stereochemistry and hydrogen bonding scheme. After an anisotropic refinement of non-hydrogen atoms, hydrogen atoms located on their calculated positions with isotropic temperature factors were included in the refinement. The quantity minimized was $\Sigma w(|F_o|-|F_c|)^2$ with $w=1.0$ for reflections with $F_o \leqq 50.0$ or with $w=0.5$ for other reflections. After several cycles some hydrogen atoms with unacceptable geometry were excluded from further calculations.

At this stage, all the magnitudes of the observed structure factors for the ($h00$) reflections with $h<12$ were consistenly smaller than those of the calculated ones. Especially, the pronounced discrepancy was observed for (100) reflection. The main reason of these systematic disagreement between the observed and calculated structure factors was most likely due to the absorption effect originated from the plate-like crystal shape and its long lattice constant a (3.811 nm) directed normal to the plate surface of the crystal. Therefore, these reflections were excluded from the reflection data set in the further refinement, which decreased the R-value by about 1%. The final R value was 0.070 (R_w=0.084) for all non-hydrogen atoms and 71 hydrogen atoms. The final atomic parameters for non-hydrogen atoms are given in Table 1.[6]

The atomic scattering factors were taken from International Tables for X-Ray Crystallography, Vol. IV.[7] Computations were done on an ACOS 700S computer at the Crystallographic Research Center, Institute for Protein Research, Osaka University and on a HITAC M-280H computer at the Computer Center, University of Tokyo.

Results and Discussion

Molecular Conformation of $2C_{18}N^+2C_1Br^-$. The molecular structure is shown in Fig. 1 with bond lengths, bond angles and dihedral angles together with atomic labelling for non-hydrogen atoms. One of the two hydrocarbon chains is bent at almost right angles at the C(33) atom. After this bending both chains have a trans zigzag conformation with their zigzag plains parallel to each other. Dihedral angles of the folding part, C(42)-C(41)-N-C(31), C(41)-N-C(31)-C(32), N-C(31)-C(32)-C(33), C(31)-C(32)-C(33)-C(34), and C(32)-C(33)-C(34)-C(35) are 64, 60, −165, 64, and 64°, respectively (Figs. 1 and 4). This folding pattern (G, G, T, G, G) has been known as the short folding model on the lamella surface of the polyethylene single crystal. To make stable packing of hydrocarbon chains in the bilayer structure, the $2C_{18}N^+2C_1Br^-$ molecule adopts the most simple and compact folding pattern. In the rest of the molecule, all the dihedral angles are within the range of 180±3°, with exception of N-C(41)-C(42)-C(43) (−173°) and C(33)-C(34)-C(35)-C(36) (−175°). The two zigzag planes are arranged in parallel fashion (Fig. 1 (b) and (c)) with about 0.40—0.43 nm separation. One zigzag chain (C(41), C(42), C(43), ···, C(418))

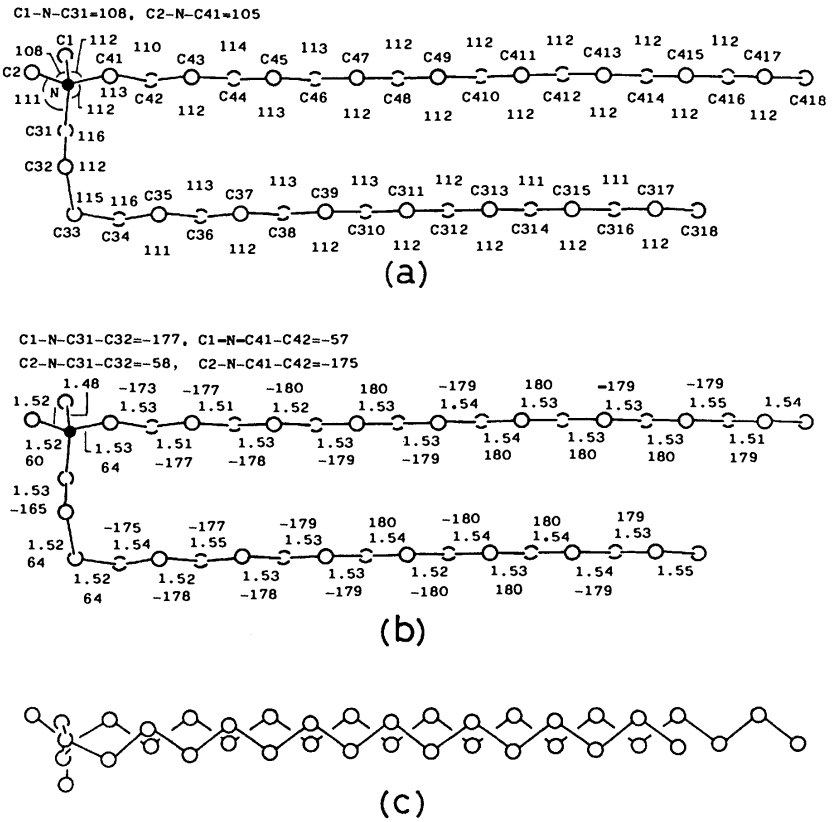

Fig. 1. (a) Atomic labelling and bond angles (ϕ/°), and (b) bond lengths (l×10/nm) and dihedral angles (ϕ/°) in $2C_{18}N^+2C_1Br^-$. Maximum estimated standard deviations for bond lengths, bond angles and dihedral angles are 0.002 nm, 1° and 1°, respectively. (c) Molecular conformation viewed from the direction normal to the zigzag plane.

is translated by three methylene unit along the chain axis to the other (C(33), C(34), C(35), ···, C(318)) (Fig. 1(c)). The average C–C bond length and C–C–C bond angle in the molecule are 0.153(1)nm and 112(1)°, respectively. There are in good agreement with values previously found in the long hydrocarbon chains of the other related amphiphilic compounds.[8,9]

Crystal Structure of $2C_{18}N^{+}2C_1Br^{-}$. The two $2C_{18}N^{+}2C_1Br^{-}$ molecules of the unit cell are related by centrosymmetry and pack tail to tail in a bimolecular layer with tilting long hydrocarbon chains (Fig. 2). The packing cross section per molecule in the layer plain (0.567 nm²) is determined by the space requirements of the hydrophilic part of the molecule, bromide anion and water molecule and coincides with the *bc*-plain of the unit cell. The dimethylammonium moiety has a chemically very simple structure compared with the hydrophilic parts of the natural amphiphilic compounds, such as phosphatidylethanolamine and phosphatidylcholine. The cross-sectional area of hydrophilic part of $2C_{18}N^{+}2C_1Br^{-}$, however, is comparatively larger than those of the above phospholipids, because of the conformationally fixed bulky dimethylammonium moiety and a bromide anion. Since the cross section of one hydrocarbon chain is about 0.20 nm², two hydrocarbon chains of $2C_{18}N^{+}2C_1Br^{-}$ molecule are tilted by 45° (=$\cos^{-1}(0.40/0.567)$) in order to accomodate to the large area of 0.567 nm² of the hydrophilic part (Fig. 2). Because of this tilting, two methyl carbon atoms at the tail end of the long alkyl chains are aligned parallel to the bilayer surface.

During the refinement procedure, statistically four water molecules with half occupancies were found in a unit cell. This number of water molecule is in good agreement with the results from chemical analysis and density measurement. Because of a short contact between OW1 and OW2 (0.18 nm), it is not possible to accomodate these four water molecules within the same unit cell. Figure 3 shows four types of their occurence and hydrogen bonding networks with bromide anions. Each unit cell in Fig. 3 contains two water molecules with full occupancy. Types A and B have no centrosymmetric relationships between water oxygens. In both cases, the water oxygen OW1 links to bromide anions by hydrogen bonds with lengths of 0.327 and 0.337 nm. Another water oxygen OW2 links to a bromide anion and a water oxygen OW1 in the

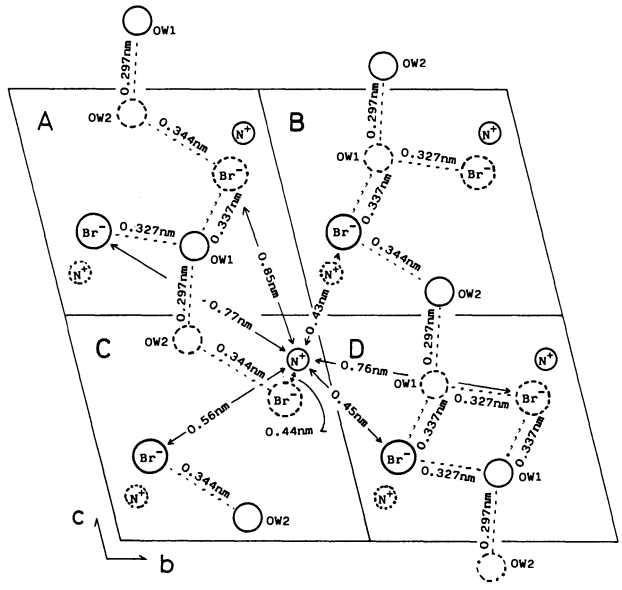

Fig. 3. Schematic illustration of hydrophillic layer of $2C_{18}N^{+}2C_1Br^{-}\cdot H_2O$ projected onto the *bc*-plane. Two water oxygen atoms are accomodated in a unit cell. Each unit cell, A, B, C, and D, has a different pair of water oxygens and hydrogen bonding scheme. Hydrogen bonds between bromide anions and water oxygen atoms are indicated by broken lines together with their bond lengths. Solid and broken circles represent atoms on the upper and lower side of the hydrophillic layer, respectively.

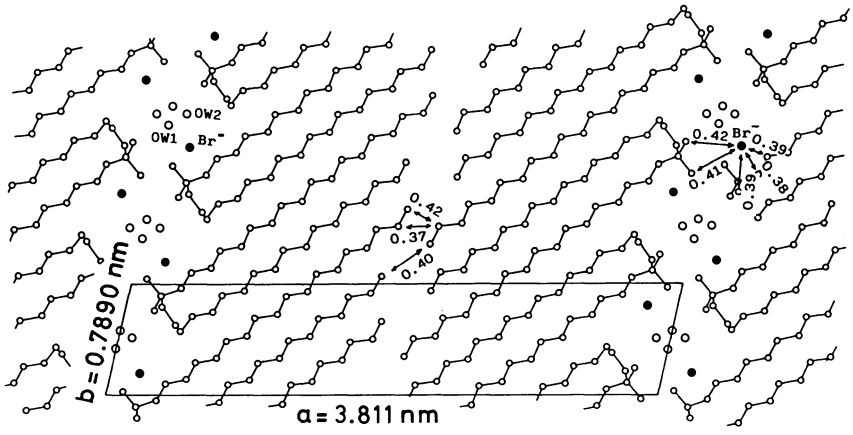

Fig. 2. Packing of $2C_{18}N^{+}2C_1Br^{-}\cdot H_2O$ projected onto the *ab*-plane (ORTEP[15] drawing). Four water oxygen atoms, OW1 and OW2 and their centrosymmetrical mates, are located on their positions in the unit cell. Distances (*l*/nm) between arrowed atoms are indicated short contacts in the structure.

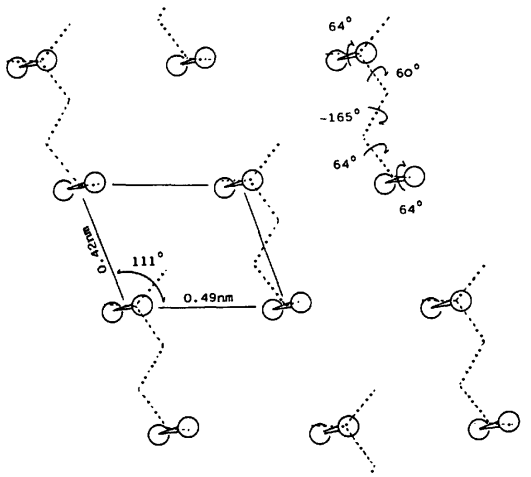

Fig. 4. The triclinic packing ($T//$) of the hydrocarbon chains in $2C_{18}N^{+}2C_1Br^{-}$. The chain axis C_s is a normal to the figure. The dotted lines denote the folding part and dimethyl groups in the molecule.

neighbouring unit cell with bond lengths 0.344 and 0.297 nm, respectively. Types C and D have a pair of oxygen atoms OW2 and OW1, respectively. In these cases, oxygen atoms are related by a centrosymmetry at the center position of each unit cell. The combination of the unit cells of AA, BB, BD, and DA along the c-axis makes a continuous hydrogen bond network along this direction within a hydrophilic layer. While the combination of BA, CA, BC, and CC is not possible because of a short OW2···OW2 contact (0.23 nm). The rest of the combination gives a discontinuous hydrogen bond network. Although there are many ways to accomodate water molecules in a unit cell, as a statistical point of view, one asymmetric unit contains two water oxygen atoms OW1 and OW2 with half occupancies as a whole.

The short intermolecular contacts between carbon atoms at the tail portions are 0.37 (C(417)···C(417)), 0.40 (C(318)···C(418)), 0.42 (C(417)···C(418)), 0.42 (C(317)···C(417)), and 0.43 nm (C(418)···C(418)) (Fig. 2). Rest of them are more than 0.48 nm. The short distances between carbon atoms in the adjacent alkyl chains are in the range of 0.39—0.43 nm including those between chains in the same molecule. On the other hand, there are several strong interactions in the hydrophilic region. Bromide anions link to water molecules by a hydrogen bonding with a distance of about 0.34 nm as mentioned above. Other short contacts of the bromide anion are with methyl carbons of C(1)(0.41 nm), C(2)(0.42 nm) and alkyl carbons of C(31)(0.39 nm), C(32)(0.40 nm), C(33)(0.40 nm), C(41) (0.38 nm), and C(42)(0.39 nm). Thus, the bromide anion is very neatly nestled among the head portions of the amphiphiles and water molecules.

Ammonium cations and bromide anions make a plane parallel to the bilayer surface within the deviation of 0.013 nm (Table 1). Two such planes are contained in one hydrophilic layer (Fig. 2). This kind of planarity among charged atoms have been reported in many other amphiphilic salt crystals.[10-13] A nitrogen cation is surrounded by six bromide anions (four on the same plane and two on the other plane in the same hydrophilic layer) (Fig. 3). Three of them are located at the place with somewhat long distances (0.56—0.77 nm) from a nitrogen cation because of the hydrogen-bonded water molecules with these bromide anions. The distances from the rest of bromide anions are rather short (0.43—0.45 nm). Therefore, the plus charge on the ammonium cation seems to be canceled exclusively by these three bromide anions.

The hydrocarbon chains pack latterally according to the triclinic ($T//$) packing mode.[14] The subcell dimensions are: a_s=0.42, b_s=0.49, c_s=0.26 nm, α_s=88, β_s=104 and γ_s=111° (Fig. 4). The packing cross section per chain perpendicular to its long chain axis is 0.193 nm^2, giving a well packed chain matrix. It is remarkable that all the hydrocarbon chains pack identically as it were no folding part in the amphiphile molecule.

The authors wish to express their deep thanks to Professor Yukiteru Katsube and co-workers at the Crystallographic Research Center, Institute for Protein Research, Osaka University for the use of a four-circle diffractometer and an ACOS 700S computer.

Preparation of SnO_2 and Nb_2O_5 Supported Vanadium Oxide Catalysts by a Column-Exchange Adsorption Method and Dispersed States of Vanadia Species

Yoshiya KERA* and Takahiro KAWASHIMA
Department of Applied Chemistry, Faculty of Science and Engineering, Kinki University, Higashiosaka, Osaka 577
(Received September 16, 1987)

SnO_2 and Nb_2O_5-supported monolayer or sub monolayer vanadium oxide catalysts were prepared by an impregnation method such as the column-exchange adsorption of oxovanadium ion at various pH(=2, 4, and 7). The deposited states of the vanadia species on SnO_2 and Nb_2O_5 surfaces were examined by ESR spectrometry using V^{4+} ion as a probe. The catalytic features were studied by measuring the 2-propanol decomposition rate as a test reaction. The deposited states of the vanadia species differed to a small extent between SnO_2 and Nb_2O_5 carriers depending upon the difference in the symmetry of the surface field. The deposited states, however, did not vary with pH upon impregnation, although the amounts of vanadium oxide deposited (coverage, θ) were much affected by the pH. The activation energy (E_a) for the dehydration of 2-propanol over these catalysts was linearly related to the reciprocal of the coverage ($1/\theta$). When both curves were extended to $1/\theta=0$, they crossed at around 5—6 kcal·mol^{-1} which was the minimum value, although the inclination differed largely between the carriers. This low activation energy was regarded as an intrinsic value that was caused by the multi-layered vanadium oxide deposited on the carriers. Through the discussion it is clearly shown that the most effective catalyst, a monolayer catalyst, was prepared on impregnation at pH=2 and the vanadia species were dispersed widely, keeping a weak interaction with the SnO_2 and Nb_2O_5 surfaces.

A column-exchange adsorption method [1] has been reported as an effective method for preparing vanadium oxide monolayer catalysts that have a superior activity and the selectivity for hydrocarbon oxidations, especially in titania-supported vanadia catalysts.[2-4] Previously the deposited state of a monolayer or sub monolayer vanadium oxide was shown to depend greatly upon the crystalline symmetry of the support. This in turn depends upon the crystal field symmetry around the cation on the surface. ESR analysis has been applied to vanadia deposited on rutile and anatase[5] by such an exchange-adsorption method. Many investigators have studied the binary V_2O_5-SnO_2 catalyst system because it has a high activity and selectivity for ammoxidation and various hydrocarbon oxidations.[6-13] The effect of pH on vanadium oxide monolayer catalysts deposited on SnO_2 (the crystal structure of which belongs to rutile type[14]) were examined by the column-exchange adsorption method. We also prepared vanadium oxide monolayer catalysts deposited on Nb_2O_5 which have a V_2O_5 type crystal structure.[15] We were interested specially in the interaction between vanadia species and Nb_2O_5 surfaces and in comparing the result with those of SnO_2 and titania (rutile and anatase). Recently many people have payed attention to Nb_2O_5 as a catalyst carrier bacause it shows a higher Strong-Metal-Support Interaction (SMSI) than TiO_2 or ZrO_2 carriers.[16]

ESR analysis for V^{4+} ion showed that vanadia deposited on SnO_2 and Nb_2O_5 appeared to interact more weakly with those carrier surfaces than TiO_2 (rutile). The interaction was similar in extent to that of TiO_2 (anatase). Of special interest is the linear relation between the apparent activation energy(E_a) for 2-propanol decomposition on the catalysts and the reciplocal of the surface coverage(θ) of the vanadia species. The E_a vs. $1/\theta$ curves for V_2O_5/SnO_2 and Nb_2O_5, which were extrapolated to $1/\theta$ both gave the lowest E_a=5—6 kcal·mol^{-1}. This should be regarded as the intrinsic activation energy for 2-propanol decomposition over the multi-layered vanadium oxide on SnO_2 and Nb_2O_5. Such a low value appeared to arise only from the vanadium oxide dispersed widely on the carrier surface with a weak interaction.

Experimental

1) **Materials and Preparation Procedures.** Four grams of Nb_2O_5 powder (Nakarai Chem. Co., Ltd., guaranteed grade) was packed into a glass column (o.d.=15 mm). About 0.5 wt% of NH_4VO_3 (Kanto Chem. Co., Ltd., guaranteed grade) aqueous solution, the pH of which were exactly adjusted at 2, 4, and 7 by adding HNO_3 and aqueous ammonia, were poured into the column to make the oxovanadium ion adsorb. Each 3 ml of the effluent solution was collected to measure the changes in the pH and the concentration of oxovanadium ion (V-ion) while passing through the column.

For the SnO_2 carrier (Kanto Chem. Co., Ltd., guaranteed grade), about 4 g were packed into the column; the NH_4VO_3 solution was added until both the pH and V-ion concentration had recovered to the original values. Those pH and V-ion concentrations were determined by the use of a pH-meter, TOA model HM-7B and the usual Mohr-titration method, respectively. After the adsorption, the samples were dried at 110 °C for 8 h, and then calcined at 400 °C for 2 h in order to prepare Nb_2O_5 and SnO_2 supported vanadium oxide catalysts, V_2O_5/Nb_2O_5 and V_2O_5/SnO_2.

2) Measurements and Computer Simulation. The surface areas of V_2O_5/Nb_2O_5 and SnO_2 were determined by N_2 gas adsorption at 77 K according to a convenient method.[17] The deposited states of the vanadia species were examined by ESR spectrometry. The ESR spectrometer used was a Nippon Denshi Model JES-PE (X-band, 9.3 GHz and 100 kHz modulation). Computer simulation of the ESR spectrum was performed using an IBM 4381 system. The catalytic activities for 2-propanol decomposition, as a test reaction, were measured in a closed circulation system (ca. 0.5 dm^3) connected directly to the gaschromatograph with a Porapac-Q column (1 m). 20 mg of the catalysts were spread widely over the bottom of the vassel and preheated at the reaction temperature in air for one hour before the reaction. The vessel containing 2-propanol was cooled by an ice-water bath during the reaction in order to maintain the vapor pressure constant at 8.4 mmHg (1 mmHg≈133.322 Pa). The intensity of the GC-peak of the main product, (that was confirmed to be propylene) was measured at intervals of 2 min. The decomposition rate was determined from the intensity change for the initial 20 min. The reaction temperature was controlled within ±0.5 °C in the range 270—350 °C.

Results

1) The Amounts of Vanadium Oxide Deposited on SnO_2 and Nb_2O_5 Carriers. When the NH_4VO_3 aqueous solutions with different pH were poured into the glass column packed with SnO_2 carrier, the pH and vanadium ion (V-ion) concentration of the effluent solution varied as shown in Fig. 1. The pH initially increased from 2 to about 4 or more in a run of pH=2 and increased only slightly in a run at pH=4, while in a run at pH=7 it decreased to near 6. The pH finally returned to the original values in all runs. Accompanied by the pH-changes, the V-ion concentrations initially decreased and then gradually recovered to the original values. The amounts of the adsorbed vanadium ion were estimated, based on these V-ion concentration vs. effluent-volume cruves. The adsorbed amounts of oxovanadium ion, which were estimated on the assumption that they were deposited in the form of V_2O_5, are given in the 3rd and 4th column of Table 1 (in units of $mg(V_2O_5)\cdot g\text{-carrier}^{-1}$ and $mg(V_2O_5)\cdot m^{-2}$, respectively). The surface area and surface coverage are also given in the 2nd and 5th column in Table 1, respectively. The coverage was estimated on the assumption that the V–O–V network of V_2O_5 extends two-dimensionally on the SnO_2 carrier and the V–O bond distance is 2.0 Å.[18]

With respect to the Nb_2O_5 carrier, the changes in the pH and the V-ion concentration of the effluent solutions are shown in Fig. 2. The pH change is small in all pH runs. The V-ion concentration initially

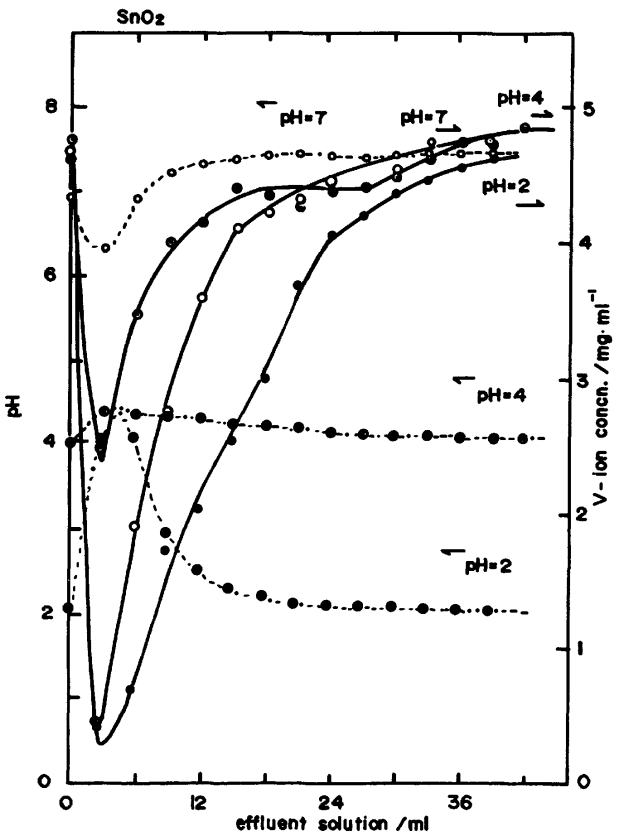

Fig. 1. The variations of pH and vanadium ion concentration in ammonium metavanadate effluent solution during passing through SnO_2-packed column for various pH runs. ----: pH change and —: V-ion concentration change.

Table 1. Surface Areas, the Amounts of Vanadium Oxide Deposited (Reduced to V_2O_5), and the Surface Coverages of V_2O_5/SnO_2 and V_2O_5/Nb_2O_5

Catalyst	Surface area	Deposited amounts		Surface coverage
	$m^2\cdot g^{-1}$	$mg(V_2O_5)\cdot g\text{-car.}^{-1}$	$mg\cdot m^{-2}$	(θ)
SnO_2 carrier	32	—	—	—
V_2O_5/SnO_2 (pH=2)	36	29	0.80	0.42
V_2O_5/SnO_2 (pH=4)	39	10	0.25	0.14
V_2O_5/SnO_2 (pH=7)	35	15	0.42	0.22
Nb_2O_5 carrier	3.9	—	—	—
V_2O_5/Nb_2O_5 (pH=2)	3.6	9.5	2.6	1.4
V_2O_5/Nb_2O_5 (pH=4)	3.4	5.9	1.7	0.90
V_2O_5/Nb_2O_5 (pH=7)	3.7	1.4	0.38	0.19
V_2O_5 powder	8.5	—	—	—

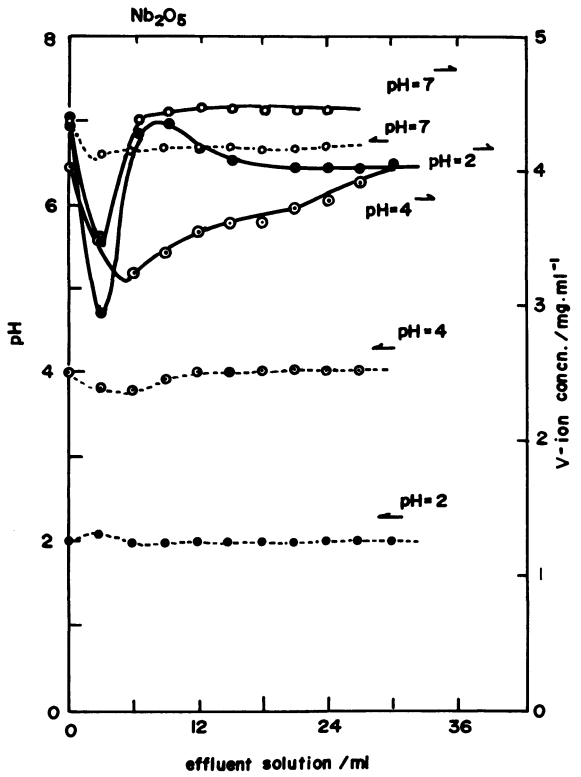

Fig. 2. The variations of pH and vanadium ion concentration in ammonium metavanadate effluent solution during passing through Nb_2O_5-packed column for various pH runs. ----: pH change and —: V-ion concentration change.

decreases slightly relative to the case of SnO_2 because of the small surface area. The concentration curve does not fully return to the original value except for a run at pH=7. The adsorbed amounts of vanadium ion were similarly estimated as given in the 3rd and 4th column of Table 1. The surface areas and the coverage are also given in the 2nd and 5th column of Table 1, respectively.

2) **ESR Spectra of V(IV) Ion on V_2O_5/SnO_2 and Nb_2O_5.** The ESR spectrum of the supported vanadia catalysts did not basically differ with the pH upon impregnation. The ESR spectra for V_2O_5/SnO_2 impregnated at pH=2 and 7, which were measured at 77 K after the evacuation at room temperature, are illustrated in Fig. 3-a and b, respectively. The spectrum for V_2O_5/SnO_2(pH=7), which was measured at 77 K after the evacuation at 400 °C, is shown in Fig. 3-c. The spectrum is considered to contain 8 hf-lines due to the ^{51}V-nucleus (I=7/2). After heat treatment at 400 °C, however, the spectrum varies in a complex manner; the other ESR species are added to the original one. V_2O_5/SnO_2 (pH=2) shows a composite spectrum even upon pretreatment at room temperature.

The ESR spectra for V_2O_5/Nb_2O_5 impregnated at pH=2 and 7, which are measured at 77 K after evacuation at room temperature, are illustrated in Figs. 4-a and b. The spectrum of V_2O_5/Nb_2O_5(pH=2), the surface coverage (θ) of which is larger than unity, shows specially unresolved hfs upon evacuation at

Fig. 3. room temperature. V_2O_5/Nb_2O_5(pH=7) shows a relatively clear hfs upon evacuation at room temperature, but after evacuation at 400 °C the hfs completely disappeared and a very broad spectrum appeared.

A computer simulation was applied to the spectra of Figs. 3-b and 4-b which were measured for V_2O_5/SnO_2 and Nb_2O_5 impregnated at pH=7 at 77 K after evacuation at room temperature. The first derivative curve was calculated according to the usual simulation method at intervals of 10 G (1 G=10^{-4} T) in a magnetic field of 2600—4300 G, as described previously.[5] The intensity of the microwave absorption at each resonance field was obtained by numerical inte-

Table 2. The Best Fitting Parameters Used for Simulating the ESR Spectra of V(IV) Ion on V_2O_5/SnO_2 and V_2O_5/Nb_2O_5 Catalysts Evacuated at Room Temperature

Catalyst	Species	g value		A value		Line width
		$g_{//}$	$g_{\perp}$	$A_{//}$/G	$A_{\perp}$/G	d/G
V_2O_5/SnO_2	V(IV)	1.9265	1.9807	200.5	74.0	27
V_2O_5/Nb_2O_5	V(IV)	1.9100	1.9780	200.0	70.0	40

Table 3. Arrhenius Parameters of 2-Propanol Decomposition over V_2O_5/SnO_2 and V_2O_5/Nb_2O_5 Catalysts Impregnated at pH=2, 4, and 7

Catalyst	$\log V_o$ molecules·m^{-2} s^{-1}	E_a kcal·mol^{-1}
SnO_2 carrier	23.7	16.2

grations at intervals of 1.5° to θ and ϕ for all directions under the assumption of a Gaussian shape function and 27 G of the half width for V_2O_5/SnO_2 and 40 G for V_2O_5/Nb_2O_5. The best-fit parameters are given in Table 2 and the simulated spectra are shown by the broken line in Figs. 5-b and 6-b.

3) **Decomposition Rates of 2-Propanol over V_2O_5/SnO_2 and Nb_2O_5.** The reaction rates of 2-propanol decomposition over the SnO_2 and Nb_2O_5-supported vanadium oxide catalysts were determined from changes in the GC-peak intensity for the produced propylene in the temperature range 270—350 °C. Arrhenius plots for the initial mean rates, thus obtained, are summarized in Fig. 7(Arrhenius relation: $V=V_o\exp(-E_a/RT)$ and $\log V=\log V_o-E_a/RT$). Arrhenius parameters, $\log V_o$ and E_a, estimated from those plots, are given in Table 3. The minimum activation energy was found to be 7.2 kcal·mol^{-1} for V_2O_5/Nb_2O_5 prepared at pH=2, while the maximum was 18.2 kcal·mol^{-1} for V_2O_5/Nb_2O_5 prepared at pH=7. The activation energy tends to decrease with the amounts of vanadium oxide deposited in any series of catalysts.

The reaction rates in units of molecules·m^{-2}·s^{-1} and molecules·mg$(V_2O_5)^{-1}$·s^{-1}, which were estimated at 300 °C in Fig. 7, are shown in Figs. 8 and 9, respec-

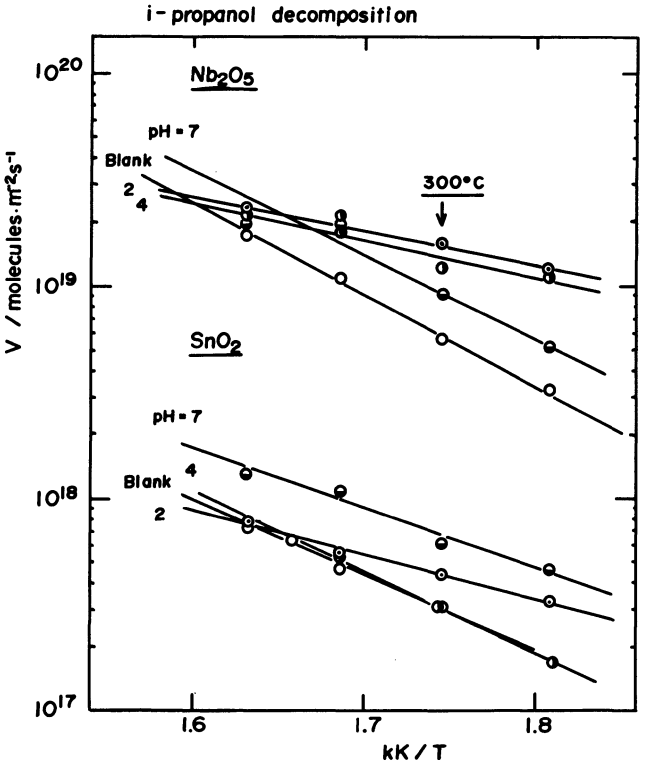

Fig. 7. Arrhenius plots for the 2-propanol decomposition rates over V_2O_5/SnO_2, Nb_2O_5 prepared at various pH and carrier themselves.

tively. In Fig. 8, the activity per m^2 of V_2O_5 powder is higher than those of the carriers, Nb_2O_5 and SnO_2, and the activity is accelerated 2—3 times in V_2O_5/Nb_2O_5 catalysts and twice or less in V_2O_5/SnO_2 relative to the carrier themselves. In Fig. 9, the activity per

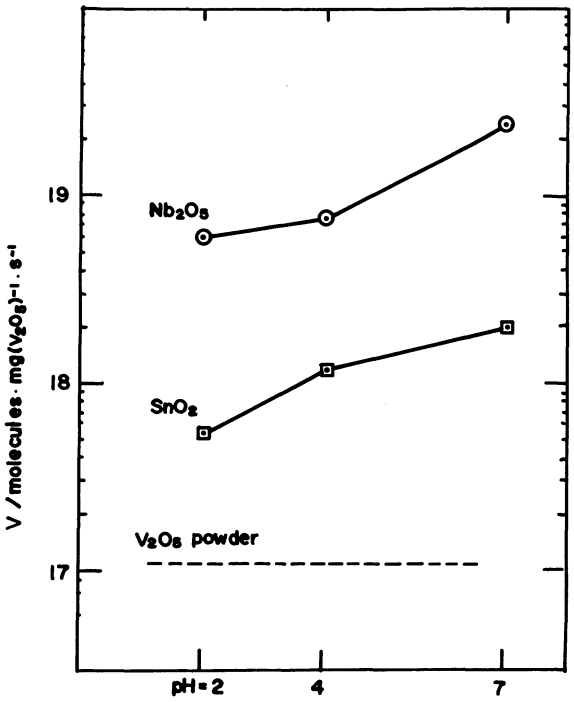

Fig. 9. Comparison of activity per $mg(V_2O_5)$ and per second for 2-propanol decomposition among V_2O_5 powder and the supported catalysts at 300°C.

$mg(V_2O_5)$ generally increases with the pH upon the impregnation and the maximum activity was attained at pH=7 in both carriers. It should be specially noted that the activity is 50—200 times higher in V_2O_5/Nb_2O_5 and 5—20 times higher in V_2O_5/SnO_2 than that of V_2O_5 powder itself. Thus, it is evident that the vanadia species spread widely over the carrier surfaces.

Discussion

Deposited States of Vanadium Oxide on SnO_2 and Nb_2O_5. The deposited states of vanadium oxide on titania (rutile and anatese) have been successfully studied through the analysis of the ESR spectra using the surface V(IV) ion as a probe. The deposited state is greatly affected by the crystal structure of the original carrier; the vanadia species on rutile differed from that on anatase.[5] SnO_2 belongs to the rutile type structure, although the radius ratio $r_{cation}:r_{anion}$ is slightly larger in $SnO_2(r_c/r_a=0.53)$ than in rutile (0.45).[14] Thus, we can also estimate the d-orbital splitting of V(IV) ion from the g-value by Eq. 1.[19]

$$g_{//} = g_o + 8\lambda/\Delta \text{ and } g_\perp = g_o + 2\lambda/\delta \quad (1)$$

where Δ and δ are the crystal field splitting constants and λ the spin-orbit coupling constant which is assumed reasonably to be 250 cm^{-1}.[20]

With respect to V(IV) ion doped into SnO_2 crystalline lattice, the coordination model and d-orbital splitting that was estimated from a reported

g-value[21] by Eq. 1 are shown in Fig. 10-a. For V(IV) ion in the vanadia species deposited on SnO_2, the $g_\perp$ component in Table 2 is large and the $g_{//}$ small ralative to those for the doped sample. The differences in the g-values indicate that the d-orbital splitting Δ, decreases and the δ increases when the V(IV) ion located in the inner bulk is brought to the top of the surface. A similar change was found in the titania-vanadia system:[5] Previously, we showed that the field symmetry around the V(IV) ion replacing the Ti ion site on the rutile surface was similar to that around the V(IV) ion placed in a distorted square pyramidal field. The V(IV) ion doped into a rutile crystal was subject to an octahedral field. Thus, accompanied by removing the V(IV) ion from inner bulk to the top of the rutile surface, the crystal field around V(IV) ion changes from octahedral to a distorted square pyramid. The coordination model and the d-orbital splittings for V_2O_5/SnO_2 are shown analogously in Fig. 10-b. However, V(IV) ion placed on an SnO_2 surface is subject to a weaker field than that on rutile, because the ratio of r_c/r_a is larger in SnO_2 than TiO_2.[14] In fact, the splitting constant, Δ and δ, for V(IV) ion deposited on SnO_2 are smaller than those on rutile (Δ=38 and δ=26 kcm^{-1}).[5] Moreover, the extent of the interaction between vanadia species and carrier surfaces can be compared, based on the hf-coupling constant for the V(IV) ion as a probe, as previously pointed out;[5] since $A_{//}$ and $A_\perp$ for V_2O_5/SnO_2 are 200.5 and 74 G, respectively, while those for $V_2O_5/R\text{-}TiO_2$ 173.1 and 55 G, the interaction for V_2O_5/SnO_2 is understood to be weaker than that for $V_2O_5/R\text{-}TiO_2$. The extent of the hf-splittings of V_2O_5/SnO_2 is similar to those of $V_2O_5/A\text{-}TiO_2$ described in the previous paper(Δ=22 and δ=24 kcm^{-1}), in which the V(IV) ion was assumed to be placed only near the Ti ion vacant site.[5]

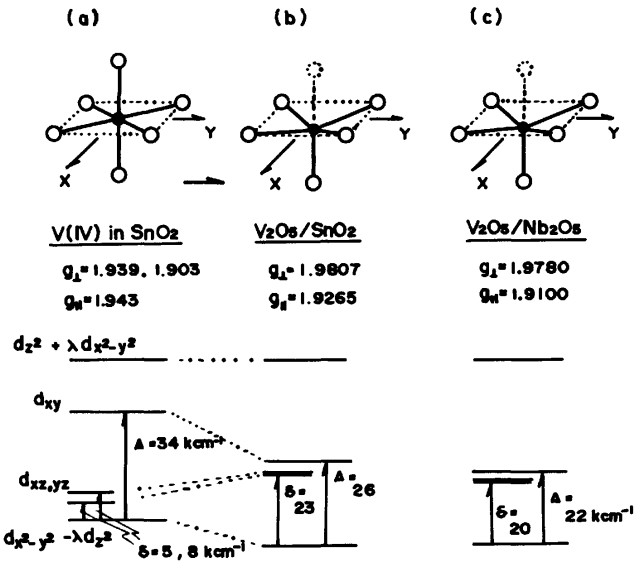

Fig. 10. Coodination model and crystal field splitting for the surface V(IV) ion in V_2O_5/SnO_2 and Nb_2O_5. Analysis for the data of V(IV) ion doped in SnO_2 lattice[21] is shown in (a) for comparison.

The spectrum for V_2O_5/SnO_2 sharpens considerably but remains complicated, after the evacuation at 400 °C, as illustrated in Fig. 3-c. Some reduced vanadia species might be formed by such evacuation treatment and spread over the surface without interacting with each other. Thus, no reduced phase was detected even upon the high temperature evacuation.

Nb_2O_5 belongs to a V_2O_5 type crystal but the oxygen ion coordination around the Nb ion is closer to octahedral symmetry than that of V_2O_5, because the ionic radius of Nb(1.43 A) is larger than that of V(1.32 A).[15] The g-value for the V(IV) ion on Nb_2O_5 surface is almost the same as on an SnO_2 surface, and also close to that for the V_2O_5 inner lattice.[22] Thus, the coordination model and the splitting constants are close to those of V_2O_5/SnO_2, as Fig. 10-c shows. When the V_2O_5/Nb_2O_5 catalyst was evacuated at 400 °C, the spectrum with hfs changed to a broad one as Fig. 4-c illustrated. The broadening might be caused by a dipole-dipole interaction between a reduced vanadia species produced by such a high temperature evacuation.

Catalytic Properties of V_2O_5/SnO_2 and Nb_2O_5. A good compensation relation was found between log V_o and E_a for 2-propanol decomposition over the titania-supported vanadia catalysts, V_2O_5/R- and $A\text{-}TiO_2$, prepared by the column-exchange adsorption of oxo-vanadium ion under different pH(=2, 4, and 7).[5] Based on such a compensation relation,[23] we could discuss the best conditions for the catalyst preparation. A compensation relation also holds between log V_o and E_a in Table 3 for the catalysts , V_2O_5/SnO_2 and Nb_2O_5, impregnated at different pH(=2, 4, and 7), as shown in Fig. 11. The lowest activation energy was obtained for both SnO_2 and Nb_2O_5 carriers on impregnation at pH=2. The most desirable conditions, thus, is impregnation at pH=2.

E_a tends to decrease with increase in the coverage, θ, as indicated previously. In fact, the E_a vs. $1/\theta$ plot gives a good linear curve, as shown in Fig. 12. The inclination of the curve for SnO_2 differs to some extent from that for Nb_2O_5, but both curves cross at around E_a=5—6 kcal·mol^{-1} upon extrapolation to $1/\theta$=0. The E_a value should correspond to such activation energy as caused by the multilayered vanadium oxide piled on SnO_2 and Nb_2O_5 surfaces; it might indicate an intrinsic activation energy for pure vanadium oxide crystallite. We have never found any linear relation between E_a and $1/\theta$ in vanadia-titania[5] and -zirconia[24] systems. With these carriers, not only the coverage (θ) but also the deposited states would be affected by the pH upon preparation, although the difference in the deposited states could never be detected by ESR-measurement.

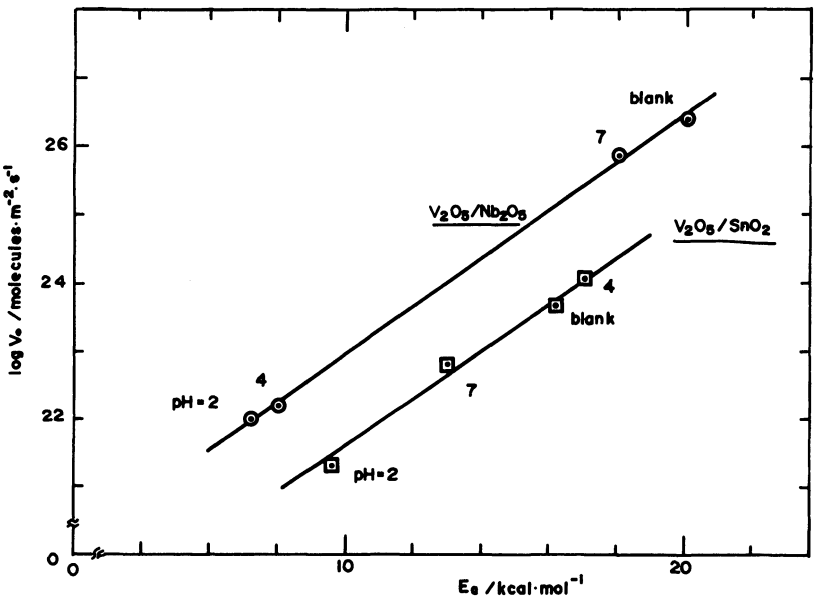

Fig. 11. Relationship between the pre-exponential factor ($\log V_0$) and the activation energy (E_a) for 2-propanol decomposition over the SnO_2- and Nb_2O_5-supported vanadium oxide catalysts.

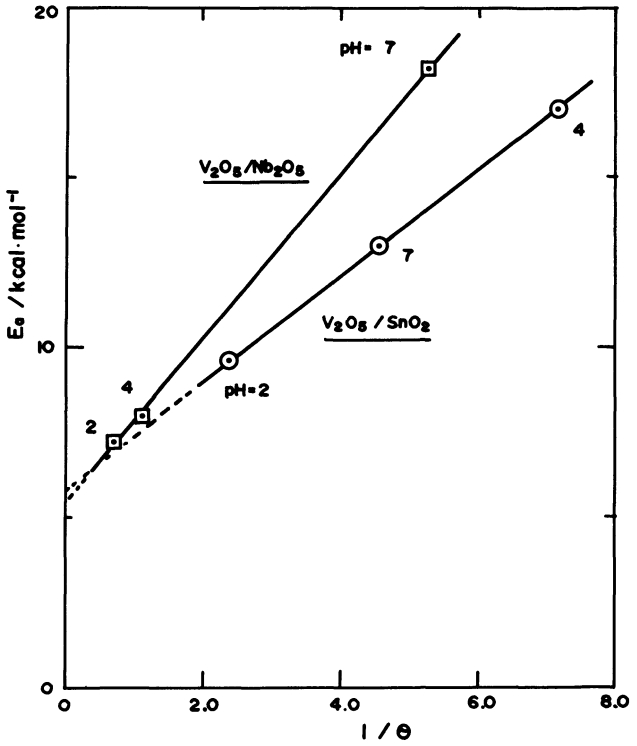

Fig. 12. Relationship between the activation energy and the reverse of the surface coverage ($1/\theta$) of vanadium oxide dispersed on SnO_2 and Nb_2O_5 carriers, see text in detail.

Hernadi et al.[12] showed that the maximum selectivity for 1-butene oxidation was obtained in the composition interval $3:1<V_2O_5:SnO_2<2:1$. Ai[9] showed that the highest activity was obtained for the V_2O_5–SnO_2 catalyst with atomic ratio V:Sn=1:1 and it was the most effective composition for production of maleic anhydride. Andersson[6] suggested in the study on ammonxidation of 3-methylpyridine on V_2O_5/SnO_2 that the catalyst with both V_2O_5 and V_6O_{13} phases is especially active and selective and that the effective catalyst has the composition $V_{0.03}Sn_{0.97}O_2$, in which the V=O bond is weakened by the incorporation of Sn^{4+} ion into the V_2O_5 lattice. Hauffe et al.[10] gave a similar suggestion for the effective working state of various metal oxide supported V_2O_5 catalysts. These authors were also concerned with the fused binary V_2O_5–SnO_2 catalyst, and the effective species were suggested to be formed by the incoporation of Sn^{4+} ion into vanadium oxide lattice. Ono et al.[11] investigated the rates of oxidation of C_3H_6, C_2H_4, C_3H_8, and CO over V-Sn oxides of various compositions. The rates showed two maxima at V/Sn= 2/1 and 1/8. Their ESR, IR, and X-ray measurements suggested that the former rate maximum arises from the formation of an amorphous compound and the latter is associated with the presence of a V^{4+} ion dissolved into SnO_2.[21,25] We have had no evidence for either the incorporations of Sn^{4+} and Nb^{5+} ions into the vanadia species or of V^{4+} ion into SnO_2 and Nb_2O_5 carriers. With the present impregnated catalysts, since the vanadia species were clearly shown to be deposited on SnO_2 and Nb_2O_5 surfaces in the same manner as vanadium ion (V^{4+}) is placed near the Sn^{4+} and Nb^{5+} vacant sites. However we can not directly compare the surface state with those of their fused catalysts. However, the V-O bond can surely be considered to be weakened in such vanadia species as are interacting with the carrier surface, even though quite weakly, as

was discussed for the titania–vanadia system in the previous paper.[5]

Finally, it should be noted that the weak interaction of vanadia species with Nb_2O_5 contrasts with the SMSI in metal supported Nb_2O_5 catalyst.[16] These V_2O_5/SnO_2 and Nb_2O_5 catalysts will be tested for ammoxidation and hydrocarbon oxidation in the near future.

The ^1H and ^{13}C NMR of 9,10-Bis(phenylethynyl)anthracene Dianion

Masatoshi HIRAYAMA,* Masaaki KOBAYASHI, and Hiroshi YAMAMOTO†
Department of Chemistry, Faculty of Science, Ibaraki University,

†Faculty of Education, Ibaraki University, 2-1-1 Bunkyo, Mito 310
(Received September 18, 1987)

The formation of 9,10-bis(phenylethynyl)anthracene dianion by contact of tetrahydrofuran-d_8 solution of its precursor with sodium in vacuo, is confirmed by the ^1H and ^{13}C NMR spectra and its reactivity. The excess π-charge-density distribution estimated by the CNDO/2 calculation for the dianion, is consistent with the observed ^1H and ^{13}C chemical shift values.

The NMR studies of the π-dianions of polycyclic aromatics and annulenes have so far been largely served to investigate the electronic structures of these π-conjugated systems,[1] as well as ESR studies on the corresponding anion radicals. It has been suggested that the ease of the formation of π-dianion correlates well with the resonance energy per atom in a dianion molecule.[2] However, in practice the line broadening due to spin exchange with a corresponding anion radical in equilibrium with dianion in solution often prevents an observation of high-resolution NMR signals of dianion. On the other hand, it may be significant that a substituent effect on π-conjugated system can be discussed in terms of the excess charge distribution of the corresponding π-dianion. However, a discussion from this point of view has not generally been of interest. In the anthracene dianion, excess charge relative to its neutral precursor has been known to be extraordinarily large at the 9 and 10 positions;[3] this observation prompted us to discuss the effect of several kinds of substituents at these positions on the excess charge distribution.

The present paper reports on the formation of the dianion of 9,10-bis(phenylethynyl)anthracene (**1**) as a unique anthracene derivative and on its electronic structure on the basis of an observation of its ^1H and ^{13}C NMR and charge density distribution estimated by a MO calculation.

Experimental

Compound **1** (Aldrich Co. Ltd.) was used without further purification and tetrahydrofuran-d_8 (THF-d_8) (Canada MSD Co. Ltd.) was vacuum-distillated after drying with sodium/potassium alloy in a high-vacuum tube. 1 ml of a 0.2 mol dm^{-3} THF-d_8 solution of **1** was introduced into a 10 mm Pyrex tube connected to high-vacuum line and degassed. A small amount of sodium metal was placed in the upper part of an NMR tube connected to the vacuum line. After the solution was transferred into the sample tube, the tube was cut off from the vacuum line. By turning the tube, the solution was brought into contact with the metal at room temperature for controlled periods of time. The NMR spectra were measured on a Varian VXR-300 pulsed FT spectrometer operating at 300 and 75 MHz for ^1H and ^{13}C, respectively, at room temperature. The ESR spectra and mass spectra were recorded on a JES-FE1XG ESR spectrometer (X-band, 100 kHz modulation) and a JMS DX-300 mass spectrometer, respectively. A calculation of the charge density distribution was performed by the MO method with Y4CB04 of the library programs in the Computer Center of the University of Tokyo on HITAC M-240H of Ibaraki University.

Results and Discussion

Immediately after the contact of the THF-d_8 solution of **1** with sodium metal in vacuo at room temperature, the solution turned green, which gave an ESR spectrum of the anion radical of **1**. Upon further contact, the color of the solution gradually became purple, while the ESR disappeared and new NMR lines developed. The ^1H spectrum of the purple

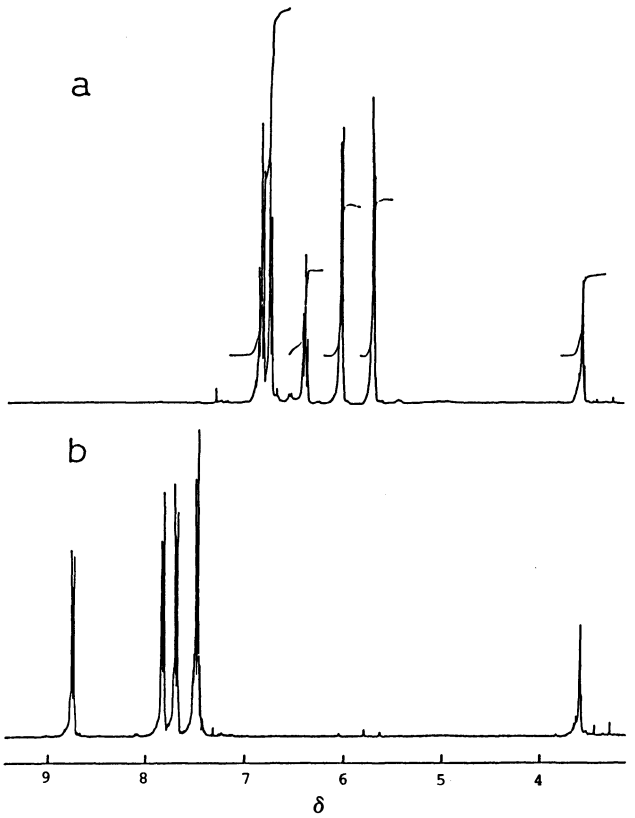

Fig. 1. ^1H NMR spectra of $\mathbf{1}^{2-}$ (a) and its neutral precursor (b) in THF-d_8.

solution measured after contact for 24 h is shown in Fig. 1, together with that of the neutral precursor **1** in THF-d_8. This spectrum exhibited the same pattern as that of **1**, which consists of an AA'BB' and an AA'BB'C systems. The center of gravity of ^{1}H signals was shifted toward 1.53 ppm higher than that for **1**. Furthermore, in order to investigate whether this species is a diamagnetic monoanion formed by subtracting a proton from the solvent or not, after a purple solution was prepared in THF with the same technique, THF was excluded by evaporation and a resulting purple residue was solved in THF-d_8. The ^{1}H spectrum of the resulting purple solution was completely identical with that produced first by contact with sodium metal in THF-d_8; that is, the latter spectrum has no other lines than the former. One can thus rule out the possibility of the formation of a monoanion. The ^{13}C spectrum of the purple species (Fig. 2) is consistent with that expected from the ^{1}H spectrum, consisting of lines of five tertiary and five quaternary carbons as well as those of **1**. The high-field shift of the center of gravity of ^{13}C signals from **1** to the purple species is 5.26 ppm.[4] Thus, from these results, one may anticipate that the purple species is identified to a π-dianion of **1**, $\mathbf{1}^{2-}$ (or a disodium salt of dianion ($\mathbf{1}^{2-}\cdot 2Na^+$)).

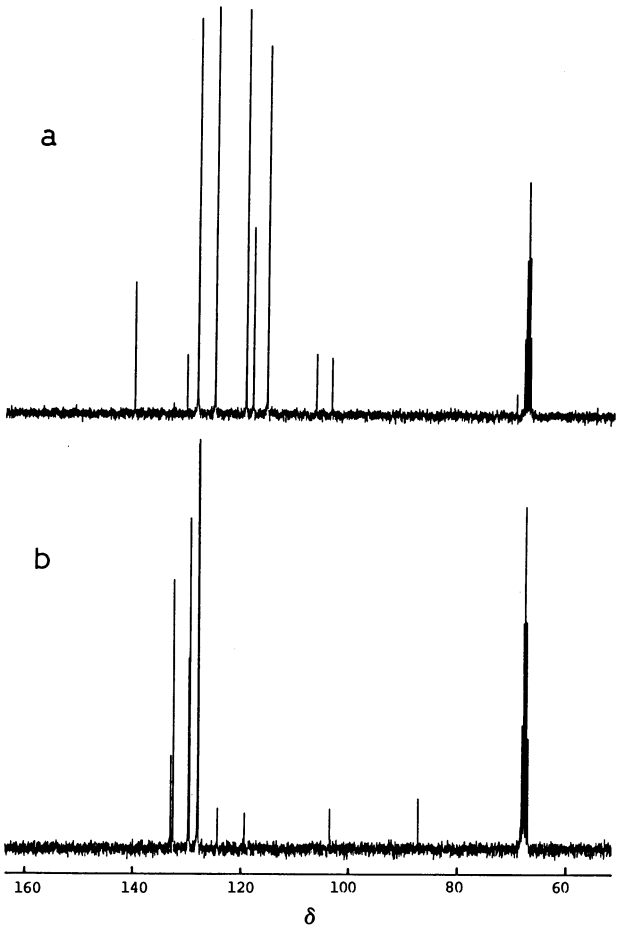

Fig. 2. ^{13}C NMR spectra of $\mathbf{1}^{2-}$ (a) and its neutral precursor (b) in THF-d_8.

For the ^{1}H spectrum of **1**, the lower-field group of the AA'BB' system was assigned to H_1, in analogy with the case of 9,10-diphenylanthracene,[5] which is similar to **1** in view of containing π-type substituents at the 9 and 10 positions. The *o*-, *m*-, and *p*-protons of phenyl groups could be straightforwardly assinged due to their coupling patterns. For the ^{1}H spectrum of $\mathbf{1}^{2-}$, the lower-field group of the AA'BB' pattern was assigned to H_1 on the basis of a combination of a C–H shift correlation 2D NMR (Fig. 4) and the ^{13}C assignment determined from a comparison of shift difference from **1** ($\Delta\delta$) with the calculated excess

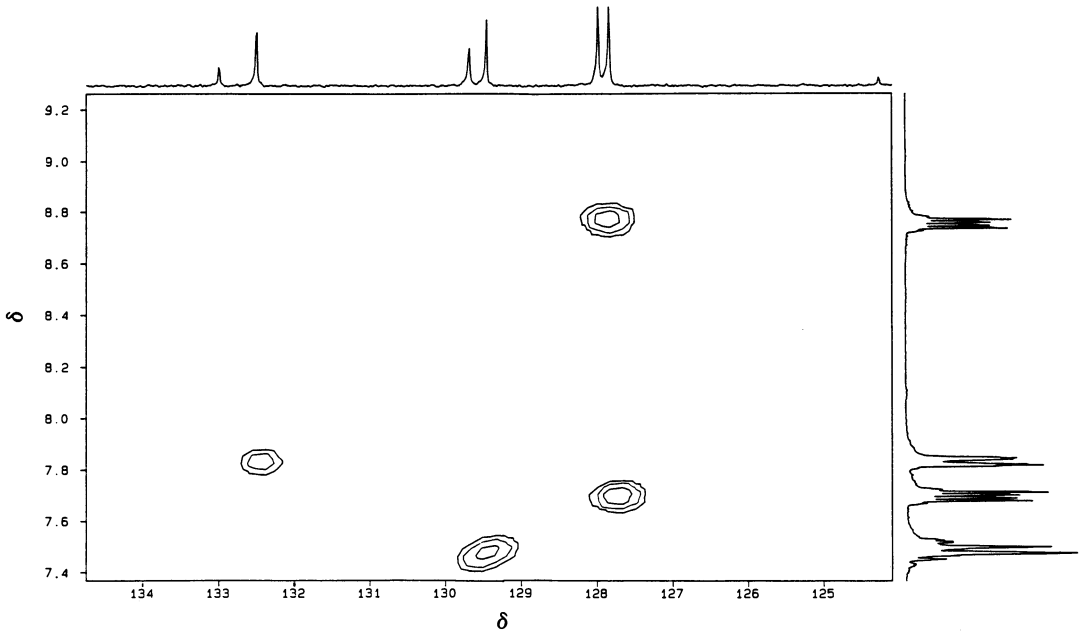

Fig. 3. H–C shift correlation 2D NMR of **1**.

charge (Δq_c^{π}) described later. The phenyl protons was easily assigned as well as **1**. For both **1** and $\mathbf{1}^{2-}$, all of tertiary carbons were assigned on the basis of the C–H shift correlation 2D NMR (Figs. 3 and 4) and ^{1}H assignments. Since assignments of the quaternary carbons of both **1** and $\mathbf{1}^{2-}$ are quite difficult, they were tentatively made by analogy with those of several phenyl derivatives of acetylene and by a comparison with the calculated excess π-charge-densities Δq_c^{π}'s (Table 1).

It was then confirmed by measuring the ESR that addition of a reducible aromatic compound, *m*-dinitrobenzene, to the purple solution in vacuo gives the anion radical of this compound. A quenching experiment with oxygen afforded a neutral precursor, while with water and deutrium oxide the dihydro (*m/z* 380) and dideuterio derivatives (*m/z* 382) of **1** were formed, respectively, as shown by mass spectrometry. All these results strongly support the above expectation that the purple species is a π-dianion of **1** or its disodium salt.

The observed mean high-field ^{13}C shift, 5.26 ppm, of $\mathbf{1}^{2-}$ from **1** is only about a half of 10.67 ppm estimated by using a commonly used value of k_c, 160 ppm/electron, in the correlation of ^{13}C shift with charge density, $\Delta\delta_c = k_c \cdot \Delta q_c^{\pi}$.[6] Recently, it was found by Eliasson et al.[7] that for 4nπ-systems the anisotropic high-field shift of a ring proton due to a paratropic ring current correlates well with a k_c value for ring carbons determined experimentally and that the anomalous deshielding of ring carbons for such a system is explained in terms of the average electronic excitation energy. For the anthracene dianion, 89 ppm/electron is given as k_c from their analysis. Since in our present system about 80% of the total excess π-charge occupies the anthracene moiety as calculated later, it may be plausible to consider that the anthracene ring carbons are affected by such the anomalous deshielding effect. Thus, this reason may explain the considerable reduction in the high-field shift of the center of gravity of ^{13}C signals from 10.67 ppm.

The MO calculations of electron density distributions were then performed on **1** and $\mathbf{1}^{2-}$ by the CNDO/2 method.[8] Since an available crystal structure of **1** has not been found in the literature, a possible molecular geometry for **1** was estimated by a combination of the crystal structures of diphenylacet-

	C_{20}	0.1090	−17.44	−11.60

a) In ppm. Positive signs denote low-field shifts. b) Excess π-charge density of 1^{2-} relative to that of **1**. c) Shifts of 1^{2-} from those of **1** calculated using k_H=10.7 ppm/electron and k_c=160 ppm/electron in $\Delta\delta_H=-k_H\cdot\Delta q_c^\pi$ and $\Delta\delta_c=-k_c\cdot\Delta q_c^\pi$, respectively. d) Shift values in parentheses are not reliable because the standard k_c value (160 ppm/electron) may not be applied to sp-hybridized carbons.

ylene[9] and anthracene[10] as a planar structure.[11] The distance between C_9 and C_{15}, R_{9-15}, was taken as the equal magnitude to R_{16-17}, by taking into account the considerable stability of the anthracene moiety.[12] The electron density at the $2p_z$ orbital of carbon is denoted by q_c^π and its change from **1** to 1^{2-} by Δq_c^π. ^1H and ^{13}C chemical shifts of 1^{2-} relative to those of **1**, $\Delta\delta_{calcd}$, were estimated using the relation $\Delta\delta_H=k_H\cdot\Delta q_c^\pi$[13] and $\Delta\delta_c=k_c\cdot\Delta q_c^\pi$, respectively. As can be seen from Table 2, the observed shifts of 1^{2-} from **1**, $\Delta\delta_{obsd}$, for the anthracene ring protons are anomalously larger (3—4 times) than $\Delta\delta_{calcd}$ obtained using the standard k_H value, 10.7 ppm/electron, in contrast to those of the phenyl protons. This may be ascribed to a contribution of the partially paratropic ring current effect of the anthracene moiety.[14] It may be plausible to consider that the change of the anisotropy of the triple bond from **1** to 1^{2-} scarecely affects the $\Delta\delta_{obsd}$ of all the ring protons owing to its location far from protons. On the other hand, for C_1 and C_2 $\Delta\delta_{obsd}$ corresponds comparatively well to $\Delta\delta_{calcd}$; this seems to imply that an anomalous deshielding was not remarkably observed. Also for C_{18}, C_{19}, and C_{20}, the pattern of $\Delta\delta_{obsd}$ approximately corresponds to that of $\Delta\delta_{obsd}$. Since for the sp-hybridized C_{15} and C_{16}, a relevant k_c value has been unknown so far, the shifts of these carbons can not sufficiently be discussed here. For C_{17}, $\Delta\delta_{obsd}$ corresponds well to $\Delta\delta_{calcd}$; while for both C_9 and C_{11} $\Delta\delta_{obsd}$ is much smaller than $\Delta\delta_{calcd}$; that is, these two carbons are much more subject to the anomalous paramagnetic ring current than the other ring carbons. On the other hand, the calculation result that most of the excess π-charge in the anthracene moiety is concentrated on the central ring of anthracene allows us to consider that the central ring may contribute considerably to the partial paratropicity of the anthracene moiety. Thus, all the shifts, except for C_{15} and C_{16}, could be consistently explained, though qualitatively, with tentative assignments for the quaternary carbons.

11) The geometric parameters used for CNDO/2 calculations are as follows: C_1C_2=1.3639 Å, C_2C_3=1.4180 Å, C_1C_{11}=1.4312 Å, C_9C_{11}=1.3968 Å, $C_{11}C_{12}$=1.4340 Å, C_9C_{15}=1.4384 Å, $C_{15}C_{16}$=1.1911 Å, $C_{16}C_{17}$=1.4384 Å, $C_{17}C_{18}$=1.3890 Å, $C_{18}C_{19}$=1.3907 Å, $C_{19}C_{20}$=1.3854 Å, $\angle C_1C_2C_3$=120.68°, $\angle C_{11}C_1C_2$=120.59°, $\angle C_1C_{11}C_{12}$=118.73°, $\angle C_9C_{11}C_{12}$=121.12°, $\angle C_{11}C_9C_{13}$=120.88°, $\angle C_{18}C_{17}C_{22}$=119.80°, $\angle C_{17}C_{18}C_{19}$=120.09°, $\angle C_{18}C_{19}C_{20}$=119.84°, $\angle C_{19}C_{20}C_{21}$=120.32°.

12) In order to examine an effect of excess π-electrons on the conjugated system, an attempt was then made of calculation of Δq_c^π with slight changes of each value of R_{9-15} and R_{15-16}. It was then found that Δq_c^π pattern is very sensitive to each of these two distances all through the molecule. However, no set of these two distances afforded Δq_c^π pattern which explaines $\Delta\delta_{obsd}$ better than original values of distances (R_{9-15}=1.4384 Å and R_{15-16}=1.1911 Å).

Adsorbing-Particle Flotation of Hg^{2+} by Combined Use of Charcoal, Polyacrylamide, and Cationic Surfactant

Tadahiko KIDOKORO,* Kotaro MATSUI, Satoshi ISHIWATA, Toshiyuki SASAKI, and Tsunetaka SASAKI
Department of Chemistry, Faculty of Science, Tokai University, 1117 Kitakaname, Hiratsuka 259-12
(Received September 24, 1987)

Adsorbing-particle flotation of Hg^{2+} ions by using active charcoal as an adsorbent, Polyacrylamide (PAA) as a coagulant, and hexadecyltrimethylammonium chloride (HTAC) as a frother was carried out. The floatability exceeded 90% in a wide range of pH and nearly 98% of Hg^{2+} ions was floated from 2.1×10^{-4} mol dm^{-3} solution by adding 2500 ppm of active charcoal, 24 ppm of PAA, 81 ppm of HTAC and with shaking. Stepwise and double flotations were further attempted which proved to distinctly increase the floatability, while sodium sulfide treatment of active charcoal showed only a slight increase and the coexistence of chloride ions showed no effect. The mechanism of adsorbing-particle flotation was discussed.

The adsorbing-particle or colloid flotation has been known as one of the effective methods to remove or concentrate dissolved ions in solution, because it enables the flotation of various organic and inorganic ions and molecules by selecting suitable adsorbent, coagulant, and surfactant as a collector and/or a frother. With regard to the practical application of such a technique, Grieves[1] published a general review in which we confirm that adsorbents mainly used are oxides, hydroxides or sulfides of Fe^{3+}, Al^{3+}, Cd^{2+}, Hg^{2+}, Mn^{4+}, and Th^{4+}. However, one of the present authors has drawn attention to different group of ion adsorbents of particulate or powder type, such as bentonite,[2,3] charcoal,[4] and poly(ethyleneimine),[5] confirming that these effectively remove inorganic and organic anions and cations. Among them charcoal is particularly promising since it can be used widely as an adsorbent. But published reports are rather scanty although the possibility of its application has been suggested.[6]

In the present study, removal of Hg^{2+} ions was attempted by using charcoal as an adsorbent, Polyacrylamide as a coagulant, and hexadecyltrimethylammonium chloride (HTAC) as a surfactant. The stepwise and double flotations were worked out to improve the flotation efficiency.

Experimental

Materials. Active charcoal mainly used as an adsorbent was the product of Wako Pure Chemicals, labelled "Chemical Activated." Some other charcoals of different origin were used for comparison. Polyacrylamides mainly used as coagulants were the products of Mitsubishi Chemical Industries, DCLE MA-3000L (DL), DCLE MA-3000H (DH), and DCLE MA-3000-3H (D3H), molecular weight being about 10^7 and the content of sodium polyacrylate 10, 20, and 30% respectively. Other coagulants used were the products of Toagosei Chemical Industries, sodium polyacrylate (AR) of molecular weight of $2-6\times10^6$ and PAA derivatives of Sanyokasei Industries, anionic Sanfloc AH (SA), nonionic Sanfloc N (SN), and cationic Sanfloc CH (SC) of molecular weight of 1.7×10^7 for the former two and 7×10^6 for the latter. Surfactants used were the commercial products of cationic HTAC and anionic sodium dodecyl sulfate (SDS).

Measurement. To carry out the flotation measurement, 20 cm^3 of an aqueous solution of nitric acid containing 2.1×10^{-4} mol dm^{-3} Hg^{2+} ions, 2500 ppm charcoal of different origins, coagulant and surfactant in different amounts, and NaOH for controlling the pH, was introduced into a stoppered test tube of 1.6 cm in inner diameter and 29 cm in length, equipped with a stopcock at the bottom. The test tube was gently turned upside down repeatedly for 2 min and then vigorously shaken ten times by hand to complete the flotation.

Concentration of Hg^{2+} ions in the underlying solution was determined by Hitachi Atomic Absorption Spectrometer 508 at wavelength of 248.3 nm. The floatability F (%) was calculated by the following equation:

$$F = \frac{C_0 - C}{C_0} \times Fc \times 100\%, \quad (1)$$

where C_0 and C express concentrations of solution before and after the flotation respectively, and Fc fraction of active charcoal floated.

The stepwise flotation was worked out similarly to the previous study[2] to improve the flotation efficiency. In this technique, charcoal was added to the solution at a time but coagulant and surfactant were added in two steps. After the first addition of coagulant and surfactant, flotation was carried out and the suspension below the scum was transferred to another test tube, into which remaining portions of coagulant and surfactant were added and the second flotation was conducted. From the concentration of Hg^{2+} and the amount of active charcoal in the solution after the second flotation, floatability of Hg^{2+} was calculated. A similar stepwise flotation but without transferring the solution to another test tube was carried out to simplify the operation. This procedure is called the double flotation to distinguish it from the stepwise flotation.

All the measurements were done at room temperature.

Results and Discussion

According to the preliminary measurements and the former study,[4] concentrations of coagulant and surfactant favorable for charcoal flotation were pre-

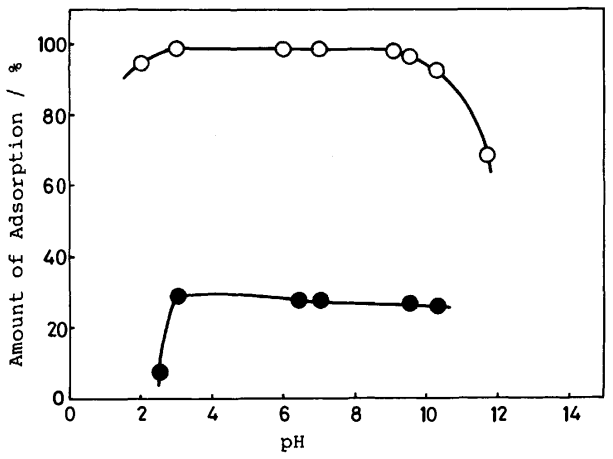

Fig. 1. Adsorption of Hg^{2+} by charcoal.
Hg^{2+}: 2.1×10^{-4} mol dm^{-3}. Charcoal ○: 2500 ppm, ●: 400 ppm.

sumed to be in the ranges of 20 to 200 ppm and 50 to 500 ppm, respectively, for 2500 ppm of charcoal. The optimum concentration range varies with the adsorbent to be used and ions to be floated.[2-5]

Adsorption of Hg^{2+} Ions by Charcoal. In order to confirm the proper amount of active charcoal required for the Hg^{2+}-ion flotation, adsorption of Hg^{2+} ions by active charcoal was measured for the solution containing various amounts of charcoal and at different pH. Figure 1 shows two such instances. Here the amount of Hg^{2+} ions adsorbed is expressed not as per unit weight of charcoal but conventionally as percent of initial Hg^{2+} concentration in agreement with $(C_0-C)/C_0$ term in Eq. 1. The figure shows a flat maximum of adsorption exceeding 98% for a wide range of pH at charcoal concentration of 2500 ppm. From this result, the concentration of charcoal was kept constant to 2500 ppm throughout the present study. It should be noted that although all of the charcoals used in the present study which are not listed here exhibited a good adsorption towards Hg^{2+} and most of them also showed a good floatability as reported in a previous paper,[4] the floatability of Hg^{2+}-adsorbed charcoal was often unsatisfactory. In the present study, the product of Wako, Charcoal Activated, was eventually used exclusively.

Adsorbing-Particle Flotation of Hg^{2+} (Simple Flotation). Adsorbing particle flotation of Hg^{2+} ions was carried out for various combinations and compositions of charcoal, coagulant, and surfactant. Figure 2 shows some results of floatability of Hg^{2+} plotted against pH. Floatability appeared to exceed 90% in a wide range of pH for the coagulant of various types of Polyacrylamide and 98% floatability was seen for the system using D3H as a coagulant. Wide pH range of high floatability is seen which is favorable because the flotation of Hg^{2+} ions has been often conducted under the conditions of excess chloride ions and low pH.[7]

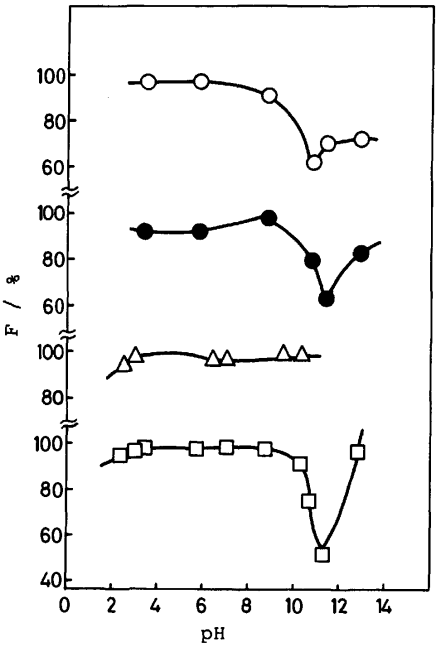

Fig. 2. Flotation of Hg^{2+} by different coagulants.
Hg^{2+}: 2.1×10^{-4} mol dm^{-3}. Charcoal: 2500 ppm. HTAC: 540 ppm. Coagulants ○: DL 210 ppm, ●: DH 160 ppm, △: D3H 210 ppm, □: SA 210 ppm.

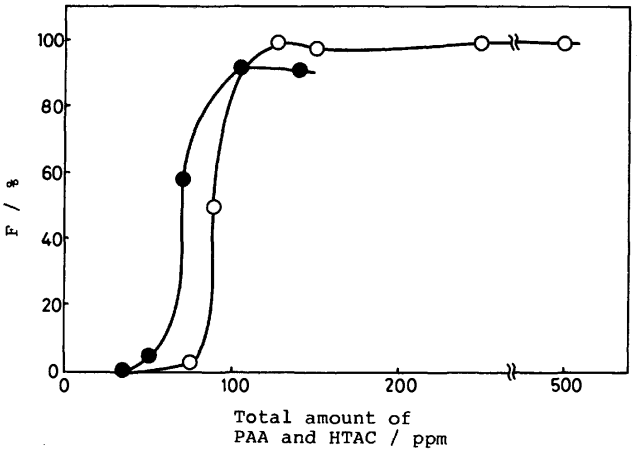

Fig. 3. Floatability vs. concn of PAA+HTAC.
Hg^{2+}: 2.1×10^{-4} mol dm^{-3}. Charcoal: 2500 ppm. ○: DL-HTAC system, weight ratio of DL/HTAC=0.388 ●: DH-HTAC system, weight ratio of DH/HTAC= 0.296.

The floatability seems to increase as a whole with the degree of both the polymerization and hydrolysis of Polyacrylamide as far as the present study is concerned.

We further attempted to reduce the amount of coagulant and surfactant without considerable decrease in the floatability. Figure 3 shows the results for DL-HTAC and DH-HTAC systems. The figure expresses the relation between the floatability of Hg^{2+} ions and the total concentration of coagulant and surfactant at a constant ratio between them and at

constant pH. As seen in Fig. 3, amounts of both coagulant and surfactant could be reduced to 35 and 90 ppm respectively for DL–HTAC system and 24 and 81 ppm respectively for DH–HTAC system without noticeable decrease in floatability.

Effects of Na_2S-Treatment of Charcoal and Coexistence of Chloride Ions on Floatability. In order to enhance the floatability of Hg^{2+}, active charcoal was immersed in an aqueous solution of 1 mol dm^{-3} sodium sulfide for 6 h, then washed with distilled water until the supernatant became neutral and dried. An instance of the floatability of Hg^{2+} ions using Na_2S-treated charcoal is shown in Fig. 4, together with the result using charcoal without the Na_2S-treatment. The increase of floatability due to the treatment was observed, but the effect was not so distinct as had been expected. Further the effect of the coexistence of chloride ions upon the floatability was examined, because halogen ions have been reported to increase the adsorption of Hg^{2+} ions by charcoal.[7,8] But such an effect did not appear as far as the present study is concerned.

Dependence of Floatability on Hg^{2+} Concentration. The effect of Hg^{2+} ion concentration upon the floatability was examined and the result is shown in Fig. 5. The coagulant AR used there was somewhat different in the degree of polymerization from that used in the previous experiments, so the results were unable to compare strictly with each other but general tendency is seen that the floatability increases slightly in the concentration range of 10^{-5} to 10^{-6} mol dm^{-3} of Hg^{2+} ions.

Ionic Interaction Between Coagulant and Surfactant. In order to examine the ionic interaction between coagulant and surfactant, which supposedly contributes to the flotation, the floatability of Hg^{2+} ions was further measured by using SA, SN, and SC as anionic, nonionic, and cationic coagulants respectively and HTAC and SDS as cationic and anionic surfactants. The results are shown in Fig. 6. As seen in Fig. 6, among the systems using cationic surfactant HTAC, the system with anionic coagulant SA exhibited most pronounced floatability in a wide range of pH, the value was distinctly small for nonionic coagulant SN and zero for cationic coagulant SC in a wide range of pH. Thus the ionic interaction between coagulant and surfactant is evident. Large floatability shown by the system of SC–SDS also confirms this fact.

Stepwise and Double Flotations. Some of the results of stepwise and double flotations are shown in Table 1, together with the simple one-step flotation hitherto mentioned. In this table we can see a general tendency of enhanced floatability of stepwise and double flotations compared with that of simple foltation, similarly to the case of stepwise flotation using bentonite as an adsorbent.[2] It is noted that the floatability increases as a whole in the order of double flotations applying stepwise additions for surfactant alone, coagulant alone and for both of them, and

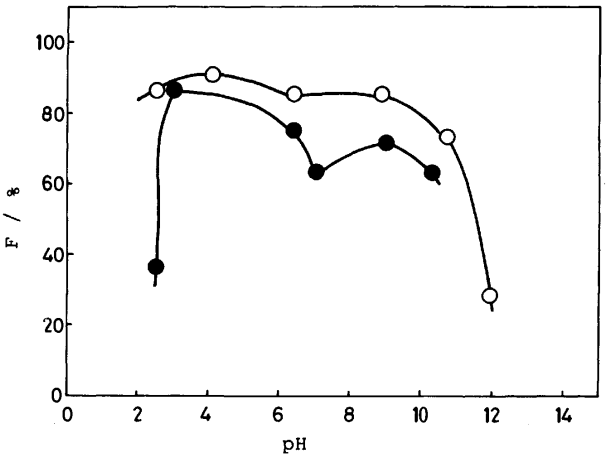

Fig. 4. Effect of Na_2S treatment on floatability.

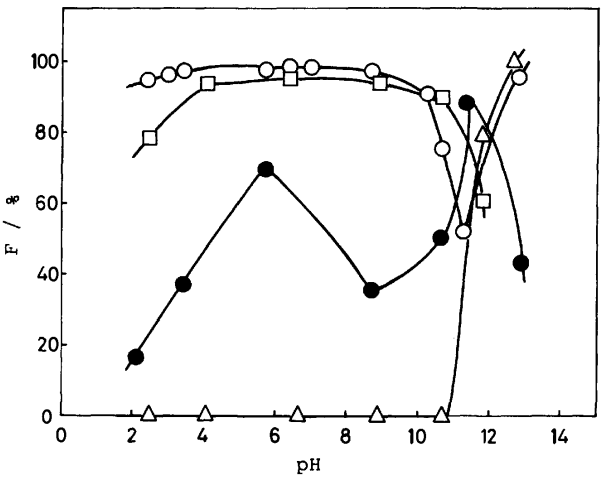

Fig. 6. Ionic interaction between coagulant and surfactant.
Hg^{2+}: 2.1×10^{-4} mol dm^{-3}. Charcoal: 2500 ppm. ○: SA 210 ppm, HTAC 540 ppm. ●: SN 210 ppm, HTAC 540 ppm. △: SC 210 ppm, HTAC 540 ppm. □: SC 210 ppm, SDS 450 ppm.

Table 1. Simple, Double, and Stepwise Flotations

SA added/ppm[a] First	SA added/ppm[a] Second	HTAC added/ppm First	HTAC added/ppm Second	F(%)
		Simple flotation		
250	0	300	0	91.7
		Double flotation		
250	0	240	60	94.8
200	50	300	0	98.5
200	50	240	60	99.3
		Stepwise flotation		
200	50	240	90	99.7

a) Amount of addition is expressed by the increase of concentration. Hg^{2+}: 2.1×10^{-4} mol dm^{-3}, charcoal: 2500 ppm, pH: 7.5—9.5.

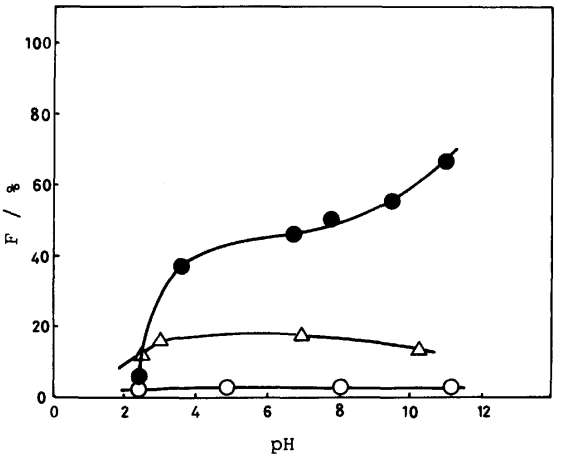

Fig. 7. Flotation without charcoal and/or coagulant. Hg^{2+}: 2.1×10^{-4} mol dm^{-3}. ○: Charcoal 2500 ppm, DL 0, HTAC 540 ppm. ●: Charcoal 0 ppm, DL 210, HTAC 540 ppm, △: Charcoal 0 ppm, DL 0, HTAC 540 ppm.

stepwise flotation. Thus, both the stepwise and double flotations are confirmed to be equally effective compared with the simple flotation. In the case of practical application, the double flotation is considered preferable compared with the stepwise one.

Mechanism of Adsorbing-Particle Flotation. In order to confirm the action of each component contributing to the adsorbing-particle flotation, flotation measurement of Hg^{2+} using HTAC without the addition of charcoal and/or coagulant was carried out. The results are show in Fig. 7. It is evident in this figure that charcoal, coagulant, and surfactant is indispensable for the adsorbing-particle flotation of Hg^{2+} ions, because the absence of any one of them results in a poor flotation. Thus the mechanism of adsorbing-particle flotation of Hg^{2+} ions is considered to be similar to the case of flotation using poly(ethyleneimine) as an adsorbent reported in a preceding paper.[5] Figure 8 illustrates the scum structure composed of Hg^{2+} ions, charcoal, anionic coagulant, and cationic surfactant together with an air bubble to which the sum is attached.

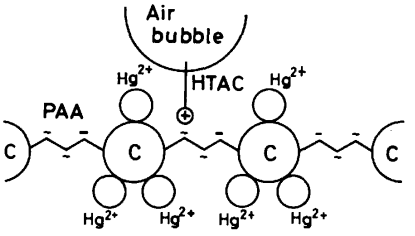

Fig. 8. Structure of scum consisting of Hg^{2+}, charcoal, PAA and HTAC. C: Charcoal.

Reactions of Cobalt Complexes of 5,10,15,20-Tetraphenylporphyrin with Peroxide Radicals Generated from Organic Peroxides and Unsaturated Fatty Acids

Masahiro KOHNO
JEOL Ltd., Akishima, Tokyo 196
(Received September 25, 1987)

The title reactions in aerated benzene solutions were investigated by using ESR and optical-absorption spectrometers. It was found that (1) a benzyl peroxide radical, bpox·, generated photochemically from dibenzoyl peroxide (DBPO) oxidizes [Co^{II}(tpp)] to produce, successively, a five-coordinate cobalt(III) complex, [Co^{III}(bpox)(tpp)]; a π cation radical, [Co^{III}(tpp)$^{+}$](bpox)$_2$, and isoporphyrin; (2) a *t*-butyl peroxide radical, bupox·, generated from di-*t*-butyl peroxide (DBuPO) oxidizes [Co^{II}(tpp)] to give only a six-coordinate cobalt(III)complex, [Co^{III}(bupox)(tpp)(dbupo)]; (3) lipid peroxide radicals (lpox·: oapox·, lapox·, lnapox·, and aapox·) produced from unsaturated fatty acids, oleic acid (OA), linoleic acid (LA), linolenic acid (LNA), or arachidonic acid (AA), do not react with [Co^{II}(tpp)]; (4) all the peroxide radicals (pox·: lpox·, bpox·, bupox·) react with [Co^{III}(Cl)(tpp)] to produce π cation radicals, [Co^{III}(tpp)$^{+}$](Cl)(pox), and (5) bpox· and lapox· react further with the π cation radicals to give isoporphyrins. Finally, the present reactions were compared with the reactions of horseradish peroxidase.

It has been well-known that horseradish peroxidase, chloroperoxidase, and cytochrome c peroxidase react with alkyl hydroperoxide, and peroxycarboxylic acid to· form intermediates, enzyme-bound-high-valent iron porphyrins (Compounds I and II).[1] It has also been known that active oxygens including hydroperoxide decompose metalloproteins both in vivo and in vitro.[2] As model reactions, a number of studies of the redox reactions of metal porphyrins have been carried out.[3-5]

Recently, we reported[6] on the reactions of a system composed of chloro(5,10,15,20-tetraphenylporphyrinato)cobalt(III), [Co^{III}(Cl)(tpp)], and its π cation radical, [Co^{III}(tpp)$^{+}$](Cl)$_2$, with several phenols. The phenols were oxidized to phenoxyl radicals. Concomitantly, the cobalt complexes were reduced in different manners, depending on the oxidation potentials of the phenols. The phenols investigated were classified into two groups after taking into account the differences in their reaction activities and their redox potentials: the phenols mainly reacting with [Co^{III}(tpp)$^{+}$](Cl)$_2$, and those reacting with both [Co^{III}(tpp)$^{+}$](Cl)$_2$ and [Co^{III}(Cl)(tpp)]. The reaction schemes of cobalt porphyrins [Co^{II}(tpp)], [Co^{III}(Cl)(tpp)], and [Co^{III}(tpp)$^{+}$](Cl)$_2$ with phenols showed a clear correspondence to the oxidation reactions of horseradish peroxidase (HRP).

In this study, we will investigate the inverse reactions of cobalt porphyrins ([Co^{II}(tpp)] and [Co^{III}(Cl)(tpp)]) with organic peroxides and unsaturated fatty acids in aerated benzene solutions by using ESR and optical absorption techniques. As the results, the reaction mechanisms between the cobalt porphyrins and the peroxide radicals will be presented. Finally, the reaction mechanisms of cobalt porphyrins with the peroxide radicals will be discussed in comparison with the formation mechanism of Compound I, and Compound II of HRP.[7]

Experimental

Materials. The chloro(5,10,15,20-tetraphenylporphyrinato)cobalt(III), [Co^{III}(Cl)(tpp)], and (5,10,15,20-tetraphenylporphyrinato)cobalt(II), [Co^{II}(tpp)],[8] were provided by Dr. Kiyoko Yamamoto of the Institute of Physical and Chemical Research.

The dibenzoyl peroxide (DBPO) and di-*t*-butyl peroxide (DBuPO) were supplied by Nakarai Chemical Industries. 99%-pure oleic acid (OA), linoleic acid (LA), linolenic acid (LNA), and arachidonic acid (AA) were supplied from the Sigma Chemical Co., Ltd., and were used without further purification. The nitrosodurene, a spin-trapping reagent, was supplied by Mr. Naohiro Takahashi of the Sumitomo Chemical Co., Ltd.

Preparation of Sample Solutions. Benzene was used as the solvent throughout this study.

The [Co^{II}(tpp)] and [Co^{III}(Cl)(tpp)] were dissolved in 2×10^{-3} mol dm^{-3} in the cases of reactions with all peroxide radicals except DBuPO. The solution of [Co^{III}(Cl)(tpp)] contains 2.7×10^{-5} mol dm^{-3} of the π cation radical, [Co^{III}(tpp)$^{+}$](Cl)$_2$.[6] In the case of the reaction with DBuPO, [Co^{II}(tpp)] and [Co^{III}(Cl)(tpp)] were dissolved in 2×10^{-4} mol dm^{-3}. DBPO, DBuPO, OA, LA, LNA, and AA were dissolved just before use (DBPO, 2×10^{-3} mol dm^{-3}; DBuPO, 1×10^{-1} mol dm^{-3}; OA, LA, LNA, and AA, 10%).

Measurements. The ESR spectra were measured by means of a JEOL FE-2XG spectrometer equipped with a Takeda Riken TR-5211 microwave counter. The ESR spectra of the π cation radical, [Co^{III}(tpp)$^{+}$](x)(y), measured in this work show the pair of the maximum and the minimum separated by a wide plateau. Such spectra are due to eight unresolved, hyperfine lines. In this work, therefore, the *g* values were determined from the midpoint of the maximum and the minimum of the spectra. The spacings between maximum and minimum points, ΔH, are the measure of the hyperfine line of cobalt:

$$\Delta H \simeq 7 \times a_{Co^{III}} + \Delta H_{msl}, \quad (1)$$

where ΔH_{msl} is the intrinsic line width. Hereafter, we will

adopt these values as the ESR parameters.

For a quantitative analysis of the π cation radicals, a computer system of JES ES-PRIT23 was used. The optical absorption spectra were measured by means of a Hitachi 330 spectrophotometer using quartz cells with optical path lengths of 1 and 0.1 cm.

Simultaneous measurements of the ESR and the optical absorption spectra were carried out by using an ESRET system combining a Spectro Multi-Channel Photo Detector MCPD-100 (Otsuka Electronics) with a JES FE-2XG apparatus equipped with a transmission cavity, ES-MCX-3B.[9] By the use of the ESRET, one can measure simultaneously both the ESR and the optical spectra of a sample solution under the same conditions. This apparatus is very useful for mesurement of a solution containing an unstable sample or a small amount of a sample. A quartz cell with an optical path length of 0.3 mm, 10 mm in width, and 40 mm in height, was used for the ESRET measurements. To 0.1 cm^3 of a [Co^{II}(tpp)] or [Co^{III}(Cl)(tpp)] solution was added 0.1 cm^3 of a peroxide or fatty-acid solution. The ESR and absorption spectra of the mixed solution were simultaneously measured at intervals of 1 min after mixing. The absorption spectra obtained from the ESRET were checked with those obtained by means of a Hitachi 330 spectrophotometer. The time dependent ESR spectra were measured using a rapid detection system.[6] 0.2 cm^3 of neat unsaturated fatty acids were added to 0.2 cm^3 of a [Co^{III}(Cl)(tpp)] solution, which was bubbled in by dry nitrogen gas.

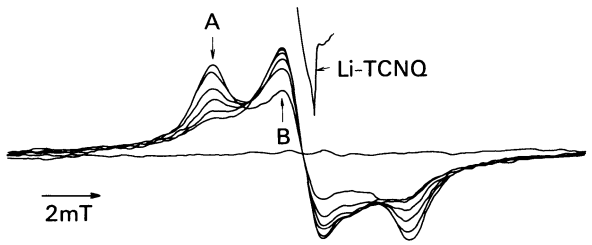

Fig. 1a. ESR spectra measured before and after (the interval of 1 min) addition of DBPO to [Co^{II}(tpp)] in a benzene solution. A: [Co^{III}(tpp)$^+$](bpox)$_2$, B: bpox·. Li-TCNQ is internal standard, g=2.0026.

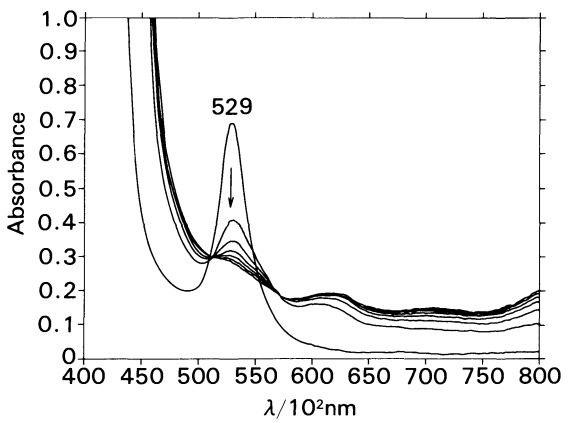

Fig. 1b. Absorption spectra measured before and after (the interval of 1 min) addition of DBPO to [Co^{II}(tpp)] in a benzene solution.

Results and Discussion

Reaction of [Co^{II}(tpp)] with DBPO or DBuPO. To a benzene solution of [Co^{II}(tpp)] were added the same amount of a DBPO solution; the ESR and the optical absorption spectra of the mixed solution were then measured by using the ESRET apparatus at intervals of 1 min after adding DBPO to the [Co^{II}(tpp)]. The ESR spectra thus measured are shown in Fig. 1a. The solution of [Co^{II}(tpp)] gave no ESR signals at room temperature because of the short relaxation time. One minute after the addition of DBPO, two signals, A and B, appeared. The ESR parameters of the A signal are g=2.0048 and ΔH=6.89 mT. This signal was assigned to a π cation radical, [Co^{III}(tpp)$^+$](bpox)$_2$ on the basis of the ESR parameters.[10,11] The ESR parameters of the B signal are g=2.0082 and ΔH=0.65 mT. It is well-known that DBPO decomposes easily to produce the peroxide radical under these ambient conditions: natural light, air, and room temperature. In order to confirm the B signal, DBPO in an aerated benzene solution was irradiated by using a mercury lamp as a light source without a filter; the ESR spectrum was then measured at 5 °C. An ESR signal of g=2.0155(±0.0002) and ΔH=0.75 mT was obtained. The g value is typical of peroxide radicals,[12,13] so the signal was identified as a peroxede radical of DBPO (bpox·: $C_6H_5(CO)OO\cdot$). The same signal was observed for a deaerated benzene solution of irradiated DBPO. The g value of the B signal is somewhat smaller than that of bpox· obtained in neat benzene by irradiation. This might be because of an interaction between the radical and the tpp ligand of [Co^{II}(tpp)]. With an increase in the time, the intensity of the A signal decreased, while that of the B signal increased. This suggests that bpox· successively generated oxidizes [Co^{II}(tpp)] to produce [Co^{III}(tpp)$^+$](bpox)$_2$ and then further decomposes the π cation radical. The corresponding optical absorption spectra are shown in Fig. 1b. With an increase in the time, the characteristic absorption band at 529 nm of [Co^{II}(tpp)] decreased in intensity, while weak and broad bands appeared at longer wavelengths. The bands in the near infrared-region are interpreted as being due to the formation of isoporphyrin,[14-16] because the optical-absorption spectrum measured for the solution by means of the Hitachi 330 spectrophotometer showed absorption maxima at 700 and 800 nm. The absorption bands in the visible region may be due to those of [Co^{III}(tpp)]$^+$ and the π cation radical of Co^{III}(tpp). From both the ESR and the optical-absorption-spectral changes, it is concluded that bpox· oxidizes [Co^{II}(tpp)] to produce [Co^{III}(tpp)]$^+$, then the π cation radical, and finally isoporphyrin.

The optical-absorption spectra observed for the reaction mixture of [Co^{II}(tpp)] and DBuPO by using the

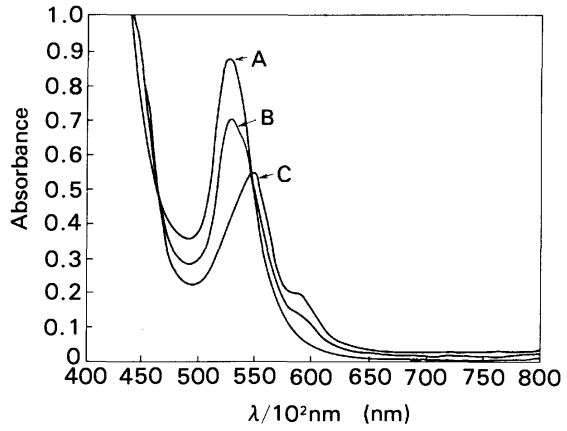

Fig. 2. Absorption spectra measured beore (A) and after (B: 7 min, C: 15 min) addition of DBuPO to [Co^{II}(tpp)] in a benzene solution.

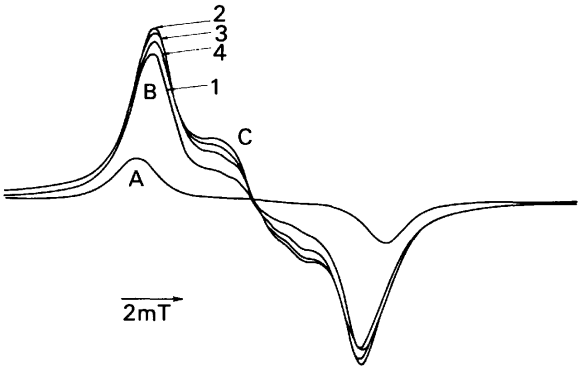

Fig. 3a. ESR spectra measured beore (A) and after (B: 1, 2, 3, 4) addition of BPO to [Co^{III}(Cl)(tpp)] in a benzene solution at the interval of 1 min.
A: [Co^{III}(tpp^{+}](Cl)$_2$, B: [Co^{III}(tpp)$^{+}$](Cl)(bpox$_2$), C: bpox·.

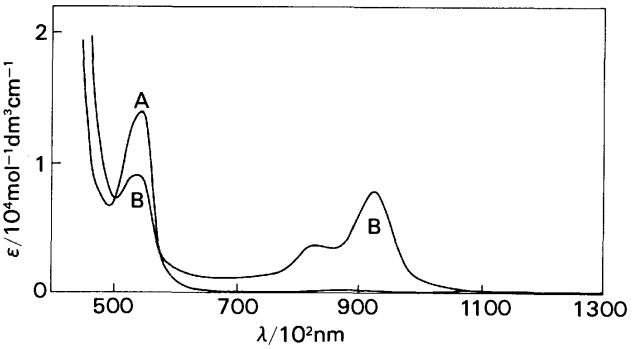

Fig. 3b. Absorption spectra measured beore (A) and after (B) addition of BPO to [Co^{III}(Cl)(tpp)] in a benzene solution.

ESRET apparatus are shown in Fig. 2. The reaction mixture gave no ESR spectrum of the π cation radical. Upon the addition of DBuPO to [Co^{II}(tpp)] in a benzene solution, the intensity of the absorption band of [Co^{II}(tpp)] at 529 nm (A) decreased and the absorption maximum shifted towards longer wavelengths, showing one set of isosbestic points at 465 and 545 nm, and new bands appeared at 550 and 590 nm. The absorption spectrum represents the characteristic absorption of the six-coordinate [Co^{III}-(tpp)]$^{+}$ complex.[17] The spectrum was an unchanged with the increase in time. It is also well-known that DBuPO decomposes under ambient conditions. DBuPO in an aerated benzene solution was irradiated by using a mercury lamp as a light source without a filter, and the ESR spectrum was measured at 5 °C. The ESR signal of g=2.0155(±0.0002) and ΔH=0.3 mT appeared; it was identified as a peroxide radical, bupox·(C_4H_9OO·), on the basis of the g value. From the results of the optical-absorption-spectral change and the lack of any ESR spectra, it is concluded that [Co^{II}(tpp)] is oxidized by bupox· to produce five-coordinate [Co^{III}(bupox)(tpp)]; then excess DBuPO coordinates as the 6th ligand to form a six-coordinate complex, [Co^{III}(bupox)(tpp)(dbupo)].

The reactions of [Co^{II}(tpp)] with unsaturated fatty acids, OA, LA, LNA, and AA, in aerated benzene solutions gave no ESR or absorption-spectral changes.

Reaction of [Co^{III}(Cl)(tpp)] with DBPO, DBuPO, OA, LA, LNA, and AA. The ESR spectra measured for a mixed solution of [Co^{III}(Cl)(tpp)] and DBPO are shown in Fig. 3a. Signal A in Fig. 3a represents the signal of [Co^{III}(tpp)$^{+}$](Cl)$_2$ (g=2.0047 and ΔH=8.98 mT) that is contained in the solid [Co^{III}(Cl)(tpp)].[18] In the ESR spectrum obtained after the addition of DBPO, the signal of [Co^{III}(tpp)$^{+}$](Cl)$_2$ disappeared, and new two signals, B and C, appeared. The ESR parameters of the B signal are g=2.0062 and ΔH= 6.37 mT. This showed the species to be a π cation radical, [Co^{III}(tpp)$^{+}$](Cl)(bpox), on the basis of the ESR parameters. The C signal represents the signal of bpox·. When an increase in the time, the signal intensity of B decrease, while that of C increases, as in the case of the reaction of [Co^{II}(tpp)] with DBPO.

The optical-absorption spectra observed before and after the addition of DBPO, (A) and (B), respectively, are shown in Fig. 3b. The characteristic absorption band of [Co^{III}(Cl)(tpp)] at 540 nm decrease in intensity upon the addition of DBPO, and new bands appeared at 815 and 915 nm. The bands in the near-infrared region are attributed to isoporphyrin. From the results of the ESR and the absorption spectra, it is concluded that bpox· oxidizes [Co^{III}(Cl)(tpp)] to [Co^{III}-(tpp)$^{+}$](Cl)(bpox) and then to isoporphyrin, while [Co^{III}(tpp)$^{+}$](Cl)$_2$ is oxidized to isoporphyrin.

The ESR spectra and optical absorption spectra of a reaction mixture of [Co^{III}(Cl)(tpp)] and DBuPO were measured as in the case of the reaction with DBPO. The ESR spectra showed that the signal of [Co^{III}-(tpp)$^{+}$](Cl)$_2$ disappeared and a new signal appeared. Based on the ESR parameters obtained from the spectrum, the B signal, g=2.0062 and ΔH=7.78 mT, can be interpreted as being to the formation of a π cation

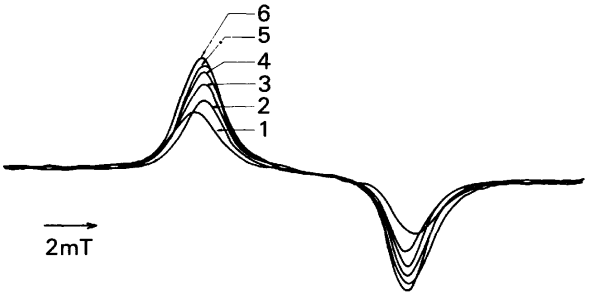

Fig. 4a. ESR spectra measured after addition of OA (1: 0%, 2: 2%, 3: 4%, 4: 6%, 5: 8%, and 6: 10%) to [Co^{III}(Cl)(tpp)] in a benzene solution.

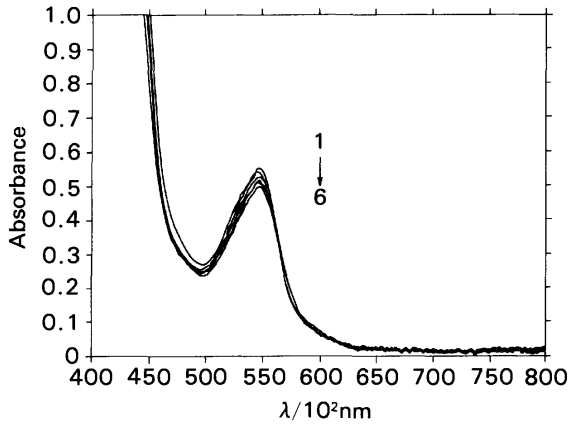

Fig. 4b. Absorption spectra measured after addition of OA (1: 0%, 2: 2%, 3: 4%, 4: 6%, 5: 8%, and 6: 10%) to [Co^{III}(Cl)(tpp)] in a benzene solution.

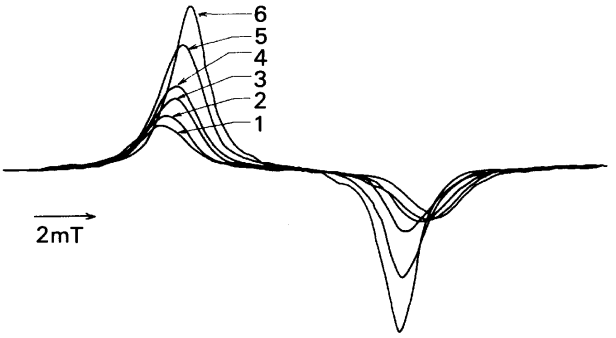

Fig. 5a. ESR spectra measured after addition of LA (1: 0%, 2: 1.25%, 3: 2.5%, 4: 5%, 5: 10%, and 6: 20%) to [Co^{III}(Cl)(tpp)] in a benzene solution.

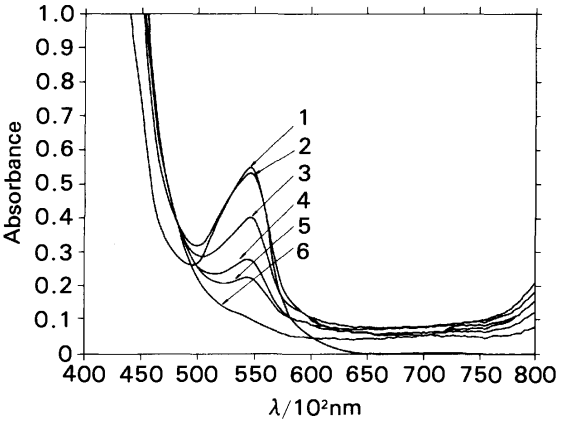

Fig. 5b. Absorption spectra measured after addition of LA (1: 0%, 2: 1.25%, 3: 2.5%, 4: 5%, 5: 10%, and 6: 20%) to [Co^{III}(Cl)(tpp)] in a benzene solution.

radical, [Co^{III}(tpp)$^{+}$](Cl)(bupox). The corresponding optical-absorption spectra showed that, with an increase in the time, the intensities of the characteristic absorption bands of [Co^{III}(Cl)(tpp)] at 406 and 540 nm decrease and a new shoulder appears at 436 nm which may be attributable to the formation of a π cation radical.[19] The ESR and optical-absorption-spectral changes suggest that [Co^{III}(Cl)(tpp)] reacts with DBuPO to form a π cation radical, [Co^{III}(tpp)$^{+}$](Cl)(bupox).

The ESR spectra measured for aerated benzene solutions of [Co^{III}(Cl)(tpp)] with various amounts of OA (0, 2, 4, 6, 8, and 10%) are shown in Fig. 4a. Upon the addition of OA, the signal (1 in the figure) due to [Co^{III}(tpp)$^{+}$](Cl)$_2$ disappeared and a new signal (2—6) appeared. The new signal is identified as a π cation radical, [Co^{III}(tpp)$^{+}$](Cl)(oapox), due to the ESR parameters obtained from the spectrum. With the increase in the amount of OA, the intensity of the signal increased. The concentration of [Co^{III}(tpp)$^{+}$](Cl)(oapox) produced by the addition of 10% of OA is 8×10^{-5} mol dm^{-3}. The corresponding optical absorption spectra showed only a slight decrease in the absorption intensity of [Co^{III}(Cl)(tpp)] at 540 nm (Fig. 4b). The ESR and optical absorption spectral changes suggest that [Co^{III}(Cl)(tpp)] is oxidized by a peroxide radical (oapox·) generated from OA under the ambient conditions (to be described below) to produce [Co^{III}(tpp)$^{+}$](Cl)(oapox). The reactions of [Co^{III}(Cl)(tpp)] with LNA and AA also gave rise to the formation of π cation radicals, [Co^{III}(tpp)$^{+}$](Cl)(lnapox) and [Co^{III}(tpp)$^{+}$](Cl)(aapox) respectively.

The ESR and optical-absorption spectra of aerated benzene solutions of [Co^{III}(Cl)(tpp)] with various amounts of LA (0, 1.25, 2.5, 5, 10, and 20%) were also measured. The spectra are shown in Fig. 5a. Upon the addition of LA, the signal (1 in the figure) of [Co^{III}(tpp)$^{+}$](Cl)$_2$ disappeared and a new signal (2—6) appeared. The new signal is identified as a π cation radical, [Co^{III}(tpp)$^{+}$](Cl)(lapox), on the basis of the ESR parameters obtained from the spectrum. With the increase in the amount of LA, the intensity of the signal increased. The concentration of [Co^{III}(tpp)$^{+}$](Cl)(lapox) produced by the addition of 10% of OA is ca. 6×10^{-5} mol dm^{-3}. The corresponding optical-absorption spectra (Fig. 5b) obtained by using ESRET apparatus showed that the intensity of the absorption band of [Co^{III}(Cl)(tpp)] at 540 nm rapidly decreased and the new bands appeared at 825 and 912 nm

attributable to the formation of isoporphyrin. The ESR and optical-absorption-spectral changes lidicate that the peroxide radical of lapox· oxidizes [Co^{III}(Cl)(tpp)] to [Co^{III}(tpp)$^{+}$](Cl)(lapox) and then afterward to isoporphyrin.

The ESR parameters of the π cation radicals obtained are summarized in Table 1.

Reaction Rates. In the reactions of [Co^{III}(Cl)(tpp)] (2×10^{-3} mol dm^{-3}) with unsaturated fatty acids (10^{-1} mol dm^{-3}) in aerated benzene solutions, the formation rate of the π cation radical, [Co^{III}(tpp)$^{+}$](Cl)(lpox), was estimated by using a rapid-detection system.[6] In Fig. 6, the concentrations of the π cation radicals formed are plotted against the reaction time. In the cases of the reactions with OA, LNA, and AA, the amounts of the π cation radicals, [Co^{III}(tpp)$^{+}$](Cl)(oapox), [Co^{III}(tpp)$^{+}$](Cl)(lnapox), and [Co^{III}(tpp)$^{+}$](Cl)(aapox), increase with the time in the early stage of the reaction. However, in the case of the reaction with LA, the amount of [Co^{III}(tpp)$^{+}$](Cl)(lapox) is the largest, though it decreases rapidly. The reaction rates were estimated from the linear portion in Fig. 6, the reaction rates were obtained as 3.5×10^{-5}, 2.5×10^{-5}, and 3×10^{-6} mol s^{-1} for OA, LNA, and AA respectively. The rate for LA was larger than 2.4×10^{-4} mol s^{-1}. The decrease in the π cation radicals which may be seen in Fig. 6 may show that lpox· oxidizes the π cation radicals further to isoporphyrin and also that the oxidation activity of lapox· is distinctly large among lpox··. It should also be noted here that the formation rates of the π cation radical, [Co^{III}(tpp)$^{+}$](Cl)(lpox), are not ralated to the autooxidation rates of unsaturated fatty acids (OA<LA<LNA<AA),[21] but rather with the oxidation potentials of unsaturated fatty acids, as in the reactions between cobalt porphyrins and phenols.[6]

Table 1. The ESR Parameters of the π Cation Radicals Obtained, [Co^{III}(tpp)$^{+}$](x)(y), in Benzene

x	y	g (±0.0002)	ΔH[a] / mT
Cl	Cl	2.0047	8.98
Cl	bpox	2.0062	6.37
Cl	bupox	2.0058	7.78
Cl	oapox	2.0054	7.63
Cl	lapox	2.0063	6.93

Detection of Peroxide Radicals Generated from Unsaturated Fatty Acids under Ambient Conditions. It has been well-known that unsaturated fatty acids, when subjected to autooxidation in air, produce peroxide radicals. The active species generated from unsaturated fatty acids were investigated by using the spin-trapping method. Nitrosodurene (3 mg) was added to neat OA (and LA), after which the solution was irradiated under degassed conditions by using a mercury lamp as a light source; then the ESR spectrum was measured. A signal with an anisotropic pattern in the high magnetic field was obtained, as is shown in Fig. 7. The ESR parameters obtained from the spectrum are a_N=1.36 mT and a_H=0.64 mT. These parameters coincide with the values of the adduct with the alkyl radicals (R·).[20] In order to examine the effect of air, nitrosodurene dissolved in OA was irradiated under aerated condition and the ESR spectrum was measured. The spectrum showed the same radical; however, the amount of spin adducts observed was smaller than that observed in degassed conditions, as is shown in Fig. 8. This is interpreted as showing

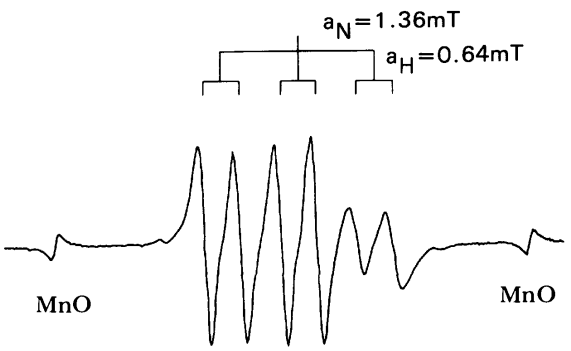

Fig. 7. ESR spectrum of spin adduct of nitrosodurene with alkyl radical of OA. MnO is internal standard signal.

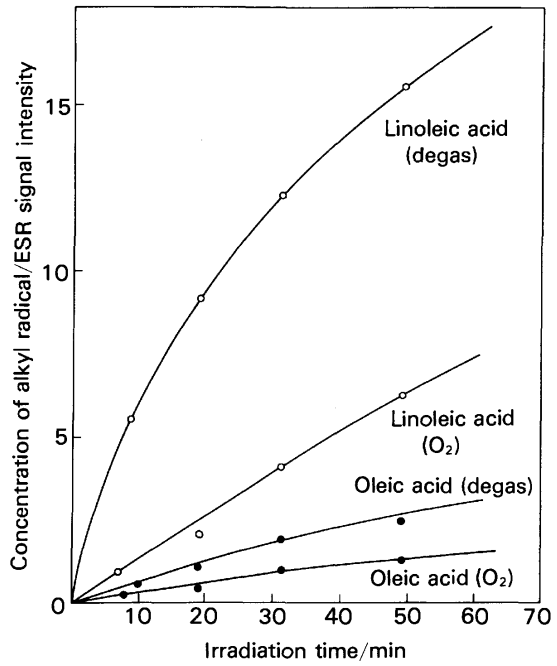

Fig. 8. Effect of oxygen molecule on concentration of formed spin adducts of nitrosodurene with alkyl radical of OA or LA in aerated and deaerated conditions.

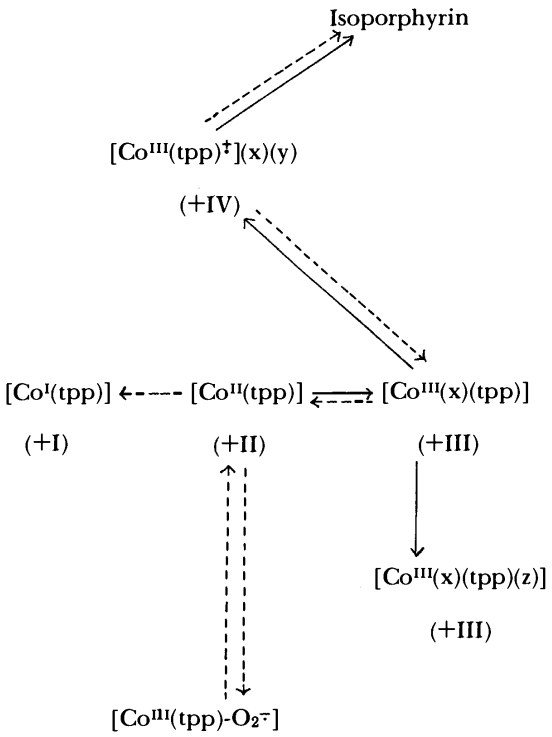
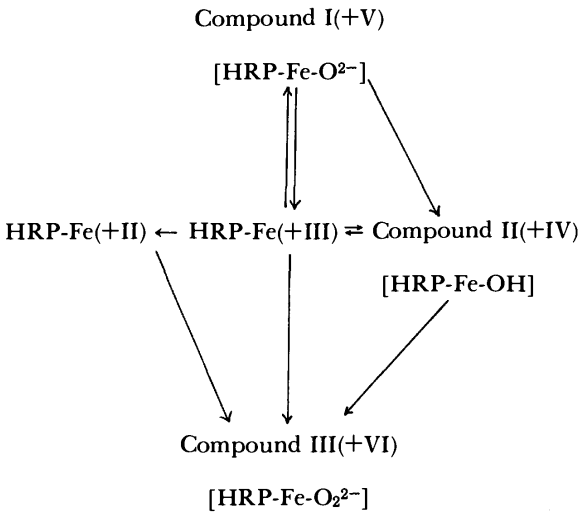


Scheme 1. Redox system of cobalt porphyrins. —: present oxidation process, -----: reduction and oxidation process as previously reported.[6,22]

that the alkyl radicals generated from unsaturated fatty acids combine with oxygen molecules to form stable peroxide radicals (lpox·).

The present reactions may be summarized as follows: (1) the bpox· oxidizes both [Co^{II}(tpp)] and [Co^{III}(Cl)(tpp)] to π cation radicals; (2) the bupox· oxidizes [Co^{II}(tpp)] to [Co^{III}(bupox)(tpp)(dbupo)], while the cobalt(III) species is not subjected to any further oxidation of the bupox·; however, [Co^{III}(Cl)-(tpp)] is oxizided to form π cation radicals; (3) the lpox· (oapox·, lapox·, lnapox·, and aapox·) oxidizes [Co^{III}(Cl)(tpp)], but not [Co^{II}(tpp)], to π cation radicals and (4) the bpox· and the lapox· further react with π cation radicals to give isoporphyrins. These results indicate that the oxidation reactions proceed depending on the oxidation potentials of both cobalt porphyrins and peroxide radicals.



Scheme 2. Redox system of HRP.[7]

Cobalt tpp and Horseradish Peroxidase(HRP)

We will now compare our results with the reaction of a typical enzyme, HRP. The function of cobalt porphyrins, [Co^{II}(tpp)] and [Co^{III}(Cl)(tpp)], and the enzymatic reaction of HRP are written in Schemes 1 and 2. The numbers in parentheses in these schemes represent the apparent oxidation states estimated on the basis of data from earlier studies.[6,7] [Co^{III}(tpp)$^{+}$]$^{2+}$ and Compound I of HRP are both π cation radicals. Here, we assume a correspondence (1) of [Co^{II}(tpp)] to native HRP, (2) of [Co^{III}(tpp)]$^{+}$ to Compound II, and (3) of [Co^{III}(tpp)$^{+}$]$^{2+}$ to Compound I.

In the HRP system, it has been known that native HRP is subjected to two-electron oxidation to produce Compound I, and also that Compound I reacts with such substrates as phenol derivatives and is reduced to native HRP through Compound II. In the present study, we found that peroxide radicals oxidize [Co^{II}(tpp)] to produce, successively, [Co^{III}(tpp)]$^{+}$, [Co^{III}(tpp)$^{+}$]$^{2+}$, and isoporphyrin. This fact suggests that, in the system of HRP and alkyl hydroperoxide, Compound I is formed by the successive oxidation of native HRP with the peroxide radicals (·OOR).

Furthermore, Compound II has been known to be [HRP-Fe-OH] which is coordinated with the OH generated from hydroperoxide or alkyl hydroperoxide. Taking into account the fact that [Co^{II}(tpp)] is oxidized by a peroxide radical (bpox·) to produce [Co^{III}(bpox)(tpp)], it is considered that the Compound II formed in the system of HRP and alkyl hydroperoxide may be [HRP-Fe-OOR]. The formation of isoporphyrins in the reactions suggests that the degradation of HRP is caused by the peroxide radicals formed in the process of the autooxidation of lipids.

The author wishes to express his deep gratitude to Professor Hiroaki Ohya-Nishiguchi of Kyoto University and Dr. Kiyoko Yamamoto of The Institute of Physical and Chemical Research for their helpful discussion during the course of this study.

Study of Ion Transport across Amphoteric Ion-Exchange Membrane.[1] V. Nonequilibrium Thermodynamic Analyses of Ion Selectivity

Kozue KAIBARA,* Hiroyoshi INOUE, Shigeru TSURUYAMA, and Hideo KIMIZUKA
Department of Chemistry, Faculty of Science, Kyushu University,
Hakozaki, Higashi-ku, Fukuoka 812
(Received September 28, 1987)

Ion-transport processes across an amphoteric ion-exchange membrane were investigated by means of estimating the membrane permeability matrix, a set of modified linear phenomenological coefficients, from the electrochemical and the ion flux data. Systematic comparisons of phenomenological analyses on an amphoteric ion-exchange membrane system with those on an ordinary cation-exchange membrane system were carried out to investigate the correlations of singly- and binary-charged membrane structures to characteristic transport properties. The modes of ion permselectivity of an amphoteric ion-exchange membrane in the metal chloride concentration-cell systems are characterized by the potentiometric selective response due to the ion-sieve effect, the low membrane conductance, and the large ion flux, while those of an ordinary cation-exchange membrane are characterized by the totally charge-dependent potential response, the high conductance, and the extremely small ion flux. The cross elements of the membrane permeability matrix, which represent the partial contributions of cation-anion interactions to the membrane permselectivity, are positive for an amphoteric membrane and negative for a cation-exchange membrane. The positive cross matrix elements act deceleratively on the membrane permeability, whereas the negative elements do acceleratively. It was pointed out based on the nonequilibrium thermodynamic theory that the preferable and efficient permeation mechanism is the simple diffusion process in an amphoteric ion-exchange membrane, whereas the electroconductive process in a cation-exchange membrane.

The linear phenomenological analysis is a powerful tool to characterize membrane transport processes on the basis of the nonequilibrium thermodynamics (see e.g., Refs. 2, 3). A variety of nonequilibrium thermodynamic theories on the membrane transport processes have been developed to investigate meterial transport phennomena arising across membranes. These membrane theories are useful to describe quantitatively the selective transport performance in some particular membrane samples by evaluating the linear phenomenological coefficients from the available experimental data. However, there seem to be some uncertain factors, even now, in the generalized correlations of phenomenological coefficients with membrane properties such as permeability, selectivity, polymeric and charged structures, and phase behavior of membrane substances. Therefore, it is still worth to examine differences in the linear phenomenological coefficients between the membrane systems showing distinguishable transport characteristics with each other.

As shown in earlier reports of this series, an amphoteric ion-exchange membrane, in which almost equal amounts of positively and negatively charged sites are homogeneously and regularly dispersed at high densities, shows unique transport characteristics different from those of a uniform ion-exchange membrane. By introducing equal amounts of positively and negatively charged sites into the membrane phase, the permselectivities to cations or anions are deteriorated inevitably; however, potentiometric permselectivities were demonstrated even for ions of the same charge as the most interesting transport properties of the homogeneous type amphoteric ion-exchange membrane, unlike the usual uniform ion-exchange membrane.[1,4] It has been pointed out that a useful amphoteric ion-exchange membrane should have the membrane structure in which both the cation- and anion-exchange regions are as small as possible[5] and also that the transport phenomena specific to an amphoteric ion-exchange membrane are observed when the ratio of cationic to anionic exchange capacity ranges from 0.8 to 1.[6] Recently developed amphoteric ion-exchange membranes, in which cationic and anionic exchange sites are distributed homogeneously over the functionalized polymer network in microscopic dimensions with high density, are proved to be applicable to the processes separating organic compounds of low molecular weight from inorganic electrolyte mixtures.[7,8]

In the present investigations, ion transport characteristics of an amphoteric ion-exchange membrane are examined by means of estimating the membrane permeability matrix as a principal membrane permselectivity parameter. The transport process analyses utilizing the membrane permeability matrix, of which element is recognized as a modified linear phenomenological coefficient describing a partial contribution of correlation between permeating ions on the membrane selectivity to respective ions, provide a quantitative description of ion transport process on the basis of nonequilibrium thermodynamics.[9–11] The estimated membrane permeability matrix of an amphoteric ion-exchange membrane was compared with that of an ordinary cation-exchange membrane, since the present discussion also aims at inspecting how the charged membrane structure reflects on

qualitative and quantitative aspects of the phenomenological coefficients.

Experimental

An amphoteric membrane used in the present experiments is 1.0-PA-29 amphoteric ion-exchange membrane (Kanegafuchi Chemical Industry Co., Ltd.) and CK-1, 1.0t cation-exchange membrane (Asahi Chemical Industry Co., Ltd.) was used as a reference membrane sample of ordinary highly selective cation-exchange membrane. Fundamental physicochemical properties and an outline of preparation procedures of these membranes were described in earlier papers.[1,4,7,10] Both the ion-exchange membranes have the same cation-exchange site, usual sulfonic acid type, and comparable ion-exchange capacities, ca. 1.7—2.0 eq·(kg wet-membrane)$^{-1}$. Accordingly, systematic and generalized discussions are available to investigate substantial differences in the ion transport characteristics of a binary-charged amphoteric ion-exchange membrane as compared with those of an ordinary singly-charged cation-exchange membrane.

Electrochemical properties, such as transmembrane potential and conductance, and inter-compartmental ion fluxes were measured for the concentration-cell systems to evaluate the membrane transport parameters based on the nonequilibrium thermodynamic theory. Experimental systems consisted of solution phase I, in which electrolyte concentration was varied from 10^{-1} to 10^{-3} mol dm^{-3}, and phase II with a fixed concentration of 10^{-2} mol dm^{-3} separated by a membrane phase. Electrolyte used in the present measurements included metal chlorides such as CsCl, KCl, NaCl, LiCi, $CaCl_2$, and $SrCl_2$. Electrolyte solutions were prepared from extra-pure salts with conductivity water. Measurements were carried out with a setup, essentially the same as reported in an earlier paper.[10] A high-input-impedance digital voltmeter (TR6877D, Takeda Riken Co.) and impedance measuring equipments (YHP4255A and YHP4440B, Yokogawa-Hewlett-Packard Co.; KC-530, Kokuyo Electric Co.) were employed to measure the electrochemical properties of the concentration-cell systems with the ion-exchange membrane by the ordinary methods. Inter-compartmental ion flux was estimated by means of tracing the time changes in solution conductivities of the solution phases I and II. All the measurements were carried out at regulated temperature, 25.0±0.1 °C, using a water-jacket glass-made measurement cell throughout the present experiments.

Results and Discussion

Membrane Transport Phenomena. Figure 1 summarizes the results obtained in the present experiments. Transmembrane potential data in Fig. 1-A indicate that the 1.0-PA-29 amphoteric ion-exchange membrane reveals potentiometric selectivities even to permeant metal cations of the same charge. It has been pointed out that these potentiometric selectivities are due to an "ion-sieve effect" to hydrated permeant ion demonstrated for all ions regardless of the electrolyte species and of positive or negative charges.[1,4] The ion-sieve effect responsible for shifting out the hydrated cations and anions permeating across the 1.0-PA-29 amphoteric ion-exchange membrane was suggested to be dependent upon the three-dimensional-array ion-exchange groups with an alternately charged regular arrangement.

Providing that equal numbers of the cation- and anion-exchange sites are introduced into the membrane phase and that both the ion-exchange sites

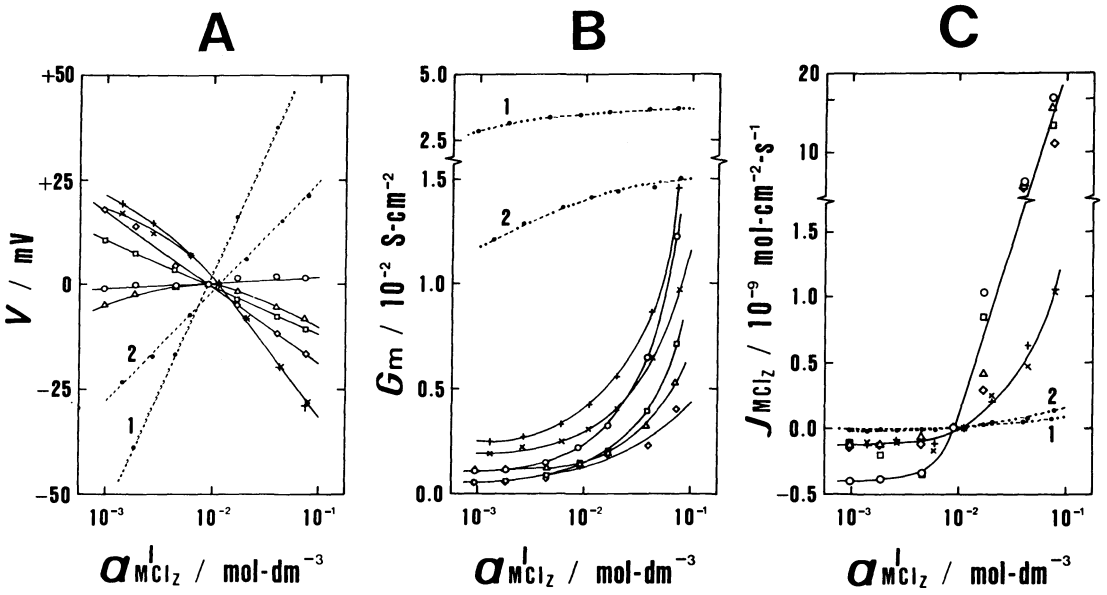

Fig. 1. Transmembrane potential (A), membrane conductance (B), and inter-compartmental ion flux (C) as a function of the mean electrolyte activity of phase I for a variety of aqueous metal chloride concentration-cell systems with an amphoteric ion-exchane membrane, 1.0-PA-29. ○: CsCl; △: KCl; □: NaCl; ◇: LiCl; ×: $CaCl_2$; +: SrCl. The broken lines 1 and 2 refer to the data for NaCl and $CaCl_2$ systems with a cation-exchange membrane, CK-1, 1.0t.

interact equivalently with oppositely charged permeant ions, the zero transmembrane potential should be observed for a 1–1 electrolyte system as an ideal amphoteric ion-exchange membrane potential, since the membrane permeabilities to cation and anion are identical with each other. In the present case, the CsCl system, in which transport numbers to Cs^+ and Cl^- are estimated at 0.51 and 0.49, respectively, from the membrane potential data, realizes apparently these situations as can be seen in Fig. 1-A. The Cs^+/Cl^- hydrated radius ratio is 0.99. The 1.0-PA-29 membrane also demonstrated almost ideal potential responses for an amphoteric ion-exchange membrane in the $NaClO_3$ concentration-cell systems, in which transport numbers to Na^+ and ClO_3^- are 0.51 and 0.49, and the Na^+/ClO_3^- hydrated radius ratio is 1.05.[1)] In case of KCl systems composed of cation and anion with comparable hydrated radii, the 1.0-PA-29 membrane exhibited a biphasic ion selectivity in which cations are more permeable than anions at lower electrolyte concentrations, but at higher concentrations, the ion permselectivity is reversed. Transport numbers to cations are decreased with an increasing radius of hydrated cation as: K^+ (transport number, 0.43—0.54), Na^+ (0.40), and Li^+ (0.35). In the 1.0-PA-29 membrane, the ionic selectivity balance leans slightly toward an anion-selective side (see also Refs. 1 and 4).

Similar situations, such as the cation transport number sequence depending upon the hydrated ionic radius, the slight unbalance of ionic permselectivity shifted to anion selective side, and the resultant potentiometric selective response to 1–1 metal chloride systems, were observed also in the different samples of an amphoteric ion-exchange membrane fabricated by the block copolymerization method.[12)] In this amphoteric ion-exchange membrane composed of a pentablock copolymer having sulfonic acid type and quaternary ammonium type ion-exchange sites, it was reported that the permeabilities to cation and anion are balanced well in the KCl concentration-cell systems with an external electrolyte concentration ratio of 2 and that the transport numbers to cation decrease as: $K^+ > Na^+ > Li^+$.

The practical cation to anion permselectivity balance of an amphoteric ion-exchange membrane seems to be controlled by a variety of factors, such as the specific interactions of cation and anion with oppositely charged ion-exchange sites, detailed balance in numbers of cation- and anion-exchange sites, properties of functionalized network polymer, etc. Furthermore, it is one of the most interesting characteristics of an amphoteric ion-exchange membrane that the permselectivities to cations and anions shift either side depending upon the external electrolyte species and their concentrations.

In case that the permeating cation is bivalent, the 1.0-PA-29 amphoteric ion-exchange membrane showed more anion selective transport properties than the case of univalent cation as shown in Fig. 1-A. Transport numbers to Ca^{2+} and Sr^{2+} ranged from 0.27 to 0.45. Attractive interactions of permeating ions with the oppositely charged exchange sites, as well as repulsive interactions with equally charged sites, within the binary-charged amphoteric ion-exchange membrane phase are expected to be improved as an increase in the charge of permeating ions. Accordingly, the modes of ionic permselectivity of an amphoteric ion-exchange membrane are affected inevitably and definitely by ionic charges of permeants, as a common property of ion transport process across charged membranes. The present results suggest that the repulsive interactions of bivalent metal cations with fixed sites of the same charge exceed the attractive interactions with oppositely charged fixed sites (see also Ref. 1).

Membrane conductance and inter-compartmental ion flux data of the concentration-cell systems for a series of metal chlorides are given in Figs. 1-B and 1-C. The membrane conductances were larger in the bivalent cationic systems, while the inter-compartmental cationic flux was larger in the univalent cationic systems. External electrolyte concentration dependences of these data, increasing with an increasing external concentration, were observed also in the singly-charged ion-exchange membrane. Interesting and substantial differences in these transport properties, as well as in the membrane potential responses mentioned above, between the binary-charged amphoteric ion-exchange membrane, 1.0-PA-29, and the singly-charged cation-exchange membrane, CK-1, 1.0t, are discussed in a latter part of this section.

Membrane Permeability Matrix. A variety of the membrane transport theories based on the nonequilibrium thermodynamics provide an appropriate set of the linear phenomenological coefficients describing the transport phenomena across membranes. The membrane permeability matrix theory is shown to be useful to analyze quantitatively the permselective ion transport across a charged membrane.[9–11,13)] According to these theoretical formulations, the membrane permeability matrix, which is introduced to describe partial contributions of correlations between the permeating ions on the membrane permselectivity to ions, can be expressed for the concentration-cell systems containing Z-valent metal cation M and chloride ion as:

$$\begin{bmatrix} J_M \\ J_{Cl} \end{bmatrix} = -\begin{bmatrix} P_{M\cdot M} & P_{M\cdot Cl} \\ P_{Cl\cdot M} & P_{Cl\cdot Cl} \end{bmatrix} \times \begin{bmatrix} a_M^{II}\exp(ZFV/2RT) - a_M^{I}\exp(-ZFV/2RT) \\ a_{Cl}^{II}\exp(-FV/2RT) - a_{Cl}^{I}\exp(FV/2RT) \end{bmatrix} \quad (1)$$

where J is the ionic flux, V is the transmembrane

potential, a is the ionic activity, F is the Faraday constant, R is the gas constant, and T is the absolute temperature; the superscripts I and II indicate the two solution phases separated by the membrane phase, respectively; the subscripts M and Cl refer to metal cation and chloride ion, respectively. The 2×2 matrix in Eq. 1 is the membrane permeability matrix. Each element represents a partial contribution on the permselective transport process due to the correlations between permeating ion species indicated by the subscript index. The cross coefficients of membrane permeability matrix, $P_{M\cdot Cl}$ and $P_{Cl\cdot M}$, are related with each other as:[9]

$$\frac{P_{M\cdot Cl}}{P_{Cl\cdot M}} = \frac{(a_M^I a_M^{II})^{1/2}}{(a_{Cl}^I a_{Cl}^{II})^{1/2}} \times \frac{\sinh[ZF(V-V_M)/2RT]/[ZF(V-V_M)/2RT]}{\sinh[-F(V-V_{Cl})/2RT]/[-F(V-V_{Cl})/2RT]} \quad (2)$$

The electroconductive membrane permeabilities to metal cation M and to Cl^-, P_M and P_{Cl}, are defined as a function of the elements of the 2×2 membrane permeability matrix and estimated from the transmembrane potential and conductance data as:

$$P_M = P_{M\cdot M} - (1/Z)P_{Cl\cdot M} = \frac{t_M G_m RT}{Z^2F^2(a_M^I a_M^{II})^{1/2}} \frac{[ZF(V-V_M)/2RT]}{\sinh[ZF(V-V_M)/2RT]} \quad (3)$$

$$P_{Cl} = P_{Cl\cdot Cl} - ZP_{M\cdot Cl} = \frac{t_{Cl} G_m RT}{F^2(a_{Cl}^I a_{Cl}^{II})^{1/2}} \frac{[-F(V-V_{Cl})/2RT]}{\sinh[-F(V-V_{Cl})/2RT]} \quad (4)$$

where t is the transport number, G_m is the membrane conductance; V_M and V_{Cl} is the Nernstian equilibrium membrane potentials to metal cation M and Cl^-, respectively.

In a special case where total electric current across membrane is zero, Eq. 1 can be reduced to the next modified phenomenological equation:

$$\begin{bmatrix} J_M \\ J_{Cl} \end{bmatrix}_{I=0} = -\begin{bmatrix} P_M^0 & 0 \\ 0 & P_{Cl}^0 \end{bmatrix} \times \begin{bmatrix} a_M^{II}\exp(ZFV_0/2RT) - a_M^I\exp(-ZFV_0/2RT) \\ a_{Cl}^{II}\exp(-FV_0/2RT) - a_{Cl}^I\exp(FV_0/2RT) \end{bmatrix} \quad (5)$$

where V_0 is the transmembrane potential in absence of membrane electric current. The diffusional membrane permeabilities to M^{z+} and to Cl^-, P_M^0 and P_{Cl}^0, which can be estimated directly from the transmembrane potential and inter-compartmental ion flux data, are expressed as a function of the membrane permeability matrix elements:

$$P_M^0 = (P_{M\cdot M}P_{Cl\cdot Cl} - P_{M\cdot Cl}P_{Cl\cdot M})/P_{Cl} \quad (6)$$

$$P_{Cl}^0 = (P_{M\cdot M}P_{Cl\cdot Cl} - P_{M\cdot Cl}P_{Cl\cdot M})/P_M \quad (7)$$

The electroconductive and diffusional membrane permeabilities are related with each other as:

$$P_M^0/P_M = P_{Cl}^0/P_{Cl} = 1 + (P_{Cl\cdot M}/ZP_M) + (ZP_{M\cdot Cl}/P_{Cl}) \quad (8)$$

The electroconductive membrane permeability defined by Eqs. 3 and 4 should be discriminated on the basis of nonequilibrium thermodynamics from the diffusional membrane permeability defined by Eqs. 6 and 7.[9-11,13] The electroconductive permeability as a function of the ionic mobility across membrane phase represents the electrical conductive process of membrane transport, whereas the diffusional permeability as a function of the diffusion coefficient across membrane phase represents the ionic diffusion process. As discussed in latter part of this section, relative magnitudes of these two permeabilities prescribe characteristics of the modes of ion migration across

Fig. 2. membrane and also provide a practical index indicating the efficient way of the membrane utilization.

The membrane permselectivity parameters, such as the permeability matrix elements, $P_{M\cdot M}$, $P_{Cl\cdot M}$, $P_{M\cdot Cl}$, and $P_{Cl\cdot Cl}$, electroconductive permeabilities, P_M and P_{Cl}, and diffusional permeabilities, P^0_M and P^0_{Cl}, can be estimated from the membrane potential, the membrane conductance, and the inter-compartmental ion flux data based on these thermodynamic relationships, Eqs. 2—8. These parameters indicate the membrane permselectivities to respective ions by referring the apparent permeation speed across membrane. The membrane potential can be expressed as a function of the membrane permeability ratio or relative membrane permebility, $P_{Cl}/P_M(=P^0_{Cl}/P^0_M)$.[1,11,13] The membrane conductance and the ionic membrane conductance, product of the transport number and membrane conductance, are proportional directly to the electroconductive membrane permeability as indicated in Eqs. 3 and 4, while the diffusional membrane permeability is proportional to the ionic flux under the conditions of $ZJ_M=J_{Cl}$.

Figure 2 summarizes the values of membrane permeability matrix elements for a series of metal chlorides. In case of the univalent metal chloride systems, all the four membrane permeability matrix elements increased with increasing external concentrations, while in the bivalent metal systems, the matrix elements remained at almost constant levels. A sequence in the matrix element was $P_{Cl\cdot Cl}\geqq P_{M\cdot M}>P_{Cl\cdot M}$, $P_{M\cdot Cl}$; however, differences in the matrix element values between the terms based on a correlation of equally charged ions and those of oppositely charged ions are quite small. As indicated by Eqs. 3 and 4, the positive $P_{Cl\cdot M}$ and $P_{M\cdot Cl}$ contribute deceleravively to the respective permeabilities to metal cation and chloride ion. The positive values of these cross elements, in addition, result in the situations where the diffusional permeabilities exceed the electroconductive permeabilities as illustrated in Fig. 3. As expected from the results of transmembrane potential measurements, the 1.0-PA-29 amphoteric ion-exchange membrane is, in general, more permeable to chloride ions than to respective metal cations. Detailed discussion on the characteristic ion transport process across an amphoteric ion-exchange membrane is carried out in the following part of this section based on these membrane permeability parameters.

Comparisons with an Ordinary Singly-Charged Cation-Exchange Membrane. Systematic comparisons of the transport parameters for the 1.0-PA-29 membrane systems with those for the CK-1, 1.0t membrane are useful to investigate further the ionic transport processes across an amphoteric ion-exchange membrane. It is also interesting to clarify substantial differences in the ionic transport processes between singly- and binary-charged ion-exchange membranes.

In Fig. 1, the transmembrane potential, conductance, and ion flux data for the NaCl and $CaCl_2$ concentration-cell systems with the CK-1, 1.0t cation exchange membrane are presented as typical examples of 1–1 and 2–1 electrolyte systems. As discussed already, the 1.0-PA-29 amphoteric ion-exchange membrane reveals potentiometric selectivities even to ions of the same charge due to the ion-sieve effect based on the binary-charged membrane structure, in which the alternately charged sites seem to form the networks of three-dimensional-array ion-exchange groups responsible for shifting out the cations and anions. On the contrary to the potentiometric selective responses of the 1.0-PA-29 membrane, the CK-1, 1.0t membrane demonstrated a strictly charge-dependent potential response. An almost ideal

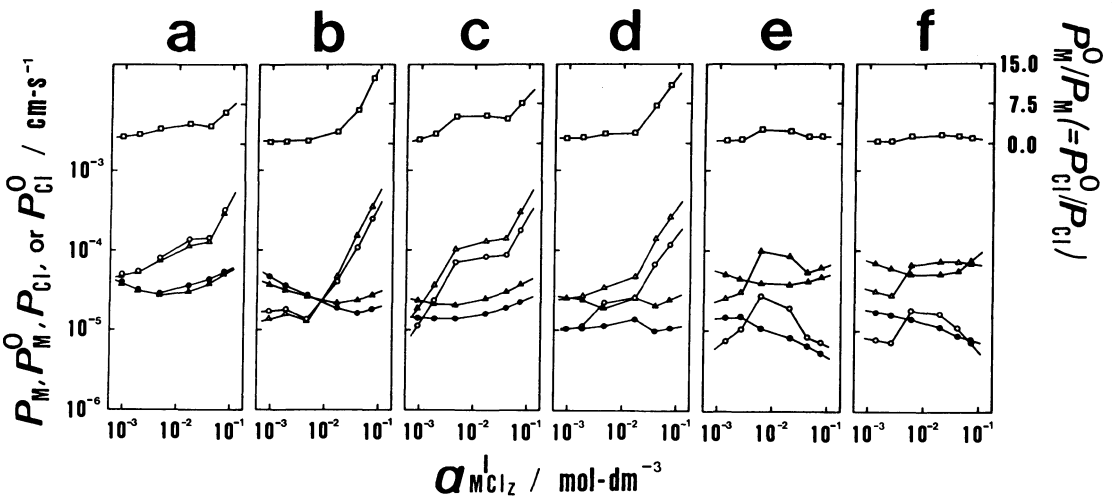

Fig. 3. Electroconductive and diffusional membrane permeabilities and diffusional/conductive permeability ratio as a function of the mean electrolyte activity of phase I for the 1.0-PA-29 amphoteric ion-exchange membrane systems. ●: P_M; ○: P^0_M; ▲: P_{Cl}; △: P^0_{Cl}; □: P^0_M/P_M $(=P^0_{Cl}/P_{Cl})$. a: CsCl; b: KCl; c: NaCl; d: LiCl; e: $CaCl_2$; f: $SrCl_2$.

Nernstian potential response was observed for the concentration-cell systems with the CK-1, 1.0t membrane containing univalent cations, even for the system containing bulky cations such as tetrabutylammonium cation. The transport number of the CK-1, 1.0t membrane to univalent cation estimated from the potential data for a variety of systems is ranged from 0.97 to 0.99 regardless of the electrolyte species in the concentration range studied, 10^{-1}—10^{-3} mol dm^{-3}. These situations are the same as in an ordinary highly permselective anion-exchange membrane system. An almost ideal Nernstian potential response was observed in simple inorganic univalent anion systems as well as in univalent long-hydrocarbon-chain surfactant anion systems.[14-16] The CK-1, 1.0t membrane developed for a desalination process is less permeable to bivalent cations than univalent cations. The membrane potential response showing the transport number of 0.90—0.98 to bivalent cations were observed in the concentration-cell systems containing $CaCl_2$, $SrCl_2$, or $MgCl_2$. In case of the $LaCl_3$ concentration-cell systems with the CK-1, 1.0t membrane, the transport number to La^{3+} was suppressed further to 0.72—0.83.

As seen in Figs. 1-B and 1-C, there is a great difference in the membrane conductance and inter-compartmental ion flux data between the 1.0-PA-29 and CK-1, 1.0t membrane systems. The membrane conductance changes in the 1.0-PA-29 membrane depending upon the external concentration are due to the fact that the membrane-solution distribution factors of ions (cation concentration within membrane phase [mol·(kg-wet membrane)$^{-1}$]/cation concentration in external solution [mol·dm^{-3}]) are almost unity in the concentration ranges studied.[17] Whereas high and relatively constant conductance values of the CK-1, 1.0t membrane are caused from the high and constant cation concentrations within membrane phase corresponding to the ion-exchange capacity. One of the objects to develop an amphoteric ion-exchange membrane was to get a large salt flux by means of the specific and unique transport mechanisms based on the binary-charged membrane structure.[5,18] On the other hand, only a fairly small ion flux can be observed across the singly-charged CK-1, 1.0t membrane as shown in Fig. 1-C, since the membrane systems are close to the equilibrium conditions as expected from the membrane potential data. Considering the thickness of these two membranes (1.0-PA-29: 0.1 mm; CK-1, 1.0t: 1.09 mm), the membrane conductance and inter-compartmental ion flux of the 1.0-PA-29 membrane are less than 1/10—1/100 and more than 10—100 times of those of the CK-1, 1.0t membrane, respectively.

Figures 4 and 5 summarizes the permselectivity parameters estimated for the NaCl and $CaCl_2$ concentration-cell systems with the CK-1, 1.0t cation-exchange membrane, corresponding to Figs. 2 and 3 for the 1.0-PA-29 amphoteric ion-exchange membrane system. Calculated results of other univalent metal chloride systems were comparable with those of the NaCl system in Figs. 4-a and 5-a, and the $SrCl_2$ system, with the $CaCl_2$ system in Figs. 4-b and 5-b. The sequences in the membrane permeability matrix elements were $P_{M\cdot M} \gg P_{Cl\cdot Cl} > P_{M\cdot Cl} > P_{Cl\cdot M}$ in the CK-1, 1.0t membrane system, since the exchange-sites-bound cations come up to 99% of the total cation concentrations within the

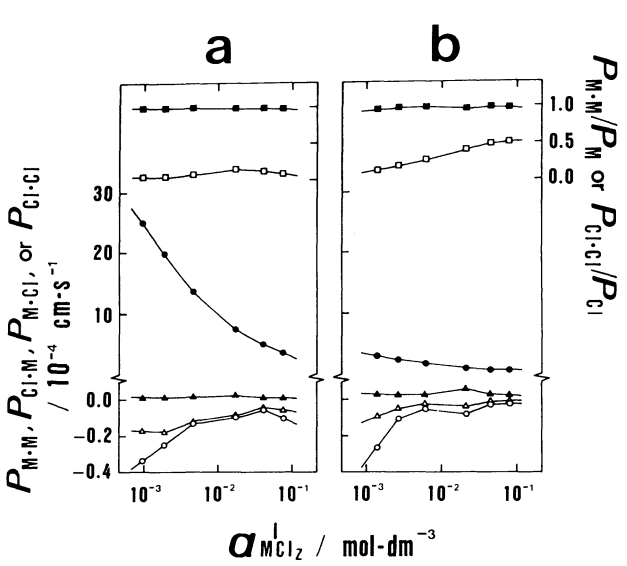

Fig. 4. Membrane permeability matrix elements and, $P_{M\cdot M}/P_M$ and $P_{Cl\cdot Cl}/P_{Cl}$ ratios as a function of the mean electrolyte activity of phase I for the CK-1, 1.0t cation-exchange membrane systems. Symbols are the same as those in Fig. 2. a: NaCl; b: $CaCl_2$.

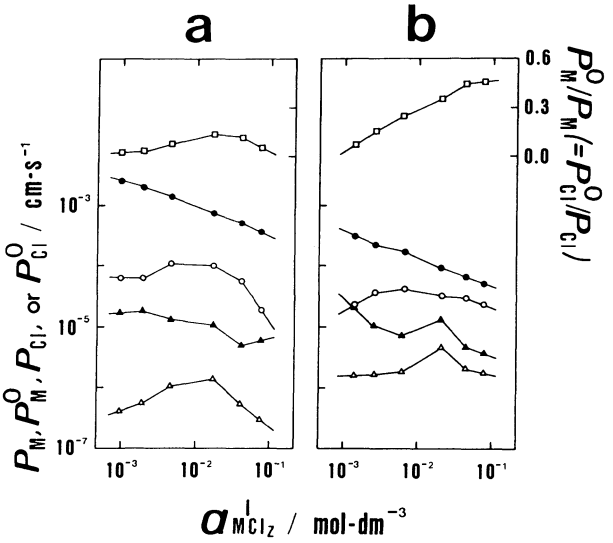

Fig. 5. Electroconductive and diffusional membrane permeabilities and diffusional/conductive permeability ratio as a function of the mean electrolyte activity of phase I for the CK-1, 1.0t cation-exchange membrane systems. Symbols are the same as those in Fig. 3. a: NaCl; b: $CaCl_2$.

membrane and chloride ions are almost perfectly excluded from the membrane phase.[17] In case of the binary-charged 1.0-PA-29 membrane, almost equal amounts of cations and anions are distributed within the membrane phase, so the four permeability matrix elements contribute comparably to the permselective ion transport process as $P_{Cl\cdot Cl} \cong P_{M\cdot M} > P_{Cl\cdot M}, P_{M\cdot Cl}$. The membrane permeability to metal cation is dependent upon the major contributions of the cation-cation correlation term, $P_M \cong P_{M\cdot M}$, as indicated in Fig. 4 and negative values of cross elements, $P_{Cl\cdot M}$ and $P_{M\cdot Cl}$, act acceleratively on the permeabilities to cation and anion as expected from Eqs. 3 and 4 in the singly-charged CK-1, 1.0t membrane system.

Drastic increases in the membrane/solution partition factor of cations in the CK-1, 1.0t membrane with decreasing external concentration cause an improvement of permselectivity with decreasing external concentrations. As discussed in an earlier part, the cross matrix elements are positive in the 1.0-PA-29 membrane, and accordingly, the permselective transport process across a binary-charged membrane depends upon the accelerative contributions based on the correlations between equally charged ions and upon the decelerative contributions based on the correlations between oppositely charged ions. Both of these positive and negative contributions in the 1.0-PA-29 membrane system containing univalent metal chlorides, as seen in Fig. 2, increased with increasing ion concentration of the membrane phase which are proportional to the external concentrations. Then, almost constant electroconductive permeabilities to cation and anion are revealed in the 1.0-PA-29 membrane system.

It has been a theoretically and experimentally established concept that the ionic permselectivity across charged membrane is a function of the permeation speed across membrane and of the membrane/solution partition factor of respective ions. The binary-charged membrane structure results in the totally different situations of ions in membrane phase from those in the singly-charged membrane phase as an origin of the unique ion transport characteristics of an amphoteric ion-exchange membrane.[17] Nonequilibrium thermodynamic analyses on the electrolyte transport process in free aqueous media pointed out that the correlation terms between cation and anion contribute negatively to the transport process similarly as in the binary-charged 1.0-PA-29 membrane.[19]

Equation 8 deduces that the signs of $P_{Cl\cdot M}$ and $P_{M\cdot Cl}$ prescribe a preferential transport mechanism across membranes, the electroconductive or diffusional processes. If these two cross elements are zero, namely none of the interactions between cation and anion exists, both the membrane permeabilities coincide with each other.[9,13] The diffusional/conductive membrane permeability ratio, $P^0_M/P_M (=P^0_{Cl}/P_{Cl})$, can be recognized as a practical index judging whether the electro-dialytic or mechano-dialytic application is efficient for some membrane samples. As shown in Fig. 3, these ratios were larger than unity and increased with an increasing external concentration in the univalent metal chloride system with the 1.0-PA-29 membrane, and in case of the bivalent metal chloride system, these ratios charged from 0.5 to 2.5 depending upon the external concentration. On the other hand in the CK-1, 1.0t membrane system as seen in Fig. 5, the diffusional/conductive membrane permeability ratios were smaller than unity, 0.025—0.17 for univalent metal chloride system and 0.07—0.5 for bivalent system. Whether the diffusional/conductive membrane permeability ratio is larger than or smaller than unity, the sign of the cross elements of membrane permeability matrix is dependent upon the balance of magnitudes of electrical membrane conductance and ionic flux.

Transmembrane potential can be expressed, in general, as a function of the membrane permeability ratio between permeating ions. According to the present membrane transport theory, the following equation for the membrane potential in absence of electric membrane current is obtained from Eqs. 1, 3, and 4:

$$Za^{II}_M \exp[(Z+1)FV_0/2RT] + (P_{Cl}/P_M)a^I_{Cl}\exp(FV_0/RT) - Za^I_M \exp[-(Z-1)FV_0/2RT] - (P_{Cl}/P_M)a^{II}_{Cl} = 0 \quad (9)$$

Identical equation for P^0_{Cl}/P^0_M can be also derived from Eq. 5. In case of the univalent metal chloride systems, Eq. 9 is reduced to the next equation, which is equivalent in form to the well known membrane potential equations for a symmetrical electrolyte such as the Goldman equation, Eisenman equation, etc.:[3]

$$V_0 = -(RT/F)\ln[(a^{II}_M + (P_{Cl}/P_M)a^I_{Cl})/(a^I_M + (P_{Cl}/P_M)a^{II}_{Cl})] = -(RT/F)\ln[(a^{II}_M + (P^0_{Cl}/P^0_M)a^I_{Cl})/(a^I_M + (P^0_{Cl}/P^0_M)a^{II}_{Cl})]. \quad (10)$$

Figure 6 summarizes the chloride ion/metal cation membrane permeability ratios, P_{Cl}/P_M $(=P^0_{Cl}/P^0_M)$, estimated for the 1.0-PA-29 and CK-1, 1.0t membrane systems. As expected from the membrane potential data and Eqs. 9 and 10, the P_{Cl}/P_M values varied with electrolyte species in the 1.0-PA-29 membrane system. As shown in Fig. 3, the electroconductive membrane permeabilities to univalent metal cations and chloride ion are decreased as $P_{Cs} \cong P_K \cong P_{Cl} > P_{Na} > P_{Li}$ with increasing radius of the hydrated ion due to the ion-sieve effect (see also Ref. 1). It has been an established concept that the permeant ion size is one of the dominant factors to control the membrane permselectivity.[20] Indeed also in the CK-1, 1.0t membrane system, the permeability sequences to univalent metal cations were the same as those in the 1.0-PA-29 membrane. However the P_{Cl} values were also changed

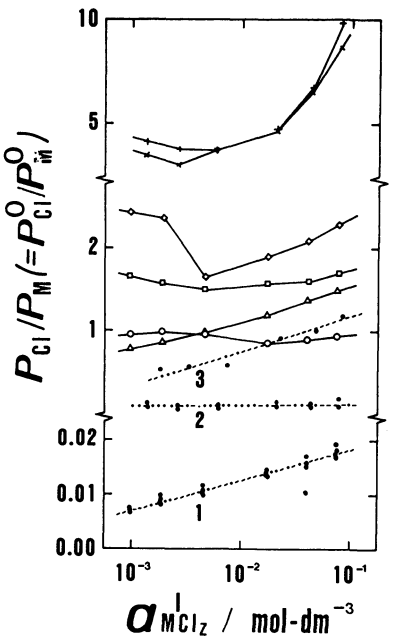

Fig. 6. Chloride ion/metal cation membrane permeability ratio, P_{Cl}/P_M, as a function of the mean electrolyte activity of phase I for the 1.0-PA-29 amphoteric ion-exchange membrane. Symbols are the same as those in Fig. 1. The broken lines 1, 2, and 3 refer to P_{Cl}/P_M values for univalent metal (Cs, K, Na, and Li) chloride, bivalent metal (Ca and Sr) chloride, and $LaCl_3$ concentration-cell systems with the CK-1, 1.0t cation-exchange membrane, respectively.

proportionally with the changes in P_M values as expected from Eq. 10, since the CK-1, 1.0t membrane shows an identical Nernstian response to all the univalent cation systems. Membrane permeability sequences for the Ck-1, 1.0t membrane are as: $P_{Cs}>P_K>P_{Na}>P_{Li}\gg P_{Cl(Cs)}>P_{Cl(K)}>P_{Cl(Na)}>P_{CL(Li)}$, where $P_{Cl(M)}$ indicates the chloride permeability in 1-1 electrolyte, MCl, system. Accordingly, the ion transport process across the binary-charged 1.0-PA-29 membrane is characterized as: the permeabilities both to cation and to anion depend upon the size of the hydrated ions and the permeability to a given ion has a definite value regardless of the electrolyte species. On the contrary, a highly selective cation transport across the CK-1, 1.0t membrane is characterized by the quite low anion/cation permeability ratio, in which the ion size effects on membrane permselectivity are shielded due to tight interactions between oppositely charged ion and fixed site, and accordingly, a potentiometric response to ions of the same charge cannot be observed.

In the ion transport processes across charged membranes, whether the singly- or binary-charged membranes, interactions between permeating ions and fixed ion-exchange sites control the permselectivity as a primary physicochemical factor. Therefore, in a nontreated singly-charged ion-exchange membrane, it has been well-known that the permeability and selectivity parameters to multivalent ions exceed those of univalent ions. In case of the singly-charged membrane developed for the concentration processes of sea water such as the CK-1, 1.0t cation-exchange membrane, the membrane surface was treated by polycationic substance to suppress the permeation of multivalent cations to prevent from $CaSO_4$ scale formation. Figure 6 shows a stepwise increase in P_{Cl}/P_M values with an increasing cation valency from 1 to 3. Once a large amount of multivalent cation has penetrated into the membrane phase; however, the multivalent cations are more permselective than univalent cations due to the tight interaction with oppositely charged exchange sites, as reported in the NaCl-$CaCl_2$, NaCl-$LaCl_3$, and $CaCl_2$-$LaCl_3$ biionic systems with the CK-1, 1.0t membrane.[11,21] As already discussed, the permeability to bivalent metal cation in the binary-charged 1.0-PA-29 membrane is decelerated due to the repulsive interactions with positively charged exchange site, while the permeability to Cl^- is accelerated almost as twice as those in the univalent metal chloride system (see also Ref. 1).

Present results suggest that a qualitative improvement of the membrane permselectivity to ions can be provided by means of introducing the carefully selected pairs of oppositely charged ion-exchange sites into the membrane phase with high densities. Further investigations on the detailed aspects of ion transport process across a binary-charged amphoteric ion-exchange membrane will be achieved by examining the ion conditions within membrane phase such as membrane/solution partition and diffusion process of permeating ions.[17] These studies contribute also to the developments of more useful and efficient membrane-related processes.

ESR Study on the Reactions of 1,3-Diene Cation Radicals in Low-Temperature Matrices

Jun FUJISAWA, Toshiyuki TAKAYANAGI, Shin SATO,* and Kazuo SHIMOKOSHI†
Research Laboratory for Nuclear Reactors, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received October 3, 1987)

The reactions of the cation radicals of 1,3-butadiene, *cis*- and *trans*-1,3-pentadienes, 2-methyl-1,3-butadiene, and 2,3-dimethyl-1,3-butadiene have been investigated by low-temperature matrix ESR. The cation radicals produced in the irradiated solid solutions of CCl_2FCCl_2F were found to react with their neutral parents at temperatures above ca. 110 K, forming radicals with allylic ends. On the other hand, 1,3-pentadiene cation radicals in the matrices of CCl_4, CCl_3F, and CCl_3CF_3 were found to isomerize into cyclopentene cation radicals, irrespective of the cis and trans forms. The possible mechanisms for the reactions and their implications in the cationic polymerization of dienes are discussed.

The primary process in radiation-induced polymerization has long been a subject in radiation chemistry.[1] Traditional approaches, however, have mostly been confined to speculation about the mechanisms, since the high reactivity of the cation radicals prohibited any spectroscopic detection of the primary processes.

The method of radiolytic generation and stabilization of cation radicals in Freons has now widely been applied to a variety of organic compounds.[2] By measuring the ESR spectra of the cation radicals, thus prepared over a wide temperature range, direct information concerning their reactions has often been obtained.[3,4]

This technique, as it applies to the cation radicals of unsaturated hydrocarbons, is of special interest since some of them are supposed to initiate polymerization.[1] In fact, we have found that the cation radicals of ethylene and isobutene easily associate with their neutral parents to form chain end radicals.[5,6] This is in remarkable contrast to the deprotonation observed for the cation radicals of other olefins[6] and paraffins[3] giving neutral radicals.

In the present study, we have examined the reactions of a series of 1,3-diene cation radicals by the same method mentioned above. The isolated cation radicals of 1,3-pentadienes and 2,3-dimethyl-1,3-butadiene were newly observed by ESR, as well as those of 1,3-butadiene and 2-methyl-1,3-butadiene. The ESR observation for the formations of chain end allylic radicals from these cation radicals and the isomerization found for the cation radicals of 1,3-pentadiene are described.

Experimental

1,3-Butadiene from Takachiho Kagaku Kogyo Co., 2-methyl-1,3-butadiene, 2,3-dimethyl-1,3-butadiene, and cyclopentene from Tokyo Kasei Co. were used as received. Cis and trans isomers of 1,3-pentadiene were kindly supplied by Nippon Zeon Co. Ltd. All the dienes, except for 1,3-butadiene, can polymerize easily, even at room temperature. About 30 ppm of a polymerization inhibitor was kept incorporated with these compounds. Preliminary measurements using samples from which the inhibitor had been removed immediately before preparation gave the same results as described in this paper. The high purity (>97%) of each isomer was checked by NMR spectroscopy. Commercially available halocarbons (CCl_4, CCl_3F, CCl_3CF_3, and CCl_2FCCl_2F from Tokyo Kasei Co.) were used as a matrix media without further purification.

The procedure of sample preparation and ESR measurement have been described previously.[4-6] Solid solutions containing small amounts of the dienes (0.2—0.5 mol%) in various halocarbons were prepared in quartz tubes at 77 K, then irradiated to generate the cation radicals. The ESR measurement was carried out with a JES FE-2XG spectrometer calibrated with an NMR probe and a digital frequency counter. The sample temperature was regulated with a temperature controller, and the spectra were recorded at temperatures between 77 K and the melting point of each matrix with suitable intervals.

