the line is sensitive to errors in $E^{o\prime}$. The kinetic parameters from this straight line are α=0.43 and $k^{o\prime}$=0.07 cm s^{-1}. We attempted to measure voltammograms of $[Fe(CN)_6]^{4-}$ at an electrode with a radius less than 1 μm. Voltammograms were almost the same as in Fig. 1A, suggesting that the kinetic effect is vague. Consequently, $[Fe(CN)_6]^{4-}$ belongs to the reversible group rather than the quasi-reversible one at microelectrodes employed here. The kinetic values determined above may involve large errors.

We simulated the voltammograms through use of Eq. 2 for kinetic parameters obtained from the modified log-plot. Since Eq. 2 is non-linear with respect to both E and I, we valuated I/I_d at a given value of E through the following algorithm based on the Newton method:

$$x_{k+1}=x_k-f(x_k)/f'(x_k) \tag{5}$$

with

$$x_k=(I/I_d)_k$$
$$f(x)=[1-x\{1+\exp(-\zeta)\}]^{1.11}/x - \exp[-(1-\alpha)(nF/RT)(E-E^*)]$$
$$f'(x)=[1-x\{1+\exp(-\zeta)\}]^{0.11}[0.11\{1+\exp(-\zeta)\}x]/x^2$$
$$\zeta=(nF/RT)(E-E^{o\prime})$$

Starting at an initial value, x_0, less than $\exp[(1-\alpha)(nF/RT)(E-E^*)]$, we could successfully computed converged values of I/I_d. Values for the parameters employed for the simulation are $k^{o\prime}$=0.07 cm s^{-1}, α=0.43, $D=6.32\times10^{-6}$ cm^2 s^{-1}, a=7.5 μm for curve A, $k^{o\prime}=3.0\times10^{-3}$ cm s^{-1}, α=0.48, $D=4.4\times10^{-6}$ cm^2 s^{-1}, a=7.5 μm for curve B, $k^{o\prime}=6.5\times10^{-3}$ cm s^{-1}, α=0.65, $D=4.4\times10^{-6}$ cm^2 s^{-1}, a=0.88 μm for curve C. In Fig 1, simulated curves (---) are drawn, in good agreement with experimental waves. This fact indicates that the kinetic parameters obtained here are reasonable although there is no consistency in the kinetic parameters for curves B and C.

Structure Images of a Nickel Fine-Particle Catalyst and Analysis of a Moiré Pattern

Michio NODA,* Hideki ICHINOSE, Yasukazu SAITO, and Yoichi ISHIDA
Institute of Industrial Science, University of Tokyo, 7-22-1 Roppongi, Minato-ku, Tokyo 106
(Received March 29, 1988)

Conventional HR-TEM was applied to a nickel fine-particle catalyst that had been prepared by means of a gas-evaporation method. A structure image of the nickel fine particle showed that the particle consisted of an fcc nickel crystal and thin oxide layers of the surfaces. A platinum-deposited nickel fine particle exhibited a moiré pattern, which was analyzed by the use of the Cowley-Moodie dynamical theory of diffraction. An accurate solution of the equations showed that a platinum lattice obliquely piled on a surface lattice of the particle.

High-resolution transmission-electron microscopy (HR-TEM) enables one to see a crystal lattice as it is in real space, though the interplanar spacing cannot be exactly measured.[1] The technology for HR-TEM has been sufficiently developed.[2] If a particle has a diameter of some ten nm, it can be observed without any slicing procedure. For example, γ-alumina particles were prepared by means of a gas-evaporation method, and photographs of them were taken with a high resolution.[3]

Nickel fine particles were produced using the same method. They had a spherical shape and a sharp distribution of size.[4] These nickel fine particles catalyzed liquid-phase dehydrogenation of 2-propanol.[5] Further, platinum-deposited nickel fine particles were more active than nickel alone.[6] In the present study, the two catalysts were observed by means of HR-TEM after a reaction, and their structure was analyzed.

Experimental

1. Materials. Nickel fine particles were supplied by Vacuum Metallurgical Co., Ltd. (Chiba Pref., Japan). They were black and light powder that had been prepared by evaporating molten nickel metal under argon at a low pressure. Their surfaces had been slowly oxidized before taking them out of the reactor. The oxide layers prevented the particles from burning in air. The oxygen content was about 10 wt%, that is, about 30 mol%. The average diameter of the nickel fine particles was 19.7 nm, and their BET surface area was 43.8 $m^2 g^{-1}$.

Bis(acetylacetonato)platinum(II) ($Pt(acac)_2$) was purchased from Nippon Engelhard Ltd.

2. Procedure. The nickel fine particles were heated under hydrogen in order to reduce the surface oxide partly, and then they were used as a catalyst of the liquid-phase dehydrogenation of 2-propanol. The technique was described in previous papers.[5,6] The nickel fine particles were collected by filtration after a reaction and preserved in air.

Platinum was deposited on a nickel fine-particle catalyst by reducing the divalent platinum in $Pt(acac)_2$ before the catalysis. Though 9 mg of $Pt(acac)_2$ revealed a sufficient promoter effect for 200 mg of nickel fine particles,[6] 100 mg of $Pt(acac)_2$ was used for a sample of HR-TEM.

3. Measurement. Nickel fine particles were suspended in ethanol and then scooped up with a micromesh. The particles on a micromesh were dried under a vacuum and then used as a specimen.

Samples were observed with a JEM-200CX HR-TEM apparatus, with the aberrations of C_s=0.7 mm and C_c=1.2 mm. The accelerating voltage was 200 kV, and the aperture of the electron beam was 5×10^{-4} rad. The error in the length was some ten %.

Results and Discussion

1. An Electron Micrograph of Nickel Fine Particles. Nickel fine particles were observed by means of HR-TEM after a catalytic reaction. Although TEM does not give an accurate value of the length, the ratio of the length is correct. Since nickel fine particles gathered and formed secondary particles, it was necessary to look for an isolated particle on the periphery of

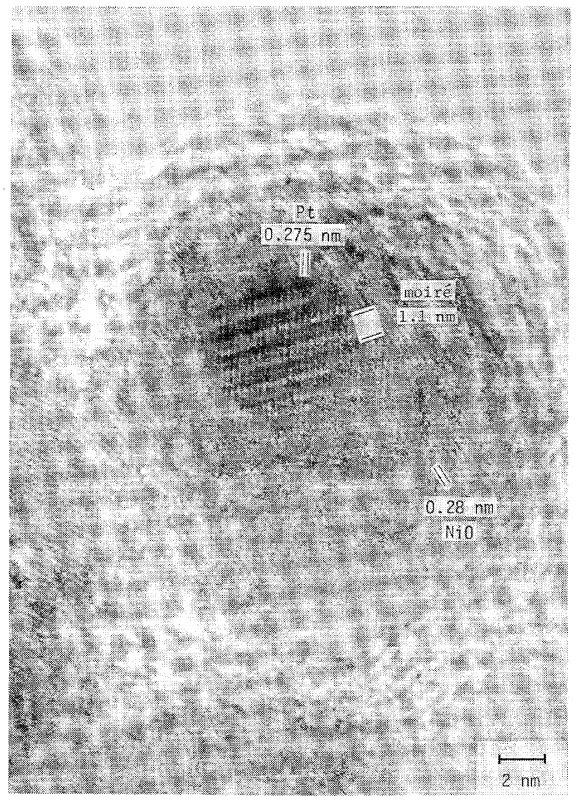

Fig. 2. A structure image of platinum-deposited nickel fine particles by HR-TEM.

a lump in order to obtain a clear picture.

Figure 1 is a tomogram of nickel fine particles. The Miller index of a lattice plane was identified by the comparison of an observed interplanar spacing with one in the literature of X-ray crystal-structure analysis.[7] The observed and cited spacings are summarized in Table 1.

A lattice of fcc Ni(111) appeared in the middle of a particle in Fig. 1. Thin layers of NiO(111) enclosed the nickel metal. The thickness of NiO was consistent with the oxygen content. Catalytically active sites on the surfaces of a particle were oxidized again, since the particle was preserved in air after a reaction.

Thick amorphous layers surrounded a particle. Probably they were organic compounds, because those amorphous layers were not found in a micrograph of the particle that was not used for a catalytic reaction.

2. Platinum-Deposited Nickel Fine Particles. When 9 mg of $Pt(acac)_2$ was reduced on 200 mg of nickel fine particles, the platinum was deposited on the active sites of the particles. This was because the number of active sites of a platinum-deposited nickel catalyst equaled that of a nickel-alone catalyst.[6] Since no image of platinum was observed in micrographs of those platinum-deposited particles, the amount of $Pt(acac)_2$ was increased to 100 mg. Thick layers of platinum were produced on a nickel fine particle and could be observed by means of HR-TEM, though excessive platinum coagulated to make a characteristic peak in the X-ray diffraction pattern.

These platinum-deposited nickel fine particles exhibited a moiré pattern, as shown in the middle of Fig. 2. The TEM was focused on a particle surface on this occasion. The lattice with an interplanar spacing of 0.275 nm was a Pt(111) lattice, judging from a comparison in Table 1. The observed interplanar spacing of Pt(111) was slightly larger than the value to be expected from a bulk crystal, because the observed platinum lattice was influenced by the layers under it.

The moiré crossed the Pt(111) lattice obliquely. This shows that another lattice was obliquely superposed on or under the Pt(111) lattice. On the basis of the analysis to be described below, a lattice of NiO(111) piled at an angle of 14° to the platinum. Probably surface nickel metal was oxidized again in spite of the covering of platinum.

When the amount of $Pt(acac)_2$ was 9 mg, platinum probably formed thin layers on the active sites of a nickel fine particle. In this case, the platinum layers were so thin that neither a platinum lattice nor a moiré pattern was observed.

3. Analysis of a Moiré Pattern. A micrograph of lattices is often analyzed using the Cowley-Moodie dynamical theory, because a beam of electrons is scattered many times.[8,9] Here, crystals were assumed to be set exactly at the Braggs angle. Further, a two-wave approximation dealing with only one incident beam and one diffracted beam was adopted in order to simplify the derivation of formulae.

According to the theory, the intensity distribution of a thick crystal with an interplanar spacing of d_1 is given by

$$\psi^*\psi = 1 - C_1 \cos \frac{2\pi}{d_1}\left(x - \frac{d_1}{4}\right),$$

where ψ is a wave function and x is a position. The coefficient C_1 can be regarded as a constant. When another thin crystal with an interplanar spacing of d_2 is superposed on or under the thick crystal in parallel near a focus, the reflection from the thin crystal causes a moiré pattern by interference. The intensity distribution of the moiré is given by

$$\psi^*\psi = C_2 - C_3 \cos \frac{2\pi x}{A}, \qquad (1)$$

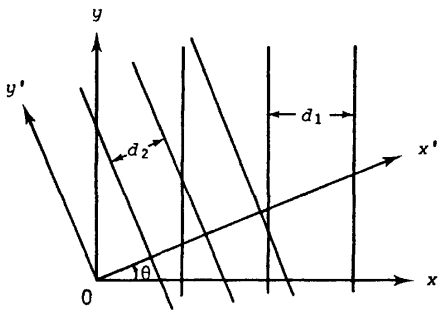

Fig. 3. Definition of the coordinates of crystal lattices.

where $1/A=1/d_1-1/d_2$. The coefficients of C_2 and C_3 are similar to C_1, and C_3 is in proportion to the thickness of the thin crystal.[9] If C_3 is very small, no moiré pattern appears.

In the present study, the theory was extended to a case in which the two crystals were obliquely superposed. The coordinates of the two crystals were defined as illustrated in Fig. 3. When θ was the angle from the x axis of a thick crystal to the x' axis of a thin crystal, the relation between the coordinates was given by

$$x'=x\cos\theta+y\sin\theta.$$

Thus, Eq. 1 was changed as follows:

$$\psi^*\psi=C_2-C_3\cos 2\pi\left(\frac{x}{d_1}-\frac{x\cos\theta+y\sin\theta}{d_2}\right)$$

$$=C_2-C_3\cos 2\pi\left\{\left(\frac{1}{d_1}-\frac{\cos\theta}{d_2}\right)x-\frac{\sin\theta}{d_2}y\right\}$$

$$=C_2-C_3\cos\frac{2\pi}{A}(x\cos\Theta+y\sin\Theta),$$

where

$$\frac{1}{A}=\sqrt{\left(\frac{1}{d_1}-\frac{\cos\theta}{d_2}\right)^2+\left(\frac{\sin\theta}{d_2}\right)^2},$$

$$\cos\theta=A\left(\frac{1}{d_1}-\frac{\cos\theta}{d_2}\right) \tag{2a}$$

and

$$\sin\theta=A\left(-\frac{\sin\theta}{d_2}\right). \tag{2b}$$

The variable Θ was the angle from the x axis to the X axis of a moiré. Since

$$X=x\cos\Theta+y\sin\Theta,$$

the intensity distribution of the moiré was given by

$$\psi^*\psi=C_2-C_3\cos\frac{2\pi X}{A},$$

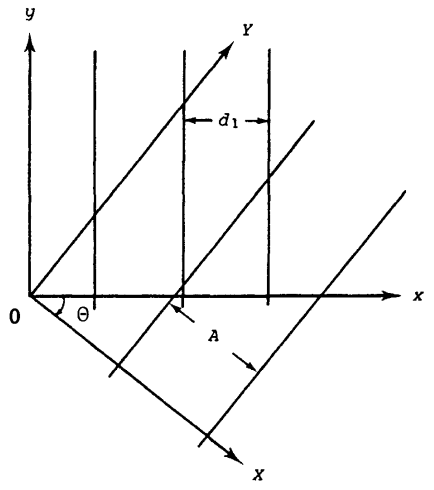

Fig. 4. Definition of the coordinates of lattice images.

as shown in Fig. 4. If θ was positive, Θ became negative. Transforming Eqs. 2 brought the solutions:

$$\theta=\arctan\left(\frac{d_1\sin\theta}{d_1\cos\theta-A}\right) \tag{3a}$$

and

$$d_2=\frac{Ad_1}{\sqrt{(A-d_1\cos\theta)^2+(d_1\sin\theta)^2}}. \tag{3b}$$

The values of d_1, A, and Θ in Fig. 2 were 0.275 nm, 1.1 nm, and $-74°$ respectively. Substituting these values into Eqs. 3 led to

$$\theta=14° \text{ and } d_2=0.28 \text{ nm}.$$

These results showed that NiO, with an interplanar spacing of 0.28 nm, was superposed under Pt at the angle of 14°.

Time-Dependent Metastable Fragmentations. The $\dot{C}H_2OH$ Loss from Methyl Acetate Ions

Ryuichi ARAKAWA
Institute of Chemistry, College of General Education, Osaka University, Toyonaka 560
(Received April 2, 1988)

The metastable ion intensity for the loss of $\dot{C}H_2OH$ from ionized methyl acetate has been measured as a function of the ion-source residence time up to 100 μs by means of the ion-trapping technique. The decay of the metastable ion intensity was adequately interpreted by the use of a prior isomerization mechanism on the basis of RRKM calculations. It was suggested that the intermediate precursor for the generation of CH_3CO^+ and $\dot{C}H_2OH$ from ionized methyl acetate is not a hydrogen-bridged complex structure, $CH_3CO\text{-}H\text{-}OCH_2^{+\cdot}$, but a distonic ion structure, $CH_3\overset{+}{C}(OH)O\dot{C}H_2$.

The unimolecular gas-phase chemistry of ionized methyl acetate has been the subject of a number of studies.[1-6]

$$CH_3COOCH_3^{+\cdot} \rightarrow CH_3CO^+ + COH_3^{\cdot} \quad (1)$$

This interest has been directed toward determining what configuration is a reacting precursor in the complexity of isomerization/dissociation paths, and also the structure of the neutral product, $COH_3^{\cdot}$. A variety of experimental techniques[1-3] have suggested that the structure of the neutral product is a hydroxymethyl $\dot{C}H_2OH$ radical rather than the methoxyl $CH_3\dot{O}$ which would be expected from a simple bond cleavage. However, recent studies[3,4] have shown that the neutral product is a mixture of these radicals. Moreover, the rearrangement of the $CH_3\dot{O}$ radical into $\dot{C}H_2OH$ is a possible process. Thus, the structure of the neutral product is still an unresolved question.

Extensive labeling experiments[3,5] on methyl acetate and its enol isomer have led to the proposal that the distonic ion $CH_3\overset{+}{C}(OH)O\dot{C}H_2$, in which the charge and radical site are separated by more than one atom, is the key intermediate. This intermediate accounts for the considerable, but incomplete, loss of the positional identity of H and D atoms in the labeled isomers. Moreover, ^{18}O-labeling and collisional activation experiments by Burgers et al.[5] have led to the similar conclusion that the distonic ion is the intermediate precursor for Reaction (1). However, their time-resolved mass spectra of ionized methyl acetate indicated that the isomerization of methyl acetate ions into other isomers is a rate-determining step in a microsecond time-frame. On the other hand, ab initio calculations at a sufficiently high level of theory were used for resolving the ionized methyl acetate problem of a multistep isomerization/dissociation pattern.[6] The theoretical analysis showed that the hydrogen-bridged radical ion/dipole complex, $CH_3CO\text{-}H\text{-}OCH_2^{+}$, is probably a precursor ion decomposing to the observed $CH_3CO^+ + \dot{C}H_2OH$.

There is, therefore, an unsettled problem regarding the isomerization/dissociation paths of ionized methyl acetate. The apparent activation energy (appearance energy—ionization energy) is as small as ca. 0.7 eV; RRKM theory predicts a minimum rate of ca. 10^7 s^{-1}. Thus, such a rate yields no metastable peak for the dissociation of ionized methyl acetate. One way of accounting for the unusual characteristics of Reaction (1) is to assume a mechanism in which the reaction path involves isomerization to a more stable structure prior to dissociation. This idea of a prior isomerization has been applied by Baer to explain the complex dissociation of several molecular ions.[7] We have investigated which isomer serves as the intermediate precursor by assuming a prior isomerization mechanism, based on RRKM calculations, so as to explain the experimental time-resolved metastable fragmentation. The decay of metastable ions is principally dependent on the rate vs. energy curve; thus, it is affected by the reaction mechanism.

Experimental

The ion-trapping technique has been described in detail elsewhere.[8] Briefly, the space charge formed by a continuous 5 eV electron beam was used to trap the ions produced when a negative pulse was applied to a filament. At a known delay time after the ionizing pulse, a positive pulse, 4 μs in duration and 5 eV in height, was applied to a repeller electrode to remove ions for mass analysis. The ionizing pulse was applied to the filament at 0.5 ms intervals. The delay time was successively varied at 3.6-μs steps. These pulse-sequence and data-acquisition systems were both computer-controlled. The measurement of the metastable-ion intensities was performed with a home-made tandem-type mass spectrometer. The temperature of the ion source was 423 K. The ion-source pressure was kept at 2×10^{-6} Torr (1 Torr≈133.322 Pa). A collision-induced reaction in the field-free region was negligible, because the pressure was maintained at less than 5×10^{-7} Torr.

Results and Discussion

The production of CH_3CO^+ was the predominant process in the metastable fragmentation of ionized methyl acetate. Figure 1 shows the metastable-to-main-beam intensity ratio against the delay time at the

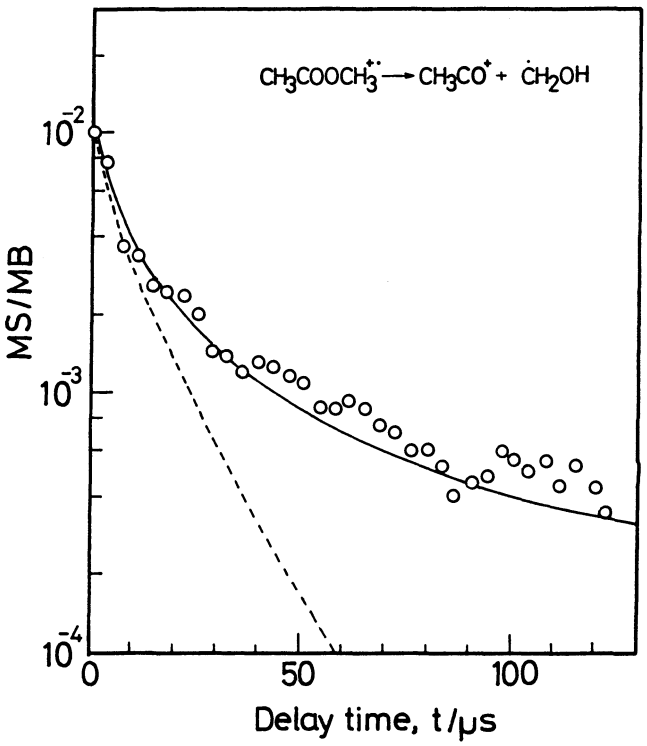

Fig. 1. A plot of the metastable to main beam intensity ratios, MS/MB, vs. the delay time for CH_3CO^+ from ionized methyl acetate: experiment (O) and calculated with the distonic precursor model (——), and the hydrogen-bridged complex model (----).

electron-impact energy of 40 eV. The metastable-ion intensity at the delay time of t is given by:[9]

$$m^*(t) \propto \int_0^\infty f(E)\, w(E)\, dE.$$

Here, $f(E)$ is the internal energy distribution, $w(E)=\exp(-t_1k(E))-\exp(-t_2k(E))$ is the time window in the present experiment ($t_1=6.5+t$ and $t_2=11.7+t$ μs), and $k(E)$ is the unimolecular rate constant. According to the threshold behavior of ionization,[10] $f(E)$ was approximated by the photoelectron spectrum of methyl acetate.[11]

The lowest energy path for ionized methyl acetate to CH_3CO^+ and $\dot{C}H_2OH$ was obtained by Heinrich et al.[6] using a high level of ab initio calculations. In the first step, methyl acetate ions isomerize into the distonic ion $CH_3\overset{+}{C}(OH)O\dot{C}H_2$, followed by rearrangement to the hydrogen-bridged complex, $CH_3CO\text{-}H\text{-}OCH_2^+$. Along their potential energy profile and the previous result[3] regarding barrier height (Fig. 2), we suppose two prior isomerization models for calculating $k(E)$ by the use of the RRKM theory: the distonic ion and the hydrogen-bridged complex serve as precursor ions, whose activation energies of E_0 for the generation of $CH_3CO^+ + \dot{C}H_2OH$ are assumed to be 1.27 and 0.64 eV respectively. The RRKM calculation was carried out by a direct counting method of the state and sum densities.[12]

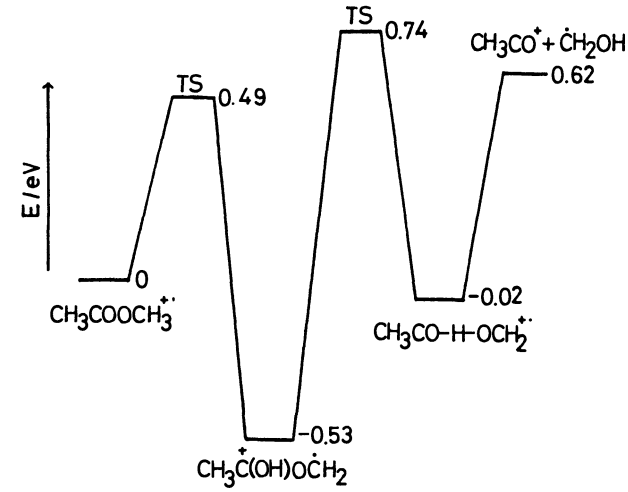

Fig. 2. A potential energy diagram of ionized methyl acetate and its isomers for the prior isomerization. This indicates a part of results previously determined from ab initio calculation by Heinrich et al.[6]

Another adjustable parameter is the set of vibrational frequencies for the reactant and transition states. Their vibrational frequencies are obtained by a vibrational analysis[13] for the assumed geometries and approximate simple-valence force fields (Appendix 1). For the distonic precursor model, the H atom of the OH bond migrates to another oxygen, and at the same time the bond order of C-OCH_2 decreases b 0.5. The hydrogen-bridged precursor model is described as a simple C-$HOCH_2$ bond cleavage for the H bridged bond. The bond orders of the hydrogen-bridged C-H and H-O bonds are assumed to be 0.5 in the reactant state. In both cases, the bond cleavage for the O-H stretching mode is employed as the reaction coordinate for the transition state; its bond order was taken as $n=0.1$. The vibrational frequencies obtained from the vibrational analysis are given in Appendix 2. The activation entropy, ΔS^*, is calculated from the set of vibrational frequencies for the reactant and transition state, and it is related to the Arrhenius preexponential factor.

The experimental results are well reproduced by the distonic-ion model (Fig. 1). The activation entropy is $\Delta S^*_{1000}=4.0$ e.u. (cal/mol/deg) if we adopt $T=1000$ K. This seems a reasonable value for the "tight" transition model, which involves a four-center cyclic moiety. For example, the loss of a halogen atom from a halobenzene ion proceeds via a simple bond cleavage and a "loose" transition state. Its activation entropy is known to be $\Delta S^*_{1000}=7—10$ e.u.[14] As may be seen in Fig. 3, the rate constants obtained by the prior isomerization models are metastably slow ($\leqq 10^5$ s^{-1}), but if the isomerization of methyl acetate ions is a rate-determining step, its rate is much greater than those obtained by the prior isomerization models. This is mainly because the distonic-ion model exhibits a high activation energy and because the hydrogen-bridged

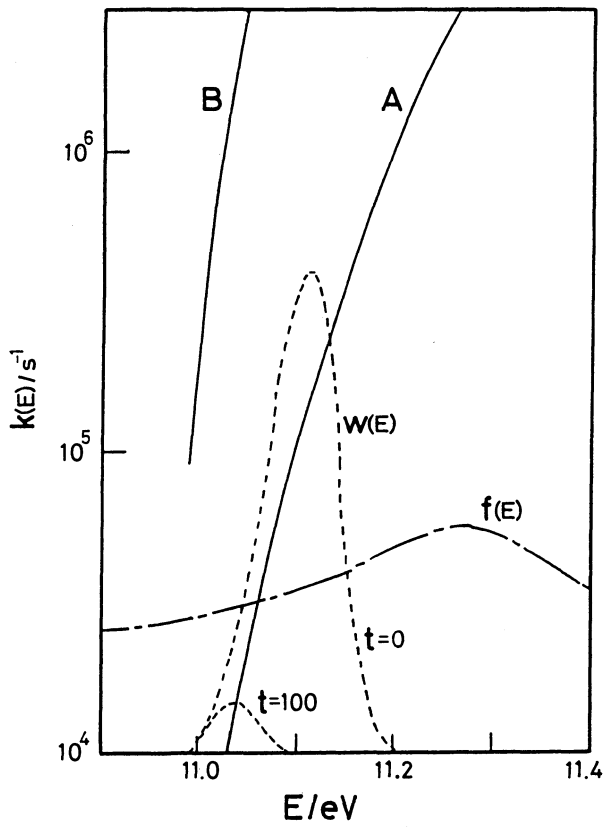

Fig. 3. The dissociation rate, $k(E)$, vs. energy, E; the rates derived from the distonic precursor model (A) and the hydrogen-bridged complex model B). $w(E)$ indicates the metastable time windows at t=0 and 100 μs. $f(E)$ represents the internal energy distribution. $w(E)$ and $f(E)$ are plotted on a linear scale.

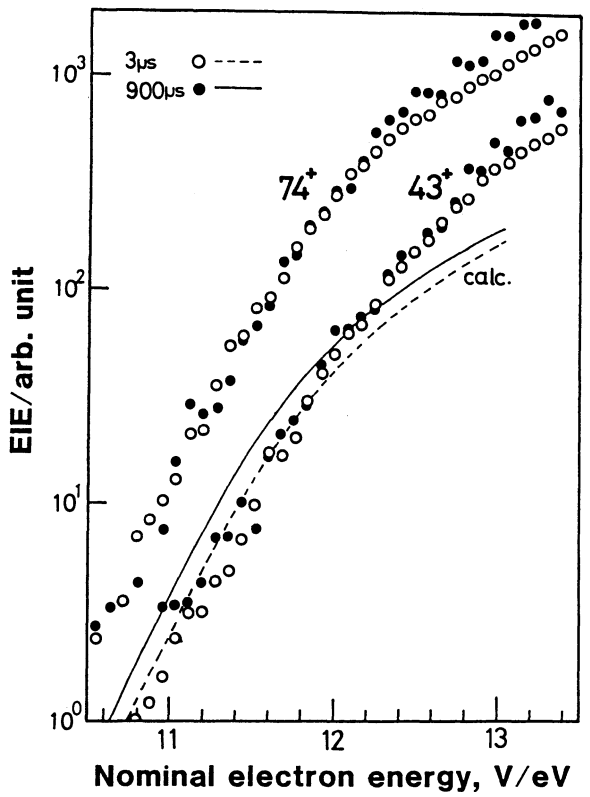

Fig. 4. The time-dependent electron ionization efficiency (EIE) curve vs. nominal electron energy, V, for methyl acetate ion (74^+) and CH_3CO^+ (43^+): experiment (O, ●) and calculated (----, ——) at the ion-source-residence time of t=3 and 900 μs.

complex model has a loose structure, e.g., small vibrational frequencies, in spite of the low activation energy. The prior isomerization models cause the higher state density of the reactant state at the threshold energy. The decay of metastable ions depends upon the two adjustable parameters of E_0 and ΔS^*. However, from actual calculations, the decay was found to be much more dependent on E_0 than ΔS^*. The activation entropy increases with the decrease in the bond order of the reaction coordinate.

The "kinetic shift," which is called the excess energy required to produce a detectable dissociation, usually in several μs, is attributable to a slope of $k(E)$ vs. the energy; a steeply-rising slope gives a less kinetic shift. In order to determine the kinetic shift, the time-dependent electron ionization efficiency (EIE) curves were measured for t=3 and 900 μs; they are shown on a semilogarithmic plot in Fig. 4. The EIE curves for the parent ion were used for normalization. There is no shift observed in the time-resolved EIEs of the CH_3CO^+ fragments. It can be reproduced, within the limits of experimental error, by use of the distonic-ion model. Naturally, the EIE shift decreases with the steepness of the $k(E)$ vs. energy plot. The energy distribution of electron impact should be considered for the EIE calculation.[9] Its distribution, as estimated from the second derivative of the helium EIE curve,[15] was found to be 0.8 eV at a half-maximum. Because of the poor energy resolution, the most significant result is not the EIE curve itself, but only its shift. The appearance energy of 10.9±0.1 eV obtained from the EIE difference near the threshold agrees with the previous result.[16]

In a system of ionized methyl acetate, the prior isomerization mechanism was examined in order to explain the present results of time-resolved metastable fragmentations and EIEs. It is suggested that the distonic structure among several isomers is the plausible precursor decomposing metastably to $CH_3CO^+ + \dot{C}H_2OH$.

Appendix

1. The geometry of the reactant state is most conveniently specified in terms of the bond orders and bond angles. The reacting bond length for the transition state is modified from the standard length, r_0, and adjusted by Pauling's expression, $r=r_0-0.31$ n (n), where n is the bond order. The stretching and angle bending force constants for the transition state are modified by $F_r=nF_r^0$ and $F_a=g(\theta)n_in_jF_a^0$, where F^0 is the standard force constant, n_i and n_j are the bond orders in the bending mode, and $g(\theta)=1.39+1.17\cos(\theta)$ is the hybridization factor for the bond angle θ. The torsional and

out-of-plain bending force constants are not modified from the reactant force constants. For a simple bond cleavage, the force constant for the stretching mode of the reacting bond in the reaction coordinate is negative. This provides an imaginary frequency because of a negative curvature at barrier.

2. The following vibrational frequencies (cm^{-1}) for the reactant and the transition state were obtained by means of vibrational analysis using a simple vibrational force field; they were used in the RRKM calculations.

(Received April 8, 1988)

The reaction mechanisms of the photocatalytic oxidation of several different alcohols on TiO_2 were investigated by three experimental techniques: spin trapping, photocurrent measurement, and product analysis. The results are interpreted according to the band model of a semiconductor and current doubling. It was found that alcohols with α-hydrogens gave low concentrations of spin adducts since their photoproduced radicals have short lifetimes on TiO_2 due to a current-doubling process. Also, it was found that oxygen participated in a radical chain mechanism in the photocatalytic oxidation of ethanol to acetaldehyde.

The application of photoelectrochemistry and photocatalysis to organic synthesis has been recently reviewed.[1-3] In these reviews many kinds of organic reactions on photocatalysts have been introduced. Principally, reactions on photocatalyst are understood to be short-circuited electrolytic reactions. However, there are some reactions which afford different products from those obtained in electrolysis on metal electrodes or in chemical reactions with redox reagents. For example, the photocatalytic oxidation of diphenylethylene on TiO_2 gives diphenylketone, while the electrolysis on Pt attains oxidative dimerization.[4] Many attractive reactions, such as phenol formation from benzene[5] and N-alkylation of amines,[6] have also been reported. In some cases alcohols are involved in these reactions. Therefore, it is necessary to understand how alcohols react on a photocatalyst. In this work we investigated the reaction mechanism of the photocatalytic oxidation of several different alcohols on TiO_2 by correlating the results from three experimental techniques: spin trapping, photocurrent measurement, and product analysis.

In the current study, TiO_2 was used as the semiconductor since it is stable; a wealth of information has been developed concerning photocatalysis on its surface. Different alcohols were chosen for the reactants in order to obtain information on the effect of the molecular structure on the reaction mechanism.

Information on the reaction of organic substances on the irradiated surface of semiconductors was obtained by the spin-trapping technique.[7,8] This technique involves the reaction of a diamagnetic spin-trapping reagent with short-lived radicals to produce relatively stable paramagnetic spin adducts which can be detected and identified by electron spin resonance (ESR). For example, a spin-trapping reagent such as 5,5-dimethyl-4,5-dihydro-3*H*-pyrrole *N*-oxide (DMPO) reacts with various radicals to give spin adducts whose ESR spectra have hyperfine structures. From the hyperfine structure, information concerning the structure of the trapped radical can be deduced. In this way, we can obtain information about the kind of radicals involved in the reactions. Recent investigations concerning photocatalytic oxidations of alcohols on semiconductor powder using the spin-trapping method were reported by this laboratory[9] and Leaustic et al.[10]

Photocurrent doubling is another important technique[11] for investigating photocatalytic reaction mechanisms on semiconductors. This type of reaction on an n-type semiconductor is illustrated as follows. A photon ($h\nu$) whose energy is equal or larger than that of the band gap of semiconductor produces an electron-hole pair. The current-doubling reagent (R_{cd}) donates an electron to the valence band and the resultant radical species($R_{cd}^{\cdot}$) is then converted into species ($R_{cd}^{\cdot}$*), which has a sufficiently high electronic potential that another electron is injected from $R_{cd}^{\cdot}$* into the conduction band. The whole reaction is that R_{cd} donates two electrons to the semiconductor electrode; as a result, the photocurrent is theoretically double that which is usually observed when only the first electron is injected. Current-doubling reactions have been investigated using many different semiconductors and substances.[11-18] For alcohols on TiO_2, Miyake et al. reported that alcohols with α-hydrogens react as current-doubling reagents, but those without α-hydrogens do not.[13]

Since oxygen may play a significant role in photocatalytic reactions, we studied this effect under air and nitrogen.

Experimental

Spin Trapping Experiment. Slurries of TiO_2 were prepared in pure alcohols since the presence of water, even at a 50% level, causes losses in the ESR sensitivity and, hence, very weak ESR spectra result. Titanium dioxide powder (10 mg; P-25 Nippon Aerosil, 30 nm diameter) was dispersed in one of six alcohols (1 ml), and mixed ultrasonically for more than 20 min in order to produce a slurry that was stable during the course of the experiments. To remove dissolved oxygen, the slurry was freeze-pumped at least three times and back-filled with dry nitrogen. A spin-trapping reagent (DMPO 5 μl, Sigma, used as-received) was added to the slurry, an aliquot of which was introduced into a quartz ESR flat cell (volume 0.52 cm^3, spacing 0.3 mm) by means of a rubber squeeze bulb. To prevent oxygen from entering the

slurry, preparations were made under flowing nitrogen gas. The cell was placed in a TM_{110} cavity of an X-band electron spin resonance spectrometer (JEOL, JES-PE-1X). The microwave power was 10 mW and the modulation amplitude was 1.0 Gauss for all experiments. ESR measurements were made immediately after irradiation for 30 s and 1 min was required to scan the spectrum. Ultraviolet irradiation was directed to the window of the cavity using a 500 W high-pressure mercury lamp with a glass filter which cut off wavelengths shorter than 390 nm and a water filter which absorbed infrared radiation. Light with wavelengths <390 nm caused a decomposition of DMPO or its spin adducts to give a complicated ESR spectra. All alcohols used in these experiments were at least of 98% purity.

Current Doubling Experiment. The photocurrent was measured in a solution containing 0.05 M HCl in an alcohol-water mixture (1:1 in volume). The usual three-electrodes method[13] was employed, where a single crystal of TiO_2 was the working electrode, Pt was the counter electrode, and a saturated calomel electrode (S.C.E.) was the reference electrode, respectively. The light source was a 500 W Xe-lamp with a water filter to decrease infrared radiation.

Photoelectrochemical Oxidation of Ethanol and Product Analysis. The electrolyte for the photoelectrolysis was a mixture of aqueous HCl solution (0.1 M, 2 ml) and ethanol (2 ml). The working electrode (W.E.) was thin-layer TiO_2, deposited on tin oxide-coated glass by spray pyrolysis using titaniumoxy acetylacetonate. A Pt counter electrode and an S.C.E. reference electrode were incorporated in the cell. Irradiation to the TiO_2 was performed through the glass and the tin oxide. Quantitative analyses of a small aliquot of the solution were performed periodically by gas chromatography (Hitachi 163; column: PEG 4000). Qualitative analyses were performed using a GC-MS (Shimazu QP-1000; column: PEG 1500) after distillations of the electrolyte in order to condense the oxidation products. The amount of oxygen in solution was controlled by bubbling nitrogen or oxygen into the solution.

Results and Discussion

The role of oxygen in the mechanism of the photocatalytic oxidation of alcohols was studied by controlling the relative amount of oxygen in solution. Two main sets of experiments were performed: 1) in the "absence" of oxygen by prior purging the solution with nitrogen and 2) in the "presence" of oxygen by bubbling of the solution with oxygen or air. The four lower alcohols were investigated in the absence of oxygen, but only ethanol was studied in the presence of oxygen.

1. Photocatalytic Oxidation of Alcohols in the Absence of O_2. A. Spin Trapping Reaction: Prior to irradiation, the intensity of the ESR spectrum was insignificant. UV irradiation to the slurry of TiO_2 containing 2-methyl-2-propanol and DMPO gave the ESR spectrum shown in Fig. 1(a). The peak-to-peak values (indicated by the arrows in the figure) were used as a measure of the relative concentration of the spin adducts. Methanol, ethanol, and 2-propanol gave similar ESR spectra, but their adduct concentrations were much smaller than that of 2-methyl-2-propanol, as shown in Table 1. Slurries of C_5 alcohols, such as 2-methyl-2-butanol and 3-methyl-2-butanol, also gave concentrations of spin adducts about equal to that of 2-methyl-2-propanol. However, in the case of these higher alcohols, the ESR spectra were more complicated, suggesting that several kinds of radicals were formed and subsequently trapped by DMPO. The hyperfine splitting constants of the spectra of the alcohol-TiO_2-DMPO slurries in the absence of oxygen (Fig. 1, curve a) indicate that the radical trapped by DMPO is a carbon-centered radical.[19] The production of carbon-centered radicals in photocatalytic reaction

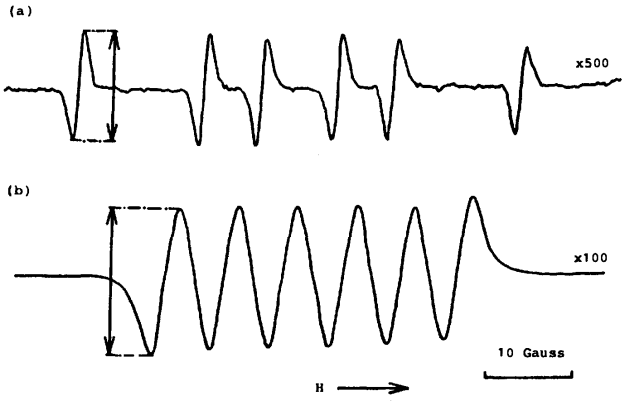

Fig. 1. ESR spectra observed after illumination of a slurry of 2-Me-2-PrOH, TiO_2, and DMPO; (a) spectrum in the absence of oxygen; (b) spectrum in the presence of oxygen.

Table 1. Comparison of Results of Spin Trapping and Current Doubling Experiments. The Relative Spin Adduct Concentrations were Determined from the Peak to Peak Values of ESR Spectra, and the Percent of the Photocurrent Increase Due to the Addition of an Alcohol was Determined from the Photocurrent Increase with Respect to Photocurrent in the Absence of Alcohol

Alcohol	Experimental method	
	Spin adduct concn. (a.u.)	Photocurrent increase (%)
MeOH	<1	25
EtOH	<1	27
2-PrOH	<1	30
2-Me-2PrOH	8	0

has also been suggested from product analyses of the slurries of 2-methyl-2-propanol and Pt-loaded TiO_2 by Nishimoto et al.[20]

Our results suggest that the radical species produced from 2-methyl-2-propanol have a sufficiently long lifetime to be trapped by DMPO, whereas those produced from methanol, ethanol, and 2-propanol had much shorter lifetimes and, hence, were not trapped. The fact that the latter three alcohols gave low concentrations of spin adducts suggests that the photocatalytically produced radicals were involved in another process whose reaction rate is faster than that of the spin-trapping reaction. The other process will be discussed in the section on current doubling. The significant difference among these alcohols is due to the fact that 2-methyl-2-propanol does not have an α-hydrogen, whereas the other three alcohols do. The results concerning the two C_5 alcohols, one of which has an α-hydrogen, can propably be explained by a rapid fragmentation of the photocatalytically produced radicals.

B. Current Doubling Reactions: We made current doubling measurements on the four lower alcohols in order to comfirm the work of Miyake et al.,[13] and also on the two higher C_5-alcohols. The results of the current-doubling experiments with the four lower alcohols in the absence of oxygen are shown in Table 1. The photocurrent was not increased by the addition of 2-methyl-2-propanol; however, upon by the addition of the other three alcohols the photocurrent increased within a range of 25 to 30%. Incidentally, the increase in current doubling was not as large with TiO_2 as with ZnO.[13-15] Our results with the six alcohols agree with the conclusions of Miyake et al.,[13] namely that an alcohol with an α-hydrogen reacts as a current-doubling reagent, but that an alcohol without α-hydrogen does not.

The results of the current-doubling experiments can be interpreted according to the band model theory, as shown in Fig. 2. This figure shows two mechanisms for oxidation, one for an alcohol with an α-hydrogen and the other for an alcohol without an α-hydrogen. The redox potentials of all alcohols are sufficiently low to be oxidized by the hole in the valence band of TiO_2. Therefore, regardless of whether the alcohols have an α-hydrogen or not, photoproduced holes oxidize the alcohols by electron transfer to the valence band of TiO_2, and an initial radical is produced. The redox potential of the produced radical determines whether the radical species can inject another electron into the conduction band of TiO_2 or not. An alcohol with α-hydrogen affords a radical which can inject another electron, while an alcohol without α-hydrogen does not.[21]

The results of spin trapping and current doubling shown in Table 1 (that is, current doubling reagents do not give a high concentration of spin adducts) suggest that the rate of second-electron injection into the conduction band is faster than that of spin trapping by DMPO under our conditions.

2. Photocatalytic Oxidation of Ethanol in the Presence of O_2. A. Spin Trapping Reactions: The introduction of oxygen into a spin-trapping slurry system containing 2-methyl-2-propanol changed both the hyperfine splitting (h.f.s.) constants and the intensities of the ESR spectra. The ESR spectrum is shown in Fig. 1 (curve b), where it is compared with the spectrum (curve a) observed when nitrogen was introduced into the slurry. In the presence of oxy en the hyperfine structures of the ESR spectra observed for all four alcohols were similar, and the h.f.s. constants indicated that oxygen-centered radicals were traped.[21] The concentrations of the spin adducts from all four alcohols could be increased by oxygen bubbling, and the intensity of the spectrum was significantly greater for 2-methyl-2-propanol than the other alcohols, as was the case in the absence of oxygen (Table 2).

There are two possible mechanisms for the formation of oxygen-centered radicals: (1) molecular oxygen reacts with the photocatalytically produced C-centered

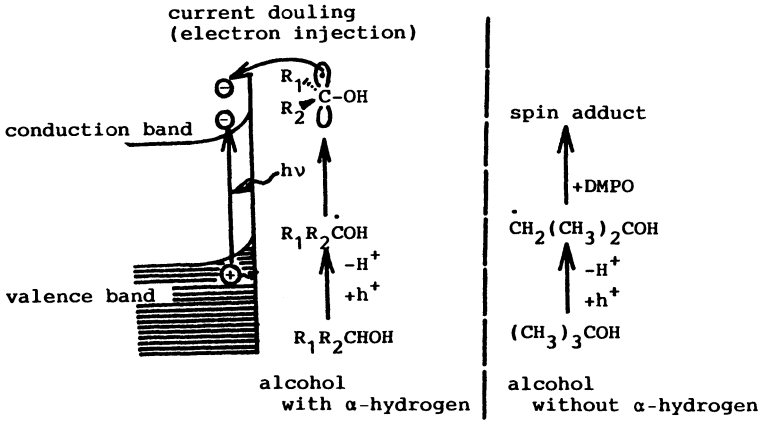

Fig. 2. Reaction mechanism of the current doubling and the spin trapping reactions of alcohols with and without α-hydrogens on TiO_2.

Table 2. Relative Spin Adduct Concentrations of Slurries of Alcohols TiO_2, and DMPO upon Irradiation in the Presence of Oxygen or Nitrogen. Spin Adduct Results under Nitrogen Were Taken from Table 1

Alcohol	Spin adduct concentration (a.u.)			
	MeOH	EtOH	2-PrOH	2-Me-2-PrOH
Under N_2	<1	<1	<1	8
Under O_2	4	4	4	56

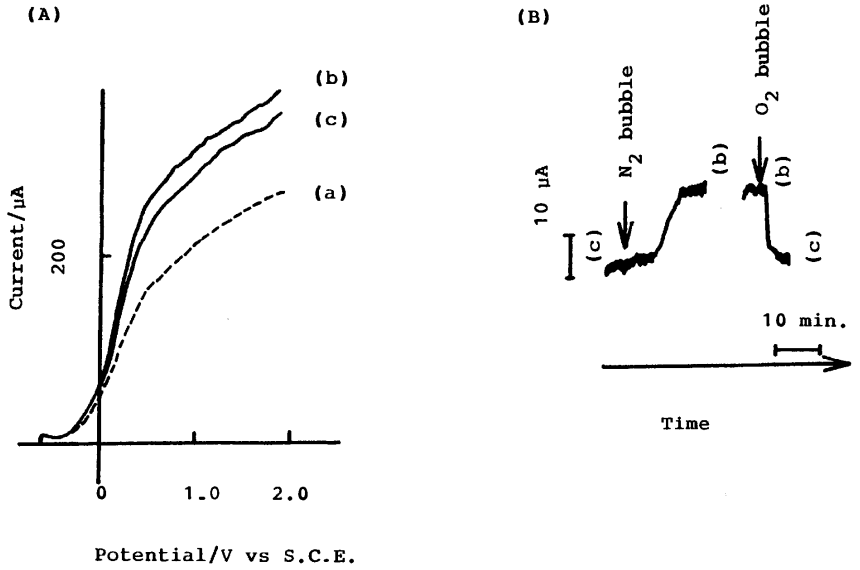

Fig. 3. Oxygen effect on the current doubling reaction of ethanol. (A) current-potential curves under illumination (a) without ethanol under nitrogen or oxygen, (b) with ethanol under nitrogen, and (c) with ethanol under oxygen; (B) time profile of photocurrent under oxygen or nitrogen in the presence of ethanol measured at 0.0 V vs S.C.E.

radicals, and (2) an oxygen anion radical, which is produced through the reduction of molecular oxygen by electrons from the conduction band, reacts with an alcohol molecule to produce a radical species. However, hydrogen atom abstraction from alcohol by a superoxide ($O_2^{\cdot-}$) is unlikely.[22] In this case a hydroperoxyl radical ($HO_2^{\cdot}$) or a hydroxyl radical ($\cdot OH$) produced by a cathodic reaction from oxygen molecule[5] may play a significant role. In both cases the formation of a C-centered radical is the first step and the reaction of this radical with oxygen molecule may give an O-centered radical.

The fact that oxygen increased the concentrations of the spin adducts for all alcohols, even for alcohols with an α-hydrogen, suggests that the rate of a second-electron injection step (i.e., current doubling) is not much faster than that of the reaction of the radicals with oxygen species. In this study we were not able to specify the reason why the concentrations of the spin adducts were increased by oxygen. However, we can propose several mechanisms, as follows, which may account for these results. First, an oxygen adsorbed on TiO_2 accepts a photoexcited electron from the conduction band and this results in a decrease of the recombination of the photoproduced hole with the electron. The resulting larger concentration of holes react with an alcohol to produce radicals more efficiently than the holes in the absence of oxygen. Secondly, an oxygen reacts with a photoproduced radical by a radical chain mechanism which is discussed later. By means of this chain mechanism the concentration of radicals increased and, hence, a higher concentration of spin adducts resulted. Thirdly, the reduction of an oxygen molecule leads to the formation of radical species which abstract a hydrogen atom from ethanol to give more radical species. Lastly, the trapping rate constant of DMPO differs according to the type of radical. For example, DMPO traps O-centered radicals more efficiently than C-centered radicals, which suggests even at the same concentration O-centered radicals give more spin adducts than C-centered radicals do.[23]

B. Current Doubling Reactions: The introduction of oxygen gas into the electrolyte containing ethanol partially reduced the current increase due to the addition of alcohol, as shown in Fig. 3 (A). The difference in the photocurrent increase under nitrogen and oxygen is small but significant. It was further substantiated by the time profile of the photocurrent

with ethanol under nitrogen or oxygen bubbling into an electrolyte, as shown in Fig. 3(B). In this experiment, when oxygen gas was replaced with nitrogen, the photocurrent increased slowly. Later, when the nitrogen was replaced with oxygen, the photocurrent decreased rapidly. Both these changes were reversible. The difference in the time profile between the photocurrent increase and decrease can be attributed to the oxygen adsorbed on the TiO_2. The radical species which injects another electron is adsorbed on the TiO_2. Therefore, effective oxygen should also be found on the TiO_2. It takes more time to remove the oxygen from the surface of TiO_2 by nitrogen gas bubbling than to provide adsorbed oxygen by oxygen gas bubbling. Consequently, the photocurrent increased slowly and decreased rapidly.

The reduction of the photocurrent by introducing oxygen into the photoelectrochemical system suggests that oxygen or an oxygen radical species reacted with the initial radical species. To account for the fact that oxygen did not completely eliminate the photocurrent increase, we propose that the reaction rate of electron injection from the alcohol radical species is comparable to that of the reaction of the radicals with oxygen species. Since these results were obtained with an electrode system in which most of the electrons in the conduction band were collected by the counter electrode and consumed to produce hydrogen, we conclude that the active species at the TiO_2 surface is probably molecular oxygen and not an oxygen anion radical.

C. Photoelectrochemical Oxidation of Ethanol and Product Analysis: A photoelectrolysis of an ethanol-HCl solution under nitrogen or oxygen led to a product with the same retention time in gas chromatograms. GC-MS revealed that the only product was acetaldehyde, the amount of which was about ten-times greater in the presence of oxygen, as shown in Fig. 4. The current efficiency for the production of acetaldehyde under nitrogen is about 20%. The low efficiency may be attributed to a competitive oxidation of water.

Acetaldehyde is reported to be produced by the current-doubling reaction with ethanol.[13] Moreover, our results show that acetaldehyde formation is enhanced by the presence of oxygen. This result and the discussions in the previous section lead us to conclude that molecular oxygen is the active species for the enhanced production of acetaldehyde compared to that in the absence of oxygen. To account for the photoelectrochemical oxidation of ethanol we propose the reaction mechanism shown in Fig. 5. Molecular oxygen reacts with a C-centered radical(I), which is produced photocatalytically to give a peroxyl radical (II), which in turn decomposes by an autoxidation step to produce acetaldehyde and hydroperoxyl radical(III). This radical(III) abstracts hydrogen from ethanol and leads to the production of another C-centered radical(I). According to this reaction mechanism, one photon results in the formation of several acetaldehyde

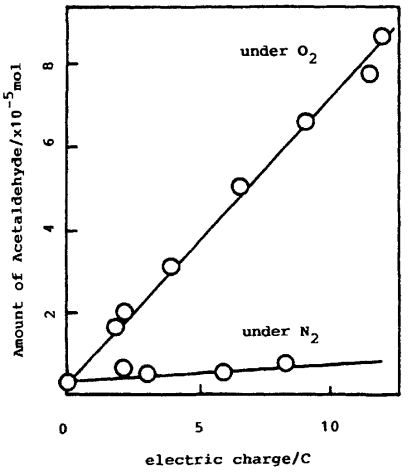

Fig. 4. The effect of oxygen on the amount of acetaldehyde produced by photoelectrolysis of ethanol in aqueous 0.1 M HCl (1:1). W.E.:TiO_2 on SnO_2 coated glass; C.E.:Pt; R.E.:S.C.E.; photoelectrolysis at 2.5 V vs. S.C.E.

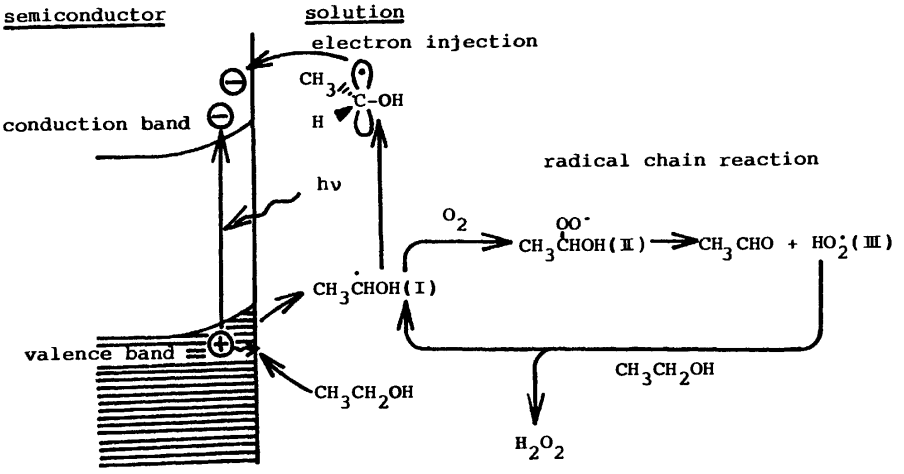

Fig. 5. Reaction mechanism of ethanol oxidation on illuminated TiO_2 in the presence of oxygen. The reduction processes are omitted.

molecules. This increase in the amount of acetaldehyde results from a free radical chain reaction mechanism involving molecular oxygen. Such a free radical chain mechanism has been suggested for photoirradiated slurries containing olefins and TiO_2 or CdS.[1] The formation of another product, H_2O_2, was also reported on photoexcited TiO_2, although it has only a transient existence in aqueous dispersion of TiO_2.[24]

Conclusion

In this article, we compared the photocatalytic reactions in slurries and on photoelectrodes and obtained a good correlation between the results from both systems. An alcohol with an α-hydorgen is oxidized to the radical species which can inject another electron into the conduction band of TiO_2. The rate of electron injection is faster than that of a spin-trapping reaction by DMPO and is comparable with that of the reaction with oxygen. The reaction process becomes a radical chain process under oxygen. An alcohol without an α-hydrogen is oxidized to the radical species which can not inject another electron. Therefore, this radical is trapped by DMPO. These results indicate a criterion for the application of photocatalytic reactions of alcohols to organic syntheses. Alcohols with α-hydrogen can be used for the in situ preparation of carbonyl compound for the *N*-alkylation of amines[6] since they are subjected to a rapid two-electron oxidation. On the other hand, alcohols without α-hydrogen can be used for the generation of radical species for the radical coupling reactions[20] because the produced radicals are relatively stable. The oxidation of 2-methyl-2-propanol on Pt electrode does not produce a new C-C bond like on photocatalyst, but gives acetone and 2-methylpropane.[25]

In our discussions of the photooxidation of alcohols we have stated that oxidation starts from direct reaction with the photoproduced holes in the valence band of TiO_2. However, it is equally possible that the oxidation occurs by an indirect process involving hydroxy radicals produced by oxidation of surface OH groups by holes, which we do not distinguish from the direct reaction with a hole.

We acknowledge valuable discussoins with Dr. Yorihiro Yamamoto of the Faculty of Engineering, University of Tokyo.

Thermotropic Liquid Crystal Properties of Alkylammonium Alkanesulfonates

Yoshio MATSUNAGA* and Kiyoshi NISHIDA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received April 15, 1988)

Alkylammonium methane-, ethane-, 1-propane-, and 1-butanesulfonates exhibit a smectic A phase when the cation carries a dodecyl or longer alkyl group. The temperature range of the existence decreases in the following order: methanesulfonates > 1-propanesulfonates > ethanesulfonates > 1-butanesulfonates. In the last series, the mesophase is entirely metastable. The layer spacing in the 1-propanesulfonate is shorter by about 0.30 nm than that of the corresponding methanesulfonate, even though the alkyl chain length in the anion is increased by 0.25 nm.

Several series of long-chain alkylammonium salts have been known to exhibit mesophases. For example, alkylammonium tetrahalometallates, $(RNH_3)_2MX_4$, in which the alkylammonium ions form a double layer between MX_4 sheets, have been extensively examined and often considered as crystalline models of lipid bilayers.[1] Furthermore, the isotropic liquid of some alkylammonium chlorides is known to be preceded by a smectic A phase.[2] Since the role of a counter ion in the liquid crystal formation must be important in a system as simple as the above-mentioned salts, we have undertaken studies regarding the influence of the range of anions on the thermal properties of alkylammonium salts. Various sulfonic acids are readily available and form mesomorphic salts when combined with many long-chain alkylamines; therefore, these salts seemed to be particularly suitable for our purpose. This paper, the first of this series, reports on the properties of four series of alkanesulfonates.

Experimental

Materials. Equimolar amounts of an alkylamine and an alkanesulfonic acid dissolved in boiling alcohol were mixed. The precipitated salt was purified by recrystallization and kept in a vacuum desiccator. For example, Found: C, 59.40; H, 11.59; N, 4.33%. Calcd for $C_{15}H_{31}NH_3^+CH_3SO_3^-$: C, 59.40; H, 11.53; N, 4.33%.

Measurements. Calorimetric curves were recorded on a Rigaku Thermoflex differential scanning calorimeter at a heating or cooling rate of 5 K min^{-1}. The mesomorphic-isotropic transition was well defined on the curve; its reversal at the same temperature assured us of the purity of our salts. Enthalpy changes were estimated by comparing the peak areas with that due to the melting of indium, 3.26 kJ mol^{-1}. Phase diagrams were determined by the calorimetric curves of mixtures. X-Ray diffractions were measured with a Rigaku auto-diffractometer, model RAD IVB, using filtered copper radiation. The temperature of the sample holder was regulated as described in our earlier paper.[3]

Results and Discussion

The melting and clearing points and the associated enthalpies are summarized for alkylammonium methane-, ethane-, 1-propane-, and 1-butanesulfonates in Table 1. In the case of the methanesulfonates, the melting point decreases according to the sequence from dodecyl to tetradecylammonium and, then, remains at 143 °C. A plot of the clearing point against the number of carbon atoms (n) in the cation produces a curve which is slightly convex upwards. Conse-

quently, the widest temperature range of stable existence is achieved when the cation carries pentadecyl to heptadecyl groups. The clearing point of the ethanesulfonate is lower by 58 to 75 °C than that of the corresponding methanesulfonate and increases smoothly with the number of carbon atoms in the alkyl group; the melting point is lower by 48 to 63 °C. As a result, the mesophase is metastable when n is fifteen or less. Even when the phase is stable the temperature range of stable existence is no more than 5 °C. Both the melting and clearing points of the 1-propanesulfonates are located at temperatures several degrees lower than those of the ethanesulfonates. The mesophase given by the 1-propanesulfonate is stable when n is thirteen or more but the existence range is merely two to eight degrees. It may be noted that the clearing point of this series shows a marked even-odd alternation which provides an additional check on the purity. The transition temperatures are further lowered in the 1-butanesulfonates. As the depression of the clearing point is more pronounced than that of the melting point, all the mesophases observed for this series are metastable. The enthalpy change at the clearing point increases slightly with the number of carbon atoms in the sulfonate ion, but not with that in the ammonium ion.

The X-ray diffraction pattern recorded for the mesophases of the methane- and 1-propanesulfonates within or a little below the temperature range of the stable existence consists of a sharp inner peak and a diffuse outer one, indicating that the phase is of the smectic A- or C-type. The inner peak is sometimes accompanied by weak peaks assignable to second- and third-order reflections, since the specimen spread in the form of a thin layer over an aluminum holder is not free from orientation. The layer spacing measured for the methanesulfonates (see Table 1) agrees well with the sum of lengths of the cation and anion. For example, Found: 3.26 nm. Calcd for $C_{18}H_{37}NH_3^+ + CH_3SO_3^-$: 2.59+0.64=3.23 nm. The former length is estimated for an all-trans conformation of the alkyl group, employing a C-C bond length of 0.154 nm, a C-N bond length of 0.147 nm, a tetrahedral angle, a van der Waals radius of methyl group of 0.20 nm, and a thermochemical radius of ammonium ion of 0.14 nm (the latter employing a C-S bond length of 0.182 nm and a thermochemical radius of sulfate ion of 0.26 nm). The thermochemical radii were taken from a table compiled by Jenkins and Thakur.[4] Therefore, one may conclude that the mesophase given by the methanesulfonates is of the smectic A-type and that the schematic representation given in Fig. 1a may be a reasonable model. Here, the large circle represents the ionic end of methanesulfonate ion, the small circle that of the alkylammonium ion, and the wavy line the alkyl chain. This conclusion is consistent with the strong tendency shown by the mesophase to be homeotropic. The smectic phases of 4-alkylpyridinium

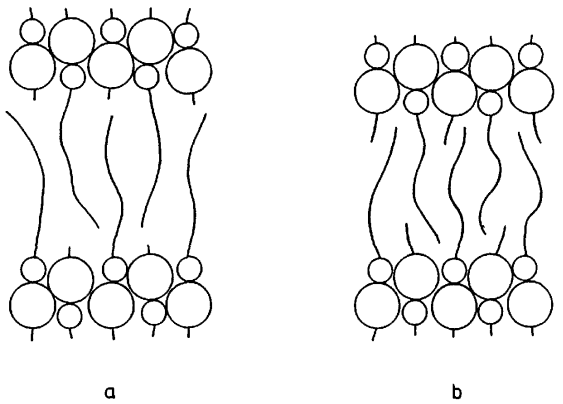

Fig. 1. Schematic representation of the proposed structure for (a) the smectic A phase of the methanesulfonate and (b) that of the 1-propanesulfonate. Large circle: the ionic end of the anion; small circle: the ionic end of the cation; wavy line: alkyl chain.

hydrochloride and 1-alkyl-4-methylpyridinium halides have been proposed to be represented by similar models by Sudhölter et al. and by Bazuin et al. respectively.[5,6] A plot of the layer spacing in the mesophase of the methanesulfonates against the number of carbon atoms in the alkylammonium ion can be fit to a slope of 0.125 nm, agreeing with the value calculated for a fully-extended configuration. The same slope appears to be applicable to a plot for the 1-propanesulfonates; however, the layer spacings, themselves, are shorter by about 0.30 nm than those of the corresponding methanesulfonates. Since the observed slope, and also the tendency to be homeotropic, strongly indicate that the mesophases are of the smectic A-type, the alkyl group attached to this anion (the whole length of which is estimated to be about 0.89 nm) must be dissolved into the layer formed by the paraffinic parts of the cations as sketched in Fig. 1b. The stable or metastable mesophases of the remaining alkanesulfonates also exhibit diffraction patterns of the same type. Although the data are scanty, the spacing seemingly decreases as the alkyl group on the anion becomes longer. The lateral spacing shrinks from about 0.47 nm for the methanesulfonates to about 0.45 nm for the 1-propanesulfonates. This change may indicate a crowding of the alkyl chains in the latter series.

The identification of the mesophases given by the ethane- and 1-butanesulfonates was supplemented by a demonstration of complete miscibility with the smectic A phase of hexadecylammonium methanesulfonate. Phase diagrams of the binary systems, consisting of hexadecylammnium ethane- and 1-butanesulfonates and a reference compound, are presented in Figs. 2a and b, respectively. In these diagrams, K, M, and I stand for crystalline, mesomorphic, and isotropic phases, respectively, and the reference compound is placed on the left-hand side. The complete miscibility between the two mesophases in the former system is

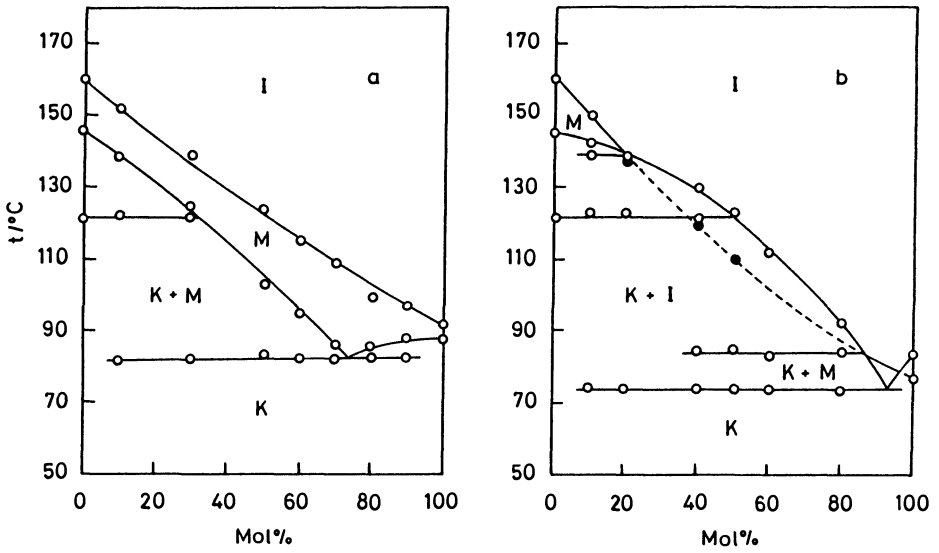

Fig. 2. Phase diagrams of (a) the hexadecylammonium methanesulfonate–ethanesulfonate and (b) the hexadecylammonium methanesulfonate–1-butanesulfonate systems. The reference compound is located on the left-hand side. The open and shaded circles are transitions observed in the processes of heating and cooling respectively.

shown by the fact that the curve smoothly connects the two clearing points. The eutectic is located at 82 °C and 73 mol% of the ethanesulfonate. The horizontal line at 121 °C on the left-hand side is due to the solid-solid transition of the reference compound. The mesophase of the 1-butanesulfonate in Fig. 2b is metastable and the major part of the M–I transition point curve is beneath the freezing-point curve of the reference compound. The shaded circles are the I–M transitions observed during the process of cooling. The intersections between these transition point curves give rise to the appearance of horizontal lines at 84 and 138 °C. The eutectic in this system is located at 73 °C and 93 mol% of the 1-butanesulfonate. The mesophase is stable only in two small regions near the melting point of the reference compound and above the eutectic point. The crystalline phase of the methanesulfonate coexists with the mesophase in the temperature range from 73 to 84 °C, with the isotropic melt in the range from 84 to 138 °C, and again with the mesophase in the range from 138 °C to the melting point (143 °C).

The present work was supported by a Grant-in-Aid for Scientific Research No. 60470001 from the Ministry of Education, Science and Culture.

The Zinc-Photosensitized Reaction of Propane

Shunzo YAMAMOTO,* Mitsuru KOZASA, Yoshimi SUEISHI, and Norio NISHIMURA
Department of Chemistry, Faculty of Science, Okayama University, 3-1-1, Tsushima-naka, Okayama 700
(Received April 25, 1988)

The zinc-photosensitized reaction of propane has been studied at a wavelength of 307.6 nm, a temperature of 633 K and pressures from about 67 to 40000 Pa. The major products were hydrogen, methane, ethylene, and dimethylbutane, while minor products detected were propylene, isobutane, ethane, butane, and hexane. The yield of hydrogen fell off with time. The quantum yield calculated from the initial rates is about unity and almost independent of the propane pressure, while the quantum yield obtained at 20 min increased with increasing propane pressure and approached about unity at higher pressures. The methane/hydrogen ratio was always smaller than unity and was independent of the propane pressure. The yield of ethylene increased linearly with an increase in that of methane. It has been concluded that the decomposition of propane is initiated through a hydrogen atom abstraction by an excited zinc atom from both the primary and secondary hydrogen of propane. Possible mechanisms are discussed.

Although there has been a considerable amount of work carried out on the mercury-[1-6] and cadmium-photosensitized decomposition[7,8] of propane, almost no attention has been paid to the zinc-photosensitized reaction of alkanes.

In a previous paper,[9] a remarkable dependence of the quenching cross section of 307.6-nm zinc resonance line by alkanes on the C–H bond strength was reported. It was pointed out that the quenching cross section of a certain alkane can be estimated as the sum of the quenching cross section for each individual quenching site (C–H bond). These findings show that the excited zinc atoms attack all kinds of C–H bonds with efficiencies which depend on the bond strength.

Recently, we have further pointed out that the differences of activation energies for the quenching for primary, secondary, and tertiary C–H bond can be well interpreted in terms of a modified bond energy-bond order method by assuming the following reaction:[10]

$$Zn^* + RH \rightarrow Zn \cdots H \cdots R \rightarrow ZnH + R.$$

These results strongly suggest that hydrogen atom abstraction from alkanes by excited zinc atoms plays an important role in the quenching of $Zn(^3P_J)$.

We have examined the products from a zinc-photosensitized reaction of propane. Here, we report on the details of analytical results.

Experimental

A zinc-photosensitized reaction of propane was carried out in a cylindrical quartz cell. A spiral Pyrex zinc-discharge lamp filled with 2000-Pa argon was used as the source of the 307.6-nm resonance line. The cell and the lamp were inserted in an electric furnace kept at 360±2 °C in order to obtain a sufficient vapor pressure of zinc.

The zinc metal used was high-purity zinc (99.9999%) manufactured by the Osaka Asahi Metal Co. Research-grade propane (Tokyo Kasei K.K. 99.5%) was used after degassing at liquid-nitrogen temperature. The impurities detected by gas chromatography were ethane and propylene; the amount of propylene was below 0.1% of that of propane. Zinc metal was heated in vacumm and the zinc vapor was sealed into capillaries. The capillary and a known amount of propane were enclosed in the cell, and the capillary was broken just before each run.

Product analyses were carried out by fractionation at −196 °C, gas burette measures, and gas chromatography. The gases non-condensable at −196 °C (hydrogen and methane) were collected by a Toepler pump, and were analyzed by combustion over copper(II) oxide at 260 °C. The products which were condensable at −196 °C, were analyzed by gas chromatography, using a 6 m column of vz-7 (Gasukuro Kogyo Co., Ltd.) at 0 °C and a 2 m column of Gasukuro-pack 55 (Gasukuro Kogyo Co., Ltd.) at 30 °C.

The light intensity at 307.6 nm from the lamp was determined by diethyl ketone actinometry,[11] by assuming that the quantum yield of carbon monoxide production at 360 °C and 307.6 nm was unity, and by correcting for any contribution from photolysis by the 328.2- and 330.2-nm lines from the lamp.

Results and Discussion

The major products from the zinc-photosensitized decomposition of propane were hydrogen, methane, ethylene, and 2,3-dimethylbutane (DMB). The minor products detected were propylene, isobutane, ethane,

33300	1.049	0.72	0.80	—	—	—	—	—	—

butane, and hexane. Their yields were less than 10% of that of hydrogen (Table 1). Some products such as hydrogen, methane, and ethylene were detected when 6700-Pa propane was kept at 360 °C for 2 hours with zinc vapor in the dark; however, their yields were less than 2% of those from zinc-photosensitized reaction. Therefore, the thermal decomposition of propane and its reaction with zinc at 360 °C could be neglected.

The yields of hydrogen, methane, and ethylene increased linearly with the light intensity, while that of DMB showed a second-order dependence on the light intensity (Fig. 1). As Fig. 2 shows, the yield of hydrogen falls off with the reaction time, and the decrease in the yield is larger at lower pressures. This suggests that the influence of the products on hydrogen production is important at lower pressures.

The quantum yield of hydrogen production calculated from the initial rates is about unity and almost independent of the propane pressure, while the quantum yield obtained at a reaction time of 20 min increases asymptotically with increasing propane pressure to unity at high pressures (Fig. 3).

Appreciable amounts of methane are formed. The ratio of Φ_{CH_4}/Φ_{H_2} is almost independent of the propane pressure (Fig. 4). A roughly equal amount of ethylene to that of methane was produced. As Fig. 5 shows, the yield of ethylene increases linealy with an increase in methane.

As mentioned above, the quantum yield of hydrogen is about unity during the initial stage of the reaction and, as Fig. 3 shows, the quantum yield of hydrogen obtained at 20 min is close to unity at higher pressures and decreases with decreasing propane pressure. The experimental results obtained in the case of high propane pressures are very similar to those of mercury-

photosensitized decomposition of propane at high temperatures,[1] and also to those of cadmium-photosensitized decomposition of propane obtained at the initial stage of reaction.[8] By following the mechanisms of $Hg(^3P_1)$-C_3H_8 and $Cd(^3P_1)$-C_3H_8 reactions, the zinc-photosensitized decomposition of propane could be discussed in terms of the following reactions:

$$Zn(^1S_0) + h\nu(307.6\ nm) \rightarrow Zn(^3P_1) \quad (1)$$
$$Zn(^3P_1) \rightarrow Zn(^1S_0) + h\nu(307.6\ nm) \quad (2)$$
$$Zn(^3P_1) + C_3H_8 \rightarrow ZnH + \alpha 1\text{-}C_3H_7 + (1-\alpha)2\text{-}C_3H_7 \quad (3)$$
$$ZnH \rightarrow Zn(^1S_0) + H \quad (4)$$
$$H + C_3H_8 \rightarrow H_2 + \beta 1\text{-}C_3H_7 + (1-\beta)2\text{-}C_3H_7 \quad (5)$$
$$1\text{-}C_3H_7 \rightarrow CH_3 + C_2H_4 \quad (6)$$
$$CH_3 + C_3H_8 \rightarrow CH_4 + \gamma 1\text{-}C_3H_7 + (1-\gamma)2\text{-}C_3H_7 \quad (7)$$
$$(H, CH_3, 1\text{-}C_3H_7, 2\text{-}C_3H_7) \rightarrow \text{recombination and disproportionation products} \quad (8)$$

Production of DMB and minor products is explained by Reactions (8).

From the above mechanism, the following relationships can be derived by neglecting Reactions (8):

$$\Phi_{H_2} = \frac{k_3[C_3H_8]}{k_2 + k_3[C_3H_8]} \quad (9)$$

and

$$\frac{\Phi_{CH_4}}{\Phi_{H_2}} = \frac{\Phi_{C_2H_4}}{\Phi_{H_2}} = (\alpha+\beta)(1+\gamma+\gamma^2+\cdots). \quad (10)$$

The quenching cross section of $Zn(^3P_J)$ by propane at 578 K was reported to be 6.94×10^{-16} cm^2.[9] This shows that k_2 in Eq. 9 can be neglected at all pressures examined here. This indicates that Φ_{H_2} is unity and is independent of the pressure. These findings are in agreement with observations during the initial stage of the reaction. As Fig. 3 shows, Φ_{H_2} is almost unity and is hardly dependent on the propane pressure at pressures higher than 20000 Pa. At lower pressures, however, Φ_{H_2} is considerably smaller than unity and depends on the propane pressure. This anomalous behavior at lower pressures and the nonlinear dependence of the hydrogen yield on time (espetially at lower pressures) shown in Fig. 2 seems to be due to the influence of the products. This point will be discussed later.

As Fig. 5 shows, the yield of ethylene is almost equal to that of methane under all conditions examined; this is in agreement with the prediction from Eq. 10. This shows that Reactions (8) can be neglected concerning the formation of methane and ethylene.

From the quenching cross sections of $Zn(^3P_J)$ by various hydrocarbons, the effective cross sections per primary C-H bond and secondary C-H bond were found to be 0.62×10^{-16} and 2.4×10^{-16} cm^2 at 578 K respectively.[9] As has been described previously,[10] the quenching rate of $Zn(^3P_1)$ by alkanes depends on the temperature. From the activation energies reported for the quenching of $Zn(^3P_1)$ by primary and secondary C-H bonds,[10] the cross sections per primary and secondary C-H bond at 633 K were estimated to be 1.1×10^{-16} and 3.9×10^{-16} cm^2, respectively. Using these values the value of α can be calculated as follows:

$$\frac{\alpha}{1-\alpha} = \frac{1.1\times6}{3.9\times2}, \text{ then } \alpha = 0.46.$$

Gunning et al.[12] gave a ratio of $\beta/(1-\beta)$ as 1.29 $\exp(-2000/1.987T)$, which is equal to 0.26 at 633 K. This value gives β=0.21. By assuming that γ is also equal to 0.21, we obtained $\Phi_{CH_4}/\Phi_{H_2}=\Phi_{C_2H_4}/\Phi_{H_2}=0.84$ from Eq. 10. This value is in fair agreement with the experimental values (0.72 for Φ_{CH_4}/Φ_{H_2} and 0.78 for $\Phi_{C_2H_4}/\Phi_{H_2}$). DMB is formed from a recombination of isopropyl radical and the steady-state concentration of this radical is probably proportional to the light intensity. This is in agreement with the tendency shown in Fig. 1.

Table 2 shows a comparison of the product formation in zinc-, cadmium-, and mercury-photosensitized decompositions of propane. The dependences of product formation on the time and propane pressure in the zinc-photosensitized decomposition of propane is different from those in the cadmium-photosensitized decomposition, but is similar to those in the mercury-photosensitized decomposition at high temperature. The dissimilarity of the cadmium-photosensitized decomposition to two other photosensitized decompositions can be ascribed to the large difference in the quenching cross section of propane and hydrogen in the case of cadmium ($\sigma_Q(H_2)/\sigma_Q(C_3H_8)$=6.2, 1500, and 3.7, for Zn,[9] Cd,[13] and Hg[14]). It was pointed out that the effect of hydrogen on the decomposition of propane must be important in the cadmium-photosensitized decomposition.[8]

We examined the effect on the product formation of the addition of *cis*-2-butene as a radical scavenger, of which the zinc-photosensitized reaction was studied in detail.[15] When *cis*-2-butene was added to propane, the quantum yields of hydrogen, methane, and ethylene

Table 2. Comparison of Product Formation in Zinc-, Cadmium-, and Mercury-Photosensitized Decomposition of Propane

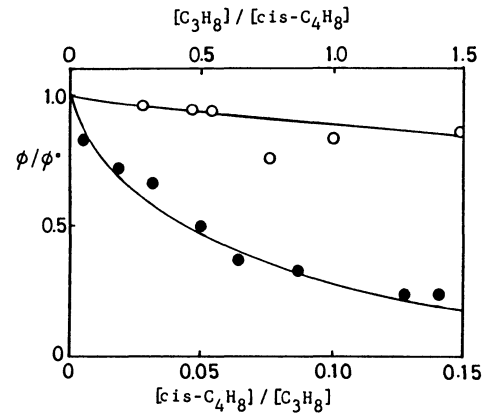

Fig. 6. Plots of $\Phi_{t\text{-}C_4H_8}/\Phi^{\circ}_{t\text{-}C_4H_8}$ against $[C_3H_8]/[cis\text{-}C_4H_8]$ (○), and of $\Phi_{H_2}/\Phi^{\circ}_{H_2}$ against $[cis\text{-}C_4H_8]/[C_3H_8]$ (●).

decreased as the quantum yield of *trans*-2-butene formation increased with an increase in the *cis*-2-butene pressure. Figure 6 shows the effect of *cis*-2-butene on the yield of hydrogen and the effect of propane on the yield of *trans*-2-butene. The following reactions are proposed to explain these effects:

$$Zn(^1S_0) + h\nu(307.6\ nm) \rightarrow Zn(^3P_1) \quad (1)$$
$$Zn(^3P_1) + C_3H_8 \rightarrow ZnH + \alpha 1\text{-}C_3H_7 + (1-\alpha)2\text{-}C_3H_7 \quad (3)$$
$$ZnH \rightarrow Zn(^1S_0) + H \quad (4)$$
$$Zn(^3P_1) + cis\text{-}C_4H_8 \rightarrow Zn\text{-}C_4H_8^* \quad (11)$$
$$H + C_3H_8 \rightarrow H_2 + \beta 1\text{-}C_3H_7 + (1-\beta)2\text{-}C_3H_7 \quad (5)$$
$$H + cis\text{-}C_4H_8 \rightarrow C_4H_9 \quad (12)$$
$$1\text{-}C_3H_7 \rightarrow CH_3 + C_2H_4 \quad (6)$$
$$CH_3 + C_3H_8 \rightarrow CH_4 + \gamma 1\text{-}C_3H_7 + (1-\gamma)2\text{-}C_3H_7 \quad (7)$$
$$Zn\text{-}C_4H_8^* \rightarrow Zn(^1S_0) + \delta trans\text{-}C_4H_8 + (1-\delta)cis\text{-}C_4H_8 \quad (13)$$

In the above, $Zn\text{-}C_4H_8^*$ is a transient triplet addition complex formed between an excited zinc atom and a *cis*-2-butene molecule. The value of δ has been reported to be 0.6 at 633 K.[15] From the above reactions, the quantum yields of *trans*-2-butene and hydrogen can be expressed as follows:

$$\Phi_{t\text{-}C_4H_8} = \delta \frac{k_{11}[cis\text{-}C_4H_8]}{k_3[C_3H_8] + k_{11}[cis\text{-}C_4H_8]} \quad (14)$$

and

$$\Phi_{H_2} = \frac{k_3[C_3H_8]}{k_3[C_3H_8] + k_{11}[cis\text{-}C_4H_8]} \cdot \frac{k_5[C_3H_8]}{k_5[C_3H_8] + k_{12}[cis\text{-}C_4H_8]} \quad (15)$$

Therefore,

$$\frac{\Phi_{t\text{-}C_4H_8}}{\Phi^{\circ}_{t\text{-}C_4H_8}} = \frac{1}{1 + \dfrac{k_3[C_3H_8]}{k_{11}[cis\text{-}C_4H_8]}} \quad (16)$$

and

$$\frac{\Phi_{H_2}}{\Phi^{\circ}_{H_2}} = \frac{1}{1 + \dfrac{k_{11}[cis\text{-}C_4H_8]}{k_3[C_3H_8]}} \cdot \frac{1}{1 + \dfrac{k_{12}[cis\text{-}C_4H_8]}{k_5[C_3H_8]}} \quad (17)$$

Here, $\Phi^{\circ}_{t\text{-}C_4H_8}$ is the quantum yield of *trans*-2-butene in the absence of propane and $\Phi^{\circ}_{H_2}$ is the quantum yield of hydrogen in the absence of *cis*-2-butene.

As has been described previously,[10] the quenching rate of $Zn(^3P_J)$ by alkane depends on the temperature. The values of k_3 and k_{11} at 578 K were reported to be 4.74×10^{-11}[9] and 8.58×10^{-10} ml molecule^{-1} s^{-1}.[15] From the activation energies for the quenching of $Zn(^3P_J)$ by primary and secondary C-H bonds, the k_3-value at 633 K was estimated to be 1.0×10^{-10} ml molecule^{-1} s^{-1}. By assuming that k_{11} is not temperature dependent, the value of k_{11}/k_3 at 633 K can be obtained (k_{11}/k_3=8.58). The upper solid line in Fig. 6 shows the value of $\Phi_{t\text{-}C_4H_8}/\Phi^{\circ}_{t\text{-}C_4H_8}$ calculated by using the above value for k_{11}/k_3. The agreement between the observed and calculated values is fair.

The value of k_5 at 633 K has been estimated to be 2.86×10^{-10} ml molecule^{-1} s^{-1} from the equation $k_5=10^{14.16}\exp(-8350/1.987T)$ ml mol^{-1} s^{-1} reported by Baker et al.[16] Unfortunately, the value of k_{12} at 633 K has not been obtained. We estimated this value as follows: The rate constant at 633 K for the $H + C_2H_4 \rightarrow C_2H_5$ reaction has been estimated to be 3.65×10^{-12} ml molecule^{-1} s^{-1} from the equation $10^{12.9}\exp(-1500/1.987T)$ ml mol^{-1} s^{-1} obtained by Penzhonn and Darwent.[17] If we assume that the ratio of $k_{12}(c\text{-}C_4H_8)/k_{12}(C_2H_4)$ obtained at 298 K by Cvetanovic[18] is independent of temperature, we obtain k_{12}/k_5=10.5. By using this value, we calculated $\Phi_{H_2}/\Phi^{\circ}_{H_2}$ as a function of $[c\text{-}C_4H_8]/[C_3H_8]$. This is shown in Fig. 6 by a solid line. The calculated value of $\Phi_{H_2}/\Phi^{\circ}_{H_2}$ is in fair agreement with the observed one.

Figure 7 shows the pressure dependence of the quantum yield for hydrogen production obtained at irradiation time of 20 min, and Fig. 8 shows the time dependence of the quantum yield obtained at 1700 and 30000 Pa. As mentioned above, the influence of products on the hydrogen yield can not be neglected. Of the products formed, hydrogen and ethylene seem to have large effects because of their large amounts compared with those of other products, their large cross sections for quenching of excited zinc atoms, and their high reactivities to hydrogen atom produced in the initial stage of reaction. The following reactions are considered to explain the pressure and time dependences of the hydrogen yield:

$$Zn(^3P_1) + C_3H_8 \rightarrow ZnH + \alpha 1\text{-}C_3H_7 + (1-\alpha)2\text{-}C_3H_7 \quad (3)$$

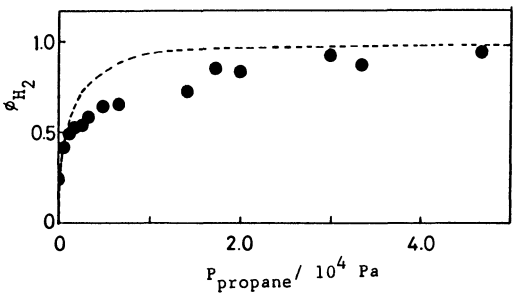

Fig. 7. Pressure dependence of quantum yield of hydrogen.

$$Zn(^3P_1) + H_2 \rightarrow ZnH + H \quad (18)$$
$$Zn(^3P_1) + C_2H_4 \rightarrow Zn\text{-}C_2H_4^* \quad (19)$$
$$ZnH \rightarrow Zn(^1S_0) + H \quad (4)$$
$$H + C_3H_8 \rightarrow H_2 + \beta 1\text{-}C_3H_7 + (1-\beta)2\text{-}C_3H_7 \quad (5)$$
$$H + C_2H_4 \rightarrow C_2H_5 \quad (20)$$

From the above reactions, the rate of hydrogen production can be expressed as follows:

$$R_{H_2} = I_0 \frac{k_3[C_3H_8] + 2k_{18}[H_2]}{k_3[C_3H_8] + k_{18}[H_2] + k_{19}[C_2H_4]} \cdot \frac{k_5[C_3H_8]}{k_5[C_3H_8] + k_{20}[C_2H_4]} \quad (21)$$

Here, we assume that hydrogen and ethylene are produced linearly with time and that their rates are independent of the initial propane pressure as a first approximation (at 20 min 1.8×10^{-6} mol of ethylene and 2.0×10^{-6} mol of hydrogen were obtained, therefore, at 633 K and in the 57 ml reaction cell at irradiation time of t min, $[C_2H_4]=6.3\times10^{14}\ t$ molecule/ml and $[H_2]=7.0\times10^{14}\ t$ molecule/ml). At 633 K and p Pa of propane $[C_3H_8]=1.14\times10^{14}\ p$ molecule/ml. By using following rate constants,

$k_3 = 10.0\times10^{-11}$ ml molecule^{-1} s^{-1},
$k_{18} = 106.6\times10^{-11}$ ml molecule^{-1} s^{-1},
$k_{19} = 121.7\times10^{-11}$ ml molecule^{-1} s^{-1},
$k_5 = 2.86\times10^{-13}$ ml molecule^{-1} s^{-1},

and

$k_{20} = 3.65\times10^{-12}$ ml molecule^{-1} s^{-1},

the rate for hydrogen formation can be rewritten as

$$R_{H_2} = I_0 \frac{1.14p + 14.9t}{1.14p + 15.1t} \cdot \frac{3.26p}{3.26p + 23.0t} \cdot \quad (22)$$

The value of $(1.14p+14.9t)/(1.14p+15.1t)$ is close to unity in the region of the pressure (67—40000 Pa) and time (0—40 min) examined here. Therefore, the quantum yield for hydrogen production can be expressed approximately by

$$\Phi_{H_2} = \frac{\int_0^t R_{H_2}\,dt}{I_0 t} = \frac{\int_0^t \frac{3.26p}{3.26p + 230t}\,dt}{t} = \frac{3.26p}{t} \frac{1}{230} \ln\left(1 + \frac{230t}{3.26p}\right) = \frac{0.0141p}{t} \ln(1 + 70.8\frac{t}{p}). \quad (23)$$

In Figs. 7 and 8, the dashed lines indicate the pressure dependence and the time dependence of the quantum yield of hydrogen calculated according to the above equation. The agreement between the observed and the calculated values is not very good, but the decrease in the quantum yield with decreasing propane pressure and with increasing reaction time could be explained qualitatively by the above treatment regarding the influence of the products.

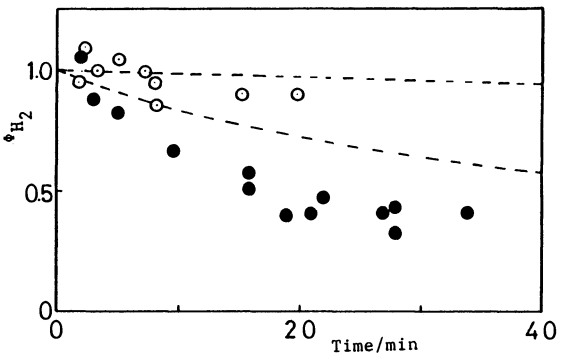

Fig. 8. Time dependence of quantum yield of hydrogen. ○: 30000 Pa, ●: 1700 Pa.

The quantum yield of hydrogen is somewhat smaller than the value predicted from the correlation mentioned above. In this manner, the decrease in the quantum yield of hydrogen must be mainly explained by the influence of ethylene on the production of hydrogen, but partly by other factors. The additional factors may include the influence of propylene and other products which react easily with hydrogen atom. We tried to identify these factors, were not successful. The origin of these factors remains an open question.

Molar Volumes and Electrostriction Behavior of Dicarboxylate, Disulfonate, Tartrate, and Bis(ethylenediamine)-glycinatocobalt(III) Ions in Water

Haruhiko YOKOYAMA,* Midori MOCHIDA, and Yuko KOYAMA
Department of Chemistry, Yokohama City University, 22-2 Seto, Kanazawa-ku, Yokohama 236
(Received April 30, 1988)

The ionic partial molar volumes at infinite dilution, V^{∞}(ion), were determined for several dicarboxylate ions, disulfonate ions, tartrate ions, and $[Co(gly)(en)_2]^{2+}$ (gly=glycinate ion and en=ethylenediamine) from density measurements at 25°C. The values of V^{∞}(ion) obtained for the divalent anions generally increased with their van der Waals volumes. Significant differences in V^{∞}(ion) were observed between geometrical isomers with dicarboxylate and disulfonate ions and were attributed to those in both of electrostriction volume and the void space volume around the anions. The former volume was decreased and the latter was increased with increasing distance between two negatively charged groups in the anions. A relatively strong electrostriction behavior of the tartrate ions, compared to the dicarboxylate ions, suggested the presence of an extra electrostriction caused by hydroxyl groups. The electrostriction strength of $[Co(gly)(en)_2]^{2+}$ was significantly large compared to that of $[Ni(en)_3]^{2+}$, rather close to those of $[Cr(en)_3]^{3+}$ and $[Co(en)_3]^{3+}$, and was attributed to the dissymmetrically localized charge distribution in the $[Co(gly)(en)_2]^{2+}$ ion. The effective ionic radii and apparent van der Waals volumes were estimated by using Glueckauf's equation from the ionic partial molar volume and were discussed in comparison with those calculated from the van der Waals increments of atoms.

The ionic partial molar volumes at infinite dilution, V^{∞}(ion), provide useful information about ion-solvent interactions and the effective volumes of ions in solutions,[1] and are helpful for an estimation of the ion-size parameter in the theoretical equations regarding the activity coefficient and molar conductivity of ions.[2] The partial molar volumes of a series of dicarboxylate ions or disulfonate ions are of interest in connection with how the effective ionic volumes and ion-solvent interactions depend on the configuration and conformation of the ions in aqueous solutions. In the present study we measured the densities of aqueous solutions of sodium, potassium, or bis(ethylenediamine)-glycinatocobalt(III) complex salts of the several divalent anions in order to obtain the ionic partial molar volumes at 25 °C. The anions investigated were as follows: oxalate^{2-}, malonate^{2-}, succinate^{2-}, fumarate^{2-}, maleate^{2-}, phthalate^{2-}, 2,6-naphthalenedicarboxylate^{2-} (2,6-NDC^{2-}), (*R*,*R*)-tartrate^{2-}, *meso*-tartrate^{2-}, *o*-benzenedisulfonate^{2-} (*o*-BDS^{2-}), *m*-benzenedisulfonate^{2-} (*m*-BDS^{2-}), 2,6-naphthalenedisulfonate^{2-} (2,6-NDS^{2-}), and 2,7-naphthalenedisulfonate^{2-} (2,7-NDS^{2-}). We discuss the electrostriction volume and the void space (or dead space) around the ion through the effective ionic radius, or the apparent van der Waals volume, estimated from the observed ionic partial molar volume, in connection with the configuration and conformation of the ions in aqueous solutions. The adequacy of using the effective ionic radii for an estimation of the ion-size parameter is also examined.

Experimental

Materials. Chloride, sulfate, malonate, succinate, fumarate, maleate, phthalate, and *meso*-tartrate of $[Co(gly)(en)_2]^{2+}$ were prepared by a double decomposition between the silver salt of anions and the iodide of the complex obtained according a method described in the literature.[3] The oxalate was prepared similarly from the chloride. These salts[4] were recrystallized twice from a water-ethanol mixture and air-dried at room temperature. The numbers of water of crystallization, $n(H_2O)$, were 1.0, 3.0, 0.1, 2.0, 2.0, 2.0, 3.0, 3.7, and 4.9 for chloride, sulfate, oxalate, malonate, succinate, fumarate, maleate, phthalate, and *meso*-tartrate, respectively. The molar extinction coefficients of these complex salts at λ=488 nm were confirmed to be in agreement with one another by studies using a Hitachi 340 spectrophotometer: their average was 97.7±0.2 mol^{-1} dm^{3}cm^{-1}. Potassium oxalate (reagent grade), sodium malonate, sodium succinate, sodium fumarate, and sodium maleate (extra pure grade) were obtained from Wako Pure Chemical Industries, Ltd. and used without further purification; $n(H_2O)$ were 1.0, 0.0, 5.8, 0.0, and 0.2, respectively. Sodium (*R*,*R*)-tartrate (reagent grade) and sodium salts of *m*-BDS^{2-}, 2,6-NDS^{2-}, and 2,7-NDS^{2-} (obtained from the same company) were recrystallized twice from water and air-dried; $n(H_2O)$ were 2.0, 1.6, 0.2, and 3.5, respectively. Potassium salts of *o*-BDS^{2-} and 2,6-NDC^{2-} (obtained from Aldrich Chemical Company, Inc.) were similarly purified and dried; $n(H_2O)$ were 1.0 and 0.0, respectively. The determination of $n(H_2O)$ values was carried out by the dehydration at ca. 150 °C under reduced pressure with an Abderhalden dryer and by the Karl-Fischer method with an AQ-5 Aquacounter of Hiranuma Sangyo Co., Ltd.

Measurements. All aqueous solutions were made by weight. The concentrations of solutions were as follows: 0.0008—0.0045 mol dm^{-3} with sodium and potassium salts of the divalent anions and 0.0003—0.0040 mol dm^{-3} with the salts of $[Co(gly)(en)_2]^{3+}$. The density measurements were carried out at 25 °C by using a vibrating-tube SS-D-200 twin-type densimeter of Shibayama Scientific Co., Ltd. with two external measuring cells immersed in a water bath controlled to 25.00±0.01 °C. The apparatus constants were determined by using water and dry air as standard substances. The errors in the density measurements were usually within 2×10^{-6} g cm^{-3}.

Results and Discussion

The density of a solution, d, can be expressed by the equation:[1]

$$d = d_0 + 10^{-3}[M - d_0 V^\infty(\text{salt})]\, c - 10^{-3} S_v d_0 c^{3/2} - 10^{-3} b_v d_0 c^2, \quad (1)$$

where M is the molecular weight of the solute, c is the molar concentration, d_0 is the density of the solvent, V^∞(salt) is the partial molar volume of the salt at infinite dilution, S_v and b_v are constants. The values of S_v are theoretically given as 9.706 and 14.944 $cm^3 dm^{3/2} mol^{-3/2}$ in water at 25 °C for 2 : 1 or 1 : 2 and 2 : 2 electrolytes, respectively.[1] The values of b_v are usually in the range of −40 to 10 $cm^3 dm^3 mol^{-2}$.[1] The last term including b_v in Eq. 1 can be neglected in this study, since its values are considered to be smaller than 1×10^{-6} $g\,cm^{-3}$ for solutions of concentrations below 0.005 mol dm^{-3}. Thus, we can use the following approximate equation:

$$d + 10^{-3} S_v d_0 c^{3/2} = 10^{-3}[M - d_0 V^\infty(\text{salt})]\, c + d_0. \quad (2)$$

This equation indicates a linear relationship between the left side and the concentration. Using Eq. 2, we analyzed the observed densities.[5] The values of V^∞(salt) were obtained from the linear slope, $10^{-3}[M - d_0 V^\infty(\text{salt})]$, by a least-squares calculation,[8] and are shown in Table 1.[7]

The ionic partial molar volumes of the anions, V^∞(anion), were evaluated in the following way, and are shown in Table 1. The V^∞(anion) values from sodium or potassium salts were obtained by taking $V^\infty(Na^+)$ and $V^\infty(K^+)$ as −6.6 and 3.6 $cm^3 mol^{-1}$, respectively.[1] By subtracting these V^∞(anion) values from V^∞(salt) of the complex salts, the ionic partial molar volumes of $[Co(gly)(en)_2]^{2+}$ were obtained to be 126.7±0.6 $cm^3 mol^{-1}$ (on the average). Subtracting this value from V^∞(salt) with each complex salt, we also obtained the V^∞(anion) values. Significant differences in V^∞(anion) were observed between the geometrical isomers: fumarate^{2-} and maleate^{2-}; o-BDS^{2-} and m-BDS^{2-}; 2,6-NDS^{2-} and 2,7-NDS^{2-}. The V^∞(anion) of an isomer possessing two negatively charged groups (two carboxylato groups or two sulfonato groups) situated more distantly from each other is larger than that of another isomer. We discuss later why such differences arise.

Table 1. Partial Molar Volumes, V^∞(salt) and V^∞(anion), in Water at 25 °C

Salt	(cation)[a]	V^∞(salt) / $cm^3 mol^{-1}$	V^∞(anion) / $cm^3 mol^{-1}$
Chloride	(M^{2+})	172.2±0.4	23.2[b]
Sulfate	(M^{2+})	152.1±0.6	24.8[b]
Oxalate	(K^+)	42.6±0.4	35.4
	(M^{2+})	161.3±0.4	34.6
Malonate	(Na^+)	35.4±0.4	48.6
	(M^{2+})	176.1±0.5	49.4
Succinate	(Na^+)	53.6±0.4	66.8
	(M^{2+})	194.4±0.6	67.7
Fumarte	(Na^+)	54.0±0.4	67.2
	(M^{2+})	192.8±0.4	66.1

2,7-NDS	(Na^+)	159.3±0.4	172.5

a) M^{2+} denotes the $[Co(gly)(en)_2]^{2+}$ ion. b) Ref. 1.

Glueckauf[8] expressed the partial molar volume of a spherical monoatomic ion by

$$V^\infty(\text{ion}) = V^\infty(\text{int}) + V^\infty(\text{el}) = 2.52(r+0.55)^3 - 33 z_i^2/(r+1.38), \quad (3)$$

where r is the crystallographic radius in Å and z_i is the charge number of the ion. V^∞(int) is the molar intrinsic volume of an ion involving a void space (or dead space) around it, and V^∞(el) is the molar electrostriction volume. Assuming that polyatomic anions are approximately spherical, we applied Eq. 3 in order to estimate radius r, which refers (here) to the effective ionic one (represented as r_{ef}(obsd)). The r_{ef}(obsd) values obtained from V^∞(anion) (from their average when plural values are given in Table 1) are shown in Table 2. The differences in V^∞(anion) between the geometrical isomers result in those in r_{ef}(obsd). An isomer that shows a greater deviation from the spherical approximation has a larger r_{ef}(obsd) than that of another isomer. According to Eq. 3, this means that the former isomer has a relatively large V^∞(int) and a small negative V^∞(el), compared to the latter; the V^∞(el) values estimated from Eq.3 are shown in Table 3. The differences in V^∞(el) between the isomers are slight compared to those in V^∞(anion). This indicates that the differences in V^∞(anion) can largely be attributed to those in V^∞(int). The increase of V^∞(int) with a deviation from the spherical shape of the ion is due to that of the effective ionic surface, which results in an increase in the void space volume around the ion.

By using the values of the van der Waals increments of atoms, v_0(atom), given by Edward,[9] we calculated the molar van der Waals volumes of the polyatomic anions, which are shown in Table 2 as V_0(calcd).[10] By assuming

$$V_0(\text{calcd}) = 4\pi N_A r_{ef}(\text{calcd})^3/3,$$

the effective ionic radii, r_{ef}(calcd), were calculated and are shown in Table 2. The r_{ef}(obsd) values are in agreement with those of r_{ef}(calcd) within about 0.1 Å. The apparent molar van der Waals volumes, V_0(app), were estimated from r_{ef}(obsd) by assuming

$$V_0(\text{app}) = 4\pi N_A r_{ef}(\text{obsd})^3/3$$

Table 2. Effective Ionic Radii, r_{ef}(calcd), and r_{ef}(calcd),and Molar van der Waals Volumes, V_0(app) and V_0(calcd), of the Divalent Anions[a)]

Anion		r_{ef}(obsd) Å	r_{ef}(calcd) Å	V_0(app) $cm^3\,mol^{-1}$	V_0(calcd) $cm^3\,mol^{-1}$
Oxalate^{2-}	$(COO^-)_2$	2.46_8	2.41_5	$37._9$	35.5
Malonate^{2-}	$CH_2(COO^-)_2$	2.64_0	2.62_8	$46._4$	45.8
Succinate^{2-}	$(CH_2COO^-)_2$	2.84_4	2.81_1	$58._1$	56.0
Fumarate^{2-}	*trans*-$(CHCOO^-)_2$	2.83_8	2.73_6	$57._6$	51.7

2,6-NDC^{2-}	2,6-$C_{10}H_6(COO^-)_2$	3.49_5	$3.44._9$	$107._7$	103.5
(*R,R*)-Tartrate^{2-}	(*R,R*)-$(CH(OH)COO^-)_2$	2.86_3	2.95_8	$59._2$	65.3
meso-Tartrate^{2-}	*meso*-$(CH(OH)COO^-)_2$	2.85_2	2.95_8	$58._5$	65.3
o-BDS^{2-}	*o*-$C_6H_4(SO_3^-)_2$	3.33_9	(3.33_9)	$93._8$	(93.9)
m-BDS^{2-}	*m*-$C_6H_4(SO_3^-)_2$	3.39_4	(3.33_9)	$98._6$	(93.9)
2,6-NDS^{2-}	2,6-$C_{10}H_6(SO_3^-)_2$	3.74_6	(3.62_1)	$132._6$	(119.8)
2,7-NDS^{2-}	2,7-$C_{10}H_6(SO_3^-)_2$	3.73_5	(3.62_1)	$131._5$	(119.8)

a) Values in the parentheses were obtained by assuming V_0(calcd)=V_0(app) for *o*-BDS^{2-}.

and are shown in Table 2. Although the V_0(app) is not so much different from that of V_0(calcd), the former is, more or less, larger than the latter in each case of the dicarboxylate and disulfonate ions. The positive deviations of V_0(app) from V_0(calcd) generally increase with increasing distance between two negatively charged groups in the anions, due to the expansion of the void space around the ion (as described above). The negative deviation of V_0(app) from V_0(calcd) for the tartrate ions are attributed to the presence of an extra electrostriction volume caused by the hydroxyl groups (not considered by the second term of Eq. 3, which is expressed as a function of the formal charge). This phenomenon is similar to that observed for neutral compounds containing such hydroxyl groups as glucose.[9)]

We assumed the void space volume, V^∞(void), can be expressed by

$$V^\infty(\text{void}) = V^\infty(\text{int}) - V_0(\text{calcd}), \quad (4)$$

and showed the values of V^∞(void) in Table 3. Considerably smaller V^∞(void) of the tartrate ions (derivatives of succinate^{2-}) than that of succinate^{2-}, fumarate^{2-}, or maleate^{2-} supports the presence of an extra electrostriction (as described above). The relatively small V^∞(void) of succinate^{2-}, compared to fumarate^{2-}, are consistent with the fact that the succinate ion exists partly in gauche form about two carboxylato groups in aqueous solutions.[11)] The slightly small V^∞(void) of *meso*-tartrate^{2-}, compared to (*R,R*)-tartrate^{2-}, may be due to the fact that the *meso*-tartrate ion exists predominantly in gauche form.[12)] In order to estimate the overall electrostriction volume for the tartrate ions, we assumed the following equation:

$$V^\infty(\text{el}) = V^\infty(\text{ion}) - 2.52[r_{ef}(\text{calcd}) + 0.55]^3, \quad (5)$$

and obtained the values of $-39._7$ and $-40._8$ $cm^3\,mol^{-1}$ for V^∞(el) of (*R,R*)-tartrate^{2-} and *meso*-tartrate^{2-}, respectively. These values are more negative than V^∞(el) given in Table 3 and by $-9._3$ and $-10._4$ $cm^3\,mol^{-1}$ than $-30._4$ $cm^3\,mol^{-1}$ obtained from V^∞(el) in Eq. 3 by putting r_{ef}(calcd) into r. The procedure concerning Eq. 5 is identical to taking the void space volume of the tartrate ions as $43._5$ $cm^3\,mol^{-1}$, slightly larger than V^∞(void) of succinate^{2-}. Consequently, the above differences in the volumes correspond to extra electrostriction volumes caused by the hydroxyl groups.

Table 3. Elecrostriction Volumes, V^∞(el), and Void Space Volumes, V^∞(void), of the Divalent Anions Obtained by Use of Eqs. 3 and 4[a)]

Anion	V^∞(el) $cm^3\,mol^{-1}$	V^∞(void) $cm^3\,mol^{-1}$
Oxalate^{2-}	$-34._3$	$33._8$
Malonate^{2-}	$-32._8$	$36._0$
Succinate^{2-}	$-31._3$	$42._5$
Fumarate^{2-}	$-31._3$	$46._3$
Maleate^{2-}	$-31._8$	$40._5$
Phthalate^{2-}	$-29._2$	$49._9$
2,6-NDC^{2-}	$-27._1$	$63._3$
(*R,R*)-Tartrate^{2-}	$-31._1(-39._7)$	$34._9(43._5)$
meso-Tartrate^{2-}	$-31._2(-40._8)$	$33._9(43._5)$
o-BDS^{2-}	$-28._0$	$54._4$
m-BDS^{2-}	$-27._7$	$60._7$
2,6-NDS^{2-}	$-25._8$	$80._1$
2,7-NDS^{2-}	$-25._8$	$78._5$

a) Values in the Parentheses were obtained by assuming Eq. 5.

In the same manner as for the divalent anions, we estimated r_{ef}(obsd) and V_0(app) for $[Co(gly)(en)_2]^{2+}$ from its ionic partial molar volume by use of Eq.3. The obtained values are shown in Table 4 and are compared with those estimated for $[Ni(en)_3]^{2+}$, $[Cr(en)_3]^{3+}$, $[Co(en)_3]^{3+}$, and $[Co(NH_3)_6]^{3+}$. Although of the ionic partial molar volume of $[Ni(en)_3]^{2+}$ is considerably larger than those of $[Co(en)_3]^{3+}$ and $[Cr(en)_3]^{3+}$, the r_{ef}(obsd) values of these complex ions are very near to one another (within 0.1 Å). This is consistent with that the crystallographic metal-nitrogen bond lengths are not so largely different from one

Table 4. Partial Molar Volumes, V^{∞}(cation), Effective Ionic Radii, r_{ef}(obsd), Apparent Molar van der Waals Volumes, V_0(app), Difference Volumes, V_0(dif), and Crystallographic Metal-Ligand Bond Lengths, r_c(M-N) and r_c(M-O), of the Complex Ions[a]

Complex Ion	V^{∞}(cation)	r_{ef}(obsd)	V_0(app)	V_0(dif)	r_c(M-N)	r_c(M-O)
	$cm^3\,mol^{-1}$	Å	$cm^3\,mol^{-1}$	$cm^3\,mol^{-1}$	Å	Å
$[Co(gly)(en)_2]^{2+}$	$126._7$	3.39_2	$98._4$	$-9._7$	1.96[d]	1.916[e]
$[Ni(en)_3]^{2+}$	160.3[b]	3.64_9	$122._5$	$12._7$	2.11[f]	
$[Cr(en)_3]^{3+}$	123.1[b]	3.62_3	$120._2$	$10._2$	2.081[g]	
	124.5[c]					
$[Co(en)_3]^{3+}$	119.9[b]	3.58_8	$116._5$	$6._7$	1.978[h]	
	117.6[c]					
$[Co(NH_3)_6]^{3+}$	55.3[b]	3.09_6	$74._9$	$12._5$	1.972[h]	
	56.3[c]					

a) The reference values of V^{∞}(cation) were obtained from V^{∞}(salt) of the chlorides by using V^{∞}(anion) given in Table 1; The values of r_{ef}(obsd), V_0(app), and V_0(dif) for $[Cr(en)_3]^{3+}$, $[Co(en)_3]^{3+}$, and $[Co(NH_3)_6]^{3+}$ were obtained by using the averaged values of V^{∞}(cation). b) Ref. 19 and the value cited therein. c) Ref. 20. d) An average of the values given by Ref. 21. e) Ref. 21. f) An average of the values given by Ref. 22. g) Ref. 23. h) Ref. 16.

another as shown in Table 4. Such agreement suggests that the V^{∞}(el) in Eq. 3 is a good approximate expression of electrostriction for the tris(en) complexes.

The ionic partial molar volume of $[Co(gly)(en)_2]^{2+}$ is significantly smaller than that of $[Ni(en)_3]^{2+}$, rather close to those of $[Cr(en)_3]^{3+}$ and $[Co(en)_3]^{2+}$, the value of r_{ef}(obsd) is considerably smaller than those of the tris(en) complex ions. Accordingly, the value of V_0(app) of $[Co(gly)(en)_2]^{2+}$ becomes smaller by 24 $cm^3\,mol^{-1}$ than that of $[Ni(en)_3]^{2+}$. This difference in V_0(app) is too large to be explained by their molar van der Waals volumes. That is, an extra electrostriction is considered to be present in the case of $[Co(gly)(en)_2]^{2+}$. If the effective ionic radius of $[Co(gly)(en)_2]^{2+}$ can be approximated to be 3.59 Å (obtained for r_{ef}(obsd) of $[Co(en)_3]^{3+}$) the value of V^{∞}(el) is estimated to be -52 $cm^3\,mol^{-1}$ by using Eq. 5; the values of V^{∞}(el) for $[Ni(en)_3]^{2+}$, $[Cr(en)_3]^{3+}$, and $[Co(en)_3]^{3+}$ are calculated to be -26, -59, and -60 $cm^3\,mol^{-1}$, respectively. This means that the V^{∞}(el) value of $[Co(gly)(en)_2]^{2+}$, though a divalent ion, is close to that of $[Cr(en)_3]^{3+}$ or $[Co(en)_3]^{3+}$ rather than $[Ni(en)_3]^{2+}$. The such strong electrostriction is considered to be related to the dissymmetrically localized charge distribution in the $[Co(gly)(en)_2]^{2+}$ ion: the negative charge is on the carboxylato group of glycinato ligand and the positive charge is on the amino groups of ethylenediamine and glycinato ligands. If the $[Co(gly)(en)_2]^{2+}$ ion is regarded as being a dipolar ion (such as an ion pair formed between a trivalent cation and a monovalent anion), we can understand that the ion-solvent interaction of $[Co(gly)(en)_2]^{2+}$ is similar to that of $[Cr(en)_3]^{3+}$ or $[Co(en)_3]^{3+}$ rather than $[Ni(en)_3]^{2+}$. Such a strong interaction of $[Co(gly)(en)_2]^{2+}$ with the solvent is supported by its relatively large Stokes radius, 3.73 Å,[13] compared to 3.13 Å for $[Ni(en)_3]^{2+}$; the former value is in good agreement with 3.73 Å for $[Cr(en)_3]^{3+}$ and 3.72 Å for $[Co(en)_3]^{3+}$.[14]

By using the van der Waals increments of atoms,[9] the molar van der Waals volumes of free ligands can be calculated to be 41.7, 38.6, and 13.7 $cm^3\,mol^{-1}$ for ethylenediamine, glycinate ion, and ammonia, respectively.[15] However, the total volume of ligands constituting the complex ion exceeds the V_0(app) value in each case. This disagreement is due to a neglect of the effective charges on the ligands. It has been known that the central metal atom is largely neutralized by the donation of electrons from the ligating atoms, according to Pauling's electroneutrality rule and the formal charge of the complex ions is largely distributed on the ligand atoms.[16] Thus, assuming the ionicity of each metal-ligand bond to be about 50%, we obtained 36.6, 34.9, and 10.4 $cm^3\,mol^{-1}$ for the molar van der Waals volumes of ethylenediamine, glycinato, and ammine ligands coordinated to the metal atoms, respectively.[17] In Table 4, we show the volume differences, V_0(dif), obtained by subtracting the total volume of the ligands from V_0(app). The negative V_0(dif) for $[Co(gly)(en)_2]^{2+}$ is due to the extra electrostriction described above. The V_0(dif) values for the tris(en) complex ions are $6._7$ to $12._7$ $cm^3\,mol^{-1}$, somewhat larger than 4.9 $cm^3\,mol^{-1}$ for a sphere estimated from 1.25 Å for the metallic bond radii of Cr, Co, and Ni.[18] Such results are thought to be satisfactory, considering that the calculation process involves various assumptions.

Glueckauf's equation (Eq. 3) is valid as a standard expression for the partial molar volume of the ions examined in this study, and is useful for an estimation of their effective ionic radii; the values of r_{ef}(obsd) usually obtained are in agreement with those of r_{ef}(calcd) within about 0.1 Å, though for $[Co(gly)(en)_2]^{2+}$ the former is smaller by about 0.2 Å than the latter. This means that Eq. 3 can be satisfactorily used for an estimation of the ion-size parameter in the theoretical equations of the activity coefficient and molar conductivity of ions.

The authors are gratefully indebted to Professor Kunio Tamaki of Yokohama City University for his helpful advice and suggestions. We would also like to thank Mr. Kiyoshi Yamamoto and Mr. Hiroyuki Kon for their assistance.

Surface Potential of Mixed Micelles Composed of Prostaglandin B_2 and Heptaethylene Glycol Dodecyl Ether by the Fluorescence Method

Shoko YOKOYAMA,* Akiko KANEKO, and Tadao FUJIE
Kyoritsu College of Pharmacy, 1-5-30, Shibakoen, Minato-ku, Tokyo 105
(Received May 10, 1988)

The surface state of negatively charged mixed micelles prepared by addition of prostaglandin B_2 (PGB_2) to nonionic heptaethylene glycol dodecyl ether (HED) has been investigated and the surface potential ($\Delta\psi$) of the micelles has been estimated by measuring the fluorescence intensity of ammonium 8-anilino-1-naphthalenesulfonate (ANS) as a fluorescent probe. Since the binding constant of ANS, k, is dependent on the surface potential of the micelle, the value of $\Delta\psi$ was determined according to the equation $\Delta\psi=-59.16\log(k_0/k)$ at 25°C, where k_0 is the k of HED micelle. The value of $|-\Delta\psi|$ increases with increasing mole fraction of PGB_2 (X_{PGB_2}) and decreases with increasing ionic strength (J). These changes are due to the effects of the negative charge of PGB_2 and of ionic atmosphere of Na^+, respectively. Surface charge density (σ) was, therefore, determined from $\Delta\psi$ according to the Gouy-Chapman theory, with a result that σ is nearly independent of J and proportional to X_{PGB_2}. These results have led to a conclusion that the state of the diffuse layer surrounding the Stern layer on the micelle surface is represented well by the Gouy-Chapman theory as well as a previous result for the system of sodium dodecyl sulfate (SDS) and HED. The value of $|-\sigma|$ for PGB_2 micelle is less than that for SDS micelle, which suggests that PGB_2 forms a loosely packed micelle.

Regarding physicochemical properties of prostaglandins, critical micelle concentration, tilting angle, the area occupied by a molecule at air-water interface, solubility behavior, and ionization constant have been studied.[1-3] No surface potential of prostaglandin micelle has been determined, except a value[2] of −41 mV for prostaglandin $F_{2\alpha}$ as the maximum surface potential of micelle.

We have been studying the degradation of prostaglandins under such a condition that prostaglandins may form mixed micelles with a nonionic surfactant, heptaethylene glycol dodecyl ether. For accurate analysis of data in relation to catalysis in micellar systems, it is absolutely necessary to know the surface potential of mixed micelles composed of prostaglandins and heptaethylene glycol dodecyl ether.

From these points of view, we have studied the surface potential of mixed micelles composed of prostaglandin B_2 and heptaethylene glycol dodecyl ether, and compared with previous results[4] obtained for mixed micelles composed of sodium dodecyl sulfate and heptaethylene glycol dodecyl ether.

Experimental

Materials. Prostaglandin B_2 (PGB_2) of 99% purity was purchased from Sigma Chemical Company. Heptaethylene glycol dodecyl ether (HED) as a nonionic surfactant and ammonium 8-anilino-1-naphthalenesulfonate (ANS) as a fluorescent probe were the same as those used for a previous study.[4] Mixed micelles composed of PGB_2 and HED were prepared as previously described,[4] and dissolved in a phosphate buffer containing NaH_2PO_4 and Na_2HPO_4 (pH 7.0 with ionic strength 0.02 mol dm^{-3}) when fluorescence intensity was measured. All PGB_2 molecules were considered form mixed micelles with HED, on the basis of a previous result[4] that all sodium dodecyl sulfate (SDS) molecules formed mixed micelles with HED and of the less solubility of PGB_2 than that of SDS in phosphate buffer.

The degradation of PGB_2 at pH 7.0 and 25 °C in course of measurement was considered to be negligible because of its stability described in a previous paper.[1]

Measurement of Fluorescence Intensity. Mixed micelles were dissolved in a phosphate buffer (pH 7.0 with ionic strength 0.02 mol dm^{-3}). The total concentration of PGB_2 and HED was kept constant at 1 mmol dm^{-3}. A solution of ANS as a fluorescent probe was added to solutions of PGB_2 and HED up to 5×10^{-5} mol dm^{-3}. The fluorescence intensity was measured by use of a Hitachi F-4000 spectrofluorometer equipped with a pump-circulating water at a constant temperature through an outer tube. The temperature of the thermostat was maintained at 25±0.2 °C. The wavelength of excitation and emission are 360 and 480 nm, respectively. The measured fluorescence intensity was corrected as described in a previous paper.[4] Sodium chloride was used to control the ionic strength of buffer solution.

Results

Fluorescence Intensity. The relationship between the corrected fluorescence intensity, F, and the concentration of ANS, D, is shown in Fig. 1. As can be seen in Fig. 1, the plot of F vs. D is linear.

Adsorption of ANS on Micelle Surface. It is considered that fluorescence intensity is proportional to the amount of ANS adsorbed on micelle surface, because ANS fluoresces when adsorbed on micelle surface. The Langmuir adsorption isotherm can, therefore, be applied. The equation may be written as

$$\Gamma = \frac{D_m}{C} = \frac{\Gamma_s k D_f}{1+kD_f}\ , \qquad (1)$$

where Γ is the adsorbed amount of ANS per mole of micelle, Γ_s is the saturated adsorbed amount, k is the association constant related to the strength of adsorption, C is the total concentration of PGB_2 and HED which are in the form of micelle, D_m is the concentration of bound ANS, and D_f is the concentration of free

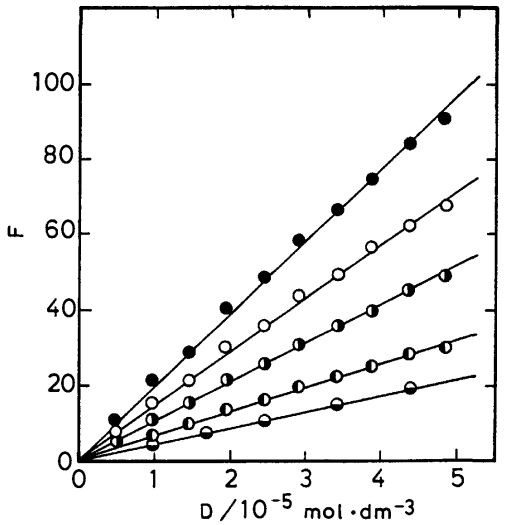

Fig. 1. Relationship between fluorescence intensity with correction and concentration of ANS. Mole fraction of PGB_2: ●; 0 (HED only), ○; 0.2, ◑; 0.4, ◐; 0.6, ◒; 0.8. Total concentration of PGB_2 and HED: 1 mmol dm^{-3}. Ionic strength: 0.02 mol dm^{-3}.

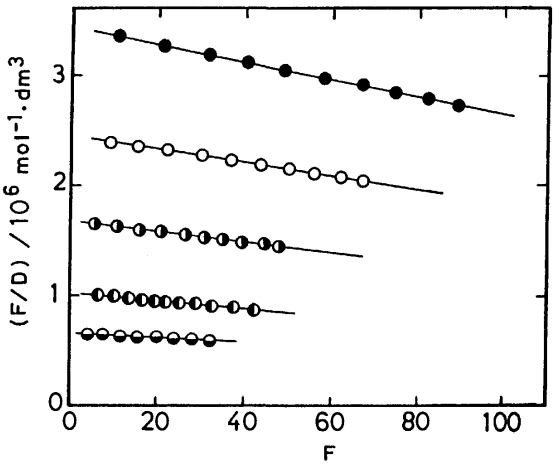

Fig. 2. Langmuir plots of F/D vs. F. Mole fraction of PGB_2: ●; 0 (HED only), ○; 0.2, ◑; 0.4, ◐; 0.6, ◒; 0.8. Total concentration of PGB_2 and HED: 1 mmol dm^{-3}. Ionic strength: 0.02 mol dm^{-3}.

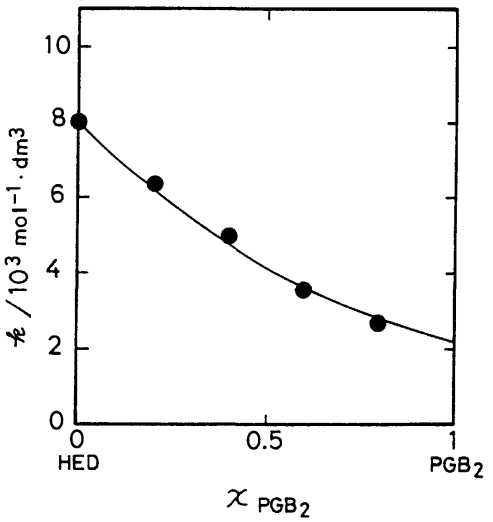

Fig. 3. Relationship between k and mole fraction of PGB_2. Total concentration of PGB_2 and HED: 1 mmol dm^{-3}. Ionic strength: 0.02 mol dm^{-3}.

ANS; $D=D_m+D_f$. Fluorescence intensity F is related to D_m by

$$F=fD_m, \tag{2}$$

where f is the fluorescence coefficient of ANS.

F_∞ is defined by

$$F_\infty=\lim_{D\to\infty} F=Cf\Gamma_s. \tag{3}$$

Equation 4 is, therefore, derived from Eqs. 1—3:

$$\frac{1}{F_\infty-F}=k\left(\frac{D}{F}-\frac{1}{f}\right). \tag{4}$$

Under our experimental conditions, D is sufficiently large. Therefore, Eq. 4 is reduced to

$$\frac{F}{D}=k(F_\infty-F). \tag{5}$$

Plots of F/D against F are presented in Fig. 2, which show a good linear relationship in accord with Eq. 5. From the values of slope and intercept, k and F_∞ are evaluated.

Values of F_∞ and k. The values of F_∞ are 439, 400, 351, 306, and 270 for the samples whose mole fractions of PGB_2 are 0 (HED alone), 0.2, 0.4, 0.6, and 0.8, respectively. The value of F_∞ decreased with increasing mole fraction of PGB_2. This is because the value of F_∞ depends on the concentration of HED, as described in a previous paper.[4]

Values of k are shown in Fig. 3 against the mole fraction of PGB_2. The value of k decreased with increasing mole fraction of PGB_2. This is due to the electrostatic repulsion between PGB_2 and ANS on the micelle surface. The value of k for HED obtained in this paper is consistent well with the value for HED obtained in a previous paper[4] at the same ionic strength, so that the results obtained in this paper may be taken to be reasonable.

Discussion

Surface Potential of Micelles. On the assumption described in a previous paper,[4] the binding constant of ANS to HED-PGB_2 mixed micelles, k, depends on the surface potential of the micelle, $\Delta\psi$. The relation is, therefore, written as

$$k=k_0\exp(-zF_A\Delta\psi/RT), \tag{6}$$

where z is the valency of ANS, F_A is the Faraday constant, R is the gas constant, and k_0 is the k for nonionic HED micelle. By substituting $z=-1$, $F_A=e\cdot N_A=9.648\times10^4$ (C mol^{-1}), $R=k_BN_A=8.314$ (J mol^{-1}K^{-1}), and $T=298.15$ K at 25 °C, we obtain

$$\Delta\psi = -59.16 \cdot \log \frac{k_0}{k} \quad (7)$$

The surface potential of the micelle, $\Delta\psi$, as calculated from the values of k shown in Fig. 3 by using Eq. 7, is plotted with closed circles against the mole fraction of PGB_2 in Fig. 4. To investigate the effect of ionic strength on the surface potential of the micelle, experiments were carried out with buffer solutions containing sodium chloride so that their ionic strengths are 0.06 and 0.20 mol dm^{-3} as well as 0.02 mol dm^{-3}, plots of $\Delta\psi$ against the mole fraction of PGB_2 being shown by symbols ◑ and ○ in Fig. 4.

No micelles composed of PGB_2 molecules alone are formed under these experimental conditions that the total concentration of PGB_2 and HED is 1 mmol dm^{-3}. The critical micelle concentration of PGB_2 is about 6 mmol dm^{-3}.[1] The surface potential of PGB_2 micelle is, therefore, obtained by extrapolation of the theoretical curve based on the Gouy-Chapman equation, which will be described in a later section. The surface potential of PGB_2 micelle thus obtained at ionic strength 0.02 mol dm^{-3} is −33 mV. This value |−33 mV| for PGB_2 micelle is less than the value[4] |−73 mV| for SDS micelle at the same ionic strength, which suggests that PGB_2 forms a loosely packed micelle.

The surface potential of the micelle becomes more negative with increasing mole fraction of PGB_2. On the other hand, the surface potential of the micelle, $|-\Delta\psi|$, becomes smaller as the ionic strength is increased by adding sodium chloride. These changes may be considered due to the effects of the negative charge of PGB_2 and of ionic atmosphere of Na^+, respectively.

Surface Charge Density of Micelles. According to the Gouy-Chapman theory, the relation between surface potential, $\Delta\psi$, and surface charge density, σ, is expressed as

$$\frac{\sigma}{\mathrm{C \cdot cm^{-2}}} = -5.8673 \times 10^{-6} \sqrt{\sum_i \left[\left(\frac{C_i}{\mathrm{mol \cdot dm^{-3}}} \right) \left\{ \exp\left(-0.03892\, z_i \frac{\Delta\psi}{\mathrm{mV}} \right) - 1 \right\} \right]}, \quad (8)$$

where 78.54[5] is used as the value for the relative dielectric constant of water at 25 °C. The relationship between surface charge density and the mole fraction of PGB_2 is shown in Fig. 5, The value of σ was found proportional to X_{PGB_2}, and thus the relation can be written as

$$\sigma = -1.044 \times 10^{-6} \cdot X_{PGB_2}. \quad (9)$$

By using this relation and Eqs. 7 and 8, theoretical values of the surface potential of the micelles and the binding constant were calculated, the results being shown in Figs. 3 and 4 by solid lines, respectively.

On the other hand, the surface charge density, σ, was found nearly independent of ionic strength.

These results indicate that the state of the diffuse layer surrounding the Stern layer on the micelle surface is represented well by the Gouy-Chapman theory as well as a previous result[4] obtained for the system of sodium dodecyl sulfate and HED.

Dissociation Degree of Micelles. The relationship

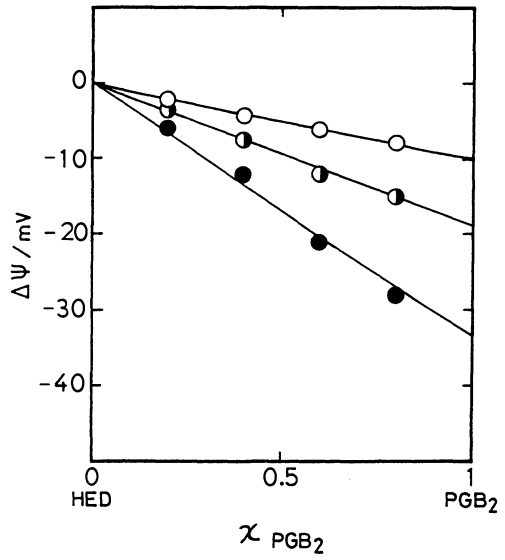

Fig. 4. Effect of ionic strength on the plots of surface potential of micelle, $\Delta\psi$, vs. mole fraction of PGB_2. Ionic strength: ●; 0.02, ◑; 0.06, ○; 0.20 mol dm^{-3}. Total concentration of PGB_2 and HED: 1 mmol dm^{-3}. Solid lines: theoretical curves by the Gouy-Chapman equation for $\sigma = -1.044 \times 10^{-6} \cdot X_{PGB_2}$ C cm^{-2}.

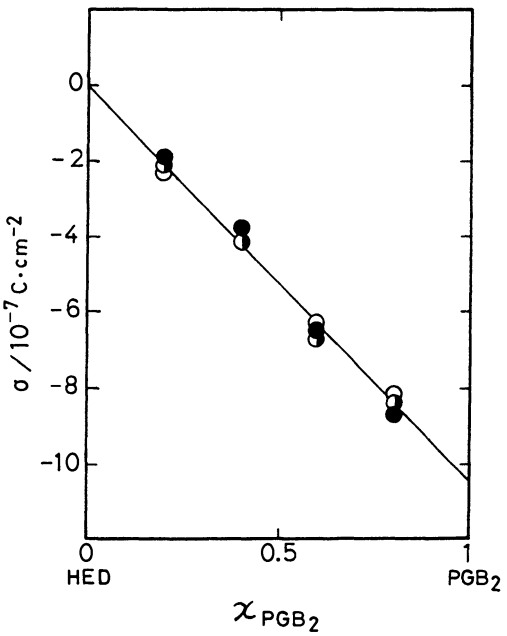

Fig. 5. Effect of ionic strength on the plots of surface charge density of micelle, σ, vs. mole fraction of PGB_2. Ionic strength: ●; 0.02, ◑; 0.06, ○; 0.20 mol dm^{-3}. Total concentration of PGB_2 and HED: 1 mmol dm^{-3}.

between surface charge density, $|\sigma|$, and dissociation degree, α, of micelles can be expressed by

$$\alpha = \frac{|\sigma| \cdot A}{X_{PGB_2} \cdot e}, \quad (10)$$

where A is the area occupied by a PGB_2 molecule, and $e=1.6021\times10^{-19}$ C. The area occupied by a PGB_2 molecule has been reported to be 54 Å^2 [1] as a value for maximum compression. A value of 80 Å^2 has been derived from a 3-dimensional model of prostaglandin molecule.[2,3] If a calculation is developed for the system of PGB_2 and HED in terms of these values (54—80 Å^2), the dissociation degree of PGB_2 in HED micelle is approximately 4—5%. The value of dissociation degree is found nearly independent of the mole fraction of PGB_2. This value ($\alpha\fallingdotseq4.5\%$) is a bit smaller than those obtained for sodium dodecyl sulfate in HED micelle (α=10%,[4] 8%[6]), so that the results obtained in this paper may be taken to be quite reasonable.

Effect of Electrolyte on the Surface Potential of Micelles. To investigate the effect of electrolyte on the surface potential of the micelle in a little more detail, experiments at various ionic strengths were carried out for a mixed micelle composed of PGB_2 and HED at X_{PGB_2}=0.6, the results being shown in Fig. 6. As shown in Fig. 6, the surface potential of the micelle, $|-\Delta\psi|$, becomes smaller as the ionic strength is increased by adding sodium chloride. By using the value of σ defined by Eq. 9 and the equation of Gouy-Chapman, theoretical values of the micellar surface potential are calculated, and represented by the solid line in Fig. 6. Thus, the relationship between ionic strength and micellar surface potential was found to be represented well by the Gouy-Chapman theory.

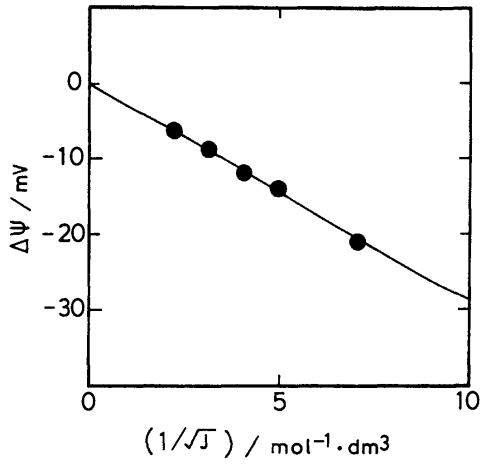

Fig. 6. Effect of ionic strength on surface potential of micelle composed of PGB_2 and HED at X_{PGB_2}=0.6. Total concentration of PGB_2 and HED: 1 mmol dm^{-3}. Solid line: theoretical curve by the Gouy-Chapman equation for $\sigma=-6.263\times10^{-7}$ C cm^{-2}.

Conclusion

The surface potential of mixed micelles composed of PGB_2 and HED has been determined by the fluorescence method.

The surface potential of the micelle, $|-\Delta\psi|$, increases with increasing mole fraction of PGB_2 (X_{PGB_2}), and decreases with increasing ionic strength. The surface state of the micelles is, therefore, represented well by the Gouy-Chapman theory. The value of $|-\Delta\psi|$ for PGB_2 micelle is less than that for sodium dodecyl sulfate micelle at the same ionic strength, which suggests that PGB_2 forms a loosely packed micelle.

(Received May 16, 1988)

An organic compound $TSeC_n$-TTF [tetrakis(alkylseleno) tetrathiafulvalenes] with n=2, crystallizes in the monoclinic space group $P2_1/a$, a=23.218(5), b=8.960(3), c=10.489(3) Å, β=96.61(2)°, V=2168(1) Å^3, and Z=4; the compound with n=4 crystallizes in the triclinic space group $P\bar{1}$, a=9.198(1), b=10.539(2), c=8.248(2) Å, α=113.16(2), β=96.02(2), γ=90.61(2)°, V=729.9(3) Å^3 and Z=1. The molecule with n=2 has a bent structure, like a boat; and the molecule with n=4 has a structure in which each of the four alkyl chains is stretched towards different directions. The temperature dependence of electrical resistivity and the charge-carrier mobility have been measured, and the resistivities at room temperature are $\rho_a/\rho_b/\rho_c$=3.3×10^9/2.0×10^9/6.0×10^{11} and 2.2×10^{11}/1.0×10^{11}/1.3×10^{11} (Ω cm) for $TSeC_2$-TTF and $TSeC_4$-TTF, respectively. The quite isotropic character in the resistivities of a $TSeC_4$-TTF crystal may originate from its rather strange molecular structure.

Nowadays relatively high conductivities have been realized even in one-component organic materials under the presence of the columnar structures with the effective overlaps of π orbitals between molecules.[1] The physicochemical studies on the organic materials with long alkyl chains, such as TTC_n-TTF, $TTeC_n$-TTF, and $TSeC_n$-TTF (n=1—18)[2-4] have been widely carried out. A new function named as "molecular fastener effect" has been found. Comparing with TTC_n-TTF and $TTeC_n$-TTF, the electrical and thermal properties of $TSeC_n$-TTF series for large n ($n\geqq 8$) are similar to those of TTC_n-TTF and $TTeC_n$-TTF, in which the intermolecular interactions associated with alkyl chains play an important role. For the compounds with small n ($n\leqq 7$), the electrical and thermal properties of $TSeC_n$-TTF series are just in between TTC_n-TTF and $TTeC_n$-TTF series, in which the intermolecular interactions between chalcogen atoms and between C_6S_4 parts play an important role. In the present paper, we report the results of the single crystal X-ray structure analysis, the electrical conductivities and the charge-carrier mobilities of $TSeC_n$-TTF with n=2 and 4.

Experimental

Single crystals of $TSeC_2$-TTF and $TSeC_4$-TTF were prepared by a slow cooling method in a hexane solution. Dark yellow $TSeC_2$-TTF crystals were grown in a plate-like form after several days. For $TSeC_4$-TTF keeping the solution in a refrigerator for several days, dark red crystals were obtained in a block-like form.

The crystal structure analysis was carried out with a Rigaku automated four-circle X-ray diffractometer AFC-5R and AFC-5 for $TSeC_2$-TTF and $TSeC_4$-TTF, respectively. For the compound of $TSeC_2$-TTF the crystal data is: $C_{14}H_{20}S_4Se_4$, F.W. 631.84, monoclinic, space group $P2_1/a$, a=23.218(5), b=8.960(3), c=10.489(3)Å, β=96.61(2)°, V=2168(1)Å^3, Z=4, D_x=1.937 g cm^{-3} and μ(Mo $K\alpha$)=70.671 cm^{-1}. Intensity data were measured by the θ-2θ scan technique on the diffractometer with graphite monochromatized Mo $K\alpha$ radiation ($2\theta<60°$). The structure was solved by the direct method using MULTAN 78 program system[5] and refined by the block-diagonal least-squares procedure using 1354 independent reflections $|F_o|>3\sigma(|F_o|)$. After absorption correction the refinement was limited to a final R value of 0.079. Anisotropic thermal parameters were adopted for all nonhydrogen atoms, and the hydrogen atoms were refined isotropically. For the compound of $TSeC_4$-TTF, the crystal data is: $C_{22}H_{36}S_4Se_4$, F.W. 743.84, triclinic, space group $P\bar{1}$, a=9.198(1), b=10.539(2), c=8.248(2) Å, α=113.16(2), β=96.02(2), γ=90.61(2)°, V=729.9(3)Å^3, Z=1, D_x=1.69 g cm^{-3}, μ(Mo $K\alpha$)=52.609 cm^{-1}. Intensity data were measured by the θ-2θ scan technique on the diffractometer with graphite monochromatized Mo $K\alpha$ radiation ($2\theta<60°$). The structure was solved also by the direct method using MULTAN 78 program system[5] and refined by the block-diagonal least-squares procedure using 2743 independent reflections $|F_o|>3\sigma(|F_o|)$. The refinement was limited to a final R value of 0.065. Anisotropic thermal parameters were adopted for all nonhydrogen atoms, and the hydrogen atoms were refined isotropically.[10]

The electrical resistivities were measured by a two probe method from room temperature to just above the each melting point under a vacuum of 10^{-4} Pa to avoid an oxidation effect. The electrical contacts to the specimen crystals were made with gold paint. The mobilities were measured by a time-of-flight method for charge carriers generated by irradiation from a pulsed nitrogen laser.

Results and Discussion

$TSeC_2$-TTF. The atomic coordinates are listed in Table 1. The crystal structure is shown in Figs. 1 and 2. Along the a axis, the $TSeC_2$-TTF molecules are stacked with overlapping as shown in Fig. 2(b), where the distance between the two C_2S_4 molecular planes is 3.41 Å. The shortest intermolecular S-S contact is 3.72(1) Å (Fig. 1b) which is a little longer than the sum of the van der Waals radii (3.70 Å). The shortest intermolecular S-Se contact is 3.804(8) Å, which is a little shorter than the sum of the van der Waals radii (3.85 Å). Along the c axis the shortest intermolecular Se-Se distance between the neighboring two molecules is 3.618(5) Å, which is much shorter than the sum of the van der Waals radii (4.00 Å) (Fig. 1). The molecule has a bent structure like a boat (Figs. 3(a) and(b)), and

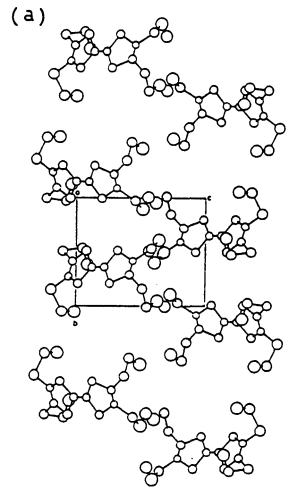
the dihedral angles between the optimal plane of the central C_2S_4 part and the planes of the two C_2Se_2 part are 8.5(2) and 12.0(2)°, respectively. The terminal Se-C-C bonds are strongly bent towards the central



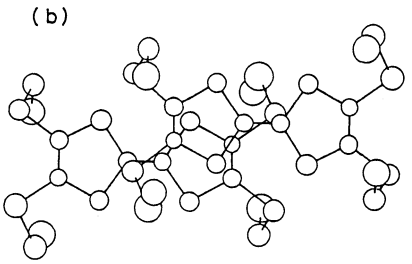


Fig. 2. Crystal structure of $TSeC_2$-TTF projected along the a axis(a) and the mode of overlaps of $TSeC_2$-TTF along the a axis (b).

plane and the molecules are overlapped along the stacking axis a.

The resistivities at room temperature are 3.3×10^9, 2.0×10^9, and 6.0×10^{11} (Ω cm) along the a, b, and c axis, respectively. The resistivity along the a axis is the same order as that along the b axis. The anisotropy between a or b and c directions is not so large, about 10^2, because of the absence of a special direction for easy electrical conduction. According to the crystal structure, it can be understood clearly. The easier axis for electrical conduction (ρ_a) corresponds to the stacking direction of C_6S_4 moiety (parallel to the a-axis), while the harder axis corresponds to the c-axis, where is almost no stacking but exist short Se-Se contacts (3.618(5)Å). These two factors give rise to the rather small anisotropy of about 10^2. Along the b-axis, adjacent $TSeC_2$-TTF molecules are arranged side by side which leads to about the same magnitude of ρ_b as ρ_a. The temperature dependence of the electrical resistivity along the a axis is shown in Fig. 4, in which the resistivity decreases with the temperature increase until the melting point, with an activation energy $E_a=3.7\times10^{-1}$ (eV).

Mobility measurements for single crystals at room temperature have indicated that the electron and hole mobilities along the c axis are $\mu_c^e=1.7$ cm^2 V^{-1} s^{-1} and

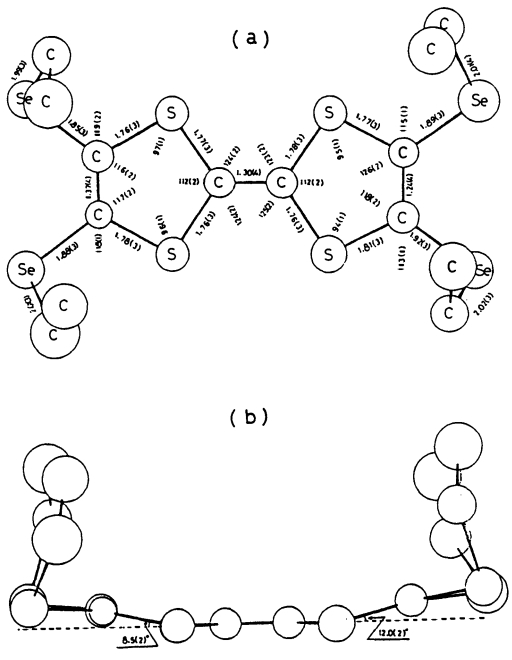

Fig. 3. Molecular structure of $TSeC_2$-TTF (a) and the side view (b).

μ_c^h=1.4 $cm^2 V^{-1} s^{-1}$, respectively. Taking into account of the resistivity data, we can estimate fairly high mobilities along the a or b axis. The charge-carrier mobilities in an anthracene crystal are 0.3 and 1.5 $cm^2 V^{-1} s^{-1}$ along the c and a or b axis, respectively. Comparing these values with the present data, we can conclude that the effect of chalcogen atoms is still important in $TSeC_2$-TTF crystals.

$TSeC_4$-TTF. The atomic coordinates are listed in Table 2. The crystal structure is shown in Fig. 5. The stacking axis with respect to the central molecular planes is c axis, along which the distance between the two molecular planes is as far as 4.82 Å, because the two isobutyl chains, which are just between the two molecular planes, are directed up and down from the optimal plane of the central S_4C_6 part, as shown in Figs. 5(b) and 6(b). The intermolecular interactions between adjacent C_6S_4 moieties are weak and can be described in terms of the van der Waals interactions because of the absence of discernible intermolecular overlaps between adjacent π systems. Therefore, the high resistivity along the stacking c axis can be understood by taking account of this fact. Along the b and a axis the interaction between two molecules is still rather weak, Fig. 5(c), so that no good conducting path can be formed in any direction. The distances between Se-Se, Se-S, Se-C, S-S, S-C, and C-C are all longer than the sum of van der Waals radii.

In the TYC_n-TTF family the $TSeC_4$-TTF molecule gives a quite special structure, neither of the chair nor boat form, in which the four isobutyl chains are almost perpendicular to each other. Such kind of molecular shape may lead to three dimensionally isotropic molecular packing form. Actually the electrical

resistivities appear as 2.2×10^{11}, 1.0×10^{11}, and 1.3×10^{11} Ω cm along the a, b, and c axis, respectively, which clearly shows the isotropic character.

Therefore, in $TSeC_n$-TTF system both the physical properties[4] and the molecular packing form have been much influenced by the length of alkyl chains and the chalcogen atoms. The higher resistivity of $TSeC_4$-TTF can be understood with the crystal structure. The shortest Se-Se distance, 4.03 Å, is considerably longer as compared with 3.618(5) Å in $TSeC_2$-TTF and the interplanar distance (4.82 Å) between C_6S_4 parts is also much longer than 3.41 Å in $TSeC_2$-TTF. The quite different physical properties between $TSeC_2$-TTF and $TSeC_4$-TTF can be ascribed to the different molecular

structure; one is in a boat form, and another is in the form in which each of the four alkyl chains are stretched towards different directions. The molecular structure of $TSeC_2$-TTF is similar to that of TTC_2-TTF,[6] both in boat form, and different from the chair form of $TTeC_2$-TTF.[7] The molecular structure of $TSeC_4$-TTF is not only different from that of TTC_4-TTF,[8] which is in a chair form, but also different from any other of the TYC_n-TTF family. It means that the selenium atoms play an important role to determine their crystal structures. Furthermore, although the intermolecular interactions in a $TSeC_4$-TTF crystal are rather weak just as stated above, it should be noted that they are almost isotropic. The three dimensionally isotropic character is rather unusual in the family of organic semiconductors or conductors, and in the history of developing organic conductors much efforts for increasing the dimensionality have been pursued. In this sense the molecular structure of $TSeC_4$-TTF may give a key to solve this problem, and the preparation of charge transfer complexes based on $TSeC_4$-TTF could give rise to a new type of organic conduc-

tors.

So far, three kinds of molecular structure, chair form, boat form and $TSeC_4$-TTF-like form, have been realized in TYC_n-TTF family. The chair form structure is favorable to decrease the distance between two molecular planes and build up a good conducting path along the stacking axis. The intermolecular overlaps between adjacent π systems are effectively large because there exists a columnar stacking consisting of the conjugated π systems, which can not be found in the crystals which have molecules of other structure forms. The compounds, such as TTC_n-TTF for n=4, 5, 7, 9, 10[6,8,9] and $TTeC_1$-TTF,[7] are in chair form structures and have relatively low resistivities in each own series. On the other hand, the boat form structure usually leads to a large interplane distance, in such compounds as $TSeC_2$-TTF, TTC_1-TTF, and TTC_2-TTF of which crystals have relatively high resistivities. In the case of $TSeC_4$-TTF-like form having rather weak intermolecular interactions, however, it is a good form to obtain a three dimensionally isotropic structure. If we can introduce much stronger intermolecular interactions to this system with keeping its isotropic character, for example, by applying a high pressure, we could obtain a new type of organic semiconductor. In the sense, the $TSeC_4$-TTF-like form has an unique significance.

In summary, we have analyzed the crystal structures of $TSeC_n$-TTF (n=2 and 4), and found out some specific factors to understand their properties. We have measured the electrical properties of both crystals and discussed them in correlation with their crystal structures. We are now proceeding with the preparation of charge-transfer complexes based on $TSeC_2$-TTF and $TSeC_4$-TTF.

Phosphorescence Properties of Pyridine and Its Methyl Derivatives in the Vapor Phase

Masayuki SUZUKI, Masahisa FUJITA, Takeshi TAKEMURA,* and Hiroaki BABA
Division of Chemistry, Research Institute of Applied Electricity, Hokkaido University, Sapporo 060
(Received June 3, 1988)

The phosphorescence spectra, lifetimes, and quantum yields of pyridine and its methyl derivatives, 2-picoline, 3-picoline, and 2,6-lutidine in the vapor phase have been measured with the aid of a specially designed circuit by means of control of the voltage imposed on the photomultiplier. The phosphorescence spectrum shifts to shorter wavelengths with increasing methylation. The phosphorescence lifetimes and quantum yields of pyridine and the picolines are of the order of 1 μs and 10^{-7} both values being one order of magnitude smaller than the corresponding values for the lutidine. These observations are explained by assuming that (1) the lowest triplet state (T_1) and the next lowest triplet (T_2) are of $^3(\pi,\pi^*)$ and $^3(n,\pi^*)$ types respectively, (2) the energy gap between T_1 and T_2 is small, especially in the unsubstituted pyridine, and (3) the potential energy curve for T_1 is distorted according to the energy gap, as the result of a pseudo-Jahn-Teller type of interaction between T_1 and T_2.

The phosphorescence spectrum from the pyridine molecule was first observed in the vapor phase by the present authors in 1983.[1,2] The phosphorescence properties of pyridine vapor are as follows: (a) In spite of the high intersystem crossing quantum yield,[3] the phosphorescence quantum yield is as anomalously low as 10^{-6}; (b) the phosphorescence spectrum has an onset near 350 nm, which is similar in position to the one of the benzene phosphorescence, but shows an anomalously red-shifted intensity maximum near 450 nm; and (c) the phosphorescence lifetime is anomalously short (1.2 μs) compared with those for vapors of other azines such as pyrazine (63 μs) and pyrimidine (50 μs).

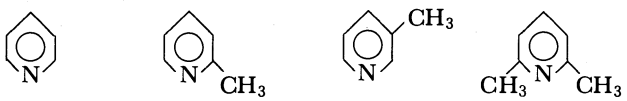
These anomalous characteristics of the phosphorescence of pyridine were attributed to strong vibronic coupling between the lowest triplet state (T_1) of $^3(\pi, \pi^*)$ type and a close-lying $^3(n, \pi^*)$ state which is assigned to the second lowest triplet state (T_2).[4,5] It was supposed that the coupling may be strong enough to give rise to a pseudo-Jahn-Teller type of interaction between the two states.[2,6,7] Such an interaction would cause distortion of the potential surface of the $T_1(\pi, \pi^*)$ state and enhance the radiationless decay from T_1,[8,9] resulting in the extremely weak phosphorescence of pyridine.

Weisman et al.[10,11] have reported recently the decay of the triplet-triplet absorption in pyridine vapor at various pressures and explained the nonradiative behavior of the triplet pyridine in terms of the strong pseudo-Jahn-Teller interaction between the $T_1(\pi,\pi^*)$ and $T_2(n, \pi^*)$ states.

With pyridine in the vapor phase, the lowest triplet state, thus, is supposed to be of a (π, π^*) type. This assignment has received further supports from the experimental results of absorption measurements on pyridine.[12,13]

On the other hand, Schmidt et al.[14,15] have studied the lowest triplet state of pyridine in a single crystal of benzene by using electron-spin-echo spectroscopy, and reached the conclusion that the pyridine molecule is nonplanar in this state owing to the pseudo-Jahn-Teller coupling between the $T_1(n, \pi^*)$ state and a close-lying $^3(\pi, \pi^*)$ state. Thus, although the properties of the lowest triplet state of pyridine could be interpreted in terms of a pseudo-Jahn-Teller interaction, there is still a controversy about the character of the lowest triplet state.

For understanding fully the phosphorescence properties of pyridine, we attempted in this study to investigate the changes of the phosphorescence properties caused by introduction of the methyl group into pyridine; that is, the phosphorescence and excitation spectra, phosphorescence lifetimes, and quantum yields were measured for pyridine (**1**), 2-picoline (**2**), 3-picoline (**3**), and 2,6-lutidine (**4**) in the vapor phase.



1 **2** **3** **4**

In order to obtain extremely weak phosphorescence emission of pyridine and its methyl derivatives, special care was directed to the purification of these compounds. Furthermore, a new circuit was employed which made it possible to measure time-resolved spectra in the microsecond or submicrosecond region of extremely weak emission by means of control of the voltage imposed on the photomultiplier; from now on this circuit will be called CVIPM circuit.

Experimental

Pyridine first treated after a method described in a previous paper[2] was purified by gas chromatography, and then distilled under reduced pressure. 2-Picoline, 3-picoline, and 2,6-lutidine were purified by fractional distillation under reduced pressure and were further purified by gas chromatography.

The optical experiments were carried out in the tempera-

ture range 0—40 °C and in the pressure range 2—20 Torr† with the sample vapor sealed into a 3.5 cm square quartz cell.

Absorption, emission, and excitation spectra were measured with a laser spectrophotometric system, which is essentially the same as the one described in a previous paper[16] except that a pulsed tunable dye laser (Lambda Physik FL 2002E) pumped by a XeCl excimer laser (Lambda Physik EMG 103 MSC) was used as the exciting light source in the present study. The frequency of the dye laser was doubled by a KDP crystal. The resulting UV laser pulses had an output energy of 1 mJ/pulse, a repetition rate of 20 pulses/s, a spectral bandwidth of 0.2 cm^{-1}, and a duration of 10 ns. The energy density of the pulsed UV laser beam was so high that the sample vapor was subject to chemical changes. Therefore, before reaching the sample cell, the laser beam was expanded in one direction by the use of a cylindrical lens.[17] The emission was dispersed by a Nikon G-250 monochromator and then detected by a Hamamatsu R106 photomultiplier.

Actually, the emission and excitation spectra were obtained in the form of time-resolved spectra by applying the CVIPM circuit to the laser spectrophotometric system. In the CVIPM circuit,[17] a part of the voltage imposed on the photomultiplier (PM) is pulsed so that the PM may operate (i.e., the PM may be sensitive to the incident light) only in a certain time range, e.g., 0.5—5 μs, after photoexcitation of the sample. Note that, with the present CVIPM circuit, the shorter limit of time is 0.5 μs. Under the ordinary conditions of the PM, owing to an after-effect of the irradiation of the PM by the fluorescence of pyridine, the lifetime of which is of the order of 10 ps, delayed output pulses emerge from the PM to yield a false delayed fluorescence with a lifetime of about 0.5 μs and a quantum yield comparable to that of the pyridine phosphorescence.[2] When the CVIPM circuit is used, such a delayed fluorescence does not occur. This is one of the advantages of the CVIPM circuit over the delay-and-gate circuit.[2] Thus, by measuring a time-resolved phosphorescence spectrum with the aid of the CVIPM circuit, one can eliminate the original and delayed fluorescence as well as the emissions from the cell and impurities.

Emission decays (or lifetimes) were measured by attaching a single photon counting lifetime apparatus,[16] equipped with a time-to-amplitude converter, to the laser spectrophotometric system. In this study, the delay-and-gate circuit[2] or the above-mentioned CVIPM circuit was applied to the original lifetime apparatus. For emission with a lifetime longer than 10 μs, the decay measurement was made by means of a phosphorimetric system using a circuit of a digital boxcar type.[18]

Results

Phosphorescence and Excitation Spectra. Figure 1 shows time-resolved phosphorescence spectra of pyridine and its methyl derivatives. These spectra were obtained with 6 nm emission bandwidth in the time range 0.5—5 μs for pyridine and the picolines and in the range 0.5—40 μs for 2,6-lutidine. The excitation of the sample vapors was carried out at the 0-0 band of the $S_1 \leftarrow S_0$ absorption for all compounds except 2,6-lutidine. With 2,6-lutidine, since the 0-0 band is not resolved, the excitation was carried out at 285 nm near the onset of the absorption.[3] The phosphorescence spectra have onsets near 350 nm for all the compounds concerned, but the intensity maximum is shifted to the blue with the increase in number of the methyl groups: The wavelengths of the phosphorescence maxima, λ^{P}_{max} are 450 nm for the unsubstituted pyridine, 420 and 430 nm for the monomethyl derivatives 2-picoline and 3-picoline, respectively, and 415 nm for the dimethyl derivative 2,6-lutidine. These values of λ^{P}_{max} are given in Table 1.

It should be noted here that the phosphorescence spectra of all the compounds concerned remain essentially unchanged in position and in shape upon changing the excitation wavelength and the sample vapor pressure.

† 1 Torr≈133.322 Pa.

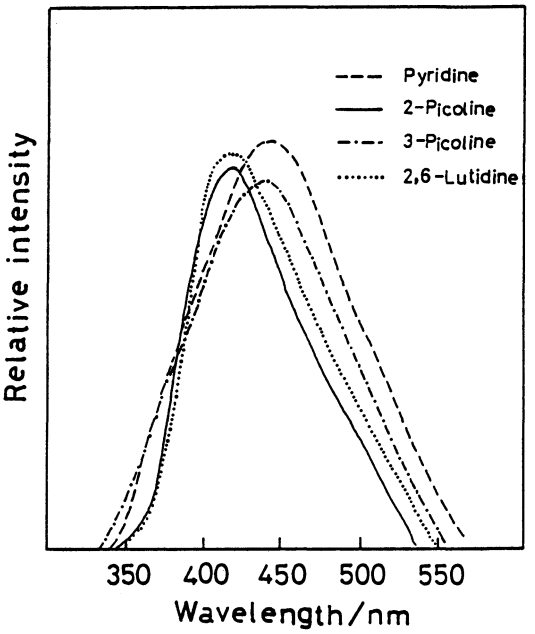


Fig. 1. Time-resolved phosphorescence spectra of pyridine and its methyl derivatives in the vapor phase. The spectra for 2 Torr of pyridine (----), 15 Torr of 2-picoline (——), and 8 Torr of 3-picoline (-·-·-) were obtained by excitation at the 0-0 band of the $S_1 \leftarrow S_0$ absorption and by observation in the time range 0.5—5 μs after pulse excitation; the spectrum for 8 Torr of 2,6-lutidine (------) was obtained by excitation at 285 nm near the onset of the $S_1 \leftarrow S_0$ absorption and by observation in the range 0.5—40 μs. The emission bandwidth is 6 nm in every case.

Table 1. Phosphorescence Characteristics of Pyridine and Its Methyl Derivatives in the Vapor Phase

Compound	λ^{P}_{max} / nm	τ_P / μs	Φ_P
Pyridine	450	1.2	4.4×10^{-7}
2-Picoline	420	4.2	2.4×10^{-7}
3-Picoline	430	1.4	
2,6-Lutidine	415	37	2.0×10^{-6}

It was already shown that the absorption and time-resolved phosphorescence-excitation spectra for pyridine agree reasonably well with each other.[1,2] In Figs. 2 and 3 are shown the absorption and time-resolved phosphorescence-excitation spectra in the region near the 0-0 band of the S_1-S_0 transition of 2-picoline and 3-picoline, respectively. The excitation spectrum of each of the compounds agrees very well with the corresponding absorption. This confirms that the observed phosphorescence spectra are attributable to the ones originating from the picolines. For 2,6-lutidine vapor also, the absorption and time-resolved phosphorescence-excitation spectra were measured and found to be in agreement with each other, though both spectra were completely structureless.

Figure 4 shows the phosphorescence spectrum of 2,6-lutidine in a rigid glass of 2-methylpentane (2-MP) at 77 K, together with the same spectrum in the vapor phase for the sake of comparison. The onset of the spectrum in the rigid glass is not very different from the one in the vapor phase, but the spectral maximum is shifted to the blue by about 15 nm in passing from the vapor phase to the rigid glass.

Phosphorescence Lifetimes. Figure 5 shows the phosphorescence decay curves for pyridine, 2-picoline, 3-picoline, and 2,6-lutidine vapors. The decay measurements were carried out using the delay-and-gate circuit for pyridine and 2-picoline, the CVIPM circuit for 3-picoline, and the digital boxcar type of circuit for 2,6-lutidine. The observed lifetimes τ_P are given in Table 1. The lifetime seems to become longer with increasing number of the methyl groups; i.e., the values of τ_P are 1.2 μs for pyridine, 4.2 μs for 2-picoline, 1.4 μs for 3-picoline, and 37 μs for 2,6-lutidine.

Phosphorescence Quantum Yields. Since there is a

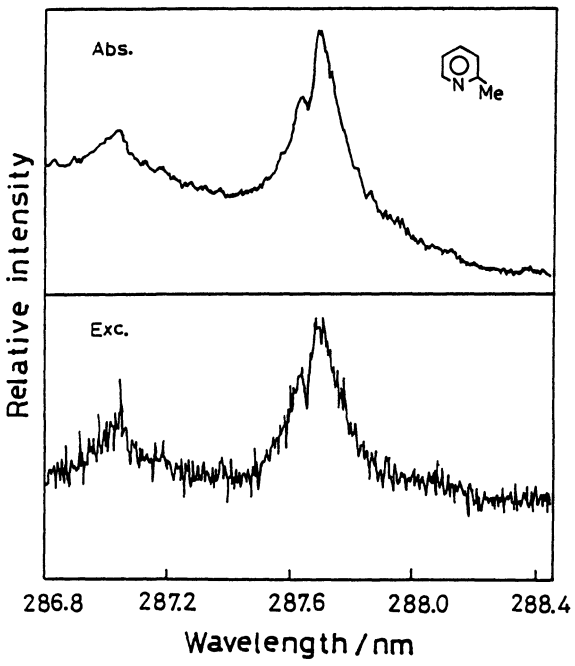

Fig. 2. Spectra near the 0-0 band of the $S_1 \leftarrow S_0$ absorption of 2-picoline vapor. (Abs.), absorption spectrum with the relative intensity representing the relative absorbance. little excitation-wavelength dependence of the fluorescence quantum yield for 2,6-lutidine compared with pyridine and picolines, the phosphorescence quantum yield (Φ_P) of 2,6-lutidine was first determined in the same way as that described in Ref. 2, by combining the known value of its fluorescence quantum yield (Φ_F) and the ratio of Φ_P to Φ_F. The resulting value of Φ_P for 2,6-lutidine along with the relative Φ_P values that were obtained for pyridine, 2-picoline, and 2,6-lutidine enabled us to determine the absolute values of Φ_P for pyridine and 2-picoline. In these experiments, to obtain desirable absorbance values, the pyridine vapor was cooled to 0 °C (pressure, 2 Torr), while the 2-picoline and 2,6-lutidine vapors were warmed to 40 °C (pressures, 15 and 8 Torr, respectively). The Φ_P values thus determined are shown in Table 1. It may be noted that Φ_P of pyridine given in Table 1 is about one third of that reported in our previous paper.[2]

Discussion

As is seen in Fig. 1, the phosphorescence spectra of pyridine and its methyl derivatives are similar in shape to each other. Further, it is seen from Fig. 4 that the phosphorescence spectrum of 2,6-lutidine vapor is also similar to the one in 2-MP at 77 K, which has been confirmed to originate from the $^3(\pi, \pi^*)$ state.[19] In addition, roughly speaking, all the spectra given in Figs. 1 and 4 are located in the same wavelength region. These observations suggest that the phosphorescent states for these four compounds, the unsubstituted, monomethyl-substituted, and dimethyl-substituted pyridines, are of $^3(\pi, \pi^*)$ type; in other words, T_1 is the $^3(\pi, \pi^*)$ state and T_2 is the $^3(n, \pi^*)$ in these pyridines.

The radiative phosphorescence lifetime (τ_P^R) of a molecule is given by $\tau_P^R = \Phi_{ISC}\tau_P/\Phi_P$, where Φ_{ISC} is the $S_1 \rightsquigarrow T$ intersystem crossing quantum yield. The experimental values of Φ_{ISC} are 0.30 and 0.6 for pyridine[20] and 2-picoline,[3] respectively. Although Φ_{ISC} for 2,6-lutidine has not been determined, one may tentatively assume it to be about 0.5. Then τ_P^R is 0.82 s for pyridine, 10 s for 2-picoline, and about 10 s for 2,6-lutidine. These values are one to two orders of magnitude larger than the values of τ_P^R for other azabenzenes the T_1 state of which is known to be of (n, π^*) character. In fact, $\tau_P^R \approx 70$ ms for pyrazine and pyrimidine in rigid-glass solution,[21] and $\tau_P^R = 30$ ms for pyrazine vapor;[22] in any of these three cases, it has been established that T_1 is of $^3(n, \pi^*)$ type. Thus, the data concerning τ_P^R support the view described above that the T_1 states in pyridine and its derivatives under study are $^3(\pi, \pi^*)$ states.

It is known, on the other hand, that the excitation energies of singlet and triplet (π, π^*) states in aromatic compounds are generally lowered by methyl substitution. We then have to explain the reason why the methyl substitution shifts the pyridine phosphorescence, which has been assigned to $T_1(\pi, \pi^*) \rightarrow S_0$, toward the blue (see Table 1). We shall discuss this problem in terms of the pseudo-Jahn-Teller interaction which is likely to occur between the two nearby triplet states, $T_1(\pi, \pi^*)$ and $T_2(n, \pi^*)$.

If T_1 in pyridine is essentially of $^3(\pi, \pi^*)$ nature, it is to be assigned to ^3L_a in Platt's notation.[23] It is here desirable to know effects of the methyl substitution on the zero-order $^3L_a(\pi, \pi^*)$ state which is hypothetically supposed to be free from the pseudo-Jahn-Teller interaction. For aromatic hydrocarbons, there is correlation between molecular-size dependence of the energy of the ^1L_a state and that of the ^3L_a state. Thus, as the molecular size increases the ^1L_a-^3L_a interval monotonically decreases and approaches a limiting value; the interval seems to be primarily size-dependent and virtually structure-independent.[23]

In view of the above fact, we examined the effects of methyl substitution on the excitation energies of the

^1L_a and ^3L_a states of benzenes, i.e., the parent hydrocarbon of pyridine, to guess the energies of the zero-order ^3L_a states of the substituted pyridines. The results are summarized in Table 2, where ΔE denotes the energy shift caused by methyl substitution. In Table 3 are shown the observed excitation energies of the $^1(n, \pi^*)$ and ^1L_a states of pyridine and its mono- and dimethyl-derivatives. The values of ΔE for the zero-order ^3L_a states were estimated by comparing the data given in Tables 2 and 3; the results are also shown in Table 3.

As is seen in Table 3, on introducing the methyl group(s) into pyridine, the energy of the $^1(n, \pi^*)$ state remains almost unchanged. It may then be assumed that practically no change is produced in the $^3(n, \pi^*)$ state energy by the methyl substitution.

The $^3L_a(\pi, \pi^*)$ and $^3(n, \pi^*)$ states in pyridine (and also in 2,6-lutidine) belong to the irreducible representations A_1 and B_1 of the symmetry group C_{2v}, respectively, so that the vibronic coupling will be induced by a non-totally symmetric, out-of-plane bending vibration of b_1 symmetry, such as ν_{16b}.[11] The potential energy curves distorted by the vibronic coupling of the pseudo-Jahn-Teller type are illustrated schematically in Fig. 6, with pyridine and 2,6-lutidine taken as examples. Here, Q represents the cordinate of the coupling vibrational mode. It is assumed that, especially in the case of pyridine, the coupling is so strong that the potential curve for the T_1 state takes the form of a distinct double minimum. The phosphorescence is considered to be emitted, with the highest probability, from the potential minimum that corresponds to a nonplanar structure of the molecule concerned. It should be noted that the energy of the zero-order ^3L_a state corresponds to the energy of T_1 at Q=0 in Fig. 6.

Inspection of Fig. 6 will reveal the following: The T_2-T_1 energy gap at Q=0 is larger and the energy of T_1 at Q=0 is lower, but the $T_1\rightarrow S_0$ transition energy is larger, in 2,6-lutidine than in pyridine. The situation in 2- and 3-picolines may be understood in a similar way, though the molecular symmetry deviates from C_{2v} owing to the presence of the methyl group. Thus, the

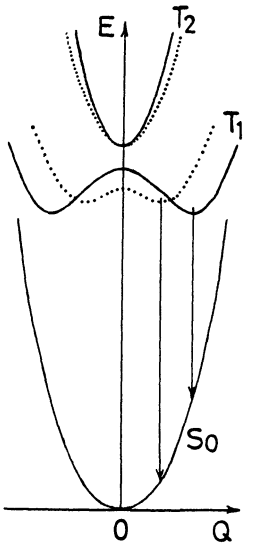

Fig. 6. Schematic potential energy curves resulting from the pseudo-Jahn-Teller interaction between T_1 and T_2: ——, pyridine; ·····, 2,6-lutidine.

potential curve for T_1 (and also for T_2) of the picolines would become intermediate, with respect to the form and location, between the corresponding curves of pyridine and 2,6-lutidine. To sum up, the $T_1\rightarrow S_0$ transition energy increases, and hence the phosphorescence spectrum shifts toward shorter wavelengths, in going from pyridine to 2- or 3-picoline and then to 2,6-lutidine, in general agreement with the experimental results.

The experimental results shown in Fig. 4 can also be explained by the same reasoning. On account of the general solvent effect, the $^3L_a(\pi, \pi^*)$ state energy (relative to the ground state energy) of 2,6-lutidine in the rigid glass is expected to be lower than that in the vapor phase. At the same time, however, this lowering of the state energy will give rise to an additional increase in the T_2-T_1 energy gap as measured at Q=0, so that little distortion will occur in the potential energy curve in the rigid glass. This explains the observation that the phosphorescence spectrum of 2,6-lutidine shifts further toward shorter wavelengths on changing the phase from the vapor to the rigid glass solution.

The observed phosphorescence lifetimes τ_P of pyridine and its derivatives, shown in Table 1, are only 10^{-6} times the radiative lifetimes τ_P^R mentioned previously. This means that in each case the rate constant for the decay of the phosphorescent triplet state, given by $1/\tau_P$, is practically equal to the rate constant for the nonradiative decay of that triplet state. In the case of pyridine, owing to the great distortion of the potential curve (Fig. 6), the frequency of the coupling vibration and the equilibrium nuclear configuration should be changed considerably on changing the electronic state from $T_1(\pi, \pi^*)$ to S_0.[6,9] As a result, the vibrational factor[9] for the $T_1 \rightsquigarrow S_0$ radiationless transition

increases to reach an extent that $1/\tau_P$ for pyridine is exceptionally large, and hence Φ_P as well as τ_P is exceptionally small.[2] As has been mentioned, the methyl substitution will reduce the degree of the potential distortion, resulting in an increase in τ_P in conformity with the experimental results (Table 1). This is particularly true of 2,6-lutidine, the τ_P value of which is 30 times as large as that of pyridine.

In the foregoing descriptions, the triplet states T_1 and T_2 have been expressed simply as $T_1(\pi, \pi^*)$ and $T_2(n, \pi^*)$. However, owing to the vibronic coupling, the $^3(\pi, \pi^*)$ and $^3(n, \pi^*)$ states are to be mixed with each other. Actually, therefore, the T_1 state partly has the character of $^3(n, \pi^*)$. This accounts for the observation that the values of τ_P^R for the pyridines given in Table 1 are smaller than τ_P^R for aromatic hydrocarbons,[24] the T_1 state of which can be regarded as a pure $^3(\pi, \pi^*)$ state. Furthermore, since the vibronic coupling should be strongest in the unsubstituted pyridine, one may readily understand the fact that the value of τ_P^R is smallest in pyridine.

We should here refer to recent reports by Schmidt and his co-workers,[14,15] who performed an electron paramagnetic resonance study of the triplet state of pyridine present as a guest in a single crystal of benzene at 1.2 K by using electron-spin-echo spectroscopy. According to these authors, the lowest triplet state (T_1 in our notation) of pyridine is the $^3B_1(n, \pi^*)$ state considerably admixed with the close-lying $^3A_1(\pi, \pi^*)$ state, the lifetime of T_1 being of the order of 1 ms, and the pyridine molecule is nonplanar in T_1 owing to the pseudo-Jahn-Teller coupling between the two triplet states mentioned above. Obviously their assignment of T_1 as the $^3B_1(n, \pi^*)$ state disagrees with our assignment of T_1 in pyridine vapor as $^3A_1(\pi, \pi^*)$; the latter assignment is supported by some other authors.[10-13] We are here not in a position to explain the reasons for the disagreement between the two assignments. Probably, however, one of the reasons would be that there is a large difference between the experimental conditions adopted. We used pyridine vapor at room temperature for our phosphorescence study, while Schmidt et al. used pyridine in a crystal at 1.2 K for their magnetic resonance study. The relative positions of the close-lying $^3(\pi, \pi^*)$ and $^3(n, \pi^*)$ levels in question will vary, depending upon the environment in which the pyridine molecule is placed.

In connection with the above problem, mention should be made of a very recent theoretical study by Kitao and Nakatsuji.[25] These authors have applied the SAC (symmetry-adapted cluster) and SAC-CI theories to ab initio calculations of the valence excitations and ionizations of pyridine. The results of their calculations indicate that (1) the lowest triplet state of pyridine is the $^3A_1(\pi, \pi^*)$ state, and (2) the second lowest is the $^3B_1(n, \pi^*)$ state, which exists higher by 0.15 eV than the $^3A_1(\pi, \pi^*)$ state.

A New Permanganate-Nitrite-Formic Acid-Methanol Oscillator

Makoto MORITA, Kazutoshi IWAMOTO, and Manabu SENŌ*
Contribution from the Institute of Industrial Science, University of Tokyo, 7-22-1, Roppongi, Minato-ku, Tokyo 106
(Received June 3, 1988)

Sustained oscillation and birhythmicity have been observed when aqueous solutions of potassium permanganate, potassium nitrite, formic acid, and methanol were mixed in a continuous-flow stirred tank reactor. A detailed phase diagram is shown. This new oscillator is composed of non-halogen compounds and the first example of the nitrogen-based oscillator.

In recent years much attention has been attracted to oscillators in chemical reactions,[1] and a number of examples of oscillations and related phenomena, e. g., multiple stationary states,[2-4] simple and complex oscillations,[5,6] aperiodic oscillation (chaos),[6,7] and the growth of traveling waves,[8,9] suggest that these dynamical phenomena are not exceptional but universal behavior sufficiently far from equilibrium. The majority of known oscillators are based on the reactions of oxohalogenate anions, which have been studied mainly by Epstein and co-workers.[10] Examples are the chlorite-bromate-iodide reaction,[11] the bromate-iodide reaction,[12] the arsenite-iodate reaction,[2,3] and the chlorite-thiosulfate reaction.[6]

On the other hand, there are some oscillators without oxohalogenate compounds, examples of which are the oxidation of benzaldehyde by oxygen in glacial acetic acid with $CoBr_2$ catalyst,[13] the oxidation of Methylene Blue by oxygen in a strongly alkaline medium in the presence of sulfite and sulfide,[14] the oxidation of sulfide ion by hydrogen peroxide in nearly neutral solutions,[15] the reduction of permanganate by hydrogen peroxide in phosphoric acid,[16] and the oxidation of oxalate[17,18] or ninhydrin[19] by permanganate. Many efforts have been made to find new oscillators, because discovery of a new chemical oscillator brings further understanding of the mechanism of chemical oscillation.

We have checked the reaction mechanisms of known chemical oscillators and noticed that these oscillators are composed of reducing and oxidizing reagents which include atoms with multiple oxidation states available. This suggests a possibility that a new oscillator could be made from reducing and oxidizing reagents suitably selected. Along these considerations, we have found a new halogen-free redox reaction which exhibits oscillatory behavior in a continuous flow stirred tank reactor (CSTR). Permanganate and nitrite ions were selected for the oxidizing and the reducing reagents, respectively, because manganese and nitrogen atoms have multiple oxidation states available. It was found that the addition of formic acid and methanol is needed to produce oscillations. Without them only vague and noisy oscillations with small amplitudes appear. The oscillations were monitored as changes in Pt-electrode potential. To our knowledge, the nitrite-permanganate oscillatory system is the first example of nitrogen-based oscillator. It exhibits not only complex periodic oscillations but also birhythmicity.[12,20,21]

Experimental

All experiments were carried out in a thermally regulated CSTR with a reaction cell of 9.5 cm^3 volume. Each of stock solutions of $KMnO_4$ (10^{-4}—10^{-2} mol dm^{-3}), KNO_2(10^{-4}—10^{-2} mol dm^{-3}), HCOOH (1.05 mol dm^{-3}) or CH_3OH (1.24 mol dm^{-3}) was prepared by dissolving the highest-purity-grade chemicals (Wako Chemicals) in doubly distilled water. Four syringe pumps (Micro Feeder, Furue Science) were used to feed simultaneously the respective stock solutions into the CSTR at controlled flow rates. In all experiments, the flow rate was set to be equal for the four pumps. The solution in the CSTR was mixed well with a magnetic stirrer at a constant stirring rate. The redox potential of the solution was monitored on an electrometer (Takeda Riken, TR-8651) as a potential difference between a standard Ag/AgCl reference electrode (TOA Electonics) and a platinum electrode. The temperature of the CSTR was kept constant at 25.0±0.1 °C throughout the experiments.

Results and Discussion

The system shows a stable stationary state and an oscillatory state, depending on the feed rate of the reagent solutions. Figure 1 shows typical behavior of the system. In this figure, the reciprocal residence time k_0 is used instead of the feed rate. The value of k_0 was calculated from $k_0=4J/V$, where J is the flow rate of the stock solution and V is the volume of the cell. When k_0 is lower than 6×10^{-3} s^{-1}, the potential difference is low (ca. 250 mV vs. Ag/AgCl). In this case, manganese is mainly in its reduced form (Mn^{2+}) and the solution is colorless in the CSTR. On increasing k_0 beyond 6×10^{-4} s^{-1}, the system enters into an oscillatory region. The amplitude of the oscillations is shown with bars in Fig. 1. With an increase in k_0 from 6×10^{-4} s^{-1} to 2×10^{-3} s^{-1}, the amplitude and the period of oscillations become large. It should be noted that the minimum potential in each cycle is almost constant, but the maximum potential tends to increase gradually. On the contrary, when k_0 increases beyond 2×10^{-3} s^{-1}, the maximum potential is nearly unchanged and the minimum potential increases.

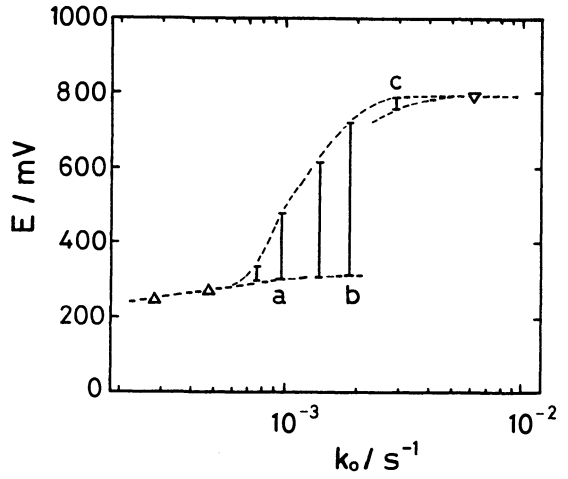

Fig. 1. Plots of the redox potential E vs. the reciprocal residence time k_0. Amplitudes of oscillations are shown with bars. The amplitude varies abruptly at about $k_0=2.3\times10^{-3}\,s^{-1}$. Fixed conditions; $[KMnO_4]_0=6.0\times10^{-4}\,mol\cdot dm^{-3}$, $[KNO_2]_0=1.0\times10^{-3}\,mol\cdot dm^{-3}$, $[HCOOH]_0=1.05\,mol\cdot dm^{-3}$, $[CH_3OH]_0=1.24\,mol\cdot dm^{-3}$, and the temperature in the CSTR is 25.0°C. The notation $[A]_0$ is used to show the concentration of a reagent A in the stock solution hereafter.

Finally the system falls into a stable steady state with a high redox potential (ca. 800 mV) when k_0 reaches $5\times10^{-3}\,s^{-1}$. In this steady state the manganese is in the form of MnO_4^-.

Characteristics of these oscillations is strongly dependent of the experimental conditions such as concentrations of the reagent solutions and k_0. The period of oscillation ranges from 30 s to 15 min, and the amplitude changes from 50 mV to 450 mV. Typical oscillatory traces are shown in Fig. 2. At lower values of k_0, a simple oscillation with a short period is exhibited, as illustrated in Fig. 2(a). Figure 2(b) shows a complicated periodic oscillation consisting of small and large period oscillations. Interestingly, the small period oscillation diminishes as k_0 increases. For example, when $k_0=2\times10^{-3}\,s^{-1}$, a simple oscillation with a large period continues stably, as shown in right-hand part of Fig. 3. At higher values of k_0, the system exhibits a simple high-potential-based oscillation of small amplitude (Fig. 2(c)).

When $k_0=2.3\times10^{-3}\,s^{-1}$, the amplitude of oscillation changes drastically and the presence of birhythmicity is suggested in this region. Detailed experiments show that either of two oscillations having different amplitudes appears depending on the initial state. These results are shown in Fig. 3, where k_0 is $2.3\times10^{-3}\,s^{-1}$. The concentrations of the reagent solutions were the same with those of Fig. 1. Initially, the potential of the Pt electrode oscillates with a small amplitude. At the time denoted by an asterisk in the figure, all the pumps were stopped for a few seconds and then turned on again. The potential then began to oscillate with a

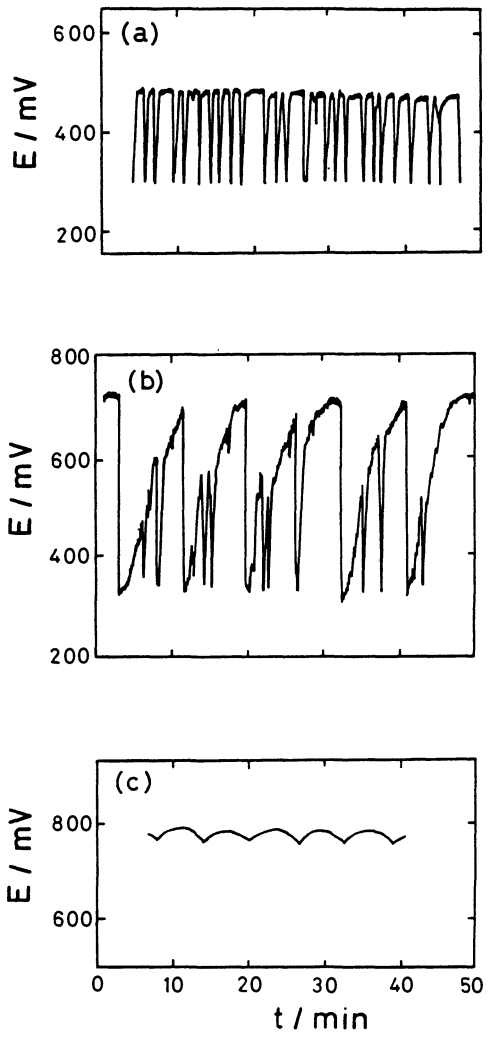

Fig. 2. Modes of oscillations vs. time t at **a**, **b**, and **c** marked in Fig. 1. The reciprocal residence time k_0; (a) $9.6\times10^{-4}\,s^{-1}$, (b) $1.7\times10^{-3}\,s^{-1}$, and (c) $2.9\times10^{-3}\,s^{-1}$.

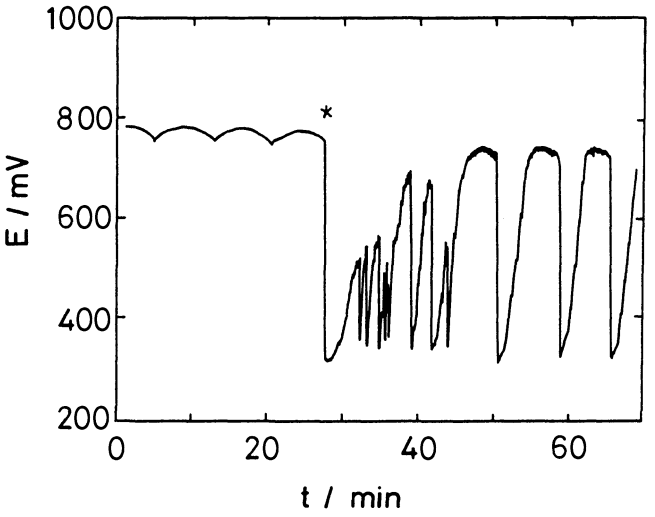

Fig. 3. Birhythmicity observed at $k_0=2.3\times10^{-3}\,s^{-1}$ in Fig. 1: All the pumps were stopped at (*) for a few second. Both two different oscillatory states are stable under the same conditions.

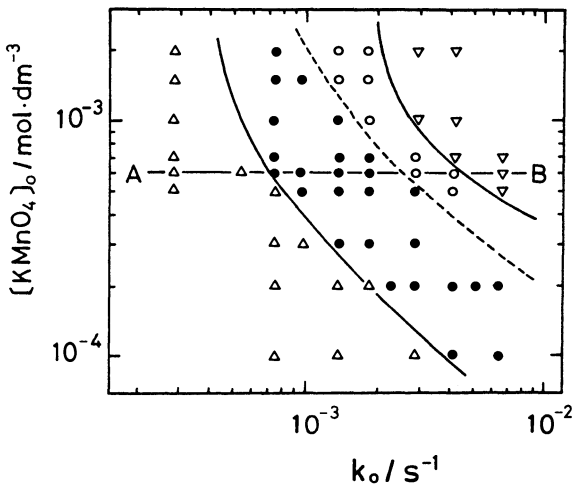

Fig. 4. Phase diagram in the reciprocal residence time k_0–$[KMnO_4]_0$ plane with $[KNO_2]_0=1.0\times10^{-3}$ mol·dm^{-3}, $[HCOOH]_0=1.05$ mol·dm^{-3}, $[CH_3OH]_0=1.24$ mol·dm^{-3}, and the temperature in the CSTR is 25.0 °C. Symbols; (△) lower potential steady state, (▽) higher potential steady state, (●) lower potential-based oscillations, (○) higher potential-based oscillations. Figure 1 shows the behavior of the system along the broken line A-B in this figure.

large amplitude, even though the conditions including the flow rate were exactly the same as before. Thus, this is birhythmicity.

Figure 4 shows a phase diagram of the system obtained by changing the concentration of the stock solution of potassium permanganate and k_0. The concentrations of other stock solutions were fixed. The phase diagram is divided into three regions; a region of oscillation and two regions of stable steady states. In the lower left-hand corner of Fig. 4, the system is in a reduced and stable steady state of lower potential. In the upper right-hand corner, it is in an oxidized and stable steady state of higher potential. Large amplitude oscillations are observed in the center of the oscillatory region. Lower potential-based oscillations are observed in the left part of the oscillatory region, and higher potential-based osillations appear in the right-hand region of the broken line in Fig. 4. In the region around the broken line, the system exhibits birhythmicity.

Without continuous supply of the reagent solutions, no oscillation takes place, probably because permanganate ions are reduced rapidly and an equilibrium state is attained immediately. By introducing constant flow of reactants, the system is kept far from equilibrium and a bifurcation takes place, producing oscillation.

Both manganese and nitrogen atoms have several oxidation states, and it is supposed that there exists a positive feedback mechanism between different oxidation states. According to the literature of inorganic chemistry,[22,23] we could give an example of the key mechanism of the system by the following process of reactions. In the first stage of the process, permanganate ions are reduced to manganese dioxide by formic acid:

$$2MnO_4^- + 3HCOOH + 2H^+ \rightarrow 2MnO_2 + 3CO_2 + 4H_2O. \quad (R1)$$

The second step is the reduction of manganese dioxide by nitrite ions:

$$MnO_2 + NO_2^- + 2H^+ \rightarrow Mn^{2+} + NO_3^- + H_2O. \quad (R2)$$

At the third step the oxidation of manganous ions by permanganate ions is followed:

$$2MnO_4^- + 3Mn^{2+} + 2H_2O \rightarrow 5MnO_2 + 4H^+. \quad (R3)$$

Then, 3(R2)+(R3) gives

$$3MnO_2 + 2MnO_4^- + 3NO_2^- + 2H^+ \rightarrow 5MnO_2 + 3NO_3^- + H_2O.$$

Therefore, three molucules of MnO_2 yield five molecules of MnO_2 in the process. This autocatalytic process may be the key mechanism of our system, because an autocatalytic reaction plays an essential role in chemical oscillation. Further studies are under way on the detailed mechanism and behavior of this chemical oscillator.

The Contents and Distributions of Arsenic, Antimony, and Mercury in Geothermal Waters

Hayao SAKAMOTO,* Masaakira KAMADA, and Norinobu YONEHARA
Department of Chemistry, Faculty of Science, Kagoshima University, Koorimoto, Kagoshima-shi, Kagoshima 890
(Received September 9, 1987)

The contents and distributions of arsenic, antimony, and mercury in geothermal water samples taken from various geothermal areas in Japan were investigated. Since the existing forms of arsenic, antimony, and mercury in geothermal waters are complex and can change during sample storage, it is difficult to determine all of the chemical forms. In this study, therefore, the arsenic(III+V), antimony(III+V), and total mercury contents were determined. In geothermal water, there is a high positive correlation between the contents of arsenic and antimony. However, there is no correlation at all between the contents of mercury and arsenic, or between those of mercury and antimony. It can be assumed that mercury behaves differently from either arsenic or antimony in geothermal water.

In keeping pace with the development of geothermal energy, attention has been paid to the various components of geothermal water, such as that of thermal water or hot spring water. Arsenic, antimony and mercury are included in these components. However, information on the contents, existing forms and distributions of these elements are insufficient. Investigations concerning arsenic have been continuing in view of the environmental contamination caused by the drainage of hot spring water[1] and the use of hot spring water for drinking.[2,3] In some sources of thermal well water obtained for geothermal power generation, there are high concentrations of arsenic; such thermal water is being recharged into underground regions as a counterplan. Investigations into the exclusion treatment of arsenic have also begun.[4]

Since antimony, the homologous element of arsenic, is found in relatively low content, compared to arsenic, and is difficult to analyze, there have not been many reports on antimony in geothermal water compared to those on arsenic. After Holak[5] developed atomic absorption spectrometry for arsenic hydroguret in 1969, determinations of arsenic and antimony in ppb-ppt levels became possible through the work of Fernandedz et al.[6] and Yamamoto et al.[7]

To determine the mercury content, cold vapor atomic absorption spectrometry has been widely employed.[8,9]

Nakagawa[10] and Awaya et al.[11] produced data concerning the mercury content in hot spring water at various locations in Japan.

There have been many reports concerning the arsenic and antimony contents in hot spring water at various specific areas.[12-18] There have also been reports by Watanuki et al.[19] and Sato[20] concerning the arsenic and antimony contents in acidic thermal water. However, there have been no reports concerning measurements of the contents of arsenic, antimony and mercury in the geothermal water found over a wide range of geothermal areas. In this study, we determined the contents of arsenic, antimony and mercury in geothermal water (thermal water, hot spring water and condensed water) sampled at various geothermal areas in Japan. We discuss their existing forms, mutual relations and distributions.

Experimental

Preservation of Sample. Geothermal water samples used for determining arsenic and antimony contents were kept in polyethylene bottles(1 l), which were exuded beforehand by approximately 3 mol dm^{-3} nitric acid for two weeks and then washed thoroughly with water. 10 ml of 35% hydrochloric acid was added to each 1 l of sample at the sampling place as quickly as possible. Samples were then brought back to the laboratory and analyzed.

The samples used in determinations of the mercury content were taken in hard glass bottles, which had been washed in a manner similar to that of the polyethylene bottles used for arsenic and antimony, equipped with Teflon packing. For every 1 l of sample, 10 ml of (1 : 1) (97%) sulfuric acid was added. Samples were then brought back to the laboratory and analyzed. When a sample containing much chloride, such as geothermal water, was preserved at less than pH 1, the loss of mercury was hardly observable. However, for samples containing much sulfide, the loss of arsenic, antimony, and mercury could be observed. In this case, the sulfide and its related compounds were oxidized by a sulfuric acid-potassium permanganate solution and determinations of arsenic, antimony, and mercury were quickly undertaken.

The acids(hydrochloric acid, sulfuric acid) and the potassium permanganate, which were used for measurements of arsenic, antimony and mercury were all analytical, special-reagent grade.

The present investigation aimed to provide a practical method for determining the contents of arsenic and antimony. Regarding arsenic and antimony determination we used the method of Yamamoto et al.,[7] and applied a differential determination of arsenic and antimony to geothermal waters. The procedures are as follows.

Determination of Arsenic. One method for a differential determination of arsenic(III+V) and arsenic(III) is described.

A sample solution (≦40 ml), containing less than 0.5 μg of arsenic(III+V), was placed in a reaction vessel and diluted with water, bringing it to 40 ml. Into this solution, 10 ml of

35% hydrochloric acid and 5 ml of 40% potassium iodide solution were added and the reaction vessel was then put into a hydroguret generator. Then, 1 ml of 3% sodium borohydride in 0.01 mol dm^{-3} sodium hydroxide solution was injected with a syringe over a period of 20 s while stirring with a bar. Arsine was evolved by passing nitrogen through the reaction vessel 70 s after injecting 3% sodium borohydride. The arsine was atomized in a hydrogen-nitrogen flame of an atomic absorption spectrometer and the arsenic(III+V) was determined at a wavelength of 193.7 nm. By using a calibration curve prepared in the same way as the sample, the arsenic(III+V) content could be determined.

In order to determine the content of arsenic(III), the sample solution was diluted with water, bringing it to 40 ml, in a reaction vessel. This solution was adjusted to pH 5—6 by the addition of 1 ml of 40% citric acid and 5 ml of 1 mol dm^{-3} sodium citrate tribasic, set into the hydroguret generator, and treated in the same way as in the procedure for arsenic(III+V).

Determination of Antimony. One method for a differential determination of antimony(III+V) and antimony(III) is described. A sample solution (≦40 ml), containing less than 0.5 μg of antimony(III+V), was placed in a reaction vessel and diluted with water, bringing it to 40 ml. Then, 5 ml of 35% hydrochloric acid and 2.5 ml of 40% potassium iodide solution were added. The vessel was then put into a hydroguret generator and the antimony(III+V) was treated in the same way as during the determination of arsenic(III+V). The amount of antimony(III+V) was determined by a hydrogen-nitrogen flame. The atomic absorption was done at a wavelength of 217.6 nm.

In order to determine the content of antimony(III), a 40 ml sample solution containing less than 0.5 μg was placed in a reaction vessel as in the determination of antimony(III+V). The sample solution was then adjusted to pH 2 by the addition of 2.5 ml of 40% citric acid solution; the antimony(III) was treated in the same way as treating antimony(III+V).

Determination of Mercury. The determination of mercury was achieved according to the method described previously.[9]

Results and Discussion

Existing Forms of Arsenic and Antimony in Geothermal Waters. Geothermal water was sampled and brought back to the laboratory. Then, the change in the arsenic(III) and arsenic(III+V) contents were examined during storage.

The analytical results are shown in Table 1. The contents of arsenic(III) in some samples decreased rapidly while standing after sampling; however, the contents of arsenic(III+V) remained almost constant. A similar result was obtained for antimony.

The underground regions where geothermal water exists are strongly reductive and the abundance ratios of arsenic(III) to arsenic(III+V) and antimony(III) to antimony(III+V) are higher than those of surface

a) Stored in a polyethylene bottle. b), c), d), e): Condensed water.

water. After sampling, the arsenic(III) and antimony(III) were exposed to an oxidative atmosphere and may have been converted to arsenic(V) and antimony(V), respectively.

Since arsenic(III) and antimony(III) in geothermal water can change, depending on the storage conditions of the sample, any determination of arsenic(III) and antimony(III) must be carried out in as short a time as possible after sampling.

Existing Forms of Mercury in Geothermal Waters. The analytical results of the existing chemical forms are shown in Table 2.

In thermal water and hot spring water, there is no great difference in the contents of soluble inorganic mercury, soluble inorganic plus organic mercury, and total mercury. It may be noted that mercury in thermal water and hot spring water exists in almost soluble inorganic mercury. However, for volcanic gas condensed water, which contains much hydrogen sulfide, the amount of soluble inorganic plus organic mercury and the total amount of mercury is more than that of soluble inorganic mercury. This does not suggest that there is not much soluble inorganic mercury in volcanic gas condensed water, but implies that the reduction of soluble inorganic mercury is difficult because of the interference of sulfide ion. Therefore, it is difficult to determine the amount of soluble inorganic mercury and organic mercury in geothermal water samples which contain much sulfide ion.

Table 4. Arsenic, Antimony, and Mercury Contents in Geothermal Waters

Element	Range[a]	n[b]	$\bar{X}_A$[c]	$\bar{X}_G$[d]
As	0.35—9500	75	1230	141
Sb	0.05— 244	75	$35._4$	2.5_0
Hg	2.6 — $89._8$	69	$19._1$	$13._8$

a—c) in $\mu g\,l^{-1}$ for As, Sb and $ng\,l^{-1}$ for Hg. b) Number of samples. c) Arithmetic mean. d) Geometric mean.

The Arsenic, Antimony, and Mercury Contents in Geothermal Waters. The arsenic(III+V), antimony(III+V), and total contents of mercury were determined for geothermal water sampled from various geothermal areas in Japan. The sampling stations are illustrated in Fig. 1 and analytical results are tabulated in Table 3. Below, we discuss the data listed in Table 3.

The range, arithmetic and geometric mean of the arsenic, antimony, and mercury contents and the

number of samples measured, except for gas condensed water, are shown in Table 4.

Using the mean content of arsenic, antimony, and mercury in igneous rocks, accepted to be 1.5,[21] 0.2,[22] and 0.08[23] ppm, respectively, the gravimetric ratios of As/Sb, Sb/Hg, and As/Hg can be calculated as being 7.5, 2.5, and 19, respectively. From the values listed in Table 4, the gravimetric ratios of As/Sb, Sb/Hg, and As/Hg in geothermal water were calculated to be 56, 179 and 10000, respectively. Watanuki et al.[19] have reported that the gravimetric ratio of As/Sb in the Tamagawa and Kusatsu hot springs to be 100 and 50, respectively.

The antimony and mercury contents in geothermal water are smaller compared to the arsenic content. The reasons involve (assuming the differences of the composition of thermal water which comes into contact with igneous rock) the ease of sulfide precipitation and gas scattering in the atmosphere.

Mutual Relation of Arsenic, Antimony, and Mercury in Geothermal Waters. The mutual relation among arsenic, antimony and mercury contents in geothermal waters is shown in Figs. 2—4.

In geothermal water, there is a high positive correlation between the arsenic and antimony contents (correlation coefficient, 0.87). However, the correlation coefficients between the contents of arsenic and mercury or between that of antimony and mercury were 0.065 and 0.15, respectively, showing no correlation between arsenic and mercury or between antimony and mercury. This suggests that mercury behaves differently from arsenic and antimony in geothermal water.

Distributions of Arsenic, Antimony, and Mercury in Geothermal Waters. The frequency distributions of the arsenic, antimony, and mercury contents in geothermal water are shown in Figs. 5—7.

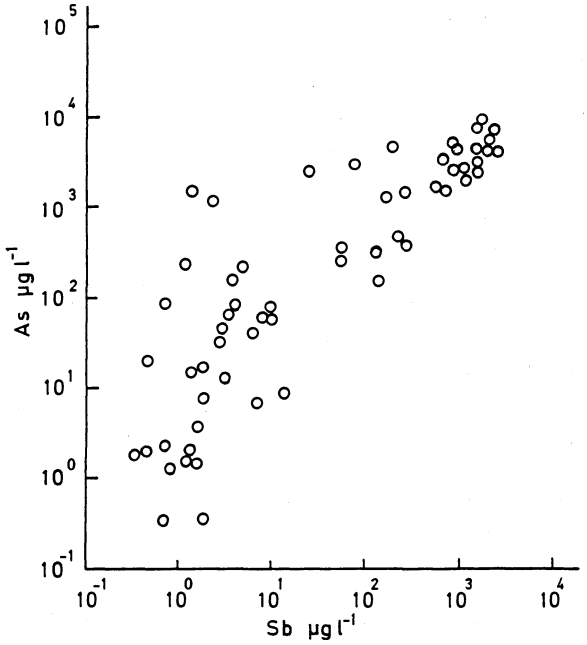

Fig. 2. Relation between arsenic and antimony in geothermal waters.

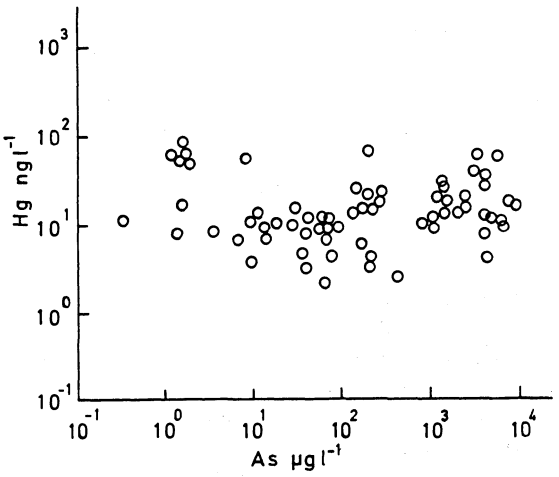

Fig. 3. Relation between mercury and arsenic in geothermal waters.

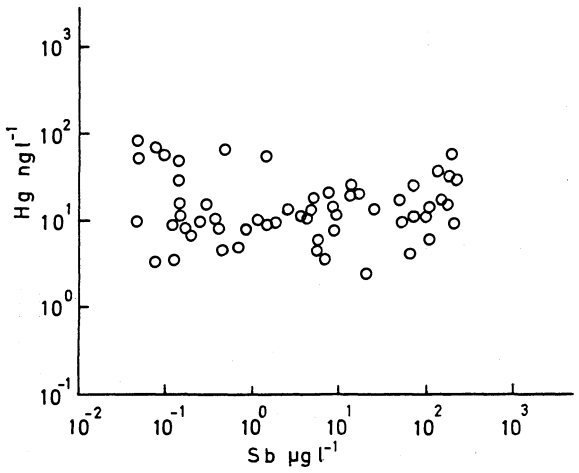

Fig. 4. Relation between mercury and antimony in geothermal waters.

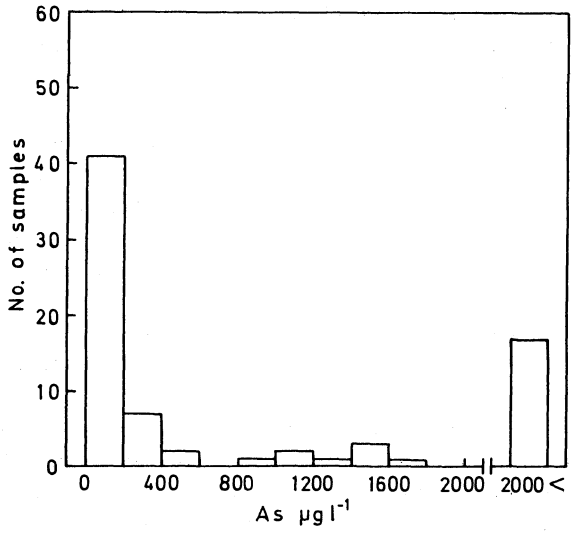

Fig. 5. Frequency for arsenic content distributions of geothermal waters.

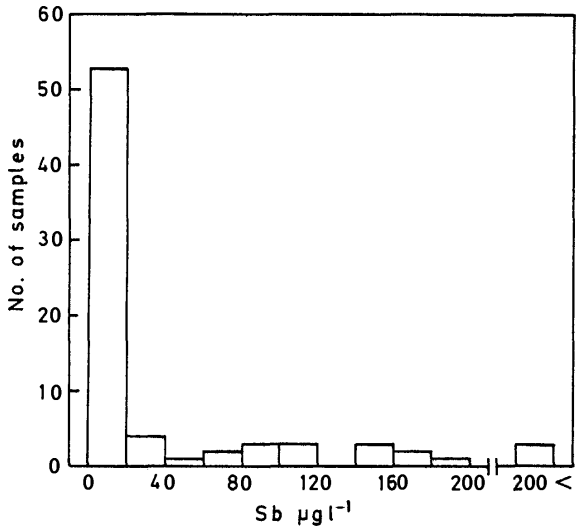

Fig. 6. Frequency for antimony content distributions of geothermal waters.

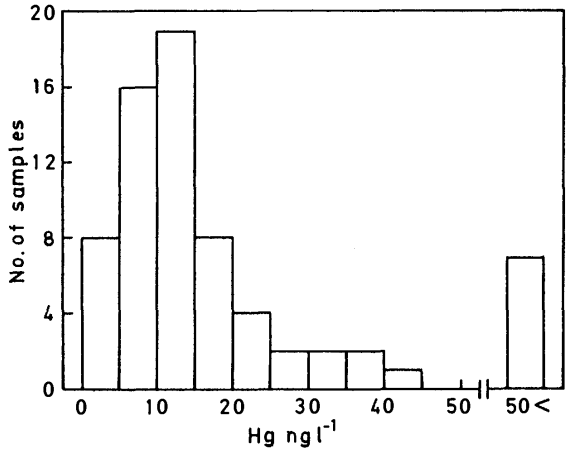

Fig. 7. Frequency for mercury content distributions of geothermal waters.

The distributions of arsenic and antimony are similar in the sense that they are spread over wide concentration range. On the other hand, except for a few of the samples, the mercury is limited to an extremely narrow concentration range.

One of the specificities of arsenic and antimony contents (cf. Table 3) in geothermal water is that the arsenic and antimony contents in a thermal water system (Ōnuma, Kakkonda, Onikoube, Ōtake, and others) tend to be larger than those in a vapor dominated system (Matsukawa).

The arithmetic and geometric means of the total mercury content in geothermal water for 69 samples, except for gas condensed water, are $19._1$ ng l^{-1} and $13._8$ ng l^{-1} respectively. Except for a few samples, there was no great difference in the mercury content from different geothermal areas; the mercury content in geothermal water was smaller than that of the arsenic and antimony contents. The range of the mercury content in the gas condensed water at Matsukawa was 11400—15900 ng l^{-1}; this concentration in gas condensed water is as much as a 1000 times higher than that found in general thermal waters. This seems to correlate with the fact that mercury is a component which changes easily to the gas phase.

No correlation between pH and the content of arsenic, antimony or mercury in geothermal water could be observed.

Conclusion

We have determined the arsenic, antimony, and mercury contents in geothermal water. The range of arsenic(III+V), antimony(III+V), and the total contents of mercury in geothermal water were 0.35—9500 μg l^{-1}, 0.05—244 μg l^{-1}, 2.6—$89._8$ ng l^{-1}, respectively, their arithmetic means were 1230 μg l^{-1}, 35.4 μg l^{-1}, and $19._1$ ng l^{-1}, respectively, and their geometric means were 141 μg l^{-1}, 2.5_0 μg l^{-1}, and $13._8$ ng l^{-1}, respectively.

There is a high positive correlation between the arsenic and antimony contents in geothermal water, but there is no correlation between the mercury and arsenic contents or between the mercury and antimony contents. It is assumed that mercury behaves differently from arsenic or antimony in geothermal water.

The arsenic and antimony contents in geothermal water tend to be larger in the thermal water of thermal water systems compared to the thermal water (condensed water) of vapor dominated systems.

On the other hand, except for a few cases, there is not much difference in the total mercury content of geothermal water in different geothermal areas. Mercury is thought to be a component which can not exit in high concentrations in geothermal water (thermal water and hot spring water).

The authors wish to express their thanks to Professor Yuroku Yamamoto of Fukui Institute of Technology (previously Hiroshima University) and Professor Takejiro Ozawa of Saitama University for their helpful advice.

Thanks are also due to my many colleagues with whom we have discussed the problems of analytical methodology. The present work was partially supported by a Grant-in-Aid for Scientific Research Nos. 56030070, 57030066, and 58030061 from the Ministry of Education, Science and Culture.

^{57}Fe-Mössbauer and ^{13}C-CP-MAS NMR Spectroscopic Studies of the Reaction Products of Ferrocene Derivatives with Mercury(II) Salts

Masanobu WATANABE, Yuichi MASUDA, Izumi MOTOYAMA, and Hirotoshi SANO*
Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Fukasawa, Setagaya-ku, Tokyo
(Received January 26, 1988)

The unstable adducts of ferrocene and methylferrocene and the stable adducts of biferrocene, diferrocenylmethane, 1,2-diferrocenylethane, and [*n*]ferrocenophane (*n*=2, 3) with HgX_2 (X=Cl, Br, I, and BF_4) were studied by means of ^{57}Fe-Mössbauer and high-resolution solid-state ^{13}C NMR spectroscopies. The large quadrupole splitting (Q. S.) values in the ^{57}Fe-Mössbauer and the large low-field shifts in the ^{13}C-CP-MAS NMR, spectroscopy suggest the presence of a direct chemical bond between the Fe and Hg atoms.

All attempts to prepare a stable $HgCl_2$ adduct of ferrocene have been unsuccessful and have given green-colored paramagnetic ferrocenium-type salts after standing for a day. However, stable light-colored diamagnetic adducts of biferrocene, diferrocenylmethane, and 1,2-diferrocenylethane with $HgCl_2$ could be prepared.[1,2] It was shown in our previous reports that [2]ferrocenophane derivatives give much more stable adducts in reactions with Lewis acids, $SnCl_4$, $HgCl_2$, $CdCl_2$, and I_2,[3-6] whereas binuclear ferrocene derivatives could be oxidized to their ferrocenium-type salts in reactions with Lewis acids other than $HgCl_2$. These results can be explained by assuming that [2]ferrocenophanes have less steric hindrance in donating e_{2g} electrons than ferrocene and binuclear ferrocene derivatives, on the basis of ^{57}Fe- and ^{119}Sn-Mössbauer spectroscopics, which provide direct information concerning the iron and tin atoms concerned with bond formation. X-Ray diffraction studies of the I_2 adduct with 1,1,2,2-tetramethyl[2]ferrocenophane show that the Fe atoms squeezed out of the tilted cyclopentadienyl (Cp) structure have I atoms at a short distance (2.675 Å),[6] much shorter than the sum of the van der Waals radii of the Fe and I atoms. Applications of ^{13}C-CP-MAS NMR spectroscopy to the reaction products of ferrocene and ruthenocene derivatives with various Lewis acid adducts have proved its sensitivity to the changes in structural distortion caused by adduct formation and have provided additional information; e.g., the large low-field shift of peaks ascribed to Cp rings of the ruthenocene suggests the formation of direct chemical bonds between the Ru atom and the Lewis acids (I^+, Hg^{2+}, and Sn^{4+}) in the adducts, as has already been verified by means of X-ray diffraction[8,9] and ^{119}Sn-Mössbauer spectroscopic studies.[10] The present studies were carried out in order to cross-examine the bond formation between the metal atoms in ferrocene derivative adducts with HgX_2 and the structural distortion associated with adduct formation by using both ^{57}Fe-Mössbauer spectroscopy and high-resolution ^{13}C-CP-MAS NMR spectroscopy.

Experimental

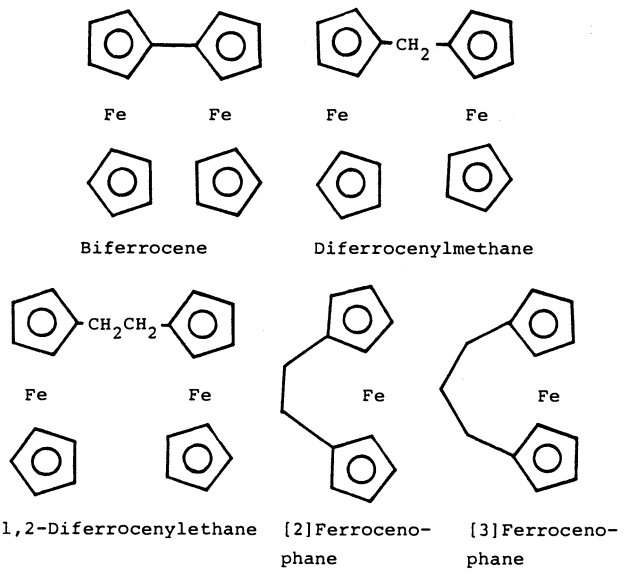
Materials: The reaction products of ferrocene,[8] biferrocene,[1] diferrocenylmethane,[2] 1,2-diferrocenylethane,[2] and [2]ferrocenophane[4] with $HgCl_2$ were prepared by the previously reported methods. The $HgCl_2$ adducts of methylferrocene and [3]ferrocenophane were first prepared by a method similar to that used in the case of ferrocene-7$HgCl_2$ adduct.[8] The purities of the adducts were confirmed by elemental analysis. Found: C, 7.03; H, 0.75%. Calcd for methylferrocene-6$HgCl_2$, $C_{11}H_{12}FeHg_6Cl_{12}$: C, 7.22; H, 0.66%. Found: C, 8.54; H, 0.84%. Calcd for [3]ferrocenophane-6$HgCl_2$, $C_{13}H_{14}FeHg_6Cl_{12}$: C, 8.42; H, 0.76%. Adducts of [2]ferrocenophane with $HgBr_2$ and HgI_2 were prepared in diethyl ether and benzene solution, respectively, by a method similar to that used in the preparation of [2]ferrocenophane-3$HgCl_2$ adduct.[4] A red-orange precipitate was filtered, washed with diethyl ether, and dried under vacuum. Found: C, 12.57; H, 1.16%. Calcd for [2]ferrocenophane-2.5$HgBr_2$, $C_{12}H_{12}FeHg_{2.5}Br_5$: C, 12.93; H,1.08%. Found: C, 11.86; H, 1.02%. Calcd for [2]ferrocenophane-2.2HgI_2, $C_{12}H_{12}FeHg_{2.2}I_{4.4}$: C, 11.89; H, 0.99%.

Measurements: ^{57}Fe-Mössbauer spectroscopic measurements were carried out by using a ^{57}Co(Rh) source moving in a constant acceleration mode. The isomer shift (I. S.) value for the ^{57}Fe-Mössbauer spectroscopic measurements was taken with respect to metallic iron; the experimental error of the I. S. and Q. S. values was estimated to be within ±0.02 mm s^{-1}.

The ^{13}C-CP-MAS NMR spectra were obtained under the same conditions as in the case of our previous reports.[7] The chemical-shift values were measured with respect to external adamantane and then converted to the shift values from TMS. Both the ^{1}H and ^{13}C NMR spectra in solution were measured by using a JEOL FX-200 spectrometer at 200.0 and 50.1 MHz, respectively, using TMS as a standard. The assignment of the ^{13}C signals of the metallocenes was carried out by selective proton decoupling experiments.

Results and Discussion

It has already been known that ferrocene gives an unstable orange-yellow diamagnetic ferrocene-7$HgCl_2$ adduct in a reaction with $HgCl_2$ in diethyl ether.[9] No ^{1}H NMR signals of the ferrocene-7$HgCl_2$ adduct could be obtained in acetonitrile solution because of oxida-



tion to the ferrocenium salt of the adduct. This smaller stability of the adduct in solution is one of the large differences from that of ruthenocene-3$HgCl_2$ adduct (i.e., the $HgCl_2$ adduct of ruthenocene is stable in the acetonitrile, giving a large low-field shift ($\Delta\delta$; 0.84 ppm)[7] caused by the direct chemical bond between the Ru and Hg atoms as already verified from X-ray diffraction studies[8]). In order to avoid the experimental difficulties associated with the lower stability of the ferrocene-7$HgCl_2$ adduct in solution, ^{13}C-CP-MAS NMR spectroscopic measurements of the solid adduct were carried out in the present studies.

A π-C_5H_5 ring carbon signal (δ) in the ferrocene appears at δ=69.8, while a broader signal of the $HgCl_2$ adduct appears at δ=79.7, as shown in Figs. 1-a, and b and Table 1. A large low-field shift ($\Delta\delta$; 9.9 ppm) has

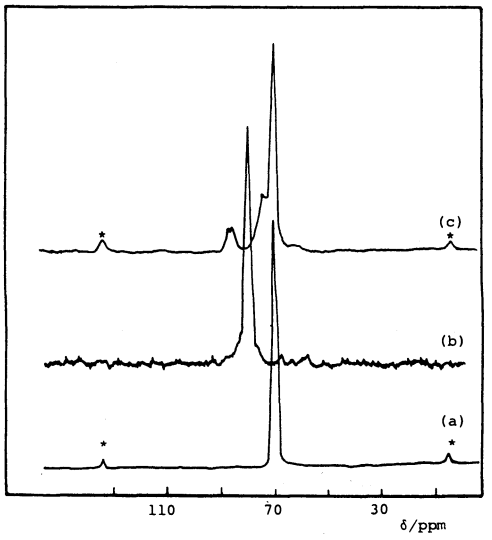


Fig. 1. ^{13}C-CP-MAS NMR spectra of ferrocene(a), its 7$HgCl_2$(b) adduct, and chloromercurioferrocene(c). The sample spinning side band (SSB) is represented by * in the Figure.

Table 1. ^{13}C-Chemical Shift Values of Ferrocene Derivatives and Their Mercury(II) Halides Adducts

Compound	Chemical shift value δ/ppm
Ferrocene	69.8(C_5H_5)
Ferrocene-7$HgCl_2$	79.7(C_5H_5)

	24.6(CH_2*CH_2CH_2*)

been found in ferrocene-7$HgCl_2$ adduct, as in the case of ruthenocene-3$HgCl_2$ adduct ($\Delta\delta$; 8.0 ppm).[7] On the other hand, no low-field shift has been observed for the chloromercurioferrocene, (C_5H_5)(C_5H_4HgCl)Fe, in which a chloromercurio group (HgCl) is attached to the Cp-ring.[11] The ^{13}C chemical-shift value of the Cp-ring in the chloromercurioferrocene (δ=70.5) is very similar to that of ferrocene itself (δ=69.8) in the solid state, as can be seen in Figs. 1-a and c. These facts clearly indicate that the large low-field shift observed in the ferrocene-7$HgCl_2$ adduct can be ascribed to a chemical bond formed between the Fe and Hg atoms, as previously indicated on the basis of the anomalously large Q. S. value (3.09 mm s^{-1} at 80 K) in the

^{57}Fe-Mössbauer spectrum of the $HgCl_2$ adduct.[12]

It is suggested that an enhanced ligand-to-metal donation of the electrons from the Cp-ring associated with the Fe-Hg or Ru-Hg bond formation should result in a decreased in the electron density around Cp-ring carbons in the adducts, giving the large low-field shift of the Cp-ring observed in the adducts.

Similar Fe-Hg bond formation has also been found for the $HgCl_2$ adduct of methylferrocene. Methylferrocene reacts with $HgCl_2$ in diethyl ether and gives an orange-yellow $HgCl_2$ adduct, expressed as methylferrocene-6$HgCl_2$ on the basis of an elemental analysis. The $HgCl_2$ adduct is less stable than the ferrocene-7$HgCl_2$ adduct; i.e., its color changes to green for a few hours at room temperature, suggesting the oxidation of methylferrocene, while the color of the ferrocene-7$HgCl_2$ remains unchanged for a slightly longer period than that of methylferrocene-6$HgCl_2$. Attempts to obtain a clear ^{13}C-CP-MAS NMR spectrum of the methylferrocene-6$HgCl_2$ adduct have been unsuccessful, probably because of the formation of paramagnetic oxidized species. However, an anomalously large Q. S. value (3.02 mm s^{-1} at 78 K) is actually found in the ^{57}Fe-Mössbauer spectroscopy of the methylferrocene- 6$HgCl_2$ adduct. These facts indicate the presence of a less-stable bond formed between the Fe and Hg atoms in the adduct.

The $HgCl_2$ adduct of biferrocene has been found to be much more stable than the ferrocene-7$HgCl_2$ adduct; i.e., its color remains unchanged for more than 200 days upon standing at room temperature.[1] The ^{13}C chemical-shift values of the biferrocene in $CDCl_3$ solution have been found to be δ=83.9 (C_1), 69.2 (C_5H_5), 67.6 ($C_{3,4}$), and 66.4 ($C_{2,5}$), as illustrated in Fig. 2-c. Relatively sharp signals are observed for the biferrocene in the solid state and broader signals for the $HgCl_2$ adduct, as shown in Fig. 2-b. The signals of $C_{2,5}$, $C_{3,4}$, and C_1 of the $HgCl_2$ adduct cannot be well-resolved, being superimposed on the main C_5H_5-ring signal. Therefore, only the low-field shift values of π-C_5H_5 will be discussed. The large low-field shift of the main C_5H_5-ring signal ($\Delta\delta$; 9.0 ppm) is observed and the value is a little smaller than that of ferrocene-7$HgCl_2$ ($\Delta\delta$; 9.9 ppm). The result of ^{13}C-CP-MAS NMR spectroscopy is in line with that of the ^{57}Fe-Mössbauer study; i.e., the Q. S. value of the biferrocene-2$HgCl_2$ adduct (2.93 mm s^{-1} at 78 K) is a little smaller than that of the ferrocene-7$HgCl_2$ adduct (3.09 mm s^{-1} at 80 K).[12] Both results indicate that the chemical bond between the Fe and Hg atoms in the biferrocene-2$HgCl_2$ adduct is slightly weaker than that of

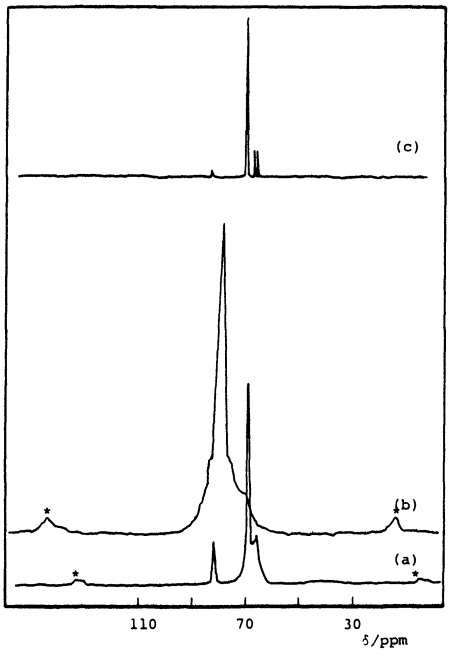

Fig. 2. ^{13}C-CP-MAS NMR spectra of biferrocene(a), its 2$HgCl_2$(b) adduct, and ^{13}C NMR spectrum of biferrocene(c) in chloroform solution.

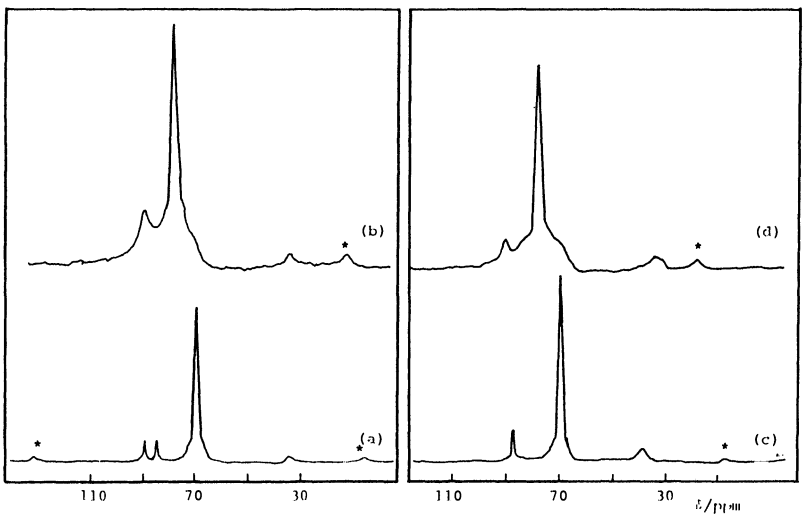

Fig. 3. ^{13}C-CP-MAS NMR spectra of diferrocenylmethane(a), its 6$HgCl_2$(b), 1,2-diferrocenylethane(c), and its 6$HgCl_2$(d) adduct.

the ferrocene-7$HgCl_2$ adduct. One of the possible explanations for the much larger stability of the biferrocene-2$HgCl_2$ adduct, than the ferrocene-7$HgCl_2$ adduct, can be given by assuming that biferrocene reacts with a mercury(II) atom as a chelating agent, such as $[(C_5H_5)(\overline{C_5H_4})Fe\rightarrow HgCl_2\leftarrow Fe(\overline{C_5H_4})(C_5H_5)]$.

Similar large Q. S. components (3.02 and 3.00 mm s^{-1} both at 78 K) have been observed for diferrocenylmethane-6$HgCl_2$ and 1,2-diferrocenylethane-6$HgCl_2$ adducts, respectively,[2] suggesting a chemical bond formation between the Fe and Hg atoms in the adducts. Slightly smaller but similar $\Delta\delta$ values of the Cp-rings have been observed ($\Delta\delta$; 8.8 and 8.4 ppm for the $HgCl_2$ adducts of diferrocenylmethane and 1,2-diferrocenylethane, respectively) compared with the value for biferrocene-2$HgCl_2$ adduct ($\Delta\delta$; 9.0 ppm). The slightly smaller $\Delta\delta$ values of these Cp-rings may be expected for a slightly weaker bond between the Fe and Hg atoms in the adducts. Changes in the color of the diferrocenylmethane and 1,2-diferrocenylethane-6$HgCl_2$ adducts from orange-yellow to blue-green within several days at room temperature after preparation also suggest a less-stable Fe-Hg bond formation.

All of the above-mentioned results lead us to the conclusion that there is a direct interaction between the Fe and Hg atoms in the $HgCl_2$ adducts of ferrocene, methylferrocene, biferrocene, diferrocenylmethane, and 1,2-diferrocenylethane. The smaller stability of the adducts of diferrocenylmethane and 1,2-diferrocenylethane, compared with that of biferrocene-2$HgCl_2$ adduct, may be ascribed to a larger distance between the Fe-Fe atoms for chelation in the adducts.

Table 2. ^{57}Fe-Mössbauer Parameters of Ferrocene Derivatives and Their Mercury(II) Salt Adducts

Compound	Temperature K	Q. S. mm s^{-1}	I. S. mm s^{-1}
Ferrocene	78	2.41	0.52

a) Date was taken from Ref. 12.

As mentioned in the introduction, [2]ferrocenophane gives stable adducts with some Lewis acids. The adducts were investigated by means of the same methods used for the binuclear ferrocene derivative-Lewis acid adducts for the sake of comparison. Slightly smaller Q. S. values for [2]ferrocenophane-HgX_2 (3.08 and 3.12 mm s^{-1} at 78 K for $HgBr_2$ and HgI_2, respectively) than the value of the $HgCl_2$ adduct (3.29 mm s^{-1} at 78 K) were found, but these values are much larger than the value of [2]ferrocenophane itself (2.41 mm s^{-1} at 78 K), as can be seen in Table 2. These facts indicate the presence of a stable bond between the Fe and Hg atoms in the $HgBr_2$ and HgI_2 adducts, as in the case of the $HgCl_2$ adduct.

The ^{13}C chemical shift values of [2]ferrocenophane in $CDCl_3$ were found to be δ=91.2 (C_1), 72.2 ($C_{2,5}$), 67.9 ($C_{3,4}$), and 33.7 (CH_2CH_2). The assignment of the carbon signals was made by using the same method as that in the case of biferrocene on the basis of the results of [n]ferrocenophane (n=1,2) derivatives.[13] Relatively sharp signals have been found for [2]ferrocenophane and broader signals for the HgX_2 adducts in the solid state. The ^{13}C chemical-shift values of $C_{2,5}$ and $C_{3,4}$ for the $HgCl_2$ adduct (δ=78.6) are almost the same as those of the $HgCl_2$ adducts of ferrocene (δ=79.7) and biferrocene (δ=79.7). One of the most striking features is the low-field shift value of the C_1 signal (about $\Delta\delta$; 21.6) in the adduct. This value is anomalously large in com-

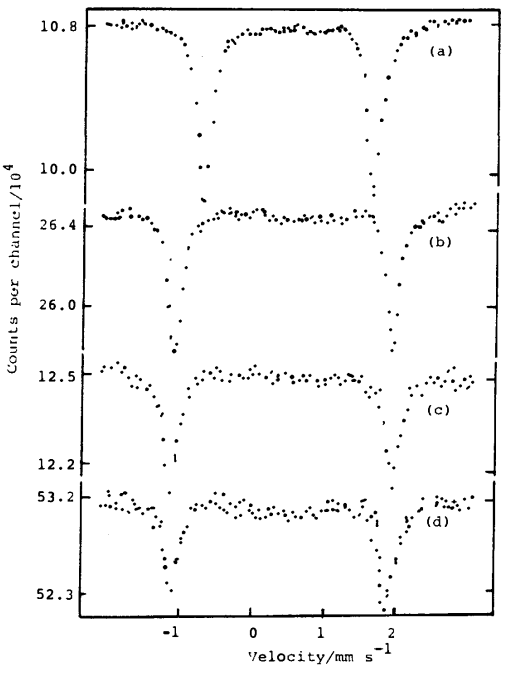

Fig. 4. ^{57}Fe-Mössbauer spectra of [2]ferrocenophane(a), its 2.5$HgBr_2$(b), 2.2HgI_2(c) adducts, and [3]ferrocenophane-6$HgCl_2$(d) adducts.

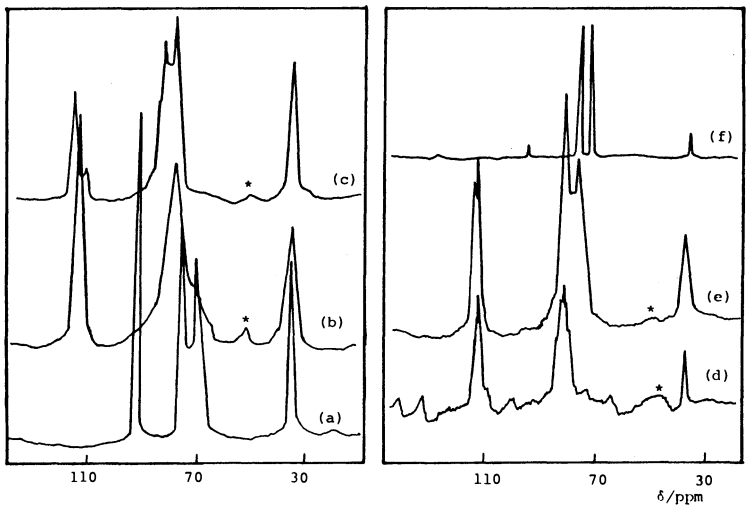

Fig. 5. ^{13}C-CP-MAS NMR spectra of [2]ferrocenophane(a), its $3HgCl_2$(b), $2.5HgBr_2$(c), $2.2HgI_2$(d), $0.5Hg(BF_4)_2$(e) adducts, and ^{13}C NMR spectrum of [2]ferrocenophane(f) in chloroform solution.

parison with the values of most adducts of ferrocene and ruthenocene derivative; i.e., most low-field shift values of the $HgCl_2$ adducts of ferrocene and ruthenocene derivatives are within the range 8.0 to 10.0 ppm.[7] Anomalously large low-field shifts of the C_1 signal were also observed for other [2]ferrocenophane-$2.5HgBr_2$ and -$2.2HgI_2$ adducts ($\Delta\delta$; 27.0 and 24.1 ppm, respectively). Moreover, the splittings (δ=118.8 and 117.3) and large low-field shifts of the C_1 signal ($\Delta\delta$; 26.2 and 24.7 ppm), shown in Fig. 5-f for a [2]ferrocenophane-$0.5Hg(BF_4)_2$ adduct, suggest the presence of two kinds of conformations of the Cp rings in the $Hg(BF_4)_2$ solid adduct.

A large low-field shift of the C_1 signal was also observed in the [3]ferrocenophane-$6HgCl_2$ adduct. [3]Ferrocenophane gives a less stable $HgCl_2$ adduct than the adduct of [2]ferrocenophane in a reaction with $HgCl_2$ in diethyl ether; i.e., the color of the [3]ferrocenophane-$6HgCl_2$ adduct was found to change to green within several days at room temperature. A slightly smaller Q. S. value of the $HgCl_2$ adduct (2.93 mm s^{-1} at 78 K) than the value of the [2]ferrocenophane-$3HgCl_2$ adduct (3.29 mm s^{-1} at 78 K) was found using ^{57}Fe-Mössbauer spectroscopy; however, this value (2.93 mm s^{-1}) is much larger than the value for [3]ferrocenophane, itself (2.29 mm s^{-1}). This fact suggests that the bond formed between the Fe and Hg atoms is weaker than the bond of the [2]ferrocenophane-$3HgCl_2$ adduct, as in the case of the ferrocenophane-$7HgCl_2$ adduct. The reason why [3]ferrocenophane forms a less-stable adduct with $HgCl_2$ has been interpreted on the basis of the fact that the Cp-rings in [3]ferrocenophane are only slightly inclined (ca. 9°) from each other;[14] i.e., the Fe-Hg bond is less stabilized by an increased steric hindrance of Cp-rings, while the Cp-rings in [2]ferrocenophane are greatly tilted (22.2°) from each other.[15] Relatively sharp signals (δ=86.6, 70.5, 36.0, and 25.4) have been found for [3]ferrocenophane and three broader signals (δ=78.8—72.6 for $C_{2,5}$ and $C_{3,4}$; δ=35.7 and 24.6 for methylene group's carbon) and a relatively strong, sharp signal (δ=110.7 for C_1) have been observed in the $HgCl_2$ adduct, as illustrated in Fig. 6. The spectral line shape and position of the methylene group in the [3]ferrocenophane-$6HgCl_2$ adduct correspond to those of [3]ferrocenophane, itself; however, those of the Cp-rings are much different from those of [3]ferrocenophane.

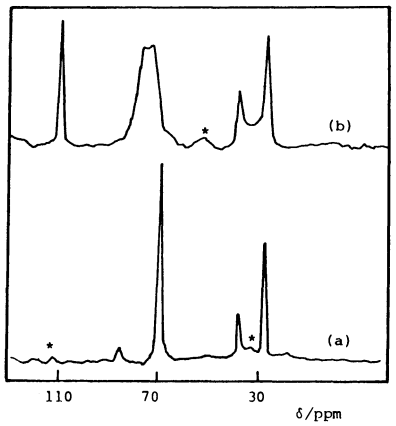

Fig. 6. ^{13}C-CP-MAS NMR spectra of [3]ferrocenophane(a) and its $6HgCl_2$(b) adduct.

The $\Delta\delta$ values (26.0—24.0) of the C_1 signal in [n]ferrocenophane (n=2,3) adducts with Hg(II) are much larger than the values of the ferrocenylmethane and 1,2-diferrocenylethane adducts with Hg(II). The structural distortion at the C_1 atoms of the [2]ferrocenophane-$n HgX_2$ (X=Cl, Br, I, and BF_4) and [3]ferrocenophane-$6HgCl_2$ adducts, caused by Fe-Hg bond formation, may be responsible for the large $\Delta\delta$ values in the C_1 signal in the [n]ferrocenophane adducts,

although further structural investigations are required in order to confirm these conclusions.

This work was partly supported by a Grant-in-Aid from the Ministry of Education, Scientific and Culture (No. 60430014).

Seasonal Changes in Eicosapentaenoic and Arachidonic Acid Contents in Bivalves and Plankton Collected from Lake Hamana†

Kyoko ADACHI, Norio ICHINOSE,* Chiaki SHIMIZU,†† and Ken OKAMOTO††
Department of Chemistry, Hamamatsu University School of Medicine, Handa-cho, Hamamatsu 431-31
††Fisheries Laboratory, Faculty of Agriculture, the University of Tokyo, Maisaka, Hamana, Shizuoka 431-02
(Received February 22, 1988)

Bivalves and plankton samples were collected monthly for one year from brackish Lake Hamana in Japan, and contents of 5,8,11,14,17-eicosapentaenoic acid (EPA) and 5,8,11,14-eicosatetraenoic acid (arachidonic acid, AA) and their weight percentage to total fatty acids were determined by fluorescence high-performance liquid chromatography. The results regarding bivalves showed that the EPA and AA levels are approximately ten-times higher in liver than in adductor on the average for one year, and are remarkably dependent upon the season. The seasonal changes of EPA and AA contents in bivalve liver are seemingly related to those of plankton, which are the diet of bivalves. From these facts, it can be seen that plankton is the main origin of EPA and AA in bivalve bodies and supply these fatty acids all the way up to humans through a food chain.

Fatty acids are one of the important substances constituting living cells; especially, 5,8,11,14,17-eicosapentaenoic acid (EPA) and 5,8,11,14-eicosatetraenoic acid (arachidonic acid, AA) of C_{20} serve as precursors of prostaglandins (PG) and thromboxanes (TX). In human blood vessels, EPA changes to PGI_3 and TXA_3, and AA to PGI_2 and TXA_2. Both PGI_2 and PGI_3 have the ability to suppress platelet aggregation and vascular smooth muscle contraction; whereas TXA_2 has a strong action on platelet aggregation and vascular smooth muscle contraction, TXA_3 shows almost no such action.[1-3] In addition, EPA can block TXA_2 synthesis;[4] thus, EPA is effective in preventing thrombosis and myocardial infraction.

The fatty acid content or composition in a human body depends upon both nutritional and physiological conditions. The EPA contents in human blood and plasma are much lower than AA contents, and the relative content of EPA can be increased by dieting on fish rich in EPA.[5,6] Thus, it is suggested that the main source of EPA in humans is marine organisms such as fish.

The food chain in marine environments has been an interesting subject: e.g., since fish cannot biosynthesize linoleic acid ($C_{18}^{2=}$) and linolenic acid ($C_{18}^{3=}$),[7] they obtain these fatty acids from phytoplankton or algae. In addition, a freshwater fish can produce long-chain fatty acids of C_{20} and C_{22} from the shorter chain precursors, C_{18} fatty acids, contained in diets, whereas marine fish cannot.[8-10] In contrast, bivalves cannot biosynthesize such long-chain fatty acids as EPA and AA.[11,12]

Thus, in a marine system, plankton plays a role of primary producer for long-chain fatty acids. The fatty acid content or composition in plankton varies in relation to such environmental conditions as temperature and light intensity.[13,14] Therefore, an investigation on the behavior of these long-chain fatty acids in plankton and the other marine organisms under the natural conditions is important for a better understanding of the food chain in marine environments.

The present authors have already established a fluorescence high-performance liquid chromatographic (HPLC) method using 9-anthryldiazomethane(ADAM) as a pre-labeling reagent,[15] and have determined the fatty acids of C_{18} and C_{20} in various marine organisms.[16,17] Although the free fatty acid level is much lower than the esterified fatty acid level, a highly sensitive and selective determination is possible by using this method. These studies have shown that the EPA contents and the EPA/AA ratios in plankton and Mollusca, such as cuttlefish, are higher than those in marine fishes.

We have studied C_{18} and C_{20} fatty acids in bivalves, a kind of Mollusca, and plankton collected monthly from brackish Lake Hamana, Japan, during 1985. Here, we present data on seasonal changes of the fatty acid contents and discuss the relationship between the EPA and AA contents in bivalves and those in plankton from the viewpoint of a food chain.

Experimental

Standards and Reagents. All standard fatty acids of $C_{18}^{0-3=}$ and $C_{20}^{0-5=}$ were purchased from Sigma (St. Louis, MO, USA), and ADAM was purchased from Funakoshi Chemical (Tokyo, Japan). All other reagents were of commercially analytical grade. The preparation techniques of a standard solution of fatty acids and an ADAM solution have been previously described in detail.[15-17]

Samples. Clam(*Tapes (Amygdala) japonica*) (3.5—4 cm long) and oyster (*Crassostrea gigas*) (8—12 cm long) were collected monthly during the year of 1985 from the southern inshore part (water depth: about 1 m) of brackish Lake Hamana. On the same sampling date, plankton samples of different size were collected by horizontal hauls (0.5—1 m layer from the surface) with 20, 40, and 94 μm mesh-sized nets from the same area, and separated into plankton A (20 μm), B (40 μm), and C (94 μm). These plankton samples were filtrated on a Millipore filter (pore size: 0.45 μm). All samples were stored in a freezer (−10 °C) before use.

† A part of this paper was presented at the 36th Annual Meeting of the Analytical Chemical Society of Japan, October, 1987.

As the representative organs to be examined in bivalve body, liver and adductor were selected from parts of viscera and muscle, respectively. Bivalve liver acts as a digestive organ, different from that of Vertebrate. Moreover, whole bodies were examined.

Analytical Procedure. Bivalve liver and adductor were isolated from bodies with a small knife. The homogenate of a whole body was obtained by grinding in a mortar. The liver, adductor and homogenate of a whole body of bivalve samples (10—20 mg) were weighed as wet weight in a glass homogenizer (volume: 1 ml). One ml of a mixture of chloroform and methanol (2:1) was added, and the sample was homogenized. The homogenate was transferred into a graduated centrifugal tube with a stopper, and diluted to 1 ml with the above-mentioned solvent since some part of the solvent evaporated during the homogenization. After centrifuging at 3000 rpm for 5 min, the supernatant was filtrated through a disposable filter (pore size: 0.45 μm).

An aliquot of the sample filtrates was derivatized with an ADAM and analyzed by the HPLC method using a Shimadzu Model LC-4A liquid chromatograph (Zorbax C_8 column) equipped with a Shimadzu Model RF-510LC fluorescence spectromonitor and a Shimadzu Model C-R1A(S) chromatopac as described in the previous papers.[16,17] In the determination of EPA and AA in living-body samples, the recovery was 90—100% and the coefficient of variation by repeated experiments was about 7%. The detection limit was 1—2 ng for $C_{18}{}^{0-3=}$ and $C_{20}{}^{0-5=}$ fatty acids.

Plankton samples (10—50 mg), which remained on the filter were homogenized after adding about 1 ml of the mixture of chloroform and methanol (2:1). The homogenates were transferred into the centrifugal tube, diluted with the same solvent up to 3 ml and then vortexed for 3 min. The procedure from centrifugation was the same as that mentioned above. The contents of fatty acids in plankton were obtained on a dry-weight basis, by determining the moisture in the sample.

Measurements of Chlorophylls, Carbon and Nitrogen in Plankton. For the extraction of pigments, the plankton together with the filter was ground in a mortar with 3—5 ml of acetone and water (9:1) and then transferred into a graduated centrifugal tube. After centrifugation at 3000 rpm for 5 min, the absorbance of the supernatant was measured at 630, 647, 664, and 750 nm. The contents of chlorophyll *a*, *b*, and *c* were calculated, without standards, according to the equation of Jeffrey and Humphrey.[18]

The carbon and nitrogen contents were measured using a Yanagimoto Model MT-500 CN corder with hippuric acid as a standard.

Results and Discussion

Figure 1 shows the seasonal changes of the EPA and AA contents in bivalves. In both clam and oyster, the EPA and AA contents in the liver are higher than those in the adductor and homogenate of a whole body; the ratio of EPA or AA content in the liver to that of the adductor was approximately ten on the average for one year. The contents of EPA and AA show seasonal fluctuations. In the case of liver, the EPA and AA contents remarkably increase in the late spring when bivalves breed, and again in the early winter. In the adductor and homogenate of a whole body, the variations of these fatty acid levels are not significant. Differences between clam and oyster were not significant regarding these results.

On the other hand, the EPA and AA contents in plankton increase during midsummer and early winter for plankton A or B, and in the above-mensioned seasons and late spring for plankton C as shown in Fig. 2(a). Since sand and mud in water may have been collected together with plankton by the plankton net, the fatty acid content per carbon weight was calculated in order to exclude any error due to sand or mud contamination. The peaks during midsummer (Fig. 2(b))

are clear in comparison with those of Fig. 2(a).

Since collected plankton consists of various species, plankton A, B, and C were characterized by the chlorophyll content and C/N ratio (Fig. 3). On the average, the chlorophyll content, which is an index of

Table 1. Relation of Chlorophyll Contents to EPA and AA Contents in Plankton

Combination	Correlation coefficient		
	Plankton A	Plankton B	Plankton C[a)]
Chlorophyll *a*-EPA	0.687	0.764	0.527
Chlorophyll *b*-EPA	0.056	−0.386	−0.285
Chlorophyll *c*-EPA	0.484	0.590	0.556
Chlorophyll *a*-AA	0.893	0.927	0.611
Chlorophyll *b*-AA	0.512	0.249	−0.157
Chlorophyll *c*-AA	0.814	0.813	0.673

a) The correlation coefficients for the data except for April were calculated, since the data in April for plankton C were apparently predicted to deviate from the relationship of the data in other months.

phytoplankton, becomes higher in the order plankton C<B<A; thus, the size becomes smaller, since the size of phytoplankton is generally smaller than zooplankton.

The C/N ratio corresponds to adipose/protein ratio in the body. As can be seen in Fig. 3, the C/N ratio in plankton A and B in May is approximately 9, which is significantly high for a plankton value. This high C/N ratio could be due to the resuspension of bottom sediments (C/N ratios of which are higher than those of plankton) into overlying water. Lower EPA and AA contents in the sample of May (Fig. 2) seem to be consistent with higher C/N ratios.

In a comparison between Fig. 2(b) and Fig. 3, the peaks in the seasonal changes of the chlorophyll contents of plankton appear in roughly the same months as the peaks of EPA or AA contents. Then, their corre-

lation coefficients were calculated (Table 1). The seasonal changes of chlorophyll *a* and *c* contents were considerably related to that of the EPA and AA contents in Fig. 2(b), except that the EPA and AA contents in plankton C increase in April. This increase of EPA and AA is probably attributable to zooplankton, since the chlorophyll content in plankton C (94 μm) was very low during April. It is likely that zooplankton breeds by feeding on phytoplankton, which proliferates in March, as suggested from the significant increase in chlorophyll *a* and *c* contents (Fig. 3); consequently, zooplankton accumulates EPA and AA in its body.

When considering plankton as a diet of bivalve, the unit (ppm/dry weight) for fatty acid content in Fig. 2(a) is more adequate, rather than the unit (mg/gC) in Fig. 2(b) since bivalve cannot selectively feed on only plankton. Comparing Fig. 1 with Fig. 2(a), it is evident that when the EPA and AA contents increase in the bivalve liver, those in plankton C, which is the main diet for bivalve, also increase. This suggests that EPA and AA in bivalves are obtained from relatively large phytoplankton, zooplankton and their fecal pellets.

The averaged fatty acid composition and its degree of variation during one year, as a coefficient of the variation (the percentage of standard deviation to average), are given in Table 2 for the bivalve liver and plankton. The fatty acid compositions of clam and oyster were almost the same and the degree of year-round variation in the composition of the bivalve liver was smaller than that of plankton. This result can be explained by the fact that the dominant plankton species change depending on the season and that these plankton are different regarding fatty acid composition. In each plankton sample the variation of the $C_{18}^{1=}$ weight percentage was remarkable. Consequently, in Lake Hamana, it is considered that some plankton species, of which populations vary during the year, show $C_{18}^{1=}$ weight percentages different from

Table 2. Averaged Fatty Acid Composition in Bivalves and Plankton for a Year (1985)

Sample	Weight percentage[a] (Coefficient of variation(%))								
	$C_{18}^{0=}$	$C_{18}^{1=}$	$C_{18}^{2=}$	$C_{18}^{3=}$	$C_{20}^{1=}$	$C_{20}^{2=}$	$C_{20}^{3=}+C_{16}^{0=}$	$C_{20}^{4=}$ (AA)	$C_{20}^{5=}$ (EPA)
Clam liver	13.4	18.0	8.2	9.5	4.1	1.4	20.4	4.3	20.7
	(21.7)	(28.0)	(31.1)	(23.8)	(21.7)	(26.1)	(19.5)	(30.6)	(38.8)
Oyster liver	8.6	20.7	10.1	10.9	7.3	0.8	17.0	3.3	21.3
	(25.5)	(12.3)	(16.4)	(20.2)	(24.2)	(28.8)	(19.2)	(35.6)	(36.0)
Plankton A	13.1	13.6	3.4	24.7	ND	ND	20.1	3.5	21.6
	(52.5)	(115.7)	(73.1)	(37.3)			(19.6)	(31.9)	(49.3)
Plankton B	10.6	19.7	4.2	20.9	0.7	ND	18.6	3.4	21.9
	(43.0)	(89.9)	(76.7)	(40.4)	(47.5)		(20.9)	(34.3)	(49.5)

	(35.0)	(60.4)	(46.2)	(37.6)	(74.2)	(76.4)	(16.8)	(27.1)	(30.7)

a) Weight percentage to total fatty acids($C_{16}^{0=}$, $C_{18}^{0-3=}$, and $C_{20}^{0-5=}$)
$C_{20}^{0=}$ was not detected in all samples.

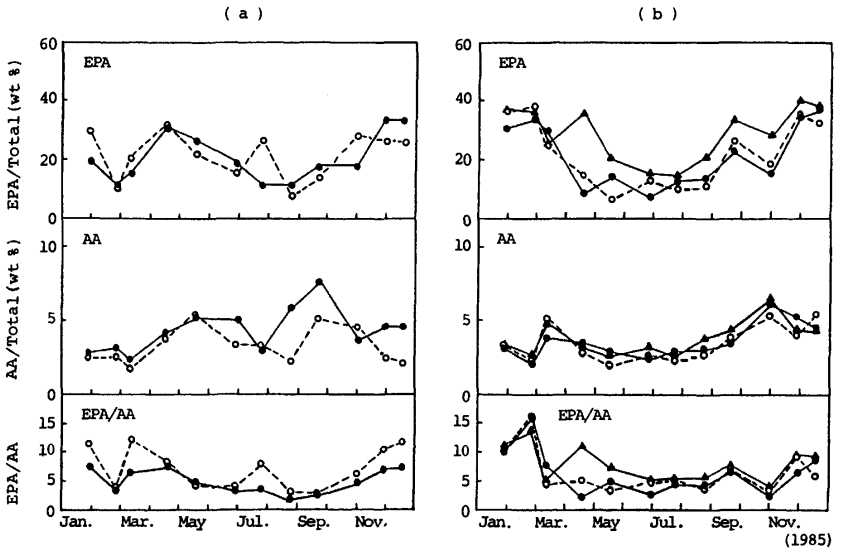

Fig. 4. Seasonal changes of EPA and AA weight percentage to total fatty acids ($C_{16}^{0=}$, $C_{18}^{0-3=}$, and $C_{20}^{0-5=}$) and EPA/AA ratio in (a) bivalve liver and (b) plankton. (a) ●—●: clam, ○--○: oyster, (b) ●—●: plankton A, ○--○: plankton B, ▲—▲: plankton C.

each other. In the bivalve liver, the variations of the EPA and AA weight percentages were larger than those of the other fatty acids.

Figure 4 shows the seasonal changes of the EPA and AA weight percentage to the total fatty acids ($C_{16}^{0=}$, $C_{18}^{0-3=}$, and $C_{20}^{0-5=}$) and the EPA/AA ratio for bivalve liver and plankton. The seasonal changes of the EPA weight percentage in individual samples were different from those of AA, whereas there was no significant difference in the behavior between clam and oyster, or among plankton A, B, and C. Between bivalve liver and plankton, a clear relationship was not found for the each seasonal change of the EPA and AA weight percentage.

Since all trends regarding the fatty acids for clam and oyster in this experiment were closely similar to each other, they are considered to be just as adequate for discussion as the typical data of bivalves.

We wish to thank late Emeritus Professor Dr. Hidehiro Gotô of Tôhoku University for his kind and ever continuing guidance.

The structures of *cis*- and *trans*-dinitrobis(1,4-butanediamine)cobalt(III) nitrates were determined by the single-crystal X-ray diffraction method. *cis*-$[Co(NO_2)_2(tmd)_2]NO_3$ (tmd=$H_2N(CH_2)_4NH_2$) is monoclinic with the space group $P2_1/a$; the cell constants are a=23.878(4), b=8.403(1), c=16.675(3) Å, β=103.24(1)°; Z=8, and the final R value was 0.051. *trans*-$[Co(NO_2)_2(tmd)_2]NO_3 \cdot H_2O$ is triclinic with the space group $P\bar{1}$; the cell constants are a=9.753(3), b=13.909(4), c=6.327(1) Å, α=102.07(2), β=91.05(2), γ=87.83(3)°; Z=2, and the final R value was 0.058. Both complexes have a slightly distorted octahedral geometry around the cobalt center. The conformations of the seven-membered chelate rings have twist-chair and chair forms for the cis and trans complexes, respectively.

Chelate rings containing more than six atoms have been scarce until recently, whereas numerous examples of five- and six-membered chelate rings have been known.[1] The stability of a chelate ring depends on its size. Thus, reactions between $[CoCl_2(en)_2]Cl$[2] and α,ω-alkanediamines in dimethyl sulfoxide gave no monomeric $[Co(en)_2(H_2N(CH_2)_nNH_2)]^{3+}$ for n=5—8, whereas the corresponding complexes were obtained for n=2—4 and 9—14.[1,3] Similar results were also obtained for the reaction of $[Co(H_2O)(NH_3)_5]^{3+}$ with α,ω-alkanediamines.[4] 1,4-Butanediamine (tetramethylenediamine) has the longest chain in the smaller chelate ring family.[2] Therefore the conformations of tmd chelate rings are of great interest. Only the structure of $(+)_{589}$-$[Co(tmd)_3]^{3+}$ was reported.[5,6] The conformation is 'lel$_3$' and the seven-membered rings take twist-chair forms. Preliminary reports on the crystal structures of *trans*-$[CoCl_2(tmd)_2]Cl \cdot H_2O$[7] and Δ-$[Co(en)(tn)(tmd)][Co(CN)_6] \cdot H_2O$[8] do exist but the full report is still lacking.

We have succeeded in the preparation of both *cis*- and *trans*-$[Co(NO_2)_2(tmd)_2]^+$ complexes using dimethyl sulfoxide as a solvent. The geometrical configurations were determined on the basis of their electronic and Raman spectra.[9] To elucidate the conformation of the seven-membered chelate rings we have determined the crystal structures of *cis*- and *trans*-$[Co(NO_2)_2(tmd)_2]NO_3 \cdot nH_2O$ (n is 0 for the cis and 1 for the trans complex).

Experimental

The compounds were prepared by the method reported in a previous paper,[9] and recrystallized from water. The reflections were collected on a Rigaku AFC-6A automated four-circle X-ray diffractometer with graphite-monochromated Mo $K\alpha$ radiation (the scan speed was 4° min^{-1}). The crystal data and the conditions of data collection are shown in Table 1.

The structures were solved by the heavy-atom method. For the trans complex, the reflections with odd $h+k$ indexes were very weak. Two models were therefore taken into consideration for this pseudo C lattice. In the first model the two crystallographically independent molecules were situated at the centers of symmetry: (0, 0, 0) and (1/2, 1/2, 0). In the second model the complex was situated in the general position, the two molecules being separated by about (0.5, 0.5, 0) and related through the center of symmetry. The second model gave a satisfactory result.

The positions of the central metal atoms and some coordinated atoms were deduced from the three-dimentional Patterson maps. The positional and thermal parameters were refined by the block-diagonal least-squares method. The positions of the hydrogen atoms, except for the amine and

the water hydrogens in the trans complex, were deduced from difference Fourier synthesis, and refined with isotropic thermal parameters. The positions of the amine hydrogens in the trans complex were calculated and fixed; they were included in the calculation of structure factors.

All the calculations were carried out on a Nippon Electric Co. ACOS-1000 computer at the computer center of Tohoku University, using the Universal Crystallographic Computation Program System UNICS III.[10] The atomic-scattering factors were taken from Ref. 11 for non-hydrogen atoms and from Ref. 12 for hydrogen atom.

a) The equivalent isotropic temperature factors for non-hydrogen atoms were computed using the following expression: $B_{eq}=4/3(B_{11}a^2+B_{22}b^2+B_{33}c^2+B_{12}ab\cos\gamma+B_{13}ac\cos\beta+B_{23}bc\cos\alpha)$. The B_{ij}'s are defined by: $\exp[-(h^2B_{11}+k^2B_{22}+l^2B_{33}+2hkB_{12}+2hlB_{13}+2klB_{23})]$.

Results and Discussion

Final atomic parameters for the cis and trans complexes are listed in Tables 2 and 3, respectively. Relevant interatomic distances and angles are summarized in Tables 4 and 5.[13] The structures of complex cations with atom numbering scheme are depicted in Figs. 1 and 2. The configurations of the complexes agree with those proposed previously.[9]

The crystal of *cis*-$[Co(NO_2)_2(tmd)_2]NO_3$ consists of two crystallographically independent complex cations and nitrate ions. The structures of both cations were essentially the same as shown in Fig. 1 and Table 4. The coordination geometry around the cobalt atom is a slightly deformed octahedron and resembles the structure of $[Co(tmd)_3]^{3+}$ [5,6] except for the nitro groups. The Co-N(NO_2) bond lengths range from 1.943(3) to 1.953(3) Å, and are a little longer than the values for *cis*-$[Co(NO_2)_2(en)_2]^+$ complexes (1.887—1.936 Å)[14-16] and *cis*-$[Co(NO_2)_2(tn)_2]^+$ (1.924 and 1.936 Å).[17] The Co-N(amine) bond lengths span the range between 1.959(3) and 1.990(3) Å and are normal, although the Co-N(amine) bond lengths trans to NO_2 ligands are longer than those cis to NO_2 ligands by 0.014—0.023 Å. These differences are attributable to trans-influence of NO_2 as observed for the *cis*-

$[Co(NO_2)_2(en)_2]^{2+}$ complexes.[14,15]

As shown in Fig. 2, the complex cation in the crystal of *trans*-$[Co(NO_2)_2(tmd)_2]NO_3 \cdot H_2O$ is pseudo-centrosymmetric and the coordination geometry is also a slightly distorted octahedron. Co-N(NO_2) bond lengths, 1.931(4) and 1.936(4) Å, are normal and a little shorter than in the cis-isomer. Both NO_2 ligands are almost in a plane containing the cobalt atom: The deviations from the least-squares plane are Co −0.016, N(1) 0.015, N(2) −0.013, O(1) −0.002, O(2) −0.002, O(3) 0.009, and O(4) 0.009 Å. Such coplanarity is a common feature of trans-dinitro cobalt complexes.[15,18—21] Co-N(amine) bond lengths range between 1.970(4) and 1.992(3) Å.

Figures 3 and 4 show the packing diagrams for the two complexes. Some hydrogen bonding was observed between the amine nitrogens, nitrate ions, and water

molecules. Interatomic distances for hydrogen bonded atoms are listed as the supplementary data.[13]

Conformations of Chelate Rings. Bond lengths and angles in the chelate rings are almost the same for the cis and trans complexes, as shown in Tables 4 and 5. All the chelate rings in the cis complexes have a similar conformation. The two chelate rings in the trans complex are also similar to each other, but different from those in the cis complex. Figure 5 shows the projections of the chelate rings along the bisectors of the N-Co-N angle and the atom deviations from the N-Co-N plane.

The conformations of the chelate rings in the cis complex are quite similar to those in $[Co(tmd)_3]^{3+}$ [5,6]: The carbon atoms next to the nitrogens are displaced by 0.73—0.88 Å on the opposite sides of the plane formed by the cobalt and two nitrogen atoms, and the remaining carbon atoms are nearly in this plane. The deviations from the plane are 0.03 to 0.25 Å. This conformation corresponds to the twist-chair form of the cycloheptane ring.[22] The torsion angles shown in Table 6 indicate that only the central C-C bonds take gauche conformation. In contrast to the cis complex, the chelate rings of the trans complex take the chair form. One of the carbon atoms next to the nitrogen lies almost on the N-Co-N plane, and the other three carbon atoms deviate from the plane by more than 0.97 Å.

A conformation analysis of cycloheptane revealed that the chair form is less stable than the twist-chair form for seven-membered alkane ring, although the energy difference is quite small (2.16 kcal mol^{-1}).[22] Repulsion between hydrogen atoms across the ring is serious, especially in the chair-form.

However, such transannular interaction is not important in the chelate rings, because the corresponding H···H interatomic distances in the trans complex are only slightly shorter than the sum of the van der Waals radii: H(C4A)···H(N4A) 2.32(4) and H(C8A)···H(N6A) 2.18(5) Å. The difference in the conformations of the chelate rings in cis and trans complexes

a) Looking from atom 2 to atom 3, the clockwise rotation of bond 3-4 with reference to bond 2-1 is given.

may be due to the interaction of the NO_2 ligands and the chelate rings. The oxygen atoms of the NO_2 ligands form intramolecular hydrogen bonds to amine groups of the chelate rings as shown in Tables 4 and 5. Such hydrogen bonds have been observed for *trans*-$[Co(NO_2)_2(en)_2]NO_3$,[15] *cis*-$[Co(NO_2)_2(en)_2]Cl$,[16] and *cis*-$[Co(NO_2)_2(tn)_2]Cl \cdot H_2O$.[17] Furthermore, the oxygen atoms of the nitro groups interact with the methylene groups adjacent to the tmd-nitrogens. Figure 6 shows the projection of the trans complex along the Co-N(NO_2) axis. The two nitro groups lie in a plane containing the cobalt atom, and the angle between Co-N(3) and the plane is 30.0°. Broken lines show the hypothetical structure with the twist-chair form for the chelate rings. To minimize the repulsion between the oxygen atoms of the nitro groups and the carbon atoms adjacent to the tmd-nitrogens in the hypothetical structure, the NO_2 ligands should lie in the plane bisecting the angle N(3)-Co-N(6). Even for this conformation, four O···C interatomic distances

Table 7. Comparison of Bond Angles between 5-, 6-, and 7-Membered Chelate Rings

Complex	ϕ/°			
	N-Co-N	Co-N-C	N-C-C	C-C-C
$[Co(en)_3]^{3+}$ a)	85.4	108.4	105.8

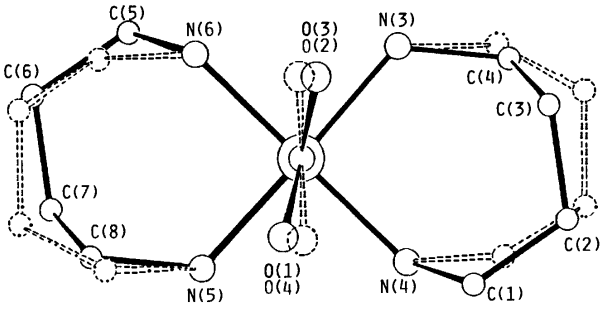

Fig. 6. Projection of the *trans*-$[Co(NO_2)_2(tmd)_2]^+$ ion along the Co-N(NO_2) axis. Broken lines show the hypothetical molecular structure with the chelate rings in the twist-chair form.

(O(1)···C(1), O(1)···C(8), O(3)···C(4), and O(3)···C(5)) are about 3.19 Å, i.e. shorter than the sum of the van der Waals radii, 3.40 Å. The adopted chair form and the inclination of the nitro groups help with alleviating this repulsion: Only two O···C distances in the real complex are shorter than the sum of the van der Waals radii, O(1)···C(1) 3.196(6) and O(3)···C(5) 3.172(5) Å.

There exists only one such O···C interatomic distance in the cis complex (O(22)···C(24) 3.167(4) Å).

Table 7 compares the bond angles for the five-, six-, and seven-membered chelate rings. The larger deviations from the tetrahedral angle for nitrogen and carbon atoms in tmd complexes clearly show the instability of seven-membered chelate rings.

Hongo, Bunkyo-ku, Tokyo 113
(Received June 11, 1988)

Stable complexes of the type $[Co(aldonato)(en)_2]^+$, where en is ethylenediamine and aldonato is the diacid anion of D-gluconic acid or L-mannonic acid, were prepared by the reaction of aldonic acid lactones with *rac*-$[Co(CO_3)(en)_2]^+$. Two diastereomers (Δ and Λ) have been separated by ion-exchange chromatography from each of the aldonato complexes. These complexes were characterized by NMR, electronic absorption, and circular dichroism spectra. The structures of all four complexes were found to have an aldonato ligand which coordinates bidentately through an oxygen atom of the carboxylato group and an oxygen atom of the deprotonated hydroxyl group on C(2).

It has been widely known for a long time that aldonic acids form stable complexes with metal ions.[1] Especially, gluconic acid and its salts have been used extensively as sequestering agents for metal ions in alkaline media. Numerous industrial applications have been reported.[2] These ligands have many functional groups which can bind to metal ions. However little has been reported on the coordination chemistry of aldonic acid complexes. Several crystal structures of aldonic acid salts have been reported,[3] but only two of the transition metal aldonic acid complexes, those are lead gluconate[4] and manganese gluconate,[5] have been clarified. Both complexes are polymer, in which the gluconato ligands bridge two metals. Because of the lability of these metal complexes, it seems that these complexes have no fixed chelate in solution.

Accordingly, substitution inert cobalt(III) complexes are suitable to study the coordination behavior of these ligands. It is interesting to examine the coordination behavior of metal complexes of the C-2 epimers, gluconic acid and mannonic acid, since the chelate ring formation via hydroxyl group on C(2) atom is expected.

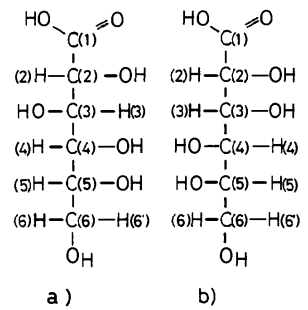

Fig. 1. Structure of (a) D-gluconic and (b) L-mannonic acid.

We report the first successful isolation of several Co(III) complexes of D-gluconic acid and L-mannonic acid (Fig. 1), and the coordination geometry of the complexes were studied by visible-UV absorption, CD, and NMR spectra as a part of our study to investigate sugar transition metal complexes.[6]

Experimental

Materials, Measurements and Analyses. D-Glucono-1,5-lactone and L-manno-1,4-lactone were purchased from Tokyo Kasei Kogyo and Sigma Co., respectively.

^1H NMR spectra were recorded on a JEOL GX-400 spectrometer using 2,2-dimethyl-1-propanol as an internal reference. ^{13}C NMR spectra were obtained on this instrument or JNM-PFT-100 spectrometer using tetramethylsilane as an external reference.

Visible-UV absorption spectra were obtained with a HITACHI model 340 spectrophotometer. Circular dichroism spectra were measured with a JASCO J-500 spectropolarimeter.

Preparation of Δ and Λ-$[Co(D\text{-gluconato})(en)_2]ClO_4 \cdot H_2O$. *Caution!* These perchlorate salts are stable under the experimental conditions as described below. However these complexes are potentially explosive, so that these materials should be handled with great care.

Aldonic acid complexes were prepared by a method analogous to that reported for the lactic acid complexes.[7,8] 1.38 g of $[Co(CO_3)(en)_2]Cl$[9] was dissolved in 10 mL of water, 0.89 g of D-glucono-1,5-lactone was added. The solution was heated to 90 °C and refluxed on a steam bath for 4 h. After cooling, the solution was diluted with water (500 mL) and poured onto a column of SP-Sephadex C25 gel (Na^+ form; 4×30 cm). The column was washed with water (1 L), and the adsorbed products were eluted with 0.05 M sodium perchlorate solution (1 M=1 mol dm^{-3}). A red band of unipositive charged complexes was eluted, this was made of a mixture of two isomers. Sodium perchlorate was partially removed from the red eluted solution by a Sephadex G-10 gel permiation chromatography, then the solution collected were separated again by Dowex 50W X-8 resin (Na^+ form; 3×60 cm) with 0.25 M NaH_2PO_4-0.25 M Na_2HPO_4 buffer solution. It was impossible to separate two isomers with one pass through the column, so that the isomers were separated by recycled elution using a peristaltic tube pump. After the complete separation in the resin, each band was eluted with 0.1 M sodium perchlorate. Sodium perchlorate was removed

from each of the separated red solution by passing three times through a Sephadex G-10 gel column (3.5×50 cm). Each red liquor was evaporated under reduced pressure to a syrup, this was dissolved in a small amount of water, then ethanol was added to incipient turbidity. The solution was kept in a refrigerator. *Λ*-[Co(D-gluconato)(en)$_2$]ClO$_4$·H$_2$O (**1**) was obtained as a little hygroscopic reddish powder (100 mg) from the latter fractions of the Dowex eluents, and *Δ*-[Co(D-gluconato)(en)$_2$]ClO$_4$·H$_2$O (**2**) was obtained as red needles (180 mg) from the former fractions. Anal. Found for *Λ*-isomer: **1**: C, 24.61; H, 5.73; N, 11.48; Cl, 7.27%, for *Δ*-isomer **2**: C, 24.48; H, 5.50; N, 11.08; Cl, 6.97%. Calcd for $CoC_{10}H_{28}O_{12}N_4Cl$: C, 24.47; H, 5.75; N, 11.42; Cl, 7.22%.

Preparation of *Δ* and *Λ*-[Co(L-mannonato)(en)$_2$]ClO$_4$·H$_2$O. These complexes were prepared from [Co(CO$_3$)(en)$_2$]Cl and L-manno-1,4-lactone by the above mentioned procedure. The *Λ*-isomer **3** (160 mg) was also obtained from the latter fractions separated by a Dowex 50W X-8 cation-exchange column chromatography, and the *Δ* isomer **4** (130 mg) was obtained from the former fractions. Both of the isomers were isolated as somewhat hygroscopic red powder. Anal. Found for *Λ*-isomer **3**: C, 24.05; H, 5.35; N, 10.94; Cl, 7.83%, for *Δ*-isomer **4**: C, 23.63; H, 5.08; N, 10.59; Cl, 6.29%. Calcd. for $CoC_{10}H_{28}O_{12}N_4Cl$: C, 24.47; H, 5.75; N, 11.42; Cl, 7.22%.

Results and Discussions

Isolation of Aldonic Acid Complexes. Aldonic acid complexes were prepared by the reaction of [Co(CO$_3$)-(en)$_2$]Cl complex with aldonic acid lactones. In an aqueous solution, D-glucono-1,5-lactone and L-manno-1,4-lactone, which were used in this study, were known to have the equilibrium between the lactones and acid forms.[10] When D-glucono-1,5-lactone was used, two +1 charged red complexes (complex **1** and **2**) were separated from the reaction mixture by ion exchange chromatography, both of these complexes were isolated as perchlorate salts. When L-manno-1,4-lactone was used, two red complexes **3** and **4** were also obtained.

Analytical results indicated that all these complexes obtained have one dinegative charged aldonato ligand, two ethylenediamine ligands, a perchlorate counter anion, and a solvated water molecule. Two isomers were obtained for both the aldonic acid complexes. These isomers are found to be *Δ* and *Λ* isomers whose absolute configurations were determined by CD spectra as described later.

UV-Visible Absorption Spectra. The absorption and CD spectra for the series of complexes are shown in Fig. 2, and their spectral data are presented in Table 1. These absorption spectra all show two peaks in the d-d transition region. The band positions and the intensities of the absorption spectra for these complexes are nearly identical. Each lowest energy peak shows a symmetrical curve without any shoulder in the first absorption region, which is characteristic for

the *cis*(*O*-*O*)-[CoN_4O_2] type.[11] The spectral results for Λ-[Co((*R*)-lactato)(en)$_2$]$^{+}$[7] and Λ-[Co(L-tartrato)(en)$_2$]$^{+}$[12] are also shown in Table 1. The similarity of band maxima and molar absorption coefficients of these aldonato complexes to those of lactato or tartrato complexes supports that the aldonic acids coordinate to cobalt atom through a carboxylato group and a deprotonated hydroxyl group of the aldonato ligand.

NMR Spectra and Coordination Structures. The ^{13}C NMR spectral data of these complexes together with those of sodium aldonate are given in Table 2. Because ^{1}H and ^{13}C NMR spectra of these complexes resemble each other, the following discussion applies equally to all of the complexes. The ^{13}C NMR spectra of these complexes show ten signals. The higher-field four signals and the lower-field six signals can be ascribed to the two ethylenediamine units and to the aldonic acid unit, respectively. The coordination points of the aldonato ligand were determined from these NMR data.

As a typical example, we deal with Λ-[Co(D-gluconato)(en)$_2$]$ClO_4 \cdot H_2O$ (**1**). The complete ^{1}H decoupled ^{13}C NMR spectrum of **1** in the range of 60—200 ppm is shown in Fig. 3. The C(1) and C(6) carbons of aldonato ligands were easily assigned by using non ^{1}H decoupling with NOE measurement. The C(2) carbon centered at about δ 82 was assigned by using selective decoupling methods as described below.

The ^{1}H NMR spectral data of the gluconato units of these complexes are tabulated in Table 3. A doublet at about δ 4.2 could be assigned to the H2 proton on C(2) atom. All other peaks were assigned by using double resonance techniques. In the ^{13}C NMR spectra, a selective irradiation of the proton resonance at about δ 4.2 gave one singlet peak at about δ 82. Accordingly, the ^{13}C signal at about δ 82 was assigned to C(2) atom.

Both C(1) and C(2) carbons shift clearly to the lower-field in comparison with those of sodium gluconate (Fig. 3). These low-field shift of the carbon nuclei may be caused by the coordination of the adjacent oxygen atom to the cobalt atom. In fact, we observed the similar low-field shift of ^{13}C signal for cobalt(III) complexes.[13]

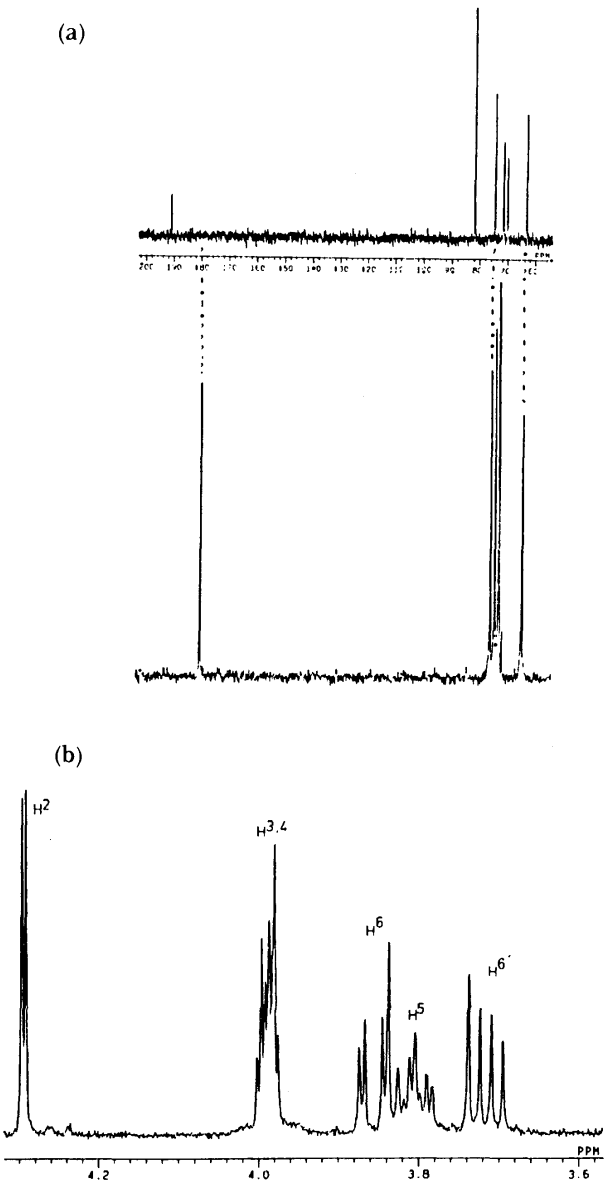

Fig. 3. (a) Upper, ^{13}C NMR spectrum of Λ-[Co(D-gluconato)(en)$_2$]$^{+}$ (60—200 ppm region). Lower, ^{13}C NMR spectrum of sodium D-gluconate. (b) ^{1}H NMR of Λ-[Co(D-gluconato)(en)$_2$]$^{+}$ (3.7—4.3 ppm). All spectra were obtained in D_2O solution.

Table 3. ^{1}H NMR Data for Aldonato Complexes

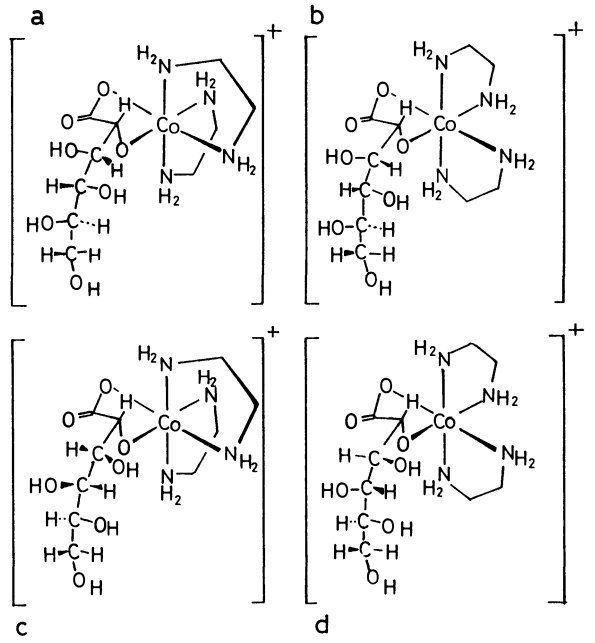

Fig. 4. Structures of (a) *Λ*-[Co(D-gluconato)(en)$_2$]$^+$, (b) *Δ*-[Co(D-gluconato)(en)$_2$]$^+$, (c) *Λ*-[Co(L-mannonato)(en)$_2$]$^+$, and (d) *Δ*-[Co(L-mannonato)-(en)$_2$]$^+$ ions.

From the above arguments we concluded that aldonato ligands coordinate to the cobalt at two points through the carboxylato oxygen atom and through the deprotonated hydroxyl oxygen atom on C(2) forming a five-membered chelate ring. The same discussions can be done for all of the other aldonato complexes (**2**, **3**, and **4**), their structures are shown in Fig. 4. No other complexes except these complexes containing five-membered aldonato chelate were detectable on the +1 charged reaction products. This fact points out that five-membered chelate formation is the most favorable coordination of the aldonato ligands.

Some interesting information concerning the conformation of the aldonato ligands can be drawn from the NMR J_{HH} coupling constant values. The values $J_{H4,5}$ and $J_{H5,6}$ are comparatively large, but $J_{H2,3}$ and $J_{H3,4}$ are small, so that it is deduced that the conformation of the carbon skeleton of aldonato ligands is not completely flexible, but it is somewhat fixed even in aqueous solution. There are no significant differences between the coupling constants of the gluconato complexes and the mannonato complexes except some differences in $J_{H2,3}$ values. This difference is reasonable because gluconato and mannonato ligands can originally be regarded as C(2) epimer, and only H2-H3 relative configuration is different between those ligands (see Fig. 1).

Circular Dichroism Spectra and Stereochemistry of the Complexes. Two diastereomers can be obtained from each of these aldonato complexes. The CD spectra in the first d-d absorption region of the two isomers give nearly mirror image curves. For both the D-gluconato and L-mannonato complexes, the compounds in the former eluted fractions from the Dowex cation exchange column are assigned to *Δ* isomers because these complexes have a minus CD peak in the region, on the other hand, those in the latter eluted fractions are assigned to *Λ* isomers.[14]

It is well-known that the contributions to the optical activity from the configurational and vicinal effects are essentially additive in considering the CD spectra of the octahedral metal complexes.[15] The vicinal effect ($\Delta\varepsilon(R)$ or $\Delta\varepsilon(S)$) includes the conformational effect of the chelate rings (δ or λ) and the effect induced from the asymmetric centers (R or S) in the ligand. The following relationships will then hold: $\Delta\varepsilon(\Lambda)=1/2[\Delta\varepsilon(\Lambda R)-\Delta\varepsilon(\Delta R)]$ and $\Delta\varepsilon(R)=1/2[\Delta\varepsilon(\Lambda R)+\Delta\varepsilon(\Delta R)]$, where $\Lambda\varepsilon(R)$ is the CD contribution due to the vicinal effect of the coordinated (R) chelate such as (R)-amino acids, (R)-hydroxy acids, or (R)-aldonic acids and $\Delta\varepsilon(\Lambda)$ is the contribution of *Λ* configuration. In general, the configurational effect is much greater than the vicinal effect in cobalt complexes. But, Kipp and Haines, however, reported that the CD spectra of *Λ*-[Co((R)-lactato)(en)$_2$]$^+$ and its *Δ* isomer are not mirror image, so the vicinal effect of the hydroxy acid ligand is more intense than would be expected from

comparison with similar amino acid complexes.[7]

In our aldonato complexes, however, the calculated configurational contribution to the circular dichroism $\Delta\varepsilon(\Lambda)$ is much greater than the vicinal contribution, $\Delta\varepsilon(R)$. In fact, $\Delta\varepsilon(\Lambda)$ are 3.1 for D-gluconato complexes and 2.5 for L-mannonato complexes and $\Delta\varepsilon(R)$ are 0.4 for D-gluconato complexes and 0.1 for L-mannonato complexes, respectively. Accordingly, the configurational effect is the main effect in these aldonato complexes as observed for other related complexes containing amino acids.

The formation ratio of Δ and Λ diastereomers of these aldonato complexes was determined on the basis of their absorption strength.

Λ: Δ (complex **1**: complex **2**), was determined to 52:48 for D-gluconato complexes and complex **3**: complex **4** was 67:33 for L-mannonato complexes. It is well-known that only a small stereoselectivity was observed in the preparation of $[Co(en)_2$(L-amino acidato)$]^{2+}$ in comparison with $[Co(en)_2$(chiral diamine)$]^{3+}$.[16] The hydroxy acid ligand seems to give a nearly planer five membered chelate ring as well as the amino acid. Therefore, the stereoselectivity of the aldonato complexes due to the conformational preferences is not expected so much. The isomers ratio (Λ:Δ) for the gluconato complexes is, indeed, nearly 50:50. However, small stereoselectivity was observed in the formation of the mannonato complexes. Accordingly, it is suspected that small stereoselectivity is given by the interaction between the hydroxylmethylene chain of the mannonato ligand and diamine ligands.

It is well-known that chiral amino acid ligands in the complex such as $[Co(ala)(en)_2]^+$ (ala=L- or D-alaninato) are easily epimerized in mild alkaline solution (pH 9—10).[17] The stability of these aldonato complexes in alkaline solution were monitored by CD measurement. The CD spectral curves of all these complexes do not change after heating at 40 °C even in 0.1 M Na_2CO_3 solution (pH 12). Thus, α-proton of aldonato chelate is found to be remarkably inactive in comparison with that of amino acid chelate. Since in the first stage of base catalyzed epimerization OH^- ions would smoothly attack to complexes which have large positive charges, one of the reasons of the stability is suspected to be more negative charge of the aldonato ligands than amino acid ligands.

Conclusion

Both Δ and Λ-$[Co(aldonato)(en)_2]^{2+}$ complexes containing five-membered aldonato chelate were obtained from the reaction between aldonic acid lactones and *rac*-$[Co(CO_3)(en)_2]^+$. Some stereoselectivity between the diastereomers (Δ and Λ) is observed although it is relatively low. α-Protons of these aldonato chelates are remarkably inactive in alkaline solution in comparison with the $[Co(\text{amino acidato})(en)_2]^{2+}$ complexes.

Preparation and Stereochemistry of Cobalt(III) Complexes Containing 1,1,11,11-Tetraphenyl-4,8-diaza-1,11-diphosphaundecane or (3*S*,9*S*)-3,9-Dimethyl-1,1,11,11-tetraphenyl-4,8-diaza-1,11-diphosphaundecane, $(C_6H_5)_2PCH_2CHRNHCH_2CH_2CH_2NHCHRCH_2P(C_6H_5)_2$ (R=H or CH_3)

Min-Ho JUNG, Masamichi ATOH,† Kazuo KASHIWABARA, and Junnosuke FUJITA*
Department of Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya 464
(Received June 11, 1988)

Two new quadridentate phosphine ligands 1,1,11,11-tetraphenyl-4,8-diaza-1,11-diphosphaundecane (pp-232PNNP) and (3*S*,9*S*)-3,9-dimethyl-1,1,11,11-tetraphenyl-4,8-diaza-1,11-diphosphaundecane (*SS*(*C*)-pp-232PNNP), and several their cobalt(III) complexes were prepared and characterized. The *RS*(*N*) isomers of *trans*-$[CoCl_2$(pp- or *SS*(*C*)-pp-232PNNP)$]^+$ were formed by oxidation of cobalt(II) complexes of these ligands in dichloromethane with chlorine, while the *RR*,*SS*(*N*), and *RR*(*N*) isomers of the pp-232PNNP and *SS*(*C*)-pp-232PNNP complexes, respectively, were derived from the corresponding carbonato complexes and hydrochloric acid. The $[Co(O\text{-}O)$(pp- or SS(C)-pp-232PNNP)$]^{n+}$ (O-O= CO_3^{2-}, $C_2O_4^{2-}$, $C_5H_7O_2^-$) complexes yielded only a cisβ isomer. The stereochemistry of the complexes was discussed on the basis of the absorption, circular dichroism and NMR spectra.

In our previous papers, we have reported a number of new cobalt(III) complexes containing the following quadridentate aminoalkylphosphine ligands; pp- and mm-222PNNP=$R_2PCH_2CH_2NHCH_2CH_2NHCH_2CH_2PR_2$ (R=C_6H_5 and CH_3),[1] *SS*(*C*)-pp- and SS(C)-mm-222PNNP= (*S*,*S*)-$R_2PCH_2CH(CH_3)NHCH_2CH_2NHCH(CH_3)CH_2PR_2$ (R=C_6H_5 and CH_3),[2] mp- and SS(C)-mp-222PNNP=$(C_6H_5)(CH_3)PCH_2CHRNHCH_2CH_2NHCHRCH_2P(CH_3)(C_6H_5)$ (R=H and CH_3),[3] and 222NPPN and SS(C)-222NPPN=$NH_2CHRCH_2P(C_6H_5)CH_2CH_2P(C_6H_5)CH_2CHRNH_2$ (R=H and CH_3).[4] The properties such as stereoselectivity and the relation between circular dichroism spectra and the absolute configuration observed for these complexes have often been found to differ from those reported for complexes containing the corresponding tetramine ligand $NH_2CH_2CH_2NHCH_2CH_2NHCH_2CH_2NH_2$ (trien) and its derivatives.[5] To elucidate properties of cobalt(III)-polydentate phosphine complexes in more detail, further preparative studies will be necessary on related complexes. This paper deals with the preparation and characterization of cobalt(III) complexes formed with two new ligands of the PNNP type, 1,1,11,11-tetraphenyl-4,8-diaza-1,11-diphosphaundecane (pp-232PNNP) and (3*S*, 9*S*)-3,9-dimethyl-1,1,11,11-tetraphenyl-4,8-diaza-1,11-diphosphaundecane (*SS*(*C*)-pp-232PNNP), which form two five-and one six-membered chelate rings upon coordination.

Experimental

Quadridentate phosphine ligands pp-232PNNP and SS(C)-pp-232PNNP were prepared and handled under an atmosphere of nitrogen until they formed cobalt(III) complexes. All solvents used for the preparation were made oxygen-free by bubbling nitrogen for 20 min immediately before use. 1,9-Dichloro-3,7-diazanonane dihydrochloride,[6] diphenylphosphine[7] and (*S*)-alaninol (2-amino-1-propanol)[8] were prepared according to the literature methods. Absorption, circular dichroism (CD), and ^1H and ^{13}C NMR spectra were recorded on Hitachi 323 and U3400 spectrometers, a Jasco J-40CS spectropolarimeter, and Jeol JNM PMX-60 and Hitachi R-90HS spectrometers, respectively.

Preparation of Ligands. 1,1,11,11-Tetraphenyl-4,8-diaza-1,11-diphosphaundecane (pp-232PNNP). To liquid ammonia (150 cm^3) containing metallic sodium (1.7 g, 74 mmol) in a 500 cm^3 round-bottom flask was added dropwise diphenylphosphine (12.1 g, 65 mmol) at −78 °C. After stirring for 20 min, 1,9-dichloro-3,7-diazanonane dihydrochloride (4.0 g, 14.7 mmol) was added in small portions with stirring. After 1 h, liquid ammonia was evaporated. To the residue were added water (50 cm^3) and then diethyl ether (60 cm^3) with stirring. The ethereal layer was separated and dried over $MgSO_4$ (ca. 10 g) overnight. A viscous liquid was obtained by removing the solvent and unreacted diphenylphosphine under vacuum. The oily product (ca. 4 g) thus obtained was used for the preparation of cobalt(III) complexes without further purification.

(2*S*,8*S*)-2,8-Dimethyl-3,7-diaza-1,9-nonanediol Dihydrochloride. To an ethanol solution (130 cm^3) of (*S*)-alaninol (31 g, 0.41 mol) in a 500 cm^3 round-bottom flask was added a solution of 1,3-dibromopropane (21 g, 0.106 mol) in ethanol (10 cm^3) over 30 min at 70 °C with stirring. Stirring was continued for 4 h. The solution was cooled to 0 °C and then was mixed with KOH (11.9 g, 0.212 mol) in ethanol (200 cm^3). After 1 h precipitated KBr was filtered off, and ethanol was removed under reduced pressure. The oily residue was distilled at ca. 130 Pa, giving unreacted (*S*)-alaninol (bp 68 °C, 17.95 g) and the desired material (bp 168 °C). Yield: 8.85 g (49.1 mmol, 46.5%). Since the product was very hygroscopic, it was converted into the dihydrochloride. A methanol solution (150 cm^3) of the product was mixed with concd HCl (15 cm^3) at 0 °C, and then the solvent was removed under reduced pressure. On addition of isopropyl alcohol the oily residue gave white crystals, which were filtered and recrystallized from isopropyl alcohol containing a

† Present address: Department of General Education, School of Commerce, Senshu University, Higashi-mita 2-1-1, Tama-ku, Kawasaki 214.

small amount of water. Yield: 7.6 g. Found: C, 40.88; H, 9.09; N, 10.89%. Calcd for $C_9H_{24}N_2Cl_2O_2$: C, 41.07; H, 9.19; N, 10.64%.

(2*S*,8*S*)-2,8-Dimethyl-1,9-dichloro-3,7-diazanonane Dihydrochloride. To a mixture of (2*S*,8*S*)-2,8-dimethyl-3,7-diaza-1,9-nonanediol dihydrochloride (7.6 g, 29 mmol) and chloroform (30 cm^3) was added $SOCl_2$ (22 cm^3) dropwise over 20 min at 0 °C. The mixture was stirred for 30 min at 0 °C, and then refluxed for 2 h at 70 °C. Excess $SOCl_2$ and chloroform were removed by distillation, and the residue was dissolved in hot methanol (50 cm^3). The solution was filtered and the filtrate was cooled in ice to give colorless crystals, which were filtered, washed with diethyl ether, and dried in vacuum. Yield: 1.85 g. An additional amount of products (4.85 g) was obtained from the filtrate by adding excess diethyl ether. Total yield: 6.7 g (77%). Found: C, 36.57; H, 7.22; N, 9.62%. Calcd for $C_9H_{22}N_2Cl_4$: C, 36.02; H, 7.39; N, 9.33%. The compound is very hygroscopic.

(3*S*,9*S*)-3,9-Dimethyl-1,1,11,11-tetraphenyl-4,8-diaza-1,11-diphosphaundecane (*SS*(*C*)-pp-232PNNP). To liquid ammonia (150 cm^3) containing metallic sodium (2.4 g, 104 mmol) in a 500 cm^3 round-bottom flask was added dropwise diphenylphosphine (18 g, 97 mmol), and the mixture was stirred for 1 h at −78 °C. To the resulting orange solution was added (2*S*,8*S*)-2,8-dimethyl-1,9-dichloro-3,7-diazanonane dihydrochloride (6.7 g, 22 mmol) in small portions with stirring. Stirring was continued for 2.5 h. Liquid ammonia was evaporated, and water (33 cm^3) and then diethyl ether (30 cm^3) were added to the residue with stirring. The ethereal layer was separated from the aqueous layer and dried over $MgSO_4$ (ca. 2.0 g) overnight. The solvent and unreacted diphenylphosphine were removed by distillation under vacuum. The oily residue (4.3 g) thus obtained was used for the preparation of cobalt(III) complexes without further purification.

Preparation of Cobalt(III) Complexes.[††] ***RS*(*N*)-*trans*-[$CoCl_2$(pp-232PNNP)]X(Isomer A, X=Cl, ClO_4). Method 1.** To $[CoCl(NH_3)_5]Cl_2$ (500 mg, 2.0 mmol) in a mixture of methanol (100 cm^3) and water (100 cm^3) was added pp-232PNNP (1.0 g, 2.0 mmol) in methanol (10 cm^3) with stirring. After 30 min concd HCl (2 cm^3) was added to the mixture, and stirring was continued overnight. The resulting green solution was filtered and the filtrate was evaporated to dryness under reduced pressure. The green residue was dissolved in water (300 cm^3), the solution was shaken with diethyl ether (300 cm^3), and the aqueous layer was separated and evaporated to dryness under reduced pressure. From the residue the green complex was extracted with a small amount of methanol, and the extract was evaporated again to dryness under reduced pressure to give the complex. Yield: 680 mg (51%). Found: C, 56.06; H, 5.94; N, 3.93%. Calcd for $C_{31}H_{36}N_2Cl_3P_2Co$: C, 56.09; H, 5.47; N, 4.22%. The complex is soluble in water, methanol, ethanol, acetone and dichloromethane, but insoluble in diethyl ether and benzene.

Method 2. To a methanol solution (10 cm^3) of $Co(ClO_4)_2 \cdot 6H_2O$ (470 mg, 1.28 mmol) was added pp-232PNNP (636 mg, 1.28 mmol) in methanol (10 cm^3). After a while the resulting orange-brown solution was evaporated to dryness under reduced pressure, and the residue was dissolved in dichloromethane (50 cm^3). Chlorine gas was bubbled into the solution for 10 min, and then excess chlorine was removed by bubbling nitrogen for 20 min. The solution was filtered, mixed with methanol (30 cm^3), evaporated to a small volume (ca. 20 cm^3) under reduced pressure, then mixed with $NaClO_4 \cdot H_2O$ (7.0 g), and concentrated again to ca. 10 cm^3 under reduced pressure. (The solution should not be evaporated to dryness.) On addition of water (10 cm^3) the solution gave a green precipitate, which was filtered, washed with water and air dried. Yield: 676 mg (72.5%). Absorption and NMR spectra of this [$CoCl_2$(pp-232PNNP)]ClO_4 complex coincide with those of the above chloride salt. The solubility of the complex is similar to that of the chloride salt except insoluble property in water.

***RR,SS*(*N*)-*trans*-[$CoCl_2$(pp-232PNNP)]Cl (Isomer B).** A solution of [Co(C_2O_4 or CO_3)(pp-232PNNP)]X (X=PF_6, $B(C_6H_5)_4$) (0.13 mmol) (see below) in a mixture of methanol (25 cm^3), water (25 cm^3) and concd HCl (5 cm^3) was warmed at 40 °C for 15 min. The resulting green solution was diluted with a mixture of methanol (500 cm^3) and water (500 cm^3), and applied on a column (ϕ 3 cm×10 cm) of SP-Sephadex C-25. The column was washed with water, and the adsorbed product was eluted with 1 mol dm^{-3} HCl in a mixture of methanol and water (1 : 1). The green eluate was evaporated to dryness under reduced pressure to give the complex, which was collected, washed with a small amount of water and then diethyl ether. Yield: 82 mg (97%). Found: C, 56.04; H, 5.75; N, 4.20%. Calcd for $C_{31}H_{36}N_2Cl_3P_2Co$: C, 56.09; H, 5.47; N, 4.22%. The solubility of the complex is similar to that of the corresponding RS(N) isomer.

***cis*β-[Co(C_2O_4)(pp-232PNNP)]PF_6.** To $K_3[Co(C_2O_4)_3] \cdot 3H_2O$ (500 mg, 1.0 mmol) in a mixture of water (50 cm^3) and methanol (5 cm^3) was added pp-232PNNP (500 mg, 1 mmol) in methanol (2 cm^3), and the mixture was stirred overnight. The resulting red solution was evaporated under reduced pressure to remove methanol, and then shaken with diethyl ether (100 cm^3). The separated aqueous layer was diluted with water (1 dm^3) and applied on a column (ϕ 3cm×30 cm) of SP-Sephadex C-25. The adsorbed product was eluted with 0.05 mol dm^{-3} NaCl, and the eluate of the main red band was concentrated to 20 cm^3 and filtered. The filtrate was mixed with NH_4PF_6 (200 mg) in water (5 cm^3), yielding a red precipitate, which was filtered, washed with a small amount of cold water, and air dried. Yield: 410 mg (52%). Found: C, 50.07; H, 4.74; N, 3.61%. Calcd for $C_{33}H_{36}N_2O_4F_6P_3Co$: C, 50.14; H, 4.59; N, 3.54%. The complex is soluble in methanol, ethanol, acetone, dichloromethane, and acetonitrile, slightly soluble in water, but insoluble in diethyl ether.

***cis*β-[Co(CO_3)(pp-232PNNP)]$B(C_6H_5)_4$.** To $K[Co(CO_3)_2(C_5H_5N)_2]$[9] (400 mg, 1.0 mmol) in methanol (50 cm^3) was added pp-232PNNP (500 mg, 1.0 mmol) in methanol (5 cm^3), and the mixture was stirred for 6 h. The resulting red solution was diluted with water (1.5 dm^3), filtered, and the filtrate was applied on a column (ϕ 3 cm×30 cm) of SP-Sephadex C-25. The adsorbed product was eluted with 0.1 mol dm^{-3} NaCl, and the eluate of the main red band was concentrated to ca. 20 cm^3 under reduced pressure. The concentrate was filtered, and the filtrate was mixed with $NaB(C_6H_5)_4$ (350 mg) in water (5 cm^3), yielding a red precipitate, which was filtered, washed with water, and air dried. Yield: 470 mg (50%). Found: C, 71.84; H, 6.25; N, 2.55%. Calcd for $C_{56}H_{56}N_2O_3BP_2Co$: C, 71.80; H, 6.03; N, 2.99%. The complex is soluble in acetone and acetonitrile, slightly soluble in methanol and dichloromethane, but insoluble in water.

[††] Caution; All of the perchlorate salts of cobalt(III)-phosphine complexes are potentially explosive, and should be handled carefully.

***cisβ*-[Co(acac)(pp-232PNNP)]$(ClO_4)_2 \cdot 4.5H_2O$ (acac=Acetylacetonate Ion).** An ethanol solution (60 cm^3) containing *RS(N)*- or *RR,SS(N)-trans*-[$CoCl_2$(pp-232PNNP)]X (X=Cl, ClO_4) (0.28 mmol) and Li(acac) (35 mg, 0.33 mmol) was warmed at 30 °C for 1 h. The resulting red solution was diluted with water (300 cm^3) and applied on a column (ϕ 2 cm×40 cm) of SP-Sephadex C-25. By elution with 0.2 mol dm^{-3} NaCl, the eluate of the main red band was collected , evaporated to dryness under reduced pressure, mixed with ethanol (50 cm^3), and the mixture was filtered. The filtrate was again evaporated to dryness under reduced pressure, and the residue was dissolved in water (50 cm^3). On addition of $NaClO_4 \cdot H_2O$ (0.5 g) in water (5 cm^3) the solution gave a red precipitate, which was filtered, washed with cold water then a small amount of ethanol, and air dried. Yield: 55 mg (23%). Found: C, 49.52; H, 5.78; N, 3.28%. Calcd for $C_{36}H_{52}N_2Cl_2O_{10.5}P_2Co$: C, 49.55; H, 6.01; N, 3.21%. The complex is soluble in methanol, ethanol and dichloromethane, slightly soluble in water, but insoluble in diethyl ether and benzene.

The hexafluorophosphate *cisβ*-[Co(acac)(pp-232PNNP)]-$(PF_6)_2$ was obtained by addition of NH_4PF_6 instead of $NaClO_4 \cdot H_2O$. Found: C, 45.77; H, 4.63; N, 2.97%. Calcd for $C_{36}H_{43}N_2O_2F_{12}P_4Co$: C, 45.68; H, 4.58; N, 2.96%. The solubility of this complex is similar to that of the perchlorate.

***RS(N)-trans*-[$CoCl_2$(SS(C)-pp-232PNNP)]$ClO_4 \cdot 1.5H_2O$ (Isomer C).** This complex was prepared from $Co(ClO_4)_2 \cdot 6H_2O$ (410 mg, 1.12 mmol) and *SS(C)*-pp-232PNNP (590 mg, 1.12 mmol) by a method similar to Method 2 for the corresponding pp-232PNNP complex. Yield: 250 mg (29%). Found: C, 50.47; H, 5.16; N, 3.45%. Calcd for $C_{33}H_{43}N_2O_{5.5}P_2Co$: C, 50.62; H, 5.54; N, 3.58%. The solubility of the complex is similar to that of the corresponding pp-232PNNP complex.

***RR(N)-trans*-[$CoCl_2$(SS(C)-pp-232PNNP)]$ClO_4 \cdot 1.5H_2O$ (Isomer D).** A solution of *Λ-cisβ*-[$Co(CO_3)$(SS(C)-pp-232PNNP)]$ClO_4 \cdot 0.5(NaClO_4)$ (50 mg, 0.062 mmol) (see below) in a mixture of methanol (20 cm^3) and concd HCl (2.5 cm^3) was warmed at 50 °C for 5 min to give a green solution. On addition of $NaClO_4 \cdot H_2O$ (5g) in water (20 cm^3) the solution gave a green precipitate, which was filtered, washed with cold water, and air dried. Yield: 44 mg (91%). Found: C, 50.74; H, 5.26; N, 3.69%. Calcd for $C_{33}H_{43}N_2Cl_3O_{5.5}P_2Co$: C, 50.62; H, 5.54; N, 3.58%. The solubility of the complex is similar to that for the corresponding *RS(N)* isomer.

***Λ-cisβ*-[$Co(CO_3)$(SS(C)-pp-232PNNP)]$ClO_4 \cdot 0.5(NaClO_4)$.** A mixture of *RS(N)-trans*-[$CoCl_2$(*SS(C)*-pp-232PNNP)]$ClO_4 \cdot 1.5H_2O$ (200 mg, 0.26 mmol), $(NH_4)_2CO_3$ (133 mg, 1.4 mmol) and active charcoal (ca. 50 mg) in methanol (40 cm^3) was stirred for 2 h at room temperature. Active charcoal was filtered off, the filtrate was diluted with water (1 dm^3) and applied on a column (ϕ 2.5 cm×100 cm) of SP-Sephadex C-25. By elution with 0.05 mol dm^{-3} NaCl the eluate of the main red band was collected and concentrated to ca. 40 cm^3 under reduced pressure. The concentrate was filtered, and the filtrate was mixed with $NaClO_4 \cdot H_2O$ (3.0 g) to yield a pink precipitate, which was filtered, washed with cold water, and air dried. Yield: 55 mg (27%). Found: C, 51.00; H, 5.14; N, 3.68%. Calcd for $C_{34}H_{40}N_2Cl_{1.5}O_9P_2Na_{0.5}Co$: C, 50.65; H, 5.00; N, 3.47%. The complex is soluble in water, methanol, ethanol and acetone, but insoluble in diethyl ether and benzene. The complex can also be prepared from $K[Co(CO_3)_2(C_5H_5N)_2]$ and the ligand by a method similar to that for the corresponding pp-232PNNP complex.

***Λ-cisβ*-[Co(acac)(SS(C)-pp-232PNNP)]$(PF_6)_2 \cdot 2(NaPF_6) \cdot 2H_2O$.** A methanol solution (50 cm^3) containing *RS(N)*-trans-[$CoCl_2$(*SS(C)*-pp-232PNNP)]$ClO_4 \cdot 1.5H_2O$ (200 mg, 0.26 mmol) and Li(acac) (30 mg, 0.28 mmol) was stirred for 1 h at room temperature. The resulting red solution was diluted with water (1 dm^3) and applied on a column (ϕ 2.5 cm×100 cm) of SP-Sephadex C-25. The adsorbed product was eluted with 0.4 mol dm^{-3} NaCl, the main red eluate was collected, concentrated to nearly dryness under reduced pressure, and the residue was mixed with methanol (ca. 100 cm^3) to extract the complex. The extract was evaporated again to dryness under reduced pressure, and the residue was dissolved in a small amount of water. On addition of NH_4PF_6 (ca. 100 mg) the solution gave a red precipitate, which was filtered, washed with a small amount of cold water and air dried. Yield: 174 mg (50.6%). Found: C, 33.85; H, 3.53; N, 2.20%. Calcd for $C_{38}H_{51}N_2F_{24}O_4P_6Na_2Co$: C, 33.89; H, 3.52; N, 2.08%. The complex is soluble in water, methanol, ethanol, acetone and dichloromethane, but insoluble in diethyl ether and benzene.

Results and Discussion

Preparation of Ligands. The quadridentate ligands pp-232PNNP and *SS(C)*-pp-232PNNP were prepared by methods similar to those for pp-222PNNP[1] and *SS(C)*-pp-222PNNP,[2] respectively. The yields of these ligands seem to depend largely on the purity of reactants and the presence of moisture.[1] The lower yield of *SS(C)*-pp-232PNNP may be attributable to moisture contained in the very hygroscopic starting material

*: Shoulder absorption.

(2*S*,8*S*)-2,8-dimethyl-1,9-dichloro-3,7-diazanonane dihydrochloride. The ligands could not be purified by distillation because of their high boiling points.

trans-Dichloro Complexes. For each quadridentate ligand, two kinds of green [$CoCl_2$(L)]$^+$ (L= pp-232PNNP or SS(C)-pp-232PNNP) were obtained by different preparative methods; one is oxidation of the Co(II)-L complex in CH_2Cl_2 with chlorine, and the other is reaction of [Co(CO_3 or C_2O_4)L]$^+$ with hydrochloric acid. Each method yielded only one kind of green complex. Absorption spectra of these complexes shown in Fig. 1 are very similar to that of *trans*(*Cl,Cl*),*cis*(*P,P*)-[$CoCl_2$(edpp)$_2$]$^+$ (edpp=NH_2CH_2-$CH_2P(C_6H_5)_2$) whose structure has been determined by X-ray analysis.[10,11] Thus the two complexes of each pp-232PNNP and *SS*(*C*)-pp-232PNNP can be assigned to isomers of the *trans*(*Cl,Cl*) complex. Table 1 lists the data of absorption and CD spectra. For *trans*-[$CoCl_2$(pp-232PNNP)]$^+$, a small difference in absorption spectra is observed between one isomer (A) obtained from oxidation with chlorine and the other isomer (B) derived from the CO_3^{2-} or $C_2O_4^{2-}$ complex. The ^{13}C NMR spectra show a more clear difference for these two isomers. Isomer A in CD_3CN shows signals at δ 28.5 (-CH_2-$\underline{C}H_2$-CH_2-), δ 30.7 (P-CH_2-: triplet), and δ 49.6 and 52.4 (-$\underline{C}H_2$-NH-$\underline{C}H_2$-), while isomer B in the same solvent gives the corresponding signals at δ 23.8, 28.3, and 45.5 and 51.5. The chemical shifts of signals due to the phenyl groups are also different between the isomers. In *trans*-[$CoCl_2$(pp-232PNNP)]$^+$ there are three possible isomers arising from the absolute configuration of the nitrogen atoms, the *RS*(*N*), *RR*(*N*) and *SS*(*N*) isomers, the latter two being a pair of enantiomers (Fig. 2). Thus two isomers A and B will be the *RS*(*N*) and *RR,SS*(*N*) isomers, although the assignment for the isomers can not be made from the

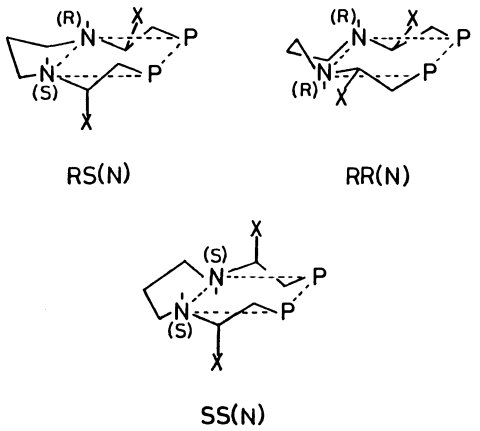

Fig. 2. Three possible isomers for *trans*-[$CoCl_2$(pp-232PNNP)]$^+$ (X=H) and *trans*-[$CoCl_2$(SS(C)-pp-232PNNP)]$^+$ (X=CH_3).

absorption and NMR spectra. However, it is assumed that isomer B which was prepared from *cis*β-[Co(CO_3 or C_2O_4)L]$^+$ (see below) and hydrochloric acid is the *RR,SS*(*N*)isomer, since molecular models suggest that the cisβ complex is more stable in the *RR,SS*(*N*) isomer than the *RS*(*N*) one, and the configuration of the nitrogen atom will be retained in strongly acidic solution. Thus the other isomer A can be assigned to the *RS*(*N*) isomer. The *trans*-[$CoCl_2$(232tet)]$^+$ complex (232tet=3,7-diazanonane-1,9-diamine) which has the same skeletal structure as the pp-232PNNP complex yields the same *RR,SS*(*N*) and *RS*(*N*) isomers, and the former is obtained from *cis*β-[Co(CO_3)(232tet)]$^+$.[12] All *cis*-[CoX_2 (232tet)]$^{n+}$ complexes so far known have a *RR,SS*(*N*) structure, no *RS*(*N*)-*cis*β and *cis*α isomers being reported. The pp-232PNNP complex seems to show the same stereoselectivity as the 232tet complex.

Possible isomers of *trans*-[$CoCl_2$(*SS*(*C*)-pp-

232PNNP)]$^+$ are three diastereomers with the *RS(N)*, *RR(N)*, and *SS(N)* configurations (Fig. 2). The *RR(N)* and *SS(N)* isomers have a C_2 axis, while the *RS(N)* isomer belongs to C_1 symmetry. Isomer C prepared by oxidation with chlorine shows two kinds of the methyl signal at δ 1.47 and 1.83 in the ^{1}H NMR spectrum in $CDCl_3$. On the other hand, the other isomer D derived from *cisβ*-[$Co(CO_3)$(*SS(C)*-pp-232PNNP)]$^+$ exhibits only one methyl signal at δ 1.83. Thus isomer C can be assigned to the *RS(N)* isomer, and isomer D to either *RR(N)* or *SS(N)* isomer. In the *RS(N)* isomer one of the two methyl groups is equatorial to the chelate ring, while the other is axial (Fig. 2). The axial methyl group comes fairly close to the phenyl ring and will receive its shielding effect. The methyl signal at the high field (δ 1.47) can be assigned to this axial methyl group, and the signal at δ 1.83 to the equatorial methyl group. Isomer D which shows the methyl signal at δ 1.83 should be the *RR(N)* isomer in which two methyl groups have an equatorial disposition. The *SS(N)* isomer has two axial methyl groups and will be less stable than the *RR(N)* isomer.[13] The assinment of *RR(N)* for isomer D indicates that its starting [$Co(CO_3)$(*SS(C)*-pp-232PNNP)]$^+$ complex has a *Λ-cisβ-RR(N)* configuration. As shown later this carbonate complex exhibits CD spectrum typical of a *Λ* configuration. Similar *RR(N)* and *RS(N)* isomers have been obtained for a structurally related tetramine complex *trans*-[$CoCl_2$((2*S*,10*S*)-Me_2-232tet)]$^+$ ((2*S*,10*S*)-Me_2-232tet= (2*S*,10*S*)-4,8-diazaundecane-2,10-diamine).[14]

As described before, the two isomers (A and B, or C and D) of each pp-232PNNP or *SS(C)*-pp-232PNNP dichloro complex show a small difference in absorption spectra, but the differences between the isomers

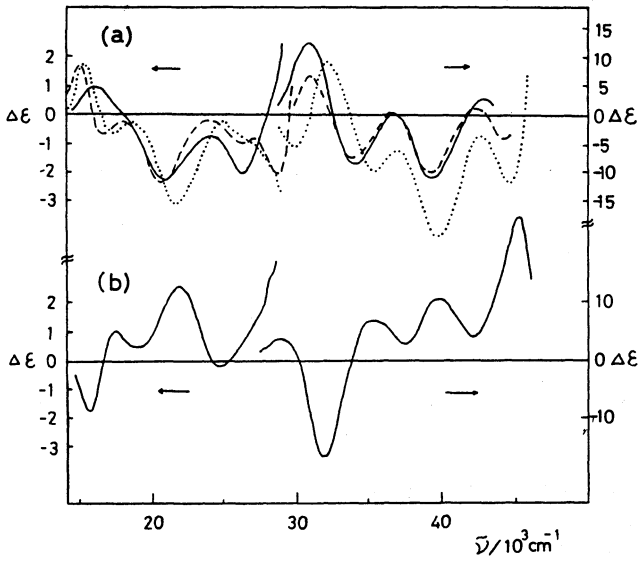

Fig. 3. CD spectra, (a) *RS(N)* (----) and *RR(N)* (——) isomers of *trans*-[$CoCl_2$(SS(C)-pp-232PNNP)]$^+$, and *trans*-[$CoCl_2$(S-pdpp)$_2$]$^+$ (·····), (b) *RR(N)-trans*-[$CoCl_2$(SS(C)-pp-222PNNP)]$^+$.

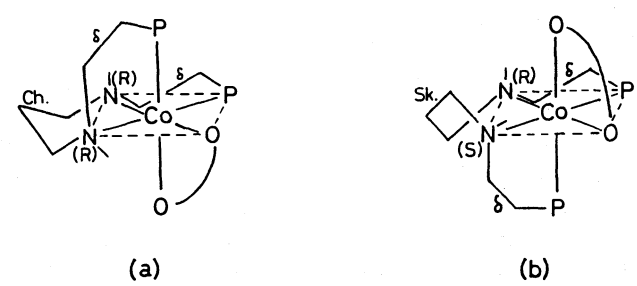
are very similar for both pp-232PNNP and *SS(C)*-pp-232PNNP complexes as seen in Fig. 1. This result supports the assignments of *RR,SS(N)* and *RS(N)* configurations for two pp-232PNNP complexes based on only stereochemical consideration.

Figure 3(a) shows CD spectra of *RR(N)* and *RS(N)* isomers of *trans*-[$CoCl_2$(*SS(C)*-pp-232PNNP)]$^+$. The spectra are rather similar except the region around 15000 cm^{-1} (the I_a absorption band region). The chiral sources of the isomers indicated by molecular models are as follows; the *RR(N)* isomer has two (*R*)-nitrogen and two (*S*)-carbon atoms, and δ-gauche, λ-skew and δ-gauche conformations for the five-, six-, and five-membered chelate rings, respectively, while the *RS(N)* isomer has one (*R*)- and one (*S*)-nitrogen and two (*S*)-carbon atoms, and δ-gauche, chair and λ-gauche conformations. The chiral sources are thus different between the isomers, but their CD spectra are similar and quite resemble that of *trans(Cl,Cl)cis(P,P)*-[$CoCl_2$-(S-pdpp)$_2$]$^+$ (*S*-pdpp=(*S*)-$NH_2CH(CH_3)CH_2P(C_6H_5)_2$) shown in Fig. 3(a) whose chiral sources are two (*S*)-carbon and two δ-gauche chelate rings.[11] On the other hand, the CD spectrum of a related complex *RR(N)-trans*-[$CoCl_2$(*SS(C)*-pp-222PNNP)]$^+$ [2] is nearly enantiomeric to those of the present isomers as shown in Fig. 3(b), although the chiral sources of this complex (two(*R*)-nitrogen and two (*S*)-carbon atoms, and δ-, λ- and δ-gauche conformations) are similar to those of the *RR(N)* isomer of the *SS(C)*-pp-232PNNP complex. No reasonable explanation can be given for these CD spectra at present. The complexes of the *trans(Cl,Cl)*-type have no chirality in the arrangement (*Δ,Λ*) of chelate rings around the metal ion, and their CD will be induced by a chiral field produced by chiral atoms and/or chiral conformations of ligands (vicinal effect). Little CD work has been reported for the vicinal effect of polydentate ligands.

O-O Chelate Complexes. All the complexes of [Co(O-O)(pp- or *SS(C)*-pp-232PNP)]$^{n+}$ were assigned to the cisβ isomer from the ^{1}H NMR spectra. For example, [Co(acac)(pp-232PNNP)]$^{2+}$ shows two kinds of methyl signals of acac at δ 1.84 and 2.29 in D_2O, indicating the cisβ structure (C_1 symmetry). Each of [Co(CO_3 or acac)(*SS(C)*-pp-232PNNP)]$^{n+}$ yielded only one optical isomer stereoselectively. These isomers



(a) (b)

Fig. 4. Two possible isomers, (a) *Λ-RR(N)* and (b) *Λ-RS(N)*, for *cisβ*-[$Co(CO_3$ or acac)(SS(C)-pp-232PNNP)]$^{n+}$

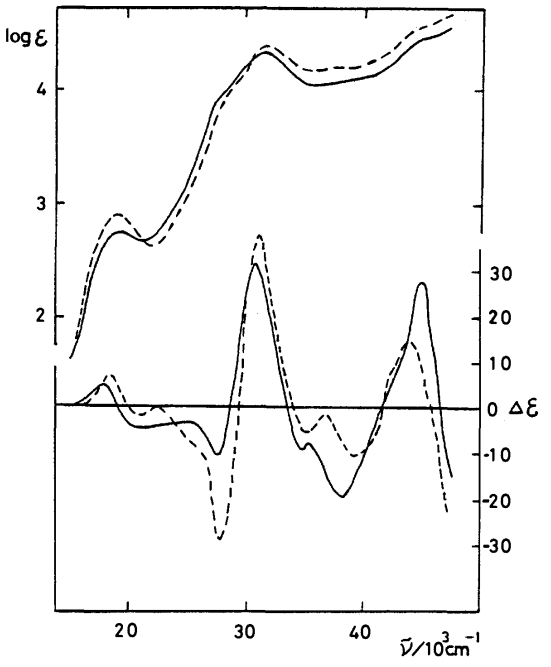


Fig. 5. Absorption and CD spectra of $(+)_{589}$-*Λ-cisβ*-[Co(acac)(SS(C)-pp-232PNNP)]$^{2+}$ (——) and $(+)_{589}$-*Λ-cisβ*-[Co(acac)(SS(C)-pp-222PNNP)]$^{2+}$ (------).

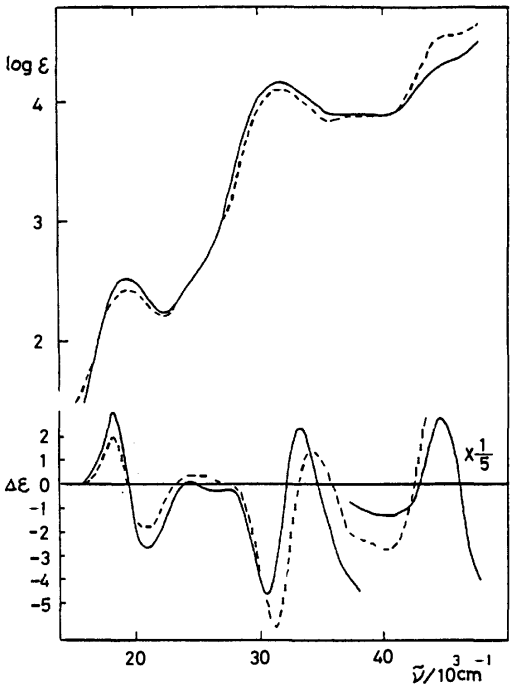

Fig. 6. Absorption and CD spectra of $(+)_{589}$-*Λ-cisβ*-[Co(CO_3)(SS(C)-pp-232PNNP)]$^{+}$ (——) and $(+)_{589}$-*Λ-cisβ*-[Co(CO_3)(SS(C)-pp-222PNNP)]$^{+}$ (------).

give two doublet methyl signals of the phosphine ligand at δ 1.67 ($^4J_{PH}$= 5 Hz) and at a fairly high field δ 0.85 ($^4J_{PH}$= 5 Hz).

Figure 4 shows structures of two probable cisβ isomers in which both methyl groups of the phosphine ligand have an equatorial disposition. The other two cisβ isomers will be unstable because of two axial methyl groups. Of the two probable isomers, the *Λ-cisβ-RR(N)* one has one methyl group disposed very close to one phenyl ring on the phosphorus atom. The signal at δ 0.85 can be assigned to the methyl group shielded by the phenyl group, and both carbonato and acac complexes can be assigned to the *Λ-cisβ-RR(N)* isomer. The *Λ* configuration of the isomers is confirmed by the CD spectra. Figures 5 and 6 compare CD spectra of the acac and carbonato complexes, respectively with those of the corresponding *Λ-cisβ-RR(N)* isomers of the *SS(C)*-pp-222PNNP complexes.[2] The absolute configurations of the latter complexes have been assigned from a comparison of CD spectra with that of *Λ-cisβ-RR(N)*-[Co(acac)(SS(C)-Me_2-mm-222PNNP)]$^{2+}$ (*SS(C)*-Me_2-mm-222PNNP=(4*S*,9*S*)-2,4,9,11-tetramethyl-5,8-diaza-2,11-diphosphadodecane) whose absolute configuration has been determined by the X-ray method.[2] In contrast to CD spectra of the *trans(Cl,Cl)*-type complexes, the *SS(C)*-pp-232PNNP and *SS(C)*-pp-222PNNP complexes show CD spectra very similar to each other over the whole region and give CD patterns characteristic of a *Λ* configuration in the first absorption band region. From *Λ-cisβ-RR(N)*-[Co(CO_3)(*SS(C)*-pp-232PNNP)]$^{+}$ the *RR(N)-trans(Cl,Cl)* complex was derived by reaction with hydrochloric acid. The [Co(CO_3)(pp-232PNNP)]$^{+}$ complex should also have the *cisβ-RR,SS(N)* structure, since it affords the *RR,SS(N)-trans(Cl,Cl)* complex by the same reaction. Thus cis-complexes containing the pp-232PNNP-type ligand yield selectively the cisβ-isomer with (*R,R*)- or (*S,S*)-nitrogen atoms and the six-membered chelate ring of a chair conformation. The same selectivity has been observed for the corresponding 232-tetramine complexes.[14]

(Received March 7, 1988)

Ternary cobalt(III) complexes with a general formula β_2-[Co(tfac$_2$en)(L-aa)], where tfac$_2$en is the titled Schiff base ligand and L-aa denotes L-ala, L-leu, L-phe, L-tyr, and L-trp, were synthesized and separated into two diastereoisomers. On the bases of X-ray crystal analysis of the L-phe complex, CD, and ^{1}H and ^{19}F NMR spectra, the structure of $(-)_{435}$- and $(+)_{435}$-isomers was determined to be *Λ*- and *Δ*-cis-β_2-forms, respectively, and preferred conformation of the coordinated L-amino acidates was assummed to be *h*-form in solution. All the complexes showed stereoselectivity for the *Λ*-isomer in acetone and methanol, but the selectivity decreased or reversed with addition of water. The solvent-dependent stereoselectivity was explained in terms of steric repulsion and hydrophobic interligand interactions between CF_3 group of tfac$_2$en and side chain of L-aa.

Of various interligand interactions in metal complexes, hydrophobic intramolecular ligand-ligand interactions had been regarded as extremely weak. However, it has recently been proved that this kind of interaction plays an important role in molecular recognition and/or chiral recognition in some metal chelates.[1-7] For instances, Sigel and his co-workers,[3] and Yamauchi and his co-workers[4] found that the ternary metal(II) complexes with diamines such as 1,10-phenanthroline and amino acidates show a high ligand selectivity due to intramolecular hydrophobic interligand interaction between the diamine chelate ring and the side chain of amino acidates. Okawa et al.[6] demonstrated that metal(III) chelates with *l*-menthol derivatives exhibit a high stereoselectivity for *Λ*-configuration on the basis of intramolecular interligand CH-π interactions.

In order to elucidate the effect of hydrophobic interligand interactions on the stereoselectivity of metal complexes with chiral amino acidates, we prepared the cobalt(III) complexes described in the title containing Schiff base ligand with hydrophobic CF_3 groups (tfac$_2$en) and L-amino acidates (L-aa) with hydrophobic side chains as shown in Fig. 4, and investigated their steric structure and solvent dependency of stereoselectivity.

Experimental

Preparation of Complexes. Complexes were prepared from [Co(tfac$_2$en)] (0.01 mol) and amino acids (0.011 mol) by air oxidation in methanol-water by means of a similar method to that for β_2-[Co(tfac$_2$en) (L-met)].[8] The crude reaction products were purified and/or separated into pure diastereoisomers by the following methods. The data of elemental analysis and the optical rotation of all the complexes are summarized in Tables 1 and 2, respectively.

1) β_2-[Co(tfac$_2$en)(L-phe)], β_2-[Co(tfac$_2$en)(L-leu)], and β_2-[Co(tfac$_2$en)(L-met)]. The crude reaction product (3.0 g) was dissolved in methanol (100 cm^3) and filtered. The filtrate was slowly concentrated to a small volume at room temperature in 3—5 days to give massive dark green crystals ($(-)_{435}$-isomer, about 2.5 g). A single crystal of L-phe complex, thus obtained, was used for X-ray diffraction study.

The $(-)_{435}$-isomer (2.0 g) was dissolved in hot methanol (100 cm^3) and water (10 cm^3) was added to it. The solution was slowly concentrated to almost dryness at room temperature to give a large amount of massive crystals ($(-)_{435}$-isomer) and a small amount of needle-shaped crystals ($(+)_{435}$-isomer). The needle-shaped crystals were sorted by hand. Yield of $(+)_{435}$-isomer; 0.05—0.1 g for L-phe and L-met complexes, 0.3—0.5 g for L-leu complex.

2) β_2-[Co(tfac$_2$en)(L-tyr)]. The crude reaction product was recrystallized from methanol to give light green needle-shaped crystals ($(+)_{435}$-isomer) in about 90% yield.

The recrystallization of the $(+)_{435}$-isomer from methanol-water (15 : 1 in volume) produced a large amount of $(+)_{435}$-isomer and a small amount of massive crystals ($(-)_{435}$-isomer, 0.05 g).

3) β_2-[Co(tfac$_2$en)(L-ala)] and β_2-[Co(tfac$_2$en)(L-trp)]. Recrystallization of the crude reaction product from methanol gave a 1 : 1 mixture of $(-)_{435}$- and $(+)_{435}$-isomers in about 90% yield. Acetone solution of the 1 : 1 mixture (0.2 g) was charged on a silica-gel column (Wakogel C-200, 15(ϕ)×120 mm), and was eluted with acetone at a flow rate of ca. 0.1 cm^3 s^{-1}. The first green fraction (40 cm^3) was collected and concentrated to dryness. In the case of L-trp complex, pure $(-)_{435}$-isomer was obtained by this procedure, but in the case of L-ala complex, a 4 : 1 mixture of $(-)_{435}$- and $(+)_{435}$-isomers of 70 mg was obtained.

Crystal Structure Determination. A Rigaku AFC-5 automated four-circle diffractometer was used at 25±1 °C. Crystal data and details of the data collection are given in Table 4. Lattice constants were determined by the least-squares refinement based on 40 reflections with $20 < 2\theta < 30°$.

†† Present address: Department of Chemistry, Faculty of Science, Kwansei Gakuin University, Uegahara, Nishinomiya 662.

The intensity data were corrected for Lorentz-polarization effects and for absorption. The structure was solved by the direct method. Refinements were carried out by the block-diagonal least-squares method. The absolute configuration was determined on the basis of the known configuration of L-phenylalanine. The absolute structure was further checked by performing cycles on two possible configurations, of which lower R factor was considered as the correct one. Hydrogen atoms were inserted in their calculated positions and fixed at their positions with B of 7Å^2. The final discrepancy factors are R(F) 0.054 and R_w(F) 0.059 for 2294 unique reflections.

The atomic scattering factors and anomalous dispersion corrections were taken from Ref. 9. All the calculations were carried out on HITACHI M-680H computer at the Computer Center of the Institute for Molecular Science using a local version of MULTAN 78,[10] UNIX-III,[11] and ORTEP[12] programs. Atomic coordinates are listed in Table 5. The anisotropic thermal parameters of non-hydrogen atoms, the atomic coordinates and thermal parameters of hydrogen atoms, and the F_o—F_c tables have been deposited as a Document No. 8827 at the office of Editor.

Measurements. The ^{1}H and ^{19}F NMR spectra were measured with Hitachi R-20 (60MHz), JEOL GSX-400 (400MHz), and Varian CFT-20 (80MHz) spectrometers at an ambient probe temperature using TMS or fluorobenzene as internal references. The electronic absorption spectra and CD spectra were recorded with JASCO UBIDEC-1 spectrometer and JASCO J-20 spectropolarimeter, respectively, at room temperature. The optical rotations at 435 nm were measured with a JASCO DIP-140 polarimeter with 1 cm cell by the use of a thermostated cell-holder (the deviation of the solution temperature $=\pm 0.1$ °C). When the mutarotation was slow, the solutions were placed in a thermostated bath, and picked up one by one at proper intervals. The observed isomerization rate constant was calculated from the slope of plots for $\ln(\alpha_\infty-\alpha_t)$ vs. time, where α_∞ and α_t denote the optical rotations under the equilibrium conditions and time t, respectively. The isomeric ratio, K=[$(-)_{435}$-isomer]/[$(+)_{435}$-isomer], under the equilibrium conditions was calculated from the equation, $K=([M]^T_\Delta-[M]^T_\infty)/([M]^T_\infty-[M]^T_\Lambda)$, where $[M]^T_\Delta$, $[M]^T_\Lambda$, and $[M]^T_\infty$ represent the molar rotations at a temperature T of $(+)_{435}$-isomer, $(-)_{435}$-isomer, and under equilibrium conditions, respectively. In the cases of L-ala and L-trp complexes, the K values were estimated by assuming $[M]^T_\Delta=-[M]^T_\Lambda$. The isomeric composition of all the isolated diastereoisomers was determined on the basis of their ^{1}H NMR spectra in CD_3OD.

Table 1. Elemental Analyses Data and Isomeric Composition of Complexes

Number of complex	Composition of isomer	Formula	Found(Calcd)		
			C(%)	H(%)	N(%)

Results and Discussion

Properties of Complexes. All the complexes exhibited a mutarotation in methanol to show a minus rotation under equilibrium conditions (Table 2). For each amino acidato complex, the rotation in the equilibrium conditions of $(-)_{435}$-isomer was the same as that of $(+)_{435}$-isomer, and the plots of $\ln(\alpha_\infty-\alpha_t)$ vs. time gave a linear relation in which the slope for $(-)_{435}$-isomer was identical as that for $(+)_{435}$-isomer. Hence, the observed mutarotation corresponds to the isomerization between two species of isomer, and the following equilibrium is established for each complex in methanol:[13)]

$$(+)_{435}\text{-isomer} \rightleftharpoons (-)_{435}\text{-isomer}.$$

The isomerization occurred readily in methanol, ethanol, 1-propanol, and a mixed solvent of acetone and water, but was very slow in pure acetone, chloroform, *N*,*N*-dimethylformamide, and dimethyl sulfoxide.

The ^{1}H NMR spectra (Table 3) of complexes **3**—**11** soon after dissolution in methanol correspond to the spectra of only one species of isomer, indicating that the complexes **3**—**11** were isolated as pure isomer. On the other hand, the ^{1}H NMR of complexes **1** and **12** soon after dissolution correspond to the spectra of a 1 : 1 mixture of two isomeric species, and the ^{1}H NMR of complex **2** to that of a 4 : 1 mixture. The isomeric compositions for all the complexes are listed in Table 1.

As the complexes are labile for isomerization in methanol, the ^{1}H NMR of all the complexes exhibited a time dependence in CD_3OD. The ^{1}H NMR under the equilibrium conditions corresponded to those for a mixture of two species of isomer, and the isomeric ratio of each amino acidato complex coincided with that determined from the optical rotation (Table 2). The isomeric ratios in Table 2 indicate that all the complexes show a stereoselectivity for *Λ*-isomer in methanol and the selectivity increases in the order of L-leu < L-met < L-ala < L-phe < L-tyr < L-trp. This order is almost parallel with the increasing order of steric bulkiness of the side chain of L-amino acidates, hence the steric repulsion between the side chain and Schiff base ligand seems to be responsible mainly to the stereoselectivity, as has been seen in β_2-[Co(α-Me-sal$_2$en) (L-aa)].[14-17)] However, the stereoselectivity of β_2-[Co(tfac$_2$en)(L-aa)] is much lower than that of β_2-[Co(α-Me-sal$_2$en)(L-aa)]. This lower selectivity is due to the presence of CF_3 groups on the tfac$_2$en skelton, and will be discussed later in detail.

The complexes readily isomerize in methanol, and when they are recrystallized from methanol, only one diastereoisomer or the 1 : 1 mixture of two isomers crystallized preferentially, as mentioned in Experimental section. Since the solubility of the preferentially crystallizing isomer in methanol was clearly

lower than that of the other isomer, the observed preferential crystallization corresponds to the second-order asymmetric transformation. Thus, in order to isolate more soluble isomer, we used a mixed solvent of methanol and water to lower the solubility. L-Ala and L-trp complexes were subjected to silica-gel column chromatography by use of acetone as an eluent to separate two isomers. However, silica-gel promoted isomerization of the complexes in acetone, so that only the $(-)_{435}$-isomer was separated.

Structure of Complexes. The results of X-ray structual analysis for $(-)_{435}$-[Co(tfac$_2$en)(L-phe)] are shown in Fig. 1 and numerical data are summarized in Tables 4, 5, and 6. The tfac$_2$en ligand takes cis-β- configuration and L-phenylalaninate coordinates as a bidentate ligand in forming a meridional N_3O_3 structure (cis-β_2 structure). The absolute configuration was determined to be Λ on the basis of the known absolute configuration, *S*(C), of the asymmetric carbon atom of L-phenylalaninate. The Λ-β_2-structure has been observed also for the $(-)_{435}$-isomer of [Co(tfac$_2$en)(L-met)][8] and [Co(α-Me-sal$_2$en) (L-ile)].[15] The bond lengths (Co-N and Co-O) and angles (N-Co-O, N-Co-N, and O-Co-O) of $(-)_{435}$-[Co(tfac$_2$en)(L-phe)] are close to those of $(-)_{435}$-[Co(tfac$_2$en)(L-met)], indicating that the steric structures of both complexes are essentially the same. In fact, not only they take the Λ-β_2-structure but also they take *t* conformation for coordinated amino acidates.[17,18] However, the bond length of Co-O(3), 1.891(4) Å, of L-phe complex is longer than that of L-met complex, 1.849(9) Å. Since the phenyl group of L-phe seems to approach to some extent to the π-conjugation system of β-diketone-iminate part of tfac$_2$en (the closest interatomic distances; C(17)···C(7)=3.617 (9) Å, C(17)···C(11)=4.050(9) Å, C(16)···C(8)=4.624(9) Å, and C(18)···F(6)=5.030(10) Å), the elongation of Co-O(3) bond length in L-phe complex may come from weak stacking between phenyl group and π-conjugation system of tfac$_2$en, although the dihedral angle between them is 132.5°.

The data for electronic absorption and CD spectra of the complexes are summarized in Table 7, and the representative spectra are shown in Fig. 2, together with the vicinal CD curves. Since the AB and CD spectra of $(-)_{435}$-isomers are very similar to those of $(-)_{435}$-Λ-β_2-isomer of L-phe complex whose structure

a) Solvent: DMF+$CHCl_3$(1 : 4 in volume). Wavenumbers are given in 10^3 cm^{-1}. The data of L-met complexes have been published in Ref. 8. b) 4 : 1 mixture of Λ- and Δ-β_2-isomers.

has been verified by X-ray analysis, the Λ-β_2-structure can safely be assigned to all the $(-)_{435}$-isomers. The AB spectra of $(+)_{435}$-isomers are also nearly identical with those of $(-)_{435}$-isomers, and the CD spectra of $(+)_{435}$-isomers are almost the mirror image of those of $(-)_{435}$-isomers. Accordingly, Δ-β_2-structure can be assigned to the $(+)_{435}$-isomers. Since the vicinal CD's of coordinated L-amino acidates show similar patterns with (−),

(+), and (−), signs from lower to higher energy in the first absorption region (16—23 kcm^{-1}), the coordinated amino acidates are assumed to take a very similar coordination structure to each other.

Generally, amino acids can take three conformations, *t*, *g*, and *h*, around the C(α)-C(β) bond.[17,18] In the cases of coordinated L-amino acidates in β_2-[Co(Schiff base)(L-aa)], they take the *t* conformation exclusively in the solid state.[8,15] Thus, the *t* rotamer seems to be very stable in this system. However, this is not the case in solution. In solution, the Λ-β_2-isomers of L-phe , L-tyr, and L-trp complexes show NMR spectra in which one of CH_3 and one of CH=C signals for $tfac_2en$ shift to a higher field due to the ring current effect of aromatic ring of amino acidates (Table 3). In the case of Δ-β_2-isomers, one of CF_3 signals shifts to a higher field. These high-field shifts are expected only when the conformation of coordinated amino acidates is *h* form, and in fact 400 MHz ^{1}H NMR spectral analysis of the L-phe complex indicates that the *h* conformer is predominant in acetone (Table 8). Therefore, we assume that all the complexes prepared here prefer the *h* conformation for the coordinated amino acidates in solution.

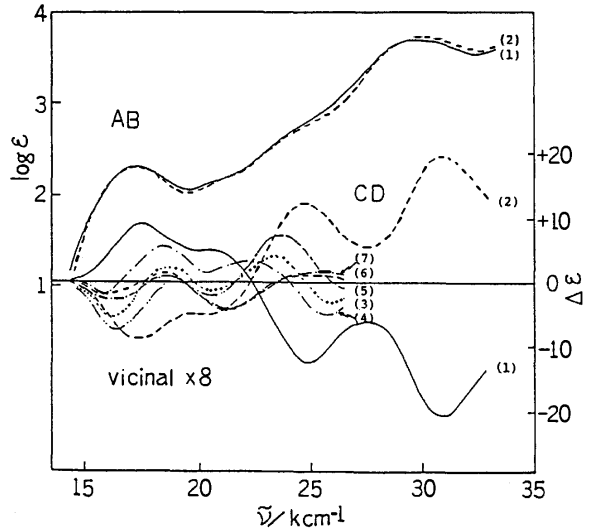

Fig. 2. Absorption (AB) and CD spectra of complexes in DMF-$CHCl_3$ (1:4) mixture. (1): (−)$_{435}$-Λ-β_2-[Co($tfac_2en$)(L-phe)], (2): (+)$_{435}$-Λ-β_2-[Co($tfac_2en$)-(L-phe)], (3): vicinal CD of L-phe, (4), (5), (6), and (7) are vicinal CD's of L-trp, L-tyr, L-ala, and L-leu, respectively.

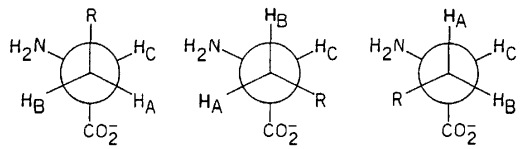
Stereoselectivity of Complexes. When the coordinated amino acidates take the *h* conformation, the side chain of amino acidates approaches to CH_3 group of chelate ring **A** (Fig. 3) in the case of Λ-β_2-isomer. Whereas, in the case of Δ-β_2-isomer, the side chain approaches to CF_3 group of chelate ring **A'**. Since the approach is closer in Δ-β_2-isomer than in Λ-β_2-isomer in the model consideration, the main reason why the complexes prefer the Λ-configuration rather than the Δ will be that the steric repulsion between the side chain of amino acidates and $tfac_2en$ ligand is stronger in Δ-isomer than in Λ.

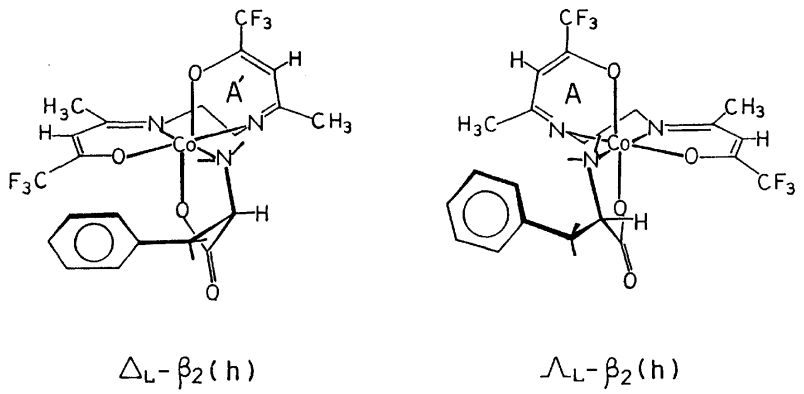
On the other hand, both the side chain of amino acidates and CF_3 group of $tfac_2en$ ligand are hydrophobic. Thus, when we use a hydrophilic solvent, hydrophobic interaction, especially solvophobic interaction, may occur between side chain and CF_3. In order to confirm the above assumption, the solvent effect on the stereoselectivity was investigated. The results are shown in Fig. 4. Here, we selected acetone

Table 8. Rotamer Populations about C_α-C_β Bond of Coordinated L-Phenylalaninate[19]

Complex	J_{AC}	J_{BC}	Rotamer/%		
			t	*g*	*h*
Λ-L-Phe	4.8	5.6	29.4	22.0	48.6
Δ-L-phe	4.4	6.8	18.3	40.4	41.3



t *g* *h*



Δ_L-β_2(h) Λ_L-β_2(h)

Fig. 3. Stereochemical relation between side chain of coordinated L-amino acidate (*h*-conformation) and $tfac_2en$ ligand of Δ- and Λ-β_2-isomers in solution.

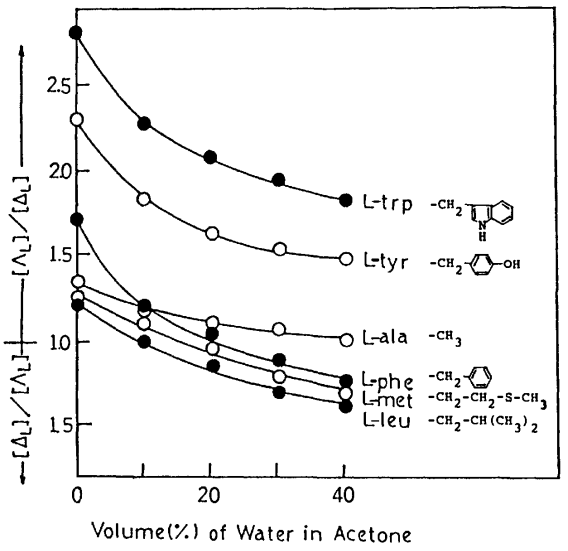


Fig. 4. Solvent dependence of stereoselectivity of β_2-[Co(tfac$_2$en)(L-aa)] at 25°C.

as a relatively hydrophobic solvent and investigated the effect of addition of water. Figure 4 indicates that 1) all the complexes prefer Λ-isomer in acetone, and the degree of the stereoselectivity is higher than that in methanol, and 2) the stereoselectivity decreases with addition of water and changes from Λ to Δ for L-leu, L-met, and L-phe complexes. The effect of addition of water is sensitive in the hydrophobic order of side chain of amino acidates, ala<met<leu<tyr<phe<trp, and the stereoselectivity for Λ-isomer increases in the hydrophilic order of solvents, acetone<methanol<water. Accordingly, hydrophobic interactions clearly contribute to the stereoselectivity of the employed complexes in water-acetone mixtures. The variation of the stereoselectivity with addition of water is the smallest for L-ala complex of all the complexes. This is due to the CH_3 group of L-alaninate, which is too small to cause hydrophobic interaction with CF_3 group of tfac$_2$en. In comparison with L-ala, L-leu, and L-met complexes, the variation of stereoselectivity with addition of water is much larger in L-phe, L-tyr, and L-trp complexes. This fact indicates that the hydrophobic interactions with CF_3 group are stronger for aromatic side chains than for aliphatic ones. The stereoselectivity of L-tyr and L-trp complexes remains in favor of Λ-isomer even at 40% water content. This may be due to the fact that the side chain of L-tyr and L-trp have electronegative OH and NH groups, respectively, near aromatic rings, so that the electrostatic repulsion between CF_3 group and OH and NH groups reduces hydrophobic interactions.

From the above results and discussion, we conclude that 1) the complexes investigated here prefer Λ-isomer in acetone and methanol, and the selectivity is based mainly on the steric repulsion between the side chain of coordinated L-amino acidates and CF_3 group of tfac$_2$en ligand in Λ-isomer, the counterpart of isomerization equilibrium, 2) in more hydrophilic solvents, the hydrophobic interactions occur between the above mentioned groups so as to increase the stereoselectivity for Λ-isomer, and 3) the hydrophobic interactions with CF_3 group is more effective when the side chain of amino acidates is aromatic group than aliphatic one.

The X-Ray Structure of Sodium *trans*-1,2-Cyclohexanediamine-*N,N,N',N'*-tetraacetatochromate(III) 4.5-Hydrate, Na[Cr(cydta)]·4.5H_2O

Sumio KAIZAKI,*,† Mariko HAYASHI, Keisuke UMAKOSHI,†† and Shun-ichiro OOI††

†† Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka 558
(Received March 22, 1988)

The crystal structure of the title compound has been determined from the X-ray diffraction data. This complex crystallizes in the monoclinic space group with unit-cell parameters of a=17.724(2), b=8.084(1), c=14.025(2) Å, β=95.06(1)°, and Z=4, and with a space group of $P2/c$. The structure converged to R=0.043 for 2898 reflections. In the complex anion, the chromium is coordinated by the sexadentate cydta ligand, producing a distorted octahedral CrN_2O_4 geometry. The glycinate chelates of the in-plane G(girdling) rings in the CrN_2O_2 plane are more distorted with respect to the Cr-O bond lengths and internal bond angles than are those of the out-of-plane R(relaxed) rings in the $CrNO_3$ plane. This may be responsible for the lability to dissociation of the G-ring acetate chelates. A close proximity of non-bonded hydrogen atoms (ca. 1.90 Å) is found between the methylene groups in the R ring and the cyclohexane ring. There are two nonequivalent sodium ions in the unit cell, which link the cydta complex anions to form an anion layer along the c axis.

Only two X-ray structure studies have been reported for six-coordinated sexadentate *trans*-1,2-cylcohexanediamine-*N,N,N',N'*-tetraacetatometallate ([M(cydta)]$^{n-}$); Manganate(III)[1] and cupurate(II), [2] both of which are severely distorted from a regular octahedron, though in opposite direction from each other, as a result of the Jahn-Teller effect. For non Jahn-Teller distorted cydta complexes, the X-ray structure data will make it possible to understand some characteristics of the thermodynamic, kinetic, and NMR and chiroptical spectroscopic behavior, which has suggested that the G-ring chelates are more labile to dissociation than the R-ring ones and that the sexadentate coordination of the cydta ligand in metal complexes is more favorable than that of the ethylenediamine-*N,N,N',N'*-tetraacetate (edta) one.[3-10] For such a study, the cydta Cr(III) complex is appropriate, because there have been reported some X-ray structure data of edta-like Cr(III) complexes[11-15] including K[Cr(edta)]·2H_2O, the solution structure of which has been well investigated, though there has long remained a controversy over whether it has a sexa- or quiquedentate edta coordination.[7-10]

This paper will report the determination of the crystal and molecular structure of Na[Cr(*rac*-cydta)]·4.5H_2O by means of X-ray structure analysis.

Experimental

X-Ray Analaysis of Na[Cr(cydta)]·4.5H_2O. Violet crystals of this complex suitable for X-ray analysis were obtained by the literature method[16] and then grown from a concentrated aqueous solution in a refrigerator for a few days. The elemental analysis showed 4.5 hydrate of this complex, in accord with the crystallographic result, though Tanaka et al. reported 4 hydrate.[16] Anal Calcd for Na[Cr(cydta)]·4.5H_2O: C, 33.74; H, 5.46; N, 5.62%. Found: C, 33.64; H, 5.44; N, 5.62%.

† Present address: Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560.

The crystal data and experimental details are shown in Table 1. Weissenberg photography was used for the determination of the space group. The unit-cell parameters were derived by a least-squares analysis of 2θ values of the reflections in the $14<2\theta<23°$ range, measured on a Philips PW1100 diffractometer by the use of Mo$K\alpha$ radiation (λ=0.7107 Å). The intensity data were collected on the diffractometer by using graphite-monochromated Mo$K\alpha$ radiation at room temperature. The intensities of three standard reflections (600, 010, 004), monitored every 4h, showed no appreciable decay during the data collection. Of the 4814 unique reflections measured in the h, k, $\pm l$ region, 2898 with $F_o^2>3\sigma(F_o^2)$ were used for the structural analysis. No correction was made for absorption.

The crystal structure was solved by the direct method

a) $R_F=\sum||F_o|-|F_c||/\sum|F_o|$.
b) $R_{WF}=[\sum w(|F_o|-|F_c|)^2/\sum w|F_o|^2]^{1/2}$; $w=\sigma(|F_o|)^{-2}$.

(MULTAN).[17] The positional and thermal parameters were refined by the block-diagonal least-squares method. The minimized function was $\sum w(|F_o|-|F_c|)^2$, where $w=\sigma(F_o)^{-2}$. Hydrogen atoms were introduced in the calculated positions (C-H=0.97 Å), but those of the water molecules were located on a difference synthesis map except for one of the H atoms bonded to O(W1). These H atoms were included in the least-squares calculation, but their parameters were not refined. Each H atom was assigned an isotropic temperature factor equal to that of the atom to which it is bonded. The convergence was attained with the R_F and R_{WF} values listed in Table 1. All the parameter shifts in the final cycle of the refinement were $<0.2\sigma$. The final difference synthesis showed no peak greater than 0.7 e Å^{-3}. The atomic scattering factors, with correction for the real part of the anomalous dispersion effect for Cr and Na^+, were taken from Ref. 18. Tables of the observed and calculated structure factors, thermal parameters, and hydrogen-atom coordinates are deposited as Document No. 8828 at the Office of the Editor of the Bull. Chem. Soc. Jpn. The computational work was carried out by using standard programs.[19] The atomic coordinates are given in Table 2.

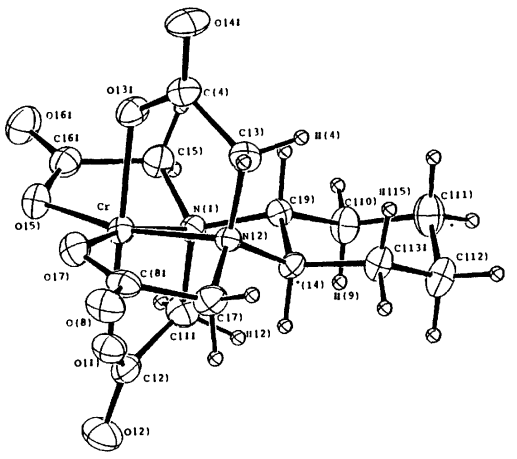

Fig. 1. The molecular structure of $[Cr(cydta)]^-$ ion in its sodium 4.5-hydrate. Thermal elipsoids are drawn at 50% probability level. Hydrogen atoms are represented as spheres of arbitrary radius. Besides Cr, C, N, and O atoms, only four hydrogen atoms which exhibit the close contact are numbered for clarity (see Text).

Results and Discussion

The Complex Anion $[Cr(cydta)]^-$. A perspective drawing of $[Cr(cydta)]^-$ is shown in Figure. 1. The bond lengths and angles are summarized in Table 3. The average bond lengths and angles, together with the torsion angles, are listed in Tables 4 and 5. The crystal structure analysis confirmed the sexadentate six-coordination mode of *trans*-1,2-cyclohexanediaminetetraacetate in this chromium(III) complex, as evidenced by our recent chiroptical study[8] and as found in $K[Cr(edta)]\cdot 2H_2O$.[11] The bond lengths and angles of the edta sub-unit in $[Cr(cydta)]^-$ are almost identical with those of the edta complex. The coordination geometry of the present complex anion is a distorted octahedron, with N-Cr-O and O-Cr-O angles of 81.2 and 112.9° respectively in the CrN_2O_2 plane. The Cr-N bond distances (2.058 Å) are as long as those of the edta complex[11] and the 1,3-propanediaminetetraacetato chromate(III) ($[Cr(1,3-pdta)]^-$)[12] and *cis*(*N*)-bis(iminodiacetato)chromate(III)-($[Cr(ida)]^-$)[13] complexes, but are shorter than those (average 2.085 Å) of *trans*(O_5)-(ethylenediamine-*N*,*N*′-diacetato-*N*,*N*′-dipropionato) chromate(III) ($[Cr(eddda)]^-$)[14] and *trans*(O_6)-(1,3-propanediamine-*N*,*N*′-diacetato-*N*,*N*′-dipropionato)chromate(III) ($[Cr(1,3-pddda)]^-$).[15] The Cr-O bonds fall into two classes with a mean bond length of 1.97 Å. The Cr-O bonds in G-ring chelates (average 1.992 Å) are longer than those (1.95—1.97 Å) usually found for the 1,3-pdta, bis(ida), and 1,3-pddda complexes,[12-15] whereas those in the R-ring chelates (average 1.953 Å) are almost the same. In other words, the differences between the Cr-O(R) and Cr-O(G) bond lengths for the edta and cydta complexes are larger than those for the bis(ida)[13] and 1,3-pdta[12] complexes, though these differences are smaller than those for the corresponding Mn(III) and Cu(II) complexes, the structures of which are susceptible to Jahn-Teller distortion[1,2] The sums of the G-ring bond angles in the cydta complex (average 524.0°) are samller than those of the R-ring ones (average 536.4°). The torsion anlges for the Cr-N-C-C chains

in the G rings are considerably different from those in the R rin s(average 38.73° for the G rings and average 4.21° for the R rings, as shown in Table 5). These facts indicate that the G-ring chelates are more strained than the R ones, since the ring strain may be evaluated in terms of the torsion anlges as well as the deviation from the sum of the ideal chelate bond angles for five-membered rings.[20] On the other hand, the quinquedentate edta-type Cr(III) complexes such as [Cr(H_2O)-(Hedta)] exhibit a sum of the G-ring chelate bond angles similar to that for the cydta complex, but the Cr-O(G) bond (1.935—1.959 Å) is found to be shorter than that (1.99 Å) in the sexadentate edta complex.[21] There seems to be no correspondence between the G-ring strain and the Cr-O(G)-bond lengthening. Hence, it is probable that the cooperation of the chelate-ring strain and the Cr-O(G)-bond lengthening results in the lability to the dissociation of the G-ring chelates in the sexadentate edta and cydta Cr(III) complexes.

In general, the sexadentate edta complexes are less stable than the cydta complexes, forming the quinquedentate edta complexes with an uncoordinated G-ring acetate and one coordinated water molecule more readily than the cydta complexes.[3-5,7-14] This difference in stability of the G-ring chelates between these complexes may be brought about by a small change in the structure of the edta sub-unit around the Cr(III) ions; e.g., the O(G)-Cr-O(G) angles of the cydta Cr(III) complex is smaller by 1.4° than that of the edta complex. Another possible explanation for it is a steric interaction between the R rings and the cyclohexane backbone, a stereochemical requirement or steric compression responsible for the increased ring-closure rates of the cydta complexes over those of the edta ones, as has been discussed in connection with the kinetic differences between the cydta and edta complexes.[4a,5b,22] The present X-ray analaysis substantiates this possibility; short intramolecular nonbonding H-H distances (1.90 Å) are found betweeen the glycinate methylene groups in the R ring and the

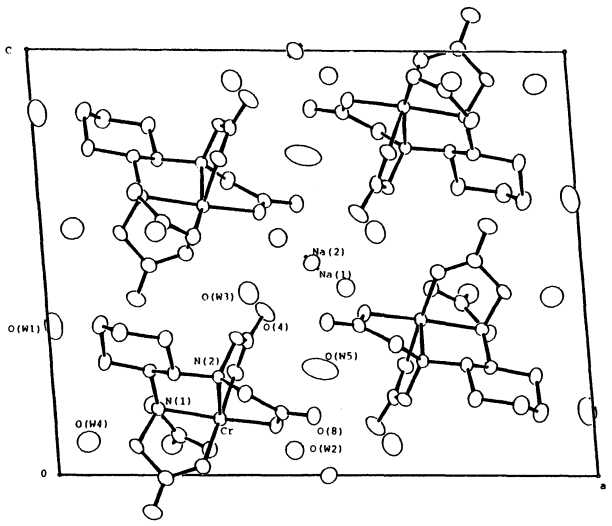

Fig. 2. Crystal structure of Na[Cr(cydta)]·4.5H_2O viewed down the b-axis. All hydrogen atoms are omitted for clarity. Na(2) at (1/2, 1/2, 1/2) overlaps just above Na(1) at (1/2, 0, 1/2) in this plane.

Table 4. Averaged Bond Lengths and Angles within the Complex Anion

CH, E, R, and G stand for cyclohexane, diamine chelate, and the R and G rings of the acetate chelates, respectively. The subscripts c and u refer to coordinated and uncoordinated oxygen atoms respectively.

methylene groups in the 3 and 6 positions of the cyclohexane ring: C(1)-H(2) and C(10)-H(9) or C(3)-H(4) and C(13)-H(15), as is shown in Fig. 1.

The cyclohexane ring takes the chair conformation, and its bond lengths and angles agree with those found for cydta complexes of six-coordinate Mn(III), Cu(II), and seven-coordinate Fe(III).[1,2,23] The torsion angles for the C-C-C-C chains in the cyclohexane ring range from 47 to 63° in absolute value, with a mean magnitude of 54.28°, approximating those of other cydta complexes.[1,2]

The Crystal Structure. A projection of the structure of Na[Cr(cydta)]·4.5H_2O down the b-axis is shown in Fig. 2. There are two inequivalent sodium ions in the unit cell. Each sodium ion is surrounded by six oxygens in an octahedral configuration; for Na(1) at

(1/2, 0, 1/2), four from uncoordinated oxygens of carboxylates in the anions and two from water molecules, and for Na(2) at (1/2, 1/2, 1/2), two from uncoordinated carboxylates and four from water molecules. The octahedral environment around the Na(2) is more deformed than that around the Na(1). The average Na(1)-O and Na(2)-O distances are 2.389 and 2.467 Å respectively. The values of the former bond are shorter than the range observed for the other $Na(O)_6$ polyhedra, but the latter one is within this range. The interbond angles of the $Na(O)_6$ polyhedra have mean deviations from the ideal octahedral values of 0.887° and 9.62° for Na(1) and Na(2) ions respectively. A cationic layer at around 1/2 with the Na(1) and Na(2) polyhedra, linking four and two complex anions respectively, is formed by hydrogen bonds between two crystalline water molecules, O(W5) and O(W2), the oxygen-oxygen distance of which is 2.892 Å. Consequently, this array of sodium ions combines two layers of the complex anions by forcing the hydrophilic moieties of the anions to be directed toward the cations. Hence, it seems to minimize contacts between the hydrophobic cyclohexane rings of the anions in the unit cell. Similar cationic arrangements in the unit cells are observed for K[Mn(cydta)]·H_2O[1] and Ca[Fe(H_2O)(cydta)]$_2$·8H_2O.[23]

(Received June 10, 1988)

A unique micro-enzyme sensor for the determination of glucose has been prepared by incorporating glucose oxidase into the micropores of a platinized microelectrode. The electrode diameter is in the range from 10 μm to 200 μm. The detection limit is 5×10^{-7} mol L^{-1} for glucose, and an excellent linearity is obtained in the concentration range from 5×10^{-7} to 10^{-2} mol L^{-1} in the case of micro-enzyme electrode whose diameter is larger than 50 μm. In the case of micro-enzyme electrode whose diameter is 10 μm, the detection limit for glucose is 10^{-5} mol L^{-1}, and the linearity is observed in the concentration range from 10^{-5} to 5×10^{-2} mol L^{-1}. The sensor responds to every glucose sample of different concentration in 3 s or less, and the coefficients of variation for glucose (1 mM) determination were within 2%. The sensor output was stable over 4 weeks. This unique microfabrication approach to micro-enzyme electrodes enables the immobilization of intact enzyme molecules by a simple procedure.

Since the introduction of the enzyme electrode by Clark and Updike,[1,2] a wide variety of biosensors have been developed. In the early stage of biosensor research many enzyme-immobilized membranes have been attached to a Clark-type oxygen electrode.[3-5] In addition, antibodies,[6-9] organelles,[10,11] plant tissues,[12] animal tissues,[13] and microorganisms[14,15] have been immobilized for the preparation of a wide variety of Clark-type oxygen electrode-based biosensors.

The further practical application of enzyme electrodes has been extended by the microfabrication of electrode-based biosensors, since multifunctional biosensors can be developed by taking advantage of silicon technology.[16-18] Disposable biosensors can also be constructed.

In almost all areas of chemical measurement the philosophy "the smaller, the better" seems to be prevailing. Well-known examples are capillary columns for gas and liquid chromatography, and microelectrodes for in vivo neurochemical sensors.[19,20] These microinstruments have been gradually replacing the conventional ones because of their increased resolution, sensitivity, and saving in running cost. Miniaturization of biosensors is particularly important for the realization of not only high performance autoanalyzing systems with compactness in clinical laboratory but sensing devices for artificial organs.

Microelectrodes the size of which are less than 10 μm radius have been investigated and employed to obtain neurochemical information.[19,20] Small size also has many advantages in electrochemical analysis particularly with biosensors by virtue of specific reaction of an enzyme, and specific binding between an antigen and its corresponding antibody. Microfabrication of enzyme sensors has been mainly pursued by employing field effect transistors as potentiometric transducers.[16-18] This semiconductor-based approach is promising, since disposable enzyme electrodes are prepared by covering the gate of a field effect transistor with an enzyme-immobilized membrane by employing the conventional immobilization techniques. However, as long as the conventional immobilization techniques of enzymes are employed, enzyme electrodes with sizes in the μm range are beyond realization. By the conventional techniques the authors mean the polymer matrix-supported enzyme membranes. In our previous rapid communication,[21] we have reported fundamental properties of an enzyme electrode (diameter=200 μm) prepared by incorporating enzyme molecules on a platinized surface of platinum electrode.

Here we describe the details and further information on micro-enzyme sensors (diameter=10—200 μm) based on platinized microplatinum electrode, especially with the additional information of our world-smallest enzyme electrode which can be applied as an in vivo micro-enzyme sensor for glucose sensitive neurons. The relationship between the porosity of platinized microelectrode and the sensor output as well as long term stability are also described. Enzyme molecules are intactly inmobilized in the micropores of a transducer electrode. It is the platinization technique that enables the microfabrication of the biosensor. It is a well-known fact that platinized platinum, porous microparticles of platinum, possesses very huge surface and high catalytic activities for electrolytic processes. By employing a microelectrode as a base electrode for platinization and enzyme immobilization, a micro-enzyme sensor can be easily fabricated. Therefore, the size of the micro-enzyme sensor is directly related to that of the base electrode. Enzyme molecules are stably retained in the porous platinum particles with active surface. In other words, the platinum particles play the dual roles of transducing material and matrix for enzyme immobilization.

† Present address: Department of Bioengineering, Tokyo Institute of Technology, O-okayama 2-12-1, Meguro-ku, Tokyo 152.

Experimental

Reagents and Materials. Hexachloroplatinic acid and lead acetate were purchased from Wako Chem. Co. (Osaka). Glucose was the product of Nakarai Chem. Co. (Kyoto), and glucose oxidase (110 u mg^{-1}) was purchased from Toyobo Co. (Osaka). Bovine serum albumin and glutaraldehyde were obtained from Tokyo Kasei (Tokyo). All the chemicals were analytical reagent grade, and all solutions were prepared with glass-distilled water.

Platinum wires (diameter=10—200 μm) were the products of Sanwa Metal Co. (Tokyo). Imperial™ wrapping films of alumina powders of different particle sizes were obtained from Sumitomo 3M Co. (Tokyo).

Preparation of Glucose Oxidase-Immobilized Platinized Microelectrode. Platinum wire whose diameter is in the range from 50 μm to 200 μm was sealed by heating a platinum wire-inserted small soda glass tubing and then polished with the polishing films to prepare a flat surface. In the case of 10 μm platinum electrode, a 10 μm platinum wire was placed in a glass capillary tubing and then sealed at a mild heating temperature. The glass tubing was pulled gently by creeping for several minutes. This was performed by a glass microelectrode puller for patch-clamp pipet (type PP-83) of Narishige Scientific Instrument Laboratory (Tokyo). After sufficient encapsulation of the platinum wire in the capillary tubing, the wire-encapsulating tubing was cut into two microelectrodes. The tip of every platinum electrode was polished with a film of 30 μm alumina powder and then with a film of 9 μm alumina powder. At the last stage, the tip was polished with alumina powder of 1 μm diameter with the exception of the 10 μm microplatinum electrodes, which are polished carefully with 0.1 μm alumina powder. After the smoothing of the surface of the platinum microelectrode, platinization was carried out by reducing hexachloroplatinate (33 mg mL^{-1}) in the presence of lead acetate (0.6 mg mL^{-1}). The electrode potential is referred to a Ag/AgCl reference electrode in the following description. A platinum wire (d=200 μm, l=5 mm) was employed as an auxiliary electrode. The electrolytic reduction of the platinum complex was performed either potentiostatically or galvanostatically. In the potentiostatic preparation, the potential was varied from −0.15 to −0.20 V, and the deposition time was 10 min. On the other hand, in the case of galvanostatic preparation, the deposition current was changed in the range from −0.5 to −60 μA, and the deposition time was 5 min. After the reductive deposition of platinum particles, the platinized electrode was thoroughly washed in 0.1 M phosphate buffer (pH 6.8; 1 M=1 mol dm^{-3}). Enzyme incorporation was then carried out by immersing the electrode in a phosphate-buffered solution (pH 6.8) containing 50 mg glucose oxidase for 10 min. The enzyme-incorporated platinized microelectrode was rinsed thoroughly in 0.1 M phosphate buffer (pH 6.8) for over 12 hours. The electrode, if necessary, was then immersed in a bovine serum albumin solution (20 mg in 1 mL of 0.1 M phosphate buffer of pH 6.8) for 10 min. The albumin-incorporated platinized surface was then immersed in a glutaraldehyde solution (2% in 0.1 M phosphate buffer) for 10 min to form a thin albumin film over the platinized surface. The electrochemical microfabrication technique is schematically shown in Fig. 1.

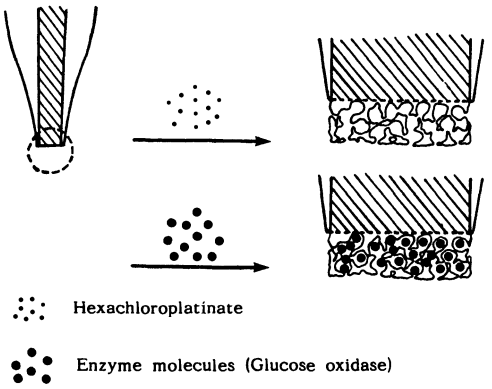

Fig. 1. Schematic illustration of the fabrication technique for the preparation of micro-enzyme sensor. After the encapsulation of micro-platinum wire, platinization is performed by electrochemical reduction of hexachloroplatinate, which is followed by the incorporation of enzyme molecules. The electrode was immersed in an albumin solution and then treated with glutaraldehyde.

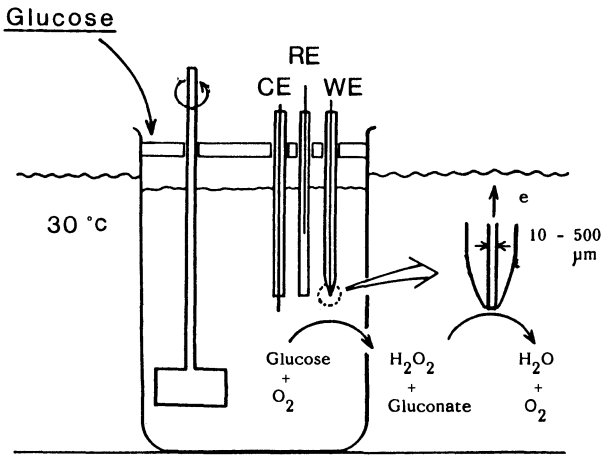

Fig. 2. Measuring apparatus for glucose determination with a micro-enzyme electrode. Glucose oxidase generates hydrogen peroxide from glucose, and the peroxide is oxidized by the transducer electrode of which potential is kept at 0.6 V vs. Ag/AgCl reference electrode. The anodic current is the sensor output.

Observation of Enzyme-Immobilized Microelectrode. A typical micro-enzyme electrode was observed by a SZH optical microscope of Olympus Co. (Tokyo). The surface of the platinized electrode was observed by a Hitachi S-450 scanning microscopy before and after enzyme incorporation. Each electrode was coated with gold by a Eiko IB-3 ion coater after the lyophylization of the electrodes. All the electrodes were kept at −60 °C overnight and then lyophylized with a freeze dryer (Model DC-55A) of Yamato Scientific Co., Ltd. (Tokyo). The gold coating (5 min) was repeated three times to keep the coating at moderate temperature.

Glucose Determination by Micro-Enzyme Electrode. Glucose was determined with a three electrode system by applying 0.6 V to the working micro-enzyme electrode. At the applied potential the hydrogen peroxide generated by glucose oxidase is oxidized to give anodic current. Figure 2

shows the measuring apparatus for glucose determination with micro-enzyme electrodes. A series of glucose samples were injected into the measuring buffer solution (0.1 M phosphate of pH 6.8) under the stirring with a motor-driven screw mixer. The mixing with a motor-driven screw was required to obtain a good signal to noise ratio especially in the case of an enzyme electrode of 10 μm diameter. The glucose determination was performed at 30 °C.

Results

Evaluation of Platinized Platinum Surface. After platinization the microelectrode was cleaned by sweeping the electrode potential repeatedly in 0.5 M sulfuric acid for the estimation of electrode surface area. A oxygen and hydrogen adsorption/desorption curve for a platinized electrode (diameter=10 μm) was investigated and compared with the curve for a flat electrode of the same diameter. From the two voltammograms the surface area of a platinized electrode is estimated to be about 5000 times that of a plain electrode. The surface area of a platinum electrode is easily controllable by changing the deposition time. The platinization is also controlled by choosing the applied potential in the case of potentiostatic preparation and by choosing the reducing current in the case of galvanostatic prepartation.

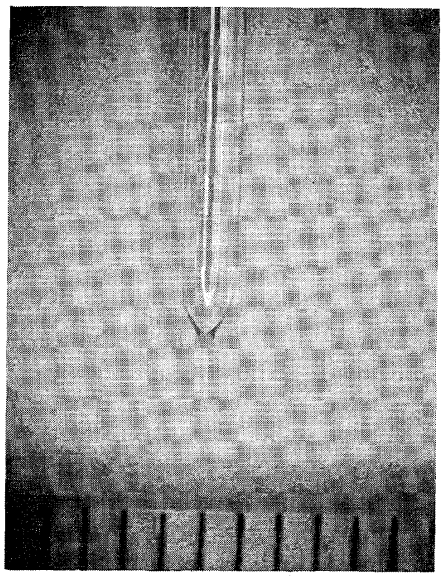

Fig. 3. A typical micro-enzyme electrode (diameter=10 μm) encapsulated in a soda glass tubing. The graduation lines of the scale is 1 mm.

Observation of Enzyme-Immobilized Microelectrode. A typical micro-enzyme electrode (10 μm) was observed by the microscope. Figure 3 shows that a 10 μm platinum wire is encapsulated in a capillary tubing. The surfaces of three different electrodes were observed by the scanning electron microscope. Figure 4 shows the surface of a platinized electrode before enzyme incorporation. Microparticles of platinum were seen on the surface. A photograph of a glucose oxidase-incorporated platinized electrode is shown in Fig. 4(B). Despite considerable enzyme activity in the porous electrode surface, no membrane-like structure was observed on the platinized surface. The last photograph, Fig.4(C), shows the surface of the enzyme-incorporated platinized electrode treated in the albumin solution and in the glutaraldehyde solution. A very thin protein layer was observed over the electrode surface after the crosslinking of albumin molecules by the bifunctional aldehyde.

The thickness of the albumin film was estimated to be a few hundred A from the cross section of the broken protein film during lyophylization.

Determination of Glucose by the Micro-Enzyme Electrode. The micro-enzyme electrode (diameter: 50 μm) was immersed in 0.1 M phosphate buffer (pH 6.8). After the residual current became a constant value, each glucose sample was injected. The output current increased promptly after the injection of a glucose

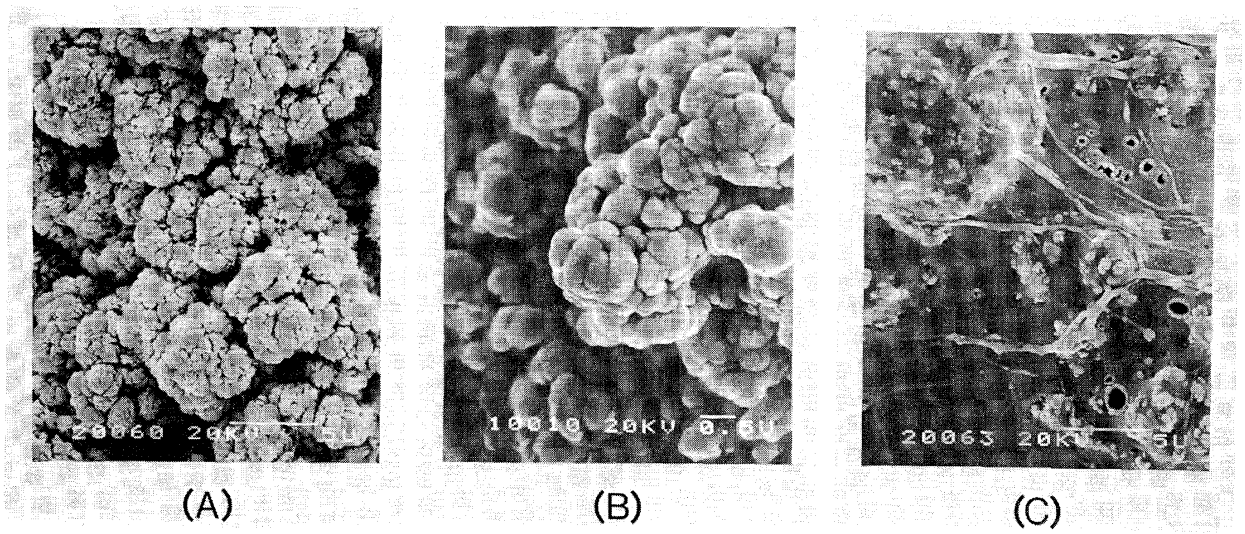

Fig. 4. SEM photographs of a platinized microelectrode (A), an enzyme-incorporated platinized microelectrode (B), and an enzyme-incorporated platinized microelectrode treated with albumin and glutaraldehyde (C).

sample as illustrated in Fig. 5. The output of a micro-enzyme electrode reached a steady state current in 3 s or less. The increase in the oxidizing current was caused by the oxidation of the hydrogen peroxide generated by immobilized glucose oxidase molecules. The response in Fig. 5 was measured repeatedly by changing the glucose concentration.

The change in sensor output was plotted versus glucose concentration to give a calibration curve for glucose as shown in Fig. 6. The lowest and highest detectable glucose concentrations were 0.5 μM and 10 mM,

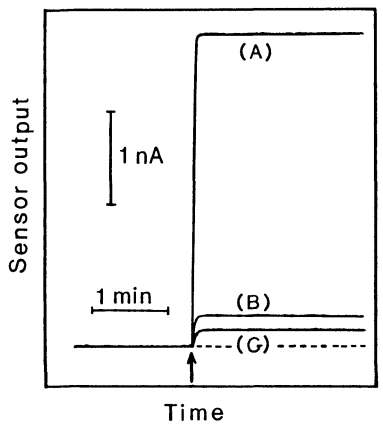

Fig. 5. Typical responses of a micro-enzyme electrode (diameter=50 μm). Glucose concentrations were 100 μM (A), 10 μM (B), and 5 μM (C).

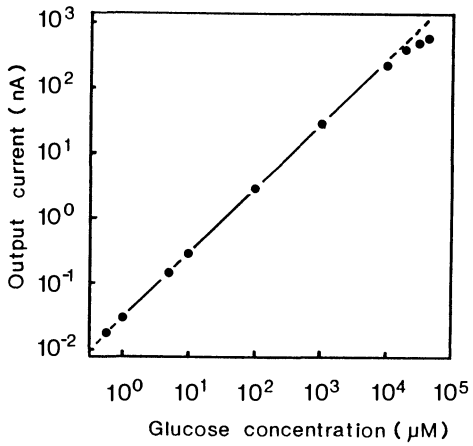

Fig. 6. Calibration curve for glucose with a micro-enzyme electrode (diameter=50 μm).

respectively. When the microenzyme electrode diameter is larger than 50 μm, the calibration curve and dynamic range of a given micro-enzyme electrode were not influenced by the size of a base platinum micro-electrode.

However, the 10 μm enzyme electrode showed a narrower dynamic range between 5 μM and 10 mM, although good linearity and rapid-response was observed within this range. Since the determination of 5 μM glucose sample caused a sensor output of only a few pA, the authors believe that a more sensitive recorder could make the 10 μm enzyme electrode more sensitive because of the high signal to noise ratio of the 10 μm enzyme electrode.

Three different enzyme electrodes (diameter: 10, 50, 200, 500 μm) prepared under different conditions were studied for the comparison of sensor characteristics such as response to 1 mM glucose and the Michelis-Menten constant with respect to the porosity of the platinized electrode and the electrode diameter. The calibration curves obtained by four enzyme electrodes allow the calculation of apparent Michaelis-Menten constants. These values are listed in Table 1. All the enzyme electrodes were prepared by following the galvanostatic conditions described in the experimental section. The charge, i.e., the product of reducing current and reducing time, needed for the platinization is also listed in Table 1. The relation between the peak current for hydrogen adsorption wave and the response to 1 mM glucose was compared for every enzyme electrode. One can understand that the electrode response to 1 mM glucose is related to the porosity of the platinized electrode where the enzyme molecules are immobilized. The relation was more clearly investigated by using three platinum electrodes of the same diameter (200 μm). Figure 7 shows the relation between the sensor response to 1 mM glucose and the total charge required for platinization.

The coefficients of variation for glucose analysis are also shown in Table 1. Here micro-enzyme electrodes prepared by using four different diameter electrodes were employed to evaluate the precision of the micro-enzyme sensors. The sensor response to 1 mM glucose was repeated studied. A micro-enzyme electrode prepared by greater reducing current for platinization showed greater response to 1 mM glucose. However,

Table 1. Relation between the Fabrication Conditions and the Characteristics of Micro-Enzyme Electrode

Fabrication condition		Characteristics of micro-enzyme electrode			
Electrode diameter	Peak height of H_2 adsorption wave/μA	Mean response to 1 mM glucose/nA	Detectable range	K_m	CV(N)
μm			M	mM	%
10	7	5.0	10^{-5}—5×10^{-2}	60	2.5(10)
50	20	29.2	5×10^{-7}— 10^{-2}	45	1.5(20)
200	65	166	5×10^{-7}— 10^{-2}	35	0.8(20)
500	105	278	5×10^{-7}— 10^{-2}	30	0.6(20)

The deposition currents for the platinization were −0.5 μA, −3 μA, −15 μA, and −60 μA for 10 μm, 50 μm, 200 μm, and 500 μm platinum electrode, respectively. And the deposition time was 5 min in every electrode.

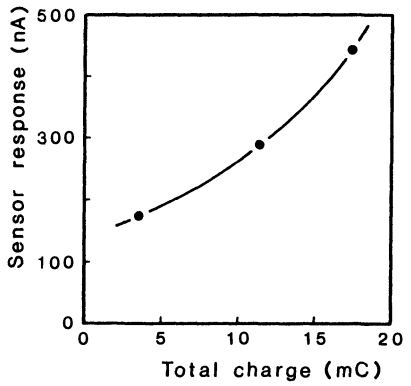

Fig. 7. The relation between the sensor response to 1 mM glucose and total charge required for the platinization. The diameter of the enzyme sensors is 200 μm, and the total current is shown in Coulomb.

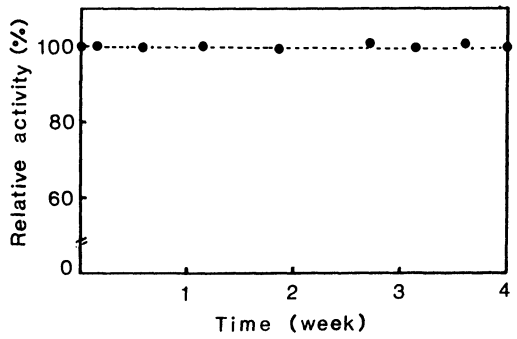

Fig. 8. Time stability of a typical micro-enzyme electrode (diameter=50 μm). The response of the micro-enzyme electrode (diameter=50 μm) was studied by the two injections of 1 mM glucose.

the microelectrodes which have greater output showed greater residual current. The mean response in Table 1 corresponds to the mean current increase when the same glucose sample (1 mM) was repeatedly determined, and the number of repeated analysis is shown in parenthesis.

Time Stability of Micro-Enzyme Electrode. The stability of the micro-enzyme electrode (diameter: 50 μm) was studied by measuring the sensor response to 1 mM glucose. The measuring conditions were the same as described in the above description. The enzyme electrode was kept in the refrigerator when not in use. The storage buffer was 0.1 M phosphate of pH 6.8. The sensor output on the first day was normalized to 100%.

Figure 8 is the time stability of one of the typical micro-enzyme electrode that was mainly stood in a refrigerator. On the 28th day the sensor output still demonstrated nearly 100% response, of which detailed reason is now being investigated. The time stability for an enzyme electrode that was repeatedly used was also studied. All the electrodes tested showed almost same response to the same glucose samples after six hundred injections.

The time-stability of the micro-enzyme electrode was improved by the crosslinking of the incorporated enzyme molecules by glutaraldehyde. The stability of the albumin membrane-coated enzyme electrode was almost the same as that of the glutaraldehyde-treated one. That fact suggests that the enzyme molecules after crosslinking are effectively retained on the microparticles because of the formation of conglomerate enzyme within the porous transducer matrix. On the other hand, without the glutaraldehyde treatment, the enzyme-incorporated electrode lost its activity gradually. The enzyme electrodes without glutaraldehyde treatment retained their activity of approximately 80% on the 28th day when they were kept in a refrigerator when not in use.

Discussion

The microfabrication technique described here is a unique approach by which method micro-enzyme electrodes are easily prepared in a simplified manner. The miniaturized enzyme electrode can be applied to the fabrication of a micro-biosensing device by which stationary trace glucose can be determined in 2 ms.[22] By micro-enzyme electrode the authors do not necessarily mean that the micro-enzyme electrode behaves as a conventional microvoltammetric electrode where the steady-state current is observed when the electrolysis rate is approximately equal to the rate of diffusion of molecules to the electrode surface.[20] Although the size of the electrode is in the range of a microelectrode (diameter=10 μm), the platinized electrode smaller than 10 μm in diameter is shown to behave as a macroelectrode as is shown in Fig. 2. The high sensitivity of the present enzyme electrodes can be explained by the behaviors as macroelectrodes. The smallest size of the enzyme electrode the authors have ever tried to fabricate is 10 μm, because of the difficulty in the preparation of the platinum wire. However, smaller enzyme electrode can be fabricated by either using a carbon fiber electrode or an electropolished platinum microelectrode on which surfaces platinization can also be easily carried out.

The main reason for the remarkable improvement of the long term stability by the bifunctional aldehyde treatment seems to have been caused by the crosslinking of the enzyme molecules, by which the polymerized enzyme can be retained stably in the micropores of the transducer electrode.

One of the advantages of the present fabrication technique is that the sensor response is easily controllable by selecting the current for platinization. Another advantage is the efficient transduction of biochemical signal to electric signal, since the porous surface provides efficient mass transfer from bulk solution to the electrode itself and the hydrogen peroxide generated within the electrode is efficiently oxidized to give sensor response, since the enzyme is embodied

with the porous matrix electrode. These can be the reasons of the fast response and the high sensitivity of the enzyme electrode.

The authors express their gratitude to Prof. William R. Heineman of the Department of Chemistry, University of Cincinnati, for his review of this manuscript and helpful suggestions throughout the course of this study.

(Received May 11, 1987)

The photochemical introduction of trifluoromethyl group with CF_3Br in aromatic and heteroaromatic rings was investigated for 9 compounds. Naphthalene, anthracene, anisole, *N*,*N*-dimethylaniline, ferrocene, benzo[*b*]thiophene, isoquinoline, and *N*-methylpyrrole gave trifluoromethylated products in 6.5—100% yields. In one step from uracil, a pharmacologically important 5-trifluoromethyluracil can be synthesized by this method in 11% yield. Based on the mechanistic study carried out for the naphthalene-CF_3Br-CH_3CN system, the reaction is found to proceed via the electron transfer from an excited singlet state of naphthalene to CF_3Br.

The introduction of trifluoromethyl group into aromatic and heteroaromatic compounds has been of recent interest,[1,2] because the strong electron-withdrawing ability and the high lipophilicity of the trifluoromethyl group will enhance the biological activity of the molecule. Several synthetic methods[3-16] including coupling reactions in the presence[3-8] and in the absence[9] of metal catalysts and several photochemical reactions[10-16] have been reported.

The photochemical trifluoromethylation hitherto reported requires expensive CF_3I[11,12,15,16] or hazardous[13,14] reagents so that a simple trifluoromethylation with a cheap, less hazardous and easy to handle reagent is needed. In view of this interest, we have undertaken a direct trifluoromethylation of aromatic and heteroaromatic compounds by a photochemical method using trifluoromethyl bromide, a cheap and easily available reagent.

We wish to report here the results of a one step photochemical trifluoromethylation of some aromatic and heteroaromatic compounds, together with the results of a mechanistic study of the excited states involved in the phototrifluoromethylation of these compounds.

Experimental

Materials. Bromotrifluoromethane was used as received from Japan Halon Co. Naphthalene (Wako Junyaku Co., G.R.) was recrystallized from ethanol. Anthracene (BDH Chemical Co., microanalytical reagent), *N*-methylpyrrole (Tokyo Kasei Co., G.R.), benzo[*b*]thiophene (Tokyo Kasei Co., G.R.), and ferrocene (Tokyo Kasei Co., G.R.) were used as purchased. Anisole (Wako Junyaku Co., G.R.), *N*,*N*-dimethylaniline (Junsei Yakuhin Co., G.R.), isoquinoline (Wako Junyaku Co., G.R.) were distilled under reduced pressure just before use. Uracil and 5-trifluoromethyluracil were supplied from Japan Halon Co. and were used as received. Acetonitrile (Wako Junyaku Co., G.R.) was dried over calcium hydride (Wako Junyaku Co., G.R.) and distilled twice in the presence of a small amount of phosphorus pentaoxide (Wako Junyaku Co., G.R.). Then the distillate was redistilled just before use with a 1 m Widmer distilling column in the presence of potassium carbonate (Junsei Yakuhin Co., G.R.). This distillate was used for photoreactions and measurements.

Measurements. IR-spectra were obtained by use of a Hitachi 260-50 grating spectrophotometer. ^1H NMR spectra were taken on a Hitachi R-22 (90 MHz) spectrometer or a JEOL-FX-200 (200 MHz) spectrometer. ^{19}F NMR spectra were obtained by using a Varian XL-100A spectrometer. GC-MS spectra were obtained by using JEOL JMA D-300 GC-MS spectrometer. Quantitative gas chromatography was performed on a Shimadzu GC-6A gas chromatograph, and preparative gas chromatography was done on a Shimadzu GC-5A gas chromatograph. UV-spectra were obtained on a Hitachi 228 spectrophotometer.

For the measurement of the fluorescence spectra, two sample solutions were prepared: one is the hexane solution of naphthalene (4.0×10^{-4} mol dm^{-3} deaerated with Ar by bubbling for 10 min), and the other is the similarly prepared hexane solution (4.0×10^{-3} mol dm^{-3}, deaerated with Ar) into which CF_3Br was bubbled for 10 min. The fluorescence spectra were recorded for these two solutions (excitation: 310 nm; recording wavelength range: 315—440 nm) on a Hitachi 650-60 fluorescence spectrophotometer.

Continuous Irradiation. An acetonitrile solution (170 cm^3) of aromatic or heteroaromatic compound (0.4—6.1 mmol) was irradiated in an immersion type photoreactor with a high pressure mercury lamp (a 100 W lamp of Taika Kogyo Co., with a pyrex jacket for water cooling) for 6 h under bubbling of CF_3Br (equipped with a cooling trap using Dry Ice-acetone at the outlet of the photoreactor).

In the cases of *N*-methylpyrrole and uracil the acetonitrile solutions of the substrates in a quartz tube (50 cm^3, equipped with a septum to introduce CF_3Br) was irradiated from outside of the tube with a low pressure mercury lamp (Riko-sha, UVL-160LA, 160 W) for 3 h.

Work-up Procedure. After the irradiation, water (ca. 300 cm^3) was added to the reaction mixture and the products were extracted with diethyl ether. The etherial solution was washed well with water to remove acetonitrile, then ether was removed under reduced pressure. The residual solid or liquid was dissolved in a small amount of diethyl ether and the etherial solution was submitted to preparative gas chromatography (for the photoproducts from naphthalene, 1-bromonaphthalene, anthracene, anisole, *N*-methylpyrrole, benzo[*b*]thiophene, and isoquinoline), or to column chromatography (for the photoproducts from ferrocene and *N*,*N*-dimethylaniline), or to thin-layer chromatography (for the photoproducts from uracil).

Isolation of the Products. Except for the photoproducts from uracil, the isolation of the trifluoromethylated products were all done by means of gas chromatography using a Shimadzu GC-5A (column, PEG-20M, 20%, 2 m, temp, 190 °C, for the photoproducts from naphthalene; PEG-20M, 5%, 2 m, temp, 230 °C, for the photoproducts from anthracene; PEG-20M, 20%, 2 m, temp, 130 °C, for the photoproducts from anisole; PEG-20M, 5%, 2 m, temp, 120 °C, for the photoproducts from *N,N*-dimethylaniline; OV-1, 5%, 2 m, temp, 160 °C, for the photoproducts from ferrocene; PEG-20M, 20%, 2 m, temp, 80 °C, for the photoproducts from *N*-methylpyrrole; PEG-20M, 20%, 2 m, temp, 190 °C, for the photoproducts from isoquinoline; and PEG-20M, 20%, 2 m, temp, 160 °C, for the photoproducts from benzo[*b*]thiophene). In the case of uracil the photoproduct was isolated by means of TLC (Merck, RP-18 F_{254}) and the quantitative analysis was done by using HPLC (Hitachi 655 liquid chromatograph, column: RP-18, solvent, CH_3CN-H_2O=3:7; monitoring wavelength, 254 nm; pressure, 3.5 kg cm^2) with 4-cyanopyridine as an internal standard.

Identification of the Photoproducts. Trifluoromethylnaphthalenes: 1- and 2-Trifluoromethylnaphthalene were obtained as a mixture (colorless oil, 153.5 mg, 0.78 mmol). ^{19}F NMR spectra of the mixture show one singlet ($CDCl_3$/$CFCl_3$, ϕ=−62.64) and one doublet peak ($CDCl_3$/$CFCl_3$, ϕ=−60.19, $J_{F\text{-}H}$=2 Hz). The latter peak is identical with that observed for 1-trifluoromethylnaphthalene by Matsui[7] (ϕ=−60.40, $J_{F\text{-}H^8}$=2 Hz). The chemical shifts of the two peaks were in nearly the same region as the reported ones[5] (ϕ=−60.6 for 2-CF_3, and −58.5 for 1-CF_3). The isomer ratio, 1-CF_3: 2-CF_3, calculated based on the peak area of ^{19}F NMR spectra was 78:22. Found: *m/z* 196.0492.

Trifluoromethylanthracenes: 9-, 1-, and 2-Trifluoromethylanthracene were obtained as a mixture (pale yellow oil, 19.6 mg, 0.08 mmol): ^{1}H NMR (200 MHz, $CDCl_3$) δ=7.45 (m, 4H, H^2, H^7, H^3, and H^6), 8.01 (d, J=8.0 Hz, 2H, H^5 and H^4), 8.51 (d, J=10 Hz, 2H, H^1 and H^8) and 8.59 (s, 1H, H^{10}); ^{19}F NMR ($CDCl_3$/$CFCl_3$) ϕ=−48.91 (t, $J_{F\text{-}H}$=1.5 Hz, 9-CF_3), −60.73 (d, $J_{F\text{-}H}$=2.0 Hz, 1-CF_3), and −63.20 (s, 2-CF_3). The ratio of the isomer, 9-CF_3: 1-CF_3: 2-CF_3, calculated based on the peak area of ^{19}F NMR spectra is 85:12:3. GC-MS (PEG-20M, 5%, 1 m, 200 °C, 70 eV) (rel intensity) 246 (M^+, 100), 227 ($(M-F)^+$, 7.4), 196 ($(M-CF_2)^+$, 21.4), and 177 ($(M-CF_3)^+$, 1.8). Found: *m/z* 246.0656. Calcd for $C_{15}H_9F_3$: M, 246.0657. Based on the GC-MS data a small amount of bis(trifluoromethyl)anthracene was also found.

Trifluoromethylanisole: 2-Trifluoromethylanisole was obtained as a colorless liquid substance (70 mg, 0.40 mmol): IR (neat) 3080, 2960, 2940, and 2840 cm^{-1} ($\nu_{C\text{-}H}$), 1320, 1170, and 1120 cm^{-1} ($\nu_{C\text{-}F}$); 1060 and 1040 ($\nu_{C\text{-}O\text{-}C}$), and 808, 760, and 740 cm^{-1} (out of plane C-H stretching); ^{1}H NMR (90 MHz, $CDCl_3$) δ=3.89 (s, 3H, -OCH_3), 6.96—7.03 (m, 2H, H^3 and H^5), and 7.57 (m, 2H, H^4 and H^6); GC-MS (PEG-20M, 20%, 1 m, 110 °C, 70 eV) (*m/z*, rel intensity) 176 (M^+, 100), 157 ($(M-F)^+$, 4.4), 145 ($(M-OCH_3)^+$, 17.0), 126 ($(M-CF_2)^+$, 5.6), and 107 ($(M-CF_3)^+$, 3.6). Found: *m/z* 176.0453. Calcd for $C_8H_7OF_3$: M, 176.0448.

3-Trifluoromethylanisole was obtained as a colorless liquid substance (27.5 mg, 0.156 mmol): IR (neat) 3080, 3020, 2970, and 2850 cm^{-1} ($\nu_{C\text{-}H}$), 1300, 1170, and 1130 cm^{-1} ($\nu_{C\text{-}F}$), 1070 and 1040 cm^{-1} ($\nu_{C\text{-}O\text{-}C}$), 880, 860, and 755 cm^{-1} (out of plane C-H stretching); ^{1}H NMR (90 MHz, $CDCl_3$) δ=3.80 (s, 3H, -OCH_3), 7.08—7.43 (m, 4H, H^2, H^4, H^5, and H^6); GC-MS (PEG-20M, 20%, 1 m, 110 °C, 70 eV) (*m/z*, rel intensity) 176 (M^+, 100), 157 ($(M-F)^+$, 8.3), 145 ($(M-OCH_3)^+$, 23.0), 126 ($(M-CF_2)^+$, 4.1), and 107 ($(M-CF_3)^+$, 2.4). Found: *m/z* 176.0452. Calcd for $C_8H_7OF_3$: M, 176.0448.

Trifluoromethyl-*N,N*-dimethylanilines: 2-Trifluoromethyl-*N,N*-dimethylaniline was obtained as a colorless liquid substance (47.6 mg, 0.252 mmol): IR (neat) 3100, 2950, and 2850 cm^{-1} ($\nu_{C\text{-}H}$), 1320, 1180, and 1110 cm^{-1} ($\nu_{C\text{-}F}$), 770 cm^{-1} (out of plane C-H stretching of 1,2-disubstituted benzene); ^{1}H NMR (90 MHz, $CDCl_3$) δ=2.73 (s, 6H, -$N(CH_3)_2$), 7.02—7.79 (m, 4H, H^3, H^4, H^5, and H^6); GC-MS (PEG-20M, 5%, 1 m, 100 °C, 70 eV) (*m/z*, rel intensity) 189 (M^+, 63), 188 ($(M-H)^+$, 100), 170 ($(M-F)^+$, 3.2), 145 ($(M-N(CH_3)_2)^+$, 10.6), 138 ($(M-CF_2)^+$, 3.5), 127 ($(M-N(CH_3)_2-F+H)^+$, 14), 120 ($(M-CF_3)^+$, 2.2), and 95 ($(M-N(CH_3)_2-CF_2)^+$, 3.2). Found: *m/z* 189.0764. Calcd for $C_9H_{10}NF_3$: M, 189.0766.

4-Trifluoromethyl-*N,N*-dimethylaniline was obtained as a white crystalline solid (92.4 mg, 0.489 mmol): mp 69.0—69.4 °C (lit.[18] 70.3—70.8 °C). Found: *m/z* 189.0763.

Bis(4-dimethylaminophenyl)methane was obtained as a white crystalline solid (142 mg, 0.559 mmol): mp 86.5—87 °C (lit.[19] 88.5—89.5 °C). ^{1}H NMR spectra of this compound are identical with the reported spectra.[19]

Trifluoromethylferrocene: This compound was obtained as a yellow liquid substance (115.6 mg, 0.455 mmol): IR (KBr) 3100, 2950, 2930, and 2860 cm^{-1} ($\nu_{C\text{-}H}$), 1310, 1145, and 1120 cm^{-1} ($\nu_{C\text{-}F}$), 1100, 1020, and 1000 cm^{-1} (monosubstituted ferrocene); ^{1}H NMR (90 MHz, $CDCl_3$) δ=4.15 (m, 7H, H_β to -CF_3, and unsubstituted ring 5H), and 4.37 (t, 2H, H_α to -CF_3); GC-MS (PEG-20M, 5%, 1 m, 140 °C, 70 eV) (*m/z*, rel intensity) 254 (M^+, 54), 235 ($(M-F)^+$, 3.6), 189 ($(M-C_5H_5)^+$, 4.8), 140 ($(M-C_5H_4CF_2)^+$, 75), and 121 ($(M-C_5H_4CF_3)^+$, 3.0). Found: *m/z* 254.0001. Calcd for $C_{11}H_9F_3Fe$: M, 254.0005.

2-Trifluoromethyl-*N*-methylpyrrole: The compound was obtained as a colorless oily substance (51 mg, 0.34 mmol). The ^{1}H NMR spectral data of this compound are consistent with those reported by Kobayashi.[12]

2-Trifluoromethylbenzo[*b*]thiophenes: 2-Trifluoromethylbenzo[*b*]thiophene was obtained as a white crystalline solid (18.2 mg, 0.09 mmol): mp 49.2—49.8 °C; IR (KBr) 3080, 2940, and 2870 cm^{-1} ($\nu_{C\text{-}H}$), 1310, 1170, and 1120 cm^{-1} ($\nu_{C\text{-}F}$), 880, 860, 760, and 740 cm^{-1} (out of plane C-H bending); ^{1}H NMR (200 MHz, $CDCl_3$) δ=7.43—7.48 (m, 2H, H^5 and H^6), 7.70 (s, 1H, H^3), and 7.85—7.91 (m, 2H, H^4 and H^7); GC-MS (PEG-20M, 5%, 1 m, 90 °C, 70 eV) (*m/z*, rel intensity) 202 (M^+, 100), 201 ($(M-H)^+$, 7.4), 183 ($(M-F)^+$, 29.2), 152 ($(M-CF_2)^+$, 20.0), and 101 ($(M-S-CF_3)^+$, 7.6). Found: *m/z* 202.0058. Calcd for $C_9H_5SF_3$: M, 202.0063.

3-Trifluoromethylbenzo[*b*]thiophene was obtained as a colorless oil (6 mg, 0.03 mmol): IR (neat) 3120, 3080, 2930, and 2870 cm^{-1} ($\nu_{C\text{-}H}$), 1320, 1170, and 1120 cm^{-1} ($\nu_{C\text{-}F}$), 850, 810, 760 and 740 cm^{-1} (out of plane C-H bending); ^{1}H NMR (200 MHz, $CDCl_3$) δ=7.43—7.49 (m, 2H, H^5 and H^6), 7.87—7.94 (m, 2H, H^4 and H^7), and 7.91 (s, 1H, H^2); GC-MS (PEG-20M, 5%, 1 m, 90 °C, 70 eV) (*m/z*, rel intensity) 202 (M^+, 100), 201 ($(M-H)^+$, 10.4), 183 ($(M-F)^+$, 28.6), 152 ($(M-CF_2)^+$, 17.0), and 101 ($(M-S-CF_3)^+$, 6.4). Found: *m/z* 202.0060. Calcd for $C_9H_5SF_3$: M, 202.0063.

4-Trifluoromethylbenzo[*b*]thiophene was obtained as a colorless oil (17 mg, 0.084 mmol): IR (neat) 3100 and 2940 cm^{-1} ($\nu_{C\text{-}H}$), 1310, 1170, and 1120 cm^{-1} ($\nu_{C\text{-}F}$), 870, 840, 780, and 710 cm^{-1} (out of plane C-H bending); ^{1}H NMR (200 MHz, $CDCl_3$) δ=7.38—7.70 (m, 4H, H^2, H^3, H^5, and H^6), and

8.06 (d, J=8 Hz, 1H, H^7); GC-MS (PEG-20M, 5%, 1 m, 90 °C, 70 eV) (m/z, rel intensity) 202 (M^+, 100), 183 ($(M-F)^+$, 22.4), 152 ($(M-CF_2)^+$, 20.6), 133 ($(M-CF_3)^+$, 3.4), 101 ($(M-S-CF_3)^+$, 7.1), and 89 ($C_6H_4CH^+$, 7.7). Found: m/z 202.0064. Calcd for $C_9H_5SF_3$: M, 202.0063.

7-Trifluoromethylbenzo[b]thiophene was obtained as a colorless oil (34 mg, 0.168 mmol): IR (neat) 3100 and 2940 cm^{-1} (ν_{C-H}), 1310, 1170, and 1120 cm^{-1} (ν_{C-H}), 870, 840, 800, 780, and 710 cm^{-1} (out of plane C-H bendiing); ^1H NMR (200 MHz, $CDCl_3$) δ=7.33—7.67 (m, 4H, H^2, H^3, H^5, and H^6), and 7.94 (d, J=8 Hz, 1H, H^4); GC-MS (PEG-20M, 10%, 2 m, 120 °C, 70 eV) (m/z, rel intensity) 202 (M^+, 100), 183 ($(M-F)^+$, 22.6), 152 ($(M-CF_2)^+$, 15.8), 133 ($(M-CF_3)^+$, 3.4), 101 ($(M-S-CF_3)^+$, 6.1), and 89 ($C_6H_4CH^+$, 6.6). Found: m/z 202.0049. Calcd for $C_9H_5SF_3$: M, 202.0063.

Trifluoromethylisoquinolines: The compounds were obtained by means of repeated preparative gas chromatography.

1-Trifluoromethylisoquinoline was obtained as a colorless liquid substance (3.1 mg, 0.015 mmol): IR (neat) 3040 cm^{-1} (ν_{C-H}), 1310, 1170, and 1120 cm^{-1} (ν_{C-F}), 980, 940, 820, 790, and 740 cm^{-1} (out of plane C-H bending); ^1H NMR (200 MHz, $CDCl_3$) δ=7.58—8.20 (m, 5H, H^4, H^5 H^6 and H^8), and 8.60 (d, J=5.5 Hz, 1H, H^3); GC-MS (PEG-20M, 5%, 1 m, 130 °C, 70 eV) (m/z, rel intensity) 197 (M^+, 100), 196 ($(M-H)^+$, 9.9), 178 ($(M-F)^+$, 11.7), 147 ($(M-CF_2)^+$, 25.4), and 128 ($(M-CF_3)^+$, 7.2). Found: m/z 197.0451. Calcd for $C_{10}H_6NF_3$: M, 197.0452.

4-Trifluoromethylisoquinoline was obtained as a colorless liquid substance (3.4 mg, 0.017 mmol): IR (neat) 3040 cm^{-1} (ν_{C-H}), 1320, 1170, and 1120 cm^{-1} (ν_{C-F}), 980, 930, 900, 820, 780, and 730 cm^{-1} (out of plane C-H bending); GC-MS (PEG-20M, 5%, 1 m, 130 °C, 70 eV) (m/z, rel intensity) 197 (M^+, 100), 196 ($(M-H)^+$, 10.2), 178 ($(M-F)^+$, 12.7), 147 ($(M-CF_2)^+$, 27.1), and 128 ($(M-CF_3)^+$, 23.3). Found: m/z 197.0449. Calcd for $C_{10}H_6NF_3$: M, 197.0452.

5-Trifluoromethylisoquinoline was obtained as a colorless liquid substance (17.4 mg, 0.088 mmol): ^1H NMR (200 MHz, $CDCl_3$) δ=7.39—8.20 (m, 5H, H^3, H^4, H^6, H^7, and H^8), and 8.94 (d, J=3.1 Hz, 1H, H^1). The compound readily converted to an unknown product in air.

8-Trifluoromethylisoquinoline was obtained as a colorless liquid substance (4.5 mg, 0.023 mmol): IR (neat) 3050 cm^{-1} (ν_{C-H}), 1310, 1180, and 1120 cm^{-1} (ν_{C-F}), 980, 940, 830, 810, 790, and 740 cm^{-1} (out of plane C-H bending); ^1H NMR (200 MHz, $CDCl_3$) δ=7.38—8.19 (m, 5H, H^3 H^4, H^5, H^6, and H^7), and 8.93 (dd, $J_{H^1H^3}$=4.3 Hz, J_{F-H^1}=1.5 Hz, 1H, H^1); GC-MS (PEG-20M, 5%, 1 m, 130 °C, 70 eV) (m/z, rel intensity) 197 (M^+, 100), 196 ($(M-H)^+$, 5.1), 178 ($(M-F)^+$, 11.7), 147 ($(M-CF_2)^+$, 17.5), and 128 ($(M-CF_3)^+$, 33.0). Found: m/z 197.0452. Calcd for $C_{10}H_6NF_3$: M, 197.0452.

5-Trifluoromethyluracil: The compound was isolated from the second fraction of TLC (Merck, RP-18 F_{254}, developing solvent: CH_3CN-H_2O=4:6). ^1H NMR spectra ($CDCl_3$, δ=7.78, s, H^6) and mass spectra (70 eV, m/z 180 (M^+)) are identical with those of the authentic sample.

Flash Photolysis. An acetonitrile solution of naphthalene (1.0×10^{-3} mol dm^{-3}, 5 cm^3) in a quartz cell (1 cm×1 cm, equipped with a solvent reservoir) was degassed by repeated (4 times) freeze-pump-thaw cycles, and the glass neck was sealed. The sample solution containing CF_3Br was prepared by introduction of CF_3Br into the degassed solution prepared as described above using needle and septum. These sample solutions were irradiated with a pulse of 266 nm light from a Nd-YAG laser and the transient absorption was monitored in the wavelength region of 360—670 nm.

Calculations by means of CNDO/2. Th CNDO/2 calculations of naphthalene, benzo[b]thiophene, and isoquinoline were carried out at Tokyo University Computer Center according to the Tokyo University Computer Center Library Program YT/TC/CB03 prepared by J.A. Pople, D.L. Beveridge, and P.A. Dobosh (Q.C.P.E. 141) arranged by H. Kihara, T. Fujikawa, and T. Aoyama.

Results and Discussion

Photo-Trifluoromethylation of Aromatic Compounds. The acetonitrile solution of aromatic compound was irradiated with a high-pressure mercury lamp for 1.5—6 h under bubbling of CF_3Br. Naphthalene, anthracene, anisole, N,N-dimethylaniline, and ferrocene gave trifluoromethylated products in 6.5—100% yields (Table 1).

The photo-trifluoromethylation of naphthalene occurs quantitatively and the ratio of the 1- and 2-trifluoromethylnaphthalene is 78:22.

In the case of anisole, 2- and 3-trifluoromethylanisole were obtained in 20 and 8% yields, respectively. Although 4-trifluoromethylanisole was detected by

Table 1. Photo-Trifluoromethylation of Some Aromatic Compounds with CF_3Br

Aromatic compound		Solvent[b]	Irrad. time	Conversion	Substituent introduced	Yield[c]
10^{-3} mol			h	%		%
Naphthalene	(6.0)	CH_3CN	6	13	1-CF_3	78[d]
					2-CF_3	22[d]
Anthracene	(0.6)	CH_3CN	1.5	16	9-CF_3	70[d]
					1-CF_3	10[d]
					2-CF_3	3[d]
Anisole	(6.1)	CH_3CN[a]	6	32	2-CF_3	20
					3-CF_3	8
N,N-Dimethylaniline	(6.1)	CH_3CN[a]	1.5	77	2-CF_3	5.5
					4-CF_3	11
					(p-Me_2N-C_6H_4)$_2$-CH_2	12
Ferrocene	(5.4)	CH_3CN	6	19	1-CF_3	43

a) Sodium acetate (2.4 mmol) was added. b) 170 cm^3. c) Yields are calculated based on the consumed aromatic compounds. d) Calculated based on the peak area of ^{19}F NMR spectra.

Table 2. Photo-Trifluoromethylation of Some Heteroaromatic Compounds with CF_3Br

Heteroaromatic compound		Solvent[b]	Irrad. time	Conversion	Substituent introduced	Yield[c]
10^{-3} mol			h	%		%
N-Methylpyrrole	(6.0)	CH_3CN[a]	3	85	2-CF_3	6.5
Benzo[*b*]thiophene	(6.0)	CH_3CN	6	20	2-CF_3	7.5
					3-CF_3	2.5
					4-CF_3	7.0
					7-CF_3	14
Isoquinoline	(6.0)	CH_3CN	6	18	1-CF_3	1.5
					4-CF_3	1.6
					5-CF_3	8.2
					8-CF_3	2.1
Uracil	(0.1)	CH_3CN	6	56	5-CF_3	11

a) Sodium acetate (2.4 mmol) was added. b) 170 cm^3. c) Yields are calculate based on the consumed starting material.

GC-MS analysis, the isolation of this isomer was not possible because of the contamination of the recovered anisole.

The photo-trifluoromethylation of *N,N*-dimethylaniline afforded 2- and 4-trifluoromethyl-*N,N*-dimethylaniline in 5.5 and 11% yields, respectively. Together with the trifluoromethylated products bis(4-dimethylaminophenyl)methane[19] was obtained in 12% yield.

The photo-trifluoromethylation of ferrocene gave selectively 1-trifluoromethylferrocene in 43% yield.

Photo-Trifluoromethylation of Heteroaromatic Compounds. In Table 2 are shown the results of the photo-trifluoromethylation of three heteroaromatic compounds and uracil.

In the case of *N*-methylpyrrole, only 2-trifluoromethyl-*N*-methylpyrrole was obtained in 6.5% yield.

In the case of benzo[*b*]thiophene and isoquinoline, the photo-trifluoromethylation occurs both in the heteroaromatic ring and benzene ring. The site reactivity of these compounds will be discussed later.

5-Fluorouracil has attracted much attention because of its significant tumor-inhibition activity and one-step fluorination of uracil has been developed.[1] However, little has been investigated about the biological activities of 5-trifluoromethyluracil, which is similar to 5-fluorouracil, because of difficulties of preparation of the compound.[20] Recently a convenient synthetic method of 5-trifluoromethyluracil has been reported by Fuchikami.[21] The convenient one-step trifluoromethylation of uracil might be possible if this photochemical trifluoromethylation can be applied for uracil. The photo-trifluoromethylation of uracil gave 5-trifluoromethyluracil in 11% yield.

Mechanistic Study on the Photo-Trifluoromethylation of Naphthalene. The excited state involved in the photo-trifluoromethylation of the aromatic compounds was examined using the naphthalene-CF_3Br-CH_3CN system, since the emission and T-T absorption spectra of naphthalene have been well-investigated.[22]

On the basis of the fact that the photoreaction proceeds under the irradiation with the light of wavelength longer than 300 nm, which is not absorbed by CF_3Br, the excited states which initiate the reaction can be considered as follows: (1) an excited state of a CT complex which is formed between naphthalene and CF_3Br in the ground state, and (2) the excited singlet state or the excited triplet state of naphthalene.

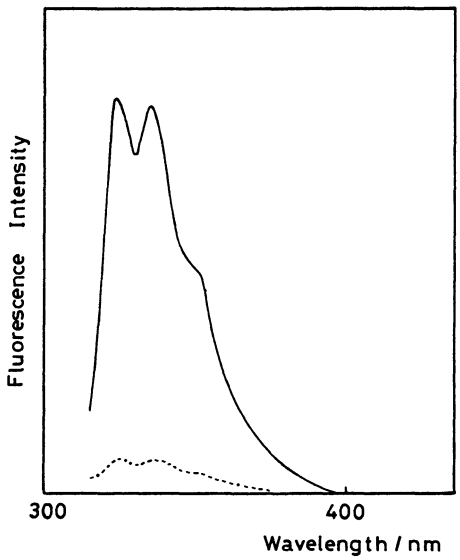

Fig. 1. Fluorescence spectra of naphthalene (4×10^{-4} mol dm^{-3} in CH_3CN) (excitation: 310 nm). (——): in the absence of CF_3Br, (------): in the presence of CF_3Br.

The first possibility can be excluded on the basis of the following results: the careful examination of the independently measured UV-spectra of naphthalene and CF_3Br in acetonitrile and those of the mixture of them in the same solvent shows no indication of the formation of CT complex between the two components in the ground state. In the cases of other aromatic and heteroaromatic compounds used in this photo-trifluoromethylation, except for uracil and *N*-methylpyrrole, similar results were obtained.

One of the second possibilities, in which the excited triplet state is involved, can also be excluded, based on

the following results: (1) the fluorescence intensity of naphthalene is strongly lowered by addition of CF_3Br (Fig. 1), (2) no increment of T-T absorption intensity was observed in the system containing CF_3Br (Fig. 2, —●—) compared to the system without CF_3Br (Fig. 2, ···●···), (3) the energy required for cleaving C-Br bond of CF_3Br (289 kJ mol^{-1})[23] is higher than the triplet energy of naphthalene (E_T=254 kJ mol^{-1}).[24]

In order to obtain further evidence for the excited states and reactive intermediates involved in this reaction, flash photolysis experiments (with 266 nm light from Nd-YAG laser) were carried out for the naphthalene-CF_3Br system.

The transient absorption spectra at 50—100 ns after a flash and their assignments[25d] are shown in Fig. 2. The lifetimes of fluorescence and $S_n \leftarrow S_1$ absorption are also shown in Table 3. The results obtained from flash photolysis experiments are as follows: (1) in the presence of CF_3Br, the lifetimes of fluorescence are

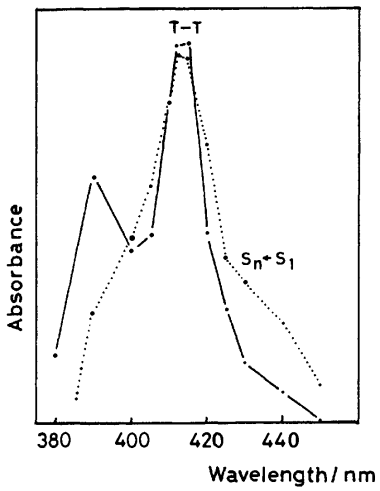

Fig. 2. Transient absorption spectra of naphthalene (1×10^{-3} mol dm^{-3} in CH_3CN). Irradiation: 266 nm light from Nd-YAG laser. (····●····): in the absence of CF_3Br, (—●—): in the presence of CF_3Br. 405—420 nm: T-T absorption; 420—450 nm: $S_n \leftarrow S_1$ absorption.[25d]

agreed with those of $S_n \leftarrow S_1$ absorption, (2) no new absorption which rises with the same rate as that of fluorescence decay was observed under this flash photolysis conditions, and (3) the intensity of T-T absorption was unchanged when CF_3Br was introduced and the T-T absorption decays with a second order rate constant (T-T annihilation: $k/\varepsilon l=(1.0\pm0.1)\times10^{-5}$ s^{-1}) both in the presence and in the absence of CF_3Br.

These results indicate that excited singlet state of naphthalene initiates the reaction. No new absorption which can be ascribed to an exciplex of naphthalene and CF_3Br, a cation radical of naphthalene,[25a-c] or to the CF_3 adduct to naphthalene formed by the addition of $\cdot CF_3$ to the cation radical of naphthalene was observed. These facts indicate that the process between the interaction of the singlet state of naphthalene with the ground state of CF_3Br and the product formation are so rapid that transient spectra of intermediates are not observed under our experimental conditions. However, an electron-transfer process from the excited singlet state of naphthalene to CF_3Br can be postulated based on the approximate oxidation potential of the excited singlet state of naphthalene (−2.45 V vs. SCE)[26] and the reduction potential of CF_3Br (−0.92 V vs. SCE) estimated from the reported values of CF_2BrCF_2Br,[27] since this process is an exothermic one from an energetic point of view ($\Delta G_{et}=E^{ox}(D^+/D)-E^{red}(A/A^-)-E_{0\text{-}0}-C<0$).[28]

As the oxidation potentials of excited singlet state of anthracene,[26] anisole,[26] isoquinoline,[27] and aniline[26] are all lower than −2.0 V (vs. SCE), the similar energetic relations can be considered for these compounds. On the basis of the results described above, the most probable reaction pathway for the photo-trifluoromethylation of naphthalene can be considered as illustrated in Scheme 1.

Site Reactivities of Naphthalene, Benzo[*b*]thiophene, and Isoquinoline. As discussed in the reaction mechanism, the photo-trifluoromethylation of naphthalene proceeds via the electron transfer from the excited singlet state of naphthalene to the ground state-CF_3Br to give a cation radical of substrate and

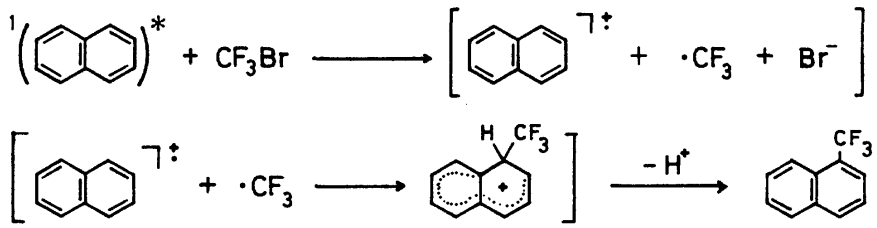

Scheme 1.

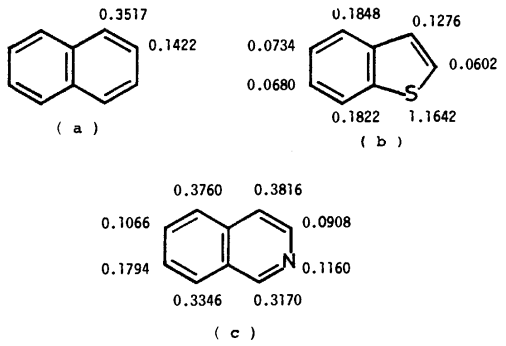

Fig. 3. HOMO Electron densities of naphthalene(a), benzo[*b*]thiophene(b), and isoquinoline(c).

a trifluoromethyl radical. The orientation of the trifluoromethylation should be determined by the succeeding process: the combination of the radical cation and $\cdot CF_3$. Thus, the site reactivities of the trifluoromethylation would be correlated with the densities of unpaired electron in HOMO orbital of the substrate. The HOMO electron densities of naphthalene, benzo[*b*]thiophene, and isoquinoline calculated by CNDO/2 method are shown in Fig. 3. In the case of benzo[*b*]-thiophene, a good correlation between the site selectivity and the electron densities in HOMO was obtained: the 4- and 7-positions which are in the benzene ring and 3-position in the heteroaromatic ring with higher electron densities are trifluoromethylated.

In the case of isoquinoline, a similar tendency is found: The sites where the higher electron density in HOMO orbital is found(1-, 4-, 5-, and 8-positions) are preferentially trifluoromethylated.

In the case of naphthalene, 1-position where the higher electron density in HOMO orbital was found is preferentially trifluoromethylated. These results also support the reaction mechanism in which an electron transfers from the excited singlet state of substrate to CF_3Br and then forms a cation radical of the substrate and a $\cdot CF_3$ radical.

Mechanistic Study on the Photo-Trifluoromethylation of *N*-Methylpyrrole and Uracil. In the cases of *N*-methylpyrrole and uracil, on the other hand, the excitation of the charge transfer complexes between the substrates and CF_3Br initiates the reaction. The UV-spectra of *N*-methylpyrrole and uracil in acetonitrile solutions to which CF_3Br was introduced showed increments of absorptions in the wavelength region of 300—500 nm. These absorptions could not be observed in the spectra measured independently for each of the components. When the photo-trifluoromethylation of *N*-methylpyrrole was carried out using a low pressure mercury lamp (16 W, 3 h) only a trace of trifluoromethylated product was obtained (conversion: 99%) and the decomposition of the substrate occurred, whereas the irradiation of the *N*-methylpyrrole-CF_3Br-CH_3CN system with a high pressure mercury lamp afforded 6.5% of 2-trifluoromethyl-*N*-methylpyrrole (conversion: 85%). In the case of uracil, the similar effect was also observed. In contrast to the irradiation with a high pressure mercury lamp (5-trifluoromethyluracil: 11%, conversion: 56%), the irradiation of the uracil-CF_3Br-CH_3CN system with a low pressure mercury lamp (16 W, 3 h) brought about the lowering of the yield of trifluoromethylated product (6.4%, conversion: 56%) accompanied by the decomposition of uracil. These results indicate that the direct excitation of *N*-methylpyrrole and uracil using 254 nm light brings about decomposition, whereas the excitation of the charge transfer complexes between the substrate and CF_3Br using the light of wavelength longer than 300 nm affords the trifluoromethylated products. The results described above seemed to suggest that in these two cases the reaction proceeds via the mechanism different from that considered for naphthalene. However, the reason for the difference of these mechanisms in the same type of reactions is not clear.

We thank Dr. Masao Onda of Sophia University for the assistance for the CNDO/2 calculation and Professor Sumio Tokita of Saitama University for sending us the geometrical data of benzo[*b*]thiophene and isoquinoline. We also thank Dr. Hiromichi Kono of Japan Halon Co. for supplying CF_3Br, uracil, and 5-trifluoromethyluracil and Dr. Mitsutoshi Tanimoto of Sagami Chemical Research Center for the measurement of ^{19}F NMR.

(Received January 20, 1988)

Mesobiliverdin IXα dimethyl ester (**7**) was obtained by hydrogenation of protobiliverdin IXα dimethyl ester (**8**). Zinc 5-oxamesoporphyrin IX dimethyl ester tetrafluoroborate (**6**) was prepared by the cyclization of **7** with zinc acetate in acetic anhydride followed by a treatment with aqueous sodium tetrafluoroborate. Bis(pyridine) mesoverdohemochrome IXα dimethyl ester (**4**) was obtained by the cyclization of **7** with both iron(II) sulfate and iron(III) chloride in acetic anhydride containing a small amount of pyridine. Bis(tosylmethyl isocyanide) mesoverdohemochrome IXα dimethyl ester (**5**) was prepared by the addition of excess tosylmethyl isocyanide ($TsCH_2NC$) to **4**. Both **4** and **5** reacted with ammonia to give iron(III) 5-azamesoporphyrin IX dimethyl ester (**10**). The Mössbauer spectra of bis(pyridine) verdohemochromes (**4**, **13**, and **14**) showed doublet peaks having parameters of δ=0.41—0.43 mm s^{-1} and ΔE_Q=1.24—1.26 mm s^{-1}, indicating that the oxidation states of the central irons of these complexes are iron(II). Bis($TsCH_2NC$) verdohemochromes (**5**, **15**, and **17**) showed single peaks having parameters of δ=0.21—0.28 mm s^{-1}. Unstable intermediate and stable final bis($TsCH_2NC$) octaethyl verdohemochromes, obtained by the addition of $TsCH_2NC$ to **4**, were compared with the ^{1}H NMR and Mössbauer spectra.

Heme oxygenase catalyzes the oxidative cleavage of the endogenous heme (protoheme IX) to give a blue pigment, biliverdin IXα, in both humans and many animals;[1] the latter is ultimately reduced enzymatically to bilirubin IXα.[2] Verdohemochrome IX (5-oxaprotoporphyriniron(II) complex) was posturated as being an intermediate in the reaction process.[1b,3,4] Verdohemochromes are obtained by a coupled oxidation, termed by Lemberg et al.,[3] of the corresponding hemes with oxygen in the presence of ascorbate in pyridine solution.[5] Because of having no labile vinyl group, mesohemin IX dimethyl ester (**1**) is used as a model compound for the elucidation of the reaction mechanism; a coupled oxidation of **1** with ascorbic acid in aqueous pyridine solution under air gives a mixture of mesoverdohemochromes (α, β, γ, and δ) [bis(pyridine)iron(II) 5-, 10-, 15-, and 20-oxamesoporphyrin complexes]. The mixture gives four mesobiliverdin IX isomers (α, β, γ, and δ)[6] after successive treatments with KOH–MeOH and mineral acid. Many attempts to isolate the four verdohemochrome isomers from the mixture obtained by the coupled oxidation were unsuccessful.

The oxidation state of the central iron of verdohemochromes obtained by a coupled oxidation of the corresponding hemins has been assigned to be iron(II).[7] Jackson et al.[8] obtained mesoverdohemin IXα dimethyl ester (**2**) (iron(III) 15-oxamesoporphyrin IX chloride dimethyl ester) by a reaction of β-hydroxymesohemin IX dimethyl ester (**3**) with oxygen in pyridine. The absorption spectrum of (**2**) was, however, similar to that of a mixture of mesoverdohemochrome IX isomers obtained by a coupled oxidation of mesohemin IX dimethyl ester.[9]

In this paper, we report on the preparation of bis(pyridine)-(**4**), and bis(tosylmethyl isocyanide) mesoverdohemochrome IXα dimethyl ester (**5**). The preparation of zinc 5-oxamesoporphyrin IX dimethyl ester (**6**) is also reported for a comparison of its ^{1}H NMR and FAB mass spectra with those of **4** and **5**. Furthermore, the oxidation state of the central iron of mesoverdohemochrome IXα and related porphyrins will be discussed in more detail in terms of Mössbauer, ^{1}H NMR, and electronic absorption spectroscopies.

Results and Discussion

Preparations of Zinc 5-Oxamesoporphyrin IX Dimethyl Ester (6) and Bis(pyridine)- (4) and Bis(tosylmethyl isocyanide) Mesoverdohemochrome IXα Dimethyl Ester (5). Metal porphyrins **4**, **5**, and **6** were prepared by a ring closure of mesobiliverdin IXα dimethyl ester (**7**) with corresponding metal ions. Previously, mesobiliverdin IXα was obtained by the oxidation of *d*-urobilin IXα under air[10] and by the oxidation of mesobilirubin IXα with iron(III) chloride.[11] In this study, compound **7** was obtained by the hydrogenation of biliverdin IXα dimethyl ester (**8**) according to a method of Muir and Neuberger;[12] this method was used for the preparation of mesoporphyrin IX from protoporphyrin IX.

Hydrogenation of biliverdin IXα dimethyl ester (**8**) gave compound **7**; the ^{1}H NMR spectrum of compound **7** showed the proton signals of two ethyl groups and three *meso*-methine groups (Table 1). The EI mass spectrum of **7** showed a molecular ion peak at *m/z* 614 (base peak). Compound **7** was heated together with $Zn(OAc)_2$ in acetic anhydride at 120 °C under argon, followed by a treatment with an aqueous $NaBF_4$ solution to give zinc 5-oxamesoporphyrin IX dimethyl ester tetrafluoroborate (**6**). The oxamesoporphyrin structure of **6** was supported by the peaks at *m/z* 659 (60.3% of base peak at *m/z* 140), 661 (26.7%), and 663 (24.7%) in FAB mass spectrum, which corre-

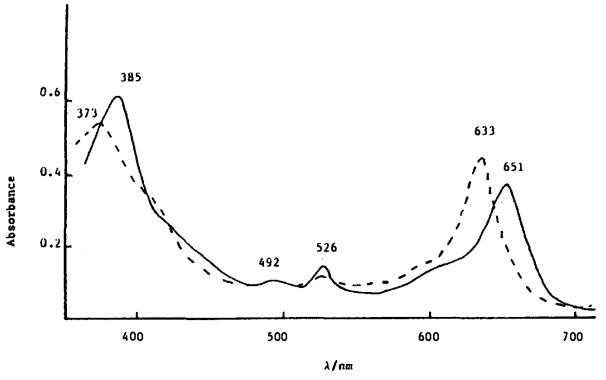

Fig. 1. Absorption spectra (CH_2Cl_2) of the (——) bis(pyridine) (**4**) (1.4×10^{-5} M) and (----) bis($TsCH_2NC$)iron(II) 5-oxamesoporphyrin IX dimethyl ester (**5**).

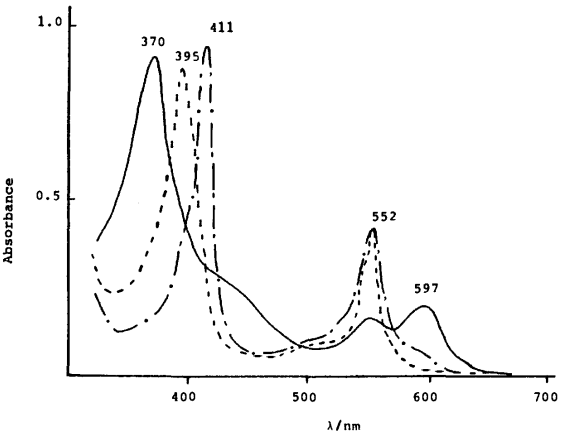

Fig. 2. Absorption spectra (1% pyridine-CH_2Cl_2, v/v) of 5-azamesoporphyrin IX iron(III) (**10**) (——) (2.5×10^{-5} M) and bis(pyridine) (**11**) (----) and bis($TsCH_2NC$)iron(II) 5-azamesoporphyrin IX dimethyl ester (**12**) (-·-·-).

spond to the cations $C_{35}H_{39}N_4O_5{}^{64}Zn^+$, $C_{35}H_{39}N_4O_5{}^{66}Zn^+$, and $C_{35}H_{39}N_4O_5{}^{68}Zn^+$, respectively, and the diamagnetic ring-current shifts of the *meso*-protons (δ 9.25, 9.00, and 8.96) in its ^{1}H NMR spectrum (Table 1). The cyclization of **7** with iron(II) sulfate in acetic anhydride containing a small amount of pyridine at 120 °C under argon, followed by treatment with aqueous $NaBF_4$, gave a green pigment **4**. The FAB mass spectrum of **4** showed a fragment ion peak at m/z 651 (19.2% of the base peak at m/z 140), which corresponds to the unliganded cation $C_{35}H_{39}N_4O_5Fe^+$ of **4**. The absorption spectrum of **4** showed the peaks at 385, 492, 526, and 651 nm (Fig. 1); this spectrum was similar to that of mesoverdohemin IXβ dimethyl ester (**2**) obtained by Jackson et al. These results indicated that the green pigment was mesoverdohemin IXα dimethyl ester (**9**). However, its ^{1}H NMR spectrum was similar to that of the zinc complex **6**, except for the presence of the signals of pyridine ligands; the spectrum showed diamagnetic ring-current shifts of the *meso*-protons (δ 8.98, 8.96, and 8.64) and the proton signals assigned to the pyridine ligands (δ 6.44, γ; 5.82, β; 3.33, α). In analogy with compound **14**,[14] the pyridine complex **4** was easily hydrolyzed to open the tetrapyrrole ring to obtain **7** and was susceptible to oxidation at the *meso*-methine group to give tripyrrins which showed pink spots on TLC (data were not shown). The pyridine ligands of compound **4** easily exchange with tosylmethyl isocyanide ($TsCH_2NC$), which is known to bind to iron(II), but not to iron(III), porophyrins;[13] addition of $TsCH_2NC$ to the solution of **4** resulted in the spectrum of bis($TsCH_2NC$) mesoverdohemochrome IXα dimethyl ester (**5**) with maxima at 373, 492, 526, and 633 nm (Fig. 1). The FAB mass spectrum of **5** showed a base peak at m/z 651 and a fragment ion peak at m/z 1041 (2.7% of the base peak), which correspond to the unliganded cation $C_{35}H_{39}N_4O_5Fe^+$ and to the cation of the bis($TsCH_2$-NC) complex of **5**, respectively. These results suggest that the oxidation state of the central iron of **4** is iron(II), not iron(III). The ^{1}H NMR spectrum of **5** showed the diamagnetic ring-current shifts of *meso*-methine protons (δ 9.04, 9.03,

and 9.02) and of the protons of two $TsCH_2NC$ ligands (Table 1). Both oxaporphyrins **4** and **5** reacted with ammonia to give, after methylation, iron(III) 5-azamesoporphyrin IX dimethyl ester (**10**). The electronic absorption spectrum of compound **10** in 1% pyridine-CH_2Cl_2 showed peaks at 370, 553, and 579 nm (Fig. 2). Addition of sodium dithionite to the solution of **10** resulted in the spectrum of bis(pyridine)iron(II) 5-azamesoporphyrin IX dimethyl ester (**11**) with maxima at 395 and 552 nm. Compound **11** gave, upon an addition of excess $TsCH_2NC$, bis($TsCH_2NC$)iron(II) 5-azamesoporphyrin IX dimethyl ester (**12**), which was identified by FAB mass spectrum data and elemental analysis, as well as the ^1H NMR spectral data (Table 1). Thus, both products obtained by the cyclization of mesobiliverdin IXα dimethyl ester (**7**) with iron(II) sulfate and by a coupled oxidation of mesohemin IX dimethyl ester (**1**) showed the same absorption spectra and had the same oxidation state of the central iron.

Attempts to Obtain Iron(III) 5-Oxaporphyrin Derivatives. We tried to obtain iron(III) 5-oxamesoporphyrin complex by ring closure of mesobiliverdin IXα dimethyl ester (**7**) with iron(III) chloride instead of iron(II) sulfate; compound **7** was reacted with iron(III) chloride in acetic anhydride containing a small amount of pyridine to give a green pigment. The ^1H NMR and absorption spectra of the pigment, however, were the same as those of iron(II) 5-oxamesoporphyrin IX (**4**) obtained by the cyclization of **7** with iron(II) sulfate. Previously, we obtained 5-azamesoporphyrin (**20**) by the treatment of 5-azaprotoporphyrin-iron(III) chloride (**10**) with iron(II) sulfate in acetic acid which contained a small amount of concd HCl; in this reaction, the vinyl groups of **10** was reduced to give **20**. In the cyclization of **7**, iron(III) chloride was dissolved in a small amount of methanol, this mixture then was dissolved in acetic anhydride. Under these conditions, hydrogen might have evolved to reduce iron(III) to iron(II).

It is known that $K_3[Fe(CN)_6]$ oxidizes iron(II) porphyrin to give iron(III) porphyrin. The electronic absorption spectrum of bis($TsCH_2NC$)iron(II) protoporphyrin IX dimethyl ester (**16**) in CH_2Cl_2 showed peaks at 369, 406, 431, 558, and 606 nm (Fig. 3). The addition of $K_3[Fe(CN)_6]$ to the solution of **16** resulted in the spectrum of iron(III) protoporphyrin IX complex with maxima at 404, 578, and 602 nm. The absorption spectrum of bis(pyridine)iron(II) 5-oxaprotoporphyrin IX dimethyl ester (**14**) in pyridine showed peaks at 397, 495, 531, and 657 nm (Fig. 4). The addition of $K_3[Fe(CN)_6]$ to the solution of **14** resulted in a new spectrum with maxima at 418 and 658 nm. The large-scaled reaction of **14** with $K_3[Fe(CN)_6]$ was performed, and the mixture was worked-up according to the procedure for **4**. Most of the products of this reaction were tripyrrin derivatives,[14,15] and the starting material was found as a minor component; however, no iron(III) oxaporphyrin complex. Thus, attempts to obtain iron(III) oxaporphyrin were unsuccessful.

Mössbauer Spectra of Oxa- and Azaporphyriniron Complexes. Since the reactions of **7** with both iron(II) sulfate and iron(III) chloride gave the same product, the oxidation state of the central iron of mesoverdohemochrome IXα was reinvestigated by a comparison of the Mössbauer spectra with those of related porphyrins. Mössbauer parameters, isomer shifts (δ) and quadrupole splittings (ΔE_Q), of normal porphyrins and oxa- and azaporphyrins are listed in Tables 2 and 3, respectively. Figures 5a and 5b show typical Mössbauer spectra of bis(pyridine)iron(II)- (**13**) and bis($TsCH_2NC$)iron(II) octaethyl-5-oxaporphyrin (**17**), respectively. The parameters (δ and ΔE_Q) of **13** and bis(pyridine)iron(II) 5-oxaprotoporphyrin IX dimethyl ester (**14**) were close to those of bis(pyridine)iron(II) protoporphyrin IX ($Fe(pp)py_2$) and bis(pyridine)-iron(II) tetraphenylporphyrin ($Fe(tpp)py_2$). These results, together with the ^1H NMR spectra[9] of **13** and

Table 2. Mössbauer Parameters[16]

i) For low-spin iron(II) porphyrin complexes (S=0)

Compound	Temperature / K	δ[a] / mm s^{-1}	ΔE_Q[b] / mm s^{-1}
$Fe(pp)py_2$[c]	77	0.45	1.21
$Fe(oep)py_2$	85	0.46	1.14
$Fe(tpp)py_2$	77	0.40	1.15
ii) For high-spin iron(III) porphyrin complexes (S=5/2)			
Fe(pp)Cl	4.2	0.35	0.83
Fe(oep)Cl	4.2	0.41	0.93
iii) For diamagnetic carbonyl complexes			
Fe(tpp)(pip)(CO)	115	0.25	0.47
	295	0.18	0.53
Fe(pp)(pip)(CO)	115	0.26	0.57
	295	0.18	0.62

a) δ= isomer shift. b) ΔE_Q=quadrupole splitting. c) Porphyrin and ligand abbreviations: pp, protoporphyrin IX; oep, octaethylporphyrin; tpp, tetraphenylporphyrin; py, pyridine; pip, piperidine.

Table 3. Mössbauer Parameters for Oxo- and Azaporphyriniron Complexes and Protoheme Complex at 78 K

Compound	δ / mm s^{-1}	ΔE_Q / mm s^{-1}
i) Bis(pyridine)iron(II) complexes		
4	0.41	1.26
13	0.43	1.25
14	0.41	1.24
ii) Bis($TsCH_2NC$)iron(II) complexes		
5	0.26	0
17	0.28	0
15	0.21	0
iii) Azaporphyriniron(III) complexes		
18	0.40	0.50
19	0.39	0.49

14, were consistent with the idea that the oxidation state of the central iron of compounds **13** and **14** is low-spin iron(II). The parameters (δ and ΔE_Q) of bis(pyridine)iron(II) 5-oxamesoporphyrin dimethyl ester (**4**) under consideration were also close to those of **13**, **14**, Fe(pp)py_2, and Fe(tpp)py_2. These results indicate that the product obtained by the cyclization of mesobiliverdin IXα dimethyl ester (**7**) with both iron(II) sulfate and iron(III) chloride, are low-spin iron(II) but not high-spin iron(III), 5-oxamesoporphyrin IX complex.

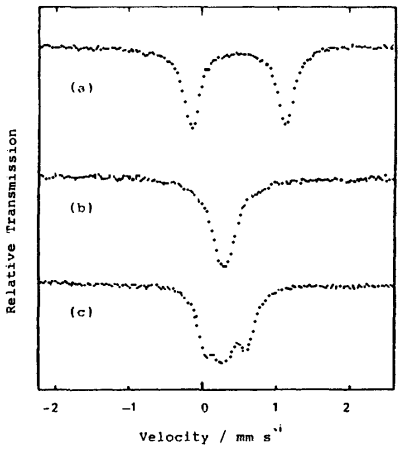

Fig. 5. Mössbauer spectra of bis(pyridine) and bis($TsCH_2NC$)iron(II) octaethyl-5-oxaporphyrins.

The Mössbauer spectra of bis($TsCH_2NC$)iron(II) protoporphyrin IX dimethyl ester (**15**) and bis($TsCH_2NC$)iron(II) 5-oxaporphyrins (**5**, **16**, and **17**) showed a singlet peak having parameters of ΔE_Q=0 mm s^{-1} and δ=0.21—0.28 mm s^{-1} (Table 3). These parameters differed completely from those of the corresponding bis(pyridine) complexes (ΔE_Q=1.24—1.26 mm s^{-1} and δ=0.41—0.43 mm s^{-1}). In general, in going from an Fe(por)L_2 complex (por=porphyrinate dianion, L=amine base) to the corresponding Fe(por)L(CO) derivative, δ decreases by about 0.2 mm s^{-1} and ΔE_Q by about 0.8—1.0 mm s^{-1}. Sams and Tsin[16] explained these phenomena as follows: the quadrupole splitting is small with a decrease in the *d*-electron density on the iron, arising from a strong Fe→CO π back bonding; an increase in the CO→Fe σ bonding decrease δ. Our experiments on the Mössbauer spectra showed that both parameters (δ and ΔE_Q) of the bis($TsCH_2NC$) complexes (**5**, **15**, **17**) decreased compared with those of the corresponding bis(pyridine) complexes (**4**, **14**, and **13**); δ decreases by 0.13—0.22 mm s^{-1} and ΔE_Q by 1.24—1.26 mm s^{-1}. These results seemed to coincide with the explanation for carbon monoxide heme complexes and indicate that bis-

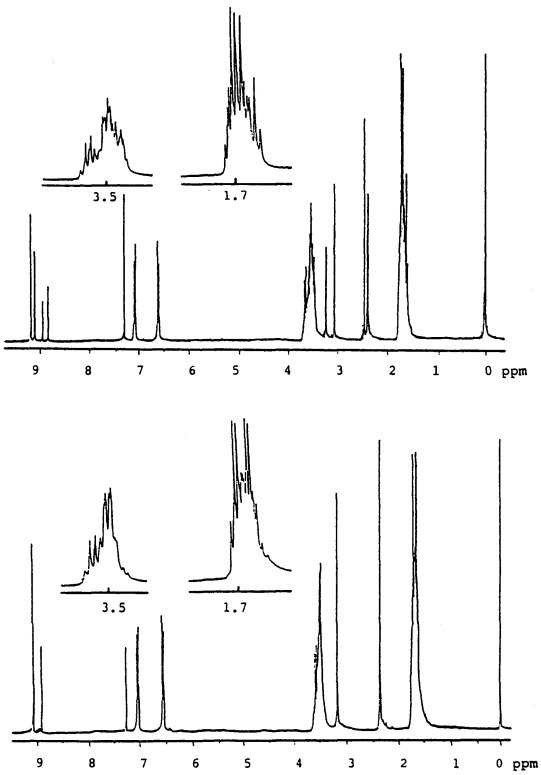

Fig. 6. ^{1}H NMR (270 MHz) spectra of bis($TsCH_2$-NC)iron(II) octaethyl-5-oxaporphyrin complexes.