Results

1,3-Butadiene. The spectrum shown in Fig. 1a was recorded at 77 K after the irradiation of a solid solution of 1,3-butadiene in CCl_3CF_3. The spectrum consists of a quintet with an hfc (hyperfine coupling) constant of 10.4 G (1 G=10^{-4} T), which can readily be assigned to the cation radical of 1,3-butadiene. Essentially the same spectrum was observed for the solutions of CCl_3F and CCl_2FCCl_2F at 77 K. The cation radical of 1,3-butadiene in other matrices has been studied by several workers.[7-9] The present result is in good agreement with the previous results, as shown in Table 1.

The 1,3-butadiene cation radicals in CCl_3F and CCl_3CF_3 were found to remain isolated up to about 145 K. A further elevation of the temperature resulted in a uniform decay of the cation radical without giving any new paramagnetic species. This may be attributed to the neutralization between the cation radical and the chloride anion. On the other hand, the irradiated solution of 1,3-butadiene in CCl_2FCCl_2F

showed an irreversible change at around 110 K from the initial spectrum of the cation radical to a new one. Figure 1b shows the spectrum observed upon warming to 128 K. The spectrum was well reproduced by the simulation shown in Fig. 1c when an allylic structure **1** was assumed.[7]

1

At elevated temperatures, it has often been observed that an irradiated CCl_2FCCl_2F solution allows molecular diffusion which may cause ion-molecule reactions.[4-6] The irreversible change of the spectrum, therefore, strongly suggests that the cation radical reacts with its neutral parents to form species whose radical end has an allylic structure **1**.

***cis*- and *trans*-1,3-Pentadienes.** The irradiated solutions of *cis*- and *trans*-1,3-pentadienes in CCl_2FCCl_2F exhibited the spectra shown in Figs. 2a and 3a, respectively. The former was successfully analyzed by using hfc constants of 15.2 G (3H), 10.4 G (3H), and 5.9 G (1H), as shown in Fig. 2b. Based on the results of INDO calculations (values in the parentheses in the diagrams **2**, **5**, and **6**),[10] the species giving the spectrum was assigned to the cation radical of *cis*-1,3-pentadiene (**2**). The analysis of the spectrum for the trans isomer (Fig. 3a) is less straightforward because of its low resolution. It was found, however, that the essential features of the spectrum closely resemble those of the cis isomer. This suggests the formation of

a *tarns*-1,3-pentadiene cation radical, though the cause of the apparent difference in the resolution between the isomers is not clear.

The essential differences between cis and trans isomers of the cation radicals were characterized by their reactions. Upon warming, the spectra of these cation radicals changed irreversibly into different patterns, as shown in Figs. 2c and 3b, respectively. Taking the small variations of the hyperfine interaction into account, both could be reproduced by simulations, as shown in Figs. 2d and 3c. Such a variation has often been observed for allylic radicals with different conformations;[6,11] the spectra can consistently be assigned to the allylic ends with cis **3** and trans **4** skeletons.

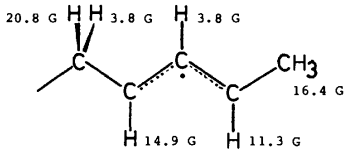
3



4

When the matrix of CCl_4, CCl_3F, or CCl_3CF_3 was used instead, a completely different spectral pattern was observed. The spectrum shown in Fig. 4a was recorded at 77 K immediately after the irradiation of a solution of a *cis*-1,3-pentadiene in CCl_3F. Upon warming, the resolution of the spectrum was improved to give the spectrum shown in Fig. 4b at 128 K. Essentially the same spectra were obtained for *trans*-1,3-pentadiene, as shown in Figs. 4c and 4d. The spectra shown in Fig. 4 closely resemble that of a cyclopentene cation radical, reported by Shida and co-

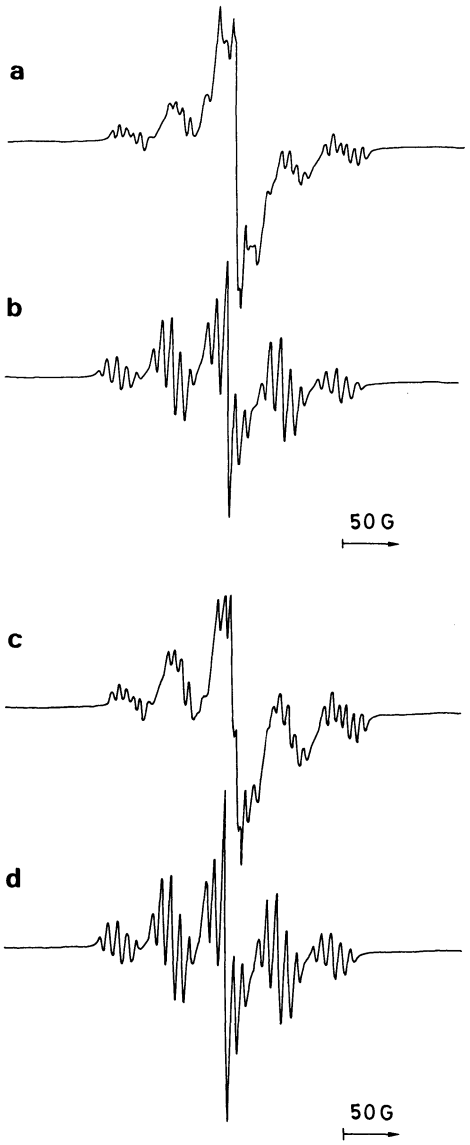


Fig. 4. (a) ESR spectrum of the irradiated CCl_3F solution of *cis*-1,3-pentadiene at 77 K, showing the features assigned to the cation radical of cyclopentene. (b) Same as (a) at 128 K. (c) Same as (a) for *trans*-1,3-pentadiene. (d) Same as (c) at 123 K.

workers.[9] We performed the same experiment and confirmed that these spectra coincide almost exactly with the spectra from cyclopentene. Therefore, it may be concluded that the cation radical of cyclopentene was formed immediately after the irradiation of the CCl_3F solutions of *cis*- and *trans*-1,3-pentadienes. The employment of other matrices of CCl_4 and CCl_3CF_3 also gave similar results.

2-Methyl- and 2,3-Dimethyl-1,3-butadienes. The irradiated 2-methyl-1,3-butadiene in CCl_3CF_3 yielded the spectrum shown in Fig. 5a at 128 K. The spectrum is quite similar that previously observed in CCl_4.[12] The hfc constants of 13.1 G (2H), 8.7 G (2H), and 4.3 G (3H) were derived from the simulation shown

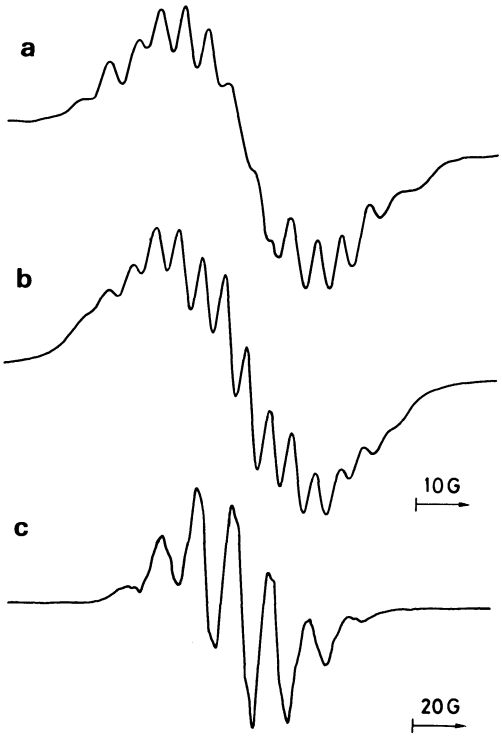

Fig. 5. (a) ESR spectrum of the cation radical of 2-methyl-1,3-butadiene in CCl_3CF_3 at 128 K. (b) Simulation for (a) using the parameters given in Table 1 and a Lorentzian line width of ΔH_{msl}=7.5 G. (c) ESR spectrum of the irradiated CCl_2FCCl_2F solution of 2-methyl-1,3-butadiene at 133 K, showing the features assigned to the allylic end **7**.

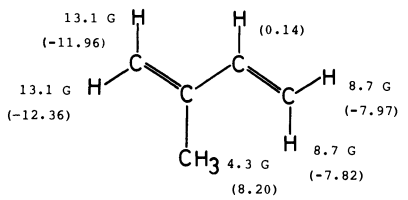
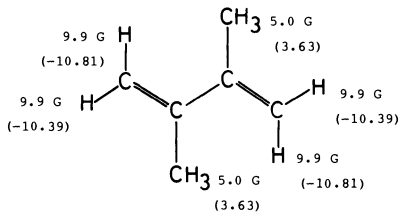
in Fig. 5b and were ascribed to the 2-methyl-1,3-butadiene cation radical (**5**).



5

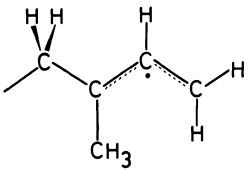
For an irradiated solution of 2,3-dimethyl-1,3-butadiene in CCl_3CF_3, a poorly resolved spectrum was obtained. Well-resolved structures were observed by using CCl_4 instead (Fig. 6a). Although some background signals due to the matrix radicals[13] are superimposed at the low-field side of the spectrum, the main spectral pattern can easily be identified as a quintet of septets with hfc constants of 9.9 G (4H) and 5.0 G (6H) (Fig. 6b); those agree well with the values expected for the cation radical of 2,3-dimethyl-1,3-butadiene (**6**).

Irreversible spectral changes were also observed for these systems upon warming. Figure 5c shows the spectrum observed for an irradiated CCl_2FCCl_2F solution of 2-methyl-1,3-butadiene at 118 K. The

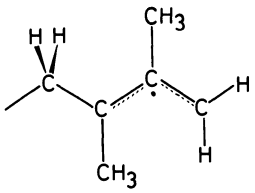


6

septet structure separated by about 13 G may be assigned to the allylic end **7**, though possible differences in hfc constants among six protons are not clear from the spectrum. A similar septet pattern was also obtained for an irradiated solution of 2,3-dimethyl-1,3-butadiene at 128 K (Fig. 6c). The formation of another type of allylic end **8** may be responsible.



7



8

The observed ESR parameters for the cation radicals of dienes and the allylic end radicals are summarized in Tables 1 and 2, respectively.

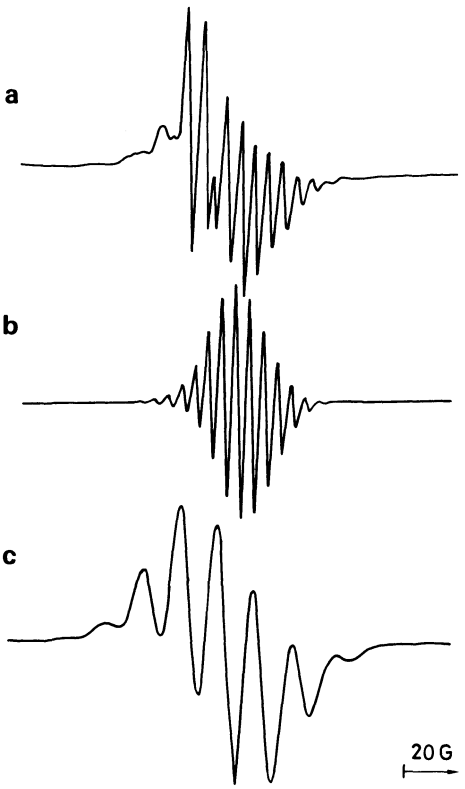


Fig. 6. (a) ESR spectrum of the cation radical of 2,3-dimethyl-1,3-butadiene in CCl_4 at 183 K. Discussion

The cation radicals of 1,3-butadiene and its methyl and dimethyl derivatives were stabilized in halocarbon matrices upon irradiation at 77 K. From the results of ESR measurements (Table 1), it can be seen that the coupling constants of CH_2 protons vary little among the species. This indicates that the cation radicals of 1,3-dienes possess essentially the same π-structures as that of 1,3-butadiene, where an unpaired electron is located mainly on the terminal (1,4-position) carbons.

The radicals derived from these cation radicals were characterized by their allylic ends, which reflect the conformations of the corresponding parent cation radicals. In particular, cis and trans isomers of 1,3-pentadiene cation radicals in CCl_2FCCl_2F were found to give allylic ends with cis and trans skeletons, respectively. This indicates that the radicals formed by reactions, as well as the parent cation radicals, retain their geometrical identities of neutral dienes. A similar stereospecificity has also been found for reactions of the *cis*- and *trans*-2-butene cation radicals.[6]

Regardings the ESR parameters of the radical from the 1,3-butadiene cation radical, there is a noticeable difference between the present result and the previous one;[7] i.e., large inequivalence between the two β-methylene proton couplings, 20.3 and 3.0 G, has not been previously observed (see Table 2). The difference may be ascribed to the lower temperature at which the present measurement was carried out. In this case, the motional averaging between two protons may be prohibited. Such an inequivalence of β-methylene proton couplings has been observed for other allylic end radicals,[14] and the present values seem to be appropriate for this type of radical.

So far, a number of studies have been reported concerning the primary processes in the radiation-induced polymerization of 1,3-butadiene.[1a,7,8,15] The formation of primary cation radicals or allylic end radicals has been observed, depending on the conditions. The concentration effect on the processes was investigated by Lund et al.[7] for the irradiated 1,3-butadiene adsorbed on silica gel. They reported that the cation radical was observable at a low 1,3-butadiene content, but absent when the allylic end radical occurred at high concentrations. The following reaction scheme has been proposed for 1,3-butadiene:[7,8,15c]

$$CH_2{=}CH{-}CH{=}CH_2 \longrightarrow CH_2{=}CH{-}CH{=}CH_2^{\ddagger} + e^-, \quad (1)$$

$$CH_2{=}CH{-}CH{=}CH_2^{\ddagger} + CH_2{=}CH{-}CH{=}CH_2 \longrightarrow \dot{C}H_2{-}CH{=}CH{-}CH_2{-}CH_2{-}CH{=}CH{-}CH_2^+, \quad (2)$$

$$\dot{C}H_2{-}CH{=}CH{-}CH_2{-}CH_2{-}CH{=}CH{-}CH_2^+ + n[CH_2{=}CH{-}CH{=}CH_2] \longrightarrow \dot{C}H_2{-}CH{=}CH{-}CH_2\text{-}(CH_2{-}CH{=}CH{-}CH_2)_n CH_2{-}CH{=}CH{-}CH_2^+. \quad (3)$$

In the present study, the formation of the allylic end was characterized as the ion-molecule reaction of 1,3-butadiene cation radical. This may be considered as direct evidence for the initiation reaction 2. During the subsequent step, the polymerization has been thought to proceed cationically as in reaction 3. The present result is compatible with this scheme in that the spectra of allylic end radicals can be assigned without taking into account any branched structures which often occur in radical propagation.

The reaction scheme implies two possible candidates for species with an allylic end: i.e., the dimer cation radical from reaction 2 and the propagating radical formed by reaction 3. Though the ESR measurement does not provide any direct information about this, the latter seems more probable since reaction 3 is known to take place with a nominal activation energy and, hence, at low temperature.[1a,15a]

The results suggest that similar mechanisms are also applicable to the methyl and dimethyl derivatives of 1,3-butadiene. This was demonstrated by the formation of radicals with the specific conformations of methyl groups, as expected from the 1,4-addition reactions. The observed hfc constants of all the diene cation radicals indicate that the unpaired electron is mainly located on positions 1 and 4, which also accords well with this scheme.

For reactions of the cation radicals of 1,3-pentadienes and 2-methyl-1,3-butadiene, there are two possible structures in forming allylic ends, as illustrated in Fig. 7. These two structures are

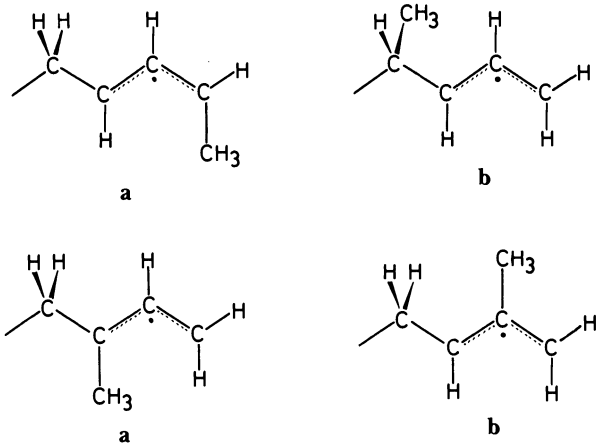

Fig. 7. Two possible structures of the allylic ends which may be formed by the polymerization of *cis*-1,3-pentadiene and 2-methyl-1,3-butadiene. Only the structures (a) were observed (see text). Similar scheme is applicable also to the reaction of *trans*-1,3-pentadiene cation radical.

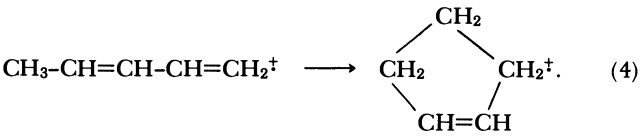
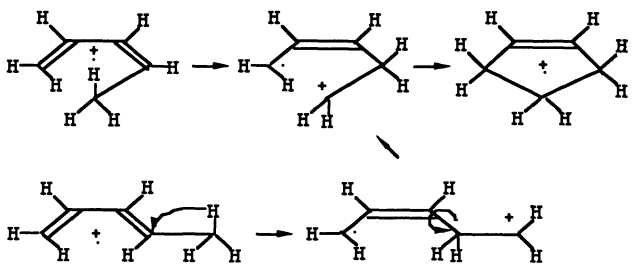
distinguishable from their ESR spectra. The results indicate that a specific structure **a** is formed exclusively for both of the cation radicals. This may be explained in terms of possible differences in hyperconjugative effects; i.e., the formation of the allylic ends **a** may be preferable because of their higher conjugation in π-systems.

As for the reactions of the cation radicals of 1,3-pentadienes, an alternative possibility of cation radical Diels–Alder reaction[16] has been discussed by Shiga and Okamura.[12] They observed a spectrum with a quintet structure separated by as much as 48.5 G for an irradiated CCl_4 solution of *cis*-1,3-pentadiene at 77 K and assigned it to a vinylcyclohexene-type cation radical. We obtained a similar spectra for irradiated solutions of *cis*- and *trans*-1,3-pentadienes in CCl_4, CCl_3F, and CCl_3CF_3 but found that these spectra could more reasonably be assigned to the cation radical of cyclopentene. Therefore, the absence of the primary cation radicals in these systems should be considered as being due to unimolecular isomerizations of the cation radicals of 1,3-pentadiene into the cation radical of cyclopentene.



It is noteworthy that the above reaction took place irrespective of the cis and trans forms of 1,3-pentadiene. They, in turn, have two possible conformations around the single bond: s-cis and s-trans. In forming the cyclopentene ring, however, the s-cis conformations seem preferable to s-trans conformations for both forms. In this case, the following mechanisms could illustrate the processes.



These mechanisms include 1,2-hydrogen atom shifts in froming the cation radical of cyclopentene. Another possible mechanism is a 1,4-hydrogen atom shift process. However, the necessary rearrangement of the carbon skeleton for the trans form is not conceivable in that case because of the double-bond nature of the 2,3-bond. Since isomerization was observed for both forms, the 1,2-hydrogen atom shift process is more appropriate.

As for the neutral molecules of 1,3-pentadienes, it is known that the s-trans is more stable from the results of the microwave spectra[17] and UV spectra.[18] In order to elucidate the stable conformations for the cation radicals of 1,3-pentadienes, we calculated the energies of these cation radicals by using the INDO method.[10] The result shows that the s-trans is more stable than s-cis conformation by ca. 10 kcal mol^{-1}. In a low-temperature matrix, nevertheless, these cation radicals might possibly have s-cis conformations as a result of matrix effects. In fact, it has been reported that the cation radicals of some alkanes do not have extended conformations but have less stable gauche conformations in the matrices of CCl_3F and CCl_3CF_3.[3,19] Therefore, we tentatively considered that the cation radicals of 1,3-pentadiene in CCl_4, CCl_3F, and CCl_3CF_3 specifically have s-cis conformations and are subject to the immediate isomerization into cyclopentene cation radicals. On the other hand, the cation radicals of 1,3-pentadiene in CCl_2FCCl_2F might remain as they are because of their s-trans conformations.

H_2 Evolution from Various Aqueous Solutions over Thermally Reduced TiO_2 and Pt-TiO_2 Powder

Akihiko KUDO, Kazunari DOMEN, Ken-ichi MARUYA, and Takaharu ONISHI*

(Received October 5, 1987)

The reduction of H_2O (or H^+) to form H_2 by reduced TiO_2 and Pt-TiO_2 was studied in distilled water and aqueous solutions of HCl, H_2SO_4, HNO_3, and NaOH. Over the reduced TiO_2 powder, H_2 evolved moderately in distilled water and Ti^{3+} ions on the surface were presumed to be active sites for the reaction. The reaction in aqueous NaOH solution proceeded similarly to that in water while it was strongly suppressed in aqueous HCl and H_2SO_4 solutions. It was found that the suppression of H_2 evolution is due to protons in the solution. Over reduced Pt-TiO_2, H_2 evolved rapidly from all solutions, except HNO_3. In aqueous HNO_3 solution, NO_3^- was reduced to NH_3 over reduced TiO_2 and Pt-TiO_2.

Recently TiO_2 has been extensively studied from several view points. It is well-known that TiO_2 has a photocatalytic activity under the band gap irradiation.[1] For example, the partial oxidation of hydrocarbons by O_2 on TiO_2 powder,[2,3] the photo-Kolbe reaction of acetic acid in aqueous media on platinized TiO_2,[4,5] the evolution of H_2 from aqueous solution of organic compounds,[6,7] and the photodecomposition of water on Pt-TiO_2[8] and NiO-TiO_2[9] were reported. The photoelectrochemical cell which consisted of a TiO_2 photoanode and a Pt cathode was also proved to decompose water into H_2 and O_2.[10,11] Although detailed mechanisms of these reactions have not been well-understood, the initiation of each reaction is recognized to generate an excited electron-hole pair by the absorption of a photon (>3 ev) in TiO_2. The generation of e^- and h^+ would be also regarded as the formation of Ti^{3+} and O^- species in TiO_2.

TiO_2 has been widely used also as supports for various heterogeneous catalysts, especially in recent years for the purpose of the study of the so-called strong metal support interaction (SMSI).[12] This phenomenon occurs when metals such as Ni and Pt supported on TiO_2 are reduced at high temperatures (>773 K). It is interpreted that the SMSI state is caused by the generation of Ti^{3+} by the high temperature reduction,[13-15] the migration of titanium oxide to metal surfaces[16-19] and so on.

Thus Ti^{3+} ions play an important role in the chemistry of TiO_2. The nature of Ti^{3+} produced by the band gap irradiation[20-25] and also by the thermal reduction[26-28] was investigated by some workers. However, few studies have been reported on the reaction of Ti^{3+} on TiO_2 powder in a liquid phase. In this paper, the behavior of H_2 evolution over thermally reduced TiO_2 and Pt-TiO_2 in various aqueous solutions, liquid water and water vapor was studied in order to reveal the activity of Ti^{3+} on the surface under the dark condition.

Experimental

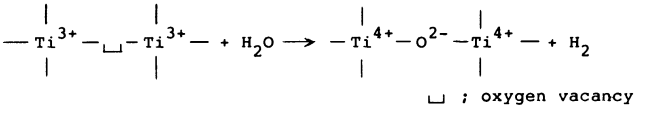
TiO_2 powder (aerosil; P-25) used was a mixture of rutile and anatase, and its surface area was 53 $m^2 \cdot g^{-1}$. Pt(1 wt%)-TiO_2 was prepared by mechanical mixing of Pt black (Kojima Chemical, purity; 99.99%) and TiO_2.

Pretreatments of TiO_2 and Pt(1 wt%)-TiO_2, and reactions with various solutions were carried out in a closed gas circulation system connected to a vacuum line. TiO_2 or Pt(1 wt%)-TiO_2 (1 g) was dispersed on a flat bottom reaction cell made of quartz. They were reduced by H_2 (ca. 40 kPa) at 773 K for 1 h and then H_2 was evacuated at the same temperature. The aqueous solution was degassed thoroughly and then introduced onto the reduced powder in the reaction cell without exposing to air.

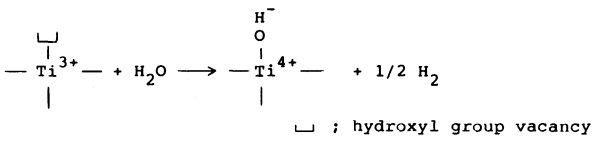
The amount of evolved H_2 was determined by gas chromatography (Ar carrier, MS-5A column) directly connected to the circulation system.

Results and Discussion

H_2 Evolution in the Reaction of Reduced TiO_2 and Pt-TiO_2 with Water. Behavior of H_2 evolution at 300 K from liquid and vapor water over reduced TiO_2 and Pt(1 wt%)-TiO_2 is shown in Fig. 1. The Pt-TiO_2 powder shows higher activity than TiO_2 and there is almost no difference in the activity between the reactions of liquid and vapor water. The evolution of H_2 on reduced TiO_2 is slow while that on reduced Pt-TiO_2 occurs immediately after the introduction of water. It is well-known that the reduced TiO_2 powder has Ti^{3+} ions and oxygen vacancies. When H_2 evolved from H_2O over the reduced TiO_2 powder the oxygen vacancies would be occupied by oxygen derived from H_2O. Therefore, a mechanism of H_2 evolution over the reduced TiO_2 surface is proposed as follows;



and/or



The driving forces are the reducing power of Ti^{3+} ions and stabilization energy of oxygen from water into the lattice oxygen. When TiO_2 powder is irradiated in aqueous solution containing a reducing agent such as alcohol, it is often observed that the color of TiO_2 changes from white to blue or gray, and a small amount of H_2 evolves. In this case, TiO_2 was reduced by a reducing agent with formation of oxygen vacancies on the surface and H_2 seems to evolve by a similar mechanism as stated above. On the other hand, in the case of Pt-TiO_2, the evolution of H_2 proceeds on the Pt surface after the electron transfers from reduced TiO_2 to Pt. This phenomenon is similar to that of the photocatalytic reaction for H_2 evolution from aqueous solutions. It was reported that the SMSI state of the Pt-TiO_2 system disappears when water exists.[29,30] This phenomenon may be explained by the oxidation of reduced TiO_2 by water via a similar process.

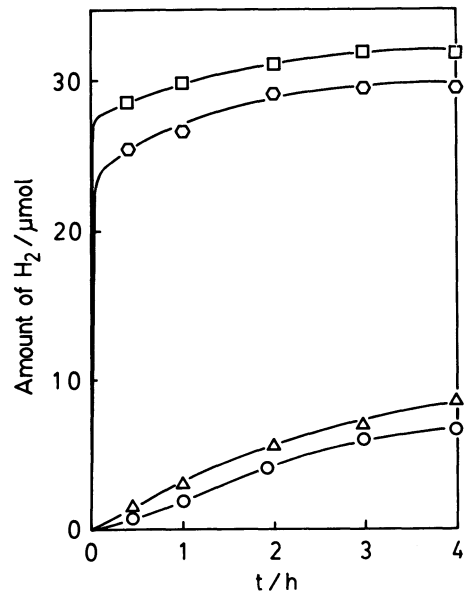


Fig. 1. H_2 evolution from liquid (10 ml) and vapor (3.2 kPa) water over reduced TiO_2 (1 g) and Pt(1 wt%)-TiO_2 (1 g) at room temperature.
□; liquid and ○ ; vapor over Pt-TiO_2, ○; liquid and △; vapor over TiO_2.

In Table 1, the amount of consumed H_2 by the reduction at 773 K and that of evolved H_2 from water are summarized. The extent of the reduction of TiO_2 by H_2 is different from that of Pt-TiO_2. In both cases, the amount of evolved H_2 is less than that of H_2 consumed during the reduction. The rate of H_2 evolution and the total amount of evolved H_2 increased with increasing the reaction temperature. The color of reduced TiO_2 was blue indicating the existence of Ti^{3+}, which was confirmed by ESR. After the reaction, the color was not completely recovered to original white at room temperature and even at 773 K. Furthermore, the evolution of H_2 was completely suppressed by the contact with O_2 (ca. 40 kPa) for 5 min at room temperature. The color was still blue in this case while it was rapidly turned into white by exposing to O_2 at 773 K. These results suggest that only Ti^{3+} existing close to the surface can react with H_2O, and the most of Ti^{3+} accompanied by oxygen vacancies in the bulk remains unchanged at room temperature. On the other hand, Ti^{3+} in the bulk can also react partially at 773 K. The apparent activation energy calculated from the initial rate of H_2 evolution over reduced TiO_2 was about 21 kJ·mol^{-1} below 473 K and about 50 kJ·mol^{-1} above 473 K. The activation energy is probably required for the H_2 evolution on reduced TiO_2 and the diffusion of a lattice oxygen from H_2O into the oxygen vacancy of the bulk respectively.

H_2 Evolution from the Reactions over Reduced TiO_2 and Pt-TiO_2 with Various Aqueous Solutions. The evolution of H_2 on the reactions of distilled water and aqueous solutions of NaOH, HCl, H_2SO_4, and HNO_3 over reduced TiO_2 is shown in Fig. 2. The evolution of H_2 from acidic solutions is much slower than those from distilled water and aqueous alkaline solution.

The rates of H_2 evolution at various concentrations of NaOH over reduced TiO_2 are shown in Fig. 3. The rate of H_2 evolution is moderately suppressed with increacing the NaOH concentration. On the contrary, in the case of reduced Pt-TiO_2, a large amount of H_2 evolves at the beginning of the reaction.

The evolution of H_2 from aqueous HCl solution

Table 1. The Amount of Ti^{3+} and That of Evolved H_2

	Consumed H_2 by the reduction at 773 K	Degree of reduction	Ti^{3+} total	Ti^{3+} surface[a]	Evolved H_2	
					at r.t.	at 773 K
	μmol	%	μmol	μmol	μmol	μmol
TiO_2	70	1.1	140	9	7	33
Pt-TiO_2	130	2.1	260	17	30	52

a) The amount of titanium ions on the surface was estimated to be ca. 800 μmol g^{-1} from a surface area by assuming a rutile (110) surface.

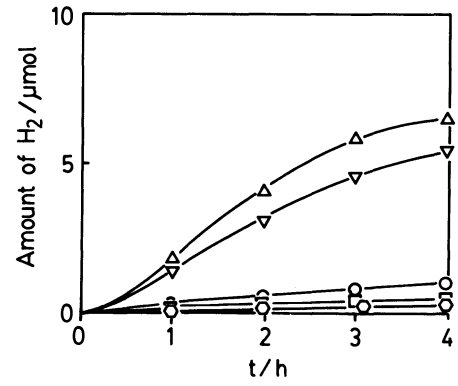

Fig. 2. H_2 evolution from various aqueous solutions (10 ml) over reduced TiO_2 (1 g) at room temperature. △; distilled water, ▽; 0.1 mol·dm^{-3} NaOH, ○; 0.1 mol·dm^{-3} HCl, □; 0.1 mol·dm^{-3} HNO_3, ○; 0.1 mol·dm^{-3} H_2SO_4.

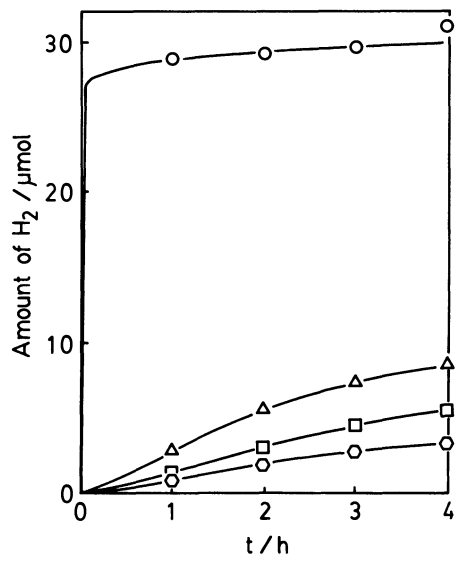

Fig. 3. H_2 evolution from aqueous NaOH solutions (10 ml) over reduced TiO_2 (1 g) and Pt(1 wt%)-TiO_2 (1 g) at room temperature.
○; 1 mol·dm^{-3} over Pt-TiO_2, △; 0.01 mol·dm^{-3}, □; 0.1 mol·dm^{-3}, ○; 1 mol·dm^{-3} over TiO_2.

over reduced TiO_2 and Pt(1 wt%)-TiO_2 is shown in Fig. 4. It was found that the reaction over reduced TiO_2 is strongly suppressed by HCl. Only a small amount of H_2 evolves in aqueous HCl solution (1 mol·dm^{-3}). The suppression effect of HCl on H_2 evolution is more remarkable than that of NaOH. The reaction in aqueous NaCl solution shows similar behavior to that in distilled water, which means the suppression was not owing to Cl^- ions. To examine the effect of HCl in more detail, the neutralization of aqueous HCl solution by NaOH solution was carried out during the reaction as shown in Fig. 5. Over reduced TiO_2 only a small amount of H_2 evolved in aqueous HCl solution (1 mol·dm^{-3}) in contrast to Pt which is a better catalyst for H_2 evolution. As soon as

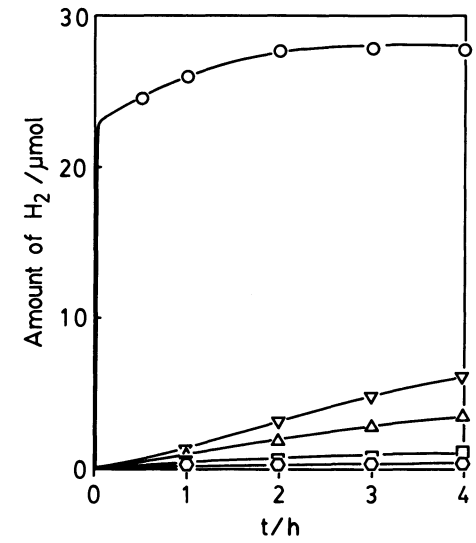

Fig. 4. H_2 evolution from aqueous HCl solutions (10 ml) over reduced TiO_2 (1 g) and Pt(1 wt%)-TiO_2 (1 g) at room temperature.
○; 1 mol·dm^{-3} over Pt-TiO_2, ▽; 0.01 mol·dm^{-3} (NaCl), △; 0.01 mol·dm^{-3}, □; 0.1 mol·dm^{-3}, ○; 1 mol·dm^{-3} over TiO_2.

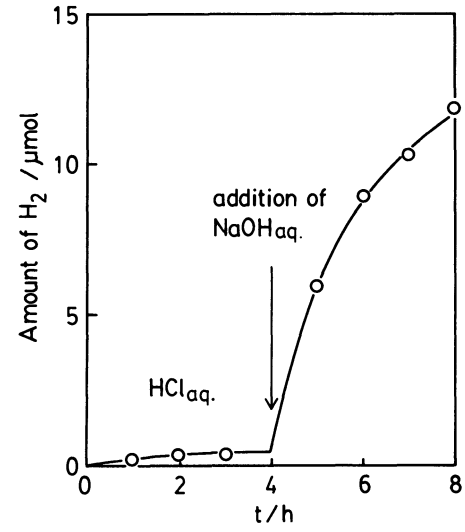

Fig. 5. Effect of addition of aqueous NaOH solution (1 mol·dm^{-3}, 10 ml) on H_2 evolution from aqueous HCl solution (1 mol·dm^{-3}, 5 ml) over reduced TiO_2 (1 g).

aqueous NaOH solution (1 mol·dm^{-3}) was added into the system, H_2 evolved rapidly. The resultant solution was in alkaline condition. From these results, it is inferred that H^+ suppresses the H_2 evolution over reduced TiO_2. Excess protons seem to poison the basic site which works as an electron donar center for H_2 evolution. Grätzel et al.[16] reported that Ti^{3+} species are produced when colloidal TiO_2 in acidic and alkaline solutions are irradiated, and ESR signals are different in acidic and in alkaline solutions. On the basis of these results it is concluded that the state of

Ti^{3+} on TiO_2 in acidic solution differs from that in alkaline solution. However, the detailed mechanism of the suppression of H_2 evolution by protons is not clear at present.

The reactions of aqueous HNO_3 solution over reduced TiO_2 and Pt(1 wt%)-TiO_2 were quite different from those of aqueous HCl and H_2SO_4 solutions. Instead of H_2 evolution, NH_3 was detected by the Nessler reagent in the solution after the reactions in both cases. This means that NO_3^- was preferentially reduced to NH_3 by Ti^{3+}. The photocatalytic reduction of NO_3^- into NH_3 by water over Pt-TiO_2 powder has already been reported.[31]

Structure of Platinum Particles Deposited on Titanium Dioxide (110) Surface Studied by X-Ray Photoelectron Diffraction

Koji TAMURA,* Masanori OWARI, and Yoshimasa NIHEI
Institute of Industrial Science, University of Tokyo,
7-22-1 Roppongi, Minato-ku, Tokyo 106
(Received October 9, 1987)

Platinum atoms deposited on a TiO_2 (110) surface were studied by X-ray photoelectron diffraction, and the structure of the platinum particles was clarified. It was found that after annealing at 823 K for 30 min the platinum particles coalesced and that the structural model of platinum particles based on the (111) surface of the fcc crystal explained the experimental XPED patterns very well.

Small metal particles are an interesting subject in the field of chemistry and physics.[1] Especially, the structure and the chemical state of noble metal particles on metal oxides are important in connection with supported metal catalysts.[2,3]

In general, in order to obtain structural information about small metal particles, transmission electron microscopy (TEM) or extended X-ray absorption fine structure (EXAFS) have been used. In order to obtain a TEM micrograph or microdiffraction pattern, the irradiation of small metal particles by an electron beam is essential. However, the damage caused by the high energy electron beam is serious. Iijima has studied ultrafine particles of gold by electron microscopy, and emphasized that the structure of the gold particles became unstable because of charge fluctuations when they were exposed to intense electron-beam irradiation.[4] It is also difficult for TEM measurement to use a well defined single crystal sample as a support. From EXAFS measurements, information on the surrounding atoms about a particular type of atom is obtained such as the number of neighboring atoms and their distance from the reference atom. This information is, however, insufficient to create a three dimensional structural model or determine the directional relation between overlayer and substrate.

X-Ray photoelectron diffraction (XPED) has been shown to be a promising new method for surface structural and chemical state analysis,[5,6] and does not have these drawbacks. The advantages of XPED measurement compared with other surface analytical methods are summarized as follows: 1) the charging of a sample does not prevent obtaining clear diffraction patterns; 2) long-range ordering is not necessary to obtain structural information; 3) the contribution as an emitter atom from each component can be distinguished. From these features, XPED measurement is considered to be a more desirable method to analyze the metal particles deposited on insulating materials like metal oxides than other conventional methods. Kudo et al. have applied XPED measurement to gold atoms evaporated on a semiconductor, namely, GaAs(110), (001), Ge(110), and GaSb(110), and characterized the surface layer of metal-semiconductor contacts.[7]

In this study, the XPED patterns for platinum atoms deposited on a TiO_2 (110) surface were obtained, and the structure of the platinum particles was analyzed by a theoretical calculation. This sample was studied as a well-defined model system of Pt/TiO_2 catalyst which is one of the most important systems among supported metal catalysts. When one attemps to explain catalysis, the phenomenon becomes ambiguous for practical catalysts, because of uncertainty about the impurities, or atomic structure of the substrate etc. To clarify the essential nature of catalysis, the investigation of model catalysts is very useful.

Experimental

All experiments were performed with an angle-resolved X-ray photoelectron spectrometer, which was equipped with a hemi-spherical electron energy analyzer and computer controlled multichannel detection system.[8] Aluminum $K\alpha$ radiation was used to excite photoelectrons. The base pressure of the system was less than 2.7×10^{-8} Pa.

A (110) oriented TiO_2 rutile single crystal, obtained from the Nakazumi Crystal Laboratory, was aligned to within $\pm0.5°$ of the desired orientation. This was checked by the Laue back reflection. The crystal was then mechanically polished, and chemically etched. Before measurements, the sample was cleaned by Ar^+-ion bombardment (700 eV) and annealing (1010 K) cycles. The temperature was monitored with a chromel-alumel thermocouple spotwelded to the sample holder. Since oxygen atoms diffused out from the bulk of the sample because of the annealing treatment, the surface stoichiometry change caused by the selective sputtering was sufficiently restored. This was checked from the shape of Ti2p spectra and the valence spectra. The cleanliness of substrate surface was checked by X-ray photoelectron spectroscopy, and no carbon nor other impurities were detected.

The platinum was evaporated in vacuum by resistively heating from a pure platinum ribbon onto the titanium dioxide. The deposition rate of platinum was approximately 0.08 Å min^{-1}. To eliminate the apparent shift caused by the charging of the sample, the binding energy of platinum 4f was calibrated from the $Ti2p_{3/2}$ peak (458.8 eV).

Results and Discussion

The azimuthal dependences of Ti2p emission from TiO_2 (110) at a polar angle θ=50° relative to the surface normal are shown in Fig.1(a). The XPED pattern exhibited much fine structure, which indicated that the crystal regularity was sufficiently restored after the annealing treatment. The XPED pattern was mirror symmetric about the azimuthal angle ϕ=0° ([1$\bar{1}$0] direction of TiO_2) and 90° ([001] direction), which reflected the crystal structure. Though it was impossible to obtain full 360° azimuthal dependences by one scan with our system, different part of the azimuthal dependences which are not shown in this figure was checked by another experiment. These results indicated that the XPED pattern of TiO_2(110) has two-fold symmetry.

Figure 2 shows the XPS signal intensity (a) and the binding energy (b) of the Pt4f level as a function of the metal coverage. It was evident from these results that the binding energy of $Pt4f_{7/2}$ level decreased as the metal coverage increased. The decrease of the binding energy was caused mainly by the change of the degree of the screening of a core-hole by the electrons of

neighboring atoms.[3] In larger particles, since there were more neighboring electrons, the screening was more effective than in smaller particles, and the binding energy lowered. The amount of platinum deposited after the final step of the deposition was equivalent to the layer 15.8 Å in thickness, if layer growth was assumed. This thickness was roughly estimated from the XPS signal intensity ratio of Pt4f peak to Ti2p peaks assuming that the mean free path is 20 Å. XPED patterns were measured at this final point.

The azimuthal dependences of Pt4f emission at polar angles θ=53° (Fig.1(b)) and θ=33° (Fig. 3(a)) just after deposition were obtained. As can be seen in these XPED patterns, the photoelectron intensity maxima were already observed at ϕ=0°, 60°, 120°, which indicated that the platinum had structural regularity to some degree.

The sample was then annealed at 823 K for 30 min, which caused some significant changes. First, the XPS intensities for titanium and oxygen atoms relative to platinum atoms increased. Thus, the average thickness of the platinum, determined from the XPS signal intensity ratio, decreased to 7.6 Å. Second, as shown in Fig. 1 (c) for θ=53° and Fig. 3 (b) for θ=33°, the modulation of the XPED patterns increased and the patterns became clear. The amplitude of the anisotropy, defined as the ratio of (maximum−minimum)/maximum for θ=53°(Fig. 1 (b), (c)), increased from 16% to 29%. In contrast to the pattern from the titanium atom (Fig.1 (a)), these patterns can be regarded as having six-fold symmetry rather than two-fold symmetry.

These results indicated that most of platinum particles coalesced and became larger (metal agglomeration) on heat treatment, and simultaniously the degree of crystallization of the Pt particles and the degree of epitaxial relation between overlayer and substrate increased. Since the exposed area of the substrate surface increased on coalescence of the platinum particles, the XPS intensity from the substrate increased. On the other hand, since the exposed surface area of the platinum particles decreased on coalescence, the intensity from overlayer decreased. As a result, the Pt/Ti signal ratio decreased.

The diffusion of platinum atoms into the substrate may also decrease the Pt/Ti signal ratio, but this contribution was not so large, because 1) the chemical state of the platinum atom in the substrate must be different from that on the substrate, and these differences must be reflected in the platinum spectra. But no significant changes were observed in the platinum 4f spectral region. 2) if platinum atoms diffused into the substrate, the XPED pattern shows two-fold symmetry (selective incorporation case) or smaller modulation (random incorporation case), which were different from the experimental observation.

Assuming the coalescence is due to annealing only, the degree of coalescence could be estimated roughly based on a simple model as follows. The model is shown in Fig. 4 (a),(b). Hemi-spherical particles were assumed on the basis of the experimental observation by electron microscopy that the platinum particles grew in an island-like fashon on TiO_2.[9] The highly dispersed particles (a) just after deposition coalesced and became larger particles (b) because of annealing. Based on this model, the XPS signal intensity of the platinum atom for normal exit angle after annealing was written as

$$I_{Pt} = 2\pi I^{\infty}_{Pt}\left[\frac{1}{2}N^{2/3}a^2 - \int_0^{N^{1/3}a} r\cdot\exp(-\sqrt{N^{2/3}a^2 - r^2}/\lambda)\mathrm{d}r\right]. \quad (1)$$

The XPS intensity of the titanium atom in the exposed substrate was written as

$$I_{Ti}(1) = I^{\infty}_{Ti}(2\sqrt{3}N - \pi N^{2/3})a^2, \quad (2)$$

and the intensity of the titanium under the platinum particle was

$$I_{Ti}(2) = 2\pi I^{\infty}_{Ti}\left[\int_0^{N^{1/3}a} r\cdot\exp(-\sqrt{N^{2/3}a^2 - r^2}/\lambda)\mathrm{d}r\right], \quad (3)$$

where I^{∞}_{Pt} and I^{∞}_{Ti} were the XPS intensities of platinum and titanium from a semi-infinite platinum and TiO_2 layer, respectively; λ was the attenuation length, and a

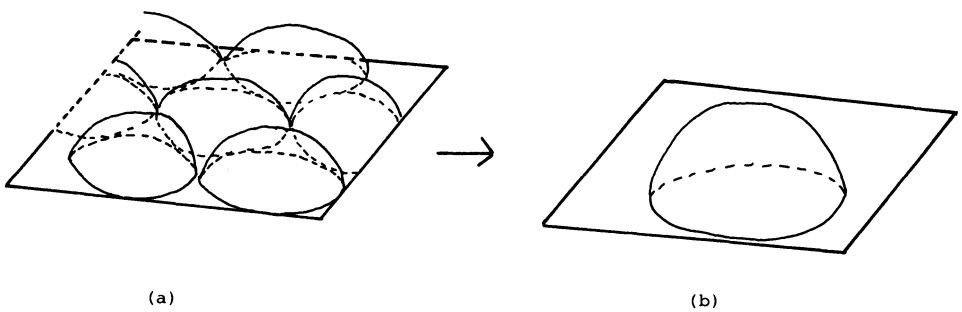

Fig. 4. Schematic representation of platinum particles on TiO_2(110) (a) just after deposition and (b) after annealing at 823 K for 30 min.

the radius of a particle just after deposition. N was the number of particles which gathered and became one larger particle because of the annealing treatment. Thus, the relative intensity of Pt to Ti after annealing became (1)/((2)+(3)), and the degree of coalescence N could be determined from the experimental signal ratio. It was estimated from the experimental XPS data that because of the heat treatment the volume of a particle increased about 26 times, and the exposed surface area of the platinum particles decreased to about 34% of that before annealing.

Ocal et al. have observed that annealing at 800 K in vacuum, which was almost the same treatment as our study, caused the suppression of CO adsorption for a Pt/TiO_2 sample and the uptake of CO per Pt atom was reduced by a factor of 2.[10] They suggested its relation to, what is called, strong metal-support interaction (SMSI), which recently attracted much interests in the field of catalysis.[11] The predominant model to explain this phenomenon is called the migration or decoration model, in which, titanium sub-oxide TiO_x migrates from a substratum and covers the surface area of the dispersed metal.[12] This may also decrease the Pt/Ti signal ratio. Ocal et al. also observed the Ti^{3+} state after vacuum annealing of a Pt/TiO_2 sample at 800 K, and the relative concentration of Ti^{3+} to Ti^{4+} ion was about 20%.[10] Greenlief et al. have observed the Ti^{3+} state after the vacuum annealing of TiO_2 overlayer on Pt at 1300 K,[13] which was higher than our temperature. They suggested a model in which the reduced titania species diffused into the platinum layer. Figure 5 shows the experimental spectra of Ti2p emission before platinum deposition (a) and after the annealing treatment (b). The height of these spectra was normalized and all of the spectra were smoothed. After annealing under these experimental conditions, namely, platinum deposited on TiO_2 (110) single crystal annealed in UHV at 823 K for 30 min, a small amount of a lower binding energy state did appear. But even if it covered the surface of the Pt particle because of migration, its contribution to the decrease of the Pt/Ti signal intensity ratio after the annealing was small. This indicated that the large decrease of the Pt/Ti ratio was not caused by the migration of sub-oxide onto the Pt particle.

The structural analysis of the platinum particles was next investigated by theoretical calculations. The calculations were performed within the double scattering approximation, in which the total photoelectron wave was expressed as a sum of a direct wave, a single-scattering wave and a double-scattering wave. The scattering amplitude for the double-scattering wave was a product of each scattering amplitude. Inelastic damping factors were derived from a sum of each path. Elastic scattering amplitudes were obtained from tabular form data.[14] The cluster of atoms used in this calculation consisted of a hemi-spherical platinum cluster 15 Å in radius

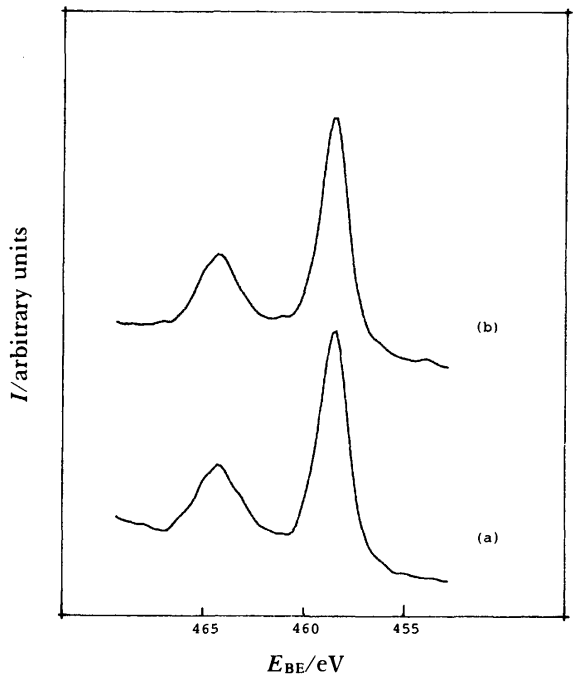

Fig. 5. XPS spectra of Ti2p from (a) clean TiO_2(110) surface and (b) Pt/TiO_2(110) annealed at 823 K for 30 min.

and a substrate cluster whose atoms were within 10 Å to the emitter atom. Since the six-fold symmetry of the experimental results was explained by the multiple of two fold-symmetry of the substrate and three-fold symmetry of the overlayer, it was sufficient to assume only the structural model based on the (111) plane of fcc platinum crystal. Two cluster models No. 1 and No. 2 were assumed and they are shown in Fig. 6(a),(b). The cluster model No. 1 is expressed as follows; (111) plane of platinum is parallel to the (110) surface of titanium dioxide (Fig. 6(c)) and [$\bar{2}$11] direction of the former is parallel to [1$\bar{1}$0] direction of the latter. The cluster model No. 2 is mirror symmetric with the model No. 1 about the (1$\bar{1}$0) plane of the substrate. The calculated patterns obtained from model No. 1 and No. 2 are shown in Fig. 7(b) and (c), respectively, for θ=53°, together with corresponding experimental pattern (a). For θ=33° Fig. 3(c) and (d) show the calculated patterns from model No. 1 and No. 2, respectively. These platinum patterns were three-fold symmetric and did not agree with the experimental pattern. These two models were equivalent from the standpoint of the structural relationships between substrate and overlayer. When two clusters exist with equal probability on the surface of titanium dioxide, corresponding patterns were obtained as shown in Fig. 7(d) for θ=53° and Fig. 3(e) for θ=33°. From the comparison, it was found that the calculated patterns at θ=53° and θ=33° agreed well with the experimental pattern. This model also explained other experimental results very well which were obtained by the different angular scans. Since the XPED pattern is sensitive to the crystal structure, it was concluded from the XPED analysis that after the platinum deposition the two orientations of clusters based on the (111) surface of the fcc crystal existed with equal probability on the TiO_2(110) surface.

The amplitude of the anisotropy for the calculated pattern for θ=53° was 96%, and was much larger than that of the experimental pattern. This deviation was explained as follows. First, in this calculation, thermal vibration of the platinum lattice was neglected. Second, emitter atoms were assumed to exist only in the center of the cluster. As a result, the contributions from the platinum atoms, which existed in the near surface region of the platinum particle, were not included. Since the intensity modulation for these platinum atoms is less than that of in the center, the modulation of the calculated pattern was overestimated. On the other hand, the degree of ordering of the real platinum particles was possibly lower than that of ideal bulk crystal, which diminished the modulation of the experimental pattern.

Figure 7(e) shows the calculated pattern which involved only a single scattering of the electrons. From the comparison it was found that the agreement of the pattern was worse and the double scattering was proved to be more accurate.

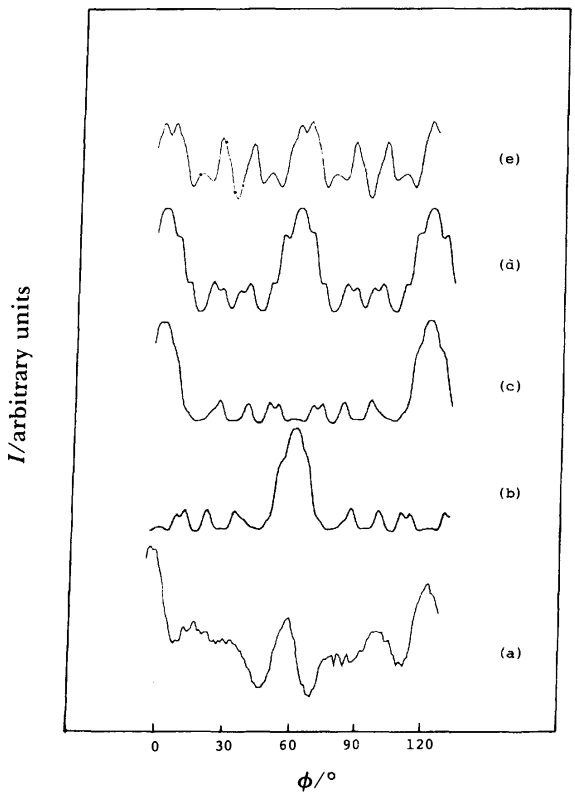

Fig. 7. (a) Azimuthal pattern of Pt4f at θ=53° after annealing at 823 K for 30 min. (b) Calculated pattern from platinum No. 1 considering double scattering. (c) Calculated pattern from platinum No. 2. (d) Calculated pattern when two types of particles exist. (e) Calculated pattern considering only single scattering.

Wang et al. have observed by transmission electron microscopy (TEM) that Pt particles on SiO_2 were produced with predominantly (100) and (110) planes if grown and treated in H_2, contrary to the prospect from surface free energy.[15] Our experimental results, however, showed that, when annealed in UHV, the (111) plane was the most favored, as expected for an ideal surface structure of a fcc crystal. Since the modulation of the XPED pattern of platinum after annealing was large, the contributions from the different structural particles or randomly oriented particles were small, and the structure of most of the particles was expressed by the model shown in Fig. 6. Also, the dynamic movement of the platinum particles, such as gold particles under the TEM observation, did not occur, because clear XPED patterns could not be obtained from the unstable particles.

As shown above, the structure of platinum particles deposited on a TiO_2 (110) surface was determined by XPED measurements. Moreover, the XPED analysis proved to be a useful technique for structural analysis

of the dispersed metal particles on the metal oxide, which were very difficult to analyze by any other technique.

We thank Dr. Masahiro Kudo for his technical assistance and for useful discussion.

Effect of Counterionic Species on the Adsorption of Tetradecyltrimethylammonium Ion at the Polarized Nitrobenzene-Water Interface

Takashi KAKIUCHI, Miki KOBAYASHI, and Mitsugi SENDA*
Department of Agricultural Chemistry, Faculty of Agriculture, Kyoto University, Sakyo-ku, Kyoto 606
(Received October 16, 1987)

The effect of counterions, F^-, Cl^-, and Br^- on the adsorption of the hexadecyltrimethylammonium ion ($HTMA^+$) at the polarized nitrobenzene-water interface has been studied by measuring electrocapillary curves. The interfacial tension in the negative branch of the electrocapillary curve, where the interface is polarized such that the potential in the aqueous phase is negative with respect to that in the nitrobenzene phase, was lowered due to the specific adsorption of $HTMA^+$ ion at the interface. The magnitude of interfacial tension depression in the negative branch became larger in the order F^-, Cl^-, and Br^-, indicating a specific counterion binding at the interface in this order. The adsorption free energy of the $HTMA^+$ ion, ΔG_a^0, for the adsorption of $HTMA^+$ ion at the interface from the nitrobenzene phase was found to depend markedly on the anionic species present in the aqueous side of the interface. This ΔG_a^0 values can be taken as a quantitative measure of the counterion specificity at the interface. The meaning of the fact that the change in the shape of the electrocapillary curves depends on the counterion species is discussed in detail in terms of the thermodynamics of the oil-water interface.

The counterion specificity in interfacial chemistry and colloid chemistry has long been recognized. For example, the critical micelle concentration of cationic surfactants with different counterionic species decreases, while its micelle size increases, in accordance with the Hofmeister series of counterions.[1] A similar counterion specificity has been observed in a wide variety of surface phenomena, including surface pressure-area curves at air-water interfaces,[2] flocculation of colloidal particles,[3] and the rate of a chemical reaction at the interface.[4] However, only a few attempts have been made to quantitatively estimate the counterion specificity on the surface activity of surfactants.[5-7] Particular attention has recently been focused on the counterion binding at micelle surfaces in relation to micellar catalysis.[8] In these studies, the micelle was treated as a pseudophase and the relative affinity of counterions to the micelle surface has been estimated in terms of the ion-exchange constants of counterions.[8] In the previous paper we reported on the adsorption behavior of hexadecyltrimethylammonium ion at the polarized nitrobenzene-water interface, where an electrical double layer structure can be studied in the well defined electrical conditions of the interface.[9] This type of an interface provides us with a useful means to study the effect of counterion specificity to the surface properties of ionic surfactants. The present paper deals with the effect of counterion species on the adsorption of hexadecyltrimethylammonium ion ($HTMA^+$) at the polarized nitrobenzene-water interface. The advantage of this approach is that the counterion specificity can be quantitatively estimated through the adsorption free energy, which is obtainable as a function of the potential drop across the interface. Furthermore, in this approach the surfactant and its counterion to be studied reside in separate phases; they interact with each other only at the interface. This makes the interpretation of the experimental data much simpler, since the effect of the counterionic species in the bulk phase, e.g., salting out effect which may exists when both of them are in the same phase, needs not be considered.

Experimental

The interfacial tension of the nitrobenzene-water interface was measured with the drop time method using a dropwise ascending electrolyte solution electrode.[10] This electrode was also used to record current vs. potential curves using a four-electrode potentiostat with a positive feedback circuit for iR compensation. Details of the measurements and the method of calculation to convert the drop time into the interfacial tension value have been described previously.[10] All measurements were made at 25.00±0.05 °C. Methods for the preparation of hexadecyltrimethylammonium tetraphenylborate(HTMATPB), tetrapentylammonium tetraphenylborate(TPnATPB), and lithium tetraphenylborate (LiTPB) have been described elsewhere.[9,11] Lithium bromide and lithium fluoride were of Spurpur grade(Merck). Nitrobenzene was distilled under reduced pressure and then treated with active alumina. Triply distilled water was used to prepare the aqueous solutions.

Results and Discussion

0.5 M LiBr (W)	AgBr	Ag	(II)

where M=mol dm^{-3}. The saturated solution of LiF whose concentration is 0.499 mol dm^{-3} at 25 °C[12] was used for the aqueous phase in Cell (I). The concentration of HTMATPB was varied from 0 to 0.1 mol dm^{-3} while keeping the total concentration of TPnATPB and HTMATPB in the nitrobenzene phase constant at 0.1 mol dm^{-3}. This mixed electrolyte method[13] has been conveniently used for obtaining a specifically adsorbed amount of $HTMA^+$ ion from the electrocapillary curves.[9]

The potential of the right-hand side of the Cells (I) and (II) with respect to the left is indicated as E^{W-}_{O-}, where the super- and subscripts indicate that the reference electrodes in the aqueous phase and the nitrobenzene phase are reversible to the anion (Cl^-) and the anion (TPB^-), respectively.[9] Figures 1a and 1b show the current vs. potential curves recorded for Cells (I) and (II). The polarized potential ranges for Cell (I) in the presence and the absence of HTMATPB

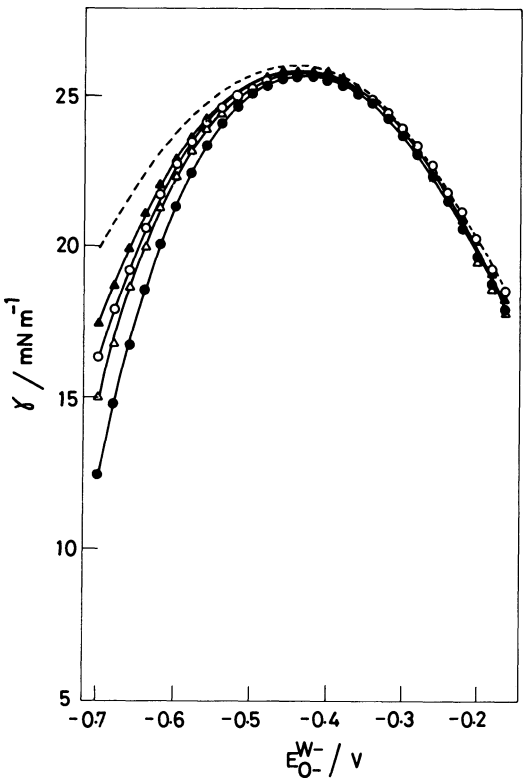

Fig. 2. Electrocapillary curves for the interface between aqueous solution of 0.05 mol dm^{-3} LiF and nitrobenzene solution of (0.1−a) mol dm^{-3} TPnATPB and a mol dm^{-3} HTMATPB, where a=0(-----), 0.01(−△−), 0.02(−○−), 0.04(−△−), and 0.10(−●−).

in the nitrobenzene phase were the same (Fig. 1a). On the other hand, the polarized potential range for Cell (II) was narrower in comparison with those for Cell (I) irrespective of the presence of HTMATPB (Fig. 1b). This is probably due to the transfer of Br^- ions from the aqueous phase to the nitrobenzene phase in the negative extreme range of the polarized potential. The standard ion transfer potential of Br^- ion is -0.295 V and is at least 30 mV more positive than that of Cl^- ion.[11] Figure 1b shows that there still remains a polarized potential range of about 300 mV. The electrocapillary measurements for Cells (I) and (II) were made within these polarizable potential ranges.

The electrocapillary curves were recorded at intervals of 20 mV for seven different concentrations of HTMATPB, from $x=0$ to 0.1. Some of the results are shown in Figs. 2 and 3. For both cases the interfacial tension was lowered with the increase of the HTMATPB concentration in the negative branch, i.e., $E^{w-}_{o-}-E_{pzc}<0$, where E_{pzc} is the potential of zero charge at $x=0$. This lowering of the interfacial tension indicates the existence of the specific adsorption of $HTMA^+$ ion at the interface.[9]

The electrocapillary curves at $x=0.1$ mol dm^{-3} for LiF, LiCl, and LiBr as the electrolyte in aqueous phase are compared in Fig. 4, in which the potential scale is relativized with respect to the E_{pzc} obtained with different reference electrodes. The degree of interfacial tension depression was larger in the sequence of LiF, LiCl, and LiBr. The result in Fig. 4 indicates that the specific adsorption of $HTMA^+$ ion is enhanced in this order. Since in the negative branch the potential of the aqueous phase is negative with respect to the nitrobenzene phase and the anionic species (F^-, Cl^-, or Br^-) exceeds the cationic species in the vicinity of the aqueous side of the interface, this enhancement of the adsorption strongly suggests the existence of a specific interaction between the charged head group of the adsorbed $HTMA^+$ ions and the anions in the aqueous side of the interface. This anion effect ensures that the polar head groups of the adsorbed $HTMA^+$ molecules are exposed to the aqueous phase so that it can interact with the counterion in the aqueous phase. The trend of the counterion effect in Fig. 4 is in marked contrast with the results reported by Watanabe et al.[6] They studied the adsorption of $HTMA^+$ ion at the methyl isobutyl ketone–water interface under the less polarized conditions compared with Cells(I) and (II) and found that the interfacial tension in the negative branch was decreased in the order, I^-, Br^-, Cl^-, and F^-.

The specifically adsorbed amount of the $HTMA^+$

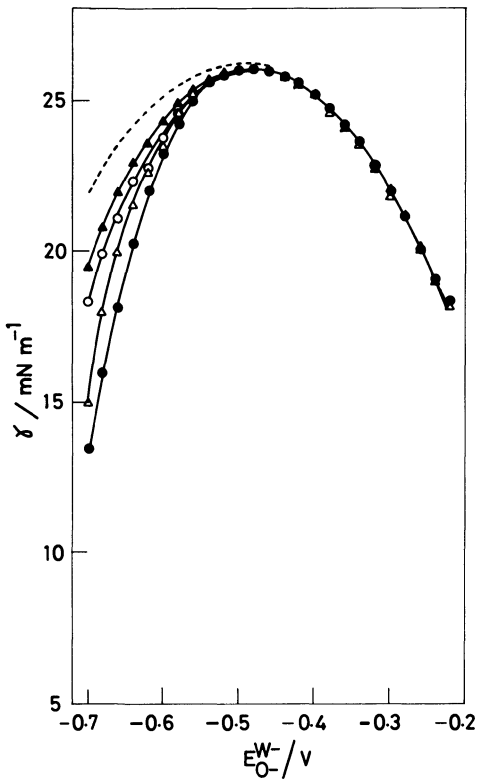

Fig. 3. Electrocapillary curves for the interface between aqueous solution of 0.05 mol dm^{-3} LiBr and nitrobenzene solution of (0.1−a) mol dm^{-3} TPnATPB+a mol dm^{-3} HTMATPB, where a= 0(-----), 0.02(−△−), 0.03(−○−), 0.05(−△−), and 0.10(−●−).

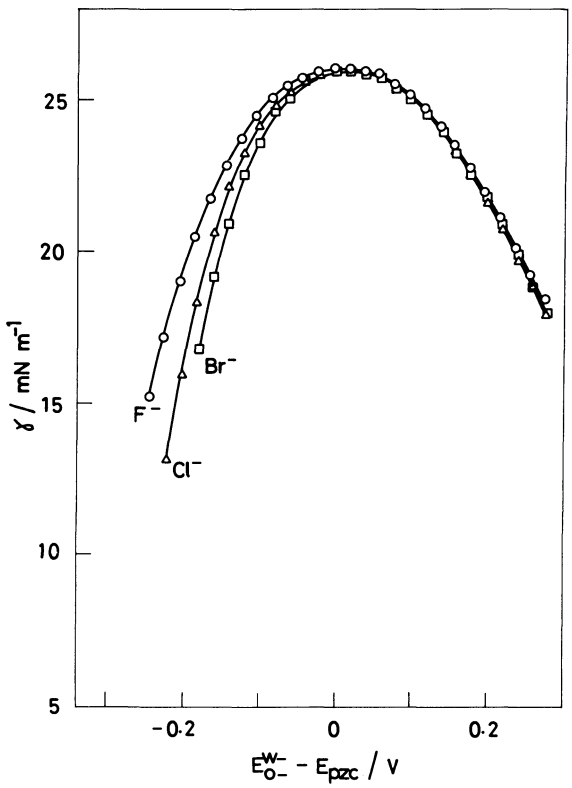

Fig. 4. Comparison of the electrocapillary curves for the interface between nitrobenzene solution of 0.1 mol dm^{-3} HTMATPB and aqueous solution of 0.05 mol dm^{-3} LiF(−○−), LiCl(−△−), or LiBr(−□−).

ions at a given potential was obtained from the electrocapillary curves by applying the electrocapillary equation modified for mixed electrolyte method.[9] The adsorption isotherms for both cases were well described by the Vorotyntsev's isotherm[14] which is a virial type isotherm of the form:

$$\ln(c/q^*) = \frac{\Delta G_a^0}{RT} + 2vq^*, \quad (1)$$

In Eq. 1, c is the bulk concentration of the surface active compound, v is the interaction parameter, and q^* is the adsorbed amount expressed in $\mu C\,cm^{-2}$ and is defined by $F\Gamma$, where F is Faraday and Γ the surface concentration. The adsorption free energy of $HTMA^+$ ion, ΔG_a^0, referrs to the standard states of 1 mol dm^{-3} and 1 $\mu C\,cm^{-2}$ for the nitrobenzene solution and the adsorption layer, both based on infinite dilution. From the intercepts of $\ln(c/q^*)$ vs. q^* plots at the different potentials, ΔG_a^0's were obtained (Fig. 5). The results for LiCl reported previously are also included in Fig. 5. ΔG_a^0's were linearly dependent on the potential difference, which was also the case for LiCl. The slopes of the straight lines were 5.0×10^4, 5.0×10^4, and 3.8×10^4 C mol^{-1} for F^-, Cl^-, and Br^-, respectively. Thus, the curves for F^- and Cl^- are in parallel with each other, suggesting that the effect of the applied voltage on the ΔG_a^0 value is essentially in electrostatic nature.[9] The slope for Br^- is smaller than these, but the difference is not very significant because of the experimental uncertainty. The vertical distance between these straight lines in Fig. 5 at a given potential can be seen as a direct and quantitative measure of the relative affinity of the polar head group of the $HTMA^+$ ion with the counterion in the aqueous phase. The difference in ΔG_a^0, $\Delta\Delta G_a^0$, is a quantitative measure of the affinity of the trimethylammonium head group of $HTMA^+$ ion with a counterion at the interface, provided that the maximum adsorptions of $HTMA^+$ for various counterions are the same. The maximum adsorption of the $HTMA^+$ ion is not likely to depend on the counterionic species. $\Delta\Delta G_a^0$'s at $E_{O-}^{W-}-E_{pzc}=-0.2$ V are shown in Table 1. $\Delta\Delta G_a^0$ for F^-–Br^- pair is four times greater than $\Delta\Delta G_a^0$ for F^-–Cl^- pair, suggesting the strong affinity of the trimethylammonio group and Br^- ion at the interface. Larsen and Magid have found that the enthalpy change of Br^- with respect to F^- for the transfer of ion from water to 0.1 mol dm^{-3} $HTMA^+$ aqueous solution is also four times larger than the corresponding value of Cl^- ion transfer.[15] This correspondence suggests the enthalpic nature of the factor that determines the counterion specificity.

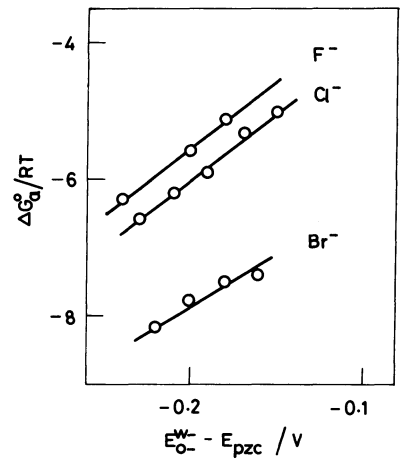

Fig. 5. Dependence of ΔG_a^0 of $HTMA^+$ ion on the potential drop across the interface between nitrobenzene and aqueous solution containing 0.05 mol dm^{-3} LiF, LiCl, or LiBr.

F^-–Br^-	—	2.9	8.7	4.6

a) Davies.[5] b) Watanabe et al.[6] c) Goddard et al.[7] d) Present results.

Table 1 also includes the energies of the interaction between the counterion and the trimethylammonio head group of alkyltrimethylammonium ion surfactant in the monolayer estimated from various methods by Davies,[5] Watanabe et al,[6] and Goddard et al.[7] As shown in Table 1 all values obtained from three independent methods have the same order of magnitude. However, quantitatively there are discrepancies between them. Davies calculated the value from surface viscosity of the octadecyltrimethylammonium ion monolayer at the air-water interface. The value, therefore, involves the simplified assumptions which became necessary in order to estimate the interaction energies from kinetic data. Goddard et al. used the change in the surface pressure vs. area curves of docosyltrimethylammonium ion at the air-water interface at various subphase compositions. Their data also show the strong affinity of the trimethylammonio head group with Br^-. However, the values of $\Delta\Delta G_a^0$ are twice larger than ours. They assumed that the decrease of the surface pressure due to the specific interaction of $HTMA^+$ with the counterion was realized equivalently by increasing the ion concentration exhibiting no specific interaction with the head group. Since the specific adsorption, if any, cannot be solely attributed to the surface concentration term, their assumption is not likely to be valid in general.

Watanabe et al. calculated the ΔG_a^0 value employing the electrocapillary equation. It is interesting that they obtained a trend for ΔG_a^0 similar to ours, in spite of the fact that the effect of counterion on the surface tension depression in the electrocapillary curves they

found was reverse to the present result as described above. They interpreted the lesser degree of interfacial tension depression in the negative branch as a decrease in the surface charge density caused by the counterion binding with the head group of the adsorbed surfactant. However, their interpretation contradicts the following thermodynamic reasoning of the surface charge density obtained from an electrocapillary curve. At constant temperature, pressure, and the potential, the electrocapillary equation may be written in the integral form:

$$\gamma^0 - \gamma = RT\int_0^c \Gamma \mathrm{d}\ln c, \tag{2}$$

where Γ is the surface excess, γ is the interfacial tension, and c is the concentration of a surface active substance. Thus, the magnitude of the interfacial tension depression is directly related to the adsorbed amount of the surfactant, rather than to the amount of ion-pairs formed at the interface. Secondly, the change in the surface charge density accompanied by the adsorption of a surface active substance can generally be expressed in terms of the adsorbed amount of the substance at the interface without resorting to the concept of counterion binding. It is known that the adsorption of most of the surface active substances at an electrified interface follows an adsorption isotherm of the form:[16]

$$\Gamma = \Gamma(\beta c) \tag{3}$$

where β is the adsorption coefficient and is related to ΔG_a^0 through $\Delta G_a^0 = -RT\ln\beta$. Then the change in the surface charge density, q, due to the adsorption of a surface active substance can be expressed through[17]

$$q - q^0 = RT\frac{\mathrm{d}\ln\beta}{\mathrm{d}E}\Gamma \tag{4}$$

where E is the electrical potential difference. Since $\mathrm{d}\ln\beta/\mathrm{d}E$ is not much different for F^-, Cl^-, and Br^- in the present results, the change in the slope of the electrocapillary curves can be attributed to the difference in the adsorbed amount of $HTMA^+$ ion and is not directly related to the counterion binding.

Further insight concerning counterion binding may be obtained from the electrocapillary equation in the presence of ion-pair formation at the interface. Suppose that a cation $\bar{i}$ in the oil phase and an anion $\bar{q}$ in the aqueous phase form a neutral species $\bar{i}_{\nu_{\bar{i}q}^+}\bar{q}_{\nu_{\bar{i}q}^-}$ due to ion-pair formation,

$$\nu_{\bar{i}q}^+(\bar{i}) + \nu_{\bar{i}q}^-(\bar{q}) = (\bar{i})_{\nu_{\bar{i}q}^+}(\bar{q})_{\nu_{\bar{i}q}^-}, \tag{5}$$

where $\nu_{\bar{i}q}^+$ and $\nu_{\bar{i}q}^-$ are the stoichiometric numbers. If we assume for simplicity that the ion-pair exists only at the interface and is present neither in the oil phase nor in the aqueous phase, the following additional terms appear in the right-hand side of the basic electrocapillary equation for oil-water interface (Eq. 16 in Ref. 18):

$$\Gamma_{\bar{i}q}\left[\frac{\nu_{\bar{i}q}^+}{\nu_{\bar{i}\bar{j}'}^+}\mathrm{d}\mu_{\bar{i}\bar{j}'} + \frac{\nu_{\bar{i}q}^-}{\nu_{\bar{p}\bar{q}}^-}\mathrm{d}\mu_{\bar{p}'\bar{q}} - \frac{\nu_{\bar{i}q}^+ z_{\bar{j}}}{\nu_{\bar{i}'\bar{j}'}^-|z_{\bar{j}'}|}\mathrm{d}\mu_{\bar{i}'\bar{j}'} - \frac{\nu_{\bar{i}q}^-|z_{\bar{q}}|}{\nu_{\bar{p}'q'}^+ z_{\bar{p}'}}\mathrm{d}\mu_{\bar{p}'q'}\right]$$
$$+ z_{\bar{i}}\nu_{\bar{i}q}^+\Gamma_{\bar{i}q}\left(\frac{1}{z_{\bar{i}'}}\mathrm{d}\tilde{\mu}_{\bar{i}'} + \frac{1}{|z_{q'}|}\mathrm{d}\tilde{\mu}_{q'}\right), \tag{6}$$

where $\tilde{\mu}$ is the chemical potential and z is the ionic charge. Equation 16 in Ref. 18 as well as these additional terms are derived for the case in which the reference electrodes in the oil phase and aqueous phase are reversible to the ions i' and q', respectively. The last term in the above expression shows that the term $z_{\bar{i}}\nu_{\bar{i}q}^+\Gamma_{\bar{i}q}$ contributes to the derivative of γ with respect to the potential, i.e.,

$$-\frac{1}{F}\left(\frac{\partial\gamma}{\partial E_{O-}^{W-}}\right)_{T,P,\mu} = \sum_p z_p\Gamma_p - \sum_q z_q\Gamma_q - z_{\bar{i}}\nu_{\bar{i}q}^+\Gamma_{\bar{i}q} \tag{7}$$

where p and q represent cations and anions in the aqueous phase. The first two terms on the r.h.s. of this equation represent the excess surface charge density in the aqueous phase. The surface charge density in the aqueous phase is negative in the potential range where the adsorption of the $HTMA^+$ ion takes place. Therefore, the additional term $z_{\bar{i}}\nu_{\bar{i}q}^+\Gamma_{\bar{i}q}$ contributes in this case to the derivative such that the decrease of the surface charge density due to ion-pair formation at the interface is compensated for. Thus, the ion-pair formation does not necessarily lead to the decreae of the apparent surface charge density given by the slope of the electrocapillary curve. Equation 7 shows that the slope of the electrocapillary curve at a given potential cannot be an unequivocal measure of the ion-pair formation at the interface, as was claimed by Watanabe et al.[6] The importance of the possible ion-pair formation at the oil-water interface was first pointed out by Girault and Schiffrin.[19]

Equation 7 also shows that when the ion-pair formation occurs at the interface, the second derivative of an electrocapillary curve with respect to the potential, $-\partial^2\gamma/\partial(E_{O-}^{W-})^2$, does not generally accord with the double layer capacitance defined by $\partial q/\partial E$, where q is the excess free surface charge density.[20] The decrease of the excess free surface charge density caused by the ion-pair formation thus leads to a decrease in the double layer capacitance in comparison with that in the absence of the charge neutralization. In other words, the differential capacitance can be a useful means for detecting the ion-pair formation at the interface, if one combines the capacitance data with the electrocapillary curve data.

††Department of Chemistry, Faculty of Science, Fukuoka University, Fukuoka 814-01
(Received October 27, 1987)

The critical micelle concentration, cmc, of sodium perfluorooctanoate, SPFO, and sodium dodecyl sulfate, SDS, in the presence of two homologous series of alkanols (1-alkanols and ω-phenyl-1-alkanols) at very low concentrations of the alkanols C_a, was measured by a differential specific conductivity method. The free energy of transfer per CH_2 group in the alkanols from water to the respective micelles, $\Delta G°(CH_2)$, has been estimated from a linear relation of the rate of cmc-decrease, $\Delta cmc/\Delta C_a$, with the number of carbon atoms in the alkyl chain of alkanols. The respective values of $\Delta G°(CH_2)$ obtained for two series of homologues added to a given surfactant are in good agreement with each other: $\Delta G°(CH_2)$ is -1.73 kJ mol^{-1} in the SPFO system and -2.30 kJ mol^{-1} in the SDS system. The former has been found to be smaller in magnitude than the latter. On the basis of $\Delta G°(CH_2)$, a thermodynamic parameter has been proposed which characterizes the degree of modification of a medium from its pure liquid state to surfactant micelles or to interfaces composed of a hydrocarbon or a fluorocarbon.

Fluorocarbons are unique in their phobicity not only to water but also to hydrocarbons. Mixtures of a fluorocarbon and a hydrocarbon exhibit a positive deviation from the ideal solution behavior and there occurs partial miscibility as can be seen, for example, in n-C_4F_{10}–n-C_4H_{10} system.[1] The unique properties have tempted some workers to study the mixed micelle formation of a fluorocarbon surfactant and a hydrocarbon surfactant,[2-8] and the solubilization of hydrocarbon derivatives in fluolocarbon surfactant solutions.[9] One of the interesting results obtained is that the relation of the critical micelle concentration, cmc, with the composition of surfactants gives a maximum,[2-4,7] or a minimum.[8] It has been ascribed to the nonideality of mixing, i.e., to the coexistence of two types of mixed micelles in mutual solution; the regular solution theory has been applied to explain cmc data.[3]

It is known that the standard free-energy change of transfer of some homologous series of hydrocarbon derivatives from water to various environments, such as oil phases, micelles, and interfaces, has a linear dependence on the number of carbon atoms in the homologues; the transfer free energy per CH_2 group, $\Delta G°(CH_2)$, gives information about the interaction of the hydrocarbon chain with the respective environments.[10] However, few studies on $\Delta G°(CH_2)$ between water and fluorocarbon media have so far been made.[11] Such studies will afford a better understanding of the nonideal behavior of mixed surfactant solutions of fluorocarbon and hydrocarbon surfactants.

In the present study, the initial rate of decrease of the cmc of a fluorocarbon surfactant and a hydrocarbon surfactant upon the addition of two homologous series of alkanols has been determined in order to estimate $\Delta G°(CH_2)$ between water and the respective surfactant micelles.

Experimental

Materials. Sodium perfluorooctanoate, SPFO, was prepared as follows. Commercially available perfluorooctanoic acid (P.C.R Research Chemicals, U.S.A.) was recrystallized twice from CCl_4. Its aqueous solution was neutralized with NaOH; then, the crude crystals obtained were recrystallized twice from water and then dried in a vacuum. Sodium dodecyl sulfate, SDS, was synthesized and purified using the same procedure as described elsewhere.[12] Each surfactant gave no minimum around its critical micelle concentration, cmc, in a plot of the surface-tension against concentration. Purchased 1-alkanols (C_2—C_7; Tokyo Kasei, Japan) and ω-phenyl-1-alkanols ($C_6H_5(CH_2)_mOH$: m=1—3; Tokyo Kasei) were used as additives after fractional distillation; the phenylalkanols (m=4, 5: 99%; Aldrich, U.S.A.) were used without further purification. The water for solvent was purified by means of ion exchange and distillation. Its specific conductivity was lower than 2 μS cm^{-1} at 298.15 K.

Conductivity Measurements for cmc Determination. An aqueous solution with a given concentration of each alkanol was prepared and used as a solvent. A portion of the solvent was poured into a conductivity cell (cell constant: 0.4743 cm^{-1}). A concentrated surfactant solution was prepared with the other portion of the solvent, and successively added into the conductivity cell. Upon each addition, the conductivity of the solution was measured on a conductivity metel (Model MY-8; Yanagimoto, Japan). The temperature of the water bath was controlled at 298.15±0.005 K.

Results and Discussion

In order to determine the critical micelle concentration, cmc, of the surfactants in the presence of alkanols, the differential specific conductivity method[2,13] was applied. Figure 1 illustrates the dependence of the differential conductivity, $\Delta\kappa/\Delta C_s$, on the mean concentration of surfactants, $\bar{C}_s$, just around the cmc, in an SPFO–1-hexanol system. At a given concentration of alkanol, C_a, $\Delta\kappa/\Delta C_s$ decreases slowly and

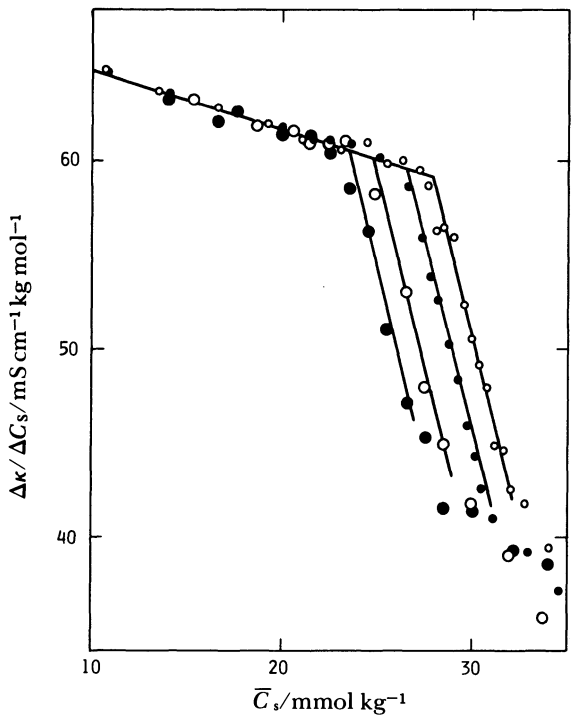

Fig. 1. The dependence of differential specific conductivity on the mean concentration of SPFO. Concentration of 1-hexanol in mmol kg^{-1}: 0 (○); 4.995 (●); 10.60 (○); 15.00 (●).

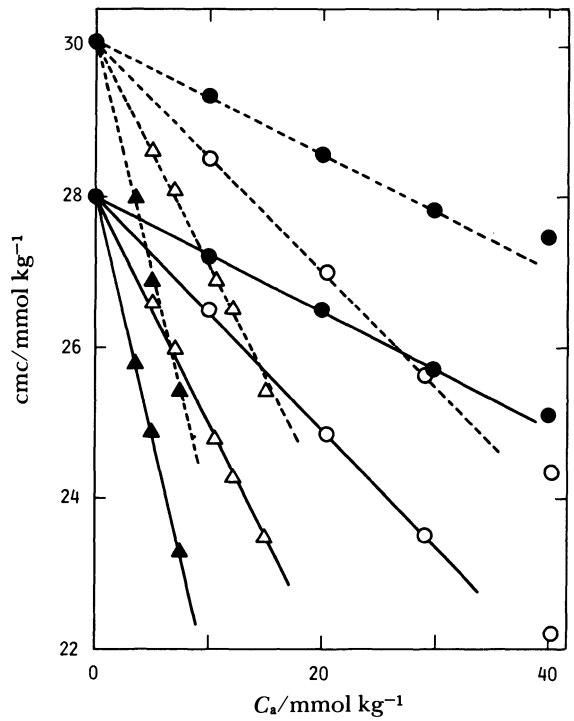

Fig. 2. The dependence of cmc of SPFO on 1-alkanol concentration. cmc determination method: equivalent conductivity (broken line); differential conductivity (solid line). Added 1-alkanols: 1-butanol (●); 1-pentanol (○); 1-hexanol (△); 1-heptanol (▲).

linearly until a break point; then it decreases sharply in a linear fashion whthin a narrow region of $\overline{C}_s$. The value of $\overline{C}_s$ at the intersection of the two straight lines is taken as the cmc. It is apparent that the points of $\Delta\kappa/\Delta C_s$ below the cmc fall on the same line, at any C_a studied, whereas the lines above the cmc are regarded as being parallel to each other. The latter finding indicates that the break remains clear, even if C_a increases; this is in marked contrast to a plot of the equivalent conductivity against the square root of the surfactant concentrations, C_s, (equivalent conductivity method) and a plot of specific conductivity against C_s (specific conductivity method), which are often employed for cmc determinations. In the latter two plots, as is well-known, the break around cmc becomes less distinct with increasing C_a. Therefore, it is claimed that the differential conductivity method is better for a cmc determination than those other conductivity methods, especially in the presence of some additives.

The cmc of SPFO determined by the differential conductivity method and the equivalent conductivity method is plotted in Fig. 2 against C_a of 1-alkanols, where the cmc value by the former method can be ascertained with more accuracy than by the latter method because of the more distinct break in Fig. 1. It is obvious that at a definite C_a of a certain alkanol, the cmc values are different from each other determined by the respective methods: the values are higher in the order of those by the specific, equivalent, and differential conductivity method, although cmc by the specific conductivity method is not shown in Fig. 2. In line with the reported results,[14,15] the cmc decreases linearly with C_a up to a certain C_a; this decreasing tendency becomes more marked with an increase in the alkyl-chain length of alkanols. The limiting slopes, Δcmc/ΔC_a, shown by the straight lines, are found to be almost identical, irrespective of the determination methods. The values of Δcmc/ΔC_a estimated from the cmc data by the differential conductivity method are listed in Table 1.

Table 1. Δcmc/ΔC_a and $\Delta G°(CH_2)$ for 1-Alkanols and ω-Phenyl-1-alkanols Added in SDS and SPFO at 298.15 K

The relation between log ($-\Delta$cmc/ΔC_a) and the

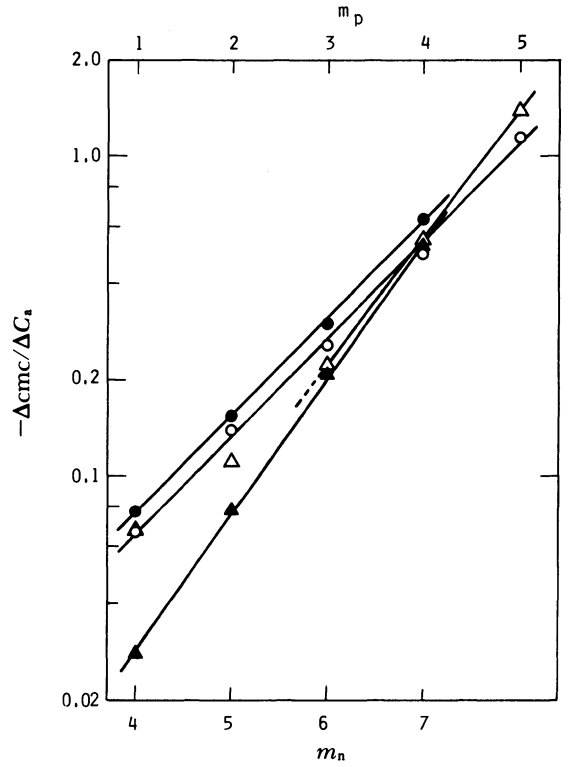

Fig. 3. The dependence of $\log(-\Delta cmc/\Delta C_a)$ on the number of carbon atoms in the alkylchain of added alkanols. Surfactant: SPFO (circle); SDS (triangle). Alkanol: 1-alkanol (closed mark); ω-phenyl-1-alkanol (open mark).

number of carbon atoms in the alkyl chain of added homologous alkanols (denoted by m_n for 1-alkanols, and m_p for ω-phenyl-1-alkanols) is shown in Fig. 3 where literature data for the SDS-1-alkanol systems[15] are also plotted. It is apparent that, as has been known in other systems,[14,15] a linear relation holds in each system, except for some short-chain alkanols (m_p=1, 2). It is perceived that the respective straight lines of 1-alkanols and phenylalkanols for each surfactant are parallel to each other and that the slopes of the straight lines for SPFO are less steep than those for SDS.

It is found that at a given value of $\Delta cmc/\Delta C_a$ for each surfactant, m_p is higher by about 3 than m_n, i.e., $m_p=m_n+3$. This result implies that the phenyl group is hydrophobic and its hydrophobicity corresponds to that of three methylene groups in the alkyl-chain. The difference of 3 is in agreement with that assigned to the phenyl group in a homologous series of sodium alkylbenzenesulfonates by comparison in cmc with homologous sodium alkanesulfonates.[16]

Manabe et al.[17] described the relation between $\Delta cmc/\Delta C_a$ and K_x (partition coefficient of a solubilizate between the bulk water and micelle phases, in mole fraction unit). When C_a is very low, the relation is expressed as

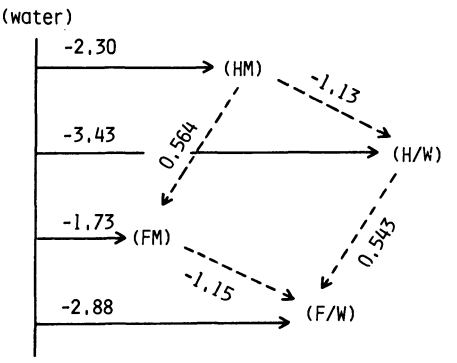

Fig. 4. Free energy of transfer per CH_2 group at 298.15 K. Values are in kJ mol^{-1}. Data for H/W and F/W are taken from Ref. 11.

$$-\Delta cmc/\Delta C_a = (cmc_0/n_w)\theta K_x, \quad (1)$$

where cmc_0, n_w, and θ refer to the cmc in water (in molality unit), the mole number of water, and a constant, respectively. In the SDS-1-alkanol systems (m_n=4—7), the value of θ (0.69,[17] 0.82[18]) was reported to be independent of the chain-length of alkanols. Assuming that θ is constant in each present system, the standard free-energy change of transfer per CH_2 group in the alkanols from the bulk water to micelles, $\Delta G°(CH_2)$, can be calculated through Eq. 1 as

$$\Delta G°(CH_2) = -RT\, d\ln(-\Delta cmc/\Delta C_a)/dm. \quad (2)$$

Here, R, T, and m are the gas constant, the absolute temperature, and the carbon number (m_n or m_p), respectively. The values of $\Delta G°(CH_2)$ calculated by Eq. 2 from the linear relation in Fig. 3 are shown in Table 1. It is noticed that $\Delta G°(CH_2)$ for the respective homologous series with a given surfactant are in agreement, as can also be seen in Fig. 3; also the value for SPFO (mean value, −1.73 kJ mol^{-1}) is smaller in magnitude than that for SDS (−2.30 kJ mol^{-1}). These figures indicate that a hydrocarbon derivative is more difficult to be solubilized in fluorocarbon surfactant micelles than in hydrocarbon surfactant ones. This is consistent with the fact that a liquid hydrocarbon is partially miscible with a liquid fluorocarbon, as observed in the n-C_4H_{10}-n-C_4F_{10} system.[1]

Mukerjee and Handa[11] measured the interfacial tension of dilute aqueous solutions of some homologous sodium alkyl sulfates as well as some sodium perfluoroalkanoates at air-water (A/W), hydrocarbon-water (H/W), and fluorocarbon-water (F/W) interfaces, and estimated the free-energy change for a CH_2 group as well as a CF_2 group in the surfactant molecules transferring from water (W) to each interface. For the CH_2 group, their data are schematically compared in Fig. 4 with the present data for $\Delta G°$ (CH_2) in the transferring process from W to hydrocarbon surfactant micelles (HM) and to fluorocarbon surfactant micelles (FM). Figure 4 suggests that

the oil-water interface has a greater affinity for the CH_2 group than the micelle when both media consist of the same substance (hydrocarbon or fluorocarbon). Further, it is apparent that the difference of the free energy of transfer between HM and H/W (1.13 kJ mol^{-1}) is in agreement with the difference between FM and F/W (1.15 kJ mol^{-1}). In addition, the difference between HM and FM (0.564 kJ mol^{-1}) is also regarded as being identical with that between H/W and F/W (0.543 kJ mol^{-1}). Accordingly, the four broken lines in Fig. 4 form a parallelogram. The parallelogrammic relation suggests that the modification of a type of medium, such as micelle or interface, characterizes a unique affinity for the CH_2 group.

The difference, 0.543 kJ mol^{-1}, between F/W and H/W in Fig. 4 was attributed by Mukerjee and Handa[11] to a nonideality of the mixing of hydrocarbon and fluorocarbon, by a comparison with the following excess free energy. By the regular solution approach, the incremental change per methylene group in the partial molar excess free energy of homologous hydrocarbons dissolved at infinite dilution in perfluorohexane was estimated to be 0.585 kJ mol^{-1}, which was in agreement with the value 0.543 kJ mol^{-1}. It should be noted that in the calculation for the respective free energies, different standard states of the solute were used, i.e., an extrapolated state from a limiting dilution for the adsorption free energy and the pure state of solute for the excess free energy. Then, we will propose an alternative explanation for the thermodynamic relation between the different standard states.

We consider a solute such as a hydrocarbon derivative distributed between two phases, α and β, at mole fractions of the solute, x^α and x^β, in respective phases. At a certain temperature and pressure, the chemical potential of the solute in each phase, μ^α and μ^β, can be expressed on the basis of two different reference systems. The one is that the activity coefficient (γ) of the solute is equal to unity in its pure liquid state (so called, Raoult's reference system) and the other is that the activity coefficient (f) of the same solute approaches unity as the solution becomes more and more dilute (Henry's reference system). Representing standard chemical potentials in, e.g., α phase as $\mu^{\alpha 0}$ and $\mu^{\alpha\ominus}$ by respective reference systems, the chemical potentials can be expressed as

$$\mu^\alpha = \mu^{\alpha 0} + RT\ln(\gamma^\alpha) + RT\ln(x^\alpha)$$
$$= \mu^{\alpha\ominus} + RT\ln(f^\alpha) + RT\ln(x^\alpha)$$

and

$$\mu^\beta = \mu^{\beta 0} + RT\ln(\gamma^\beta) + RT\ln(x^\beta)$$
$$= \mu^{\beta\ominus} + RT\ln(f^\beta) + RT\ln(x^\beta). \quad (3)$$

It should be noticed that in the above equations $\mu^{\alpha 0}$ is identical with $\mu^{\beta 0}$ since they concern the same pure solute. When in equilibrium, $\mu^\alpha = \mu^\beta$; therefore, from Eq. 3,

$$\mu^{\beta 0} - \mu^{\alpha 0} = 0 = -RT\ln(\gamma^\beta/\gamma^\alpha) - RT\ln(x^\beta/x^\alpha)$$

and

$$\mu^{\beta\ominus} - \mu^{\alpha\ominus} = -RT\ln(f^\beta/f^\alpha) - RT\ln(x^\beta/x^\alpha). \quad (4)$$

Under the conditions of infinite dilution of the solute in both phases, both f^α and f^β can be taken to be unity. Form Eq. 4, it follows that

$$\mu^{\beta\ominus} - \mu^{\alpha\ominus} = -RT\ln(x^\beta/x^\alpha) = RT\ln(\gamma^\beta/\gamma^\alpha). \quad (5)$$

This equation reveals a significant point that the standard free energy change, $\mu^{\beta\ominus} - \mu^{\alpha\ominus}$, for an ideal solution based on Henry's system is correlated with the excess free-energy change on Raoult's system.

These considerations can be applied to the present data as follows. The standard free energy of transfer, corresponding to $\mu^{\beta\ominus} - \mu^{\alpha\ominus}$ in Eq. 5, between any pair of media in Fig. 4 is calculated as the difference of $\Delta G°(CH_2)$. The quantity of $\Delta G°(CH_2)$ in the transferring process from water to each medium is denoted by $\Delta G°(CH_2{:}W)$; the values are arranged according to the order of magnitude in Table 2. When the CH_2 group transfers from a hydrocarbon medium to another one, the free energy of transfer, denoted by $\Delta G°(CH_2{:}H)$, may be given as the difference between $\Delta G°(CH_2{:}W)$ and -3.59 kJ mol^{-1} determined from the partition coefficients of homologous 1-alkanols between water and dodecane at infinite dilution at 298.15 K.[19] The values of $\Delta G°(CH_2{:}H)$ are also

Table 2. Thermodynamic Quantities for CH_2 Group in Transfering Processes at 298.15 K

Medium	$-\Delta G°(CH_2{:}W)$ / kJ mol^{-1}	$\Delta G°(CH_2{:}H)$[b] / kJ mol^{-1}	γ^ω	$((RT\ln(\gamma^\omega))/\bar{V})^{1/2}$ / (cal cm^{-3})$^{1/2}$[c]
H	3.59[a]	0	1	0
H/W	3.43	0.040	1.07	1.55
F/W	2.88	0.711	1.33	3.19
A/W	2.59	1.00	1.50	3.80
HM	2.30	1.30	1.69	4.33
FM	1.73	1.86	2.12	5.18
W	0	3.59	4.27	7.20

Notations are defined in text. a) From Ref. 19. b) $\Delta G°(CH_2{:}H) = \Delta G°(CH_2{:}W) - (-3.59)$. c) 1 cal = 4.184 J.

shown in Table 2. If the hydrocarbon medium and another one are represented by superscripts h and ω instead of α and β in the above equations, respectively, $\Delta G°(CH_2{:}H)$ can be rewritten along with Eq. 5 as

$$\Delta G°(CH_2{:}H) = \mu^{\omega\ominus} - \mu^{h\ominus} = RT\ln(\gamma^{\omega}/\gamma^{h}). \quad (6)$$

Assuming that the hydrocarbon solution of the CH_2 group is a perfect solution, γ^h as well as f^h may be regarded to be unity. Then, we obtain

$$\Delta G°(CH_2{:}H) = RT\ln(\gamma^{\omega}). \quad (7)$$

This equation is in line with that derived by Butler et al.[20] The values of γ^{ω} calculated by Eq. 7 are listed in Table 2. It is recognized that the medium with a higher value of γ^{ω} has a lower affinity to the CH_2 group. Therefore, the activity coefficient, γ^{ω}, based on Raoult's reference system, is a parameter which numerically characterizes each type of media (the degree of modification of a solvent), such as micelle or interface, in which the CH_2 group is dissolved.

According to the regular solution theory by Hildebrand,[21] the activity coefficient of a solute (γ^R) which is originally related to the energy of mixing is expressed by the quantities, i.e., solubility parameters of a solute (δ_2) and a solvent (δ_1), molar volume of the solute (V_2), and volume fraction of the solvent (ϕ_1), as $RT\ln(\gamma^R)=V_2\phi_1^2(\delta_2-\delta_1)^2$. Present data concerning γ^{ω} and the literal value of the partial molar volume of the CH_2 group, $\overline{V}$, 16.6 $cm^3\,mol^{-1}$,[22] which is the incremental change of partial molar volumes of homologous alkanols in a hydrocarbon, allow us to estimate the quantity $(RT\ln(\gamma^{\omega})/\overline{V})^{1/2}$, which corresponds to the difference of the solubility parameter, $|\delta_2-\delta_1|$. The values of $|\delta_2-\delta_1|$ for some representative substances (hexane($\delta_1=\delta_2=7.3$),[23] perfluorohexane ($\delta_1=5.9$),[23] and water ($\delta_1=24$)[24]) are 0, 1.4, and 16.7, respectivelly. It is seen that this order is consistent with that of $(RT\ln(\gamma^{\omega})/\overline{V})^{1/2}$ in Table 2. In the regular solution theory, the activity coefficient of a solute depends only on the properties of the solute and solvent in their pure states. However, for a given solute (CH_2 group), γ^{ω} reflects the characteristics of its solvent not only in the pure state but also in the modified states such as micelle or interface. In this respect, it is claimed that γ^{ω} is more useful than γ^R in the regular solution approach. Further, the parallelogram relation in Fig. 4 suggests that the modification of the solvent is uniquely determined and the degree of modification is reflected on γ^{ω}.

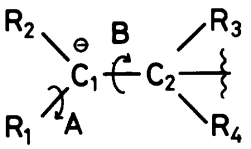
Proton and Carbon-13 NMR Study of Dimer Dianions Produced from 1,1-Diphenylethylene Derivatives

Yukihiro YOKOYAMA, Masahiro USHIO, Kenji GOTO, Mikio TAKAKI, Kensuke TAKAHASHI,* and Ryuzo ASAMI
Department of Applied Chemistry, Nagoya Institute of Technology, Gokiso-cho, Showa-ku, Nagoya 466
(Received October 28, 1987)

^{1}H and ^{13}C NMR spectra have been observed for the carbanions produced from 1,1-diphenylethylene derivatives. Among five precursors, three have been reduced to corresponding dimer dianions in contact with alkali metal in THF; however, the rest could not be dimerized. Failure in dimerization is controlled by a steric effect of substituents at the 2-position. DNMR measurements were also carried out for 1,1-di-*p*-tolylpropene dimer dianions. The results are discussed in terms of two internal rotations around the bonds between the C_1 and C_2, and the C_1 and C_i atoms.

Many NMR studies have been carried out in order to obtain structural information concerning benzyl-type carbanions which are important in synthetic chemistry. Throughout these studies, NMR parameters have been shown to vary with carbanion structures, cations, solvents and temperatures.[1)]

The dimerization of the radical anions produced from styrene, α-methylstyrene, or 1,1-diphenylethylene has been studied by ESR with dynamic stopped-flow techniques.[2)] The NMR parameters of these dimeric anions have also been partly reported.[3)] The NMR method is especially effective for structural studies of these carbanions since they are unstable when in contact with air or moisture. However, there have not yet been any systematic NMR studies concerning the formations and structures of these dimeric carbanions. This study was aimed at obtaining the NMR parameters of three dimeric carbanions produced from the 1,1-diphenylethylene derivatives. In the measurements of the two dianions at lower temperatures, two phenyl rings were not equivalent because of a hindered rotation around the bond between the C_1 and C_2 atoms. This situation is shown in Scheme 1, where



$R_1=R_2=C_6H_4X$
(X=H or p-CH_3)
R_3, R_4=H or CH_3

Scheme 1.

the two restricted internal rotations are differentiated as A and B. Several articles have been written concerning rotations, such as A,[4–11)] but not on those, such as B, in carbanions.

Experimental

Five starting materials, 1,1-di-*p*-tolylpropene (**1a**), 1,1-diphenylpropene (**2a**), 1,1-di-*p*-tolylethylene (**3a**), 1,1-dimethyl-2,2-di-*p*-tolylethylene (**5a**), and 1,1-dimethyl-2,2-diphenylethylene (**6a**), were prepared using a conventional method involving reactions of Grignard reagents produced from the corresponding alkyl bromides or iodides with substituted benzophenones. The solvents used for the preparation, THF, THF-d_8, and DME, were refluxed upon sodium metal, distilled, degassed, and finally kept on a sodium-potassium alloy.

An example of the preparation of the carbanions is as follows: 0.95 g of 1,1-diphenylpropene (**2a**) was melted, degassed in vacuum, and dissolved in 10 ml of dried THF. The solution was in contact with a sodium-potassium alloy in vacuum at room temperature. Immediately after contact, the solution became colored dark red. After standing for 24 h, the colored solution was filtered and sealed in an NMR tube and in a stocking glass container with a breakable seal. The concentration of the carbanion solution was about 0.5 or 1 M (1 M=1 mol dm^{-3}).

In order to obtain a chemical evidence, the potassium salt of 1,1-diphenylpropene dimer dianion (**2**) in THF was quenched by water. The quenched product was shown to have a structure consistent with 2,3-dimethyl-1,1,4,4-tetraphenylbutane, based on its ^{1}H NMR parameters ($\delta(CH_3)$= 0.92, δ(2-CH)=2.64, δ(1-CH)=3.91, and $\delta(C_6H_5)$=7.2—7.5 in THF-d_8).

The NMR spectra were measured with a Hitachi R-20B or with a Varian XL-200 FT NMR spectrometer. Variable-temperature spectra were measured in the range from 60 to −110 °C. The ^{1}H and ^{13}C NMR chemical shifts were evaluated from the solvent peak used as an internal reference and then converted to δ_H and δ_C values from TMS, by taking δ_H 1.79 and δ_C 26.4 for THF, δ_H 3.28 and δ_C 58.8 for DME, and δ_H 2.58 and δ_C 37.0 for HMPA.

Results and Discussion

Formation of Dimer Dianions. Typical NMR spectra of the carbanions obtained in this study are given in Figs. 1, 2, and 3, together with spectra of the neutral precursors. From these spectra, each carbanionic sample solution was found to consist of mainly a single species. When the precursors of **1a**, **2a**, and **3a** reacted with alkali metal in THF solutions they produced their dimer dianions, **1**, **2**, and **3**, which were ascertained by their NMR spectra. The same was true

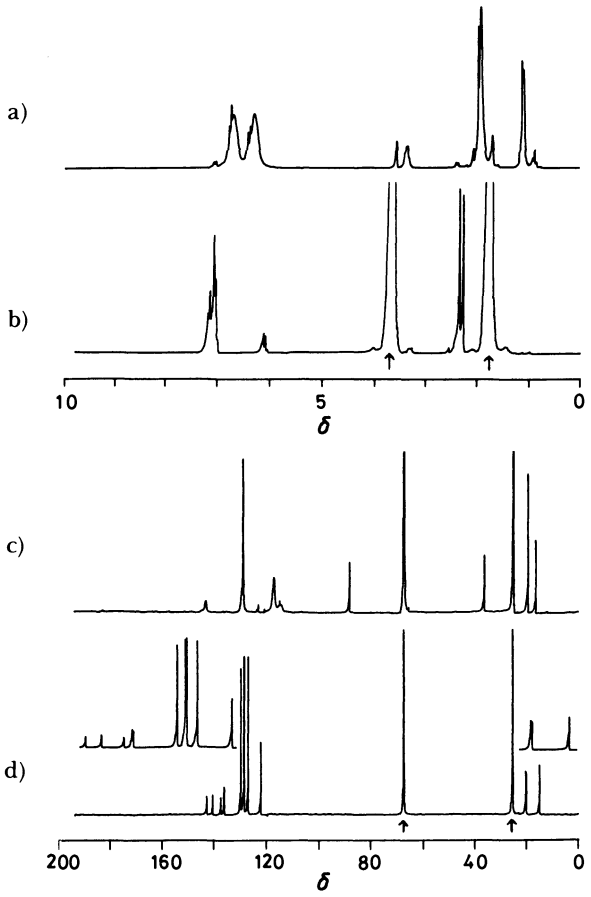


Fig. 1. ^{1}H and ^{13}C NMR spectra of **1** and **1a**. (a) ^{1}H spectrum of **1** in THF-d_8, (b) ^{1}H spectrum of **1a** in THF at 200 MHz and 25 °C, (c) ^{13}C spectrum of **1** in THF, and (d) ^{13}C spectrum of **1a** in THF at 50.3 MHz and 25 °C. The signals of the solvent were denoted by arrows.

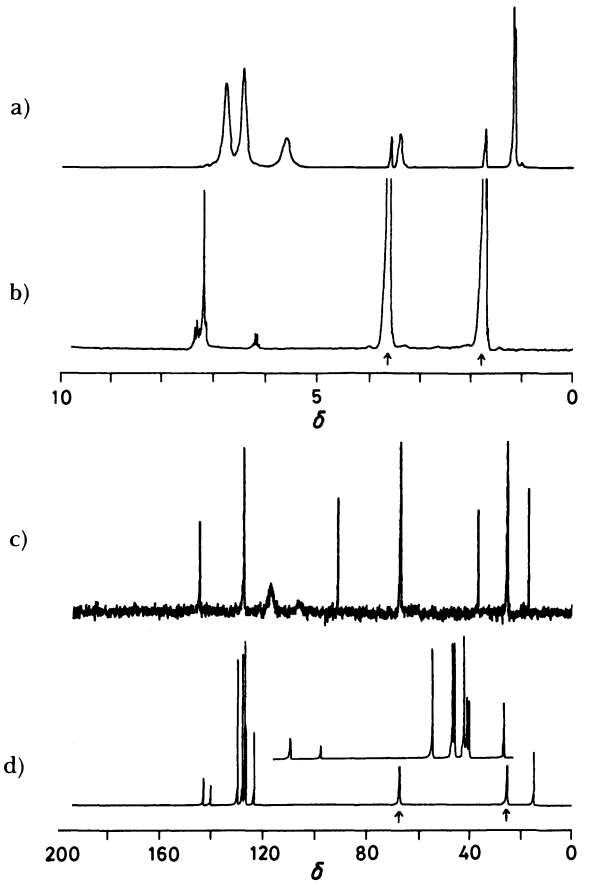

Fig. 2. ^{1}H and ^{13}C NMR spectra of **2** and **2a**. (a) ^{1}H spectrum of **2** in THF-d_8, (b) ^{1}H spectrum of **2a** in THF at 200 MHz and 25 °C, (c) ^{13}C spectrum of **2** in THF, and (d) ^{13}C spectrum of **2a** in THF at 50.3 MHz and 25 °C.

of 1,1-diphenylethylene (**4a**); we have already reported on its dimer dianion **4**.[3] The situation, however, was different for **5a** or **6a** in which the NMR spectrum of a solution treated similarly with metal was complex and its quenched product was multiplex. In every case, an anionic radical species is produced immediately after a precursor is dissolved in THF and comes into contact with metal. The reactant solution changes in color from colorless to dark red. When a C_2 atom of a precursor is substituted by a group, such as a phenyl ring, the radical anion is easily reduced further and becomes a monomeric dianion, as does tetraphenylethylene.[12]

When a substituent at C_2 is a hydrogen or a methyl group, which is not an effective electron-delocalizable group, two-electron reduction does not occur; instead, dimerization occurs between the anion radicals. The latter case has occurred in reactions of **1a**, **2a**, **3a**, and **4a**. In the cases of **5a** and **6a** such dimerization has not occurred. The reason seems to be due to their steric circumstances around the C_2 atoms. The dimerization of the radical anions is known to be an essentially reversible process which can be controlled thermodynamically.[2] The ^{1}H NMR spectra of the dianions observed in this study show that the anions are stable at room temperature and that their line widths are narrow. In this respect the equilibrium between the dimer dianion and the radical anion is largely shifted to the former.

Further, both the dianions **1** and **2** have two asymmetric carbons in a molecule. Therefore, it is a problem whether they are in either racemic or meso form. In the NMR spectra of several 2,3-disubstituted butanes, the two forms are differentiated in their chemical shifts. For example, the differences in ^{13}C chemical shifts between the two forms of 2,3-dichlorobutanes are reported to be 1.09 and 1.99 ppm for the C_1 and C_2 in the backbone butane skeleton.[13] As shown in Table 2, the C_1 and C_2 chemical shifts of **1** and **2** are attributed to those of a single species. It is therefore estimated that **1** or **2** exists either as the racemic or meso form. This may be controlled sterically. As stated before, dimerization did not occur in the cases of **5a** and **6a**. In other words, two methyl

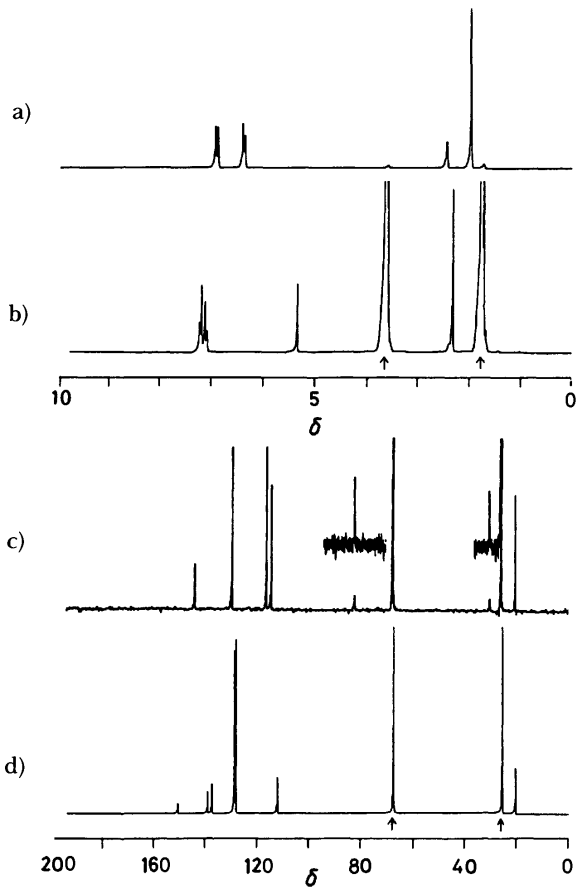

Fig. 3. ^{1}H and ^{13}C NMR spectra of **3** and **3a**. (a) ^{1}H spectrum of **3** in THF-d_8, (b) ^{1}H spectrum of **3a** in THF at 200 MHz and 25 °C, (c) ^{13}C spectrum of **3** in THF, and (d) ^{13}C spectrum of **3a** in THF at 50.3 MHz and 25 °C.

groups at the C_2 of **5a** and **6a** inhibited the dimerization. Therefore, one methyl group at the C_2 of **1a** and **2a** can be said to control the way of dimerization, sterically. This is one reason why only a racemic or meso form of **1** or **2** is prepared. The racemic form is more probable because of a steric reason. However, this is not clear at present and must be studied in the future. Anyhow, it is considered that the anion, **1** or **2**, is in a highly crowded situation.

^{1}H and ^{13}C NMR Parameters. The NMR parameters obtained for the anions and their precursors are summarized in Tables 1 and 2. All the ^{1}H chemical shifts of the anions are shielded by about 0.3 to 3.0 ppm, as compared with those of the precursors. This tendency is consistent with that reported previously.[1] However, the protons attached to the C_2 atoms are shifted upfield by about 3 ppm. This large shift is attributed to a hybridization change of the C_2 atom from sp^2 to sp^3, accompanied with dimerization. This fact has also been verified from changes in the ^{13}C NMR parameters. The changes of the chemical shifts of the C_2 are about 82—90 ppm. The values are similar to those observed for triphenyl- and diphenylmethanide ions (92 and 97 ppm).[14] However, a corresponding change of the ^{13}C NMR parameters for the carbons of the anions without hybridization change is about 17 ppm in the case of 1,1,4,4-tetraphenylbutadiene dianion (**7**).[15] Therefore, from the viewpoint of the chemical shift parameters, the C_2 of **1**, **2**, and **3** are considered to be sp^3-hybridized. Additional evidence of hybridization of the C_2 is given by measuring the one-bond J_{CH} coupling constants, which are about 123, 121, and 122 Hz for **1**, **2**, and **3**, respectively. These

a) The values for the methyl carbons are not shown in the table because of their small values, but they are included into the evaluation of S_1 and S_2. b) A total sum for a monomer unit. c) $S_2=S_1-\Delta\delta C_2$. d) The value in parentheses is the excess electron density on the carbon atom, which was evaluated by a method used in Ref. 18. e) The values are cited from Ref. 15 for the sodium salt.

values are consistent with those of typically sp^3-hybridized carbons.[16] The excess charge distribution of the anions can be evaluated from the differences of the chemical shifts between the anions and the corresponding precursors (Table 3), using an equation proposed by Fraenkel et al.[17] and a factor presented by Spiesecke and Schneider.[18] In a total sum for a monomer unit, S_1 has an uncertainty due to the hybridization change of the C_2 atom of the anion, **1**, **2**, **3**, or **4**. Therefore S_2 is evaluated as a total sum for a monomer unit, except for the difference of the C_2 atom. It is considered that the hybridization of the C_1 atom of the anion does not change from that of the precursor, as disscussed previously.[14] The S_2 values of **3** and **4** are larger than those of **1** and **2**. This is mainly ascribed to the difference of the C_1 chemical shift. This means that **3** or **4** has a larger electron density at the C_1 than **1** and **2** has, suggesting that the counter-cation is nearer to the C_1 for **3** or **4** than for **1** or **2**. This is ascribed to a steric effect of the 2-methyl group for **1** and **2**. The S_2 values are approximately 139 ppm as a mean. This is nearly equal to the S_1 value of **7**. Thus, the excess charge of the dimer dianions is mostly delocalized into the phenyl rings and on the C_1 (or C_4) carbon.

Temperature Dependency of the Chemical Shifts. For three carbanions (**1**, **2**, and **3**), there are two different internal rotations, A and B, as shown in Scheme 1. The ^1H NMR signals of the H_o, H_m, and p-CH_3 hydrogens of **1** were broad at 25 °C, as shown in Fig. 1a. When the temperature was lowered, each signal split into two. Similarly, all ^{13}C signals of the phenyl groups of **1** were split into two at −70 °C. Therefore, two geminal phenyl rings of **1** are not magnetically equivalent at this temperature. The chemical shift values at −70 °C are also given in Tables 1 and 2. The values arranged in the same line are those for the protons or carbons belonging to the same phenyl ring.

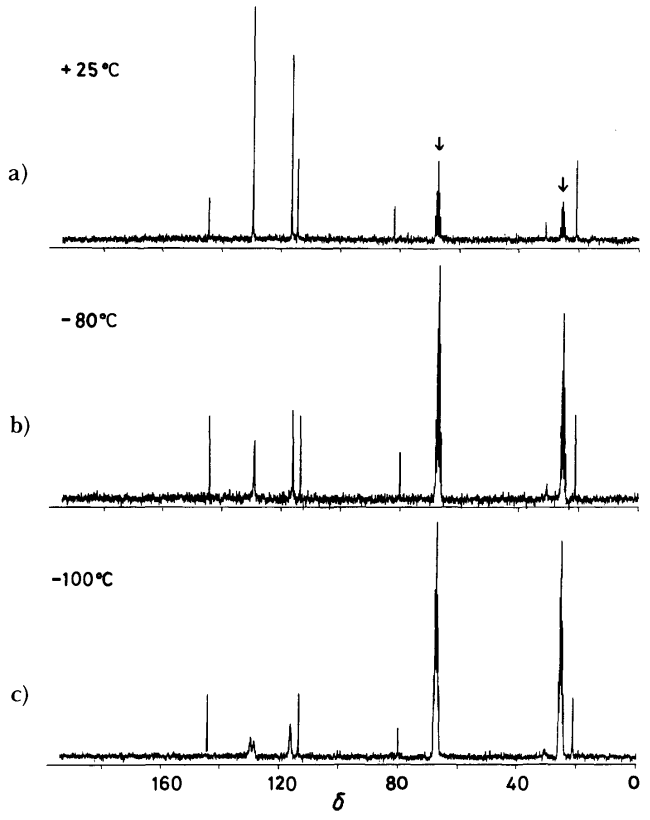

Fig. 4. ^{13}C NMR spectral changes of **3** in THF-d_8 at 50.3 MHz. (a) At 25 °C, (b) at −80 °C, and (c) at −100 °C.

Similarly, the splittings of the signals were also observed at a lower temperature in **2** but not **3**. Therefore, the cause of the nonequivalence is attributed to the presence of a methyl group at the C_2 and to hindered rotation around the bond between the C_1 and C_2 atoms, which is denoted as B in Scheme 1. When the temperature was lowered, **3** showed a broad C_o signal and two broad split C_m signals at −100 °C, as shown in Fig. 4. The peak heights of the C_o and C_m signals are low as compared with those of other carbon signals (C_i and C_p). Therefore, the signal splitting is considered to be caused by the restriction of rotation about the bond between the C_1 and C_i, which is denoted as A in Scheme 1. Even at −110 °C, the C_o signals were not separated into two. Therefore, the thermodynamic parameters of this hindered rotation could not be obtained. The temperature-dependent ^{13}C chemical shifts of **1** are given in Fig. 5. In the figures the vertical line at each temperature shows an approximate line width of each signal. Coalescences were observed for the signals of all carbons in two phenyl rings in the temperature range from −20 to 20 °C, accompanied by signal broadening. This is due to the rotation B. The chemical shift changes of the C_o and C_p carbons of **1** behave in a strange manner. For example, the C_p signals of **1** showed another coalescence phenomenon at −80 °C. This coalescence is quite different from those at higher temperatures. It was not accompanied by broadening of the signals like that as shown at a temperature near 0 °C in Fig. 5. The same is true for the C_o signals. Therefore, this coalescence is explained by temperature-dependent chemical shift changes. However, the origin of this chemical shift change is not clear at present. It seems to be concerned with the active center of the anion: that is, the C_1 atom. Thus, the difference of the chemical shifts is the largest at the C_i which is the nearest carbon from the active center. It must be noted, however, that two C_p atoms have the same chemical shift value at −100 °C, though they have different chemical shifts at −20 °C. The chemical shift differences of the two split signals are about 2.1, 1.0, 0.8, and 1.8 ppm for C_i, C_o, C_m, and C_p atoms at −20 °C, respectively. The difference is larger for the C_i and C_p than for the C_o and C_m. Therefore, the two former carbons are more sensitive to their circumstances than the two latter carbons. This behavior is characteristic in the ^{13}C chemical shifts of monosubstituted benzenes.[19] Another reason for these relative magnitudes is considered to be due to the rotation A, which causes an averaging of the chemical shifts for the C_o and C_m. Thus, the C_p and C_i atoms are on the axis of the rotation A, but the C_o and C_m atoms are not. Further, evidence of the presence of the rotation A in **1** is as follows: the line widths of the C_o and C_m resonances of **1** are about twice those of the C_p and C_i atoms at −70 °C. An effect of the methyl substituent can be evaluated from a comparison of the ^{13}C spectra of **1** and **2**. However, the effect could not be obtained quantitatively. Visually, the signal widths of the ring carbons of **2** are quite larger than those of **1** at about −80 °C. This suggests that a temperature of −80 °C is near the coalescence temperature of **2**, but far from that of **1**. Therefore, the methyl group lowers the potential barrier of the rotation A of **1**, as expected from the electron-donating property of substituent, as reported by Bushweller et al.[8] As a conclusion two internal rotations, A and B, are differentiated for **1**. The former does not stop, even at −100 °C, though the latter stops approximately at −20 °C. The phenomenon observed for **1** at about 0 °C was explained by the restricted rotation B. However, it may be considered to be explained by any other reasons such as the presence of two different aggregation states or two different species (for example, racemic and meso forms). These explanations, however, were denied for the following two reasons. First, two split signals were observed only for the atoms concerning the aromatic rings. Second, they appeared with equal intensity.

Line-Shape Analyses. The temperature-dependent ^1H and ^{13}C NMR spectra were analyzed as simple two-site exchanging problems. The line widths were

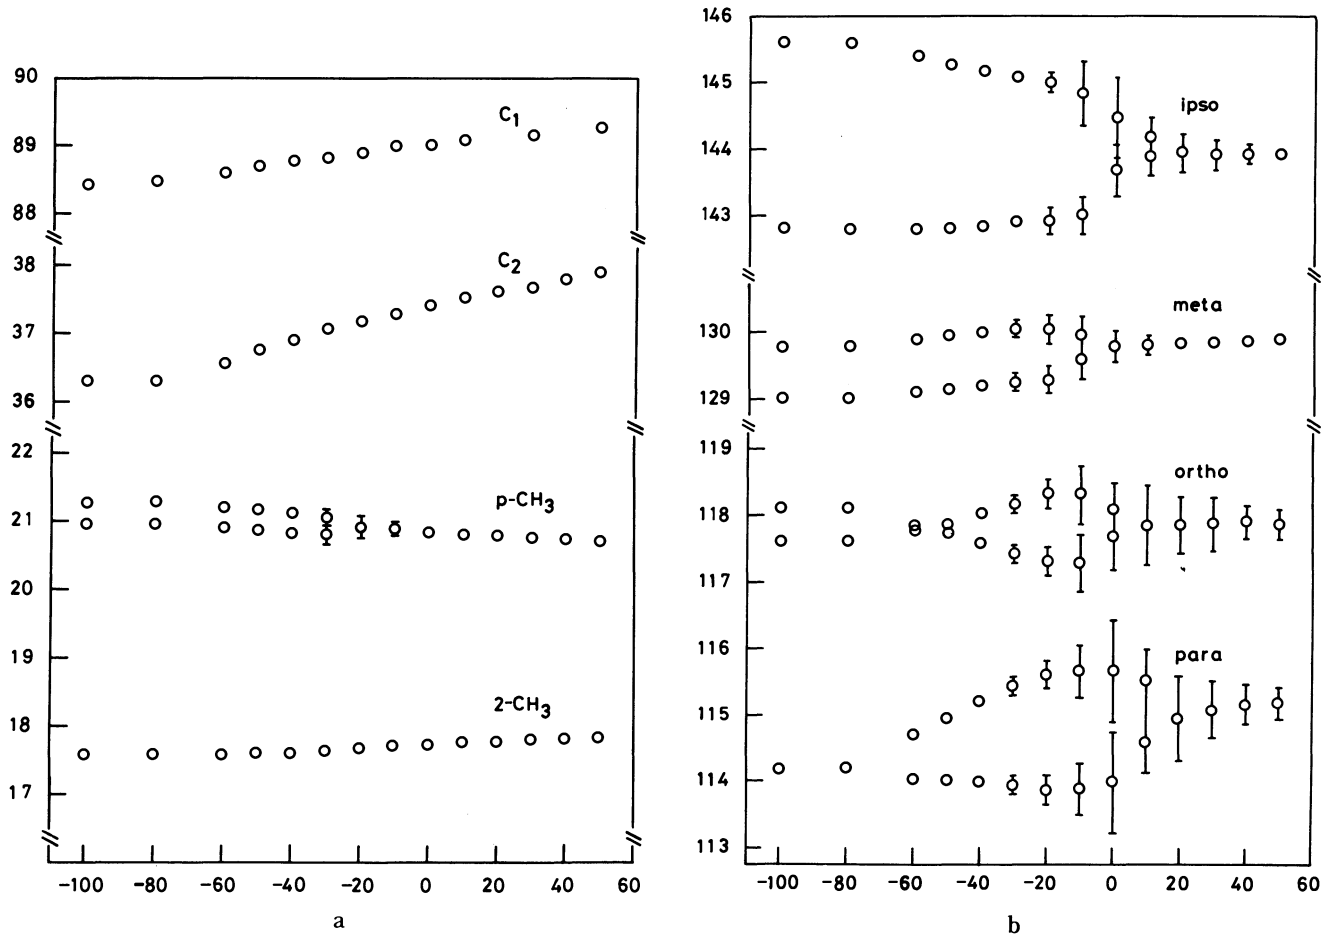

Fig. 5. ^{13}C chemical shifts (ordinate in ppm) of **1** in THF as a function of temperature (abscissa in °C) at 50.3 MHz, (a) Aliphatic and (b) aromatic carbon regions.

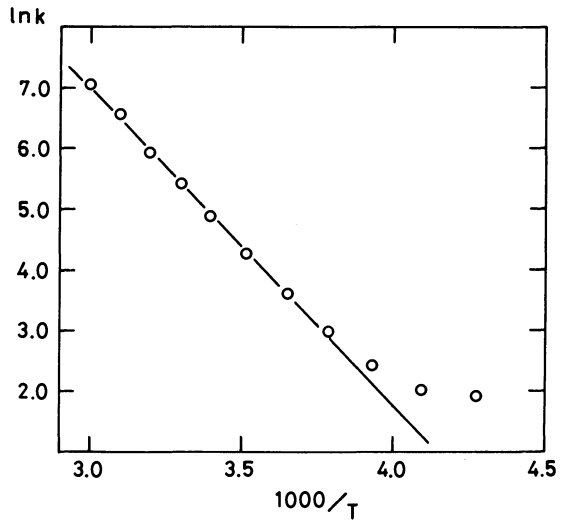

Fig. 6. An Arrhenius plot for the rotation B of **1** in THF.

estimated from the observed spectra. The calculated and experimental line shapes were compared visually. The thermodynamical parameters for the rotation (B) were obtained by Arrhenius and Eyring plots. An example of the analyses is shown in Fig. 6 for an Arrhenius plot of the kinetic parameters obtained for the exchange of the two *p*-CH_3 protons of **1**. However, the plotted points are divergent at the temperatures lower than −20 °C. A reason for this divergence seems to be due to an interaction between the two rotations, A and B, in the molecule. It must also be noted that errors in the DNMR method will become appreciable at two extremes of the range.[20] Therefore, although several trials were carried out, the parameters for other peaks could not be obtained unambiguously, except for the *p*-CH_3 protons. The thermodynamical parameters are given in Table 4, which were obtained for the temperature ranges between −10 and 60 °C

concerning the rotation, B. The coalescence temperature can be used to evaluate the change in the free energy of activation for the rotation in the molecule using the following equation:

$$\Delta G_c^{\ddagger} = aT_c[9.972 + \log(T_c/\Delta\nu)],$$

where T_c, $\Delta\nu$, and a are the coalescence temperature, the chemical-shift difference of two exchanging sites, and a constant of 19.14 J mol^{-1} respectively.[21] In the case of **1**, the $\Delta G_c^{\ddagger}$ value is 58.3 kJ mol^{-1} when the values of T_c and $\Delta\nu$ are adopted as ca. 278 K and 28.5 Hz. This value is consisent with that calculated from the parameters given in Table 4.

Effect of Polyethylene Glycol Monoalkyl Ethers on Phase Transition Temperature of Dipalmitoylphosphatidylcholine Vesicle Membrane

Tohru INOUE,* Kohsuke FUKUSHIMA, and Ryosuke SHIMOZAWA
Department of Chemistry, Faculty of Science, Fukuoka University,
Nanakuma, Jonan-ku, Fukuoka 814-01
(Received October 28, 1987)

The gel-to-liquid-crystalline phase transition temperature of a dipalmitoylphosphatidylcholine vesicle membrane was measured in the presence of polyethylene glycol monoalkyl ethers (C_nE_m) of various chain lengths of hydrophobic (n) and hydrophilic (m) groups. All of the surfactants, except of $C_{12}E_1$, depressed the transition temperature almost linearly with the concentration. The depression of the phase-transition temperature was analyzed by applying the van't Hoff model for the freezing-point depression; also, the partition coefficients of the surfactants between bulk water and the membrane phase were estimated. Discussions were given concerning the dependence of the partition coefficients on the chain lengths of both oxyethylene and alkyl groups.

The interaction of surfactants with a phospholipid bilayer has been investigated in relation to the solubilization[1,2] or fusion[2-4] of biological membranes and to the preparation of lipid vesicles by detergent removal method.[5-7] Most of these studies deal with the mixed micelles formed by the addition of surfactants at a concentration higher than the critical micelle concentration. Recently, Goñi et al.[8] have paid attention to the effect of surfactants on the structure and properties of the lipid bilayer at rather lower concentration range. Such studies may have a significance different from the above-mentioned practical interest. Surfactants are typical amphiphiles, and the amphiphilicity can be readily controlled by combining various types of head groups and hydrocarbon tails. Hence, the surfactant-lipid bilayer system may provide a useful model system for us to understand the biologically significant interaction between amphiphilic ligands and a biological membrane.

Along the line of this interest, we have been studying the interaction of surfactants with model membranes in terms of their effect on the membrane properties.[9-11] As an extension of this series of studies, in the present work we investigated the effect of polyethylene glycol monoalkyl ethers, nonionic surfactants, on the gel-to-liquid-crystalline phase transition of dipalmitoylphosphatidylcholine vesicle membrane. Interest was focused on the dependence of the effect on both the alkyl and oxyethylene chain lengths.

Experimental

Synthetic dipalmitoylphosphatidylcholine (DPPC) was obtained from Sigma. The following polyethylene glycol monoalkyl ethers with homogeneous chain lengths were used (abbreviated as C_nE_m, where n and m represent the carbon number of alkyl chain and the number of oxyethylene unit, respectively): n=10, m=6, 8; n=12, m=1, 3, 4, 5, 6, 7, 8; n=14, m=6, 8. All the surfactants were obtained from Nikko Chemicals Co.

A stock suspension of DPPC vesicle in water was prepared by sonication in the cup-horn of a Branson Sonifier Model 185 at 45 °C for about 30 min. The sample suspension was prepared by mixing the DPPC suspension and surfactant solution to give the desired surfactant concentration, and by sonicating again at 45 °C for about 5 min. The sizes of vesicles were estimated from quasielastic light-scattering measurements to be about 160 nm in diameter; taking into account the size and the phase-transition pattern,[12] these vesicles may be regarded as being multilamellar. The DPPC concentration was kept at about 5×10^{-4} M† throughout the experiments.

The gel-to-liquid-crystalline phase transition of a DPPC vesicle membrane was followed by the scattered-light intensity from the vesicle suspension. Details concerning the procedure have been described previously.[9] Typical traces of the scattered-light intensity with temperature are

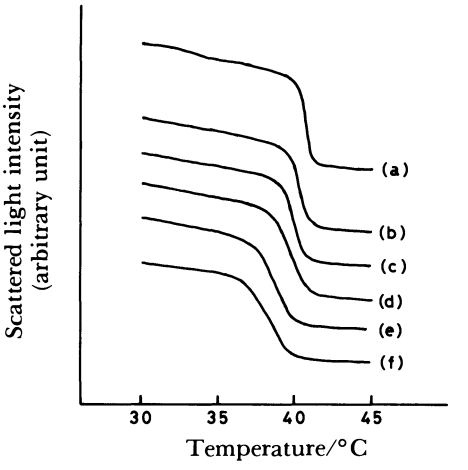

Fig. 1. Typical traces of the change in scattered light intensity at 400 nm with the temperature rise observed with DPPC–$C_{12}E_5$ system. Heating rate is 0.5 °C min^{-1}. DPPC concentration is 5.2×10^{-4} M. $C_{12}E_5$ concentrations (10^{-5} M) are (a) 0, (b) 2.52, (c) 3.37, (d) 5.05, (e) 6.73, and (f) 8.42.

† 1 M=1 mol dm^{-3}.

shown in Fig. 1. A drastic change in the scattered-light intensity was found corresponding to the phase transition. The transition temperature, T_m, was taken as the temperature at the half-height between two intersections of a line drawn through the steep portion of the transition region and the two lines drawn through the rather flat portions above and below the transition. The measurements were repeated at least three times for a given sample; a good reproducibility (typically within ±0.1 °C) was obtained for the transition temperature.

Results and Discussion

Figure 1 illustrates the effect of added $C_{12}E_5$ on the phase transition of a DPPC vesicle membrane. It can be seen that the transition temperature decreases with increasing $C_{12}E_5$ concentration. It was observed that at a higher concentration of the surfactant, the change in the scattered-light intensity at the transition region became small accompanied with the deformation of the transition curve; a further increase in the concentration led to an extremely low intensity of the scattered-light, probably due to the formation of a mixed micelle. This was also the case for other surfactants. Thus, the concentration ranges of added surfactants were limited to those where normal phase-transition patterns were observed.

Some examples of the relation between the transition temperature and the surfactant concentration are shown in Figs. 2a—c. In these figures, the depression of the transition temperature, $-\Delta T = -(T_m - T_{m0})$, is plotted against the surfactant concentration, where T_m and T_{m0} are the transition temperatures with and without the surfactants. As can be seen in these figures, $-\Delta T$ increases linearly with increasing added surfactant concentration.

The depression of the phase-transition temperature of lipid bilayers induced by additives of the small molecule has been successfully analyzed by applying the van't Hoff model for the freezing-point depression.[13-15] This model describes the transition temperature as being depressed as a result of the lowering of the chemical potential of lipid molecule in a liquid-crystalline phase due to the mixing with the additive molecules. According to this interpretation, ΔT is proportional to the mole fraction of additives in the lipid bilayer for the case of a sufficiently low additive concentration, which in turn allows an estimation of the partition coefficient of the additives between bulk water and a lipid bilayer when the additives are partitioned between these phases. Based on this treatment, ΔT is related to the partition coefficient, K, by the following equation:[9]

$$-\Delta T = \frac{RT_{m0}^2}{\Delta H} \cdot \frac{K}{55.5 + C_L K} C_A^0, \qquad (1)$$

where ΔH is the enthalpy change associated with the phase transition, R the gas constant, and C_L and C_A^0 the total concentrations of lipid and additives in molarity scale, respectively. K is defined as $K = x_A'/x_A$, where x_A' and x_A are the mole fractions of the additives in membrane and water phases, respectively.

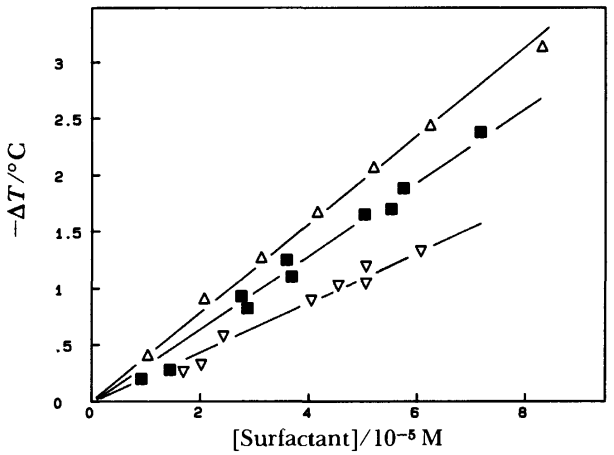

Fig. 2a. Plot of the depression of the phase transition temperature, $-\Delta T$, against the concentration of added surfactants. Surfactants are $C_{12}E_4$ (△), $C_{12}E_6$ (■), and $C_{12}E_8$ (▽).

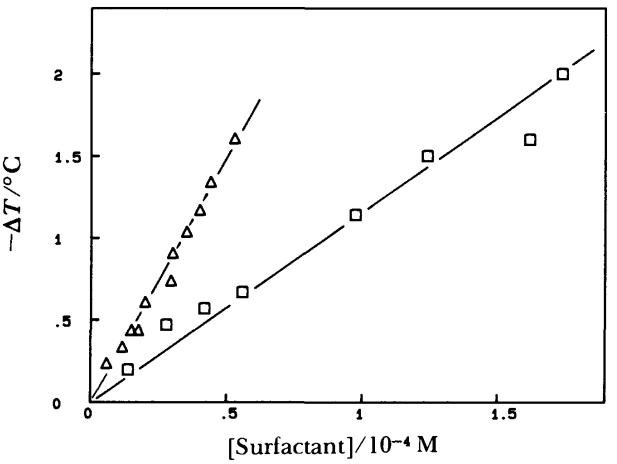

Fig. 2b. Plot of $-\Delta T$ against the added concentration of $C_{10}E_6$ (□) and $C_{14}E_6$ (△).

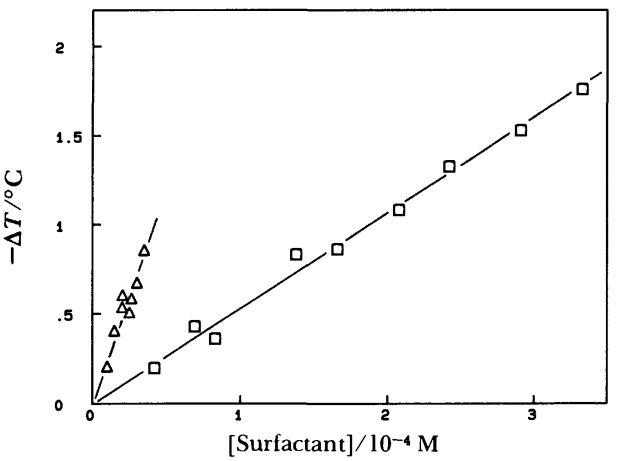

Fig. 2c. Plot of $-\Delta T$ against the added concentration of $C_{10}E_8$ (□) and $C_{14}E_8$ (△).

Equation 1 predicts a linear relationship between $-\Delta T$ and C_A^0, and allows an evaluation of the partition coefficient, K, from the slope. The partition coefficients of C_nE_m were estimated from the slopes of straight lines, as shown in Figs. 2a—c, using the values of T_{m0}=314 K and ΔH=36.4 kJ mol^{-1}.[16] Below, we examine the dependence of these K values on the oxyethylene chain length and the alkyl chain length.

Dependence of K on the Oxyethylene Chain Length. In Fig. 3, log K obtained with $C_{12}E_m$ is plotted against the number of oxyethylene unit, m. It can be seen that log K decreases almost linearly with increasing m in the range from m=4 to 8. The slope of this straight line provides $0.46RT$ as the contribution of an oxyethylene unit to the standard free energy change for the transfer of the surfactants from bulk water to the lipid bilayer. The critical micelle concentration (cmc)[17] of $C_{12}E_m$ is also shown in Fig. 3 for comparison. log cmc exhibits very weak dependence on m. This means that the contribution of oxyethylene unit to the standard free energy of micelle formation is negligibly small. For DPPC–surfactant systems previously studied,[9,11] there observed a good correlation between K and cmc; log K vs. log cmc plot gives straight lines with the slope of -1, the intercept of which weakely depends on the type of hydrophilic group. Comparing the present results for $C_{12}E_m$ with those for other surfactant systems, it is a wonder why the effect of oxyethylene chain length appears only in the partitioning into the lipid bilayer but not in the micelle formation. It is reasonable to consider that when surfactant molecules are incorporated in the lipid membrane, the hydrophilic head group of the surfactant is anchored at the membrane surface and the alkyl chain intercalates between the acyl chains of the lipid. The difference in the dependence on the oxyethylene chain length between K and cmc may be ascribed to a difference in the environment between the bilayer surface and the micellar surface.

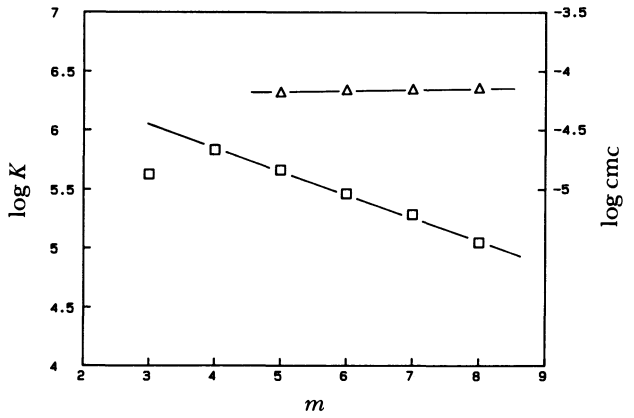

Fig. 3. Plot of log K (□, left scale) and log cmc (△, right scale) against the number of oxyethylene unit, m, for $C_{12}E_m$.

Considering the fact that the interior of lipid bilayer consists of the hydrocarbon region, it is of interest to compare the present partition data between water and lipid bilayer with those between water and hydrocarbon. Some partition data for nonionic surfactants with an oxyethylene chain between water and the hydrocarbon media are available in the literature.[18–20] From values of the partition coefficients, the free energies of the transfer from water to isooctane[18] and from water to cyclohexane[19,20] per oxyethylene unit are estimated to be $1.08RT$ and $0.96RT$, respectively. These are larger by a factor of about 2 than those of the transfer from water to DPPC bilayer. This difference may be attributed to the environmental difference between the partitions into the bulk hydrocarbon (water–hydrocarbon system) and into the water/hydrocarbon interface (water-bilayer system). The oxyethylene chain of the surfactants incorporated in the lipid bilayer locates at the bilayer surface and may be exposed to interfacial water; hence, the free energy loss may become less compared with the partition into the bulk hydrocarbon.

Another remarkable feature in Fig. 3 is the downward deviation of $C_{12}E_3$ from a straight line. This may be interpreted as follows. Equation 1 is based on the assumption that the amount of additives partitioned into the gel state bilayer is much smaller than those into the liquid-crystalline state, or even though the additives are incorporated substantially in gel phase, they are not randomly mixed but dispersed as aggregates (phase separation). It is likely that when the hydrophilicity of additives is reduced, the affinity to gel state bilayer becomes substantial, and the partitioning and mixing in gel state membrane becomes appreciable. In this case, Eq. 1 gives an underestimate of the partition coefficient. It may be

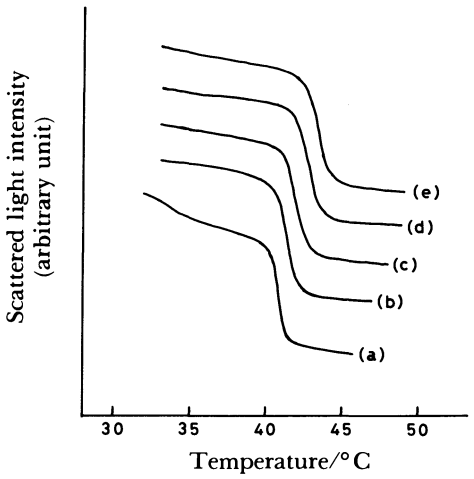

Fig. 4. Phase transition curves obtained with DPPC–$C_{12}E_1$ system. DPPC concentration is 5.0×10^{-4} M. $C_{12}E_1$ concentrations (10^{-4} M) are (a) 0, (b) 1.25, (c) 1.54, (d) 2.56, and (e) 3.42.

regarded that the K value obtained with $C_{12}E_3$ by applying Eq. 1 is not correct, but underestimated. When the oxyethylene chain length is further reduced, the effect of an additive on the phase transition becomes reversed; $C_{12}E_1$ elevated the transition temperature, as shown in Fig. 4. According to the van't Hoff model (described above) the elevation of the transition temperature can be interpreted as being due to the partitioning and mixing of the additives in the gel state bilayer, exceeding that in the liquid-crystalline state. A similar behavior of the additives concerning the phase-transition temperature of phosphatidylcholine vesicle membrane is well known for 1-alkanols; long-chain 1-alkanols with an alkyl chain length exceeding about 10 carbon atoms elevate the transition temperature, although shorter 1-alkanols depress it.[21–23] This suggests that the smaller hydrophilicity of 1-alkanols with longer alkyl chains favors their distribution in the gel state bilayer rather than liquid-crystalline state. The present results demonstrate that a similar reverse effect on the transition temperature is also induced by decreasing the hydrophilic oxyethylene chain length as the effect observed for 1-alkanol by increasing the hydrophobic chain length. Thus, the following general feature may be drawn for long-chain amphiphilic additives; reducing the hydrophilicity of the amphiphile below a certain critical level, it tends to partition into the gel state bilayer and mix with gel state lipids.

Dependence of K on the Alkyl Chain Length. Figure 5 shows the relation between $\log K$ and the carbon number of alkyl chain, N_c, obtained with C_nE_6 and C_nE_8. The increments of $\log K$ with N_c on going from 10 to 12 are similar for C_nE_6 and C_nE_8, which provide about 1 RT for the transfer free energy from the bulk water to the lipid bilayer per methylene unit. This increment of $\log K$ per methylene unit in alkyl chain is just the same as that obtained with other nonionic long-chain amphiphiles,[10] and the contribution of methylene unit to the transfer free energy is comparable to the free energy per methylene unit for the hydrophobic interaction.[24] On the contrary, from N_c=12 to 14, the increments of $\log K$ with N_c fall down for both C_nE_6 and C_nE_8, the extent of which is larger for C_nE_6 than C_nE_8. This deviation of $\log K$ for N_c=14 from the extraporated values from the lower N_c may be explained by the same way as the deviation of $C_{12}E_3$ from the linear relationship between $\log K$ and m in a series of $C_{12}E_m$ (Fig. 3). The hydrophilicity of $C_{14}E_6$ and $C_{14}E_8$ is weakened, relatively, due to their increased alkyl chain length, hence the partitioning and mixing in the gel state bilayer may occur substantially, and the K values obtained with these surfactants may be underestimated. The larger deviation for $C_{14}E_6$, whose hydrophilicity is less than $C_{14}E_8$, is consistent with this interpretation; i.e., the extent of underestimation of K is larger when the relative hydrophilicity is lower. A similar deviation of $\log K$ with increasing alkyl chain length was also observed for alkyltrimethylammonium salts.[9,11]

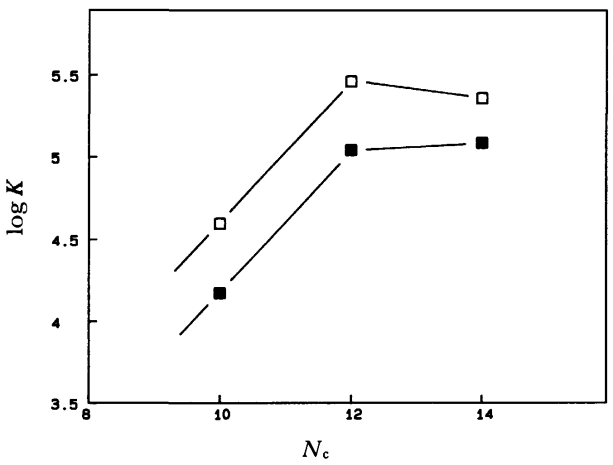

Fig. 5. Plot of $\log K$ against the carbon number in alkyl chain, N_c, for C_nE_6 (□) and C_nE_8 (■).

Conclusion

In this study, the partition coefficients of C_nE_m between bulk water and a DPPC bilayer were estimated from the depression of the phase transition temperature of a DPPC vesicle membrane by applying the van't Hoff model. The conclusion derived by examining the chain-length dependence of K is summarized as follows: (i) For a series of $C_{12}E_m$, $\log K$ decreased linearly with increasing m in the range between m=4 and 8. This suggests that the bilayer surface provides an energetically unfavorable fields for oxyethylene group compared with bulk water. (ii) $C_{12}E_3$ deviates from the linear plot of $\log K$ vs. m. $C_{14}E_6$ and $C_{14}E_8$ deviate from the linear plot of $\log K$ vs. N_c plot. These findings, along with the observation that $C_{12}E_1$ elevated the transition temperature, suggest that the decrease in the relative hydrophilicity of long-chain amphiphilic additives leads to partitioning into a gel state bilayer and mixing with the gel state lipids.

The authors wish to thank Mr. Akira Ogawa for his assistance in the experimental work. This work was supported in part by funds from the Central Research Institute of Fukuoka University.

(Received November 5, 1987)

Single crystals of a (tetrabenzoporphyrinato)nickel hexafluoroarsenate, $(NiTBP)_3(AsF_6)_2$ were prepared by the use of an electrochemical technique. NiTBP is stacked one-dimensionally with a periodic unit composed of three macrocycles. This stacking mode is a new type among the one-dimensionally stacked macrocyclic complexes. The experimental results on reflectance spectrum and ESR indicate that this material is a one-dimensional semiconductor with a small electron correlation.

Study on highly conducting quasi-one-dimensional solids of metallomacrocyclic compounds has been extensively conducted by the group of Northwestern University.[1-7] They explored mainly iodine complexes by changing the central metals from Fe to Zn. They also studied on (tetrabenzoporphyrinato)nickel iodide. The family of the one-dimensionally stacked macrocycles will be expanded by selecting the combination of the central metals, the porphyrin ligands, and the counter anions. We have prepared metallic (phthalocyaninato)nickel salts by the use of an electrochemical technique to change the counter anions, and found a new complexes with a different chemical composition from iodine complexes.[8,9] This time we prepared a one-dimensional complex by using a (tetrabenzoporphyrinato)nickel as a macrocycle and several octahedral, tetrahedral, and linear anions as counter anions. In this paper we present the crystal structure, electrical, optical, and magnetic properties of $(NiTBP)_3(AsF_6)_2(C_{10}H_7Cl)$, and briefly describe the preliminary results on the other salts.

Experimental

NiTBP was synthesized by exchanging the central metal of ZnTBP according to the method given by Martinsen et al.,[6] and was purified by means of vacuum sublimation. The result of the chemical analysis was as follows; Found: C, 76.07; H, 3.42; N, 9.79, Calcd for $C_{36}H_{20}N_4Ni$: C, 76.22; H, 3.55; N, 9.88. Single crystals of the NiTBP radical salts were grown by oxidizing NiTBP electrochemically in the 1-chloronaphthalene solution, $(n\text{-}Bu)_4X$ (X=BF_4, ClO_4, ReO_4, PF_6, AsF_6, SbF_6, Br_3, I_3) being used as the supporting electrolytes. 1-Chloronaphthalene were refluxed with CaH_2 under the Ar atmosphere and then distilled in vacuum. The electrolytes were recrystallized from methanol solution for several times. The electrochemical oxidation were performed at 120±2 °C with a constant current of 2—5 μA for about two weeks. The concentrations of NiTBP and the electrolytes were 2×10^{-4} mol l^{-1} and 1.6×10^{-3} mol l^{-1}, respectively. NiTBP is more soluble to 1-chloronaphthalene than NiPc ((phthalocyaninato)nickel), and almost all NiTBP seems to be consumed after two weeks because the deep color of the starting material disappeared. The needle-

like crystal was elongated to the c-axis developing {100}, {010}, and {110} planes. The chemical analysis of Ni and As in the crystal were conducted by the use of the ICP atomic emission spectrometer, Jarrel Ash ICAP-575II.

The intensities of X-ray diffraction were collected with a Rigaku automated diffractometer using Cu $K\alpha$ radiation monochromatized with a graphite plate. The crystal data were listed in Table 1. The structure was solved by the heavy atom method and was refined by the block-diagonal least-squares method. All hydrogen atoms were neglected in the analysis. The absorption collection was made with a program ACACA written by C. T. Prewitt. R-value was 11.7% without a solvent molecule. The difference synthesis map revealed that solvent molecules are included in the crystal and the solvent molecule was located around (1/2, 1/2, 1/2) in the unit cell. Since the solvent molecule was disordered around the center of symmetry, two atoms, Cl(70) and C(71), overlap other carbon atoms related by the inversion symmetry. In order to avoid the divergence of the overlapped atoms, we refined Cl(70) by using an average atomic scattering factor between chlorine and carbon, and fixed the positional parameters of C(71) at the inversion center. Therefore, the geometry of 1-chloronaphthalene was determined to be heavily distorted. The final R-value decreased to 8.3% by refining the parameters of 1-chloronaphthalene. The molecular geometry of NiTBP did not change significantly before and after including a solvent molecule in the analysis. The temperature factor of fluorine atoms of AsF_6 is very large probably due to the orientational disorder, so that the positions of fluorine atoms could not be accurately determined. Since we are mainly interested in the column structure of NiTBP, we stopped the analysis at this

stage. The final atomic coordinates were shown in Table 2. The computer program used in this analysis was the UNICS system.[10]

The electrical resistivity was measured along the needle axis by using a two-probe method. The contact between the sample and the 20 μm gold wire were made by carbon paint. The polarized reflectance spectrum of the single crystal were measured in the spectral region from 2000 cm^{-1} to 25000 cm^{-1} by using a microspectro-photometric technique.[11,12] ESR were measured with JEOL, JES-FElXG by the use of X-band.

Results and Discussion

$(NiTBP)_3(AsF_6)_2(C_{10}H_7Cl)$. The ratio of the chemical composition between NiTBP and AsF_6 was determined to be 1.4±0.1:1 by means of ICP atomic emission spectrometry of Ni and As atoms. The 3:2 composition was supported also by crystal structure analysis. This chemical composition between a macrocycle and a counter anion is a new one in the family of the radical salts based on the metallo-macrocyclic compounds. Figure 1 shows the side view of the molecular columns of NiTBP. NiTBP's are stacking along the c-axis with their molecular planes parallel to each other. The unit of this molecular column is a trimer of NiTBP which is composed of a molecule, A, on the center of symmetry and two molecules, B and B′, which are interrelated by the center of symmetry. The dihedral angle between the molecules A and B is 0.6°. Table 3 shows the mean bond lengths which were calculated by averaging the chemically equivalent bonds. Significant difference in the molecular geometry was not observed between the molecules A and B, and also between the molecules of $(NiTBP)_3(AsF_6)_2(C_{10}H_7Cl)$ and NiTBPI.[6] The neighboring molecules within the trimer is overlapping with a twisted angle of 45.0° as shown in

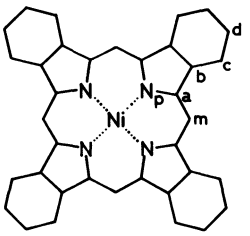

Fig. 2a. This type of overlap is commonly found in the metallo-phthalocyanine iodide (MPcI)[1-3,5] and NiTBP iodide (NiTBPI).[6] The interplanar distance is 3.16 Å, and the Ni-Ni distance is 3.221(2) Å. The molecular overlap between the adjacent trimer is shown in Fig. 2b. The porphyrin skeleton is not twisted but shifted with the interplanar distance of 3.45 Å. This overlapping mode is found in the α-modification of platinum phthalocyanine.[13] The Ni-Ni distance is 3.608(2) Å. The intermolecular atomic distances shorter than 3.4 Å were listed in Table 4. These distances suggest that a charge-transfer interaction exists not only between the molecules A and B but also between B and B'. Figure 3 shows the arrangement of the molecular columns viewed nearly along the c-axis. The NiTBP column is packed pseudo-hexagonally and this packing mode is quite different from those of MPcI and NiTBPI complexes and $(NiPc)_2SbF_6$.[8] The 1-chloronaphthalene molecule is not drawn in Figs. 1 and 3 not to complicate the figure. The solvent molecule is located at the central space, (1/2, 1/2, 1/2) in Fig. 3, the molecular plane making an angle of 57.2° against the NiTBP molecule. The molecular geometry, the an-

isotropic temperature factors, and F_o-F_c data are deposited as Document No. 8791 at the Office of the Editor of Bull. Chem. Soc. Jpn.

The electrical resistivity along the c-axis was 400—1000 ohm cm at room temperature. Figure 4 shows a typical example of the temperature dependence, which indicates the semiconductive behavior. The activation energy of the electrical resistivity was obtained to be 0.26—0.28 eV. If we assume that it is equal to twice the activation energy, the band-gap is estimated to be 0.52—0.56 eV. Figure 5 shows the reflectance spectrum polarized parallel and perpendicular to the c-axis. The //c spectrum exhibited a strong dispersion at about 5000 cm^{-1}, the excitation energy of which is much lower than the lowest intramolecular transition (Q-band) which shows up at 17000 cm^{-1} in the $\perp$c spectrum. Furthermore, this dispersion is completely polarized to the stacking direction. Therefore, this electronic transition is assignable to the charge-transfer (CT) transition. The appearance of the CT transition indicates directly the presence of a strong CT interaction along the stacking direction, in addition to the short intermolecular atomic distances shown in Table 3. Figure 6 shows the optical conductivity spectrum calculated through the Kramers-Kronig transformation of the reflectance spectrum. The FWHM of the CT band is about 1000 cm^{-1} at room temperature, which is extraordinary narrow as compared with organic radical salts.[14-16] The sharp line shape of the CT band means that the electron-molecular vibration coupling is very small. In other words, the distortion of the molecular geometry accompanying the charge transfer is very small. The oscillator strength of the CT absorption band was calculated to be 0.75 per one cation by integrating the conductivity spectrum. This value is considerably larger than the corresponding values: 0.34 for $(BPDT\text{-}TTF)_3(PF_6)_2$[17] and 0.35 of Cs_2TCNQ_3.[18]

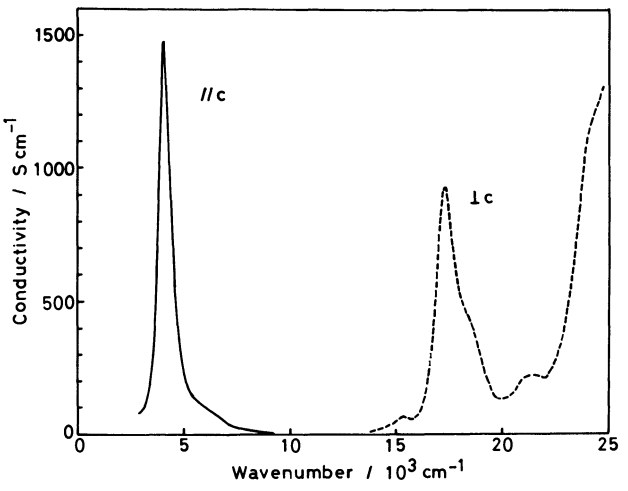

Fig. 6. Optical conductivity spectrum of $(NiTBP)_3(AsF_6)_2(C_{10}H_7Cl)$.

The oscillator strength of the CT band is the measure of the transfer integral. The average transfer integral of $(NiTBP)_3(AsF_6)_2(C_{10}H_7Cl)$ was roughly estimated to be larger than 0.3 eV.[17] A weak ESR signal with a Lorentzian line shape was observed. The g-values were $g//=2.0035$ and $g\perp=2.0014$, and the line widths were $\Gamma//=4.2$ G and $\Gamma\perp=8.0$ G (1G=10^{-4} T), where the static magnetic field was applied parallel and perpendicular to the c-axis. Angle dependence of g-value around the c-axis was very small, and neither g-value nor line width were dependent on temperature. The temperature dependence of the intensity of this signal was Curie-like. The concentration of the unpaired electrons estimated from the temperature dependence of the ESR intensity was 1/1000 molecule^{-1}. Therefore, the large majority of spins on NiTBP forms pairs making non-magnetic ground state, and the origin of the ESR signal is probably attributed to the unpaired electrons trapped at the lattice defects. The g-value of NiTBPI were reported to be $g//=2.060$ and $g\perp=2.018$, and the half width, $\Gamma//=110$ G and $\Gamma\perp=75$ G.[6] In the case of NiTBPI, the unpaired electrons are located both at the Ni atom and at the TBP ligand. The small g-value and the narrow half width of ESR signal in $(NiTBP)_3(AsF_6)_2$-$(C_{10}H_7Cl)$ indicate that the unpaired electrons are located at the TBP ligand. Since the orbital energy of the d_{z^2} is expected to be pressed up by the Ni-Ni interaction, the oxidation part depends probably on the Ni-Ni distance. However, the Ni-Ni distance of this material is almost the same as that (3.217 Å) of NiTBPI.[6] Thus the Madelung energy may also contribute to determine the oxidation part.

The experimental results on the optical spectrum and ESR are quite different from those of organic radical salts like $(BPDT\text{-}TTF)_3(PF_6)_2$[17] and Cs_2-$TCNQ_3$, which are expected to have equivalent electronic structures. For example, Cs_2TCNQ_3 exhibits two CT bands at about 4000 cm^{-1} and 10000 cm^{-1},[18] and presents an ESR signal at room temperature which is attributed to a thermally excited triplet exciton.[19] The appearance of the CT band at higher wavenumber and the small excitation energy of the triplet exciton comes from the large on-site Coulomb energy ($U/4t>1$).[20] However, this material does not exhibit the second CT band despite that the unpaired electrons are making pairs. Therefore, the electronic structure of this material should be understood on the basis of an uncorrelated one-dimensional band model. In this model the CT transition is reinterpreted to be an interband transition and the magnetic activation energy is given by the band gap. This model is in accord with the fact that the band gap estimated from the electrical resistivity agrees quite well with the excitation energy of the optical spectrum. Therefore, we consider that this material have a small on-site Coulomb energy

Table 5. Crystal Growth of Ni(TBP) Complexes by Electrochemical Oxidation

	SbF_6 □	ReO_4 ○	

○: Single crystal, the typical dimension of which is (0.02—0.09)×(0.02—0.09)×(1—4) mm³. □: Microcrystal, the dimension of which is less than 0.01×0.01×0.5 mm³.

($U/4t<1$), which is related to the large size of the TBP ligand and the large transfer integral.

Other Radical Salts. We prepared several radical salts by using other counter anions. The results on the preparative experiment are shown in Table 5. We examined the structural, electrical, and magnetic properties of the large size of single crystals (X=PF_6, BF_4, ClO_4, and ReO_4) shown in Table 5. The X-ray oscillation photographs showed that the periodic unit along the needle axis were about 9.6 Å. All of these salts are semiconductors with the specific resistivities of 10^3—10^4 ohm cm, and exhibited no ESR signal. These properties quite resembles $(NiTBP)_3(AsF_6)_2$-$(C_{10}H_7Cl)$ which we characterized in this paper. Therefore, we consider that the NiTBP radical salts with octahedral and tetrahedral counter anions shown in Table 5 belong to the same family with $(NiTBP)_3$-$(AsF_6)_2(C_{10}H_7Cl)$.

We deeply thank Prof. Hiroki Haraguchi, Department of Chemistry, the University of Tokyo, and Mr. Yoshimasa Kasahara, Japan Jarrel Ash, Co., for the elemental analysis of Ni and As by means of ICP atomic emission spectroscopy. We are grateful to Prof. Takeshi Miyamoto, Department of Chemistry, the University of Tokyo, for kindly providing us 2-acetylbenzoic acid which is the starting material to synthesize NiTBP.

Formation of Graphite Single Crystal from Iron Solution by the Slow Cooling Method

Yoshihiro SUMIYOSHI, Masumi USHIO,* and Sadao SUZUKI
Department of Applied Chemistry, Faculty of Engineering, Gunma University,
Tenjin-cho, Kiryu-shi 376
(Received April 10, 1987)

Graphite single crystals with maximum dimensions of 40 mm in diameter and 0.04-mm thick were prepared from an iron solution by a slow-cooling method. The cell parameters of the product were a_o=2.462±0.002 and c_o=6.708±0.001 Å. A flux of 200 g of electrolytical iron and 8 g of graphite were charged in the graphite crucible. The iron melt, saturated with carbon, was slowly cooled from maximum temperatures ranging between 1800 and 2500 °C to near 1150 °C at cooling rates ranging from 5 to 30 °C min^{-1}. Large graphite single-crystal films of better quality were formed after quick cooling rather than slow cooling. Large graphite crystal films were formed at above 1850 °C; temperatures greater than 1950 °C were needed in order to grow the crystal films with good quality. From in-situ observations through a hole, the growth of the small graphite crystals was seen to occur on the surface of the melt at about 1550 °C; these were gathered in a constant direction, initiating the incorporation of small crystals. The incorporation of the small crystals was promoted at about 1700 °C and the surface of the melt was covered with a single-crystal film. For the formation mechanism of the graphite single-crystal film, a heating process was played an important role.

In recent years, industrial carbon materials have entered the spotlight because of the following interesting properties. Such structures are unique, including amorphous carbon to graphite single crystals; the electrical resistances vary from 10^5—10^6 Ω cm, close to that of a semiconductor to about 10^{-4} Ω cm, comparable with that of a metal. The thermal conductivity of carbon materials expand from ones larger than that of the steel to ones close to that a thermal insulator. The melting point of carbon is 3800 °C and is thus a material having resistance against high temperatures.

These special characteristics are depend on the chemical bonding form of carbon atoms and the crystal structure of graphite based on the carbon atom. Therefore, in order to study such properties as chemical, physical, and mechanical, it is necessary to study the formation of graphite single crystals and to clarify the formation mechanism.

Studies on the formation of graphite single crystals have been reported by many researchers. These formation methods are as follows: (1) A method in which graphite is directly melted and then cooled while crystallizing.[1-3] (2) A method in which graphite is crystallized from a metal melt which is saturated with carbon.[4-9] (3) A method involving the thermal decomposition of metal carbides.[10-12]

In these methods, (2) is most suitable for the formation of large graphite single crystals. Nickel, iron, and many other metals are used as a flux. In these metals, since graphite is highly soluble in iron and iron is more economical than other metals, iron is used as a flux in this experiment.

Studies on the formation of graphite single crystals from an iron melt have been reported by Austerman et al.[7] and Noda et al.[8,9] Austerman et al. synthesized graphite single crystals by slow cooling an iron melt which was saturated with carbon using an electric precision furnace with a temperature gradient control. Noda et al. grew graphite single crystal films of about 30 mm in diameter and about 0.06-mm thick in which the c-axis was parallel to the surface of the iron melt, by slow cooling the iron melt with 1 wt% Si. However, the formation of these large graphite single crystal films was hard to reproduce and the formation conditions have not yet been clearly understood.

The purpose of this study was to clarify the formation conditions and mechanisms of large single crystal films and to elucidate the formation conditions under which graphite single-crystal films become thickened in the direction of the c-axis. The reproducibility was also investigated. Grown graphite single-crystal films were examined by the X-ray Laue photograph method.

Experimental

In the present experiment, carbon-saturated iron was slowly cooled from a maximum temperature ranging between 1800 and 2500 °C, to nearly 1150 °C at a cooling rate ranging between 5 and 30 °C min^{-1}.

An outline of the experimental apparatus is shown in Fig. 1. A Tunman furnace (1.5 kW, Max.current 1000 A) was used as a heating apparatus; it could obtain a maximum temperature of 2500 °C after supplying an electric current to a graphite heater. The dimension of the graphite heater was 260-mm long, 60-mm inner diameter, and 5-mm thick. The graphite crucible (40-mm inner diameter, 5-mm thick, and 50-mm high) was made from a graphite rod by machining. A graphite tube (12-mm inner diameter, 4-mm thick, and 200-mm long) used for observations was made and installed in the graphite crucible.

The surface temperature of the melt was measured using a pyrometer through this graphite tube. Temperature errors were within ±20 °C.

Iron prepared electrolytically (purity above 98%) was used

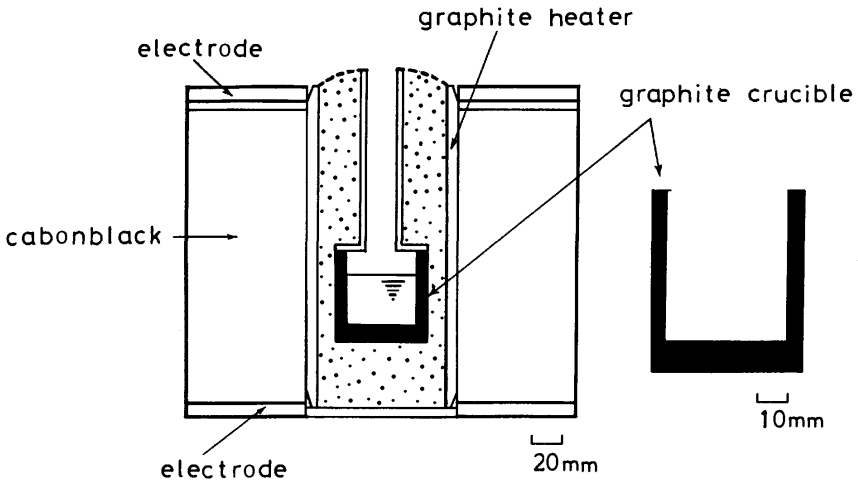

Fig. 1. Arrangement of an electric furnace for the growth of graphite single-crystal film.

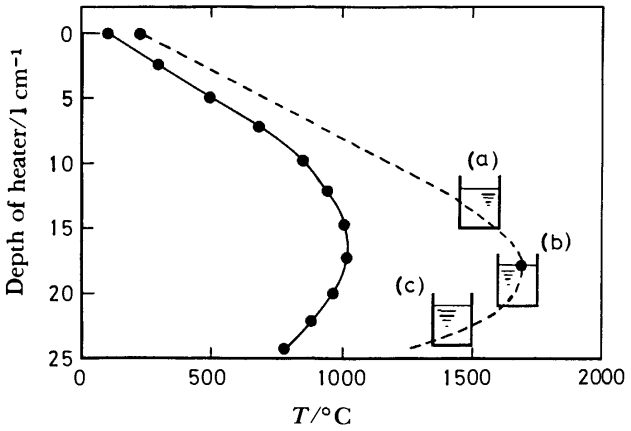

Fig. 2. Temperature distribution in an electric furnace and the positions of the graphite crucibles. -----; estimated curve, —; measured curve, ●; measured value.

as the flux. Graphite powder under 100 mesh, which shaved the graphite rod, was added because the graphite crucible became eroded by the iron melt. The lattice parameters of graphite added in a quantity of about 4 wt% were a_o=2.483±0.002 Å and c_o=6.727±0.002 Å. Powdered iron (200 g) and graphite (8 g) were charged in the graphite crucible.

The experimental process was divided into three steps: a heating process, a constant-temperature process, and a cooling process. The formation conditions of graphite single-crystal films were investigated by considering these three processes.

Temperature Distribution in the Melt. The temperature distribution in the melt significantly affected the formation of a graphite single-crystal film. However, since the graphite heater was fixed at a certain position, the required temperature distribution in the melt was obtained by varing the position of the crucible. The temperature distributions inside the graphite heater and in the melt were measured by a Pt-Pt 13%Rh thermocouple in order to determine the position of the maximum temperature in the heater. The experimental results are shown in Fig. 2. Since the limits of use of the thermocouple is below about 1500 °C, a higher temperature distribution of this experiment can be gained from measurements using a pyrometer. In an experiment involving a slow-cooling method, the crucible was placed at three positions (a, b, and c) as shown in Fig. 2. In the a-position, the lower part of the melt was located at a position of maximum temperature in the heater. On the other hand, the higher part of the melt was located as a position of maximum temperature for the b- and c-positions. In the former, the bottom of the graphite crucible was liable to erode. However, since a thermal convection current was produced in the melt since the lower part of the melt was located at a position of higher temperature, the temperature of the inside of the crucible was liable to make it uniform. On the other hand, for the b- and c-positions, the wall of the graphite crucible was liable to erode; it is therefore thought that a temperature difference between the lower and the higher parts of the melt was generated.

Results

Growth of Graphite Single-Crystal Film. The grown graphite single-crystal films can be classified roughly into the following classes: a large graphite single-crystal film, a small graphite single crystal, and a fine crystal in a solidified flux brick.

In the case of growing a large graphite single-crystal film all over the surface of the melt, it was shown the state of graphite formation as shown in Fig. 3. In this appearance, a graphite single-crystal film could be easily separated from the brick of iron flux.

In the case in which a cooling experiment was carried out at the a-position, a flux brick was created which was supposed to spout from the inside of the crucible through the center of the graphite crystal film, as shown in Fig. 4. Since it was difficult to grow a large graphite single-crystal film and to prevent this phenomenon, the graphite crucible was put in the temperature distribution at the b- and c-positions instead of the a-position. In the b- and c-positions of the crucible, solidification of the melt occured from

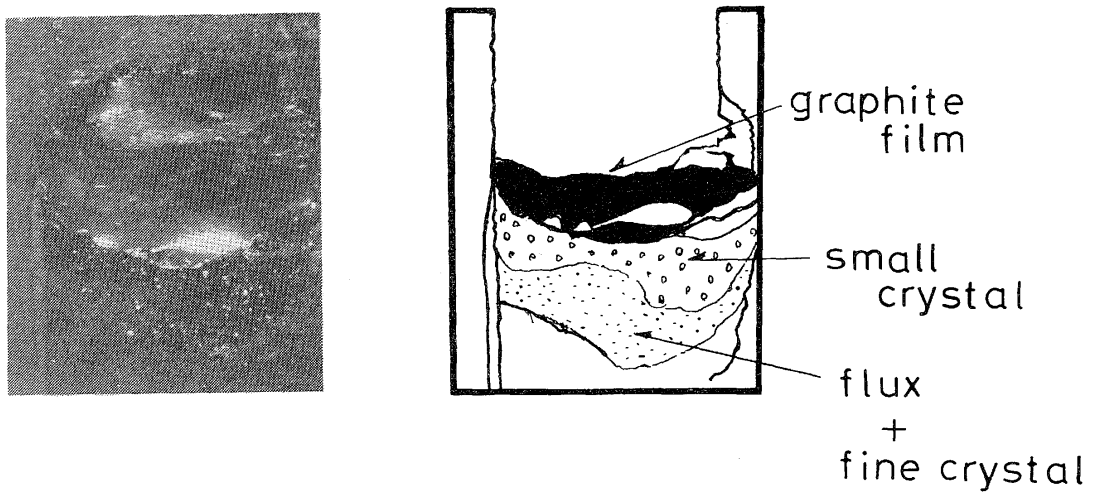

Fig. 3. Typical appearance after the growth of graphite single-crystal film.

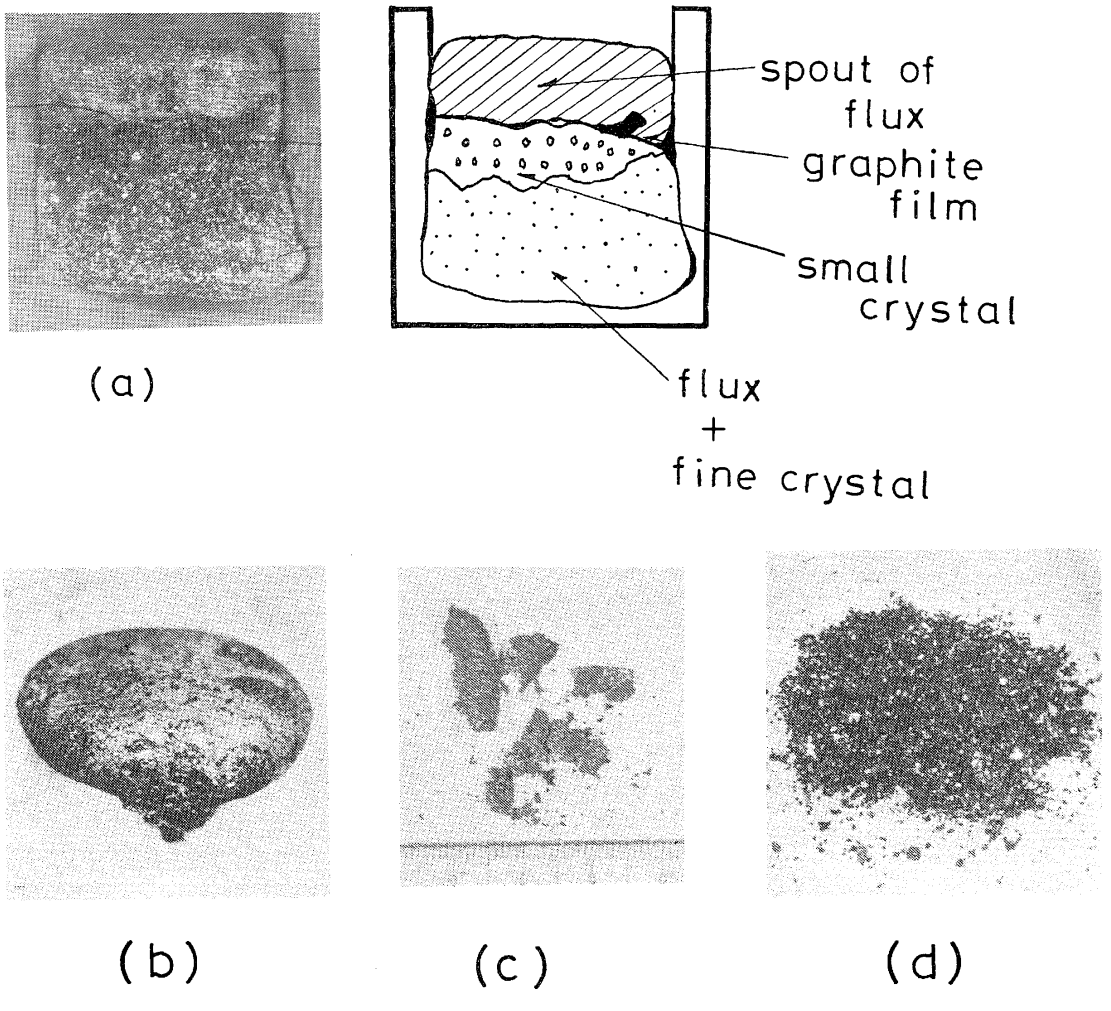

Fig. 4. Typical appearance after the growth of graphite single-crystal film.
(a) The spout of the flux through the center of graphite single-crystal film. (b) Spout of the flux. (c) Graphite single-crystal film. (d) Small graphite crystal.

the lower part, since the temperature at the higher part was higher than at the lower part; thus, the eutectic melt was not spouted out on the graphite single-crystal film. In this case, the single-crystal film could easily be separated from the solidified flux.

The experimental results using the slow-cooling method are shown in Table 1. In this table, the heating rate results from dividing the temperature difference between 1400 °C and the maximum temperature T_m by the time (minute) taken to heat; the cooling rate results from dividing the temperature difference between the maximum temperature T_m and 1400 °C by the cooling time. In order to obtain precise values, it is necessary to use temperature-time relation curves.

In this table, the double circles represent the case in which a large graphite single-crystal film (greater than 2.5 cm in diameter) was grown; the circle represents the case in which small single crystals (less than 1 cm in diameter) were prepared. As is evident from Table 1, when the heating rate was comparatively slow, a large graphite single-crystal film could not be grown at above a heating rate of 10 °C min^{-1}. On the other hand, heating rates between 5 and 9 °C min^{-1} were closely related to the growth of graphite single-crystal films. Regarding the position of the crucible, a large graphite single-crystal film could more easily be grown at the b-position than the a-position.

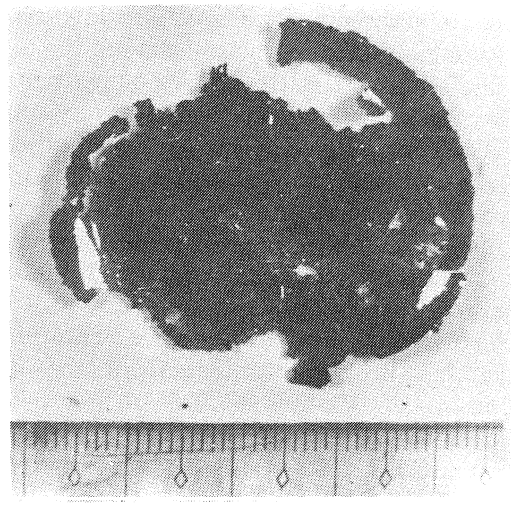

Fig. 5. Grown graphite single-crystal film for Run No. (S-1-14).

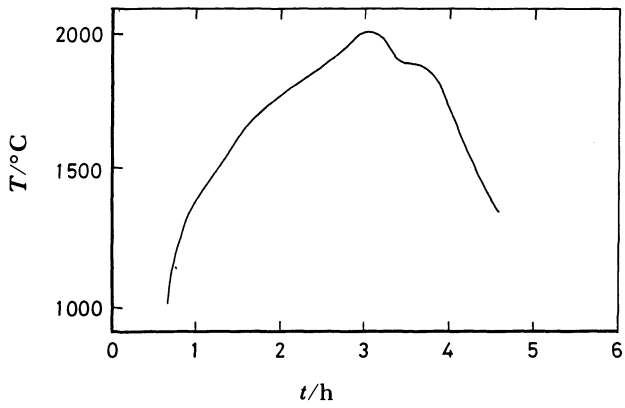

Fig. 6. A heating curve during the growth of graphite single-crystal film for Run No. (S-1-14).

Fig. 7. An appearance of the graphite crucible just after the growth of graphite single-crystal film for Run No.(S-1-17).

The photograph of a single-crystal film obtained from Run No. (S-1-14) and the heating curve are shown in Figs. 5 and 6, respectively. A large single-crystal film with a metallic luster and the dimensions of 4 mm in diameter and 0.03_5 mm thick, could be grown. The circumference of this single-crystal film curved at a state of meniscus. The grown graphite single-crystal film had good quality, judging from the Laue X-ray pattern.

A photograph of experimental Run No. (S-1-17) and the heating curve are shown in Fig. 7. The spout of a flux melt was formed through a single-crystal film with metallic luster. This depended on quick cooling: that is, a cooling rate of 30 °C min^{-1}.

Laue X-Ray Photographs and Electron Diffraction Patterns. From a Laue X-ray photograph of the product of Run No. (S-1-5), it was presumed that the grown graphite single-crystal film had a good quality, judging from the spots of hexagonal symmetry. Though the grown single-crystal film from Run No.

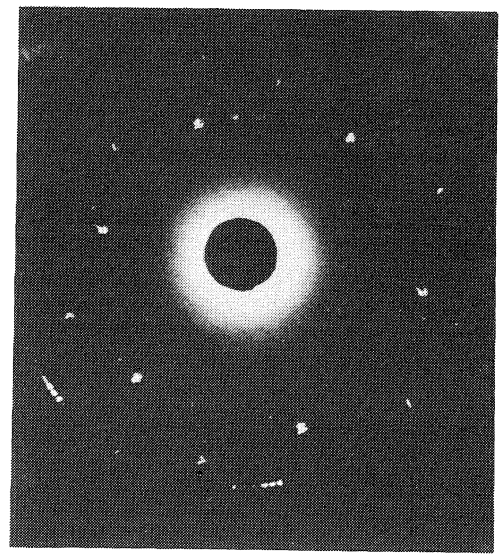

Fig. 8. Laue photograph of the graphite single-crystal film for Run No. (S-1-14).

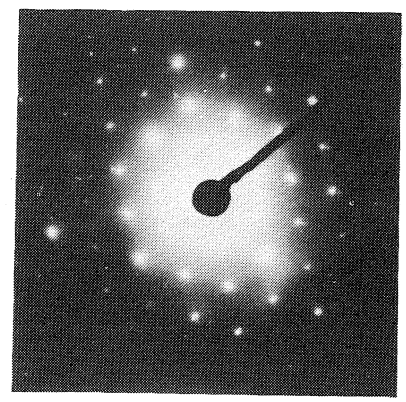

Fig. 9. An electron diffraction pattern of the graphite single-crystal film for Run No. (S-1-14).

(S-1-6) had good crystallinity, it was hard to say whether it was a single crystal from a Laue X-ray photograph and the electron diffraction pattern.

A Laue X-ray photograph and an electron diffraction pattern of the single-crystal film from Run No. (S-1-14) are shown in Figs. 8 and 9. It appears that the grown crystal had very a good quality.

Discussion

The reason that the flux spout formed above the graphite single crystal film (Fig. 4) is thought to be due to a solidification of the melt that occured from its surface. The internal pressure resulted from a contraction of iron flux upon solidifying; then, the eutectic melt of the flux plus graphite gushed out to the surface of the single-crystal film.

Formation Condition and Mechanism of a Graphite Single-Crystal Film. Graphite single-crystal films with good quality were obtained from Runs No. (S-1-5), (S-1-6), (S-1-10), (S-1-12), (S-1-14), (S-1-16), and (S-1-17), as is shown in Table 1. From these results, the formation conditions and mechanism of graphite single-crystal films are discussed in detail.

In an experiment involving the slow-cooling method, it was widely noted that the iron-flux method saturated when the graphite was cooled; it then separated the saturated graphite as crystals. This process, which separated the crystals from the iron flux, can be classified into two classes: the nucleation and the crystal growth. These two phenomena were strongly dependent on the temperature. The rate of nucleation was generally faster as the cooling rate increased, and the growth rate of crystal was faster as the temperature increased. Consequently, it is necessary to grow a single crystal in which nucleation occurs as much as possible and the crystals grow. As described above, the experimental process was thought to classified into three large steps: heating, constant-temperature and cooling processes. The correlation between these processes and the formation of a large graphite single-crystal film was investigated.

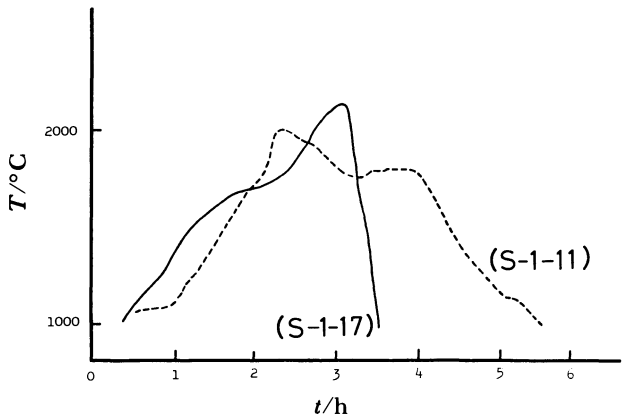

Fig. 10. Comparison of Run No. (S-1-17) quenched quickly with Run No. (S-1-11) cooled slowly.

Cooling Process. The cooling process, which was believed to be very important and a strong governing factor, was examined in terms of the cooling method. Figure 10 summarizes the results of both the temperature curves of an experiment involving rapid cooling (Run No. (S-1-17)) and an experiment involving slow cooling (Run No. (S-1-11)). Although it is generally said that for a slower cooling rate the better is the graphite single-crystal film quality, a large graphite single crystal with good quality was formed for Run No. (S-1-17), compared to Run No. (S-1-11) involving slow cooling. The assumption was compatible with these results. Note that a large

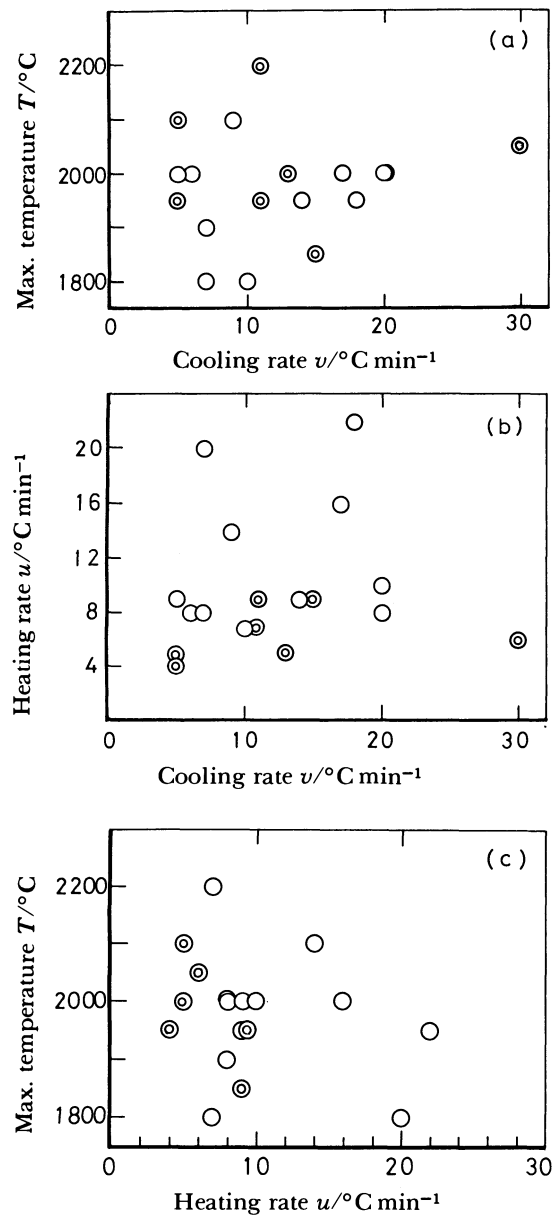

Fig. 11. Relationship among the growth ease of the graphite single-crystal film and the cooling rate, the heating rate, and the maximum temperature.
O: small film below 1 cm dia., ◎: large film above 2.5 cm dia.

graphite could be formed, even if the slow cooling was fairly well controlled. An adequate correlation based upon the cooling rate could not be found, as is shown in Fig. 11. Thus, there was little possibility of a factor which determines the formation of a graphite single-crystal film. In the cooling process, small crystals were formed below the graphite single-crystal film. Therefore, an apparatus that could control the cooling process was used; small crystals were thought to grow to some degree. A cooling process was far from a factor influenced to the growth of graphite single-crystal film.

A Constant Temperature Process. The next factor examined was the influence of the maximum temperature and its holding time. The experimental results are shown in Table 1. The influence of the maximum temperature are not shown to have a certain correlation. A large graphite single-crystal film could be formed if the maximum temperature was above 1850 °C as shown in Table 1.

We could not determine the correlation in terms of the holding time at the maximum temperature (Fig. 12). However, this constant-temperature process shows a very attractive tendency, which is obvious by comparing the temperature curves of Run No. (S-1-5) and Run No. (S-1-6), as shown in Fig. 13. In the case of Run No. (S-1-5), the temperature was held constant at a value which fell slightly from the maximum temperature (1950 °C); under this condition a graphite single-crystal film with good quality was formed. However, in Run No. (S-1-6) with a constant temperature of 1850 °C, a graphite single-crystal film of good quality could not be grown.

Generally, in the case of the type as shown in Fig. 14(a), a single-crystal film with good quality could form (Run No. (S-1-5), (S-1-14), and (S-1-16)). On the other hand, as for the temperature curve of the type shown in Fig. 14(b), Runs No. (S-1-7), (S-1-10), and (S-1-13), large graphite single-crystal films of good quality could not be formed. From these results, it appears to act as the annealing if the constant temperature, which lowered slightly from the maximum temperature, held. However, it seems to be true that another dominant factor existed.

A Heating Process. Finally, the more important factor was the heating process. The experimental results are shown in Fig. 11. In case that the heating rate was below 9 °C min^{-1}, a large graphite single crystal with good quality could form. The relation between graphite single-crystal film growth and the heating process could be determined by observing the surface of the melt from a hole. The experimental results are schematically shown in Fig. 15. It was observed that graphite single crystals rose to the surface of the melt at a temperature of about 1550 °C, and gathered in the constant direction; then, the incorporation of crystals was initiated. This incor-

poration was promoted at about 1700 °C and the graphite single crystal covered the surface areas. Also, wrinkled patterns on the surfaces of the grown small graphite crystals were observed. These patterns were in agreement with that of a grown single-crystal film observed after the experiment. It was thus found that a single-crystal film is formed during the heating processes.

This formation mechanism of graphite single-crystal films is new and quite different from the so-called mechanism of the crystal growth by slow-cooling.

As previously stated, small graphite crystals were observed to gather in a constant direction, as is shown in Fig. 15. To investigate the cause, the temperature distribution in the horizontal direction of the graphite heater was observed. As a result, the temperature difference between sides in the central sections of the heater was several 10 °C. It seems that the graphite heater was wasted unequally during many repeated experiments; consequently, a temperature difference in the horizontal direction of the heater was produced. Accordingly, it is obvious that a temperature difference was produced in the horizontal direction in the same manner in the vertical direction as the temperature was increased.

The crystal growth of graphite is considered to be as follows. As is shown in Fig. 16, the graphite became saturated from the melt while precipitating and migrating from the lower-temperature (T_L) parts to the high-temperature (T_M) parts, owing to a difference in the specific gravities. It then floated to the surface of the melt. Then, graphite crystals were incorporated the opposite side (T_{M_2}) of the crucible wall (T_{M_1}), where the graphite heater was fairly wasted. A graphite single-crystal film with good quality was obtained by holding these incorporated crystals at a constant temperature.

From this point of view, the heating process was very significant. Therefore, the incidence of a nucleus could be slightly lowered by the decreasing the temperature difference, thus, decreasing the heating rate within 6 °C min^{-1}. It is possible that a large graphite single-crystal film with good quality was obtained by increasing the growth rate of the crystal as the temperature increased, within the scope of the heating process. In conclusion, when making use of a temperature difference in both horizontal and vertical directions, by controlling the heating rate to be 6 °C min^{-1}, and holding the maximum temperature above about 1950 °C, a large graphite single-crystal film was obtained with good reproducibility. Such hitherto performed experiments as the slow-cooling method are described; however, from a practical point of view it could be called a sort of temperature-gradient method which made use of the both temperature difference between in the horizontal and vertical directions.

Transmission Laue Photograph and Electron Diffraction Patterns. The graphite single-crystal films formed were examined by X-ray and electron diffraction methods as to whether these crystals had good quality or not.

The crystal structure of graphite has a stratified layer structure. The regular hexagonal rings of the carbon atoms are numerously linked together and make the enormous network plane. These alternate layers fall vertically above one another. Owing to the way these layers are piled, the graphite structure has two polytypes: a hexagonal system with an ABABAB structure (2H) and a rhombohedral system with an ABCABCABC structure (3R). The hexagonal system is the most common in graphite crystals with a unit cell of a_o=2.4612 Å and c_o=6.708 Å; the 3R-type unit cell is a_o=2.4612 Å and c_o=10.062 Å, by expressing it by the hexagonal cell. In the grown graphite single-crystal films with the high crystallinity, the Laue spots show a 6-fold axis of symmetry of the distinct {101} and {112} forms.

In the case of experimental Run No. (S-1-14), as

shown in Fig. 8, a Laue pattern of the distinct 6-fold axis of hexagonal symmetry was obtained, indicating that a graphite single-crystal film with good quality was obtained.

The indices of these spots were evaluated by making use of a gnomonic projection method. By closely observing the Laue spots of the graphite single-crystal film for Run No. (S-1-14), it is obvious that these spots were split. When an electron diffraction photograph of the same graphite single-crystal film was taken and magnified, the spots were certainly split. In this case, the split spots of a graphite single-crystal film should be based on either twised two sheet-like networks or on the incompatibility of these networks in the a- and the b-directions. Perhaps, we suppose that the small crystals were adhered to the surface of the graphite single-crystal films.

Conversely, there was also a case in which the spots on a concentric circle were not split; the split spots appeared at the inside or outside of the circle. There is a reason that the graphite crystal was expected as a single one; however, graphite single-crystal films were piled up and the spots of the Laue photograph were split and then appeared at the inside or outside of the concentric circle, or small crystals adhered to the surface of the single-crystal film.

When we examine the Laue spots of the graphite single-crystal film curved to meniscus for Run No. (S-1-14), many spots could be recognized at the insides and outsides of the spots of 6-fold symmetry, except that of the 6-fold symmetry for {101} and {112} groups. These many spots could not index with a hexagonal system. From data of the powdered X-ray diffraction patterns, the Laue photograph, etc., we determined that these many spots corresponded to a rhombohedral structure and also that many spots on a concentric circle, except for the 6-fold symmetry, corresponded to a twisted structure like the aberration of the positions of card as a spiral stairs. There are a few cases in which a rhombohedral structure was created by a shear-stress deformation.[13]

In the present experiment, the outside circumference of the graphite single-crystal film was curved by accepting a deformation stress during the cooling time; it was also thought that a rhombohedral structure was partially created.

It is recognized that a rhombohedral structure existed several per cent in a natural graphite crystal as well as in an artificial graphite crystal with good quality. Therefore, it could be thought that the rhombohedral structure also partly existed in the large graphite single-crystal film with good quality.

Unit Cell Parameters of a Graphite Single-Crystal Film. The parameters, a_0 and c_0 values, of the graphite single-crystal film were 2.462±0.002 Å and 6.708±0.001 Å, respectively, according to the present data from the powdered X-ray diffraction method and agreed with that of a natural graphite crystal.

Liquid-Liquid Extraction of Some Class *b* Metal Ions with a Thiacrown Compound, 1,4,7,10,13,16-Hexathiacyclooctadecane

Eiichi SEKIDO,* Hideo KAWAHARA, and Kaoru TSUJI
Department of Chemistry, Faculty of Science, Kobe University, Rokkodai, Nada-ku, Kobe 657
(Received July 20, 1987)

The liquid-liquid extraction of various metal ions, especially of soft class *b* metal ions with a thiacrown compound, 1,4,7,10,13,16-hexathiacyclooctadecane (HTCO) using picrate ion (Pic^-) was examined and compared with that of 1,4,8,11-tetrathiacyclotetradecane (TTCT). Although the extraction behavior of the class *a*, *ab*, and *b* metals with HTCO is fundamentally similar to that with TTCT, that of some metals belonging to class *b* metals with HTCO is different from that with TTCT. The extraction percentages of copper(II) and palladium(II) with HTCO are a few times larger than those with TTCT. Copper(I) and silver(I) are extracted with HTCO as the 1:1 complexes such as $[Cu(htco)]^+Pic^-$ and $[Ag(htco)]^+Pic^-$, respectively, regardless of the relative concentration of the ligand to the metal. On the other hand, copper(I) and silver(I) complexes with TTCT are extracted with different compositions depending upon the relative concentration of the ligand to the metal.

The extraction behavior of various metal ions, especially of the class *b* metal ions, with the thiacrown compound, 1,4,8,11-tetrathiacyclotetradecane (TTCT) was examined using perchlorate ion as the counter anion and dichloroethane or chloroform as the extraction solvent.[1,2] It was found that class *a* metal ions were not extracted at all, and *ab* metal ions, except the copper(II) ion, were hardly extracted but class *b* metal ions were extracted.

Although the formation of the metal thiacrown cation complex might be primarily governed by the softness of the metal ion to bond with the sulfur atom in a thioether type ligand (R-S-R), it will depend also on the size ratio of the metal ion to the cavity of the thiacrown ligand and on the favourable stereochemistry of the metal ion with minimal strain of the cyclic ligand molecule. Moreover, the extraction of the metal ion is associated with the formation of the ion pair between the formed metal complex cation and the counter anion and also with the affinity of the generated ion pair for the organic solvent. Consequently, it is interesting to investigate how the extraction behavior of various metals alters (especially the *b* metals) according to the number of sulfur atoms and to the number of the constituent atoms in the cyclic thiacrown ligand. This can help to separate the class *b* metals by the solvent extraction with thiacrown compounds.

In this paper, the extraction behavior of metal ions with 1,4,7,10,13,16-hexathiacyclooctadecane (HTCO) which has six sulfur atoms in its 18-membered ring is examined and compared with that of 1,4,8,11-tetrathiacyclotetradecane (TTCT) which has four sulfur atoms in its 14-membered ring.

Experimental

Reagents. The reagent, HTCO, was synthesized according to the method by Black and McLean,[3] and recrystallized twice from ethyl acetate-hexane. The reagent, TTCT, synthesized according to the method by Rosen and Bush[4] was recrystallized three times from chloroform-ethanol. HTCO as well as TTCT were dissolved in 1,2-dichloroethane immediately prior to use. Metal sulfates (guaranteed-reagent grade) were used except for thallium(I) nitrate and the 1×10^{-2} mol dm^{-3} stock solution of each metal ion was prepared. The concentration of each metal was determined by potentiometric titration with chloride. 1,2-Dichloroethane was shaken three times with 2 mol dm^{-3} potassium hydroxide and with distilled water, dried with calcium chloride and distilled. Other reagents were of guaranteed-reagent grade.

Apparatus. A Taiyo M incubator was used for shaking the solutions. A Seiko SAS-725 atomic absorption spectrophotometer was used for the determination of metal ions. UV and visible absorption spectra were measured with a Shimadzu UV-240 recording spectrophotometer. The IR spectra of isolated metal thiacrown complexes were taken with a Hitachi 207 EPI-G2 type grating IR spectrophotometer. The pH of the aqueous phase was measured with a Hitachi-Horiba H-5 pH meter.

Liquid-Liquid Extraction of Various Metals. Ten ml of the aqueous solution containing 5×10^{-5} mol dm^{-3} metal ion, 1×10^{-3} mol dm^{-3} picrate ion and 1×10^{-2} mol dm^{-3} acetate buffer, were kept at an ionic strength of 0.1 with sodium sulfate. This solution was kept in a stoppered 50 ml glass cylindrical tube. For the copper(I) solution, hydroxylammonium sulfate was added to copper(II) sulfate solution to give 0.1 mol dm^{-3} hydroxylamine solution. To the resulting aqueous solution 10 ml of 5×10^{-3} or 5×10^{-4} mol dm^{-3} HTCO or TTCT 1,2-dichloroethane solution was added and the mixture was shaken for 30 min on 200 strokes/min at 25±0.1 °C. The mixture was then centrifuged for 5 min at 2000 rpm, the pH of the aqueous phase was measured and the concentration of the picrate ion in the aqueous phase was determined spectrophotometrically at 354 nm. The concentrations of the metal ion in the aqueous and organic phases were determined by atomic absorption spectrophotometry. The metal concentration in an organic phase was determined as follows: A definite quantity of the organic phase was allowed to evaporate, the

residue was treated with small amounts of concentrated nitric acid and diluted with water to a standard volume and the concentration of the metal was then determined by atomic absorption spectrophotometry.

Isolation of Metal-HTCO and -TTCT Complexes. **Copper(I)-HTCO Complex:** Twenty ml of an aqueous solution containing copper sulfate (1×10^{-2} or 5×10^{-3}), hydroxylammonium sulfate (0.1 mol dm^{-3}), sodium picrate (1×10^{-2} mol dm^{-3}) and acetic acid-sodium acetate buffer (0.1 mol dm^{-3}, pH 4.4—5.0) was stirred with 20 ml of HTCO 1,2-dichloroethane solution (1×10^{-2} mol dm^{-3}) for 30 min at 25 °C in a 50 ml separation funnel. The yellow-orange deposit which formed between the two phases was filtered, washed with ethanol and 1,2-dichloroethane and dried in vacuo.

Silver(I)-HTCO Complex: The silver(I)-HTCO complex was extracted by the same method described in the isolation of copper(I)-HTCO complex, using silver nitrate instead of copper sulfate. After stirring, the mixed solution was centrifuged. When carbon tetrachloride was added to the separated organic phase, a yellow deposit was obtained. The filtered deposit was washed with ethanol and dried in vacuo.

Silver(I)-TTCT Complex: Twenty ml of the aqueous solution adjusted with acetic acid-sodium acetate to pH 5.0 containing silver sulfate (1×10^{-2} or 5×10^{-3} mol dm^{-3}) and sodium picrate (2×10^{-2} mol dm^{-3}) was placed in a 50 ml separation funnel and stirred with 20 ml of HTCO 1,2-dichloroethane solution (1×10^{-2} mol dm^{-3}) for 30 min at 25 °C. After centrifugation of the mixed solution, the organic phase was separated. On addition of 40 ml of carbon tetrachloride to the organic phase, a yellow solid deposit was obtained. It was washed with carbon tetrachloride and dried in vacuo.

Determination of the Composition of Metal Thiacrown Complexes. In order to determine the amount of the picrate ion contained in copper(I) and silver(I) thiacrown complexes, a definite amount of each complex was dissolved in DMF and the concentration of the picrate ion was spectrophotometrically determined by measuring the absorbance at 378 nm. To determine each metal ion concentration, metal thiacrown complexes were dissolved in DMF or were decomposed with sulfuric acid and then the resulting solution was then adequately diluted and the concentration of each metal was determined by atomic absorption spectrophotometry. The contents of HTCO and TTCT in the copper(I) and silver(I) complexes were estimated by subtracting of the amounts of both the metal and picrate ion from the initial amounts of the complex.

Results and Discussion

Liquid-Liquid Extraction of Various Metals with HTCO. The following metals were examined: Na(I) and Mg(II) as the class *a* metal; Mn(II), Co(II), Ni(II), Cu(II), Zn(II), and Tl(I) as the class *ab* metal; Cd(II), Cu(I), Ag(I), and Pd(II) as the class *b* metal. The results are shown in Table 1 with those for the extraction with TTCT.[1] It was found that the extraction

a) Ref. 6. b) Ref. 7. c) Ref. 1.

behavior of the class *a*, *ab*, and *b* metal groups with HTCO is fundamentally similar to that with TTCT. That is, Na(I) and Mg(II) were not extracted at all, Mn(II), Co(II), Ni(II), Zn(II), Tl(I), and Co(II) were very weakly extracted Cu(II) and Pd(II) were extracted in some degree and Cu(I) and Ag(I) were extracted very well. The increases of both the constituent atoms of the thiacrown ring from 14 members for TTCT to 18 for HTCO and the sulfur ligand atoms from 4 for TTCT to 6 for HTCO had hardly any effect on the extraction behavior of the class *a* and *ab* metals. This fact means that the class *a* and *ab* metals except for copper(II), do not bind at all or very little with the sulfur atoms of the thioether type (R-S-R), regardless of other factors such as the number of sulfur atoms in the ligands, the number of constituent ring atoms, the molecular structure of the ligand, the kinds of the counter anion and the extraction solvent. However, the extraction behavior of some metals belonging the class *b* metals and copper(II) with HTCO is different from that with TTCT. For example, it was found that the percent extraction of Cu(II) and Pd(II) with HTCO is a few times larger than that with TTCT.

Extraction of Copper(I) and Silver(I). Copper(I) and silver(I) are almost completely extracted at pH 4.0 and 5.4 as shown in Table 1. Further, the dependence on pH and on the concentrations of the ligand and the picrate ion on the extraction of copper(I) and silver(I) were examined.

Dependence on pH: Plots of the logarithmic distribution ratio of copper(I) and silver(I) with HTCO against the pH of the aqueous phase are shown in Fig. 1. The decrease of the copper(I) extraction below pH 4 can be attributed to the decrease of the reducing power of hydroxylamine in acidic medium as well as in the case of Cu(I) extraction with TTCT.[1)]

Dependence on the Concentration of the Ligand and Picrate: If the species extracted into an organic phase is represented by $M(htco)_mPic_n$ (Pic^-: picrate ion), the extraction equilibrium and the extraction constant, K_{ex}, are given by Eqs. 1 and 2, respectively,

$$M^n + m\,htco(o) + nPic^- \overset{K_{ex}}{\rightleftharpoons} M(htco)_m(Pic)_n(o) \quad (1)$$

$$K_{ex} = [M(htco)_m(Pic)_n]_o/[M^{n+}][htco]_o^m[Pic]^n \quad (2)$$

where (o) and subscript o indicate the species in the organic phase. The logarithm of the distribution ratio of a metal, $\log D_M$ is represented by the Eq. 3.

$$\log D_M = \log K_{ex} + m\log[htco]_o + n\log[Pic^-] \quad (3)$$

The extraction of copper(I) and silver(I) at pH 4.4 was examined at various concentrations of picrate ion under constant concentration of HTCO, 5×10^{-4} mol dm^{-3}. The relationships between the logarithmic distribution ratio of copper(I) and silver(I), $\log D_M$, and the logarithm of the picrate concentration in the aqueous phase, $\log[Pic^-]$, are shown in Fig. 2. Two straight lines were obtained with slopes close to +1.0, indicating that $n=1$.

Similarly, the value of "*m*" in Eq. 3 should be given by the slope of the straight line obtained by the plots of $\log D_M$ vs. $\log[htco]$. However, these plots gave a straight line which is independent of [htco]. As examples, plots of $\log D_{Ag}$ vs. $\log[htco]$ in various organic

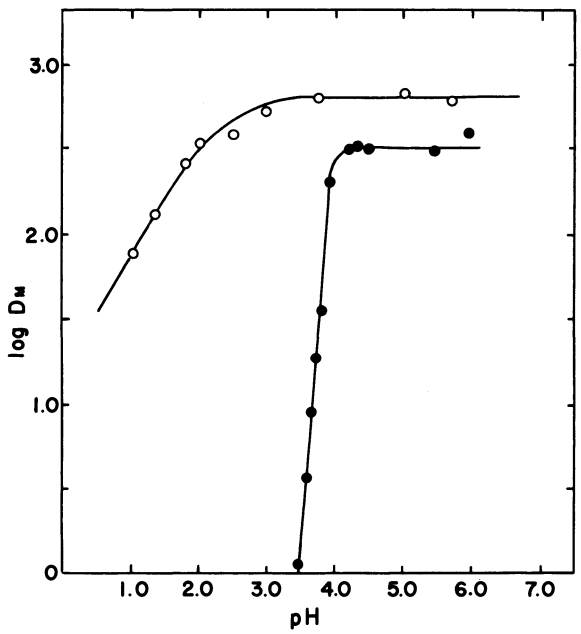

Fig. 1. Plots of distribution ratio of copper(I) (●) and silver(I) (○) vs. pH. Initial concentration: HTCO; 5×10^{-3} mol dm^{-3}, copper(I) and silver(I); 5×10^{-5} mol dm^{-3}.

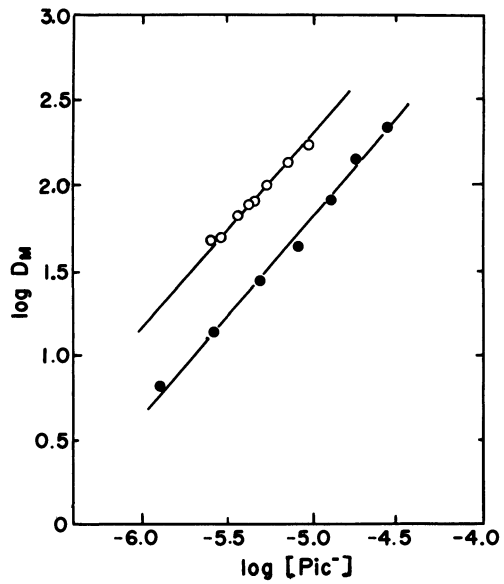

Fig. 2. Plots of $\log D_M$ vs. $\log[Pic^-]$ for copper(I) (●) and silver(I) (○). Initial concentration: HTCO; 5×10^{-4} mol dm^{-3}, copper(I) and silver(I); 5×10^{-5} mol dm^{-3}. pH 4.4.

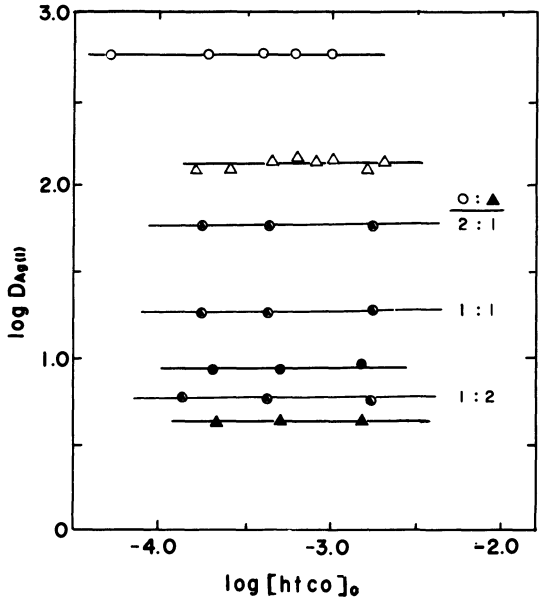

Fig. 3. Plots of $\log D_{Ag(I)}$ vs. $\log[htco]_o$ for various organic solvents. Initial concentration: silver(I); 5×10^{-5} mol dm^{-3}, picrate; 5×10^{-4} mol dm^{-3}. Organic solvent: O; 1,2-dichloroethane, △; chloroform, ●; benzene, ▲; carbon tetrachloride, ◭; mixture of 1,2-dichloroethane and carbon tetrachloride. pH: 5.4.

solvents such as 1,2-dichloroethane, chloroform, benzene and carbon tetrachloride, are shown in Fig. 3. The straight lines are independent of the concentration of HTCO and the values of $\log D_{Ag}$ increase in the order of 1,2-dichloroethane>chloroform>benzene> carbon tetrachloride, which is the order of their dielectric constants. The reason that values of the $\log D_{Ag}$ are below 1.0 for benzene and carbon tetrachloride will be owing to the formation of the yellow precipitate on the boundary of two layers. It is thought that the solubility of their ion-pair compound, $[M(htco)_m]^+Pic^-$, is limited in solvents having a low dielectric constant. This supposition is also supported by the facts that the values of the $\log D_{Ag}$ in a mixture of 1,2-dichloroethane and carbon tetrachloride do not vary with the concentration of HTCO and that their values decrease with the increase of the fraction of carbon tetrachloride in the mixture as shown in Fig. 3. The reason why the values of $\log D_M$ for copper(I) and silver(I) do not depend on the concentration of HTCO can be explained as follows. The ability of the complex formation of HTCO to copper(I) and silver(I) is so high that the equilibrium of

$$M^+ + m\,htco \rightleftharpoons [M(htco)_m]^+ \quad (4)$$

lies far to the right. Therefore, it is considered that the concentration of uncomplexed copper(I) or silver(I) in the aqueous phase is too low to be determined by atomic absorption spectrophotometry. Thus, the

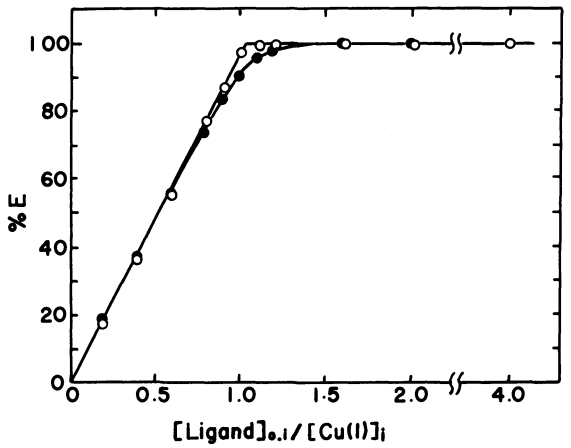

Fig. 4. Molar ratio study for copper complexes with HTCO (O) and TTCT (●). Initial concentration: copper(I); 5×10^{-5} mol dm^{-3}, picrate; 5×10^{-4} mol dm^{-3}. pH: 4.0.

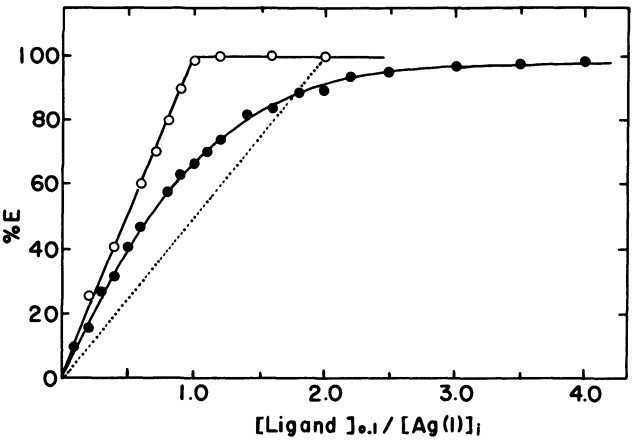

Fig. 5. Molar ratio study for silver(I) complexes with HTCO (O) and TTCT (●). Initial concentration: silver(I); 5×10^{-5} mol dm^{-3}, picrate; 5×10^{-4} mol dm^{-3}. pH: 4.0 Dotted line represents the case of formation of the stable 1:2 complex alone.

extractions of these metals appear to depend only upon the distribution of the ion-pair complex, $M(htco)_m^+Pic_n^-$.

In order to determine the value of m, the molar ratio method was tried. The plots of the %E for copper(I) vs. the ratio of $[htco]_{o,i}$ or $[ttct]_{o,i}$ to $[Cu(I)]_i$ and similar plots for silver(I) are shown in Figs. 4 and 5, respectively. The subscript i represents the initial concentration. In Fig. 4, the %E of copper(I) increases linearly with the increase of the ratio, $[htco]_{o,i}/[Cu(I)]$, and reaches almost 100% at the ratio=1. The distinct break point at $[htco]_{o,i}/[Cu(I)]_i=1$ means $m=1$. It is obvious that copper(I) forms the very stable 1:1 cationic complex, $[Cu(htco)]^+$, and the ion pair, $[Cu(htco)]^+Pic^-$, which is effectively extracted into 1,2-dichloroethane. The fact that the break point for HTCO is clearer than for TTCT as shown in Fig. 4

Table 2. Composition of Copper(I) and Silver(I) Complexes with HTCO

Metal	Initial condition	Metal:HTCO:Pic (Found)	Proposed formula
Cu(I)	Cu : HTCO = 1 : 1	1.0 : 1.0 : 0.9	[Cu(htco)]Pic
	Cu : HTCO = 1 : 2	1.0 : 1.1 : 0.9	[Cu(htco)]Pic
Ag(I)	Ag : HTCO = 1 : 1	1.0 : 0.9 : 0.9	[Ag(htco)]Pic
	Ag : HTCO = 1 : 2	1.0 : 0.8 : 0.9	[Ag(htco)]Pic

Table 3. Composition of Copper(I) and Silver(I) Complexes with TTCT

Metal	Initial condition	Metal:TTCT:Pic (Found)	Proposed formula
Cu(I)	Cu : TTCT = 1 : 1	1.0 : 1.3 : 1.0	[Cu(ttct)]Pic
	Cu : TTCT = 1 : 2	1.0 : 1.6 : 0.9	[Cu(ttct)]Pic + [Cu(ttct)$_2$]Pic
Ag(I)	Ag : TTCT = 1 : 1	1.0 : 0.4 : 0.8	[Ag$_2$(ttct)]Pic$_2$
	Ag : TTCT = 1 : 2	1.0 : 0.6 : 0.8	[Ag$_2$(ttct)]Pic$_2$ + [Ag(ttct)]Pic

indicates the copper(I)-HTCO complex is more stable than the copper(I)-TTCT complex. From both Eq. 3 and the result shown in Fig. 2, log K_{ex}=8.7±0.4 for the extraction of copper(I) with HTCO was estimated, of which value is larger than the value, 7.3±0.3 for copper(I)-TTCT.[1]

As shown in Fig. 5, the results of the molar ratio study for silver(I) to HTCO and TTCT seem to be different. In the case of HTCO, a distinct break point is found at $[htco]_{o,i}/[Ag(I)]=1$, which indicates that the extracted species is [Ag(htco)]Pic. On the other hand, in the case of TTCT, it seems to form the more stable [Ag(ttct)$_2$]Pic than [Ag(ttct)]Pic which may form on the ratio of $[ttct]_{o,i}/[Ag(I)]<1$. This estimation accords with the previous report[5] that silver(I) is extracted as the ion-pair complex compound, [Ag(ttct)$_2$]$^+$Pic$^-$, under the presence of the excess TTCT. The composition of the extracted silver(I) complex species seems to be different between TTCT and HTCO. The comparison of the curves of silver(I)-HTCO and -TTCT in Fig. 5, indicates that the 1:1 silver(I)-HTCO complex is more stable than the 1:1 or 1:2 silver(I)-TTCT complex.

Isolated Copper(I) and Silver(I) Complexes with HTCO and TTCT. The results of the determination of the compositions of copper(I) and silver(I)-HTCO and -TTCT complexes isolated from their extracts into 1,2-dichloroethane solution are shown in Table 2 for HTCO complexes and Table 3 for TTCT complexes. As seen in Table 2, regardless of the initial concentration ratios of copper(I) to HTCO, the molar ratio of copper(I), HTCO and picrate ion of the isolated complex is 1:1:1, corresponding to a proposed formula [Cu(htco)]Pic. This accords with the results of the above mentioned solvent extraction. Similarly, the composition of silver(I)-HTCO complex is [Ag(htco)]Pic, regardless of the initial concentration ratio of silver(I) to HTCO. However, as seen in Table 3, the composition of the copper(I) and silver(I)-TTCT complexes was not simple. Increasing the initial concentration of TTCT increases the content of TTCT and the complex seems to be a mixture of [Cu(ttct)]Pic and [Cu(ttct)$_2$]Pic. According to the study of the extraction equilibria for the copper(I)-TTCT-Pic complex,[1] it was estimated that copper(I) is extracted as the 1:1:1 complex, [Cu(ttct)]$^+$Pic$^-$, into 1,2-dichloroethane solution, regardless of the initial concentration of TTCT. Probably, the extracted 1:1:1 complex transforms to the 1:2:1 complex, [Cu(ttct)$_2$]$^+$Pic$^-$, under the condition of the excess TTCT in the 1,2-dichloroethane solution.

In the case of silver(I), the obtained complexes will be the mixture of [Ag$_2$(ttct)]Pic$_2$ and [Ag(ttct)]Pic. The complex, [Ag(ttct)$_2$]Pic could not be obtained.

Reactions of Bis(β-diketonato)platinum(II) and -palladium(II) with Diphosphines $Ph_2PCHRPPh_2$ (R=H, Me): Unexpected Formation of the Homoleptic Bis(diphenylphosphino)-methanido and Related Complexes

Hiromasa HASHIMOTO, Seichi OKEYA,† and Yukio NAKAMURA*
Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka 558

(Received August 12, 1987)

The reactions of $[M(\beta\text{-dik})_2]$ (M=Pt(II), Pd(II); β-dik=acetylacetonate (acac), dipivaloylmethanate (dpm), hexafluoroacetylacetonate (hfac) ions) with dppm (dppm=$Ph_2PCH_2PPh_2$) and mdppm (mdppm=$Ph_2PCH(Me)PPh_2$) have been investigated. $[M(hfac)_2]$ complexes react with dppm to afford the stable cationic complexes, $[M(dppm)_2](hfac)_2$. By contrast, $[M(acac)_2]$ complexes react to give the homoleptic bis(diphenylphosphino)methanido complexes, $[M(Ph_2PCHPPh_2)_2]$, through deprotonation of dppm by the displaced acac anions. The analogous complexes, $[M(Ph_2PC(Me)PPh_2)_2]$, are obtained using mdppm, instead of dppm. A complete reaction scheme leading to these products is proposed, based on the IR and ^1H, ^{13}C, and ^{31}P NMR spectral data. Some consideration is given to the dependence of these reactions on the metals and the β-diketonate ligands, employed.

Bis(diphenylphosphino)methane, dppm, is known to act as a monodentate ligand, as a chelating bidentate ligand, or as a bridging ligand, and hence extensive studies have been made on structures and reactivities of complexes containing dppm as a ligand.[1] This ligand, when free, is readily deprotonated by a strong base to give $Ph_2PCHPPh_2^-$ and the resulting anion can also serve as a ligand towards transition metals with a variety of bonding modes, including P,P′-chelated,[2] P,P′- or P,C-bidentate bridged,[3,4] and P,P′,C-tridentate bridged[5] forms, thus constituting recent interesting chemistry. These hitherto isolated complexes are mostly obtained by deprotonation of a coordinated dppm with a strong base such as *n*-BuLi, if $Li(Ph_2PCHPPh_2)$ is not used as a reactant.

Here we describe the novel reactions of $[M(\beta\text{-dik})_2]$, especially $[M(acac)_2]$ (M=Pt(II) (**1a**), Pd(II) (**1b**)), with dppm, during which the coordinated dppm is readily deprotonated without strong bases. A preliminary report of this work was published in a short communication.[6]††

Experimental

Infrared spectra were obtained in Nujol mulls with a JASCO DS701G infrared spectrophotometer. Proton NMR spectra were recorded on a JEOL MH100 (100 MHz) or a GX400 (400 MHz) spectrophotometer. Carbon-13 and phosphorus-31 NMR spectra were recorded on a JEOL FX60Q instrument operating at 15 and 24 MHz, respectively. Chemical shifts are described in ppm relative to tetramethylsilane (for ^1H, ^{13}C) and 85% phosphoric acid (for ^{31}P).

†† In this paper, dppm−H and mdppm−H represent bis(diphenylphosphino)methanide ($Ph_2PCHPPh_2^-$) and 1,1-bis(diphenylphosphino)ethanide ($Ph_2PC(Me)PPh_2^-$) ions, respectively.

Preparation of Complexes. Bis(diphenylphosphino)-methane, dppm, was purchased from Strem Co. and used without further purification.· 1,1-Bis(diphenylphosphino)-ethane, mdppm,[7] was prepared according to the literature. The starting complexes, **1a**, **1b**, $[Pt(hfac)_2]$, $[Pd(hfac)_2]$, and $[Pd(dpm)_2]$, were prepared by the methods described in the previous papers.[8] Diphosphine complexes, $[PdCl_2(dppm)]$[9] and $[Pd(dppm)_2]X_2$ (X=Br, PF_6),[10] were prepared according to the literature. Solvents were dried over an appropriate drying agent and distilled under an atmosphere of argon before use.

Bis[bis(diphenylphosphino)methanido]platinum(II), [Pt(dppm−H)$_2$] (3a): When dppm (0.600 g, 1.56 mmol) was added to a solution of **1a** (0.305 g, 0.776 mmol) in dichloromethane (3 cm^3) at room temperature, a yellow precipitate began to deposit after a while. The mixture was stirred for 2—3 h under reflux and the precipitate was filtered, washed with acetone, and dried in vacuo (yield 0.70 g, 94%). The product was insoluble in common organic solvents such as benzene, acetone, diethyl ether, and haloalkanes.

Found: C, 62.12; H, 4.40%. Calcd for $C_{50}H_{42}P_4Pt$: C, 62.44; H, 4.37%.

Similarly, bis[1,1-bis(diphenylphosphino)ethanido]platinum(II), [Pt(mdppm−H)$_2$] (**3c**), was prepared as a yellow powder, using mdppm instead of dppm (yield 51%). The product was also insoluble in common organic solvents described above.

Found: C, 62.89; H, 4.59%. Calcd for $C_{52}H_{46}P_4Pt$: C, 63.09; H, 4.65%.

[Pd(dppm−H)$_2$] (3b): A solid dppm (0.602 g, 1.57 mmol) was added to a solution of **1b** (0.239 g, 0.785 mmol) in dichloromethane (5 cm^3) at room temperature. The resulting solution was stirred for a few minutes and petroleum ether was added to deposit a yellowish orange solid, which was filtered, washed with petroleum ether, and dried in vacuo (yield 0.58 g, 85%). The product was slightly soluble in chloroform but after a while equilibrated in the solvent with other species, as evidenced by ^{31}P NMR spectroscopy. $^{31}P\{^1H\}$ NMR ($CDCl_3$) δ=−36.7 (s).

Found: C, 68.31; H, 4.91%. Calcd for $C_{50}H_{42}P_4Pd$: C, 68.78; H, 4.85%.

[Pd(mdppm−H)$_2$] (3d): A solid mdppm (0.379 g, 0.952 mmol) was added to a solution of **1b** (0.145 g, 0.476 mmol) in dichloromethane (5 cm^3), and the resulting solution was stirred for 10 min to separate out reddish orange crystals, which were filtered, washed with dichloromethane, and dried in vacuo (yield 0.30 g, 70%). The product was slightly soluble in common organic solvents such as benzene and haloalkanes. ^{1}H NMR (C_6D_6, 400 MHz)[11] δ=1.78 (quintet, J_B(PH)=7.8 Hz, 3H, CH_3). ^{31}P{^{1}H} NMR (C_6D_6) δ=−25.5 (s).

Found: C, 69.40; H, 5.07%. Calcd for $C_{52}H_{16}P_4Pd$: C, 69.30; H, 5.14%.

Acetylacetonato[bis(diphenylphosphino)methanido]palladium(II), [Pd(acac)(dppm−H)] (2b): Method A: After dissolving dppm (0.633 g, 1.65 mmol) in a solution of **1b** (0.500 g, 1.64 mmol) in dichloromethane (5 cm^3), the resulting solution was diluted with pentane (30 cm^3) and allowed to stand in a freezer (ca. −5 °C). The yellow orange plates which separated out were filtered, washed with diethyl ether, and dried in vacuo. During the filtration, the crystals changed to a yellow powder with devitrification (yield 0.438 g). On standing the washing in a freezer, another crop was separated out as a reddish orange crystalline solid including no solvent of crystallization. Total yield: 0.581 g (50%). The melting point and the NMR and analytical data for the reddish orange crystals were as follows: mp: 157—159 °C. ^{1}H NMR ($CDCl_3$, 400 MHz) δ=5.27 (s, 1H, acac-CH), 2.56 (br, 1H, PCHP), and 1.94 (s, 6H, acac-CH_3). ^{13}C NMR (CD_2Cl_2)[11] δ=187.2 (t, J_A=1 Hz, CO), 99.4 (s, acac-CH), 28.1 (t, J_A=4.5 Hz, acac-CH_3), and 16.8 (t, J(PC)=65 Hz, ^1J(CH)=177 Hz, PCHP). ^{31}P{^{1}H} NMR ($CDCl_3$) δ=−55.7 (s).

Found: C, 61.27; H, 4.82%. Calcd for $C_{30}H_{28}O_2P_2Pd$: C, 61.19; H, 4.79%.

Method B: Thallium(I) acetylacetonate (0.243 g, 0.801 mmol) was added to a suspension of [$PdCl_2$(dppm)] (0.225 g, 0.401 mmol) in dichloromethane (50 cm^3). After being stirred for 20 min at room temperature, the mixture was filtered, the filtrate was concentrated to dryness, and then the residue was extracted with toluene. The solvent was evaporated to dryness and the product was washed with pentane, and dried in vacuo (yield 0.20 g, 85%).

[Pd(acac)(dppm)](PF_6): To a dichloromethane solution (8 cm^3) containing **2b** (0.050 g, 0.085 mmol) and *p*-toluenesulfonic acid monohydrate ($TsOH\cdot H_2O$, 0.017 g, 0.089 mmol) was added a methanol solution (4 cm^3) of potassium hexafluorophosphate (0.016 g, 0.087 mmol). The resulting KOTs was removed by filtration, pentane was added to the filtrate, and then the solution was kept in a freezer to deposit yellowish orange needles, which were collected, washed with diethyl ether, and air-dried (yield 0.028 g, 45%). ^{1}H NMR ($CDCl_3$) δ=5.62 (s, 1H, acac-CH), 4.67 (t, J(PH)=12 Hz, 2H, PCH_2P), and 2.16 (s, 6H, acac-CH_3). ^{13}C NMR ($CDCl_3$)[11] δ=187.2 (t, J_A=1.5 Hz, CO), 100.2 (s, acac-CH), 33.7 (t, J(PC)=32 Hz, PCH_2P), and 27.7 (t, J_A=5 Hz, acac-CH_3). ^{31}P{^{1}H} NMR (CD_2Cl_2) δ=−52.3 (s, dppm) and −144.0 (heptet, J(FP)=711 Hz, PF_6). The same compound was also obtained as an orange red precipitate on addition of pentane to an equimolar mixture of [Pd(acac)-(Et_2NH)$_2$](PF_6) (vide infra) and dppm in dichloromethane (yield 49%).

[Pt(dppm−H)(dppm)](PF_6): A solid dppm (0.138 g, 0.359 mmol) was added to a solution of [Pt(acac)(PPh_3)$_2$]-(PF_6) (vide infra) (0.157 g, 0.160 mmol) in dichloromethane (3 cm^3). The resulting solution was diluted with pentane and kept in a freezer to deposit yellow needles, which were filtered, washed with diethyl ether, and dried in vacuo (yield 0.120 g, 64%). Mp: 233—235 °C (decomp). Inclusion of one molecule of dichloromethane per platinum atom as solvent of crystallization was confirmed by the ^{1}H NMR spectroscopy. ^{1}H NMR ($CDCl_3$, 400 MHz) δ=5.33 (s, 2H, CH_2Cl_2), 5.07 (br, t, J(PH)=11 Hz; J(PtH)=indiscernible, 2H, PCH_2P), and 3.85 (br, t, J(PH)=7 Hz; J(PtH)=171 Hz, 1H, PCHP). ^{31}P{^{1}H} NMR (CD_2Cl_2) δ=−144.2 (heptet, J(FP)=711 Hz, PF_6). The signal assigned to (dppm+dppm−H) appeared as a AA'BB' spin system, of which the center was located at δ=−42.2 (J(PtP)=ca. 1916 Hz.).

Found: C, 52,18; H, 3.82%. Calcd for $C_{50}H_{43}F_6P_5Pt\cdot CH_2Cl_2$: C, 51.35; H, 3.80%.

The corresponding BF_4 salt was obtained in a similar manner using [Pt(acac)(PPh_3)$_2$](BF_4) as a starting material, which was readily synthesized by the reactions of **1a** with triphenylphosphine and sodium tetrafluoroborate in methanol. In this case, chloroform was used as a solvent and the product included one molecule of chloroform per platinum atom as solvent of crystallization. Yellow fine needles (yield 83%). Mp: 152—154 °C (decomp). ^{1}H NMR ($CDCl_3$) δ=5.16 (br, t, J(PH)=8 Hz; J(PtH)=48 Hz, 2H, PCH_2P) and 3.86 (br, t, J(PH)=5 Hz; J(PtH)=171 Hz, 1H, PCHP). The ^{31}P{^{1}H} NMR spectrum in $CDCl_3$ showed a signal assignable to (dppm+dppm−H) with a AA'BB' spin system, of which the center was located at δ=−41.9 (J(PtP)=ca. 1916 Hz).

Found: C, 52.74; H, 3.83%. Calcd for $C_{50}H_{43}BF_4P_4Pt\cdot CHCl_3$: C, 52.39; H, 3.79%.

[Pt(acac)(PPh_3)$_2$](PF_6): Compound **1a** (0.222 g, 0.565 mmol) was dissolved in hot methanol (10 cm^3) and allowed to react with triphenylphosphine (0.296 g, 1.13 mmol) under continued heating for 30 min. After cooling to room temperature, ammonium hexafluorophosphate (0.276 g, 1.69 mmol) was added and the resulting solution was further stirred for 30 min. The solution was concentrated and diethyl ether was added to deposit a white solid, which was filtered, washed with water, and dried in vacuo (yield 0.40 g, 72%). Recrystallization from dichloromethane–pentane gave the product including one fourth of dichloromethane molecule per platinum atom as solvent of crystallization.

Found: C, 50.38; H, 3.85%. Calcd for $C_{41}H_{37}F_6O_2P_3Pt\cdot 1/4CH_2Cl_2$: C, 50.30; H, 3.84%.

[Pd(acac)(Et_2NH)$_2$](PF_6): The compound was prepared by adding [Pd(acac)(Et_2NH)$_2$](acac)[12] (0.177 g, 0.393 mmol) to an aqueous solution (2 cm^3) of potassium hexafluorophosphate (0.089 g, 0.48 mmol). The yellow precipitate which separated out of the chilled solution was filtered, washed with methanol and diethyl ether, successively, and air-dried (yield 0.16 g, 81%). Recrystallization from dichloromethane–diethyl ether gave yellow plates. ^{1}H NMR ($CDCl_3$) δ=5.45 (s, 1H, acac-CH), 3.53 (br, 2H, NH), 2.72 (m, 8H, Et_2NH-CH_2), 2.01 (s, 6H, acac-CH_3), and 1.55 (t, J(HH)=7 Hz, 12H, Et_2NH-CH_3). ^{13}C NMR ($CDCl_3$) δ=186.6 (s, CO), 101.2 (s, acac-CH), 47.2 (s, Et_2NH-CH_2), 26.0 (s, acac-CH_3), and 14.1 (s, Et_2NH-CH_3).

Found: C, 31.53; H, 5.92; N, 5.68%. Calcd for $C_{13}H_{29}F_6N_2O_2PPd$: C, 31.43; H, 5.88; N, 5.64%.

[M(dppm)$_2$](hfac)$_2$ (M=Pd(II), Pt(II)): A solid dppm (0.268 g, 0.697 mmol) was added to a solution of [Pd(hfac)$_2$] (0.179 g, 0.344 mmol) in dichloromethane (2 cm^3). The

resulting solution was diluted with pentane and kept in a freezer to deposit a white or colorless crystalline solid, $[Pd(dppm)_2](hfac)_2$,[13] which was filtered and washed with diethyl ether, and air-dried (yield 0.28 g, 63%). ^1H NMR (CD_3CN)[11] δ=5.40 (s, 2H, hfac-CH) and 5.16 (quintet, J_B=5 Hz, 4H, PCH_2P). ^{13}C NMR (CD_3CN)[11] δ=172.9 (quartet, J(FC)=28 Hz, CO), 119.4 (quartet, J(FC)=293 Hz, hfac-CF_3), 82.5 (s, hfac-CH), and 38.4 (quintet, J_B=13 Hz, ^1J(CH)=141 Hz, PCH_2P). $^{31}P\{^1H\}$ NMR (CD_3CN) δ=−33.6 (s).

Found: C, 55.47; H, 3.57%. Calcd for $C_{60}H_{46}F_{12}O_4P_4Pd$: C, 55.90; H, 3.60%.

Starting from $[Pt(hfac)_2]$, $[Pt(dppm)_2](hfac)_2$ was prepared, analogously (yield 88%).

Found: C, 51.84; H, 3.36%. Calcd for $C_{60}H_{46}F_{12}O_4P_4Pt$: C, 52.30; H, 3.36%.

$[M(dppm)_2](OTs)_2$ (M=Pd(II), Pt(II)): The Pd(II) salt was obtained by adding acetone solutions (1 cm^3) of $TsOH\cdot H_2O$ (0.072 g, 0.38 mmol) and dppm (0.12 g, 0.32 mmol), successively, to a solution of $[Pd(dpm)_2]$ (0.075 g, 0.16 mmol) in dichloromethane (1 cm^3). The white solid which separated out was filtered, washed with diethyl ether, and dried in vacuo (yield 0.11 g, 56%). Recrystallization from methanol–diethyl ether gave colorless cubes, which changed to a white powder on vacuum drying.

Found (for powder): C, 62.78; H, 4.73%. Calcd for $C_{64}H_{58}O_6P_4PdS_2$: C, 63.13; H, 4.80%.

Starting from **1a**, $[Pt(dppm)_2](OTs)_2$ was obtained as a white powder, analogously.

Formation of the Cationic Complexes, $[Pt(dppm)_2]X_2$ (X=Cl, BF_4, NO_3), by Protonation of 3a. $[Pt(dppm)_2]Cl_2$: To a suspension of **3a** in ethanol was added an excess of 6 M hydrochloric acid (1 M=1 mol dm^{-3}), and the mixture was stirred for 1 h prior to evaporation of the solvent. The dichloromethane-extract of the residue was concentrated and pentane was added to produce a white precipitate, which was filtered, washed with pentane, and dried in vacuo. The compound included one molecule of dichloromethane per platinum atom as solvent of crystallization.

Found: C, 54.35; H, 4.19%. Calcd for $C_{50}H_{44}Cl_2P_4Pt\cdot CH_2Cl_2$: C, 54.71; H, 4.14%.

$[Pt(dppm)_2](BF_4)_2$: An excess of 42% tetrafluoroboric acid was added to a suspension of **3a** in ethanol and the mixture was stirred for 1 h to produce a white precipitate, which was collected, washed with water, and dried in vacuo.

Found: C, 52.44; H, 3.88%. Calcd for $C_{50}H_{44}B_2F_8P_4Pt$: C, 52.80; H, 3.90%.

$[Pt(dppm)_2](NO_3)_2$: Similarly, a suspension of **3a** in ethanol was allowed to react with an excess of 16 M nitric acid for 1 h. The solvent was evaporated to produce a white precipitate, which was filtered, washed with water, and dried in vacuo.

Found: C, 54.83; H, 4.02; N, 2.60%. Calcd for $C_{50}H_{44}N_2O_6P_4Pt$: C, 55.20; H, 4.08; N, 2.58%.

Yields of all these products were almost quantitative.

Regeneration of 3a and 3b by the Reactions of $[M(dppm)_2]^{2+}$ (M=Pt(II), Pd(II)) with Tl(acac) and Some Aqueous Bases. With Tl(acac): When two equivalents of Tl(acac) were allowed to react with $[Pt(dppm)_2]Cl_2$ in dichloromethane, a yellow precipitate was produced immediately, together with that of TlCl. The IR spectrum of the product confirmed the formation of **3a** by the appearance of its characteristic bands (vide infra). Similarly, $[Pd(dppm)_2]Br_2$ reacted with two equivalents of Tl(acac). After removal of the precipitated TlBr, organic soluble **3b** was isolated from the filtrate by the addition of hexane. The formation of **3b** was also confirmed by the IR data.

With Aqueous Bases: To a suspension of $[Pt(dppm)_2](NO_3)_2$ in methanol was added an excess of 5% aqueous solution of sodium carbonate as a base, and the mixture was stirred for 35 min at room temperature. The solvent was evaporated completely and the residue was extracted with dichloromethane. The extract was concentrated to dryness to leave a yellow powder, which was collected, washed with water and pentane, successively, and dried in vacuo. The yield was almost quantitative and the IR spectrum was in accord with that of **3a**. The use of triethylamine and sodium methoxide as bases was also effective on deprotonation of the coordinated dppm to produce **3a**.

Equimolar Reaction between 1a and dppm. When a dichloromethane solution (2 cm^3) containing equimolar amounts of **1a** (0.156 g, 0.400 mmol) and dppm (0.154 g, 0.400 mmol) was stirred for 30 min, a yellow precipitate began to deposit. Stirring was further continued for 3.5 h until no further precipitation occurred. The yellow precipitate obtained was filtered, washed with dichloromethane, and dried in vacuo. This product was identified as **3a** by IR assay. The yield was 0.155 g (0.161 mmol). The filtrate was evaporated to dryness and the residue was washed with diethyl ether to leave a deep yellow solid (0.067 g). This crude product was placed on the column (silica gel, 200 mesh) and eluted with dichloromethane. The eluate was again evaporated to dryness to give a yellow crystalline solid. This solid was identified as **1a** by IR spectroscopy. The recovered **1a** was 0.055 g (0.140 mmol), 35% of **1a** employed.

Another experiment was performed to confirm the intermediate species in this reaction. Equimolar amounts of **1a** and dppm were dissolved in CD_2Cl_2 in an NMR tube and the reaction was followed by $^{31}P\{^1H\}$ NMR spectroscopy at room temperature. Signal intensities were accumulated from 20 min after the initiation of the reaction over a 34-min period and from 60 min over a 90-min period, and those spectral data were recorded. These results are shown in Fig. 1.

Results and Discussion

Reactions of $[M(\beta\text{-dik})_2]$ (M=Pt(II), Pd(II)) with dppm and mdppm in the 1:2 Mole Ratio. In dichloromethane, $[M(hfac)_2]$ reacted with dppm to afford the stable cationic complexes, $[M(dppm)_2](hfac)_2$, by displacement of the coordinated hfac ligands (Eq. 1), whereas $[M(acac)_2]$ (M=Pt(II) (**1a**), Pd(II) (**1b**)) gave the homoleptic bis(diphenylphosphino)methanido complexes, $[M(dppm-H)_2]$ (M=Pt(II) (**3a**), Pd(II) (**3b**)) (Eq. 2), which were previously prepared from $[MCl_2(PMe_3)_2]$ and $Li(Ph_2PCHPPh_2)$[2d] or from $K_2[PtCl_4]$, dppm, and KOH.[2f]

$$[M(hfac)_2] + 2dppm \longrightarrow [M(dppm)_2](hfac)_2 \quad (1)$$

$$[M(acac)_2] + 2dppm \longrightarrow [M(dppm-H)_2] + 2acacH \quad (2)$$

Table 1. IR Bands (cm^{-1}) Characteristic of the Deprotonated dppm and mdppm Complexes[a]

Complex	dppm−H/mdppm−H	ν(C=O)+ν(C=C)
[Pd(acac)(dppm−H)] (**2b**)	1007(s), 853(vs), 553(vs)	1578(vs), 1510(vs)
[Pt(dppm−H)$_2$] (**3a**)	1113(vs), 889(vs), 858(vs), 558(w)	
[Pd(dppm−H)$_2$] (**3b**)	1117(vs), 882(s), 866(vs), 546(vs)	
[Pt(mdppm−H)$_2$] (**3c**)	1110(s), 847(vs)	
[Pd(mdppm−H)$_2$] (**3d**)	1110(s), 851(vs)	

a) In Nujol; v=very, s=strong, w=weak.

The IR spectra of **3a** and **3b** showed no absorption bands assignable to ν(C=O), but exhibited new bands which had not appeared for free or coordinated dppm. Table 1 lists these IR bands, which are characteristic of deprotonated dppm complexes. Protonation of **3a** with an acid HX (X=Cl, BF_4, or NO_3) in ethanol led to the formation of a cationic complex [Pt(dppm)$_2$]X$_2$ (Eq. 3), of which the IR spectrum coincided with that of the authentic sample,[14] demonstrating that the diphosphines in **3a** were certainly deprotonated.

$$[Pt(dppm-H)_2] + 2HX \longrightarrow [Pt(dppm)_2]X_2 \quad (3)$$

A reverse reaction, i.e., deprotonation of [Pt(dppm)$_2$]X$_2$ to give **3a**, readily occurred by Tl(acac) (Eq. 4), as well as some other bases like NEt_3, NaOMe, and Na_2CO_3, suggesting that the acac anion was working as a base to deprotonate.

$$[Pt(dppm)_2]Cl_2 + 2Tl(acac) \longrightarrow [Pt(dppm-H)_2] + 2acacH + 2TlCl \quad (4)$$

When mdppm instead of dppm was allowed to react with [M(acac)$_2$], analogous complexes [M(mdppm−H)$_2$] (M=Pt(II) (**3c**), Pd(II) (**3d**)) were obtained. The characteristic IR bands are also listed in Table 1.

Although the platinum complexes **3a** and **3c** were insoluble in common organic solvents probably because of their polymeric nature as reported previously,[2d] the palladium complexes **3b** and **3d** prepared by us were organic soluble and the $^{31}P\{^1H\}$ NMR spectra of these complexes showed a single resonance line, disclosing the existence of four magnetically equivalent phosphorus atoms. No useful ^1H NMR data were obtained for **3b** because of its low solubility in any appropriate solvent. However, the methyl-substituted complex **3d** showed the methyl proton resonance as a quintet due to virtual coupling to the four phosphorus atoms, thus indicating that the complex is a symmetric bis-chelate.

As described in the Experimental section, the $^{31}P\{^1H\}$ NMR spectrum of **3b** in $CDCl_3$ gradually changed with time, although no appreciable change was observed for that of **3d** in C_6D_6. After about 45 min, the signal originally assigned to **3b** completely disappeared and many other weak signals appeared, instead. This spectral change was not elucidated further, but the reaction of the coordinated bis(diphenylphosphino)methanido carbanions with the haloalkane solvent employed to form the cationic species like [Pd(dppm−H)(Ph$_2$PCHRPPh$_2$)]Cl and [Pd(Ph$_2$PCHRPPh$_2$)$_2$]Cl$_2$ (R=$CDCl_2$) might be assumed, since the carbanions in **3a** are methylated by excess methyl iodide to give similar cationic species.[15]

Characterization of Some Reaction Intermediates. Although the equimolar reaction between **1a** and dppm afforded **3a** exclusively, leaving about 35% of **1a** employed as unreacted, we succeeded, in the palladium case, in isolating the intermediate species, [Pd(acac)(dppm−H)] (**2b**), in high yield. This was fully characterized by elemental analysis and ^1H, ^{13}C, and ^{31}P NMR spectroscopy (see the Experimental section). When the dipivaloylmethanido complex, [Pd(dpm)$_2$], was allowed to react with an equimolar amount of dppm in $CDCl_3$, the same type of complex, [Pd(dpm)(dppm−H)], was also formed in solution as evidenced by its NMR data.[16] The IR spectrum of **2b** exhibited the absorption bands characteristic of both the *O,O'*-chelated acac and deprotonated dppm ligands as represented in Table 1.

In order to elucidate what kind of platinum-containing intermediate is formed in solution, we followed the reaction of **1a** with dppm in the 1:1 mole ratio by $^{31}P\{^1H\}$ NMR spectroscopy as described in the Experimental section. A yellow precipitate of **3a** began to deposit within 10 min after mixing both reactants in CD_2Cl_2. Figure 1 shows two spectra recorded at an appropriate time (see the figure caption) after the initiation of the reaction. The first spectrum (Fig. 1A) exhibited a sharp and most intense resonance line at δ −22.8. This coincided with the chemical shift of free dppm, suggesting that significant amounts of dppm still remained unreacted in this stage of the reaction. The spectrum also revealed the existence of two kinds of intermediates. One of them appeared at δ −5.4 (P_A) and −29.2 (P_B) as two doublets coupled each other with $^2J(P_A\text{-}P_B)$=73 Hz, each being flanked by the ^{195}Pt satellites with $^1J(Pt\text{-}P_A)$=4457 and $^3J(Pt\text{-}P_B)$=53 Hz, whereas the other showed a broad resonance line, of which the center was located at δ −42.3, with $^1J(PtP)$=1912 Hz. In the second spectrum (Fig. 1B), the signals of the intermediates increased in their intensities, whereas the free dppm disappeared. Based on both the signal pattern described above and the similarity of the $^1J(Pt\text{-}P_A)$ value to that of [Pt(tfac)(tfac-*O*){P(*o*-tolyl)$_3$}][17] (tfac=trifluoroacetylaceton-

ate ion) or [Pt(acac)(acac-*O*){P(C_6H_{11}}$_3$)],[18] the former intermediate was supposed to be of the type **A-2** (see Scheme 1). It seems reasonable to assume that the latter intermediate will be formed in the course of reaction process from **2** to **3**. If this is true, the intermediate would be expected to be of the type **B-3** because the strong trans effect of a phosphorus atom makes the existence of the *O*-unidentate acac intermediate of the type **B-2** very unlikely (see Scheme 1). In fact, the signal of the latter intermediate coincided both in chemical shift and in coupling constant, ^1J(PtP), with that of [Pt(dppm−H)(dppm)](PF_6), which was isolated incidentally from the reaction mixture of [Pt(acac)(PPh_3)$_2$](PF_6) and dppm in the mole ratio of 1:2.24 in CH_2Cl_2.

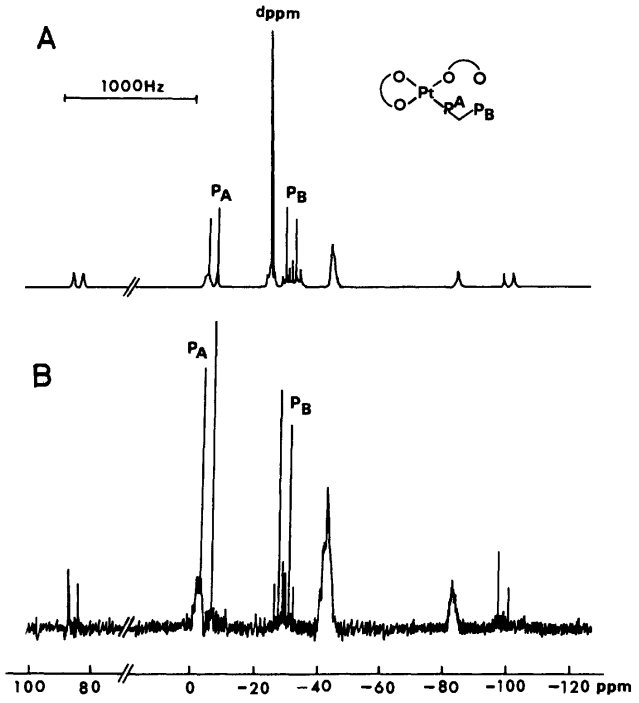

Fig. 1. ^{31}P NMR spectra obtained in the equimolar reaction between **1a** and dppm in CD_2Cl_2 at room temperature. The signal intensities accumulated from 20 min after the initiation of the reaction over a 34-min period (in A) and from 60 min over a 90-min period (in B) are shown. The signal for the final product, [Pt(dppm−H)$_2$] (**3a**), is not observed due to the insoluble character of the complex in CD_2Cl_2.

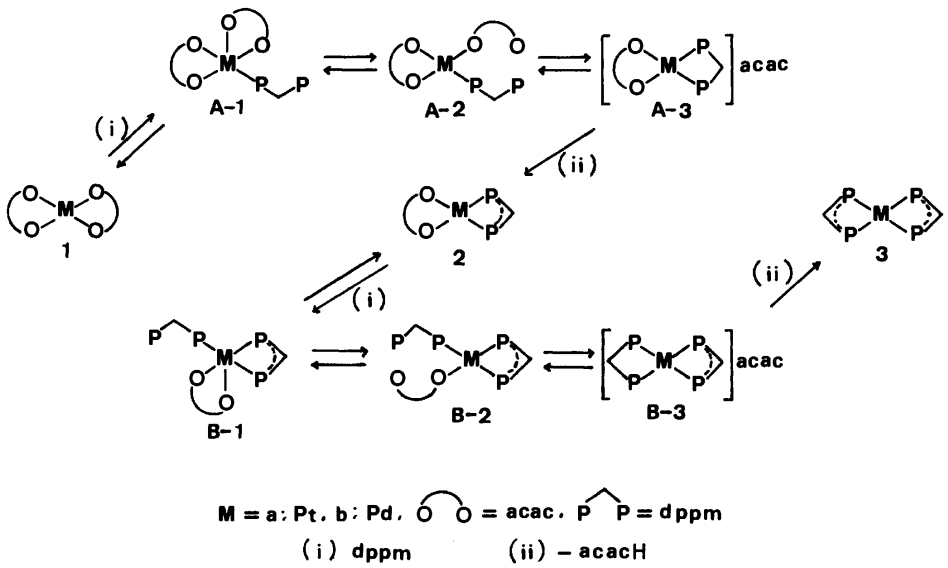
The Proposed Reaction Mechanism. On the basis of the results described above we can propose the processes represented in Scheme 1 as the likely mechanism for formation of [M(acac)(dppm−H)] and [M(dppm−H)$_2$] by the reactions of [M(acac)$_2$] (M=Pt(II), Pd(II)) with dppm. Although no intermediates of **A-1** to **A-3** were isolated in the present case, complexes of these types including the central-carbon-bonded β-diketonato complexes have been obtained by the reactions of [M(β-dik)$_2$] (M=Pt(II), Pd(II)) containing various β-dik ligands with unidentate tertiary phosphines.[17,19]

Isolation of the mixed ligand complex **2b** is especially noteworthy since the reactions of **1a** and **1b** with tricyclohexylphosphine and triphenylphosphine, respectively, in the 1:2 mole ratios in aprotic solvents such as benzene and diethyl ether afforded complexes of the type [M(acac)(acac-*O*)L] (L=unidentate tertiary phosphines), alone.[19b,c] However, when **1a** and **1b** were allowed to react with two equivalents of triphenylphosphine in methanol, the almost quantitative formation of [M(acac)(PPh_3)$_2$](acac) (M=Pt(II), Pd(II)) was recognized in situ by NMR probe.[20] Although we failed in isolating the acac salts, the PF_6 salt with M=Pt(II) was isolated from the reaction mixture and utilized as a starting complex for the preparation of [Pt(dppm−H)(dppm)](PF_6) (see the Experimental section). The formation of the latter com-



Scheme 1.

plex was also recognized in situ when $[Pt_2(PPh_3)_2(\mu\text{-dppm})_2](PF_6)_2$ was treated with **3a**, but its isolation was not attempted.[4]

The most important step to form the bis(diphenylphosphino)methanido complexes **2** and **3** is the deprotonation process from intermediate **A-3** to **2** or from **B-3** to **3**. This key step will be discussed in a succeeding paragraph.

Ligand and Metal Control in the Key Step. Deprotonation of the coordinated dppm by the acac anion is particularly interesting from the view point of the relative acidity of acacH and free dppm, whose pK_a values are 9.0[21] and 29.9,[22] respectively. Therefore, the above-mentioned chemical change is probably due to the electronic effect caused by coordination of dppm to the metal atom (vide infra).

In order to examine how the stability of intermediates of the type **A-3** varies with different β-dik ligands and with different metals, we conducted equimolar reactions of $[M(\beta\text{-dik})_2]$ with dppm in $CDCl_3$ and determined the species produced in solution by NMR spectroscopy. The effect of the β-dik ligand on the key step appeared as follows. When $[M(hfac)_2]$ was a starting complex, deprotonation of the coordinated dppm never occurred and either the stable product, [Pd(hfac)(dppm)](hfac)[23] or $[Pt(dppm)_2](hfac)_2$, was obtained, whereas for $[M(acac)_2]$, the deprotonation was effected, giving **2b** or **3a**, unless some strong acids were present. These results are clearly attributable to the difference in pK_a between hfacH (pK_a=4.3) and acacH (pK_a=9.0).[21] The reaction forming **2b** from $[PdCl_2(dppm)]$ and two equivalents of Tl(acac) also seems to take place via the precursor complex, [Pd(acac)(dppm)](acac) (Eq. 5).

$$[PdCl_2(dppm)] + 2Tl(acac) \xrightarrow{-2TlCl} [Pd(acac)(dppm)](acac) \xrightarrow{-acacH} \mathbf{2b} \qquad (5)$$

The relative thermodynamic stability of the intermediates depends on the metal. As noted above, a treatment of $[Pd(hfac)_2]$ with dppm in $CDCl_3$ resulted in the quantitative formation of [Pd(hfac)(dppm)](hfac) in an NMR tube,[23] while $[Pt(hfac)_2]$ did not afford [Pt(hfac)(dppm)](hfac) but $[Pt(dppm)_2](hfac)_2$ in a 50% yield. In the case of platinum(II), it is conceivable that the intermediate of type **A-3** is thermodynamically unstable, and hence the reaction proceeds ultimately to give the bis(dppm)-chelate. A similar situation was encountered in the reactions of **1a** and **1b** with dppm. Thus **1b** reacted with dppm to form **2b**, while **1a** afforded **3a** via intermediates of types **A-2** and **B-3**. In this case, the partially produced **2a** may be attacked by the second dppm to result in the formation of **3a**. In any event, it is certain that in contrast with the strong M–O bonds of **1**, those of the type-**A-3** intermediate and **2** are destabilized by the trans phosphorus donor atoms.

We may note here that, although complexes of the type **A-3** were never isolated, protonation of **2b** with a strong acid $TsOH\cdot H_2O$ led to the quantitative formation of [Pd(acac)(dppm)](OTs) in situ as evidenced by the NMR data.[24] The PF_6 salt was also readily isolated in the presence of potassium hexafluorophosphate.

Relationship between Diphosphine Coordination Modes and NMR Spectra. Mono(chelating dppm) Complexes: The PCH_2P protons in complexes of the type $[Pd(\beta\text{-dik})(dppm)]X$ resonated at δ 4.7—5.0 as a triplet with $J(PH)$=12 Hz and the corresponding carbon did at δ 32—34 as a triplet with $J(PC)$=32—33 Hz. For the ^1H-nondecoupled ^{13}C spectra of these complexes, the $^1J(CH)$ coupling constant was found to be 146 Hz, reflecting the situation of sp^3 carbon.

Bis(chelating dppm) Complexes: For complexes of the type $[M(dppm)_2]X_2$, the PCH_2P proton signal appeared at δ 4.9—5.7 as a quintet with J_B=5 Hz[11] and the corresponding carbon signal at δ 38—43 as a quintet with J_B=13—17 Hz. The $^1J(CH)$ of ca. 140 Hz, observed for these complexes, is also appropriate to sp^3 carbon. The quintet pattern comes from the virtual coupling with the second dppm-phosphorus-31 atoms. If $^4J(PH)$ and $^3J(PC)$ are considered negligibly small compared with $^2J(PH)$ and $^1J(PC)$, respectively, the latter coupling constants are evaluated to be ca. 10 and 28 Hz, respectively, according to the equation defined in Ref. 11. The values are comparable to those for the mono(chelating dppm) complexes, indicating that the M–P bonding characters of both types of complexes resemble each other.

Mono(chelating dppm–H) Complexes: In the case of $[Pd(\beta\text{-dik})(dppm{-}H)]$, we could not observe a well-resolved signal for the PCHP proton, but the corresponding carbon signal appeared at δ 15—17 as a clear triplet with $J(PC)$=65 Hz. The $^1J(CH)$ was found to be ca. 176 Hz. The signal is largely shifted to the higher-field compared with that of the above-mentioned PCH_2P carbon. This upfield shift reflects an increase in net electron density on the carbon atom caused by deprotonation. The coupling constant $J(PC)$ becomes twice in the value and the $^1J(CH)$ is also increased by ca. 30 Hz. These results reflect an increase in double-bond character of the P–C bonds, as well as increased sp^2 character of the carbon atom.

Complexes Bearing Both Chelating dppm and dppm–H: The PCH_2P protons in complexes of the type $[Pt(dppm{-}H)(dppm)]X$ resonated at δ 5.1—5.2 as a triplet with $J(PH)$=8—11 Hz, both the chemical shift and the coupling constant being close to those for the dppm complexes described above. In contrast with the case of $[Pd(\beta\text{-dik})(dppm{-}H)]$, the PCHP proton of the $[Pt(dppm{-}H)(dppm)]X$ complexes resonated at δ 3.86 as a well-resolved triplet with $J(PH)$=5—7 Hz. It is interesting to note that three bond coupling ($^3J(PtH)$=171 Hz) of the PCHP proton

Table 2. The CH_2-Proton Chemical Shifts of the Various dppm Complexes with Palladium in the Different Oxiation Numbers[a)]

Complex	Solvent	$\delta(CH_2)$	Lit
dppm	c)	2.80	g)
	Oxidation Number 0		
$[Pd_2(dppm)_3]$	d)	3.00	h)
	Oxidation Number 1		
$[Pd_2Br_2(dppm)_2]$	d)	4.22	h)
	Oxidation Number 2		
$[PdBr_2(dppm)]$	d)	4.33	h)
$[Pd(acac)(dppm)](PF_6)$	c)	4.67	g)
$[Pd(acac)(dppm)](OTs)$[b)]	c)	5.13	g)
$[Pd(hfac)(dppm)](hfac)$[b)]	c)	5.60	g)
$[Pd(dppm)_2]Br_2$	c)	4.26	g)
$[Pd(dppm)_2](PF_6)_2$	e)	4.92	g)
$[Pd(dppm)_2](hfac)_2$	e)	5.16	g)
$[Pf(dppm)_2](OTs)_2$	f)	ca. 5.3	g)

a) δ in ppm from internal TMS. b) Not isolated. c) $CDCl_3$. d) CD_2Cl_2. e) CD_3CN. f) CD_3OD. g) This work. h) H. C. Hunt and A. L. Balch, *Inorg. Chem.*, **20**, 2267 (1981).

to the platinum atom is more than three times as large as that ($^3J(PtH)$=48 Hz for X=BF_4) of the PCH_2P protons. It seems reasonable to assume that the bis(diphenylphosphino)methanido ligand coordinates more strongly to the central metal atom than does the neutral dppm.

Estimation of the Coordination Effect on Deprotonation of dppm. In order to estimate to what extent the C–H bond in dppm is activated when the diphosphine is coordinated to a metal, we examined the CH_2-proton chemical shifts of the various dppm complexes with palladium in the different oxidation states and compared those with that of free dppm. As shown in Table 2, the chemical shifts move to lower field on coordination of dppm to the metal and with increasing oxidation number of the metal, especially for the cationic complexes. These results imply that the CH_2 protons are largely deshielded in the cationic complexes with palladium(II), thus facilitating deprotonation of the dppm ligand. Although the counteranion dependence of the CH_2-proton chemical shift does not appear so clearly because the chemical interaction between the cation and the anion may be conceivable,[25)] the CH_2 signal of the $[Pd(dppm)_2]X_2$ complexes tends to cause a downfield shift with decreasing acidity of the conjugate acid HX.

We can not compare the CH_2 chemical shift data for complexes with X=hfac and acac since even if $[Pd(dppm)_2](acac)_2$ is formed in solution, it will be deprotonated immediately to give **3b**. Although the behavior of $[Pd(tfac)_2]$ towards dppm is particularly interesting for pK_a of tfacH is intermediate between those of hfacH and acacH, the reaction profile is not so simple and the details will be reported separately.

The authors wish to express their thanks to Professor Kiyoshi Isobe of Institute for Molecular Science for his helpful discussion, and to Mr. Junichi Gohda for elemental analyses. This work was supported by a Grant-in-Aid for Scientific Research No. 59470036 from the Ministry of Education, Science and Culture.

S-Bridged Polynuclear Complexes. II. Formation and Some Properties of [M{Co(L-cys-*N*,*S*)$_3$}$_2$]-Type Complexes (M=Fe(III), Co(III), and Ni(II); L-cys=L-cysteinate)

Sen-ichi AIZAWA,* Ken-ichi OKAMOTO, Hisahiko EINAGA,† and Jinsai HIDAKA
Department of Chemistry, University of Tsukuba, Tsukuba, Ibaraki 305
†Institute of Materials Science, University of Tsukuba, Tsukuba, Ibaraki 305
(Received August 29, 1987)

Three trinuclear complexes with Δ_{LLL}- and/or Λ_{LLL}-*fac*(*S*)-[Co(L-cys-*N*,*S*)$_3$] terminals, $\Delta_{LLL}\Delta_{LLL}$-, $\Delta_{LLL}\Lambda_{LLL}$-, and $\Lambda_{LLL}\Lambda_{LLL}$-[Fe{Co(L-cys-*N*,*S*)$_3$}$_2$]$^{3-}$, $\Delta_{LLL}\Lambda_{LLL}$-[Co{Co(L-cys-*N*,*S*)$_3$}$_2$]$^{3-}$, and $\Delta_{LLL}\Delta_{LLL}$-[Ni{Co(L-cys-*N*,*S*)$_3$}$_2$]$^{4-}$, were newly prepared. These complexes were characterized from their electronic absorption, CD, and ^{13}C NMR spectra. Each reaction of Δ_{LLL}-*fac*(*S*)-[Co(L-cys-*N*,*S*)$_3$]$^{3-}$ with Fe(II) and Co(II) was accompanied by the inversion of the absolute configuration of the one or both terminals to give the $\Delta_{LLL}\Lambda_{LLL}$ and $\Lambda_{LLL}\Lambda_{LLL}$ isomers, while the reaction with Fe(III), Co(III), or Ni(II) proceeded with the retention of the terminal to give the $\Delta_{LLL}\Delta_{LLL}$ isomer. The voltammetric study revealed that the formal potential of $\Delta_{LLL}\Delta_{LLL}$-[Fe{Co(L-cys-*N*,*S*)$_3$}$_2$]$^{3-}$ (−0.16 V) is more anodic than that of $\Delta_{LLL}\Delta_{LLL}$-[Co{Co(L-cys-*N*,*S*)$_3$}$_2$]$^{3-}$ (−0.43 V). These redox potentials are discussed in relation to the formation ratios of the isomers for the trinuclear complexes.

A few transition metal complexes with thiolate type ligands, such as 2-aminoethanethiolate (aet) and L-cysteinate (L-cys), have some unique properties in an aqueous solution. For example, the sulfur donor atoms of the ligands bridge two metal ions to give trinuclear complexes with μ-thiolato structure.[1-10] We previously reported that $\Lambda_{LLL}\Lambda_{LLL}$-[Co{Co(L-cys-*N*,*S*)$_3$}$_2$]$^{3-}$ was formed selectively by the reaction of Δ_{LLL}-*fac*(*S*)-[Co(L-cys-*N*,*S*)$_3$]$^{3-}$ with an excess amount of Co(II).[9,10] The inversion of the absolute configuration of the terminals seems to be related to the redox property of the central metal. From this point of view, the present authors have attempted to introduce a transition metal such as iron and nickel as the central metal of the trinuclear complex. In the present work, the formations of the trinuclear complexes, $\Delta_{LLL}\Delta_{LLL}$-, $\Delta_{LLL}\Lambda_{LLL}$-, and $\Lambda_{LLL}\Lambda_{LLL}$-[Fe{Co(L-cys-*N*,*S*)$_3$}$_2$]$^{3-}$, $\Delta_{LLL}\Lambda_{LLL}$-[Co{Co(L-cys-*N*,*S*)$_3$}$_2$]$^{3-}$, and $\Delta_{LLL}\Delta_{LLL}$-[Ni{Co(L-cys-*N*,*S*)$_3$}$_2$]$^{4-}$, were confirmed by the reaction of Δ_{LLL}-*fac*(*S*)-[Co(L-cys-*N*,*S*)$_3$]$^{3-}$ with Fe(III), Fe(II), Co(II), and Ni(II) respectively. These complexes are characterized on the basis of their electronic absorption, CD, and ^{13}C NMR spectral behavior. The configurational inversions, which were observed for each reaction of Δ_{LLL}-*fac*(*S*)-[Co(L-cys-*N*,*S*)$_3$]$^{3-}$ with Fe(II) and Co(II), are discussed in relation to the redox properties of these trinuclear complexes.

Experimental

Preparation of Complexes. 1) Δ_{LLL}-*fac*(*S*)-K$_3$[Co(L-cys-*N*,*S*)$_3$]·9H$_2$O·0.5KCl: This complex was prepared by the method described in the literature.[11]

2) $(+)^{CD}_{600}\cdot(+)^{CD}_{530}$-$\Delta_{LLL}\Delta_{LLL}$-K$_3$[Fe{Co(L-cys-*N*,*S*)$_3$}$_2$]·9H$_2$O·0.25KCl: To a solution containing 0.6 g (2.2 mmol) of $FeCl_3\cdot6H_2O$ in 40 cm^3 of water was added a solution containing 2.8 g (3.8 mmol) of Δ_{LLL}-*fac*(*S*)-K$_3$[Co(L-cys-*N*,*S*)$_3$]·9H$_2$O·0.5KCl in 50 cm^3 of water, whereupon the color of the solution immediately turned from deep green to reddish brown. The solution was then stirred at room temperature for 15 min. To this was added a large amount of ethanol in an ice bath. the resultant complex was recrystallized twice from water by adding ethanol in an ice bath. It was found, from the QAE-Sephadex A-25 column chromatographic technique and from absorption and CD spectral measurements, that the complex contained only $(+)^{CD}_{600}\cdot(+)^{CD}_{530}$-$\Delta_{LLL}\Delta_{LLL}$-[Fe{Co(L-cys-*N*,*S*)$_3$}$_2$]$^{3-}$. Found: C, 18.19; H, 4.08; N, 7.14%. Calcd for $C_{18}H_{48}N_6O_{21}S_6Cl_{0.25}K_{3.25}FeCo_2$: C, 18.22; H, 4.08; N, 7.08%.

3) $(-)^{CD}_{600}\cdot(-)^{CD}_{530}$-$\Delta_{LLL}\Delta_{LLL}$-H$_3$[Fe{Co(L-cys-*N*,*S*)$_3$}$_2$]·5H$_2$O·3HCl: To a solution containing 0.19 g (0.68 mmol) of $FeSO_4\cdot7H_2O$ in 10 cm^3 of water was added a solution containing 1.0 g (1.36 mmol) of Δ_{LLL}-*fac*(*S*)-K$_3$[Co(L-cys-*N*,*S*)$_3$]·9H$_2$O·0.5KCl in 30 cm^3 of water. The mixture was stirred at room temperature for 15 min and then poured onto a column of QAE-Sephadex A-25 (Cl^- form, 3.5 cm×90 cm). After the column had been swept with water, the adsorbed band was eluted with a 0.1 mol dm^{-3} aqueous solution of NaCl. A large amount of the brownish red band (B-1) and small amounts of the brownish green (B-2) and brown (B-3) ones were eluted in this order. The B-2 eluate showed absorption and CD spectra identical with those of $(-)^{CD}_{600}\cdot(-)^{CD}_{360}$-$\Delta_{LLL}\Delta_{LLL}$-[Co{Co(L-cys-*N*,*S*)$_3$}$_2$]$^{3-}$,[9,10] while the B-1 and B-3 eluates contained $(-)^{CD}_{600}\cdot(-)^{CD}_{530}$-$\Delta_{LLL}\Lambda_{LLL}$-[Fe{Co(L-cys-*N*,*S*)$_3$}$_2$]$^{3-}$ and a by-product respectively. The B-1 eluate was concentrated to ca. 50 cm^3 with a rotary evaporator below 25 °C. This solution was adjusted to pH 2—3 by adding a 1 mol dm^{-3} hydrochloric acid in an ice bath. The resultant complex was collected by filtration and washed with ethanol and ether. Found: C, 19.76; H, 4.13; N, 7.59%. Calcd for $C_{18}H_{46}N_6O_{17}S_6Cl_3FeCo_2$: C, 19.82; H, 4.25; N, 7.70%.

4) $(-)^{CD}_{600}\cdot(+)^{CD}_{530}$-$\Delta_{LLL}\Lambda_{LLL}$-H$_3$[Fe{Co(L-cys-*N*,*S*)$_3$}$_2$]·5H$_2$O·3HCl·0.5NaCl: This complex was prepared and chromatographed by a procedure similar to that used in **3**) under dilute conditions ($FeSO_4\cdot7H_2O$ 0.095 g (0.34 mmol)), water 160 cm^3; the starting Δ_{LLL}-*fac*(*S*) complex 0.50 g (0.68 mmol), water 160 cm^3). The four bands, reddish brown (C-1), brownish red (C-2), brownish green (C-3), and brown (C-4), were eluted in this order. The C-2 and C-3 eluates showed absorption and CD spectra identical with $(-)^{CD}_{600}\cdot(-)^{CD}_{530}$-$\Lambda_{LLL}\Lambda_{LLL}$-[Fe{Co(L-cys-*N*,*S*)$_3$}$_2$]$^{3-}$ and $(-)^{CD}_{600}\cdot(-)^{CD}_{360}$-$\Delta_{LLL}\Delta_{LLL}$-

$[Co\{Co(L\text{-}cys\text{-}N,S)_3\}_2]^{3-}$ [9,10] respectively. The C-1 and C-4 eluates contained $(-)^{CD}_{600}\cdot(+)^{CD}_{530}$-$\Delta_{LLL}\Delta_{LLL}$-$[Fe\{Co(L\text{-}cys\text{-}N,S)_3\}_2]^{3-}$ and a by-product respectively. The formation ratio of $\Delta_{LLL}\Delta_{LLL}$- and $\Lambda_{LLL}\Lambda_{LLL}$-$[Fe\{Co(L\text{-}cys\text{-}N,S)_3\}_2]^{3-}$ was about 37:63. After moving only the C-1 eluate into another column of QAE-Sephadex A-25 (Cl^- form, 3.5 cm×25 cm), the adsorbed band was eluted with a saturated aqueous solution of NaCl. The eluate was immediately adjusted to pH 2—3 by adding a 1 mol dm^{-3} hydrochloric acid in an ice bath. The resultant complex was collected by filtration and washed with ethanol and ether. Found: C, 19.09; H, 3.91; N, 7.61%. Calcd for $C_{18}H_{46}N_6O_{17}Na_{0.5}S_6Cl_{3.5}FeCo_2$: C, 19.30; H, 4.14; N, 7.50%.

5) $(-)^{CD}_{600}\cdot(+)^{CD}_{360}$-$\Delta_{LLL}\Delta_{LLL}$-$K_3[Co\{Co(L\text{-}cys\text{-}N,S)_3\}_2]\cdot 8.5H_2O$: This complex was prepared and chromatographed by a procedure similar to that used in **3**), but using $CoCl_2\cdot 6H_2O$ instead of $FeSO_4\cdot 7H_2O$ ($CoCl_2\cdot 6H_2O$ 0.082 g (0.34 mmol), water 40 cm^3; the starting Δ_{LLL}-*fac*(*S*)-complex 0.50 g (0.68 mmol), water 40 cm^3). After the eluate had been circulated in the same column twice, three bands, brown (A-1), brownish green (A-2), and a small amount of brownish green (A-3), were eluted in this order. The A-2 and A-3 eluates showed absorption and CD spectra identical with those of $(+)^{CD}_{600}\cdot(+)^{CD}_{360}$-$\Delta_{LLL}\Delta_{LLL}$- and $(-)^{CD}_{600}\cdot(-)^{CD}_{360}$-$\Delta_{LLL}\Delta_{LLL}$-$[Co\{Co(L\text{-}cys\text{-}N,S)_3\}_2]^{3-}$ respectively,[9,10] while the A-1 eluate contained $(-)^{CD}_{600}\cdot(+)^{CD}_{360}$-$\Delta_{LLL}\Delta_{LLL}$-$[Co\{Co(L\text{-}cys\text{-}N,S)_3\}_2]^{3-}$. The formation ratio of the three isomers, A-1, A-2, and A-3, was about 23:72:5. The A-1 eluate was concentrated to a small volume with a rotary evaporator below 25 °C. The deposited NaCl was then filtered off, and the filtrate was passed through columns of Sephadex G-10 (3.5 cm×90 cm) and then SP-Sephadex C-25 (K^+ form, 3.5 cm×25 cm) by elution with water. The eluate was then concentrated to a small volume again. To this was added a large amount of ethanol in an ice bath. The resultant complex was collected by filtration and washed with ethanol and ether. Found: C, 18.57; H, 4.14; N, 7.22%. Calcd for $C_{18}H_{47}N_6O_{20.5}S_6K_3Co_3$: C, 18.60; H, 4.08; N, 7.22%.

When the above reaction was carried out under a nitrogen atmosphere and the reaction solution was oxidized by exposure to air, the $\Delta_{LLL}\Delta_{LLL}$ isomer was formed selectively.

6) $(+)^{CD}_{600}$-$\Delta_{LLL}\Delta_{LLL}$-$H_4[Ni\{Co(L\text{-}cys\text{-}N,S)_3\}_2]\cdot 3H_2O\cdot 2HCl$: To a solution containing 0.087 g (0.37 mmol) of $NiCl_2\cdot 6H_2O$ in 5 cm^3 of water was added a solution containing 0.50 g (0.68 mmol) of Δ_{LLL}-*fac*(*S*)-$K_3[Co(L\text{-}cys\text{-}N,S)_3]\cdot 9H_2O\cdot 0.5KCl$ in 20 cm^3 of water, whereupon the color of the solution immediately turned from deep green to brownish green. The solution was stirred at room temperature for 10 min and then filtered. The filtrate was adjusted to pH 2—3 by adding a 1 mol dm^{-3} hydrochloric acid in an ice bath. The resultant complex was collected by filtration and washed with ethanol and ether. It was found, from the QAE-Sephadex A-25 column chromatographic technique and the absorption and CD spectral measurements, that the complex contained only $(+)^{CD}_{600}$-$\Delta_{LLL}\Delta_{LLL}$-$[Ni\{Co(L\text{-}cys\text{-}N,S)_3\}_2]^{4-}$. Found: C, 21.06; H, 4.14; N, 8.24%. Calcd for $C_{18}H_{42}N_6O_{15}S_6Cl_2Co_2Ni$: C, 21.15; H, 4.14; N, 8.22%.

Formation Ratio of Isomers. a) It was found, under the same reaction conditions as those described in **5**), that the formation ratio of the three isomers of $[Co\{Co(L\text{-}cys\text{-}N,S)_3\}_2]^{3-}$ depends on the concentration of Co(II). That is, when 0.162 g (0.68 mmol) and 0.324 g (1.36 mmol) of $CoCl_2\cdot 6H_2O$ were used instead of 0.081 g (0.34 mmol) in **5**), the formation ratios of $\Delta_{LLL}\Delta_{LLL}$-, $\Delta_{LLL}\Lambda_{LLL}$-, and $\Lambda_{LLL}\Lambda_{LLL}$-$[Co\{Co(L\text{-}cys\text{-}N,S)_3\}_2]^{3-}$ were about 0:9:91 and 0:6:94 respectively.

The formation ratio for the isomers of $[Fe\{Co(L\text{-}cys\text{-}N,S)_3\}_2]^{3-}$ was confirmed by using 0.095 g (0.34 mmol) of $FeSO_4\cdot 7H_2O$ instead of $CoCl_2\cdot 6H_2O$ as in **5**); the ratio of $\Delta_{LLL}\Delta_{LLL}$-, $\Delta_{LLL}\Lambda_{LLL}$-, and $\Lambda_{LLL}\Lambda_{LLL}$-$[Fe\{Co(L\text{-}cys\text{-}N,S)_3\}_2]^{3-}$ was 0:5:95.

b) In an acidic solution (40 cm^3) adjusted to ca. pH 1 by the addition of a 1 mol dm^{-3} hydrochloric acid was suspended 0.50 g (0.68 mmol) of Δ_{LLL}-*fac*(*S*)-$K_3[Co(L\text{-}cys\text{-}N,S)_3]\cdot 9H_2O\cdot 0.5KCl$. To this was then added an acidic solution (ca. pH 1) containing an excess amount of $CoCl_2\cdot 6H_2O$ (0.324 g, 1.36 mmol) in 40 cm^3 of water. While the mixture was stirred for 15 min, the starting complex was gradually dissolved and the color of the solution turned to deep greenish brown. The solution was chromatographed in the same manner as in **5**). The formation ratio of $\Delta_{LLL}\Delta_{LLL}$-, $\Delta_{LLL}\Lambda_{LLL}$-, and $\Lambda_{LLL}\Lambda_{LLL}$-$[Co\{Co(L\text{-}cys\text{-}N,S)_3\}_2]^{3-}$ was 62:38:0.

Measurements. The electronic absorption spectra were recorded with JASCO UVIDEC-1 and JASCO UVIDEC-610C spectrophotometers, and the CD spectra with a JASCO J-20 spectropolarimeter. The ^{13}C NMR spectra were recorded with a JEOL JNM-FX-100 or FX-90Q NMR spectrometer at the probe temperature in D_2O solvent. Sodium 2,2-dimethyl-2-silapentane-5-sulfonate (DSS) was used as an internal reference. The pH of the aqueous solution was measured with a Hitachi-Horiba pH meter, model F7-SS, equipped with a glass and saturated calomel electrodes. The cyclic voltammograms were recorded with a Hokuto Denko potentiogalvanostat, model HA-201, to which a linear potential scanner, model HB-103, was attached. A hanging Hg drop microelectrode or a Pt working electrode, a Pt wire counter electrode with a sufficiently large surface area, and a 3.33 mol dm^{-3} KCl calomel reference electrode were used for the potentiostatic measurements in a 0.01 mol dm^{-3} sodium nitrate solution at room temperature (25±1 °C). The electrode potential data were corrected to those for the standard hydrogen electrode (SHE).

Results and Discussion

Structural Assignment. Three isomers, $\Delta_{LLL}\Delta_{LLL}$, $\Delta_{LLL}\Lambda_{LLL}$, and $\Lambda_{LLL}\Lambda_{LLL}$, are expected for $[M\{Co(L\text{-}cys\text{-}N,S)_3\}_2]$-type complexes (M=Fe(III) and Ni(II)), considering the absolute configuration of the two terminal moieties, *fac*(*S*)-$[Co(L\text{-}cys\text{-}N,S)_3]$ (Fig. 1), as in the case of $[Co\{Co(aet)_3\}_2]^{3+}$ and $[Co\{Co(L\text{-}cys\text{-}N,S)_3\}_2]^{3-}$.[3,9,10] The absorption and CD spectra of the isomers are shown in Figs. 2—4, and their data are summarized in Table 1. Of the two isomers, $(+)^{CD}_{600}\cdot(+)^{CD}_{360}$ and $(-)^{CD}_{600}\cdot(+)^{CD}_{360}$, which were obtained by the reaction of Δ_{LLL}-*fac*(*S*)-$[Co(L\text{-}cys\text{-}N,S)_3]^{3-}$ with a stoichiometric amount of Co(II), the $(+)^{CD}_{600}\cdot(+)^{CD}_{360}$ isomer exhibits absorption and CD spectra identical with those of the isomer determined to be $\Delta_{LLL}\Delta_{LLL}$-$[Co\{Co(L\text{-}cys\text{-}N,S)_3\}_2]^{3-}$ by X-ray structure analysis[10] (Fig. 2). The $(-)^{CD}_{600}\cdot(+)^{CD}_{360}$ isomer exhibits an absorp-

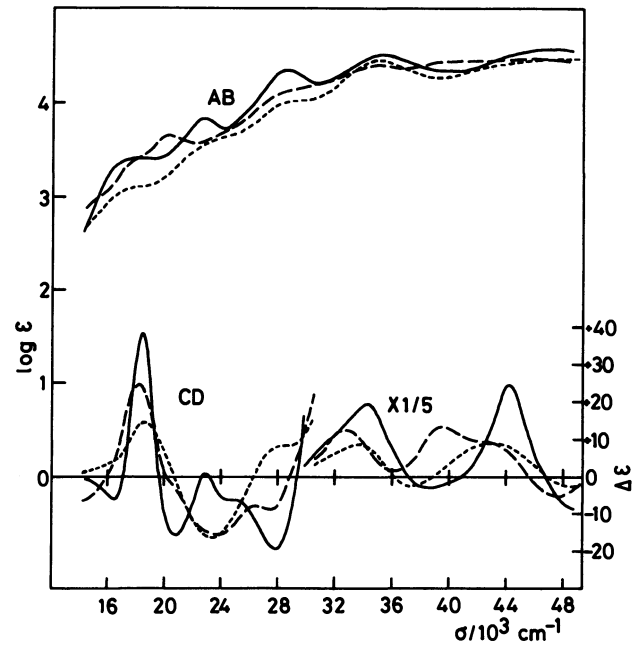

Fig. 4. Absorption and CD spectra of $\Delta_{LLL}\Delta_{LLL}$ isomers; $(-)^{CD}_{600}\cdot(-)^{CD}_{360}$-[Co{Co(L-cys-*N*,*S*)$_3$}$_2$]$^{3-}$ (——), $(+)^{CD}_{600}\cdot(+)^{CD}_{530}$-[Fe{Co(L-cys-*N*,*S*)$_3$}$_2$]$^{3-}$ (-----), and $(+)^{CD}_{600}$-[Ni{Co(L-cys-*N*,*S*)$_3$}$_2$]$^{4-}$ (·····).

tion spectrum quite similar to that of $\Delta_{LLL}\Delta_{LLL}$-[Co{Co(L-cys-*N*,*S*)$_3$}$_2$]$^{3-}$, but it exhibits quite a different CD spectrum from $\Delta_{LLL}\Delta_{LLL}$- and $\Delta_{LLL}\Delta_{LLL}$-[Co{Co(L-cys-*N*,*S*)$_3$}$_2$]$^{3-}$ [9,10] (Fig. 2). Furthermore, the ^{13}C NMR spectrum of the $(-)^{CD}_{600}\cdot(+)^{CD}_{360}$ isomer exhibits six resonance lines (38.2, 38.8, 63.3, 66.4, 178.0, and 179.0 ppm) due to the methylene, methine, and carboxylato carbon atoms, whereas each of the $\Delta_{LLL}\Delta_{LLL}$ and $\Delta_{LLL}\Delta_{LLL}$ isomers exhibits three resonance lines (D_3 symmetry).[9,10] According to the model construction, the symmetry of the $\Delta_{LLL}\Delta_{LLL}$ isomer is lower than or equal to C_3, therefore, this isomer can be expected to exhibit six or more resonance lines. These facts

suggest that the $(-)^{CD}_{600}\cdot(+)^{CD}_{360}$ isomer is $\Lambda_{LLL}\Lambda_{LLL}$-$[Co\{Co(L\text{-cys-}N,S)_3\}_2]^{3-}$.

The three isomers which were obtained by the reaction of Δ_{LLL}-*fac*(*S*)-$[Co(L\text{-cys-}N,S)_3]^{3-}$ with Fe(III) or Fe(II) exhibit absorption spectral behavior quite similar to one another (Fig. 3 and Table 1), as in the case of $[Co\{Co(L\text{-cys-}N,S)_3\}_2]^{3-}$. The two isomers, $(+)^{CD}_{600}\cdot(+)^{CD}_{530}$ and $(-)^{CD}_{600}\cdot(-)^{CD}_{530}$, exhibit intense CD bands which are almost enantiomeric over the whole region, while the remaining one, $(-)^{CD}_{600}\cdot(+)^{CD}_{530}$, exhibits weak CD bands (Fig. 3). The CD spectral pattern of the $(+)^{CD}_{600}\cdot(+)^{CD}_{530}$ isomer approximately coincides with that of $\Delta_{LLL}\Delta_{LLL}$-$[Co\{Co(L\text{-cys-}N,S)_3\}_2]^{3-}$,[9,10] except for the ambiguity around 20—27×10³ cm^{-1} (Fig. 3). On the other hand, the $(-)^{CD}_{600}\cdot(-)^{CD}_{530}$ isomer exhibits a CD spectral pattern similar to that of $\Lambda_{LLL}\Lambda_{LLL}$-$[Co\{Co(L\text{-cys-}N,S)_3\}_2]^{3-}$ [9,10] (Fig. 3). These facts suggest that the $(+)^{CD}_{600}\cdot(+)^{CD}_{530}$ isomer is $\Delta_{LLL}\Delta_{LLL}$-$[Fe\{Co(L\text{-cys-}N,S)_3\}_2]^{3-}$ and that the $(-)^{CD}_{600}\cdot(-)^{CD}_{530}$ isomer is the $\Lambda_{LLL}\Lambda_{LLL}$ one. Accordingly, the remaining $(-)^{CD}_{600}\cdot(+)^{CD}_{530}$ siomer can be assigned to $\Delta_{LLL}\Lambda_{LLL}$-$[Fe\{Co(L\text{-cys-}N,S)_3\}_2]^{3-}$.

The reaction of Δ_{LLL}-*fac*(*S*)-$[Co(L\text{-cys-}N,S)_3]^{3-}$ with Ni(II) formed only the $(+)^{CD}_{600}$ isomer, exhibiting intense absorption bands over the whole region similar to those of $[Co\{Co(L\text{-cys-}N,S)_3\}_2]^{3-}$ and $[Fe\{Co(L\text{-cys-}N,S)_3\}_2]^{3-}$ (Fig. 4). Furthermore, the CD spectral behavior of the $(+)^{CD}_{600}$ isomer agrees with that

of $\Delta_{LLL}\Delta_{LLL}$-[Fe{Co(L-cys-*N*,*S*)$_3$}$_2$]$^{3-}$ (Fig. 4). Accordingly, the $(+)^{CD}_{600}$ isomer is tentatively assigned to $\Delta_{LLL}\Delta_{LLL}$-[Ni{Co(L-cys-*N*,*S*)$_3$}$_2$]$^{4-}$.

CD Spectra. In the energy region higher than ca. 32×10^3 cm^{-1}, the CD spectral patterns of the three $\Delta_{LLL}\Delta_{LLL}$-[M{Co(L-cys-*N*,*S*)$_3$}$_2$]$^{n-}$ complexes (M=Fe(III), Co(III), and Ni(II)) are similar to that of the mononuclear complex, Δ_{LLL}-*fac*(*S*)-[Co(L-cys-*N*,*S*)$_3$]$^{3-}$, as in the case of their absorption spectral patterns (Figs. 4 and 5). The absorption bands at ca. 34×10^3 cm^{-1} are probably related to the sulfur-to-metal charge transfer bands[12-14] in the terminals, and the CD bands in the corresponding region are commonly positive. Though the overall CD spectral patterns resemble one another in the region of $14-32\times10^3$ cm^{-1}, some absorption and CD spectral deviations are observed in the region of $20-30\times10^3$ cm^{-1}. The deviations in this region are probably due to the characteristic chromophore, FeS_6, CoS_6, or NiS_6, at the center of $\Delta_{LLL}\Delta_{LLL}$-[M{Co(L-cys-*N*,*S*)$_3$}$_2$]$^{n-}$ (M=Fe(III), Co(III), or Ni(II)), besides the common chromophore, CoS_3N_3, in the terminals.

The similarity in the CD spectral patterns of the present trinuclear complexes led us to attempt a CD curve analysis on the assumption that the CD contributions of the chiralities in the trinuclear complexes are additive, as in the case of the mononuclear cobalt(III) complexes.[15-17] The trinuclear complexes in this work formally have the following three CD contributions; (1) the configurational chirality (Δ or Λ) arising from the skew pair of the chelate rings in the terminals, (2) the chirality due to the asymmetric carbon atoms in the L-cys ligands, and (3) the chirality (*R* or *S*) due to the asymmetric sulfur donor atoms bridging the two metal ions. Of the three types of chiralities, the three asymmetric sulfur donor atoms in the Δ_{LLL}-*fac*(*S*)-[Co(L-cys-*N*,*S*)$_3$] terminal are regulated to the *R* configuration for the Fe(III) trinuclear complex and to the *S* configuration for the Co(III) one, while those in the Λ_{LLL}-*fac*(*S*)-[Co(L-cys-*N*,*S*)$_3$] terminal are regulated to the *S* configuration for the Fe(III) complex and to the *R* configuration for the Co(III) one. Accordingly, the CD contributions due to the asymmetric sulfur donor atoms of both terminals in $\Delta_{LLL}\Delta_{LLL}$ trinuclear complex cancell each other out, as in the case of the configurational chiralities, Δ and Λ. Taking this assumption into consideration, the observed CD curves of $\Delta_{LLL}\Delta_{LLL}$-[M{Co(L-cys-*N*,*S*)$_3$}$_2$]$^{3-}$ (M=Fe(III) and Co(III)) seem to exhibit only a vicinal CD contribution due to the asymmetric carbon atoms in the L-cys ligands. In fact, the calculated vicinal CD curves, $1/2\{\Delta\varepsilon(\Delta_{LLL}\Delta_{LLL})+\Delta\varepsilon(\Lambda_{LLL}\Lambda_{LLL})\}$, for the Fe(III) and Co(III) trinuclear complexes are, over the whole region, quite similar to the observed curves of $\Delta_{LLL}\Delta_{LLL}$-[Fe{Co(L-cys-*N*,*S*)$_3$}$_2$]$^{3-}$ and $\Delta_{LLL}\Delta_{LLL}$-[Co{Co(L-cys-*N*,*S*)$_3$}$_2$]$^{3-}$ respectively, as is shown in Fig. 6. These results indicate that the observed CD curves of the $\Delta_{LLL}\Delta_{LLL}$ complexes are composed mainly of the contribution due to the asymmetric carbon atoms of the L-cys ligands, and probably suggest that the additivity on the CD curve is substantiated for the present trinuclear complexes.

Inversion and Redox Reaction. The reaction of Δ_{LLL}-*fac*(*S*)-[Co(L-cys-*N*,*S*)$_3$]$^{3-}$ with Co(III),[9,10] Fe(III), or Ni(II) proceeded with a retention of the Δ_{LLL}-*fac*(*S*) configuration to give $\Delta_{LLL}\Delta_{LLL}$-[M{Co(L-cys-*N*,*S*)$_3$}$_2$]$^{n-}$. By contrast, the reaction with Co(II) or Fe(II) was accompanied by the inversion to the Λ_{LLL} of the Δ_{LLL}-

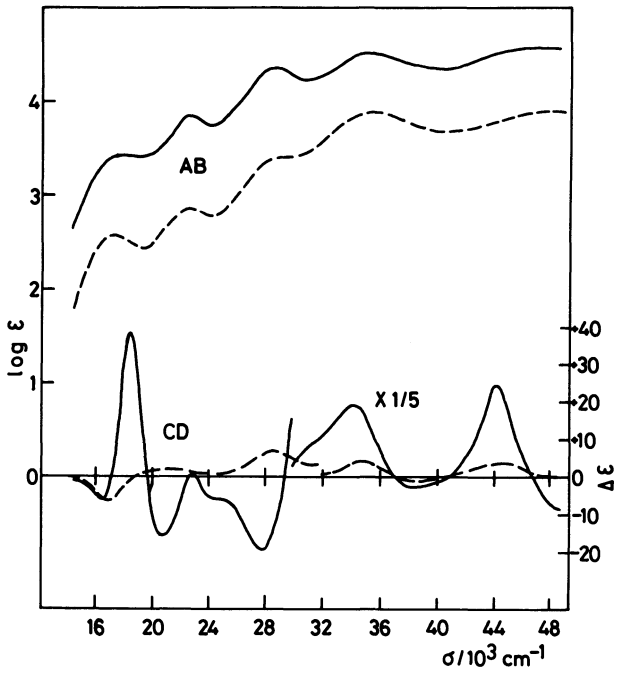

Fig. 5. Absorption and CD spectra of $\Delta_{LLL}\Delta_{LLL}$-[Co{Co(L-cys-*N*,*S*)$_3$}$_2$]$^{3-}$ (—) and Δ_{LLL}-*fac*(*S*)-[Co(L-cys-*N*,*S*)$_3$]$^{3-}$ (-----).

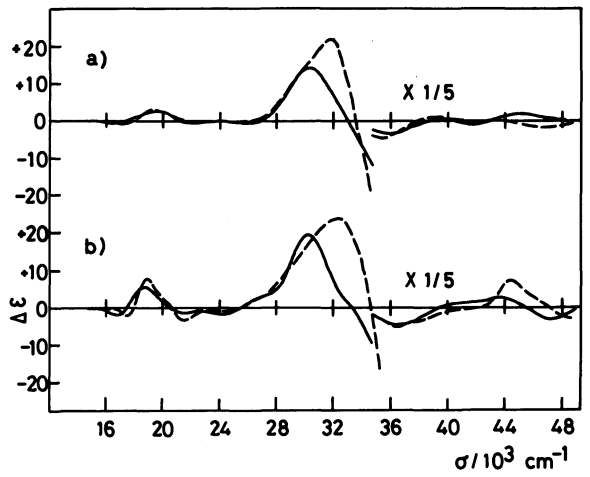

Fig. 6. The observed CD curves of $\Delta_{LLL}\Delta_{LLL}$-[M{Co(L-cys-*N*,*S*)$_3$}$_2$]$^{3-}$ (—) and the calculated CD curves for $1/2\{\Delta\varepsilon(\Delta_{LLL}\Delta_{LLL})+\Delta\varepsilon(\Lambda_{LLL}\Lambda_{LLL})\}$ (-----); a) M=Fe and b) M=Co.

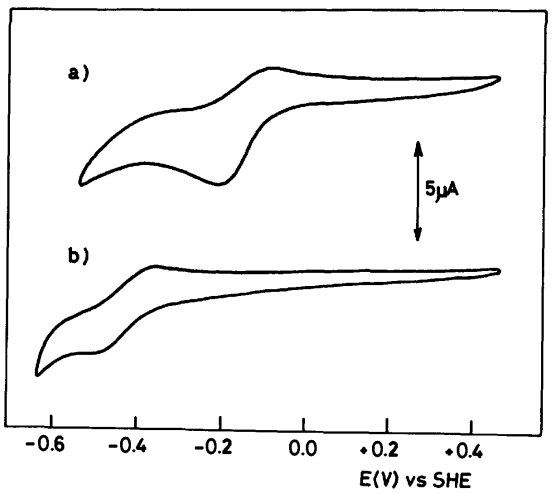

Fig. 7. Cyclic voltammograms of $\Delta_{LLL}\Delta_{LLL}$-[M{Co(L-cys-N,S)$_3$}$_2$]$^{3-}$: scan rate, 10 mV s^{-1}; 0.01 mol dm^{-3} $NaNO_3$ soln.; Hg electrode; 25 °C; a) M=Fe, $E°$=−0.16 V, ΔE_p=100 mV and b) M=Co, $E°$=−0.43 V, ΔE_p=90 mV.

fac(S)-[Co(L-cys-N,S)$_3$] terminals. The inversion ratio runs parallel to the concentration of Co(II) or Fe(II) in the reaction, and under a nitrogen atmosphere these reactions are completely accompanied by the inversion to give only $\Delta_{LLL}\Delta_{LLL}$-[Co{Co(L-cys-N,S)$_3$}$_2$]$^{3-}$. It is obvious that Fe(II) and Co(II) promote the inversion of the Δ_{LLL}-*fac*(S)-[Co(L-cys-N,S)$_3$] terminals, consequently, the $\Delta_{LLL}\Delta_{LLL}$ isomer forms easily.

The reaction of Δ_{LLL}-*fac*(S)-[Co(L-cys-N,S)$_3$]$^{3-}$ with Fe(II) was accompanied by a more remarkable inversion to Δ_{LLL} than that with Co(II). In order to elucidate the difference in inversion for the reactions with Fe(II) and Co(II), the redox potentials of $\Delta_{LLL}\Delta_{LLL}$-[M{Co(L-cys-N,S)$_3$}$_2$]$^{3-}$ (M=Fe(III) and Co(III)) were measured in a 0.01 mol dm^{-3} sodium nitrate solution at the hanging Hg drop microelectrode. All the potentials were referred to the SHE, and the symbols denote the following: E_{pa} is the anodic peak potential, E_{pc} is the cathodic peak potential, and ΔE_p is (E_{pa}−E_{pc}). The formal potential, $E°_{298}$, is taken as the average of E_{pa} and E_{pc}. $\Delta_{LLL}\Delta_{LLL}$-[Fe{Co(L-cys-N,S)$_3$}$_2$]$^{3-}$ and $\Delta_{LLL}\Delta_{LLL}$-[Co{Co(L-cys-N,S)$_3$}$_2$]$^{3-}$ display a quasi-reversible (ΔE_p=90—100 mV) cyclic response in different potential ranges, and no other redox process is observed in the potential range of −0.6—+0.9 V (Fig. 7). These results are interpreted in terms of the following one-electron redox reaction.

$$[M^{III}\{Co(L\text{-}cys\text{-}N,S)_3\}_2]^{3-} + e^- \rightleftharpoons [M^{II}\{Co(L\text{-}cys\text{-}N,S)_3\}_2]^{4-} \quad (M = Co \text{ or } Fe)$$

The formal potential of [Fe{Co(L-cys-N,S)$_3$}$_2$]$^{3-}$ (−0.16 V) is more anodic than that of [Co{Co(L-cys-N,S)$_3$}$_2$]$^{3-}$ (−0.43 V). This relationship corresponds to that of the formal potentials for the $Co^{III}N_6$- and $Fe^{III}N_6$-type complexes with the cyclic amine ligands.[18,19] These facts indicate that the central metal M is presumably redox active and that the redox potential of the Fe(II) center is more anodic than that of the Co(II) center. Taking these electrochemical properties into consideration, it is suggested that, in the formation process of the trinuclear complex by the reaction with the bivalent metal ion, the Fe(II) bridged with sulfur donor atoms of Δ_{LLL}-*fac*(S)-[Co(L-cys-N,S)$_3$]$^{3-}$, namely, $Fe^{II}(S_3CoN_3)$, has a lower oxidation tendency than the Co(II) one, $Co^{II}(S_3CoN_3)$. This suggestion is consistent with the fact that the formation of the $\Delta_{LLL}\Delta_{LLL}$ isomer is promoted more remarkably by the reaction of Δ_{LLL}-*fac*(S)-[Co(L-cys-N,S)$_3$] with Fe(II) than by that with Co(II), because the Δ_{LLL}-*fac*(S) terminals in the reaction with Fe(II) are labilized more than those in the reaction with Co(II).

(Received September 11, 1987)

The crystal and molecular structures of the chloroacetato-dimethyl sulfoxide (dmso) mixed complex of neodymium(III) indicated in the title were determined by the single-crystal X-ray diffraction method. The crystal is monoclinic, space group $P2_1/n$, a=21.106(21), b=15.871(8), c=15.748(7) Å, β=93.29(5)°, Z=4 (including 12 metal atoms in a unit cell). There are three kinds of crystallographically independent metal atoms, Nd(1), Nd(2), and Nd(3): Nd(1) and Nd(3) are ennea-coordinated (approximately tricapped trigonal-prism geometry), and Nd(2) is deca-coordinated (approximately bicapped square-antiprism geometry) including a slightly long M–O bonding. All dmso molecules are directly coordinated to the metal atoms as unidentate, while all the carboxylate ions bridge metal atoms acting as bidentate or tridentate ligands. The bridging atoms are arranged in a chain which is approximately formed along the [101] axis. Also, the isomorphous lanthanum(III) and praseodymium(III) complexes were obtained and their structures were elucidated.

The variety of polymeric structures as well as the high coordination numbers of the metal atoms are characteristic of carboxylato complexes of lanthanoids.[1-10] Among them, the structures of the hydrated chloroacetates of more than half the lanthanoids and yttrium, as well as of the scandium salt (anhydride) have been reported in previous papers.[1-3] The light lanthanoids (La—Eu), the heavy lanthanoids (Gd—Yb) and yttrium, and the scandium salts have the respective types of chain structures.

It is well-known that many transition metals can form Lewis base adducts of their salts. Many of them are mixed complexes in which Lewis base molecules are also directly coordinated to the metal atoms; however, in the other adducts, the base molecules are not bonded to the metal atoms directly. In cases of lanthanoid complexes, although a great variety of adducts have already been synthesized,[11-16] only a few reports have so far been published concerning their structures.

On the line of our structural research concerning the lanthanoid(III) carboxylates, we could synthesize the dimethyl sulfoxide (dmso) adducts of some lanthanoid(III) chloroacetates, which did not include water.

It is interesting to compare their structures with those of the hydrated salts, which have already been elucidated, as well as of other carboxylates. Therefore, the authors have tried to determine the structures of the title complexes by the single-crystal X-ray diffraction method.

Experimental

Synthesis of the [Enneakis(chloroacetato)tetrakis(dimethyl sulfoxide)trineodymium(III)], $[Nd_3(ClCH_2CO_2)_9\{(CH_3)_2SO\}_4]$, and its Isomorphous Complexes. The hydrated neodymium(III) chloroacetate, $Nd(ClCH_2CO_2)_3 \cdot 5/3H_2O$ (0.90 g, 2.5 mmol)[1] were dissolved into ethanol (10 cm³), then dmso (0.40 g, 5.1 mmol) as well as benzene (10 cm³) were added to it. The solution was evaporated off by a vacuum rotary evaporator at about 80 °C. To the gummy residue, 15 cm³ of the ethanol–benzene mixture (1:1=v/v) was added and was evaporated once more in the same way. The residue was dissolved into 10 cm³ of methanol, and left standing in a desiccator over silica gel until about two-thirds of the solvent was evaporated off. The deposited crystals were separated, washed with a small portion of methanol, and dried in a silica gel desiccator. Yield, 0.9 g (6.7 mmol, 68%). By the same method, the isomorphous praseodymium(III) and lanthanum(III) mixed complexes were obtained (the yields of the lanthanum and praseodymium complexes were, 1.1 g (2.1 mmol, 75%) and 1.8 g (3.4 mmol, 85%), starting at 1.0 g (2.8 mmol) and 1.4 g (4.0 mmol) of the respective hydrated salts).

Analyses of the complexes (the calculated values were obtained assuming the formula of $M_3C_{26}H_{42}O_{22}Cl_9S_4$): M=Nd, Found, Nd, 27.36; C, 19.40; H, 2.59%. Single Crystal X-Ray Structure Analysis. Their crystallographic data are shown in Table 1, together with some experimental conditions regarding the collection of intensity data. The reflections were collected on a Rigaku AFC-6A automated 4-circle X-ray diffractometer with graphite-monochromated Mo $K\alpha$ radiation (λ=0.71073 Å; scan speed, 4° min⁻¹ (θ)). During the preliminary intensity data-collection process, since some (though only a few) peaks were found to overlap partially with the vicinal ones, the ω-scan technique was used.

Structure Determination. The structure of the neodymium(III) complex was solved by the heavy-atom method. The positions of metal and some chlorine atoms were deduced from a three-dimensional Patterson map, while all the other non-hydrogen atoms were located by means of successive Fourier syntheses, and refined by a block-diagonal least-squares method. In the last-cycle of the

a) The equivalent isotropic temperature factors were computed using the following expression: $B_{eq}=4/3(B_{11}a^2+B_{22}b^2+B_{33}c^2+B_{13}ac\cos\beta)$. The B_{ij}'s are defined by: $T=\exp[-(h^2B_{11}+k^2B_{22}+l^2B_{33}+2hlB_{13}+2klB_{23}+2hkB_{12})]$.

refinement with anisotropic temperature factors for all the non-hydrogen atoms, all the parameter-shifts were less than one-third of the corresponding standard deviations. All hydrogen atoms were excluded from the structure factor calculations. The structures of the isomorphous complexes were solved by starting with the final parameters of the neodymium(III) complex, and were refined in the same way. All of their parameters converged within one-third of the respective standard deviations, too.

Some chlorine atoms of the ligands were found to have relatively large thermal parameters, and some Cl-C bond lengths were a little shorter than the sum of the Pauling's covalent bonding radii (1.76 Å),[17] although the average of the all Cl-C bond lengths of all the three complexes is not short, 1.76 Å. We tried to divide the positions of some such chlorine atoms into disordered structures, but failed. Probably their large temperature factors are due to their low positional restrictions: no atoms are very near such chroline atoms in the crystal. Such a phenomenon has also been found in other lanthanoid complexes, about the atoms in the tail part of the coordinating ligands.[18,19]

All the calculations were carried out on a HITAC M-682H apparatus at the Computer Center of the University of Tokyo, using the local version of the UNICS program.[20] The atomic scattering factors are taken from Ref. 21.

Infrared Spectrum Measurements. Their infrared spectra were obtained by means of a JASCO A202 grating infrared spectrophotometer, using liquid paraffin or hexachloro-1,3-butadiene mull.

Results and Discussion

The final atomic parameters of the neodymium(III) complex are listed in Table 2, while selected bond lengths and bond angles as well as some inter-metal-atomic distances are tabulated in Table 3.[22] The perspective drawing of the neodymium(III) complex around the metal atoms (Nd(1), Nd(2), and Nd(3)), as well as the numbering scheme of the atoms are shown in Figs. 1—3, and the projection of the unit cell to the ac-plane in Fig. 4, respectively.

The Nd(1) and Nd(3) atoms are ennea-coordinated being approximately in a tricapped trigonal-prism geometry, while the Nd(2) atom is deca-coordinated being approximately in a cis-bicapped square-antiprism geometry;[24] however, Nd(2)-O(15) (2.988(8) Å) is a little longer than the other Nd-O bonds. The averages of the Nd-O bond lengths, together with those of the other isomorphous complexes are summarized in Table 4. The average Nd-O bond lengths around Nd(1) and Nd(3) atoms (2.513 and 2.499 Å) are not much different from each other, and they are approximately the same as the sum of the Shannon's ionic radii, 2.51 Å (where the coordination number of the Nd atoms is 9).[25] The Nd(1,3)-O(dmso)$_{av.}$ (from now on, "av." means the average of the values) is

a) av. means the average of the M-O bond lengths between the metal atom and the group of coordinating oxygen atoms. b) See Ref. 25. II, X, IX means their coordination number.

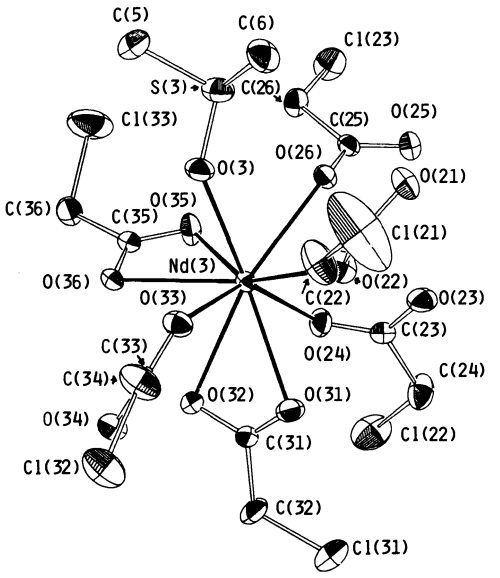

Fig. 3. A perspective drawing of the neodymium(III) complex around the Nd(3) atom.

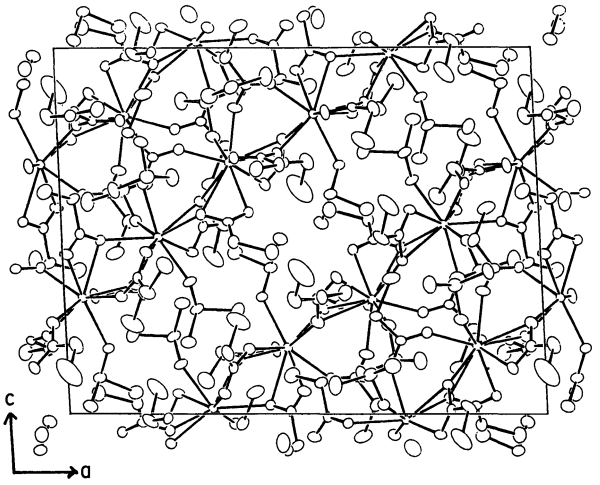

Fig. 4. A projection of the unit-cell to the ac-plane.

2.441 Å, which is shorter than the Nd(1,3)-O(acid)$_{av.}$, 2.519 Å. Therefore, in these complexes, the former bonds are likely to be stronger than the latter ones.

The average of all ten Nd-O bond lengths around the Nd(2) atom is 2.574 Å, which is longer than the sum of the Shannon's ionic radii, 2.56 Å (the coordination number of the Nd atom is 10).[25] Even when the longest bond, Nd(2)-O(15), is rejected, the average of the other nine bond lengths is 2.528 Å, which is longer than the average Nd-O bond lengths around the ennea-coordinated Nd(1) or Nd(3) atoms. Therefore, atom O(15) should be regarded as the ligating atom, or at least, it also affects the coordination geometry around the Nd(2) atom. The Nd-(2)-O(2) (dmso oxygen atom) is 2.434 Å, which is much shorter than the Nd(2)-O(acid)$_{av.}$, 2.590 Å. Consequently, the Nd-O(dmso) bond is stronger than the

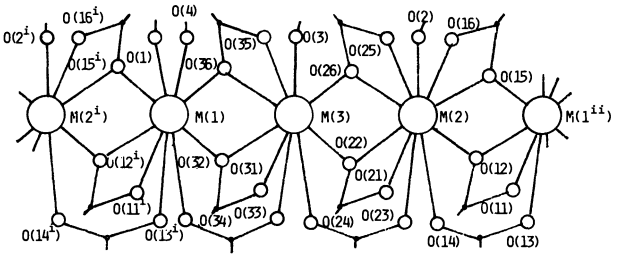

Fig. 5. A schematic presentation of the bridgings between the metal atoms.[23]

Nd–O(acid) bonds around the deca-coordinated Nd(2) atom, too.

The metal atoms are arranged approximately along the [101] axis in the order of Nd(1^{ii}), Nd(2), Nd(3), Nd(1), Nd(2^{i})···,[23] as shown schematically in Fig. 5. The interatomic distance is 4.317 Å (on the average); this is shorter than the average inter-metal-atomic distance of the chain in the hydrated neodymium chloroacetate, 4.435 Å.[1]

It is very interesting that this dmso adduct has an average M···M′ distance of the complex chain shorter than that of the hydrate, though the dmso adduct has a larger unit-cell, and smaller density (5267(8) Å^3 and 2.00 g cm^{-3} for the dmso adduct, and 3986(2) Å^3 and 2.27 g cm^{-3} for the hydrate). Moreover, since the Nd–O(dmso)$_{av.}$ lengths are shorter than the Nd–O(acid)$_{av.}$ lengths in the dmso adduct, while the Nd–O(water)$_{av.}$ lengths are about the same as the Nd–O(acid)$_{av.}$ lengths in the hydrate, the approaching dmso ligands in this adduct are expected to prevent any approaching of neighboring complexes in the linear polymer: however this expectation did not prove to be correct.

Probably, the dmso methyl groups in this adduct, which are non-polar and are intercalated between complex chains, act to pack the chain in the limited space between the hydrophobic layers of the hydrocarbon groups: the inter-chain separations are kept large, but the inter-metal atomic distances in the chains are shortened.

The bridging structure, the numbers and the types of the bridging carboxylate ions between respective neighboring metal atoms in the chain of the title dmso adduct, is much different from that of the hydrated salt of the same metal;[1] this type of chain structure has not yet been found in any other linear polymeric chains of the other lanthanoid carboxylates. In the titled complex, all the pairs of the neighboring metal atoms are bridged by three carboxylate ions respectively: one in bidentate (approximately in the *Z,Z*-type, but some of them are quite deformed), and two in the tridentate types.[26] In some deformed bidentate bridges between Nd(1) and Nd(3), as well as Nd(3) and Nd(2), one of the C–O–M angles in very small, only about 110—125°, and some atomic positions are much deviated from the mean-square plane of the MOCO′M′ bridging. All the tridentate bridges of these complexes are also more or less deformed from the ideal form (here the ideal form means the bridge, where the three metal-oxygen bondings, M–O, M–O′, and M′–O′, are about the same in their lengths, and the bond angles of M–O–C as well as M–O′–C are about the same (95—100°), while that of M′–O′–C is larger (150—160°)).[26]

Although there are no fundamental differences between their structures, the isomorphous lanthanum(III) and praseodymium(III) complexes have larger unit cells than the neodymium(III) complex: their cell dimensions decrease depending on the atomic number of the central metal atom. The decrease of the cell-volume is mainly caused by packing the coordination sphere around the central metal atom: the M–O bond lengths decrease. Therefore, as shown in Table 4, almost all M–O bond lengths are generally shorter in a higher atomic number metal complex, although the lengths of some weak bonds, such as M(1)–O(15) and M(1)–O(12^{i}), rather increase with the metal atomic number.

The infrared spectra of these complexes were examined, but there are almost no differences between them. The ν_{as}(COO) and ν_{s}(COO) peaks appear as the respective doublets of the maximum wavenumbers of 1598, 1573 cm^{-1}, and of 1418, 1402 cm^{-1}, respectively. In the spectra of the hydrated chloroacetates of lanthanum(III), and neodymium(III), these bands appear at about 1580 and 1415—1420 cm^{-1}, respectively. Therefore, these peak maximum wavenumbers of both types of complexes are not much different from each other.

The ν(SO) band of the titled complexes appear at about 1000 cm^{-1} as a sharp strong peak, while the band of free dmso appears at about 1050 cm^{-1} as a broad band: the peak of the complexes is much red-shifted. This fact corresponds with the strong M–O(dmso) bond in the complexes, as was expected from the results of the X-ray structure analysis.

The authors wish to thank Shin-Etsu Ind. Co., Ltd., for presenting us with the highly pure lanthanoid oxides.

(Received December 17, 1987)

Heterometal binuclear complexes, [CuLn(fsaen)(H_2O)$_n$](NO_3) (Ln=La, Pr, Nd, Sm, Eu, Gd, Tb, Dy, Ho, Er, Tm, Yb, or Lu; n=4—5) and [CuLn(fsapn)(H_2O)$_4$](NO_3) (Ln=La, Pr, Nd, Sm, Eu, Gd, Tb, or Dy) have been synthesized and characterized, where H_4fsaen and H_4fsapn denote *N,N'*-bis(3-carboxysalicylidene)ethylenediamine and *N,N'*-bis(3-carboxysalicylidene)-1,2-propanediamine, respectively. The ligand field band due to the copper(II) ion bound to the N_2O_2-site is at 18.5×10^3—19.5×10^3 cm^{-1} for [CuLn(fsaen)(H_2O)$_n$](NO_3) and 18.4×10^3—19.2×10^3 cm^{-1} for [CuLn(fsapn)(H_2O)$_4$](NO_3), which are higher frequencies than those of the mononuclear complexes, [Cu(H_2fsaen)](H_2O)$_{0.5}$ and [Cu(H_2fsapn)](H_2O)$_{0.5}$ (18.3×10^3 and 18.4×10^3 cm^{-1}, respectively). When the complexes are dissolved in pyridine (Py), dimethyl sulfoxide (DMSO), or *N,N*-dimethylformamide (DMF), the d-d band frequency decreases in the order of the solvent DMSO>DMF>Py for the binuclear complexes, whereas it decreases in the order of DMF>DMSO>Py for the mononuclear complexes. These trends were discussed in terms of the different affinities of solvent molecules for copper(II) and lanthanoid(III) ions. No significant magnetic spin-exchange interaction occurred between metal ions.

Various rare earth perovskite or garnet type compounds have been widely studied because of their growing possible use as the magnetic material, electrical semiconductor, catalysis, and so on.[1] However, the role of rare earth metal ions in these materials seems not to be still well-defined. For the understanding of their interesting properties, heterometal binuclear complexes comprising a transition metal and a lanthanoid ions are presumed to be good simple models.

A general method for obtaining heterometal binuclear complexes is the stepwise addition of two different metal ions to a coordinatively selective binucleating ligand, in which two coordinating sites differ from each other in the ligand field strength or in the stereochemistry of coordination. A number of such compartmental ligands have been synthesized[2-8] and studies on binuclear complexes with dissimilar d-transition metal ions have been developed with these ligands.[3,5,6,9-15] On the other hand, very few reports[8] are available on the heterometal binuclear complexes containing a d-transition metal ion and a lanthanoid ion.

Since Okawa et al.[3] first used *N,N'*-bis(3-carboxysalicylidene)ethylenediamine (H_4fsaen) as an excellent binucleating ligand possessing dissimilar coordination sites, this ligand and its homologs have been extensively utilized for the syntheses of homo- and heterometal binuclear complexes to investigate their magnetic, optical, electrochemical, and structural properties.[3,5,9,10,13-16] In those studies, it was revealed that physicochemical properties of the metal ion bound at N_2O_2-site (inside coordination site) are very sensitive to the second metal ion at the O_4-site (outside coordination site).[5] Since the outside coordination site seems favorable for binding lanthanoid ions, these ligands are expected to be applicable to the syntheses of heterometal binuclear complexes comprising a d-transition metal and a lanthanoid metal ions.

In this work we have prepared copper(II)-lanthanoid(III) complexes of H_4fsaen and *N,N'*-bis(3-carboxysalicylidene)-1,2-propanediamine (H_4fsapn), in which copper(II) and lanthanoid(III) ions are bound at the inside and outside coordination sites, respectively (Fig. 1). The effect of the presence of a lanthanoid(III) ion at the outside site upon the ligand field around copper (II) ion at the inside site has been discussed mainly on the basis of electronic spectra. The IR, ESR, and magnetic data of these complexes are also reported.

Experimental

Syntheses. 3-Formylsalicylic acid was prepared after the method of Duff and Bills.[17] The mononuclear copper(II) complexes, [Cu(H_2fsaen)](H_2O)$_{0.5}$ and [Cu(H_2fsapn)](H_2O)$_{0.5}$, were obtained by the method of Okawa et al.[4]

CuLn(fsaen)(NO_3)(H_2O)$_4$ and CuLn(fsapn)(NO_3)(H_2O)$_4$ (Ln=La—Nd): The corresponding mononuclear copper(II) complex (1 mmol) was dissolved in a methanolic solution (50 cm^3) of lithium hydroxide monohydrate (2 mmol). To this solution was added a methanolic solution (50 cm^3) of lanthanoid nitrate hydrate (1 mmol) with stirring. After the mixture was refluxed for 2—3 h with stirring, the precipitate formed was filtered, washed with methanol and then with diethyl ether, and dried in the open air.

CuLn(fsaen)(NO_3)(H_2O)$_n$ (Ln=Sm—Ho, n=4—5): The procedure was the same in principle as that described above, except for the use of 25 cm^3 methanol for each treatment.

CuLn(fsaen)(NO_3)(H_2O)$_5$ (Ln=Er—Lu) and CuLn(fsapn)(NO_3)(H_2O)$_4$ (Ln=Sm—Dy): These binuclear complexes were synthesized in the same way as that for the above complexes, except that the mononuclear copper(II) complex (1 mmol) was dissolved in a methanolic solution (25 cm^3) of

lithium hydroxide monohydrate (2 mmol), followed by the addition of methanolic solution (5 cm^3) of lanthanoid nitrate hydrate (1 mmol).

Elemental analyses for the complexes are given in Tables 1 and 2.

Measurements. Elemental analyses of carbon, hydrogen, and nitrogen were carried out at the Service Center of Elemental Analysis, Kyushu University or Advanced Instrumentation Center for Chemical Analysis, Ehime University. Metal contents were determined by EDTA titration. Infrared spectra were measured with a JASCO IR-G Spectrometer on KBr disks or on nujol mulls. Electronic spectra were obtained on nujol mulls and in dimethyl sulfoxide, *N,N*-dimethylformamide, or pyridine with a Shimadzu UV-VIS Recording Spectrophotometer Model 240. Magnetic susceptibilities were measured by the Gouy method or the Faraday method from liquid nitrogen temperature to room temperature. Diamagnetic correction was done using the Pascal's constants. Magnetic moments were calculated from the equation, $\mu_M=2.828\sqrt{x_M T}$, where x_M is the susceptibility per molecule. The ESR spectra were recorded with a JES-ME-3X Spectrometer by the X-band in dimethyl sulfoxide, *N,N*-dimethylformamide, or pyridine at liquid nitrogen temperature.

Results and Discussion

Infrared spectra of the binuclear complexes are essentially similar to each other as far as the same ligand is concerned. The absorption band at 1630—1640 cm^{-1} is assignable to the C=N stretching mode. The band due to the free carboxyl group was reported to appear at 1705 cm^{-1} for both $[Cu(H_2fsaen)](H_2O)_{0.5}$ and $[Cu(H_2fsapn)](H_2O)_{0.5}$.[4] However, this band disappeared in the spectra of $CuLn(fsaen)(NO_3)(H_2O)_n$ and $CuLn(fsapn)(NO_3)(H_2O)_4$. Instead a broad and strong band was observed around 1540 cm^{-1}. The binuclear d-transition metal complexes of 3-formylsalicylic acid[18] and its Schiff bases[3-5,9,19] are known to exhibit the absorption band at 1540—1580 cm^{-1} which is attributable to the C=O stretching vibration. Therefore, it seems reasonable to assign the band around 1540 cm^{-1} to the coordinated carboxylato group.

It is well-known that for the phenoxo-bridged binuclear complexes one of the skeletal vibrations (near 1540 cm^{-1}) is by 15—20 cm^{-1} higher than that of the corresponding mononuclear complexes.[2] For example, the mononuclear copper(II) complex of a macrocycle, 24,25-dihydroxy-10,22-dimethyl-3,6,14,18-tetraazatricyclo[18.3.1.1^{8,12}]pentacosa-1(24),2,6,8(25),9,11,13,18,20,22-decaene, shows the skeletal band at 1543 cm^{-1}, whereas its binuclear copper(II) complex shows the corresponding band at 1560 cm^{-1}.[2] For the present Cu(II)-Ln(III) complexes, however, such a marked shift of the skeletal band was not observed. That is, the band for the Cu(II)-Ln(III) complexes appeared around 1560 cm^{-1}, whereas the band for $[Cu(H_2fsaen)](H_2O)_{0.5}$ and $[Cu(H_2fsapn)](H_2O)_{0.5}$ appeared around 1555 cm^{-1}.