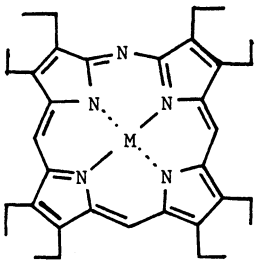
($TsCH_2NC$) complexes have strong Fe→CN π back bonding and Fe←CN σ bonding.

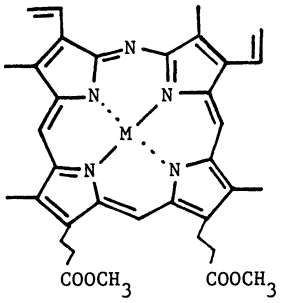
In the course of an investigation of the ^{1}H NMR spectra of bis($TsCH_2NC$)iron(II) octaethyl-5-oxaporphyrin, we found that two kinds of bis($TsCH_2NC$)iron-(II) complexes existed. Bis(pyridine) complex **13** was reacted with excess $TsCH_2NC$, and the reaction mixture was evaporated at lower temperature (<10 °C) according to the method for **4** to give a blue mixture whose ^{1}H NMR spectrum showed two pairs of *meso*-protons due to compounds A and B (ca. 3 : 1, respectively) (δ 9.15 and 8.81 for compound A, 9.05 and 8.89 for compound B) (Table 4 and Fig. 6). Although compound A was not isolated (because of an easy conversion into compound B), compound B was isolated; in the ^{1}H NMR spectrum, the *meso*-proton at δ 9.15 and 8.81 for compound A disappeared after the mixture (A+B) was heated at 50 °C in benzene, and the intensity of two peaks at δ 9.05 and 8.89 of *meso*-protons of compound B increased. The FAB mass spectra of both products (the mixture of A and B and compound B) showed the similar spectra showing a base peak at m/z 591, which corresponds to the cation of $C_{35}H_{43}FeN_4O^+$. Furthermore, the absorption spectra of the mixture and compound B were not appreciably different (see experiment section). These results suggest that both compounds A and B have the same oxaporphyrin ring structure. Compound B was identified with **17** by FAB mass, ^{1}H NMR, and absorption spectra.

The Mössbauer spectrum of compound **17** showed a single peak (δ=0.28 mm s^{-1}). On the other hand, the spectrum of the mixture (A and B) showed a triplet peak which consisted of a singlet peak (δ=0.28 mm s^{-1}) and a doublet peak (δ=0.31 mm s^{-1} and ΔE_Q=0.55 mm s^{-1}) (Fig. 5c). These results suggest that an unstable intermediate (compound A) is first produced by binding $TsCH_2NC$ to iron(II), then the compound A converts to the stable compound B (**17**). The resonating structures of bis($TsCH_2NC$) complex were thought as follows: $Fe{=}C{-}\ddot{N}{-}R \leftrightarrow Fe{-}\bar{C}{\equiv}\overset{+}{N}{-}R$.[17] The Mössbauer parameters for the stable compound B indicate that the electronic structure of the bonding between iron(II) and isocyanide ligand can be assigned as a double-bonded structure, due to the strong Fe→CN π and Fe←CN σ bonding. On the other hand, the fact that the Mössbauer parameters of the unstable compound A are larger than those of the stable compound B suggests a decrease in the Fe→CN π back donation for compound A. Though the electronic structure of the bonding between iron(II) and isocyanide ligands for the unstable intermediate A has not yet been confirmed, we may presume that $TsCH_2NC$ binds to iron-(II) to initially form an unstable bonding, such as Fe←CN σ or $Fe{\leftarrow}\overset{C}{\underset{N}{|||}}$ bonding. In this case the bonding is formed between the π electrons of CN group and Fe; these unstable structures then convert to the stable double-bonded structure, resulting in the formation of compound B.

The Mössbauer spectra of (octaethyl-5-azaporphyrinato)iron(III) chloride (**18**) and 5-azaprotoporphyrin IX iron(III) chloride dimethyl ester (**19**) were obtained at 78 K. The parameters of the spectra are listed in



(18) M = Fe(III)·Cl



(19) M = Fe(III)·Cl

Table 3-iii. It is generally said that because of a second-order Doppler shift, the isomer shift decreases with an increase in the temperature, while the quadrupole splitting does not appreciably change upon a variation of the temperature in complexes of this type. From this suggestion, our experiments showed that the δ values of **18** and **19** were larger than that of Fe(III)(oep)Cl, and ΔE_Q values of **18** and **19** were smaller than that of Fe(III)(oep)Cl.[18] These effects seem to be due to the substitution of a nitrogen atom for a carbon atom of the porphyrin moiety. These effects will be discussed later in further detail.

Experimental

Materials. Protohemin IX dimethyl ester was prepared by methylation of protohemin IX, purchased from Aldrich. Biliverdin IXα was prepared by oxidation of bilirubin IXα, purchased from Aldrich, with 2,3-dichloro-5,6-dicyano-*p*-benzoquinone. Bis(pyridine) octaethylverdohemochrome was prepared according to a published procedure. Tosylmethyl isocyanide ($TsCH_2NC$), purchased from Aldrich, was recrystallized from ethanol after treatment with active carbon in ethanol. The solvents for analyses were of analytical grade. All other solvents and chemicals were of reagent grade. Analytical thin-layer chromatography (TLC) was performed on DC-Alufolien Kieselgel 60 HF254 (Merck). Wacogel C-200 was used for column chromatograph.

Measurements. Melting points were determined with a Yanoko micro melting-point apparatus. Electronic absorption spectra were recorded with a Hitach U-3200 Spectrophotometer. EI and FAB mass spectra were obtained with a JEOL JMS 300 mass spectrometer. ^1H NMR spectra at 270 MHz of samples in $CDCl_3$ solution containing Me_4Si were recorded with a JEOL JNM-GX 270 FT NMR spectormeter. The Mössbauer spectra were recorded with an Austin Science Associated Mössbauer Spectrometer Controller. A 20 mCi single-line ^{57}Co source in Rh matrix was used. The velocity scale of the spectrometer was calibrated by using the spectra of the metallic iron. Isomer shifts are reported relative to metallic iron at room temperature. By fitting the resonance line-shape to a Lorentzian function, the obtained Mössbauer parameters are within ± 0.002 mm s^{-1} for isomer shifts and ± 0.005 mm s^{-1} for quadrupole splittings. Low-temperature measurements were performed using a CA thermocouple embedded in a copper sample holder with an Air Products and Chemicals Model LT-3-110 Liquid Transter Helitran. The precision of the temperature measurement was with approximately ± 0.1 K over a period of several hours.

Preparation of Mesobiliverdin IXα Dimethyl Ester (7). In 50 ml of anhydrous formic acid, methyl methacrylate (400 mg) was dissolved, and 10% Pd-charcoal (75 mg) was added. The mixture was added with biliverdin IXα dimethyl ester (**8**) (350 mg) and passed with H_2 at 50 °C for 50 min. The mixture was filtered. The filtrate was diluted with H_2O (50 ml) and extracted with CH_2Cl_2 (50 ml×3). The combined organic extracts were washed with H_2O, dried over Na_2SO_4, and filtered. The filtrate was evaporated to give a residue which was subjected to column chromatography (benzene-acetone, gradient up to 10%) to isolate mesobiliverdin IXα dimethyl ester (**7**) (220 mg, 62.5%). EI MS *m/z* (rel intensity) 614 (M^+, 100), 598 (19.5), 583 (23.8), 555 (26.2), 541 (47.6), 527 (17.1), 467 (85.7), 454 (47.6). Found: C, 68.30; H, 6.89; N, 9.03%. Calcd for $C_{35}H_{42}N_4O_6$: C, 68.38; H, 6.89; N, 9.11%.

Zinc 5-Oxamesoporphyrin IX Dimethyl Ester Tetrafluoroborate (6). To a solution of mesobiliverdin IXα dimethyl ester (**7**) (150 mg), a solution of zinc acetate dihydrate (185 mg) in MeOH (5 ml) was added. The mixture was warmed at 60 °C for 30 min and filtered. The filtrate was evaporated and the residue was dissolved in CH_2Cl_2 (5 ml) and acetic anhydride (30 ml). After the mixture had been heated at 120 °C for 30 min under argon, the solvent was removed with a vigorous stream of argon at 140 °C. The resulting residue was chromatographed on silica gel with CH_2Cl_2-MeOH (gradient up to 5%) to give the major green pigment. The pigment was dissolved in CH_2Cl_2, washed with saturated aqueous $NaBF_4$ and water, dried, and evaporated to give a residue, which was subjected to column chromatography to isolate compound **6** (125.2 mg, 68.5%), mp 300 °C. Found: C, 56.03; H, 5.29; N, 7.35%. Calcd for $C_{35}H_{39}N_4O_5ZnBF_4$: C, 56.21; H, 5.26; N, 7.49%. FAB MS *m/z* (rel intensity) 659 (60.3), 661 (26.7), 663 (24.7), 406 (40.0), 252 (38.5), 140 (100).

Cyclization of 7 with Iron(III) Sulfate. To a solution of compound **7** (110 mg) in acetic anhydride (50 ml) and pyridine (5 ml), a solution of iron(II) sulfate heptahydrate (100 mg) in methanol (7 ml) was added under argon. The reaction mixture was heated for 30 min at 120 °C under argon, and the solvent was removed by a vigorous flow of argon at 140 °C to give a residue. The residue was extracted with 2% pyridine-CH_2Cl_2 (50 ml×3) and the combined organic extracts were washed succesively with saturated aqueous $NaBF_4$ and water, dried, and evaporated to give a green residue. The residue was chromatographed on silica gel with CH_2Cl_2 containing 1% pyridine-MeOH (gradient up to 5%) to give bis(pyridine)iron(II) mesoverdohemochrome IXα dimethyl ester (**4**) (94.1 mg, 58.6%). FAB MS *m/z* (rel intensity) 651 (17.8), 252 (56.2), 235 (28.8), 140 (100). Calcd

for $C_{45}H_{49}N_6O_5FeBF_4$: C, 60.28; H, 5.51; N, 9.37%. Found: C, 59.90; H, 5.60; N, 9.22%.

Cyclization of 7 with Iron(III) Chloride. To a solution of **7** (50 mg) in acetic anhydride (50 ml) and pyridine (5 ml), a solution of iron(III) chloride monohydrate (100 mg) in methanol (3 ml) was added. The reaction mixture was treated and worked-up according to the procedure just described above for **4**. The resulting green pigment (36.3 mg, 47.7%) was identified with **4** by TLC and ^{1}H NMR spectroscopy.

Bis($TsCH_2NC$)iron(II) Complex (5). Compound **4** (102 mg) was dissolved together with $TsCH_2NC$ (350 mg) in CH_2Cl_2 (5 ml). The solution was subjected to column chromatography (CH_2Cl_2-MeOH, gradient up to 5%) to give compound **5** (98.4 mg, 76.6%), mp>300 °C (after recrystallization from benzene-peteroleum ether). Found: C, 56.11; H, 5.12; N, 7.15%. Calcd for $C_{53}H_{57}N_6O_9S_2FeBF_4$: C, 56.39; H, 5.09; N, 7.44%. FAB MS *m/z* (rel intensity) 1041 (2.7, M^+-BF_4), 651 (100, $M^+-2\times TsCH_2NC-BF_4$).

Iron(III) 5-Azamesoporphyrin IX Dimethyl Ester (10). a) To a solution of compound **4** (53 mg) in pyridine (15 ml) and concd aqueous ammonia (10 ml) was added. The reaction mixture was stirred overnight at room temperature. The mixture was diluted with water (50 ml) and extracted with CH_2Cl_2 (50 ml×3). The combined organic extracts were washed with saturated aqueous NaCl and water, dried, and evaporated to give a residue. The residue was dissolved in 5% H_2SO_4-MeOH (100 ml) and allowed to stand overnight at room temperature. The reaction mixture was extracted with CH_2Cl_2 (100 ml×3). The extract was worked-up in the usual way. After recrystallization from CH_2Cl_2-peteroleum ether, compound **10** (32 mg, 39.5%) was obtained, mp>300 °C. Found: C, 61.43; H, 5.44; N, 9.93%. Calcd for $C_{35}H_{39}N_5O_4$-FeCl: C, 61.37; H, 5.34; N, 10.22%. b) To a solution of **5** (30 mg) in pyridine (1 ml) and concd aqueous ammonia (10 ml) was added. The reaction mixture was stirred overnight at room temperature. The reaction mixture was worked-up according to the procedure of a). The compound **10** (6 mg, 33%) was obtained.

Bis($TsCH_2NC$)iron(II) Complex (12). The solution of compound **10** (100 mg) in CH_2Cl_2 (50 ml) containing pyridine (5 ml) was washed with aqueous $Na_2S_2O_4$ and water. The organic solution was added with $TsCH_2NC$ (30 mg) and subjected to column chromatography (CH_2Cl_2-acetone, gradient up to 5%) to give **12** (103 mg, 67.8%). FAB MS *m/z* 649 (base peak, $M^+-2\times TsCH_2NC$) Found: C, 61.17; H, 5.53; N, 9.40%. Calcd for $C_{53}H_{57}N_7O_8S_2Fe$: C, 61.21; H, 5.52; N, 9.43%.

5-Azamesoporphyrin IX Dimethyl Ester (20). To a solution of compound **12** (40 mg) in pyridine (0.5 ml) and acetic acid (15 ml), a solution of iron(II) sulfate heptahydrate (40 mg) in concd HCl (1 ml) was added under argon, and the reaction mixture was poured into ice water (30 ml) and extracted with CH_2Cl_2 (25 ml×3). The combined organic extracts were washed with water, dried over Na_2SO_4, and filtered. The filtrate was evaporated to give a residue. The residue was dissolved in 5% H_2SO_4-MeOH (50 ml) and allowed to stand overnight. The mixture was poured into ice water (100 ml) and extracted with CH_2Cl_2 (50 ml×3). The combined organic extracts were washed successively with saturated aqueous sodium hydrogencarbonate and water, dried over Na_2SO_4, and filtered. The filtrate was evaporated to give a residue which was subjected to column chromatography (CH_2Cl_2) to obtain azaporphyrin (**20**) (15 mg, 52.4%). Compound **20** was identified with authentic sample[14] by TLC, ^{1}H NMR and mass spectra.

Bis($TsCH_2NC$)iron(II) Protoporphyrin IX Dimethyl Ester (16). To a solution of protohemin IX dimethyl ester (**21**) (100 mg) in pyridine (10 ml), a solution of $Na_2S_2O_4$ (50 mg) in water (1 ml) was added. The mixture was poured into ice water (50 ml) and extracted with CH_2Cl_2 (50 ml×3). The combined organic extracts were washed with H_2O, dried over Na_2SO_4, and filtered. The filtrate was evaporated to give a residue. The residue was dissolved in CH_2Cl_2 (2 ml) and was added with $TsCH_2NC$ (80 mg). The mixture was subjected to column chromatography (CH_2Cl_2-MeOH, gradient up to 5%) to obtain compound **16** (115.4 mg, 75.8%). Compound **16** was recrystallized from benzene-light peteroleum ether (1 : 1). Found: C, 62.63; H, 5.26; N, 8.07%. Calcd for $C_{54}H_{54}N_6O_8S_2Fe$: C, 62.66; H, 5.26; N, 8.12%. ^{1}H NMR ($CDCl_3$) δ=9.77, 9.73, 9.66, and 9.55 (each, 1H, s, *meso*-H), 8.25 (2H, dd, J=17.6, 11.7 Hz, H_C and H_F), 6.92 (4H, broad s, *ortho*-protons on $TsCH_2NC$×2), 6.23 (2H, d, J=17.8 Hz, H_A and H_D), 6.00 (2H, dd, J=11.7, 1.5 Hz, H_B and H_E), 5.69 (4H, broad s, *meta*-protons on $TsCH_2NC$×2), 4.27 (4H, t, J=7.2 Hz, $-CH_2-$×2), 3.63, 3.60, 3.54, and 3.52 (each 3H, s, CH_3), 3.22 (4H, t, J=7.2 Hz, $-CH_2CO-$×2), 2.40 (6H, s, CH_3×2 on $TsCH_2NC$×2), 2.23 (4H, s, CH_2×2 on $TsCH_2NC$×2).

Bis($TsCH_2NC$)iron(II) Octaethyl-5-oxaporphyrin (17). Bis(pyridine)iron(II) octaethyl-5-oxaporphyrin (**13**, 50 mg) was dissolved in CH_2Cl_2 (2 ml) and added with $TsCH_2NC$ (50 mg). The mixture was subjected to column chromatography (CH_2Cl_2-acetone, gradient up to 10%). The blue coloured eluant was evaporated at below 10 °C to give a blue oil (48.4 mg, 76%) which showed one spot on TLC (R_f 0.37; benzene-acetone 85 : 15). UV λ_{max} (CH_2Cl_2) nm (ε_{mM}) 628 (45.2), 583sh (13.1), 529 (11.5), 494 (10.5), 402sh (35.5), 372 (54.5). FAB MS *m/z* 591 ($M^+-2\times TsCH_2NC-BF_4$, 100%). IR ($CHCl_3$) 2960, 2930, 2860. 2140, 1708, 1610, 1595, 1560, 1450, 1400, 1380, 1340, 1260, 1145, 1095, 1060, 1005, 980, 960 cm^{-1}. The blue oil was dissolved in benzene and warmed at 50 °C for 30 min. The solution was evaporated to give a residue which showed the same R_f value and FAB mass spectrum as those of the blue oil obtained at the lower temperature. UV λ_{max} (CH_2Cl_2) nm (ε_{mM}) 627 (46.3), 582sh (13.0), 530 (12.4), 496 (12.1), 404 (37.0), 372 (56.3). IR ($CHCl_3$) 3080, 3000, 2960, 2950, 2860, 2140, 1960, 1817, 1605, 1595, 1480, 1380, 1340, 1263, 1150, 1480, 1060, 1030, 980, 960 cm^{-1}.

We thank Dr. Ronald L. Cerny, Assistant Director of the Midwest center for Mass Spectrometry at University of Nebraska, Lincoln, for several FAB mass spectra.

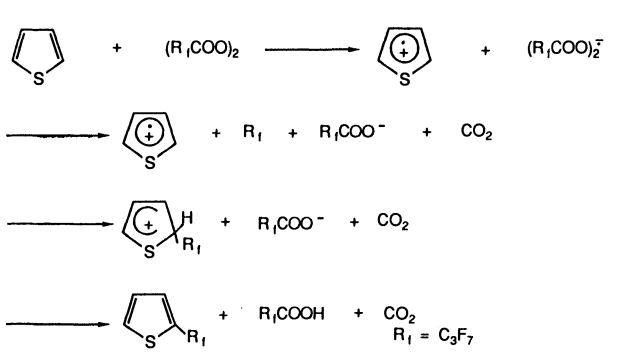
Heptafluoropropylation of Various Substituted Thiophenes with Bis(heptafluorobutyryl) Peroxide. Preparation of 3-Heptafluoropropylthiophene

Masato YOSHIDA,* Tatsuro YOSHIDA, Nobumasa KAMIGATA, and Michio KOBAYASHI
Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Fukazawa, Setagaya-ku, Tokyo 158
(Received February 24, 1988)

The heptafluoropropylations of several substituted thiophenes with bis(heptafluorobutyryl) peroxide were studied. The orientations of the heptafluoropropylation were examined and compared with those of usual electrophilic substitution. The method for the preparation of 3-heptafluoropropylthiophene was also explored.

The introduction of perfluoroalkyl groups has been the subject of much research in organofluorine chemistry, since the usual methods for alkylation cannot be applied to perfluoroalkylation. We have been studying perfluoroalkylation with bis(perfluoroalkanoyl) peroxide and have succeeded in introducing a heptafluoropropyl group into electron-rich compounds such as electron-rich benzenes, naphthalene, anthracene,[1] electron-rich olefins,[2] furan, and thiophene,[3] with bis(heptafluorobutyryl) peroxide (**1**). In this paper, we report on the orientation of the heptafluoropropylation in several substituted thiophenes with **1** as well as the method for the preparation of 3-heptafluoropropylthiophene.[4]

As described in our previous paper, a heptafluoropropyl group was introduced into the 2-position of thiophene regioselectively, with 98% yield.[3] The decomposition of bis(heptafluorobutyryl) peroxide **1** was accelerated in the presence of thiophene and the activation entropy for the decomposition of **1** in the presence of thiophene showed a negative value. From these results we propose the mechanism shown in Scheme 1.[3] The reaction is initiated by electron transfer from thiophene to the peroxide. The radical anion of the peroxide decomposes to the heptafluoropropyl radical, heptafluorobutyrate, and carbon dioxide. The heptafluoropropyl radical is coupled with the radical cation of thiophene to give heptafluoropropylthiophene. The reaction proceeds in a solvent cage, so the heptafluoropropyl group is introduced in good yield. Due to the high electronegativity of a perfluoroalkyl group, perfluoroalkylation involving a perfluoroalkyl cation as an intermediate are limited,[5] and the development of cationic perfluoroalkylation is very valuable. The method described in Scheme 1 is superficially equivalent to cationic perfluoroalkylation.



Scheme 1.

The factor for determining the orientation of the heptafluoropropylation with **1** should be the spin density distribution of a radical cation of thiophene[6] or the stability of cationic Wheland intermediates.[7] Thus, we were interested in examining the orientation of the heptafluoropropylation of various substituted thiophenes with peroxide **1** and compared with those of the usual electrophilic substitution.

3-Substituted thiophenes are important for polymeric materials and the exploitation in the preparation of 3-substituted thiophenes is valuable.[8] From results concerning the orientation of the heptafluoropropylation with **1**, we also explored the method for the preparation of 3-heptafluoropropylthiophene.

Results and Discussion

The reactions of **1** and several thiophenes were performed in Freon-113; results are summarized in Table 1. Generally, in electrophilic substitution reactions with thiophenes, an orienting effect is common for both substituents; +I and +M effect such as a methyl group and −I and +M effect such as a bromine group. Thus, for 2-substituted thiophenes further substitution occurs at position 5; for the 3-substituted type, substitution occurs preferentially at 2, unless a steric requirement forces an incoming substituent at position 5.[7] In the heptafluoropropylation of both 2-methylthiophene and 2-bromothiophene with peroxide **1**, heptafluoropropyl group was introduced into the 5-position. In a reaction of 3-bromothiophene and **1**, a heptafluoropropyl group was introduced into both the 2 and 5 positions in yields of 49% and 30%, respectively. When a substituent, such as a formyl group with −I and −M effect, are present at position 2, a further substitution occurs at the 4- or 5-position;[7] sulfur of thiophene activates the 5-position, while the 4-position is the least deactivated by an electron-withdrawing 2-substituent. However, in a reaction of 2-formylthiophene and **1**, a heptafluoropropyl group

a) The yields were determined by GC based on peroxide. b) The data from Ref. 3. c) This product was not isolated and its structure was estimated by GC-MS.

was introduced into the 3- and 5-position in a ratio of about 1 : 1; heptafluoropropylation at the 4-position did not occur. An electron-withdrawing formyl group decreases the electron-transfer tendency; thus, on the whole, the yield of the heptafluoropropylation was low in 2-formylthiophene. An electrophilic attack on benzothiophene occurs at the β-position of the thiophene ring prior to the α-position.[7] However, in a reaction of benzothiophene and **1**, 2-heptafluoropropylbenzothiophene and 7-heptafluoropropylbenzothiophene were formed, with no 3-heptafluoropropylbenzothiophene.

As described in our previous paper, heptafluoropropylations of benzenes, especially electron-rich benzenes, were achieved with **1**; the orientations and partial rate factors were much different from those for the usual free radical substitutions, but similar to those for electrophilic aromatic substitutions. We therefore proposed an electron-transfer mechanism for the heptafluoropropylation, but not a free radical aromatic substitution mechanism by a heptafluoropropyl radical produced by a homolytic cleavage of **1**.[1] In this study, we found that a heptafluoropropyl group was introduced into substituted thiophenes with **1** regioselectively. The orientations were similar to those expected from the usual electrophilic substitutions in 2-methylthiophene, 2- or 3-bromothiophenes. However, some differences were found in the orientations for the heptafluoropropylation of 2-formylthiophene and benzothiophene with **1** from those for the usual electrophilic substitutions; the orientations for the heptafluoropropylation cannot be explained in terms of the stabilities of cationic intermediates, and may be characteristic for an electron-transfer reaction.

Electrophilic ipso-substitutions of arylsilanes are well known.[9] Thus, it is interesting to examine whether ipso-substitution occurs in a reaction of 2-trimethylsilylthiophene and **1**. Regarding this reaction, however, the heptafluoropropyl group was found to enter into a 5-position (Table 1, run 7).

There are three expected products in the reaction of **1** and 2,5-dimethylthiophene, as shown in Scheme 2. It is known that the radical cation of 2,5-dimethylthiophene electrochemically produced gives those three types of compounds.[10] As a result, a heptafluoropropyl group was solely introduced into the 3-position of the thiophene to give 2,5-dimethyl-3-heptafluoropropylthiophene (Table 1, run 8), although the spin density of the radical cation of 2,5-dimethylthiophene is higher at the α-position than at the β-position.[6] These results suggested that we should use 2,5-disubstituted thiophene in order to prepare 3-heptafluoropropylthiophene: 2,5-disubstituted thiophenes are fluoroalkylated with **1**; then, substituents at the 2 and 5 positions are removed to give

		1.5	15	35
5.0	27	30
1.5[c]	47	5
5.0[c]	55	13

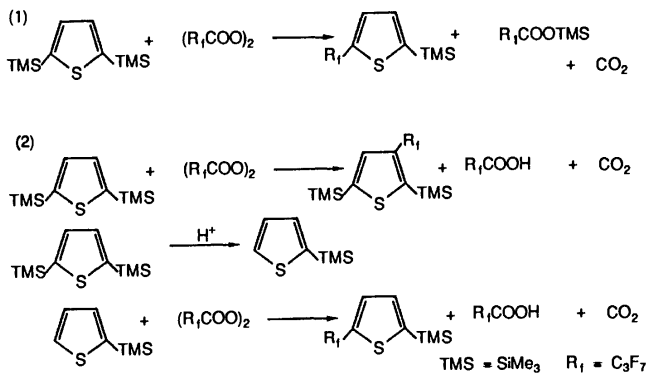
a) One mmol of the peroxide was used. b) The yields were determined by GC based on the peroxide. c) Ten mmol of MgO was added.

3-heptafluoropropylthiophene. At first, the reaction of commercially available 2,5-dibromothiophene was examined. The yield of 2,5-dibromo-3-heptafluoropropylthiophene was less than 40% (Table 2). Regarding electron transfer, it may not be adequate to use a bromine group as a protecting group of the 2,5-position. We also examined a reaction of 2,5-bis(trimethylsilyl)thiophene and peroxide **1**. In this reaction, the main product was 2-trimethylsilyl-5-heptafluoropropylthiophene; the yield of the desired 2,5-bis(trimethysilyl)-3-heptafluoropropylthiophene was low. There are two plausible reaction mechanisms for the formation of 2-trimethylsilyl-3-heptafluoropropylthiophene. One is an ipso-substitution of trimethylsilyl group, as shown in Scheme 3 (1). The other is shown in Scheme 3 (2). The acid-promoted desilylation of 2,5-bis(trimethylsilyl)thiophene occurred first. Since 2-trimethylsilylthiophene is more reactive than 2,5-bis(trimethylsilyl)thiophene in a reaction with **1**, 2-trimethylsilyl-5-heptafluoropropylthiophene is formed preferentially.

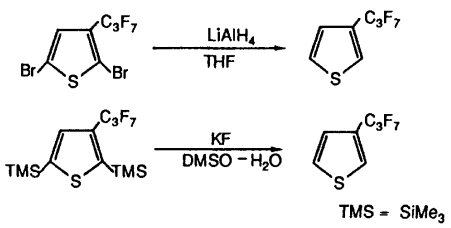
In order to trap the produced heptafluorobutyric acid, MgO was added. The yield of 2,5-bis(trimethylsilyl)-3-heptafluoropropylthiophene was improved in the presence of MgO, as shown in Table 2. This may imply the acid-promoted desilylation.

Bromine atoms of 2,5-dibromo-3-heptafluoropropylthiophene were reduced by $LiAlH_4$ in THF and 3-heptafluoropropylthiophene was obtained in 60% yield. Trimethylsilyl groups were removed from 2,5-bis(trimethylsilyl)-3-heptafluoropropylthiophene with KF in DMSO in the presence of water almost quantitatively.

It is known that, in a direct heptafluoroalkylation of thiophenes, 2-isomers are obtained as the main products.[11] Only one example is known for the preparation of 3-perfluoroalkylthiophene; the reaction of 3-halogenothiophene, perfluoroalkyl iodide and copper-bronze in DMF gave 3-perfluoroalkylthiophene in the yield of 17—50%.[12] We have so far explored novel methods for the introduction of a heptafluoropropyl group into the 3-position of thiophene.



Scheme 3.



Scheme 4.

Experimental

^{1}H NMR spectra were taken with a JEOL JNM PMX 60Si (60MHz) spectrometer. ^{13}C NMR and ^{19}F NMR spectra were taken with a JEOL JNM FX90Q FTNMR spectrometer. IR spectra were recorded on a Hitachi 260-10 spectrometer. Gas chromatography was performed by using a Hitachi 163 or 263-30 gas chromatograph with SE-30 (10%) 1- or 2-m stainless columns. Gel permeation chromatography was performed by means of a JAI Model LC-08 liquid chromatograph equipped with two JAIGEL-1H columns and using chloroform as an eluent. MS spectra were obtained with JEOL JMS D-300 spectrometer by an electron-impact (EI) ionizing technique at 70 eV.

Materials. Thiophenes, except for 2-trimethylsilylthiophene and 2,5-bis(trimethylsilyl)thiophene, were commercially available and used after purification. 2-Trimethylsilylthiophene and 2,5-bis(trimethylsilyl)thiophene were synthesized from 2-lithiothiophene and 2,5-dilithiothiophene with trimethylsilyl chloride. The lithiothiophenes were synthesized according to methods described in the literature.[13] Bis(heptafluorobutyryl) peroxide was prepared from heptafluorobutyryl chloride and hydrogen peroxide in Freon-113 and water according to the literature.[14] The peroxide was not isolated and used as a solution of Freon-113.

General Procedure for Reactions of 1 and Thiophenes. A solution of **1** (1.0 mmol) and thiophenes (1.5 mmol) in 10 ml Freon-113 was degassed by a freeze-thaw cycle, sealed in an ampoule and kept at 40 °C for adequate time (until the peroxide was consumed). The reaction mixture was washed two times with 5% aq NaOH or $NaHCO_3$ and then with water. An organic layer was separated and dried over $MgSO_4$. The yields of the products were determined by GC using chlorobenzene as an internal standard. The products were isolated from the reaction mixture by the use of gel permeation chromatography and/or column chromatography over silica gel (Wakogel C-60), and identified by IR, NMR, and MS.

2-Heptafluoropropyl-3-bromothiophene: ^{1}H NMR ($CDCl_3$) δ=7.03, 7.42 (ABq, J=6.3 Hz); ^{13}C NMR ($CDCl_3$) δ=113.9 (C_3, t, J_{CCCF}=4.3 Hz), 129.1 (C_5), 133.2 (C_4); IR (cm^{-1}) 1350 (CF_3), 1230 (CF_2); MS m/z 332 (M^++2), 330 (M^+); Exact MS: m/z 329.8928. 2-Formyl-5-heptafluoropropylthiophene: ^1H NMR ($CDCl_3$) δ=7.44, 7.67 (ABq, J=4.2 Hz), 9.85 (1H, s); ^{13}C NMR ($CDCl_3$) δ=130.7 (C_4, t, J_{CCCF}=5.5 Hz), 134.6 (C_3), 147.4 (C_2), 182.5 (CHO); ^{19}F NMR ($CDCl_3$) −4.1, −27.7, −50.2; IR (cm^{-1}) 1350 (CF_3), 1230 (CF_2); MS m/z 280 (M^+); Exact MS: m/z, 279.9832. Calcd for $C_8H_3F_7OS$: M, 279.9792.

2-Heptafluoropropylbenzothiophene: ^1H NMR ($CDCl_3$) δ=7.2—7.9 (5H, m), ^{13}C NMR ($CDCl_3$) δ=122.5 (C_7), 125.2 (C_4), 125.3 (C_5), 126.7 (C_6), 127.6 (C_3, t, J_{CCCF}=6.1 Hz), 138.3 (C_8), 141.0 (C_9); IR (cm^{-1}) 1350 (CF_3), 1230 (CF_2); MS m/z 302 (M^+); Exact MS: m/z 301.9992. Calcd for $C_{11}H_5F_7S$: M, 302.0000.

7-Heptafluoropropylbenzothiophene: One of the possible isomers heptafluoropropylated at the benzene ring of benzothiophene was isolated and tentatively identified as 7-heptafluoropropylbenzothiophene, the possibility of 4-heptafluoropropylbenzothiophene cannot be denied. ^1H NMR ($CDCl_3$) δ=7.4—8.2 (5H, m); ^{13}C NMR ($CDCl_3$) δ=122.9 (C_5), 123.4 (C_3), 124.4 (C_6, t, J_{CCCF}=8.5 Hz), 126.5 (C_2), 128.7 (C_4), 141.7 (C_8); IR (cm^{-1}) 1350 (CF_3), 1230 (CF_2); MS: m/z 302 (M^+); Exact MS: m/z 301.9971. Calcd for $C_{11}H_5F_7S$: M, 302.0000.

2-Heptafluoropropyl-5-trimethylsilylthiophene: ^1H NMR ($CDCl_3$) δ=0.39 (9H, s), 7.17,* 7.41 (ABq, J=3.6 Hz, $*J_{HF}$=1.2 Hz); ^{13}C NMR ($CDCl_3$) δ=−0.4 ($SiCH_3$), 131.2 (C_3, t, J_{CCCF}= 4.9 Hz), 133.9 (C_4), 140.8 (C_5); IR (cm^{-1}) 1350 (CF_3), 1230 (CF_2); MS m/z 324 (M^+); Exact MS: m/z 324.0278. Calcd for $C_{10}H_{11}F_7SiS$: M, 324.0239.

2,5-Dimethyl-3-heptafluoropropylthiophene: ^1H NMR ($CDCl_3$) δ=2.36 (3H, s), 2.44 (3H, t, J_{HF}=2.4 Hz),[15] 6.58 (1H, s); ^{13}C NMR ($CDCl_3$) δ=13.7 (2-CH_3), 14.9 (5-CH_3), 124.7 (C_2, t, J_{CCCF}=3.0 Hz), 127.3 (C_5), 137.0 (C_4); ^{19}F NMR ($CDCl_3$) −4.3, −30.8 (J_{HF}=2.4 Hz), −50.8; IR (cm^{-1}) 1340 (CF_3), 1230 (CF_2); MS m/z 280 (M^+); Exact MS: m/z 280.0119 Calcd for $C_9H_7F_7S$: M, 280.0156.

2,5-Dibromo-3-heptafluoropropylthiophene: ^1H NMR ($CDCl_3$) δ=6.97 (s); ^{13}C NMR ($CDCl_3$) δ=113.0 (C_5), 115.1 (C_2, t, J_{CCCF}=4.9 Hz), 130.1 (C_4); IR (cm^{-1}), 1360 (CF_3), 1230 (CF_2); MS m/z 408 (M^+); Exact MS: m/z 407.8067. Calcd for $C_7HF_7SBr_2$: M, 407.8055.

2,5-Bis(trimethylsilyl)-3-heptafluoropropylthiophene: ^1H NMR ($CDCl_3$) δ=0.3 (18H, br), 7.31 (1H, t, J_{HF}=1.5 Hz); ^{13}C NMR ($CDCl_3$) δ=−0.2 (5-$SiCH_3$), 0.4 (2-$SiCH_3$, t),[15] 135.1 (C_4, m for CF coupling), 147.3 (C_5), 150.1 (C_2, t, J_{CCCF}=4.3 Hz); IR (cm^{-1}) 1370 (CF_3), 1230 (CF_2); MS m/z 396 (M^+); Exact MS: m/z 396.0642. Calcd for $C_{13}H_{19}F_7Si_2S$: M, 396.0635.

The Removal of Trimethylsilyl Group from 2,5-Bis-(trimethylsilyl)-3-heptafluoropropylthiophene. 2,5-Bis-(trimethylsilyl)-3-heptafluoropropylthiophene (120 mg), KF (175 mg), and water (0.1 ml) were dissolved in 5 ml DMSO, and the solution was heated at 100 °C for 24 h. From the DMSO solution the resulting 3-heptafluoropropylthiophene was extracted with Freon-113; the Freon-113 solution was washed with 20 ml of water two times in order to completely remove any DMSO. Freon-113 was carefully removed and almost pure 3-heptafluoropropylthiophene was obtained.

3-Heptafluoropropylthiophene: ^1H NMR ($CDCl_3$) δ= 7.1—7.2 (2H, m), 7.6 (1H); ^{13}C NMR ($CDCl_3$) δ=125.5 (C_4, t, J_{CCCF}=3.7 Hz), 127.4 (C_5), 128.1 (C_2, t, J_{CCCF}=6.7 Hz); IR (cm^{-1}), 1350 (CF_3), 1230 (CF_2); MS m/z 252 (M^+); Exact MS: m/z 251.9871. Calcd for $C_7H_3F_7S$: M, 251.9844.

The Removal of a Bromo Group from 2,5-Dibromo-3-heptafluoropropylthiophene. A standard solution of lithium aluminum hydride in THF (1.5 mol l^{-1}) was prepared according to a method described in the literature.[16] A standard solution (0.77 ml) and then 2,5-dibromo-3-heptafluoropropylthiophene were added to THF; the resulting solution was refluxed for 24 h. The reaction flask was cooled in an ice bath; then a 1 : 1 mixture of water and THF 20 ml was added slowly, drop by drop. Then, a 0.1 g NaOH pellet was added. The aqueous phase was extracted five times with 20 ml portions of ether. The formation of 3-heptafluoropropylthiophene was confirmed by GC-MS.

Crystal and Molecular Structures of Tetraisopropyl 1,1′-(1,8-Naphthylene)-bis[1*H*-1,2,3-triazole-4,5-dicarboxylate] and Diisopropyl 1-(1-Naphthyl)-1*H*-1,2,3-triazole-4,5-dicarboxylate

National Chemical Laboratory for Industry, 1-1, Higashi, Tsukuba, Ibaraki 305
(Received March 2, 1988)

Molecular structures of the title compounds, which belong to the class of peri-substituted naphthalenes, have been determined by means of X-ray diffraction. Tetraisopropyl 1,1′-(1,8-naphthylene)bis[1*H*-1,2,3-triazole-4,5-dicarboxylate] (**1**), monoclinic, space group $C2/c$, a=35.034(3), b=9.717(1), c=18.504(1) Å, β=96.43(1)°, Z=8; Diisopropyl 1-(1-naphthyl)-1*H*-1,2,3-triazole-4,5-dicarboxylate (**2**), monoclinic, space group $P2_1/n$, a=16.246(2), b=10.115(1), c=12.390(1) Å, β=96.67(1)°, Z=4. The dihedral angles between the mean plane of the naphthalene ring and that of the triazole ring are 88° and 85° for **1** and **2**, respectively. The naphthalene framework of **1** is much more distorted than that of **2** because of a steric repulsion between the two triazole rings with bulky ester groups of **1**.

Owing to a steric repulsion between two substituents, the naphthalene framework is distorted to some degree from a planar structure in 1,8-disubstituted naphthalenes. Among them, such a distorsion of 1,8-bis(trimethylelement) naphthalenes has been shown to be very large by an X-ray diffraction study.[1] However, there have been few X-ray analyses of compounds having aromatic rings in the 1 and 8 positions of the naphthalene moiety.[2]

Recently, we synthesized novel 1,8-bis(heteroaromatic substituted)naphthalenes, 1,1′-(1,8-naphthylene)bis[1*H*-1,2,3-triazoles], and investigated their spectroscopic properties.[3] A structure determination of the parent compound, 1,1′-(1,8-naphthylene)bis[1*H*-1,2,3-triazole], showed that the naphthalene framework in this molecule is very distorted because of a steric repulsion between the two triazole rings.[4]

In this paper, we report on the crystal and molecular structures of more overcrowding compounds, tetraisopropyl 1,1′-(1,8-naphthylene)bis[1*H*-1,2,3-triazole-4,5-dicarboxylate] (**1**), and the corresponding monotriazolylnaphthalene, diisopropyl 1-(1-naphthyl)-1*H*-1,2,3-triazole-4,5-dicarboxylate (**2**).

Experimental

Compounds **1** and **2** were prepared and purified according to a previous report.[3] Colorless needle-like crystals of **1** and **2** were obtained by a slow evaporation from diethyl ether-hexane solution at room temperature.

Crystal Data. 1; $C_{30}H_{34}N_6O_8$, M=606.6, monoclinic, space group $C2/c$, a=35.034(3), b=9.717(1), c=18.504(1) Å, β=96.43(1)°, V=6259.7(6) Å^3, D_m=1.28 g cm^{-3} (by floatation in carbon tetrachloride and hexane), D_c=1.29 g cm^{-3} for Z=8, μ(Mo $K\alpha$)=1.02 cm^{-1}. **2**; $C_{20}H_{21}N_3O_4$, M=367.4, monoclinic, space group $P2_1/n$, a=16.246(2), b=10.115(1), c=12.390(1) Å, β=96.67(1)°, V=2022.2(3) Å^3, D_m=1.20 g cm^{-3} (by floatation in carbon tetrachloride and hexane), D_c=1.21 g cm^{-3} for Z=4, μ(Mo $K\alpha$)=0.92 cm^{-1}.

Crystallographic Measurements. The cell dimensions and diffraction intensities of both crystals were measured on a Rigaku AFC-4 four-circle diffractometer with graphite-monochromated Mo $K\alpha$ radiation (λ=0.71069 Å) at room temperature. The crystals, approximate dimensions of 0.8×0.3×0.1 and 0.7×0.3×0.2 mm for **1** and **2**, were used for intensity data measurements. Unit-cell dimensions of both crystals were determined by least-squares fits using 25 reflections in the range $20°<2\theta<30°$. Intensity data were collected by the ω-2θ scan mode at a rate of $2°(2\theta)$ min^{-1}. The scan range (2θ) was from 2° to 55° for both crystals. Three standard reflections were measured after every 50 reflections, showing no significant intensity decay throughout the data collection for both crystals. Totals of 7793 and 5080 (including systematically absent) reflections were measured, of which 3024 and 2303 were observed ($|F_o| > 3\sigma(|F_o|)$) for **1** and **2**, respectively. The usual Lorentz and polarization corrections were applied, but no absorption corrections were made.

Structure Determination of 1. The structure was solved by direct methods using MULTAN 78.[5] An E-map using 276 ($|E| > 1.2$) revealed all the non-hydrogen atoms. Hydrogen atoms were placed at the calculated positions. The structure was refined by a block-diagonal least-squares method, using the UNICS III system.[6] Anisotropic thermal parameters were assumed for the non-hydrogen atoms, and isotropic parameters, for the hydrogen atoms. The final refinement, employing a weighting scheme of $w=(0.0024|F_o|^2-0.0156|F_o|+6.413)^{-1}$, led to R and R_w values of 0.058 and 0.056, respectively. The final atomic parameters are listed in Table 1.

Strucure Determination of 2. The solution and refinement of the structure of **2** was accomplished in the same way as that of **1**. The weighting scheme used in the final cycle of the refinement was $w=(0.0024|F_o|^2+0.054|F_o|+0.313)^{-1}$. The final R and R_w value was 0.069 and 0.067, respectively; the final atomic parameters are listed in Table 2.

Atomic scattering factors were taken from International Tables for X-Ray Crystallography.[7] All the calculations were carried out on a FACOM M-380 computer at Tsukuba Research Center.

Results and Discussion

Molecular Structure. The molecular structures and the atom labelings of **1** and **2** are presented by an ORTEP[8] drawing in Fig. 1. The selected bond distances and angles of **1** and **2** are given in Tables 3 and 4, respectively.[9]

The deviations of the each atom of the triazole rings from the mean plane are within 0.01 Å in both **1** and **2**, which suggests that they are almost planar due to an aromatic ring system. The dihedral angles between the mean plane of the naphthalene ring and those of two triazole rings in **1** are 87.1(1)° for the one triazole ring and 89.3(1)° for the other. In the case of **2**, the angle is 85.1(1)°, which is slightly smaller than that in **1**. The angles are nearly ninety degrees while in the parent compounds, 1,1′-(1,8-naphthylene)bis[1*H*-1,2,3-

triazole] and 1-(1-naphthyl)-1*H*-1,2,3-triazole, the corresponding angles are 50.6(2)° and 56.8(2)°, respectively.[10] These results indicate that the repulsion between the isopropoxycarbonyl group in the 5-position of the triazole ring and the hydrogen in the 2′-position of the naphthalene ring is very large. The two triazole rings of **1** face each other with a dihedral angle of 33.1(2)°, and assume a trans conformation.

The fusion angle, Cl-C9-C8, is 129.0(4)° in **1**, while the angle in **2** is 124.3(3)°. The enlargement of this angle in **1** indicates that a severe steric strain is caused by a repulsion between two triazole rings with bulky ester groups. The angles C9-Cl-N1 and C9-C8-N4 in **1**, which are related to the pivot bond between the triazole ring and the naphthalene ring, are 121.3(3)° and 122.0(4)°, respectively. These are large compared with that in **2** (117.8(3)°), also suggesting a large repulsion between the two triazole rings of **1**. Similar relationships have been observed for the parent compounds.[10]

The equations of the least-squares planes of the naphthalene ring and the deviations of the atoms are listed in Table 5. The planarity of the naphthalene ring in **1** is as good as that in **2**.

group at the 4-position exists in the triazole plane, but that at the 5-position it twists from the triazole plane. Because the latter group is situated between the ester group at the 4-position and the naphthalene ring, coplanarity cannot be maintained owing to severe steric overcrowding. In the case of **1**, the arrangements of four carbonyl groups and two triazole rings are more complicated than those of **2**. The torsion angles C12-C11-C13-O1, C11-C12-C17-O3, C22-C21-C23-O5, and C21-C22-C27-O7 are 49.1(7)°, −2.4(7)°, 144.8(4)°, and 160.5(5)°, respectively. Although the results reflect the requirements of intramolecular contacts, the influence of intermolecular packing can not be ignored.

Comparison with Other Peri-Substituted Naphthalenes. Typical data regarding the effects of the distorsion on the naphthalene ring in **1** are listed in Table 6 along with data for the other peri-substituted naphthalenes. In this Table, Z1 and Z8 are the atoms in substituents and there bound to C1 and C8, respectively. In order to avoid any steric overcrowding of two bulky peri-substituents, the nonbonding distance between C1 and C8 as well as that between Z1 and Z8 is enlarged. Accordingly, fused angle C1-C9-C8 expands more than 120°, and C1 and C8 are displaced in opposite directions from the naphthalene ring with torsion angle C1-C9-C10-C4 not equal to 0°. In order to lengthen the distance between Z1 and Z8, angle C9-C1-Z1 expands more than 120°, and torsion angle C10-C9-C1-Z1 becomes less than 180°.

Considering the data in Table 6, there are various modes in which the strain of bulky substituents affect the naphthalene framework. The distorsion of the naphthalene ring in 1,3,6,8-tetra-*t*-butylnaphthalene is remarkably large because of severe steric overcrowding. Compared with other peri-substituted naphthalenes, the displacement of C1 and C8 from the naphthalene ring of **1** is very small. However, the two angles, C1-C9-C8 and C9-C1-Z1, are significantly large. Therefore, it may be pointed out that the above-described distorsions in **1** relieve the severe steric repulsion between the two triazole rings with bulky ester groups.

Crystal Structure. The packing modes of molecules in both crystals are shown in Fig. 2. The crystal structures are stabilized mainly by van der Waals forces; the shortest intermolecular distances are 3.209(5) Å for O(1) (*x*,*y*,*z*)-C(12) (1−*x*,*y*,0.5−*z*) and 3.286(4) Å for O(3) (*x*,*y*,*z*)-C(12) (−*x*,−*y*,1−*z*) in **1** and **2**, respectively.

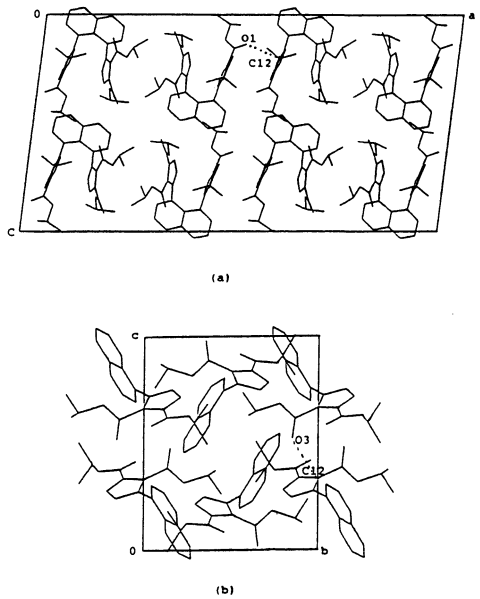

Fig. 2. Crystal structures. Hydrogen atoms are omitted for clarity. (a) Compound **1**, projected along the b axis. (b) Compound **2**, projected along the a* axis.

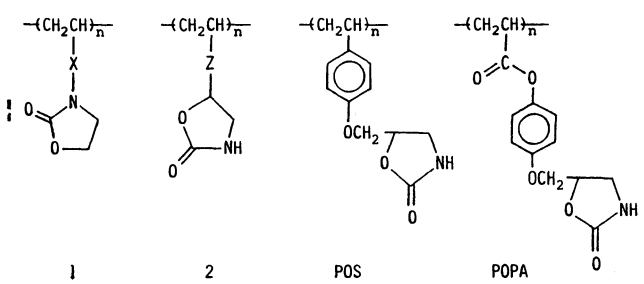
Preparation and Complex Formation of Polymers Anchoring 2-Oxazolidinone

Tomomichi Ishikawa,* Hidehiko Nishizuka, and Tadashi Kawai
Department of Industrial Chemistry, Faculty of Technology, Tokyo Metropolitan University, Fukasawa, Setagaya-ku, Tokyo 158
(Received March 18, 1988)

Polymers anchoring 3-unsubstituted 2-oxazolidinone were prepared and their complex formation with phenol and mercury(II) acetate were investigated. Preformed poly(4-hydroxystyrene) was treated with tris(2,3-epoxypropyl) isocyanurate to give a polymer containing 2-oxazolidinone residues within the limits of 57.7 mol%. Polymers carrying 2-oxazolidinone were also prepared through the homopolymerization and copolymerization of 4-(2-oxo-5-oxazolidinylmethoxy)phenyl acrylate. The effective concentration of 2-oxazolidinone residue in the polymers, which is accessible to phenol, was determined on the assumption that the polymer-bound 2-oxazolidinone and phenol formed a 1 : 1 complex. 2-Oxazolidinone and a mercury atom formed a 2 : 1 complex; this relation on the molar ratio applies to all forms of complexes between the mercury atom and the 2-oxazolidinone residue in the polymers.

2-Oxazolidinone has a reactive carbamoyl group, and its reactions lead to the formation of various useful compounds such as biocides,[1] surface active agents,[2] reactive reagents,[3] and reaction intermediates.[4] Polymers containing 2-oxazolidinone residues have also been reported. Walls and co-worker[5] previously noted that poly(3-vinyl-5-methyl-2-oxazolidinone) absorbed phenol, alkyl halides, and halogens. The complexes between 5-alkyl-3-vinyl-2-oxazolidinones and chlorine are useful as bactericides, fungicides, and bleaches.[6] Further, we have reported that a polymer containing 2-oxazolidinone rings in the main chain, prepared from 2,4-diisocyanatotoluene and 1,4-bis(2-oxo-5-oxazolidinylmethoxy)benzene, formed complexes with phenol and halogens.[7] Okawara and co-workers[8] have reported on a complex formation between tin(II) chloride and 2-oxazolidinone or 3-glycidyl-2-oxazolidinone; however, a complex of the salt with the polymer obtained from the latter compound is not examined in its paper. We have discovered the fact that a precipitate is formed when treating 2-oxazolidinone with mercury(II) acetate in methanol. This is, presumably, a complex between 2-oxazolidinone and mercury(II) acetate; its structure has been confirmed in this present work. Most of the polymers anchoring 2-oxazolidinone studied until now were of polymer type **1**:[5,8-12] almost no polymers in which a nitrogen atom adjacent to a carbonyl group holds a reactive hydrogen, such as polymer **2**, has been reported, except for poly(5-vinyl-2-oxazolidinone).[13] Polymer **2** must be capable of a complex formation with phenol and mercury(II) acetate. In this paper, therefore, we also report on the syntheses and complex formations of new polymers, poly[4-(2-oxo-5-oxazolidinylmethoxy)styrene](POS) and poly[4-(2-oxo-5-oxazolidinylmethoxy)phenyl acrylate](POPA), owing to interest in the characteristic properties of polymer-bound 3-unsubstituted 2-oxazolidinone (polymer **2** type). This work gives fundamental information on the use as carriers for biocides, as ligands for a polymer-metal complex catalyst, and as agents for heavy metal ions recovery in solutions.



Experimental

Materials. Poly(4-hydroxystyrene)(PHS) was purchased from the Maruzen Petrochemical Corp., $\overline{M}_w$ 5850, $\overline{DP}$ 49, hydroxyl equivalent 120, and $[\eta]$ 0.0906 dl g^{-1} (at 30 °C in DMSO). Tris (2,3-epoxypropyl) isocyanurate (TEPIC) was offered by the Nissan Chemical Corp. and was recrystallized from methanol, mp 102—104 °C (lit,[14] 103—104.5 °C). Acryloyl chloride was distilled prior to use. 5-(4-Hydroxyphenoxymethyl)-2-oxazolidinone was prepared from hydroquinone and TEPIC in a way similar to that mentioned in a previous paper.[6] 3-Phenylcarbamoyl-2-oxazolidinone was prepared from 2-oxazolidinone and phenyl isocyanate according to a previously published report.[15] 3,5-Diphenyl-2-oxazolidinone was prepared from styrene oxide and phenyl isocyanate.[16] 5-Phenoxymethyl-2-oxazolidinone (2-oxo-5-oxazolidinylmethoxybenzene, abbreviated to OMB), was prepared from phenol and TEPIC.[17] Solvents were dried and distilled before use. Other chemicals of reagent grade were used without further purification.

General Procedure for Reaction of PHS with TEPIC. A 300 cm^3, four-necked round-bottomed flask equipped with a stirrer, reflux condenser, and thermometer was charged with the desired amount of PHS, TEPIC, sodium hydroxide, and DMF. The reaction mixture was stirred at 158 °C for 7 h, followed by treating with phenol for 5 h. After evaporation of the solvent under reduced pressure, the residue was poured into water. The precipitate was washed with ethyl acetate, followed by reprecipitation from an acetone solution with water. The reprecipitate was washed with diethyl ether and dried under reduced pressure. The obtained content in 2-oxazolidinone residue in the polymers was determined by an

IR absorption analysis at 1740 cm^{-1}.

Synthesis of 4-(2-Oxo-5-oxazolidinylmethoxy)phenyl Acrylate (OPA). A 300-cm^3, round-bottomed flask equipped with a stirrer, reflux condenser, thermometer, and a inlet tube for nitrogen gas was charged with 3.5 g (0.017 mol) of 5-(4-hydroxyphenoxymethyl)-2-oxazolidinone and 150 cm^3 of tetrahydrofuran; then 1.5 g (0.17 mol) of acryloyl chloride and 2.4 g (0.023 mol) of triethylamine were added. After stirring under nitrogen for 3 h, the precipitate was removed by filtration. The filtrate was treated first with a 5% aqueous solution of sodium hydrogencarbonate, followed by two extractions using diethyl ether. The ether-layer was washed with water, and dried over anhydrous sodium sulfate, followed by distillation. The residue was recrystallized from ethanol. Yield 31.8%; mp 141—142 °C (colorless needle). Found: N, 5.18%. Calcd for $C_{13}H_{13}NO_5$: N, 5.32%. IR(KBr) 3270 (NH), 1750 (C=O), 1730 (C=O), 1630 (C=C), 1500, 1405, 1300, 1250, 1200, 1165, 1150, 825, and 805 cm^{-1}.

Procedure for Polymerization of OPA. OPA 0.8 g, 1,4-dioxane 6 cm^3 and 1 mol% AIBN were charged into a reaction tube. The mixture was treated at 50 °C under nitrogen in a sealed tube. After 24 h, the contents of the tube had gelled. The obtained polymer was washed with 1,4-dioxane and diethyl ether, followed by vacuum drying. Yield 86%.

Copolymerization with styrene was carried out in a way similar to the homopolymerization method. Yield 48.3%. The composition of the copolymer was determined by an elementary analysis. Found: C, 59.51; H, 5.32; N, 4.91%.

General Procedure for the Complex Formation between 2-Oxazolidinones and Phenol. The 2-oxazolidinones (200 mg) were added to 5 cm^3 of an aqueous solution of phenol; the specimens were kept at 30 °C with shaking. After 2 days, the solids were separated by filtration, and the concentration of phenol in the liquid phase was evaluated by measuring the absorption at 280 nm.

General Procedure for the Complex Formation between 2-Oxazolidinones and Mercury(II) Acetate. The 2-oxazolidinones (200 mg) were added to 10 cm^3 of 0.08×10^{-3} mol dm^{-3} aqueous solution of mercury(II) acetate, and the specimens were kept at 30 °C with shaking. After 2 days, the solids were separated by filtration; then, the amount of mercury(II) acetate in the liquid phase was determined by atomic absorption analysis.

Reaction of 2-Oxazolidinone with Mercury(II) Acetate in Methanol. 2-Oxazolidinone (1.51 g, 1.74×10^{-3} mol) was dissolved in 20 cm^3 of methanol. The solution was poured into a solution containing mercury(II) acetate (2.82 g, 8.84×10^{-3} mol) in 30 cm^3 of methanol. The mixture was permitted to stand overnight. The precipitate was collected by filtration. The filtrate was washed with methanol, and dried under reduced pressure. Yield 2.05 g (colorless needle); Atomic absorption analysis Hg 48.6%; ^1H NMR (DMSO-d_6) δ=4.30 (2H, t, CH_2) and 3.60 (2H, t, CH_2); For IR(KBr) see Fig. 5.

Results and Discussion

Preparation of POS and POPA. It has been reported that OMB[17] was obtained by treating phenol with TEPIC in the presence of sodium hydroxide. Previously, we had also succeeded in synthesizing 5-(4-hydroxyphenoxymethyl)-2-oxazolidinone[6] from hydroquinone and TEPIC. Therefore, the reaction of PHS with TEPIC was studied in order to prepare POS. PHS is prepared through a polymerization of 4-hydroxystyrene; however, the proportion of the side reaction, such as chain-transfer and termination, becomes higher with an increase in the degree of polymerization, and an insoluble polymer is finally formed. It was attributed to forming a cross-linked polymer caused by a chain-transfer to phenolic hydroxyl groups.[18] Therefore, though its molecular weight is low, a linear soluble PHS was used for the reaction with TEPIC, since the number of phenolic hydroxyl groups in the polymer can be accurately measured. The reaction was carried out under homogeneous conditions in DMF in the presence of sodium hydroxide. Unreacted TEPIC was transformed into OMB by treating with phenol; the produced OMB was removed from the reaction products through washing with ethyl acetate and reprecipitation. The IR spectra of the reaction products show two characteristic absorption bands at 3400 (O-H of phenol) and 1740 cm^{-1} (C=O of 2-oxazolidinone). If the reaction was completed, the absorption attributed to the O-H bond should disappear. The results of the IR spectra are, thus, indicative of the presence of unreacted phenolic hydroxyl groups. The content in 2-oxazolidinone residue in the polymers was determined spectrophotometrically by using the absorbance at 1740 cm^{-1} with 5-phenoxymethyl-2-oxazolidinone as a standard.

The results are summarized in Table 1. It was confirmed that the 2-oxazolidinone content for POS 3 is nearly equal to that determined by elementary analysis. In stoichiometric reactions between TEPIC and phenolic hydroxyl groups in the polymer, the 2-oxazolidinone content was a maximum value, and could not rise beyond 58%, despite long reaction times (14 hours) and the use of excess TEPIC. These results can be explained by suggesting that the polymer-bound 2-oxazolidinones surrounding fresh active phenolic oxygens hinder, to some extent, a further reaction of TEPIC with these phenolic active sites. However, the results shown in Table 1 suggest that the use of a smaller amount of TEPIC than the stoichiometric molar ratio allows the 2-oxazolidinone content in the polymer to be controlled. All these polymers were soluble in acetone, benzene, THF, DMF, and DMSO.

As previously described, significant amounts of the unreacted phenolic hydroxyl groups are present in the polymers anchoring 2-oxazolidinone, prepared from the preformed PHS. Therefore, a vinyl monomer containing a 2-oxazolidinone moiety, OPA, was preformed from 5-(4-hydroxyphenoxymethyl-2-oxazolidinone and acryloyl chloride, and was homo- and copolymerized in 1,4-dioxane by using AIBN as initiator. Little and Pickens[7] have reported that homopolymerization of 5-vinyl-2-oxazolidinone for a type-2 polymer should be impossible, except for a copolymerization

Table 1. Preparation of the Polymers Anchoring 2-Oxazolidnone

Abbreviation[a]	Material[b] mole ratio	Reaction condition[c]			Product

a) PHS: Poly(4-hydroxystyrene); POS: Poly[4-(2-oxo-5-oxazolidinylmethoxy)styrene] prepared from PHS; POPA: Homopolymer of 4-(2-oxo-5-oxazolidinylmethoxy)phenyl acrylate(OPA); OPA-St: Copolymer of OPA and styrene (St). b) HSU: Constitutional repeating unit in PHS; TEPIC: tris(2,3-epoxypropyl) isocyanurate. c) In the presence of ca. 4 mol% NaOH for POS 1, 2, and 3; used AIBN as an initiator for POPA, and OPA-St. d) Measured at 30 °C in DMSO. e) In DMF, DMSO, and NMP.

with methyl methacrylate. However, the monomer OPA obtained in this paper did homopolymerize, and gel. Homopolymerization gave a 86% conversion. The OPA-homopolymer (POPA) was swollen by, but insoluble in, pyridine, *m*-cresol, DMF, DMSO, and NMP, in contrast to water soluble poly(3-vinyl-2-oxazolidinone).[10] On the other hand, the equimolar reaction between OPA and styrene gave a copolymer (OPA-St) containing 15 mol% styrene, and it can be seen that the reactivity for OPA was higher than that for styrene. However, this should be judged more exactly on the basis of a reactivity ratio determination for OPA and styrene. The obtained copolymer was soluble in the solvents mentioned above.

Complex Formation of the Polymer-Bound 2-Oxazolidinone with Phenol. Several types of polymer-bound 2-oxazolidinone were incubated with an aqueous solution of phenol at 30 °C for 2 days. In confirmation of the attainment of equilibrium, several phenol determinations were performed after 2 and 7 days incubation: both values were identical.

The results were analyzed by applying an equation which Komiyama and co-workers[19] proposed for the complex formation between a β-cyclodextrin residue in immobilized catalysts and phenol. Namely, if the 2-oxazolidinone residue in the polymers and phenol formed a 1 : 1 complex, the following equation could be effective:

$$[\text{Phenol}]=[\text{OX}]_{\text{eff}}\,[\text{Phenol}]/[\text{Complex}]-K_{\text{d}}. \quad (1)$$

Here, [Phenol] and [Complex] are the equilibrium concentrations of phenol and the 1 : 1 complex between the 2-oxazolidinone residue and phenol, respectively. K_{d} is the equilibrium constant for the dissociation of the complex between the 2-oxazolidinone residue in the polymers and phenol. $[\text{OX}]_{\text{eff}}$ is the effective concentration of the 2-oxazolidinone residue in the polymers, which is accessible to phenol. Thus, the values of K_{d} and $[\text{OX}]_{\text{eff}}$ were determined from the intercepts and the slopes, respectively, for the straight lines in the plots of [Phenol] vs. [Phenol]/[Complex].

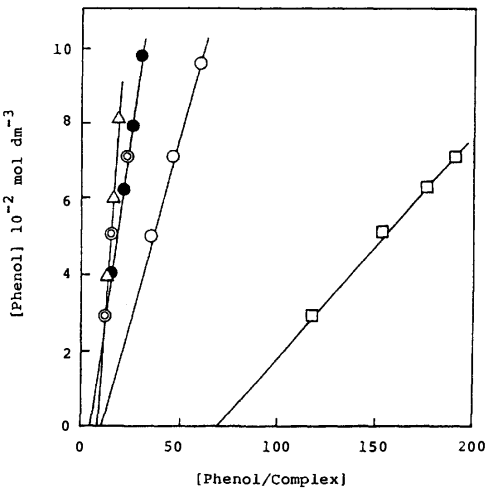

Fig. 1. Plots of [Phenol] vs. [Phenol]/[Complex] according to Eq. 1. △, data for POPA; ○, data for POS 1; ◎, data for POS 2; ●, data for POS 3; □, data for PHS.

Table 2. Complex Formation between the Polymer-Bound 2-Oxazolidinones and Phenol[a]

Substrate	K_{d} 10^{-2} mol dm^{-3}	Concentration of 2-oxazolidinone residue/10^{-3} mol dm^{-3}	
		$[\text{OX}]_{\text{eff}}$	$[\text{OX}]_{\text{charged}}$
PHS	3.83	0.564[b]	33.3[b]
POS 1	1.62	3.79	13.0
POS 2	1.60	3.77	11.9
POS 3	2.12	1.90	7.71
POPA	8.27	8.61	15.2

a) Reacted at 30 °C by using 200 mg of substrate. b) Showed as an amount of repeating unit in poly(4-hydroxystyrene).

The plots of [Phenol] vs. [Phenol]/[Complex] according to Eq. 1 for the polymers anchoring 2-oxazolidinone are shown in Fig. 1. As can be seen from this figure, a definitely linear correlation between [Phenol] and [Phenol]/[Complex] was observed for all the samples. These facts indicate that the 2-oxazolidinones generate a 1 : 1 complex with phenol.

The values of K_{d} and $[\text{OX}]_{\text{eff}}$ evaluated from the

plots in Fig. 1 are summarized in Table 2. It appears that the amount of complex generated between PHS and phenol is sufficiently low to be neglected. The $[OX]_{eff}$ value for POPA containing the OMB moiety indicates that about 57% of 2-oxazolidinone residues in the polymer generated the complex with phenol, while in the case of POS-polymers the amount of reacted phenol increased with an increase in the content of the 2-oxazolidinone residue in the polymers; however, only 20—30% of the polymer-bond 2-oxazolidinones were effectively complexed with phenol. Moreover, the K_d values for POS-polymers decreased with an increase in the content of the 2-oxazolidinone moieties. The variations of the K_d value and the low efficiency for the POS-polymers might be explained as follows: since, as previously described, the 2-oxazolidinone and phenol residues coexist in the POS-poymers, they interact with each other through inter- and intramolecular hydrogen bonding between carbonyl group in 2-oxazolidinone ring and phenolic hydrogen in the polymers; the number of free 2-oxazolidinone moieties decreases pronouncedly, and further complex formation between the previously coordinated 2-oxazolidinone moiety and fresh phenol becomes more difficult; i.e., this difficulty increases with an increase in the number of phenolic hydroxyl groups in the POS-polymer molecule. This explanation also supports the fact that 3-phenycarbamoyl-2-oxazolidinone gave only a small amount of the complex with phenol,[2] because of the intramolecular hydrogen bonding (Fig. 2). On the other hand, the reaction of POPA with phenol gave the highest K_d values of the series. POPA swells in organic solvents, but shrinks in water. The shrinkage of the polymer molecules prevents any effective segregation of the 2-oxazolidinone residues, and enhances the steric repulsion between two bulky phenolic substituents. This logical analysis allows us to conclude that K_d for POPA reaches large values. These results also suggest that the stability of the complexes is associated with the environmental conditions in the vicinity of the 2-oxazolidinone residue, rather than the 2-oxazolidinone content in the polymers.

As described above, the complex formation between polymer-bound 2-oxazolidinone and phenol has been reported only concerning *N*-substituted derivatives, such as polymer **1**. The polymer-phenol complexes were formed through hydrogen bonding between the carbonyl group in the 2-oxazolidinone ring and phenolic hydrogen. In these cases, 41—67% of the polymer-bound 2-oxazolidinones were effectively interacting with phenol.[6,12] However, since the reaction of 3-phenylcarbamoyl-2-oxazolidinone with phenol yielded only a small amount of the complex,[2] and no complex was formed by treating 3,5-diphenyl-2-oxazolidinone with phenol, 3-substituted 2-oxazolidinones are not, necessarily, effective ligands for phenol. On the other hand, the polymer-bound 2-oxazolidinone in this work has a hydrogen on a nitrogen atom adjacent to a carbonyl group in the 2-oxazolidinone ring. In this case, there is a possibility of forming an intramolecular hydrogen bonding between phenolic hydrogen and both N-H and C=O groups in the 2-oxazolidinone ring, as shown in Fig. 3. The IR spectra of the original OMB and the OMB-phenol complex are shown in Fig. 4. Several characteristic shifts observed near 3300 cm^{-1} and in the region 1800—1200 cm^{-1} support the idea that the complex was, indeed, formed through hydrogen bonding (Fig. 3).

Complex Formation of the Polymer-Bound 2-Oxazolidinone with Mercury(II) Acetate. When methanol was used as a solvent for mixing mercury(II) acetate and 2-oxazolidinone, a white precipitate was obtained. The mercury content (48.6%) for the precipitate suggests that one mercury atom formed a 1:2 complex with two moelcules of 2-oxazolidinone (see Table 3). The IR spectra of the starting 2-oxazolidinone and complex are shown in Fig. 5. The

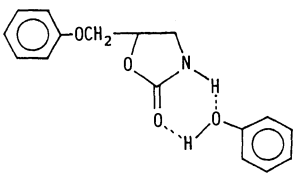

Fig. 3. Structure of the complex between PMO and phenol.

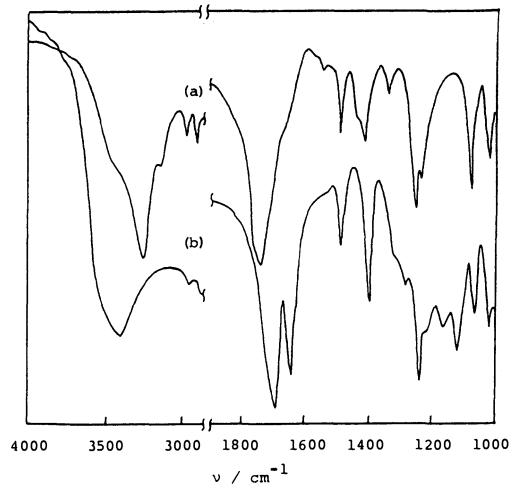

Fig. 5. IR spectra of 2-oxazolidinone (chart a) and the complex obtained from 2-oxazolidinone and mercury(II) acetate (chart b).

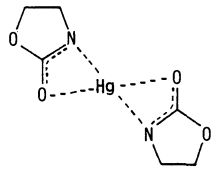

Fig. 6. Structure of the complex obtained from 2-oxazolidinone and mercury(II) acetate.

1740 cm^{-1} absorption band corresponds to the carbonyl stretching of 2-oxazolidinone shifted to 1705 cm^{-1} for the complex. In the case of the complex, furthermore, the 3280 cm^{-1} (N-H of 2-oxazolidinone) absorption band for the 2-oxazolidinone disappeared, and new absorption bands appeared at 1660 cm^{-1} and in the region 1200—1100 cm^{-1}. These two bands correspond to the C=N and C-O stretching vibration in the enol-type form of 2-oxazolidinone, respectively. Endo and co-workers[10] have reported on the formation of a 2 : 1 complex between 2-oxazolidinone and tin(II) chloride, with shifts of the IR absorption bands similar to those for the complex mentioned in this work.

In an ^1H NMR analysis, the chemical shifts of the pertinent protons in 2-oxazolidinone were observed at δ=3.45(t), 4.31(t), and 7.47(s). These signals have been assigned to the protons (H_a) attached to the ring carbon linked to nitrogen, to the protons (H_b) on a carbon atom attached to ring oxygen, and to the proton on the nitrogen atom, respectively.[20] However, the chemical shifts of the pertinent protons in the complex were observed at δ=3.60(t), and 4.30(t). The shift of the signal assigned to protons H_a and the disappearance of the signal assigned to proton on the nitrogen atom suggest that there is a considerable interaction between the mercury atom and the nitrogen atom adjacent to the protons H_a. Since no signal assigned to the pertinent protons in mercury(II) acetate was observed in the ^1H NMR spectrum of the complex, it is evident that the complex does not contain acetate ions.

Table 3. Complex Formation between the Polymer-Bound 2-Oxazolidinones and Mercury(II) Acetate[a]

Substrate	Amount of charged 2-oxazolidinone residue	Amount of mercury forming the complex	
	mmol	mmol[b]	mmol[c]
POS 1	0.328	0.007	0.164
POPA	0.381	0.160	0.191
OPA-St	0.359	0.079	0.180
OMB	0.262	0.095	0.131
2-Oxazolidinone	0.500[d]	0.226	0.250

a) Reacted at room temp in 10 cm^{-3} of 0.08 mol dm^{-3} mercury(II) acetate aq. solution. b) Determined by the change of absorbance in atomic absorption analysis. c) Calculated on the basis of assumption that the 2-oxazolidinone residue in the polymers and mercury atom formed a 2 : 1 complex. d) Reacted in methanol.

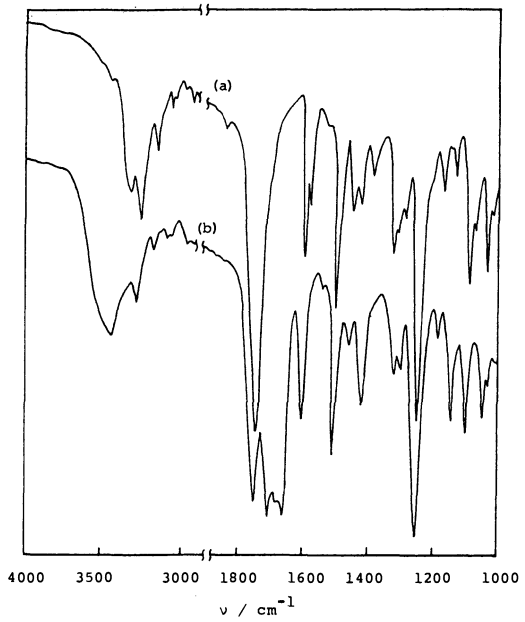

Fig. 7. IR spectra of PMO (chart a) and the complex obtained from PMO and mercury(II) acetate (chart b).

From these results, the reaction of 2-oxazolidinone (OxH) with mercury(II) acetate may be expressed in the form of Eq. 2; it seems reasonable to imagine that the structure of the resulting mercury compound is represented by the formula shown in Fig. 6.

$$2\,OxH + Hg(CH_3COO)_2 \rightarrow Hg(Ox)_2 + 2\,CH_3COOH \quad (2)$$

However, no precipitate was observed in the solution upon treating 2-oxazolidinone with several metal salts, which was tested by other means than mercury(II) acetate in this work. Spectrophotometrical evidence for the complex formation was not obtained.

On the other hand, OMB, POS 1, POPA, and OPA-St were treated with mercury(II) acetate under heterogeneous conditions in water, respectively. The results are listed in Table 3. The mercury content for the

OMB complex was only about 70% of the expected amount on the basis of an assumption that the polymer-bound 2-oxazolidinone and mercury atom formed a 2 : 1 complex. The IR spectra of the original OMB and OMB complex are shown in Fig. 7. As can be seen from the figure, the variations of absorption in both the 3500—3200 and 1740—1660 cm^{-1} regions indicate that the product obtained from OMB and mercury(II) acetate is a mixture of the original OMB and OMB complex, in comparison with Fig. 4. This is believed to be due to the formation of a complex on the solid surface of OMB.

The mercury content for the POPA complex reaches the highest value of the series, except for 2-oxazolidinone, and POPA absorbed about 80% of the amount originally expected. However, the mercury content was larger than that estimated on the basis of the $[OX]_{eff}$ value for complex formation between POPA and phenol. This result suggests that all the mercury atoms absorbed do not necessarily form a 2:1 complex, as shown in Fig. 6. It is thought that a mercury atom that chemically binds one mole of 2-oxazolidinone residue or/and is physically absorbed into polymer networks is present in the POPA-mercury complex. However, in the case of the polymer-mercury complexes, the IR-shifts were not so clearly observed. POS 1 and OPA-St, in spite of 58 and 85 mol% 2-oxazolidinone content, respectively, were not as absorptively effective as we had expected. The mercury contents for the polymers are in the order POPA->OPA-St->POS-complex; this order agrees with the 2-oxazolidinone content in the polymers. As can be seen in Table 3, a slight decrease in the 2-oxazolidinone content in the polymers affects the complex formation in a striking manner. The large discrepancies between the values calculated and determined for POS 1 and OPA-St can be explained on the basis of the assumption that, even if the polymers were used, two 2-oxazolidinone moieties in the polymers are consumed for binding one mercury atom. Since two 2-oxazolidinone moieties in the polymer are very far apart (as a function of the decrease in the 2-oxazolidinone content), their mutual cooperation in forming a 2 : 1 complex is effectively nil. In the case of POPA, therefore, the presumed 1 : 1 complex between the mercury atom and the 2-oxazolidinone residue may be neglected. As described above, POPA is insoluble and swelling in organic solvents and appears to be composed of networks of cross-linked polymers. Mercury(II) acetate which has permeated into the cross-linked POPA would be very difficult to remove, even by repeated washing with water, in comparison with soluble POS 1 and OPA-St.

It is, finally, concluded that one mercury atom forms a 1 : 2 complex with two molecules of 2-oxazolidinone. This relation concerning the molar ratio must apply to all forms of complexes between the mercury atom and the 2-oxazolidinone residue in polymers.

Synthesis and Cation-Complexing Ability of Ferrocene or Ruthenocene Functionalized Crown Ethers Possessing 2,6-Pyridino Moieties

Taeko IZUMI,* Satoshi MURAKAMI, and Akira KASAHARA
Department of Applied Chemistry, Faculty of Engineering, Yamagata University, Yonezawa 992
(Received March 26, 1988)

Keto crown ethers that contain ferrocene or ruthenocene and 2,6-disubstituted pyridine unit as part of the major ring have been reported. These keto crown ethers were synthesized by a reaction of 1,1′-metallocenedicarbonyl dichloride (ferrocene or ruthenocene) with 2,6-bis[ω-hydroxyoligo(oxyethylene)-α-ylmethyl]pyridine by using a high-dilution method. Their complexing ability with metal cations was measured by a solvent-extraction method, and was found to be poor with alkali metal cations but excellent with Ag^+, In^{3+}, and Zr^{4+} cations.

In view of the current interest in the functionality of crown ethers, many research groups have attempted investigations of new-type crown ethers[1] which contain sulfur or nitrogen atoms as well as heterocyclic or metallocene compounds and so on. We have previously described the synthesis and properties of ferrocene-incorporated keto crown ethers;[2] collected information indicates that the pyridyl unit in their crown ethers can be expected to be very efficient regarding cation extraction. Concerning macrocycles possessing subheterocyclic units, it has only been recently that these compounds have been shown to possess unique chemical and biochemical properties.[3] Furthermore, for the purpose of synthesizing crown compounds possessing specific properties, a number of ferrocene-incorporated crown ethers have already been reported; however, a crown ether containing a ruthenocene unit is rare.[4] We herein describe the preparation of multiheteromacrocycles that contain, as part of the major ring, metallocene (ferrocene or ruthenocene) and 2,6-disubstituted pyridine units combined with diester and $-OCH_2CH_2O-$ units, and their ability for forming complexes with various metal cations, including transition metals. In this work we considered (1) the influence of the pyridine unit depending on the ring size, and (2) the difference between ferrocene and ruthenocene on the complexing ability as a macrocycle.

Results and Discussion

Synthesis. Most of the hitherto reported macrocyclic diester compounds have been prepared by reactions between bis(acid chloride)s and diols in various yields, depending upon the ease of cyclization of substrates. In the present study, syntheses of **3** and **3′** were carried out in the presence of triethylamine by a modification of Bradshaw's method.[5]

Compounds **3a—d**, shown in Fig. 1, were prepared from 1,1′-ferrocenedicarbonyl dichloride **1** and an appropriate diol, **2a—d**. The dichloride (**1**) was generated from dicarboxylic acid with oxalyl dichloride in dichloromethane, and used immediately after extraction with hot hexane. Compound **3b**, for example,

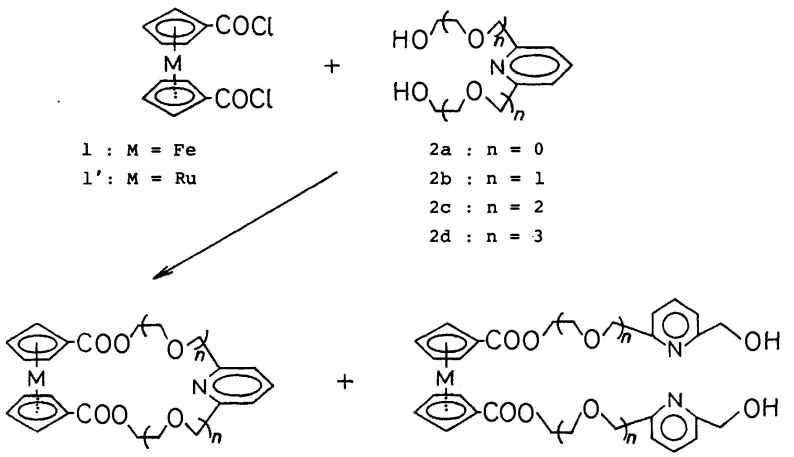

Fig. 1.

was prepared as follows: the reaction was run under high-dilution techniques; **1** was added dropwise to 1.7 equivalents of **2b** at 80 °C for 15 hours then stirred for 24 hours to generate the crown ester compound **3b** (16%) together with 1,1′-ferrocenedicarbonyl-linked bis(pyridinemethanol) **4b** (34%). Furthermore, we initially intended a synthesis to binuclear ferrocenophane[2] using this **4b**; thus, this reaction mole ratio was not optimum for mononuclear ferrocenophane **3b**. An equimolar reaction and prolonged reaction times (36 h) at this esterification stage resulted in a yield of **3b** that approached 30%. The structural assignments for **3a—d** were based on spectral evidence and elemental analyses. The IR spectra of **3a—d** exhibit the characteristic absorption of an ester carbonyl (1715—1725 cm^{-1}), a pyridine ring (1590—1600, 1570—1585 cm^{-1}), and a 1,1′-disubstituted ferrocene ring (3100, 815—840 cm^{-1}).

In the ^1H NMR spectra, all of the pyridinoferrocenophanes (**3a—3d**) showed a similar pattern: ether OCH_2 groups at δ 3.99—3.70, ester $COOCH_2$ groups at δ 4.62—4.36, α-methylene protons of pyridine as sharp singlet at δ 5.36—4.62, α and β ring protons of the ferrocene as the A_2B_2 pattern at δ 4.92—4.77 and 4.43—4.38, and pyridine protons at δ 7.76—7.06. For example, the ^1H NMR spectrum of **3b** has seven signals: doublet of doublets at δ 4.40 and 3.99 for the methylene protons of bridges, two triplets centered at δ 4.77 and 4.43 for the ferrocene ring protons, a singlet at δ 4.86 for α-methylene protons of pyridine, a double doublet at δ 7.76 for γ-protons, and a doublet at δ 7.38 for β-protons of the pyridine ring, respectively. A distinct downfield shift for α-methylene protons of a pyridine ring, could be explained by a deshielding effect by the pyridine π face. The mass spectra and elemental analyses also confirmed the structures.

The case of pyridinoruthenocenophane (**3′a—3′d**) also afforded a similar result (see Table 1). The general procedure was conducted in an analogous manner to the synthesis of pyridinoferrocenophane, except for the substitution of 1,1′-ruthenocenedicarbonyl dichloride (**1′**) for 1,1′-ferrocenedicarbonyl dichloride (**1**). In the ^1H NMR spectral data for **3′a—3′d**, very little change in the chemical shifts for the β-protons and α-methylene protons of pyridine ring were observed.

Extraction Ability. Concerning the influence of the functional parts of crown ethers toward the complexing ability, we already know the following. The introduction of carbonyl to crown ethers produces a product that is different from a simple crown ether. The characteristics include: 1) a destabilizing effect on the complex and/or 2) a reversal of the K^+-Ba^{2+} selectivity sequence, distinguishing features of naturally occurring antibiotic macrocycles.[6] Furthermore, complexes of a pyridine-incorporated cyclic polyether compound with Na^+, K^+, Ag^+, and Ba^{2+} showed unusual stabilities,[7] even though nitrogen-incorporated crown ethers caused a considerable drop in the stability of the K^+ complexes.[8] The complexing ability of the synthesized pyridinometallocenophanes were assessed by a solvent extraction of alkali, alkaline earth, and heavy-metal picrates with dichloromethane solutions of the ligands. The data are summarized in

Table 2. Extraction Data (Water-Dichloromethane)[a]

Compound	Extracted/%

a) Equal volumes of water and dichloromethane, and picric acid at 7.0×10^{-5} M(1M=1 mol dm^{-3}). Concentration of ferrocenophane: 7.0×10^{-4} M. Concentration of metal nitrate: 0.1 M.

Table 2. These two groups of pyridinometallocenophanes (M=Fe and Ru) showed a similar tendency regarding a low extractability toward alkali metal and alkaline earth metal cations, and a high extractability toward heavy-metal cations, in particular for Ag^+. Ferrocenophane, as a whole, however, showed a higher cation-binding ability compared to ruthenocenophane. For example, regarding the extractability toward a K^+ cation, **3a**, **3c**, and **3d** (M=Fe), expect **3b**, showed a moderate extractability and a similar K^+-Ba^{2+} selectivity sequence as was described above (due to an ester carbonyl); however, **3'a—3'd** (M=Ru) showed almost no extractability. These results indicate the distinction between ruthenium and iron(II) as the central metal of metallocene, as well as the cavity size. It is also interesting that the extraction ability of almost all pyridinometallocenophanes showed a remarkable dependence on the cavity size in the macrocycle of **3a—3d** and **3'a—3'd**; especially **3d** (n=3) and **3'c** (n=2) showed the best ability for Ag^+.

Furthermore, our original intention to introduce a pyridine moiety to metallocenophane in order to enhance the cation binding ability and selectivity has been accomplished. The effects of this pyridine are clear, compared with the results of the 1,1'-ferrocenyl keto crown ether, which we reported before.[2] A similar trend of affinity toward transition metal cations has been observed regarding hitherto reported "crowned" ferrocenophane as well as synthesized pyridinometallocenophanes; this suggests that the metal atom of the metallocene nucleus participates in the complexation process. It should be emphasized that all synthesized pyridinometallocenophanes are capable of forming stable complexes with silver (not an oxidative decomposition).

Experimental

Materials and Measurements. All melting points are uncorrected. 2,6-Bis(hydroxymethyl)pyridine, diethylene glycol, triethylene glycol were commercial products.

1,1'-Ferrocenedicarboxylic acid[9] and 1,1'-ruthenocenedicarboxylic acid[10] were prepared by methods described in the literature. The other reagents employed were commercial materials or were prepared by the usual methods. All inorganic compounds were reagents grade. The IR, ^{1}H NMR, and mass spectra were recorded on Hitachi 260-10, Hitachi R-22, and Hitachi RMU-6M spectrometers, respectively.

Synthesis of 2,6-Bis(ω-hydroxy substituted)pyridine (2) (n=1—3). Sodium 2-hydroxyethoxide was prepared from sodium methoxide (0.02 mol, 1.1 g) and dry ethylene glycol (0.05 mol, 3.1 g) in 20 cm^3 of ether with stirring at 40 °C for 4 h. Ether was removed in vacuo, and the residue was dissolved in 50 cm^3 of dry THF. To the solution, 2,6-bis(chloromethyl)pyridine (0.01 mol, 1.76 g) in 150 cm^3 of dry THF was added dropwise for 12 h at 55 °C; additional refluxing took place for 8 h. Sodium chloride salt was filtered off; the filtrate was then concentrated in vacuo, and the residue purified by silica-gel column chromatography. The first fraction yielded unreacted ethylene glycol; the second fraction gave 1.8 g (80%) of diol **2b** (n=1) as a pale-yellow viscous oil.

Diols **2c** (n=2) and **2d** (n=3) were also prepared by the above-mentioned procedure, except that diethylene glycol and triethylene glycol were used as a substitute for ethylene glycol, respectively. Along with unreacted diethylene glycol and triethylene glycol, the major isolated fraction was diol **2c** (74%) and **2d** (75%) as a pale-yellow viscous oil, respectively.

2,6-Bis[(2-hydroxy)methyl]pyridine (2b).[11] **2,6-Bis[[2-(2-hydroxyethoxy)ethoxy]methyl]pyridine (2c).** IR (neat) 3430—3350, 2930—2860, 1600, 1580 cm^{-1}. ^{1}H NMR ($CDCl_3$): δ=3.63—3.72 (m, -C<u>H</u>$_2$-C<u>H</u>$_2$-, 16H), 3.83 (s, -O<u>H</u>, 2H), 4.66 (s, Py-C<u>H</u>$_2$-, 4H), 7.35 (d, 3,5-Py<u>H</u>, 2H, J=8 Hz), 7.72 (d-d, 4-Py<u>H</u>, 1H, J=8 and 9 Hz). MS (70 eV) m/z 315 [M$^+$].

2,6-Bis[[[2-(2-hydroxyethoxy)ethoxy]ethoxy]methyl]pyridine (2d). IR (neat) 3400, 2900—2850, 1570, 1590 cm^{-1}. ^{1}H NMR ($CDCl_3$) δ=2.85 (br-s, -O<u>H</u>, 2H), 3.70—3.75 (m, -C<u>H</u>$_2$C<u>H</u>$_2$-, 24H), 4.68 (s, Py-C<u>H</u>$_2$-, 4H), 7.37 (d, Py-<u>H</u>, 2H, J=8 Hz), 7.73 (d-d, Py-<u>H</u>, 1H, J=8 and 9 Hz). MS (70 eV) m/z 403 [M$^+$].

Synthesis of 3a—d and 3'a—d. General Procedure. 1 was prepared from 1,1'-ferrocenedicarboxylic acid and oxalyl dichloride by a method described in the literature.[12] Under an atmosphere of nitrogen, to a solution of **1** (2.2 g, 7 mmol) and triethylamine (1.2 g, 12 mmol) in dry benzene (150 cm^3), diol **2** (n=0—3) (12 mmol) diluted with dry benzene (100 cm^3) and dry THF (50 cm^3) was added dropwise over 15 h with stirring. An additional 24 h period of gentle refluxing followed. After removing the solvent under reduced pressure, the residue was purified by silica-gel column chromatography. The first fraction eluted with benzene or chloroform gave pyridinoferrocenophane (**3a—d**); the second fraction eluted with chloroform-methanol (20 : 1) gave 1,1'-ferrocene dialcohol (**4a—d**) as a reddish oil. The crude product was recrystallized from benzene-hexane.

Pyridinoruthenocenophane (**3'a—d**) was also prepared by a reaction of **1'** (1.1 g, 3.1 mmol) and diol **2** (n=0—3) (6.2 mmol) through the above-mentioned method. The results are summarized in Table 1.

(Received April 14, 1988)

Thermal stabilities of the colored forms at 80 °C and photochemical fatigue resistances against coloration-discoloration cycles were measured in PMMA thin film, using 14 derivatives of fulgide with different heterocyclic structures. The indolyl (**12**), oxazolyl (**13**), and thiazolyl (**14**) derivatives showed very low thermal degradabilities (TD≦1.5%/day) while **12** and pyrazolyl derivative (**9**) showed low photochemical fatigues (PF≦0.2%/cycle), as compared with the furyl (**1**), thienyl (**2**), and pyrrolyl (**3**) derivatives. However, many of them featured low photo-responsiveness and low absorptivities for coloration on UV irradiation.

Molecular-structural modifications are powerful and interesting methods for research and development of photochromic materials, e.g., thermally stable and photochemically fatigue-resistant 1,2-diarylethenes,[2)] spiropyrans,[3)] and highly photoresponsive heterocyclic fulgides[4-6)] and spiropyrans.[7)]

Though furyl (**1**),[8)] thienyl (**2**),[9,10)] and pyrrolyl (**3**)[4)] derivatives have been studied in some detail in solution as well as in polymeric media,[5,10)] other heterocyclic fulgides seem to have been scarcely studied. Nor has been the relationship between the heteroaromatic ring structure and the photochromic properties clarified. In order to realize the potential utility of photochromic organic compounds in optical memory devices, extensive studies in solid polymers are needed,[11)] clarifying the medium effects as well as the structure-activity relationships.

This work has been undertaken to investigate the effects of the heteroaromatic ring structure (Ar) on the photochromic properties, particularly thermal stabilities and photochemical fatigue resistances, in PMMA†† thin film as compared in dilute solution, using a wide variety of fulgides **1**—**14** (Scheme 1).

Results and Discussion

Absorption Spectra and Photochromic Properties. Figure 1 illustrates the spectra of **1** and their changes on alternative irradiations of UV and visible light in dilute toluene solution (a) and PMMA thin film (b). A photostationary state (pss) of coloration was attained by irradiation of **1E** (curve 0) with UV light in 30—60 s, hereafter the absorbance value in the visible band (A_0, curve 1) was no more increased on further UV irradiation. Subsequent irradiation with visible light led to rapid discoloration (in ca. 60 s). Similar colora-

Heterocyclic fulgides. Methyl substituents on carbon atoms are denoted by bars for simplification.

†† PMMA=poly(methyl methacrylate).

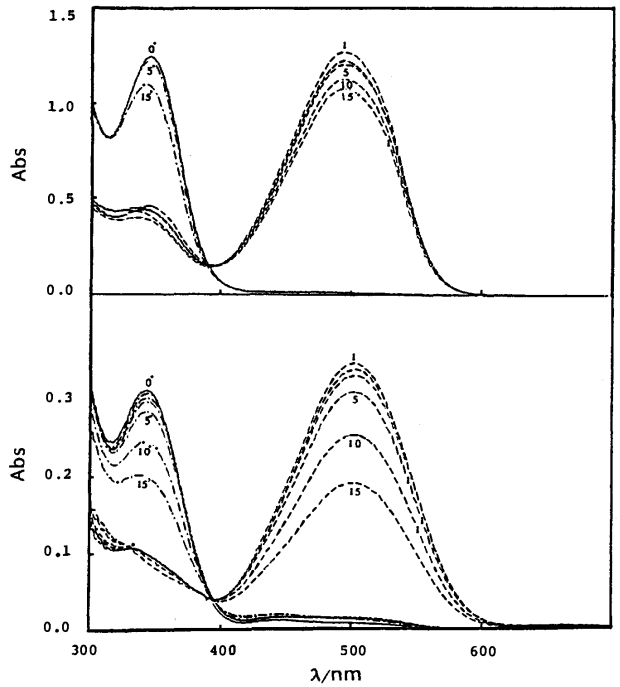

Fig. 1. Reversible changes in the absorption spectra of **1** on alternative irradiations with UV and visible light. (a) 2.0×10^{-4} mol dm^{-3} solution in toluene, (b) 15 wt% in PMMA film of 1.0 μm thickness. Curve 0: **1E** before irradiation, curve 1: after UV irradiation for 30 s. Absorption curves around 500 nm refer (from the top) to the colored forms after 2, 3, 5, 10, and 15 cycles of repeated coloration-discoloration reaction, while curves around 340 nm refer to the uncolored forms.

Table 1. Absorption Properties of Fulgides in PMMA Film[a)]

Fulgide	Uncolored form[b)]		Colored form[c)]

8[e)]	336	0.35	546	0.04
9[e)]	336	0.38	539	0.04
10			545	0.06
11[e)]	304	0.27	435	0.04
12[e)]	392	0.35	589	0.07
13	338	0.52	462	0.45
14[d)]	305(Z310)	0.55(Z0.70)	486	0.29

a) PMMA film of 1.0 μm thickness containing 15 wt% of fulgide. b) Values in parentheses refer to *Z*-isomers. c) A_0 refers to the absorbance value at photostationary state attained on UV irradiation. d) Initial form was *Z*-isomer, which rapidly isomerized into *E*-isomer on UV irradiation. e) Initially a mixture of *E*/*Z* isomers, which rapidly changed into *E*-isomer on UV irradiation.

tion-discoloration cycles were repeated a number of times (curves *n*). The absorption properties of the colored forms (λ_C and A_0), obtained at the initial pss of coloration, are summarized in Table 1 together with those of the uncolored (*E*)-isomers (λ_E and A_E). The absorption maxima of the colored forms tend to red shift with the electron-donating ability of the heterocyclic groups, e.g., the λ_C increases in the order **1C**<**2C**<**3C**, **6C**<**7C**<**3C**, and **9C**<**8C**≪**4C**<**3C**, respectively. This suggests that the electronic transitions of the colored forms involve intramolecular electron migration from the heteroatoms to the carbonyl groups.

The absorbance values (A_0) attained at pss for coloration are low with **7**—**12**. The ^{1}H NMR spectra of the photolyzed mixtures (pss) of **9**, **12**, and **14** in $CDCl_3$ implied that the mole fractions of the colored forms were in the range of 15—40%. Also, a molecular model suggests that the steric repulsions between the 4-methyl groups and the 3-substituents of **8**—**12C** should hinder the coplanar configuration. Such poor coplanarity would lead to a poor overlapping of the pertinent orbitals and lower the transition probability (or extinction coefficient) for light absorption.[12] Further, **9**, **12**, and **14** featured rather low photo-responsiveness for coloration, thus their quantum yields (below 0.1) were significantly lower compared with 0.20 of **1**.[5,8]

It is speculated that the steric hindrance of the substituents (**9**, **12**) and/or the higher stabilities of the heteroaromatic groups depress the rate of the cyclization reaction as well as the C/E ratio at pss.

Photochemical Fatigues. As illustrated in Fig. 1 the reversibilities of the absorption spectra of **1**, on repeated coloration-discoloration cycles, are rather poor in PMMA film (b) while moderate in dilute toluene solution (a). This implies a significant effect of the medium and/or concentration of the solute on the photochemical fatigue. As a numerical measure for relative photochemical fatigue, a quantity PF=$(A_0-A)/nA_0$ was evaluated where A_0 and A are the absorbance values at pss attained on the lst and nth cycles of coloration, respectively. Table 2 lists the PF values of various fulgides obtained within half-lives, while Fig. 2 illustrates the plots of the fatigue resistance A/A_0 over a wide range of cycles. Fulgides **8**, **9**, and **12** show excellent fatigue resistances compared with **1**—**3**. The PF values of **4**—**12** are little affected by the medium and/or concentration. The high fatigue resistances and low medium dependences of **8**—**10**, **12**, and **13** are attributable to the high chemical stabilities of the heterocyclic groups.

Thermal Stabilities of the Colored Forms. Figure 3 illustrates thermal degradations of the colored forms in PMMA film at 80 °C in the dark. Similar tendence was obtained at 50 °C though more stable. As a measure for relative thermal degradability of the colored forms, a quantity TD=$(A_0-A)/dA_0$ has been evaluated, where A_0 refers to the initial absorbance value of the colored form and A is that measured after d days of

Table 2. Photochemical Fatigues and Thermal Degradabilities of Fulgides in PMMA Film[a)]

a) Experimental conditions are shown in the legends of Figs. 2 and 3. b) $PF=(A_0-A)/n\,A_0$, as a measure for photochemical fatigue, where n is the number of repeated cycles. Values in parentheses refer to the data in dilute toluene solution (2×10^{-4} mol dm^{-3}). c) $TD=(A_0-A)/d\,A_0$, as a measure for thermal degradability of colored forms, where d refers to the heating time (day) at 80 °C in the dark.

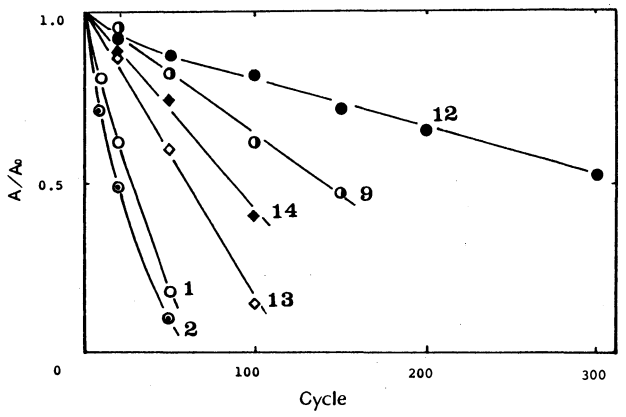

Fig. 2. Photochemical fatigues of fulgides by repeated coloration-discoloration cycles in PMMA film. PMMA film was of 1.0 μm thickness containing 15—20 wt% of fulgide.

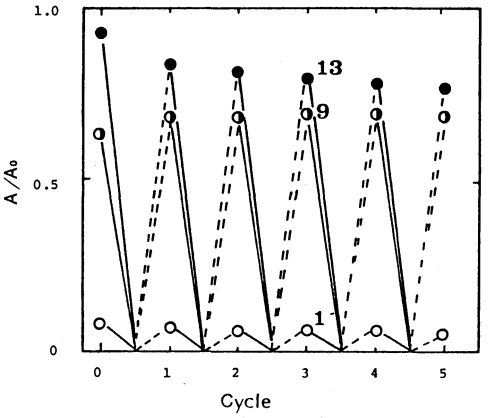

Fig. 4. Photochromic properties of the fulgides which had previously been heated at 80 °C for 10 days in PMMA film. Irradiated with visible (——) and UV (----) light at room temperature; **1** (○), **9** (◑), **13** (●).

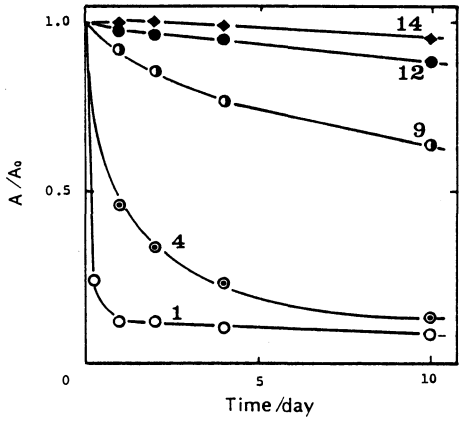

Fig. 3. Thermal degradations of the colored forms in PMMA film at 80 °C. PMMA film containing fulgide (15—20 wt%) had been previously irradiated with UV light leading to the photostationary state for coloration.

heating at 80 °C. The TD values of different fulgides are listed in Table 2. Figure 3 and Table 2 show a wide variation in the thermal stability: excellent stabilities with **12—14C**, fairly good with **2C** and **8—10C**, but poor with **1C** and **3—5C**.

Figure 4 shows the photochromic properties of the colored forms which had been heated at 80°C for 10 days in PMMA film. While **1** show little, **9** and **13** show substantial retainments of their photochromic properties, demonstrating their excellent thermal and photochemical fatigue resistances. With the fused benzene ring (**12**) or electronegative heteroatoms (**9**, **13**, **14**), the heterocyclic double bonds (both in the colored and uncolored forms) are considered to be stabilized and resistant to photochemical and thermal side reactions such as bimolecular cycloadditions[6)] and oxida-

a) Melting points and ^{1}H NMR spectra of **1E—4E** were consistent with those reported in the literature. **11** was out-of-stock. b) *E*-isomers were obtained by UV irradiation of the *E/Z* isomeric mixtures. c) *E*-isomer was obtained by photochemical isomerization of the *Z*-isomer with UV light.

tions. The higher chemical stabilities of the heterocyclic groups, however, would inevitably feature lower photochemical responsiveness as described above. Thus we are now put into a dilemma in molecular architecturing of *highly-responsive and highly-resistant* photochromic compounds.

Contrary to the high thermal stability in PMMA film, **14** (both colored and uncolored forms) underwent substantial degradations in hydroxylic solvents at room temperature in the dark, as readily as **1**. A major degradation product of **14C** in ethanol solution, isolated on silica gel, showed UV spectrum and R_f value (TLC on silica gel) different from those of **14E** or **Z**. From its UV (λ_{max}410, $\varepsilon\approx$5500) and ^{1}H NMR spectra (e.g., methylene protons of the ethyl ester group at 3.6 ppm), the half-ester of the colored form was implied. Thus, it is assumed that the anhydride groups of both colored and uncolored forms are subject to rapid solvolysis in hydroxylic solvents, regardless of the structure of the heterocyclic groups.

Experimental

Melting points were uncorrected. UV and ^{1}H NMR spectra were recorded on a Hitachi U-3200 spectrophotometer and a JEOL JNM-PMX 60 NMR spectrometer, respectively. Solvents were freshly distilled before use. PMMA film (ca. 1.0 μm thickness) was prepared on a glass plate by spin-coating of a deaerated cyclohexanone solution containing fulgide and PMMA (15—20:85—80 by weight). For the measurement of the thermal stability, the surface of the PMMA film was coated with acrylic polymer (SD-17 Dainihon-Inki) in 4—5 μm thickness to protect from sublimation. This treatment did not affect the photochromic properties, except that some intermixing appeared to take place and the absorbances of fulgides were somewhat reduced. The UV light beams of 310—380 nm isolated through a glass filter (Toshiba UV-D36C), were irradiated at a 50-cm distance from a 80-W cm^{-1} metal halide lamp (Ushio Electric). Visible light beams were irradiated at a 15-cm distance from a 50-W halogen lamp (Philips) through a glass filter (Toshiba Y-50, Y-45, or L-39). The incident light intensities were in the range of 10—40 mJ cm^{-2} s^{-1} both with UV and visible lights. Absorption spectra were measured at 10-s intervals during coloration and discoloration reactions.

Materials. Heterocyclic fulgides were prepared by the Stobbe condensation reaction of diethyl isopropylidenesuccinate with 3-(or 4-)acetyl derivatives of heteroaromatic compounds, according to the methods described in the literature.[8,9] The analytical data and other physical constants are summarized in Table 3.

Arylation of Olefins by Arylazo Aryl Sulfones under Palladium(0) Catalysis[1)]

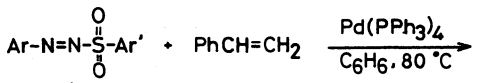
Nobumasa KAMIGATA,* Akira SATOH, Tetsuya KONDOH, and Masayuki KAMEYAMA
Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Fukazawa, Setagaya-ku, Tokyo 158
(Received April 19, 1988)

The palladium(0)-catalyzed reaction of arylazo aryl sulfones with olefins in benzene at 80 °C gave aryl-substituted olefins in good yield. Diarylpalladium(II) species was proposed as an intermediate in this reaction.

The arylation of unsaturated compounds by arenediazonium salts with copper salt catalysis was first disclosed by Meerwein et al.[2)] The Meerwein arylation is a useful synthetic procedure, because of the availability of a variety of arylamines and good product yield. However, it generally requires the olefins to be activated by an electron-withdrawing group, such as carbonyl, cyano, aryl, vinyl, ethynyl or chloro group. Doyle et al. reported a modified Meerwein arylation with significant yield improvement by the use of free arylamines and alkyl nitrite in place of arenediazonium salts.[3)] However, the limitation of olefinic compounds still remains. Arylpalladium reagents obtained from aryl halides or arylmercurials have been utilized extensively for arylation of olefins,[4)] and the arylation is known to be free from the requirement for activation in the olefinic substance. Recently, Kikukawa et al. reported a novel arylation of olefins by arenediazonium salts[5)] or *N*-nitroso-*N*-arylacetamides[6)] in the presence of a catalytic amount of palladium(0). In a preliminary paper we reported that arylazo aryl sulfones react with styrene in the presence of tetrakis(triphenylphosphine)palladium(0) as a catalyst under mild conditions to give (*E*)-1-aryl-2-phenylethene and 1-aryl-1-phenylethene in good yields.[7)] We give here a full account for the palladium(0)-catalyzed arylation of olefins by arylazo aryl sulfones.

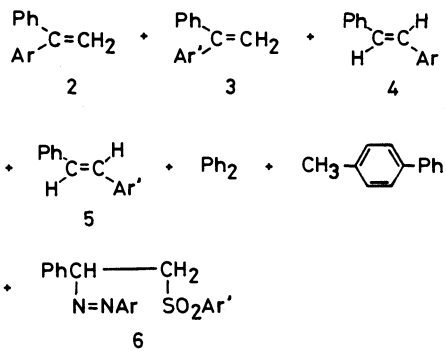
Results and Discussion

Dropwise addition of phenylazo *p*-tolyl sulfone (**1a**) in benzene to a stirred solution of styrene and tetrakis(triphenylphosphine)palladium(0) in benzene resulted in evolution of nitrogen. TLC analysis showed that the crude products are separated in roughly two spots, and these components were separated by column chromatography. The products of the former fraction were determined as 1,1-diphenylethylene (**2**) 10%, 1-phenyl-1-(*p*-tolyl)ethylene (**3**) 10%, (*E*)-stilbene (**4**) 32%, (*E*)-1-phenyl-2-(*p*-tolyl)ethylene (**5**) 32%, biphenyl 1%, and 4-methylbiphenyl 1%. The latter fraction was recrystallized from ethanol to give pale yellow crystals which were identified as 2-phenyl-2-(phenylazo)ethyl *p*-tolyl sulfone (**6a**) (yield, 21%). The products **2**—**6** seem to be formed by the catalytic reaction of **1a** by the palladium(0) complex since the thermal reaction of **1** with styrene without catalyst is known not to form such arylated compounds **2**—**6** but to form an aryl radical as an intermediate which acts as an initiator for the polymerization of styrene.[8)] The other transition metal catalysts such as $Pd(OAc)_2$, $Pd(dba)_2$, $PdCl_2$, $RhCl(PPh_3)_3$, and $RuCl_2(PPh_3)_3$ have showed little catalytic effect for the arylation of styrene by **1a**. It is interesting to note that both phenyl and *p*-tolyl groups of **1a** are arylated at the α- and β-position of styrene in almost equal amount to give **2** or **3**, and **4** or **5**, respectively.



1

(1a: Ar=Ph, Ar'=p-$CH_3C_6H_4$)



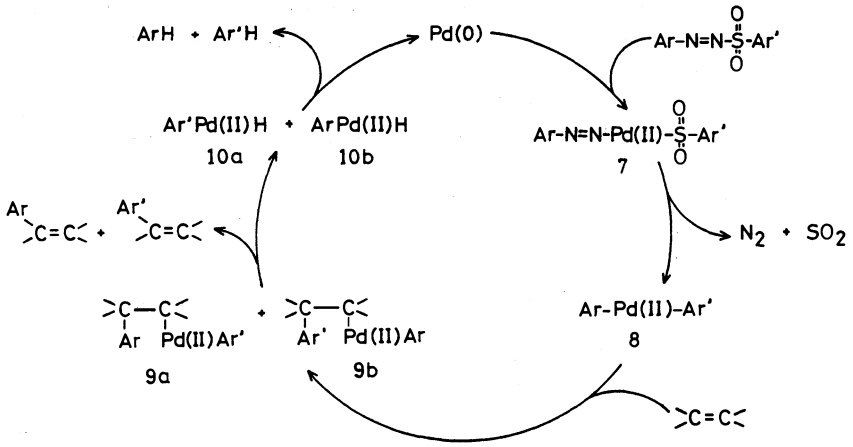
Similarly, the reactions of *p*-tolylazo phenyl sulfone (**1b**), phenylazo phenyl sulfone (**1c**), and *p*-tolylazo *p*-tolyl sulfone (**1d**) with styrene were carried out in the presence of tetrakis(triphenylphosphine)palladium(0) in benzene solution under nitrogen at 80 °C. The results are summarized in Table 1. It is noteworthy that the yields of the products **2**, **3**, **4**, and **5** were almost the same both in the reactions of **1a** and **1b**, respectively. The result suggests that a common reactive intermediate is formed from either reaction of **1a** and **1b** by the palladium(0) catalysis, and the Ar and Ar' groups of the intermediate have the same reactivity. When the Ar and Ar' groups of the azosulfone **1** are the same (Entries 3 and 4), the products are simplified.

These reactions may be accounted for by the oxidative addition of arylazo aryl sulfone to palladium(0) catalyst giving Ar-N=N-Pd(II)-SO_2-Ar' (**7**), which splits off nitrogen and sulfur dioxide to form a diarylpalladium(II) complex, Ar-Pd(II)-Ar' (**8**). The reactive intermediate **8** adds to an olefin giving adducts **9a** and **9b** which afford arylated olefin **2**—**5** and Ar'-Pd(II)-H (**10a**) or Ar-Pd(II)-H (**10b**). The reductive elimination of arenes (ArH and Ar'H) from **10** follows,

Table 1. Reaction of Arylazo Aryl Sulfones with Styrene Catalyzed by Tetrakis(triphenylphosphine)palladium(0) in Benzene at 80 °C[a)]

	Ar and Ar′ in **1**		Product, Yield[b)]/%					
	Ar	Ar′	**2**	**3**	**4**	**5**	**6**	Biaryls
1a	C_6H_5	*p*-$CH_3C_6H_4$	10	10	32	32	21	c
1b	*p*-$CH_3C_6H_4$	C_6H_5	11	12	33	32	22	c
1c	C_6H_5	C_6H_5	17	—	56	—	32	d
1d	*p*-$CH_3C_6H_4$	*p*-$CH_3C_6H_4$	—	15	—	49	35	e

a) The reactions were performed by addition of arylazo aryl sulfone (2.0 mmol) in benzene (8.0 cm^3) to a stirred solution of styrene (10 mmol) and $Pd(PPh_3)_4$ (0.02 mmol) in benzene (2.0 cm^3) under nitrogen at 80 °C for 2 h. b) The yield was determined by GC analysis based on the arylazo aryl sulfone used. c) Biphenyl (1%) and 4-methylbiphenyl (1%) were formed. d) Biphenyl (2%) was formed. e) 4-Methylbiphenyl (2%) and 4,4′-dimethylbiphenyl (4%) were formed.



Scheme 1.

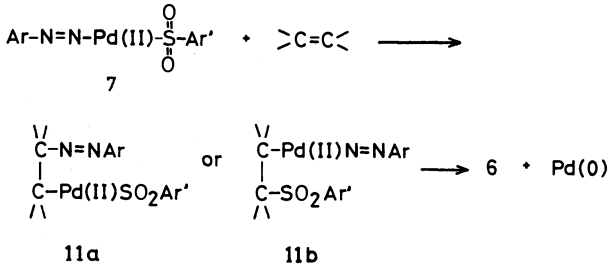
and Pd(0) is regenerated (Scheme 1).

The diarylpalladium(II) species **8** successfully interprets the product ratio 2/3=1 and 4/5=1 both in the reaction of **1a** and **1b** since Ar and Ar′ groups in **8** are expected to have the same reactivity toward olefin and it is also to be expected that **10a** and **10b** will eliminate from **9a** and **9b** in the same rate, respectively. The formation of the diarylpalladium(II) species was supported by detection of biphenyl, 4-methylbiphenyl, and 4,4′-dimethylbiphenyl (Table 1) since these products are considered to be formed by the reductive elimination from **8** accompanying with regeneration of Pd(0) (Scheme 2).

Scheme 2.

The formation of arene (ArH and Ar′H) by the reductive elimination from **10** is difficult to detect when the aryl group of **1** is phenyl. Next, the reaction of *p*-methoxyphenylazo *p*-tolyl sulfone with styrene was carried out in the presence of the palladium(0) catalyst in benzene, and the formation of both anisole and toluene was found by GC-MS.

The formation of **6** is accounted for by the addition of arylazo(arylsulfonyl)palladium(II) species **7** (shown in Scheme 1) to olefin to give the adduct **11a** or **11b** which followed by the reductive elimination of **6** accompanying with regeneration of Pd(0) species (Scheme 3).

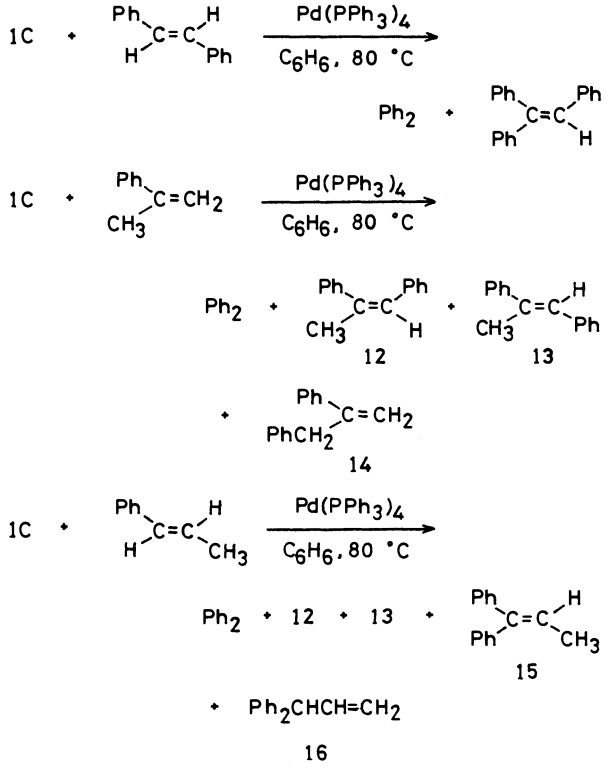


Scheme 3.

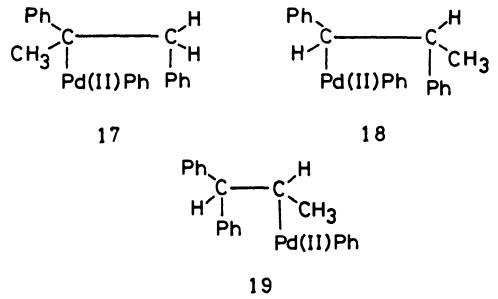
The regioselectivity for the arylation of styrene by **1** is different from that of the related arylation of styrene by *N*-nitroso-*N*-arylacetamide under palladium(0) reported by Kikukawa et al.[6)] They obtained the arylation products at the α- and β-position of styrene in the ratio of 5 : 95. On the other hand, in our case, the ratio of the arylation at the α- and β-position of styrene is 1 : 3. These differences may be attributed to the difference of the reductive-eliminating group from the adduct.

The reactions of **1c** with (*E*)-stilbene, 2-phenylpro-

pene, and (*E*)-1-phenylpropene in the presence of a catalytic amount of the palladium(0) catalyst in benzene were also carried out at 80 °C for 2 h. The reaction of **1c** with (*E*)-stilbene gave biphenyl 6% and triphenylethylene 44%. The reaction of **1c** with 2-phenylpropene afforded biphenyl 7%, (*Z*)-1,2-diphenylpropene (**12**) 6%, (*E*)-1,2-diphenylpropene (**13**) 30%, and 2,3-diphenylpropene (**14**) 35%. The reaction of **1c** with (*E*)-1-phenylpropene formed biphenyl 11%, **12** 4%, **13** 25%, 1,1-diphenylpropene (**15**) 20%, and 3,3-diphenylpropene (**16**) 7%.



The formation of the compounds **12**—**16** is accounted for by the reaction of the diphenylpalladium(II) species, formed from **1c** and Pd(0), with 2-phenylpropene or (*E*)-1-phenylpropene giving the adduct **17** and **18** or **19**, respectively. The PhPd group can eliminate with all possible β-hydrogen from this intermediate: **17** affords **12**, **13**, and **14**; similarly, **18** affords **12** and **13**; and **19** affords **15** and **16**.



The palladium(0)-catalyzed arylation of cycloalkenes with **1** is also carried out under similar conditions. The results are summarized in Table 2. In this case, 3-arylcycloalkene **20** and 1-arylcycloalkene **21** were obtained in good yield with minor by-products, biaryls; although alicyclic olefins are known to be poor substrates in the Meerwein arylation.[2] It is of interest that 1-arylcyclopentene was formed in a little higher yield than 3-arylcyclopentene in each of the reactions of arylazo aryl sulfone with cyclopentene. The isomer distribution of the arylation products obtained here were considerably different from those of related phenylation of cyclopentene by aniline and *t*-butyl nitrite catalyzed by bis(dibenzylideneacetone)-palladium(0).[5e] Whereas, the reaction of arylazo aryl sulfone with cyclohexene, cycloheptene, and cyclooctene afforded 3-arylcyclohexene, 3-arylcycloheptene,

Table 2. Reaction of Arylazo Aryl Sulfones with Cycloalkenes Catalyzed by Tetrakis(triphenylphosphine)palladium(0) in Benzene at 80 °C[a]

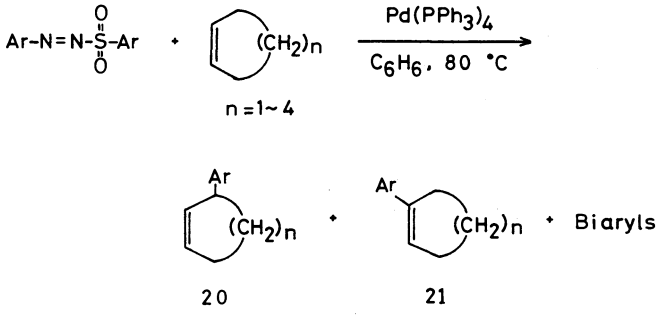
a) The reactions were carried out by addition of arylazo aryl sulfone (2.0 mmol) in benzene (8.0 cm^3) to a stirred solution of cycloalkene (10.0 mmol) and $Pd(PPh_3)_4$ (0.02 mmol) in benzene (2.0 cm^3) under nitrogen at 80 °C for 24 h. b) The yield was determined by GC analysis based on the arylazo aryl sulfone employed.

and 3-arylcyclooctene, respectively, as the major arylation product, the corresponding 1-arylcycloalkene was obtained in much lower yield to zero, although the reason is not clear at the present time.



Experimental

Measurement. Melting points and boiling points are uncorrected. The infrared absorption spectra were determined on a Hitachi Model 260-10 spectrophotometer with samples as either neat liquids or in KBr disks. ^{1}H NMR spectra were recorded at 60 MHz by using a JNM-PMX 60 SI spectrometer with Me_4Si as an internal standard in $CDCl_3$. Mass spectra were determined with a JEOL JMS-DX300 mass spectrometer with JEOL JMA-5000 Mass Data System at an ionizing voltage of 20—70 eV. Gas chromatography was carried out with Hitachi Models 163 and 263-30 gas chromatographs (FID) using a 1 m column packed with 10% SE-30. The gel permeation chromatography was performed by using a JAI LC-08 liquid chromatograph with a JAIGEL-1H column (20 ϕ×600 mm×2, chloroform as eluent).

Materials. All solvents were distilled and stored under nitrogen. Palladium chloride of Wako Chemicals was used without further purification. Tetrakis(triphenylphosphine)-palladium(0),[9] palladium acetate(II),[10] bis(dibenzylideneacetone)palladium(0),[11] chlorotris(triphenylphosphine)rhodium(I),[12] and dichlorotris(triphenylphosphine)rutheniumm-(II),[13] were prepared by the method described in the literature. Phenylazo *p*-tolyl sulfone (**1a**), *p*-tolylazo phenyl sulfone (**1b**), phenylazo phenyl sulfone (**1c**), *p*-tolylazo *p*-tolyl sulfone (**1d**), *p*-methoxyphenylazo *p*-methoxyphenyl sulfone (**1e**), and *p*-chlorophenylazo *p*-chlorophenyl sulfone (**1f**) were prepared by the published procedures.[14] Styrene, 2-phenylpropene, (*E*)-1-phenylpropene, cyclopentene, cyclohexene, cycloheptene, cyclooctene of Tokyo Kasei Chemicals were purified by distillation under nitrogen prior to use.

General Procedure for the Reaction of Arylazo Aryl Sulfone with Styrenes. A solution containing arylazo aryl sulfone (2.0 mmol) in benzene (5.0 cm^3) was added dropwise to a stirred solution containing styrene or a styrene derivative (10 mmol) and tetrakis(triphenylphosphine)palladium(0) (0.02 mmol) in benzene (2.0 cm^3) heated at 80 °C under nitrogen over a period of 30 min, and the mixture was further stirred for 2 h. The crude reaction mixture was chromatographed on silica gel using hexane-ethyl acetate as eluent. The stereo- and regioisomers of the arylation products were isolated by GC. The structure of biphenyl, 4-methylbiphenyl, 4,4′-dimethylbiphenyl, 1,1-diphenylethylene (**2**), 1-phenyl-1-(*p*-tolyl)ethylene (**3**), (*E*)-stilbene (**4**), (*E*)-1-phenyl-2-(*p*-tolyl)ethylene (**5**), triphenylethylene (**11**), (*Z*)-1,2-diphenylpropene (**12**), (*E*)-1,2-diphenylpropene (**13**), 2,3-diphenylpropene (**14**), 1,1-diphenylpropene (**15**), and 3,3-diphenylpropene (**16**) were identified by comparison of their retention times of GC; IR, ^{1}H NMR, and GC mass spectra with those of authentic samples. The adducts **6** were isolated as the corresponding [1,3]sigmatropic hydrogen shifted isomer, and the structure was determined by the following spectroscopic data.

2-Phenyl-2-(phenylhydrazono)ethyl *p*-Tolyl Sulfone: Mp 179—180 °C; IR (KBr) 3340, 1310, and 1145 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=2.35 (3H, s), 4.58 (2H, s), 7.21 (2H, d, J=7.8 Hz), 7.24 (10H, s), 7.75 (2H, d, J=7.8 Hz), and 9.35 (1H, s); MS, m/z 364 (M^+); HRMS, m/z 364.1258 ($C_{21}H_{20}O_2N_2S$ requires 364.1245). This compound is easily converted to **6a** by treating with an acid. 2-Phenyl-2-(phenylazo)ethyl *p*-tolyl sulfone (**6a**): mp 139—140 °C; IR (KBr) 1450, 1310, and 1150 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=2.25 (3H, s), 3.5—3.9 (1H, m), 4.2—4.6 (1H, m), 5.3—5.6 (1H, m), 7.10 (2H, d, J=7.8 Hz), 7.25 (5H, s), 7.38 (5H, s), and 7.64 (2H, d, J=7.8 Hz); MS, m/z 364 (M^+); HRMS, m/z 364.1242 ($C_{21}H_{20}O_2N_2S$ requires 364.1245).

2-Phenyl-2-(*p*-tolylhydrazono)ethyl Phenyl Sulfone (Isomer of 6b): Mp 170—171 °C; IR (KBr) 3340, 1300, and 1150 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=2.31 (3H, s), 4.61 (2H, s), 7.2—7.8 (14H, m), and 9.36 (1H, s); MS, m/z 364 (M^+); HRMS, m/z 364.1239 ($C_{21}H_{20}O_2N_2S$ requires 364.1245).

2-Phenyl-2-(phenylhydrazono)ethyl Phenyl Sulfone (Isomer of 6c): Mp 153—154 °C; IR (KBr) 3350, 1300, and 1160 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=4.65 (2H, s), 7.2—8.0 (15H, m), and 9.40 (1H, s); MS, m/z 350 (M^+); HRMS, m/z 350.1119 ($C_{20}H_{18}O_2N_2S$ requires 350.1089).

2-Phenyl-2-(*p*-tolylhydrazono)ethyl *p*-Tolyl Sulfone (Isomer of 6d): Mp 172—173 °C; IR (KBr) 3340, 1300, and 1140 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=2.31 (3H, s), 2.37 (3H, s), 4.60 (2H, s), 7.1—7.8 (13H, m), and 9.38 (1H, s); MS, m/z 378 (M^+); HRMS, m/z 378.1409 ($C_{22}H_{22}O_2N_2S$ requires 378.1402).

Arylation of Cycloalkenes. General Procedure. All procedures were carried out under nitrogen, although aerobic conditions also gave satisfactory results. To a stirred solution containing cycloalkene (10 mmol), tetrakis(triphenylphosphine)palladium(0) (0.02 mmol) in benzene (2.0 cm^3) heated at 80 °C was added dropwise a solution containing of arylazo aryl sulfone (2.0 mmol) in benzene (5.0 cm^3) over a period of 30 min, and the solution was further stirred for 24 h. The crude reaction mixture was subjected to elution chromatography on silica gel using hexane-ethyl acetate as eluent. The regioisomers of the arylation products **20** and **21** were isolated by gel permeation chromatography, and the structures were determined on the basis of their spectroscopic data.

3-Phenylcyclopentene[15] (20a): IR(neat) 2940, 2850, 1605, 1495, 1450, 755, and 695 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.53—2.90 (4H, m), 3.63—4.10 (1H, m), 5.63—6.02 (2H, m), and 7.12 (5H, m); MS, m/z 144 (M^+), 129, and 115.

3-(*p*-Tolyl)cyclopentene (20b): A colorless oil; IR (neat) 3060, 2930, 2855, 1615, 1515, 820, and 715 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.52—2.85 (4H, m), 2.28 (3H, s), 3.62—4.08 (1H, m), 5.58—6.08 (2H, m), 6.82—7.23 (4H, m); MS, m/z 158 (M^+), 143, and 128; HRMS, m/z 158.1098 ($C_{12}H_{14}$ requires 158.1095).

3-(*p*-Methoxyphenyl)cyclopentene (20c): A colorless oil; IR (neat) 2960, 2910, 2850, 1615, 1515, 1250, 830, and 720 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.45—2.87 (4H, m), 3.30—4.98 (1H, m), 3.65 (3H, s), 5.43—5.97 (2H, m), 6.65 (2H, d, J=9.0

Hz), and 6.95 (2H, d, J=9.0 Hz); MS, m/z 174 (M^+) and 159; HRMS, m/z 174.1046 ($C_{12}H_{14}O$ requires 174.1044).

3-Phenylcyclohexene[16] **(20d):** IR (neat) 3030, 2930, 1610, 1500, 1460, 765, and 700 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.70—3.05 (6H, m), 3.13—3.60 (1H, m), 5.40—6.30 (2H, m), and 7.13 (5H, s); MS, m/z 158 (M^+), 143, and 129.

3-(*p*-Tolyl)cyclohexene (20e): A colorless oil; IR(neat) 3030, 2920, 1515, 1435, and 825 cm^{-1}; ^1H NMR ($CDCl_3$) δ= 1.22—3.02 (6H, m), 2.27 (3H, s), 3.10—3.50 (1H, m), 5.43—5.83 (2H, m), and 6.83—7.23 (4H, m); MS, m/z 172 (M^+), 157, and 144; HRMS, m/z 172.1250 ($C_{13}H_{16}$ requires 172.1252).

3-(*p*-Methoxyphenyl)cyclohexene (20f): A colorless oil; IR (neat) 3060, 2970, 1635, 1530, 1260, and 845 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.90—3.03 (6H, m), 3.27 (1H, m), 3.72 (3H, m), 5.35—5.98 (2H, m), 6.72 (2H, d, J=9.0 Hz), and 7.05 (2H, d, J=9.0 Hz); MS, m/z 188 (M^+), 173, and 160; HRMS, m/z 188.1208 ($C_{13}H_{16}O$ requires 188.1201).

3-Phenylcycloheptene[17] **(20g):** IR (neat) 3040, 2940, 2860, 1610, 1500, 1450, 760, and 705 cm^{-1}; ^1H NMR ($CDCl_3$) δ= 1.10—3.00 (8H, m), 3.23—3.77 (1H, m), 5.50—6.15 (2H, m), and 7.17 (5H, s); MS, m/z 172 (M^+), 157, 144, and 130.

3-(*p*-Tolyl)cycloheptene (20h): A colorless oil; IR (neat) 3010, 2925, 2855, 1510, 1440 and 810 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.87—2.95 (8H, m), 2.25 (3H, s), 3.17—3.72 (1H, m), 5.47—6.05 (2H, m), and 6.98 (4H, m); MS, m/z 186 (M^+), 171, and 158; HRMS, m/z 186.1417 ($C_{14}H_{18}$ requires 186.1408).

3-(*p*-Methoxyphenyl)cycloheptene (20i): A colorless oil; IR(neat) 2930, 1615, 1520, 1245, 1040, and 825 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.83—3.03 (8H, m), 3.42 (1H, m), 3.70 (3H, s), 5.60—5.93 (2H, m), 6.68 (2H, d, J=9.0 Hz), and 7.02 (2H, d, J=9.0 Hz); MS, m/z 202 (M^+), 187, and 173; HRMS, m/z 202.1336 ($C_{14}H_{18}O$ requires 202.1357).

3-(*p*-Chlorophenyl)cycloheptene (20j): A colorless oil; IR (neat) 2925, 1600, 1495, 1095, and 820 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.82—3.00 (8H, m), 3.25—3.65 (1H, m), 5.63—5.93 (2H, m), and 6.90—7.35 (4H, m); MS, m/z 206 (M^+) 191, 178, and 171; HRMS, m/z 206.0845 ($C_{13}H_{15}Cl$ requires 206.0862).

3-Phenylcyclooctene[15b,18] **(20k):** IR (neat) 3030, 2940, 2870, 1605, 1490, 1440, 750, and 695 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.00—3.05 (10H, m), 3.47—4.03 (1H, m), 5.35—6.17 (2H, m), and 7.17 (5H, s); MS, m/z 186 (M^+), 171, and 158.

3-(*p*-Tolyl)cyclooctene (20l): A colorless oil; IR (neat) 3020, 2940, 2870, 1520, 1470, and 810 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.92—2.95 (10H, m), 2.25 (3H, s), 3.23—3.95 (1H, m), 5.30—6.05 (1H, m), and 6.67—7.40 (4H, m); MS, m/z 200 (M^+), 185, and 172; HRMS, m/z 200.1568 ($C_{15}H_{20}$ requires 200.1565).

3-(*p*-Methoxyphenyl)cyclooctene (20m): A colorless oil; IR (neat) 2950, 1620, 1520, 1260, and 830 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.13—2.93 (11H, m), 3.68 (3H, s), 5.33—5.92 (2H, m), 6.70 (2H, d, J=9.0 Hz), and 7.00 (2H, d, J=9.0 Hz); MS, m/z 216 (M^+), 201, and 188; HRMS, m/z 216.1515 ($C_{15}H_{20}O$ requires 216.1514).

3-(*p*-Chlorophenyl)cyclooctene (20n): A colorless oil; IR (neat) 2930, 1490, 1095, and 820 cm^{-1}; ^1H NMR ($CDCl_3$) δ= 0.73—3.00 (10H, m), 3.38—3.97 (1H, m), 5.25—6.07 (2H, m), and 6.85—7.37 (4H, m); MS, m/z 220 (M^+), 192, and 185; HRMS, m/z 220.1017 ($C_{14}H_{17}Cl$ requires 220.1019).

1-Phenylcyclopentene[19] **(21a):** IR (neat) 2940, 2850, 1605, 1495, 1450, 755, and 695 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.53—2.90 (6H, m), 6.02—6.28 (2H, m), and 7.12—7.57 (5H, m); MS, m/z 144 (M^+), 129, and 115.

1-(*p*-Tolyl)cyclopentene[17,19] **(21b):** IR(neat) 2970, 2940, 2870, 1510, and 805 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.62—2.93 (6H, m), 2.28 (3H, s), 5.92—6.23 (1H, m), 7.02 (2H, d, J=8.0 Hz), and 7.25 (2H, d, J=8.0 Hz); MS, m/z 158 (M^+), 143, and 128.

1-(*p*-Methoxyphenyl)cyclopentene (21c): Mp 84.5—85.5 °C (lit, mp 81 °C):[19] IR (KBr) 2960, 2850, 1610, 1515, 1260, 840, and 805 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.50—2.28 (6H, m), 3.78 (3H, s), 5.88—6.07 (1H, m), 6.73 (2H, d, J=9.0 Hz), and 7.27 (2H, d, J=9.0 Hz); MS, m/z 174 (M^+), and 159.

The following 1-arylcycloalkenes **21d—g** and **21i—m** were determined only by the retention times of GC and GC mass spectra comparing with those authentic samples since these products were formed in very low yield.

1-Phenylcyclohexene[16,18] **(21d):** MS, m/z 158 (M^+), 143, and 128.

Aryliminodimagnesium Reagents. XIV.[1] Reactions with Nitrobenzenes Having Electronegative *ortho*-Substituents. Effects of Reaction Conditions on Condensation, Replacement, and Substitution

Masao Ōkubo,* Yoshito Inatomi, Naoki Taniguchi, and Kaori Imamura
Department of Chemistry, Faculty of Science and Engineering, Saga University, Honjō-machi, Saga 840
(Received April 25, 1988)

In reactions of $ArN(MgBr)_2$ with *o*-MeO- and *o*-halo-substituted nitrobenzenes, types and yields of products were different from those in its reactions with *m*- and *p*-substituted substrates. Condensation (leading to unsymmetrical azoxy- and azobenzenes), *o*-substituent replacement, and nuclear substitution took place. Relative yields of products were greatly affected by substituents and reaction conditions. *o*-MeO and *o*-F favor replacement, while *o*-Cl, *o*-Br, and *o*-I favor substitution. Replacement and/or substitution predominate when small molar excess of reagent and low concentration are used, while condensation predominates when large molar excess of reagent and high concentration are used, which phenomenon is mechanistically discussed.

The aryliminodimagnesium ($ArN(MgBr)_2$, aryl-IDMg) derived from aniline and EtMgBr condenses with *m*- and *p*-substituted nitrobenzenes (cf. Scheme 1),[2] and provides a convenient method for the independent preparation of *ONN* and *NNO* isomers of unsymmetrical (*unsym*-) azoxybenzenes (**1**).[3] **1** undergoes simple deoxygenation by molar excess of IDMg to give the corresponding *unsym*-azobenzene (**2**).[2] IDMg molecules are oxidatively dimerized, via single electron transfer (SET), to afford symmetrical (*sym*-) azobenzene (**3**).[2,4] The relative yield of **1**—**3** depends mainly on the relative efficiency of SET.[5,6]

The first purpose of the present study is to examine the formation of *o*-substituted azoxybenzene isomers which have so far been difficultly accessible. The second purpose is to examine the replacement of electronegative *o*-substituents on nitrobenzene via SET. 1-MeO and 1-Br substituents on the 9-fluorenylidene system are replaced by Grignard and IDMg reagents,[7] but no similar examples have been reported in reactions of nitroarenes with magnesium reagents. In IDMg reactions with *o*-MeO- and *o*-halo-nitrobenzenes, the expected azoxy formation and replacement as well as nuclear substitution took place, and relative yields of products depended greatly on reaction conditions. The results obtained will be summarized and discussed.

Results and Discussion

The results obtained by use of small and large molar excesses of IDMg will be separately described.

Relative Yields of Replacement, Substitution, and Condensation Products from *o*-MeO- and *o*-Halo-Nitrobenzenes in the Reaction with Small Molar Excess of Noncrowded IDMg. Effects of *o*-Substituted IDMg. The four products **4**—**7** in addition to **1**—**3** were obtained by the treatment of *o*-MeO- and *o*-halo-nitrobenzenes with small molar excess of *p*-MeC_6H_4-IDMg in tetrahydrofuran (THF, 50 ml). The product **4** is formed via replacement, **5** via substitution, **6** via

Table 1. Product Distribution in the Reaction with Small Excess of *p*-MeC_6H_4-IDMg

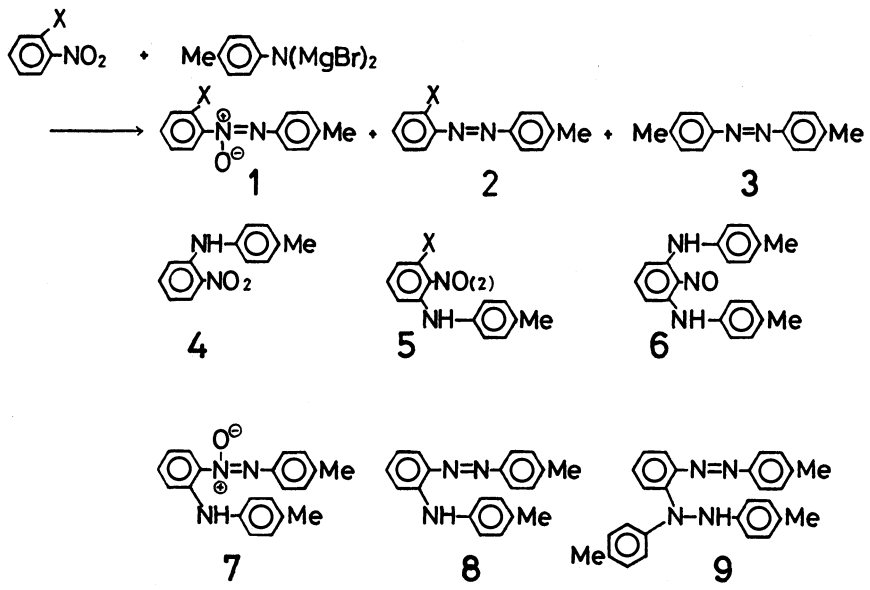
a) N: "Normal" addition of substrate to reagent at 0 °C, followed by heating at 55 °C for 3 h. R: "Reverse" addition of reagent to substrate at room temp (12—15 °C) for 0.5 h, followed by heating at 55 °C for 1.5 h. b) 250 ml of THF was used. c) *o*-$MeOC_6H_4$-IDMg was used. d) *o*-EtC_6H_4-IDMg was used.



Scheme 1.

substitution-replacement, and **7** via substitution-condensation (limited to *o*-F substrate). $\mathbf{5}^{MeO}$ and $\mathbf{5}^{F}$ are nitro compounds, while $\mathbf{5}^{Cl}$, $\mathbf{5}^{Br}$, and $\mathbf{5}^{I}$ are nitroso compounds. The yields of **1**—**7** are summarized in Table 1 (Runs S1—S12).

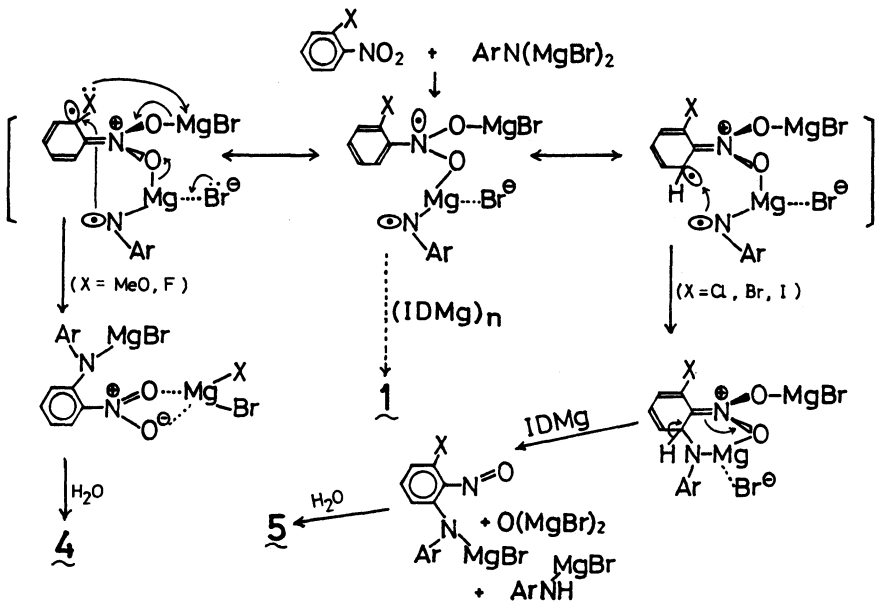
By the "reverse" addition of slight molar excess of IDMg to substrate at room temperature (12—15 °C) for 30 min (S2—S9), the products **4** and **5** become predominant, while **6** and **7** remain as minor. The replacement is almost completely limited to *o*-MeO and *o*-F (S2—S4), while the substitution is limited to *o*-Cl, *o*-Br, and *o*-I (S5—S9). This cannot be explained in terms of the redox potentials (MeO, −1.540; F, −1.324; Cl, −1.321; Br, −1.348; I, −1.377 V),[6] but is probably due to the different leaving abilities of these substituents as anions (as their Mg salts) from the radical anion of substrate.[8] The replacement requires 1.2—1.5 mol of reagent and the substitution requires 1.5—2.0 mol (S1—S4 and S5—S9). The reason for the almost no replacement of *o*-Br on nitrobenzene (S7 and S8), in contrast to the facile replacement of 1-Br on 9-fluorenylidene system,[7] is equivocal. The replacement and substitution solely at ortho positions arise from tight coordination of the nitro group to the Mg atom of reagent.

In Runs S6 and S10—S12, the effect of reaction conditions on the conversion of *o*-Cl substrate is made disclosed. By the "normal" addition of substrate to 2.0 mol of IDMg (S10), the yields of **1** and **2** increase, while that of **5** decreases (cf. S6). By use of 5.0 mol of IDMg (S11), **1**—**3** become predominant at the expense of **5**. The use of 250 ml of THF (S12) causes a decrease in yield of **1** and **2**, but almost no effect on that of **5** (cf. S6).

The results of S1—S12 indicate that, under an ideal condition,[9] the replacement requires one molecule of IDMg, whereas the substitution requires two molecules; the second one may be consumed for eliminating the nitro-oxygen and ortho-hydrogen (Scheme 2). For the condensation, two or more IDMg molecules may cooperate via a complicated pathway and not via a simple addition-elimination. Since larger moles and/or higher concentrations of reagent favor also the deoxygenation of **1** (S11),[2,3] the optimum condition for the preparation of *o*-substituted **1** must be carefully explored.

The comparably bulky *o*-Et and *o*-MeO groups "on reagent" affect noticeably the yield of **1** and **2** in comparison with the same groups "on substrate" (S1 and S13—S15). In the "on substrate" cases (S1 and S14), the two groups lead to comparable yields of **1** and **2** lower than those in S13 (**4** is also formed in S1). In the "on reagent" cases, the *o*-MeO group (S13) favors the condensation, while the *o*-Et group (S15) leads to a poor combined amount of **1** and **2** and a poor recovery. The *o*-MeO group on reagent, probably chelating with its Mg atom, assists the IDMg nitrogen to access to the nitro group. The *o*-Et group on reagent causes interference with the access, resulting in self-decomposition of substrate via SET.[10]

Relative Yields of Condensation Products in the Reaction with Large Molar Excess of IDMg. By use of 8.0 mol of *p*-Me-C_6H_4-IDMg (L1—L7, Table 2), the other minor products **7**—**9** appeared at the expense of **4**—**6**. The products **7** and **8** are formed from **4** via condensation and deoxygenation, and **9** having a hydrazino group via replacement, probably by a dimeric salt ((ArN(MgBr)-)$_2$). Their formation in yields lower than 10% only in the case of *o*-MeO and *o*-F substrates (L1, L5, and L6) is in accord with the results of S1—S4. The products **1**—**3** are major ones (L1—L6), and the yields differ from those in the case of the *p*-substituted substrates (L8—L12), as specified by the following two features.



Scheme 2.

Table 2. Product Distribution in the Reaction with Large Excess (8.0 mol) of *p*-MeC_6H_4-IDMg

Run No.	$XC_6H_4NO_2$ X	Yields/%					
		1	**2**	**3**	**7**	**8**	**9**
L1	*o*-F	7	48	38	8	0	0
L2	*o*-Cl	16	35	40	0	0	0
L3	*o*-Br	7	36	39	0	0	0
L4	*o*-I	16	25	59	0	0	0
L5	*o*-MeO	0	57	33	6	0	3
L6	2,5-$(MeO)_2$	0	62	25	3	7	3
L7	*o*-Me	28	48	24	0	0	0
L8	*p*-F	27	39	22	0	0	0
L9	*p*-Cl	28	45	12	0	0	0
L10	*p*-Br	33	42	19	0	0	0
L11	*p*-I	36	39	19	0	0	0
L12	*p*-MeO	24	52	14	0	0	0
L13	2,4,6-Me_3	0[a] 16[b]	39	23	0	0	0
L14[c]	2,4,6-Me_3	36[a] 16[b]	23	20	0	0	0
L15[d]	2,4,6-Me_3	11[a] 2[b]	18	5	0	0	0

a) *ONN*-Isomer. b) *NNO*-Isomer. c) 4.0 mol of *p*-MeC_6H_4-IDMg was used. d) 1.2 mol of *p*-MeC_6H_4-IDMg was used. Product **4** was isolated in 29% yield.

The first feature is that shift of substituents from the para to ortho position causes decrease in combined yield of **1** and **2** from 66—76% (L8—L12) to 41—57% (L1—L5) and increase in that of **3** from 12—22% to 33—59%. The feature arises from the effect of lone-pair electrons of *o*-substituents favorable for the dimerization and not from that of steric repulsion against condensation, as indicated by the comparable yields caused by *o*-Me- (L7) and *p*-substituents (L8—L12). The formation of **3** is observed in IDMg reaction with ortho-quinones, but not with para-quinones.[11] According to the mechanism of two-electron oxidation of IDMg molecules,[4] all the adjacent halogeno, methoxyl, carbonyl, and nitro groups may coordinate to the Mg atoms of IDMg molecules to assist the arylaminyl radicals (Ar(MgBr)N·) to be produced in the proximity of each other in favor of the dimerization.

The second feature is the evidently lower yields of **1** in L1—L6 (0—16%) than those in L7—L12 (24—36%). The feature arises also from the effect of lone-pair electrons of *o*-substituents of **1** favoring its deoxygenation. The reciprocal of λ_{max}'s of *m*- and *p*-substituted azoxybenzenes are correlated with their reactivity in IDNg deoxygenation.[3] Thus the reduced electron-repelling resonance effect of *o*-substituent by steric hindrance causes the enhancement of positive charge on azoxy nitrogen to facilitate the attack of anionic IDMg nitrogen.[3]

Determination of *ONN* and *NNO* Structures of Azoxybenzenes, and Unique *ONN-NNO* Isomerization Caused by 2,6-Me_2 Groups. The *ONN*-structure of *o*-substituted *unsym*-azoxyarenes, having azoxy oxygen combined to the original "nitro" nitrogen, was confirmed by means of ^1H NMR spectra different from those of the known *NNO*-isomer obtained by the reaction of *o*-substituted phenyl-IDMg with *p*-Me-nitrobenzene. Comparison of photo-Wallach rearrangement products with authentic *o*-hydroxyazobenzenes[12,13] was also useful. X-Ray crystallography was not used because almost all the azoxyarenes are oil. A solid one having 2,6-Me_2 groups tends to form fluffy needles, and no single crystals of sufficient size with clean surface were obtained.

Similarly to *p*- and *m*-substituted azoxybenzenes,[3] the *o*-monosubstituted ones undergo no *ONN-NNO* isomerization even by being heated with large molar excess of IDMg. A unique *ONN-NNO* isomerization under the same conditions was observed in the case of the most crowded 2,4,6-Me_3-nitrobenzene (L13, Table 2). The less crowded azoxy product $\mathbf{1}^{3Me}_{NNO}$ is formed via isomerization of the much crowded "normal" isomer $\mathbf{1}^{3Me}_{ONN}$ by an interaction with IDMg. Even by use of 4.0 or 1.2 mol of IDMg (L14 and L15), both $\mathbf{1}^{3Me}_{ONN}$ and $\mathbf{1}^{3Me}_{NNO}$ were isolated.

Conclusion

The various effects of coordination proposed are in line with those given for modifying relative efficiency of SET estimated by oxidation and reduction potentials.[6] The reasons given for yield variations with leaving abilities and positional change of substituents are still equivocal, but the cooperation of reagent molecules for condensation is possibly an important clue to the mechanism of the essential reaction pathway of Scheme 1. Though optimum conditions remain to be studied, the IDMg method has proved to be useful for the preparation of crowded azoxyarenes available for studying the photoinduced[12,13] and acid-catalyzed[14] rearrangements as well as the deoxygenation by PX_3-type reagents.[15]

Experimental

Materials and Procedures. The reactions of Scheme 1 were carried out using 3—5 mmol of nitroarenes and calculated amounts of IDMg reagent in 50 ml of THF,[2,3] except in Run S12 where 250 ml of THF was used. The reaction conditions applied to the individual runs are given in Tables 1 and 2. Products were separated by column and preparative thin-layer chromatographies on silica gel and then recrystallized. Physical data of products **1** and **4—9** are summarized in Table 3, melting points being uncorrected. Elemental analyses gave satisfactory results. An identification of *ONN* and *NNO* structures of azoxyarenes by indirect means using photoreactions was carried out by comparison with authentic samples of *o*-hydroxyazoarenes.[13]

The authors wish to thank the Advanced Instrumentation Center for Chemical Analysis, Ehime University, for the elemental analyses. A part of this work was financially supported by a Grant-in-Aid for Scientific Research (No. 60470026).

Synthesis of Skeleton of Antitumor Quassinoid

Makoto SASAKI, Tatsushi MURAE,* Hisaaki MATSUO, Toshiyuki KONOSU, Naoko TANAKA, Kiyoshi YAGI, Yoshinosuke USUKI, and Takeyoshi TAKAHASHI†

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received April 27, 1988)

A compound having a skeleton of an antitumor quassinoid, bruceantin, was prepared according to the following strategy; 1) construction of ring ABC from ring AB by cyclization of a hindered 1,5-diketone; 2) construction of ring E (ether ring) by opening of a 12,13-epoxide ring followed by attack of oxygen at C-20 toward C-13; 3) formation of ring D (hemiacetal ring) by treatment of a 7α-hydroxy-16-al dimethyl acetal with PPTS.

Quassinoids, highly degraded triterpenes which are isolated from Simaroubaceae plants specifically, have a wide spectrum of biological properties.[1] Among a large number of quassinoids,[1,2] bruceantin (**1**) and bruceantinol (**2**) which have a skeletal structure **A** exhibit remarkable antileukemic activity.[3] Although a large number of efforts for syntheses of antitumor quassinoids have been reported,[4] none of them accomplished the total synthesis. The first synthesis of a compound having the skeletal structure **A** has been achieved by the authors.[4] The synthetic plan was based on AB → ABC → ABCE → ABCDE ring strategy. The details of the synthesis of compound **3** which has the skeletal structure **A** bearing functional groups at suitable positions for syntheses of antitumor quassinoids are described in this paper.

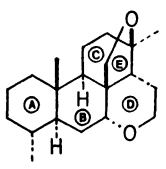
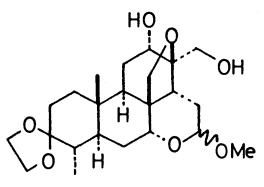
2: R=OH



A



3

The first problem of our strategy was the construction of ABC ring from AB ring. It has been reported by Snitman et al.[5] that on Robinson annulation the hindered 1,5-diketone **4** did not yield **5** giving the retro-Michael product as the principal one and the similar compound **6** afforded cyclized compound **7** in only 15% yield. It was eventually found that a 1,5-diketone bearing a conjugated diene system at C-3 through C-6[6] gave a cyclized product in better yield than that of **7** from **6**. Steric compression around the carbonyl group at C-9 may have been decreased by the introduction of the diene system. The conjugated double bond is also useful for further syntheses because the diene system is stable on treatments with acid and base and introduction of oxygen functional groups into suitable positions in rings **A** and **B** (C-3 and C-7) utilizing the diene system is possible.

The retro-Michael reaction occurs hardly when 1,5-diketones having a methyl group instead of the methoxycarbonyl group are used for the cyclization reaction. Therefore, reaction of 1,5-diketone **11** was examined first to check the feasibility of the cyclization reaction. The tricyclic compound **12** was smoothly obtained from **11** which was prepared by the following sequences. Reduction of the known monoacetal **8**[7] with sodium borohydride was followed by an acid treatment to yield a diene **9** in a quantitative yield. The diene **9** was monomethylated by the treatment with methyl iodide in the presence of lithium diisopropylamide (LDA) to give **10** in 85% yield. The Michael addition reaction of methyl vinyl ketone to **10** proceeded in the presence of 0.3 equivalent of sodium methoxide in methanol at room temperature to afford **11**. The cyclization of the adduct **11** was accomplished to give tricyclic compound **12** by heating at reflux in methanol with 1 equivalent of sodium methoxide. The reactions to obtain **12** from **10** were carried out in one pot and the yield was 89%.

As the cyclization reaction of the 1,5-diketone **11** proceeded in high yield, the 1,5-diketone **14** having a methoxycarbonyl group and the diene system was examined next. The 1,5-diketone **14** was prepared by addition of methyl vinyl ketone to the β-keto ester **13** which was obtained by the methoxycarbonylation of the ketone **9**. The diketone **14** gave retro-Michael reaction product as major one on heating with sodium methoxide in methanol or on heating with pyrrolidine in benzene. However, on treatment with the same reaction conditions (a combination of pyrrolidine and benzoic acid) as those with which **6** afforded the cyclization product **7** in 15% yield,[5] **14** yielded the cyclization product **15** in 52% yield.

Several combinations of benzoic acid derivatives and

† Present address: Department of Agricultural Chemistry, Faculty of Agriculture and Veterinary Medicine, Nihon University, Shimouma, Setagaya-ku, Tokyo 154.

amines were examined to obtain **15** from **14** in better yield. Although couples of benzoic acid and secondary amines (pK_a) [pyrrolidine (11.3), piperidine (11.1), diethylamine (10.9), and morpholine (8.3)] did not show any remarkable change of the yield of **15**, couples of pyrrolidine and benzoic acid derivatives (pK_a) [*m*-toluic acid (4.94), *o*-toluic acid (4.79), benzoic acid (4.21), *m*-hydroxybenzoic acid (4.08), salicylic acid (3.00), and 3,5-dinitrobenzoic acid (2.82)] exhibited serious change of the yield of **15**. The weaker acid coupled with the amine gave **15** in the better yield. When salicylic and 3,5-dinitrobenzoic acids were used, only retro-Michael reaction occurred. The reason why the couple of pyrrolidine with the weaker benzoic acid gives **15** in better yield is not clear, but we consider that the weaker acid makes more tight complex with amines in benzene and suppresses base-catalyzed retro-Michael reaction.[8] It was also found that the use of excess amount of the acid made the yield better. And the treatment of **14** with 1.2 equivalent of *m*-toluic acid and 0.2 equivalent of pyrrolidine in benzene heated at reflux through Molecular Sieves 4A to remove water gave **15** in good yield (80—90%). By these reaction conditions, cyclization of **11** was accomplished in 6 h to give **12** in almost quantitative yield.

The stereochemistry of the methoxycarbonyl group of **15** was supposed to be β, because the Michael addition of methyl vinyl ketone to **13** was considered to proceed from less hindered opposite side to the angular methyl group. This was confirmed by conversion of the methoxycarbonyl group at C-8 of **15** into methyl group to give **12** and conversion of **12** into the α,β-unsaturated ketone **21**. The authentic specimen of **21** was derived from the known tricyclic compound **16**[9] via conjugated diene **17**, ketone **18**, tosylhydrazone **19**, and the enol thioether **20** according with the method developed by Nakai and Mimura.[10] The tricyclic compound **16** has been used for the construction of picrasane skeleton (skeletal structure **A** without ring E) by the authors.[9]

The UV absorption maximum at 302 nm indicates the presence of a conjugated enol thioether structure in **20**. This means that 1,3-shift of the proton at C-12 to C-14 occurred on the reaction of the tosylhydrazone **19** into the enol thioether **20**. Although hydrolysis of the enol thioether **20** using mercury(II) chloride gave the product in very poor yield and treatment of the thioether with titanium tetrachloride in acetic acid[11] afforded a complex mixture, on treatment with titanium tetrachloride in THF followed by addition of aqueous acetic acid **20** yielded the conjugated ketone **21** as a major product.

The transformations of **15** into **21** via **12** were carried out by the following reactions. Protection of the carbonyl group of **15** to give acetal **22**, whose methoxycarbonyl group was reduced with lithium alminium hydride (LAH) to yield alcohol **23**, which was oxidized with Collins' reagent to give aldehyde **24**. Wolff-Kishner reduction of **24** followed by treatment with

dilute hydrochloric acid gave the tricyclic compound **12**. The tricyclic compound **12** was converted into the conjugated ketone **21** via tosylhydrazone **25** and the enol thioether **20** using similar methods as those used for the conversion of **18** into **21**.

Although the diene system at C-3 through C-6 was very effective for the construction of the ring ABC, efficient methods for introduction of oxygen functions into C-3 and C-7 utilizing the diene system remained to be developed. A selective introduction of an oxygen function in a protected form into C-3 was desirable and it was performed by epoxidation with *m*-chloroperbenzoic acid (MCPBA) followed by a treatment under acetalization conditions. Hydrolysis of the acetal **23** gave ketone **26**, whose hydroxyl group was acetylated by the usual method to give acetate **27**. The acetate **27** afforded a 3 : 1 mixture of the α-epoxide **28**α and β-epoxide **28**β on epoxidation with MCPBA. The proton at C-3 was observed as a broad singlet ($W_{1/2}$=4.5 Hz) and a doublet (J=3.6 Hz) for **28**α and **28**β, respectively. Although **28**α afforded the acetal **29** in 90% yield by the treatment with ethylene glycol and boron trifluoride etherate ($BF_3 \cdot Et_2O$) in benzene at room temperature, **28**β gave a complex mixture by the same treatment. The fact suggests that the acetal at C-3 can be derived only from the α-epoxide and the use of a compound which gives α-epoxide in high selectivity is desirable.

On epoxidation with MCPBA the monoacetal **22** afforded a 5 : 1 mixture of α- and β-epoxides (**30**α and **30**β). On treatment with ethylene glycol and $BF_3 \cdot Et_2O$ in benzene, the mixture yielded a 6 : 1 mixture of monoacetal **31** and diketone **32**. On acetalization under standard conditions the mixture of **31** and **32** afforded diacetal **33**. The overall yield of **33** from **22** was 64%. The diacetal **33** was obtainable from **15** by two steps (epoxidation and acetalization), but the ratio of the α- and β-epoxides (**34**α and **34**β) obtained by epoxidation of **15** with MCPBA was 2 : 1 and the final yield of **33** was low.

Allylic oxidation of some tricyclic compounds obtained so far was tried to introduce an oxygen function into C-7. Oxidation of diacetal **33** yielded diketone **35**, but the yield (27%) was too low to continue the further syntheses. Oxidation of the acetate **29** afforded ketone **36** in poor yield. In our previous synthetic studies of quassinoids, it has been experienced that the yield of allylic oxidation at C-7 was seriously affected by the substituents of ring C. Therefore, we decided to examine the introduction of oxygen function into C-7 at the later stage.

Introduction of two carbon appendage into C-14 position through 1,4-addition was our strategy and so the presence of the double bond at C-9 (11) was undesirable. As introduction of oxygen function into the double bond at C-9 (11) was unsuccessful, reduction of the double bond was examined. Reduction of the double bond at C-9 (11) of the tetrahydropyranyl (THP) ether **38** derived from the α,β-unsaturated ketone **37** was tried by three methods. The saturated ketone **39** was given in 48%, 77%, and 99% yield on catalytic hydrogenation using 10% palladium on carbon, Birch reduction using lithium, and reduction with sodium hydrogentelluride (NaHTe),[12] respectively. The stereochemistry of the newly generated chiral center (C-9) of **39** was suggested to be α-H, because hydrogen attacks from less hindered α-side on catalytic hydrogenation. Although the protecting group of the hydroxyl group at C-20 was necessary to be removed without significant effect on the acetal at C-3, the selective removal of the THP group of **39** was hard. After several trials, it was found that 1-ethoxyethyl (EE) group was a satisfactory protecting group which could be removed selectively in almost quantitative yield. The EE ether **40** obtained by the treatment of **37** with ethyl vinyl ether and pyridinium *p*-toluenesulfonate (PPTS) was reduced with NaHTe to give ketone **41** in 98% yield.

Introduction of a double bond at C-13 was necessary prior to addition of two carbon unit to C-14. Regioselectivity of phenylselenylation of the EE ether **41** was poor, but a methoxycarbonyl group was regioselectively introduced into C-13 of **41** giving **42** (83% yield) by treatment with dimethyl carbonate and sodium hydride containing catalytic amount of potassium hydride.[13] When the reaction was carried out without potassium hydride, the yield of **42** was very low. The ratio of keto and enol forms of β-keto ester **42** produced is variable. Phenylselenylation of **42** and successive oxidative elimination of the phenylseleno group

afforded α,β-unsaturated ester **43**.[14] Heathcock et al.[15] reported that addition of ketene acetal **44** to the "very reactive" Michael acceptor **45**, whose structure is very close to **43**, required 15 kbar for 24 h to do drive the reaction to completion. But a vinyl group was successfully introduced into the C-14 position of **43** to give **46** by conjugate addition of vinylmagnesium bromide catalyzed with a complex of copper(I) iodide and tributylphosphine[16] at −45 °C in 80% yield along with 1,2-addition product **47** (12% yield). The stereochemistry of the vinyl group of **46** was assumed to be α-axial, because the attack of the Grignard reagent was considered to occur from less hindered side. After our preliminary report it has been reported by Grieco et al.[17] that conjugate addition of C_2-unit to octalone **48** proceeded smoothly in ether at −78 °C, giving rise to **49** in 95% yield using an organocopper reagent derived from equimolar amounts of copper(I) iodide and vinyllithium and 2.6 equivalent of tributylphosphine. The compound **46** has all carbons contained in the skeletal structure **A** with desired stereochemistry.

Construction of ring E by attack of hydroxyl group at C-20 to C-13 was our selected strategy to be tried at first and introduction of a double bond at C-12 was necessary prior to the trial. Conversion of **46** into the α,β-unsaturated ester **51** via a mixture of stereoisomers of the alcohol **50** was carried out by the successive treatments with sodium borohydride in ethanol, methanesulfonyl chloride and triethylamine in dichloromethane, and then 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) in refluxing benzene. The overall yield of **51** from **46** was 73%. The EE group of **51** was removed by treatment in ethanol containing catalytic amount of PPTS to give alcohol **52** in 81% yield. The tricyclic compound **52** is ready to form bruceantin skeleton **A**.

52: R=H

The modest yield we encountered when scaling up the synthesis of the diacetal **33** led us to search for another route for the synthesis of **51**. If the double bond at C-9(11) is reduced prior to the introduction of an oxygen function into C-3, the use of the unstable acetals such as **33** can be avoided. It was eventually found that the double bond of the α,β-unsaturated ketone of **15** could be reduced selectively to give ketone **53** in a quantitative yield with NaHTe in ethanol at room temperature (the conjugated diene system of **15** was reduced on Birch reduction and catalytic hydrogenation). The keto alcohol **55** was obtained by LAH reduction of acetal **54** and following acid treatment of the product. The yield of **55** from **53** was almost quantitative. The hydroxyl group of **55** was protected with EE to give **56** in 94% yield. The α,β-unsaturated ester **60** was synthesized from **56** via **57**, **58**, and **59** by the same methods used to obtain **51** from **41**, namely methoxycarbonylation to give **57**, phenylselenylation followed by oxidative elimination to afford **58**, conjugate addition reaction of vinylmagnesium bromide to yield **59**, reduction with sodium borohydride, mesylation, and treatment with DBU to give **60**. The overall yield of **60** from **56** was 58%.

Before introduction of an oxygen function into C-3, the EE group of **60** was replaced with an acetyl group to give **61** in 90% yield, because the EE group was affected with MCPBA giving a complex mixture. On oxidation with MCPBA the acetate **61** afforded epoxide **62**. No other product was detected in the ^1H NMR spectrum of the crude **62**. The signal of the proton at C-3 in the ^1H NMR was observed as a singlet ($W_{1/2}$= 4.5 Hz) suggesting the configuration of the epoxide to be α which is preferable stereochemistry for introduc-

tion of an acetal group into C-3 as shown in the case of **28**. The epoxide **62** yielded the acetal **63** on treatment with 2-ethyl-2-methyl-1,3-dioxolane and $BF_3 \cdot Et_2O$ in dichloromethane. The yield of **63** from **61** was 87%. The replacement of the acetyl group of **63** with EE group was accomplished in 93% yield to afford **51**. Thus the preparation of enough amount of the tricyclic compound **51** for further syntheses toward antitumor quassinoids has become possible.

The next step in our strategy toward bruceantin skeleton was the construction of the epoxide ring E. The direct formation of tetracyclic triol **65** on MCPBA oxidation of triol **64** has been reported by Ziegler et al.[18] Therefore it was considered that the acid-catalyzed opening of 12,13-epoxide ring would provide a convenient access to ring E. For the regio- and stereospecific introduction of the epoxide into the C-12 double bond utilizing a hydroxyl group at C-21, the ester **51** was reduced to allylic alcohol **66** with DIBAL. The allylic alcohol **66** was oxidized with *t*-butyl hydroperoxide using titanium(IV) isopropoxide as a catalyst[19] to give epoxide **67** as a sole product in almost quantitative yield. The stereochemistry of the epoxide ring of **67** was hard to be determined by its NMR spectrum. On treatment with catalytic amount of PPTS in ethanol **67** afforded the diol **68** as nice crystalline compound in a quantitative yield. The similarity of the NMR spectra of **68** [^{1}H NMR signals for C-20H_2 (AB quartet at δ 3.33 and 4.36 with J=8 Hz) and C-12H (broad doublet at δ 4.05 with J=4 Hz) and ^{13}C NMR signals for C-12, C-13, C-20, and C-21] to those of the known compound **69**[20] suggested that the stereochemistry of the hydroxyl group at C-12 is α-axial. Therefore, the configuration of the epoxide ring of **67** was suggested to be α.

Even though the stereochemistry of the hydroxyl group at C-12 is axial, **68** gave diacetate **70** very easily. This facile acetylation of the axial hydroxyl group is compatible with acetylation of the primary hydroxyl group at C-21 followed by the migration of the acetyl group to the hydroxyl group at C-12 and successive acetylation of the regenerated primary hydroxyl group.

Migration of the protecting group of the hydroxyl group at C-21 to the hydroxyl group at C-12 was observed also for the *t*-butyldimethylsilyl (tBDMS) ether **71**. The acetate **72** derived from **71** showed the ^{1}H NMR signal of C-12H at δ ca. 5.0 suggesting the presence of the acetoxyl group at C-12. Although the silyl ether **71** was not affected by the treatment with chrolomethyl methyl ether (MOMCl) and *N,N*-diisopropylethylamine in refluxing dichloromethane, on treatment with MOMCl and potassium hydride in a mixed solvent of THF and *N,N*-dimethylformamide (DMF) **71** afforded methoxymethyl (MOM) ether **73**. On selective removal of the silyl protecting group with tetrabutylammonium fluoride followed by acetylation, **73** afforded the acetate **74** whose ^{1}H NMR spectrum suggested the presence of the acetoxyl group at C-12

69

(C-12H: δ ca. 5.0). These observations indicate that the migration of the silyl group[21] from the hydroxyl group at C-21 to that of at C-12 occurred during the reaction of **71** to **73**.

The final step for the synthesis of the bruceantin skeleton was the construction of ring D (lactone or hemiacetal ring). Oxidation at C-7 and C-16 and reduction of the double bond at C-5 were inevitable in order to construct the ring D. Protection of the hydroxyl groups at C-12 and C-21 was necessary prior to these reactions. Silyl groups were considered to be desirable for the protection. The monosilyl derivative **71** was treated with potassium hydride in the mixed solvent of THF and DMF and then the solution of tBDMSCl in THF was added to the reaction mixture to give the disilyl derivative **75** in 96% yield.

Selective introduction of a hydroxyl group into C-16 of **75** was carried out by hydroboration-oxidation using thexylborane to yield alcohol **76**. Simultaneous oxidation of the hydroxyl group and the allylic position (C-7) of **76** was hard, and so **76** was converted into aldehyde **77** by Collins' oxidation. Although protection of the formyl group of **77** using trimethyl orthoformate in methanol containing PPTS was inefficient because of concurring hydrolysis of the acetal group at C-3, dimethyl acetal **78** was obtained in 94% yield by the use of dichloromethane instead of methanol as the solvent in the above reaction conditions.

Allylic oxidation of the acetal **78** with the complexes of chromium trioxide and 3,5-dimethylpyrazole[22] gave the α,β-unsaturated ketone **79** in 68% yield. The enhanced yield of allylic oxidation at C-7 of **78** compared with those of **29** and **33** is probably due to decrease of strain energy around the carbonyl at C-7 caused by saturation of the ring C and not due to simple change of steric hindrance around C-7. Birch reduction of **79** gave saturated ketone **80**. The stereo-

a) Determined by difference NOE. b) Undetermined because of overlapping with other signals.

chemistry at C-5 of **80** was supposed to be 5α-H, because the 5α-H compound is more stable than the 5β-H isomer.

For the completion of ring D, stereoselective reduction of the carbonyl group at C-7 into α hydroxyl group was necessary. Although bulky hydride reagents such as diisobutylaluminium hydride (DIBAL) were considered to give 7α-OH derivative selectively, 7β-OH derivative was obtained as the sole product on reduction of the ketone **80** with DIBAL and sodium borohydride. Chelation between the dimethyl acetal group and the hydride reagent may have controlled the stereochemistry of the reaction. On reduction with lithium triethylhydroborate the ketone **80** gave 7α-OH derivative **81** stereoselectively. The anomeric mixture at C-16 of the hemiacetal **82** was obtained smoothly by the treatment of **81** with catalytic amount of PPTS in MeOH at room temperature. The mixture could not be separated into each isomer, but an isomer of the anomeric mixture of the diol **3** obtained by the treatment of **82** with tetrabutylammonium fluoride could be separated.

Precise decoupling (Table 1) and difference NOE (Fig. 1) experiments using 270 MHz ^{1}H NMR confirmed the structure of the isolated isomer of **3** bearing 16β-methoxyl group to be that shown in Fig. 2. The stereochemistries of the epoxymethano bridge and the methyl group at C-4 are shown to be β-axial and α-equatorial, respectively, by the NOEs among $C_{(10)}$-Me, $C_{(20)}$-βH, and $C_{(4)}$-H (Fig. 1 A and B). The NOEs among $C_{(10)}$-Me, $C_{(20)}$-βH, and $C_{(11)}$-βH (Fig. 1 A and B) indicate that $C_{(11)}$-βH has axial conformation and the large coupling constant (14 Hz) between $C_{(9)}$-H and the $C_{(11)}$-βH suggests that the stereochemistry of the $C_{(9)}$-H is α-axial. The coupling constant (12 Hz) between $C_{(4)}$-H and $C_{(5)}$-H shows the α-axial nature of the $C_{(5)}$-H. The NOEs among $C_{(20)}$-αH, $C_{(14)}$-H, and $C_{(7)}$-H (Fig. 2 C, D, and E) indicate that these protons are located near place each other, therefore both of the protons at C-7 and C-14 have β-equatorial stereochemistry. This is also supported with the small coupling constants between the proton at C-7 and the protons at C-6. All of the NMR data of the isolated isomer of **3** are best compatible with the molecular structure (Fig. 3) having minimized steric energy (348.695 kJ mol^{-1}) given by MM2 force field calculation[23] for the 16β-methoxy isomer of **3** and unequivocally confirmed the stereochemical assignment.

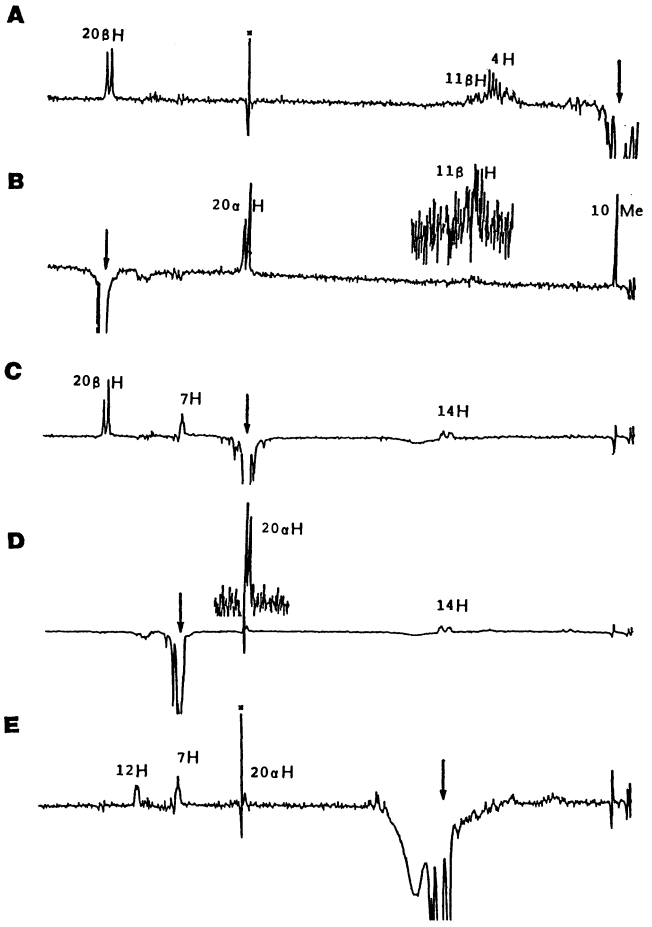

Fig. 1. Difference NOE spectra (270 MHz in $CDCl_3$) of 16β-methoxy isomer of **3**. ↓: Irradiated frequency. The NOE of 12H in E was induced by simultaneous irradiation on overlapping signal of 12-OH.

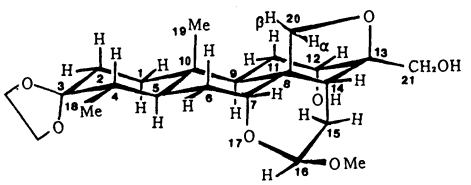

Fig. 2. Perspective drawing of the isolated isomer of **3**.

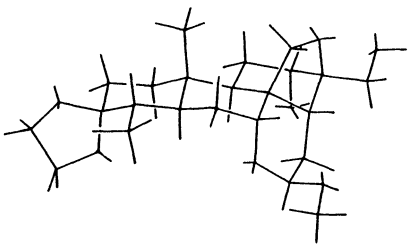

Fig. 3. Wire model generated by computer based on MM2 force field calculation for the 16β-methoxy isomer of **3** bearing minimum steric energy. Short lines from ether oxygen indicate lone pairs.

Experimental

General. All reactions were run under a nitrogen atmosphere with magnetic stirring unless otherwise noted. Unless otherwise noted, materials were obtained from commercial suppliers and used without further purification. Ether and tetrahydrofuran were distilled from lithium aluminium hydride immediately prior to use. Dichloromethane was distilled from P_2O_5. Absolute ethanol (EtOH) and methanol (MeOH) were distilled from magnesium. Hexane, benzene, toluene, pyridine, 1,2-dimethoxyethane (DME), acetonitrile, *N*,*N*-dimethylformamide (DMF), triethylamine, *N*,*N*-di-

isopropylethylamine, and dimethyl carbonate were distilled from calcium hydride. Chromium trioxide was dried overnight at reduced pressure and stored over P_2O_5. Liquid ammonia was distilled from sodium. Preparative chromatography was carried out on open column of silica gel (Wako, C-200). Thin-layer chromatography (TLC) was performed on E. Merck Kieselgel GF_{254} Art 7730.

Melting points were measured on Laboratory Devices Meltemp and are uncorrected.

^1H NMR spectra were determined with Varian EM 390 (90 MHz), JEOL FX 90Q (90 MHz), or Brucker WH 270 (270 MHz) spectrometers in $CDCl_3$ solutions with tetramethylsilane as internal standard. ^{13}C NMR spectra were recorded on JEOL FX 90Q spectrometer. ^1H NMR data are tabulated in order number of protons, multiplicity (s, singlet; brs, broad singlet; d, doublet; t, triplet; brt, broad triplet; q, quartet; m, multiplet), coupling constants in hertz. IR spectra were recorded on a Hitachi Model 260-30 grating infrared spectrometer. UV spectra were obtained on a Hitachi Model 340 instrument. Low- and high-resolution mass spectra were measured using JEOL JMS-D300 mass spectrometer equipped with JMA-2000 data analysis system.

3,7,8,8a-Tetrahydro-5,8a-dimethyl-1(2*H*)-naphthalenone (9): To a solution of monoacetal **8** (11.0 g, 46 mmol) in methanol (200 ml) was added sodium borohydride (3 g, 79 mmol) in portions under drying tube. The mixture was stirred at room temperature for 3 h. Acetic acid (200 ml) and 1 mol dm^{-3} HCl (100 ml) were added. After being set aside overnight, the solution was neutralized with 30% aqueous NaOH, extracted with ether, washed with water (×3) and then dried over $MgSO_4$. Removal of the solvent under reduced pressure and subsequent distillation afforded the diene **9** (6.1 g, 74%) as an oil: bp 83—94 °C (80.0 Pa); IR (oil) 1715 cm^{-1}; UV (EtOH) 237 nm (ε 16000); ^1H NMR δ=1.18 (3H, s, 10-CH_3), 1.81 (3H, brs, 4-CH_3), 5.50 (1H, m), and 5.75 (1H, brt, J=4 Hz); MS (70 eV) m/z (rel intensity) 176 (M^+, 36.5), 161 (13), and 118 (100); Found m/z 176.1217. Calcd for $C_{12}H_{16}O$: M, 176.1201.

3,7,8,8a-Tetrahydro-2α,5,8aβ-trimethyl-1(2*H*)-naphthalenone (10): To a solution of LDA (6.8 mmol) in THF (20 ml) was added a solution of **9** (1.11 g, 6.29 mmol) in THF (20 ml) dropwise with stirring at −78 °C. The mixture was stirred at room temperature for 30 min and to the solution was added MeI (0.8 ml, 13 mmol) which was passed through a neutral alumina column prior to use. After stirring at room temperature for 30 min the reaction was quenched by the addition of brine. The reaction mixture was acidified with dil HCl and extracted with ether. The ether solution was washed with brine and then dried (Na_2SO_4). Concentration in vacuo gave a residue that was chromatographed on silica gel (eluent: benzene) to give methylated compound **10** (1.02 g, 85%) which afforded colorless needles on crystallization from aqueous methanol: mp 47.0—48.8 °C; IR (oil) 1712 cm^{-1}; ^1H NMR δ=1.02 (3H, d, J=6 Hz, 8-CH_3), 1.16 (3H, s, 10-CH_3), 1.74 (3H, brs, 4-CH_3), 5.34 (1H, m), and 5.38 (1H, brt, J=4 Hz); MS (70 eV) m/z (rel intensity) 190 (M^+, 30), 175 (11), 134 (41), and 119 (100): Found: m/z 190.1357. Calcd for $C_{13}H_{18}O$: M, 190.1357.

1,4b,5,6,10,10a-Hexahydro-4bβ,8,10aβ-trimethyl-3(2*H*)-phenanthrenone (12): To a solution of 0.5 mol dm^{-3} NaOMe in MeOH (2.5 ml) was added **10** (0.70 g, 3.7 mmol) and then methyl vinyl ketone (0.65 ml). The mixture was stirred at room temperature for 20 h. (Michael adduct **11** could be obtained from the reaction mixture by usual work up.) To the reaction mixture was added 1 mol dm^{-3} NaOMe (2.5 ml) and the mixture was heated at reflux for 4 d. Brine was added into the mixture, which was extracted with ether and dried over Na_2SO_4. Evaporation of the solvent gave a residue which was purified by silica-gel column chromatography (50 g; eluent: 2% acetone in benzene) to give tricyclic compound **12** as a colorless oil (0.79g, 89%): IR (oil) 1672 and 1603 cm^{-1}; ^1H NMR δ=1.23 (3H, s), 1.42 (3H, s), 1.83 (3H, brs, 4-CH_3), 5.51 (1H, m), 5.66 (1H, brt, J=4 Hz), and 6.01 (1H, s, 11-CH); MS (70 eV) m/z (rel intensity) 242 (M^+, 100), and 227 (59); Found m/z 242.1689. Calcd for $C_{17}H_{22}O$: M, 242.1670.

3,7,8,8a-Tetrahydro-2-methoxycarbonyl-5,8a-dimethyl-1(2*H*)-naphthalenone (13): To a suspension of NaH (60 g, 1.5 mol 60% oil dispersion) and KH (1 g, 12 mmol, 50% oil dispersion) and dimethyl carbonate (110 ml) in DME was added **9** (200 g, 1.1 mol) in DME (250 ml) with stirring in an ice bath and releasing the hydrogen evolved by the reaction through mercury valve. The mixture was stirred in an ice bath until practical finish of evolution of hydrogen and then heated at reflux for 1 h. The reaction mixture was poured into saturated aqueous NH_4Cl and extracted with ether (11×1, 0.5 1×2). The ether solution was washed with saturated aqueous NH_4Cl (100 ml) and then brine (100 ml×2). Drying over Na_2SO_4 and evaporation of the solvent gave an orange oil, which crystallized upon standing. An analytical sample of **13**, mp 51.8—53 °C, was obtained as colorless plates (colored slightly yellow on exposure to air) by crystallization from methanol: IR (KBr) 1663, 1640, and 1618 cm^{-1}; UV (EtOH) 232 (ε 30000) and 238 nm (sh 25000); ^1H NMR δ=1.17 (3H, s, 10-CH_3), 1.76 (3H, brs, 4-CH_3), 2.92 (2H, brd 7-CH_2), 3.70 (3H, s, CO_2CH_3), and 5.30—5.65 (2H, m); MS (70 eV) m/z (rel intensity) 234 (M^+, 32), 219 (69), and 187 (100); Found m/z 234.1268. Calcd for $C_{14}H_{18}O_3$: M, 234.1256.

3,7,8,8a-Tetrahydro-2β-methoxycarbonyl-5,8aβ-dimethyl-2α-(3-oxobutyl)-1(2*H*)-naphthalenone (14): To a solution of **13** (4.24 g, 18 mmol) in MeOH (50 ml) was added 0.5 mol dm^{-3} NaOMe in MeOH (3.0 ml) and methyl vinyl ketone (4.0 ml). The mixture was stirred at 40 °C for 3 h. The solvent was distilled off under reduced pressure. The residue was dissolved in ether and brine. The ether solution was washed with brine and dried (Na_2SO_4). Evaporation of the solvent gave 5.50 g (100%) of crude **14** pure enough for further use. An analytical sample of **14**, mp 78.5—80 °C, was obtained by crystallization from hexane as colorless needles: IR (KBr) 1742, 1715, and 1708 cm^{-1}; UV (EtOH) 240 nm (ε 19000); ^1H NMR δ=1.17 (3H, s, 10-CH_3), 1.83 (3H, brs, 4-CH_3), 2.09 (3H, s, $COCH_3$), 3.70 (3H, s, CO_2CH_3), 5.60 (1H, m), and 5.72 (1H, dd, J=7 and 3 Hz); MS (70 eV) m/z (rel intensity) 304 (M^+, 5.8), 286 (5), 257 (9.2), 233 (94), and 201 (100); Found: C, 70.87; H, 7.82%. Calcd for $C_{18}H_{24}O_4$: C, 71.03; H, 7.95%.

1,4b,5,6,10,10a-Hexahydro-10aβ-methoxycarbonyl-4bβ,8-dimethyl-3(2*H*)-phenanthrenone (15): To a solution of diketone **14** (30.4 g, 0.1 mol) and *m*-toluic acid (16.3 g, 0.12 mol) in benzene (750 ml) was added pyrrolidine (1.7 ml, 0.02 mol) and the mixture was refluxed for 14 h passing through Molecular Sieves 4A. The cooled mixture was washed with 5% aqueous potassium hydroxide (100 ml×3) and the combined aqueous layers were extracted with ether (100 ml×3). The combined organic extracts were washed with 2 mol dm^{-3} HCl (100 ml×3) and the combined aqueous layers

were extracted with ether (100 ml×2). The combined organic extracts were washed with brine (100 ml), dried (Na_2SO_4-$MgSO_4$), filtered through a silica-gel column (70 g in benzene) and evaporated. The brown residue was chromatographed on silica-gel column (150 g in hexane, eluent: 2% AcOEt in hexane) to afford enone **15** (22.86 g, 80%) as a pale yellow solid. An analytical sample was obtained as colorless plates by recrystallization from ether-hexane: mp 80—82 °C; IR (Nujol) 1731, 1675, and 1608 cm^{-1}; UV (EtOH) 236.5 nm (ε 26000); ^1H NMR δ=1.05 (3H, s, 10-CH_3), 1.79 (3H, s, 4-CH_3), 3.72 (3H, s, CO_2CH_3), 5.53 (1H, m), 5.61 (1H, dd, J=7 and 3 Hz), and 6.18 (1H, s, 11-CH); ^{13}C NMR δ=198.67, 173.62, 166.44, 138.92, 130.30, 124.69, 123.75, 117.06, 51.88, 44.94, 38.82, 36.46, 35.59, 33.48, 31.45, 23.84, 22.13, and 19.56; MS (70 eV) m/z (rel intensity) 286 (M^+, 58) and 227 (100); Found: C, 75.46; H, 7.61%. Calcd for $C_{18}H_{22}O_3$: C, 75.49; H, 7.74%.

1,2,3,4b,5,6,10,10a-Octahydro-4bβ,8,10aβ-trimethyl-1-phenanthrenol (17): To a solution of **16** (6.0 g) in MeOH (180 ml) was added $NaBH_4$ (1.2 g) in portions with stirring in ice bath. After stirring at room temperature for 1 h, to the reaction mixture was added acetic acid (10 ml) and then 2 mol dm^{-3} hydrochloric acid (60 ml). After stirring for 1 h at room temperature, the reaction mixture was cooled in ice bath and was added 10% aqueous NaOH (120 ml). The reaction mixture was concentrated to ca. 150 ml with rotary evaporator and extracted with ether (100 ml×3). The combined ether extracts were washed with brine (100 ml×1) and dried over $MgSO_4$. Evaporation of the solvent afforded the alcohol **17** (5.88 g): IR (Nujol) 3400 and 1642 cm^{-1}; UV (MeOH) 239 nm (ε 10510) and 232 nm (ε 9716); ^1H NMR δ= 1.17 (3H, s), 1.20 (3H, s), 1.78 (3H, m, 4-CH_3), 3.50 (1H, dd, J=7 and 9 Hz, 14-CH), and 5.31—5.71 (3H, m); MS (70 eV) m/z (rel intensity) 244 (M^+, 89), 229 (69), 226 (26), and 211 (100); Found: m/z 244.1824. Calcd for $C_{17}H_{24}O$: M, 244.1825.

3,4b,5,6,10,10a-Hexahydro-4bβ,8,10aβ-trimethyl-1(2*H*)-phenanthrenone (18): To a solution of the alcohol **17** in CH_2Cl_2 (175 ml) was added pyridinium chlorochromate (13.0 g) and the mixture was stirred at room temperature for 1 h. The reaction mixture was decanted and the residue was washed with ether. The combined solution was passed through a florisil column and the solvent was evaporated to give a residue, which was chromatographed on a silica-gel column (50 g, eluent: benzene) to give the ketone **18** (3.4 g): IR (Nujol) 1720 cm^{-1}; UV (MeOH) 238 nm (ε 18660) and 232 nm (ε 17270); ^1H NMR δ=1.21 (3H, s), 1.43 (3H, s), 1.78 (3H, m, 4-CH_3), and 5.32—5.88 (3H, m); MS (70 eV) m/z (rel intensity) 242 (M^+, 64), 227 (20), 209 (77), and 184 (100); Found: m/z 242.1671. Calcd for $C_{17}H_{22}O$: M, 242.1671.

3,4b,5,6,10,10a-Hexahydro-4bβ,8,10aβ-trimethyl-1(2*H*)-phenanthrenone Tosylhydrazone (19): To a solution of the ketone **18** (3.4 g) in hot 95% EtOH (10 ml) was added a solution of tosylhydrazine (3.0 g) in hot 95% EtOH (6 ml) and the mixture was stirred for 10 min and then stood at room temperature for 12 h. Washing with 50% aqueous EtOH and crystallization from ether afforded the tosylhydrazone **19** as colorless crystals: mp 173—175 °C; IR (Nujol) 3215, 1602, and 1176 cm^{-1}; ^1H NMR δ=1.15 (3H, s), 1.30 (3H, s), 1.75 (3H, m, 4-CH_3), 2.37 (3H, s), 5.37—5.85 (3H, m), 7.28 (2H, d, J=8 Hz), and 7.86 (2H, d, J=8 Hz); MS (70 eV) m/z (rel intensity) 410 (M^+, 15), 395 (13), and 225 (100); Found: m/z 410.2071. Calcd for $C_{24}H_{30}N_2O_2S$: M, 410.2029.

1,4b,5,6,10,10a-Hexahydro-4bβ,8,10aβ-trimethyl-2-methylthiophenanthrene (20): To a solution of the tosylhydrazone **19** (869 mg) in THF (10 ml) and TMEDA (10 ml) was added 2 equiv of butyllithium in hexane dropwise with stirring at −78 °C and the mixture was stirred for 30 min at the temperature. After addition of dimethyl disulfide (0.22 ml, 1.1 equiv) dropwise at −78 °C, the reaction mixture was stirred at −30 °C for 1 h. *n*-Butyllithium (1.3 equiv) in hexane was added into the reaction mixture with stirring at −50 °C. The mixture was warmed to room temperature over 1 h and stirred at the temperature for 6 h. The reaction mixture was poured into saturated aqueous NH_4Cl (50 ml) and extracted with ether (50 ml×3). The combined extracts were washed with brine (20 ml×2) and dried over Na_2SO_4. The residue obtained by evaporation of the solvent was chromatographed on a silica-gel column (eluent: hexane) to give the enol thioether **20** (pale yellow viscous oil): IR (oil) 1620 and 1565 cm^{-1}; UV (MeOH) 302 nm (ε 8440), 238 nm (ε 16990), and 232 nm (ε 16780); ^1H NMR δ=1.13 (3H, s), 1.19 (3H, s), 1.77 (3H, m, 4-CH_3), 2.28 (3H, s, S-CH_3), 5.32—5.70 (3H, m), and 5.78 (1H, a part of ABq, J=6 Hz); MS (70 eV) m/z (rel intensity) 272 (M^+, 100) and 257 (74); Found: m/z 272.1594. Calcd for $C_{18}H_{24}S$: M, 272.1597.

4a,4b,5,6,10,10a-Hexahydro-4bβ,8,10aβ-trimethyl-2(1*H*)-phenanthrenone (21): To a solution of the enol thioether **20** (690 mg) in THF (6 ml) was added $TiCl_4$ (600 mg) in THF (20 ml) and the mixture was stirred at room temperature for 1 h. To the reaction mixture was added 80% aqueous acetic acid, stirred at room temperature for 4 d, poured into brine (20 ml), and then extracted with ether (40 ml×3). The combined ether layer was washed with brine (20 ml), saturated aqueous $NaHCO_3$ (50 ml×2), and then brine (20 ml) and dried over Na_2SO_4. The residue obtained by evaporation of the solvent was chromatographed on a silica-gel column (eluent: benzene) to give the α,β-unsaturated ketone **21** (410 mg) as colorless prisms (ether-hexane): mp 98—99.5 °C; IR (Nujol) 1680 cm^{-1}; UV (MeOH) 232 nm (ε 19000); ^1H NMR δ=0.99 (3H, s), 1.07 (3H, s), 1.80 (3H, m, 4-CH_3), 5.35—5.70 (2H, m), 6.11 (1H, dd, J=10 and 3.5 Hz, 12-CH), and 6.92 (1H, dd, J=10 and 2 Hz, 11-CH); MS (70 eV) m/z (rel intensity) 242 (M^+, 100) and 227 (50); Found: m/z 242.1665. Calcd for $C_{17}H_{22}O$: M, 242.1670.

1,4b,5,6,10,10a-Hexahydro-10aβ-methoxycarbonyl-4bβ,8-dimethyl-3(2*H*)-phenanthrenone 3-(Ethylene Acetal) (22): A mixture of enone **15** (2.162 g, 7.56 mmol), ethylene glycol (11.55 ml), and *p*-toluenesulfonic acid monohydrate (222 mg) in benzene (85 ml) was refluxed under Dean-Stark water separator for 9.5 h. The mixture was cooled to room temperature and the benzene layer was separated, and passed through an alumina column (eluent: benzene) to give monoacetal **22** (2.3661 g, 95%) as pale yellow crystals. An analytical sample was prepared by recrystallization from hexane to give colorless prisms: mp 121—122 °C; IR (Nujol) 1787 cm^{-1}; ^1H NMR δ=0.96 (3H, s, 10-CH_3), 1.78 (3H, brs, 4-CH_3), 3.66 (3H, s, CO_2CH_3), 3.96 (4H, m, acetal), 5.43 (1H, m), 5.57 (1H, dd, J=3 and 7 Hz), and 5.66 (1H, s, 11-CH); MS (70 eV) m/z (rel intensity) 330 (M^+, 35) and 271 (100); Found: C, 72.46; H, 7.74%. Calcd for $C_{20}H_{26}O_4$: C, 72.70; H, 7.93%.

Conversion of 15 into 12: A solution of the acetal **22** (2.88 g) in DME (5 ml) was added into a refluxing solution of LAH (230 mg) in ether (5 ml) dropwise. After refluxing for 10 min ethyl acetate (1 ml) was added into the reaction mixture. Ether and water were added into the mixture and then the mixture was filtered through a celite column. The filtrate was extracted with ether and the extract was dried over

Na_2SO_4. The residue obtained by evaporation of the solvent was purified by florisil column chromatography (eluent: benzene-acetone) to give 2.1 g of the alcohol **23**: ^{1}H NMR δ=1.10 (3H, s, 10-CH_3), 1.77 (3H, brs, 4-CH_3), 3.62 (2H, s, 20-CH_2), 3.92 (4H, s, acetal), 5.26—5.60 (2H, m), and 5.62 (1H, s, 11-CH).

The alcohol **23** (122 mg) in CH_2Cl_2 (0.5 ml) was added into the Collins' reagent prepared from CrO_3 (244 mg) and pyridine (0.39 ml) in CH_2Cl_2 (5 ml). After stirring for 15 min at room temperature the reaction mixture was decanted and the residue was washed with ether. The CH_2Cl_2 solution was combined with ether washes and the combined solution was washed with 5% aqueous NaOH (15 ml×3) and then water (10 ml×4) and dried over Na_2SO_4. Removal of the solvent gave a residue (84.5 mg) which was chromatographed on florisil (eluent: benzene-acetone) to give the aldehyde **24** (57.8 mg): IR (Nujol) 1718 cm^{-1}.

A mixture of **24** (50 mg), diethylene glycol (2 ml), 80% hydrazine hydrate (0.4 ml), and KOH (0.1 g) was heated under reflux at 160—180 °C for 3 h. After heating at 85—90 °C for 1 h under reduced pressure using rotary evaporator, the residual mixture was heated at 170 °C for 6 h. Water was added into cooled reaction mixture and the mixture was extracted with ether. The ether layer was washed three times with dil HCl and dried over Na_2SO_4. The residue (32 mg) given by evaporation of the solvent was chromatographed on preparative TLC to afford the major product which was identified with **12**.

Conversion of 12 into 21: A mixture of **12** (0.94 g) and tosylhydrazine (1.0 g) in EtOH (4.5 ml) was stirred for 10 min and set aside overnight. Evaporation of the solvent, silica-gel column chromatography of the residue and crystallization from ether gave tosylhydrazone **25** as colorless crystals (0.75 g): mp 160—165 °C; IR (Nujol) 3210 and 1170 cm^{-1}; ^{1}H NMR δ=1.14 (3H, s), 1.23 (3H, s), 1.79 (3H, brs, 4-CH_3), 2.43 (3H, s, -$SO_2C_6H_4$-$\underline{CH_3}$), 5.50 (1H, m), 5.60 (1H, m), 6.08 (1H, s, 11-CH), 7.29 (2H, d), and 7.88 (2H, d).

To a solution of the tosylhydrazone **25** (250 mg, 0.61 mmol) in a mixed solvent of THF (2.1 ml) and *N,N,N',N'*-tetramethylethylenediamine (TMEDA) (2.1 ml) was added 2.5 equiv of butyllithium in hexane and then dimethyl disulfide (0.1 ml, 1.5 equiv) with stirring at −78 °C. The mixture was stirred at −30 °C for 30 min. Hexane solution of butyllithium (1.7 equiv) was added to the reaction mixture at −78 °C to give deep red solution and the solution was warmed to room temperature over one hour and stirred at the temperature overnight. To the reaction mixture was added 15% aqueous ammonium chloride (50 ml) and extracted with hexane twice and with ether twice. The combined extracts were dried over $MgSO_4$ and the residue given on evaporation of the solvent was chromatographed on a silica-gel column (eluent: hexane-ether) to give a enol thioether (30 mg) whose spectra were identical with those of the enol thioether **20** derived from **16**.

To the enol thioether (30 mg) in THF (0.4 ml) was added a solution of $TiCl_4$ (30 mg) in THF (1 ml) and the mixture was stirred at room temperature for 90 min. Acetic acid (0.4 ml) and water (0.14 ml) were added into the reaction mixture and the mixture was stirred at room temperature for 4 d. The reaction mixture was cooled in ice bath and added NaOH (0.3 g) in water (2 ml). Extraction with ether, drying with Na_2SO_4, evaporation of the solvent and purification of the residue with preparative TLC gave an α,β-unsaturated ketone (13 mg), whose spectra were identical with those of the conjugated ketone **21** derived from **16**.

1,4b,5,6,10,10a-Hexahydro-10aβ-hydroxymethyl-4bβ,8-dimethyl-3(2*H*)-phenanthrenone (26): To a solution of LAH (230 mg, 6.06 mmol) in ether (5 ml) was added **22** (2.88 g, 8.73 mmol) in DME (5 ml) dropwise. The mixture was heated at reflux for 10 min and then AcOEt (1 ml) was added. Ether (50 ml) and water (20 ml) were added into the reaction mixture and the mixture was filtered through a column of celite. Aqueous 1 mol dm^{-3} HCl (30 ml) was added into the filtrate and stirred vigorously at room temperature for 30 min. The aqueous layer was extracted with ether, and combined organic layer was washed with brine and dried (Na_2SO_4). Removal of the solvent afforded keto alcohol **26** (2.25 g, 100%): IR (Nujol) 1655 and 1600 cm^{-1}; UV (EtOH) 237.5 nm (ε 24000); ^{1}H NMR δ=1.14 (3H, s, 10-CH_3), 1.80 (3H, brs, 4-CH_3), 3.74 (2H, ABq, J=13.5 Hz, $\Delta\nu_{AB}$=8.5 Hz, 20-CH_2), 5.48 (1H, m), 5.63 (1H, t, J=4 Hz), and 6.12 (1H, s, 11-CH); MS (70 eV) m/z (rel intensity) 258 (M^+, 69) and 227 (100); Found: m/z 258.1612. Calcd for $C_{17}H_{22}O_2$: M, 258.1620.

1,4b,5,6,10,10a-Hexahydro-10aβ-acetoxymethyl-4bβ,8-dimethyl-3(2*H*)-phenanthrenone (27): A solution of 209 mg (0.81 mmol) of alcohol **26** in 1 ml of pyridine and 0.5 ml of acetic anhydride was stirred at room temperature overnight. The reaction mixture was quenched by the addition of methanol. The solvent was evaporated in vacuo and the residue was chromatographed on a silica-gel column (10 g in hexane, eluent: ethyl acetate-hexane (1 : 2)) to afford 184 mg (76%) of acetate **27** as a colorless oil. An analytical sample was obtained by crystallization from ether-hexane as colorless prisms: mp 81—82.5 °C; IR (oil) 1740 and 1670 cm^{-1}; ^{1}H NMR δ=1.18 (3H, s, 10-CH_3), 1.82 (3H, brs, 4-CH_3), 2.10 (3H, s, $OCOCH_3$), 4.23 (2H, s, 20-CH_2), 5.50 (1H, m), 5.62 (1H, m), and 6.15 (1H, s, 11-CH); MS (70 eV) m/z (rel intensity) 300 (M^+, 23), 240 (43), and 227 (100); Found: C, 75.87; H, 7.93%. Calcd for $C_{19}H_{24}O_3$: C, 75.97; H, 8.05%.

1,4b,5,6,7,8,10,10a-Octahydro-10aβ-acetoxmethyl-7,8-epoxy-4bβ,8-dimethyl-3(2*H*)-phenanthrenone (28): To a cold (−15 °C) solution of **27** (208 mg, 0.69 mmol) in CH_2Cl_2 (4 ml) was added 80% MCPBA (165 mg, 0.76 mmol) in portions under drying tube. The mixture was stirred at −15 °C for 30 min and then at room temperature for 1 h. The reaction was quenched by the addition of saturated aqueous $NaHCO_3$ (2 ml) containing KI (ca. 20 mg). The mixture was taken up in ether, washed with aqueous Na_2SO_3, saturated aqueous $NaHCO_3$, and brine. Drying ($MgSO_4$) and evaporation of the solvent gave a mixture of α- and β-epoxide **28** (220 mg) in a 3 : 1 ratio (the ratio being determined by the ^{1}H NMR), which were separated by silica-gel column chromatography (5g in hexane, 20% to 50% ether-hexane) to afford α-epoxide **28α** (80 mg, more polar) and β-epoxide **28β** (48 mg, less polar) as colorless oil, respectively. **28α**: IR (oil) 1735 and 1665 cm^{-1}; ^{1}H NMR δ=1.13 (3H, s, 10-CH_3), 1.50 (3H, s, 4-CH_3), 2.28 (3H, s, $OCOCH_3$), 3.10 (1H, brs, $W_{1/2}$=4.5 Hz, 3-CH), 4.37 (2H, s, 20-CH_2), 6.05 (1H, m, 6-CH), and 6.32 (1H, s, 11-CH); MS (70 eV) m/z (rel intensity) 316 (M^+, 100), 256 (26), and 91 (86); Found: m/z 316.1705. Calcd for $C_{19}H_{24}O_4$: M, 316.1664. **28β**: IR (oil) 1740 and 1665 cm^{-1}; ^{1}H NMR δ=1.26 (3H, s, 10-CH_3), 1.52 (3H, m, 4-CH_3), 2.10 (3H, s, $OCOCH_3$), 3.60 (1H, d, J=3.6 Hz, 3-CH), 4.10 (2H, ABq, J=11 Hz, $\Delta\nu_{AB}$=7 Hz, 20-CH_2), 5.80 (1H, m, 6-CH), and 5.90 (1H, s, 11-CH); MS (70 eV) m/z (rel intensity) 316 (M^+, 56) and 91 (100); Found: m/z 316.1663. Calcd for $C_{19}H_{24}O_4$: M, 316.1664.

1,3,4,4a,7,8,8a,9-Octahydro-8aβ-acetoxymethyl-1α,4aβ-dimethyl-2,6-phenanthrenedione 2-(Ethylene Acetal) (29): To a solution of α-epoxide **28** (80 mg, 0.25 mmol) and ethylene glycol (0.5 ml) in benzene (2 ml) was added 2 drops of boron trifluoride etherate. The mixture was stirred at room temperature overnight and poured into saturated aqueous $NaHCO_3$ (5 ml), extracted with ether (10 ml), washed with saturated aqueous $NaHCO_3$ (5 ml) and brine (5 ml). The aqueous layer was reextracted twice with ether and washed as above. The combined ether layers were dried ($MgSO_4$) and concentrated in vacuo to afford 85.7 mg (94%) of **29** pure enough for further use: IR (oil) 1745 and 1675 cm^{-1}; ^1H NMR δ=1.00 (3H, d, J=6.6 Hz, 4-CH_3), 1.28 (3H, s, 10-CH_3), 2.06 (3H, s, $OCOCH_3$), 3.90 (4H, m, acetal), 4.34 (2H, brs, 20-CH_2), 5.40 (1H, m, 6-CH), and 6.34 (1H, s, 11-CH); MS (70 eV) m/z (rel intensity) 360 (M^+, 0.7) and 99 (100); Found: m/z 360.1931. Calcd for $C_{21}H_{28}O_5$: M, 360.1936.

1,3,4,4a,7,8,8a,9-Octahydro-8aβ-methoxycarbonyl-1α,4aβ-dimethyl-2,6-phenanthrenedione 2,6-Bis(ethylene acetal) (33): To a cold solution (−10 °C) of acetal **22** (135 mg, 0.409 mmol) in 1 ml of CH_2Cl_2 was added 97.1 mg (0.45 mmol) of 80% MCPBA in 1 ml of CH_2Cl_2 under drying tube. After being stirred at the same temperature for 30 min, the mixture was poured into saturated aqueous $NaHCO_3$ containing KI and extracted with ether. The organic layer was washed with saturated aqueous $NaHCO_3$ containing a small amount of sodium hydrogensulfide and then with brine, dried (Na_2SO_4) and concentrated in vacuo to afford a mixture of α-epoxide and β-epoxide (**30α** and **30β**) in a 5 : 1 ratio (the ratio being determined by the ^1H NMR) as colorless solids (150.9 mg), which were used directly in the next step. For analytical purposes, the pure α-epoxide **30α** was separated by crystallization from ether-hexane: mp 116.2—118.0 °C; IR (Nujol) 1620, 1246, 1102, 1020, 1010, and 922 cm^{-1}; ^1H NMR δ=0.98 (3H, s, 4-CH_3), 1.41 (3H, s, 10-CH_3), 1.95 (1H, dd, J=3 and 18 Hz, 7-CH), 2.99 (1H, dd, J=6 and 18 Hz, 7-CH), 3.04 (1H, brs, 3-CH), 3.66 (3H, s, CO_2CH_3), 4.00 (4H, m, acetal), 5.63 (1H, s, 11-CH), and 6.04 (1H, dd, J=3 and 6 Hz); MS (70 eV) m/z (rel intensity) 346 (M^+, 58), 287 (100), 269 (28), 243 (32), and 231 (16).

To a solution of the above mixture of epoxides **30** (150.9 mg) in benzene (8 ml) was added six drops of boron trifluoride etherate with vigorous stirring. After being stirred at room temperature for 15 min, the reaction was quenched with saturated aqueous $NaHCO_3$. The benzene layer was separated and washed with saturated aqueous $NaHCO_3$ and then brine. The combined aqueous layers were extracted with ether and the ether solution was washed with saturated aqueous $NaHCO_3$ and then brine. The combined organic extracts were dried (Na_2SO_4) and concentrated in vacuo to give a pale yellow solid which contained monoacetal **31** as a major component along with a small amount of diketone **32**.

A mixture of the above crude residue, ethylene glycol (1.5 ml), and a catalytic amount of p-toluenesulfonic acid monohydrate in benzene (15 ml) was refluxed under Dean-Stark water separator for 4.5 h. To the cooled mixture was added saturated aqueous $NaHCO_3$ and the aqueous layer was extracted with ether. Combined organic layer was washed with brine, dried (Na_2SO_4) and concentrated in vacuo. The residue was chromatographed on a silica-gel column (5 g in benzene, eluent: 10% to 30% ether-benzene) to afford diacetal **33** (94.8 mg, 64% overall from **22** in 3 steps) as a colorless oil: IR (KBr) 1736 and 1652 cm^{-1}; ^1H NMR δ=0.98 (3H, d, J=7 Hz, 4-CH_3), 1.20 (3H, s, 10-CH_3), 2.6 (1H, m, 4-CH), 2.82 (1H, dd, J=6 and 18 Hz, 7-CH), 3.63 (3H, s, CO_2CH_3), 3.9 (8H, m, acetal), 5.46 (1H, ddd, J=6, 1.5, and 1.5 Hz, 6-CH), and 5.63 (1H, s, 11-CH); MS (70 eV) m/z (rel intensity) 390 (M^+, 2), 346 (2.4), 331 (1), 302 (3.2), and 99 (100); Found: m/z 390.2096. Calcd for $C_{22}H_{30}O_6$: M, 390.2041.

3,4,4a,7,8,8a-Hexahydro-8aβ-methoxycarbonyl-1α,4aβ-dimethyl-2,6,9(1*H*)-phenanthrenetrione 2-(Ethylene Acetal) (35): To a solution of diacetal **33** (422 mg, 1.08 mmol) in CH_2Cl_2 (8 ml) was added a solution of $CrO_3 \cdot 2Pyr$ complex in CH_2Cl_2 (0.4 mol dm^{-3}, 40 ml) with vigorous stirring. The mixture was stirred at room temperature for 40 h and then quenched with $NaHSO_3$. The supernatant was filtered through a short column of florisil and the tarry solid in the flask was rinsed thoroughly with ether and the washings were filtered through a florisil column. The combined organic solutions were evaporated to give a residue, which was chromatographed on a silica-gel column (20 g in benzene, eluent: 10% to 40% ether-benzene) to afford 102.1 mg (27%) of **35** as a pale yellow oil and 170.5 mg (45%) of **31**. **35**: IR (oil) 1732, 1680, and 1668 cm^{-1}; ^1H NMR δ=1.12 (3H, d, J=7 Hz, 4-CH_3), 1.43 (3H, s, 10-CH_3), 3.73 (3H, s, CO_2CH_3), 3.95 (4H, m, acetal), 6.07 (1H, brs, 6-CH), and 6.23 (1H, s, 11-CH); MS (70 eV) m/z (rel intensity) 360 (M^+, 1.4), 301 (0.8), 99 (94), and 57 (100); Found: m/z 360.1567. Calcd for $C_{20}H_{24}O_6$: M, 360.1572.

1,3,4,4a,7,8,8a,9-Octahydro-8aβ-hydroxymethyl-1α,4aβ-dimethyl-2,6-phenanthrenedione 2-(Ethylene Acetal) (37): To a solution of diacetal **33** (10.1 g, 25.6 mmol) in THF (200 ml) was added LAH (1 g, 26.3 mmol). The mixture was stirred at room temperature for 1 h. To the reaction mixture was added AcOEt (5 ml) and then saturated aqueous NH_4Cl (20 ml). The mixture was filtered and the solid was washed with THF. The filtrate and washings were combined and washed with brine and then dried (Na_2SO_4). Removal of the solvent afforded a residue which was dissolved in acetone (50 ml). Pyridinium p-toluenesulfonate (PPTS, 0.1 g) was added to the solution and stirred at room temperature for 1 h. To the reaction mixture were added $NaHCO_3$ (1 g) and benzene (100 ml). The mixture was condensed to ca. 70 ml under reduced pressure. Ether (100 ml) was added to the condensed mixture and the organic layer was washed with half-saturated aqueous NaCl (100 ml×2) and dried (Na_2SO_4). Evaporation of the solvent gave a residue which was purified with silica-gel chromatography (100 g, eluent: 2% acetone in benzene) to give **37**. An analytical sample of **37** was obtained by recrystallization from acetone-hexane as colorless prisms: mp 184—184.5 °C; IR (Nujol) 3420 and 1650 cm^{-1}; ^1H NMR δ=1.02 (3H, d, J=7 Hz, 4-CH_3), 1.30 (3H, s, 10-CH_3), 3.68 (2H, brs, 20-CH_2), 3.90 (4H, m, acetal), 5.45 (1H, m, 6-CH), and 6.13 (1H, s, 11-CH); MS (70 eV) m/z (rel intensity) 318 (M^+, 4) and 99 (100); Found: m/z 318.1982. Calcd for $C_{23}H_{26}O_4$: M, 318.1982.

1,3,4,4a,7,8,8a,9-Octahydro-1α,4aβ-dimethyl-8aβ-[(tetrahydro-2-pyranyloxy)methyl]-2,6-phenanthrenedione 2-(Ethylene Acetal) (38): To a solution of **37** (706.9 mg, 2.22 mmol) in CH_2Cl_2 (30 ml) was added 55 mg of PPTS and 0.5 ml of dihydropyran. The mixture was stirred at room temperature for 5 h. The mixture was diluted with ether, washed with brine, dried over $MgSO_4$, and concentrated in vacuo. The residue was chromatographed on a silica-gel column (15 g in benzene, eluent: ether-benzene) to afford 904.5 mg (100%) of **38** as a pale yellow oil: IR (oil) 1672 cm^{-1}; ^1H NMR δ=1.02

(3H, d, J=7 Hz, 4-CH_3), 1.26 and 1.36 (1.5H each, s, 10-CH_3), 3.2—4.3 (8H, m), 4.53 (1H, m), 5.45 (1H, ddd, J=6, 2, and 2 Hz, 6-CH), and 6.13 (1H, s, 11-CH); MS (70 eV) m/z (rel intensity) 402 (M^+, 16), 318 (12), 99 (over), and 85 (100); Found: m/z 402.2423. Calcd for $C_{24}H_{14}O_5$: M, 402.2406.

1,3,4,4a,4b,5,7,8,8a,9-Decahydro-1α,4aβ-dimethyl-8aβ-[(tetrahydro-2-pyranyloxy)methyl]-2,6-phenanthrenedione 2-(Ethylene Acetal) (39): (a) Hydrogenation: A mixture of **38** (408 mg, 1.02 mmol) and palladium on carbon (10%, 45 mg) in 20 ml of ethanol was stirred at room temperature under an atmosphere of hydrogen for 45 h. The catalyst was removed by filtration and washed with ethanol, and the filtrate was evaporated. The residue was chromatographed on a silica-gel column (5 g in benzene, eluent: ether-benzene) to afford 195 mg (48%) of **39** as colorless oil: IR (oil) 1706 cm^{-1}; ^1H NMR δ=0.98 (3H, d, J=7 Hz, 4-CH_3), 1.04 (3H, s, 10-CH_3), 4.54 (1H, m), and 5.37 (1H, ddd, J=6, 2, and 2 Hz, 6-CH); MS (70 eV) m/z (rel intensity) 404 (M^+, 2.3), 320 (2.3), and 99 (100); Found: m/z 404.2569. Calcd for $C_{24}H_{36}O_5$: M, 404.2536. (b) Birch reduction: Lithium metal (150 mg, 21 mmol) was dissolved in 40 ml of liquid ammonia. To this solution was added **38** (905 mg, 2.25 mmol) in THF (10 ml). The mixture was stirred at −33 °C for 30 min and then quenched by the addition of NH_4Cl (5 g). The ammonia was allowed to evaporate to afford a residue, which was extracted with CH_2Cl_2 and washed with brine. Drying ($MgSO_4$) and evaporation of the solvent gave a residue, which was chromatographed on a silica-gel column to afford 705 mg (77.5%) of **39**. (c) Reduction with NaHTe: A mixture of tellurium powder (3.49 g, 27 mmol) and $NaBH_4$ (2.44 g, 64 mmol) in EtOH (80 ml, deoxygenated with argon) was heated to reflux under argon. After refluxing for 15 min, the resulting dark purple solution was cooled to −20 °C and a deoxygenated solution of acetic acid (1.4 ml) in EtOH (5.6 ml) was added to the mixture. After 5 min, to the above mixture was added **38** (4.31 g, 10 mmol) in EtOH (55 ml) and the resulting solution was stirred at 70 °C for 4.5 h followed by reflux for 3.5 h. The cooled mixture was filtered through a column of Celite with CH_2Cl_2. The solvent was evaporated to give a residue, which was extracted with ether, washed with brine, and dried ($MgSO_4$). Removal of the solvent gave 4.29 g (99%) of crude **39** pure enough for further use.

1,3,4,4a,7,8,8a,9-Octahydro-8aβ-[(1-ethoxyethoxy)methyl]-1α,4aβ-dimethyl-2,6-phenanthrenedione 2-(Ethylene Acetal) (40): A solution of **37** (132 mg, 0.41 mmol) and ethyl vinyl ether (0.3 ml, 3.14 mmol) in CH_2Cl_2 (5 ml) containing PPTS (13 mg) was stirred at room temperature for 1 h. The solution was diluted with CH_2Cl_2 (30 ml) and washed with brine (10 ml). The aqueous layer was extracted with CH_2Cl_2 (20 ml) and the combined organic extracts were dried ($MgSO_4$). Removal of the solvent in vacuo gave pure **40** (173 mg, 100%) as a pale yellow oil: IR (oil) 1670 cm^{-1}; ^1H NMR δ=1.02 (3H, d, J=7 Hz, 4-CH_3), 1.08—1.40 (9H, 3×CH_3), 3.2—3.8 (4H, m), 3.8—4.1 (4H, m, acetal), 4.65 (1H, m), 5.5 (1H, m, 6-CH), and 6.12 (1H, s, 11-CH); MS (70 eV) m/z (rel intensity) 390 (M^+, 5.7), 345 (3.6), 318 (2.7), 288 (6), 99 (over), and 73 (100); Found: m/z 390.2395. Calcd for $C_{23}H_{34}O_5$: M, 390.2404.