For the nitrates of lanthanoid complexes it is reported that IR bands appear around 1450—1500, 1300, 1030, and 815 cm^{-1} if the nitrate ion functions as a bidentate ligand.[8,20] Such bands could not be clearly seen in the IR spectra of the present binuclear complexes. Instead the sharp bands appeared at 1380 and 805 cm^{-1} which are characteristic of free nitrate ion.[21] Furthermore, the splitting of combination bands in the region of 1700—1800 cm^{-1}, which has been often utilized as a diagnosis of the bonding mode of nitrate ion,[22] was not recognized for the complexes. These observations indicate that the nitrate ion does not coordinate to the metal ion. The spectra on nujol mulls for the binuclear complexes showed two bands at 3350 and 3250 cm^{-1} assignable to the asymmetric and symmetric stretching vibrations of H_2O molecule, respectively, whereas $[Cu(H_2fsaen)](H_2O)_{0.5}$ and $[Cu(H_2fsapn)](H_2O)_{0.5}$ showed a band at 3400 cm^{-1} attributable to a lattice water. Judging from these facts, the present binuclear complexes can be formulated as $[CuLn(fsaen)(H_2O)_n](NO_3)$ and $[CuLn(fsapn)(H_2O)_4](NO_3)$ in which lanthanoid ions are presumably of eight or nine coordination with O_4-donor atoms of the Schiff base and four or five H_2O molecules, though the detailed structure is unclear at the present stage.

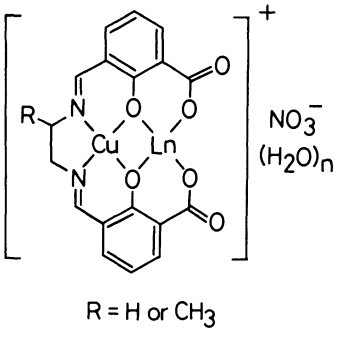

Fig. 1. The structure of copper(II)–lanthanoid(III) heterometal binuclear complexes.

Some of the electronic spectra determined on nujol mulls are shown in Fig. 2. The absorption maxima of the complexes are summarized in Figs. 3 and 4. $[Cu(H_2fsaen)](H_2O)_{0.5}$ and $[Cu(H_2fsapn)](H_2O)_{0.5}$ show the ligand field band due to the copper(II) ion at 18.25×10^3 and 18.38×10^3 cm^{-1}, respectively, which are very close to those determined by reflection on powder samples by Okawa et al.[4] The d-d band is shifted to higher frequency on binuclear complex formation. This is in accord with that $[Cu(H_2fsaen)](H_2O)_{0.5}$ and $[Cu(H_2fsapn)](H_2O)_{0.5}$ are purple while the Cu(II)-Ln(III) complexes are red-purple. Such a blue shift of the d-d band may be attributed to the enhanced

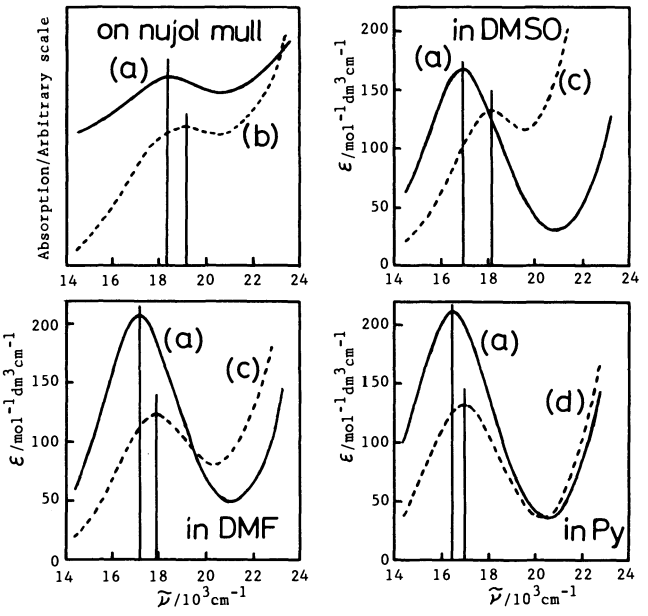

Fig. 2. The electronic spectra. (a): $[Cu(H_2fsaen)](H_2O)_{0.5}$, (b): $[CuLu(fsaen)(H_2O)_5](NO_3)$, (c): $[CuSm(fsaen)(H_2O)_4](NO_3)$, (d): $[CuGd(fsaen)(H_2O)_4](NO_3)$.

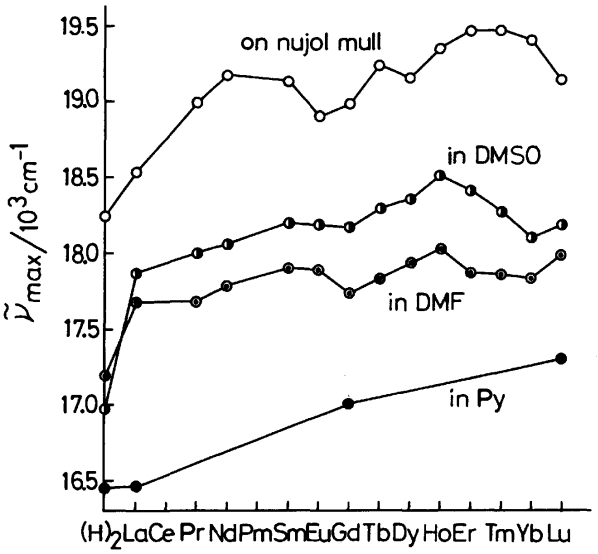

Fig. 3. The d-d band absorption maxima of [Cu(H2fsaen)](H2O)0.5 and [CuLn(fsaen)(H2O)n](NO3). (H)2, La, Pr, ···, and Lu of abscissa denote the mononuclear copper(II), copper(II)-lanthanum(III), copper(II)-praseodymium(III), ···, and copper(II)-lutetium(III) binuclear complexes, respectively.

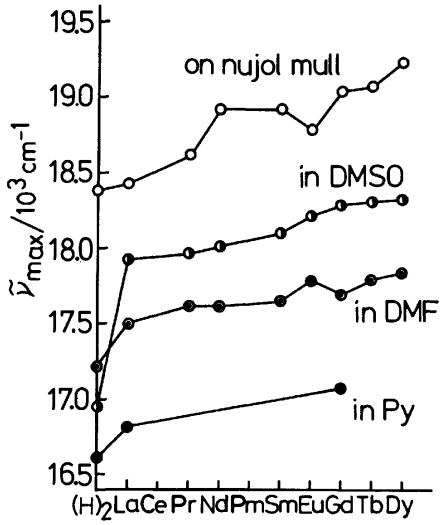

Fig. 4. The d-d band absorption maxima of [Cu(H2fsapn)](H2O)0.5 and [CuLn(fsapn)(H2O)4](NO3). (H)2, La, ···, and Dy of abscissa denote the mononuclear copper(II), copper(II)-lanthanum-(III), ···, and copper(II)-dysprosium(III) binuclear complexes, respectively.

planarity of the $[CuN_2O_2]$ chromophore on forming a binuclear complex with a lanthanoid ion at the outside coordination site as was observed for Cu(II)-M(II) (M=Co,Ni,Cu,Zn,Mg) heterometal binuclear complexes of *N,N'*-bis(3-carboxysalicylidene)-1,1-dibenzylethylenediamine.[5] The relatively small shift of the band for the CuLa complexes suggests that large lanthanum ion cannot reside in the outside coordination site and causes more or less a distortion of the $[CuN_2O_2]$ plane.

When the mononuclear copper(II) complexes were dissolved in pyridine (Py), dimethyl sulfoxide (DMSO), or *N,N*-dimethylformamide (DMF), the solutions were all blue. Their absorption spectra are given in Fig. 2. The frequency of the d-d band is in the following order of solvent: DMF>DMSO>Py(see also Figs. 3 and 4). This is quite understandable when one recalls the facts that the coordination at the apical site causes a red shift of the d-d band for planar copper(II) complexes and that the donating ability of the solvent increases in the order, DMF<DMSO<Py. On the other hand, solutions of the Cu(II)-Ln(III) complexes in Py are blue but those in DMSO or DMF purple. Accordingly, the spectra showed that the frequency of the d-d band is in the order, DMSO>DMF>Py. This may be explained by taking into consideration the difference in coordination affinity of a solvent molecule to copper(II) and lanthanoid(III) ions. Since pyridine has a higher affinity for copper(II) ion than for lanthanoid(III) ions, the pyridine molecule selectively coordinates to the copper(II) ion to result in the shift of the d-d band to lower frequency. On the other hand, DMSO and DMF have similar affinities for both copper(II) and lanthanoid(III) ions. If these solvents preferentially coordinate to the lanthanoid ion rather than the copper(II) ion to afford a high coordination number around the lanthanoid ion, then the coordinated solvent molecules block the apical part of the copper(II) ion and hence hinder the approach of other solvent molecules to the copper-(II) ion. Such a shielding must be more effective in DMSO than in DMF because the former solvent generally coordinates more strongly to lanthanoid ions. Planar copper(II) complexes of *N,N'*-disalicylideneethylenediamine and its homologs show the d-d band at 17.8×10^3—18.2×10^3 cm^{-1} in nondonative solvents.[5,24-26] These frequencies are comparable to those of the present binuclear complexes in DMSO, indicating that the coordination geometry of copper is essentially planar even in DMSO. It is presumed that the situation is nearly the same in DMF, judging from the d-d band frequency.

We have measured the ESR spectra of [Cu(H2fsaen)](H2O)0.5 and [CuLn(fsaen)(H2O)n](NO3) (Ln=La, Lu) in Py, DMSO, or DMF at liquid nitrogen temperature and found that ESR parameters, $g_{//}$ and $A_{//}$, are essentially the same for the mononuclear and binuclear complexes irrespective of the change of the solvent. This may be explained by that the axial coordination of the solvents (Py, DMSO, DMF) to the mononuclear complexes and the axial coordination of Py to the binuclear CuLn-complexes may destabilize the d_{z^2} orbital but this is not clearly detected by ESR because the d_{z^2} orbital is EPR-innocent.

The magnetic moments of the Cu(II)-Ln(III)

Table 3. Magnetic Moments of Complexes[a)]

Complex	Magnetic moment		Complex	Magnetic moment	
	μ_M[b)]	μ_M^{calcd}[c)]		μ_M[b)]	μ_M^{calcd}[c)]
$CuLa(fsaen)(NO_3)(H_2O)_4$	1.85	1.85	$CuYb(fsaen)(NO_3)(H_2O)_5$	4.80	5.20
$CuPr(fsaen)(NO_3)(H_2O)_4$	3.81	3.87	$CuLu(fsaen)(NO_3)(H_2O)_5$	1.81	1.85

$CuEr(fsaen)(NO_3)(H_2O)_5$	9.68	9.58	$CuDy(fsapn)(NO_3)(H_2O)_4$	10.43	10.56
$CuTm(fsaen)(NO_3)(H_2O)_5$	7.32	7.34			

a) Moments are given in Bohr magneton, $\mu_B(=9.274\times10^{-24}\,Am^2$ in SI units). b) Experimental values at 287 K. c) Calculated from the equation, $\mu_M^{calcd}=\sqrt{(\mu_{Cu})^2+(\mu_{Ln})^2}$, where μ_{Cu} denotes the values,[4)] 1.85 μ_B (294.3 K) and 1.84 μ_B (292.9 K) for $Cu(H_2fsaen)(H_2O)_{0.5}$ and $Cu(H_2fsapn)(H_2O)_{0.5}$, respectively and μ_{Ln} are those reported[27)] for the general lanthanoid(III) compounds.

complexes at room temperature are summarized in Table 3, together with the moments calculated from the equation, $\mu_M^2=\mu_{Cu}^2+\mu_{Ln}^2$ using the reported moments, μ_{Cu}, for the mononuclear complexes[4)] and the common values, μ_{Ln}, of tervalent lanthanoid ions.[27)] The moments observed coincide approximately with the calculated values. The cryomagnetic investigations down to liquid nitrogen temperature ruled out the possibility of the operation of a spin-exchange interaction in these complexes: That is, their magnetic moments were practically independent of temperature in the range 78—300 K (except for the case of Cu(II)-Sm(III) and Cu(II)-Eu(III) complexes). It is known that the magnetic spin-exchange interaction between lanthanoid ions is very weak because the 4f-electrons are shielded by the outer-shell electrons. The present work reveals that no significant magnetic spin-exchange interaction is operating also between copper(II) and lanthanoid(III) ions.

The authors wish to express their hearty thanks to Professor Sigeo Kida of Institute for Molecular Science (Present: Kyushu University) and Associate Professor Yuzo Nishida of Yamagata University for their helpful discussions. They also would like to thank Mr. Masayuki Koikawa and Mr. Toshiro Kamiusuki of Kyushu University for measuring ESR spectra and magnetic susceptibilities, respectively.

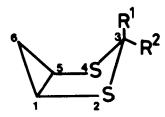
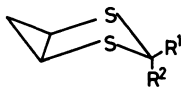
(Received June 8, 1987)

Ab initio calculations have been carried out for 2,4-dithia- (**5**), 2,4-dioxa- (**6**), 6-oxa- (**8**), 6-thiabicyclo-[3.1.0]hexanes (**9**), bicyclo[3.1.0]hexane (**7**), and some of the corresponding cyclohexane derivatives **10—12** using 3-21G, 3-21G(*), and 6-13G* basis sets. Relative total energies and geometries have been obtained for both boat and chair forms of these compounds. The calculated geometries are in good agreement with observed ones for **7—9**. The boat form is more stable than the chair form in the bicyclic systems **7—9**, while both the forms have almost equal stability for **5** and the chair form of **6** is slightly more stable than the boat form. The relative stability of the boat form in the bicyclic systems compared with that in the monocyclic cyclohexane derivatives can be explained in terms of the stabilizing orbital interaction. Inversion barriers between the boat and chair forms for **5—7** have also been estimated and are briefly discussed. A similar calculation for bicyclo[3.2.0]hept-6-ene also shows that the boat form is much more stable than the chair form contrary to the conclusion derived from the analysis of experimental results.

In our previous study on stereoselective reactions of carbanions of dithiabicyclo[3.1.0]hexanes, we performed ab initio calculations of the dithiabicyclohexanes and the corresponding dithianes and revealed that the carbanion **1** of boat form is most stable among isomeric carbanions **1—4** and that the boat and chair forms of the corresponding neutral molecules **5B** and **5C** have almost equal stability.[1] The structures of similar bicyclic systems, such as bicyclo[3.1.0]hexane (**7**),[2] 6-oxabicyclo[3.1.0]hexane (**8**),[3] and 6-thiabicyclo[3.1.0]hexane (**9**),[4] have been determined spectroscopically to be a boat form. These computational and experimental results suggest that the high stability of the boat form is a general trend in bicyclo[3.1.0]hexane systems, which stands in a sharp contrast to the well-established fact that the chair form is much more stable in the case of the corresponding monocyclic six-membered systems.[5]





1	R^1=H, R^2=—	**3**	R^1=H, R^2=—
2	R^1=—, R^2=H	**4**	R^1=—, R^2=H
5B	R^1=R^2=H	**5C**	R^1=R^2=H

We have become interested in why the boat form in the bicyclic systems has relatively high stability in spite of the unfavorable steric interaction between inward hydrogens on C_3 and C_6, and have carried out accurate ab initio geometry optimizations on these bicyclohexane derivatives and some related compounds. The main purpose of this account is to elucidate the factors determining the stability of the boat form from the standpoint of orbital interaction. We also report on inversion barriers between boat and chair forms in some representative bicyclohexane systems.[6]

Computational Details. The geometries for all the structures considered were completely optimized by energy gradient method at the Hartree-Fock level of theory. The standard split-valence 3-21G and 3-21G(*) basis sets (including a set of d-type polarization functions for sulfur atoms) were used in these optimizations. This level of theory has been demonstrated

to be reliable in the calculation of molecular geometries for a wide variety of systems.[7] In order to obtain more reliable energy estimates we have repeated the calculations with 6-31G* basis at the 3-21G or 3-21G(*) optimized geometries.

Calculated Relative Energies and Geometries. Relative energies obtained for **5**—**12** are listed in Table 1. The pertinent points in Table 1 are as follows: (1) For monocyclic systems **10**—**12**, the chair form is much more stable than the boat form, as is well known experimentally.[5] (2) In contrast to the monocyclic systems, the boat form is definitely more stable than the chair form in the bicyclic systems **7**—**9** where the five-membered ring consists of only carbon atoms. This also agrees with the experimental results that each of them exists only as a boat-form conformation.[2-4] (3) For bicyclic compounds having heteroatoms at 2- and 4-positions, **5** and **6**, although the stability of a boat form becomes less pronounced than in the case of **7**—**9**, the boat form has the stability almost equal to the chair form in the sulfur heterocycle **5**, and the boat form of the oxygen heterocycle **6** is very slightly less stable than its chair form.

Comparison of Calculated and Observed Geometries. Calculated geometries obtained for **5**—**9** are listed in Table 2[8] along with the observed geometries for **7**—**9**. As mentioned previously each of **7**—**9** has been reported to exist as the boat conformer in keeping with the present calculations. The calculated geometries are in good agreement with the experimental ones with the only exception of C_1—C_5 bond length of **7B** where the calculated value is longer than the observed one by 0.06 Å. The reason for this discrepancy has not been clear up to the present. There are some interesting features in the geometries of these compounds. (1) The angles between the planes $C_1C_5X_6$ and $C_1X_2X_4C_5$ (X=C, O, or S) in **5**, **6**, **7**, and **9** (denoted as α hereafter) are almost constant, ca. 110°, while those for **8B** and **8C** are 103—105°. (2) The angle between the planes $C_1X_2X_4C_5$ and $X_2C_3X_4$ (X=C, O, or S) (denoted as β hereafter) is constant, 150—152°, in the boat form except for 161° in **6B**. In the chair form, however, those having carbon atoms at 2- and 4-positions have β of 161° while those having heteroatoms at these positions have a smaller β (151—154°). (3) When the boat form is more stable than the chair form, β in the boat form is always smaller than β in the chair form. Conversely, when the chair form is more stable than the boat form, β in the chair form is smaller than that in the boat form. In an intermediate case where both the boat and chair forms have a

similar stability, β's in the both forms are similar. (4) As for bond lengths, there is no essential difference between those for the boat and the chair conformers.

Rationale for the High Stability of Boat Forms. In view of the high stability of a chair form of monocyclic six-membered systems, it is remarkable that the boat form is highly stabilized in bicyclohexane systems. Although the chair form is more stable than the boat form in the case of **6**, the difference in energy between the two conformers is only 0.9 kcal mol^{-1}, which is much smaller than the corresponding difference for **11**, i.e., 6.6 kcal mol^{-1}.

In order to explain this high stabilization of the boat form, we have considered the orbital interactions between the three membered ring and the XCH_2X parts (X=CH_2, O, S). In Figs. 1 and 2 are shown some occupied and unoccupied orbitals of these parts pertinent to the following discussion.

The figures indicate that there exists an in-phase orbital interaction between LUMO of the three-membered ring and HOMO or next HOMO of the XCH_2X group. This orbital interaction mainly contributes to the relative stabilization of the boat form. On the other hand, in the chair forms such an efficient orbital interaction cannot exist, because the downside lobe of HOMO (or next HOMO) on the XCH_2X group is tilted outward in contrast with the case of the boat form as illustrated in Fig. 3 with **5** as an example.

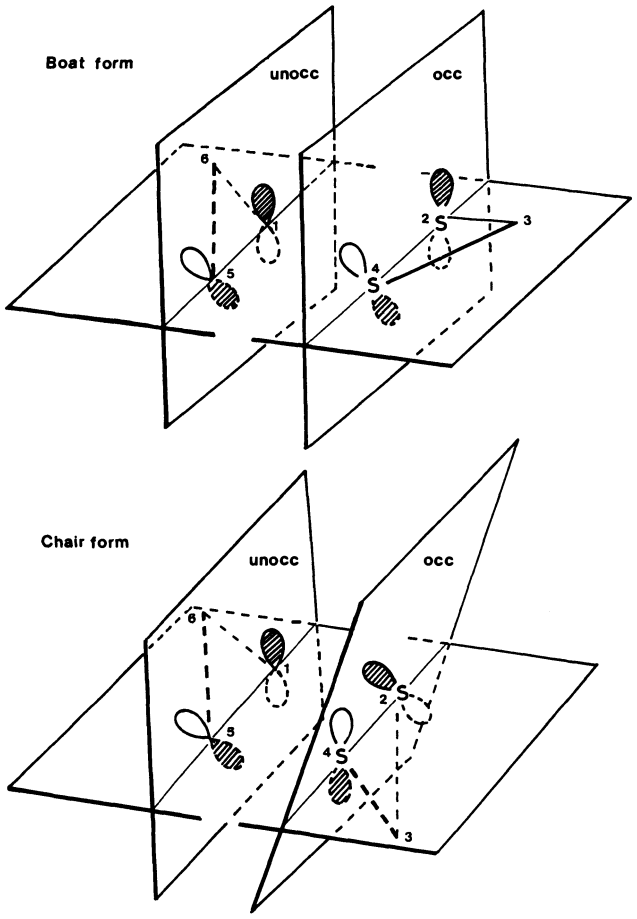

Fig. 3. Molecular orbital interaction between cyclopropane and SCH_2S moieties in **5B** and **5C**.

Dithiabicyclohexane 5B and Dioxabicyclohexane 6B: In **5B**, the most favorable interaction is that between LUMO on C_1—C_5 (antisymmetric, denoted as (A) hereafter) of the cyclopropane and the next HOMO of the lone pair on sulfur atoms, (A), of SCH_2S moiety the orbital energy of which is very close to that of HOMO (Fig. 2). The cyclopropane HOMO (S)-SCH_2S LUMO(S) interaction is also conceivable but it is not efficient because the lobe of LUMO on sulfur atoms is pointed to the direction almost perpendicular to the cyclopropane orbital.

The stabilizing interaction in **6B** is similar to that of **5B** except that the HOMO-LUMO energy difference is larger because of the higher electronegativity of oxygen. This larger difference is probably responsible for the less stability of the boat form **6B** than **5B**.

6-X-Bicyclohexanes (X=CH_2, O, S), 7B, 8B, and 9B: In **7B**, there exists an in-phase interaction between cyclopropane LUMO (A) and large back lobes (HOMO(A)) of pseudo-equatorial C-H bonds at 2- and 4-positions. The stabilization of the boat form is mainly attributed to this type of interaction. The cyclopropane HOMO(S)-$CH_2CH_2CH_2$ LUMO(S) cannot cause the stabilization, because LUMO of $CH_2CH_2CH_2$ moiety is directed toward C_1-C_2 (or C_4-C_5) bond axis(i.e., z-axis). As can be seen from HOMO and LUMO of ethylene oxide and ethylene sulfide shown in Fig. 1, the stabilizing interaction in **8B** and **9B** can be explained in a manner similar to **7B**, namely, the interaction between cyclopropane-like Walsh-type orbital and the back lobes of C-H bonds at 2- and 4-positions.

The higher stability of cyclohexane **10C** vs. **10B** has traditionally been explained in terms of the two pairs of unfavorable eclipsed interaction in the CH_2CH_2 bond and the steric repulsion between inward hydrogens of the bow and stern carbons in the boat form.[9] Inspection of the molecular model of bicyclo[3.1.0]-hexane suggests that the former type of eclipsed interaction exists between C_1H and quasi-equatorial C_2H in the chair form, **7C**, while the relationship between those hydrogens becomes gauche in the boat form, **7B**. The relative stability of **7B** vs. **7C** has exclusively been attributed to this type of unfavorable interaction in **7C**.[10] However, the latter type of steric interaction between inward hydrogens on C_1 and C_4 in **10B** should be more conspicuous in **7B** because the presence of the cyclopropane ring makes the distance between inward hydrogens on C_3 and C_6 shorter as judged by the molecular model. The calculated geometries of **10B** and **7B** also support the above argument since the distance in question is 2.355 Å in

10B and 2.231 Å in **7B** which is rather close to the sum of the van der Waals radii of two hydrogen atoms. This implies that the boat forms in **7—9** must be stabilized by some other factors in spite of this severe repulsive interaction. It is strongly suggested, therefore, that the above-mentioned stabilization due to stereoelectronic effect plays an important role in these compounds. In this connection, it is interesting that β in the boat form is always smaller than β in the chair form when the boat form is more stable than the chair form (see point (3) in the previous section). Since the HOMO-LUMO interaction becomes more effective in parallel with decrease of β in **7B**, **8B**, and **9B**, the values of β are considered to become small in spite of the repulsive interaction between C_3H-C_6H (or C_3H-X_6 lone pair). The reason for the large β value in **6B** is not very clear at present, but it is most likely that the large β is a consequence of a compromise between the HOMO-LUMO interaction and C_3H-C_6H repulsion which becomes relatively serious in this case because of shorter C-O (1.427 and 1.440 Å) than C-C bond distances (1.524 and 1.554 Å).

Conformation of Bicyclo[3.2.0]hept-6-ene. Chiang and Bauer studied the structure of bicyclo[3.2.0]hept-6-ene (**13**) by microwave spectroscopy and reported that it has a chair form.[11] In view of the above-mentioned general trend that bicyclo[3.1.0]hexane

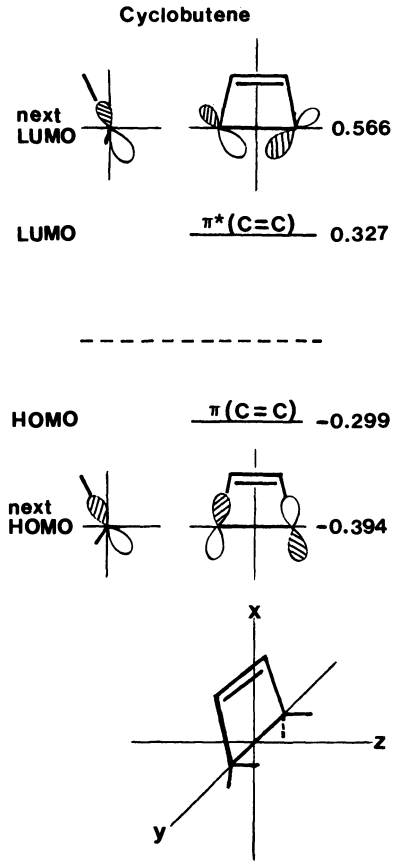

Fig. 4. Some important molecular orbitals in cyclobutene.

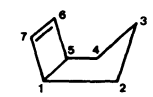

13B

13C

derivatives have a boat form, we have become interested in why the bicycloheptene **13** prefers the chair form to the boat form and have carried out ab initio calculations for this compound. The results are shown in Tables 1 and 2. The calculation indicates that the boat form is obviously more stable than the chair form, and indeed here again exists the stabilizing interaction between the cyclobutene ring and the $(CH_2)_3$ moiety similar to that for **7B** discussed above (Figs. 2 and 4). In view of the fact that the present calculations correctly reproduce experimental results both in the relative energies and geometries of **7—9**, we think that there is some room for doubt in the structual analysis of Chiang and Bauer and reexamination of the structure of **13** is highly desirable.

Energy Barrier of Boat-Chair Interconversion. In order to obtain information on the barrier of boat-chair interconversion, we have carried out ab initio calculations for the representative bicyclic systems, **5**, **6**, and **7**. In the calculations, atoms 1, 2, 4, and 5 are fixed on the same plane and atom 3 is fixed so as to be x Å apart from the plane. Under this constraint geometry optimizations have been performed at several x values. As can be seen from Fig. 5, the barrier height for the boat-chair conversion of **6** and **7** are almost zero in each case and hence it is suggested that the boat form of **6** and the chair form of **7** actually cannot exist as a stable conformer. In the case of **5** there is a definite barrier for interconversion between the boat and chair forms. However, it is so small that each conformer is considered to be able to undergo

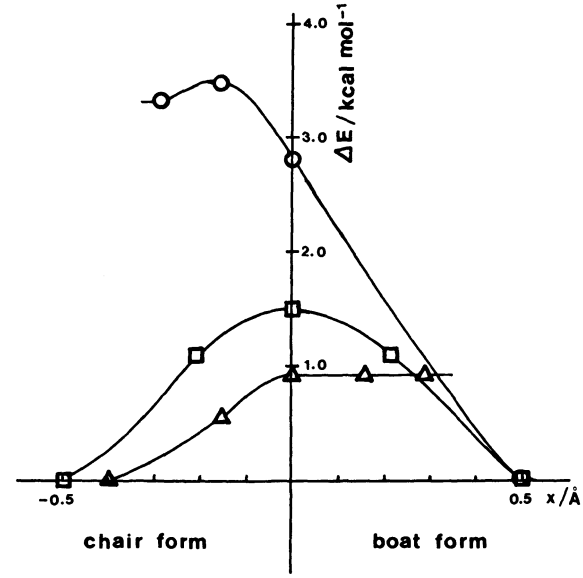

Fig. 5. Energy barrier of boat-chair interconversion in **5**, **6**, and **7**. □: **5**, △: **6**, ○: **7**.

almost free interconversion at least at ambient temperature.[12]

Conclusion

Relative energies and geometries have been calculated by ab initio method for boat and chair forms of bicyclohexane derivertives **5**—**9**. Contrary to monocyclic cyclohexane derivatives **10**—**12** which exist as a chair conformer, the stability of a boat form is much increased in the bicyclic compounds and in the case of **7**—**9** the boat conformer becomes a more stable one. The stability of the boat conformer has been found to result from the stabilizing orbital interaction between HOMO of the three-membered ring and LUMO of the $Y_3CH_2Y_4$($Y=CH_2$, O, or S) group. Calculation on bicyclo[3.2.0]-hept-6-ene has revealed that the boat conformer is preferred again in this case contrary to the conclusion derived from the experimental result, thus necessitating reexamination of the structural analysis of this compound. Calculated energy barriers for **5**—**7** have indicated that **6** and **7** exist only as the chair and boat forms, respectively, while **5** undergoes free interconversion between the boat and chair conformers.

The numerical calculations were carried out with the IMSPACK program at the Nagoya University Computation Center.

Preparation of Fluorine-Containing Phenylacetylenes by the Method of Introduction of the Ethynyl Group Using 1,1-Dichloro-2,2-difluoroethene

Kazuo KODAIRA and Kunio OKUHARA*
Government Industrial Research Institute, Nagoya, Hirate-cho, Kita-ku, Nagoya 462
(Received June 29, 1987)

Phenylacetylenes (ArC≡CH) having fluoro- or trifluoromethyl substituents (*o*-, *m*-, *p*-F; *o*-, *m*-, *p*-CF_3; 2,4-, 2,5-, 2,6-, 3,5-$(CF_3)_2$) have been prepared from bromobenzenes (ArBr) and benzenes (ArH) using 1,1-dichloro-2,2-difluoroethene (**1**) by a two-step route: ArLi or ArMgBr→ArCF=CCl_2→ArC≡CLi. Upon careful treatment at −70 °C with **1**, *o*-fluorophenyllithium gave *o*-$FC_6H_4CF{=}CCl_2$ in good yield, together with benzyne-derived products, such as *o*-(*o*-FC_6H_4)$C_6H_4CF{=}CCl_2$. Lithiation of *m*-bis(trifluoromethyl)benzene at 0 °C for 9 h (24 h) followed by treatment with bromine gave 1-bromo-2,4-, 2,6-, and 3,5-bis(trifluoromethyl)benzene in 35 (38), 31 (36), and 8% (6%) yield, respectively.

In connection with projects to prepare polymers of fluorine-containing acetylenes and diacetylenes and to examine their applications, it became neccessary to prepare phenylacetylenes having fluoro or trifluoromethyl substituents. Previously, such phenylacetylenes were prepared mostly[1] from the corresponding acetophenones[2–4] and styrenes.[5,6] When relatively inexpensive bromofluorobenzenes and bromo(trifluoromethyl)benzenes are used as the starting material,[7] these routes require at least four steps,[5,6,8] and the overall yields of these multistep preparations are often low. Palladium-catalyzed coupling with ethynyltrimethylsilane followed by a hydrolytic removal of the trimethylsilyl group is a recently developed method for the conversion of aryl bromides (or iodide) into the corresponding arylacetylenes.[9,10] *m*-(Trifluoromethyl)-phenylacetylene was prepared by this method with an overall yield of 40%.[10]

The method of introduction of the ethynyl group using 1,1-dichloro-2,2-difluoroethene ($CF_2{=}CCl_2$, **1**), presented previously by one of us,[11,12] seemed to be easily applicable for the preparation of phenylacetylenes having fluoro or trifluoromethyl subsituents. A subsequent study has shown that not only the phenylacetylenes having *m*-F, *p*-F, *o*-CF_3, *m*-CF_3, and *p*-CF_3 as substituents are prepared in overall yields ranging from 48 to 69%, starting with the corresponding bromobenzenes, but also this method is applicable for the preparation of *o*-fluorophenylacetylene, for which the reaction of unstable *o*-fluorophenyllithium with **1** is involved. Furthermore, among the six isomeric bis(trifluoromethyl)phenylacetylenes, on which little information is available, four compounds were obtained. Considerable efforts have also been devoted toward a clarification of complications encountered in the lithiation of *m*-bis(trifluoromethyl)benzene and in the reaction of the resulting phenyllithiums with **1**.

The course of the present synthesis is given in Scheme 1. It consists of the first step: the preparation of the 2,2-dichloro-1-fluoroethenyl intermediates (**6**) and the second step: the conversion of these intermediates into the corresponding terminal acetylenes **8**.[11] The second step was carried out in good yield in every case by using the standard conditions. For the first step, however, the reaction conditions had to be examined in individual cases in order to obtain satisfactory results.

m- and *p*-$FC_6H_4CF{=}CCl_2$ (**6b** and **6c**) were prepared from *m*- and *p*-bromofluorobenzene, respectively, both via the Grignard reagents and via the corre-

Scheme 1. Course of preparation of fluorine-containing phenylacetylenes (**8**).

sponding organolithium reagents. The yields of **6b** and **6c** obtained via the Grignard reagents **5** were substantially higher than those obtained via the fluorophenyllithiums (**4**). The yields of **6b** and **6c** via the fluorophenyllithiums, when ethereal solutions of the fluorophenyllithiums were not kept cold before and during the addition to solutions of **1**, were even considerably lower than those given in Table 1. It appears that these fluorophenyllithiums[13] have a tendency to form polyphenyls with an elimination of lithium fluoride.

Initially, no attempt was made for the preparation of *o*-$FC_6H_4CF{=}CCl_2$ (**6a**) because of the known tendency of *o*-fluorophenyllithium (**4a**) to lose lithium fluoride to form benzyne.[14] Later, a careful low-temperature treatment of **4a** with **1** was found to give **6a** in a good yield. The method consists of the preparation of *o*-fluorophenyllithium (**4a**)[15] at −80 °C, the addition of **1** at lower temperatures, and allowing the reaction of **4a** with **1** to proceed within a temperature range between −80 and −70 °C until **4a** is mostly consumed. This reaction should be conducted on a small scale with great precaution (see the section of **6a** in Experimental). In this procedure, the formation of products **6k** and **10k** derived from *o*-(*o*-fluorophenyl)phenyllithium (**4k**), which results from a decomposition of **4a** into benzyne (**9**) followed by addition of another molecule of **4a**, was more or less unavoidable (Scheme 2). We also obtained a compound to which the structure *o*-$(CF_2{=}CCl)C_6H_4CF{=}CCl_2$ (**12**) was assigned on the basis of spectroscopic data. The formation of **12** could be explained in terms of the addition of $CF_2{=}CClLi$, which is formed from **1** by a Cl–Li exchange,[11] to **9** followed by a reaction of the resulting lithium compound **11** with **1**.

For the preparation of *o*-, *m*-, and *p*-$CF_3C_6H_4CF{=}CCl_2$ (**6d**, **6e**, and **6f**) from the respective isomers of bromo(trifluoromethyl)benzenes, both the route via the

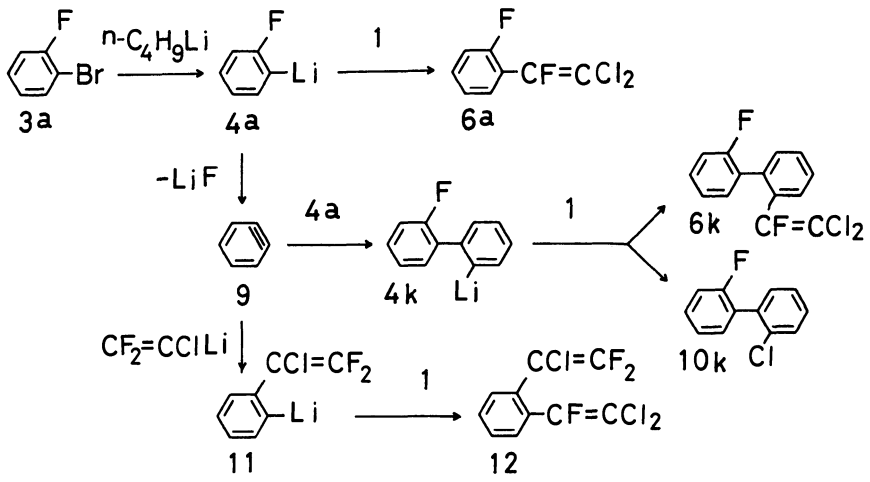
a) Based on charged starting material. b) Total refluxing times (h) with **1** in ether are indicated in parentheses; continuous (unmarked), with one overnight interruption in 2 days (*), with two overnight interruptions in 3 days (**). Where no parenthesized figure is given, the reaction mixture was hydrolyzed without refluxing. c) Determined yield was 0.1%. d) Hexane–ether was used as solvent. Compound **13i** (2,6-$(CF_3)_2C_6H_3C{\equiv}CCl$) in 4% yield was also obtained. e) Yield obtained as by-product of the reaction where **6a** was the main product (75%).



Scheme 2. Reaction of *o*-fluorophenyllithium (**4a**) with **1**.

Grignard reagents and the route via the corresponding lithium reagents were examined. In the case of the *m*-isomer **6e**, the use of the Grignard reagent gave a higher yield, as has been already reported.[11] However, the yield of the *p*-isomer **6f** obtained from the Grignard reagent was the same as that obtained from the corresponding lithium reagent. Furthermore, *o*-(trifluoromethyl)phenylmagnesium bromide (**5d**) gave no more than a trace amount of *o*-$CF_3C_6H_4CF{=}CCl_2$ (**6d**) upon treatment with **1** under reflux for 30 h, whereas *o*-(trifluoromethyl)phenyllithium (**4d**) gave **6d** in 77% yield.

The use of (trifluoromethyl)benzene (benzylidyne trifluoride: IUPAC; benzotrifluoride: trivial) as the starting material for the preparation of (trifluoromethyl)phenylacetylenes has two disadvantages: Slow lithiation and the formation of isomers.[16,17] Nevertheless, the low cost and easy availability of (trifluoromethyl)benzene makes this route worth examining. In a typical experiment, 0.9 mol of (trifluoromethyl)-benzene was refluxed for 23 h in an ethereal solution of butyllithium prepared from 1 mol of butyl bromide. A subsequent treatment with **1** afforded a mixture of **6d**, **6e**, and **6f**. Since a mutual separation of isomers at this stage was difficult, the mixture was converted into an isomeric mixture of (trifluoromethyl)phenylacetylenes (35% yield of **8d** and 15% yield of **8e**+**8f** based on unrecovered (trifluoromethyl)benzene) by a treatment with butyllithium. A fractional distillation of this isomeric mixture under reduced pressure gave nearly pure *o*-(trifluoromethyl)phenylacetylene (**8d**, higher boiling), although the *m*-isomer **8e** was obtained only as a mixture containing the *o*-isomer as well as the *p*-isomer.

The activation of the benzene ring by an additional trifluoromethyl group para to the original trifluoromethyl group makes the lithiation definitely easier. Thus, *p*-bis(trifluoromethyl)benzene was readily lithiated by a treatment with butyllithium under reflux for 4 h, and subsequent reaction with **1** afforded 2,5-$(CF_3)_2C_6H_3CF{=}CCl_2$ (**6h**) in 72% yield. The relatively high yield is attributed not only to the formation of a single isomer **4h** from the lithiation of *p*-bis(trifluoromethyl)benzene but also to the apparent high stability of **4h** in the lithiated mixture. The latter point is in sharp contrast to the instability of **4g** and **4j** in the mixture obtained from *m*-bis(trifluoromethyl)-benzene by lithiation (vide infra).

Lithiation of *m*-bis(trifluoromethyl)benzene[18,19] gives 2,4- (**4g**), 2,6- (**4i**), and 3,5-bis(trifluoromethyl)-phenyllithium (**4j**). Initial attempts to obtain the isomers of $(CF_3)_2C_6H_3CF{=}CCl_2$ (**6g**, **6i**, and **6j**) by the treatment of such lithiated mixtures with **1** were met with unpredictable and sometimes unreproducible results. After a considerable number of experiments, it was found that 3,5-bis(trifluoromethyl)phenyllithium (**4j**), first, and the 2,4-isomer **4g**, next, tended to disappear when reaction mixtures obtained by lithiation of *m*-bis(trifluoromethyl)benzene under refluxing conditions were further refluxed or left standing.[20] The nature of the reaction(s) where **4j** and **4g** are consumed is not clear at present. In addition, a considerable difference in the reactivity with **1** exists between the 2,6-isomer **4i** and the 2,4-isomer **4g** or 3,5-isomer **4j**. These facts, coupled with isomer separation problems, prompted us to examine the preparation of the three isomers **3g**, **3i**, and **3j** of bromobis(trifluoromethyl)benzene, from which individual isomers of bis(trifluoromethyl)phenyllithium are obtained.

The lithiation of *m*-bis(trifluoromethyl)benzene under ice-cooling for 9 h followed by quenching with bromine and fractional distillation gave 1-bromo-2,4-(**3g**), 2,6- (**3i**), and 3,5-bis(trifluoromethyl)benzene (**3j**) in 35, 31, and 8% yield, respectively. When the time of the lithiation was extended to 24 h under otherwise the same conditions, the yields of **3g**, **3i**, and **3j** were 38, 36, and 6%, respectively. The change in the isomer distribution of the bromobis(trifluoromethyl)benzenes seems to reflect the relative stabilities (durabilities) of the isomeric bis(trifluoromethyl)phenyllithiums in the lithiated mixture stated above. 1-Bromo-3,5-bis-(trifluoromethyl)benzene (**3j**), which was formed only in small yield in the above reactions, was commercially obtained and smoothly converted into 3,5-$(CF_3)_2C_6H_3CF{=}CCl_2$ (**6j**) in good yield via the corresponding lithium compound **4j**. The yield of the equivalent transformation of 1-bromo-2,4-bis(trifluoromethyl)benzene (**3g**) into 2,4-$(CF_3)_2C_6H_3CF{=}CCl_2$ (**6g**) was considerably lower.

The reaction of 2,6-bis(trifluoromethyl)phenyllithium (**4i**) with **1** was much slower than those of the other isomers **4g**, **4h**, and **4j** and required hours of refluxing. In initial experiments, 2,6-$(CF_3)_2C_6H_3Cl$ (**10i**) was the predominant product accompanied by a smaller proportion of 2,6-$(CF_3)_2C_6H_3CF{=}CCl_2$ (**6i**). The Cl-Li exchange represented by Eq. 2 was initially regarded as the main route of **10i** since reaction (2) is suggested to be relatively favored when the substitution reaction (1) is sterically retarded.[11] In this particular case, course (3) is also considered important in view of the formation of 2,6-$(CF_3)_2C_6H_3C{\equiv}CCl$ (**13i**) and 2,6-$(CF_3)_2C_6H_3C{\equiv}CC_6H_3(CF_3)_2$-6,2. However, in some of the initial experiments **6i** was obtained in relatively good yield. In order to elucidate the factors responsible for such a variation in the yield of **6i**, we carried out a number of experiments and finally found experimental conditions under which 2,6-$(CF_3)_2C_6H_3CF{=}CCl_2$ (**6i**) was obtained consistently in about 50% yield based on **3i** (see Experimental).

a) All the compounds listed in the table showed the molecular peaks in mass spectroscopy. b) Not neccessarily accurate enough to give a correct boiling point order for isomers due to the uncertainty in pressure measurement in mutually independent experiments. c) Literature values given in parentheses. d) 20% solution in $CDCl_3$. ^{1}H and ^{19}F chemical shifts measured downfield relative to internal tetramethylsilane and relative to external CF_3CO_2H, respectively. Splitting pattern and (apparent) coupling constant (Hz) indicated in parentheses. e) ^{19}F chemical shift for the trifluoromethyl group and the fluorine atom on the benzene ring. f) ^{19}F chemical shift for $-CF=CCl_2$. g) ^{1}H chemical shift for $-C\equiv CH$. h) ^{1}H chemical shif for ring protons. i) ν(C=C) of $-CF=CCl_2$ and ν(C≡C) (in bold face) and ν(C–H) of $-C\equiv CH$ are given. Neat for liquid and in KBr pellet for crystals. w, weak; sh, shoulder. j) Center of complex signals spreading over 25—31 Hz (0.45—0.55 ppm). k) Ref. 11. l) AB pattern. m) A sharp signal with a broad base (δ=7.66—7.94). n) AB_2 pattern. The upper value represents A. o) Ref. 5 (n_D^{25}). p) Ref. 2. q) Ref. 6. r) Probably the center signals of an AB pattern though the outer signals are not clear.

$$ArCF{=}CClLi \longrightarrow ArC{\equiv}CCl\ (\mathbf{13}) + LiF \qquad (4)$$

Unexpectedly, the use of a freshly prepared sample of **1**[21] was found to be the most important requirement for the formation of **6i** with a reasonable yield. It appears that partially deteriolated samples of **1** contain a compound or compounds (possibly, the epoxide of **1** and/or its secondary products) which gives ArCl upon reaction with ArLi, probably by a Cl–Li exchange. Generally, the reaction of an aryllithium with such a compound is not considered important since the reaction of the aryllithium with **1** proceeds rapidly. In the case of 2,6-bis(trifluoromethyl)phenyllithium, however, the reaction with **1** giving **6i** is slow and, thus, the suspected reaction will become important. If this is the case, the use of a large excess of a (deteriolated) sample of **1** is particularly undesirable for the preparation of **6i**.

The dichlorofluoroethenyl intermediates **6** prepared as mentioned above were converted into the corresponding phenylacetylenes (**8**) in good yield in all cases by treatment with 2 equivalents of butyllithium[11] in ether at about −50 °C. Pure products **8** were isolated by vaccum distillation. For an easy isolation of pure **8** by distillation, it is essential to use a sample of $ArCF{=}CCl_2$ (**6**) free from ArCl(**10**), which is a by-product of the reaction of ArLi (**4**) with **1** and has a boiling point close to that of $ArC{\equiv}CH$ (**8**).

The present study has proved that the method of introducing the ethynyl group using **1**[11] is suitable for the laboratory preparation of fluorine-containing phenylacetylenes **8a** through **8j**. Preparations on up to a 0.5—1 mol scale were relatively easily performed with no apparent danger, except for the reaction of *o*-fluorophenyllithium (**4a**) with **1**. The inverse addition method, which is relatively safe and generally used for the preparation of the dichlorofluoroethenyl intermediates **6** as well as for their conversion into acetylenes **8** involving **8a**, is difficult to apply for the preparation of **6a** from unstable **4a**. The reaction procedure described in the experimental section of **6a**, if the temperature control fails, can be hazardous and, thus , has to be carried out with great precaution on a small scale.

The ^1H chemical shift of the acetylenic protons (Table 2) seems to be closely related to the acidity of the prepared phenylacetylenes (**8**). The trifluoromethyl group, when it is in the *o*-position, has a marked effect on the ^{19}F chemical shift of the $-CF{=}CCl_2$ group. The trifluoromethyl group present ortho to the dichlorofluoroethenyl group is also clearly indicated by a relatively large constant of coupling with the fluorine atom of the dichlorofluoroethenyl group. A clear difference was also found in the mass spectroscopy between the dichlorofluoroethenyl compounds with and without the *o*-trifluoromethyl group. For each of **6a**, **6b**, **6c**, **6e**, **6f**, and **6j**, which has no *o*-CF_3 group, the molecular peak is the strongest (100%), and the intensity of the M−Cl peak is in the range 23—45%. In contrast, for each of **6d**, **6g**, **6h**, and **6i**, which has at least one *o*-CF_3 group, the M−Cl peak is the strongest (100%), and the intensity of the molecular peak is in the range 59—85%.

Experimental

Temperature readings are uncorrected. Pressure readings are given in terms of mmHg (1 mmHg=133.322 Pa). ^{19}F NMR[22] and ^1H NMR spectra were recorded on a Hitachi R-20BK operated at 56.451 MHz and on a Hitachi R-22 operated at 90 MHz, respectively. IR spectra were recorded on a Hitachi EPI-G3 or 285H, and mass spectra on a Shimadzu GCMS-7000. For an integration of the GC peak area, a Shimadzu C-R2AX was used. Compound **1** was prepared as described previously.[11] Other fluoro chemicals were obtained from PCR Inc., Lancaster Synthesis Ltd., Fluorochem Ltd., Yarsley Research Laboratories, and Central Glass Co. Ltd. (Tokyo). All reactions of organolithium and Grignard reagents were conducted under an atmosphere of nitrogen using sodium-dried ether. Ethereal butyllitium was generally prepared from butyl bromide with cut pieces of lithium in ether under nitrogen. However, an argon atmosphere was neccessary for a smooth preparation of butyllithium from more recently obtained samples of lithium. The amount of butyllithium is calculated from the nominal concentration. In the case where a portion of the worked-up mixture was reserved, the fraction (e.g., 0.90) actually subjected to vaccum distillation is necessary for a yield calculation and is indicated as "÷0.90".

***o*-(2,2-Dichloro-1-fluoroethenyl)fluorobenzene (6a).** To a solution of *o*-bromofluorobenzene (40.0 g, 0.229 mol) in ether (300 ml) mechanically stirred and cooled between −90 °C and −100 °C in a liquid-nitrogen bath (a stainless steel Dewar), ethereal butyllithium (160 ml, 0.267 mol) was added. The temperature was then maintained at about −80 °C for 1 h, lowered to about −90 °C, and **1** (59 g, 0.44 mol) was added. The temperature of the resulting mixture was carefully watched and maintained at −70 °C (±3 °C) for 1 h by an occassional adjustment of the bath height with a lab jack. The mixture was then allowed to warm to −60 °C over 30 min and to −50 °C over another 30 min. (*Caution: The temperature should not be allowed to approach −60 °C before the reaction for at least 1 h at −70 °C (or at least 2 h at −80 °C). Otherwise, uncontrolably rapid temperature rise may be started resulting in dangerous sudden vaporization of the flask content.*) When the temperature reached −27 °C after an additional 30 min, the mixture was hydrolyzed by pouring it onto a mixture of concd hydrochloric acid (27 ml) and crushed ice. Workup and fractional distillation afforded **6a** (35.0 g, ÷0.98, 75%), bp 107 °C(30 mmHg). Also obtained were 1-(1-chloro-2,2-difluoroethenyl)-2-(2,2-dichloro-1-fluoroethenyl)benzene (**12**, 1.2 g, 2%), bp 60 °C(1 mmHg), 2-chloro-2′-fluorobiphenyl (**10k**, 0.3 g, 1%), bp ca 90 °C(1 mmHg), and 1-(2,2-dichloro-1-fluoroethenyl)-2-(*o*-fluorophenyl)benzene (**6k**, 2.9 g, 9%), bp ca. 109 °C(1 mmHg).

10k: Mp 76—77 °C. ^1H NMR δ=6.92—7.47. ^{19}F NMR δ=−34.58 (m). Found: C, 69.96; H, 3.76; M^+, 206. Calcd for

$C_{12}H_8ClF$: C, 69.74; H, 3.90; M, 206.

12: n_D^{20} 1.5289. IR (neat) 1738 (CF_2=CCl–) and 1658 cm^{-1} (CCl_2=CF–). ^1H NMR δ=7.41 (a sharp signal with a broad base: δ=7.24—7.52). ^{19}F NMR δ=−6.1 (1F, d, J=31 Hz), −9.5 (1F, dd, J=31 and 2 Hz), and −11.0 (1F). Found: C, 41.61; H, 1.31; M^+, 286. Calcd for $C_{10}H_4Cl_3F_3$: C, 41.77; H, 1.40; M, 286.

***m*-(2,2-Dichloro-1-fluoroethenyl)fluorobenzene (6b). a) Via *m*-Fluorophenyllithium (4b).** To a Dry Ice-acetone cooled solution of *m*-bromofluorobenzene (98.4 g, 0.562 mol) in ether (100 ml) was added ethereal butyllithium (380 ml, 0.63 mol) while keeping the internal temperature between −30 °C and −40 °C. The resulting solution of **4b** was kept cold until its addition to an ice-cooled solution of **1** (121 g, 0.91 mol) in ether (100 ml) was started. The addition was conducted through a dropping funnel, briefly cooled with Dry Ice over 23 min while keeping the internal temperature of the reaction flask at about 20 °C. The resulting mixture was stirred for an additional 1 h, hydrolyzed, and worked up. Fractional distillation afforded **6b** (55.9 g, ÷0.98, 48%), bp 108 °C (28 mmHg).

b) Via *m*-Fluorophenylmagnesium Bromide (5b). A solution of *m*-fluorophenylmagnesium bromide (**5b**) was prepared from *m*-bromofluorobenzene (96.7 g, 0.552 mol) and magnesium (14.5 g, 0.60 g atom) in ether (300 ml). The addition of **1** (120 g, 0.90 mol) to the solution resulted in a mild refluxing, which lasted for 2 h. The resulting mixture was refluxed for an additional 16 h by external heating and hydrolyzed by pouring it onto a mixture of conc hydrochloric acid (50 ml) and crushed ice. The workup and fractional distillation afforded **6b** (92.2 g, ÷0.97, 82%), bp 111 °C(30 mmHg).

1-(2,2-Dichloro-1-fluoroethenyl)-2-(trifluoromethyl)benzene (6d). Ethereal butyllithium (330 ml, 0.55 mol) was added to a solution of *o*-bromo(trifluoromethyl)benzene (112.5 g. 0.500 mol) in ether (100 ml) over a period of 38 min below 7 °C (internal). The resulting solution was added to a Dry Ice-acetone cooled solution of **1** (105 g, 0.79 mol) in ether (100 ml) over 28 min while keeping the internal temperature at about −25 °C. The resulting mixture was allowed to warm to room temperature, refluxed for 1 h, and poured onto a mixture of crushed ice and concd hydrochloric acid (55 ml). The ether layer was separated, washed (with water and then with aq $NaHCO_3$), and dried (Na_2SO_4). Fractional distillation afforded **6d** (98.6 g, ÷0.98, 77%), bp 110 °C (30 mmHg), together with *o*-$CF_3C_6H_4Cl$ (2.4 g, 3%), bp ca. 60 °C (30 mmHg).

1-(2,2-Dichloro-1-fluoroethenyl)-2,5-bis(trifluoromethyl)-benzene (6h). A solution obtained by the addition of ethereal butyllithium (230 ml, 0.38 mol) to a solution of *p*-bis(trifluoromethly)benzene (63.8 g. 0.298 mol) in ether (100 ml) was refluxed for 4 h. It was then added to a Dry Ice-acetone cooled solution of **1** (90 g, 0.68 mol) in ether (100 ml) over 13 min while keeping the internal temperature between −20 °C and −30 °C. The resulting mixture was stirred for an additional 1 h without cooling and then poured onto a mixture of concd hydrochloric acid (40 ml) and crushed ice. The workup and fractional distillation afforded **6h** (69.3 g, ÷0.98, 72%), bp 96 °C(30 mmHg).

Lithiation of *m*-Bis(trifluoromethyl)benzene Followed by Treatment with Bromine. A solution (ca. 600 ml) of butyllithium prepared from 1.00 mol of butyl bromide was added to an ice-cooled solution of *m*-bis(trifluoromethyl)-benzene (170 g, 0.794 mol) in ether (100 ml). Stirring and ice cooling were continued for 9 h. The reaction mixture was then cooled with Dry Ice-acetone, and bromine (165 g, 1.03 mol) was carefully added while the internal temperature was kept below −46 °C. The resulting mixture was rapidly warmed to 0 °C using a water bath, poured onto crushed ice; then aqueous sodium sulfite was added, and the whole mixture was thoroughly agitated in order to release butane. The ether layer was separated, washed with aqueous Na_2SO_3 and then with aqueous $NaHCO_3$, and dried with sodium sulfate. (The simultaneous use of $NaHCO_3$ and Na_2SO_3 was avoided since in a preliminary experiment, in which these reagents were used simultaneously, a portion of the $(CF_3)_2C_6H_3Br$ was reduced to *m*-$(CF_3)_2C_6H_4$.) The solvent was removed, and the remaining liquid was fractionally distilled using a 50-cm metal-packed column at a high reflux ratio (mostly 60:1 or 120:1) until the solid product (**3i**) came out, which was rapidly collected by vacuum distillation. The following compounds were obtained: butyl bromide, 14.5 g (13.6%); *m*-bis(trifluoromethyl)benzene, bp ca. 113 °C, 21.1 g (12.7%); 1-bromo-3,5-bis(trifluoromethyl)benzene (**3j**), bp ca. 151 °C, 17.4 g (7.6%); 1-bromo-2,4-bis(trifluoromethyl)benzene (**3g**), bp 161.5 °C, 79.1 g (34.7%); 1-bromo-2,6-bis(trifluoromethyl)benzene (**3i**), bp 86 °C (29 mmHg) (bp ca. 173 °C), 70.9 g (31.1%). The above yields include individual compounds in mixed fractions, the calculation being based on the assumed proportionality of the weight to the GC peak area. The yields of essentially purely isolated **3g** and **3i** were 31% (70.9 g) and 29% (65.6 g), respectively. Compound **3j** was obtained at a purity of less than 88%. In another run, during which the time of the lithiation was extended to 24 h under otherwise the same conditions, the yields were as follows: butyl bromide, 3.6 g (3.4%); *m*-bis(trifluoromethyl)benzene, 8.4 g (5.1%); **3j**, 13.5 g (5.9%); **3g**,86.0 g (37.8%); **3i**,81.6 g (35.9%). The yields of essentially purely isolated **3g** and **3i** were 35% (80.1 g) and 34.5% (78.5 g), respectively.

3g: n_D^{20} 1.6363. ^1H NMR δ=7.60, (1H), 7.83 (1H), 7.92 (1H). The signals of the chemical shifts 7.60 and 7.83 seem to constitute an AB pattern (J=8 Hz) though the signal at 7.92 and the outer signal of the chemical shift 7.83 are unresolved. The signals of the chemical shift 7.83 show an additional splitting (d, J=2 Hz). ^{19}F NMR δ=15.33, 15.29 (partially resolved). Found: C, 32.58; H, 0.98; M^+, 292. Calcd for $C_8H_3BrF_6$: C, 32.79; H, 1.03; M, 292.

3i: Mp 51—52 °C, ^1H NMR δ=7.49 (1H), 7.81 (2H), J=ca. 8 Hz (results of approximate analysis as AB_2). ^{19}F NMR δ=16.2(s). Found: C, 32.55; H, 0.87; M^+, 292. Calcd for $C_8H_3BrF_6$: C, 32.79; H, 1.03; M, 292.

1-(2,2-Dichloro-1-fluoroethenyl)-2,6-bis(trifluoromethyl)-benzene (6i). To an ice-cooled solution of 1-bromo-2,6-bis(trifluoromethyl)benzene (**3i**, 16.1 g, 0.055 mol) dissolved in a mixed solvent of ether (50 ml) and hexane (20 ml) was added a hexane solution of butyllithium (a 1.6 mol dm^{-3} Aldrich product, 37 ml, 0.059 mol) over 1 h. After a freshly prepared sample of **1** (19 g, 0.14 mol) was added to the solution, the resulting mixture was refluxed for a total of 15 h over two days and then hydrolyzed. Fractional distillation afforded **6i** (7.9 g, ÷0.91, 48%), bp 110 °C (30 mmHg). The minor products involved 1-chloro-2,6-bis(trifluoromethyl)benzene (**10i**, 1.1 g, 9%), bp ca. 70 °C (30 mmHg), and 1-(chloroethynyl)-2,6-bis(trifluoromethyl)-benzene (**13i**, 0.6 g, 4%), bp ca. 100 °C (30 mmHg). The latter

compound was contained in the first fractions of **6i**. Samples of **6i** containing **13i** are usable for the preparation of the corresponding acetylene **8i** since **13i** is the intermediate of the conversion of **6i** into **8i** (see the section of **8i**).

***o*-Trifluoromethylphenylacetylene (8d).** To a Dry Ice-acetone cooled solution of **6d** (69.9 g, 0.27 mol) in ether (100 ml) was added butyllithium (380 ml, 0.63 mol) over 2 h while keeping the internal temperature below −50 °C. In GC monitoring, **6d** and *o*-$CF_3C_6H_4C{\equiv}CCl$ were essentially absent. The resulting mixture was stirred for an additional 1.4 h without cooling and then hydrolyzed by pouring it onto a mixture of concd hydrochloric acid (65 ml) and cushed ice. The ether layer was washed (with water and then with aq $NaHCO_3$), dried (Na_2SO_4), and distilled, giving **8d** (38.5 g, ÷0.98, 86%), bp 68 °C(30 mmHg).

2,6-Bis(trifluoromethyl)phenylacetylene (8i). This particular run was conducted starting with a sample (43.0 g, 0.130 mol) consisting of 87.2% of **6i**, 9.9% of 2,6-$(CF_3)_2$-$C_6H_3C{\equiv}CCl$ (**13i**), and 2.9% of impurities. The sample was dissolved in ether (50 ml) and treated (at about −50 °C) as above with ethereal butyllithium (200 ml, 0.334 mol). Compound **8i**, bp ca. 76 °C(29 mmHg), mp 56—57 °C, was obtained in 83% yield (24.8 g, ÷0.96).

7) Although the two-step conversion of acetophenones into the corresponding phenylacetylenes is a well-established procedure, commercial fluoroacetophenones and (trifluoromethyl)acetophenones are apparently too expensive to be used for the preparation of relatively large amounts of phenylacetylenes. The Friedel-Crafts acetylation, which is used for the preparation of *p*-fluoroacetophenone, is generally not applicable for the preparation of (trifluoromethyl)acetophenones since aluminium chloride reacts with the trifluoromethyl group on the benzene ring to convert it into the trichloromethyl group: A. L. Henne and M. S. Newman, *J. Am. Chem. Soc.*, **60**, 1697 (1938).

8) *m*-(Trifluoromethyl)acetophenone was prepared in 3 steps from *m*-bromo(trifluoromethyl)benzene: J. W. Corse, R. G. Jones, Q. F. Soper, C. W. Whitehead, and O. K. Behrens, *J. Am. Chem. Soc.*, **70**, 2837 (1948).

18) Lithiation of *m*-bis(trifluoromethyl)benzene with butyllithium: G. Hallas, D. E. Grocock, and J. D. Hepworth, *J. Soc. Dyers Colour.*, **86**, 200 (1970).

19) Lithiation of *m*-bis(trifluoromethyl)benzene with butyllithim-TMEDA gave only 2,6-bis(trifluoromethyl)-phenyllithium as judged from the results of carbonation: D. E. Grocock, T. K. Jones, G. Hallas, and J. D. Hepworth, *J. Chem. Soc. C*, **1971**, 3305. This appears to be a result of disappearance of the 3,5-isomer **4j** and 2,4-isomer **4g** rather than preferential formation of the 2,6-isomer **4i**.

20) The tendency of disappearance of **4j** and **4g** was confirmed by the following experiment: Ethereal butyllithium (62 ml, 0.104 mol) was added to an ice-cooled solution of *m*-bis(trifluoromethyl)benzene (17.0 g, 0.079 mol) and undecane (internal standard, 5 ml) in ether (40 ml), and stirring and ice cooling were continued for 9 h. Then, with occassional monitoring, the resulting mixture was stirred for 24 h at ambient temperature (ca. 30 °C) and left standing for additional 24 h. In each case of monitoring, a 10 ml portion of the reaction mixture was transferred to a special vessel, diluted with ether, treated with bromine (2 g) under an inert atmosphere with Dry Ice-acetone cooling, and worked up. The GC peak areas changed as shown below, the peak area of *m*-$(CF_3)_2C_6H_4$ relative to that of undecane in the initial solution being taken as 100%. At 0 h (ca. 10 min after discontinuation of ice cooling), *n*-C_4H_9Br 8%, *m*-$(CF_3)_2C_6H_4$ 17%, **3j** 6%, **3g** 34%, **3i** 37%; at 3 h, *n*-C_4H_9Br 0%, *m*-$(CF_3)_2C_6H_4$ 12%, **3j** 5%, **3g** 38%, **3i** 38%; at 12 h, *m*-$(CF_3)_2C_6H_4$ 14%, **3j** 0%, **3g** 34%, **3i** 39%; at 24 h, *m*-$(CF_3)_2C_6H_4$ 18%, **3g** 19%, **3i** 38%; and at 48 h, *m*-$(CF_3)_2C_6H_4$ 22%, **3g** 4%, **3i** 38%. (Compound **4i** was unreactive to chlorotrimethylsilane, a reagent commonly used for monitoring organolithiums.)

21) Samples of **1** which were sealed soon after the preparation and have been stored at −20 °C may be used equally well.

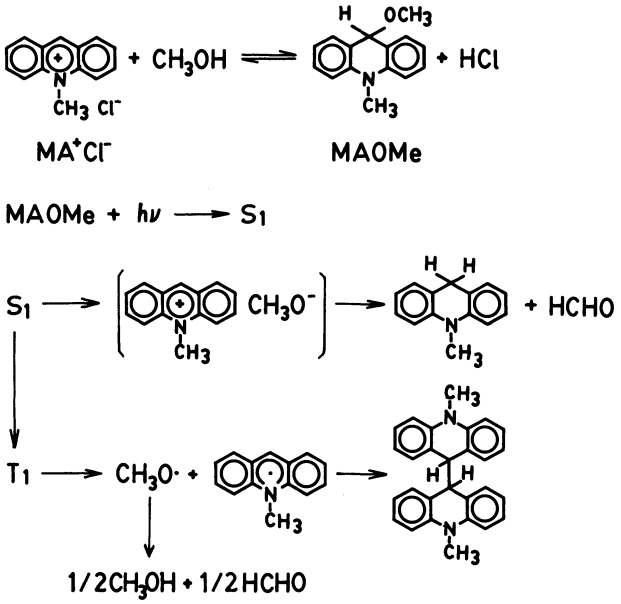
22) The ^{19}F chemical shifts given in this paper are measured downfield relative to external CF_3CO_2H although those given in Refs. 11 and 12 are measured upfield relative to the same standard.

Thermal and Photochemical Reactions of 10-Methyl-9-phenylacridinium Chloride in Alcohols

Bin ZHOU, Koji KANO,* and Shizunobu HASHIMOTO
Department of Applied Chemistry, Faculty of Engineering, Doshisha University, Kamikyo-ku, Kyoto 602
(Received July 13, 1987)

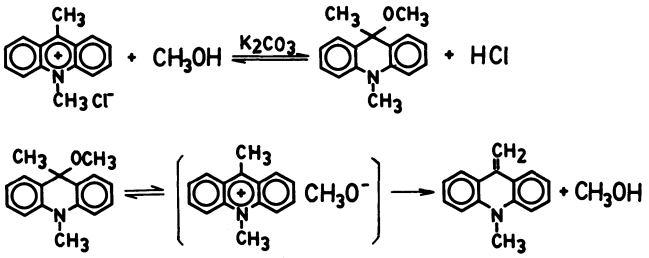
The photoreduction of 10-methyl-9-phenylacridinium chloride in methanol containing K_2CO_3 involves the nucleophilic addition of methanol to the 9-position of the acridinium cation, the photoinduced heterolysis of the methanol adduct, and the hydride transfer from the alkoxide anion to the acridinium cation in the nonrelaxed ground states to give 9,10-dihydro-10-methyl-9-phenylacridine.

In the previous paper, we postulated the photoreduction mechanism of 10-methylacridinium chloride (MA^+Cl^-) in methanol (Scheme 1):[1]



Scheme 1.

This mechanism is different from that for acridine whose n, π^* excited state can abstract a hydrogen atom from alcohols.[2] The mechanism involving the hydrogen abstraction of photoexcited acridinium cation from alcohols[3] is not understandable because the acridinium cation has no odd electrons which can participate in the n-π^* transition. Our mechanism can explain reasonably the formation of 9,10-dihydro-10-metylacridine (MAH_2) and 10,10′-dimethyl-9,9′, 10,10′-tetrahydro-9,9′-biacridinyl ($(MAH)_2$). From a different point of view, the reduction of the acridinium cation by alcohols is interesting because of its analogy with the $NADP^+$ alcohol dehydrogenase reactions. The light energy, however, needs to promote the reduction of MA^+Cl^- to MAH_2. One of the key steps to realize the $NADP^+$-mimic reaction is heterolysis of the alcohol adduct, which is formed by a nucleophilic attack of the alcohol to the carbon atom at the 9-position of the acridinium cation. A possibility to achieve spontaneous heterolysis of the alcohol adduct is utilization of strain energy at the 9-position of the acridine ring. Next we examined the reaction of 9,10-dimethylacridinium chloride (MMA^+Cl^-) with methanol.[4] Indeed, the methanol adduct provided by a K_2CO_3-catalyzed reaction of MMA^+Cl^- with methanol dissociates into MMA^+ and CH_3O^- in the dark. Unfortunately, however, a proton abstraction from the CH_3 group at the 9-position of MMA^+ of CH_3O^- proceeds to give 9,10-dihydro-10-methyl-9-methyleneacridine (Scheme 2):[4]



Scheme 2.

These aspects led us to study the reactions of 10-methyl-9-phenylacridinium chloride (MPA^+Cl^-) with alcohols. Although the $NADP^+$-mimic reactions could not be realized, we obtained important results which strongly support the photoreduction mechanism shown in Scheme 1.

Experimental

9-Phenylacridine (PA) was prepared by a Bernthsen method.[5] MPA^+Cl^- (mp 187—189 °C) was obtained by passing an aqueous solution of 10-methyl-9-phenylacridinium iodide, (which was prepared by the reaction of PA with methyl iodide), through a Dowex 1X8 ion-exchange column and recrystallization from water. 9,10-Dihydro-10-methyl-9-phenylacridine (mp 109—110 °C) (MPAH) was prepared according to procedures described in the literature.[6] 9,10-Dihydro-9-methoxy-10-methyl-9-phenylacridine (MPAOMe) was obtained by the following procedures. MPA^+Cl^- (1.6 g) in methanol (20 ml) was poured into methanol (50 ml) containing 1 M (1 M=1 mol dm^{-3}) NaOH and the solution was stirred for 5 min at room temperature. The colorless precipitates were filtered, washed with water, and recrystallized from hexane, giving MPAOMe (1.2 g, 74 %): mp 149—150 °C; ^1H NMR (acetone-d_6) δ=2.94 (3H, s, OCH_3), 3.57 (3H, s, N-CH_3), and 6.88—7.33 (13H, m,

aromatic); UV (C_2H_5OH) 332 (ε 4900), 319 (5100), 300 (sh), and 285 nm (19600). Found: C, 83.71; H, 6.29; N, 4.63%. Calcd for $C_{21}H_{19}NO$: C, 83.69; H, 6.35; N, 4.65%. All solvents used were of spectroscopic grades.

The absorption spectra were taken on a Shimadzu UV-200S spectrophotometer. The 400 MHz ^1H NMR spectra were measured by a JEOL JNM-GX400 spectrometer. The ESR spectrum was kindly measured by Professor K. Maruyama and Dr. T. Katagiri of Kyoto University using a JEOL PE-3X spectrometer. The methods of photolysis and analysis of the products have been described in the previous paper.[1]

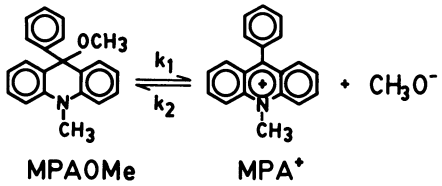
Results

Nucleophilic Addition of Alcohols to MPA$^+$Cl$^-$. Bunting and Meathrel[7] reported ^1H NMR of MPAOMe obtained from the reaction of MPA$^+$Cl$^-$ with sodium methoxide without mention of mp and yield. We also isolated and purified MPAOMe as is described in the Experimental Section.

A dilute methanolic solution of MA$^+$Cl$^-$ (1×10^{-5}M) does not show the characteristic absorption spectrum of the acridinium ion because most of MA$^+$Cl$^-$ molecules are converted to MAOMe.[1] As Fig. 1 shows, however, MPA$^+$Cl$^-$ in methanol exhibits the ^1L_a, ^1L_b, and ^1B_b transition bands due to the acridinium ring. Comparing the absorption spectrum of MPA$^+$Cl$^-$ in methanol with that in acetonitrile, it was found that an additional absorption band appears at around 285 nm in methanol. The spectrum of an authentic sample suggests that the absorption band with λ_{max} at 285 nm is ascribed to MPAOMe. Upon addition of K_2CO_3, MPAOMe was formed at the expense of MPA$^+$Cl$^-$ (Fig. 1).

The pseudo-first-order rate constants for the alcohol addition (k) and the infinite yield of the alcohol adducts could be determined from the changes in the optical densities of MPA$^+$Cl$^-$ (5×10^{-5} M) in alcohols containing K_2CO_3 (5×10^{-4}). The results are summarized in Table 1. The alcohol addition was depressed in the order of methanol, ethanol, 2-propanol, and t-butyl alcohol.

Spontaneous Heterolysis of MPAOMe. When MPAOMe (5×10^{-5} M) was dissolved in methanol, the intensity of the absorption band due to MPAOMe (285 nm) gradually decreased and the bands due to 10-methyl-9-phenylacridinium methoxide (MPA$^+$MeO$^-$) appeared at 362 and 424 nm. After a definite time, the system reached a stationary state where MPAOMe and MPA$^+$MeO$^-$ coexist:



(1)

The rate constant for the dissociation of MPAOMe (k_1) could be obtained from Eq. 2:

$$\ln\frac{C_e + C(1 - C_e/C_0)}{C_e - C} = \left(\frac{2C_0}{C_e} - 1\right)k_1 t \qquad (2)$$

where C_0 is the initial concentration of MPAOMe, C_e is the MPA$^+$MeO$^-$ concentration at the equilibrium state, and C is the MPA$^+$MeO$^-$ concentration at time t. Equation 2 can be applied to the reactions in methanol and aprotic solvents. When alcohols other than methanol are used, the exchange reactions such

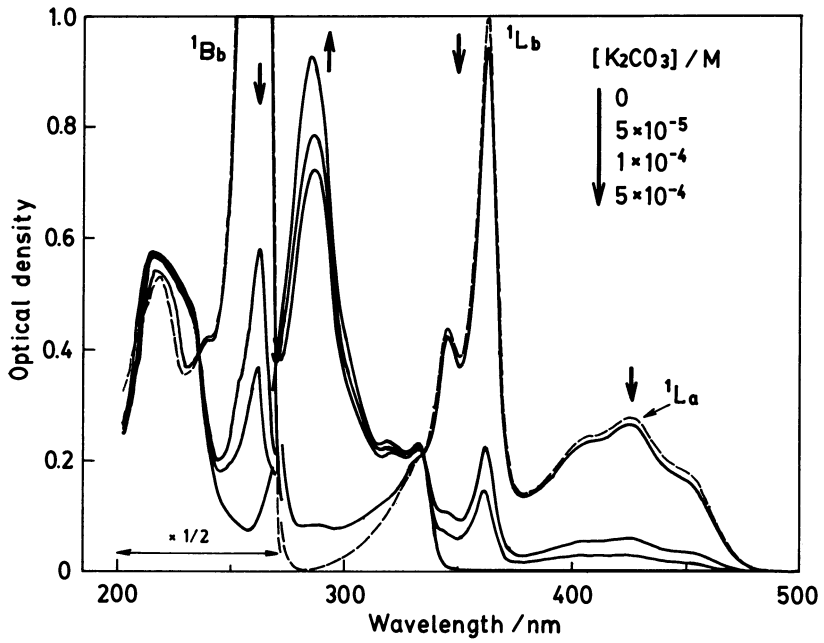


Fig. 1. Absorption spectra of MPA$^+$Cl$^-$ (5×10^{-5} M) in methanol with and without K_2CO_3 (——) and in acetonitrile (– – –) at 22 °C.

as $CH_3O^-+ROH \rightleftarrows CH_3OH+RO^-$ may take place necessitating a more complex treatment. The k_1 values in the methanol and acetonitrile are shown in Table 2 together with the yields of MPA+MeO$^-$ at the equilibrium states and the dissociation constants of MPAOMe (K_D). As Table 2 clearly indicates, the dissociation of MPAOMe occurs effectively only in methanol. This may be ascribed to the stabilization of the polar transition state and the ionic products by the polar protic solvent. A polar aprotic solvent, such as acetonitrile, is a poor solvent for dissociation because of the absence of a hydrogen bond between CH_3O^- and the solvent.

Although MPAOMe dissociates spontaneously to MPA+MeO$^-$ in methanol at room temperature, no formation of MPAH was detected by means of HPLC.

Photoinduced Heterolysis of MPAOMe. In the case of MAOMe, the photochemical dissociation of this pseudo base into MA+MeO$^-$ is observed only in a solvent matrix at 77 K[1,8] As is reported by Grigoreva et al.,[9] however, the photolysis of MPAOMe in aerated alcohols and acetonitrile at 22 °C caused the rapid formation of MPA+MeO$^-$. The relationship between the yield of MPA+MeO$^-$, which was determined by means of absorption spectroscopy, and the irradiation time is shown in Fig. 2. Figure 2 indicates that the formation of MPA+MeO$^-$ is saturated and photostationary states are reached. The yields of MPA+MeO$^-$ at the stationary states were 44% in methanol, 45% in ethanol, 49% in 2-propanol, and 17% in acetonitrile.

A 30-s irradiation of the ethanolic MPAOMe (5×10^{-5} M) solution gave MPA+MeO$^-$ in 12% yield. The dissociation was followed by a slow recombination to the alcohol adduct in the dark. After the recombination was completed, the photolyzed solution was analyzed by means of HPLC which reveals the formation of a trace amount of MPAH. For the photolysis of MAOMe in solution, we postulated the mechanism for formation of MAH_2 shown in Scheme 1.[1] If this mechanism is applicable for the photolysis of MPAOMe, it can be considered that the hydride transfer from CH_3O^- to MPA$^+$ occurs in low quantum yield. Although the 2-min irradiation of MAOMe (5×10^{-5}M) in aerated methanol provides MAH_2 and MA=O in 35 and 5% yields respectively, the yield of MPAH in the photolysis of MPAOMe under the same conditions is only <1%.

Photochemical Reactions of MPA+Cl$^-$ and MPAOMe in the Presence of K_2CO_3. Figure 3 shows the rates of MPAH formation when MPA+Cl$^-$ (5×10^{-5} M) in aerated methanol was irradiated in the absence and the presence of K_2CO_3. A slow photoreduction occurred in the absence of K_2CO_3, whereas the formation of MPAH was markedly accelerated by K_2CO_3. These results clearly indicate that MPAH is produced via

Table 1. Pseudo-First-Order Rate Constants for Nucleophilic Addition of Alcohols to MPA+Cl$^-$ (k) and Yields of Alcohol Adducts at Infinite Time at 22 °C[a]

Alcohol	$10^4\,k/s^{-1}$	Yield/%
Methanol	very fast	100
Ethanol	58.3±0.7	100
2-Propanol	7.55±0.03	100
t-Butyl alcohol[b]	4.77±0.11	58

Table 2. First-Order Rate Constants for Dissociation of MPAOMe to MPA+MeO$^-$ (k_1), Yields of MPA+MeO$^-$ at Equilibrium States, and Dissociation Constants of MPAOMe (K_D) in Alcohols and Acetonitrile at 22 °C[a]

Solvent	$10^7\,k_1/s^{-1}$	Yield of MPA+MeO$^-$/%	K_D/M
Methanol	7870±73	37	5000
Ethanol	(840±14)[b]	6	230
2-Propanol	(35.6±0.6)[b]	4	120
Acetonitrile	3.7±1.3	2	9

a) The initial concentration of MPAOMe was 5×10^{-5} M. b) The apparent k_1 value was obtained by assuming that the exchange reaction, $CH_3O^-+ROH=CH_3OH+RO^-$, does not occur (see text).

photolysis of MPAOMe. Under similar conditions, the photolysis of MPAOMe yielded MPAH (Fig. 4). Upon irradiation in methanol without K_2CO_3, about 50% of MPAOMe rapidly dissociated into MPA^+MeO^- which is inactive toward photoreduction. In the presence of K_2CO_3, however, the MPA^+ generated reverts instantaneously to the original MPAOMe which is the precursor of MPAH. The prolonged irradiation, therefor, seems to result in an accumulation of MPAH. The yield of MPAH was 68% when MPAOMe (5×10^{-5} M) in aerated methanol containing K_2CO_3 (5×10^{-4} M) was irradiated for 3 h. The photochemical behavior of MPAOMe in aerated ethanol was essentially the same as that in methanol (Table 3). In this case, MPA^+ photochemically generated may be attacked by surrounding ethanol to yield 9,10-dihydro-9-ethoxy-10-methyl-9-phenylacridine (MPAOEt) by the aid of K_2CO_3. MPAOEt may also be a precursor of MPAH.

As Table 3 shows, the yield of MPAH was significantly lowered during photolysis in aerated 2-propanol containing K_2CO_3. Since the nucleophilic attack of 2-propanol to MPA^+ is slower than the photoinduced heterolysis of MPAOMe (see Table 1), the formation of MPA^+MeO^- was detected by absorption spectroscopy at the initial stage of the photolysis. Prolonged irradiation caused the decomposition of MPA^+, giving small amounts of MA=O along with various unknown products. Complex photoreactions of MPAOMe also proceeded in aerated acetonitrile without K_2CO_3. From the photolyzed solution, PA and MA=O were isolated by means of a silica-gel column chromatography. These products were identified by ^1H NMR, absorption, and emission spectroscopy. The changes in the yields of MPAH, MA=O, and PA with irradiation time are shown in Fig. 5.

The yields of MPAH in the photolyses of MPAOMe decreased under anaerobic conditions (Table 3). The

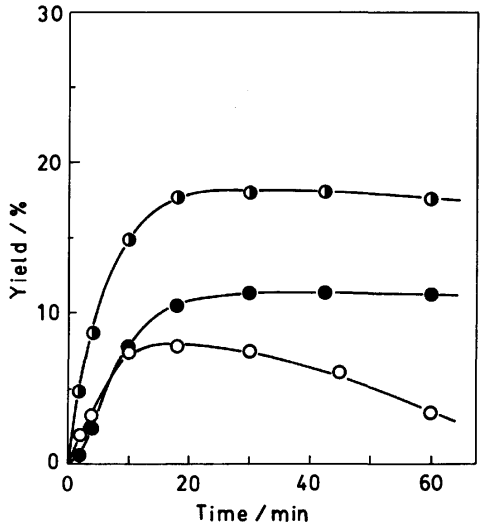

Fig. 5. Yields of MPAH (○), PA (◑), and MA=O (●) in the photolysis of MPAOMe (5×10^{-5} M) in aerated acetonitrile without base at 22°C.

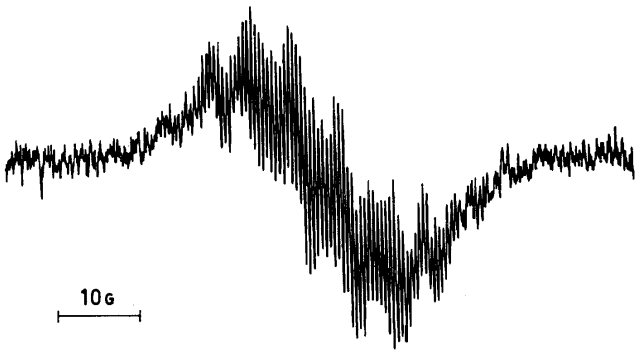

Fig. 6. ESR spectrum of MPA· generated by the photolysis of MPAOMe (5×10^{-4} M) in deaerated ethanol containing ca. 1×10^{-3} M K_2CO_3. The spectrum was measured after the solution was irradiated with a 500-W super high-pressure Hg lamp for ca. 20 s at room temperature.

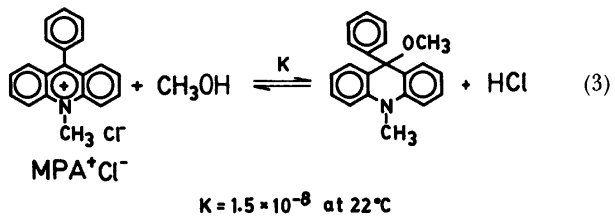
formation rate of MPAH in deaerated methanol containing K_2CO_3 is shown in Fig. 4. The initial rate in deaerated methanol was slightly slower than that in aerated methanol and the subsequent photodecomposition of MPAH proceeded. The HPLC analysis of the photolyzed solution indicated that various unknown products are produced along with MPAH upon irradiation in deaerated methanol. Most of these unknown products were the same as those produced by the photolysis of MPAH. During irradiation, the photolyzed solution became red-violet (λ_{max}=518 and 487 nm) which faded upon contact with air. The ESR spectrum (Fig. 6) clearly showed that the red-violet color is due to 10-methyl-9-phenylacridinyl radical (MPA·). The ESR spectrum shown in Fig. 6 is in good agreement with that of MPA· produced by electrochemical reduction of MPA+Cl⁻.[10] MPA· gradually disappeared in the dark. The lifetimes of MPA· in alcohols and acetonitrile are listed in Table 3.

Photochemical Reaction of MPAOMe in Ethanol Matrix at 77 K. MPAOMe (5×10^{-5} M) in an ethanol matrix at 77 K was irradiated for 70 min. The absorption spectrum indicated the disappearance of MPAOMe and the appearance of an absorption band having its maximum wavelength at 360 nm, which corresponds to that of PA. The HPLC analysis showed the formation of MPAH and PA in 29 and 15% yields, respectively.

Thermal Reaction of MPAOMe in Methanol and Acetonitrile. The acetonitrile solution of MPAOMe (5×10^{-5} M) was refluxed for 3.5 h under the aerobic conditions. The reaction mixture became yellowish during heating and the formation of MPA+MeO⁻ (ca. 80% yield) was confirmed by absorption spectroscopy. Interestingly, MPAH, MA=O, and PA were also produced in 11, 2, and 8% yields, respectively. Any other products were not detected by HPLC. Under anaerobic conditions, however, no MPA+MeO⁻ was formed and MPAH (2%) was the sole product which was detectable by HPLC, while most of the MPAOMe decomposed in refluxing acetonitrile. No generation of MPA· was observed by absorption spectroscopy. Although the dissociation of MPAOMe to MPA+MeO⁻ occurred in boiling methanol under aerobic conditions, neither MPAH nor MA=O and PA were produced. In the presence of K_2CO_3, MPAOMe in boiling methanol did not react at all.

Discussion

It is well-known that the electrophilicity of 10-alkylacridinium cations is so strong that nucleophiles such as hydroxide and alkoxide anions attack the carbon atom at the 9-position of the acridinium ring to give corresponding pseudo bases.[11–19] Bunting et al.[7,17] have found that the nucleophilic addition of OH⁻ to the 9-aryl-10-methylacridinium cations occurs about 30-fold faster than that to the corresponding triphenylmethyl cation analogues and the bulky substituents at the 9-position do not seriously prevent the addition of OH⁻. In the present study, we isolated and purified the methanol adduct of MPA+Cl⁻, MPAOMe, in moderate yield (see Experimental Section). It was also found that an equilibrium shown in Eq. 3 is established in methanol even in the absence of base:

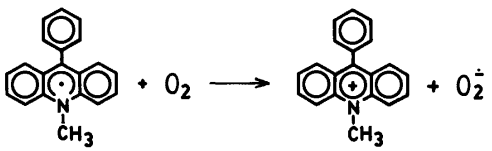


(3)

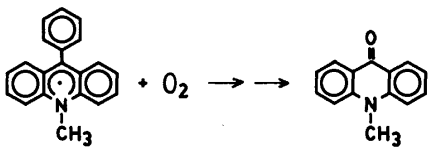
In dilute solution, MPA^+Cl^- could be converted quantitatively to MPAOMe in methanol in the presence of K_2CO_3 (see Table 1). As Table 1 shows, the addition of alcohols to MPA^+Cl^- is greatly affected by the kind of alcohol. Since the positive charge of the acridinium cation distributes in the transition state, the nucleophilic addition of alcohol is expected to be accelerated in a nonpolar solvent. The experimental results, however, are opposite to this expectation. One of the factors which dominates the alcohol addition may be a steric hindrance. The hydrogen atoms at the 1- and 8-positions as well as the phenyl substituent at the 9-position of the acridinium ring may inhibit ability to reach the transition state. Meanwhile, since the carbon atom at the 9-position of the alcohol adducts is a sp^3 orbital, the steric hindrance is greatly weakened. The alcohol adducts, therefore, are considerably more stable in the cases of the primary and secondary alcohols when a weak base is present in the system.

We expected the spontaneous heterolyses of the alcohol adducts followed by the hydride transfer from the alkoxide anions to MPA^+. The spontaneous heterolyses could be realized in alcohols and acetonitrile (see Table 2). As is expected theoretically, the dissociation of MPAOMe into MPA^+MeO^- favors a polar protic solvent such as methanol. In ethanol, 2-propanol, and acetonitrile, however, MPAOMe hardly dissociates. Since the phenyl ring at the 9-position of MPA^+ is not coplanar with the acridinium ring, the change in the hybrid orbital of the carbon atom from sp^3 to sp^2 upon dissociation of MPAOMe to MPA^+MeO^- seems to require relatively large energy. Although the spontaneous heterolysis of MPAOMe in methanol was appreciable, the hydride transfer between MPA^+ and CH_3O^- does not occur at all.

MPAH could be obtained photochemically from MPAOMe. In aerated methanol without base, the photolysis of MPAOMe led to the effective heterolysis to MPA^+MeO^- and the ineffective reduction to MPAH (see Fig. 2). In the presence of K_2CO_3, the photochemical formation of MPAH became a predominant reaction (see Fig. 4 and Table 3). Under anaerobic conditions, the formation of MPAH was depressed because of the photodecomposition of MPAH (see Fig. 4). If the photoreduction proceeds by a radical mechanism via the triplet state of MPAOMe, the rate of the MPAH formation should be faster, at least at the initial stage of the photolysis, in deaerated methanol than in aerated methanol. The experimental results disagree with this expectation (see Fig. 4). It can be concluded, therefore, that an ionic mechanism via the lowest excited singlet state of MPAOMe accounts for the formation of MPAH. In photolyses under anaerobic conditions, however, the formation of MPA· was detected by adsorption and ESR spectroscopy. In the presence of oxygen, MPA· is expected to be quenched (Eq. 4) or converted to MA=O (Eq. 5):

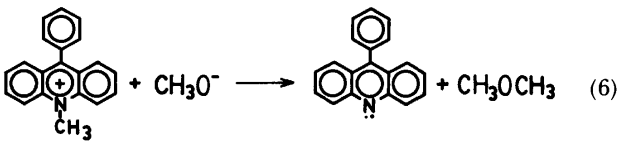


(4)



(5)

Indeed, small amounts of MA=O were produced in the photolyses of MPAOMe in aerated 2-propanol and acetonitrile (see Table 3). In neither methanol and ethanol, could MA=O be detected. Another reaction of MPAOMe in acetonitrile is the elimination of the CH_3 group at the 10-position of the acridine ring to give PA. The most plausible mechanism for the PA formation is S_N2 reaction between MPA^+ and CH_3O^- photochemically generated:

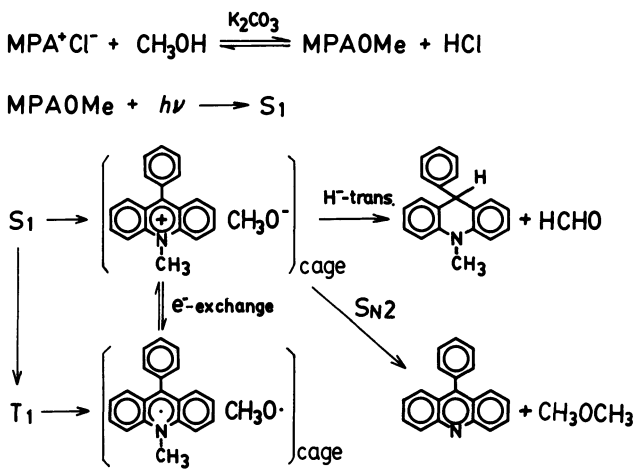


(6)

PA was not produced in alcoholic solutions (see Table 3). This may be due to the stabilization of CH_3O^- by strong solvation with alcohols through hydrogen bonding.

Important information was obtained from the photolysis of MPAOMe in an ethanol matrix at 77 K. In the rigid matrix, the formation of MPA^+MeO^- and MPA· was not observed by the absorption spectroscopy. The main photoproducts are MPAH and PA. MPA^+MeO^- photochemically generated should be a contact ion pair without solvation in the rigid matrix. Such an ion pair, therefore, is so active that the recombination to MPAOMe, the hydride transfer from CH_3O^- to MPA^+ giving MPAH and formaldehyde, and the S_N2 reaction giving PA and CH_3OCH_3 are expected to occur competitively.

Let us return to the mechanism in fluid solutions. A plausible mechanism for the photoreaction of MPA^+Cl^- in methanol is shown in Scheme 3. In the presence of base, photochemically inactive MPA^+Cl^- is converted to MPAOMe which dissociates into MPA^+MeO^- from its lowest excited singlet state. Most of the ion pairs in the Franck–Condon ground states will be solvated rapidly by a polar solvent. It seems that a part of the ion pairs in the nonrelaxed states transfers a hydride from CH_3O^- to MPA^+ to give MPAH even in very low quantum yield. Solvated MPA^+MeO^- is inactive and MPA^+ is returned to the original MPAOMe by the aid of K_2CO_3. In both 2-



Scheme 3.

propanol and acetonitrile, the formation of the alcohol adduct is so slow that the electron transfer from CH_3O^- to MPA^+ takes place to generate MPA· and CH_3O· whose subsequent reactions may provide MA=O and unknown products. Since the electron transfer occurs through a long-distance interaction between MPA^+ and CH_3O^-, the formation of MPA· and CH_3O· may not be inhibited so sereously as hydride transfer from CH_3O^- to MPA^+ by solvation. MPA· therefore, was generated in all solvents tested in the present study under anaerobic conditions.

Another mechanism for MPAH formation is a radical mechanism which involves the homolysis of MPAOMe in the lowest excited singlet state to yield a singlet radical pair, MPA·MeO·, and subsequent hydrogen abstraction of MPA· from CH_3O· to form MPAH. This mechanism can be excluded on the basis of the results on the thermal reactions of MPAOMe in boiling methanol and acetonitrile. Although no reaction of MPAOMe occurred in aerated methanol except for the dissociation to MPA^+MeO^-, the products which are the same as those in the photolysis (MPA^+MeO^-, MPAH, MA=O, and PA) were obtained in refluxing acetonitrile. Under anaerobic conditions, heating in acetonitrile provided unknown products along with a small amount of MPAH; neither MPA^+MeO^- nor MPA· was detected. If the thermal reaction of MPAOMe to MPAH proceeds via the singlet radical pair, MPAH should also be produced in the reaction of MPAOMe in boiling methanol because the yield of MPAH photochemically formed is higher in methanol than in acetonitrile. The solvent effect on the thermal reaction of MPAOMe can be interpreted in terms of the ionic mechanism, but not the radical mechanism. Since acetonitrile is an aprotic polar solvent, the stabilization of CH_3O^- by this solvent should be much weaker than by methanol. The thermal dissociation of MPAOMe to MPA^+MeO^-, therefore, may be followed by the hydride transfer and the nucleophilic substitution to give MPAH and PA, respectively, in boiling acetonitrile. Presumably, an electron transfer from CH_3O^- to MPA^+ occurs to generate the radical pair composed of MPA· and CH_3O·. Under aerobic conditions, MPA· should be quenched by oxygen to regenerate MPA^+ (see Eq. 4). In the absence of oxygen, however, the radical species may induce complex reactions to give unknown products in refluxing acetonitrile. It can be concluded, therefore, that the radical pair, MPA·CH_3O· is not a precursor of both MPAH and PA. It is clear that the solvation to MPA^+MeO^- plays an important role to promote the subsequent hydride transfer and nucleophilic substitution reactions. In alcoholic solvents, CH_3O^- generated as a counter anion of MPA^+ is stabilized so extensively by alcohols through hydrogen bonding that neither intramolecular hydride transfer nor nucleophilic substitution of MPA^+MeO^- take place. The photochemical processes of MPAOMe, however, can provide a nonrelaxed ground state of MPA^+MeO^- to promote hydride transfer to form MPAH.

The present study was supported by Grant-in-Aids for Science Research No. 61550647 from the Ministry of Education, Science and Culture.

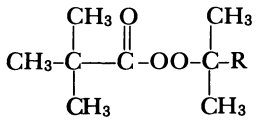
Homolytic Decomposition of *t*-Alkyl 2,2-Dimethylperoxypropionates

Takeshi KOMAI, Kazuo MATSUYAMA,* and Masaru MATSUSHIMA
Chemicals & Explosives Research Laboratory, Nippon Oil & Fats Co., Ltd.,
Taketoyo-cho, Chita-gun, Aichi-ken 470-23
(Received August 3, 1987)

Decomposition rates and products of *t*-alkyl 2,2-dimethylperoxypropionates were measured in cumene at several temperatures. The peroxyesters decomposed homolytically, depending on the structure of the *t*-alkyl moiety. The relative rates of the *t*-alkyl moieties to the 1,1-dimethylethyl one were: 1,1-dimethylbutyl (1.14), 1,1-dimethylpropyl (1.19), 1,1,2-trimethylpropyl (1.85), 1,1,3,3-tetramethylbutyl (2.10), and 1,1-dimethyl-2-phenylethyl (2.34). The decomposition showed an isokinetic relationship and the importance of stabilization by hyperconjugation. Based on these data, the decomposition mechanism, which contains a slight stretching of the C_α–C_β bond to the peroxyl oxygen at the transition state is, discussed.

A large number of investigations concerning the decomposition mechanism of *t*-alkyl peroxyesters have been concerned with the relationship between the structure of the peroxyesters and the mode of decomposition.[1] However changes in the structure have been restricted to the acyl moiety. Only a few reports concerning the structure of the *t*-alkylperoxyl group exist.[2] Sheldon and Kochi indicated that there is a small influence of the *t*-alkylperoxyl group on the decomposition of di-*t*-alkyl diperoxyoxalates, and the variation of the solvent from pentane to acetonitrile enhances the rate and the formation of heterolytic decomposition products.[2a] Difficulties in studying the influence of the *t*-alkylperoxyl moiety can be attributed to the possibility that radical decompositions are accompanied by heterolytic ones.[3] It has also been known that peroxyesters are acceptable to heterolytic decompositions when the acidity of the parent acid is large.[4]

We have studied the homolytic decomposition of *t*-alkyl 2,2-dimethylperoxypropionates (**1**) which could be expected to decompose more homolytically because of the slight acidity of the parent acid. One of the compounds studied, 1,1-dimethylethyl 2,2-dimethylperoxypropionate (**1a**) has been used as a standard compound.



1a; R = CH_3, **1b**; R = CH_3CH_2, **1c**; R = $CH_3CH_2CH_2$, **1d**; R = $(CH_3)_2CHCH_2$, **1e**; R = $(CH_3)_2CH$, **1f**; R = $PhCH_2$

Results and Discussion

The peroxyesters were synthesized by the acylation

Table 1. Rate Constants and Activation Parameters for Decomposition of *t*-Alkyl 2,2-Dimethylpropionates at Concentration of 0.05 mol dm^{-3} in Cumene[a]

Peroxyester	Temperature	Rate constant	Activation parameter	
	°C	$10^5 k_d/s^{-1}$	ΔH^*/kJ mol^{-1}	ΔS^*/J K^{-1} mol^{-1}

a) Rate constants and their standard deviations were calculated by the method of least squares. b) Ref. 19.

of the correspoding hydroperoxides with 2,2-dimethylpropionyl chloride in the presence of potassium hydroxide at low temperatures. The hydroperoxides were prepared from the corresponding alcohols or olefins by using 50% hydrogen peroxide in the presence of sulfuric acid.

The rates for the decomposition of the peroxyesters were measured by iodometric titration of the active oxygen. Good first-order rate constants were obtained over 10—80% conversion in all cases. Rate data concerning cumene are given in Table 1 together with calculated activation parameters; data concerning acetonitrile are given in Table 2. The decomposition products formed from the *t*-alkylperoxyl moiety in cumene were analyzed with GC and are shown in Table 3, together with the relative rates of β-scission of the corresponding alkoxyl radicals.[4,5] The total yields of the corresponding alcohol and the acetone were upper 90%. The inversion product ($C(CH_3)_3CO_2$-$C(CH_3)_2$-OR) and the hydrolysis product (ROH) from the heterolyic decomposition could not be recognized with detectable amounts. The solvent effect in cumene and acetonitrile was similar to that of *p*-substituted 1,1-dimethylethyl 2-methyl-2-phenylperoxypropionates.[1f] These facts indicate that the decomposition of **1** in cumene proceeds mainly by a homolytic path. The formation ratio of the acetone to the corresponding alcohol in Table 3 changes with the alkyl group (R), and the order of these ratios is similar to those in the decomposition of di-*t*-alkyl diperoxyoxalates and in β-scission of the corresponding alkoxyl radicals (Table 3). However, the ratios of **1d** and **1e** are considerably different in the order and size from those of the relative rate (k_β/k'_A) in the β-scission. The ratio of **1d** increases regardless of whether there is less β-scission, and the ratio of **1e** is very small, compared with the remarkable β-scission. The decomposition rates of **1** change with the *t*-alkyl group, of which the effect is not large. The ratio of the rate constant for the slowest **1a** against the fastest **1f** is 0.43 at 60 °C. This corresponds to that reported for the decomposition of di-*t*-alkyl diperoxyoxalates in pentane.

Figure 1 shows an isokinetic relationship for the decomposition of **1** in cumene. A good linear free-energy relation exists for five electron-donating alkyl substituents, except **1f** (electron-withdrawing one). This suggests that the difference of decomposition rates except **1f** (discussed later) takes place with a single interaction mechanism of the substituents.[6]

The relative rates in the decomposition of **1** in cumene are found to depend on the nature of the substituents and follow the order: **1a**<**1c**<**1b**<**1e**<**1d**<**1f** (Table 1). The data in Table I could be analyzed by the following Taft equation:[7]

$$\log (k_d/k_{d0}) = \rho^*\sigma^* + (\Delta n)h, \quad (1)$$

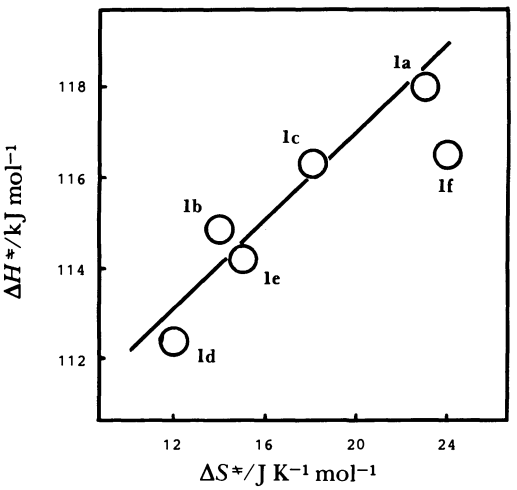

Fig. 1. Isokinetic relationship for the decomposition of *t*-alkyl 2,2-dimethylpropionates in cumene.

Table 2. Rate Constants in Acetonitrile and Relative Rates with Variation of Solvent at 60 °C[a]

Peroxyester	Rate constant $10^5 k_d/s^{-1}$	Relative rate[b]
1a	5.18±0.04	1.76
1c	7.39±0.14	2.19
1d	11.43±0.13	1.85

a) Initial concentration of peroxyester is 0.05 mol dm^{-3}.
b) Relative rate of acetonitrile against cumene.

Table 3. Decomposition Products Formed from *t*-Alkyl Moiety at 60 °C

Peroxyester	Product/mol		Ratio[a]	Ratio in peroxyoxalate[b]	k_β/k'_A in β-scission[c]
	Acetone	Corresponding alcohol			
1a	0	0.88	0	<0.02	0.053
1b	0.28	0.66	0.42	0.09	2.9
1c	0.17	0.76	0.22	—	2.4
1d	0.43	0.59	0.73	—	1.4
1e	0.54	0.38	1.42	2.92	96
1f	0.54	0.40	1.35	1.25	2.2

a) Ratio of acetone to the corresponding alcohol formed per the decomposed peroxyester **1** (mol/mol) in cumene.
b) In pentane at 40 °C.[2a] c) Relative rate of β-scission to hydrogen abstraction with cyclohexane of alkoxyl radical.[5] These values were calculated by using data in Ref. 4.

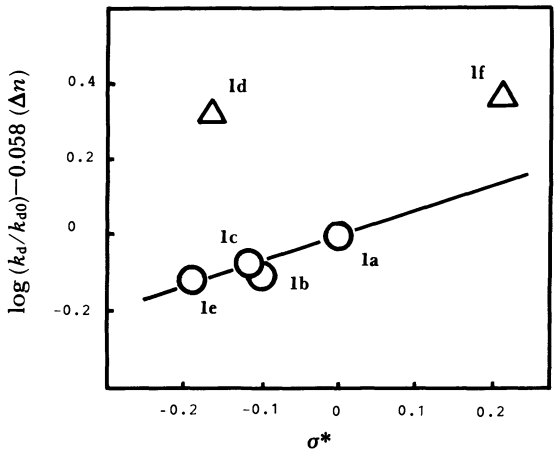

Fig. 2. A plot of [log (k_d/k_{d0})=0.058 (Δn)] against σ^* in the decomposition of *t*-alkyl 2,2-dimethylpropionates in cumene at 60°.

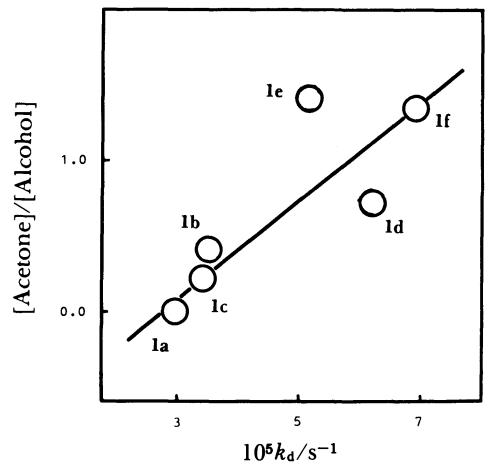

Fig. 3. A plot of [Acetone]/[Alcohol] against k_d in the decomposition of *t*-alkyl 2,2-dimethylpropionates in cumene at 60°C.

where k_d/k_{d0} is relative rate of the related peroxyester to **1a**, σ^*, the polar substituent constant by Taft, ρ^*, reaction constant, (Δn), the difference between the related peroxyester and **1a** for the number of the hydrogen atoms participating in C–H hyperconjugation, and h, an emperical constant. A plot of [log (k_d/k_{d0})−(Δn)h] vs. σ^* in Fig. 2 shows good linearity for **1a**, **1b**, **1c**, and **1e**, and the values of ρ^*= 0.67 and h=0.058 are estimated by using a least-squares method. These are interpreted in terms of C–H hyperconjugative and inductive stabilizing effects of the substituents at the transition state.

On the basis of the decomposition rates and products, the isokinetic relationship and the importance of the hyperconjugation, the following scheme for the main reactions may be considered as a decomposition mechanism of **1**:

$$\mathbf{1} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} [CH_3\text{-}\overset{CH_3}{\overset{|}{C}}\cdots\overset{O}{\overset{\|}{C}}\text{-}O\cdots O\text{-}\overset{CH_3}{\overset{|}{C}}\cdots R]_{cage} \quad (2)$$

2

$$[\mathbf{2}]_{cage} \xrightarrow{k_c} CH_3\text{-}\overset{CH_3}{\overset{|}{C}}\text{=}CH_2 + CO_2 + HO\text{-}\overset{CH_3}{\overset{|}{C}}\text{-}R \quad (3)$$

3

$$[\mathbf{2}]_{cage} \xrightarrow{k_{DA}} CH_3\text{-}\overset{CH_3}{\overset{|}{C}}\cdot + CO_2 + \cdot O\text{-}\overset{CH_3}{\overset{|}{C}}\text{-}R \quad (4)$$

$$[\mathbf{2}]_{cage} \xrightarrow{k_{D\beta}} CH_3\text{-}\overset{CH_3}{\overset{|}{C}}\cdot + CO_2 + O\text{=}\overset{CH_3}{\overset{|}{C}} + \cdot R \quad (5)$$

4

$$R\text{-}\overset{CH_3}{\overset{|}{C}}\text{-}O\cdot + R'H \xrightarrow{k_A} \mathbf{3} + R'\cdot \quad (6)$$

$$R\text{-}\overset{CH_3}{\overset{|}{C}}\text{-}O\cdot \xrightarrow{k_\beta} R\cdot + \mathbf{4} \quad (7)$$

$$CH_3\text{-}\overset{CH_3}{\overset{|}{C}}\cdot + R'H \longrightarrow CH_3\text{-}\overset{CH_3}{\overset{|}{C}}\text{-}H + R'\cdot \quad (8)$$

$$2R'\cdot \longrightarrow R'\text{-}R' \quad (9)$$

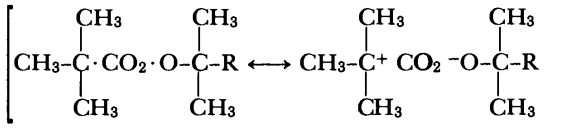
Here, k_1 is the rate constant for the bond homolysis, k_{-1} the rate constant for the cage return, **2** a reaction intermediate, k_c the rate constant for the disproportionation between the 1,1-dimethylethyl and the alkoxyl radicals within a solvent cage, k_{DA} the rate constant for the diffusion of the alkoxyl radical out of the solvent cage, $k_{D\beta}$ the rate constant for the outwared diffusion of the acetone formed within the solvent cage, k_A the rate constant for hydrogen abstraction of the alkoxyl radical with cumene (R'H), and k_β the rate constant for β-scission of the alkoxyl radical outside the solvent cage, respectively.

The decomposition prcducts of **1a** in cumene included isobutylene and isobutane in approximately equal amounts;[8] most of them may be considered from the

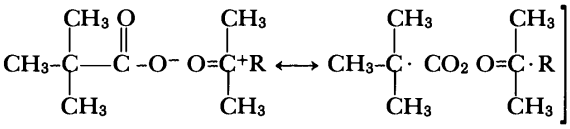
amount of 2,3-dimethyl-2,3-diphenylbutane to be formed exclusively within (Eq. 3) and outside the solvent cage (Eq. 8), respectively. The coupling products between the 1,1-dimethylethyl and the alkoxyl radicals within the solvent cage, and between these radical species outside it were negligibly small in the photodecomposition of **1**.[2c] Since the cage return (Eq. 2) can be neglected in a concerted decomposition ($k_1 \gg k_{-1}$)[9] the observed rate constant of the decomposition, k_d, is as follows:

$$k_d = k_1(k_{DA} + k_{D\beta} + k_c)/(k_{-1} + k_{DA} + k_{D\beta} + k_c) \simeq k_1, \quad (10)$$

The formation ratio of the acetone to the corresponding alcohol ([**4**]/[**3**]) in Table 3 is plotted against the decomposition rate constant, k_d, shown in Fig. 3. The decomposition of **1d** yield much more acetone than that estimated from the β-scission, compared with those of **1b** and **1c**. This can be explained by the fact that a part of the acetone is formed by the β-scission within the solvent cage or directly from the intermediate 2 (Eq. 5). Figure 3 suggests that the formation of acetone is apt to increase with the decomposition rate of **1** and is based on the direct one from the intermediate **2**. The points of **1e** and **1d** in Fig. 3 deviate greatly from a linear line (correlation coefficient=0.8676)[10] which passes through the points of **1c** and **1f**, and the corresponding alkoxyl radicals to **1c** and **1f** have the similar values of k_β/k'_A with each other (Table 3). These deviations may be understood by the difference of the β-scission outside the solvent cage.[10]



2a **2b**



(11)

2c **2d**

The intermediates of **2a** and **2b** at the transition state had been confirmed by the relationships between the structure of the acyl group and the reactivity.[1] The positive value of ρ^* in the Taft equation (Eq. 1) shows an inductive stabilizing effect more by an electron-withdrawing substituent on the intermediate **2**. The importance of the hyperconjugation (Eq. 1) and the formation of the β-scission product from the intermediate **2** (Eq. 5) indicate that, in addition to **2a** and **2b**, there exist intermediates of **2c** and **2d** at the transition state. The intermediate of **2c** is correlated to that in the heterolytic decomposition of *t*-alkyl *p*-nitroperbenzoates.[3] Walling et al. had proposed that all of radical and ionic decomposition products arise from a common rate-determining transition state to partition into radical and ionic pairs occurring at a later stage in the decomposition of diacyl peroxides.[11] The decompositions of 1-methyl-1-phenylethyl peracetate and di-*t*-alkyl diperoxyoxalates follow heterolytic, homolytic, or their mixed pathways, depending on the polarity of the solvent and the presence of acid catalysis.[12] The similarities between the homolytic and the heterolytic decompositions (as shown in this work) support the Walling hypothesis in the same manner as diacyl peroxides. Deviations of **1f** from the isokinetic relationship and the Taft equation (Figs. 1 and 2) may probably result from the stabilization of the intermediate **2d** of which the benzyl radical is the most stable. The deviation of **1d** from the Taft equation (Fig. 2) may be understood to be similar to the rate enhancement in neopentyl solvolysis, in which γ-carbon atoms to the cationic center participate in the stabilization at the transition state.[13] Thus, the influence of the *t*-alkylperoxyl moiety could be explained by inductive and resonance effects without any consideration of steric effects. In conclution, it may be suggested that the C_α–C_β bond to the peroxyl oxygen is only slightly streched, together with the C_α–CO and O–O bonds at the transition state.

Experimental

IR and NMR spectra were recorded on JASCO A-3 and JEOL JNM-MH-100 spectrometers, respectively. GC analysis was carried out using Shimadzu GC-6A and GC-2D gas chromatography using five columns: (A), Silicone GE-30 on Shimalite (NAW), 2.4 m; (B), PEG 20M 25% on Shimalite (NAW), 2 m; (C), PEG 20M 5% on Shimalite (NAW), 2 m; (D), Sorbitol 30% on Shimalite (NAW), 3 m; (E), PEG 20 M 25% on Shimalite (NAW), 3 m.

Materials. 2,2-Dimethylpropionyl chloride was purified by the distillation (bp 103 °C) of a commercial product. Sixty-nine per cent 1,1-dimethylethyl, 90% 1,1-dimethylbutyl, and 86% 1,1,3,3-tetramethyl-butyl hydroperoxides were the products of Nippon Oil & Fats Co., Ltd. 1,1-Dimethylpropyl alcohol was prepared by the reaction of 2-methyl-1-pentene with an excess of 65% H_2O_2 for 30 min at 0—5 °C and the hydrolysis of the reaction mixture with an aqueous solution of 5% NaCl under a temperature of 10 °C. The alcohol was distilled after drying over anhydrous $MgSO_4$ (bp 66 °C/76 mmHg (1mmHg=133.322 Pa)).[14] In a similar method 1,1,3,3-tetramethylbutyl alcohol was prepared (bp 54 °C/16 mmHg).[14]

Preparation of Hydroperoxides. The purities of hydroperoxides were checked by iodometric titration and GC. The titration procedure involved the use of a mixture (20:2) of isopropyl alcohol and acetic acid as the solvent, and saturated potassium iodide as the source of iodide.[15]

1,1-Dimethylpropyl hydroperoxide was prepared from a reaction of the corresponding alcohol with 50% H_2O_2 by the method of Milas and Surgenor[16] and the purification by distillation (bp 50 °C/20 mmHg).[17] **1,1-Dimethylbutyl hydroperoxide** was purified by distillation (bp 41 °C/3 mmHg)[18] of the commercial product. **1,1,3,3-Tetramethylbutyl hydroperoxide** was purified from a commercial product by the isolation of sodium salt with sodium amide,

regeneration of the hydroperoxide with carbon dioxide and vacuum distillation (bp 46 °C/1 mmHg).

1,1,2-Trimethylpropyl hydroperoxide was prepared by the reaction of olefin with H_2O_2 in the presence of H_2SO_4 and acetonitrile. To an aquous solution of 44% H_2O_2 (115.0 g, 1.50 mol) there was added dropwise concd H_2SO_4 (80.0 g, 0.82 mol) for 30 min at 0 °C and added continuously acetonitrile (32.8 g, 0.80 mol) and chloroform (50 g). Then, to the mixture there was added dropwise 2,3-dimethyl-2-butene (67.4 g, 0.80 mol) for 30 min at 0—5 °C. The mixture was stirred for 30 min at 5 °C and continuously for 30 min at 10 °C in order to complete the reaction. After the reaction mixture was added by petroleum ether (50 g) and washed three times with an aquous solution of 40% $(NH_4)_2SO_4$, a crude product was obtained by the evaporation of the solvent at reduced pressure. Because dangerous materials (ketone peroxides) were contained in the crude product,[3] they were eliminated by a separation of the oily material from the crude product (32.2 g), which was added by petroleum ether (6.0 g) after the neutralization with 35% KOH (45.0 g) and methanol (30 cm^3). After regeneration of the hydroperoxide by carbon dioxide and washing with an aqueous solution of 40% $(NH_4)_2SO_4$, the crude product was distilled (bp 30—33 °C/2 mmHg) in the presence of polyethylene glycol oligomer ($\bar{n}$=300) to give 1,1,2-trimethylpropyl hydroperoxide (6.2 g) of 82.0% purity analyzed by GC using column A. IR (neat): ν_{O-H} 3400 cm^{-1}; ^1H NMR (CCl_4): δ=1.00 (6H, d, >C(CH_3)$_2$), 1.13 (6H, s, -C(CH_3)$_2$-), and 2.02 (H, m, >CH-).

1,1-Dimethyl-2-phenylethyl hydroperoxide was prepared by a reaction of the corresponding alcohol with 50% H_2O_2. A mixture of 1,1-dimethyl-2-phenylethyl alcohol (300.4 g, 2.0 mol) and THF (100 cm^3) was added dropwise to 72% H_2SO_4 (272.6 g, 2.0 mol) under a temperature of 10 °C to give the sulfonate. Then after the addition of 50% H_2O_2 (272.0 g, 4.0 mol) for 90 min under a temperature of 10 °C, the mixture was stirred for 3 h at 40 °C and for 2 h at 30 °C. The 15.4% crude material (623.0 g, containing 0.57 mol of the hydroperoxide) was obtained by washing with water after the addition of petroleum ether (300 g), and drying over anhydrous $MgSO_4$. The hydroperoxide (29.6 g) of 97.0% purity was obtained by the isolation of the sodium salt with sodium amide, regeneration of the hydroperoxide by carbon dioxide and recrystallization from petroleum ether. Mp 40—41 °C (lit,[3] mp 44 °C); IR (CCl_4): ν_{O-H} 3400 cm^{-1}, phenyl 1600 cm^{-1}; ^1H NMR (CCl_4): δ=1.16 (6H, s, -C(CH_3)$_2$-), 2.83 (2H, s, -CH_2-), 7.20 (5H, s, phenyl), and 8.02 (1H, s, -OOH).

Preparation of Peroxyesters. Purities of peroxyesters were checked by iodometric titration which involved the use of an acetic acid solution containing a saturated aqueous solution of NaI and a small amount of iron(III) chloride.[19]

Peroxyester 1a was prepared by a Schotten-Baumann reaction of 2,2-dimethylpropionyl chloride with the corresponding hydroperoxide. To a mixture of 69% 1,1-dimethylethyl hydroperoxide (20.9 g, 0.16 mol) and 30% KOH (30.0 g, 0.16 mol) there was added dropwise the acid chloride (16.1 g, 0.13 mol) for 30 min at 2 °C; the mixture was then stirred for 30 min to complete the reaction. After the reaction mixture was washed twice with 5% NaOH for 5 min at 0 °C, three times with water and dried with anhydrous $MgSO_4$, the peroxyester (18.5 g, yield 76.9%) of 93.8% purity was obtained. The distilled material (bp 50.5 °C/5 mmHg) was shown to be 97.0% purity. IR (CCl_4): $\nu_{C=O}$ 1762 cm^{-1}; ^1H NMR (CCl_4): δ=1.24 (9H, s, acyl t-Bu) and 1.20 (9H, s, peroxyl t-Bu).

Peroxyester 1b was prepared by a Schotten-Baumann reaction of the acid chloride with the corresponding hydroperoxide. To a mixture of 95.0% 1,1-dimethylpropyl hydroperoxide (7.7 g, 0.07 mol) and 20% KOH (25.3 g, 0.09 mol) there was added dropwise acid chloride (10.9 g, 0.07 mol) containing petroleum ether (2.5 g) for 30 min at 0—5 °C and stirred for 30 min to complete the reaction. Then, the reaction mixture was washed once with 5% NaOH, once with an aqueous solution which contained Na_2SO_4 (4.2%), sodium acetate (8.3%) and acetic acid (4.2%), and twice with water. After drying over anhydrous $MgSO_4$ and evaporation of the solvent, the crude product of 11.5 g (yield 83.0%) was obtained and further purified by distillation (bp 51 °C/3 mmHg) to give the peroxyester of 95.8% purity. IR (CCl_4): $\nu_{C=O}$ 1765 cm^{-1}; ^1H NMR (CCl_4): δ=0.94 (3H, m, peroxyl -CH_3), 1.24 (15H, s, acyl t-Bu and peroxyl t-Bu) and 1.53 (2H, q, -CH_2-).

Peroxyester 1c was prepared by the method according to 1,1-dimethylpropyl peroxyester. Yield 81.4%; purity 96.1%; IR (CCl_4): $\nu_{C=O}$ 1765 cm^{-1}; ^1H NMR (CCl_4): δ=0.95 (3H, m, peroxyl-CH_3), 1.24 (15H, s, acyl t-Bu and peroxyl -C(CH_3)$_2$-O), and 1.52 (4H, m, -CH_2CH_2-).

Peroxyester 1a was prepared by the method according to 1,1-dimethylpropyl peroxyester. The purity and yield of the crude product were 83.7 and 65.0%, respectively. The crude product was purified by flash chromatography on Merck Kieselgel 60 using hexane-ethyl acetate (95:5) as the eluent to give 93.1% purity. IR (CCl_4): $\nu_{C=O}$ 1765 cm^{-1}; ^1H NMR (CCl_4): δ=0.96 (6H, d, peroxyl >C(CH_3)$_2$), 1.20 (6H, s, peroxyl -C(CH_3)$_2$-O), 1.24 (9H, s, acyl t-Bu), and 1.88 (1H, m, >CH-).

Peroxyester 1d was prepared by a Schotten-Baumann reaction of the acid chloride with the corresponding hydroperoxide. To a mixture of 98.0% 1,1,3,3-tetramethylbutyl hydroperoxide (22.3 g, 0.15 mol) and 35% KOH (31 g, 0.23 mol) there was added dropwise the acid chloride (21.7 g, 0.18 mol) for 35 min at 0—5 °C to complete the reaction. The reaction mixture was washed once with 5% NaOH, once with an aqueous solution which contained Na_2SO_4 (4.2%), sodium acetate (8.3%) and acetic acid (4.2%), twice with water, and dried over anhydrous $MgSO_4$ to give the peroxyester of 94.7% purity (21.0 g, yield 48.9%). IR (CCl_4): $\nu_{C=O}$ 1765 cm^{-1}; ^1H NMR (CCl_4): δ=1.03 (9H, s, peroxyl t-Bu), 1.22 (9H, s, acyl t-Bu), 1.32 (6H, s, -C(CH_3)$_2$-O), and 1.60 (2H, s, -CH_2-).

Peroxyester 1f was prepared by a Schotten-Baumann reaction of the acid chloride with the corresponding hydroperoxide. To a mixture of 97.0% 1,1-dimethyl-2-phenylethyl hydroperoxide (17.1 g, 0.10 mol) there was added dropwise the acid chloride (14.5 g, 0.12 mol) for 15 min at 25 °C, and stirred for 10 min at 10 °C to complete the reaction. The reaction mixture was washed once with 5% NaOH, three times with water and dried over anhydrous $MgSO_4$. After the evaporation of the solvent under vacuum, a crude product of 90.0% purity (24.0 g, yield 72.0%) was obtained and purified by flash chromatography on Merck Kieselgel 60 using hexane-ethyl acetate (95:5) as the eluent to give the peroxyester of 94.0% purity. IR (CCl_4): $\nu_{C=O}$

1762 cm^{-1}; phenyl 1600 cm^{-1}; ^1H NMR (CCl_4): δ=1.25 (9H, s, acyl *t*-Bu), 2.83 (2H, s, $PhCH_2$-), and 7.12 (5H, s, phenyl).

Kinetic Procedure. A dilute solution of peroxyester in cumene or acetonitrile was placed in sealed tubes under vacuum and heated in a constant-temperature bath. The remaining amount of peroxyester was determined by the above-mentioned iodometric titration for peroxyester, in which the sample solutions were allowed to stand at room temperature for 15—30 min. The reaction was followed up to 70—80% decomposition and exhibited first-order kinetics.

Decomposition Products. Peroxyester at the concentration of 0.05 mol dm^{-3} in cumene was decomposed completely at 60 °C over 50 h and the solution were analyzed by GC using nonane and decane as internal standards. The following are the conditions used in determining yield of products (product, column): acetone, 1,1-dimehylethyl alcohol, 1,1-dimethylpropyl alcohol, 1,1-dimethylbutyl alcohol and 1,1,2-trimethylpropyl alcohol for **1a**, **1b**, **1c**, and **1e**, column B; acetone and 1,1-dimethyl-2-phenylethyl alcohol for **1f**, column C; 1,1,3,3-tetramethylbutyl alcohol for **1d**, column D; acetone for **1d**, column E.

Synthesis of Cyclic Polysulfides. Reactions of Dithiols and Related Compounds with Elemental Sulfur in Liquid Ammonia[1)]

Ryu SATO,* Satoru SAITO, Hiroshi CHIBA, Takehiko GOTO, and Minoru SAITO
Department of Resource Chemistry, Faculty of Engineering, Iwate University, Morioka 020
(Received August 31, 1987)

Many cyclic polysulfides, i.e., benzopentathiepins (**3a—d**), 6*H*-1,2,3,4,5-benzopentathiocin, 5*H*-1,2,3,4-benzotetrathiepin, 3*H*-1,2-benzodithiole, 1,5-dihydro-2,3,4-benzotrithiepin, 1,4-dihydro-2,3-benzodithiin, naphtho[1,8-*cd*]-1,2-dithiole, 1,2,3-trithiane, 1,2-dithiane, 2,3,4,5-tetrathiabicyclo[4.4.0]decane, and 2,3,4,5,6-pentathiabicyclo[5.4.0]undecane, were synthesized in high yields by new reactions of their corresponding dithiols and related compounds, 1,3-benzodithiole-2-thiones (**5**) and 1,3-dithiolane-2-thione, with elemental sulfur in liquid ammonia at ambient temperature. In the synthesis of **3a—d** from 1,2-benzenedithiol or **5**, considerable increase in the product yield was observed upon adding 1,3-dinitrobenzene to the solvent used in work-up.

Much interest of organic sulfur chemists has centered on cyclic polysulfides from the viewpoint of synthesis of natural products which show biological activity, such as lenthionine (**1**)[2)] and sporidesmin (**2**)[3)]. Various procedures for the synthesis of these compounds have been developed in the past few years.[4)]

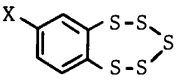
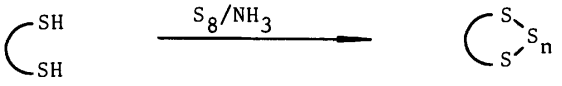
2



3

Scheme 1.

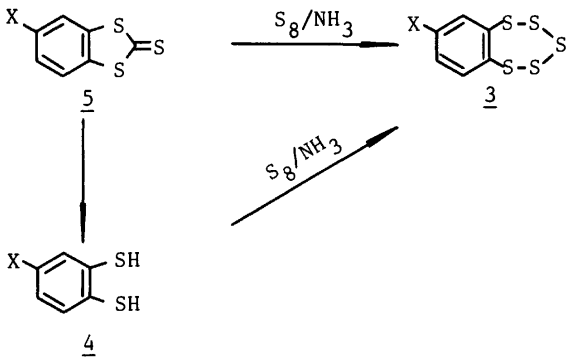
There have been published a few reports[5)] on the synthesis of sulfur containing compounds such as benzopentathiepins (**3**). Very recently, Chenard et al.[5)] reported the synthesis of **3** from benzothiadiazoles with elemental sulfur in the presence of 1,4-diazabicyclo[2.2.2]octane (DABCO) at high temperatures such as 180 °C in moderate yields, and **3** were shown to have acaricidal and fungicidal effects.[6)] In the course of our studies on the reactions of organic compounds with elemental sulfur in liquid ammonia,[7)] we have reported on synthesis of polysulfides from corresponding thiols.[8)] The above situation urged us to pursue a new synthesis of various cyclic polysulfides from corresponding dithiols and related compounds with elemental sulfur in liquid ammonia. Consequently, we could obtain many cyclic polysulfides **3, 7, 8, 9, 11, 12, 14, 17, 19, 21**, and **22** in moderate to excellent yields (Scheme 2). Moreover, in the case of synthesis of **3**, addition of 1,3-dinitrobenzene in the work-up procedure was found to increase the yield of **3**. This effect was explained in terms of the electron-transfer effect of thiolate species which accelerates the formation of sulfur–sulfur bond.



Scheme 2.

Results and Discussion

1,2-Benzenedithiols **4a** and **4b** and other dithiols **6, 10, 13, 15, 16,** and **18** or their synthetic equivalents such as 1,3-dithiole-2-thiones **5a—d** and 1,3-dithiolane-2-thione **20** were chosen as substrate for the synthesis of cyclic polysulfides and allowed to react with elemental sulfur in liquid ammonia, affording desired cyclic polysulfides together with an unidentified polymer (Scheme 3). As a typical synthesis of cyclic polysulfides, an optimization of the synthesis of **3** was studied.



Scheme 3.

1,3-Benzodithiole-2-thione (**5a**) as a substrate gave better yields of **3** than **4** did (Runs 2, 4, 7, 12, and 13, Table 1). The quantity in equivalents of elemental sulfur used affected considerably the yields of **3**. For example, a use of 3 or 5 mg atom of elemental sulfur (6 or 10 milli equivalents, respectively) gave **3a** quantitatively (Runs 4 and 5), but in a reaction using 0.5 mg-atom of elemental sulfur the desired **3a** was

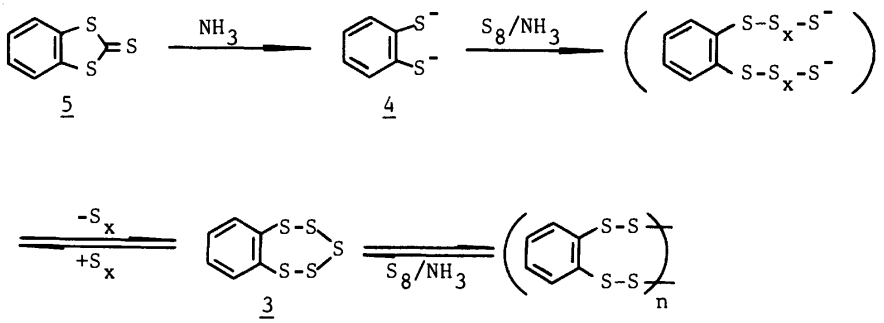
a) Reaction conditions: reaction temp, 20 °C; reaction time, 0.5 h; liquid ammonia, 30 ml; substrate, 0.5 mmol; solvent, 80 ml. b) These solvents were used in work up. c) 1,3-Dinitrobenzene. d) Isolated yield based on the substrate. Yields in the absence of 1.3-dinitrobenzene are shown in parentheses.



Scheme 4.

obtained only in 2% yield (Run 6). Only a trace of **3a** was obtained when no solvent was used in the work up of reaction and a use of an organic solvent such as dichloromethane or benzene significantly improved the yield of **3a** as shown in Table 1 (Runs 1—4; see Experimental). Moreover the kind of the solvent used in the work up also influenced the yield of benzopentathiepin **3**. Thus, the best yield was achieved when benzene was employed (Runs 2—4). These solvent effects may be accounted for in terms of the dilution effect of solvent which inhibits the collision of reactive species such as thiolate. A generality of the synthesis of **3** is indicated by Runs 7—11. We could not, however, obtain 5-nitro-1,2,3,4,5-benzopentathiepin (**3e**) by the present method. It should be noted that **3a** is obtained in a better yield (Run 4) from **5** than from **4** (Run 12), which is generally obtained by solvolysis of **5** (Scheme 3). In these reactions seven-membered benzopentathiepin **3a** was the sole isolated and stable product. Our further important finding is that a considerable increase in the yield of **3** was observed by addition of 1,3-dinitrobenzene to the solvent used in the work up (Runs 2, 7—10, and 12; see Experimental). In the absence of 1,3-dinitrobenzene, the amount of unidentified polymer increased. Interestingly, **3a** was also obtained by treating the polymer with elemental sulfur in liquid ammonia under similar conditions. Based on the above results, it seems that there are certain equilibriums between **3** and the polymer in both the reaction mixture and the work-up solution, and that 1,3-dinitrobenzene serves as a trapper of electron from thiolate intermediates to accelerate the formation of sulfur-linked product **3**, since it is well-known that 1,3-dinitrobenzene can trap one electron in electron-transfer systems. Plausible pathways of this reaction are depicted in Scheme 4.

To extend this method to other compounds, some dithiols, e.g., 1,2-bis(mercaptomethyl)benzene (**10**) and 1,3-propanedithiol (**16**), were treated with elemental sulfur in liquid ammonia similarly to **3**. Ten desired cyclic polysulfides **7, 8, 9, 11, 12, 14, 17, 19, 21,** and **22** were consequently obtained in moderate yields as shown in Table 2. It is noteworthy that the first two cyclic polysulfides having one benzylic methylene group were obtained by the reaction of 2-(mercaptomethyl)benzenethiol (**6**). Thus, an eight-membered ring product, 6*H*-1,2,3,4,5-benzopentathiocin (**7**), and a seven-membered ring compound, 5*H*-1,2,3,4-benzotetrathiepin (**8**), were obtained together with a five-membered ring product, 3*H*-benzo[*d*]-1,2-dithiole (**9**).

The ^{1}H NMR spectra of **8** showed a peak at δ=4.77 (AB pattern, $\Delta\delta$=0.96, J=16 Hz, 2H) characteristic of the two protons of the methylene group, whereas the methylene group in **7** appeared in a singlet peak at δ=4.41. Measurements of the molecular weights of the new compounds **7** and **8** by the Rast method gave the values of 283 and 235 respectively,[9] suggesting that the products **7** and **8** were not dimerized compounds. Similarly, a six-membered cyclic disulfide, 1,4-dihydro-2,3-benzodithiin (**12**), and 1,5-dihydro-2,3,4-benzotrithiepin (**11**) were obtained as expected when **10** was treated with elemental sulfur in liquid ammonia under similar conditions, as shown in Table 2. These results suggest that one, two, or three sulfur atoms in the molecule were incorporated from elemental sulfur to form the stable seven- or eight-membered ring compounds **7, 8, 9, 11,** and **12**. 1,8-Naphthalenedithiol (**13**) did not incorporate any sulfur atoms at all upon being treated with elemental sulfur, but naphtho[1,8-*cd*]-1,2-dithiole (**14**) was formed quantitatively. The formation of **14** may be explained on the basis of facile sulfur–sulfur bond formation to give the stable product **14**, since the two sulfur atoms in **13** lie close to each other at the peri position of the naphthalene ring. Subsequently, cyclizations of α,ω-alkanedithiols, 1,2-ethanedithiol (**15**), **16** and 1,4-butanedithiol (**18**), with elemental sulfur in liquid ammonia were carried out in a similar manner. Except the reaction of **15**, two expected six-membered cyclic polysulfides, 1,2,3-trithiane (**17**) and 1,2-dithiane (**19**), were obtained from the corresponding dithiols **16** and **18**, respectively. An unidentified polymer was mainly formed in the reaction of **15**. The results of the reactions of **16** or **18** suggest that these six-membered products are very stable in this system, in contrast to the results of the reactions of **6** or **10**.

Table 2. Synthesis of Cyclic Polysulfides **7, 8, 9, 11, 12, 14, 17, 19, 21,** and **22** with Elemental Sulfur in Liquid Ammonia

Run	Substrate	Condition	Solvent	Product (Yield/%) and Mp θ_m/°C (lit)		
1	 **6**	A	CH_2Cl_2	 **7** (18) 61	 **8** (31) 49	**9** (36) oil[15]
2	 **10**	A	CH_3CN	 **11** (57) 101 (101)[16]	 **12** (26) 78 (78)[17]	
3	**13**	B	Benzene	 **14** (98) 122 (123)[13]		
4	HS-CH_2CH_2-SH **15**	B	Benzene	Polymer		
5	HS-$(CH_2)_3$-SH **16**	B	CH_3CN	**17** (38) 46 (46)[18]		
6	HS-$(CH_2)_4$-SH **18**	C	DMF	**19** (50) 34 (31)[19]		
7	 **20**	D	CH_3CN	 **21** (28) 88 (89)[20]	 **22** (35) 68 (67)[20]	

a) Substrate, 0.5 mmol; liquid ammonia, 30 ml; solvent, 80 ml. b) Reaction conditions, A: r.t., 0.5 h, and 6 equiv of S_8. B: r.t., 2 h, and 6 equiv of S_8. C: r.t., 2 h, and 3 equiv of S_8. D: 40 °C, 3 h, and 6 equiv of S_8.

The 1,3-dithiolane-2-thione containing a cyclohexane ring, **20**, also reacted with elemental sulfur in liquid ammonia at 40 °C to give two correspoding cyclic polysulfides **21** and **22** in moderate yields (Run 7, Table 2).

In conclusion, **3** and analogous cyclic polysulfides **7**, **8**, **9**, **11**, **12**, **14**, **17**, **19**, **21**, and **22** were synthesized by this new method, which has a great advantage over precedent methods in that high yields may be obtained under mild conditions. Since these cyclic polysulfides are well known to exhibit remarkable properties and especially **3** are soluble in usual organic solvents, the use of **3** as sulfurization reagents is extensively applicable. These studies are now under progress in our laboratory.[10]

Experimental

All melting points were measured by the capillary method and uncorrected. IR spectra were obtained on a Hitachi 295 spectrophotometer, and ^{1}H NMR spectra were obtained on a Hitachi R-22 spectrometer by using tetramethylsilane as an internal standard. All reactions were monitered by TLC (Merck Kieselgel 60-GF). The silica gel used for column chromatography was Wako gel C-200. Mass spectra were taken with a Hitachi RMU-6M mass spectrometer. Elemental analyses were carried out with a Yanagimoto MT-3.

Materials. All reagents were obtained from Wako Pure Chemical Industries Ltd., Tokyo Kasei Co., Ltd., or Aldrich Chemical Co. The reagents were further purified by general methods. 1,3-Benzodithiole-2-thiones (**5**) were synthesized from 2-aminobenzenethiol by the literature method.[11] 1,2-Benzenedithiols (**4**) were obtained by hydrolysis of **5**.[11] **6** was synthesized from bis(2-carboxyphenyl) disulfide by thiation with phosphorus pentasulfide followed by reduction with lithium aluminium hydride.[12] **10** was obtained from 1,2-bis(bromomethyl)benzene by the literature method.[4] **13** was given by two-step synthesis from 1,8-dichloronaphthalene.[13] **15**, **16**, and **18** were commecially available. Hexahydro-1,3-benzodithiole-2-thione (**20**) was prepared from cyclohexene oxide with potassium hydroxide and carbon disulfide by the literature method.[14]

Reactions of Dithiols 4a-b, 6, 10, 13, 15, 16, and 18, 1,3-Benzodithiole-2-thiones 5a—e or 1,3-Dithiolane-2-thione 20 with Elemental Sulfur in Liquid Ammonia. A typical procedure is as follows: **5a** (0.5 mmol) and elemental sulfur (3.0 mg atom) were taken into a titanium autoclave (volume 50 ml) and the autoclave was evacuated. Liquid ammonia (30 ml) was charged and then the mixture was stirred at 20 °C for 0.5 h. After completion of the reaction, the reaction mixture in liquid ammonia was added dropwise to benzene (80 ml) containing 1,3-dinitrobenzene (0.5 mmol) through a needle bulb and the solution was stirred at room temperature until liquid ammonia was evaporated completely (for about 2 h). An evaporation of benzene under vacuum and a subsequent column chromatography on silica gel (Wako gel C-200) using CCl_4/hexane as an eluent gave the desired benzopentathiepin **3a** (114 mg) as yellow crystals. The products were identified with ^{1}H NMR, IR, mass spectra, and elemental analyses. In the reaction of **6** with elemental sulfur in liquid ammonia, the yields of the products, **7** and **8**, were determined by the proton ratio for methylene groups in ^{1}H NMR spectra after separation of reaction mixture by column chromatography.

7-Amino-1,2,3,4,5-benzopentathiepin (3d): Yellow crystals (ether); mp 123 °C; IR (KBr) 1020, 1235, 1570, and 1620 cm^{-1}; ^{1}H NMR (CDCl) δ=4.01 (2H, br, $-NH_2$), 6.49 (1H, dd, J=9.0 and 3.0 Hz, arom), 7.02 (1H, d, J=3.0 Hz, arom) and 7.53 (1H, d, J=9.0 Hz, arom); MS m/z 251 (M^+). Found: C, 28.42; H, 1.92%. Calcd for $C_6H_5NS_5$: C, 28.66; H, 2.00%.

7: Yellow crystals (hexane/ether); mp 61 °C; IR (KBr) 450, 540, and 1400 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=4.41(2H, s, $-CH_2-$) and 7.18—7.72(4H, m, arom); MS m/z 250 (M^+). Found: C, 33.77; H, 2.39%. Calcd for $C_7H_6S_5$: C, 33.57; H, 2.42%.

8: Yellow crystals (hexane/ether); mp 49 °C; IR (KBr) 445, 735, and 1390 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=4.28 (1H, d, J=15.0 Hz, $-CH_2-$), 5.26 (1H, d, J=15.0 Hz, $-CH_2-$) and 7.03—7.73 (4H, m, arom); MS m/z 218 (M^+). Found: C, 38.43; H, 2.74%. Calcd for $C_7H_6S_4$: C, 38.50; H, 2.77%.

Compounds 3a—c, 9, 11, 12, 14, 17, 19, 21, and 22: These were identified by comparing spectral and physical data with those of authentic samples. See Tables 1 and 2.

Reactions of Polymer obtained from 4 or 5 with Elemental Sulfur in Liquid Ammonia. The polymer (100 mg) obtained by reaction of **4a** or **5a** with elemental sulfur in liquid ammonia was taken into titanium autoclave (volume 50 ml) and then, after evacuation, liquid ammonia (30 ml) was charged into the autoclave. The mixture was allowed to react at 20 °C for 0.5 h. The reaction mixture obtained was treated in a similar manner as in the reaction of **5a** with elemental sulfur in liquid ammonia. **3a** of 53 mg was obtained.

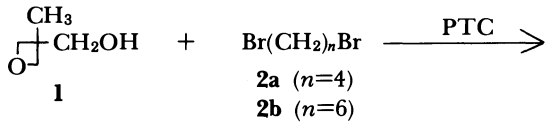
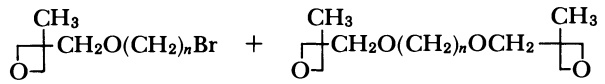
(Received September 16, 1987)

3-(6-Bromo-2-oxahexyl and 8-bromo-2-oxaoctyl)-3-methyloxetanes, and 1,8- and 1,10-bis(3-methyl-3-oxetanyl)-2,7-dioxaoctane and -2,9-dioxadecane were readily prepared in fairly good yields by the reaction of 3-hydroxymethyl-3-methyloxetane (**1**) with tetra- and hexamethylene dibromides in the presence of a phase-transfer catalyst. The formation of the mono- and disubstituted products depends upon the molar ratios of the dibromide to **1**. The optimum reaction conditions for the etherification of **1** with tetramethylene dibromide were searched. The (ω-bromo-2-oxaalkyl)oxetanes were polymerized to give soluble polyoxetanes ($\bar{M}_n$ 3500—5500) by cationic ring-opening polymerization. The use of the bisoxetanes, a new cross-linking agent, as a comonomer gave insoluble elastic polyoxetane resins having a pendant bromide at the spacer end.

In the course of our studies on the polymerization of the oxetanes and other cyclic ethers,[1-7] we hoped to synthesize oxetane derivatives for producing soft, somewhat polar polyoxetane resins; we found that the oxetane derivatives **3a**, **3b**, **4a**, and **4b** can be readily prepared by the etherification of 3-hydroxymethyl-3-methyloxetane (**1**) with α,ω-dibromoalkanes **2a** and **2b** in the presence of a phase-transfer catalyst (PTC).





So far, several chemical reactions of the substituents attached to the oxetane rings have been reported. Chlorine of the chloromethyl group at the C-3 position of the oxetane ring was replaced into alkoxyl, aryloxyl, acetoxyl, and azido groups by displacement reactions.[8-11] Macroheterocycles bearing one or two spiro-oxetane rings were synthesized from base-induced condensations of 3,3-bis(chloromethyl)oxetane with heteropolymethylene glycols.[12] Recently, several preparation methods for the oxetane ring with various substituents have also been reported.[13-19]

Oxetanes **3a** and **3b** seem to be very useful for designing a variety of the functional polyethers since the polymers possess long spacers of oxapolymethylenes, $-CH_2O(CH_2)_n-$ where n=4 or 6, and the terminal bromine that can be readily converted into various other functional groups. It is also known that lengthening the spacers having catalytic sites is important for realizing improved catalytic activities.[20] Furthermore, the bisoxetanes **4a** and **4b** are expected to react as bifunctional monomers to give insoluble polyoxetane resins. In this paper, we describe a facile preparation of new oxetane derivatives, which give their soluble and insoluble polymers by cationic ring-opening polymerization; we also discuss reaction courses for obtaining the optimum conditions for preparing such oxetanes by phase-transfer catalysis. Related to the present study, compounds containing two oxetane rings were reported: bis[(3-methyl- and 3-ethyl-3-oxetanyl)methyl] hexanedioates[21] and 2,6-dioxaspiro[3.3]heptane.[22]

Results and Discussion

Preparation of Monomers. The monomers, **3a** and **3b**, carrying ω-bromo-2-oxaalkyl groups were synthesized by the reaction of **1** with α,ω-dibromoalkanes **2a** and **2b** in the presence of tetrabutylammonium bromide (TBAB) or hydrogen sulfate (TBHS) as PTC. **3a** and **3b** reacted further with **1** to give bisoxetanes **4a** and **4b** under the same reaction conditions. The formation of these oxetane derivatives as a main product depends on the mole ratio of the dibromide to **1**. The etherification reaction was examined under several conditions concerning the mole ratio, the PTC, and the solvent. The yield of the product was determined at a given reaction time by gas chromatography (GC) using hexadecane as an internal standard. The results are summarized in Table 1. When the reaction of **1** with a threefold molar equivalent of **2a** was carried out under refluxing in hexane and 50% aqueous NaOH with TBAB (5% molar respect to **1**), **3a** and **4a** were produced in 81.1 and 14.6% yields, respectively, indicating that more than 96% of **1** was consumed to produce the two products (Run no. 7). **2a** remained unchanged in a 29% recovery, suggesting that a considerable amount of **2a** is consumed by side reactions (vide infra). The decrease in the mole ratio was favorable for the formation of **4a**. The reaction at

a) **1**, 2.06 mmol; PTC, 5% molar respect to **1**; n-$C_{16}H_{34}$ (as internal standard), 1.06 mmol; volume of organic layer was adjusted to 3 ml by adding hexane; 50% NaOH, 2.7 g; under reflux. b) Phase-transfer catalyst (PTC): TBAB and TBHS refer to tetrabutylammonium bromide and hydrogen sulfate, respectively. c) Determined by GC. Value in parenthesis indicates isolated yield of reaction using 10 or 30 g of **1**. d) After 1.5 h, **2a** was not detected and **5** was formed in 17.0% yield. e) After 0.5 h, 29.2% of **2a** fed was left unchanged and no **5** was detected.

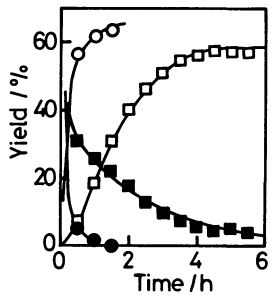

Fig. 1. Time-yield curves of **3a** (●, ■) and **4a** (○, □) in the reaction between **1** and **2a** at a 1:1 mole ratio in the presence of TBAB: (■, □) 0.7; (●, ○) 5.0 mol% to **1**.

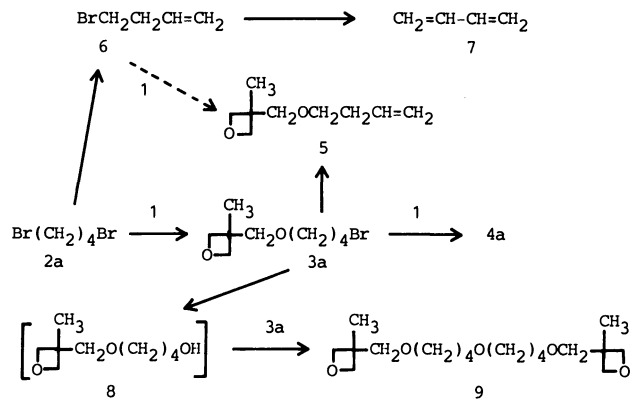
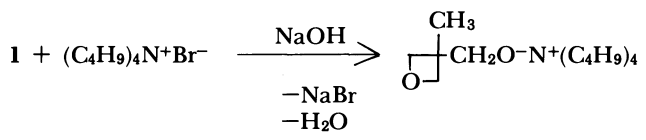


Scheme 1.

mole ratios of 1.0 to 1.2 gave **4a** in maximum yield of about 63% (Run nos. 3 and 4), which is higher than the yield of the reaction at the stoichiometric mole ratio of 0.5 (Run no. 1). At mole ratios below 1.0, all of the **2a** fed was consumed to form **4a** and by-products within at least 1.5 h. However, **1** remained, even when **2a** was completely consumed, as indicated from the following fact: when **2a** (half the amount used in the original reaction) was added into the reaction mixture upon the complete consumption of **2a** and was then allowed to react for 2 h, the yield of **4a** increased from 52 to 68% (Run no. 2). The etherification of **1** with **2a** proceeded very slowly in the absence of PTC: the yield of **3a** was only 5% after 1.5 h (Run no. 12). Therefore, PTC is obviously required for preparing oxetane derivatives. Figure 1 shows the time-product yield curves in the reaction of **1** with **2a** at a **2a**/**1** mole ratio of 1.0 in the presence of TBAB in 0.7 and 5.0 mol% to **1**. As shown in the curve of the reaction with 0.7 mol% TBAB, the yield of **4a** increases with an increase of the reaction time, while the yield of **3a**, which is produced as a main product in the early period of the reaction, decreases. This fact indicates that **3a** is an intermediate in the formation of **4a**, the rate of which can be lowered by decreasing the amount of PTC.

3-Methyl-3-(2-oxa-5-hexenyl)oxetane (**5**) was obtained as a low-boiling fraction of the reaction mixture from **1** and **2a**. Therefore, it should be considered that the such bromides as **2a** and **3a** are led to elimination products under applied phase-transfer catalytic condi-



tions. The alkoxide anion of **1**, formed in a concentrated alkaline solution, transfers to an organic layer, together with a quarternary ammonium countercation. In the organic layer the alkoxide anion acts not only as a nucleophile in the substitution but also as a base in the elimination of the bromides. Actually, the odor of 1,3-butadiene (**7**) came out from the top of a water-cooled condenser during the early stage of the reaction of **1** with **2a**.

To investigate the material balance, reactions of the bromides as a substrate were carried out in hexane and 50% aqueous NaOH in the presence of TBAB (Table 2). In reactions at **3a**/**1** mole ratios of 0.5 and 1.0 (Run nos. 13 and 14), **4a** was detected in about 55% yield together with **5** in 32% yield after 1.5 h, at which time the starting material, **3a**, disappeared completely. The reaction between **3a** and **1** at a ratio of 2.0 gave **4a** in a 80.7% yield (40.4% conversion of **3a**) after 1.5 h; an additional 1-h reaction resulted in an increase of only 2% yield of **4a**, while the **3a** recovery decreased from 14.4 to 8.3% (Run no. 15). In these reactions of **3a** with **1** (Run nos. 13, 14, and 15), therefore, 13 to 21% of **3a** was consumed to produce unknown products. When **3a** was heated in a concentrated alkaline solution, no **3a** and a 32% yield of **5** were detected after 14 h, although at an early stage of the 0.5-h reaction, **5** was hardly detectable in spite of the consumption of 21% of the **3a** which was fed (Run no. 16). A pot residue of distillation from this reaction mixture was identified as being 1,13-bis(3-methyl-3-oxetanyl)-2,7,12-trioxatridecane (**9**). This product is probably formed from an etherification reaction of **3a** with the alcohol **8** derived from the bromide **3a** by its hydrolysis (Scheme 1). On the other hand, 98% of **3a** was left unchanged after heating a mixture of **3a** and threefold molar equivalent of **2a** under the same conditions as above (Run no. 17). In the absence of **1**, **2a** itself was stable under the present conditions (Run no. 18). The oxetane ring was also found to be stable under the present conditions, because the structure of 3-methyl-3-(2-oxadecyl)oxetane (**10**) was not altered upon treatment with the alkaline solution (Run no. 19). These findings lead to the following: (1) The existence of a sufficient amount of **2a** under phase-transfer catalytic conditions seems to prevent side reactions of bromide **3a**, though it is difficult at this point to explain why **2a** prevents the side reactions. (2) The reaction of **1** with 4-bromo-1-butene (**6**) is unimportant, since **5** is not produced in the reaction at a **2a**/**1** mole ratio of 3.0. Presumably, **6** is almost exclusively consumed to give **7** by an elimination reaction, but not to form **5** by a substitution reaction from **1** and **6**. (3) The elimination reaction of **3a**, which occurs during the existence of **1** (or its alkoxide anion), is also restrained by using a sufficient amount of **2a**. (4) In the reaction for preparing the bisoxetanes, the existence of an adequate amount of **2a** is required in

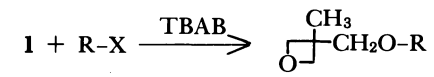
				2.0	(99.7)[c]			

a) Reactant A, 2.11 mmol; PTC, TBAB in 5% molar respect to reactant B (to reactant A in Run nos. 16, 18, and 19); 50% NaOH, 2.7 g; volume of organic layer was adjusted to 3 ml by addition of hexane; under reflux. b) As internal standard of GC determination, n-$C_{16}H_{34}$ (1.05 mmol) was used for **3a** and **4a**, and n-$C_{10}H_{22}$ (3.15 mmol) for **2a** and **5**. Value in parenthesis indicates recovery of the reactants. c) Value for remaining **10**.

order to avoid an elimination reaction of **3a**, until **1** is completely consumed to give **4a** from **3a** as an intermediate.

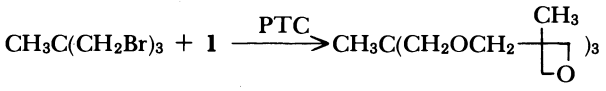
The use of ether as a solvent gave a yield of **3a** comparable to that in a reaction using hexane, though the use of benzene resulted in a lower yield (Run nos. 8 and 9). With TBHS, a slightly lower yield of **3a** was determined by GC, even when using hexane and ether (Run nos. 10 and 11).

Thus, **3a** and **4a** were isolated in 76.2 and 63.7% yields, respectively, from reactions at mole ratios of 3.0 and 1.2 on a preparative scale using 10 or 30 g of **1** and hexane as a solvent (Run nos. 7 and 4). The preparation results concerning the other ocetane derivatives are indicated in Table 3. In the same way as above, **3b** and **4b** were isolated, respectively, in 73.4 and 62.8% yields from the reactions at mole ratios of 3.0 and 1.0. Octyl bromide (**11a**) and benzyl chlorides **12a** and **12b** are used well as halides for the etherification of **1**. With the bromide **11a**, **10** was isolated in 92.9% yield, although the reaction with the chloride **11b** gave **10** in only 2% yield. The reaction of **1** with benzyl chlorides should be performed at a mole ratio of 1.0 to give sufficient yields. The use of a molar excess of benzyl chlorides toward **1** resulted in the formation of a considerable amount of dibenzyl ethers, which could hardly be removed from the desired products by fractional distillation.



11a R=*n*-C_8H_{17}, X=Br **10** R=*n*-C_8H_{17}
11b R=*n*-C_8H_{17}, X=Cl **13a** R=$C_6H_5CH_2$
12a R=$C_6H_5CH_2$, X=Cl **13b** R=(*p*)-$CH_3C_6H_4CH_2$
12b R=(*p*)-$CH_3C_6H_4CH_2$, X=Cl

An etherification reaction of **1** with tribromide **14** did not take place to give the desired product **15**, resulting in a 86% recovery of **14**, isolated by distillation. This indicates that a nucleophilic attack of the alkoxide anion of **1** onto the α-carbon of the bromide **14** is difficult, since this α-carbon is quite similar to that of neopentyl bromide which has difficulty in being susceptible to the S_N2 reaction.



14 **15**

The etherification of **1** with **2a** gave a remarkably low yield by the Williamson synthesis using dry solvents, since the sodium alkoxide of **1**, which was prepared from **1** and sodium metal or sodium hydride, was hardly soluble in tetrahydrofuran (THF), *N,N*-dimethylformamide (DMF), and ether. On the contrary, the desired ethers were obtained in fairly good

yields by a facile operation using less expensive reagents under the present phase-transfer catalytic conditions.

Polymerization. Oxetanes, thus obtained, were polymerized to give their polymers ($\bar{M}_n$2000—5500) via a cationic ring-opening polymerization in dichloromethane (DCM) at 0 °C with trifluoroborane (BF_3)–THF complex as an initiator (Table 4). The polyoxetanes were viscous oily materials soluble in DCM, chloroform, ether, acetone, benzene, toluene, and DMF, and reprecipitated from a solution of the polymer in DCM by adding it into methanol. The IR spectra of **3a**, poly(**3a**), and poly(**4a**) are shown in Fig. 2. In Fig. 2A, the bands at 980 and 835 cm^{-1} are assignable to the cyclic ether linkage of the oxetane ring. These bands disappear in the spectra of poly(**3a**) and poly(**4a**), in which the band due to the acyclic ether linkage of the resultant polyether chain appears at 1100—1120 cm^{-1}. Methylene protons of the oxetane ring of **3a** show signals of an AB qualtet in δ 4.25—4.65; however, the signals disappear in the spectrum of poly(**3a**) (Fig. 3). Use of bisoxetanes **4a** and **4b** as a comonomer in the polymerization of **3a** and **3b** gave gel products which were insoluble in the solvents, indicating that these polymeric products have the cross-linked structures of a polyether network. These polyoxetane resins are considered to be soft, somewhat polar polymer supports bearing a bromide at the spacer end, which will be used for preparing functional polyethers according to the way employed for the functionalization of a hard, less polar, crosslinkd polystyrene having a chloromethyl group.[23–25]

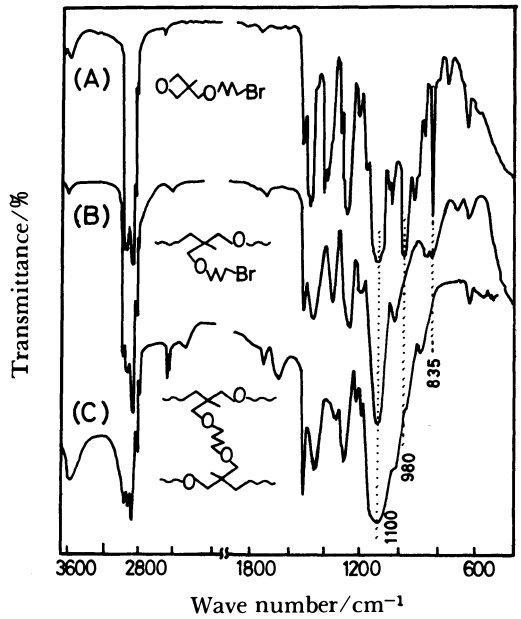

Fig. 2. IR spectra of (A) **3a**, (B) poly(**3a**), and (C) poly(**4a**).

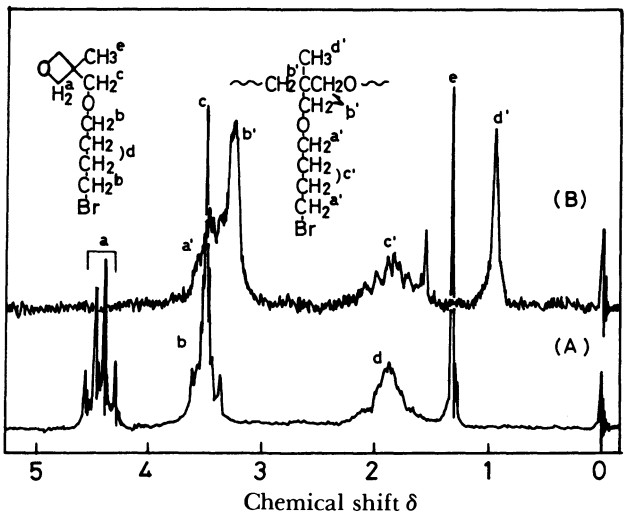

Fig. 3. ^1H NMR spectra of (A) **3a** and (B) poly(**3a**).

Experimental

Materials. 3-Hydroxymethyl-3-methyloxetane (**1**) was prepared in 60—62% yield according to a method described in the literature.[14] Oxetane (OX) and 3,3-dimethyloxetane (DMOX) were synthesized according to a method reported in the literature.[26] Halides **2a**, **2b**, **11a**, **11b**, **12a**, and **12b**, and hexane of extra pure grade reagents were used without further purification. DCM as a solvent of polymerization was twice distilled over calcium hydride in a nitrogen atmosphere. A BF_3–THF complex was obtained by passing BF_3 gas into dried THF, followed by distillation of the saturated solution: bp 87.8 °C (1.60 kPa) [lit,[27] 79.0 °C (0.96 kPa)]. Commercially available TBAB and TBHS (Tokyo Kasei Kogyo) were used as PTC without further purification.

3-(6-Bromo-2-oxahexyl)-3-methyloxetane (3a): In a three-necked flask, equipped with a mechanical stirrer, a thermometer, and a reflux condenser, a 50% aqueous NaOH solution (390 g), TBAB (4.7 g, 14.7 mmol), and hexane (300 ml) were placed and cooled in an ice-bath. A mixture of **1** (30.0 g, 0.29 mol) and **2a** (190 g, 0.88 mol) was added into it with efficient stirring and cooling. It was kept at room temperature for 30 min and then refluxed for 1.5 h. It was cooled below 5 °C and 600 ml of water was added. The organic layer, which was separated by means of separatory funnel, was dried over anhydrous Na_2SO_4. After removing the solvents and recovering **2a** (52 g) by distillation, the residue was distilled to give 53.1 g (76.2%) of **3a**: bp 110—112 °C (63—64 Pa); IR (neat) 1115 (acyclic ether), 980 and 835 (cyclic ether) cm^{-1}; ^1H NMR($CDCl_3$) δ=1.32 (3H, s, CH_3), 1.5—2.3 [4H, m, $OCH_2(C\underline{H}_2)_2CH_2Br$], 3.3—3.7 [4H, m, $OC\underline{H}_2(CH_2)_2C\underline{H}_2Br$, containing a singlet (2H) of CH_2 adjacent to oxetane ring at δ 3.49], and 4.25—4.65 (4H, q, J=6 Hz, CH_2 of oxetane ring).

Found: C, 45.77; H, 7.45; Br, 33.43%. Calcd for $C_9H_{17}BrO_2$: C, 45.58; H, 7.24; Br, 33.69%.

3-(8-Bromo-2-oxaoctyl)-3-methyloxetane (3b): 3b was prepared from **1** (14.0 g, 0.14 mol) and **2b** (100 g, 0.41 mol) in a 73.4% yield in the same way as that described for preparing **3a**: bp 95—97 °C (67 Pa); IR (neat) 1120 (acyclic ether), 985 and 840 (cyclic ether) cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.22—2.22 [8H, m, OCH_2 $(C\underline{H}_2)_4CH_2Br$, containing a singlet (3H) of

CH_3 at δ 1.32], 3.30—3.70 [4H, m, $OCH_2(CH_2)_4CH_2Br$, containing a singlet (2H) of CH_2 adjacent to oxetane ring at δ 3.52], 4.33—4.63 (4H, q, J=6 Hz, CH_2 of oxetane ring).

Found: C, 50.07; H, 8.12; Br, 30.20%. Calcd for $C_{11}H_{21}BrO_2$: C, 49.81; H, 8.00; Br, 30.13%.

1,8-Bis(3-methyl-3-oxetanyl)-2,7-dioxaoctane (4a): Bis-oxetane **4a** was prepared from **1** (10.0 g, 97.9 mmol) and **2a** (25.4 g, 0.12 mol) in the same way as that described for the **3a** preparation. Working up the reaction mixture followed by distillation of the crude product gave pure **4a** in a 63.7% yield: bp 124—126 °C (69—71 Pa); IR (neat) 1110 (acyclic ether), 985 and 840 (cyclic ether) cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.32 (6H, s, CH_3), 1.53—2.02 [4H, m, $OCH_2(CH_2)_2CH_2O$], 3.33—3.76 [4H, m, $OCH_2(CH_2)_2CH_2O$, containing a singlet (4H) of CH_2 adjacent to oxetane ring at δ 3.50], and 4.31—4.62 (8H, q, J=6 Hz, CH_2 of oxetane ring).

Found: C, 65.12; H, 10.20%. Calcd for $C_{14}H_{26}O_4$: C, 65.07; H, 10.16%.

1,10-Bis(3-methyl-3-oxetanyl)-2,9-dioxadecane (4b): This compound was prepared from **1** (10.0 g, 97.9 mmol) and **2b** (23.9 g, 97.9 mmol) using the same procedure as above: yield, 62.8%; bp 129—130 °C (55 Pa); IR (neat) 1110 (acyclic ether), 980 and 830 (cyclic ether) cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.15—1.95 [8H, m, $OCH_2(CH_2)_4CH_2O$, containing a singlet (6H) of CH_3 at δ 1.31], 3.25—3.75 [4H, m, $OCH_2(CH_2)_4CH_2O$, containing a singlet (4H) of CH_2 adjacent to oxetane ring at δ 3.49], 4.25—4.65 (8H, q, J=6 Hz, CH_2 of oxetane ring).

Found: C, 66.80; H, 10.74%. Calcd for $C_{16}H_{30}O_4$: C, 67.08; H, 10.58%.

3-Methyl-3-(2-oxadecyl)oxetane (10): In the presence of TBAB (4.9 mmol), **1** (10.0 g, 97.9 mmol) and **11a** (56.7 g, 0.29 mol) were heated for 12 h in a 50% NaOH solution (130 g) and hexane (100 ml) with stirring under reflux. The ordinary work-up and distillation gave pure **10** in a 92.9% yield: bp 152.5—153.0 °C (2.4 kPa); IR (neat) 1110 (acyclic ether), 980 and 830 (cyclic ether) cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.72—1.97 [total 18H, CH_3 adjacent to oxetane ring and $OCH_2(CH_2)_6CH_3$], 3.31—3.71 [total 4H, a singlet of CH_2 adjacent to oxetane ring and multiplet of $OCH_2(CH_2)_6CH_3$], and 4.31—4.61 (4H, q, J=6 Hz, CH_2 of oxetane ring).

Found: C, 72.68; H, 12.40%. Calcd for $C_{13}H_{26}O_2$: C, 72.83; H, 12.25%.

3-Methyl-3-(3-phenyl-2-oxapropyl)oxetane (13a): **1** (20.0 g, 0.196 mol) and **12a** (24.8 g, 0.196 mol) were allowed to react under reflux for 2 h in hexane (200 ml) and 50% NaOH in the presence of TBAB (9.8 mmol). The desired product **13a** boiling at 82—86 °C (72—83 Pa) was obtained in a 85.7% yield by fractional distillation: IR (neat) 3060, 3030, 1600, 1585, 1500 (aromatic CH and C=C), 1100 (acyclic ether), 980, 840 (cyclic ether), 740 and 700 (monosubstituted aromatic ring) cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.34 (3H, s, CH_3), 3.56 (2H, s, CH_2OCH_2Ph), 4.31—4.61 [4H, q, J=5.5 Hz, CH_2 of oxetane ring, containing a singlet (2H) of CH_2Ph at δ 4.59], and 7.38 (5H, s, aromatic).

Found: C, 74.95; H, 8.41%. Calcd for $C_{12}H_{16}O_2$: C, 74.95; H, 8.40%.

3-[3-(4-Methylphenyl)-2-oxapropyl]-3-methyloxetane (13b): An equimolar mixture of **1** and **12b** in hexane was refluxed for 3 h under phase-transfer catalytic conditions. The ordinary work-up gave pure **13b** boiling at 86—88 °C (43 Pa) in a 73.9% yield: IR (neat) 1620, 1520 (aromatic C=C), 1100 (acyclic ether), 985, 840 (cyclic ether), 810 and 755 (para-substituted aromatic ring) cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.27 (3H, s, aliphatic CH_3), 2.30 (3H, s, aromatic CH_3), 3.44 (2H, s, CH_2 adjacent to oxetane ring), 4.22—4.70 [4H, q, J=6 Hz, CH_2 of oxetane ring, containing a singlet (2H) of CH_2Ar at δ 4.99], and 7.28 (4H, s, aromatic).

Found: C, 75.58; H, 9.08%. Calcd for $C_{13}H_{18}O_2$: C, 75.68; H, 8.81%.

3-Methyl-3-(2-oxa-5-hexenyl)oxetane (5): This compound was contained in a low-boiling fraction of the reaction mixture from **1** and **3a**. Repeated fractional distillation of this fraction gave **5** (98% purity by GC analysis): bp 75—80 °C (2.53 kPa); IR (neat) 1640 (C=C), 1110 (acyclic ether), 980 and 830 (cyclic ether) cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.30 (3H, s, CH_3), 2.13—2.57 (2H, m, $CH_2CH_2CH=CH_2$), 3.44—3.65 (2H, t, $CH_2CH_2CH=CH_2$, containing a singlet (2H) of CH_2 adjacent to oxetane ring at δ 3.50), 4.27—4.57 (4H, q, J=6 Hz, CH_2 of oxetane ring), 4.89—5.36 (2H, m, $CH=CH_2$), and 5.52—6.25 (1H, m, $CH=CH_2$).

1,13-Bis(3-methyl-3-oxetanyl)-2,7,12-trioxatridecane (9): **3a** (2.07 g, 8.73 mmol) was heated under reflux for 8 h in hexane (20 ml) and 50% NaOH (11 g) in the presence of TBAB (0.44 mmol). The contents was mixed with water (50 ml) and extracted with ether. The organic layer was separated from the aqueous layer and 0.96 g of **9** was obtained as a pot residue by distilling the organic layer at 200 °C (muximum temperature of bath)/33 Pa: IR (neat) 1115 (acyclic ether), 980 and 835 (cyclic ether) cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.32 (6H, s, CH_3); 1.45—1.90 [8H, m, $OCH_2(CH_2)_2CH_2O$], 3.20—3.70 [8H, m, $OCH_2(CH_2)_2CH_2O$, containing a singlet (4H) of CH_2 adjacent to oxetane ring at δ 3.48], and 4.28—4.57 (8H, q, J=6 Hz, CH_2 of oxetane ring).

2-Bromomethyl-2-methyl-1,3-dibromopropane (14): Into powdered 1,1,1-tris(hydroxymethyl)ethane (5.96 g, 49.6 mmol) in a three-necked flask, phosphorus tribromide (20.1 g, 74.3 mmol) was added drop by drop at 80 °C and the mixture was heated at 170 °C for 10 h. After adding ice (30 g) into the reaction mixture and standing overnight, a volatile fraction was collected by steam-distillation. An organic layer of the distillate was separated and distilled to obtain **14** boiling at 105—108 °C (1.60 kPa) in 31—37% yield: IR (neat): 1460, 1420, 1375, and 1270 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.29 (3H, s, CH_3) and 3.52 (6H, s, CH_2Br).

Cationic Ring-Opening Polymerization of Oxetanes. In a ground-glass test tube, dried and flashed with dry nitrogen gas, an oxetane was introduced by using a hypodermic injection under a nitrogen atmosphere. The monomer was diluted with DCM, and chilled at −50 °C, and mixed with a catalytic amount of BF_3–THF (as a 0.27 mol l^{-1} solution in DCM). After being closed with a ground-glass stopper, the test tube was transferred to an ice-bath and allowed to stand for 20 h. The contents, in the case of soluble polymer, was poured into methanol, and, in the case of gel product, filtered and washed with 10% aqueous methanol and methanol successively. The polymer was collected and dried at 80 °C for 8 h in vacuo.

Measurement. GC analysis of the products was performed in a Shimadzu GC-8A apparatus: glass column (3.2ϕ×1 m) packed with Silicone High Vaccum Grease (30%)/celite (80—100 mesh); carrier gas, He (66 ml min^{-1}); temp, 140 or 250 °C. The IR spectra were recorded on a JASCO A-202 spectrometer and ^1H NMR on a 60 MHz instrument (Hitachi R-24B) using TMS as an internal

standard. Molecular weight measurements were made by VPO in a Corona molecular weight apparatus (model 117).

Hydrolytic Metalloenzyme Models. Effects of AOT Reverse Micelles on the Hydrolysis of *p*-Nitrophenyl Picolinate Catalyzed by Zn^{2+} and Cu^{2+} Complexes of *N*-Alkyl-2-hydroxymethylimidazoles

Tsunehisa FUJITA, Yoichi INABA, Kenji OGINO, and Waichiro TAGAKI*
Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sugimoto 3, Sumiyoshi-ku, Osaka 558
(Received September 26, 1987)

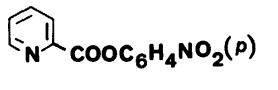
The catalytic effects of bivalent metal ion (Zn^{2+} and Cu^{2+}) complexes of *N*-alkyl-2-hydroxymethylimidazoles on the hydrolysis of *p*-nitrophenyl picolinate (PNPP) have been studied kinetically in the reverse micelles of AOT/hexane/water at 25 °C. The results were compared with those obtained in the non-micellar aqueous media and aqueous micelles. The hydrolysis was observed to occur through the acyl group transfer from PNPP to the ligand hydroxyl group in both cases of Zn^{2+} and Cu^{2+} ions and in all three non-micellar and micellar systems. However, the ligand:metal ion ratio in the kinetically active complexes was found to differ significantly in the three systems: there seems to exist general trends of 1:1, 2:1, and 4:1 stoichiometry in the ligand:metal ion ratio, depending on non-micellar aqueous media, aqueous micelles and reverse micelles, respectively. It was also noticed that the hydrolysis is always faster in micellar systems than in non-micellar aqueous media. Furthermore, a lipophilic ligand (*N*-dodecyl, Lig-12) was found to be more active than a hydrophilic ligand (*N*-methyl, Lig-1) under two micellar conditions.

The micellar catalysis has been extensively studied for the past two decades as the model of enzyme catalysis.[1] However, as for the micellar models of hydrolytic metalloenzymes, the studies appear to begin only recently.[2-7] In 1980, we reported that *N*-dodecyl-2-hydroxymethylimidazole (Lig-12) is remarkably active for the hydrolysis of *p*-nitrophenyl picolinate (PNPP) when complexed with Zn^{2+} ion and co-micelled in surfactant micelles in aqueous media.[2] Later studies revealed that Lig-12 is even more active in the presence of Cu^{2+} ion.[3]

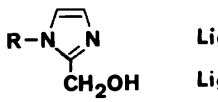
Besides the aqueous micelles, there are also known reverse micelles in apolar solvents. Namely, certain surfactants such as sodium 1,2-bis(2-ethylhexyloxycarbonyl)ethanesulfonate (AOT) can solubilize water in apolar organic solvents to form reverse micelles.[1] In such reverse micelles, the surfactant polar heads entrap water molecules as water pools in the cores, while the surfactant hydrocarbon chains extend toward the outer bulk organic solvent. Such water pools are said to resemble somewhat those entrapped in the active sites of enzymes. Therefore, it may be interesting to see what happen when the above hydrolysis is carried out in reverse micelles. To the best of our knowledge, there has been no such a study in the literature except those in aqueous micelles[2-7] as mentioned above. We now wish to report that the bivalent metal ion (Zn^{2+} and Cu^{2+}) complexes of *N*-alkyl-2-hydroxymethylimidazoles (Lig-1 and Lig-12) are very active for the hydrolysis of PNPP in the reverse micelles of AOT/hexane/water. The results were also compared with those obtained in the previous studies in aqueous micelles.[2,3] One might ask why the two metal ions, Zn^{2+} and Cu^{2+}, are particularly selected for comparison in this work. One reason is that they are widely different in the ability to activate coordinated hydroxyl group as a nucleophile. Another and more interesting reason comes from our recent finding that Zn^{2+} ion requires a tetrahedral geometry for the activation of hydroxyl group of bis(imidazole) ligands, while Cu^{2+} ion requires square planar geometry for the activation.[8]

Results and Discussion

The metal ion salts ($Zn(NO_3)_2$ and $Cu(NO_3)_2$) could be solubilized in hexane, only in the presence of both AOT and water. The water component of reverse micelles was the acetate buffer solution (0.1 mol·dm^{-3}, pH 4.9). The use of other buffer solutions of higher pH, such as lutidine buffer (pH 7) tended to cause the



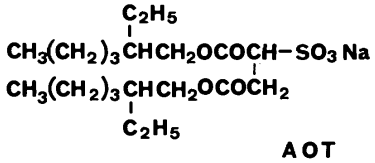
PNPP



Lig−1 R = CH_3

Lig−12 R = $C_{12}H_{25}$

metal ions : Zn^{2+}, Cu^{2+}



AOT

precipitation of metal ion hydroxide. Hence only acetate buffer was used in this study. Rates of hydrolysis were determined by measuring released *p*-nitrophenol spectrophotometrically at 310 nm. In all cases, under the conditions containing excess amount of ligand over the substrate (PNPP), good pseudo-first-order rate constants (k_{obsd}) were obtained up to the completion of hydrolysis.

Effects of AOT and Water. As shown in Fig. 1, the rates (k_{obsd}) increased initially up to a maximum, then decreased with increasing AOT concentration. Here the concentrations of water and Lig-12 also increased with increasing AOT, while their ratios w_o=[water]/[AOT] and [AOT]/[Lig-12] were kept constant. The curve in Fig. 1 appears to be rather common in the reactions of both aqueous and reverse micelles,[1,9-11] and may be accounted for in the following way. It is generally considered that the size of reverse micelles or

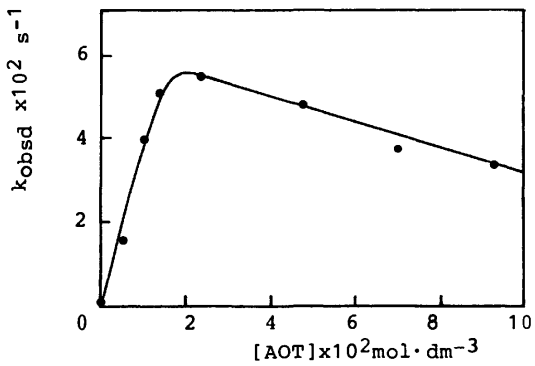


Fig. 1. Pseudo-first-order rate constants for the hydrolysis of PNPP at 25°C as the function of AOT concentration. w_o=[H_2O]/[AOT]=14.1, [AOT]/[Lig-12]=22.5, [PNPP]=5×10^{-5} mol·dm^{-3}, [Zn^{2+}]=1×10^{-4} mol·dm^{-3}.

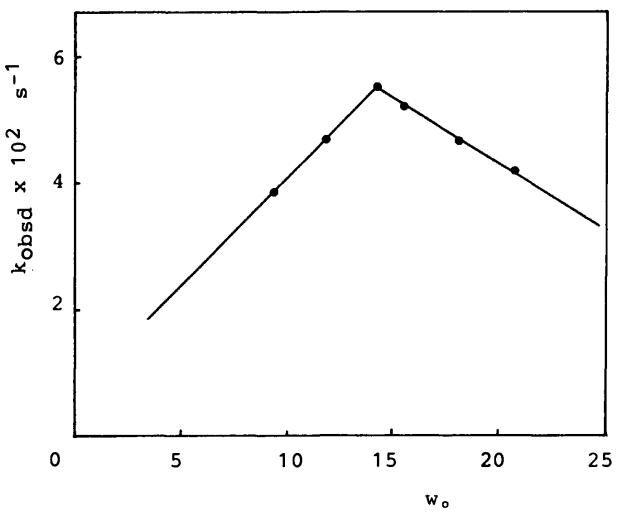

Fig. 2. Pseudo-first-order rate constants for the hydrolysis of PNPP at 25°C as the function of w_o value. [AOT]=0.022 mol·dm^{-3}, [Zn^{2+}]=1×10^{-4} mol·dm^{-3}, [PNPP]=5×10^{-5} mol·dm^{-3}, [AOT]/[Lig-12]=22.5.

the size of water pools is determined by the w_o ratio, so that at a constant w_o as in Fig. 1, the increase in AOT concentration results in the increase in micelle concentration of the same size.[1] Thus the curve of Fig. 1 shows the saturation of rates due to the saturation of incorporation of reactants into micelles (Zn^{2+} ion, Lig-12 and PNPP). A slow decrease in rates after the maximum is explained by the dilution of reactants (Zn^{2+} and PNPP) per micelle, although the concentration of Lig-12 remaines constant.

Next, the effect of w_o on the rates was examined as shown in Fig. 2. It shows the presence of an optimum value at about w_o=14. In the case of AOT, it is considered that the water molecules (in the water pools) up to perhaps w_o=6—8 are tightly bound to the head groups of the surfactant,[12,13] and above this value the water molecules become free water and the micelles swell when the water content increases.[13,14] Thus the above value w_o=14 suggests that an appropriate amount of free water is necessary for faster rates. The micellar molecular weight based on the light scattering data will be discussed later.

Stoichiometry of the Reactive Complexes. In order to know the stoichiometry of the kinetically reactive complexes, the kinetic version of Job plots[15,16] was examined by plotting the k_{obsd} values as a function of mole fraction of ligand (γ), maintaining the total concentration of ligand and metal ion constant. The results shown in Fig. 3 indicate that in the case of Zn^{2+} ion and Lig-12 the rate maximum was observed at γ=0.8 which corresponds to a stoichiometry of ligand:Zn^{2+}=4:1. The figure also indicates that the rates are very slow in the presence of metal ion

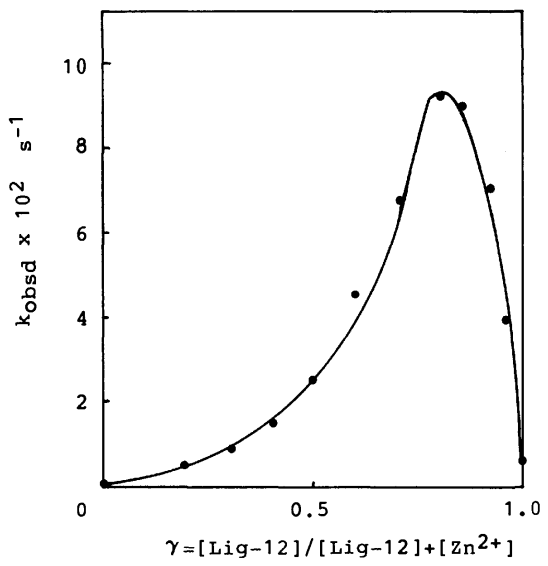

Fig. 3. Job plots for the ligand and Zn^{2+} ion complexation as measured by the rates of hydrolysis of PNPP as 25°C. [AOT]=0.022 mol·dm^{-3}, [H_2O]=0.35 mol·dm^{-3}, [PNPP]=5×10^{-5} mol·dm^{-3},([Lig-12]+[Zn^{2+}])=1× 10^{-3} mol·dm^{-3}.

or ligand alone (i.e. γ=0 or 1.0). Very similar plots were also obtained in the cases of Cu^{2+} ion as shown in Fig. 4, although the absolute values of rates were much larger than those in the case of Zn^{2+} ion. Here it should be noticed that lipophilic Lig-12 is more active than hydrophilic Lig-1.

The above 4:1 stoichiometry for Lig-12 is quite different from the 2:1 stoichiometry observed previously for Lig-12 catalysis in aqueous micelles.[2,3] In the case of a hydrophilic Lig-1, the stoichiometry in Fig. 4 is also 4:1. However, this ligand showed a 1:1

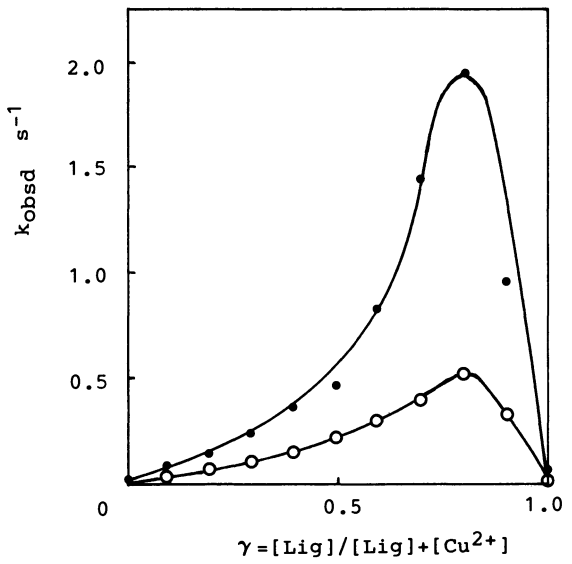

Fig. 4. Job plots for the ligand and Cu^{2+} ion complexation as measured by the rates of hydrolysis of PNPP at 25 °C. [AOT]=0.022 mol·dm^{-3}, [H_2O]=0.35 mol·dm^{-3}, [PNPP]=5×10^{-5} mol·dm^{-3}, ([Lig]+[Cu^{2+}])=5×10^{-4} mol·dm^{-3}, (○): Lig-1, (●): Lig-12.

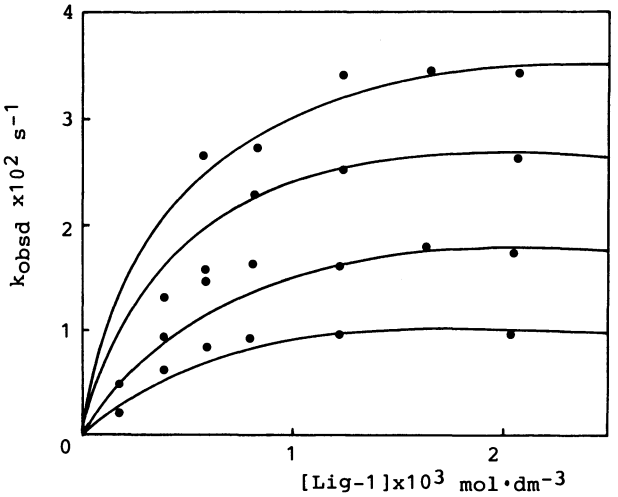

Fig. 5. Pseudo-first-order rate constants for the hydrolysis of PNPP at 25 °C as the function of Lig-1 concentration. [AOT]=0.022 mol·dm^{-3}, [H_2O]=0.35 mol·dm^{-3}, [PNPP]=5×10^{-5} mol·dm^{-3}, [Zn^{2+}]×10^4 mol·dm^{-3} from the top: 2.0, 1.5, 1.0, and 0.5.

stoichiometry in the previous catalysis in non-micellar aqueous solutions.[3,17] Thus, although it was difficult to see the stoichiometry for lipophilic Lig-12 in non-micellar aqueous media because of a low solubility of the ligand, it appears that there exist general trends of 1:1, 2:1, and 4:1 stoichiometry, depending on non-micellar aqueous media, aqueous micelles, and reverse micelles used, respectively. The reason for these differences in stoichiometry is not clear at present. It seems important to know more details about the hydration of metal ions under these different conditions before making any concrete discussions.

Second-Order Rate Constant, k_c. The k_{obsd} values were dependent on the concentrations of both Zn^{2+} ion and ligand as shown by four saturation curves in Fig. 5. These curves can be accounted for by assuming the following reaction Scheme 1.

$$M + nL \underset{}{\overset{K}{\rightleftharpoons}} \text{Complex} \quad (1)$$

$$S + \text{Complex} \xrightarrow{k_c} \text{Products} \quad (2)$$

$$S \xrightarrow{k'_o} \text{Products} \quad (3)$$

Scheme 1.

In Scheme 1, metal ion (M) and n ligand (L) form a complex with an association constant (K). Then the complex reacts with the substrate (S) to give products with the second-order rate constant (k_c). The substrate also goes to the products by other pathways with the rate constant (k'_o). The contributing pathways to k'_o may be the uncatalyzed (k_o) and the catalyzed by metal ion (k_M[M]) and ligand (k_L[L]).

The Scheme 1 leads to the rate equations, Eqs. 4—7.

Thus the pseudo-first-order rate constants, k_{obsd}, can be represented by Eq. 5. This equation would allow to obtain the k_c value if the complex concentration could be calculated.

$$\text{Rate} = k_{obsd}[S] \quad (4)$$

$$k_{obsd} = k'_o + k_c[\text{Complex}] \quad (5)$$

$$k'_o = k_o + k_L[L] + k_M[M] \quad (6)$$

$$k^{sat}_{obsd} = k'_o + k_c[M]_T \quad (7)$$

However, such was difficult because of the difficulty in determining the association constant, K in Eq. 1. Therefore, we assumed the Eq. 7 in order to calculate k_c value on the following ground. Namely, we assumed in Figs. 5 and 6 that the complex concentration at the rate saturation (k^{sat}_{obsd}) is equal to the total metal ion concentration ([M]$_T$). In the case of Zn^{2+} ion, it was also assumed that the 4:1 ligand:metal ion (n=4) complex is formed at the rate saturation. The Eq. 7 requires a straight line relationship in the plots of k^{sat}_{obsd} vs. metal ion concentration. This was

confirmed by the plots shown in Fig. 7. The k_c values obtained from the slope of these straight lines are shown in Table 1. Figure 7 also indicates k'_o, the intercepts of the straight lines, to be negligibly small.

In the case of Cu^{2+} ion, the plots of k_{obsd} vs. ligand concentration are shown in Figs. 8 and 9. The figures indicate that the rates increase steeply to a peak, then decrease sharply with increasing ligand concentration. At first glance, it seems difficult to make reasonable analysis of such complicated curves. More carefull look, however, indicates that with increasing Cu^{2+} ion concentration (from the lower to the upper), the ligand concentration at the peak position approaches to such a value to give [ligand]/[Cu^{2+}]=4. For example, in Fig. 8 the top curve of [Cu^{2+}]=2×10^{-4} mol·dm^{-3} shows the peak at [ligand]=8×10^{-4} mol·dm^{-3}. This ratio of 4 is the stoichiometry for the reactive complex (n=4 in Scheme 1) determined from Job plots (Fig. 4). Thus the decreasing in rates after the peak in Figs. 8 and 9 suggests the formation of

unreactive or less reactive complex(es) chelated with more than four ligands ($n>4$). It is reasonable to consider such unreactive complexes to be important for Cu^{2+} ion, but not for Zn^{2+} ion, since it is well-known that the complexation with imidazoles is much stronger for the former than for the latter metal ion. With these limitations in mind, the k_{obsd} values at the peaks (k_{obsd}^{max}) were plotted as the function of Cu^{2+} concentration to give straight lines as shown in Fig. 10. The slopes are the k_c' values of Cu^{2+} complexes which are perhaps slightly smaller than the real k_c values (see Table 1).

General Discussion—Mechanism of Catalysis: a) Two-Step Mechanism Involving Acyl-Intermediate. The reaction occurs through the acyl group transfer from the substrate (PNPP) to the ligand hydroxyl group in both cases of Zn^{2+} and Cu^{2+} ions. This was confirmed in two ways for Lig-12 by carrying out the reaction under the conditions of excess substrate over the ligand: (1) kinetically, burst kinetics were observed as described previously,[3] and (2) the acylated intermediate (Ac-Lig-12) was detected by HPLC analysis.[8] Thus the catalytic cycle in the present reverse micelles are essentially the same as reported previously,[3,8] and as illustrated in Scheme 2.

b) The Stoichiometry in the Ligand-Metal Ion Complexation. The results are summarized in Table 1, together with those reported previously for the reactions in non-micellar aqueous media and aqueous micelles.[2,3,17] The table shows no particular difference in the stoichiometry of ligand-metal ion between Zn^{2+} and Cu^{2+} ions, regardless of the reaction conditions. However, the table clearly indicates that the reaction conditions are important in determining such stoichiometry. It seems likely that the hydration

of metal ions becomes weaker in the order of non-micellar aqueous media≫aqueous micelles≫reverse micelles, concomitantly with increasing number of ligand coordination. The 1:1 and 2:1 complexes may form the reactive complexes at the transition state by replacing the hydrated water with the substrate as illustrated in Fig. 11 (A and B). The situation seems to be more complicated in the cases of 4:1 complexes in reverse micelles. If they have a tetrahedral structure as generally considered for Zn^{2+} complexes, then the ligand exchange with the substrate appears to be necessary before attaining the transition state as illustrated in Fig. 12.[18]

c) The Molecular Weight of the Present AOT Reverse Micelle—an Attempt to Visualize the Catalytic Site. Self aggregation in AOT reverse micelles has been relatively well-investigated,[1] as compared to that in other surfactants. As mentioned above, it is considered that the size and the aggregation number (N) of AOT reverse micelles are determined by the w_o value. In this study, the weight average molecular weight (M_w) of AOT reverse micelles in hexane was determined by light scattering method, under the conditions of w_o=13 and by treating a composite micellar aggregate (AOT plus water) to be a single molecule. The M_w found is 8.96×10^4 which corresponds roughly to the composition of 130 of AOT molecules (N=130) and 1700 molecules of water. Day et al. reported the characterization of water-containing reverse micelles of AOT by viscosity and dynamic light scattering methods.[19] Their data indicate that there is the same straight line relationship between N and w_o in the range of w_o=3—8 for three solvents (cyclohexane, toluene, and chlorobenzene), and the extrapolated value is approximately N=170 at w_o=13 which may be in fair agreement with the present N=130. The above M_w value practically unchanged in the presence of metal ions and ligand in the present concentration range.

The above data may be used to visualize the catalytic site of the present reverse micelles as in the following way: the use of [AOT]=0.022 mol·dm^{-3} with w_o=13, [Lig]=4×10^{-4} mol·dm^{-3}, [M^{2+}]=1×10^{-4} mol·dm^{-3}, and [PNPP]=5×10^{-5} mol·dm^{-3} results in the formation of [micelle]=$0.022/130=1.7\times10^{-4}$ mol·dm^{-3} and each micelle contains about one molecule of 4:1 ligand-metal ion complex, and 0—1 molecule of substrate.

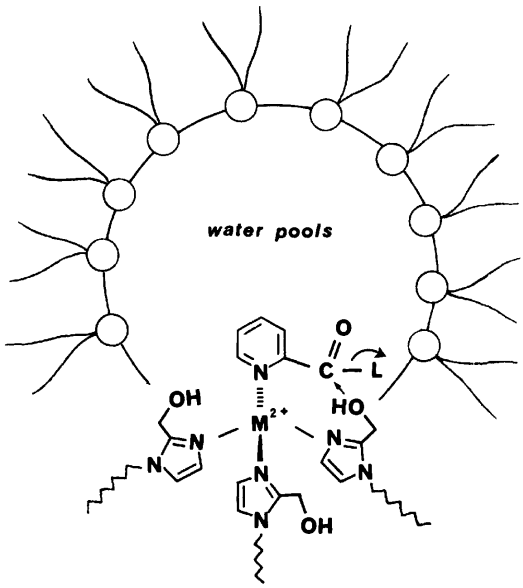

Fig. 13. Oversimplified picture of the catalytic site of AOT reverse micelles composed of bivalent metal ion-ligand complex.

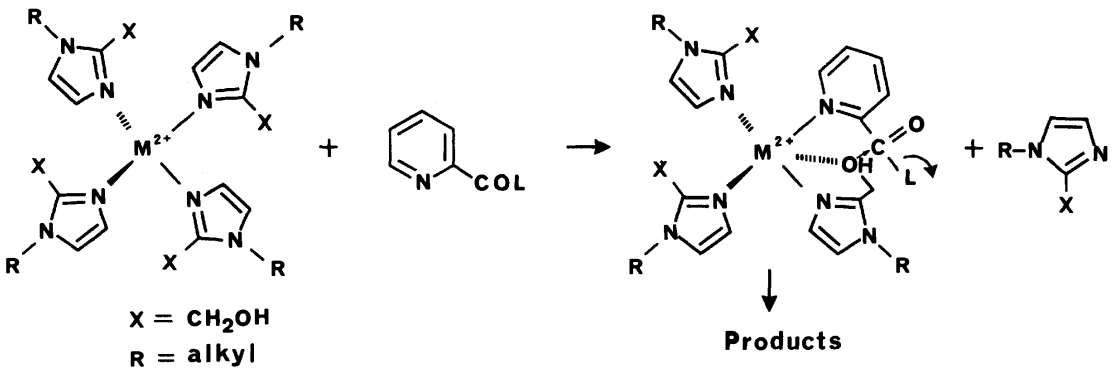

Fig. 12. Very speculative illustration of reaction pathway for 4:1 complexes.

Such a catalytic site at the transition state may be drawn schematically as in Fig. 13.

Experimental

Material. The water used for kinetics was obtained by distilling deionized water. Benzene and hexane were distilled from sodium metal (wire) before use. Acetonitrile was distilled from phosphorus pentaoxide. Buffer reagents of acetic acid and sodium acetate were commercial extra pure reagents. Commercially available metal salts, $Zn(NO_3)_2 \cdot 6H_2O$ and $Cu(NO_3)_2 \cdot 6H_2O$ were used without further purification. Commercially available sodium 1,2-bis(2-ethylhexyloxycarbonyl)ethanesulfonate (AOT, Nakarai Chemicals, Ltd.) was used without further purification. *N*-Methyl(Lig-1) and *N*-dodecyl-2-hydroxymethylimidazole (Lig-12) were prepared according to the previous method:[2,3] Lig-1, mp 118—120 °C; Lig-12, mp 56 °C.

Water Content Analysis. The water contents of the AOT solutions in hexane were determined by the Karl Fischer method, using an apparatus of Kyoto Electronics Manufacturing Co., Ltd. (MKA-3).

Examination of Micellar Aggregate by Light Scattering. The weight average molecular weight (M_w) of AOT/water aggregate in hexane was determined by light scattering photometry using Union Giken light scattering apparatus (LS-601). The light source (632.8 nm) was an Ne-He laser. The differential refractive increments of the sample solutions were measured in a Union Giken differential refractometer (RM-102). The sample solutions ([AOT]= 0.0022—0.018 mol·dm^{-3}, w_o=13) were prepared by sealing them in a quartz glass cell after optical purification by repeated filtration through 0.5 μm millipore filter (Nihon Millipore Kogyo). The M_w=8.96×10^4 (at w_o=13) was obtained by Debye plots using Rayleigh ratio, R_{90}.[20]

Kinetic Measurements.[2,3,8,17] The reaction was initiated by introducing 15 μl of a substrate stock solution in benzene into 3 ml of a reverse micellar solution of AOT in hexane/aqueous buffer containing the metal ions and the ligand of desired concentrations and maintained at 25 °C. The rate of hydrolysis of PNPP was followed by monitoring the increase of absorbance at infinite time determined for each run and by using the integrated first-order equation $k_{obsd}=(2.03/t)\log[(OD_\infty-OD_t)/(OD_\infty-OD_0)]$.

The authors thank Prof. Takayuki Ohtsu and Mr. Akikazu Matsumoto for their assistance in carrying out the light scattering experiments.

Synthesis of Oligoribonucleotides by Use of 4,4′,4″-Tris(acyloxy)trityl Groups for Protection of the 6-Amino Group of Adenosine

Mitsuo SEKINE,* Reiko IWASE, Narihiro MASUDA, and Tsujiaki HATA*
Department of Life Chemistry, Tokyo Institute of Technology,
Nagatsuta, Midoriku, Yokohama 227
(Received October 17, 1987)

Two kinds of substituted trityls, i.e., 4,4′,4″-tris(benzoyloxy)trityl (TBTr) and 4,4′,4″-tris(*p*-anisoyloxy)-trityl (TAnTr), have been examined as protecting groups of the amino group of adenosine in oligoribonucleotide synthesis. The former was used for a 3′-terminal adenosine unit and the latter was introduced into an building block of internal adenosine. These protecting groups were successfully applied to the liquid-phase synthesis of pGUA and pGUAUUA which were the 5′-terminal oligoribonucleotide fragments of brome mosaic virus mRNA 4.

In the liquid-phase synthesis of oligoribonucleotides the phosphotriester approach has been most frequently adopted as a highly reproducible method to afford large quantities of target RNA oligomers required for physicochemical studies.[1] We have also employed this strategy to obtain synthetic mRNA fragments[2] which have been used as substrates for biological studies[3] of interaction with ribosomal RNAs in connection with the initiation mechanism of peptide synthesis in eukaryotic cells.[4] In order to facilitate purification of synthetic intermediates of fully protected building blocks, the 6-amino group of adenosine has been protected with the 4-methoxytrityl (MMTr)[2c,2e] or 4,4′-dimethoxytrityl[2d] (DMTr) group as an acid-labile protecting group. Especially, the former enabled us to use protic acids for selective removal of the DMTr group used for protection of the 5′-hydroxyl group so that rapid removal of the 5′-DMTr group was achieved. However, careful treatments were required for selective removal of the 5′-protecting group, since both the N^6-MMTr and 5′-*O*-DMTr groups were essentially removed under acidic conditions.[2c]

When the DMTr group was used for protection of the amino group of adenosine, it is necessary to use rather mild conditions such as 0.5 M $ZnBr_2/CH_2Cl_2$–2-propanol (85:15, v/v)[5] (1 M=1 mol dm^{-3}) for selective removal of the 5′-DMTr group.[2d] However, this Lewis acid cleaved rather slowly the 5′-terminal dimethoxytrityl ether bond when a 5′-terminal nucleoside was cytidine.[2d]

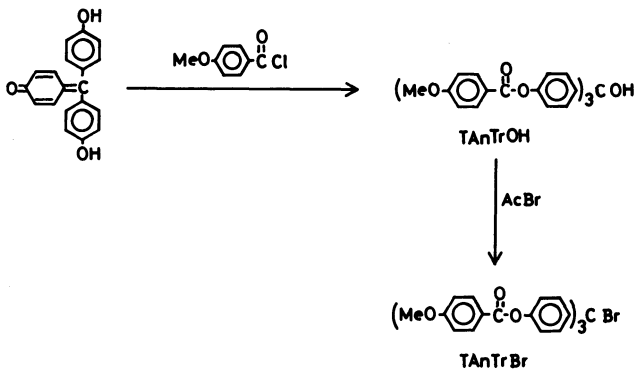
Recently, we have shown the utility of the 4,4′,4″-tris(benzoyloxy)trityl (TBTr) group as a protecting group of the amino group of deoxyadenosine.[6] The tritylating reagent TBTrBr can be prepared as crystals in a large scale from commercially available rosolic acid according to the facile procedure involving benzoylation and bromination.[7] This is one of advantageous points over the MMTr and DMTr groups. This protecting group has proved to have a unique property that it could be removed by dilute alkali via 1,6-elimination while it is rather resistant to acidic conditions.[7]

Based on these facts, we decided to apply the TBTr group to protect the amino group of adenosine to facilitate the selective removal of the 5′-DMTr group. We have chosen two 5′-terminal RNA fragments, pGUA and pGUAUUA, of brome mosaic virus mRNA 4 for synthetic targets during this study.

Results and Discussion

First, we prepared a 3′-terminal adenosine unit **4** bearing the TBTr group at the N^6 position in a manner similar to that described in the preparation of N^6-TBTr deoxyadenosine[6] as shown in Scheme 1. N^6-[4,4′,4″-Tris(benzoyloxy)trityl]adenosine (**2**) was obtained in 74% yield from adenosine (**1**). Reaction of **2** with 4,4′-dimethoxytrityl chloride gave the 5′-tritylated compound **3** in 94% yield. The successive benzoylation followed by detritylation afforded the 5′-hydroxy derivative **4** in 77% yield.

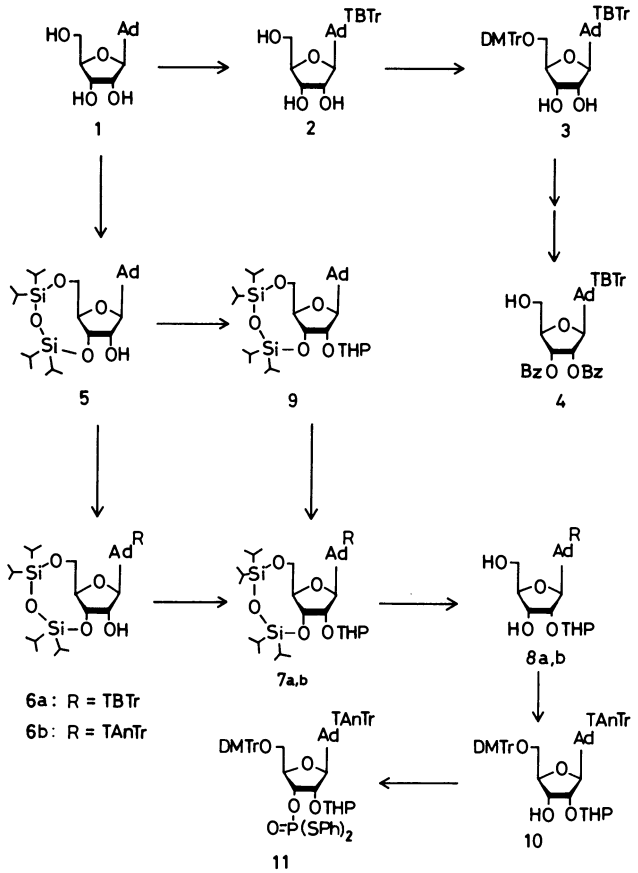
Next, in order to synthesize a key building block of adenosine unit **11**, 3′,5′-*O*-(1,1,3,3-tetraisopropyldisiloxane-1,3-diyl)adenosine (**5**)[9] was tritylated with TBTrBr in DMF in the presence of silver nitrate and lutidine. The tritylated product **6a** was obtained in 68% yield. Pyranylation of **6a** gave a fully protected adenosine derivative **7a** in 96% yield. However, when the cyclic silyl (TIPS) group was removed from **7a** by treatment with KF–Et_4NBr–H_2O/CH_3CN[2d] in the usual manner, the benzoyl group was partially eliminated from the TBTr group and the 3′,5′-diol **8a** was obtained in a low yield of 29%. This is probably because of the remaining basicity of the fluoride ion.



Therefore, to increase the stability of the benzoate, the benzoyl group was replaced for the *p*-anisoyl group at the 4-positions of the trityl group. The corresponding tritylating reagent 4,4′,4″-tris(anisoyloxy)trityl bromide (TAnTrBr) was synthesized in a manner similar to that described in the preparation of TBTrBr.

Similarly, compound **6b** was obtained in 54% yield by treatment of **5** with TAnTrBr. The successive pyranylation of **6b** followed by desilylation gave **8b** in 56% yield. The yields of **6b** and **8b** were unexpectedly low but this was not caused by the instability of the TAnTr group. It is due mainly to difficult separation of **6b** or **8b** from the by-products. To avoid such problems, the tetrahydropyranyl group was introduced into the 2′-oxygen prior to the N^6-tritylation. Upon the TFA-catalyzed tetrahydropyranylation of **5**, the 2′-tetrahydropyranylated adenosine derivative **9** was obtained in 74% yield. Tritylation of **9** followed by desilylation of **7b** gave **8b** as pure material in 77% yield. Furthermore, the total yield of **8b** from **5** was improved from 57% to 80%, when all the reactions (**5**–**9**–**7b**–**8b**) were in situ carried out without chromatographic separation and the tritylation was carried out at 0 °C.

An internal synthetic unit **11** of adenosine was prepared as follows. The 5′-dimethoxytritylation of **8b** gave a 5′-*O*-tritylated product **10** in 66% yield.



Scheme 1.

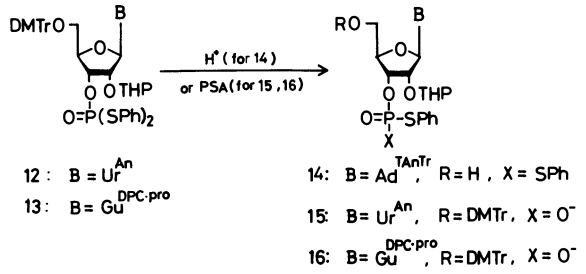
Treatment of **10** with cyclohexylammonium *S,S*-diphenyl phosphorodithioate (PPS)[10] in the presence of mesitylenedisulfonyl dichloride (MDS)[11] and tetrazole (Tet)[2f] gave the adenosine unit **11** in 85% yield.

For the synthesis of fully protected oligoribonucleotide blocks, 5′-hydroxyl and 3′-phosphodiester components **14**—**16** were prepared from the uridine and guanosine monomer units **12** and **13** by the literature method.[2d]

Next, to demonstrate the synthetic utility of **4** in oligoribonucleotide synthesis in the phosphorothioester approach[12] using *S,S*-diphenyl ribonucleoside 3′-phosphorodithioates, a fully protected UpA dimer **17** was synthesized by condensation of **4** with the phosphodiester unit **15** of uridine. A combined reagent of isodurenedisulfonyl dichloride (DDS)[11b] and 3-nitro-1,2,4-triazole (NT)[13] was employed as the condensing agent. Consequently, the dimer **17** was obtained in 88% yield. The dimer **17** could be detected as a distinct spot on TLC by spraying 10% H_2SO_4 followed by heating or by spraying dilute NaOH solution (be careful) owing to the dye character of the TBTr group. The purification was facilitated by its great lipophilicity. Treatment of **17** with TFA at 0°C for 33 min gave the 5′-hydroxyl component **18** in 82% yield. In a similar manner, a fully protected trimer **19** of GUA was obtained in 63% yield by condensation of **18** with the diester unit **16** of guanosine. In order to obtain a 5′-phosphorylated trimer **21** of pGUA, **19** was treated with TFA in CH_2Cl_2 to give the 5′-hydroxy derivative **20** in 82% yield, which was in turn phosphorylated with PSS-DDS-Tet. The fully protected pGUA (**21**) was synthesized in 88% yield.

A fully protected RNA fragment **23** of pGUAUUA was also synthesized according to the synthetic strategy as depicted in Scheme 4. The details of fragment condensation to construct this protected hexamer are shown in Table 1.

With the help of liphophilicity of the TBTr and TAnTr groups, these synthetic intermediates (fragments **1**—**6**) could be easily isolated in high yields without adsorption on silica gel. These tris(acyloxy)-trityl groups were apparently superior to the benzoyl or MMTr group in this point. At the hexamer level, the ease of its elution from silica gel was essentially



Scheme 2.

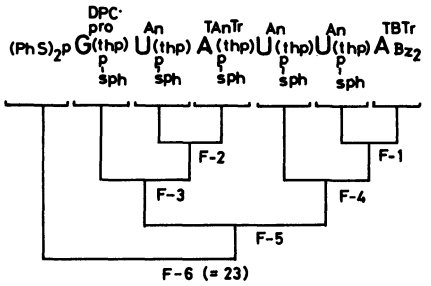
the same as that of dimers. The steric hindrance of the TBTr and TAnTr groups did not affect the condensation as shown in Table 1. This is because the TBTr group is in the remote position from the condensation site, i.e., on the adenine moiety. Expectedly, it was also confirmed that the TBTr and TAnTr groups on the adenine moiety were sufficiently stable during acid treatment for removal of the 5′-

DMTr group from fully protected oligoribonucleotide derivatives so that the loss of the THP group was essentially negligible to give 5′-hydroxyl products in high yields.

Deprotection of 21 and 23. Treatment of **21** with silver nitrate in aqueous pyridine gave an unesterified trimer as a sole product. The product was in situ treated with concentrated aqueous ammonia to remove the TBTr group of adenosine and the other base-labile protecting groups. Subsequent chromatography on Whatman 3 MM papers gave the THP containing trimer **22** in 64% yield. It was observed that the THP group of **22** was somewhat unstable during the workup after the ammonical treatment. When a mixture containing **22** was coevaporated with water to remove pyridine used as the solvent, a considerable loss of the THP group was observed so that paper chromatography often gave additional two bands of pG(thp)UA (or pGU(thp)A) and pGUA. Therefore, the partial deprotection was done in the presence of pyridine through all the process to avoid the loss of the THP group. Compound **22** appeared as a set of four peaks at ca. 17 min in reversed-phase HPLC as shown in Fig. 1-A, since it has two THP groups. Upon treatment with 0.01 M HCl, the quartet peaks were changed to one major peak at 9.2 min, which was corresponding to pGUA as shown in Fig. 1-B. Finally, the unprotected trimer was obtained in 20% overall yield from **21**.

It should be noted that, during treatment with ammonia, color of the mixture due to rosolic acid liberated became deep as the TBTr group was eliminated. This change in color is also a good visible indicator for judgement if the other acyl-type of protecting groups such as diphenylcarbamoyl (DPC), propionyl, anisoyl, and benzoyl could be removed completely since they were eliminated under similar or milder conditions. The structure of the trimer was confirmed by enzyme assay with snake venom phosphodiesterase and nuclease P_1 as shown in



Scheme 4. The strategy for synthesis of the fully protected hexaribonucleotide (**23**).

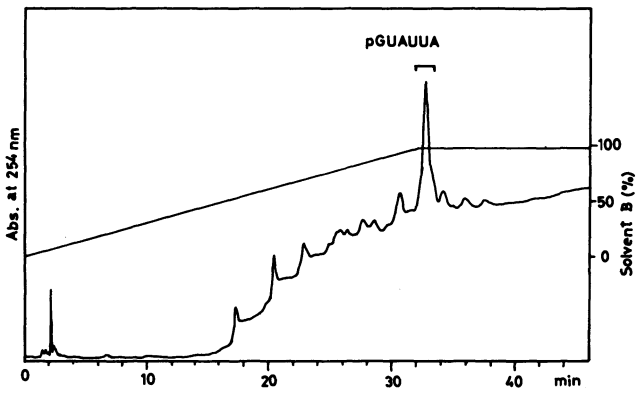

Fig. 3. The ion-exchage HPLC profile of crude pGUAUUA obtained by paper chromatography after full deprotection of **23**.

Fig. 2.

In a similar manner, pGUAUUA was obtained in 18% yield from **23** but the corresponding THP containing hexamer was not isolated and all the deprotection procedures were in situ done. In this case, the internal TAnTr group was completely removed by treatment with concentrated ammonia–pyridine (1 : 1, v/v) at room temperature for 24 h.

Purification of pGUAUUA was performed by paper chromatography followed by ion-exchange HPLC as shown in Fig. 3. The enzyme assay of the hexamer isolated is shown in Fig. 2-B.

The use of the TBTr and TAnTr groups in our approach to the synthesis of RNA fragments helped isolation of synthetic intermediates because of their great contribution to liphophilicity of the whole molecule. In addition to this merit, the choice of these protected-protecting groups also enabled us to make partially protected oligoribonucleotide derivatives which had the only THP group at each 2′-hydroxyl position of the RNA chain. Such THP containing oligoribonucleotides might be used for the synthesis of capped mRNAs if the capping reaction can be carried out in homogeneous media without protection of the exo-amino groups of A, G, and C. In this direction, we are now studying further application of partially protected oligoribonucleotides to the synthesis of capped mRNAs.

Experimental

General Remarks. ^{1}H NMR spectra were recorded at 100 MHz on a JNM-PS-100 spectrometer using ppm according to tetramethylsilane as an internal reference. UV spectra were obtained on a Hitachi 124 spectrophotometer. Column chromatography was performed with silica gel C-200 purchased from Wako Co., Ltd. Thin-layer chromatography was performed on precoated TLC plates, silica gel 60 F-254 (Merck). Reagent grade pyridine was distilled twice from *p*-toluenesulfonyl chloride and CaH_2 and then stored over Molecular Sieves 4A. Dichloromethane was dried over phosphorus pentoxide overnight, decanted, distilled from potassium carbonate and then stored over Molecular Sieves 4A.

For extraction of phosphodiester components after treatment of fully protected monomers or oligomers with phosphinic acid, two separatory funnels (A and B) were used to remove effectively the phosphinate reagent. First, the reaction mixture was diluted with dichloromethane and transferred to separatory funnel A, while CH_2Cl_2 was put in advance in separatory funnel B. The CH_2Cl_2 solution in separatory funnel A was washed with water, which was then transferred to separatory funnel B for back-extraction. After shaking, the aqueous layer was discarded from separatory funnel B. Further washing with water, 0.2 M triethylammonium hydrogencarbonate (TEAB) (×2), water (×2) was done in a similar manner when each aqueous layer was put first in separatory funnel A, transferred to separatory funnel B, and finally discarded. This extractive workup was used also for removal of excess phosphodiester components and arenedisulfonic acids after the condensation was completed but 5% sodium hydrogencarbonate was used in place of 0.2 M TEAB. The procedure was also effective for removal of DMF in the synthesis of **2**.

Ion-exchange HPLC was performed on a Partisil 10 SAX (Whatman) column using a linear gradient of 0.005 M KH_2PO_4 (pH 4.1), 20% CH_3CN to 0.5 M KH_2PO_4 (pH 4.5), 20% CH_3CN for 32 min at a flow rate of 1.5 ml ml^{-1}. Reversed-phase HPLC was performed on a μBondapak C_{18} (Waters) using a linear gradient of 0.1 M NH_4OAc to 30% CH_3CN in the same buffer for 30 min at a flow rate of 1.5 ml at 50 °C.

Elemental analysis was performed by the Microanalytical Laboratory, Tokyo Institute of Technology, at Nagatsuta.

N^6-[4,4′,4″-Tris(benzoyloxy)trityl]adenosine (2). To a solution of adenosine (2.68 g, 10 mmol) coevaporated twice with dry DMF were added 2,6-lutidine (4.86 ml, 72 mmol) and trimethylsilyl chloride (4,.56 ml, 36 mmol). After the mixture was stirred for 1 h, 2,6-lutidine (2.32 ml, 20 mmol), silver nitrate (3.40 g, 20 mmol), and TBTrBr (14.4 g, 20 mmol) were added successively to the mixture. After 1 h, 2,6-lutidine (4.17 ml, 36 mmol) and silver nitrate (6.12 g, 36 mmol) were added to complete the reaction. The mixture was stirred for 30 min, and then the resulting precipitate was removed by filtration and washed with DMF (100 ml). The filtrate and washing were combined and treated with water (32 ml). After being kept for 40 min, the solution was partitioned between dichloromethane and water for extraction, which was performed in the same manner as described in General Remarks to remove DMF completely. The organic layer was dried over sodium sulfate, filtered, and evaporated to dryness. The residue was coevaporated with six times with toluene and chromatographed on a column of silica gel (300 g) with dichloromethane–methanol. The fractions containing 2 were collected and evaporated. The residue was reprecipitated from dichloromethane into hexane to give **2** (6.41 g, 74%) as colorless powder; mp 165—170 °C; ^{1}H NMR ($CDCl_3$) δ=3.60—3.88 (2H, m, 5′-H), 4.16 (1H, m, 4′-H), 4.28 (1H, m, 3′-H), 4.82 (1H, m, 2′-H), 5.74 (d, 1H, 1′-H), 7.09 (6H, d, *J*=8 Hz, ArH), 7.46 (15H, m, ArH), 7.60 (1H, s, 2-H), 7.94 (1H, s, 8-H), 8.12 (6H, d, *J*=8 Hz).

Found: C, 68.07; H, 4.52; N, 7.62%. Calcd for $C_{50}H_{39}O_{10}N_5 \cdot H_2O$: C, 67.64; H, 4.43; N, 7.89%.

5′-*O*-(4,4′-Dimethoxytrityl)-N^6-[4,4′,4″-tris(benzoyloxy)trityl]adenosine (3). To a solution of **2** (5.90 g, 6.79 mmol), coevaporated several times with dry pyridine, in dry pyridine (19.5 ml) was added 4,4′-dimethoxytrityl chloride (2.64 g, 7.8 mmol). After being kept for 9 h, the mixture was quenched by addition of ice. The usual workup involving extraction with dichloromethane and coevaporation with toluene followed by silica-gel column chromatography (eluent: dichloromethane–methanol) gave **3**. The compound was reprecipitated from its dichloromethane solution into hexane gave pure **3** (7.45 g, 94%); mp 143.5—147 °C; ^{1}H NMR ($CDCl_3$) δ=3.72 (3H, s, OCH_3), 3.76 (3H, s, OCH_3), 4.22—4.34 (2H, m, 5′-H), 4.36 (1H, m, 4′-H), 4.64—5.00 (2H, m, 2′-H and 3′-H), 5.84 (1H, m, 1′-H), 6.77 (4H, m, ArH), 7.12 (9H, m, ArH), 7.45 (15H, m, ArH), 7.70 (s, 1H, 2-H), 8.00 (1H, s, 8-H), 8.14 (6H, d, J=8 Hz, ArH).

Found. C, 72.65; H, 5.20; N, 5.56%. Calcd for $C_{71}H_{57}O_{14}N_5 \cdot 1/2H_2O$: C, 72.19; H, 4.95; N, 5.93%.

2′,3′-*O*-Dibenzoyl-N^6-[4,4′,4″-tris(benzoyloxy)trityl]adenosine (4). Compound **3** (2.35 g, 2 mmol) was coevaporated three times with dry pyridine and finally dissolved in dry pyridine (20 ml). Benzoyl chloride (6.96 μl, 6 mmol) was added to the solution. After the mixture was stirred for 1 h, benzoyl chloride (232 μl, 2 mmol) was added. The mixture was stirred for an additional 1 h. The usual workup followed by chromatography gave the dibenzoylated product (2.96 g, quant.) as foam. This material was treated with 2% trifluoroacetic acid in dichloromethane (200 ml) at 0 °C for 17 min. After the reaction was quenched by addition of 5% sodium hydrogencarbonate (200 ml), the organic phase was collected, washed with 5% sodium hydrogencarbonate, dried over sodium sulfate, and filtered. The filtrate was evaporated and the last traces of pyridine were removed by repeated coevaporation with toluene. The residue was chromatographed on a column of silica gel with dichloromethane–methanol to give **4**. This material was reprecipitated from its dichloromethane solution into hexane to give **4** (1.65 g, 77%); mp 146.5 °C; ^{1}H NMR ($CDCl_3$) δ=4.01 (3H, m, 4′-H and 5′-H), 4.57 (1H, m, 3′-H), 6.04 (1H, m, 2′-H), 6.27 (1H, m, 1′-H), 7.12 (6H, m, ArH), 7.48 (21H, m, ArH), 7.80 (1H, s, 2-H), 7.91 (4H, m, ArH), 8.02 (1H, s, 8-H), 8.16 (6H, m, ArH).

Found: C, 70.40; H, 4.39; N, 6.31%. Calcd for $C_{64}H_{47}O_{12}N_5 \cdot H_2O$: C, 70.13; H, 4.51; N, 6.39%.

3′,5′-*O*-(1,1,3,3-Tetraisopropyldisiloxane-1,3-diyl)-N^6-[4,4′,4″-tris(benzoyloxy)trityl]adenosine (6a). Compound **5**[9] (1.02 g, 2 mmol) was rendered anhydrous by repeated coevaporation with dry DMF and dissolved finally in dry DMF (20 ml). To the solution were added successively 2,6-lutidine (463 μl, 4 mmol), silver nitrate (683 mg, 4 mmol), and TBTrBr (2.89 g, 4 mmol). After being stirred at room temperature for 25 min, the mixture was quenched with water. The resulting precipitate was removed by filtration and the filtrate was transferred to a separatory funnel. The extractive workup was done to remove DMF as described in General Marks. The combined dichloromethane layer was dried over sodium sulfate, filtered, and evaporated in vacuo. The resulting residue was chromatographed on a column of silica gel with dichloromethane–methanol. The product thus obtained was reprecipitated from dichloromethane into hexane to give a pure material (1.51 g, 68%); ^{1}H NMR ($CDCl_3$) δ=1.04 (28H, m, $C(CH_3)_2$), 3.36 (br, 1H, 2′-OH), 4.05 (3H, m, 4′- and 5′-H), 4.58 (1H, m, 3′-H), 5.08 (1H, m, 2′-H), 5.89 (1H, m, 1′-H), 6.96 (1H, s, NH), 7.14 (6H, m, ArH), 7.48 (15H, m, ArH), 7.96 (1H, s, 2-H), 8.00 (1H, s, 8-H), 8.20 (6H, m, ArH).

3′,5′-*O*-(1,1,3,3-Tetraisopropyldisiloxane-1,3-diyl)-N^6-[4,4′,4″-tris(*p*-anisoyloxy)trityl]adenosine (6b). The same procedure as described in the case of **6a** was performed except for the reaction time (6 h). The yield was 54%; ^{1}H NMR ($CDCl_3$) δ=1.09 (24H, m, $C(CH_3)_2$), 1.59 (4H, m, SiCH), 3.21 (2H, m, 5′-H), 3.92 (s, 6H, OCH_3), 4.12 (1H, m, 4′-H), 4.68 (1H, m, 3′-H), 5.20 (1H, m, 2′-H), 5.94 (1H, m, 1′-H), 7.09 (6H, d, J=8.8 Hz, ArH), 7.22 (6H, d, J=8.8 Hz, ArH), 7.50 (6H, d, J=8.8 Hz, ArH), 7.92 (1H, s, 2-H), 8.04 (1H, s, 8-H), 8.20 (6H, d, J=8.8 Hz, ArH).

Found: C, 64.82; H, 5.96; N, 5.73%. Calcd for $C_{65}H_{71}O_{14}N_5Si_2$: C, 64.93; H, 5.95; N, 5.82%.

2′-*O*-(Tetrahydro-2-pyranyl)-3′,5′-*O*-(1,1,3,3-tetraisopropyldisiloxane-1,3-diyl)-N^6-[4,4′,4″-tris(benzoyloxy)trityl]adenosine (7a). To a solution of **6a** (1.17 g, 1.05 mmol) in dry dichloromethane (4.5 ml) were added Molecular Sieves 4A (1 g), 3,5-dihydro-2*H*-pyran (2.30 ml, 22.5 mmol), and trifluoroacetic acid (174 μl, 2.26 mmol). After the mixture was stirred at room temperature for 5 h, pyridine (0.5 ml) was added. The Molecular Sieves were removed by filtration and the filtrate was evaporated in vacuo. The residue was partitioned with dichloromethane and water. The organic phase was collected, dried over sodium sulfate, filtered, and evaporated to dryness. The residue was chromatographed on a silica-gel column with dichloromethane–methanol to give **7a** as foam (1.21 g, 96%); ^{1}H NMR ($CDCl_3$) δ=1.07 (24H, m, $C(CH_3)_2$), 1.56 (6H, m, THP), 1.72 (4H, m, SiCH), 3.46 (2H, m, THP), 4.18 (3H, m, 4′-H and 5′-H), 4.70 (1H, m, 3′-H), 5.00 (1H, m, 2′-H), 5.23 (1H, m, THP), 6.00 (1H, m, 1′-H), 6.93 (1H, s, NH), 7.22 (6H, m, ArH), 7.54 (15H, m, ArH), 7.95 (1H, s, 2-H), 8.04 (1H, s, 8-H), 8.20 (6H, m, ArH).

Found: C, 66.61; H, 6.12; N, 5.45%. Calcd for $C_{67}H_{73}O_{12}N_5Si_2 \cdot 1/2H_2O$: C, 66.75; H, 6.19; N, 5.81%.

2′-*O*-(Tetrahydro-2-pyranyl)-3′,5′-*O*-(1,1,3,3-tetraisopropyldisiloxane-1,3-diyl)-N^6-[4,4′,4″-tris(*p*-anisoyloxy)trityl]adenosine (7b). This compound was prepared in the same way described in the case of **7a** starting from **6b** (536 mg, 0.45 mmol) except for the reaction time (26 h). The yield was 581 mg (100%); ^{1}H NMR ($CDCl_3$) δ=1.08 (24H, m, $C(CH_3)_2$), 1.56 (6H, m, THP), 1.82 (1H, m, SiCH), 3.48 (2H, m, THP), 3.90 (9H, s, OCH_3), 4.16 (3H, m, 4′-H and 5′-H), 4.52—4.83 (2H, m, 2′-H and 3′-H), 5.24 (1H, m, THP), 6.01 (1H, m, 1′-H), 6.98 (6H, d, J=8.4 Hz, ArH), 7.14 (d, J=9 Hz), 7.48 (6H, d, J=8.4 Hz, ArH), 7.97 (1H, s, 2-H), 8.07 (1H, s, 8-H), 8.16 (6H, d, J=9 Hz, ArH).

2′-*O*-(Tetrahydro-2-pyranyl)-N^6-[4,4′,4″-tris(benzoyloxy)trityl]adenosine (8a). To a solution of **7a** (506 mg, 423 μmol) in acetonitrile (2.2 ml) were added potassium fluoride (155 mg, 2.67 mmol), tetraethylammonium bromide (565 mg, 2.69 mmol), and water (48.2 μl, 2.67 mmol). The mixture was stirred at 50 °C for 3 h and then the precipitate was removed by filtration. The filtrate was evaporated and the residue was partitioned with dichloromethane and water. The organic phase was collected, dried

over sodium sulfate, filtered, and evaporated in vacuo to dryness. The residue was chromatographed on a column of silica gel with dichloromethane–methanol to give **8a**. Reprecipitation from dichloromethane into hexane gave a pure material (124 mg, 29%); ^{1}H NMR ($CDCl_3$) δ=1.60 (8H, m, THP), 3.40 (2H, m, THP), 3.82 (2H, m, 5′-H), 4.44 (2H, m, 3′-H and 4′-H), 4.88 (1H, m, 2′-H), 4.90 (1H, m, THP), 5.96 (1H, m, 1′-H), 7.22 (6H, m, ArH), 7.54 (15H, m, ArH), 7.87 (1H, s, 2-H), 8.10 (1H, s, 8-H), 8.22 (6H, d, J=8 Hz, ArH).

Tris[4-(*p*-anisoyloxy)phenyl]methanol (TAnTrOH). To a solution of rosolic acid (14.5 g, 50 mmol) in dry pyridine (200 ml) was added *p*-anisoyl chloride (42.7 g, 250 mmol). The mixture was heated at 80—90 °C for 1.5 h. After being cooled to room temperature, the mixture was quenched with ice-water and extracted with CH_2Cl_2. The organic phase was washed several times with 5% $NaHCO_3$, dried over sodium sulfate, filtered, and evaporated under reduced pressure to a gum. The gummy residue was coevaporated several times with toluene to remove the last traces of pyridine. The solid material was recrystalized from benzene to give TAnTrOH (15.3 g, 44%); mp 175.5—176.5 °C; ^{1}H NMR ($CDCl_3$) δ=3.05 (1H, s, OH), 3.86 (9H, s, OCH_3), 6.88—7.38 (18H, m, ArH), 8.05 (3H, s, ArH), 8.13 (3H, s, ArH).

Found: C, 73.41; H, 4.86%. Calcd for $C_{43}H_{34}O_{10}$: C, 72.67; H, 4.82%.

4,4′,4″-Tris(*p*-anisoyloxy)trityl Bromide (TAnTrBr). To a suspension of TAnTrOH (4 g, 5.6 mmol) in dry benzene (10 ml) was added acetyl bromide (1 ml, 13.5 mmol). The mixture was refluxed for 1.5 h and the hot solution was filtered to remove a small amount of insoluble material. Dry hexane was added portionwise to the hot filtrate. After cooling, the resulting precipitate was collected by filtration and washed with dry hexane–benzene (2:1, v/v) and then with dry hexane to give TAnTrBr (3.9 g, 90%): mp 96—97 °C; ^{1}H NMR ($CDCl_3$) δ=3.88 (9H, s, OCH_3), 6.90—7.39 (18H, m, ArH), 8.02 (3H, s, ArH), 8.13 (3H, s, ArH).

2′-*O*-(Tetrahydro-2-pyranyl)-*N*^{6}-[4,4′,4″-tris(*p*-anisoyloxy)trityl]adenosine (8b). This compound was synthesized in the same way as described in the above experiment except for the reaction time (1 h). The yield was 56%; ^{1}H NMR ($CDCl_3$) δ=1.52 (6H, m, THP), 3.90 (9H, s, OCH_3), 4.25—4.64 (4H, m, 3′,4′, and 5-H), 4.90 (1H, m, 2′-H), 5.10 (1H, m, THP), 5.92 (1H, m, 1′-H), 6.98 (6H, d, J=9 Hz, ArH), 7.16 (6H, d, J=9 Hz, ArH), 7.48 (6H, d, J=9 Hz, ArH), 7.83 (1H, s, 2-H), 8.08 (1H, s, 8-H), 8.16 (6H, d, J=9 Hz).

Found: C, 66.59; H, 5.33; N, 6.56%. Calcd for $C_{58}H_{53}O_{16}N_5$: C, 66.72; H, 5.12; N, 6.71%.

Synthesis of 8b from 5 without Purification of the Synthetic Intermediates 7b and 9. To a solution of **5**[9] (5.61 g, 11 mmol) in dry dichloromethane (110 ml) were added 3,4-dihydro-2*H*-pyran (22.5 ml, 220 mmol) and trifluoroacetic acid (1.7 ml, 22 mmol). The mixture was stirred at room temperature for 17 h. Then, additional trifluoroacetic acid (0.85 ml, 11 mmol) was added and the mixture was further stirred for 4 h. Five per cent sodium hydrogencarbonate (100 ml) was added to the mixture and the solution was extracted with dichloromethane (100 ml). The organic phase was collected, dried over sodium sulfate, filtered, and evaporated in vacuo to dryness. The residue was coevaporated several times successively with ethanol and dry DMF, and finally dissolved in dry DMF (110 ml). To the solution were added 2,6-lutidine (2.55 ml, 22 mmol), silver nitrate (3.74 g, 22 mmol), and TAnTrBr (17 g, 22 mmol) with vigorous stirring at 0 °C. The precipitate was removed by filtration and washed with dichloromethane. The filtrate and washing were combined and washed with water to remove DMF in a manner similar to that described in General Remarks. The dichloromethane layer was dried over sodium sulfate, filtered, and evaporated in vacuo to dryness. The residue was coevaporated several times with toluene and dissolved in acetonitrile (55 ml). To the solution were added potassium fluoride (3.83 g, 66 mmol), tetraethylammonium bromide (13.9 g, 66 mmol), and water (1.19 ml). The mixture was stirred at 50 °C for 1 h. The precipitate was removed by filtration. The filtrate was transferred to a separatory funnel and diluted with water. Extraction was performed with dichloromethane, in a manner similar to that described for extractive removal of DMF in General Remarks, to remove the quarternary ammonium salt. The dichloromethane phase was dried over sodium sulfate, filtered, and evaporated in vacuo to dryness. The usual workup followed by chromatography on silica gel with dichloromethane–methanol and reprecipitation gave **8b** (9.24 g, 80%).

***S,S*-Diphenyl 2′-*O*-(Tetrahydro-2-pyranyl)-5′-*O*-(4,4′-dimethoxytrityl)-*N*^{6}-[4,4′,4″-tris(*p*-anisoyloxy)trityl]adenosine 3′-Phosphorodithioate (11).** Compound **8b** (7.76 g, 7.43 mmol) was rendered anhydrous by repeated coevaporation with dry pyridine and finally dissolved in dry pyridine (22 ml). To the solution was added 4,4′-dimethoxytrityl chloride (3.03 g, 8.92 mmol). The mixture was stirred at room temperature for 1.5 h. After the usual extractive workup, chromatography on a column of silica gel with dichloromethane–methanol gave **10** (6.60 g, 66%). This compound was used in the next reaction without further characterization. Compound **10** (6.60 g, 4.9 mmol) was mixed with cyclohexylammonium *S,S*-diphenyl phosphorodithioate (2.80 g, 7.35 mmol) and 1-*H*-tetrazole (1.37 g, 19.6 mmol), and the mixture was coevaporated several times with dry pyridine and finally dissolved in dry pyridine (30 ml). To the mixture was added MDS (3.11 g, 9.8 mmol). After being stirred at room temperature for 1 h, the mixture was quenched by diluted with dichloromethane (100 ml). The solution was washed with water and 5% sodium hydrogencarbonate as described in General Remarks. The usual workup followed by chromatography (silica gel, eluent: dichloromethane–methanol) and reprecipitation from dichloromethane into hexane gave **11** (6.66 g, 85%); ^{1}H NMR ($CDCl_3$) δ=8.11 (6H, d, J=8 Hz, ArH), 8.01 (1H, s, 8-H), 7.80 (1H, s, 2-H), 6.72—7.68 (41H, m, ArH, 2H), 5.77 (d, 1H, 1′-H), 5.07—5.28 (2H, m, 2′-H and THP), 4.56 (1H, m, 3′-H), 4.18 (1H, m, 4′-H), 3.85 (9H, s, OCH_3 of TArTr), 3.75 (6H, s, OCH_3 of DMTr), 3.72 (2H, m, 5′-H), 2.85 (2H, m, THP), 1.24—1.80 (6H, m, THP).

Found: C, 69.48; H, 6.56; N, 3.88; S, 3.78%. Calcd for $C_{91}H_{80}O_{17}N_5S_2P \cdot 2.5C_6H_{14}$: C, 69.72; H, 6.35; N, 3.84; S, 3.51%.

General Procedure for Fragment Condensation. Preparation of Phosphodiester Components: An appropriately

protected monomer unit or oligomer block was rendered anhydrous by repeated coevaporation with dry pyridine and dissolved in a solution of 2 M phosphinic acid (60 equiv) in pyridine containing triethylamine as shown in Table 1. After the reaction was completed, 0.2 M TEAB was added and extracted with dichloromethane. The excess phosphinate reagent was removed by the extractive workup as described in General Remarks. In this case, washing was performed with water (×2) and 0.2 M TEAB (×2). The organic phase was dried over sodium sulfate, filtered, and evaporated in vacuo to dryness. The residue containing a mixture of the phosphodiester component and benzenethiol was used in the successive condensation without further purification.

Preparation of Hydroxyl Components: A fully protected monomer or oligomer block was dissolved in 0.5% or 0.75% (v/v) trifluoroacetic acid in dichloromethane at 0 °C. After the reaction was completed, 5% sodium hydrogencarbonate was added for neutralization. The solution was extracted with dichloromethane. The organic phase was dried over sodium sulfate, filtered, evaporated, and chromatographed on a column of silica gel for isolation of the hydroxyl component. The details of the results are listed in Table 1.

Fragment Condensation: The hydroxyl component obtained by the above procedure was mixed with the diester component and 3-nitro-1,2,4-triazole, and the mixture was rendered anhydrous by repeated coevaporation with dry pyridine and finally dissolved in dry pyridine (10 ml mmol^{-1} of hydroxyl component). DDS was added to the solution and stirring was continued until the hydroxyl component had disappeared. Then, extractive workup was performed with dichloromethane as described in General Remarks. Washing was performed each twice with water, 5% sodium hydrogencarbonate, and water. After the usual workup chromatographic separation (silica gel, eluent:dichloromethane–methanol) gave an condensation product as summarized in Table 1.

Deprotection of the Fully Protected Trimer 21. To a solution of the trimer **21** (232 mg, 0.088 mmol) in pyridine (2.25 ml) were added successively water (2.25 ml) and silver acetate (2.20 g, 13.2 mmol). The mixture was stirred vigorously at 50 °C for 5 h. After cooling to room temperature, the solution was diluted with pyridine–water (2:1, v/v, 45 ml) and treated with hydrogen sulfide gas at 0 °C for 15 min. The excess gas was removed under reduced pressure by an aspirator for 30 min. The resulting precipitate was removed by centrifugation. The supernatant was collected and passed through Dowex 50 W×2 (pyridinium form, 5 ml). The resin was washed with pyridine–water (2:1, v/v, 50 ml). The eluant and washings were combined and evaporated in vacuo after addition of pyridine (70 ml). The residue was coevaporated with pyridine (5×20 ml) to remove the last traces of acetic acid and then in dissolved pyridine (5 ml). The solution was mixed with concentrated aqueous ammonia (45 ml). The mixture was warmed at 50 °C for 5 h. After cooling, pyridine (20 ml) was added and the solution was evaporated under reduced pressure to its half volume. The concentrated solution was extracted with CH_2Cl_2 (5×20 ml). Each organic layer was washed with the same aqueous solution put in another separatory funnel. The two aqueous layers were combined and three hold of pyridine was added. The solution was evaporated in vacuo, the residue being coevaporated three times with pyridine and chromatographed on Whatman 3 MM papers with 2-propanol–concentrated aqueous ammonia–water (6:1:3, v/v/v). A broad band which moved around AMP was eluted with water to give pG(thp)pU(thp)pA (1752 OD at 260 nm, 64%). This compound was stored as its pyridine solution (5.6 μmol ml^{-1}). An aliquot of this solution (5.0 μmol) was taken and evaporated under reduced pressure. The residue was coevaporated with MeOH–toluene (1:1, v/v, 3×5 ml) and treated with 0.01 M HCl in dioxane–water which was finally adjusted to pH 2.0 by addition of 0.1 M HCl. After being stirred for 16 h, the solution was neutralized with concentrated aqueous ammonia and concentrated under reduced pressure to half the volume. The concentrate was partitioned between ether and water. The aqueous layer was collected and washed twice with ether. The aqueous solution was concentrated and applied to a column of Sephadex A-25 (triethylammonium salt, 1 ml). The column was first washed with water (50 ml) and eluted with 1 M TEAB buffer (50 ml). Fractions containing UV were combined, concentrated under reduced pressure, and the residue was covaporated several times with water to give pGUA (153 OD at 260 nm, 4.95 μmol, 98%). This compound (20 OD) was finally purified by reversed-phase HPLC (Fig. 1-B). The peak eluted at 9.2 min was collected and evaporated under reduced pressure. The residue was dissolved in water so as to adjust the concentration of ammonium acetate to less than 0.05 M and applied to a column of Sephadex A-25, 2 ml). After washing with water (100 ml), the trimer was eluted with 1 M TEAB buffer. The eluant was concentrated under reduced pressure and coevaporated repeatedly with water to give pGUA (6.4 OD at 260 nm, 0.207 μmol, 32%): UV: λ_{max}=257 nm, λ_{min}=234 nm.

Enzymatic Assay of pGUA. The trimer (1.0 OD) was incubated with shake venom phosphodiesterase (1 mg ml^{-1}, 10 μl) in 0.05 Tris–HCl buffer (pH 8.0, 50 μl) containing 1 M $MgCl_2$ (2.5 μl) at 37 °C for 3 h. The mixture was analyzed by reversed-phase HPLC, which showed three peaks of pU, pG, and pA in a ratio of 1.1:1.0:0.9.

The trimer (1.0 OD) was incubated with nuclease P_1 (2 mg ml^{-1}, 15 μl) in 0.05 M sodium acetate buffer (pH 5.4, 35 μl) at 37 °C for 30 min. A similar HPLC analysis gave a mixture of pU, pG, and pA in a ratio of 1.1:1.0:0.8.

Deprotection of the Fully Protected Hexamer 23. The fully protected hexamer **23** (25.9 mg, 5 μmol) was dissolved in pyridine (450 μl), and water (150 μl) and silver acetate (251 mg, 1.5 mmol) were successively added. The resulting mixture was vigorously stirred at 50 °C for 5 h and bubbled with hydrogen sulfide gas at 0 °C until a clear supernatant had been obtained (ca. 15 min). The excess gas was removed under reduced pressure by an aspirator. The precipitate was removed by centrifugation and the supernatant was passed through a column of Dowex 50 W×2 (Py form, 3 ml). The resin was eluted with pyridine–water (2:1, v/v, 20 ml). The eluant was evaporated under reduced pressure and coevaporated several times with pyridine to remove the last traces of acetic acid. The residue was dissolved in pyridine (25 ml) and concentrated aqueous ammonia (25 ml) was added. The mixture was stirred at room temperature for 24 h. The precipitate was removed by filtration and washed with pyridine (20 ml). The filtrate and washing were com-

bined, evaporated under reduced pressure, and coevaporated with water–dioxane (1:2, v/v, 10 ml). The residue was treated with 0.01 M HCl in water–dioxane (1:1, v/v, 10 ml) which was adjusted to pH 2.0 by addition of 0.1 M HCl. The mixture was stirred at room temperature for 1 day and then neutralized by addition of 1 M aqueous ammonia. After being evaporated under reduced pressure, the mixture was chromatographed on Whatman 3 MM papers with 2-propanol-concentrated aqueous ammonia–water (55:10:35, v/v/v) to give crude material of pGUAUUA (178 OD at 260 nm, 59%). This crude material (30 OD) was purified by anion-exchange HPLC as described in the case of the synthesis of pGUA to give pure hexamer (5.5 OD at 260 nm, 18.3%); λ_{max}=257 nm, λ_{min}=232 nm.

Enzymatic Assay of pGUAUUA. The hexaribonucleotide (0.2 OD) was incubated with nuclease P_1 (2 mg ml^{-1}, 6 μl) in 0.05 M sodium acetate (pH 5.4, 14 μl) at 37 °C for 80 min. The HPLC analysis showed a mixture of pU, pG, and pA in a ratio of 3.0:1.3:2.2.

We wish to thank The Ministry of Education, Science and Culture for its generous support (Grant-in-Aid for Scientific Research, 61470031) of our programs and also Mrs. Chieko Sugimura for preparation of this manuscript.

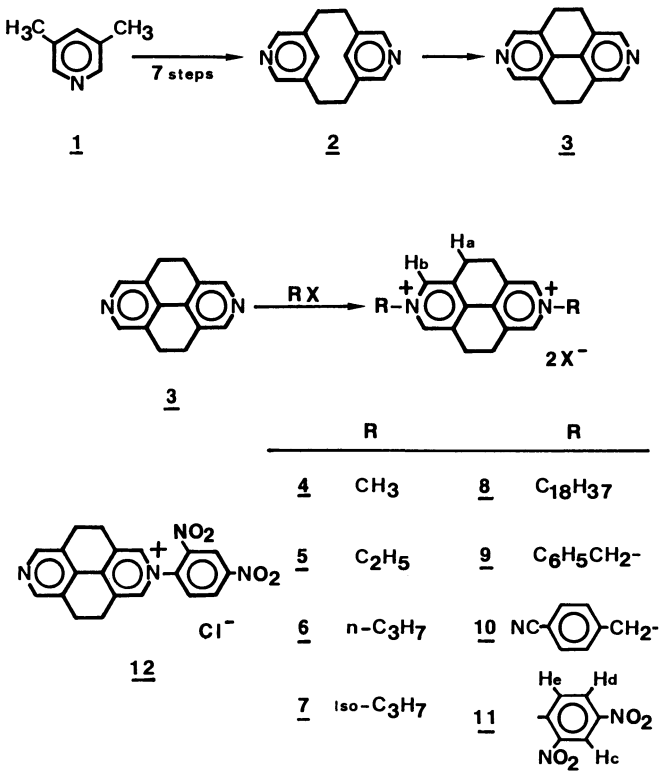
(Received October 20, 1987)

Several viologen analogs having good coplanarity were synthesized and their redox potentials were measured by cyclic voltammetry.

A viologen has attracted much attention in various fields as it shows two reversible one-electron reductions with very ease.[2)] Recently we reported synthesis and some properties of analog **4** of methylviologen(MV^{2+}), expecting that the increased resonance in the bipyridyl system may lower the redox potential.[3)] The present paper describes the syntheses of novel analogs of viologen **4**—**11** in detail and their electronic properties.



Scheme 1.

Results and Discussion

As described previously,[3)] [2.2](3,5)pyridinophane (**2**) was chosen as a starting material for our purpose. The compound **2** was prepared from the corresponding cyclic disulfone by pyrolytic procedure as reported.[4)] Pyridinophane **2** was converted into 4,5,9,10-tetrahydro-2,7-diazapyrene (**3**), a key intermediate for the following synthesis, by a transannular reaction. It is well-known that [2.2]metacyclophane is subject to the transannular reaction by treatment with various reagents, e.g. electrophiles, radical species, etc. to give tetrahydropyrene derivative.[5)] Pyridinophane **2**, on the other hand, was treated with these reagents but it produces none of the desired compound **3**. After various examinations, a modified transannular reaction with acetic anhydride, zinc dust, and $FeCl_3$ catalyst[6)] gave **3** in 53% yield, that corresponds to 2.1% in over-all yield from 3,5-lutidine (**1**). The structure of compound **3** was confirmed by elemental analysis and ^1H NMR spectroscopy. In the spectrum no other signal than two singlets (δ 2.87 and 8.39) was observed in $CDCl_3$. The former is assigned to H_a, a proton of ethylene bridge, and the latter to H_b, aromatic proton as shown in Scheme 1.

Quaternarization of **3** with alkyl halides was carried out in polar solvent, methanol or *N*,*N*-dimethylformamide (DMF), to yield the target compounds **4**—**11** in the conditions as shown in Table 1. For example,

Table 1. Reaction Conditions and Yield of Products **4**—**11**

Entry	Reagent	Solvent	Temp/°C	Time/h	Product	Yield/%
1	CH_3I	M[c)]	55—60	14.0	**4**	79
2	C_2H_5Br	D[d)]	95—100	3.0	**5**	87
3	C_3H_7Br	D	90—95	3.5	**6**	87
4	$(CH_3)_2CHBr$	D	100—105	3.0	**7**	68

8	2,4-DNCB[b)]	M	Reflux	12.5	**11**	84
9	2,4-DNCB	M	50—55	7.0	**12**	60

a) 4-Cyanobenzyl bromide. b) 1-Chloro-2,4-dinitrobenzene. c) Methanol. d) DMF.

ethylation of **3** with ethyl bromide in DMF at 95—100 °C for 2 h gave 2,7-diethyl-4,5,9,10-tetrahydro-2,7-diazoniapyrene dibromide (**5**) in 87% yield. While arylation of **3** with 1-chloro-2,4-dinitrobenzene in methanol at 50—55 °C for 7 h gave mono-onium compound, 7-(2,4-dinitrophenyl)-4,5,9,10-tetrahydro-2-aza-7-azoniapyrene chloride (**12**) in 60% yield, the same reaction under reflux for 12.5 h afforded the desired bis-onium compound, 2,7-bis(2,4-dinitrophenyl)-4,5,9,10-tetrahydro-2,7-diazoniapyrene dichloride (**11**) in 84%. In the ^{1}H NMR spectrum of **11**, the aromatic proton appears at very low field (δ 9.35) in DMSO-d_6. The remarkable downfield shift of the aromatic protons is observed in all of the spectra of **4—11**, indicating the quaternarization of each two nitrogen atoms in the diazapyrene **3**. The redox potentials measured by cyclic voltammetry and the ^{1}H NMR characteristic shifts of **4—11** are summarized in Table 2.

Any cyclic voltammogram of the products **4—11** shows two reversible one-electron reductions except that of **11**. Cyclic voltammogram of **11**, on the other hand, shows diffusion-controlled and irreversible reduction, which is probably due to feature of nitro group. The redox potentials of **4—10** are almost equal to that of methylviologen in any case. This fact suggests that the increased resonance in the bipyridyl system and the electron-releasing effect of ethylene bridges are compensated each other in these diazoniapyrene derivatives **4—10**.

It is well-known that *N,N'*-bis(2,4-dinitrophenyl)-4,4'-bipyridinium salt is an available precursor for the other viologen derivatives by a facile ring transformation reaction with an amine.[7] From this point of view, the compounds **11** and **12** are assumed to be useful as valuable precursors for synthesis of a symmetrical and an unsymmetrical viologen analogs having good coplanarity.

Experimental

Measurements. All melting points were measured on a Yanako melting point apparatus and were uncorrected. ^{1}H NMR spectra were recorded with a Hitachi R-20B spectrometer, IR spectra with a Hitachi 260-10 spectrophotometer, and UV spectra with a Shimadzu UV-240 spectrophotometer. Cyclic voltammograms were obtained with a Yanako polarographic analyzer P-1100.

4,5,9,10-Tetrahydro-2,7-diazapyrene (3): To a mixture of 1.00 g (4.75 mmol) of [2.2](3,5)pyridinophane (**2**), 27 ml of acetic anhydride, 0.5 ml of acetic acid, and a catalytic amount of iron(III) chloride contained in a 100 ml three-necked flask was added a 136 mg portion of zinc powder(90% assay) with vigorous stirring at 30—40 °C under a nitrogen atmosphere. The temperature was maintained at 30—40 °C, an additional amount of zinc (1.362 g) was added in three portions at every half an hour. The mixture was stirred another 15 h at 30—40 °C, and then heated to 90 °C within 5 min. Upon ice-cooling to ca. 30 °C, stirring was continued further for 5 h under introduction of air. After evaporation, a little of water was added to the mixture and then neutralized till pH 9 with an aqueous solution of sodium hydroxide. The resulting mixture was stirred for additional 6 h at 40 °C. After filtration with Hyflo Super-Cel, the filtrate was extracted with chloroform. The organic layer was washed and dried over anhyd magnesium sulfate. The solvent was evaporated up to give a crystalline solid. It was purified by column chromatography on a silica gel to give 527 mg (yield: 53%) of **3**; colorless plates from acetone; mp 227.5—228.5 °C. ^{1}H NMR ($CDCl_3$) δ=2.94 (8H, s, benzylic CH_2), 8.39 (4H, s, aromatic H). Found: C, 80.98; H, 5.87; N, 13.33%; Calcd for $C_{14}H_{12}N_2$: C, 80.74; H, 5.81; N, 13.45%.

2,7-Dimethyl-4,5,9,10-tetrahydro-2,7-diazoniapyrene Diiodide (4): A solution of 118 mg (0.570 mmol) of 4,5,9,10-tetrahydro-2,7-diazapyrene (**3**) and 460 mg (3.2 mmol) of methyl iodide in methanol (5 ml) was stirred at 55 °C for 4 h. Then 460 mg (3.2 mmol, total 920 mg) of methyl iodide was added and the mixture was stirred for another 5 h. A red crystalline solid was collected by filtration and recrystallized from methanol to give 220 mg (yield: 79%) of **4** as red plates; mp>300 °C. UV(CH_3OH) 300 nm (log ε=4.14). ^{1}H NMR (DMSO-d_6) δ=3.19 (8H, s, benzylic CH_2), 4.37 (6H, s, CH_3), 9.06 (4H, s, aromatic H). Found: C, 38.76; H, 3.62; N, 5.59%; Calcd for $C_{16}H_{18}N_2I_2$: C, 39.05; H, 3.69; N, 5.69%.

2,7-Diethyl-4,5,9,10-tetrahydro-2,7-diazoniapyrene Dibromide (5): A solution of 120 mg (0.576 mmol) of **3** and 380 mg (3.46 mmol) of ethyl bromide in DMF (5 ml) was heated at 95—100 °C for an hour with magnetic stirring. After the addition of ethyl bromide (380 mg, 3.46 mmol), the mixture was further heated at 95—100 °C for 2 h. After cooling, the mixture was filtered and the collected solid was

a) 60 MHz in DMSO-d_6. b) Volts vs. saturated calomel electrode at a glassy carbon electrode and the counter electrode was a Pt wire; 0.1 M Et_4NClO_4–DMF, scan rate 0.1 V s^{-1}.

recrystallized from benzene–ethanol (2:1) to give 203 mg (yield: 87%) of **5** as pale yellow fine crystals; mp 282—285 °C (decomp). UV (CH_3OH) 300 nm (log ε=4.29). ^1H NMR (DMSO-d_6) δ=1.63 (6H, t, J=7 Hz, CH_3), 3.23 (8H, s, benzylic CH_2), 4.69 (4H, q, J=7 Hz, N^+–CH_2), 9.23 (4H, s, aromatic H). Found: C, 50.75; H, 5.30; N, 6.59%; Calcd for $C_{18}H_{22}N_2Br_2$: C, 50.73; H, 5.20; N, 6.57%.

The other 2,7-disubstituted 4,5,9,10-tetrahydro-2,7-diazoniapyrene salts were prepared in a similar way to that used for **5** under the conditions as shown in Table 1.

2,7-Dipropyl-4,5,9,10-tetrahydro-2,7-diazoniapyrene Dibromide (6): Pale yellow fine crystals from benzene–ethanol (yield: 87%), mp 270—280 °C (decomp). UV (CH_3OH) 313 nm (log ε=4.49). ^1H NMR (DMSO-d_6) δ=0.95 (6H, t, J=7 Hz, CH_3), 2.05 (4H, sext, J=7 Hz, CH_2 in propyl), 3.21 (8H, br. s, benzylic CH_2), 4.60 (4H, t, J=7 Hz, N–CH_2), 9.21 (4H, s, aromatic H). Found: C, 52.85; H, 5.75; N, 6.24%; Calcd for $C_{20}H_{26}N_2Br_2$: C, 52.88; H, 5.77; N, 6.17%.

2,7-Diisopropyl-4,5,9,10-tetrahydro-2,7-diazoniapyrene Dibromide (7): Pale yellow columns from ethanol (yield: 68%), mp 270—275 °C (decomp). UV (CH_3OH) 300 nm (log ε=4.28). ^1H NMR (DMSO-d_6) δ=1.69 (6H, d, J=7 Hz, CH_3), 3.23 (8H, s, benzylic H). 5.07 (2H, hept, J=7 Hz, N–CH), 9.30 (4H, s, aromatic H). Found: C, 52.12; H, 5.62; N, 6.19%; Calcd for $C_{20}H_{26}N_2Br_2 \cdot 1/2\,H_2O$: C, 51.85; H, 5,89; N, 6.05%.

2,7-Dioctadecyl-4,5,9,10-tetrahydro-2,7-diazoniapyrene Dibromide (8): Pale yellow fine crystals from acetone–chloroform (yield: 91%), mp 261—268 °C (decomp). UV (CH_3OH) 301 nm (log ε=4.31). ^1H NMR (DMSO-d_6) δ=0.7—2.9 (66H, m, CH_3 and CH_2 in stearyl except N–CH_2), 3.38 (8H, br. s, benzylic H), 4.6—5.1 (4H, m, N–CH_2), 9.69 (4H, br. s, aromatic H). Found: C, 65.41; H, 9.54; N, 3.05%; Calcd for $C_{50}H_{86}N_2Br_2 \cdot 1/2H_2O$; C, 65.91; H, 9.97; N, 3.07%.

2,7-Dibenzyl-4,5,9,10-tetrahydro-2,7-diazoniapyrene Dichloride (9): Pale yellow fine crystals from benzene–ethanol (yield: quant.), mp 195—200 °C (decomp). UV (CH_3OH) 302 nm (log ε=4.28). ^1H NMR (DMSO-d_6) δ=3.20 (8H, s, bridge CH_2), 5.92 (4H, s, N–CH_2), 7.3—7.8 (10H, m, Aromatic H of benzene), 9.50 (4H, s, aromatic H of pyridine). Found: C, 72.12; H, 5.89; N, 5.94%; Calcd for $C_{28}H_{26}N_2Cl_2 \cdot 1/4H_2O$: C, 72.17; H, 5.74; N, 6.01%.

2,7-Bis(4-cyanobenzyl)-4,5,9,10-tetrahydro-2,7-diazoniapyrene Dibromide (10): Yellow needles from methanol (yield: 53%), mp 194—196 °C (decomp). UV (CH_3OH) 303 nm (log ε=4.30). IR(Nujol) 2240 cm^{-1} (ν_{CN}). ^1H NMR (DMSO-d_6) δ=3.20 (8H, br. s, bridge CH_2), 6.00 (4H, br. s, N–CH_2), 7.82 and 7.96 (8H, AA'BB', J_{AB}=8 Hz, aromatic H of benzene), 9.31 (4H, s, aromatic H of pyridine). Found: C, 59.33; H, 4.08; N, 9.25%; Calcd for $C_{30}H_{24}N_4Br_2 \cdot 1/2H_2O$: C, 59.13; H, 4.14; N, 9.15%.

2,7-Bis(2,4-dinitrophenyl)-4,5,9,10-tetrahydro-2,7-diazoniapyrene Dichloride (11): A mixture of 500 mg (1.33 mmol) of **4**, 3.90 g (19.2 mmol) of 1-chloro-2,4-dinitrobenzene, and methanol (2.5 ml) was refluxed with magnetic stirring for 12.5 h under a nitrogen atmosphere. After cooling, the mixture was evaporated. To the oily residue, some benzene was added. A resulting solid was collected and recrystallized from methanol to give 1.24 g (yield: 84%) of **11** as yellow prisms; mp 156—164 °C (decomp). UV (CH_3OH) 313 nm (log ε=4.49). IR(Nujol) 1550 and 1345 cm^{-1} (ν_{NO_2}). ^1H NMR (DMSO-d_6) δ=3.48 (8H, s, Ha), 8.43 (2H, d, J=8 Hz, He), 8.95 (2H, dd, J=2 and 8 Hz, Hd), 9.29 (2H, d, J=2 Hz, Hc), 9.35 (4H, s, Hb). Found: C, 50.15, H, 3.10; N, 13.46%; Calcd for $C_{26}H_{18}N_6O_8Cl_2 \cdot 1/2H_2O$: C, 50.17; H, 3.08; N, 13.50%.

7-(2,4-Dinitrophenyl)-4,5,9,10-tetrahydro-2-aza-7-diazoniapyrene Chloride (12): A mixture of 200 mg (0.96 mmol) of **4**, 1.556 g (7.68 mmol) of 1-chloro-2,4-dinitrobenzene, and methanol (1 ml) was heated at 50—55 °C with magnetic stirring for 7 h under a nitrogen atmosphere. After cooling, the mixture was evaporated up to give an oily residue and acetone was added.

Recrystallization of the resulting solid from benzene–ethanol gave 238 mg (yield: 60%) of **12** as a pale yellow powder, mp 165—170 °C (decomp). ^1H NMR (CH_3OH-d_4) δ=3.48 (8H, br. s, bridge CH_2), 8.34 (1H, d, J=8 Hz, He), 8.64 (2H, br. s, aromatic H of pyridine), 8.92 (1H, dd, J=2 and 8 Hz, Hd), 9.14 (2H, s, aromatic H of pyridinium ring), 9.26 (1H, d, J=2 Hz, Hc). Found: C, 57.36; H, 3.79; N, 13.16%; Calcd for $C_{20}H_{15}N_4O_4Cl \cdot 1/2H_2O$: C, 57.21; H, 3.84; N, 13.34%.

The authors wish to express their thanks to Dr. Kunihiko Yokoi of Osaka Kyoiku University for his kind measurement of cyclic voltammetry.

Preparation and Properties of Pyridine-Analogue of TCNQ Dianion Salt

Yoshiyuki HAMA, Yukikazu NOBUHARA, Yoshio ASO, Tetsuo OTSUBO, and Fumio OGURA*
Department of Applied Chemistry, Faculty of Engineering, Hiroshima University, Saijo, Higashi-Hiroshima 724
(Received October 23, 1987)

Bis(tetrapropyl- and tetrabutylammonium) 1,1′-(2,5-pyridinediyl)bis[dicyanomethanide] (**4a** and **4b**) were prepared in order to investigate the properties of pyridine-analogue **3** of TCNQ as a new electron acceptor and its complexation with TTF. Although **3** was not isolated, the cyclic voltammetry of the salt **4** indicated that **3** was a stronger electron acceptor than TCNQ. The charge-transfer complex of TTF and **3** was prepared by mixing TTF with **3** which was generated in situ from the electrolytic oxidation of **4** or from the oxidation of 2,5-bis(dicyanomethyl)pyridine, a precursor of **4**, with hydrogen peroxide. It consisted of 1:1 composition of donor and acceptor and showed a high electrical conductivity of 19 S cm^{-1}. The 2:1 complex was prepared by metathesis of $(TTF)_3(BF_4)_2$ and **4**, and also highly conductive.

The pyridine analogue of 7,7,8,8-tetracyanoquinodimethane (TCNQ) (**1**) attracts much attention as a modified electron acceptor with an enhanced electron affinity due to a large electronegativity of the pyridinoid nitrogen. 1-AzoniaTCNQ (**2**) has so far been studied as one example, but exists as an anionic form involving a $\overset{+}{C}-\overset{-}{N}$ ylide bond.[1] 2,5-Bis(dicyanomethylene)-2,5-dihydropyridine, so-called 2-azaTCNQ (**3**) is an intriguing candidate for the real pyridine-analogue of TCNQ. We have undertaken the synthesis of **3**, which is, however, not isolated in a neutral state but as its dianion salts **4**. The electrochemical study of **4** provides an information on the acceptor character of neutral **3**. Here we would like to report the preparation and properties of bis(tetrapropyl- and tetrabutylammonium) 1,1′-(2,5-pyridinediyl)bis[dicyanomethanide] (**4a** and **4b**) as well as charge-transfer complexation of **3** and tetrathiafulvalene (TTF).

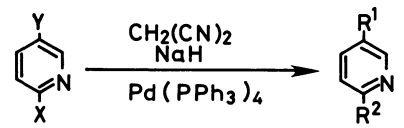
4b, X = $Bu_4\overset{+}{N}$

Results and Discussion

Recently Takahashi et al. developed a direct synthetic method of 2,2′-(*p*-phenylene)bis[malononitrile] from dihalobenzene and malononitrile anion.[2] We have applied a similar method for the present pyridine case (Scheme 1). First, commercially available 2,5-dibromopyridine (**5**) was treated with



5 X=Y=Br 8 R^1 = Br, R^2 = $CH(CN)_2$
6 X=Br, Y=I 9 R^1 = $CH(CN)_2$, R^2 = Br
7 X=Y=I 10 R^1 = R^2 = $CH(CN)_2$
11 R^1 = I, R^2 = $CH(CN)_2$

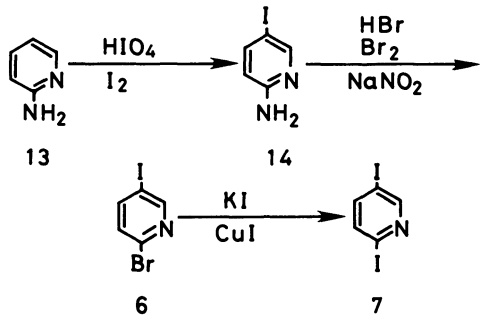
Scheme 1.

malononitrile anion in the presence of tetrakis(triphenylphosphine)palladium(0) as a catalyst in refluxing tetrahydrofuran (THF), giving 5-bromo-2-(dicyanomethyl)pyridine (**8**) as a sole product in 94% yield. Neither 2-bromo-5-(dicyanomethyl)pyridine (**9**) nor 2,5-bis(dicyanomethyl)pyridine (**10**) was detected. When the reaction was carried out at a higher temperature of refluxing 1,2-dimethoxyethane (DME) for a prolonged time of 24 h, a trace of the desired 2,5-disubstituted product **10** was formed together with **8** as main product (73%). In contrast to a preliminary experiment in which 3-bromopyridine was readily convertible into 3-(dicyanomethyl)pyridine,[3] an attempted conversion of **8** into **10** failed. This suggests that **10** must have been formed via 5-substituted isomer **9**. The inertness of **8** to further substitution is probably related to its structure which exists as a tautomeric form **12** as indicated by absorptions due to

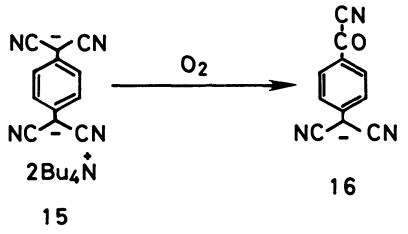
12

N–H at around 3200 cm^{-1} and conjugated C≡N at 2210 and 2186 cm^{-1} in the infrared absorption bands.[4]

Since iodoarenes are more reactive to the palladium-catalyzed substitution,[5] we next examined 2-bromo-5-iodopyridine (**6**) and 2,5-diiodopyridine (**7**), both of



Scheme 2.



Scheme 3.

which were long known but accesible by an improved procedure as shown in Scheme 2. A similar reaction of **6** in refluxing THF gave a mixture of 5-substituted products **9** (45%) and **10** (12%), while that of **7** gave a mixture of 2-substituted products **11** (45%) and **10** (18%). Alternative treatment of either compound in refluxing DME gave a high yield of **10**. A shorter reaction time (8 h) and a somewhat higher yield (71%) for **6** than those (24 h, 64%) for **7** again support the advantage of the first substitution at 5-position for the 2,5-disubstitution.

Dehydrogenation of **10** to **3** with a common oxidizing agent, i.e., H_2O_2, chloranil, DDQ, Br_2, NBS, NCS, or $Pb(OAc)_4$ was attempted, giving only unidentified colored materials which were presumably derived from **3**. Treatment of **10** with tetrapropylammonium iodide in O_2-free aq. NaOH solution gave the ammonium salt **4a** of pyridine-analogue of TCNQ dianion in an excellent yield. The tetrabutylammonium salt **4b** was similarly obtained. They with hydrochloric acid returned to the precursor **10**. The electrolytic oxidation of **4** to **3** was furthermore attempted, but **3** was not isolated because of its air-sensitivity.

Both salts **4a** and **4b** are hydrated yellow crystals which gradually decompose on prolonged exposure to air, but are extremely sensitive to oxygen in solution, immediately turning orange. The electronic spectra of **4a** and **4b** are almost identical and have two strong absorptions at 238 and 325 nm together with a weak one at 403 nm as shown in Fig. 1. For comparison, bis(tetrabutylammonium) 7,7,8,8-tetracyanoquinodimethanide (**15**), prepared according to the literature,[6] absorbs light at 207, 244, and 326 nm. The close

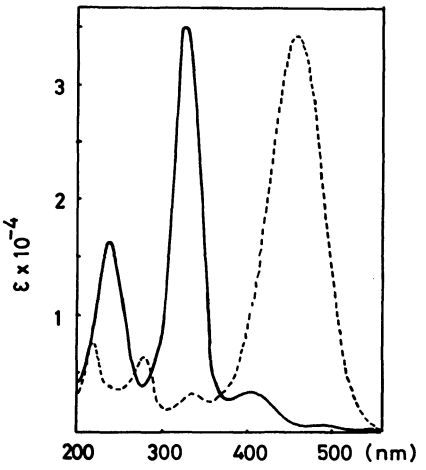


Fig. 1. Electronic absorption spectra of **4a** (—) and its decay product (------) in acetonitrile.

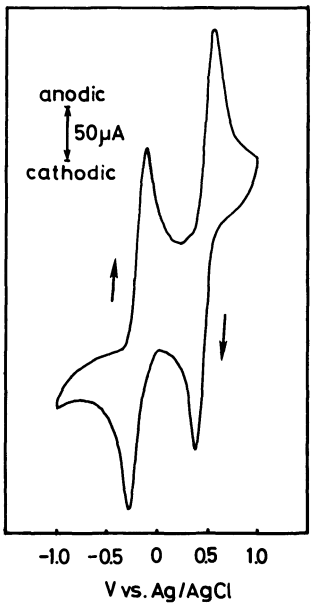

Fig. 2. Cyclic voltammogram of **4a** in 1.6 mol m^{-3} dichloromethane solution containing 0.1 mol dm^{-3} n-Bu_4NClO_4 at scan rate 0.1 V s^{-1} using a platinum working electrode and a Ag/AgCl reference electrode.

spectral resemblance of **4** and **15** reflects a similarity in their electronic structures. The light yellow solution of TCNQ dianion salt (**15**) turns orange in the presence of oxygen, too. Suchanski and Van Duyne assigned its decay product to be α,α-dicyano[*p*-(cyanocarbonyl)phenyl]methanide (**16**) (Scheme 3).[7] The considerable resemblance of both decay spectra (λ_{max} 276, 336, 458 nm from **4** and 282, 330, 480 nm from **15**) indicates that the same decay process is operative for **4**.

The cyclic voltammetry of **4** exhibits two reversible redox waves corresponding to two steps of one-electron oxidations (Fig. 2). The half-wave potentials are +0.48, −0.18 V, indicating that the neutral species

3 is a stronger electron acceptor than TCNQ ($E_{1/2}$+0.25, −0.35 V), as was expected. The charge-transfer complex of TTF and **3** was prepared by the following two methods. One used the mixing of TTF and **3** generated in situ from the electrolytic oxidation of **4** or from the dehydrogenation of **10** with hydrogen peroxide. The resulting complex consisted of 1:1 composition of donor and acceptor, and showed a high electrical conductivity of 19 S cm^{-1} which was measured on a compressed pellet at r.t. by a four probe method. Another used the metathesis of the dianion salt **4** and $(TTF)_3(BF_4)_2$.[8] In this case, the complex followed the 2:1 stoichiometry rich in donor and was also highly conductive (5.9 S cm^{-1}).

Experimental

General. Melting points are uncorrected. NMR measurements were made on a JEOL PMX-60 (60 MHz) using TMS as an internal standard. IR spectra were taken on a Hitachi 260-30 spectrophotometer, MS spectra on a Shimadzu QP-1000 spectrometer at 70 eV using a direct insertion technique, and electronic spectra on a Shimadzu UV-160 spectrophotometer.

2-Amino-5-iodopyridine (14). A mixture of 2-aminopyridine (**13**) (47.02 g, 0.50 mol), periodic acid dihydrate (22.82 g, 0.10 mol), and iodine (51.0 g, 0.20 mol) was heated in a mixed solution of acetic acid (300 cm^3), water (60 cm^3) and sulfuric acid (9 cm^3) at 80 °C for 4 h. It was then poured into aq. dil. $Na_2S_2O_3$ to remove unreacted iodine and extracted with ether. The extract was washed with aq. dil. NaOH, dried (K_2CO_3), and concentrated in vacuo. The residue was purified by column chromatography on silica gel with ethyl acetate as eluent and then recrystallization from ethanol to give colorless prisms of **14** (74.15 g, 67%): mp 132.0—132.7 °C (lit,[9] mp 129 °C).

2-Bromo-5-iodopyridine (6). Bromine (10 cm^3) and aq. solution (50 cm^3) of $NaNO_2$ (11.22 g, 0.163 mol) were succesively added into a stirred solution of 2-amino-5-iodopyridine (**14**) (13.79 g, 0.063 mol) in 47% hydrobromic acid (100 cm^3), the temperature being kept below 0 °C during the addition. The reaction was then continued for 2 h at 5—10 °C and quenched by addition of aq. solution (300 cm^3) of NaOH (36 g). The mixture was poured into aq. dil. $Na_2S_2O_3$ to remove unreacted bromine and extracted with ether. The extract was washed with water, dried (K_2CO_3), and concentrated in vacuo. The residue was purified by column chromatography on silica gel with chloroform as eluent and then recrystallization from ethanol to give colorless plates of **6** (11.65 g, 65%): mp 125—126 °C (lit,[10] mp 122.5 °C).

2,5-Diiodopyridine (7). A mixture of 2-bromo-5-iodopyridine (**6**) (2.27 g, 8.0 mmol), copper(I) iodide (7.75 g, 40.7 mmol), and potassium iodide (13.1 g, 78.5 mmol) in dry hexamethylphosphoric triamide (25 cm^3) was heated at 140—145 °C for 18 h under nitrogen. The reaction was quenched by addition of 10% HCl until the solution became neutral. Benzene (30 cm^3) was added and the insoluble copper salt was filtered off. The organic phase was separated, washed with water, dried (K_2CO_3), and evaporated. The residue was purified by column chromatography on silica gel with chloroform and then recrystallization from the same solvent to give colorless plates of **7** (1.96 g, 74%): mp 148—149.7 °C (lit,[10] mp 154 °C).

5-Bromo-2-(dicyanomethyl)pyridine (8). A solution of malononitrile (0.626 g, 9.48 mmol) in dry THF (10 cm^3) was mixed with a suspension of NaH (60% in oil, 0.667 g, 16.68 mmol) in dry THF (20 cm^3) and stirred at r.t. for 10 min in a nitrogen atmosphere. 2,5-Dibromopyridine (**5**) (0.911 g, 3.84 mmol) in dry THF (10 cm^3) and tetrakis(triphenylphosphine)palladium(0) (0.201 g, 0.174 mmol) were succesively added. The mixture was refluxed for 3 h and concentrated in vacuo. The residue was taken up with water (50 cm^3), washed with benzene, and acidified to pH 1 with 10% HCl. The resulting yellow precipitate was collected by filtration and dried. It was then purified by column chromatography on silica gel with chloroform and recrystallization from acetonitrile to give yellow prisms of **8** (0.80 g, 94%): decomp 216 °C; IR (KBr) 3200—2900 (N-H, C-H), 2210, 2186 cm^{-1} (C≡N); ^{1}H NMR (DMSO-d_6) δ=7.01 (d, J=9.6 Hz, 1H), 7.75 (dd, J=9.6 and 1.8 Hz, 1H), 7.89 (d, J=1.4 Hz, 1H); MS (70 eV) m/z 221, 223 (M$^+$). Anal. ($C_8H_4N_3Br$) C, H, N.

When the same reaction was conducted in refluxing DME for 24 h, a mixture of **8** (73%) and **10** (2%) was formed.

2-Bromo-5-(dicyanomethyl)pyridine (9), 2,5-Bis(dicyanomethyl)pyridine (10), and 2-(Dicyanomethyl)-5-iodopyridine (11). The same reaction as described in the preparation of **8** was carried out using either 2-bromo-5-iodopyridine (**6**) or 2,5-diiodopyridine (**7**) instead of **5**. The usual work-up gave a mixture of **9** (45%) and **10** (12%) from **6** and a mixture of **10** (18%) and **11** (45%) from **7**. The mixtures were separated by column chromatography on silica gel, which first eluted the monosubstituted product with chloroform and then the disubstituted one with 1:5 acetone–chloroform.

Recrystallization of **9** from acetonitrile afforded colorless prisms: decomp 142 °C; IR (KBr) 3100—3000, 2900 (C-H), 2273 cm^{-1} (C≡N); ^{1}H NMR (acetone-d_6) δ=6.17 (s, 1H), 7.80 (d, J=8.4 Hz, 1H), 8.03 (dd, J=8.4 and 3.4 Hz, 1H), 8.65 (d, J=2.6 Hz, 1H); MS (70 eV) m/z 221, 223 (M$^+$); Anal. ($C_8H_4N_3Br$) C, H, N.

Recrystallization of **10** from acetonitrile afforded yellow plates: decomp 204 °C; IR (KBr) 3100—2800 (N-H, C-H), 2214, 2188 cm^{-1} (C≡N); ^{1}H NMR (acetone-d_6) δ=5.98 (s, 1H), 7.28 (d, J=9.4 Hz, 1H), 7.85 (dd, J=8.6 and 3.0 Hz, 1H), 8.13 (d, J=2.6 Hz, 1H), 12.6—11.5 (bs, 1H); MS (70 eV) m/z 207 (M$^+$); Anal. ($C_{11}H_5N_5$) C, H, N.

Recrystallization of **11** from acetonitrile gave yellow needles: decomp. 245 °C; IR (KBr) 3200—2900 (N-H, C-H), 2222, 2198 cm^{-1} (C≡N); ^{1}H NMR (acetone-d_6+DMSO-d_6) δ=6.93 (d, J=8.6 Hz, 1H), 7.83 (dd, J=8.6 and 1.8 Hz, 1H), 7.91 (d, J=1.8 Hz, 1H); MS (70 eV) m/z 269 (M$^+$); Anal. ($C_8H_4N_3I$) C, H, N.

Bis(tetrapropyl- and tetrabutylammonium) 1,1′-(2,5-Pyridinediyl)bis[dicyanomethanide] (4a) and (4b). 2,5-Bis(dicyanomethyl)pyridine (**10**) (0.105 g, 0.51 mmol) was dissolved in 1 mol dm^{-3} NaOH solution (10 cm^3) in a nitrogen atmosphere. As soon as a solution of tetrapropylammonium iodide (0.471 mg, 1.50 mmol) in water (8 cm^3) was added, the yellow plates of **4a** precipitated. It was collected by filtration and dried in vacuo (0.264 g, 89%): decomp 133 °C; IR (KBr) 3400 (H_2O), 2974, 2888 (C-H),

2165, 2127, 2118 cm^{-1} (C≡N); Found: C, 71.61; H, 10.02; N, 15.99%. Calcd for $C_{35}H_{59}N_7 \cdot 1/2H_2O$: C, 71.63; H, 10.30; N, 16.71%. The ^1H NMR spectrum of **4a** showed some dintinct absorptions due to the propyl protons at δ 0.7—1.3 (t, 24H), 1.3—2.4 (m, 16H), 2.9—3.7 (m, 16H) and a very broad absorption due to the pyridinyl protons at δ 6.7—7.9. The latter broadening suggests that the dianion is apt to become a radical species.

The tetrabutylammonium salt **4b** was similarly obtained as yellow plates (97%): decomp 111 °C; IR (KBr) 3400 (H_2O), 2974, 2888 (C-H), 2159, 2121, 2108 cm^{-1} (C≡N); Found: C, 71.04; H, 10.92; N, 13.26%. Calcd for $C_{43}H_{75}N_7 \cdot 2H_2O$: C, 71.13; H, 10.97; N, 13.50%.

Complexation of TTF and Pyridine-Analogue 3 of TCNQ. A) Mixing Method Using Bis(tetrapropylammonium) 1,1′-(2,5-Pyridinediyl)bis[dicyanomethanide] (4a). A 20 cm^3 of H-type glass cell with a fine frit dividing the anolyte and catholyte compartments was used for electrolyses. It was equipped with platinum plates (1 cm^2 in area) as electrodes for the potentiostatic experiment and with platinum needles (3 cm in length, 1 mm in diameter) for the galvanostatic experiment. A 0.1 mol dm^{-3} solution of tetrabutylammonium perchlorate in dry acetonitrile (20 cm^3) was placed in the cell and thoroughly saturated with nitrogen gas. TTF (20.8 mg, 0.1 mmol) and **4a** (57.5 mg, 0.1 mmol) were added in the anolyte compartment and electrolyzed at +0.45 V for 1.5 h. The resulting black powder was collected, washed with dichloromethane, and dried (23.1 mg): mp>300 °C; IR (KBr) broad nitrile absorptions at 2188, 2129 cm^{-1}; σ=18.8 S cm^{-1}; Found: C, 49.68; H, 1.70; N, 16.90%. Calcd for TTF·**3**: C, 49.86; H, 1.72; N, 17.10%.

The galvanostatic electrolysis was carried out under a constant current of 0.5 mA for 12 h, giving black fine needles (14.6 mg): mp>300 °C; IR (KBr) broad nitrile absorptions at 2194, 2160, 2128 cm^{-1}; σ=19.3 S cm^{-1}; Found: C, 49.26; H, 1.63; N, 16.34%.

B) Mixing Method Using 2,5-Bis(dicyanomethyl)pyridine (10). 30% Hydrogen peroxide (2 cm^3) was added into a stirred solution of **10** (50.2 mg, 0.24 mmol) and TTF (43.1 mg, 0.21 mmol) in dry acetonitrile (5 cm^3) in a nitrogen atmosphere. After stirring for 10 min at r.t., the resulting reddish black powder was collected by filtration, washed with a small amount of acetonitrile, and dried (8.6 mg): decomp>300 °C; IR (KBr) broad nitrile absorptions at 2154, 2122 cm^{-1}; σ=1.0 S cm^{-1}; Found: C, 50.17; H, 1.74; N, 17.16%. Calcd for TTF·**3**: C, 49.86; H, 1.72; N, 17.10%.

C) Metathesis Method. A hot solution of **4a** (56 mg, 0.1 mmol) in dry acetonitrile (1.5 cm^3) was mixed with a hot solution of $(TTF)_3(BF_4)_2$ (78 mg, 0.1 mmol) in dry acetonitrile (6 cm^3) in a nitrogen atmosphere. After cooling, the resulting black powder was obtained (26.9 mg): decomp> 300 °C: IR (KBr) broad nitrile absorptions at 2187, 2156 cm^{-1}; σ=5.9 S cm^{-1}; Found: C, 45.08; H, 1.66; N, 12.32%. Calcd for $(TTF)_2 \cdot$**3**: C, 45.00; H, 1.81; N, 11.41%.

Synthesis and X-Ray Crystal Structure of [5₄](1,2,3,4)Ferrocenophane[1)]

Masao HISATOME,* Rin-ichi YAMASHITA, Jun WATANABE, Koji YAMAKAWA, and Yoichi IITAKA†
Faculty of Pharmaceutical Sciences, Science University of Tokyo, Ichigaya-Funagawara, Shinjuku-ku, Tokyo 162

(Received October 31, 1987)

The title compound bridged with four pentamethylene chains has been synthesized by stepwise construction of a pentamethylene bridge via formation of a three-carbon bridge followed by insertion of two carbon units. Crystal structure of the phane has been determined by X-ray diffraction. The compound crystallizes in the monoclinic system, space group $P2_1/n$ with unit cell parameters a=16.691(10), b=9.858(5), c=15.237(8) Å, β=112.43(6)°, and z=4. The structure parameters of the ferrocene moiety fall in normal ranges. Characteristic features are noted in the methylene bridges. The γ-methylene carbons undergo large thermal vibration, and apparent shortening of the bond lengths by oscillatory motions of atoms is seen.

A number of intramolecularly multibridged [3$_n$]- and [4$_n$]ferrocenophanes[2,3)] with tri- and tetramethylene chains have been synthesized[4,5)] since the discovery of ferrocene. Especially, recent years have seen developments in the preparation of tetra- and pentabridged ferrocenophanes,[6–10)] and symmetrically perbridged [4$_5$](1,2,3,4,5)ferrocenophane, which was named superferrocenophane, was reported by the authors[11)] in 1986. On the other hand, there have been only two reports[12,13)] on multibridged [5$_n$]ferrocenophanes (n>1) with pentamethylene chains; the one reported by Nesmeyanov et al.[12)] is [5$_2$]ferrocenophane with substituents on the bridge and the others by one of the authors[13)] are [5$_2$]- and [5$_3$]ferrocenophanes. One of the reason why [5$_n$]ferrocenophane could not be easily prepared is the difficulty of construction of additional pentamethylene bridges. Condensations between the two substituents in the two cyclopentadienyl (Cp) rings, described by several groups[12,14–17)] for the preparation of monobridged [5]ferrocenophanes, are unfavorable for synthesis of multibridged phanes, because selective substitution at the desired positions of the Cp rings is impossible. One of the authors[13)] succeeded in the formation of the pentamethylene chain by extension of α-oxotrimethylene bridge, and reported the synthesis of [5$_3$](1,2,4)ferrocenophane (**1**) via stepwise formation of pentamethylene bridges. In this paper, the synthesis of tetrabridged [5$_4$](1,2,3,4)-ferrocenophane (**2**) from **1** by application of the bridge enlargement is reported, and its molecular structure determined by X-ray diffraction is described.

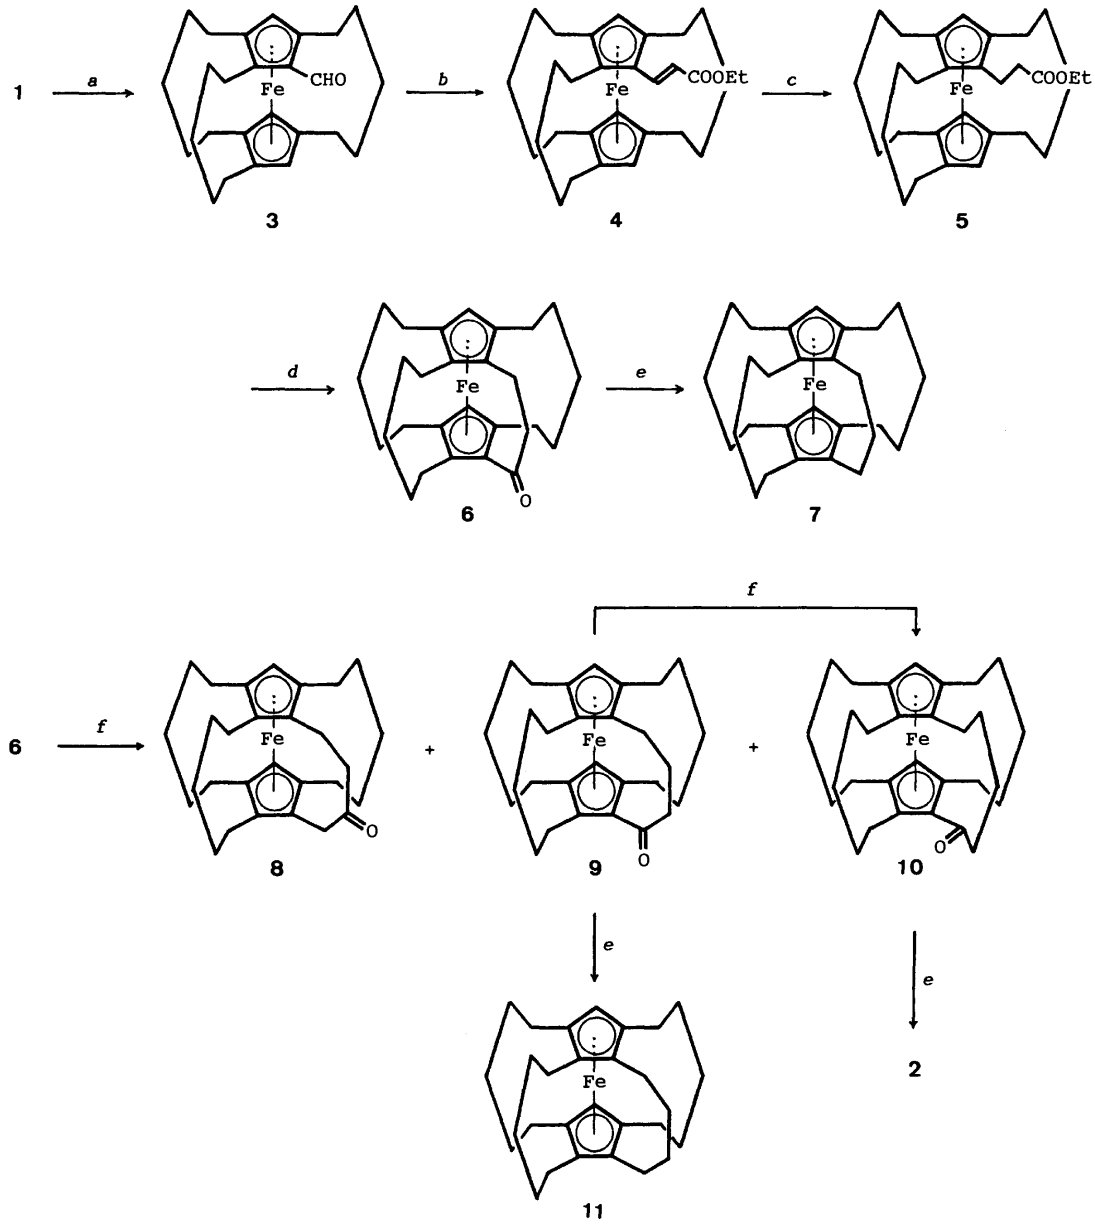
2

Results and Discussion

Synthesis. The synthetic method of [5$_4$]ferrocenophane (**2**) and the related compounds from [5$_3$]ferrocenophane (**1**) is summarized in Scheme 1. In the preparation of tribridged ferrocenophane **1**,[13)] malonic acid/piperidine and trifluoroacetic anhydride were used for condensation of formylferrocene and bridging reaction of propionic acid, respectively. However, these conventional methods were inapplicable to the construction of fourth bridge because of much more steric hindrance of the existing bridges. Accordingly, Reformatsky reaction and cyclization with polyphosphoric acid ethyl ester (PPE) were applied to these steps.

The starting material **1** was formylated according to Vilsmeyer reaction followed by Reformatsky reaction and catalytic hydrogenation to give [5$_3$]ferrocenophanepropionate (**5**) in a good yield (86% from **1**). Cyclization of propionic acid, prepared by hydrolysis of **5**, with PPE (concn 50%) in 1,2-dichloroethane under the conditions free from oxygen and moisture afforded tetrabridged compound **6** in quantitative yield. Running the reaction in the presence of a trace amount of oxygen and moisture resulted in considerable decrease in the yield of **6** (44%). Therefore, the cyclization must be carried out under strict control of reaction conditions. The signals of the Cp rings in the ^{1}H NMR spectrum of **6** appeared at δ 3.68 and 3.63 as two singlets. The NMR spectrum of phane **7** derived by reduction of **6** showed only one singlet of the Cp ring protons and eleven carbon signals of the methylene groups. The spectral pattern indicates that **7** has a C_s symmetric structure.

Treatment of ketone **6** with a large excess of diazomethane (over 10 equiv to the substrate) in the presence of BF_3 etherate (3.5 equiv) afforded three bridge-enlarged products **8**, **9**, and **10** in 35, 33, and 30% yields, respectively. β-Ketone **8** was contaminated with minor compounds, which were presumably further enlarged compounds, and attempted purification was unsuccessful. When 1.2 equivalent of BF_3 etherate to the substrate was used, the yield of α-oxo[5]ferrocenophane **10** was only 3.3%. Bridge enlargement of α-oxo[4]ferrocenophane **9** in a similar manner to the reaction of **6** also gave the desired compound **10** (42%).



Scheme 1. Synthesis of [5$_4$](1,2,3,4)ferrocenophane (**2**) and related compounds. *a*. DMF/$POCl_3$. *b*. $BrCH_2COOEt$/Zn. *c*. H_2/Pd-C. *d*. 1) aq. NaOH, 2) PPE. *e*. $LiAlH_4/AlCl_3$. *f*. $CH_2N_2/BF_3 \cdot OEt_2$ in benzene.

Reduction of **9** and **10** with $LiAlH_4/AlCl_3$ afforded the corresponding tetrabridged ferrocenophanes **11** and **2**. In the ^1H NMR spectrum of **2**, the two protons of the Cp rings appeared as a singlet at δ 3.70. The C_{2v} symmetric structure of **2** was confirmed by observation of a simple ^{13}C NMR spectral pattern consisting of six and three signals of the methylene and Cp ring carbons, respectively.

Molecular Structure. The crystal structure of [5$_4$]ferrocenophane (**2**) was determined by X-ray diffraction. The structural parameters are given in Tables 1—6. The molecular structure and the numbering of the atoms used in this section are shown in Fig. 1.[18]

As is clear from Fig. 1, the bridging methylene chains C1···C6 and C4···C9 are in a "boat" conformation, whereas the chains C2···C7 and C3···C8 are in a "zigzag-like" conformation. In the crystal structure of tribridged phane **1** reported by Hillman et al.,[19] the conformations of the methylene chains are all boat forms. From the results it is noted that boat conformation is favorable for bridging between two Cp rings with pentamethylene chains when one of the neighboring positions of the bridge, at least, is unoccupied with other bridge. The pentamethylene chains in a boat form bend in a

manner as the γ-methylene group approaches to the ferrocene moiety. The chains C1···C6 and C4···C9 can take such a conformation, because there is no substituent at the 5- and 10 positions. However, the chains C2···C7 and C3···C8 which are surrounded with the two bridges cannot take a boat form. Therefore, the two chains are forced to have a zigzag-like conformation to avoid steric effect of the bridges in both sides.

The β- and β'-carbon atoms C17, C19, C22, and C24 of the methylene bridges undergo large thermal vibrations. The root-mean-square displacement of these atoms along the thermal ellipsoid principal axes are listed in Table 4. Most of the largest axes lie nearly along the line bisecting the bonds linking the methylene carbon atoms. This is probably due to the disorder of these bridging carbon atoms. Apparent torsion angles along each chain are listed in Table 5 which were calculated by assuming the methylene carbon atoms situated at their mean position (Table 1). It is clear that the bridging methylene chains C1···C6 and C4···C9 are much more relieved situation since there is no bridge in the neighboring position

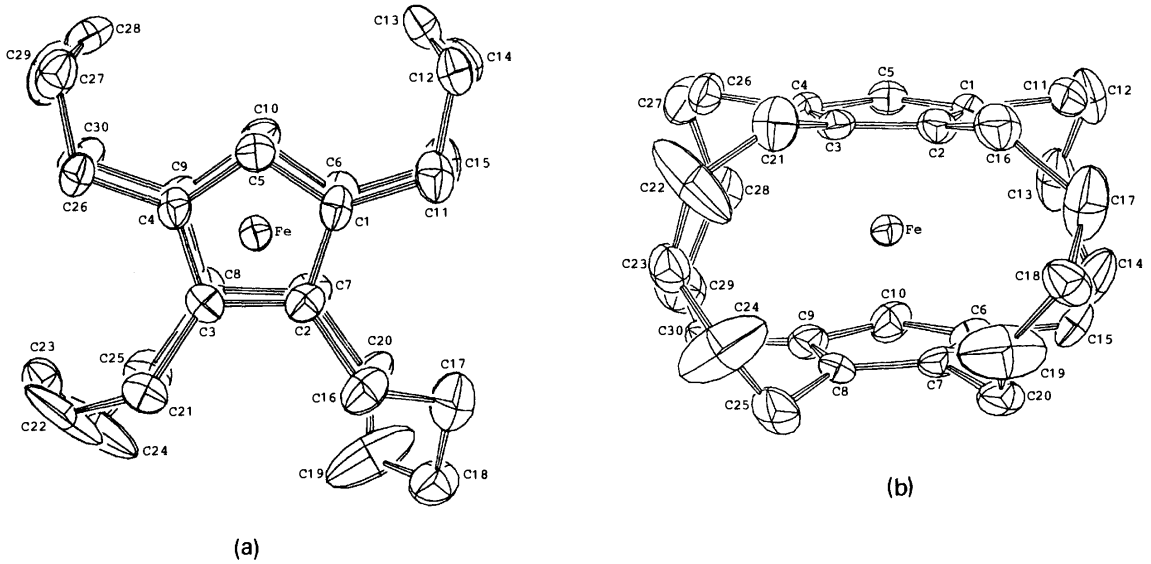

Fig. 1. (a) An ORTEP drawing[18] of the molecule viewed perpendicular to the plane formed by the two lines C1–C4 and C3–C5. The thermal ellipsoid encloses the region where the center of each atom will be found with probability 30%. Hydrogen atoms are omitted. (b) Same as (a) but rotated 90° about the horizontal line through C1 and C4.

C24	0.704	0.296	0.189

(C5···C10) and the torsion angles along these chains are more close to those of the normal gauche conformation. Apparent shortening by oscillatory motions[20] of atoms is clearly seen in the bond lengths between the central two carbon atoms for each methylene chain (see Table 2).

Table 6 shows the planarity of the Cp rings and the deviations of atoms from the planes. The deviations of the α-methylene carbons linked directly to the Cp rings are in a direction expanding the ferrocene cage and the magnitude of the deviation is less remarkable for the above mentioned two relieved methylene chains. Based on these facts it may be clear that the pentamethylene chains are too long to accommodate between the two Cp rings, and that the chains in a boat conformation can link the ferrocene nucleus with less strain than that in a zigzag form.

The conformation of the ferrocene moiety is almost similar to that of tribridged phane **1**.[19] The two Cp rings are in an eclipsed conformation about the Cp–Fe–Cp axis. The Cp rings show a good planarity and the average value of the atomic deviations from its

own least-squares plane is about 0.009 Å (root mean square). The distance between the two Cp rings through the Fe atom (3.336(16) Å) is slightly extended in comparison with that of **1** (3.293(2) Å). It is reasonable that addition of a pentamethylene chain which is too long to link between the two Cp rings results in the extension of the Cp ring distance.

Electronic Spectrum. The electronic spectrum of **2** exhibits a fairly large bathochromic shift of the d-d* absorption band in the visible region (460 nm). We have observed a linear relationship between the wavelength of the d-d* absorption and the number of tetramethylene bridges in [4$_n$]ferrocenophanes (n=0—5),[11,21,22] but there is no analogous relation in [5$_n$]ferrocenophanes. The wavelengths of the bands in mono-, di-, and tribridged phanes with pentamethylene chains are almost similar to that of ferrocene (443, 447, 446, 444, and 442 nm for ferrocene, [5]-, [5$_2$](1,2)-, [5$_2$](1,3)-, and [5$_3$](1,2,4)ferrocenophanes, respectively), but that of tetrabridged phane **2** is 18 nm higher than the same band of **1**. A linear relationship between the hypsochromic shift of the d-d* band and the compression of the Cp-Fe-Cp distance has been found in the study on the electronic spectra of various multibridged ferrocenophanes.[21] If the relation also holds for [5$_n$]ferrocenophanes, the slight elongation of the Cp-Fe-Cp distance in **2** as compared with that of **1** should result in a bathochromic shift of the band in **2**. However, we have not yet found a definitive explanation for the cause of the unusual shift in compound **2**.

The successive hypsochromic shift with the decrease of the methylene group of the 3,3′-bridge was shown in tetrabridged phanes (460, 454, and 447 nm for **2**, **11**, and **7**, respectively). Barr and Watts[23] reported that the d-d* band responded to a ring tilt deformation of the ferrocene nucleus and shifted to a long wavelength with increasing dihedral angle between the two Cp rings in ferrocenophanes. Accordingly, the shift behavior in tetrabridged phane would be reasonably explained by the "tilting effect," because the tiltings of the phanes presumably increase with the decrease of the length of the bridge at the 3,3′-position though the dihedral angles are not confirmed by structural analysis.

Experimental

All melting points were uncorrected. IR spectra were measured using a Hitachi model 215 grating infrared spectrometer. NMR spectra were measured on a JEOL JNM-FX100 spectrometer relative to tetramethylsilane as an internal standard. The figures in the parentheses of ^{13}C NMR spectral data represent the number of the peaks overlapping each other. Mass spectra were obtained with a Hitachi RMU-7M or a Hitachi M-80 double focusing mass spectrometer by electron impact ionizing technique at 70 eV. High-resolution mass spectra were analyzed on a Hitachi M-003 data processing system. Electronic spectra were measured on a Hitachi 330 spectrometer in tetrahydrofuran.

3-Formyl[5$_3$](1,2,4)ferrocenophane (3). A solution of [5$_3$](1,2,4)ferrocenophane (**1**)[13] (348 mg) and *N*,*N*-dimethylformamide (525 mg) in freshly distilled chloroform (15 ml) was stirred at 0 °C. To the cooled solution phosphoryl chloride (1.11 g) was added dropwise under a nitrogen atmosphere. The reaction mixture was stirred at 55 °C for 17 h, and then evaporated to dryness. Water was added to the residue, and the aqueous mixture was neutralized with aq. 20% NaOH. The mixture was extracted with benzene several times, and the extracts were washed with saturated aq. NaCl, dried over Na_2SO_4, and evaporated. The residue was column-chromatographed over alumina to be separated into two bands. The first band eluted with benzene yielded the starting material (44 mg, 13%). The second band eluted

with benzene-ethyl acetate (20:1) yielded aldehyde **3** (320 mg, 86%), which was recrystallized from ethyl acetate to give orange-red prisms; mp 145—148 °C. IR (KBr) 1670 (C=O) cm^{-1}; ^1H NMR ($CDCl_3$); δ=1.40—3.30 (30H, m, $-CH_2-$), 3.65 and 3.84 (each 1H, an AX system, J=1.6 Hz, 3'- and 5'-H), 4.16 (1H, s, 5-H), 10.33 (1H, s, -CHO); MS m/z (rel intensity), 418 (100, M^+), 389 (7), 388 (5).

Found: C, 74.70; H, 8.29%; m/z 418.1936. Calcd for $C_{26}H_{34}OFe$: C, 74.64; H, 8.19%; M, 418.1956.

Ethyl [5$_3$](1,2,4)Ferrocenophane-3-acrylate (4). To a solution of aldehyde **3** (100 mg) in dry benzene-ether (5:1, 6 ml) was added activated zinc (313 mg) and a small amount of iodine, and the mixture was stirred at room temperature under a nitrogen atmosphere. Ethyl bromoacetate (160 mg) was added dropwise to the suspension. The reaction mixture was refluxed on an oil bath at 110 °C for 10 min. After water was added, the mixture was extracted with benzene. The extracts were treated with concd HCl and then with aq. Na_2CO_3 containing ascorbic acid. The organic layer was washed with saturated aq. NaCl, dried over Na_2SO_4, and evaporated. The residue was eluted through a column of silica gel with benzene to yield acrylate **4** (120 mg, quant.), which was recrystallized from ethyl acetate to give red-violet flakes; mp 114—116 °C. IR (KBr) 1715 and 1625 (C=O and C=C) cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.40—3.00 (30H, m, $-CH_2-$), 1.34 (3H, t, J=7 Hz, $-CH_3$), 3.49 and 3.59 (each 1H, an AX system, J=1.6 Hz, 3'- and 5'-H), 4.02 (1H, s, 5-H), 4.27 (2H, q, J=7 Hz, $-OCH_2-$), 6.08 and 7.87 (each 1H, an AX system, J=16 Hz, olefin-H); MS m/z (rel intensity) 488 (100, M^+), 460 (2).

Found: C, 73.46; H, 8.33%; m/z 488.2396. Calcd for $C_{30}H_{40}O_2Fe$: C, 73.76; H, 8.25%; M, 488.2376.

Ethyl [5$_3$](1,2,4)Ferrocenophane-3-propionate (5). Acrylate **4** (1.16 g) was reduced with H_2 gas (1 atm) and 10% Pd-C (350 mg) in acetone (80 mg) at room temperature for 24 h. The reaction mixture was evaporated and the residue was eluted through a short column of silica gel with benzene-ethyl acetate (3:1). The eluted propionate **5** (1.20 g, quant.) was recrystallized from ethyl acetate to give yellow prisms; mp 91.5—95 °C. IR (KBr) 1740 (C=O) cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.40—3.00 (34H, m, $-CH_2-$), 1.27 (3H, t, J=7.5 Hz, $-CH_3$), 3.27 (1H, bs, 5-H), 3.62 (2H, bs, 3'- and 5'-H), 4.11 (2H, q, J=7.5 Hz, $-OCH_2-$); MS m/z (rel intensity) 490 (100, M^+), 4.76 (2), 461 (3), 417 (2), 388 (3).

Found: C, 73.46; H, 8.70%; m/z 490.2526. Calcd for $C_{30}H_{42}O_2Fe$: C, 73.46; H, 8.63%; M, 490.2532.

[5$_2$]-α-Oxo[3][5](1,2,3,4)ferrocenophane (6). Propionate **5** (100 mg) was dissolved into ethanol (20 ml) and the solution was added dropwise to 20% aq. NaOH (20 ml) which was heated at 90 °C. The reaction mixture was stirred at 90 °C for 10 min, and then neutralized with concd HCl. The mixture was extracted with benzene. The extracts were washed with saturated aq. NaCl, dried over Na_2SO_4, and evaporated. The residue, which was crude [5$_3$](1,2,4)ferrocenophane-3-propionic acid, was immediately used for the following reaction without further purification, because the acid was very sensitive to air.

The crude acid was dissolved into 1,2-dichloroethane, and oxygen in the solution was removed as much as possible by ultrasonic vibration. 1,2-Dichloroethane (25 ml) was added to 50% polyphosphoric acid ethyl ester (PPE) prepared in the usual way,[24] and the mixture was refluxed under an argon atmosphere for 1 h to remove oxygen in the reagent. The above solution of the acid was added dropwise to the refluxing solution of PPE, and the reaction mixture was refluxed on an oil bath at 80 °C under an argon atmosphere for 30 min. After 20% aq. NaOH containing ascorbic acid were added to be neutralized, the mixture was stirred at room temperature for 1 h and extracted with 1,2-dichloroethane. The extracts were washed with saturated aq. NaCl, dried over Na_2SO_4, and evaporated. To a solution of the residue in benzene was added a solution of diazomethane in ether. The mixture was stirred and evaporated, and the residue was dissolved into benzene again. Alumina was added to the benzene solution. The suspension was placed in a column packed with silica gel and eluted with benzene. The orange band yielded bridged product **6** (91 mg, quant.), which was recrystallized from ethyl acetate to give orange prisms; mp 225—228 °C. IR (KBr) 1665 (C=O) cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.30—3.70 (34H, m, $-CH_2-$), 3.63 (1H, s, 5-H), 3.68 (1H, s, 5'-H); ^{13}C NMR ($CDCl_3$) δ=20.65, 21.24, 21.94, 22.06, 22.29, 22.41, 22.58, 23.17, 24.16, 24.34, 25.98 (3C), 26.21, 26.79, 33.35, and 47.80 (methylene-C), 70.67 and 73.30 (unsubstd. Cp-C), 70.26, 79.39, 83.54, 86.00, 86.12, 90.39, 90.68, and 93.02 (substd. Cp-C), 213.48 (C=O); MS m/z (rel intensity) 444 (100, M^+), 416 (24).

Found: C, 75.70; H, 8.13%; m/z 444.2093. Calcd for $C_{28}H_{36}OFe$: C, 75.71; H, 8.17%; M, 444.2112.

[5$_2$][3][5](1,2,3,4)Ferrocenophane (7). A solution of ketone **6** (100 mg) in absolute ether (10 ml) was added to a suspension of $LiAlH_4$ (100 mg) and $AlCl_3$ (200 mg) in ether (10 ml). The reaction mixture was stirred at room temperature for 3 h. Saturated aq. NH_4Cl was added to the mixture and the hydrolyzate was extracted with benzene. The extracts were washed with saturated aq. NaCl, dried over Na_2SO_4, and evaporated. Column chromatographic purification of the residue over alumina gave compound **7** (97 mg, quant.), which was recrystallized from ethyl acetate to give yellow prisms; mp 212—214 °C. ^1H NMR ($CDCl_3$) δ=1.20—3.20 (36H, m, $-CH_2-$), 3.56 (2H, s, Cp-H); ^{13}C NMR ($CDCl_3$) δ=18.81, 20.57, 21.05, 21.83, 22.61, 22.91, 24.61, 25.83, 26.07, 32.22, and 33.87 (methylene-C), 70.18 (unsubstd. Cp-C), 82.81, 86.41, and 91.53(2C) (substd. Cp-C); λ_{max} (THF)=447 nm (ε=245); MS m/z (rel intensity) 430 (100, M^+).

Found: C, 78.14; H, 8.88; m/z 430.2320. Calcd for $C_{28}H_{38}Fe$: C, 78.17; H, 8.90; M, 430.2320.

[5$_2$]-α-Oxo[4][5]- and [5$_2$]-α-Oxo[5][5](1,2,3,4)ferrocenophanes (9 and 10). Ketone **6** (500 mg) was dissolved into dry benzene (50 ml) and BF_3 etherate (0.7 ml) was added to the solution under a nitrogen atmosphere. The mixture was cooled on an ice-water bath. To the vigorously stirring solution of the complex was rapidly added an ether solution of alcohol-free diazomethane (50 ml), which had been prepared in the usual way[13] and stored over KOH. Water containing ascorbic acid and then 20% aq. NaOH was added and the mixture was extracted with benzene. The extracts were washed with saturated aq. NaCl, dried over Na_2SO_4, and evaporated. The residue was column-chromatographed over silica gel with benzene. The first band yielded [5$_2$]-β-oxo[4][5](1,2,3,4)ferrocenophane (**8**) (180 mg, 35%). IR (KBr) 1700 (C=O) cm^{-1}. The ketone **8** was contaminated with further enlarged products, which could not be removed by

means of various methods for purification.

The second band yielded ketone **10** (160 mg, 30%), which was recrystallized from ethyl acetate to give orange prisms; mp>300 °C. IR (KBr) 1650 (C=O) cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.60—3.00 (38H, m, $-CH_2-$), 3.69 (1H, s, 5-H), 4.00 (1H, s, 5′-H); ^{13}C NMR ($CDCl_3$) δ=21.70, 22.00, 22.52, 22.70 (3C), 22.93 (3C), 24.63, 24.75, 25.16(2C), 25.57, 25.68, 25.80, 26.68, 28.37, and 39.84 (methylene-C), 69.68 and 73.07 (unsubstd. Cp-C), 81.03, 82.78, 85.47, 86.06, 87.52, 88.51, 88.92, and 89.10 (substd. Cp-C), 210.84 (C=O); MS *m/z* (rel intensity) 472 (100, M^+), 458 (7), 444 (15).

Found: C, 76.13; H, 8.29%; *m/z* 472.2420. Calcd for $C_{30}H_{40}OFe$: C, 76.30; H, 8.54%; M, 472.2426.

The third band yielded ketone **9** (170 mg, 33%), which was recrystallized from ethyl acetate to give orange prisms; mp 258—261 °C. IR (KBr) 1660 (C=O) cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.40—3.00 (36H, m, $-CH_2-$), 3.68 (1H, s, 5-H), 3.91 (1H, s, 5′-H); ^{13}C NMR ($CDCl_3$) δ=21.41, 21.82, 22.23, 22.46, 22.64, 22.87, 23.05, 23.34, 23.64, 24.22, 24.45, 25.62, 25.74(2C), 26.09, 30.13, 31.01, and 43.29 (methylene-C), 69.21 and 73.25 (unsubstd. Cp-C), 79.97, 82.90, 85.12, 85.53, 86.88, 89.16(2C), and 89.74 (substd. Cp-C), 210.08 (C=O); *m/z* (rel intensity) 458 (100, M^+).

Found: C, 75.90; H, 8.21; *m/z* 458.2271. Calcd. for $C_{29}H_{38}OFe$: C, 76.01; H, 8.36; M, 458.2270.

The ketone **9** (100 mg) was converted into the desired ketone **10** (45 mg, 42%) by bridge enlargement in benzene (20 ml) with BF_3 etherate (0.14 ml) and diazomethane (ether solution 10 ml), according to the same procedure as the reaction of **6**.

[5₂][4][5](1,2,3,4)Ferrocenophane (11). Reduction of ketone **9** (100 mg) with $LiAlH_4$ (100 mg) and $AlCl_3$ (200 mg) in ether (20 ml) was carried out according to the same procedure as in the preparation of **7**. The crude product **11** (84 mg, 87%) was recrystallized from ethyl acetate to give yellow prisms; mp 242—243 °C. ^1H NMR ($CDCl_3$) δ=1.30—2.90 (38H, m, $-CH_2-$), 3.63 (2H, s, Cp-H); ^{13}C NMR ($CDCl_3$) δ=21.20, 21.69, 22.47, 22.86, 23.10, 24.32, 25.64, 26.17(2C), 27.24, and 27.78 (methylene-C), 68.67 (unsubstd. Cp-C), 81.59, 81.78, 85.83, and 87.58 (substd. Cp-C); λ_{max}(THF)=454 nm (ε=130); MS *m/z* (rel intensity) 444 (100, M^+).

Found: C, 78.34; H, 9.04%; *m/z* 444.2467. Calcd for $C_{29}H_{40}Fe$: C, 78.37; H, 9.07%; M, 444.2470.

[5₄](1,2,3,4)Ferrocenophane (2). Reduction of ketone **10** (290 mg) with $LiAlH_4$ (233 mg) and $AlCl_3$ (490 mg) in ether (10 ml) was carried out according to the same procedure as in the preparation of **7**. The crude product **2** (223 mg, 80%) was recrystallized from ethyl acetate to give yellow prisms; mp 245 °C (decomp). ^1H NMR ($CDCl_3$) δ=1.30—2.90 (40H, m, $-CH_2-$), 3.70 (2H, s, Cp-H); ^{13}C NMR ($CDCl_3$) δ=21.88, 22.76, 22.96, 25.20, 25.29, and 28.22 (methylene-C), 68.43 (unsubstd. Cp-C), 83.39 and 87.09 (substd. Cp-C); λ_{max}(THF)= 460 nm (ε=124); MS *m/z* (rel intensity) 458 (100, M^+).

Found: C, 78.88; H, 9.23%; *m/z* 458.2613. Calcd for $C_{30}H_{42}Fe$: C, 78.59; H, 9.23%; M, 458.2633.

X-Ray Crystallographic Analysis of 2. Crystals of **2** were grown in a dichloromethane–hexane solution as pale orange prisms elongated along the c axis. A specimen with approximate dimensions 0.5×0.1×0.05 mm was chosen for X-ray diffraction measurement. Crystal data and intensity data were collected on a Philips PW 1100 diffractometer using graphite monochromated Mo $K\alpha$ radiation.

Crystal data: [5₄](1,2,3,4)Ferrocenophane, $C_{30}H_{42}Fe$, MW= 458.5. Monoclinic, space group $P2_1/n$, Z=4, D_{cal}=1.314 g cm^{-3}. Lattice constants, a=16.691(10), b=9.858(5), c= 15.237(8) Å, β=112.43(6)°, U=2317 Å^3. μ for Mo $K\alpha$=6.6 cm^{-1}.

Intensities of 1710 reflections were measured as above the $2\sigma(I)$ level out of 3737 independent reflections within the 2θ angle range 6° through 50°. No absorption correction was applied.

The crystal structure was solved by the heavy atom method and refined by the block-diagonal-matrix least-squares calculations including 30 hydrogen atoms with isotropic temperature factors and dispersion terms of the atomic scattering factor of Fe for Mo $K\alpha$ radiation.[25] Twelve hydrogen atoms attached to C17, C18, C19, C22, C23, and C24 were not included because these were not found on the diffraction electron-density map due to the disorders described in results and discussion. The final R value was 0.085 for 1710 reflections. Bond lengths and bond angles calculated from the refined atomic coordinates (Table 1) are listed in Tables 2 and 3.††

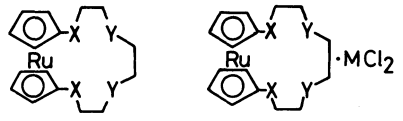
(Received November 12, 1987)

Dichlorobis(4,7,10-trioxa-1,13-dithia[13](1,1′)ruthenocenophane)palladium(II) (**6**) was obtained by the reaction of 4,7,10-trioxa-1,13-dithia[13](1,1′)ruthenocenophane (**5**) with dichlorobis(acetonitrile)palladium(II) in 72% yield. The crystal structures of the complex **6** and its metal free ligand **5** were determined by the X-ray method. The crystal data: **5**, monoclinic, $P2_1/a$, a=18.783(2), b=7.895(1), c=12.892(1) Å, β=93.53(1)°, U=1908.2 Å^3, Z=4, D_c=1.58 g cm^{-3}, μ(Mo $K\alpha$)=10 cm^{-1}. **6**, triclinic, $P\bar{1}$, a=13.956(2), b=9.174(1), c=8.770(1) Å, α=86.61(1), β=75.54(1), γ=94.37(1)°, U=1080.6 Å^3, Z=2, D_c=1.94 g cm^{-3}, μ(Mo $K\alpha$)=20 cm^{-1}. The Pd atom of **6** bonded to the two sulfur atoms of the ligand and the torsion angle (69.2°) around the z-axis of the ruthenocenophane nucleus in the metal-free ligand is much larger than the corresponding one (0.4°) in the complex. These results are completely opposite of the case of 1,4,7,10-tetrathia[10](1,1′)ruthenocenophane and its Pt complex. Furthermore, the intramolecular atomic distance (3.697 Å) between the Ru and Pd atoms in **6** suggests the absence of the Ru–Pd dative bond.

Although a number of crown, thiacrown, and azacrown ether complexes of alkali, alkaline earth, and transition metal ions have already been reported,[1] only a few complexes of platinum group metals with the above macrocyclic compounds are known.[2] Furthermore, few conformational studies of the complexes of metallocenophanes containing polyether and polythiaether moieties with metal ions by X-ray analyses have been carried out,[3–7] although many metallocenophanes have been described.[8–16] A comparison of the X-ray structures of the metal-free ligand with its metal complex can often reveal changes in the molecular conformation which is caused by complexation. In connection with the above viewpoints, we have reported the crystal structures of 1,10-dioxa-4,7-dithia- and 1,4,7,10-tetrathia[10](1,1′)ruthenocenophanes (**1** and **2**) and their platinum and/or palladium complexes (**3** and **4**).[5,6] The torsion angle (68°) between the C(1)–S(6) and S(15)–C(16) bond around the z-axis of the ruthenocene nucleus in the palladium complex **4** is much larger than the corresponding one (5.3°) in the metal-free ligand **2**, although the two Cp rings for these compounds take an eclipsed conformation and the dihedral angles between them are 2.5 and 2.4° for **2** and **4**. Also very similar results were obtained in the cases of [10](1,1′)ruthenocenophane (**1**) and its platinum complex **3**. Furthermore, we have reported on the preparation of polyoxa-1,n-dithia[n](1,1′)ruthenocenophanes by the reaction of disodium ruthenocene-1,1′-dithiolate with dihalide.[4] In this paper[17] we report the X-ray analysis of 4,7,10-trioxa-1,13-dithia[13](1,1′)ruthenocenophane (**5**) and its palladium complex **6**.



1: X=O, Y=S
2: X=Y=S
3: X=O, Y=S, M=Pd
4: X=Y=S, M=Pt

A solution of $PdCl_2\cdot(CH_3CN)_2$ in acetonitrile was reacted with a equimolar amount of **5** in acetonitrile to give 1 : 1 complex **6** in 72% yield. The melting point of the palladium complex **6** was higher than that of the corresponding metal free ligand **5**. The ^{1}H NMR spectrum of **5** in DMSO-d_6 showed a pair of triplets corresponding to the α- and β-ring protons of the ruthenocene nucleus at δ 4.64 (J=1.7 Hz, 4H) and 4.77 (J=1.7 Hz, 4H), in addition to a singlet at δ 3.75 (OCH_2CH_2O, 8H) and two triplets at δ 2.85 (J=6.6 Hz, SCH_2, 4H) and 3.60 (J=6.6 Hz, OCH_2, 4H). These results suggest that **5** in the solution takes a symmetrical structure which differs from its conformation in the solid state as described below. Furthermore, the differences in the chemical shifts between all the protons of **5** and **6** were not observed in DMSO, because the complex **6** in the solution seems to take a solvolytic form. The result is consistent with those of [10](1,1′)ruthenocenophanes and their complexes.[5,6] Measurements of the ^{1}H NMR spectra of **6** in less polar solvents such as CD_3CN and $CDCl_3$ were unsuccessful because the low solubility of the complex **6** in such solvents.

The metal free ligand **5** and its Pd complex **6** were further characterized by X-ray crystallographical studies. The final atomic parameters for **5** and **6** are listed in Tables 1 and 2, and bond lengths as well as bond and torsion angles are given in Tables 3 and 4 for **5** and **6**, respectively. The molecular structures of **5** and **6** are illustrated in Fig. 1.

In spite of the steric hindrance due to the two Cp rings the interesting selective coordination of the S(6) and S(18) atoms in **6** on the Pd atom suggests that the Pd atom has a higher complexation ability on the S atoms than the O atoms. The Pd atom bonded to the two S atoms of the oxathiacrown ether moiety has a slightly distorted cis square-planar configuration. The dihedral angle between the planes defined by S(6)–Pd–S(18) and Cl(1)–Pd–Cl(2) is 4.1(1)°. The coordination geometry of the Pd atom is similar to that found in the platinum complex of [10]ruthenocenophane **4**[6] except for the difference of the coordinated site in the macrocyclic ring. The intramolecular atomic distance between the Ru and Pd atoms is 3.697(1) Å. This value is much longer than that of the Ru–Pd dative bond (2.692(1) Å) in (1,1′-ruthenocenedithiolato-S,S′,Ru)(triphenylphosphine)palladium(II)[18] and its analogues,[19] and indicates no direct metal–metal interaction between the coordinated palladium atom and the ruthenium atom of the ruthenocene nucleus in the complex **6**. This finding is very different from the result[20] obtained in the 1:1 complex **8** of 1,4,7-trithia[7](1,1′)-ferrocenophane (**7**) with $(CH_3CN)_4 \cdot Pd(BF_4)_2$. Palladium atom was incorporated in the cavity of the macrocyclic moiety of **7** and coordinated by the three sulfur atoms to form the Fe–Pd dative bond. The absence of the Ru–Pd dative bond in **6** attributed to the strong bonding force of the Pd–Cl bond compared with Pd–B bond, because the two Pd–Cl bond length in **6** are 2.303(2) and 2.308(2) Å, respectively, which are consistent with the sum of the covalent radii[21] of Pd and Cl atoms.

The conformation of the organic ligand moiety of the complex **6** differs greatly from that of the metal-free ligand **5**. The main conformational changes are reflected in the overlapping patterns between the two Cp rings and in the torsion angles of the macrocyclic moiety. The Cp rings take an eclipsed conformation, in which the dihedral angles between them are 5.5(4) and 4.4(3)° for **5** and **6**, respectively. The torsion angle C(1)–Cp1–Cp2–C(19) (Cp1 and Cp2 are the centroids of the Cp rings) in **5** is 69.2°, although that in **6** is only 0.4°. As shown in Fig. 2, these results are just the opposite of the cases of [10](1,1′)ruthenocenophanes and their platinum and palladium complexes;[5,6] the metal-free ligand **2** has a small torsion angle (5.3°), while the torsion angle of its platinum complex is a large one (68°). The torsion angles in [3](1,1′)- and [4](1,1′)ruthenocenophanes are 14.8(2) and 1.7(2)°, respectively.[9,10] However, Cameron et al.[8] reported that the torsion angle in [4](1,1′)ferrocenophane is

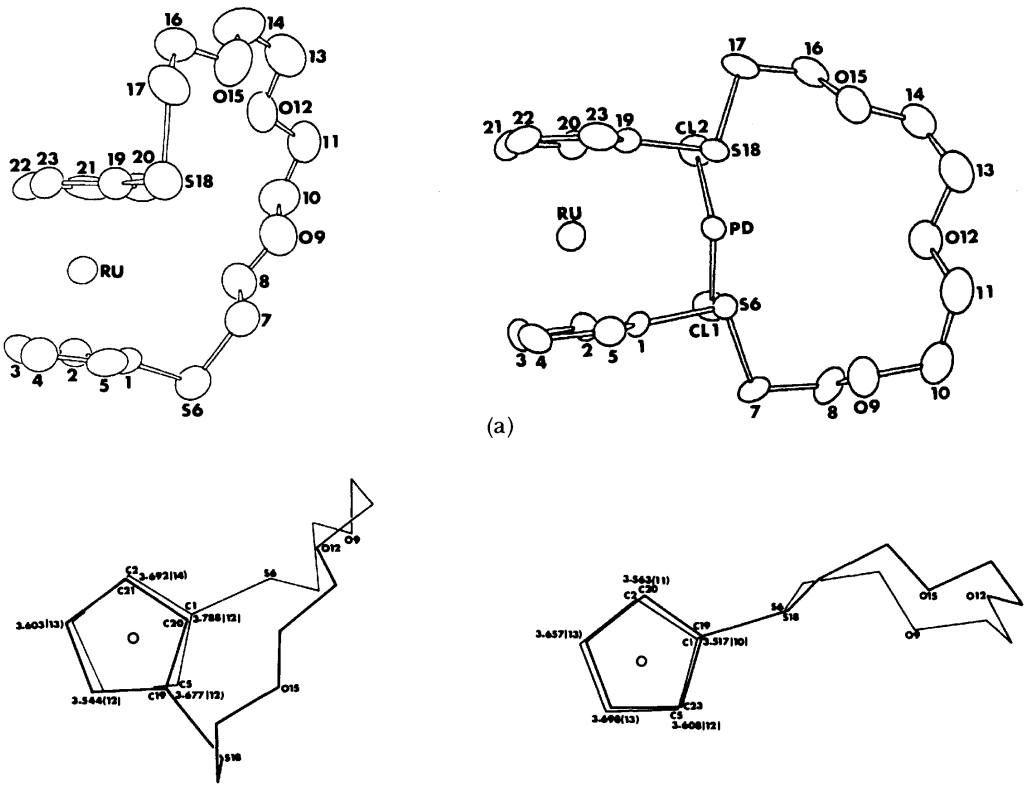

Fig. 1. (a) ORTEP (Johnson, 1965) drawings of molecules **5** and **6** with atom numbering scheme. (b) Projections of the organic ligand moieties on the Cp ring containing the C(1) atom with the C····C distances (Å) between the rings. An open circle denotes the Ru atom.

approximately 36°. Therefore, the conformational stability around the *z*-axis of the ruthenocene nucleus in the metal-free ligands is attributable to the ring size of the macrocyclic rings. The large rotational angle (69.2°) between the two Cp rings in the metal-free ligand **5** causes the two S atoms attached to each Cp ring to separate by more than 4.5 Å from each other, and this distance is too long to form the complex. In order to form the complex **6**, it is necessary to approach the two S atoms more closely and the lobes of lone pair electrons are rotate in the same direction. It was reported that the energy barrier of the rotation around the *z*-axis (Cpl–Ru–Cp2) of ruthenocene is only 3—6 kcal mol^{-1}.[22] Therefore, the energy of the rotation around the *z*-axis of the ruthenocene nucleus is compensated by the conformational changes of the macrocyclic moiety. Indeed, the three torsion angles, C(1)–S(6)–C(7)–C(8), S(6)–C(7)–C(8)–O(9), and C(16)–

C(17)–S(18)–C(19), in **6** are remarkably changed by the complexation, compared with those of the corresponding metal-free ligand **5** as shown in Fig. 1.

Experimental

The decomposition point has not been corrected. ^{1}H NMR spectra were obtained on a JEOL FX-90Q spectrometer with TMS as an internal standard.

Materials. 4,7,10-Trioxa-1,13-dithia[13](1,1′)ruthenocenophane (**5**) was prepared according to the previously reported method.[4]

Dichlorobis(acetonitrile)palladium(II) was prepared according to methods described in the literature.[23]

Dichloro(4,7,10-trioxa-1,13-dithia[13](1,1′)ruthenocenophane)palladium(II) (**6**). A solution of 14 mg (54 mmol) of dichlorobis(acetonitrile)palladium(II) in 1 cm^3 of acetonitrile was added, dropwise, to a solution of 1 cm^3 of acetonitrile containing 23 mg (51 mmol) of **5**. The resulting precipitates were filtered and washed with a small amount of acetonitrile to give a 1:1 metal complex **6** in 72% yield. Mp 200 °C (decomp).

Found: C, 34.26; H, 3.84. Calcd for $C_{18}H_{24}O_3S_2RuPdCl_2$: C, 34.27; H, 3.84.