1,3,4,4a,4b,5,7,8,8a,9-Decahydro-8aβ-[(1-ethoxyethoxy)-methyl]-1α,4aβ-dimethyl-2,6-phenanthrenedione 2-(Ethylene Acetal) (41): A mixture of tellurium powder (16.58 g, 0.13 mol) and sodium borohydride (10.78 g, 0.29 mol) in EtOH (200 ml, deoxygenated with argon) was cautiously heated to reflux under argon. After refluxing for several min, the resulting dark brown solution was cooled to −20 °C and acetic acid (6.7 ml) in EtOH (28.3 ml) was added. The mixture was warmed to room temperature. To the mixture was added **40** (18.81 g, 0.048 mol) in EtOH (220 ml) and the reaction mixture was heated to reflux for 17 h. The cooled mixture was filtered through a pad of Celite using CH_2Cl_2, AcOEt, and acetone. The solvent was evaporated to give a residue, which was partitioned between CH_2Cl_2 (500 ml) and brine (300 ml). The aqueous layer was extracted with CH_2Cl_2 (200 ml×2). The combined organic extracts were dried ($MgSO_4$), filtered and concentrated in vacuo. The residue was chromatographed on a silica-gel column (200 g in benzene, eluent: 10% to 40% ether-benzene) to give 18.39 g (98%) of **41** as a pale yellow oil: IR (oil) 1705 cm^{-1}; ^1H NMR δ=0.9—1.4 (12H, 4×CH_3), 3.92 (4H, m, acetal), 4.67 (1H, m), and 5.39 (1H, m, 6-CH); MS (70 eV) m/z (rel intensity) 392 (M^+, 1.2), 346 (12), 320 (8), 302 (8), 99 (over), and 73 (100).

1,3,4,4a,4b,5,7,8,8a,9-Decahydro-8aβ-[(1-ethoxyethoxy)-methyl]-7-methoxycarbonyl-1α,4aβ-dimethyl-2,6-phenanthrenedione 2-(Ethylene Acetal) (42): To a suspension of sodium hydride (5.03 g, 12.5 mmol, 60% oil dispersion), potassium hydride (1 g, 8.7 mmol, 35% oil dispersion), and dimethyl carbonate (10 ml) in DME (150 ml) was added dropwise a solution of ketone **41** (18.39 g) in DME (270 ml) over 15 min. The mixture was refluxed for 2 h and then cooled to room temperature, poured into saturated aqueous NH_4Cl (200 ml), extracted with ether (500 ml, 300 ml×3) and dried ($MgSO_4$). Removal of the solvent gave an oily residue, which was chromatographed on a silica-gel column (200 g in benzene, eluent: 5% to 10% ether-benzene) to afford keto ester **42** (17.61 g, 83%) as a pale yellow oil: IR (oil) 1745, 1710, 1660, and 1620 cm^{-1}, ^1H NMR δ=0.9—1.3 (12H, 4×CH_3), 3.74 (3H, s, CO_2CH_3), 3.8—4.0 (4H, m, acetal), 4.65 (1H, m), 5.37 (1H, m, 6-CH), and 12.05 (0.5H, s, enol-OH); MS (70 eV) m/z (rel intensity) 450 (M^+, 3), 404 (22), 377 (20), 360 (14), 99 (over), and 73 (100); Found: m/z 450.2612. Calcd for $C_{25}H_{38}O_7$: M, 450.2615.

1,3,4,4a,4b,5,8a,9-Octahydro-8aβ-[(1-ethoxyethoxy)-methyl]-7-methoxycarbonyl-1α,4aβ-dimethyl-2,6-phenanthrenedione 2-(Ethylene Acetal) (43): To a cold (0 °C) suspension of sodium hydride (1.95 g, 48.75 mmol, 60% oil dispersion) in THF was added a solution of keto ester **42** (10.87 g, 24.15 mmol) in THF (70 ml) over 15 min. The mixture was stirred at room temperature for 15 min and then cooled to 0 °C. A solution of benzeneselenenyl chloride (6.97 g, 35.3 mmol) in THF was added rapidly, and the reaction mixture was quenched with saturated aqueous $NaHCO_3$ (50 ml), extracted with ether (500 ml) and washed with brine. The aqueous layer was saturated with NaCl and extracted with ether (200 ml). The combined organic extracts were dried over $MgSO_4$, filtered and concentrated in vacuo. To the crude product in 120 ml of CH_2Cl_2 was added 30% hydrogen peroxide (10 ml, 88 mmol) in 10 ml of water over 5 min at 0 °C. After being stirred at 0 °C for 30 min, the reaction mixture was diluted with CH_2Cl_2 (400 ml) and washed with saturated aqueous $NaHCO_3$ (200 ml). The aqueous layer was extracted with CH_2Cl_2 (200 ml) and the combined organic extracts were dried ($MgSO_4$) and concentrated in vacuo. The residue was chromatographed on a silica-gel column (100 g in benzene, eluent: 5% to 50% ether-benzene) to afford **43** (7.37 g, 67%) as a pale yellow oil: IR (oil) 1740, 1710, 1680, and 1620 cm^{-1}; ^1H NMR δ=0.9—1.3 (12H, 4×CH_3), 3.82 (3H, s, CO_2CH_3), 3.83—4.03 (4H, m, acetal),

4.58 (1H, m), 5.36 (1H, m, 6-CH), and 7.35 and 7.37 (1H, each s, 14-CH); MS (70 eV) *m/z* (rel intensity) 448 (M^+, 0.4), 404 (0.5), 403 (0.8), 377 (0.4), 347 (2), 314 (0.8), and 99 (100); Found: *m/z* 448.2460. Calcd for $C_{25}H_{46}O_7$: M, 448.2459.

1,3,4,4a,4b,5,7,8,8a,9-Decahydro-8aβ-[(1-ethoxyethoxy)-methyl]-7-methoxycarbonyl-1α,4aβ-dimethyl-8α-vinyl-2,6-phenanthrenedione 2-(Ethylene Acetal) (46) and 3,4,4a,4b,5,6,8a,9-Octahydro-8aβ-[(1-ethoxyethoxy)methyl]-6-hydroxy-7-methoxycarbonyl-1α,4aβ-dimethyl-6-vinyl-2(1*H*)-phenanthrenone 2-(Ethylene Acetal) (47): To a solution of $(Bu_3P \cdot CuI)_4$ complex (2.03 g) in THF (30 ml) was added vinylmagnesium bromide (from magnesium (700 mg, 29 mmol) and vinyl bromide (3 ml, 42 mmol)) in THF (50 ml) at −45 °C dropwise over a period of 15 min. The resulting solution was stirred at −45 °C for 15 min, and then keto ester **43** (6.54 g, 14.6 mmol) in THF (70 ml) was added over a period of 15 min. The solution was stirred for 2 h, during which time the temperature of the bath came to −20 °C. Saturated aqueous NH_4Cl (50 ml) was added and the mixture was extracted with ether (400 ml) and washed with brine. The aqueous layer was extracted with ether (100 ml×3) and the combined organic layers were dried ($MgSO_4$). Evaporation of the solvent gave a residue which was chromatographed on a silica-gel column (100 g in benzene, eluent: 5% to 50% ether-benzene) to afford 1,4-adduct **46** (5.81 g, 80%) and 1,2-adduct **47** (0.87 g, 12%). **46**: IR (oil) 1650 and 1615 cm^{-1}; ^1H NMR δ=0.93—1.30 (12H, 4×CH_3), 3.71 (3H, s, CO_2CH_3), 3.8—4.1 (4H, m, acetal), 4.54 (1H, m), 4.8—5.1 (2H, m, 16-CH_2), 5.2—5.9 (2H, m, 6-CH and 15-CH), and 12.28 and 12.30 (1H, each s, enol-OH); MS (70 eV) *m/z* (rel intensity) 476 (M^+, 0.6), 430 (22), 403 (4), 371 (6), 99 (over), and 73 (100); Found: *m/z* 430.2361. Calcd for $C_{25}H_{34}O_6$: M−EtOH, 430.2356. **47**: IR (oil) 3500, 1740, 1700, and 1650 cm^{-1}; ^1H NMR δ=0.9—1.3 (12H, 4×CH_3), 3.77 (3H, s, CO_2CH_3), 3.92 (4H, m, acetal), 4.61 (1H, m), 4.89 (1H, d, *J*=17 Hz), 5.02 (1H, d, *J*=11 Hz), 5.35 (1H, m, 6-CH), 5.96 (1H, dd, *J*=17 and 11 Hz), and 7.06 (1H, s, 14-CH); MS (70 eV) *m/z* (rel intensity) 476 (M^+, 1), 450 (1.3), 430 (10), 404 (6), 386 (7), 356 (42), 99 (over), and 73 (100).

3,4,4a,4b,5,8,8a,9-Octahydro-8aβ-[(1-ethoxyethoxy)methyl]-7-methoxycarbonyl-1α,4aβ-dimethyl-8α-vinyl-2(1*H*)-phenanthrenone 2-(Ethylene Acetal) (51): To a solution of keto ester **46** (9.48 g, 19.9 mmol) in EtOH (300 ml) was added sodium borohydride (0.91 g, 24 mmol) at 0 °C. The mixture was stirred at 0 °C overnight. Acetone (50 ml) was added to the reaction mixture and the solvent was evaporated to afford a residue, which was partitioned between ether (500 ml) and saturated aqueous NH_4Cl (100 ml). The aqueous layer was extracted with $CHCl_3$ (200 ml×2) and the combined organic extracts were dried ($MgSO_4$). Evaporation of the solvent gave a mixture of stereoisomers of the alcohol **50** which was used for further reaction without any purification. To a stirred solution of the above mixture of alcohols and triethylamine (20 ml, 0.14 mol) in CH_2Cl_2 (200 ml) was added methanesulfonyl chloride (6.5 ml, 84 mmol) over a period of 15 min at 0 °C. After being stirred at 0 °C for 1 h and at room temperature for 3 h, the mixture was diluted with water (100 ml) and extracted with $CHCl_3$, and the extract was dried ($MgSO_4$). Removal of the solvent gave a crude mesylate, which was dissolved in benzene (400 ml) and DBU (40 ml). The mixture was heated to reflux for 5 h. The cooled mixture was diluted with saturated aqueous NH_4Cl and extracted with ether (300 ml×3). The combined organic extracts were dried ($MgSO_4$) and evaporated to afford a residue which was chromatographed on silica-gel column (300 g dry, eluent: 5% to 20% ether-benzene) to give conjugated ester **51** (6.71 g, 73% yield from **46**). Recrystallization from ether-hexane gave colorless prisms: mp 116—118 °C; IR (Nujol) 1720 and 1660 cm^{-1}; ^1H NMR δ=0.9—1.3 (12H, 4×CH_3), 3.69 (3H, s, CO_2CH_3), 3.91 (4H, m, acetal), 4.56 (1H, m), 4.86—5.20 (2H, m, 16-CH_2), 5.26—6.00 (2H, m, 6-CH and 15-CH), and 7.04 (1H, t, *J*=3.6 Hz, 12-CH); MS (70 eV) *m/z* (rel intensity) 460 (M^+, 0.6), 429 (1.1), 414 (21), 370 (40), 99 (over), and 73 (100); Found: *m/z* 460.2841. Calcd for $C_{27}H_{40}O_6$: M, 460.2826; Found: C, 70.67; H, 8.77%. Calcd for $C_{27}H_{40}O_6$: C, 70.41; H, 8.75%.

1,4,4a,4b,5,6,10,10a-Octahydro-10aβ-methoxycarbonyl-4bβ,8-dimethyl-3(2*H*)-phenanthrenone (53): Reactions were carried out under argon atmosphere and the solvent was deoxygenated with argon prior to use. A mixture of tellurium powder (20.58 g, 0.16 mol) and sodium borohydride (12.17 g, 0.32 mol) in EtOH (500 ml) was stirred at room temperature. After the finish of evolution of hydrogen, the mixture was heated to reflux for 30 min. The resulting solution was cooled to 0 °C and acetic acid (10 ml) was added to the mixture. To the above solution of NaHTe was added **15** (22.86 g, 80 mmol) in EtOH (600 ml) and the reaction mixture was stirred at room temperature for 48 h. As TLC monitoring showed that the conversion was not complete, additional NaHTe solution (2.5 g (20 mmol) of tellurium, 1.5 g (40 mmol) of $NaBH_4$, and 1.2 ml of acetic acid in 80 ml of EtOH) was added to the reaction mixture. The starting material was consumed on stirring at room temperature for 18 h. Then the reaction mixture was stirred for 3 h under open air. The resulting black precipitate was filtered and the filtrate was evaporated to give a residue, which was taken up in ether (300 ml) and water (300 ml). The aqueous layer was extracted with ether (200 ml×2), and the combined organic extracts were washed with brine (100 ml). After drying (Na_2SO_4), the solvent was evaporated to give 22.81 g (99%) of **53** as colorless crystals pure enough for further use. An analytical sample was obtained by recrystallization from ether-hexane as colorless needles: mp 107—109 °C; IR (KBr) 1720 and 1215 cm^{-1}; ^1H NMR δ=0.78 (3H, s, 10-CH_3), 1.80 (3H, brs, 4-CH_3), 3.72 (3H, s, CO_2CH_3), 5.43 (1H, m), and 5.61 (1H, m); MS (70 eV) *m/z* (rel intensity) 288 (M^+, 14), 228 (40), and 161 (100); Found: *m/z* 288.1713. Calcd for $C_{18}H_{24}O_3$: M, 288.1725; Found: C, 74.68; H, 8.33%. Calcd for $C_{18}H_{24}O_3$: C, 74.97; H, 8.39%.

1,4,4a,4b,5,6,10,10a-Octahydro-10aβ-methoxycarbonyl-4bβ,8-dimethyl-3(2*H*)-phenanthrenone 3-(Ethylene Acetal) (54): A solution of **53** (22.81 g, 79.2 mmol), *p*-toluenesulfonic acid (1.3 g), and ethylene glycol (80 ml) in benzene (500 ml) was refluxed under Dean-Stark water separator for 1.5 h. The mixture was cooled to room temperature, quenched by the addition of $NaHCO_3$ (3 g), and the ethylene glycol layer was separated and extracted with benzene (200 ml×2). The combined benzene layers were washed with saturated aqueous $NaHCO_3$ (100 ml) and brine (100 ml), dried (Na_2SO_4), and evaporated to give a residue (27.82 g), which afforded crystalline **54** on standing. The crystals were pure enough for further use. An analytical sample was obtained by recrystallization from ether-hexane as colorless needles: mp 101.5—102.5 °C; IR (KBr) 1730 cm^{-1}; ^1H NMR δ=0.72 (3H, s, 10-CH_3), 1.78 (3H, brs, 4-CH_3), 3.66 (3H, s, CO_2CH_3), 3.96 (4H, brs, acetal), 5.39 (1H, m), and 5.58 (1H, m); MS (70 eV)

m/z (rel intensity) 332 (M^+, 100), 272 (66), and 99 (53); Found: C, 72.22; H, 8.28%. Calcd for $C_{20}H_{28}O_4$: C, 72.26; H, 8.49%.

1,4,4a,4b,5,6,10,10a-Octahydro-10aβ-hydroxymethyl-4bβ,8-dimethyl-3(2*H*)-phenanthrenone (55): To a solution of **54** (27.82 g) in THF (300 ml) was added $LiAlH_4$ (3 g) in portions. After being stirred at room temperature for 1 h, to the reaction mixture was added ethyl acetate (15 ml) and then saturated aqueous NH_4Cl (25 ml). The mixture was stirred for 30 min. The resulting precipitate was filtered, dissolved in 4 mol dm^{-3} HCl (200 ml), and extracted with ether (100 ml×2). The above filtrate, the washings, and the ether extracts were combined and evaporated. The residue was dissolved in 600 ml of 10% aqueous acetone containing *p*-toluenesulfonic acid (3 g). The mixture was stirred at room temperature for 20 h and then $NaHCO_3$ (3 g) was added. Removal of the solvent gave a yellow residue, which was taken up in 200 ml of water, filtered and washed with water (100 ml). The filtrate and the washings were combined, extracted with ether (200 ml×2). The above solid was dissolved in ether (500 ml) and combined with the ether extract and dried (Na_2SO_4). Evaporation of the solvent gave a crude residue, which was crystallized from ether-hexane to afford **55** (15.31 g). Chromatography on a silica-gel column (eluent: 5% acetone in benzene) followed by crystallization afforded 3.45 g of **55** from the mother liquor. The yield of the crystals of **55** was 90% overall from **15**. An analytical sample was obtained by recrystallization from ether as colorless prisms: mp 124—126 °C; IR (KBr) 3450 and 1715 cm^{-1}; ^1H NMR δ=0.93 (3H, s, 10-CH_3), 1.82 (3H, brs, 4-CH_3), 3.93 (2H, brs, 20-CH_2), and 5.50 (2H, m, 3-CH and 6-CH); MS (70 eV) *m/z* (rel intensity) 260 (M^+, 100) and 242 (27); Found: C, 78.43; H, 9.02%. Calcd for $C_{17}H_{24}O_2$: C, 78.42; H, 9.29%.

1,4,4a,4b,5,6,10,10a-Octahydro-10aβ-[(1-ethoxyethoxy)-methyl]-4bβ,8-dimethyl-3(2*H*)-phenanthrenone (56): To a solution of **55** (13.21 g, 50.8 mmol) in CH_2Cl_2 (250 ml) was added PPTS (3.4 g) and ethyl vinyl ether (10 ml). After being stirred at room temperature for 1 h, the mixture was washed with saturated aqueous $NaHCO_3$ (50 ml), dried ($MgSO_4$), and concentrated in vacuo. The residue was chromatographed on a silica-gel column (eluent: 20% ether in hexane) to afford 15.83 g (94%) of **56** as a pale yellow oil: IR (oil) 1710 cm^{-1}; ^1H NMR δ=0.95 (3H, s, 10-CH_3), 1.1—1.4 (6H, 2×CH_3), 1.74 (3H, brs, 4-CH_3), 4.70 (1H, q, *J*=5 Hz), and 5.4—5.6 (2H, m, 3-CH and 6-CH); MS (70 eV) *m/z* (rel intensity) 332 (M^+, 1.6), 286 (76), 260 (26), and 73 (100); Found: *m/z* 286.1932. Calcd for $C_{19}H_{26}O_2$: M−EtOH, 286.1932.

1,4,4a,4b,5,6,10,10a-Octahydro-10aβ-[(1-ethoxyethoxy)-methyl]-2-methoxycarbonyl-4bβ,8-dimethyl-3(2*H*)-phenanthrenone (57): To a suspension of NaH (5.85 g, 0.146 mol, 60% oil dispersion), KH (550 mg, 4.8 mmol, 35% oil dispersion), and dimethyl carbonate (15 ml) in DME (300 ml) was added **56** (15.83 g, 47.7 mmol) in DME (180 ml). The mixture was refluxed for 1 h, cooled to 0 °C, and quenched with the addition of saturated aqueous NH_4Cl (100 ml). The organic layer was separated, washed with brine, and dried (Na_2SO_4). Removal of the solvent gave a residue, which was chromatographed on a silica-gel column (150 g in hexane, eluent: 10% ether in hexane) to afford 17.84 g (96%) of **57** as a pale yellow oil: IR (oil) 1750, 1720, 1665, and 1625 cm^{-1}; ^1H NMR δ=0.94 (3H, s, 10-CH_3), 1.05—1.40 (6H, 2×CH_3), 1.77 (3H, brs, 4-CH_3), 3.73 (3H, s, CO_2CH_3), 4.58 (1H, m), and 5.3—5.6 (2H, m, 3-CH and 6-CH); MS (70 eV) *m/z* (rel intensity) 344 (M^+−EtOH, 2.6), 300 (14.6), and 73 (100); Found: *m/z* 344.2005. Calcd for $C_{21}H_{28}O_4$: M−EtOH, 344.1987.

4a,4b,5,6,10,10a-Hexahydro-10aβ-[(1-ethoxyethoxy)methyl]-2-methoxycarbonyl-4bβ,8-dimethyl-3(4*H*)-phenanthrenone (58): To a cold (0 °C) suspension of NaH (3.96 g, 99 mmol, 60% oil dispersion) in THF (200 ml) was added **57** (17.84 g, 46 mmol) in THF (170 ml) dropwise with stirring. The mixture was stirred at room temperature for 1 h and cooled to 0 °C. A solution of benzeneselenenyl chloride (10.80 g, 56 mmol) in THF (70 ml) was added rapidly to the mixture. After 5 min, saturated aqueous NH_4Cl (100 ml) was added to the reaction mixture and the mixture was extracted with ether. The extract was washed with brine, dried ($MgSO_4$), and concentrated in vacuo. The residue was dissolved in CH_2Cl_2 (200 ml) and cooled to 0 °C. Hydrogen peroxide (30%, 5.5 ml) was added and the mixture was stirred at 0 °C for 1.5 h. The mixture was washed with brine (100 ml), dried over $MgSO_4$, and concentrated in vacuo to give a residue, which was chromatographed on a silica-gel column (150 g in hexane, eluent: 30% ether in hexane) to afford 12.98 g (73%) of **58** as a yellow oil. IR (oil) 1745, 1720, and 1685 cm^{-1}; ^1H NMR δ=0.9—1.3 (9H, 3×CH_3), 1.80 (3H, brs, 4-CH_3), 3.83 (3H, s, CO_2CH_3), 4.60 (1H, q, *J*=5.4 Hz), 5.50 (2H, m, 3-CH and 6-CH), and 7.38 and 7.39 (1H, each s, 14-CH); MS (70 eV) *m/z* (rel intensity) 388 (M^+, 2), 342 (9), 316 (13), 298 (14), 285 (28), 254 (23), 253 (22), and 73 (100); Found: *m/z* 388.2246. Calcd for $C_{23}H_{32}O_5$: M, 388.2249.

1,4,4a,4b,5,6,10,10a-Octahydro-10aβ-[(1-ethoxyethoxy)-methyl]-2-methoxycarbonyl-4bβ,8-dimethyl-1α-vinyl-3(2*H*)-phenanthrenone (59): To a cold (−45 °C) solution of $(Bu_3P \cdot CuI)_4$ complex (3.2 g) in THF (50 ml) under nitrogen was added vinylmagnesium bromide (from 190 mg (32.5 mmol) of magnesium and 4.3 ml (61 mmol) of vinyl bromide) in THF (50 ml) dropwise. The resulting mixture was stirred at −45 °C for 20 min, and **58** (10.48 g, 27.01 mmol) in dry THF (100 ml) was added over a period of 30 min. After being stirred at −45 °C for 1.5 h, the mixture was washed with saturated aqueous NH_4Cl (100 ml) and then with brine (100 ml). Drying ($MgSO_4$) followed by evaporation of the solvent gave a residue, which was chromatographed on a silica-gel column (150 g in hexane, eluent: 5% to 10% ether-hexane) to afford 9.78 g (87%) of **59** as a colorless oil: IR (oil) 1655 and 1620 cm^{-1}; ^1H NMR δ=0.9—1.3 (3×CH_3), 1.78 (3H, brs, 4-CH_3), 3.73 (3H, s, CO_2CH_3), 4.57 (1H, m), 4.85—5.15 (2H, m, 16-CH_2), 5.3—5.9 (3H, m, 3-CH, 6-CH, and 15-CH), and 12.30 and 12.32 (0.8H, each s, enol-OH); MS (70 eV) *m/z* (rel intensity) 370 (M^+−EtOH, 16), 326 (19), 294 (10), 171 (48), and 73 (100); Found: *m/z* 370.2145. Calcd for $C_{23}H_{30}O_4$: M−EtOH, 370.2140.

1,4,4a,4b,5,6,10,10a-Octahydro-10aβ-[(1-ethoxyethoxy)-methyl]-2-methoxycarbonyl-4bβ,8-dimethyl-1α-vinylphenanthrene (60): To a cold (0 °C) solution of **59** (6.55 g, 15.7 mmol) in EtOH (150 ml) was added $NaBH_4$ (0.71 g, 18.7 mmol) in portions. The mixture was stirred at 0 °C overnight. Acetone was added to the mixture and the solvent was evaporated to afford a residue, which was partitioned between CH_2Cl_2 (200 ml) and saturated aqueous NH_4Cl (50 ml). The aqueous layer was extracted with CH_2Cl_2 (200 ml×2) and the combined organic extracts were dried ($MgSO_4$). Removal of the solvent gave a residue, which was dissolved in CH_2Cl_2 (100 ml) containing triethylamine (10 ml, 71 mmol). To the above cold (0 °C) mixture was added

methanesulfonyl chloride (3 ml, 39 mmol) dropwise over 10 min. After being stirred at 0 °C for 3.5 h, additional triethylamine (5 ml, 36 mmol) and methanesulfonyl chloride (2 ml, 26 mmol) was added to the mixture. The mixture was diluted with ether (300 ml) and washed with saturated aqueous NH_4Cl and then with brine. The aqueous layer was extracted with ether (100 ml×2) and the combined organic extracts were dried over $MgSO_4$. Removal of the solvent gave a residue, which was dissolved in benzene (100 ml) and DBU (20 ml). The mixture was refluxed until the mesylate was consumed. The cooling mixture was diluted with ether (300 ml) and washed with saturated aqueous NH_4Cl (100 ml). The aqueous layer was extracted with ether (100 ml×2) and the combined organic extracts were washed with water (100 ml) and brine (100 ml) and dried ($MgSO_4$). Removal of the solvent gave a residue which was chromatographed on a silica-gel column (60 g in hexane, eluent: 20% ether-hexane) to afford 4.82 g (76.5%) of **60** as a colorless oil: IR (oil) 1725 cm^{-1}; ^1H NMR δ=0.98 (3H, s, 10-CH_3), 1.09—1.39 (6H, 2×CH_3), 1.80 (3H, brs, 4-CH_3), 3.72 (3H, s, CO_2CH_3), 4.61 (1H, m), 4.89—5.24 (2H, m, 16-CH_2), 5.3—6.0 (1H, m, 15-CH), and 7.07 (1H, m, 12-CH); MS (70 eV) *m/z* (rel intensity) 368 (M^+—MeOH, 10), 354 (36), 310 (51), 295 (68), and 73 (100); Found: *m/z* 368.2359. Calcd for $C_{24}H_{32}O_3$: M—MeOH, 368.2351.

1,4,4a,4b,5,6,10,10a-Octahydro-10aβ-acetoxymethyl-2-methoxycarbonyl-4bβ,8-dimethyl-1α-vinylphenanthrene (61): A mixture of **60** (5.40 g, 13.5 mmol) and *p*-toluenesulfonic acid (0.5 g) in EtOH (100 ml) was stirred at room temperature for 30 min. The solvent was evaporated and the residue was diluted with ether (200 ml), washed with saturated aqueous $NaHCO_3$ (50 ml), and dried ($MgSO_4$). Removal of the solvent gave a residue, which was dissolved in pyridine (50 ml) and acetic anhydride (5 ml). The mixture was stirred at room temperature overnight. Excess acetic anhydride was decomposed by the addition of MeOH (10 ml) at 0 °C and the solvent was evaporated under reduced pressure. The residue was chromatographed on a silica-gel column (100 g in hexane, eluent: 20% to 40% ether-hexane) to afford 4.50 g (90%) of **61** as colorless crystals. An analytical sample of **61**, mp 108—108.5 °C, was obtained as colorless prisms by crystallization from ether-hexane: IR (KBr) 1740, 1715, and 1660 cm^{-1}; ^1H NMR δ=0.99 (3H, s, 10-CH_3), 1.78 (3H, brs, 4-CH_3), 2.06 (3H, s, $OCOCH_3$), 3.71(3H, s, CO_2CH_3), 3.96 and 4.17 (2H, ABq, *J*=10 Hz, 20-CH_2), 4.9—5.2 (2H, m, 16-CH_2), 5.3—5.9 (3H, m, 3-CH, 6-CH, and 15-CH), and 7.03 (1H, t, *J*=4 Hz, 12-CH); MS (70 eV) *m/z* (rel intensity) 370 (M^+, 1.6), 310 (100), and 171 (96); Found: *m/z* 370.2158. Calcd for $C_{23}H_{30}O_4$: M, 370.2144. Found: C, 74.35; H, 8.22%. Calcd for $C_{23}H_{30}O_4$: C, 74.56; H, 8.16%.

3,4,4a,4b,5,8,8a,9-Octahydro-8aβ-acetoxymethyl-7-methoxycarbonyl-1α,4aβ-dimethyl-8α-vinyl-2(1*H*)-phenanthrenone 2-(Ethylene Acetal) (63): To a cold (0 °C) solution of **61** (5.34 g, 14.4 mmol) in CH_2Cl_2 (100 ml) was added MCPBA (80%, 3.27 g, 15.1 mmol). After being stirred at 0 °C for 30 min under drying tube, the reaction mixture was poured into aqueous saturated Na_2SO_3 and extracted with ether (500 ml). The organic layer was washed with aqueous saturated $NaHCO_3$ (100 ml×2) and brine (60 ml), dried ($MgSO_4$) and concentrated in vacuo to afford the crude epoxide **62** (^1H NMR δ=0.97 (3H, s, 10-CH_3), 1.47 (3H, s, 4-CH_3), 2.09 (3H, s, $OCOCH_3$), 3.08 (1H, brs, $W_{1/2}$=4.5 Hz, 3-CH), 3.72 (3H, s, CO_2CH_3), 4.00 (2H, ABq, *J*=10 Hz, $\Delta\nu_{AB}$=5 Hz, 20-CH_2), 4.9—5.2 (2H, m, 16-CH_2), 5.4—5.9 (1H, m, 15-CH), 5.97 (1H, dd, *J*=5 and 3.5 Hz, 6-CH), and 7.00 (1H, *t*-like, 12-CH)), which was dried over P_2O_5 under reduced pressure for several hours. To a cold (0 °C) solution of the above epoxide and 2-ethyl-2-methyl-1,3-dioxolane (10 ml) in CH_2Cl_2 (100 ml) under argon was added boron trifluoride etherate (0.09 ml, 0.6 mmol) dropwise. The mixture was stirred at 0 °C for 1 h and additional $BF_3 \cdot Et_2O$ (0.04 ml, 0.3 mmol) was added. After being stirred at 0 °C for 30 min, the mixture was poured into saturated aqueous $NaHCO_3$ (100 ml), extracted with CH_2Cl_2 (200 ml×3), dried ($MgSO_4$), and concentrated in vacuo. The residue was chromatographed on a silica-gel column (eluent: ether-hexane) to afford **63** (5.39 g, 87% from **61**) as colorless crystals. An analytical sample was recrystallized from ether-hexane: mp 173—174 °C; IR (KBr) 1735, 1715, and 1655 cm^{-1}; ^1H NMR δ=1.00 (3H, d, *J*=7 Hz, 4-CH_3), 1.13 (3H, s, 10-CH_3), 2.06 (3H, s, $OCOCH_3$), 3.72 (3H, s, CO_2CH_3), 3.93 (4H, m, acetal), 4.9—5.2 (2H, m, 16-CH_2), 5.3—5.9 (2H, m, 6-CH and 15-CH), and 7.01 (1H, m, 12-CH); MS (70 eV) *m/z* (rel intensity) 430 (M^+, 0.8), 386 (0.8), 370 (3.2), and 99 (100); Found: *m/z* 430.2335. Calcd for $C_{25}H_{34}O_6$: M, 430.2355. Found: C, 69.60; H, 8.02%. Calcd for $C_{25}H_{34}O_6$: C, 69.74; H, 7.96%.

Conversion of Acetate 63 into 1-Ethoxyethyl Ether 51: A solution of **63** (2.22 g, 5.16 mmol) in MeOH (50 ml) was mixed with a solution of K_2CO_3 (0.5 g, 3.6 mmol) in water (10 ml). The mixture was stirred at room temperature overnight. The solvent was evaporated and the residue was taken up in saturated aqueous NH_4Cl (50 ml) and extracted with ether (100 ml×4). The combined organic layers were dried ($MgSO_4$) and concentrated in vacuo to afford crude alcohol **52**, which was dissolved in 50 ml of CH_2Cl_2. To this solution was added PPTS (350 mg) and ethyl vinyl ether (2 ml). The mixture was stirred at room temperature for 1 h. The solution was washed with saturated aqueous $NaHCO_3$ (30 ml), dried ($MgSO_4$) and evaporated. The residue was chromatographed on a silica-gel column (20 g in hexane, eluent: 30% ether-hexane) to afford 2.20 g (93%) of **51**.

3,4,4a,4b,5,8,8a,9-Octahydro-8aβ-[(1-ethoxyethoxy)methyl]-7-hydroxymethyl-1α,4aβ-dimethyl-8α-vinyl-2(1*H*)-phenanthrenone 2-(Ethylene Acetal) (66): To a cold (−78 °C) solution of conjugated ester **51** (2.35 g, 5.11 mmol) in toluene (50 ml) was added dropwise 16 ml of a ca. 1 mol dm^{-3} solution of diisobutylaluminium hydride (DIBAL) in hexane. After 1.5 h at this temperature, the mixture was quenched by the addition of methanol (25 ml) and stirred at room temperature for 30 min. The resulting precipitate was filtered and washed thoroughly with methanol. The combined filtrates were evaporated to give a residue, which was chromatographed on a silica-gel column (50 g in $CHCl_3$, eluent: 1% to 3% MeOH-$CHCl_3$) to afford allylic alcohol **66** (2.23 g, quant.) as a colorless oil: IR (oil) 3470 cm^{-1}; ^1H NMR δ=0.9—1.3 (12H, 4×CH_3), 3.8—4.0 (6H), 4.53 (1H, m), 4.85—5.20 (2H, m, 16-CH_2), 5.37 (1H, m, 6-CH), 5.74 (1H, m, 12-CH), and 5.3—5.9 (1H, m, 15-CH); MS (70 eV) *m/z* (rel intensity) 432 (M^+, 0.1), 414 (0.4), 386 (7), 342 (19), 99 (over), and 73 (100); Found: *m/z* 386.2426. Calcd for $C_{24}H_{34}O_4$: M—EtOH, 386.2458.

1,2,3,4,4a,4b,5,6,8,10-Decahydro-3α-hydroxy-2α-hydroxymethyl-4bβ,8α-dimethyl-1α-vinyl-7*H*-2β,10aβ-(epoxymethano)-phenanthren-7-one 7-(Ethylene Acetal) (68): To a cold (−20 °C) solution of allylic alcohol **66** (1.19 g, 2.75 mmol) in CH_2Cl_2 (30 ml) was added dropwise titanium(IV) isopropoxide (4 ml, 13.44 mmol). After 15 min, an anhydrous solution

of *t*-butyl hydroperoxide (5.9 M in 1,2-dichloroethane, 3.5 ml, 20.65 mmol) was added and the mixture was stirred at −20 °C for 3.5 h. Dimethyl sulfide (3 ml) and aqueous saturated sodium fluoride (5 ml) was added to the mixture at −20 °C and the mixture was stirred at room temperature for 1 h to result in white emulsion, which was filtered through a pad of Celite. The filtrate was extracted with $CHCl_3$ (100 ml×3), dried over $MgSO_4$, and concentrated in vacuo. The crude epoxy alcohol **67** without purification was dissolved in ethanol (100 ml) and treated with PPTS (70 mg, 0.28 mmol). The mixture was stirred at 40—50 °C for 30 min. Removal of the solvent gave a residue, which was chromatographed on a silica-gel column (40 g in $CHCl_3$, eluent: 1% to 3% MeOH-$CHCl_3$) to provide diol **68** (1.10 g, quant.) as colorless crystals. An analytical sample was obtained by recrystallization from acetone as colorless needles: mp 213—214 °C; IR (KBr) 3430, 1645, 1090, and 1045 cm^{-1}; ^1H NMR δ=0.99 (3H, d, J=6 Hz, 4-CH_3), 1.19 (3H, s, 10-CH_3), 3.33 (1H, d, J=8 Hz, 20-CH), 3.74 (2H, brs, 21-CH_2), 3.93 (4H, m, acetal), 4.05 (1H, brd, J=4 Hz, 12-CH), 4.36 (1H, d, J=8 Hz, 20-CH), 4.96—5.25 (2H, m, 16-CH_2), 5.36 (1H, m, 6-CH), and 6.1—6.6 (1H, m, 15-CH); ^{13}C NMR δ=9.89 (q), 19.72 (q), 29.88 (t), 30.82 (t), 31.07 (t), 36.81 (s), 37.08 (t), 40.47 (d), 40.90 (d), 44.04 (s), 58.29 (d), 64.79 (t), 64.95 (t), 65.22 (t), 70.64 (d), 76.38 (t), 84.51 (s), 111.14 (s), 117.99 (d), 118.86 (t), 134.99 (d), and 142.67 (s); MS (70 eV) m/z (rel intensity) 376 (M^+, 16), 358 (3), 292 (4), 100 (100), and 99 (over); Found: m/z 376.2226. Calcd for $C_{22}H_{32}O_5$: M, 376.2251.

1,2,3,4,4a,4b,5,6,8,10-Decahydro-3α-acetoxy-2α-acetoxymethyl-4bβ,8α-dimethyl-1α-vinyl-7*H*-2β,10aβ-(epoxymethano)phenanthren-7-one 7-(Ethylene Acetal) (70): A mixture of diol **68** (8.5 mg, 0.022 mmol), a catalytic amount of 4-dimethylaminopyridine (DMAP), acetic anhydride (0.3 ml), and pyridine (0.5 ml) was stirred at room temperature overnight. An excess acetic anhydride was decomposed by the addition of methanol and the volatiles were removed in vacuo. The residue was chromatographed on a silica-gel column (3 g in $CHCl_3$, eluent: 1% to 3% MeOH-$CHCl_3$) to afford diacetate **70** (7.9 mg, 76%): IR (oil) 1745 cm^{-1}; ^1H NMR δ=1.00 (3H, d, J=6 Hz, 4-CH_3), 1.16 (3H, s, 10-CH_3), 2.01 (3H, s, $OCOCH_3$), 2.08 (3H, s, $OCOCH_3$), 3.43 (1H, d, J=8 Hz, 20-CH), 3.83 (1H, d, J=12 Hz, 21-CH), 3.93 (4H, m, acetal), 4.38 (1H, d, J=12 Hz, 21-CH), 4.44 (1H, d, J=8 Hz, 20-CH), 4.83—5.35 (3H, m, 12-CH and 16-CH_2), 5.36 (1H, m, 6-CH), and 5.8—6.5 (1H, m, 15-CH); MS (70 eV) m/z (rel intensity) 460 (M^+, 1.6) and 99 (100); Found: m/z 460.2476. Calcd for $C_{26}H_{36}O_7$: M, 460.2462.

1,2,3,4,4a,4b,5,6,8,10-Decahydro-2α-(*t*-butyldimethylsiloxymethyl)-3α-hydroxy-4bβ,8α-dimethyl-1α-vinyl-7*H*-2β,10aβ-(epoxymethano)phenanthren-7-one 7-(Ethylene Acetal) (71): To a cold (0 °C) solution of diol **68** (1.4321 g, 3.81 mmol) and imidazole (0.549 g, 8.06 mmol) in DMF (15ml) was added *t*-buthyldimethylchlorosilane (tBDMSCl, 0.8625 g, 5.72 mmol). After being stirred at room temperature for 2 h, additional imidazole (0.39 g, 5.73 mmol) and tBDMSCl (0.57 g, 3.78 mmol) was added. After another 1 h, the mixture was poured into water (100 ml) and extracted with ether (100 ml×4). Drying ($MgSO_4$) and evaporation of the solvent gave a residue, which was chromatographed on a silica-gel column (40 g in hexane) with ether-hexane (1 : 2 to 1 : 1) to afford monosilyl ether **71** (1.8298 g, 98 %) as a colorless oil, which crystallized upon standing. An analytical sample was obtained by recrystallization from hexane as colorless prisms: mp 98—99 °C; IR (oil) 3500 cm^{-1}; ^1H NMR δ=0.90 (9H, s, *t*-Bu), 0.97 (3H, d, J=7 Hz, 4-CH_3), 1.15 (3H, s, 10-CH_3), 3.29 (1H, d, J=8 Hz, 20-CH), 3.77 (2H, ABq, J=10 Hz, $\Delta\nu_{AB}$=10 Hz, 21-CH_2), 3.91 (4H, m, acetal), 4.08 (1H, m, 12-CH), 4.32 (1H, d, J=8 Hz, 20-CH), 4.9—5.2 (2H, m, 16-CH_2), 5.33 (1H, m, 6-CH), and 6.2—6.7 (1H, m, 15-CH); MS (70 eV) m/z (rel intensity) 490 (M^+, 3), 433 (50), 415 (8), 99 (over), and 75 (100); Found: m/z 490.3107. Calcd for $C_{28}H_{46}O_5Si$: M, 490.3148. Found: C, 68.76; H, 9.68%. Calcd for $C_{28}H_{46}O_5Si$: C, 68.53, H, 9.45%.

1,2,3,4,4a,4b,5,6,8,10-Decahydro-3α-acetoxy-2α-(*t*-butyldimethylsiloxymethyl)-4bβ,8α-dimethyl-1α-vinyl-7*H*-2β,10aβ-(epoxymethano)phenanthren-7-one 7-(Ethylene Acetal) (72): A mixture of monosilyl ether **71** (12 mg), a catalytic amount of DMAP, acetic anhydride (0.5 ml), and pyridine (1 ml) was stirred at room temperature for 2.5 h. After the addition of methanol, the volatiles were removed in vacuo to give a residue. Chromatography on a silica-gel column (3 g in hexane) with ethyl acetate-hexane (1 : 5) afforded acetate **72** (11 mg, 84 %): IR (oil) 1745 cm^{-1}; ^1H NMR δ=0.90 (9H, s, *t*-Bu), 0.99 (3H, d, J=6 Hz, 4-CH_3), 1.15 (3H, s, 10-CH_3), 1.99 (3H, s, $OCOCH_3$), 3.33 (1H, d, J=8 Hz, 20-CH), 3.48 and 3.68 (2H, ABq, J=11 Hz, 21-CH_2), 3.92 (4H, m, acetal), 4.37 (1H, d, J=8 Hz, 20-CH), 4.95—5.25 (3H, m, 12-CH and 16-CH_2), 5.35 (1H, m, 6-CH), and 5.8—6.4 (1H, m, 15-CH); MS (70 eV) m/z (rel intensity) 532 (M^+, 0.1), 475 (3), 415 (8), and 99 (100); Found: m/z 475.2513. Calcd for $C_{26}H_{39}O_6Si$: M, 475.2517.

1,2,3,4,4a,4b,5,6,8,10-Decahydro-3α-(*t*-butyldimethylsiloxy)-2α-(methoxymethoxymethyl)-4bβ,8α-dimethyl-1α-vinyl-7*H*-2β,10aβ-(epoxymethano)phenanthren-7-one 7-(Ethylene Acetal) (73): Potassium hydride (1 g, 8.75 mmol, 35% oil dispersion) was washed with hexane (6 ml). To a suspension of the potassium hydride in a mixture of THF (20 ml) and DMF (10 ml) was added dropwise a solution of monosilyl ether **71** (1.00 g, 2.04 mmol) in THF (20 ml) at 0 °C. After 15 min, chloromethyl methyl ether (0.7 ml, 9.22 mmol) was added dropwise and the resulting mixture was stirred at room temperature for 80 min. The mixture was poured into saturated aqueous $NaHCO_3$ (60 ml), extracted with $CHCl_3$ (100 ml×1, 70 ml×2), and dried over $MgSO_4$. Removal of the solvent gave a residue, which was chromatographed on a silica-gel column (30 g in $CHCl_3$, eluent: 1% to 3% MeOH-$CHCl_3$) to afford methoxymethyl ether **73** (0.96 g, 88%) as a colorless viscous oil: IR (oil) no absorption due to hydroxyl group; ^1H NMR δ=0.90 (9H, s, *t*-Bu), 0.97 (3H, d, J=7 Hz, 4-CH_3), 1.15 (3H, s, 10-CH_3), 3.36 (3H, s, OCH_3), 3.37 (1H, 20-CH: broad signal due to overlapping with other signal), 3.57 (2H, brs, 21-CH_2), 3.92 (4H, m, acetal), 4.02 (1H, m, 12-CH), 4.34 (1H, d, J=8 Hz, 20-CH), 4.64 (2H, s, OCH_2O), 4.85—5.15 (2H, m, 16-CH_2), 5.34 (1H, m, 6-CH), and 6.1—6.6 (1H, m, 15-CH); MS (70 eV) m/z (rel intensity) 534 (M^+, 2), 503 (5), 477 (95), 445 (29), 415 (29), 99 (over), and 73 (100); Found: m/z 477.2673. Calcd for $C_{26}H_{41}O_6Si$: M, 477.2674.

1,2,3,4,4a,4b,5,6,8,10-Decahydro-3α-acetoxy-2α-(methoxymethoxymethyl)-4bβ,8α-dimethyl-1α-vinyl-7*H*-2β,10aβ-(epoxymethano)phenanthren-7-one 7-(Ethylene Acetal) (74): To a solution of **73** (25.8 mg, 0.048 mmol) in THF (1 ml) was added tetrabutylammonium fluoride (65 mg, 0.25 mmol) in THF (2 ml). The mixture was stirred at 50 °C for 23 h. The solvent was evaporated in vacuo to give a brown residue, which was filtered through florisil short column with ethyl acetate. The resulting crude alcohol was dissolved in pyri-

dine (1 ml) and acetic anhydride (0.3 ml) containing a catalytic amount of DMAP, and the mixture was stirred at room temperature for 95 min. After the addition of methanol, the volatiles were evaporated in vacuo to give a residue, which was chromatographed on a silica-gel column (5 g in hexane) with ether-hexane (1 : 1) to afford acetate **74** (21.1 mg, 94%) as colorless crystals. An analytical sample was obtained by recrystallization from ether-hexane as colorless prisms: mp 158—159 °C; IR (KBr) 1745, 1380, and 1250 cm^{-1}; ^1H NMR δ=0.99 (3H, d, J=6 Hz, 4-CH_3), 1.17 (3H, s, 10-CH_3), 2.03 (3H, s, $OCOCH_3$), 3.35 (3H, s, OCH_3), 3.36 (1H, d, J=8 Hz, 20-CH), 3.41 and 3.63 (2H, ABq, J=10 Hz, 21-CH_2), 3.92 (4H, m, acetal), 4.39 (1H, d, J=8 Hz, 20-CH), 4.60 (2H, brs, OCH_2O), 4.9—5.3 (3H, m, 12-CH and 16-CH_2), 5.35 (1H, m, 6-CH), and 5.9—6.4 (1H, m, 15-CH); MS (70 eV) m/z (rel intensity) 462 (M^+, 1), 431 (0.4), 402 (1.1), and 99 (100); Found: m/z 462.2622. Calcd for $C_{26}H_{38}O_7$: M, 462.2617.

1,2,3,4,4a,4b,5,6,8,10-Decahydro-3α-(*t*-butyldimethylsiloxy)-2α-(*t*-butyldimethylsiloxymethyl)-4bβ,8α-dimethyl-1α-vinyl-7*H*-2β,10aβ-(epoxymethano)phenanthren-7-one 7-(Ethylene Acetal) (75): To a cold (0 °C) suspension of potassium hydride (3.13 g, 27.4 mmol, 35% oil dispersion) in a mixture of THF (40 ml) and DMF (20 ml) was added dropwise a solution of **71** (2.76 g, 5.63 mmol) in THF (40 ml) over the period of 15 min. After 15 min, a solution of tBDMSCl (2.6 g, 17.2 mmol) in THF (5 ml) was added to the solution. The mixture was stirred at room temperature for 1 h, poured into brine (100 ml), and extracted with ether (150 ml×4). Drying ($MgSO_4$) and evaporation of the solvent gave a residue, which was chromatographed on a silica-gel column (60 g in hexane) with ether-hexane (1 : 4) to afford disilyl ether **75** (3.26 g, 96%) as a colorless viscous oil: IR (oil) no absorption due to hydroxyl group; ^1H NMR δ=0.04 (12H, s, 2×$Si(CH_3)_2$), 0.86 (9H, s, *t*-Bu), 0.90 (9H, s, *t*-Bu), 0.91 (3H, d, J=7 Hz, 4-CH_3), 1.12 (3H, s, 10-CH_3), 3.25 (1H, d, J=8 Hz, 20-CH), 3.60 (2H, s, 21-CH_2), 3.90 (4H, m, acetal), 4.29 (1H, d, J=8 Hz, 20-CH), 4.8—5.2 (2H, m, 16-CH_2), 5.33 (1H, m, 6-CH), and 6.0—6.6 (1H, m, 15-CH); MS (70 eV) m/z (rel intensity) 604 (M^+, 0.2), 547 (28), 503 (6), 415 (7), and 99 (100); Found: m/z 604.3997. 1,2,3,4,4a,4b,5,6,8,10-Decahydro-3α-(*t*-butyldimethylsiloxy)-2α-(*t*-butyldimethylsiloxymethyl)-1α-(2-hydroxyethyl)-4bβ,8α-dimethyl-7*H*-2β,10aβ-(epoxymethano)phenanthren-7-one 7-(Ethylene Acetal) (76): In a 200 ml three-necked flask was placed ca. 2 mol dm^{-3} borane-THF solution (9.5 ml) and THF (50 ml) under argon atmosphere. To the solution was added dropwise 2,3-dimethyl-2-butene (6.5 ml, 54 mmol) at 0 °C and this solution was stirred at 0 °C for 2h. To this solution was added disilyl ether **75** (3.26 g, 5.40 mmol) in THF (40 ml) and the mixture was stirred at 0 °C for 3 h, then at room temperature for 1 h. The solution was cooled to 0 °C, quenched by the careful addition of water (6 ml), followed by 3 M NaOH solution (17 ml) and 30% H_2O_2 (17 ml). After being stirred at ca. 50 °C for 1.5 h, the mixture was cooled to room temperature and the aqueous layer was saturated with NaCl, extracted with ether (150 ml×3), and dried over $MgSO_4$. Evaporation of the solvent gave a residue, which was chromatographed on a silica-gel column (60 g in hexane) with ether-hexane (1 : 4 to 1 : 1) to afford alcohol **76** (2.71 g, 81%) as a colorless oil. An analytical sample was obtained by crystallization from ether-hexane as colorless prisms: mp 145—146 °C; IR (oil) 3500cm^{-1}; ^1H NMR δ=0.02 and 0.04 (12H, each s, 2×$Si(CH_3)_2$), 0.87 (9H, s, *t*-Bu), 0.93 (9H, s, *t*-Bu), 0.99 (3H, d, J=6 Hz, 4-CH_3), 1.12 (3H, s, 10-CH_3), 3.26 (1H, d, J=8 Hz, 20-CH), 3.95 (4H, m, acetal), 4.24 (1H, d, J=8 Hz, 20-CH), and 5.40 (1H, m, 6-CH); MS (70 eV) m/z (rel intensity) 622 (M^+, 1.8), 565 (6), 490 (15), 433 (26), and 99 (100); Found: m/z 622.4077. Calcd for $C_{34}H_{62}O_6Si_2$: M, 622.4087.

1,2,3,4,4a,4b,5,6,8,10-Decahydro-3α-(*t*-butyldimethylsiloxy)-2α-(*t*-butyldimethylsiloxymethyl)-1α-(2-oxoethyl)-4bβ,8α-dimethyl-7*H*-2β,10aβ-(epoxymethano)phenanthren-7-one 7-(Ethylene Acetal) (77): To a Collins' reagent, prepared from chromium trioxide (2 g, 20 mmol) and pyridine (5 ml, 62 mmol) in CH_2Cl_2 (50 ml), was added alcohol **76** (1.95 g, 3.10 mmol) in CH_2Cl_2 (35 ml). The mixture was stirred at room temperature for 1 h, then diluted with ether. The supernatant was filtered through florisil column and washed thoroughly with ether and ethyl acetate. The dark brown residue was dissolved in saturated $NaHCO_3$ solution (70 ml) and extracted with ether (150 ml), washed with aqueous $NaHSO_3$, saturated aqueous $NaHCO_3$, and brine, dried over $MgSO_4$. The combined filtrate and organic extract were concentrated in vacuo to give a residue, which was chromatographed on a silica-gel column (40 g in hexane) with ether-hexane (1 : 2) to afford aldehyde **77** (1.81 g, 93%) as a colorless amorphous solid: IR (oil) 2720 and 1725 cm^{-1}; ^1H NMR δ=0.90 (18H, s, 2×*t*-Bu), 0.98 (3H, d, J=6 Hz, 4-CH_3), 1.13 (3H, s, 10-CH_3), 3.33 (1H, d, J=8 Hz, 20-CH), 3.64 (2H, s, 21-CH_2), 3.7—4.0 (5H, m, 12-CH and acetal), 4.35 (1H, d, J=8 Hz, 20-CH), 5.34 (1H, m, 6-CH), and 9.73 (1H, *t*-like, 16-CH); MS (70 eV) m/z (rel intensity) 620 (M^+, 2), 563 (7), 519 (2), 431 (14), and 99 (100); Found: m/z 620.3906. 1,2,3,4,4a,4b,5,6-Octahydro-3α-(*t*-butyldimethylsiloxy)-2α-(*t*-butyldimethylsiloxymethyl)-1α-(2,2-dimethoxyethyl)-4bβ,8α-dimethyl-7*H*-2β,10aβ-(epoxymethano)phenanthrene-7,10(8*H*)-dione 7-(Ethylene Acetal) (79): To a cold (−20 °C) suspension of chromium trioxide (409 mg, 4.09 mmol) in CH_2Cl_2 (5 ml) was added 3,5-dimethylpyrazole (390 mg, 4.06 mmol) in one portion. The mixture was stirred at −20 °C for 20 min, and a solution of acetal **78** (135 mg, 0.20 mmol) in CH_2Cl_2 (10 ml) was added dropwise. After stirring at −20 °C

for 4 h, 3M NaOH solution (3 ml) was added and the mixture was stirred at 0 °C for 30 min. The solution was diluted with brine (20 ml), extracted with ether (50 ml×3), dried over $MgSO_4$, and concentrated in vacuo. The residue was chromatographed on a silica-gel column (10 g in benzene, eluent: 10% to 20% ether-benzene) to afford enone **79** (93.8 mg, 68%) as a pale yellow viscous oil: IR (oil) 1660 cm^{-1}; ^1H NMR δ=0.09 (12H, s, 2×Si(CH_3)$_2$), 0.91 (9H, s, *t*-Bu), 0.93 (9H, s, *t*-Bu), 1.08 (3H, d, J=7 Hz, 4-CH_3), 1.23 (3H, s, 10-CH_3), 3.13 (3H, s, OCH_3) 3.26 (3H, s, OCH_3), 3.95 (4H, m, acetal), and 5.95 (1H, d, J=2 Hz, 6-CH); MS (70 eV) m/z (rel intensity) 680 (M^+, 0.8), 649 (2), 623 (35), 591 (28), 459 (35), 99 (over), 75 (95), and 73 (100); Found: m/z 623.3412. 12α,21-Bis(*t*-butyldimethylsiloxy)-13,20-epoxy-16-methoxy-3-picrasanone 3-(Ethylene Acetal) (82): To a cold (−78 °C) solution of ketone **80** (195.5 mg, 0.287 mmol) in THF (6 ml) was added lithium triethylhydroborate (1 mol dm^{-3} solution in THF, 2.5 ml) and the mixture was stirred at −78 °C, then allowed to warm to room temperature overnight. The mixture was quenched by the addition of water, followed by 3 mol dm^{-3} aqueous NaOH (2 ml) and 30% H_2O_2 solution (2 ml), and stirred at room temperature for 2 h. The solution was poured into brine and extracted with $CHCl_3$ (70 ml×3), dried over $MgSO_4$, and concentrated in vacuo to give a crude alcohol **81**, which without purification was dissolved in methanol (10 ml) and treated with a catalytic amount of PPTS. The reaction mixture was stirred at room temperature for 1 h and the solvent was evaporated in vacuo. The residue was chromatographed on a silica-gel column (15 g in hexane, eluent: 50% ether-hexane) to afford methylated hemiacetal **82** (168.3 mg, 90%) as an inseparable 1 : 1 (by NMR) mixture of diastereomers at C-16: IR (oil) no absorption due to hydroxyl and carbonyl group: ^1H NMR δ=−0.1—0.1 (12H, 2×Si(CH_3)$_2$), 0.8—1.0 (24H, 4-CH_3, 10-CH_3, and 2×*t*-Bu), 3.26 and 3.42 (3H, each s, OCH_3), and 3.93 (4H, m, acetal); MS (70 eV) m/z (rel intensity) 652 (M^+, 0.1), 637 (1), 595 (79), 563 (35), and 99 (100).

13,20-Epoxy-12α,21-dihydroxy-16-methoxy-3-picrasanone 3-(Ethylene Acetal) (3): To a cold (0 °C) solution of methylated hemiacetal **82** (187.5 mg, 0.287 mmol) in THF (6 ml) was added tetrabutylammonium fluoride (380 mg, 1.45 mmol) in THF (3 ml). After being stirred at room temperature for 18 h, the mixture was poured into saturated $NaHCO_3$ solution and extracted with $CHCl_3$ (50 ml×3). Drying ($MgSO_4$) and evaporation of the solvent gave a residue, which was chromatographed on a silica-gel column (15 g dry, eluent: 0% to 6% MeOH-$CHCl_3$) to afford 85.6 mg (70%) of a mixture of diastereomers **3** and 36.1 mg (30%) of a pure diastereomer (more polar, $C_{(16)}$ β-OMe isomer of **3**). An analytical sample of the more polar isomer of **3** was obtained by recrystallization from acetone-hexane as colorless needles: mp 213—216 °C; IR (KBr) 3420 cm^{-1}: ^1H NMR Table 1; MS (70 eV) m/z (rel intensity) 424 (M^+, 3), 374 (20), 361 (8), 100 (100), and 99 (over); Found: m/z 424.2446. Calcd for $C_{23}H_{36}O_7$, 424.2462.

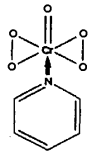
(Received April 28, 1988)

Bis(trimethylsilyl) peroxide (BTSP) serves as an effective oxidant of alcohols in the presence of chromium(VI) or ruthenium(II) complexes as catalysts in dichloromethane. Selective oxidation of primary alcohols in preference to secondary ones using $RuCl_2(PPh_3)_3$ as a catalyst is also described.

Dehydrogenative oxidation of alcohols to the corresponding carbonyl compounds is one of the most important reactions in organic synthesis. Many transition metal reagents have been widely employed[1] as stoichiometric oxidants or catalysts. Here we wish to report catalysis of pyridinium dichromate(VI) and dichlorotris(triphenylphosphine)ruthenium(II) for oxidation of alcohols by means of $Me_3SiOOSiMe_3$ as an oxidant.[2]

(1) Oxidation of Alcohols with $Me_3SiOOSiMe_3$ Catalyzed by Pyridinium Dichromate(VI). Hexavalent chromium reagents are commonly utilized in the oxidation of primary and/or secondary alcohols. Pyridinium chlorochromate (PCC),[3] pyridinium dichromate (PDC),[4] chromyl chloride,[5] the Collins reagent,[6] as well as the Jones reagent[7] are well-known ones used in the laboratories.[8] However, there are some significant difficulties associated with each oxidant. Particularly, the Collins reagent became popular because of the excellent yields of products, however, a large excess of the chromium complex was required due to the precipitating gummy product which occluded the oxidant and often provided troubles in carrying out the oxidation manipulation as well as workup. Moreover, toxicity of excess chromium trioxide is also a serious problem. A solution to these problems is to find out a suitable co-oxidant which can convert alcohols to the corresponding carbonyl compounds in the presence of a catalytic amount of chromium(VI) species.

The failure in the attempted oxidation of alcohols with a catalytic amount of chromium(VI) complex has been ascribed to the fact that the popular organic or inorganic oxidants can not reoxidize the resulting trivalent chromium into hexavalent because of its high oxidation potential (E^0=1.33 V in acid solutions).[9] Thus, we have turned our attention to utilize the peroxochromium-chromium(VI) trioxide cycle in which an oxodiperoxochromium complex (**1**) is a key reactant for the oxidation of alcohols.



1

Wiede reported the generation of oxodiperoxochromium-pyridine complex (**1**) in 1897.[10] Treatment of chromium trioxide with hydrogen peroxide in the presence of pyridine gave the peroxo reagent as a deep blue solid. This was used only as a damp complex[11] because of the danger of explosion upon drying. It is desirable to generate the oxodiperoxochromium complex in highly diluted conditions and to utilize it in situ for the oxidation from the viewpoint of safety. We have examined suitable co-oxidants, which will oxidize chromium trioxide or its equivalent to the desired oxodiperoxychromium complex. Formation of the "peroxo complex" was checked by a visible absorption arround 580 nm.[12] Among such peroxides as *t*-BuOOH, *t*-BuOOBu-*t*, PhC(O)OOC(O)Ph, and aqueous hydrogen peroxide examined, only hydrogen peroxide produced desired oxodiperoxochromium species. In the case of hydrogen peroxide (30% in water), however, the transformation of primary alcohols to aldehydes accompanied overoxidation into carboxylic acid. Finally, the $Me_3SiOOSiMe_3$-pyridinium dichromate system has proved to be effective for the generation of the oxodiperoxochromium complex in dichloromethane solutions. As the peroxo complex decomposed easily, the oxidant $Me_3SiOOSiMe_3$ was added dropwise using a syringe drive to the reaction mixture. Bis(trimethylsilyl) peroxide was stable enough even upon contact with metallic surface of the syringe needle when it was diluted with dichloromethane (0.5 mol dm^{-3}). The typical results for the conversion of alcohols into carbonyl compounds are summarized in Table 1.

Each substrate was oxidized to the corresponding carbonyl compound in good yields. Moreover, the coexisting olefinic linkage remained intact upon treatment with the oxodiperoxochromium complex and no epoxy compounds were observed among the reaction mixture. Other hexavalent chromium reagents such as anhydrous chromium trioxide and pyri-

a) $Me_3SiOOSiMe_3$ (3.0 mmol) and pyridinium dichromate (0.1 mmol) were employed per one mol of alcohol. b) Isolated and purified yield. c) GLPC yields using decane, tridecane, or tetradecane as an internal standard.

dinium chlorochromate were examined as catalysts, and found to be less effective than pyridinium dichromate. For instance, oxidation of 4-*t*-butylcyclohexanol with CrO_3-$Me_3SiOOSiMe_3$ or PCC-$Me_3SiOOSiMe_3$ gave 4-*t*-butylcyclohexanone in 30% or 55% yield, respectively under the same reaction conditions as pyridinium dichromate-$Me_3SiOOSiMe_3$ system. These results show that oxodiperoxochromium complex is rather unstable either under acidic conditions or in the absence of pyridine.[13]

(2) Selective Oxidation of Primary Alcohols with Ruthenium Catalyst. Ruthenium complex is also a popular catalyst for the oxidation of alcohols. Many organic and inorganic co-oxidants such as amine oxide,[14] *t*-BuOOH,[15] hypervalent iodine compound,[16] molecular oxygen,[17] as well as inorganic $NaBrO_3$,[18] and periodate[19] were widely examined for the oxidation of alcohols. Dehydrogenative oxidation with hydrogen acceptor such as α,β-unsaturated carbonyl compounds has also been studied.[20] Being encouraged with the results obtained with chromium(VI)-catalyzed oxidation, we examined the combination of

$Me_3SiOOSiMe_3$ with a ruthenium complex, $RuCl_2(PPh_3)_3$ to find that simple mixing of the substrate, the catalyst, and the oxidant in one portion gave results as summarized in Table 2.[21] Olefinic double bonds in the substrate were completely inert under the reaction conditions. This observation shows that ruthenium is not oxidized to octavalent oxidation state with $Me_3SiOOSiMe_3$, in sharp contrast with the ruthenium catalysis reaction using periodate as oxidant.[19]

It is worth noting that the allylic alcohols are oxidized with retained configuration of the olefinic bond. Geraniol and nerol were oxidized to the corresponding (*E*)- and (*Z*)-α-enals, respectively. The ruthenium complex, when used stoichiometrically, has proved to be an efficient reagent for the selective oxidation of primary alcohols in the presence of secondary ones.[22] For instance, treatment of 1,10-undecanediol with $RuCl_2(PPh_3)_3$ in benzene gave 10-hydroxyundecanal in 89% yield. The oxidation presumably involves formation of a ruthenium alkoxide which undergoes β-elimination to produce the carbonyl compound and hydridochlorotris(triphenylphosphine)ruthenium. The oxidation of alcohols was completed with half mol of $RuCl_2(PPh_3)_3$, so that this hydridochloro complex is supposedly capable to oxidize another mol of the alcohol to the carbonyl compound. In fact, treatment of a mixture of 1-dodecanol and 4-dodecanol (1.0 mmol each) with $HRuCl(PPh_3)_3$ (1.0 mmol)[23] in benzene provided dodecanal in 75% yield along with a trace of 4-dodecanone (<2%). Possibly, the formation of a ruthenium alkoxide is a rate-determining step and bulkiness of triphenylphosphine ligand plays an important role for this selectivity.

$$RCH_2OH + RuCl_2(PPh_3)_3 \longrightarrow RCH_2O\text{-}RuCl(PPh_3)_3 + HCl$$
$$RCH_2O\text{-}RuCl(PPh_3)_3 \longrightarrow RCHO + HRuCl(PPh_3)_3$$
$$RCH_2OH + HRuCl(PPh_3)_3 \longrightarrow RCH_2O\text{-}RuH(PPh_3)_3 + HCl$$
$$RCH_2O\text{-}RuH(PPh_3)_3 \longrightarrow RCHO + H_2Ru(PPh_3)_3$$

Some attempted selective oxidations of primary alcohols with a catalytic amount of $RuCl_2(PPh_3)_3$ resulted in failure. Such usual co-oxidants as *t*-BuOOH, *N*-methylmorpholine *N*-oxide were effective not only for reoxidation of reduced ruthenium complex to higher oxidation state, but also for oxidation of triphenylphosphine to phosphine oxide which was no more a ligand of ruthenium metal. With *N*-methylmorphorine *N*-oxide-$RuCl_2(PPh_3)_3$ system, 1-dodecanol reacted at only three times the rate of

Table 2. Oxidation of Alcohols with $RuCl_2(PPh_3)_3/Me_3SiOOSiMe_3$ System[a]

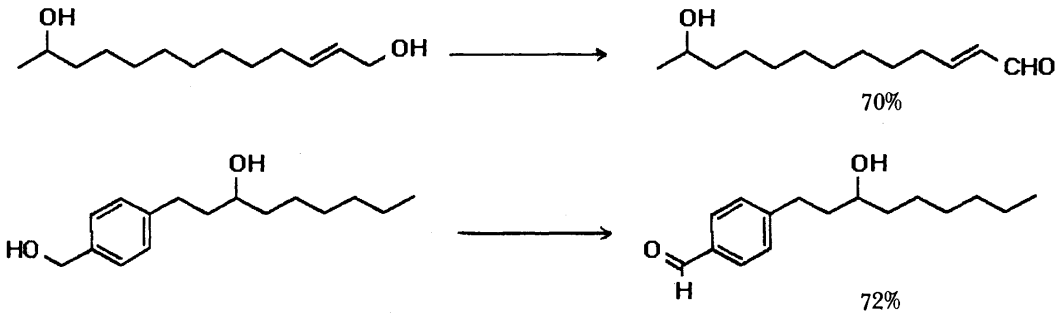
a) $Me_3SiOOSiMe_3$ (2.0 mmol) and $RuCl_2(PPh_3)_3$ (0.05 mmol) were employed per one mmol of alcohol. b) Isolated and purified yield. c) GLPC yield using decane as an internal standard. b) Reaction mixture was stirred for 20 h. Starting material (60%) was recovered.

4-dodecanol. Meanwhile, in our new system, $Me_3SiOOSiMe_3$ was not too much strong to oxidize triphenylphosphine into triphenylphosphine oxide, so that the expected catalytic oxidation proceeded selectively. As expected, primary alcohols were oxidized faster than secondary ones with $RuCl_2(PPh_3)_3$-$Me_3SiOOSiMe_3$ system.[24] The relative rate of oxidation between 1-dodecanol and 4-dodecanol was 20 : 1 at the stage of 5% completion of the reaction.[25,26] Benzylic and allylic alcohols were more reactive than its saturated counterparts, and the ratio of reaction rate was more than 2/1. As a result, primary benzylic or allylic alcohols were oxidized more than 40 times as fast as saturated secondary alcohols. Table 3 shows the results of selective oxidation of benzylic and allylic primary alcohols to α-enals. Coexisting secondary alcohols were recovered unchanged nearly quantitatively.

The following Scheme 1 shows that the new system was applicable for the primary-secondary diols. Only hydroxy aldehyde was obtained in good yield.

Experimental

Infrared spectra of neat liquid film samples were determined on a Hitachi grating infrared spectrometer 215, or JASCO IR-810, mass spectra and exact masses on a Hitachi M-80. NMR spectra were recorded on a Varian EM-390, or Varian XL-200 spectrometer using TMS as an internal



Scheme 1.

Diol (1.0 mmol), $RuCl_2(PPh_3)_3$ (0.1 mmol), and $Me_3SiOOSiMe_3$ (2.0 mmol) were combined in dichloromethane (10 ml) and the reaction mixture was stirred for 2 h at 25 °C.

Table 3. Selective Oxidation of Allyic Primary Alcohols in the Presence of Secondary Ones[a]

Run	Starting mixture of alcohols		Yields(%) of aldehyde and ketone[b]			
1				99		3(92)

4				85		6(92)
5				63		40

a) The hydroxy compounds (1.0 mmol each), $RuCl_2(PPh_3)_3$ (48 mg, 0.05 mmol), and $Me_3SiOOMe_3$ (0.45 g, 2.5 mmol) were combined in dichloromethane (15 ml) and the mixture was stirred for 3 h at 25 °C. b) Yields were calculated on the basis of GLPC (PEG 20 M, 20% on Celite 545, 1.5 m) using dodecane or tetradecane as an internal standard. Figures in parentheses vere recovery of starting secondary alcohols.

standard unless otherwise noted. Multiplicity is designated as s, singlet; d, doublet; t, triplet; q, quartet; m, multiplet. Preparative TLC plates were prepared with Merck Kiesel gel PF_{254}. Column chromatography was carried out with silica gel (Wakogel C-200) at atmospheric pressure.

Preparation of Bis(trimethylsilyl) Peroxide. The peroxide was prepared from hydrogen peroxide according to the reported procedure.[27] Bp 42—44 °C/30 Torr (1 Torr=133.322 Pa): IR (neat) 2960 (s), 1250 (s), 920 (w), 840 (s), 730 (s) cm^{-1}.

General Procedure for the Oxidation of Primary and Secondary Alcohols with Pyridinium Dichromate/Bis(trimethylsilyl) Peroxide. A solution of $Me_3SiOOSiMe_3$ (79 mg, 0.5 mmol) in dichloromethane (2.0 ml) was added to a solution of pyridinium dichromate (37 mg, 0.1 mmol) in the same solvent (5.0 ml). The color changed immediately from dark orange to deep blue, which indicated the formation of oxoperoxochromium complex. Substrate alcohol (1.0 mmol) in dichloromethane (1.0 ml) was added to the solution and the rest of $Me_3SiOOSiMe_3$ (0.45 g, 2.5 mmol) in dichloromethane (5.0 ml) was added dropwise over 1 h by syringe pump at 25°C. The resulting brown reaction mixture was stirred more than 30 min after the completion of the addition of peroxide. The mixture was poured into ice-cooled saturated aqueous sodium hydrogensulfite and extracted with ether (3×20 ml). The combined organic layers were washed with brine, dried over Na_2SO_4, and concentrated. Purification of crude product by silica-gel column chromatography gave a corresponding carbonyl compound in excellent yield (Table 1).

General Procedure for the Oxidation of Primary Alcohols to Aldehyde with $RuCl_2(PPh_3)_3/Me_3SiOOSiMe_3$ System. Oxidation of benzyl alcohol to benzaldehyde is representative. Benzyl alcohol (0.22 g, 2.0 mmol) and $Me_3SiOOSiMe_3$ (0.71 g, 4.0 mmol) were added to a solution of $RuCl_2(PPh_3)_3$ (96 mg, 0.1 mmol) in dichloromethane (15 ml) and the whole was stirred for 2 h at 25 °C. The resulting mixture was diluted with dichloromethane (20 ml) and poured into ice-cooled water. The organic layer was separated and water layer was extracted with dichloromethane and the combined organic layers were washed with saturated aqueous sodium hydrogensulfite and brine successively. Concentration followed by purification on preparative thin-layer chromatography gave benzaldehyde (0.19 g) in 91% yield (Table 2).

General Procedure for the Selective Oxidation of Allylic Primary Alcohols in the Presence of Secondary Ones. Selective oxidation of geraniol to (*E*)-citral in the presence of 4-dodecanol is representative. A solution of $Me_3SiOOSiMe_3$ (0.45 g, 2.5 mmol) in dichloromethane (5 ml) was added to a solution of geraniol (0.15 g, 1.0 mmol), 4-dodecanol (0.18 g, 1.0 mmol), and $RuCl_2(PPh_3)_3$ (0.05 g, 0.05 mmol) in dichloromethane (10 ml). The whole mixture was stirred for 3 h at 25 °C, and the resulting mixture was poured into ice water. The organic layer was separated and dried over Na_2SO_4. The yield of aldehyde and recovered secondary alcohol were checked by GLPC using tridecane as an internal standard (Table 3).

12-Hydroxy-2-tridecenal: To a solution of $RuCl_2(PPh_3)_3$ (96 mg, 0.1 mmol) in dichloromethane was added a mixture of $Me_3SiOOSiMe_3$ (0.37 g, 2.0 mmol) and 2-tridecene-1,12-diol (0.21 g, 1.0 mmol) in dichloromethane at 25 °C. The oxidation completed within 1.5 h and the reaction mixture was poured into ice water. Workup followed by purification gave 12-hydroxy-2-tridecenal in 70% yield: Bp 112—114 °C (0.05 Torr, bath temp); IR (neat) 3370, 2940, 2740, 1697, 975 cm^{-1}; ^1H NMR (CCl_4) δ=1.11 (d, 3H, J=6.0 Hz), 1.1—1.8 (m, 14H), 2.2—2.6, (m, 3H), 3.5—3.9 (m, 1H), 6.01 (dd, 1H, J=15.0 and 7.5 Hz), 6.68 (dt, 1H, J=15.0 and 7.0 Hz), 9.39 (d, 1H, J=7.5 Hz); exact mass spectrum m/z 211.1608. Calcd for $C_{13}H_{23}O_2$: M−1, 211.1698.

4-(3-Hydroxynonyl)benzaldehyde: Bp 116—118 °C (0.06 Torr, bath temp); IR (neat) 3380, 2933, 2740, 1700, 1608, 1218, 1167, cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.85 (t, 3H, J=7.5 Hz), 1.05—1.85 (m, 11H), 2.43—3.0 (m, 2H), 3.75—3.95 (m, 1H), 7.05—7.50 (m, 2H), 7.7—7.95 (m, 2H), 10.0 (s. 1H); exact mass spectrum m/z 248.1720. Calcd for $C_{16}H_{24}O_2$: M, 248.1777.

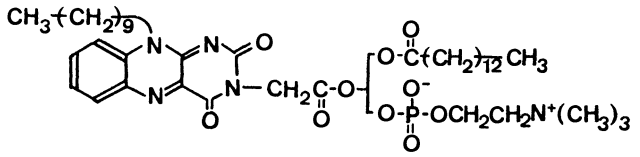
Efficient Electron Flux Conversion from Strongly Hydrophilic NADH Model in the Transmembrane Electron Transfer by Flavolipid

Itaru HAMACHI, Yoshiaki KOBUKE,* and (the late) Iwao TABUSHI
Department of Synthetic Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Kyoto 606
(Received April 30, 1988)

By using a strongly hydrophilic NADH model, BzNAHCOOK in the external electron donor, a transmembrane electron transport to the internal acceptor, $K_3[Fe(CN)_6]$ through the flavolipid (**1**) was observed. BzNAHCOOK was proved to be an appropriate NADH model in the transmembrane electron transport study because of (i) the very low permeability through the bilayer membrane (k=1.0×10^{-3} s^{-1}) and (ii) the slow hydration rate (k=1.1×10^{-5} s^{-1}). The artificial liposome modified with the flavolipid showed a 6—7 times more efficient electron flux conversion from BzNAHCOOK to $K_3[Fe(CN)_6]$ than the liposome modified with the ubiquinone 10, a biologically important electron carrier. In association with the electron transport, electrochemical oxidation and reduction peaks of the flavolipid incorporated into the liposomal membrane were observed clearly by using Hg-electrode.

In the previous communications, we have reported a successful electron transport across the bilayer membrane of liposome functionalized with the flavolipid (**1**) from the external electron source to the internal acceptor.[1] This represents an artificial flavoprotein



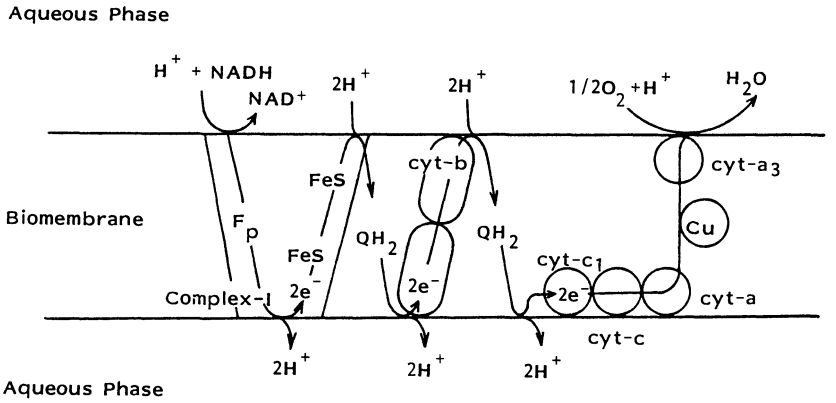
1

model which accepts electrons from $Na_2S_2O_4$ and donates them to $K_3[Fe(CN)_6]$. In an energetic view point, this means a large transmembrane driving force since $Na_2S_2O_4$ ($E_{1/2}$=−1.13 V vs. NHE) is a powerful reducing agent toward the flavin ($E_{1/2}$=−0.12 V and −0.37 V vs. NHE) and $K_3[Fe(CN)_6]$ ($E_{1/2}$=+0.36 vs. NHE). In native systems, the use of such an excess driving force is carefully avoided by choosing electron donors having appropriate reduction potentials. Dihydronicotinamide ($E_{1/2}$=−0.32 V vs. NHE) is the most important electron donor as seen in various NAD(P)H (hereafter abbreviated generally as RNAH) linked reductases, e.g. the NADH branch of the respiratory chain.[2] Here, RNAH interacts first with the membrane bound flavoprotein to initiate the transmembrane electron transport. RNAH molecular "flux" from the bulk aqueous to the membrane phase is converted to the electron "flux". This process is the first event of the respiratory chain and of primary importance even in the viewpoint of whole bioenergetics.[3]

According to the above considerations, it seems interesting and significant to construct an artificial Complex I of the respiratory chain.[4] The authors wish to report here a successful transmembrane electron transport through the flavoliposome system by using a RNAH model.

Results and Discussion

On the basis of the discussions described in the introductory section, the external electron donor



F_p: flavoprotein
FeS: iron-sulfur cluster
cyt: cytochrome
QH_2: ubiquinone 10

should be changed from a strong reducing agent such as $Na_2S_2O_4$ to RNAH derivatives. NADH itself is not a suitable reducing agent since it gives a too slow electron transport rate in the present flavoliposome system. This is not unusual and it is generally accepted that various NADH models give about 10^2 times faster rates toward flavin reduction than NADH itself in homogeneous solution.[5] This significant decrease of the reactivity of NADH is ascribed to the nature that a bulky and too hydrophilic NAD(P)H cannot get a molecular configuration appropriate for the electron transfer to flavin moiety without an assistance of the enzymatic binding. Therefore, a simple NADH model, 1-methyl-1,4-dihydronicotinamide (MeNAH) was considered as a candidate for the reductant. However the leakage rate of MeNAH through the lecithin bilayer membrane was too large (Table 1) to make practically difficult to estimate the net electron transport rate mediated by flavolipid because the material (MeNAH) transport overshadows the electron transport via flavolipid. MeNAH can not therefore be an appropriate NADH model. Introduction of stronger hydrophilicity is certainly required for the reductant to be used in the present membrane process. Therefore, we tested the potassium salt of *N*-(carboxymethyl)-1-benzyl-1,4-dihydronicotinamide (BzNAHCOOK)[6] as a reductant in the transmembrane electron transport study. The leakage rate of BzNAHCOOK was suppressed by a factor of 60 compared to that of MeNAH.

One of the disadvantages of the use of NADH model in the aqueous system arises often from its hydration.[7] BzNAHCOOK exhibited a superior characteristic in this point of view. The hydration rate of BzNAHCOOK in 5 mmol dm^{-3} Tris·HCl (pH=7.0) (k=1.1×10^{-5} s^{-1}) was 10^2 times slower than that of MeNAH in 5 mmol dm^{-3} Tris·HCl (pH=7.0) (k=1×10^{-3} s^{-1}). As will be illustrated later, this hydration

rate of BzNAHCOOK is slow compared with rates of the facilitated electron transport across the membrane modified with flavolipid, the latter being 10^{-2}—10^{-1} s^{-1}. In the following, the electron transport through the artificial membrane functionalized with an efficient electron transport catalyst was investigated by using BzNAHCOOK as the external reductant. This electron transport system containing $K_3[Fe(CN)_6]$ in its internal aqueous phase ($^{(o)}$BzNAHCOOK|fl-Lip|$^{(i)}$ $K_3[Fe(CN)_6]$) is expected to give a simplified, isotopochemical model of the NADH dehydrogenase in the Complex I of the respiratory chain in the mitochondrial inner membrane.

Effective Flux Conversion of NADH Model by Flavolipid. Electron influx ($J_{o\to m}$) from the external BzNAHCOOK to the flavolipid (fl^{ox}: the oxidized form of the flavin moiety) locating in the membrane phase, was monitored by the reduction of flavolipid, which was incorporated into the liposome without $K_3[Fe(CN)_6]$ in its interior ($^{(o)}$|fl^{ox}-Lip|$^{(i)}$), by the external BzNAHCOOK. In the same way, the electron efflux ($J_{m\to i}$) from the reduced flavolipid (fl^{red}) locating in the bilayer membrane phase to the internal $K_3[Fe(CN)_6]$ was obtained by monitoring the oxidation of fl^{red} in the membrane by $K_3[Fe(CN)_6]$ in the external aqueous phase. The apparent flux constants of $k_{o\to m}$ and $k_{m\to i}$ were obtained from the following equation:

$$J_{o\to m} = -k_{o\to m}\, S(o)[fl^{ox}]$$
$$J_{m\to i} = -k_{m\to i}\, S(i)[fl^{red}]$$

where the inner and the outer surface areas, S(i) and S(o) were estimated from the observation that the mean radius and the thickness of the liposome used were 35

Table 2. Oxidation of fl^{red} and Reduction of fl^{ox} in the Membrane

Reductant	Oxidant	$k_{o\to m}$[a,b)]	$k_{m\to i}$[a,b)]

4.3		2.7 ×10^{-7}	
8.8		5.6 ×10^{-7}	
$Na_2S_2O_4$	—		
1.0		6.9 ×10^{-5}	
—	$K_3[Fe(CN)_6]$	—	
	0.9		1.2×10^{-5}

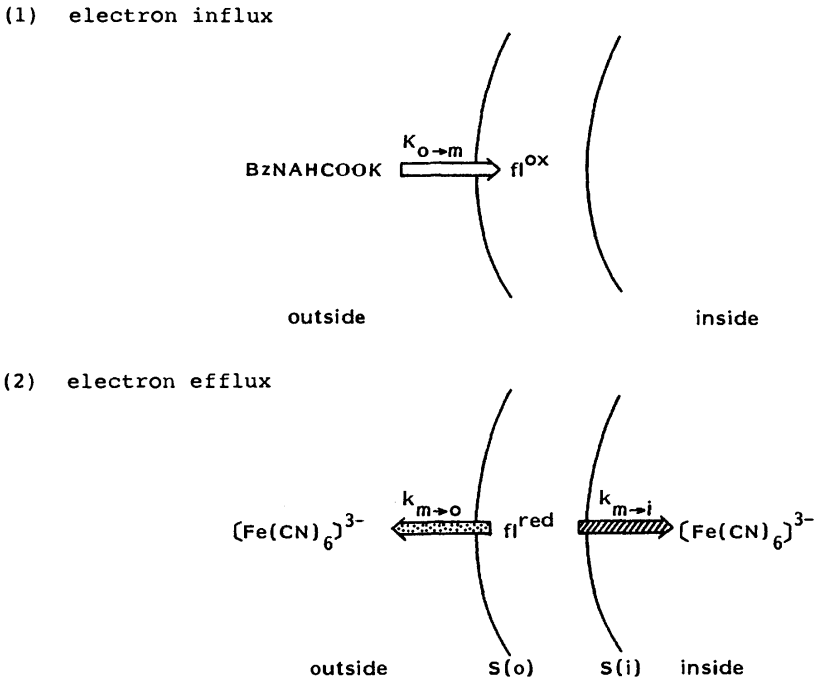
a) [liposome]=1.0×10^{-6} mol dm^{-3}, outer surface area=9×10^4 cm^2. b) $J_{o\to m}=-k_{o\to m}\cdot S(o)\,[fl^{ox}]$, $J_{m\to i}=-k_{m\to i}\cdot S(i)[fl^{red}]$.

and 4 nm, respectively. Since the apparent electron efflux constant ($k_{m\to i}$) can not be determined directly, it was estimated from the following:

$$k_{m\to i}=k_{m\to o}\cdot S(i)/S(o)=2/3\cdot k_{m\to o}$$

where $k_{m\to o}$ is a value determined by the oxidation of the reduced flavolipid by the externally added $K_3[Fe(CN)_6]$ (see Scheme 1). It should be mentioned that the local concentration of $K_3[Fe(CN)_6]$ in the internal aqueous phase was in the order of 10^{-1} mol dm^{-3} in the oxidation of fl^{red} by the internal $K_3[Fe(CN)_6]$ ($J_{m\to i}$), while the concentration of $K_3[Fe(CN)_6]$ in the external aqueous phase was in the order of 10^{-3} mol dm^{-3} in the oxidation of fl^{red} by the external $K_3[Fe(CN)_6]$ ($J_{m\to o}$). It is practically impossible to determine the value of $k_{m\to o}$ at the concentration range of 10^{-1} mol dm^{-3} $K_3[Fe(CN)_6]$. Therefore, $k_{m\to i}$ determined by this way may give an underestimated value. Even so, it is safely concluded that the apparent $J_{m\to i}$ from fl^{red} to Fe^{III} was much larger than the apparent $J_{o\to m}$ from BzNAHCOOK to fl^{ox}.

The apparent electron influx constant ($k_{o\to m}$) from BzNAHCOOK to fl^{ox} was 10^3—10^4 times slower than that from $Na_2S_2O_4$ to fl^{ox}, when compared at a similar reductant concentration (ca. 1.0×10^{-3} mol dm^{-3}). The much slower reduction rate of flavolipid by BzNAHCOOK than by $Na_2S_2O_4$ (−1.13 V vs. NHE)[8c] may reflect the nature of a much weaker electron donor



S(o) : outer surface area of the liposome

S(i) : inner surface area of the liposome

Scheme 1. Measurement of electron influx and electron efflux.

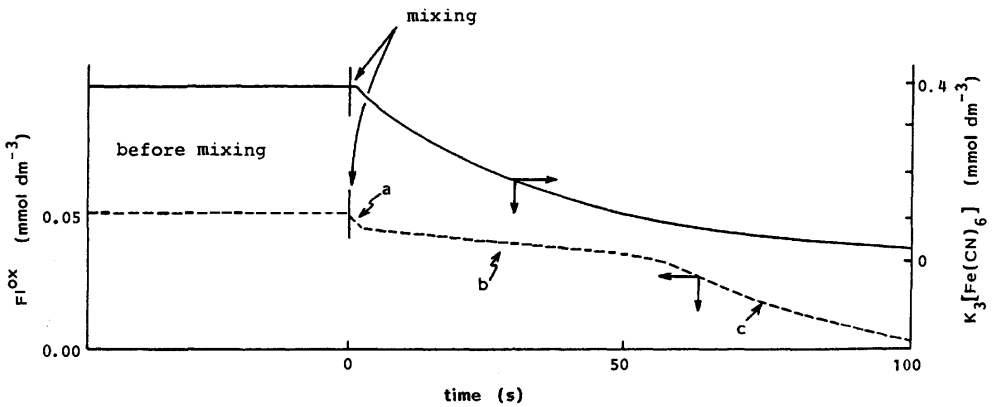


Fig. 1. Change of the concentration of the fl^{ox}-lip in the bilayer membrane (----) and the internal $K_3[Fe(CN)_6]$ (——) during the electron transport reaction by BzNAHCOOK. For a,b, and c, refer the text.

to the flavolipid than the latter.

In the reduction of internal $K_3[Fe(CN)_6]$ by the external BzNAHCOOK across the flavomembrane, a fast reduction of the flavin moiety to the corresponding dihydroflavin was observed at the very initial stage of the reaction (region "a" in Fig. 1). This process was followed by an apparent steady state, where the ratio fl^{red} to fl^{ox} was kept practically constant (region "b", fl^{red}/fl^{ox}=1/9—3/7), while most of the $K_3[Fe(CN)_6]$ was consumed during the period. This fl^{red}/fl^{ox} ratio was much smaller than that in the reduction of internal $K_3[Fe(CN)_6]$ by the external $Na_2S_2O_4$ (6/4=fl^{red}/fl^{ox}) under the same reductant concentration. This reflects the slower electron influx from the outside BzNAHCOOK to the fl^{ox} in the membrane than that from $Na_2S_2O_4$. When most of the $K_3[Fe(CN)_6]$ was reduced, the steady state disappeared and a first order decrease of the flavin (fl^{ox}) was followed (region "c"). In the above steady state, the rate-determining step of the total electron-transport reaction must be the electron influx step from the external BzNAHCOOK to the flavolipid in the membrane because the rate was first order with respect to the concentration of the external BzNAHCOOK as seen from Table 3 and Fig. 2. Even at the highest concentration of BzNAHCOOK, the rate was not saturated as observed. As reported previously for the case of $Na_2S_2O_4$, the saturation of the reduction rate of the internal $K_3[Fe(CN)_6]$ indicated that the rate determining step of the overall reaction was shifted from the electron influx process ($J_{o\to m}$) to the flavin-flavin electron transfer one (see Fig. 3).[1] Furthermore the rate observed here (k) was far slower than the $k_{m\to i}\cdot S(i)$. These observations are compatible with the idea of rate-determining influx. The rate constants of the overall electron transport are summarized in Table

Table 3. Reduction Rate Constants of Internal $K_3[Fe(CN)_6]$ by BzNAHCOOK in the Functionalized Liposomes

a) $-d[K_3[Fe(CN)_6]]/dt=k[K_3[Fe(CN)_6]]$, at 30 °C, pH 7.0. b) Flavolipid/Lecithin=UQ 10/Lecithin=2.5/97.5 (mol/mol), $[K_3[Fe(CN)_6]]$=0.39 mmol dm^{-3}. Local concentration of $K_3[Fe(CN)_6]$ was 0.75 mmol dm^{-3}. c) DTT: Dithiothreitol.

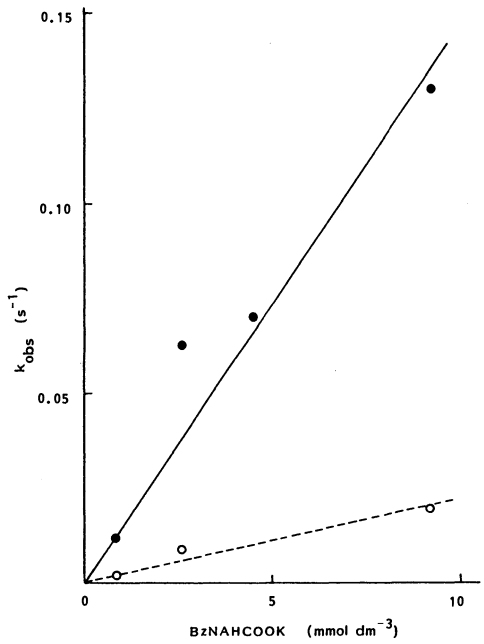

Fig. 2. $K_3[Fe(CN)_6]$ reduction by external BzNAHCOOK across the membrane modified with flavolipid or ubiquinone 10: fl-Lip (—●—), UQ 10 (--○--).

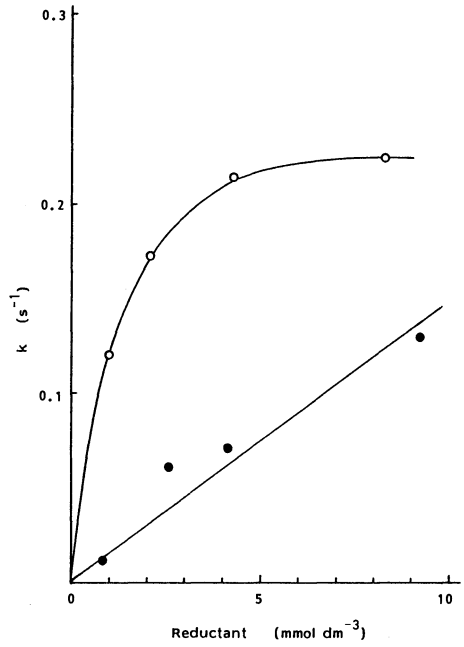

Fig. 3. Dependence of k on the concentration of the external reductant: $Na_2S_2O_4$ (—○—), BzNAHCOOK (—●—).

3 together with those of liposomes modified with ubiquinone 10 (UQ 10) and dibutylviologen (C_4V^{2+}). The flavolipid is a better catalyst for the electron transport from the external BzNAHCOOK to the internal $K_3[Fe(CN)_6]$ than ubiquinone 10. It is interesting to recall that in the case of $Na_2S_2O_4$, the liposome modified with ubiquinone 10 showed more than four time faster rate for the transmembrane electron

transport than the present flavoliposome. This rate order is reversed when the NADH model is employed as the reducing agent. In the electron transfer through the flavoliposome, it was demonstrated that the rate determining step was an influx, from the external reductant to the outer fl^{ox} (out) in the membrane in the case of BzNAHCOOK, while it was an efflux, from the inner fl^{red} to the $K_3[Fe(CN)_6]$ in the case of $Na_2S_2O_4$. Although the rate-determining step was determined to be the influx when BzNAHCOOK was employed, there is no information on it for the case of ubiquinone 10 modified liposome by the reductant of $Na_2S_2O_4$.[9] Therefore it is difficult to make a direct comparison of the overall electron-transfer rates for the flavoliposome and the ubiquinone 10 modified liposome in the case of $Na_2S_2O_4$. It is interesting that the flavoliposomes gave faster electron-transfer rates by the combination with a biologically important reducing agent such as NADH model than the ubiquinone 10 modified liposome system did. One of the important roles of the flavoprotein in the Complex I in the respiratory chain is the more efficient flux conversion from NADH in the bulk aqueous phase to the flavin moiety locating in the membrane phase than the direct flux conversion from NADH to ubiquinone 10. The result presented here may suggest a possible operation of such an electron relay system.

Dibutylviologen which is a moderately efficient electron-transport catalyst in the case of $Na_2S_2O_4$, showed only a poor catalytic activity in this case. This may reasonably be accounted for by considering the potential differences. The redox potential of C_4V^{2+} is -0.44 V vs. NHE,[8b] which means the reduction by BzNAHCOOK ($E_{1/2}=-0.36$ V vs. NHE at pH 7, two electron reduction-oxidation potential)[8a] is a thermally unfavorable reaction. Thus, the very slow electron-transport rate of C_4V^{2+} using BzNAHCOOK can be ascribed to the slow reduction rate of C_4V^{2+} by BzNAHCOOK.

The present flavoliposome can be reduced also by other weak electron donors. As a hydrogen-metabolizing system, hydrogen/colloidal platinum was used as a reducing agent in this system.[10] Dithiothreitol (DTT) also reduced this system, suggesting the possibility that the flavoliposome could work as a lipoyl dehydrogenase model.[11] From these various electron transport systems, the artificial liposome modified with the flavolipid was demonstrated to work as an effective model system for the study of biological electron transport.

Electrochemistry of Flavolipid Incorporated into the Bilayer Membrane. In order to know the oxidation states of the flavolipid in the electron transport process across the lipid membrane, electrochemical redox reactions of the flavolipid were examined. The cyclic voltammogram (CV) of the flavolipid incorporated into the lecithin bilayer membrane in water ($^{(o)}|$fl-Lip$|^{(i)}$) (pH 7.0) showed two clear pairs of cathodic and anodic

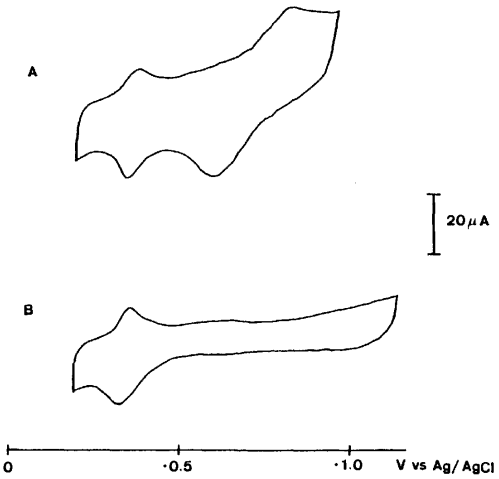

Fig. 4. Cyclic voltammograms on Hg-pool of the flavoliposome in 5 mmol dm^{-3} Tris HCl (pH=7.0). A: ($^{(o)}|$fl-Lip$|^{(i)}$), B: ($^{(o)}|$fl-Lip$|^{(i)}$ $K_3[Fe(CN)_6]$).

waves at -0.35 and -0.70 V vs. Ag/AgCl using a Hg-pool as a working electrode (Fig. 4). It is reported previously[12] that lecithin and other surfactants in water are adsorbed on a Hg electrode surface to inhibit the normal redox reactions of Cd^{2+} on the electrode.[13] In spite of such an inhibitory effect of lecithin, the present flavoliposome (0.025 mmol dm^{-3} flavolipid) afforded clear oxidation-reduction peaks. This may be explained by the idea that the flavin unit (redox site of the liposome) locates in the vicinity of the Hg-lecithin membrane interphase to favor the electron uptake and release from Hg to flavin and vice versa, respectively. In a contrast to the above case, the flavoliposome containing $K_3[Fe(CN)_6]$ in its internal aqueous phase ($^{(o)}|$fl-Lip$|^{(i)}$ $K_3[Fe(CN)_6]$) afforded only one redox couple of cathodic and anodic waves at -0.35 V vs. Ag/AgCl. Assignment of clearly separated two-step redox conversion is now under investigation in relation to the electron transfer reaction from BzNAHCOOK and/or $Na_2S_2O_4$ to $K_3[Fe(CN)_6]$ across the flavomembrane.

Experimental

Instruments. ^{1}H NMR spectra were obtained with a JEOL JNM PMX 60 SI NMR spectrometer, a JEOL JNM FX90Q FT NMR spectrometer or a JEOL JNM GX400 spectrometer. Mass spectra were obtained with a JEOL JMS-DX300 mass spectrometer. IR spectra were recorded on a Hitachi model 260-50 spectrophotometer. Fluorescence spectra were measured with a Shimadzu difference spectrofluorophotometer RF-503A. Electronic spectra were measured with either a Union SM-401 high sensitivity spectrometer or a Hitachi U-3400 spectrophotometer. Sonication was performed with an ultrasonic disruptor, Model UR-200P (Tomy Seiko). Centrifugation was carried out with a refrigerated centrifuge, Tomy Seiko Model RS-20III. Measurement of pH was performed on a Toa pH meter, Model HM 5-ES instrument.

Materials. Unless otherwise noted, all reagents and chemicals were obtained commercially and used without further purification. Egg yolk lecithin was carefully purified according to the literature method[14] and stored at −75 °C under Ar in the dark until its use. BzNAHCOOK was prepared according to the literature method[6] and identified by ^{1}H NMR, IR, electronic spectra and mass spectra.

Preparation of Artificial Single-Wall Bilayer Liposome. The artificial egg lecithin liposome containing $K_3[Fe(CN)_6]$ in its internal aq. phase ($^{(o)}$|lecithin|$^{(i)}$ $K_3[Fe(CN)_6]$), the artificial liposome modified with the flavolipid ($^{(o)}$|fl-Lip|$^{(i)}$) and the liposome modified with the flavolipid containing $K_3[Fe(CN)_6]$ in its internal aqueous phase ($^{(o)}$|fl-Lip|$^{(i)}$ $K_3[Fe(CN)_6]$) were prepared according to the sonication method reported previously by us.[16]

Measurement of Leakage Rate of NADH and its Models through the Bilayer Membrane. Leakage rates of NADH and its model compounds through the lecithin bilayer membrane were measured by observing the reduction of internal $K_3[Fe(CN)_6]$ in the lecithin liposome without the flavolipid ($^{(o)}$|lecithin|$^{(i)}$ $K_3[Fe(CN)_6]$). Into the 2.0 mL of the deaerated liposome solution (5 mmol dm^{-3}. Tris HCl, pH=7.0) was added 0.2 mL of the deaerated NADH model solution freshly prepared using a syringe stopped flow apparatus.[15] Reduction of the internal $K_3[Fe(CN)_6]$ was followed by monitoring the change in the absorbance at 425 nm.

Reduction of Flavolipid (fl^{ox}) Incorporated into the Bilayer Membrane by External BzNAHCOOK. Reduction of the flavolipid incorporated into the bilayer membrane by BzNAHCOOK was performed using the freshly prepared flavoliposome ($^{(o)}$|fl-Lip|$^{(i)}$) in a way similar to the reduction by $Na_2S_2O_4$ described previously.[15]

Oxidation of Flavolipid (fl^{red}) Incorporated into the Bilayer Membrane by External $K_3[Fe(CN)_6]$. A freshly prepared flavoliposome solution ($^{(o)}$|fl-Lip|$^{(i)}$), 2.0 mL) was placed in a 10 mm quartz cell equipped with a three-way stopcock. After the solution was deaerated by the usual method, 0.2 mL of a freshly prepared $Na_2S_2O_4$ (2.0 mmol dm^{-3}) solution was added. The reduction of fl^{ox} was ascertained to be complete within one minute by monitoring the change of absorbance at 444 nm. Then, into the reduced flavoliposome solution ($^{(o)}$ $Na_2S_2O_4$|fl^{red}-Lip|$^{(i)}$) at 25 °C, 0.2 mL of a deaerated $K_3[Fe(CN)_6]$ solution (11.0 mmol dm^{-3}) was added by using a specially designed syringe.[15] The reoxidation of fl^{red} in the bilayer membrane was followed by monitoring the change of the fluorescence intensity at 510 nm excited at 340 nm.

Reduction of $K_3[Fe(CN)_6]$ in the Internal Aqueous Phase of the Flavoliposome by External BzNAHCOOK. Reduction of the internal $K_3[Fe(CN)_6]$ by the external BzNAHCOOK was carried out by using the method similar to the reduction by $Na_2S_2O_4$, except that the ratio of fl^{red} to fl^{ox} was 1/9—3/7 in the steady state reduction.

Cyclic Voltammetry of the Flavoliposome. A Bioanalytical system CV-1B cyclic voltammograph was employed for the cyclic voltammetric determination of the flavolipid incorporated into the bilayer membrane. A freshly prepared flavoliposome solution (5 mL) was degassed by nitrogen bubbling for 0.5 h. As a supporting electrolyte, a KCl solution (0.1 mol dm^{-3}) was used and a Hg-pool electrode was used as a working electrode. Potentials were determined at 25 °C vs. an Ag/AgCl electrode as a reference.

Measurement of Hydration Rate of NADH Models in Tris Buffer Solution. Hydration rate of NADH models was monitored by the first order decrease of the intensity of the absorbance at 360 nm, characteristic of the reduced form of NADH models by using a freshly prepared solution of NADH model compound in 5 mmol dm^{-3} Tris·HCl (pH 7.0).

Synthesis, Structure, and Hypochromism of Pyrimidinopurinophanes[1)]

Kazuo Doyama, Takayuki Higashii, Fumio Seyama, Yoshiteru Sakata,* and Soichi Misumi
The Institute of Scientific and Industrial Research, Osaka University, Ibaraki, Osaka 567
(Received May 12, 1988)

Seventeen pyrimidinopurinophanes in which a pyrimidine and a purine ring are fixed with different mode of stacking were prepared. The synthesis was carried out by stepwise introduction of two bridging chains. In the final ring closure reaction, two isomers, i.e., isomers bridged at 9-position of a purine ring and those having the bridge at 7-position of a purine ring were obtained. The structures of the isomers were determined on the basis of ^{1}H NMR, IR, and UV spectra and X-ray analysis. In ^{1}H NMR spectra the bridge protons of the pyrimidinopurinophanes show complex multiplets, in contrast to the first order splittings in singly bridged reference compounds. This shows clearly the fixation of the conformations of the present cyclic compounds at room temperature. All of the pyrimidinopurinophanes show relatively large hypochromism (H) values. Even the compounds **2a—2d**, **4**, and **6** where the two base rings are not stacked in parallel, but inclined with the dihedral angle of around 50°, show H values of 10—20%. The H values did not change among the compounds **1c**, **1e—1g**, and **3** which have similar parallel-stacking structures of the two base rings. The results are well explained by the simplified equation of Ts'o et al.

Hypochromism — a decrease in the absorption intensity per unit chromophore — is observed frequently in various π-systems and biologically important substances such as proteins and DNA, where chromophores involved are stacked in a parallel fashion.[2)] The relationship between the stacking orientation and hypochromism values, however, has not been well-understood so far. Recently, we prepared a series of purinophanes where two purine rings are fixed with different mode of stacking.[3)] By analyzing the relationship between their hypochromism values and geometrical parameters from the X-ray results, we presented empirical formulas to estimate the hypochromism values for a given geometry of two stacked purine rings.

We set forward our study for the general understanding of the interaction between two nucleic acid bases other than two purine rings. Since purine-pyrimidine interaction is the greatest after purine-purine interaction,[4)] we planned to synthesize various pyrimidinopurinophanes, in which a purine and a pyrimidine ring is fixed with different modes of relative orientation. Related compounds, prepared so far, are singly bridged compounds, i.e., (pyrimidine)-$(CH_2)_n$-(purine)[4)] with changing the length of the chain and connecting positions at the base rings. They are, however, conformationally not frozen in solution and therefore, not well-suited for the quantitative treatment of hypochromism values in relation to the precise stacking orientation. The present rigid systems are expected to serve useful information about the structural dependence of hypochromism values.

Synthesis

All the pyrimidinopurinophanes **1—6** were prepared by step-wise introduction of the bridging chains. Thus, the singly bridged compounds **7—13** were first prepared starting from the corresponding pyrimidine and purine derivatives as shown in Chart 1. The second chain was introduced by ring closure with α,ω-

dibromoalkanes in the presence of sodium hydride in DMF (method A) and/or potassium carbonate in DMSO (method B). The coupling reaction gave two isomeric products, i.e., (1′,3′)pyrimidino(6,9)purinophanes **1** and (1′,3′)pyrimidino(6,7)purinophanes **2**. These structures were determined on the basis of spectral data and X-ray analysis as described later. The ratios of the two isomers are different in A and B methods as shown in Table 1. In all runs except for the ratio of **1b**/**2b** by the method B, the isomers **2** (bridged at 7-position of the purine ring) are the major or sole product. The other pyrimidino-purinophanes **1e**—**1g**, **2e**—**2g**, and **3**—**6** were prepared by the method A and the yields are summarized in Table 1.

Monomeric and dimeric references **27**,[3] **28**,[3] **29**,[5] **30**,[6] **31**,[7] **32**, and **33** were also prepared.

Structure

NMR Spectra. ^{1}H NMR spectra of the present molecules were measured in deuteriochloroform. The bridge protons of all the pyrimidinopurinophanes **1**—**6** show complex multiplets in contrast to the first order splitting patterns of acyclic reference compounds **32** and **33**. These results clearly indicate that the conformations of **1**—**6** are almost frozen at room temperature. The chemical shifts of the ring protons (H2, H8, H5′, and H6′) of the pyrimidinopurinophanes and reference compounds are summarized in Table 2. Since H2 and H8 protons of **27** or **28** resonate at higher field than the corresponding protons of **29** or **30**, the isomers which show the similar tendency in the chemical shifts of H2 and H8 to those of **27** or **28** were assigned to the structure having a linkage at 9-position of the purine ring, i.e., **1b**—**1g**, **3**, and **5** and the others were assigned to **2a**—**2g**, **4**, and **6**. The assignments were supported by IR and UV spectra and finally confirmed by X-ray analysis for **1d** and **2c**, described later. In Table 2, the protons H8 and H6′ of **1**, **3**, and **5** show high field shift, except for H8 of **5**, compared with the monomeric references, suggesting that the purine and the pyrimidine rings are stacked in face-to-face. On the other hand, **2**, **4**, and **6** might have the non-stacked orientation of the two base rings, because of the small $\Delta\delta$ values of the ring protons. The magnitude of $\Delta\delta$ values for all the ring protons of **1b**—**1g** in Table 3 are close with each other, indicating that the orientation of the purine and the pyrimidine ring in a molecule is not so different from that of **1d**, whose structure was determined by X-ray analysis. Similarly, the orientation of the two base rings in **2a**, **2b**, **2d**—**2g** might have close resemblance to that of **2c**, the structure of which was also determined by X-ray analysis.

Marked high field shift ($\Delta\delta$=−2.25 ppm) was observed for H6′ of **5**. One possible structure of **5** is that the two rings are hold in a orientation similar to that of [2.2]metaparacyclophane-1,9-diene, where the two aromatic rings are inclined to each other by 41°.[8] If **5** takes such conformation, H6′ locates closely above the center of the purine ring and hence, the large negative value of $\Delta\delta$ for H6′ and small positive one for H8 are reasonably accepted. In order to examine the rigidity of the conformation, temperature dependence of

the protons of **5** was measured in the range of −80—+150 °C. The signals of aromatic protons remain almost unchanged both in chemical shifts (less than 0.2 ppm) and in their shapes. Furthermore, the patterns of the complex multiplets due to the bridge protons of **5** did not change in the same temperature range. These results suggest that the conformation of **5** is much stable than that of [2.2]metaparacyclophane, where the coalescence temperature is 146 °C.[9]

IR Spectra. We found the easiest way to distinguish the isomers **1** (X=S) from **2** (X=S) by IR spectra. According to our empirical rule, there is only one absorption band in the region of 1500—1600 cm^{-1} for 9-substituted thiopurines **1** (X=S), **3**, **5**, and **28**, while two peaks are present for 7-substituted thiopurines **2** (X=S), **4**, **6**, and **30**. The results are summarized in Table 3. From the table the exceptions of the rule are only for **1g** and **2g**, where the nitro group is responsible for the additional peak.

UV Spectra. Based on the difference (2 nm) of the longest-wavelength absorption band between 9-methyl- and 7-methyl-6-(methylamino)purines (**27** and **29**), the structures of the isomers **1b** and **2a**, **b** are assigned as shown in Table 4.[10]

X-Ray Analysis. In order to confirm the assignments of the structures of **1** and **2** in Tables 3 and 4, X-ray analysis was carried out for **1d** and **2c**. The crystal structures were solved[11] by a program MULTAN-78[12] and refined by least-squares method. The final R values are 0.038 for **1d** and 0.047 for **2c**. The resulting ORTEP drawings are shown in Figs. 1 and 2. The two base planes are almost parallel in **1d** (dihedral angle: 12.5°) with the interplanar distance of about 3.8 Å, while in **2c** they incline with each other with the dihedral angle of 50.4°. The bond angles and bond lengths of the two rings in **1d** and **2c** are almost the same values as those of 6-(methylthio)purine[13] and 1,3-dimethyluracil,[14] indicating that there is no special ring strain in the composite rings of **1d** and **2c**.

Hypochromism

Electronic spectra of the pyrimidinopurinophanes described above and reference compounds are mea-

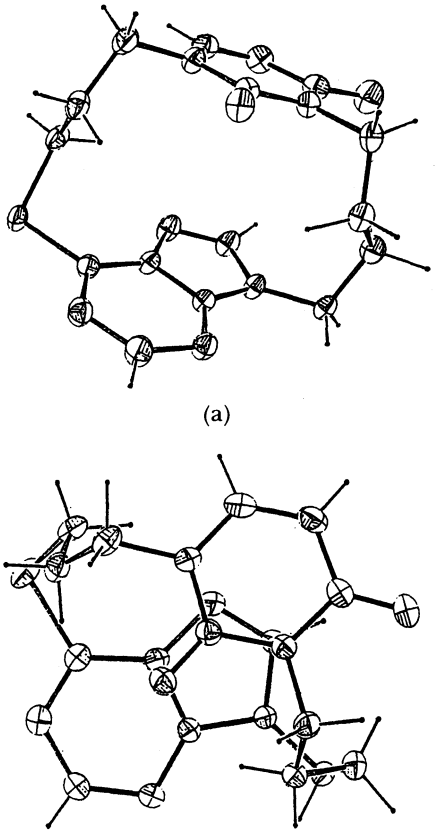

Fig. 1. Molecular structure (a) and views on the least-squars plane defined with a purine ring (b) in **1d**.

sured in ethanol and in water. Typical examples are shown in Figs. 3—6. In the figures difference spectra, which were obtained by subtracting the intensities of a given pyrimidinopurinophane from the sum of the values of the two consisting monomeric references. Hypochromism values were calculated according to the following equations:

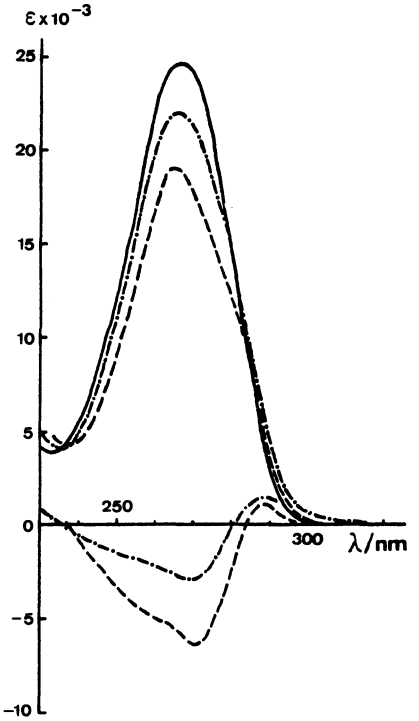

Fig. 3. Electronic spectra of **1b** (----), **32** (-·-·-), and (**27**+**31**) (——) in water and difference spetra of **1b** and **32** vs. (**27**+**31**).

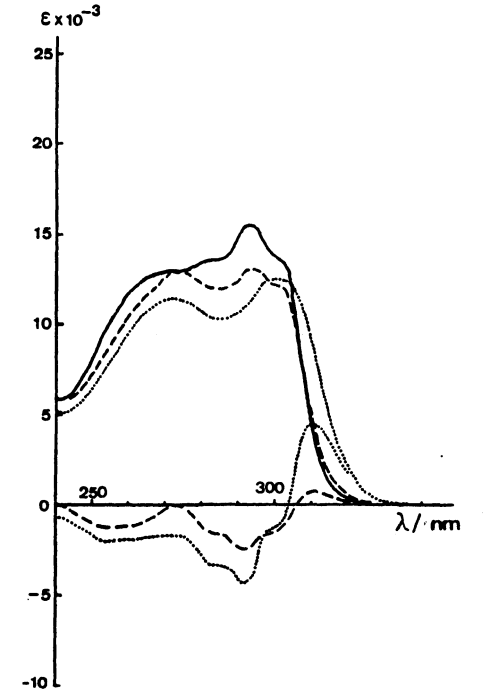

Fig. 6. Electronic spectra of **2c** (------), **2d** (----), and (**30**+**31**) (——) in water and difference spectra of **2c** and **2d** vs. (**30**+**31**).

$$\%H = (1 - (f_D/2f_M)) \times 100$$

$$f = 4.32 \times 10^{-9} \int (\varepsilon(\lambda)/\lambda^2) d\lambda, \quad (1)$$

where f_M and f_D are oscillator strength of monomer and dimer, respectively and these values were obtained by dividing the absorption curves into rectangles at intervals of 2 nm. The results are summarized in Table 5. In marked contrast to the small values for the linear dimers **32** and **33**, the hypochromism values of all the pyrimidinopurinophanes are relatively large and remain almost unchanged in ethanol and in water. This indicates that the structures of the present doubly bridged compounds in solution are almost the same as in the crystalline state. It is worthy of emphasis that **2a—2d** show relatively large hypochromism values in spite of the nonparallel orientation of the two base rings.

The almost parallel stacking of the two chromophores in **1a—1g** brings about larger hypochromism values than those of the corresponding isomers **2** having nonparallel orientation. However, the values of **1a—1g** are still smaller than those of purinophanes where two purine rings are held in face-to-face, due to the smaller interaction in pyrimidine-purine than in purine-purine.

The origin of hypochromism is the interaction between the lowest excited electronic state of a given chromophore and different electronic states of the neighboring chromophores. The theoretical calculation is very difficult since a number of configurational interactions must be taken into account. Ts'o et al.,[15] presented a simplified equation of evaluating hypochromism values (H%) for homodimers with parallel stacking:

$$H = A(1 - 3\cos^2\theta)/R_{ij}^3 \quad (2)$$

where R_{ij} is the distance between the center of i and j rings, θ is the angle between R_{ij} and the transition moment, and A is a constant. From the Eq. 2, H value is independent on the magnitude of the transition moments and if the two base rings of the pyrimidinopurinophanes are fixed with the same orientation, they should have the same H value. This is valid when the hypochromism values of **1c** and **1e—1g** in Table 5 are compared. Thus, the values of these compounds are almost identical with each other. The compounds should have very similar structure because of the same carbon framework, although the transition moments of the pyrimidine rings are different in magnitude owing to the introduction of the substituents. On the basis of molecular model considerations the stacking

Table 5. Hypochromism Values H(%) of Pyrimidinopurinophanes and Related Compounds in Two Solvents

	1b	**1c**	**1d**	**1e**	**1f**	**1g**	**2a**	**2b**	**2c**	**2d**	**3**	**5**	**32**	**33**
H_2O	24	28	20	27	30	26	15	17	11	8	29	27	9	2
EtOH	27	35	31	23	25	23	21	14	20	11	27	23	0	5

orientation of **3** is presumed that the two rings are kept in parallel with the same interplanar distance as that of **1c**, but one chromophore is rotated in its plane by 120° for **3**. In spite of the stacking geometry different from **1c**, *H* values of **3** are very similar to those of **1c**, supporting the validity of Eq. 2. These facts clearly show that the simplified Eq. 2 for homodimers is also applicable to the evaluation of H values for the parallel stacking of a pyrimidine and a purine ring without tedious molecular orbital calculations including a number of configurational interactions.

It is somewhat strange that the *H* values of **5**, where the two base rings seem to be not in parallel as discussed in NMR spectra, are identical with those of **1c**. Presumably, this is derived incidentally and the quantitative treatment of the H value in relation to the structure must wait for the structural determination of **5** by X-ray analysis.

The value of A in Eq. 2 is estimated to be around 1.2×10^3 by assuming that $\theta=90°$ and $R=3.5$ (from molecular model considerations) and 4.0 Å (from X-ray results) for **1c** and **1d**, respectively. The values are in good agreement with those estimated for the homodimers of 6-thiopurine ($A=1.30\times10^3$).[3]

The present and previous[3] results demonstrate that we can use Eq. 2 for the evaluation of *H* values of parallel-stacked nucleic acid base pairs, i.e., purine-purine and purine-pyrimidine rings.

Experimental

All melting points were uncorrected. NMR spectra were measured on a Hitachi R-24A (60 MHz), a JNM FX-100 (100 MHz), and a Bruker WH-360 (360 MHz). IR and mass spectra were recorded on a Hitachi EPI-G2 and a Hitachi RMU-7, respectively. Electronic spectra were taken on a Hitachi EPS-3T and a Hitachi 330. Liquid chromatography was performed on Nihon Bunsekikogyo LC-08 and LC-09.

1-(3-Aminopropyl)uracil, Formate Salt (15). To a stirred mixture of **14**[16] (3.0 g, 10 mmol) in ethanol (150 ml) heated to reflex was added hydrazine monohydrate (1.1 g, 22 mmol). The mixture was stirred at reflux for 8 h and ethanol was removed. To the residue was added 2 M HCl (30 ml; 1M=1 mol dm^{-3}) and the suspension was stirred at room temperature for 30 min. Insoluble solid was filtered off and the filtrate was concentrated. The solid was dissolved in a minimum amount of distilled water and the solution was passed through a column of Dowex 1-X8, formate form. Water was removed and the residue was recrystallized from absolute ethanol to give 1.66 g (77% yield) of **15**. **15**: Colorless solid; mp 152—155 °C; MS *m/z* 169 (M^+); ^{1}H NMR (DMSO-d_6, 60 MHz) δ=1.8 (q, *J*=7.0 Hz, 2, $NCH_2\underline{CH_2}$), 2.7 (t, *J*=7.0 Hz, 2, $\underline{CH_2}$-NH_3^+), 3.7 (t, *J*=7.0 Hz, 2, NCH_2), 5.6 (d, *J*=8.0 Hz, 1, ArH(5)), 7.7 (d, *J*=8.0 Hz, 1, ArH(6)), 8.4 (s, 1, CHO).

N^6-[3-(Uracil-1-yl)propyl]adenine (7). 6-Chloropurine (0.72 g, 4.6 mmol) and **15** (1.0 g, 4.6 mmol) was dissolved into ethanol (30 ml) containing triethylamine (1.4 ml, 10 mmol) and the solution was refluxed for 40 h under nitrogen atmosphere. After the reaction was over, the mixture was cooled at 0 °C for 2 h and yielded solid was filtered and washed well with cold water. This was dissolved into dil acetic acid (90 ml) with heating. After treatment with active carbon, the solution was neutralized with concd NH_3. Precipitates were filtered, washed with water and then, with acetone, and dried to give crude **7** (1.1 g, 80% as half hydrate). **7**: white solid from methanol-acetic acid, decomp>291 °C; MS *m/z* 287 (M^+); ^{1}H NMR (DMSO-d_6, 100 MHz) δ=1.91 (q, *J*=6.8 Hz, 2, $NCH_2\underline{CH_2}$), 3.54 (br.s, 2, $NH\underline{CH_2}$), 3.75 (t, *J*=6.8 Hz, 2, NCH_2), 5.53 (d, *J*=7.8 Hz, 1, ArH(5′)), 7.61 (br.t, 1, NH(6)), 7.70 (d, *J*=7.8 Hz, 1, ArH(6′)), 8.07 (s, 1, ArH(8)), 8.17 (s, 1, ArH(2)), 11.3 (br.s, 1, NH(3′)), 12.7 (br.s, 1, NH(9)); UV (EtOH) λ_{max} 268 nm ($\varepsilon=26.7\times10^3$). Found: C, 48.68; H, 4.61; N, 32.83%. Calcd for $C_{12}H_{13}N_7O_2\cdot1/2H_2O$: C, 48.64; H, 4.76; N, 33.09%. After heating of the above compound at 180 °C for 30 min, **7** without water of crystallization was obtained. Found: C, 50.22; H, 4.59; N, 33.91%. Calcd for $C_{12}H_{13}N_7O_2$: C, 50.17; H, 4.56; N, 34.13%.

6-[3-(Uracil-1-yl)propylthio]purine (8). A solution of **16**[4] (500 mg, 2.15 mmol) and thiourea (170 mg, 2.23 mmol) in ethanol (20 ml) was refluxed for 8 h. After reaction was over, ethanol was removed under reduced pressure. To the resulted semisolid was added water (15 ml) and nitrogen gas was passed through the apparatus to displace the air. To the heated mixture at 90 °C was added sodium hydroxide (170 mg, 4.3 mmol) and after ten minutes followed by the addition of 6-chloropurine (660 mg, 4.3 mmol) and the mixture was heated for 1 h. After cooling, yielded solid was filtered, washed with water and dried to give 540 mg (84% yield) of **8**. **8**: White powder from methanol-acetic acid; decomp >260 °C. MS *m/z* 304 (M^+). ^{1}H NMR (DMSO-d_6, 100 MHz) δ=2.04 (q, *J*=6.9 Hz, 2, $SCH_2\underline{CH_2}$), 3.35 (t, *J*=6.9 Hz, 2, SCH_2), 3.81 (t, *J*=6.9 Hz, 2, NCH_2), 5.56 (d, *J*=7.8 Hz,1, H5′), 7.67 (d, *J*=7.8 Hz, 1, H6′), 8.42 (s, 1, H8), 8.64 (s, 1, H2), 11.2 (br. s, 1, U-NH), 12.4 (br.s, 1, Pu-NH).

Found: C, 47.47; H, 4.05; N, 27.53; S, 10.42%. Calcd for $C_{12}H_{12}N_6SO_2$: C, 47.36; H, 3.98; N, 27.61; S, 10.53%.

6-[3-(Thymin-1-yl)propylthio]purine (9). Compound **9** was prepared starting from 1-(3-bromopropyl) thymine[3] by the similar procedure described for **8**. **9**: 89% yield; colorless fine needles from DMF-water; mp 279.0—282.5 °C with decomp. MS *m/z* 318 (M^+). ^{1}H NMR (DMSO-d_6, 360 MHz) δ=1.74 (d, *J*=1.0 Hz, 3, CH_3), 2.04 (q, *J*=7.0 Hz, 2, $SCH_2\underline{CH_2}$), 3.35 (t, *J*=6.8 Hz, 2, SCH_2), 3.78 (t, *J*=6.8 Hz, 2, Th-NCH_2), 7.53 (s, 1, H6′), 8.41 (s, 1, H8), 8.64 (s, 1, H2), 11.19 (br. s, 1, Th-NH).

Found: C, 49.09; H, 4.50; N, 26.18; S, 10.31%. Calcd for $C_{13}H_{14}N_6SO_2$: C, 49.05; H, 4.43; N, 26.40; S, 10.07%.

1-(3-Bromopropyl)-5-methoxyuracil (18). To a solution of 5-methoxyuracil[17] (7.1 g, 50 mmol) and trimethylsilyl chloride (10.9 g, 100 mmol) in dry benzene (150 ml) was added dropwise triethylamine (10.1 g, 100 mmol) and white suspension was stirred for 18 h. After filtration under atmosphere of dry nitrogen, the filtrate was concentrated under reduced pressure. To the resulted oil was added 1,3-dibromopropane (70 ml) and it was stand for a week at room temperature under nitrogen atmosphere. Water (200 ml) was added to the solution and it was extracted with chloroform. Organic phase was washed with water and dried over anhydrous sodiumsulfate. Evaporation of the solvent under reduced pressure gave yellow solid. Recrystallization from ethanol yielded **18** (3.5 g, 27% yield) as colorless columns; mp 130—131 °C. MS *m/z* 262 (M^+ for ^{79}Br). ^{1}H NMR ($CDCl_3$, 360 MHz) δ=2.34 (m, 2, $NCH_2\underline{CH_2}$), 3.47 (t, *J*=6.1 Hz, 2, CH_2Br), 3.76 (s, 3, OCH_3), 3.90 (t, *J*=6.6 Hz, 2, N-CH_2), 6.82

(s, 1, ArH), 9.61 (br, s, 1, NH).

Found: C, 36.52; H, 4.37; Br, 29.51; N, 9.95%. Calcd for $C_8H_{11}BrN_2O_3$: C, 36.52; H, 4.22; Br, 30.37; N, 10.65%.

6-[3-(5-Methoxyuracil-1-yl)propylthio]purine (10). Compound **11** was prepared in a yield of 75% by the similar procedure described for **8**. **10**: Colorless fine needles from water; decomp>190°C. MS *m/z* 334 (M^+). ^{1}H NMR (DMSO-d_6, 360 MHz) δ=2.06 (q, J=7.0 Hz, 2, $SCH_2\underline{CH_2}$), 3.36 (t, J=7.0 Hz, 2, SCH_2), 3.60 (s, 3, CH_3), 3.78 (t, J=6.9 Hz, 2, NCH_2), 7.36 (s, 1, H6'), 8.41 (br.s, 1, H8), 8.63 (s, 1, H2), 11.36 (br. s, 1, NH).

Found: C, 45.24; H, 4.21; N, 24.23; S, 9.57%. Calcd for $C_{13}H_{14}N_6O_3S \cdot 1/2\ H_2O$: C, 45.48; H, 4.40; N, 24.48; S, 9.34%.

1-(3-Bromopropyl)-5-nitrouracil (19). A mixture of 5-nitrouracil[18] (4.71 g, 30 mmol), 1,3-dibromopropane (60.0 g, 100 mmol), and anhydrous potassium carbonate (2.07 g, 15 mmol) in dry DMSO (70 ml) was stirred at room temperature for 1.5 d. The solvent was distilled off under reduced pressure. Water (200 ml) was added to the residue and it was extracted with chloroform and the extracts were dried over anhydrous sodium sulfate. The solution was concentrated under reduced pressure until about 100 ml of the solvent was left. Yielded precipitates of **19** was collected (2.67 g, 32% yield). Recrystallization from 2-propanol gave pure **19** as colorless prisms; mp 172—174 °C. MS *m/z* 277 (M^+ for ^{79}Br). ^{1}H NMR ($CDCl_3$, 360 MHz) δ=2.37 (m, 2, $NCH_2\underline{CH_2}$), 3.47 (t, J=6.0 Hz, 2, CH_2Br), 4.11 (t, J=6.8 Hz, 2, NCH_2), 8.79 (s, 1, ArH).

Found: C, 30.82; H, 3.16; N, 15.48%. Calcd for $C_7H_8BrN_3O_4$: C, 30.23; H, 2.90; N, 15.11%.

6-[3-(5-Nitrouracil-1-yl)propylthio]purine (11). A solution of **19** (1.39 g, 5 mmol), 6-mercaptopurine (0.84 g, 4.9 mmol), and sodium hydroxide (0.6 g, 15 mmol) in water (20 ml) was stirred for 3.5 h at room temperature. The solution was neutralized by dil HCl and then, few drops of ethanol were added. Yielded pale yellow solid was filtered, washed with water, and dried to give 1.51 g (87% yield) of **11**. **11**: Pale yellow powder from water; mp 270—271 °C with decomp. ^{1}H NMR (DMSO-d_6, 360 MHz) δ=2.13 (q, J=7.1 Hz, 2, $NCH_2\underline{CH_2}$), 3.37 (t, J=6.7 Hz, 2, SCH_2), 4.01 (t, J=6.7 Hz, 2, NCH_2), 8.41 (s, 1, H8), 8.63 (s, 1, H2), 9.31 (s, 1, H6'), 11.99 (br. s, 1, NH).

Found: C, 41.40; H, 3.36%. Calcd for $C_{12}H_{11}N_7O_4S$: C, 41.26; H, 3.17%.

3-(3-Bromopropyl)-*S*-methyl-2-thiouracil (21). To a stirred solution of **20**[19] (5.68 g, 40 mmol) in dry DMF (100 ml) was added 60% sodium hydride (1.68 g, 42 mmol). After stirring for 1 h, 1,3-dibromopropane (40 ml, 400 mmol) was added to the mixture and it was stirred for 1 h at room temperature and then, at 60 °C for 24 h. The solvent was removed under reduced pressure. The residue was purified by column chromatography on silica gel with chloroform to give **21** (8.67 g, 82% yield). **21**: Colorless prisms from methanol; mp 50.0—50.5 °C. MS *m/z* 263 (M^+ for ^{79}Br). ^{1}H NMR ($CDCl_3$, 100 MHz) δ=2.30 (m, 2, $NCH_2\underline{CH_2}$), 2.58 (s, 3, CH_3), 3.48 (t, J=6.6 Hz, 2, CH_2Br), 4.19 (m, 2, NCH_2), 6.18 (d, J=6.5 Hz, 1, ArH(5)), 7.75 (d, J=6.5 Hz, 1, ArH(6)).

Found: C, 36.57; H, 3.95; N, 10.75; S, 12.32%. Calcd for $C_8H_{11}N_2OSBr$: C, 36.51; H, 4.22; N, 10.65; S, 12.18%.

6-[3-(*S*-Methyl-2-thiouracil-3-yl)propylthio]purine (22). A solution of **21** (4.18 g, 15.9 mmol), 6-mercaptopurine monohydrate (2.70 g, 15.9 mmol), and sodium hydroxide (0.83 g, 20.8 mmol) in water (40 ml)-ethanol (10 ml) was stirred for 3 h at room temperature. The solution was neutralized by dil HCl and it was extracted by chloroform. The organic layer was dried over anhydrous sodium sulfate and concentrated. Crude product was purified by column chromatography on silica gel with chloroform-methanol (19:1) to give white solid (3.9 g, 73% yield). **22**: Colorless needles from methanol; mp 182.0—183.5 °C. MS *m/z* 334 (M^+). ^{1}H NMR ($CDCl_3$, 100 MHz) δ=2.29 (m, 2, $NCH_2\underline{CH_2}$), 2.54 (s, 3, CH_3), 3.50 (t, J=7.2 Hz, 2, SCH_2), 4.27 (m, 2, NCH_2), 6.23 (d, J=6.3 Hz, 1, H5'), 7.76 (d, J=6.6 Hz, 1, H6'), 8.21 (s, 1, H8), 8.71 (s, 1, H2).

6-[3-(Uracil-3-yl)propylthio]purine (12). A solution of **22** (1.67 g, 5 mmol) in ethanol (20 ml)-2 M HCl (10 ml) was stirred for 2 d at room temperature. Yielded precipitates were filtered, washed with water, and dried to give 1.36 g (89% yield) of crude **12**. **12**: Colorless fine needles from water; mp 293—298 °C with decomp. MS *m/z* 304 (M^+). ^{1}H NMR (DMSO-d_6, 360 MHz) δ=1.97 (q, J=7.0 Hz, 2, $NCH_2\underline{CH_2}$), 3.34 (t, J=7.0 Hz, 2, SCH_2), 3.91 (t, J=7.0 Hz, 2, NCH_2), 5.58 (dd, J=1.4 Hz, 7.6 Hz, 1, H5'), 7.42 (m, 1, H6'), 8.39 (s, 1, H8), 8.63 (s, 1, H2), 10.21 (br. s, 1, NH(9)), 11.07 (br. d, 1, NH(1')).

Found: C, 47.39; H, 4.23; N, 27.90; S, 10.74%. Calcd for $C_{12}H_{12}N_6O_2S$: C, 47.36; H, 3.98; N, 27.61; S, 10.53%.

5-(3-Hydroxypropyl)-3-methyluracil (25). A mixture of 5-(3-hydroxypropyl)-2-thiouracil **23**[20] (14.88 g, 80 mmol), methyl iodide (25 ml, 400 mmol), and anhydrous potassium carbonate (24.29 g, 176 mmol) in dry DMF (50 ml) was stirred for 20 h at room temperature. Salts were filtered off and the filtrate was concentrated to dryness under reduced pressure. Water (100 ml) was added to the residue and it was extracted with chloroform. The organic phase was washed well with water and dried over anhydrous sodium sulfate. Evaporation of the solvent gave pale yellow solid of **24**. To the solid was added 20 ml of 1 M HCl and the mixture was refluxed for 1 h. After cooling, the solution was neutralized by sodium hydrogencarbonate and was concentrated to dryness. Yielded solid was extracted with chloroform. The extracts were dried and evaporated. The crude product was purified by column chromatography on silica gel with chloroform-methanol (19:1) to yield 9.3 g (63% yield) of **25**. Recrystallization from ethanol gave pure **25** as colorless prisms; mp 124—126 °C. MS *m/z* 184 (M^+). ^{1}H NMR ($CDCl_3$, 100 MHz) δ=1.76 (m, 2, $ArCH_2\underline{CH_2}$), 2.28 (t, J=6.0 Hz, 1, OH), 2.48 (t, J=7.1 Hz, 2, $ArCH_2$), 3.35 (s, 3, CH_2), 3.36 (q, J=5.9 Hz, 6.0 Hz, 2, $\underline{CH_2}OH$), 7.07 (d, J=5.6 Hz, 1, ArH), 9.22 (br. s, 1, NH).

Found: C, 51.95; H, 6.49; N, 15.23%. Calcd for $C_8H_{12}N_2O_3$: C, 52.16; H, 6.57; N, 15.21%.

5-(3-Bromopropyl)-3-methyluracil (26). A solution of **24** (1.84 g, 10 mmol) in concd hydrobromic acid (15 ml) and concd sulfuric acid (2 ml) was heated at 110 °C for 3 h with stirring. After cooling, the mixture was poured into cold water and it was extracted with chloroform. The organic layer was washed well with aqueous solution of sodium hydrogencarbonate and dried over anhydrous sodium sulfate. Evaporation of the solvent gave 1.54 g (62% yield) of **26**. **26**: Colorless columns from ethanol; mp 152.5—153.5°C. MS *m/z* 246 (M^+ for ^{79}Br). ^{1}H NMR ($CDCl_3$, 360 MHz) δ=2.12 (m, 2, $ArCH_2\underline{CH_2}$), 2.50 (t, J=7.1 Hz, 2, $ArCH_2$), 3.34 (s, 3, CH_3), 3.34 (t, J=6.3 Hz, 2, CH_2Br), 7.14 (d, J=5.7 Hz, 1, ArH), 9.64 (br, s, 1, NH).

Found: C, 38.74; H, 4.50; N, 11.25; Br, 32.07%. Calcd for

6-[3-(3-Methyluracil-5-yl)propylthio]purine(13). A solution of **26** (0.99 g, 4 mmol), thiourea (0.32 g, 4.2 mmol) in ethanol (10 ml) was refluxed for 8 h. After removal of ethanol, water (20 ml) was added to the residue. To the stirred mixture was added, at 90 °C under nitrogen atmosphere, sodium hydroxide (40 g, 10 mmol) and then (after 10 min), 6-chloropurine (1.24 g, 8 mmol). Heating and stirring were continued for 1 h. After cooling, yielded precipitates were collected to give 0.95 g (75% yield) of **13**. **13**: Colorless powder from water; mp 283—286 °C. MS m/z 318 (M^+). ^{1}H NMR (DMSO-d_6, 360 MHz) δ=1.89 (q, J=7.1 Hz, 2, $NCH_2\underline{CH_2}$), 2.39 (t, J=6.3 Hz, 2, $ArCH_2$), 3.33 (t, J=6.3 Hz, 2, SCH_2), 7.33 (d, J=5.8 Hz, 1, ArH(6')), 8.40 (s, 1, ArH(8)), 8.66 (s, 1, ArH(2)), 10.93 (d, J=5.8 Hz, 1, NH).

Found: C, 48.78; H, 4.61; N, 26.40; S, 10.32%. Calcd for $C_{13}H_{14}N_6O_2S$: C, 49.05; H, 4.43; N, 26.40; S, 10.07%.

General Procedure of Method A for the Synthesis of 1—6. To a suspension of **8—13** (3 mmol) in dry DMF (100 ml) was added 60% sodium hydride (259 mg, 6.25 mmol). After continuous stirring for 1 h at room temperature, the mixture became transparent solution. The solution was diluted with dry DMF until the total volume became 150 ml. The solution and a solution of 1,3-dibromopropane (0.305 ml, 3 mmol) in dry DMF (150 ml) were added simultaneously to dry DMF (300 ml) at room temperature in a period of 36—48 h (see Table 6) under nitrogen atmosphere. After addition was over, stirring was continued for 25—60 h (see Table 6). DMF was removed under reduced pressure and the residue was extracted with chloroform. The isomers having the bridge at 9-position of a purine ring (**1**, **3**, **5**) could be separated from the other isomers (**2**, **4**, **6**) by column chromatography on silica gel with chloroform-methanol (ratio: see Table 6).

General Procedure of Method B. To a stirred mixture of dry DMSO (400 ml) and potassium carbonate (0.9 g, 6.6 mmol) was added a solution of **7** or **8** (1 mmol) and 1,3-dibromopropane (1 mmol) in a period of 15 h at room temperature under nitrogen atmosphere. After addition was over, stirring was continued for 3 d. Salts were filtered off and the solvent was removed under reduced pressure. Crude product was separated into two isomers by column chromatography on silica gel with methanol-chloroform. Spectral and analytical data of **1c**, **1d**, **2c**, and **2d** are shown in Table 6.

(Received June 1, 1988)

Denitrohydrogenation reaction of aliphatic nitro compounds with tributyltin hydride (Bu_3SnH) is accelerated in the presence of radical initiators. ESR and electrochemical measurements reveal that the reductive cleavage of the carbon-nitrogen bond proceeds not via anion radicals of nitro compounds such as $S_{RN}1$ reaction but via β-scission of (tributylstannyloxy)nitroxyl radicals. The relative reactivities of tin radicals toward substituted α-nitrocumenes, α-nitroethylbenzenes, and α-nitropropiophenones exhibits excellent Hammett correlations with positive ρ values. This tendency has also been found in the reaction of benzyl halides with tin radical. These results suggest that the carbon-nitrogen bond breaking from nitroxyl radical intermediates should take place in rate-determining step for the reaction.

Recently we and Tanner have reported that aliphatic nitro groups are readily replaced by hydrogen in good yield on treatment with tributyltin hydride (Bu_3SnH) in the presence of radical initiators.[2,3)] As Bu_3SnH can replace the nitro group by hydrogen without affecting other reducible groups such as carbonyl, alkoxycarbonyl, formyl, cyano, sulfinyl, or sulfonyl groups, this reaction has been widely used in organic synthesis.[4)] Mechanism of the reductive cleavage of the carbon-nitrogen bond with tin radicals has been of interest for recent years because of high chemoselectivity of the reaction. An electron-transfer mechanism is postulated from the analogy to $S_{RN}1$ reaction of nitro compounds.[2,3)] Namely, Tanner and co-workers have proposed that the reaction proceeds via mechanism A (see below) without concrete evidences, where anion radicals of nitro compounds are assumed as intermediates of the reaction.[5)] We have proposed two possible mechanism, mechanism A and B as shown in Scheme 1.[2)] The difference between mechanism A and B is that alkyl radicals are formed from anion radicals of nitro compounds in mechanism A, whereas alkyl radicals are formed from (tributylstannyloxy)nitroxyl radicals in mechanism B.

Mechanism A

$$\mathrm{R\text{-}NO_2 + Bu_3Sn\cdot \longrightarrow R\text{-}NO_2^{\cdot-} + Bu_3Sn^+}$$
$$\mathrm{R\text{-}NO_2^{\cdot-} \longrightarrow R\cdot + NO_2^-}$$
$$\mathrm{R\cdot + Bu_3SnH \longrightarrow R\text{-}H + Bu_3Sn\cdot}$$

Mechanism B

$$\mathrm{R\text{-}NO_2 + Bu_3Sn\cdot \longrightarrow R\text{-}N(O\cdot)O\text{-}SnBu_3}$$
$$\mathrm{R\text{-}N(O\cdot)O\text{-}SnBu_3 \longrightarrow R\cdot + Bu_3SnONO}$$
$$\mathrm{R\cdot + Bu_3SnH \longrightarrow R\text{-}H + Bu_3Sn\cdot}$$

Scheme 1.

The mechanism A is proposed based on following two facts.[3)] The reaction is catalyzed by radical initiators such as azobisisobutyronitrile (AIBN) and inhibited by the presence of a catalytic amount of *m*-dinitrobenzene (*m*-DNB). However, these evidences cannot exclude the mechanism B, for all radical reactions induced by tin radicals are catalyzed by AIBN and inhibited by *m*-DNB. For example, the reduction of alkyl bromides with tributyltin hydride, the typical radical reaction induced by tin radicals is inhibited by the presence of *m*-DNB. This reaction proceeds via S_H process and it is not certain whether electron-transfer mechanism is operated or not in the reduction of alkyl bromides with tributyltin radicals. Thus, there have been no concrete evidences for the reaction mechanism of denitration with tributyltin hydride.

Recently, Giese and co-workers also have shown that this reaction undergoes via mechanism B through their ESR and kinetic studies.[6)] Independently, we have reached the same conclusion and found that the (tributylstannyloxy)nitroxyl radicals undergo the different reaction from that of the anion radicals of nitro compounds. In this paper, we report that this reaction proceeds via nitroxyl radical intermediates and that kinetic studies support the carbon-nitrogen bond breaking from nitroxyl radical intermediates takes place in the transition state for the reaction.

Results and Discussion

The replacement of tertiary nitro groups by hydrogen with CH_3SNa[7)] or 1-benzyl-1,4-dihydronicotinamide (BNAH)[8)] involves anion radical intermediates. This mechanism has been well-established (Scheme 2). Collapse of anion radical of nitro compounds into a alkyl radical and nitrite ion is fundamental process of $S_{RN}1$ reaction of nitro compounds.[9)]

$$\mathrm{R\text{-}NO_2 + BNAH \longrightarrow R\text{-}NO_2^{\cdot-} + BNAH^{\ddagger}}$$
$$\mathrm{R\text{-}NO_2^{\cdot-} \longrightarrow R\cdot + NO_2^-}$$
$$\mathrm{R\cdot + BNAH \longrightarrow R\text{-}H + BNA\cdot}$$
$$\mathrm{BNA\cdot + R\text{-}NO_2 \longrightarrow R\text{-}NO_2^{\cdot-} + BNA^+}$$

Scheme 2.

On the other hand, the reaction of α-nitro sulfone **1** with BNAH gives 2-nitropropane, where the carbon-sulfur bond was cleaved in preference to the carbon-nitrogen bond (Eq. 1).[10)]

$$\underset{\mathbf{1}}{Me_2C(NO_2)SO_2Ph} + BNAH \longrightarrow Me_2CHNO_2 \quad (1)$$

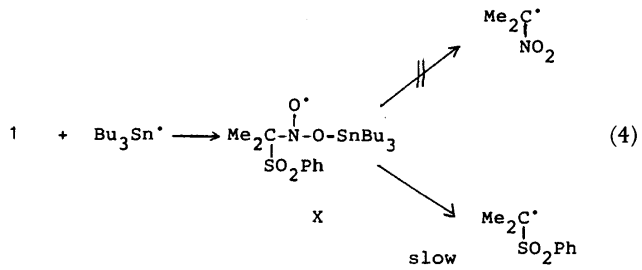
Thus, the anion radicals of α-nitro sulfones collapsed to the α-nitroalkyl radicals and sulfinate ions (Eq. 2).

$$\mathbf{1}^{\cdot-} \longrightarrow Me_2\dot{C}NO_2 + PhSO_2^- \quad (2)$$

However, α-nitro sulfones do not react with tributyltin hydride under the conditions that the nitro groups of other nitro compounds are replaced by hydrogen. Namely, heating a mixture of **1**, Bu_3SnH (2 equiv), and AIBN (0.3 equiv) in toluene at 110 °C for 3 h resulted in clean recovery of **1** (Eq. 3).[11]

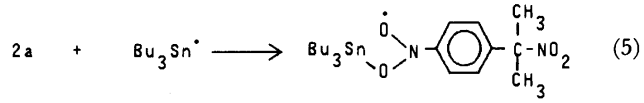
$$\mathbf{1} + Bu_3SnH \longrightarrow \text{No reaction} \quad (3)$$

In general, Bu_3SnH is much more reactive to nitro compounds for denitration than BNAH.[4] The low reactivity of **1** toward tin radicals suggest that the anion radicals are not intermediates for the reaction of nitro compounds with tin radicals. If the nitroxyl radicals **X** are intermediates, the above results are explained. The cleavage of carbon-sulfur bond is impossible from **X**, being easy from the corresponding anion radicals. And also the cleavage of carbon-sulfur bond is inhibited due to destabilization of radicals by the adjacent sulfonyl groups (Eq. 4).[12]



(4)

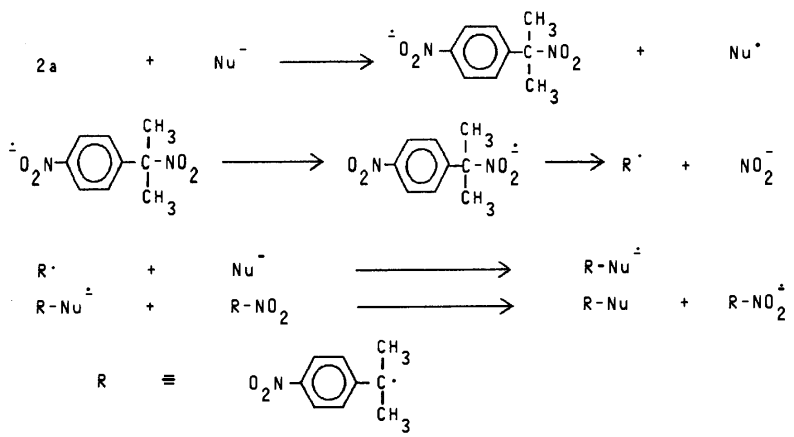
The reaction of α,*p*-dinitrocumene **2a** is also a good diagnosis for an electron-transfer process. This compounds react with various nucleophiles via electron-transfer processes and it is generally more reactive than other nitro compounds for $S_{RN}1$ reaction.[9] For example, **2a** react with various nucleophiles quite rapidly to give the substitution products in good yield, but α-nitrocumene **2b** does not undergo the $S_{RN}1$ reaction with most nucleophiles. *p*-Nitro group is essential for a smooth $S_{RN}1$ reaction.[9] However, **2a** was inert to Bu_3SnH for denitration, and the nitro group of **2b** is readily replaced by hydrogen on treatment with Bu_3SnH. Thus, these results show that the reaction of nitro compounds with Bu_3SnH proceeds via the completely different pathway from that of $S_{RN}1$ reaction. It is well-established that the $S_{RN}1$ reaction of nitro compounds proceeds via an electron-transfer process as shown in Scheme 3. Intramolecular electron transfer takes place in $S_{RN}1$ reaction.[13] The reaction of **2a** with tin radicals does not give $\mathbf{2a}^{\cdot-}$, for if anion radical is formed alkyl radical should be formed in the similar pathway as in Scheme 3. Tin radicals may attack the aromatic nitro group to give the nitroxyl radical, which is stable and does not collapse to alkyl radical. In fact, ESR measurements of the reaction mixture of **2a**, Bu_3SnH, and AIBN gave the spectra of the nitroxyl radical as shown in Fig. 1. It was reported that the similar ESR spectra was obtained by photolysis of hexamethyldistannane in the presence of aromatic nitro compounds (Eq. 5).[14] As the nitroxyl radicals



(5)

derived from aromatic nitro compounds are more stable than those derived from aliphatic ones, denitration does not proceeds from this intermediate. If observed spectra is from an anion radical, the α-nitro group should be eliminated very quickly. Consequently, aromatic nitro compounds act as excellent inhibitors for radical reduction with tin radicals. Although inhibition by *m*-DNB has been used as the diagnosis of an electron-transfer process from tin radicals in several cases,[3] it cannot be used as the diagnosis of an electron-transfer process as discussed here.

ESR measurements of the reaction mixture of various nitro compounds **3**—**7** and Bu_3SnH in benzene were carried out under the same reaction conditions as in denitration of nitro compounds in preparative works. When nitro compounds were mixed with



Scheme 3.

Bu_3SnH and AIBN in benzene and they were irradiated with UV light or heated at 65 °C, strong triplet or sextet [a(N)=27—28 G, a(H)=4—5 G (1G=10^{-4}T)] was detected. Typical spectra are shown in Fig. 2 and the ESR parameters are summarized in Table 1.

Me_3CNO_2 **3** Me_2CHNO_2 **4** $PhCH(Me)NO_2$ **5**

$Ph(C{=}O)CH(Me)NO_2$ **6** $Ph(C{=}O)CMe_2NO_2$ **7**

The ESR spectra also can be interpreted in terms of the formation of (tributylstannyloxy)nitroxyl radical as well as nitro anion radicals. Recently, Giese and his co-workers reported the similar ESR spectra by the reaction of several nitro compounds with Bu_3SnH.[6] They concluded that they were (tributylstannyloxy)-nitroxyl radicals. A weak coupling of tin isotope (^{119}Sn and ^{117}Sn) was detected in ESR spectra as shown in Fig. 2, where a triplet was surrounded by a weak doublet. This suggests that the tin radical adds to the nitro group to form tin-oxygen covalent bond. The ESR parameters obtained here are very close to those of anion radicals of nitro compounds. Considering these facts and low reactivity of **1** and **2a** for denitration, the observed spectra should be (tributylstannyloxy)-nitroxyl radicals. The detected radicals are real intermediates for denitration of nitro compounds, for they are not detected by ESR in the absence of AIBN. Further, Giese has reported that observed radicals decay by first order process.[6] In the photolytic experiment, the ESR signal disappears immediately, if the light is switched off, but comes back on further irradiation. Thus, the observed radicals are short-lived intermediates which decompose to give alkyl radicals.

Table 1. ESR Parameters in the Reaction of Nitro Compounds with Tin Radicals

Nitro compd	Initiator	g Factor	hfs/G	
			a_N	a_H
3	AIBN	2.0050	27.9	—

5	AIBN	2.0049	27.8	4.44
6	AIBN	2.0050	27.1	5.56
7	UV	2.0049	27.5	—

Electrochemical measurements were carried out for various kinds of nitro compounds. It is well-known that single electron reduction of aliphatic nitro compounds forms corresponding anion radicals of nitro compounds, which decompose readily to give alkyl radicals and nitrite ion.[15] As expected, cyclic voltammetry of α-nitroethylbenzene shows irreversible wave as shown in Fig. 3. The half wave reduction potentials ($E_{1/2}$) of various nitro compounds were measured by polarography. The results are summarized in Tables 2—4. Relative low reduction potentials were observed:

compared to trifluoroacetophenone ($E_{1/2}$=−2.00 V) and acetophenone ($E_{1/2}$=−2.61 V):[16] α-nitropropiophenones, $E_{1/2}$=ca.−1.37 V; α-nitrocumenes $E_{1/2}$=ca. −1.58 V. These results are reasonable because the nitro group is strong electron acceptor. The positive ρ value was observed in Hammett plots of $E_{1/2}$. However, the value is very small (ρ=ca. 0.1—0.2), compared to that of the corresponding bromides (ρ=ca. 0.40).[17] This means that substituents have few effects on easiness of the electron transfer to the nitro groups.

Relationship between the relative reactivity of nitro compounds with Bu_3SnH and substituent constants σ was examined. The relative reactivities of substituted α-nitrocumenes **2** with Bu_3SnH in benzene at 80 °C were obtained by competitive reactions of **2** vs. **2b** on

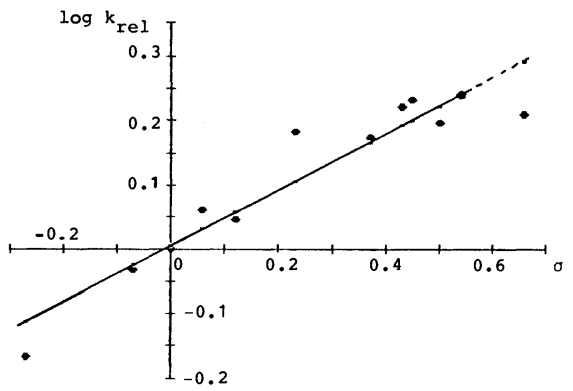

Fig. 4. Hammett plots of log k_{rel} vs. substituent constants σ for the reaction of **2** with Bu_3SnH.

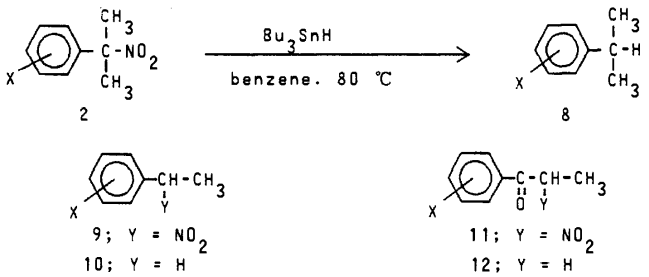
the basis of measurement of appearance of products cumenes **8** and **8b**. The results are summarized in Table 2, and their Hammett plots are shown in Fig. 4. Hammett plots of log k_{rel} vs. substituent constants σ exhibits quite good correlation except for *p*-cyano-α-nitrocumene **2m**. ρ Value of **2** can be calculated by the least squares method (ρ=0.54, r=0.98). Similarly, the relative reactivities of substituted α-nitroethylbenzenes **9** and α-nitropropiophenones **11** with Bu_3SnH were obtained in the same way as above mentioned. The results are summarized in Tables 3 and 4. Good Hammett correlations between log k_{rel} and σ are obtained except *p*-cyano derivatives, which are less reactive than expected from the correlations. Obtained ρ values are as following; ρ=0.25 (r=0.97) for **9**, ρ=0.33 (r=0.96) for **11**. A positive Hammett correlations are



obtained both in any denitration reaction with Bu_3SnH and reduction potentials of nitro compounds. However, ρ values for the reaction with tin radicals are larger than those for electrochemical reduction. This result suggests that the formation of the anion radicals is not so much affected by variation of substituents. Thus, the larger ρ values for denitration with tin radical also support that this denitration reaction with tin radical proceeds not via the electron-transfer pathway but via the nitroxyl radical intermediates.

As related reactions, reductive cleavage of alkyl halides, sulfides, selenides, and xanthates with Bu_3SnH is well-known. The formation of alkyl radicals by tin radicals may be considered as shown in Scheme 4, where abstraction of X by tin radicals takes place via S_H process.[18,19]

$$R\text{-}X + Bu_3Sn^{\cdot} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} R\text{-}X\text{-}SnBu_3 \xrightarrow{k_2} R^{\cdot} + Bu_3SnX$$

X=Cl, Br, I

Scheme 4.

Hammett correlation for halogen abstraction with tin radical[19] and germyl radical[20] has been studied by Tanner and Sakurai, where positive ρ values are also obtained. They have concluded that these positive ρ values are attributed to following two reaction mechanism; an electron-transfer mechanism (Scheme 5) or polar effects on the halogen abstraction step (Scheme 6). In particular, carbon-halogen bond breaking step is considered as the rate-determining step of the reaction in the latter case.

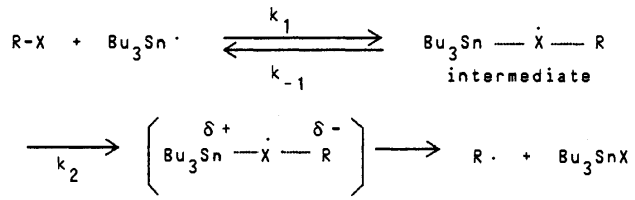
$$R\text{-}X + Bu_3Sn^{\cdot} \overset{\text{single electron transfer}}{\rightleftharpoons} R\text{-}X^{\cdot-} + Bu_3Sn^{+}$$

anion radical

$$\longrightarrow R^{\cdot} + X^{-} + Bu_3Sn^{+}$$

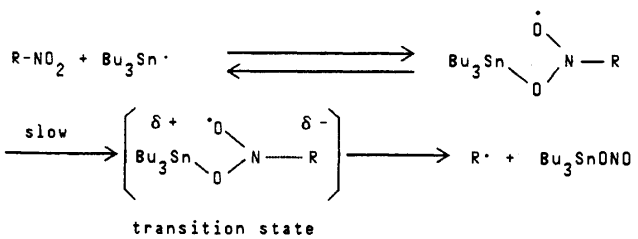
X=Cl, Br, I

Scheme 5.



Scheme 6.

The denitration with tin radicals are quite similar to these results. As the electron-transfer mechanism is excluded as discussed above, the positive ρ values are attributed to the polar effects on the carbon-nitrogen bond scission. Although carbon-halogen bonds are so weak as to give alkyl radicals very quickly, carbon-nitrogen bond cleavage is so difficult that nitroxyl radical intermediates are readily observed by ESR spectroscopy. Thus, the carbon-nitrogen bond scission may be the rate-determining step of the denitration reaction. Considerable reaction process is depicted in Scheme 7.



Scheme 7.

Experimental

Measurement. All melting points were uncorrected. ^{1}H NMR spectra were measured at 100 MHz with JEOL JNM-PS-100 spectrometer. IR spectra were recorded on Hitachi 215 spectrometer. GLC analyses were carried out with Shimadzu GC-8A gas chromatograph. Elemental analyses were performed by Kyoto University microanalyses center.

ESR Studies. ESR spectra were recorded using JEOL PX-3E spectrometer after mixing R-NO_2 (0.25 mmol), Bu_3SnH (0.25 mmol) and AIBN (0.05 mmol) in 0.5 ml of benzene under argon atmosphere, degassed and heating at 65 °C. ESR spectra were also recorded under irradiation of a solution of R-NO_2 (0.25 mmol) and Bu_3SnH (0.25 mmol) in 0.5 ml of benzene with high-pressure mercury lamp.

Polarography. PAR model 174 polarograph analyzer was used. The capillary constant for the dropping mercury electrode was 1.41 mg at −0.5 V vs. Ag/$AgClO_4$ in acetonitrile containing 2×10^{-2} M (1 M=1 mol dm^{-3}) Bu_4NClO_4. The anode was a 10 cm length of 1 mm diameter silver wire. All polarograms were determined at 25 °C with thoroughly deaerated solutions which was between 4×10^{-4} and 5×10^{-4} M in substrate and 2×10^{-2} M in Bu_4NClO_4.

Preparation of Nitro Compounds. α-Nitro sulfone **1** was prepared by the reaction of corresponding iodide with sodium benzenesulfinate.[21] α-Nitrocumene derivatives **2** substituted by electron-withdrawing groups were prepared by the reaction of the corresponding substituted nitrobenzenes with the lithium salt of 2-nitropropane in dimethyl sulfoxide (DMSO).[22] Other substituted nitrocumenes were prepared by the reaction of corresponding aryl lead(IV) compounds or diaryliodonium salts with the lithium salt of 2-nitropropane.[23] Physical properties of new compounds are summarized.

2c: ^{1}H NMR ($CDCl_3$) δ=1.91 (s, 6H), 3.72 (s, 3H), 6.83 (d, 2 H), 7.32 (d, 2H). IR (neat): 1250, 1350, 1530 cm^{-1}. Found: C, 61.38; H, 6.65; N, 7.13%. Calcd for $C_{10}H_{13}NO_3$: C, 61.53; H, 6.71; N, 7.18%.

2d: ^{1}H NMR ($CDCl_3$) δ=1.92 (s, 6H), 2.36 (s, 3H), 7.1—7.3 (m, 4H). IR (neat): 1350 and 1540 cm^{-1}. Found: C, 67.14; H, 7.39; N, 7.93%. Calcd for $C_{10}H_{13}NO_2$: C, 67.02; H, 7.31; N, 7.82%.

2e: ^{1}H NMR ($CDCl_3$) δ=1.98 (s, 6H), 7.1—7.6 (m, 4H). IR (neat): 1230, 1350, 1540 cm^{-1}. Found: C, 59.17; H, 5.45; N, 7.78%. Calcd for $C_9H_{10}NO_2F$: C, 59.01; H, 5.50; N, 7.65%.

9e: ^{1}H NMR ($CDCl_3$) δ=1.84 (d, 3H, J=7 Hz), 3.78 (s, 3H), 5.53 (q, 1H, J=7 Hz), 6.84—7.40 (m, 4H). IR (neat): 1250, 1350, 1540 cm^{-1}. Found: C, 59.79; H, 6.19; N, 7.90%. Calcd for $C_9H_{11}NO_3$: C, 59.66; H, 6.12; N, 7.73%.

9f: ^{1}H NMR ($CDCl_3$) δ=1.84 (d, 3H, J=7 Hz), 5.56 (q, 1H, J=7 Hz), 7.40 (m, 4 H). IR (neat): 1090, 1350, 1540 cm^{-1}. Found: C, 51.97; H, 4.54; N, 7.51%. Calcd for $C_8H_8NO_2Cl$: C, 51.77; H, 4.34; N, 7.55%.

9g: ^{1}H NMR ($CDCl_3$) δ=1.87 (d, 3 H, J=7 Hz), 5.56 (q, 1H, J=7 Hz), 7.36—7.48 (m, 4H). IR (neat): 1080, 1350, 1540 cm^{-1}. Found: C, 51.85; H, 4.38; N, 7.67%. Calcd for $C_8H_8NO_2Cl$: C, 51.77; H, 4.34; N, 7.55%.

9h: ^{1}H NMR ($CDCl_3$) δ=1.94 (d, 3H, J=8 Hz), 3.96 (s, 3H), 5.69 (q, 1 H, J=7 Hz), 7.58 (d, 2H, J=8 Hz), 8.12 (d, 2H, J=8 Hz). IR (neat): 1350, 1540, 1705 cm^{-1}. Found: C, 57.28; H, 5.53; N, 6.93%. Calcd for $C_{10}H_{11}NO_4$: C, 57.41; H, 5.30; N, 6.70%.

9i: ^{1}H NMR ($CDCl_3$) δ=1.93 (d, 3H, J=8 Hz), 5.69 (q, 1 H, J=8 Hz), 7.70 (d,d, 4H). IR (neat): 1350, 1540, 2200 cm^{-1}. Found: C, 61.16; H, 4.68; N, 16.00%. Calcd for $C_9H_8N_2O_2$: C, 61.36; H, 4.58; N, 15.90%.

Preparation of α-nitro ketones **11** was carried out by oxidation of the corresponding nitro alcohols, which were prepared by the reaction of aldehydes with nitroethane.[25] Physical properties of new compounds are shown here.

11e: mp 86—86.5 °C. ^{1}H NMR ($CDCl_3$) δ=1.81 (d, 3H, J=7 Hz), 3.92 (s, 3H), 6.13 (q, 1H, J=7 Hz), 8.08 (q, 4H). IR (Nujol): 1350, 1560, 1700, 1720 cm^{-1}. Found: C, 55.56; H, 4.72; N, 5.90%. Calcd for $C_{11}H_{11}NO_5$: C, 55.70; H, 4.67; N, 5.90%.

11f: mp 119—120 °C. ^{1}H NMR ($CDCl_3$) δ=1.86 (d, 3H, J=7 Hz), 6.16 (q, 1H, J=7 Hz), 7.86 (d, 2H, J=8 Hz), 8.08 (d, 2H, J=8 Hz). IR (Nujor): 1350, 1540, 1700, 2250 cm^{-1}. Found: C, 58.78; H, 3.92; N, 13.86%. Calcd for $C_{10}H_8N_2O_3$: C, 58.83; H, 3.95; N, 13.72%.

Denitration of Compounds 2, 9, and 11. Denitration of these compounds with Bu_3SnH was described in a previous paper.[26] Denitrated products were obtained in 80—90% yield in most cases.

Competitive Reactions of 2. The substituted α-nitrocumene (0.25 mmol), α-nitrocumene (0.25 mmol), AIBN (0.01 mmol), and Bu_3SnH (0.02 mmol) were dissolved in 0.2 ml of benzene. The solution was degassed and sealed in a Pyrex tube. The tube was heated at 80 °C for 30 min, then opened and the products **8** were analyzed by GLC. Other compounds **9** and **11** were treated in the same way. The results are summarized in Tables 2, 3, and 4, respectively.

The authors wish to thank Professor Kazuhiro Maruyama for his helpful discussion concerning the ESR study. The authors also wish to thank Dr. Satoshi Okazaki, Dr. Kiminori Ushida, and Mr. Hideto Kato for measuring polarography and ESR. The present work was supported by a Grant-in-Aid for Scientific Research (No. 57540281) from the Ministry of Education, Science and Culture.

General Reactivity of 2-Lithiobenzothiazole to Various Electrophiles and the Use as a Formyl Anion Equivalent in the Synthesis of α-Hydroxy Carbonyl Compounds

Hidenori CHIKASHITA,* Megumi ISHIBABA, Keiji ORI, and Kazuyoshi ITOH
Department of Applied Chemistry, Faculty of Engineering, Kansai University, Suita, Osaka 564
(Received June 7, 1988)

The reaction of 2-lithiobenzothiazole with a variety of electrophiles such as aldehydes, ketones, carboxylic esters, lactones, nitriles, and amides afforded the expected addition and substitution products. Trimethylsilyl chloride readily reacted with the benzothiazolyl anion to give 2-trimethylsilylbenzothiazole, while common alkyl halides including primary iodide and benzyl halides, as well as epoxides, did not react with the anion. This characteristic nucleophilicity of the anion was also demonstrated by its reaction with phenacyl halides and 5-chloro-2-pentanone leading to the formation of benzothiazolyl-substituted small-ring ethers. In order to demonstrate the value of 2-lithiobenzothiazole as a masked formyl anion, 2-(α-hydroxyalkyl)benzothiazoles were transformed into α-hydroxy carbonyl compounds in three reaction steps without masking the α-hydroxy groups. Quaternization of various 2-(α-hydroxyalkyl)benzothiazoles with methyl iodide in DMF afforded the corresponding 2-(α-hydroxyalkyl)-3-methylbenzothiazolium iodides in high yields and the subsequent alkylation or reduction of the C=N$^+$ link was readily accomplished with organolithium and Grignard reagents or sodium borohydride leading to the corresponding 2-(α-hydroxyalkyl)-3-methylbenzothiazolines with or without another 2-substituents. Hydrolysis of former compounds performed in aqueous acetonitrile, buffered to pH 7 and containing $AgNO_3$, gave the desired α-hydroxy ketones.

Umpolung[1] of the normal reactivity by modifying structural units has become one of the prevailing methods of choice in synthetic organic chemistry. Particularly, carbanions stabilized by adjacent sulfur atoms have been well-documented,[2] since Corey and Seebach[3] first utilized 2-lithio-1,3-dithiane as a formyl anion equivalent. Carbanions of cyclic imines stabilized by an adjacent heteroatom can also be regarded as an important formyl anion equivalent candidate due to the convertibility of the imine function with an adjacent heteroatom into a carbonyl group. However, notable differences in chemical stability between the cyclic imine adjacent oxygen atom and one adjacent sulfur atom have appeared. That is, the metalated oxazoline was reported to be unstable even at −78 °C,[4] while the corresponding benzothiazolyl anion seems to be stable as a masked formyl anion.[5] Despite much work in the benzothiazole field, however, only one example[6] of the use of 2-lithiobenzothiazole as a formyl anion equivalent has been described and there has been no study regarding its general reactivity to various electrophiles in spite of its importance and necessity. It is a purpose of the present paper to describe the fundamental and detailed studies of the general reactivity of 2-lithiobenzothiazole (**2**) toward different electrophiles (Scheme 1) and show the interesting differences in chemical reactivity between 2-lithio-1,3-dithiane or related reagents and **2**. We will also examine the utility of the lithium reagent **2** as a formyl anion equivalent with respect to the synthesis of α-hydroxy carbonyl compounds.

Preparation and Properties of 2-Lithiobenzothiazole (2). The conversion of benzothiazole (**1**) into the anion **2** was most conveniently achieved by adding 1.1 equiv of *n*-BuLi to a solution of **1** in THF at −78 °C which gave rise to a clear orange-colored solution. The progress of the lithiation was followed by deuteration of the reaction mixture with D_2O. When the solution was quickly quenched with D_2O after the addition of *n*-BuLi, the ^1H NMR spectrum of the product **3** (E=D), which had been isolated in 95% yield, showed 98% deuterium incorporation. This indicates that

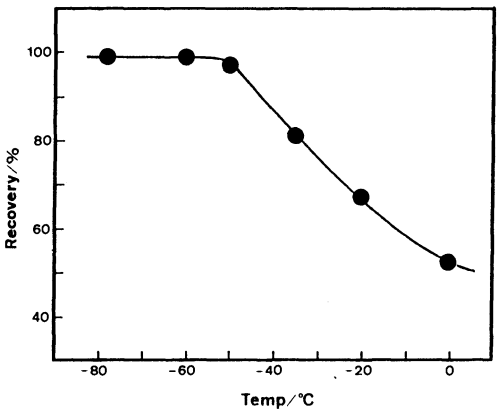

Fig. 1. Stability of 2-lithiobenzothiazole (**2**) in THF. Recovery percentages of benzothiazole (**1**) after quenching the anion solution with water at various temperatures.

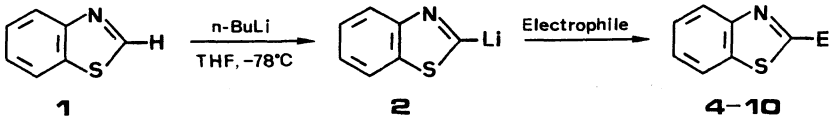

Scheme 1.

nearly quantitative metalation of **1** in THF at −78 °C occurs instantaneously. It is important and necessary for the reaction of **2** with a variety of electrophiles together with its operation to examine the stability of the anion **2** in THF at various temperatures. Thus, the yield of recovered **1** was monitored by quenching the THF solution containing the anion **2** with water after warming from −78 °C to several different temperatures (Fig. 1). As clearly indicated in Fig. 1, the anion **2** in THF is very stable below −50 °C, while it decomposes

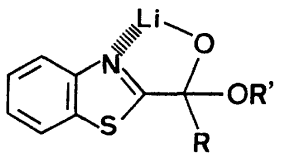
a) In all cases, 2-lithiobenzothiazle (**2**) was reacted with 1.1 equiv of esters or lactones in THF at −78 °C to room temperature. b) Yields of pure products after recrystallization unless otherwise noted. c) Yield of pure product after short-column chromatography on silica gel.

considerably above −50 °C and the degree of this decomposition increased in proportion to the temperature of the solution. Accordingly, in the following experiments, electrophiles were added immediately to the anion solution after the addition of *n*-BuLi and the temperature of the reaction mixture was kept below −50 °C until the reaction was almost completed.

Hydroxyalkylation of 2 with Aldehydes and Ketones. Aldehydes and ketones reacted readily with the anion **2** to give the corresponding 2-(α-hydroxyalkyl)benzothiazoles in high yields. Table 1 lists a number of reaction products **4a—j** and **5a—m** together with their yields. The reactions were almost completed within 1 h at −78 °C and the reaction time did not vary with the steric and electronic character of the carbonyl compounds. Under the present conditions, a readily enolized ketone, such as cyclohexanone, produced the product **51** in high yield by carbonyl addition (Entry 22). This demonstrates the very effective nucleophilicity of the lithium reagent **2**. When α,β-unsaturated ketones were employed as carbonyl substrates (Entries 18—21), the α-hydroxy products **5h—k** were selectively obtained in good yields showing a high preference of the anion **2** for nonconjugate 1,2-addition to α,β-unsaturated carbonyl compounds.

Acylations of 2 with Esters and Lactones. The reactions of the anion **2** with esters effectively lead to the formation of 2-acylbenzothiazole derivatives **6a—e**. Lactones constituted with a variety of ring sizes can also be employed as an acylating reagent of the anion **2** producing the corresponding 2-(hydroxyacyl)benzothiazoles (**7a—d**) in excellent yields. These results are summarized in Table 2. In contrast to acylations of 2-lithio-1,3-dithianes in which a large excess of acylating reagents is required in order to avoid the proton abstraction of the primary product by the unreacted lithium reagent or the formation of diadduct, 1.1 equiv of esters or lactones were effectively used in the present reactions with no limitations on the acylations of **2**. Therefore, in the present acylations, the acylating reagents could be added to the anion solution at −78 °C. The reason for the efficient acylations in the present cases should ascribe to the high stability of the initial adducts **11** derived from the chelating effect peculiar to the benzothiazole ring shown in Scheme 2. In fact, in some cases, the adducts **11** separated from the reaction mixture and even an acidic hydrolysis of them was needed for effectively obtaining the acylated product.



11

Scheme 2.

Reaction of 2 with Other Electrophiles. As well as esters and lactones, *N,N*-disubstituted amides and nitriles could also be used as acylating reagents as shown in Table 3. It is noteworthy that the reaction of the anion **2** with enolizable *N,N*-disubstituted amide, *N,N*-dimethylacetamide, proceeded effectively without enolization of the acylating reagent to afford 2-acetylbenzothiazole (**6f**) in excellent yield (Entry 2). This is in contrast to the similar acylation of 2-lithio-1,3-dithianes in which *N,N*-disubstituted amide as an acylating reagent is limited to a nonenolizable compound such as *N,N*-dimethylformamide. Alkylation of a formyl anion equivalent by using alkyl halides is one of useful and frequently encountered reactions. Many carbanions stabilized by adjacent heteroatoms have been known to be well-alkylated with common alkyl halides. However, we have found that alkylation of the anion **2** at −78—−50 °C could not proceed even with primary alkyl iodides or benzyl halides and in these reaction benzothiazole (**1**) was almost always rec-

Table 3. Reaction of 2-Lithiobenzothiazole (**2**) with Various Electrophiles[a]

Entry	Electrophile	Product	E	Yield/%[b]
1	C_6H_5CN	**6a**	C_6H_5CO-	82[c]
2	$(CH_3)_2NCOCH_3$	**6f**	CH_3CO-	77[c]

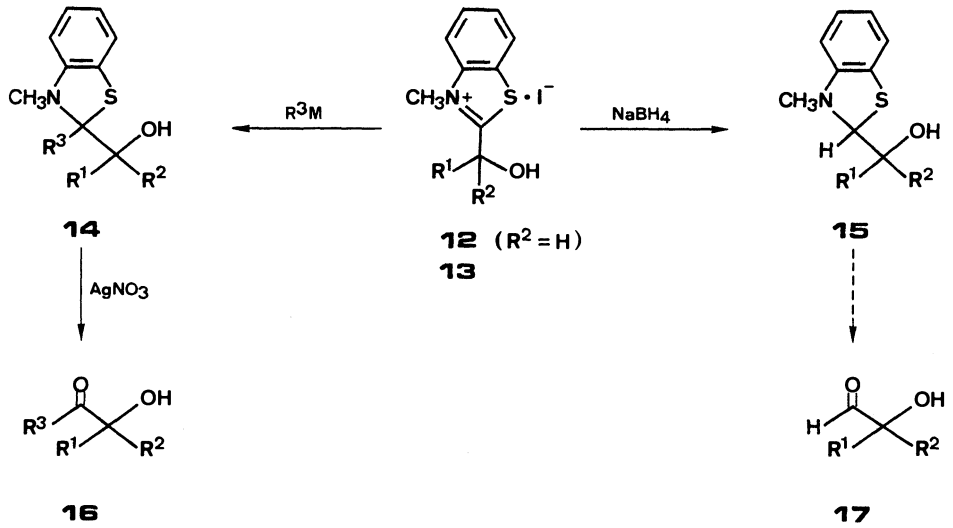
4	$C_6H_5COCH_2Br$	**9**		67
5	$C_6H_5COCH_2Cl$	**9**		92
6	$CH_3CO(CH_2)_3Cl$	**10**		90

a) In all cases, 2-lithiobenzothiazole (**2**) was reacted with 1.1 equiv of electrophiles in THF at −78 °C to room temperature. b) Yields of pure products after short-column chromatography on silica gel unless otherwise noted. c) Yield of pure product after recrystallization. d) Yield of crude, nearly pure product.

overed after quenching with water. On the other hand, trimethylsilylation of **2** proceeded rapidly at −78 °C with trimethylsilyl chloride (Entry 3). Accordingly, common alkyl halides can not be used successfully in alkylations of the anion **2**. In order to assess the nucleophilic nature of **2**, the reactions with phenacyl bromide, phenacyl chloride, or 5-chloro-2-pentanone were carried out (Entries 4—6). Interestingly, the cyclic ether derivatives **9** and **10** were selectively obtained in excellent yields. These results show that the products are formed by the nucleophilic attack of **2** at the carbonyl carbon followed by intramolecular cyclization. This emphatically suggests that nucleophilicity of **2** towards the halogenated carbon is very low. The reaction of epoxides with **2** was also examined but this did not lead to the formation of the expected 2-(β-hydroxyalkyl)benzothiazole derivatives. In this case, **1** was recovered after quenching with



Scheme 3.

c) Yield from benzothiazole (**1**).

water. Therefore, the reaction of 2-(lithiomethyl)-benzothiazole with carbonyl compounds is much more available rather than this reaction for obtaining 2-(β-hydroxyalkyl)benzothiazole derivatives.[7] It should be noted that the reaction of the anion **2** with alkyl halides or small-ring ethers at higher temperature (>−50 °C) was generally unavailable and unsatisfactory because the nucleophilicity of **2** towards the alkyl halides or the small-ring ethers did not depend on temperature and the reaction was not exempted from the decomposition of the anion itself as previously shown.

Table 5. Alkylation[a] of 2-(α-Hydroxyalkyl)-3-methylbenzothiazolium Salts (**12** and **13**) to 2-Substituted 2-(α-Hydroxyalkyl)-3-methylbenzothiazolines (**14**) and Hydrolysis[b] to α-Hydroxy Ketones (**16**)

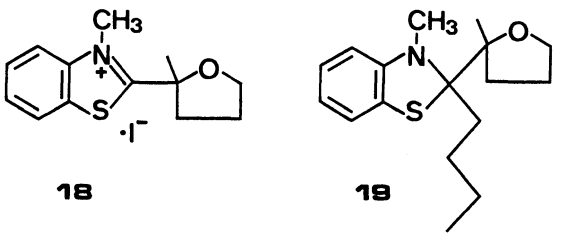
a) All the reactions were carried out with 2.2 equiv of organometalic reagents in THF at −78 °C (30 min) to room temperature (1 h). b) All the reactions were carried out with 3 equiv of $AgNO_3$ in aqueous acetonitrile buffered to pH 7 at room temperature to 45°C. c) Yields of isolated nearly pure products unless otherwise noted. d) Isolated yields from the corresponding benzothiazolium salts unless otherwise noted. e) Yield from **14b** after purification by short-colum chromatography on silica gel.

An Application to the Synthesis of α-Hydroxy Carbonyl Compounds. We have further investigated the synthetic utility of the lithium reagent **2** as a formyl anion equivalent in the synthesis of α-hydroxy carbonyl compounds. As outlined in Scheme 3, the methodology comprises the quaternization of 2-(α-hydroxyalkyl)benzothiazoles (**4** and **5**) and the subsequent alkylation or reduction of the resulting salts **12** and **13** with organolithium and Grignard reagents or $NaBH_4$ leading to the corresponding 2,2-disubstituted benzothiazolines (**14**) or 2-substituted benzothiazolines (**15**), followed by their hydrolysis under mildly neutral conditions.

Methylation of **4** and **5** is very important not only for the present methodology but for our different methodology reported previously.[8] Therefore, we have examined this reaction with a variety of selected 2-(α-hydroxyalkyl)benzothiazoles (Table 4). It was found that these quaternizations could be conveniently and efficiently performed by the treatment with 6 equiv of methyl iodide in DMF at reflux temperature affording the desired iodides **12** and **13** in high yields, although the reaction of **5** derived from ketones (Entries 9—16) was generally more sluggish than that of **4** derived from aldehydes (Entries 1—8) and required a longer reaction time.

In order to obtain the 2-substituted 2-(α-hydroxyalkyl)benzothiazolines (**14**), we have studied the direct alkylation at the C-2 position of the thiazolium ring of **12** and **13** and discovered that 2 equiv of alkyl or alkynyllithium and Grignard reagents reacted cleanly with the several test α-hydroxy salts **12a**, **b**, **d**, **e**, and **13b** to give, after aqueous workup, the expected products **14a—f** in excellent yields (Table 5). Moreover, when the 2-(2-furyl)benzothiazolium iodide (**18**), which resulted from the aforementioned methylation of **10** (90% yield), was used in the reaction with *n*-BuMgBr (1.1 equiv), the benzothiazoline **19** was obtained in nearly quantitative yield (Scheme 4). However, we observed that the reaction of 2-(α-hydroxybenzyl)-3-methylbenzothiazolium iodide (**12g**) with *n*-BuLi or *n*-BuMgBr in THF gave considerable amounts of benzaldehyde together with the expected alkylation prod-



Scheme 4.

Table 6. $NaBH_4$ Reduction of 2-(α-Hydroxyalkyl)-3-methylbenzothiazolium Salts (**12** and **13**) to 2-(α-Hydroxyalkyl)-3-methylbenzothiazolines (**15**)[a]

Salt	Product		Yield/%[b]
12a		**15a**	88
12c		**15b**	Quant.

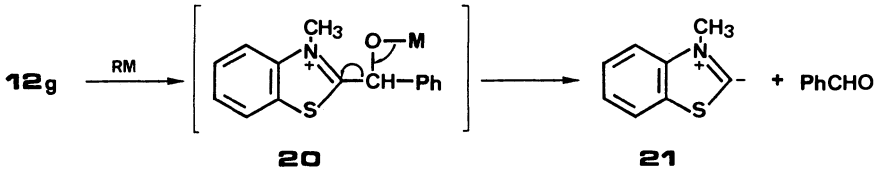
12h		**15f**	71
13b		**15g**	82

a) All the reactions were carried out with 5 equiv of $NaBH_4$ in ethanol at 0 °C (30 min) to room temperature (1 h). b) Yields of isolated, nearly pure products.



Scheme 5.

uct. This reaction most likely involves the elimination of the ylide **21** from the alkoxy intermediate **20** (Scheme 5).[9] Hydrolysis of crude 2-(α-hydroxyalkyl)-benzothiazolines (**14**) obtained here to the α-hydroxy ketones **16** was examined at the same time (Table 5). This could be effectively accomplished under mildly neutral conditions using $AgNO_3$ in an aqueous acetonitrile-phosphate buffer (0.05 M,† pH 7) solvent system,[10] affording the corresponding α-hydroxy ketones **16a—f** in good yields without any evidence of dehydration.

On the other hand, for obtaining the 2-substituted benzothiazolines (**15**), the reduction of the salts **12** and **13** with $NaBH_4$ was found to be very easy. Thus, the several test substances **12a**, **c**, **d**, **e**, **f**, h, and **13b** were cleanly reduced with no limitations by using 5 equiv of $NaBH_4$ in ethanol at 0 °C to room temperature to give **15a—g** in excellent yields (Table 6). In the present study, we did not examine the direct hydrolysis of **15** to α-hydroxy aldehydes **17**, since the latter compounds were well known to be generally unstable. However, it should be expected that these thiazolines **15** could be useful as a protected form of α-hydroxy aldehydes **17** because of easy convertibility of 2-substituted 3-methylbenzothiazoline function into a formyl group.[10]

Experimental

Melting points were recorded on a Yanagimoto micro melting-point apparatus and are uncorrected. ^1H NMR spectra were measured with a JEOL PMX-60 spectrometer at 60 MHz using tetramethylsilane as an internal reference. IR spectra were recorded on a JASCO A-202 spectrophotometer. GLC analyses were carried out on a Shimadzu Gas Chromatograph GC-6AM equipped with a hydrogen flame ionization detector using glass columns (1.5 m) packed with 2% Silicone OV-7 on Uniport HP (60—80 mesh). Silica gel (Wakogel C-300) was used for short-column chromatography. TLC was carried out on Merck precoated silica gel plates (Merck silica gel 60 F_{254}).

Materials. Tetrahydrofuran (THF) was freshly distilled over $LiAlH_4$ before use. Commercially available benzothiazole was purified by distillation. Butyllithium was obtained commercially as a 1.6 M solution in hexane. 0.05 M Phosphate buffer was prepared by dilution of the 0.1 M solution (pH 7, 0.4 M Na_2HPO_4+0.4 M KH_2PO_4) which was commercially available. The other reagents and solvents were obtained as high-grade commercial products and purified by the usual methods.

General Procedure for the Preparation of 2-Lithiobenzothiazole (2) Solution in THF. A stirred solution (0.5 M) of benzothiazole (**1**) in dry THF under nitrogen was cooled to −78 °C (Dry Ice/methanol bath) and 10% excess of butyllithium in hexane (1.6 M) was added dropwise (ca. 5 ml min^{-1}). Just before the addition had been completed, the anion solution gave rise to a clear and orange-colored solution. At the completion of the butyllithium addition, benzothiazole (**1**) was metalated quantitatively (>98% by ^1H NMR) as determined by deuteration of the solution with D_2O. The reaction vessel was continuously purged with nitrogen until the workup after the reaction with electrophiles.

The stability of the anion solution was determined by quenching the solutions (5 mmol scales) with a large excess of water after warming (ca. 5 °C min^{-1}) to several different temperatures. The aqueous mixtures were extracted with dichloromethane and the organic layers were dried with $MgSO_4$. Recovered yields of benzothiazole (**1**) were determined by GLC using pentylbenzene as an internal standard (Fig. 1).

General Procedure for the Reaction of the Anion 2 with Aldehydes and Ketones. A solution (0.55 M) of carbonyl compound (1.1 equiv to **1**) in dry THF was slowly added to the stirred solution of the anion **2** at −78 °C and the stirring was continued at the same temperature for 1 h. After removing the cold bath, the mixture was stirred for an additional 10 min and then quenched with a large excess of water. The aqueous mixture was extracted with benzene and the organic layer was washed thoroughly with water and then dried with $MgSO_4$. The mixture was evaporated under reduced pressure and the residue was completely dried in vacuo to give crude 2-(α-hydroxyalkyl)benzothiazoles (**4** and **5**). Purification of the products were performed by recrystallization for compounds **4a—c**, **4e**, **4h**, **4j**, **5c—e**, **5g—j**, **5l**, and **5m** or short-column chromatography for compounds **4d**, **4g**, **4i**, **5a**, **5b**, and **5k**. The results are summarized in Table 1. The ^1H NMR and physical data of the products are as follows (compounds **4f** and **5f** were characterized after conversion into the corresponding 3-methylbenzothiazolium iodides **12e** and **13e**).

4a: Colorless needles (acetone); mp 102—102.5 °C; ^1H NMR ($CDCl_3$) δ=1.00 (t, 3H, CH_3, J=7 Hz), 1.93 (m, 2H, CH_2), 4.50 (brs, 1H, OH), 4.90 (t, 1H, CH, J=6 Hz), 7.17 (m, 2H, Arom), and 7.68 (m, 2H, Arom). Found: C, 62.02; H, 5.80; N, 7.21%. Calcd for $C_{10}H_{11}NOS$: C, 62.15; H, 5.74; N, 7.25%.

4b: Colorless needles (acetone/hexane); mp 89—90 °C; ^1H NMR ($CDCl_3$) δ=0.92 (t, 3H, CH_3, J=7 Hz), 1.17—2.13 (m, 4H, $2CH_2$), 3.93 (d, 1H, OH, J=5 Hz), 4.95 (q, 1H, CH), 7.17 (m, 2H, Arom), and 7.67 (m, 2H, Arom). Found: C, 63.81; H, 6.30; N, 6.56%. Calcd for $C_{11}H_{13}NOS$: C, 63.73; H, 6.32; N, 6.76%.

4c: Colorless needles (acetone/hexane); mp 62.5—63 °C; ^1H NMR ($CDCl_3$) δ=0.67—2.17 (brm, 11H, n-C_5H_{11}), 3.27 (d, 1H, OH, J=5 Hz), 4.97 (q, 1H, CH), 7.27 (m, 2H, Arom), and 7.77 (m, 2H, Arom). Found: C, 66.37; H, 7.27; N, 5.86%. Calcd for $C_{13}H_{17}NOS$: C, 66.35; H, 7.28; N, 5.95%.

4d: Colorless oil; ^1H NMR ($CDCl_3$) δ=0.97 (d, 6H, $2CH_3$, J=7 Hz), 2.15 (m, 1H, CH), 4.77 (d, 1H, CHOH, J=5 Hz), 5.05 (brs, 1H, OH), 7.25 (m, 2H, Arom), and 7.80 (m, 2H, Arom). Found: C, 63.69; H, 6.21; N, 6.75%. Calcd for $C_{11}H_{13}NOS$: C, 63.73; H, 6.32; N, 6.76%.

4e: Colorless needles (acetone); mp 110—111 °C; ^1H NMR ($CDCl_3$) δ=1.00 (s, 9H, $3CH_3$), 4.35 (brs, 1H, OH), 4.60 (brs, 1H, CH), 7.26 (m, 2H, Arom), and 7.75 (m, 2H, Arom). Found: C, 65.05; H, 6.87; N, 6.34%. Calcd for $C_{12}H_{15}NOS$: C, 65.12; H, 6.83; N, 6.33%.

4g: Colorless oil; ^1H NMR ($CDCl_3$) δ=0.67—2.17 (brm, 16H), 3.73 (d, 1H, OH, J=5 Hz), 4.67, (brm, 1H, CHOH), 5.00 (brm, 1H, HC≡C), 7.23 (m, 2H, Arom), and 7.73 (m, 2H, Arom). Found: C, 70.52; H, 7.98; N, 4.65%. Calcd for $C_{17}H_{23}NOS$: C, 70.55; H, 8.01; N, 4.84%.

† 1M=1 mol dm^{-3}.

4h: Colorless needles (acetone/hexane); mp 124.5—125 °C; ^{1}H NMR ($CDCl_3$) δ=4.56 (brs, 1H, OH), 5.96 (s, 1H, CH), 7.19 (m, 7H, C_6H_5 and Arom), and 7.64 (m, 2H, Arom). Found: C, 69.73; H, 4.71; N, 5.69%. Calcd for $C_{14}H_{11}NOS$: C, 69.68; H, 4.60; N, 5.80%.

4i: Colorless needles; mp 78—79 °C; ^{1}H NMR ($CDCl_3$) δ=3.73 (s, 6H, $2CH_3O$), 4.67 (brs, 1H, OH), 5.93 (brs, 1H, CH), 6.70 (s, 1H, Arom), 6.87 (m, 2H, Arom), 7.20 (m, 2H, Arom), and 7.67 (m, 2H, Arom). 5h: Colorless needles (acetone/hexane); mp 169.5—170 °C; ^{1}H NMR ($CDCl_3$) δ=3.93 (s, 1H, OH), 6.78 (m, 2H, CH=CH), 7.20 (m, 12H, $2C_6H_5$ and Arom), and 7.77 (m, 2H, Arom). Found: C, 76.76; H, 4.95; N, 3.99%. Calcd for $C_{22}H_{17}NOS$: C, 76.94; H, 4.99; N, 4.08%.

5i: Colorless needles (acetone/pentane); mp 134.5—135 °C; ^{1}H NMR ($CDCl_3$) δ=2.07 (s, 3H, CH_3), 4.20 (brs, 1H, OH), 7.17 (m, 7H, C_6H_5 and Arom), and 7.79 (m, 2H, Arom). Found: C, 73.01; H, 4.77; N, 4.71%. Calcd for $C_{17}H_{13}NOS$: C, 73.09; H, 4.69; N, 5.01%.

5j: Colorless needles (acetone); mp 144—144.5 °C; ^{1}H NMR ($CDCl_3$) δ=1.57—1.87 (m, 9H, $3CH_3$), 3.38 (s, 1H, OH), 5.62 (m, 1H, HC=C), 7.20 (m, 2H, Arom), and 7.73 (m, 2H, Arom). Found: C, 66.87; H, 6.57; N, 5.82%. Calcd for $C_{13}H_{15}NOS$: C, 66.92; H, 6.48; N, 6.00%.

5k: Colorless needles; mp 105—106 °C; ^{1}H NMR ($CDCl_3$) δ=0.97 (s, 3H, CH_3), 1.13 (s, 3H, CH_3), 1.73 (s, 3H, CH_3), 1.88 (brd, 2H, CH_2, J=4 Hz), 2.00 (s, 1H, C<u>H</u>H), 2.01 (s, 1H, CH<u>H</u>), 3.47 (brs, 1H, OH), 5.52 (m, 1H, H-C=C-), 7.17 (m, 2H, Arom), and 7.72 (m, 2H, Arom). Found: C, 70.03; H, 7.12; N, 4.93%. Calcd for $C_{16}H_{19}NOS$: C, 70.29; H, 7.00; N, 5.12%.

5l: Colorless needles (acetone/hexane); mp 106.5—107 °C; ^{1}H NMR ($CDCl_3$) δ=1.10—2.43 (m, 10H, $5CH_2$), 3.27 (s, 1H, OH), 7.19 (m, 2H, Arom), and 7.73 (m, 2H, Arom). Found: C, 66.83; H, 6.56; N, 5.84%. Calcd for $C_{13}H_{15}NOS$: C, 66.92; H, 6.48; N, 6.00%.

5m: Colorless needles (acetone/hexane); mp 148—148.5 °C; ^{1}H NMR ($CDCl_3$) δ=1.40 (br, 18H, $9CH_2$), 2.00 (br, 4H, $2CH_2$), 2.97 (s, 1H, OH), 7.23 (m, 2H, Arom), and 7.77 (m, 2H, Arom). Found: C, 71.73; H, 8.65; N, 4.23%. Calcd for $C_{19}H_{27}NOS$: C, 71.88; H, 8.57; N, 4.41%.

General Procedure for the Reaction of the Anion 2 with Esters and Lactones. A solution (0.55 M) of ester or lactone (1.1 equiv to **1**) in dry THF was slowly added to the stirred solution of the anion **2** in THF at −78 °C and the mixture was stirred for 1 h. After removal of the cold bath, the mixture was continuously stirred for 30 min and then quenched with a large excess of water (in experiments with lactones, 0.1 M hydrochloric acid was used in place of water for the quenching). The aqueous mixture was extracted with benzene and the extract was washed thoroughly with water. The organic layer was dried with $MgSO_4$ and concentrated under reduced pressure to give crude 2-acylbenzothiazoles (**6** and **7**). Purification of the products was performed by recrystallization for compounds **6a—c** and **7a—d** or short-column chromatography for compounds **6d** and **6e**. The results are summarized in Table 2. The ^{1}H NMR and physical data of the products are as follows.

6a: Pale yellow needles (ethanol); mp 103.5—104.5 °C (lit,[5] mp 102.5 °C); ^{1}H NMR ($CDCl_3$) δ=7.30 (m, 5H, C_6H_5), 7.63 (m, 2H, Arom), and 8.10 (m, 2H, Arom).

6b: Colorless needles (ethanol); mp 76—77 °C; ^{1}H NMR ($CDCl_3$) δ=1.27 (t, 3H, CH_3, J=7 Hz), 3.25 (q, 2H, CH_2), 7.33 (m, 2H, Arom), and 7.85 (m, 2H, Arom). Found: C, 62.73; H, 4.65; N, 7.39%. Calcd for $C_{10}H_9NOS$: C, 62.80; H, 4.74; N, 7.32%.

6c: Colorless needles (ethanol); mp 61—62 °C; ^{1}H NMR ($CDCl_3$) δ=1.00 (t, 3H, CH_3, J=7 Hz), 1.12—1.73 (m, 6H, $3CH_2$), 3.20 (t, 2H, CH_2CO, J=6 Hz), 7.30 (m, 2H, Arom), and 7.82 (m, 2H, Arom). Found: C, 66.93; H, 6.45; N, 5.90%. Calcd for $C_{13}H_{15}NOS$: C, 66.92; H, 6.48; N, 6.00%.

6d: Colorless oil; ^{1}H NMR ($CDCl_3$) δ=1.30 (d, 6H, $2CH_3$, J=7 Hz), 3.92 (m, 1H, CH), 7.30 (m, 2H, Arom), and 7.83 (m, 2H, Arom). Found: C, 64.37; H, 5.38; N, 6.70%. Calcd for $C_{11}H_{11}NOS$: C, 64.36; H, 5.40; N, 6.82%.

6e: Colorless needles; mp 54.5—55.5 °C; ^{1}H NMR ($CDCl_3$) δ=1.53 (s, 9H, $3CH_3$), 7.33 (m, 2H, Arom), and 7.87 (m, 2H, Arom). Found: C, 65.75; H, 5.94; N, 6.29%. Calcd for $C_{12}H_{13}NOS$: C, 65.72; H, 5.97; N, 6.39%.

7a: Colorless needles (hexane/acetone); mp 93—93.5 °C; ^{1}H NMR ($CDCl_3$) δ=2.02 (m, 2H, CH_2), 3.30 (t, 2H, CH_2CO, J=7 Hz), 3.67 (t, 2H, C<u>H</u>$_2$OH, J=6 Hz), 3.67 (br, 1H, OH), 7.33 (m, 2H, Arom), and 7.85 (m, 2H, Arom). Found: C, 59.82; H, 5.06; 6.15%. Calcd for $C_{11}H_{11}NO_2S$: C, 59.71; H, 5.01; N, 6.33%.

7b: Colorless needles (acetone/hexane); mp 81—82 °C; ^{1}H NMR ($CDCl_3$) δ=1.23 (d, 3H, CH_3, J=6 Hz), 1.97 (q, 2H, CH_2), 3.32 (t, 2H, CH_2CO, J=7 Hz), 3.83 (m, 1H, CH), 4.35 (d, 1H, OH, J=8 Hz), 7.27 (m, 2H, Arom), and 7.83 (m, 2H, Arom). Found: C, 61.26; H, 5.50; N, 5.84%. Calcd for $C_{12}H_{13}NO_2S$: C, 61.25; H, 5.57; N, 5.95%.

7c: Colorless needles (acetone/hexane); mp 89.5—90.5 °C; ^{1}H NMR ($CDCl_3$) δ=1.33—2.50 (m, 4H, $2CH_2$), 3.22 (t, 2H, CH_2CO, J=7 Hz), 3.62 (t, 2H, $C\underline{H}_2OH$, J=6 Hz), 3.62 (br, 1H, OH), 7.27 (m, 2H, Arom), and 7.87 (m, 2H, Arom). Found: C, 61.24; H, 5.51; N, 5.89%. Calcd for $C_{12}H_{13}NO_2S$: C, 61.25; H, 5.57; N, 5.95%.

7d: Colorless needles (acetone/hexane); mp 81.5—82.5 °C; ^{1}H NMR ($CDCl_3$) δ=1.17—2.17 (m, 6H, $3CH_2$), 3.20 (t, 2H, CH_2CO, J=7 Hz), 3.50 (br, 1H, OH), 3.57 (t, 2H, $C\underline{H}_2OH$, J=6 Hz), 7.33 (m, 2H, Arom), and 7.85 (m, 2H, Arom). Found: C, 62.64; H, 6.18; N, 5.54%. Calcd for $C_{13}H_{15}NO_2S$: C, 62.63; H, 6.06; N, 5.62%.

Reaction of the Anion 2 with Benzonitrile. A solution of benzonitrile (2.84 g, 27.5 mmol) in dry THF (5 ml) was added to the stirred solution of the anion **2** (prepared from 25 mmol of **1**) at −78 °C and the mixture was continuously stirred for 1 h. After removing the cold bath, the mixture was stirred for an additional 10 min and then hydrolyzed with concd hydrochloric acid (5 ml). The acidic solution was continuously stirred until the temperature reached room temperature. The mixture was poured into same amount of water and the aqueous mixture was extracted with benzene. The benzene extract was washed thoroughly with water and the organic layer was dried with $MgSO_4$. The crystals obtained by evaporation of the organic layer under reduced pressure were triturated in pentane and filtered to give the crude 2-benzoylbenzothiazole (**6a**). Recrystallization from ethanol afforded pure **6a** as pale yellow needles (5.33 g, 82%); mp 103.5—104.5 °C (lit,[5] mp 102.5 °C).

Reaction of the Anion 2 with *N,N*-Dimethylacetamide. A solution of *N,N*-dimethylacetamide (2.40 g, 27.5 mmol) in dry THF (50 ml) was added to the stirred solution of the anion **2** (prepared from 25 mmol of **1**) at −78 °C and the mixture was continuously stirred for 1 h. The mixture was allowed to warm to room temperature and continuously stirred for an additional 30 min. The mixture was quenched with a large excess of water and extracted with benzene. The organic layer was washed thoroughly with water and dried with $MgSO_4$ and then evaporated under reduced pressure to give the crude crystalline 2-acetylbenzothiazole (**6f**). Recrystallization from acetone afforded pure **6f** as colorless needles (3.22 g, 73%); mp 108.5—109.5 °C; ^{1}H NMR ($CDCl_3$) δ=2.72 (s, 3H, CH_3), 7.30 (m, 2H, Arom), and 7.83 (m, 2H, Arom). Found: C, 60.83; H, 3.80; N, 7.78%. Calcd for C_9H_7NOS: C, 60.99; H, 3.98; N, 7.90%.

Reaction of the Anion 2 with Trimethylsilyl Chloride. Trimethylsilyl chloride (3.26 g, 30 mmol) was added to the stirred solution of the anion **2** (prepared from 25 mmol of **1**) at −78 °C and the mixture was continuously stirred for 1 h. The mixture was allowed to warm to room temperature and continuously stirred for 1 h. The mixture was concentrated under reduced pressure and the residue was extracted with hexane. The hexane extract was washed thoroughly with water and the organic layer was dried with $MgSO_4$. After evaporation of the solvent under reduced pressure gave the nearly pure (monitored by GLC) 2-trimethylsilylbenzothiazole (**8**) as a pale yellow oil (4.98 g, 96%). Purification by distillation afforded pure **8** as a colorless oil; bp 121—122 °C/ 5 mmHg†† (lit,[11] bp 139 °C/15 mmHg).

Reaction of the Anion 2 with Phenacyl Halides. A solution of phenacyl bromide or chloride (27.5 mmol) in dry THF (5 ml) was added to the stirred solution of the anion **2** (prepared from 25 mmol of **1**) at −78 °C and the mixture was then stirred for 1 h. The mixture was allowed to warm to room temperature and continuously stirred for 1 h. The mixture was concentrated under reduced pressure and the residue was diluted with benzene and then washed thoroughly with water. The organic layer was dried with $MgSO_4$ and evaporated under reduced pressure to give the crude oily 2-(2-phenyl-2-oxiranyl)benzothiazole (**9**). Purification by short-column chromatography afforded pure **9** as a colorless oil; ^{1}H NMR ($CDCl_3$) δ=3.15 (d, 1H, C$\underline{H}$H, J=6 Hz), 3.43 (d, 1H, CH$\underline{H}$, J=6 Hz), 7.17 (m, 7H, C_6H_5 and Arom), and 7.50 (m, 2H, Arom). Found: C, 70.83; H, 4.69; N, 5.48%. Calcd for $C_{15}H_{12}NOS$: C, 70.84; H, 4.76; N, 5.51%.

Reaction of the Anion 2 with 5-Chloro-2-pentanone. A solution of 5-chloro-2-pentanone (3.32 g, 27.5 mmol) in dry THF (5 ml) was added to the stirred solution of the anion **2** (prepared from 25 mmol of **1**) at −78 °C and the mixture was stirred for an additional 50 min at the same temperature. The mixture was allowed to warm to room temperature and continuously stirred for 2 h. The mixture was concentrated under reduced pressure and the residue was extracted with benzene. The benzene extract was washed thoroughly with water and the organic layer was dried with $MgSO_4$. Evaporation of the solvent under reduced pressure gave the crude oily 2-(2-methyltetrahydro-2-furanyl)benzothiazole (**10**). Purification by distillation afforded pure **10** as a colorless oil (4.94 g, 90%); bp 138.2 °C/2.5 mmHg; ^{1}H NMR ($CDCl_3$) δ=1.32 (s, 3H, CH_3), 1.84 (m, 4H, $2CH_2$), 3.83 (t, 2H, CH_2O), 7.16 (m, 2H, Arom), and 7.72 (m, 2H, Arom). Found: C, 65.72; H, 5.97; N, 6.39%. Calcd for $C_{12}H_{13}NOS$: C, 65.76; H, 6.18; N, 6.41%.

General Procedure for the Preparation of 2-(α-Hydroxyalkyl)-3-methylbenzothiazolium Iodides (12 and 13). The solution of 2-(α-hydroxyalkyl)benzothiazole (**4** or **5**) (48 mmol) in dimethylformamide (18 ml) and methyl iodide (18 ml) was refluxed with stirring for the appropriate times (see Table 4). After cooling to room temperature, the mixture was diluted with diethyl ether (50 ml) and cooled in an ice bath to completely precipitate the salt. The separated needles were collected by filtration, washed thoroughly with diethyl ether, and then dried in vacuo to afford the crude 2-(α-hydroxyalkyl)-3-methylbenzothiazolium salt (**12** or **13**). Recrystallization was performed from methanol to afford pure **12** and **13**. The results are summarized in Table 4. ^{1}H NMR and physical data of the products are as follows.

12a: Colorless needles (methanol); mp 206—209 °C (decomp); ^{1}H NMR (DMSO-d_6) δ=1.03 (t, 3H, CH_3, J=7 Hz), 1.85 (m, 2H, CH_2), 4.27 (s, 3H, CH_3N), 5.42 (q, 1H, CH), 7.31 (br, 1H, OH), 7.67 (m, 2H, Arom), and 8.23 (m, 2H, Arom). Found: C, 39.47; H, 4.21; N, 4.06%. Calcd for $C_{11}H_{14}NOSI$: C, 39.42; H, 4.21; N, 4.18%.

12b: Colorless needles (methanol/acetone); mp 126.5—127 °C (decomp); ^{1}H NMR (DMSO-d_6) δ=0.67—2.00 (br, 11H, n-C_5H_{11}), 4.22 (s, 3H, CH_3N), 5.42 (br, 1H, CH), 7.34 (br, 1H, OH), 7.72 (m, 2H, Arom), and 8.23 (m, 2H, Arom). Found: C, 44.33; H, 5.31; N, 3.62%. Calcd for $C_{14}H_{20}NOSI$: C, 44.57; H, 5.34; N, 3.71%.

12c: Colorless needles (methanol/acetone); mp 188.5—189 °C (decomp); ^{1}H NMR (DMSO-d_6) δ=1.12 (d, 3H, CH_3, J=7 Hz), 1.42 (d, 3H, CH_3, J=7 Hz), 2.53 (m, 1H, CH), 4.58 (s, 3H, CH_3N), 5.67 (br, 1H, C$\underline{H}$OH), 7.27 (br, 1H, OH), 8.02 (m, 2H, Arom), and 8.57 (m, 2H, Arom). Found: C, 41.33; H,

†† 1 mmHg≈133.322 Pa.

4.62; N, 3.84%. Calcd for $C_{12}H_{16}NOSI$: C, 41.27; H, 4.62; N, 4.01%.

12d: Colorless needles (methanol); mp 212—212.5 °C (decomp); ^{1}H NMR (DMSO-d_6) δ=1.33 (s, 9H, $3CH_3$), 4.67 (s, 3H, CH_3N), 5.63 (d, 1H, CH, J=4 Hz), 7.17 (d, 1H, OH, J=4 Hz), 8.03 (m, 2H, Arom), and 8.53 (m, 2H, Arom). 13f: Colorless needles (methanol/acetone); mp 139—140 °C (decomp); ^{1}H NMR (DMSO-d_6) δ=2.10 (s, 3H, CH_3), 3.57 (brs, 1H, OH), 3.92 (s, 3H, CH_3N), 6.47 (q, 1H, Furan-H), 6.77 (d, 1H, Furan-H, J=3 Hz), 7.50—8.00 (m, 3H, Furan-H and Arom), and 8.23 (m, 2H, Arom). Found: C, 43.44; H, 3.65; N, 3.67%. Calcd for $C_{14}H_{14}NO_2SI$: C, 43.42; H, 3.64; N, 3.62%.

13g: Colorless needles (methanol/acetone); mp 179.5—180 °C (decomp); ^{1}H NMR (DMSO-d_6) δ=2.07 (s, 10H, $5CH_2$), 3.27 (br, 1H, OH), 4.43 (s, 3H, CH_3N), 7.77 (m, 2H, Arom), and 8.28 (m, 2H, Arom). Found: C, 44.82; H, 4.81; N, 3.69%. Calcd for $C_{14}H_{18}NOSI$: C, 44.81; H, 4.83; N, 3.73%.

13h: Colorless needles (methanol); mp 221—221.5 °C (decomp); ^{1}H NMR (DMSO-d_6) δ=1.33 (brs, 18H, $9CH_2$), 2.03 (br, 4H, $2CH_2$), 3.57 (br, 1H, OH), 4.67 (s, 3H, CH_3N), 7.80 (m, 2H, Arom), and 8.27 (m, 2H, Arom). Found: C, 51.96; H, 6.51; N, 2.83%. Calcd for $C_{20}H_{30}NOSI$: C, 52.29; H, 6.58; N, 3.05%.

18: Colorless needles (methanol/acetone); mp 195—195.5 °C (decomp); ^{1}H NMR (DMSO-d_6) δ=1.50 (s, 3H, CH_3), 2.00 (m, 4H, $2CH_2$), 3.99 (m, 2H, CH_2O), 4.25 (s, 3H, CH_3N), 7.69 (m, 2H, Arom), and 8.20 (m, 2H, Arom). Found: C, 43.33; H, 4.45; N, 3.94%. Calcd for $C_{13}H_{16}NOSI$: C, 43.22; H, 4.46; N, 3.88%.

General Procedure for the Alkylation of 2-(α-Hydroxyalkyl)-3-methylbenzothiazolium Iodides (12 and 13). A solution (1.6 M) of butyllithium (4.4 mmol) in hexane or a solution (0.8 M) of Grignard reagents (4.4 mmol; prepared from the corresponding bromide or chloride in THF) was added dropwise to a stirred and cooled suspension of 2-(α-hydroxyalkyl)benzothiazolium salt (**12** or **13**) (2 mmol) at −78 °C in the same solvent (10 ml). The mixture was stirred for 30 min at −78 °C and then allowed to warm to room temperature. After being stirred for 1 h, the mixture was quenched with large excess of water. After separation of the organic layer, the aqueous layer was extracted with dichloromethane. The combined organic layer was dried with $MgSO_4$ and filtered through silica gel (Wakogel C-300). Concentration of the solvent under reduced pressure afforded the nearly pure (monitored by TLC) 2-substituted 2-(α-hydroxyalkyl)-3-methylbenzothiazoline (**14**) as a viscous oil. A THF solution of 1-nonynyllithium (prepared by lithiation of 1,1-dibromo-1-nonene with butyllithium) was similarly used, giving the corresponding 2-(α-hydroxyalkyl)benzothiazolines (**14b**) which was isolated by short-column chromatography. These results are summarized in Table 5.

These compounds were used in the next hydrolysis step without further purification and identified at the same time by means of this hydrolysis transformation to the corresponding α-hydroxy ketones.

General Procedure for the Reduction of 2-(α-Hydroxyalkyl)-3-methylbenzothiazolium Iodides (12 and 13) with $NaBH_4$. The benzothiazolium salt **12** or **13** (2.0 mmol), dissolved in ethanol (8 ml), was treated with sodium borohydride (0.38 g, 10 mmol) at 0 °C. After stirring for 30 min at 0 °C and then 1 h at room temperature, the reaction mixture was diluted with water (30 ml) and the aqueous mixture was extracted with dichloromethane. The dichloromethane extract was dried with $MgSO_4$ and filtered through silica gel (Wakogel C-300). Concentration of the filtrate under reduced pressure afforded the nearly pure (monitored by TLC) 2-(α-hydroxyalkyl)-3-methylbenzothiazolines (**15**). The results are summarized in Table 6. ^{1}H NMR data of the products are as follows: **15a**: Viscous oil; ^{1}H NMR ($CDCl_3$) δ=1.05 (t, 3H, CH_3), 1.57 (m, 2H, CH_2), 2.62 (br, 1H, OH), 3.00 (s, 3H, CH_3N), 3.57 (m, 1H, CHOH), 4.81 (d, 1H, NCHS),

and 6.91 (m, 4H, Arom). **15b**: Viscous oil; ^{1}H NMR ($CDCl_3$) δ=0.87 (d, 3H, CH_3), 0.98 (d, 3H, CH_3), 1.93 (m, 1H, CH), 2.70 (s, 1H, OH), 2.87 (s, 3H, CH_3N), 3.30 (dd, 1H, CHOH), 4.60 (d, 1H, NCHS), and 6.67 (m, 4H, Arom). **15c**: Viscous oil; ^{1}H NMR ($CDCl_3$) δ=0.97 (s, 9H, $3CH_3$), 2.80 (s, 3H, CH_3N), 3.28 (dd, 1H, CHOH), 3.33 (s, 1H, OH), 4.54 (d, 1H, NCHS), and 6.73 (m, 4H, Arom). **15d**: Viscous oil; ^{1}H NMR ($CDCl_3$) δ=0.71—2.38 (br, 11H, cyclohexyl), 2.86 (s, 3H, CH_3N), 3.00 (br, 1H, OH), 3.33 (dd, 1H, CHOH), 4.71 (d, 1H, NCHS), and 6.79 (m, 4H, Arom). **15e**: Viscous oil; ^{1}H NMR ($CDCl_3$) δ=0.71—2.29 (m, 16H), 2.90 (s, 3H, CH_3N), 3.00 (br, 1H, OH), 3.81 (m, 1H, CHOH), 4.67 (d, 1H, NCHS), 5.00 (m, 1H, CH=C), and 6.72 (m, 4H, Arom). **15f**: Viscous oil; ^{1}H NMR ($CDCl_3$) δ=2.57 and 2.83 (s, 3H, CH_3N), 3.29 (br, 1H, OH), 3.76 (s, 6H, $2CH_3O$), 4.43 and 4.69 (d, 1H, CHOH), 4.86 and 5.04 (d, 1H, NCHS), and 6.10—7.00 (m, 7H, Arom). **15g**: Viscous oil; ^{1}H NMR ($CDCl_3$) δ=0.95 (s, 6H, $2CH_3$), 2.90 (s, 3H, CH_3N), 3.33 (dd, 1H, OH), 4.67 (d, 1H, NCHS), and 6.79 (m, 4H, Arom).

General Procedure for the Hydrolysis of 2-Substituted 2-(α-Hydroxyalkyl)-3-methylbenzothiazolines (14) to α-Hydroxy Ketones (16) with $AgNO_3$. Silver nitrate (0.51 g, 3.0 mmol), dissolved in water (5 ml), was added to the stirred solution of 2-substituted 2-(α-hydroxyalkyl)benzothiazoline (**14**) (prepared from 2.0 mmol of **12** or **13**) in acetonitrile (30 ml) and 0.05 M-pH 7-phosphate buffer (6.0 ml). After 15 min at room temperature, additional silver nitrate (0.51 g, 3.0 mmol), dissolved in water (5 ml), was added to the solution (in some cases, a yellow precipitate began to form during this second addition). After another 20 min at room temperature, triethylamine (0.20 g, 2.0 mmol) was added in order to neutralized the released acid (HNO_3) and stirring was continued for further 1 h at 45 °C. Saturated aqueous NaCl solution was added to the reaction mixture and the mixture was filtered through Celite. The filtrate was extracted with diethyl ether and ether extract was filtered through silica gel (Wakogel C-300). Evaporation of the solvent under reduced pressure gave the almost pure α-hydroxy ketones (**16**) that was free of 2-(methylamino)benzenethiol. The results are summarized in Table 5. Spectral data of the products are as follows: **16a**: Viscous oil; IR (neat) 3450 (OH) and 1700 cm^{-1} (C=O); ^{1}H NMR ($CDCl_3$) δ=1.00 (t, 6H, $2CH_3$), 1.13—2.10 (m, 6H, $3CH_2$), 2.40 (t, 2H, CH_2C=O), 3.50 (d, 1H, OH), and 4.12 (q, 1H, CHOH). **16b**: Viscous oil; IR (neat) 3450 (OH), 1695 (C=O), and 1590 cm^{-1} (C≡C); ^{1}H NMR ($CDCl_3$) δ=1.00 (t, 6H, $2CH_3$), 1.12—2.12 (m, 12H, $6CH_2$), 2.48 (t, 2H, CH_2C≡C), 4.33 (t, 1H, CHOH), and 5.33 (s, 1H, OH). **16c**: Viscous oil; IR (neat) 3450 (OH) and 1700 cm^{-1} (C=O); ^{1}H NMR ($CDCl_3$) δ=0.90 (m, 6H, $2CH_3$), 1.14—2.00 (m, 12H, $6CH_2$), 2.50 (t, 2H, CH_2C=O), 3.62 (d, 1H, OH), and 4.14 (q, 1H, CHOH). **16d**: Viscous oil; IR (neat) 3450 (OH) and 1670 cm^{-1} (C=O); ^{1}H NMR ($CDCl_3$) δ=1.06 (s, 9H, $3CH_3$), 1.06 (t, 3H, CH_3), 1.10—1.86 (m, 4H, $2CH_2$), 2.52 (t, 2H, CH_2C=O), 3.40 (d, 1H, OH), and 3.81 (d, 1H, CHOH). **16e**: Viscous oil; IR (neat) 3480 (OH) and 1710 cm^{-1} (C=O); ^{1}H NMR ($CDCl_3$) δ=0.71—2.10 (m, 18H, cyclohexyl and *n*-C_3H_7), 2.48 (t, 2H, CH_2C=O), 3.52 (d, 1H, OH), and 4.00 (dd, 1H, CHOH). **16f**: Viscous oil; IR (neat) 3450 (OH) and 1700 cm^{-1} (C=O); ^{1}H NMR ($CDCl_3$) δ=0.79 (t, 3H, CH_3), 1.14 (s, 6H, $2CH_3$), 1.20—1.90 (m, 4H, $2CH_2$), 2.48 (t, 2H, CH_2C=O), and 3.48 (d, 1H, OH).

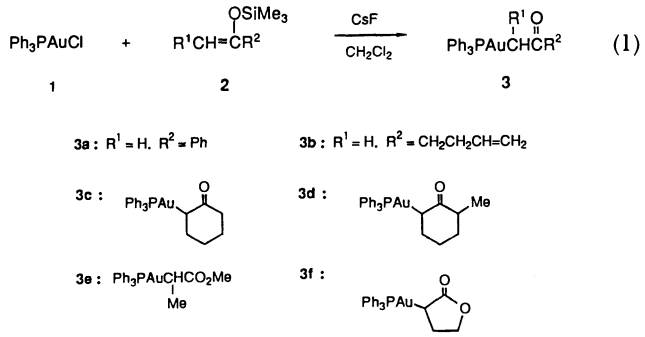
Reactions of (Triphenylphosphine)gold(I) Enolates and Homoenolates

Masahiro MURAKAMI, Masahiko INOUYE, Michinori SUGINOME, and Yoshihiko ITO*
Department of Synthetic Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Kyoto 606
(Received June 8, 1988)

Some reactions of (triphenylphosphine)gold(I) enolates and homoenolates, which are respectively prepared by the reaction of trimethylsilyl ethers of enols and cyclopropanols with (triphenylphosphine)gold(I) chloride in the presence of cesium fluoride, are described. The aldol reaction of (triphenylphosphine)gold(I) enolates with carbonyl compounds is efficiently promoted by Lewis acids such as titanium tetrachloride and diethylaluminum chloride to produce β-hydroxy carbonyl compounds. (Triphenylphosphine)gold(I) enolate reacts with phenyl acetylene to afford (triphenylphosphine)gold(I) phenylacetylide in good yield. Reaction of (benzoylmethyl)(triphenylphosphine)gold(I) (**3a**) with chlorotrimethylsilane produces α-(trimethylsilyloxy)styrene and (triphenylphosphine)gold(I) chloride, which is the reverse of the formation of **3a**. Gold(I) enolate undergoes an isocyanide insertion reaction into the linkage of carbon and gold. (2-Benzoylethyl)(triphenylphosphine)gold(I) reacts with 2-methyl-2-propanethiol to afford (triphenylphosphine)gold(I) *t*-butyl sulfide together with propiophenone.