X-Ray Crystallography. Crystals of dimensions 0.4×0.2×0.1 mm for the metal free ligand **5** and 0.4×0.3×0.15 mm for the Pd-complex **6** were used for X-ray crystallography. Crystal data are as follows: **5**, $C_{18}H_{24}O_3S_2Ru$, M_w=456.3, Monoclinic, $P2_1/a$, a=18.783(2), b=7.895(1), c=12.892(1) Å, β=93.53(1)°, U=1908.2 Å^3, Z=4, D_x=1.58 g cm^{-3}, μ(Mo $K\alpha$)=10 cm^{-1}. **6**, $C_{18}H_{24}O_3S_2RuPdCl_2$, M_w=630.9, triclinic, $P\bar{1}$, a=13.956(2), b=9.174(1), c=8.770(1) Å, α=86.61(1), β=75.54(1), γ=94.37(1)°, U=1080.6 Å^3, Z=2, D_x=1.94 g cm^{-3}, μ(Mo $K\alpha$)=20 cm^{-1}.

Intensity data for $2\theta \leq 50°$ were recorded on a Rigaku AFC-5R with graphite-monochromatized Mo $K\alpha$ radiation. A total of 3362 (**5**) and 3424 (**6**) independent reflections were corrected for Lorentz and polarization factors but not for absorption. Both structures **5** and **6** were solved by the heavy-atom method, and refined by block-diagonal least squares methods. The positions of the hydrogen atoms were estimated using standard geometry. The final refinements with anisotropic temperature factors for the nonhydrogen atoms and isotropic temperature factors for the hydrogen atoms were lowered R values 0.054 (R_w=0.049, $w=1/\sigma(F_o)$, 2511 observed reflections with $F_o \geq 2\sigma(F_o)$) and 0.039 (R_w=0.049, $w=1/\sigma(F_o)$, 3129 observed reflections with $F_o > 2\sigma(F_o)$) for **5** and **6**, respectively. Anomalous dispersion corrections were applied to the scattering factors of Pd, Ru, Cl, and S.[24]

List of structural factors, anisotropic thermal parameters and H-atom coordinations are kept at the Chemical Society of Japan (Document No. 8792)

(Received October 28, 1987)

The heat-stable enterotoxin (ST_h) of enterotoxigenic *Escherichia coli* consists of 19 amino acid residues and is linked intramolecularly by three disulfide bonds between Cys^6 and Cys^{11}, Cys^7 and Cys^{15}, and Cys^{10} and Cys^{18} (Y. Shimonishi et al., *FEBS Lett.*, **215**, 165 (1987)). The syntheses and biological assays of various analogs of ST_h with one or two of the three disulfide bonds showed that a disulfide bond between Cys^7 and Cys^{15} and another between Cys^6 and Cys^{11} or Cys^{10} and Cys^{18} are necessary for construction and stabilization of the spatial structure of ST_h to express its toxicity.

Various strains of enterotoxigenic *Escherichia coli* from animal hosts produce two kinds of heat-stable enterotoxins (STI and STII) that cause acute diarrhea in man and domestic animals.[1] STI is thought to bind to membrane receptors of intestinal cells[2] and stimulate guanylate cyclase, which is coupled to or present near the receptors, resulting in the induction of fluid accumulation. The mechanism of the biological action of STII is unknown. We have been studying the primary structure of STI (ST_h and ST_p), the positions of disulfide linkages (Fig. 1), and its structure-activity relation for several years.[3–7] We have found that peptides with the same sequences as those of the 13 amino acid residues from Cys near the N-terminus to Cys near the C-terminus in ST_h and ST_p have full enterotoxigenic activities, that the three intramolecular disulfide bonds are between Cys^6 and Cys^{11}, Cys^7 and Cys^{15}, and Cys^{10} and Cys^{18} in ST_h, and that the positions of the disulfide bonds affect the extent of toxicity of ST_h. These findings prompted us to examine which of these three intramolecular disulfide bonds are important for the spatial structure of ST_h and expression of its toxicity. Studies on the toxicities of analogs of ST_h with various combinations of disulfide bonds should be helpful in elucidating the spatial structure necessary for expression of toxicity, the contribution of amino acid residues to the spatial structure of ST_h and its binding site(s) for receptors on the membrane of intestinal cells.

This paper reports that a disulfide bond between Cys^7 and Cys^{15} in ST_h is essential for expression of the toxicity of ST_h and that another disulfide bond between Cys^6 and Cys^{11} or Cys^{10} and Cys^{18} is important for stabilization of the spatial structure and expression of toxicity.

Materials and Methods

The general and analytical methods used were described in the preceeding papers.[7,9] All chemicals used for preparative experiments were of reagent grade, those used for analysis were of guaranteed grade and solvents were distilled before use. All amino acids used were of the L-configuration except glycine. The abbreviations used in this paper are those recommended by the IUPAC-IUB [*J. Biol. Chem.*, **261**, 1 (1986)]. Additional abbreviations are: MBzl, *p*-methylbenzyl; Acm, acetamidomethyl; TFA, trifluoroacetic acid.

Synthesis of Peptides. Peptides were synthesized manually by the solid-phase method.[10] Briefly, Boc-Cys(MBzl)-, Boc-Cys(Acm)-, or Boc-Ala-polystyrene (2% divinylbenzene) (0.2—0.3 mmol of amino acid per 1 g of resin) was used with the following side-chain protecting groups: Bzl for threonine and glutamic acid and MBzl or Acm for cysteine. All couplings were carried out with 4-fold excess of Boc-amino acid and DCC, and the coupling of Boc-Asn-OH was repeated twice with 2 equiv of 1-hydroxybenzotriazole. The amino acids were coupled one by one in order from the C-terminus of peptide sequences. After coupling the N-terminal amino acid,

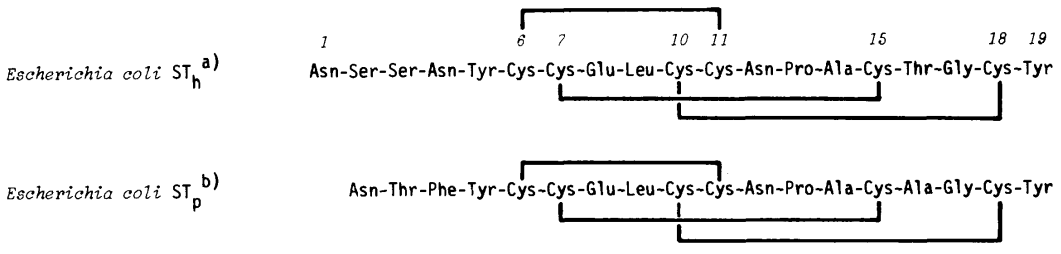

Fig. 1. Amino acid sequences and mode of disulfide bond formation of heat-stable enterotoxins produced by enterotoxigenic *Escherichia coli*: a) see Refs. 3 and 7; b) see Refs. 4 and 8.

the protected peptide-resin was removed from the reaction vessel and treated with the same amount of anisole in anhydrous hydrogen fluoride at 0 °C for 1 h. After removal of the hydrogen fluoride under reduced pressure, the peptide deprotected except for Acm on the mercapto groups of cysteine residues was extracted with 10% formic acid in an ice-water bath and washed three times with hexane. The extract was diluted with water to a final peptide concentration of 5×10^{-5} M (1 M=1 mol dm^{-3}). The solution was adjusted to pH 8.0 by adding aqueous ammonia and stood at room temperature with occasional stirring until no free mercapto groups were detectable. The crude peptide thus obtained was purified by high-performance liquid chromatography, as described below. The purified peptide with Acm groups at given Cys residues was dissolved at 5×10^{-4} M in a mixture of MeOH and H_2O (v/v, 4/1), then mixed with the same volume of a mixture of MeOH and 1M HCl (v/v, 4/1) containing iodine (40 equiv of the sample peptide), and kept for 15 min at room temperature. The reaction was stopped by adding L-ascorbic acid and the reaction product was purified by high-performance liquid chromatography, as described below.

Enzymatic Digestion. Synthetic peptides **16** and **18** were each dissolved in 0.02 M ammonium acetate (pH 7.0) and digested with aminopeptidase M (Pierce) and carboxypeptidase A (Boehringer, Mannheim), respectively, at a substrate:enzyme ratio (w/w) of 40:1 at 37 °C for 24 h.

High-Performance Liquid Chromatography (HPLC). The synthetic peptide was purified on a reversed-phase column (YMC-ODS, S-5, 8×300 mm, Yamamura Chemical Industries Ltd., Kyoto) using a high-performance liquid chromatography system consisting of a Waters M600 multisolvent delivery system (Milford, MA) and Hitachi 655A variable wavelength UV monitor and D-2000 chromato-integrator (Tokyo). The peptide was eluted with a linear gradient of 10—40% CH_3CN in 0.05% TFA or 0.01 M ammonium acetate (pH 5.7) with increase in CH_3CN of 1% min^{-1} at a flow rate of 2 ml min^{-1}. Fractions of the eluate were monitored for absorbance at 220 nm.

Amino Acid and Fast Atom Bombardment (FAB) Mass Analyses. The amino acid compositions and molecular weights of purified synthetic peptides were examined by amino acid analysis and FAB mass spectrometry, as described in Refs. 7 and 11, respectively.

Biological Assay. Toxicity was assayed in suckling mice (1.7±0.1 g) of 2 days old as described previously.[12]

Results and Discussion

To examine the effects of the three disulfide bonds on the toxicity of ST_h, we synthesized peptides with all possible combinations of two disulfide bonds, as shown in Table 1. Peptides **1—9** with two disulfide bonds other than that between the two Cys residues protected by Acm groups were synthesized as intermediates in the syntheses of peptides with three disulfide bonds in a previous study.[7] Peptides **10—15**, which had two disulfide bonds between four Cys differing for those in peptides **1—9** and in which the other two Cys were replaced by Ala, were newly synthesized in this work. That is, we synthesized protected peptide resins with the sequences listed in Table 1 where MBzl group was employed as a protecting group for mercapto groups of four Cys residues (Fig. 2). All protecting groups were removed

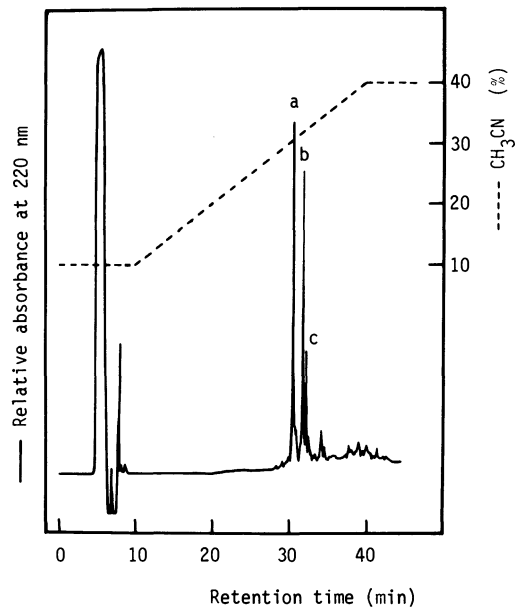

Fig. 3. Reversed-phase HPLC of peptide **11**. For chromatographic conditions, see text.

simultaneously at the stage of cleavage of peptides from the resins by their treatment with anhydrous hydrogen fluoride. The resulting free linear peptides were oxidized by air in dilute aqueous solution (5×10^{-5} M) until no free mercapto groups were detectable. Each peptide should theoretically be a mixture of monomeric peptides with three kinds of disulfide linkages. Figure 3 shows the HPLC profile of peptide **11** with two Ala at positions 6 and 10 and two disulfide bonds between four Cys at positions 7, 11, 15, and 18 (Fig. 2). By analyses of all peaks, monomeric peptides with two disulfide bonds were found in peaks a, b, and c. The results of amino acid and FAB mass spectrometric analyses of these peaks are shown in Table 2. Other peptides were synthesized by a similar procedure to that described in Fig. 2.

We examined the biological activities of all the synthetic peptides shown in Table 1 and found that peptides **1** and **9** had weak, but distinct toxicity, while the other peptides showed no toxicity at a dose of less than 1 μg. Previously[7] we found that peptides **1** and **9** yielded peptides that were identical with standard ST_h peptide in physicochemical and biological properties when the third disulfide bond was formed between Cys^6 and Cys^{11} and Cys^{10} and Cys^{18}, respectively, whereas other peptides did not yield a peptide that was identical with standard ST_h peptide when the third disulfide bond was formed. These findings indicate that peptides **1** and **9** contained peptides with the same two disulfide bonds as those in standard ST_h peptide, that they were between Cys^7 and Cys^{15} and Cys^{10} and Cys^{18} in peptide **1** and between Cys^6 and Cys^{11} and Cys^7 and Cys^{15} in peptide **9**, and that the toxicities of peptides **1** and **9** were due to peptides with these two disulfide bonds. These findings suggest that one or two of these three disulfide bonds are closely related to formation of the spatial structure of the ST_h molecule, which is necessary for expression of its toxicity.

To examine this possibility, we synthesized peptides **16—18** with two disulfide bonds at specific positions between four Cys and two Ala instead of the two remaining Cys, as shown in Table 3. Peptides **16** and **18** correspond to peptides in peptides **1** and **9**, respectively. We synthesized these peptides using two different types of protecting groups and selective and stepwise formation of disulfide bonds. Figure 4 shows the scheme for synthesis of peptide **18**, in which the two Cys at positions 10 and 18 are replaced by two Ala, the mercapto groups of the two Cys at positions 7 and 15 are protected by MBzl groups, and the mercapto groups of the two Cys at positions 6 and 11 are

a) Cys* denotes a Cys residue in which the thiol group is blocked by an Acm group. b) MED: Minimum effective dose.[12]

protected by Acm groups. The first disulfide bond was formed between the two Cys at positions 7 and 15 after removal of the MBzl groups by treatment with HF, and the second disulfide bond was formed between the two Cys at positions 6 and 11 by oxidation with iodine. The HPLC profile of peptide **18** is shown in Fig. 5. Other peptides were synthesized by a similar procedure. We found that peptides **16** and **18** which had two disulfide bonds between residues 7 and 15, and 6 and 11 or 10 and 18 were toxic, while peptide **17** with no disulfide bond at positions 7 and 15 was inactive, as shown in Table 3. Digestion of peptide **16** with aminopeptidase M, and of peptide **18** with carboxypeptidase A gave peptides **19** and **20**, respectively, which lack their N-terminal amino acid residue and C-terminal three amino acid residues. These peptides were about twice as toxic as their original peptides. These results indicated that a disulfide bond between Cys^7 and Cys^{15} is necessary for the toxicity of ST_h. Analytical data on peptides **16—20** are shown in Table 4.

Next, we synthesized a peptide with two disulfide bonds between Cys^6 and Cys^{11} and Cys^7 and Cys^{15}, but without the peptide bond between Cys^6 and Cys^7 (peptide **21**) and three kinds of peptides with only one disulfide bond between Cys^6 and Cys^{11}, Cys^7 and Cys^{15} or Cys^{10} and Cys^{18} (peptides **22—24**). Peptide **21** was prepared by oxidative coupling of peptide **25** and Boc-Cys(Acm)-OH followed by deprotection of the Boc group. Peptides **22** and **23** were synthesized as intermediates in the synthesis of peptide **18**, and peptide **24** as an intermediate in the synthesis of peptide **17**, by a similar procedure to that shown in Fig. 3. Analytical data on these synthetic peptides are presented in Table 4. All these peptides were inactive, as shown in Table 3. Therefore, the spatial structure of ST_h with two disulfide linkages between Cys^7 and Cys^{15}, and Cys^6 and Cys^{11} or Cys^{10} and Cys^{18} is essential for the toxicity of ST_h. In other words, the spatial structure of ST_h cannot be maintained by only one disulfide bond between Cys^7 and Cys^{15}, but requires one other disulfide bond between Cys^6 and Cys^{11} or Cys^{10} and Cys^{18}.

Figure 6 shows a CPK-model of a short peptide of ST_h with 13 amino acid residues, which was constructed from its three disulfide linkages[7] and

nuclear Overhauser effects (NOE) data measured by two-dimensional ^1H NMR spectroscopy.[13,14] The main chain of the peptide viewed from the front in Fig. 6 is seemingly folded in a twisted "8"-shape and there are two loop structures consisting of two turns between residues 9 to 11 and 12 to 15. The three disulfide linkages are located in the hinge region binding these two loops and presumably stabilize the spatial structure of ST_h. Cleavage of the disulfide bond between Cys^6 and Cys^{11} or Cys^{10} and Cys^{18} does not appreciably disrupt the spatial structure necessary for expression of toxicity, and the twisted "8"-structure shown in Fig. 6 is still maintained, at least partially. However, cleavage of the disulfide bond between Cys^7 and Cys^{15} may completely loosen the spatial conformation of ST_h, because peptide **17** was completely inactive. Cleavage of any two of the disulfide bonds shown in Fig. 6 may completely disrupt the structure fixed by the hinge region. Therefore, a twisted "8"-structure of the main chain seems important for the toxicity of ST_h or for stabilization of its spatial structure. In particular, maintenance of the spatial structure of the peptide chain from Cys^7 to Cys^{15} may be necessary for expression of the toxicity of ST_h. For further elucidation of the effect of the spatial structure of ST_h on its toxicity, attempts should be made to build a reliable molecular model of ST_h and identify the amino acid residues that bind ST_h to membrane proteins of intestinal cells.

Note Added in Proof. After submittion of this paper, Gariepy et al. (*Proc. Natl. Acad. Sci. U.S.A.*, **84**, 8907 (1987)) reported the importance of disulfide linkages in an enterotoxin and the result was the same as described here.

Syntheses and Reactions of Allylic and Homoallylic Pyrophosphate Tetraesters

Yasuo BUTSUGAN,* Kenji NAGAI, Fumitoshi NAGAYA, Hiroki TABUCHI, Katsuhisa YAMADA, and Shuki ARAKI
Department of Applied Chemistry, Nagoya Institute of Technology, Gokiso-cho, Showa-ku, Nagoya 466
(Received December 2, 1987)

Pyrophosphate tetraesters possessing allylic and homoallylic side chains were synthesized. Reaction of alkyl allyl (and 3-methyl-3-butenyl) phosphorochloridates with sodium hydrogencarbonate gave P^1,P^2-dialkyl P^1,P^2-diallyl [and P^1,P^2-bis(3-methyl-3-butenyl)] pyrophosphates. Condensation of alkyl allyl (and 3-methyl-3-butenyl) phosphorochloridates with dialkyl phosphates gave trialkyl allyl (and 3-methyl-3-butenyl) pyrophosphates. Reactions of crotyl (2-butenyl) pyrophosphates with various nucleophiles such as phenolic ethers, aromatic amines, and nitrogen-containing heterocycles in the presence of boron trifluoride etherate gave good to moderate yields of crotylated products. The crotyl pyrophosphates were found to be much more reactive than the corresponding orthophosphate esters.

In our continuous studies on the reaction of allylic phosphate esters, it has been revealed that allylic phosphates are useful and versatile reagents in synthetic chemistry.[1] They possess several advantages over allylic halides in regard to reactivity, selectivity, and ease of preparation and handling. It is well-known that naturally occurring terpenoids are biosynthesized via allylic and homoallylic pyrophosphate esters in a regio- and stereospecific manner.[2] Therefore, the use of pyrophosphates in place of orthophosphate esters is expected to improve the reactivity and selectivity in synthetic reactions. In this connection, pyrophosphate monoester salts possessing an allylic polyprenyl residue have been successfully used for enzymatic transformation to natural products.[3] However, the use of such pyrophosphate salts in preparative-scale synthesis is strictly limited owing to the difficulties in manipulation and the poor solubility in organic solvents. From these viewpoints, we were interested in the syntheses and reaction behavior of allylic and homoallylic pyrophosphate tetraesters. Although a number of workers reported the syntheses and applications of tetraalkyl pyrophosphates,[4] pyrophosphate tetraesters bearing allylic and/or homoallylic side chains have been scarcely studied.[5] In this paper, we describe the syntheses of such pyrophosphate tetraesters and discuss their reactivities toward phenolic ethers, aromatic amines, and nitrogen-containing heterocycles in comparison with that of the corresponding orthophosphate ester.

Scheme 1.

Results and Discussion

Syntheses. The synthesis of symmetrical P^1,P^2-dialkyl P^1,P^2-diallyl pyrophosphates (**2**) was achieved by the treatment of alkyl allyl phosphorochloridates (**1**) with sodium hydrogencarbonate in the presence of a catalytic amount of water.[6] The crude products were purified first by vacuum distillation and then by column chromatography on silica gel. The starting alkyl allyl phosphorochloridates (**1**) in turn were prepared by the triethylamine-induced condensation of alkyl phosphorodichloridates with allyl alcohol. The overall reaction scheme is as Scheme 1. Of the four pyrophosphate tetraesters prepared, P^1,P^2-diallyl P^1,P^2-dipropyl pyrophosphate (**2b**) is the most stable and the highest yield was achieved. The corresponding diethyl pyrophosphate **2a** is considerably unstable and all attempts to isolate P^1,P^2-diallyl P^1,P^2-dimethyl

Scheme 3.

pyrophosphate failed owing to the rapid decomposition during purification. P^1,P^2-Di-2-butenyl (crotyl) P^1,P^2-dipropyl pyrophosphate (**3**) was similarly prepared from crotyl propyl phosphorochloridate in 86% yield (Scheme 2). The pyrophosphate is thermally labile and sensitive to silica gel, so it was used for next reactions without further purification.

A series of symmetrical homoallylic pyrophosphates, P^1,P^2-dialkyl P^1,P^2-bis(3-methyl-3-butenyl) pyrophosphates (**5**) were also obtained by the same method (Scheme 3). Again, the maximum yield was achieved when R=propyl.

Condensation of alkyl allyl phosphorochloridates (**1**) with dialkyl phosphates in the presence of triethylamine furnished the second type of pyrophosphate tetraesters, trialkyl allyl pyrophosphates (**6**) (Scheme 4). By this method, crotyl tripropyl pyrophosphate (**7**) was synthesized in 76% yield (Scheme 5). Pyrophosphate tetraesters (**8**) of this type bearing a homoallylic 3-methyl-3-butenyl group were analogously prepared and isolated.

Reactions. We have reported that allylic orthophosphate esters readily allylate phenolic ethers in the presence of boron trifluoride etherate.[7] In order to compare the reactivity of allylic pyrophosphates with that of allylic orthophosphates, the reactions of crotyl pyrophosphates **3** and **7** with various phenolic ethers were carried out and the yields were compared with those of the reactions of crotyl dipropyl phosphate (**9**) under the same reaction conditions. The Friedel–Crafts type alkenylations were conducted at 0—−23 °C using five-fold excess of phenolic ethers to avoid polycrotylation. Yields and product distributions were determined by GLC analysis. Results are shown in Table 1. The reactions of **3**, **7**, and **9** with anisole gave all possible four regio (α and γ) and positional isomers (ortho and para). There were no important differences in the product distributions of

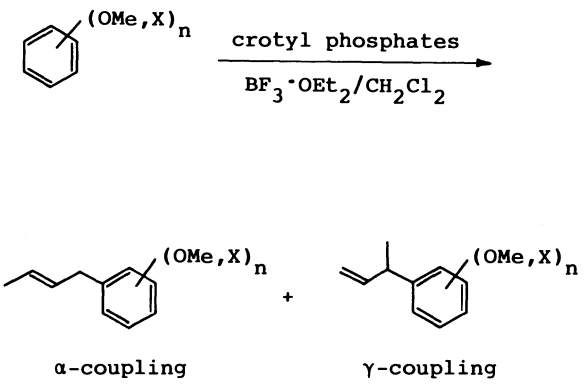
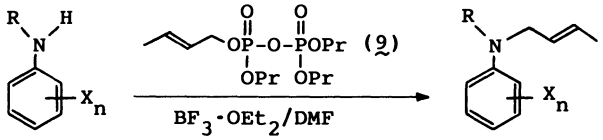
the three reactions, but the yield using the orthophosphate (**9**) was largely depressed compared to those of pyrophosphate cases. It must be noted that only one crotyl group of the dicrotyl pyrophosphate (**3**) was used for alkenylation of phenolic ethers under the reaction conditions employed. The results obtained here clearly show that pyrophosphate residues are excellent leaving groups and hence the reactivity of the pyrophosphates **3** and **7** are markedly higher than that of the orthophosphate (**9**).



Scheme 6.



Scheme 7.

Crotyl tripropyl pyrophosphate (**7**) also allylated aromatic amines in *N,N*-dimethylformamide (DMF) in the presence of boron trifluoride etherate at room temperature. As shown in Table 2, *N*-crotylation occurred predominantly and the corresponding amines were isolated in moderate yields. In the cases of diphenylamine and 1-naphthylamine, trace amounts of nucleus-crotylated products were also obtained. Under the reaction conditions employed, crotyl orthophosphate (**9**) gave, if any, only poor yields of *N*-crotylamines,[8] owing to the lower reactivity of **9** than **7**.

Pyrrole and indole reacted with crotyl pyrophosphate (**9**) to give nucleous-crotylated products. In these reactions, *N*-crotylated products could not be found. Again, no reactions occurred when orthophosphate (**9**) was used in place of **7**.

In summary, it has been shown that allylic pyrophosphates have much higher reactivity toward various nucleophiles than the corresponding orthophosphate and that they serve as useful allylating reagents in synthetic chemistry.

Experimental

General. Infrared spectra were recorded on a JASCO IRA-102 spectrometer. ^{1}H NMR spectra were recorded on a Hitachi R-24A spectrometer (60 MHz) or on a Varian XL-200 spectrometer (200 MHz) with Me_4Si as an internal standard. ^{13}C NMR spectra were obtained on a Varian XL-200 spectrometer (50 MHz). Multiplicities refer to those of proton-decoupled spectra. Mass spectra (MS) were determined at 20 eV using a Hitachi M-52 or ESCO EMD-05B instrument. GLC analyses were performed on a Yanaco G1800 gas chromatograph. Elemental analyses were performed at the Elemental Analysis Center of Kyoto University. Dialkyl phosphates,[6] alkyl phosphorodichloridates,[9] and dialkyl phosphorochloridates[10] were prepared by the literature methods.

Alkyl Allyl (and 3-Methyl-3-butenyl) Phosphorochloridates (1 and 4). The following preparation of allyl ethyl phosphorochloridate represents the general procedure. To a solution of ethyl phosphorodichloridate (9.8 g, 60 mmol) in anhydrous ether (20 cm^3) was slowly added a mixture of allyl alcohol (3.6 g, 62 mmol) and triethylamine (6.4 g, 63 mmol) in ether (20 cm^3) with cooling in an ice-salt bath. The reaction mixture was stirred at that temperature for 4 h. Triethylammonium chloride which formed was filtered off and the filtrate was concentrated. The residue was distilled [bp 60—69 °C/1.1×10^{-3} Torr(1 Torr=133.322 Pa)] to give allyl ethyl phosphorochloridate (9.02 g, 81%) as a pale yellow liquid. Other alkyl allyl (and 3-methyl-3-butenyl) phosphorochloridates (**1** and **4**) were similarly prepared and purified by distillation. Crotyl propyl phosphorochloridate is thermally unstable, so the crude product was used for the next reactions without distillation.

Allyl ethyl phosphorochloridate (**1a**): 81% yield; bp 60—69 °C/1.1×10^{-3} Torr; IR (neat) 3100, 2990, 2950, 2930, 1650, 1415, 1395, 1370, 1300, 1165, 1030 cm^{-1}; ^{1}H NMR (CCl_4) δ=1.40 (t, J=7 Hz, 3H, Me) 3.97—4.73 (m, 4H, CH_2), 5.17—5.52 (m, 2H, =CH_2), 5.68—6.30 (m, 1H, =CH); Found: C, 32.84; H, 5.67%. Calcd for $C_5H_{10}ClO_3P$: C, 32.54; H, 5.46%.

Allyl propyl phosphorochloridate (**1b**): 82% yield; bp 54—64 °C/6.1×10^{-4} Torr; IR (neat) 3080, 2980, 2950, 2910, 2890, 1650, 1465, 1425, 1300, 1150, 1020 cm^{-1}; ^{1}H NMR (CCl_4) δ=1.01 (t, J=7 Hz, 3H, Me), 1.32—2.10 (m, 2H, CH_2), 3.79—4.36 (m, 2H, CH_2), 4.41—4.78 (m, 2H, CH_2), 5.10—5.54 (m, 2H, =CH_2), 5.59—6.30 (m, 1H, =CH); Found: C, 36.48; H, 6.31%. Calcd for $C_6H_{12}ClO_3P$: C, 36.29; H, 6.09%.

Allyl butyl phosphorochloridate (**1c**): 81% yield; bp 83—95.5 °C/1.3×10^{-4} Torr; IR (neat) 3100, 2980, 2950, 2890, 1650, 1465, 1430, 1385, 1300, 1160, 1150, 1030 cm^{-1}; ^{1}H NMR (CCl_4) δ=0.98 (t, J=7 Hz, 3H, Me), 1.30—1.85 (m, 4H, CH_2), 3.98—4.73 (m, 4H, CH_2), 5.17—5.50 (m, 2H, =CH_2), 5.68—6.29 (m, 1H, =CH); Found: C, 40.60; H, 7.00%. Calcd for $C_7H_{14}ClO_3P$: C, 39.54; H, 6.64%.

Allyl isobutyl phosphorochloridate (**1d**): 75% yield; bp 85—93 °C/2.3×10^{-3} Torr; IR (neat) 3100, 2980, 2905, 2895, 1650, 1473, 1426, 1374, 1300, 1162, 1130, 1025 cm^{-1}; ^{1}H NMR (CCl_4) δ=0.98 (d, J=6 Hz, 6H, Me), 1.59—2.28 (m, 1H, CH), 3.90 (dd, J_{HP}=8 Hz, J_{HH}=7 Hz, 2H, CH_2), 4.59 (dd, J_{HP}=10 Hz, J_{HH}=5 Hz, 2H, CH_2), 4.99—5.54 (m, 2H, =CH_2), 5.59—6.24 (m, 1H, =CH); Found: C, 39.77; H, 6.79%. Calcd for $C_7H_{14}ClO_3P$: C, 39.54; H, 6.64%.

Ethyl 3-methyl-3-butenyl phosphorochloridate (**4a**): 65% yield; bp 80 °C/1.5×10^{-3} Torr; IR (neat) 3070, 2980, 2940, 2910, 1640, 1445, 1390, 1375, 1295, 1165, 1025 cm^{-1}; ^{1}H NMR (CCl_4) δ=1.40 (t, J=7 Hz, 3H, Me), 1.87 (s, 3H, Me), 2.43 (t, J=7 Hz, 2H, CH_2), 3.86—4.52 (m, 4H, CH_2), 4.78 (s, 2H, =CH_2); Found: C, 39.79; H, 6.87%. Calcd for $C_7H_{14}ClO_3P$: C, 39.54; H, 6.64%.

3-Methyl-3-butenyl propyl phosphorochloridate (**4b**): 73% yield; bp 87—95 °C/4×10^{-4} Torr; IR (neat) 3100, 2990, 2960, 2930, 1655, 1465, 1380, 1300, 1155, 1020 cm^{-1}; ^{1}H NMR (CCl_4) δ=0.99 (t, J=7 Hz, 3H, Me), 1.51—2.00 (m, 2H, CH_2), 1.77 (s, 3H, Me), 2.41 (t, J=7 Hz, 2H, CH_2), 3.90—4.50 (m, 4H, CH_2), 4.75 (s, 2H, =CH_2); Found: C, 42.69; H, 7.35%. Calcd for $C_8H_{16}ClO_3P$: C, 42.39; H, 7.12%.

Butyl 3-methyl-3-butenyl phosphorochloridate (**4c**): 61% yield; bp 95—99 °C/4.8×10^{-4} Torr; IR (neat) 3080, 2970, 2940, 2880, 1650, 1470, 1380, 1295, 1150, 1120, 1030 cm^{-1}; ^{1}H NMR (CCl_4) δ=0.93 (bt, J=6 Hz, 3H, Me), 1.18—2.00 (m, 4H, CH_2), 1.74 (s, 3H, Me), 2.39 (t, J=7 Hz, 2H, CH_2), 3.78—4.58 (m, 4H, CH_2), 4.74 (s, 2H, =CH_2); Found: C, 44.91; H, 7.70%. Calcd for $C_9H_{18}ClO_3P$: C, 44.92; H, 7.54%.

Isobutyl 3-methyl-3-butenyl phosphorochloridate (**4d**): 62% yield; bp 90—108 °C/8.5×10^{-4} Torr; IR (neat) 3090, 2990, 2930, 2890, 1655, 1470, 1380, 1305, 1185, 1170, 1130, 1030 cm^{-1}; ^{1}H NMR (CCl_4) δ=0.98 (d, J=6 Hz, 6H, Me), 1.79 (s, 3H, Me), 1.90—2.23 (m, 1H, CH), 2.44 (t, J=7 Hz, 2H, CH_2), 3.77—4.42 (m, 4H, CH_2), 4.79 (s, 2H, =CH_2); Found: C, 45.55; H, 7.90%. Calcd for $C_9H_{18}ClO_3P$: C, 44.92; H, 7.54%.

Crotyl propyl phosphorochloridate: 88% yield; IR (neat) 2970, 2940, 2880, 2850, 1673, 1460, 1378, 1287, 1010 cm^{-1}; ^{1}H NMR (CCl_4) δ=0.99 (t, J=7 Hz, 3H, Me), 1.32—2.12 (m, 2H, CH_2), 1.75 (d, J=5 Hz, 3H, Me), 3.82—4.27 (m, 2H, CH_2), 4.52 (dd J_{HP}=10 Hz, J_{HH}=5 Hz, 2H, CH_2), 5.22—6.12 (m, 2H, =CH); ^{13}C NMR ($CDCl_3$) δ=9.9 (s, Me), 17.7 (s, Me), 23.3 (d, J=8 Hz, CH_2), 70.1 (d, J=6 Hz, CH_2), 71.3 (d, J=8 Hz, CH_2), 124.3 (d, J=7 Hz, =$\underline{C}$HCH$_2$), 133.3 (s, =$\underline{C}$HMe).

***P*^{1},*P*^{2}-Dialkyl *P*^{1},*P*^{2}-Diallyl [and *P*^{1},*P*^{2}-Bis(3-methyl-3-butenyl)] Pyrophosphates (2 and 5).** The following preparation of *P*^{1},*P*^{2}-diallyl *P*^{1},*P*^{2}-diethyl pyrophosphate (**2a**) represents the general procedure. A mixture of allyl ethyl phosphorochloridate (**1a**) (736 mg, 4 mmol), sodium hydrogencarbonate (373 mg, 4.4 mmol) and a catalytic amount (ca. 10 mol%) of water (7 mg, 0.39 mmol) was stirred for 2 h at room temperature. After sodium chloride which formed was filtered, the reaction mixture was distilled (bp 137—142 °C/4.3×10^{-3} Torr) and then column chromatographed on silica gel (eluant: ether) to give *P*^{1},*P*^{2}-diallyl *P*^{1},*P*^{2}-diethyl pyrophosphate (**2a**) (139 mg, 22%) as a viscous colorless oil. Other dialkyl diallyl [and bis(3-methyl-3-butenyl)] pyrophosphates (**2** and **5**) were similarly prepared and purified. *P*^{1},*P*^{2}-Dicrotyl *P*^{1},*P*^{2}-dipropyl pyrophosphate (**3**) is unstable and used for the next reactions without further purification.

P^1,*P*^{2}-Diallyl *P*^{1},*P*^{2}-diethyl pyrophosphate (**2a**): 22% yield; bp 137—142 °C/ 4.3×10^{-3} Torr; IR (neat) 3080, 2980, 2925, 2905, 1645, 1367, 1290, 1160, 1100, 1024, 967 cm^{-1}; ^{1}H NMR (CCl_4) δ=1.34 (t, J=7 Hz, 6H, Me), 3.80—4.80 (m, 8H, CH_2), 4.80—5.60 (m, 4H, =CH_2), 5.60—6.40 (m, 2H, =CH); ^{13}C NMR ($CDCl_3$) δ=15.9 (m, Me), 65.4 (m, CH_2), 69.2

(m, CH_2), 118.8 (s, $=CH_2$), 131.8 (m, =CH); MS *m/z* (rel intensity) 314 (M^+, 11), 189 (100); Found: C, 37.71; H, 6.66%. Calcd for $C_{10}H_{20}O_7P_2$: C, 38.22; H, 6.42%.

P^1,P^2-Diallyl P^1,P^2-dipropyl pyrophosphate (**2b**): 54% yield; bp 130—135 °C/7.7×10^{-5} Torr; IR (neat) 3080, 2975, 2945, 2910, 2880, 1650, 1465, 1425, 1295, 1155, 1025, 960 cm^{-1}; ^{1}H NMR (CCl_4) δ=0.99 (t, *J*=6 Hz, 6H, Me), 1.30—2.09 (m, 4H, CH_2), 3.83—4.38 (m, 4H, CH_2), 4.38—4.83 (m, 4H, CH_2), 5.06—5.63 (m, 4H, $=CH_2$), 5.63—6.28 (m, 2H, =CH); ^{13}C NMR ($CDCl_3$) δ=9.9 (s, Me), 23.5 (m, CH_2), 69.2 (m, CH_2), 70.8 (m, CH_2), 118.8 (s, $=CH_2$), 132.0 (m, =CH); MS *m/z* (rel intensity) 342 (M^+, 7), 217 (100); Found: C, 41.83; H, 7.18%. P^1,P^2-Diallyl P^1,P^2-diisobutyl pyrophosphate (**2d**): 23% yield; bp 146—150 °C/4.1×10^{-3} Torr; IR (neat) 3090, 2970, 2900, 2880, 1650, 1470, 1370, 1290, 1023, 960 cm^{-1}; ^{1}H NMR (CCl_4) δ=0.97 (d, *J*=6 Hz, 12H, Me), 1.70—2.35 (m, 2H, CH), 3.60—4.04 (m, 4H, CH_2), 4.30—4.90 (m, 4H, CH_2), 4.90—5.60 (m, 4H, $=CH_2$), 5.60—6.35 (m, 2H, =CH); ^{13}C NMR ($CDCl_3$) δ=18.5 (s, Me), 29.0 (m, CH), 69.2 (m, CH_2), 118.8 (s, $=CH_2$), 131.9 (m, =CH); MS *m/z* (rel intensity) 370 (M^+, 24), 259 (100); Found: C, 45.24; H, 7.72%. Calcd for $C_{14}H_{28}O_7P_2$: C, 45.41; H, 7.62%.

P^1,P^2-Diethyl P^1,P^2-bis(3-methyl-3-butenyl) pyrophosphate (**5a**): 26% yield; bp 140—150 °C/1.0×10^{-3} Torr; IR (neat) 3085, 2990, 2940, 2920, 1645, 1445, 1395, 1375, 1295, 1166, 1040, 985, 960 cm^{-1}; ^{1}H NMR (CCl_4) δ=1.35 (t, *J*=7 Hz, 6H, Me), 1.75 (s, 6H, Me), 2.39 (t, *J*=6 Hz, 4H, CH_2), 3.90—4.50 (m, 8H, CH_2), 4.75 (s, 4H, $=CH_2$); ^{13}C NMR ($CDCl_3$) δ=16.0 (m, Me), 22.4 (s, Me), 38.1 (m, CH_2), 65.3 (m, CH_2), 67.1 (m, CH_2), 112.9 (s, $=CH_2$), 140.7 (s, $-\overset{|}{C}=$); MS *m/z* (rel intensity) 370 (M^+, 0.8), 235 (100); Found: C, 45.18; H, 7.73%. Calcd for $C_{14}H_{28}O_7P_2$: C, 45.41; H, 7.62%.

P^1,P^2-Dipropyl P^1,P^2-bis(3-methyl-3-butenyl) pyrophosphate (**5b**): 66% yield; bp 135—140 °C/4.2×10^{-5} Torr; IR (neat) 3070, 2975, 2940, 2900, 1650, 1460, 1375, 1290, 1020, 960 cm^{-1}; ^{1}H NMR (CCl_4) δ=1.00 (t, *J*=7 Hz, 6H, Me), 1.40—2.10 (m, 4H, CH_2), 1.75 (s, 6H, Me), 2.40 (t, *J*=7 Hz, 4H, CH_2), 3.70—4.55 (m, 8H, CH_2), 4.73 (s, 4H, $=CH_2$); ^{13}C NMR ($CDCl_3$) δ=9.9 (s, Me), 22.4 (s, Me), 23.5 (m, CH_2), 38.1 (m, CH_2), 67.1 (m, CH_2), 70.7 (m, CH_2), 112.9 (s, $=CH_2$), 140.7 (s, $-\overset{|}{C}=$); MS *m/z* (rel intensity) 398 (M^+, 0.7), 179 (100); Found: C, 48.40; H, 8.32%. Calcd for $C_{16}H_{32}O_7P_2$: C, 48.24; H, 8.10%.

P^1,P^2-Diisopropyl P^1,P^2-bis(3-methyl-3-butenyl) pyrophosphate (**5c**): 54% yield; bp 130 °C/9.2×10^{-5} Torr; IR (neat) 3090, 2990, 2950, 1655, 1470, 1455. 1380, 1290, 1185, 1145, 1110, 1010, 960 cm^{-1}; ^{1}H NMR (CCl_4) δ=1.32 (d, *J*=7 Hz, 12H, Me), 1.76 (s, 6H, Me), 2.39 (t, *J*=7 Hz, 4H, CH_2) 3.99—4.33 (m, 4H, CH_2), 4.42—4.92 (m, 6H, CH and $=CH_2$); ^{13}C NMR ($CDCl_3$) δ=22.5 (s, Me), 23.5 (s, Me), 38.1 (m, CH_2), 66.9 (m, CH_2), 74.6 (m, CH), 112.8 (s, $=CH_2$), 140.8 (s, $-\overset{|}{C}=$); MS *m/z* (rel intensity) 398 (M^+, 0.8), 179 (100); Found: C, 48.08; H, 8.05%. Calcd for $C_{16}H_{32}O_7P_2$: C, 48.24; H, 8.10%.

P^1,P^2-Dibutyl P^1,P^2-bis(3-methyl-3-butenyl) pyrophosphate (**5d**): 50% yield; bp 140—150 °C/7.0×10^{-5} Torr; IR (neat) 3080, 2970, 2920, 2880, 1650, 1465, 1380, 1295, 1150, 1120, 1030, 965 cm^{-1}; ^{1}H NMR (CCl_4) δ=0.95 (bt, *J*=6 Hz, 6H, Me), 1.21—2.02 (m, 8H, CH_2), 1.75 (s, 6H, Me), 2.39 (t, *J*=7 Hz, 4H, CH_2), 3.82—4.42 (m, 8H, CH_2), 4.76 (s, 4H, $=CH_2$); ^{13}C NMR ($CDCl_3$) δ=13.5 (s, Me), 18.6 (s, CH_2), 22.4 (s, Me), 32.1 (m, CH_2), 38.1 (m, CH_2), 67.1 (m, CH_2), 68.9 (m, CH_2), 112.9 (s, $=CH_2$), 140.6 (s, $-\overset{|}{C}=$); MS *m/z* (rel intensity) 426 (M^+, 0.5), 179 (100); Found: C, 50.52; H, 8.72%. Calcd for $C_{18}H_{36}O_7P_2$: C, 50.70; H, 8.51%.

P^1,P^2-Diisobutyl P^1,P^2-bis(3-methyl-3-butenyl) pyrophosphate (**5e**): 64% yield; bp 130 °C/2.1×10^{-5} Torr; IR (neat) 3090, 2990, 2930, 2890, 1655, 1465, 1375, 1300, 1035, 965 cm^{-1}; ^{1}H NMR (CCl_4) δ=0.94 (d, *J*=6 Hz, 12H, Me), 1.75 (s, 6H, Me), 1.85—2.17 (m, 2H, CH), 2.38 (t, *J*=7 Hz, 4H, CH_2), 3.85 (t, J_{HH}=J_{HP}=6 Hz, 4H, CH_2), 4.19 (dd, J_{HH}=J_{HP}=7 Hz, 4H, CH_2), 4.76 (s, 4H, $=CH_2$); ^{13}C NMR ($CDCl_3$) δ=18.5 (s, Me), 22.4 (s, Me), 29.0 (m, CH), 38.1 (m, CH_2), 67.1 (m, CH_2), 74.9 (m, CH_2), 112.9 (s, $=CH_2$), 140.6 (s, $-\overset{|}{C}=$); MS *m/z* (rel intensity) 426 (M^+, 1), 68 (100); Found: C, 50.86; H, 8.80%. Calcd for $C_{18}H_{36}O_7P_2$: C, 50.70; H, 8.51%.

P^1,P^2-Dicrotyl P^1,P^2-dipropyl pyrophosphate (**3**): 86% yield; IR (neat) 3040, 2980, 2950, 2900, 2870, 1677, 1460, 1380, 1278, 1018, 968 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.86—1.08 (m, 6H, Me), 1.54—1.86 (m, 10H, CH_2 and Me), 3.84—4.24 (m, 4H, CH_2), 4.36—4.72 (m, 4H, CH_2), 5.50—6.00 (m, 4H, =CH); MS *m/z* (rel intensity) 370 (M^+, 3), 141 (100).

Trialkyl Allyl (and 3-Methyl-3-butenyl) Pyrophosphates (6 and 8). The following preparation of allyl triethyl pyrophosphate (**6a**) represents the general procedure. To a mixture of diethyl hydrogenphosphate (466 mg, 3 mmol) and triethylamine (0.49 cm^3, 3.5 mmol) in anhydrous ether (10 cm^3) was slowly added a solution of allyl ethyl phosphorochloridate (583 mg, 3.2 mmol) in ether (10 cm^3) with cooling in an ice-salt bath. After the addition was complete, the reaction mixture was stirred at that temperature for 2 h and then triethylammonium chloride which formed was filtered. The filtrate was concentrated and the residue was distilled (bp 155 °C/3.0×10^{-4} Torr) to give an almost pure product. This was further purified by column chromatography on silica gel (eluant: ether) to afford pure allyl triethyl pyrophosphate (**6a**) (611 mg, 67%) as a colorless oil. Other trialkyl allyl (and 3-methyl-3-butenyl) pyrophosphates (**6** and **8**) were similarly prepared and purified. Crotyl tripropyl pyrophosphate (**7**) is thermally unstable, so the crude material was used for the next reactions without further purification.

Allyl triethyl pyrophosphate (**6a**): 67% yield; bp 155 °C/3.0×10^{-4} Torr; IR (neat) 3100, 3000, 2950, 2920, 2825, 1650, 1480, 1445, 1373, 1290, 1167, 1032, 963 cm^{-1}; ^{1}H NMR (CCl_4) δ=1.38 (t, *J*=7 Hz, 9H, Me), 3.90—4.50 (m, 6H, CH_2), 4.55—4.90 (m, 2H, CH_2), 5.10—5.70 (m, 2H, $=CH_2$), 5.70—6.40 (m, 1H, =CH); ^{13}C NMR ($CDCl_3$) δ=16.0 (m, Me), 65.3 (m, CH_2), 69.2 (bt, 4 Hz, CH_2), 118.7 (s, $=CH_2$), 131.8 (bt, *J*=2 Hz, =CH); MS *m/z* (rel intensity) 302 (M^+, 6), 161 (100); Found: C, 35.65; H, 6.66%. Calcd for $C_9H_{20}O_7P_2$: C, 35.77; H, 6.67%.

Allyl tripropyl pyrophosphate (**6b**): 77% yield; bp 130—135 °C/1.4×10^{-5} Torr; IR (neat) 3090, 2980, 2950, 2920, 2890, 1650, 1465, 1425, 1380, 1295, 1155, 1030, 960 cm^{-1}; ^{1}H NMR (CCl_4) δ=0.99 (t, J=7 Hz, 9H, Me), 1.32—2.12 (m, 6H, CH_2), 3.84—4.34 (m, 6H, CH_2), 4.35—4.74 (m, 2H, CH_2), 5.05—5.54 (m, 2H, =CH_2), 5.62—6.81 (m, 1H, =CH); ^{13}C NMR ($CDCl_3$) δ=9.9 (s, Me), 23.5 (m, CH_2), 69.2 (bt, J=3 Hz, CH_2), 70.6 (m, CH_2), 118.7 (s, =CH_2), 132.0 (bt, J=3 Hz, =CH); MS m/z (rel intensity) 344 (M^+, 10), 219 (100); Found: C, 41.88; H, 7.91%. Calcd for $C_{12}H_{26}O_7P_2$: C, 41.87; H, 7.61%.

Allyl tributyl pyrophosphate (**6c**): 72% yield; bp 165—167 °C/2.0×10^{-4} Torr; IR (neat) 2975, 2950, 2925, 2890, 1650, 1467, 1383, 1293, 1153, 1120, 1033, 960 cm^{-1}; ^{1}H NMR (CCl_4) δ=0.75—1.30 (bt, J=6 Hz, 9H, Me), 1.30—2.35 (m, 12H, CH_2), 3.85—4.39 (m, 6H, CH_2), 4.39—4.75 (m, 2H, CH_2), 5.01—5.57 (m, 2H, =CH_2), 5.57—6.29 (m, 1H, =CH); ^{13}C NMR ($CDCl_3$) δ=13.5 (s, Me), 18.5 (s, CH_2), 32.1 (m, CH_2), 68.8 (m, CH_2), 68.9 (bt, J=4 Hz, CH_2), 118.7 (s, =CH_2), 131.9 (bt, J=3 Hz, =CH); MS m/z (rel intensity) 386 (M^+, 3), 179 (100); Found: C, 46.66; H, 8.65%. Calcd for $C_{15}H_{32}O_7P_2$: C, 46.63; H, 8.35%.

Allyl triisobutyl pyrophosphate (**6d**): 81% yield; bp 157 °C/3.0×10^{-4} Torr; IR (neat) 3110, 3000, 2960, 2920, 2900, 1650, 1475, 1375, 1300, 1170, 1135, 1032, 970 cm^{-1}; ^{1}H NMR (CCl_4) δ=0.98 (d, J=6 Hz, 18H, Me), 1.73—2.33 (m, 3H, CH), 3.84 (t, J_{HH}=J_{HP}=7 Hz, 6H, CH_2) 4.33—4.73 (m, 2H, CH_2), 5.03—5.53 (m, 2H, =CH_2), 5.53—6.13 (m, 1H, =CH); ^{13}C NMR ($CDCl_3$) δ=18.4 (s, Me), 28.9 (m, CH), 69.0 (bt, J=3 Hz, CH_2), 74.8 (m, CH_2), 118.6 (s, =CH_2), 131.9 (bt, J=3 Hz, =CH); MS m/z (rel intensity) 386 (M^+, 1), 219 (100); Found: C, 46.65; H, 8.53%. Calcd for $C_{15}H_{32}O_7P_2$: C, 46.63; H, 8.35%.

Triethyl 3-methyl-3-butenyl pyrophopshate (**8a**): 13% yield; bp 135—140 °C/4.0×10^{-5} Torr; IR (neat) 3080, 2990, 2940, 2920, 1650, 1480, 1445, 1395, 1370, 1295, 1065, 1030, 980, 960 cm^{-1}; ^{1}H NMR (CCl_4) δ=1.35 (t, J=7 Hz, 9H, Me), 1.75 (s, 3H, Me), 2.38 (t, J=7 Hz, CH_2), 3.81—4.48 (m, 8H, CH_2), 4.72 (s, 2H, =CH_2); ^{13}C NMR ($CDCl_3$) δ=16.0 (m, Me), 22.4 (s, Me), 38.1 (bt, J=4 Hz, CH_2), 65.2 (m, CH_2), 67.1 (bt, J=3 Hz, CH_2), 112.9 (s, =CH_2), 140.7 (s, -C=); MS m/z (rel intensity) 330 (M^+, 2), 179 (100); Found: C, 39.90; H, 7.59%. Calcd for $C_{11}H_{24}O_7P_2$: C, 40.00; H, 7.33%.

3-Methyl-3-butenyl tripropyl pyrophosphate (**8b**): 85% yield; bp 140—145 °C/7.3×10^{-5} Torr; IR (neat) 3090, 2990, 2960, 2920, 2900, 1655, 1465, 1395, 1380, 1295, 1155, 1030, 965 cm^{-1}; ^{1}H NMR (CCl_4) δ=0.99 (t, J=7 Hz, 9H, Me), 1.39—2.09 (m, 6H, CH_2), 1.77 (s, 3H, Me), 2.40 (t, J=7 Hz, 2H, CH_2), 3.88—4.44 (m, 8H, CH_2), 4.76 (s, 2H, =CH_2); ^{13}C NMR ($CDCl_3$) δ=9.9 (s, Me), 22.4 (s, Me), 23.5 (m, CH_2), 38.1 (m, CH_2), 67.1 (m, CH_2), 70.6 (m, CH_2), 112.9 (s, =CH_2), 140.7 (s, -C=); MS m/z (rel intensity) 372 (M^+, 2), 179 (100); Found: 45.27; H, 8.36%. Calcd for $C_{14}H_{30}O_7P_2$: C, 45.16; H, 8.12%.

Tributyl 3-methyl-3-butenyl pyrophosphate (**8c**): 66% yield: bp 150—155 °C/5.0×10^{-5} Torr; IR (neat) 3080, 2970, 2940, 2920, 2880, 1650, 1465, 1385, 1290, 1150, 1120, 1030, 965 cm^{-1}; ^{1}H NMR (CCl_4) δ=0.97 (bt, J=6 Hz, 9H, Me), 1.23—2.08 (m, 12H, CH_2), 1.78 (s, 3H, Me), 2.40 (t, J=7 Hz, 2H, CH_2), 3.88—4.48 (m, 8H, CH_2), 4.77 (s, 2H, =CH_2); ^{13}C NMR ($CDCl_3$) δ=13.5 (s, Me), 18.6 (s, CH_2), 22.5 (s, Me), 32.1 (m, CH_2), 38.1 (m, CH_2), 67.1 (m, CH_2), 68.9 (m, CH_2), 112.9 (s, =CH_2), 140.7 (s, -C=); MS m/z (rel intensity) 414 (M^+, 1), 179 (100); Found: C, 49.16; H, 8.85%. Calcd for $C_{17}H_{36}O_7P_2$: C, 49.26; H, 8.76%.

Triisobutyl 3-methyl-3-butenyl pyrophosphate (**8d**): 42% yield; bp 120 °C/1.8×10^{-5} Torr; IR (neat) 3090, 2980, 2890, 1655, 1475, 1365, 1300, 1185, 1170, 1135, 1030, 965 cm^{-1}; ^{1}H NMR (CCl_4) δ=0.95 (d, J=6 Hz, 18H, Me), 1.76 (s, 3H, Me), 1.87—2.19 (m, 3H, CH), 2.40 (t, J=7 Hz, 2H, CH_2), 3.84 (t, J_{HH}=J_{HP}=7 Hz, 6H, CH_2), 4.00—4.35 (m, 2H, CH_2), 4.74 (s, 2H, =CH_2); ^{13}C NMR ($CDCl_3$) δ=18.6 (s, Me), 22.4 (s, Me), 29.0 (m, CH), 38.1 (bt, J=4 Hz, CH_2), 67.1 (bt, J=3 Hz, CH_2), 74.9 (m, CH_2), 112.9 (s, =CH_2), 140.6 (s, -C=); MS m/z (rel intensity) 414 (M^+, 2), 179 (100); Found: C, 49.04; H, 8.86%. Calcd for $C_{17}H_{36}O_7P_2$: C, 49.26; H, 8.76%.

Crotyl tripropyl pyrophosphate (**7**): 76% yield; IR (neat) 2975, 2950, 2890, 2860, 1675, 1460, 1380, 1290, 1153, 1018, 957 cm^{-1}; ^{1}H NMR (CCl_4) δ=0.97 (t, J=7 Hz, 9H, Me), 1.36—1.91 (m, 9H, CH_2 and Me), 3.78—4.25 (m, 6H, CH_2), 4.31—4.71 (m, 2H, CH_2), 5.31—6.01 (m, 2H, =CH); ^{13}C NMR ($CDCl_3$) 9.9 (s, Me), 17.7 (s, Me), 23.5 (m, CH_2), 69.4 (dd, J=3, 2 Hz, CH_2), 70.6 (m, CH_2), 125.1 (dd, J=4, 2 Hz, =CH), 132.3 (s, =CH); MS m/z (rel. intensity) 358 (M^+, 15), 179 (100).

Reactions of P^1,P^2-Dicrotyl P^1,P^2-Dipropyl Pyrophosphate (3) and Crotyl Tripropyl Pyrophosphate (7) with Phenolic Ethers. Following reaction of P^1,P^2-dicrotyl P^1,P^2-dipropyl pyrophosphate (**3**) with anisole represents the general procedure. Into a mixture of anisole (1.1 cm^3, 10 mmol) and P^1,P^2-dicrotyl P^1,P^2-dipropyl pyrophosphate (**3**) (741 mg, 2 mmol) in anhydrous dichloromethane (7 cm^3) was added boron trifluoride etherate (0.25 cm^3, 2 mmol) at 0 °C, and the mixture was stirred at 0 °C for 3.5 h. The reaction was quenched by the addition of water and the products were extracted with dichloromethane. The extracts were washed with brine, and then dried over anhydrous sodium sulfate. The solvent was evaporated and the residue was analyzed by GLC using p-methylanisole as an internal standard. Pure samples of the products were isolated by preparative GLC and the structures were deduced by their spectral data.

Reactions with other phenolic ethers were similarly carried out and the products were analyzed using adequate internal standards. The reaction conditions and the results are summarized in Table 1.

(E)-1-(2-Butenyl)-2-methoxybenzene:[11] ^{1}H NMR ($CDCl_3$) δ=1.68 (d, J=6 Hz, 3H, Me), 3.33 (d, J=6 Hz, 2H, CH_2), 3.85 (s, 3H, OMe), 5.41—5.75 (m, 2H, =CH), 6.81—7.01 (m, 2H, Ar), 7.11—7.29 (m, 2H, Ar); MS m/z (rel intensity) 162 (M^+, 100).

1-Methoxy-2-(1-methyl-2-propenyl)benzene:[12] MS m/z (rel intensity) 162 (M^+, 96), 147 (100).

(E)-1-(2-Butenyl)-4-methoxybenzene:[13] ^{1}H NMR ($CDCl_3$) δ=1.68 (d, J=5 Hz, 3H, Me), 3.27 (bd, J=5 Hz, 2H, CH_2), 3.80 (s, 3H, OMe), 5.40—5.74 (m, 2H, =CH), 6.87 (d, J=9 Hz, 2H, Ar), 7.14 (d, J=9 Hz, 2H, Ar); MS m/z (rel intensity) 162 (M^+, 100).

1-Methoxy-4-(1-methyl-2-propenyl)benzene:[12] ^{1}H NMR ($CDCl_3$) δ=1.34 (d, J=7 Hz, 3H, Me), 3.34—3.54 (m, 1H, CH), 3.80 (s, 3H, OMe), 4.96—5.16 (m, 2H, =CH_2), 5.84—6.12 (m, 1H, =CH), 6.88 (d, J=9 Hz, 2H, Ar), 7.16 (d, J=9 Hz, 2H, Ar).

(E)-2-(2-Butenyl)-1,4-dimethoxybenzene:[14] IR (neat) 3030, 3000, 2950, 2920, 2860, 2840, 1590, 1503, 1465, 1286, 1220, 1177, 1155, 1048, 1027, 800 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.68

(d, J=6 Hz, 3H, Me), 3.30 (d, J=5 Hz, 2H, CH_2), 3.78 (s, 3H, OMe), 3.80 (s, 3H, OMe), 5.40—5.72 (m, 2H, =CH), 6.66—6.90 (m, 3H, Ar); MS m/z (rel. intensity) 192 (M^+, 100).

1,4-Dimethoxy-2-(1-methyl-2-propenyl)benzene:[14] ^1H NMR ($CDCl_3$) δ=1.31 (d, J=7 Hz, 3H, Me), 3.78 (s, 3H, OMe), 3.82 (s, 3H, OMe), 3.60—4.00 (m, 1H, CH), 5.00—5.16 (m, 2H, $=CH_2$), 5.94—6.16 (m, 1H, =CH), 6.60—6.88 (m, 3H, Ar); MS m/z (rel intensity) 192 (M^+, 100).

(*E*)-2-(2-Butenyl)-1,3,5-trimethoxybenzene: ^1H NMR ($CDCl_3$) δ=1.62 (d, J=6 Hz, 3H, Me), 3.26 (bd, J=5 Hz, 2H, CH_2), 3.82 (s, 9H, OMe), 5.35—5.71 (m, 2H, =CH), 6.17 (s, 2H, Ar); MS m/z (rel intensity) 222 (M^+, 100).

1,3,5-Trimethoxy-2-(1-methyl-2-propenyl)benzene: ^1H NMR ($CDCl_3$) δ=1.34 (d, J=7 Hz, 3H, Me), 3.80 (s, 6H, OMe), 3.81 (s, 3H, OMe), 3.98—4.18 (m, 1H, CH), 4.82—5.04 (m, 2H, $=CH_2$), 6.16 (s, 2H, Ar), 6.06—6.38 (m, 1H, =CH); MS m/z (rel. intensity) 222 (M^+, 54), 207 (100).

(*E*)-2-(2-Butenyl)-3,4,5,6-tetramethoxytoluene: IR (neat) 2960, 2940, 2860, 2830, 1645, 1463, 1350, 1258, 1195, 1073, 1040, 1010, 970 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.64 (d, J=6 Hz, 3H, Me), 2.16 (s, 3H, Me), 3.32 (d, J=5 Hz, 2H, CH_2), 3.80 (s, 3H, OMe), 3.82 (s, 3H, OMe), 3.92 (s, 3H, OMe), 3,93 (s, 3H, OMe), 5.28—5.64 (m, 2H, =CH); MS m/z (rel intensity) 266 (M^+, 100).

2,3,4,5-Tetramethoxy-6-(1-methyl-2-propenyl)toluene: ^1H NMR ($CDCl_3$) δ=1.38 (d, J=7 Hz, 3H, Me), 2.18 (s, 3H, Me), 3.78 (s, 3H, OMe), 3.80 (s, 3H, OMe), 3.90 (s, 3H, OMe), 3,92 (s, 3H, OMe), 3.60—4.08 (m, 1H, CH), 4.92—5.12 (m, 2H, $=CH_2$), 6.02—6.26 (m, 1H, =CH); MS m/z (rel intensity) 266 (M^+, 100).

(*E*)-2-(2-Butenyl)-1,4-dimethoxy-3-methylnaphthalene: IR (neat) 3075, 3030, 2940, 2850, 1590, 1450, 1375, 1353, 1263, 1197, 1097, 1067, 1015, 970, 768 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.64 (dd, 3H, J=6, 1 Hz, Me), 2.40 (s, 3H, Me), 3.50—3.66 (m, 2H, CH_2), 3.88 (s, 3H, OMe), 3.91 (s, 3H, OMe), 5.28—5.54 (m, 1H, =CH), 5.54—5.78 (m, 1H, =CH), 7.44—7.58 (m, 2H, Ar), 8.00—8.18 (m, 2H, Ar); MS m/z (rel intensity) 256 (M^+, 100).

Reactions of Crotyl Tripropyl Pyrophosphate (7) with Aromatic Amines, Pyrrole, and Indole. Following reaction of crotyl tripropyl pyrophosphate (**7**) with aniline represents the general procedure. To a mixture of aniline (225 mg, 2.4 mmol) and crotyl tripropyl pyrophosphate (**7**) (866 mg, 2.4 mmol) in DMF (8 cm^3) was added boron trifluoride etherate (0.61 cm^3, 4.8 mmol) at room temperature and the reaction mixture was stirred overnight (20 h). Saturated sodium hydrogencarbonate was added and the products were extracted with hexane. The extracts were washed with brine and dried over anhydrous sodium sulfate. The solvent was removed under reduced pressure and the residual oil was chromatographed on silica gel (eluant: benzene) to give *N*-crotylaniline (202 mg, 57%) and *N*,*N*-dicrotylaniline (21 mg, 9%).

Reactions for other aromatic amines, pyrrole, and indole were similarly carried out and the products were isolated by silica-gel column chromatography. The yields and physical data of the products are summarized in Table 2.

(*E*)-*N*-(2-Butenyl)aniline: IR (neat) 3420, 3060, 3025, 2960, 2930, 2880, 2850, 1603, 1505, 1465, 1450, 1377, 1320, 1250, 964 cm^{-1}; ^1H NMR (CCl_4) δ=1.47—1.87 (m, 3H, Me), 3.34 (bs, 1H, NH), 3.47—3.87 (m, 2H, CH_2), 5.27—5.72 (m, 2H, =CH), 6.17—6.62 (m, 3H, Ph), 6.71—7.14 (t, J=7 Hz, 2H, Ph); MS m/z (rel intensity) 147 (M^+, 68), 93 (100).

(*E*)-*N*,*N*-Di(2-butenyl)aniline: IR (neat) 3100, 3070, 3040, 2970, 2930, 2860, 1720, 1600, 1507, 1450, 1380, 1353, 1260, 966, 862, 745, 692 cm^{-1}; ^1H NMR (CCl_4) δ=1.45—1.85 (m, 6H, Me), 3.35—4.05 (m, 4H, CH_2), 5.05—5.75 (m, 4H, =CH), 6.21—7.25 (m, 5H, Ph); MS m/z (rel intensity) 201 (M^+, 81), 77 (100).

(*E*)-*N*-(2-Butenyl)-*N*-methylaniline: IR (neat) 3090, 3060, 3020, 2930, 2920, 2875, 2850, 1665, 1598, 1505, 1446, 1368, 1350, 1250, 1030, 990, 960, 935, 857, 745, 687 cm^{-1}; ^1H NMR (CCl_4) δ=1.52—1.77 (m, 3H, Me), 2.78 (s, 3H, Me), 3.57—3.92 (m, 2H, CH_2), 5.26—5.57 (m, 2H, =CH), 6.27—6.66 (m, 3H, Ph), 6.72—7.14 (m, 2H, Ph); MS m/z (rel. intensity) 161 (M^+, 80), 120 (100).

(*E*)-*N*-(2-Butenyl)-*p*-anisidine: ^1H NMR ($CDCl_3$) δ= 1.72 (d, J=4 Hz, 3H, Me), 2.60—3.00 (bs, 1H, NH), 3.65 (d, J=4 Hz, 2H, CH_2), 3.76 (s, 3H, OMe), 5.54—5.84 (m, 2H, =CH), 6.63 (d, J=8 Hz, 2H, Ar), 6.82 (d, J=8 Hz, 2H, Ar); MS m/z (rel intensity) 177 (M^+, 15), 108 (100).

(*E*)-*N*,*N*-Di(2-butenyl)-*p*-anisidine: ^1H NMR ($CDCl_3$) δ= 1.68 (d, J=4 Hz, 6H, Me), 3.70—3.90 (m, 7H, CH_2 and OMe), 5.40—5.72 (m, 4H, =CH), 6.64—6.90 (m, 4H, Ar); MS m/z (rel intensity) 231 (M^+, 56), 122 (100).

(*E*)-*N*,*N*-Diphenyl-2-butenylamine: IR (neat) 3080, 3060, 3040, 3000, 2960, 2930, 2880, 2850, 1590, 1497, 1447, 1364, 1240, 962, 745, 690 cm^{-1}; MS m/z (rel intensity) 223 (M^+, 27), 77 (100).

N,*N*-Diphenyl-1-methyl-2-propenylamine: MS m/z (rel intensity) 223 (M^+, 25), 77 (100).

(*E*)-*N*-Phenyl-4(or 2)-(2-butenyl)phenylamine: ^1H NMR ($CDCl_3$) δ=1.66—1.84 (m, 3H, Me), 3.22—3.48 (m, 2H, CH_2), 5.48—5.73 (m, 2H, =CH), 6.86—7.42 (m, 9H, Ar).

(*E*)-*N*-(2-Butenyl)-1-naphthylamine: IR (neat) 3450, 3070, 2980—2870, 1580, 1520, 1370, 1340, 1270, 965, 765 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.62—1.87 (m, 3H, Me), 3.72—4.00 (m, 2H, CH_2), 4.24 (bs, 1H, NH), 5.60—5.96 (m, 2H, =CH), 6.61 (d, J=7 Hz, 1H, Ar), 7.16—7.60 (m, 4H, Ar), 7.74—7.96 (m, 2H, Ar); MS m/z (rel intensity) 197 (M^+, 63), 115 (100).

(*E*)-2-(2-Butenyl)-1-naphthylamine: IR (neat) 3450, 3400, 3070, 3040, 2980, 2930, 2860, 1620, 1510, 1400, 970, 800 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.66—1.83 (m, 3H, Me), 3.34—3.52 (m, 2H, CH_2), 3.60—4.40 (m, 2H, NH_2), 5.46—5.80 (m, 2H, =CH), 7.20—7.55 (m, 4H, Ar), 7.76—7.94 (m, 2H, Ar); MS m/z (rel intensity) 197 (M^+, 100).

(*E*)-2-(2-Butenyl)pyrrole:[15] IR (neat) 3400, 3110, 3040, 2980, 2950, 2930, 2900, 2860, 2830, 1567, 1438, 1470, 1380, 1092, 1040, 1025, 970, 790, 717 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.71 (d, J=4 Hz, 3H, Me), 3.22—3.46 (m, 2H, CH_2), 5.48—5.72 (m, 2H, =CH), 5.86—6.03 (m, 1H, pyrrole H^4), 6.10—6.24 (m, 1H, pyrrole H^3), 6.66—6.78 (m, 1H, pyrrole H^5), 7.98 (bs, 1H, NH); MS m/z (rel intensity) 121 (M^+, 100).

2-(1-Methyl-2-propenyl)pyrrole:[15] ^1H NMR ($CDCl_3$) δ= 1.38 (d, J=7 Hz, 3H, Me), 3.40—3.56 (m, 1H, CH), 5.00—5.20 (m, 2H, $=CH_2$), 5.72—6.04 (m, 2H, =CH and pyrrole H^4), 6.10—6.20 (m, 1H, pyrrole H^3), 6.66—6.78 (m, 1H, pyrrole H^5); MS m/z (rel intensity) 121 (M^+, 76), 106 (100).

(*E*)-3-(2-Butenyl)pyrrole:[16,17] IR (neat) 3410, 3040, 2980, 2950, 2930, 2860, 2850, 1557, 1435, 1380, 1066, 1053, 970, 770, 710 cm^{-1}; H NMR ($CDCl_3$) δ=1.69 (d, J=6 Hz, 3H, Me), 3.08—3.38 (m, 2H, CH_2), 5.40—5.72 (m, 2H, =CH), 6.00—6.20 (m, 1H, pyrrole H^4), 6.54—6.70 (m, 1H, pyrrole H^5), 6.70—7.84 (m, 1H, pyrrole H^2), 8.04 (bs, 1H, NH); MS

m/z (rel intensity) 121 (M^+, 100).

(*E*)-3-(2-Butenyl)indole: ^1H NMR ($CDCl_3$) δ=1.70 (d, *J*=6 Hz, 3H, Me), 3.46 (d, *J*=4 Hz, 2H, CH_2), 5.00—5.90 (m, 2H, =CH), 7.00 (s, 1H, indole H^2), 7.08—7.28 (m, 2H, indole H^5 and H^6), 7.38 (d, *J*=8 Hz, 1H, indole H^4), 7.64 (d, *J*=8 Hz, 1H, indole H^7), 7.84—8.10 (bs, 1H, NH); MS *m/z* (rel intensity) 171 (M^+, 100).

3-(1-Methyl-2-propenyl)indole: MS *m/z* (rel intensity) 171 (M^+, 54), 156 (100).

Oxidoreduction between Cycloalkanols and the Corresponding Cycloalkanones in the Cultured Cells of *Nicotiana tabacum*. Simulation of the Time Courses in the Oxidoreduction

Shunsuke Izumi and Takayuki Suga*
Department of Chemistry, Faculty of Science, Hiroshima University,
Higashisenda-machi, Naka-ku, Hiroshima 730
(Received December 16, 1987)

A method for the simulation of the time courses in the oxidation of cycloalkanols and the reduction of cycloalkanones in the cultured cells of *Nicotiana tabacum* was developed on the basis of the permeability of these compounds into the cultured cells and the ^{13}C NMR chemical shift of the carbonyl carbon of the cycloalkanones. Further, the method has been applied to the simulation of the time courses in the oxidation of (+)-borneol and (+)-isopinocampheol and the reduction of (−)-carvomenthone in the cultured cells of *N. tabacum*.

Recently, we reported that the balance in the equilibrium of the oxidoreduction between 5- to 7- membered cycloalkanols and their corresponding cycloalkanones in the cultured cells of *Nicotiana tabacum* depends on the carbon number in the carbocyclic ring of the cyclic compounds.[1] It was further found that the oxidoreduction between the cycloalkanols and their corresponding cycloalkanones in the cultured cells is governed by an NAD^+-dependent alcohol dehydrogenase which is similar to the dehydrogenase from tea seeds and horse liver. We have developed a method for the simulation of the time courses in the oxidation of cycloalkanols and the reduction of cycloalkanones in the cultured cells on the basis of the permeability of these compounds into the cultured cells and the ^{13}C NMR chemical shift of the carbonyl carbon of the cycloalkanones.[2] Furthermore, the method has been applied to the oxidation of (+)-borneol (**1**) to (+)-camphor (**2**) and (+)-isopinocamphenol (**3**) to (−)-isopinocamphone (**4**) and the reduction of (−)-carvomenthone (**5**) to (+)-carvomenthol (**6**) in the cultured cells of *N. tabacum*.[3,4] The results have been partly outlined in the preliminary communications,[1-4] but we wish to describe *en bloc* details of the results together with newly obtained results.

Results and Discussion

Reaction Rates of the Oxidoreduction of Cycloalkanols and Cycloalkanones in the Enzyme System of *N. tabacum*. Firstly, the enzyme system responsible for the oxidoreduction of cycloalkanols and their corresponding cycloalkanones in the cultured cells of *N. tabacum* was characterized. An enzyme system was partially purified prepared from the cultured cells of *N. tabacum* by treating a cell-free extract of the cells with cold acetone and then ammonium sulfate as described in the experimental section. The substrate specificity of the enzyme system was tested for the oxidation of alkanols. The alkanols used as substrate were ethanol, 1-propanol, 1-butanol, 1-pentanol, 1-hexanol, cyclopentanol, and cyclohexanol. Relative rates observed in the oxidation of these substrates are given in Table 1; ethanol was the best substrate for this enzyme system. The substrate specificity was quite similar to the specificity of alcohol dehydrogenase isolated from tea seeds[5] and horse liver.[6,7]

The reaction rates of the oxidation of cycloalkanols with this enzyme system were determined in 0.1 M† glycine-NaOH buffer (pH 9.0) by tracing the decrease in the UV absorption at 340 nm due to the reduced form of nicotinamide-adenine dinucleotide (NADH).[8] The cycloalkanols used as substrate were cyclopentanol (**7**), cyclohexanol (**8**), 2-methylcyclohexanol (**9**),

Table 1. Substrate Specificity[a]

	Relative V_{max}
Ethanol	1.0
1-Propanol	0.49
1-Butanol	0.36
1-Pentanol	0.20
1-Hexanol	0.07

a) Determined in 0.1 M glycine-NaOH buffer, pH 9.0, at 25 °C.

† 1 M=1 mol dm^{-3}.

Table 2. The Rate Constant and the Equilibrium Constant of the Oxidoreduction between Cycloalkanols and the Corresponding Cycloalkanones with the Enzyme System

Compound	k_{+1}[a)]/s^{-1}	k_{-1}[b)]/s^{-1}	K
Cyclopentanol	2.53×10^{-4}	7.09×10^{-5}	3.57
Cyclohexanol	9.52×10^{-4}	1.81×10^{-3}	0.53
2-Methylcyclohexanol	1.22×10^{-3}	5.01×10^{-3}	0.24
3-Methylcyclohexanol	1.03×10^{-3}	3.16×10^{-3}	0.33
Cycloheptanol	3.69×10^{-4}	1.20×10^{-4}	3.08

a) Determined in 0.1 M glycine–NaOH buffer, pH 9.0, at 25 °C. b) Determined in 0.1 M potassium phosphate buffer, pH 7.0, at 25 °C.

3-methylcyclohexanol (**10**), and cycloheptanol (**11**). The reaction rates of the reduction of cycloalkanones with the enzyme system were determined in 0.1 M potassium phosphate buffer (pH 7.0) by tracing the increase in the UV absorption at 340 nm due to NADH.[8] The cycloalkanones used were cyclopentanone (**12**), cyclohexanone (**13**), 2-methylcyclohexanone (**14**), 3-methylcyclohexanone (**15**), and cycloheptanone (**16**). Table 2 gives the rate constant of the oxidation of the cycloalkanols (k_{+1}), the rate constant of the reduction of the cycloalkanones (k_{-1}), and the equilibrium constant in the oxidoreduction between the cycloalkanols and the cycloalkanones (K). The equilibrium constants indicate that the equilibrium of the oxidoreduction of the 6-membered cyclic compounds shifts toward the side of the reduction, while the equilibrium of the oxidoreduction of the 5- and 7-membered cyclic compounds does toward the side of the oxidation. Such a ring-size effect on the equilibrium was quite similar to the effect on the equilibrium in the bioconversion of the cycloalkanols and the cycloalkanones in the cultured cells of *N. tabacum*.

Simulation of the Time Courses in the Oxidoreduction between the Cycloalkanols and the Corresponding Cycloalkanones in the Cultured Cells of *N. tabacum*. Figures 1 and 2 show the time courses in the oxidation of cyclohexanol to cyclohexanone and the reduction of cyclohexanone to cyclohexanol, respectively. The half lives of these substrates in the oxidation and the reduction in the cultured cells were 3 days, whereas those of the substrates in the oxidation and the reduction with the enzyme system were 10 and 45 min, respectively, as deduced from the rate constants given in Table 2. The reaction rate of the oxidoreduction in the enzyme system was much faster than that of the oxidoreduction in the cultured cells. Such a time lag is probably due to a delay arising from permeation of the cycloalkanols and the cycloalkanones into the cells. The rate of permeation is known to depend on a gradient between intra- and extracellular concentrations of the cycloalkanols;[9–12] the permeability constant can be estimated by use of Hill's equation,[11]

$$[S] = [S]_0 \cdot e^{-p \cdot t}, \quad (1)$$

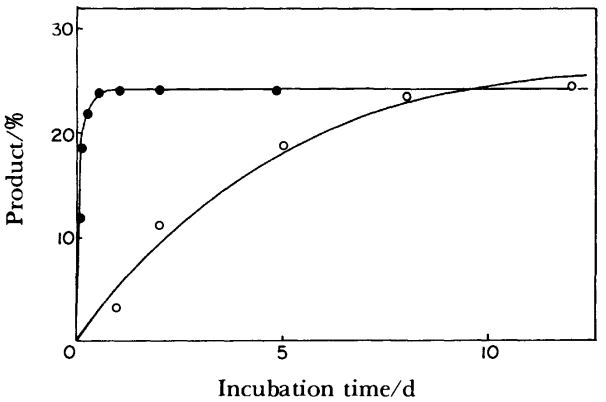

Fig. 1. Time courses in the oxidation of cyclohexanol into cyclohexanone with the enzyme system (—●—) and in the cultured cells (—○—).

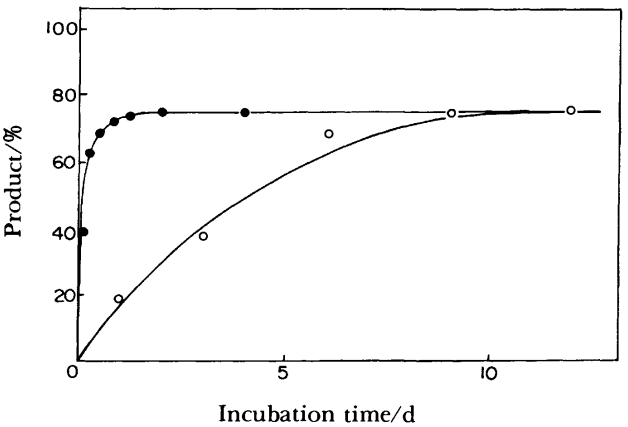

Fig. 2. Time courses in the reduction of cyclohexanone into cyclohexanol with the enzyme system (—●—) and in the cultured cells (—○—).

where [S],[S]$_0$, and p denote the concentration of the foreign substrate (cycloalkanol) at the time "t", the initial concentration of the foreign substrate, and the permeability constant, respectively. The permeability constants for permeation of the cycloalkanols and the corresponding cycloalkanones into the cultured cells were determined by substituting the data of the time courses in the bioconversion of 5- to 7-membered cycloalkanols to their corresponding cycloalkanones in the cultured cells[4] for Hill's equation; the average

of the permeability constants in the oxidation of 5- to 7-membered cycloalkanols to their corresponding cycloalkanones was 4.82×10^{-6} s^{-1}.

On the basis of the permeability constants and the rate constants, the time courses in the oxidation of the cycloalkanols in the cultured cells were simulated as follows. Temporal infinitesimal change in the concentration of the product [P] at the time "t" is given by

$$d[P] = \{[S]_0 \cdot p \cdot k_{+1}/(k_{+1} + k_{-1}) - [P] \cdot p\} \cdot dt, \quad (2)$$

where k_{+1} and k_{-1} denote the rate constant of the oxidation of the cycloalkanols and the rate constant of the reduction of the cycloalkanones, respectively. The initial term shows the infinitesimal change in the concentration of the product which is formed by oxidation of the foreign substrate and the last term shows the infinitesimal change in the concentration of the product which is permeated into the cells. The solution of this differential Eq. 2 is

$$[P] = \{[S]_0 \cdot k_{+1}/(k_{+1} + k_{-1})\}(1 - e^{-p \cdot t}). \quad (3)$$

Thus, it was established that the concentration of the product can be simulated by the permeability constant, the rate constant of the oxidation of the cycloalkanols, and the rate constant of the reduction of the cycloalkanones.

Correlation between the Reaction Rate of Enzymatic Oxidoreduction and the ^{13}C NMR Chemical Shift. The rate constants of the oxidation of the cycloalkanols (k_{+1}) and the reduction of the cycloalkanones (k_{-1}) and the equilibrium constants of the oxidoreduction between the cycloalkanols and the corresponding cycloalkanones (K) were correlated with ^{13}C NMR chemical shifts of the carbon atom bearing a hydroxyl group in the cycloalkanols and the carbonyl carbon in the cycloalkanones.[2] The correlations of ln k_{+1}, ln k_{-1}, and ln K against the ^{13}C NMR chemical shifts of the cycloalkanols are represented by the following empirical formulas (4)—(6) with r (the correlation coefficient)=0.75, 0.71, and 0.68, respectively.

Rate constants;

$$k_{+1} = \exp(-0.195\delta_{c-o} + 6.4) \quad (4)$$

$$k_{-1} = \exp(-0.515\delta_{c-o} + 29.2) \quad (5)$$

Equilibrium constant;

$$K = (k_{+1}/k_{-1}) = \exp(0.318\delta_{c-o} - 22.6) \quad (6)$$

where δ_{c-o} denotes the ^{13}C NMR chemical shift of the carbon atom bearing the hydroxyl group. However, these ^{13}C NMR chemical shifts were not well-correlated with the rate constants and the equilibrium constants.

On the other hand, a plot of ln k_{+1}, ln k_{-1}, and ln K against the ^{13}C NMR chemical shift of the carbonyl carbon yielded a straight line, as shown in Figs. 3 and 4. These correlations are represented by the following empirical formulas (7)—(9) with r (the correlation coefficient)=0.97, 0.95, and 0.94, respectively.

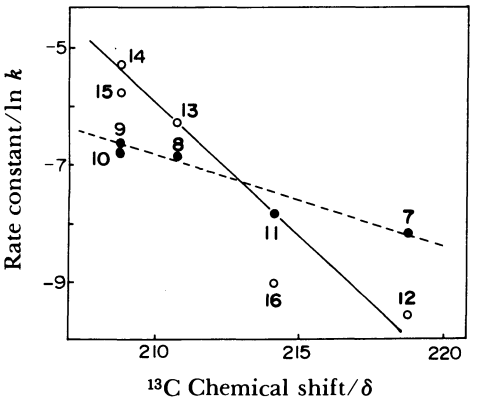

Fig. 3. Correlation of the rate constants of the oxidation of cycloalkanols (k_{+1}; --●--; cyclopentanol (**7**), cyclohexanol (**8**), 2-methylcyclohexanol (**9**), 3-methylcyclohexanol (**10**), and cycloheptanol (**11**)) and the reduction of cycloalkanones (k_{-1}; —○— cyclopentanone (**12**), cyclohexanone (**13**), 2-methylcyclohexanone (**14**), 3-methylcyclohexanone (**15**), and cycloheptanone (**16**)) with the ^{13}C NMR chemical shift of the carbonyl carbon of the cycloalkanones involved in the reaction.

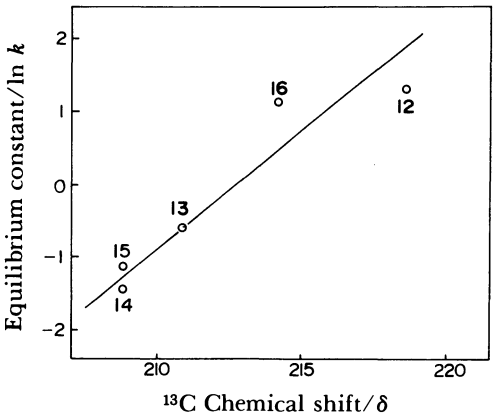

Fig. 4. Correlation of the equilibrium constant of the oxidoreduction between cycloalkanols and corresponding cycloalkanones with the ^{13}C NMR chemical shift of the carbonyl carbon of the cycloalkanones (cyclopentanone (**12**), cyclohexanone (**13**), 2-methylcyclohexanone (**14**), 3-methylcyclohexanone (**15**), and cycloheptanone (**16**)).

Rate constants;

$$k_{+1} = \exp(-0.162\delta_{c=o} + 27.1) \quad (7)$$

$$k_{-1} = \exp(-0.447\delta_{c=o} + 87.7) \quad (8)$$

Equilibrium constant;

$$K = (k_{+1}/k_{-1}) = \exp(0.284\delta_{c=o} - 60.5) \quad (9)$$

where $\delta_{c=o}$ denotes the ^{13}C NMR chemical shift of the carbonyl carbon of the cycloalkanones. The rate

constants and the equilibrium constants were predicted by the ^{13}C NMR chemical shifts of the carbonyl carbon of the cycloalkanones. This indicates a dependence of the reaction rate of the enzymatic oxidoreduction on the electron density of the carbonyl carbon of the cycloalkanones.

When we use this indication, Eq. 3 can be related with the ^{13}C NMR chemical shift of the carbonyl carbon of the cycloalkanones given in Eqs. 7 and 8. For the time courses in the oxidation of the cycloalkanols and their related compounds, the proportion of the concentration of product [P] (cycloalkanone) to the initial concentration of substrate $[S]_0$ (cycloalkanol) is found to be

$$P = [P]/[S]_0 = \{1 - \exp(-4.82 \times 10^{-6} \cdot t)\}/ \{1 + \exp(-0.284\delta_{c=o} + 60.5)\}. \quad (10)$$

The time courses in the reduction of the cycloalkanones and their related compounds were simulated in a manner similar to that described above. The simulated equation is as follows:

$$P = \{1 - \exp(-4.82 \times 10^{-6} \cdot t)\}/ \{1 + \exp(0.284\delta_{c=o} - 60.5)\}. \quad (11)$$

Therefore, the time courses in the oxidation of the cycloalkanols and the reduction of the cycloalkanones in the cultured cells were found to be simulated on the basis of the permeability of the cycloalkanols and their corresponding cycloalkanones into the cultured cells and the ^{13}C NMR chemical shift of the carbonyl carbon of the cycloalkanones or the corresponding carbonyl compounds.

Application of the Simulation to the Oxidation of (+)-Borneol and (+)-Isopinocampheol and the Reduction of (−)-Carvomenthol. The equation for the simulation of the time courses in the oxidation of the cycloalkanols was applied to the oxidation of (+)-borneol (**1**) to (+)-camphor (**2**) in the cultured cells. Figure 5 shows the time course in the bioconversion of borneol to camphor in the cultured cells[4] and the time course simulated by use of Eq. 10 with the ^{13}C NMR chemical shift of the carbonyl carbon of camphor ($\delta_{c=o}$ 218.9). The simulation curve well fits with the bioconversion curve. Furthermore, the time course in the oxidation of (+)-isopinocampheol (**3**) to (−)-isopinocamphone (**4**) was simulated by use of Eq. 10 with the ^{13}C NMR chemical shift of the carbonyl carbon of isopinocamphone ($\delta_{c=o}$ 214.3) and is shown in Fig. 6. This simulation curve well fits with the bioconversion curve of isopinocampheol in the cultured cells, as seen in Fig. 6.

On the other hand, the time course in the reduction of (−)-carvomenthone (**5**) to (+)-carvomenthol (**6**) was simulated by use of Eq. 11 with the ^{13}C NMR chemical shift of the carbonyl carbon of carvomenthone ($\delta_{c=o}$ 211.8), as shown in Fig. 7. The simulation curve also well fits with the time course in the bioconversion of carvomenthone to carvomenthol in the cultured cells.

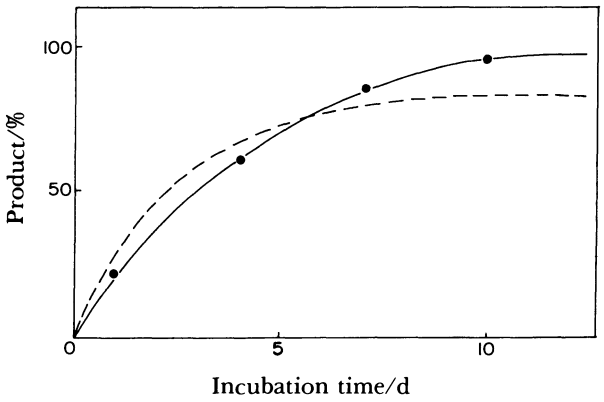

Fig. 5. Comparison of the bioconversion of (+)-borneol (**1**) into (+)-camphor (**2**) in the cultured cells (—●—) with its simulation (-----).

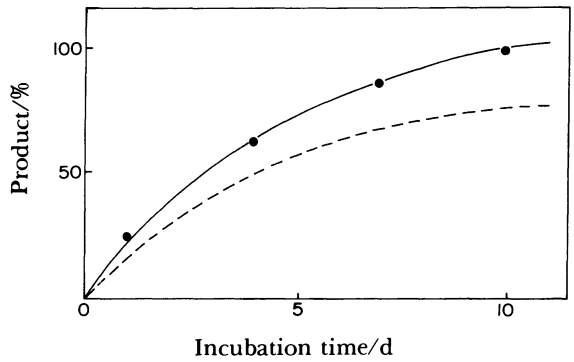

Fig. 6. Comparison of the bioconversion of (+)-isopinocampheol (**3**) into (−)-isopinocamphone (**4**) in the cultured cells (—●—) with its simulation (-----).

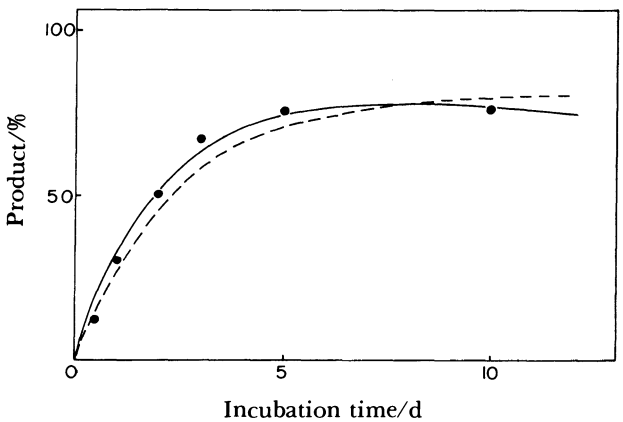

Fig. 7. Comparison of the bioconversion of (−)-carvomenthone (**5**) into (+)-carvomenthol (**6**) in the cultured cells (—●—) with its simulation (-----).

It was thus established that the time courses in the oxidation of the cycloalkanols and the related alcohols and the reduction of the cycloalkanones and the related ketones in the cultured cells can be simulated on

Table 3. The Purification of the Enzyme System

	Total protein	Total act.	Sp. act.	Purification
	mg	U	U mg^{-1}	Fold
Cell-free extract	75.6	17.8	0.23	1.0
Acetone fraction	5.0	9.8	1.92	8.3
$(NH_4)_2SO_4$ fraction	0.8	8.2	10.2	44

the basis of the permeability of the cycloalkanols, the cycloalkanones, and their related compounds into the cells and the carbonyl carbon ^{13}C NMR chemical shifts of the cycloalkanones and the related carbonyl compounds involved in the equilibrium of the oxidoreduction between the cycloalkanols and the cycloalkanones.

Experimental

GLC analyses were performed on an instrument equipped with an FID and a glass column (3 mm×2 m) packed with 15% DEGS or 2% OV-17 on Chromosorb W (AW-DMCS; 80—100 mesh), varying the column temperature over the range of 80—200 °C at the rate of 3 °C min^{-1}. ^{13}C NMR spectra were obtained at 22.6 MHz in $CDCl_3$ with tetramethylsilane as an internal reference.

Materials. Cyclopentanol, cyclohexanol, 2-methylcyclohexanol, 3-methylcyclohexanol, and cycloheptanol and their corresponding cycloalkanones were of commercial origin from Wako Pure Chemical Ind., Ltd. The chemical shifts of the carbonyl carbon of the cycloalkanones in their ^{13}C NMR spectra were 218.6, 210.8, 208.8, 208.8, and 214.2, respectively. (+)-Camphor (**2**) was purchased from Tokyo Kasei Co., Ltd. and purified by recrystallization followed by sublimation; mp 176—178 °C, $[\alpha]_D^{25}$ +42.9° (*c* 1.1, EtOH) (lit,[13] $[\alpha]_D^{25}$ −44.2°); ^{13}C NMR ($CDCl_3$) δ=218.9 (C=O). (+)-Borneol (**1**) was prepared from (+)-camphor (**2**) by reduction with $NaBH_4$ in methanol; mp 201—202 °C, $[\alpha]_D^{25}$ +37.6° (*c* 1.0, EtOH) (lit,[13] $[\alpha]_D^{25}$ +37.9°). (+)-Isopinocampheol (**3**) was synthesized from (−)-α-pinene by hydroboration;[14] mp 55—57 °C, $[\alpha]_D^{25}$ +31.6° (*c* 5.1, EtOH) (lit,[3] $[\alpha]_D^{25}$ −31.0° for the (−)-enantiomer). (−)-Isopinocamphone (**4**) was prepared from (+)-isopinocampheol (**3**) by oxidation with sodium dichromate;[15] $[\alpha]_D^{25}$ −9.8° (neat) (lit,[3] $[\alpha]_D^{25}$ −9.9°); ^{13}C NMR ($CDCl_3$) δ=214.3 (C=O). All the samples used as substrate were >99% pure on GLC.

Enzyme System from the Cultured Cells of *N. tabacum*. The cultured cells of *N. tabacum* (100 g) were homogenized in 50 mM Tris-HCl buffer (pH 7.2, 1000 ml) containing 10 mM 2-mercaptoethanol. The homogenate was stirred for 3 h at 25 °C. After filtration through several layers of cheesecloth, the filtrate was centrifuged at 13000 g for 10 min to give a cell-free extract. Into the cell-free extract, cold acetone (0 °C) was poured with vigorous stirring under ice-cooling. The soln, after standing for 30 min, was centrifuged at 17000 g for 15 min to give a precipitate, which was suspended in 50 mM Tris-HCl buffer (pH 7.2, 300 ml) containing 10 mM 2-mercaptoethanol. The suspension was treated with ammonium sulfate to give a 25—60% ammonium sulfate fraction. The salting-out product was suspended in 0.1 M potassium phosphate buffer (pH 7.0). The suspended material, after dialysis for 15 h against the same buffer solution, was centrifuged at 30000 g for 20 min. The supernatant was used as an enzyme system. The enzyme system was purified 44-fold against the cell-free extract in the activity for the conversion of ethanol to acetaldehyde by oxidation, as given in Table 3. The properties of the enzyme system were characterized as follows.

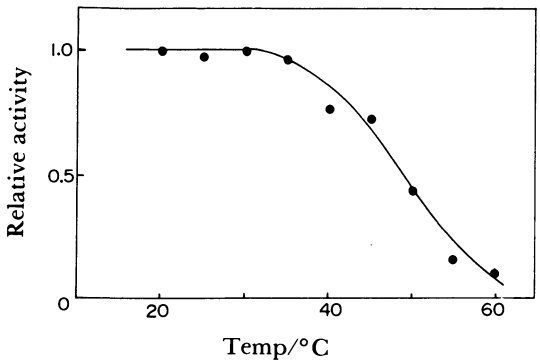

Fig. 8. Thermal stability of the enzyme system partially purified from the cultured cells of *N. tabacum*.

Substrate Specificity in the Oxidation of Alkanols. The mixture containing the enzyme system (0.6 μg protein), alkanol (0.1 M), such as ethanol, 1-propanol, 1-butanol, and 1-hexanol, and NAD^+ (0.05 mM) was diluted with 3 ml of 0.05 M Tris-HCl buffer (pH 8.5) containing 10 mM 2-mercaptoethanol and then the solution was incubated at 25 °C for 2 h. The reaction was monitored by means of UV absorption measurements. The initial rates in the oxidation of the alkanols were determined by measuring the change in the UV absorption at 340 nm for NADH. Table 1 gives the relative rates in the oxidation of the alkanols.

Thermal Stability: The enzyme system was held at various temperatures (20—60 °C) for 15 min prior to incubation. The enzyme activity in the oxidation of ethanol was determined by measuring the change in the UV absorption at 340 nm. Figure 8 shows the thermal stability of the enzyme system.

Optimum pH: The enzyme activity in the oxidation of ethanol was determined in three kinds of buffer solutions as follows: 0.1 M potassium phosphate buffer, pH 5.5—7.8; 0.1 M Tris-HCl buffer, pH 7.5—9.0; glycine-NaOH buffer, pH 8.6—11.6. Figure 9 shows the effect of pH on the enzyme activity.

Effect of 2-Mercaptoethanol: The enzyme system (5 ml, 3.0 μg protein) was dialysed for 4 days at 5 °C against (i) Tris-HCl buffer (pH 8.5) containing 10 mM 2-mercaptoethanol and (ii) Tris-HCl buffer (pH 8.5) lacking 2-mercaptoethanol. A part of each enzyme system was pipetted out at a regular time interval and the enzyme activity in the oxidation of ethanol was determined in the same manner as above. Figure 10 shows the effect of 2-

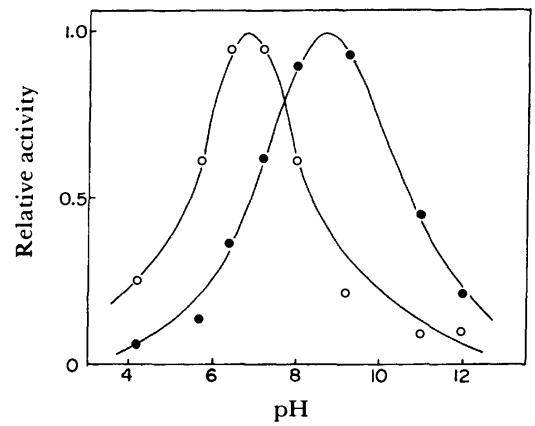

Fig. 9. Effect of pH on the activity of the enzyme system partialy purified from the cultured cells of *N. tabacum*. —○—; NADH-dependent reaction, —●—; NAD-dependent reaction.

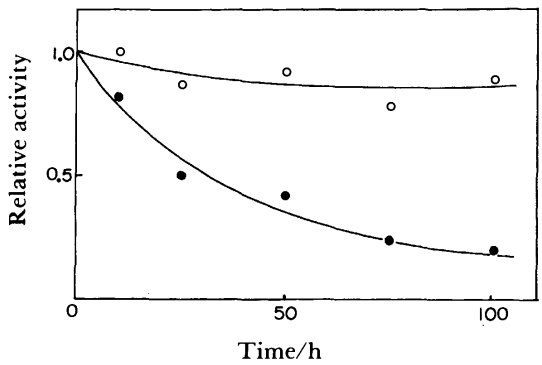

Fig. 10. Effect of dialysis on the activity of the enzyme system partially purified from the cultured cells of *N. tabacum*. —○—; Containing 10 mM 2-mercaptoethanol, —●—; Lacking 2-mercaptoethanol.

mercaptoethanol on the enzyme activity.

Oxidoreduction between Cycloalkanols and the Corresponding Cycloalkanones with the Enzyme System. The initial rates of the oxidoreduction were determined by measuring the change in the UV absorption at 340 nm for NADH and by calculating on the least square method with the Lineweaver-Burk's equation.[16]

Oxidation: To a solution of cycloalkanol (0.01—4.0 mM) and NAD^+ (0.5 mM) in 0.1 M glycine-NaOH buffer (3 ml, pH 9.0), the enzyme system (0.6 μg protein) was added. The mixture was incubated at 25 °C for 2 h. During the incubation, the reaction was monitored by means of the UV absorption measurements. Table 2 gives the rate constants of the oxidation of the cycloalkanols.

Reduction: To a solution of cycloalkanone (0.5—10 mM) and NADH (0.2 mM) in 0.1 M potassium phosphate buffer (3 ml, pH 7.0), the enzyme system (0.6 μg protein) was added. The incubation was carried out at 25 °C for 2 h under monitoring by the UV spectrometry as above. The rate constants of the reduction of the cycloalkanones are given in Table 2.

Time Courses in the Bioconversion of the Cycloalkanols in the Cultured Cells of *N. tabacum*. A suspension of the cultured cells of *N. tabacum* "Bright Yellow" was prepared as described in Refs. 2 and 17; the cells were cultured in a 300-ml conical flask containing 100 ml of Murashige and Skoog's medium[18] in each case. Each substrate (10 mg) was administered to the flask containing the precultured suspension cells (50 g fresh wt/100 ml Murashing-Skoog's medium). The culture was incubated at 25 °C for 10 days in the dark with shaking at 70 rpm. A part (10 ml) of the incubated mixture was pipetted out under sterile conditions at a regular time interval, ground in a mortar, and extracted with ether. Products in each ether extract were identified, after removal of the solvent, by GLC and co-GLC with authentic samples. Amounts of the products and the unchanged substrate were determined on the basis of the peak areas on GLC and are expressed as the relative percentage for the total amount of a whole reaction mixture obtained.

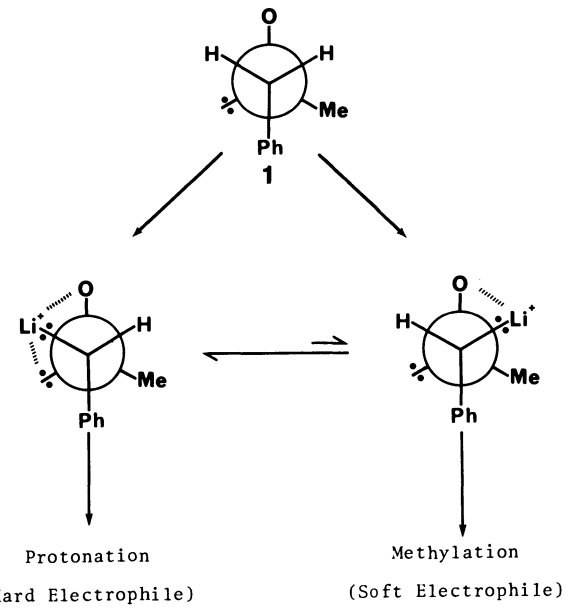
t-Butylsulfinyl Phenylmethyl Carbanion. Conformation in Nonpolar Solvent

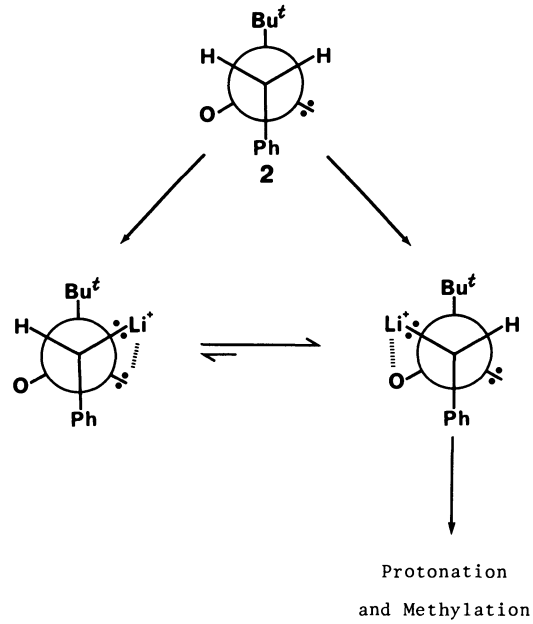
Atsuyoshi Ohno,* Masato Higaki, and Shinzaburo Oka
Institute for Chemical Research, Kyoto University, Uji, Kyoto 611
(Received December 24, 1987)

^{1}H NMR spectra were studied for a carbanion derived from *t*-butyl phenylmethyl sulfoxide in tetrahydrofuran. It has been concluded that the conformation of the carbanion in solution is the same as that in a crystal. The carbanion exists in two diastereomeric dimeric forms in the presence of an equivalent amount of countercation, but it becomes a monomer when excess base exists in the solution.

A recent report on neutron diffraction crystallography on *t*-butyl phenylmethyl sulfoxide[1] casted a doubt on the configurations and reactivities of α-sulfinyl carbanions so far accepted.[2] Stereochemistry of the reaction from an α-sulfinyl carbanion changes irregularly depending on the property of attacking electrophile and the steric bulk of substituent on the sulfur atom as well as on the polarity of solvent.[2-4]

Reinvestigation of stereochemistry of the products derived from α-sulfinyl carbanions made us propose[5] that 1) the major conformation of the carbanion is determined primarily by steric bulk of the substituents on the sulfur and the carbanionic carbon atom, then 2) a conformation is preferred so that the countercation of the carbanion can maintain a maximum interaction with a lone pair on the sulfinyl oxygen. 3) An interaction between the countercation and the sulfinyl lone pair exerts a minor effect. Since solvent-separated and dissociated ion pairs become popular in polar solvents, the importance of the role of the countercation decreases in such solvents. 4) Hard electrophiles such as water and a carbonyl compound attack the carbanion from its hard face; the attacking reagent interacts with the countercation initially and the population of a particular conformation of the carbanion controls the steric course of the reaction. 5) A soft electrophiles such as an alkyl halide, on the other hand, prefer to attack the carbanion from its soft face; the carbanion lone pair anti to the lone pair on the sulfinyl sulfur becomes more polarizable due to an α-effect.[6] The reaction courses are illustrated in Scheme 1 for the protonations and methylations of carbanions derived from (*S*)-methyl phenylmethyl sulfoxide (*S*-**1**) and (*R*)-*t*-butyl phenylmethyl sulfoxide (*R*-**2**). It is important to note that the *R*,*S*-notation appears different in methyl and *t*-butyl phenylmethyl sulfoxides because of definition.





Although the proposal described above can explain the reactions of α-sulfinyl carbanions sufficiently, we have had no information on the conformation of the carbanion in solution. In order to obtain further insight into the conformation, we studied ^{1}H NMR spectroscopy of **2** in tetrahydrofuran (THF) and the results will be described in this paper. The hybridization of carbanionic carbon in α-sulfenyl, sulfinyl, and sulfonyl carbanions was extensively studied by Chassaing and Marquet by means of ^{13}C and ^{1}H NMR spectroscopies.[7,8]

Results and Discussion

When 1.2 equivalent amounts of butyllithium was added to a solution of racemic mixture of **2** in tetrahydrofuran-d_8 (THF-d_8) at −100 °C, two ^{1}H

NMR signals for the benzylic proton appeared as singlets of approximately equal intensity at δ 3.34 and 3.36 in addition to signals for the aromatic protons at 5.86 (t, para), 6.11 and 6.13 (two doublets, ortho), 6.53 (q, meta), and 6.79 (d, ortho). The spectrum is shown in Fig. 1a and hereafter this solution will be called as the standard system. As shown in Fig. 1b, however, when the same solution with optically pure *R*-**2** instead of racemic **2** was subjected to the ^{1}H NMR spectroscopy, the benzylic proton resulted in only one singlet at δ 3.34 and the doublets for ortho-protons at δ 6.11 and 6.13 converged into a single doublet at δ 6.11.

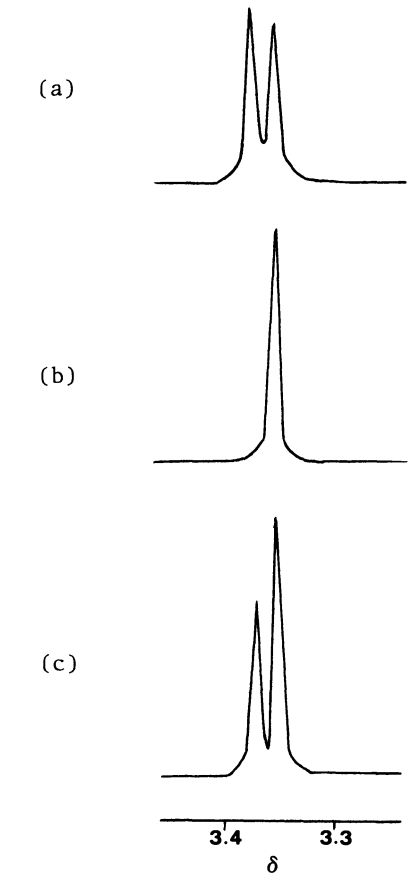


Fig. 1. ^{1}H NMR spectra of a benzylic proton of (a) racemic, (b) optically pure *R*-, and (c) 55% optically pure *R*-lithium salt of *t*-butylsulfinyl phenylmethyl carbanion in THF at −100°C.

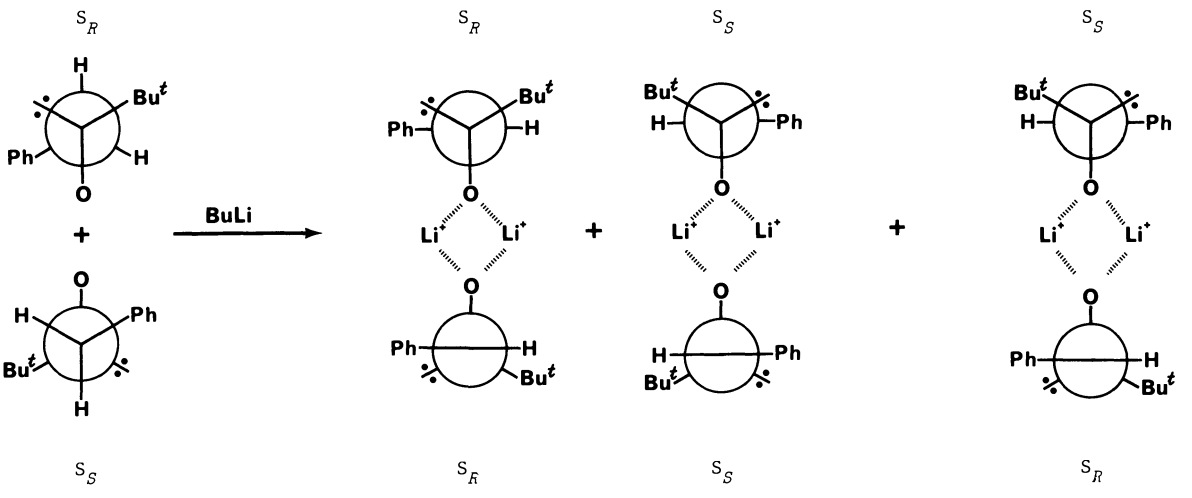
The appearance of two singlets from the racemic system suggests the existence of two or more diastereomeric isomers. Since optically pure **2** shows only one singlet and two doublets for the benzylic proton and for the two ortho-protons, respectively, and since it has been confirmed that the abstraction of a benzylic proton in **2** by a base results in highly diastereospecific carbanion thermodynamically,[5] there is no doubt that the two singlets observed for the benzylic proton in racemic **2** is *not* due to diastereomerism of benzylic protons with respect to the chirality on a single sulfur. That is, the spectra indicate that the lithiated carbanions produced from racemic **2** in THF are dimerized[9] to form *dl* (S_RS_R and S_SS_S)- and meso (S_RS_S)-isomers (**3** and **4**, respectively), whereas those from *R*-**2** can dimerize to only one S_RS_R form. That 2-methylbutyllithium displays two ^{1}H NMR signals (quartets) for α-protons in diastereomeric hexamers has been documented as well.[10]

Although the dimer of the carbanion from 1-phenylethyl phenyl sulfoxide has been known in crystalline state[11] and the possibility of its existence in a solution was suggested,[7,8] the present result is the first one to confirm that the carbanion from **2** prefers to be in dimeric form even in a solution. It is known that benzylic carbanion tends to exist as a monomeric ion pair with a lithium cation.[12–14] The preference of the dimeric form in the present benzylic carbanion with the bridge of lithium ions seems to suggest that the coordination of lithium ion onto the lone pair of sulfinyl oxygen is more important interaction than the coordination onto the lone pair on the benzylic carbon.[7,8,15] The present result suggests that the negative charge induced on the carbanion on the



abstraction of a benzylic proton delocalizes largely onto the sulfinyl oxygen as well as on the phenyl group and the conformation of this benzylic carbon may be close to planar, in accord with the result reported previously.[7,8]

The coalescence temperature of two singlets (−40 °C) elucidates that free energy of activation for intermolecular exchange of the carbanion is 51 kJ mol^{-1}, which is almost equivalent to 56 kJ mol^{-1} for 2-methylbutyllithium.[15] Thus, the present result indicates that the SO···Li interaction in the dimer of sulfinyl carbanions is reasonably strong.

Figure 1c shows a spectrum obtained from the solution with *R*-**2** in 55% optical purity. The ratio in intensities of two singlets at δ 3.34 and 3.36 is 6:4, which is almost equivalent to the ratio of 7.5:4 calculated for the ratio in abandance of *dl*- and meso-dimers assuming random pairing of the carbanions. Thus, although thermodynamic stabilities of *dl*- and meso-dimers are equivalent in solution within experimental error, the X-ray crystallography predicted that the carbanion from a racemic mixture of 1-phenylethyl phenyl sulfoxide crystallizes as the meso-dimer.[11]

Not only the qualitative similarity in the dimeric form, but also the similarity in the conformation of individual (monomeric) carbanion can be seen between the carbanions in the solid and liquid phases; a nuclear Overhouser effect observed for the carbanion in THF at −50 °C by irradiating the signal from the methyl protons showed 13.5% increase in the intensity of the signal for the benzylic proton, whereas the effect was only 4.7% in the spectrum from the mother species, **2**.[5] This result indicates that the benzylic proton in the carbanion is set in more proximity to the *t*-butyl group than that in the original sulfoxide **2**. Thus, the conformations of carbanions derived from *S*- and *R*-**2** in THF are those shown in **3** and **4** in accord with that elucidated by X-ray crystallography.[11]

The discussion described above has been developed on the basis of assumption that the carbanion is in dimeric form in THF and not in tetramer or higher aggregate. The validity of this assumption can be tested experimentally. No change in the spectrum was observed when two equivalent amounts of *N,N,N′,N′*-tetramethylethylenediamine was added to the standard system, in contrast to the observation on butyllithium, where the presence of tetrameric aggregate is suggested.[12] Since the free energy of activation for ligand exchange in α-sulfinyl and alkyl carbanions are similar, the present observation indicates that the α-sulfinyl carbanion chelated by lithium cations are not in tetrameric or higher aggregation.[12] Instead, the sulfinyl oxygen in the dimeric form coordinates onto the lithium cation quite strongly so that the other chelating reagent can only substitute the solvent molecule on the lithium ion without destroying the dimeric form into monomers.

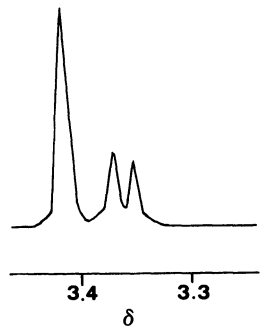


Fig. 2. ^{1}H NMR spectrum of a benzylic proton of racemic, *t*-butylsulfinyl phenylmethyl carbanion with one more equivalent excess butyllithium in THF at −100 °C.

When one more equivalent amount of butyllithium was added to the standard system, however, another singlet appeared at δ 3.40 as the signal from the benzylic proton at the sacrifice of intensities of signals from protons in the dimers. The appearance of the singlet is accompanied by the appearance of another pair of four signals from the aromatic protons (Fig. 2). That is, all the benzylic protons in the solution become magnetically equivalent by forming a new species, which means that the dimeric carbanions dissociate into monomers in the presence of excess base, or more precisely, butyllithium substituted to a half portion of the dimer forming a sulfinylalkyl mixed aggregate.

Experimental

Instruments. ^{1}H NMR spectra were recorded at 400 MHz on a JEOL GX-400 Fourier Transform NMR Spectrometer with a low-temperature equipment. δ-Values in ppm were internally related to that of the residual α-protons (δ 3.5) in the THF-d_8 solvent. The optical purity was measured on a Perkin-Elmer 241 Polarimeter. Elemental analyses were performed with a Yanako MT-3 Elemental Analyzer and gave satisfactory results for all compounds used.

Materials. (S_R)-*t*-butyl phenylmethyl sulfoxide was prepared according to the literature procedure.[16] Tetrahydrofuran-d_8 and a hexane solution of butyllithium were obtained from a commercial source.

Preparation of α-Sulfinyl Carbanion. An NMR sample tube containing 4.9 mg (0.025 mmol) of *t*-butyl phenylmethyl sulfoxide was sealed by a rubber stopper under atmosphere of nitrogen, then 700 μl of THF-d_8 was poured into the tube through a syringe. The solution was cooled to an appropriate temperature under a streem of nitrogen in order to keep the pressure inside the tube atmospheric. Since 3.57 mM dm^{-3} water was detected on the ^{1}H NMR spectrum of the solution, 1.6 μl of butyllithium in hexane was added to the solution in order to quench all the water molecule present. Then 1.2 equivalent amounts of butyllithium in hexane (19.2 μl, 0.03 mmol) was added to this solution through a syringe.

Measurement of Nuclear Overhauser Effect. The lithiated *t*-butylsulfinyl phenylmethyl carbanion (**2**) in THF-d_8 was kept at −50 °C. Irradiation on the methyl protons in the *t*-butyl group led to the enhancement in the intensity of signal from the benzylic proton in the difference NOE experiment.

The Effect of the Heat Treatment of Pd Thin Film Alloy on the Hydrogenation of Olefins

Jun TAMAKI, Masashi YAMAMURA, and Toshinobu IMANAKA*
Department of Chemical Engineering, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560
(Received August 31, 1987)

Pd-(B, P) thin film alloys have been prepared by an RF sputtering method. Before heat treatment, the selectivity for the partial hydrogenation of olefins increased with the increase in the B or P concentration in the Pd-(B, P) films. After the heat treatment, on the other hand, the selectivity for the partial hydrogenation was reduced over the Pd films with a low B or P concentration. However, in the case of the Pd films with a high B or P concentration, the selectivity was enhanced by the heat treatment. The high selectivity after the heat treatment was explainable in terms of the small ensemble size, the low electron density of Pd, and the appearance of a Pd_3B, $Pd_{4.8}P$, or Pd_5P_2 phase in the Pd films with a high B or P concentration. A sputtered film is known to have a columnar structure. This columnar structure was deduced to be controlled both by the alloying of Pd with B or P and by the heat treatment, so as to exhibit the high selectivity for the partial hydrogenation of olefins.

It is well-known that palladium shows a high selectivity in the hydrogenation of diolefins and acetylenes to monoolefins[1] and so is extensively utilized in industrial processes. Alloyed palladium catalysts are often used in order to enhance the properties of palladium by alloying, e.g., Pd-Pb,[2] Pd-Cu,[3-5] Pd-Au,[6] and Pd-Sn[7] alloys.

In a previous investigation,[8] boron (B) and phosphorus (P) were employed as partner elements of Pd alloys; Pd-(B, P) thin film alloys with various compositions of B or P could easily be prepared by changing the RF sputtering conditions. Since boron and phosphorus acted as the electron donor and the acceptor in the Pd alloys respectively, the electronic state of palladium could easily be modified by alloying with B or P. The palladium in the Pd-B alloys was in a high electron density, while the palladium in the Pd-P alloys was in a low density. The change in the electron density of Pd affected the selectivity for the partial hydrogenation of olefins. When the electron density of Pd was decreased by alloying by, for example, the Pd-P alloys, the selectivity was considered to be raised by the enhancement of the difference in the adsorption abilities of diene and monoene.[9] On the other hand, the ensemble effect in the alloy must be considered as well.[10] The ensemble size of Pd is invariably decreased by alloying with B or P, according to the results of investigations using the single-crystal surfaces of noble metals.[11-14] Since the small ensemble size of Pd caused a decrease in the number of adsorptive sites of hydrogen,[15] diolefins and acetylene were considered not to be readily hydrogenated up to paraffins, resulting in an enhancement of the selectivity for the partial hydrogenation. In the Pd-(B, P) alloys, the selectivity of the partial hydrogenation was controlled by the ensemble and by the ligand effect.

Thornton[16] reported that the structure of a sputtered film consisted of an aggregate of tapered columnar crystallites and that each column was separated by grain boundaries or voids so that the surface of film was not flat. The surface microstructure of the columnar crystallites is assumed to influence the catalysis by the film. Annealing by heat treatment would change the microstructure of the films. In this study, the effect of the heat treatment on the activity and the selectivity in the partial hydrogenation of olefins was examined in terms of the surface microstructure and the electronic state of the Pd film alloys.

Experimental

The Pd-(B, P) alloys were prepared using the RF sputtering method; the details of the film preparation were described in previous reports.[9,17] A Pd plate (99.95%) was used as a target for the sputtering. The boron and phosphorus sources were B_2H_6 diluted with H_2 (5.25 vol%), and PH_3 diluted with H_2 (5.37 vol%), respectively. The sputtering atmosphere was a mixed gas with a high purity of Ar (99.9995%) at a pressure of 0.05 Torr and $B_2H_6+H_2$ for the preparation of Pd-B films or a mixed gas of Ar and PH_3+H_2 for the preparation of Pd-P films. The glow discharge was carried out under various B_2H_6 or PH_3 partial pressures. The Pd thin film alloys were deposited on Pyrex glass substrates opposite the target. The average film thickness was 200 nm for all the Pd thin film alloys.

The hydrogenation of diolefins (cyclopentadiene and 1,3-butadiene) and acetylene was carried out over the Pd-(B, P) films at 273 K using a closed circulation system. The H_2/hydrocarbon ratio and the total pressure in the system were controlled to 6 and 140 Torr respectively. The products of the hydrogenation were analysed by means of a gas chromatograph (Shimadzu GC-8A) with a thermal conductivity detector. The columns used were a 3 m 2,4-dimethylsulfolane column for the hydrogenation of cyclopentadiene, a 5 m sebaconitrile column for 1,3-butadiene, and a 3 m activated charcoal column for acetylene. The heat treatment of the Pd thin film alloys was carried out at 573 K for 1 h in a vacuum ($<10^{-3}$ Torr (1 Torr=133.322 Pa)). The

surface analysis and the hydrogenation activity and selectivity were examined again after the treatment. The surface analysis was performed using a Shimadzu VD-1 X-ray diffractometer and a Shimadzu ESCA-750 X-ray photoelectron spectrometer.

Results and Discussion

Effect of the Heat Treatment on the Hydrogenation of Olefins. The highest activity in the hydrogenation was obtained over the pure Pd film. However, it steeply decreased with an increase in the B or P concentration. After the heat treatment, the hydrogenation activity decreased by about 1/3. This might be attributable to the decrease in the surface area resulting from the heat treatment.

The selectivity for the partial hydrogenation of cyclopentadiene to cyclopentene changed with the B or P concentration, as is shown in Figs. 1 and 2.

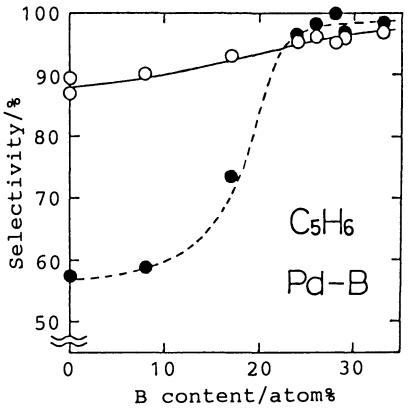

Fig. 1. Selectivity of the partial hydrogenation of cyclopentadiene as a function of the boron content.
—○—; before heat treatment. ---●---; after heat treatment.

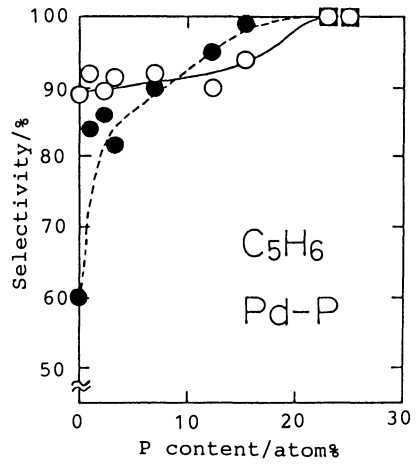

Fig. 2. Selectivity of the partial hydrogenation of cyclopentadiene as a function of the phosphorus content.
—○—; before heat treatment. ---●---; after heat treatment.

Before the heat treatment, as is shown by the solid line, the selectivity was satisfactorily high, even for the pure Pd film, and it further increased with the enhancement of the B or P concentration. The selectivity reached 96.7% for the $Pd_{67}B_{33}$ film and 100% for the $Pd_{75}P_{25}$ film. After the heat treatment, as is shown by the broken line, a selectivity drop was observed for the Pd–B films below 20 atom% of B and for the Pd–P films below 10 atom% of P. However, the selectivity increased in the region of the higher B or P concentration and reached 98.4% for the $Pd_{67}B_{33}$ film and 99.5% for even the $Pd_{85}P_{15}$ film. The selective hydrogenation of cyclopentadiene is a significant process for the utilization of the C_5 fraction in naphtha-cracking products. In the study by Hirai et al.[18] using colloidal Pd supported on a chelate resin, the selectivity for the partial hydrogenation of cyclopentadiene was 97.1% for a batch reactor in a liquid phase and 96% in a gas phase using a closed circulation system. In another study by Chaouki et

al.[19] using the Cu/Al_2O_3 aerogel catalyst, the selectivity was about 100% for an integral plug flow reactor. Better results were obtained in our investigation in the gas phase.

The selectivity for the partial hydrogenation of 1,3-butadiene to butenes altered with the B or P concentration, as is shown in Figs. 3 and 4. Before the heat treatment, the selectivity was at its maximum at 20 atom% of B in the Pd–B films, and the maximal selectivity was 97.1%. The selectivity in the Pd–P films increased monotonously with the P concentration until it reached 96.0% for the $Pd_{75}P_{25}$ film. After the heat treatment, similar results on the hydrogenation of cyclopentadiene were observed. The selectivity was reduced below 10 atom% of B for the Pd–B films and below 17 atom% of P for the Pd–P films. However, the selectivity was enhanced in the region of a higher B or P concentration, reaching 98.3% for the $Pd_{80}B_{20}$ film and 98.0% for the $Pd_{75}P_{25}$ film.

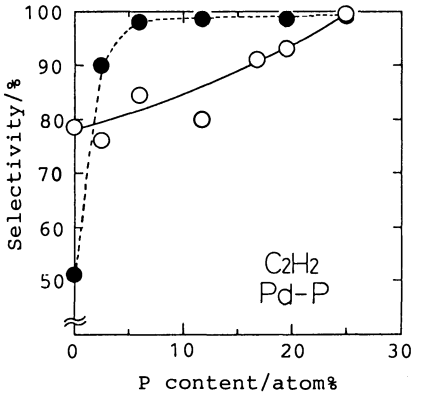

Fig. 6. Selectivity of the partial hydrogenation of acetylene as a function of the phosphorus content.
—○—; before heat treatment. ---●---; after heat treatment.

The selectivity for the partial hydrogenation of acetylene to ethylene changed with the B or P concentration, as is shown in Figs. 5 and 6. With the Pd–B films, the selectivity before the heat treatment was at its maximum at 20 atom% of B, much as in the hydrogenation of 1,3-butadiene, and the maximal selectivity was 89.0%. In the case of the Pd–P films, the selectivity increased with the increase in the P concentration. After the heat treatment, analogous to the hydrogenation of cyclopentadiene and 1,3-butadiene, the selectivity dropped in the region of a lower B or P concentration. However, it was raised in a higher B or P concentration range. The selectivity reached 98.0% for the $Pd_{84}B_{16}$ film and 99.0% for the $Pd_{75}P_{25}$ film. The partial hydrogenation of acetylene has been investigated for the sake of the commercially significant ethylene formation and the purification of ethylene by hydrogenating the acetylene contaminant. A higher selectivity of ethylene was obtained over the Pd–(B, P) films after the heat treatment in comparison to the conventional supported Pd catalysts[20] and other Pd alloy catalysts.[2–6]

Change in the Film Structure. The structure of the Pd thin film alloys was investigated by using X-ray diffraction analysis (XRD). Below 15 atom% of B in the Pd–B films, two peaks appeared at about 40 and 46 degrees; they corresponded to the Pd(111) and Pd(200) faces respectively. Below 25 atom% of P in the Pd–P films, only one peak appeared at about 40 degrees. In this region, the structure of the Pd–(B, P) films was found to be analogous to Pd fcc structure. In the higher B or P concentration range, three small peaks typically appeared at 38.6, 39.4, and 40.5 degrees in the Pd–B films (Fig. 7), while no peak was recognized in the Pd–P films (Fig. 8). The peculiar structure in the Pd–B films was found to resemble the Pd_3B crystal,

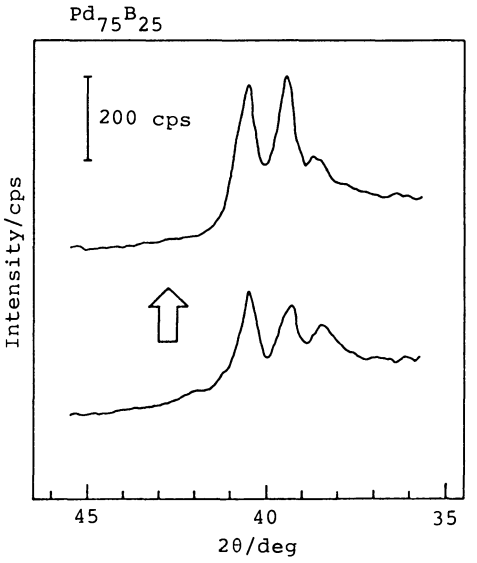

Fig. 7. Change in the X-ray diffraction pattern of $Pd_{75}B_{25}$ film by the heat treatment.

one of the stable palladium boride crystals,[21] whereas the structure of the Pd–P films was an amorphous structure.

Table 1 tabulates the changes in the peak positions and the full widths at half maximum (FWHM) of the XRD peak attributable to the Pd(111) face for the Pd–(B, P) films with the low B or P concentration upon heat treatment. After the heat treatment, the XRD peaks of the Pd fcc-like structure in the lower B or P concentration range increased in its intensity and became narrower. This indicates that Pd fcc structure develops in the Pd–(B, P) films with a low B or P concentration after the heat treatment. On the other hand, the small three peaks in the Pd–B films with a high B concentration increased a little at the same position after the heat treatment (Fig. 7). This reveals that the Pd_3B-like structure of the Pd–B film with a high B concentration grows slightly after the treatment. In the Pd–P films with a high P concentration, new six peaks appeared—at 33.0, 37.5, 38.2, 39.2, 40.0, and 43.0 degrees—after the heat treatment (Fig. 8). These peaks indicate the appearance of new crystalline Pd–P phases. The structure of the Pd–P film is assumed to be a mixed phase of the $Pd_{4.8}P$[22] and the Pd_5P_2[23] crystals, which are the stable palladium phosphide crystals. In the region of a high B or P concentration, the Pd alloy crystal was found to grow after the heat treatment, especially the amorphous structure in the Pd–P film crystallized. No growth of Pd fcc structure or separation of a Pd phase and a B or P phase were observed after the treatment in the region of a high B or P concentration.

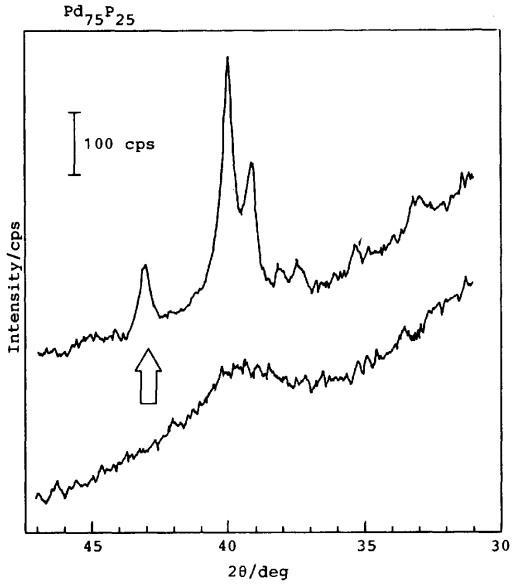

Fig. 8. Change in the X-ray diffraction pattern of $Pd_{75}P_{25}$ film by the heat treatment.

Change in the Film Composition and the Electronic State. The surface composition and the electronic state were evaluated by the use of an X-ray photoelectron spectroscope (XPS) equipped with an Ar-ion gun. The films were etched by Ar^+ for 30 sec, viz., by about 6 nm. The film composition was evaluated on the basis of the XPS peak area ratios of Pd3d5/2 to B1s or P2p level. The film composition and the binding energies (BE) of the surface and the bulk were compared before and after the heat treatment. These results are tabulated in Table 2. BE was

corrected by the use of a contaminant carbon (C1s=285.0 eV).

In the Pd–B films with a low B concentration, little enrichment of boron to the surface was observed. However, the extent of enrichment increased with the increase in the B concentration. The surface composition of Pd was only 16 atom% in a high B concentration. On the contrary, the surface enrichment of phosphorus in the Pd–P films was not as notable as that of boron. In the region of a low P concentration, the somewhat high P concentration at the surface was attributable to the adsorption of PH_3 on the surface, for the P concentration steeply reduced after only 5 s etching. It was found that the mobility of P in the film was smaller than that of B.

The BE of the Pd3d5/2 level for the Pd–B films was unchanged by the heat treatment in a low B concentration. However, the BE in a high B concentration shifted to the higher BE side after the heat treatment. This obviously indicates that the electron density of Pd in the Pd–B films with a high B concentration becomes lower after the heat treatment, although B donates electrons to Pd before the heat treatment. On the other hand, the BE of the Pd3d5/2 level for the Pd–P films was increased with the enhancement of the P concentration even before the heat treatment. After the heat treatment, it was slightly shifted to the higher BE side in a high P concentration. The electron density of Pd was also found to decrease further in the Pd–P films with a high P concentration after the heat treatment.

Model of the Pd Thin Film Alloy. The following model may explain the above results. As has been described above, the selectivity for the partial hydrogenation of olefins over the Pd alloys can be explained in terms of the ensemble and the ligand effect. The smaller ensemble size and the lower electron density of Pd for the Pd thin film alloys would result in the higher selectivity of the partial hydrogenation.

In a lower B or P concentration range, it can readily be supposed that the surface defects, i.e., the grain boundaries in the columnar structure, etc., are decreased by the heat treatment and that the columns are collapsed to large ones. Therefore, the ensemble size of Pd on the surface of the film would become larger, resulting in the decrease in the selectivity of the partial hydrogenation. Because the electronic state of Pd is unchanged by the heat treatment in a low B or P concentration, the decrease in the selectivity seems to be mainly caused by the increase in the ensemble size of Pd. In a higher B or P concentration range, B or P prevents the growth of the column during the heat treatment because the proportion of B or P is increased in the film. The ensemble size, therefore, would be almost unaltered, even after the heat treatment. This is supported by the results of XRD. The Pd_3B, $Pd_{4.8}P$, and Pd_5P_2 phases formed by the heat treatment may exhibit a high selectivity of the partial hydrogenation. Furthermore, the results of the XPS measurement suggest that the high selectivity after the heat treatment is attributable to the low electron density of Pd in the region of a higher B or P concentration.

Preparation of Poly(*p*-phenylene) by Electrooxidative Polymerization in Acidic Media

Kimihisa YAMAMOTO, Toshio ASADA, Hiroyuki NISHIDE, and Eishun TSUCHIDA*
Department of Polymer Chemistry, Waseda University, Tokyo 160
(Received November 5, 1987)

The electro-oxidative polymerization of benzene in the presence of strong acids yields poly(*p*-phenylene) efficiently. A strong protonic acid such as trifluoromethanesulfonic acid or Lewis acid such as an aluminum trichloride forms a complex with benzene and reduces the oxidation potential of benzene to 1.7 V, which brings about the high current efficiency. The acids act both as an electrolyte and as a catalyst in this polymerization of benzene.

There is much interest in the electrochemical preparation of aromatic conjugated polymers such as polypyrrole[1,2] polythiophene,[3,4] polyaniline,[5] poly(oxyphenylene),[6,7] poly(thiophenylene),[8] and polyazulene.[9] These polymers exhibit significant electrical conductivity and are potentially useful materials.[10,11] However, benzene is not polymerized under the same electrolytic conditions, and even under a large given potential.

Some attempts to electrooxidatively polymerize benzene to poly(*p*-phenylene) (PPP) have been reported: the electrochemical oxidation of benzene in liquid SO_2,[12] with HF,[13] with $AlCl_3$,[14] with $LiAsF_6$ and $CuCl_2$,[15] and with BF_4^-.[16] However, their yield and current efficiency were extremely low and the electrooxidative polymerization of benzene has not been studied quantitatively. We previously reported[17] that *p*-dimethoxybenzene with a lower oxidation potential is efficiently polymerized to poly(2,5-dimethoxy-1,4-phenylene) and that its polymerization proceeds via a cationic mechanism and is suppressed by basic additives. We recently found and preliminarily reported[18] that the electrooxidative polymerization of benzene is the presence of trifluoromethanesulfonic acid (FSA) gave PPP in high yield. This paper describes the efficient preparation of PPP by the electrooxidative polymerization of benzene in the presence of strong acids as well as the mechanism of this polymerization.

Experimental

Materials. Benzene was purified by distillation twice after contaminated thiophene was removed. Tetraethylammonium tosylate and other supporting electrolytes were recrystallized from ethanol–water and dried in vacuo for 1 d at 80 °C. All solvents were distilled before the electrolysis. Lewis acids, protonic acids and 9-phenylanthracene were guaranteed reagents and were used without further purification.

Electrolysis. One pair of platinum plate (2×5 cm) was set in the Cell[19] with 1 cm spacing as a working and an auxiliary electrode. The reference electrode was Ag/AgCl. The benzene solution (75 ml) of acid was kept at 20 °C under a nitrogen atmosphere in the cell. The preparative electrolysis was carried out under a controlled current with a potentiogarvanostat (Nikko Keisoku NPGS-301) without stirring. The electricity was measured by a digital coulomb meter (Nikko Keisoku NDCM-1). After the electrolysis, the adhered product was de-doped by supplying a cathodic potential at −0.1 V, and then removed from the working electrode. The product was washed with alkaline methanol and dried in vacuo for 1 d at 80 °C.

The current efficiency of the electrolysis was calculated as follows. One mole of benzene was quantitatively polymerized to PPP by two-electron oxidation. The current efficiency (%) was calculated by dividing the polymer yield by the theoretical value. Theoretical yield=$(Q/2nF)\times100$ (n: molar number, F: 96484 (c), Q: electricity (c))

Spectroscopies on the Polymer. The polymer was characterized by IR (Jasco IR-810) and Solid ^{13}C NMR (JEOL FX-100). Poly(*p*-phenylene): Solid ^{13}C NMR (ppm): 130 (broaden); IR (KBr, cm^{-1}): ν_{C-H}=3020, $\nu_{C=C}$=1600, 1480, δ_{C-H}=1000, 805.

Cyclic Voltammetry (CV). Cyclic voltammetry was carried out in a two-compartment cell. Platinum disk (0.126 cm^2), platinum wire and Ag/AgCl were used as a working, an auxiliary and a reference electrode, respectively. The concentration of benzene was 1 mmol l^{-1}. The potential was controlled with a dual potentiogarvanostat (Nikko Keisoku DPG-3) and a function generater (Nikko Keisoku NFG-3). The scanning rate of the potential was 100 mV s^{-1}. The i–E curve was recorded with a X-Y recorder.

Electrical Conductivity Measurement. After the electrolysis, PPP adhering to the anode was peeled off and washed with dry hexane. The d.c. conductivity of the PPP tablet was measured using a two-point probe method. The as-grown PPP was doped with the anions used as electrolytes and exhibited an electrical conductivity as high as 10^{-3}—10^{-4} S cm^{-1}. The doping was confirmed by the IR spectrum and fluorescence X-ray.

Results and Discussion

IR and ^{13}C NMR spectroscopic data of the de-doped sample are given in Experimental. The PPP shows the absorption band at 805 cm^{-1}, which is ascribed to a C–H out-of-plane deformation vibration of 1,4-disubstitued benzene and no strong absorptions at 840 cm^{-1} and 860 cm^{-1}, which are ascribed to trisubstituted and tetrasubstituted benzene, respectively. This IR absorption spectrum agrees with that reported for chemically prepared PPP[20,21] and indicates that the main structure of the polymer is

poly(*p*-phenylene) without crosslinking. A weak absorption of C–H out-of-plane vibration of mono-substituted phenyl rings appeared at 760 cm^{-1} in the IR spectrum. The ratio of the transmittance at the C–H out-of-plane vibration of di-substituted to that of monosubstituted one suggests that the degree of polymerization of PPP is over 7.

Table 1 shows the current efficiency for the electrooxidative polymerization of benzene in the presence of acids. The polymerization proceeds efficiently with a strong acid like FSA and a Lewis acid such as aluminum trichloride, but does not with a weak acid such as acetic acid. FSA which is one of the strongest protonic acids yields PPP with the highest current efficiency.

In the absence of acids, the electropolymerization does not sufficiently proceed with tetraethylammonium tosylate (TEATs), perchlorate, chloride or hydrogensulfate as an electrolyte. These results indicate that the polymerization of benzene is associated with the acidity of the electrolytic mixture and is retarded by the supporting electrolyte in the absence of acid.

Table 2 shows that this electropolymerization is suppressed by a strongly basic solvent such as propylene carbonate and *N*,*N*-dimethylformamide.

Table 1. Electrooxidative Polymerization[a] of Benzene in the Presence of Acids under Controlled Current

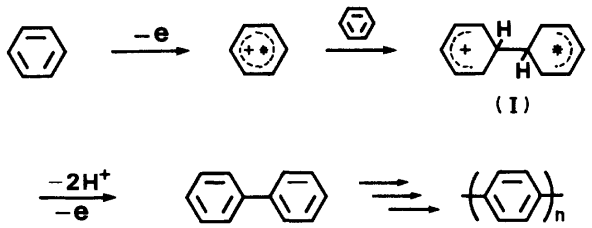
Acid	Current density	Current efficiency
	mA cm^{-2}	%
CF_3SO_3H	10	63
CF_3COOH	5	8
H_2SO_4	5	6
CCl_3COOH	5	0
CH_3COOH	5	0
HNO_3[b]	5	0
HCl[c]	5	0
$AlCl_3$	17.5	54
$BF_3 \cdot O(C_2H_5)_2$	17.5	58
$SbCl_5$	17.5	16
$FeCl_3$	17.5	10
$SnCl_4$	17.5	20
HF[13]	12.0	>1
None[d]	17.5	0
CF_3SO_3H/TEATs[e]	10	64
CF_3COOH/TEATs[e]	5	0
$AlCl_3$/TEATs[e]	17.5	54

a) Starting solutions composed: [Benzene]=1.4 mol l^{-1}, [Acid]=2.0 mol l^{-1} Electricity: 0.6 F mol l^{-1}, Solvent: Nitromethane. Polymerization in the presence of Lewis acid carried out in addition of small amount of water (1 ml) due to increase of the solution conductivity. b) 12 mol l^{-1} concd HNO_3. c) 12 mol l^{-1} concd HCl. d) The electrolyte was used as tetraethylammonium tosylate, perchlorate, chloride, or hydrogensulfate (0.2 mol l^{-1}). e) TEATs: Tetraethylammonium tosylate (0.2 mol l^{-1}).

The current efficiency was not influenced by oxygen bubbling through the electrolytic mixture, which often deactivates a radical species. These results support the idea that this polymerization proceeds via a cationic mechanism.

At a lower concentration, the polymerization is retarded probably because a reaction between benzene and an activated benzene does not easily occur. Then the current efficiency increases with the benzene concentration and becomes saturated at a concentration of 1.5 mol l^{-1}.

The above-mentioned results suggest a mechanism of this electropolymerization as given in Scheme 1. Benzene is one-electron oxidized to its cation radical. The cation radical electrophilically reacts with benzene to form a hydrodimer (**I**). It is oxidized to biphenyl accompanied by a proton elimination. The biphenyl is repeatedly oxidized to PPP.



Scheme 1.

The cationic mechanism of the polymerization is consistent with the results that the polymerization is affected by a coexisting electrolyte anion and is suppressed by the basic solvent. This was further studied by UV spectroscopy and cyclic voltammetry. Since the cation radical of benzene is not stable and rapidly reacts with benzene, the effect of electrolyte species was studied by using a stable cation radical of 9-phenylanthracene[22] (9-PA) as a model for the benzene cation radical (Eq. 1). During the electrolysis

Table 2. Solvent Effect on Current Efficiency of the Electropolymerization of Benzene in the Presence of CF_3SO_3H

Solvent	Solvent donor number	Current efficiency
		%
CH_2Cl_2	—	79
CH_3NO_2	2.7	64
$C_6H_5NO_2$	4.4	56
CH_3CN	14.1	0
PC[a]	15.1	0
DMF[b]	26.6	0

a) Propylene carbonate. b) *N*,*N*-Dimethylformamide.

of 9-PA in the presence of trifluoroacetic acid or tin tetrachloride, the electrolytic solution was colored dark bluish (λ_{max}=722, 642, 569 nm), indicating the formation of the 9-PA cation radical. Immediately after a small amount addition of TEATs or DMF, the absorption of 9-PA cation radical disappeared. This suggests that the electrolyte anions and basic solvents nucleophilically react with the 9-PA cation radical.

Figure 1 shows a cyclic voltammograms of 9-PA in an acidic medium. The 9-PA cation radical is produced by a one-electron oxidation at 1.1 V, which is corresponds to the redox potential of 9-PA. The cathodic peak current coincided with the anodic one: I_{pc}/I_{pa}=1.0, which indicates that the 9-PA cation radical is stable in the acidic mixture. However, the anodic peak potential of 9-PA shifted anodically and the reduction peak of 9-PA cation radical was not observed in the presence of a small amount of such basic species as TEATs or DMF. These facts also support the observation that the 9-PA cation radical is not able to exist stable in the presence of a basic species. That is, the cation radical as an active species for the polymerization of benzene is strongly influenced by a supporting electrolyte and the acidity of the electrolytic mixture.

PPP was not given upon the addition of TEATs in a weakly acidic medium. However, in the presence of a strong acid such as FSA or $AlCl_3$, the polymerization yields PPP efficiently, even with the coexistence of an electrolyte such as TEATs and is not entirely retarded. The effect of a strong acid such as FSA and $AlCl_3$, in this polymerization process is remarkable in comparison with that of weak acids. This suggests a specific role of a strong acid in this polymerization process.

Figure 2 shows cyclic voltammograms of benzene in nitromethane. The virgin oxidation of benzene is initiated at 1.7 V and the oxidation peak potential (2.3 V) shifts toward less anodic potential in the presence of FSA, compared with a voltammogram in the absence of one (E_{pa}=2.8 V). Benzene was also oxidized above 1.7 V in the presence of $AlCl_3$. Upon the addition of benzene to strong acid solutions, the mixtures turned light brown (λ_{max}=380 nm) from colorless. Benzene is electropolymerized in the presence of these acids at a lower potential in comparison with that in the absence of ones. In the presence of a weak acid such as trifluoroacetic acid, the oxidation potential did not shift cathodically: The voltammogram was the same as in the absence of a weak acid, and the mixture remained colorless. The remarkable decrease in the oxidation potential of benzene in the presence of the strong acids can be explained as follows: Benzene forms a complex[23]

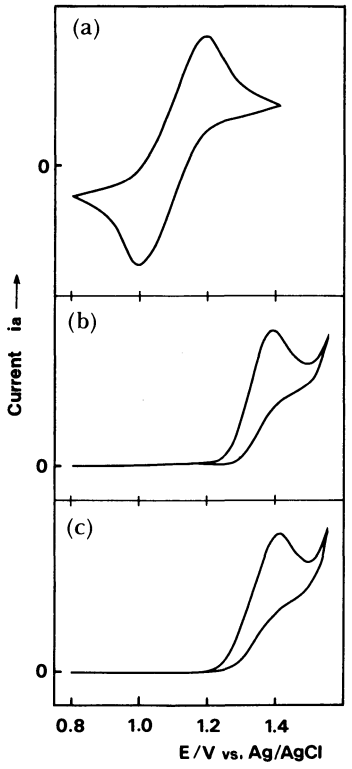

Fig. 1. Cyclic voltammograms of 9-phenylanthracene in the presence of CF_3COOH (a), tetraethylammonium tosylate (b), and DMF (c). Sweep rate: 0.1 V s^{-1}.

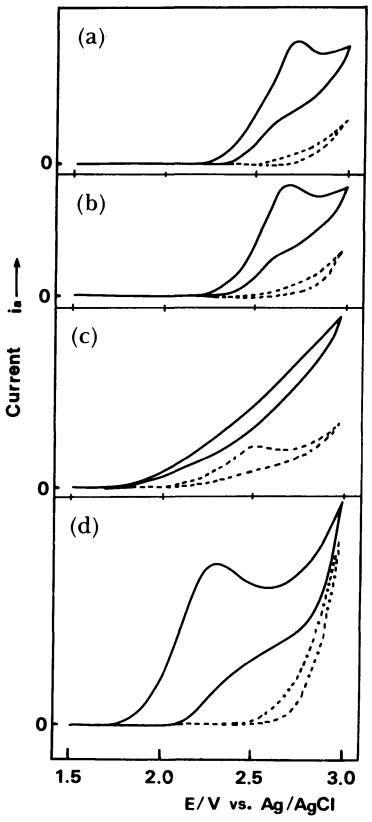

Fig. 2. Cyclic voltammograms of benzene in CH_3NO_2–TBAP (a) containing CF_3COOH (b), $AlCl_3$ (c), CF_3SO_3H (d). Dotted lines are background *i*–*E* curves in the same medium. Sweep rate: 0.1 V s^{-1}.

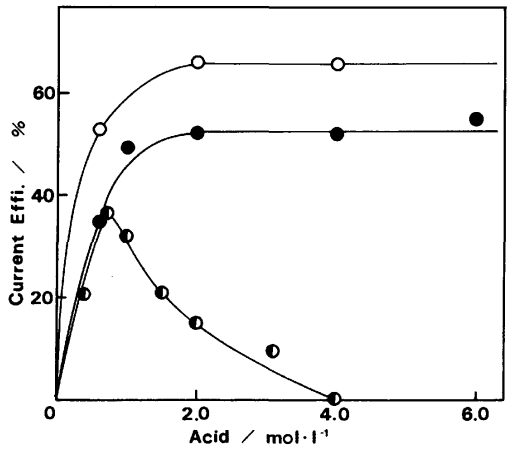

Fig. 3. Effect of the added amount of $AlCl_3$ (●), $SbCl_5$ (◐), and CF_3SO_3H (○) on the current efficiency of benzene-polymerization. [benzene] 2.0 mol l^{-1}, [tetrabutylammonium tosylate] 0.2 mol l^{-1} in nitromethane, at 17.5 mA cm^{-2}.

with a strong acid and Lewis acid such as FSA and $AlCl_3$, and the resonance stabilization of the benzene ring is reduced. That is, the oxidation potential slightly shifts toward less anodic potential in the presence of these strong acids, which corresponds to the current efficiency in the polymerization.

Figure 3 shows the effect of the concentration of FSA or $AlCl_3$. The current efficiency becomes saturated upon an equimolar addition of the acid: an equimolar addition of acid is required for a high current efficiency in PPP formation, which corresponds to the formation of a complex with an acid.

The roles of the acid for this electropolymerization of benzene are summarized as follows. The acid suppresses a nucleophilic reaction of the cation radical produced by a one-electron oxidation of benzene with basic species. The strong acid, such as FSA or $AlCl_3$, forms a cationic complex with benzene, which promotes an electrophilic attack of the cation radical to benzene and increases the polymerization efficiency. These strong acids also act as an electrolyte in this electrooxidative polymerization of benzene.

Relative Standard Electrode Potentials of I_3^-/I^-, I_2/I_3^-, and I_2/I^- Redox Couples and the Related Formation Constants of I_3^- in Some Pure and Mixed Dipolar Aprotic Solvents

Jayati DATTA, Abhijit BHATTACHARYA, and Kiron Kumar KUNDU*
Physical Chemistry Laboratories, Jadavpur University, Calcutta-700032, India
(Received February 12, 1987)

Standard potentials of I_3^-/I^- and I_2/I_3^- redox couples relative to that of aqueous saturated calomel reference electrode SCE (W), $E_{SCE(w)}$ have been determined in propylene carbonate (PC), *N*,*N*-dimethylformamide (DMF), acetonitrile (ACN), and their binary mixtures at 25 °C from potentiometric measurements. The results helped evaluate the standard potentials of the redox couple I_2/I^- relative to $E_{SCE(w)}$ as well as the related formation constant (K_f) of I_3^- in these solvent systems. The solvent effects on the formation equilibrium $I_2+I^- \rightleftharpoons I_3^-$ were analyzed in the light of the transfer free energies of I_2, $\Delta G_t^\circ(I_2)$, as obtained from solubility measurements of I_2 in the solvents, that of I^-, $\Delta G_t^\circ(I^-)$, as obtained earlier by use of the widely used TATB reference electrolyte assumption and that of I_3^-, $\Delta G_t^\circ(I_3^-)$, as obtained by subtracting these two contributions from the respective transfer free energies of formation equilibrium in the mixed solvents relative to a chosen reference solvent in each solvent system. The solvation behavior of these individual iodine species viz. I_2, I^-, I_3^- was interpreted in terms of involved interaction viz. Born, ion-dipole, ion-induced dipole, dispersion type soft-soft interactions, CTTS complexation and also the cavity effect as computed by the scaled particle theory (SPT).

The electrochemical behavior of the halogen/halogenide ion (X_2/X^-) redox couples in different nonaqueous media has lately become increasingly important due to their potential use in some high energy nonaqueous primary[1] and secondary batteries[1,2] and also in nonaqueous photoelectrochemical (PEC) cells.[3,4] In this context the knowledge of the intensive factor such as the standard potential (E°) of the galvanic elements X_2/X^-, and that of the involved X_3^-/X^- and X_2/X_3^- redox couples as well as the formation constant (K_f) of X_3^- in different dipolar aprotic solvents and their binary mixtures should be of particular interest. These, or at least their relative values, will be helpful to characterize the Fermi levels of these redox couples as required for the potential nonaqueous PEC cells, to elucidate their influence on the charging-discharging characteristics of the potential nonaqueous batteries and also to evaluate the kinetic parameters of the involved galvanic reactions in both the cases. This knowledge will then help judge the relative potentiality of the solvents for their use in the nonaqueous batteries or PEC cells comprising these redox couples.

Of the widely used battery fluids propylene carbonate (PC) and *N*,*N*-dimethylformamide (DMF) have attracted increasing attention.[5] Acetonitrile (ACN), though not so widely used, has got the distinction of being a protophobic dipolar aprotic solvent like PC, but nearly isodielectric to DMF. Very recently Kuznetsova et al.[6] reported the values of $E^\circ_{I_3^-/I^-}$ and $E^\circ_{I_2/I_3^-}$ and the formation constant K_f of I_3^- in DMF and its mixtures with PC at different temperatures. But their data, based on a potentiometric titration procedure using a reference half cell, Pt, I_2 solvent //, seems quest ionable, as I_2 solution without any added I^- would hardly act as a suitable redox couple. Moreover, appreciable ionization of I_2 to I^- in these aprotic solvents unlike in protic solvents like water, is somewhat doubtful, although charge transfer complex formation with these solvents cannot be ruled out. Further, the so-called electrode potential (E°) values reported, appear to be relative to the emf of the reference half-cell mentioned above. In the present paper we therefore report the standard electrode potentials (E°) of I_3^-/I^-, I_2/I_3^-, and I^-/I_2 redox couples relative to aqueous saturated calomel reference electrode SCE(w) and the related formation constant (K_f) or I_3^- in these dipolar aprotic solvents and their binary mixtures containing 25, 50, and 75 wt% of the cosolvents.

The cells used for this purpose are

$$\text{SCE(w)}//I^-(m),\ I_3^-(m),\ \text{solvent/Pt} \qquad \text{(A)}$$

$$\text{SCE(w)}//I_2(m),\ I_3^-(m),\ \text{solvent/Pt} \qquad \text{(B)}$$

where m stands for the molal concentration of I^-, I_2, and I_3^-. The emf's of the cells were measured for several values of m so that the ionic strength (μ) could be varied from 0.01 to 0.1.

Admittedly, the use of SCE(w) as the reference half-cell has resulted in the introduction of a liquid junction potential (E_j) in the final E° values of the redox couples in each solvent. While the E_j values based on TATB methods[7] are known for these pure solvents,[8] those for the mixed solvents could be estimated at least approximately by assuming linear dependence with mole per cent cosolvent composition and hence accounted for, if required (vide footnote under Table 1). Moreover, in most of the electrochemical measurements viz. cyclic voltammetry, polarography etc. the most commonly used reference half-cell is the SCE(w) itself,[9] of course with

Table 1. Standard Electrode Potentials ($E°$) (in Volt) of I_3^-/I^-, I_2/I_3^-, and I_2/I^- Redox Couples Relative to ($E_{SCE(w)}+E_j$) as well as to $E°_{SHE(w)}$ in Pure Solvents PC, ACN, DMF, and Their Binary Mixtures at 25 °C

The values in parentheses for the mixed solvents were tentatively estimated by assuming linear variation of E_j (TATB) values with mole percent cosolvent compositions in the respective solvent systems, the E_j (TATB) values for the pure solvents being known (Ref. 8). This assumption is however based on the fact that E_j (TATB) values caused by aqueous sat. KCl and 0.1 M Et_4N Pic at hetero-solvent interfaces comprising H_2O and methanol, ethanol, ACN, PC, DMSO, and DMF fall on a single straight line. Moreover, a recent study[26] reveals that E_j (TATB) values for the same system at interfaces, between H_2O/H_2O+ACN mixtures bear a fairly good linear relationship with mole percent ACN.

appropriate measure for minimizing the contamination of solvents across aqueous–nonaqueous interface. Thus, even if these E_j values are present, these are not likely to pose any serious problem at least from the operational point of view.

In the present study the derived formation constant (K_f) of I_3^- will be of course free from any uncertainty as the values of E_j as well as $E_{SCE(w)}$ will be eliminated. Moreover, the prime discussion being related to K_f values the contention derived thereof will have little effect on the uncertainties in E_j values.

In order to gain insight into the solvent effect on the formation equilibrium of I_3^-, $\delta[\Delta G°(I_3^-)]$ the transfer free energies $\Delta G_t°(i)$ of the involved individual species (i) from a chosen reference solvent (R) to the solvent (S) concerned are useful[10,11] as

$$\delta[\Delta G°(I_3^-)] = 2.303\,RT\,[p_S K_f(I_3^-) - p_R K_f(I_3^-)] = \Delta G_t°(I_3^-) - \Delta G_t°(I^-) - \Delta G_t°(I_2). \quad (1)$$

To facilitate the splitting, $\Delta G_t°(I_2)$ values were determined by measuring the solubilities of I_2 in the solvents, as the $\Delta G_t°(I^-)$ values based on the widely used tetraphenylarsonium tetraphenylborate (TATB)[11,12] reference electrolyte assumption:

$$\Delta G_t°(Ph_4As^+) = \Delta G_t°(Ph_4B^-) = 1/2\Delta G_t°(Ph_4\,As\,BPh_4)$$

have been evaluated earlier[13] for these solvent systems.

Experimental

PC (Koch light) was first dried over activated Molecular Sieves 4A (E. Merck) for about a week and then fractionally distilled twice under reduced pressure.[8] ACN (AR, SD) and DMF (E. Merck) were purified by methods described earlier.[8] I_2 (E. Merck) was purified by sublimation. KI (GR. E. Merck) was pretreated by heating at 150 °C for a few hours and then dried in vacuum before use.

For measuring the solubilities of I_2 in different solvents, saturated solutions of I_2 were prepared by mild shaking of the suspension of I_2 and allowed to equilibriate at 25°±0.1 °C. At 2—3 d intervals aliquots of each solution were withdrawn and I_2 concentration was estimated by titrating with a standard thiosulfate solution. The operations were repeated till two successive readings agreed within ±1%.

Stock solutions of I_2 and KI were made with the pretreated I_2 and KI in solvents of different compositions, namely 100, 75, 50, 25 wt% of each binary mixture. Solutions of cell A were prepared by adding appropriate amount of I_2 solution to known amount of standard KI solution so that $m_{I^-}=m_{I_3^-}=m$ and that of cell B by adding requisite amount of KI solution to a known amount of I_2 solution, so that $m_{I_2}=m_{I_3^-}=m$. And the solutions of different ionic strengths were prepared by appropriately diluting a suitable amount of stock mixture with the solvent.

The reference SCE(w) was of Fisher calomel reference electrode (model E 6A) with a porous ceramic junction and fitted within a jacket containing the cell solution. The jacket is connected to the rest of the cell solution through a G-2 gooch junction, similar to that used by Gritzner[14] and

the upper end allowed the insertion of the reference electrode through a tightly fitted Teflon stopper. The flow rate through the ceramic junction of the Fisher calomel reference electrode for 8 cm head being 1—5 μl per hour, the uncertainties possible for contamination of the solvents hardly affected the observed potential beyond the experimental error±1 mV.

The cell was essentially similar to the conventional[15] three necked polarographic/cyclic voltammetric cell and fitted with three standard joint mouths, through which the Pt-wire electrode as well as the jacketed reference electrode were introduced, keeping the third one closed by a standard joint stopper. The cell containing the working solution was fitted with the Pt-wire electrode and the stoppered jacket with the cell solution inside it. The system was first thermally equilibriated at 25 °C. The Fisher calomel reference electrode was then introduced into the jacket by replacing the stopper. The emf values were measured with a Kiethley Electrometer (Model 616). The equilibrium potential was attained within 15—20 min of dipping the reference electrode. Some of the readings were also checked by using Elico (India) calomel reference electrode (Type ER-70) and found to agree within the experimental error with those obtained with the jacketed reference electrode.

Results

In the case of cell (A) the half-cell reaction is essentially

$$I_3^- + 2e^- \longrightarrow 3I^-, \tag{2}$$

and the observed emf, E_A of cell is given by

$$E_A = [E^\circ_{I_3^-/I^-} - (E_{SCE(w)} + E_j)] - \frac{RT}{2F} \ln m_{I^-}^3/m_{I_3^-} - \frac{RT}{2F} \ln \gamma_{I^-}^3/\gamma_{I_3^-}, \tag{3}$$

and the extrapolation function $E_A^{\circ\prime}$ by

$$E_A^{\circ\prime} = E_A + \frac{2.3\,RT}{F} \log m - \frac{2.3\,RT}{F} S_f \mu^{1/2} = [E^\circ_{I_3^-/I^-} - (E_{SCE(w)} + E_j)] + b\mu, \tag{4}$$

where $m_{I^-} = m_{I^-} = m$, by experimental conditions, γ_i is the activity coefficient of the species i and is being computed by the limiting form of Debye-Hückel equation,[16] S_f the Debye-Hückel constant, b the emperical parameter depending upon the solvent and temperature, and the other terms are having usual significance. The extrapolation function $E^{\circ\prime}$ on extrapolation to $\mu=0$ yielded $E^\circ_{I_3^-/I^-}$ relative to $[E_{SCE(w)}+E_j]$ which on elimination of the respective E_j values as well as $E_{SCE(w)}$, furnished $E^\circ_{I_3^-/I^-}$ values in the solvents relative to $E^\circ_{SHE(w)}$.

In the case of cell (B), the half-cell reaction is essentially

$$3I_2 + 2e^- \longrightarrow 2I_3^-, \tag{5}$$

and the observed emf, E_B of the cell is given by

$$E_B = [E^\circ_{I_2/I_3^-} - (E_{SCE(w)} + E_j)] - \frac{RT}{2F} \ln m_{I_3^-}^2/m_{I_2}^3 - \frac{RT}{2F} \ln \gamma_{I_3^-}^2/\gamma_{I_2}^3, \tag{6}$$

and the extrapolation function $E_B^{\circ\prime}$ by

$$E_B^{\circ\prime} = E_B - \frac{2.3\,RT}{F} \log m - \frac{2.3\,RT}{F} S_f \mu^{1/2} = [E^\circ_{I_2/I_3^-} - (E_{SCE(w)} + E_j)] + b\mu, \tag{7}$$

where $m_{I_3^-} = m_{I_2} = m$ and other terms are having usual significance. As before, the extrapolation of the observed linear plots of $E_B^{\circ\prime}$ vs. μ to $\mu=0$ yielded $E^\circ_{I_2/I_3^-}$ relative to $[E_{SCE(w)}+E_j]$. The $E^\circ_{I_2/I_3^-}$ relative to $E^\circ_{SHE(w)}$ are

Table 2. Values of $\log K_f(I_3^-)$, $\Delta G_f^\circ(I_3^-)$, $-\log S$, and $\delta[\Delta G_f^\circ(I_3^-)]$ in Pure Solvents PC, DMF, ACN, and Their Binary Mixtures at 25 °C

Values in parentheses are taken from a) J. Courtot-Coupez et M. L'Her, Comptes rendus, 266 series C, 1968, p. 1286; b) B. G. Cox, G. R. Hedwig, A. J. Parker, and D. W. Watts, *Aust. J. Chem.*, **27**, 477 (1979).

then obtained in a similar manner as described earlier.

The value of formation constant (K_f) of I_3^- in these solvents which are identical with the equilibrium constant values of the reaction

$$I_2 + I^- \rightleftharpoons I_3^- \quad (8)$$

were then obtained by the relation

$$\log K_f(I_3^-) = \frac{2}{3} \cdot \frac{F}{2.3RT} [E^\circ_{I_2/I_3^-} - E^\circ_{I^-/I_3^-}]. \quad (9)$$

The standard electrode potential $E^\circ_{I_2/I^-}$ of the redox couple I_2/I^- in these solvents relative to $E^\circ_{SHE(w)}$ were then obtained by proper coupling of the actual standard electrode potentials $E^\circ_{I_3^-/I^-}$ and $E^\circ_{I_2/I_3^-}$ relative to $E^\circ_{SHE(w)}$ with the help of the relation

$$E^\circ_{I_2/I^-} = \frac{1}{3}[2E^\circ_{I_3^-/I^-} + E^\circ_{I_2/I_3^-}] \quad (10)$$

The E° values of the three redox couples thus obtained relative to $[E_{SCE(w)} + E_j]$ and also to $E^\circ_{SHE(w)}$ are listed in Table 1. The estimated uncertainties of the values are about ± 1 mV. In Table 2 are presented the values of $\log K_f(I_3^-)$, $\Delta G_f^\circ(I_3^-)$, and $\delta[\Delta G_f^\circ(I_3^-)]$.

The transfer free energies of I_2 from the chosen reference solvent R (R=PC in PC+DMF and PC+ACN mixtures and R=ACN in ACN+DMF mixtures) to the respective solvent mixtures were computed on mole fraction scale from the measured

a) These values are taken from Ref. 13.

solubilities (S) (mol kg^{-1} of solvent) of I_2 in the solvents by use of Eq. 11.

$$\Delta G_t^\circ(I_2) = RT \ln {}_RS/{}_SS + RT \ln {}_R\gamma_{I_2}/{}_S\gamma_{I_2} + RT \ln {}_RM/{}_SM = RT \ln {}_RS/{}_SS + RT \ln {}_RM/{}_SM \quad (11)$$

where M=molar and mean molar mass of pure and mixed solvents respectively. The activity coefficients ${}_R\gamma_{I_2}$ and ${}_S\gamma_{I_2}$ being referred to the corresponding states of saturated solution in the respective solvents are likely to be more or less equal and hence the activity coefficient factor $RT\ln {}_R\gamma_{I_2}/{}_S\gamma_{I_2}$ is assumed to be zero. The log S values are presented in Table 2 and the $\Delta G_t^\circ(I_2)$ values in Table 3.

Moreover, recently Kundu and co-workers[13] have also determined the ΔG_t° values of I^- in these solvents [vide Table 3]. So utilizing these values of I^- and those of I_2 as obtained in the present study, the corresponding values of I_3^- were computed by use of the relation (1) and are presented in Table 3.

Discussion

Variation of $\delta[\Delta G_f^\circ(I_3^-)]$ with mole percent cosolvent from PC to PC+DMF and PC+ACN mixtures are shown in Figs. 1 and 2 respectively and those from ACN to ACN+DMF mixtures in Fig. 3. While $\delta[\Delta G_f^\circ(I_3^-)]$ values are found to increase sharply at first but slowly later in PC+ACN mixtures, those for PC+DMF mixtures pass through a broad maximum as the cosolvent concentration increases. Evidently, the formation of I_3^- is less favored in both the cases, as compared to that in pure PC, the extent, however, depends upon the cosolvent composition. On the other hand, $\delta[\Delta G_f^\circ(I_3^-)]$ from ACN to ACN+DMF mixtures (Fig. 3) passes through a slight maximum around 20 mole percent DMF and gradually acquires a negative trend at high DMF content. Thus on addition of DMF to the reference solvent ACN, the equilibrium (Eq. 8) is at first shifted towards left and at higher DMF composition it is shifted towards right compared to that in ACN. Now, $\delta[\Delta G_f^\circ(I_3^-)]$ being a composite parameter, more informative, and meaningful interpretation of these results awaits the dissection of this parameter into less composite individual quantities. For this purpose the solvent effect on the formation equilibrium (Eq. 8) can be expressed as in Eq. 1.

The $\Delta G_t^\circ(i)$-composition curves for PC+ACN and PC+DMF are shown in Figs. 1 and 2 respectively, whereas those from ACN to ACN+DMF mixtures in Fig. 3. Notably, all the three iodine species are stabilized with addition of DMF to either PC or ACN,

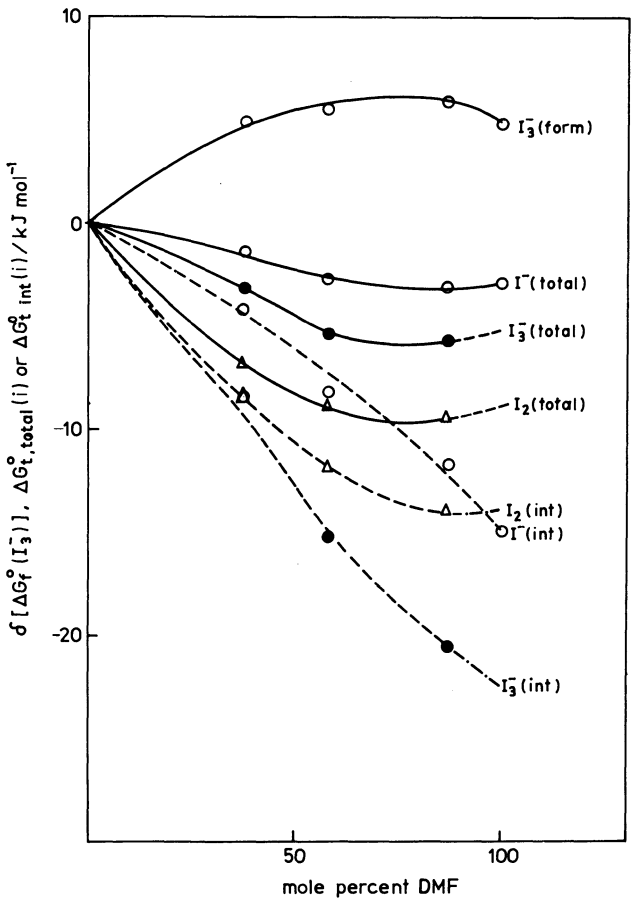

Fig. 1. Variations of $\delta[\Delta G_f^\circ(I_3^-)]$ and $\Delta G_t^\circ(i)$ [i=I^-, I_2, or I_3^-] total (solid lines) and int. (broken lines) with mole percent DMF in PC+DMF mixtures at 25 °C.

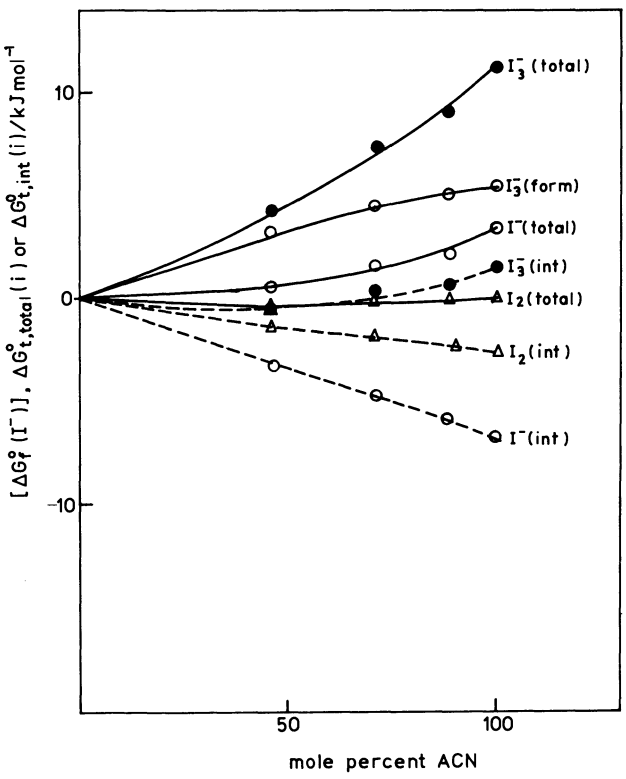

Fig. 2. Variations of $\delta[\Delta G_f^\circ(I_3^-)]$ and $\Delta G_t^\circ(i)$ [i=I^-, I_2, or I_3^-] total (solid lines) and int. (broken lines) with mole percent ACN in PC+ACN mixtures at 25 °C.

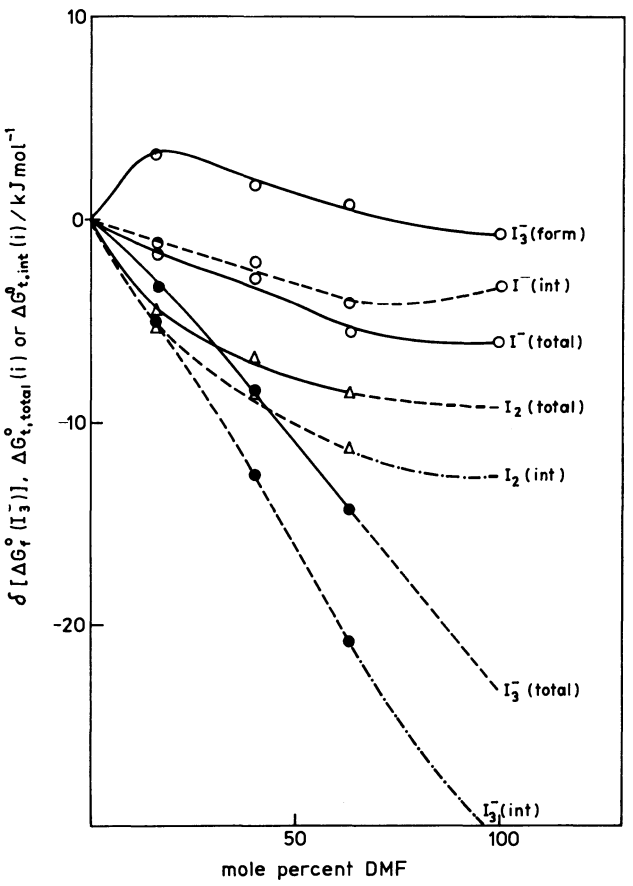

Fig. 3. Variations of $\delta[\Delta G_f^\circ(I_3^-)]$ and $\Delta G_t^\circ(i)$ [i=I^-, I_2, or I_3^-] total (solid lines) and int. (broken lines) with mole percent DMF in ACN+DMF mixtures at 25 °C.

the order of stabilization being $I_2>I_3^->I^-$ in PC+DMF mixtures (Fig. 1) and $I_3^->I_2>I^-$ in ACN+DMF mixtures (Fig. 3). On the other hand in PC+ACN mixtures (Fig. 2) as the ACN content increases, both I^- and I_3^- are increasingly destabilized in the order $I_3^->I^-$, and $\Delta G_t^\circ(I_2)$ passes nearly through the zero line. To rationalize the observed behavior a detailed analysis of the different forces and factors that are likely to be operative to different extents on these iodine species is in order. These are the electrostatic and nonelectrostatic contributions. The electrostatic part consists of a) Born-type electrostatic interaction,[17] corresponding transfer free energy term being designated by $\Delta G_{t,Born}^\circ$, b) ion-dipole interaction[18] [$\Delta G_{t,i\text{-}d}^\circ$], c) ion-quadrupole interaction[18] [$\Delta G_{t,i\text{-}q}^\circ$], and d) ion-induced dipole interaction[18] [$\Delta G_{t,i\text{-}id}^\circ$]. All of these electrostatic contributions would be highest for I^- with highest charge density, followed by I_3^- but absent for I_2. The nonelectrostatic contributions are a) the well-known cavity effect[19] due to the formation of solvent-cage or highly ordered skin-phase inside which solute molecules are caged, b) dispersion or 'soft-soft' interaction[20] dictated by the size and polarizability of both the solute and solvent molecules. In a common solvent, the solvation behavior of the solute species may be expected to be guided by the softness of the solute itself, which is in the order of $I_3^->I_2>I^-$, c) specific complexation effects of charge transfer (CT)[21] or charge transfer to solvent (CTTS)-type.[22] I_2 with a low lying LUMO is known to be a good acceptor of charge and hence often forms stable CT-complex with donor solvents like PC, DMF, and ACN, whereas I^- and I_3^- are expected to form CTTS complexes of the type $(X^-)_{solv}\rightarrow(X+e)_{solv}$ in the order $I^->I_3^-$. These complexation effects are known[21] to depend on the first two nonelectrostatic factors mentioned above, apart from the electrostatic factors for the ions I^- and I_3^-.

It is apparent from the nature of $\Delta G_t^\circ(i)$-composition profiles that none of the above-mentioned factors shows a sole predominance over the others towards the observed behavior. Evidently the evaluation of the individual ΔG_t° terms related to these factors by suitable methods wherever possible may be, at least partially, rewarding in the final analysis.

The widely used simple Born-equation.[17]

$$\Delta G_{t,Born}^\circ = \frac{1}{2} N_A (Z_i e)^2 r_i^{-1}(\varepsilon_S^{-1} - \varepsilon_R^{-1}) \qquad (12)$$

where N_A=Avogadro's number, Z_ie is the charge, r_i=radius of the ion i and ε_S and ε_R the dielectric constant of the solvent and the reference solvent respectively, though somewhat approximate, may be used to evaluate $\Delta G_{t,Born}^\circ$ values. These values in PC+DMF and PC+ACN mixtures are presented in Table 3. ACN and DMF being nearly isodielectric (ε_{ACN}=36.37 and ε_{DMF}=36.71)[16] $\Delta G_{t,Born}^\circ$ values for the transfer from ACN to ACN+DMF mixtures are practically zero. The ion-dipole contribution $\Delta G_{t,i\text{-}d}^\circ$ may be expressed[18] as

$$\Delta G_{t,i\text{-}d}^\circ = -N_A q[\mu_S/\sigma_S^2 - \mu_R/\sigma_R^2] \qquad (13)$$

where q=the charge on the ion, taken as that of electron as no appreciable shielding is presumably possible in the cases under consideration, σ=inter nuclear distance between ion and the solvent molecule, and μ=dipole moment of the solvent. The subscript 'S' stands for the solvent to which transfer is performed from the reference solvent 'R'. For mixed solvents however, $\Delta G_{t,i\text{-}d}^\circ$ values were obtained following Kim[18] by multiplying the quantity obtained above for pure solvent by X_{S_i} where,

$$X_{S_i} = X_S[\mu_S/\sigma_S^2)/(\mu_R/\sigma_R^2)] \qquad (14)$$

and X_s is the mole fraction of the cosolvent in the mixed solvent. The $\Delta G_{t,i\text{-}d}^\circ$ values thus obtained are also given in Table 3. It was not possible to estimate the magnitude of ion-quadrupole interactions due to the absence of quadrupole moment for these solvents though their significance could not be ruled out particularly for single ions. However, $\Delta G_{t,i\text{-}id}^\circ$ values were computed by using[18]

$$\Delta G^{\circ}_{t,i\text{-}id} = \frac{1}{2} Nq^2[(\alpha_S/\sigma_S^4) - (\alpha_R/\sigma_R^4)] \quad (15)$$

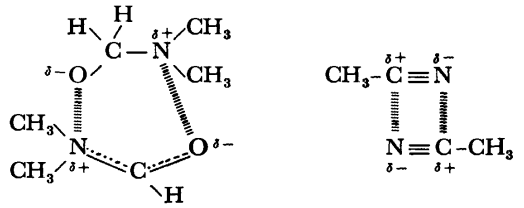
where α is the molecular polarizability of the respective solvents. And for the mixed solvents these values were obtained by multiplying the quantity obtained above for pure solvent[18] by X_{S_2} where,

$$X_{S_2} = X_S[(\alpha_S/\sigma_S^4)/(\alpha_R/\sigma_R^4)] \quad (16)$$

These $\Delta G^{\circ}_{t,i\text{-}id}$ values are also given in Table 3. Lastly, $\Delta G^{\circ}_{t,cav}$ values are computed following Triener's formulae[19] and are presented in the same table. The transfer free energies of the iodine species thus free from nearly all the electrostatic contributions barring ion-quadrupole interaction, and the solvent-cage effect as well, is likely to reveal the specific complexation effects along with 'soft-soft' interaction and is denoted by ΔG_t°(int) [vide Table 3]. Variations of ΔG_t°(int) with solvent compositions are depicted in Figs. 1—3 for the respective solvent systems.

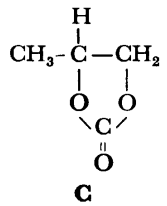
From the variation of ΔG_t°(int) in Figs. 1 and 3 it is observed that all the three iodine species are increasingly stabilized with the addition of DMF to either PC or ACN, the order being $I_3^- > I_2 > I^-$ in both the cases. On the other hand, while I_3^- is slightly destabilized with addition of ACN to PC, the other two species are stabilized to some extent in the sequence $I^- > I_2$ (vide Fig. 2).

Now polarizability (α) of the pure solvents when computed from refractive index values[23] assuming monomeric solvent entities, are 4.41, 7.88, and 8.56×10^{-24} cm^3 for ACN, DMF and PC respectively. But the experimental α value of pure DMF is found to be abnormally high (11.02×10^{-24} cm^3).[24] Thus it was suggested[24] that DMF exists as dimers **A** in pure liquid, a part of which however may be converted to monomers in the mixed solvents. Similarly some dimeric species **B** are also found[25] to exist in ACN. No such evidence for dimerization is however found for PC. The dimeric entities obviously make DMF



A

B



C

the softest among the three solvents. And α values for ACN may rise to some extent but not so as to exceed that of DMF. So on addition of DMF to either PC or ACN, all the iodine species will get stabilized in the order of their relative softness $I_3^- > I_2 > I^-$ as a result of dispersion interaction. The CT or CTTS complexation effect may also be present which will be in the order $I_2 > I^- \gg I_3^-$. The destabilization of I_3^- in PC+ACN mixtures (Fig. 2) is probably due to the difference in dispersion interaction resulting from the difference in effective polarizability between the two solvents concerned. But stabilization of I_2 and I^- though not to a greater extent, may be the result of CT or CTTS complexation or of ion-quadrupole interaction which we have failed to compute.

Notably, while discussions on ΔG_t°(int) are really meaningful in the cases where these values are rather large, as is the case of DMF admixtures, that for low ΔG_t°(int) values will be somewhat less meaningful because of the involved uncertainties in the computation of various ΔG_t° components, the combined effects of which may be as high as[18] ±5 kJ or more. Even then, in a complex situation, where various forces and interactions are at play, the dissection, though very tentative, helps elucidate at least a good qualitative picture of the interactions involved, as is observed in the present paper.

Second Virial Coefficients of Axially Symmetric Molecules

Ali BOUSHEHRI* and A. Mohammad ATTARAN
Department of Chemistry, Shiraz University, Shiraz, Iran
(Received March 24, 1987)

The paper presents a contribution to the second virial coefficient due to the asphericity of the molecular charge distribution. This contribution is conveniently divided into terms representing the classical electrostatic interaction between the two charge distributions, the anisotropy of dispersion forces, and the shape of the molecular core. These are considered quantitatively. Results from recalculating the nonspherical contributions to the second virial coefficients with a good spherical core are obtained from statistical mechanics and applied to the CO_2 gas. Explilcit formulas are given for the simple cases of axially symmetric molecules.

The potential energy between two polyatomic molecules is usually assumed to consist of a spherically symmetric component plus a contribution due to the aspherically of the molecular charge distribution. A method of integration for B(T) developed by Pople[1] viewed the orientation-dependent parts of the potential as perturbations on the central-force part. Later the applications to various polar gases were worked out in some detail by Buckingham and Pople.[2] Using Orcutt's method, reasonable values of molecular quadrupole moments could be obtained even by neglecting the effect of the shape component (i.e., the anisotropy of the repulsive part of the potential) on the second virial coefficient.[3]

Spurling and Mason obtained the parameters of the spherical component of the potential from the viscosity data, then, used in conjunction with second virial coefficient data, determined the quadrupole moments and "shape" parameters of the molecules.[4] It was found that one could get rid of the effect of the quadrupole moment on viscosity by simply assigning sligthly different values of ε_0 and σ_0 and using Najafi's correlation curve for the viscosity.[5,6]

The greatest virtue of the virial equation of state lies in the direct relation of the virial coefficients to the intermolecular forces. We provide a quantitative discussion of some of these forces and obtain corresponding expressions for the second virial coefficients. Here, results of recalculating the nonspherial contributions to the second virial coefficients with a spherical core, similar to that used by Boushehri, et al.,[7] are obtained from statistical mechanics and applied to a polyatomic gas.

Calculation

An indirect procedure is usually used to determine intermolecular forces from virial coefficients due to the failure of the direct approach. Many kinetic theory transport properties (viscosity, heat conductivity, ordinary diffusion) depend primarily on the fact that a force exists between molecules, and only secondarily on the nature of the force. But whether the force is one of attraction or repulsion can be an essential point for the virial coefficients, whose very sign depends on the nature of force.

It should be mentioned that while much progress in describing the thermodynamic properties of assemblies of molecules with spherical symmetry has been made, there are many molecules whose force fields depend on relative orientation. The potential model for the calculation of the second virial coefficients may be written as.[7]

$$V(r) = V_0(\text{spherical}) + V(\mu\mu) + V(\mu\theta) + V(\theta\theta) + V(\mu, \text{ind}\mu) + V(\mu\theta, \text{ind}\mu) + V(\theta, \text{ind}\mu) + V(C_6\,\text{anis}) + V(\text{shape}) \quad (1)$$

where

$$V(\mu\mu) = -\frac{\mu^2}{r^3}(2C_1C_2 - S_1S_2C), \quad (2\text{-a})$$

$$V(\mu\theta) = \frac{3\mu\theta}{2r^4}(C_2 - C_1)(3C_1C_2 - 2S_1S_2C + 1), \quad (2\text{-b})$$

$$V(\theta\theta) = \frac{3\theta^2}{4r^5}[1 - 5C_1^2 - 5C_2^2 - 15C_1^2C_2^2 + 2(4C_1C_2 - S_1S_2C)^2], \quad (2\text{-c})$$

$$V(\mu, \text{ind}\mu) = -\frac{\mu^2\bar{\alpha}}{2r^6}(3C_1^2 + 3C_2^2 - 2) - \frac{\mu^2\bar{\alpha}^2}{r^9}(8C_1C_2 - S_1S_2C), \quad (2\text{-d})$$

$$V(\mu\theta, \text{ind}\mu) = -\frac{12\mu\theta\bar{\alpha}}{r^7}(C_1^3 + C_2^3), \quad (2\text{-e})$$

$$V(\theta, \text{ind}\mu) = -\frac{9\theta^2\bar{\alpha}}{8r^8}(4C_1^4 + 4C_2^4 + S_1^4 + S_2^4 - \frac{8}{3}), \quad (2\text{-f})$$

$$V(C_6\,\text{anis}) = \frac{KC_6}{r^6}[1 - \frac{3}{2}(1 - K)(C_1^2 + C_2^2) - \frac{3}{2}K(2C_1C_2 - S_1S_2C)^2]. \quad (2\text{-g})$$

The simplest force field reproducing the orientation effect of the shape of an axially symmetric nonspherical molecule is

$$V(\text{shape}) = \frac{A}{r^n}(3C_1^2 + 3C_2^2 - 2), \quad (2\text{-h})$$

where A is a constant and n is an integer (usually 12). There is no particular theoretical basis for the form of V(shape). The average polarizability $\bar{\alpha}$ is given by $\bar{\alpha}=(\alpha^{11}+2\alpha^{\perp})/3$ and the anisotropy K is defined by $K=(\alpha^{11}-2\alpha^{\perp})/3\bar{\alpha}$, where α^{11} is the polarizability along the axis of symmetry and $\alpha^{\perp}$ that perpendicular to it. The quadrupole moment θ is defined by

$$\theta=\sum_i e_i(Z_i^2-X_i^2)$$

where e_i is the ith element of charge and Z_i and X_i are its coordinates in a system where Z axis is the symmetry axis and the origin is the center of mass. The angle-dependent abbreviations used in Eq. 2 are

$$C_1=\cos\theta_1,\ C_2=\cos\theta_2,\ S_1=\sin\theta_1,\ S_2=\sin\theta_2,$$
$$\text{and } C=\cos\phi.$$

Here θ_1, θ_2, and ϕ are the usual angles describing the mutual orientation of two linear molecules.

The nonspherical contribution to the second virial coefficient, ΔB^*, is obtained using a good spherical core (HFD-I) given in Table 1 of Ref. 8. In conjunction with this model and in terms of the dimensionless quantities $T^*=T/(\varepsilon_o/k)$, $B^*=B/(2\pi N_A\sigma_o^3/3)$, $\mu^*=\mu/(\varepsilon_o\sigma_o^3)^{1/2}$, $\theta^*=\theta/(\varepsilon_o\sigma_o^5)^{1/2}$, $\alpha^*=\bar{\alpha}/\sigma_o^3$, and $C_6^*=C_6/\varepsilon_o\sigma_o^6$

$$\begin{aligned}\Delta B^* = {} & B^*(\mu\mu)+B^*(\mu\theta)+B^*(\theta\theta)+B^*(\mu,\text{ ind}\mu)\\ & +B^*(\mu\theta,\text{ ind}\mu)+B^*(\theta,\text{ ind}\mu)+B^*(C_6\text{ anis})\\ & +B^*(\mu X\theta)+B^*(\mu,\text{ ind}\mu\, X\theta,\text{ ind}\mu)\\ & +B^*(\mu\mu X\mu,\text{ ind}\mu)+B^*(\mu\mu X\theta,\text{ ind}\mu)\\ & +B^*(\theta\theta X\ C_6\text{ anis})+B^*(\mu,\text{ ind}\mu\ X\ C_6\text{ anis})\\ & +B^*(\theta,\text{ ind}\mu\ X\ C_6)\text{ anis}).\end{aligned}\tag{3}$$

Where

$$B^*(\mu\mu)=-\frac{2}{3}\left(\frac{\mu^{*2}}{T^*}\right)^2\left[J_6+\frac{1}{25}\left(\frac{\mu^{*2}}{T^*}\right)^2J_{12}+\cdots\right]\tag{4-a}$$

$$B^*(\mu, \text{ ind}\mu X\ C_6 \text{ anis}) = -\frac{4}{15}\left(\frac{\mu^{*2}}{T^*}\right)\left(\frac{C_6^*}{T^*}\right)\alpha^* K J_{12} + \cdots \quad \text{(4-m)}$$

$$B^*(\theta, \text{ ind}\mu X\ C_6 \text{ anis}) = -\frac{144}{385}\left(\frac{\theta^{*2}}{T^*}\right)\left(\frac{C_6^*}{T^*}\right)\alpha^* K J_{14} + \cdots \quad \text{(4-n)}$$

Here

$$J_n(T^*) \equiv \frac{n-3}{2}\int_0^\infty \frac{dr^*}{(r^*)^{n-2}} \exp\left(-V_o^*/T^*\right)$$

where $V_o^* \equiv V_o/\varepsilon_o$ and $r^* \equiv r/\sigma_o$

The $J_n(T^*)$'s are functions tabulated in Table 2 and B_o^* (spherical) are given in Table 3. Boushehri et al. have tabulated $J_n(T^*)$ using (HFD-C) given by Aziz and Chen[8] for n=6 through 30 and for T^* from 0.5 to 10.0.[7] In Ref. 9 results for molecules with octupole moments have also been discussed.

Results and Discussion

Various contributions to B(T) for CO_2 calculated according to Eq. 3 are given in Table 1. The scaling parameters for CO_2 are taken from Ref. 10. Comparison of present work and experimental value of CO_2 are also shown in Table 1.

It should be mentioned that in Ref. 7 the J_n integrals for the nonspherical contributions were calculated for

the HFD-C potential while in the present paper they are calculated for the HFD-I potential.

In Ref. 7, a set of J_n tables is justified by the argument that the values will be insensitive to the details of the potential. Comparison of the new J_n tables with the earlier J_n tables confirms this observation.

Theoretical Study of Some Non-Benzenoid Hydrocarbons: Benzo-[3′,4′]cyclobuta[1′,2′:6,7]cycloocta[1,2,3,4-*def*]-biphenylene and Related Compounds

Sukanta K. PAL, Archana DAS GUPTA, and Nanda K. DAS GUPTA*
Department of Chemistry, Visva-Bharati University,
Santiniketan, West Bengal, 731235, India
(Received April 30, 1987)

Benzo[3′,4′]cyclobuta[1′,2′:6,7]cycloocta[1,2,3,4-*def*]biphenylene (**1**), benzo[6,7]cycloocta[1,2,3,4-*def*]biphenylene (**2**), dibenzo[*a*,*c*]benzo[3,4]cyclobuta[1,2-*f*]cyclooctene (**3**), and biphenyleno[8′,1′:4,5,6,7]cycloocta[1,2-*l*]-phenanthrene (**4**) have been studied by semiempirical SCFMO method of Pariser and Parr and Pople. Core resonance intergral values of Lo and Whitehead, Dewar et al. and Yamaguchi et al. have been used. It has been observed that $\pi^*\leftarrow\pi$ spectra predicted by the methods of Lo and Whitehead and Chung and Dewar suitable for the prediction of ground state properties are in good agreement with experimental results and comparable to those predicted by the method of Yamaguchi et al. developed for the prediction of spectral transitions. For comparison values obtained by configuration interaction method has also been included. Resonance stabilization of the molecules has been studied along with other properties such as bond length, ionization potential, electron affinity, and half-wave reduction potential.

The properties of polycyclic hydrocarbons formed by the fusion of $(4n+2)$ π-electron rings have been studied extensively with special reference to six π-electron systems. However, little is known about the properties of hydrocarbons composed of fused $4n$, or of $4n$ and $(4n+2)$, π-electron rings. Few polycyclic compounds have been known with fused $4n$ π-electron rings.[1,2] These molecules are interesting because their properties suggest that it is the nature of the individual $4n$ rings and not the overall number of π-electrons which determine the behavior of such systems. In this paper we report the results of our calculations on benzo[3′,4′]cyclobuta[1′,2′:6,7]cycloocta-[1,2,3,4-*def*]biphenylene (molecules **1**), benzo[6,7]cycloocta[1,2,3,4-*def*]biphenylene (molecules **2**), dibenzo[*a*,*c*]-benzo[3,4]cyclobuta[1,2-*f*]cyclooctene (molecules **3**), and biphenyleno[8,′1′:4,5,6,7]cycloocta[1,2-*l*]phenanthrene (molecules **4**) using the method of Pariser and Parr[3] and Pople.[4] The molecules studied here belong to those class of compounds mentioned above and moreover all of them contain bicyclo[6.2.0]decapentaene (**5**) ring in the moiety. Molecule **5**[5] is isomeric to azulene and naphthalene and obeys Huckel's $(4n+2)$ rule. On these grounds it might be aromatic. But actually it is not. Hence it would be worthwhile to theoretically predict the stability, $\pi^*\leftarrow\pi$ spectra, ionization potential, electron affinity, and half-wave reduction potential of the hydrocarbons **1**—**4**.

2: Benzo[6,7]cycloocta[1,2,3,4-*def*]biphenylene (**2**).
3: Dibenzo[*a*,*c*]benzo[3,4]cyclobuta[1,2-f]cyclooctene (**3**).
4: Biphenyleno[8′,1′:4,5,6,7]cycloocta[1,2-*l*]phenanthrene (**4**).
5: Bicyclo[6.2.0]decapentaene (**5**).

Methods and Parameter

The method has been described elsewhere.[6] Only the salient features are described herein. The resonance integrals, β_{ij} were calculated by the following methods: (I) In the first method, designated as SCF(a), β_{ij} was estimated using the method of Lo and Whitehead;[7] (II) in the second one, designated as SCF(b), β_{ij} was given a value of -1.7901 eV proposed by Chung and Dewar[8] and modified by Birss and Das Gupta.[9] In the SCF(a) and SCF(b) methods the integrals, β_{ij} were not varied at each iteration; (III) the

third method, designated as SCF(c) method was due to Dewar and Harget[10] and (IV) fourth one was due to Yamaguchi et al.[11] In these two methods the integrals, β_{ij}, the bond lengths (r_{ij}) and the two center two electron repulsion integrals (Υ_{ij}) for bonded atoms were adjusted according to the following relations:

In the SCF(c) method[10] the relations used were

$$r_{ij}(\text{Å}) = 1.512 - 0.174\, p_{ij} \quad (1)$$

$$\beta_{ij} = -6.927\, S_{ij} \quad (2)$$

where p_{ij} is the π-bond order and S_{ij} is the overlap integral between $2p_\pi$ Slater-type of orbitals.

In the SCF(d) method[11] the relations used were

$$r_{ij}(\text{Å}) = 1.520 - 0.186\, p_{ij} \quad (3)$$

$$\beta_{ij} = \beta_o \exp[a(r_o - r_{ij})] \quad (4)$$

where r_o=1.397 Å, a=−1.7 Å^{-1} and β_o is the resonance integral of benzene. The value of β_o decreased as the number of ring[12] increased.

For the calculation of bond lengths in the SCF(a) and SCF(b) methods the bond order–bond length relations (Eq. 5), due to Dewar and Gleicher[13] was used.

$$r_{ij}(\text{Å}) = 1.504 - 0.166\, p_{ij} \quad (5)$$

One-center two-electron repulsion integrals Υ_{ii} were calculated using the relation (Eq. 6) of Pariser[14]

$$\Upsilon_{ii} = I_i - A_i \quad (6)$$

where I and A represent the valence state ionization potential and electron affinity of carbon atoms respectively. The values have been taken from the work of Hinze and Jaffe.[15] The values of Υ_{ii} and I for carbon atoms are 11.136 and 11.16 eV respectively.

Except for SCF(d) method the two-center two-electron repulsion integrals, Υ_{ij} were evaluated using the method of Ohno[16] and for SCF(d) method the formula of Mataga and Nishimoto[17] was used. In the SCF(c) and SCF(d) methods the values Υ_{ij} were also not varied for nonbonded centers, but were kept at the values calculated from the initial geometry of the molecules which were assumed to be planar with ideal geometry and bond lengths equal to 1.40 Å.

Spectral transitions have been predicted by both SCF and configuration interaction (CI) methods. The final vectors, resonance integrals and two-center two-electron repulsion integrals obtained at the end of SCF(d) method were transferred in the CI procedure. The value of β_o used in the SCF(d) method was −2.15 eV.[18] In the CI procedure the configurations arising from one-electron excitation has been considered. Except molecule **2** ten highest occupied and ten lowest unoccupied orbitals and for molecule **2** all the occupied and unoccupied orbitals have been considered.

Results and Discussion

Charge Density and Bond Length. All the hydrocarbons **1**—**4** are alternant hydrocarbons. Hence calculated charge densities on each carbon atom is unity. Except molecule **3** all have biphenylene nucleus. The calculated bond lengths of the benzene rings of the biphenylene moiety have aromatic character lying between 1.39 and 1.41 Å. All the hydrocarbons have one eight-membered ring where bond length alternation exists and the bonds have alternately single bond and double bond character. However, the common bonds with the six-membered ring of biphenylene and eight-membered ring have aromatic character. But the common bond between eight-membered ring and six-membered ring other than the biphenylene moiety of molecules **2** and **4** has single-bond character and the predicted bond length is equal to 1.45 and 1.46 Å for these molecules respectively. This suggests that the π-electrons are localized here. In the biphenylene moiety (**1**, **2**, and **4**) the bonds joining the two six-membered rings have single bond character and the length lies between 1.48—1.49 Å same as in the biphenylene itself. The bond length joining the two six-membered rings (molecule **3**) has also single-bond character having length equal to 1.46—1.47 Å. In the molecules **1** and **3** there is a four-membered ring attached in between the eight-membered and six-membered rings. The bond common to the four-membered and six-membered ring has aromatic character with bond length 1.41 Å and the other three bonds of the four-membered ring have single bond character (1.46 Å). Thus π-electrons are not delocalized in this region of the molecules.

$\pi^* \leftarrow \pi$ Spectra. Table 1 presents the theoretical and experimental spectral transitions along with the oscillator strengths (f). The theoretical results have been predicted using the SCF methods and CI procedure. The oscillator strengths were obtained from the relation[19]

$$f = 1.095 \times 10^{-5} \bar{\nu}\, \mu^2 \quad (7)$$

where $\bar{\nu}$ is the transition energy in (cm^{-1}) and μ is the dipole length (in Å) for the corresponding transition.

Literature survey shows that only molecules **1** and **3** have experimental spectral transitions. The experimental spectra of the molecule **1** have a large number of peak maxima many of which are not clearly resolved. Therefore the best one can expect in a comparison of the theoretical and observed transition energies is a general correlation over quite wide spectral regions. Table 1 displays this comparison. In addition to the observed peak maxima included in the table there is a number of observed maxima at low transition energies for which no theoretical counterpart was found. Table 1 also contains the theoretical spectral transitions of molecule **3** along with

experimental ones. In all these molecules (**1** and **3**) the results predicted by the CI method is better than those predicted by the SCF methods. Table 2 contains the theoretical transitions of the molecules **2** and **4** for which no experimental transitions are available in the literature.

Molecular Properties such as Ionization Potentials, Electron Affinities, Half-Wave Reduction Potentials, and Stability. According to Koopmans' theorem[20] ionization potential (IP) could be represented by the highest occuopied orbital energy (HOOE). Electron affinity (EA) could also be represented by the lowest unoccupied orbital energy (LUOE). It has been found[21] that the values obtained by this method are 1 or 2 eV higher than the experimental values of IP and EA. Hence a correction term is to be added to the HOOE and LUOE in order to get the correct value of IP and EA respectively. Correction terms are displayed in Table 3. The half-wave reduction potential ($E_{1/2}$) has been evaluated from the relation[22] (Eq. 8) in the context of SCF(c) method

Table 3. Values of Correction Terms, '*C*' and '*D*'

Method	Value of C[a]	Value of D[a]
SCF(a)	1.29[b]	1.49[c]
SCF(b)	1.28[b]	1.50[c]
SCF(c)	1.88 (Ref. 22)	1.28[c]
SCF(d)[d]	1.06	1.90

a) The values are in eV. b) The values are due to difference between the HOOE and experimental value of IP of some standard molecule. Here it is chrysene the value of which is 8.01 eV (Ref. 29). c) The values are due to difference between the LUOE and experimental value of electron affinity of some standard molecule. Here it is chrysene. The value of which is 0.397 eV (Ref. 30). d) Ref. 31.

$$E_{1/2} = -0.833\, e_j - 3.46 \qquad (8)$$

where e_j is the LUOE. The values of IP, EA, and $E_{1/2}$ are presented in Table 4. For lack of experimental value we can not compare our results with

experimental ones.

Stability or aromaticity of the molecules has been studied using the criteria of resonance energy (E_R) and resonance energy per carbon-carbon bond (E_R/C-C) or resonance energy per π-electron (RE/PE). The values of E_R of the hydrocarbons have been obtained using the methods of Lo and Whitehead,[7] Chung and Dewar,[8] Dewar and de Llano,[23] Dewar and Harget,[10] and Hess and Schaad.[24]

The values of heat of atomization (ΔH_a) and bond energies of the hydrocarbons have been presented in Tables 5 and 6 contains the values of E_R, E_R/C-C, and

a) a, b, c, d, and e represent SCF(a), SCF(b), SCF(c), Dewar-de Llano and Hess, and Schaad method respectively. For a, b, c, and d E_R is in eV and for e it is in β.

Table 7. Criteria of Aromaticity or Stability of Hydrocarbons

Method[a]	Range of E_R/C-C or RE/PE for the hydrocarbons to be aromatic
a	0.26—0.31
b	0.25—0.30
c	0.075—0.112
d	0.041—0.095
e	0.03—0.04

a) a, b, c, d, and e represent the SCF(a), SCF(b), SCF(c), Dewar-de Llano and Hess, and Schaad methods respectively. (Refs. 25 and 32).

RE/PE of the molecules. The hydrocarbons belong to semibenzenoid[25] type of compounds. The criteria for stability of this type of hydrocarbons with respect to E_R/C-C or RE/PE have been discussed by Das Gupta and Das Gupta and are displayed in Table 7.

The molecule **1** is thermally stable[26] and melts without decomposition at 192—193 °C. It exhibits diamagnetic ring current suggesting that it might be aromatic. From Table 6 E_R and E_R/C-C bond calculated by SCF(a), SCF(b), and SCF(c) methods and Dewar-de Llano method[23] suggest also that the molecule might be aromatic. On the other hand resonance energy and RE/PE (0.0113) calculated by Hess and Schaad method predict it to be not aromatic. However, stability[25] predicted by Dewar-de Llano method is better than any other methods.

Resonance energy, E_R/C-C bond calculated by all the SCF methods[7,8,10,23] and RE/PE suggest that the molecule **2** might be unstable one. It predicts paramagnetic ring current[26] which points it out to be not an aromatic compound. Synthesis of **2** has not yet been found in the literature.

Hydrocarbon **3** has been synthesized by Garratt et al.[27,28] They have also studied the properties. According to them the molecule is an aromatic one which is in agreement with the results obtained from the values of E_R, E_R/C-C bond calculated by the SCF methods and E_R and RE/PE calculated by the Hess and Schaad method.

Molecule **4** is an interesting one. It has not yet been synthesized. However, ring current criteria[26] and E_R, E_R/C-C suggest it to be aromatic and stable compound. As in molecule **1**, RE/PE predicts it to be not aromatic.

Biphenylene is an aromatic compound and hydrocarbon **5** is not. The molecules **1**—**4** either contain biphenylene or molecule **5** or both in their nucleus. But aromatic character or not of these molecules is not governed by the presence of biphenylene or molecule **5**. As for example **1** and **3** contain molecule **5** in their nucleus. From the above discussion it is clear that both the molecules **1** and **3** are aromatic. Again **1**, **2**, and **4** contain biphenylene moiety. But as discussed earlier it is clear that the hydrocarbons **1** and **4** are aromatic and **2** is not. Although molecule **4** has not yet been synthesized still we expect that either it or some of its derivatives will be synthesized in near future.

The authors are grateful to the University Grants Commission, New Delhi for the award of offering a Junior Research Fellowship to one of them (SKP).

Thermochemistry of Cobalt(III) β-Diketonates

Manuel A. V. Ribeiro da Silva* and Maria Luisa C. C. H. Ferrão
Chemistry Department, Faculty of Sciences, University of Oporto, P-4000 PORTO, Portugal
(Received May 25, 1987)

The standard molar enthalpies of formation of the crystalline complexes of cobalt(III) with 1-phenyl-1,3-butanedione (Hbzac), 2,2,6,6-tetramethyl-3,5-heptanedione(Hdpm), and 1,1,1-trifluoro-2,4-pentanedione (Htfac) were determined, at 298.15 K, by solution-reaction calorimetry:

$$\Delta_f H^\circ_m[Co(bzac)_3, cr] = -877.1 \pm 8.7 \text{ kJ} \cdot \text{mol}^{-1}$$

$$\Delta_f H^\circ_m[Co(dpm)_3, cr] = -1708 \pm 12 \text{ kJ} \cdot \text{mol}^{-1}$$

$$\Delta_f H^\circ_m[Co(tfac)_3, cr] = -3191 \pm 15 \text{ kJ} \cdot \text{mol}^{-1}.$$

The enthalpies of sublimation of $Co(dpm)_3$ and $Co(tfac)_3$, at 298.15 K, determined by high-temperature microcalorimetry were 126±3 and 114±2 kJ·mol^{-1}, respectively. From the enthalpies of formation of the gaseous complexes, the average molar bond-dissociation enthalpies, $\langle D \rangle$(Co–O), were derived.

Previous thermochemical studies of cobalt(III) β-diketonates are limited to tris(2,4-pentanedionato)-cobalt(III), made by Wood and Jones,[1] using static-bomb calorimetry. These early combustion results have been shown to be unreliable,[2] probably because insufficient attention was paid to controlling the combustion with auxiliary combustion aids and in defining the completeness of combustion and the nature of the combustion products.

The solution-reaction calorimetric method has proved bo be reliable for determining enthalpies of formation of metal β-diketonates.[3] In this paper, using the solution-reaction calorimetric method, the standard molar enthalpies of formation of three cobalt(III) β-diketonates were determined, to permit consideration of the effect of structural changes in the ligand upon the mean molar (Co–O) bond-dissociation enthalpies.

Experimental

The Solution Calorimeter. The isoperibol LKB 8700 reaction-and-solution precision calorimeter was used. The operation and calculations methods have been reported.[4] The molar enthalpy of reaction was calculated from the relation $\Delta H = \varepsilon \Delta R / n R_m$, where $\Delta R = R_i - R_f$, $R_m = (R_i + R_f)/2$, n=number of moles of reactant, and R_i and R_f are the initial and final thermistor resistances (Ω) as determined by the Dickinson method.[5] The energy constant, ε, of the calorimetric system is given by $\varepsilon = Q_c R_{mc} / \Delta R_c$, where Q_c is an accurately defined quantity of heat supplied electrically via the built-in heater, $Q_c = R_h I^2 t$(R_h is the resistance of the calibrating heater (Ω), I the calibratrion current (A), and t the heating time (s)), and R_{mc} and ΔR_c have the same significance in a calibration experiment as R_m and ΔR have in a reaction. The ratio $\Delta R / R_m$ is directly proportional to the temperature change. The accuracy of the calorimeter was checked by measuring the molar enthalpy of solution of tris(hydroxymethyl)aminomethane (THAM) in aqueous 0.1000 mol·dm^{-3} HCl at 298.15 K: $\Delta_{sol}H_m = -29.769 \pm 0.024$ kJ·mol^{-1}, in agreement with the value of Kilday and Prosen,[6] $\Delta_{sol}H_m = -29.770 \pm 0.032$ kJ·mol^{-1}.

High-Temperature Microcalorimeter. The enthalpies of sublimation of the complexes were measured by the "vacuum sublimation" drop-microcalorimetric method.[7] Samples (about 4 mg) of each complex contained in a small thin-glass capilary tube sealed at one end, were dropped, at room temperature, into the hot reaction vessel in the Calvet High-Temperature Microcalorimeter held at constant temperature, between 407 and 490 K, and then removed from the hot zone by vacuum sublimation. At these temperatures, the complexes showed no signs of decomposition, and sublimed completely in less than 30 min. The observed standard molar enthalpies of sublimation [H°_m(g, T)−H°_m(cr,298.15K)] were corrected to 298.15 K using values of [H°_m(g, T)−H°_m(g, 298.15K)] estimated by group-additivity methods based on data given by Stull et al.[8] The microcalorimeter was calibrated in situ for the measurements by making use of the known molar enthalpies of sublimation of iodine,[9] naphthalene,[8] and benzoic acid.[10,11]

All uncertainty intervals given are twice the standard deviation of the mean.

Materials. 1-Phenyl-1,3-butanedione: Hbzac (Koch-Light Laboratories Ltd.) was purified by repeated recrystallization from ethanol–water; mp 56 °C (lit, 56 °C[12]). Found: C, 73.89; H, 6.25%. Calcd for $C_{10}H_{10}O_2$: C, 74.06; H, 6.22%.

2,2,6,6-Tetramethyl-3,5-heptanedione: Hdpm was prepared by Claisen condensation according to the methods of Adams and Hauser[13] and of Kopecky et al.,[14] was purified by fractional distillation in vacuum and the purity was assessed as better than 99.9 mole per cent by GLC using two different columns.

1,1,1-Trifluoro-2,4-pentanedione: Htfac (Kock-Light Laboratories Ltd.) was purified by fractional distillation and the purity was assessed as greater than 99.9 mole per cent by GLC using two different columns. The purified liquid β-diketones were stored under nitrogen in the dark and were freshly distilled prior to use.

Tris(1-phenyl-1,3-butanedionato)cobalt(III): $Co(bzac)_3$ was prepared as described by Bauer and Drinkard[15] and was purfied by crystallization from acetone–hexane; mp 184—185 °C(lit, 213 °C[15]). Found: C, 66.45; H, 4.89; Co, 10.78%. Calcd for $C_{30}H_{27}O_6Co$: C, 66.42; H, 5.03; Co, 10.87%.

Tris(2,2,6,6-tetramethyl-3,5-heptanedionato)cobalt(III): Co(dpm)$_3$ was prepared as described by Bauer and Drinkard[15] and was purified by vacuum sublimation; mp 244—245 °C (lit, 244—245 °C[16]). Found: C, 65.11; H, 9.38; Co, 9.54%. Calcd for $C_{33}H_{57}O_6Co$: C, 65.11; H, 9.44; Co, 9.68%.

Tris(1,1,1-trifluoro-2,4-pentanedionato)cobalt(III): Co(tfac)$_3$ (Koch-Light Laboratories Ltd.) was crystallized from carbon tetrachloride; mp 152 °C (lit, 156 °C[17]). Found: C, 34.72; H, 2.19; Co, 11.30%. Calcd for $C_{15}H_{12}O_6Co$: C, 34.77; H, 2.33; Co, 11.37%.

Cobalt(II) Sulfate Hexahydrate: Cobalt(II) sulfate heptahydrate (AnalaR BDH) was dried over silica gel; its composition was determined by means of cobalt analyses and found to be $CoSO_4 \cdot 6.00H_2O$.

Iron(II) and Iron(III) Chloride: CERAC samples of $FeCl_2$ and $FeCl_3$(stated minimum purity 99.99%) were used.

Sulfuric Acid: A 1 mol·dm^{-3} H_2SO_4 was made from Merck concentrated volumetric solution; the concentration was checked by titration against $Na_2B_4O_7 \cdot 10H_2O$ and found to be (series of six titrations) 1.000±0.003 mol·dm^{-3}, which corresponds[12] to the composition $H_2SO_4 \cdot 53.54H_2O$.

Hydrochloric Acid: Concentrated HCl (AnalaR BDH) was diluted with distilled water. The concentration was determined by titration against $Na_2B_4O_7 \cdot 10H_2O$ and found to be (series of six titrations) 4.590±0.003 mol·dm^{-3}, which corresponds[12] to the composition $HCl \cdot 10.98H_2O$.

1,4-Dioxane: 1,4-Dioxane (Carl Erba) was purified according to Ref. 18.

Analyses: Carbon and hydrogen analyses were carried out in the Microanalytical Service of the University of Surrey; cobalt was analyzed by the ethylenediaminetetracetic acid method.[19]

For the hydrolysis and oxidation reaction the solvents were degassed and saturated with purified nitrogen prior to each determination.

The relative atomic masses used were the recommended by the IUPAC Commission.[20]

Results and Discussion

Preliminary tests of solubility showed that rapid hydrolyses and oxidation occurred using [0.90(1,4-dioxane)+0.10HCl(aq, 3.0 mol·dm^{-3})] by volume, as the initial calorimetric solvent.

The thermochemical reaction for determining the standard molar enthalpy of formation of Co(bzac)$_3$, Co(dpm)$_3$, and Co(tfac)$_3$ was:

$$CoL_3(cr) + HCl \cdot 10.98H_2O(l) + H_2SO_4 \cdot 53.54H_2O(l) + FeCl_2(cr) = 58.52H_2O(l) + FeCl_3(cr) + 3HL(cr \text{ or } l) + CoSO_4 \cdot 6.00H_2O(cr) \quad (1)$$

The reaction was studied in the presence of an excess of $FeCl_3$: to the calorimetric solvent (100.0 cm^3), 1.00 cm^3 of $FeCl_3$ 0.1 mol·dm^{-3} was added. The same batch of solvent was used for the three cobalt(III) complexes.

The enthalpies of the thermochemical reactions were determined by measuring the enthalpies of reaction and solution of the reactants and products, $\Delta_i H_m$, in succession in the initial calorimetric solvent. The thermochemical cycle and the general procedure for the calorimetric study of the cobalt(III) complexes

$$HCl \cdot 10.98H_2O(l) + H_2SO_4 \cdot 53.54H_2O(l) + FeCl_2(cr) + CoL_3(cr) = 58.52H_2O(l) + FeCl_3(cr) + 3HL(cr \text{ or } l) + CoSO_4 \cdot 6.00H_2O(cr)$$

$$\downarrow \Delta_1 H_m \quad \downarrow \Delta_2 H_m \quad \downarrow \Delta_3 H_m \quad \downarrow \Delta_4 H_m \quad \downarrow \Delta_5 H_m \quad \downarrow \Delta_6 H_m \quad \downarrow \Delta_7 H_m \quad \downarrow \Delta_8 H_m$$

$$\text{Solvent}\{0.90(\text{dioxane}) + 0.10HCl(aq, 3.0 \text{ mol} \cdot \text{dm}^{-3})\} + FeCl_3 \quad \text{Solvent}\{0.90(\text{dioxane}) + 0.10HCl(aq, 3.0 \text{ mol} \cdot \text{dm}^{-3})\} + FeCl_3$$

$$\text{Solution } A_4 \xrightarrow{\Delta_9 H_m = 0} \text{Solution } B_4$$

$$\text{Solvent} + HCl \cdot 10.98H_2O(l) \xrightarrow{\Delta_1 H_m} \text{Solution } A_1$$

$$\text{Solution } A_1 + H_2SO_4 \cdot 53.54H_2O(l) \xrightarrow{\Delta_2 H_m} \text{Solution } A_2$$

$$\text{Solution } A_2 + FeCl_2(cr) \xrightarrow{\Delta_3 H_m} \text{Solution } A_3$$

$$\text{Solution } A_3 + CoL_3(cr) \xrightarrow{\Delta_4 H_m} \text{Solution } A_4$$

$$\text{Solvent} + H_2O(l) \xrightarrow{\Delta_5 H_m} \text{Solution } B_1$$

$$\text{Solution } B_1 + FeCl_3(cr) \xrightarrow{\Delta_6 H_m} \text{Solution } B_2$$

$$\text{Solution } B_2 + HL(cr \text{ or } l) \xrightarrow{\Delta_7 H_m} \text{Solution } B_3$$

$$\text{Solution } B_3 + CoSO_4 \cdot 6.00H_2O(cr) \xrightarrow{\Delta_8 H_m} \text{Solution } B_4$$

$$\Delta_r H_m = \Delta_1 H_m + \Delta_2 H_m + \Delta_3 H_m + \Delta_4 H_m - 58.52\Delta_5 H_m - \Delta_6 H_m - 3\Delta_7 H_m - \Delta_8 H_m$$

Scheme 1.

is given in the Scheme 1. The difference between the molar enthalpies of solution of the products and reactants in the correct stoichiometric ratio gives the enthalpy of the thermochemical reaction, $\Delta_r H^\circ_m$, provided equilibrium is reached from either side within the period of the experiment. The amounts of reactants in a particular series of experiments were determined by the amount of CoL_3(cr), approximately 2.5×10^{-4} mol for Co(bzac)$_3$ and Co(tfac)$_3$ and 1.2×10^{-4} mol for Co(dpm)$_3$. Since the amounts used for the reactants in the study of the Co(dpm)$_3$ complex were different from the other complexes, this made necessary remeasurement of the enthalpies of solution of $HCl\cdot10.98H_2O$(l), $H_2SO_4\cdot53.54H_2O$(l), $FeCl_3$(cr), $FeCl_2$(cr), H_2O(l), and $CoSO_4\cdot6.00H_2O$(cr). These results were found to be the same, within the experimental errors, as determined previously in the study of Co(bzac)$_3$ and Co(tfac)$_3$, hence the previously determined values were used.

The detailed calorimetric results required for determination of the enthalpies of the thermochemical reactions are given in Tables 1—3.

The enthalpies of the thermochemical reactions were derived from the values presented in Tables 1—3

and the equation in the Scheme 1, leading to

$$\Delta_rH°_m[Co(bzac)_3] = -105.8\pm1.0 \text{ kJ·mol}^{-1}$$

$$\Delta_rH°_m[Co(dpm)_3] = +32.3\pm1.0 \text{ kJ·mol}^{-1}$$

$$\Delta_rH°_m[Co(tfac)_3] = +60.2\pm1.3 \text{ kJ·mol}^{-1}$$

The experimental results for determination of the standard molar enthalpies of sublimation of $Co(dpm)_3$ and $Co(tfac)_3$ are listed in Table 4. Attempts to measure the enthalpy of sublimation of $Co(bzac)_3$ were unsuccessful because, for temperatures at which vapour pressure was sufficiently high to permit vacuum sublimation, partial thermal decomposition occurred.

To derive the standard molar enthalpies of formation of the crystalline cobalt(III) complexes, the following auxiliary data, at 298.15 K, was used: $\Delta_fH°_m(H_2O, l)$=−285.83±0.04 kJ·mol^{-1};[21] $\Delta_fH°_m$(HCl in 10.98H_2O, l)=−161.77±0.01 kJ·mol^{-1};[22] $\Delta_fH°_m$(H_2SO_4 in 53.54H_2O, l)=−886.87±0.01 kJ·mol^{-1};[22] $\Delta_fH°_m$($FeCl_3$, cr)=−399.49±0.29 kJ·mol^{-1};[22,23] $\Delta_fH°_m$($FeCl_2$, cr)=−341.79±0.21 kJ·mol^{-1};[22,23] $\Delta_fH°_m$($CoSO_4$·6.00H_2O, cr)=−2683.6±2.1 kJ·mol^{-1};[22] as well as the standard enthalpies of formation of the ligands (Table 5), and the above derived molar enthalpies of the thermochemical reactions. Table 6 lists the derived standard molar enthalpies of formation of the crystalline cobalt(III) complexes, their standard molar enthalpies of sublimation and of formation in the gaseous state. The molar enthalpy of sublimation of $Co(bzac)_3$ was estimated on the basis of its structure, molecular weight and other known values for similar complexes, using an estimation scheme.[3]

From the molar enthalpies of the homolytic dissociation of the gaseous molecules into metal atoms and ligand radicals

$$CoL_3(g) = Co(g) + 3L(g) \quad (2)$$

the mean cobalt–oxygen bond-dissociation enthalpies, $\langle D\rangle$(Co–O), were derived. Since the oxygens atoms in metal β-diketonates are equivalent,[27] $\langle D\rangle$(Co–O) may be defined as 1/6 of the molar enthalpy of the disruption Reaction 2.

$$\Delta_{disr}H°_m(2) = \Delta_fH°_m(Co, g) + 3\Delta_fH°_m(HL, g) - 3\Delta_fH°_m(H, g) - \Delta_fH°_m(CoL_3, g) + 3D(O\text{–}H, HL, enol)$$

where D(O–H, HL, enol) is the molar enthalpy of dissociation of the enolic hydrogen in the parent ligand

Table 7. $\langle D \rangle$(Co-O) at 298.15 K

Complex	$\Delta_{disr}H°_m$	$\langle D \rangle$(Co-O)
	kJ·mol^{-1}	kJ·mol^{-1}
Co(bzac)$_3$	984±62	164±10
Co(dpm)$_3$	1023±62	171±10
Co(tfac)$_3$	1060±65	177±10

$$H\text{-}L(g) = L^{\cdot}(g) + H(g) \quad (3)$$

There are no measured values for the molar enthalpy of dissociation of the enolic hydrogen from β-diketones. Different values have been estimated for this parameter, and the situation has been recently reviewed.[3] In this work, for comparison reasons, the value of D(O-H, HL, enol)=418±20 kJ·mol^{-1} [3] is used.

With $\Delta_f H°_m$(H, g)=218.00±0.01 kJ·mol^{-1} [22] and $\Delta_f H°_m$(Co, g)=424.7±4.2 kJ·mol^{-1} [22] the derived values of $\Delta_{disr}H°_m$ and $\langle D \rangle$(Co-O), for the complexes studied are given in Table 7.

As noted previously[28,29] in attempting a rigorous determination of bond-dissociation enthalpies, estimates of some enthalpies of formation were necessary, as well as the enthalpy of dissociation of the enolic hydrogen from the parent β-diketone. The resulting bond-dissociation enthalpies, therefore, have a large uncertainty attached to them, and this makes almost impossible a definite conclusion concerning the magnitude of the bond dissociation enthalpies. Within the uncertainties attached to the mean cobalt(III)-oxygen bond-dissociation enthalpies, there are no significant differences in $\langle D \rangle$(Co-O) for the three cobalt(III) β-diketonates studied in this paper. This shows that there is no effect, or only a very small one, of $-C(CH_3)_3$, $-C_6H_5$, or $-CF_3$ substitution in the ligand, upon $\langle D \rangle$(Co-O). This effect has already been observed for complexes of β-diketones with Be(II),[30] Al(III),[30] Cr(III),[31] Fe(III),[32] and Cu(II).[33]

Conductometric Determination of Some Metal Ions Using Oxine as Reagent

Mohamed Tarek Mohamed ZAKI,* Wageh Georgy HANNA, and Mohamed Hossam FAWZY
Department of Chemistry, Faculty of Science, Ain Shams University,
Abbassia, Cairo, Egypt
(Received January 26, 1987)

A simple and sensitive conductometric method for the determination of copper(II), iron(II) and (III), aluminum(III), chromium(III), gold(III), platinum(IV), vanadyl, zirconyl, and uranyl ions with oxine solution in ethanol–water system is described. An average recovery of 100.3% with standard deviation not exceeding 0.4% is observed. The effect of solvent, shape of titration curves and molar ratio of the chelates are studied. The proposed method shows good agreement with the conventional EDTA titration using metallochromic indicators. The advantage over the conventional method is discussed.

Despite the wide application of conductance measurement as a tool for end point detection of acid–base reactions, little attention has been given to complex formation reactions. Conductometric determination of water hardness,[1] divalent metal ions with EDTA[2] or CDTA,[3] silver and mercury ions with cyanide ion[4] and copper(II) chloride with lithium chloride in *N,N*-dimethylformamide[5] have been described.

In the present investigation, oxine (8-hydroxyquinoline) was succesfully used as a chelating agent for the conductometric determination of some metal ions in ethanol–water system (2:1).

Experimental

Reagents. All chemicals used were of analytical grade. The determined metal salts were of the chloride type except for iron (II), vanadyl and zirconyl ions which were of the sulfate type. Bidistilled water of specific conductance, 1.82×10^{-4} S m^{-1} was used throughout. 0.1 M† oxine stock solution in ethanol–water solvent (2:1) was prepared and potentiometrically standardized with a base.[6] 10^{-2} M stock solutions of aqueous metal ions were prepared and standardized using EDTA and metallochromic indicators.[7]

Apparatus. The YSI Model 32M conductance meter [Yellow Spring Co., Inc. (USA)] was used. The measuring range was from 1.0 to 200.0 microsiemens with a maximum error of ±0.2%. Model YSI 3417 cell was used with cell constant K=100/m.

Procedure. 10.0 ml of 10^{-3} M aqueous metal salt solution was transferred to a 50-ml beaker contained 20.0 ml absolute ethanol. The conductance cell was immersed in the solution, which was titrated with 10^{-2} M oxine solution. The conductance was determined after each addiction of the oxine solution. Stirring after each addition was carried out. For an ordinary conductometric titration, a few readings on each side of the anticipated end point are enough. The end point was determined from a graphical plot of conductance vs. milliliters of oxine solution added. All conductance measurements were carried out at 25 °C.

† 1 M=1 mol dm^{-3}.

Results and Discussion

Conductometric titration of metal ions with EDTA in buffer media has been described.[2] However, the presence of high electrolyte concentration affects the end point detection because of the relatively small change in conductance values determined against a relatively high background conductance of the buffer system.[7]

In the present investigation, a conductometric study of the interaction of some metal ions with oxine in absence of buffer has been carried out.

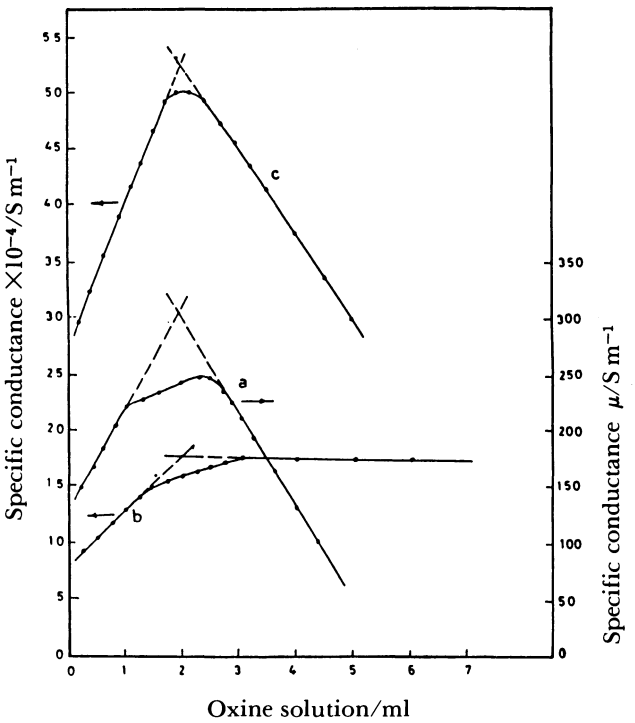

Fig. 1. Conductometic titration curves of (a) 10^{-3} M aqueous copper(II) chloride with 10^{-2} M ethanolic oxine solution, (b) 10^{-3} M ethanolic copper(II) chloride with 10^{-2} M ethanolic oxine solution, and (c) 10^{-3} M copper(II) chloride with 10^{-2} M oxine in ethanol–water system (2:1).

Effect of Solvent. Exploration of the conductometric titration of aqueous copper(II) chloride with ethanolic oxine solution was carried out (Fig. 1-a). However, a wide curvature around the end point was noticed. This is attributed to the formation of a precipitated chelate in aqueous medium. The presence of a precipitate affects conductance value due to the fact that accuracy depends on the speed of precipitation, composition and solubility of the precipitate.

A small curvature around the end point was observed in the titration of ethanolic copper(II) or iron(III) solutions with ethanolic oxine solution (Figs. 1-b and 2-b). However, most of the metal salts studied were insoluble in ethanol.

To overcome the problems of chelate and free metal ion solubility, an ethanol–water system (2:1) was used to prepare the oxine solution and as a medium for the titration.

Shape of Titration Curves. The shape of the titration curve depends on all the species present during the titration. Factors such as viscosity, dielectric constant, solvation, ion-pair association and proton transfer change the shape of the curve.

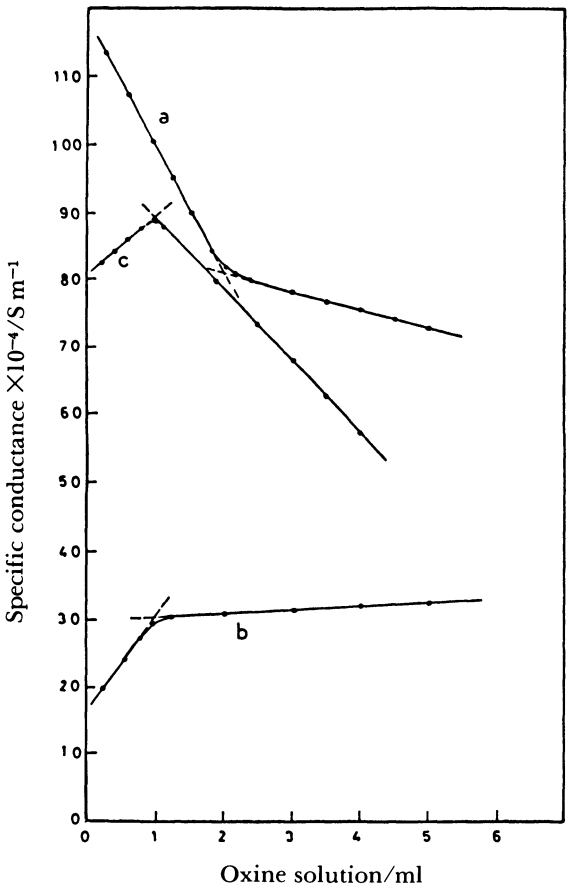

Fig. 2. Conductometric titration curves of (a) 10^{-3} M iron(III) chloride with 10^{-2} M oxine in ethanol–water (2:1), (b) 10^{-3} M ethanolic iron(III) chloride with 10^{-2} M ethanolic oxine solution, and (c) 10^{-2} M iron(III) chloride with 0.1 M oxine in ethanol–water system (2:1).

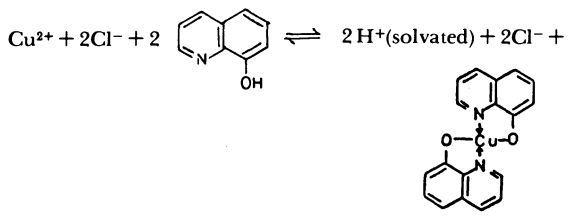
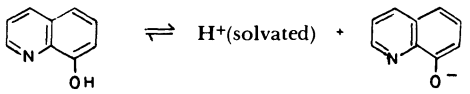
The conductometric titration of 10^{-3} M copper(II) chloride with 10^{-2} M oxine solution in ethanol–water system (2:1) was performed (Fig. 1-c). The results show an obvious maximum in the conductance curve at a copper(II)–oxine mole ratio of 1:2. The reaction may be represented by the equation:

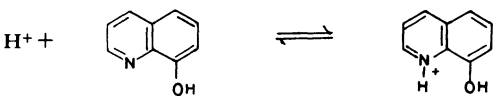


The specific conductance increased at first because each copper(II) ion is replaced by two solvated protons. The interaction of the protons with the solvent depend on the ratio of ethanol–water used.[8]

It was expected that the conductance values would remain constant or slightly increase after the equivalence point, due the the partial dissociation of oxine solution added:



However, after the equivalence point, the conductance of the solution decreased. The decrease may be due to the interaction of the protons available in the titration medium with the added oxine solution:



Measurement of the pH before and after the end point shows an increase of about 0.25 pH units indicating the probability of the above reaction. In addition, titration of 10^{-2} M hydrochloric acid in ethanol–water solvent (2:1) with 10^{-2} M oxine solution shows a continuous decrease of specific conductance.

The species which presumably existed before, at, and after the equivalence point are given in Table 1. Similar titration curves were observed for the titration of iron(II), aluminum(III), and vanadyl ions with oxine.

A different behavior in the conductometric titration curve of 10^{-3} M iron(III) chloride with 10^{-2} M oxine solution in ethanol–water solvent was observed (Fig. 2-a). The specific conductance continuously decreased throughout the titration. However, the two rectilinear curves formed gave an easily detected end point. The ions which presumably present through out the titration are given in Table 2. The decrease of conductance before the end point may be attributed to the replacement of the highly mobile iron(III) ions,

Table 1. Species Involved in the Conductometric Titration of Copper(II) Chloride with Oxine Solution in Ethanol-Water (2:1)

Species present before addition of oxine:	Cu^{2+} + 2 Cl^-
	↓ + 2 oxine
Species present at the equivalence point:	2 H^+(solvated) + 2 Cl^- + $[Cu(oxine)_2]$
	↓ + 2 oxine
Species present after the equivalence point:	2 Cl^- + 2 $[H\text{-oxine}]^+$ + $[Cu(oxine)_2]$

Table 2. Ions Involved in the Conductometric Titration of Up to 10^{-3} M Iron(III) Chloride with 10^{-2} M Oxine in Ethanol-Water System (2:1)

Ions present before addition of oxine:	Fe^{3+} + 3 Cl^-
	↓ +2 oxine
Ions present at the equivalence point:	2 H^+(solvated) +3 Cl^- + $[Fe(oxine)_2]^+$
	↓ +2 oxine
Ions present after the equivalence point:	2 $[H\text{-oxine}]^+$ + 3 Cl^- + $[Fe(oxine)_2]^+$

Table 3. Speies Involved in the Conductometric Titration of 10^{-2} M Iron(III) Chloride with 0.1 M Oxine in Ethanol-Water System (2:1)

Species present before addition of oxine:	$FeCl_2^+$ + Cl^+
	↓ + 1 oxine
Species present at the equivalence point:	$[FeCl_2(oxine)]$ + Cl^- + H^+(solvated)
	↓ + 1 oxine
Species present after the equivalence point:	$[FeCl_2(oxine)]$ + Cl^- + $[H\text{-oxine}]^+$

which show abnormally high molar conductance in this medium, by solvated protons and $[Fe(oxine)_2]^+$ ions. The molar conductance of iron(III) chloride in ethanol-water solvent (2:1) is greater than that of hydrochloric acid over the same concentration range of titration. The observed low molar conductance of the formed acid in this solvent is in accordance with that for sulfuric acid in the same solvent.[9] After the end point, the decrease in conductivity is relatively small compared with that noticed in the titration of copper(II)-oxine. This may be attributed to the presence of the charged $[Fe(oxine)_2]^+$ chelate.

However, increasing the concentration of iron(III) chloride ten folds reversed the shape of the titration curve before the end point. Figure 2-c represent the titration of 10^{-2} M iron(III) chloride with 0.1 M oxine solution under identical experimental conditions. This behavior could be explained on the view of incomplete ionization of iron(III) chloride at this relatively higher concentration in the following manner:

$$FeCl_3 \rightleftharpoons FeCl_2^+ + Cl^-$$

Evidence in support of incomplete dissociation as uni-univalent electrolyte in acetone was reported.[10] Also, lanthanum chloride behaves similarly in ethanol.[11] Table 3 shows the expected ions throughout the titration stages. The increase in conductance values before the end point may be attributed to the replacement of $Fe\,Cl_2^+$ ion by H^+(solvated) ion.

A study of the concentration effect for copper(II) chloride solutions was carried out. No change of the shape of the titration curve of 10^{-2}—10^{-3} M copper-(II) chloride with 10^{-1}—10^{-2} M oxine solution were observed. Titration of less than 10^{-3} M copper(II) chloride was not successful.

Similar titration curves to (Fig. 2-a) were observed for the titration of 10^{-3} M chromium(III), gold(III), platinum (IV), zirconyl and uranyl solutions with 10^{-2} M oxine solution using the same experimental conditions.

Metal-Ligand Mole Ratio of the Chelates. The mole ratio of metaloxine chelates were determined from the conductometric titration curves (Table 4-a). It was found that copper(II), platinum(IV), and zirconyl ions form (1:2) chelates with oxine. On the

a) 0.1 M oxine soution is used as titrant.

other hand, iron(II), chromium(III), aluminum(III), gold(III), vanadyl, and uranyl ions form (1:1) chelates with the ligand. The mole ration of iron(III)–oxine chelate depends on the original iron(III) concentration (Table 4-b). It was found that up to 10^{-3} M iron (III) forms a (1:2) chelate with oxine while a higher concentration forms a (1:1) chelate. The metal ion octet in the chelate is completed with solvent molecules.

Sensitivity and Precision Down to 0.3 mg of metal ions were successfully determined by conductometric titration with 10^{-2} M oxine solution. The titrant concentration was about ten times that of the metal ion solutions to minimise dilution effect on conductance values throughout the titration. Moreover, dilution correction was carried out using the equation:

$$L_{\text{corrected}} = L_{\text{observed}} \times [(V_1 + V_2)/V_1]$$

where L is the conductance, V_1 the initial volume in the cell and V_2 the volume of added titrant.

Analysis of the data show an average recovery of 100.3% with a standard deviation not exceeding 0.4% (four determinations for each metal ion). However, an average recovery of 103.2% with a standard deviation of 3.7% was observed for the titration of iron(II) sulphate (Table 4-b). The high recovery may be due to the partial oxidation of iron(II) ions. Iron(II) forms (1:1) chelate with oxine whereas low concentrations of iron(III) form (1:2) chelates (Table 4-b).

All experiments have been carried out in a medium of low ionic strength. However, real samples may contain indifferent ions. A study of potassium chloride effect on the conductometric titration curves showed that the method is applicable up to ten fold potassium chloride concentration. Attempts to determine silver(I), thallium(I), nickel(II), palladium-(II), zinc(II), magnesium(II), barium(II), calcium(II), strontium(II), cerium(IV), and molybdenum(VI) were unsuccessful.

Conclusion

The conductometric titration results were in good agreement with the conventional titrimetric method of EDTA using metallochromic indicators. Moreover, the proposed method has the advantage of eliminating the buffer medium and the back titration technique required for some of the measured ions with the conventional method.

We would like to acknowledge the assistance of Dr. W. H. Lee, Department of Chemistry, Surrey University, Guildford, U. K., for his valuable advice.

Kinetic Study of the Oxidation of Substituted Benzyl Alcohols by Ethyl Chlorocarbamate

Suman JAIN (nee Mittal) and Kalyan K. BANERJI*
Department of Chemistry, University of Jodhpur, Jodhpur 342001, India
(Received February 23, 1987)

The kinetics of the oxidation of twenty-four monosubstituted benzyl alcohols by ethyl chlorocarbamate (ECC) have been studied in aqueous acetic acid solution, in the presence of perchloric acid. The main product of the oxidation is the corresponding benzaldehyde. The reaction is first order with respect to the alcohol, ECC, and hydrogen ion. The oxidation of [α,α-D_2]benzyl alcohol indicated a primary kinetic isotope effect, k_H/k_D=5.40 at 298 K. The value of solvent isotope effect, $k(H_2O)/k(D_2O)$, is 1.85 at 298 K. Addition of ethyl carbamate does not affect the reaction rate. $[EtOC(OH)NHCl]^+$ has been postulated as the reactive oxidizing species. The rates of oxidation of para- and meta-substituted benzyl alcohols show excellent correlation in Taft's dual substituent parameter equation, with negative reaction constants. The rates of the ortho-substituted compounds correlate well in Charton's equation of inductive, resonance and steric substituent parameters. A mechanism involving simultaneous transfer of a hydride ion from the C–H bond and of a proton from the O–H bond to the oxidant is proposed.

The use of halocarbamates in preparative organic chemistry is well documented.[1] We have been interested in the elucidation of the mechanism of the oxidations by *N*-halogeno reagents for quite some time[2] and have reported the oxidation of aliphatic alcohols by sodium ethyl chlorocarbamate recently.[3] In this article, we report the oxidation of several ortho-, meta-, and para-substituted benzyl alcohols by ethyl chlorocarbamate (ECC) in aqueous acetic acid solution, in the presence of perchloric acid. Attempts have been made to correlate rate and structure in this reaction. The mechanistic aspects are discussed.

Experimental

General. Acetylaminobenzyl alcohols were prepared by the reported methods.[4-6] All other alcohols were commercial products. They were purified by either recrystallization or distillation. [α,α-$^2D_2$]Benzyl alcohol was prepared by the reduction of ethyl benzoate by lithium aluminium deuteride.[7] ECC was prepared by treating ethyl carbamate (Merck) with sodium hypochlorite.[8] Perchloric acid (Merck) was used as a source of hydrogen ions. Deuterium oxide (99.4%) was supplied by BARC, Bombay.

Product Analysis. The product analysis was carried out under kinetic conditions i.e., with an excess of the alcohol over ECC.

In a typical experiment, benzyl alcohol (4.9 g, 0.05 mol) and ECC (1.46 g, 0.01 mol) were made up to 100 ml in 1:1 (v/v) acetic acid–water, in the presence of 0.5 M perchloric acid (1 M=1 mol dm^{-3}). The reaction mixture was allowed to stand in the dark for ca. 12 h to ensure completion of the reaction. It was then treated with an excess of (250 ml) of a saturated solution of 2,4-dinitrophenylhydrazine in 2 M HCl and kept in refrigerator for ca. 10 h. The precipitated 2,4-dinitrophenylhydrazone (DNP) was filtered off, dried, weighed, recrystallized from ethanol, and weighed again. The product was identical (mp and mixture mp) with an authentic sample of DNP of benzaldehyde. The yields of DNP, before and after recrystallization, were 2.75 g (96%) and 2.57 g (90%) respectively. In similar experiments, with other alcohols, the yields of DNP, after recrystallization, were 84 to 93%.

Kinetic Measurements. The pseudo-first-order conditions were attained by keeping a large excess (10-fold or greater) of the alcohol over ECC. The reactions were carried out at constant temperature (±0.1 K) and in flasks blackened from the outside to prevent any photochemical reaction. The reactions were followed iodometrically up to 70% of the reaction. The solvent was 1:1 (v/v) acetic acid–water. The pseudo-first-order rate constant, k_1, was computed from the linear (r>0.98) plots of log[ECC] versus time. The specific rate constant, k, was obtained by the relation $k=k_1/[H^+]\times$[Alcohol]. Preliminary experiments showed that the reaction is not sensitive to ionic strength (0.1—1.0 M) hence no attempt was made to keep it constant. Duplicate kinetic runs showed that the rates were reproducible to within ±3%. The average errors in the values of ΔH^*, ΔS^*, and ΔG^* (at 298 K) are ±3 kJ mol^{-1}, ±5 J mol^{-1} K^{-1}, and ±4 kJ mol^{-1} respectively.

Results

The oxidation of benzyl alcohols by ECC in acid solutions results in the formation of the corresponding benzaldehydes. The overall reaction may be written as follows (Eq. 1).

$$PhCH_2OH + EtOOCNHCl \longrightarrow PhCHO + EtOOCNH_2 + H^+ + Cl^- \quad (1)$$

Rate Laws. The reaction was found to be first order with respect to ECC. Individual kinetic runs were strictly first order with respect to ECC. Further the first-order rate coefficients do not vary with the initial concentration of the oxidant. The effect of variation of the concentration of alcohol on the reaction shows that the reaction is of first order with respect to the alcohol also. The reaction rate increases linearly with an increase in the concentration of hydrogen ion (Table 1).

Isotope Effects. To ascertain the importance of the cleavage of α-C–H bond in the rate-determining step, the oxidation of [α,α-D_2]benzyl alcohol was studied. The results show that the value of primary kinetic isotope effect, k_H/k_D, is 5.40 at 298 K (Table 2).

The oxidation of benzyl alcohol was studied in 95% deuterium oxide. The rate constants for the oxidation in H_2O and D_2O are 10^7k=15.3 and 8.27 $M^{-2}s^{-1}$ respectively at 298 K. The value of solvent isotope effect, $k(H_2O)/k(D_2O)$=1.85. No acetic acid was added in this set of experiments.

Effect of Ethyl Carbamate. Addition of ethyl carbamate has no effect on the rate of oxidation (Table 3).

Induced Polymerization of Acrylonitrile. The oxidation of the alcohols by ECC in an atmosphere of nitrogen, failed to induce polymerization of acrylonitrile. Thus a one-electron oxidation, giving rise to free radicals, is unlikely.

Effect of Substituents. The rates of the oxidation of a series of monosubstituted benzyl alcohols were obtained at different temperatures between 298 and 318 K and the activation parameters were evaluated (Table 4).

Discussion

The activation enthalpies and entropies of the oxidation of the alcohols are linearly related (r=0.9864). The correlation was tested and found genuine by applying Exner's criterion.[9] The value of isokinetic temperature determined by Exner's method is 371 K. Current views do not attach much significance to the value of isokinetic temperature.[10] The linear correlation however, is a necessary condition for the validity of linear free energy relationships. It also implies that all the alcohols are oxidized by the same mechanism and the changes in rates are governed by changes in both enthalpy and entropy of activation.

There seems to be no report about the various equilibria and species present in an acidified aqueous solution of ECC. However, based on the reactions of structurally related *N*-haloarenesulfonamides,[11] one can visualize the following equilibria:

$$EtOOCNHCl + H_2O \rightleftharpoons EtOOCNH_2 + HOCl \quad (2)$$

$$2EtOOCNHCl \rightleftharpoons EtOOCNH_2 + EtOOCNCl_2 \quad (3)$$

Hence the probable oxidizing species are ECC, $EtOOCNCl_2$, and HOCl. Ethyl dichlorocarbamate can be ruled out as the oxidizing species in view of the strict first order dependence of the reaction rate on ECC. Moreover, the absence of an effect of ethyl carbamate on the reaction precludes both HOCl and $EtOOCNCl_2$ as the reactive species. Thus, the most likely oxidizing species is EtOOCNHCl. The linear increase in the oxidation rate with acidity suggests that ethyl chlorocarbamate is protonated to give a stronger oxidant and electrophile (Eq. 4).

$$EtOOCNHCl + H_3O^+ \rightleftharpoons \overset{+}{E}tOC(OH)NHCl + H_2O \quad (4)$$

The presence of a primary kinetic isotope effect confirms that the C–H bond is cleaved in the rate-determining step.

The rate of an acid-catalyzed reaction involving the pre-equilibrium proton transfer step[12] is expected to be 2.5—3.0 times faster in D_2O than in H_2O. Labile hydrogens like those present in hydroxyl group undergo rapid exchange in D_2O, and the O–H/O–D isotope effect may neutralize the rate-enhancing effect of D_2O or even result in a slower rate in D_2O. The observed solvent isotope effect ($k(H_2O)/k(D_2O)$=1.85) shows that the k_{OH}/k_{OD} isotope effect is substantially large enough to cancel the effect of D_2O on pre-equilibrium(4). Thus a O–H bond rupture in the rate-determining step is indicated.

Correlation Analysis of Reactivity. (i) Para- and Meta-Substituted Benzyl Alcohols: Since the rates of the oxidation of para- and meta-monosubstituted benzyl alcohols failed to show satisfactory correlation with any single substituent parameter, the rates were subjected to analysis by Taft's[13] and Swain's[14] dual substituent parameter (DSP) equations. The oxidation rates of the *p*- and *m*- substituted compounds were separately correlated with σ_I and four different σ_R substituted constants in Taft's equation[13] and with the field and resonance substituents constants of Swain et al.[14] The results are summarized in Table 5. Both *p*- and *m*-series of substituted benzyl alcohols meet the basic requirements of minimum number of substituents required for the analysis by ESP equation,[15]

The results show that the rates of *p*-substituted benzyl alcohols show excellent correlation with σ_I and σ_R^{BA} values. The correlation with the other σ_R values and in Swain's equation[14] is relatively poor. We have used the standard deviation (SD) and f as the measure of goodness of fit. f has been defined by Dayal, et al.[13] as f=SD/RMS, where RMS is the root mean square of the data points (here $\log k/k_o$). The coefficient of multiple correlation, R, was also determined. The comparison on the f values shows that f is smaller for the σ_R^{BA} scale than those for other scales by the factors of ca. 3 to ca. 7. Therefore, it is apparent that the rates of the oxidation of *p*-substituted benzyl alcohols by ECC correlate best with σ_I and σ_R^{BA} values.

The rates of the oxidation of *m*-substituted compounds show excellent correlation with σ_I and σ_R^o

Table 5. Correlation of the Rates of the Oxidation of Para- and Meta-Substituted Benzyl Alcohols by ECC with Dual Substituent Parameters[a]

σ_R^o		σ_R^{BA}		σ_R^-[b]		σ_R^+		Swain et al.[c]	
SD	f	SD	f	SD	f	SD	f	SD	f
				Para-substituted					
0.09	0.11	0.03	0.04	0.21	0.24	0.21	0.26	0.11	0.13
				Meta-substituted

a) Temperature 298 K, SD=standard deviation, f=SD/RMS of $\log k/k_o$, σ_I and σ_R values are from Ref. 13. b) Data for NHCOMe and OPh were not considered, σ_R^- values are not available. c) Field and resonance substituents constants are from Ref. 14.

Table 6. Temperature Dependance of the Reaction Constant[a]

Temp/K	ρ_I	ρ_R[b]	λ	R	SD	f
			Para-substituted			
298	−2.27	−2.35	1.04	0.9996	0.03	0.04
308	−1.87	−2.00	1.07	0.9923	0.10	0.11
318	−1.51	1.58	1.05	0.9986	0.04	0.06
			Meta-substituted			
298	−2.70	−1.28	0.47	0.9995	0.03	0.03
308	−2.06	−1.10	0.53	0.9944	0.07	0.09
318	−1.73	−1.05	0.61	0.9825	0.11	0.16

a) R=Coefficient of multiple correlation, $\lambda=\rho_R/\rho_I$, SD=standard deviation, f=SD/RMS of $\log k/k_o$. b) ρ_R is ρ_R^{BA} and ρ_R^o for para- and meta-substituted compounds respectively.

substituent constants, though the discriminating factor for the precision of fit with the other σ_R scales or in Swain's equation[14] is not as sharp as in the case of *p*-substituted compounds. In fact the correlation with σ_R^{BA}, $\sigma_{\bar{R}}$, and in Swain's equation meet the requirement[16] for a satisfactory fit ($f<0.1$). Even the correlation with σ_R^+ is not very poor. This agrees with the observation of Ehrenson, Brownlee and Taft[16] that the correlation of *m*-substituted compounds is generally best with σ_R^o constants and *m*-substituted compounds are less discriminating.

The reaction constants and statistical data at different temperatures are given in Table 6.

The value of λ^p (1.05) shows that the oxidation of *p*-substituted compounds is almost equally susceptible to localized and delocalized effects. The selectivity of the reaction decreases at higher temperatures and the decrease is of similar order for both the localized and delocalized effects, reflected in the almost constant value of λ^p at different temperatures.

In the oxidation of *m*-substituted compounds, the values of λ are between 0.47 and 0.61, suggesting the greater importance of the localized effect. In this case, at higher temperatures, the decrease is more pronounced in the localized reaction constant, resulting in a gradual increase in the value of λ^m with an increase in the temperature.

(ii) **Ortho-Substituted Benzyl Alcohols:** The rates of the oxidation of *o*-substituted benzyl alcohols were analyzed in the terms of Taft's polar and steric substituent constants separately.[17] The results are given in Eqs. 5 and 6.

$$\log k/k_o = -2.10\,\sigma_o^* \quad (5)$$

$R=0.9324$; SD=0.41; $n=8$

$$\log k/k = -0.33\,E_s \quad (6)$$

$R=0.2783$; SD=0.54; $n=8$

The substituent NHCOMe was not included since the substituent constants are not available. The results show that the observed reactivity is not compatible with either the size of the substituents or with their Taft's polar substituent constant.

Since the single parameter equations did not yield satisfactory correlations, the rates were analyzed using Charton's method.[18] The rate constants were correlated with Eqs. 7 and 8, where σ_I, σ_R, and V are inductive, resonance, and steric substituent constants respectively and the values used were those compiled by Aslam et al.[19]

$$\log k_{ortho} = \alpha\sigma_I + \beta\sigma_R + h \quad (7)$$

$$\log k_{ortho} = \alpha\sigma_I + \beta\sigma_R + \phi V + h \quad (8)$$

In multiple regression analysis using Eq. 7, the correlation coefficient is poor and the standard deviation is high (Eq. 9).

$$\log k_{ortho} = -2.66\sigma_I - 2.21\,\alpha_R - 4.66 \quad (9)$$

$R=0.8714$; SD=0.45; $n=9$

The absence of a significant correlation with Eq. 7 leads to the conclusion that the electrical effects alone are not sufficient to account for the ortho-substituent effect in this reaction.

The correlation with Eq. 8 were performed at temperatures 298, 308, and 318 K. The results are given in Eqs. 10—12 respectively.

$$\log k = -3.01\,\sigma_I - 2.04\sigma_R + 1.58V - 5.10 \quad (10)$$

$R=0.9962$; SD=0.09; $n=9$

$$\log k = -2.57\sigma_I - 1.79\sigma_R + 1.27V = 4.96 \quad (11)$$

$R=0.9877$; SD=0.14; $n=9$

$$\log k = -1.97\sigma_I - 1.25\sigma_R + 0.98V - 4.30 \quad (12)$$

$R=0.9827$; SD=0.15; $n=9$

The effect of *o*-NO_2 group is consistent with the orthogonal conformation.

The significance of the correlation was tested by means of an F-test. The confidence levels for the F-test are greater than 99%. The confidence levels for

the significance of α, β, and ϕ terms were obtained by means of a Student's T-test. The confidence level of the T-test is >99%, indicating the operation of significant inductive, resonance and steric effects. These results show that this reaction belongs to Case 1 of the classification given by Charton.[18]

The contribution of the resonance effect to the polar effect[18] is given by Eq. 13.

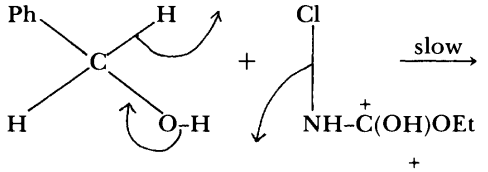
$$p_R = \frac{100|\beta|}{|\alpha| + |\beta|} \quad (13)$$

The value of P_R is found to vary between 38.8 and 41.1. This shows that the inductive effect is more pronounced than the resonance effect. The contribution of the steric effect, p_S, was calculated using the Eq. 14.

$$p_S = \frac{|\phi|\ 100}{|\alpha| + |\beta| + |\phi|} \quad (14)$$

The percentage contribution of the steric effect is ca. 23%, pointing to a considerable steric effect in the reaction.

Mechanism. The presence of a primary kinetic isotope effect confirms that in the rate-determining step, α-C–H bond is cleaved. In this respect this reaction resembles the oxidation by chloramine-B and bromamine-B.[2] However, it differs from the other oxidations in the observation of a solvent isotope effect. In the oxidations by chloramine-B and bromamine-B[2] the rate in D_2O is more than that in H_2O. This indicates that the rupture of the O–H bond is also taking place in the rate-determining step. Thus a simultaneous transfer of a hydride ion from the C–H bond and a proton from hydroxyl groups is indicated (15). The negative polar reaction constants points to an electron-deficient carbon center in the transition state. The correlation of the rates of *p*-substituted benzyl alcohols with σ_R^{BA} constants also suggests a weak resonance interaction between a developing positive center and the substituent. Thus it seems that in the transition state the cleavage of the C–H is somewhat ahead of the rupture of the O–H bond. However, it may be mentioned here that the formation of a carbonyl group is also expected to be favored by an electron-releasing substituent.



$$PhCHO + HCl + H_2N\overset{+}{C}(OH)OEt \quad (15)$$

$$H_2N\overset{+}{C}(OH)OEt \xrightarrow{fast} H_2NCOOEt + H^+ \quad (16)$$

The positive regression coefficient for the steric term corresponds to a steric acceleration of the reaction by the ortho-substituent. This can be explained on the basis of high ground state energy level of the starting material. Since the crowding is relieved in the product aldehyde as well as in the transition state leading to it, the transition state energy of the crowded (ortho-stbstituted) and uncrowded alcohols do not differ much and steric acceleration, therefore, results.

Thanks are due to the University Grants Commission, India, for the financial support.

Liquid Crystalline Catalysis. Kinetics of the Rearrangement of Allyl *p*-(Dimethylamino)benzenesulfonate in a Smectic B-Solvent

Paolo De Maria,* Bruno Samorì,† Anna Tampieri,† and Paolo Zani†
Dipartimento di Chimica Organica, Via Archirafi 20, 90123 Palermo, Italy
†Dipartimento di Chimica Organica, Viale Risorgimento 4, 40136 Bologna, Italy
(Received March 9, 1987)

Allyl *p*-(dimethylamino)benzenesulfonate (ASE) was found to promptly rearrange to the corresponding quaternary zwitterion (AZWI) in a smectic, liquid crystalline solvent (OS 35) 4-pentylcyclohexyl 4-propylcyclohexanecarboxylate. On the contrary, this reaction does not occur in isotropic solvents. In the present study we investigate the effect of temperature and of reactant concentration on the reaction rate. A plot of log k vs. $1/T$ shows a strog upward curvature. In addition, the rate constant, k, strongly depends on ASE concentration: relevant rate depression occurs beyond a threshold value of solute concentration, which in turns depends on temperature. These results are interpreted in terms of reaction mechanism and solute-solvent interaction. From these results we can conclude that smectic B phase has a strong catalytic effect on this particular kind of nucleophilic displacement. Furthermore, catalysis does not depend on solute expulsion from the bulk of the phase; finaly, the detailed mechanism of the catalytic effect may depend on the different location of the solute in distinct solubilization sites existing within the smectic mesophase.

In view of the interest in the field of reactivity within anisotropic media,[1a—e] we have recently exploited the use of smectic (Sm) mesophases in order to prove catalytical effects that the internal organization of these mesomorphic solvents can exert on properly chosen model reactions. Particularly we have reported that smectic B (SmB) solvents (ZLI 1409;[2a,b] ZLI 1544;[2a] ZLI 1756;[2c] OS 44;[2b] OS 53;[2d] OS 35;[2d]) can induce relevant rate variations on the quaternization reaction of *p*-(dimethylamino)benzenesulfonic esters (Scheme 1). The rearrangement of pure solid methyl *p*-(dimethylamino)benzenesulfonate (MSE) to the corresponding quaternary ammonium zwitterion (Scheme 1) was previously described as an example of reaction promoted by appropriate intermolecular orientations in the solid phase.[3] On the contrary allyl *p*-(dimethylamino)benzenesulfonate (ASE) does not rearrange in its crystalline state because of a different kind of molecular orientation within the crystal lattice.[4]

When both esters (MSE and ASE) are dissolved in SmB mesophases a very clean quaternization reaction (Scheme 1) is promoted at a rate higher than that in the melts. On the other hand MSE and ASE do not react at any detectable rate when dissolved in common organic (isotropic) solvents or even in the nematic (N) phases of the investigated liquid crystals. This is the first instance in which Sm solvents are shown to promote a rearrangement which requires a precise orientational control to take place.

Now we report here a more complete kinetic treatment showing the peculiar effects of solute concentration and temperature on the rate of ASE quaternization which are not explainable in the framework of reactivity in common (isotropic) solvents but require a detailed knowledge of the phase equilibria within the SmB liquid crystalline solvent.

OS 35

Scheme 1.

Results

We have published preliminary results[2] from which it stems that the quaternization reactions of ASE and MSE (Scheme 1) are simple second order processes and that the mechanisms, most likely, are dimeric, S_N2' type pathways. However these are limited results as those concerning MSE were obtained in a liquid-crystalline solvent (ZLI 1409) which is not transparent in the spectral region where reactant and product do absorb. The opacity of the solvent to UV light prevented us from following the reaction course directly. The results concerning ASE were obtained at a single temperature and within a narrow range of solute concentrations. From our previous work it emerged that most kinetic features remained to be clarified. A study of the change of the observed rate constant, k, with temperature was still to be done in order to provide useful information on the activation parameters, and, therefore, on the mechanistic details of the assistance assured by the liquid crystalline solvent to the reaction. In fact, interesting temperature effects have been recently observed by Weiss and collaborators in reactions performed within liquid crystalline phases.[5]

Temperature Effect. Kinetic measurements on ASE conversion to AZWI were carried out in the temperature interval $44>T>28$ °C in the SmB phase of the OS-35 liquid crystalline solvent. Provided that the concentration of ASE was less than that of the threshold value (see below), k is strictly second order at each individual temperature. The values of k at the different temperatures and the investigated concentration ranges where k turned out to be strictly second order are reported in Table 1. An Arrhenius-type plot of log k vs. $1/T$ (Fig. 1) shows a strong upward curvature. Apparently log k tends to infinity when T approaches the transition (SmB→N) temperature of 49 °C. However because of the superimposed concentrations effect (see following section) the temperature interval $44<T<49$ °C is not experimentally accessible to our kinetic technique. For example, even at 44 °C k is rigorously independent of ASE concentration only when [ASE]$<10^{-2}$ mol·dm^{-3}.

Concentration Effect. The observed second order rate constant, k, is by no means independent of total solute concentration at "high" initial ASE concentration. It sharply decreases beyond a definite value of concentration, which, in turn, depends on temper-

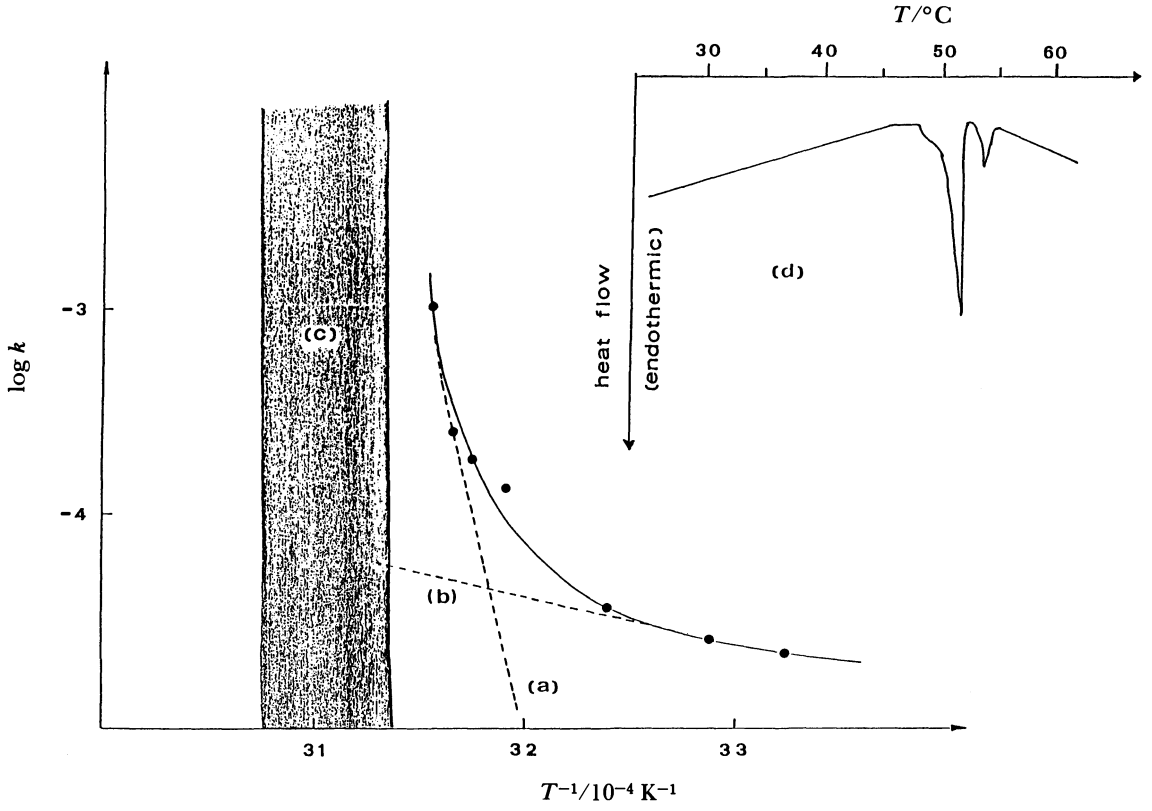

Fig. 1. Arrhenius-type plot for the ASE quaternization in OS 35 SmB phase at ASE concentrations lower than those of the temperature-dependent threshold values (see text and Fig. 2). Lines (a) and (b) are hypothetical straight lines extrapolated from the higher- and lower-temperature data, respectively. The shaded area (c) represents the temperature interval corresponding to the width of the Differential Scan Calorimetry (DSC) peak in (d). Profile (d) is the DSC trace showing the Smectic→Nematic and Nematic→Isotropic transition for the reacting solution at ASE concentration equal to 1.05×10^{-2} mol·dm^{-3}.

ature. The dependence of k on concentration, at one temperature (40 °C), is graphically depicted in Fig. 2. We have evidence that the concentration value at which rate depression starts (threshold concentration), dramatically decreases with increasing temperature. For example, while k is practically coincident with the values determined in more dilute solutions at 36 °C and initial [ASE] 10^{-1} mol·dm^{-3}, at 44 °C and initial [ASE] $2\cdot10^{-2}$ mol·dm^{-3} k is some 20 times lower than the values determined in dilute solutions (Table 1). More dramatically, at 47 °C, where the solvent is still in its smectic phase, disappearance of ASE was not detected after 11 days even at initial [ASE] as low as 5×10^{-4} mol·dm^{-3}

Discussion

The "real" catalytic effect of OS 35 SmB mesophase

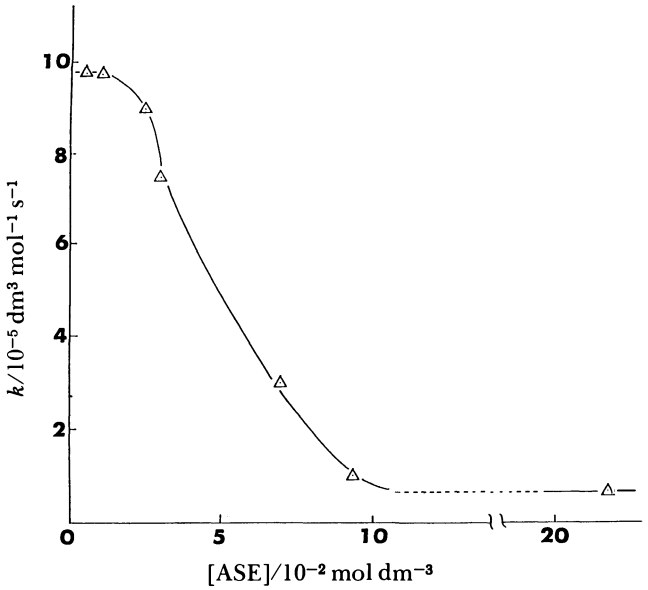

Fig. 2. Dependence of the kinetic constant on the solute concentration at 40 °C. The threshold value of ASE concentration at which rate depression starts and the second-order constant becomes dependent on total solute concentration is clearly displayed.

on the ASE quaternization is clearly displayed by the following data. Whereas 15% conversion to AZWI is achieved in one day at 44 °C in the melt phase, 67% conversion can be obtained in SmB diluted solutions under the same conditions of temperature and time. Moreover we found total conversion of ASE after five days in OS 35 at 44 °C and only after 26 days in the pure melt. From the kinetic data at different temperatures (Fig. 1) it can be seen that the second-order rate constant increases with temperature far more than predicted by a "normal" Arrhenius behavior. To explain this anomalous curvature the most likely reason is that the assistance provided by the SmB solvent is varying with temperature and that this effect is being superimposed upon the "normal" Arrhenius behavior.

The rate breakdown observed with increasing "total" solute concentration also deserves some comments. The sigmoidal shape (Fig. 2) can be explained by a very sudden loss of solvent cooperative effects on the reaction. This discontinuity resembles those observed for thermodynamic parameters in phase transitions.[6] In addition this is further clearcut evidence that the liquid crystalline catalysis cannot be ascribed only to solute bulk aggregation out of the solution. Optical microscopy shows[7] that such solute aggregation occurs only at the highest [ASE] concentrations where the reaction rate becomes very low. Turning again to the temperature effect, one can recall that in general cases the simplest explanation of a curved Arrhenius plot (as in Fig. 1) is the existance of two competitive reaction mechanisms[8] each with its own A and E_a values (sketched by lines (a) and (b) in Fig. 1) and dominating in two different temperature intervals. Therefore a breakdown from linearity occurs at intermediate temperatures when both mechanisms are operating. However this often happens over a temperature interval much wider than the present one. Furthermore two independent mechanisms are hardly conceivable for ASE quaternization. On the contrary our results can be better explained considering that our reaction was not a single-step process due to the occurrence of the reaction in more than one catalytic site provided by

Table 1. Temperature Effect on the Second-Order Rate Constant k in the Quaternization Reaction of ASE in OS 35 SmB-Solvent

Temperature/°C	k/dm^3 mol^{-1} s^{-1}	[ASE]/mol dm^{-3}(intervals)[a]	
28	2.5×10^{-5}	9.8×10^{-3}	2.45×10^{-2}
31	2.7×10^{-5}	9.8×10^{-3}	2.45×10^{-2}
36	3.3×10^{-5}	9.8×10^{-3}	1.00×10^{-1}
40	9.8×10^{-5}	9.8×10^{-3}	1.00×10^{-2}
42	13.0×10^{-5}	4.9×10^{-3}	9.8×10^{-3}
43	15.0×10^{-5}	4.9×10^{-3}	9.8×10^{-3}
44	45.0×10^{-5}	4.9×10^{-3}	9.8×10^{-3}

a) Investigated concentration intervals of ASE where k is strictly second order. At higher values, depending upon temperature, k decreases with [ASE] as discussed in concentration effect.

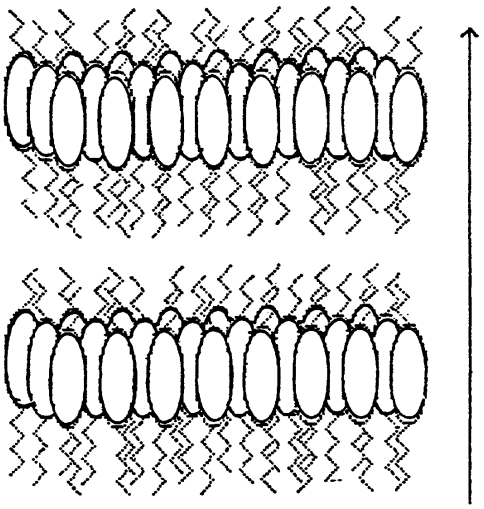

Fig. 3. Layered structure of Sm liquid crystalline media. The rigid-core- and alkyl-chain-sublayers are sketched by ellipsoids and tails respectively.

the solvent. In fact we recently presented evidence[7] arising from linear dichroism (LD) that ASE molecules are located in two different sites within the SmB phase of OS 35.

OS 35 molecules have a fairly rigid core and flexible alkyl chains. This molecular shape leads to a layered structure for the SmB, in which alternating sequencies of sublayers are determined by the alignment in planes of the centers of gravity of adjacent cores or of adjacent tails (Fig. 3). The rigid cores and the more flexible aliphatic tails may therefore provide two distinct solubilization sites for ASE. The LD technique revealed that one site, (characterized by an ASE absorption maximum at 263 nm in the LD spectrum) is more ordered and differently populated than the other (LD maximum at 277 nm). This more ordered site is likely provided by the core. In addition it appears from the same LD data that the partition of ASE between these two sites strongly depends upon temperature. These results may be interpreted in kinetic terms as a sort of pre-equilibrium type situation in which the nature and relative population of the two sites are strongly temperature dependent. Within this framework the concave shape of Fig. 1 should be explained as a positive deviation at lower temperature from the Arrhenius line (a). Similar but far less pronounced effects played by cooperative solvent assistance were recently found even in isotropic solvents such as 2-buthoxyethanol–water and *t*-butyl alcohol–water neutral ester hydrolysis.[9a,b] These effects also led to curvatures in the Arrhenius plots and were attributed to the assistance by aggregates (called "moving units") whose formation depends in a nonlinear manner upon temperature and molar fraction of the solvents.

Experimental

ASE was prepared as previously described.[2b,3] After 2 recrystallizations from petroleum ether (bp 40—60 °C) a material of mp 39—40 °C was obtained. OS 35 was kindly supplied by E. Merck (Darmstädt).

Kinetic Measurements. The general procedure employed can be summarized as follows: ASE was dissolved in the OS 35 solvent (0.1 g. samples) at 50 °C by quick injections of volumes of a diethyl ether solution of known concentration. After complete evaporation of the ether, the homogeneous solution of ASE was rapidly cooled down into its SmB phase by immersion in a bath thermostatted at the desired temperature. Portions (ca. 0.01 g) of the reaction mixture were taken at appropriate intervals and the reaction quenched by dilution with RS-grade ethanol (5 cm^3). The absorbance of these ethanolic solutions of ASE was determined with a Beckmann DU or a Varian spectrophotometer at λ=284 nm. The kinetics were followed[2d] over at least three half lives and were second order according to the equation $-d[ASE]/dt=k[ASE]^2$

Least-squares-slopes of these second order plots gave average rate constants, k, accurate to ±8% at worst.

DSC Measurements. DSC measurements were carried out on a Perkin Elmer Calorimeter Model DSC-2. scan rate was 1 °C min^{-1}. Aluminium containers of 20×10^{-6} dm^3 capacity were used.

We thanks Prof. D. Spinelli (Bologna) and Dr. B. G. Cox (University of Stirling) for helpful discussions. Technical assistance by Dr. Teresa Mutalipassi is also gratefully acknowledged.

Molecular Rearrangements. XXIX.† Thermolysis of Aromatic Ketoximes

M. Z. A. Badr,* M. M. Aly, S. A. Mahgoub, A. M. Fahmy, and A. A. Atallah
Chemistry Department, Faculty of Science, Assiut University, Assiut, A. R. E.
(Received March 30, 1987)

Thermolysis of benzophenone *O*-benzoyloxime leads to the formation of NH_3, CO_2, benzene, biphenyl, benzophenone, benzanilide, benzonitrile, benzoic acid, 2-phenylbenzoxazole, salicylaldehyde and its *p*-isomer. Analogous results were also obtained on thermolysis of acetophenone *O*-benzoyloxime. Similarly, benzophenone and/or acetophenone *O*-benzyloximes give pyrolysis products of the same nature in addition to others corresponding to the benzyl moiety. Thermolysis of deoxybenzoin oxime gives NH_3, toluene, benzonitrile, bibenzyl, benzil, benzyl alcohol, and 2-phenylindole. Moreover, its *O*-benzoyl ether affords in addition to these products, benzoic acid and benzyl benzoate. The main feature of these pyrolyses is the homolysis of the N–O bond together with either *O*-benzyl or *O*-benzoyl bonds providing free radicals that undergo different reactions involving H-abstraction, dimerization, fragmentation, rearrangement and cyclization to form the identified products.

Benzophenone oxime was reported earlier not to undergo the well-known Beckmann rearrangement on heating between 100 and 150 °C although the oxime salt is characterized by this reaction irreversibly to give mainly benzanilide.[1] However, prolonged heating under these conditions leads to hydrolysis of benzanilide into aniline and benzoic acid. The photo-Beckmann rearrangement of benzaldehyde oximes to the corresponding amides was suggested at one time to proceed through the intermediate oxaziridines.[2] On the other hand, other workers found that *N,O*-diacylhydroxylamines on pyrolysis can act as free-radical initiators for polymerization.[3]

Recently, flash vacuum pyrolysis of acetophenone and/or benzophenone oximes[4] affords nitriles, benzoxazoles, arenes and biaryls which were presumably formed from both iminyl and iminoxyl radicals. Moreover, isomerization of benzophenone oxime into benzanilide was also observed to take place in the ion source of mass spectrophotometer and the process was attributed to a Beckmann-type rearrangement of the corresponding molecular ion via a thermal mechanism.[5] Such results prompted us to reinvestigate the thermal Beckmann rearrangement in order to add more clear mechanistic information. The present work deals with the thermolysis of *O*-benzoyl- and/or *O*-benzyl oximes of acetophenone and benzophenone.

Pyrolysis of benzophenone *O*-benzoyloxime by reflux in air for 30 min leads to the formation of ammonia, carbon dioxide, benzene, biphenyl, benzophenone, benzanilide, benzonitrile, and benzoic acid.

When thermolysis was affected by heating in a sealed tube under nitrogen atmosphere, at 200 °C for 8 h, the previous products were obtained in addition to 2-phenylbenzoxazole, salicylaldehyde and its *p*-isomer; whereas the yield of benzoic acid was greatly suppressed.

Thermolysis of acetophenone *O*-benzoyloxime gives ammonia, carbon dioxide, biphenyl, acetophenone, acetanilide, acetonitrile, 2-methylbenzoxazole, and benzoic acid.

The formation of these products can be assumed to follow the series of reactions shown in Scheme 1, which implies the preliminary homolysis of benzoyl–O bond (route a) forming iminoxyl and benzoyl radicals. The iminoxyl radicals may undergo the Beckmann rearrangement into the corresponding *N*-acylanilide which is rationalized to proceed through a mechanism involving an oxaziridine intermediate **1** and a biradical intermediate **2**.[6]

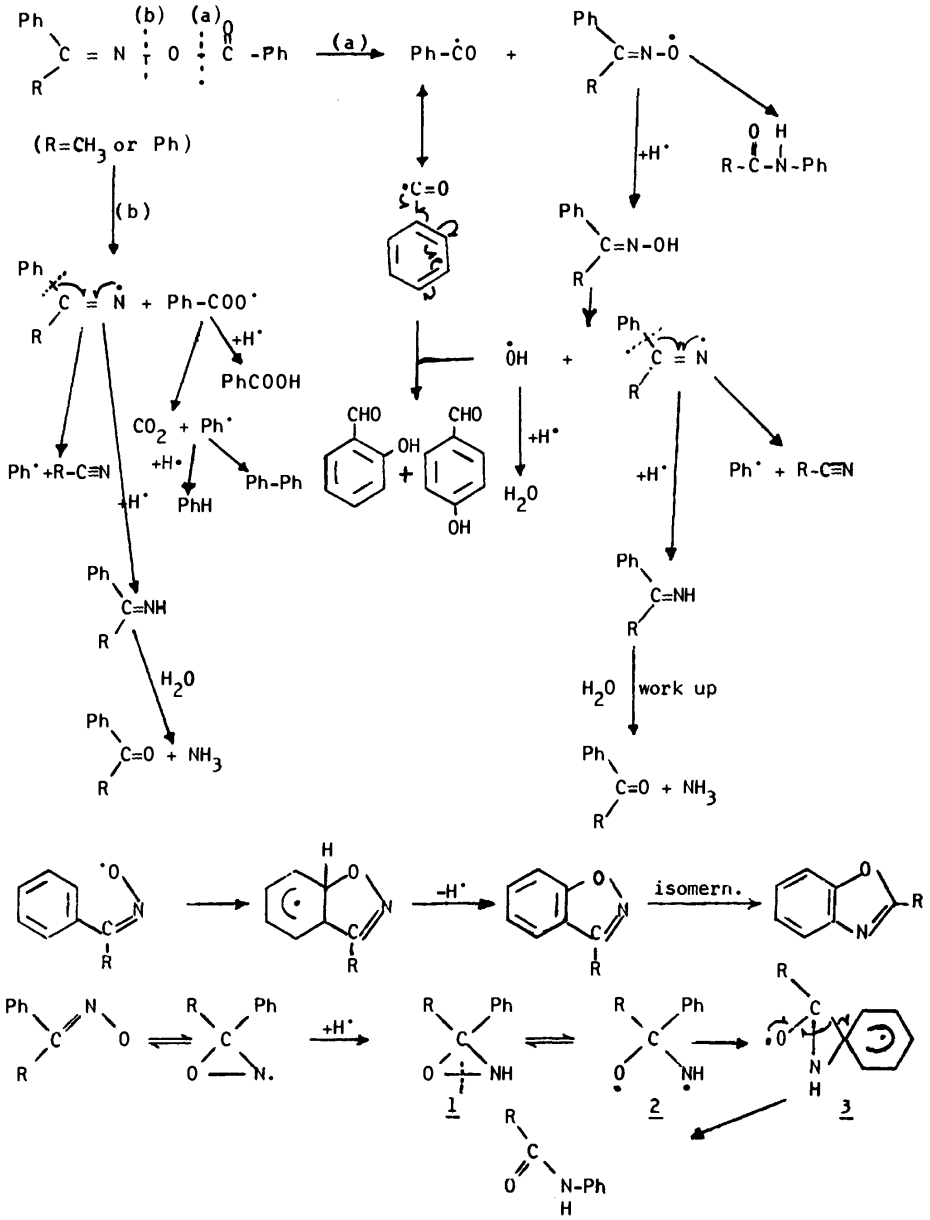
The formation of acetanilide, in case of acetophenone oximes under the present conditions, rather than its isomer *N*-methylbenzamide provides strong evidence for the selective migration of the phenyl as compared with the methyl group. This result is in agreement with the observed migratory aptitude values of such groups and can be explained in terms of the stability of the bridged intermediate radical **3** as compared with the corresponding intermediate of methyl migration.[7] In other cases alkyl migration has been recorded.[8] The iminoxyl radicals may abstract hydrogen forming the corresponding unsubstituted oxime, which subsequently undergoes homolysis of the N–O bond to form iminyl and hydroxyl free radicals. The iminoxyl radicals can undergo cyclization into benzoxazole derivative.[4]

The iminyl radicals may abstract hydrogen forming the corresponding imine which is considered to be the precursor of ammonia and the corresponding ketone during working-up processes.

The formation of salicylaldehyde and its *p*-isomer may be due to coupling of hydroxyl radicals in the *o*- and/or *p*-positions of the tautomeric benzoyl radicals.

Such a mechanism was further emphasized by the results obtained from the thermolysis of unsubstituted benzophenone oxime where ammonia, benzophen-

† Part (XXVIII), Photolysis and Thermolysis of Aryl Hydroxamic Acids. M. Z. A. Badr, A. M. Fahmy, S. A. Mahgoub, and M. M. Aly; XI IUPAC Symposium on Photochemistry; July 27 (1986); Lisboa; Portugal.

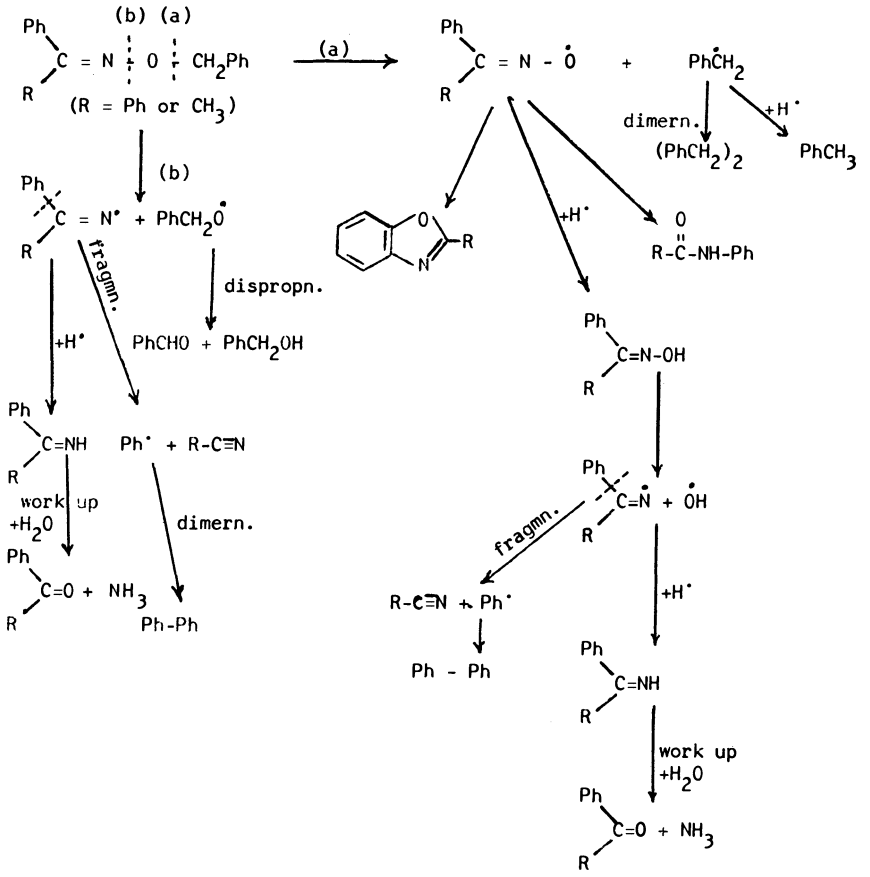


Scheme 1.

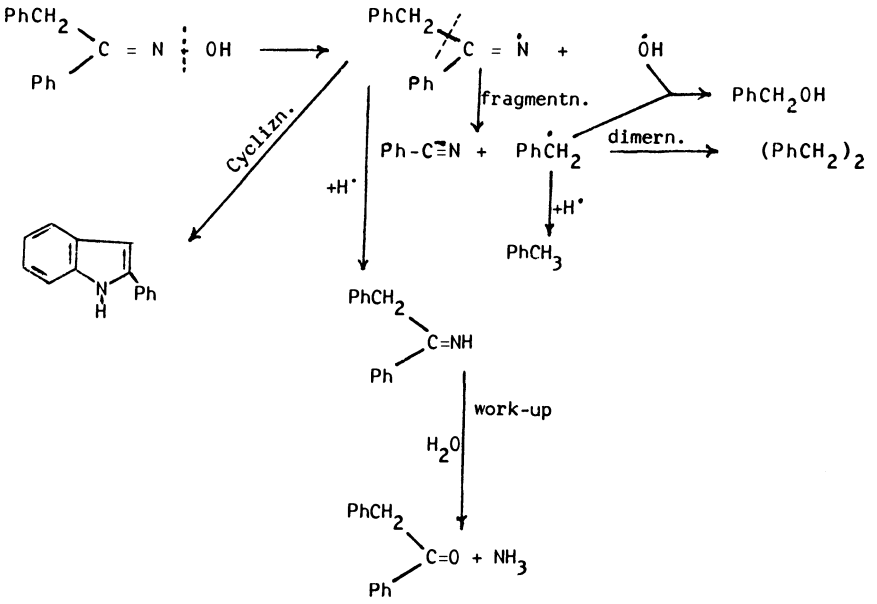
one, benzanilide and 2-phenylbenzoxazole were obtained, but no salicylaldehydes were detected among the products. However, such a mechanism cannot correlate for the formation of other products, namely; benzoic acid, biphenyl and carbon dioxide. Consequently, we have to take into consideration an alternative mode for homolysis of the benzophenone *O*-benzoyloxime molecules involving the N–O bond (route b) forming iminyl and benzoyloxyl radicals.

The normal fate of the iminyl radicals has been discussed previously, whereas the benzoyloxyl radicals may undergo decarboxylation into phenyl radicals which are the precursor of benzene and biphenyl through processes of H-abstraction or dimerization respectively. Furthermore, the benzoyloxyl radicals undergo predominantly H-abstraction forming benzoic acid. Although benzoic acid can be suggested to be formed from benzonitrile through hydrolysis, yet attempted hydrolysis of benzonitrile under comparable conditions does not afford benzoic acid.

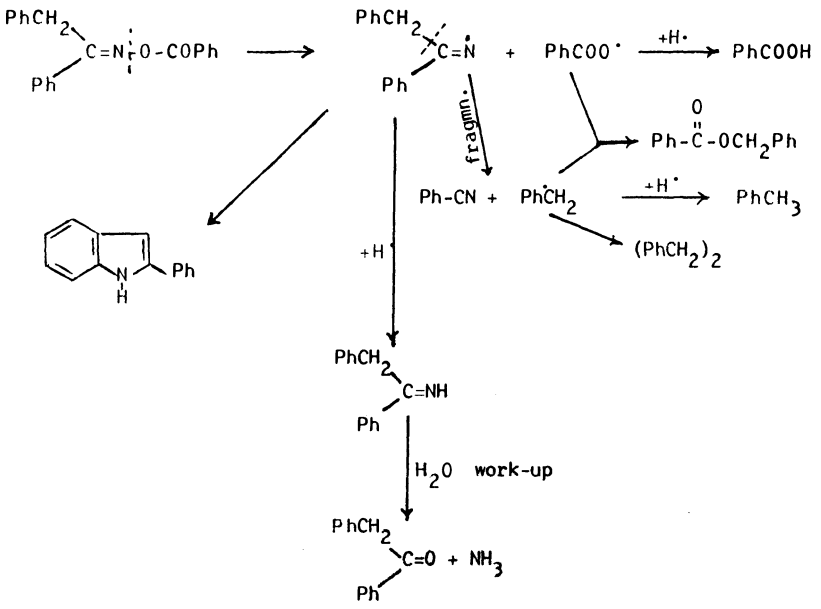
Thermolysis of benzophenone *O*-benzyloxime on heating in a sealed tube at 200 °C for 8 h. in absence of air gives, ammonia, toluene, benzaldehyde, benzyl alcohol, bibenzyl, biphenyl, benzophenone, and 2-phenylbenzoxazole. The formation of such products can be explained on basis of homolysis of benzyl–O bond (Scheme 2, route a) into iminoxyl and benzyl free radicals to a lesser extent than (route b) as shown by the relative amounts of products formed from both routes (cf. Table 1). Such bond homolysis although unfavorable as compared with the N–O bond as shown from bond energy values which are of the order of 68 and 48 kcal·mol^{-1}, yet the resonance stabilization of the benzyl radical so formed gives a driving



Scheme 2.



Scheme 3.



Scheme 4.

force for such process.

The normal fate of the iminoxyl radicals has been discussed previously, whereas the benzyl radicals are the precursor of toluene and bibenzyl through processes of H-abstraction and dimerization respectively. The formation of benzaldehyde and benzyl alcohol can be assumed to proceed through disproportionation of benzyloxyl radicals originating from the suspected homolysis of N–O bond (Scheme 2, route b).

Analoguous results were also obtained in case of acetophenone *O*-benzyloxime. Thermolysis of deoxybenzoin oxime under the same conditions leads to the formation of ammonia, toluene, benzonitrile, bibenzyl, benzil, benzyl alcohol, and 2-phenylindole. Similar results were also obtained in case of deoxybenzoin *O*-benzoyloxime where the previous products were also formed in addition to benzoic acid and benzyl benzoate. The formation of these products can be explained on similar grounds as shown in Schemes 3 and 4.

The main feature of deoxybenzoin oximes pyrolyses is the absence of the Beckmann rearrangement products, namely; α-phenylacetanilide ($PhCH_2-\overset{O}{\overset{\|}{C}}-NHPh$) or *N*-benzylbenzamide ($Ph-\overset{O}{\overset{\|}{C}}-\overset{H}{\overset{|}{N}}-CH_2Ph$), may be attributed to their thermal instabilities or more likely to the absence of the corresponding iminoxyl radical and consequently absence of its cyclization product, 2-benzylbenzoxazole, which implies that homolysis of deoxybenzoin oximes takes place in the N–O rather than the *O*-benzoyl bond.

Experimental

Melting points were measured with a Gallenkamp apparatus and are uncorrected. Thin-layer chromatography was carried out on glass plates covered with silica gel (25—40 mesh) and eluted with benzene–cyclohexane (2:1 v/v). Gas-liquid chromatography was carried out on a Perkin-Elmer Sigma 3B. Columns used are 4 ft.×4 mm. packed with 30% SE 30 on Chromosorb W (35—80 mesh), or 10% SE 30 on Celite (60—80 mesh), using nitrogen as a carrier gas. Molecular weight determination of some reaction products was carried out by Mass spectrophotometer, Model A. E. I. M. S. 902. Oximes were prepared by standard methods in the literature.[9] Acetophenone *O*-benzoyloxime, mp 98—100 °C. Benzophenone *O*-benzoyloxime, mp 101 °C. Acetophenone *O*-benzyloxime, bp 230 °C/20 mmHg (1 mmHg=133.322 Pa); mp 24 °C. Benzophenone *O*-benzyloxime, mp 55—56 °C. Deoxybenzoin oxime, mp 98 °C. Deoxybenzoin *O*-benzoyloxime, mp 75 °C.

Thermolysis of Oximes: The oxime (20 g) was heated either under reflux in air or in a sealed tube under nitrogen atmosphere at 250 °C for 24 h. The gases evolved were detected by standard chemical means (NH_3 detected by Nessler's reagent and CO_2 by baryta solution). The pyrolysate was first distilled under normal pressure up to 120 °C where the voltatile materials such as benzene, toluene are collected and identified. The remaining oil was separated into its constitutents by means of column chromatography over silica gel using gradient elution technique. The separated products were identified by physical constants; bps, mps, TLC, GLC, IR as compared with authentic samples.

The results are shown in Tables 1 and 2.

Preparation of Reference Compounds: α-Phenylacetanilide:[10] crystals from dilute ethanol, mp 117 °C. *N*-Benzylbenzamide:[11] needles from ethanol mp 105—106 °C. *N*-Methylbenzamide:[11] crystals from ethanol mp 82 °C. 2-Phenylindole:[12] crystals from ethanol mp 188—189 °C. 2-Methylbenzoxazole:[13] colorless oil, bp 200—201 °C. 2-Phenylbenzoxazole:[13] crystals from ethanol mp 101—102 °C.

(Received September 30, 1987)

Synopsis. The static magnetic susceptibilities of the stable cubane-type compounds of $[Mo_4S_4]^{m+}$ with a set of consecutive oxidation numbers have been measured in the temperature range from 2 to 300 K at the field strength of 0.5 T. $Na_3[Mo_4S_4(edta)_2]\cdot 10H_2O$ (m=5) has been found to be paramagnetic with S=1/2, whereas $Mg_2[Mo_4S_4(edta)_2]\cdot 22H_2O$ (m=4) and $Mg[Mo_4S_4(edta)_2]\cdot 12H_2O$ (m=6) to be diamagnetic. The electronic structure of the $[Mo_4S_4]^{m+}$ clusters is discussed on the basis of the MO theory from the magnetic properties of these compounds.

The cubane-type $[Mo_4S_4]^{m+}$ clusters have recently been synthesized and found to be stable for a set of consecutive oxidation numbers, m=4, 5, and 6.[1-3] A comparative investigation of $[Mo_4S_4]^{m+}$ clusters will lead to understanding the electronic structure of the clusters. We report herein the temperature dependence of static magnetic susceptibilities of the compounds including $[Mo_4S_4(edta)_2]^{n-}$ anions[4] in the three oxidation states over the range from 2 to 300 K. From the results, we discuss the electronic structure of the clusters.

Experimental

$Mg_2[Mo_4S_4(edta)_2]\cdot 22H_2O$ (m=4), $Na_3[Mo_4S_4(edta)_2]\cdot 10H_2O$ (m=5), and $Mg[Mo_4S_4(edta)_2]\cdot 12H_2O$ (m=6) were prepared by the methods described elsewhere.[1,2] These chemical compositions, particularly the contents of water, were determined by the X-ray crystallographical analyses[1,2] on referring to the results of the elemental analyses.[5] The magnetic susceptibility χ was measured by means of a Faraday-type magnetic balance[6] under the field at 0.5 T. To avoid loss of water of crystallization during the susceptibility measurements, we used the polycrystalline sample in the form of a compressed pellet immersed in liquid paraffin. The spin susceptibilities χ_s of the three compounds were obtained by subtracting the diamagnetic contribution χ_d from χ after correction for liquid paraffin. The diamagnetic susceptibility was determined experimentally from a $\chi-T^{-1}$ plot.

Results and Discussion

The spin susceptibilities of all the compounds, plotted as a function of temperature in Fig. 1, can be fitted to the Curie-Weiss law $\chi=C/(T-\theta)$ over the whole temperature range examined. The Curie constant C and the Weiss constant θ for the $[Mo_4S_4]^{m+}$ clusters are summarized in Table 1 together with the

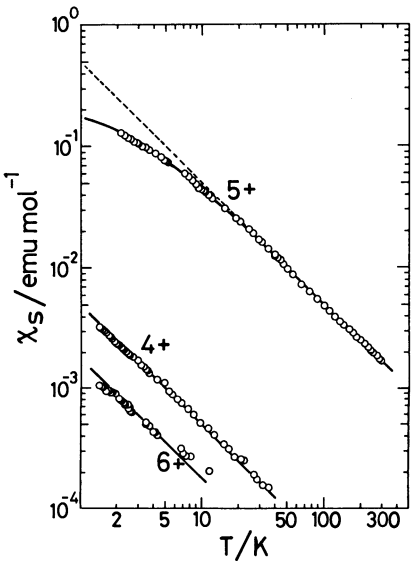

Fig. 1. Temperature dependence of spin susceptibilities of molybdenum compounds consisting of a cubane-type Mo_4S_4 cluster. Open circles represent experimental data. The susceptibilities calculated using Curie-Weiss law are shown by solid lines. The notations 4+, 5+, and 6+ stand for the compounds including $[Mo_4S_4]^{4+}$, $[Mo_4S_4]^{5+}$, and $[Mo_4S_4]^{6+}$ clusters, respectively.

Table 1. Curie Constant C, Weiss Constant θ, and Diamagnetic Susceptibility χ_d for the Molybdenum Compounds Including $[Mo_4S_4]^{m+}$ Clusters[a]

Compound	10^3C / emu K mol^{-1}	θ / K	$10^6\chi_d$ / emu mol^{-1}
$Mg_2[Mo_4S_4(edta)_2]\cdot 22H_2O$ (m=4)	4.9±0.3	0.0±0.2	−1000±20
$Na_3[Mo_4S_4(edta)_2]\cdot 10H_2O$ (m=5)	525±20	−2.0±0.2	−300±20
$Mg[Mo_4S_4(edta)_2]\cdot 12H_2O$ (m=6)	1.7±0.3	0.0±0.2	−410±20

a) 1 emu K mol^{-1}=4π cm^3 K mol^{-1}; 1 emu mol^{-1}=4π cm^3 mol^{-1}.

diamagnetic susceptibility χ_d. The Curie constant for $[Mo_4S_4]^{5+}$ is significantly large and is consistent with the presence of an $S=1/2$ moment per cluster with $g=2.32\pm0.02$; the g-factor being determined by the electron paramagnetic resonance measurements at room temperature. In contrast, the Curie constants for the other compounds are very small. There is a moment with $S=1/2$ per about 100 clusters for $[Mo_4S_4]^{4+}$ and a moment per about 300 clusters for $[Mo_4S_4]^{6+}$. The very small Curie constants observed in $[Mo_4S_4]^{4+}$ and $[Mo_4S_4]^{6+}$ are probably ascribed to extrinsic origin such as chemical impurities. Thus it is concluded that $[Mo_4S_4]^{4+}$ and $[Mo_4S_4]^{6+}$ are essentially diamagnetic, whereas $[Mo_4S_4]^{5+}$ is in the paramagnetic $S=1/2$ ground state.

X-Ray crystal structure analyses of the compounds consisting of $[Mo_4S_4(edta)_2]^{n-}$ ($n=2$, 3, 4) anions have revealed that the structures of the anions are very similar to each other except for a slight difference in the mean Mo–Mo bond distance and the volume of the cubane core.[2] Since the four Mo–Mo distances are almost completely identical in each compound, Mo tetramer can approximately be regarded as belonging to the T_d symmetry. Under this symmetry 4d electrons from the four Mo atoms could occupy six bonding orbitals (a_1+e+t_2) which have mainly Mo 4d character.[7–9] Energy difference between the bonding and antibonding orbitals would be on the order of magnitude of 25000 cm^{-1}, since the lowest energy transition is observed near 400 nm ih $[Mo_4S_4]^{4+}$ as a weak absorption band.[2]

The magnetism of the cubane-type clusters consisting of four transition-metal atoms and four chalcogen atoms has been commonly explained by assuming different values of antiferromagnetic interactions between the magnetic moments localized on the metal atoms.[10,11] This approach seems to be quite natural for those compounds having appreciable difference among the metal–metal distances and among the angles of chalcogen–metal–chalcogen bridges. However, the same approach would not be applicable for the molybdenum cluster compounds, because such appreciable difference in bond length and angle is not observed, although the magnetism changes quite drastically. It seems to be unnatural to assume significantly different values of the antiferromagnetic interactions for the series of compounds having approximately identical mean Mo–Mo distances and quite different magnetic properties.

For the reasons mentioned above, we here adopt the approach based on the MO theory to explain the magnetism of the molybdenum compounds. All the bonding orbitals are fully occupied by the twelve electrons in the case of $m=4$ and hence the Mo_4S_4 cluster has to be diamagnetic as actually observed in $Mg_2[Mo_4S_4(edta)_2]\cdot22H_2O$. Removal of one electron from the orbitals yields an unpaired electron whether HOMO is degenerate or not. Therefore, $[Mo_4S_4]^{5+}$ is expected to be in a paramagnetic ground state with $S=1/2$. This is also consistent with the result observed in $Na_3[Mo_4S_4(edta)_2]\cdot10H_2O$. Removal of two electrons from the orbitals of the $m=4$ state yields different situations depending on the energy sequence of the bonding orbitals. If HOMO of the $[Mo_4S_4]^{4+}$ cluster is not degenerate (i.e., a_1), it becomes empty by removal of two electrons and consequently $[Mo_4S_4]^{6+}$ is diamagnetic. If HOMO is degenerate (i.e., e or t_2), the ground state should be paramagnetic with $S=1$ because of Hund's rule. The experimental result that $Mg[Mo_4S_4(edta)_2]\cdot12H_2O$ is diamagnetic is favorable for the former situation. Although tetragonal distortion from the idealized symmetry ($T_d\rightarrow D_{2d}$) also results in diamagnetic state, there has been no evidence for large distortion in the $[Mo_4S_4]^{6+}$ cluster.[2] Therefore, it is most probable that the HOMO of $[Mo_4S_4]^{4+}$ belongs to the a_1 representation.

Phosphorescence Excitation Spectra in the Singlet-Triplet Absorption Region of Pyrazine and Pyrimidine Vapors

Masahisa FUJITA,† Nobuhiro OHTA,* Takeshi TAKEMURA,* and Hiroaki BABA
Division of Chemistry, Research Institute of Applied Electricity,
Hokkaido University, Sapporo 060
(Received December 23, 1987)

Synopsis. Phosphorescence excitation spectra in the $S_0 \rightarrow T_1$ absorption region of pyrazine and pyrimidine have been observed in the vapor phase at room temperature. In pyrimidine vapor, the origin of the $S_0 \rightarrow T_1$ transition has been determined to be at 350.42 nm, and the T_1 state is assigned to the $n\pi^*$ state.

Relaxation dynamics in the triplet states of pyrazine and pyrimidine in the vapor phase seems to be extremely different from the dynamics in rigid media. For example, the phosphorescence quantum yields of these molecules in the vapor phase are much smaller than those in rigid media,[1-3] indicating that a fast nonradiative process occurs in T_1 only in the vapor phase. This suggests that there is a difference in electronic property and/or molecular geometry between the T_1 states of the isolated molecules and the molecules in rigid media. However, these problems remain unsettled.

The purpose of this note is to report the phosphorescence excitation spectra in the $S_0 \rightarrow T_1$ absorption region of pyrazine and pyrimidine in the vapor phase at room temperature. The T_1 states of both compounds are well-known to be of the $n\pi^*$ type in low temperature matrices.[4] In pyrimidine vapor, however, the possibility was suggested that the T_1 state is the $\pi\pi^*$, since the radiative lifetime evaluated from the yield and decay of the phosphorescence in the vapor phase is more than ten times as long as that in a rigid glass.[2] In this note, therefore, the assignment of the T_1 state of pyrimidine vapor is discussed, based on the rotational contour of the absorption band. The excitation spectrum of pyrazine vapor is compared with the absorption spectra.[5,6]

Experimental

The excitation light source is a pulsed dye laser (Lambda Physik FL2002), pumped by a XeCl excimer laser (Lambda Physik EMG 103 MSC). The intensity of phosphorescence dispersed by a monochromator was measured by using a photon counting detection system which is equipped with a circuit for a time-gated high voltage imposed on the photomultiplier (TGHV circuit).[7] With this system, the scattered light is eliminated, and the number of photons which are emitted from the sample in a certain time range after a pulse excitation can be counted. Emission decays were also measured by using the above-mentioned TGHV circuit and a photon counting lifetime apparatus equipped with a time-to-amplitude converter. In the present experiments, the phosphorescence at 390 nm emitted in the time range from 4 μs to 50 μs after pulse excitation was monitored to obtain the excitation spectra and decays of phosphorescence for the two compounds studied.

Results and Discussion

Figure 1 shows the phosphorescence excitation spectrum of pyrazine vapor. The phosphorescence lifetime of pyrazine, which is independent of the excited level, was determined to be ca. 60 μs, in agreement with the result of excitation into S_1.[1] The absorption spectrum of the $S_0 \rightarrow T_1$ transition of pyrazine vapor was observed by Innes and Giddings by using a 70 m absorption path.[5] They reported that the structure of the 0-0 band is predominantly of a parallel type, indicating that the direction of the transition dipole is perpendicular to the molecular plane, i.e., T_1 is the $n\pi^*$ state. Later, the $S_0 \rightarrow T_1$ absorption spectrum of pyrazine vapor was remeasured by Fischer,[6] and recently the $S_0 \rightarrow T_1$ transition in a supersonic jet was detected with a multiphoton ionization technique.[8,9] In the present spectrum, the strong band at 372.77 nm is assigned to the $S_0 \rightarrow T_1$ origin, and the strong bands at 625 and 1140 cm^{-1} above the origin are assigned to the $6a_0^1$ and $9a_0^1$ bands, respectively. Thus, the observed excitation spectrum is essentially the same as the absorption spectrum reported by Fischer, except that the intensity ratios between the 0-0 and the $6a_0^1$ bands in both spectra are different from each other. As is seen in Fig. 2(a), the 0-0 band exhibits a parallel-type rotational contour, in agreement with the report by Innes and Giddings.

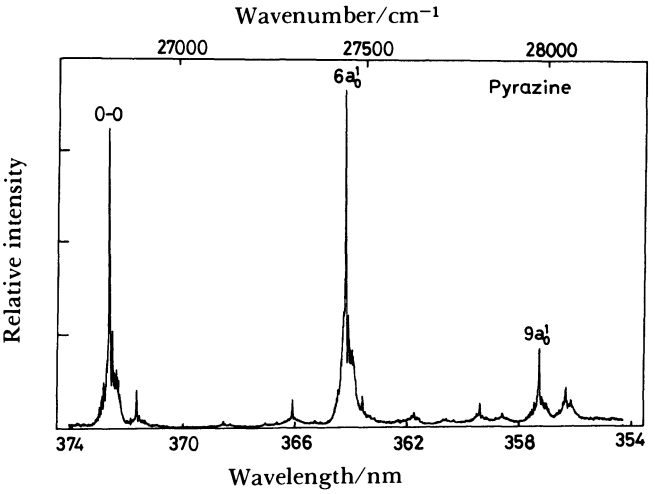

Fig. 1. Phosphorescence excitation spectrum in the $S_0 \rightarrow T_1$ absorption region of pyrazine vapor. The sample pressure is 2 Torr (1 Torr≈133.322 Pa). The 0-0 band is at 372.77 nm.

† Present address: Department of Applied Physics, Faculty of Engineering, Hokkaido University, Sapporo 060.

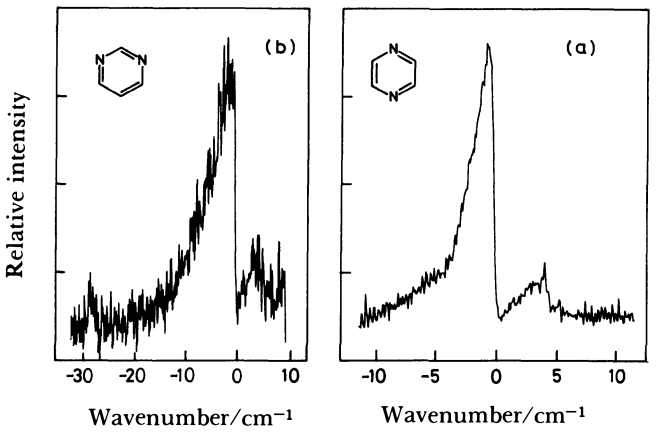

Fig. 2. Rotational contour of the 0-0 band belonging to the $S_0 \rightarrow T_1$ transition of pyrazine (a) and pyrimidine (b) vapors at room temperature.

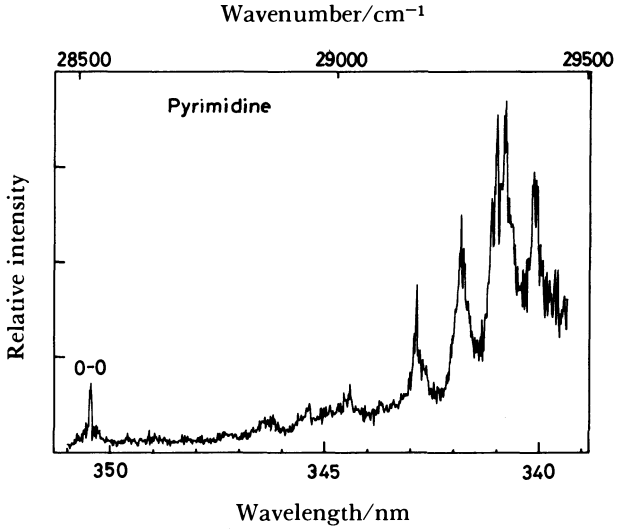

Fig. 3. Phosphorescence excitation spectrum in the $S_0 \rightarrow T_1$ absorption region of pyrimidine vapor at ca. 5 Torr. The 0-0 band is at 350.42 nm.

Figure 3 shows the phosphorescence excitation spectrum in the $S_0 \rightarrow T_1$ absorption region of pyrimidine vapor. The phosphorescence lifetime was determined to be ca. 60 μs, in fair agreement with the previous result of excitation into S_1.[2] In the previous paper,[2] the vibrational structure of the phosphorescence spectrum of pyrimidine vapor observed with excitation into S_1 was analyzed by assuming tentatively that the phosphorescence band at 350.5 nm corresponds to the 0-0 band of the $T_1 \rightarrow S_0$ transition. It is seen in Fig. 3 that in the excitation spectrum a distinct band exists at 350.42 nm, which is in good agreement with 350.5 nm. From these observations we are naturally led to the conclusion that the band at 350.42 nm in the phosphorescence excitation spectrum is the 0-0 band for the $S_0 \rightarrow T_1$ transition of pyrimidine vapor. If the T_1 state of pyrimidine vapor is the $\pi\pi^*$ type, the 0-0 band for the $S_0 \rightarrow T_1$ transition is expected to exhibit a perpendicular-type rotational contour which is similar to the contour observed for the $10a_0^1$ band belonging to the $S_0 \rightarrow S_1$ transition of pyrazine.[10] As is shown in Fig. 2(b), however, the 0-0 band of pyrimidine vapor exhibits a parallel-type rotational contour. Therefore, the T_1 state of pyrimidine vapor is assigned to the $n\pi^*$ state, as in the case of pyrazine.

In pyrazine, the spectral shapes of the $S_0 \rightarrow T_1$ excitation spectra in the vapor phase and in a rigid glass are analogous to each other.[11] However, the excitation spectrum of pyrimidine vapor shown in Fig. 3 is not analogous to the $S_0 \rightarrow T_1$ absorption spectrum of crystal.[12] The excitation (absorption) spectrum of pyrimidine vapor shows more complicated structure for excess energies of more than 600 cm^{-1} above the $S_0 \rightarrow T_1$ origin, as is seen in Fig. 3. The energy separation between S_1 and T_1 of pyrimidine is as small as ca. 2500 cm^{-1}. Then, the intense bands lying above 600 cm^{-1} from the origin may be attributed to the hot bands associated with transitions to S_1 from higher vibronic levels of S_0.

Chemistry of Germanium Atoms. III. Reactions of Thermally Evaporated Germanium Vapor with Hydrogermanes[1)]

Kunio MOCHIDA* and Yasuhiro YOSHIDA
Department of Chemistry, Faculty of Science, Gakushuin University,
1-5-1 Mejiro, Tokyo 171
(Received September 19, 1987)

Synopsis. Thermally generated germanium atoms were found to react with hydrogermanes by insertion into germanium-hydrogen bonds. The resulting germylenes were inserted again in a germanium-hydrogen bond to form trigermanes.

We previously reported on the reactions of germanium atoms, thermally generated from a tungsten filament, with organic halides (polyhalomethanes, alkyl halides, and aryl halides), and the characterization of several new organogermanium halides.[1)] We now describe the reactions of germanium atoms with hydrogermanes (R_3GeH, R=Me; Et).

The fact that compounds containing group-4B element-hydrogen bonds like carbon-halogen bonds are good trapping agents for carbon atoms[2)] and silicon atoms[3)] made this class of substrates a logical choice for a germanium atom reaction. The present study is valuable for understanding not only the chemical properties of germanium atoms but also of the reactive intermediates in solutions.

Results and Discussion

Germanium atoms were generated by evaporation from a tungsten filament using essentially the same apparatus as has been described in the literature (ca. 1200—1300 °C and 5×10^{-3} Torr, 1 Torr=133.32 Pa).[4)] Germanium metal was evaporated at a rate of ca. 10 mg min^{-1} for 50 min, while an excess of hydrogermane was co-condensed on the walls of a quartz reaction flask containing the crucible and a perforated inlet tube through which the hydrogermane was introduced. The reaction flask was immersed in liquid nitrogen during germanium evaporation. After the germanium evaporation and introduction of the hydrogermane was completed, the reaction flask was warmed to room temperature and allowed to stand for 1.5 h. After removing the reaction flask from a vacuum line, the products were identified by comparing their GC-MS and retention times on GLC with those of authentic and similar samples. The yields of products were calculated by GLC with an internal-standard method.

The reaction of germanium atoms with trimethylgermane (Me_3GeH) produced 1,1,3,3-tetramethyltrigermane, $(Me_3Ge)_2GeH_2$, (0.2%) and hexamethyldigermane, $Me_3GeGeMe_3$, (1.0%). With triethylgermane (Et_3GeH) as the substrate, germanium atoms produced 1,1,3,3-tetraethyltrigermane, $(Et_3Ge)_2GeH_2$, (0.2%) and hexaethyldigermane, $Et_3GeGeEt_3$, (0.4%). Very small quantities of several unidentified products were formed in both reactions. This is the first observation of the insertion of germanium atoms into germanium-hydrogen bond of hydrogermanes by thermally vaporized germanium atom, so far as we know.

The condensation of hydrogermanes alone was carried out under identical conditions, except for germanium vaporization. As a result, hexamethyldigermane and hexaethyldigermane were formed in 0.1 and 0.2% yields, respectively. No trigermanes were detected.

The mechanism of double insertion is reasonable for the formation of products (Eqs. 1—3):[5)]

$$\dot{G}\dot{e}: + H\text{-}GeR_3 \longrightarrow {}^3[H\text{-}\dot{G}e\text{-}GeR_3] \quad (1)$$

$${}^3[H\text{-}\dot{G}e\text{-}GeR_3] \longrightarrow {}^1[H\text{-}\dot{G}\dot{e}\text{-}GeR_3] \quad (2)$$

$${}^1[H\text{-}\dot{G}\dot{e}\text{-}GeR_3] + H\text{-}GeR_3 \longrightarrow H_2Ge(GeR_3)_2 \quad (3)$$

R = Me; Et

Thus, germanium atoms of the ^3P ground state, thermally evaporated, were inserted into germanium-hydrogen bonds of hydrogermanes (Eq. 1). The initially formed triplet germylenes rapidly relaxed to their singlet states, since the ground states of germylenes have been shown to be singlets by quantum chemical calculations and chemical reactions[6-8)] (Eq. 2). The singlet germylenes insert again into germanium-hydrogen bonds to form trigermanes (Eq. 3).

The digermanes are considered to be derived from the germyl radicals generated by the hydrogen-abstraction of the hydrogermanes with singlet germylenes ($HGeGeR_3$) or germanium atoms. Therefore, the formation of trihydrogermanes (H_3GeGeR_3) or tetrahydrogermane (GeH_4) may be expected. However, these germanium compounds could not be detected. A similar mechanism has been proposed for the co-condensation of thermally vaporized germanium atoms with organic halides.[1)]

Experimental

^1H NMR spectra were recorded on a Varian FT 80A, with tetramethylsilane as an internal standard. GC-MS spectra were obtained on a JEOL JMS-DX 303 mass spectrometer. Infrared spectra were recorded on a Hitachi 260-10 spectrometer. Gas chromatography was performed on a Shimadzu GC-6A and 8A with lm 20% SE30 and 30% Apiezon L columns.

Materials. Me_3GeH and Et_3GeH were prepared by the reduction of the corresponding chlorides with lithium aluminum hydride in ether.[9)] Me_6Ge_2[10)] and Et_6Ge_2[11)] were prepared as described in the cited references.

Reactions of Germanium Atoms with Hydrogermanes. As a typical example, the reaction of germanium atoms with trimethylgermane (Me_3GeH) is described. Germanium

atoms were produced by using essentially the same apparatus and conditions as described in the literature.[1] Germanium metal (0.5 g, 6.9 mmol) was vaporized at a temperature of 1200—1300 °C by using a resistively heated, alumina-coated tungsten spiral crucible, in vacuo (ca. 5×10^{-3} Torr), at a rate of 10 mg min^{-1}. During vaporization of the germanium metal, Me_3GeH (ca. 10 cm^3) was co-condensed on the walls of a quartz reaction flask. The color of the co-condensation product of germanium vapor and Me_3GeH vapor at 77 K is bluish-black. The crucible was maintained at 1200—1300 °C and reaction flask was immersed in liquid nitrogen during germanium the vaporization and the introduction of Me_3GeH. Then, the reaction flask was warmed to room temperature and allowed to stand for 1.5 h. The co-condensation products were characterized by comparing their GC-MS and retention times on GLC with those of authentic and similar compounds. The amounts of products were determined by GLC with an internal standard method. Me_6Ge_2 and $(Me_3Ge)_2GeH_2$ were formed in 1.0 and 0.2% yields, respectively. Small quantites of several unidentified products were also produced. The yields of products were determined on the basis of the germanium metal consumed by supposing that the germanium metal, except for germanium metal that remained in the crucible, completely reacted with Me_3GeH vapor. Therefore, by taking into consideration that the unreacted germanium metal becomes attached to the walls of a reaction flask, the yields of products may be underestimated.

Identification of Products. The known compounds (Me_6Ge_2 and Et_6Ge_2) were identified by comparing their GC-MS and retention times on GLC with those of authentic samples. The unknown compounds were carefully identified by comparing their GC-MS with those of similar samples and parent peaks and cleavage patterns while considering the natural abundance of germanium (ratio, $^{70}Ge/^{72}Ge/^{73}Ge/^{74}Ge/^{76}Ge=56/75/21/100/21$). $(Me_3{}^{74}Ge)_2{}^{74}GeH_2$ (parent ion at peak $m/z=314$); $m/z=309$ (11), 206 (39), 191 (21), and 119 (100). $(Et_3{}^{74}Ge)_2{}^{74}GeH_2$ (parent ion peak at $m/z=394$); $m/z=394$ (28), 365 (3), 312 (4), 223 (17), 161 (100), 133 (82), and 105 (16).

The authors thank Mitsubishi Metal Corporation for a gift of germanium metal. This work was supported in part by Grant-in-Aid for Special Project Research (Nos. 61125004 and 62115003) provided by the Ministry of Education, Science and Culture.

A Convenient Synthesis of 3-Phenacylidenephthalides

Kimihiko HORI and Naotake TAKAISHI*
Tochigi Research Laboratories, Kao Corporation, 2606 Akabane, Ichikaimachi, Tochigi 321-34
(Received December 3, 1987)

Synopsis. 3-Phenacylidenephthalides were prepared by the dehydration of 2-(1,3-dioxo-3-phenylpropyl)benzoic acids, obtained in turn by the condensation of phthalic anhydride with acetophenones.

3-Phenacylidenephthalides (**4**) have attracted wide attention on account of their biological activities as plant growth regulants[1-5] and their reducing effects on the herbicidal injury to plants.[6] Several methods to prepare **4** have been developed.[2,7,8] However, these procedures need complex operations and the yields are often unsatisfactory. The Wittig reaction of phthalidylphosphonium bromide with phenylglyoxal has been reported to give *Z*-**4a** in 40% yield. We now report a convenient procedure for the synthesis of **4** by the dehydration of 2-(1,3-dioxo-3-phenylpropyl)benzoic acids (**3**).

The starting materials, 2-(1,3-dioxo-3-phenylpropyl)benzoic acids (**3**), were prepared in high yields by the reaction of acetophenones (**2**) with phthalic anhydride (**1**) in the presence of sodium methoxide[9] (Table 1). The dehydration was examined by several halogenating or dehydrating reagents (Table 2). Treatment of **3** with thionyl chloride in chloroform at reflux temperature gave **4** in excellent yields as a mixture of *E*- and *Z*-isomers, which was easily separated by silica-gel column chromatography. The stereochemistry of each isomer was determined by a consideration of the ^{1}H NMR spectrum.[8] Similar

1 2 3

(E)-4 (Z)-4

results were obtained by using acetyl chloride, *p*-toluenesulfonic acid or triphenylphosphine, while the use of dicyclohexylcarbodiimide (DCC) afforded the *Z*-isomer exclusively.

The advantages of this dehydration procedure for the large scale preparation of **4** over existing literature procedures are that the starting materials are readily available, and the procedure is simple, short, and requires only mild conditions.

Experimental

General. All melting points were uncorrected. IR spectra were taken on a Hitachi 270-30 spectrometer. ^{1}H NMR spectra (270 MHz) were taken on a JEOL JNM-GX270 spectrometer.

General Procedure for 2-(1,3-Dioxo-3-phenylpropyl)benzoic Acids (3). A stirred mixture of anhydrous xylene (700 ml) and 28% methanol solution of sodium methoxide (99.2 g, 0.51 mol) was heated at 110 °C until the distillation of methanol had ceased. The mixture was cooled to 60 °C, and then acetophenones (**2**) (0.2 mol) and phthalic anhydride (**1**) (35.0 g, 0.24 mol) were added successively. The reaction mixture was again heated at 110—120 °C for 2 h and cooled to room temperature. The mixture was poured into cooled 12% aqueous hydrochloric acid (160 ml) and extracted with methyl ethyl ketone (350 ml×2). The combined extracts were washed with water (300 ml) and dried over sodium sulfate. The crude product obtained after the evaporation of the solvent was purified by recrystallization from suitable solvents (Table 1).

2-(1,3-Dioxo-3-phenylpropyl)benzoic Acid (3a): Mp 110—112 °C (benzene) (lit,[2] 111—113 °C); IR (KBr) 3046, 1725, 1608, 1575, 1542, 1497, 1461, 1416, 1299, 1245, 1125, 1050, 891, 768 cm^{-1}.

2-[3-(4-Methylphenyl)-1,3-dioxopropyl]benzoic Acid (3b): Mp 154—156 °C (C_2H_5OH/benzene); IR (KBr) 3130, 1713, 1647, 1602, 1575, 1490, 1422, 1311, 1254, 1167, 990, 864, 759 cm^{-1}.

Found: C, 72.20; H, 4.95%. Calcd for $C_{17}H_{14}O_4$: C, 72.33; H, 5.00%.

2-[3-(4-Methoxyphenyl)-1,3-dioxopropyl]benzoic Acid (3c): Mp 152—154 °C (C_2H_5OH); IR (KBr) 3000, 1690, 1595, 1500, 1460, 1440, 1415, 1290, 1260, 1225, 1180, 1020, 930, 850, 805, 775 cm^{-1}.

General Procedure for 3-Phenacylidenephthalide (4). A stirred mixture of 2-(1,3-dioxo-3-phenylpropyl)benzoic acids (**3**) (0.34 mol) and thionyl chloride (60.94 g, 0.51 mol) in chloroform (400 ml) was heated under reflux for 3 h. Removal of solvent and excess thionyl chloride in vacuo left the crude product, which was chromatographed on silica-gel column using chloroform as eluent. The pure *E*- and *Z*-isomers of 3-phenacylidenephthalides (**4**) were obtained as slightly yellow crystals (Table 2).

(*E*)-3-Phenacylidenephthalide (*E*-4a): Mp 116—117 °C (lit,[8] 116—118 °C); IR (KBr) 1795, 1665, 1610, 1250, 970 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=7.21 (s, 1H), 7.48—8.11 (m, 8H), 9.03 (d, 1H, J=8.1 Hz).

A New Reaction of Tris(alkylthio)cyclopropenium Salt with *m*-Substituted Anilines Affording Quinoline Derivatives

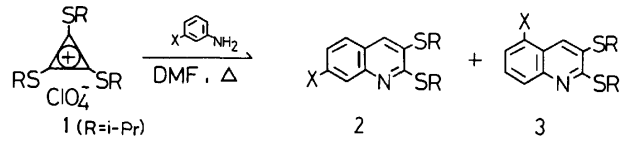
Shigeo YONEDA* and Hideo KOJIMA
Department of Applied Chemistry, University of Osaka Prefecture,
Sakai, Osaka 591
(Received December 17, 1987)

Synopsis. The reaction of tris(alkylthio)cyclopropenium salt with *m*-substituted anilines gave quinoline derivatives.

Owing to its high strain and aromatic character, the tris(alkylthio)cyclopropenium ion (**1**) undergoes a wide range of reactions including substitution,[1] ring opening,[1] and one-electron oxidation reactions.[2] We have recently reported that the reaction of tris(*t*-butylthio)cyclopropenium salt with dialkylamines ($R^1NHCH_2R^2$) resulted in the formation of the corresponding bis(*t*-butylthio)pyrroles.[3] This finding led us to explore a new "one-pot" synthesis of heterocyclic compounds using tris(alkylthio)cyclopropenium salt as a building block.

We now report the successful synthesis of quinolines from **1** and *m*-substituted anilines under mild reaction conditions.

The reactions were carried out in *N*,*N*-dimethylformamide (DMF) at 85 °C for 5—100 h to give 7- and 5-substituted quinolines **2a—d** and **3a—d** in good yields. The results are summarized in Table 1.