Some gold(I) enolate complexes have been hitherto reported.[1] Carbon-bound gold(I) enolates of so-called active methylene compounds were prepared with thallium salts of active methylene compounds.[2] Carbon-bound gold(I) enolates of methyl ketones such as acetone and acetophenone were prepared by the reaction of methyl ketones with (triphenylphosphine)gold(I) bromide and silver oxide or with $(Ph_3PAu)_3O^+BF_4^-$.[3] Recently we reported a new preparative method for regioselectively forming carbon-bound (triphenylphosphine)gold(I) enolates (**3**) and homoenolates (**5**), in which trimethylsilyl ethers of enols **2** and cyclopropanols (**4**) are respectively treated with (triphenylphosphine)gold(I) chloride (**1**) in the presence of cesium fluoride (Eqs. 1, 2).[4] No reaction of **2** or **4** with **1** occurred in the absence of cesium fluoride.

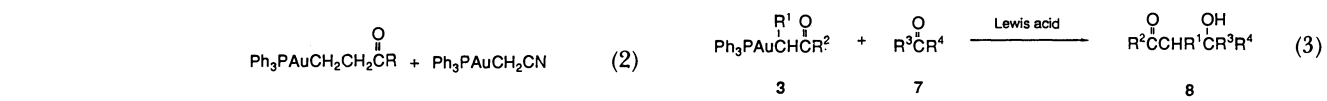


Unlike the previous method, our method features a regioselective formation of carbon-bound gold(I) enolates via trimethylsilyl ethers of enols from unsymmetrical ketones. X-Ray analyses of (benzoylmethyl)(triphenylphosphine)gold(I) (**3a**) and (2-benzoylethyl)(triphenylphosphine)gold(I) (**5a**) thus prepared unambiguously disclosed the carbon-bound gold(I) enolate and homoenolate structures with almost linear C-Au-P.[4]

Herein, we wish to report some reactions of gold(I) enolates and homoenolates.

Results and Discussion

Reactions of (Triphenylphosphine)gold(I) Enolates. [a] Lewis Acid Promoted Aldol Reactions: (Triphenylphosphine)gold(I) enolates (**3**) did not react with aldehydes. However, addition of Lewis acids efficiently promoted the aldol reaction of (triphenylphosphine)gold(I) enolates with carbonyl compounds to produce β-hydroxy carbonyl compounds (Table 1). Among a variety of Lewis acids, titanium tetrachloride and diethylaluminum chloride gave good results. It is noteworthy that gold(I) enolates readily reacted at −78 °C even with ketones, which are generally unreactive in aldol reaction, in the presence of titanium tetrachloride. Stereoselectivities of the Lewis acid promoted aldol reaction of gold(I) enolates were generally disappointing except for the high diastereoselectivity (91 : 9) observed in the titanium tetrachloride mediated reaction of gold(I) enolate of cyclohexanone with benzaldehyde. Intermediacy of titanium enolate generated by transmetallation of gold(I) enolate with titanium tetrachloride may be suggested in the present reaction, because the very similar diastereoselectivity was found in the reaction of titanium enolate of cyclohexanone with benzaldehyde.[5]



[b] Miscellaneous Reactions: (Triphenylphosphine)gold(I) enolates were relatively stable to oxygen and moisture and could be handled quickly in the open air, but gradually decomposed in solution. Some reactions with (benzoylmethyl)(triphenylphosphine)-gold(I) (**3a**) are shown in Eq. 4. Gold(I) enolate **3a** was inert to alcohol. But 2-methyl-2-propanethiol reacted

Table 1. Lewis Acid Promoted Aldol Reaction

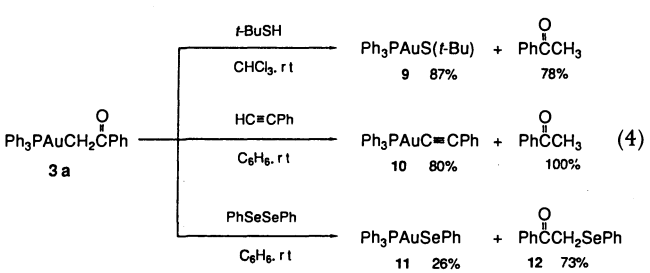
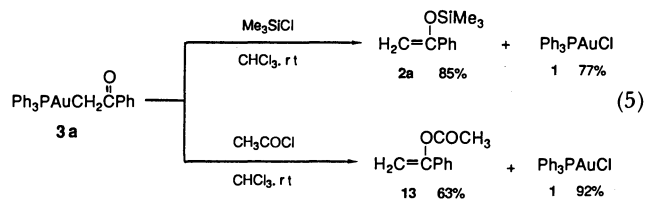
a) Determined by ^1H NMR. b) Ref 6. c) Ref 7. d) Ref 8. e) Ref 9. f) Ref 10.

with **3a** at room temperature to give (triphenylphosphine)gold(I) *t*-butyl sulfide (**9**) together with acetophenone. Similarly, reaction of **3a** with phenylacetylene afforded (triphenylphosphine)gold(I) phenylacetylide (**10**) with acetophenone. Gold(I) enolate **3a** did not react with diphenyl disulfide but reacted with diphenyl diselenide to give (triphenylphosphine)-gold(I) phenyl selenide (**11**) with (phenylseleno)acetophenone (**12**).



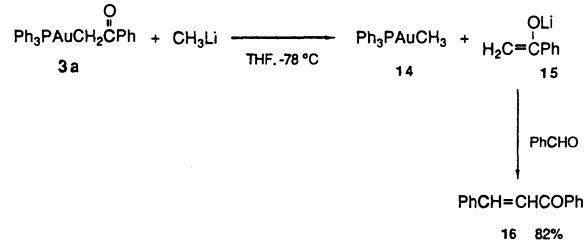
(4)

Reaction of **3a** with chlorotrimethylsilane produced α-(trimethylsilyloxy)styrene (**2a**) and (triphenylphosphine)gold(I) chloride (**1**). The reaction is the reverse of the formation of (triphenylphosphine)gold(I) enolate (**3a**). A similar reaction was observed with acetyl chloride.[3a] The gold(I) enolate (**3a**) was treated with acetyl chloride to give 1-phenylvinyl acetate (**13**) with (triphenylphosphine)gold(I) chloride (**1**).



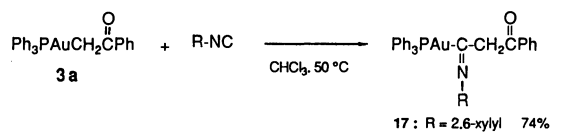
(5)

Reaction of **3a** with methyllithium in tetrahydrofuran (THF) at 0 °C gave rise to the formation of methyl-(triphenylphosphine)gold(I) (**14**) after workup with H_2O. Lithium enolate (**15**) of acetophenone, which may be concomitantly generated in the reaction, was indeed trapped. When **3a** was treated with methyllithium in THF at −78 °C and subsequently with benzaldehyde, chalcone (**16**) was isolated in 82% yield.



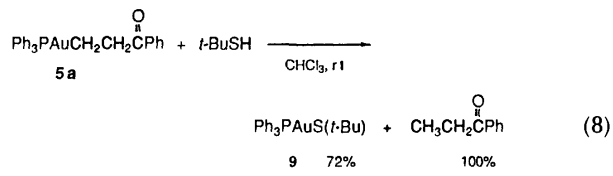
(6)

Gold(I) enolate **3a** underwent an isocyanide insertion reaction into the linkage of carbon and gold according to Eq. 7. NMR spectra revealed that the insertion product **17** exists in an enolized form.



(7)

Reaction of (Triphenylphosphine)gold(I) Homoenolates. In contrast to gold(I) enolates, gold(I) homoenolates were rather unreactive and attempted reactions with gold(I) homoenolates were unsuccessful except for the reaction with 2-methyl-2-propanethiol shown in Eq. 8.



(8)

Experimental

General. Melting points were determined on a Yanaco MP-S3 apparatus and are uncorrected. ^{1}H NMR spectra were recorded on a JEOL JNM-MH 100 spectrometer (100 MHz) with Me_4Si as an internal standard. ^{13}C NMR spectra were obtained on a JNM-GX 400 spectrometer (100 MHz). Infrared spectra were obtained on a Hitachi 270-30 spectrophotometer. Cesium fluoride (Aldrich) was used after drying at ca. 200 °C in vacuo.

Preparation of Gold(I) Enolates 3a—e. Gold(I) enolates **3a—e** were prepared according to the procedure described.[4]

(2-Oxo-5-hexenyl)(triphenylphosphine)gold(I) (3b): 99%; ^{1}H NMR ($CDCl_3$) δ=2.00—2.61 (m, 4H), 2.61—2.87 (br. s, 2H), 4.73—5.12 (m, 2H), 5.61—6.10 (m, 1H), 7.03—7.80 (m, 15H); IR (neat) 1642, 1482, 1102, 910 cm^{-1}.

(2-Oxocyclohexyl)(triphenylphosphine)gold(I) (3c): 81%; ^{1}H NMR ($CDCl_3$) δ=0.86—2.84 (m, 8H), 3.13—3.26 (m, 1H), 7.06—7.85 (m, 15H); IR (neat) 1620, 1440, 1102, 910 cm^{-1}.

(3-Methyl-2-oxocyclohexyl)(triphenylphosphine)gold(I) (3d): 67%; ^{1}H NMR ($CDCl_3$) δ=0.75—2.96 (m, 7H), 1.07 (d, 3H, J=7 Hz), 3.08—3.35 (m, 1H), 7.04—7.86 (m, 15H); IR (neat) 1636, 1482, 1440, 1102 cm^{-1}.

[1-(Methoxycarbonyl)ethyl](triphenylphosphine)gold(I) (3e): 99%; ^{1}H NMR ($CDCl_3$) δ=1.16 (dd, 3H, J_{H-H}=6 Hz and J_{H-P}=6 Hz), 2.65 (dq, 1H, J_{H-H}=6 Hz and J_{H-P}=12 Hz), 3.66 (s, 3H), 7.16—7.69 (m, 15h); IR (neat) 1682, 1438, 1156, 1102 cm^{-1}.

(2-Oxotetrahydro-3-furyl)(triphenylphosphine)gold(I) (3f). To a suspension of anhydrous cesium fluoride (76 mg, 0.5 mmol) and (triphenylphosphine)gold(I) chloride (50 mg, 0.1 mmol) in acetonitrile (1.5 mL), 2-trimethylsilyloxy-4,5-dihydrofuran (**2f**, 32 mg, 0.2 mmol) was added. The mixture was stirred overnight at room temperature and filtered to remove insoluble inorganic salts. The filtrate was evaporated, washed with CH_2Cl_2, and subjected to column chromatography on silica gel pretreated with triethylamine to give **3f**; 28 mg, 51%; mp 149 °C (decomp); ^{1}H NMR ($CDCl_3$) δ=2.42—3.09 (m, 3H), 4.29—4.56 (m, 2H), 7.32—7.74 (m, 15H); ^{13}C NMR ($CDCl_3$) δ=31.1 (J_{C-P}=5 Hz), 42.2 (J_{C-P}=76 Hz), 68.5, 185.4; IR (KBr) 1692 cm^{-1}. Found: C, 48.28; H, 3.61; P, 5.43%. Calcd for $C_{22}H_{20}AuO_2P$: C, 48.54; H, 3.70; P, 5.69%.

(2-Benzoylethyl)(triphenylphosphine)gold(I) (5a). To a suspension of anhydrous cesium fluoride (286 mg, 1.95 mmol) and (triphenylphosphine)gold(I) chloride (193 mg, 0.390 mmol) in acetonitrile (6 mL), 1-phenyl-1-(trimethylsilyloxy)cyclopropane (111 mg, 0.539 mmol) was added and the mixture was stirred for 4 h at 50 °C. The resulting orange suspension was filtered and the filtrate was evaporated to leave brown oil, which was subjected to column chromatography on silica gel pretreated with triethylamine to give (2-benzoylethyl)(triphenylphosphine)gold(I) (**5a**, 176 mg, 76%) and (cyanomethyl)(triphenylphosphine)gold(I) (**6**, 34 mg, 17%). **5a**: mp 121—122 °C (decomp); ^{1}H NMR ($CDCl_3$) δ=1.48—1.79 (m, 2H), 3.28—3.58 (m, 2H), 7.22—7.74 (m, 18H), 7.99—8.15 (m, 2H); ^{13}C NMR ($CDCl_3$) δ=25.7 (d, J_{C-P}=95.5 Hz), 40.6 (d, J_{C-P}=4 Hz), 204.9 (d, J_{C-P}=5 Hz); IR (KBr) 1670 cm^{-1}. Found: C, 54.47; H, 3.98; P, 5.41%. Calcd for $C_{27}H_{24}OPAu$: C, 54.74; H, 4.08; P, 5.23%. **6**: mp 131—133 °C (decomp); ^{1}H NMR ($CDCl_3$) δ=1.66 (d, 2H, J=10.0 Hz), 7.31—7.76 (m, 15H); IR (KBr) 2200 cm^{-1}. Found: C, 48.00; H, 3.36; N, 2.65; P, 6.07%. Calcd for $C_{20}H_{17}AuNP$: C, 48.11; H, 3.43; N, 2.81; P, 6.20%.

[2-(Ethoxycarbonyl)ethyl](triphenylphosphine)gold(I) (5b): 78%; ^{1}H NMR ($CDCl_3$) δ=1.18 (t, 3H, J=7 Hz), 1.54 (m, 2H), 2.73 (m, 2H), 4.07 (q, 2H, J=7 Hz), 7.40—7.61 (m, 15H); IR (neat) 1728, 1484, 1440, 1100 cm^{-1}.

Lewis Acid Promoted Aldol Reaction. Representative procedure of Lewis acid promoted aldol reaction is given by the preparation of methyl 3-hydroxy-2-methyl-3-phenylpropanoate: To a dichloromethane solution (1 mL) of [1-(methoxycarbonyl)ethyl](triphenylphosphine)gold(I) (48 mg, 0.087 mmol) and benzaldehyde (11 mg, 0.10 mmol), a dichloromethane solution (0.13 mL) of titanium tetrachloride (0.13 mmol) was added at −78 °C, and the reaction mixture was stirred for 5 h at that temperature. Saturated aq. $NaHCO_3$ solution (5 mL) was added and, after usual extractive workup, methyl 3-hydroxy-2-methyl-3-phenylpropanoate (14 mg, 81%) was isolated by preparative TLC on silica gel.

(Triphenylphosphine)gold(I) *t*-Butyl Sulfide (9). A chloroform solution (0.3 mL) of (benzoylmethyl)(triphenylphosphine)gold(I) (**3a**, 24 mg, 0.041 mmol) and 2-methyl-2-propanethiol (5 mg, 0.05 mmol) was sonicated in a sealed tube at room temperature. After 1 h, hexane (0.9 mL) was added to give **9** as colorless crystals: 20 mg, 87%; mp 166—168 °C; ^{1}H NMR ($CDCl_3$) δ=1.60 (s, 9H), 7.27—7.71 (m, 15H). Found: C, 48.08; H, 4.35; P, 5.66%. Calcd for $C_{22}H_{24}AuPS$: C, 48.18; H, 4.41; P, 5.65%.

(Triphenylphosphine)gold(I) Phenylacetylide (10). A chloroform solution (0.3 mL) of **3a** (23 mg, 0.040 mmol) and phenylacetylene (7 mg, 0.07 mmol) was sonicated in a sealed tube at room temperature for 4 h. Then the reaction mixture was subjected to column chromatography on silica gel to give **10**: 18 mg, 80%; mp 165—166 °C (lit, 163—164 °C).[11]

Formation of (Triphenylphosphine)gold(I) Phenyl Selenide (11) and (Phenylseleno)acetophenone (12). In a sealed tube, a benzene solution (0.3 mL) of (benzoylmethyl)(triphenylphosphine)gold(I) (**3**, 23 mg, 0.040 mmol) and diphenyl diselenide (13 mg, 0.04 mmol) was sonicated at room temperature. After 12 h, the mixture was subjected to preparative TLC on silica gel to give **11** (6.3 mg, 26%) and **12** (8.0 mg, 73%). **11**: mp 146—149 °C (decomp); ^{1}H NMR ($CDCl_3$) δ=6.70—7.90 (m, 20H). Found: C, 46.81; H, 3.21; P, 5.03%. Calcd for $C_{24}H_{20}AuPSe$: C, 46.85; H, 3.28; P, 5.03%.

Formation of α-Trimethylsilyloxystyrene (2a). In a sealed tube, a $CDCl_3$ solution (0.3 mL) of (benzoylmethyl)-(triphenylphosphine)gold(I) (**3**, 23 mg, 0.040 mmol) and chlorotrimethylsilane (9 mg, 0.08 mmol) was sonicated at room temperature for 2.5 h. The formation of **2a** was observed by ^{1}H NMR [δ=0.25 (s), 4.47 (d, J=2 Hz), 4.95 (d, J=2 Hz)] and the yield was determined using an internal standard. (Triphenylphosphine)gold(I) chloride (**1**, 15 mg, 77%) was isolated by column chromatography on silica gel pretreated with triethylamine.

Formation of 1-Phenylvinyl Acetate (13). In a sealed tube, a chloroform solution (0.3 mL) of (benzoylmethyl)(triphen-

ylphosphine)gold(I) (**3**, 23 mg, 0.040 mmol) and acetyl chloride (5 mg, 0.06 mmol) was sonicated at room temperature. After 1 h, the mixture was subjected to column chromatography on silica gel pretreated with triethylamine to give **1** (18 mg, 92%) and **13** (4 mg, 63%).

Formation of Chalcone (16). To a solution of (benzoylmethyl)(triphenylphosphine)gold(I) (25 mg, 0.043 mmol) in THF (1 mL), an ether solution (0.14 mL) of methyllithium (0.055 mmol) was added at −78 °C under a nitrogen atmosphere. After stirring for 30 min, benzaldehyde was added (6.4 mg, 0.06 mmol) and the reaction mixture was allowed to warm gradually to room temperature and quenched with methanol (10 mL). The mixture was subjected to preparative TLC on silica gel to give chalcone (7.3 mg, 82%).

[2-Benzoyl-1-(2,6-xylylimino)ethyl](triphenylphosphine)-gold(I) (17). Under a nitrogen atmosphere, chloroform solution (2 mL) of **3a** (35 mg, 0.060 mmol) and 2,6-xylyl isocyanide (12 mg, 0.090 mmol) was heated at 50 °C for 6 h. Resulting yellow mixture was subjected to column chromatography on silica gel pretreated with triethylamine to give **17**: 32 mg, 74%; mp 160 °C (decomp); ^{1}H NMR ($CDCl_3$) δ= 2.37 (s, 6H), 6.08 (s, 1H), 6.95—8.12 (m, 23H); ^{13}C NMR ($CDCl_3$) δ=19.09, 101.22, 185.2, 209.1; IR (KBr) 1506, 1438 cm^{-1}. Found: C, 59.07; H, 4.58; N, 1.74: P, 4.62%. Calcd for $C_{35}H_{31}AuNOP$: C, 59.24; H, 4.40; N, 1.97, P, 4.37%.

Peptide Synthesis in Alcohol Solvents by the Mixed Anhydride Method Using Dimethylphosphinothioyl Chloride

Masaaki UEKI,* Takashi SAITO, Jun SASAYA, Shigeru IKEDA,† and Hidekazu OYAMADA
Department of Applied Chemistry, Science University of Tokyo, 1-3 Kagurazaka, Shinjuku-ku, Tokyo 162
(Received July 1, 1988)

The formation and coupling of the dimethylphosphinothioic mixed anhydrides of protected amino acids can be performed in alcohol solvents. Sparingly soluble protected C-terminal segments of vasoactive intestinal peptide (VIP) up to the heptapeptide stage were synthesized by this technique and fully characterized.

In peptide synthesis low solubility of even small peptides can result in incomplete reaction giving unpurifiable materials with lack of purification method. Thus, solubility problems may prevent further elongation of the peptide chain. The solid phase method[1] is one solution to this problem. For solution syntheses various kinds of organic solvents having high solubilizing power such as *N,N*-dimethylformamide, dimethyl sulfoxide, and hexamethylphosphoric triamide, all of which are classified as dipolar aprotic solvents, have been utilized. Among polar protic solvents alcohols, especially methanol, have high solubilizing ability for peptides, although their use as solvents in peptide bond formation is not normally possible because of their high reactivity toward the activated amino acid derivatives.

Recently we reported that dimethylphosphinothioic mixed anhydrides (Mpt-MAs), formed from protected amino acids by reaction with dimethylphosphinothioyl chloride (Mpt-Cl)[2] in the presence of a base, were stable toward isolation and reacted very selectively toward amino functions.[3]

Mpt-MAs react with alcohols only in presence of basic catalysts such as 4-dimethylaminopyridine and imidazole.[4] Such high stability toward alcohols and selectivity toward the amino group can be attributed to the presence of the P=S bond. In this study we applied the Mpt-MA method to peptide synthesis in alcohol solvents in order to determine whether the selectivity was high enough for use in practical peptide syntheses. If this were the case it would represent an efficient solution to the often serious solubility problem.

Results and Discussion

The possibility of using alcohol solvents in peptide synthesis was first investigated by examination of the synthesis of model peptides. The results are summarized in Table 1.

In these experiments the Mpt-MAs were generated in situ. Generally the formation of Mpt-MAs can be easily followed by thin layer chromatography (TLC) since these compounds can be visualized, without removing the amino protecting group, simply by spraying with ninhydrin reagent followed by warming. For reasons not yet clear a color reaction toward ninhydrin arises from the Mpt mixed anhydride group itself.

Methanol (Entries 3 and 6) and ethanol (Entry 7) could be used as well as chloroform (Entries 1, 2, 4, and 5) in the mixed anhydride formation. However, when 2,2,2-trifluoroethanol was used (Entry 8) formation of ester was observed even during the activation step. Methanol (Entries 3 and 6) and ethanol (Entry 7) could be used in both activation and coupling steps and yields of peptides obtained in this way were high. Since methanol is a more effective solvent than ethanol for the peptide segments, the former was used in the following experiments.

Vasoactive intestinal peptide (VIP), isolated in 1970 by Said and Mutt from the small intestine of the hog,[5] is a linear octacosapeptide amide.[6] Total synthesis of VIP has been achieved by many groups by solution[7,8] and solid phase[9-11] methods. In all previous solution syntheses much effort was required to overcome the solubility problem.[12] In a recent synthesis Schaaper and Beyerman temporarily substituted Asn[28] by the corresponding β-*t*-butyl aspartate ester which was subsequently converted to Asn.[13] Clearly for such sparingly soluble peptides the development of a generally applicable solvent would offer significant improvements over current techniques. As an example to demonstrate the efficiency of methanol as a solvent for peptide bond formation, stepwise synthesis of the relatively insoluble C-terminal segments of VIP up to the heptapeptide stage was investigated. Results obtained in the case of di-, tri-, and tetrapeptide amides are

a) Ref. 12.

summarized in Table 2.

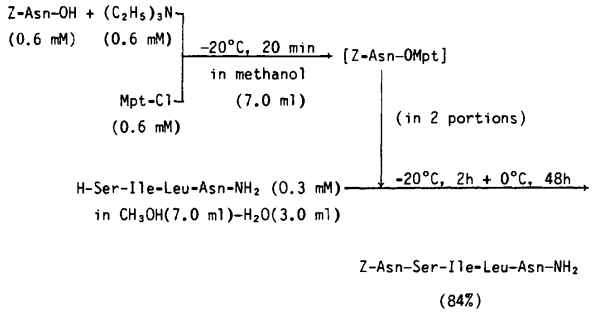
In these reactions the desired products precipitated during the reaction. Z-Leu-Asn-NH_2 was obtained in 88% yield when Z-Leu-OMpt, generated in situ in chloroform, was added to a solution of H-Asn-NH_2·HBr in methanol containing triethylamine (Entry 1). However, when synthesis of the related tripeptide was carried out by the same method (Entry 5) the yield of Z-Ile-Leu-Asn-NH_2 was only 52%. In this case precipitation of the product began too early thus causing coprecipitation of the free amino component which was difficult to remove from the tripeptide. In order to avoid this problem Z-Ile-OMpt was first freed from triethylamine hydrochloride by washing the solution with water and then coupled with free H-Leu-Asn-NH_2 in methanol (Entry 6). This technique gave Z-Ile-Leu-Asn-NH_2 in a yield of 95%. Similar result was also obtained in the case of dipeptide synthesis (Entry 2). These results compare favorably with those obtained by Bodanszky, et al., which involved coupling of the *p*-nitrophenyl active ester in *N*,*N*-dimethylformamide.[12)]

At the tetrapeptide stage a somewhat different situation emerged. Serine is found as the fourth amino acid from the C-terminal position. As previously reported[3)] incorporation of serine into a peptide chain is possible without protecting the side-chain hydroxyl group when using the Mpt-MA method. However the isolated yield of Z-Ser-OMpt is exceptionally low because of the lactone formation. Since yields using isolated and in-situ-generated Z-Ser-OMpt are nearly the same, the method involving in situ activation is more convenient.

At the pentapeptide stage another difficulty was encountered. Solubility of the free tetrapeptide amide, H-Ser-Ile-Leu-Asn-NH_2, in methanol is much lower than the free C-terminal mono-, di-, and tripeptide amides. This may limit the use of methanol as a sole solvent in the synthesis of peptide segments containing asparagine and glutamine. However, it is known that peptides containing these amino acids, although not soluble in a single organic solvent, often dissolve in aqueous organic solvents. Synthesis was therefore examined in aqueous methanol.

When a methanolic solution of Z-Leu-OMpt was added, in 2 portions with a 20 min interval between additions, to a methanol-water (2 : 3) solution of asparaginamide, the dipeptide Z-Leu-Asn-NH_2 was obtained in 98% yield. This result shows that aqueous methanol can be more effective solvent than methanol itself for the synthesis of longer peptides containing asparagine and glutamine.

At the 24-position of VIP is found asparagine whose activation via the Mpt technique required some caution. Mpt-MA formation is usually performed at room temperature except in the case of serine which requires cooling to 0 °C in order to avoid lactone formation. In the case of asparagine, complex reactions, possibly including nitrile formation, were observed even at 0 °C. Fortunately this side-reaction could be suppressed by carrying out the reaction at −20 °C in either methanol or chloroform. These conditions were applied to the synthesis of Z-VIP(24—28)-NH_2.



When a methanolic solution of Mpt-MA prepared from Z-Asn and Mpt-Cl at −20 °C for 20 min in the presence of triethylamine was added to a solution of H-Ser-Ile-Leu-Asn-NH_2 in methanol-water and the mixture stirred at the same temperature for 2 h and then at 0 °C for 48 h the pentapeptide Z-Asn-Ser-Ile-Leu-Asn-NH_2 was obtained in 84% yield in an analytically pure form.

The sixth amino acid, Leu, could be introduced without any problem using the salt-free, washed Mpt-MA along with free H-Asn-Ser-Ile-Leu-Asn-NH_2 dissolved in a methanol-water mixture. However, when Z-Tyr was coupled to H-Leu-Asn-Ser-Ile-Leu-Asn-NH_2 in a similar manner the crude product was contaminated with the free amino component and obtained in only 48% yield. Reprecipitation of the crude product from DMSO-H_2O or DMSO-methanol did not give pure material. Except for special amino acids such as Ser and Asn Mpt-MAs are sufficiently stable to be used for coupling reactions above room temperature thus avoiding premature precipitation. For example, when Z-Tyr-OMpt in methanol was added to a solution of H-Leu-Asn-Ser-Ile-Leu-Asn-NH_2 in a methanol-water mixture followed by stirring at 38—40 °C for 2 h and at room temperature for 46 h the desired product was obtained in 74% yield without contamination by the free amino component. In this case the unprotected tyrosine side-chain hydroxyl group caused no difficulty.

In the report of Bodanszky, et al.,[12] intermediates involved in the VIP synthesis could not be characterized except for the trifluoroacetates of *N*-deprotected peptide amides and for protected peptide amides longer than tripeptide only melting points and amino acid analyses were recorded. In the present study it was possible to characterize all of the protected and free peptide amides by amino acid analysis, elemental analysis and TLC. In addition melting points and optical rotation values could be recorded for the first time as shown in Tables 3 and 4.

In conclusion, peptide synthesis by the Mpt-MA method using methanol or methanol-water mixtures as solvents provides a convenient and efficient solution to the solubility problem in peptide synthesis.

Experimental

Amino acids and their derivatives used here are all of the L configuration. Abbreviations given by the IUPAC-IUB Commission (*J. Biol. Chem.*, **247**, 977 (1972)) are used throughout. Additional abbreviations: Z, benzyloxycarbonyl; Boc, *t*-butyloxycarbonyl; DCHA, dicyclohexylamine; TEA, triethylamine; AcOH, acetic acid; DMF, *N,N*-dimethylformamide; DMSO, dimethyl sulfoxide. DMF (Kokusan Chemical Works, special grade) was distilled at reduced pressure and stored over molecular sieves. Amino acid analyses were performed on the Atto Model MLC 203 Amino Acid Analyzer. Peptides were hydrolyzed in 6 mol dm^{-3} HCl in sealed, evacuated tubes at 110 °C for 24 h. TLC was carried out on precoated silica gel 60 (F-254) plates (Merck) in the following solvent systems: (A) 1-butanol-acetic acid-water (4:1:1); (B) chloroform-methanol-water (8:3:1).

Salt-Free, Washed Z-Amino Acid-Dimethylphosphinothioic Mixed Anhydrides (General Procedure): To a solution of Z-amino acid (2.0 mmol) and triethylamine (2.0 mmol) in chloroform (3.0 ml) was added Mpt-Cl[2] (2.2 mmol) in chloroform (1.0 ml) and the mixture stirred at room temperature for 20 min. Chloroform was removed under reduced pressure and the residue divided between ethyl acetate and water. The organic layer was successively washed with 5% aqueous citric acid solution (3 times), water (3 times), saturated NaCl solution, 5% aqueous sodium hydrogencarbonate solution (3 times), water (3 times), and saturated NaCl solution, and dried over anhydrous sodium sulfate. Removal of the solvent gave the Mpt-MAs as oils.

In the case of tyrosine 1.0 equiv of the Mpt-Cl was used in the presence of DCHA in order to avoid undesirable formation of *O*-dimethylphosphinothioylated product. The washing procedures were carried out without changing the solvent. After removal of the solvent Z-Tyr-OMpt was obtained as amorphous solid.

Thus obtained Mpt-MAs were used in the following experiments without further purification.

Preparation of Z-Ser-OMpt was already described in the previous communication.[3]

Preparation of Z-Leu-Asn-NH_2 (1): (A) To a suspension of Z-Asn-NH_2[12] (530.4 mg, 2.0 mmol) in AcOH (2.0 ml) was added 25% HBr/AcOH (8.3 ml). After 1 h the solution was diluted with ether to give a precipitate, which was dissolved in water and dehydrobrominated by stirring for 5 min with Dowex 1 resin. The resin was filtered and washed with water. The filtrate and washings were collected and evaporated under reduced pressure. The residue was dissolved in methanol and purified by gel filtration on Sephadex LH-20 to give the free asparaginamide as a white powder; 229.1 mg (87%), mp 138—139 °C, $[\alpha]_D^{27}$ +4.7° (*c* 2.0, H_2O), R_f(A) 0.12, R_f(B) 0.01.

To an ice-cooled solution of H-Asn-NH_2 (131.1 mg, 1.0 mmol) in methanol (6.5 ml) and TEA (209 μl, 1.5 mmol) was added Z-Leu-OMpt (536.1 mg, 1.5 mmol) in methanol (1.2 ml) and the mixture stirred at 0 °C for 24 h. The precipitate was collected by filtration and washed with chloroform, water and ether, and dried to give **1** as a white powder. After concentration of the filtrate and washings a second crop was obtained giving a total yield of 359.4 mg (95%). Physical properties and analytical data are given in Tables 3 and 4.

(B) H-Asn-NH_2 (19.7 mg, 0.15 mmol) and TEA (21 μl, 0.15 mmol) were dissolved in methanol (0.2 ml) and water (0.3 ml). To this solution was added at 0 °C a solution of Z-Leu-OMpt (53.6 mg, 0.15 mmol) in methanol (0.7 ml). After stirring for 20 min the same amounts of TEA and Z-Leu-OMpt were again added. After the mixture was stirred at 0 °C for 24 h the precipitate was collected as described above. Yield 55.5 mg (98%), mp 235—236 °C (decomp), $[\alpha]_D^{23}$ −7.6° (*c* 1, DMF).

(C) To a solution of Z-Leu-OH·DCHA (147.4 mg, 0.33 mmol) in chloroform (1.0 ml) was added Mpt-Cl (42.4 mg, 0.33 mmol) in chloroform (1.0 ml) and the mixture stirred at room temperature for 45 min. The solution was cooled to 0 °C and treated with a solution of asparaginamide hydrobromide (71.1 mg, 0.33 mmol) in methanol (2.5 ml) containing TEA (92.0 μl, 0.66 mmol) and the mixture stirred at the same temperature for 24 h. The precipitate was collected as described above to give 109.2 mg (88%) of the amide, mp 234—235 °C (decomp), $[\alpha]_D^{22}$ −7.6° (*c* 1.0, DMF).

Preparation of H-Leu-Asn-NH_2 (2): To a suspension of **1** (473.5 mg, 1.25 mmol) in AcOH (2.5 ml) was added 25% HBr/AcOH (5.2 ml) and the mixture kept standing at room temperature for 1 h and diluted with ether. The precipitate was collected, dehydrobrominated and purified as described for H-Asn-NH_2. Yield 257.0 mg (84%). Physical properties and analytical data are given in Tables 3 and 4.

Preparation of Z-Ile-Leu-Asn-NH_2 (3): (A) To an ice-cooled solution of **2** (244.3 mg, 1.0 mmol) and TEA (209 μl, 1.5 mmol) in methanol (6.7 ml) was added a solution of Z-Ile-OMpt (536.1 mg, 1.5 mmol) in methanol (1.1 ml), and the mixture stirred at 0 °C for 24 h. The precipitate was collected by filtration, washed as described for compound **1** and dried. Yield 468.3 mg (95%). Physical properties and analytical data are given in Tables 3 and 4.

(B) To a solution of Z-Ile-OH·DCHA (223.3 mg, 0.5 mmol) in chloroform (1.0 ml) was added a solution of Mpt-Cl (64.3 mg, 0.5 mmol) in chloroform (0.5 ml) and the mixture stirred for 1 h. The solution was cooled to 0 °C and treated with a solution of **2** hydrobromide (162.5 mg, 0.5 mmol) and TEA (140 μl, 1.0 mmol) in methanol (2.0 ml). The mixture was stirred at 0 °C for 24 h and worked up as described in (A). Yield 128.3 mg (52%), mp 262—263 °C (decomp).

Preparation of H-Ile-Leu-Asn-NH_2 (4): To a suspension of **3** (453.6mg, 0.92 mmol) in AcOH (5.0 ml) was added 25% HBr/AcOH (5.0 ml) and the mixture kept standing at room temperature for 1 h and diluted with ether. The precipitate was collected, dehydrobrominated and purified as described for H-Asn-NH_2. Yield 270.7 mg (82%). Physical properties and analytical data are given in Tables 3 and 4.

Preparation of Z-Ser-Ile-Leu-Asn-NH_2 (5): (A) To an ice-cooled solution of Z-Ser-OH (71.8 mg, 0.3 mmol) and TEA (41.8 μl, 0.3 mmol) in chloroform (1.0 ml) was added a solution of Mpt-Cl (38.5 mg, 0.3 mmol) in chloroform (0.5 ml). After stirring for 20 min the resulting solution was added to an ice-cooled solution of **4** (71.5 mg, 0.2 mmol) and TEA (41.8 μl, 0.3 mmol) in methanol (4.4 ml) and the mixture stirred at 0 °C for 24 h. The precipitate was collected by filtration and washed with chloroform, water and ether, and dried to give **5** as a white powder. After concentration of the filtrate and washings a second crop was obtained giving a total amount of 112.2 mg (94%). Physical properties and analytical data are given in Tables 3 and 4.

(B) To an ice-cooled solution of **4** (89.4 mg, 0.25 mmol) and TEA (52.2 μl, 0.375 mmol) in methanol (4.8 ml) was added a solution of Z-Ser-OMpt (124.3 mg, 0.375 mmol) in methanol (1.2 ml) and the mixture stirred at 0 °C for 24 h. Work up as described above gave **5**; 136.3 mg (94%), mp 257—258 °C (decomp).

Preparation of H-Ser-Ile-Leu-Asn-NH_2 (6): Compound **5** (597.2 mg, 1.03 mmol) was hydrogenolyzed for 4 h in the presence of 10% Pd-C in 80% AcOH (45 ml). The catalyst was filtered and washed with the same solvent. The filtrate and washings were combined and evaporated under reduced pressure. The residue was dissolved in water by addition of the minimum amount of methanol and the solution treated for 5 min with Dowex 1 resin. The resin was removed and washed with water, and the combined filtrate and washings were evaporated under reduced pressure. The residual mass was washed with ether to give **6**; 424.9 mg (93%). Physical properties and analytical data are given in Tables 3 and 4.

Preparation of Z-Asn-Ser-Ile-Leu-Asn-NH_2 (7): A solution of Z-Asn-OH (79.8 mg, 0.3 mmol) and TEA (41.8 μl, 0.3 mmol) in methanol (2.6 ml) was cooled to −20 °C, and treated with a solution of Mpt-Cl (38.5 mg, 0.3 mmol) in methanol (0.9 ml), and the mixture stirred for 20 min. The solution was added to a solution of **6** (133.3 mg, 0.3 mmol) and TEA (41.8 μl, 0.3 mmol) in methanol (7.0 ml) and water (3.0 ml) at −20 °C. After the mixture had been stirred for 40 min the Z-Asn-OMpt solution and TEA (0.3 mmol each) were added and the stirring continued at −20 °C for 2 h and at 0 °C for 48 h. The precipitate was filtered and washed with chloroform, ethanol, water, and ether, and dried to give **7**; 173.7 mg (84%). Physical properties and analytical data are given in Tables 3 and 4.

Preparation of H-Asn-Ser-Ile-Leu-Asn-NH_2 (8): Compound **7** (291.0 mg, 0.42 mmol) was hydrogenolyzed for 24 h in the presence of 10% Pd-C in 80% AcOH (45 ml). The same work up described for compound **6** gave **8**; 197.5 mg (82%). Physical properties and analytical data are given in Tables 3 and 4.

Preparation of Z-Leu-Asn-Ser-Ile-Leu-Asn-NH_2 (9): Compound **8** (55.9 mg, 0.1 mmol) and TEA (14.0 μl, 0.1 mmol) were dissolved in methanol (3.0 ml) and water (1.0 ml) and the solution cooled to 0 °C. To the solution was added Z-Leu-OMpt (35.8 mg, 0.1 mmol) in methanol (0.9 ml) and the mixture stirred at 0 °C for 20 min. After the same amounts of the Z-Leu-OMpt solution and TEA were again added the mixture was stirred at 0 °C for 48 h. Filtration, washing and drying as described for the compound **7** gave **9**; 64.5 mg (80%). Physical properties and analytical data are given in Tables 3 and 4.

Preparation of H-Leu-Asn-Ser-Ile-Leu-Asn-NH_2 (10): Compound **9** (133.5 mg, 0.165 mmol) was hydrogenolyzed for 8 h in the presence of 10% Pd-C in 80% AcOH (17 ml). The same work up described for compound **6** gave **10**; 97.0 mg (83%). Physical properties and analytical data are given

Preparation and Characterization of Large Surface Area $BaO \cdot 6Al_2O_3$

Masato MACHIDA, Koichi EGUCHI, and Hiromichi ARAI*
Department of Materials Science and Technology, Graduate School of Engineering Sciences, Kyushu University, 39, Kasuga, Fukuoka 816
(Received April 4, 1988)

Barium hexaaluminate, $BaO \cdot 6Al_2O_3$, exhibited excellent heat resistance in maintaining a large surface area. Preparation from hydrolysis of metal alkoxides was a superior process in deriving the large surface area of $BaO \cdot 6Al_2O_3$, to that from mixtures of $BaCO_3/\gamma$-Al_2O_3. Direct formation of $BaO \cdot 6Al_2O_3$ phase at low temperature plays the key role in retaining the fine particle size. The amount of water added for hydrolysis and the aging period of hydrolyzed precursors strongly influenced the surface area of alkoxide-derived $BaO \cdot 6Al_2O_3$. These effects of the preparation conditions originated from the difference in microstructure and chemical structure of the hydrolyzed precursors. Monodispersed fine precursor particles with high oxide content generated large surface area $BaO \cdot 6Al_2O_3$.

Catalytic combustion has many advantages over conventional flame combustion in suppressing NO_x emission and in improving combustion efficiency. Recently, much interest has arisen in new application of this technology in gas turbines, jet engines, and boilers above 1000 °C.[1,2] In maintaining catalytic activity under such a severe condition, high heat resistance is necessary in the catalytic materials. But this is not satisfied by the catalysts at present in use for low temperature combustion. One of the crucial problems is how to suppress sintering of the oxide support in a high temperature combustion catalyst. Our research has been focused on developing a support material endowed with high heat and thermal shock resistance which also maintains a large surface area even above 1400 °C.

Alumina is one of the most common support materials used around 1000 °C. Additive oxides, such as La_2O_3, BaO, CaO, MgO, SiO_2 etc., have been reported to aid in maintaining the large surface area at elevated temperatures.[3-6] We have previously reported[7,8] that the addition of BaO greatly increases the surface area of alumina above 1000 °C. The effect of BaO depends strongly on the oxide composition. The optimum composition agrees with the stoichiometric one for the formation of $BaO \cdot 6Al_2O_3$, at which the surface area reached more than 6 $m^2 g^{-1}$ even after calcination at 1450 °C. But the improvement is still unsatisfactory in practical use for high-temperature combustion. In this paper, we report the marked elevation of high-temperature surface area retention of $BaO \cdot 6Al_2O_3$ by employing the preparation from metal alkoxides. The powder characteristics of sol-gel prepared $BaO \cdot 6Al_2O_3$ were compared with the sample from the conventional technique. It has become evident that the formation process of $BaO \cdot 6Al_2O_3$ plays a key role in the retention of large surface area.

Experimental

Sample Preparation. Barium hexaaluminate ($BaO \cdot 6Al_2O_3$) was prepared from mixtures of $BaCO_3$ (99%, Kishida Chemical) and γ-Al_2O_3 (99.9%, Catalysis Soc. Jpn., JRC-ALO4). The average crystallite size of $BaCO_3$ and γ-Al_2O_3 were 0.8 μm and 5 nm, respectively. They were mixed with an automatic mortar grinder for 2 h before firing. The mixture was heated in air at a constant rate of 5 deg min^{-1} and kept at a desired temperature for 5 h in a high-density alumina crucible.

A sample with the same composition was prepared by hydrolysis of the corresponding metal alkoxides. Barium isopropoxide, $Ba(OC_3H_7)_2$, was prepared by the reaction between Ba metal (99%, Kishida Chemical) and 2-propanol (99.5%, Kishida Chemical) in N_2 stream at 80 °C.[9]

$$Ba + 2\,C_3H_7OH \rightarrow Ba(OC_3H_7)_2 + H_2$$

Calculated amounts of $Ba(OC_3H_7)_2$ and $Al(OC_3H_7)_3$ (99%, Kishida Chemical) were dissolved together in 2-propanol and refluxed at 80 °C for 5 h with vigorous stirring. All the procedure before the hydrolysis has been carried out in a dried N_2 atmosphere. As distilled water was slowly added to the resulting solution, gelation was observed immediately accompanied by a rise in temperature from 80 to 90 °C. After several hours of aging under stirring at 80 °C, the hydrolyzed alkoxides were evaporated to dryness in vacuo and the powders thus obtained were calcined in the above mentioned manner. In this study, the surface areas of alkoxide-derived $BaO \cdot 6Al_2O_3$ were investigated as a function of the amount of water for hydrolysis and the aging period of hydrolyzed alkoxides. Thus, a series of hydrolysis reactions were performed to demonstrate these optimum conditions.

Sample Characterization. The surface areas of oxide powders were determined by the BET method using nitrogen adsorption. The surface area thus obtained was reproducible within a 10% relative error on the average. The pore size distributions were also obtained from the nitrogen adsorption isotherms at 77 K. The crystal structures of the calcined samples were determined by X-ray diffraction (Rigaku Denki, 4011). The microstructures of the powder samples were measured by a scanning electron microscope (JEOL, JSM-50).

Thermal decomposition of the hydrolyzed precursors to the corresponding oxides was observed by differential thermal analysis and thermal gravimetry (ULVAC, TGD 5000RH) in air. The samples were heated at a constant rate of 10 deg min^{-1} up to 600 °C. The infrared spectra were taken on a JASCO IR 810 spectrometer before and after the thermal decomposition. Mixtures of the hydrolyzed precursors (30 mg) and KBr powder (300 mg) were pressed into

disks of 20 mm diameter and placed in the temperature-controlled in situ cell. The infrared spectra were recorded after evacuation at elevated temperatures and subsequent cooling to room temperature.

Results

The Surface Area of $BaO \cdot 6Al_2O_3$. γ-Alumina and the two BaO-Al_2O_3 precursors, which were prepared from powder mixtures and metal alkoxides, were heated at elevated temperatures for 5 h. The decrease in surface area during the heat treatment was measured as a function of the calcination temperature (Fig. 1). The present investigation was performed only on the samples with a composition of $(BaO)_{0.14}(Al_2O_3)_{0.86}$ at which the effect of BaO on the surface area is most prominent, as has been reported previously.[7,8] The three samples in Fig. 1 had similar surface areas after calcination at 1100 °C, but the surface area significantly decreased with a rise in calcination temperature. The decrease was most significant in pure alumina. The addition of BaO was obviously effective in maintaining the surface area at higher temperatures. The effect of BaO is related to the formation of a hexagonal layered aluminate ($BaO \cdot 6Al_2O_3$).[7,8] The surface area of barium hexaaluminate prepared from $BaCO_3/\gamma$-Al_2O_3 was 4 times larger than that of pure alumina above 1300 °C.

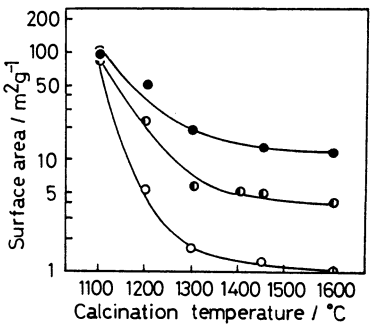

Fig. 1. Temperature dependence of surface areas of $(BaO)_{0.14}(Al_2O_3)_{0.86}$ and Al_2O_3. ● $(BaO)_{0.14}(Al_2O_3)_{0.86}$ (alkoxide), ◐ $(BaO)_{0.14}(Al_2O_3)_{0.86}$ ($BaCO_3/\gamma$-Al_2O_3), ○ Al_2O_3.

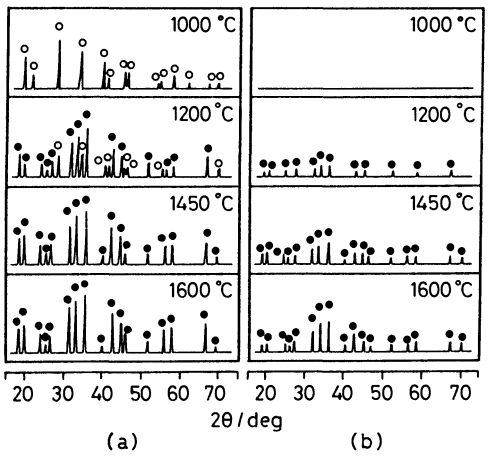

Fig. 2. X-Ray diffraction patterns of $(BaO)_{0.14}$-$(Al_2O_3)_{0.86}$ after calcination at various temperatures. (a) Powder mixture of $BaCO_3$ and γ-Al_2O_3. (b) Hydrolyzed alkoxides. ● $BaO \cdot 6Al_2O_3$, ○ $BaO \cdot Al_2O_3$.

Preparation from alkoxide precursors, which sometimes gives rise to the formation of ultrafine particles and/or low temperature processing of mixed oxides, was applied to the present system. The data for a typical alkoxide-derived sample are shown in Fig. 1. The loss of surface area upon heating was more gradual than that of the powder mixtures. The surface area was 3 times larger than that from $BaCO_3/\gamma$-Al_2O_3 mixtures above 1300 °C.[10] The value of 11 m^2g^{-1} after heating at 1600 °C has not been achieved by any oxide supports so far reported.

The Crystal Structure of BaO-Al_2O_3. The phase diagram of the system BaO-Al_2O_3 indicates that the $(BaO)_{0.14}(Al_2O_3)_{0.86}$ sample consists of a single phase of $BaO \cdot 6Al_2O_3$ in the equilibrium state.[11] However, the $BaCO_3/\gamma$-Al_2O_3 precursor underwent a complicated formation process to evolve this phase during the heating process, as shown in Fig. 2(a). After calcination at 1000 °C, the phase observed in $BaCO_3/\gamma$-Al_2O_3 was the equimolar compound ($BaO \cdot Al_2O_3$) and a trace amount of $BaCO_3$, instead of the equilibrium phase ($BaO \cdot 6Al_2O_3$). The sample at this calcination condition is almost completely composed of a mixture of $BaO \cdot Al_2O_3$ and Al_2O_3, though the diffraction lines from the latter phase are too weak to be observed by X-ray diffraction due to its poor crystallinity. With a rise in calcination temperature, the diffraction lines from $BaO \cdot 6Al_2O_3$ appeared and became intense. The formation of the equilibrium $BaO \cdot 6Al_2O_3$ phase was completed after heating at 1450 °C.

The samples from alkoxides, on the other hand, showed no diffraction lines after heating at 1000 °C. At 1200 °C, the diffraction lines which appeared in this case were only from the $BaO \cdot 6Al_2O_3$ phase (Fig. 2(b)). They became sharp and intense at elevated calcination temperatures, but the $BaO \cdot Al_2O_3$ phase was not observed at any temperature.

Microstructures and Pore Size Distributions. After calcination at 1450 °C, the particle morphology of alumina and $BaO \cdot 6Al_2O_3$ was observed by a scanning electron microscope (SEM), as shown in Fig. 3. The particle size of alumina (ca. 2 μm) was considerably larger than that of the $BaO \cdot 6Al_2O_3$ samples. Significant grain growth of alumina is evident from the large particle size and the smooth powder surface. In contrast, the $BaO \cdot 6Al_2O_3$ powder was clearly fine and possessed a rough surface. It is noted that the two $BaO \cdot 6Al_2O_3$ samples are obviously different in their particle sizes and microstructures. When the mixture of $BaCO_3$ and γ-Al_2O_3 was calcined at 1450 °C, the resultant particles (0.5—1.0 μm) were strongly agglomerated (Fig.3(b)). Such large agglomerates were absent in the sample obtained from hydrolyzed alkoxides. The particles were in a granular shape with uni-

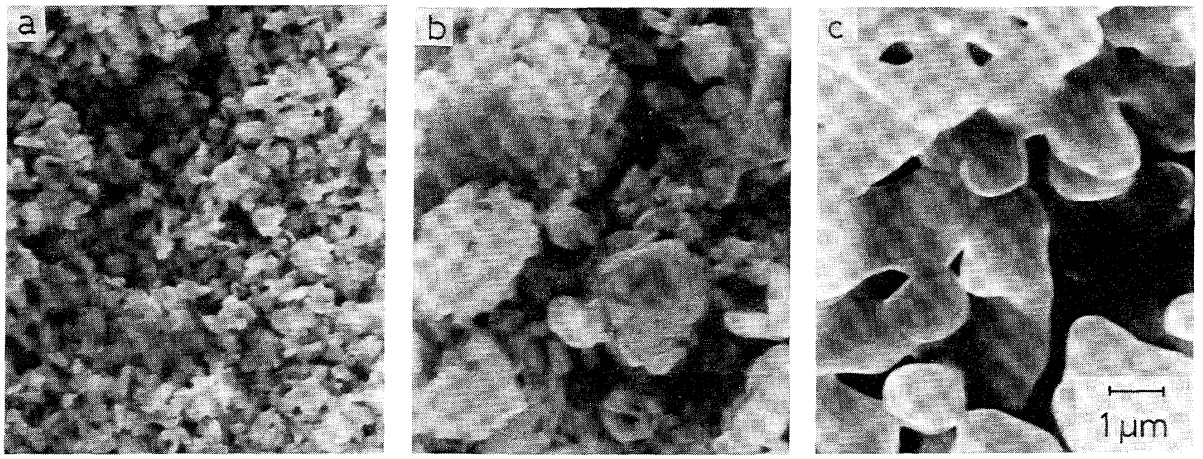

Fig. 3. SEM photographs of $BaO \cdot 6Al_2O_3$ and Al_2O_3 after calcination at 1450°C. a) $BaO \cdot 6Al_2O_3$ from alkoxides, b) $BaO \cdot 6Al_2O_3$ from $BaCO_3/\gamma\text{-}Al_2O_3$, c) Al_2O_3.

form (0.3 μm) size (Fig. 3(a)).

Pore size distributions of alumina and the $BaO \cdot 6Al_2O_3$ samples were measured after calcination at 1450 °C. The distribution was maximum at the pore size smaller than 10 nm (Fig. 4). The relative pore volume gradually decreased with increasing pore size. The barium hexaaluminate sample, in particular, that was prepared from alkoxides possessed obviously larger total pore volume than alumina. The sequence of total pore volume of three samples agreed with that of the surface area. The difference in surface area among the three alumina-based samples largely resulted from the population of pores with radius of ca. 10 nm or less.

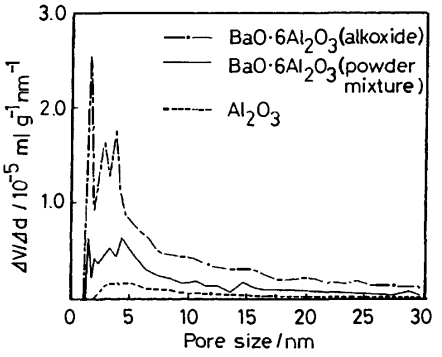

Fig. 4. Pore size distributions of $BaO \cdot 6Al_2O_3$ and Al_2O_3 after calcination at 1450°C.

Effect of Hydrolysis Conditions on Surface Area. The surface area of $BaO \cdot 6Al_2O_3$ is also sensitive to some preparation conditions during the alkoxide process such as the aging period of the hydrolyzed products and the amount of water. The surface area of alkoxide-derived $BaO \cdot 6Al_2O_3$ increased at the initial stage of aging and became almost constant after 12 h as shown in Fig. 5 ($R(H_2O/MOC_3H_7)$=10.0). After 12 h of aging and subsequent calcination at 1300 °C, the sample retained the surface area of 18.5 m^2g^{-1} which is about double that of the sample with 30 min of aging.

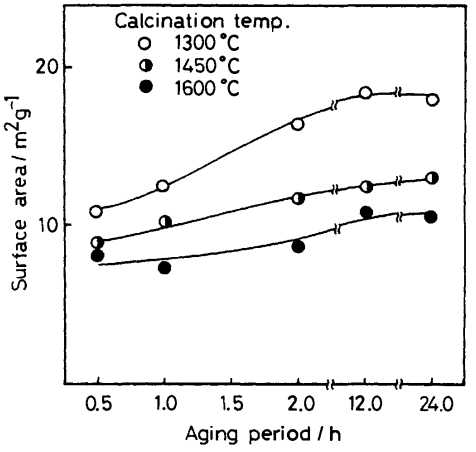

Fig. 5. Effect of the aging period of hydrolyzed precursors on the surface area of $BaO \cdot 6Al_2O_3$. ($R(H_2O/MOC_3H_7)$=10.0)

The amount of water added for hydrolysis is expressed as a molar ratio per metal isopropoxyl group ($R(H_2O/MOC_3H_7)$). The number of metal isopropoxyl groups, $-MOC_3H_7$, is the sum of $-AlOC_3H_7$ and $-BaOC_3H_7$. Figure 6 shows the effect of $R(H_2O/MOC_3H_7)$ on the surface area of $BaO \cdot 6Al_2O_3$. The surface area was maximum (20.2 m^2g^{-1}) at $R(H_2O/MOC_3H_7)$= 0.5, but it decreased either by an increase or by a decrease in the amount of water. The optimum condition, $R(H_2O/MOC_3H_7)$=0.5, agrees with the stoichiometric ratio for the hydrolysis of alkoxides. The effect of the amount of water is obvious especially when calcination was performed at lower temperatures such as 1300 °C.

The effect of the aging period was investigated by microscopic observation of the hydrolysis precursors (Fig. 7). In the initial stage, the sample contained large agglomerates (larger than 10 μm) which consisted of submicron primary particles. With the aging progress, the size of the agglomerate was significantly reduced. After aging for 24 h, the sample consisted

almost entirely of equal sized particles and agglomerates were rarely observed.

Figure 8 shows SEM photographs of precursors after a given amount of water was added to the alkoxide solution for hydrolysis. Corresponding to the two regions observed in the surface area changes (Fig. 6), the particle morphology was different between the sample with $R(H_2O/MOC_3H_7)<0.5$ and $R(H_2O/MOC_3H_7)>0.5$. The hydrolyzed sample at $R(H_2O/MOC_3H_7)>0.5$ consisted of submicron particles, but the particle morphology and size were almost unchanged with the amount of water so far as should be observed by SEM. In contrast, the particle size was obviously larger when less water ($R(H_2O/MOC_3H_7)<0.5$) was used for hydrolysis. In this region, the amount of water is not enough for complete hydrolysis of the alkoxides. Thus, the microstructures of the hydrolysis products well reflect the surface area of the $BaO \cdot 6Al_2O_3$. Large agglomerates and large precursor particles appear to result in low surface areas after calcination.

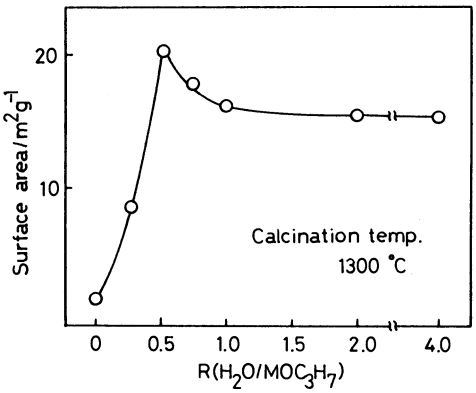

Fig. 6. Effect of the amount of water added to alkoxides on the surface area of $BaO \cdot 6Al_2O_3$. (12 h aging)

Thermal Behavior of Hydrolyzed Alkoxides. The decomposition of the hydrolyzed products was examined by in situ IR measurements. The IR spectra obtained after heating in vacuo at various temperatures are shown in Fig. 9. At room temperature, the hydrolyzed product showed the absorption band of the

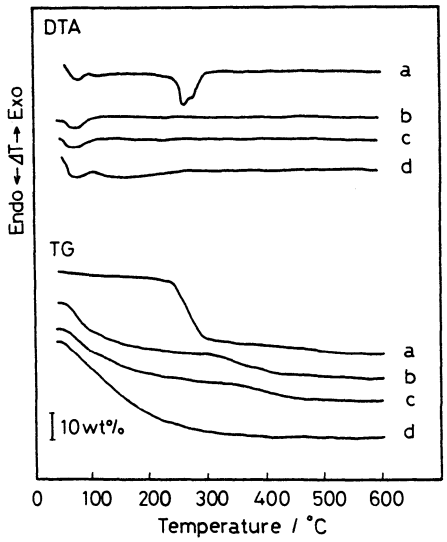

Fig. 10. DTA/TG analyses of the hydrolyzed precursors prepared under various $R(H_2O/MOC_3H_7)$ conditions. a) $R(H_2O/MOC_3H_7)=10.0$, b) 2.0, c) 1.0, d) 0.5.

H-O-H bending vibration around 1640 cm^{-1}. This band, being attributed to the physisorbed water, completely disappeared after evacuation at 200 °C. The bands at 3000—3500 cm^{-1} probably correspond to the O-H stretching mode of the metal hydroxides in the hydrolyzed precursors. These peaks were weakened at elevated temperatures due to the thermal decomposition of metal hydroxides to mixed oxides. The O-H bands disappeared at 400 °C after complete decomposition.

Figure 10 shows the DTA/TG curves of hydrolyzed precursors prepared under various $R(H_2O/MOC_3H_7)$ conditions. A broad endothermic peak below 100 °C, which was observed in every alkoxide-derived sample, is attributed to elimination of physisorbed water. A large and sharp endothermic peak with a 25% weight loss appeared for the sample with $R(H_2O/MOC_3H_7)=10$ around 250 °C. From the IR result, this weight loss can be attributed to dehydration accompanied by thermal decomposition of the metal hydroxides. Similar weight loss was observed in the samples with $R(H_2O/MOC_3H_7)<2.0$ at 250—400 °C, but they were small, corresponding to the small content of metal hydroxides.

Discussion

Effect of $BaO \cdot 6Al_2O_3$ Formation on Surface Area. Although a large surface area is one of the most important properties for combustion catalysts, only little is known about the support material for high-temperature combustion. Most support materials, which have been used so far below 1000 °C, sinter into particles with only a small surface area. γ-Alumina, which is most commonly used as a catalyst support below 1000 °C, is not adequate because of its significant decrease in surface area, as shown in Fig. 1. The decrease in the surface area around 1200 °C is accompanied by a phase transition from metastable states into the equilibrium phase (α-phase). In contrast, BaO added alumina is effective in maintaining the large surface area by forming the $BaO \cdot 6Al_2O_3$ phase.

The structure of $BaO \cdot 6Al_2O_3$ has been described as the intermediate of magnetoplumbite and β-alumina structures (Fig. 11).[12,13] But the detailed refinement of the crystal structure with this composition reported by Kimura et al.[14,15] revealed the existence of two compounds near the stoichiometric $BaO \cdot 6Al_2O_3$ composition. It was suggested that they are essentially β-alumina structures on the basis of the electron diffraction and crystallographic data. Both the magnetoplumbite and β-alumina structures are grouped into a layered aluminate type, but they differ from each other in the atomic arrangement in the mirror plane. In our previous reference on a series of alkaline earth oxide-alumina systems,[8] the aluminate samples which crystallize in the layered aluminate structures generally possessed the large surface area. It was also reported[16] that some rare earth metal aluminates with these layered structures exhibited large surface areas after heating at high temperatures. However, the $BaO \cdot 6Al_2O_3$ system is the most prominent in main-

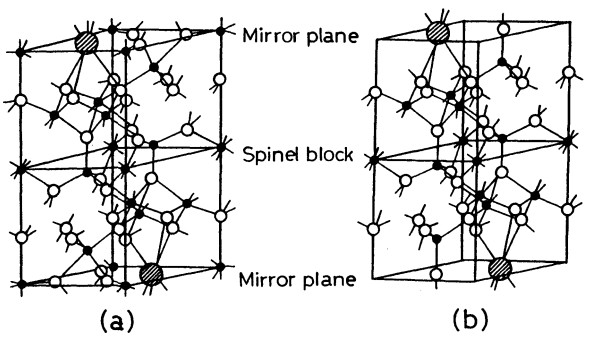

Fig. 11. Crystal structure of (a) magnetoplumbite and (b) β-alumina. ● Al^{3+}, ○ O^{2-}, ◉ Ba^{2+}.

taining the large surface area among the series of layered aluminates with large di- or trivalent cations. The real reason for such high thermal resistance against sintering is not sufficiently understood at present, but it is probably related to the crystal structure. In the layered aluminate structure, each layer is separated by the mirror plane (Fig. 11). The structure may suppress interlayer diffusion of atoms and crystal growth along the *c* direction (perpendicular to the mirror plane). In fact, polycrystalline sodium β-alumina, which is used as a solid electrolyte, grows as plate-shaped particles with their flat sides perpendicular to the *c* axis. Powers et al.[17] suggested that the stacking of layers in sodium β-alumina is very slow in comparison to the Al-O spinel formation. It was deduced that the mirror planes, which separate each spinel block, seem to play a key role in the large surface area of the layered aluminate family.

Effect of Preparation Procedure of $BaO \cdot 6Al_2O_3$. There are some superior points of an alkoxide process as compared with a conventional method, i.e., 1. high purity, 2. very fine primary particle, and 3. uniform mixing of components.[18,19] The first factor seems not to be so important for the high surface area of the system, because small amount of additives, such as Cr, Mn, and Co did not promote sintering.[20] Particles are desired to be fine to obtain a large surface area, but ultrafine particles are apt to sinter due to their large surface energy. At present, the third point is expected to be the most important in achieving the large surface area of $BaO \cdot 6Al_2O_3$. As mentioned above, the formation of barium hexaaluminate is essential for the large surface area of the present system. The alkoxide process permits direct formation of this phase by uniform mixing of the components at a molecular level (Fig. 2). To make a comparison with hydrolysis of the alkoxide mixture, barium isopropoxide and aluminium isopropoxide were separately hydrolyzed in 2-propanol solutions and the resulting hydroxide suspensions were mixed and evaporated to dryness. The phases appearing after calcination at 1300 °C were not only $BaO \cdot 6Al_2O_3$ but also $BaO \cdot Al_2O_3$. This indicates that high chemical homogeneity is attained only when a mixture of the two alkoxides is hydrolyzed simultaneously. In other words, the mixing at a particle level does not reduce the formation temperature of $BaO \cdot 6Al_2O_3$. It is likely that the mixing of the two alkoxides in 2-propanol leads to formation of mixed alkoxides;[21] but direct evidence for the formation of mixed alkoxides has not been obtained. The high chemical homogeneity in the alcoholic solution should be retained in alkoxide-derived precursors as a consequence of solution gelation.

On the other hand, in the case of powder mixtures, barium hexaaluminate is formed through the solid state reaction between $BaO \cdot Al_2O_3$ and alumina by diffusion. Since the excellent heat resistance is not achieved by the $BaO \cdot Al_2O_3$ phase, the $BaO \cdot Al_2O_3$ particles grow in size during the solid state reaction until they are converted to $BaO \cdot 6Al_2O_3$. Thus, it is concluded that the high surface area of the alkoxide-derived sample is a result of the low temperature formation of $BaO \cdot 6Al_2O_3$.

The difference in the reaction history is well reflected in the microstructures of the powders. The SEM photographs demonstrated a marked contrast in microstructure of the two barium hexaaluminate samples (Fig. 3). Although large agglomerates and unequal particle size are observed commonly in the powder mixtures, the alkoxide-derived samples consist of submicron particles with a uniform size. The difference in microstructure is reflected by the pore size distribution. Large primary particles in the powder mixture result in small overall pore volume as shown in Fig. 4. The pores smaller than 10 nm in diameter largely contribute to the difference in the total pore volume of the three samples. Pores of this size are in fact seen in the SEM photograph of the alkoxide-derived $BaO \cdot 6Al_2O_3$ sample as interparticle voids.

Effect of Preparation Condition in Alkoxide Process. The surface areas of samples from the alkoxide process were affected by the amount of water and the aging period after hydrolysis. The change in surface area with the amount of water is apparently divided into two regions as shown in Fig. 6. The stoichiometric amount of water for the decomposition of alkoxides is $R(H_2O/MOC_3H_7) = 0.5$.

$$2\text{-M-}(OC_3H_7) + H_2O \rightarrow \text{-M-O-M-} + 2\,C_3H_7OH \quad (1)$$

At $R(H_2O/MOC_3H_7) < 0.5$, the oxide is produced partly by hydrolysis (Reaction(1)) and partly by pyrolysis of the alkoxides. The increase in surface area in this region indicates that pyrolysis of the alkoxides does not contribute to the large surface area. Namely, a substantial amount of hydrolysis is required to produce a large surface area. The particle size of the incompletely hydrolyzed product is two orders of magnitude larger than that of the sample at $R(H_2O/MOC_3H_7) > 0.5$ (Fig. 8).

At the second region ($R(H_2O/MOC_3H_7) > 0.5$), the surface area decreases with an increase in $R(H_2O/MOC_3H_7)$ (Fig. 6). The partial formation of hydroxides (Reaction(2)) is included, due to the presence of excessive water in this region.[22]

$$M(OC_3H_7)_n + nH_2O \rightarrow M(OH)_n + nC_3H_7OH \quad (2)$$

As the amount of water increases, the reaction (2) becomes dominant, resulting in a high content of hydroxide groups in the product. The hydroxides thus formed are thermally decomposed into oxides accompanying elimination of water in the temperature range 250—400 °C as was observed by TG. The weight loss in this temperature range increased with $R(H_2O/MOC_3H_7)$, corresponding to the increase in the hydroxide content in the precursors. The formation temperature of $BaO \cdot 6Al_2O_3$ for the sample with a low

extent of hydrolysis ($R(H_2O/MOC_3H_7)<1.0$) was near 1100 °C, while it is above 1200 °C for the hydroxide-rich sample ($R(H_2O/MOC_3H_7)=10.0$). The decrease in surface area in the second region resulted from the hydroxide formation in precursors. This also elevates the temperature for the formation of $BaO \cdot 6Al_2O_3$

The effect of the aging period in Fig. 5 is somewhat smaller than that of the amount of water. The increase in surface area with aging is related to the extent of agglomeration of hydrolyzed products as was revealed by SEM observation in Fig. 7. The aging of hydrolyzed products in the presence of excessive water likely reduces the agglomeration of particles and brings about a high dispersion state. Large agglomerates, which are observed at a short aging period, grow into large particles in the course of heating. This only leads to the decrease in the surface area of the resultant $BaO \cdot 6Al_2O_3$

The authors are greatly indebted to the Center of Advanced Instrumental Analysis of Kyushu University for support in SEM measurements. This research was partially supported by a Grant-in-Aid for Scientific Research No. 61550598 from the Ministry of Education.

State of Polarization of Light Scattered by Anisotropic Spherical Particles

Yoh SANO
National Institute of Agrobiological Resources, Tsukuba Science City, Ibaraki 305
(Received March 25, 1988)

Using the light-scattering theory of Rayleigh-Gans, theoretical expressions were derived for the state of the polarization of light scattered by anisotropic spherical particles in the case of linearly polarized incident light with its electric vector inclined by an angle ψ to the scattering plane. The azimuth angle of the ellipse of the light scattered is a function of only the scattering angles, θ and ψ; the ellipticity of the ellipse of the scattered light is always equal to zero, meaning that the scattered light is linearly polarized for linearly polarized incident light. The degree of polarization of the scattered light, P, defined as the ratio of the polarized component to the total intensity of the scattered light, depends on the intrinsic anisotropy, p_m, the relative refractive index of the sphere to the solvent, m, and θ together with the angle ψ. Although P for isotropic spherical particles is always equal to 1 at any θ, P for anisotropic spherical particles is smaller than 1.0, but close to 1.0 if the incident light is unpolarized or linearly polarized with ψ=30°. If ψ is smaller than 30°, P varies from 1.0 to 0, depending strongly on the p_m and m of the anisotropic sphere. It has been suggested that the determination of P as a function of ψ and θ would provide good information about the optical intrinsic anisotropy of anisotropic spherical particles.

A particle may have two kinds of optical anisotropy: one is an "intrinsic" anisotropy and the other is a "form" anisotropy.[1] The form anisotropy is an optical anisotropy due to an anisometry. In other words, it is due to the anisotropic shape of a particle made of the isotropic phase. If the shape of the particle is non-spherical and is assumed to be a spheroid, the anisometry can be expressed by the ratio of the length of semiaxis of symmetry to the length of semitransverse axis of the spheroid. For an anisometric particle, the refractive index of the dispersed phase may be independent of the vibration direction of the electric vector. On the other hand, an intrinsic anisotropy occurs when the dispersed phase (the material composing the particle), itself, has an optical anisotropy because of, e.g., the orientation of valence bonds in the phase. For an intrinsic anisotropic particle, the refractive index of the dispersed phase depends on the vibration direction of the electric vector, and, even if the particle is spherical, the effect of the intrinsic anisotropy must be taken into consideration.

The light scattered by optically anisotropic scatterers will generally be partially polarized and contain some unpolarized component. To give a complete description of a partially elliptically polarized state of scattered light, we should analyze the intensities associated with both polarized and unpolarized components, and also give full specifications of the polarization ellipse.

In the case of randomly oriented, optically isotropic and anisometric particles, the state of the polarization of scattered light had already been calculated[2,3] on the basis of the Rayleigh[4]-Gans[5] theory (referred to as the Rayleigh-Gans theory of spheroids (RGS theory)). The RGS theory is used to avoid any confusion with the well-known Rayleigh-Gans (RG) theory of scattering, which involves a restrictive assumption that the refractive index of the particles is close to that of the surrounding medium.[6]

In the present paper, the effect of the intrinsic optical anisotropy to the state of polarization of light scattered by optically anisotropic spherical particles, such as spherical plant viruses, is discussed on the basis of the RGS theory and a set of parameters: i.e., the degree of polarization, ellipticity, azimuth, and handedness of the ellipse of the polarized component of scattered light is examined.

Theory

General Consideration. Let's consider light scattering by an optically anisotropic spherical particle. If a dispersed sphere is optically uniaxial, the excess polarizability can be expressed by a spheroid.[7] If the principal axes of the spheroid are α_a, α_b, α_b, the optical anisotropy is given by the ratio p_g,

$$p_g = \alpha_a/\alpha_b = g_a/g_b, \tag{1}$$

where

$$g_i = (3/4\pi)\,(m_i^2-1)/(m_i^2+2) \quad (i = a \text{ or } b), \tag{2}$$

and m_i is the relative refractive index of the i-direction.

When linearly polarized incident light with an electric vector oriented obliquely to the scattering plane (observation plane) reaches the scattering-volume element, the light scattered will be, in general, elliptically polarized and contain some unpolarized component as well.

All possible states of the scattered light are most easily analyzed by making use of the Stokes parameters as well as the Mueller or scattering matrix, which depends only on the characteristics of the scattering medium. The Stokes parameters(I, Q, U, and V) which completely characterize the intensity and polarization properties of a beam of light, including partially polarized and unpolarized light, are defined in terms of time averages of the electric field components of an electromagnetic wave.[8]

$$\begin{aligned} I &= \langle E_\pi E_\pi^* + E_\sigma E_\sigma^* \rangle, \\ Q &= \langle E_\pi E_\pi^* - E_\sigma E_\sigma^* \rangle, \\ U &= \langle E_\pi E_\sigma^* + E_\sigma E_\pi^* \rangle, \\ V &= \mathrm{i}\langle E_\pi E_\sigma^* - E_\sigma E_\pi^* \rangle. \end{aligned} \tag{3}$$

The subscripts π and σ refer to components of the electric field parallel and perpendicular, respectively, to the scattering plane, the brackets denote time averages, and the asterisks denote conjugate complex values. The four elements of the Stokes vector can be thought of as describing the total intensity (I), the excess of π-polarized over σ-polarized intensity (Q), the excess intensity of +45° linearly polarized over −45° linearly polarized light (U), and the excess of right (as opposed to left) circularly polarized intensity (V).

The Stokes vectors describing the incident and scattered light, $\boldsymbol{S}_0$ and $\boldsymbol{S}$, respectively, are connected by a 4×4 matrix called a Mueller's matrix or a scattering matrix, $\boldsymbol{M}$,

$$\boldsymbol{S} = \boldsymbol{M}\boldsymbol{S}_0, \tag{4}$$

where $\boldsymbol{S}=[I, Q, U, V]$ and $\boldsymbol{S}_0=[I_0, Q_0, U_0, V_0]$

Scattering Matrix. If the particle is sufficiently small compared to the wavelength of light, the scattering matrix $\boldsymbol{M}$ for a randomly oriented spheroid is given by RGS theory:[9]

$$\boldsymbol{M} = \begin{pmatrix} S_{11} & S_{12} & 0 & 0 \\ S_{12} & S_{22} & 0 & 0 \\ 0 & 0 & S_{33} & 0 \\ 0 & 0 & 0 & S_{44} \end{pmatrix}, \tag{5}$$

where the matrix elements S_{11}, S_{12}, S_{22}, S_{33}, S_{44} are given by

$$\begin{aligned} S_{11} &= F_1(1+\cos^2\theta) + 2F_2, \\ S_{12} &= F_1(\cos^2\theta - 1), \\ S_{22} &= F_1(\cos^2\theta + 1), \\ S_{33} &= 2F_1\cos\theta, \text{ and} \\ S_{44} &= 2(F_1 - F_2)\cos\theta, \end{aligned} \tag{6}$$

with

$$\begin{aligned} F_1 &= (\alpha^6/15)(p_g^2 + 3p_g + 7/2)F_0, \\ F_2 &= (\alpha^6/15)(p_g - 1)^2 F_0, \text{ and} \\ F_0 &= [(1+2p_m)(m^2-1)]^2/[(m^2-1) + p_m(2m^2+7)]^2. \end{aligned} \tag{7}$$

The α is the size parameter defined by

$$\alpha = 2\pi a/\lambda, \tag{8}$$

where a is the radius of the sphere and λ is the wavelength of light in the medium.

If the principal refractive indices in the a- or b-directions of the excess polarizabilities n_a and n_b are divided by the refractive index of the solvent n_0 and are represented by (m_a, m_b, m_b), the intrinsic (structural) anisotropy p_m is defined by

$$p_m = (m_a^2 - 1)/(m_b^2 - 1), \tag{9}$$

and the mean relative refractive index m of the spherical particle is defined by[1]

$$1/(m^2-1) = [1/(m_a^2-1) + 2/(m_b^2-1)]/3; \tag{10}$$

therefore, the optical anisotropy p_g defined by Eq. 1 for spherical anisotropic particles is given by

$$p_g = [p_m(2m^2+7) + (m^2-1)]/[2p_m(m^2-1) + (m^2+8)]. \tag{11}$$

State of Polarization of the Scattered Light. The scattered light is, in general, partially polarized and is an incoherent sum of the polarized, I_p (subscript "p" signifies the polarized component), and the unpolarized, I_u (subscript "u" signifies unpolarized), components. Both components are related to the Stokes parameters of scattered light by

$$I_p = (Q^2 + U^2 + V^2)^{1/2}, \tag{12}$$

and

$$I_u = I - I_p.$$

If we consider linearly polarized incident light with an electric vector which makes an angle ψ with the scattering plane, the Stokes vector can be expressed by the normalized Stokes parameters of the incident light beam as

$$\boldsymbol{S}_0 = [1, \cos 2\psi, \sin 2\psi, 0]. \tag{13}$$

By substituting the value of $\boldsymbol{S}_0$ in Eq.4, we obtain the values for each of the Stokes parameters of partially polarized scattered light as follows:

$$\begin{aligned} I_p &= I_p^\circ(1 - \cos^2\psi \sin^2\theta), \\ I &= I_p^\circ(1 - \cos^2\psi \sin^2\theta) + I_u, \\ I_p^\circ &= 2F_1, \; I_u = 2F_2, \text{ and} \\ \eta &= 0. \end{aligned} \tag{14}$$

The ellipticity, η, defined by the ratio of the semiminor to the semimajor axis of the ellipse of the polarized component of scattered light is always equal to 0, which means that the polarized component is linearly polarized in the case of linearly polarized incident light.

The azimuth angle, ζ, of the linearly polarized component of the scattered light, is given by

$$\tan\zeta = \tan\psi/\cos\theta, \tag{15}$$

and is only a function of ψ and θ.

The degree of polarization, P, is defined as the ratio of the intensity of the polarized portion to the total intensity,

$$P_\psi(\theta) = I_p/I. \tag{16}$$

Therefore, we obtain with Eq. 14

$$P_\psi(\theta) = (1 - \sin^2\theta\cos^2\psi)/[(1 - \sin^2\theta\cos^2\psi) + (F_2/F_1)]. \tag{17}$$

Since

$$F_2/F_1 = (p_g - 1)^2/(p_g^2 + 3p_g + 7/2), \tag{18}$$

and p_g is given by Eq. 11, the $P_\psi(\theta)$ depends on p_m, m, θ, and ψ. For anisotropic spherical particles ($p_m \neq 1$),

the $P_\psi(\theta)$ is smaller than 1.0 and is independent of α, as far as RGS theory holds.

A particle composed of isotropic material has a relative refractive index m equal in all directions of the electric vector of light, independently of the particle form. Therefore, in this case, p_m=1 (and p_g=1) and

$$F_1 = (\alpha^6/2)\, F_0,$$
$$F_2 = 0, \text{ and} \qquad (19)$$
$$F_0 = [(m^2-1)/(m^2+2)]^2.$$

The $P_\psi(\theta)$ is always equal to 1 over the entire range of θ in this case.

Numerical Results and Discussion

Variation of the Intensity of the Scattered Light. Numerical calculations were made with an ACOS 850/20 computer at the Computer Center of the Ministry of Agriculture and Forestry. Figure 1 shows the variation in the intensities of the scattered light for the unpolarized component I_u and the maximum of the polarized component $I_p{}^\circ$ as a function of the intrinsic anisotropy p_m for m=1.20. Here, the quantity I (and I_p and I_u as well) is called the "intensity" of the scattered light; however, it is a dimensionless quantity which is equal to the Rayleigh ratio per particle multiplied by k^2 (where $k=2\pi/\lambda$), and is usually expressed by i.

Bovine serum albumin is known to be somewhat asymmetrical and to possess an intrinsic (structural) anisotropy. The intrinsic anisotropy parameter of bovine serum albumin in the native state was calculated to be p_m=1.46.[10] Spherical plant viruses such as tomato bushy stunt virus, southern bean mosaic virus, satellite tobacco necrosis virus et al. contain different amounts of nucleic acids and proteins, although some of these viruses produce nucleic acid-free isometric particles. In some of the viruses the particles consist of various kinds of amino acid residues and in others the particles consist of a long backbone of alternating sugar and phosphate residues with one of five different purine or pyrimidine bases attached to each sugar residue. These residues have an anisotropic structure. Therefore, spherical plant viruses possess an intrinsic anisotropy due to the orientation of valence bonds of the amino acid and/or nucleic acid residues. Taking into account the experimental results of these spherical plant viruses, it is satisfactory to think about the values of p_m<1.9 and also to think the case of m_a>m_b, that is, the values of p_m>1.

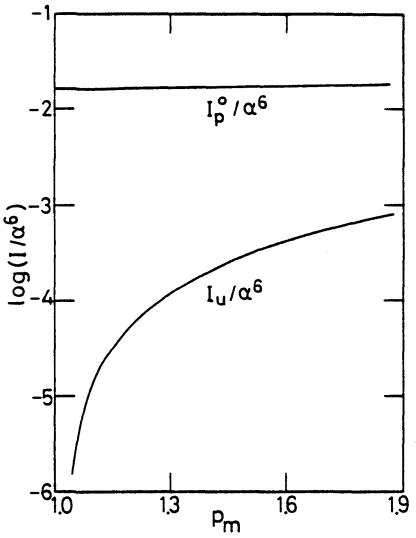

Fig. 1. Variation of $\log(I_u/\alpha^6)$ and $\log(I_p{}^\circ/\alpha^6)$ with the intrinsic anisotropy p_m>1 for m=1.20.

Variation of the Azimuth Angle ζ. Figure 2 shows the variation of the azimuth angle, ζ, with ψ for various θ. As is shown in Eq. 15, the value of ζ is independent of m, α and p_m. The ζ has the same sign as ψ for forward scattering ($0<\theta<90°$) and has the opposite sign for the backward scattering ($90°<\theta<180°$). ζ becomes greater as θ approaches 90°, and at θ=90° the value of ζ is equal to 90° for any value of ψ.

Variation of the Degree of Polarization. The degree of polarization at θ=90° given by Eq. 17 is

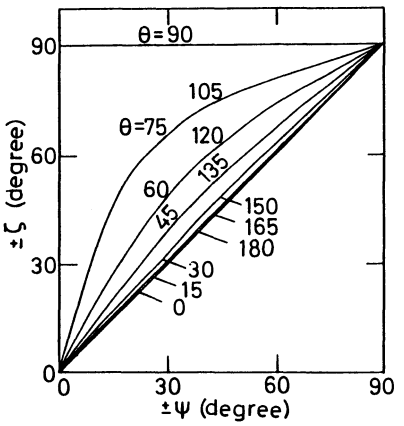

Fig. 2. Variation of the azimuth angle, ζ(degree), with ψ(degree) at various scattering angles θ(degree). For $\theta<90°$, ζ and ψ have the same sign, and for $\theta>90°$, ζ and ψ have the opposite sign.

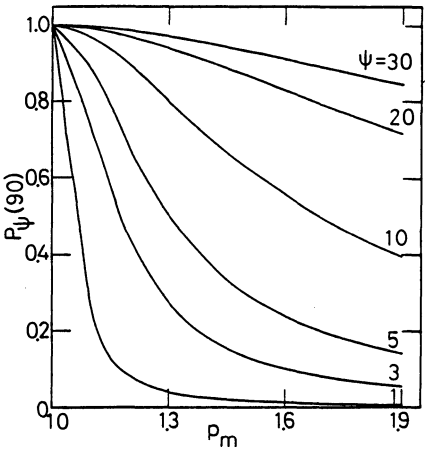

Fig. 3. Variation of the degree of polarization at θ=90°, $P_\psi(90)$, with the intrinsic anisotropy p_m>1 and m=1.20 for various values of ψ(degree).

$$P_\psi(90)=\sin^2\psi/(\sin^2\psi+F_2/F_1). \quad (20)$$

Figure 3 shows the variation of $P_\psi(90)$ with the intrinsic anisotropy p_m and ψ, at $m=1.20$. $P_\psi(90)$ depends strongly on p_m and ψ, especially in cases in which the ψ is smaller than 10°. When ψ is larger than 30°, the change of the $P_\psi(90)$ is relatively small. The $P_\psi(90)$ for isotropic spherical particles ($p_m=1$) is equal to 1.0 irrespective of the value of ψ.

Figure 4 shows the variation of $P_\psi(90)$ with $\pm\psi$. The $P_\psi(90)$ increases monotonously from 0 to almost 1 with the increase of $\pm\psi$, and its value becomes smaller as the p_m deviates from the isotropic materials ($p_m=1$).

Figure 5 shows the variation of $P_\psi(\theta)$ with $\pm\psi$ at various scattering angle θ for $p_m=1.4$. The $P_\psi(\theta)$ is symmetric around $\theta=90°$ since the intensities, I and I_p, are functions of $\sin^2\theta$, as is shown in Eq. 17. The dependence of $P_\psi(\theta)$ on $\pm\psi$ becomes smaller as the deviation of θ from 90° becomes larger. In the case of $\theta=0°$ or 180° the $P_\psi(\theta)$ is constant independent of $\pm\psi$.

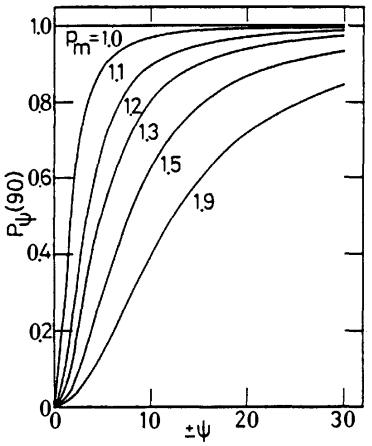

Fig. 4. Variation of the degree of polarization at $\theta=90°$, $P_\psi(90)$, with ψ(degree) and $m=1.20$ for various values of $p_m\geq 1$.

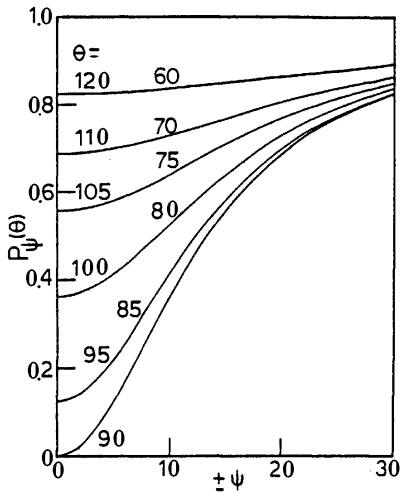

Fig. 5. Variation of the degree of polarization, $P_\psi(\theta)$, with ψ(degree) for $p_m=1.4$ and $m=1.20$. Parameters are scattering angle θ(degree).

Variation of the Degree of Depolarization. The intensity of the scattered light is measured practically by the irradiance transmitted through the analyzer with a transmission axis inclined by χ to the scattering plane. The degree of depolarization is defined by the ratio of the intensity of the parallel (i.e., $\chi=0°$) to the perpendicular (i.e., $\chi=90°$) component of the scattered light.

For unpolarized incident light, the degree of depolarization is given by

$$\rho_u(\theta)=[\cos^2\theta+F_2/F_1]/[1+F_2/F_1], \quad (21)$$

which is equal to $\cos^2\theta$ and is not equal to zero when the scattering angle θ is other than 90°, even if the unpolarized component I_u is zero for the optically isotropic particles ($p_m=1$). At $\theta=90°$, it becomes

$$\rho_u(90)=F_2/(F_1+F_2)=1-P_{90}(90), \quad (22)$$

where $P_{90}(90)$ is the degree of polarization for $\psi=90°$ and $\theta=90°$.

Instead of unpolarized light, if linearly polarized light with an azimuth angle of ψ is used as incident light, the degree of depolarization for $\theta=90°$ is

$$\rho_\psi(90)=F_2/[2F_1\sin^2\psi+F_2]. \quad (23)$$

The variation of $\rho_\psi(90)$ with p_m is shown in Fig. 6, which seems to be very similar to Fig. 3 if the direction of the ordinate is inverted. The value of $\rho_\psi(90)$ is very small if ψ is 30° or larger. The value, however, could become larger, if ψ is decreased.

For the Determination of Parameter Values. As is shown in Figs. 3—6, the degree of polarization, or degree of depolarization, depends strongly on the intrinsic anisotropy p_m, and is independent of α. If we measure a $P_\psi(\theta)$ or $P_\psi(90)$ value, and/or $\rho_\psi(\theta)$ or $\rho_\psi(90)$ value, the intrinsic anisotropy can be determined directly if the value of m is known. If we measure $P_\psi(\theta)$ or $\rho_\psi(\theta)$ values at several values of ψ and θ, it is possible to determine both m and p_m by fitting these values to the theoretical curves.

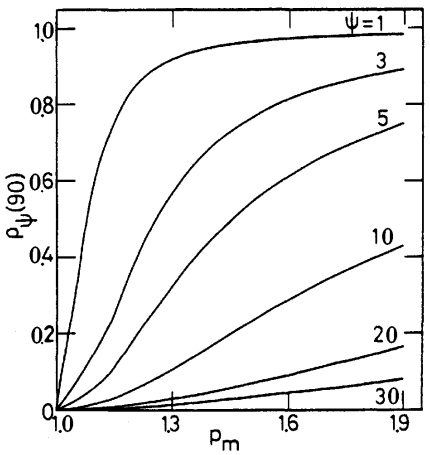

Fig. 6. Variation of the degree of depolarization at $\theta=90°$, $\rho_\psi(90)$, with the intrinsic anisotropy $p_m>1$ and $m=1.20$.

Knowledge about p_m and m immediately gives information regarding the refractive index of both the a- and b-axis of the intrinsic (structural) anisotropic spherical particle, n_a and n_b (according to Eqs. 9 and 10) if the refractive index of the solvent n_0 is known.

In conjunction with knowledge concerning the intrinsic anisotropy, p_m, the value of α is also obtained from the intensities (I, I_p, and I_u) according to Fig. 1. Also, knowledge concerning α immediately gives information on the molecular weight, M, if the partial specific volume is known.

The theory presented in this paper can be efficiently applied to small spherical plant viruses. However, plant virus particles sometimes form by a process, analogous to crystallization, by an orderly aggregation of similarly sized units into three-dimensional arrays. The nucleic acid of viruses also has a definite structure and is not simply a randomly coiled thread, stimulating the crystallization structure. In these cases the effect of the intrinsic anisotropy is large, and a slight modification is necessary for any determination of the intrinsic anisotropy, due to the nonrandom orientation of the segments.

Measurement of Degree of Polarization with the Analyzer. When the transmission axis of the analyzer χ is changed, the intensity of the scattered light $I_{\psi\chi}(\theta)$ is given by[8,11]

$$I_{\psi\chi}(\theta)=(I_u/2)+(I_p/2)[1+\cos^2(\chi-\zeta)],$$
$$=(I/2)[1+P_\psi(\theta)\cos^2(\chi-\zeta)], \quad (24)$$

where ζ is the azimuth angle of the linearly polarized, scattered component. The $I_{\psi\chi}(\theta)$ has a maximum, $I_{max}(\theta)$, and a minimum, $I_{min}(\theta)$, values at $\chi=\zeta$ and $\chi=\zeta+\pi/2$, respectively. The degree of polarization can, therefore, be experimentally measured using the equation

$$P_\psi(\theta)=[I_{max}(\theta)-I_{min}(\theta)]/[I_{max}(\theta)+I_{min}(\theta)]. \quad (25)$$

This is equivalent to thinking of the beam as being made up of two linearly polarized orthogonal incoherent beams of intensities $I_{max}(\theta)$ and $I_{min}(\theta)$.

If another kind of the degree of linear polarization is considered, which is defined directly by the experimentally measurable intensities of the irradiance through the transmission axis of the analyzer at χ and at $(\chi+\pi/2)$, respectively,

$$P_{\psi\chi}(\theta)=[I_{\psi\chi}(\theta)-I_{\psi(\chi+\pi/2)}(\theta)]/[I_{\psi\chi}(\theta)+I_{\psi(\chi+\pi/2)}(\theta)], \quad (26)$$

the deviation of $P_{\psi\chi}(\theta)$ from $P_\psi(\theta)$ is given by

$$P_{\psi\chi}(\theta)=P_\psi(\theta)\cos2(\chi-\zeta). \quad (27)$$

The maximum and minimum values of $P_{\psi\chi}(\theta)$ occur when χ is equal to the azimuth angle ζ and is equal to the orthogonal direction to the azimuth angle, respectively. The $P_{\psi\chi}(\theta)$ is equal to zero at $\chi=(\zeta+\pi/4)$.

Radiation Diagram of Intensity of the Transmitted Light through the Analyzer. The intensity of the irradiance transmitted through the analyzer can also be rewritten as

$$I_{\psi\chi}(\theta)=F_2+F_1\cdot F_{\psi\chi}(\theta), \quad (28)$$

and

$$F_{\psi\chi}(\theta)=(1-\sin^2\theta\cos^2\psi)+(\cos^2\theta\cos^2\psi-\sin^2\psi)\cos2\chi,$$

where both F_2 and F_1 are functions of p_m, m, and α (as explained before), while $F_{\psi\chi}(\theta)$ is a function which depends only on angles θ, ψ, and χ. Figures 7 and 8 are radiation diagrams of the function, $F_{\psi\chi}(\theta)$, which shows a maximum and a minimum, depending on ψ, χ, and θ.

For $\theta=0°$, the $F_{\psi\chi}(0)$ can be simplified as

$$F_{\psi\chi}(0)=2\cos^2(\psi-\chi). \quad (29)$$

If the angle between the transmission direction of the

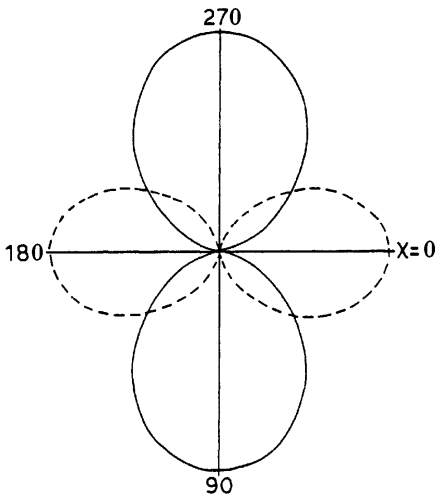

Fig. 7. Radiation diagram of the function of $F_{\psi\chi}(\theta)$. Parameters in the figure are transmission angles of analyzer χ(degree) to the scattering plane. Solid line represents the case for $\psi=90°$ without depending on θ. Broken line represents the case for $\psi=0°$ and $\theta=30°$ or 150°. The $F_{\psi\chi}(\theta)$ at $\theta=0°$ and $\theta=90°$ is situated on an origin.

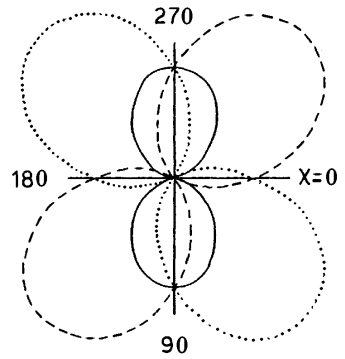

Fig. 8. Radiation diagram of the function of $F_{\psi\chi}(\theta)$ for $\psi=45°$ or $\psi=-45°$. Parameters in the figure are transmission angles of analyzer χ(degree). Solid line represents the value at $\theta=90°$ for $\psi=\pm45°$. Broken line indicates the value at $\theta=150°$ for $\psi=+45°$, and at $\theta=30°$ for $\psi=-45°$. Dotted line represents the value at $\theta=30°$ for $\psi=+45°$, and at $\theta=150°$ for $\psi=-45°$.

polarizer and the analyzer is $\pm\delta$,

$$I_{\psi\chi}(0) = (I_u/2) + I_p^\circ \cos^2\delta. \quad (30)$$

The second term in Eq. 30 is called Malus' law, which was discovered experimentally by Etienne Louis Malus in 1808.[8] Only the polarized component of the forward scattered light (θ=0°) follows Malus' law; half of the intensity of the unpolarized component of the scattered light must, furthermore, be introduced to the total intensity of the forward scattered light.

Quenching of Excited Singlet and Triplet States of Some Polyfused Arenes by Dihalobenzenes

G. K. MALLIK, T. K. PAL, T. GANGULY, and S. B. BANERJEE*
Department of Spectroscopy, Indian Association for the Cultivation of Science, Jadavpur, Calcutta 700 032, India
(Received July 27, 1987)

External heavy atom effect on the emission spectra of naphthalene, phenanthrene, and chrysene by perturbers dihalobenzenes are investigated to estimate different nonradiative rate constants associated with the depletion of the singlet and the triplet states of the fluorescers. The bimolecular fluorescence quenching rate constant k_q has been evaluated at 300 K by applying Stern-Volmer relation. The dihalobenzene quenchers have triplet states lying below the singlet states of the fluorescers and the overall quenching rate k_q is composed of two rate constants, namely, the intramolecular intersystem crossing rate k_q^{ISC} and the singlet-triplet energy transfer rate constant k_q^{ST}. The relative magnitudes of the two rate constants k_q^{ISC} and k_q^{ST} have been examined in the light of the energy conditions controlling the associated processes. At 77 K, the phosphorescence decay curve of the fluorescers in the presence of dihalobenzenes is biexponential and the triplet decay of the perturbed fraction of the fluorescers is exponential. It is concluded that at the low temperature, heavy atom interaction in the systems studied mainly proceeds through CT mechanism. Speculative suggestion has been made to account for enhancement of phosphorescence emission of polyfused arenes in EtOH solution.

It is generally believed that the quenching of the excited singlet states of aromatic molecules (AM) in presence of another molecular species containing heavy atom like Cl, Br, and I proceeds via intermediate contact exciplex of charge transfer (CT) nature.[1-15] This CT exciplex is formed in a singlet state which may be higher than the singlet S_1 of the fluorescer AM. The reported observations were made mainly in dilute solutions and in a few cases in vapour phase[10,11] also. This intermediate contact CT exciplex increases the spin-orbit coupling as a result of which the spin forbiddeness of the intercombinational process decreases and consequently intramolecular intersystem crossing (ISC) rate increases. This intramolecular ISC $T_1 \leftrightsquigarrow S_1$ rate depends upon the energy gap between the singlet S_1 and triplet T_1 of the fluorescer AMs, the closer the gap, the greater will be the nonradiative transition probability from singlet to triplet.[16,17] In the presence of external heavy atom perturber another mechanism may be operative in causing depletion of singlet state. This is intermolecular singlet-triplet energy transfer depicted by the scheme[18]

$$S_d^1 + S_q^0 \rightarrow\rightarrow S_d^0 + T_q^1 \qquad (1)$$

where the subscripts d and q stand for donor and quencher molecules respectively. This transfer occurs by means of an exchange mechanism and is of short range nature. A required condition is that the triplet T_1 of the quencher should lie well-below the singlet S_1 of the fluorescer.

Heavy atom perturbation also modifies phosphorescence spectra of AMs[19-30] through the second order interactions which proceed via (1) electron exchange and (2) CT mechanism. There is still some controversy whether CT or electron exchange mechanism would be dominant in spin orbit interaction. Castino et al.[31] proposed exchange mechanism for pyrene-iodine system in cyclohexane solution. Lessard and Durocher[32] studied phosphorescence decay of indole and concluded that when halocarbons were used as quenchers heavy atom interaction proceeded through CT exciplex formation whereas in the case of the quencher propyl bromide the electron-exchange mechanism prevailed. Najbar et al.[28] stressed on second order electron exchange mechanism for the external heavy atom interaction between several AMs and KI.

The present paper reports the emission spectra of naphthalene, phenanthrene, and chrysene in ethanol (EtOH) at 300 and 77 K in presence of different concentrations of *p*-dichlorobenzene (DCB), *p*-dibromobenzene (DBB), and *p*-diiodobenzene (DIB). One of the objectives was to estimate the rates of the bimolecular fluorescence quenching proceeding via intramolecular ISC and intermolecular singlet-triplet energy transfer processes. It was also intended to determine the various photophysical parameters involved in the heavy atom interaction and to examine the role of CT or electron exchange in inducing depletion of singlet and triplet states of the fluorescer molecules.

Experimental

Source and method of purification of naphthalene, phenanthrene, and chrysene (used as fluorescer) were the same as described in our previous paper.[14] Both *p*-dichlorobenzene (DCB) and *p*-dibromobenzene (DBB) obtained from BDH were used after vacuum sublimation. *p*-Diiodobenzene (DIB) from Aldrich Chemical Ltd. was used without further purification. Solvent EtOH (E. Merck) of spectroscopic grade was used as such. 1,2-Dichloroethane (1,2-DCE) obtained from B D H London (LR Grade) was treated with calcium chloride for two days and then distilled over P_2O_5. 1,3-Dibromopropane (1,3-DBP) purchased from the same source was fractionally distilled at atmospheric pressure before use. The samples, quenchers, and solvents were tested for any possible interfering emission.

The concentrations of naphthalene, phenanthrene, and chrysene were chosen approximately at 10^{-4} mol dm^{-3} for all emission experiments at 300 and 77 K. The concentrations of the perturbers DCB, DBB, and DIB were varied between

0.32—2.30, 10^{-2}—0.25, and 10^{-4}—10^{-2} mol dm^{-3} respectively and those of 1,2-DCE and 1,3-DBP varied between 10^{-2}—10^{-1} and 0.41—4.00 mol dm^{-3} respectively.

The fluorescence and phosphorescence spectra were recorded with a Perkin Elmer model MPF 44 A fluorescence spectrophotometer provided with corrected spectra unit and the absorption spectra with a Shimadzu UV-VIS spectrophotometer model 210 A.

Naphthalene, phenanthrene, and chrysene were excited at 300, 295, and 320 nm, respectively when fluorescence and phosphorescence spectra were recorded both at 300 and 77 K. For phosphorescence decay study the emission wavelengths of naphthalene, phenanthrene, and chrysene were chosen at 469, 497, and 540 nm, respectively. After the phosphorescence intensity achieved a steady state, the exciting radiation was cut off to obtain the dark decay on the recorder.

Results and Discussion

The intensity of fluorescence emission of naphthalene, phenanthrene, and chrysene in EtOH falls off in a regular way when DCB, DBB, and DIB are added gradually (Fig. 1) to the binary mixtures. But the same dihalogen molecules do not produce any change in the absorption spectra of the polyfused arenes in EtOH. So, for these systems the static quenching may be ignored and the dynamic fluorescence quenching rate constant can be determined from the well-known relation (2)

$$f_o/f = 1 + K_{SV}[Q] = 1 + k_q\tau_o[Q]. \quad (2)$$

Here f_o and f refer to relative fluorescence intensities of fluorescer in EtOH without quencher [Q] and with quencher of concentration [Q] respectively, and K_{SV} is the Stern-Volmer (S-V) constant. Figure 2 gives the S-V plots and in Table 1 are given the k_q values measured in ternary solutions containing the dihalogens and also in solutions containing monohalogen quenchers chlorobenzene (ClB), bromobenzene (BrB), and iodobenzene (IB). The dihalogen perturbers are seen to be more efficient than the monohalogens in quenching fluorescence. The dependence of quenching efficiency on the number of chlorine, bromine, or iodine atoms in the quencher molecules or in other words on the electron affinities of the quencher molecules indicates that a possible route of depletion of the excited states of the fluorescer polyfused arenes is through contact exciplex of CT nature formed between fluorescer and quencher molecules. In the systems under study, the transfer of charge necessary for CT exciplex formation would be from the electron donor naphthalene, phenanthrene, or chrysene to the electron acceptor DCB, DBB, or DIB molecules. The CT interaction would induce large ISC with rate constant k_q^{ISC} in the chromophore. Another possible mechanism for nonradiative deactivation capable of significant con-

a) Ref. 14.

tribution is singlet-triplet energy transfer, with rate constant k_q^{ST}, from the chromophore to the quencher. This energy transfer occurs through exchange mechanism and is of short range nature.[18] The dynamic rate constant may be assumed to be composed of mainly two independent rate constants k_q^{ISC} and k_q^{ST} and one may write

$$k_q = k_q^{ISC} + k_q^{ST}. \quad (3)$$

For the polyfused arene-dihalobenzene systems studied, it is not possible to estimate individual contribution of k_q^{ISC} and k_q^{ST} to k_q. Therefore, the fluorescence spectra of naphthalene, phenanthrene, and chrysene in EtOH have been measured with 1,2-DCE and 1,3-DBP as quenchers. In these aliphatic molecules the halogen atoms are well separated from each other by CH_2 group and, what is more important, these two molecules do not have any singlet or triplet state lying near the fluorescent state of naphthalene, phenanthrene, or chrysene. Therefore, energy transfer between the fluorescers and 1,2-DCE or 1,3-DBP should have no role in the deactivation process and only ISC would be operative through CT mechanism. The measured dynamic quenching rate constants, k_q', of the fluorescer in these aliphatic solvents (Table 1) would be composed of only k_q^{ISC}. If the k_q^{ISC} values of the aromatic fluorescers in dihalobenzene solvents are assumed to have the same values as k_q' then an estimate of k_q^{ST} for these systems may be made from the relation (3). The k_q^{ST} values thus determined are included in Table 1. The analysis of the rates k_q^{ST} and k_q^{ISC} so made, can only be very approximate and admittedly the procedure is open to criticism because it involves the tacit assumption that the external heavy atom effects induced by the aliphatic dihalogens and the aromatic dihalogens are the same. At the same time all other possible deactivation processes are disregarded. Nevertheless, such analysis may give a qualitative idea about the relative importance of the two processes in these systems and the relative magnitudes of the rate constants k_q^{ST} and k_q^{ISC} determined by the above procedure may be examined in the light of the energy condition controlling the associated processes. The triplet state T_1 of DCB and of DBB lies well below the singlet state S_1 of naphthalene and phenanthrene (Table 2) and the rate constant k_q^{ST} is large for two fluorophores in DCB and DBB, whereas T_1 states of DCB and DBB have energies higher than S_1 of chrysene and the singlet-triplet energy transfer process is less probable. Expectedly, for chrysene-DCB and chrysene-DBB systems the estimated k_q^{ST} is smaller than k_q^{ISC}. The intramolecular ISC rate k_{ISC} is, in general, large or small depending on whether the singlet-triplet energy interval ($\nu_f - \nu_p$) in a fluorescer is small or large. The k_q^{ISC} values of naphthalene, phenanthrene, and chrysene perturbed by DCB are in the expected order (Table 3), but in DBB the

a) Ref. 36.

values calculated for naphthalene, phenanthrene, and chrysene are not so. Perhaps in the case of the aliphatic and aromatic quenchers containing bromine, the objections noted above are more valid. So far as relative magnitudes of k_q^{ST} and k_q^{ISC} for the individual polyfused arene fluorophores in DCB and DBB are concerned the following facts may be noted. For naphthalene in DCB as heavy atom perturber with large $(\nu_f-\nu_p)$ and $\Delta\nu$ (Tables 2 and 3), the k_q^{ST} rate process is more important than k_q^{ISC} (Table 1) while in the case of phenanthrene, the k_q^{ISC} is only marginally smaller than k_q^{ST}. In DBB, on the other hand, k_q^{ST} and k_q^{ISC} are of nearly the same magnitude for both naphthalene and phenanthrene. In the case of chrysene, where the energy condition for energy transfer from the singlet of the fluorescer to the triplet states of the heavy atom perturbers DCB and DBB is unfavourable, k_q^{ST} is smaller than k_q^{ISC} in both DCB and DBB. It is seen from Table 3 that k_q^{ST} is small when $\Delta\nu$ is small. This dependence of k_q^{ST} on $\Delta\nu$ is consistent with the expectation that small energy gap between the singlet of the fluorescer and the triplet of the quencher facilitates back transfer from the latter to the former. It is to be pointed out here that 1,2-diiodoethane or any other suitable aliphatic iodo compound of desired purity and stability, which does not have singlet or triplet level below S_1 state of the polyfused arenes, was not available. So individual contribution of k_q^{ST} and k_q^{ISC} with DIB as quencher could not be determined seperately. But it may be speculated that because of favorable energy condition, the S-T energy transfer (k_q^{ST}) in the case of chrysene in DIB will be larger than in DCB or DBB. The proposed quenching process may be represented by,

$$^1A^* + Q \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} {}^1(A^{\delta+} \cdots\cdots Q^{\delta-})^* \xrightarrow{k_{ISC}} {}^3A^* + Q \rightarrow {}^1A + Q \qquad (3a)$$

The dihalobenzenes have favorable π-electronic structure efficiently forming CT complex and indicating quenching via process (3a). The low temperature measurements at 77 K discussed below favor this reaction.

Another process that might have some role is

$$^1A^* + Q \rightarrow\rightarrow {}^1A + {}^3Q^* \qquad (3b)$$

because the fluorescers and the quenchers have singlet and triplet states with favorable condition for energy transfer. But no direct evidence of ^3Q could be found. It may be pointed out that careful examination showed that the halobenzenes in EtOH did not phosphoresce at 300 K and even at 77 K, emission from these molecules was very weak.

The two second order mechanisms, charge transfer and electron exchange, through which external heavy atom perturbation by the dihalobenzenes on emission of the polyfused arenes proceeds, are known to affect the lowest triplet state of the aromatic polyfused arene fluorescers. Generally, these processes enhance the radiative character of $S_0 \leftarrow T$ transition of aromatic molecules (AM).[28,37] Study of decay of emissions from

the molecules and kinetic analysis of photophysical parameters of the singlet and triplet states of the molecules would therefore be expected to yield interesting information. With this idea in mind, the luminescence emissions of naphthalene, phenanthrene, and chrysene in EtOH rigid glass matrix at 77 K have been measured with and without addition of dihalobenzenes. When DCB is added to the binary mixture of phenanthrene or chrysene in EtOH at 77 K, both the fluorescence and phosphorescence emissions are reduced (Fig. 3). Only in the case of naphthalene, fluorescence is quenched and the phosphorescence is enhanced (Fig. 4). With DBB as quencher, fluorescence emission of all three polyfused arene fluorescers is quenched but their phosphorescence emission is enhanced (Fig. 5) while DIB quenches both the fluorescence and phosphorescence of the polyfused arenes (Fig. 6). In all the systems studied no change occurs in the shape and position of emission bands. The phosphorescence decay curves of polyfused arene-dihalobenzene systems are of biexponential nature. In the decay curve given in Fig. 7, $I_p(t)$ and $I_p(0)$ refer to time-dependent and stationary state phosphorescence intensity respectively. After a considerable time the decay curves become linear and identical with the unperturbed decay. The perturbed decay function which is obtained by subtracting the exponential decay component from the observed phosphorescence decay function is of exponential nature (Fig. 7). This lends support to the conclusion that the dominant process in external heavy atom perturbation in the systems investigated is charge transfer, because a nonexponential perturbed decay function would mean that major contribution comes through electron exchange mecha-

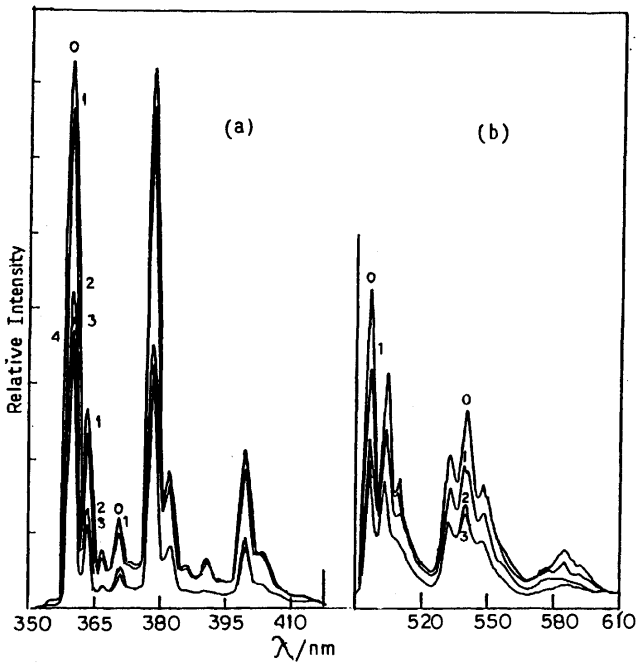

Fig. 3. Fluorescence (a) and phosphorescence (b) spectra of chrysene in EtOH (1.80×10^{-4} mol dm^{-3}) at 77 K (excitation wavelength: 320 nm). Concentration (mol dm^{-3}) of DCB in 0,0; 1, 0.34; 2, 0.67; 3, 0.81.

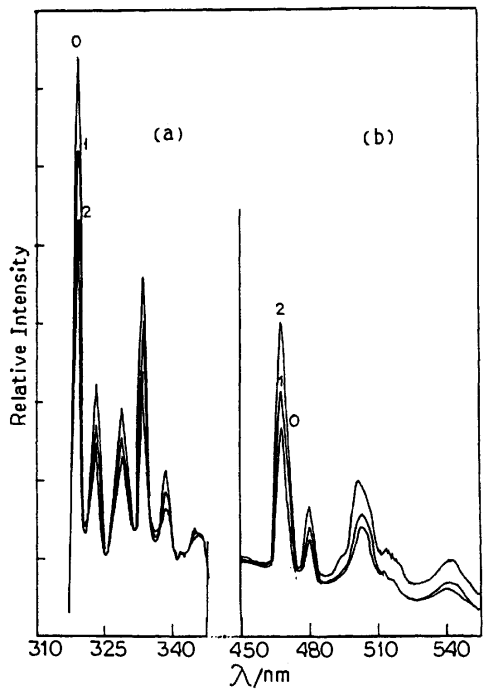

Fig. 4. Fluorescence (a) and phosphorescence (b) spectra of naphthalene in EtOH (5.20×10^{-4} mol dm^{-3}) at 77 K (excitation wavelength: 300 nm). Concentration (mol dm^{-3}) of DCB in 0,0; 1, 0.57, 2, 1.13.

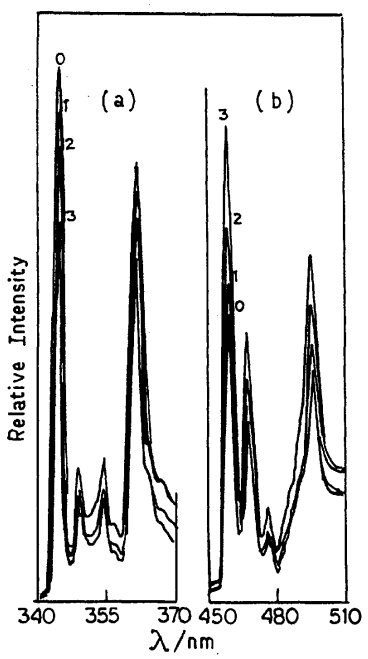

Fig. 5. Fluorescence (a) and phosphorescence (b) spectra of phenanthrene in EtOH (3.50×10^{-4} mol dm^{-3}) at 77 K (excitation wavelength: 295 nm). Concentration (mol dm^{-3}) of DBB in 0,0; 1, 0.11; 2, 0.18; 3, 0.25.

nism.[28,32] Referring to the decay curves, the phosphorescence intensity can be expressed as[13,22]

$$I_p(t)/I_p(0) = \beta e^{-t/\tau_p} + (1-\beta)e^{-t/\tau_p'}. \quad (4)$$

From the biexponential nature of the phosphorescence decay curve it is evident that the CT complex which may be formed in excited singlet state is also formed in the triplet state. But absence of any change in shape and position of phosphorescence bands of the polyfused arenes after addition of *p*-dihalobenzenes may mean that the triplet complex quickly dissociates into free molecules. With regard to possible phosphorescence emission from perturbed complex which has its own decay rate it may be that the peak positions and structure of phosphorescence spectra of the complex molecules are similar to those of the electron donor polyfused arenes. Cases of complexes showing donor type phosphorescence have been discussed and reviewed by previous authors.[32,38]

The values of β and other photophysical parameters are obtained by usual methods described earlier[13] are given in Tables 4—6. The photophysical parameters are all found to depend on concentration of the quenchers. The phosphorescence decay time τ_p' of a perturbed fluorescer molecule decreases regularly with increase of quencher concentration (Tables 4—6). Concomitantly relative intramolecular ISC rate k_i'/k_i (Prime sign denoting perturbed species) and the triplet

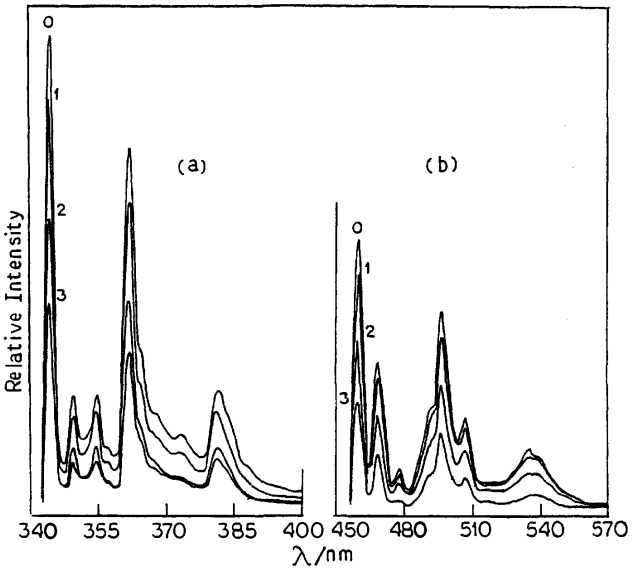

Fig. 6. Fluorescence (a) and phosphorescence (b) spectra of phenanthrene in EtOH (3.37×10^{-4} mol dm^{-3}) at 77 K (excitation wavelength: 295 nm). Concentration (mol dm^{-3}) of DIB in 0,0; 1, 1.88×10^{-2}; 2, 2.63×10^{-2}; 3, 2.78×10^{-2}.

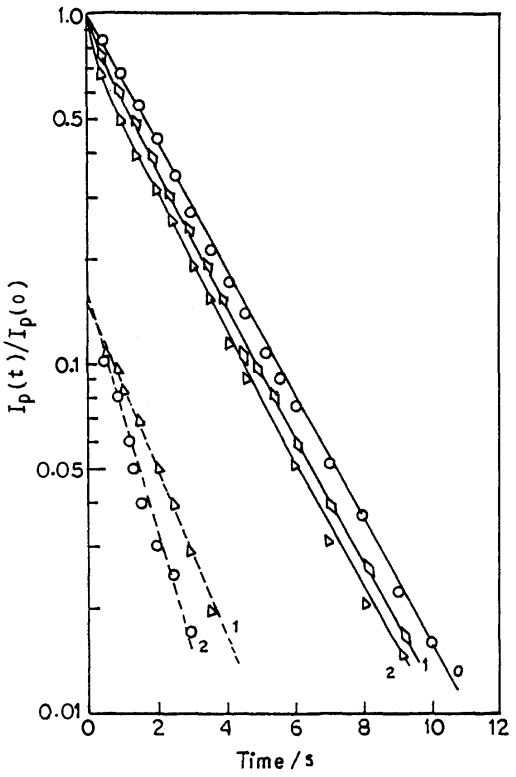

Fig. 7. Phosphorescence decay function of chrysene in EtOH (1.80×10^{-4} mol dm^{-3}) at 77 K without the perturber DIB (O); with the perturber DIB molecules of concentration (mol dm^{-3}) in (1) 1.73×10^{-2}; (2) 2.71×10^{-2}. Dotted curves 1 and 2 represent phosphorescence decay functions of the perturbed chrysene molecule by DIB.

yield Φ_t' increase. The k_{ISC} rate is highly sensitive to concentration of the quencher (Tables 4—6). It has been noted above, that DBB enhances the intensity of phosphorescence bands of all three polyfused arenes whereas DCB enhances the phosphorescence of naphthalene only. On the other hand, DIB quenches phosphorescence of all three compounds. According to Eisenthal[39] electronic mixing of the donor triplet with the CT singlet may lead to an enhancement of the 0-0 band as well as all successive totally symmetric vibrational bands of the donor fluorescer molecule through borrowing of intensity from CT interaction by $S_0 \leftarrow T$ transition of the fluorescer. The mixing of the donor triplet with the CT singlet of the complex occurs via the CT triplet of the complex provided the mixing of the donor and CT triplets is permitted. A necessary condition is that the phosphorescence of the fluorescer is polarized parallel to the CT absorption.[39] It is tempting to speculate that these conditions are satisfied in the cases of those polyfused arene-dihalogen systems in which enhancement of intensity of phosphorescence emissions of polyfused arenes due to external heavy atom effect has been observed. These conditions might not be satisfied in the other systems such as phenanthrene and chrysene in DCB and the three polyfused arenes in DIB. In the case of these systems, addition of heavy atom quencher DCB or DIB to arenes concerned reduces phosphorescence radiative rates k_p'/k_p and simultaneously increases the non-radiative rates k_{ip}'/k_{ip} (Tables 4 and 6). The net result is quenching of phosphorescence on complexation in the triplet state.

Studies on Dielectric Permittivities, Refractive Indices for 1,1′-Bicyclohexyl Liquid Crystals in the Nematic and Isotropic Phases

Sushmita SEN, Krishnakoli KALI, and Subir K. ROY*
Department of Spectroscopy, Indian Association for the Cultivation of Science, Calcutta 700032, India
(Received September 7, 1987)

The dielectric permittivities $\varepsilon_{\parallel}$ and $\varepsilon_{\perp}$ and the refractive indices n_e, n_o of five 4-cyano-4′-alkyl-1,1′-bicyclohexyls (CCH 2, CCH 3, CCH 4, CCH 5, CCH 7 where 2, 3, 4, 5, 7 means ethyl, propyl, butyl, pentyl, heptyl respectively) have been measured at different temperatures in the nematic and isotropic phases. The orientational order parameter from the refractive indices data, calculated from (1) Vuks' method and (2) Neugebauer's method were in good agreement. At any reduced temperature, the order parameter for CCH 2 is largest and that of CCH 7 is smallest and those for the others are in between them. Unlike for cyanobiphenyls or cyclohexylbenzenes, the dielectric permittivity $\varepsilon_{\parallel}$ is obtained for $\vec{E} \perp \vec{H}$ and $\varepsilon_{\perp}$ for $E \parallel H$, where $\vec{E}$ is the electric and $\vec{H}$ is the magnetic field, and has been explained as due to these molecules having negative diamagnetic anisotropy. The dielectric anisotropy, $\Delta\varepsilon$ and optical anisotropy Δn for all the CCH's is much less than that of the corresponding CB or PCH molecules. All the CCH's show pretransitional permittivity just above the transition temperature T_{NI}.

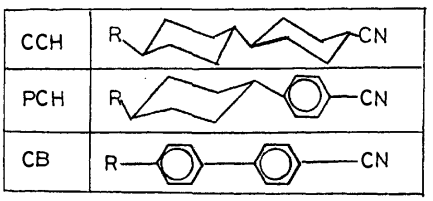
Dielectric permittivities and refractive indices of liquid crystals are required for their selection for practical uses. The data for dielectric permittivities and refractive indices for alkylcyanobiphenyls,[1-3] cyclohexylbenzenes,[4] phenylcyclohexanecarboxylates[5] have been reported earlier. Such data for CCH's are rather scanty. The object of the present investigations were to study how the dielectric properties and refractive indices change when both the phenyl rings are replaced by cyclohexyl rings.

Studies on the temperature dependence of dielectric permittivities in the isotropic phase for nematics with strong dipole moments show pretransitional effects while in nonpolar nematics pretransitional effect is absent.[5,6] It was thought worthwhile to study the pretransitional effects in dielectric permittivity in the isotropic phase of 1,1′-bicyclohexyl liquid crystals. The results are discussed in this paper.

Experimental

Five CCH liquid crystals (CCH 2, CCH 3, CCH 4, CCH 5, CCH 7) procured from E. Merck, Germany were used in the investigations without further purification. Mesomorphic range of the samples,

Sample	Nematic range/°C
CCH 2 (4-cyano-4′-ethyl-1,1′-bicyclohexyl)	46—49
CCH 3 (4-cyano-4′-propyl-1,1′-bicyclohexyl)	50—80
CCH 4 (4-cyano-4′-butyl-1,1′-bicyclohexyl)	54—79
CCH 5 (4-cyano-4′-pentyl-1,1′-bicyclohexyl)	62—85
CCH 7 (4-cyano-4′-heptyl-1,1′-bicyclohexyl)	71—83



R=alkyl group

Measurement of Refractive Indices. The method of measurement of the refractive indices n_e, n_o for the extraordinary and ordinary rays with the help of ABBE refractometer and density measurements by means of capillary tube were de-

scribed elaborately in an earlier publication.[7]

Measurement of Dielectric Permittivities. The dielectric permittivities $\varepsilon_{\parallel}$ and $\varepsilon_{\perp}$ polarized parallel and perpendicular to the long molecular axes of the liquid crystals were measured at 1 kHz with a GR-1620 capacitance bridge using a capacitor of stainless steel electrodes of radius 1 cm separated by a 1 mm thick Teflon spacer. A magnetic field of 1.0 T was used to allign the molecules of the liquid crystals parallel and perpendicular to the electrode surfaces. The temperature of the sample was measured with a thermocouple mounted directly on one of the electrodes. The temperature of the cell was maintained constant within ±0.02 °C by means of a thermostat. The cell was calibrated with freshly distilled toluene and chlorobenzene and the values agree to 0.1% of the standard value.

Results

The experimental values of refractive indices n_e, n_o and the densities of the liquid crystals at different temperatures are given in Table 1. The effective polarizabilities α_e and α_o in the nematic phase calculated by using two methods Vuks[8] and Neugebauer[9] are included in Table 1. The principal polarizabilities $\alpha_{\parallel}$ and $\alpha_{\perp}$ parallel and perpendicular to the long axis of the molecules in the crystalline state were obtained from Hallers' et al.[10] graphical method. The orientational order parameters S were calculated from the relation $S=(\alpha_e-\alpha_o)/(\alpha_{\parallel}-\alpha_{\perp})$ and are included in Table 1.

Discussion

The values of the dielectric anisotropy, $\Delta\varepsilon$, Table 3b, Fig. 4b for CB,[11] PCH,[4] and CCH compounds in the present paper shows that $\Delta\varepsilon$ gradually decreases from CB to PCH to CCH by the progressive replacement of one phenyl ring in PCH and both the phenyl rings in the CCH compounds by cyclohexyl groups. This may be attributed to the decrease in the degree of conjuga-

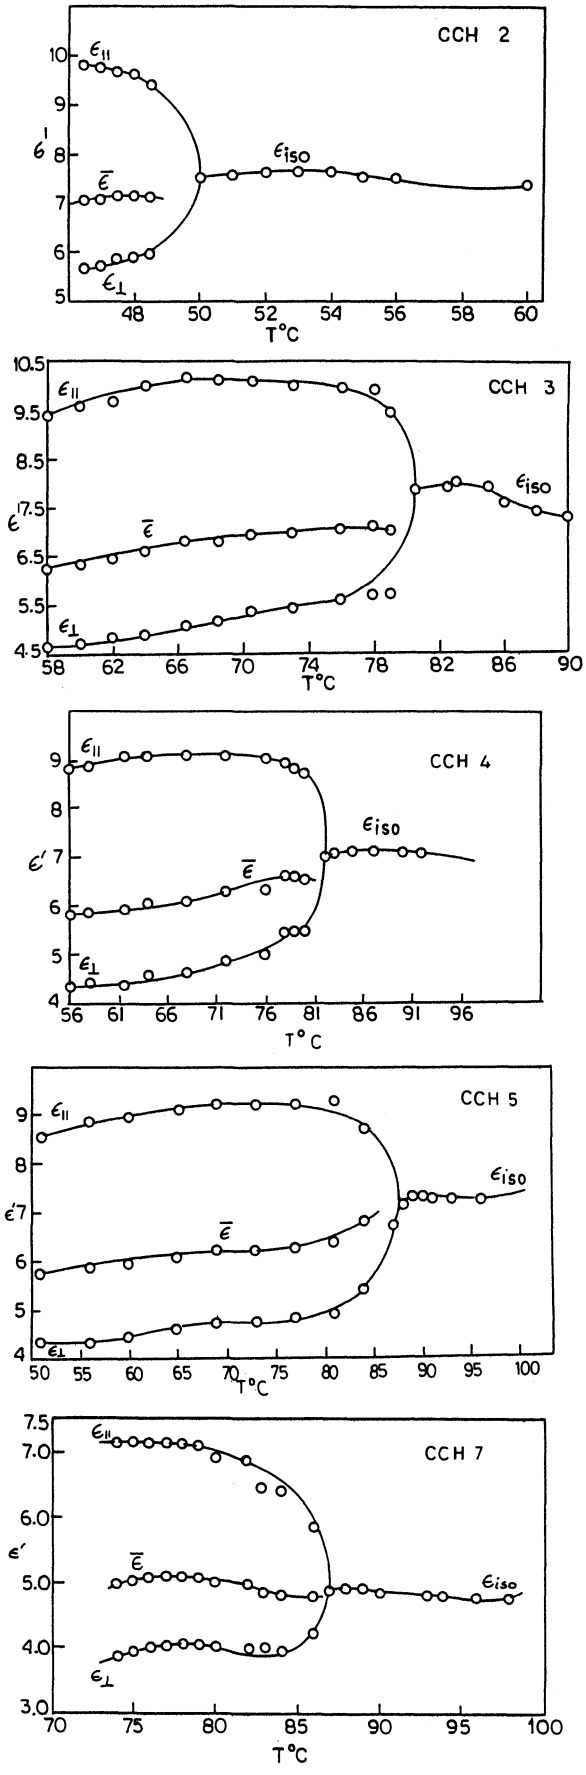

Fig. 2. Dielectric anisotropy plots for CCH 2, CCH 3, CCH 4, CCH 5, CCH 7 respectively.

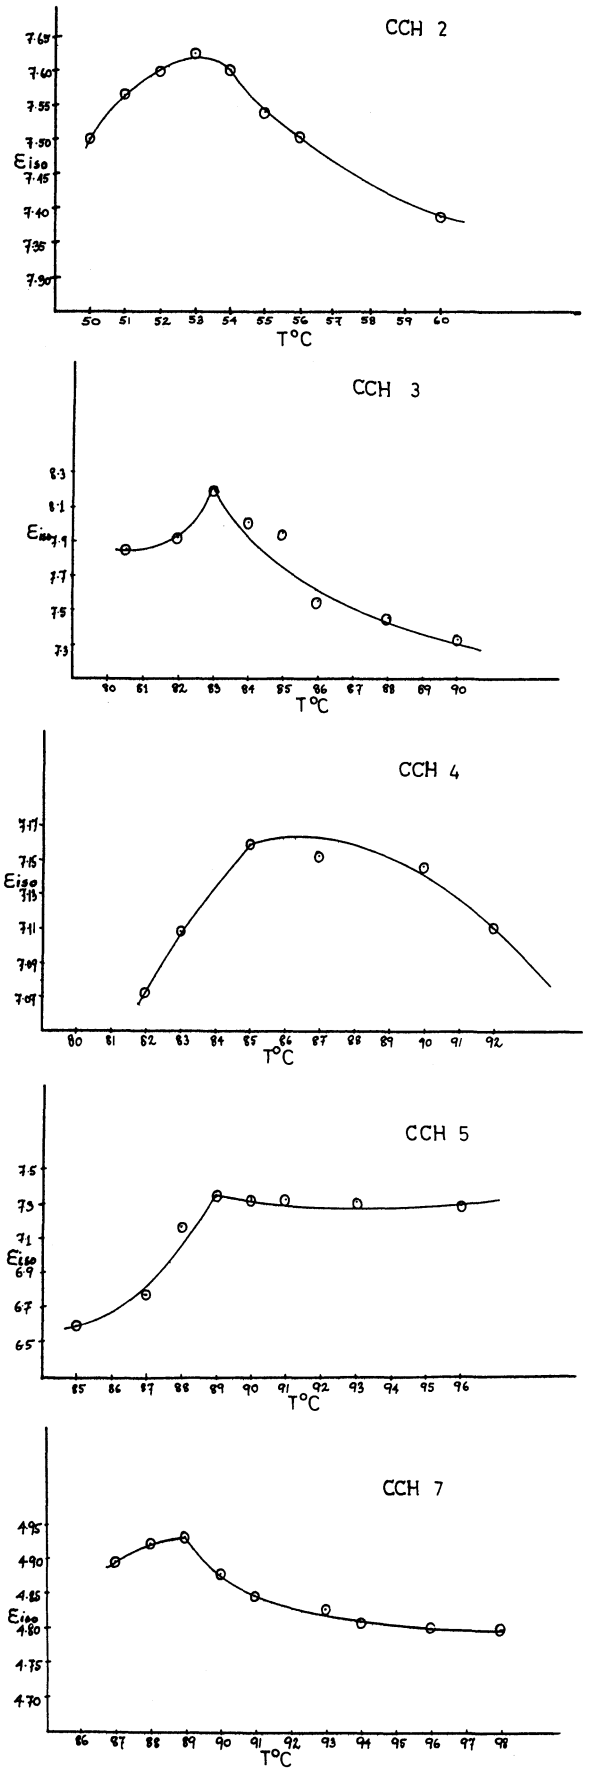

Fig. 3. Pretransition effect plots for CCH 2, CCH 3, CCH 4, CCH 5, CCH 7 respectively.

tion by progressive replacement of phenyl rings. This decrease of conjugation is more pronounced in the CCH compounds which are completely lacking in free π electrons.

The values of $\Delta\varepsilon$ within the CCH compounds, Table 3a, Fig. 4a, decreases with the increase of chain length which is also found in the case of PCH compounds by Schad et al.[11]

Schad[11] found that the experimental data for the PCH compounds hold the relation $\Delta\varepsilon(t_r) \alpha S(t_r)$, considering only the contribution of the predominant dipolar part of the dielectric polarization to $\Delta\varepsilon$, though one would expect that $S(t_r)/T$ should depend on $\Delta\varepsilon$. A possible explanation of the result was given[1] by a model of antiparallel dipole correlation.

In the case of the CCH compounds (Fig. 5a) the decrease of order parameter at any reduced temperature, with the increase of alkyl chain length may also be explained from the above relation.

From Table 1a—e, it can be seen that the order parameter S for each of the CCH liquid crystals evaluated from refractive indices and density data using Vuks' and Neugebauer's methods are in good agreement. Figure 5a, a comparison of the order parameter of the CCH liquid crystals at any common reduced temperature, $t_r=T/T_{NI}$, shows that the order parameter of CCH 2 is the largest and that for CCH 7 is the smallest and those for others are in between them. It appears that the larger the alkyl chain length the smaller is the order parameter.

The values of the order parameters at any reduced temperature t_r in CB, is the largest and in PCH is the smallest, Fig. 5b. But in the case of CCH compounds it is nearer to that of the CB compounds but greater than that for PCH. This cannot be explained from the above relation.[11]

The antiparallel local ordering in CCH compounds found by X-ray measurement[12] corresponds to the overlap of cyano group, which is quite different from

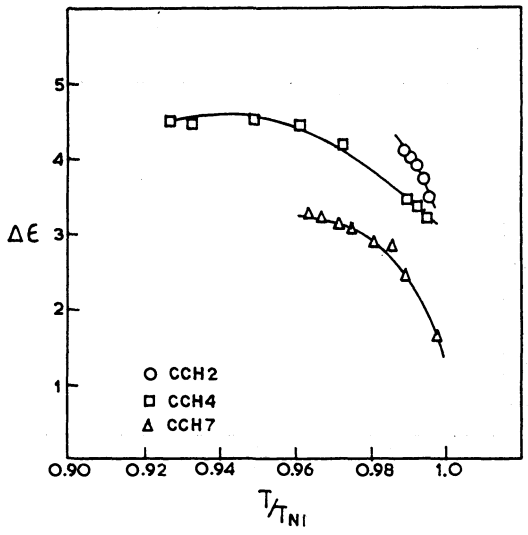

Fig. 4(a). Plots of $\Delta\varepsilon$ vs. T/T_{NI} for CCH 2, CCH 4. CCH 7.

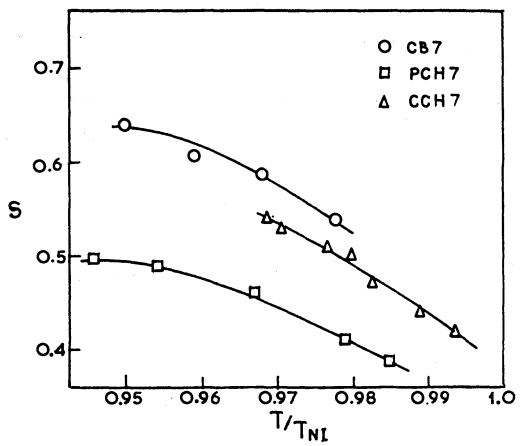

Fig. 5(b). Plots of S vs. T/T_{NI} for CB 7, PCH 7, CCH 7.

the core overlap in the case of CB and PCH compounds. This type of different local ordering in CCH compounds must affect the value of the order parameter and this may be the cause of the unexpected value of the order parameter in the CCH compound.

This type of unexpected observation of the ratio of Bend/splay (k_{33}/k_{11}) value of the elastic constant of the CCH compounds was found by Bradshaw et al.[5]

It is to be noted that for all the CCH liquid crystals, the dielectric permittivity $\varepsilon_{\parallel}$ is obtained for $\vec{E} \perp \vec{H}$ and $\varepsilon_{\perp}$ is obtained when $\vec{E} \parallel \vec{H}$ unlike the cyanobiphenyls, cyclohexylbenzenes, and other thermotropic liquid crystals, all of which have positive diamagnetic anisotropy. 1,1′-Bicyclohexyls have got negative diamagnetic anisotropy as was shown by Schad[11] in CCH 7 ($\Delta\chi=-2\times10^{-8}$ cm^3 g^{-1}). The negative diamagnetic anisotropy in CCH 5 was also confirmed by Pohl et al.[12] from the studies of the dependence of electric threshold voltage and switching time of a twisted layer of CCH 5, with the strength of the magnetic fleld.

Because of the negative anisotropy of the susceptibility, the CCH molecules orient themselves with the long molecular axis perpendicular to the magnetic field and this is why dielectric permittivity $\varepsilon_{\parallel}$ is obtained when $\vec{E} \perp \vec{H}$.

The anisotropy of the dielectric permittivity of the CCH's are shown in Fig. 2a—e. The average value of the dielectric permittivities $\bar{\varepsilon}$; shown in Table 2a—e in each case is found to increase with increase in temperature and is discontinuous with the isotropic value ε_{iso} at T_{NI}, Fig. 2a—e. This indicates the presence of strong antiparallel local ordering of the CCH molecules in the nematic phase in strongly polar molecules as reported earlier.[13]

Temperature dependence of dielectric permittivity ε_{iso} for the CCH liquid crystals in the isotropic phase is shown in Fig. 3a—e. It can be clearly seen that there is a peak in ε_{iso}, a little above the transition temperature T_{NI}. Such pretransition effects in dielectric permittivity in nematics with cyano end groups were reported by Bradshaw and Raynes,[5] Theon and Menu,[6] and recently by Krishnakoli et al.[14] The reduced contribution to dielectric permittivity ε_{iso} from dipole moment μ was attributed to apparent reduction in μ-values due to formation of dimers in antiparallel local ordering.[15] The pretransition in ε_{iso} near T_{NI} showing a maximum was explained as due to appreciable concentration of dimers in a dynamic dimer-monomer equilibrium.

Spectrophotometric Determination of Bismuth(III) and Indium(III) with 2,4,6-Tris(2-hydroxy-4-sulfo-1-naphthylazo)-1,3,5-triazine Trisodium Salt (THT)

Ishwar SINGH* and Pratap Singh KADYAN
Department of Chemistry, M. D. University, Rohtak-124001, India
(Received July 30, 1987)

Reaction behavior of bismuth(III) and indium(III) with 2,4,6-tris(2-hydroxy-4-sulfo-1-naphthylazo)-1,3,5-triazine trisodium salt (THT) is established under various conditions. Bismuth(III) forms a 2:3 dark red complex (absorption maximum at 530 nm) with the reagent at pH 4—6.5. Indium(III) reacts with THT to form a 1:2 dark red complex at pH 3—4.7 (λ_{max} 530 nm) and a 1:3 purple blue complex at pH ca. 10.5 (λ_{max} 620 nm). The molar absorptivities for the color reactions are 5.5×10^4 for bismuth(III), 8.4×10^4 for indium(III) at pH 3.5 and 7.9×10^4 L·mol^{-1}·cm^{-1} for indium(III) at pH ca. 10.5 (in sodium carbonate medium). Other physicochemical characteristics of the complexes are established. A number of foreign ions are tested for their interference and the use of masking agents wherever necessary is tabulated.

Recently, we proposed a water-soluble azo dye 2,4,6-tris(2-hydroxy-4-sulfo-1-naphthylazo)-1,3,5-triazine trisodium salt (THT) as chromogenic reagent for antimony and sulfide[1] and thorium and phosphate.[2] This reagent forms dark red color with bismuth(III) in weakly acidic medium and dark red and purple blue with indium(III) in weakly acidic and alkaline media, respectively. We propose spectrophotometric determination for these two elements in this communication.

Less attention has been given for microdetermination of bismuth and indium. Conventional iodide and thiourea methods[3,4] for bismuth are simple but lack sensitivity. Dithiocarbamate[5] is specific but is rather insensitive. Dithizone[3,4,6,7] has high sensitivity but the method is tedious and suffers lot of interferences. For indium, most of the methods are unselective and require separation of metals. Oxine[8,9] and bromo-substituted oxine[10-12] have been used as extractive reagents. However, PAR[13] is a better sensitive reagent for indium(III) at pH 6, but not selective. At pH 3, the selectivity increases, but sensitivity decreases.[14,15] The present reagent has been found to be highly sensitive, as well as selective for the determination of the two elements.

Experimental

Apparatus: A Bausch and Lomb Spectronic 2000 spectrophotometer with 10 mm matched glass cells was used for recording spectra and a Beckman Φ 60 pH meter was used for pH measurements.

Reagents: THT Solution: THT was synthesized as described earlier[1] and its 1×10^{-3} M solution (1M=1 mol dm^{-3}) was prepared by dissolving 0.900 g of THT in 1L of double-distilled water.

Bismuth(III) and Indium(III) Solution (1000 μg mL^{-1}): Standard solutions of bismuth(III) and indium(III) were prepared by dissolving an appropriate amount of bismuth nitrate pentahydrate $Bi(NO_3)_3\cdot5H_2O$ and indium sulfate monohydrate $In_2(SO_4)_3\cdot H_2O$ in double-distilled water and standardized by conventional methods.[16]

Acetate Buffer Solutions: Acetate buffer solution of pH 3.5 was prepared by diluting 940 mL 0.2 M acetic acid to 1L with 0.2 M sodium acetate and for pH 5.5, diluting 120 mL 0.2 M acetic acid to 1L with 0.2 M sodium acetate.

Sodium Carbonate Solution (0.02 M): Anhydrous sodium carbonate (2.12 g) was dissolved in 1L doubly distilled water for this concentration.

All the reagents used were of analytical grade during the experimental studies.

Procedures and Calibration Curves. Determination of Bismuth(III): To a suitable volume of sample containing 14—75 μg of bismuth(III) and 2 mL 1×10^{-3}M THT followed by 2 mL buffer solution of pH 5.5. Dilute to 25 mL with water and measure the absorbance at 530 nm against a corresponding reagent blank (2 mL 1×10^{-3}M THT+2 mL buffer diluted to 25 mL).

Determination of Indium(III): To a suitable volume of sample containing 6—35 μg of indium(III) add 2 mL 1×10^{-3}M THT followed by 2 mL of buffer solution of pH 3.5 or to an aliquot containing 6—27.5 μg of indium(III) and 2 mL 1×10^{-3}M THT followed by 2 mL 0.02 M carbonate solution. Make up the volume to 25 mL with water and measure the absorbance at 530 nm in the former case or at 620 nm for the latter against a corresponding reagent blank.

Deduce the amount of the metal ion from the standard calibration curve drawn under similar conditions.

Results and Discussion

Color Formation and Absorption Spectra. Bismuth(III) formed a dark red complex (absorption maximum at 530 nm) with an aqueous solution of THT at pH 4—6.5, while indium(III) formed two water soluble complexes, a dark red at pH 3—4.7 which absorbed maximally at 530 nm and a purple blue with a λ_{max} 620 nm. Color formation was instant and stable for several hours in each case. Acetate buffers were found siutable for maintaining weakly acidic pH's and thus 2 mL buffer of pH 5.5 for bismuth(III) and 2 mL buffer of pH 3.5 for indium(III) determinations were used. For determination of indium(III) at high pH, 2—8 mL 0.02 M sodium carbonate was found suitable and thus 2 mL of it was used in subsequent studies.

The effect of THT concentration was investigated in each case at their respective λ_{max}'s containing a constant amount of bismuth(III) or indium(III) and varying amounts of the reagent. It was found that 2 times molar excess of THT was required for bismuth(III), while 3—4 times molar excess of THT was necessary for complete complexation for indium(III) at both pH levels. All further experiments were carried out with at least 5-fold molar excess of the reagent solution.

Other Characteristics of the Complexes. The complexes obeyed Beer's law over the range 0—3.8 ppm of bismuth(III) and 0—1.8 ppm at pH 3.5 and 0—1.3 ppm at pH ca. 10.5 of indium(III). The optimum concentration ranges as evaluated by Ringbom's plot are 0.56—3.0 ppm of bismuth(III) and 0.24—1.4 or 0.24—1.1 ppm of indium(III), at low and high pH, respectively. These are the optimum ranges in which the metal ions could be accurately determined. The respective Sandell's sensitivities of the bismuth(III) complex and indium(III) complexes at low and high pH are 0.0038, 0.0013, and 0.0014 $\mu g\,cm^{-2}$ with their respective molar absorptivities (ε), 5.5×10^4, 8.4×10^4, and 7.9×10^4 $L \cdot mol^{-1} \cdot cm^{-1}$. Table 1 gives a comparison of the sensitivities of some methods used for the determination of bismuth(III) and indium(III).

The stoichiometric ratios of metal to ligand in the complexes under the conditions mentioned above, were determined by Job's method of continuous variations. In case of indium(III) complexes, it was confirmed that the metal to ligand ratio was 1:2 for the dark red and 1:3 for the purple blue complexes. However, bismuth(III) unusually formed 2:3 com-

Effect of Diverse Ions on the Determination of Bismuth(III) and Indium(III). In the determination of bismuth(III) at the 1.7 $\mu g\,mL^{-1}$ level, nitrite, nitrate, sulfite, sulfate, thiosulfate, phosphate, citrate, tartrate, oxalate, thiourea, thiosemicarbazide up to 1000-fold excess, alkaline earths, lanthanoids, aluminium(III), chromium(III), and platinum metals up to 50-fold excess did not interfere. However, sulfide, EDTA, zinc(II), manganese(II), uranyl(VI), and indium(III) were found to interfere.

In the determination of indium(III) at the 0.86 $\mu g\,mL^{-1}$ level, fluoride, chloride, bromide, iodide, nitrite, nitrate, sulfite, thiosulfate, borate, phosphate, thiourea, thiosemicarbazide, cyanide, thiocyanate up to 1000-fold excess and alkaline earths, lanthanoids, aluminium(III), chromium(III), platinum metals up to 50-fold excess did not interfere. However, sulfide, EDTA, manganese(II), uranyl(VI), and bismuth(III) interfered at pH 3.5, while only sulfide and EDTA were found to interfere at high pH (ca. 10.5).

Tables 2 and 3 represent the tolerance limits in ppm of various ions in solution that caused a deviation smaller than ±2% in absorbance for the determination of bismuth(III) and indium(III) respectively.

One of the authors (PSK) is thankful to the Council of Scientific and Industrial Research, New Delhi, India for financial assistance.

Antimony(V) Arsenatophosphate as a Thermally Stable Cation Exchanger: Selective Adsorption of Alkaline Earth and Transition Metal Ions on Its Column

K. G. VARSHNEY,* A. A. KHAN, and A. R. KHAN
Chemistry Section, Faculty of Engineering & Technology, Aligarh Muslim University, Aligarh-202001, India
(Received October 12, 1987)

A new inorganic ion exchanger based on antimony has been prepared viz. antimony(V) arsenatophosphate, which has shown a peculiarly high thermal stability and selectivity for alkaline earth and transition metal ions. As a result, its column use has been demonstrated for the separation of mercury from magnesium and zinc and of iron from other transition metals. A tentative formula has also been proposed for the material, on the basis of its chemical analysis and other characterization studies.

Antimony(V) salts have received attention because of their exceedingly good reproducible characteristics[1-4] and analytical potential[5,6] as inorganic ion exchangers. Antimony(V) silicate, synthesized in these laboratories,[7] has shown excellent stability and ion-exchange behavior. Since the mixed salts are found to show enhanced ion exchange properties over the single salts[8-10] it is important to study the properties of double salts based on antimony. In continuation of our such an effort the present paper deals with the synthesis, characterization and column applications of a thermally stable phase of the new inorganic ion exchanger viz. antimony(V) arsenatophosphate, exceptionally selective for some alkaline earths and transition metals.

Experimental

Reagents. Antimony pentachloride used in this study was of the 95% purity obtained from Fluka Switzerland. Trisodium orthophosphate and disodium hydrogenarsenate were of AnalaR grade (98.5—99%) obtained from B. D. H. Poole (England) and E. Merck (Darmstadt) respectively. All other reagents and chemicals were also of AnalaR grade.

Instruments Used. The following instruments were used for the various studies: A Philips X-ray diffraction unit with Cu$K\alpha$ target, an Elico (India) pH-meter Model LI-10, a Bausch and Lomb Spectronic-20 spectrophotometer, a Beckman IR-20 spectrophotometer, a Pye Unicam Model Sp-2900 atomic absorption spectrophotometer, a Systronics (India) flame photometer and a water bath incubator shaker with a temperature variation of ±0.5 °C.

Preparation of the Reagent Solutions. A stock solution (1M†) of antimony pentachloride ($SbCl_5$) was prepared in 4 M HCl. Further dilutions to the desired concentration were also made by 4 M HCl. Disodium hydrogenarsenate and trisodium phosphate were dissolved directly in demineralized water (DMW).

Synthesis of the Ion Exchange Material. Various samples of antimony(V) arsenatophosphate were prepared by mixing 0.05 M solutions of $SbCl_5$, disodium hydrogenarsenate and trisodium orthophosphate in different volume ratios and adjusting the pH of the mother liquor at 0 to 1 by adding aqueous ammonia with constant stirring. The gels thus obtained were conditioned for 24 h at room temperature before being separated with suction. The excess acid was washed off with DMW and the material was dried in an air oven at 40 °C before cracking in DMW to obtain granules of uniform size suitable for column operation. They were converted into the H^+-form by putting in 1M HNO_3 at least for 24 h with intermittently replacing the supernatant liquid. After washing off the excess acid the material was dried at 40 °C and passed through different sieves to obtain the various mesh sized particles. On the basis of the appearance and Na^+-ion exchange capacity (i.e.c.) determined by the column process, a sample obtained by mixing the Sb, arsenate and phosphate solutions in the volume ratio 3 : 1 : 1 was selected for all the studies. Its i.e.c. was found to be 2.2 meq (g dry)$^{-1}$.

Chemical Stability. The solubility of antimony(V) arsenatophosphate in various solvents was determined as given below:

250 mg portions of the material were kept with 25 ml of the solvent for 24 h at room temperature with intermittent shaking. 5 ml of the supernatant liquid was evaporated to dryness and the residue was dissolved in 10 ml DMW. Antimony, arsenic and phosphorus were then determined separately using the standard methods given below.

(1) Determination of Antimony. To the 2 ml portion of the above solution were added 1.6 ml of 18 M H_2SO_4 and 5 ml of KI reagent (11.2 g of KI+2 g of ascorbic acid in 100 ml water). The colored solution thus obtained was diluted to 10 ml with water in a standard volumetric flask and the absorbance was measured after 2—3 minutes at 420 nm against a reagent blank.[11]

(2) Determination of Arsenic. It was done by the molybdenum blue method.[12] The reagent solution was prepared by mixing 10 ml of solution A (1 g ammonium molybdate in 100 ml of 2.5M H_2SO_4) with 1 ml of solution B (0.15 g of hydrazine sulfate in 100 ml DMW) and diluting the mixture to 100 ml. Fresh reagent solution was prepared every time. 10 ml of this reagent solution was added to the sample solution (2 ml) and the mixture was heated on a steam bath for 15 min. After cooling to the room temperature, it was transferred to a 25 ml volumetric flask and diluted to the mark with DMW. The absorbance was taken at 840 nm.

Determination of Phosphorus. A teaspoonful carbon black was added to the sample solution (10 ml) followed by 100 ml of 0.5 M $NaHCO_3$. The contents of the flask were shaken for 30 min on a mechanical shaker and filtered through a Whatman No.42 filter paper. 15 ml of the filtrate

† 1M=1 mol dm^{-3}.

Table 1. Chemical Stability of Antimony(V) Arsenatophosphate in Various Solvents

Solvent (25ml)	Amount dissolved in mg

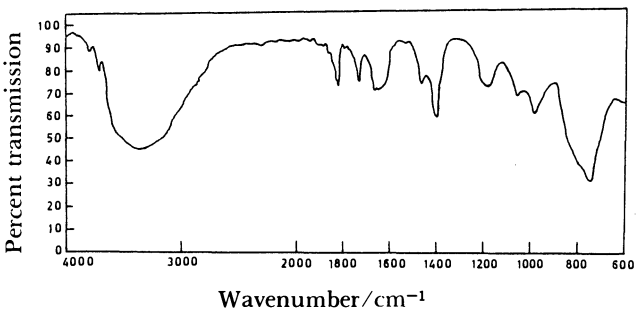

Fig. 3. Infrared spectra of antimony(V) arsenatophosphate in H^+ form.

was taken in a 25 ml volumetric flask followed by 5 ml of ammonium molybdate solution (1.5 g ammonium molybdate+100 ml of 3.2 M HCl+5 ml concd HCl). The sides of the flask were washed with distilled water and the solution was shaken thoroughly. 1 ml of $SnCl_2$ solution (10 g $SnCl_2 \cdot 2H_2O$ dissolved in 25 ml concd HCl diluted to 1320 ml with DMW) was then added to it and the volume was made up to the mark. The absorbance was taken at 660 nm, against a blank prepared in the similar manner.[13] Table 1 summarized the results.

Thermal Stability. Several 1 g portions of the exchanger were heated at various temperatures in a muffle furnace for 1 h each, and the i.e.c. was determined by the column process as usual after cooling them to room temperature. Percent weight loss was also recorded, the results of which are shown in Table 2 and Fig. 1.

Characterization of the Material. (A) Chemical Composition: 500 mg of the exchanger was dissolved in 20 ml concd HCl in a beaker by heating. The solution was further diluted to 50 ml by adding 4 M HCl. The amounts of antimony, arsenic and phosphorus were determined by the methods described above. The determinations were further confirmed by atomic absorption spectrophotometry. The mole ratio was found to be 6 : 1 : 5 for Sb, As, and P.

(B) pH Titrations: 500 mg of the exchanger in H^+-form was placed in each of the several 250 ml conical flasks, followed by the equimolar solutions of alkali metal chlorides and their hydroxides in different volume ratios, the final volume being 50 ml to maintain the ionic strength constant. The pH of the solution was recorded after equilibrium

(attained on keeping them for overnight) and plotted against the milliequivalents of the OH^- ions added as shown in Fig. 2.

(C) IR and X-Ray Studies: The IR spectrum of the exchanger in H^+-form was taken by the KBr disc method and is shown in Fig. 3. The X-ray diffraction patterns show the amorphous nature of the material.

Distribution Studies. 250 mg of the exchanger in H^+-form was shaken in an electric shaker at 30±2 °C for 4 h with 25 ml of the metal solution, adjusting the initial metal ion concentration less than 3% of the total ion-exchange capacity of the material. The metal ion concentrations in the solution before and after the equilibrium were determined by the standard volumetric methods using EDTA as the titrant.[14] The distribution coefficient (K_d) for alkaline earth and transition metal ions in DMW, $HClO_4$, and HNO_3 systems are summarized in Table 3.

The following formula was used for the calculation of the K_d values:

$$K_d = \frac{I-F}{F} \times \frac{V}{M} \text{ ml g}^{-1}$$

where

I = initial volume of the EDTA used,
F = final volume of the EDTA used,
V = total volume of the solution (ml),
M = mass of the exchanger (g).

Elution Behavior. 250 ml of the various $NaNO_3$ solutions (0.2, 0.4, 0.5, 0.8, 1.0, 1.2 M) were passed through the several columns (i.d. ca. 1 cm), each containing one gram of the exchanger in H^+-form with a flow rate ca. 0.5 ml min^{-1}. The H^+-ion thus eluted out was titrated against a standard (0.1M) NaOH solution. Maximum elution was observed with a 1M NaOH solution. Then, a similar column in H^+-form was eluted with a 1M $NaNO_3$ solution and the effluent collected in several 10 ml fractions, the total volume being again 250 ml. It was observed that the majority of the H^+-ion was released in the first 60 ml of the effluent.

Column Applications. Since the material appears to be highly selective for some transition metals such as Cu, Cd, Mn, and Zn, adsorption of these metal ions can be achieved on columns from a solution containing several other metal ions. Iron and mercury are not adsorbed appreciably and are excluded from the column of antimony(V) arsenatophosphate. Thus, the material can be used for exclusion of mercury, a chief pollutant, from an aqueous system by a simple column chromatographic method. Similarly, the method is applicable for some separations of analytical importance such as Fe(III) from Mn(II), Zn(II), Cu(II), Mg(II), Co(II), and Ba(II). Table 4 summarized the results of such separations on a column of i.d. ca. 0.6 cm containing 2 g of the 50—70 mesh size exchanger beads in H^+-form.

Results and Discussion

The main feature of this study has been to synthesize a chemically and thermally stable cation exchanger selective for certain heavy metals. As the results point out antimony(V) arsenatophosphate appears to have a high chemical stability in acids and alkalies (Table 1) and ion-exchange behavior. The most striking feature is, however, its extraordinary thermal stability (Table 2). It shows its original i.e.c. (2.20 meq (g dry)$^{-1}$) up to 200 °C and then loses slowly retaining 60% on heating upto 400 °C and 18% up to 600 °C. It is a peculiar behavior of this exchanger when compared with other materials of this class (Fig. 4).

Chemical analysis of the material points to the following emperical formula:

$$(Sb_2O_5)_3 \cdot H_3AsO_4 \cdot (H_3PO_4)_5 \cdot nH_2O$$

If it is assumed that whole of the external water is lost at 200 °C, then on the basis of the thermal studies (Table 2) we have the following expression for the number of external water molecules per molecule of the material, n

$$\frac{1800n}{M + 18n} = x$$

where x is the percent weight loss at 200 °C and M is the molecular weight of the exchanger excluding the

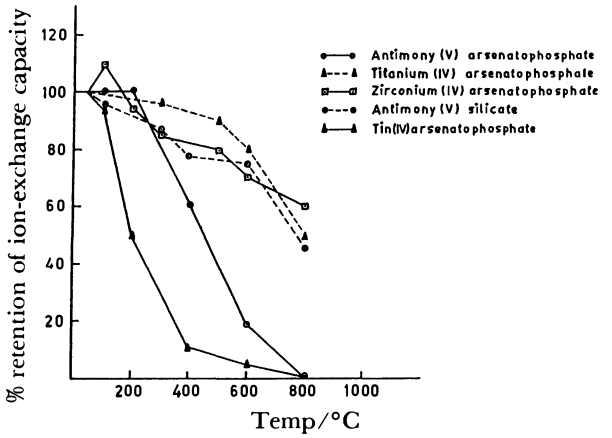

Fig. 4. Percent retention in the i.e.c. of antimony(V) arsenatophosphate and some other ion-exchangers on heating.

external water molecules. It gives the value of n as 16.

The pH-titration curves for alkali metals (Fig. 2) illustrate the maximum adsorption for Li^+ ions, which is obvious because of its highest hydrated radii ($Li^+_{(aq)}$=3.4 Å, $Na^+_{(aq)}$=2.76 Å, $K^+_{(aq)}$=2.32 Å). However, there is no appreciable difference in the adsorption behavior for Na^+ and K^+. It is also clear from the figure that the adsorption is a single step process. It is possible because the two acids, H_3AsO_4 and H_3PO_4 which provide the protogenic sites to the material, ionize almost to the same extent (pK_a for H_3PO_4=2.15 and pK_a for H_3AsO_4=2.3) thus releasing the H^+ ions simultaneously.

Infrared spectrum (Fig. 3) shows the peaks at wavenumbers 750, 950, 1100, 1200, 1400, 1700, 1750, 1800, and 3300 cm^{-1} representing the Sb-O stretchings (750), arsenate group (950), phosphate group (1100 and 1200) and the external water molecules (rest peaks) respectively.[15]

The most important aspect of an ion-exchange material is its analytical applications. Antimony(V) arsenatophosphate prepared in these studies has shown a maximum selectivity for Cu(II), Cd(II), Mg(II), Mn(II), and Zn(II) and a minimum selectivity for Hg(II), Ni(II), Fe(III). On the basis of these observations the following separations have been successfully achieved.

Hg(II)-Mg(II), Hg(II)-Zn(II), Fe(III)-Mg(II), Fe(III)-Ba(II), Fe(III)-Cu(II), Fe(III)-Zn(II), Fe(III)-Mn(II), Fe(III)-Ca(II).

Table 4 gives the salient features of these separations. Thus the material is useful for the separation of mercury from magnesium and zinc and of iron from magnesium, barium, copper, zinc manganese, and calcium.

The authors thank Prof. A. U. Malik for research facilities. The University Grants Commission and the Council of Scientific and Industrial Research (India) are thanked for the financial assistance to A.A.K. and A.R.K.

Organophosphorus Analogues and Derivatives of the Natural L-Amino Carboxylic Acids and Peptides. I. Enzymatic Synthesis of D-, DL-, and L-Phosphinothricin and Their Cyclic Analogues

Ivan A. NATCHEV
Research Centre "Konstrukcionni Polymeri", 5-003 Gara Iskar, 1528 Sofia, Bulgaria
(Received April 28, 1987)

Acetylation of D-, DL-, and L-3-amino-2-pyrrolidinone (**1**) to the 3-acetamido derivative **2** and treatment with ethyl methylphosphinate afforded the addition product **3**. Strict selectivity was observed in the enzyme-catalyzed hydrolysis with the enzyme phosphodiesterase I, acylase, glutaminase, and α-chymotrypsin. The ester **7** and 1,2-azaphospholidine (**8**) were isolated by esterification of L-phosphinothricin (**6**).

The tripeptide γ-(hydroxymethylphosphinyl)-L-α-aminobutyryl-L-alanyl-L-alanine,[1] usually called Bialaphos (SF-1293), belongs to the small group of known natural phosphino analogues of the amino carboxylic acids. The antibiotic is produced from *Streptomices viridochromogenes strains* and has been found to possess herbicidal and fungicidal activity.[2,3] Upon enzyme decomposition with *E. coli* protease with a view to its structure elucidation, the unusual amino carboxylic acid 4-(hydroxymethylphosphinyl)-L-2-aminobutanoic acid (**6**), known as L-phosphinothricin, has been isolated.[4] It is produced[5] from *Streptomices hydroscopicus strains.*

The tripeptide Bialaphos has been synthesized[6] as a phosphonoethyl ester by the participation of the DL-forms of phosphinothricin and alanine, following a multistep procedure. In this case the yields were rather low. L-Phosphinothricin (**6**) has been synthesized[7] by Michael addition of chiral glycine Schiff base to a vinylphosphorus compound, $CH_2{=}CH{-}P(CH_3)(=O)OH$ The racemic phosphinothricin, widely used as herbicide and fungicide,[8] is produced synthetically. The introduction of the ethoxymethylphosphinyl, $EtO{-}P(CH_3){=}O$ group is achieved by the Arbuzov reaction. Thus, Wasielewski and Antczak[9] treated 4-bromobutanoic acid with diethyl methylphosphonite $CH_3P(OEt)_2$ and obtained the product after α-amination. Recently, Logusch[10] suggested that methyl DL-4-bromo-2-phtalimidobutanoate, could be used in a similar interaction, so that phosphinothricin is finally obtained by hydrolysis.

It is interesting to note that the biological activity of the natural L-phosphinothricin is twice as strong as that of the racemic mixture.[8]

The key approach in the pathway we chose to the synthesis of phosphinothricin (**6**) is a variant of the reaction of Michaelis-Becker,[11] usually applied to the alkylation hydrophosphoryl compounds, $>P(=O)H$ Despite the abundant data that have been published about this reaction, many of its aspects are still inadequately studied. Surprisingly, no one has as yet taken up McConnel and Coover[12] on their suggestion that lactams could be used in interactions of this type.

In view of the synthetic purposes in hand, the γ-lactam **1** of the D-, DL-, and L-2,4-diaminobutanoic acid was chosen as the starting material. It is very easily obtained[13] by dehydration.

In his work,[13] Adamson reports the acetylation of **1** with acetic anhydride, but his yields were very low and therefore unsatisfactory. It was found that, in the subsequent stages, any protective group, other that an acetyl group, caused considerable complications. The best acetylating agent proved to be acetic phosphoric anhydride, $AcOPO_3H_2$,[14] obtained immediately before use. The reaction proceeds at 60—70 °C for 15—20 min in the reagent medium the acetylated product **2** is isolated in a very high yield (95—98%).

The interaction of the lactam **2** with ethyl methylphosphinate takes 2.0—2.5 h of heating of the components at 120—130 °C in a closed steel cylinder and in an ambience of dry argon or nitrogen. Here, the presence of a catalyst is essential. Boron trifluoride etherate proved to be the most suitable catalyst in this case. Without it, the result is a resinous mass, from which the organophosphorus product is isolated in a very low yield (6—10%). To enhance the reaction, it is important that the temperature should be increased gradually, starting from ambient and going up to 120 °C for the duration of 1.0—1.5 h. When the process is completed, the volatile components are distilled off (100 °C/6×10^{-2} Torr (1 Torr=133.322 Pa)). The reaction product is then purified by column chromatography (silica gel and eluent chloroform : methanol=9 : 1). The product 2-acetamido-4-(ethoxymethylphosphinyl)butanamide (**3**) is obtained in a yield of 50—55%.

When the optically active D- and L-lactams **2** were used under the above conditions, no racemization was observed.

In our laboratory, we carried out analogous interactions, not only with the lactam of 2,4-diaminobutanoic acid, but also with the lactams of L-ornithine and L-lysine, where a cobalt-complex of 5-amino-1,10-

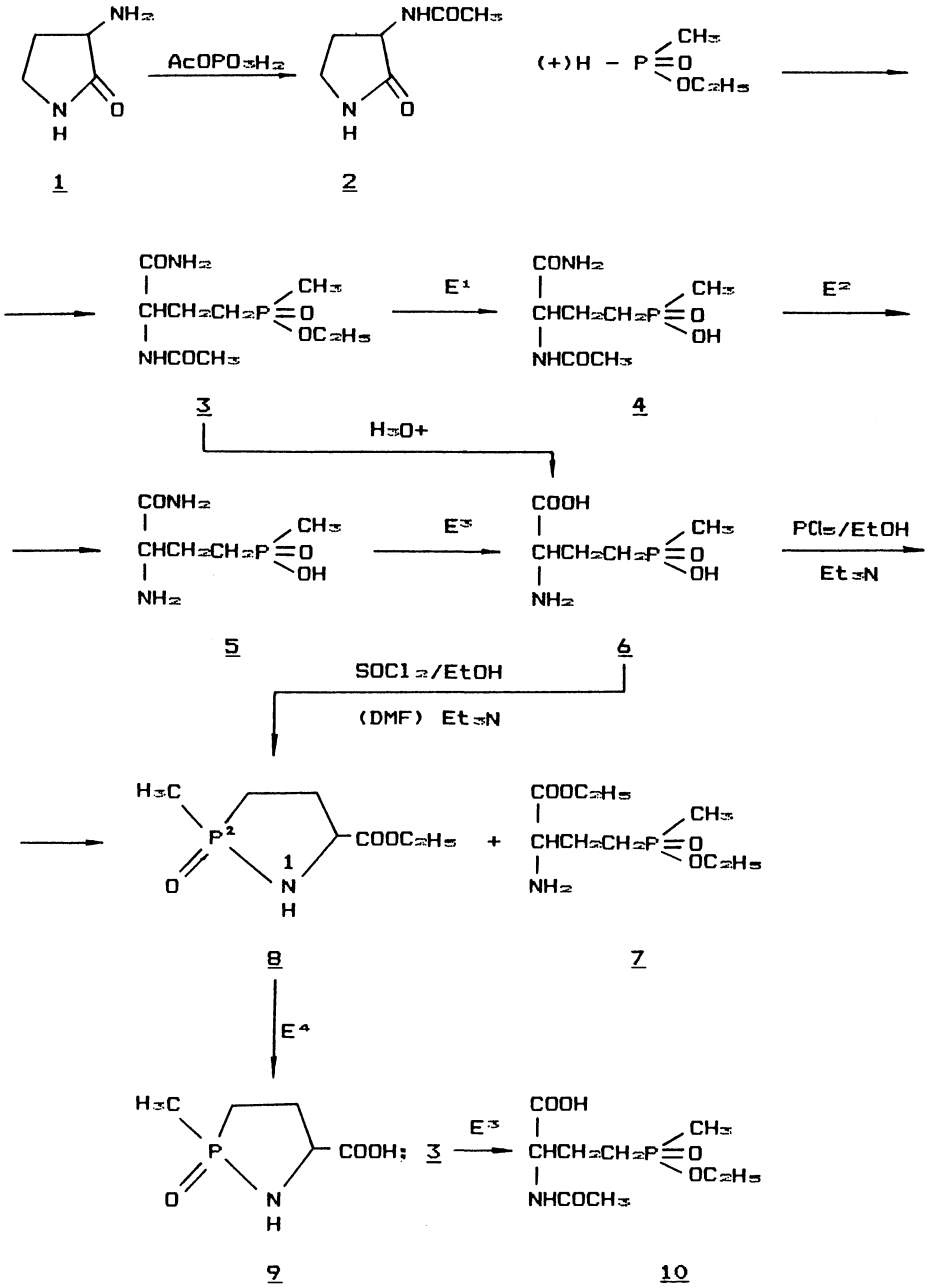
phenanthroline was used as catalyst. The results will be published separately.

The mineral hydrolysis of **3** is extremely difficult, due to the presence of an ethoxyphosphoryl group. Complete hydrolysis would require at least 8 h of boiling in 20—22% hydrochloric acid. Unfortunately, when the optically active starting esters **3** (D- or L-forms) were used, complete racemization of the product phosphinothricin (**6**) (approx. 90% yield) was observed.

We concentrated our efforts on such approaches as would help us to avoid the complications accompanying the hydrolysis of the esters of organophosphinic acids, at the same time preserving their optical activity.

The phosphoesterase enzymes, exo- and endonuclease, are widely employed in biochemical routine investigations of nucleic acids. To this moment, however, they have never been used to catalyzed the hydrolysis of the esters of organophosphinic acids. This approach was developed in our laboratory and will be discussed in a number of consecutive papers.

It was empirically established that the most favorable conditions for enzyme-catalyzed hydrolysis processes are as follows: 20 g substrate and 5 mg enzyme



E^1 - Phosphodiesterase I; E^2 - Acylase I;
E^3 - Glutaminase; E^4 - α-Chymotrypsin.

Scheme 1.

are stirred for 6 h in an aqueous buffer solution, or emulsion, at the pH and temperature optimum of the enzyme. Naturally, larger of smaller quantities of the substrate can be used, provided that the ratio of substrate/enzyme remains the same. To ensure the easier manipulation and subsequent regeneration of the enzyme, especially if it is not easily available, a polymer carrier should be used, on which to spread the enzyme. In this case, 20 g substrate would require 10—15 mg enzyme. With very few exceptions, the enzyme-catalyzed hydrolysis affords practically quantitative yields and is strictly selective. If not inhibited, one and the same enzyme can be used in at least ten reactions. It is characteristic for the enzyme approach that no racemization occurs with optically active substrates, while the traditional hydrolysis methods usually lead to a complete loss of the optical activity. Of course, the different enzymes could be kinetically studied and the above conditions additionally refined to accomodate each separate type of enzyme. Where the synthesis of organophosphorus compounds is comcerned, however, this method is quite applicable. In our laboratory, we conducted experiments, using substrates that contain esters of the types R-P(=O)(H)OR^1, R-P(=O)(CH$_3$)OR^1, R-P(=O)(OR^1)OR^1, and R-P(=O)(OR^1)NHR^2 and other hydrolyzable groups (R, R^1, and R^2), with not only the enzymes phosphodiesterase I and alkaline phosphatase, but also with α-chymotrypsin, protease, mesintericopeptidase, acylase, urease, crude bee venom, and glutaminase. The concrete applications of these will be discussed separately.

With the phosphinic ester **3** we used the enzyme phosphodiesterase I in its free state and spread over polyacrylamide. As **3** is water-insoluble, a good initial homogenization of the substrate was achieved with 2—3 ml Tween-80^R per 20 g substrate the aqueous buffer (pH 8.8, 800 ml) was gradually added to the obtained jelly mass by continuous stirring. The homogeneous mixture was then tempered at 37 °C, and 5 mg (or 10—15 mg, if spread on polyacrylamide) phosphodiesterase I were added. After stirring for 6 h at the same temperature, the enzyme was removed by dialysis (ultrafiltration), or centrifugation, and was ready to use in next experiment. The buffer was acidified to pH 5.0 and extracted with diisopropyl ether. The acid **4** was isolated in a practically quantitative yield after drying with anhydrous magnesium sulfate and distillation of the extraction agent. Surprisingly, it was found that the catalytic action of the enzyme was not affected by the type of the optically active form: both the D- and L-forms of the D-, DL- and L-substrates **3** were hydrolyzed. It is interesting to note that alkaline phosphatase, which has a very similar activity, does not catalyze the hydrolysis of the substrate in question.

Acylase I was the next enzyme we applied to a rather unusual substrate, containing a phosphinic-acidic function. Under the above-mentioned conditions, at pH 7.0 and 25 °C, the enzyme catalyzed the hydrolysis of the *N*-acetyl group of the substrate L-**4** to the free amino phosphinic acid L-**5**, which was isolated in an approx. 80% yield after acidification, concentration and cooling. As a raw enzyme ("Sigma") was used, 25 mg of it were necessary for 25 g substrate **4**.

When trifluoroacetyl was used to protect the amino group in the starting lactam **1**, and when methyl methylphosphinate was employed in the reaction described above, the resultant trifluoroacetyl derivative (not given in the Scheme 1) was easily hydrolyzed in a practically quantitative yield after treatment with aqueous ammonia at pH 10.0. This is one of the rare cases (cf. also the case with acylase I above) when the classical methods for liberating the protective groups are to be preferred to the enzyme approach. However, when optically inactive (racemic) mixtures are used, the enzyme acylase I is quite suitable for the separation of optically active antipodes. The substrate DL-**4** leads to the isolation of the unchanged D-form D-**4**, and the hydrolysis product L-**5**.

The third enzyme investigated was glutaminase. Apart from the fact that this enzyme hydrolyzes the γ-amide function of glutamine to glutamic acid, it was found that using the α-amide of the modified glutamic acid, i.e. the substrate L-**5**, afforded the phosphinothricin L-**6** in a 95% yield. This is not very surprising, as in a separate experiment we used the diamide of the L-glutamic acid and obtained L-glutamic acid under the same conditions as for the enzyme-catalyzed hydrolysis of L-**5**. We discovered still another possible application of glutaminase, when a number of mono- and diamides of saturated and unsaturated dicarbonylic acids (malonoamide, succinamide, adipamide, pimelamide, fumaramide, citric 1,5-diamide, mesaconamide, ect.) were subjected to the catalytic action of glutaminase and gave the corresponding carboxylic acids. Sulfonamides R-SO_2NH_2 and amides of the type R-P(=O)(OR)NHR^2, as also aromatic mono- and diamides and cyclic imides, are not affected by the enzyme glutaminase.

In contrast to phosphodiesterase I, glutaminase is inactive towards the D-form of phosphinothricinamide **5**. It is interesting to note that, when the methylphosphinyl group of the substrate **5** is replaced with a dihydroxyphosphinyl group, the substrate 2-amino-4-phosphono-L-butanamide inhibits the enzyme completely. We have come to the conclusion that all experiments, involving glutaminase-catalyzed hydrolysis of carboxamides containing PO_3H_2 or P(O)(OH)H groups, should be approached with caution. Protection of the phosphono and phosphino groups as esters, however, does not result in the enzyme inhibition and a subsequent separation of the ester functions

with phosphonodiesterase I is easily possible.

In our case, the inevitable contamination of the enzyme does not seriously affect the enzyme-catalyzed hydrolysis process and glutaminase from *E. coli* can therefore be used, with an enzyme-content of about 50%.

In our laboratory, we developed a variant of the above method, where D-, DL-, and L-phosphinothricin are obtained by enzyme-catalyzed hydrolysis of the phosphinic ester **3** and a subsequent alkaline hydrolysis of the amide **4**. In this case, unlike the mineral hydrolysis of the ester **3**, no racemization of the optically active forms was observed. This method for production of phosphinothricin will be discussed separately.

Esterification was carried out with a view to obtaining derivatives of L-phosphinothricin, suitable for peptide synthesis. Treatment of the acid **6** with phosphorus pentachloride afforded a chloro-containing compound, which proved extremely unstable upon air-exposure and decomposed quickly releasing hydrogen chloride. For that reason, chlorination and esterification were conducted simultaneously in the presence of triethylamine as acceptor for the released hydrogen chloride. After the usual work-up for separation of the reaction products, we isolated the main product L-phosphinothricin *O,P*-diethyl ester (**7**) (yield approx. 65%) and 1,2-azaphospholidine (**8**) (yield approx. 20%). When a 1 equivalent phosphorus pentachloride was used, the yield of the 1,2-azaphospholidine (**8**) went up to 50%, whereas the diester of L-phosphinothricin (**7**) was found only in traces. Most probably, the improved experimental conditions have caused the initial chlorination, after which the carboxyl group is esterified and the phosphinyl and amino groups of phosphinothricin form an azaphospholidine cycle. If the *P*-ester of phosphinothricin is placed under the same conditions, no such cyclization occurs. An indirect was to proving the possible mechanism of this ring-formation is the isolation of 1,2-azaphospholidine (**8**) by treatment of L-phosphinothricin (**6**) with thionyl chloride and a catalytic quantity of *N,N*-dimethylformamide, followed by treatment with absolute ethanol. The product is obtained in a yield of about 60%.

When the fourth enzyme α-chymotrypsin, was used in an enzyme-catalyzed hydrolysis, the free acid **9** was isolated in a practically quantitative yield. The same product (cf. our subsequent publications) has been obtained by a variant of the reaction of Ugi: from 3-(hydroxymethylphosphinyl)propanal, ammonium, and cyclohexyl isocyanide, followed by enzyme hydrolysis. That enzyme-catalyzed hydrolysis should be preferred to mineral hydrolysis was due to the fact that the cyclic PONH-bond of 1,2-azaphospholidine (**8**) turned out to be highly sensitive to all interactions with acids or salts under the conditions accompanying the hydrolysis of the ethoxycarbonyl group. The enzyme-catalyzed hydrolysis is conducted by the method described above: 20 g substrate **8**, 15 mg raw α-chymotrypsin, stirring for 6 h at 25 °C in 500 ml buffer (pH 7.8). The enzyme could, of course, be spread over a polymer carrier, but as it is readily available, this was not actually necessary. An analogous deesterification occurred also when the enzyme alkaline mesintericopeptidase and protease were used.

The enzyme approach was again employed to obtain L-phosphonothricin with a free carboxyl function and protected $-P\lesssim^{CH_3}_{OEt}$ and amino groups. When the amide **3** was used as substrate of the enzyme glutaminase under the above conditions, the free carboxylic acid **10** was isolated in a practically quantitative yield.

Thus, by the slightly modified reaction of Michaelis-Becker and the new enzyme approach to the hydrolysis of alkoxymethylphosphinyl groups, carboxylic esters and amides, we succeeded in isolating L-phosphinothricin (**6**) in satisfactory yields. This product is rather valuable for its biological activity.

Experimental

General Notes: IR spectra, elemental analysis, HPLC, and determination of optical activity—on a Perkin-Elmer instrument; ^{1}H NMR spectra—on Jouel-100 MHz; mass-spectra—on LKB-900; melting point—measured on a Köfler apparatus; TLC—silica-gel film "Merck"; reagents and solvents— "Aldrich", "Merck"; enzymes and buffers—"Sigma"; α-chymotrypsin— "Pharmachim", Bulgaria. Special credit goes to Dr. N. Stambolieva, who kindly supplied the author with alkaline mesintericopeptidase.

Analytical data of all compounds, with their names, numbers in the text, schemes, and formulae, are given in the following order: yield; IR spectrum (*a.* KBr tablet, *b.* film, cm^{-1}); ^{1}H NMR spectrum taken in *c.* DMSO-d_6, *d.* $CDCl_3$, *e.* D_2O+NaOD, TMS standard, δ-scale, ppm (number of protons, calculated by the integral curve, multiplicity, position of proton in the molecule); mass-spectrum—*m/z*, Calcd/Found, %; elemental analysis for % C, H, N-Calcd/Found; mp; $[\alpha]_D^{20}$; R_f—phosphomolybdic acid ($12MoO_3 \cdot H_3PO_4 x H_2O$)—"Aldrich" or ninhydrin detection (for compounds containing an amino group), developed in systems:

A : *n*-BuOH: AcOH: H_2O=9 : 1 : 1;
B : *n*-BuOH: 25% aq. NH_3=4 : 1;
C : DMF: $CHCl_3$: MeOH=5 : 1 : 2;
D : $CHCl_3$: MeOH=9 : 1

The IR-spectra of the known natural compounds were compared with those of the compounds, obtained by the original methods described in the text, and elemental analysis was carried out. Full coincidence was observed in the range 4000—400 cm^{-1} and elemental analysis was satisfactory. For the optically active forms, which lack descriptions in the literature, mp's and $[\alpha]_D^{20}$ are also given.

Preparation of D-, DL-, and L-3-Acetamido-2-pyrrolidinone (2). Phosphorus pentaoxide (113 g) is dissolved at 60—70 °C in orthophosphoric acid (150 g). The obtained phosphoric acid (H_3PO_4) is stored in a refrigerator at −10 °C and is quickly melted in a hot oil bath immediately before use.

Phosphoric acid (8 ml) is dissolved in acetic anhydride (32 ml) (mole ratio 1.0:1.7) and D-, DL-, or L-3-amino-2-pyrrolidinone (10.01 g, 0.1 mol), is added. The mixture is stirred for 15—20 min at 80—85 °C and is then poured over crushed ice (approx. 50 g). Rapid cooling of the liquid phase occurs and the product 3-acetamido-2-pyrrolidinone (**2**) crystallizes: $C_6H_{10}N_2O_2$; 13.96 g (98.2%); D-form, 182—184 °C, L-form, 176—178 °C, DL-form, 175—177 °C (lit,[11] 176 °C); D-: =49.2°, L-: +43.5°, (*c* 0.1, MeOH).

Synthesis of Butanamide 3. A mixture of the lactam **2** (14.22 g, 0.1 mol), ethyl methylphosphinate (12.97 g, 0.12 mol), and boron trifluoride etherate (1 ml) is gradually heated for 1—1.5 h to 120 °C in a closed steel cylindrical container in an ambience of dry argon or nitrogen. Heating is kept up for another 2—2.5 h at 125—130 °C. After cooling, the reaction mixture is extracted with boiling benzene and the undissolved portion is decanted off. Cooling affords an oil, which crystallizes after being kept for a prolonged period at 0 °C over ethyl acetate/cyclohexane. L-3-Acetamido-4-(ethoxymethylphosphinyl)butanamide (**3**): $C_9H_{19}N_2O_4P$; 14.26 g (56.3%); *a*: 3350—3300, 3170—3010, 1650, 1640, 1320 (P-CH_3), 1280 (P=O), 1110—980 (P-O-C); *c*: 1.28 (3H, s, $COCH_3$), 1.38 (3H, t, *J*=7 Hz, $OC\underline{H}_2CH_3$), 2.03 (3H, d, *J*=17 Hz, PCH_3), 2.1—2.7 (4H, m, $PC\underline{H}_2C\underline{H}_2$), 4.12 (2H, q, $OC\underline{H}_2CH_3$), 4.52 (1H, t, *J*=8 Hz, $C\underline{H}CH_2$), 6.28 (1H, s, NH), 6.46 (2H, s, NH_2); after D_2O-exchange the protons N$\underline{H}$ and NH_2 do not appear; 250.23/250 (19%); 43.20/43.26, 7.65/7.39, 11.19/10.99; +43.9°, (*c* 0.1, MeOH); 162—164 °C (decomp); 0.43-A.

D-**3**: 11.96 g (50.8%); −40.2°, (*c* 0.1, MeOH); 162—164 °C (decomp).

DL-**3**: 12.54 g (53.3%); 149—152 °C (decomp).

Preparation of Phosphinothricin (6). Method A: The phosphinyl ester DL-**3** (25.02 g, 0.1 mol) is boiled for 8 hours in hydrochloric acid (150 ml, 22%). It is then evaporated in vacuum (80 °C/6×10^{-2} Torr) to dryness and placed in a column Dowex 50W-X8 H^+ resin. The column is washed with water, the first strongly acidic eluate is thrown away and washing continues with 0.5 M HCl (1 M=1 mol dm^{-3}). The ninhydrin-positive fraction is evaporated in vacuum to dryness and the residue is crystallized from ethanol/diethyl ether; DL-2-amino-4-(hydroxymethylphosphinyl)butanoic acid hydrochloride (**6**): $C_5H_{12}NO_4P \cdot HCl$; 20.02 g (92.1%); mp 203—205 °C (lit,[9] 202—204 °C).

Method B: Enzyme-Catalyzed Hydrolysis of D-, DL-, and L-3. 800 ml buffer (pH 8.8) are added to a well-homogenized mixture of D-, DL-, or L-**3** (20 g), and "Tween-80" (2 ml). After tempering at 37 °C, about 5 mg (or 10—15 mg, of spread on polyacrylamide) of the enzyme phosphodiesterase I are added. The mixture is stirred at the same temperature for 6 hours and the enzyme is then removed. Concentration and extraction with diisopropyl ether result in the isolation of: L-2-acetamido-4-(hydroxymethylphosphinyl)butanamide (L-**4**): $C_7H_{15}N_2O_4P$; 17.29 g (97.4%); *a*: 3350—3300, 3180—3025, 2845—2435, 1655, 1640, 1300, 1250, 765, 635; *c*: 1.21 (3H, s, $COCH_3$), 1.96 (3H, d, *J*=18 Hz, PCH_3), 2.2—2.7 (4H, m, PCH_2CH_2), 4.50 (1H, t, *J*=8 HZ, $CHCH_2$), 6.06 (1H, s, NH), 6.52 (2H, s, NH_2), 10.2—10.6 (1H, br., POOH); after D_2O-exchange no signals for the N$\underline{H}$, NH_2, and POOH protons appear; 222.18/222 (36%); 37.84/37.55, 6.80/7.01, 12.61/12.55; +64.8°, (*c* 0.1, MeOH); 185—189 °C (decomp).

D-**4**: 17.07 g (96.3%); −63.7 °, (*c* 0.1, MeOH); 192—194 °C (decomp).

DL-**4**: 17.39g (98.1%); 180—183 °C (decomp).

Enzyme-Catalyzed Hydrolysis of L-4. A mixture of the substrate L-**4** (20 g), "Tween-80" (2 ml) and raw acylase (25 mg, 50% enzyme content) is stirred for 6 h at 25 °C in 500 ml buffer (pH 70). After acidification, passing through an ion-exchange resin (eluent 0.5 M HCl) and evaporation in vacuum to dryness, the reaction residue is crystallized with ethanol/diethylether: L-2-amino-4-(hydroxymethylphosphinyl)butanamide hydrochloride (L-phosphinothricinamide hydrochloride) (L-**5**: $C_5H_{12}N_2O_3P \cdot HCl$: 15.52 g, (79.6%); *a*: 1550 (NH_3^+); *e*: 1.95 (3H, d, *J*=18Hz, PCH_3), 2.2—2.7 (4H, m, PCH_2CH_2), 4.33 (1H, t, $C\underline{H}CH_2$); 180.14/180 (25%); as hydrochloride — 27.73/27.65, 6.51/6.48, 12.93/13.11; +52.3°, (*c* 0.1, H_2O); 250 °C (decomp); 0.43-B.

Enzyme-Catalyzed Hydrolysis of 5. A mixture of the substrate L-**5** (21.65 g, 0.1 mol) and the enzyme glutaminase (5 mg) is stirred for 6 h at 25 °C in 500 ml buffer (pH 4.9). The enzyme is then removed and the reaction mixture is worked up as per Item 4, Method A. Yield of L-phosphinothricin hydrochloride: 21.24 g (97.6%).

Synthesis of Phosphinothricin *O,P*-Diethyl Ester- (7) and 1,2-Azaphospholidine (8). A suspension of D-, DL-, or L-phosphinothricin hydrochloride (**6**) (21.76 g, 0.1 mol), in 200 ml dry dioxane is continuously stirred in a humidity proof vessel, while phosphorus pentachloride (45.81 g, 0.22 mol) in dry dioxane and triethylamine (33.38 g, 0.33 mol) in 200 ml absolute ethanol are simultaneously and gradually added for 120 min at 40—45 °C. The mixture is boiled for 1 h and filtered. The filtrate is evaporated in vacuum to dryness. The reaction residue is dissolved in chloroform and a hydrogenchloride current is passed through it until no more oil is released from the D-, DL-, or L-phosphinothricin *O,P*-diethyl ester (**7**), which is then decanted out and, with some difficulty, crystallized. Yield 62—65%.

The mother layers, obtained after the isolation of the diester **7**, are evaporated in vacuum to dryness and the residue is placed in a silica-gel column and eluted with chloroform: methanol 9:1. The eluent is removed by evaporation and the product is crystallized, with some difficulty, from ethyl acetate/hexane. Ethyl (5*S*)-2-methyl-1,2-azaphospholidine-5-carboxylate 2-oxide (L-**8**): $C_7H_{14}NO_3P$; 3.69 g (19.3%); *a*: 1730, 1385 (P-N), 1320 (P-CH_3), 1270—1100 (P=O, C-O-C); *c*: 1.18 (3H, t, $OOH_2C\underline{H}_3$), 1.73 (3H, d, *J*=17 Hz, PCH_3), 2.2—2.7 (4H, m, PCH_2CH_2), 4.1—4.5 (3H, m, $CHCH_2OCH_2CH_3$), 7.03 (1H, s, NH); 191.17/191 (33%); 43.28/43.18, 7.38/7.03; 7.33/7.69; +74.3°; (*c* 0.1, MeOH); 93—95 °C; 0.72-D.

D-**8**: 3.85 g (21.5%); −70.2°; 90—92 °C.

DL-**8**: 3.65 g (20.4%); 89—91 °C.

Enzyme-Catalyzed Hydrolysis of the Ester 8. A well-homogenized mixture of the substrate L-**8** (19.71 g, 0.1 mol) and 2 ml "Tween-80" is added to a solution (thermostabilized at 25 °C) of the enzyme α-chymotrypsin (10 mg, raw, pancreatic), or 10 mg alkaline mesintericopeptidase, in 500 ml buffer (pH 7.8 and 8.2). The mixture is stirred for 6 h at the same temperature until pH 6.0 is reached and is then condensed. The product is filtered out after prolonged strage in a refrigirator: (5*S*)-2-methyl-1,2-azaphospholidine-5-carboxylic acid 2-oxide-(L-pyrophosphinothricin)-(L-**9**): $C_5H_{10}NO_3P$; 15.19 g (94.2%); *a*: 3320—2800, 1385, 1320, 1255; *e*: 1.71 (3H, d, *J*=17Hz. PCH_3), 2.2—2.7 (4H, m, PCH_2CH_2), 4.48 (1H, t, *J*=6 Hz,$CHCH_3$); 163.1/163 (26%); 36.82/37.05,

6.18/6.01, 859/8.63; +69.7°, (*c* 0.1, H_2O); 186—190 °C (decomp); 0.63-C.

Enzyme-Substrate Interaction of the Amide L-3 with Glutaminase. The method in Item 4.3 is employed. The following product is isolated: L-2-acetamido-4-(ethoxymethyl)-butanoic acid (**10**): $C_9H_{18}NO_5P$; 96.4%; *a*: 3510—3050, 1745, 1645, 1305, 1255, 1110—980; *c*: 1.18 (3H, t, *J*=7 Hz, OCH_2CH_3), 1.38 (3H, s, $COCH_3$), 2.18 (3H, d, *J*=18 Hz, PCH_3), 2.2—2.7 (4H, m, PCH_2CH_2), 4.18 (2H, q, OCH_2CH_3), 4.55 (1H, t, *J*=6 Hz, $CHCH_2$), 6.33 (1H, s, NH), 10.9—11.3 (1H, br., COOH); 251.22/251 (18%); 43.03/42.78, 7.22/7.36, 5.58/5.71; 46.7°, (*c* 0.1, MeOH); 132—135 °C; 0.33-A.

Synthesis of 1,2-Azaphospholidine L-8. Method-A: The method in Item 5 is employed, only now phosphorus pentachloride (22.91 g, 0.11 mol) and triethylamine (22.25 g, 0.22 mol) are used. L-**8** is obtained with a 50.6% (9.67 g) yield and its spectral data are identical with those of the same product obtained earlier.

Method B: A mixture of L-phosphinothricin hydrochloride (L-**6**) (21.76 g, 0.1 mol) and 2 ml *N,N*-dimethylformamide is stirred in dry benzene (200 ml) at room temperature. Thionyl chloride (13.09 g, 0.11 mol) is added in portions for the duration of 1 h, accompanied by a continuous current of dry nitrgen through the reaction mixture. The temperature is then increased to 40—45 °C and, while stirring is kept up, triethylamine (15.15 g, 0.15 mol) in 150 ml absolute ethanol is gradually added. The mixture is boiled for 1 h, filtered and worked up as above. Yield of L-**8**; 11.71 g (61.2%).

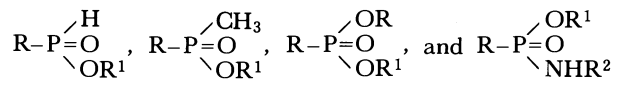
Organophosphorus Analogues and Derivatives of the Natural L-Amino Carboxylic Acids and Peptides. II. Synthesis, Enzyme-Substrate Interactions of "Bialaphos" (SF-1293) and Its Cyclic and Phosphinic Amide Type Analogues

Ivan. A. NATCHEV
Research Centre "Konstrukcionni Polymeri", 5-003 Gara Iskar, 1528 Sofia, Bulgaria
(Received April 28, 1987)

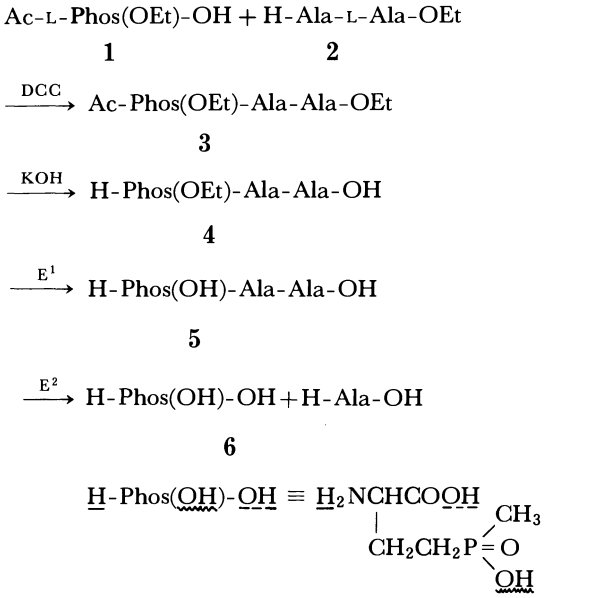
The natural tripeptide antibiotic "Bialaphos" (**5**) has been synthesized by condensation of the protected L-phosphinothricin (**1**) with the dipeptide alanylalanine ethyl ester. The dicyclohexylcarbodiimide method has been used, followed by enzyme-catalyzed hydrolysis. Analogously, a cyclic analogue and the phospha^{C}-peptide (phosphinic amide type) analogue (**14**) of the antibiotic (**5**) have been found to possess antitumour activity.

The tripeptide antibiotic γ-(hydroxymethylphosphinyl)-L-α-aminobutyryl-L-alanyl-L-alanine ("Bialaphos") (**5**) was isolated for the first time[1] from *Streptomices viridochromogenes strains* and it is known to possess herbicidal and fungicidal activity. The phosphinic acid analogue of glutamic acid: 2-amino-4-(hydroxymethylphosphinyl)butanoic acid (phosphinothricin), has a very wide application in agriculture. It should be noted that, while scientific literature abounds in methods for the synthesis of this compound, very limited information about the synthesis pathways of the tripeptide "Bialaphos" can be found. This is due to the complications that arise when attempts are made to release the blocking groups of the phosphinic function. Thus, researchers from Japan[2] synthesized the *P*-ester of "Bialaphos" (with the participation of the DL-forms of phosphinothricin and alanine), but when they tried to hydrolyze the ethoxymethylphosphinyl group to a free phosphinic acid, the "hard" hydrolysis conditions led to the hydrolysis of the peptide bonds. To solve this problem, we devised a method for enzyme-catalyzed hydrolysis[3] of esters of the type:



As starting compounds in the synthesis of "Bialaphos" we used protected phosphinothricin (**1**), prepared in our laboratory,[3] and the commercially available dipeptide L-alanyl-L-alanine ethyl ester. Condensation was carried out without complications by the dicyclohexylcarbodiimide method and the completely protected tripeptide **3** was isolated in an approx. 80% yield. Hydrolysis of the blocking *N*-acetyl and ethoxycarbonyl groups was also carried out by a standard method for peptide synthesis, i.e. mineral hydrolysis to the tripeptide **4**, obtained in an approx. 85% yield.

In our previous paper,[3] the enzyme phosphodiesterase I was successfully used in the enzyme-catalyzed hydrolysis of the *P*-ester of L-phosphinothricin. It could therefore be assumed that this enzyme would retain its catalytic activity in the case of the tripeptide **4**



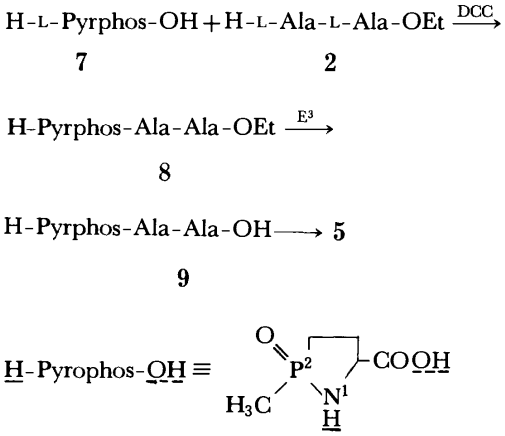
Scheme 1.

as well. Under the empirically confirmed most favorable hydrolysis conditions, i.e. 20 g substrate, 5 mg enzyme (of 15 mg enzyme, if spread on a polymer carrier), stirring for 6 h at 37 °C in 500 ml buffer (pH 8.8), the free tipeptide **5** was isolated in a yield of over 90%. Its spectral data were found to be identical with those of its natural counterpart. No additional purification of the phosphodiesterase I, supplied by "Sigma," was necessary. Its inevitable contamination did not noticeably affect the enzyme-catalyzed hydrolysis, despite the fact that, after the termination of the process, 6—8% phosphinothricin was isolated as a result of the hydrolysis of the phosphinothricin-alanyl peptide bond. It is interesting to note that when D-phosphinothricin (D-**1**) was used in an analogous synthesis, no presence of phosphinothricin was observed during the last phase of the enzyme hydrolysis. The occurence of the side hydrolysis process could be caused by some impurities of the commercial product, because phos-

phodiesterase I has never been found to possess any proteolytic activity. All our attempts to purify the phosphodiesterase I led to a marked decrease of its hydrolytic activity. When, under the same conditions, crude dried venom from *Crotalusatrox* was used, which hydrolyzes minimum 0.1 mmol bis(*p*-nitrophenyl)hydrogenphosphate per mg solid per minute at pH 8.8 and 37 °C, complete decomposition of the tripeptide **5** was observed and the only products that were isolated phosphinothricin and alanine.

The tripeptide "Bialaphos" **5** and its cyclic analogue "Pyrobialaphos" **9** (cf. below) have also been synthesized in our laboratory by the method of the activated esters and an *N*-protective group, *t*-butoxycarbonyl (*t*-BOC). This approach, though it is by no means better than the one described here, will be discussed separately.

With a view to elucidating the relationship of chemical structure-physiological activity, the cyclic analogue of phosphinothricin-2-amino-1,2-azaphospholidine-5-carboxylic acid **7**, recently synthesized by us,[3] was chosen as the N-terminal component of the tripeptide "Bialaphos". Condensation of **7** with the dipeptide alanylalanine ethyl ester was carried out by the dicyclohexylcarbodiimide method. The modified dipeptide **8** was isolated in an approx. 85% yield. When mineral hydrolysis was attempted of the ethoxycarbonyl group, the cyclic phosphinic amide group  turned out to be highly unstable and the tripeptide "Bialaphos" **5** was isolated in a very good yield. This made it clear that the enzyme approach should in this case be used. Alkaline mesintericopeptidase was chosen as the esterase enzyme, as it is known to hydrolyze the peptide C-terminal pro-group rather faster, than the peptide bonds. Nevertheless, strict control of the hydrolysis process is essential until alanine is detected chromatographically. When 20 g substrate and 15—20 mg enzyme were used in a buffer medium



E^3 = Mesintericopeptidase.

Scheme 2.

(pH 7.8), the tripeptide 9 was isolated in about 70% yield. It differs from its natural counterpart in the presence in it of an N-terminal cyclic bond between the nitrogen and the phosphorus.

This modification leads to considerable changes in the physiological activity. Laboratory tests showed a marked decrease of the herbicidal activity. Surprisingly, the modified tripeptide **9** does not appear to have any bactericidal activity, which is characteristic for "Bialaphos". This fact can probably be accounted for by the absence of a free phosphinic acid group  . The *P*-esterified tripeptide **4** shows a certain decrease of its bactericidal activity.

It would be interesting to try still another approach to bonding the unusual amino acid L-phosphino thricin with alanylalanine by creating a PONH bond.

Such di- and tripeptide were synthesized for the first time and quite independently from Imoto et al.[4] and Martell et al.[5] Unfortunately, no peptides with free terminal or side functional groups can be obtained, as "they are very sensitive to any mild alkaline or acidic treatment, aimed at the removal of the blocking groups".[5] Some Soviet researchers[6] were confronted with the same problem. They used the DCC-method to condense the phosphone analogue of phenylalanine, (1-acetamido-2-phenylethyl)phosphonic acid,  , with the methyl ester of phenylalanine.

Recently, it was reported in the patent literature that Issleib et al.[7] have succeeded in obtaining free phospha^C-peptides by condensation of the mono (trimethylsilyl) ester of 2-(benzyloxycarbonylamino)-ethylphosphonic acid,  , with ethyl isocyanoacetoacetate $C^{\leftarrow}\equiv N\text{-}CH_2COCH_2COOEt$, and subsequent hydrogenation and hydrolysis of the trimethylsilyl protective group.

To this moment, no information is available in the literature about phospha^C-peptides with phosphinic acids.

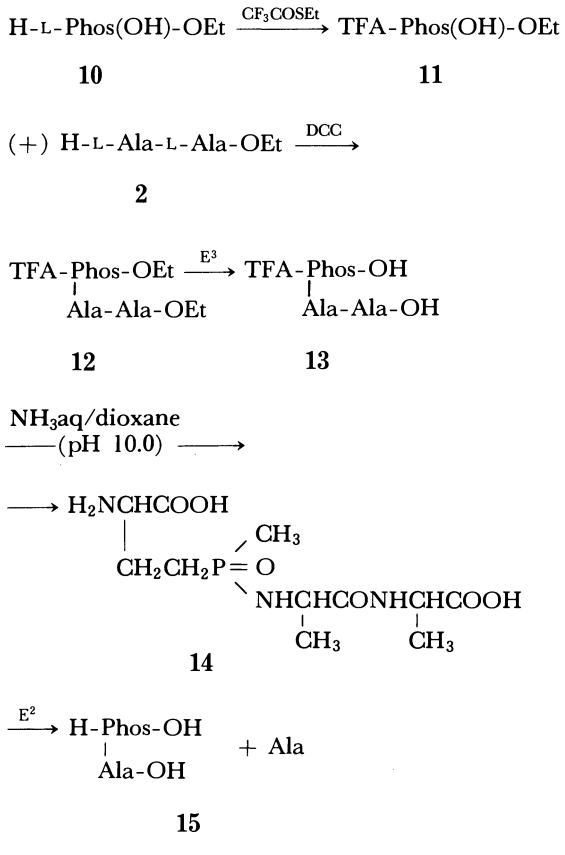
The major problem in the synthesis of a phospha^C-peptide analogue of "Bialaphos" is finding a suitable protective group, which can be removed under such conditions, as do not noticably affect the PONH bond. Urethane-type protective groups provided to be unsuitable, because these derivatives of phosphinothricin are difficult to obtain and, besides, they lead to some side reactions upon treatment with hydrogen bromide-iced acetic acid. The use of an *N*-acetyl protective group is also undesirable, due to the instability

of the phosphinic amide group under conditions of mineral hydrolysis. Enzyme-catalyzed hydrolysis with α-chymotrypsin, protease, peptidase, etc., is also to be avoided, as in this case nonselective hydrolysis of the peptide alanylalanin bond occurs. Protective groups, released by hydrogenolysis, are ineligible as well, because they cause side reactions. The only group found suitable for the protection of the amino group of phosphinothricin, and with some reservations at that, is the trifluoroacetyl group.

The synthesis of the starting material **11**, having a free phosphinic acid function, $-P\begin{matrix}=O\\ \diagdown OH\end{matrix}$, and protected amino and carboxyl groups, was carried out by the method given in Ref. 8, where *N*-trifluoroacetyl protection has been applied to amino carboxylic acids.

Treatment of L-phosphinothricin ethyl ester, synthesized by us earlier, with *N*-ethyl trifluorothioacetate was carried out at room temperature in a borate buffer. The ester amide **11** was isolated in a yield of approx. 90%.

The dicyclohexylcarbodiimide method was used to condense the protected L-phosphinothricin **11** with the dipeptide L-alanyl-L-alanine ethyl ester. Conditions were analogous to those for the conventional peptide synthesis. The phospha^C-tripeptide **12** was isolated in an yield of about 75%. One equiv phosphinothricin **11**, 1 equiv dipeptide, and 1.1 equiv dicyclohexylcarbodiimide were kept for 12 h in an ambience of dry ethyl acetate and then the separated *N,N'*-dicyclohexylurea was filtered off. The filtrate was consecutively washed with 5% aqueous solution of sodium carbonate-water-1M HCl-water (1M=1 mol dm^{-3}), dried over anhydrous magnesium sulfate, evaporated to dryness in vacuum, and purified by column chromatography on silica gel.



Scheme 3.

The carboxyl groups were released by the above-described method of enzyme-catalyzed hydrolysis with mesintericopeptidase to the protected phospha^C-peptide **13**, isolated in an approx. 80% yield. This yield, which is somewhat low for an enzyme-catalyzed process, is due to the fact that certain hydrolysis of the peptide bonds is observed as well.

The *N*-trifluoroacetyl protective group is removed by treatment with aqueous ammonia at pH 10.0. At lower pH values no hydrolysis occurs, whereas higher pH values lead to hydrolysis of the phosphinic amide bond. Despite the numerous experiments performed, the free phospha^C-peptide **14** was never isolated in a yield of over 40%.

In spite of the fact that the tripeptide **14** readily undergoes mineral hydrolysis, we failed in our attempts to find an enzyme that catalyzes the hydrolysis of the PO-NH bond. When alkaline phosphatase was used, the presence of about 10% phosphinothricin was established in the hydrolysate, but this was probably due to the alkalinity of the medium (pH 10.4), and not to the action of the enzyme.

The proteolytic enzymes α-chymotrypsin and protease catalyze the hydrolysis of the alanylalanine bond and as a result the phospha^C-dipeptide **15** is isolated in approx. 90% yield.

The tripeptide **14** has been statistically proved to possess antitumour activity. When applied to an experimental tumour L1210 in mice in doses of 20 (mg/kg) d^{-1} for the duration of 5 d, T/C of 168% was established (T/C%=ratio of median survival time, expressed as percent of untreated controls). The T/C ratio of the dipeptide **15** is 172%. When the tripeptide "Bialaphos" and phosphinothricin were subjected to parallel tests, no antitumour activity was registered. The relatively low toxicity of **14** (LD_{50}=428 mg/kg) and **15** (LD_{50}=523 mg/kg) promises very good results, should further studies in this direction be undertaken.

Experimental

General Notes: IR spectra, elemental analysis, and HPLC—on a Perkin-Elmer instruments; mp's—on a Kofler apparatus; TLC—silica-gel film "Merck". Solvents and reagents—"Aldrich", "Merck"; enzymes and buffers—"Sigma". The compounds obtained have been also proved by measuring the total and enzyme hydrolysate content. The IR-spectra and mp's of the known natural products have been compared with those of authentic samples.

Synthesis of Bialaphos *O,P*-Diethyl Ester (3). 2-Acet-

amido-4-(ethoxymethylphosphinyl)-L-butanoic acid (**1**) (23.52 g, 0.1 mol), L-alanyl-L-alanine ethyl ester (**2**) (19.02 g, 0.1 mol), and dicyclohexylcarbodiimide (22.69 g, 0.11 mol) are mixed in dry ethyl acetate (250 ml). The mixture is then stirred on a magnetic stirrer for 24 h in a closed Erlenmeier flask at room temperature. The *N,N'*-dicyclohexylurea is filtered out, 5—6 drops of 50% aqueous acetic acid are added and the filtrate is kept for 6 h at room temperature. After another filtration, the filtrate is washed with 5% aqueous solution of sodium carbonate-water-5% hydrochloric acid-water. It is then dried over anhydrous magnesium sulfate and distilled in vacuum to dryness. The obtained oil is dissolved in dry ethyl acetate and hexane is added until the solution becomes dull. After a prolonged storage in a refrigerator, the product is filtered out: γ-(Ethoxymethylphosphinyl)-L-α-acetamidobutyryl-L-alanyl-L-alanine ethyl ester (**3**): $C_{17}H_{32}N_3O_6P$; 33.69 g (83.1%); IR (KBr): 1745, 1650, 1520, 1305, 1200, 1110—970 cm^{-1}. Elemental analysis, % C, H, N, Calcd/Found: 50.36/50.48, 7.96/7.77, 10.36/10.77; mp 96—98 °C; total hydrolysate (after 12 hours' heating at 110 °C in 6 M HCl in a sealed ampule): phosphinothricin and alanine; enzyme hydrolysate (after 6 hours' stirring of 2 g substrate and 1 mg protease at pH 7.5 and 37 °C: phosphinothricin *P*-ethyl ester and alanine.

Isolation of Bialaphos *P*-Ethyl Ester 4.[2] The tripeptide **3** (20.54 g, 0.05 mol) is suspended in 200 ml 5% aqueous potassium hydroxide and the mixture is heated for 1 h at 40—50 °C. After cooling, acidification and extraction with diisopropyl ether, the organic extract is distilled in vacuum and the amorphous mass crystallized from dioxane/ethanol. The tripeptide **4** is obtained in an 84.6% yield (14.86 g).

Total hydrolysate-phosphinothricin, alanine; enzyme hydrolysate (protease)-phosphinothricin *P*-ethyl ester and alanine; satisfactory elemental analysis.

Isolation of Bialaphos (5).[1] The enzyme phosphodiesterase I (5 mg) is added to a buffer medium (500 ml, pH 8.8), containing the tripeptide **4** (20 g), at 37 °C. The mixture is stirred for 6 h at the same temperature. After dialysis, acidification and evaporation in vacuum (40—50 °C) to dryness, the solid mass is extracted with hot ethanol. The tripeptide **5** is isolated after cooling in a 90.6% yield. Its spectral data are identical with those of an authentic sample. Enzyme hydrolysis of Bialaphos with α-chymotrypsin: phosphinothricin (**6**) and alanine.

Synthesis of Pyrrobialaphos (9). The method described in Item 2 is employed, only now L-2-methyl-1,2-azaphospholidine-5-carboxylic acid 2-oxide (**7**) is used. The following product is isolated: *N*-/L-(2-methyl-1,2-azaphospholidine-5-carbonyl 2-oxide)/-L-alanyl-L-alanine ethyl ester (**8**): $C_{13}H_{24}N_3O_5P$; 29.10 g (87.3%); IR 1320 cm^{-1} (P-N); Calcd/Found (%): 46.84/46.59, 7.26/7.40, 12.61/12.55; mp 173—176 °C; total hydrolysate—phosphinothricin; enzyme hydrolysate (protease and α-chymotrypsin)-1,2-azaphospholidine analogue (pyrrophosphoshricin) (**7**) 20 g of the substrate, i.e. the protected tripeptide **8**, are well homogenized with 4—5 drops of "Tween-80" and added to a water-buffer medium (500 ml, pH 7.8), containing alkaline mesintericopeptidase (20 mg). Stirring is kept up for 3 h. The mixture is extracted with diisopropyl ether and the water layer is acidified and evaporated in vacuum to dryness. The residue is extracted with hot methanol to the product: *N*-/L-(2-methyl-1,2-azaphospholidine-5-carboxyl 2-oxide)/-L-alanyl-L-alanine (**9**): $C_{11}H_{20}N_3O_5P$; 21.16 g (69.3%); IR 3580—2920 cm^{-1} (COOH); Calcd/Found (%): 43.28/43.44, 6.60/6.51, 13.76/13.39; total hydrolysate—phosphinothricin, alanine; "mild" mineral hydrolysis (1 M HCl, 30 min., 50 °C)—Bialaphos (**5**); enzyme hydrolysis (α-chymotrypsin)-1,2-azaphospholidine (**7**), alanine; the product melts with decomposition at about 220 °C.

Synthesis of the Ester Amide 11. A mixture of L-phosphinothricin ethyl ester (**10**) (20.92 g, 0.1 mol) and *S*-ethyl trifluorothioacetate (24.71 g, 0.15 mol) in 100 ml 1 M NaOH and 400 ml borate buffer solution is shaken for 8 h on a mechanical shaker at room temperature. It is then acidified with 1M HCl, extracted with diisopropyl ether, dried over anhydrous magnesium sulfate, and distilled in vacuum to dryness. The following product is recrystallized from ethanol: L-2-trifluoroacetamido-4-(hydroxymethyl)butanoic acid ethyl ester **11**: $C_9H_{15}F_3NO_5P$; 27.56 g (90.3%); IR (KBr): 2860—2540, 2340—2100, 1740, 1650, 1520, 1310, 1170, 930, 840 cm^{-1}; Calcd/Found (%): 35.42/35.27, 4.95/5.01, 4.59/4.67; mp 163—165 °C; $[\alpha]_D^{22}$ +43.7°, (*c* 0.1, MeOH), R_f 0.43 (DMF: dioxane: MeOH=9:2:1).

Synthesis of the Phospha^C-peptide 14. A mixture of L-phosphinothricin (**11**) (30.52g, 0.1 mol), L-alanyl-L-alanine ethyl ester (**2**) (19.02 g, 0.1 mol) and dicyclohexylcarbodiimide (22.69 g, 0.11 mol) is stirred for 12 h in dry ethyl acetate (250 ml) at room temperature. This mixture is then filtered and the filtrate is washed with 5% aqueous solution of sodium carbonate, then with water, 0.5% aqueous solution of oxalic acid, again with water, and followed by drying over anhydrous magnesium sulfate and distillation in vacuum to dryness. The residue is dissolved in dry ethyl acetate and cooled. Hexane is added until the solution becomes dull. Crystallization is initiated by rubbing the flask walls with a glass stick and then leaving the solution in a refrigerator at −5 °C for prolonged period the following product is then filtered out: *N*-/L-3-ethoxycarbonyl-3-(trifluoroacetamido)-propyl/methylphosphinyl/-L-alanyl-L-alanine ethyl ester (**12**): $C_{17}H_{29}F_3N_3O_7P$; 35.56 g (74.8%); IR 1750, 1640, 1520, 1320—1270, 1189—940, 810, 720, 640, 560 cm^{-1}; Calcd/Found (%): 42.95/43.18, 6.18/6.01, 8.84/8.20; total hydrolysate—phosphinothricin, alanine; mp 93—95 °C.

A well homogenized mixture of the tripeptide **12** (47.54 g, 0.1 mol) and 5—6 drops of "Tween-80" is added to an aqueous buffer medium (800 ml, pH 7.8), which has been previously tempered at 30 °C and which contains 20 mg alkaline mesintericopeptidase. Stirring is kept up for 3 h at the same temperature (until a ninhydrin-positive detection occurs), the mixture is extracted with diisopropyl ether, acidified to pH 6.0, and evaporated in vacuum to dryness. The solid residue is extracted with boiling ethanol to the product: *N*-/L-3-carboxy-3-(trifluoroacetamido)propyl/methylphosphinyl/-L-alanyl-L-alanine (**13**): $C_{13}H_{21}F_3N_3O_7P$; 34.09 g (81.3%); IR 3200—2600 cm^{-1}; Calcd/Found (%): 34.24/37.56, 5.05/4.88, 10.02/10.13; total hydrolysate—phosphinothricin, alanine; mp 188—191 °C.

The tripeptide **13** (18.63 g, 0.05 mol) is stirred for 12 h at room temperature in a mixture of dioxane (200 ml) and aqueous ammonia, pH 9.6. After evaporation in vacuum to dryness (50 °C/18 mmHg) the reaction residue is passed through a silica-gel column, which results in the separation of phosphinothricin, the dipeptide alanylalanine and the tripeptide: *N*-/(L-3-carboxy-3-aminopropyl)methylphosphinyl/-L-alanyl-L-alanine (**14**): $C_{11}H_{22}N_3O_6P$; 6.24 g (38.6%); IR 3400—2860, 2340—2100, 1750, 1650, 1520, 1340, 1305, 1170, 930, 845, 620, 510 cm^{-1}; Calcd/Found (%): 40.87/40.90

6.86/6.49, 13.00/13.11; total hydrolysate—phosphinothricin, alanine; mp 216—219 °C (decomp).

Synthesis of the Phospha^{C}-dipeptide 15. The tripeptide **14** (3233 g, 0.1 mol) is stirred for 6 h at 25 °C in 800 ml aqueous buffer medium (pH 7.8), containing α-chymotrypsin (10 mg). After acidification (pH 6.0), the reaction mixture is evaporated in vacuum to dryness and the resultant organic mass is treated with hot dioxane to give: *N*-/(L-3-carboxy-3-aminopropyl)methylphosphinyl/-L-alanine (**15**): $C_8H_{17}N_2O_5P$; 24.01 g (95.2%); IR 3360—2840, 2320—2100, 1750, 1650, 1525, 1340, 11300,1170, 920, 840, 620, 515 cm^{-1}; Calcd/Found (%): 38.10/38.43, 6.79/6.62, 11.11/11.17; mp approx. 200 °C (decomp).

Organophosphorus Analogues and Derivatives of the Natural L-Amino Carboxylic Acids and Peptides. III. Synthesis and Enzyme-Substrate Interactions of D-, DL-, and L-5-Dihydroxyphosphinyl-3,4-didehydronorvaline and Their Cyclic Analogues and Derivatives

Ivan A. NATCHEV
Research Centre "Konstrukcionni Polymeri", 5-003 Gara Iskar, 1528 Sofia, Bulgaria
(Received April 28, 1987)

The unusual natural amino acid phosphorus containing didehydronorvaline (**5**) has been synthesized by consecutive treatment of the 4-bromo-2-butenal (**1**) with potassium cyanide and ammonium carbonate to the hydantoin (**2**), converted into the organophosphorus derivative **3**, followed by enzyme-catalyzed hydrolysis of the diethoxyphosphinyl group to the phosphonic acid **4**, and hydrolysis. The tetrahydro-1,2-azaphosphorine (**8**) and the protected didehydronorvaline derivatives **6**, **7**, **9**, and **10**, have been synthesized.

The tripeptide antibiotics Plumbemicin A: *N*-(*N*-L-alanyl-L-α-aspartyl)-3,4-didehydro-5-phosphono-D-norvaline, and Plumbemicin B: *N*-(N^2-L-alanyl-L-asparaginyl)-3,4-didehydro-5-phosphono-D-norvaline, have been isolated from *Streptomices plumbens strains* by Japanese researchers[1,2] and their biological activity has been studied.[3] To this moment, no information is available in the scientific and patent literature about the synthesis of the two tripeptides and of the unusual allylphosphonic acid **5**. The latter has been isolated and identified[2] by hydrolysis of the tripeptides. It is our intention, in two consecutive papers, to demonstrate the possibilities for their synthesis.

4-Bromo-2-butenal (**1**)[4] was chosen as the starting material for the synthesis of norvaline (**5**). Upon condensation with potassium cyanide/ammonium carbonate under the conditions of the Bucherer-Bergs reaction, the hydantoin (**2**) was obtained in a satisfactory yield (85%).

The next step was the Arbuzov reaction with the bromo-derivative **2** and triethyl phosphite. Despite the fact that a number of variations were introduced into the working conditions, the yield of the organophosphorus product never exceeded 50—55%. This could be explained with the rather "hard" conditions (3 h in boiling xylene) and with the sensitivity of the double bond. Varlet et al.[5] have synthesized the very similar structural analogue of the hydantoin (**3**), which has a saturated side chain, by using the Bucherer-Bergs 4-(diethoxyphosphinyl) butanal in their reaction. We employed an alternative approach, i.e. treatment of the acetal of 4-bromo-2-butenal, $BrCH_2CH{=}CHCH(OR)_2$ with triethyl phosphite, releasing the aldehyde and a subsequent treatment with potassium cyanide/ammonium carbonate. The yields were satisfactory and the approach will be discussed separately, accompanied with a demonstration of the catalytic activity of the enzyme α-chymotrypsin and urease towards the hydantoin (**3**) and its hydrolysis product.

We failed to achieve selective mineral hydrolysis of the diethoxyphosphinyl groups and the hydantoin ring. Under the markedly "hard" hydrolysis conditions, no individual products were obtained.

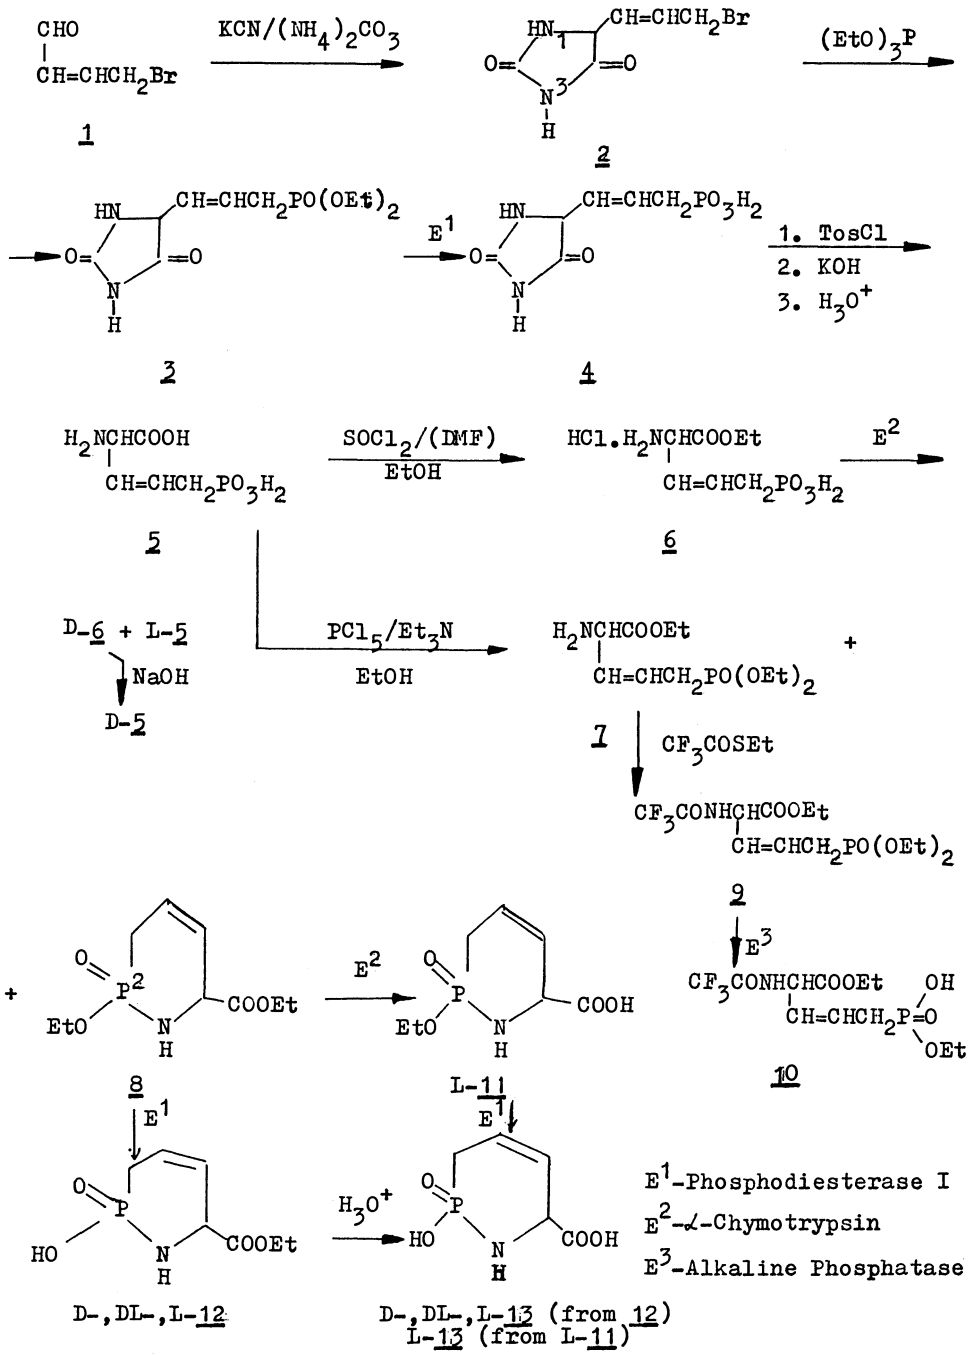
When the phosphonic diester **3** was treated with the enzyme phosphodiesterase I under conditions, described in our previous papers,[6] the free phosphonic acid **4** was isolated in a practically quantitative yield.

Patent data[7] report that 5-substituted hydantoins can be hydrolyzed by enzyme-catalyzed hydrolysis with dihydropyrimidinase to the corresponding carbamoyl derivatives. When the same enzyme was applied to the hydantoin (**3**), no enzyme-substrate interaction was observed. Furthermore, when the free phosphonic acid **4** was used as substrate, complete inhibition of the enzyme occurred.

To hydrolyze the hydantoin (**4**), we employed the method of Hiroi et al.[8] for preliminary N^3-tosylation, followed by mild mineral hydrolysis. It was found that isolation of the tosyl derivatives was unnecessary (cf. Experimental). Hydrolysis afforded the norvaline (**5**) as a racemic mixture in a yield of approx. 60%. Its spectral data were identical with those of an authentic sample.

It our laboratory, we succeeded in obtaining the same product **5**, as well as the tetrahydro-1,2-azaphosphorine analogue discussed below, by a four-component isonitrile condensation after the reaction of Ugi and a modified three-component condensation after the same reaction. This approach will be discussed separately.

With a view to obtaining optically active antipodes of 3,4-didehydronorvaline (**5**) and such derivatives as would be suitable for peptide synthesis, treatment was carried out with 1 equiv thionyl chloride in a medium of ethanol and in the presence of *N*,*N*-dimethylformamide in catalytic quantities. Thionyl chloride was gradually added to a cooled suspension of didehydronorvaline (**5**) in ethanol, which was continuously stirred. An argon, or nitrogen, current was passed through the reaction mixture, in order to carry off the released gases (sulfur dioxide and hydrogen chloride). The reaction mixture was then quickly brought to the boil,



Scheme 1.

which was accompanied by dissolution and an intense release of gases, carried out of the reaction mixture by the argon (nitrogen). When a slight vacuum was applied to the reaction vessel and the released gases were collected in absorbers, it was found that sulfur dioxide and hydrogen chloride had been removed almost quantitatively, which clearly indicated that they could not have reacted with the starting material, or with the reaction product. Cooling resulted in spontaneously precipitation of the ethyl ester hydrochloride of the 3,4-didehydro-DL-norvaline (**6**), which was isolated in a yield of about 90%.

The separation of optically active antipodes was achieved by enzyme-catalyzed hydrolysis with α-chymotrypsin. When the method in reference[6] was used, the enzyme catalyzed hydrolysis of only the L-form of the racemic mixture DL-**6** to the 3,4-didehydro-L-norvaline L-**5**, while the D-form D-**6** remained unchanged. The D-form-**5**, free from its ester protection, was easily obtained by mineral hydrolysis of the ester D-**6**.

Norvaline with protected phosphono and carboxyl functions was obtained by treatment of D-, DL- and L-didehydronorvaline (**5**) with phosphorus pentachloride. Without isolating the rather unstable chlorinated products, we subjected them to treatment with

ethanol, with triethylamine as the condensation agent. As it was the case with our previous studies of phosphinothricin,[6] here, analogously, the interaction led to two products: triethyl ester **7** as the major one (yield of about 60%), and the ethyl ester of tetrahydro-1,2-azaphosphorinecarboxylic acid (**8**) (yield approx. 10%). All our attempts to increase the yield of **8** by using alternative synthetic methods were unsuccessful and even protection of the reactive double bond brought no results.

We succeeded in obtaining a completely protected norvaline by treating the triester **7** with *S*-ethyl trifluorothioacetate by the method in reference.[6] Thus, the *N*-trifluoroacetylated triester of the didehydronorvaline (**9**) was isolated in a yield of about 80%.

The enzyme alkaline phosphatase is very suitable when strict selectivity is needed in the enzyme-catalyzed hydrolysis of the diethoxyphosphinyl groups. When taken at its pH optimum (10.4) and at 37 °C, the enzyme enhances the hydrolysis of only one of the two ethoxyl groups to the phosphonic monoester **10**. The enzyme-substrate interaction was carried out under conditions which have been empirically proved effective in our laboratory: 20 g substrate, about 5 mg enzyme, 6 h. Of course, larger or smaller amounts of substrate can be used, provided that the quantitative ratio substrate/enzyme is kept within the prescribed limits. When one and the same enzyme is used repeatedly, or when larger amounts of substrate are involved, it is better to spread the enzyme on a polymer carrier, as for instance the polyacrylamide gel "Sigma", which is very good for the purpose. In this case, the quantity of the enzyme should be twice as much (10—15 mg per 20 g substrate) and it can be regenerated simply by centrifugation.

We already observed that the optical form of the substrate is quite independent of the catalytic action of phosphodiesterase I. The same was found to be also true about alkaline phosphatase. This enzyme, however, catalyzes both the D- and the L-forms of 5-(diethoxyphosphinyl)-3,4-didehydronorvaline.

When we tried to hydrolyze the ethoxy carbonyl and ethoxyphosphinyl groups of tetrahydro-1,2-azaphosphorine (**8**) by treatment with mineral acids and bases, it turned out that the cyclic phosphinic amide group was the most easily hydrolyzable. To overcome this problem, which occurred also with the cyclic analogue of phosphinothricin,[6] again we used the enzyme approach. The ethoxycarbonyl derivative **8**, as substrate of the enzyme α-chymotrypsin, affords the free acid L-**11** in a practically quantitative yield. As expected, the D-form-D-**8** does not participate in the interaction.

We already discussed some particular characteristics of the enzyme phosphodiesterase I. It is capable of catalyzing the substartes, irrespective of the type (D- or L-) of their optical activity. Thus, with the phosphonamidic ester (**8**) as substrate, the free acids D-, DL-, and L-**12** were isolated in practically quantitative yields. The free carbonyl group of the substrate L-**11** with the enzyme phosphodiesterase I afforded the free tetrahydro-1,2-azaphosphorine L-**13**, again with a quantitative yield.

Alkaline phosphatase does not have any catalytic action on the substrates **8**, **11**, **12**, and **13**.

It seems that the presence of a free hydroxyphosphinyl group, $O=P(HO)<$, increases, to a certain extent, the stability of the cyclic PO-NH bond. Thus, mineral hydrolysis of the esters D-, DL-, and L-**13**, although in yields of about 40%.

Studies on the physiological activity of the newly-synthesized products, as well as of the natural didehydro-D-norvaline (**5**), are under way and will be published soon.

Experimental

General Notes: IR-spectra, elemental analysis, optical activity and HPLC—on a Perkin-Elmer instrument; ^{1}H NMR-spectra—on Jouel-100 MHz; mass-spectra—on LKB-900; TLC—silica-gel film "Merck"; reagents and solvents—from "Aldrich" and "Merck"; enzymes and buffers—from "Sigma"; α-chymotrypsin—from "Pharmachim", Bulgaria. Special credit goes to Dr. N. Stambolieva of the Institute of Organic Chemistry, Bulgarian Academy of Sciences, for kindly supplying the mesintericopeptidase. The IR-spectra and mixed mp's of known compounds have been compared with those of authentic samples.

Synthesis of the Hydantoin (2). A mixture of 4-bromo-2-butenal (**1**) (14.90 g, 0.1 mol, potassium cyanide (7.81 g, 0.12 mol) and ammonium carbonate (14.41 g, 0.15 mol) is heated for 6 h at 55—60 °C in 150 ml 50% aqueous ethanol. A crystalline product is gradually released. After filtration, the filtrate is placed in a ventilation cupboard and strong draught is applied. The filtrate is then carefully acidified (the unreacted potassium cyanide releases hydrogen cyanide). After cooling, an additional quantity of the product is filtered out: 5-(3-bromo-1-propenyl)-2,4-imidazolidinedione (**2**): $C_6H_7BrN_2O_2$; 18.71 g (85.4%); IR (KBr, cm^{-1}): 3320—2860, 1750—1680, 860, 620; ^{1}H NMR ($CDCl_3$, TMS): δ=4.20 (3H, m, CHCO and CH_2Br), 6.20 and 6.76 (2H, m, C<u>H</u>=C<u>H</u>), 7.52 and 9.61 (2H, br.,NHX2); MS, *m/z* Calcd/Found: 219.04/219; elemental analysis, % C, H, N-Calcd/Found: 32.90/33.11, 3.22/3.46, 12.79/13.02; mp 183—186 °C (EtOH). (All analytical data to follow are given in the same order.)

Synthesis of the Diester 3. A mixture of the hydantoin (**2**) (21.90 g, 0.1 mol) and triethyl phosphite (19.94 g, 0.12 mol) is boiled for 3 h in 500 ml dry xylene in an ambience of dry argon, or nitrogen. The volatile components are evaporated in vacuum and the oily residue is passed first through florisil and then through a silica-gel column: 3-(2,5-dioxo-4-imidazolidinyl)-2-propenylphosphonic acid diethyl ester (**3**): $C_{10}H_{17}N_2O_5P$; 14.84 g (53.7%); IR (cm^{-1}) 3350—3200, 3030, 1750—1690, 1300, 1255, 1110—980, 865, 630; ^{1}H NMR (DMSO-d_6): δ=1.18 and 1.36 (6H, t, J=7 Hz, $OCH_2C\underline{H}_3$X2), 2.80 (2H, m, PCH_2), 3.50 and 3.62 (4H, q, $OC\underline{H}_2CH_3$X2), 4.18 (1H, d, J=8Hz, CHN), 5.62 and 6.12 (2H, m, C<u>H</u>=C<u>H</u>), 7.52 and 9.60 (2H, br., NHX2); MS, *m/z* Calcd/Found: 276.31/276; % C, H, N Calcd/Found: 43.48/43.56, 6.70/6.93,

10.14/10.16; mp 183—186 °C; R_f: 0.33 ($CHCl_3$: MeOH=9 : 1) and 0.83 (*n*-BuOH : AcOH : H_2O=9 : 1 : 1).

Enzyme Hydrolysis of the Phosphonic Diester 3. A homogeneous mixture of the substrate **3** (27.63 g, 0.1 mol) and the emulgator "Tween-80" is added to an aqueous buffer solution (500 ml, pH 8.8) of phosphodiesterase I (7 mg), tempered at 37 °C. Stirring is kept up for 6 h at the same temperature. After acidification, condensation and cooling, the following product is filtered out: 3-(2,5-dioxo-4-imidazolidinyl)-2-propenylphosphonic acid (**4**): $C_6H_7N_2O_2P$; 21.24 g (97.4%); IR (cm^{-1}) 2860—2430 (PO_3H_2); ^1H NMR (D_2O-NaOD): δ=2.98 (2H, m, PCH_2), 5.70 and 6.21 (2H, m, CH=CH-); MS *m/z* Calcd/Found: 218.11/218; % C, H, N Calcd/Found: 33.04/32.84, 3.24/3.56, 12.84/12.96; mp about 250 °C (decomp); R_f: 0.42 (*n*-BuOH : AcOH : H_2O=9 : 1 : 1).

Synthesis of Didehydronorvaline (5).[2] *p*-Toluenesulfonyl chloride (20.98 g, 0.11 mol) is gradually added for 1 h to 300 ml 80% aqueous ethanol, containing sodium hydroxide (10 mg) and the hydantoin (**4**) (21.81 g, 0.1 mol). After 30 min the reaction mixture is evaporated in vacuum to dryness, 20 g potassium hydroxide in 110 ml water are added and the mixture is heated for 30 min in a water bath. After acidification, heating for 30 min and elution through Amberlite IR-120 resin with 0.1 M (1 M=1 mol dm^{-3}) HCl, the following product is isolated: 3,4-didehydro-5-phosphono-DL-norvaline (**5**): $C_5H_{10}NO_5P$; 11.45 g (58.7%); spectral data coincided with those of an authentic sample; MS *m/z* Calcd/Found: 195.11/195; % C, H, N Calcd/Found: 30.78/31.01, 5.17/5.02, 41.00/39.78.

Synthesis of the Ethyl Ester 6. Thionyl chloride (13.09 g, 0.11 mol) is added dropwise to a continuously stirred suspension, cooled to 5 °C, of didehydronorvaline (**5**) (19.81 g, 0.1 mol) in 200 ml ethanol, containing 5 ml *N,N*-dimethylformamide. A swift current of dry argon, or nitrogen, is simultaneously passed through the reaction mixture. The cooling bath is replaced with a warmed-up heater. Gasses are removed from the system by a continuous flow of inert gas. After 5 min of boiling (highly-effective condenser), complete dissolution is observed. The product crystallizes after cooling: 3,4-didehydro-5-phosphono-DL-norvaline ethyl ester hydrochloride (**6**): $C_7H_{14}NO_5P \cdot HCl$; 20.31 g (91.0%); IR (cm^{-1}) 1750 (CO), 1550 (NH_3^+);% C, H, N Calcd/Found: 36.67/36.99, 6.32/6.11, 6.28/6.35; mp 210 °C (decomp).

Enzyme Hydrolysis and Separation of Optical Antipodes of the Ester 6. A mixture of the ester **6** (22.31 g, 0.1 mol) and α-chymotrypsin (6 mg) is stirred for 6 h at 25 °C in an aqueous buffer medium (pH 7.8, 500 ml). After acidification, evaporation to dryness and extraction with boiling ethanol, the following products are fractionally isolated: 3,4-didehydro-5-phoshono-D-norvaline ethyl ester hydrochloride D-**6**: $C_7H_{14}NO_5P \cdot HCl$; 9.00 g (96.4%); spectral data coicide with those of DL-**6**; mp: approx. 220 °C (decomposition); $[\alpha]_D^{20}$ +55.3°, (*c* 0.1, MeOH): 3,4-didehydro-5-phosphono-L-norvaline (L-**5**): $C_5H_{10}NO_5P$; 9.47 g (97.1%); spectral data identical with those of DL-**5**; mp 188—190 °C; $[\alpha]_D^{20}$ −53.3 (*c* 1, H_2O).

Hydrolysis of the Ester D-6. The ester D-**6** (22.32 g, 0.1 mol) is heated for 30 min at 40—45 °C in aqueous NaOH (2 M, 200 ml). After acidification, evaporation in vacuum to dryness and crystallization from ethanol, the following product is isolated: 3,4-didehydro-5-phosphono-D-norvaline (D-**5**): $C_5H_{10}NO_5P$; 17.57 g (90.1%); spectral data identical with those of D- and DL-**5**; $[\alpha]_D^{20}$ −53.3° (lit,[2] +51.4°), (*c* 1, H_2O).

Synthesis of the Triester 7 and Tetrahydro-1,2-azaphosphorine (8). Portions of phosphorus pentachloride (68.72 g, 0.33 mol) in 200 ml dry tetrachloromethane are added for 1 h at 80 °C to 300 ml dry tetrachloromethane, containing D-, DL-, or L-didehydronorvaline (**5**) (19.51 g, 0.1 mol). A current of dry argon, or nitrogen, is simultaneously passed through the suspension. After 30 min, the reaction mixture is evaporated in vacuum to dryness and mixed, first with 500 ml absolute ethanol, and then with 50 ml triethylamine. It is then boiled for 30 min, filtered and evaporated in vacuum to dryness. The residue is dissolved in dry chloroform and saturated with dry hydrogen chloride. The resultant residue is filtered and recrystallized from ethanol: 3,4-didehydro-5-diethoxyphosphinyl-(D-, DL-, L-)norvaline ethyl ester hydrochloride (**7**): $C_{11}H_{22}NO_5P \cdot HCl$; 18.72 g (59.3%); IR ($cm^{-1}$) 3020, 1740, 1525, 1255, 1110—975; ^1H NMR ($CDCl_3$, free base) δ=1.2—1.9 (9H, m, CH_3×2), 2.22 (2H, s, NH_2), 2.80 (2H, m, PCH_2), 3.20—3.60 (6H, m, OCH_2×3), 4.82 (1H, d, *J*=7 Hz, CHN), 578 and 6.20 (2H, m, CH=CH); MS *m/z* Calcd/Found 279.30/279; % C, H, N Calcd/Found: 41.85/42.01, 7.34/7.12, 4.44/4.69; R_f 0.55 (DMF: $CHCl_3$: MeOH=5 : 1 : 2); mp D-, DL-, D-: 140—146 °C (decomp); $[\alpha]_D^{20}$ +59.3°, (*c* 0.1, MeOH).

The filtrate, left after the filtration of the triester **7**, is evaporated in vacuum and eluted in a silica-gel column (eluent chloroform:hexane=5:2). Fractions of 50 ml each are collected. The fourth, fifth, and sixth fractions are combined, evaporated and passed through the columun: D-, DL-, L-2-ethoxy-6-ethoxycarbonyl-1,2,3,6-tetrahydro-1,2-azaphosphorine-2-oxide (**8**): $C_9H_{16}NO_4P$; 2.61 g (11.2%); IR (cm^{-1}) 1760, 1390, 1250, 920, 840; ^1H NMR ($CDCl_3$): δ=1.18 and 1.32 (6H, t, OCH_2CH_3×2), 2.46 (2H, m, PCH_2), 3.4—3.9 (4H, m, OCH_2CH_3×2), 4.62 (1H, d, *J*=8 Hz, CHCO), 5.82 and 6.35 (2H, m, CH=CH); MS *m/z* Calcd/Found: 233.20/233; % C, H, N Calcd/Found: 46.35/46.28, 6.91/7.07, 6.01/5.79; R_f: 0.72 ($CHCl_3$: *n*-C_6H_{14}=5 : 2); mp D-, DL-, L-: 86—90 °C; $[\alpha]_D^{20}$ +78.2° and −77.6°, (*c* 0.1, MeOH).

Synthesis of *N*-Trifluoroacetyl-(D-, DL-, L-)didehydronorvaline (9). The triester **5** (D-, DL-, or L-) (19.51 g, 0.1 mol) and *S*-ethyl trifluorothioacetate (24.72 g, 0.16 mol) are shaken for 8 h at room temperature in 100 ml 2 M NaOH, 600 ml borate buffer and 500 ml chloroform. The layers are separated and the aqueous layer acidified and extracted with chloroform (3×20 ml) and the combined organic extracts are dried over anhydrous magnesium sulfate and distilled in vacuum to dryness. The product is isolated as a noncrystallizing oil. For analytical purposes, purification is carried out by passing through a silica-gel column (eluent dioxane: chloroform=5 : 3): *N*-trifluoroacetyl-3,4-didehydro-5-diethoxyphosphinyl-(D-, DL-, L-)norvaline ethyl ester (**9**): $C_{13}H_{21}F_3NO_6P$; 28.87 g (average for the three forms, 79.6%); IR (film, cm^{-1}) 1760, 1520, 1210, 1110—860; % C, H, N Calcd/Found: 41.61/41.33, 5.64/5.81, 3.73/4.12; R_f: 0.65 (dioxane : chloroform=6 : 1); mp decomposes upon attempts at distillation; $[\alpha]_D^{20}$ +72.3° and −70.6°, (*c* 0.1, MeOH).

Enzyme Hydrolysis of the Didehydronorvaline (9). A homogeneous mixture of the ester **9** (18.77 g, 0.05 mol) and emulgator "Tween-80" is added to a buffer medium (pH 10.4, 800 ml), containing alkaline phosphatase (10 mg on agarose) and tempered at 37 °C. The mixture is stirred for 6 h and the enzyme is removed. The mixture is acidified, evaporated in vacuum to dryness and extracted with chloroform. The organic extract is dried over anhydrous magne-

sium sulfate and distilled in vacuum to dryness. The oily residue slowly crystallizes after a prolonged period in a refrigerator on hexane: *N*-trifluoroacetyl-3,4-didehydro-5-ethoxyhydroxyphosphinyl-(D-, DL-, L-)norvaline ethyl ester (**10**): $C_{11}H_{17}F_3NO_6P$; 16.86 g, (97.1%); IR (cm^{-1}) 2860—2420, 1760, 1540, 1260, 1110—840; ^1H NMR ($CDCl_3$): δ=1.13 and 1.30 (6H, t, $OCH_2C\underline{H}_3\times2$), 2.95 (2H, m, PCH_2), 4.1—4.4 (5H, m, $OC\underline{H}_2CH_3\times2$, C<u>H</u>NH), 5.38 (1H, m, CH=CHCH$_2$), 6.30 (2H, m, CH=C<u>H</u>CH$_2$, N<u>H</u>), 10.2—10.6 (1H, br., POOH); MS *m/z* Calcd/Found: 247.23/247; % C, H, N Calcd/Found: 38.05/34.44, 4.93/4.88, 4.03/3.96; R_f: 0.46 (dioxane : chloroform=6 : 1); $[\alpha]_D^{20}$ +76.2° and −73.1°, (*c* 0.1, MeOH); mp D-, DL-, L-: 95—96 °C (decomp).

Enzyme-Substrate Hydrolysis of the Ester 8: Each of the D-, DL-, and L-**8** substrates (23.32 g, 0.1 mol) is subjected to hydrolysis by the above method and using the enzymes α-chymotrypsin and phosphodiesterase I. The substrate L-**8** and α-chymotrypsin (6 mg) afford the product L-**1**, whereas D-, DL-, and L-**8** plus phosphodiesterase I (5 mg) afford the products D-, DL-, and L-**12**: L-2-ethoxy-1,2,3,6-tetrahydro-1,2-azaphosphorine-6-carboxylic acid 2-oxide L-**11**: $C_7H_{12}NO_4P$; 18.94 g (92.3%); IR (cm^{-1}) 3480—3200, 3025, 1760, 1390, 1250, 1110—960, 870, 640; ^1H NMR (DMSO-d_6) δ=1.21 (3H, t, *J*=7 Hz, $OCH_2C\underline{H}_3$), 2.36 (2H, m, PCH_2), 3.43 (2H, q, $OC\underline{H}_2CH_3$), 4.51 (1H, d, *J*=8 Hz, CHCO), 5.68 and 6.33 (2H, m, CH=CH), 10.4—11.0 (1H, br., COOH); MS *m/z* Calcd/Found: 205.15/205; % C, H, N Calcd/Found: 40.98/41.16, 5.90/5.71, 6.83/6.92; R_f: 0.72 (*n*-BuOH : 25%NH_3aq=8 : 1); mp 183—185 °C (decomp); $[\alpha]_D^{20}$ −82.6°, (*c* 0.1, MeOH), D-, DL-, L-6-ethoxycarbonyl-hydroxy-1,2,3,6-tetrahydro-1,2-azaphosphorine 2-oxide-D-, DL-, L-**12**: $C_7H_{12}NO_4P$; 19.92 g (97.1%); 2840—2420 (P-OH); MS *m/z* Calcd/Found: 205.15/205; % C, H, N Calcd/Found: 40.98/40.73, 5.90/6.11, 6.83/6.66; R_f: 0.52 (dioxane : chloroform=5 : 2); mp D-, DL-, L-: 118—121 °C (decomp); $[\alpha]_D^{20}$ +80.3° and −81.6°, (*c* 0.1, MeOH).

Enzyme-Substrate Hydrolysis of the Ester L-11. The above method for enzyme-catalyzed hydrolysis is used with phosphodiesterase I and the ester L-**11** (20.52 g, 0.1 mol) as substrate. The following product is isolated: L-2-hydroxy-1,2,3,6-tetrahydro-1,2-azaphosphorine-6-carboxylic acid 2-oxide L-**13**: $C_5H_8NO_4P$; 17.39 g (98.2%); IR (cm^{-1}) 3530—3200, 2840—2470, 1760, 1400, 1255, 870, 630; ^1H NMR (D_2O-NaOD): δ=2.31 (2H, m, PCH_2), 4.52 (1H, d, *J*=8 Hz, CHCO), 5.76 and 6.38 (2H, m, C<u>H</u>=C<u>H</u>), and three exchangeable protons — N<u>H</u>, PO<u>H</u>, and COOH; MS *m/z* Calcd/Found: 171.11/171; % C, H, N Calcd/Found: 33.91/34.11, 4.56/4.38, 7.91/8.06; R_f: 0.75 (*n*-BuOH : AcOH : H_2O= 9 : 1 : 1); mp approx. 230 °C (decomp); $[\alpha]_D^{20}$ −61.2° (*c* 0.1, 1 M NaOH).

Alkaline Hydrolysis of the Ester D-, DL-, and L-12. Each of the esters D-, DL-, and L-**12** (20.51 g, 0.1 mol) is stirred for 30 min at 40—45 °C in 2 M MaOH (150 ml). The reaction mixture is acidified, evaporated in vaccum to dryness and extracted with boiling ethanol. The esters D-, DL-, and L-**6** and D-, DL-, and L-**13**, respectively, are fractionally isolated in an average yield of 6.60 g (38.6%). Their spectral data are identical with those of the product L-**13**: mp D-, DL-, and L-: approx. 230 °C (decomp) $[\alpha]_D^{20}$ +59.8°, (*c* 0.1, 1 M NaOH).

Mechanistic Study of the Oxidation of Substituted Benzylamines by *N*-Bromoacetamide

Kalyan K. BANERJI
Department of Chemistry, University of Jodhpur, Jodhpur 342 001, India
(Received October 22, 1987)

The oxidation of ortho-, meta-, and para-substituted benzylamines by *N*-bromoacetamide (NBA), to the corresponding benzaldehydes, is first order with respect to NBA and the amine. The pH dependence of the reaction rate suggests that the unprotonated benzylamine is the reductant. There is no effect of added acetamide. NBA itself has been postulated as the reactive oxidizing species. The oxidation of benzylamine-α,α-d_2 exhibited a substantial primary kinetic isotope effect (k_H/k_D=5.81). The rates of the oxidation of the meta- and para-substituted benzylamines were separately correlated in Taft's and Swain's dual substituent parameter equations. For the para-substituted compounds, the best correlation is obtained with σ_I and σ_R^+ values, while meta-substituted compounds correlated best with σ_I and σ_R° values. The reaction constants have negative values. The oxidation rates of the ortho-substituted compounds yield excellent correlation in a triparametric equation involving Taft's σ_I and σ_R^+ values and Charton's steric parameter, V. A mechanism involving transfer of a hydride ion from the amine to NBA, in the rate-determining step has been proposed.

We have been interested in the mechanisms of the oxidation of organic compounds by *N*-haloamides.[1-3] The oxidation of benzylamine also presents interesting possibilities. It is known to yield a large number of products including those resulting from condensation of intermediate products of the oxidation with the parent amine.[4] In addition benzamide, benzaldehyde, and benzoic acid are also formed.[4] Wei and Stewart have studied the oxidation of some substituted benzylamines with permanganate ion.[5] We now report the oxidation of a series of ortho-, meta-, and para-substituted benzylamines by *N*-bromoacetamide (NBA) in buffered alkaline solutions. Attempts have been made to correlate structure and reactivity in this reaction.

Experimental

General. Benzylamine-α,α-d_2 ($PhCD_2NH_2$) was prepared by the reduction of benzonitrile by lithium aluminium deuteride.[6] *m*-Amino- and *o*-nitrobenzylamines were prepared by the reported methods.[7,8] The other amines were commercially available. Borate buffers were used to keep the pH constant. NBA and its aqueous solutions were stored in dark brown bottles. The aqueous solutions of the amines were prepared from the freshly distilled amines and doubly distilled water. The concentrations of the amines were determined by titration with standard hydrochloric acid, using Methyl Red as an indicator.

Product Analysis. Ammonia was obtained in 93% yield by the oxidation of benzylamine at pH 10.6 as shown by partial distillation of the aqueous reaction mixture and titration of the distillate with standard acid. Benzaldehyde was isolated as the 2,4-dinitrophenylhydrazone (DNP).

Freshly distilled benzylamine (5.35 g, 0.05 mol) and NBA (1.4 g, 0.01 mol) were made up to 100 ml in water at pH 10.6. The reaction mixture was allowed to stand for ca. 8 h to ensure completion of the reaction. It was treated with an excess (250 ml) of a saturated solution of 2,4-dinitrophenylhydrazine in 2 M HCl (1 M=1 mol dm^{-3}) and kept overnight in a refrigerator. The precipitated DNP was filtered off, dried, weighed, recrystallized, and weighed again. The DNP was identical (mp and mixture mp) with an authentic sample of DNP of benzaldehyde. The yield of the DNP before and after recrystallization were 2.70 g (94%) and 2.52% (88%) respectively. In similar experiments with the other amines, the yields of DNP, after recrystallization, were 84—95%.

Kinetic Measurements. The reactions were studied under pseudo-first-order conditions by keeping a large excess of the amine over NBA. The reaction were carried out in flasks blackened from the outside to prevent any photochemical reaction. Preliminary experiments showed that the reaction is not sensitive to ionic strength (0.05—1.0 M) and hence no attempt was made to keep the ionic strength constant. The reactions were followed at pH 10.6, were the amines are almost completely unprotonated. Corrections were applied to the rate constants for the partial ionization of the amines. The reactions were followed iodometrically for up to 70% of the extent of the reactions. The psudo-first-order rate constant, k_1, was determined from the linear plots of log[NBA] vs. time. The second order rate constant, k_2, was obtained from the relation $k_2=k_1/$[benzylamine]. Duplicate kinetic runs showed that the rates were reproducible to within ±3%.

Results

The rate laws and other data were obtained for all the compounds investigated. Since results are similar only representative data are reproduced here.

The oxidation of the amines by NBA results in the formation of corresponding benzaldehydes and ammonia (Eq. 1).

$$PhCH_2NH_2 + MeCONHBr + H_2O \rightarrow PhCHO + NH_3 + HBr + MeCONH_2 \quad (1)$$

Rate Laws. The reactions are found to be of first order with respect to NBA and the amine (Table 1). The rate of oxidation of benzylamine increases with increasing pH but the dependence is not linear and the rate reaches a limiting value of $k_2=3.40\times10^{-2}\ M^{-1}\ s^{-1}$ at pH 11.3. The limiting rate is represented by k'. A plot of the rate constant vs. pH produces a typical ionization curve (Fig. 1).

Table 1. Rate Constants of the Oxidation of Benzylamine by NBA at 298 K, pH 10.6

$[PhCH_2NH_2]$	10^3[NBA]	10^4k_1
M	M	s^{-1}

10^4k_H=41.6±0.1 M^{-1} s^{-1}
10^4k_D=7.14±0.09 M^{-1} s^{-1}
k_H/k_D=5.81±0.06
k_H and $k_D=k_1$/[amine]

Table 3. Effect of Acetamide on the Oxidation of Benzylamine by NBA, ([NBA]=0.005 M, [amine]=0.10 M, pH=10.6, Temp 298 K)

10^2[acetamide]/M	0	2.5	4.0	5.0	7.5	10.0
$10^4k_1/s^{-1}$	4.21	4.12	4.30	4.40	4.30	4.12

The curve in Fig. 1 indicates that neutral benzylamine is the reactive reducing species. In that case, it has been shown[5] that a plot of $\log[k_2/(k'-k_2)]$ vs. pH, where k' is the rate maxima, should be linear with a unit slope, whose intercept is the pK_{BH^+} of the benzylammonium ion. Figure 2 presents the plot (r=0.9981, slope=1.02±0.02), the pK_{BH^+} of benzylamine is 9.45±0.02, close to the literature value of 9.34.[9]

Kinetic Isotope Effect. To ascertain the importance of the cleavage of α-C-H bond in the rate-determining step, the oxidation of $PhCD_2NH_2$, was studied. The results showed the presence of a substantial primary kinetic isotope effect (Table 2).

Effect of Acetamide. The rate of the reaction is not affected by the addition of acetamide (Table 3).

Effect of Substituents. The rates of the oxidation of benzylamine, nine para-substituted, ten meta-substituted, and ten ortho-substituted benzylamines were

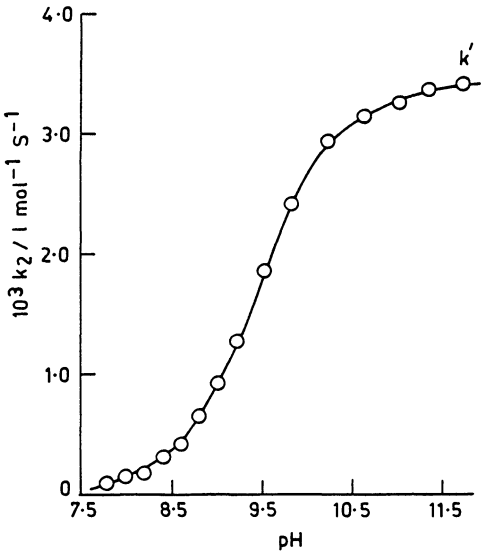

Fig. 1. Dependence of the rate of the oxidation of benzylamine on pH; temp 293 K.

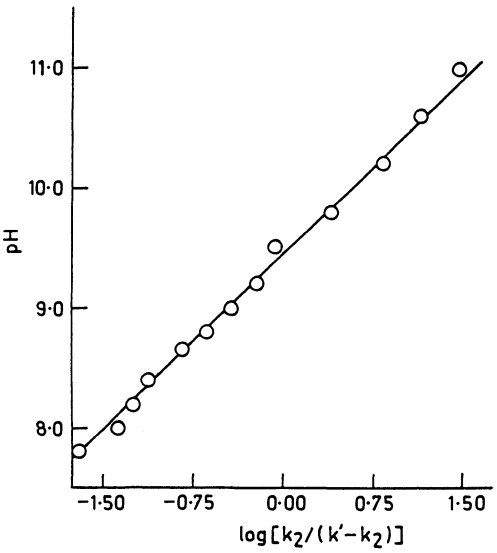

Fig. 2. Plot of pH against the function log $[k_2/(k'-k_2)]$ for the oxidation of benzylamine by NBA.

determined at different temperatures and the activation parameters were evaluated (Table 4).

Discussion

The linear correlation between log k_2 at 288 K and 308 K (r=0.9977, slope=0.8574) for the oxidation of the 30 amines shows that all the amines are oxidized by the same mechanism.[10] The value of isokinetic temperature is 529 K.

N-Haloamides are known to hydrolyzed and/or disproportionate in aqueous solutions to give hypohalous acids,[1-3] and hypohalous acids have been proposed as the reactive species in many reactions [1-3,11] of *N*-haloamides. However, no effect of the parent

amide on the reaction rate rules out the involvement of such preequilibria in the oxidation process and NBA itself seems to be the oxidizing species in the oxidation of benzylamines.

Correlation Analysis of the Reactivity. (i) Para- and Meta-Substituted Benzylamines: Since the rates of oxidation of the mono-substituted benzylamines failed to show satisfactory correlation with any single substituent parameter equation, the rates were subjected to analysis by Taft's[12] and Swain's[13] dual substituent parameter (DSP) equations. The rates of oxidation of the meta- and para-substituted benzylamines were separately correlated with σ_I and the four different σ_R substituent constants in Taft's equation[12] and with the field and resonance substituent constants of Swain et.al.[13] The results are summarized in Table 5. Both the meta- and para-series of substituted benzylamines meet the minimal basic requirements of substituents for the analysis by DSP equations.[14]

The results show that the rates of para-substituted amines show excellent correlation with σ_I and σ_R^+ values. The correlations with the other three σ_R values and in Swain's equation are relative poor. We have used the standard deviation (SD), coefficient of multiple correlation (R), and f as the measure of the goodness of fit. f has been defined by Dayal et al.[12] as

Table 5. Correlation of the Rates of Oxidation of Substituted Benzylamines by NBA with Dual Substituent Parameters[a]

Substituent constant	Para-substituted						Meta-substituted					
	ρ_I	ρ_R	R	SD	f	n	ρ_I	ρ_R	R	SD	f	n
σ_I, σ_R°	−1.57	−3.16	0.9364	0.323	0.42	10	−1.76	−1.02	0.9951	0.053	0.09	11
σ_I, σ_R^{BA}	−1.62	−2.62	0.9617	0.252	0.33	10	−1.76	−0.70	0.9849	0.093	0.15	11
σ_I, σ_R^-	−1.17	−1.81	0.9136	0.351	0.72	9[b]	−1.67	−0.70	0.9890	0.084	0.13	10[b]
σ_I, σ_R^+	−1.43	−1.73	0.9984	0.053	0.07	10	−1.71	−0.38	0.9746	0.121	0.20	11
Swain et al.[c]	−0.36	−0.89	0.9914	0.120	0.16	10	−0.93	−0.30	0.9784	0.112	0.18	11

a) Temp 298 K, R=coefficient of multiple correlation; SD=standard deviation; f=SD/root mean squares of log k/k_0; n=No. of data points; σ_I and σ_R values are from Ref. 12. b) Data of NHCOMe substituted compounds not considered, no σ_R^- value is available. c) Field and resonance constants are from Ref. 13.

f=SD/RMS, where RMS is the root mean square of the data points (here log k/k_0). The comparison of f values shows that f is smaller for σ_R^+ scale than those for other scales by factors of ca. 3 to ca. 10. Therefore, it is apparent that the rates of the oxidation para-substituted benzylamines by NBA correlate best with σ_I and σ_R^+.

The rates of meta-substituted benzylamines show excellent correlation with σ_I and σ_R°, though the discriminating factor for the precision of fit with the other σ_R scales or with Swain's equation is not as sharp as in the case of para-substituted compounds. The comparison of f values shows that f is smaller for σ_R° scale than those for other scales by factors of ca. 1.5 to ca. 2.5. This agrees with the observation of Ehrenson, et al.[15] that the correlation of meta-substituted compounds is generally best with s_R° scale and meta-substituted compounds are less discriminating.

The reaction constants and the statistical data at different temperature are given in Table 6. The values of λ^p (ca. 1.24) showed that the oxidation of para-substituted benzylamines is more susceptible to the resonance effect than to the field effect. The selectivity of the reaction is decreased at higher temperature, but this decreases is of similar order for both the field and resonance effects resulting in the almost constant value of λ^p at different temperature.

In the oxidation of the meta-substituted compounds, the value of λ^m is ca. 0.56 indicating greater importance of the field effect. In the case meta-substituted compounds there is a small increase in the magnitude of the reaction constants with an increase in the temperature but this increase is of similar order for both the effects, reflected in the almost constant value of λ^m at different temperatures, the ratio of λ^m/λ^p is ca. 0.45.

(ii) Ortho-Substituted Benzylamines. It was found that the rates of oxidation of ortho-substituted benzylamines failed to yield any significant correlation with either Taft's polar or steric substituent constants.[16] The rates were, therefore, analyzed using Charton's method.[17] The rates were correlated using Eqs. 2 and 3, where σ_I, σ_R, and V are field, resonance and steric substituent constants and the values used were those compiled by Aslam et al.[18] h is the intercept term. α, β, and ϕ represent the susceptibility of the reaction to field, resonance, and steric effects respectively.

The results of correlation analysis in the terms of Eq. 2 are given in Eq. 4.

$$\log k_{ortho} = \alpha\,\sigma_I + \beta\,\sigma_R + h \quad (2)$$

$$\log k_{ortho} = \alpha\,\sigma_I + \beta\,\sigma_R + \phi V + h \quad (3)$$

$$\log k_2 = -0.85\,\sigma_I - 0.66\,\sigma_R - 1.74 \quad (4)$$

$$R = 0.5001;\ \mathrm{SD} = 0.48;\ n = 11.$$

where n is number of data points.

In the multiple linear regression using Eq. 2, the coefficient of correlation is poor and the standard deviation is high. The lack of a significant correlation with Eq. 2 leads to the conclusion that electric effects alone are not sufficient to account for the ortho-substituent effect in this reaction.

The correlation in the terms of Eq. 3 was performed assuming both orthogonal and planar conformations for NO_2 and COOMe groups. It was observed that the correlation was better with planar conformation of both the groups. The results Eq. 5 showed that the correlation with Eq. 3 is also not good.

$$\log k_2 = -2.19\sigma_I - 2.15\sigma_R + 1.29\,V - 2.43 \quad (5)$$

$$R = 0.9599;\ \mathrm{SD} = 0.17;\ n = 11.$$

It may be recalled that the rates of oxidation of para- and meta-substituted benzylamines showed excellent correlation in Taft's[12] DSP equation with σ_R^+ and σ_R° constants respectively. Therefore, the rates of the oxidation of ortho-substituted benzylamines were correlated in triparametric equations using Taft's σ_I, $\sigma_R^+/\sigma_R^\circ$ and Charton's steric parameters. The results showed that excellent correlations were obtained with Taft's σ_I, σ_R^+, and Charton's V values. The reaction constants and the statistical data are recorded in Table 7. The series of ortho-substituted benzylamines also meet the basic minimal requirements for the analysis by Taft's equation.[12]

The behavior of o-NO_2 and o-COOMe is consistent

Table 6. Temperature Dependence of the Reaction Constants

Temp / K	ρ_I	ρ_R[a]	λ[b]	R	SD	f

Table 7. Temperature Dependence of the Reaction Constants of the Oxidation of Ortho-Substituted Benzylamines by NBA

Temp / K	ρ_I	ρ_R^+	ϕ	R	SD	p_S	p_R
288	−1.81	−1.18	1.08	0.9988	0.028	39.5	26.5
293	−1.77	−1.15	1.04	0.9990	0.025	39.4	26.3
298	−1.72	−1.12	1.02	0.9987	0.030	39.4	26.4
303	−1.69	−1.09	0.99	0.9989	0.025	39.2	26.3
308	−1.64	−1.07	0.96	0.9988	0.026	39.5	26.2

with their planar conformation.

The significance of the correlation, tested by the F-test,[19] is >99.9%. Similarly the confidence level for the significance of σ_I, σ_R^+, and V terms, obtained by the Student's t-test,[19] is > 99.9%. This indicates the operation of significant field, resonance, and steric effects in the reaction.

To test the significance of the three substituent constants, multiple linear regression analyses were carried out with Taft's σ_I and σ_R^+, Taft's σ_I and V, and with σ_R^+ and V. The absence of significant correlations (Eqs. 6—8) showed that all the three σ_I, σ_R^+, and V substituent constants are significant.

$$\log k_2 = -0.79\sigma_I - 0.60\sigma_R^+ - 1.84 \quad (6)$$
$$R = 0.6518;\ \mathrm{SD} = 0.42;\ n = 11$$
$$\log k_2 = -1.39\sigma_I + 0.46V - 1.78 \quad (7)$$
$$R = 0.5731;\ \mathrm{SD} = 0.45;\ n = 11$$
$$\log k_2 = -0.97\sigma_R^+ + 0.58V - 2.61 \quad (8)$$
$$R = 0.7366;\ \mathrm{SD} = 0.37;\ n = 11$$

There is no significant colinearity between Taft's σ_I and V, σ_R^+ and V, and between Taft's σ_I and σ_R^+ (r= 0.4694, 0.3029, and 0.1076) for the eleven substituents.

The regression coefficients of σ_I and σ_R^+ terms are negative indicating that electron-releasing groups accelerate the reaction. The positive regression coefficient for the steric term indicates that the reaction is subject to steric acceleration by the ortho-substituents. The contribution of the resonance effect[17] to the total polar effect of the ortho-substituents was calculated using Eq. 9.

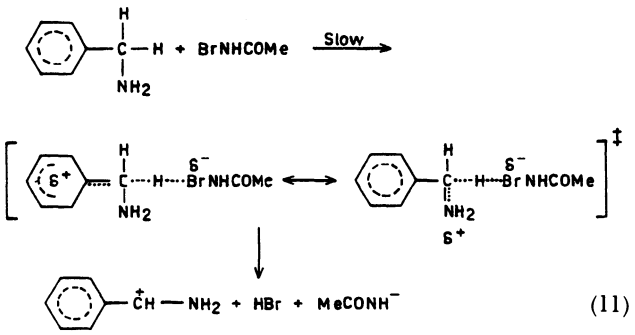
$$p_R = \frac{100 \times |\rho_R^+|}{|\rho_I| + |\rho_R^+|} \quad (9)$$

The contribution of steric parameter[17] to the total effect of the substituents, p_S, was determined using Eq. 10.

$$p_S = \frac{|\phi| \times 100}{|\rho_I| + |\rho_R^+| + |\phi|} \quad (10)$$

The values of p_R and p_S are also listed in Table 7. The values of p_R is ca. 39%. The value of p_R for the para-substituted compounds in ca. 55%. This shows that the balance of field and resonance effect is different for ortho- and para-positions, resonance effects being less pronounced in the former case. This may be due to the twisting away of the aminomethyl group from the plane of the benzene ring. The value of p_S shows that there is considerable steric effect in this reaction.

Mechanism. The kinetics are consistent with a mechanism in which as molecule each of the amine and NBA participate in the rate-determining step. The observed kinetic isotope effect confirms the rupture of the α-C-H bond in the rate-determining step. The large negative polar reaction constants and the correlation of the rates of para- and ortho-substituted benzylamines with σ_R^+ point to a transition state in which there is a strong resonance interaction between the substituent and a developing positive charge. This suggests the transfer of a hydride ion from the methylene group to the oxidant. There is no doubt that the amino group strongly activates the adjacent methylene and this supports the idea of hydride transfer. Thus the following mechanism may be proposed Eqs. 11—13.



$$PhCHNH_2 + H_2O \xrightarrow{\text{Fast}} PhCHO + NH_4^+ \quad (12)$$

$$MeCONH^- + H^+ \xrightarrow{\text{Fast}} MeCONH_2 \quad (13)$$

The steric acceleration of the reaction may be explained on the basis of high ground state energy of the sterically crowded amines. Since the crowding is relieved in the product aldehyde as well as the transition state leading to it, the transition state energy of the crowded and uncrowded amines do not differ much and steric acceleration, therefore, result.

It is of interest the compare the oxidations of benzylamine by permanganate ion[5] and NBA. The rates of oxidation of 8 (out of 11 studied) meta- and para-substituted benzylamines by permanganate[5] correlate with σ^+ values, the reaction constant, ρ, being −0.28. The small value of ρ suggested the possibility of a one-electron oxidation. In the oxidation by NBA, the rates of 30 substituted benzylamine exhibited large negative polar reaction constants. A strong resonance interaction between the substituent and a developing positive charge, in the transition state, is also indicated. Hence a one-electron oxidation can be excluded.

Conductivity of Iron(II) Sulfate in Aqueous Solution at Various Temperatures

Eiji KUBOTA,* Yoshiaki MOCHIZUKI, and Masatoki YOKOI
Department of Chemistry, Faculty of Science, Shinshu University, Asahi, Matsumoto 390
(Received March 24, 1988)

Synopsis. The molar conductivity of iron(II) sulfate, $FeSO_4$, in water was measured in the temperature range 10—35 °C. Data were analyzed by the Quint-Viallard equation, and the resulting ion association constant, K_A, was applied to the Bjerrum equation to determine the contact ion size, R_B. The limiting ionic molar conductivity of iron(II) at 25 °C is $\lambda_0(1/2Fe^{2+})=53.8$ S cm^2 mol^{-1}. Thermodynamic properties of ion association reactions are $\Delta G^\circ_{298}=-13.7$ kJ mol^{-1}, $\Delta H^\circ=9.7$ kJ mol^{-1}, and $\Delta S^\circ_{298}=78.0$ J K^{-1} mol^{-1}.

Divalent metal sulfates have long been utilized as the most typical 2 : 2 type of electrolytes for the study of aqueous electrolyte solutions.[1-6] Regarding iron(II) sulfate, however, precise conductivity data of its aqueous solution are not available, except the work of Demassieux and Fedroff[3] at 25 °C. Conductivity data for the other iron(II) salts are not available either in the literature. This is probably because the salts undergo oxidation markedly on exposure to atmospheric oxygen. Thus we attempted to redetermine molar conductivities of iron(II) sulfate in aqueous solution at several temperatures by avoiding oxidation as carefully as possible.

Experimental

The preparation and purification of $FeSO_4$ were conducted in nitrogen atmosphere. A reagent grade $FeSO_4$ was recrystallized from water by adding a small amount of ethanol. The purified salt was dried at room temperature to obtain crystals of heptahydrate. The crystals were pulverized before use. Conductivity water was prepared by distilling water three times, and the distilled water was allowed to pass through a mixed bed ion-exchange resin shortly before use.

Measurements were made at a frequency of 1 kHz with a linear type bridge,[7] temperature variation being ±0.003 °C. The conductivity cell was equipped with a platinized electrode, and the cell constant was 0.99074±0.00001 cm^{-1} at 25 °C. No detectable change in the cell constant was observed in the temperature range 10—35 °C.

On starting each run, a nitrogen gas stream was bubbled gently through the conductivity water in the cell for about 30 to 40 min, and the conductivity of the water was measured after it reached an equilibrium value, which was less than 1.0×10^{-7} S cm^{-1}. The concentration (10^{-4} to 10^{-3} mol dm^{-3}) of $FeSO_4$ was adjusted by direct dissolution of pulverized specimen into the cell by utilizing Hawes-Kay's cup-dropping device[8] in an atmosphere of nitrogen. The variation in conductivity of the solution with time was 0.02% or less in 5 h after the preparation of the solution.

Results and Discussion

Conductivity data of aqueous solutions in the temperature range 10—35 °C are given in Table 1.

The conductivity data were analyzed by the Quint-Viallard conductivity theory in the form of Eq. 1:[9]

$$\Lambda=\gamma[\Lambda_0-Sc^{1/2}\gamma^{1/2}+Ec\gamma\log c\gamma+J_1c\gamma-J_2c^{3/2}\gamma^{3/2}], \quad (1)$$

$$K_A=(1-\gamma)/c\gamma^2f_\pm^2, \quad (2)$$

$$-\log f_\pm=Ac^{1/2}\gamma^{1/2}/(1+B\mathring{a}c^{1/2}\gamma^{1/2}), \quad (3)$$

where c is the concentration, γ is the degree of dissociation, K_A is the ion association constant, and $f_\pm$ is the mean ionic activity coefficient given by the extended Debye-Hückel theory of Eq. 3.[10] In Eq. 3, A and B depend upon solvent properties, and $\mathring{a}$ is the ion size

parameter. The coefficients J_1 and J_2 are functions of ion size parameter δ_{J2}, and S, E, and J contain solvent properties.[10] The ion size parameters appearing in the J_1 and $f_\pm$ terms were fixed as equal to Bjerrum's q values, and the best fit δ_{J2} values for J_2 were calculated.[11] Table 2 shows the best fit parameters at the minimum value of $\sigma\Lambda$. $\sigma\Lambda(\%)$ is defined as

$$\sigma\Lambda=[\sum(\Lambda_{obsd}-\Lambda_{calcd})^2/(N-3)]^{1/2}, \quad (4)$$

where N is the number of experimental points.

When a conductivity equation containing a $c^{3/2}$ term is applied, the fitting of the data is generally better, but the ion size parameter δ_{J2} for the 2:2 type electrolyte is usually as large as 10—20 Å. In the present work δ_{J2} of 11—13 Å was obtained.[11] If one assumes the validity of Bjerrum's Eq. 5, the contact ion size R_B can be calculated from the resulting K_A:[12,13]

$$K_A(\text{calcd})=\frac{4\pi N}{1000}\int_{R_B}^{q} r^2\exp(e^2/rDkT)\mathrm{d}r. \quad (5)$$

The results are also given in Table 2. The parameters, Λ_0 and K_A increase with increasing temperature. The limiting molar conductivity of Fe^{2+} ion at 25 °C is obtained as λ_0 ($1/2\ Fe^{2+}$)=53.8 S $cm^2\,mol^{-1}$ by subtracting the value λ_0 ($1/2SO_4^{2-}$)=80.0 of SO_4^{2-} ion from the Λ_0 value.[10] Demassieux and Fedroff's data[3] give λ_0 ($1/2Fe^{2+}$)=49.8. Table 3 shows a comparison with other divalent transition metal ions. The ion size parameter δ_{J2} has a relatively large value, more than 10 Å, whereas R_B has a substantially reasonable value (the sum of the ionic crystal radii is ≈3.3 Å).[15] The log K_A-$1/T$ plot gives a good linearity. The resulting thermodynamic properties of ion association reaction are shown in Table 4 with data of other sulfate solutions. It can be seen that the properties of $Fe^{2+}\cdot SO_4^{2-}$ are in parallel with those of the other sulfates, though the absolute values are a little larger than the others. The positive ΔS° has been considered as due to the decreased orientation of water molecules when the ion-pair forms.[16]

The authors wish to thank the staffs of the Shinshuu University, Nagoya University, and Tokyo University Computation Centers for the use of the computers. The Photochemical Debromination of Bromocyclopropane in the Presence of Amine

Hideo TOMIOKA* and Osamu INOUE
Department of Industrial Chemistry, Faculty of Engineering, Mie University, Tsu, Mie 514
(Received March 2, 1988)

Synopsis. The irradiation of bromoarylcyclopropanes (**1**) in the presence of tertiary amine resulted in the formation of the debrominated cyclopropanes as a mixture of geometrical isomers, whose ratios were essentially similar regardless of the stereochemistry of the bromide. The reactions were not, however, observed in the absence of amine. The results are interpreted as indicating that the reactions proceed through an initial single-electron transfer to the excited **1**, followed by debromination and hydrogen-abstraction.

Since the early 1980s, the scope of cyclopropane photochemistry has been greatly broadened by electron-transfer-sensitized reactions.[1] However, in most of these reactions cyclopropanes have been used as electron donors, which transfer single electrons to the excited-state acceptors (e.g., cyanoaromatics) to generate cyclopropane cation radicals. Recently we found, however, that some cyclopropanes can act as electron acceptors as well in the excited state when irradiated with an appropriate electron donor (e.g., amines). Thus, the irradiation of an arylcyclopropane bearing electron-withdrawing group in the presence of tertiary amine resulted in the regioselective addition of the amine, which can be explained as proceeding through a single-electron transfer mechanism.[2] As an extension of such works, we studied the photochemistry of halocyclopropanes in the presence of amine and found that bromocyclopropanes underwent efficient photodebromination,[3] most probably via single-electron transfer.

The irradiation of *r*-1-bromo-1,*t*-2-diphenylcyclopropane (**1a**) in acetonitrile or cyclohexane with a 300 W Hg lamp through a Pyrex filter did not result in the formation of any appreciable products, more than 95% of the starting compound being recovered unchanged even after a 16 h irradiation. In marked contrast, a similar irradiation of **1a** in the presence of a 5 molar excess of triethylamine led to the rapid disappearance of **1a** and the concurrent formation of the debrominated cyclopropanes (**2** and **3**) as a 6.1 : 1 mixture of geometrical isomers, predominantly **2**. Similarly, the irradiation of *r*-1-bromo-1,*c*-2-diphenylcyclopropane with the amine also afforded the debrominated cyclopropanes (**2** and **3**) in an isomer ratio almost identical with that observed in the irradiation of the trans isomer. 1-Bromo-3-methyl-1,2-diphenylcyclopropanes (**1b**) also underwent smooth photo-debromination in the presence of amine, although the yield and stereoselectivity of the reduction decreased considerably.[4] Control experiments showed that the reduction did not occur in the absence of light and that the product cyclopropanes did not isomerize under these conditions.

b: R=Me

In order to get insight into the mechanism of the present photoreduction, we carried out some additional experiments. First, the reactions were found to be somewhat sensitive to the solvent employed, as is summarized in Table 2. Thus, the photodebromination proceeded quite smoothly in acetonitrile, while the reduction was relatively inefficient in cyclohexane. This is, however, in marked contrast with the situation observed[2] in the photochemical addition of amines to electrophilic cyclopropanes, where the reactions did not proceed in any of those solvents listed in Table 2 except acetonitrile. Second, the bromocyclopropane fluorescence was quenched by the amine, indicating that the excited singlet state is involved in the present photoreduction.

The above findings can be better explained in terms of a mechanism involving electron transfer, as is

Table 1. Photodebromination of Bromocyclopropane (**1**) in the Presence of Amine[a]

1	R	1-Br/ 2-Ph	Conv/%[b]	Yield/%[b]		2/3
				2	3

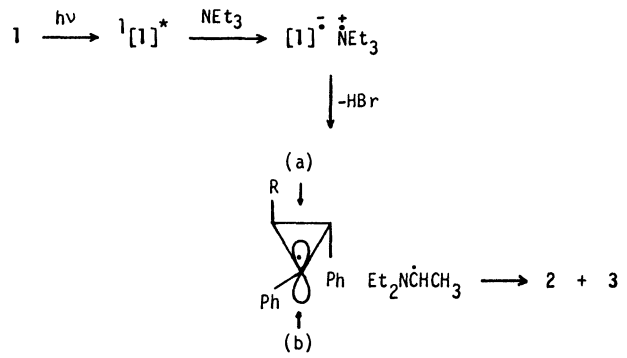

Scheme 1.

summarized in Scheme 1, rather than in terms of simple free-radical mechanism. Thus, **1** is first excited to its singlet state, which accepts an electron from the ground state amine to generate a cyclopropane-anion radical and an amine-cation radical. The cyclopropane anion radical, which had no bromine substituent, underwent efficient protonation by the amine cation radical, resulting in the ring cleavage.[2] The absence of any appreciable formation of such ring-opened products in the present photoreaction implies that the bromocyclopropane anion radical releases bromide, leaving the cyclopropyl radical, before it undergoes protonation. The solvent effects are worthy of comment in this connection. The effects of solvents in the electron-transfer reactions are usually explained in terms of the dissociation of the primary geminate-ion-radical pair, leading to a separated radical ion.[1a] Thus, a high polarity of the medium is usually required to solvate the separated radical ions. The moderate effect of solvents on the present photoreduction is in marked contrast with the fatal effects of solvent on the photoaddition[2] of amine to cyclopropane: this would indicate that the elimination of bromide ion is so efficient as to occur within the primary geminate pair. The abstraction of hydrogen from the resulting α-aminoalkyl radical by the cyclopropyl radical then affords the final products.

The fact that essentially similar isomer ratios are observed, regardless of the stereochemistry of the starting bromide, indicates that the geometry of the radical is planar rather than pyramidal. Apparently the attack of the hydrogen atom from a side (a) opposite to the 2-phenyl group leading to **2** is favored over that from the other side (b) giving **3**, since there is interference between the attacking hydrogen and the 2-phenyl group in the latter case. Obviously, the preference for the formation of **2** will be decreased by the introduction of the 3-methyl group since side (a)-attack is also subjected to steric hindrance by the methyl group, as was observed.

Experimental

Instrumentation. The UV and fluorescence spectra were recorded on a Hitachi 220-S spectrophotometer and a Hitachi MPF-2A spectrofluorometer respectively. The IR spectra were determined with a JASCO A-100 spectrometer, while the ^{1}H NMR spectra were measured on a JEOL JNM-MH-100 NMR spectrometer in CCl_4 with Me_4Si, as the internal reference. The mass spectra were recorded on a Shimadzu QP-1000 mass spectrometer (70 eV). The GC analyses were performed on a Yanagimoto instrument, Model G-80. The GC column A was prepared from 10% SE-30 on Diasolid L (5.0 mm×2.0 m); column B consisted of 5% PEG-20M on Diasolid L (5.0 mm×1.0 m).

Materials. The bromocyclopropanes (**1a** and **b**) were prepared by refluxing phenylbromodiazirine with alkenes (styrene and *trans*-β-methylstyrene respectively) in benzene according to the method of Padwa.[5] Geometrical isomers were separated by column chromatography (silica gel) eluted with ether. The data are show below.

trans-**1a:** Yield, 37%; yellow oil; ^{1}H NMR δ=7.5—6.6 (10H, m), 2.78 (1H, dd), 1.90 (1H, dd), 1.23 (1H, dd).

cis-**1a:** Yield, 42%; yellow oil; ^{1}H NMR δ=7.6—6.9 (10H, m), 2.42 (1H, dd), 1.93 (1H, dd), 1.83 (1H, dd).

trans-**1b:** Yield, 35%; yellowish semisolid; ^{1}H NMR δ=7.1—6.9 (10H, m), 2.46 (1H, bd), 1.69 (1H, d), 1.66 (3H, bs).

cis-**1b:** Yield, 27%; yellow oil; ^{1}H NMR δ=7.5—7.0 (10H, m), 2.11 (1H, d), 2.08 (1H, dq), 1.07 (3H, d).

The debrominated cyclopropanes **2a**[6] and **2b**[7] were prepared according to the reported procedures.

Irradiation for Product Identification. In a typical run, a solution of **1** (1 mmol) and triethylamine (5 mmol) in MeCN (50 cm^3) was placed in a quartz tube and irradiated using a high pressure, 300 W, Hg lamp with a water-cooled quartz jacket. The progress of the reaction was monitored by means of TLC. After irradiation for 5 h, the irradiation mixtures were concentrated on a rotary evaporator, chromatographed on preparative TLC (silica gel), and eluted with chloroform-hexane. The fast-moving fraction was found to contain the debrominated cyclopropanes as a mixture of geometrical isomers.

Irradiation for Analysis Purposes. All the irradiations outlined in the tables were carried out on 10 mM (1 M= 1 mol dm^{-3}) solutions of **1** in a quartz tube with a capacity of 5 cm^3 at 15 °C. The yields were conveniently determined by standard GC techniques, and the identity of the products was confirmed by GC using both A and B columns as well as GC-MS comparison with authentic samples prepared as above.

Stereochemistry of the Reactions of Trimethylgermyl Anions with 4-*t*-Butylcyclohexyl Derivatives

Kunio MOCHIDA* and Tsuyoshi KUGITA
Department of Chemistry, Faculty of Science, Gakushuin University, 1-5-1 Mejiro, Tokyo 171
(Received March 28, 1988)

Synopsis. The stereochemistry of trimethylgermyllithium, -sodium, and -potassium with *cis*- and *trans*-4-*t*-butylcyclohexyl bromides and trimethylstannanes was investigated by ^{1}H NMR spectroscopy. With the 4-*t*-butylcyclohexyl derivatives trimethylgermyl anions gave mixtures of *cis*- and *trans*-4-*t*-butylcyclohexyltrimethylgermanes. These results confirmed that free-radical pathways are important in such reactions.

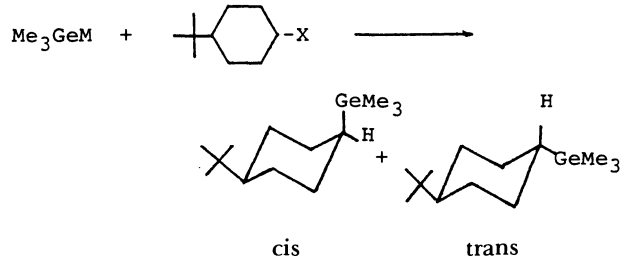
In earlier reports we described the reactions of trialkylgermyl anions with aryl halides[1] and aryltrialkylstannanes.[2] These results revealed that free-radical pathways are important on the basis of the formation of products and radical trapping experiments.

Stereochemical studies also provide valuable mechanistic information concerning substitution reactions of trialkylgermyl anion with cyclohexyl derivatives. Recently, Kitching et al. reported that the reactions of trimethylgermyllithium with 4-methylcyclohexyl bromides gave mixtures of *cis*- and *trans*-4-methylcyclohexyltrimethylgermanes.[3,4] Since 4-methylcyclohexyl bromides exist as an equilibrium mixture of conformations, two steric courses of the reaction, i.e. axial and equatorial approaches of trimethylgermyl groups to cyclohexyl derivatives, cannot be distinguished. The introduction of a *t*-butyl group on the ring prevents a ring inversion. Then, a distinction of such two steric courses of the reaction may be possible.

In this paper, the stereochemical courses of the substitution reactions of trimethylgermyl anions with conformationally stable 4-*t*-butylcyclohexyl derivatives are described.

Results and Discussion

The stereochemistry of the substitution reactions of trimethylgermyllithium, -sodium, and -potassium with *cis*- and *trans*-4-*t*-butylcyclohexyl bromides and trimethylstannanes was examined by ^{1}H NMR spectroscopy.



M=Li, Na, K; X=Br, $SnMe_3$

^{1}H NMR spectroscopy has been widely employed to determine the stereochemistry of 4-*t*-butylcyclohexyl derivatives, particularly, when electronegative groups, such as bromine atom, significantly deshield the methine proton (>C(H)X; X=Br) from the general cyclohexyl absorption and axial protons give rise to a resonance upfield from their counter parts.[5] In germanium and tin compounds, the methine proton (>C(H)Ge≤ and >C(H)Sn≤) would be of rather limited use. However, studies of the ^{13}C and ^{1}H NMR spectra of cyclohexyl and related organogermanes and -stannanes have shown that equatorial trimethylgermyl and trimethylstannyl groups give rise to a resonance upfield from their counterparts.[6]

trans-4-*t*-Butylcyclohexyl bromide (100%), prepared by the triphenylphosphine-bromine procedure for transforming an alcohol, reacted with trimethylgermyllithium to give *cis*- and *trans*-4-*t*-butylcyclohexyltrimethylgermanes in the ratio of 86 : 14. With *cis*-4-*t*-butylcyclohexyl bromide (100%), trimethylgermyllithium gave the corresponding trimethylgermanes (cis/trans=76 : 24).

trans-4-*t*-Butylcyclohexyltrimethylstannane (100%), prepared by a reaction of *cis*-4-*t*-butylcyclohexylmagnesium bromide with trimethylchlorostannane, reacted with trimethylgermyllithium to give *cis*- and *trans*-4-*t*-butylcyclohexyltrimethylgermanes in the ratio of 80 : 20. With *cis*-4-*t*-butylcyclohexyltrimethylstannane (100%), prepared by a treatment of *trans*-4-*t*-butylcyclohexyl tosylate with lithium trimethylstannate, reacted with trimethylgermyllithium to give the corresponding trimethylgermanes (cis/trans=81 : 19).

Reactions of trimethylgermylsodium and -potassium with *cis*- and *trans*-4-*t*-butylcyclohexyl bromides and trimethylstannanes were also examined. These results

Table 1. Reactions of Trimethylgermyl Anions with 4-*t*-Butylcyclohexyl Derivatives

No.	Reactants: Me_3GeM	Reactants:	Product: (isomeric purity/%) cis : trans
	M=	X=	
1	Li	*cis*-Br (100)	76 : 24
2		*trans*-Br (100)	86 : 14
3		*cis*-$SnMe_3$ (100)	81 : 19
4		*trans*-$SnMe_3$ (100)	80 : 20
5	Na	*cis*-Br	75 : 25
6		*trans*-Br	85 : 15
7		*cis*-$SnMe_3$	81 : 19
8		*trans*-$SnMe_3$	82 : 18
9	K	*cis*-Br	77 : 23
10		*trans*-Br	82 : 18
11		*cis*-$SnMe_3$	81 : 19
12		*trans*-$SnMe_3$	81 : 19

are summarized in Table 1.

The *cis*- and *trans*-4-*t*-butylcyclohexyltrimethylgermanes were conformationally stable with trimethylgermyl anions under these reaction conditions.

The counterions and leaving groups have little influence on the ratio of cis and trans products shown in Table 1.

Either cyclohexyl derivatives provided a mixture of the germanes, with the cis isomer being predominant. The present results are consistent with the electron-transfer and free-radical processes previously proposed by Kitching and co-workers, as well as us. Thus, an electron-transfer from trimethylgermyl anions to 4-*t*-butylcyclohexyl derivatives leads to a trimethylgermyl radical and anion radicals of 4-*t*-butylcyclohexyl derivatives. A subsequent dissociation of the 4-*t*-butylcyclohexyl radical from unstable radical anions of 4-*t*-butylcyclohexyl derivatives was followed by a combination with the trimethylgermyl radical. The trimethylgermyl radical approaches the 4-*t*-butylcyclohexyl radical from an axial direction.

Steric effects clearly do not explain the product distributions shown in Table 1. These reaction preferences may be explained by torsional effects.[7,8] A 4-*t*-butylcyclohexyl radical has a chair conformation with a dihedral angle between C-H_{2ax} and the axis of the p orbital of about 20°. For an axial attack of the trimethylgermyl radical (the cis germane), no torsional interactions occur since the hydrogen on the C_1 atom does not eclipse the equatorial hydrogens on the C_2 and C_6 atoms, On the other hand, the reaction of the 4-*t*-butylcyclohexyl radical from an equatorial attack of the germyl radical (the trans germane) results in the development of torsional interactions. Therefore, the cis germane is formed predominantly.

However, S_N2 displacement and four-center processes are not always excluded.

Experimental

NMR Spectra. ^1H NMR spectra were recorded on a JEOL GX-270 at 270 MHz for $CDCl_3$ solutions, and chemical shifts are with reference to internal Me_4Si.

Materials. Me_3GeCl[9] and Me_3SnCl[10] were prepared by established methods. *cis*-[11] and *trans*-4-*t*-Butylcyclohexyl bromides,[7] *cis*- and *trans*-4-*t*-butylcyclohexyltrimethylstannanes,[6] and *cis*- and *trans*-4-*t*-butylcyclohexyltrimethylgermanes[6] were prepared according to methods cited in the literature.

Preparation of Trimethylgermyl Anions. Trimethylgermyllithium, -sodium, and -potassium were prepared from reactions of trimethylchlorogermane with alkali metals in HMPA-ether in the manner described by Bulten and Noltes.[12]

Reactions of 4-*t*-Butylcyclohexyl Derivatives with Trimethylgermyl Anions. In a typical reaction, 10 cm^3 (ca. 0.4 mmol) of trimethylgermyllithium, prepared from a reaction of trimethylchlorogermane and lithium metal in HMPA-ether, was added by syringe to 100 mg (0.4 mmol) of 4-*t*-butylcyclohexyl bromide. Reactions were carried out under an atmosphere of argon at 15 °C for 30 min; then, the system was quenched with water. The ethereal layer was separated and the aqueous layer was extracted with ether. The combined organic layers were dried over sodium sulfate. The germane was obtained by a Varian 920 preparative GLC (6 mm×2 m column, 20% SE30 on celite 545).

Stability of 4-*t*-Butylcyclohexyltrimethylgermane. 4 cm^3 (ca. 1.6 mmol) of trimethylgermyllithium was added by syringe to 50 mg (0.20 mmol) of *trans*-4-*t*-butylcyclohexyltrimethylgermane (98% pure). Reactions were carried out under an atmosphere of argon at 15 °C for 1 h. After hydrolysis of the reaction mixture with water, the ethereal layers were dried over sodium sulfate. The germane product was recovered by a preparative GLC, which was unchanged to have a trans/cis ratio of 98:2.

The authors thank Professor Yasuhiro Nakadaira of the University of Electro-Communications for the JEOL GX-270 MHz NMR spectra.

Chemistry of Germanium Atoms. V. Deoxygenation of Carbonyl Compounds by Germanium Vapor (Atom)

Kunio MOCHIDA* and Yasuhiro MIZUNO
Department of Chemistry, Faculty of Science, Gakushuin University, 1-5-1 Mejiro, Tokyo 171
(Received April 8, 1988)

Synopsis. The co-condensation of thermally evaporated germanium vapor with carbonyl compounds was found to yield olefins and germanium monoxide.

Studies of metal-vapor reactions have been of considerable interest in organometallic chemistry and organic synthesis during the last few decades.[1] With this type method, it is proving to be feasible to synthesize organometallic compounds which would be difficult, if not impossible, to prepare by other methods and to study their reactive intermediates.

The study of a carbon atom as the homologue of a germanium atom has been well investigated, while the chemical properties of a germanium atom have been little studied.[2-7] In studying the reaction of germanium atoms in the condensed phase, we have found that germanium vapor (atom) abstracts oxygen atom from carbonyl compounds.

In this paper, we first describe the deoxygenation of carbonyl compounds by germanium vapor (atom).

Results and Discussion

The reaction of thermally vaporized germanium atoms with carbonyl compounds was examined. The results are summarized in Table 1.

The reaction of germanium atoms with acetone produced propylene (1.0%) and germanium monoxide.[8] Other aliphatic ketones showed a similar behavior; the reactions of germanium atoms with 3-pentanone, 2-pentanone, and 4-heptanone gave 2-pentene (3.6%), 1-pentene (3.6%) and 2-pentene (5.0%), and 3-heptene (2.6%), respectively, shown in Table 1. With cyclohexanone and methylcyclohexanones, germanium atoms gave cyclohexene and methylcyclohexenes (0.4—2.0%) as expected, and germanium monoxide. Other products, in addition to olefins and germanium monoxide, were negligible (>0.1%) in the reactions of germanium atoms with carbonyl compounds.

Table 1. The Reaction of Germanium Atoms with Carbonyl Compounds

Substrate	Product (Yield/%)[a]

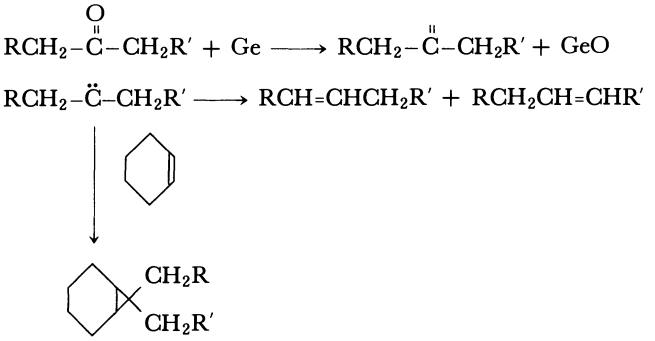
a) GLC yields. Yields of products were determined on the basis of the amount of the germanium metal consumed on the assumption that all of the germanium metal completely reacted with carbonyl compounds.

Blank experiments were carried out under identical conditions. As a result, the products shown in Table 1 were attributable to the interaction of germanium atoms with the starting carbonyl compounds.

The products, olefins shown in Table 1 are strong evidence for the intermediacy of carbenes in the deoxygenation of carbonyl compounds by germanium vapor (atoms). The carbenes are known to rearrange to isomeric olefins.[9,10]

When a mixture of carbonyl compounds and a large excess of cyclohexene as a carbene trapping reagent was used as a matrix for germanium vapor (atoms), no peak of 7,7-dialkylnorcaranes was detected by GC-MS. The yields of the olefins produced were almost



Scheme 1.

constant, despite the presence of cyclohexene. These results indicate that a ketone may complete for germanium atoms in the presence of an olefin and that intramolecular stabilization of alkylcarbenes by product formation is more rapid than an olefin addition, even at −196 °C.

The deoxygenation of oxygen-containing compounds by germanium vapor (atoms) can be rationalized in terms of the large value of the heat of combination of a germanium atom with an oxygen atom (155 kcal mol^{-1}, 1 cal=4.184 J).[11]

Similar results have been reported for the co-condensation of carbon atoms with carbonyl compounds.[12-14]

It is interesting that our results indicate no distinction between thermally generated germanium atoms

and nucleogenetic carbon atoms based on the reaction with carbonyl compounds.

Experimental

The reaction apparatus and conditions employed in this study have been described previously (ca. 1200—1300 °C, 5×10^{-3} Torr, 1 Torr=133.322 Pa).[5] In a typical experiment 0.5 g (6.9 mmol) of germanium metal was evaporated at a rate of ca. 10 mg·min^{-1} while an excess of acetone (ca. 15 cm^3) was co-condensed on the walls of a reaction flask containing an alumina-coated tungsten crucible and a perforated inlet tube through which acetone was introduced as vapor. The reaction flask was immersed in liquid nitrogen during the germanium evaporation. After germanium evaporation and the introduction of acetone were completed, the flask was warmed to room temperature and allowed to stand for 1.5 h.

The reaction mixture was fractionated by low-pressure trap-to-trap distillation on a vacuum line. The products were identified by comparing their GC-MS and retention times on GLC with those of authentic samples. The amounts of products were calculated by GLC with an internal-standard method.

GLC analyses were performed on a Shimadzu GC-4A and 8A gas chromatograph equipped with a 2-m column packed with 20% SE-30 or 20% squalane. GC-MS were obtained with a JEOL JMS-DX 303 mass spectrometer and data analyses were performed on a JMN-DA 5000 mass data system.

The authors thank Mitsubishi Metal Corporation for a gift of germanium metal. This work was supported in part by Grant-in-Aid for Specially Project Research (Nos. 61125004 and 62115003) provided by the Ministry of Education, Science and Culture.

A Michael Reaction Product of Cyclohexylidenemalononitrile

Yoshiharu NAKANO,* Hiroaki YOKOTA, Minoru IGARASHI, and Shoichi SATO†
Depertment of Chemistry, Faculty of Science, Ibaraki University, Mito 310
†The Institute for Solid State Physics, The University of Tokyo, Roppongi 7-22-1, Tokyo 106
(Received March 31, 1988)

Synopsis. Cyclohexylidenemalononitriles dimerize and cyclize to give 3-amino-2,4-dicyano-2-[imino(methoxy)-methyl]spiro[bicyclo[4,4,0]deca-3,5-diene-1,1′-cyclohexane] (**3**). The crystal structure of **3** was determined by an X-ray diffraction method.

Alkylidenecyanoacetates and cyclohexanone undergo a Michael reaction to give cyclization products.[1] We investigated similar Michael-type cycloaddition reactions of alkylidenemalononitriles using sodium methoxide, and found that acyclic alkylidenemalononitriles dimerized and cyclized to give 2-azabicyclo[2.2.2]-octadiene derivatives (**1**)[2] whose crystal structure could be determined by an X-ray diffraction method, as shown in Fig. 1.[3] The bridged compounds release

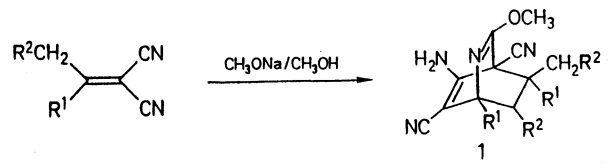

Fig. 1. Reactions of acyclic alkylidenemalononitliles.

alkene to give pyridine derivertives. Contrary to acyclic compounds, cyclohexylidenemalononitrile was found to give an imidate derivertive **3** which was different from expected bridged compounds (Fig. 2). We

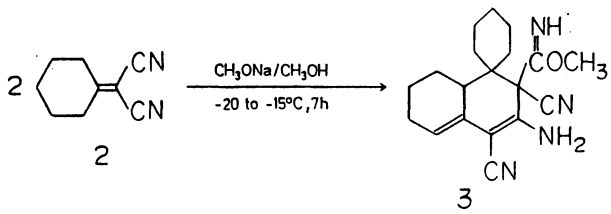

Fig. 2. Reaction of cyclohexylidenemalononitrile.

report here the results of an X-ray crystal diffraction of 3.

Experimental

Cyclohexylidene malononitriles were obtained according to usual Knoevenagel reaction procedure. Sodium methoxide was purchased from Kanto Chemical, and methanol was dried with magnesium methoxide.

Preparation of 3. To a solution of cyclohexylidenemalononitrile (2.92 g, 0.02 mol) in methanol (20 ml) was added sodium methoxide (0.54 g, 0.01 mol) at 5—7 °C with stirring. Stirring was continued for 6 h and then the reaction mixture was left for 6 h at 5—7 °C. The precipitate formed was filtered, washed with cold methanol, dried in vacuo, and recrystallized from acetone to give 0.9 g (yield 30%) of **3** (mp 227—230 °C. Found: C, 69.99; H, 7.35; N, 16.97%. Calcd for $C_{19}H_{24}N_4O$: C, 70.34; H, 7.46; N, 17.27%).

X-Ray Crystallography. A single crystal obtained from ethanol with approximate dimensions of 0.30×0.25×0.43 mm was used for data collection. The crystal data are as follows; $C_{19}H_{24}N_4O$, M_w=324.2, monoclinic, $P2_1/c$, a=16.141 (2), b=9.078(1), c=11.942(2) Å, β=100.45(2)°, U=1720.8(5) Å^3, Z=4, D_x=1.252 g cm^{-3}, D_m=1.258 g cm^{-3}, μ(Mo $K\alpha$)=0.867 cm^{-1}. The crystal was mounted on a Rigaku AFC 5R diffractometer at Institute for Molecular Science and intensity data were collected up to 2θ=60° with graphite monochromated Mo $K\alpha$ radiation. Unit cell parameters were determined by a least-squares refinement from setting angles of 42 accurately adjusted reflections ($27 \leq 2\theta \leq 41°$). In total, 2670 reflections ($|F_o| > 2.5\sigma(F_o)$) out of 5480 independent reflections ($0 \leq h \leq 22$, $0 \leq k \leq 12$, $-16 \leq l \leq 16$) were used for the refinement. Three standard reflections were measured at every 100 reflections, and no significant deterioration was observed. Lorentz and polarization corrections were applied. Subsequent calculations were carried out using a universal program (UNICS III)[4] at Institute for Molecular Science and at the University of Tokyo. The structure was solved by a direct method. All the non-hydrogen atoms appeared and almost all the interpeak distances were reasonable. The refinements were carried out by a block-diagonal least-squares method with anisotropic thermal parameters for non-hydrogen atoms. All the hydrogen atoms were located on the difference Fourier Maps and were refined isotropically to final R values

$0.060[R_w=0.088$, $w=1/(3.0+0.01|F_o|^2)$ for $|F_o|<15$ and $w=1/(\sigma^2(F_o)+0.0013|F_o|^2)$ for $|F_o|\geq 15]$. There was no residual peak greater than 0.7 e Å^{-3}.

Table 1 lists the non-hydrogen atomic coordinates with equivalent isotropic temperature factors.[5]

Results and Discussion

Molecular Structure. A perspective view of **3** is shown in Fig. 3. Table 2 lists selected bond distances and angles. We expected that **3** is a bridged compound, as described earlier,[2] on the basis of ^{1}H NMR spectra. Contrary to our expectation, it had a free imidate and a double bond instead of a bridged structure. We could not find any remarkable structural characteristics that favor a bicyclo compound instead of a bridged structure and stabilize the imidate group. The bond distances, C(17)-N(2) and O-C(17), are rather shorter than usual C-N double bond and C-O single bond, respectively. Thus, electrophilicity of C(17) should be rather small. A cyclohexane ring attaches perpendiculary to an almost planar hexalin system. The bond distances, C(7)-C(8) and C(8)-C(9), are elongated, probably due to a steric interaction among the substitutents. Other bond distances and angles are all normal. We are investigating similar reactions for other cycloalkylidenemalononitriles; their results will be reported elsewhere.

Fries Rearrangement in Calixarene Esters: A New Entry for the Synthesis of *p*-Substituted Calixarenes

Takashi ARIMURA, Seiji SHINKAI,* Tsutomu MATSUDA, Yoshimi HIRATA,†

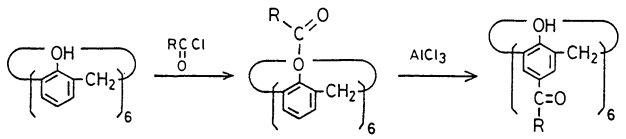
(Received June 23, 1988)

Synopsis. The Fries rearrangement was found to be a convenient method to synthesize *p*-acylcalixarenes from *O*-acylcalixarenes, the yields being relatively good (29—34%) as a synthetic method for *p*-substituted calixarenes.

Calixarenes are cyclic oligomers made up of benzene units as cyclodextrins are made up of glucose units. Since calixarenes possess a novel cylindrical architecture, they are expected to be useful for designing cavity-shaped host molecules.[1,2] In order to obtain functionalized calixarenes for host molecules, it is indispensable to find new synthetic methods to introduce various substituents into calixarenes. The first method is the direct substitution of the *p*-position (sulfonation, nitration, etc.).[1-5] However, this method is hampered by a fact that it is fairly difficult to isolate a fully-substituted product from lower-substituted by-products. Thus, the application of this method is limited to the very clean reactions. The second method is the rearrangement of the substituents on the OH groups to the *p*-position. Gutsche and Levine[6] introduced the Claisen rearrangement of the allyl ether of calixarenes to *p*-allylcalixarenes, but the allyl group is rather useless as an intermediate for functionalized calixarenes. We here address a new method to synthesize *p*-acylcalixarenes by the Fries rearrangement from esters of calix[6]arenes. The acyl group is a more versatile functional group to derive alcohols, imines, oximes, etc.



a: R = $CH_3(CH_2)_4$- b: R = $CH_3CH_2CH(CH_3)$-

Experimental

Acylation of calix[6]arene (**1**) was carried out according to the method of Gutsche and Lin for 25,26,27,28-tetraacetoxycalix[4]arene.[7] 37,38,39,40,41,42-Hexakis(hexanoyloxy)calix[6]arene (**2a**); recrystallized from hexane, mp 198—200 °C, yield 50%. IR (KBr): $\nu_{C=O}$ 1755 cm^{-1}, no ν_{OH} ^1H MNR (Me_2SO-d_6, 100 °C): CH_3, δ=0.84, 3H; $(CH_2)_3$, 1.24—1.49, 6H; $COCH_2$, 2.98, 2H; $ArCH_2Ar$, 3.66, 2H; aromatic protons, 6.80, 3H. Found: C, 76.42; H, 7.84%. Calcd for $(C_{13}H_{16}O_2)_6$: C, 76.44; H, 7.89%.

37,38,39,40,41,42-Hexakis[(2-methylbutanoyl)oxy]calix[6]arene (**2b**); recrystallized from *N*,*N*-dimethylformamide (DMF), mp 332—335 °C, yield 51%. IR(KBr): $\nu_{C=O}$ 1750 cm^{-1}, no ν_{OH}. ^1H NMR (Me_2SO-d_6, 160 °C): CH_3, δ=0.83 and 1.02, 3H each; CH_2, 1.42 and 1.63, 1H each; CH, 2.68, 1H; $ArCH_2Ar$, 3.62, 2H; aromatic protons, 6.84, 3H. Found: C, 75.17; H, 7.44; N, 0.41%. Calcd for $(C_{12}H_{14}O_2)_6 \cdot 0.35$DMF: C, 75.18; H,7.47; N, 0.42%. It was difficult to remove a trace amount of DMF which is possibly included in **2b** as a clathrate complex.

A typical experimental run for the Fries rearrangement of **2** to **3** is as follows: a mixture of **2** (0.88 mmol) and $AlCl_3$ (2.3 g, 15.8 mmol) was stirred in 40 ml of chlorobenzene at 45—50 °C for 17 h under a nitrogen atmosphere. After cooling water was added to the reaction mixture and the organic phase was diluted with 100 ml of chloroform, washed with 1 mol dm^{-3} HCl and water, and then dried over $MgSO_4$. The solution was concentrated in vacuo, and the oily residue was recrystallized from acetone. The crystals **3** were collected by centrifugation and then recrystallized from tetrahydrofuran for **3a** and chloroform-methanol for **3b**. The products gave satisfactory elemental analyses and spectral properties (IR, NMR) consistent with **3**.

5,11,17,23,29,35-Hexahexanoylcalix[6]arene (**3a**); mp 227—230 °C, yield 29%. IR (KBr): ν_{OH} 3375 cm^{-1}, $\nu_{C=O}$ 1670 cm^{-1}. ^1H NMR ($CDCl_3$, 25 °C): CH_3, δ= 0.91, 3H; $(CH_2)_3$, 1.38—1.72, 6H; $COCH_2$, 2.91, 2H; $ArCH_2Ar$, 4.00, 2H; aromatic protons, 7.87, 2H; OH, 10.42, 1H. Found:C, 76.41; H, 7.84%. Calcd for $(C_{13}H_{16}O_2)_6$:C, 76.44; H,7.89%.

5,11,17,23,35-Hexakis(2-methylbutanoyl)calix[6]arene (**3b**); >mp 360 °C, yield 34%. IR (KBr): ν_{OH} 3370 cm^{-1}, $\nu_{C=O}$1665 cm^{-1}. ^1H NMR ($CDCl_3$, 25 °C): CH_3, 0.89 and 1.13, 3H each; CH_2, 1.50 and 1.79, 1H each; CH, 3.36, 1H; $ArCH_2Ar$, 4.01, 2H; aromatic protons, 7.88, 2H; OH, 10.47, 1H. Found: C, 75.15; H, 7,14%. Calcd for $(C_{12}H_{14}O_2)_6 \cdot 0.09CHCl_3$: C, 75.15; H, 7.36%. A weak peak of included $CHCl_3$ was observed in the NMR spectrum when ^1H NMR was taken in Me_2SO-d_6.

All the ^1H NMR spectra were measured with JEOL GX-400.

Results and Discussion

We first tried the Fries rearrangement of 37,38,39,40,41,42-hexaacetoxycalix[6]arene. However, the rearrangement did not take place under the reaction conditions described in Experimental. When the more drastic reaction conditions (high temperature, increase in $AlCl_3$, etc.) were employed, the product was black resin insoluble in any solvents.** We thus used **2a** and **2b** as starting esters and found that the Fries rearangement really takes place.

It is not easy to enhance the yield for the synthesis of *p*-substituted calixarene derivatives. If the rearrange-

** It is not clear why the Fries rearrangement of the acetyl derivative does not take place. It is known that Friedel-Crafts acylation of benzocrown ethers catalyzed by aluminium chloride is impractical: W. W. Parish, P. E. Scott, and C. W. McCausland, *J. Org. Chem.*, **43**, 4597 (1978) and F. Wada and T. Matsuda, *Bull. Chem. Soc. Jpn.*, **53**, 421 (1980). The peculiar behavior may be attributable to an interaction between the smaller $AlCl_3$-CH_3COCl complex with the ionophoric calixarene ester.

Table 1. Melting Points, Yields, and Coalescence Temperatures of **2** and **3**

Calix[6]arene	Appearance	Mp θ_m/°C	Yield/%	T_c/°C[a]
2a	Colorless prisms	198—200	50	5
2b	Colorless prisms	332—335	51	50
3a	Colorless powder	227—230	29	−3
3b	Colorless powder	>360	34	0
p-Hexylcalix[6]arene[b]	Colorless powder	305—307	22[b]	−70

a) Pyridine-d_5. The methylene protons in these compounds (except **2a**) gave a singlet above T_c, whereas those in **2a** gave the two peaks in 2 : 1 ratio. b) This compound was synthesized from *p*-hexylphenol and formaldehyd[9].

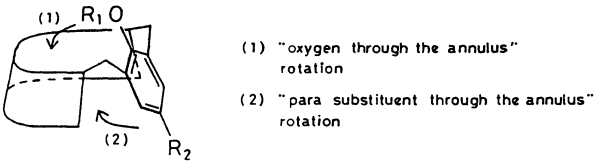


Fig. 1. Two possible rotation mechanisms in calixarenes.

ment is assumed to occur successively, the total yield for fully-substituted calix[6]arene becomes only 26.2% (=0.80^6) even though the yield for each benzene unit is 80%. This is a special situation in the modification of cyclic compounds. The yields obtained in the Fries rearrangement (29—34%) are apparently low. But, they are classified as good yields for the synthesis of *p*-substituted calix[6]arenes since these values imply that the rearrangement in each benzene unit occurs in 81—85% yields (i.e., 0.81^6=29%, 0.85^6=34%). The yields are higher than that for the Claisen rearrangement in calix[6]arene (21%).[7] This suggests that the Fries rearrangement well competes with or is superior to the Claisen rearrangement as a synthetic method for *p*-substituted calixarenes. Since the yield for **3b** is comparable with that for **3a**, this reaction is not so subject to the steric effect.

It is known that the temperature-dependent ^{1}H NMR spectrum of calix[6]arenes displays a few sets of overlapping pairs of doublets for the $ArCH_2Ar$ methylene hydrogens at low temperature and a singlet resonance at high temperature.[8] This behavior is interpreted in terms of conformational change form "cone" (or "hinged cone") to "alternate",[1,2] resulting in a coalescence temperature (T_c) at the intermediate. Determination of the T_c of **2** and **3** in pyridine-d_6 (−70—90 °C) (Table 1) showed that compounds **2** have the T_c higher than **3**, indicating that increased freezing of the partial conformations can be observed for the ester derivatives. In particular, **2b** has the very high T_c (50 °C) probably due to the bulky *s*-butyl group. Two possible mechanisms have been proposed for the rotation of the benzene unit, (1) oxygen through the annulus rotation and (2) para substituent through the annulus rotation (Fig. 1).[8] The fact that the T_c becomes higher only when the substituent is introduced into the OH group supports that the conformational change occurs according to the "oxygen through the annulus" rotation mechanism: that is, the T_c is sensitive to steric bulkiness of the substituent (R_1) on the oxygen but not so much to that of the para substituent (R_2).

Interestingly, the T_c values for **3a** and **3b** are surprisingly higher than those for calix[6]arene (−70 °C),[8] *p-t*-butylcalix[6]arene (−54 °C),[8] and *p*-hexylcalix[6]arene (−70 °C)[9] in pyridine-d_5. The origin of the remarkable T_c difference between *p*-acylcalix[6]arenes and *p*-alkylcalix[6]arenes is still a matter of controversy. We believe that the most probable rationale is the lower shift of the pK_a of the OH groups due to the electron-withdrawing *p*-acyl groups, which would strengthen the hydrogen-bonding interaction among the OH groups and stabilize accordingly the "cone" conformation in solution.

In conclusion, the present paper indicated that the Fries rearrangement is very useful for the synthesis of *p*-acylcalixarene derivatives. Further functionalization of *p*-acylcalixarenes is now under investigation in these laboratories.

Facile Reaction of *Te*-Aryl Benzenecarbotelluroates, ArCOTeAr', with Methyl Iodide and Halogens

Harkesh B. SINGH* and Narasimhan SUDHA
Department of Chemistry, Indian Institute of Technology, Powai, Bombay 400076, India
(Received November 26, 1987)

Synopsis. Reaction of *Te*-aryl benzenecarbotelluroates of the type ArCOTeAr' (Ar=phenyl *p*-tolyl, *p*-bromophenyl; Ar'=phenyl, *p*-methoxyphenyl) with methyl iodide was found to give symmetrical telluronium salts, $[Ar'Te(CH_3)_2]^+I^-$ in good yields. The reactivity of one of these benzene carbotelluroates towards halogens was also examined.

Although diaryl and dialkyl tellurides are known to react with methyl iodide to form the corresponding telluronium salts (Scheme 1),[1] it has been newly found that reaction of *Te*-aryl benzenecarbotelluroates with methyl iodide results in cleavage of the Te-CO bond.

$$R_2Te + CH_3I \rightarrow [R_2(CH_3)Te]^+I^-$$

Scheme 1.

When benzenecarbotelluroates (**1a—d**) were treated with excess of methyl at room temperature for 48 h, colorless $[Ar'Te(CH_3)_2]^+I^-$ (**2a—b**) were formed in yields of 70—90% based on the used tellurides **1**, together with trace amounts of as yet uncharacterized dark-violet compounds (Scheme 2) which contain carbonyl function. In no reaction was obtained the expected product **3**.

$$ArCTeAr' + CH_3I \longrightarrow \begin{cases} [Ar'Te(CH_3)_2]^+I^- & \mathbf{2} \\ [ArCTeAr'(CH_3)]^+I^- & \mathbf{3} \end{cases}$$

1a: Ar'=C_6H_5, Ar=C_6H_5 **2a**: Ar'=C_6H_5
1b: Ar'=C_6H_5, Ar=*p*-BrC_6H_4 **2b**: Ar'=*p*-$CH_3OC_6H_4$
1c: Ar'=C_6H_5, Ar=*p*-$CH_3C_6H_4$
1d: Ar'=*p*-$CH_3OC_6H_4$, Ar=*p*-$CH_3C_6H_4$

Scheme 2.

Whereas the halogenolysis reactions of similar compounds, tellurophthalide and tellurophthalic anhydride have been reported earlier,[2] to the best of our knowledge no reaction of benzenecarbotelluroates with methyl iodide has been previously described.

The scheme which most reasonably accounts for the results can be written as follows:

$$ArCTeAr' \xrightarrow[\text{Slow}]{CH_3I} [ArCTe^+CH_3Ar'\cdot I^-] \quad \mathbf{3}$$

$$\xrightarrow[\text{Fast}]{-ArCOI} [CH_3TeAr'] \xrightarrow[\text{Fast}]{CH_3I} (CH_3)_2Te^+Ar'\cdot I^- \quad \mathbf{2}$$

In order to learn more about the behavior of the Te-CO bond, we have investigated the halogenolysis reactions of **1d**. It was found that the benzenecarbotelluroate reacted with excess of SO_2Cl_2, Br_2, or I_2 at room temperature to afford the corresponding $Ar'TeX_3$ (X=Cl, Br, I) via cleavage of the Te-CO bond.

Experimental

Materials and Instruments. The *Te*-aryl benzenecarbotelluroates were prepared by the reaction of a benzoyl chloride with NaTeAr'.[3] All compounds had melting points and ν_{CO}'s in good agreement with those reported in the literature. IR spectra (4000—600 cm^{-1}) were obtained in KBr discs with Perkin Elmer 681. ^1H NMR (100 MHz) were obtained with a JEOL FX 100 instrument. Elemental analysis was by the Analytical Services Section, Regional Sophisticated Instrumentation Centre, Lucknow.

Reaction of $C_6H_5TeCOC_6H_5$ with CH_3I. To the benzenecarbotelluroate (0.25 g, 0.8 mmol) was added methyl iodide (2—3 ml) in a 50 ml flask and then capped. The resulting solution was allowed to stand for 48 h at ambient temperature during which time yellowish crystals separated out and the color of the solution turned dark-red. After 48 h absolute ether (10 ml) was added to the reaction mixture and allowed to stand for additional 12 h. The crystals were filtered, washed with ether, recrystallized from ethanol/water (1:1) to yield white crystals of $[C_6H_5Te(CH_3)_2]^+I^-$; yield 0.2 g (70% based on **1a** used), mp 168 °C.[4] Calcd (Found): C, 26.5 (25.9%); H, 3.06 (3.51%). ^1H NMR (DMSO-d_6) δ=2.38 (s, 6H), 7.5—7.9 (m, 5H). The red mother liquor was evaporated to dryness and the residue was washed with petroleum ether (40—60 °C) to give a dark violet solid of indefinite composition. IR (KBr) 1685 cm^{-1} (ν_{CO}). Reactions of $C_6H_5TeCOC_6H_4Br$-*p* and $C_6H_5TeCOC_6H_4CH_3$-*p* with CH_3I also gave $[C_6H_5Te(CH_3)_2]^+I^-$ in excellent yields (ca. 90%) and trace quantities of the brownish red solids. Reaction of *p*-$CH_3OC_6H_4TeCOC_6H_4CH_3$-*p* with CH_3I yielded [*p*-$CH_3OC_6H_4Te(CH_3)_2]^+I^-$ in excellent yield (ca. 86%), mp 172 °C (lit,[5] 170—172 °C). Calcd (Found): C, 27.5 (26.9%); H, 3.34 (3.57%). ^1H NMR (DMSO-d_6) δ=2.3 (s, 6H), 3.8 (s, 3H), 7.0—7.8 (m, 4H). A brownish red solid of indefinite composition was also obtained.

Halogenolysis Reactions. In a typical reaction, to a solution of *p*-$CH_3OC_6H_4TeCOC_6H_4$-*p* (0.4 g, 1.13 mmol) in chloroform (25 mL) was added dropwise iodine (0.28 g, 1.13 mmol) dissolved in chloroform at room temperature during 30 min. *p*-$CH_3OC_6H_4TeI_3$ is continuously precipitated as a dark violet solid, mp 130 °C (d), yield 0.35 g (91%) (based on **1d** used). Analogous reactions of Br_2 and SO_2Cl_2 with **1d** afforded *p*-$CH_3OC_6H_4TeBr_3$ and *p*-$CH_3OC_6H_4TeCl_3$ which were characterized by comparison with authentic samples (mp, IR, ^1H NMR).[1]

The authors would like to thank one of the referee(s) for his valuable suggestions.

The Vapor-Phase Preparation of V-P-O Catalysts Effective for Butane Oxidation to Maleic Anhydride

Yusaku TAKITA,* Takao HASHIGUCHI, and Hitoshi MATSUNOSAKO
Department of Environmental Chemistry and Engineering, Faculty of Engineering, Oita University, Oita 870-11
(Received February 29, 1988)

Synopsis. Almost pure α-$VOPO_4 \cdot 2H_2O$ powder was obtained by a vapor-phase reaction between $POCl_3$, $VOCl_3$, and water at about 763K in the presence of oxygen. Although α-$VOPO_4 \cdot 2H_2O$ changed into α- and β-$VOPO_4$ in the calcination in N_2, it was transformed into $(VO)_2P_2O_7$ and a small amount of β-$VOPO_4$ by in situ activation at 733 K at the heating rate of 10 K min^{-1} in a C_4H_{10}-O_2-N_2 stream, the resulting catalysts effected the selective oxidation of butane to maleic anhydride comparable to pure $(VO)_2P_2O_7$.

The production of maleic anhydride (MA) has been achieved practically by the oxidation of benzene and butenes (1-butene, *cis*-2-butene, *trans*-2-butene), MA production by the oxidation of butane has, however, been magnified since it has distinct economical merit.

V-P-O catalysts have been claimed to be effective for the oxidation of butane[1] and there are many studies on the catalysis of the V-P-O system from the viewpoint of the active phases for the reaction,[2] the role of a small excess of phosphorus in catalysts,[3,4] the differences in composition between bulk and surface,[5] the reaction path[6] and so on.

There also are much patent literature concerning the preparation method of the selective catalysts.[7] The preparation methods published so far can be classified into two large categories. One is the method using V_2O_5 as a starting material and the other is the method using organic or inorganic vanadium compounds. Each category can be further subdivided into many groups in terms of the reducing agents. Common to all is the use of a liquid reaction medium.

In this paper, the authors deal with a new vapor-phase preparation of V-P-O catalysts effective for MA synthesis from butane using vanadium chloride oxide and phosphoryl chloride as the starting materials.

First, the reaction conditions suitable for the preparation of powders containing V and P were explored extensively. The following conclusions were abstracted from the experiments.

(1) N_2 is suitable for the carrier gas of both $VOCl_3$ and $POCl_3$ vapor.

(2) $VOCl_3$ and $POCl_3$ should be mixed in a vapor phase at the place just before the entrance of a reactor.

(3) O_2 is favorable for the carrier gas of water vapor.

(4) The collector of the powders formed should be kept at about 420 K to prevent the condensation of the hydrochloric and phosphorus containing acids formed.

An improved apparatus for the catalyst preparation is shown in Fig. 1. The length of the reactor used here was about 15 cm which was sufficient to form oxide powders. The optimum flow rates of the introducing gases were dependent on the length and diameter of the reactor. The adoption of 1 ± 0.2 as the flow rate ratio, $F_{(O_2+H_2O)}/F_{(N_2)}$, and 9—10 as the linear velocity ratio, $L_{(O_2+H_2O)}/L_{(N_2)}$, maintained the powder formation for at least 17 h.

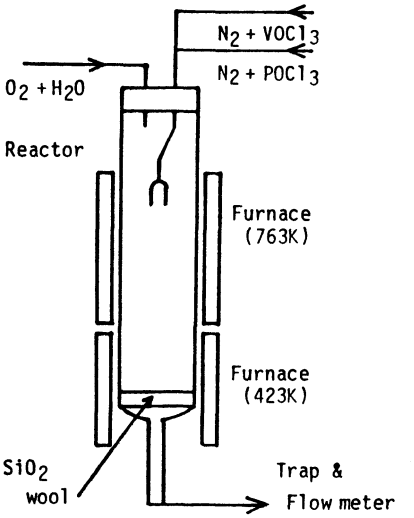

Fig. 1. Schematic diagram of the apparatus for powder preparation.

All of the vanadium atoms fed is seemed to be incorporated into the powders since no vanadium oxide was recovered from the effluent gas, however, phosphorus compounds were partly passed through the reactor and were recovered in a trap with a NaOH aqueous solution in most of the experiments. 0.06—0.15 g of the powders were formed per hour in each experiment.

The powders formed in this manner were subjected to XRD measurement and the results are summarized in Table 1. The mixture of α-$VOPO_4$ and V_2O_5 was obtained when the $POCl_3/VOCl_3$ ratio of the reactant gas was lower than unity (Run 1), on the contrary, a large $POCl_3/VOCl_3$ ratio gave the peaks assigned to $(VO)_2P_2O_7$, though the intensities were small. It is of interest that $(VO)_2P_2O_7$ with V(IV) ions was formed when an excess amount of $POCl_3$ was supplied.

The adoption of an intermediate $POCl_3/VOCl_3$ ratio brought about the formation of almost pure α-$VOPO_4 \cdot 2H_2O$ (ASTM Card 27-949) and the reproducibility of the experiments was fairly good (Runs 10—15). The P/V ratios of some of the powders obtained were examined by EPMA and these results are also shown in Table 1. The P/V ratio of the powder formed in Run 1 was 0.34 which is very close to the 0.33 of the $POCl_3/VOCl_3$ ratio of the feed gas. This suggests that all the $POCl_3$ in the feed gas was incorporated into the powder formed.

The ratios of the powders formed in Runs 13 and 15,

however, were 1.09 and 1.02 which were coincided the chemical formula of α-$VOPO_4 \cdot 2H_2O$ and the ratio of the former powder was unaltered after having been used for the oxidation of butane for 27 h. It can be inferred from these results that the 2.0—2.5 fold excess of $POCl_3$ to $VOCl_3$ is sufficient to form vanadium phosphate powder with a P/V ratio just exceeding unity. The powders formed in Runs 2, 3, and 6 contained a $(VO)_2P_2O_7$ phase in which vanadium atoms were reduced to V(IV) from the original V(V) of $VOCl_3$. According to Bordes and Courtine,[8] the reduction of α- and β-$VOPO_4$ begins at 920 K even in a N_2 stream. So that it is believed to be difficult for the reduction of V(V) of the powders to take place in the furnace kept at 763K. The Cl/V ratio of some catalysts were also determined by EPMA and were listed in Table 1. The powders formed in Runs 1 and 13 contained a small amount of chlorine, which was the extent of ca. 0.2% of the vanadium atoms but no chlorine was detected from the powder formed in Run 15. Although the chlorine content of the powders of Runs 2, 3, and 6 are not known, it can be inferred that the HCl formed by the hydrolysis of chloride oxides may play a role in the reduction.

The effects of the temperature and the surrounding gas in calcination on the phase of the α-$VOPO_4 \cdot 2H_2O$ were studied in order to obtain the optimum conditions of pretreatment suitable for the preparation of selective butane oxidation catalysts.

The portions of the powder formed in Run 13 were heated to 773 K at the different heating rates such as 2 K min^{-1} and 10 K min^{-1} in a N_2 or C_4H_{10}-O_2-N_2 (1.5, 9.0, and 89.5 vol% respectively) stream, and kept at 773 K for 2 h, and then steeply cooled down to the ambient temperature. The samples calcined in the N_2 stream were changed into α-$VOPO_4$ and β-$VOPO_4$ despite the heating rates in agreement with the results reported by Bordes and Courtine.[8]

The samples calcined in the C_4H_{10}-O_2-N_2 stream gave features different from those in N_2 stream. The XRD spectrum of the sample heated by 10 K min^{-1} consisted of sharp peaks of $(VO)_2P_2O_7$ in addition to weak peaks of β-$VOPO_4$, on the other hand the spectrum obtained at 2 K min^{-1} was mainly composed of β-$VOPO_4$ and α-$VOPO_4$. It can be concluded from these results that in situ pretreatment in the reactant gas mixture of butane oxidation and higher heating rates are favorable to obtain $(VO)_2P_2O_7$ which has been claimed to be the active phase for MA formation.

The results of the butane oxidation over several catalysts prepared by the method mentioned above are shown in Table 2 together with the results over $(VO)_2P_2O_7$ which was prepared from V_2O_5, $NH_2OH \cdot HCl$, and H_3PO_4 by the method described in the literature[2] and over pure V_2O_5 prepared by the thermal decomposition of ammonium metavanadate at 823 K.

Butane was mainly oxidized to carbon oxides over the pure V_2O_5 catalyst and MA was formed with only 13.5% selectivity under the reaction conditions. The MA selectivity reached 58.3% over the $(VO)_2P_2O_7$ catalyst. Although Catalyst 3 showed a considerably high activity, the distribution of products was much similar to that of pure V_2O_5. As shown in Table 1, Catalyst 3 was composed of an amorphous phase and a small amount of $(VO)_2P_2O_7$. The XRD spectrum from Catalyst 3 after the reaction was almost the same as that before pretreatment.

Catalysts 10 and 13, both derived from α-

Others[b]	—	—	0.44	0.06	0.76	—	—	—	—

a) Maleic anhydride. b) C_1—C_3 Alkane, reaction temperature: 733 K, W/F: 0.46 g $\cdot$ s $\cdot$ cm^{-3}, feed gas composition: 1.5 vol% n-C_4H_{10}, 9.0 vol% O_2, 89.5 vol% N_2.

$VOPO_4 \cdot 2H_2O$ showed selectivities as high as that of the $(VO)_2P_2O_7$ catalyst. It can be seen from Table 2 that the activity and selectivity of Catalyst 13 improved with the reaction time. The XRD spectra from Catalysts 10 and 13 after the reaction were composed of many small broad peaks and a half of these peaks could be assigned to those of $(VO)_2P_2O_7$ and α-$VOPO_4$ but the rest could not be assigned. Observations of high base line position and the small broad peaks in all spectra suggested that the catalysts obtained by the gas phase reaction have an abundance of an amorphous solid or a very small crystalline. Since Catalyst 10 overcame the $(VO)_2P_2O_7$ catalyst in the conversion of butane, Catalyst 10 was superior to the $(VO)_2P_2O_7$ catalyst in MA yield.

It is concluded from these results that the vapor phase preparation of α-$VOPO_4 \cdot 2H_2O$ powder is one of the better methods of obtaining precursor of the selective catalysts.

Experimental

The $VOCl_3$ (Wako Pure Chem. 99+%) and $POCl_3$ (Wako Pure Chem., Special Grade) were used for powder preparation without further purification. The determination of the composition of the samples was carried out by means of either of a TN 5500 EPMA system or chemical analysis in conformity with a reference.[9] Reference files of the EPMA system were prepared using K lines from V, GaP, and KCl standards at 25 kV and were checked by analyzing mixtures of V_2O_5 and ammonium dihydrogen phosphate. Catalytic oxidation of butane was carried out using an ordinary flow type reaction system with fixed catalyst bed. The catalysts were in situ pretreated in the stream of a reaction gas mixture at a temperature which was regulated to raise to 773 K at the rate of 10 $K\,min^{-1}$ and then hold at 773 K for 2 h. The MA formed was collected for ca. 1 h after which the concentration of its aqueous solution was analyzed by means of GC (Thermon 1000 column, 423 K) or by titration with a NaOH aqueous solution.

Electronic and ESR Spectral Studies of a Series of Phosphine and Phosphite Adducts with Cobaloxime Analog

Keisuke MITA,* Kazuhiko HOTTA, and Takeji TAKUI†
Osaka Municipal Technical Research Institute, Morinomiya, Joto-ku, Osaka 536
†Faculty of Science, Osaka City University, Sugimoto, Sumiyoshi-ku, Osaka 558
(Received November 30, 1987)

Synopsis. Electronic and ESR spectra were measured for solutions of $Co(dmgBF_2)_2$ in the presence of PX_3, where $Co(dmgBF_2)_2$ is a BF_2 capped species of bis(dimethylglyoximato)cobalt(II) ($Co(Hdmg)_2$) and PX_3 is PBu_3, PPh_3, $P(OEt)_3$, or $P(OPh_3)_3$. ^{31}P hyperfine splittings of their ESR spectra demonstrated that $Co(dmgBF_2)_2$ forms only 1:1 adducts with PX_3. The visible absorption spectrum of the dichloromethane solution of $Co(dmgBF_2)_2$ showed an absorption band at 444 nm at 20 °C. Upon PX_3 being added to the solution, the band shifted to a longer wavelength; the band shift increased with increasing the electron-donating ability of PX_3.

Bis(dimethylglyoximato)cobalt(II) complex ($Co(Hdmg)_2$) and its related compounds have been known as model compounds for vitamin B_{12}[1] or as hydrogenation catalysts.[2] Recently, during our investigation of the catalytic properties of those complexes, the methanol solution of $Co(dmgBF_2)_2$ (the BF_2 capped species of $Co(Hdmg)_2$, Fig. 1) was found to be thermochromic in the presence of tributylphosphine (PBu_3).[3] It was also found that the thermochromism is due to a shift of equilibrium between the Co^{II} and Co^{I} species.[3,4] On the other hand, no thermochromic behavior was observed for the methanol solution of $Co(dmgBF_2)_2$ in the presence of triphenylphosphine (PPh_3), triethylphosphite ($P(OEt)_3$), or triphenylphosphite ($P(OPh)_3$). In the present study, the electronic and ESR spectra of $Co(dmgBF_2)_2$ were measured in a methanol or dichloromethane solution in the presence of the above-mentioned four trivalent phosphorus ligands (PX_3); the influence of these phosphorus ligands is discussed in terms of the bonding properties between $Co(dmgBF_2)_2$ and PX_3.

Experimental

The ESR spectra were observed at 77 K with a Bruker ESP-300 and a JES ME-1X type spectrometer in the X band with a field modulation of 100 kHz. $Co(dmgBF_2)_2(2H_2O)$ was prepared according to the method of Bakac and Espenson.[5] The preparation of ESR samples was carried out under a dry atmosphere of argon. $Co(dmgBF_2)_2(2H_2O)$ was dissolved in methanol, and an amount of phosphorus ligand was added. A 1 ml solution was transferred to a quartz ESR tube, and the tube was then sealed. The visible absorption spectra were measured at 20 °C by a method described in a previous paper.[4]

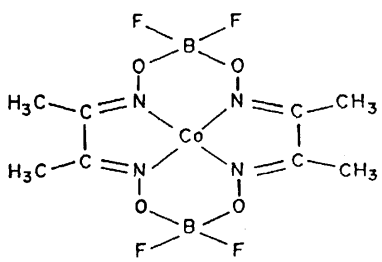

Fig. 1. The structure of $Co(dmgBF_2)_2$.

Results and Discussion

Figure 2a shows the ESR spectrum of $Co(dmgBF_2)_2$ observed in a frozen methanol solution at 77 K. The spectrum is characterized by the lineshape for a random orientation of paramagnetic species with anisotropic g values ($S=1/2$) and the hyperfine structure due to the magnetic interaction between an unpaired electron and a nucleus of $I=7/2$, where S and I denote an electron and a nuclear spin quantum number, respectively. No superhyperfine structure was resolved.

Figure 2b shows the ESR spectra of $Co(dmgBF_2)_2$ observed at 77 K in a frozen methanol solution in the presence of $P(OEt)_3$. The spectrum is distinctly different from that of the parent $Co(dmgBF_2)_2$ and is diagnostic for adduct formation. The additional doublet splitting of the hyperfine structure can be attributed to the superhyperfine structure due to the magnetic interaction of an unpaired electron with a ^{31}P nucleus ($I=1/2$). Assuming a tetragonal symmetry, $Co(Hdmg)_2$ is in the low-spin $^2A_1$ state and the unpaired electron is

$P(OPh)_3$	2.00	89	230

a) 1 G=10^{-4} T.

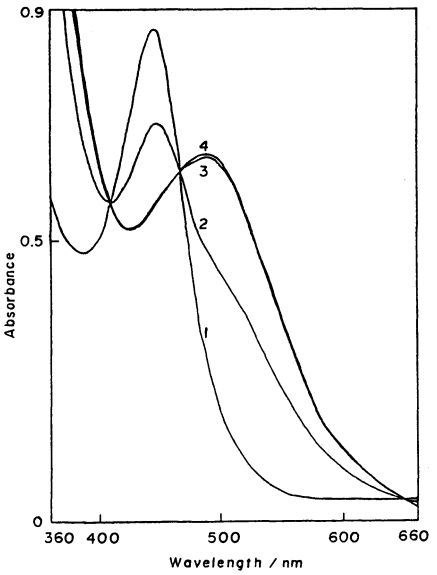

Fig. 3. Visible absorption spectra, 1, 2, 3, and 4 of 0.33 mM $Co(dmgBF_2)_2$ (1M=1 mol dm^{-3}) in the dichloromethane solution containing $P(OEt)_3$ with the concentration of 0, 0.22, 0.49, and 3.2 mM, respectively.

localized mainly in the d_{z^2} orbital.[6,7] Thus, the superhyperfine structure arises from the axial coordination of the phosphorus ligand, $P(OEt)_3$. The superhyperfine structure was not affected by the addition of excess of $P(OEt)_3$ to the solution, suggesting that $Co(dmgBF_2)_2$ forms only 1 : 1 adducts with $P(OEt)_3$ in the methanol solution. This finding parallels observations with $Co(Hdmg)_2(PX_3)$,[6,8] $Co(tpp)(PX_3)$,[9] and $Co(salen)(PX_3)$,[10-13] where Co(tpp) and Co(salen) are tetraphenylporphinatocobalt(II) and (*N,N'*-disalicylideneethylenediaminato)cobalt(II), respectively. A similar superhyperfine structure due to a ^{31}P nucleus was observed at 77 K for $Co(dmgBF_2)_2$ in a frozen methanol solution in the presence of the other phosphorus ligands, viz., PBu_3, PPh_3, or $P(OPh)_3$, conforming the 1 : 1 adducts formation of $Co(dmgBF_2)_2$ with these phosphorus ligands. (In the presence of excess PBu_3, however, the ESR signal could not be observed, because under that condition $Co^{II}(dmgBF_2)_2(PBu_3)$ is reduced to Co^{I} species.) The ESR parameters are shown in Table 1. A similar superhyperfine structure was observed for the 1 : 1 adducts in dichloromethane solution. The ESR parameters are quite the same as those listed in Table 1.

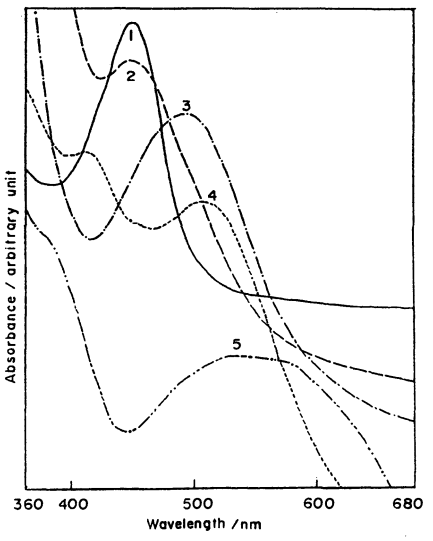

Fig. 4. Visible absorption spectra, 1, 2, 3, 4, and 5 of 0.30 mM $Co(dmgBF_2)_2$ in the dichloromethane solution containing none, 6.0 mM of $P(OPh)_3$, 6.0 mM of $P(OEt)_3$, 6.0 mM of PPh_3 and 1.1 mM of PBu_3, respectively.

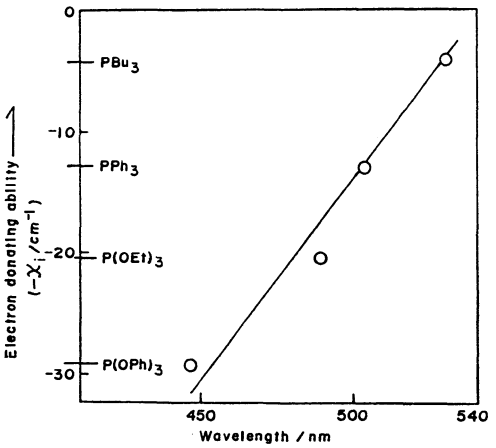

Fig. 5. Relationship between the electron-donating ability ($-X_i$) of PX_3 and the wavelength of the absorption band of $Co(dmgBF_2)_2(PX_3)$.

The visible absorption spectra of the methanol solution of $Co(dmgBF_2)_2$ showed an absorption band at 462 nm. When PBu_3 was added to the parent solution, the band shifted to 530 nm.[3] On the other hand, when PPh_3, $P(OEt)_3$, or $P(OPh)_3$ were added to the parent solution, no appreciable amount of the band shift was observed, suggesting that the interaction between these phosphorus ligands and $Co(dmgBF_2)_2$ is weak compared with that between PBu_3 and $Co(dmgBF_2)_2$ in the methanol solution.

The visible absorption spectra of the dichloromethane solution of $Co(dmgBF_2)_2$ showed an absorption band at 444 nm. Upon adding the trivalent phosphorus ligands to the parent solution, the band shifted to a longer wavelength while exhibiting isosbestic points. Figure 3 examplifies the spectral change observed upon increasing the amount of $P(OEt)_3$ from zero to 32×10^{-4} mol l^{-1} in a 3.3×10^{-4} mol l^{-1} of $Co(dmgBF_2)_2$

solution (the band at 444 nm shifted to 489 nm while exhibiting three isosbestic points at 408, 467, and 650 nm).

Figure 4 shows the visible absorption spectra (1, 2, 3, 4, and 5) of $Co(dmgBF_2)_2$ in the presence of none, $P(OPh)_3$, $P(OEt)_3$, PPh_3, and PBu_3, respectively, with the concentration; no more spectral change was observed upon a futher addition of each phosphorus ligand. Sice $Co(dmgBF_2)_2$ forms only 1 : 1 adducts with the phosphorus ligand, it is concluded from Fig. 4 that $Co(dmgBF_2)_2(PBu_3)$, $Co(dmgBF_2)_2(PPh_3)$, $Co(dmgBF_2)_2(P(OEt)_3)$, and $Co(dmgBF_2)_2(P(OPh)_3)$ have an absorption band at 530 nm (18900 cm^{-1}), 503 nm (19900 cm^{-1}), 489 nm (20400 cm^{-1}) and 446 nm (22400 cm^{-1}), respectively.

Figure 5 shows a relationship between the wavelength of the absorption band of $Co(dmgBF_2)_2(PX_3)$ and the electron-donating ability of PX_3 (the electron-donating ability is represented in units of Tolman X_i parameter).[14] This relationship shows that the absorption band of $Co(dmgBF_2)_2(PX_3)$ shifts to a longer wavelength upon increasing the electron-donating ability of PX_3 (namely with decreasing the Tolman X_i parameter of PX_3). The electronic configuration of square-pyramidal d^7 complexes is $(d_{xz})^2(d_{yz})^2(d_{xy})^2(d_{z^2})^1(d_{x^2-y^2})^0$ in the ground state. If the electron-donating ability of PX_3 (as an axial ligand) increases, the energy level of the d_{z^2} orbital would be increased. Thus, from the fact that the absorption bands of $Co(dmgBF_2)_2(PX_3)$ shift to a much longer wavelength upon increasing the electron donating ability of PX_3 (Fig. 5), the absorption band in Fig. 4 was assigned to the $d_{z^2} \rightarrow d_{x^2-y^2}$ transition. It was consequently concluded that the order of d_{z^2} σ-donor orbital mixing is $PBu_3 > PPh_3 > P(OEt)_3 > P(OPh)_3$.

Organic Derivatives of Layered Polysilicates. II.[1] Reaction of Magadiite and Kenyaite with Diphenylmethylchlorosilane

Tsuneo YANAGISAWA, Kazuyuki KURODA, and Chuzo KATO*
Department of Applied Chemistry, Waseda University, Ohkubo-3, Shinjuku-ku, Tokyo 160
(Received February 19, 1988)

Synopsis. Silanol groups on the interlayer surface of layered polysilicic acids (H-magadiite and H-kenyaite) were silylated by reaction with diphenylmethylchlorosilane. Dodecyltrimethylammonium magadiite and kenyaite intercalation compounds were used as the intermediates for the conversion. The interlayer modification was confirmed by XRD, IR, ^{29}Si-MAS NMR and elemental analysis.

Interlayer modification of layered materials by organic groups has attracted much attention from the viewpoint of the design of advanced materials with regulated structures. Layered polysilicates such as magadiite ($Na_2Si_{14}O_{29}\cdot xH_2O$) and kenyaite ($Na_2Si_{20}O_{41}\cdot xH_2O$) have exchangeable interlayer cations and acid treatment yields the corresponding layered polysilicic acids (H-magadiite ($H_2Si_{14}O_{29}\cdot xH_2O$) and H-kenyaite ($H_2Si_{20}O_{41}\cdot xH_2O$)). Since the layered polysilicic acids as well as the original layered polysilicates have interlamellar silanol groups,[2] they are expected to be one of the host materials for interlayer modification. In order to design the interlayer space freely, it is necessary to investigate the possibility of various types of interlayer modification. However, in the previous studies,[3,4] only trimethylsilylation was reported as the organic derivatizing method for polysilicic acids.

$$(\equiv Si\text{-}OH + ClSi(CH_3)_3 \rightarrow \equiv Si\text{-}O\text{-}Si(CH_3)_3)$$

These reports also showed that a bulky silylating agent such as diphenylmethylchlorosilane ($(C_6H_5)_2CH_3SiCl$, abbreviated as DPMCS) could not be intercalated.[4] These previous studies used only DMSO (or NMF) intercalated polysilicic acids as intermediates for the derivatization. In our previous study,[1] dodecyltrimethylammonium ($C_{12}H_{25}(CH_3)_3N^+$, abbreviated as DTMA) magadiite and kenyaite were preferable for the trimethylsilylation of the layered polysilicic acids. The advantage of the tetraalkylammonium intercalated polysilicic acids as intermediates for the organic derivatization was their relative stabilities and the variable enlargement of the interlayer space by variation in the number of carbon atoms in the organoammonium ions employed. Therefore, in this study, DPMCS was allowed to react with DTMA-magadiite and -kenyaite intercalation compounds and the silylated products were analyzed.

Experimental

Materials. The starting materials, Na-magadiite and K-kenyaite ($K_2Si_{20}O_{41}\cdot xH_2O$), were synthesized by the method described by Lagaly et al.[5,6] The exchange reaction of interlayer Na and K ions for DTMA ions to form the organoammonium intercalation compounds was also followed by the procedure by Lagaly et al.[5,7] The formation of the organoammonium intercalated compounds was checked by elemental analysis, X-ray, and IR data. Commercially available DPMCS was used in this study.

Silylation Reaction. The DTMA-magadiite and -kenyaite were mixed with DPMCS and the reaction mixtures were refluxed for 72 h. After the mixtures were filtered with suction, they were washed thoroughly with acetone and air-dried.

Analyses. X-Ray powder diffraction patterns were obtained by using Rigaku Rad IB (Cu $K\alpha$ radiation, Ni filtered). IR spectra were recorded on a Shimadzu IR-435 infrared spectrometer. ^{29}Si-MAS NMR spectra were obtained with a JEOL GSX-270 spectrometer at 53.67 MHz. The external standard was tetramethylsilane. Gated high power proton decoupling technique was employed with a 45° pulse, and the pulse repetition time was 7 s. Cross polarization (CP) technique with matched rf field amplitudes of 45 kHz was also employed. CP contact times were 5 and 8 ms, depending upon the sample, and the pulse repetition time was 5 s.

Results and Discussion

Table 1 shows the basal spacings of Na-magadiite, K-kenyaite, their DTMA complexes, and their silylated products. The spacing of DTMA-magadiite (29.4 Å) was larger than that of Na-magadiite (15.6 Å) by 13.8 Å. After the reaction with DPMCS, the spacing of the derivative decreased to 24.6 Å from 29.4 Å. However, the value was still larger than that of H-magadiite (11.2 Å) by 13.4 Å. The expansion of the layer spacing was retained after the heat treatment of the silylated products at 300—400 °C, suggesting the formation of $\equiv Si\text{-}O\text{-}SiCH_3(C_6H_5)_2$. The diphenylmethylsilylation of DTMA-kenyaite also gave similar results, although the d_{001} values were different because of the different layer thickness of kenyaite.

After the diphenylmethylsilylation, the IR absorption bands due to DTMA ions disappeared and new bands due to diphenylmethylsilyl (abbreviated as DPMS) groups appeared at 1430, 1270, 740, and 700 cm^{-1}. After the heat treatment up to 400 °C with a DTA instrument, the absorption peaks due to DPMS groups remained. Thus, these IR absorption peaks were not ascribed to by-products (ex. $(C_6H_5)_2CH_3SiOSiCH_3(C_6H_5)_2$) or the unreacted species, because

Table 1. Basal Spacings of Layered Polysilicates and Their Derivatives

	Na-magadiite(Å)	K-kenyaite(Å)

their boiling points were lower than 350 °C. The IR results of the silylated kenyaite also showed similar evidence of the linkage of the DPMS groups and the interlayer silanol groups.

Figure 1 shows the ^{29}Si-MAS NMR spectra of Na-magadiite, DTMA-magadiite, and the diphenylmethylsilylated magadiite. The NMR spectrum of Na-magadiite indicated the presence of two different SiO_4 units normally designated as Q^3 and Q^4 at −99.0 and −110.7 ppm, respectively. (Q^n means the SiO_4 having n siloxane bonds.) The spectrum was similar to the previous data reported by Pinnavaia et al.[8] The spectrum of the DTMA-magadiite did not show any significant changes in the chemical shifts and the intensities. However, in the spectrum of the diphenylmethylsilylated product, a remarkable change was observed. At first, the width of the peak due to Q^4 was broadened, indicating the presence of the newly formed Q^4 by silylation, (O_3SiOH (Q^3) → O_3SiO-SiR_3 (Q^4)). Secondly, the new peaks at −28 and −65 ppm appeared. With a further measurement using the cross polarization (CP) technique, these peaks were split, as shown in Fig. 1(d), although the reason for the splittings can not be explained definitely at present because the precise structure has not yet been clarified. The intensities of these peaks decreased with the combustion of the organic groups and finally unified into a single but relatively broad peak at −107 ppm (Fig. 2). Therefore, the peaks at −28 ppm were ascribed to the silicon atoms (Q^1) in the bonded DPMS groups. The latter signals at −65 ppm were thought to be assigned tentatively as the unsilylated Q^3 units strongly affected by the interlayer aromatic groups which usually caused an anisotropic magnetic effect. Possible bond distortion in the interlayer space may also influence the chemical shift.

Figure 3 shows the ^{29}Si-CP MAS NMR spectra of K-kenyaite, DTMA-kenyaite, and the silylated product. In the spectrum of the K-kenyaite, the Q^3 peak appeared at −98.5 ppm and the peak due to Q^4 at −109.7 ppm. In the spectrum of the DTMA-kenyaite, the peak due to Q^3 appeared at a similar position to that of K-kenyaite. However, the peak due to Q^4 was split into two peaks at −110.5 and −112.5 ppm. This difference between magadiite and kenyaite is probably ascribable to the difference in the layer structures. The spectrum of the silylated kenyaite indicated the presence of the Q^1 peak due to DPMS groups at −32.9 ppm. The signal at −64.9 ppm was tentatively assigned to Q^3. The peak due to Q^4 appeared at −110.2

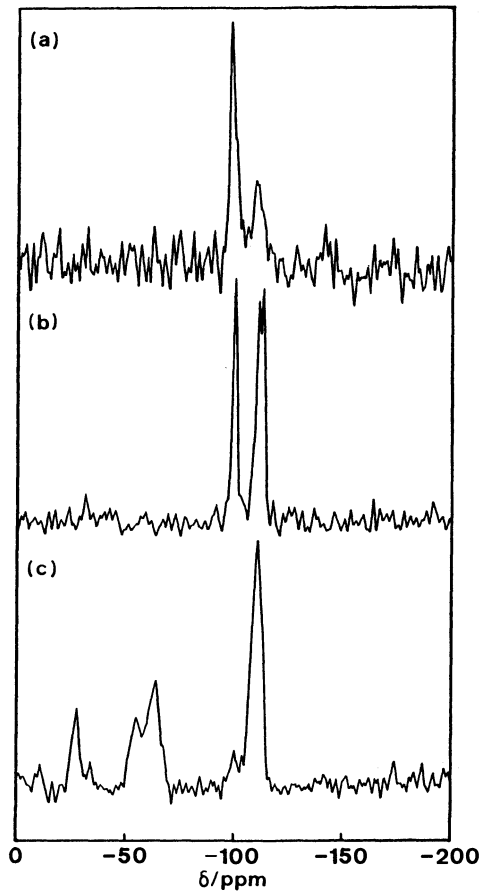

Fig. 3. ^{29}Si-CPMAS NMR spectra of (a) K-kenyaite, (b) dodecyltrimethylammonium kenyaite, and (c) diphenylmethylsilylated kenyaite.

ppm with a little broad peak width. These variations in the spectra corresponded to the partial diphenylmethylsilylation of interlamellar silanol groups.

The elemental analysis of the silylated magadiite and kenyaite also supported the silylation, though very small amounts of nitrogen due to remaining DTMA were detected. The H, C, and N contents (H, 2.01; C, 13.81; N, 0.15%) of the silylated magadiite indicated the ratio of DPMS group/$Si_{14}O_{29}$ was 0.79. The data of the silylated kenyaite (H, 1.39; C, 11.34; N, 0.10%) showed the ratio of DPMS group/$Si_{20}O_{41}$ was 0.92. As compared with the data on the trimethylsilylation of magadiite and kenyaite,[1] the values were lower because of the bulky nature of the DPMS groups.

The process of the diphenylmethylsilylation of DTMA-magadiite and -kenyaite can be expressed as a consecutive reaction. Since the silanol groups are present in the interlayer space of DTMA-magadiite and - kenyaite,[5,7] the silylating reagent can react with these silanol groups to form siloxane bonds;

$$\equiv Si\text{-}OH + (C_6H_5)_2CH_3SiCl \rightarrow \equiv Si\text{-}O\text{-}SiCH_3(C_6H_5)_2 + HCl.$$

The HCl produced can attack the DTMA silicate sites to form silanol groups. Then, the newly formed silanol groups can be silylated further.

In conclusion, the interlayer surface of magadiite and kenyaite was silylated with DPMCS using DTMA-magadiite and -kenyaite as intermediates, providing the possibility of various modifications of interlayer silanol groups.

We are indebted to Dr. Kenzo Deguchi and Mr. Katuya Hioka (JEOL) for their measurement and interpretation of ^{29}Si-MAS NMR spectra. One of the authors (K.K.) was supported financially by Nippon Sheet Glass Foundation for Materials Research. Waseda University also supported us financially as a Special Project Research.

An ^{27}Al NMR Study on the Complexes Present in the Solutions of Potassium Hexathiocyanatoaluminate(III)

Noriyuki KOMATSU, Masatoki YOKOI,* and Eiji KUBOTA
Department of Chemistry, Faculty of Science, Shinshu University, Asahi, Matsumoto 390
(Received May 9, 1988)

Synopsis. The species present in the solutions of potassium hexathiocyanatoaluminate(III) in various solvents were identified by ^{27}Al NMR spectra of the solutions. In dimethyl sulfoxide solution containing excess KSCN, the spectrum consists of 7 resonances due to $[Al(NCS)_n(DMSO)_{6-n}]^{(3-n)+}$ (n=0—6), whereas a single resonance arising from $[Al(NCS)_6]^{3-}$ was observed in propylene carbonate or acetone.

The ^{27}Al NMR spectrum of an aqueous solution containing aluminum chloride and potassium thiocyanate shows a resonance at about 6 ppm upfield from the line due to $[Al(H_2O)_6]^{3+}$. The spectrum is similar to that of aqueous aluminum sulfate solution in which a separate resonance is located at 3 ppm upfield from the main one.[1] The upfield resonance of the former solution may be assigned to a species like $[Al(SCN)(H_2O)_5]^{2+}$.

Wehrli and Wehrli[2] studied species present in $AlCl_3$ solution of acetonitrile (AN) by ^{27}Al NMR. They showed that $AlCl_4^-$ and various hexacoordinated solvation complexes exist in the solutions and the relative amount of the species depends on the concentration of the solute. ^{27}Al NMR spectra of AN solution containing $KAlCl_x(SCN)_{4-x}$ have been reported.[3] It was shown that Cl^- and SCN^- mixed ligand tetracoordinated Al(III) species are in these solutions.

Since potassium hexathiocyanatoaluminate(III), is soluble in a variety of solvents, it seems interesting to identify the complexes present in aqueous and nonaqueous solutions. We have attempted to study the ^{27}Al NMR spectra of the solutions of the complex salt in various solvents.

Experimental

The preparation of potassium hexathiocyanatoaluminate(III) was almost similar to that described in the literature.[4] Anhydrous $AlCl_3$ was added to a solution of six equivalent KSCN in AN and the precipitated KCl was filtered off. The solvent was then removed with distillation under reduced pressure. The residue was recrystallized from acetone. ^{27}Al NMR spectra were recorded on a JEOL FT-90Q at 23.3 MHz or on a Bruker AC-250 at 65.18 MHz. The temperature of the sample was 28 °C. The Al NMR shift was measured with an external standard of aqueous $NaAlO_2$ solution. The shift data were then converted to the values with reference to the usual standard of $[Al(H_2O)_6]^{3+}$ line. The error in the shift was estimated as ±1 ppm.

Results and Discussion

Figure 1 reproduces ^{27}Al NMR spectra of the solutions of potassium hexathiocyanatoaluminate(III) and of the solutions containing the salt and excess KSCN in dimethyl sulfoxide (DMSO), *N,N*-dimethylacetamide (DMA), and AN. In these solutions, ^{27}Al NMR

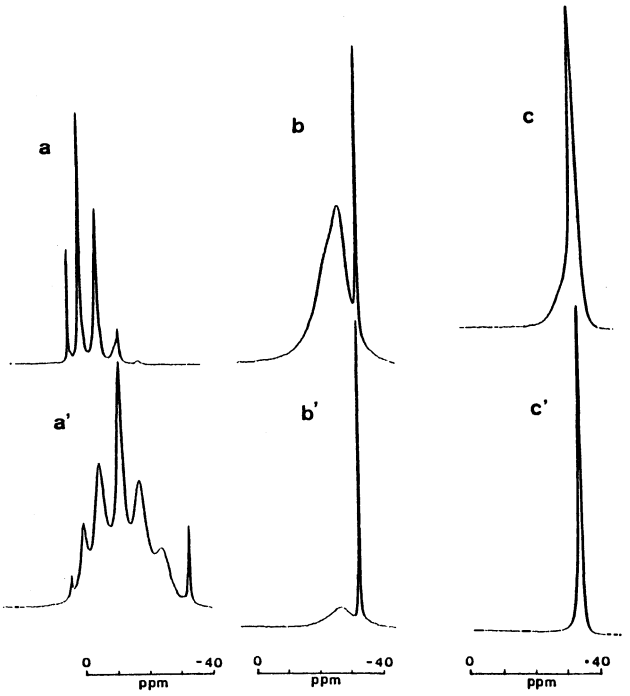

Fig. 1. ^{27}Al NMR spectra at 65.18 MHz of potassium hexathiocyanatoaluminate(III) in a) DMSO, a') DMSO containing KSCN, b) DMA, b') DMA containing KSCN, c) AN, c') AN containing KSCN. The concentration of the solutions are indicated in Tables 1 and 2.

resonances were observed only in the region of hexacoordinated Al(III) species.[5] In DMSO with excess KSCN the spectrum consists of 7 resonances, which can be assigned to the hexacoordinated SCN^- and DMSO mixed ligand complexes. Since two upfield lines newly appear by adding excess KSCN, the most upfield narrow line at −34.0 ppm should be the resonance caused by hexathiocyanatoaluminate(III) ion. In DMA a broad resonance was located at downfield of the narrow resonance at −34.2 ppm, the relative intensity of which was increased by adding excess KSCN. A shoulder was observed at downfield side of the resonance of −33.0 ppm in AN solution. It disappeared in the solution containing excess KSCN. As is shown in Fig. 2, in propylene carbonate (PC), the spectrum consists of only one narrow resonance at −33.9 ppm which was unchanged by addition of excess KSCN. Addition of DMSO to the PC solution produces lines of SCN^--DMSO mixed ligand complex that are seen in the DMSO solution. The intensity of the lines increased with the increase of DMSO content in the solution. This will be the evidence for the fact that hexathiocyanatoaluminate(III) ion is the only Al spe-

cies present in the solvent of low coordinating ability. In acetone (AC) the situation was similar to that in PC. The solution and that containing excess KSCN gave a single resonance at −33.9 ppm. In this way the shift of Al species containing six SCN^- in its coordination sphere was determined as −34 ppm.

The shift of $[Al(AN)_6]^{3+}$, in which AN coordinates to Al through N atom is reported as −32.7 ppm.[2] Since the shifts of hexaethylisocyanatoaluminum ion, $[Al(SCNEt)_6]^{3+}$, and tris(dimethyldithiocarbamato)-aluminum, $[Al(S_2CNMe_2)_3]$, are reported as 20[8] and 22 ppm,[9] respectively, the shift of $[Al(SCN)_6]^{3-}$ would be around 20 ppm, if SCN^- coordinates to Al through S atom. Thus it can be concluded that SCN^- coordinates to Al^{3+} through N atom in these solutions and we will write the formula of the complex as $[Al(NCS)_6]^{3-}$.

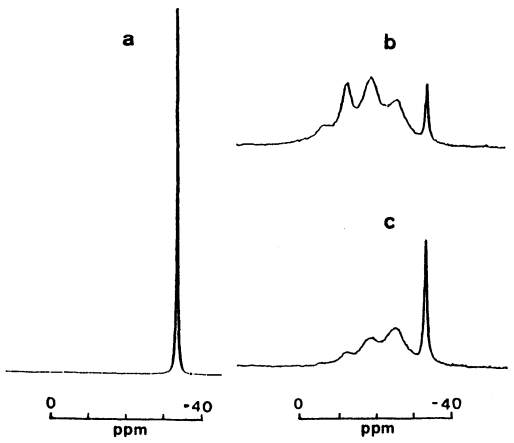

Fig. 2. ^{27}Al NMR spectra at 23.3 MHz of potassium hexathiocyanatoaluminate(III) in a) PC, b) PC-DMSO, Al:PC:DMSO mole ratio=1:122:10, and c) PC-DMSO, Al:PC:DMSO mole ratio=1:126:4.4.

All of the Al NMR shift of species coordinated octahedrally to ligands through O atom such as $[Al(DMF)_6]^{3+}$ (−2.6 ppm)[5] and $[Al(H_2O)_6]^{3+}$ (0 ppm) are around 0 ppm. Thus the most downfield resonance at 3.1 ppm in the DMSO solution can be assigned to $[Al(DMSO)_6]^{3+}$. Other 5 lines located between 3.1 and −34 ppm due to $[Al(NCS)_6]^{3-}$ may be assigned to $[Al(NCS)_n(DMSO)_{6-n}]^{(3-n)+}$, where n=1 to 5. Table 1 compares the observed shifts with those calculated by applying the pairwise additivity model.[6] In the present octahedral complex with two kinds of ligand, NCS^- and DMSO, the pairwise additivity parameters to be evaluated are $\eta_{O\text{-}O}$, $\eta_{N\text{-}N}$, and $\eta_{O\text{-}N}$, and the chemical shift of Al was calculated by summing the appropriate combination of twelve parameters corresponding to twelve edges of the octahedral complex in question. Although our spectra could not resolve lines from cis and trans isomers with n of 2, 3, and 4, the observed shifts are consistent with those calculated for cis isomers which were predicted[7] as giving narrower lines than those of trans isomers.

Table 1. Comparison between Observed and Calculated ^{27}Al Chemical Shifts of Al^{3+}- SCN^-- DMSO Mixed Ligand Complexes

Species	Obsd. shift/ppm (half width/Hz)		Calcd. shifts/ppm applying pair additive approximation[a]
	$K_3[Al(NCS)_6]$[b]	$K_3[Al(NCS)_6]$ +KSCN[c]	
$[Al(DMSO)_6]^{3+}$	3.1(25)	3.1(65)	3.10
$[Al(DMSO)_5(NCS)]^{2+}$	−0.7(52)	−0.7(80)	−0.70
$[Al(DMSO)_4(NCS)_2]$	−5.8(70)	−5.3(108)	cis −5.7 trans −4.5
$[Al(DMSO)_3(NCS)_3]$	−12.2(100)	−12.3(75)	cis −11.9 trans −10.7
$[Al(DMSO)_2(NCS)_4]^-$	−18.4(100)	−18.3(—)	cis −18.1 trans −16.9
$[Al(DMSO)(NCS)_5]^{2-}$	—	−25.3(—)	−25.4
$[Al(NCS)_6]^{3-}$	—	−34.0(52)	−34.00

a) Additivity parameter values(ppm): $\eta_{O\text{-}O}$=0.258; $\eta_{N\text{-}N}$=−2.833; $\eta_{O\text{-}N}$=−0.691. These values are estimated from the observed shifts of $[Al(DMSO)_6]^{3+}$, $[Al(NCS)_6]^{3-}$, and $[Al(DMSO)_5(NCS)]^{2+}$. b) 0.1 M. c) 0.3 M $K_3[Al(NCS)_6]$ and 3 M KSCN (1 M= 1 mol dm^{-3}).

	0.2 M $K_3[Al(NCS)_6]$, 2 M KSCN		−33.9(15)
AC	0.2 M $K_3[Al(NCS)_6]$		−33.9(65)
	0.2 M $K_3[Al(NCS)_6]$, 2 M KSCN		−33.9(41)

In DMA, the main species present in the solution of $K_3[Al(NCS)_6]$ appear to be $[Al(NCS)_n(DMA)_{6-n}]^{(3-n)+}$ of n of 5 or 4. Since the shift of $[Al(AN)_6]^{3+}$ is very close to that of $[Al(NCS)_6]^{3+}$, no definite conclusion could be drawn for the species present in the AN solution. It seems interesting that while a solvent of high coordinating ability like DMSO competes with SCN^- in coordinating Al^{3+}, a solvent of relatively low coordinating ability like AN competes with Cl^- in occupying the octahedral sites of Al^{3+}.[2] Table 2 gives the shifts of the complexes.

The authors wish to express their thanks to Prof. Ryozo Irie of Faculty of Agriculture, Shinshu University for obtaining NMR spectra at 65.18 MHz. The present work was partially supported by a Grant-in-Aid for Science Research No. 62540459 from the Ministry of Education, Science and Culture.

Oxidation of Benzylic and Allylic Alcohols with Cobalt(III) Acetate in Acetic Acid in the Presence and Absence of Sodium Bromide

Masao HIRANO, Takashi MORIMOTO,* and Keiko ITOH
Department of Industrial Chemistry, Faculty of Technology, Tokyo University of Agriculture and Technology, Koganei, Tokyo 184
(Received December 19, 1987)

Synopsis. Benzyl alcohol and its *o*-, *m*-, and *p*-substituted derivatives afforded fairly good yields of the corresponding benzaldehydes through a reaction with a Co(III)-NaBr system. With allylic alcohols, this system failed in a selective formation of unsaturated carbonyl compounds. In the latter cases, the products were effectively obtained by using a higher concentration of cobalt(III) acetate in the absence of NaBr.

Cobalt(III) acetate is a potent oxidant; on kinetic grounds,[1,2] the oxidation of organic compounds with it has been considered via an electron-transfer mechanism. Compared with other metal oxidants such as Pb(IV), Tl(III), Hg(II), Cr(VI), Se(IV) salts etc., some advantages in terms of relatively low cost, simple manipulation and, especially lower toxicity of cobalt(III) acetate make it considerably attractive in the oxidation of various olefins.[3-5] The present paper describes the oxidation of benzylic and allylic alcohols with cobalt(III) acetate in acetic acid since, hitherto, there has only been little data on this subject. In addition, the effect of added sodium bromide on the reaction rate as well as on the product yield is reported.

Results and Discussion

The oxidation of benzyl alcohol (**1**) in acetic acid with a stoichiometric amount (2 equiv. per mole of **1**) of cobalt(III) acetate was conducted under an inert atmosphere (argon) since the main product, benzaldehyde (**2**), is highly susceptible to autoxidation. After heating the reaction mixture at 60 °C for 2 h, it was observed that cobalt(III) acetate was not completely consumed, as judged from the dark-green color of the solution. A GLC analysis revealed that **1**, **2**, and a minor amount (GLC selectivity; 4.2%) of benzyl acetate (**3**) was involved in the product mixture. Then, the reaction was carried out in the presence of NaBr, known as a promoter in cobalt-catalyzed autoxidation of alkylbenzenes.[6,7] In this case, the initially dark-green solution became blue-black as the NaBr gradually disappeared. When the reaction mixture was poured into brine, the aqueous layer became cobaltous pink, suggesting that almost all the cobalt(III) acetate had been consumed. Indeed, the conversion of **1** was considerably increased upon the addition of a small amount of NaBr (Table 1), whereas **3** decreased to a trace amount. These observations imply that NaBr contributes not only to accelerate the reaction, but to inhibit any side-reaction. The yield of **2** gradually increased upon increasing the amount of NaBr and reached a maximum at NaBr/**1**=0.5. However, a further addition of NaBr no longer contributed to the formation of **2**.

The oxidation of substituted benzyl alcohols was performed in a manner similar to that of **1**, resulting in a predominant formation of the corresponding benzaldehydes. Compared with the other substrates, the oxidation of nitrobenzyl alcohols did not proceed so readily in the absence of NaBr, viz. the conversion of *p*-nitrobenzyl alcohol (**4**) was 65% at 60 °C for 2 h. On the other hand, *p*-methoxybenzyl alcohol (**5**) showed a higher reactivity. Thus, 77% of **5** was converted under comparable conditions.

As with the case of **1**, an addition of NaBr usually accelerated the oxidation of substituted benzyl alcohols, leading to a selective formation of the corresponding benzaldehydes. Indeed, the conversion of **4** increased to 97% upon the addition of NaBr(NaBr/**4**=

0.5) under the same conditions as mentioned above. The results of various substituted benzyl alcohols are summarized in Table 2. The reaction conditions (temperature, time, and concentration of NaBr) were determined on the basis of the reactivity of the substrates as well as the yield of the aldehydes. In all cases, GLC analyses showed that no neutral product, other than the aldehydes, was formed in a significant amount under the conditions employed. As shown in Table 2, substituted benzaldehydes were obtained in excellent yields, irrespective of the nature of the substituents or of the position of those on the benzene-ring. Consequently, the present procedure was proved to be applicable to a wide variety of substituted benzyl alcohols.

The reaction of allylic alcohol was also promoted upon the addition of NaBr. For example, conversions of 1-octen-3-ol in reactions with a stoichiometric amount of cobalt(III) acetate at 60 °C for 2 h were 26, 63, 70, and 77% when the mole ratios of NaBr/substrate were 0, 0.1, 0.5, and 1.0, respectively; at this time the GLC selectivities of the main product, 1-octen-3-on (**6**), were 24, 49, 52, and 50%, respectively. However, the unknown products increased and, thus, the selectivity of **6** decreased in proportion to the amount of NaBr added. The failure of a selective formation of **6** in the presence of NaBr might be explained by the facts that an olefinic double bond has been suggested to be as susceptible to cobalt(III) acetate as hydroxyl group[2)] and that cobalt(III)-NaBr system is an effective reagent for allylic oxidation.[8)] A close inspection of the reaction conditions revealed that a reaction with an excess amount of cobalt(III) acetate in the absence of NaBr for a relatively long time is appropriate for an effective formation of unsaturated carbonyl compounds from allylic alcohols (Table 3).

In connection with the initial stage of the reaction, cobalt monobromide has been suggested as being an active species in the autoxidation of hydrocarbons catalyzed by cobalt(II) acetate in the presence of NaBr.[6)] However, an intervention of the bromine radical cannot be ruled out, since any product study regarding the oxidation of alicyclic olefins with a cobalt(III)-NaBr system can be rationally interpreted in terms of a participation of the bromine radical.[8)] The specification of an active species is now under way in our laboratory.

The present reaction requires stoichiometric or higher amounts of cobalt(III) acetate and is of limited utility for large-scale oxidation. However, the oxidation of benzylic alcohols with a cobalt(III) acetate-NaBr system offers a conventional method for synthesizing benzaldehydes, since products can be selectively obtained within a reasonable period of time, regardless of nature or the position of the substituents on the benzene-ring.

Experimental

^{1}H NMR spectra were obtained with a JEOL model PMX-60 spectrometer for solutions in carbon tetrachloride. IR spectra were recorded for thin films or KBr disks on a JASCO DS-403G spectrophotometer. GLC was carried out on a Shimadzu GC-6A or GC-4CM instrument with a 2 m column packed with 5% PEG-20M or 1.5% OV-17, respectively, on Chromosorb WAW-DMCS.

Materials. All alcohols were commercially available and were purified by conventional procedures just before use. Cobalt(III) acetate in acetic acid was prepared according to method described in the literature;[9)] the concentration was determined by Fe(II) and back titration with Ce(IV).

Oxidation Procedures. The following procedures are representative. To a mixture of benzyl alcohol (ca. 0.5 g) and NaBr (0.5 mol equiv) in a round-bottomed flask was added cobalt(III) acetate in acetic acid (2 mol equiv); the flask was then flushed with argon. The reaction was carried out at a controlled temperature in a thermostat with magnetic agitation. After a given period, the reaction mixture was poured into brine and extracted three times with ether. The combined extract was successively washed with brine, 10% aqueous sodium carbonate, and brine and then dried (Na_2SO_4). Removing the ether on a rotary evaporator yielded a light-yellow oil, which was chromatographed on silica gel (hexane-AcOEt).

All products, so obtained, were known compounds and were identified by comparisons of their NMR and IR spectra with those of authentic samples.

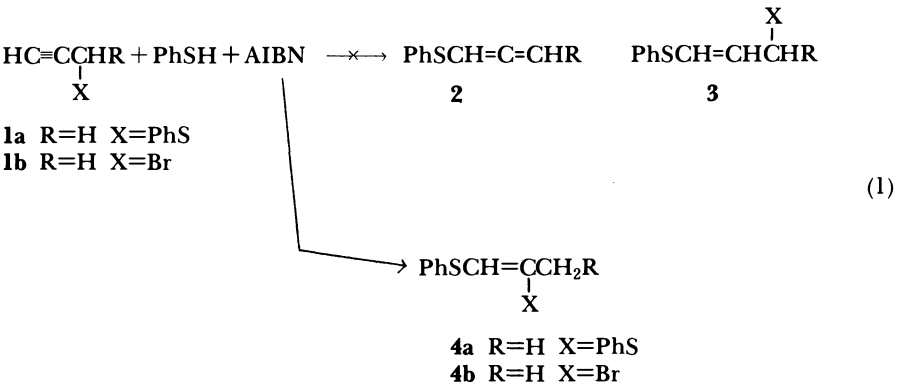
Free Radical Addition of Thiophenol to 3-Substituted 1-Alkyne with or without Migration of the Substituents

Hideyoshi MIYAKE* and Kimiaki YAMAMURA
Department of Chemistry, College of General Education, Kobe University, Nada, Kobe 657
(Received February 9, 1988)

Synopsis. Thiophenol reacts with 3-phenylthio- and 3-bromo-1-alkyne in the presence of radical initiator to give 1,2-bis(phenylthio)-1-alkene and 2-bromo-1-phenylthio-1-alkene.

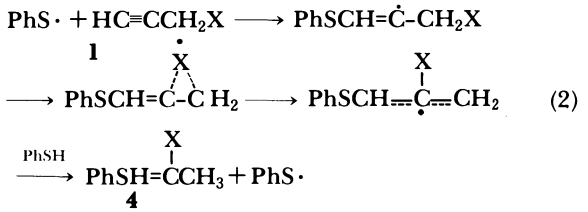
The free radical addition of a thiol to carbon-carbon double or triple bond is a well-established reaction.[1] It is one of the most useful methods to synthesize sulfides, under mild conditions. We studied further application of this reaction. We wish to report that the radical addition of thiophenol to 3-substituted 1-alkyne proceeds with or without migration of the substituents.

By heating thiophenol and 3-substituted 1-propyne such as **1** (X=SPh and Br; R=H), in benzene in the presence of azobis-isobutyronitrile (AIBN), we obtained neither 1-(phenylthio)allene (**2**) nor 3-substituted 1-phenylthio-1-alkene (**3**), but rearranged products **4** (Eq. 1). When the substituent (X) was PhS, 1,2-bis(phenylthio)-1-propene (**4a**) was obtained in an almost quantitative yield. However, when X was Br, 2-bromo-1-phenylthio-1-propene was obtained only in 45% yield with evolving HBr gas.



(1)

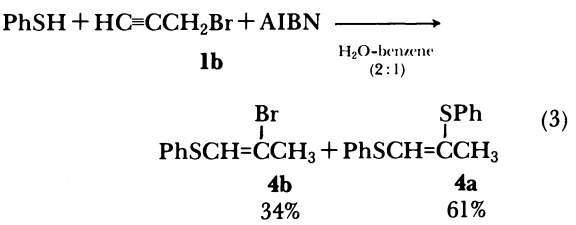
At first glance, this reaction seems to proceed with migration of the substituent (X) with a bridged radical intermediate (Eq. 2).[2] However, a more plausible mechanism is suggested as Scheme 1. It involves an initial attack of PhS· to triple bond followed by elimination of Br· or PhS·, because β-bromo or β-phenylthio radical easily eliminates Br· or PhS· to form double bond,[3] and the formation of 1-(phenylthio)allenes is quite reasonable. 1-(Phenylthio)-allenes are more reactive than **1**, and addition of HBr or PhSH occurs smoothly to give the adducts (**4a**, **b**).



(2)

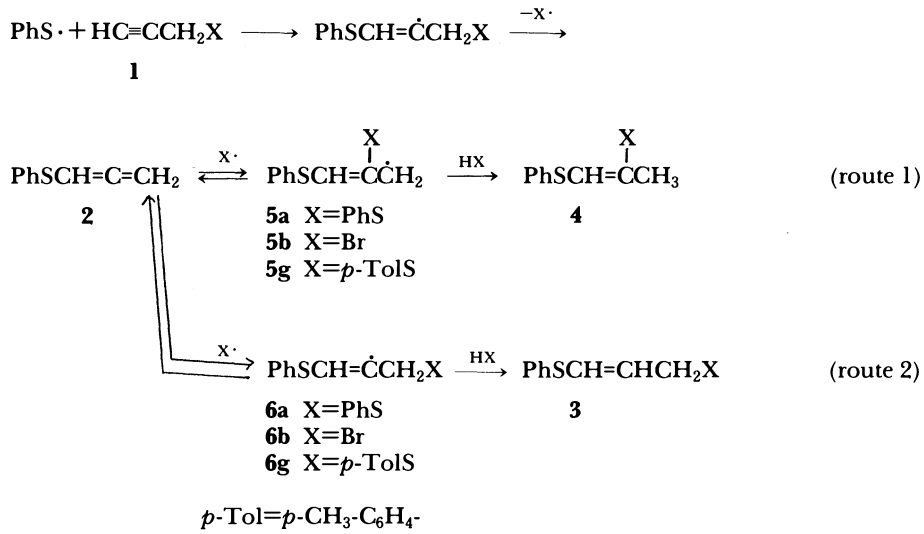
Regioselectivity and the mechanism of the addition of PhSH to allenes have been discussed by Heiba.[4] According to his discussion, the reaction involves (a) an initial attack of PhS· to allene and (b) hydrogen transfer to transient radical. The free radical intermediate formed by route 2 should undergo the reverse reaction.[5] However, the initial radical intermediate formed via route 1, although it may be initially non-allylic, undergoes rapid rotation of 90° around the C-C axis to form the conformation of the stable allylic radical. Such a rotation must have a very low activation energy and the resonance energy of allylic radical will make the reaction via route 1 faster than that via route 2.

This mechanism was supported by the following results. In the case of propargyl bromide, a small amount (<5%) of 1,2-bis(phenylthio)-1-propene (**4a**) was obtained as a by-product, and generation of HBr gas was observed. When two phase system of benzene-H_2O was used as solvent to remove HBr from the organic layer, the yield of **4b** decreased to 34%, and that of **4a** increased to 61% (Eq. 3).



(3)

When 3-(4-methylphenylthio)-1-propyne (**1g**) was



Scheme 1.

treated with 2 equivalent amount of thiophenol and 0.3 equivalent of AIBN, **4a** was obtained in 15% yield (Eq. 4). Although 1-(phenylthio)allene was not isolated, these results indicated the formation of 1-(phenylthio)allene intermediate. However, to our surprise, 2-(4-methylphenylthio)-1-phenylthio-1-propene (**4g**) was not obtained, but 3-(4-methylphenylthio)-1-phenylthio-1-propene (**3g**) was obtained in 66% yield.

$$p\text{-TolSCH}_2\text{C}{\equiv}\text{CH} + \text{PhSH} \xrightarrow{\text{AIBN}} \underset{\textbf{1g}}{} \quad \underset{(2\ \text{equiv})}{} \tag{4}$$

$$\textbf{4a} + p\text{-TolSCH}_2\text{CH=CHSPh}\ (\textbf{3g})$$

15% 66%

These results were explained as follows. Allylic radical **5g** was more stable than **5a**, and the activation energy of **5g** for hydrogen abstraction must be higher than that of **5a**. It suggests that the reaction of **1g** via route 1 is slower than that of **1a**. However, the stability of allylic radical **6** was not so influenced by aryl groups of the sulfides as that of **5**. And when **1g** was used, the relative reaction rate via route 2 became faster than that via route 1.

Although R in **1** is H, no simple adduct of thiophenol was obtained, when R is an alkyl group such as CH_3, n-C_3H_7, or n-C_5H_{11}, and X is SPh, a simple adduct like **3** was also obtained. The formation of such by-products as **3c**, **3d**, and **3f**, was similarly explained: Allylic radical **7** was more stable than **5a**, and the relative reaction rate to give **4** became slower. Results were summarized in Table 1.

Experimental

Reaction Procedure. As a typical experiment, the reaction of 3-phenylthio-1-propyne (**1a**) with thiophenol is as follows: 3-Phenylthio-1-propyne (**1a**) (1.48 g, 10 mmol), thiophenol (1.20 g, 10 mmol), and AIBN (0.49 g, 3 mmol) in benzene (10 ml) were stirred at 80 °C for 1 h. After removing the solvent under a reduced pressure, the product was purified by column chromatography on silica gel to give (*E*)-1,2-bis(phenylthio)-1-propene (1.74 g, 6.7 mmol) and (*Z*)-1,2-bis(phenylthio)-1-propene (0.80 g, 3.1 mmol) (**4a**).

Addition of *N*-(Hydroxymethyl)phthalimide to Methacrylates by Carbon-Carbon Bond Formation

Department of Industrial Chemistry, Faculty of Engineering, Seikei University, Musashino-shi, Tokyo 180
(Received February 26, 1988)

Synopsis. *N*-(Hydroxymethyl)phthalimide undergoes addition to the carbon-carbon bond of methacrylates effectively in sulfuric acid, resulting in the formation of a new carbon-carbon bond.

The hydroxymethyl group attached to the nitrogen of imides exhibits an interesting reactivity owing to a distinct cationic nature of the methylene group in an acidic medium such as sulfuric acid. Compounds having such a group are thus interesting intermediates in organic synthesis as electrophiles. *N*-(Hydroxymethyl)phthalimide is, for example, capable of electrophilic addition to cyano groups to form amide-imide compounds.[1] It also undergoes dehydration reaction with amines, while affording amine-imide derivatives.[2] These characteristic reactions have proved useful in providing convenient methods for synthesizing various types of polyamide-imides[3] and polyamine-imides.[4] This peculiar electrophilicity of hydroxymethylimides suggests the possibility of additions to carbon-carbon double bonds, if adequately polarized to permit the electrophilic attack, leading to new addition products by carbon-carbon bond formation.

N-(Hydroxymethyl)phthalimide (**1**) was subjected to the reactions with various kinds of compounds having a carbon-carbon double bond in concentrated sulfuric acid at 18 °C. The reaction with methyl methacrylate (**2a**) resulted in the formation of two products. Structural analysis revealed the major product to be a 1 : 1 adduct **3a** (78.5% yield) formed as a result of the electrophilic attack of **1** to the β-position of **2a**.

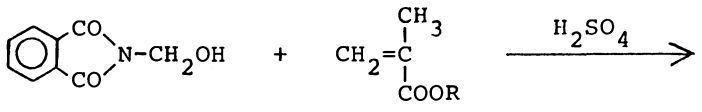
The minor product, on the other hand, was characterized by the presence of a carbon-carbon double bond and no hydroxyl group. Moreover, the ^{1}H NMR spectrum unambiguously indicated the double bond to be an exo methylene type. All these data supported the structure of **4a** (3.4% yield), which is formally a dehydrated form of **3a**. However, **3a** was not converted to **4a** when treated with sulfuric acid under the same conditions, suggesting **4a** to be formed by deprotonation from the intermediate species which results from the cationic attack of **1**, not by dehydration of **3a**. There is another possibility of deprotonation to give an alternate product having an endo double bond; however, **4a** was the only by-product we could isolate.

Since **1** seems to undergo decomposition in concentrated sulfuric acid in various fashions, the addition reaction would probably be dependent on the reaction temperature. When the temperature was lowered to 5 °C, the yield of **3a** increased to 82.0% as a result of suppression of side reactions at lower temperatures. Higher temperatures caused a marked reduction in the yield as shown in Table 1. In contrast, the formation of **4a** was not appreciably influenced by the reaction temperature. The reactions were also attempted in organic acidic solvents to prevent the possible degradation of **1** in sulfuric acid. No addition was, however, observed and only the starting materials were recovered in formic and dichloroacetic acids.

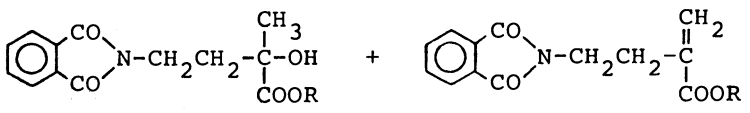
Ethyl methacrylate (**2b**) behaved quite similarly to **2a** in the reaction with **1** in sulfuric acid, giving the same kinds of addition products, **3b** and **4b**, in similar yields. Again, the minor product, **4b**, has an exo double bond.

Table 1. Reaction of *N*-(Hydroxymethyl)-phthalimide **1** with Methacrylates **2**

Methacrylate	Condition		Yield	
	Temp/°C	Time/h	%	
2a	5	20	**3a**, 82.0	**4a**, 3.2
2a	5	40	**3a**, 80.0	**4a**, 3.0
2a	18	20	**3a**, 78.6	**4a**, 3.4
2a	30	20	**3a**, 60.0	**4a**, 2.5
2a	43	20	**3a**, 23.6	**4a**, 2.5
2b	18	20	**3b**, 82.0	**4b**, 5.0



1 + **2a**, R=CH_3; **2b**, R=C_2H_5 $\xrightarrow{H_2SO_4}$



3a, R=CH_3; **3b**, R=C_2H_5 + **4a**, R=CH_3; **4b**, R=C_2H_5

If the addition of **1** also takes place to the carbon-carbon double bond as well as to the cyano group of acrylonitrile (**5a**) and methacrylonitrile (**5b**), these nitriles will afford 2 : 1 adducts. The addition reaction, however, turned out to proceed only at the cyano group even with two-fold excess **1**, and 1 : 1 adducts, **6a** and **6b**, were obtained in high yields along with three kinds of by-products formed from excess **1** by the elimination of formaldehyde and intermolecular dehydration. This indicates that the cyano group is more susceptible to electrophilic attack than the vinyl or vinylidene group on account of high electron density at the nitrogen atom and also that the resulting acrylamide and methacrylamide derivatives are resistive to the addition reaction.

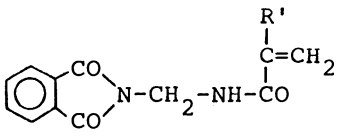
5b, R'=CH_3



6a, R'=H

6b, R'=CH_3

Other vinyl compounds including methyl acrylate (**7**), ethyl acrylate (**8**), acrylic acid (**9**), methacrylic acid (**10**), methyl vinyl ketone (**11**), methyl isopropenyl ketone (**12**), acrylamide (**13**), vinyl acetate (**14**), butyl vinyl ether (**15**), styrene (**16**), fumaric acid (**17**), and cyclohexene (**18**) were also subjected to the reaction to understand the general scope of the reaction. No addition products were, however, detected in the reaction mixtures in all the cases, and only the by-products from **1** were isolated by column chromatography. It is noteworthy that while methacrylates **2a** and **2b** gave adducts in high yields, structurally similar vinyl compounds such as acrylates (**7** and **8**) and vinyl ketones (**11** and **12**) afforded no addition products, and only **1** and its degradation products were recovered. In the reaction with **11**, for example, most of the starting **1** was converted to the three kinds of by-products which were obtained in a total yield of 71%. This is probably ascribable to the higher electron availability at the α-position than β-position, as opposed to methacrylates,[8] which would make the reaction reluctant because of steric hindrance. Some reaction mixtures assumed dark colors and only small amounts of the by-products were recovered, indicating considerable extents of decomposition. The feasibility of the addition reaction thus appeared to be interpreted in terms of the electron availability at the β-position and the stability of the adducts; it is interesting to note that only the methacrylates meet these requirements among the vinyl compounds we examined.

Consequently, a new type of cationic addition of the hydroxymethyl group to C-C double bonds was effected, being quite sensitive to the substituents on the double bonds, and methacrylates were quite suitable for achieving a highly selective reaction.

Experimental

N-(Hydroxymethyl)phthalimide was prepared from phthalimide and formalin according to the procedure reported by Buc.[1]

^{1}H NMR spectra were recorded on a JEOL JNM-PMX60 (60 MHz) or JEOL JNM-GX270 (270 MHz) spectrometer, and ^{13}C NMR spectra on a JEOL PFT100 (25 MHz) or JEOL JNM-GX270 (68 MHz) spectrometer. Chemical shifts are relative to tetramethylsilane. IR spectra were taken with a JASCO IRA-1 spectrophotometer. Mass spectra were obtained with a Finnigan-MAT 4530 GC/MS spectrometer. Melting points were uncorrected.

Reaction of *N*-(Hydroxymethyl)phthalimide (1) with Methyl Methacrylate (2a). To 30 cm^3 of concentrated sulfuric acid kept at 0 °C was added 3.19 g (18 mmol) of pulverized **1**, which went into solution in 20 min with stirring. **2a** (1.80 g, 18 mmol) was added at 0 °C, and the solution was stirred at 18°C for 20 h. It was poured into ice-water, and the mixture was extracted with chloroform. The extract was washed with aqueous sodium hydrogencarbonate and then with water to neutral, dried over sodium sulfate, and evaporated to give 4.14 g of a white solid (mp 95—97 °C), whose TLC showed two spots. From the faster-moving band in column chromatography of the crude product on silicic acid in chloroform, an oily product was obtained and crystallized from acetone/petroleum ether to give 0.16 g (3.4% yield) of **4a** as colorless granules: mp 84—86 °C; IR (KBr) 1770, 1720 (shoulder), and 1700 cm^{-1} (C=O); ^{1}H NMR ($CDCl_3$) δ=2.72 (t, 2H, J=6 Hz, CH_2), 3.78 (s, 3H, OCH_3), 3.91 (t, 2H, J=6 Hz, CH_2), 5.53 (d, 1 H, J=1 Hz, =CH_2), 6.15 (d, 1H, J=1 Hz, =CH_2), and 7.76 (m, 4H, Ar H). Found: C, 64.67; H, 4.96; N, 5.38%. Calcd for $C_{14}H_{13}NO_4$: C, 64.86; H, 5.05; N, 5.40%.

The slower-moving band gave 3.92 g of adduct **3a** (78.6% yield): mp 102—104 °C. Recrystallization from cyclohexane afforded colorless needles: mp 105—106 °C; IR (KBr) 3470 (OH), 1770, 1730 (shoulder), and 1710 cm^{-1} (C=O); ^{1}H NMR ($CDCl_3$) δ=1.47 (s, 3H, CH_3), 2.13 (m, 2H, CH_2), 3.48 (br s, 1H, OH, exchangeable with D_2O), 3.69 (s, 3H, OCH_3), 3.80 (t, 2H, J=7 Hz, CH_2), and 7.78 (m, 4H, Ar H); ^{13}C NMR (DMSO-d_6) δ=25.97 (q, CH_3), 33.25 (t, CH_2), 37.67 (t, CH_2), 51.91 (q, OCH_3), 72.76 (s, -C-), 122.86 (d, Ar C), 131.74 (s, Ar C), 134.23 (d, Ar C), 167.61 (s, imide C=O), and 175.66 (s, C=O); MS m/z 277 (M^+). Found: C, 60.95; H, 5.37; N, 5.26%. Calcd for $C_{14}H_{15}NO_5$: C, 60.64; H, 5.45; N, 5.05%.

Reaction of *N*-(Hydroxymethyl)phthalimide (1) with Ethyl Methacrylate (2b). The reaction was carried out in the same way at 18°C for 20 h, and on chromatography, two products were isolated. One from the faster-moving band was an oil (adduct **4b**) which did not solidify (5.0% yield): IR (neat) 1770, 1730 (shoulder), and 1710 cm^{-1} (C=O); ^{1}H NMR ($CDCl_3$) δ=1.31 (t, 3H, J=7 Hz, CH_3), 2.70 (t, 2H, J=7 Hz, CH_2), 3.88 (t, 2H, J=7 Hz, CH_2), 4.22 (q, 2H, J=7 Hz, OCH_2), 5.51 (d, 1H, J=1 Hz, =CH_2), 6.12 (d, 1H, J=1 Hz, =CH_2), and 7.72 (m, 4H, Ar H).

The other from the slower-moving band was a white solid (adduct **3b**, 82.0% yield): mp 90—92 °C. Recrystallization from cyclohexane gave colorless needles: mp 93—95 °C; IR (KBr) 3500 (OH), 1770, 1725 (shoulder), and 1705 cm^{-1} (C=O); ^{1}H NMR ($CDCl_3$) δ=1.26 (t, 3H, J=7 Hz, CH_3), 1.45 (s, 3H, CH_3), 2.12 (m, 2H, CH_2), 3.41 (s, 1H, OH, exchangeable with D_2O), 3.78 (t, 2H, J=7 Hz, CH_2), 4.11 (q, 2H, J=7 Hz, OCH_2), and 7.73 (m, 4H, Ar H). Found: C, 62.01; H, 5.89; N, 5.24%. Calcd for $C_{15}H_{17}NO_5$: C, 61.85; H, 5.88; N, 4.81%.

Reaction of *N*-(Hydroxymethyl)phthalimide (1) with Acrylonitrile (5a) or Methacrylonitrile (5b). After the reaction of **5a** with two equivalents of **1** under the same reaction conditions, products were separated by column chromatography. The major product was **6a** (89.7% yield based on **5a**): mp 195—196 °C (lit,[5] 193 °C). Others are by-products formed from excess **1**: phthalimide (23% yield), bis(phthalimide)methane (1% yield); mp 227—229 °C (lit,[6] 226 °C), and bis(phthalimidemethyl) ether (2% yield); mp 205—207 °C (lit,[7] 207—209 °C).

With **5b** and two equivalents of **1**, the reaction proceeded in a similar manner giving rise to the formation of **6b** along with the by-products from **1** as in the case of **5a**. The yield of **6b** was 83.6% on the basis of **5b**: mp 159—161 °C; IR (KBr) 3390 (NH), 1775, 1720 (shoulder), and 1710 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ=1.95 (s, 3H, CH_3), 5.27 (d, 2H, J=6 Hz, CH_2), 5.38 (s, 1H, =CH_2), 5.74 (s, 1H, =CH_2), 6.85 (br s, 1H, NH), and 7.72—7.87 (m, 4H, Ar H); ^{13}C NMR ($CDCl_3$) δ=18.4 (CH_3), 42.8 (CH_2), 120.7 (=CH_2), 123.5 (Ar C), 131.8 (Ar C), 134.2 (Ar C), 139.2 (=C), 167.4 (imide C=O), and 167.6 (C=O). Found: C, 64.06; H, 4.78; N, 11.65%. Calcd for $C_{13}H_{12}N_2O_3$: C, 63.92; H, 4.95; N, 11.47%.

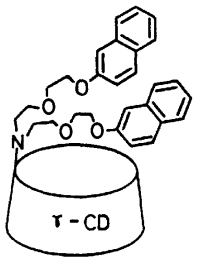
(Received March 5, 1988)

Synopsis. Circular dichroism and fluorescence studies of γ-cyclodextrin bearing two naphthyl moieties (**1**) suggest that **1** exists as two intramolecular self-complexation forms in water-rich solutions with one or two of the naphthyl moieties included in its cavity. Upon addition of (−)-borneol as a guest, **1** forms a 1 : 1 host-guest complex, exhibiting slightly diminished excimer and circular dichroism bands. Ethylene glycol converts the intramolecular complexes into a relaxed form, in which two naphthyl moieties dangle outside the cavity.



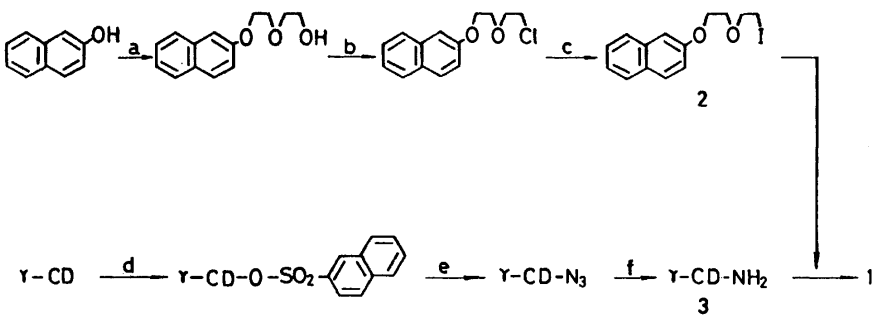
1

Many spectroscopic studies have shown that γ-cyclodextrin (γ-CD, cyclooctaamylose) can include two guest molecules in its large cavity.[1] When an aromatic moiety is covalently linked to γ-CD, it was suggested to enable γ-CD to form 1 : 1 host-guest complexes by narrowing the large cavity as a spacer.[2] When γ-CD has two naphthyl moieties located apart on its rim, the host accommodates one guest molecule in its cavity by moving the two naphthyl moieties outward from the interior of the cavity.[3] We describe here fluorescence and circular dichroism properties of another type of bi-chromophoric γ-CD (**1**), in which two naphthyl moieties are branched out from the nitrogen atom of amino-γ-CD.

The double armed γ-CD **1** was prepared as shown in Scheme 1. Since the reaction of γ-CD with 2-naphthalenesulfonyl chloride in pyridine is known to give a γ-CD derivative sulfonated regiospecifically at a primary hydroxyl, the amino moiety bearing two naphthalene rings is located at the narrower mouth of the primary hydroxyls of γ-CD.

Figure 1 shows the circular dichroism spectra of **1** in an aqueous 10% ethylene glycol solution. The spectrum of **1** at 8.42×10^{-5} mol dm^{-3} exhibits peaks around 220 nm and 280 nm and a trough around 240 nm. The dichroism intensities of the peak and the trough below 250 nm were reduced with decreasing concentration of **1**, and the spectrum, which has no trough around 240 nm, is eventually obtained. This concentration-dependency suggests that **1** associates with each other at its high concentrations. The change in the dichroism sign from negative to positive from the longer wavelength side below 250 nm may be related to the exciton coupling of S-helicity[4] arising from the electronic interaction between two naphthalene rings involved in the associated forms of **1**. Since no concentration-dependency was observed at lower concentrations than 2×10^{-5} mol dm^{-3} (Fig. 1 (B)), **1** is likely to exist as a monomer species in the concentration range. Upon addition of (−)-borneol to a dilute solution of **1**, the intensity of the positive peak around 218 nm was found to diminish, but the spectrum obtained in the presence of excess (−)-borneol still has the peak with a considerable intensity (Fig. 1). The analysis of the (−)-borneol-induced circular dichroism variations gave 720 mol^{-1} dm^3 as the binding constant.[3]

Figure 2 shows the fluorescence spectra of **1** in an aqueous 10% ethylene glycol solution, alone or in the presence of (−)-borneol. It is noted that the fluorescence pattern is hardly dependent on the concentration of **1**. The spectra exhibit a broad band around 410 nm in addition to the normal fluorescence around 358 nm. Since the broad band was observed even in acidic solu-



a, $ClCH_2CH_2OCH_2CH_2OH$, NaOH, 1-BuOH; b, $SOCl_2$; c, NaI, DMF; d, 2-$C_{10}H_7SO_2Cl$, pyridine; e, NaN_3; f, H_2/Pd-C

Scheme 1.

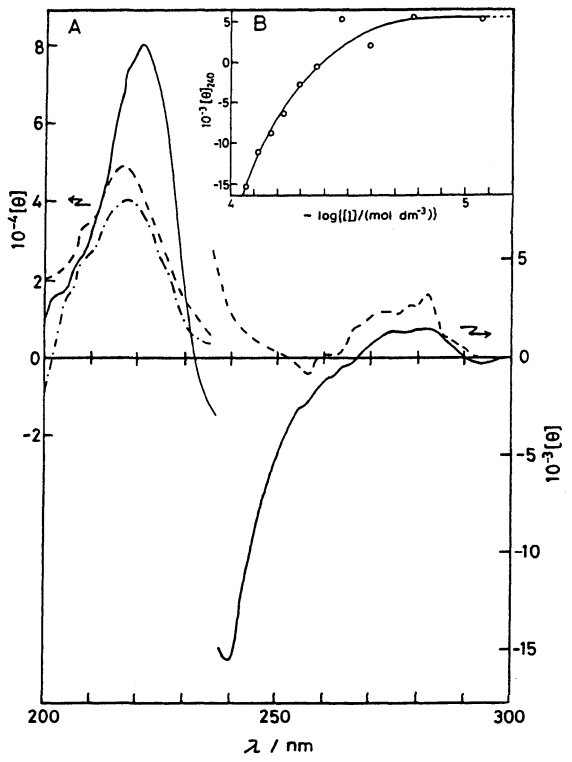


Fig. 1. Circular dichroism spectra of **1**, alone (——, 8.42×10^{-5} mol dm^{-3}; ----, 1.68×10^{-5} mol dm^{-3}) or in the presence of (−)-borneol (–·–: **1**, 1.68×10^{-5} mol dm^{-3}; (−)-borneol, 2.17×10^{-4} mol dm^{-3}) in an aqueous 10% ethylene glycol solution. The concentration-dependency of 240-nm dichroism intensity is shown in B.

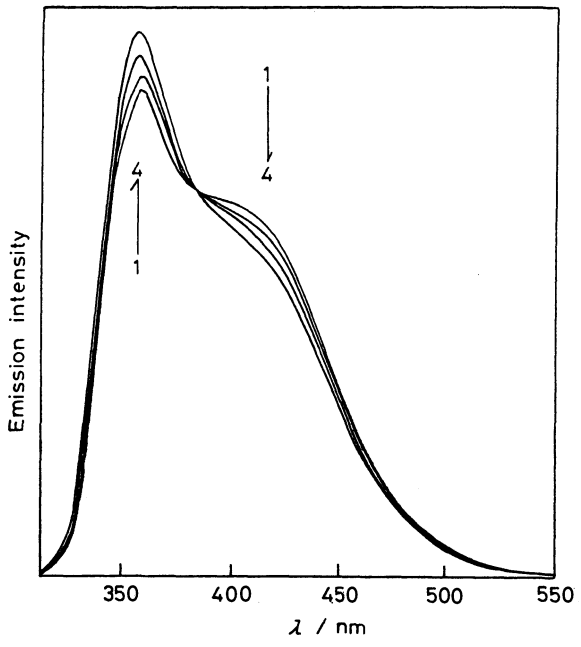

Fig. 2. Fluorescence spectra of **1** (7.68×10^{-6} mol dm^{-3}) in an aqueous 10% ethylene glycol solution at various (−)-borneol concentrations (1, 0; 2, 5.0×10^{-4}; 3, 2.0×10^{-3}; 4, 4.0×10^{-3} mol dm^{-3}).

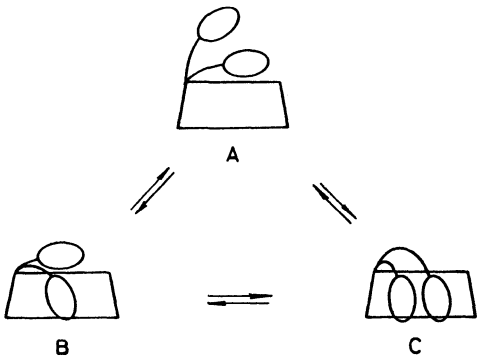
tions, it was assigned to excimer emission, in other words, the band cannot be assigned to exciplex emission, which might have been caused by excited-state electronic interaction between the naphthyl chromophore and the nitrogen atom.[5] With increasing (−)-borneol concentration, the excimer intensity decreases while the monomer intensity increases. These (−)-borneol-induced variations are slight and suggest that excimer formation is possible even in the complexes.

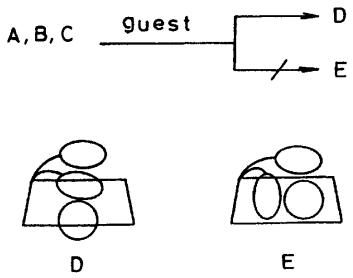
When fluorescence spectra of **1** were measured at various ethylene glycol contents, the relative intensity of the excimer emission diminished with increasing ethylene glycol, and almost pure monomer fluorescence band was obtained in ethylene glycol. The absence of the excimer emission in ethylene glycol indicates that the two naphthyl moieties of **1** are separated from each other outside the cavity in the organic solvent.

Compound **1** may take three equilibrium forms **A**, **B**, and **C** in its dilute solutions as shown in Scheme 2. In **B** and **C**, **1** accommodates one or two of the pendant naphthyl moieties in its own cavity (intramolecular self-complexation). Since **1** exhibits induced circular dichroism in the naphthalene absorption regions, the naphthyl moiety is likely to be involved in the chiral CD cavity, and **B** and **C** forms are candidates for predominant species in water-rich solutions. In **B**, one of two naphthyl moieties acts as a cap[6] for another naphthyl moiety, which is included in the cavity, stabilizing the intramolecular complex. In **C**, the two naphthyl



Scheme 2.

moieties are involved into the cavity together. The excimer emission observed in water-rich solutions confirms that **1** can take **C** form with two naphthyl moieties included in the cavity. On the other hand, the considerable intensity of the monomer emission suggests that **1** can also take **B** form, in which excimer is hardly formed because of the difficulty in face-to-face interactions between the two naphthyl moieties.[7] In ethylene glycol, **1** exhibits no excimer emission and may take **A** form due to weak hydrophobic interactions. The complex formation with (−)-borneol may convert **1** from intramolecular self-complexation forms **B** and **C** to an intermolecular complexation form **D** as shown in Scheme 3. Since excimer emission of **1** was still observed in the presence of (−)-borneol, the two naphthyl moieties are likely to be closely located in complex **D**. Examination of molecular



Scheme 3.

models indicates that complex form **E**, in which one of the two naphthyl moieties acts as a typical spacer for (−)-borneol, cannot be formed due to bulky size of (−)-borneol. The fact that the circular dichroism intensity of **1** is still large in the presence of excess (−)-borneol, suggests that one or two of the naphthyl moieties are likely to be involved partly in the γ-CD cavity in complex **D**, acting as flexible caps for the included guest.

Experimental

The circular dichroism and fluorescence spectra were measured at 25 °C using a JASCO J-400X spectrodichrometer and a Shimadzu RF-500 spectrofluorophotometer, respectively. The circular dichroism intensities were expressed as molar ellipticity (in degree cm^2dmol^{-1}) on the basis of the total concentration of **1**. Due to the poor solubility of **1** in pure water, an aqueous 10% ethylene glycol solution was used as the solvent. 2-Naphthylsulfonyl-γ-CD was prepared according to the reported method.[2b] Azido and amino derivatives of γ-CD were prepared by the methods similar to those reported by Melton et al.[8] for preparation of the corresponding α-CD derivatives.

Synthesis of 1. A mixture of the iodide **2** (2.7 g, 7.5 mmol), amino-γ-CD **3** (1.2 g, 0.93 mmol), K_2CO_3 (0.98 g), and *N*,*N*-dimethylformamide (40 ml) was heated at 80 °C for 40 h under nitrogen. After cooling, the reaction mixture was filtered and the filtrate was poured into 500 ml of acetone. The precipitates were collected by filtration, dissolved in water, and subjected to CM-Sephadex C-50 column chromatography with water as the eluting solvent. Recrystallization from methanol gave the desired product (0.202 g, 12%): R_f=0.46 (*n*-BuOH, EtOH, H_2O 5 : 4 : 3); ^1H NMR (DMSO-d_6) δ=2.6—3.8 (m, 64H), 4.50 (m, 7H, O_6H), 4.88 (m, 8H, C_1H), 5.63—5.96 (br. s, 16H, O_2H, O_3H), 7.13—7.88 (m, 14H, Ar); IR (KBr): 1628, 1600 cm^{-1}. Found: C, 50.76; H, 6.25; N, 0.76%. Calcd for $C_{76}H_{109}NO_{43}\cdot 4H_2O$: C, 50.80; H, 6.56; N, 0.78%.

Configurational Stability of Optically Active Selenoxides; Racemization via Achiral Hydrate

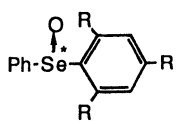
Toshio SHIMIZU,[1] Michio KOBAYASHI, and Nobumasa KAMIGATA*
Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Fukazawa, Setagaya-ku, Tokyo 158
(Received March 10, 1988)

Synopsis. Configurational stabilities of optically active diaryl selenoxides are examined under several conditions such as acidic, basic, or in the presence of water. It is found that the diaryl selenoxide which has two hindered *t*-butyl groups on the ortho positions is relatively stable toward racemization even under acidic conditions. Mechanism of racemization is ascertained to be via formation of the achiral hydrate ($R\text{-}Se(OH)_2\text{-}R'$) by the observation of oxygen exchange on the selenium atom.

Although optically active sulfoxides have been known for a long time, there has been no example of the isolation of an optically active selenoxide until recently. Davis et al. first reported the preparation of enantiomerically active selenoxides several years ago, although the enantiomeric excesses of the selenoxides were low.[2] Since then several optically active selenoxides were synthesized.[3-7] We reported the synthesis of optically active selenoxides by fractional recrystallization of diastereomeric mixture[4] or chromatographic separation using optically active column.[6] In addition, we obtained optically pure selenoxide as a stable solid by transesterification of the diastereomerically pure selenoxide.[7] The difficulty of the optical resolution of selenoxide has been attributed to its facile racemization.[8] Two mechanisms for the racemization of selenoxide are considered. One is the mechanism by the pyramidal inversion and the other is the mechanism via formation of its achiral hydrate ($R\text{-}Se(OH)_2\text{-}R'$). We previously estimated the stability of asymmetric selenoxides toward the pyramidal inversion. Optically active diaryl selenoxides were found to become more stable toward the pyramidal inversion by substitutions of bulky groups on the ortho positions.[9] However, the second mechanism of racemization involving the achiral hydrate is anticipated to be also important. We report here the configurational stability of optically active diaryl selenoxides which possess ortho substituents of various sizes under several conditions such as acidic, basic, or in the presence of water.

Results and Discussion

The optically active selenoxides were prepared by chromatographic resolution (optically active column) of the racemic samples.[6] Racemizations of selenoxides were measured at 26 °C in chloroform or methanol. Progress of the racemization was monitored by means of the circular dichroism spectrum. The racemizations in chloroform were examined, to begin with. However, no racemization was observed and the optical activities of selenoxides **1**—**4** were unchanged even after 5 days. When the racemizations were measured in



1 : R = Me
2 : R = Et
3 : R = i-Pr
4 : R = t-Bu

methanol, selenoxide **1**—**3** were found to racemize. The rate constants of the racemizations of **1**—**3** were 6.00×10^{-6}, 1.85×10^{-6}, 1.33×10^{-6} s^{-1} and the half-lives of the optical activities were 32.1, 104, 145 h, respectively. Larger ortho substituents were found to be more effective for retardation of the racemization. The selenoxide **4** which possessed the most bulky ortho substituents in this series was quite stable in methanol. The rate constants and half-lives of the racemizations are summarized in Table 1.

Influences of water, acid, and base were also examined. In the presence of water, racemizations were accelerated in the cases of selenoxides **1**—**3**, however selenoxide **4** was still stable even in the presence of water (Entries 3 and 4). The racemizations of selenox-

ides **1**—**3** in dry methanol (distilled after drying with CaH_2) are suspected to be due to the presence of small traces of water in the methanol, because the racemizations were accelerated in aqueous methanol and no racemization occurred in chloroform which was a hydrophobic solvent. Remarkable acceleration of the racemization was observed in all selenoxides under acidic conditions (Entry 5). In the cases of selenoxides **1**—**3**, the racemizations were fast and completed within 1 min. The selenoxide **4** also racemized under these conditions, however, the half-life was long (10.4 h). Therefore, bulky ortho substituents of diaryl selenoxide particularly *t*-butyl groups were found to be effective to retard or prevent the racemization catalyzed by the acid and water. The racemization of selenoxide **1** was also examined in basic media. The racemization of the selenoxide was not accelerated by the addition of sodium hydroxide into aqueous methanol solution (Entry 6).

Since all the racemizations were examined at room temperature and no racemization occurred in chloroform and the racemizations were observed in aqueous conditions, the racemizations of selenoxides under these conditions are considered to proceed via its achiral hydrate. To clarify the mechanism via the hydrate, the racemization of selenoxide **2** with ^{18}O-labeled water was studied. A methanol solution of selenoxide **2** in the presence of $H_2{}^{18}O$ (97 atom%) was stirred at room temperature. The mass spectrum of selenoxide **2** after 10 days indicated the formation of ^{18}O-labeled selenoxide (M^+ 336(^{80}Se), 334(^{78}Se)) (Fig. 1). The high-resolution mass spectrum also supported the formation of the selenoxide-^{18}O. This result indicates the formation of the achiral hydrate. Though the achiral hydrate itself expected to be formed by hydration of the selenoxide **2** could not be detected by mass spectroscopy, it is attributed to the lability of the hydrate.

The results that the racemization was accelerated under acidic conditions and not accelerated in basic

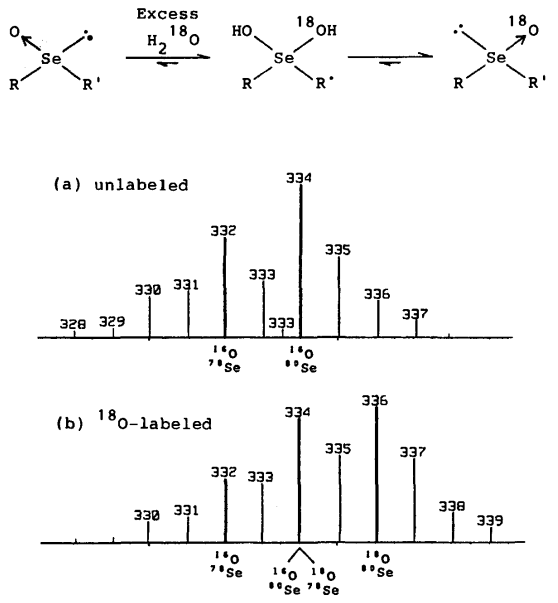

Fig. 1. Mass spectrum analysis of heavy oxygen exchange on selenium atom of selenoxide 2.

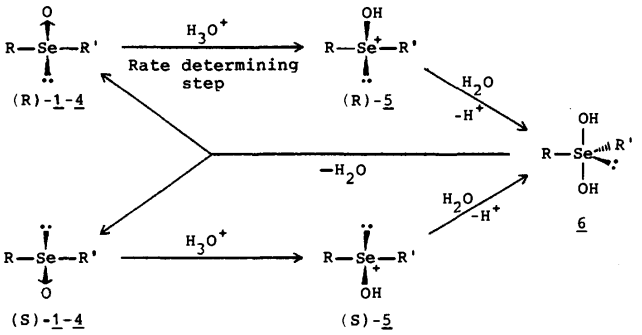

Scheme 1. Mechanism of racemization via achiral hydrate.

media suggest that the protonation on the oxygen atom of the selenoxide is the rate-determining step as shown in Scheme 1. This protonation on the selenoxide corresponds to the protonation of sulfoxide in strong acidic media.[10] The second step of the racemi-

$$Ph_2S{\rightarrow}O + H_2SO_4 \rightleftharpoons Ph_2S^+{-}OH + HSO_4^-$$

zation is fast addition of water to the hydroxy selenonium cation (*R*)-**5** or (*S*)-**5**. The addition of water to the hydroxy selenonium ion (*R*)-**5** or (*S*)-**5** followed by elimination of proton to give the achiral hydrate **6**. Finally, dehydration of the achiral hydrate **6** give the racemic mixture of selenoxide (*R*)-**1**—**4** and (*S*)-**1**—**4** resulting the exchange of the oxygen atom.

In conclusion, it was ascertained that the racemization of optically active selenoxides occurred through the achiral hydrate in aqueous media. Configurational stabilities of the optically active diaryl selenoxides toward the racemization via its achiral hydrate were found to be dependent on the ortho substituents.

Experimental

Materials. The optically active selenoxides **1**—**4** were prepared by optical resolution of racemic samples[3,11] using an optically active column.[6] Enantiomeric excesses (e.e.) of optically active selenoxides **1** and **2** were determined by ^1H NMR using Eu(hfc)$_3$ as an optically active shift reagent.[6] In the cases of optically active selenoxides **3** and **4**, e.e. were determined by HPLC using an optically active column.[11] The optical rotations and enantiomeric excesses (e.e.) of selenoxides used in the measurements of racemizations are shown below.

Phenyl Mesityl Selenoxide (1): $[\alpha]_D$ +40.2° (*c* 0.95, chloroform). E.e.=16%.

Phenyl 2,4,6-Triethylphenyl Selenoxide (2): $[\alpha]_D$ −29.0° (*c* 0.90, chloroform). E.e.=12%.

Phenyl 2,4,6-Triisopropylphenyl Selenoxide (3): $[\alpha]_D$ +58.4° (*c* 1.35, chloroform). E.e.=66%.

Phenyl 2,4,6-Tri-*t*-butylphenyl Selenoxide (4): $[\alpha]_D$ +96.5° (*c* 1.30, chloroform). E.e.=49%.

Measurement of Racemization. All racemizations of the selenoxides were carried out in 1 mmol l^{-1} concentration at 26 °C. Progress of the racemization was monitored by means of the circular dichroism spectrum (JASCO J-40A) at ca. 290 nm. The measurements of the racemizations were continued until about one half-life time.

Heavy Oxygen Exchange of Selenoxide. Heavy oxygen exchange of selenoxide **2** was carried out in methanol in the presence of ^{18}O-labeled water (Merck, 97 atom%). Concentra-

tions of selenoxide and the labeled water were 5 mmol l^{-1} and 0.5 mol l^{-1}, respectively. Formation of the ^{18}O-labeled selenoxide **2**-^{18}O was confirmed by the mass spectrum (JEOL JMS-DX300) after 10 days. M^+ 336(^{80}Se), 334(^{78}Se). Exact MS, Found: m/z 336.0867 (^{80}Se), Calcd for $C_{18}H_{22}{}^{18}O^{80}Se$: 336.0878. The relative intensities of the mass spectra shown in Fig. 1 are summarized below. Enriched oxygen-18 contained in the selenoxide **2**-^{18}O was estimated by measurements of both its low and high mass spectroscopy. The enriched oxygen-18 was calculated to be 38% by low mass spectroscopy based on intensities of the mass spectrum, m/z 328 ($C_{18}H_{22}{}^{16}O^{74}Se$, relative intensity: 3.5) and 338 ($C_{18}H_{22}{}^{18}O^{82}Se$, relative intensity: 22.3), since these mass numbers do not contain other isotope of oxygen and selenium. The oxygen-18 contained was also estimated to be 46% by high mass spectroscopy based on m/z 332 ($C_{18}H_{22}{}^{16}O^{78}Se$), 334 ($C_{18}H_{22}{}^{18}O^{78}Se$ and $C_{18}H_{22}{}^{16}O^{80}Se$), and 336 ($C_{18}H_{22}{}^{18}O^{80}Se$).

The Synthesis of *Se*-Alkyl Alkaneselenoates via (1-Iodo-1-alkenyl)dialkylboranes

Masayuki HOSHI, Yuzuru MASUDA, and Akira ARASE*
Department of Industrial Chemistry, Kitami Institute of Technology, Kitami 090
(Received April 4, 1988)

Synopsis. *Se*-Alkyl alkaneselenoates were formed in moderate to good yields by successive reactions of (1-iodo-1-alkenyl)bis(1,2-dimethylpropyl)boranes with alkylselenomagnesium bromides and alkaline hydrogen peroxide.

Se-Alkyl alkaneselenoates (**5**) are receiving considerable attentions in organic syntheses.[1] A synthetic method for **5** has been developed employing carboxylic acid derivatives or selenocarboxylic acid derivatives as the substrates in most cases.[2] In our previous work, the reaction of (1-iodo-1-alkenyl)dialkylboranes (**1**) with alkylthiomagnesium bromides proceeded with inversion of configuration to give (*E*)-(1-alkylthio-1-alkenyl)dialkylboranes, which provided *S*-alkyl alkanethioates on alkaline hydrogen peroxide oxidation.[3] The above results led us to examine the synthesis of (*E*)-(1-alkylseleno-1-alkenyl)dialkylboranes (**4**) and, further, a new synthesis of **5** via **4**.

Preliminarily, (1-iodo-1-hexenyl)bis(1,2-dimethylpropyl)borane (**1a**), prepared by the hydroboration of 1-iodo-1-hexyne with bis(1,2-dimethylpropyl)borane in THF, was treated with an equimolar amount of butylselenomagnesium bromide (**2a**),[4] and the reaction mixture was then oxidized by alkaline hydrogen peroxide in the presence of *N,N,N′,N′*-tetramethylethylenediamine (TMEDA). As expected, *Se*-butyl hexaneselenoate (**5a**) was obtained in 58% yield. It was isolated from the oxidized mixture by column chromatography using silica gel (eluted by a mixture of benzene and hexane, 1 : 4). It was then identified by a comparison of its ^{1}H NMR, ^{13}C NMR, IR, and MS spectra with those of an authentic sample prepared by another method.[2a] The yield increased to 95% by employing a two-fold amount of **2a** under the same reaction conditions, though dibutyl selenide and dibutyl diselenide were competitively formed. These contaminants were easily separated from **5a** during the above-mentioned column chromatography. An addition of TMEDA was necessary; otherwise, the yield became nearly zero. A migration of 1,2-dimethylpropyl group from the boron atom to the α-alkenyl carbon atom,[5] a possible side reaction, did not occur under any cases. As shown in Table 1, several types of alkylselenomagnesium bromides may be employed in the present reaction. Thus, in the cases of primary and secondary alkylselenomagnesium bromides, the selenoates **5** were produced in 50—90% yields. The unsatisfactory results, which appeared in the case of 1,1-dimethylethyl-

magnesium bromide, may be attributed to a difficulty regarding the presence of this reagent under the reaction conditions employed.

In a similar manner to the reaction of **1** with alkylthiomagnesium bromides,[3] **4** were suggested to be formed as precursors of **5**. Therefore, the boranes **4** would be expected to provide the corresponding (*E*)-1-alkylseleno-1-alkenes (**6**) on protonolysis of carbon-boron bond. Thus, an attempt to provide (*E*)-1-butylseleno-1-hexene (**6a**) was made by a protonolysis of **4a** with various carboxylic acids. A GLC examination of the protonolyzed mixture failed to show any detectable **6a**. However, a treatment of the same mixture successively with butyllithium and aqueous sodium hydroxide, a method reported by Negishi et al. for the conversion of the carbon-boron bond of alkenylboranes into a carbon-hydrogen bond with retention of configuration,[6] afforded highly pure **6a** in 67% yield, estimated by GLC. Compound **6a**, thus obtained, isomerized very easily to (*Z*)-isomer during the isolation procedure using column chromatography to give a mixture of *E*- and *Z*-isomer (*E*/*Z*=74/26). The *E*-isomer was assigned by an absorption band at 945 cm^{-1} in the IR spectrum and a coupling constant of 15 Hz between olefinic protons in the ^1H NMR spectrum. The *Z*-isomer was assigned by a coupling constant of 10 Hz between olefinic protons in the ^1H NMR spectrum. In similar reactions, several types of **6** were produced stereoselectively (Table 1); however, they also gave mixtures of *E*- and *Z*-isomer respectively in the isolation process. Thus, the above results strongly suggest an intermediary formation of **4**, though they have not yet been isolated and, thus, have not been directly analyzed. Accordingly, the reaction was speculated to proceed in the following way. Thus, with the alkylseleno anion, the boranes **1** form borate-complexes (**3**) which are transformed to **4** with an inversion of configuration; then, the boranes **4** are converted to **5** and **6**, respectively.

The present reaction not only offers a new synthetic method for *Se*-alkyl alkaneselenoates but also suggests the formation of alkenylboranes having the alkylseleno group on the α-alkenyl carbon atom. These alkenylboranes are expected to be versatile intermediates for various organoselenium compounds.

Experimental

Instruments. ^1H and ^{13}C NMR spectra were recorded on a Jeol FX-200 (200 MHz) spectrometer and obtained from a $CDCl_3$ solution containing TMS as the internal standard. IR spectra (film) were recorded with a Hitachi 285 spectrometer. Mass spectra were recorded with a Hitachi M-52 mass spectrometer.

Materials. Commercial 2-methyl-2-butene was purified by distillation over lithium aluminium hydride under an argon stream, and stored under an argon atmosphere. 1-Iodo-1-alkynes were prepared as described in the literature,[7] and used after drying over Molecular Sieves-4A. Commercial alkyl, phenyl, and benzyl bromides were dried with calcium chloride, purified by distillation, and stored over Molecular Sieves-4A under an argon atmosphere. Commercial selenium powder was used after drying in a vacuum desiccator containing phosphorus pentoxide. THF and diethyl ether were distilled over lithium aluminium hydride under argon stream, and stored under an argon atmosphere. TMEDA was purified by vacuum distillation over calcium hydride, and stored under an argon atmosphere. A THF solution of BH_3 was prepared by a method described in the literature.[8] Hexane and benzene, used as eluent for column chromatography, were distilled over sodium.

Representative Procedure. A solution of bis(1,2-dimethylpropyl)borane (10 mmol) in THF was prepared in a 50-ml argon-flushed round-bottom flask, and to the stirred solution was added 2.08 g of 1-iodo-1-hexyne (10 mmol) at −15 °C. The reaction mixture was stirred for 1 h at 0 °C and for additional 1 h at room temperature to complete the reaction. On the other hand, 0.48 g of magnesium turnings (20 mmol) was placed in a 100-ml round-bottom flask; the flask was then flushed with argon. The flask was charged with 20 ml of dry THF, and 2.74 g of butyl bromide (20 mmol) was slowly added to the vigorously stirred solution at room temperature giving a solution of butylmagnesium bromide in THF. After an addition of 40 ml of dry THF, the solution was cooled to −30 °C. Then, 1.58 g of selenium powder (20 mmol) was added through a sample inlet under argon flow to the vigorously stirred suspended solution of butylmagnesium bromide. After stirring for 1 h at −30 °C, the color of the suspension changed from black to cream. The resulting suspension of butylselenomagnesium bromide was further cooled to −50 °C.

The THF solution of (1-iodo-1-hexenyl)bis(1,2-dimethylpropyl)borane in the 50-ml round-bottom flask was then transferred to the suspended solution with a double-ended needle. The reaction mixture was stirred for 1 h at −50 °C and allowed to warm to room temperature. The reaction mixture was then oxidized by a successive addition of 5 ml of TMEDA, 5 ml of 3 mol dm^{-3} aqueous sodium hydroxide and 5 ml of 30% hydrogen peroxide for 1 h at 0 °C. The resulting mixture was extracted with diethyl ether; extract was then washed with brine, and dried over anhydrous magnesium sulfate. The solvent was removed on a rotary evaporator under reduced pressure, and the residue was put on a silica-gel column. The *Se*-butyl hexaneselenoate (2.12 g) was isolated by elution with a mixture of hexane and benzene (4 : 1) (90% yield).

The spectral data of the products are as follows:

***Se*-Ethyl Hexaneselenoate:** ^1H NMR ($CDCl_3$) δ=0.80—0.98 (m, 6H), 1.05—1.80 (m, 6H), 2.60 (t, *J*=7 Hz, 2H), and 2.89 (q, *J*=7 Hz, 2H); ^{13}C NMR ($CDCl_3$) δ=13.84, 15.97, 22.30, 25.17, 29.69, 30.98, 48.26, and 202.17 (>C=O); IR (film) 1715 (C=O) cm^{-1}; MS *m*/*z* 206 and 208 (M^+).

***Se*-(1-Methylethyl) Hexaneselenoate:** ^{1}H NMR δ=0.83—0.96 (m, 3H), 1.20—1.80 (m, 6H), 1.46 (d, J=7 Hz, 6H), 2.57 (t, J=7 Hz, 2H), and 3.50—3.75 (m, 1H); ^{13}C NMR δ=13.86, 22.33, 24.32 (CH_3-, 2C), 25.17, 31.00, 33.22 (>CH-), 48.44, and 202.99 (>C=O); IR 1710 (C=O) cm^{-1}; MS m/z 220 and 222 (M^+).

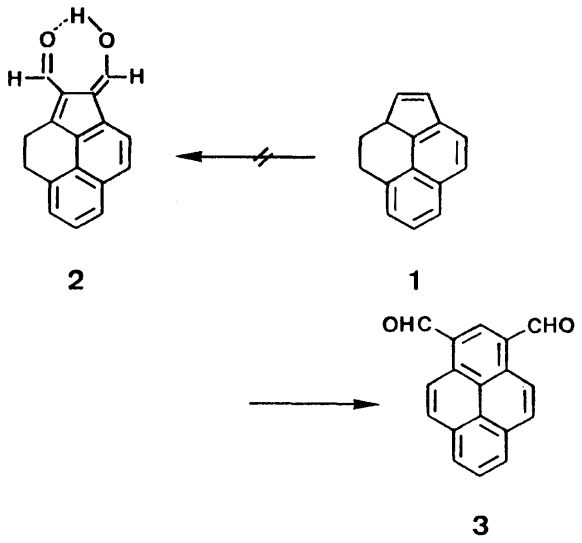
A Convenient Synthesis of 1,3-Pyrenedicarbaldehyde

Michael GOLTZ† and Ichiro MURATA*
Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560
(Received April 14, 1988)

Synopsis. A convenient and preparatively useful access to the unknown 1,3-pyrenedicarbaldehyde is presented. When treated with an excess amount of *N,N*-dimethylformamide and phosphoryl chloride, 3,4-dihydro-2a*H*-cyclopenta[*cd*]phenalene was smoothly converted into dialdehyde in 57% yield. A plausible mechanism for this transformation was suggested from a labeling experiment using *N,N*-dimethylformamide-d_7.

Although pyrene is a reactive aromatic hydrocarbon and readily gives mono-, di-, tri-, and tetra-substitution in positions 1-, 1,6-, (and 1,8-), 1,3,6-, and 1,3,6,8-, respectively, by various electrophilic substitution reactions,[1] 1,3-disubstituted derivatives are hardly accessible. Quite recently, Harvey et al. reported that the acetylation of pyrene produced a mixture of 1,6- and 1,8-diacetylpyrene together with the 1,3-derivative, which was difficult to separate.[2] However, a selective introduction of carbon functionalities in these positions has not been reported so far. The only known 1,3-dialkyl derivatives are the 1,3-dimethylpyrene, which has been isolated together with its 1,8-isomer from a Vilsmeier formylation and reduction sequence of 1-methylpyrene,[3] and the 1,3-dipropylpyrene derived from 1-(2-chloro-1,3-dipropyl-2-cyclopropenyl)-1*H*-phenalene in poor yield.[4] During the course of our studies on nonalternant polycyclic hydrocarbons, we have found a convenient access to 1,3-pyrenedicarbaldehyde (**3**).

In order to synthesize the tetracyclic aldehyde **2** as a potential building block for the construction of various nonalternant hydrocarbons including a phenalene ring system,[5] the Vilsmeier reaction of 3,4-dihydro-2a*H*-cyclopenta[*cd*]phenalene (**1**)[6] was carried out. When treated with a large excess of *N,N*-dimethylformamide and phosphoryl chloride at room temperature for 14 h, compound **1** was smoothly converted into a stable crystalline product, yellow needles, mp 245—246 °C as the sole product in 57% yield. In contrast to our expectation, the structure of the obtained product was unambiguously established not as **2** but as 1,3-pyrenedicarbaldehyde (**3**), as shown in Scheme 1, from an elemental analysis and the following spectroscopic data. The electronic spectrum of **3** exhibits absorption bands similar to those of 1-pyrenecarbaldehyde.[7] Its IR spectrum shows the characteristic absorptions of aromatic aldehydes at 2700 and 1650 cm^{-1}. The presence of two formyl groups was established by its mass spectral fragmentation of *m/z* 258 (M^+, 33%), 229 (M^+ −CHO, 25%), and 200 (M^+ −2CHO, 100%). The NMR spectra reflect the C_{2v} symmetry. Thus, in $CDCl_3$ at 500 MHz, the two aldehyde protons appear as one singlet at δ 10.78 and the



Scheme 1.

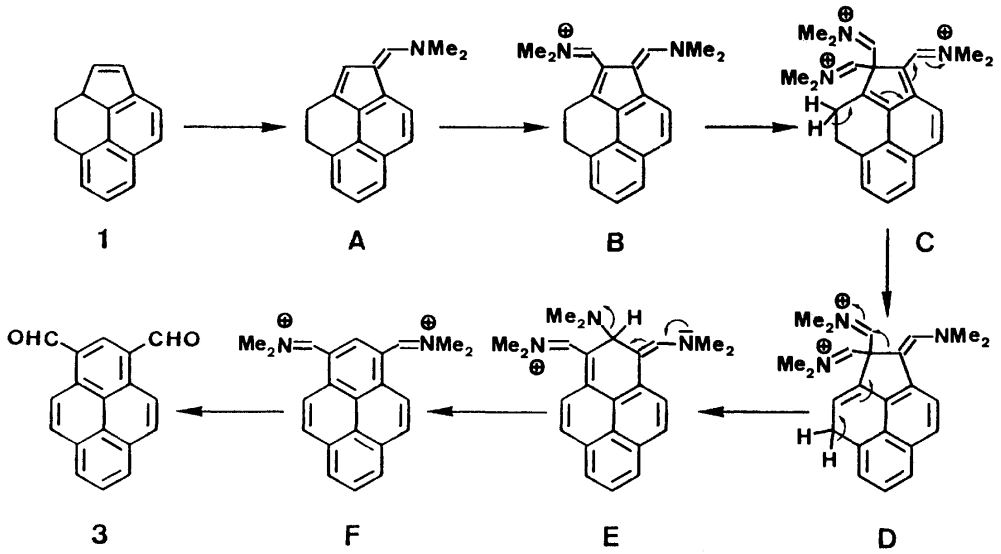
aromatic protons show an AB-quartet (4H) at δ 8.46 (H-5 and 9) and 9.49 (H-4 and 10) with *J*= 9.15 Hz, AX_2 pattern (3H) at δ 8.19 (H-7) and 8.43 (H-6 and 8) with *J*= 7.63 Hz, and 1H singlet at δ 8.83 (H-2). Its eleven carbon types was also revealed by the ^{13}C NMR spectrum (see Experimental).

The mechanism for the transformation of **1** to **3** is of particular interest. It should be noted that one CH-unit was incorporated into the ring skeleton of **1** and that the dehydrogenation took place during a reaction at room temperature under nitrogen.

The origin of the additional carbon atom was confirmed by a Vilsmeier reaction of **1** using *N,N*-dimethylformamide-d_7. Thus, the ^1H NMR spectrum of product **3**-d_3 from this reaction clearly reveals the deuterium incorporation at the 2-position of the pyrene skeleton in addition to the two formyl groups. Hence, the CH-unit at the 2-position must have arisen from the Vilsmeier reagent.

From a labeling experiment, together with the well-documented Vilsmeier reaction of cyclopentadiene derivatives,[8] we propose a plausible mechanism that might account for the transformation of **1** to **3** involving multi-step reactions, as shown in Scheme 2. As for the first and second steps, several precedents for the formation of 6-dimethylamino-1-[dimethyliminiomethyl]fulvenes appear in the literature.[8] Regarding the third step, we postulate that the Vilsmeier reagent attacks at the 6-position of the ring system to produce the tri-substituted intermediate **C**, which readily expels a proton owing to the generation of a naphthalene conjugation (**C**→**D**). The second deprotonation can occur with an expansion of the five-membered ring, followed by an elimination of dimethylamine to form a pyrene skeleton **F** which leads to the observed

† JSPS postdoctral fellow. M.G. expresses gratefully his thanks for a grant to the Japan Society for the Promotion of Science.



Scheme 2.

product **3** after a workup.

In summary, we have demonstrated that the Vilsmeier reaction of readily available hydrocarbon **1** provides a convenient, preparatively useful approach to **3** which might be used for the synthesis of hardly accessible [2.2]metapyrenophanes,[9] triangulenequinone,[10] and various carcinogenic polycyclic aromatic compounds.[11] We hope to report on additional experiments along this line in the near future.

Experimental

All melting points are uncorrected. IR spectra were measured in KBr with a JASCO A-100 spectrophotometer. The UV spectrum was measured with a Hitachi 340 recording spectrophotometer. Mass spectra were determined on a JEOL JMS-01SG-2 spectrometer. ^{1}H NMR spectra were recorded in $CDCl_3$ on JEOL JNM-GX 500 spectrometer (500 MHz). ^{13}C NMR spectra were taken on JEOL FX-90Q spectrometer (22.5 MHz). All chemical shifts are reported in δ units downfield from internal Me_4Si, and the J values are given in hertz. All reactions were carried out under a nitrogen atmosphere.

1,3-Pyrenedicarbaldehyde (3). To a stirred solution of 3,4-dihydro-2a*H*-cyclopenta[*cd*]phenalene (3.00 g, 15.6 mmol) (**1**) in tetrahydrofuran (20 cm^3, distilled from benzophenone ketyl) is added under nitrogen at room temperature a mixture of *N*,*N*-dimethylformamide (18.8 g, 0.25 mol, distilled from CaH_2) and phosphoryl chloride (19.8 g, 0.13 mol). The solution warms and iminium salt precipitates. After 14 h the solvent was removed under reduced pressure, 2 mol dm^{-3} sodium hydroxide (500 cm^3) was added and the mixture was extracted with dichloromethane (3×500 cm^3). The combined organic layers were dried with $MgSO_4$ and evaporated. Chromatography of the residue on silica gel (6% water) with dichloromethane gave a large yellow band which was collected. Removal of the solvent and recrystallization from dichloromethane afforded yellow crystals of 1,3-pyrenedicarbaldehyde (**3**) (2.3 g, 57% yield): yellow needles from dichloromethane, mp 245—246 °C (sealed capillary tube, sublimes at around 200 °C); IR (KBr) 1650, 2700 cm^{-1}; UV/VIS (in CH_2Cl_2) λ_{max} (ε) 244 (17200), 285 (25200), 292 (28000), 396 (29900), 400 (sh, 31500), 403 (32000), 407 (sh, 29900) nm; MS, (70 eV) *m*/*z* (rel intensity) 258 (M^+, 33%), 229 (M^+—CHO, 25%), 202 (30%), 201 (65%), 200 (M^+—2CHO, 100%), 199 (34%), 198 (30%); ^{1}H NMR ($CDCl_3$), δ= 10.78 (s, 2H, 1-CHO, 3-CHO), 9.49 (d, 2H, J= 9.15 Hz, H-4 and -10), 8.83 (s, 1H, H-2), 8.46 (d, 2H, J= 9.15 Hz, H-5 and -9), 8.43 (d, 2H, J= 7.63 Hz, H-6 and -8), 8.19 (t, 1H J= 7.63 Hz, H-7); ^{13}C NMR ($CDCl_3$), δ= 192.06, 137.34, 134.63, 133.98, 130.51, 129.04, 127.37, 127.14, 125.24, 123.81, 123.17. Found: C, 83.69; H, 3.90%. Calcd for $C_{18}H_{10}O_2$: C, 83.71; H, 3.90%.

A Vilsmeier reaction of the isomeric 3,4-dihydro-1*H*-cyclopenta[*cd*]phenalene gave comparable results. The treatment of **1** with two equivalents of *N*,*N*-dimethylformamide/phosphoryl chloride likewise leads to **3** and a recovery of the starting hydrocarbon **1**, while hydroxyfulvene **2** was not observed.

1,3-Pyrenedicarbaldehyde-d_3 (3-d_3). This compound was obtained from the Vilsmeier reaction of **1** with *N*,*N*-dimethylformamide-d_7 and phosphoryl chloride.

Exact mass, Found: *m*/*z* 261.0850; Calcd for $C_{18}H_7O_2D_3$; M, 261.0869. ^{1}H NMR signals at δ= 10.78 and 8.83 in **3** were completely disappeared.

The present study was partially supported by a Grant-in-Aid for Special Project Research No. 60129030 from the Ministry of Education, Science and Culture.

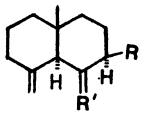
A Short-Step Synthetic Approach to Eudesmane Skeleton. A Synthesis of (±)-β-Eudesmol and Related Eudesmane Sesquiterpenes

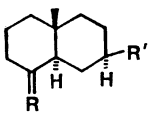
Takeshi KAWAMATA,* Kenzo HARIMAYA, and Seiichi INAYAMA
Pharmaceutical Institute, School of Medicine, Keio University, 35 Shinanomachi, Shinjuku-ku, Tokyo 160
(Received April 18, 1988)

Synopsis. The formal total syntheses of (±)-β-eudesmol and its related sesquiterpenes such as cryptomeridiol and neointermediol were accomplished by an efficient method using aldol cyclization as the key step starting from the known 3-vinyl-2-cyclohexen-1-one.

Although several different syntheses of eudesmane sesquiterpenes including (±)-β-eudesmol (**1**), one of the representatives of this class[1-3] have been reported, most of these approaches involved construction of the decalin ring system via the conventional Robinson annelation reaction. In the synthetic trial of **1**, approaches without recourse to this reaction have been reported recently.[4-7]

In connection with our interest in the development of an efficient general method for the synthesis of the eudesmane class of sesquiterpenoids, we have developed a short step approach to construct the eudesmane skeleton. This has enabled us to synthesize formally the well-known β-eudesmol (**1**) as well as cryptomeridiol (**4**)[8] and neointermediol (**5**).[9]





1 R: -C(OH)(CH$_3$)$_2$, R′: =H$_2$

2 R: -CH(CH$_3$)$_2$, R′:

3 R: -CH(CH$_3$)$_2$, R′: =O

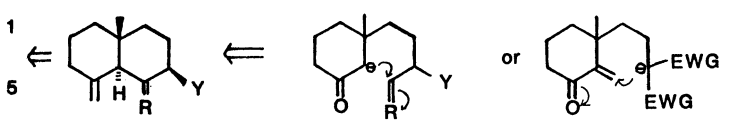
4 R: , R′: -C(OH)(CH$_3$)$_2$

5 R: , R′: -CH$_2$=CHCH$_3$

Our synthetic strategy (Scheme 1) is based on the device of synthon like A or B as a common key intermediate and its intramolecular cyclization by aldol condensation (A) or Michael reaction (B) for the general construction of the eudesmane type of sesquiterpenes. These are represented by the above-mentioned β-eudesmol (**1**) and its close relatives, **4**, **5** and selinene[10] and C(6) oxygenated compounds, juneol (**2**)[11] and acolamone (**3**).[12] In this note the study of the synthon A is described.

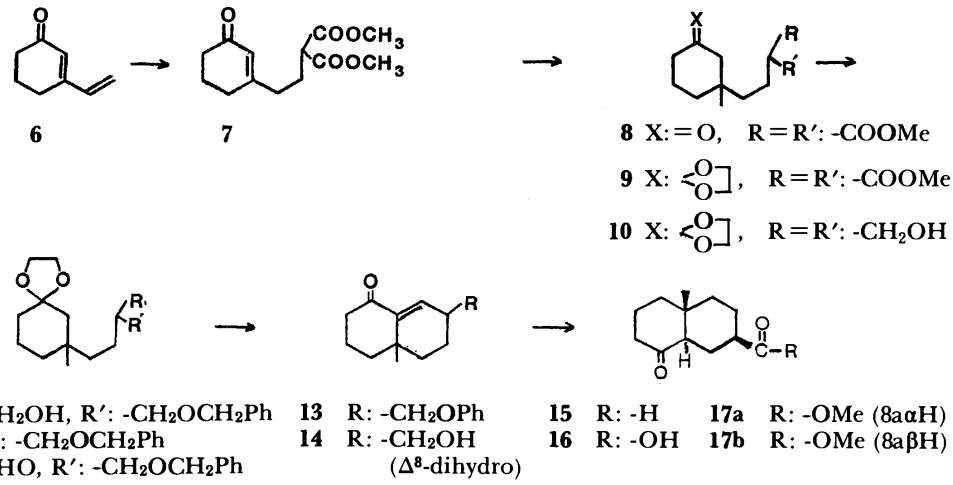
Treatment of 3-vinyl-2-cyclohexen-1-one (**6**), readily available from 1,3-cyclohexanedione, with dimethyl malonate in methanol (MeOH) in the presence of sodium methoxide (NaOCH$_3$) gave mainly the 1,6-Michael adduct (**7**) (50%) along with a small amount of a dialkylation product. Conjugate addition of lithium dimethylcuprate (I) [(CH$_3$)$_2$CuLi] in dry ether at 0 °C provided methylated cyclohexanone (**8**) in good yield (88.4%). Acetalization of **8** with ethylene glycol [*p*-toluenesulfonic acid monohydrate (TsOH)/benzene] gave acetal diester (**9**) in almost quantitative yield. This was in turn subjected to reduction with lithium aluminum hydride (LiAlH$_4$) in ether to afford the corresponding dihydroxy acetal (**10**) (78%). Selective benzylation of **10** with benzyl bromide in tetrahydrofuran (THF) in the presence of tetrabutylammonium iodide (*n*-Bu$_4$NI) furnished almost exclusively the desired monobenzyl ether (**11a**) along with the dibenzyl ether (**11b**) [**11a** : **11b**=98 : 2]. Oxidation of **11a** with pyridinium dichromate (PDC) in dichloromethane (CH$_2$Cl$_2$) at room temperature afforded acetal aldehyde (**12**) in almost quantitative yield.

With the key intermediate **12** in hand, attention was turned to the crucial intramolecular aldol condensation. When **12** was exposed to the action of a 1 M (1 M=1 mol dm^{-3}) HCl in THF (1 : 2) at room temperature overnight, the desired α,β-unsaturated ketone **13** was constructed in a single step as a result of the simultaneous aldolization and dehydration (37%) along with the intermediary keto aldehyde (20%), which upon treatment of TsOH in benzene afforded additional **13** (ca. 7.5%). **13**: C$_{19}$H$_{24}$O$_2$ (MW 284). MS *m*/*z*: 284 (M$^+$). IR (KBr): 1687, 1620 (enone), 1068 cm^{-1}. Catalytic hydrogenation of **13** in the presence of 10% Pd-C in ethanol (EtOH)/ethyl acetate (AcOEt)(1 : 1) at room temperature proceeded smoothly with the concomitant cleavage of the benzyl group to furnish the keto alcohol (**14**)(66%). Oxidation of **14** with PDC in CH$_2$Cl$_2$ at room temperature followed by immediate treatment of the resulting unstable aldehyde **15** with Jones reagent in acetone afforded the keto carboxylic acid (**16**). This was, in turn, esterified with diazomethane (CH$_2$N$_2$) in ether to give the corresponding keto carboxylic acid methyl ester (**17**), IR (KBr): 1739, 1715 cm^{-1}. The ester



R: =H$_2$ or A R: =O or B

Scheme 1. Retrosynthetic analysis for the eudesmane skeleton.



Scheme 2. Synthetic approach to (±)-β-eudesmol and its close relatives.

17 was found to be a 76 : 24 mixture of two components by the examination of its gas chromatographic data [Rt: 11.3 and 12.2]. On the other hand, ^{1}H NMR showed methyl signals at δ 1.17 and 0.82, methoxyl methyl signals at δ 3.67 and 3.68, and other signals between δ 1.1 and 2.4. The comparison of this data with that of the diastereomers[6] of **17** suggested that **17** was a mixture of **17a** and **17b** in an approximately 3 : 1 ratio. This was determined by evaluating the integration trace of the methyl and methoxyl methyl peaks described above. The ratio was in good agreement with that obtained from the GC-MS data; the presence of the C(2)-epimer of **17b** was easily ruled out since the ^{1}H NMR of **17** exhibited no signals below δ 2.4 .[6]

Since, not only the 4a-methyl-8-oxo-2-decalin carboxylic acid (**16**) and its ester **17a, b** but also the abovementioned mixture of four diastereomers of **17** have already been converted to β-eudesmol (**1**), which, in turn, has been converted to cryptomeridiol (**4**)[8] and neointermediol (**5**).[9] The synthesis of the former compounds (**16** and/or **17a, b**) constitute a formal total synthesis of (±)-β-eudesmol as well as (±)-**4** and (±)-**5**. Furthermore, since **17a** and **17b** could essentially be convertible to other isomeric eudesmols (α-, γ-eudesmol)[13] and its close relatives such as costal[14] and costic acid etc.,[14] this sequence should provide a general method of constructing the eudesmane sesquiterpenes exemplified by eudesmols.

Experimental

IR spectra were recorded on a Hitachi EPI-G3 spectrophotometer. Mass spectra were taken on a JEOL JMS-D300 instrument (JMA-2000 data analysis system). ^{1}H NMR spectra were recorded with JMN-GX-400 with TMS as an internal standard. TLC was performed on a Kieselgel 60 F_{254} plate (Merck) using ether-hexane (gradient).

Preparation of 7: To a cold (0 °C) stirred solution of $NaOCH_3$ (220 mg) in dry MeOH (15 ml) was added dropwise a solution of dimethyl malonate (2.4 g) in dry MeOH (15 ml) and then a solution of 3-vinyl-2-cyclohexen-1-one (**6**) (1.83 g) in dry MeOH (15 ml). The mixture was stirred at 0 °C for 2 h and then at room temperature overnight. The mixture was quenched with 2 M HCl, evaporated, and extracted with ether. The ether extract was washed with sat. NaCl and dried ($MgSO_4$). Removal of the solvent in vacuo left a crude oil, which was purified by chromatography on silica gel to give **7** as an oil, 1.90 g (ca. 50%), MS *m/z*: 254 (M^+). IR (KBr): 1749, 1733, 1644, 1620 cm^{-1}. From the polar fraction the dialkylation product, 371 mg (6.6%). MS *m/z*: 376 (M^+) ($C_{21}H_{28}O_6$) was obtained.

Conjugate Addition of $(CH_3)_2CuLi$ to 7 (8): To a cold (0 °C) stirred suspension of CuI (2.53 g) in dry ether (100 ml) was added dropwise CH_3Li (1.6 M hexane, 16.2 ml) under N_2 atmosphere and then **7** (1.5 g) in dry ether (120 ml). The mixture was stirred at 0 °C for 2 h and then at room temperature overnight. The mixture was quenched with sat. NH_4Cl, extracted with ether, washed with H_2O and dried over $CaCl_2$. Removal of the solvent at diminished pressure afforded 1.47 g of viscous oil, which was purified by chromatography on silica gel (ether : hexane=4 : 6) to give 1.26 g (88.4%) of an essentially pure oil, **8** (TLC homogeneous; ether : hexane=1 : 1). CI-MS *m/z*: 271 (M^++1) ($C_{14}H_{22}O_5$, MW 270). IR (KBr): 1751, 1733, 1710 cm^{-1}. ^{1}H NMR ($CDCl_3$) δ=0.98 (3H, s), 1.1—2.43 (12H, m), 3.3 (1H, d, 7), 3.75 (6H, s).

$LiAlH_4$ Reduction of 9: To a stirred suspension of $LiAlH_4$ (450 mg) in dry ether (80 ml) was added dropwise a solution of **9** (982 mg) in dry ether (60 ml) under ice-cooling. The mixture was refluxed for 2 h. The mixture was quenched carefully with sat. NH_4Cl, filtered and the filtered cake thoroughly washed with CH_2Cl_2. The filtrate was partitioned between the organic phase and the aqueous phase. The latter phase was extracted with CH_2Cl_2. The combined CH_2Cl_2 was washed with sat. NaCl and dried ($MgSO_4$). Removal of the solvent at reduced pressure left a viscous oil, which was purified by chromatography on silica gel eluting with ether to afford 630 mg (78%) of **10** as an oil. IR (KBr): 3387 (OH) cm^{-1}, which was used directly in the next step, and the recovered product, 79 mg (11.8%).

Preparation of Monobenzyl Ether (11a): To a stirred solution of **10** (600 mg) in dry THF (28 ml) was added NaH (104 mg) under N_2. After adding a catalytic amount of Bu_4NI, a solution of benzyl bromide (426 mg) in dry THF (12 ml) was added. The mixture was diluted with ether, washed with 2 M HCl and sat. NaCl and dried over $MgSO_4$. Evaporation of the solvent left a crude oil, which was purified by chromatography on silica gel. 10% ether-hexane fraction furnished 47 mg (4.6%) of dibenzyl ether (**11b**). MS *m/z*: 438 (M^+) ($C_{28}H_{38}O_4$, MW 438). IR (KBr): 1092, 1070 (sh), 1048, 944, 734, 697 cm^{-1}, and the ether eluant gave 710 mg (87.9%) of monobenzyl ether (**11a**) as an oil. MS *m/z*: 348 (M^+) ($C_{21}H_{32}O_4$, MW 348). IR (KBr): 3422, 1092, 1070 (sh), 1048,

944, 734, 697 cm^{-1}.

Cyclization of 11a (13): To a stirred solution of **11a** (100 mg) in CH_2Cl_2 (4 ml) was added PCC (80 mg) and the mixture was stirred at room temperature for 5 h. The reaction mixture was filtered through a pad of silica gel. The filtrate was evaporated to give a viscous oil **12**, IR (KBr): 1727 (-CHO), 1096 cm^{-1}, This was dissolved in 2 M HCl : THF (1 : 2) (1 ml) and stirred at room temperature overnight under an argon atmosphere. To the mixture sat. NaCl was added and it was extracted with ether, washed with sat. NaCl and dried ($MgSO_4$). Evaporation of the solvent followed by purification by chromatography on silica gel afforded 20 mg (ca. 30%) of **13** (oil), IR (KBr): 1687, 1620, 1086 cm^{-1}, MS *m/z*: 284 (M^+) ($C_{19}H_{24}O_2$, MW 284) and the intermediary keto aldehyde, 21 mg (20%), IR (KBr): 1728, 1287, 1129 (sh), 1115, 1068 cm^{-1}, which gave the additional enone **13** (5 mg, 7.5%) upon treatment with TsOH in refluxing benzene.

17a and 17b: 15 mg of **13** was dissolved in EtOH-AcOEt (1 : 1) (2 ml) and 10%-Pd/C (catalytic) was added. The mixture was stirred at room temperature under H_2 atmosphere for 4 days. After filtration of the mixture, the solvent was evaporated and the residue was purified by chromatography on silica gel to give 8 mg (66%) of **14**, which was dissolved in CH_2Cl_2 (1.5 ml), and PCC (12 mg) was added. The mixture was stirred for 3 h at room temperature. After filtration, the solvent was evaporated and the residue was purified by chromatography on silica gel to give 6 mg (79.9%) of the corresponding keto aldehyde (**15**). This was immediately dissolved in acetone (1 ml) and several drops of Jones reagent was added. After a few minutes a small amount of isopropyl alcohol was added. Filtration of the mixture followed by evaporation of the solvent left 5 mg (77.0%) of keto carboxylic acid (**16**), IR (KBr): 3500—2400, 1712 cm^{-1}. The above acid (**16**)(5 mg) was dissolved in ether (0.5 ml) and excess CH_2N_2 in ether was added. Evaporation of the solvent furnished 5 mg (ca. 100%) of the corresponding methyl ester (**17a** and **17b**). IR (KBr): 1739, 1715 cm^{-1}. GC-MS (2% OV-1, 200 °C), **17b**; R_t 11.3 min, *m/z*: 224 (M^+), 209 (M^+--15). **17a**; R_t 12 min, *m/z*: 224 (M^+), 209 (M^+—15). $C_{13}H_{20}O_3$ (MW 224). ^1H NMR (400 MHz) δ=0.82 (s), 3.67 (OCH_3) and 1.17 (s), 3.68 (OCH_3) [76 : 24]. High-resolution MS: *m/z* 224.1408 for **17a**, 224.1384 for **17b** [Theor. 224.1384 for $C_{13}H_{20}O_3$].

The authors are grateful to Hajime Yamanaka and Setuko Takei of the Joint Laboratory, School of Medicine, Keio University, for MS and IR measurements, respectively.

(Received April 20, 1988)

Synopsis. The electroreduction mechanisms of terephthalic acid and isophthalic acid in acidic solution were studied by molecular orbital (MO) calculations. Further, a practical stepwise route to 1,4-benzenedimethanol has been developed by the electroreduction of *p*-(hydroxymethyl)-benzoic acid.

1,4-Benzenedimethanol (**4**) is of importance as a component of useful polymers,[2)] though a practical synthetic method has not yet been established. Namely, as a hitherto disclosed procedure for the synthesis of **4**, the chlorination of *p*-xylene followed by hydrolysis[3)] has been reported. However, the selectivity of the chlorination of each benzylic position is not necessarily satisfactory. The hydrogenation of terephthalic acid diester[4)] has also been reported, in which there still remains serious problems regarding the practical preparation of **4**, due to the vigorous reaction conditions and low yield of the product.

Incidentally, the electroreduction of aromatic carboxylic acids is both useful and a practical technique for the preparation of benzyl alcohols. We have therefore studied the synthesis of **4** starting from easily available terephthalic acid (**1**) by electrolysis. So far, it has been reported that the electroreduction of **1** in acidic aqueous media results in a nuclear reduction which affords 2,5-cyclohexadiene-1,4-dicarboxylic acid (**3**),[5)] while the electroreduction of **1** in aqueous ammoniacal media gives *p*-(hydroxymethyl) benzoic acid (**9**).[6)] However, no successful conversion of **1** to **4** has been mentioned in the literature.

In general, the mechanism of side chain reduction of aromatic carboxylic acid seems best accommodated[7)] by protonated carboxylic acid; the reduction is known to be promoted in a more acidic solution.[8)] Therefore, in order to investigate the possibility of a side-chain reduction of dicarboxylic acid **1** under the acidic conditions, we considered the reaction pathway of the electroreduction of **1**, compared with that of isophthalic acid (**5**), in terms of molecular orbital (MO) calculations; electroreduction of **5** in an aqueous acidic solution[9)] is reported to give 1,3-benzenedimethanol (**8**). According to our calculations, a direct reduction of **1** to **4** is unlikely to occur in acidic solution. We, therefore, investigated a combination of the electroreduction of **1** to **9** and that of **9** to **4** (two step conversion through **9**). In this paper, we discuss the mechanism and practical electroreduction of **9** for **4**.

Electroreduction Mechanism of 1 and 5 in Acidic Aqueous Media. Though no mechanistic study has so far been available concerning the exceptionally specific formation of nuclear reduced product **3** from **1** in an acidic media, it might be explained by assuming two different pathways (illustrated in Scheme 1): one involves a direct electroreduction of **1** followed by protonation (Route A), the other involves the protonation of **1** prior to electroreduction (Route B). A two-electron transfer should occur rather rapidly in an equilibrium state after the diprotonation of **1**, leading to the formation of **2**. The most important key step of each pathway (Route A and B) related to the product selectivity and rate determination may be the electron-uptake process of **1** and **2**, respectively. According to a MO calculation, the LUMO electron density of **1** is highly localized in the aromatic ring. Therefore, an electron uptake would take place, preferably, at the aromatic nuclear, affording **3** (Route A). On the other hand, an electron transfer on **2** would occur at the side chain to produce **4** (Route B), owing to the higher value of the LUMO electron density observed in the side chain of **2**.

Next, in order to assess the preferable route in Scheme 1, we compared the LUMO energy level of the key intermediate in the electron transfer. An intermediate having a lower LUMO energy would undergo an electron uptake, preferentially.[10)] The estimated value of the LUMO energy of **1** and **2** are shown in Scheme 1. The LUMO energy of **1** is lower than that of **2**, indicating that the electron uptake of **1** proceeds more smoothly than that of **2**. Thus, in turn, this fact suggests that Route A is preferable to Route B.

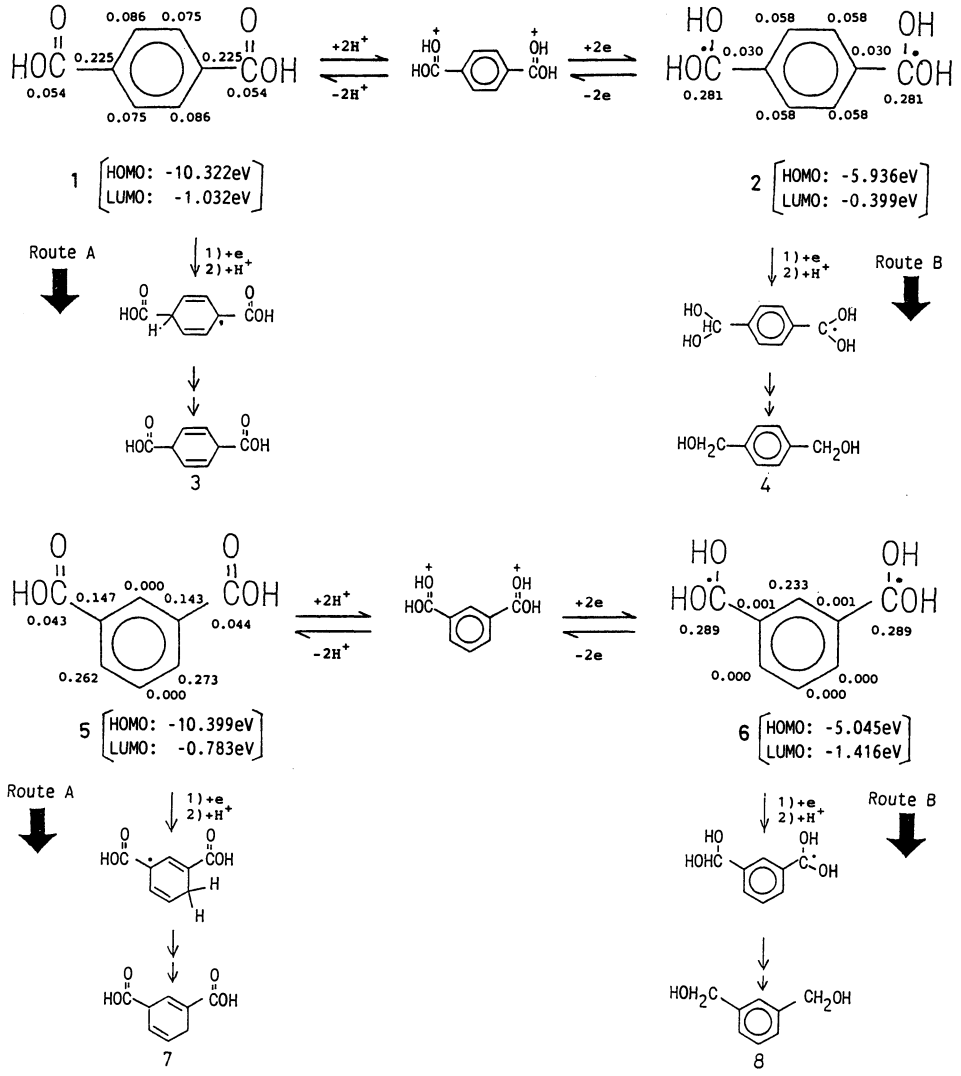
A MO calculation of meta derivative **5** was accomplished in a similar manner as that mentioned above, and opposite results were obtained. Thus, a reduction of **5** seems to occur, preferentially, according to Route B to give **8**, since the LUMO energy of **6** in Route B is lower than that of **5** in Route A.

Now, our calculations show a different reactivity of **1**, compared with that of **5**, suggesting the difficulty of a side-chain reduction of **1** in an acidic aqueous media;

Table 1. Electroreduction of Aromatic Carboxylic Acids[a)]

Entry	Substrate	Solvent electrolyte	Electricity passed / F mol^{-1}	Product (Yield/%)[b)]
1	**9**	12% aq. NH_4OH	10	—
2	**9**	10% aq. Et_4NOTs	10	**4** (3)
3	**9**	10% aq. H_2SO_4	10	**4** (68)
4	**1**	10% aq. H_2SO_4	43	**3** (3)[c)]
5	**5**	10% aq. H_2SO_4	90	**8** (6)[c)]

a) The electroreduction was carried out under constant current of 5 A dm^{-2} with an H-shaped divided cell fitted with two lead electrodes at 40 °C. b) Isolated yield based on substrate. c) Detected as a single product.



Scheme 1. LUMO electron densities are shown, and the values in parentheses represent HOMO and LUMO energy level. Molecular structures were designed by using STERIC1[14] program; equations used for calculations are as follows, 1: 1*BENZ (.1.-COOH)(.4.-COOH)**, charge of the molecule=0, 2: 1*BENZ-(.1.-C(-OH)2.+.)(.4.-C(-OH)2.+.)**, charge of the molecule=0, 5: 1*BENZ-(.1.-COOH)(.3.-COOH)**, charge of the molecule=0, 6: 1*BENZ-(.1.-C(-OH)2.+.)(.3.-C(-OH)2.+.)**, charge of the molecule=0, and RHF-AM1[15] calculations have been curried out.

the higher reactivity of **1**, in comparison with that of **2**, would displace the equilibrium to Route A. We changed the synthetic strategy in order to study the electroreduction of monocarboxylic acid (**9**) in an aqueous acidic media, which is easily synthesized by the electrolysis of **1** in an aqueous ammoniacal media.

Electroreduction of Aromatic Carboxylic Acids. Electroreduction was carried out with two lead electrodes using an H-shaped two-compartment cell divided by an ion-exchange membrane. The results under various electrolysis conditions are summarized in Table 1.

In the electroreduction of **9**, a satisfactory current efficiency was attained in an aqueous acidic media (Entry 3), while under neutral conditions (Entry 2), the reduction was very slow and no appreciable amount of **4** could be detected under ammoniacal basic conditions (Entry 1).

Incidentally, the electroreduction of **1** under the same reaction conditions as Entry 3 gave a nuclear reduced product **3** without the detection of a side chain reduction (Entry 4), whereas that of **5** afforded a single product **8** (Entry 5).

Experimental

Melting points are uncorrected and were determined in open-ended capillaries. IR spectra were recorded on a Hitachi 285 grating spectrometer.

Calculations. The calculations were performed on a Fujitsu FACOM M360R using MOPAC.[11]

Apparatus. An H-shaped cell divided by an ion-exchange membrane (Asahi Glass Co., Ltd. Selemion CMV) was used; it was equipped with two lead plate electrodes (50 cm^2, 12 cm apart), stirring bars, and a thermometer. A vessel was

immersed in a hot water bath at 40 °C and regulated dc power was supplied by Kikusui Electronics Co. Model PAD 35-60L.LP.

General Procedure. Electrochemical Reduction of *p*-(Hydroxymethyl)benzoic Acid (9). Into both the anode and cathode compartments was placed a 10% aqueous H_2SO_4 solution (200 g each). After regulated dc power (5 A dm^{-2}) was supplied at 40 °C, to the catholytes was portionwise added *p*-(hydroxymethyl)benzoic acid (**9**; 2.37 g h^{-1}, total 20.0 g, 0.131 mol) during the first 6 F mol^{-1} (8.4 h). After electrolysis (10 F mol^{-1}, 14.0 h) at 40 °C, the catholyte was extracted with diethyl ether. The extract was washed with brine, dried (Na_2SO_4), and concentrated in vacuo. The residue was purified by column chromatography (SiO_2, hexane/AcOEt, 3:1) to give **4** (13.0 g, 68.0%) as white crystal with an IR spectrums identical with that reported for the authentic material;[12] mp 113—116 °C (lit,[13] mp 118—119.4 °C).

We gratefully acknowledge Prof. Sigeru Torii, Dr. Hideo Tanaka (Okayama University), Dr. Tsuneo Hirano (The University of Tokyo), Dr. Kengo Oda (Central Research Institute), Mr. Kiyohisa Okano (Systems and Computing Department), and Dr. Akihiro Tamaki (Director of Omuta Research Institute) for support during this work. We also appreciate Mr. Masanao Esaki (Director of Omuta Factory, Mitsui Toatsu Chemicals, Inc.) for giving us an opportunity to present this work.

Synthesis and Chemiluminescence of 5-[(2-Pyridyl)-, (2-Pyrazinyl)-, and (Substituted 2-pyrazinyl)amino]-1,2,4-trioxanes

Hideshi NAKAMURA† and Toshio GOTO*
Laboratory of Organic Chemistry, Faculty of Agriculture, Nagoya University, Chikusa, Nagoya 464
(Received May 6, 1988)

Synopsis. From pyridyl- and pyradinylamines and isobutylaldehyde were prepared the corresponding 5-arylamino-1,2,4-trioxanes, whose chemiluminescence was studied by comparing with those of *Cypridina* luciferin analogs.

Cypridina luciferin (**1a**) is one of the most efficient chemiluminescent substances in addition to its bioluminescent activity.[1] Accumulated results of studies on both of the bio- and chemiluminescence suggest the light-producing mechanism (Scheme 1) involving an intermediate, 1,2-dioxetane **2a**, which decomposes rapidly to yield predominantly a singlet excited state molecule. The efficient chemiluminescence and instability of the dioxetane **2a** would be explained in terms of conjugation of the electron-donating and highly fluorescent chromophore with the dioxetane ring. Akutagawa et al. treated 9-aminoanthracene **4a** with isobutyraldehyde in the presence of atmospheric oxygen and obtained a stable peroxide,[2] the 5-(9-anthrylamino)-1,2,4-trioxane **6a**[2-8] that caused efficient chemiluminescence when it was treated with a base in a polar aprotic solvent. Aminodioxetane **7a** is assumed to be an intermediate in the light producing process.[4,8] If the anthracene moiety is replaced with a pyrazine derivative, the expected aminodioxetane intermediate would have the structural similarity to the aminodioxetane **2a** in the *Cypridina* bioluminescence. In this paper, we describe the synthesis and chemiluminescence of the trioxanes (**6b—i**) which have the chromophore similar to *Cypridina* luciferin and *Watasenia* preluciferin (coelenterazine).[1]

Arylamines (**4b—i**) were oxidized with atmospheric oxygen in the presence of a large excess of isobutyraldehyde to afford the corresponding trioxanes (**6a—i**) in 6.5—50% yields (Table 1). The trioxanes may be formed via a Shiff-base as shown in Scheme 2. These compounds were fairly stable and showed a molecular ion peak in the EI mass spectra except **6b** and **6c**. The

† Present address: The Research Institute for Life Sciences, Mitsubishi Kasei Co., Ltd., Minamiohtani, Machida, Tokyo 194.

^{1}H NMR spectrum of **6b** showed signals assignable to an isobutyl group at δ 0.98 (6H), 1.84 (1H), and 4.80(1H), and to a methine proton at δ 5.28 (1H), which was coupled with an NH proton signal at δ 4.82. In the ^{13}C NMR spectrum of **6b**, signals for an acetal methine carbon, a methine carbon bearing oxygen and nitrogen atoms, and a quaternary carbon attached to an oxygen atom were observed at δ 107.1, 84.0, and 79.9, respectively. The ^{1}H and ^{13}C NMR spectra of the trioxanes (**6c—g** and **6i**) resemble very closely those of **6b**. In the ^{1}H NMR spectra of **6a** and **6h**

having substituents at ortho position to the amino group, an anisotropic effect on a methyl signal was observed.[4]

The trioxanes (**6b**, **d**—**i**) emitted light under basic conditions in dimethyl sulfoxide as well as **6a** (Table 1), but efficiencies of chemiluminescence and singlet excited state formation were much lower than those of **6a**. The luciferin analog **lb** also produced light under the same conditions and the efficiency of singlet excited state formation was about two times larger than those of the analogous trioxane **6e**, suggesting a slight difference between the dioxetanone and the dioxetane moiety for light production. On the other hand, the luciferin analog **lc** having an indole side chain showed only very weak chemiluminescence under the condition while it gave light efficiently in diethylene glycol dimethyl ether (diglyme) containing a trace of acetate buffer (pH 5.6);[1] the efficiency of singlet excited state formation being 0.16. Efficiency of singlet excited state formation of the analogous trioxane **6i** was about 8 times larger than that of **lc** under the basic condition, indicating the presence of some side reactions or quenching processes in the chemiluminescent reaction of **lc**.

Experimental

All melting points were uncorrected. ^{1}H and ^{13}C NMR spectra were recorded on a JEOL JNM-MH100 (100 MHz) and a JNM-FX100 (25 MHz) spectrometer, respectively. Chemical shifts (δ) are given in ppm from internal TMS and coupling constants (J) in Hz. IR spectra were taken on a JASCO IR-G spectrometer. UV spectra were obtained on a HITACHI EPS-3T spectrometer. Mass spectra were measured on a JEOL JMS-D100 and a JMS-0lSG-2 instrument. Fluorescence spectra were recorded on a Hitachi MPF-3 spectrofluorometer. Dimethyl sulfoxide and diglyme were distilled from KOH and sodium metal, respectively, under reduced pressure. The other solvents were of reagent grade (Wako Chemical Co., Ltd.). 2-Aminopyrazines (**4d**—**i**) were prepared by the methods described in our previous reports.[9]

Preparation of 5-(9-Anthrylamino)-3-isopropyl-6,6-dimethyl-1,2,4-trioxane (6a). This compound was prepared according to the method of Akutagawa et al.[2] Pale yellow prisms from CH_2Cl_2-hexane, mp 122—124 °C (lit,[2] 113 °C).

Preparation of the Trioxanes (6b—h). A solution of arylamine (**4b**—**h**) (2 mmol) and isobutyraldehyde (60 mmol) in diethyl ether (20 ml) was kept in a dark with stirring under atmospheric oxygen at room temperature. After about 10 days, the solution was diluted with diethyl ether, washed with aq. $NaHCO_3$ and saturated aq. NaCl, and dried over anhydrous Na_2SO_4. The solvent was removed under reduced pressure and the residue was chromatographed on TLC plates to give the corresponding trioxane (**6**).

6b: Needles (from hexane), mp 85—86 °C; ^{1}H NMR ($CDCl_3$) δ=0.98 (6H, d, J=6.5, 10 and 11-Me), 1.20 and 1.52 (each 3H, s, 7 and 8-Me), 1.84 (1H, m, 9-H), 4.82 (1H, d, J=11, NH), 5.16 (1H, d, J=5.2, 3-H), 5.28 (1H, d, J=11, 5-H), 6.60 (1H, d, J=8, 3-H), 6.72 (1H, dd, J=8 and 4), 7.48 (1H, td, J=8 and 1), 8.18 (1H, br d, J=4); ^{13}C NMR ($CDCl_3$) δ= 16.6 and 16.8 (each q, 10 and 11-Me); 17.5 and 21.7 (each q, 7 and 8-Me); 31.0 (d, C-9), 79.9 (s, C-6), 84.0 (d, C-5), 107.1 (d, C-3), 107.9 (d), 115.2 (d), 137.8 (d), 148.0 (d), 156.8 (s). Found: C, 61.65; H, 7.86; N, 10.96%. Calcd for $C_{13}H_{20}N_2O_3$: C, 61.88: H, 7.86; N, 10.96%.

6c: Colorless oil; ^{1}H NMR ($CDCl_3$) δ= 0.99 (6H, d, J=6.9), 1.20 (3H, s), 1.52 (3H, s), 1.83 (1H, m), 5.10 (1H, d, J=5.5), 5.17 (1H, d, J=10, NH), 5.42 (1H, d, J=10), 7.8—8.4 (3H, m); ^{13}C NMR ($CDCl_3$) δ=16.6 (q), 16.8 (q), 17.4 (q), 21.6 (q), 31.0 (d), 79.8 (s), 83.0 (d), 107.2 (d), 132.5 (d), 135.2 (d), 141.8 (d), 153.1 (s).

6d: Needles (from hexane), mp 104—105 °C; ^{1}H NMR ($CDCl_3$) δ= 0.95 (6H, d, J=6.8), 1.19 (3H, s), 1.52 (3H, s), 1.85 (1H, m), 2.43 (3H, s), 4.88 (1H, d, J=10, NH), 5.17 (1H, d, J=4.9), 5.38 (1H, d, J=10), 7.98 (2H, s); ^{13}C NMR ($CDCl_3$) δ=16.7 (q), 16.8 (q), 17.5 (q), 21.7 (q), 20.2 (q, ArMe), 31.0 (d), 79.9 (s), 83.4 (d), 107.3 (d), 131.2 (d), 141.0 (d), 143.8 (s), 151.0 (s). Found: C, 58.20; H, 7.81; N, 16.00%. Calcd for $C_{13}H_{21}N_3O_3$: C, 58.41; H, 7.92; N, 15.72%.

6e: Amorphous solid (from hexane), mp 100—110 °C; MS m/z 329 (M^+); ^{1}H NMR ($CDCl_3$) δ=0.98 (6H, d, J=6.4), 1.22 (3H, s), 1.56 (3H, s), 1.85 (1H, m), 4.90 (1H, d, J=10, NH), 5.18 (1H, d, J= 4.5), 5.42 (1H, d, J=12), 7.3—8.5 (7H, m); ^{13}C NMR ($CDCl_3$) δ= 16.7 (q), 16.8 (q), 17.5 (q), 21.7 (q), 31.0 (d), 79.8 (s), 83.2 (d), 107.3 (d), 125.8 (d), 128.4 (d), 128.8 (d), 131.4 (d), 136.7 (s), 139.1 (d), 144.2 (s), 151.6 (s). Found: C, 65.33; H, 7.03; N, 12.57%. Calcd for $C_{18}H_{23}N_3O_3$: C, 65.63; H, 7.04; N, 12.76%.

6f: Pale yellow amorphous solid (from hexane), mp 157—159 °C; MS m/z 407, 409 (M^+); ^{1}H NMR ($CDCl_3$) δ= 0.98 (6H, d, J=6.8), 1.23 (s), 1.56 (s), 1.88 (1H, m), 5.14 (1H, d, J=11, NH), 5.20 (1H, d, J=5.0), 5.48 (1H, d, J=11), 7.66 (4H, AB q), 8.12 (1H, d, J=1), 8.50 (1H, d, J=1); ^{13}C NMR ($CDCl_3$) δ=16.7 (q), 16.8 (q), 17.5 (q), 21.7 (q), 31.1 (d), 79.7 (s), 83.2 (d), 107.4 (d), 122.7 (s), 127.2 (d), 131.6 (d), 132.0 (d), 135.7 (s), 138.7 (d), 142.9 (s), 151.9 (s). Found: C, 51.87; H, 5.31; N, 10.04%. Calcd for $C_{18}H_{22}N_3O_3Br \cdot 1/2H_2O$: C, 51.81; H, 5.55; N, 10.06%.

6g: Amorphous solid (from hexane), mp 129.5—130.5 °C; MS m/z 359 (M^+); ^{1}H NMR ($CDCl_3$) δ= 0.96 (6H, d, J=6.8), 1.19 (3H, s), 1.53 (3H, s), 1.85 (1H, m), 3.80 (3H, s, OMe), 5.19 (1H, d, J=11, NH), 5.21 (1H, d, J=5.0), 5.47 (1H, d, J=11), 6.99 (2H, d, J=9), 7.87 (2H, d, J=9), 8.13 (1H, d, J=1), 8.51 (1H, d, J=1); ^{13}C NMR ($CDCl_3$) δ= 16.7 (q), 16.9 (q), 17.5 (s), 21.7 (s), 31.0 (d), 55.2 (q, OMe), 79.9 (s), 83.4 (d), 107.3 (d), 114.3 (d), 127.0 (d), 129.5 (s), 131.3 (d), 138.3 (d), 144.0 (s), 151.3 (s), 160.0 (s). Found: C, 63.44; H, 6.90; N, 11.76%. Calcd for $C_{19}H_{25}N_3O_4$: C, 63.49; H, 7.01; N, 11.69%.

6h: Plates (from hexane), mp 75.5—82 °C; MS m/z 449 (M^+); ^{1}H NMR ($CDCl_3$) δ=0.84 (6H, d, J=5.6), 1.13 (3H, s), 1.79 (3H, s), 1.79 (1H, m), 3.86 (3H, s, OMe), 4.24 (2H, AB q), 4.49 (1H, d, J=11, NH), 5.12 (1H, d, J=5.5), 5.59 (1H, d, J=11), 7.00 (2H, d, J=9), 7.2—7.4 (5H, m), 7.92 (2H, d, J=9), 8.42 (1H, br s); ^{13}C NMR ($CDCl_3$) δ=16.4 (q), 16.9 (q), 17.3 (q), 21.7 (q), 31.1 (d), 41.5 (t), 55.3 (q, OMe), 79.9 (s), 82.0 (d), 107.1 (d), 114.2, 127.1, 127.3, 128.4, 129.1, 129.4, 136.5, 136.6, 140.8, 142.6, 149.3, 159.8. Found: C, 69.23; H, 6.87; N, 9.24%. Calcd for $C_{26}H_{31}N_3O_4$: C, 69.46; H, 6.95; N, 9.35%.

Preparation of Trioxane 6i. A solution of aminopyrazine **4i** (200 mg, 0.91 mmol) and isobutyraldehyde (10.4 ml, 114 mmol) in diethyl ether (21 ml) was treated as described for the preparation of **6b**. After 5 days, pale yellow precipitates of **6i** were collected by filtration. The filtrate was treated as described in the case of **6b** to give additional amount of **6i**. **6i**: pale yellow amorphous solid, mp 204.5—205.5 °C; MS m/z 368 (M^+); ^{1}H NMR ($CDCl_3$) δ=0.98 (6H, d, J=6.8), 1.24 (3H, s), 1.57 (3H, s), 1.94 (1H, m), 4.91 (1H, d, J=12, NH), 5.20 (1H, d, J=5.0), 5.40 (1H, d, J=12), 7.71 (1H, d, J=2.5), 8.16 (1H, d, J=1), 8.40 (1H, br s, NH), 8.55 (1H, d, J=1), 7.1—8.2 (4H, m); ^{13}C NMR (DMSO-d_6) δ=16.5 (q), 16.6 (q), 17.7 (q), 21.4 (q), 30.5 (d), 80.1 (s), 82.8 (d), 106.5 (d), 111.6 (d), 112.8 (s), 119.5 (d), 120.9 (d), 121.4 (d), 123.5 (d), 124.9 (s), 131.9 (d), 136.7 (s), 137.5 (d), 141.3 (s), 150.6 (s). Found: C, 65.13; H, 6.54; N, 15.21%. Calcd for $C_{20}H_{24}N_4O_3$: C, 65.20; H, 6.57; N, 15.21%.

Preparation of the Formamides (8a, b, d—i). To a solution of each of the arylamines (**4**) (0.4 mmol) in pyridine (1 ml) was added acetic anhydride (0.1 ml) under cooling in an ice-water bath. The solution was warmed to room temperature and stirred for 2 h. The solvent was evaporated under reduced pressure to give the corresponding crude formamide (**8**), which was recrystallized from the solvent given.

8a: Pale yellow needles (from MeOH), mp 189—191 °C; MS *m/z* 221 (M^+). Found: C, 81.18; H, 5.21; N, 6.39%. Calcd for $C_{15}H_{11}NO$: C, 81.43; H, 5.01; N, 6.33%.

8b: Rods (from MeOH), mp 75—76 °C; MS *m/z* 122 (M^+). Found: C, 59.17; H, 4.95; N, 22.94%. Calcd for $C_6H_6N_2O$: C, 59.01; H, 4.95; N, 22.94%.

8d: Slightly yellowish plates (from benzene), mp 121—124 °C; MS *m/z* 137 (M^+). Found: C, 52.55; H, 5.17; N, 30.84%. Calcd for $C_6H_7N_3O$: C, 52.54; H, 5.15; N, 30.64%.

8e: Leaflets (from MeOH), mp 162—164 °C; MS *m/z* 199 (M^+). Found: C, 66.27; H, 4.70; N, 20.96%. Calcd for $C_{11}H_9N_3O$: C, 66.32; H, 4.55; N, 21.10%.

8f: Plates (from MeOH), mp 212—214 °C; MS *m/z* 277, 279 (M^+). Found: C, 47.49; H, 2.75; N, 15.11%. Calcd for $C_{11}H_8N_3OBr$: C, 47.50; H, 2.90; N, 15.11%.

8g: Plates (from MeOH), mp 205—206 °C; MS *m/z* 229 (M^+). Found: C, 62.60; H, 4.70; N, 18.43%. Calcd for $C_{12}H_{11}N_3O_2$: C, 62.87; H, 4.84; N, 18.33%.

8h: Pale yellow needles (from MeOH), mp 190.5—191 °C; MS *m/z* 319 (M^+). Found: C, 71.39; H, 5.30; N, 13.07%. Calcd for $C_{19}H_{17}N_3O_2$: C, 71.45; H, 5.37; N, 13.16%.

8i: Slightly yellowish amorphous solid (from MeOH), mp 262—263 °C; MS *m/z* 238 (M^+). Found: C, 65.53; H, 4.04; N, 23.75%. Calcd for $C_{13}H_{10}N_4O$: C, 65.53; H, 4.23; N, 23.52%.

Chemiluminescence and Fluorescence Measurements. A solution of dimethyl sulfoxide or diglyme (1 ml) containing 0.85 mol l^{-1} *t*-BuOK (*t*-BuOH solution, 5 μl) or acetate buffer pH 5.6 (50 μl) was added to a solution of a trioxane or a luciferin analog in dimethyl sulfoxide or diglyme (1 ml). The resulting light emission was recorded with a luminometer. Quantum yields of chemiluminescence and fluorescence were determined as previously described.[10]

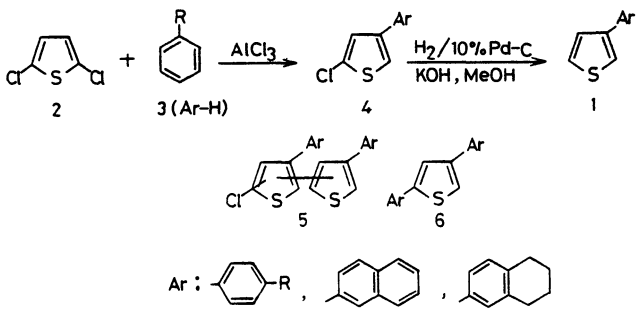
A New and Simple Route to 3-Arylthiophenes[1)]

Tyo SONE,* Manabu INOUE, and Kazuaki SATO
Department of Applied Chemistry, Faculty of Engineering, Yamagata University, Yonezawa 992
(Received May 11, 1988)

Synopsis. 3-Arylthiophenes were prepared from 2,5-dichlorothiophene in two steps. 2,5-Dichlorothiophene reacted regioselectively with various aromatic compounds in the presence of $AlCl_3$ under mild conditions to give 4-aryl-2-chlorothiophenes. The latter compounds were easily converted to the corresponding 3-arylthiophenes by catalytic dechlorination in good yields.

Electrophilic substitutions of thiophene occur predominantly at the 2-position, making access to 3-substituted thiophenes rather troublesome.[2)] This is also the case with 3-arylthiophenes (**1**), one of the thiophene analogues of biphenyls; thus, it has been desired to find a general method for the preparation of **1**.[3)] Certain 3-substituted thiophenes,[3,4)] including **1** as well as the parent thiophene, have recently attracted attention in connection with the potential electric conductivity and their electrochromic property of their electrochemically prepared polymers. We wish to report here on a new and simple route to **1**.

It has been assumed that the chlorine atom(s) of chlorothiophenes is generally unreactive under Friedel-Crafts conditions, as is true for those of aryl chlorides. However, Ramsey et al. have reported that chlorothiophenes undergo polymerization by $AlCl_3$-$CuCl_2$ through a nuclear coupling with the elimination of HCl.[5)] Recently, we have also reported that, in the presence of $AlCl_3$, 2-chlorothiophene reacts with active aromatic compounds, giving the corresponding 2-arylthiophenes.[6)] Furthermore, we have observed an unusual $AlCl_3$-catalyzed Friedel-Crafts reaction of 2,5-dichloro-3-chloromethylthiophene with benzene and its simple alkyl derivatives, which yield 4-aryl-3-arylmethyl-2-chlorothiophenes, exclusively.[7)] In an extension of our studies, we found that under similar conditions 2,5-dichlorothiophene (**2**) reacted regioselectively with various aromatic compounds (**3**) to afford the unusual products, 4-aryl-2-chlorothiophenes (**4**). Early studies suggest that chlorine atom(s) in chlorothiophenes can be removed only with difficulty.[8,9)] However, contrary to expectation, **4** were found to be successfully dechlorinated by catalytic hydrogenation. Thus, the $AlCl_3$-catalyzed reaction provides a two-step synthesis (three-step from thiophene) of **1** from readily available **2** (Scheme 1).



Scheme 1.

The procedure of the $AlCl_3$-catalyzed reaction is simple: one mole equiv of $AlCl_3$ was added to an equimolar mixture of **2** and **3** in CH_2Cl_2 under ice-cooling, and the mixture stirred below 40 °C for a total of 2 h. The results are summarized in Table 1. As shown in the Table, the reaction yielded the corresponding **4** as the major products in good yield, except for a reaction with chlorobenzene (**3f**), which yielded an inseparable mixture of 2,5-dichlorothiophene oligomers. In many cases, the presence of isomers due to the position of the substituent(s) on the aromatic ring, diarylthiophenes (**6**), and self-condensation products (**5**) which were derived from two moles of **4** with the elimination of HCl, were also suggested in the products (MS, UV, NMR). The corresponding 2-

arylthiophene derivatives, such as 2-aryl-5-chlorothiophenes, which might be expected, were not detected in the products. Interestingly, while naphthalene (**3h**) produced a mixture of the 1- and 2-naphthyl derivatives (**4h**; main product), tetralin (**3g**) yielded 2-chloro-4-(5,6,7,8-tetrahydro-2-naphthyl)thiophene (**4g**).

The structures of **4** were assigned on the basis of their elemental analyses and spectral data. The UV spectra excluded the presence of the 2-arylthiophene unit in the structures; instead, it suggested the presence of the 3-arylthiophene unit.[10] The NMR spectra showed, in addition to the absorption due to the aromatic ring protons, an AB quartet with a coupling of 1.25—1.70 Hz, characteristic for 2,4-disubstituted thiophenes[11] in the ring proton region. Further, the structure assignment of **4** was confirmed by chemical evidence. The reductive desulfurization of **4e** by Raney nickel, for example, gave *p-s*-butylanisole. Treatment of **4g** with 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ) gave **4h**, which afforded 3-(2-naphthyl)-thiophene (**1h**) by dechlorination; this indicates that 2-naphthyl and the tetrahydro-2-naphthyl moieties are included in the molecules of **4h** and **4g**, respectively. When the reaction was conducted at −50 °C between **3** and the protonated **2**[12] which was prepared at the same temperature in advance, **4** were produced in somewhat higher yield. The reaction using $SnCl_4$ instead of $AlCl_3$ gave no products under the conditions studied.

The catalytic hydrogenation of **4** under atmospheric pressure using 10% Pd-C as a catalyst gave the corresponding **1** in satisfactory yield, as shown in Table 2.

The obtained results indicate that protonated **2** serves as electrophilic species in the $AlCl_3$-catalyzed reaction. An NMR spectroscopic method revealed that, in an $AlCl_3$-HCl-CH_2Cl_2 system at low temperature, **2** produced 2*H*-2,5-dichlorothiophenium ion.[12] However, the entire reaction pathway still remains unclear.

Finally, considering that the electrophilic substitutions of **1** occur in the 5-position as well as in the 2-position,[13] **4** could also be versatile intermediates for the selective syntheses of certain isomer-free 2-substituted 3-arylthiophenes. Namely, the introduction of an appropriate group into the vacant α-position of **4**, followed by a subsequent dechlorination would yield 2-substituted 3-arylthiophenes, the chlorine atom of **4** serving as a blocking group.

Experimental

All the melting and boiling points are uncorrected. The ^1H NMR (90 MHz, TMS as an internal reference), UV (in MeOH, unless otherwise noted), IR, and MS (70 eV) spectra were obtained on Hitachi R-22, Hitachi EPU-2A, Hitachi EPI-S2, and Hitachi RMU spectrometers, respectively.

2,5-Dichlorothiophene (**2**) was prepared by a method described in the literature.[14] Commercial $AlCl_3$ was used without special precautions against moisture.

$AlCl_3$-Catalyzed Reaction of 2,5-Dichlorothiophene (2) with Aromatic Compounds (3) (General Procedure). Pulverized $AlCl_3$ (20 mmol) was added in portions over ca. 5-min period to a mixture of **2** (20 mmol) and the substrate (**3**, 60 mmol) in CH_2Cl_2 (10 ml; 20 ml in the case of naphthalene) under ice-cooling. Exothermic reactions occurred with the appearance of a coloration and the rise of the temperature of the reaction mixture. The mixture was stirred at ca. 5 °C for 30 min, then at ambient temperature for 1 h, and at the reflux temperature of the solvent for an additional 30 min. The reaction mixture was poured into ice-water (ca. 70 ml) and extracted with $CHCl_3$ (10 ml×3). The extracts were combined, washed successively with water, 5% $NaHCO_3$ solution, and water, and dried. After removal of the solvent and the starting substances by distillation, the residue was sublimed under reduced pressure (2—3 mmHg (1 mmHg= 133.322 Pa)) yielding crude 4-aryl-2-chlorothiophene (**4**) which was contaminated with a small amount of the positional isomer. Chromatography (silica gel/hexane) of the residue of the sublimation gave another crop of **4**. The crude **4** was purified by recrystallization (hexane) or distillation. In the case of naphthalene (**3h**), the reaction mixture, after removal of the solvent, was sublimed under reduced pressure (7 mmHg) to recover **3h**, and the residue was directly chromatographed.

The minor products were not investigated further, except for those produced in the reaction of **2** with anisole (**3e**).

4a: MS *m/z* 194 (M^+, 100). UV λ_{max} 232 (4.25), 261 (3.95). ^1H NMR ($CDCl_3$) δ=7.1—7.6 (m, Ph+Th (thiophene; 3-H, 5-H)). Anal. ($C_{10}H_7ClS$) C, H.

Reaction with Anisole (3e). Chromatography (silica gel/hexane-benzene (1 : 1)) of the residue of the sublimation afforded the second crop of **4e** and the self-condensation product (**5e**; 0.7 g, mp 103—104 °C after crystallization from MeOH-acetone). The combined **4e** was recrystallized from EtOH. When the reaction mixture was poured into ice-water, a small amount of precipitate was separated out, which was recrystallized from *N,N*-dimethylformamide to give 2,4-bis(*p*-methoxyphenyl)thiophene (**6e**; 0.2 g, mp 220—221 °C (lit,[6] 219—221 °C).

4e: MS *m/z* 224 (M^+, 100). UV λ_{max} 242 (4.31), 273 (4.15). ^1H NMR ($CDCl_3$) δ= 3.81 (3H, s, OMe), 6.85 and 6.95 (2H, AA'BB'm, *p*-Ph), 7.05 and 7.15 (1H, d, $J_{3,5}$=1.6 Hz each, Th (3-H, 5-H)), 7.38 and 7.47 (2H, AA'BB'm, *p*-Ph). Anal. ($C_{11}H_9ClOS$) C, H.

5e: MS *m/z* 412 (M^+, 100). UV λ_{max} 245sh (4.40), 254 (4.43), 273 (4.42), 318—331 (3.89). ^1H NMR (acetone-d_6) δ= 3.79 (6H, s, OMe), 6.89 and 6.98 (4H, AA'BB'm, *p*-Ph), 7.05 (1H, s, Th), 7.2—7.7 (6H, m, *p*-Ph+Th). Anal. ($C_{22}H_{17}ClO_2S_2$) C, H.

Catalytic Dechlorination of 4-Aryl-2-chlorothiophenes (4). The procedure is a modification of the one used by Zwanenberg et al.[9] Hydrogenation was conducted by stirring a mixture of **4** (5 mmol), KOH (1.5 g), 10% Pd-C (0.7 g), and MeOH (100 ml) at room temperature in an atmospheric pressure hydrogenation apparatus filled with H_2. Within 1 h one equivalent of H_2 was consumed. After removal of the catalyst the solution was concentrated to ca. 30 ml. Water was added to the residue and the resulting crystalline mass was purified by sublimation under reduce pressure and/or recrystallization.

1a: MS *m/z* 160 (M^+, 100). UV λ_{max} 227 (4.15), 258 (4.14) (lit,[15] (96% EtOH) 227 (4.11), 259 (4.08)). ^{1}H NMR ($CDCl_3$) δ=7.1—7.8 (m, Ph+Th).

1b: MS *m/z* 174 (M^+, 100). UV λ_{max} 227 (4.27), 260 (4.23) (lit,[15] (96% EtOH) 228 (4.17), 261 (4.17)). ^{1}H NMR ($CDCl_3$) δ=2.35 (3H, s, Me), 7.13 and 7.22 (2H, AA'BB'm, *p*-Ph), 7.35 (3H, s, Th), 7.43—7.52 (2H, AA'BB'm, *p*-Ph).

1c: MS *m/z* 188 (M^+, 100). UV λ_{max} 228 (4.20), 262 (4.21). ^{1}H NMR ($CDCl_3$) δ=1.24 (3H, t, $J_{CH_2\text{-}CH_3}$=7.6 Hz, CH_2-$C\underline{H}_3$), 2.66 (2H, q, $J_{CH_2\text{-}CH_3}$=7.6 Hz, $C\underline{H}_2$-CH_3), 7.16 and 7.24 (2H, AA'BB'm, *p*-Ph), 7.35 (3H, s, Th), 7.45 and 7.54 (2H, AA'BB'm, *p*-Ph). Anal. ($C_{12}H_{12}S$) C, H.

1d: MS *m/z* 188 (M^+, 100). UV λ_{max} 227 sh (4.17), 248 (4.01). ^{1}H NMR ($CDCl_3$) δ=2.29 and 2.33 (3H, s each, Me), 6.9—7.4 (6H, m, Ph+Th). Anal. ($C_{12}H_{12}S$) C, H.

1e: MS *m/z* 190 (M^+, 100). UV λ_{max} 230 (4.11), 269 (4.21). ^{1}H NMR ($CDCl_3$) δ=3.81 (3H, s, -OMe), 6.85 and 6.95 (2H, AA'BB'm, *p*-Ph), 7.2—7.35 (3H, m, Th), 7.45 and 7.54 (2H, AA'BB'm, *p*-Ph).

1h: MS *m/z* 210 (M^+, 100). UV λ_{max} 226 (4.58), 244 (4.51), 252 (4.53), 280 (4.05), 290 (4.13), 301 (4.05) (lit,[15] (96% EtOH) 228 (4.59), 254 (4.57), 279 (4.11), 290 (4.16), 301 (4.08)). ^{1}H NMR ($CDCl_3$) δ=7.15—8.1 (m, Naph+Th).

Dehydrogenation of 4g. A mixture of **4g** (1.24 g, 5 mmol) and DDQ (2.27 g, 10 mmol) in benzene (30 ml) was stirred for 8 h at the reflux temperature of the solvent. After removal of the solvent by distillation, the residue was chromatographed (silica gel/hexane) to afford **4h** (mp 114—115 °C, 1.1 g, 90%).

Reductive Desulfurization of 4e with Raney Nickel. A mixture of 2-chloro-4-(*p*-methoxyphenyl)thiophene (**4e**; 1 g, 4.5 mmol) and W-7 Raney nickel (prepared from 10 g of the alloy) in benzene (100 ml) was stirred at the reflux temperature of the solvent for 20 h. The reaction mixture was filtered and the nickel was extracted with hot benzene for several hours in a Soxhlet extractor. The filtrate and the extract were combined and evaporated. The residue (0.6 g) were chromatographed (silica gel/hexane-chloroform (4:1) to give *p-s*-butylanisole (oil; 0.12 g, 17%) and 3-(*p*-methoxyphenyl)thiophene (**1e**; mp 123—125 °C; 0.09 g, 10%). The IR and NMR spectra of the oily product was identical with those of the authentic sample (bp 109—112 °C (16 mmHg); lit,[16] 106—108 °C (16 mmHg)) which was obtained by the methylation of *p-s*-butylphenol with dimethyl sulfate in basic solution.

This work was supported in part by a grant from The Japan Association of Chemistry, to which the authors' thanks are due. The authors also wish to thank Professor Kensuke Takahashi of Nagoya Institute of Technology for the NMR spectral measurements of the protonated 2,5-dichlorothiophene and helpful suggestions on the spectra.

A Reinvestigation of a Sensitized Photochemical Cycloaddition of Coumarin with Cyclopentene[1)]

Hiroshi SUGINOME* and Kazuhiro KOBAYASHI
Organic Synthesis Division, Faculty of Engineering, Hokkaido University, Sapporo 060
(Received May 18, 1988)

Synopsis. A reinvestigation of a sensitized photochemical cycloaddition of coumarin with cyclopentene reported by Hanifin and Cohen indicated that the cycloaddition gives a sterically disfavored cis-cisoid-cis adduct (18%) together with a cis-transoid-cis adduct (25%) and a head-to-head coumarin dimer with a cis-transoid-cis disposition. The two adducts behaved differently in hydrolysis and recyclization.

In connection with the program we have designed to explore the potential of the β-scission of the alkoxyl radicals generated from the cyclobutanols obtained by a [2+2]photocycloaddition of 4-hydroxycoumarin and olefins,[2,4)] we have been interested in the distinctly different behavior of coumarin reported by Hanifin and Cohen in 1966[3)] and 4-hydroxycoumarin in their photochemical cycloaddition.[5)]

Thus, while both Reid and his colleagues and we ourselves have found that the [2+2]photoaddition of 4-hydroxycoumarin (**1**) and cyclopentene (**2**) on direct irradiation gives a single [2+2]photocycloadduct **3** having a sterically disfavored cis-cisoid-cis configuration in a good yield (Scheme 1),[2,6)] Hanifin and Cohen[3)] have reported that the photoaddition of coumarin itself and cyclopentene does not give any cycloadducts on direct irradiation but gives single [2+2]photocycloadduct, mp 139 °C, on a sensitized irradiation. According to Hanifin and Cohen,[3)] the cyclopentane ring and the six-membered ring of the photoadduct are probably transoid oriented.

We have therefore reinvestigated the direct and sensitized photocycloadditions of coumarin and cyclopentene. Our results which differ from the previous report[3)] are described in this paper.

Results

A sensitized irradiation of coumarin and cyclopentene carried out according to the procedure of Hanifin and Cohen [**4** (5.6 mmol), **2** (5 ml), benzophenone (1 mmol), and dioxane (1 ml)] through a Pyrex filter with a 500-W high-pressure mercury arc for 5 days gave a mixture of three products, **5** (mp 82—84 °C, 25%), **6** (mp 138—139 °C, 18%), and **7** (mp 175—176 °C, 21%), which were separable by means of preparative TLC.

Scheme 1.

^{1}H NMR spectroscopy and their behaviors in hydrolysis and regeneration of the coumarin ring indicated that the stereochemistries of adducts **5** and **6** have cis-transoid-cis for **5** and cis-cisoid-cis for **6**.

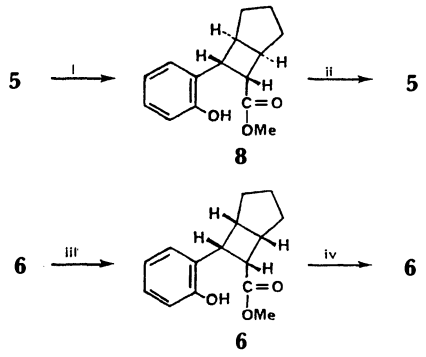
A 500 MHz ^{1}H NMR spectrum of adduct **5** exhibited four signals (each 1H) at δ 2.70, 3.05, 3.14, and 3.19. The signal at δ 3.05 assignable to 6a-H split into a doublet of a doublet with $J_{6a,9b}$=9.28 Hz, $J_{6a,6b}$=4.88 Hz, and $J_{6a,9b}$=0.98 Hz. The signal at δ 3.19 assignable to 9b-H split into a doublet of a doublet with $J_{6a,9b}$=9.28 Hz and $J_{9a,9b}$=3.91 Hz. The signals at δ 3.41 (br. td, J=6.8 and 5.9 Hz) are assigned to the 9a-H and 6b-H. These coupling constants indicated that the cyclobutane-coumarin ring fusion as well as the cyclobutane-cyclopentane ring are cis and that the coumarin and cyclopentane ring are transoid oriented. The structure of the photoadducts **5** was thus established to be 6aα,6bβ,9aβ,9bα-($\pm$)-6b,7,8,9,9a,9b-hexahydrobenzo[*b*]cyclopenta[3,4]cyclobuta[1,2-*d*]pyran-6-(6a*H*)-one (**5**).

On the other hand, the results on the ^{1}H NMR spectrum of adduct **6**, the melting point of which is nearly in agreement with that of the adduct reported by Hanifin and Cohen, indicated that the cyclobutane-coumarin ring fusion as well as the cyclobutane-cyclopentane ring fusion are cis while the coumarin and cyclopentane ring are cisoid oriented in the adduct.

Thus, 500 MHz ^{1}H NMR spectrum of adduct **6** exhibited four signals each corresponding to ^{1}H at δ 3.23, 3.41, 3.73, and 3.97. The signal at δ 3.73 assignable to 5a-H split into a doublet of a doublet with $J_{6a,6b}$=11.23 Hz, and $J_{6a,9b}$=10.74 Hz. The signal at δ 3.97 assignable to 9b-H similarly split into a doublet of a doublet with $J_{6a,9b}$=11.23 Hz, and $J_{6b,9a}$=10.74 Hz. The signal at δ 3.97 assiganble to 9b-H similarly split into a doublet of a doublet with $J_{6a,9b}$=10.74 Hz and $J_{9b,9a}$=10.25 Hz. The rest of the signals at 3.23 (dq, J=7.81 and 8.3 Hz) and at δ 3.41 (dt, J=10.25 and 7.81 Hz) can be assigned to the 6b-H and 9a-H.

The spectroscopic analysis of the third photoadduct **7** indicated that it is a head-to-head and cis-transoid-cis dimer of coumarin obtained by Schenck and his colleagues by means of a sensitized irradiation of coumarin in ethanol or in benzene.[7)]

Thus, we conclude that the cycloadduct **6** previously reported by Hanifin and Cohen[3)] has cis-cisoid-cis structure and the cycloadduct **5**, newly isolated in the



i) CH_3COONa-MeOH, r.t.
ii) *p*-toluenesulfonic acid-benzene-r.t. 10 min
iii) CH_3ONa-MeOH, r.t.
iv) concd HCl, r.t. 2 h

Scheme 2.

present work, has cis-transoid-cis structure (Scheme 1).

Irradiation of a solution of coumarin in cyclopentene and dioxane in the absence of a sensitizer for 5 days gave no [2+2]photocycloadducts: this agrees with the observation by Hanifin and Cohen.[3]

We found a clear difference between **5** and **6** in a base-catalyzed hydrolysis. Thus, while the cis-transoid-cis adducts **5** was readily hydrolyzed with sodium acetate in methanol at room temperature no hydrolysis took place when cis-cisoid-cis adduct **6** was exposed to the same conditions of hydrolysis. Hydrolysis of adduct **6** was, however, achieved with sodium methoxide in methanol for 2 h at room temperature (Scheme 2).

The molecular geometry of cis-cisoid-cis adduct **6** can be assumed to be similar to cis-cisoid-cis adduct **3**, whose molecular structure we determined by means of an X-ray crystallographic analysis.[2,3]

The difference in the behavior under hydrolysis of adducts **5** and **6** can be understood by comparing the geometries of these molecules since an inspection of the molecular models of adducts **5** and **6** indicated that the carbonyl carbon of adducts **6** is more shielded from an attacking nucleophile.

We also found a clear difference in the rates of the recyclizations of the hydrolyzed products **7** and **8**; the hydrolyzed product **8** gave the parent adduct **5** after treatment with *p*-toluenesulfonic acid in benzene at room temperature nearly spontaneously while no cyclization of **9** took place under these conditions. The ester **9** gave a more strained parent adduct **6** after treatment with concd HCl at pH 3 in ethanol at room temperature for 2 h (Scheme 2).

In has been reported as generally true that in an adduct of cycloalkenes and monocyclic enones where the cyclobutane ring fusion to the enones and alkene derived ring are cis, the rings are preferentially disposed transoid to each other.[5b]

It is worth noting that the present triplet sensitized photoaddition led to the production of a substantial proportion of the sterically disfavoured cis-cisoid-cis adduct in addition to an expected cis-transoid-cis adduct. The reason for this is not clear but the attractive interaction of an aromatic portion of coumarin and cycloalkene in the triplet exciplex or the biradical intermediate might be partly responsible for the formation of cis-cisoid-cis product.

Experimental

For the instruments and the experimental procedures see Ref. 2.

Photochemical Cycloaddition of Coumarin with Cyclopentene in the Presence of Benzophenone. Coumarin (820 mg, 6.5 mmol), cyclopentene (5 ml), benzophenone (180 mg, 1 mmol), and dioxane (1 ml) were irradiated through a Pyrex filter with a 500-W high-pressure Hg arc at room temperature for 5 days. After the removal of an excess of cyclopentene and dioxane under a reduced pressure, the product was subjected to preparative TLC with a 1:3 ethyl acetate and hexane to give three cycloadducts **5**, **6**, and **7** in the order of their mobility on the TLC plate. The most mobile adduct **5** (300 mg, 25%) was recrystallized from hexane to yield a specimen for analysis. Mp 82—84 °C. (Found: *m/z* 214.0989. Calcd for $C_{14}H_{14}O_2$: M, 214.0992). IR (Nujol) 1752 cm^{-1} (C=O); ^1H NMR (500 MHz) δ=1.57—1.67 (2H, m, 8-H), 1.86—2.02 (4H, m, 7-H and 9-H), 2.70 (1H, br. td, *J*=7.3 and 3.91 Hz, 9a-H), 3.50 (1H, ddd, *J*=9.28, 4.88, and 0.98 Hz, 6a-H), 3.14 (1H, br. td, *J*=6.8 and 5.9 Hz, 6b-H), 3.19 (1H, dd, *J*=9.28 and 3.91 Hz, 9b-H), and 7.00—7.31 (4H, m, 1,2,3,4-H); MS *m/z* (rel intensity), 214 (M^+, 4.6%), and 146 (100).

The second mobile adduct **6** (219 mg, 18%) was recrystallized from hexane. Mp 138—139 °C (lit,[3] mp 139 °C): (Found: *m/z* 214.0983. Calcd for $C_{14}H_{14}O_2$: M, 214.0992); IR (Nujol) 1746 cm^{-1} (C=O), 1172, amd 772; ^1H NMR (500 MHz), δ= 1.71—1.27 (1H, m), 1.34—1.62 (4H, m), 1.88 (1H, dd, *J*=13.67 and 6.35 Hz), 3.23 (1H, br. dq, *J*=7.81 and 8.3 Hz, 6b-H), 3.42 (1H, dt, *J*=10.25 and 7.81 Hz, 9a-H), 3.73 (1H, dd, *J*= 11.23 and 10.74 Hz, 6a-H), 3.97 (1H, dd, *J*=10.74 and 10.25 Hz, 9b-H), and 6.96—7.31 (4H, m, 1,2,3,4-H); MS *m/z* (rel intensity) 214 (M^+, 3.3%) and 146 (100).

The most polar adduct **7** (173 mg, 21%) was recrystallized from hexane. Mp 175—176 °C (lit,[6] mp 176.5 °C).

A Base-Catalyzed Hydrolysis of the Adduct 5. Adduct **5** (52 mg, 0.24 mmol) in methanol (1 ml) containing sodium acetate (20 mg, 0.24 mmol) was stirred overnight at room temperature. Examination of the solution by TLC (1:3 ethyl acetate-hexane) indicated the disappearance of the starting material. To this solution, dichloromethane (10 ml) was added and the solution was washed first with aq. saturated ammonium chloride and then with brine and dried over anhydrous magnesium sulfate. After the usual work-up, the product was dissolved in benzene (2 ml) containing *p*-toluenesulfonic acid (10 mg, 0.05 mmol). The solution was stirred for 10 min. at room temperature, washed with aq. sodium hydrogencarbonate and dried over anhydrous magnesium sulfate. The usual work-up of the solution gave the residue which was subjected to preparative TLC with a 1:3 ethyl acetate and hexane to yield the starting adduct **5** (31 mg, 60%).

A Base-Catalyzed Hydrolysis of Adduct 6. (a) Adduct **6** (26 mg, 0.12 mmol) in methanol (1 ml) containing sodium acetate (10 mg, 0.12 mmol) was stirred overnight at room temperature. The usual work-up of the solution gave the starting adduct **6** nearly quantitatively.

(b) To adduct **6** (54 mg, 0.25 mmol) in methanol (5 ml), a small amount of sodium metal was added. The solution was then stirred for 2 h at room temperature. Examination of the solution by means of TLC (a 1:3 ethyl acetate-hexane) indicated the disappearance of the starting adduct **6**. The solution was neutralized with concd hydrochloric acid (pH 3) and was stirred for another 2 h. After the removal of methanol under reduced pressure the residue was extracted with diethyl ether. The ethereal extract was washed first with aq.

sodium sulfate. The product was subjected to preparative TLC with a 1:3 ethyl acetate-hexane to yield the starting adduct **6** (41 mg, 76%).

(Received May 20, 1988)

Synopsis. Vertical arrangement of the alkyl side arm in the crystal structure of KSCN complex of *N*-heptylmonoaza-18-crown-6 is well-consonant with the effective side-arm participation in N-pivot lariat ether complexes and supports the lack of 'biscrown effect' for bis(monoaza-18-crown-6)s.

The lariat ethers are a family of the macrocyclic polyethers which bear one or more donor atoms in the side arm through a nitrogen or carbon pivot atom.[2,3] Complexation behavior of the N-pivot lariat ethers has been extensively studied in solutions by comparison with that of the *N*-alkylmonoazacrown ether, an analogue without donor atom in the side arm.[4,5] Gokel et al. have shown the unequivocal evidence for the side-arm participation in the crystal structures of N-pivot lariat ether complexes.[6,7] A similar X-ray analysis was also done for $NaClO_4$ complex of *N*-phenylmonoaza-15-crown-5[8] and KI complex of *N*-allylmonoaza-18-crown-6.[9] However, these studies could not give the arrangement of a flexible non-coordinating side arm and the conformational feature around the pivot nitrogen was also not emphasized in these complexes, while such structural information is very important for considering the interaction with a donating group in the side arm, such as a lariat group in lariat ethers or a second crown ring in bis(crown ether)s. The present paper shows a clear picture about KSCN complex of *N*-alkylmonoaza-18-crown-6, in which the non-coordinating side arm is arranged vertically to the ring plane, and the K^+ ion is located in the center of the ring. The fact in turn may give an answer for the question why a large enhanced binding can be obtained in the complexation of N-pivot lariat ethers, and why the two crown rings of bis(monoaza-18-crown-6)s could not cooperate in the complexation with larger cations.

Experimental

$C_{19}H_{39}NO_5 \cdot KSCN$. A white plate crystal was obtained from a methanol solution containing the ligand and excess KSCN by evaporating the solvent slowly at room temperature. Mp 78—80 °C; IR(Nujol): 2040, 1120, 960, 840 cm^{-1}; Calcd for $C_{20}H_{39}N_2O_5KS$: C, 52.37; H, 8.57; N, 6.11%. Found: C, 51.99; H, 8.49; N, 6.18%. The crystal used for X-ray analysis had approximate dimensions of 0.3×0.3×0.3 mm^3.

X-Ray Analysis. Crystal Data. monoclinic, $P2_1/c$, a=21.910(4), b=14.573(5), c=7.936(5) Å, β=94.36°, V=2527 $Å^3$, Z=4, D_m=1.21, D_c=1.21 g cm^{-3}. Intensity data were collected by ω-2θ scans of variable rate designed to yield measurements of equal relative precision for all significant reflections, using an Enraf-Nonius CAD4 diffractometer equipped with Mo $K\alpha$ radiation (λ=0.71073 Å) and a graphite monochromator. Data reduction included corrections for background, Lorentz, polarization, absorption. Independent 2702 reflections having $I>3\sigma(I)$ were used in the refinements. All structure were solved by MULTAN 82 and refined by full-matrix least square based on F with weights $w=\sigma^{-2}(F_o)$. Non-hydrogen atoms were refined anisotropically, and hydrogen atoms were located in calculated positions. The final residual values were R=0.052, R_w=0.077. The final atomic parameters for non-hydrogen atoms are listed in Table 1, and the selected bond distances and bond angles are shown in Fig 2. The complete tables of atomic coordinates, thermal parameters, bond distances and angles are kept as Document

Anisotropically refined atoms given in the form of the isotropic equivalent thermal parameter defined as: $(4/3)\cdot[a2\cdot B(1,1)+b2\cdot B(2,2)+c2\cdot B(3,3)+ab(\cos \text{gamma})\cdot B(1,2)+ac(\cos \text{beta})\cdot B(1,3)+bc(\cos \text{alpha})\cdot B(2,3)]$.

Present address: Department of Industrial Chemistry, Faculty of Engineering (Kyushu Campus), Kinki University, Iizuka 820.

No. 8837 at the Editor of the Bulletin of the Chemical Society of Japan. All the measurements and calculations were performed at the Center of Advanced Instrument Analysis, Kyushu University.

Results and Discussion

The structure of the KSCN complex of *N*-heptylmonoaza-18-crown-6 is shown in Fig 1. Figure 2 gives its skeletal drawing along with the selected bond distances and bond angles. The skeletal drawing shows the arrangement of donor atoms around the cation. The macroring donor atoms are located in a chair-like arrangement to give the D_{3d} conformation of the ring, which is very close to those in the K^+ complexes of *N*-(2-methoxyethyl)monoaza-18-crown-6[6] and *N*-allylmonoaza-18-crown-6.[9] Interestingly, C13–N1–K1 bond angle of the complex is 99.5°, i.e. the non-coordinating alkyl side arm is directed almost upright to the ring plane. Although some effects might come from the crystal lattice packing the direction of C13–N1 bond is considered to be determined by the preferred conformation of the ring and coordination state of the pivot nitrogen. A further examination of CPK model shows that through simple rotations around the C13–N1 and C13–C14 bonds by 180° (two anti conformations to two eclipsed conformations) C15 can be put at such the position just above the K^+ ion without any deformation of the D_{3d} conformation, and this is just the position for the lariat oxygen atom in the N-pivot lariat ether complexes. Combined with the present result and the crystal structures of lariat ether complexes, we can conclude that the pyramidal structure of the pivot nitrogen and the conformation around the pivot nitrogen atom may account for the large enhanced binding observed in N-pivot lariat ether complexes. Very recently it was reported that the binding ability of C-pivot lariat ethers can be improved by introduction of an additional substituent (ex. methyl) on the pivot carbon, suggesting that the first side arm is arranged in an equatorial position in the C-pivot lariat ether complexes in the absence of the second substituent.[10,11]

Fig. 2. Skeletal drawing of KSCN complex of *N*-heptylmonoaza-18-crown-6, along with the selected bond distances (Å) and bond angles (°).

For monoaza-18-crown-6 the presence of the pivot nitrogen differentiates each side of the macroring in D_{3d} conformation, which is so stable as to be maintained in the complexation with larger cations,[12] i.e., one side (the side below in Fig. 1) with three axial nonbonding lone pairs (n_{ax}) of oxygen, and the other side(up side in Fig. 1) with only two n_{ax}.[1,13] The vertical arrangement of the *N*-alkyl side arm makes the environment of the two sides more different, and a larger cation would be favorably located the side having three n_{ax} (below the ring in Fig. 1). So that the formation of an intramolecular sandwich complex with a larger cation is very difficult for the bis(monoaza-18-crown-6)s linked by a short bridging chain because two unfavorable sides with two n_{ax} have to be used, although there is no hindrance to form an intermolecular sandwich complex with two monoaza-18-crown-6 rings. This reasoning is consistent with the results that the bis(monoaza-18-crown-6)s behave very similarly with the corresponding monocyclic analogues in the solvent extraction, homogeneous binding constants and cation transport experiment.[1,14,15]

The position of K^+ ion in the present complex, in the center of the macroring, is also noticeable, since the cation is known to be located above the ring plane in the complexes containing a monoaza-18-crown-6 ring reported before.[6,9] It seems that the relative position of the cation to the macroring is determined not only by the ring size but also by the coordination balance of the axial ligands. In the present complex a good balance between the two axial anionic ligands makes the cation reside within the macroring.

Catalytic Upgrading of SRC from Pyrolytic Coal Liquefaction and Hydrocracking of Polycyclic Aromatic Hydrocarbons

Chunshan SONG, Kouji HANAOKA, Tomohiro ONO, and Masakatsu NOMURA*
Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadaoka 2-1, Suita, Osaka 565
(Received April 21, 1988)

Synopsis. Catalytic upgrading of SRC (solvent refined coal) derived from short contact time pyrolytic liquefaction of Wandoan subbituminous coal was carried out. The upgrading with unsulfided and sulfided nickel-molybdenum catalysts produced about 77 wt% and 85 wt% of oil plus light distillates from the SRC, respectively. The reactions occurring during the upgrading process were assessed by referring to the hydrocraking of related polycyclic aromatic hydrocarbons.

The upgrading of various coal-derived products has been the subject of much research work concerning the second stage of two- or multi-stage coal conversions.[1-3] Recently, we have found that when relatively low heating rates are used, subbituminous coal can be efficiently converted into THF-soluble products in high conversions (85—88 wt%, daf) by pyrolytic procedures in an N_2-tetralin system under high temperature and short contact time conditions.[4] The present work was conducted in order to evaluate the extent of convertibility of the pyrolytically derived SRC by upgrading over supported nickel-molybdenum catalysts. Hydrocracking of some related polycyclic aromatic hydrocarbons over the same catalysts was also carried out for assessing reactions occurring during the upgrading process.

Experimental

The SRC (Table 1) used in this work was prepared by short contact time pyrolytic liquefaction of Wandoan subbituminous coal.[4] The polycyclic aromatics used in hydrocracking reactions were reagent-grade anthracene, phenanthrene, and bibenzyl. The catalysts examined were NiO-MoO_3/Al_2O_3 (NiMo) catalyst (Ketjenfine 153S: NiO, 2.9 wt%; MoO_3, 15.8 wt%; surface area, 255 $m^2 g^{-1}$; pore volume, 0.56 ml g^{-1}) and the corresponding sulfided catalyst (S-NiMo). The upgrading was carried out at 425 °C for 1 h with 4.9 MPa H_2 in a 70-ml SUS-316 rocking autoclave with SRC (2.5 g, −32 mesh), tetralin (5 g) and a catalyst (1 g, −100 mesh) together with a small stainless-steel ball. The products were separated into gas, light distillates (LD, C_5-250 °C), oil (hexane-soluble), asphaltene (benzene-soluble), and preasphaltene (benzene insoluble). Hydrocracking of polycyclic aromatic hydrocarbons was carried out at 400 °C for 1 h with 9.8 MPa H_2 in the autoclave with a given reactant (3 g) and a catalyst (0.3 g, −100 mesh). The products were analyzed by GC and GC-MS. Experimental details concerning this work are similar to those described elsewhere.[4-6]

Results and Discussion

The results of catalytic upgrading of the SRC are shown in Fig. 1. The short-contact-time pyrolytically derived SRC showed a relatively high reactivity toward upgrading, and about 10 wt% of LD and 59 wt% of oil was obtained in the noncatalytic run (Run 1), without any consumption of gas-phase H_2. The use of a NiMo catalyst and the corresponding S-NiMo catalyst improved the conversion of preasphaltene and asphaltene to oil and LD, increased the consumption of H_2 and decreased the net hydrogen transfer from tetralin, as can be seen from Fig. 1. Relative to a noncatalytic run, the yield of LD rose from about 10 wt% to 18 wt% with a NiMo catalyst (Run 2), and to 23 wt% with a S-NiMo catalyst (Run 3). The total yields of light product, oil+LD+gas, were 87.8 wt% with S-NiMo, 80.0 wt% with NiMo and 70.9 wt% without catalyst. These results indicate the high extent of convertibility of the SRC. S-NiMo showed a higher catalytic activity than NiMo for the upgrading; such a trend was also observed in runs with asphaltene.[7]

Table 2 gives elemental analysis and structural parameters of oil products, and Fig. 2 shows the gel permeation chromatograms of oil products. As compared to a noncatalytic run, the use of NiMo and

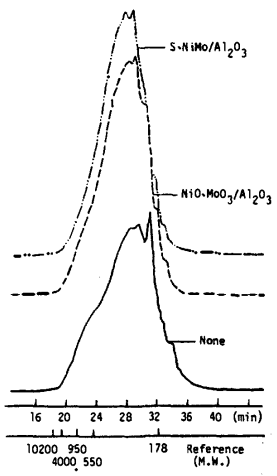

Fig. 2. Gel permeation chromatograms of oil products from catalytic upgrading (column, Shodex AC-801+AC-802; mobile phase, $CHCl_3$, 1 ml min^{-1}; UV detector, set at 254 nm).

S-NiMo facilitated a decreasing heteroatom content and aromaticity (f_a), and an increased atomic H/C ratio and the substitution extent of aromatics (σ) of oil products (Table 2), which correspond to the shift of the molecular size distribution of oil products of catalytic runs relative to a noncatalytic run toward the higher molecular size side (Fig. 2).

In order to assess the reactions occurring during the upgrading process, the hydrocracking of polyaromatics was carried out. The results in Tables 3 and 4 show that NiMo and S-NiMo significantly promoted hydrocracking reactions of phenanthrene and anthracene, whereas in the absence of catalyst a very limited amount of phenanthrene was converted (Table 3, Run 4) and anthracene was mainly converted into dihydroanthracene (Table 4, Run 7). Phenanthrene is known to have a low reactivity toward hydrogenation, and the major hydrogenated products of the catalytic runs are dihydro-, tetrahydro-, octahydrophenanthrene (Table 3). Anthracene showed much a higher reactivity, and in the catalytic runs, most of the intermediate

hydrogenation products, such as dihydro- and tetrahydroanthracene, were converted into octahydroanthracene and hydrocracked products (Table 4). The major hydrocracked products are monocyclic and bicyclic hydrocarbons. Both in runs involving phenanthrene and anthracene, S-NiMo afforded higher yields of hydrocracked products than NiMo, indicating a higher activity of the sulfided catalyst than the unsulfided one (Tables 3 and 4). In the reaction of bibenzyl, S-NiMo and NiMo also promoted conversion of the reactant to 1-cyclohexyl-2-phenylethane and 1,2-dicyclohexylethane, but the yields of hydrocracked products, such as benzene, toluene, and ethylbenzene, were only slightly higher than those of a noncatalytic run.

The above results provided a basis for assessing the hydrocracking reactions of aromatic compounds present in SRC during the upgrading process. Most of the hydrocracked products shown in Tables 3 and 4, if formed from catalytic upgrading of the SRC, would fall into the category of light distillates. On the other hand, fairly larger amounts of the products from catalytic runs (Tables 3 and 4) are hydrogenation products, which did not undergo hydrocracking (ring-opening) reactions. Therefore, apart from hydrocracking reactions, it is possible that some of the polyaromatic substances present in heavy portions of the SRC were converted into oil products by hydrogenation reactions, since an increase in naphthenic rings in asphaltene and preasphaltene can also increase their solubility in hexane.[8] This would rationalize the shift of the molecular size distribution of oil products from catalytic runs toward the higher molecular size side (Fig. 2). The SRC, of course, contains a significant percentage of heteroatom-containing compounds (heteroatom content, Table 1); their adsorption and reactions on the catalyst surface would also take place and they may partly interfere with those of aromatic compounds.[9] As can be seen from Table 2, the most considerable decrease of oxygen content of oil from catalytic runs relative to that of noncatalytic run suggests that the major reactions of heteroatom-containing compounds that occurred during the upgrading process were hydrodeoxygenation reactions. It seems that hydrodeoxygenation is easier than hydrodenitrogenation.[10]

The combination of results regarding upgrading of the SRC (Fig. 1), the hydrocracking of pure hydrocarbons (Tables 3 and 4) and the analytical results of oil products from upgrading (Table 2, Fig. 2) strongly suggest that NiMo and S-NiMo catalysts promoted hydrogenation and cracking of polyaromatic substances present in heavy portions of the SRC and, thus, enhanced their conversion to oil and light distillates. Hydrogenation reactions, such as those shown in Tables 3 and 4, decreased the aromaticity (f_a, Table 2), and hydrocracking-derived alkyl aromatics contributed to the increase of substitution extent (σ) of oil products. These reactions were simultaneously accompanied by heteroatom removal, mainly hydrodeoxygenation reactions. However, as estimated from the H_{aru}/C_{ar} values shown in Table 2, the remaining aromatic compounds in oil products after the catalytic upgrading, have (on the average) similar ring sizes as those contained in oil from a noncatalytic run.

Synthesis of 2-Aryl[1,2,4]triazolo[1,5-*a*]pyrimidines

K. KAMALA, P. JAYAPRASAD RAO, and K. KONDAL REDDY*
Department of Chemistry, Osmania University, Hyderabad 500007, India
(Received November 13, 1987)

Synopsis. 2-(Aroylamino)pyrimidines (**4**) have been converted into 1-(2-pyrimidyl)-5-aryl-1*H*-tetrazoles (**6**) by treatment with PCl_5 followed by azidolysis in aqueous acetone solution. Pyrolysis of **6** in decalin gave 2-aryl[1,2,4]triazolo-[1,5-*a*]pyrimidines (**8**). A reasonable pathway for the formation of **8** from **6** is suggested. Structures of all the compounds have been established by elemental analysis and spectral data.

1-Aminopyrimidinium salt (**1**), obtained from 2-aminopyrimidine and *O*-(mesitylsulfonyl)hydroxylamine, on reaction with benzoyl chloride is known to give 2-phenyl[1,2,4]triazolo[1,5-*a*]pyrimidine[1] (**2**, mp 185—0.5 °C) in a very low yield (8%). In view of the synthetic utility of 1,5-disubstituted tetrazoles[2] and in continuation of our studies on thermal decomposition of 1-heteroaryl-5-aryl-1*H*-tetrazoles,[3-6] we report a convenient synthesis of 2-aryl[1,2,4]triazolo[1,5-*a*]-pyrimidines by the pyrolysis of 1-(2-pyrimidyl)-5-aryl-1*H*-tetrazoles.

Results and Discussion

Benzoylation of 2-aminopyrimidine (**3**, X=H) in the presence of pyridine gave 2-benzamidopyrimidine[7] (**4a**). Treatment of **4a** with PCl_5, followed by reaction with NaN_3 of the resulting *N*-(2-pyrimidyl)arenecarboximidoyl chloride (**5a**) without isolation, led to the formation of a colorless compound, **6a**, mp 95 °C. The compound was analyzed for $C_{11}H_8N_6$. In its mass spectrum the molecular ion was observed at *m/z* 224. Its IR spectrum revealed the absence of amide and azide functions. The presence of >C=N- in the compound was indicated by the appearance of a band at 1600 cm^{-1}. Its ^1H NMR spectrum ($CDCl_3$) revealed two peaks—a multiplet at δ 7.1—7.5 and a doublet at δ 8.6 in 3 : 1 ratio. The doublet is assignable to protons in 4 and 6 positions of the pyrimidine ring. On the basis of these data the compound **6a** has been assigned as 1-(2-pyrimidyl)-5-phenyl-1*H*-tetrazole (**6a**) structure.

A number of 2-(aroylamino)pyrimidines (**4b—l**, Table 1) obtained by the reaction of 2-amino-, 2-amino-5-chloro-, and 2-amino-5-bromopyrimidines[8] with benzoyl, *p*-toluoyl, *p*-anisoyl, *p*-chlorobenzoyl chlorides in the presence of pyridine were converted into 1-(2-pyrimidyl)-5-aryl-1*H*-tetrazoles (**6b—l**) on treatment with PCl_5 followed by azidolysis.

Heating a mixture of **6a** and finely ground pure sand at 180—190 °C and column chromatography of the reaction mixture gave a colorless crystalline compound, **8a**, mp 186 °C. On the basis of the elemental analysis and spectral data [IR(KBr): 1600 cm^{-1} (>C=N), no absorptions due to >C=O, >NH, and N_3 functions. ^1H NMR ($CDCl_3$) δ 7.3—7.75 (m, phenyl protons), δ 8.2—9.0 (m, pyrimidine protons) in 5 : 3 ratio and MS: M^+ at *m/z* 196], the compound **8a** has been assigned as 2-phenyl[1,2,4]triazolo[1,5-*a*]pyrimidine

6b* ^1H NMR ($CDCl_3$): δ 2.48 (s, 3H), 7.2—7.75 (m, 5H), 8.1 (d, 2H), M^+ at *m/z* 238.
8b** ^1H NMR ($CDCl_3$): δ 2.42 (s, 3H), 7.25—7.6 (m, 5H), 8.2 (d, 2H), M^+ at *m/z* 210.

(**8a**) structure. The yield of **8a** in this reaction was 25%. Pyrolysis of 1-(2-pyrimidyl)-5-phenyl-1*H*-tetrazole was also carried out in toluene, xylene, tetralin, and decalin. The tetrazole was recovered unchanged even after prolonged refluxing in toluene (bp 110 °C) or xylene (bp 140 °C). Refluxing the tetrazole in tetralin (bp 210 °C) for 3 h yielded **8a** in 35% yield. Decomposition of the tetrazole was complete by refluxing in decalin (bp 180 °C) for 3 h to give **8a** in 50% yield. Decomposition of other 1-(2-pyrimidyl)-5-aryl-1*H*-tetrazoles (**6b—l**) in decalin resulted in the formation of the corresponding **8b—l** (Table 1). The formation of **8**, in the pyrolysis of **6**, can be reasonably explained through stepwise elimination of a molecule of nitrogen from **6** and the cyclization of the resulting nitrene intermediate **7** in singlet state.[9]

Experimental

2-(Aroylamino)pyrimidines (4). General Procedure: To a solution of 2-aminopyrimidine in pyridine was added an equimolar amount of aroyl chloride with shaking. After the addition was complete, the reaction mixture was allowed to stand at room temperature for 2 h. The crude product that separated on dilution was filtered, washed with 10% sodium hydrogencarbonate solution, then several times with water. The dry solid was recrystallized from benzene-methanol to give pure **4** as summarized in Table 1.

1-(2-Pyrimidyl)-5-aryl-1*H*-tetrazoles (6). General Procedure: A mixture of **4** (5.00 mmol) and PCl_5 (1.3 g, 5.00 mmol) was heated at 100 °C for 1 h, when the evolution of fumes of HCl ceased. Excess of $POCl_3$ was removed under reduced pressure and the residual imidoyl chloride was treated with ice-cold sodium azide (0.37 g, 5.00 mmol) and excess of sodium acetate trihydrate in water (25 cm^3) and acetone (30 cm^3) with stirring. The stirring was continued overnight, acetone was removed under reduced pressure, and the remaining aqueous portion was extracted with chloroform. The dried chloroform extract was chromatographed over a column of neutral alumina, eluting with benzene to give pure **6** (Table 1).

Thermal Decomposition of 6. General Procedure: A solution of 1-(2-pyrimidyl)-5-aryl-1*H*-tetrazole (**6**, 2.50 mmol) in decalin (25 cm^3) was refluxed for 3 h. The decalin

was removed by distillation under reduced pressure. The residue was extracted with chloroform, the extract was concentrated and the residue was subjected to chromatography over a neutral alumina column, eluting with benzene-ethyl acetate (10:1) mixture to give pure **8** (Table 1).

One of the authors, K. Kamala, is thankful to CSIR, New Delhi, India for the award of SRF.

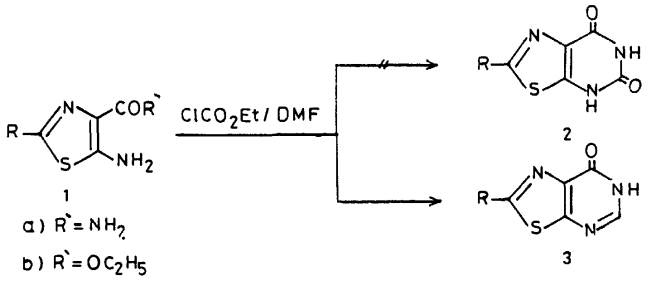
New Thiazolo[5,4-*d*]pyrimidines with Molluscicidal Properties

Khairy A. M. EL-BAYOUKI* and W. M. BASYOUNI
National Research Center, Dokki, Cairo, Egypt
(Received October 19, 1987)

Synopsis. Ethyl chloroformate/DMF mixture is used as a reagent for the facile ring closure of 5-amino-2-(ethylthio)-thiazole-4-carboxamide (**1a**) to afford an excellent yield of 2-ethylthiothiazolo[5,4-*d*]pyrimidin-7(6*H*)-one (**3**). The action of phosphoryl chloride on the latter product gave its 7-chloro derivative (**4**). The corresponding 7-(dicyanomethyl) (**5a**), 7-[cyano(ethoxycarbonyl)methyl] (**5b**), and 7-(substituted amino)derivatives (**6a—j**) are synthesized from reactions of malononitrile, ethyl cyanoacetate, and primary amines, respectively, with compound **4**. Most of the obtained products have been screened for activity against the intermediate host of schistosomiasis, *B. alexandrina* snails.

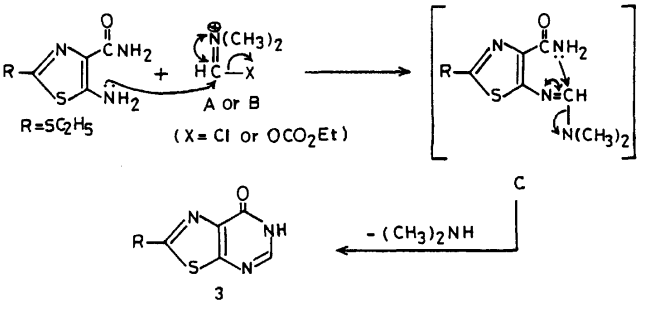
In connection with a program for preparing new purine and purine analogue derivatives with potentially useful biological properties,[1-3] the present paper reports the synthesis of some new thiazolo[5,4-*d*]pyrimidines and their molluscicidal effect.

Thus, when 5-amino-2-(ethylthio)thiazole-4-carboxamide (**1a**) was allowed to react with ethyl chloroformate/*N*,*N*-dimethylformamide (2 : 1), 2-(ethylthio)thiazolo[5,4-*d*]pyrimidin-7(6*H*)-one (**3**) was obtained in an excellent yield instead of the expected dione **2**. Compound **3** was found to be identical (mp and mixed mp) with the product obtained from the reaction of **1a** with triethyl orthoformate or from either **1a** or **1b** with formamide (2 h, 190 °C). Moreover, the ^{1}H NMR spectrum of **3** included a sharp signal at δ=8.24 representing H-5 of the thiazolopyrimidine nucleus,[4] and the mass spectrum of it observed M^+ 213 (100%). Such observations accord with structure **3** and exclude structure **2**.



A possible mechanism consistent with this result is shown in Scheme 1. It involves the formation of intermediate **A** or **B** in the reaction medium, either of which can attack (or be attacked by) the 5-amino nitrogen of the thiazole system **1a** to give the intermediate **C** which in turn can eliminate dimethylamine leaving a formate residue for incorporating as C5 of the thiazolo[5,4-*d*]pyrimidin-7(6*H*)-one (**3**). The reaction under investigation, presumably, proceeds via intermediate formation of a Vilsmeier-Haack reagent.[5]

The present work employs product of type **3** for the synthesis of new 7-substituted 2-(ethylthio)thiazolo[5,4-*d*]pyrimidines required for biological screening as antischistosomal agents. Accordingly, 7-chloro-2-



Scheme 1.

(ethylthio)thiazolo[5,4-*d*]pyrimidine (**4**) was prepared by the action of phosphoryl chloride on **3**. The chloro substituent of product **4** was easily replaced by the dicyanomethanide or the cyano(ethoxycarbonyl)methanide anion: reaction with malononitrile or ethyl cyanoacetate in DMSO and in presence of alkali gave the dinitrile **5a** and the nitrile ester **5b**,respectively. Treatment of **4** with primary amines in the presence of triethylamine likewise gave the corresponding 7-(substituted amino)-2-(ethylthio)thiazolo[5,4-*d*]pyrimidines (**6a—j**) in good yield.

6j	85—87 (ethanol)	69	$C_{12}H_{12}N_4OS_2$ (292)	49.30 (49.60)	4.10 (4.10)	19.20 (19.30)

irrigation canals that were not already treated with molluscicides.

Exposure and recovery periods are 24 h each. Standard procedures are followed throughout this study.[6,7] Control experiments for each case are carried out. These experiments showed mortality of 0%. The results are recorded in Table 1.

From Table 1 the following comments are pointed out:

1. Most of the tested compounds showed a 100% snails mortality at 100 as well as at 50 ppm dilution.

2. For compounds **4**, **5a**, **6e**, and **6j** a 50—100% snails mortality is attained at 25 ppm dilution.

3. Compounds **4** and **6j** reached, comparatively to the others, the highly active status at 12.5 ppm.

Moreover, the activity showed by products **4** and **6j** is found to be stable >12.5 ppm to pH changes "4—10", temperature changes "10—30 °C", sun radiations, and high mud concentration media (up to 10000 ppm mud).

So, incorporating a chloro or furfurylamino residue on C7 of the thiazolo[5,4-*d*]pyrimidine ring system bearing ethylthio moiety on position 2 is recommended for obtaining antischistosomal agents with a stable activity against *B. alexandrina* snails.

Experimental

Melting points are uncorrected.

2-(Ethylthio)thiazolo[5,4-*d*]pyrimidin-7(6*H*)-one (3). A) A mixture of **1a** (2 g) (prepared from 5-amino-2-mercaptothiazole-4-carboxamide[8] and ethyl iodide) and ethyl chloroformate (5 ml) in *N,N*-dimethylformamide (7 ml) was left overnight at 25 °C. The reaction mixture was then diluted with water and the obtained solid was filtered off, washed with water, dried and crystallized from ethanol to give **3** (2 g, 95%), mp 184—6 °C.

B) When the same reaction was repeated under reflux for 5—10 min, **3** (77%) was obtained.

C) A solution of **1a** (2 g) in formamide (15 ml) was heated in an oil bath (180—190 °C) for 1 h. The solid which separated on cooling, was filtered off, washed with water, dried and crystallized from ethanol to give **3** (68%), undepressed on admixture with the product above.

D) When **1b** (2 g) was allowed to react in formamide as described above, **3** (65%) was obtained. (Found: C, 39.8; H, 2.9; N, 19.7%. Calcd for $C_7H_7N_3OS_2$: C, 39.4 ; H, 3.3; N, 19.7%. IR (KBr), ν/cm^{-1}; 3300—2600 (NH and SC_2H_5), 1715 (CO-NH). UV (ethanol) λ_{max}/nm ($\varepsilon\times10^{-3}$); 325 (7.55), 311 (10.90), 270 (7.07), 223 (14.15), 214 (15.33). ^{1}H NMR (DMSO-d_6), δ=1.4 (s, t, 3H, CH_3), 3.38 (s, q, 2H, CH_2), 8.25 (s, s, 1H, C-5), 12.4 (b, s, 1H, NH). MS: *m/z* 213 (100%).

7-Chloro-2-(ethylthio)thiazolo[5,4-*d*]pyrimidine (4). A mixture of **3** (5 g) and phosphoryl chloride (30 ml) was heated in an oil bath at 120—25 °C for 1.5 h. After cooling, the reaction mixture was poured onto crushed ice. The solid was filtered off, washed with water several times, dried, then crystallized from ethanol to give **4** (4 g, 73.6%) mp 73—5 °C. Found: C, 36.1; H, 2.9; N, 17.8%. Calcd for $C_7H_6N_3S_2Cl$: C, 36.3; H, 2.6; N, 18.1%. UV (ethanol) λ_{max}/nm ($\varepsilon\times10^{-3}$); 300 (18.10), 295(18.63), 241(9.76), 229(13.54), 208—202(10.35). ^{1}H NMR ($CDCl_3$) δ=1.5 (s, t, CH_3), 3.4 (s, q, 2H, CH_2), 8.63 (s, s, 1H, C-5).

α-[2-(Ethylthio)thiazolo[5,4-*d*]pyrimidin-2-yl]malononitrile (5a). A mixture of **4** (2.3 g), malononitrile (0.73 g), and potassium hydroxide (0.5 g in 2 ml water) in dimethyl sulfoxide (15 ml) is heated on a steam-bath for 1 h. After cooling, the reaction mixture was diluted with water and then treated with cold dilute acetic acid solution. The solid was filtered off, washed with water, dried, then crystallized from ethanol to give **5a** (1.9 g, 73%) mp 258—60 °C. Found: C, 46.1; H, 2.8; N,26.4%. Calcd for $C_{10}H_7N_5S_2$: C, 46.0; H, 2.7; N, 26.8%. IR (KBr) ν/cm^{-1}, 2220, 2200 (CN). UV (ethanol) λ_{max}/nm ($\varepsilon\times10^{-3}$), 343 (24.34), 261(17.11), 231(14.54), 201 (13.72). ^{1}H NMR (DMSO-d_6) δ=1.45 (s, t, 3H, CH_3), 3.17 (s, q, 2H, CH_2), 8.3 (s, s, 1H, C-5). MS *m/z* 261(100%).

Ethyl α-Cyano-α-[2-(ethylthio)thiazolo[5,4-*d*]pyrimidin-2-yl]acetate (5b). To a solution of **4** (2.34 g) in dimethyl sulfoxide (15 ml) it was added ethyl cyanoacetate (1.24 g) and potassium hydroxide (0.5 g in 2 ml water) and the solution was heated on a steam-bath for 1 h. After cooling, the reaction mixture was treated with cold dilute acetic acid to give a solid which was filtered off, washed with water, dried, then crystallized from 1-butanol to give **5b** (2.1 g, 67.5%), mp

Theoretical Treatment of Solvent Effects on the Frequency Shifts of Fluorescence Spectra

Takehiro ABE
College of General Education, Tohoku University, Kawauchi, Sendai 980
(Received April 14, 1988)

A theoretical expression for the solvent fluorescence spectral shifts of a neutral solute molecule has been developed by following the same treatment as in Abe's expression for solvent absorption spectral shifts (*Bull. Chem. Soc. Jpn.*, **54**, 327 (1981); **58**, 3415 (1985)). Compared with all previous applicable expressions being applied to only polar solute molecules, the present expression has the advantage that it can be applied to not only the polar solute molecules but also nonpolar solute molecules. The polarizabilities of the ground and excited states concerning fluorescence are treated as being different from the corresponding values concerning absorption. Applications to nonpolar solute molecules are successfully presented.

Many theories have hitherto been proposed for solvent effects on the frequency shifts of fluorescence spectra.[1-10] All presented theoretical expressions are easily applicable except Liptay's.[4] Liptay's expression is so complicated that it is practically difficult to apply. Among the theoretical expressions, the first-appearing expression presented independently by Mataga et al.[1] and by Lippert[2] has been famous and frequently used. However, all these applicable expressions give no frequency shifts for nonpolar solute molecules having no dipole moments in both the ground and excited states, though some frequency shifts are, in fact, observed even for the nonpolar solute molecules in nonpolar solvents. In this case, the frequency shifts are obviously due to dispersion effects. Accordingly, the dispersion effects should be considered in the applicable theoretical expression for the solvent fluorescence frequency shift.

In this paper, therefore, an attempt has been made to present an expression for the solvent fluorescence spectral shift of a neutral solute molecule by explicitly considering the dispersion forces between the solute and solvent molecules on the basis of a previous theory[11] for the solvent absorption spectral frequency shift.

Theory

Fluorescence spectra of solutions are generally measured at very low concentrations of solutes. Let us, therefore, consider a system consisting of a spherical neutral solute molecule and N identical spherical neutral solvent molecules. The solvent molecules are assumed to form no hydrogen bonds or complexes with the solute and to have sufficiently small dipole moments so that they are not tightly oriented with respect to each other. In the fluorescence spectral measurements of solutes in solution, one usually chooses solvents that absorb light at much shorter wavelengths than the solutes do. One, therefore, assumes that the solvent molecules remain in their ground states when a transition from the ground state to the i-th excited state occurs in a solute molecule.

Then, one can write the ith electronic state of the system in the zeroth-order as

$$\Phi_i^\circ = \phi_i^A \prod_{s=1}^{N} \phi_0^s. \tag{1}$$

Here, the zeroth-order wave functions of ϕ_i^A and ϕ_0^s denote the i-th state of the solute and the ground state of the s-th solvent molecule, respectively. In the present paper, the suffices and shoulders of A and s denote the solute and the s-th solvent molecule, respectively. The energy of the i-th state of the system in which all the molecules interact with one another can be written by the second-order perturbation theory as

$$E_i = E_i^\circ + (\Phi_i^\circ|\boldsymbol{H}'|\Phi_i^\circ) + \sum_{m\neq i} \frac{(\Phi_m^\circ|\boldsymbol{H}'|\Phi_i^\circ)(\Phi_i^\circ|\boldsymbol{H}'|\Phi_m^\circ)}{E_i^\circ - E_m^\circ}, \tag{2}$$

where E_i° and E_m° are the unperturbed energies corresponding to Φ_i° and the m-th excited state, respectively, of the system, and $\boldsymbol{H}'$ is the perturbation due to interactions among the molecules in the system. The wave function and energy of the ground state of the system are obtained by replacing i by 0 in Eqs. 1 and 2, respectively.

From Ref. 11, one can write $\boldsymbol{H}'$ as

$$\boldsymbol{H}' = \boldsymbol{H}'_{As} + \boldsymbol{H}'_{st}, \tag{3}$$

where

$$\boldsymbol{H}'_{As} = \frac{1}{4\pi\varepsilon_0} \sum_{s=1}^{N} \boldsymbol{p}_A \cdot \boldsymbol{T}_{As} \cdot \boldsymbol{p}_s \tag{4}$$

and

$$\boldsymbol{H}'_{st} = \frac{1}{8\pi\varepsilon_0} \sum_{s=1}^{N} \sum_{t=1}^{N} \boldsymbol{p}_s \cdot \boldsymbol{T}_{st} \cdot \boldsymbol{p}_t. \tag{5}$$

Here, ε_0 is the permittivity of vacuum, $\boldsymbol{p}$ the operator of dipole moment, $\boldsymbol{T}_{As}$ the dipole-dipole interaction tensor of $R_{As}^{-3}(\boldsymbol{I}-3R_{As}^{-2}\boldsymbol{R}_{As}\boldsymbol{R}_{As})$, where $\boldsymbol{I}$ is a unit tensor, $\boldsymbol{R}_{As}$ the position vector from A to s, and t denotes the t-th solvent molecule.

When the wavenumbers of the fluorescence frequencies (cm^{-1}) of the solute molecule in vapor and in a solution are denoted by σ_{i0}° and σ_{i0}, respectively,

one obtains the following expression for the solvent fluorescence spectral frequency shift:

$$\sigma_{i0} - \sigma_{i0}^{\circ} = \frac{1}{hc}\{<E_i - E_i^{\circ}>_{av} - <E_0 - E_0^{\circ}>_{av}\}, \quad (6)$$

where c is the speed of light in vacuum, h Plank's constant, and $< >_{av}$ denotes the average over-all orientations of all the solvent molecules. In the calculation of $<E_i - E_i^{\circ}>_{av}$, terms containing powers higher than the sixth power of $1/R$ may always be neglected. Moreover, for convenience, common terms appearing in both $<E_i - E_i^{\circ}>_{av}$ and $<E_0 - E_0^{\circ}>_{av}$ may be omitted in a calculation of $<E_i - E_i^{\circ}>_{av}$.

Calculations of the terms of Eq. 6 will briefly be shown below. Using Eqs. 3—5, one can write:

$$(\Phi_i^{\circ}|\boldsymbol{H}'|\Phi_i^{\circ}) = \frac{1}{4\pi\varepsilon_0}\sum_{s=1}^{N}\boldsymbol{p}_{ii}^{A}\cdot\boldsymbol{T}_{As}\cdot\boldsymbol{p}_{00}^{s} + \frac{1}{8\pi\varepsilon_0}\sum_{s=1}^{N}\sum_{t=1}^{N}\boldsymbol{p}_{00}^{s}\cdot\boldsymbol{T}_{st}\cdot\boldsymbol{p}_{00}^{t}, \quad (7)$$

where $\boldsymbol{p}_{00}$ and $\boldsymbol{p}_{ii}$ are the ground and ith-excited state dipole moments, respectively. Accordingly, considering the Franck–Condon principle, one obtains:

$$\begin{aligned}
&<(\Phi_i^{\circ}|\boldsymbol{H}'|\Phi_i^{\circ})>_{av}\\
&=<(\Phi_i^{\circ}|\boldsymbol{H}'_{As}|\Phi_i^{\circ})\ \exp\{-(\Phi_i^{\circ}|\boldsymbol{H}'|\Phi_i^{\circ})/kT\}>_{av}\\
&+<(\Phi_i^{\circ}|\boldsymbol{H}'_{st}|\Phi_i^{\circ})\ \exp\{-(\Phi_i^{\circ}|\boldsymbol{H}'|\Phi_i^{\circ})/kT\}>_{av}\\
&\approx -\frac{1}{(4\pi\varepsilon_0)^2kT}\sum_{s=1}^{N}<(\boldsymbol{p}_{ii}^{A}\cdot\boldsymbol{T}_{As}\cdot\boldsymbol{p}_{00}^{s})(\boldsymbol{p}_{ii}^{A}\cdot\boldsymbol{T}_{As}\cdot\boldsymbol{p}_{00}^{s})>_{av}\\
&=-\frac{2(p_{00}^{s})^2(p_{ii}^{A})^2}{3(4\pi\varepsilon_0)^2kT}\sum_{s=1}^{N}\frac{1}{R_{As}^6}, \quad (8)
\end{aligned}$$

where k is Boltzmann's constant and T the thermodynamic temperature. In the same way, one obtains

$$\begin{aligned}
&<(\Phi_0^{\circ}|\boldsymbol{H}'|\Phi_0^{\circ})>_{av}\\
&=<(\Phi_0^{\circ}|\boldsymbol{H}'|\Phi_0^{\circ})\ \exp\{-(\Phi_i^{\circ}|\boldsymbol{H}'|\Phi_i^{\circ})/kT\}>_{av}\\
&\approx -\frac{2(p_{00}^{s})^2(\boldsymbol{p}_{00}^{A}\cdot\boldsymbol{p}_{ii}^{A})^2}{3(4\pi\varepsilon_0)^2kT}\sum_{s=1}^{N}\frac{1}{R_{As}^6}. \quad (9)
\end{aligned}$$

On the other hand, the calculation of the average value of the second term of Eq. 2 is quite the same as in the case of the absorption.[11] Thus, following the procedure given in Refs. 11 and 12, one finally obtains the following expression for the fluorescence frequency in solution:

$$\begin{aligned}
\sigma_{i0} = \sigma_{i0}^{\circ} &+ \frac{\pi}{hc}\left(\frac{4\pi L}{3}\right)^{2/3}\times\frac{(d^s/M_r^s)^{2/3}(p_{00}^{s})^2}{(r_A+r_s)^4}\\
&\times\left[\frac{2\{(\boldsymbol{p}_{00}^{A}\cdot\boldsymbol{p}_{ii}^{A})-(p_{ii}^{A})^2\}}{3(4\pi\varepsilon_0)^2kT}+\frac{(\alpha_{00,F}^{A}-\alpha_{ii,F}^{A})}{4\pi\varepsilon_0}\right]\\
&+\frac{\pi}{hc(4\pi\varepsilon_0)}\left(\frac{4\pi L}{3}\right)^{2/3}\times\frac{(d^s/M_r^s)^{2/3}\alpha_{00}^{s}}{(r_A+r_s)^4}\\
&\times[\{(p_{00}^{A})^2-(p_{ii}^{A})^2\}+\frac{3}{2}\\
&\times\frac{I_0^s\cdot I_0^A}{I_0^s+I_0^A}(\alpha_{00,F}^{A}-\alpha_{ii,F}^{A})], \quad (10)
\end{aligned}$$

where L is Avogadro's constant, M_r the relative molecular mass, d the density, α_{00} and α_{ii} are the electric isotropic polarizabilities of the ground and excited states, respectively, and r is the radius of a spherical molecule. The suffix F for $\alpha_{00,F}^{A}$ and $\alpha_{ii,F}^{A}$ means that these polarizabilities are not those concerning the absorption, but those concerning the fluorescence (for the reason mentioned below). In Eq. 10, the average transition energy for all transitions from the ground state or the i-th excited state to all other excited states is assumed to be equal to the ionization potential of the ground state (I_0), as shown in Ref. 12.

According to only Eq. 10, it is practically impossible to evaluate three values for p_{00}^{A}, p_{ii}^{A} and $(\alpha_{00,F}^{A}-\alpha_{ii,F}^{A})$ from data for the solvent fluorescence spectral shifts. In order to apply Eq. 10 for the fluorescence, therefore, the dipole moments of the ground and i-th excited states appearing in Eq. 10 must be assumed to be equal to the corresponding dipole moments concerning the absorption, as is usually assumed in all previous theories for fluorescence. This assumption will be approximately fulfilled, if the nuclear equilibrium configuration of the i-th excited state does not significantly differ from that of the ground state. Then, the dipole moments appearing in Eq. 10 must be estimated in advance from data for the solvent absorption spectral shifts according to an expression for the solvent absorption spectral shift. Of course, in the case of a nonpolar solute molecule, values for σ_{i0}° and $(\alpha_{00,F}^{A}-\alpha_{ii,F}^{A})$ can be estimated according to Eq. 10.

The isotropic polarizability of the i-th excited state of the solute molecule is written as $\alpha_{ii}^{A}=\{2/3(4\pi\varepsilon_0)\}\times\sum_{j\neq i}|\boldsymbol{\mu}_{ij}^{A}|^2/(E_j^{A}-E_i^{A})$, where $\boldsymbol{\mu}_{ij}^{A}$ is the transition dipole moment from the i-th state to the j-th excited state. Here, we will discuss whether or not the ground- and excited-state polarizabilities concerning the fluorescence are equal to the corresponding values concerning the absorption.

First, for the present purpose we consider the value of $\boldsymbol{\mu}_{ij}^{A}$ according to the conventional treatment of Orlandi and Siebrand[13] for the Herzberg-Teller coupling mechanism as follows. Here, the vibronic state involved in the transition of the solute molecule is written as

$$\psi_{iv}(q,Q) = \phi_i(q,Q)\chi_v^{(i)}(Q), \quad (11)$$

where q and Q denote the sets of electronic and nuclear coordinates, respectively, so that i is an electronic quantum number and v a vibrational one. Then, according to Orlandi and Siebrand,[13] the transition dipole moment from $\psi_{iv}(q,Q)$ to $\psi_{jw}(q,Q)$ (where j and w are the electronic and vibrational

quantum numbers, respectively) is approximately given by

$$\begin{aligned}\mu_{ij,vw} &= \langle \chi_v^{(i)} | P_{ij}(Q) | \chi_w^{(j)} \rangle \\ &\approx P_{ij}(Q_0) \langle \chi_v^{(i)} | \chi_w^{(j)} \rangle \\ &+ \sum_k [\sum_l (\langle \phi_j | P | \phi_l \rangle \langle \phi_l | \partial / \partial Q_k | \phi_i \rangle)_{Q_0} \\ &\times (\hbar / 2\mu_k \omega_k)^{1/2}] \times \langle \chi_{w'}^{(j)} | \chi_v^{(i)} \rangle, \end{aligned} \quad (12)$$

where

$$P_{ij}(Q) = \langle \phi_i | P | \phi_j \rangle; \; P = \sum_\mu e r_\mu, \quad (13)$$

r_μ being the position vector of the μ-th electron in the solute molecule, μ_k and ω_k denoting the reduced mass and angular frequency of induced mode k, respectively, and w' denoting the ω value in which mode k is excluded. Moreover, Q_0 is a nuclear equilibrium configuration, about which $P_{ij}(Q)$ is expanded. In the case of the absorption, Q_0 should be a nuclear equilibrium configuration of the ground state and in the case of fluorescence, Q_0 should be an equilibrium configuration of the i-th excited state.

Equation 12 shows that the value of μ_{ij} varies with both the nuclear equilibrium configuration and the vibrational quantum number v in the i-th state, even if $P_{ij}(Q_0)=0$ for forbidden electronic transitions. Accordingly, the value of $|\mu_{ij}^A|^2$ involved in the expression for the polarizability will vary with the equilibrium configuration and the vibrational quantum number v. Moreover, the polarizability of the i-th state will vary with the vibrational quantum number v through the change of the value of $1/(E_j^A - E_i^A)$ with v, because the E_i^A value varies with v. After all, the polarizability of the i-th state will vary with its equilibrium configuration and vibrational quantum number. In the same i-th electronic state, both the vibrational quantum number and equilibrium configuration of the vibronic state concerning the fluorescence may differ from the corresponding values of the vibronic state concerning absorption. These differences between the two vibronic states will cause differences between the polarizabilities of the vibronic states. Thus, the polarizabilities of the ground and i-th excited states concerning fluorescence will differ from the corresponding values concerning absorption. For this reason, the polarizabilities concerning fluorescence are clearly denoted by the subscript F in Eq. 10.

The transition energies (in cm^{-1}) of the solute molecule from the ground state to the i-th excited state in vapor and in a solution are denoted by σ_{0i}° and σ_{0i}, respectively. The polarizabilities of the ground and i-th excited states concerning absorption are denoted by $\alpha_{00,A}^A$ and $\alpha_{ii,A}^A$, respectively. For a nonpolar solute molecule having no dipole moments in both the ground and excited states, values for σ_{0i}° and $\alpha_{ii,A}^A$ can be obtained from data for the solvent absorption spectral shifts according to Ref. 12. By applying Eq. 10 to data for the solvent fluorescence spectral shifts of a nonpolar molecule, values for σ_{i0}° and $(\alpha_{00,F}^A - \alpha_{ii,F}^A)$ can be obtained by the least-squares method. On the other hand, for a polar solute molecule, values for p_{ii}^A and $\alpha_{ii,A}^A$ ought to be obtained in advance (according to Ref. 12) on the condition that the σ_{0i}° value is known. Then, by using the p_{ii}^A value, values for σ_{i0}° and $(\alpha_{00,F}^A - \alpha_{ii,F}^A)$ can be obtained by means of a least-squares analysis of data for the solvent fluorescence spectral shifts, according to Eq. 10.

Applications

Equation 10 improves on a weak point of all the previous expressions which can not be applied to nonpolar solute molecules. In this paper, therefore, examples of the applications of Eq. 10 to only nonpolar solute molecules of anthracene, *all-trans*-1,3,5,7-octatetraene and pyrazine will been shown below, although Eq. 10 was also successfully applied to some polar solute molecules.

In applying Eq. 10, as well as the expression for the absorption in Ref. 12, to nonpolar solute molecules, the temperature was always assumed to be 20 °C. All values used for $\alpha_{00,A}^A$ and α_{00}^s were calculated from values for molar refraction, which were obtained by summing up bond refractions. The calculations of r_A and r_s were made in the same way as in Ref. 12. The gas-phase dipole moments of solvent molecules and the ionization potentials of all the solute and solvent molecules, except octatetraene, were taken from the usual chemical handbooks. Only the ionization potential of the ground state of an octatetraene molecule having four conjugated double bonds was estimated to be 8.22 eV (1 eV=1.602×10^{-19} J) in the same way as in the case of a lycopene molecule,[12] since no observed ionization potential value for the molecule was found. The author excluded data for solvents lacking information regarding their ground-state dipole moments and ionization potentials and for solvents which are capable of forming hydrogen bonds and complexes with solutes.

According to the procedure described above, the expression for the absorption in Ref. 12 and Eq. 10 were applied to data for the solvent absorption- and fluorescence-spectral shifts, respectively, of anthracene,[14] *all-trans*-1,3,5,7-octatetraene[15] and pyrazine.[6] Values estimated for σ_{0i}°, σ_{i0}°, $(\alpha_{ii,A}^A - \alpha_{00,A}^A)$ and $(\alpha_{ii,F}^A - \alpha_{00,F}^A)$ are listed in Table 1. By using these values, values for σ_{0i} and σ_{i0} were calculated and compared with the corresponding observed values, as shown in Fig. 1. This figure shows that the correlation between the observed and calculated values of σ_{0i} and σ_{i0} is good.

Table 1 shows that the present values for σ_{0i}° and σ_{i0}° roughly approach the corresponding observed values. As shown in Table 1, the estimated value of $(\alpha_{ii,A}^A - \alpha_{00,A}^A)$ for anthracene agrees well with the observed values measured by electric field tech-

Table 1. Differences in Polarizabilities between the Ground- and Excited-States of Nonpolar Molecules

	Anthracene	*trans*-1,3,5,7-Octatetraene	Pyrazine
$\sigma^{\circ}_{0i}/cm^{-1}$	27470	34785	31460
(Obsd)	(27560)[a]	(35523)[b]	(30870)[c]
$(\alpha^{A}_{ii,A}-\alpha^{A}_{00,A})/10^{-24}$ cm^3	18.5	36.71	−2.35
(Obsd)	(16.7±2.3)[d]		
$\sigma^{\circ}_{i0}/cm^{-1}$	27580	25666	29280

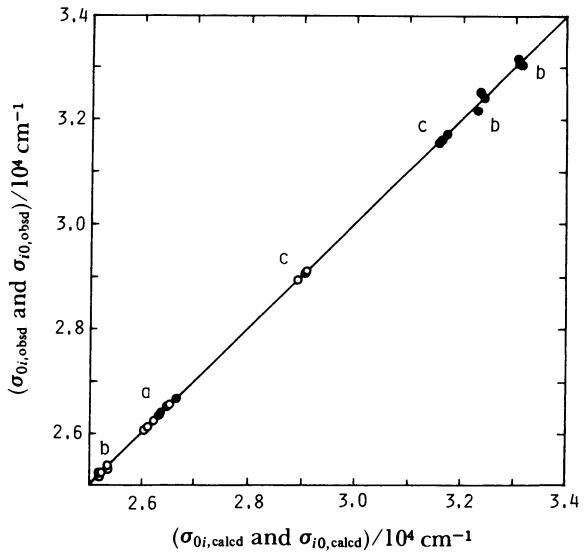

Fig. 1. Correlation between the observed and calculated values of σ_{0i} (●) and σ_{i0} (○), for anthracene (a), *all-trans*-1,3,5,7-octatetraene (b) and pyrazine (c).

niques.[17,18] The present result of $\alpha^{A}_{00,A}>\alpha^{A}_{ii,A}$ for pyrazine is probably due to the great contribution of the $|\mu_{i0}|^2/(E^{A}_{0}-E^{A}_{i})$ term to the $\alpha^{A}_{ii,A}$ value, since $(E^{A}_{0}-E^{A}_{i})<0$ in this case. Table 1 shows that the values for $(\alpha^{A}_{ii,F}-\alpha^{A}_{00,F})$ are considerably different from the corresponding values for $(\alpha^{A}_{ii,A}-\alpha^{A}_{00,A})$. This means that the ground- and excited-state polarizabilities concerning fluorescence are considerably different from the corresponding values concerning absorption. In the case of octatetraene, the absorption band is the 0–0 band. Therefore, the estimated value (51.51×10^{-24} cm^3) for $\alpha^{A}_{ii,A}$ is equal to $\alpha^{A}_{ii,F}$. In this case, therefore, the value for $\alpha^{A}_{00,F}$ can be estimated to be 44.61×10^{-24} cm^3, which is much greater than the $\alpha^{A}_{00,A}$ value (14.80×10^{-24} cm^3).

Classification of DNA Sequences by Hayashi's Quantification (III) Method. Sequences Involving 5′-Splice Signals in Pre-mRNA of Higher Eukaryotes' Genes

Yôichi IIDA
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060
(Received April 15, 1988)

Concerning the signals which direct the excision of introns from mRNA precursors in higher eukaryotes' genes, a consensus sequence, $\overset{C}{\underset{A}{}}AG/GT\overset{}{\underset{}{G}}$AGT, has been proposed with a 5′-splice site, but actual 5′-splice site sequences differ from it to a greater or lesser degree. In the present paper, we took a set of 1751 sequences, which are composed of 9-nucleotide sequences including 5′-splice signals and of other sequences including no such signals. Hayashi's quantification analysis (Class III) was applied to such a system. Assuming no external criterion for 5′-splice signals, we examined how the 1751 sequences show responses to the positions and species of nucleotides. The optimum classification led to a fair separation of the 5′-splice signal sequences from sequences including no such signals. The results were compared with those derived previously by the use of the quantification (Class II) method.

Many eukaryotic genes are interrupted by introns, which have been removed from the mRNA precursors (pre-mRNAs) by the use of the RNA splicing mechanism. It became clear that the splicing pathway could be divided into two stages. In the first stage, the pre-mRNA is cleaved at the 5′-splice site of the intron, generating the first exon and a species composed of the intron and the following exon. The latter intermediate is present in a lariat form, where the 5′-end of the intron is joind by a 2′–5′ phosphodiester linkage to an A residue upstream of the 3′-splice junction. The sequence encompassing the A residue is called "the branch-point sequence". The second stage involves cleavage at the 3′-splice site and ligation of the exons, with a concomitant release of the intron lariat. Both stages are related to several reactions which occur in a large multicomponent complex termed a "spliceosome". Small nuclear ribonucleoprotein particles (snRNPs) including U1, U2, U4—6 are important components of the spliceosome (for reviews, see Refs. 1—3).

Nucleotide sequences defining 5′- and 3′-splice junctions in pre-mRNAs have been found to share considerable homology in higher eukaryotes.[4] In the case of 5′-splice sites, a consensus sequence, 5′-(exon)-$\overset{C}{\underset{A}{}}AG/GT\overset{}{\underset{}{G}}$AGT-(intron)-3′, has been known, where the stroke (/) indicates the boundary between exon and intron. However, this is only a qualitative description of the splice signal. The consensus sequence cannot tell what degree of matching between the observed sequence and the consensus sequence is necessary to specify the exact splice site. Another major problem involves the relative importance of each of the nucleotides in the sequence. That is, mutational studies have demonstrated that the importance of nucleotide matching to the consensus sequence differs from position to position. For example, a few positions, such as the G at the 5′- end of intron, are absolutely necessary, while mutations in the other positions, though they reduce the efficiency of correct splicing, sometimes do not affect correct splicing seriously.[5,6] In order to study such splice signals more quantitatively and to ascertain the relative importance of each of the nucleotides, we previously studied multivariate statistical analysis and then performed Hayashi's quantification analysis (Class II).[7,8] For this purpose, we took 1751 samples of the 9-nucleotide sequences belonging to either of two groups. Group 1 is composed of sequences including 5′-splice signals, while sequences of Group 2 include no such signals. In the Class II analysis, using external criterion for the 5′-splice signals, we searched for the optimum condition under which sequences of the two groups could be discriminated most distinctly; we also determined the optimum weights for the position and species of nucleotides.

In the present paper, we utilizes another approach of Hayashi's quantification analysis (Class III)[9,10] to the same set of 1751 sequences. In contrast to the Class II method, the Class III method distributes the total of 1751 sequences most distinctly and determines the optimum weights for the position and species of nucleotides, assuming an absence of external criterion as to whether a sequence may belong to the 5′-splice sequence or not. It was found that the classification by this technique could well separate the sequences of Group 1 from those of Group 2. This approach enables us, to a considerable extent, to characterize 5′-splice site sequences in terms of position and species of nucleotides, even if there is no external criterion for 5′-splice signals.

Analysis by Quantification (III) Method

The nucleotide sequence data used in the present paper are the same as those used by quantification (Class II) in a previous paper.[7] In Table 1, some of the 9-nucleotide sequences are reproduced. Here, sequences belonging to Group 1 include 5′-splice signals, where nine nucleotides (composed of three at the 3′-end of the exon and six at the 5′-end of the intron) are

truncated in each sequence. In the group, we summarized 155 sequences (i_1=1, 2, ···, 155), which were taken from authentic 5′-splice site sequences in various mammalian genes containing introns: globin genes, insulin genes, etc.[11] On the other hand, Group 2 is composed of sequences other than the 5′-splice site. Those sequences were taken from the human β-globin gene, as was described in the previous paper.[7] Excluding the two sequences of the authentic 5′-splice sites in the β-globin, we gave 1596 sequences (i_1=156, 157, ···, 1751) composed of 9-nucleotides in Group 2. Therefore, a total of N_1=1751 sample sequences (i_1=1, 2, ···, N_1) are summarized in Table 1.

In constrast to the Class II analysis, the Class III method does not use the criterion of Groups 1 and 2, but examines how uniquely the 1751 sequences respond to items and categories.[9,10] This method is similar to the dual scaling approach of Maung and Guttman.[12,13] In our case, there are nine items, identified k=1, 2, ···, 9. They correspond to the positions of nucleotides in the 9-nucleotide sequence, being defined in terms of their order from the 5′ to 3′ ends of the sequence. On the other hand, the category denotes the kind of nucleotide, where A, G, C, or T is specified by α=1, 2, 3, or 4 respectively at every item.

Table 1. Some of the 9-Nucleotide Sequences Belonging to Group 1 and Group 2[a]

No.	Group	Sequence	Gene

156	2	ACATTTGCT	Human beta-Globin
157	2	CATTTGCTT	
:	:	:	
1751	2	TTTCATTGC	

a) Group 1 is composed of 5′-splice site sequences, while Group 2 is composed of sequences other than 5′-splice sites. For further details, see text.

We introduce a running suffix $i_2=4(k-1)+\alpha$, (i_2=1, 2, ···, N_2; N_2=36), and transform the sequence data of Table 1 into the item-category data by using a dummy variable, $n(i_1, i_2)$. It takes a value of 1 if the sample sequence (i_1) has a nucleotide (α) at the position (k), but otherwise it takes 0. Such item-category data are shown in Table 2.

The Class III method rearranges sample sequences and item-categories in such a way that sample sequences showing similar responses to items and categories are gathered together. If we obtain the optimum condition for this, we can find what responses to items and categories are similar to each other. Moreover, we can classify not only items and categories, but also sample sequences in the most characteristic way. For this purpose, let us give the quantity $x(i_1)$ to the i_1-th sample sequence (i_1=1, 2, ···, N_1) and a quantity $y(i_2)$ to the i_2-th item-category ($i_2=4(k-1)+\alpha$; i_2=1, 2, ···, N_2). Then we introduce the correlation coefficient, $r(X, Y)$, by the use of

$$r(X,Y) = V(X,Y)/\{S(X)S(Y)\}, \tag{1}$$

$$V(X,Y) = (1/N)\sum_{i_1=1}^{N_1}\sum_{i_2=1}^{N_2} x(i_1)y(i_2)n(i_1,i_2) - \bar{x}\bar{y}, \tag{2}$$

$$S(X) = \{(1/N)\sum_{i_1=1}^{N_1} x(i_1)^2 n_1(i_1) - (\bar{x})^2\}^{1/2}, \tag{3}$$

$$S(Y) = \{(1/N)\sum_{i_2=1}^{N_2} y(i_2)^2 n_2(i_2) - (\bar{y})^2\}^{1/2}, \tag{4}$$

where;

$$N = \sum_{i_1=1}^{N_1}\sum_{i_2=1}^{N_2} n(i_1,i_2), \tag{5}$$

$$\bar{x} = (1/N)\sum_{i_1=1}^{N_1} x(i_1)n_1(i_1), \tag{6}$$

$$\bar{y} = (1/N)\sum_{i_2=1}^{N_2} y(i_2)n_2(i_2), \tag{7}$$

$$n_1(i_1) = \sum_{i_2=1}^{N_2} n(i_1,i_2), \tag{8}$$

$$n_2(i_2) = \sum_{i_1=1}^{N_1} n(i_1,i_2). \tag{9}$$

In order to classify sample sequences together with items and categories most distinctly, we maximize $|r(X, Y)|$. That is, if the correlation coefficient

Table 2. Categorical Data to be Used in Hayashi's Quantification Analysis (Class III)[a]

No.	Group	Item 1				Item 2				···	Item 9			
		Category				Category					Category			
		1	2	3	4	1	2	3	4		1	2	3	4
1	1	0	1	0	0	1	0	0	0	···	0	1	0	0
2	1	1	0	0	0	1	0	0	0	···	0	0	1	0
:	:			:				:					:	
155	1	1	0	0	0	0	1	0	0	···	0	0	1	0
156	2	1	0	0	0	0	0	1	0	···	0	0	0	1
:	:			:				:					:	
1751	2	0	0	0	1	0	0	0	1	···	0	0	1	0

a) For the 9-nucleotide sequences given in Table 1, the position of nucleotide (item) and the kind of nucleotide (category) are specified with a dummy variable (0 or 1). In the Class III analysis, the item number (k) and the category number (α), where k=1, 2, ···, 9 and α=1, 2, 3, 4, are further combined into a parameter: $i_2=4(k-1)+\alpha$, where i_2=1, 2, ···, 36. For further details, see text.

approaches 1, the arrangements of $n(i_1, i_2)=1$ versus i_1 and i_2 become linear. In this case, the (i_1) sequence may be well characterized by the item-category (i_2). The maximization of $|r(X, Y)|$ can be done by differentiating:

$$\partial r(X, Y)^2/\partial x(i_1) = 0, \quad (i_1 = 1, 2, \cdots, N_1), \tag{10}$$
$$\partial r(X, Y)^2/\partial y(i_2) = 0, \quad (i_2 = 1, 2, \cdots, N_2), \tag{11}$$

where we can put $\bar{x}=0$ and $\bar{y}=0$ without loss of generality. These equations lead to:

$$\sum_{i_2'=1}^{N_2}\sum_{i=1}^{N_1} n(i, i_2)n(i, i_2')y(i_2')/n_1(i) = r(X, Y)^2 n_2(i_2)y(i_2), \quad (i_2 = 1, 2, \cdots, N_2), \tag{12}$$

$$x(i_1) = \{1/r(X, Y)\}\sum_{j=1}^{N_2} n(i_1, j)y(j)/n_2(j), \quad (i_1 = 1, 2, \cdots, N_1). \tag{13}$$

Eq. 12 can be solved by eigen value problem with the aid of computer calculation. It has the maximum eigen value of 1. However, this value is a trivial solution and is excluded, because it gives an inadequate value of $\bar{y}=(1/N)\sum_{i_2=1}^{N_2} y(i_2)n_2(i_2)\neq 0$. Therefore, we take the second largest eigen value of $r(X, Y)^2$. This value, together with Eq. 12, leads to the eigen vector of $\boldsymbol{y}_2=\{y(12), \cdots, y(i_2 2), \cdots, y(N_2 2)\}^t$, where the suffix 2 corresponds to the second largest eigen value and where the superscript t indicates the transposition of the vector. From $\boldsymbol{y}_2$ together with Eq. 13, we can obtain the eigen vector of $\boldsymbol{x}_2=\{x(12), \cdots, x(i_1 2), \cdots, x(N_1 2)\}^t$. If we arrange the components of $\boldsymbol{x}_2$ and $\boldsymbol{y}_2$ in the order of their magnitudes, we can classify not only items and categories, but also sample sequences most distinctly.

In a similar way, if we obtain the third and fourth largest eigen values of Eq. 12, we can calculate the corresponding eigen vectors: $\boldsymbol{y}_3$, $\boldsymbol{y}_4$, and $\boldsymbol{x}_3$, $\boldsymbol{x}_4$. If a sample sequence i_1, $(i_1=1, 2, \cdots, N_1)$, is plotted by the use of the coordinate of $\{x(i_1 2), x(i_1 3)\}$, we can map sample sequences on a two-dimensional graph most distinctly. It is also possible to distribute the items and categories i_2, $(i_2=1, 2, \cdots, N_2)$, in the most characteristic way by plotting $\{y(i_2 2), y(i_2 3)\}$.

Results and Discussion

For the item-category data of Table 2, the second, third, and fourth largest eigen values of $r(X, Y)^2$ were calculated as 0.2155, 0.1571, and 0.1511 respectively. From Eq. 12, we estimated the components of $\boldsymbol{y}_2$, $\boldsymbol{y}_3$ and $\boldsymbol{y}_4$ (normalized item-category scores), where the variance of the components was normalized to unity. In view of the magnitudes of $r(X, Y)^2$, the vector of $\boldsymbol{y}_2$ distinguishes item-categories and sample sequences most strongly, while the vectors of $\boldsymbol{y}_3$ and $\boldsymbol{y}_4$ have less distinguishing power. The degree of distinction by $\boldsymbol{y}_3$ is almost the same as that by $\boldsymbol{y}_4$. Such normalized scores are summarized for item (k) and category (α), where $i_2=4(k-1)+\alpha$, $(i_2=1, 2, \cdots, 36)$. For example, we give in Fig. 1 a graph of normalized item-category scores obtained by plotting $\{y(i_2 2), y(i_2 3)\}$ with $i_2=1, 2, \cdots, 36$. This graph corresponds to the second and third largest eight values and shows the most distinct distribution among item-categories, where some form a cluster. For item-categories $(k-\alpha)$, (4–2), (3–2), (8–2), (7–1), (2–1), (6–2), (5–4), (6–1), (1–1), and (1–3) form a cluster and show relatively high scores in the direction of the second largest eigen value. These item-categories come from G at the fourth position, G at the third position, G at the eighth position, A at the seventh position, A at the second position, G at the sixth position, T at the fifth position, A at the sixth position, A at the first position, and C at the first position respectively in the 9-nucleotide sequence of Table 1. These nucleotides and positions coincide well with the consensus sequence $\overset{C}{A}AG/GT\overset{A}{G}AGT$ proposed by Mount,[4] possessing a strong power to distinguish the 5′-splice site sequence. From the magnitudes of the $y(i_2 2)$ values, G at the fourth position seems to be most effective. This result may correspond to the invariant G nucleotide at the 5′-end of every intron. As is shown in Fig. 1, the item-categories other than those due to the consensus

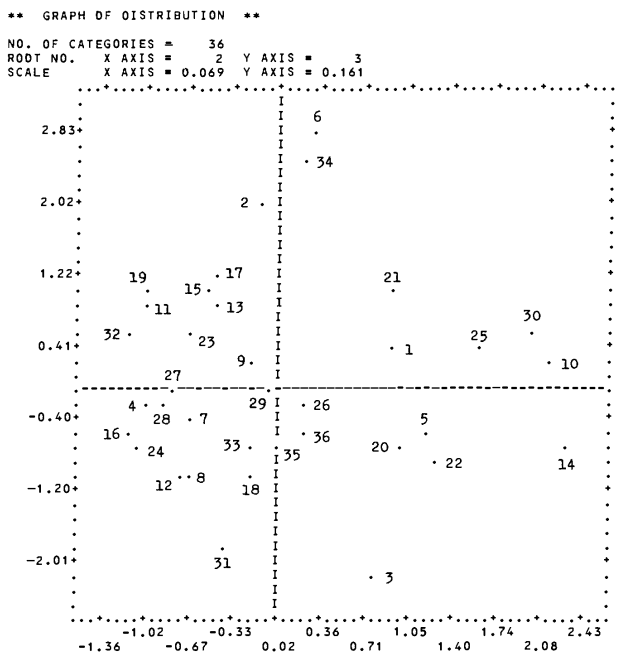

Fig. 1. Two-dimensional mapping of item-categories in Hayashi's quantification analysis (Class III) of 1751 members of 9-nucleotide sequences given in Tables 1 and 2. Abscissa shows normalized score of $y(i_2 2)$, which is calculated from the second largest eigen value of Eq. 12. Ordinate shows normalized score of $y(i_2 3)$ calculated from the third largest eigen value. Parameter i_2, $(i_2=1, 2, \cdots, 36)$, is related to item (k) and category (α) by $i_2=4(k-1)+\alpha$. Note that points of $i_2=1, 3, 5, 10, 14, 20, 21, 22, 25$, and 30 form a cluster. For further details, see text.

sequence form another cluster. Althogh some of them are located around the positive region of $y(i_2 2)$, most of the item-categories other than the consensus sequence lie in the negative region of $y(i_2 2)$. It appears that they make negative contribution to 5′-splice site signals.

Next let us examine how uniquely the 1751 sequences respond to the positions and species of nucleotides. For this purpose, we will calculate the sample scores of $x(i_1 2)$, $x(i_1 3)$ and $x(i_1 4)$, (i_1=1, 2, ···, N_1). As was mentioned above, the sample score of $x(i_1 2)$ can classify the 1751 sequences most distinctly. Therefore, we first arranged their $x(i_1 2)$ values in the order of their magnitudes, as is shown in Fig. 2. Here, we categorized the sample scores at appropriate equal intervals, and constructed a graph of the distribution and the frequency percentage versus the categorized sample score ($z=x(i_1 2)$) for the 1751 members of the 9-nucleotide sequences shown in Table 1. For the sake of comparison, the lower half of the graph illustrates a histogram of the sequences belonging to Group 1 (155 members of the 5′-splice site sequences), while the upper half illustrates those belonging to Group 2 (1596 members of sequences other than the 5′-splice sites). As has already been mentioned, the present Class III approach assumes no external criterion as to whether or not a sequence may belong to the 5′-splice site sequence. However, Fig. 2 clearly shows that the Class III approach can discriminate, to considerable extent, sequences of Group 1 from those of Group 2. In order to estimate the rate of discrimination in terms of the sample score z, we note the overlapping of the distribution curve of Group 1, $f_1(z)$, and that of Group 2, $f_2(z)$, around z=0.55. The optimum discrimination rate, P, at the critical sample score, z^*, may be determined by using this relation:

$$P=\int_{-\infty}^{z^*} f_2(z)dz=\int_{z^*}^{\infty} f_1(z)dz=1-\int_{-\infty}^{z^*} f_1(z)dz. \quad (14)$$

Here, the values for $\int_{-\infty}^{z^*} f_1(z)dz$ and $\int_{-\infty}^{z^*} f_2(z)dz$ can be obtained by estimating the cumulative frequency percentage curves for the distributions of sample scores in Groups 1 and 2 respectively. If we then plot $\int_{-\infty}^{z} f_2(z)dz$ and $1-\int_{-\infty}^{z} f_1(z)dz$ versus z, the intersect of their curves will give the values for z^* and P. In this way, z^*=0.572 and P=96.8% were estimated from the cases given in Fig. 2. This result implies that any sequence with a sample score of $z>0.572$ may be classified into Group 1 with a 96.8% probability, while a sequence with a sample score of $z<0.572$ may be placed in Group 2 with a 96.8% probability.

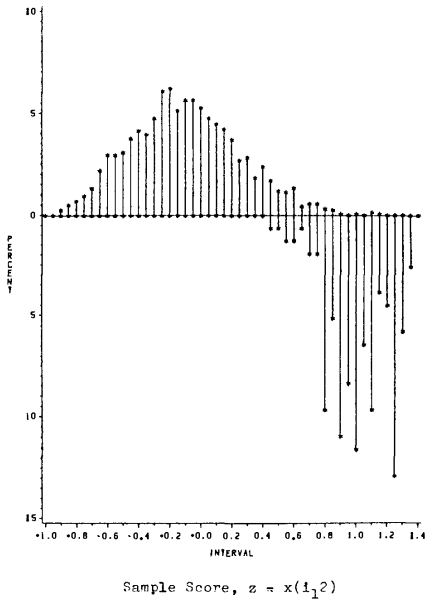

Fig. 2. Graph of distribution and frequency percentage versus categorized sample score ($z=x(i_1 2)$) for 1751 members of 9-nucleotide sequences shown in Table 1. Values of $x(i_1 2)$, (i_1=1, 2, ···, 1751), are calculated from the second largest eigen value of Eqs. 12 and 13. For purposes of comparison, the lower half of the graph shows a histogram of the sequences belonging to Group 1 (155 members of 5′-splice site sequences in Table 1), while the upper half, those belonging to Group 2 (1596 members of sequences other than 5′-splice sites). For further details, see text.

Let us compare the discrimination rate of the present Class III analysis with that of the Class II analysis reported previously.[7] The Class II analysis used an external criterion for Group 1 (5′-splice site sequences) and Group 2 (sequences other than 5′-splice sites), and discriminated the two groups most distinctly by maximizing the σ_B^2/σ^2 value, where σ^2 is the variance of the total samples and σ_B^2, the variance between Groups 1 and 2. Then, the optimum discrimination rate, P, was estimated to be as high as 98.2%. It is reasonable that this value is larger than the 96.8% value of the present Class III analysis. However, it is important to note that, even without any external criterion, Groups 1 and 2 can be discriminated as much as 96.8%. This implies that the sequences belonging to Group 1 show unique responses to the positions and species of nucleotides and that the 5′-splice signal may be composed of a particular pattern of nucleotide sequences.

In order to examine this situation more extensively, we map 1751 sequences on a two-dimensional graph by plotting the coordinates of $\{x(i_1 2), x(i_1 3)\}$, (i_1=1, 2, ···, N_1); as is shown in Fig. 3. Here, any sequence is represented by a dot (·), but multiple overlapping of dots is given by signs (*, +, etc.) (see the captions of Fig. 3). It is found that the 1751 sequences may be roughly classified into two clusters on the two-dimensional map. The first cluster lies around the origin of the coordinate: most of the members of this cluster belong to Group 2 (sequences other than 5′-splice sites). Those members are distributed almost symmetrically around the point of origin, indicating that their sequences exhibit no particular (random)

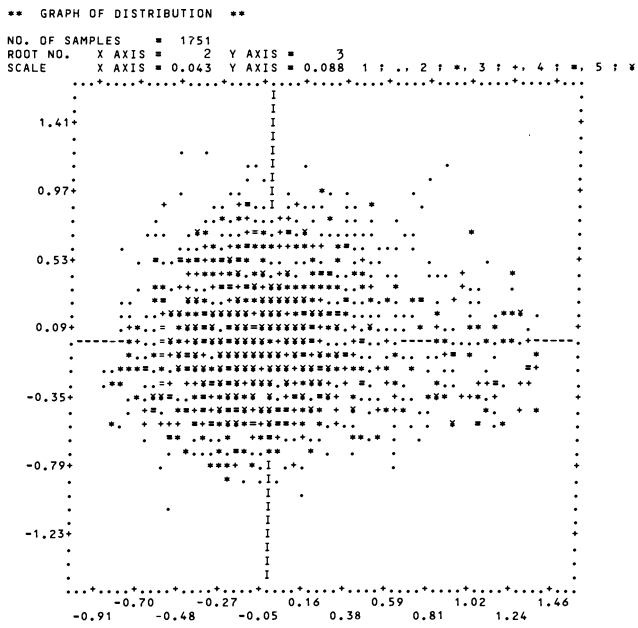

Fig. 3. Two-dimensional mapping of 1751 members of 9-nucleotide sequences (i_1=1, 2, ···, 1751) in Hayashi's quantification analysis (class III). Abscissa shows value of $x(i_12)$, which is calculated from the second largest eigen value of Eqs. 12 and 13. Ordinate shows value of $x(i_13)$ calculated from the third largest eigen value. Each sample sequence is given by a dot (·), but multiple overlapping of dots is indicated by signs (*, +, etc.). For example, the sign (*) shows double overlapping of dots. For further details, see text.

responses to the positions and species of nucleotides. On the other hand, the second cluster is out of the first cluster, deviating remarkably from the point of origin and lying around the positive region of $x(i_12)$=0.55—1.50. Most of the members of the second cluster belong to Group 1, as has been described previously. The distribution of those members versus the $x(i_13)$ axis is almost symmetrical, suggesting that the $x(i_13)$ value has no appreciable power to separate Group 1 (5′-splice site sequences) from Group 2. These observations are in good accordance with our previous calculation, where $x(i_13)$ comes from the third largest eigen value of Eq. 12 and has a lesser correlation coefficient than has $x(i_12)$. Even in the two-dimensional mapping of the 1751 sequences, the two clusters can be mostly separated by the use of the $x(i_12)$ parameter.

We further carried out two-dimensional mapping of the 1751 sequences (i_1=1, 2, ···, N_1) by plotting $\{x(i_12), x(i_14)\}$ or $\{x(i_13), x(i_14)\}$ (data not shown). In these cases also, the parameters of $x(i_13)$ and $x(i_14)$ are found to have no practical ability to discriminate: only the parameter of $x(i_12)$ is very effective.

Concluding Remarks

Hayashi's quantification analysis (Class III) is similar to the principal-component analysis for data of samples composed of continuous variables. However, the Class III analysis differs from the principal-component analysis in several points:

(1) The Class III analysis deals with samples composed of categorical data or item-category data.

(2) In the Class III analysis, we give appropriate quantities to both samples and item-categories in such a way that the correlation coefficient between samples and item-categories may be maximized (see Eq. 12).

(3) In this process, using the second largest eigen value, we can simultaneously classify not only item-categories, but also samples, in the most characteristic way. We can map them in two- or three-dimensional coordinates, using the third and fourth largest eigen values.

The Class III approach is applicable when samples have no external criterion. In the present investigation, the 1751 sample sequences composed of 5′-splice site sequences and sequences other than 5′-splice sites were analyzed with the Class III method, and a discrimination rate of up to 96.8% was attained. If there is an external criterion, the Class II method gives a higher rate of discrimination. However, if sample sequences exhibit unique responses to the positions and species of nucleotides, the Class III approach may give a satisfactory rate of discrimination even without any external criterion. In this respect, the Class III method is "an automatic classification technique" of unknown nucleotide sequences, and it may become generally useful in the analysis of nucleotide sequences other than those of splicing.

Surface Activity of Complexes Formed with *N*-Dodecyl-β-alanine and Copper(II) Ion in Aqueous Solution

Akio NAKAMURA* and Kazuo TAJIMA†
Nagoya Municipal Women's Junior College, Kitachikusa, Chikusa-ku, Nagoya 464

(Received April 21, 1988)

The surface activity of the equimolar mixed solutions of *N*-dodecyl-β-alanine (NDA) and inorganic salts was studied at 30 °C. The surface tension of the NDA-$CuCl_2$ solution decreased more than that of the single NDA solution, whereas the surface tensions of the NDA-NaCl, NDA-$CaCl_2$, and NDA-$MgCl_2$ solutions were almost the same as that of the single NDA solution in the concentration region studied. The experiments with the bulk solution have shown that the 1:1-complex ion formed with NDA and the copper(II) ion is soluble and more surface-active than NDA alone, but the 1:2-complex is not effective in the surface activity because of its extremely low solubility. The formation constant of the 1:1-complex ion was determined, by potentiometry with both copper(II) and hydrogen ion-selective electrodes, to be 5.5×10^{-5}, while the standard free energy of the complex formation was found to be 24.7 kJ mol^{-1}. The composition and structure of the 1:2-complex were studied by means of X-ray diffractometry, IR spectroscopy, and elemental analyses for the precipitate. The total amounts of NDA adsorbed at the air/aqueous solution interface were determined by radiometry using tritium-labeled NDA, and the amount of the 1:1-complex adsorbed was calculated by the Gibbs adsorption isotherm. Thus, the compositions were determined in both the adsorbed and bulk phases. It was seen that the relative adsorbability of the 1:1-complex was larger than that of NDA by a factor of about 1.5×10^2 and, further, was larger than that of a 1:1-complex formed with NDA and sodium dodecylsulfate by a factor of about 3.7.

Ampholytic surfactants of the amino-acid type have been used in various fields because of their excellent characteristics (e.g., high detergency, bactericidal effect, low irritating to the skin, definite effect of pH on the solution properties, high biodegradability, and wide compatibility with other types of surfactants).[1] In spite of such characteristics of ampholytic surfactants, however, reports of their basic surface-chemical properties seem to be rather rare compared to the cases of anionic, cationic, and nonionic surfactants.

We have investigated some of the properties of *N*-dodecyl-β-alanine (NDA), which is one of most simple surfactants of the amino-acid type (e.g., the adsorption isotherms and the interfacial tensions at the air/aqueous solution[2] and oil/aqueous solution[3] interfaces, the pH effects on the surface activity,[4] and the interactions with anionic surfactants[5,6] and with insoluble monolayers).[7]

On the other hand, it is well-known that amino acids and the transition metal ions form a number of stable complexes in their aqueous solutions, and some of their structural properties have been investigated as models of metal complexes in biological systems.[8] Therefore, a similar interaction can be expected to occur between the transition metal ions and the ampholytic surfactants of the amino-acid type. However, little has been reported concerning the surface activity of such a complex in its aqueous solution.[9]

The purpose of the present study is to elucidate the surface activity of the complex formed in the mixed solution of the copper(II) ion and NDA.

Experimental

Materials. *N*-Dodecyl-β-alanine (NDA) (i.e., 3-(dodecylammonio)propionate) was synthesized from dodecylamine and β-propiolactone in acetonitrile; also, tritiated NDA was synthesized by the same procedure except that tritiated dodecylamine was used instead of dodecylamine. The details of the synthesis and purification of the materials have been reported elsewhere.[2] The salts of NaCl, $CaCl_2$, $MgCl_2$, and $CuCl_2$ were purified by recrystallization, repeated three times, from distilled water. Water was purified by distillation after it had been refluxed overnight with acidic permanganate and subsequently with alkaline permanganate.

Methods. The adsorption of NDA was measured by the same radiometry as that reported previously.[2,10] The surface tension was measured by the Wilhelmy plate method. The time dependence of the surface tension was self-recorded to obtain an equilibrium value.[11] The activities of the copper(II) and hydrogen ions in the solutions were measured with the ion-selective electrodes connected to the ion meter (Orion Research, U.S.A., model 920). To minimize the effect of the photo-sensitivity of the copper(II) ion-selective electrode on the output current, the apparatus was set up and operated in as dark a room as possible. All the measurements were made at 30±0.2 °C in the pH region of about 4.3—5.5, where the NDA molecules are mostly zwitterionic[4] and where copper(II) hydroxide is essentially absent.

Results and Discussion

Surface Activity of the Solution. Figure 1 shows the surface tension (γ) vs. concentration curves of the NDA solution (C) with and without an equimolar amount of $CuCl_2$. The abscissa of Fig. 1 shows the

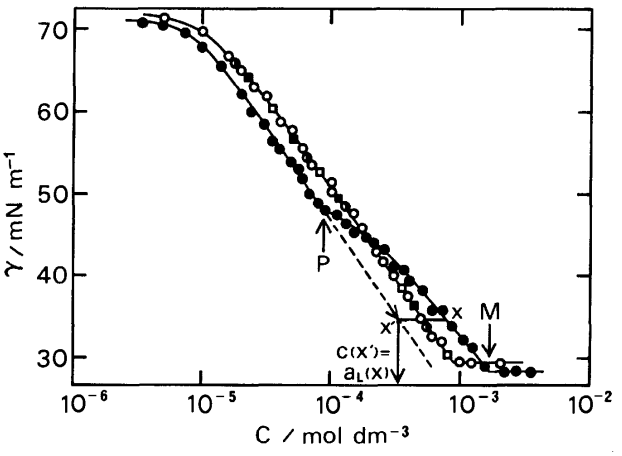

Fig. 1. Surface tension vs. concentration curves for NDA solutions alone (O), and with equimolar amount of $CuCl_2$ (●), $MgCl_2$ (□), $CaCl_2$ (■), and $NaCl_2$ (◑). Dashed line shows the extrapolation of the curve for NDA-$CuCl_2$ system above P point (see text).

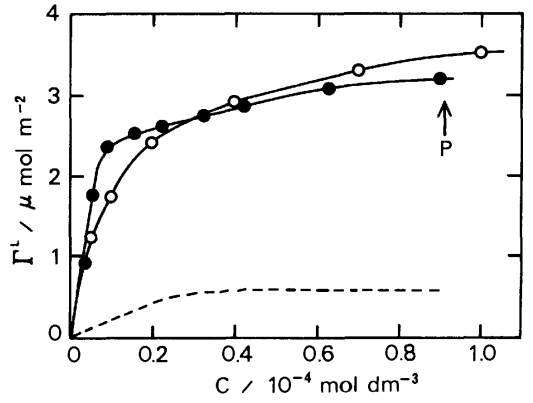

Fig. 2. Adsorption isotherms of NDA measured by a radiometry for NDA solution (O) and equimolar mixed solution of NDA-$CuCl_2$ (●). Dashed line shows the calculated adsorbed amount of the 1:1-complex ion (ML^+).

concentration of each component in the equimolar mixed solution. It is worthy of notice that the lowering of surface tension of NDA-$CuCl_2$ is larger than that of a single NDA solution and has a kink point at the concentration of 9.0×10^{-5} mol dm^{-3}. Here, we call this point P. Above the concentration of the P point, a flickering light was visible upon the irradiation of the He-Ne laser beam to the solution. This means that very fine crystalline particles would be generated, whereas a further lowering of the surface tension is observed until the micelle formation at 1.65×10^{-3} mol dm^{-3}. Here, we call this point M. On the other hand, the surface tensions of the other solutions, which had been prepared by an equimolar mixing of NDA-NaCl, NDA-$CaCl_2$, and NDA-$MgCl_2$, were almost the same as that of the single NDA solution in the corresponding concentration region. This finding indicates that the addition of such amounts of these salts caused no enhancement of the surface activity of the NDA solution. In other words, the salting-out effects were not observed in these systems. Therefore, the results obviously suggest the occurrence of a favorable and specific interaction of NDA with the copper(II) ion in the solution.

Figure 2 shows the adsorbed amounts of NDA (Γ^L) observed by radiometry at the air/solution interface with and without an equimolar amount of $CuCl_2$ in the concentration region below the P point in Fig. 1. The presence of $CuCl_2$ obviously enhanced the adsorption in the lower concentration region, but depressed it in the higher one, compared with that of the single NDA solution. This may be due to the formation of a surface-active complex, as may be expected from the results in Fig. 1. The depression of the adsorption isotherm in the higher concentration region is probably caused by both the ionic repulsion between the net charges of the adsorbed complexes and its geometrically large cross-section area due to the formation of a six-membered ring with NDA and the copper(II) ion, as will be shown later.

In general, it is well-known that the complexes of copper(II) ions and amino acids have the 1:2-composition and a planar structure, with the coordination number being 4.[8] Thus, in a dilute aqueous solution the complex-formation equilibria of NDA with the copper(II) ion are assumed to be described by the following two-step reactions:

$$M^{2+} + L^{\pm} \rightleftarrows ML^+ + H^+ \quad (1)$$

$$ML^+ + L^{\pm} \rightleftarrows ML_2 + H^+, \quad (2)$$

where M^{2+}, ML^+, ML_2, $L^{\pm}$, and H^+ denote the copper(II) ion, the 1(copper(II)):1(NDA)-complex ion, the 1:2-complex, the zwitterionic NDA, and the hydrogen ion respectively. Thus, we have presumed that the enhanced surface activity of the solution at the concentrations below the P point, as seen in Fig. 1, is due mainly to the presence of the 1:1-complex ion (ML^+), while the depression above the P point is mainly attributable to the formation of the 1:2-complex (ML_2), which is essentially insoluble because of having two long chains in a molecule. In order to confirm this reasoning, the solution properties were studied precisely, as will be described in the following sections.

1:1-Complex (ML^+) Formation. In Fig. 3 the surface tension of the mixed solution of NDA with $CuCl_2$ is plotted against the concentration of NDA (C). The total concentrations of the mixed solutions were kept at 1.0×10^{-4} mol dm^{-3}. The maximum deviation of the surface tension of the mixed solution from that of the single NDA solution is found at the equimolar ratio of NDA/$CuCl_2$; this suggests the formation of the surface-active 1:1-complex ion (ML^+) in the solution.

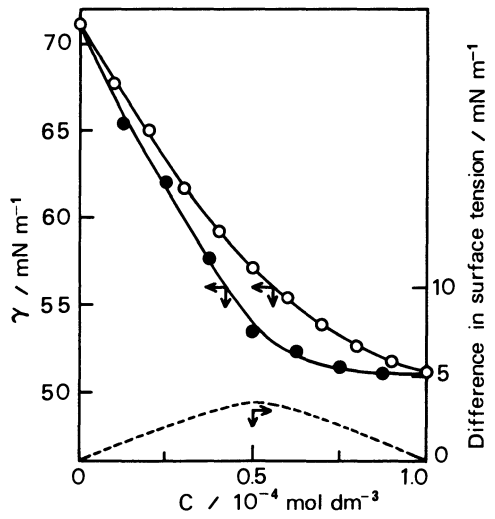

Fig. 3. Surface tensions of NDA (O) solution and NDA-$CuCl_2$ (●) solution (total concentration kept at 1.0×10^{-4} mol dm^{-3}) vs. NDA concentration curves. Dashed line shows the difference in surface tensions of NDA and NDA-$CuCl_2$ solutions.

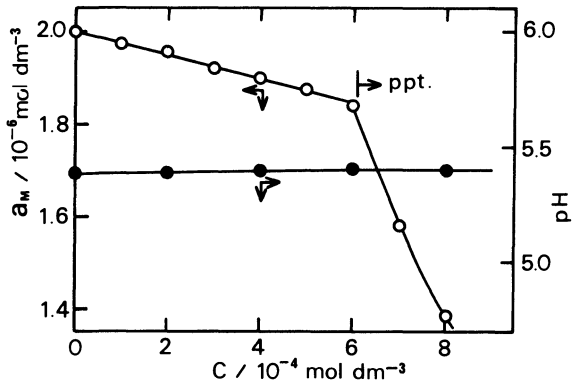

Fig. 4. Activities of copper(II) ion (a_M) (O) and hydrogen ion (pH) (●) vs. the concentration of NDA.

In order to determine the formation constant of the 1:1-complex ion, the activity measurements of the copper(II) ion (a_M) and the hydrogen ion (a_H) in the mixed solution of NDA-$CuCl_2$ were made by means of potentiometry, but the results were not so reliable as to enable us to determine accurately the trace quantities of complexes formed in a dilute concentration region, as is shown in Fig. 2. Therefore, an alternative system was introduced. Pure NDA powder in a given amount was stirred into the $CuCl_2$ solution (2.0×10^{-6} mol dm^{-3}) in a thermostat. The values of a_M and a_H were measured as a function of the C value. The results are shown in Fig. 4. The a_M value gradually decreased with the increase in the C value and steeply decreased at about 5.8×10^{-4} mol dm^{-3} above which point the precipitate was observed in the solution as has been described in the surface tension measurements. On

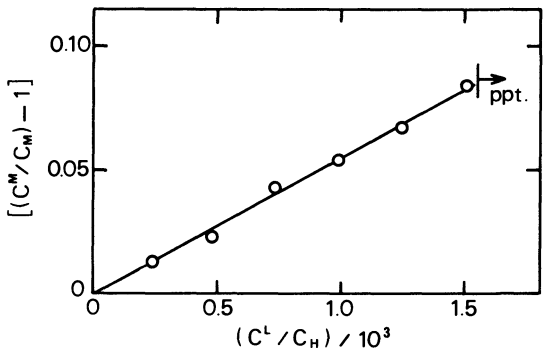

Fig. 5. $[(C^M/C_M)-1]$ vs. (C^L/C_H) plot according to Eq. 5.

the other hand, the a_H value was almost invariable at pH 5.4, in spite of the increase in the C value due to the buffer action of the solution for a small amount of the released H^+ ion. Here, we obtain from Eqs. 1 and 2:

$$a_{ML}\,a_H/a_M\,a_L = K_1 \quad (3)$$

$$a_{ML2}\,a_H/a_{ML}\,a_L = K_2, \quad (4)$$

where K_1 and K_2 denote the successive formation constants of ML^+ and ML_2 and where a_M, a_L, a_{ML}, a_{ML2}, and a_H denote the activities of M^{2+}, $L^{\pm}$, ML^+, ML_2, and H^+ respectively. Further, since the concentration of each species is of the order of magnitude of 10^{-4}—10^{-6} mol dm^{-3}, the activities in Eqs. 3 and 4 can reasonably be replaced by these concentrations:

$$C_{ML}\,C_H/C_M\,C_L = K_1 \quad (3')$$

$$C_{ML2}\,C_H/C_{ML}\,C_L = K_2 \quad (4')$$

where C_i denotes the concentration of species i. Then, under the condition of $C^L \gg C^M$, as in the case of Fig. 4, the combination of Eqs. 3′ and 4′ gives:

$$(C^M/C_M) - 1 = K_1(C^L/C_H) + K_1K_2(C^L/C_H)^2, \quad (5)$$

where C^M and C^L are the total concentrations defined as:

$$C^M = C_M + C_{ML} + C_{ML2} \quad (6)$$

$$C^L = C_L + C_{ML} + 2C_{ML2}. \quad (7)$$

If the ratio of K_2 to K_1 is assumed to be far less than unity, by analogy with the case of the β-alanine solution ($K_1 = 1.5\times10^{-3}$ and $K_2=5.9\times10^{-5}$),[12] the second term of R.H.S. in Eq. 5 is negligible. Therefore, the plot of $[(C^M/C_M)-1]$ against (C^L/C_H) should be linear, and its slope should give us the K_1 value. Here, for the actual plot, the values of a_M and a_H were used as the values of C_M and C_H respectively. The results are shown in Fig. 5; the K_1 value was found to be 5.5×10^{-5}.

Then, the standard free energy change ($\Delta G°$) in the 1:1-complex ion formation was calculated to be

24.7 kJ mol^{-1} according to this relation:

$$\Delta G^\circ = -RT \ln K_1. \quad (8)$$

This value is slightly larger than that of β-alanine (16.4 kJ mol^{-1}) calculated using the K_1 value obtained above, and fairly larger than those of some α-amino acids, for instance, glycine (7.1 kJ mol^{-1}) and α-alanine (7.7 kJ mol^{-1}).[13] This means that NDA is less reactive with the copper(II) ion than these amino acids. This result may reflect primarily the differences in the basicities of the nitrogen donors in these amino acids, and secondarily the differences in the structures of the chelate-rings of the 1:1-complexes.

Adsorbed Amount of the 1:1-Complex. In order to correlate the composition of the solution interior with that of the surface phase, the Gibbs adsorption isotherm was applied. The Gibbs adsorption isotherm is written generally[14] at a constant temperature and pressure as follows:

$$-d\gamma/RT = \sum_i \Gamma_i \, d(\ln a_i), \quad (9)$$

where γ denotes the surface tension, and Γ_i and a_i, the surface excess and the activity of the i-th species of solutes in the solution interior respectively. Here, since the formulation is limited to the concentration region below the P point in Fig. 1, the adsorbed species of solutes are assumed to be $L^\pm$, ML^+, and Cl^-; these species are related by Eq. 1, and the activity of each species can be replaced by the concentration for the reason described above. Thus, Eq. 9 can be rewritten as:

$$-d\gamma/RT = \Gamma_L \, d(\ln C_L) + \Gamma_{ML} \, d(\ln C_{ML}) + \Gamma_{Cl} \, d(\ln C_{Cl}), \quad (10)$$

where the subscript Cl denotes Cl^-.

The following relations are introduced to the total quantity (superscripts) of surface-active species in the surface phase and to the conditions of electrical neutrality in the surface and bulk phases:

$$\Gamma^L = \Gamma_L + \Gamma_{ML} \quad (11)$$

$$\Gamma_{ML} = \Gamma_{Cl} \quad (12)$$

$$C^M = (1/2)C_{Cl}. \quad (13)$$

Under the condition of equimolar mixing, from Eqs. 6 and 7, and neglecting the third terms of R.H.S. for the reason described above, we obtain:

$$C^M = C^L = C \quad (14)$$

$$C_M = C_L = C_S, \quad (15)$$

where C denotes the total concentrations of the respective solutes in the mixture (corresponding to the abscissa in Figs. 1 and 2) and where C_S denotes the single-ion concentrations of copper(II) and NDA. From Eqs. 10 and 12—15, we obtain:

$$-(d\gamma/RT)_{1:1} = \Gamma_L \, d(\ln C_S) + \Gamma_{ML} \, d(\ln C_{ML}) + \Gamma_{ML} \, d(\ln C), \quad (16)$$

where the subscript 1:1 indicates the value for the equimolar mixed solution of NDA-$CuCl_2$. Since, under the present experimental conditions, the solution pH actually remains constant, as has been described previously and as shown in the case of Fig. 4, we obtain from Eq. 3′:

$$d(\ln C_{ML}) = 2 \, d(\ln C_S). \quad (17)$$

By substituting Eqs. 11 and 17 into Eq. 16 we obtain:

$$-(d\gamma/RT)_{1:1} = (\Gamma^L + \Gamma_{ML}) \, d(\ln C_S) + \Gamma_{ML} \, d(\ln C). \quad (18)$$

By differentiating Eq. 18 with respect to $(\ln C)$, we obtain:

$$-(1/RT)[\partial\gamma/\partial(\ln C)]_{1:1} \equiv I_{1:1} = (\Gamma^L + \Gamma_{ML})[\partial(\ln C_S)/\partial(\ln C)]_{1:1} + \Gamma_{ML}, \quad (19)$$

Moreover, from Eq. 3′ we obtain:

$$[\partial(\ln C_S)/\partial(\ln C)]_{1:1} \equiv r = (q + q^{1/2})/2q, \quad (20)$$

where $q = [1 + 4K_1(C/C_H)]$.

By substituting Eq. 20 into Eq. 19, we obtain:

$$\Gamma_{ML} = (I_{1:1} - r\Gamma^L)/(r + 1). \quad (21)$$

Thus, we may calculate the adsorbed amount of the 1:1-complex ion (ML^+) from Eq. 21 by using the K_1 and Γ^L values determined by the potentiometry and radiometry respectively, and also the $I_{1:1}$ value given as the inclination of the surface tension vs. the equimolar concentration curve in Fig. 1. The amount of copper(II) in the adsorbed phase, estimated as ML^+, is shown with a dashed line in Fig. 2. While the molar ratio of ML^+ to the total NDA in the adsorbed phase, Γ_{ML}/Γ^L, is about 0.16 in the higher concentration region in Fig. 2, that in the solution interior, C_{ML}/C^L, as calculated using the K_1 value, is about 1.3×10^{-3} in the same concentration region. Consequently, it turns out that the surface activity of ML^+ is fairly larger than that of NDA alone.

Surface Activity of the 1:1-Complex. The surface activity of the 1:1-complex ion in this co-adsorption system was compared to that of NDA in terms of the relative adsorbability (α), which was defined as follows:[6]

Table 1. Relative Adsorbability of 1:1-Complexes and SDS to NDA

Adsorbate	$\lim_{C\to0}(\Gamma/C)$/m	α
NDA	3.1×10^{-4}	1
SDS	4.1×10^{-5}	0.13
NDA-SDS	1.0×10^{-2}	33[6]
NDA-Cu	3.7×10^{-2}	150

$$\alpha = \lim_{C \to 0} (\Gamma_{ML}/C_{ML})/(\Gamma_L/C_L). \quad (22)$$

The results are shown in Table 1, together with the values of the 1:1-complex ion formed between NDA and sodium dodecylsulfate (SDS).[6] It is worthy of notice that the surface activity of the 1:1-complex ion of copper(II) and NDA is larger than that of NDA by a factor of 1.5×10^2 and larger than that of the 1:1-complex of NDA and SDS by a factor of 3.6.

1:2-Complex Formation. In order to elucidate the effect of the precipitation on the surface tension of the solutions above the P point in Fig. 1, analyses of the precipitate were carried out. The precipitate which was generated in the equimolar mixed solution at 8.0×10^{-4} mol dm^{-3} was collected on a membrane filter (pore size, 3 μm) and dried in a desiccator for a week. The precipitate consisted of bluish and flaky microcrystals, and it was so hydrophobic as to repel its mother solution. The results of the elemental analyses of the precipitate are shown in Table 2.

In Table 3 the IR spectra of pure NDA and the precipitate obtained by the KBr disk method are compared. The precipitate lacks the absorption bands at 1650 cm^{-1} and 2330 cm^{-1} due to $=NH_2^+$. The absorption bands at 860 cm^{-1} due to $-(CH_2)_2-$ in the polar group of NDA, and also the absorption bands at 1400 cm^{-1} and 1570 cm^{-1} due to $-COO^-$ shift to higher frequencies. These results confirm that the precipitate is the hydrated 1:2-complex, $[Cu(NDA)_2]\cdot2H_2O$, with a ring structure formed between the hydrophilic group of NDA and the copper(II) ion.

Further, in order to obtain information on the crystal structure of the 1:2-complex, the X-ray (Cu $K\alpha$ 0.154 nm) diffraction pattern was measured for the powdery precipitate. The main peaks, at the angles of 2θ=3.93° (1.00), 7.86° (0.24), 11.82° (0.16), and 15.44° (0.05), can all be assigned to a lattice space of 2.24 nm on the basis of the Bragg condition; here, the figures in parentheses indicate the relative intensity of each peak. This long lattice spacing may correspond to the distance between copper(II) ions aligned in a adjacent layers of the 1:2-complex with a multilayer structure. Since the total length of the single ML_2 molecule with the trans-form on a plane is about 3.35 nm, as estimated from the STS molecular model, the packing of ML_2 molecules in the crystal state represented schematically in Fig. 6 may explain the X-ray data. The crystallographic structure will be described more precisely elsewhere.

Solubility Product of the 1:2-Complex. The solubility product (K_{SP}) of the 1:2-complex described above is defined from Eqs. 3 and 4 as follows:

$$K_{SP} = a_M a_L^2 / a_H^2, \quad (23)$$

As the observed values of a_M and a_H, and the calculated value of a_L from Eq. 3 have been given at the P point in Fig. 1, the value of K_{SP} is calculated to be 3.9×10^{-2} mol dm^{-3}. Figure 7 shows the activities of copper(II) and hydrogen ions in $CuCl_2$ solutions with and without equimolar NDA, whose concentration region corresponds to that below the M point in Fig. 1. When we put the data of a_M and a_H in Fig. 7 into Eq. 23, it turns out that the calculated values of a_L still increased until the M point. Consequently, the a_L value calculated at a given surface tension (e.g., X point) between P and M points in Fig. 1 nearly coincides with the C value obtained by the extrapolation of the γ vs. log C curve smoothly over the P point to the given surface tension (X′ point). The extrapolated curve is shown by a dashed line in Fig. 1. Thus, this finding explains why the surface tension lowers continuously above the P point, even after forming the precipitate of the 1:2-complex, until the

micelle is formed at the M point.

Though, the 1:2-complex can be expected to be essentially highly surface-active, the complex has been considered in the present study as if it were surface-inactive. This was because the complex is not soluble at all as a result of its large hydrophobic moiety, as is shown in Fig. 6. However, it is conceivable that apparently the same composition may be observed at the co-adsorbing surface or in the mixed micelle formed with NDA and the 1:1-complex. The discrimination of such an ambiguous effect should be made in mixed solutions of the copper(II) ion and the short-chain compounds of *N*-alkyl-β-alanine, where the 1:2-complex may become soluble as one of the surface-active species. The study performed for this purpose will be presented elsewhere.

Environmental Intensity Increments of the $S_1(n\pi^*)\leftarrow S_0$ Absorption Spectra of Benzil in Fluid Solutions[1)]

Kaori MIYATA and Motohiko KOYANAGI*
Department of Chemistry, Faculty of Science, Kyushu University,
Hakozaki, Higashi-ku, Fukuoka 812
(Received April 22, 1988)

A remarkable solvent effect on intensity of molecular electronic transitions has been found in near UV absorption spectra of benzil. Great intensity enhancement is observed in alcohols and in chloromethanes as well as in nitriles. Parameters which are required to explain the origin of those environmental intensity enhancement are neither solvent refractive indexes nor polarities. A some rotationally flexible freedom around the -OC-CO- axis of benzil in the solvent seems important. Week complex formation between the solute and the solvent molecule is likely to play an important role. Similar solvent effects are found for absorption spectra of benzophenone and dicyclohexyl ketone, but with more complexity regarding their spectral shifts in contrast to the case of benzil.

There have been reported a lot of experimental data on the originally weak electronic transitions which become substantially enhanced through interactions with environmental solvent molecules. Roughly, two types of environmental intensification in the transitions have been reported. One is associated largely with solvent polarities (and partly to dielectric constants): e.g., $^1L_b\leftrightarrow S_0$ transition spectra of pyrene[2-4)] and coronene.[3)] The other is closely related to solvent dispersion forces or refractive indexes: e.g., $^1L_b\leftrightarrow S_0$ transition spectra of benzene[5-8)] and naphthalene[5,9)] and $^1U\leftarrow S_0$ absorption spectra of *p*-benzoquinone,[5)] aliphatic monoketones[10)] and benzaldehyde.[11)] Recently, Abe has proposed experimental and theoretical expressions for the molecular electronic oscillator strength of the latter type of molecules and successfully applied those equations to several ketones and benzenes.[12,13)]

In the present work we studied the $S_1(n\pi^*)\leftarrow S_0$ absorption spectra of benzil in various solvents and found that there was a remarkable solvent intensification on the electronic transition.

Experimental

Benzil (a Tokyo Kasei Co. zone-melting reagent) was used as received. Dicyclohexyl ketone, benzophenone, cyclobutanone, and cyclopentanone (all commercially pure grade reagents) were purified through repeated vacuum distillations. These ketones were stored in sealed-off glass tubings in vacuo. Almost all of the solvents employed (Dotite spectroscopically pure grade reagents) were deoxygenated by nitrogen gas bubbling before the measurements and used without further purification. Benzonitrile was purified by vacuum distillation. Carbon disulfide was purified in the same way as reported previously.[14)]

The oscillator strength of the $S_1(n\pi^*)\leftarrow S_0$ transition for each of the aromatic ketones in fluid solutions is difficult to estimate accurately from the observed spectrum because there is almost always its overlap with the $S_2(\pi\,\pi^*)\leftarrow S_0$ transition absorption. Integration over a certain part of the absorption system may in principle give relative oscillator strengths correctly as long as there are little changes in the Franck-Condon factors and as long as there is no strong intermolecular interaction. For benzil, in almost all cases we employed a band maximum around 27—28000 cm^{-1} as the upper wavenumber limit of the integration although small spectral pattern changes are found in benzene solution and the two nitriles (especially in benzonitrile solution) probably because of band overlappings (see Fig. 1). The exception is for CS_2 which has a substantial absorption originating from the onset around 430 nm; for this case the integration was taken up to the first band maximum and then the integration value was compared to another intensity integration value over the corresponding band region in a standard solution, hexane. For benzophenone, a treatment similar to that for benzaldehyde[10)] was employed. The other experimental details are similar to those described previously.[11)]

Results and Discussion

Benzil. Although the molecular structure of benzil in fluid solutions has been reported nowhere, we may suppose that it is close to the crystal[15-18)] or the vapor[19)] structure which has proven to belong to the C_2 point group with a CO/CO torsional angle of ca. 110° (for crystal)[15,16)] or 117°±3° (for vapor)[19)] and with the phenyl rings nearly coplanar with the carbonyl groups. Under this assumed molecular symmetry, the $S_1(n\pi^*)\leftarrow S_0$ absorption transition may formally be allowed. Further, if benzil is simply assumed to be an electronically composite compound of two equivalent aromatic monocarbonyls (e.g., benzaldehyde or acetophenone), the relevant $\pi^*\leftarrow n$ transitions involve both allowed and forbidden characters. Despite this drastic assumption and the formal geometrical discussion, however, the $S_1(n\pi^*)\leftarrow S_0$ transition of benzil still retains substantial forbidden character originating from $\pi^*\leftarrow n$ transition properties; the very small oscillator strength observed confirms that this is the case.

Near UV absorption spectra of benzil were studied in various solvents at room temperature. Several spectra were picked up and shown in Fig. 1. The spectra show a few broad vibronic bands irrespective of

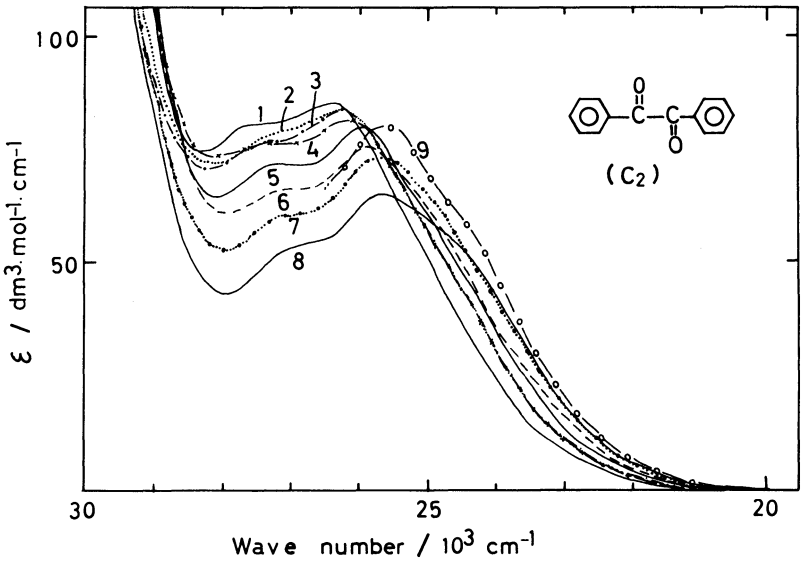

Fig. 1. $S_1(n\pi^*)\leftarrow S_0$ absorption spectra of benzil in various solvents at 20 °C. The solvents are: 1, acetonitrile; 2, 2-propanol; 3, chloroform; 4, benzonitrile; 5, benzene; 6, *p*-xylene; 7, carbon tetrachloride; 8, methylcyclohexane; and 9, carbon disulfide.

solvent polarity. Except for the spectrum in CS_2, it is generally found that toward the shorter the absorption wavelength of the peak maximum shifts, the greater the environmental intensity enhancement is. Solvents which effect such great intensity enhancement are alcohols, CH_2Cl_2, $CHCl_3$, and nitriles. With respect to the spectral increment in nonpolar and in several nearly nonpolar solvents such as hexane, methylcyclohexane, CCl_4, benzene, toluene, *p*-xylene, and CS_2, the usual refractive index or the dispersion force dependence[10–13] seems to hold qualitatively. The great intensity enhancement of the spectra in alcohols and chloromethanes differs from the case of pyrene.[2–4]

Cyclobutanone. Generally, cycloalkanones are chemically reactive and photochemically unstable.[20,21] Especially it has been known from the observation of the fluorescence excitation spectrum that cyclobutanone undergoes predissociation from its $S_1(n\pi^*)$ state.[22] As such, we were interested in observing near UV absorption spectra of cyclobutanone in fluid solutions. Similarly to the cases of acetone and cyclopentanone,[11] however, its $S_1(n\pi^*)\leftarrow S_0$ spectrum shows that the absorption transition is almost isolated from other absorption transitions lying at higher energies and gives a good example for a study on solvent intensification. The observed spectra are in part shown in Fig. 2. The deduced conclusion is in line with that reported previously for acetone and cyclopentanone[11]: The intensity enhancement observed is ascribed to the perturbation of dispersion forces between the solute and solvent molecules.

Benzophenone and Dicyclohexyl Ketone. Near UV absorption bands of benzophenone and dicyclohexyl

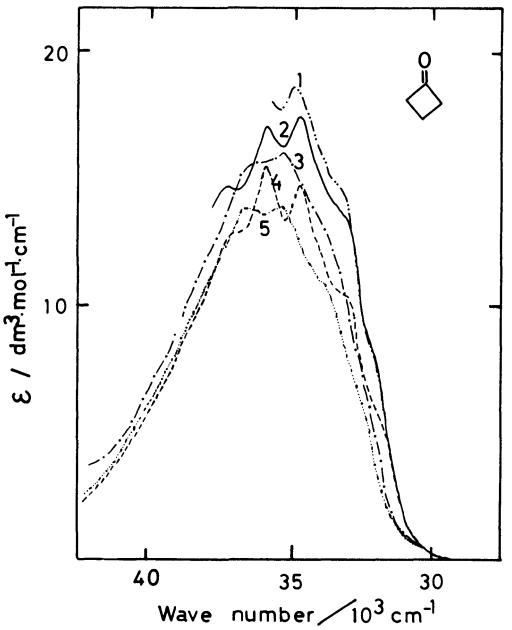

Fig. 2. $S_1(n\pi^*)\leftarrow S_0$ absorption spectra of cyclobutanone in some solvents at 20 °C. The solvents are: 1, benzene; 2, carbon tetrachloride; 3, chloroform; 4, cyclohexane; and 5, acetonitrile.

ketone in polar solvents such as dichloromethane, chloroform, and acetonitrile become much broad and undergo intensity enhancement (see Fig. 3). This is a contrast to the results obtained for cyclobutanone, loc. cit. (cf. Fig. 2), for the other aliphatic monoketones,[11] and for benzaldehyde.[10] It has been known that these polar solvents form stoichiometric complexes with several aromatic carbonyl compounds such as benzo-

phenone[23] and benzaldehyde[10] and with several aliphatic ketones.[24] Despite these facts of complex formation, however, it should be noted that the intensity enhancement of benzaldehyde (and also acetophenone) in dichloromethane and nitriles is not substantial; these solvents never belong to the most effective intensity perturbers, but are nearly in the dispersion force correlation line (for such a correlation diagram, see Fig. 3 of Ref. 10). For benzophenone, however, the great intensity enhancement in chloromethanes is quite remarkable.

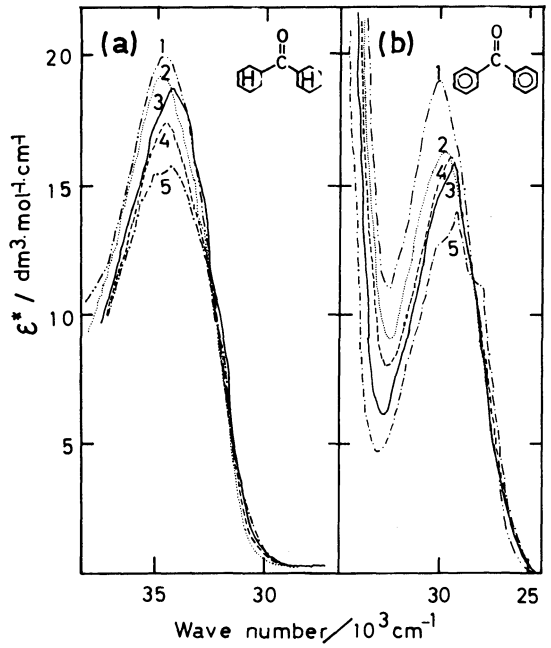

Fig. 3. $S_1(n\pi^*)\leftarrow S_0$ absorption spectra of (a) dicyclohexyl ketone and (b) benzophenone in some solvents at 20°C. Note that the ordinate axis denotes ε^*, but not ε; where ε^* is a constricted molar extinction coefficient, i.e., $\varepsilon^*=c\cdot\varepsilon$ (c: constant). For case (a), $c=1/2$; and for case (b), $c=1/9$. The solvents are: 1, chloroform; 2, acetonitrile; 3, carbon tetrachloride; 4, benzene; and 5, cyclohexane.

Although no data on the ground state geometry of dicyclohexyl ketone has been reported, the molecule is thought to be considerably skewed as is supposed from photoselection experiments by Chandler and Goodman.[25] With the help of their experimental results, we investigated the near UV spectra of the molecule. The observed spectra are partially shown in Fig. 3a. Since this absorption system is almost isolated from other higher energy transitions like the other aliphatic monoketones, it is more clearly demonstrated that the absorption spectral intensity is certainly enhanced in acetonitrile and especially chloroform (and also in dichloromethane).

Complex Formation between Ketones and Polar Solvents. By measuring near UV and IR spectra in various fluid solutions, Becker has concluded that benzophenone forms 1:1 weak complexes with certain polar solvents such as nitriles, alcohols, and halomethanes.[23] We also confirmed that benzaldehyde belongs to the case.[10] These facts necessitated a simlar investigation for benzil, acetone, dicyclohexyl ketone, and the cyclic ketones. In almost all of the cases, we measured several isosbestic points which are manifestations of such 1:1 complex formation. As an

Propionitrile concentrations in 10^{-1} M units are: (0), 0; (1), 1.41; (2), 2.83; (3), 5.66; (4), 11.3; (5), 14.2; (6), 28.3; and (7), 42.5.

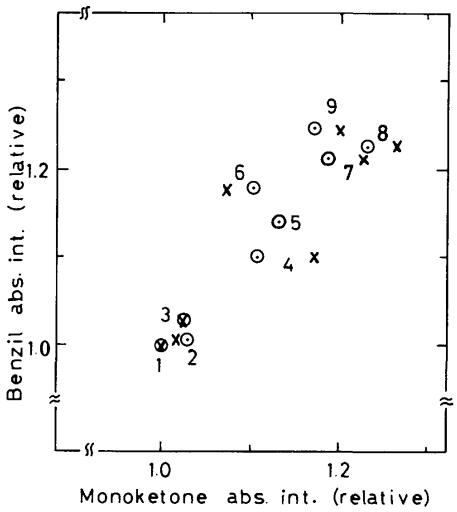

Fig. 5. Correlation between the environmental absorption intensity increment of benzil and that of each flexible monoketone: ×, for benzophenone; and ○, for dicyclohexyl ketone. The solvents are: 1, hexane; 2, cyclohexane; 3, methylcyclohexane; 4, carbon tetrachloride 5, *p*-xylene; 6, benzene; 7, dichloromethane; 8, chloroform; and 9, acetonitrile.

example, the absorption spectra of benzil in propionitrile-methylcyclohexane binary solvent solutions are shown in Fig. 4 although those are not so stoichiometric as the other monoketones' spectra (vide infra).

The absorption spectra of the ketones investigated are characterized and classified as follows:

(1) Almost all the spectra give several isosbestic (or nearly isosbestic) points when changing concentration of an active solvent in binary mixed solvent solutions. Such active solvents are: CH_3CN, C_2H_5CN, CH_2Cl_2, $CHCl_3$, ethanol, and 2-propanol. Appearance of these isosbestic points is a manifestation of 1:1 complex formation between the ketone and the solvent molecule. The equilibrium constants obtained are lying in the range of 10^0—10^{-2} M^{-1} (mostly at ca. 10^{-1} M^{-1}; 1 M=1 mol dm^{-3}).

(2) From their environmental intensity enhancement behaviors, the ketones observed are classified into two groups: (i) acetone and the cyclic ketones[26] and (ii) benzophenone, dicyclohexyl ketone, and benzil (see also Fig. 5).

(3) Despite of the existence of two carbonyl groups in benzil, nearly isosbestic points in binary mixed solvent solutions are observed even at a high concentration of such a polar solvent. This suggests that the kinetic reaction of 1:1 complex formation occurs dominantly. (An example for the benzil in propionitrile-methylcyclohexane mixed solvent system is shown in Fig. 4.)

(4) Among the group (ii) molecules, benzil seems to show a nearly linear relation between intensity enhancements and spectral shifts. This means that

Table 1. Intensities of $S_1(n\pi^*) \leftarrow S_0$ Absorptions for Some Ketones[a]

predominant environmental perturbing forces are, to a certain extent, restricted in the case of benzil. As such, benzil may be considered as a representative of the group (ii) molecules.

The environmental intensity enhancement for the group (i) ketones is interpreted in terms of the dispersion force (or the solvent refractive index) scheme[10,11] while that for the group (ii) is neither in terms of the solvent polarity nor in terms of the refractive index.

Although we can not proceed further without speculations, a comparison among the absorption oscillator strengths (or absorption molar extinction coefficients) of those ketones is very interesting (see Table 1). The intensity of dicyclohexyl ketone in a hydrocarbon is about 1.6 times as great as that of cyclobutanone or cyclopentanone (or acetone) in the same solvent while the intensity of benzophenone is about four times greater than that of benzaldehyde (or acetophenone). Similarly, the intensity of benzil is about twice as great as that of benzaldehyde (or acetophenone) and also that of 2,3-butanedione (i. e., biacetyl).[27,28] A common factor in the group (ii) ketones is a rotationally flexible freedom about the adjacent bond(s) to the carbonyl group(s). A hydrogen bond[29] or a charge transfer type complex formation may deform the ground state geometry a little bit along the relevant torsional coordinate(s). This may bring forth further intensity increment by borrowing from $^1n\sigma^* \leftarrow S_0$ (and also $^1\pi\pi^* \leftarrow S_0$ for the aromatic ketones) transitions. In order to discuss further on benzil somewhat quantitatively, we feel a need to seek a much more suitable complex system in which the spectral intensity change may surpass ordinary solvent effects.

Concluding Remarks

In this paper we used the term "solvent effects" in a broad sense. On the occasion of comparison between the theoretical and the experimental data many authors have rather kept away from solvents with a

special local interaction with guests as best as possible. As for clear-cut complex forming systems, there is no problem in selecting out such solvents. However, a problem arises when the solvent forms a very weak complex with a certain solute with its low stabilization energy which is comparable to or somewhat higher than the usual Boltzmann energy, i.e.,~kT: Even an "inert" solvent may generally form complexes (or clusters) at low temperature. Pyrene is one typical example of such cases.[30] The present case for benzil may be another one: Intensity increment observed in the present work seems to occur in most all hydrogen donating solvents.[29] This is in part supported by a preliminary work, that is in progress, on benzil in many binary solvent solutions into which 10^{-2}—10^{-3} mol dm^{-3} of trifluoroacetic acid or trichloroacetic acid added.

We are now being inclined to accept an assumption that a big deviation of an experimental data from the theory, if it is not easily explainable, is due to these weak local interactions.

We are thankful to Professor Kenichi Nakashima, University of Saga, for his helpful discussion and to the referee for his letting us know Ref. 29. This work was in part supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture (No. 62540358).

Vibrational Analysis of Tangled Spectra. II. Role of Phonon Side Band Structure in the T←S Spectra of Acetophenones

Kenichi NAKASHIMA,† Hiroshi FUTAMI, and Motohiko KOYANAGI*
Department of Chemistry, Faculty of Science, Kyushu University,
Hakozaki, Higashi-ku, Fukuoka 812
(Received May 13, 1988)

$T_{1,2}$←S_0 phosphorescence excitation spectra of acetophenone, acetophenone-*methyl-d*$_3$, and acetophenone-*phenyl-d*$_5$ have been observed in the crystals at 4.2 K. Vibration analysis for the observed tangled spectra becomes possible only by the help of calculations which allow untangling of the tangled spectra. The calculations involve interstate mixings, by vibronic and environmental interactions, among 36 crude adiabatic Born-Oppenheimer vibronic functions of $^3\pi\pi^*$ and $^3n\pi^*$ states. A new aspect of the present work is introduction of a role of intermolecular phonon side bands into the calculations; this clearly showing that the observed spectra are reproduced much better than unless otherwise.

In the preceding paper,[1] we analyzed the tangled $T_{1,2}$←S_0 spectrum of acetophenone in the crystal and showed how conventional analysis was of no use for such a tangled system. Qualitatively, the band structure was explained in terms of canonical mixture of 36 BO vibronic functions of the T_1 and T_2 states. However, several disparities remained unsettled between the observed and the calculated spectrum. These are: (i) an abrupt decrease in calculated intensity in the zeroth order 0–0 band region of the $T_2(n\pi^*)$←S_0 transition, (ii) a discrepancy in the overall spectral intensity distributions, (iii) the lack of several structured bands in the calculation, etc.

In the present paper we report on three items. The first is to give the experimental $T_{1,2}$←S_0 absorption spectra of acetophenone-*methyl-d*$_3$ (hereafter abbreviated as $\mathbf{d_3}$) and acetophenone-*phenyl-d*$_5$ ($\mathbf{d_5}$). To our knowledge, no experimental data thereof have been reported. The second is to simulate these spectra by means of a similar method as given previously for $\mathbf{d_0}$.[1] The third is to take fully into account intermolecular phonon side bands. The simulation with such a phonon correction leads to a great improvement over the earlier one. At least, the extent of the disparities (i) and (ii), loc. cit., seems to be greatly diminished.

Experimental

The guest molecules, nonlabeled acetophenone ($\mathbf{d_0}$, a GR grade reagent from Tokyo Kasei Co.) and $\mathbf{d_3}$ and $\mathbf{d_5}$ (both reagents from Merck, Sharp and Dohme of Canada), were purified by distillation in vacuo. All T←S phosphorescence excitation and absorption spectra were observed at 4.2 K in the crystals. For the measurements of the excitation spectra, ca. 10^{-3} M§ benzaldehyde was doped as an effective phosphorescence emitter while for the absorption measurements, pure crystals with ca. 5 mm thickness were used. All spectra were recorded on a 3/4 m Nalumi Spectrometer with an HTV R375 photomultiplier tube. Other experimental details were similar to those described elsewhere.[1,2]

Theoretical

First, $T_{1,2}$←S_0 spectra of the two deuterated acetophenones were simulated in almost all the same way as reported for $\mathbf{d_0}$.[1] Some suitable frequency changes for many fundamental vibrations were made according to the same procedure as given for benzaldehydes.[2] The exceptions are in the determination of three out-of-plane vibrational frequencies of T_1: ν'_{43}, ν'_{42}, and ν'_{41}. The modes, especially ν''_{43} and ν''_{41}, have been well known to be delocalized over the ring and C–$COCH_3$ framework.[1,3–6] Furthermore, it is expected that a large increase in the C–(CXO) bond order consequent to π^*←π promotion leads to an increase in the CXO-wagging vibrational frequency on going from the ground to the $\pi\pi^*$ excited state. For these reasons, the three diagonal matrix elements were treated as independent parameters. Crystal field and vibronic interaction matrix elements were determined on the basis of the phosphorescence intensity data for mixed isotopic crystal systems.[2] The final data employed for $\mathbf{d_3}$ are partially given in Tables 1 and 2. For $\mathbf{d_5}$, a part of only the diagonal elements are given in Table 1.

Secondly, intermolecular phonon bands were taken into account for the explanation of a broad, but some structured, background absorption which is presumed to dominate a large part of the total absorption intensity. It is found that a similar sub-structure always attends both on almost all prominent phosphorescence bands and on several absorption bands. On the assumption that this was due to a pile of Franck–Condon (FC) type phonon bands, we synthesized a model function for such a feature on a computer by using ten independent gaussians. The three parameters of each gaussian (i.e., location of the frequency center, weight, and bandwidth) were chosen so that the origin band structure of each T←S spectrum was reproduced as best as possible. A final model structure for $\mathbf{d_0}$ is shown in Fig. 1.

The first few bands in the T←S spectra of $\mathbf{d_3}$ and $\mathbf{d_5}$ were sharper than those in $\mathbf{d_0}$ (as demonstrated in Fig.

a) Only the representative elements are given here although 99×99 values are employed for the calculations. In cm^{-1} units.

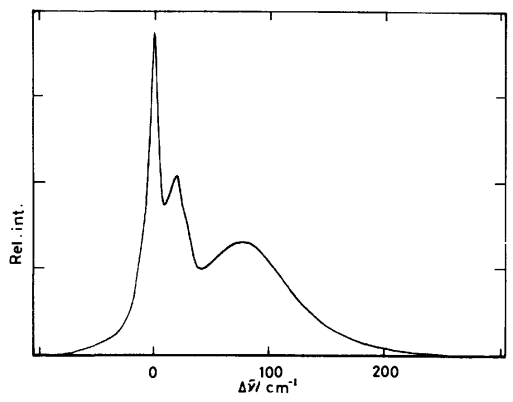

Fig. 1. A model shape function for the background FC type phonons. The fundamental zero-phonon line at $\Delta\nu$=0 cm^{-1} is lorentzian with Γ_{fwhm}=10 cm^{-1} while the other part is synthesized using ten different gaussian functions with various values of Γ_{fwhm}.

2). We thus assumed that each fundamental band of the former had a lorentzian shape with a 7 cm^{-1} fwhm while that of the latter a 10 cm^{-1} fwhm.

Results and Discussion

T←S Phosphorescence Excitation Spectra of the Deuterated Acetophenones. The observed T←S phosphorescence excitation spectra of d_3 and d_5 in the crystals[7] are shown in Fig. 2. For comparison, the spectrum of d_0 is added. At glance, most intensive bands of each spectrum appear to display one-to-one correspondence. However, the correspondence is in appearance only (vide infra).

The prominent band at the longest wavelength (26112 cm^{-1} for d_3 and 26177 cm^{-1} for d_5) is assigned to the T_1 origin band of the $T_1(\pi\pi^*) \leftarrow S_0$ transition. Energy closeness between the phosphorescence origin band of d_3 in d_5 (at 26099 cm^{-1})[3] and the crystal absorption origin band (at 26112 cm^{-1}) seems to support this assignment. The large (ca. 70 cm^{-1})

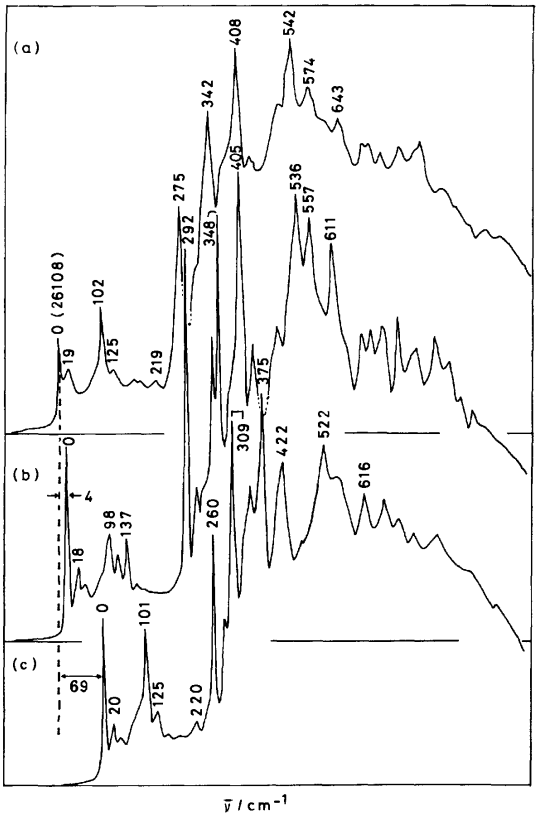

Fig. 2. Observed T←S phosphorescence excitation spectra of (a) ($\mathbf{d_0}$), (b) $\mathbf{d_3}$, and (c) $\mathbf{d_5}$ in the crystals at 4.2 K.

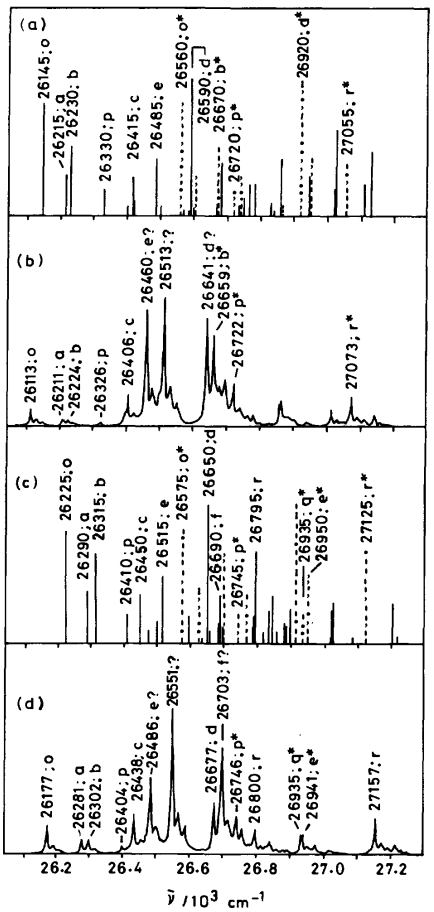

Fig. 3. (a,c) Zeroth order levels employed and (b,d) simulated T←S spectra at 0 K. (a, b) For $\mathbf{d_3}$; and (c, d) for $\mathbf{d_5}$. For band designations, see Ref. 1.

origin band deuteration shift on going from $\mathbf{d_0}$ to $\mathbf{d_5}$ allows assignment of the lowest excited triplet state to $\pi\pi^*$ since a similar deuteration shift has been established for the $\pi\pi^*$ transition of benzaldehyde-*phenyl*-d_5.[8] The very small (4 cm^{-1}) deuteration shift in $\mathbf{d_3}$ gives another piece of evidence for the validity of the $\pi\pi^*$ assignment.

Satellite bands were observed for all T←S spectra at ca. 20, ca. 40, and ca. 90 cm^{-1} from each origin band (and also first several strong false origins) to the higher wavenumber side. Similar sub-structured bands to the lower wavenumber side have also been observed in T→S spectra.[3] These are assigned to lattice vibrations in a similar way to the cases of T←S and T→S electronic spectra of *p*-dihalobenzenes[9] and *p*-benzoquinone[10] in the pure and isotopic mixed crystals. No evidence is obtained for alternative assignments: e.g., either trap bands or Davydov splitting components. The observed band broadness never contradicts our interpretation.

The bands in the 90—140 cm^{-1} region are quite interesting, but complicated (especially for $\mathbf{d_3}$). Such small frequencies may generally be ascribed to two torsional vibration modes, i.e., τ (-$COCH_3$) and τ (-CH_3). Although no information has been presented about these potential surfaces of the crystal phase acetophenones both for the ground and for the excited state, the reasonably sharp origin bands observed both in the phosphorescence and in the excitation spectrum suggest that the rotational potential barriers thereof are high relative to those for the $S_1(n\pi^*)$ state: The $S_1(n\pi^*)$←S_0 phosphorescence excitation spectra in the pure crystal and mixed crystals showed all poorly resolved features.[11,12] Recent jet works[13-15] may be helpful for obtaining information on those potentials.[16]

Simulated T←S Spectra of $\mathbf{d_3}$ and $\mathbf{d_5}$ in the Crystal. The zeroth order levels of $\mathbf{d_3}$ and $\mathbf{d_5}$ are shown in Figs. 3a and 3c, respectively. The height of the solid lines represents the relative value of the interaction between two levels of $T_1(0,0+\nu_i)$ and $T_2(0-0)$; and that of the dashed lines the interaction between the levels of $T_1(0-0)$ and $T_2(0,0+\nu_i)$. Refined calculation spectra of the two deuterated compounds are shown in Figs. 3b and 3d, respectively (for the observed spectra, see Figs. 2b and 2c). The eigenfunction corresponding to each calculated origin band (at 26113 cm^{-1} for $\mathbf{d_3}$ and 26177 cm^{-1} for $\mathbf{d_5}$) is approximately described by

$$|26113> = 0.18|0^*> - 0.96|0> + 0.10|42^*> + \cdots \quad (1)$$

and

$$|26177> = 0.23|0^*> - 0.93|0> + 0.12|42^*> + \cdots \quad (2)$$

A significant mixing of $|0^*>$ with $|0>$ is clear for each case. This explains why the origin band appears with remarkable intensity despite its substantial $\pi\pi^*$ character.

In contrast to the above, there is no convincing band which is assignable to the origin band of the $T_2(n\pi^*)\leftarrow S_0$ transition. Here we give only three eigenfunctions. These may be combined with three of the most intensive observed bands (see also Figs. 2b, 2c, 3b, and 3d):

for $\mathbf{d_3}$,

$$|26460> = 0.75|41> + 0.32|42> - 0.45|0^*> + \cdots \quad (3)$$

$$|26513> = 0.61|41> - 0.55|42> + 0.47|0^*> + \cdots \quad (4)$$

$$|26641> = 0.62|42> - 0.52|27> + 0.44|0^*> + \cdots, \quad (5)$$

and for $\mathbf{d_5}$,

$$|26486> = 0.62|41> + 0.45|44 + 30> - 0.36|0^*> + \cdots \quad (6)$$

$$|26551> = 0.59|41> - 0.46|42> + 0.51|0^*> + \cdots \quad (7)$$

$$|26703> = 0.46|40> + 0.57|41 + 31> + 0.39|0^*> + \cdots, \quad (8)$$

Despite superficial one-to-one band correspondence between the observed prominent bands of $\mathbf{d_3}$ and those of $\mathbf{d_5}$, there are considerable differences between the relevant calculated eigenvector-components of the two compounds as well as between the expansion coefficients of the corresponding components (e.g., compare Eq. 3 with Eq. 6 and Eq. 5 with Eq. 8). A similarity of these results for acetophenones to other results for aromatic aldehydes[2,17,18] leads us to a deduction that this kind of mixing is general for a molecule with a lower excited state of a strongly forbidden character. This deduction is important.

Role of Background Phonon Bands. If discussion is restricted to the spectral intensity distribution, the mimicking is poor. Here let us put aside an obvious experimental fact that spectral bands become broader on going toward shorter wavelengths. To be noted is a big difference between the observed and the calculated spectral intensity distributions: e.g., an abrupt decrease in intensity of the calculated spectra in the zeroth order 0–0 band region of the $T_2(n\pi^*)\leftarrow S_0$ transition and another decrease in intensity of 26.7—26.8×10³ cm⁻¹ region bands. In order to find a solution to the disparity, we introduced an intermolecular phonon ensemble to the calculations. The ensemble is presumed to closely concern a pile of FC type phonon vibrations.

The model structure employed is shown in Fig. 1. The revised calculation is then straightforward. The resultant spectrum for $\mathbf{d_0}$ is shown in Fig. 4 together with the uncorrected spectrum. Clearly, the revised spectrum is much close to the observed one. However, a question might be raised: Is such a band feature as shown in Fig. 1 due to another FC structure? Instead of the assumed intermolecular lattice vibrations, there are two intramolecular vibrations with small frequency as what comes under this category: the ϕ-$COCH_3$ tortional (i.e., ν_{45}) and the CH_3-rotational vibration (ν_{44}). As regards this, we have no unambiguous evidence which discriminates between them. However, we know that similar broad features also do appear for several other aromatic aldehydes with high τ (ϕ-CHO) potential barriers[2,4,17] and, further, almost all of these are explainable by FC-type phonon bands.[18] We are thus inclined to conclude that the substructure in the acetophenone crystal is also mostly explained by FC type intermolecular phonons.

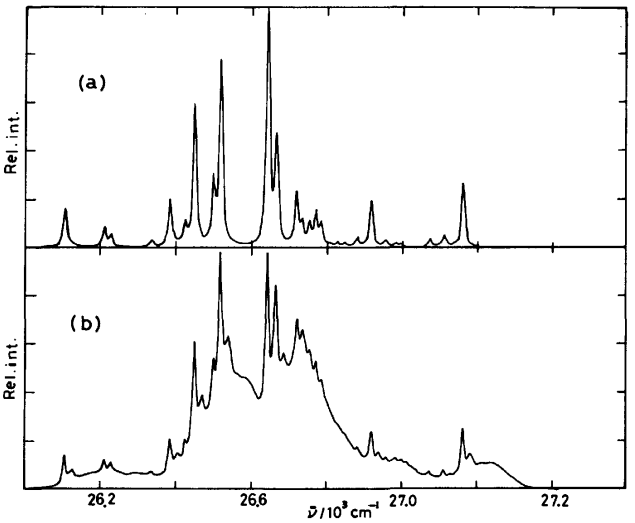

Fig. 4. Simulated T←S spectra of $\mathbf{d_0}$ at 0 K. (a) Without and (b) with the background phonon structure introduced (see the text and Fig. 1). Figure 4a is the same one as reported previously (cf. Fig. 4b of Ref. 1).

The calculations reported in this paper were carried out at the Computation Center of Kyushu University. This work was in part supported by a Grant-in-Aid from the Ministry of Education, Science and Culture (No. 62540358).

12) Despite many trials, only considerably broad bands were observed for the $S_1(n\pi^*)$←S_0 spectra of acetophenone in the crystal and in mixed crystals at 1.8 and 4.2 K. This is in big contrast to the T→S phosphorescence and T←S excitation spectra of acetophenone itself [and the $S_1(n\pi^*)$←S_0 spectra of benzaldehyde (see Ref. 4)]. The hosts employed were deuterated acetophenones, methylbenzoate, benzoic acid, pentane, hexane, methylcyclohexane, and benzene. See also Ref. 16 for a similar problem.

16) Aside from several minor points, recently reported supersonic jet T_1←S_0 spectra of acetophenone (Refs. 13 and 14) are in good accord with the predicted spectra (Ref. 19), one of which (the case of $\Delta E \approx -405\ cm^{-1}$ in the crystal where the minus means $T_1={}^3n\pi^*$) was demonstrated previously (see Fig. 5 in Ref. 1). Our preliminary calculation for the same system, but with $F_c=0$ (gas model), also shows that an almost similar band pattern is realized when $\Delta E[({}^3n\pi^*)-({}^3\pi\pi^*)]$ is small (say, less than $200\ cm^{-1}$). However, a problem is that there never appear remarkably intense two bands in the 70—90 cm^{-1} region in contrast to the observed jet spectra. According to our rough estimation, smallness in ν''_{45} frequency (e.g., $44\ cm^{-1}$ according to Ref. 3) requires that any jet experiments for a molecule with such a small fundamental frequency must be done at very low vibrational temperature [say, less than 20 K, at least, to attain a relation of I(hot-band system)<0.1×I(cold-band system)]. Because we believe that the S←S and a large part of the T←S jet spectrum of benzaldehyde (Ref. 13 and private communications from Prof. D. W. Pratt) quite resemble the corresponding spectra in methylcyclohexane matrices at 4.2 K (see Refs. 4, 6, 17 for the assignments and discussion), we wonder if an analogous discussion might be possible also for the acetophenone cases. For making the points clear, an investigation on the simulation T←S spectra of the vapor phase acetophenone is in progress.

Crystal and Molecular Structure of Double Macrocyclic Inclusion Complexes, γ-Cyclodextrin·12-Crown-4·NaCl, a Model for the Transport of Ions through Membranes

Shigehiro KAMITORI, Ken HIROTSU,* and Taiichi HIGUCHI
Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka 558
(Received April 28, 1988)

The crystal structure of a γ-cyclodextrin·12-crown-4·NaCl (3:3:1) inclusion complex was determined by an X-ray method to be space group $P42_12$, $a=b=23.816(3)$ Å, $c=23.072(3)$ Å. The inclusion complex has a C_4 symmetry, and the cation, Na^+, is coordinated by two 12-crown-4 molecules in a hydrophobic channel formed by tail-to-tail oriented two γ-cyclodextrin molecules.

γ-Cyclodextrin (CD) is a truncated cone-shaped cyclic oligosaccharide composed of eight D-glucoses. It has a hydrophobic cavity with a diameter of 8.5 Å, and eight hydroxyl groups (primary hydroxyl group) at the narrow side and sixteen hydroxyl groups (secondary hydroxyl group) at the wide side of the molecule. γ-CD has an ability to form inclusion complexes with various organic compounds, as well as α-CD and β-CD. It was therefore expected to mimic a biological function, such as enzyme catalysis.[1,2]

There have been many structural investigations of the inclusion compounds of α-CD and β-CD by X-ray crystal analyses, whose guest molecules are relatively rigid, e.g. benzene, adamantane, and their derivatives.[3,13] However X-ray structural studies of the CD's inclusion complexes which have flexible or functional molecules as guests have been very few. We expected that the structures of flexible guest molecules in the inclusion complexes are affected by the interior shape of the host molecules, and reported on an X-ray structural study of the γ-CD·12-crown-4 (1:1) inclusion complex.[14] The 12-crown-4 molecule is flexible and can have various conformations to form complexes with cations; also, its affinities to various cations are different, depending on cation diameters.[15] As expected, the 12-crown-4 molecule in a γ-CD cavity of approximate C_8 symmetry has a C_4 ring conformation, which was found in its complexes with cations, e.g. 12-crown-4·LiSCN,[16] $(12\text{-crown-4})_2NaClO_4$,[17] while free 12-crown-4 molecule has a C_i symmetry.[18] This result suggested that the 12-crown-4 molecules included in γ-CD cavities have an ability to coordinate cations.

Next, we prepared the crystals of two inclusion complexes composed of γ-CD, 12-crown-4, and Li^+ or K^+ cation,[19] and determined their crystal structures in order to reveal the cations' positions in the inclusion complexes. According to our work, a cation coordinates eight oxygen atoms of two 12-crown-4 molecules; this sandwich-type complex of $(12\text{-crown-4})_2\cdot Li^+$ or $(12\text{-crown-4})_2\cdot K^+$ was completely encapsulated in the hydrophobic channel formed by two tail-to-tail oriented γ-CD molecules. These double macrocyclic inclusion complexes showed some interesting characteristics, as follows: 1) Cations exist in a hydrophobic environment by means of 12-crown-4 molecules. 2) Because the $(12\text{-crown-4})_2$·cation complexes suffer from particular constraints of γ-CD cavities, abnormal structural changes in 12-crown-4·cation complexes occur, e.g. the cation-oxygen distances and the chirality of the 12-crown-4 ring conformation. 3) These double macrocyclic inclusion complexes may be models of the transport of ions through membranes; γ-CDs act as lipid bilayer membranes forming hydrophobic region in their interior,[3] and 12-crown-4 molecules act as ionophores.

Here, we report on the crystal structure of an inclusion complex composed of γ-CD, 12-crown-4 and Na^+, with an intermediate cation diameter between Li^+ and K^+. Na^+ forms a double macrocyclic inclusion complex as well as Li^+, K^+. We then tried to make a double macrocyclic inclusion complex with Rb^+; it was in vain because of the large cation diameter of Rb^+.

For a clear discussion, the inclusion complexes were numbered as follows:

γ-CD·12-crown-4 (1:1)	**(1)**
γ-CD·12-crown-4·LiSCN (3:3:1)	**(2)**
γ-CD·12-crown-4·NaCl (3:3:1)	**(3)**
γ-CD·12-crown-4·KCl (3:3:1)	**(4)**

Experimental

Preparation of the Crystalline Complex of γ-CD·12-Crown-4·NaCl (3:3:1) (3). Equimolar quantities of dry NaCl, 12-crown-4, and γ-CD were dissolved in a hot, aqueous solution, and left in an open test tube at 50 °C. Beautiful crystals of γ-CD·12-crown-4·NaCl appeared within 2 weeks.

X-Ray Structure Determination. A crystal for data collection, a rectangular block of 0.4×0.4×0.6 mm, was sealed in a glass capillary with a drop of mother liquor in order to avoid any crystal degradation. Diffraction intensities were measured on a Rigaku AFC-6A automatic diffractometer using Cu $K\alpha$ radiation ($\lambda=1.5418$ Å). Lattice constants were determined by least-squares methods with 20 reflections in $38°<2\theta<48°$. 3844 independent reflections (2833 with $I>3\sigma(I_0)$) were collected up to $2\theta=100°$, using a $\omega/2\theta$-scan mode at room temperature. No correction was

made for an absorption effect. Crystal data of **3** are as follows.

$C_{48}H_{80}O_{40} \cdot C_8H_{16}O_4 \cdot 1/3(NaCl) \cdot 7.7H_2O$, tetragonal, space group $P4_12_12$, $a=b=23.816$ (4)Å, $c=23.0.72(3)$Å, $Z=6$

This complex is isomorphous with the γ-CD·12-crown-4 inclusion complex **1** which we reported previously.[14] The phase problem was solved by using atomic coordinates of γ-CDs of **1**; guest molecules and water molecules were located on a difference Fourier synthesis.[20] One of the primary oxygen atoms O(6)1 is disordered at two positions (O(6)A1 and O(6)B1). The structures were refined to $R=0.168$ by full-matrix least-squares methods,[21] using isotropic temperature factors for all atoms. The R value is pretty high because of insufficient data at high angles in 2θ and the highly disordered water molecules. The quantity minimized was $\sum w(|F_o|-|F_c|)^2$ with $w=1.0$. Final atomic coordinates and temperature factors are given in Table 1. Tables of the complete bond distances and bond angles, and observed and calculated structure factor amplitudes, are deposited to the Chemical Society of Japan (Document No. 8831).

Results and Discussion

1. The Crystal Structure of γ-CD·12-Crown-4·NaCl Inclusion Complex (3). Three γ-CD molecules are stacked along the c-axis, forming a channel-type structure, and 12-crown-4 molecules are included in 1:1 stoichiometry in γ-CDs at the secondary sides of γ-CDs. Also, Na^+ is located between two γ-CD·12-crown-4 inclusion complexes, as shown in Fig. 1.[22] Host and guest molecules are centered on the four-fold crystallographic rotation axis so that three quarters of the γ-CD molecules are in an asymmetric unit. γ-CD **A** (the γ-CD molecule in the complex **A**) and γ-CD **B**, **B** and **C** and **C** and **A'** are in tail-to-tail, head-to-head, and tail-to-head orientations, respectively. Intermolec-

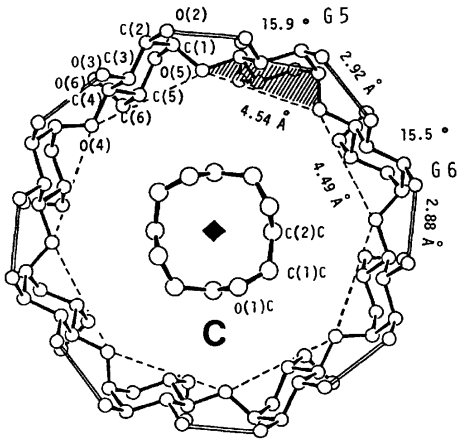

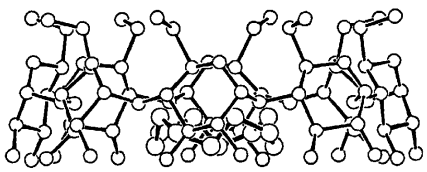

Fig. 3. The structure of the complex C with C_4 symmetry. One of O(4)'-C(1)-C(4)-O(4) atoms planes is indicated by hatching, and geometrical values are shown.

Table 2. Geometrical Data

Complex		H-Bond distance (Å)	Distance (Å)	Tilt-angle (°)
A	G1	2.81	4.45	11.9
	G2	2.80	4.55	11.3
B	G3	2.89	4.48	15.9
	G4	2.86	4.50	17.6
C	G5	2.92	4.54	15.9
	G6	2.89	4.49	15.5

a) The H-bond distance is defined as the O(3)n-O(2)n+1 distance. b) The distance is defined as the O(4)n-O(4)n+1 distance. c) The tilt-angle is defined as the angle made by (O)4 atoms plane and the plane formed by O(4)n+1, C(1)n, C(4)n, O(4)n of each glucose residue.

12-crown-4 molecules to form a 1:2 sandwich-structure complex, which is included by two tail-to-tail oriented γ-CDs **A** and **B**. Therefore, as shown in Fig. 2,[23] 12-crown-4 and γ-CD molecules could form complexs with Na^+ in a 2:2:1 ratio, as well as Li^+ and K^+. The distance between a Na^+ and Cl^- is 11.5 Å, showing a very weak electrostatic interaction between them.

The conformation of complex **B** is shown in Fig. 3, and the geometrical data of γ-CDs are given in Table 2, indicating very normal and more symmetrical structures compared with γ-CD hydrates.[24,25] As is well known, the secondary hydroxyl groups between neighboring glucose residues form intramolecular hydrogen bonds to maintain the round shape of the γ-CD ring; O(2)n···O(3)n+1 hydrogen bond distances are in the range 2.80—2.92 Å. The eight glycosidic O(4) oxygen atoms are coplanar within 0.01, 0.01, and 0.02 Å for γ-CDs **A**, **B**, and **C**, and the average distances of O(4)n···O(4)n+1 in each complex are 4.50, 4.49, and 4.51 Å. The glucose residues are inclined to the four-fold rotation axis so as to make the primary hydroxyl side narrow, and the secondary hydroxyl side wide. The tilt angles of glucose residues are defined as the angles made by the plane through O(4) atoms and the plane formed by O(4)n+1, C(1)n, C(4)n, O(4)n of each glucose.[24] The average tilt angles are 11.6, 16.8, and 15.7° for **A**, **B**, and **C**, respectively.

As pointed out in previous X-ray studies, the differences of the tilt angles among three γ-CDs are derived from the intermolecular hydrogen bonds between γ-CDs; the intermolecular hydrogen bonds between γ-CD **A** and **C** make the ring of γ-CD **A** wide at the primary site, so γ-CD **A** has more cylindrical geometry than **B** and **C**. This difference of γ-CD's geometries directly affects the locatins of 12-crown-4 molecules in **1**; the 12-crown-4 molecule is included more deeply in γ-CD **A** than in **B** and **C**, which have inclined cone structures. However, in **2**, **3**, and **4**, the existence of cations make this situation more complicated.

The interplanar distance between the four O(1) atoms plane of a 12-crown-4 molecule and the eight O(4) atoms plane of γ-CD could be adopted as an indicator of the inclusion depth. These distances in complexes **A** and **B** are given in Table 3 for **1**, **2**, **3**, and **4**. The distances of complexes **A** and **B** in **1** are 1.25 and 1.64 Å, respectively, and each value is the smallest among the corresponding complexes in Table 3, showing that each 12-crown-4 molecule of complexes **A** and **B** in **1** are deeply included in the γ-CD cavity. In the cases of **2**, **3**, and **4**, the locations of 12-crown-4 molecules depend not only on the shape of γ-CDs but also on the cation diameters. In **2** where the small cation, Li^+, exists, 12-crown-4 molecules are shallowly included in γ-CDs; on the other hand, in **4** 12-crown-4 molecules enter the γ-CD's cavities deeply due to the large cation diameter of K^+. In **3**, the distance at complex **A** is an intermediate value between the values of **2** (Li^+) and **4** (K^+), but the distance at complex **B** is almost same as in **2**. This result is due to the difference in the geometries of γ-CDs **A** and **B** mentioned above. Since γ-CD **A** is in a cylindrical structure and γ-CD **B** is in a cone-like structure, a 12-crown-4 molecule could more easily enter the cavity of γ-CD **A** than that of γ-CD **B**, as in **1**.

Table 3. Interplanar Distances

Complex	1	2	3	4
A	1.25	2.09	1.82	1.50
B	1.64	1.86	1.89	1.69

The conformation of the (12-crown-4)$_2$·Na^+ complex and the main short contacts between the γ-CD molecules and the (12-crown-4)$_2$·Na^+ complex are shown in Fig. 4. The structure of the (12-crown-4)$_2$·Na^+ complex in the hydrophobic channel of γ-CD molecules is quite normal. This complex has an approximate S_8 symmetry and the Na^+–O bond distances at the sites of complexes **A** and **B** are 2.58(5) and 2.58(4) Å, respectively. These values are normal compared with the Na^+–O distances of 2.474(8)—2.543(8) Å of (12-crown-4)$_2$·$NaClO_4$.[17] However, the Li^+–O distances of **2** are unusually long; 2.45(8) and 2.54(8) Å at complexes **A** and **B**. The Li^+–O average distance of the 12-crown-4·LiSCN 1:1 complex[26] is 2.08 Å, and that of [Li(12-crown-4)$_2$][$AsPh_2$] and

$[Li(12\text{-crown-}4)_2][PPh_2]$,[27] where Li^+ has a coordination number of 8, as in **2** is 2.35 Å. The attractive forces by the van der Waals interaction between 12-crown-4 molecules and γ-CD molecules make the Li^+–O bond distances long. The K^+–O bond distances of **3** are 2.80(8) and 2.99(9) Å at complexes **A** and **B**, respectively. Although in terms of the large esd's, these values are almost normal compared with the K^+–O distances of 2.77—2.83 Å in the 18-crown-6·KSCN complex,[28] the 12-crown-4 molecule can not form a complex with K^+ by itself.

2. Attempt to Form the Double Macrocyclic Inclusion Complex by 12-Crown-4, γ-CD and Rb^+. Comparing the interplanar distances at complexes **A** and **B** in **1** with the values in **4**, it was expected that 12-crown-4 molecules and γ-CDs might form a double macrocyclic inclusion complex with a larger cation than K^+, i.e. Rb^+. The crystal was prepared by the same procedure as in **3**, using RbCl instead of NaCl.

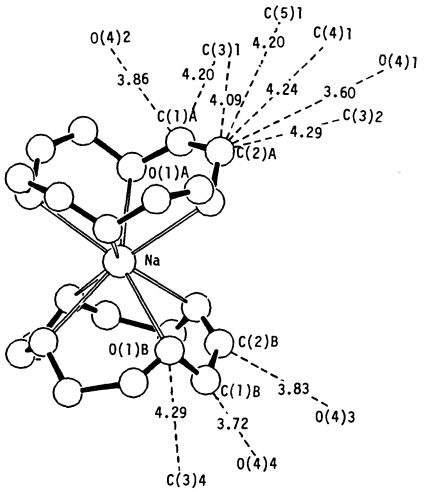

Fig. 4. The structures of $(12\text{-crown-}4)_2Na^+$ complexes. Intermolecular contacts with γ-CDs (less than 4.3 Å) are shown by dotted lines.

3845 independent reflections (2663 with $I > 3\sigma(I_0)$) were collected up to 100° in 2θ. A diffference Fourier synthesis was calculated using the atomic coordinates of the γ-CDs of **3**. Atoms of 12-crown-4 molecules were found, but the peak of cation did not appear, as is shown in Fig. 5. There was a very low peak (0.50, 0.0, 0.79) compared with the peak of Na^+. However, the peak of Rb^+ does not appear with a low ocupancy, but may be that of contaminated cation, probably Na^+ with a low occupancy, since, in **2**, a contaminated Na^+ of 1.9% was detected by atomic absorption analysis.[19] Therefore, this system composed of γ-CDs and 12-crown-4 molecules can not catch Rb^+ cations.

Conclusion

The Na^+ cation can exist in a hydrophobic circumstance of γ-CD cavities by forming a sandwich structure complex with two 12-crown-4 molecules, as well as Li^+ and K^+. The $(12\text{-crown-}4)_2\cdot Na^+$ sandwich structure complex in the γ-CDs **A** and **B** has normal Na^+–O bond distances, while unusually long Li^+–O bond distances of 2.45 and 2.54 Å were found in **2**.[19] The cation–oxygen bond distances are mainly determined by two interactions, i.e., electrostatic interaction between the cation and oxygen atoms of 12-crown-4 molecules, and van der Waals interaction between 12-crown-4 molecules and γ-CDs. The latter strongly affects the Li^+–O bond distances in **2**. The Na^+ may be more fit to enter the space between complexes **A** and **B** than Li^+, since these two interactions are reasonably balanced in **3**.

These double macrocyclic inclusion complexes catching cations may be models of the transport of ions through lipid bilayer membranes by an ionophore, such as Valinomycin. Although CD molecules are not as flexible as lipid bilayer membranes, the channel of two tail-to-tail oriented CDs, γ-CDs **A** and **B** in this paper, is analogous to lipid bilayer membranes at several points, such as the existence in

an aqueous solution and the exchange of their guest molecules, as described by Stezowski et al.[3] The presented system, that γ-CDs include cations through the intermediary of the hydrophobic methylene rings of 12-crown-4 molecules, is similar to the situation that lipid bilayer membranes permit cations caught by ionophores to diffuse in them by an interaction between the hydrophobic interior of membranes and the hydrophobic exterior of ionophore·cation complexes.

This system could also have ion selectivity by the above-mentioned interactions among γ-CDs, 12-crown-4 molecules and cations. From only the presented work about this system, it is difficult to elucidate the difference of affinities of the double macrocyclic inclusion complex to three cations (Li^+, Na^+, and K^+) in detail. However, at least, the affinity of this system to Rb^+ is very small.

We are indebted to the Crystallographic Research Center, Institute for Protein Research, Osaka University, for computer calculations. We thank Nihon Shokuhin Kako Co., Ltd., Tokyo, Japan for a supply of γ-CD. This work was supported by a Grant-in-Aid for Special Project Reseach (No. 62216018) from the Ministry of Education, Science and Culture.

(Received April 30, 1988)

A series of $La_{2-x}Sr_xNiO_4$ catalysts (x=0—1.0) with a K_2NiF_4-type structure were prepared, and the average oxidation number of the Ni ion and the stoichiometry of the oxygen in the catalysts were measured. We also investigated the relationships between the reactivity of the catalysts and their catalytic activity for oxidation. The average oxidation number of the Ni ion increased monotonously from 2.32 (x=0) to 2.90 (x=1.0) upon the Sr substitution, and the composition changed with the x value from oxygen-excess (x=0—0.2) to oxygen-deficient (x=0.6—1.0), via a stoichiometric composition at x=0.4. In the range of x=0—0.2 (oxygen excess), the desorption peaks of oxygen in TPD (temperature-programmed desorption) were observed at about 300 °C; these results were ascribable to the excess oxygen. In this range, the oxidizing power of the surface, which was measured by the reduction of the catalysts by CO, was comparatively high. For x=0.4—1.0 (stoichiometric to oxygen-deficient), the oxygen desorbed at a higher temperature, and the amounts increased in accordance with the increase in the oxygen deficiency. The oxidizing power of the surface similarly increased with x values up to x=0.8. The composition of metal on the surface generally reflected that in the bulk, as judged from XPS. The catalytic activity for the oxidation was in parallel with the oxidizing power of the surface in x=0.4—1.0.

K_2NiF_4-type mixed oxide (A_2BO_4) consists of alternating layers of ABO_3 perovskite and AO rock salt, being a kind of two-dimensional analogue of perovskite.[1] K_2NiF_4-type oxides with various A- and B-site metal ions are known,[2] as in the case of perovskite-type mixed oxides.[3] It is also possible to control the valence and stoichiometry by the appropriate substitution of constituent metal elements. Hence, a series of catalysts with a K_2NiF_4-type structure are suitable materials for research into the relationships between the reactivity of the oxygen on the surface and in the bulk and the catalytic activity, as in the case of such perovskites as $LnBO_3$ (Ln: rare earth, B: Mn, Fe, Co).[4-8]

Recently we reported the catalytic activity of $La_{2-x}Sr_xCoO_4$, a K_2NiF_4-type mixed oxide, and compared the results with those for $La_{1-x}Sr_xCoO_3$, perovskite.[9] In the case of simple 3d-transition metal oxides, nickel oxide shows a relatively high oxidation activity, coming next to cobalt and manganese oxides,[10] while $LaNiO_3$ perovskite shows an activity in the same level.[4,11] However, $LaNiO_3$ is not stable on a usual atmosphere, and the preparation of Sr-substituted $LaNiO_3$ is very difficult under ordinary conditions. Therefore, in the present study, we prepared a series of Sr-substituted La_2NiO_4 catalysts and determined the valence of the nickel ion at the B-site and the change in the nonstoichiometry of oxygen upon the Sr substitution. We also measured the catalytic activities for oxidation as well as the reactivity of the oxygen on the surface and in the bulk of the catalysts, and discussed the relationships between them.

Experimental

Preparation of $La_{2-x}Sr_xNiO_4$. The $La_{2-x}Sr_xNiO_4$ (x=0—1.5) catalysts (the actual compositions of these mixed oxides were, in general, nonstoichiometric, $La_{2-x}Sr_xNiO_{4+\delta}$, but the stoichiometric formulae will be used in this paper unless explicit presentation is necessary) were prepared from mixtures of acetates of the metal components. First, the mixed acetate solution was evaporated to dryness in a rotary evaporator (70 °C), and then the residual solid was decomposed in air at 300 °C for 3 h and finally calcined in a quartz crucible in air at 1000 °C for 10 h.

Powder X-ray diffraction patterns were recorded on a powder X-ray diffractometer (Rigaku Denki, Geigerflex, RAD-IIA) using Cu $K\alpha$ radiation. The surface area of the samples was measured by the BET method (static N_2 adsorption; Micromeritics; AccuSorb 2100).

The oxidation number of the nickel ion in the catalysts was measured by means of iodometry. This method has usually been used as a direct method for the measurement of the excess oxygen in nickel oxide[12] and for the measurement of the average oxidation number of a Co or Ni ion in mixed oxides.[13] A sample (ca. 100 mg) which was dried at 100 °C for 3 h was dissolved in 25 ml of 0.4 mol l^{-1} HCl plus 25 ml of 0.16 mol l^{-1} KI aqueous solution. The solution was then titrated with a standard thiosulfate solution.

The composition of metal ions was determined with the aid of inductively coupled plasma spectrometry (ICP) (Nippon Jarrell-Ash, ICAP-575-II). The X-ray photoelectron spectra (XPS) were obtained with a Shimadzu ESCA-750 apparatus employing Mg $K\alpha$ radiation (1253.6 eV) under a high vacuum of 10^{-6} Pa. The binding energy was calibrated by using a Cls electron line (285.0 eV) coming from the background.

Apparatus. Conventional flow and pulse systems described previously were used.[4-6]

Procedure. Temperature Programmed Desorption (TPD) of Oxygen: The TPD of oxygen was carried out with a flow system using helium as the carrier gas. Prior to each run, the sample (1.0 g) was pretreated in an O_2 stream for 1 h at 800 °C and then cooled to room temperature. Then, O_2 was replaced by He at room temperature. Any oxygen impurity in He was removed by the use of a Molecular Sieve (MS) 5A

trap kept at the temperature of liquid nitrogen. The temperature of the sample was raised at a constant rate of 20 deg min^{-1} in the He stream (25 cm^3 min^{-1}), and the oxygen desorbed was detected with a thermal conductivity detector. It was confirmed by a gas chromatograph that only oxygen existed in the effluent He gas. The TPD curves were reproduced in repeated runs (3 times) after the pretreatments above.

Reduction of Catalysts by CO: The reduction of the catalysts by CO was conducted in the pulse reactor. Prior to the reaction, the catalysts (50 mg) were treated in an O_2 stream (20 cm^3 min^{-1}) for 1 h at 300 °C, and then the O_2 stream was replaced by a He stream purified by the use of a MS-5A trap kept at the temperature of liquid N_2. The flow rate of the carrier gas (He) was 25 cm^3 min^{-1}, and the size of each pulse was 0.1 cm^3. The products were analyzed by means of a gas chromatograph.

Oxidation of Propane: The catalytic oxidation of propane was carried out with a flow system. Prior to each reaction, the catalysts (300 mg) were treated in an O_2 stream for 1 h at 300 °C. A gas mixture of propane (0.83%), O_2 (33.3%), and N_2 (balance) was fed into the reactor. The flow rate of the mixed gas was 60 cm^3 min^{-1}. The products were analyzed by means of a gas chromatograph.

Results

Catalysts and Their Physical Properties. The surface area, the crystal structure, and the compositions of the prepared catalysts, $La_{2-x}Sr_xNiO_4$, are summarized in Table 1. In the range of x=0—1.0, samples with a tetragonal K_2NiF_4-type structure were obtained, judging from the XRD patterns. At x=1.5, the sample was a mixture of K_2NiF_4-type oxide, SrO, and NiO, the content of the latter two both being about 10—20%. No XRD peaks of La_2O_3 were observed. The surface areas of the samples were all less than 3 m^2 g^{-1} because of the high calcination temperature, and they tended to increase with the x value. The bulk compositions of the metal ions measured by ICP are shown in Fig. 1. The bulk composition agreed well with the nominal composition expected from the quantities of starting materials, within the limits of experimental error. Hence, there was no substantial loss of any specific components during the preparation of the catalysts (for example, evaporation during the calcination).

Figure 2 shows the average oxidation number of the nickel ion at the B-site, as measured by iodometry. The average oxidation number of the nickel ion increased monotonously from 2.32 (x=0) to 2.90 (x=1.0) with the increase in x, as has been expected. It should further be noted that the nonstoichiometry varied from an oxygen-excess composition for x=0—0.2, through almost a stoichiometric one for x=0.4, to an oxygen-deficient one (x=0.6—1.0).

TPD of Oxygen. Figure 3 shows the TPD profiles of oxygen from the catalysts, where the rate of desorption, as calculated from the oxygen concentration in the effluent gas, is plotted against the catalyst temperature. As is shown in this figure, the amount of the oxygen desorbed below 800 °C decreased with the

Table 2. The Amount of Oxygen Desorption, the Corresponding Layers, and the Change in the Nonstoichiometry (see text)

x	Amount of oxygen desorbed/cm³ g⁻¹	Corresponding layer	$\Delta\delta$
0	2.48	8.6	0.09
0.2	1.77	5.0	0.06
0.4	0.26	0.8	0.01
0.6	0.30	0.7	0.01
0.8	0.78	1.5	0.03
1.0	3.25	6.3	0.10

a) The amount of oxygen in TPD desorbed up to 800 °C. The surface layers corresponding to the amounts of desorbed oxygen (assuming that the amount of oxygen in the surface monolayer was 0.96×10^{19} atom m^{-2}). The change in the nonstoichiometry attributed to the oxygen desorption ($\Delta\delta$: $La_{2-x}Sr_xNiO_{4+\delta-\Delta\delta}$).

increase in the Sr content in the range of x=0—0.4, showed a minimum at x=0.4, and then increased with x (x=0.4—1.0). The TPD profiles for x=0 and 0.2 were similar to each other, both having a peak at around 300 °C, but were quite different from those for x=0.4—1.0. This difference in the TPD profiles seems to correspond to the transition of the nonstoichiometry of the catalysts from an oxygen-excess (x=0—0.2) to a stoichiometric and an oxygen-deficient composition (x=0.4—1.0).

The amounts of oxygen desorbed below 800 °C, as well as the number of surface layers and the change in the nonstoichiometry (δ) corresponding to the amounts of oxygen, are shown in Table 2, where the surface layers were calculated by assuming that the density of the oxygen in the monolayer is 0.96×10^{19} atom m^{-2} and where the change of the nonstoichiometry, $\Delta\delta$, caused by desorption was expressed by; $La_{2-x}Sr_xNiO_{4+\delta-\Delta\delta}$. All of these values varied in a similar way, showing a minimum at x=0.4—0.6. The amounts of oxygen desorbed were always more than one surface monolayer except for the values of x=0.4 and 0.6. This indicates that the desorption of the lattice oxygen in the bulk took place in addition to the adsorbed oxygen. In the range of x=0.4—0.6, the nonstoichiometry and the average oxidation number

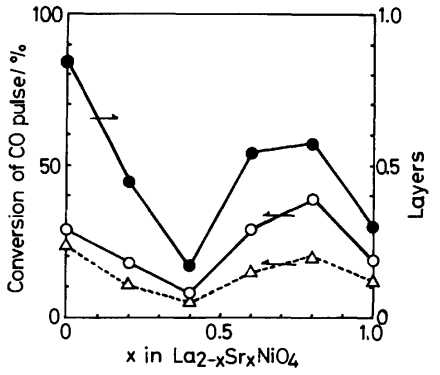

Fig. 4. The % conversion of CO to CO_2 in the first and in the fifth pulse and the amount of oxygen consumed by the first CO pulse in the unit of surface layers.
O: the first pulse, △: the fifth pulse, ●: layers.

of the Ni ion in catalysts, being nearly stoichiometric, are less influenced by the change in the atmosphere (partial oxygen pressure) or the temperature.

Reduction of the Catalyst by CO (Oxidizing Power of the Surface). The % conversions of CO to CO_2 decreased gradually upon repeated pulses (at 10 min intervals). The decrease was smaller for x=0—0.2 (oxygen-excess) than for x=0.6—1.0 (oxygen-deficient). The values in the first and fifth pulses are shown in Fig. 4, where the amount of oxygen consumed by the first CO pulse is also given in the unit of surface layers. The conversion may be regarded as a measure of the oxidizing power per unit of catalyst weight. The oxidizing power expressed by the % conversion in the first pulse decreased first with the increase in x, showing its lowest value at x=0.4. It then increased with x up to x=0.8 and decreased at x=1.0. The amount of oxygen consumed by the first CO pulse for x=0 corresponded to about 6% of the excess oxygen. As this amount was less than the monolayer, this value may express the oxidizing power of the catalyst surface (the reducibility of the surface).

Surface Composition of the Catalyst. The surface compositions of the catalysts were measured by XPS; the results are shown in Fig. 5, where Eq. 1[14] was used for the calculation.

$$(N_a/N_b) = (n_a/n_b)(\lambda_a/\lambda_b)(\sigma_a/\sigma_b)(S_a/S_b) \quad (1)$$

where N: peak intensity, n: atoms per unit volume, λ: mean free path of the electron, σ: ionization cross section, and S: instrumental factor. The peak areas of La4d, Sr3d, and Ni3p, including the satellite peak, were used for N, while the values of σ were taken from the literature.[15] "$\lambda\cdot S$" was assumed to be constant, as in a previous work.[16] The surface compositions of the catalysts, as determined by Eq. 1, are not very accurate, but they may be sufficient to compare the relative change in the surface composition for a series of catalysts. As may be seen from this figure, though the

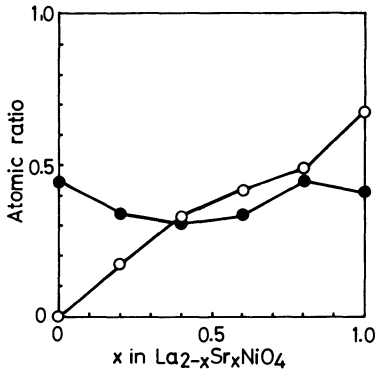

Fig. 5. The surface composition of metal ion determined by XPS.
O: Sr/La+Sr, ●: Ni/La+Sr.

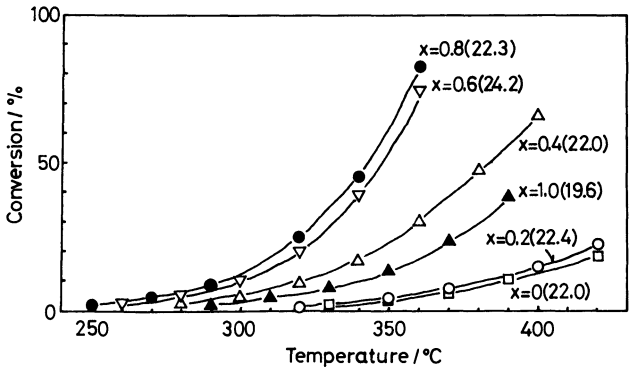

Fig. 6. The catalytic activity for propane oxidation over $La_{2-x}Sr_xNiO_4$. The activation energy in parenthesis: kcal mol^{-1}.

atomic ratio at Sr in the A-site (O) increased monotonously with x, this value was generally higher than that in the bulk composition. On the other hand, the atomic ratio of the Ni ion was considerably lower than that in the bulk, except for the values of x=0 and 0.8. The ratio of La:Sr:Ni, as calculated from Eq. 1, was 51:25:24 (54:13:33 in the bulk) at x=0.4 and 33:34:31 (bulk, 40:27:33) at x=0.8. The binding energies of La4d, Sr3d, and Ni3p in XPS changed little from one catalyst to another.

Catalytic Activity for the Complete Oxidation of Propane. The activity for the propane oxidation is shown in Fig. 6. The only reaction products were CO_2 and H_2O for all the catalysts. As is shown in this figure, the oxidation activities per unit of weight of the catalysts were very low at x=0—0.2; they then became higher with x up to x=0.8 and then decreased at x=1.0, showing a maximum at x=0.8. The activation energy obtained from the data at a low conversion level (below 10%) was 19.6—24.1 kcal mol^{-1}, as is shown in parentheses in Fig. 6.

Discussion

Structure and Composition of $La_{2-x}Sr_xNiO_4$. As K_2NiF_4-type mixed oxides often show interesting electrical properties, quite a few studies have been reported about this type of mixed oxides, formed by various A- and B-site ions.[2] The structure and the electrical properties of $La_{2-x}Sr_xNiO_4$ have also been studied.[17-19] All of these reports show that $La_{2-x}Sr_xNiO_4$ has a K_2NiF_4-type structure in the range of x=0—1.0, in agreement with the results of the present study. However, the formation of a K_2NiF_4 structure with x=1.5 has not been reported. The reason may be the necessity of an extremely high and unstable oxidation state of tetravalent Ni. This corresponds to the difficulty of Sr substitution in $LaNiO_3$ perovskite.

In the case of La_2NiO_4, a part of the Ni ion is oxidized to make it trivalent, since its tolerance factor is close to the lower limit of the tetragonal K_2NiF_4-type structure.[2] Hence, the composition becomes oxygen-excess. The average oxidation number of the Ni ion (2.32) and the oxygen-excess composition observed for x=0 in the present work are consistent with those data. It is probable that cation deficiencies at both A- and B-sites were formed in La_2NiO_4, as in the case of $LaMnO_3$.[20] The oxidation number of the Ni ion increased monotonously from 2.32 (x=0) to 2.90 (x=1.0) with the increase in the extent of the Sr substitution for the A-site (Table 1). Gopalakrishnan et al. also reported a monotonous increase in the number from 2.15 (x=0) to 3.00 (x=1.0)[17] with a change in the stoichiometry with x from an oxygen-excess to a stoichiometric composition. This trend is consistent with that found in the present work, except that the composition in the present work became oxygen-deficient at a higher x value.. This difference may be due to the different calcination conditions. In this work, the oxides were calcined in air at 1000 °C, while in the oxygen these were caclined at 1200 °C for more than 72 h for x=0.4—1.0 in their case.

The valence control of the B-site ion as well as the variation in the nonstoichiometry upon the Sr substitution obtained in this work may be compared with those results previously obtained for perovskites and $La_{2-x}Sr_xCoO_4$. In the case of $La_{2-x}Sr_xCoO_4$, the average oxidation number of the Co ion increased monotonously from 2.28 (x=0) to 3.34 (x=1.5) with the increase in x, and its composition varied from $La_2CoO_{4.14}$ to $La_{0.5}Sr_{1.5}CoO_{3.92}$.[9] This variation is very similar to that found in this study for $La_{2-x}Sr_xNiO_4$. The change in nonstoichiometry was also similar for $La_{1-x}Sr_xMnO_3$.[8] On the other hand, in the case of the $La_{1-x}Sr_xCoO_3$ or $La_{1-x}Sr_xFeO_3$ system,[6,7] although the averag oxidation number of the B-site ion increased monotonously with the x value, the composition varied from stoichiometric to oxygen-deficient. This variation corresponds to that found in the present study for $La_{2-x}Sr_xNiO_4$ above x=0.4.

Thus, it may be stated that the $La_{2-x}Sr_xNiO_4$

catalysts prepared in the present study have well-controlled oxidation numbers of the Ni ion and nonstoichiometry, in general agreement with those of the previous studies of related mixed oxides.

The Effect of Sr Substitution on the Oxidizing Power of the Surface, the Surface Composition, and the TPD. The oxidizing power of the surface, as measured by the CO pulse, varied as is shown in Fig. 4. This trend appears to correspond closely to the changes in the nonstoichiometry and the TPD profiles. The initial decrease in the oxidizing power (x=0—0.4) apparently parallels the desorption peak at about 300 °C in the TPD.[21] On the other hand, the variation in the oxidizing power of the surface in the range of x=0.4—0.8 corresponds to the variation in the oxygen desorption in TPD in the high-temperature region. The low oxidizing power of the surface at x=1.0 may be due to the stability of the oxygen-deficient composition or to the formation of a Sr^- rich phase on the surface, as will be described below.

The reactivity of the oxide ion in the bulk may be seen in the TPD profiles (Fig. 3). In x=0—0.2, the large peaks in the TPD profiles at about 300 °C are ascribed to the desorption of the excess oxygen (the amount of oxygen desorbed was about 4 times the monolayer).

For x=0.4—1.0, the TPD profiles were similar, with no peak at about 300 °C, and the amount of the desorbed oxygen increased with the x. The oxygen desorbed at a higher temperature may be assigned to the formation of the oxygen deficiency if one considers the relationship between the amounts of desorbed oxygen, the valence change in the B-site ion, and the change in the nonstoichiometry (Table 2). Consequently, the valence control by the following scheme, as in the $La_{1-x}Sr_xCoO_3$ system,[4-6] is probable for x=0.4—1.0.

$$La_2^{3+}Ni^{2+}O_4 \xrightarrow{Sr^{2+}} La_{2-x}^{3+}Sr_x^{2+}Ni_{1-x}^{2+}Ni_x^{3+}O_4 \quad (2)$$

$$La_{2-x}Sr_xNi_{1-x}^{2+}Ni_x^{3+}O_4 \longrightarrow La_{2-x}Sr_xNi_{1-x+2\delta}^{2+}Ni_{x-2\delta}^{3+}O_{4-\delta} + \delta/2O_2 \quad (3)$$

First, a some of the divalent Ni ions are oxidized to the trivalent state upon the Sr substitution (Eq. 2). With further Sr substitution, the oxygen desorbs, forming a lattice oxygen deficiency, therefore, a some of the trivalent Ni ions are reduced to the divalent state (Eq. 3). The lattice oxygen deficiency should tend to increase with the increase in x and the rise in the temperature, as reflected in the TPD profiles at x=0.4—1.0.

The concentration of Sr on the surface was higher than that in the bulk in the whole range of x values studies. Especially at x=1.0, Sr occupied about half of the metal ions on the surface layer (about 33%, in bulk). Accordingly, a Sr-rich phase on the surface, which may be formed in this catalyst, is a possible reason for the lower oxidizing power of the surface at x=1.0. The Ni concentration on the surface varied with the x value, but it accounted for 24—33% of the total metal ions; this value did not change much among the catalysts, though it was always lower than the concentration in the bulk. On the whole, though the bulk composition was generally reflected in the surface composition, caution must be exercised when the property in the bulk is used for the discussion of the surface properties.

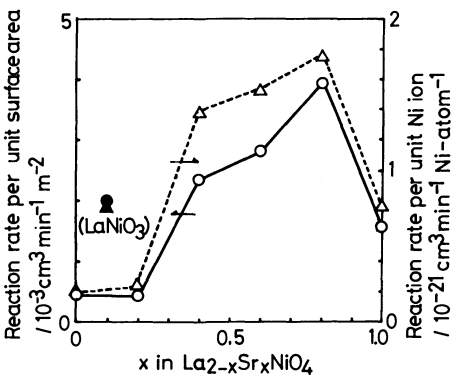

Fig. 7. The reaction rate for propane oxidation at 227 °C per unit surface area and unit Ni ion on the surface.

The Effect of Sr Substitution on the Catalytic Activity for Oxidation. Though the catalytic properties of $LaNiO_3$ perovskite have been reported in several papers,[22] there have been only a few studies of the catalysis of La_2NiO_4,[23-25] and no studies on the effect of the valence control have been reported. When the catalytic activity for oxidation is compared per unit of surface area of the catalysts, the catalytic activities of x=0.4—0.8 in this work were comparable with or higher than that of $LaNiO_3$[4] (Fig. 7). The reaction rate of the propane oxidation, normalized to the Ni atom on the surface, is also shown in Fig. 7; it was calculated from the surface composition (Fig. 5).[26] The activity per surface Ni ion thus calculated was higher for $La_{2-x}Sr_xNiO_4$ (x=0.4—0.8) than for $LaNiO_3$.

The catalytic activity for oxidation increased steeply from x=0.2 to 0.4 (Fig. 7). If one considers this result together with the changes in the composition, the TPD profiles, and the oxidizing power of the surface described above, the catalysts may be divided again into two groups, x=0—0.2 and 0.4—1.0.

First we will discuss the latter group. In this range (x=0.4—1.0), the oxygen deficiency and the reactivity of the lattice oxygen increased with the x value up to x=0.8. A similar increase in the catalytic activity has already been reported for $La_{1-x}Sr_xCoO_3$ perovskite.[4-6] Further, the oxidizing power of the surface and the oxidation activity showed parallel variations in this range of x, as in the cases of $La_{1-x}Sr_xMnO_3$ and $La_{2-x}Sr_xCoO_4$.[8,9] It is noteworthy that the oxidizing power of the surface showed a maximum where the

composition of the catalysts was slightly shifted from stoichiometric to oxygen-deficient. It is probable that, in this state, the redox cycles of the desorption and adsorption of oxygen on the surface and/or in the vicinity of the surface occurred smoothly; therefore, the catalytic activity increased. Hence, the catalytic activity in the present Ni system is closely related to the reactivity of the oxygen on the surface, as in $La_{1-x}Sr_xMnO_3$,[8] but the contribution of the oxygen in the bulk may not be neglected, especially in x=0.4—1.0, as in $La_{1-x}Sr_xCoO_3$.[4-6]

On the other hand, in the range of x=0—0.2, the oxidation activity was low, although large peaks were observed around 300 °C (due to the excess oxygen) in TPD and the oxidizing power of the surface was comparatively high. It may be suggested as the reason for this discrepancy that the excess oxygen is inactive for the catalytic oxidation reaction, although it is responsible for the TPD peaks at about 300 °C and the reducibility of the surface. In the cases of $La_{1-x}Sr_xMnO_3$ and $La_{2-x}Sr_xCoO_4$, the composition for low x values was oxygen-excess[8,9] and the catalytic activities were lower than for those with higher x values. This result also indicates that the low catalytic activity is correlated to the oxygen-excess composition. The reason for this is not clear at present, but it is possible that the ability of the dissociation or the activation of the oxygen is low because of the very small oxygen deficiency on the surface, as in the case of $La_{1-x}Sr_xMnO_3$.[8]

Conclusion

A series of $La_{2-x}Sr_xNiO_4$ (x=0—1.0) catalysts with a K_2NiF_4-type structure were prepared. With the increase in the x value, the average oxidation number of the Ni ion increased monotonously from 2.32 (x=0) to 2.90 (x=1.0) and the nonstoichiometry changed from an oxygen-excess to an oxygen-deficient composition via a stoichiometric one.

Based on the variation in the TPD of oxygen and the oxidizing power of the catalyst surface (as measured by the CO pulse), the catalysts were divided into two groups; (1) x=0—0.2 (oxygen-excess composition) and (2) x=0.4—1.0 (stoichiometric and oxygen-deficient). In Group (1), the desorption peak of oxygen ascribable to the excess oxygen was observed at about 300 °C, and the oxidizing power of the surface was comparatively high. On the other hand, in Group (2) oxygen desorbed at a relatively high temperature, with the formation of a lattice oxygen deficiency. The amount of oxygen desorbed and the oxidizing power of the surface increased from x=0.4 to x=0.8, much as with other perovskites and K_2NiF_4-type oxides.

The catalytic activity for the oxidation was in parallel with the oxidizing power of the surface in Group (2). However, the catalytic activity of Group (1) was low in spite of the considerable oxidizing power of the surface. Though the reason for this is not clear at present, it appears that the excess oxygen was inactive for the catalytical oxidation and/or that the ability of dissociation and activation of the oxygen on the surface was low.

21) Here, it must be considered that, in the CO pulse experiments, the catalysts were pretreated in a He stream at 300 °C, so the oxidation state may be different between the CO pulse and TPD experiments. In the TPD profile of x=0 after the pretreatment in the CO pulse, the peak about 300 °C did not appear, while oxygen desorption started at 320 °C. However, the composition of this sample was $La_2NiO_{4.11}$, still an oxygen-excess composition; therefore, the oxidizing power of the surface measured as in the CO pulse experiment must be related to this excess oxygen.

26) The calculation was carried out by assuming that the amounts of the surface oxygen of a perovskite and a K_2NiF_4-type oxide are the same and that the total numbers of metal ions on the surface are 2/3 (perovskite) and 3/4 (K_2NiF_4-type oxide) the number of oxygen atoms. The La:Ni ratio was used as the surface composition of $LaNiO_3$ (unpublished data by T. Nitadori and M. Misono).

Catalytic Activity of Nb-Si Mixed Oxides Induced by Reduction with Hydrogen

Yuji WADA,* Masakatsu INAIDA, Yasushi MURAKAMI, and Akira MORIKAWA
Department of Chemical Engineering, Tokyo Institute of Technology, O-okayama, Meguro-ku, Tokyo 152
(Received May 9, 1988)

Mixed oxides of niobium and silicon became catalytically active for butene isomerization by a reduction with hydrogen, and their catalytic activities depended on the duration of the reduction. The activity was irreversibly poisoned by oxygen. The formation of Nb^{4+} by the hydrogen reduction was revealed by ESR technique. Nb^{4+} was oxidized to Nb^{5+} by the admission of oxygen gas, and at the same time O_2^- was formed. It was concluded that the catalytically active site on the mixed oxide surface was Nb^{4+} ion formed by the reduction. The importance of isolation of Nb^{4+} ion in silica network was suggested for the retention of the catalytic activity.

It has been pointed out that the geometry of a surface in the molecular dimension, such as a step or kink, is an important factor for metal crystalline catalysts resulting in structure sensitive and insensitive reactions.[1] For metal oxide catalysts, however, it is still not clear whether this type of concept can be a leading principle for interpreting their catalytic activity, since most of metal oxide catalysts are amorphous in their structure in the working state. Even for some oxides of tungsten,[2] vanadium,[3] and rhenium,[4] whose catalytic activities depend on their type of crystal phase, a relation between their catalysis and the microscopic geometry of their surface has not yet been well understood.

The authors have observed that niobium oxide, which was catalytically inactive for butene isomerization, became active for a reaction through only a slight reduction in the mixture of hydrogen gas and water vapor.[5] The catalytic activity induced by the reduction depended on the extent of the reduction; it increased with the extent of the reduction up to a composition of $NbO_{2.494}$, and then decreased by a further reduction, though the niobium oxide of the compositions between $NbO_{2.500}$ and $NbO_{2.488}$ maintains a T-type crystal structure. These facts have led us to the idea that the high dispersion of niobium(IV) ions, which is achieved by a slight reduction, is important for maintaining the catalytic activity of the reduced niobium oxide.[5] In other words, the geometric environment around Nb^{4+}, which depends on its dispersion, may determine whether Nb^{4+} becomes catalytically active or not.

To elucidate the roll of the dispersion for catalysis on reduced niobium oxide, the authors have examined the catalytic properties of mixed oxides of niobium and silicon, since niobium ions are probably dispersed in an inactive matrix of silica. The amount of Nb contained in the oxide can be changed to a wide extent so that the dispersion can be controlled over a wide range.

Experimental

Preparation of Catalysts. Niobium chloride with a purity of 99.97% (kindly supplied by Prof. Nangyo at Tohoku Univ.) was dissolved into ethanol at a concentration of 0.1 mol-Nb/l under a dry nitrogen atmospher. This solution was mixed with ethyl orthosilicate(Wako Chemical Co., Research Grade) and stirred for 0.5 h. A coprecipitate obtained by adding agueous ammonia to the above-mentioned mixture was aged for 14 h at room temperature. The coprecipitate was heated at 373 K to remove ethanol and was washed with deionized water until chloride ion was undetectable by a test with an aqueous silver nitrate solution. It was then dried on a hot-water bath and calcined at 873 K for 2 h in air. The catalyst is denoted as Nb-Si(number), where the number in the parentheses indicates 100 Nb/(Nb+Si). The X-ray diffraction spectra of the catalysts showed that they maintained an amorphous structure, even after being calcined at 873 K, though pure niobium oxide was crystallized by calcination at the same temperature, indicating that niobium atoms were well dispersed in the oxides so as to be unable to form an ordered structure.

Procedures. The reaction was carried out with a conventional gas-circulation system of 320 ml. A catalyst of 50 mg was heated at 823 K in oxygen gas for 1 h and then degassed for 0.5 h. The catalyst was reduced with hydrogen gas at 823 K. Water formed by the reduction of the catalyst was collected with a trap cooled with liquid nitrogen. After cooling the catalyst to 298 K, the reaction was started by introducing *cis*-2-butene to the reaction system. The composition of the reaction mixture was determined by gas chromatography.

ESR Measurement. The ESR spectra were recorded with a JEOL-PE-1X at 77 K. The catalyst was pretreated in the same manner as described in the above section. A tube made of quartz for ESR measurements was connected to the upper part of the reaction cell. The catalyst preliminarily pretreated in the cell was transferred to the tube for ESR measurements. A small space was provided at the top of the tube to admit oxygen gas onto the catalyst. For the observation of a tetracyanoethylene (TCNE) radical, a benzene solution of TCNE (1 ml, 8×10^{-2} mol l^{-1}) was brought into contact with the pretreated catalyst in the ESR tube. The spin density was determined by a comparison of

the ESR signal of the samples with that of Mn^{2+} inserted in the ESR cavity. The latter has been frequently titrated by a standard benzene solution of DPPH in the same condition of ESR measurements applied to the samples.

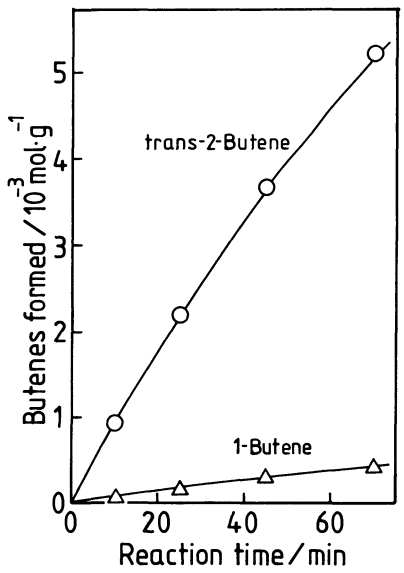

Fig. 1. Isomerization of *cis*-2-butene on the reduced Nb-Si(10). The catalyst was reduced with hydrogen gas at 823 K for 2.5 h. The reaction was carried out at 298 K with a pressure of *cis*-2-butene, 1.33×10^5 Pa.

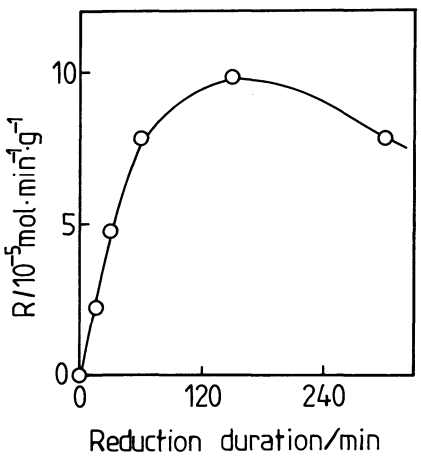

Fig. 2. Dependence of the catalytic activity of the Nb-Si(10) mixed oxide on the reduction duration at 823 K. The reaction conditions were the same as in Fig. 1.

Table 1. Poisoning of the Reduced Nb-Si(10) Mixed Oxide Catalyst

Additive	Non	O_2	NO	N_2O	CO	NH_3
Amount[a)]	—	0.8	6.0	6.0	6.0	6.0
Activity[b)]	2.3	0.2	0.0	1.2	1.8	0.7

a) The amount of the additives admitted/10^{-5} mol g^{-1}.
b) The catalytic activity/10^{-5} mol min^{-1} g^{-1}. The catalyst was reduced at 823 K for 0.25 h before the experiment.

Results and Discussion

Isomerization of *cis*-2-Butene. The Nb–Si mixed oxide, itself, was catalytically inactive for the isomerization of *cis*- 2-butene. It became catalytically active for the reaction by its reduction with hydrogen gas at 823 K. Figure 1 shows the progress of a reaction on Nb–Si(10) reduced for 2.5 h. Products were only 1-butene and *trans*-2-butene. The rate of the formation of *trans*-2-butene was 10-times faster than that of 1-butene. The average rate of the reaction calculated from the amount of *cis*-2-butene converted to 1-butene and *trans*-2-butene during the initial 10 min was taken as a measure of the catalytic activity.

Figure 2 shows the dependence of the catalytic activity on the reduction duration of the oxide (Nb–Si(10)). The catalytic activity could be increased by increasing the reduction duration (by up to 2.5 h) and slightly decreased upon further reduction. The induction of catalytic activity by reduction with hydrogen gas suggests that the catalytically active site for butene isomerization is a Nb cation with a lower oxidation state formed by reduction.

The catalytic activities observed for the reduced catalyst, which was preliminarily exposed to various compounds, are listed in Table 1. All the tested compounds (O_2, NO, NH_3, CO, and N_2O) retarded the catalytic activity. NO and O_2 were the most poisonous to the catalyst among them. Figure 3 shows the relation between the catalytic activity on Nb–Si poisoned by oxygen and the amount of oxygen admitted. The admission of oxygen of 5×10^{-6} mol g^{-1} reduced the catalytic activity to 1/10 of that of non-poisoned catalyst.

Oxidants, such as O_2 and NO, were the most effective poisons. However, NH_3 was less poisonous than these two compounds. Therefore, it is stressed

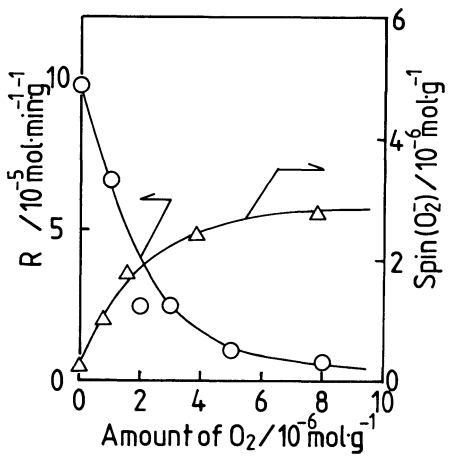

Fig. 3. Poisoning of the catalytic activity and the formation of O_2^- radical on the surface by admission of oxygen gas. The reaction conditions were the same as in Fig. 1.

that the observed activity is not attributed to the catalysis by the acidic property of the Nb–Si oxide, although Iizuka et al. have reported on the acid catalysis by hydrated niobium oxide.[6] The strong poisoning effect of the two oxidants suggests that the active site loses its catalytic activity by oxidation. Therefore, it is reasonable to assume that the active site is a Nb^{4+} ion formed by reduction with H_2. This assumption is supported by the experimental result that the formation of Nb^{4+} by reduction was assured by ESR spectroscopy for niobium oxide, which became catalytically active by reduction.[1]

ESR Investigation. While the catalysts showed no ESR absorption after a pretreatment, their reduction induced the spectrum shown in Fig. 4-a. An apparent g value of 1.91±0.02 was obtained, independent of the content of niobium, except for pure niobium oxide. Since the g value is similar to those reported for a Nb^{4+} ion in silicate glass,[7] the ESR absorption observed for the reduced Nb–Si oxide is attributed to the Nb^{4+} ion. The poor resolution of the spectrum might be due to a low symmetry and irregularity of the environment around the ions.

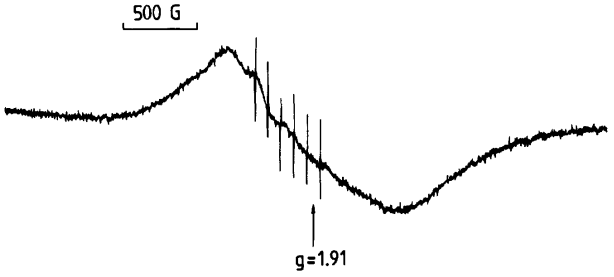

Fig. 4-a. ESR spectrum measured at 77 K of the reduced Nb-Si(50). The catalyst was reduced with hydrogen gas at 823 K for 0.25 h. The six sharp signals overlapping that of Nb^{4+} are due to Mn^{2+} as the standard.

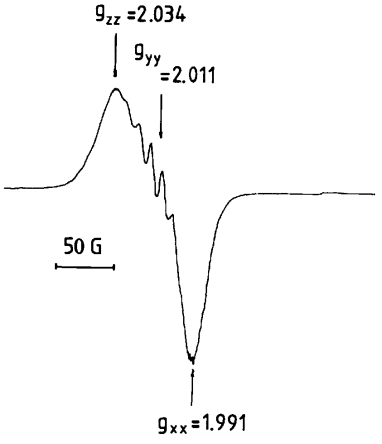

Fig. 4-b. ESR spectrum of O_2^- formed by admission of oxygen gas onto the reduced Nb-Si(10). The catalyst was reduced at 823 K for 2.5 h before the admission of oxygen gas.

When oxygen gas was admitted onto the reduced catalyst, a new signal (Fig. 4-b) appeared. The g values (g_{xx}=1.991±0.001, g_{yy}=2.011±0.001, and g_{zz}= 2.034±0.005) were obtained. The shape of the spectrum is similar to that of the O_2^- formed on La_2O_3 (reported by Wang et at.[8]) and on other materials.[9,10] When ethene or propene was brought into contact with a catalyst showing the ESR spectrum of Fig. 4-b at room temperature, no change in the spectrum occurred, that is, the species formed on the catalysts by the admission of oxygen gas did not react with the olefins. From the g values, the shape of the spectrum, and the poor reactivity with olefins, the species giving the ESR absorption spectrum of Fig. 4-b could be identified as being an O_2^- ion. Since the ESR absorption due to Nb^{4+} was decreased, in contrast with the formation of O_2^-, this O_2^- ion must be formed by electron transfer from Nb^{4+} ion as shown in Reaction 1:

$$Nb^{4+} + O_2 \rightarrow Nb^{5+} \cdots O_2^-. \quad (1)$$

That the hyperfine structure in the spectrum resulted from an interaction of O_2^- with the niobium nucleus (I=9/2) indicates that O_2^- is located at a Nb atom. It is plausible that the hyperfine structure observed in the spectrum resulted from an interaction of O_2^- with a niobium nucleus (I=9/2), although the series of hyperfine signals can not be completely identified in the spectrum because of the low resolution of the ESR spectrum. The relation between the amount of O_2 admitted and that of O_2^- formed is shown in Fig. 3. The spin density of O_2^- formed was increased linearly up to the amount of admitted O_2 (2×10^{-6} mol g^{-1}) at a slope of unity, suggesting that O_2 was stoichiometrically converted to O_2^- on the reduced catalyst.

The inverse changes of the catalytic activity and the amount of O_2^- formed by the admission of O_2 shown in Fig. 3, strongly support the idea that the

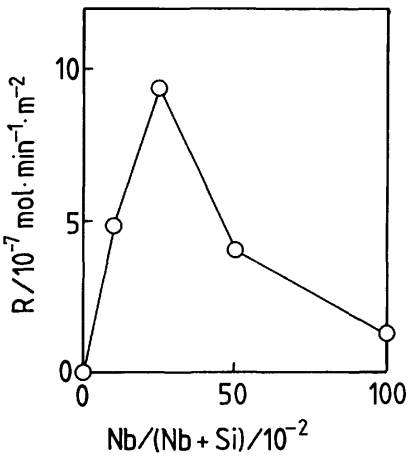

Fig. 5. Dependence of the catalytic activity on the content of Nb in the catalysts.

catalytically active site is a Nb^{4+} ion. Poisoning of the catalytic activity for butene isomerization by O_2 must be caused by the oxidation of Nb^{4+}, as indicated in Reaction 1. The number of the active sites was estimated to be 4×10^{-6} mol g^{-1} from an extrapolation of the linear part obtained at small amounts of the admitted O_2 (Fig. 3).

Catalysis and Content of Nb. Figure 5 shows the catalytic activity for *cis*-2-butene isomerization obtained on reduced Nb–Si catalysts containing various amounts of niobium. The catalytic activity showed a maximum at a content of 25%-Nb and decreased above this value. Figure 6 shows the amount of O_2^- formed on the reduced catalysts after the admission of a sufficient amount of oxygen gas to convert all Nb^{4+} to Nb^{5+} on the surface. The amount of O_2^- formed passed through a maximum at 10% of Nb and was decreased for the Nb content more than the value. Though the color change of the catalysts after a treatment with hydrogen at 823 K confirmed the occurrence of the reduction of the catalysts, almost no formation of O_2^- was observed for Nb–Si(50) and Nb–Si(100), or Nb_2O_5.

When TCNE was brought into contact with a reduced catalyst, a new ESR absorption spectrum of a single peak (g=2.011) appeared. It has been reported that TCNE is converted to its anion radical when the species with electron-donating character is present on the solid surfaces.[11,12] It is reasonable to say that a TCNE molecule, whose electron affinity is larger than that of oxygen molecule, can be converted to its anion radical on reduced Nb–Si where Nb^{4+} acts as an electron donor. Figure 7 shows the relation between the Nb content in the catalysts and the amount of TCNE radical formed on catalysts pretreated in the same manner as mentioned in Fig. 6. The TCNE radical increased linearly with an increase in the Nb content. The monotonous increase in the TCNE radical with an increase in the Nb content simply results from the increase in the amount of Nb^{4+} on the surface of the reduced catalysts. On the other hand, the O_2^- formation showed an optimum for change of the Nb atom content in the oxide. These contrasted results for the two electron acceptors, TCNE and O_2, may be explained as described below; an O_2^- radical is stable only on the isolated Nb atom on the surface, since this radical is further reduced to be an ESR inactive oxygen species, such as O_2^{2-} or O^{2-}, by a neighboring Nb^{4+}. On catalysts containing a small amount of Nb, the number of isolated Nb atoms is increased with an increase in the Nb content, since the atoms are highly dispersed. At a high content, however, the local aggregation of niobium ions occurs so as to result in a decrease in the number of isolated Nb^{4+} ions.

The resemblance in the dependences of the catalytic activity and the formation of O_2^- suggests that highly dispersed Nb^{4+} ions are catalytically more active than

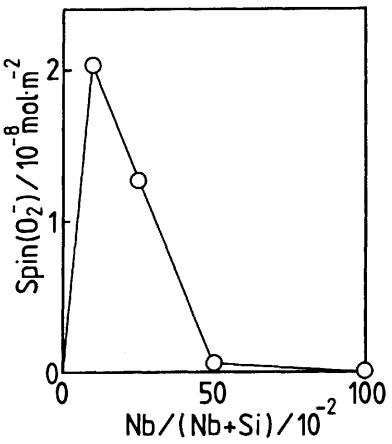

Fig. 6. Dependence of the amount of O_2^- on the content of Nb. The catalysts were reduced at 823 K for 2.5 h before the admission of oxygen gas.

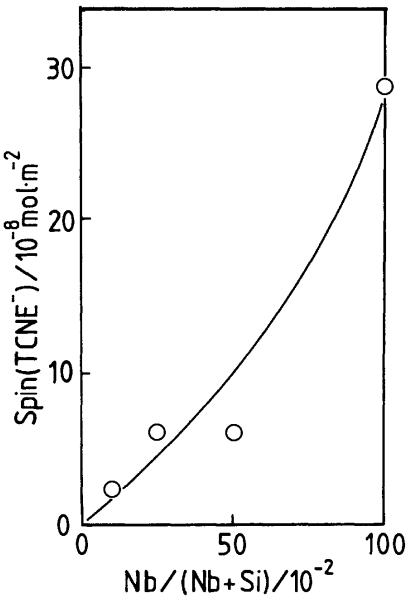

Fig. 7. Dependence of the amount of TCNE anion radical on the content of Nb in the catalysts. The catalysts were reduced at the same conditions as in Fig. 6.

aggregated ions.

The dependence of the catalytic activity observed over slightly reduced niobium oxide on the Nb/O ratio in the oxide has been explained by a change in the dispersion of Nb^{4+} formed on the surface.[5] It has been concluded that an isolated Nb^{4+} ion with coordinative unsaturation, which is formed predominantly on a highly dispersed surface, is the catalytically active site. Coordinative unsaturation is lost by coupling of two Nb^{4+} ions on a catalyst with low dispersion. It is, therefore, stressed that similarly to a reduced Nb_2O_5 catalyst[5] the catalytic activity for a Nb–Si system originates from a coordinative unsaturation of the Nb^{4+} ion.

The importance of the dispersion of active species on the surface has been reported for Nb_2O_5/SiO_2,[13] MoO_3/SiO_2,[14] MoO_3/porous Vycor glass,[15] TiO_2/porous Vycor glass,[16] Ti–Si mixed oxide,[17] and MoO_3/Al_2O_3.[18,19] Nishimura et al. have demonstrated that well-defined Nb monomers attached on SiO_2 exhibited high activity and selectivity for the dehydrogenation of ethanol.[13] Ono et al. have attributed the catalytic activity of MoO_3/SiO_2 for dehydrogenation of ethanol to tetrahedrally coordinated Mo ion formed predominantly at high dispersion.[14]

The coordination environment of metal ions in metal oxides, such as the coordination number and symmetry, which are important for the induction of catalytic activity, should depend on the dispersion for both supported oxide and mixed oxide systems. Especially for Nb–Si mixed oxide system, an isolated Nb^{4+} ion is more stable than that formed in Nb_2O_5, since a Nb atom is isolated in a matrix of silica at a low content of Nb during the preparation process.

The present research was supported by a Grant from CBMM INTERNACIONAL LTDA.

Liquid Structure of *N,N*-Dimethylformamide, Acetonitrile, and Their 1:1 Molar Mixture

Tamas RADNAI,†† Sumiko ITOH, and Hitoshi OHTAKI*,†
Department of Electronic Chemistry, Tokyo Institute of Technology at Nagatsuta, 4259 Nagatsuta, Midori-ku, Yokohama 227
(Received May 12, 1988)

Liquid structures of pure *N,N*-dimethylformamide (DMF) and acetonitrile (AN) as well as of their 1:1 molar mixture were investigated by X-ray diffraction at 25 °C. The careful reinvestigation of pure DMF led to a good reproducibility of the previous result. Slight deviations in the structural parameters are discussed and a detailed parameter table is reported. A simple model in which each AN molecule has 2 neighbors at an average distance of 330 pm describes the more ordered first neighbor structure of pure AN. The main interaction forming the structure is of dipole-dipole type, in agreement with previous findings. In the 1:1 molar mixture a dipole–dipole model also leads to a satisfactory description of the first neighbor structure. The preferred orientation is that with dipoles in the antiparallel position. A central DMF molecule has 1.75 neighboring AN molecules in average at a distance of 316 pm. The same stands for DMF around AN. No evidence for other kinds of interaction, e.g., weak H-bond type intermolecular interactions could be found in the mixture.

Both *N,N*-dimethylformamide (DMF) and acetonitrile (AN) are typical aprotic, dipolar, simple organic solvents. They are widely used in the chemical practice due to their advantageous physicochemical properties like the broad temperature range in which they are liquid; relatively high dielectric constants as well as good donor and acceptor properties which enable them to be excellent solvents for a great number of compounds. Their basic physical and chemical properties are often subjects of studies.

Recently, their liquid structure was also a matter of investigations.[1-4] An X-ray diffraction study of liquid DMF revealed the intramolecular structure,[1] while no direct evidence could be found for ordering effects between the molecules. The joined MO calculations suggested a slight tendency for dimer formation, but the interactions between the molecules were found to be weak. Generally acetonitrile is also considered as a structureless liquid, because of the lack of H-bonds, in spite of the appearance of the definite short range ordering between the molecules. The ordering is mainly due to the dipole–dipole interactions, as derived from diffraction and theoretical studies.[2-4]

Surprisingly enough, the properties of the binary mixtures of DMF and AN have not been studied extensively. They are miscible at any concentration, forming non-azeotropic mixtures, but no detailed data of the physicochemical properties as well as their structures are available up to now. It is generally assumed that the solvent structural effects are very weak and can be neglected when compared with solute-solvent interactions in their binary solutions.

Some indications, however, point to the existence of molecular associations between DMF and AN in mixtures. Comparing Gutmann's donor and acceptor numbers of the two solvents, one can conclude that a remarkable difference is in the donicity (D_N(AN)=14.1, D_N(DMF)=26.6), while the acceptor numbers are similar (A_N(AN)=19.3, A_N(DMF)=16.0). These differences lead to variations in the metal–ligand complex formation as well as to differences in the solvation of the metal ions in the pure solvents. Moreover, the solvation and complex formation phenomena can also be affected in the mixtures. Indeed, it was proved that a preferential solvation of copper(II) ions by DMF occurs in the mixtures of DMF and AN when studying the $[CuCl_n]^{(2-n)+}$ complex formation.[5] It is obvious to think that the differences in their donor and acceptor properties can also lead to a measurable degree of DMF–AN complex formation, even if the governing interaction is weak.

Literature data also support the hypothesis. Evidence of attractive interactions between DMF and AN is reported on the basis of light scattering studies.[6] These interactions are in competition with the ones between the like molecules and a great number of single molecules have also to be present in the liquid, according to the measured excess free energy data. More direct evidence for solute–solute type interactions between DMF and AN as solutes even at low concentrations in benzene solutions was found by the dielectric relaxation method[7] practically at every stoichiometric ratio of the solutes. In a previous work, however, from electro-osmotic measurements the weakness of such interactions, if any, was emphasized.[8] Indeed, guesswork on possible type of interactions suggests weak H-bond-like interactions between CH group of DMF and N atom of AN, and electric multipole–multipole interactions between the two kinds of molecules.

In order to determine the structural consequences of such presumed interactions, an X-ray diffraction measurement was performed on the 1:1 molar mixture of DMF and AN. For the sake of comparison, X-ray

measurements on pure DMF and AN were also carried out, and their structural data were compared with those reported in the literature.

Experimental

Sample Solutions. Both DMF and AN of reagent grade were distilled twice before use. A mixture of 1:1 molar ratio, corresponding to 1:1.781 mass ratio, was prepared by measuring the weights of the components. Densities of the samples were checked pycnometrically.

X-Ray Scattering Measurements. The scattering experiments were carried out with a JEOL θ-θ diffractometer by using Mo $K\alpha$ radiation (λ=71.07 pm) and a bent LiF monochromator in a room thermostated at (25±1) °C. The accessible range of scattering angle (2θ) was 2—140°, corresponding to the s-range from 0.006 pm^{-1} to 0.168 pm^{-1}, s being the scattering variable ($s=4\pi\lambda^{-1}\sin\theta$). Times requiring to accumulate 80000 counts were recorded at each angle of the measurements. Special care was taken of the low X-ray absorption as well as the high evaporation rates of the samples. The levels of the horizontal surface of the liquids were checked every 2—3 hours. Additionally, the low-angle region for the mixture and the whole experiment for the AN were measured repeatedly in order to obtain better results for data reduction. A typical result for the agreement between the data from two consecutive experiments was within 2—3%, and the deviation never exceeded 5%.

Beyond the above specialities, the method of measurements and data treatments were the same as those described in previous papers.[9]

Analysis of the Scattering Data. Experimental intensities were corrected for background, absorption, double scattering, polarization and incoherent scattering by the standard methods. The reduced intensities $i(s)$ were calculated as:

$$i(s) = KI(s) - \sum n_j\{[f_j(s) + \Delta f_j']^2 + (\Delta f_j'')^2\}, \quad (1)$$

where $I(s)$ is the experimental intensity and is normalized to the absolute scale with respect to a stoichiometric volume V containing one DMF and AN molecule in the pure liquids, and one molecule of both kinds in the mixture, K is the normalizing factor, n_j is the number of atom j in the stoichiometric volume, $f_j(s)$ is the scattering factor of atom j at s, $\Delta f_j'$, and $\Delta f_j''$ are the real and imaginary parts of anomalous dispersion of atom j. The experimental radial distribution functions $D(r)$ and pair-correlation functions $G(r)$ were calculated by the Fourier transform of the $i(s)$ functions according to

$$D(r) = 4\pi r^2\rho_0 + (2r/\pi)\int_0^{s_{max}} si(s)M(s)\sin(sr)ds, \quad (2)$$

and

$$G(r) = D(r) / (4\pi r^2\rho_0), \quad (3)$$

where ρ_0 denotes the average electron density in the sample defined as

$$\rho_0 = \sum\sum n_i n_j f_i(0) f_j(0) / V. \quad (4)$$

$M(s)$ is the modification function of the form

$$M(s) = \sum\{[f_i(0) + \Delta f_i']^2 + (\Delta f_i'')^2\} / \{[f_N(s) + \Delta f_N']^2 + (\Delta f_N'')^2\}\exp(-ks^2). \quad (5)$$

All calculations were performed by using appropriate versions of programs KURVLR[10] and NLPLSQ.[11]

Results and Discussion

Method of Structural Analysis. At first, a semi-quantitative analysis was done for each sample at the radial distribution level. $D(r)$ and $G(r)$ functions for DMF and AN were compared with those available from the literature, and the differences in the $D(r)$ functions of the three samples were discussed. As a second step, the intramolecular structural parameters for both DMF and AN were calculated by the least squares method (LSQ) at the reduced intensity level. Then models for intermolecular interactions were tested, trying to find the average configuration of the nearest neighbors by LSQ. When building up the model for the mixture, the parameters fixed previously in the LSQ analysis for the pure liquids were used for describing the intramolecular structure without changing them. Finally, the structural parameters for the random distribution of the atoms around the central ones were determined.

For the LSQ, theoretical reduced intensities $i_{th}(s)$ were calculated as

$$i_{th}(s) = \sum\sum n_{pq}c_{pq}j_0(sr_{pq})\exp(-b_{pq}s^2) - 4\pi\rho_0 / s\sum\sum n_p n_q c_{pq}R_{pq}^2 j_1(sR_{pq})\exp(-B_{pq}s^2). \quad (6)$$

where

$$c_{pq}(s) = \{[f_p(s) + \Delta f_p'][f_q(s) + \Delta f_q'] + \Delta f_p''\Delta f_q''\}M(s), \quad (7)$$

and r_{pq}, b_{pq}, and n_{pq} denote the distance, temperature factor, and frequency factor (coordination number) of the p-q atom-pair, respectively. R_{pq} is the distance beyond which a continuous distribution of atoms of type q around the p type atom in the center is assumed, while B_{pq} is the parameter describing the sharpness of the boundary at R_{pq}. For brevity, $j_m(x)$ stands for the spherical Bessel function of the mth order.

$$U = \sum_{s_{min}}^{s_{max}} \omega(s)[i(s) - i_{th}(s)]^2, \quad (8)$$

The LSQ procedure was applied in order to find the minimum of the error-square sum using the weighting functions $w(s)=s^2$. During the fitting procedure several s ranges were tried. Finally an extended range from s_{min}=0.005 pm^{-1} to s_{max}=0.16 pm^{-1} could be applied. The quality of the fit was checked through the value of U and the usually defined Hamilton R-factor.

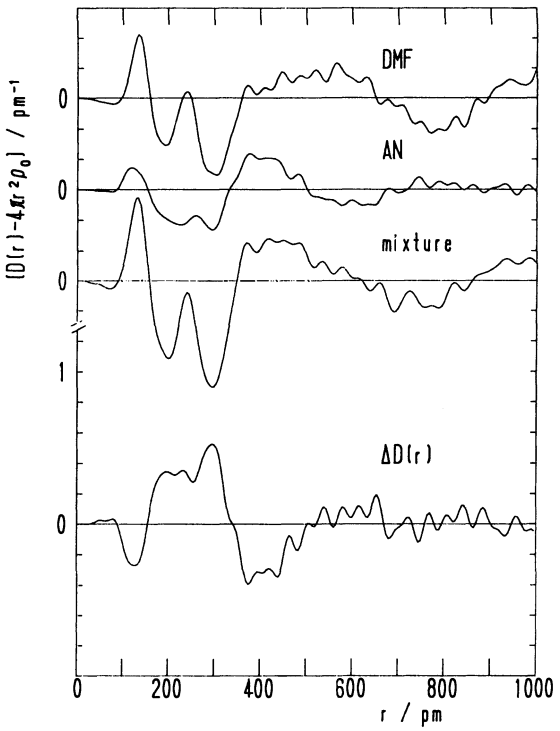

Fig. 1. Experimental RDF's for pure DMF, AN, their 1:1 molar mixture, and the weighted difference of the three curves. The RDF's are given in form of $D(r)-4\pi r^2\rho_0$, the difference curve as defined in Eq. 9.

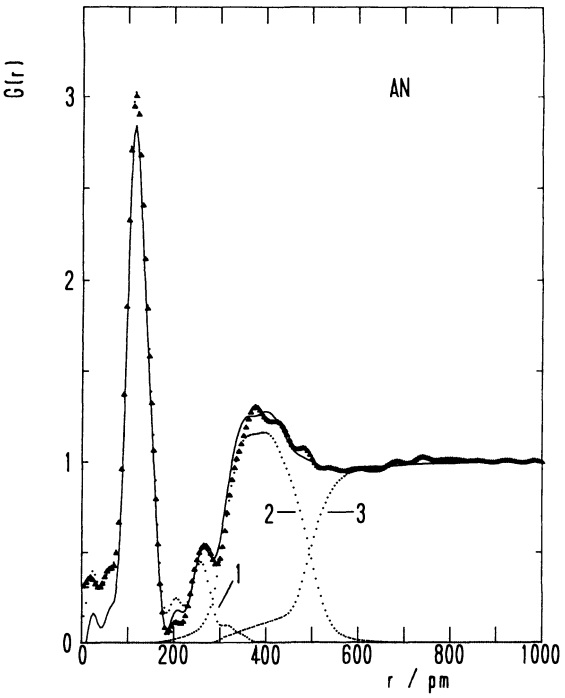

Fig. 3. Experimental $G(r)$ (triangles) is compared with the theoretical one from the best fit of the models (solid line) for pure AN. The dotted curves are: intramolecular contribution (1), intermolecular part from dipole-dipole model (2), and the continuum (3).

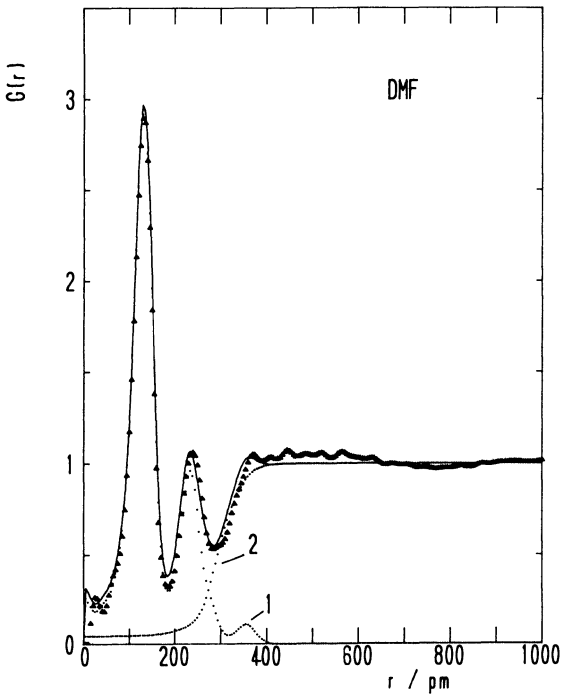

Fig. 2. Experimental $G(r)$ (triangles) is compared with the theoretical one from the best fit of the models (solid line) for pure DMF. The dots represent the intramolecular (1) and the continuum (2) contributions.

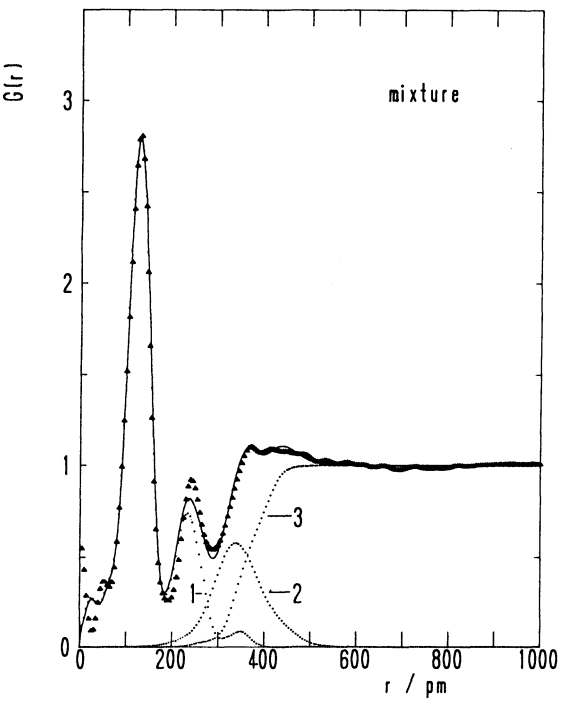

Fig. 4. Experimental $G(r)$ (triangles) is compared with the theoretical one from the best fit of the models (solid line) for 1:1 molar mixture of DMF and AN. The dotted curves are: intramolecular contribution (1), intermolecular part from the complete dipole-dipole model (2), and the continuum (3).

X-Ray Radial Distribution Functions (RDF's). The total experimental X-ray radial distribution curves of the three samples are shown in Fig. 1 in the form of $D(r)-4\pi r^2\rho_0$. The corresponding $G(r)$ functions are also shown in Figs. 2—4.

The two distinct peaks at about 130 and 230 pm for pure DMF were ascribed to the intramolecular interactions in a previous paper.[1] The peak positions are very well reproduced in the present work (the resolution of the RDF was 5 pm, the agreement is within this limit). The peak shapes also agree well, except the small ripples which still remained after that a correction had been applied to remove them as far as possible. Since only a small modulation appears from 350 to 650 pm, it witnesses about the absence of any significant interaction between the molecules.

There are also two distinct peaks at about 120 and 270 pm on the RDF of pure AN, with a small peak at about 200 pm (see Fig. 1). The last one emerges as a hump at the corresponding $G(r)$ in Fig. 3. The peak positions and their relative heights are in good agreement with those reported earlier.[2] It is obvious to ascribe these three peaks to the intramolecular distances, similar to the DMF case. The peak appearing between 300 and 500 pm is less broad and significantly higher than that of DMF. It also has a shoulder at about 320 pm, and its shape is rather complex, reflecting stronger intermolecular interactions and as a consequence, more definite short-range ordering in the liquid.

The two main peaks in the RDF of the 1:1 molar mixture obviously include the intramolecular distances both from DMF and AN. Consequently, they become broader and the peak positions are shifted from those of pure liquids. As for the peak beyond to 300 pm, it is more definite than that for pure DMF, but less pronounced than for pure AN. It seems to be rather complex, and a more quantitative analysis is needed in order to decide if it reflects only the concentration effect, i.e., the simple mixing of the AN-like and DMF-like structures (which is physically not relevant) or is a sign of a specific interaction between the two kinds of molecules.

The first step towards the solution of this problem was the construction of the weighted difference of the experimental RDF's according to

$$\Delta D(r) = [D_M(r)-4\pi r^2\rho_{0,M}] - K_1[D_{DMF}(r)-4\pi r^2\rho_{0,DMF}] - K_2[D_{AN}(r) - 4\pi r^2\rho_{0,AN}], \quad (9)$$

where $K_1=\rho_{0,M}/\rho_{0,DMF}$, $K_2=\rho_{0,M}/\rho_{0,AN}$ are two weights which account for the differences in the average atom densities between the samples (M stands for the mixture). The $\Delta D(r)$ curve is shown in Fig. 1. It is easy to prove that the function defined by Eq. 9 tends to zero when r is beyond the boundaries of the continuum. Accordingly, the ripples beyond 600 pm are clearly spurious, summing up the experimental errors after the double subtractions and determine the accuracy of the peak resolution. On the other hand, the minimum and the maximum found in the intramolecular range up to 250 pm are also physically irrelevant, and are due to the enlarged errors from the inaccuracy of the ripple correction in the low-r range. The interesting feature of this difference curve is the sharp peak near 300 pm followed by a deep minimum around 380 pm. Both are larger than those found to be irrelevant, and give a clear indication not only for the presence of the intermolecular interaction between the molecules but also a detectable shift in the average interatomic distances between adjacent molecules towards the lower-r region.

Structure of Pure DMF. In spite of the visibly good agreement between the new and the previously reported experimental results, a detailed LSQ analysis of the $i(s)$ curve was carried out in order to see the influence of minor experimental deviations on the structural parameters. The planar structure for the DMF molecule was retained. In the structural model examined in the present study only two slight modifications were applied. The non-bonding C···H distances were not neglected in the fitting procedure although they give only small contributions to the X-ray scattering, and the treatment of the continuum (the second term in Eq. 6) was employed by separated atom–atom contributions of each kind of atoms (this latter change does not influence the intramolecular parameters).

The experimental and theoretical $si(s)$ functions of

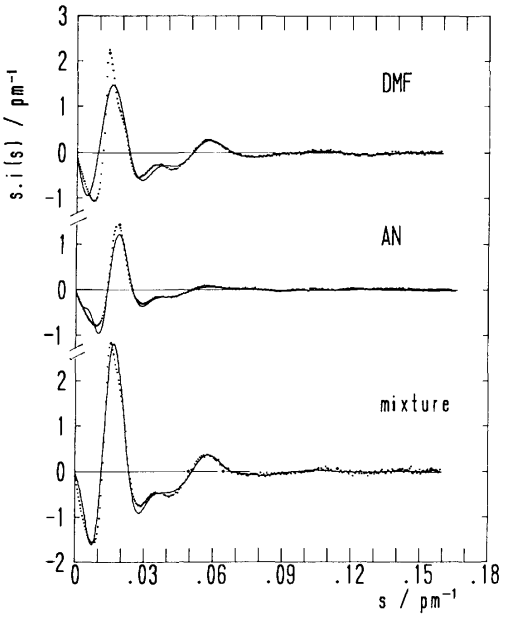

Fig. 5. Experimental structure functions $si(s)$ (dots) are compared with the theoretical ones from the best fit of the models (solid lines) for pure DMF, AN, and their 1:1 molar mixture.

the best fit are shown in Fig. 5. The intramolecular structural parameters for DMF are given in Table 1. As it is seen from the comparison with those parameters reported earlier,[1] no change occurred in the bonding distances, and only minor changes resulted in the nonbonding distances, leading to slight variation in the bond angles. For a further comparison, structural parameters derived from an independent X-ray study on pure DMF,[12] applying transmission geometry, are also given in Table 1. Although these structural parameters are somewhat different, but not contradictory to the results reported here.

The intermolecular part of the liquid structure of DMF is completely described by assuming random distribution of atoms around the central ones beyond to the boundaries given by the set of R_{pq} and B_{pq} parameters listed in Table 2. Only the C–C, C–N, and C–O contributions were fitted because of their major weights. The parameters obtained support the internal consistency of the model.

Structure of Pure AN. Intramolecular structural parameters for liquid AN were determined earlier from X-ray diffraction experiments.[2,3] Since there are slight differences between them, these parameters were also recalculated during the structural analysis. The values finally accepted are compared with the literature data in Table 3. No significant change in the intramolecular parameters was observed.

As for the intermolecular structure, the previous works employed two completely different approaches. The first one[2] interpreted the liquid structure in crystallographic terms, computing all possible interactions between eight molecules within an orthorhombic unit cell, and determining a "correlation-cluster" size resulting in a diameter of about 1300 pm. The molecules are arranged in the clusters with the parallel or antiparallel position of their dipoles. Although a decrease in the positional and orientational correlations was considered in the model, the ordering seems still to be exaggerated.

The other approach[3,4] had the aim at determining the molecular pair-correlation function of liquid AN from combined neutron and X-ray diffraction exper-

iments. From the total experimental pair-correlation function and calculations by the perturbation theory combined with it, the leading terms of the invariant series expansion could be derived, characteristic to the positional and also the orientational correlations between the molecules. This information is much more beyond to that which is accessible only by one diffraction experiment. The results showed that the dipole-dipole and quadrupole-quadrupole interactions were essential at small intermolecular distances and that the antiparallel orientation of the dipoles was preferred. The average configuration of the first neighbors, however, was not given in terms of structural parameters.

In order to derive the simplest possible model for the first-neighbor structure of AN, an LSQ analysis was carried out. In the applied model two neighbors were assumed around a central molecule, with their dipoles in the antiparallel position. The separation distance l between the centers of the molecules was a fitted parameter, together with the b values rendered to the interatomic distances. Beyond the first neighbors, a random distribution of atoms was assumed. The agreement between the experimental and theoretical $si(s)$ functions is shown in Fig. 5, and the corresponding $G(r)$ curves in Fig. 3.

As a result of the fit, a separation distance between the neighboring molecules l=330 pm was obtained. This value agreed well with that of 335 pm which can be calculated from the coordinates of atoms in the unit cell given in Ref. 2. Beyond the two nearest neighbors no more molecules were needed to obtain a good fit, and random distribution of atoms was enough to describe the remaining structure.

Intermolecular Structure of the Mixture. Since the analysis of the RDF's suggested that structural effect may occur when mixing the two pure solvents, a detailed LSQ analysis of the $i(s)$ for 1:1 molar mixture was also carried out. Various model combinations were tested. At first, a rough estimate gave the average number of 5.5 for N or C atoms at about 330 pm distant from a central one. Similarly, 8.7 N or C atoms were found around a central O atom at a distance of about 380 pm. This result would correspond to 2.7—2.9 AN molecules around a central DMF molecule. Of course, this picture is very rough, since it does not distinguish between the types of atoms and does not specify any geometry for the structure. Correspondingly, the fit was not satisfactory enough.

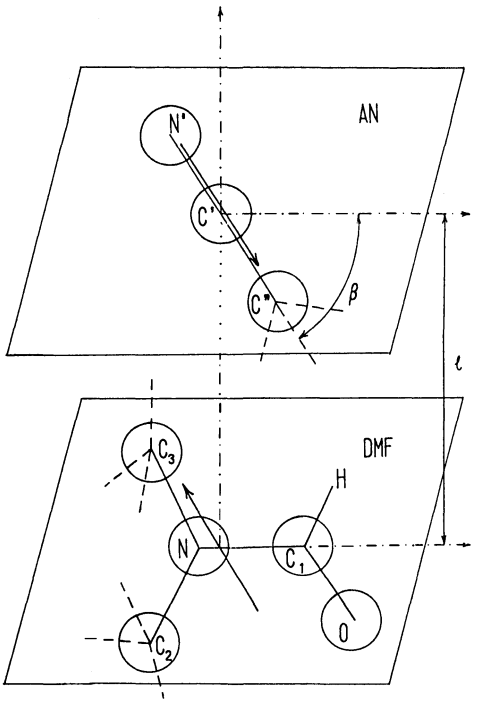

Fig. 6. Schematic drawing of the structural model for DMF-AN complexes. For the sake of simplicity, only one DMF and one AN molecules are shown, the unlike molecules above and below should be arranged accordingly. The direction of the dipoles of the molecules are indicated by arrows. The numbering of the atoms is also shown (primes always refer to atoms belonging to AN). The H atoms of the methyl groups are indicated by dashed lines.

As a second step, a complete model was constructed. From the results of pure AN it was supposed that the dominant interaction between DMF and AN molecule is via their dipoles. The idea for formulating the model was that while retaining the nearest neighbor model for pure AN, the central molecule should be changed to a DMF one in the mixture. The DMF molecule was allowed then to change its orientation to construct various types of the DMF-AN complex. Figure 6 shows the schematic drawing of the model and defines the structural parameters included. It was

supposed that the axis of the two molecules lay in parallel planes, and their centers lay on a line perpendicular to the planes. Independent parameters for the fit were: the number n of AN molecules around the central DMF, which corresponds to a set of equal atomic coordination numbers by definition, the separation distance l between the centers of the molecules, corresponding also to a set of atom–atom distances; the rotation angle β around the l-axis, and three b_{ij} values where i and j indicate different molecules. Continuum parameters for each kind of atom-pairs were also included in the fit, but later the terms of less importance (those containing H atoms) were excluded. The interactions of the central DMF molecules with those molecules which are at a distance larger than l, e.g., being within the same plane, were considered in the continuum part. This model obviously has some-rather arbitrary-restrictions, but the requirement of using the least number of structural parameters was always kept in mind during the calculations.

The corresponding pair-correlation functions $G(r)$ and the structure functions $si(s)$ after reaching the best fit are shown in Figs. 4 and 5, respectively. Table 4 shows the (dependent) interatomic distances between DMF and AN molecules calculated from the best fitted independent parameters. Parameters for describing the continuum are given in Table 2.

The final values of n=1.75±0.08, l=316±20 pm, and β=59±10 degree were obtained. The number of AN molecules around a central DMF molecule being somewhat less than 2 seems to be reasonable, because the structure of the DMF–AN mixture, in which a half of AN molecules in the pure state are replaced to DMF molecules, may have a similar, but slightly disordered molecular arrangement, to the pure liquid of AN. For a further consideration, the whole procedure was repeated when an AN molecule was placed in the middle. Similarly, a number of n=1.86±0.1 DMF molecules were determined to be around the AN.

The obtained value for the rotation angle β corresponds to the antiparallel orientation of the dipoles. The least squares sum, in fact, was not very sensitive to the variation of β alone. The R-factor change only about 10% when β varied from 0 to 60 degrees. The only sharp increase in R-factor occurred, amounting up to 300% of the minimum value obtained when the unfavorable parallel orientation was tested.

It is very interesting to note that the separation distance l proved to be less than between two neighboring molecules in pure AN. Its shift from 330 pm to 316 pm going from the pure liquid to the mixture is meaningful, without doubt. It is also noteworthy that when letting to vary l and β together, the favorable antiparallel orientation occurred by accompanying a decrease in the separation distance. It can not be concluded from this fact directly, however, that the interaction between the DMF and AN is stronger than between two AN molecules, but only that the yielded configuration is sterically the most favorable. This may be due to the fortunate coincidence of a more bulky, basically planar DMF molecule with a smaller, and essentially linear AN molecule. For determining the strength of interactions more extended, energetic studies are needed with more appropriate methods.

Several additional tries for finding evidence for other kinds of possible first neighbor configurations were also carried out, but all they failed. Especially when searching for contributions due to weak H-bond type interactions between CH groups of DMF and N atoms of AN at about their characteristic distance of 290—310 pm, no noticeable finding was obtained. The LSQ fit could not be improved, and no remaining peak in the radial distribution function could be observed in the given range neither before constructing the H-bond type model, nor looking for some minor contribution still to be considered after the complete model had been applied.

The work has been supported, in part, by the Ministry of Education, Science and Culture (Grant-in-Aid for Scientific Research on Priority Area of Macromolecular Complexes, No. 62612005). One of us (T.R.) is greatly indebted to the Tokyo Institute of Technology and the Hungarian Academy of Sciences to allow for being engaged into the present study. Computers at the Tokyo Institute of Technology were used for the calculations.

Study of the Effect of Structural Factors on Magnetism of Di-μ-alkoxodicopper(II) Complexes by Ab Initio MO Calculations[1)]

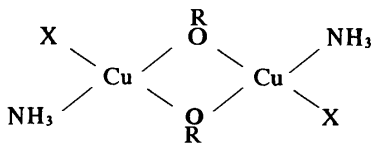
Makoto HANDA,† Nobuaki KOGA,† and Sigeo KIDA*
Department of Chemistry, Faculty of Science, Kyushu University 33, Hakozaki, Higashi-ku, Fukuoka 812
†Institute for Molecular Science, Myodaiji, Okazaki 444[2)]
(Received June 3, 1988)

The effect of variation of structural factors on the spin-exchange interaction between copper(II) centers in dialkoxo-bridged dinuclear copper complexes were studied by the ab initio MO method with UHF formalism. The calculations were performed on di-μ-methoxotetraamminedicopper(II). The *J*-values were obtained as functions of Cu-O-Cu angle, dihedral angle between two coordination planes, planarity of bonds on the bridging oxygens, tetrahedral distortion of coordination planes, and the tilt of O-C bond from the O-O axis. The results demonstrated that the Cu-O-Cu angle most effectively affect the *J*-value but the other factors are less effective.

A great number of dinuclear copper complexes have been synthesized in the recent two decades, and their structures and magnetisms have been extensively studied.

Hodgson, Hatfield, and the co-workers first showed the relation between a structural factor and magnetic coupling of dinuclear copper(II) complexes. Based on experimental data of several dihydroxo-bridged copper complexes, they showed that there is a linear relationship between the Cu-O-Cu bond angle and the *J*-value, where $-2J$ represents the energy separation between the lowest spin-triplet and singlet states.[3)] Merz and Haase,[4)] and Nieminen[5)] pointed out that a similar relation also exists for dialkoxo-bridged copper(II) complexes based on numerous experimental results. These relations were theoretically interpreted in terms of extended Hückel MO by Hoffmann et al.,[6)] and later by Kahn.[7)] Bencini and Gatteschi[8)] applied the angular overlap approach to a two-atom-bridged dinuclear copper(II) system, and obtained a result similar to that of Hoffmann et al.[6)] However, some other structural factors such as the planarity of Cu_2O_2 entity, the dihedral angle formed by two coordination planes, and the planarity of bonds about bridging oxygen, have been claimed by several workers to be important factors to determine the spin coupling as well as or rather than the Cu-O-Cu angle.[5,7-11)] Indeed, such factors seem to have a good correlation with experimentally obtained *J*-values of dialkoxo-bridged copper(II) complexes. However, in practice, such factors are not independent of other structural factors, but are linked to each other in more or less degree. Hence, it is difficult to determine which factor is the most important one for the spin-exchange interaction from the experimental data.

Thus, theoretical approaches were attempted to see the correlation between each of structural factors and *J*-value. Bencini and Gatteschi also examined effects of various structural factors on the spin coupling by the angular overlap approach.[8)] However, there is limitation in their results, since the angular overlap approach cannot expect quantitative results. De Loth et al. calculated *J*-values by an ab initio SCF MO method on copper(II) acetate monohydrate[12)] and a μ-oxalato-dicopper(II) complex.[13)] Haase et al. applied a similar approach to di-μ-hydroxo and di-μ-methoxo-dicopper(II) complexes shown below.[14)]



R = H or CH_3

X = F, Cl, or Br

They calculated *J*-values on the model complexes using ps HONDO program with pseudo potential for core electrons of copper, varying the Cu-O-Cu angle, the Cu-O distance, coordination geometry, and the planarity of bonds about the bridging oxygens, and they concluded that the magnitude of exchange coupling strongly depends on these factors. However, they did not investigate the effect of variation of the dihedral angle formed by the two coordination planes, in spite of that the importance of this factor has been pointed out by some workers.[7,11)] Furthermore, they did not discuss on which structural factor the *J* value most deeply depends.

As we have been much interested to clarify which structural factor is the major factor to determine the magnetic interaction in dialkoxo-bridged copper(II) complexes, in this study, we have calculated *J*-values

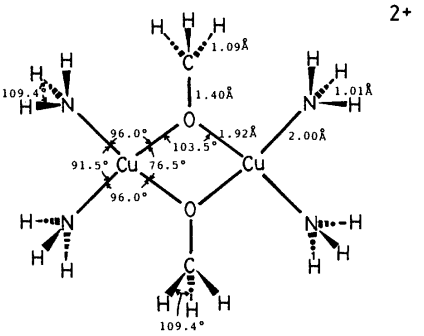


Fig. 1. Structure of the basic model.

on the model compound cited in Fig. 1 by an ab initio MO method, employing the unrestricted Hartree-Fock operator. In this calculation, in order to elucidate the effect of each structural factor on the spin coupling, we systematically varied each of various structural factors such as 1) the Cu–O–Cu angle (ϕ), 2) the dihedral angle formed by the two coordination planes (α), 3) the angle formed by the O–C vector and the Cu_2O_2 plane (θ), 4) the dihedral angle between the Cu_2O_2 plane and the plane formed by the four ammonia nitrogens (τ), and 5) the angle between the O–C and O–O vectors (δ), keeping the other factors constant as far as possible.

Calculation

The calculations were carried out by the GAUSSIAN82[15] program implemented with effective core potential code,[16a,b] the unrestricted Hartree-Fock(UHF) method being employed to estimate J value. The energies of two magnetic orbitals were calculated by the restricted Hartree-Fock (RHF) method.

The copper core electrons were described in terms of effective core potential,[16c] and the valence electrons in terms of basis function [1s1p2d] contracted from (5s2p5d).[16c] The 4-31G[16d] basis set was used for CH_3O and the STO-3G[16e] for NH_3. J values were calculated with the equation,

$$J = -(E_{TUHF} - E_{SUHF})/(\langle S^2\rangle_T - \langle S^2\rangle_S)$$

following Yamaguchi's treatment,[17] where $\langle S^2\rangle_T$ and $\langle S^2\rangle_S$ represent the spin eigenvalues of $\hat{S}^2$ for triplet and singlet states, respectively, and E_{TUHF} and E_{SUHF} are energies for the triplet and singlet states, respectively. The E_{SUHF} value was approximately represented with E_{SPUHF} which was obtained by projecting out the triplet component and using the following equation.

$$E_{SPUHF} = E_{SUHF} + \langle S^2\rangle_{SUHF}(E_{SUHF} - E_{TUHF})/(\langle S^2\rangle_{TUHF} - \langle S^2\rangle_{SUHF})$$

Results and Discussion

Throughout the calculations all bond lengths were fixed. During calculations with varying a structural parameter, all other bond angles were also fixed at the values cited in the basic model, unless there is a geometrical necessity. The results are shown diagramatically in Figs. 2—6. In each diagram the calculated J values and the energy gaps (ΔE) between the two magnetic orbitals (HOMO and LUMO) are plotted versus structural parameter. Each diagram shows that the variation of J is parallel to that of ΔE, implying that the results of the calculations by UHF and RHF are consistent with each other. The experimental data for J, ϕ, α, θ, and τ so far available are summarized in Table 1.

Effect of the Cu–O–Cu angle, ϕ. Since all the atoms

are kept in a plane, the variation of ϕ is necessarily required to vary the angles about the copper atoms to keep the summation of angles around the copper atom at 360°. In order to fulfil the requirement, the necessary angle variation was equivalently portioned out on ∠OCuN, ∠NCuN, and ∠NCuO, so that the strain due to the angle variation is made minimum.

As seen in Fig. 2, $-J$ value increases with increasing

ϕ as has been pointed out by many workers on the bases of either experimental results[3-5] or quantum mechanical approaches.[6-8,14] The experimentally obtained J values so far available were plotted versus ϕ, and shown in Fig. 7. A good agreement was obtained between our results (Fig. 2) and experimental ones (Fig. 7) in general trend with some exceptions, though the agreement in numerical values is poor. As for the exceptions, we will discuss in the later part of this paper.

Ferromagnetic interactions were observed for some hydroxo-bridged dicopper(II) complexes with small Cu–O–Cu angles,[3] and were reasonably explained in terms of Hückel MO by Hoffmann et al.[6] The present result also predicts the possibility of ferromagnetism in alkoxo-bridged copper(II) complexes with small ϕ. In fact,the complex with ϕ=97.8° bears $-2J$=65 cm^{-1} (cf. compound 15 in Table 1), suggesting that ferromagnetism may be observed for alkoxo-bridged complexes with ϕ<97°.

Angle Formed by Two Coordination Planes, α. The variation of α necessitates to vary the O–O distance in order to keep the Cu–O–Cu angle at the value of the basic structure (Fig. 1).

As seen in Fig. 3, the variation of J per degree is very small compared with that in the case of ϕ, especially, J is practically constant in the range 180—170°, inspite of that some workers[11] regarded this angle as an important factor to determine the spin coupling. According to Bencini and Gatteschi's calculations by angular overlap approach[8] $-J$ increases when α decreases from 180°. On the other hand, Kahn[7] reported the opposite trend based on the Hückel MO calculations. Kahn's result may be due to that the O–O distance was kept constant in his calculations so that the Cu–O–Cu angle also decreases with decreasing α. Such feature has been often observed in practical examples, hence in such cases the decrease in antiferromagnetic interaction should be attributed not to the change in α but to the change in ϕ which is usually linked to α.

Angle between the Cu_2O_2 Plane and O–C Vector, θ. This angle can be varied without any change of the other factors.

As seen in Fig. 4, $-J$ gradually decreases with increasing θ. Figure 4 implies that there is the transition point from antiferro- to ferromagnetic interaction at about θ=60°. However, the extent of the effect of θ on J is much small compared with that of ϕ.

Dihedral Angle between the Cu_2O_2 Plane and the Plane Formed by the Four Ammonia Nitrogens, τ. This parameter was first proposed by Sinn to represent the extent of terahedral distorsion of the coordination plane.[9] He considered this angle an important factor to determine the spin coupling.

As seen in Fig. 5, $-J$ decreases with increasing τ, and there is the antiferro—ferro transition point at about τ=35°. According to Bencini and Gatteschi's calculations the transition point exsists at about 60°.[8] However, in practical examples the variations of τ all fall in the range of 0—20°(cf. Table 1), and Fig. 5 shows that the variation of J/degree is relatively small in this range. Accordingly, the effect of τ on J value would be minor compared with that of ϕ.

Angle between O–O and O–C Vectors, δ. This angle represents the deviation of the O–C bond from the O–O axis due to the strain of chelate ring formation.

Figure 6 shows that the effect of δ on J is very small at least in the range of δ=0—10° which covers whole range of δ for practical compounds.

Concluding Remarks

J-values of dialkoxo-bridged dinuclear copper(II) complexes were obtained as functions of each of five structural parameters by ab initio MO calculations using the unrestricted Hartree-Fock method. Each parameter was varied in keeping the other ones unchanged unless there is any geometrical requirement. The results revealed that the Cu–O–Cu angle is the major factor to determine J value, and the other factors bring only minor effects on J value. This is readily seen in Table 2, in which $|\Delta J|$/degree for each parameter is summarized in the third column. Further, taking into consideration the practical range of the parameters, we have compared effects of variation of these parameters in the last column of Table 2, which shows that the Cu–O–Cu angle is still the major factor to determine J value. However, it should be noted that these structural parameters are not independent, but linked to each other. Therefore, one must be careful to discuss the variation of J as a function of a single parameter. Thus, the existence of exceptions observed in Fig. 7 may be ascribed to the above mentioned reason, i.e., J varies linking to other

Table 2. $|\Delta J|$/degree and $|\Delta J|$/(the pratically variable range of each parameter)

Structural parameter	Practically[a] variable range/°	$\|\Delta J\|$/degree[b]/cm^{-1}	$\|\Delta J\|$/range/cm^{-1}

structural parameters in practical compounds, though it is difficult to assign which factor plays the major role to cause deviation from the general rule at present.

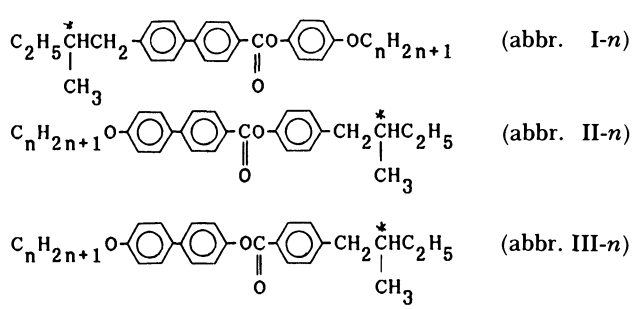
Crystal Structures of Chiral Smectogenic 4-Pentyloxyphenyl and 4-Heptyloxyphenyl 4′-[(*S*)-2-Methylbutyl]biphenyl-4-carboxylates

Kayako HORI* and Yuji OHASHI
Department of Chemistry, Ochanomizu University, Otsuka, Bunkyo-ku, Tokyo 112
(Received June 15, 1988)

Crystal structures of the title compounds, which have a Sm* C phase adjacent to a cholesteric, have been determined by single crystal X-ray analysis. 4-Pentyloxyphenyl 4′-[(*S*)-2-methylbutyl]biphenyl-4-carboxylate: monoclinic, $P2_1$, a=25.085(2), b=5.7522(3), c=18.668(1) Å, β=110.275(9)°, Z=4. 4-Heptyloxyphenyl 4′-[(*S*)-2-methylbutyl]biphenyl-4-carboxylate: triclinic, $P\bar{1}$, a=14.607(1), b=17.212(2), c=5.7322(8) Å, α=94.84(1), β=84.03(1), γ=108.607(9)°, Z=2. Final R-values were 0.113 and 0.083, respectively. Both crystals have layer structures similar to those of Sm* C phase. Two crystallographically independent molecules in each crystal are related by a pseudo-inversion. Paraffin chains with extended conformations have close contacts between layers.

The Sm* C phase of liquid crystals has become of interest because of its unique ferroelectricity. Precise structures and molecular interaction in the phase, however, are not sufficiently clear, because it is very difficult to obtain microscopic structural information due to rapid molecular motions. So, we intended to find a relationship between the mesophase characteristics (phase sequences, structures and properties) and molecular interaction revealed in the crystal structures, by X-ray crystal structure analysis for a series of compounds with various mesophase characteristics.

For this purpose, three types of compounds containing biphenyl esters were chosen, since their mesophase characteristics have already been examined.[1] The first type, 4-alkoxyphenyl 4′-[(*S*)-2-methylbutyl]biphenyl-4-carboxylates, has a Sm* C phase with iridescent color caused by a short-pitched helical structure, between crystalline and cholesteric phases.[2] Powder X-ray diffraction patterns showed that I-5 and I-7 are isomorphous with I-6 and I-8, respectively.[3] This paper describes the crystal structures of I-5 and I-7 in detail.



Experimental

The compounds were obtained in the same way as described previously.[4] Transparent long parallelepiped crystals were grown from a methanol–chloroform solution. Crystals of dimensions, 0.4×0.3×0.1 mm (I-5) and 0.5×0.4×0.1 mm (I-7) were used. The unit cell dimensions and space groups were determined from oscillation and Weissenberg photographs. Accurate cell parameters were determined by a least-squares fit for 16 reflections within the range $39°<2\theta<52°$ (I-5) and 20 reflections within the range $33°<2\theta<52°$ (I-7), measured on a Rigaku AFC-4 diffractometer with Cu $K\alpha$ radiation (λ=1.54184 Å) monochromatised by graphite. Crystal data. I-5, M_r=430.56, $C_{29}H_{34}O_3$, monoclinic, $P2_1$, T=298 K, a=25.085(2), b=5.7522(3), c=18.668(1) Å, β=110.275(9)°, V=2526.8(4) Å^3, Z=4, d_x=1.131 g cm^{-3}, μ=4.90 cm^{-1}, $F(000)$=928; I-7, M_r=458.61, $C_{31}H_{38}O_3$, triclinic, $P\bar{1}$, T=298 K, a=14.607(1), b=17.212(2), c=5.7322(8) Å, α=94.84(1), β=84.03(1), γ=108.607(9)°, V=1356.4(3) Å^3, Z=2, d_x=1.123 g cm^{-3}, μ=4.79 cm^{-1}, $F(000)$=496. Intensity data were collected by 2θ–ω scan mode, up to 2θ=125°. Scan width was $\Delta\omega=(1.0+0.15\tan\theta)°$. Backgrounds were counted for 5 s at both ends of a scan. Three standard reflections were recorded after every 50 reflections. No significant intensity variations were observed. For I-5, a total of 4497 reflections were collected at a rate of $4°(2\theta)$ min^{-1}, of which 3345 were treated as significant ($|F_o|>3\sigma(|F_o|)$). For I-7, 4345 reflections were collected at a rate of $8°(2\theta)$ min^{-1}, of which 3692 were used in the calculation. The data were corrected for Lorentz and polarization factors but not for absorption.

The structures were determined by applying the program MULTAN78[5] and refined by constrained block-matrix least-squares using SHELX76.[6] The quantity minimized was $\Sigma w(|F_o|-|F_c|)^2$, where $w=(\sigma(F_o)^2+0.004|F_o|)^{-1}$. In the course of the refinement of both structures, additional peaks of 0.5—1.0 e Å^{-3} were found around the chiral groups, whose atoms revealed considerably large temperature factors. These peaks were included as disordered atoms in further refinement. For I-5, C(22) to C(25) of the molecule A and C(23) to C(25) of B were disordered, whereas only the terminal C(24) atoms of A and B were disordered for I-7. All the non-hydrogen atoms except for the disordered ones of I-7 were refined anisotropically with loosely constrained condition to have normal geometries. Some hydrogen atoms were found in the difference Fourier maps and others were derived geometrically except for the chiral parts and the terminal atoms of the alkyl chains of I-5. Final refinement including the hydrogen atoms were performed with the program HBLS,[7] since the numbers of the parameters became too large for SHELX76. Max. Δ/σ and max. $\Delta\rho$ in the final difference map were 0.52 and 0.25 e Å^{-3} for I-5, and 0.54 and 0.30 e Å^{-3} for I-7. Final R (and R_w) were 0.113 (0.139) and 0.083 (0.098) for I-5 and I-7, respectively. Rather large R-value of I-5 is due to the disordered structures of the chiral parts. Atomic scattering factors were taken from the International Tables for X-ray Crystallography.[8] The final

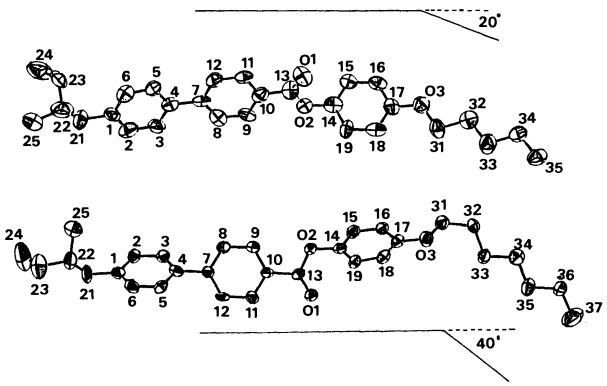

Fig. 1. ORTEP views of the molecules A of 4-pentyloxyphenyl 4'-[(*S*)-2-methylbutyl]biphenyl-4-carboxylate (I-5, upper) and 4-heptyloxyphenyl 4'-[(*S*)-2-methylbutyl]biphenyl-4-carboxylate (I-7, lower) with 50% probability thermal ellipsoids. Only one of the two conformers of the disordered part is shown for simplicity.

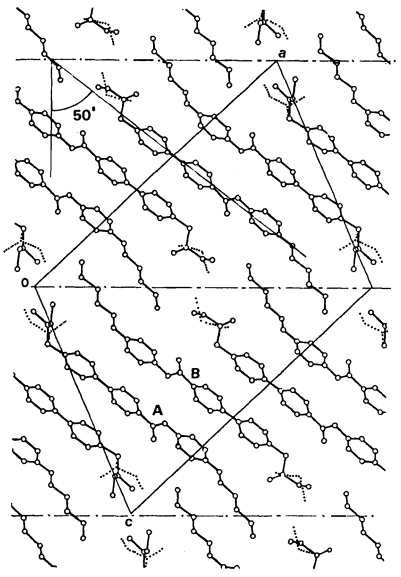

Fig. 2. Crystal structure of I-5 viewed along the b axis. The dot-and-dash lines denote interfaces of the layer. The dotted lines denote disordered conformers.

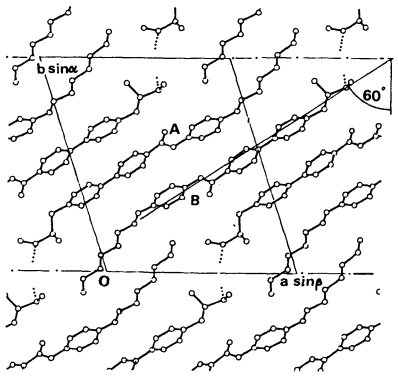

Fig. 3. Crystal structure of I-7 viewed along the c axis. The dot-and-dash lines denote interfaces of the layer. The dotted lines denote disordered conformers.

coordinates of non-hydrogen atoms are given in Tables 1 (I-5) and 2 (I-7).[9] Computations were done on a HITAC M-280H at the Computer Center of the University of Tokyo.

Results and Discussion

Molecular Conformations. There are two crystallographically independent molecules with approximately the same conformation in an asymmetric unit for both crystals. The ORTEP drawings of the molecular structures with numbering schemes are shown in Fig. 1.[10] Chiral parts are highly disordered even in the crystalline state for I-5, while they are only slightly disordered for I-7. All the bond lengths and bond angles, as given in Tables 3 and 4, are compatible with those found in other mesogens.[11] All the phenyl rings are planar within the experimental error.

Table 5 shows torsion angles characteristic to the molecular conformations. Each molecule in the I-5 crystal has an approximately coplanar biphenyl moiety and an all-trans zigzag paraffin chain, while a largely twisted biphenyl moiety and an extended paraffin chain with a twisted O–C–C–C part are found in the I-7 crystal. In each crystal, an extended alkyl chain results in a bent shape of a molecule as a whole, as shown in Fig. 1. The angles between the chains and the other part of the molecules are approximately 20° (I-5) and 40° (I-7).

Crystal Packing. Figures 2 and 3 show the crystal

a) $B_{eq}=(4/3)\sum_{ij}\beta_{ij}(a_i\cdot a_j)$. b) Isotropic temperature factors. c) Occupation factors are fixed as 0.8, 0.2, 0.7, and 0.3 for C(24A), C(24A'),C(24B), and C(24B'), respectively.

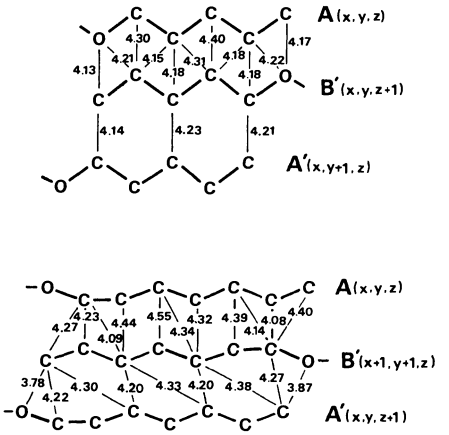

Fig. 4. Inter-chain distances (Å) of I-5 (upper) and I-7 (lower). Symmetry codes are shown in parentheses.

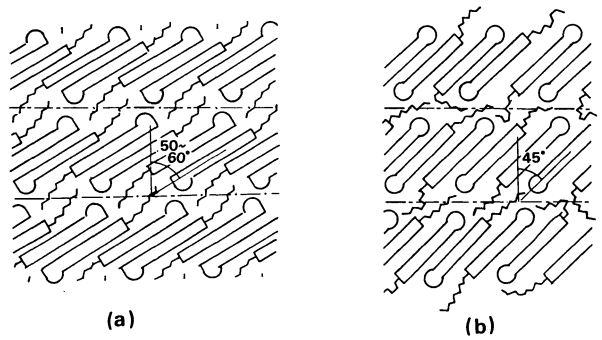

Fig. 5. Schematic diagrams of the structures of the crystal (a) and Sm* C (b). In the latter, the tilt direction forms a slightly helical distribution on moving from layer to layer. A half-rounded head in (a) denotes a static bulky 2-methylbutyl group, while a round head in (b) denotes a rotating one.

structures of I-5 and I-7, respectively. They have a similar packing mode. Layer structures similar to those of smectics are composed of two crystallographically independent molecules A and B, which are related by a pseudo-inversion except for the chiral parts. In a crystal of an achiral compound, 4,4'-bis(pentyloxy)azoxybenzene had a layer structure composed of equivalent molecules, in which a layer plane was very clear, corresponding to the existence of an "intermediately highly ordered smectics".[12] In the present case, layer planes, although less clear, are parallel to the (10$\bar{1}$) plane (I-5) and the (010) plane (I-7). The molecular long axis is largely tilted in the layer. The tilt angles are estimated to be 50° (I-5) and 60° (I-7).

Paraffin chains of adjacent molecules are in contact with each other between layers. The inter-chain distances are shown in Fig. 4. The molecules A and B' are contact in the range of 4.13—4.40 Å for I-5 and 4.08—4.55 Å for I-7. The wider range of I-7 is caused by the twisted O–C–C–C parts. Neverthless, the inter-chain distances in the two crystals are very close to the values found in the crystalline long-chain compounds; 4.14 and 4.20 Å for hexatriacontane[13] or 4.13 and 4.20 Å for normal-chain fatty acids.[14] Furthermore, the chains of the molecules B' and A' are also relatively close, though the zigzag chains are out of phase each other. Therefore, the inter-chain association between layers plays an important role in molecular aggregation in these crystals. The bent shape of each molecule mentioned above is resulted from this inter-chain contact. This bending also favors the packing of bulky 2-methylbutyl groups.

Concerning a packing mode within a layer, there are two kinds of intermolecular overlapping. Each molecule overlaps largely, i.e., from head to tail, with one of the nearest neighbor molecules. On the contrary, the overlaps with the other molecule is small and alkyl chains are related to the interlayer aggregation. So, the two molecules displace largely each other along their long axes, and the large displacement leads to a large tilt angle of the molecule in a layer. Nearest phenyl rings between adjacent molecules make angles of 60° (I-5) and 54° (I-7) in average. This fact also suggests that lateral intermolecular forces are not so strong as in the case of 4,4'-bis(pentyloxy)azoxybenzene with a more ordered smectic than Sm* C, since nearest phenyl rings of the latter crystal are parallel between adjacent molecules.

Relationship between the Crystal and Sm* C Structures. Characteristic features of the two crystal structures are summarized schematically in Fig. 5(a). This is compared with a Sm* C structure shown in Fig. 5(b), which was estimated in the previous study[4] by measuring temperature dependence of the interlayer distances in the Sm* C phase in the series I (n=6, 7, 8, 9, 10, 12, 14, and 16) by X-ray diffraction. Linear

increase in the interlayer distances with increase in temperature was attributed mainly to the large change of paraffin chain organization. However, the tilt angle of the core part is kept constant (45°), until the transition to a cholesteric phase occurs. This behavior is well interpreted by the crystal structures, as follows. The tilt angles in the crystal structures (50° and 60°) are close to that in the Sm* C phase. This fact suggests that molecular arrangements as a whole do not change largely at the transition, though the transition is of first-order with a large enthalpy change (6—7 kcal mol^{-1}).[2] Transition from crystals to Sm* C is caused by melting of the paraffin chains, which are regularly organized in the crystalline states. Each molecule begins to rotate around its long molecular axis, because the packing between adjacent phenyl rings is not so close, as is suggested by their nonparallel contact. In Sm* C phase, the chains would change their conformations largely, while the inclination angle of molecular axis should be kept relatively constant, owing to the interaction between the alkyl chains. When the chains are sufficiently disordered, molecules no longer have smectic layers because of relatively small molecular interaction of the core part. Then the transition to a cholesteric phase should occur. In the case of I-5, the chains are so short that Sm* C phase appears only monotropically; with increase in temperature the I-5 crystal transforms directly to a cholesteric phase.

It is concluded that the Sm* C phase behavior observed in a series of biphenyl esters is well interpreted by the molecular packing modes in the crystals. This fact suggests that single crystal X-ray analyses give powerful and useful information to elucidate precise mesophase structures.

Structure of Mixed Ligand Complex [Cu(pan)(phen)]BF_4 with Special Reference to the Acceleration of the Ligand Substitution Reaction

Hiroko WADA,* Motoo SHIRO,† Akio YUCHI, and Genkichi NAKAGAWA
Department of Applied Chemistry, Nagoya Institute of Technology, Gokiso-cho, Showa-ku, Nagoya 466
†Shionogi Research Laboratories, Shionogi & Co., Ltd., Fukushima-ku, Osaka 553
(Received March 22, 1988)

The crystal structures of [1-(2-pyridylazo)-2-naphtholato]copper(II) complexes, [Cu(pan)(phen)]BF_4 as well as [Cu(pan)(H_2O)]ClO_4 and [Cu_2(pan)$_2$(H_2O)$_3$](BF_4)$_2$ have been determined. In these complexes pan^- anion coordinates with copper(II) as a tridentate ligand and all complexes have square pyramidal geometry. In the mixed ligand complex [(Cu(pan)(phen)]BF_4, 1,10-phenanthroline occupies the forth position in the basal plane and the apical site, thus the structure is fairly distorted. This distorted structure is responsible for the fast substitution of [Cu(pan)(phen)]$^+$ complex with $edta^{4-}$.

In the series of studies on the ligand substitution reaction, Tanaka and his coworkers found that the reactivity of the complexes can be quantitatively accounted for by the electron donation from the ligand already bound to the metal ion.[1]

In our previous works,[2–4] it was found that the color change of 1-(2-pyridylazo)-2-naphthol (PAN, Hpan) or Xylenol Orange indicator in chelatometric titration of copper(II) with ethylenediamine-*N*,*N*,*N*′,*N*′-tetraacetic acid (EDTA, H_4edta) is accelerated by the addition of a small amount of bidentate ligand such as 1,10-phenanthroline (phen), 2,2′-bipyridine, 8-quinolinol, sodium diethyldithiocarbamate. The rate and mechanism of substitution reaction of [Cu(pan)]$^+$ complex with EDTA had been studied in detail.[3] In the absence of phen, the ligand substitution reaction with EDTA proceeds as

$$\mathrm{Cu(pan)^+ + edta' \rightleftharpoons Cu(pan)(edta) \longrightarrow Cu(edta)^{2-} + Hpan} \quad (1)$$

The rate depends on the total concentration of EDTA not combined with copper(II), [edta′], and the rate constant is; $k=1.7\times10^3$ dm^3 mol^{-1} s^{-1}, whereas in the presence of phen, the rate does not depend on the concentration of edta′, but depends mainly on the concentration of hydrogen ion. The mechanism of the substitution reaction is expressed as

$$\mathrm{[Cu(pan)(phen)]^+ + H^+ \longrightarrow Cu(phen)^{2+} + Hpan} \quad (2)$$
$$\mathrm{Cu(phen)^{2+} + edta' \rightleftharpoons Cu(edta)^{2-} + phen}$$

The rate constant is; $k=1.6\times10^6$ dm^3 mol^{-1} s^{-1}. The faster substitution Reaction (2) compared with Reaction (1) is attributed to the distorted structure of the mixed ligand complex [Cu(pan)(phen)]$^+$. Also the formation of the mixed ligand complex of [Cu(pan)]$^+$ with some other bidentate ligands such as 2,2′-bipyridine, bathophenanthroline, 8-quinolinol, diethyldithiocarbamate, etc. was found, and the stability constants of these mixed ligand complexes were determined spectrophotometrically.[5]

In this work the crystal structure of [Cu(pan)(phen)]BF_4 (**1**) was determined as well as [Cu(pan)(H_2O)]ClO_4 (**2**), [Cu_2(pan)$_2$(H_2O)$_3$](BF_4)$_2$ (**3**) for comparison. Although crystal structure of complex **2** had been determined previously by Ooi et al.,[6] the refined geometry as well as the other complexes was determined. The influence of phen on the acceleration of the substitution reaction is discussed by comparing the bond lengths of Cu–pan in the complex **1** with those in the complexes **2**, **3**, and [Cu(pan)Cl] (**4**).[7]

Experimental

Preparation of the Complexes. [Cu(pan)(phen)]BF_4(**1**) was prepared by adding an ethanol solution of equal concentration of Hpan and phen to an aqueous solution of $Cu(BF_4)_2$ in the molar ratio of 1:1. After slow evaporation of the solvent at room temperature, dark green crystals with metallic luster were obtained together with orange ones of Hpan. The results of elemental analysis of the dark green crystal: C, 55.9%; H, 2.9%; N, 12.1%, Calcd for [Cu(pan)(phen)]BF_4: C, 56.0%; H, 3.1%; N, 12.1%. [Cu(pan)(H_2O)]ClO_4 (**2**) was prepared from Hpan and $Cu(ClO_4)_2$ and [Cu_2(pan)$_2$(H_2O)$_3$](BF_4)$_2$ (**3**) from Hpan and $Cu(BF_4)_2$ in the similar way. All crystals have similar color as [Cu(pan)(phen)]BF_4.

X-Ray Analysis. Crystallographic details for **1**, **2**, and **3** are listed in Table 1. The unit cell parameters were determined by least-squares fitting of 2θ values of 20 reflections ($0.20<\sin\theta/\lambda<0.24$ Å^{-1}) measured on a Rigaku AFC-5 diffractometer equipped with a graphite monochromator.

Three-dimensional intensity data were collected by ω–2θ scan technique using Cu $K\alpha$ radiation (λ=1.54178 Å) for **1** and using Mo $K\alpha$ radiation (λ=0.71069 Å) for **2** and **3**. Three standard reflections monitored every 100 reflections showed no significant change during the data collection. All intensities were corrected for Lorentz and polarization factors, but not for absorption effects.

The structures were solved by the conventional heavy atom method, and improved by block-diagonal least-squares refinement of the positional and the thermal parameters of the non-H atoms and the positional ones of the H atoms

a) The unit cell parameters described in Ref. 6 are as follows: a=10.38, b=8.22, c=9.35 Å, α=85°20′, β=96°48′, γ=93°19′.

which were located on difference electron density maps. The temperature factor of each H atom was assumed to be isotropic and equal to the equivalent isotropic temperature factor of the attached atom. The function minimized in the refinement was $\Sigma(w|\Delta F|^2)$. The weighting scheme was $w=[\sigma^2(F_o)+c^2|F_o|^2]^{-1}$ for observed reflections with $w^{1/2}|\Delta F|<4$ and $w=0$ otherwise. The values of c^2 were 0.00381, 0.00231, and 0.00144 for **1**, **2**, and **3**, respectively. The parameter shifts in the final cycle were less than half the corresponding σ values. The atomic scattering factors were calculated using the analytical expression $f=\Sigma[a_i\exp(-b_i\sin^2\theta/\lambda^2)]+c$ (i=1—4).[8] Computations using the programs of MULTAN84, PLUTO, and XPACK86 SHIONOGI were performed by a FACOM M-340R computer at Shionogi Research Laboratories.

Structural Description

Perspective views of **1** and **2** are shown in Figs. 1 and 2, respectively. In the crystal of **3**, the two complexes which should be differently described as [Cu(pan)-(H_2O)]BF_4 (**3A**) and [Cu(pan)(H_2O)$_2$]BF_4 (**3B**) are included (Figs. 3 and 4). All the complexes have the same type of coordination geometry around Cu(II): square pyramidal geometry or square planar one with weak interaction between Cu and the atom at the position corresponding to the apex. Three corners of the basal plane are occupied by the atoms of pyridyl N, azo N adjacent to the naphthol group and naphthol O of the pan$^-$ ligand. The atoms at the fourth corner of the plane (X) and the apical position (Y) are shown in Fig. 5 along with the atom-numbering systems of the

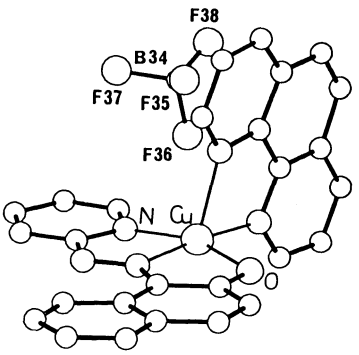

Fig. 1. Perspective drawing of **1** with atomic numbering system for BF_4^-.

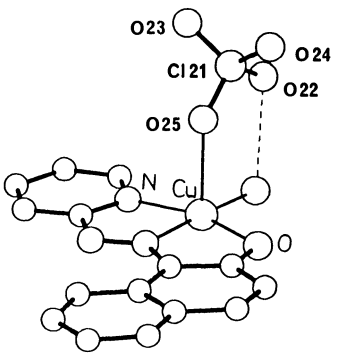

Fig. 2. Perspective drawing of **2** with atomic numbering system for ClO_4^-. Broken line represents the intramolecular hydrogen bond of O(20)···O(22).

phen and pan$^-$ ligands. The square pyramid of **1**, in which the axial Cu–N bond is considerably tilted to the basal plane [$\angle$N(20)–Cu–N(29)=79.4(1)°], is the most distorted in those of the complexes.

Atomic coordinates and equivalent isotropic temperature factors are listed in Table 2. The bond lengths and angles involving Cu, and the deviations of Cu from the basal plane are given in Table 3, where those of [Cu(pan)Cl] (**4**)[7] are listed together for comparison. The less planarity of the basal plane in **3A** and **3B**, judged based on the rms deviation of the constituent atoms from the plane, may be mainly caused by that of the pan$^-$ ligand as described later.

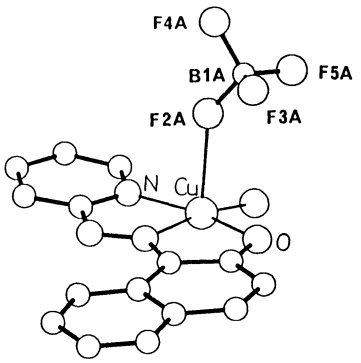

Fig. 3. Perspective drawing of **3A** with atomic numbering system for BF_4^-.

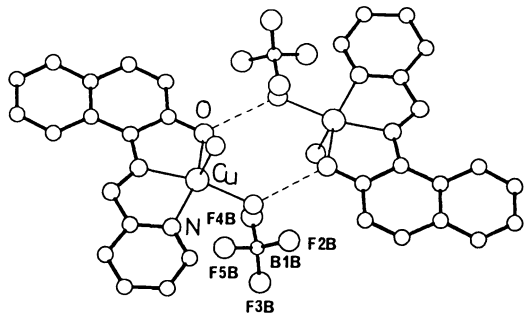

Fig. 4. Perspective drawing of **3B** with atomic numbering system for BF_4^-. Broken lines represent the intermolecular hydrogen bonds of O(19)···O(20).

The bond length of Cu–N(20) in **1** is compatible with the equatorial Cu–N bonds in [Cu(gg)(phen)]-$3H_2O$,[9] 2.009(5) Å, and in [Cu(phen)$_3$]$(ClO_4)_2$,[10] 2.00(1) and 2.02(1) Å (gg=glycylglycine dianion). However, the bond of Cu–N(29) in **1** is shorter than the axial Cu–N bonds, 2.275(5) Å in [Cu(gg)(phen)]-$3H_2O$ and 2.34(1) and 2.32(1) Å in [Cu(phen)$_3$]$(ClO_4)_2$, indicating the N(29) atom to be tightly bound to Cu.

For **2**, **3A**, and **3B** (X=H_2O), the deviation of Cu from the basal plane increases as the distance between Cu and the apical atom decreases. The bonds of Cu–N(1), Cu–N(8), Cu–O(19), and Cu–O(20), according to usual statistical tests, are respectively lengthened in the order of [**2**, **3A**]<**3B**, **2**<[**3A**, **3B**], **3A**<[**2**, **3B**], and [**2**, **3A**]<**3B**, though differences among those in [ ] are not significant. This suggests that the equatorial bonds tend to be weakened with shortening the interatomic distance between Cu and Y. The bonds in **1**, except Cu–N(8), are significantly longer than the corresponding ones in **3B**, a similar tendency having been pointed out on comparison between [Cu(gg)(phen)]$3H_2O$ and [Cu(gg)$(H_2O)_2$]-H_2O.[9]

In the crystal of **4**, the centrosymmetric binuclear complex molecule, [Cu(pan)Cl]$_2$, bridged through two Cl atoms is formed: each Cl atom lies at the basal plane of one square pyramid and at the apex of another one. The bond lengths of Cu–pan$^-$ are very similar to the corresponding one in **1**.

The bond lengths and angles of the phen and pan$^-$ ligands are normal and agree well within experimental errors with those in the respective free ligands. The phen ligand in **1** is bowed along its longest molecular axis, the dihedral angle between the two C_5N rings being 4.3°. For pan$^-$ ligand, the rms deviations of the constituent atoms from the mean plane are 0.016, 0.030, 0.055, 0.040, and 0.016 Å for **1**, **2**, **3A**, **3B**, and **4**, respectively. The less planarity of the ligand observed in **3A** and **3B** is mainly caused by the twist between the pyridine and naphthol rings: the

	1	2	3A	3B	4

dihedral angles between the two rings are 1.4, 1.9, 4.5, 3.9, and 1.2° in the above order.

The atom-numbering systems of the BF_4^- and ClO_4^- anions are presented in Figs. 1—4. The bond lengths of B–F average 1.37 Å for **1**, 1.35 Å for **3A** and 1.33 Å for **3B**, and those of Cl–O average 1.43 Å for **2**. The mean bond angles of F–B–F are all 109° for **1**, **3A**, and **3B**, and that of O–Cl–O is 110° for **2**. The temperature

factors of the atoms of the anions are larger than those of the constituent atoms of the pan⁻ and phen ligands, some of which exhibit a large anisotropy. The H atoms of all the complexes lie at the positions not far from those expected on chemical grounds.

In **2** and **3**, the two complexes related by an inversion center are linked to form a binuclear unit by the hydrogen bonds between O(19) and O(20) individually lying on different basal planes of the two square pyramids: the interatomic distances are 2.661(3), 2.666(4), and 2.688(5) Å for **2**, **3A**, and **3B**, respectively. This is represented for **3B** in Fig. 4. The basal planes of the two complexes, parallel to each other, are differently separated in each binuclear unit probably subjected to different packing effects: the distances are respectively 1.40, 0.61, and 1.14 Å for **2**, **3A**, and **3B**. The above-mentioned dihedral angle between the pyridine and naphthol rings in the pan⁻ ligand increases with decreasing distance in the order of **2**>**3B**>**3A**. Smaller angles are observed for **1** and **4** in which such hydrogen bonds are not formed. Therefore, we assumed that the distortion in the pan⁻ ligand may be caused by the formation of the intermolecular hydrogen bonds in the binuclear unit. The O(20) atom forms a hydrogen bonds with O(22) [2.741(4) Å] in **2** and a bifurcated one with F(2B) and F(5B) [2.929(4) and 3.015(4) Å] in **3B**.

Discussion

The bond lengths of Cu-pan in the mixed complex **1** were similar to those in complex **4**. However, the mixed ligand phen complex **1** is expected to have the same structure in aqueous solution, whereas in the mixed ligand chloro complex **4** Cl^- at apical position should be replaced with water molecule. The resulted complex may have the structure close to complex **3B**, because the interaction with inert anions at apical site is weak even in solid as shown in complexes **2** and **3A**.

In the ligand substitution reaction of the mixed ligand complex $[Cu(pan)(phen)]^+$ with multidentate ligand such as $edta^{4-}$, the reaction mechanism is different from that of the unidentate mixed ligand complex. The mixed ligand complex with the

unidentate ligand has at least one water molecule in X or Y position. The water molecule is labile and easily displaced by a moiety of the entering ligand before or in the rate-determining step. Thus the rate is propotional to the concentration of the entering ligand. The reaction is accelerated by the presence of unidentate ligand (L), because the bonds between Cu(II) and pan^- are weakened depending on the electron donation from L to Cu(II).

On the other hand, a bidentate ligand such as phen occupies not only the basal site but also the apical one, then there left no site for the entering ligand to attack, but Cu-pan bonds are weakened by the coordination of phen as seen from the results of the X-ray analysis. This is also found from the decreased stability constant of $[Cu(pan)(phen)]^+$ compared with that of $[Cu(pan)]^+$: $\log K^{pan}_{Cu(pan)(phen)}=12.20$ and $\log K^{pan}_{Cu(pan)}=15.58$ (5%dioxane, 0.1 mol dm^{-3} KNO_3 at 25 °C). Therefore, the Cu-pan bond in the mixed ligand complex **1** is easily broken by the attack of proton (rate-determining step). The rate of the reaction does not depend on the concentration of the entering ligand but depends on the concentration of hydrogen ion. The resulted $[Cu(phen)]^{2+}$ complex is rapidly replaced with $edta^{4-}$. As the rate constant of Reaction (2) is much larger than that of Reaction (1), the rate of the color change of PAN indicator is accelerated by the addition of phen in the chelatometric titration of copper(II).

The Synthesis and Thermal Behavior of Lithium *cyclo*-Hexaphosphate

Makoto WATANABE,* Khoichi MURATA, and Mioko MAEDA
Department of Industrial Chemistry, Chubu University,
Matsumoto-cho, Kasugai, Aichi 487
(Received April 9, 1988)

Lithium *cyclo*-hexaphosphate hexahydrate was made by heating a mixture of 85%-phosphoric acid and dilithium carbonate at an Li/P molar ratio of 1.4 at 200 (1 h), 275 (5 h), and then 420 °C (3 h). The thermal product was handled with a wet chemical method developed in this study. The *cyclo*-hexaphosphate was stable at room temperature (20—30 °C), while a small part of it decomposed to phosphates with shorter chain lengths above about 60 °C in air. The *cyclo*-hexaphosphate was transformed thermally to crystalline long-chain polyphosphates upon heating above 530 °C.

Some oligophosphates and long-chain polyphosphates have been made by the thermal condensation of orthophosphates. These polyphosphates have been used for water treatment, food additives, detergents, and so forth.[1] Griffith and Buxton have reported on the synthesis of lithium *cyclo*-hexaphosphate hexahydrate by heating a mixture of phosphoric acid and dilithium carbonate and then recrystallizing the *cyclo*-phosphate from the thermal product. They also indicated that the hydrated *cyclo*-phosphate could be dehydrated by heating at about 120 °C without decomposition.[2] The present authors followed up the method and found that there are several problems regarding the preparation of the hydrated and unhydrated *cyclo*-hexaphosphates. This paper describes the problems and an improvement in the preparation method for the *cyclo*-phosphate. The thermal property of the *cyclo*-phosphate was also studied.

Experimental

Preparation of Lithium *cyclo*-Hexaphosphate. According to Griffith and Buxton, a mixture of dilithium carbonate and 85%-phosphoric acid with an Li/P molar ratio of 1.4 was heated at 200 °C for 1 h and at 275 °C for 5—7 h; then, the resulting thermal product was dissolved in water and lithium *cyclo*-hexaphosphate hexahydrate was crystallized by adding methanol to the solution. The present authors found that it was difficult to prepare the *cyclo*-phosphate by this method and that it was necessary to study the effect of the mixing ratio of dilithium carbnate and 85%-phosphoric acid, the heating temperature, and the heating time for the distribution of phosphate species in the thermal product. It was also necessary to improve the wet process in order to purify the *cyclo*-phosphate from the thermal product.

Chemical Analysis. An atomic absorption analysis was used for a determination of any lithium ions in the sample solution by using a Shimadzu atomic absorption spectrophotometer (AA-646). Phosphorus was determined according to the Molybdenum Blue method.[3]

Paper Chromatography. A one-dimensional paper-chromatographic separation was employed by using acidic (for the separation of chain phosphates) and basic (for the separation of ring phosphates) solvents.[4] A sample (0.1 g) was dissolved in 10 cm^3 of a 6% aqueous disodium dihydrogen ethylenediaminetetraacetate dihydrate (Na_2H_2-edta·$2H_2O$) solution. The solution (8 mm^3) was spotted on Toyo No. 51A filter paper (2 by 50 cm). The development was run at 3 °C for 2 d.

Colorimetric Measurement of Phosphates. Every individual spot on the chromatogram was cut at its demarcation line and put into a 100-cm^3 beaker containing 10 cm^3 of 0.1 mol dm^{-3} aqueous ammonia. The phosphate extracted in aqueous ammonia was determined colorimetrically by a method described in our previous paper.[5]

HPLC Analysis. An HPLC technique (developed by Yoza) was also used for a separation and determination of any phosphate species in a sample solution.[6] Aqueous 0.26- and 0.40-mol dm^{-3} solutions of potassium chloride were run at a flow rate of 1 cm^3 s^{-1}.

^{31}P NMR Measurement. The ^{31}P NMR spectrum of an aqueous phosphate solution was taken by a JNM-GX270 instrument. Phosphoric acid (85%) was employed as a reference with the positive chemical shifts being downfield.

X-Ray Diffractometry. An X-ray diffraction diagram of a powder sample was taken with nickel filtered Cu $K\alpha$ radiation by using a Rigaku X-ray diffractometer, RAD-1B.

TG-DTA Measurement. The TG-DTA measurement was used to study the thermal behavior of the product by using a Cho Balance TRDA-H apparatus with the heating rate of 5 °C min^{-1} in air.

Results and Discussion

Li/P Molar Ratio and Reaction Temperature. The process of the synthesis of *cyclo*-hexaphosphate developed by Griffith and Buxton is shown in Fig. 1. Mixtures of 85%-orthophosphoric acid and dilithium carbonate with Li/P ratios of 1.0—1.5 were heated in the same manner as that of Griffith and Buxton. The compositions of the phosphate species of these thermal products are shown in Table 1. (The values listed in Tables 1—4 are average values for, at least, three times.) The main product was high polyphosphate or diphosphate. The content of *cyclo*-hexaphosphate was at most 19.0% at an Li/P ratio of 1.4. The resulting thermal products were again heated at 350 or 420 °C for 3 h. The compositions of the phosphate species of the thermal products are listed in Tables 2 and 3, respectively. The content of *cyclo*-hexaphosphate increased when the thermal products were reheated at 350 and 420 °C. The *cyclo*-phosphate content at 420 °C was higher than that at 350 °C. The best Li/P ratio was 1.4, in agreement with the result of Griffith

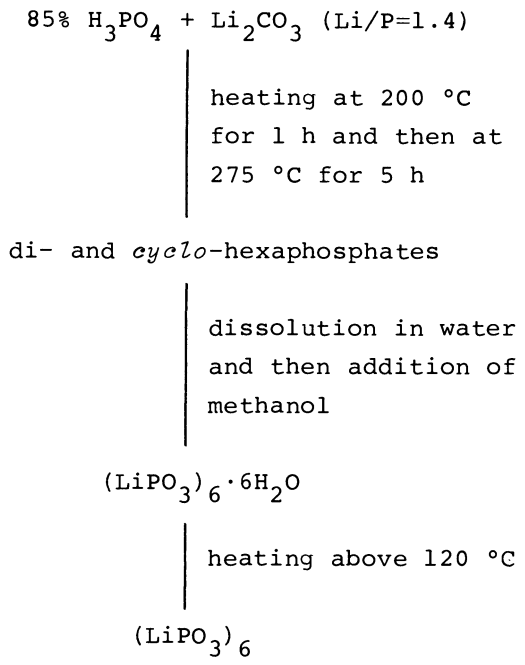

Fig. 1. Synthetic process of *cyclo*-hexaphosphate by Griffith and Buxton.

1.5	—	33.9	—	31.3	34.8

and Buxton. The effect of the reaction temperature on the content of the *cyclo*-phosphate was studied for the thermal product with an Li/P ratio of 1.4 (prepared by Griffith and Buxton's method). The results are shown in Table 4. The best reaction temperature seemed to be 420 °C. The either product at a temperature higher or lower than 420 °C showed a decrease in the *cyclo*-phosphate content.

a) The thermal product was preheated at 200 °C for 1 h and at 275 °C for 5 h.

Purification of the *cyclo*-Hexaphosphate. The highest content of the *cyclo*-phosphate in the thermal products was about 45% and a purification of the *cyclo*-phosphate was required. Griffith and Buxton described how *cyclo*-phosphate was purified by dissolving the thermal product in water and then adding methanol to the solution. The thermal product obtained by heating at 420 °C for 3 h did not dissolve in water, but dissolved in a 1% ethylenediaminetetraacetic acid (H_4edta) solution of pH 9. The pH of the solution was controlled with a 1-mol dm^{-3} aqueous lithium hydroxide solution. The thermal product (7.3 g) was dissolved in 100 cm^3 of a H_4edta solution and the residue (di- and highpolyphosphates) was filtered off. Methanol (110 cm^3) was added to the filtrate and a white precipitate was removed by filtration. Lithium chloride (8 g) was added to the filtrate. A small amount of white precipitate (*cyclo*-hexa- and highpolyphosphates) was filtered off; then, lithium chloride (18.5 g) was added to the filtrate. A white precipitate was obtained by filtration, washed with 75 vol% aqueous acetone, and dried in air. The process is shown in Fig. 2. Found: P, 29.5; Li, 6.8;

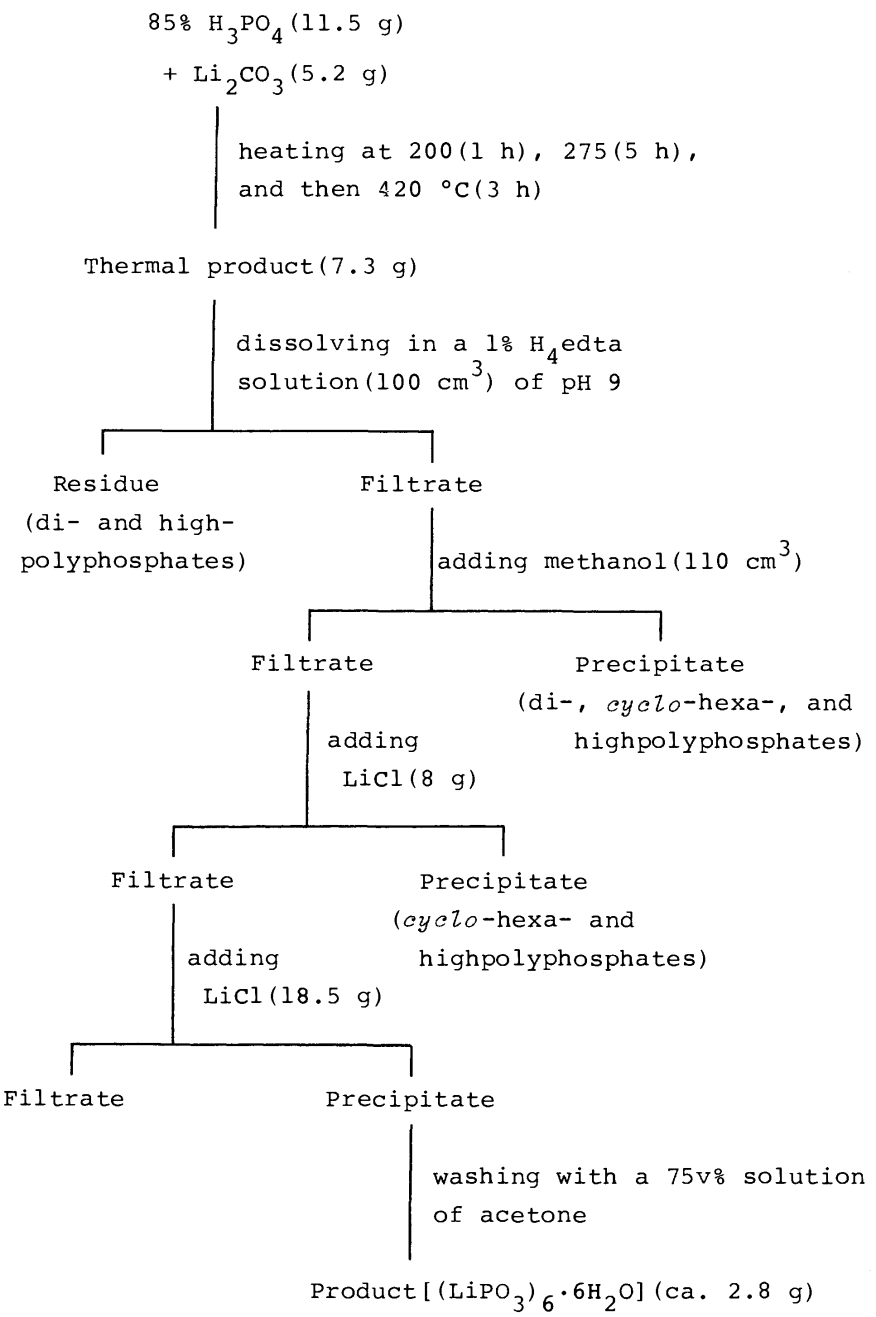

Fig. 2. Synthetic process of *cyclo*-hexaphosphate hexahydrate.

H_2O, 17.5%. Calcd for $(LiPO_3)_6 \cdot 6H_2O$: P, 29.8; Li, 6.7; H_2O, 17.3%. The ^{31}P NMR spectrum of the product shown in Fig. 3 exhibited only one singlet at −22.6 ppm and the peak is due to a middle-PO_4 group. The product also gave only one HPLC peak in the profile. Accordingly, the product is lithium *cyclo*-hexaphosphate hexahydrate, $(LiPO_3)_6 \cdot 6H_2O$. The X-ray diffraction data of *cyclo*-phosphate are presented in Table 5, together with the data of Griffith and Buxton. They gave a rough order of intensity of the peak without the I/I_0 value. The yield of the product was about 30%. The *cyclo*-phosphate was stable at room

temperature (20—30 °C), with a solubility of 3.03 at 20 °C.

TG-DTA Measurement. TG and DTA curves of lithium *cyclo*-hexaphosphate hexahydrate are shown in Fig. 4. The thermal products (as numbered in Fig. 4) were taken out of a furnace and subjected to further analysis in order to study the thermal reactions of the *cyclo*-phosphate. The first endothermic peak accompanying a small amount of weight loss seemed to be due to the removal of the adsorbed water, since the product showed an X-ray diffraction pattern of $(LiPO_3)_6 \cdot 6H_2O$. However, the results listed in Table 6 indicate that a small part of the *cyclo*-phosphate decomposed to diphosphate:

$$(LiPO_3)_6 + 3H_2O \longrightarrow 3Li_2H_2P_2O_7. \quad (1)$$

The water in the above equation might have come from the water of crystallization of the *cyclo*-phosphate. The next big endothermic reaction accompanying the weight loss was considered to be due to an elimination of the water of crystallization along with a simultaneous decomposition of the *cyclo*-phosphate. The third small endothermic peak accompanying the weight loss may have been caused by an elimination of the rest water of crystallization, and a condensation of the phosphates to phosphates with longer chain lengths, since the content of ortho-, di-, and triphosphate in the thermal product decreased and that of *cyclo*-hexaphosphate increased after the endothermic reaction. A small exothermic peak was observed at about 330 °C. As Table 6 shows, most parts of the thermal products of Nos. 2—4 were *cyclo*-hexaphosphate; the weight loss of thermal product No. 4 agrees well with the following dehydration:

$$(LiPO_3)_6 \cdot 6H_2O \longrightarrow (LiPO_3)_6 + 6H_2O. \quad (2)$$

Thermal product No. 4 gave a different X-ray diffraction diagram than those of Nos. 2 and 3. Therefore, the exothermic reaction can be attributed to a transition of *cyclo*-hexaphosphate. The X-ray diffraction pattern of No. 4 agreed with that of anhydrous lithium *cyclo*-hexaphosphate by Griffith and Buxton. After the next exothermic reaction at about 530 °C, the

crystalline *cyclo*-hexaphosphate transformed to crystalline lithium methaphosphate (highpolyphosphate). The thermal product was sintered through the next small endothermic reaction at about 590 °C. The metaphosphate melted at about 650 °C. Griffith and Buxton reported that the *cyclo*-hexaphosphate hexahydrate can be dehydrated by heating above 120 °C and pure anhydrous *cyclo*-hexaphosphate can be prepared. According to the above results, a samll part of the *cyclo*-hexaphosphate hexahydrate is decomposed to phosphates with shorter chain lengths by heating above about 60 °C and pure anhydrous *cyclo*-hexaphosphate can not be prepared by heating the hexahydrate.

Nickel(II) and palladium(II) complexes with tridentate thiolic ligands of the NNS-donor set have been prepared and characterized on the basis of elemental analyses, IR and electronic spectra, molar conductances, and magnetic susceptibilities. The crystal structure of the nickel(II) perchlorate of 3-[2-(2-pyridyl)ethylamino]-1-propanethiol was determined by single-crystal X-ray diffraction method. The structure consists of thiolate-bridged binuclear units. Each metal ion is coordinated by the amino nitrogen, pyridine nitrogen, and two bridging sulfur atoms, forming an essentially planar coordination unit, and the two N_2S_2 planes are connected at the S1-S2 edge with a dihedral angle of 136.1°.

Tridentate alcoholic ligands have been extensively utilized for synthesizing binuclear metal complexes bridged by their deprotonated alcoholic oxygens. As reported in the previous papers, we carried out systematic investigations on binuclear copper(II) complexes of tridentate alcoholic ligands of NSO-,[1-6] SNO-,[4,6,7] or SSO-donor set,[4,8] and revealed that the substitution of thioether sulfur for nitrogen donor atom substantially affects the formation, structure, magnetism, and electrochemical and spectral properties of the complexes. In this study the interest is focused on the effect of the change of the bridging atom from alcoholic oxygen to thiolic sulfur on the structure and physicochemical properties of binuclear complexes. All attempts to synthesize binuclear copper(II) complexes with thiolate-bridge have been unsuccessful, because thiols in general reduce copper(II) to copper(I) ($2R\text{-}S^- + 2Cu^{2+} \rightarrow R\text{-}SS\text{-}R + 2Cu^+$). However, formation of thiolate-bridged metal complexes is feasible by the use of other transition metal ions. In spite of great interests in structure and properties of such thiolate-bridged complexes, investigation on binuclear metal complexes with tridentate thiolic ligands is very limited.[9-12] Thus, we have initiated a systematic investigation on thiolate-bridged binuclear complexes using tridentate thiolic ligands.

In this study we have examined binuclear nickel(II) and palladium(II) complexes of thiolic ligands of NNS-donor set. The ligands utilized in this study are 2-(2-aminoethylamino)ethanethiol (HL^1), 2-(3-aminopropylamino)ethanethiol (HL^2), 2-(2-pyridylmethylamino)ethanethiol (HL^3), 2-[2-(2-pyridyl)ethylamino]ethanethiol (HL^4), and 3-[2-(2-pyridyl)ethylamino]-1-propanethiol (HL^5). Of these ligands, HL^1 and HL^2

HL^1: $NH_2CH_2CH_2NHCH_2CH_2SH$

were used for the preparation of chloride and tetraphenylborate complexes of nickel(II) by Rose et al.[9] The chloride complexes were practically diamagnetic, whereas the tetraphenylborate complexes showed a subnormal magnetic moment in solid state (1.07 B.M. for $Ni(L^1)B(C_6H_5)_4$ and 1.29 B.M. for $Ni(L^2)B(C_6H_5)_4$). They presumed that the tetraphenylborate complexes were polymeric and contained both diamagnetic nickel(II) of square plane and paramagnetic nickel(II) of a coordination number larger than four. However, the structures of the tetraphenylborate and chloride complexes have not been confirmed yet. Thus, we have reinvestigated the nickel(II) complexes (perchlorate and tetrafluoroborate) of HL^1 and HL^2 together with the new complexes of HL^3, HL^4, and HL^5. During the course of this study, we found the X-ray structural data of $Ni(L^4)ClO_4$ had been already reported by Seff et al.[10] In this complex, a five-membered chelate ring is formed by the mercapto group with Ni(II), whereas $Ni(L^5)ClO_4$ has a six-membered chelate ring. The difference in the chelate ring size may affect the thiolate-bridged binuclear structure. Therefore we have determined the X-ray crystal structure of $Ni(L^5)ClO_4$ in order to compare the structure with that of $Ni(L^4)ClO_4$.

Experimental

Preparations. The ligands except HL^5 were prepared by the literature methods.[9,13] HL^1, HL^3, and HL^4 were

† Present address: Department of Chemistry, Faculty of Science, Shimane University, Matsue 690.

purified by distillation under reduced pressure and HL^2 was purified by sublimation. HL^5 was prepared by the application of the method of Murase et al.[14] 3-[2-(2-pyridyl)ethylamino]-1-propanol[3] was converted to *N*-[2-(2-pyridyl)ethyl]-3-bromopropylamine (**1**) according to the standard method.[15] Conversion of **1** to the corresponding thiol ($HL^5 \cdot 2HBr$) was proceeded via the phosphorothioate, which was obtained by the reaction of **1** with trisodium phosphorothioate.[14] $HL^5 \cdot 2HBr$ was used for the preparation of the complex without purification.

$Ni(L)ClO_4$ ($L=L^1, L^2, L^3, L^4$). To a solution of nickel(II) perchlorate hexahydrate (1 mmol) in methanol (10 cm^3) was added a methanolic solution of the ligand (1 mmol), and the mixture was stirred for 30 min to give violet microcrystals. They were collected, washed with methanol, and dried over P_2O_5 in a vacuum desiccator.

$Ni(L^5)ClO_4$. Crude ligand ($HL^5 \cdot 2HBr$, 1.4 g, ca. 4 mmol) and nickel(II) perchlorate hexahydrate (3.0 g, 8 mmol) were dissolved in 30 cm^3 of water and the pH of the solution was adjusted to ca. 9 by the addition of triethylamine. The resulting deep brown solution was heated on a water bath for ten minutes and undissolved material was filtered off. Addition of excess sodium perchlorate to the filtrate resulted in the precipitation of reddish brown crystals, which were recrystallized from an acetonitrile-ethanol mixture and dried over P_2O_5 under vacuum.

$Ni(L)BF_4$ ($L=L^2, L^4$). To an aqueous solution (10 cm^3) of nickel(II) acetate tetrahydrate (1 mmol) was added a solution of the ligand (1 mmol) in water (10 cm^3) to form a red solution. A saturated aqueous solution of $NaBF_4$ (2 mmol) was added to this solution to give violet microcrystals, which were collected, washed with methanol, and dried over P_2O_5 in a vacuum desiccator.

$Pd(L^2)ClO_4$. An aqueous solution of $[PdCl_4]^{2-}$ was prepared by dissolving $PdCl_2$ (2 mmol) in water containing NaCl (4.4 mmol). To this were added HL^2 (2 mmol) and NaOH pellets (2.2 mmol), and the mixture was stirred for a half hour. Then, an aqueous solution of $NaClO_4 \cdot H_2O$ (large excess) was added to give a yellow precipitate. It was recrystallized from water as yellow microcrystals.

Elemental analyses of the complexes are given in Table 1.

Measurements. Infrared spectra were measured on a Hitachi 215 infrared spectrometer, and electronic spectra were recorded on a Shimadzu UV-VISIBLE recording spectrometer Model UV-240 in acetone or water. Reflectance

a) Atoms refined with occupancy factors of 0.5. b) $B_{eq}=4/3[a^2B(1,1)+b^2B(2,2)+c^2B(3,3)+ab(\cos\gamma)B(1,2)+ac(\cos\beta)B(1,3)+bc(\cos\alpha)B(2,3)]$.

spectra were recorded on Shimadzu multipurpose spectrophotometer Model MPS-5000. Conductance measurements were carried out with a Yanagimoto Conductivity Outfit Model MY-8 in acetone or in water. Magnetic susceptibilities were measured by the Faraday method. The apparatus was calibrated by the use of $[Ni(en)_3]S_2O_3$.[16] The diamagnetic corrections were made with Pascal's constants[17] and magnetic moments were calculated by the equation, $\mu_{eff}=(8\chi_A T)^{1/2}$.

X-Ray Crystal Structure Analysis of Ni(L^5)ClO$_4$. A crystal with dimensions 0.12×0.30×0.31 mm^3 was used for the X-ray analysis. The unit-cell parameters and intensities were measured on a Rigaku AFC-5R automated four-circle diffractometer with graphite-monochromated Mo $K\alpha$ radiation (λ=0.71073 Å). The intensity data were collected by the ω scan technique with a scan rate of 4° min^{-1}.

Crystal Data: $C_{20}H_{28}Cl_2N_4Ni_2O_8S_2$, F.W.=704.9; monoclinic, $P2_1/n$; a=11.303(2), b=31.142(5), c=8.104(1) Å, β=98.17(1)°; D_c=1.66 g cm^{-3}; Z=4; μ(Mo $K\alpha$)=17.2 cm^{-1}.

A total of 4254 reflections with $2\theta<46°$ were collected. The intensity data were corrected for Lorentz-polarization effects and for absorption. Independent 3125 reflections with $|F_o|>3\sigma(F_o)$ were considered as "observed" and were used for structure analysis. The structure was solved by the direct method. Refinements were carried out by the block-diagonal least-squares method. The weighting scheme $w=[\sigma_{count}^2+(0.015|F_o|)^2]^{-1}$ was employed. Hydrogen atoms were inserted in their calculated positions and fixed at their positions. The final discrepancy factors are $R=\Sigma||F_o|-|F_c||/\Sigma|F_o|=0.059$ and $R_w=[\Sigma w(|F_o|-|F_c|)^2/\Sigma w|F_o|^2]^{1/2}=0.076$.

All the calculations were carried out on the HITAC M-680H computer at the Computer Center of the Institute for Molecular Science using a local version of the MULTAN 78, UNICS-III, and ORTEP programs.[18] Atomic coordinates and thermal parameters of nonhydrogen atoms are listed in Table 2. The anisotropic thermal parameters of nonhydrogen atoms, the atomic coordinates and thermal parameters of hydrogen atoms, and the F_o-F_c tables have been deposited as a Document No. 8841 at the Office of the Editor.

Results and Discussion

Nickel(II) complexes with the general formula NiLX (X=ClO$_4^-$, L=L^1, L^2, L^3, L^4, L^5; and X=BF$_4^-$, L=L^2, L^4) were obtained. As for the palladium(II) complex, only Pd(L^2)ClO$_4$ could be isolated as crystals. Magnetic moments at room temperature and molar conductance data are given in Table 3.

The magnetic moments of the complexes are not zero. These residual paramagnetism can be ascribed to the temperature independent paramagnetism of nickel atom. Thus, we can conclude that all these complexes are diamagnetic. The S–H vibration near 2500 cm^{-1} of the free ligands was absent in the IR spectra of the complexes. This suggests that the thiol is deprotonated and coordinated to the metal. IR spectra also suggested no coodination of the perchlorate and tetrafluoroborate ions to the metal; ClO$_4^-$ and BF$_4^-$ vibrations appeared as a broad band at ca. 1100 and ca. 1050 cm^{-1}, respectively. Molar conductance data indicated that all the complexes are 2:1 electrolyte in acetone or water. Based on these facts, the complexes are presumed to be binuclear bridged by the mercaptide sulfur atoms.

The crystal structure of Ni(L^5)ClO$_4$ consists of binuclear complex cations and perchlorate ions. Perchlorate ions do not participate in any coordination as suggested from IR spectra. A perspective drawing of the binuclear cation is illustrated in Fig. 1. Selected bond distances and angles are given in Table 4. Both the nickel ions adopt an essentially planar configuration with aliphatic amino nitrogen, pyridine nitrogen, and bridging sulfur atoms. The deviations of atoms from the least-squares planes of N$_2$S$_2$ are less than 0.11 Å and the deviations of Ni1 and Ni2 from the planes are only 0.05 and 0.01 Å, respectively. The Ni–S

distances are 2.166(2)—2.180(2) Å, which are common for other thiolate-bridged bi- and oligonuclear nickel(II) complexes.[19-24] The Ni1–Ni2 distance is 3.047(1) Å, making a contrast with that of $Ni(L^4)ClO_4$ (2.739(1) Å)[10] and other thiolate-bridged binuclear nickel(II) complexes,[19-21] whose structurtes are characterized by the small dihedral angle (82.3—114.3°) between the two NiN_2S_2 planes sharing the S–S′ edge and by the small Ni–S–Ni angle (76.7—79.5°). As the result, the Ni–Ni′ distances are very short (2.733—2.795 Å).[25] In $Ni(L^5)ClO_4$, the two N_2S_2 planes are bent at the S1–S2 edge with a dihedral angle of 136.1° and the Ni–S–Ni angles are 89.02(8) and 89.27(8)°. This may be ascribed to the steric requirement of the six-membered chelate ring which favors the coplanar structure. A similar structural feature was observed in $[Ni_2\{SCH(CH_2CH_2NH_2)_2\}_2]Br_2$ which contains two adjacent six-membered chelate rings.[24]

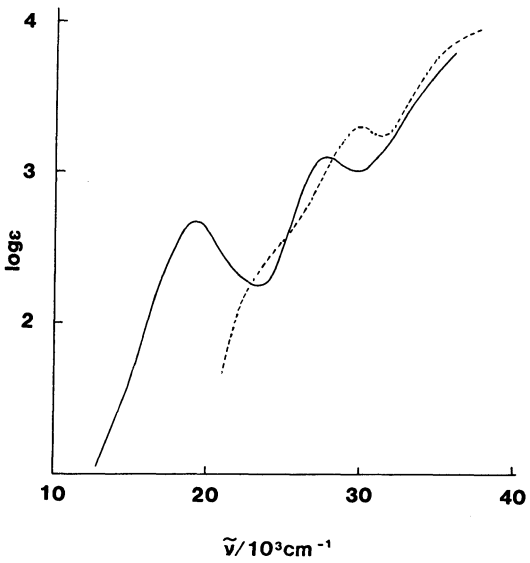

Fig. 2. Electronic spectra of (——) $Ni(L^2)ClO_4$ and (-----) $Pd(L^2)ClO_4$.

Table 4. Selected Interatomic Distances (l/Å) and Bond Angles (ϕ/°)

Ni1–Ni2	3.047(1)	Ni1–N1	1.960(6)
Ni1–S1	2.167(2)	Ni1–N2	1.928(6)
Ni1–S2	2.180(2)	Ni2–N3	1.974(6)
Ni2–S1	2.170(2)	Ni2–N4	1.923(6)
Ni2–S2	2.166(2)		
Ni1–S1–Ni2	89.27(8)	N1–Ni1–N2	87.5(3)
Ni1–S2–Ni2	89.02(8)	S1–Ni2–S2	80.9(1)
S1–Ni1–S2	80.6(1)	S1–Ni2–N4	97.3(2)
S1–Ni1–N1	96.9(2)	S2–Ni2–N3	94.0(2)
S2–Ni1–N2	95.1(2)	N3–Ni2–N4	87.9(3)

Electronic spectra of the nickel(II) complexes in acetone exhibit a d–d band near 19×10^3 cm^{-1} (ε: 400—500 dm^3 mol^{-1} cm^{-1}) (Fig. 2 and Table 5), characteristic of planar nickel(II). The spectra were also characterized by an absorption in a near-ultraviolet region (27—28×10^3 cm^{-1}), whose extinction coefficient is more than 10^3 dm^3 mol^{-1} cm^{-1}. Judging from its frequency and intensity it can not be a d–d transition band, but should be assigned to a charge-transfer transition. Such a near-ultraviolet band was also observed for other thiolate-bridged binuclear nickel(II) complex.[14]

The electronic spectrum of $Pd(L^2)ClO_4$ in water shows absorption bands at ca. 24×10^3 and 30×10^3cm^{-1}, which can be assigned to a d–d and a charge-transfer transitions, respectively.

Electronic spectra of the nickel(II) complexes in water (immediately after the dissolution) were essentially the same as the spectra in acetone. However, the purple color of the aqueous solutions faded gradually and the solutions became pale green in a day or two, suggesting the decomposition of the complexes in water. The tendency to decompose in water was prominent in $Ni(L^1)ClO_4$ and $Ni(L^3)ClO_4$, whereas the complexes with $(L^2)^-$, $(L^4)^-$, and $(L^5)^-$ were fairly stable in water. The low stability of the former complexes seems to be due to the strain in the 5–5 fused-ring system.

Each powder spectrum of the nickel(II) complexes resembles that in acetone solution in the region 14—30×10^3 cm^{-1} (Table 5). Thus, the magnetic, electronic spectral, and X-ray structural results indicate that the coordination geometries are invariably planar in solution as well as in solid state for all the present nickel complexes.

Equilibrium Study on the Characteristic Color-Changing Reaction of Lanthanum Complex of 3-[[Bis(carboxymethyl)amino]-methyl]-1,2-dihydroxyanthraquinone (Alizarin Complexon) with Fluoride Ion

Akio YUCHI,* Hiroki MORI, Hitoshi HOTTA, Hiroko WADA, and Genkichi NAKAGAWA
Department of Applied Chemistry, Nagoya Institute of Technology,

(Received April 25, 1988)

Complexation equilibria between lanthanum (M), 3-[[bis(carboxymethyl)amino]methyl]-1,2-dihydroxyanthraquinone (Alizarin Complexon, H_4L) and fluoride were studied by potentiometry with fluoride ion selective electrodes and by spectrophotometry. M_2HL_2 and a further protonated species react with fluoride to form M_2HL_2F and $M_2H_2L_2F$, whereas M_2L_2 does not. The unexpectedly large stability constant of $10^{4.12}$ for the reaction, $M_2HL_2+F^- \rightleftharpoons M_2HL_2F$, may be ascribed to the incorporation of fluoride ion in a specially organized core of M_2HL_2.

Rare earth metal (M) complexes of alizarin complexon(3-[[bis(carboxymethyl)amino]methyl]-1,2-dihydroxyanthraquinone; ALC or H_4L; Fig. 1) react with fluoride ion to show a characteristic color change from red to blue.[1] This reaction provides the selective and sensitive photometric method for fluoride.[2] Various modifications of this reaction have been proposed to overcome the disadvantages of large reagent blank, slow attainment of equilibria and insufficient affinities toward fluoride.[3] In contrast to abundance of conventional bleaching methods which utilize the dissociation of a color-forming reagent from the metal complex by the reaction with fluoride ion, no other reaction systems involving the formation of the mixed ligand complex have been found except those with the derivatives.[4-6]

Although several attempts have been made to elucidate the mechanism of this color development, they are not sufficient.[10-13] From the similarity of the absorption spectrum of the blue species to that of completely deprotonated ALC, the following equation was first proposed by Leonard and West.[10]

$$MHL + F^- \rightleftharpoons MLF + H^+$$
(Charges of the complexes are omitted)

Formation of the mixed ligand complex, MLF, by displacement of one of the water molecules with fluoride was supposed to promote the dissociation of the last proton on ALC, causing the color change. Later on, rather complicated formulas such as $M_5L_4F_4$,[11] $M_2H_2L_2F_2$,[12] and $M_5L_4F_2$[13] have been proposed as the composition of the mixed ligand complexes. Various molar ratio methods used in these studies were not suited for the system, because ALC has so many functional groups that various species can be formed in a successive manner as in the case of Xylenol Orange,[14] and because affinity to fluoride is too low to give a well-defined break point on the plots.

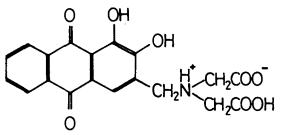

Fig. 1. Structure of ALC.

We have made systematic studies on the formation of mixed ligand complexes with fluoride and simpler ligands,[15-17] using fluoride ion-selective electrodes. The same approach is applied to this system.

Experimental

Reagents. Lanthanum solution was prepared from the nitrate hexahydrate and was standardized against Na_2H_2edta. Potassium fluoride was dried in a platinum crucible for 24 hours at 110 °C. Fluoride solutions were stored in polyethylene containers. Potassium nitrate was recrystallized twice. Carbonate-free potassium hydroxide solution was prepared as described elsewhere.[18]

ALC ($H_4L \cdot 2H_2O$) was prepared and purified as described in literature.[19,20] Purity of the reagent was confirmed by elemental analysis and potentiometric titration. It was dissolved in known amounts of carbonate-free potassium hydroxide solution. Acetate buffer has been used for the earlier equilibrium studies of this system by photometry.[10-12] As the buffer proved to alter the equilibria,[21] no buffer was used in this study except 2-morpholino-1-propanesulfonic acid.

Measurement. Details of the potentiometry were the same as described previously.[14-16] Visible absorption spectra were recorded with a UNION high-sens spectrophotometer SM-401 and a Shimadzu UV-250.

Results

Protonation Equilibria of ALC. Solutions containing 3 to 9×10^{-3} mol dm^{-3} ALC were potentiometrically titrated with a nitric acid or a potassium hydroxide solution between $-\log[H^+]$ 3 and 8. At lower $-\log[H^+]$ the reagent precipitated as H_4L, the solubility of which has been reported to be 5×10^{-4} mol dm^{-3}.[20] The average number of protons bound to the ligand, $\bar{n}_H$ was calculated by

$$\bar{n}_{H,o} = \frac{4C_L + C_H - C_{OH} - [H^+] + [OH^-]}{C_L}, \quad (1)$$

where C_L, C_H, and C_{OH} are the analytical concentrations of the ligand, hydrogen, and hydroxide ions added, respectively (Fig. 2). The third and fourth protonation constants were determined by the conventional method.

Visible absorption spectra were recorded for the solutions containing 1×10^{-4} mol dm^{-3} ALC at various $-\log[H^+]$ values between 2.0 and 7.1. A distinct isosbestic point was observed at 455 nm. The third protonation constant was determined by fitting a set of normalized curves to the plot of the absorbance change at 540 nm (squares in Fig. 3).

The constants obtained are as follows: $\log K_3=5.58$ by potentiometry, and 5.52 by spectrophotometry; $\log K_4=2.48$ by potentiometry. These are in good agreement with those in literature: $\log K_3=5.47$[13] and 5.54[22]; $\log K_4=2.54$[13] and 2.40.[22]

Complexation Equilibria of Lanthanum Ion with ALC. Complexation equilibria between lanthanum ion and ALC were potentiometrically studied. Preliminary experiments showed that addition of excess lanthanum ion over ALC causes precipitation of complexes at any $-\log[H^+]$ and that even in the presence of excess ALC precipitation occurs at lower $-\log[H^+]$. Thus, 0.2 to 1×10^{-3} mol dm^{-3} solutions containing lanthanum ion and a slight excess of ALC were subjected to potentiometry. The $\bar{n}_H$ value was likewise calculated by Eq. 1 and is shown as a function of $-\log[H^+]$ in Fig. 2. The plateau at $\bar{n}_H$ equal to 0.5 suggests the presence of polynuclear species.

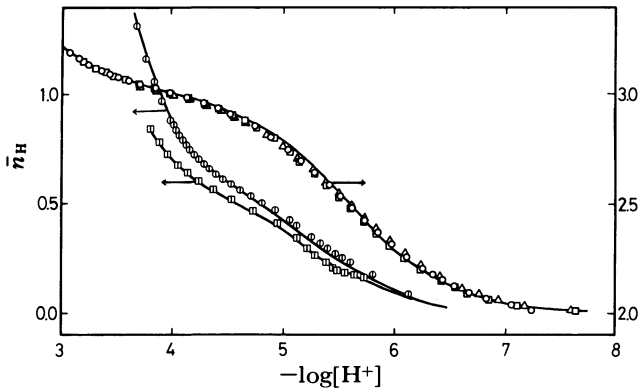

Fig. 2. Plots of $\bar{n}_H$ vs. $-\log[H^+]$ for the La^{3+}-ALC system (25 °C, 0.1 mol dm^{-3} KNO_3). $C_M/10^{-3}$ mol dm^{-3}: (○,□,△) 0; (Ⓓ) 0.19; (▣) 0.51. $C_L/10^{-3}$ mol dm^{-3}: (○) 4.8; (□) 6.7; (△) 8.6; (Ⓓ) 0.20; (▣) 0.52. The solid lines are calculated with the constants obtained.

Table 1. Average Deviation of $\bar{n}_H$ for Various Combination of Species in La-ALC System

No.	Species considered					$\Delta\bar{n}_H$[a]
	MHL	$M_2H_2L_2$	M_2HL_2	ML	M_2L_2	
1	○	×	×	○	×	0.090
2	○	×	×	×	○	0.153
3	○	×	○	○	×	0.021
④	○	×	○	×	○	0.010
5	×	×	○	○	×	0.045
6	×	×	○	×	○	0.023
7	×	○	○	○	×	0.031
⑧	×	○	○	×	○	0.015
9	×	○	×	○	×	0.162
10	×	○	×	×	○	0.225

a) $\Delta\bar{n}_H=(\Sigma(\bar{n}_{H,c}-\bar{n}_{H,o})^2/N)^{1/2}$; N: number of data.

The complexation equilibria are generally expressed by

$$pM^{3+} + rH_2L \rightleftharpoons M_pH_qL_r + (2r-q)H^+ : K_{pqr}. \quad (2)$$

Then $\bar{n}_H$ is given by

$$\bar{n}_{H,c} = \frac{\Sigma\Sigma\Sigma q[M_pH_qL_r]}{C_L}. \quad (3)$$

Various combinations of the possible complexes were assumed and K_{pqr} values in each set were refined to give a minimum error square sum about $\bar{n}_H$'s expressed by Eqs. 1 and 3 (Table 1). Both the combinations of species, Nos. 4 and 8 gave satisfactory agreement. Formation of M_2L_2 and M_2HL_2 is definite, whereas the composition of the other species present at lower $-\log[H^+]$ region could not be determined whether MHL or $M_2H_2L_2$, since $\Delta\bar{n}_H$ did not differ so much between Nos. 4 and 8. The constants obtained are summarized in Table 2.

These equilibria were also studied spectrophotometrically with the solutions containing 0.1×10^{-3} mol dm^{-3} La^{3+} and a small excess of ALC at $-\log[H^+]$ between 2 and 8 (Fig. 4). Spectral change between $-\log[H^+]$ 2—4 with an isosbestic point at 453 nm corresponds to the formation of M_2HL_2, whereas that between $-\log[H^+]$ 6—8 with an isosbestic point at

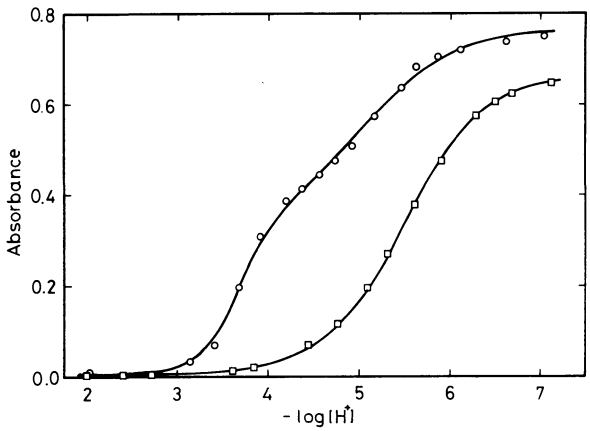

Fig. 3. Absorbance change of ALC as a function of $-\log[H^+]$ in the presence and absence of La^{3+} (25 °C, 0.1 mol dm^{-3} KNO_3). Wavelength, 540 nm. C_M: (□) 0; (○) 9.4×10^{-5} mol dm^{-3}. C_L: (□,○) 9.5×10^{-5} mol dm^{-3}. The solid lines are calculated with the constants obtained.

Table 2. Stability Constants for the Species Found in La-ALC and La-ALC-F Systems at 25 °C and at 0.1 mol dm^{-3} KNO_3

Equilibrium	Equilibrium constant
A. La-ALC system[a]	
$2M + 2H_2L \rightleftharpoons M_2L_2 + 4H^+$	$\log K_{202} = 0.28$
$2M + 2H_2L \rightleftharpoons M_2HL_2 + 3H^+$	$\log K_{212} = 5.58$
B. La-ALC-F system	
$2M + 2H_2L + F^- \rightleftharpoons M_2HL_2F + 3H^+$	$\log K_{2121} = 9.70$
$2M + 2H_2L + F^- \rightleftharpoons M_2H_2L_2F + 2H^+$	$\log K_{2221} = 14.17$

a) In more acidic medium, the third species was found (see text for details).

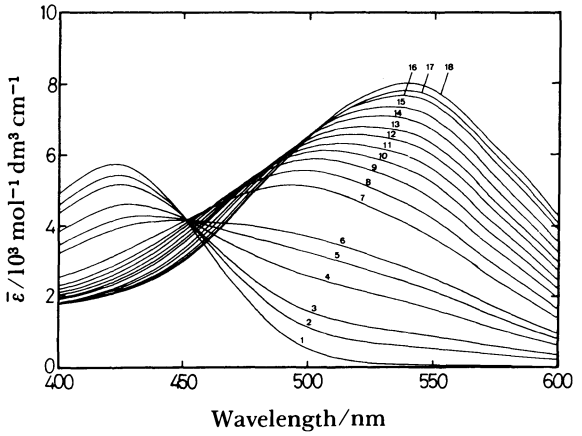

Fig. 4. Absorption spectra of La-ALC system at various −log[H$^+$] (25 °C, 0.1 mol dm^{-3} KNO_3). C_M=9.4×10^{-5} mol dm^{-3}; C_L=9.5×10^{-5} mol dm^{-3}. −log[H$^+$]: (1) 2.014; (2) 3.359; (3) 3.495; (4) 3.651; (5) 3.760; (6) 3.846; (7) 4.196 (8) 4.392; (9) 4.457; (10) 4.740; (11) 4.920; (12) 5.116; (13) 5.275; (14) 5.481; (15) 5.638; (16) 5.838; (17) 6.046; (18) 7.075.

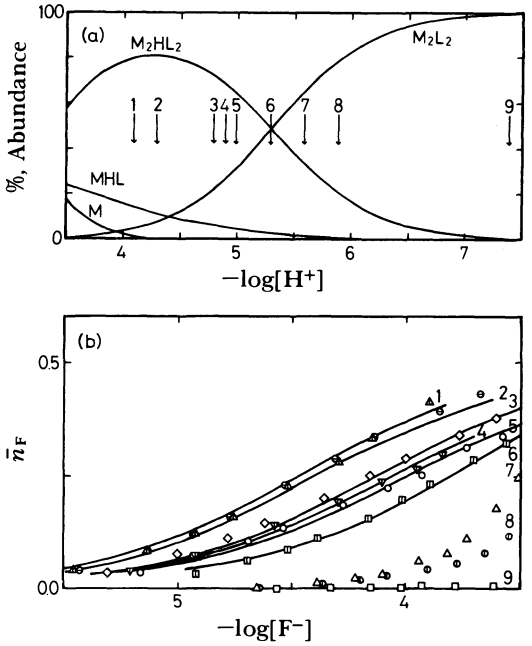

Fig. 5. (a) Distribution of species for the La-ALC system. C_M=0.5×10^{-3} mol dm^{-3}; C_L=0.55×10^{-3} mol dm^{-3}. MHL is arbitrarily taken as a minor species formed in acidic media (see text for details). The numbers in (a) correspond to the experimental conditions in (b). (b) $\bar{n}_F$ vs. −log[F$^-$] for the La-ALC-F system. The solid lines are calculated with the constants obtained.

505 nm to the deprotonation of M_2HL_2 to form M_2L_2. At intermediate −log[H$^+$], both reactions are concerned in the spectral change. The change in absorbance at 540 nm is shown as a function of −log[H$^+$] in Fig. 3. By using the constants potentiometrically obtained and refining the molar absorptivities for M_2HL_2 and MHL or $M_2H_2L_2$, this curve could be reproduced as shown by the solid curve in Fig. 3.

Mixed Ligand Complexes of La-ALC with Fluoride. The distribution of each species in the solution of C_M=0.5×10^{-3} and C_L=0.55×10^{-3} mol dm^{-3} was calculated with the constants obtained above, and was shown as a function of −log[H$^+$] in Fig. 5(a). A minor species formed in acidic media was assumed to be MHL. Even if $M_2H_2L_2$ was assumed instead of MHL, distribution of other species was practically the same. The reaction of these species with fluoride was examined at various −log[H$^+$] values indicated by arrows in Fig. 5(a). It took 30 min for equilibration at −log[H$^+$] 4, whereas 2 h at 5.5. Thus all the solutions were subjected to measurements after 3 h.

With the −log[H$^+$] and −log[F$^-$] values for each experimental point, the average number of fluoride ions bound to lanthanum complexes, $\bar{n}_F$ was calculated by

$$\bar{n}_{F,o} = \frac{C_F - [F^-] - [HF] - 2[HF_2^-]}{C_M} \quad (4)$$

and is shown as a function of −log[F$^-$] in Fig. 5(b). No increase in $\bar{n}_F$ at higher −log[H$^+$] indicates that M_2L_2 does not react with fluoride ion. At lower −log[H$^+$], on the other hand, the curves well fit a normalized curve, $X=\log x$; $Y=0.5x/(1+x)$. This suggests the formation of polynuclear species.

Formation of a mixed ligand complex is expressed by

$$pM + rH_2L + sF^- \rightleftharpoons M_pH_qL_rF_s + (2r - q)H^+ : K_{pqrs}. \quad (5)$$

Then $\bar{n}_F$ is given by

Table 3. Average Deviation of $\bar{n}_F$ for Various Combination of Species in La-ALC-F System

No.	Species considered				$\Delta\bar{n}_F$[a]
	MHLF	M_2HL_2F	$M_2H_2L_2F$	$M_4H_3L_4F_2$	
1	○	×	×	×	0.069
2	×	○	×	×	0.039
3	×	×	○	×	0.057
4	×	×	×	○	0.039
5	○	○	×	×	0.033
⑥	×	○	○	×	0.015

a) $\Delta\bar{n}_F=(\Sigma(\bar{n}_{F,o}-\bar{n}_{F,c})^2/N)^{1/2}$; N: number of data.

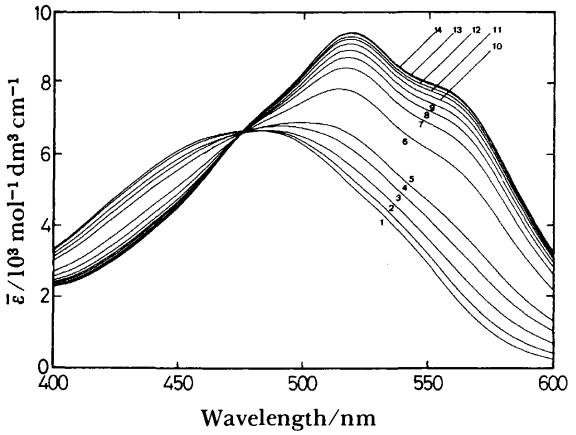

Fig. 6. Absorption spectra of La-ALC-F system at various fluoride concentrations (25°C, 0.1 mol dm^{-3} KNO_3). C_M=9.3×10^{-5} mol dm^{-3}; C_L=9.5×10^{-5} mol dm^{-3}; −log[H$^+$]=5.10. C_F/10^{-5} mol dm^{-3}: (1) 0; (2) 1.05; (3) 2.09; (4) 3.14; (5) 4.19; (6) 8.38; (7) 12.6; (8) 16.8; (9) 21.0; (10) 26.2; (11) 31.4; (12) 41.9; (13) 52.4; (14) 105.

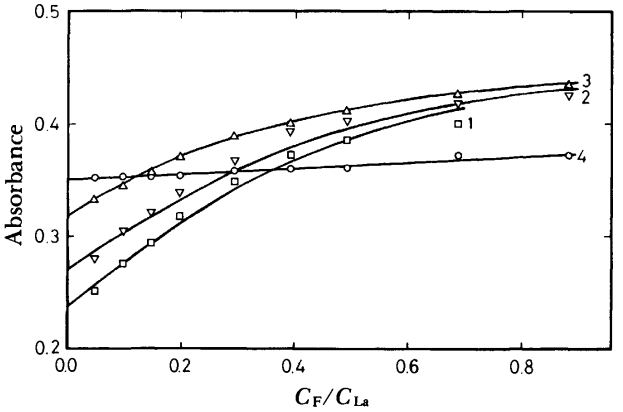

Fig. 7. Absorbance change by the addition of fluoride to La-ALC. C_M=0.5×10^{-3} mol dm^{-3}; C_L=0.55×10^{-3} mol dm^{-3}. Wavelength, 620 nm; pathlength, 1 mm. −log[H$^+$]: (1) 4.3; (2) 4.8; (3) 5.3; (4) 5.9.

$$\bar{n}_{F,c}=\frac{\Sigma\Sigma\Sigma\Sigma_s[M_pH_qL_rF_s]}{C_M} \quad (6)$$

Various combinations of the possible mixed ligand complexes were assumed and K_{pqrs} values in each set were refined to give a minimum error square sum about $\bar{n}_F$'s expressed by Eqs. 4 and 6 (Table 3). Only the combination of species, No. 6 gave satisfactory agreement. Stability constants of $M_2H_2L_2F$ and M_2HL_2F were summarized in Table 2. The constant for the latter species can be recalculated as

$$M_2HL_2 + F^- \rightleftharpoons M_2HL_2F: K^F_{M_2HL_2F} = 10^{4.12}. \quad (7)$$

Visible absorption spectra of La-ALC solutions were recorded in the presence of various amounts of fluoride. Figure 6 shows the results at −log[H$^+$] 5.10. The spectra of the mixed ligand complexes measured in the presence of appropriate amounts of fluoride varied with −log[H$^+$]. This agrees with the presence of two mixed ligand complexes deduced above. Absorbance at 620 nm was plotted against molar ratio of fluoride to lanthanum, C_F/C_M(Fig. 7). By using the constants obtained and refining the molar absorptivities, the change could be reproduced as shown by the solid curves.

Discussion

La-ALC Complexes. The La-ALC species formed at pH 4.6 was first considered to be MHL from the similarity of the absorption spectrum to that of H_2L.[10] Langmyhr et. at. later pointed out the presence of another minor species at higher pH (5.5 or 6.5) from the results of continuous variation method.[12] Anfält and Jagner obtained the $\bar{n}_H$ value of 0.56 in their potentiometric titration of ALC with La^{3+} at constant pH of 4.5, and deduced that MHL and another species coexisted.[13]

In this study, similar values for $\bar{n}_H$ were obtained under the same conditions, but are ascribed to only one species, M_2HL_2 from the detailed analysis of the equilibria. In alkaline media, this species releases the proton to form M_2L_2($\log K^H_{M_2HL_2}$=5.30). ALC has several donor atoms which cannot coordinate to one metal ion at the same time. The ligand in a 1:1 complex still keeps the coordination ability. On the other hand, La in a 1:1 complex is coordination-unsaturated and can interact with other donor atoms. Thus polynuclear species such as M_2HL_2 and M_2L_2 are formed.

Mixed Ligand Complexes. Anfält and Jagner

concluded, from their potentiometric data, that no protons were left on the mixed ligand complex.[13] If it were the case, the reactivity of La-ALC complex to fluoride would increase with pH. As shown in Figs. 5 and 7, however, the reverse trend is observed. This is just explained by that protonated species such as M_2HL_2 and MHL or $M_2H_2L_2$ do have affinities for fluoride to form M_2HL_2F and $M_2H_2L_2F$, whereas completely deprotonated species does not.

In a previous paper, we made a systematic study on the formation of the mixed ligand complexes with fluoride.[16] Reactivity of a metal ion with fluoride generally decreases by the coordination of another ligand: for example, K^F_{LaF} is $10^{2.69}$, whereas K^F_{LaLF} is $10^{2.0}$ for nta^{3-} as L, $10^{1.7}$ for $hedta^{3-}$, $10^{1.4}$ for $edta^{4-}$, and $10^{1.8}$ for $cdta^{4-}$. Compared to these values, La-ALC complexes have unexpectedly high affinities (Eq. 7), which can be ascribed to the incorporation of fluoride ion in a specially organized core of M_2HL_2. The structure is not certain at this stage.

Analytical Implication. The optimum pH for the determination of fluoride has empirically been determined to be around 4.3. This agrees with that of maximum proportion of M_2HL_2 as shown in Fig. 5(a). At lower pH the complex dissociates, whereas at higher pH it becomes M_2L_2 unreactive to fluoride ion.

Even at the optimum pH, calibration curve is straight only in lower fluoride concentration range (Fig. 7), because the conditional stability constant is not high enough. Thus large excess of the La-ALC reagent is essential.

Oxygen-17 NMR Study of the Uranyl Ion. V.[1] Kinetics and Mechanisms of Formation and Decomposition Reactions of Di-μ-hydroxo-bis-[uranyl(VI)] Ion in Aqueous Nitrate Solutions

Woo-Sik JUNG,† Masayuki HARADA, Hiroshi TOMIYASU,* and Hiroshi FUKUTOMI††
Research Laboratory for Nuclear Reactors, Tokyo Institute of Technology,
O-okayama, Meguro-ku, Tokyo 152
(Received May 11, 1988)

The rates of formation and decomposition reactions of di-μ-hydroxo-bis[uranyl(VI)] ion, $(UO_2)_2(OH)_2^{2+}$, have been measured in aqueous nitrate solutions (ionic strength=0.5 M; M=mol dm^{-3}) by ^{17}O NMR spectroscopy. In weakly acidic solutions the reactions obey the rate law:

$$d[(UO_2)_2(OH)_2^{2+}]/dt = k_2[UO_2^{2+}][UO_2OH^+] - k_{-2}K_a[H^+][(UO_2)_2(OH)_2^{2+}]/2,$$

where $K_a=[(UO_2)_2OH^{3+}]/[H^+][(UO_2)_2(OH)_2^{2+}]$. A mechanism involving a single-bridged binuclear intermediate, $(UO_2)_2OH^{3+}$, is proposed. Rate constants (M^{-1} s^{-1}) at 25 °C and activation parameters ΔH^* (kJ mol^{-1}) and ΔS^* (J K^{-1} mol^{-1}) for the formation and decomposition are as follows: 1.52×10^5, 18.9±1.5, and −82.4±5.0 for k_2 and 2.10×10^5, 23.6±1.3, and −64.0±4.2 for $k_{-2}K_a$. The rate of the decomposition reaction is compared with that in several related systems.

Thermodynamic studies of the hydrolysis reaction of uranyl ions have been carried out extensively.[2-5] Although the equilibrium quotients (Q_{11}, Q_{22}, and Q_{35}) of the reactions differ depending on the ionic medium, the following reactions have been established as main ones:[2]

$$UO_2^{2+} + H_2O = UO_2OH^+ + H^+ \qquad Q_{11} \qquad (1)$$

$$2UO_2^{2+} + 2H_2O = (UO_2)_2(OH)_2^{2+} + 2H^+ \qquad Q_{22} \qquad (2)$$

$$3UO_2^{2+} + 5H_2O = (UO_2)_3(OH)_5^+ + 5H^+ \qquad Q_{35} \qquad (3)$$

where hereafter $(UO_2)_p(OH)_q^{(2p-q)+}$ ion will be abbreviated as (p, q) and their concentrations as $[p, q]$ for brevity. There seems to be little doubt about the existence of (2,2) and (3,5) species as major ones, the former of which has been confirmed by X-ray investigations.[6] This binuclear complex has a dihydroxo-bridged and not an oxo-bridged structure. Recently the two major species have been identified by Raman spectroscopy.[7] Our recent study[8] showed that ^{17}O NMR signals of the major hydrolysis species are resolved from the signal of the uranyl ion below room temperature and the rate of the equilibrium reaction (Eq. 2) between (1,0) and (2,2) species is within the range of ^{17}O NMR measurements. Kinetic studies of the reaction have been undertaken by several workers,[9-12] but the mechanism remains unclear. We studied the kinetics of formation and decomposition reactions of (2,2) species by the ^{17}O NMR spectroscopic method and the kinetic results are reported in this paper.

Experimental

Preparation of Sample Solutions. Uranyl complex used is uranyl(VI) nitrate hexahydrate $UO_2(NO_3)_2\cdot6H_2O$, which was prepared by the same method as described in a previous paper[1] by using ^{17}O enriched water (^{17}O=42.1% atom%). ^{17}O enrichment of uranyl oxygen atoms (henceforth called uranyl oxygens) of the stock solution was so performed that oxygen isotope effects may not occur in ^{17}O NMR spectra of uranyl oxygens.[13] Therefore, the ^{17}O signal of uranyl oxygens of the stock solution consisted of a single line of Lorentzian shape, which corresponds to $[^{16}O=U=^{17}O]^{2+}$. The sample solutions for NMR measurements were prepared by diluting the stock solution with doubly distilled deionized water and adjusting the hydrogen ion concentration with either NaOH or HNO_3 solutions. The hydrogen ion concentrations of the solutions were measured with a Toa IM-20E pH meter. The pH meter readings at each temperature were calibrated to give $-\log[H^+]$ by using standard HNO_3 solutions at 0.5 M ionic strength (1 M= 1 mol dm^{-3}), which was adjusted with KNO_3. The hydrogen ion concentrations of the sample solutions increased with increasing temperature in weakly acidic solutions, while remained almost constant irrespective of temperature in strongly acidic solutions. The total uranyl ion concentration ($[UO_2^{2+}]_t$) of all sample solutions was 0.17 M. The hydrogen ion concentrations of the solutions were calculated on the assumption that the activity coefficient of the hydrogen ion in the self media is the same as that in KNO_3 media. The rates were measured at 0.5 M ionic strength because, to our knowledge, the thermodynamic parameters of equilibrium constants for hydrolysis reactions (Eqs. 1—3) of uranyl ions are available only for this ionic strength.[3]

Measurements of NMR Spectra and Kinetic Analysis. The measurements of the ^{17}O NMR spectra were carried out by JEOL JNM-GX 500 and JEOL JNM-GX 400 FT-NMR spectrometers operating at 67.83 and 54.26 MHz, respectively equipped with a GVT-3 temperature controller which was calibrated directly by use of a digital resistance thermometer (Tsuruga Electric Work, Ltd.). The measurements were performed with a 5-mm-o.d. NMR sample tube, which was

† Present address: Korea Advanced Energy Research Institure, Chung-Nam, Korea.

†† Present address: Department of Chemistry, Okayama University, Tsushima-naka, Okayama 700.

immersed in a 10-mm-o.d. concentric NMR tube containing D_2O as a lock solvent. Conditions for NMR measurement were: pulse width, 22 μs (corresponding to 45°); spectral width, 30 kHz; number of scans, 2000—30000. The kinetic analysis was carried out by using a computer program of two-site exchange model as described previously.[14] The ^{17}O transverse relaxation time of (2,2) species in the absence of chemical exchange was not measured directly in the temperature range studied, but was estimated to be 4.08×10^{-2} s at 5 °C by the computer simulation. This value was relatively smaller than the relaxation time (6.68×10^{-2} s) of (1,0) in the absence of chemical exchange. Owing to the quadrupole relaxation, the transverse relaxation time T_2 of ^{17}O changes with temperature. The relation between T_2 and temperature is usually reported by an Arrhenius-type function

$$1/T_2 = A\exp(-E_Q/RT)$$

where E_Q is an activation energy. In the earlier paper,[1] the activation energies for T_2 of free water and water coordinated to uranyl ion were determined to be 22.4±0.1 and 24.8±0.8 kJ mol^{-1}, respectively, and the activation energy for T_2 of uranyl oxygens was 24.2±0.3 kJ mol^{-1} in the temperature range from 7 to 35 °C. Based on these results, it is reasonable to assume that the activation energies for T_2 of both (1,0) and (2,2) are close to 24 kJ mol^{-1}. Therefore, the correction was made for T_2 based on the above assumption.

Results and Discussion

^{17}O resonances of uranyl oxygens in strongly acidic solutions are always observed as a single Lorentzian resonance (Fig. 1A), the chemical shift of which is ca. 1118 ppm relative to pure water at room temperature. In weakly acidic solutions the line shapes of the resonances are sensitive to [H$^+$], i.e. to the degree of hydrolysis, as shown in Fig. 1. At 25 °C two resonances were observed (Fig. 1B-D) in the range of −log[H$^+$] from 3.15 to 3.38, while three resonances (Fig. 1E) at −log[H$^+$]=3.71. The ratios of intensities of three resonances from the high field agree with [1,0]:2[2,2]:3[3,5] at 5 °C, which can be estimated on the basis of thermodynamic parameters reported by Baes and Meyer.[3] For example, the estimated ratio at −log[H$^+$] of 3.71 is 40.9:52.5:6.5, which agree well with the ratio of intensities in Fig. 1E. This fact supports our previous assignment[8] that the resonances at 2.0 and 6.7 ppm downfield relative to the uranyl ion correspond to (2,2) and (3,5) species, respectively.

Figure 2 shows that the resonances of (1,0) and (2,2) species tend to coalesce with increasing temperature. This indicates that there occurs a chemical exchange reaction between the two species. The τ values at each temperature were obtained from the best fit of the line shapes. The calculated lines are shown at the right-hand side in Fig. 2. In the calculations of τ we

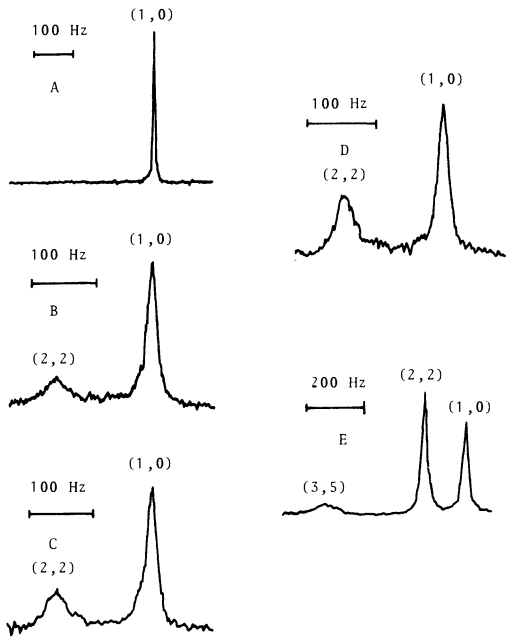

Fig. 1. ^{17}O spectra of uranyl solutions at −log[H$^+$] of 1.17 (A), 3.15 (B), 3.28 (C), 3.38 (D), 3.71 (E); $[UO_2^{2+}]_t$=0.17 M. The NMR spectra were recorded on a JEOL GX-500 at 25 °C except for (E), which was measured with a JEOL GX-400 at 5 °C.

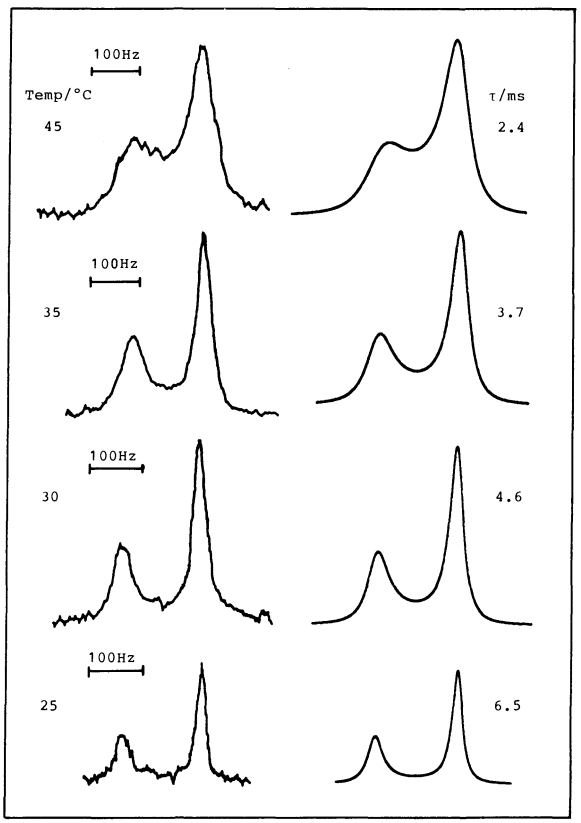

Fig. 2. Experimental (left side) and best-fit calculated ^{17}O NMR lineshapes of uranyl solutions which were recorded on a JEOL GX-500; $[UO_2^{2+}]_t$=0.17 M and −log[H$^+$]=3.38 at 20 °C. Temperatures and best-fit τ values are shown at left and right sides in the figure, respectively.

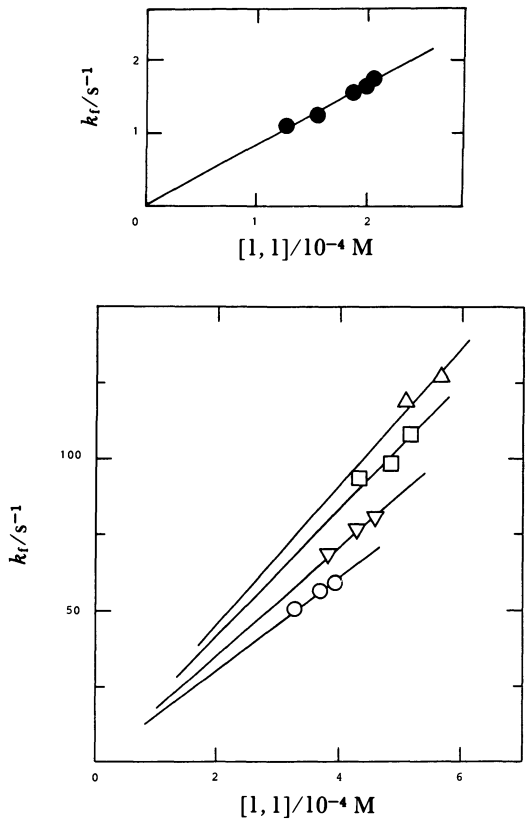

Fig. 4. a) A plot of k_f against $[UO_2OH^+]$ at 5 °C. b) Plots of k_f against $[UO_2OH^+]$ at various temperatures: (○) 25 °C; (▽) 30 °C; (□) 35 °C; (△) 40 °C. The NMR measurements were carried out by using a JEOL GX-400 (a) and a JEOL GX-500 (b).

neglected the effect of the existence of (3,5) species on τ, because the ^{17}O line-broadening of (3,5) species with increasing temperature is smaller than those of (1,0) and (2,2) species and [3,5] is much lower tha [1,1] and [2,2] in the sample solutions studied. The mean lifetimes of (1,0) and (2,2) species, $\tau_{1,0}$ and $\tau_{2,2}$, were evaluated from Eq. 4.

$$\tau = \tau_{1,0} P_{2,2} = \tau_{2,2} P_{1,0} \quad (4)$$

where the $P_{1,0}$ ($=1-P_{2,2}$) value is defined as [1,0]/([1,0]+2[2,2]). The values of P were calculated on the basis of thermodynamic parameters. The pseudo-first-order rate constants for formation and decomposition reactions, k_f and k_d, are expressed as

$$k_f = 1/\tau_{1,0} = -\mathrm{d}[1,0]/[1,0]\mathrm{d}t, \quad (5a)$$

$$k_d = 1/\tau_{2,2} = -\mathrm{d}[2,2]/2[2,2]\mathrm{d}t. \quad (5b)$$

The pseudo-first-order rate constants calculated are listed in Table 1. The rate constants for the formation of (2,2) species decrease with increasing $[H^+]$, while the rate constants for the decomposition increase linearly with $[H^+]$ (Fig. 4).

Eyring and co-workers[9] and Hurwitz and Atkinson[10] studied the kinetics of the formation reaction of (2,2) species by temperature- and pressure-jump relaxation methods and interpreted the relaxation times on the basis of the mechanism that the formation is initiated by the direct interaction of two uranyl ions, followed by fast subsequent abstraction of two hydrogen ions. This formation mechanism can be ruled out by the above results that the rate of the formation has an inverse relationship to $[H^+]$. However, it seems likely that the formation mechanism involves (1,1) species, because its concentration changes proportionally to $1/[H^+]$ as described by Eq. 1. As a result, the rate determining step in the formation of (2,2) species is postulated to be the bimolecular reaction (k_2, second-order rate constant) between (1,0) and (1,1) ions, followed by the fast abstraction of a hydrogen ion. Then k_f should be equal to $k_2(1,1)$. This is demonstrated in Fig. 4-a. A plot of k_f determined at 5 °C by use of the GX-400 NMR spectrometer vs. [1,1] gives a straight line passing through the origin and the slope corresponds to the k_2 value. In Fig. 4-b, similar plots of k_f determined at various temperatures by the GX-500 NMR spectrometer vs. [1,1] are illustrated.

Table 1. Rate Constants for the Formation and Decomposition of $(UO_2)_2(OH)_2^{2+}$ Complex at 25 °C

Solution	i	ii	iii
$-\log[H^+]$	3.15	3.28	3.38
k_f/s^{-1}	59.3	56.0	50.8
k_d/s^{-1}	93.8	117	146

A JEOL GX-500 NMR spectrometer was used for the NMR measurements.

Table 2. The Second-Order Rate Constants for the Formation and Decomposition of $(UO_2)_2(OH)_2^{2+}$ Complex

	25 °C	30 °C	35 °C	40 °C
$k_2/10^5$ M^{-1} s^{-1} [a]	1.52±0.02	1.77±0.01	2.08±0.06	2.28±0.06
$k_{-2}K_a/10^5$ M^{-1} s^{-1} [b]	2.10±0.09	2.54±0.13	3.04±0.08	3.46±0.11

a) ΔH^*=18.9±1.5 kJ mol^{-1} and ΔS^*=−82.4±5.0 J K^{-1} mol^{-1}.
b) ΔH^*=23.6±1.3 kJ mol^{-1} and ΔS^*=−64.0±4.2 J K^{-1} mol^{-1}.

A JEOL GX-500 NMR spectrometer was used for the NMR measurements.

The GX-500 spectrometer gives better resolution for the signals of (1,0) and (2,2) than the GX-400 particularly at temperatures above 25 °C. The k_2 values are calculated from Fig. 4-b on the assumption that all the plots pass through the origin. The results are listed in Table 2 together with activation parameters for k_2 path. The k_2 value in the present study is about two times larger than the value (6.4×10^4 M^{-1} s^{-1} in 0.5 M KNO_3 media at 25 °C) reported by Eyring et al.[11] using the temperature-jump relaxation method. Wendt[15,16] explained the formation reaction of dimer from $2MOH^{(z-1)+}$ (M^{z+}= Fe^{3+} and VO^{2+}) in terms of the Eigen-Wilkins mechanism[17] that the rate-determining step in the reaction is the loss of a water molecule from the inner hydration sphere of one $MOH^{(z-1)+}$ cation. The formation of (2,2) species from UO_2^{2+} and UO_2OH^+ may also be represented by

$$UO_2^{2+} + UO_2OH^+ \overset{K_E}{\rightleftharpoons} (UO_2^{2+} \cdots UO_2OH^+) \xrightarrow{k_{ex}}$$
$$[UO_2\text{-}OH\text{-}UO_2]^{3+} \xrightarrow[\text{fast}]{} (UO_2)_2(OH)_2^{2+} + H^+$$

where k_{ex} is the rate constant of water exchange in UO_2^{2+} ion, not in UO_2OH^+ ion because loss of a hydrogen ion from coordinated water is known to labilize metal ions for substitution reaction at another position,[18,19] i.e. the rate for water exchange is expected to be faster in UO_2OH^+ than in UO_2^{2+}. The mechanism of water exchange in the uranyl ion was proposed to be dissociative interchange (I_d).[20] The rate constant k_2 is given by

$$k_2 = K_E k_{ex} \tag{6}$$

The equilibrium constant, K_E, for the contact pair association between UO_2^{2+} and UO_2OH^+ ions can be estimated from the Eigen-Fuoss equation:[21]

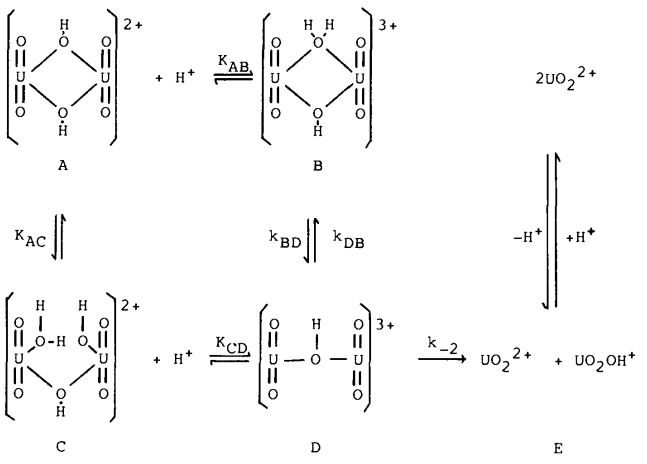
$$K_E = \frac{4\pi Na^3}{3000} \exp\left[-\left\{\frac{z_1z_2e^2}{aD} - \frac{z_1z_2e^2\kappa}{D(1+\kappa a)}\right\}/k_BT\right] \tag{7}$$

where

$$\kappa^2 = \frac{8\pi Ne^2\mu}{1000Dk_BT} \tag{8}$$

In these equations, N is Avogadro's number, a is the distance of closest approach between the two ions, e the electronic charge, D the dielectric constant, k_B the Boltzmann constant, T the absolute temperature, z_1 and z_2 the signed numbers of electronic charges on ions 1 and 2, and μ the ionic strength. In cases in which D=78.5, T=298 K, μ=0.5 M, and $a=6\times10^{-8}$ cm, Eq. 7 yields K_E=0.20 M^{-1}. Rate constant k_{ex} is thus estimated to be 7.6×10^5 s^{-1} at 25 °C from Eq. 6. This estimated value is close to the rate constant for water exchange (9.8×10^5 s^{-1} at 25 °C),[20] which was determined in water–acetone mixture by the ^1H NMR line-broadening method on the assumption that the hydration number of the uranyl ion is four. This leads to the conclusion that the rate-determining step in the k_2 path is the loss of a water molecule in the equatorial plane of the uranyl ion.

The pseudo-first-order rate constants for the decomposition reaction of (2,2) species increase linearly with $[H^+]$ in such low acid region as in this study. Frei and Wendt[12] studied the decomposition reaction by $HClO_4$ ($[H^+]<0.05$ M) with the stopped-flow method and showed that the rate constant for the reaction approaches a limiting value at $[H^+]$ in its high region. These results can be explained by the following two mechanisms: mechanism 1, the A–B–D–E pathway with B–D as the rate-determining step and mechanism 2, the A–C–D–E or A–C–D–E pathways with D–E as the rate-determining step. The basic



distinction between the two mechanisms is that the rate-determining steps in mechanisms 1 and 2 are assumed to be the cleavage of the first and second

Table 3. The Second-Order Rate Constants for the Acid Decomposition Reaction of Di-μ-hydroxo Binuclear Complexes and Rate Constants for Water Exchange of the Composite Metal Ions at 25°C

hydroxo bridges, respectively. Based on these mechanisms, k_d are given by

$$k_d = \frac{1}{2}\frac{K_{AB}[H^+]}{1+K_{AB}[H^+]}k_{BD} \quad (9a)$$

or

$$k_d = \frac{1}{2}\frac{K_a[H^+]}{1+K_a[H^+]}k_{-2} \quad (9b)$$

where K_a is defined as $[(UO_2)_2OH^{3+}]/[H^+][(UO_2)_2(OH)_2^{2+}]$. In the limiting case of $K_{AB}[H^+]\ll1$ or $K_a[H^+]\ll1$, k_d becomes $k_{BD}K_{AB}[H^+]/2$ or $k_{-2}K_a[H^+]/2$, either being the same form as the observed rate law. However, it appears unlikely that the rate for B–D step is slow to determine the whole, rate, because the dissociation of water in complex B will be labilized by the coordinated hydroxyl group and the rate is expected to be much faster than that of water exchange in the uranyl ion. Consequently we propose that the acid decomposition of (2,2) species proceeds through mechanism 2 rather than mechanism 1. According to mechanism 2 the slopes in Fig. 3 correspond to $k_{-2}K_a/2$, and the $k_{-2}K_a$ values at each temperature are listed in Table 2 along with activation parameters.

The existence of complex D, $(UO_2)_2OH^{3+}$, proposed in this study has been postulated in investigations of equilibrium reactions by several groups.[5,22,23] The approximate value of the equilibrium constant K_a can be obtained from the relationship $K_a=K_{21}/K_{22}$, where K_{21} is the equilibrium constant for the reaction $2UO_2^{2+}+H_2O=(UO_2)_2OH^{3+}+H^+$. With the use of the earlier data on K_{21} and K_{22},[5,22] K_a values at 25 °C are determined to be 63 and 28 M^{-1} in 3 and 0.1 M KNO_3 solutions, respectively. The limiting condition $K_a[H^+]\ll1$ is therefore satisfied in the range of the acid concentrations in this study. The mechanism with the breakage of the second bridge as the rate-determining step, in which a single-bridged binuclear intermediate is formed, was also proposed in the decomposition reaction of di-μ-hydroxo-tetrakis(1,10-phenanthroline)-dichromium(III) ion.[24]

The rate law for the decomposition of $(UO_2)_2(OH)_2^{2+}$ ion is different from those of $(FeOH)_2^{4+}$,[16,25,26] $(VOOH)_2^{2+}$,[16] $(VOH)_2^{4+}$,[27] and [Co(ethylenediamine)$_2$-OH]$_2^{4+}$,[28] which have both acid-independent and -dependent terms. The second-order rate constants for the acid-dependent path in the decomposition of related di-μ-hydroxo binuclear complexes are summarized in Table 3, which also contains the rate constants for water-exchange reaction in the composite metal ions. There appears to be some correlation between two rate constants, i.e. the more labile the substitution reactions, the faster the decomposition reactions.

The existence of $(UO_2)_2OH^{3+}$, which is one of the minor hydrolysis species of uranyl ions, has not been justified hitherto but is confirmed by this kinetic measurement.

The authors wish to express their thanks to Mr. Yoshiyuki Nakamura of Natural Products Laboratory Chemistry, Tokyo Institute of Technology and Mr. Naoyuki Fujii of JEOL, Ltd. for measuring NMR spectra and helpful advice. This paper is partly supported by a Grant-in-Aid for Scientific Research No. 62470039 from the Ministry of Education, Science and Culture.

Calorimetric and Raman Spectroscopic Studies of Cadmium(II) Thiocyanato Complexes in *N,N*-Dimethylformamide

Shin-ichi ISHIGURO,* Toshiyuki TAKAMUKU, and Hitoshi OHTAKI†

(Received June 17, 1988)

Formation of thiocyanato complexes of cadmium(II) ion has been calorimetrically studied in *N,N*-dimethylformamide (DMF) at 25 °C. Calorimetric data obtained were well explained in terms of the formation of a series of four mononuclear $[CdX_n]^{(2-n)+}$ (n=1—4, X=SCN) complexes, and their formation constants, enthalpies, and entropies were determined. Raman band shifts for the C-S stretching vibration of SCN^- ion indicated that SCN^- ion binds to cadmium(II) ion only with the N end within the mono- or dithiocyanato complex, $[Cd(NCS)]^+$ or $[Cd(NCS)_2]$. Within the tri- and tetrathiocyanato complexes, thiocyanate ions binds with both the N and S ends, and the coordination modes, $[Cd(NCS)_2(SCN)]^-$ and $[Cd(NCS)_3(SCN)]^{2-}$, were suggested. The coordination modes for the di- and tetrathiocyanato complexes in DMF, $[Cd(NCS)_2]$ and $[Cd(NCS)_3(SCN)]^{2-}$, are different from those in water, $[Cd(NCS)(SCN)]$ and $[Cd(NCS)_2(SCN)_2]^{2-}$.[1] It is thus shown that the N-bonding becomes more favorable in DMF than in water. Such a result may mainly be ascribed to relatively weakened solvation of the SCN^- ion in DMF, especially at the N atom site which is hydrogen-bonded with water molecules but not with DMF.