1 (R=i-Pr) 2 3

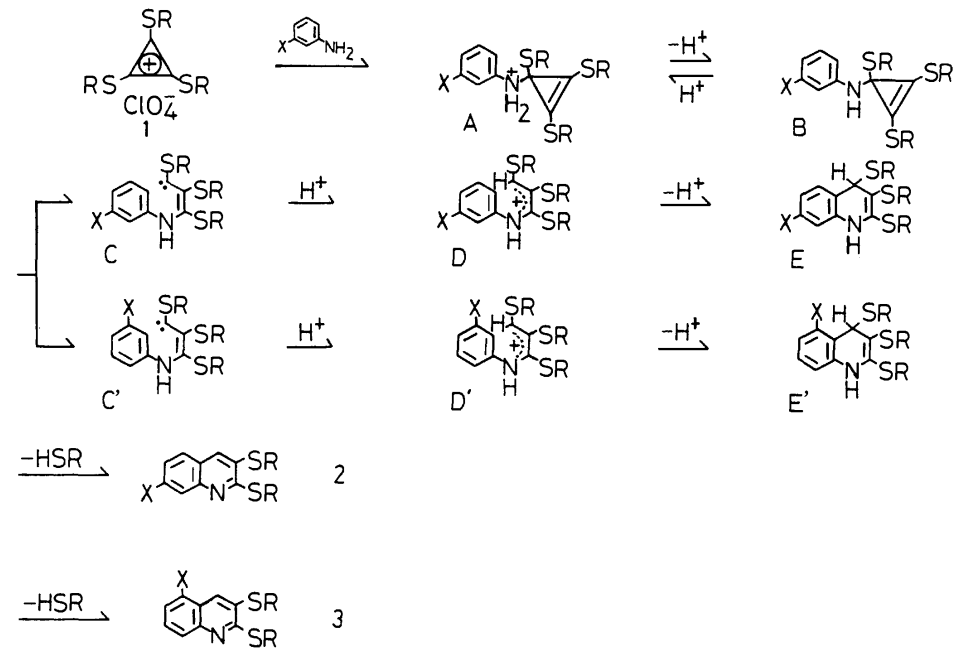
a. X = OMe
b. X = NH_2
c. X = OH
d. X = Me

Table 1. Reaction of **1** with *m*-Substituted Anilines

	X	Time/h	Yield/%[a]	
			2	**3**
a	OMe	50	68	7
b	NH_2	5	9	25
c	OH	5	85	<1
d	Me	93	52	9

a) Isolated yield except for **2d** and **3d**. The yields of **2d** and **3d** were determined by ^1H NMR.

Scheme 1 outlines a possible pathway for the formation of **2** and **3**. Reversible generation of B from the initially formed ammonium salt A leads to a facile ring opening to C and C′. Protonation of C and C′ would afford D and D′, respectively. Subsequent intramolecular electrophilic aromatic substitution would give the six-membered intermediates E and E′ and result in the formation of **2** and **3** by thiol elimination.



Scheme 1.

Experimental

^1H and ^{13}C NMR spectra were recorded on a JEOL JNM-GX 270 FT NMR spectrometer using chloroform-*d* as a solvent and tetramethylsilane as an internal standard; the chemical shifts are reported in δ values. Mass spectra were recorded on a Shimadzu LKB-9000 spectrometer(70eV). Infrared spectra were recorded on a Hitachi 215 spectrometer. Column chromatography was performed on silica gel (Wakogel C-300). Melting points were determined with a Yanaco MP-S3 melting point apparatus and were uncorrected.

General Synthetic Method of Quinoline Derivatives, 2a—d and 3a—d. All quinoline derivatives were prepared by the reaction of **1** with *m*-substituted anilines in dry DMF. The general procedure will be illustrated below by using the syntheses of **2a** and **3a**.

To a solution of *m*-anisidine (0.5 mmol) in dry DMF (15 ml) was added dropwise a solution of tris(isopropylthio)-cyclopropenium perchlorate (**1**) (0.5 mmol) in dry DMF (15 ml) at 85 °C under nitrogen. The reaction mixture was stirred at 85 °C for 50 h, then poured into water (200 ml), and extracted with ether (200 ml). The organic layer was washed with water (200 ml) and dried (Na_2SO_4). The solvent was evaporated off under reduced pressure, the residual oil was chromatographed on silica gel [hexane–chloroform (3:1) as eluent], and final purification by recrystallization from methanol gave both 7- and 5-methoxyquinolines (**2a** and **3a**) as colorless needles in 68% and 7% yields, respectively.

2a: mp 65.0—65.5 °C; IR (KBr) 1620, 1580, 1495, 1445, 1335, 1225, 1125, 1030, 850, and 825 cm^{-1}; ^1H NMR ($CDCl_3$) δ=7.94 (1H, s, 4-H), 7.55 (1H, d, *J*=9.0 Hz, 5-H), 7.24 (1H, d, *J*=2.6 Hz, 8-H), 7.06 (1H, dd, *J*=9.0 and 2.6 Hz, 6-H), 4.21 (1H, sep, *J*=6.7 Hz, CH of *i*-Pr), 3.94 (3H, s, OMe), 3.47 (1H, sep, *J*=6.7 Hz, CH of *i*-Pr), 1.48 (6H, d, *J*=6.7 Hz, CH_3 of *i*-Pr), and 1.30 (6H, d, *J*=6.7 Hz, CH_3 of *i*-Pr); ^{13}C NMR ($CDCl_3$)δ=163.3, 161.2, 149.0, 140.0, 128.2, 124.8, 120.9, 118.0, 106.6, 55.5, 38.4, 35.4, 23.0$_4$ (2C), and 23.0$_0$ (2C); MS (70 eV) *m/z* 307 (M^+).

3a: mp 66.0—68.0 °C; IR (KBr) 1620, 1575, 1560, 1465, 1335, 1270, 1210, 1130, 1010, and 805 cm^{-1}; ^1H NMR ($CDCl_3$) δ=8.38 (1H, s, 4-H), 7.51—7.49 (2H, m, benzene ring), 6.75 (1H, dd, *J*=5.8 and 2.8 Hz, benzene ring), 4.21 (1H, sep, *J*=6.7 Hz, CH of *i*-Pr), 3.97 (3H, s, OMe), 3.55 (1H, sep, *J*=6.7 Hz, CH of *i*-Pr), 1.47 (6H, d, *J*=6.7 Hz, CH_3 of *i*-Pr), and 1.34 (6H, d, *J*=6.7 Hz, CH_3 of *i*-Pr); ^{13}C NMR ($CDCl_3$) δ=162.6, 154.9, 147.8, 133.6, 129.4, 127.2, 120.1, 118.0, 103.5, 55.7, 38.2, 35.5, 23.0(2C), and 22.9(2C); MS (70 eV) *m/z* 307 (M^+).

Similar reactions of **1** with several *m*-substituted anilines were carried out. The reaction of **1** with *m*-phenylenediamine afforded **2b** as reddish brown solid and **3b** as yellow oil.

2b: mp 89—91 °C; IR (KBr) 3450, 3360, 3225, 1620, 1575, 1495, 1335, 1230, 1120, 1050, 990, 850, and 810 cm^{-1}; ^1H NMR ($CDCl_3$) δ=7.87 (1H, s, 4-H), 7.46 (1H, d, *J*=8.6 Hz, 5-H), 7.05 (1H, d, *J*=2.4 Hz, 8-H), 6.83 (1H, dd, *J*=8.6 and 2.4 Hz, 6-H), 4.16 (1H, sep, *J*=6.7 Hz, CH of *i*-Pr), 4.03 (2H, broad s, NH_2), 3.43 (1H, sep, *J*=6.7 Hz, CH of *i*-Pr), 1.46 (6H, d, *J*=6.7 Hz, CH_3 of *i*-Pr), 1.28 (6H, d, *J*=6.7 Hz, CH_3 of *i*-Pr); ^{13}C NMR ($CDCl_3$) δ=163.5, 149.1, 148.2, 140.9, 128.5, 122.9, 119.7, 116.8, 108.5, 38.6, 35.2, 23.1 (2C), and 23.0 (2C); MS (70 eV) *m/z* 292 (M^+).

3b: IR (neat) 3475, 3375, 3240, 1620, 1580, 1550, 1465, 1370, 1340, 1245, 1150, 1080, 1055, 955, and 805 cm^{-1}; ^1H NMR ($CDCl_3$) δ=8.04 (1H, s, 4-H), 7.45—7.35 (2H, m, benzene ring), 6.69 (1H, dd, *J*=7.0 and 1.5 Hz, benzene ring), 4.20 (1H, sep, *J*=6.9 Hz, CH of *i*-Pr), 4.12 (2H, broad s, NH_2), 3.51 (1H, sep, *J*=6.7 Hz, CH of *i*-Pr), 1.47 (6H, d, *J*=6.9 Hz, CH_3 of *i*-Pr), 1.31 (6H, d, *J*=6.7 Hz, CH_3 of *i*-Pr); ^{13}C NMR ($CDCl_3$) δ=162.8, 148.2, 142.1, 134.4, 130.4, 125.8, 118.7, 116.0, 109.4, 38.6, 35.4, 23.1 (2C), and 23.0 (2C); MS (70 eV) *m/z* 292 (M^+).

The reaction of **1** with *m*-aminophenol afforded **2c** and **3c** as yellow oil.

2c: IR (neat) 3375, 1620, 1580, 1560, 1495 , 1450, 1335, 1200, 1130, 1050, 995, 860, and 810 cm^{-1}; ^1H NMR ($CDCl_3$) δ=7.93 (1H, s, 4-H), 7.56 (1H, d, *J*=8.6 Hz, 5-H), 7.25 (1H, d, *J*=2.7 Hz, 8-H), 7.03 (1H, dd, *J*=8.6 and 2.7 Hz, 6-H), 5.69 (1H, broad s, OH), 4.17 (1H, sep, *J*=6.7 Hz, CH of *i*-Pr), 3.47 (1H, sep, *J*=6.7 Hz, CH of *i*-Pr), 1.45 (6H, d, *J*=6.7 Hz, CH_3 of *i*-Pr), 1.30 (6H, d, *J*=6.7 Hz, CH_3 of *i*-Pr); ^{13}C NMR ($CDCl_3$) δ=163.5, 157.4, 148.4, 140.2, 128.8, 125.0, 120.9, 117.2, 110.0, 38.5, 35.6, 23.0 (2C), and 22.9 (2C); MS (70 eV) *m/z* 293 (M^+).

3c: IR (neat) 3400, 1620, 1580, 1555, 1465, 1335, 1275, 1200, 1130, 1080, 1050, and 805 cm^{-1}; ^1H NMR ($CDCl_3$) δ=8.34 (1H, s, 4-H), 7.51—7.39 (2H, m, benzene ring), 6.73 (1H, dd, 7.3 and 1.2 Hz, benzene ring), 5.44 (1H, broad s, OH), 4.21 (1H, sep, *J*=6.7 Hz, CH of *i*-Pr), 3.56 (1H, sep, *J*=6.7 Hz, CH of *i*-Pr), 1.48 (6 H, d, *J*=6.7 Hz, CH_3 of *i*-Pr), 1.35 (6H, d,*J*=6.7 Hz, CH_3 of *i*-Pr); MS (70 eV) *m/z* 293 (M^+).

The reaction of **1** with *m*-toluidine afforded a mixture of **2d** and **3d** as colorless solid.

2d: ^1H NMR ($CDCl_3$) δ=7.93 (1H, s, 4-H), 7.69 (1H, s, 8-H), 7.54 (1H, d, *J*=8.4 Hz, 5-H), 7.22 (1H, dd, *J*=8.4 and 1.1 Hz, 6-H), 4.21 (1H, sep, *J*=7.0 Hz, CH of *i*-Pr), 3.50 (1H, sep, *J*=6.7 Hz, CH of *i*-Pr), 2.51 (3H, s, Me), 1.48 (6H, d, *J*=7.0 Hz, CH_3 of *i*-Pr), 1.31 (6H, d, *J*=6.7 Hz, CH_3 of *i*-Pr); MS (70 eV) *m/z* 291 (M^+).

3d: ^1H NMR ($CDCl_3$) δ=8.15 (1H, s, 4-H), 7.76 (1H, d, *J*=8.6 Hz, benzene ring), 7.51—7.46 (2H, m, benzene ring), 4.20 (1H, sep, *J*=7.0 Hz, CH of *i*-Pr), 3.54 (1H, sep, *J*=6.7 Hz, CH of *i*-Pr), 2.61 (3H, s, Me), 1.48 (6H, d, *J*=7.0 Hz, CH_3 of *i*-Pr), 1.33 (6H, d, *J*=6.7 Hz, CH_3 of *i*-Pr); MS (70 eV) *m/z* 291 (M^+).

Novel and Convenient Synthesis of Dioxaphospholes

Maya Shanker SINGH and Kailash Nath MEHROTRA*
Department of Chemistry, Banaras Hindu University, Varanasi 221 005, India
(Received March 9, 1987)

Synopsis. Treatment of 1,2-diketones **1a—d** with sodium in dry THF followed by addition of dry phenyl and ethyl phosphorodichloridate gave 2-phenoxy- and 2-hydroxy-4,5-diaryl-1,3,2-dioxaphosphole 2-oxides, respectively.

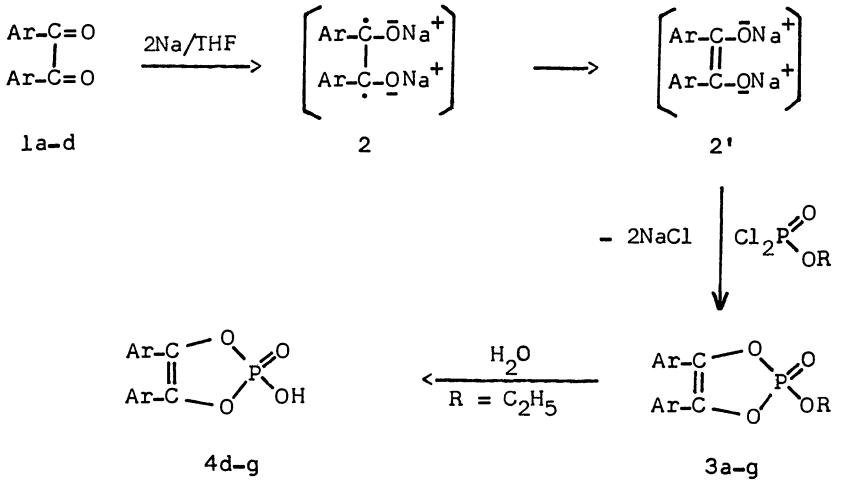
The preparation of some heterocyclic compounds containing nitrogen atoms and one four-coordinated phosphorus atom has been reported.[1] The synthesis of spiro-1,3,2-benzooxazaphospholes[2] from the reaction of 2-aminophenols with aryl phosphorodichloridates and 2,4,3-benzodiazaphosphepines[3] from the reaction of *o*-xylene-α,α'-diamines with dichlorophosphinyl carbamates have been described earlier. Five membered N,P and O,N,P-heterocyclic compounds have been obtained from benzil dianils and monoanils.[4] It has been observed that the reaction of phosphorothiodichloridate with benzil in presence of magnesium leads to the formation of 2,4,5-triphenyl-1,3,2-dioxaphosphole 2-sulfide.[5] We now wish to report a new and convenient one pot synthesis of 2-phenoxy- and 2-hydroxy-4,5-diaryl-1,3,2-dioxaphosphole 2-oxides from the dianions of 1,2-diketones. These dioxaphospholes could be used for the phosphorylation of alcohols.[6]

Results and Discussion

Treatment of 1,2-diketones **1a—d** with sodium in dry THF and subsequent addition of dry phenyl or ethyl phosphorodichloridate afforded 2-phenoxy-4,5-diaryl-1,3,2-dioxaphosphole 2-oxides **3a—c** and 2-hydroxy-4,5-diaryl-1,3,2-dioxaphosphole 2-oxides **4d—g** respectively. These products have been characterized by the satisfactory analytical and spectral data. It has been observed that using the reagents in 1:1 mole ratio, the yields of products **3** and **4** are reduced by 7 and 2%, respectively.

The formation of the products **3a—c** and **4d—g** from diketones **1a—d** is depicted in Scheme 1.

This synthesis involves the initial formation of diradical dianion **2**, by the electron teansfer from sodium to diketones, which on radical coupling would give the dianion **2'**;[7] the latter attacks phenyl or ethyl phosphorodichloridate with elimination of chloride ions (detected by the formation of silver chloride with aq. silver nitrate) to give rise to 2-phenoxy- and 2-ethoxy-4,5-diaryl dioxaphole 2-oxides, respectively. In cases of **3d—g**, the 2-ethoxy derivatives, initially formed, are hydrolyzed to 2-



Dioxaphosphole	Ar	R	Yield/%
3a	*p*-CH_3-C_6H_4	C_6H_5	41
3b	*p*-CH_3O-C_6H_4	C_6H_5	30
3c	*p*-Cl-C_6H_4	C_6H_5	36
4d	*p*-CH_3-C_6H_4	C_2H_5	36
4e	*p*-CH_3O-C_6H_4	C_2H_5	45
4f	*p*-Cl-C_6H_4	C_2H_5	44
4g	C_6H_5	C_2H_5	62

Scheme 1.

hydroxy compounds **4d—g** during the work up. A similar hydrolysis of 2-methoxy-4,5-dimethyl-1,3,2-dioxaphosphole 2-oxide at 0 °C has been reported earlier.[8] Although products **3a—c** were stable to alkaline solution for 3 h but were hydrolyzed in 7 h to the corresponding hydroxy derivatives **4a—c**.

Experimental

Measurement. All melting points were uncorrected. The IR spectra were recorded in Nujol mull on a Perkin-Elmer 720 spectrophotometer. The ^{1}H NMR spectra were obtained on a JEOL JNM-FX-90Q NMR spectrometer using $CDCl_3$ as a solvent. The chemical shifts are given in δ, with tetramethylsilane (TMS) as the internal standard. Mass spectra were determined on a CEC 110 double-focussing mass spectrometer, Purdue University, W. Lafayette, U. S. A. Elemental analyses were carried out using Coleman carbon-hydrogen analyzer.

Materials. 4,4′-Dimethylbenzil, 4,4′-dimethoxybenzil, 4,4′-dichlorobenzil, benzil, and phenyl and ethyl phosphorodichloridate were obtained from EGA Chemicals, West Germany. The sodium metal and other solvents were commercially obtained.

Preparation of 4,5-Diaryl-2-phenoxy-1,3,2-dioxaphosphole 2-Oxides 3a—c. Freshly cut sodium pieces (1.0 g, 0.044 g atom) were slowly added to dry THF (65 ml) with stirring under a nitrogen atmosphere and a solution of 1,2-diketone (1.4 g) in dry THF (10 ml) was added dropwise; stirring at reflux temperature was continued for 7 h and the contents were allowed to cool. Unreacted sodium pieces were removed. Dry phenyl phosphorodichloridate (2 ml) was slowly added and the mixture was heated to reflux. The solvent was evaporated under reduced pressure and the residual material was treated with 50 ml of ether. The ethereal suspension was washed 2—3 times with water and dried over anhydrous sodium sulfate. The solvent was removed on a rotary evaporator and the residual material was crystallized from ethanol to afford the products.

Preparation of 4,5-Diaryl-2-hydroxy-1,3,2-dioxaphosphole 2-Oxides 4d—g. In place of phenyl phosphorodichloridate in the above procedure, dry ethyl phosphorodichloridate (2 ml) was slowly added. The products were crystallized from pet. ether.

4,5-Bis(4-methylphenyl)-2-phenoxy-1,3,2-dioxaphosphole 2-Oxide (3a). A yield of 41% was obtained, mp 170—171 °C; IR (Nujol) 1620 (C=C), 1290 (P=O),[9] and 1190 (P-O-C)[9] cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=2.40 (s, 6H, two CH_3) and 7.00—8.10 (m, 13H, aromatic H); MS *m/z* 378 (M^+, 2%) and 119 (100).

Found: C, 69.59; H, 5.16%. Calcd for $C_{22}H_{19}O_4P$: C, 69.84; H, 5.06%.

4,5-Bis(4-methoxyphenyl)-2-phenoxy-1,3,2-dioxaphosphole 2-Oxide (3b). A yield of 30% was obtained, mp 181—182 °C; IR (Nujol) 1610 (C=C), 1260 (P=O),[9] and 1170 (P-O-C)[9] cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=4.00 (s, 6H, two OCH_3) and 6.75—8.20 (m, 13H, aromatic H); MS *m/z* 410 (M^+, 5%) and 135 (100).

Found: C, 64.66; H, 4.73%. Calcd for $C_{22}H_{19}O_6P$: C, 64.39; H, 4.67%.

4,5-Bis(4-chlorophenyl)-2-phenoxy-1,3,2-dioxaphosphole 2-Oxide (3c). A yield of 36% was obtained, mp 215—217 °C; IR (Nujol) 1600 (C=C), 1295 (P=O),[9] and 1200 (P-O-C)[9] cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=7.50—8.00 (m, aromatic H); MS *m/z* 418 (M^+, 7%) and 139 (100).

Found: C, 57.40; H, 3.40%. Calcd for $C_{20}H_{13}O_4Cl_2P$: C, 57.28; H, 3.12%.

4,5-Bis(4-methylphenyl)-2-hydroxy-1,3,2-dioxaphosphole 2-Oxide (4d). A yield of 36% was obtained, mp 198—200 °C; IR (Nujol) 2680—2540 (w, acid, P-OH),[9] 1610 (C=C), 1285 (P=O),[9] and 1190, (P-O-C)[9] cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=2.23 (s, 6H, two CH_3), 6.63 (br, s, 1H, hydroxyl H, which is exchangeable on D_2O shake), and 7.06—8.35 (m, 8H, aromatic H).

Found: C, 63.37; H, 4.98%. Calcd for $C_{16}H_{15}O_4P$: C, 63.58; H, 5.00%.

4,5-Bis(4-methoxyphenyl)-2-hydroxy-1,3,2-dioxaphosphole 2-Oxide (4e). A yield of 45% was obtained, mp 177—179 °C; IR (Nujol) 2660—2550 (w, acid, P-OH), 1610 (C=C), 1270 (P=O),[9] and 1190 (P-O-C)[9] cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=3.40 (s, 6H, two OCH_3), 7.10—8.10 (m, 8H, aromatic H), and 11.10 (br, s, 1H, hydroxyl H, which is exchangeable on D_2O shake).

Found: C, 57.67; H, 4.79%. Calcd for $C_{16}H_{15}O_6P$: C, 57.48; H, 4.52%.

4,5-Bis(4-chlorophenyl)-2-hydroxy-1,3,2-dioxaphosphole 2-Oxide (4f). A yield of 44% was obtained, mp 224—225 °C; IR (Nujol) 2730—2660 (w, acid, P-OH), 1615 (C=C), 1290 (P=O),[9] and 1185 (P-O-C) cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=4.25 (br, s, 1H, hydroxyl H, which is exchangeable on D_2O shake) and 7.20—8.15 (m, 8H, aromatic H).

Found: C, 48.68; H, 2.72%. Calcd for $C_{14}H_9O_4PCl_2$: C, 48.97; H, 2.62%.

4,5-Diphenyl-2-hydroxy-1,3,2-dioxaphosphole 2-Oxide (4g). A yield of 62% was obtained, mp 116—118 °C; IR (Nujol) 2680—2550 (w, acid, P-OH),[9] 1600 (C=C), 1280 (P=O),[9] and 1180 (P-O-C)[9] cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=7.20—8.35 (m, 10H, aromatic H) and 11.05 (br, s, 1H, hydroxyl H, which is exchangeable on D_2O shake).

Found: C, 61.09; H, 3.80%. Calcd for $C_{14}H_{11}O_4P$: C, 61.32; H, 4.04%.

Hydrolysis of 4,5-Bis(4-methylphenyl)-2-phenoxy-1,3,2-dioxaphosphole 2-Oxide (3a). A dilute solution containing 0.50 g of **3a** in 50 ml of ether was treated with 10 ml of a 20% solution of sodium hydroxide at room temperature for 7 h with vigorous shaking. The reaction mixture was extracted with ether and dried over anhydrous sodium sulfate. The solvent was removed on a rotary evaporator and the residual material was crystallized from pet. ether to give 0.29 g (57%) of the product, mp 197—99 °C and mmp 196—199 °C.

We thank the C.S.I.R., New Delhi, for an award of a fellowship to M.S.S.

Dielectric Losses of Dehydrated Na_{11}-ZK4 and K_3Na_8-ZK4 Zeolites

Tatsuo OHGUSHI,* Kenji NONAKA, and Tsuyoshi WATANABE
Department of Materials Science, Toyohashi University of Technology, Toyohashi 440
(Received October 28, 1987)

Synopsis. Dielectric properties of completely dehydrated Na_{11}-ZK4 and K_3Na_8-ZK4 zeolites were studied. A relaxation loss peak and a loss in the lower frequency region were observed in both zeolites. The relaxation losses were assigned to the jump of a cation from the 8-ring site to the 4-ring site. The losses in the lower frequency region were attributed to a cation movement beyond the unit cell dimension.

Zeolite ZK4 is isostructural with zeolite A and contains fewer cations than zeolite A,[1] and thus the cation distribution in zeolite ZK4 becomes simpler than that in zeolite A. This simplicity facilitates the determination as to which cation movement an observed dielectric loss is to be assigned. In a previous work,[2] the dielectric properties of the completely dehydrated Rb_3Na_8-ZK4 zeolite were studied, and a relaxation loss peak observed was tentatively assigned to a jump of a Rb^+ ion on the site of an 8-membered oxygen ring (abbreviated as the 8-ring site) to the 4-ring site. The purpose of this study is to confirm this assignment.

Experimental

The apparatus and procedures for dielectric measurements were the same as in the previous paper.[2] The starting material, $Na_{11.0}(AlO_2)_{11.0}(SiO_2)_{13.0}$ ($(AlO_2)_{11.0}(SiO_2)_{13.0}$ is abbreviated as -ZK4), was ion-exchanged with a 0.2 mol dm^{-3} solution of CH_3COOK and the composition of the resultant zeolite was shown by atomic absorption spectrometry to be $K_{3.0}Na_{8.0}$-ZK4 (K_3Na_8-ZK4). Complex dielectric constants ($\varepsilon^*=\varepsilon'-i\varepsilon''$) of Na_{11}-ZK4 and K_3Na_8-ZK4 zeolites were measured as functions of frequency f (10—2×10^6 Hz) and temperature T (room temperature—680 K), and were not corrected for the packing density. A sample placed in a vacuum system was gently heated under pumping and finally baked out at 670 K. The degree of dehydration of the sample was shown to be complete in the same manner as in the previous paper.[2]

Results

Representative spectra of loss tangent and the Cole–Cole plots are shown in Figs. 1 and 2. The figures show the presence of two kinds of dielectric losses, a relaxation loss peak and a loss in the lower frequency region. The frequency of the applied field giving the peak of loss tangent, f_{tan}, is determined on the spectrum of loss tangent and an activation energy of the cation jump, E_{tan}, is determined from Arrhenius plots of ln f_{tan} vs. $1/T$ to be 89±2 kJ mol^{-1} for Na_{11}-ZK4 and 94±3 kJ mol^{-1} for K_3Na_8-ZK4. By the method described in the previous paper,[2] the contribution of the conduction loss, ε''_c, and the apparent specific d.c. conductivity, σ, are estimated and the activation energy of the conduction process is obtained from plots of ln σ vs. $1/T$ to be 86±4 kJ mol^{-1} for Na_{11}-ZK4 and 88±5 kJ mol^{-1} for K_3Na_8-ZK4. A relaxation loss part, ε''_r, is separated from the observed dielectric loss, ε''_{obs}, by the relation of $\varepsilon''_r=\varepsilon''_{obs}-\varepsilon''_c$, as illustrated in Figs. 1(b) and 2(b). Let $f_{\varepsilon''}$ be the frequency at the maximum value of ε''_r, then the activation energy of the cation jump, $E_{\varepsilon''}$, and the frequency factor, ω_0, are determined from Arrhenius plots of ln $f_{\varepsilon''}$ vs. $1/T$, where ω_0 and $E_{\varepsilon''}$ are defined as $\ln f_{\varepsilon''}=\ln \omega_0/2\pi-E_{\varepsilon''}/RT$. The values of log ω_0 for Na_{11}-ZK4 and K_3Na_8-ZK4 are 12.1±0.4 and 11.6±0.3, respectively, and $E_{\varepsilon''}$ is 91±3 kJ mol^{-1} for Na_{11}-ZK4 and 94±4 kJ mol^{-1} for K_3Na_8-ZK4. Plots of E_{tan} vs. r and log ω_0 vs. log M are shown in Figs. 3 and 4, respectively, where r denotes a radius of cation and M a mass of the cation. For comparison, data for Rb_3Na_8-ZK4 zeolite[2] are shown in Figs. 3 and 4.

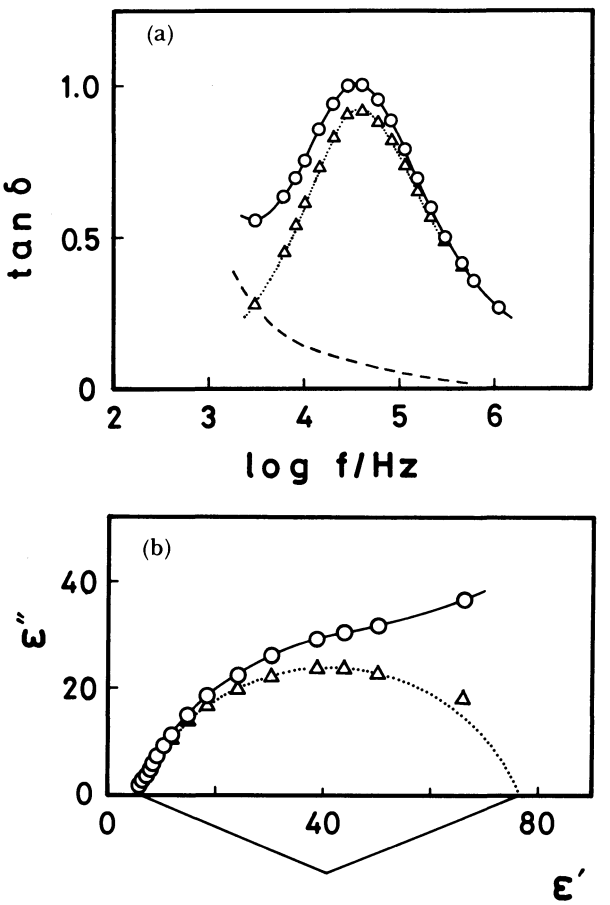

Fig. 1. Dielectric properties of Na_{11}-ZK4 zeolite. (a) Spectrum of loss tangent at 649.0 K. O: observed (tan δ_{obs}), △: loss tangent of relaxation (tan δ_r=tan δ_{obs}−tan δ_c), broken line: loss tangent of conduction (tan $\delta_c=\varepsilon''_c/\varepsilon'_{obs}$). Subscript obs denotes observed value. ε''_c is conduction loss obtained by the method described in Ref. 2. (b) Cole–Cole plots at 649.0 K. O: ε''_{obs} vs. ε'_{obs}, △: ε''_r vs. ε'_{obs}, ($\varepsilon''_r=\varepsilon''_{obs}-\varepsilon''_c$).

Discussion

Let us consider which cation, the 8-ring cation or the 6-ring cation, causes the relaxation loss. As yet the cation distribution of K_3Na_8-ZK4 zeolite has not been studied. The cation distribution in zeolite A containing Na^+ and/or K^+ ion has been studied in detail,[3-6] and it was shown that the K^+ ion prefers the 8-ring site to the 6-ring site and the Na^+ ion has a reverse site-selectivity. It is presumed that the site-selectivities of K^+ and Na^+ ions do not change in both zeolites A and ZK4 and thus K^+ and Na^+ ions occupy the 8-ring site and the 6-ring site in K_3Na_8-ZK4 zeolite, respectively. In three zeolites, Na_{11}-, K_3Na_8-, and Rb_3Na_8-ZK4,[2] all 6-rings are fully occupied by Na^+ ions. Hence, if the relaxation loss is brought about by the movement of Na^+ ion on the 6-ring site, the activation energy and the frequency factor in the relaxation process must respectively have almost the same values for all three zeolites. These expectations are in contradiction to the observations as shown in Figs. 3 and 4. Thus it is concluded that the relaxation loss is due to the jump of the 8-ring cation.

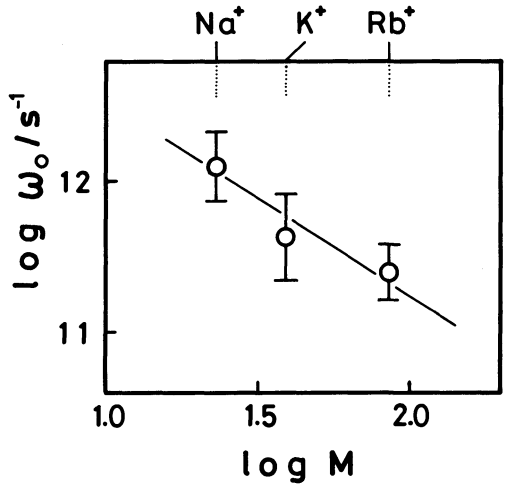

Fig. 4. Plots of frequency factor of jumping cation against mass of cation. Value concerned with Rb^+ ion is from Ref. 2.

In the next place, let us discuss the mechanism of the cation jump. Only two jumps are allowed for the 8-ring cation in the present zeolites, since a cation cannot jump to the sites occupied by the other cations. The 8-ring has four equivalent sites in its plane and can accomodate only one cation. Thus the 8-ring cation can jump to the neighbouring site in the plane. Another possible jump is the jump between the 8-ring site and the 4-ring site (the 4-ring site is vacant in the zeolite ZK4[7]). In these two jumps, the jump in the 8-ring plane is not likely to be the cause of the relaxation loss observed. The jump distance, l, between the sites in the 8-ring plane decreases with the increasing radius of the 8-ring cation and finally converges to zero when Rb^+ ion occupies the 8-ring (l=0.18 nm for Na^+, 0.063 nm for K^+ and 0 nm for Rb^+).[8-10]† Then the jump in the 8-ring plane

† The jump distances were calculated from data of X-ray structural analyses of zeolite A at room temperature. Thus the values may not be valid for zeolite ZK4 at such higher temperatures as the present experimental temperatures. However, it is considered that the dependence of the jump distance upon the ionic radius is valid for the present zeolites.

becomes impossible for the Rb_3Na_8-ZK4 zeolite. Figures 3 and 4 strongly suggest that the same mechanism operates in all three zeolites and the jump in the 8-ring plane is not the cause of the relaxation loss. Therefore, the possible mechanism as the cause of the relaxation loss observed is only the cation jump from the 8-ring site to the 4-ring site. This assignment is supported by the following. In completely dehydrated M_3Na_8-ZK4 zeolite with M= Na, K, or Rb, the allowed conduction mechanism is only the movement of the 8-ring cation through the route of 8-ring→4-ring→another 8-ring.[2] If the mechanisms of the conduction process and the relaxation process are the same, the equation, $E_{\varepsilon'}-E_c=RT$, is valid.[2,11,12] In the present systems, the above relation is satisfied within the experimental error. From the above considerations, it is concluded that the relaxation losses observed in K_3Na_8-ZK4 with M=Na, K, or Rb are caused by the cation jump from the 8-ring site to the 4-ring site.

The present authors sincerely thank Prof. Tetsuo Takaishi of Toyohashi University of Technology, for useful discussions.

Structure Dependence in the Hydrogenation of Acetylene over Columnar Pd Film

Jun TAMAKI and Toshinobu IMANAKA*
Department of Chemical Engineering, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560
(Received November 20, 1987)

Synopsis. Pd films prepared by the UHV RF sputtering system had the tapered columnar structure as observed using SEM. The microstructure of the films changed with the film thickness. This affected the hydrogenation of acetylene. The Pd films which showed the strong (220) intensity in XRD exhibited the high ethylene selectivity.

It is known that a preferred orientation of evaporated metal films on glass substrates alters with the film growth.[1] The changes in the microstructure of metal films are expected to influence their catalytic properties. Previously, structure dependence was observed in the hydrogenation of 1,3-butadiene over Ru thin films[2] prepared by an RF sputtering method.[3] The microstructure of the Ru films changed with the film thickness, that is, the (101) peak increased and the (002) peak decreased with increasing film thickness in X-ray diffraction patterns (XRD). The partial hydrogenation of 1,3-butadiene was found to proceed preferably over the (002) face of Ru.

In this investigation, similar structure dependence is examined on Pd films prepared using the new RF sputtering system equipped with a ultra high vacuum (UHV) chamber.

Experimental

A schematic drawing of the experimental apparatus is shown in Fig. 1. The UHV chamber is 200 mm in diameter and 175 mm in height in inside dimensions and evacuated up to 10^{-8} Torr (1 Torr=133.322 Pa) using a turbo molecular pump (Shimadzu TMP-150, 160 l/s). The target (70 mm in diameter) and the substrate (70 mm in diameter) are at floating and at ground potential, respectively, and placed with their distance of 60 mm at the center of the UHV chamber. A high purity gas of Ar (99.9995%) at a pressure of 0.02 Torr was introduced into the chamber through a variable leak valve. The purity of Ar was confirmed using a quadrupole mass filter (ULVAC MSQ-150A) in advance of the glow discharge. RF power (13.56 MHz) of 100 W was supplied to the target on which a Pd plate (99.95%) was mounted. The glow discharge was generated between the target and the substrate because the shield (ground potential) around the target prevented the discharge which occurred at the undesirable place. Sputtered Pd atoms were deposited on a Pyrex glass substrate. The film thickness was simultaneously measured using a film thickness monitor with a quartz oscillator (Inficon XTM) which was set in the neighborhood of the substrate. Under this condition (Ar: 0.02 Torr, RF power: 100 W), the Pd film was deposited at a rate of 13 nm min^{-1}. The target, the substrate, and the sensor head of the film thickness monitor were water-cooled and maintained at room temperature.

The structure of the Pd films with various thickness was investigated by XRD and scanning electron microscopy (SEM). These investigations were performed by using Shimadzu VD-1 X-ray diffractometer and Akashi ALPHA-30A scanning electron microscope.

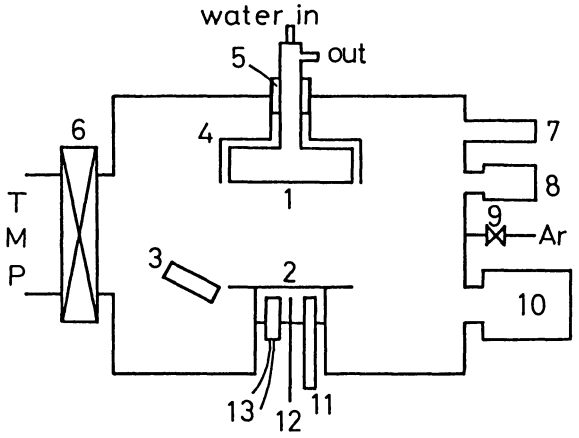

Fig. 1. Schematic drawing of the UHV RF sputtering apparatus. 1: target, 2: substrate, 3: sensor head of film thickness monitor, 4: shield, 5: insulator, 6: bellows stop valve, 7: low vacuum gauge, 8: high vacuum gauge, 9: variable leak valve, 10: mass filter, 11: cooling water tube, 12: thermocouple, 13: heater.

The hydrogenation of acetylene was carried out over the Pd films with various thickness at 273 K using a closed circulation system. A ratio of H_2/acetylene and a total pressure in the system were controlled to 6 and 140 Torr, respectively. The products of the hydrogenation were analysed by the gas chromatograph (Shimadzu GC-8A) with the thermal conductivity detector. A column used was an activated charcoal 3 m column.

Results and Discussion

In the XRD patterns of the Pd films, three peaks due to Miller indices (111), (200), and (220) of Pd fcc structure appeared at 40.3, 46.5, and 68.0 degree of 2θ. Figure 2 shows the changes in the relative intensity of these peaks with the film thickness. The (220) intensity steeply increased and the (111) intensity decreased with increasing film thickness. This indicates that the Pd film above 1 μm in thickness practically has the (220) oriented structure and that the microstructure of the Pd films is obviously changed with the film thickness. The (111) face is the most densely populated face in Pd fcc structure. The (111) face was preferentially oriented in the Pd films at the initial stage of the film growth. Then, the preferred orientation altered from the (111) orientation to the (220) orientation with the film growth. These results are agreed with the previous reports.[1,4]

Figure 3 is the SEM images of the surface view and the fracture cross section of the Pd film with 1 μm in

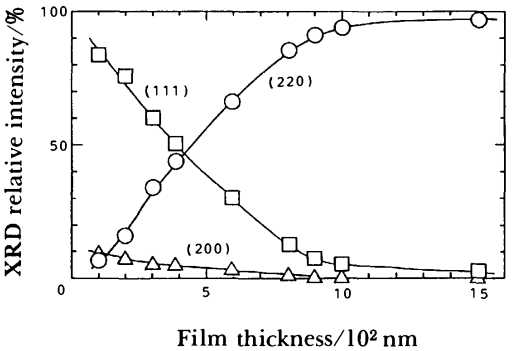

Fig. 2. Dependence of XRD relative intensity for the Pd films on film thickness.

thickness. The Pd film evidently had the tapered columnar structure as observed by Thornton.[5] The surface was not flat and the intercolumn boundaries were obviously voids. At the bottom of the Pd film, the columns were fine (about 40 nm). The diameter of the columns increased toward the top of the film. It was found that both the diameter and the length of the column increased with increasing film thickness. This was also observed in the surface view SEM images of the Pd films with various thickness. The average diameter of the columns was 200 nm in the Pd film with 1 μm in thickness. The column diameter was generally uniform except for some fine columns which had not yet grown. The SEM images elucidated the microstructure of the Pd film prepared by the RF sputtering method. XRD offers the relative composition of the crystal faces which are parallel to the substrate surface. Since the surface of the film is not flat, the (220) face, which is preferentially oriented in the Pd film with 1 μm in thickness, would not be exposed on the column surface in the SEM image. However, it is considered that each column in the SEM image has the same orientation.

The catalytic property of the microstructure of the Pd films with various thickness was evaluated in the hydrogenation of acetylene. Figure 4 shows the dependence of the activity and the initial selectivity for ethylene on the film thickness. The activity was estimated on the basis of the geometrical surface area of the substrate. The activity increased with increasing film thickness. The activity of the 1.5 μm Pd film was 5 times as great as that of the 100 nm Pd film. As observed in the SEM images, the columns grow with the film thickness and the intercolumn boundaries are voids. Therefore, the side of the column is considered to effectively participate in the hydrogenation of acetylene. The increase in the film thickness brings about the enhancement of the true Pd surface area, resulting in the high hydrogenation activity. On the other hand, the selectivity for ethylene in the hydrogenation of acetylene increased with increasing film thickness as well as the activity. The selectivity reached 96% on the Pd films above 800 nm in thickness. The Pd films which showed the stronger (220) intensity in its XRD pattern was found to exhibit the higher selectivity to ethylene. With the

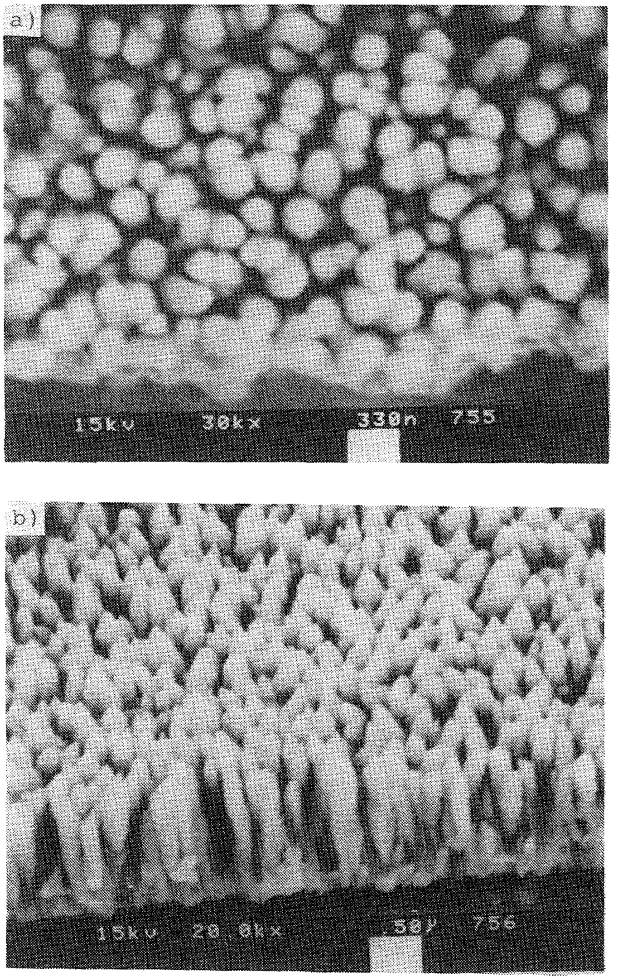

Fig. 3. Scanning electron micrographs of the Pd film with 1 μm in thickness. **a**) surface view, b) fracture cross section.

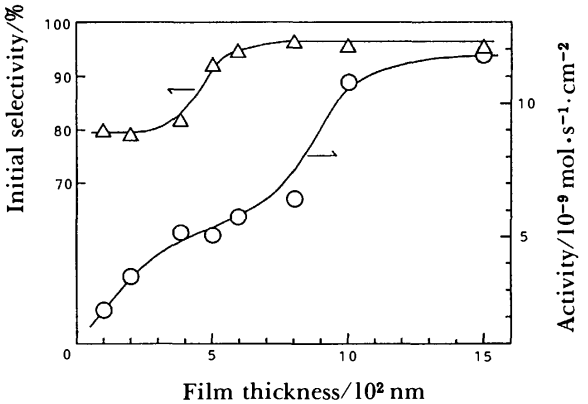

Fig. 4. Dependence of the activity and the initial selectivity for ethylene in the hydrogenation of acetylene on film thickness.

Ru film,[2] the (002) face, which was the most densely populated face of Ru hcp structure, was favorable for the partial hydrogenation of 1,3-butadiene. Although

the (111) face of Pd is the same arrangement of the atom as the (002) face of Ru, the (111) face of Pd does not seem to be suitable for the partial hydrogenation of acetylene.

Proton Magnetic Relaxation and Molecular Motion in Crystalline Tetramethylsilane

Tooru HASEBE,* Nobuo NAKAMURA,† and Hideaki CHIHARA†
Department of Chemistry, Faculty of Education, Fukushima University, Matsukawa-machi, Fukushima 960-12
†Department of Chemistry, Faculty of Science, Osaka University, Toyonaka 560
(Received November 27, 1987)

Synopsis. The molecular motion in the three modifications of tetramethylsilane was studied by the spin-lattice relaxation time measurements. The activation parameters for the methyl group reorientation, overall molecular tumbling, and the molecular self-diffusion were determined in each phase. A possible correlation between these parameters and the stability of the plastic phase was pointed out.

In our previous NMR and heat capacity measurements we established the phase relation in the crystalline tetramethylsilane, $(CH_3)_4Si$, which is hereafter abbreviated as TMS.[1,2] There are three crystalline modifications in TMS. The α phase is a metastable plastic crystal which melts at 165.9 K and, on cooling down to about 159 K, changes spontaneously into the β phase which melts at 171.0 K. The β phase can be supercooled down to very low temperatures, but transforms, on heating, into another phase, the γ phase, at about 118 K. The γ phase is the most stable phase over the whole temperature range of the crystalline state. It melts at 174.1 K. We also obtained the gross feature of the dynamic structure of the β and the γ phases of TMS by proton magnetic resonance,[1] but were not able to derive the quantitative information about the molecular motional modes in each of the three phases. The present study therefore was undertaken to investigate the characteristics of the molecular motions being excited successively in TMS with extensive measurements of the spin-lattice relaxation times in the laboratory and the rotating frames, T_1 and $T_{1\rho}$. The correlation between the molecular motion and the stability of the unique plastic phase in TMS will also be discussed.

Experimental

TMS from commercial source (Merck) was purified by vacuum distillation, outgassed by the freeze-pump-thaw technique and sealed under vacuum in a glass ampule. The NMR relaxation experiments were done at 15.0 MHz with a Bruker CXP 4-60 MHz pulsed NMR spectrometer. The T_1 was measured by the saturation-90° method. The $T_{1\rho}$ values were measured using the spin-locking method with a rotating r.f. magnetic field, B_1, of 0.7 mT for the β and the γ phases and also of 0.2 and 1.0 mT for the α phase. The estimated error in both relaxation times was less than ±4%. Temperatures were controlled to within ±0.1 K and the accuracy of the temperature measurement was better than ±0.3 K.

Results and Discussion

α Phase. Figure 1 shows the temperature dependence of T_1 and $T_{1\rho}$ in the metastable plastic α phase. The slope in T_1 below about 165 K leads to an activation energy E_a of 5.5±1.3 kJ mol^{-1} which corresponds to the overall molecular tumbling or reorientation. Above about 165 K another motion is excited. This motion shows B_1 independence of $T_{1\rho}$

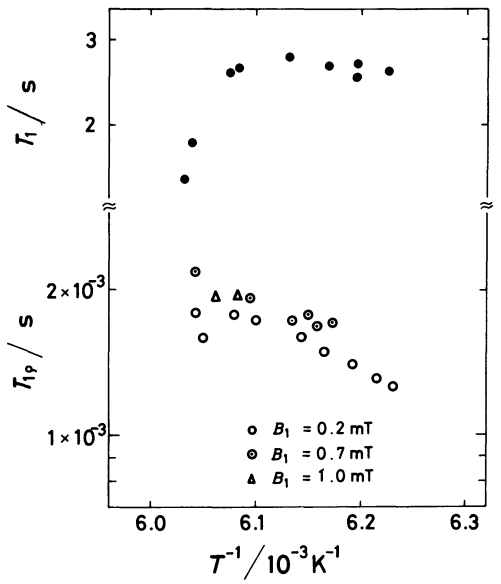

Fig. 1. Temperature dependence of T_1 (●) and $T_{1\rho}$ at B_1=0.2 mT (○), 0.7 mT (◉), and 1.0 mT (△) at the Zeeman frequency, 15.0 MHz for the α phase.

and causes to increase $T_{1\rho}$ values monotonously on heating. The slope of the $T_{1\rho}$ gives the activation energy, E_a=20.4±1.6 kJ mol^{-1}, which is certainly attributed to molecular self-diffusion.

The activation energies for the overall molecular reorientation, E_a^r, and for molecular self-diffusion, E_a^d, in some typical plastic crystals which were determined by NMR methods are listed in Table 1 together with the ratio E_a^d/E_a^r for each substance. The values of this ratio are in the range between 4 and 12 for usual plastic crystals.[3] However the values of TMS and $(CH_3)_3CBr$ are somewhat small compared with other plastic crystals; they are 3.7 and 3.8, respectively. It is remarked that the α phase of TMS is metastable as mentioned above and $(CH_3)_3CBr$ has two plastic phases.[4] It is also noted that in $(CH_3)_3CCN$ no plastic phase exists and overall molecular tumbling has not been recognized.[5] So we assume to be $E_a^r \gg E_a^d$ at a moment then we get $E_a^d/E_a^r \ll 1$ in the case $(CH_3)_3CCN$. These findings strongly suggest that this ratio is closely related to the stability of plastic phase in globular molecular crystal, giving probably a new criterion for the plastic crystal.

β and γ Phases. The relaxation data in these two phases are shown in Figs. 2 and 3, indication that the gross feature of the dynamics of the molecules is quite similar in both phases. We attributed the minima in T_1 near 80 K to the methyl group reorientation, and the minima in $T_{1\rho}$ at about 155 K (in β phase) and 170 K (in γ phase) to the overall molecular tumbling motion. Analyses of these relaxation data by a usual procedure[6,7] lead to the activation parameters for these two kinds of motions as recorded in Table 2. The solid lines in Figs. 2 and 3 show the theoretical relaxation times reproduced using the parameters in Table 2.

Although we ascribed the minima in T_1 near 80 K in the β and γ phases to the methyl group reorientation, a possibility that an anisotropic molecular rotation or reorientation of "rigid" molecule governs the relaxation at low temperatures cannot be ruled out. Our model calculation predicts, for example, that the axial rotation of $(CH_3)_3C$-group about one C-C bond gives the T_1 minimum which is only 5% shorter than that due to independent reorientation of the individual methyl groups. Therefore, we cannot distinguish these different mechanisms at the present stage without detailed structural data.

Synopsis. The crystal and molecular structure of the title complex was determined by the single-crystal X-ray diffraction method. The crystallographic data are: monoclinic, space group $P2_1/c$, a=19.164(6), b=19.020(9), c=18.649(7) Å, β=95.06(3)°, and Z=8 (16 metal atoms are in a unit cell). There are two crystallographically independent dimeric $[SbBr(C_6H_5)_3]_2O$ molecules, which are almost in the same form. Each antimony atom is bonded with three phenyl carbon atoms equatorially and one bromine as well as one bridging oxygen atoms axially, being in a trigonal-bipyramidal geometry. The Sb–O–Sb′ angles are 170.2(7) and 176.6(8)°, while the Sb–O lengths are in the range of 1.931(13)—1.958(13) Å, which are shorter than the sum of their covalent radii of the atoms: 2.15 Å.

The halogeno derivatives of organoantimony(V) have been one of the best known species since the 19th century.[1a,2] They are hydrolyzed in a solution containing water into their hydroxides or oxides,[1b] and the decomposition is quantitative in a water–acetonitrile mixed solution, even at room temperature.[3]

On the other hand, some intermediate compounds of the type $(SbXR_3)_2O$ (where X^- is a halide or acidate ion, and R is a hydrocarbon group) were obtained and some of their structures were elucidated: the compounds where R=C_6H_5, HX=2-hydroxyethanesulfonic acid[4] or HN_3;[5] R=CH_3, HX=HCl, $HClO_4$ or HN_3,[6] and R=*p*–chlorophenyl, HX=1,1,1-trifluoro-2,4-pentanedione[7] are examples. In addition to them, this time we could obtain the title compound, in spite of the fact that dibromotriphenylantimony is hydrolyzed into $[Sb(C_6H_5)_3]O$ easily and quantitatively in the moistened acetonitrile solution at ambient temperature.

Moreover, the Sb–O–Sb′ bridge of this type dimeric complex is one of the subjects of discussion. In the related compounds such as $[BiClO_4(C_6H_5)_3]_2O$,[8] $[Ge(C_6H_5)_3]_2O$,[9] and $[Sn(C_6H_5)_3]_2O$[10] the M–O–M′ angles are 142.2(7), 135.2(2), and 137.3(1)°, respectively: not 109° of the sp^3 hybridization orbital angle nor 180° to separate both side metal atoms the furthest. Among the $(SbXR_3)_2O$ type dimers, $[SbN_3(C_6H_5)_3]_2O$ has an angle of 139.8(4)°;[5] however, the others were reported to have an angle of 180°, since their oxygen atom is at the center of symmetry. As the Sb–O distances of these bridges are relatively short, the oxygen atom is assumed to be disordered into several positions around it.[6] To discuss this problem more clearly, we need more structural data concerning this type dimers.

From these viewpoints, we have determined the crystal and molecular structures of the title compound using the single crystal X-ray diffraction technique.

Experimental

Synthesis of the μ-Oxo-bis[bromotriphenylantimony(V)]. Dibromotriphenylantimony(V) (1.02 g, 2.0 mmol) was dissolved into 10 cm^3 of benzene, and triethylamine (including trace of water, 0.20 g, 2.0 mmol) was added and stirred. The precipitate (triethylammonium bromide) was filtered off, and the filtrate was dried up by the rotary vacuum evaporator at about 80 °C. The residue was recrystallized from acetonitrile (the title compound is relatively soluble into hot acetonitrile, while $[Sb(C_6H_5)_3]O$ is more insoluble at any temperature). Yield, 0.30 g (34%). Found: C, 48.86; H, 3.39%. Calcd for $Sb_2C_{36}H_{30}OBr_2$: C, 49.03; H, 3.43%.

Single Crystal X-Ray Structure Analysis. The crystal of the title compound (colorless), in the shape of parallelepiped (0.30×0.20×0.30 mm^3) was used for the intensity measurement. Crystallographic data: $Sb_2C_{36}H_{30}OBr_2$, F. W., 881.94, monoclinic, space group $P2_1/c$, a=19.164(6), b=19.020(9), c=18.649(7) Å, β=95.06(3)°, U=6711(5) $Å^3$, Z=8, D_m=1.74(3), D_x=1.74 g cm^{-3}, μ(Mo $K\alpha$)=41.8 cm^{-1}, and the final R value was 0.053.[11] Reflections within a range of $3°<2\theta<36°$ were collected on a Rigaku AFC-6A automated four-circle X-ray diffractometer, using graphite-monochromated Mo $K\alpha$ radiation (λ=0.71073 Å), the ω–2θ scan technique being employed (scan speed, 4° min^{-1} in θ; scan width 1.10+0.5 tan θ). Of the 5155 independent reflections measured, 3553 $|F_o|>3\sigma(|F_o|)$ reflections were used for the structure determination. The intensities were corrected for the Lorentz and polarization factors, but not for the absorption and extinction. The structure was solved by the heavy-atom method. Their positional and thermal parameters were refined by the least-squares method. At the final step, all non-hydrogen atoms were found: all hydrogen atoms were excluded from the structure factor calculations.

All the calculations were carried out on a HITAC M-680H computer at the Computer Center of the University of Tokyo, using the local version of the UNICS program system.[12] The atomic scattering factors were taken from Ref. 13.

Results and Discussion

The selected bond lengths and bond angles are shown in Table 1.[14] A perspective drawings of both dimeric complexes from different visual points, together with their numbering scheme of the atoms in Figs. 1 and 2, and the projection of the unit cell to the ac-plane in Fig. 3.

Although both kinds of the dimers are crystallographically independent, and the bridging oxygen atom is not at the center of symmetry, their general features, as well as the geometries around all anti-

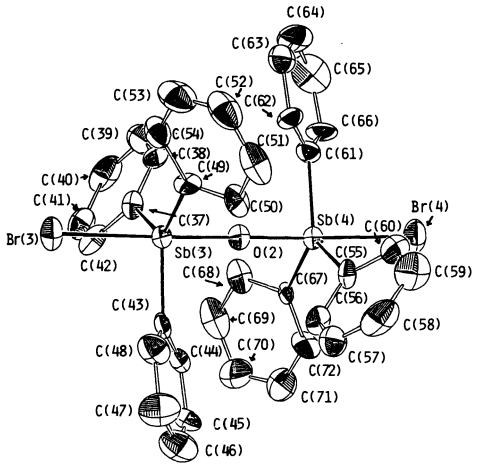

Fig. 2. A perspective drawing of the complex around the Sb(3) and Sb(4) atoms, with the numbering scheme.

mony atoms are approximately the same. Of course, there are some slight differences between them: for example, the angles Sb(1)–O(1)–Sb(2) and Sb(3)–O(2)–Sb(4) are 170.2(7) and 176.6(8)°, respectively, and the mutual dihedral angles between the three benzene ring planes around the Sb(2) atom distribute in the widest range, 49.0—70.6°.

Each antimony atom is coordinated to three phenyl-carbon atoms equatorially, and to one bromine as well as one bridging oxygen atom axially, being in a trigonal-bipyramidal geometry. The lengths of the Sb–C are in the range 2.06(2)—2.14(2) Å, which are not much different from the sum of the Pauling's covalent radii of the atoms C and O: 2.18 Å. On the other hand, the Sb–Br lengths are in the range 2.693(3)—2.722(3) Å, which are longer than the sum of their radii: 2.55 Å.[15] The Sb–O(bridge) lengths are in the range 1.931(13)—1.958(13) Å, which are much shorter than the sum of their radii: 2.15 Å. The common Sb–O bond lengths in the monomeric organoantimony(V) compounds are not so short: for example, in methoxytetraphenylantimony(V) it is 2.061(7) Å, while in dimethoxytriphenylantimony(V) they are 2.039(8) and 2.027(8) Å,[16] while in the other compounds, the bond length is sometimes longer. On the other hand, in cases of this type bridging, the bond is always very short. The Sb–O bond lengths as well as the Sb–O–Sb′ bond angles of some $[SbXR_3]_2O$ type com-

$[SbN_3(CH_3)_3]_2O$	1.872(3)	(180)[b]	6
$[Sb(ClO_4)(CH_3)_3]_2O$	1.862(2)	(180)[b]	6

a) Respective values with their standard deviations are shown in Table 1. b) The bridging oxygen atom is at the center of symmetry.

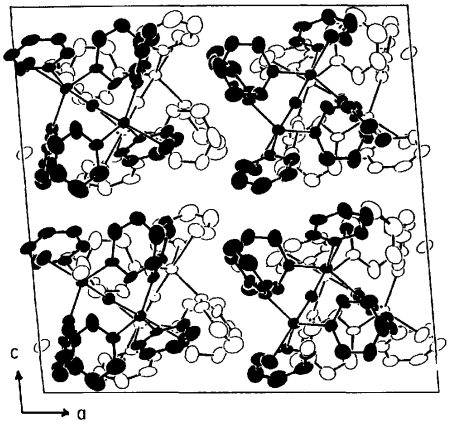

Fig. 3. A projection of the unit cell to the ac-plane. Black atoms belong to the upper, and the white atoms to the lower layers, respectively.

pounds are summarized in Table 2. As shown in this table, of the three triphenylantimony derivatives, the title compound has a bond longer than that of the sulfonato derivative, but shorter than the azido derivative. The polarizability of the bonded anion should not be the sole factor used to determine the length, because in the trimethylantimony derivatives, the Sb-O(bridge) length of the chloro derivative is longer than that of the azido derivative. Moreover, the bond lengths of the azido derivatives of the triphenyl- and trimethylantimony(V) are not the same: the former length is 0.113 Å longer than the latter. Therefore, the massive hydrocarbon groups bonded to the metal atom elongate the bridging bond length. Although the Sb-O-Sb′ angles of the title compound is not much different from 180°, but as the temperature factors of the both bridging oxygen atoms, O(1) and O(2), are not very large, the disorder of the oxygen atoms proposed by Ferguson[6] may not be true in this case. One probable reason is that, although which may not be the sole reason, the mutual steric effect of such large molecules to pack them most closely in the crystal gives the bridging oxygen atom such a large angle, almost 180°, in some of this type dimers.

As shown in Figs. 1 and 2, three benzene rings around each metal atom are situated like the three wing plates of a screw around their shaft. All the mutual dihedral angles between the three benzene ring planes bonded to each metal atom are 59.7°, on the average, and all the angles between the benzene ring planes and the respective Sb-O shafts are 54.6° on the average (in the range of 48.2—66.1°).

There are no bridging ligands nor hydrogen bondings between any dimeric complex molecules: the distances between any non-hydrogen atoms of the different molecules are more than 3.7 Å.

Thermal Cis-Trans Isomerization of Dihalogenobis[trialkyl(or aryl)-phosphine]platinum(II) in the Solid State

Masaki FUSHIMI, Masatatsu SUZUKI, and Akira UEHARA*
Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa 920
(Received October 17, 1987)

Synopsis. Solid-state thermal cis–trans isomerization of the platinum(II) complexes of the type $[PtX_2(PR_3)_2]$ were investigated by means of DSC methods, where X is Cl, Br, or I; R is CH_3, C_2H_5, n-C_3H_7, n-C_4H_9, or C_6H_5. High isomerization ratios (93—100%) were observed for the cis-complexes of $P(C_2H_5)_3$ (X: Br; I), $P(n$-$C_3H_7)_3$ (X: Br; I), and $P(n$-$C_4H_9)_3$ (X: Cl; Br).

The *cis*-dihalogenobis(phosphine)platinum(II) complexes of the type *cis*-$[PtX_2(PR_3)_2]$, where X is a halide ion and PR_3 is one of trialkyl- or triarylphosphines, have long been known to be useful homogeneous catalysts for the selective hydrogenation of unsaturated organic compounds.[1] The cis complexes can usually be prepared by the following two steps:[2] In the first step, the double complexes having a general formula of $[Pt(PR_3)_4][PtX_4]$ are prepared and then the solid double complexes are heated at appropriate temperatures to produce a mixture of *cis*- and *trans*-$[PtX_2(PR_3)_2]$. In the second step, the mixture is separated into pure *cis*- and *trans*-$[PtX_2(PR_3)_2]$ by the use of the difference in solubilities. In general, trans isomers are much more soluble than cis isomers. The ratios of cis to trans isomers in the mixture are largely dependent on the kinds of phosphines. For example, when tributylphosphine and triarylphosphine are used as the ligands, cis isomers are exclusively formed, whereas trans isomers can be obtained only by the use of the thermal isomerization of the corresponding cis isomers.

The thermal cis–trans isomerization of the platinum(II) complexes $[PtX_2(PR_3)_2]$ in the solid state has been much less thoroughly studied, although the catalyzed isomerization of such complexes in solution has extensively been investigated.[3–8] Jensen first reported the isomerization of $[PtX_2(PR_3)_2]$ in the solid state.[2a] More recently, Mastin,[9] and Lee and Stoufer[10] reported on the thermal behaviors, including cis–trans isomerization of $[PtX_2\{P(C_6H_5)_3\}_2]$. DTA/TG methods were used to investigate the isomerization and volatilization of a number of palladium(II) and platinum(II) complexes of phosphines.[11,12] Unfortunately, any study did not quantitatively determine the isomerization ratios of the phosphine complexes, in spite of the fact that the cis-to-trans isomerization in the solid phase (practically in the melting state) has been used widely as the standard synthetic procedure for trans complexes.[2b]

From the standpoint of the application of the isomerization to synthetic procedure, the present study was undertaken primarily to determine the thermal cis–trans isomerization ratios of $[PtX_2(PR_3)_2]$, where X is Cl, Br, or I, and R is CH_3, C_2H_5, n-C_3H_7, n-C_4H_9, or C_6H_5.

Experimental

Materials. Trimethylphosphine($P(CH_3)_3$), triethylphosphine($P(C_2H_5)_3$), tripropylphosphine ($P(n$-$C_3H_7)_3$), tributylphosphine($P(n$-$C_4H_9)_3$), and triphenylphosphine ($P(C_6H_5)_3$) were commercially available.

Preparation of Complexes. *cis*- and *trans*-$[PtX_2(PR_3)_2]$ were prepared by a method similar to that of literature,[2] where X is Cl, Br, or I, and R is CH_3, C_2H_5, n-C_3H_7, n-C_4H_9, or C_6H_5. The compositions of the complexes obtained were confirmed by elementary analyses; the configurations thereof were characterized by means of electronic, IR, Far-IR, and ^1H and ^{31}P NMR spectroscopies.

Measurements. IR spectra of the samples were measured by a KBr-disk method with a JASCO Model A-3 infrared spectrophotometer. Far-IR spectra were measured by a Nujol-mull method with a JASCO Model IR-F far infrared spectrophotometer. Electronic spectra of the samples were recorded on a JASCO UVIDEC-105 UV/VIS recording digital spectrophotometer. ^1H and ^{31}P NMR spectra were monitored on a JEOL-GX400 spectrometer using $(CH_3)_4Si$ as the internal standard in $CDCl_3$ and 85% H_3PO_4 as the external standard in $CDCl_3/CHCl_3$ (1/6, v/v), respectively.

Differential scanning calorimetries (DSC) were carried out with a RIGAKU DENKI Thermal Analyser. Finely powdered samples were used in each run. The measurements were carried out under a constant flow of nitrogen stream at the heating rate of ca. 1.3 °C min^{-1}. Isothermal measurements were conducted by the use of a Chyo-100-L thermobalance equipped with the heating furnace controlled by SHINYO DIGICON 1200 in static air.

Results and Discussion

Thermal Analyses. Figure 1 shows the DSC curve in the first increasing and decreasing, and the second increasing-temperature processes of *cis*-$[PtCl_2\{P(n$-$C_3H_7)_3\}_2]$. The endothermic peak (A, T_{max}: 149 °C) is

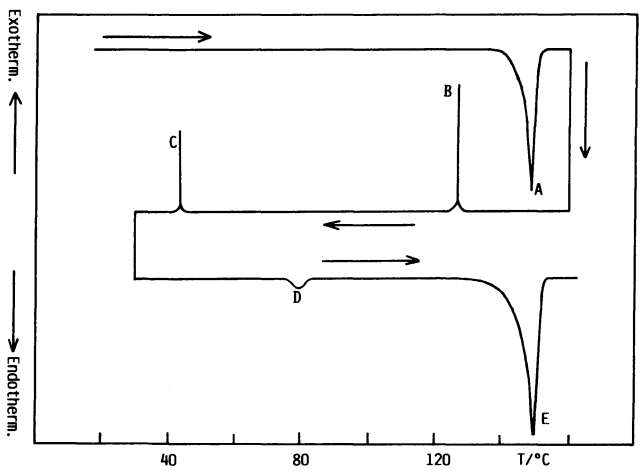

Fig. 1. DSC curve of *cis*-$[PtCl_2\{P(n$-$C_3H_7)_3\}_2]$.

observed in the first increasing-temperature process, which corresponds to the melting point of the cis isomer (mp: 149—150 °C). The product obtained at this stage was confirmed to consist of the mixture of cis and trans isomers (vide infra). The peak is thus ascribable to the melting plus the isomerization of the cis isomer. The exothermic peaks (B, T_{max}: 127 °C) and (C, T_{max}: 44 °C) in the decreasing-temperature process may correspond to the freezing point of the cis isomer and to that of the trans isomer, respectively, because preliminary experiments showed that owing to supercooling the authentic cis and trans complexes are solidified at considerably lower temperatures than their melting points (cis: 149—150 °C; trans: 85—87 °C). Then, the small endothermic peak (D, T_{max}: 80 °C) is found in the second increasing-temperature process, which may come from the melting of the trans isomer (mp: 85—87 °C). The melting point of the trans isomer is thus slightly lowered because of the presence of considerable amount of the cis isomer unchanged. Thus, the appearance of the melting peak of the trans isomer apparently suggests that the cis isomer isomerizes to the corresponding trans isomer to some extent. The endothermic peak (E, T_{max}: 149 °C) in the second increasing-temperature process is the melting point of the cis isomer.

It should be noted that both cis and trans complexes of $P(CH_3)_3$ and $P(C_6H_5)_3$ were decomposed in a complicated fashion with neither melting nor isomerization irrespective of the kind of halide ions. On the other hand, both cis and trans isomers of $P(C_2H_5)_3$, $P(n\text{-}C_3H_7)_3$, and $P(n\text{-}C_4H_9)_3$ were found to have melt to isomerize to the corresponding isomers. It is thus conceivable that the isomerization of the phosphine complexes proceeds in the melting state. This situation is in marked contrast to the case of diamminedihalogenoplatinum(II), isomerization of which takes place easily in the solid state even without melting.[13]

Identification of the Products. The symmetries of the *cis*- and *trans*-$[PtX_2(PR_3)_2]$ are clearly different from each other: the cis isomer possesses local C_{2v} symmetry, while the trans isomer posseses D_{2h} symmetry. For platinum-chloride stretching vibrations, a square planar $PtCl_2P_2$ set should give rise to two bands (A_1 and B_2) for C_{2v} symmetry (cis-configuration) and to one band (B_u) for D_{2v} symmetry (trans configuration).[14] All the cis isomers in the present study exhibit two bands at ca. 270 and 305 cm^{-1}, while the trans isomers, one band at ca. 335 cm^{-1}. On the other hand, the products obtained during heating cis and trans complexes of $P(C_2H_5)_3$, $P(n\text{-}C_3H_7)_3$ and $P(n\text{-}C_4H_9)_3$ show three bands at ca. 270, 305, and 335 cm^{-1}. This evidences that the products are the mixture of cis and trans isomers.

Determination of Isomerization Ratios. The isomerization ratios were estimated spectrophotometrically: in the case of *cis*- and *trans*-$[PtCl_2\{P(n\text{-}C_3H_7)_3\}_2]$, for example, the following simultaneous equation was employed:

$$\begin{cases} 358.5x + 136.7y = D_{330} \\ 396.7x + 821.5y = D_{290} \end{cases}$$

where x and y are the molar concentrations of cis and trans isomers, the numerical factors are the molar extinction coefficients of the pure cis and trans isomers, and the D's represent their absorbances at the wavelengths specified by each subscript. The isomerization ratios are thus given by x(or y)/(x+y).

The isomerization was monitored at varied temperatures and at several time intervals to find suitable conditions for giving maximum isomerization ratios. The results showed that the ratios are considerably altered by the heating temperatures. For example, in the case of *cis*-$[PtCl_2\{P(C_2H_5)_3\}_2]$, the maximum ratio (35%) was detected for one hour at the heating temperature of 196 °C, which is slightly higher than the melting point (191—192 °C). Increasing temperature decreased the ratios: 23 and 2% were found at 205 and 210 °C, respectively. On the other hand, the trans complexes isomerized at

Table 1. Isomerization Ratios of the Complexes $[PtX_2(PR_3)_2]$[a]

a) Each sample was heated for one hour at the specified temperatures. Prolonged heating did not increase the ratios. b) The complexes were decomposed with neither melting nor isomerization. c) Partially decomposed just after melting plus isomerization.

considerably higher temperature than the melting points. Table 1 summarizes the isomerization ratios of cis and trans complexes thus estimated together with the melting points of the complexes. The heating time of one hour was selected from the standpoint of the application of the isomerization to synthetic procedure. Prolonged heating did not improve the ratios. Thus, the ratios may be regarded as nearly maximum isomerization ratios. For $P(CH_3)_3$ and $P(C_6H_5)_3$ complexes, both cis and trans isomers were decomposed with neither melting nor isomerization regardless of halide ions. Among the trans isomers, the bromide and iodides of $P(C_2H_5)_3$ and $P(n\text{-}C_3H_7)_3$, and the bromide of $P(n\text{-}C_4H_9)_3$ complexes were partially decomposed just after melting plus isomerization. High isomerization ratios (93—100%) were observed for the cis complexes of $P(C_2H_5)_3$ (X: Br; I), $P(n\text{-}C_3H_7)_3$ (X: Br; I), and $P(n\text{-}C_4H_9)_3$ (X: Cl; Br). The sum of isomerization ratios of cis and trans isomers of the same phosphine is not exactly but approximately close to 100% except for the chloride of $P(n\text{-}C_3H_7)$, implying that the isomerization may reach equilibrium of cis and trans isomers. The sum of the ratios of the chlorides of $P(n\text{-}C_3H_7)_3$ complex amounts to only 38%. The value implys that the isomerization of the complexes incompletely reaches equilibrium under the specified conditions. An indication was detected for the complexes that application of higher heating temperatures than 160 °C for the cis and 154 °C for the trans isomers might improve the isomerization ratios. However, at such high temperatures the complexes in the melting state underwent gradual vaporization and partial decomposition so that the ratios were unable to be estimated in detail.

We expected at the beginning of this study that the bulkiness of the phosphines (steric factor) may play an important role in the isomerization. However, the expectation did not come true: as seen from Table 1, the isomerization ratios do not vary with the phosphines. Marther et al. found that there is a good correlation between NMR coupling constants and the Pt-P bond strengths in the platinum(II) complexes of phosphines.[15] Relationship between the isomerization and the Pt-P bond strengths was investigated by NMR spectroscopy, but no relationship could be found between them.

It has long been known that trans complexes of $[PtX_2(PR_3)_2]$ are isolated with more difficulty in poorer yields than the corresponding cis isomers because the trans isomers are much more soluble than the cis isomers.[2] Thus, the trans isomers have usually been prepared by the use of catalysed isomerization of the cis isomers in solution, but the method requires troublesome steps.[16] On the other hand, the results obtained in the present study declare that the trans complexes of $P(C_2H_5)_3$ (X: Br; I), $P(n\text{-}C_3H_7)_3$ (X: Br; I), and $P(n\text{-}C_4H_9)_3$ (X: Cl; Br) can be easily obtained in good yield by the use of thermal isomerization of the corresponding cis isomers in the solid state (practically in the melting state).

The Magnetic Properties of the Copper(II) Alkanoate Adducts with Cyclic Ethers and Tertiary Amines

Synopsis. Various copper(II) alkanoate adducts with cyclic ethers and tertiary amines have been prepared and characterized by means of magnetic susceptibility and IR spectroscopy measurements. The effect on the magnetic moments of the dinuclear copper(II) alkanoates of varying the base strength of the axial ligands is also discussed.

It has often been pointed out that the antiferromagnetic interaction in dinuclear copper(II) carboxylate adducts, $[Cu(RCOO)_2 \cdot L]_2$, is influenced both by the carboxylato substituent R and the axial ligand L.[1,2] As for the latter, Jotham et al. have examined the magnetic properties of the compounds with a series of axial ligands including pyridine and water and have noted that the spin-exchange coupling between the two copper(II) ions tends to increase as the axial ligands become stronger electron donors.[1] However, these magnetic properties may be obscured by other factors, such as the steric hindrance of axial coordination[3] and the intermolecular hydrogen bond between the water molecule and the carboxylato group.[4,5] Actually, the magnetic data of the copper(II) chloroacetate adducts with pyridine analogues[6] rather contradict the remark of Jotham et al.

Thus, we have now prepared various copper(II) alkanoate adducts with 1-azabicyclo[2.2.2]octane (abco), 1,4-diazabicyclo[2.2.2]octane (dabco), 1,3,5,7-tetraazatricyclo[3.3.1.1]decane (tatcd), tetrahydropyran (THP), and tetrahydrofuran (THF), and examined their magnetic moments, together with those of the adducts with 1,4-dioxane (dox). The axial ligands here considered are practically pure sigma donors, containing both oxygen and nitrogen donors. X-Ray analyses[7-9] have shown that the copper(II) propionate adduct with dox and the copper(II) acetate adducts with dabco and tatcd have polymeric structures, in which the carboxylato-bridged dinuclear units are connected by the axial ligands. In spite of this fact, these compounds are appropriate compounds in which to examine the axial-ligand effects on the magnetic properties of dinuclear copper(II) alkanoates, because the interdinuclear interactions are much weaker than the intradinuclear interactions.[10,11]

Various copper(II) alkanoate-abco (1/1), -dabco (2/1), and -tatcd (3/1) compounds were obtained, except for the cyclohexanecarboxylates, in accordance with a method employed by Tennenhouse.[12] The cyclohexanecarboxylates were prepared in a similar way, using dioxane solutions. The 2:1 species of tatcd adducts were obtained according to the procedure of Pickardt.[8] The adducts with the THP and THF were prepared by the use of the procedures reported for the corresponding dox adducts,[13] and their chemical analyses were done and their magnetic susceptibilities were measured within a few hours after preparation to avoid any fluctuations caused by their instabilities.

The effective magnetic moments of these compounds (Table 1) were evaluated from the room-temperature magnetic susceptibilities, which were corrected for the diamagnetic contribution using Pascal constants[14] and for the temperature-independent paramagnetism using the value of 60×10^{-6} emu mol^{-1} (1 emu$=4\pi\times10^{-6}$ m^3). The values determined for the copper(II) acetate adducts with abco and dabco agreed well with those reported previously.[11,15] For the copper(II) propionate-abco (1/1), -dabco (2/1), and -tatcd (3/1) compounds, the temperature dependence of their magnetic susceptibilities was measured in the temperature range of 80—300 K in order to confirm their dinuclear structures. The results agreed well with the Bleaney-Bowers equation[16] when the following parameters were used: $g=2.18$ and $2J=-323$ cm^{-1} for the abco adduct, $g=2.17$ and $2J=-329$ cm^{-1} for the dabco adduct, and $g=2.18$ and $2J=-334$ cm^{-1} for the tatcd adduct. The IR spectra of the solid compounds show characteristic bands in the ranges of 1660—1610 and 1425—1405 cm^{-1} connected with the symmetric and unsymmetric COO stretching vibrations of the carboxyl groups.[17] The magnetic and IR

Table 1. Effective Magnetic Moments (BM) at 20°C for $[Cu(RCOO)_2 \cdot L]_2$ Compounds

CH_3CCl_2		1.49			1.46	1.47

spectral data indicate that the present compounds have bridged dinuclear structures similar to that of copper(II) acetate monohydrate.[4,5]

Previously, we have shown that, for the copper(II) (monosubstituted acetate)s and copper(II) (disubstituted acetate)s with coordinated chloride ions in the axial positions, their magnetic moments decrease linearly with the pK_a values of the parent carboxylic acids,[18-20] which may be summarized as follows:

$$\mu_{eff} = -0.052(pK_a - 4.56) + \Delta\mu_\alpha + 1.37_9, \quad (1)$$

where $\Delta\mu_\alpha$ is the correction term for the substitution in the methyl group of acetic acid (−0.06 and −0.07 for the series of mono- and disubstituted acetates respectively), including the corrections for steric strain, field effect, and hyperconjugation. Similarly, the magnetic moments of a series of copper(II) alkanoates with other axial ligands may be expressed as follows.

$$\mu_{eff} = -0.052(pK_a - 4.56) + \Delta\mu_\alpha + A_{ax}, \quad (2)$$

where A_{ax} is a correction term for axial coordination; its value can be evaluated by graphic interpolation (Fig. 1). To plot the points for the 2,2-dichloropropionates, $\Delta\mu_\alpha$=−0.08 BM[21] is used tentatively, since insufficient data are available to evaluate it precisely. The obtained A_{ax} values are 1.42_2, 1.39_3, 1.38_1, and 1.35_9 BM for the abco, 1/2dabco, 1/2tatcd, and 1/3tatcd adducts respectively, and 1.37_2, 1.37_0, and 1.36_3 BM for the THP, THF, and 1/2dox adducts respectively.

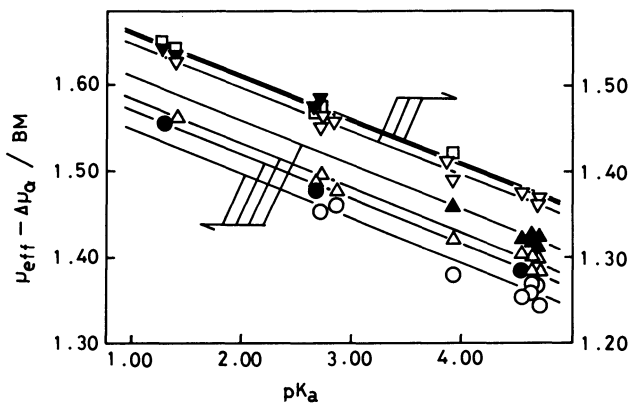

Fig. 1. The corrected magnetic moments at 20°C plotted against the pK_a values of the parent carboxylic acids for the copper(II) alkanoate adducts with abco (▲), 1/2dabco (△), 1/2tatcd (●), 1/3tatcd (○), THP (▼), THF (□), and 1/2dox (▽). The solid lines are the best fit of the data to the Eq. 2.

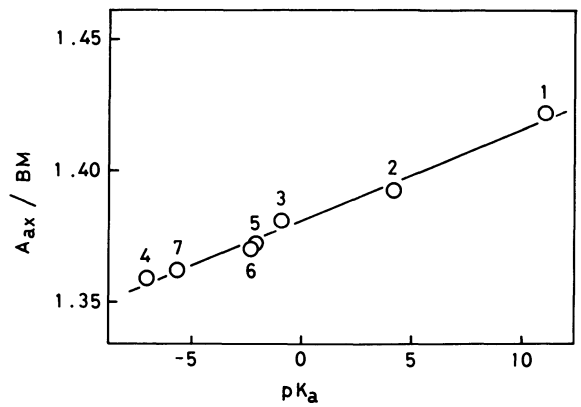

Fig. 2. The axial-coordination correction term plotted against the pK_a value of the conjugate acid of the axial ligand: abco (1), 1/2dabco (2), 1/2tatcd (3), 1/3tatcd (4), THP (5), THF (6), and 1/2dox (7).

Since typical hard bases are involved in this study, it seems likely that the axial-ligation effect of such bases correlates primarily to their donor characters. In order to examine this, the obtained A_{ax}'s are plotted against the pK_a values of the conjugate acids of axial ligands (Fig. 2). To plot the points for dabco and dox ligands, their first dissociation constants are selected, because their second coordination abilities are reduced similarly by H^+- and Cu^{2+}-coordination on the other sites. By similar reasoning, the pK_{a2} and pK_{a3} values (these values are estimated from pK_{a4}[22] by using the Branch-Calvin equation[23]) are selected for the 1/2tatcd and 1/3tatcd adducts respectively. In this series of axial ligands, the pK_a value varies from −7.1 for 1/3tatcd to −5.7, −2.26, −2.10, −1.0, 4.14, and 11.0 for 1/2dox, THP, THF, 1/2tatcd, 1/2dabco, and abco respectively. As can be seen from Fig. 2, there is a linear relation between these quantities. The best line has a slope of +0.0035 BM and the intercept of 1.38_2 BM at pK_a=0. The line in Fig. 2 goes upward to the right, and the variation in singlet-triplet separation values determined for the abco, 1/2dabco, and 1/3tatcd adducts of copper(II) propionate (−2J=323, 329, and 334 cm^{-1} respectively) indicates that the antiferromagnetic interactions decrease as the axial ligands become stronger sigma donors. This fact may be explained on the basis of weak Cu-O covalent bonds on the CuO_4 basal plane resulting from a strong sigma donation of the axial ligand.[24] The observation of the shift in the unsymmetric COO stretching bands (1623, 1620, and 1610 cm^{-1} for the abco, 1/2dabco, and 1/3tatcd adducts of copper(II) propionate) supports this explanation. The magnetic moments of copper(II) tetrahydro-2H-pyran-2-acetate[25] and the copper(II) chloroacetate adducts with 1,3-dioxolane and 2-(diethylamino)ethanol[26] were also found to vary in accord with this trend. In addition, a numerical comparison of the slopes in Figs. 1 and 2 indicates that, in the series of the present compounds, the axial ligand affects the magnetic moment about 15 times less than the bridging carboxylato does. This ratio suggests that the carboxylato substituent R in dinuclear copper(II) carboxylate adducts, $[Cu(RCOO)_2 \cdot L]_2$, affects the covalent Cu-O bonds more strongly than does the apical ligand L, for the spin-exchange coupling between the two copper(II) ions operates predominantly by superexchange interaction through the bridging carboxylato rather than by direct interaction.[27]

(Received November 24, 1987)

Synopsis. Optimum and higher resolution in flash chromatography (FC) has been realized with 20—40 μm silica gel, which gives 1.4—1.9 times larger theoretical plate numbers, than the reported one, 40—63 μm. A new FC tube is proposed and the combination of quartz-made chromatographic tube and silica gel with fluorescent indicator is conveniently used for the preparative separation of colorless but UV absorbing compounds.

Medium-pressure liquid chromatography (MPLC),[1] flash chromatography (FC),[2,3] and vacuum dry chromatography[4] have been used for rapid and preparative separation of organic compounds as routine methods. These chromatographic techniques overcome the defects encountered in traditional gravity column chromatography, which is characterized by its low resolution, long separation time, inferior recovery of sample, and requisition of large amount of solvent and adsorbent. Among these techniques, FC has been accepted as a substantially reliable one from the respect of its simplicity, acceptable resolution, and speed. Still et al. reported the optimum resolution was obtained when FC column was prepared by simple dry packing of 40—63 μm silica gel.[2] During our practical application of the FC technique, we found silica gel with smaller diameter and a slurry packing method resulted in the better resolution than the reported method; we reexamined the optimization of FC with use of several kinds of silica gel with different physical properties. We also propose the practically useful FC system which allows the convenient treatment.

We systematically prepared and used four kinds of silica gel, Nos. 1—4 shown in Table 1, with different particle distribution. For elimination of the specificity of silica gel prepared, the corresponding silica gel from E. Merck with different specific surface area, average pore size, and pore volume was also examined. Optimization studies were carried out under a set of conditions using a mixed sample of toluene and nitrobenzene (1 : 1) on a 20 mm i.d.×25 cm column. In the previous paper,[2] packing method is shown not to affect the separation efficiency. We, however, found slurry packing method gave higher and reproducible column efficiency at the pressure below 1 kg cm^{-2}.[6] Since the applied pressure on silica gel packing sensitively affected the resultant column efficiency, especially for the silica gel with the diameter below 20 μm, all FC columns examined in this report were packed at the pressure below 1 kg cm^{-2}. Resolution (R_s) and separation factor (α) of aromatic components were determined, and theoretical plate number (N) was evaluated from the peak of nitrobenzene.[5] The results are shown in Fig. 1 and the typical chromatograms are illustrated in Fig. 2. The optimum resolution was obtained with the silica gel (15—40 μm and 20—40 μm) and 1.4—1.9 times larger N values for the gel with narrow particle distribution around $D_{p50}\cong 30$ μm were achieved than the reported one (40—63 μm).[2] This difference is obvious from their chromatograms (Fig. 2). Regardless of the difference in the physical properties, three types of the silica gel (Nos. 1—4, 5—8, and 9—11 in Table 1) exhibited the similar trend and column efficiency. Thus, it is concluded the column effciency is predominantly affected by both the particle size and

Table 1. Physical Properties of Various Silica Gel Used in This Work

No.	Silica gel name	Particle distribution/μm	Mean particle diameter, D_{p50}/μm	Specific surface area, S/m^2 g^{-1}

its distribution.

For the No. 2 silica gel in Table 1, effect of eluent flow rate on the resolution was examined (Fig. 3) and its optimum value was about 15 ml min^{-1} (linear velocity ca. 5 cm min^{-1}).

Improvement of FC Column. Since the use of silica gel with finer particles under the optimum separation conditions requires increased gas pressure for elution, the reported FC apparatus[2,3] turned to be not suitable for the present purposes, e.g. compressed gas leakage from the glass joint, leakage of adsorbent from the lower end of column, and difficulty in disposal of used gel. We made a new type of glass column apparatus as shown in Fig. 4. The column head **D** can be installed on the column **G** through fluoro-rubber O-ring **F** with clamp **E**, which makes possible quick installation and removal and holds them without any observable leakage of compressed gas below 2 kg cm^{-2}. The sintered glass filter **H** (G-3) effectively holds the applied adsorbent during the chromatographic operation: as long as No. 2 silica gel was used, the particles did not clog pores of the filter. The combination of the gas-tight O-ring joint and the snap-on clamp makes possible to prepare the larger internal diameter FC columns up to 50 mm and this system has practically and repeatedly been used without any problem.

For convenient monitoring of separation process during chromatography, we used quartz FC chroma-

tographic tubes and silica gel with fluorescent indicator in combination. When the applied solute can be detectable by TLC[7] under the illumination of UV light, this mixed fluorescent material is applicable to most of solvent systems except aromatics.[8] This method is also useful for the optimization of solvent systems during chromatography.

Experimental

Material. Irregular-shaped silica gel (Nos. 1—4 in Table 1) was sorted by pneumatic classifier, Nisshin Eng. Co., Turbo Classifier TC-15N. The particle size distribution and the specific surface area were determined with Coulter Counter, Model ZB and Yuasa Battery Co., Monosorb Surface Area Analyzer, respectively. Three types of silica gel with different distribution of particle size and average particle diameter D_{p50} were prepared (Nos. 1—3 in Table 1). The silica gel used was activated at 110 °C for 2 h. Silica gel with fluorescent indicator was prepared according to the reported method.[8] Three kinds of fluorescent materials, $Sr_2P_2O_7$/Sn, Zn_2SiO_4/Mn, and YVO_4/Eu, were mixed in a 20:5:1 ratio, respectively, and 10 wt% of the mixture was added to silica gel. As one of the silica gel frequently applied for medium pressure chromatography, Wakogel C-300 (No. 4 in Table 1) was used as a reference. For elimination of the specificity of silica gel caused by the difference of its physical properties, Merck silica gel 60 and Merck LiChroPrep (Nos. 5—11 in Table 1) were used. Physical properties of various silica gel used in this work were summerized in Table 1.

Chromatographic tubes made of Pyrex or quartz were assembled as shown in Fig. 4. Solvents for HPLC grade were used in these experiments.

Evaluation of Column Efficiency. Silica gel was charged to 20 mm i.d.×25 cm chromatographic tube by a slurry packing method. Each silica gel (60 g) was suspended in hexane (300 ml) and transferred to the hexane-filled tube at the flow rate of 80—100 ml min^{-1} keeping the pressure below 1 kg cm^{-2}. The net amount of the charged silica gel was 35—40 g. A mixture of toluene (50 g) and nitrobenzene (50 g) was diluted to 100 ml with heptane and used as a stock solution of the samples. After substitution of the column with 1 vol % acetonitril in hexane, the stock solution (250 μl) was loaded to the silica-gel column and eluted with the solvent at the flow rate 15 ml min^{-1} (5 cm min^{-1}). The effect of the flow rate on separation efficiency was examined on the range 5—20 ml min^{-1} (1.6—6.4 cm min^{-1}).

The authors wish to acknowledge to Mr. Yasuyuki Mizui for his technical assistance in the preparation of FC apparatus.

Selective Conversion of 2-Mercaptoalkanols to Thiirans with Orthocarbonates

Toshikazu TAKATA and Takeshi ENDO*
Research Laboratory of Resources Utilization, Tokyo Institute of Technology,
Nagatsuta-cho, Midori-ku, Yokohama 227
(Received September 9, 1987)

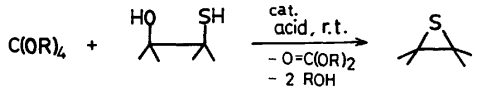
Synopsis. Tetraalkyl orthocarbonates **1** were demonstrated to serve as potent cyclodehydrating agents for 2-mercaptoalkanols **2** to give the corresponding thiirans in good yields in acid-catalyzed reactions in aprotic solvents. Effects of catalysts, solvents, and alkyl substituents of **1** were examined. Activity of the acid catalysts depended on their acidity (pK_a), and the strong Lewis acid $BF_3 \cdot OEt_2$ also had high catalytic activity. Effects of solvents and alkyl substituents of **1** were little observed.

Tetraalkyl orthocarbonates **1** have extensively been studied as useful reagents capable of reacting with both nucleophiles and electrophiles.[1,2] Especially, the characteristic reactions via carbenium ions under acidic conditions are of interest among the various reactions of **1**. Reactions with protic compounds such as phenols and carboxylic acids gave *O*-alkylation products.[1,3] We have recently utilized the acid-catalyzed alcohol-exchange reaction of **1** with some diols to obtain spiroorthocarbonates in good yields.[4] Although **1** is known to readily react with water to afford dialkyl carbonate and two moles of alcohol,[1,2,5] there is no report on the use of **1** as a dehydrating agent except for only one example of conversion of succinic acid to succinic anhydride.[3a]

In our continuing studies on the chemistry of **1**,[4] we have found that **1** is quite a potent cyclodehydrating agent for 2-mercaptoalkanols to thiirans under acidic conditions. A recent report of Evans et al. on the cyclodehydration of mercaptoalkanols to thiacycloalkanes with 1,3,2-dioxaphospholane derivatives,[6] also prompted us to report our recent results on the dehydration.

Results and Discussion

Orthocarbonate **1**, which is commercially available (R=Me) or easily prepared (R=Et and Bu^n),[7,8] was examined as a dehydrating agent in the acid-catalyzed reaction with 2-mercaptoethanol (**2a**), which often resists dehydration[9] and easily affords polymer of the product thiiran in the presence of a strong acid.[10] When **1** was mixed with an equimolar amount of **2a** in the presence of an acid catalyst such as *p*-toluenesulfonic acid (TsOH), thiiran was formed in more than 95% yield (by NMR) along with a dialkyl carbonate and an alkanol (Eq. 1). Without such an acid no reaction took place. The results examined for catalysts, solvents, and alkyl substituents of **1** are summarized in Table 1.



(1)

Using TsOH as the catalyst, the reaction (**1a**, Run 1) was completed within a few minutes, being too fast to monitor the reaction progress, unlike the case of trichloroacetic acid (TCA, Run 4) or acetic acid (AcOH, Run 5). This conversion was very clean, and the reaction gave only thiiran, dimethyl carbonate, and methanol (ratio, 1:1:2) without any by-products. TsOH monohydrate could also be used with slightly excess amount of **1** and similar products were obtained. Catalytic activity of the acids used clearly depended on their acidities: pK_a values were correlated with the effectiveness; accordingly, a strong Lewis acid (boron trifluoride etherate $BF_3 \cdot OEt_2$) was also a highly active one. All aprotic solvents listed could be used as they showed no detectable difference in the reaction progress. No serious difference was confirmed in the reaction efficiency among three orthocabonates **1a—1c** used.

Isolation of thiiran was attempted by distilling the reaction mixture (from **1a**, **2a**, and TsOH), but thiiran (bp 56 °C) was obtained in 67% yield as a mixture with methanol (bp 65 °C) and dimethyl carbonate (bp 90 °C). Part of thiiran still remained in the reaction mixture along with a small amount of white thiiran polymer, which appeared as a

Table 1. Acid-Catalyzed Cyclodehydration of 2-Mercaptoethanol (**2a**) to Thiiran[a] with Tetraalkyl Orthocarbonates (**1**)

Run	Orthocarbonate **1**, C(OR)$_4$		Acid catalyst mol%	pK_a	Solvent	Temp	Time/min
1	R=Me,	**1a**	TsOH[b] (2.0)	−7	$CDCl_3$	RT[c]	<3
2	Et,	**1b**	TsOH (4.6)		Benzene	RT	<5

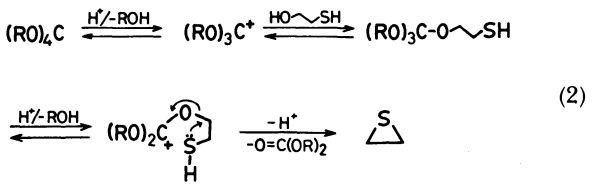
5[e]	 2c	Me	$CDCl_3$	 3c	80[b]
6[e]	 2c′	Me	CH_2Cl_2		63[f]
7	 2d	Et	$CDCl_3$	 3d	97[g]
8		Me	CH_2Cl_2		78[d]

a) Reaction with 1—3 mol% of TsOH within 10 min. at room temperature. b) NMR yield. c) A mixture of **3a**, methanol and dimethyl carbonate. d) Isolated yield by distillation. e) Mixture of **2c** and **2c′** (ratio=3:2, by ^{1}H NMR) was used. f) The yield was determined by GC and NMR.

broad peak around δ 2.3 in ^{1}H NMR. Thereby, considering the formation of by-products having higher boiling points than 90 °C, use of butyl derivative **1c** instead of **1a** eventually made the isolation of thiiran possible (Table 2, Entry 3), although the yield was low (30%).

Furthermore, a few 2-mercaptoalkanols **2b**, **2c**, and **2d** were examined and in every case it was demonstrated that the corresponding thiirans were obtained in high yields (Table 2). Bicyclic thiiran **3d** was isolated in 78% yield by distillation, while 2-phenylthiiran **3c** was obtained in 63% yield by purification with chromatography (silica gel/hexane).

The rational reaction mechanism does not involve a simple acid-catalyzed dehydration process, because the reaction hardly proceeded without **1**. Therefore, the reaction should be completed via the alcohol-exchange equilibrium[2] followed by intramolecular thiiran cyclization to eliminate a dialkyl carbonate only as a leak process, as shown in Eq. 2. This mechanism can be supported by the following two experimental results: (i) to a mixture of **1b** and methanol is added a catalytic amount of TsOH and the system reaches a certain equilibrium of alcohol-exchange and (ii) **1** does not interact with any sulfhydryl groups, since 1,2-ethanedithiol did not react with **1a** in the presence of TsOH at all under the same conditions (^{1}H NMR study). Therefore, formation of 2,2-dialkoxy-1,3-oxathiolane as an intermediate is unlikely, although monocyclic and spirocyclic orthocarbonates are the main products in the reactions of tetraalkyl orthocarbonates with an equimolar and two equimolar amounts of diols, respectively.[4]



(2)

$$(EtO)_4C + MeOH \underset{}{\overset{H^+}{\rightleftharpoons}} (EtO)_3C(OMe) + (EtO)_2C(OMe)_2 + (EtO)C(OMe)_3 + (MeO)_4C + EtOH \quad (3)$$

(54%) (25%) (13%) (10%) (trace)

Thus, in this paper the orthocarbonate **1** is suggested to be a useful dehydrating agent for 2-mercaptoalkanols to thiirans in the acid-catalyzed reactions. This method is of advantage of its easy procedure and short reaction time under mild conditions.

Experimental

^{1}H NMR spectra were recorded on a JEOL JMN-PMX60 spectrometer using tetramethylsilane (TMS) as the internal standard in deuteriochloroform. Gas chromatography was carried out with a Shimadzu GC 4CPF equipped with FID detector and a data processor (column: PEG-20M, 3 m; carrier: N_2, 30 mL min^{-1}). Catalysts (extra pure grade) were used as received without further purification, except for TsOH which was dehydrated by heating its monohydrate at 100 °C for 6 h under reduced pressure. All solvents were dried before use by usual methods. Preparation of 2-mercaptoalkanols (**2b**, **2c**, and **2d**) was carried out according to the reported method from corresponding oxiranes.[11] Commercial **2a** was available. Orthocarbonates **1b** and **1c** were synthesized according to Sakai's method using tetrachlorostannane ($SnCl_4$),[8] while **1a** was obtained from Aldrich. The products were identified by GC, ^{1}H NMR, and boiling points in comparison with their authentic samples.[12]

Reaction of 2 with 1. (a) NMR Scale Method. An example using **2a** and **1a**. A mixture of **2a** (0.39 g, 0.5 mmol) and slightly excess **1a** (0.70—0.75 g, 0.52—0.55 mmol) in $CDCl_3$ (200 μL) was subjected to measurement of ^{1}H NMR (t=0). Then, to the reaction mixture was added TsOH (ca. 2 mg) at room temperature. After mixing, ^{1}H NMR was recorded promptly (within five min) and further at some intervals in order to monitor the reaction. ^{1}H NMR indicated quantitative conversion of **2a** to thiiran within

three minutes.

(b) Preparative Scale Procedure. An example using **1a** and **2d**. To a mixture of **2d** (800 mg, 6.1 mmol) and **1a** (910 mg, 6.69 mmol) in dichloromethane (5 mL) was added TsOH (monohydrate, 23 mg, 2 mol%) in one portion at room temperature. The mixture was stirred and solid TsOH was soon dissolved. The **2d** smoothly disappeared (by GC) in a few minutes, and then triethylamine (a few drops) was added and evaporated. The resulting residue was carefully distilled using a microdistillation apparatus to give **3d** as colorless oil. Yield 540 mg (78%), bp 100 °C (bath temp)/25 mmHg (1 mmHg=133.322 Pa). Purity ≥95% by GC. Lit,[12] bp 71.5 °C/21 mmHg. ^{1}H NMR ($CDCl_3$) δ=1.45 (4H, m, CH_2), 2.15 (4H, m, CH_2), 3.20 (2H, m, CH). **3a**: bp 50—60 °C (lit,[12] 56 °C); ^{1}H NMR (CCl_4) δ=2.31 (s, CH_2). **3b**: ^{1}H NMR ($CDCl_3$) δ=1.52 (3H, d, J=2.8 Hz, CH_3), 2.12 (1H, d, J=2.7 Hz, H^a or H^b of CH_2), 2.50 (1H, d, J=3.0 Hz, H^b or H^a), 2.93 (1H, m, CH). **3c**: ^{1}H NMR ($CDCl_3$) δ=2.55 (1H, dd, J=0.7 and 2.7 Hz, H^a or H^b of CH_2), 2.74 (1H, dd, J=0.7 and 3.3 Hz, H^b or H^a), 3.79 (1H, t, J=3.0 Hz, CH), 7.17 (5H, s, phenyl).

TsOH-Catalyzed Reaction of 1b with Methanol. To a mixture of **1b** (95 mg, 0.49 mmol) and 20 μL of methanol (0.49 mmol) in 200 μL of dry benzene in a NMR tube was added anhydrous TsOH (6 mg). The resulting mixture was subjected to measurement of ^{1}H NMR and GC. The product structures were estimated by reference to the fast alcohol-exchange equilibrium.[2] The ratio of these products was determined by ^{1}H NMR integration and GC peak area (see Eq. 3).

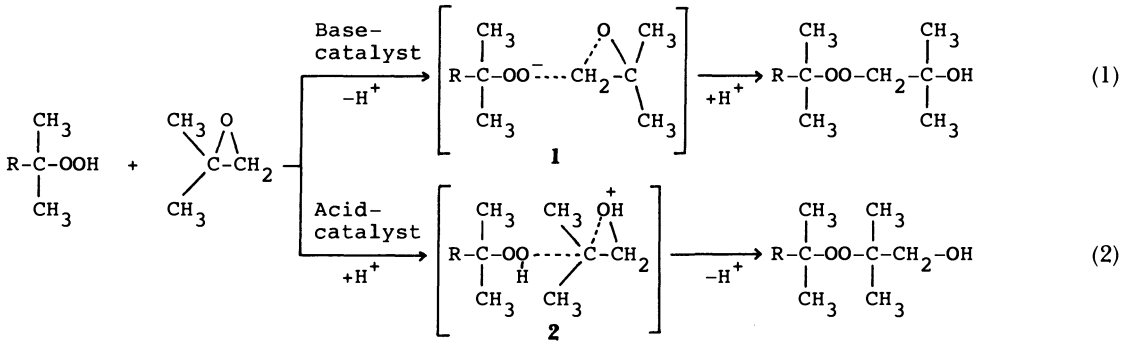
A Convenient Synthesis of 2-*t*-Alkyldioxy-2-methyl-1-propanols

Yoshiki HIGUCHI,* Kazuo MATSUYAMA, and Takeshi KOMAI
Chemical & Explosives Research Laboratory, Nippon Oil & Fats Co., Ltd.,
Taketoyo-cho, Chita-gun, Aichi-ken 470-23
(Received October 5, 1987)

Synopsis. Several 2-*t*-alkyldioxy-2-methyl-1-propanols have been synthesized conveniently by a ring-opening reaction of 1,2-epoxy-2-methylpropane with *t*-alkyl hydroperoxides in the presence of halogenated acetic acid catalysts.

Hydroxy-substituted dialkyl peroxides and their derivatives have been of interest as a radical source at high temperatures.[1] Some of them have been prepared by the reaction of epoxides with *t*-alkyl hydroperoxides.[2-5] This reaction proceeds via different paths, depending on the type of catalyst. When 1,1-dimethylethyl hydroperoxide was reacted with 1,2-epoxy-2-methylpropane, for instance, *t*-alkyl *n*-alkyl peroxide; 2-(1,1-dimethylethyldioxy)-1,1-dimethylethanol, was obtained in the presence of such base-catalysts as potassium hydroxide[2] and aluminium oxide.[3] On the other hand, *t*-alkyl *t*-alkyl peroxide; 2-(1,1-dimethylethyldioxy)-2-methyl-1-propanol, was formed in the presence of an acid catalyst such as sulfuric acid.[5] This result may be explained by the difference in the stabilization at the transition states (**1** and **2**) involved with the two types of the catalysts, as



is shown above. Although several studies have been reported on base-catalyzed reactions, there seems to have been only one report concerning an acid-catalyzed reaction, and its yield was very low (20% yield). Therefore, we studied acid-catalyzed reactions in an attempt to prepare *t*-alkyl *t*-alkyl peroxides **3** in good yields, such peroxides are suitable as radical sources at high temperatures and are not liable to undergo a radical-induced decomposition.[1e]

d: R=$(CH_3)_3CCH_2$

Results and Discussion

The synthesis of **3a** was carried out by adding 1,2-epoxy-2-methylpropane, drop by drop, to a mixture of 1,1-dimethylethyl hydroperoxide, an acid catalyst and solvent; then the mixture was stirred for 30 min at 35 °C. The yield of **3a** was determined by GC analysis with an internal standard; it is shown in Table 1. The results indicate that the yield depends significantly on the types of acid catalysts and solvents. When dichloro-, trichloro-, and trifluoroacetic acids were used as acid catalysts, **3a** was obtained in a 40—70% yield within 30 min. This reaction is influenced by the amount of the catalyst. The yield of **3a** was only 6% in the presence of trifluoroacetic acid (0.01 mol equivalent) and did not increase even though the reaction mixture was stirred more than 20 h continuously. Similarly, when *p*-toluenesulfonic acid, amberlyst, and such weak acid-catalysts as 30% sulfuric acid and chloroacetic acid were used, the yield was below 23%. The decomposition of the hydroperoxide was observed throughout the reaction in the presence of such strong acid catalysts as sulfuric acid (more than 50%), trifluoromethanesulfonic acid, chlorosulfuric acid, and aluminium chloride. The yield was higher in such nonpolar solvents as hexane, chloroform, carbon tetrachloride, benzene, and nitrobenzene than in the polar solvents. When 1,1-dimethylethyl hydroperoxide was reacted with a reaction mixture containing 2-hydroxy-2-methylpropyl trifluoroacetate,[6] which was formed by the reaction of 1,2-epoxy-2-methylpropane with trifluoroacetic acid in equivalent weights for 30 min at 35 °C, the formation of **3a** was only a trace on GC. These findings indicate that the reaction does not proceed via the addition-elimination of the acid catalyst, but via the nucleophilic attack of 1,1-dimethylethyl hydroperoxide on a protonated epoxide intermediate, such as in the normal acid-catalyzed ring-opening reactions.[7]

Three other 2-*t*-alkyldioxy-2-methyl-1-propanols were synthesized under optimum reaction conditions

Table 1. Influence of Various Acid Catalysts and Solvents on the Yield of **3a**[a]

a) 1 mmHg=133.322 Pa. b) 1,2-Epoxy-2-methylpropane of 18.7 g (0.26 mol) was used. c) Based on 1,2-epoxy-2-methylpropane. d) Lit,[5] 38—40 °C/3 mmHg.

of **3a**; the results are listed in Table 2. The peroxides were obtained in 62—72% yields. The crude products were purified by washing with water and an aqueous solution of sodium hydroxide to remove any unreacted materials and by-products and by then distilling them under vacuum pressures. The structures of **3a—d** were identified by means of their boiling points, their refractive indices, and the elemental-analysis, IR, NMR, and mass spectral data, as are shown in Table 2.

Experimental

The reaction products were analyzed by means of gas chromatography (GC) on a Shimadzu Model GC-2D chromatograph using a 1.4 m×2.6 mm glass column of 5% Silicone GE SE-30 on 60—80 mesh Uniport HP, with undecane and dodecane as internal standards. The ^{1}H NMR spectra were obtained, using chloroform-*d* as the solvent, on a JEOL Model JNM-MN-100 spectrometer. The IR spectra were recorded on a JASCO Model A-3 spectrometer.

Purification of Hydroperoxides. The corresponding hydroperoxides of **3a** and **3b** were purified by distillation. The commercial products obtained from the Nippon Oil & Fats Co., Ltd., for the corresponding hydroperoxides of **3c** and **3d** were purified by the isolation of the sodium salts, the regeneration of the hydroperoxides by carbon dioxide, and distillation.

Synthesis of Dialkyl Peroxides. A typical synthesis of **3a** was carried out as follows. 1,2-Epoxy-2-methylpropane (18.7 g, 0.26 mol) was added slowly to a solution of trifluoroacetic acid (14.8 g, 0.13 mol), 1,1-dimethylethyl hydroperoxide (46.5 g, 0.52 mol), and benzene 25 cm^3 below 10 °C, after which the reaction mixure was stirred at 35 °C for 30 min. The yield of **3a** was determined by GC, using undecane as an internal standard; it is shown in Table 2. The reaction mixture was washed with water, an aqueous solution of 5% NaOH, and a saturated solution of NaCl, and then dried over anhydrous $MgSO_4$. After the solvent had been removed, the residue (36.7 g) was distilled to give **3a** (22.4 g). The purity, as checked by GC, was 96.5%.

The syntheses of **3b—d** were carried out by using the corresponding hydroperoxides in place of 1,1-dimethylethyl hydroperoxide by a method similar to that used for **3a**. Crude products were purified by distillation after the residual hydroperoxides in the reaction mixture had been changed into the corresponding alcohols by the use of an aqueous solution of Na_2SO_3. The purities, as checked by GC, were more than 95%.

(Received October 29, 1987)

Synopsis. Treatment of the hydroxy lactone derived from (±)-*endo*-7-oxabicyclo[2.2.1]hept-5-ene-2-carboxylic acid with hydrogen bromide–acetic acid, followed by esterification, gave 48% of ethyl DL-(1,3,5/2,4)-5-bromo-2,3,4-trihydroxy-1-cyclohexanecarboxylate, from which DL-validamine and pseudo-2-amino-2-deoxy-α-DL-mannopyranose, and their uronate analogs have been synthesized as the totally acetylated derivatives.

Naturally occurring branched-chain aminocyclitols, viz. pseudo-amino sugars such as validamine,[2)] valienamine,[3)] and valiolamine[4)] were isolated from a fermentation broth of *Streptomyces hygroscopicus* sp. *limoneus*. These compounds and their derivatives[5)] show a remarkable inhibitory activity against α-glucosidase, stimulating much interest in their application for a clinical use.

We describe now a preparation of DL-validamine and a pseudo-sugar analog of 2-amino-2-deoxy-α-D-mannopyranose, by a novel sequence from the hydroxy lactone[6,7)] **1** obtained from (±)-*endo*-7-oxabicyclo[2.2.1]hept-5-ene-2-carboxylic acid.[6,7)]

Treatment of the lactone **1** with 20% hydrogen bromide–acetic acid at 95 °C gave after esterification with ethanol 48% of crystalline bromide **2**, which was converted into the methyl ester **3** and its triacetate **4** in the usual way. The ^{1}H NMR spectrum of **4** revealed three coupled triplets (J=10 Hz) at δ 5.35, 5.23, and 5.03, attributable to the axial protons at C-2, C-3, and C-4, being consistent with the structure assigned. The structure of **2** was further confirmed by conversion of **3** into the known epoxide[8)] **5** by treatment with methanolic sodium methoxide followed by acetylation.

Azidolysis of **4** with excess sodium azide in *N,N*-dimethylformamide (DMF) gave a single crystalline azide **6**, the ^{1}H NMR spectrum of which showed a narrow quartet (J=3.5 Hz) at δ 4.18, indicating that the azido group was introduced at C-5 in an axial position. Hydrogenation of **6** in ethanol containing acetic anhydride with Raney nickel gave the *N*-acetyl derivative **7** in 61% yield. On the other hand, **6** was converted, in 56% yield, into DL-penta-*N,O*-acetylvalidamine[7)] (**8**) by reduction with lithium aluminum hydride (LAH) in tetrahydrofuran (THF) followed by acetylation.

When similar azidolysis of **3** was carried out in aqueous 2-methoxyethanol, a single known azido triacetate[8)] **9** was obtained in 65% yield after acetylation. This compound was considered to be obtained through the neighboring group participation of the 4-hydroxyl group, involving a formation of the intermediate 4,5-epoxide, which was successively cleaved by an azide ion via diaxial ring-opening. Catalytic hydrogenation of **9** followed by acetylation gave the *N*-acetyl derivative **10** (84%). Reduction of **9** with LAH and successive acetylation afforded penta-*N,O*-acetyl-pseudo-2-amino-2-deoxy-α-DL-mannopyranose (**11**, 61%). These pseudo-amino sugars are of interest because their corresponding normal sugars occur in biological system.

Experimental

General Methods. Melting points were determined with a MEL-TEMP capillary melting-point apparatus and are

uncorrected. The ^{1}H NMR spectra were measured with a Varian EM-390 (90 MHz) spectrometer for solution of chloroform-*d* (TMS) or dimethyl-d_6 sulfoxide (DSS). Spectrum at 270 MHz was recorded with a Jeol GX-1 instrument. The silica gel used for column chromatography was Wakogel C-300 (Wako Co., Osaka).

Ethyl (±)-(1,3,5/2,4)-5-Bromo-2,3,4-trihydroxy-1-cyclohexanecarboxylate (2). A mixture of (±)-2-*exo*-hydroxy-4,8-dioxatricyclo[4.2.1.0^{3,7}]nonan-5-one[7] (**1**) (3.0 g, 10.6 mmol) and 20% hydrogen bromide–acetic acid (15 ml) was heated in a sealed tube at 95 °C for 24 h, and poured into ice–water (20 ml). The mixture was refluxed for 9 h and then concentrated. The residue was treated with ethanol (20 ml) at reflux for 5.5 h, and the mixture was concentrated and the residue was crystallized from ethanol to give the bromide **2** (2.6 g, 48%) as prisms: mp 155.5—156 °C.

Found: C, 38.25; H, 5.23%. Calcd for $C_9H_{15}BrO_5$: C, 38.18; H, 5.34%.

Methyl (±)-(1,3,5/2,4)-5-Bromo-2,3,4-trihydroxy-1-cyclohexanecarboxylate (3). To a solution of **2** (5.0 g, 18 mmol) in methanol (100 ml) was added acetyl chloride (1.5 ml, 21 mmol) and it was refluxed for 21 h. The mixture was neutralized with sodium hydrogencarbonate and then concentrated. The residue was crystallized from ethanol to give **3** (3.8 g, 80%) as prisms: mp 137—138 °C.

Found: C, 35.91; H, 4.76%. Calcd for $C_8H_{13}BrO_5$: C, 35.71; H, 4.87%.

Compound **3** (2.3 g, 8.5 mmol) was treated with acetic anhydride (12 ml) and pyridine (12 ml) at room temperature overnight. The mixture was concentrated and the residue was extracted with ethyl acetate. The extract was washed with water, dried, and concentrated. The residue was recrystallized from ethanol to give the triacetate **4** (3.2 g, 96%) as prisms: mp 153—154 °C. ^{1}H NMR ($CDCl_3$, 270 MHz) δ=2.00 (6H, s) and 2.08 (3H, s) (OAc), 2.21 (1H, q, $J_{1,6ax}=J_{5,6ax}=J_{6gem}$=13 Hz, H-6ax), 2.62 (1H, dt, $J_{1,6eq}=J_{5,6eq}$= 4 Hz, H-6eq), 2.69 (1H, ddd, $J_{1,2}$=11 Hz, H-1), 3.72 (3H, s, CO_2Me), 3.92 (1H, m, $J_{4,5}$=10.5 Hz, H-5), 5.03 (1H, t, $J_{2,3}=J_{3,4}$=10 Hz, H-3), 5.23 (1H, dd, H-2).

Found: C, 42.74; H, 4.80%. Calcd for $C_{14}H_{19}BrO_8$: C, 42.55; H, 4.85%.

Methyl (±)-(1,3/2,4,5)-2,3,4-Triacetoxy-5-azido-1-cyclohexanecarboxylate (6). A mixture of **4** (1.7 g, 4.3 mmol), sodium azide (1.3 g, 20 mmol), and aqueous 95% DMF (30 ml) was stirred at 90 °C for 20 h, and then concentrated. The residue was extracted with ethyl acetate, and the extract was washed with water, dried, and concentrated. The residue was recrystallized from ethanol to give **6** (0.72 g, 47%) as needles: mp 110—112 °C. ^{1}H NMR ($CDCl_3$, 90 MHz) δ=1.98 (6H, s) and 2.08 (3H, s) (OAc), 2.91 (1H, td, $J_{1,2}=J_{1,6ax}$=9.5 Hz, $J_{1,6eq}$=3.5 Hz, H-1), 3.67 (3H, s, CO_2Me), 4.18 (1H, q, $J_{4,5}=J_{5,6ax}=J_{5,6eq}$=3.5 Hz, H-5), 5.04 (1H, dd, $J_{3,4}$= 9.5 Hz, H-4), 5.20 (1H, t, $J_{2,3}$=9.5 Hz, H-2), 5.37 (1H, t, H-3).

Found: C, 47.11; H, 5.43; N, 11.57%. Calcd for $C_{14}H_{19}N_3O_8$: C, 47.06; H, 5.36; N, 11.76%.

Methyl (±)-(1,3/2,4,5)-5-Acetamido-2,3,4-triacetoxy-1-cyclohexanecarboxylate (7). A solution of **6** (0.30 g, 0.85 mmol) in ethanol (10 ml) was hydrogenated in the presence of Raney nickel T-4 (1 ml) and acetic anhydride (0.5 ml) in an initial hydrogen pressure of 50 psi at room temperature for 17 h. The catalyst was removed by filtration and the filtrate was concentrated. The residue was crystallized from ethanol to give **7** (0.19 g, 61%) as prisms: mp 231.5—233.5 °C. ^{1}H NMR (DMSO-d_6, 90 MHz) δ=1.90 (6H, s), 1.94 (3H, s), and 1.95 (3H, s) (NAc and OAc), 3.62 (3H, s, CO_2Me), 4.30—4.67 (1H, m, H-5), 4.87 (1H, dd, $J_{3,4}$=9.8 Hz, $J_{4,5}$=4.5 Hz, H-4), 5.17 (1H, t, $J_{2,3}$=9.8 Hz, H-2), 5.33 (1H, H-2), 8.07 (1H, d, $J_{5,NH}$=5 Hz, NH).

Found: C, 51.41; H, 6.06; N, 3.61%. Calcd for $C_{16}H_{23}NO_9$: C, 51.47; H, 6.21; N, 3.75%.

(±)-[(1,3/2,4,5)-5-Acetamido-2,3,4-triacetoxycyclohexyl]-methyl Acetate (8) [(±)-Penta-*N,O*-acetylvalidamine]. Compound **7** (0.30 g, 0.84 mmol) was treated with LAH (0.25 g, 6.6 mmol) in tetrahydrofuran (10 ml) at room temperature for 30 h. To the mixture was added water (1.5 ml), aqueous 15% sodium hydroxide, water (1.5 ml), and aqueous acetone (1:1, 2 ml) in turn, and then it was filtered through a bed of Celite. The filtrate was neutralized with 1 mol dm^{-3} hydrochloric acid and concentrated. The residue was acetylated in the usual way, and the product was crystallized from ethanol to give **8** (0.18 g, 56%) as prisms: mp 197—199 °C (lit,[7] mp 197—198 °C). This compound was identical to an authentic sample[7] in all respects.

Methyl (±)-(1,3,4/2,5)-2,3,5-Triacetoxy-4-azido-1-cyclohexanecarboxylate (9). A mixture of **3** (0.49 g, 1.8 mmol), sodium azide (0.49 g, 7.5 mmol), and 90% aqueous 2-methoxyethanol (20 ml) was refluxed for 3 h, and then concentrated. The residue was refluxed with methanol (50 ml) and acetyl chloride (1 ml), and then the mixture was neutralized with sodium hydrogencarbonate. The mixture was concentrated and the residue was extracted with ethyl acetate. The extract was concentrated and the residue was acetylated in the usual way and the product was crystallized from ethanol to give **9** (0.51 g, 80%) as plates: mp 95.5—96 °C. (lit,[8] mp 92.5—94 °C). This compound was identical with an authentic sample[8] in all respects.

Methyl (±)-(1,3,4/2,5)-4-Acetamido-2,3,5-triacetoxy-1-cyclohexanecarboxylate (10). Into a solution of **9** (0.14 g, 0.38 mmol) in a mixture of pyridine (5 ml) and water (5 ml) was bubbled hydrogen sulfide at room temperature for 4 h. Excess hydrogen sulfide was removed by a stream of nitrogen and the mixture was concentrated. The residue was acetylated in the usual way and the product was crystallized from ethanol to give **10** (0.11 g, 84%) as needles: mp 178.5—180.5 °C. ^{1}H NMR ($CDCl_3$, 90 MHz): δ=1.90 (3H, s), 2.07 (3H, s), 2.26 (3H, s), and 2.30 (3H, s) (NAc and OAc), 2.87 (1H, bq, J=7 Hz, H-1), 3.71 (3H, s, CO_2Me), 4.50 (1H, dt, $J_{3,4}=J_{4,5}$=4 Hz, $J_{4,NH}$=9 Hz, H-4), 5.13 (1H, dd, $J_{2,3}$=7 Hz, H-3), 5.20 (1H, m, H-5), 5.46 (1H, t, $J_{1,2}$=7 Hz, H-2), 6.75 (1H, d, $J_{4,NH}$=9 Hz, NH).

Found: C, 51.40; H, 6.13; N, 3.62%. Calcd for $C_{16}H_{23}NO_9$: C, 51.47; H, 6.21; N, 3.75%.

(±)-[(1,3,4/2,5)-5-Acetamido-2,3,4-triacetoxycyclohexyl]-methyl Acetate (11). Compound **10** (0.30 g, 0.86 mmol) was reduced with LAH in THF as in the preparation of **8**. The product was acetylated in the usual way and the acetate was purified by a silica-gel column with ethanol–toluene (1:10) to give **11** (0.20 g, 61%) as a syrup. ^{1}H NMR (DMSO-d_6, 90 MHz): δ=1.90 (3H, s), 1.91 (3H, s), 2.01 (6H, s), and 2.08 (3H, s) (NAc and OAC), 3.73—4.18 (2 H, m, CH_2OAc), 4.41 (1H, dt, $J_{3,4}=J_{4,5}$=4 Hz, $J_{4,NH}$=9 Hz, H-4), 4.65—4.87 (1H, m, H-5), 4.97 (1H, dd, $J_{2,3}$=9.7 Hz, H-3), 5.22 (1H, t, $J_{1,2}$=9.7 Hz, H-2), 7.92 (1H, d, NH). Mass spectrum, *m/z*; Found: 388.1658 (M^+). Calcd for $C_{17}H_{26}NO_9$: 388.1666 (M^+).

Found: C, 52.06; H, 6.20; N, 3.62%. Calcd for $C_{17}H_{25}NO_9 \cdot 0.25H_2O$: C, 52.10; H, 6.43; N, 3.75%.

The authors thank Mr. Akio Takahashi and Mr. Hisao Arita for elemental analyses, and Mr. Koichi Yokoyama for preparative work.

Hindered Rotation around Csp^2–Csp^3 Bonds in the Enol Forms of α-(9-Fluorenyl)-β-diketones and in 3,5-Disubstituted 4-(9-Fluorenyl)pyrazoles. An ^1H NMR Study

Marcial MORENO-MAÑAS,* Asensio GONZALEZ, Jorge MARQUET, and Francisco SANCHEZ-FERRANDO

(Received May 16, 1987)

Synopsis. Slow rotation around the Csp^2–Csp^3 bonds of the enol forms of 3-(9-fluorenyl)-2,4-pentanedione, 2-(9-fluorenyl)-1-phenyl-1,3-butanedione, and the corresponding bonds of the derived pyrazoles, was studied by variable temperature ^1H NMR. For the pyrazoles, the values T_c=315—320 K ($\Delta G^{\neq}_{T_c}$=15.1±0.1 kcal mol^{-1}) and T_c=338±5 K (corresponding to $\Delta G^{\neq}_{T_c(sp\rightarrow ap)}$=18.1±0.2 kcal mol^{-1} and $\Delta G^{\neq}_{T_c(ap\rightarrow sp)}$=16.1±0.2 kcal mol^{-1}) were found, respectively.

Hindered rotation around Csp^2–Csp^3 bonds in 9-arylfluorenes is a well-known phenomenon.[1] However, at the best of our knowledge no examples have been reported in which the group accompanying the fluorene moiety is either a five-membered heterocyclic ring (i.e. pyrazole) or a ring held together by hydrogen bonds (i.e. the enol form of a β-diketone). Some of us have reported a synthetic method, based on the use of cobalt(II) complexes of β-dicarbonyl compounds, which enables us to place bulky substituents in the α-positions of β-dicarbonyl compounds,[2-4] among them the fluorenyl radical.

The ^1H NMR spectrum of 3-(9-fluorenyl)-2,4-pentanedione (**1a**) shows in $CDCl_3$ at the ordinary probe temperature two sets of sharp peaks as indicated in Fig. 1. The enol form exhibits hindered rotation since both methyl groups give signals at different chemical shifts. The sharp signal at δ 0.99 is assigned to the methyl group protons placed above the plane of the fluorene moiety.

The major form of 2-(9-fluorenyl)-1-phenyl-1,3-butanedione (**1b**) in solid phase was an enol form (see IR in Experimental). However, in $CDCl_3$ the keto form predominates to an extent of ca. 6:1. The observed enol form exhibits the signal of the methyl group at δ 1.05. Therefore, by comparison with the chemical shift measured for **1a**, we assign the **sp** conformation to the enol form of **1b** (for nomenclature see Ref. 1).

3-(9-Fluorenyl)-5,5-dimethyl-2,4-hexanedione (**1c**) showed only peaks attributed to the keto form, both in KBr (IR) and in $CDCl_3$ (^1H NMR).

Due to the interference of the keto⇄enol equilibria we did not attempt any kinetic study of the rotation in compounds **1a** and **1b**. However, compounds **1** were converted into the pyrazoles **2** by conventional methods and the kinetic behavior at different temperatures of these fluorenyl-substituted heterocycles was studied at 80 MHz in a Bruker WP80SY spectrometer.

In the case of exchange between two equally populated, uncoupled sites, the rotational barrier $\Delta G^{\neq}$ is customarily determined at the coalescence temperature T_c, using the well-known expressions[5] $k=\pi\Delta\nu/\sqrt{2}$ and $k=(k_BT/h)[\exp(-\Delta G^{\neq}/RT)]$, in which $\Delta\nu$ is the frequency separation of the two lines at the slow rotation limit, k_B is the Boltzmann constant, h is the Planck constant, and k is the exchange (interconversion) rate at coalescence. This rather simple approach requires: i) The operation of a single exchange (interconversion) mechanism; ii) the absence of coupling; iii) equal line-widths for both lines; and iv)

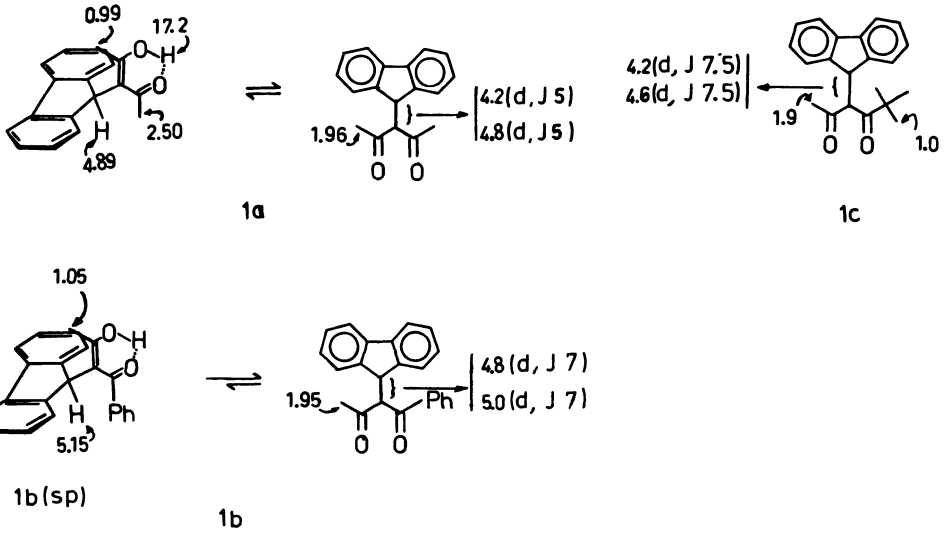

Fig. 1.

linewidths negligible compared with $\Delta\nu$.

The case of exchange between two unequally populated sites has also been solved in much the same simple way.[6] Thus, from the observed coalescence temperature T_c, and the values of $\Delta\nu$ (line separation) and Δp (population difference) obtained at a lower temperature under slow rotation, the mean lifetime at coalescence, $\tau=1/k$ can be obtained using the values tabulated in (Ref. 7), provided conditions i)—iv) above are again met. Of course, validity of this approach depends on the assumption that chemical shift differences and rotamer populations are independent of temperature, assumptions which can often be inadequate. However, if these assumptions are indeed valid, individual rate constants k_A and k_B for the two interconversion processes (A→B and B→A) are derived using the expressions $k_A=2kp_B$ and $k_B=2kp_A$, in which p_A and p_B are the populations of A and B, respectively. Finally, the corresponding barriers at coalescence are calculated in a straightforward manner[8] using the equation $\Delta G_x^{\ddagger}=8.31T[23.76+\ln(T/k_x)]$, with SI units throughout. Thus, these simple cases can be studied without using the more sophisticated methods of line shape analysis.[9]

The ^{1}H NMR spectrum of 3,5-dimethyl-4-(9-fluorenyl)pyrazole (**2a**) in $CDCl_3$ at the probe temperature (305 K) shows very broad signals for the two methyl groups. The two signals sharpen to two singlets at δ 2.59 and 1.17 upon cooling at 250 K, while they coalesce to a singlet upon heating at 365 K (Fig. 2). The T_c was found to be between 315—320 K, while the low temperature frequency separation between the two signals was $\Delta\nu=114.3$ Hz. Ignoring the effect of the N(1)–N(2) prototropic shift which is very rapid in our experimental conditions,[10] and applying the pertinent kinetic equations,[5] the degenerate conversion between the two rotamers at T_c has a rate $k=253.9$ s^{-1}. The rotation barrier at T_c was calculated to be 15.1±0.1 kcal mol^{-1} (63.1±0.4 kJ mol^{-1}).

Three different groups[11–13] have reported a value higher than 25 kcal mol^{-1} (104.5 kJ mol^{-1}) for the rotation barrier in 9-mesitylfluorene. As expected, the smaller angle in the pyrazole ring results in a marked decrease in the rotational barrier.

The ^{1}H NMR spectrum of 4-(9-fluorenyl)-3-methyl-5-phenyl-1*H*-pyrazole (**2b**) in $CDCl_3$ at 305 K shows a single peak for the methyl protons at δ 1.21, but it is not a sharp singlet ($\Delta\nu_{1/2}>5$ Hz). Upon cooling at 263 K, two methyl group signals can be seen at δ 2.58 and 1.13 with a ratio ca. 6:94, attributed respectively to the **ap** and **sp** conformers (Fig. 2). Therefore, the population difference at 263 K is $\Delta p=0.88$, while the measured frequency difference between the two peaks is $\Delta\nu=116.4$ Hz. A series of spectra at increasing temperatures shows that the minor peak at δ 2.58 disappears on heating from 233 to 303 K while both peaks broaden. For $T>303$ K the minor peak is no longer seen, but the major upfield peak continues to broaden. At a temperature between 333 and 343 K this peak reaches maximum broadening (coalescence), and it sharpens at 363 K. Assuming the T_c is 338±5 K and ignoring again the effect of the N(1)–N(2) prototropic shift,[10] we have calculated the barrier to rotation for the unequally populated rotamers by applying the pertinent equations.[6] The individual rates for conversion at T_c of major to minor ($k_{sp\to ap}$) and minor to major ($k_{ap\to sp}$) are 13.38 s^{-1} and 254.2 s^{-1}, and the individual rotation barriers at T_c, $\Delta G^{\ddagger}_{sp\to ap}$ and $\Delta G^{\ddagger}_{ap\to sp}$ are calculated[8] to be 18.1±0.2 kcal mol^{-1} (75.7±0.8 kJ mol^{-1}) and 16.1±0.2 kcal mol^{-1} (67.3±0.8 kJ mol^{-1}).

The ^{1}H NMR spectrum of 3-*t*-butyl-4-(9-fluorenyl)-5-methyl-1*H*-pyrazole (**2c**) shows a single *t*-Bu signal at δ 1.68, both at 308 K and upon cooling at 223 K. Similarly, a single methyl signal is found at δ 1.05 at both temperatures. We conclude that **2c** exists in the **sp** conformation to an extent of more than 99%.

for the purchase of the NMR spectrometer, and to "Direcció General d'Ensenyament Universitari (Generalitat de Catalunya)" for the NMR data system.

Experimental

Room temperature 80 MHz ^1H NMR spectra were taken at 32 °C, in the FT mode, using a Bruker WP80SY spectrometer, equipped with a 5 mm switchable $^1H/^{13}C$ dual probe, under Aspect 2000 computer control, and are referenced to internal TMS. Variable temperature spectra were obtained under BVT-1000 control. Temperatures were calibrated against methanol peak separation.[14] Solutions of 2—5 mg of sample in $CDCl_3$ were used in all experiments. The pulse conditions used were: spectral width, 1000 Hz; 8 K data points, with quadrature detection; pulse width, 4 μs (60 deg); acquisition time, 4.1 s, with no relaxation delay; digital resolution, 0.25 Hz per point. FIDs were weighted by exponential multiplication (line broadening 0.25 Hz) prior to Fourier transformation.

Compounds 1. Compounds **1** were prepared by treating the corresponding cobalt(II) complexes of the unsubstituted β-diketones with 9-bromofluorene in refluxing chloroform (for **1a** and **1b**) or in refluxing chlorobenzene (for **1c**), following the procedures described in Ref. 2—4.

1a: Mp 72 °C; IR (KBr) 1720, 1690, 1600—1570 (broad) cm^{-1}; MS *m/z* (rel intensity) 264 (M^+, 40), 221 (100), 203 (48), 178 (26), 176 (21), 165 (59), 43 (91).

(Received August 7, 1987)

AzaTCNQ ((4-dicyanomethyl-1-pyridinio)dicyanomethanide) is employed as an organic acceptor to form new organic conductors with a TTF family such as TTF,[1] TMTTF, TMTSF, HMTTF, and DBTTF. Among them, TMTTF and TMTSF give 2:1 single crystals and the latter affords the most conductive complex, showing a metallic characteristic down to 150 K. This can be observed by measuring the thermoelectric power and the ESR spectra. A crystal structure analysis indicates that only TMTSF molecules stack to form one-dimensional conduction pathways, while AzaTCNQ molecules are arranged side-by-side and oriented almost perpendicular to the donor molecules. There exists an orientational disorder of the nitrogen atom in the pyridine skeletone of an AzaTCNQ molecule, which may be associated with the weak temperature dependence of the electrical conductivity.

In an attempt to develop new highly conducting organic charge-transfer complexes, a number of novel donors and acceptors have been synthesized. One of the prominent acceptors is AzaTCNQ (Fig. 1). It has a similar geometry to TCNQ. However, the electronic properties of AzaTCNQ are different from those of TCNQ since the AzaTCNQ molecule contains a pyridine skeleton instead of the quinonoid ring of the TCNQ molecule. In the neutral state the spin multiplicity of AzaTCNQ is doublet. AzaTCNQ is, however, more stable as a closed-shell anion than a neutral radical and acts as one of the strongest π-electron acceptors so far obtaind. The reduced acceptor, AzaTCNQ$^-$, can be used as an organic anion instead of inorganic anions, e.g. BF_4^-, ClO_4^-, etc.

Originally, AzaTCNQ was synthesized by Wudl in order to search for conductive neutral radical complexes.[2] He prepared TTF complexes and reported relatively low electrical resistivities of the compacted specimens (1:1 and 2:1 stoichiometries) as 30—100 Ωcm. Later, Matsubayashi et al. regarded it as being an organic anion to form simple salts with cationic species.[3] Relatively high resistivities of more than 10^5 Ωcm were obtained.

We have investigated AzaTCNQ and its complexes for the following two purposes.[4] One was to search for conductive materials based on AzaTCNQ. The other was to elucidate the electronic states of AzaTCNQ in complexes: whether AzaTCNQ could be a neutral radical, a closed-shell anion, or a partially ionized state.

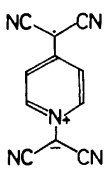

Fig. 1. Molecular structure of AzaTCNQ$^-$.

†† Present address: The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato-ku, Tokyo 106.

In this report, we discuss the preparation of several AzaTCNQ complexes with TTF derivatives and show detailed physical and structural properties of the metallic complex $(TMTSF)_2$ AzaTCNQ.

Experimental

Microcrystals of *N*-methylpyridinium AzaTCNQ ($NMPy^+$ AzaTCNQ$^-$) were prepared by the method of Tanaka et al.[3] The product was identified by its melting point (232—233 °C, lit, 233—237 °C).[3] Black crystalline complexes with TTF were obtained by direct mixing of 0.062 g of $(TTF)_2(BF_4)_3$ in 22 ml of hot acetonitrile and 0.070 g of $NMPy^+$ AzaTCNQ$^-$ in 13 ml of the same solvent. Black shiny microcrystals of the TMTTF complex were prepared by mixing 0.056 g of $(TMTTF)_{17}(BF_4)_8$ in 40 ml of hot acetonitrile and 0.026 g of $NMPy^+$ AzaTCNQ$^-$ in 10 ml of the same solvent. Complexes with TMTTF, TMTSF, DBTTF, and HMTTF were grown electrochemically in 20 ml of 1,1,2-trichloroethane with 30 mg of $NMPy^+$ AzaTCNQ$^-$ as an electrolyte and 10 mg of donors at a constant current of 1 μA under N_2. TMTTF and TMTSF complexes were obtained as shinny black single crystals in the form of elongated rods and DBTTF and HMTTF complexes had a black polycrystalline form.

For X-ray investigations, the intensity data of the TMTSF complex were measured on a Rigaku automated four-circle diffractometer with graphite monochromated Mo$K\alpha$ radiation up to 2θ=60° by using the ω-2θ scan techniqe. The sample crystal was a black plate with dimensions of 0.08×0.25×0.60 mm^3. Then, 1214 independent reflections ($|F|>3\sigma(|F|)$) were used for a structure analysis. The structure was solved by the Patterson method and refined by the block diagonal least-squares method. Atomic scattering factors were taken from International Tables for X-ray Crystallography.[5] Cell parameters were determined from least-squares applied to 25 reflections with 27°<2θ<31°. The final refinement gave R=0.0548 and R_w=0.0587 for $(TMTSF)_2$ AzaTCNQ. The positional parameters are listed in Table 1. The F_o-F_c table and the anisotropic temperature parameters are deposited as Document No. 8802 at the Office of this Bulletin.

Cyclic voltammetry was performed in acetonitrile under a nitrogen atmosphere using 0.1 M tetrabutylammonium tetrafluoroborate (1 M=1 mol dm^{-3}) as a supporting electrolyte using Pt electrodes at a scan speed of 100 mV s^{-1}.

The temperature dependences of electrical resistivities were measured by a standard four-probe d.c. technique. The contacts were applied using gold paint with 20 μm gold wires. Measurements of the thermoelectric power along the a-axis was performed by attaching single crystals with 1 μm thick gold foils to two boron nitride heat sinks.[6] ESR data for a single crystal were obtained by an X-band spectrometer Varian E112 equipped with an Oxford Instruments ESR continuous-flow helium cryostat.

Results and Discussion

A cyclic voltammogram of $NMPy^+$ $AzaTCNQ^-$ in acetonitrile under a nitrogen atmosphere showed a redox wave ($AzaTCNQ^-/AzaTCNQ^{\cdot}$) with $E_{1/2}$=+0.57 V vs. SCE; ΔE^p=90 mV,[7] which is agreeable to that of $K^+AzaTCNQ^-$ ($E_{1/2}$=+0.54 V vs. SCE; ΔE^p=60 mV)[8] in acetonitrile. No second wave corresponding to $AzaTCNQ^{2-}/AzaTCNQ^-$ appeared. Furthermore, the reversible wave of $AzaTCNQ^{\cdot}/AzaTCNQ^+$ could not be obtained, although $AzaTCNQ^+$ has a similar electronic structure to TCNQ. The redox potential is close to those of F_4TCNQ^{-}/F_4TCNQ ($E_{1/2}$=0.53 V vs. SCE; ΔE^p=59 mV) and $HCBD^{-}/HCBD$ ($E_{1/2}$=0.62 V vs. SCE; ΔE^p=68 mV) obtained under the same conditions. From those data the order of acceptor strength is $F_4TCNQ<AzaTCNQ<HCBD$.

Usually, F_4TCNQ gives 1:1 insulating complexes with TTF derivatives in which both component molecules are completely charge-transfered and face-to-face segregated stacks are formed in the TTF, HMTTF, HMTSF, and DBTTF complexes,[9] while HCBD forms not only 1:1 complexes with perylene,[10] TMTTF,[11] and TTMTTF[11] but also 2:1 CT-complexes with pyrene,[12] hexamethylbenzene,[12] TTF,[13] and TMTTF.[11] The AzaTCNQ complexes form both 1:1 and 2:1 systems like the HCBD complexes. Though the chemical structure of AzaTCNQ resembles that of F_4TCNQ, the given complexes have more similar features to those of HCBD complexes.

Table 2. Electrical Properties of the AzaTCNQ Complexes

	ρ_{RT}/Ω cm	E_a/eV
TTF·AzaTCNQ[a]	66	0.20
$(TMTTF)_2AzaTCNQ$	8.1	0.072
$(TMTSF)_2AzaTCNQ$	1.1×10^{-2}	0.015 (at low temp)
DBTTF-AzaTCNQ[b]	19	0.09
HMTTF-AzaTCNQ[b]	1.3×10^6	—

a) A compacted sample. b) The stoichiometries have not been determined.

The electrical resistivities at room temperature and the activation energies of the AzaTCNQ complexes are summarized in Table 2. AzaTCNQ complexes with DBTTF, HMTTF, TMTTF, and TTF are semiconductors and only the TMTSF complex shows a metallic character (vide infra).

It is also noticeable that the electrical resistivity of the TTF complex is rather low, 66 Ω cm, at room temperature for the compacted sample, though it is a complete-charge-transfered salt with 1:1 stoichiometry(vide infra).[14] Our resistivity data agree with those of the Wudl's TTF complex. The appearance of the 1420 cm^{-1} band of C=C stretching and the 508 cm^{-1} band of C-S streching in TTF in the Raman spectrum suggests a complete charge transfer in this complex (cf. TTF^{+1} 1420 cm^{-1} (C=C), 509 cm^{-1} (C-S)).[15] This assignment was further confirmed by the optical absorption spectrum of a complex which does not show any absorption band in the near-infrared region, characteristic of a partial charge-transfer state. Unfortunately, the single crystals have not yet been obtained.

For the TMTSF complex, which shows a metallic character, a crystal structure analysis was performed. Weissenberg photographs and a four-circle diffractometer were employed to determine the crystal data of $(TMTSF)_2AzaTCNQ$: monoclinic, space group $C2/c$, a=7.738(1), b=19.531(2), c=23.146(3) Å, β=90.03(1)°, V=3498.3(8) $Å^3$, and Z=4. The a-axis corresponds to the crystal needle axis. The oscillation photograph along the a-axis displayed strong, even layer lines due to the two-fold periodicity of the donors. All these layer lines were composed of well-defined spots, even at room temperature, and no diffuse track was observed. The crystal structure is illustrated in Figs. 2—4. The planar TMTSF molecules form face-to-face one-dimensional stacks along the a-axis with an interplanar spacing of 3.6 Å, which corresponds to a conduction column (Fig. 4). Within the one-dimensional

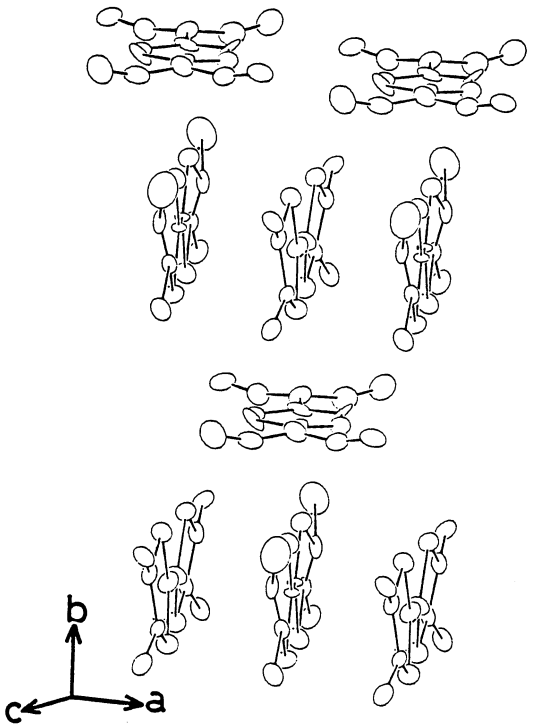

Fig. 2. Molecular arrangement of $(TMTSF)_2$ AzaTCNQ viewed along nearly the long axis of the donor molecule.

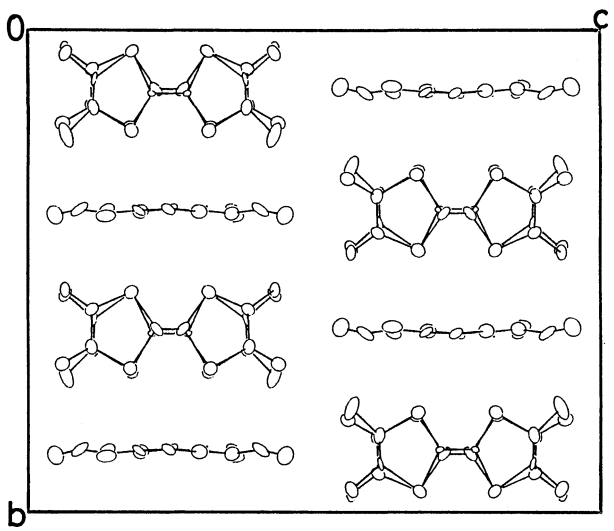

Fig. 3. Crystal structure of $(TMTSF)_2$AzaTCNQ projected along the axis perpendicular to the (100) plane.

stacks the Se···Se distances between the neighboring TMTSF molecules are 3.72—4.02 Å, which are comparable to twice the van der Waals radii of Se···Se, 3.80 Å. On the other hand, the AzaTCNQ molecular planes are arranged side-by-side along the donor stacks and the acceptor molecules surround the TMTSF columns so that the donor stacks are isolated from each other. There are no short atomic contacts between the neighboring donor columns; hence, the molecules form nearly complete one-dimensional stacks, as can

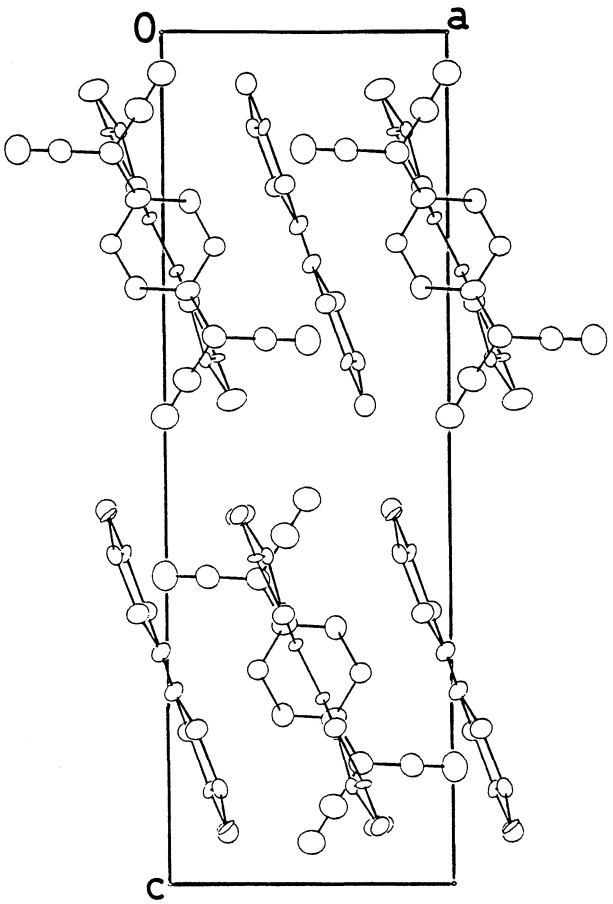

Fig. 4. Crystal structure of $(TMTSF)_2$AzaTCNQ projected along the b axis.

be seen in Fig. 3. The dihedral angle between the least-square planes of donor and acceptor molecules is 93° (Fig. 4). The AzaTCNQ molecules are oriented parallel to the ac plane, while the longitudinal axes of TMTSF molecules are tilted by approximately 20° from the [001] direction (Fig. 4).

Another remarkable feature is that the orientation of AzaTCNQ molecules has a disorder in nature. There appears a two-fold axis through the center of every AzaTCNQ molecule, so that the nitrogen atom in the pyridine skeleton of each AzaTCNQ molecule is randomly located at either position of two equivalent sites.

$(TMTTF)_2$AzaTCNQ is essentially isomorphous with the TMTSF complex. The crystal data are: monoclinic, space group $C2/c$, a=7.670(3), b=19.178(9), c=22.655(3) Å, β=90.25(2)°, V=3332.3(22) Å^3, and Z=4.

These structures have some similarities to that of $(TMTTF)_2$HCBD,[11b] in which the orientationally disordered acceptors lie almost perpendicular to the donor planes and surround the donors, showing one-dimensionality characteristics. A slight difference between $(TMTTF)_2$HCBD and $(TMTTF)_2$AzaTCNQ is that the donors in the HCBD complex stack in a dimerized manner with a molecular separation of ca. 3.5 Å within the dimer and ca. 3.7 Å between the

dimers. The HCBD complex is a semiconductor ($\rho_{RT}=3.3\times10^3$ Ωcm, $E_a=0.16$ eV). As for $(TMTTF)_2$AzaTCNQ, the electrical resistivity and the activation energy are lower than those of $(TMTTF)_2$HCBD. This may be caused by the uniform stacking of donors in $(TMTTF)_2$AzaTCNQ, where the interplanar spacing of 3.5 Å was observed.

A substitution of the selenium for sulfur atoms of donors may cause less on-site Coulomb repulsions and stronger intermolecular interactions between donors and influence the charge transport. As a consequence, $(TMTSF)_2$AzaTCNQ with uniform stackings shows a metallic character down to 200 K, as illustrated in Fig. 5. Upon lowering the temperature to below 150 K the resistivity gradually increases and is activated with a very small activation energy of $E_a=0.015$ eV.

The result of thermoelectric power (S) measurements shows positive values due to the hole conduction, which is consistent with the conducting paths of donors in the crystal (Fig. 6). The thermoelectric power linearly falls with decreasing temperature and the extrapolation tends to approach zero at 0 K, suggesting a metallic state above 150 K. The transition temperature is a little lower than that of the electrical resistivity. The higher transition temperature of the electrical resistivity may be caused by a strong sensitivity to the influence of the random potential originating from the orientational disorder of AzaTCNQ molecules. Assuming a simple one-electron tight-binding band model, the thermoelectric power along the conducting axis can be written as

$$S = \frac{-\pi^2 k_B^2 T}{6|e|t} \cdot \frac{\cos(\pi\rho/2)}{1-\cos^2(\pi\rho/2)},$$

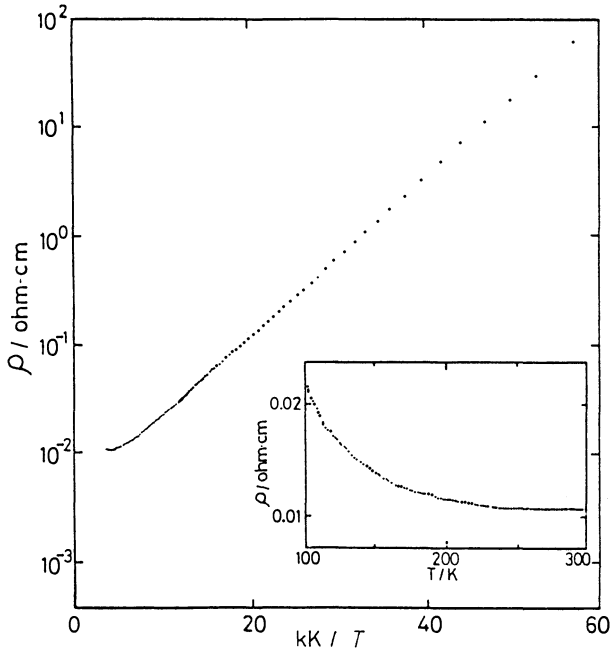

Fig. 5. Temperature dependence of the electrical resistivity of $(TMTSF)_2$AzaTCNQ along the a axis.

where e is the electron charge, k_B is the Boltzmann constant, and ρ is the electron density (in our case $\rho=2-1/2=3/2$).[16] From the slope of S vs. T plots at high temperatures, the transfer integral(t) was obtained as 0.25 eV ($4t=1.0$ eV). Below the metal-semiconductor transition, S gradually increases. For a simple semiconductor, the thermoelectric power can be described as

$$S = \text{constant} - \frac{k_B}{e} \cdot \frac{b-1}{b+1} \cdot \frac{E_g}{2k_B} \cdot \frac{1}{T},$$

where E_g is the energy gap and $b=\mu_e/\mu_h$, i.e., the ratio of an electron to a hole mobility.[16] From the positive values of the thermoelectric power and the one-dimensional conduction pathways composed of the only donor component shown by the crystal structure analysis, $-(b-1/b+1)$ can be regarded as 1. The activation energy was found to be $E_a=0.018$ eV from the slope of S vs. $1/T$ plots below 55 K. This value of the activation energy is in a good agreement with the derived value from the electrical conductivity.

Only one signal of the ESR spectra of $(TMTSF)_2$AzaTCNQ has been observed and the line shape was found to be Lorentzian all the way down to 34 K. The

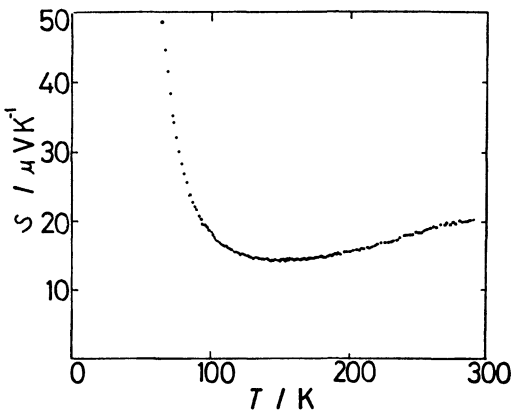

Fig. 6. Temperature dependence of the thermoelectric power S of $(TMTSF)_2$AzaTCNQ along the a axis.

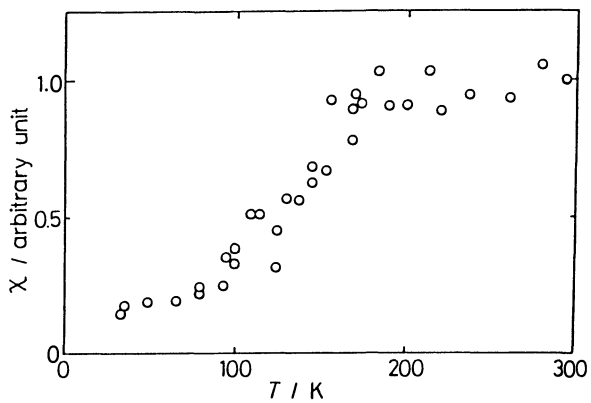

Fig. 7. Temperature dependence of the ESR magnetic susceptibility of $(TMTSF)_2$AzaTCNQ.

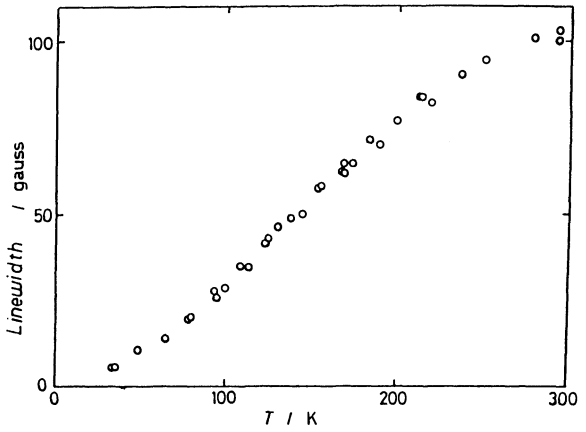

Fig. 8. Temperature dependence of the ESR linewidth of $(TMTSF)_2AzaTCNQ$.

magnetic susceptibility obtained from the ESR intensity of $(TMTSF)_2AzaTCNQ$ is almost constant, indicating a Pauli-like paramagnetism above 150 K (Fig. 7). Below that temperature the susceptibility behaves in an activated manner with E_a=0.03 eV. This value agrees fairly well with those of the electrical resistivity and thermoelectric power. Judging from the charge-transport and magnetic properties, a metal-semiconductor transition is considered to occur at ca. 150 K. It is regarded as being the Peierls transition.

Figure 8 illustrates the temperature dependence of the ESR line width for the applied field H_0 approximately parallel to the a-axis. The line width (ΔH) at 293 K is almost 95 G (1G=10^{-4} T) which is a little narrower than those of $(TMTSF)_2X$ (X=PF_6, BF_4, NO_3, and etc. ΔH>150 G),[17] suggesting a lower dimensionality of the AzaTCNQ complex than those of $(TMTSF)_2X$. Below room temperature the width decrease approximately linearly with the temperature down to about 250 K, below which the temperature dependence becomes stronger and the width decrease linearly to 5 G at 34 K. The temperature dependences are reminiscent of those of single-chain conducting complexes $(TMTSF)_2X$, which show knees at a little bit lower temperature (100—180 K) than that of the AzaTCNQ complex. The anisotoropy in the linewidth becomes smaller as the temperature becomes lower (ΔH=28 G (*//a*), 36 G (*//b*) at 99 K and 95 G (*//a*), 127 G (*//b*) at 293 K). The line width of the AzaTCNQ complex shows no drastic behavior in the temperature region of the metal-semiconductor trasition, which may indicate a gradual transition of this complex due to the orientational disorder of AzaTCNQ molecules.

The angular dependence of the g values is similar to that of the linewidth. The g values are usually different in the direction of the applied H_0 to the donor molecules. The maximum, intermediate, and minimum g values are generally found when H_0 is applied to a long axis, a short axis and perpendicular to a molecular plane, respectively. The observed g-value is

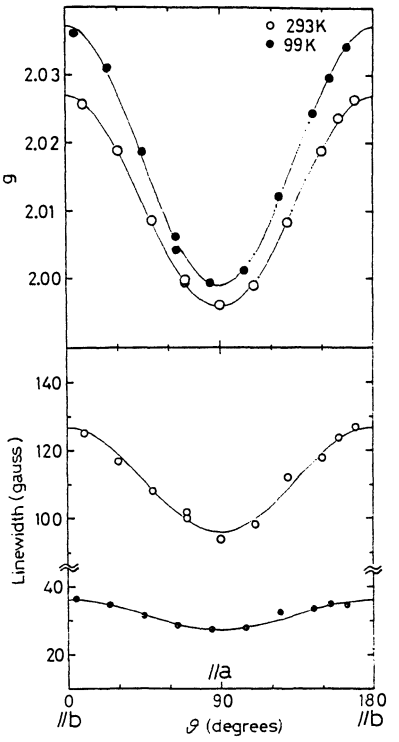

Fig. 9. Angular dependences of the g values and linewidth of $(TMTSF)_2AzaTCNQ$ at 293 and 99 K.

intermediate when H_0 is parallel to the b-axis (g_{int} ca. 2.026), which is approximately parallel to the short axis of the TMTSF molecules in the crystal. However, the minimum g-value is observed for H_0 parallel to the a-axis (g_{min} ca. 1.996), which is nearly normal to the molecular plane of TMTSF and, hence, along the conducting direction. Those values compare well to those of $(TMTSF)_2PF_6$ (g_{int} ca. 2.027, g_{min} ca. 1.989), strongly suggesting that AzaTCNQ behaves as a closed-shell counter anion. The anisotropy of the g-values is in good accordance with those previously reported ones in $(TMTSF)_2X$[18,19] and $(BEDT\text{-}TTF)_2X$[19] in that the intermediate g-value corresponds to the short axis of the donor molecule and the minimum g is perpendicular to the molecular plane. More precise anisotropy studies of the line width and the g-values of the AzaTCNQ complex are presently being carried out.

In summary, AzaTCNQ has been found to form conducting organic compounds with TTF derivatives. Among them $(TMTSF)_2AzaTCNQ$, in which AzaTCNQ most likely acts as a closed-shell counter anion, is the most conductive and the transport properties indicate its metallic character down to 150 K, where the Peierls-type instability takes place.

The authors wish to express their thanks to Professor Gen-etsu Matsubayashi of Osaka University for his valuable advice concerning the synthesis and Mr. Kenichi Imaeda for his helpful advice concerning electrical and ESR measurements.

Basis Set Dependency of Energy Components in Hartree-Fock MO Theories. II.[1] Conservability of Virial Ratio between Different Conformations

Hiroshi ICHIKAWA* and Atsushi SHIGIHARA
Hoshi College of Pharmacy, Ebara, Shinagawa, Tokyo 142
(Received August 8, 1987)

The authors examined 22 different basis sets in order to determine exactly how they reproduce the relative kinetic and potential energies. In an attempt to find the calculation error of such energy components, the virial relationship has been used between two conformations in which all bond lengths are optimized with respect to the total energy: i.e., the relationship, $\Delta V=-2\Delta T$, where ΔV and ΔT are the differences in the potential and kinetic energies. The degree of error was compared in terms of the relative virial error ($(\Delta E+\Delta T)/\Delta E$) to the difference in the total energies (ΔE). STO-*N*G was found to give a large amount of casual error, up to 500% to ΔE. Such an error could be dramatically improved by using a split-valence method. It should be noted that 4-31G and 6-31G methods resulted in a small amount of error and that the inclusion of polarization functions does not always improve the amount of error.

Ruedenberg and co-workers have pointed out that the nature of the chemical bond can be fully understood by only taking into account the kinetic and potential energies.[2-4] The basic energies which govern chemical phenomena are electrostatic potentials and kinetic energies of nuclei and electrons. The kinetic energy of nuclear motion may be considered separately;[5] thus, the major and important energies in a molecule are the potential energy and the kinetic energy of electrons. Therefore, it is possible, in principle, to interpret chemical phenomena in terms of the potential and kinetic energies in a system using MO theories.

Quantum chemists have provided a large number of basis sets for ab initio MO calculation.[6] However, care concerning components of the totel energy has been neglected or considered to be less important. Besides, it has been shown that the kinetic and potential energies are very sensitive to the scaling factor of the wave function, indicating that one must be more careful when analyzing the energy components than when analyzing the total energy.[7,8] The purpose of this paper is to show whether or not the potential energy and the kinetic energy of electrons are meaningful to quote and how they are dependent on the adopted basis set. For this purpose, we have examined 22 different basis sets in the GAUSSIAN 80 program.[9,10]

Theory

Evaluation of the Kinetic and Potential Energies. Since via a Fock matrix three- and four-center integrals out of two-electron integrals can be reduced to two-center terms, the kinetic energy (T) and the electronic potential energy (V) can be expressed in terms of the density (P_{rs}), kinetic energy (T_{rs}), and Fock (F_{rs}) matrices as follows;

$$T=\sum_{r,s} P_{rs}\,T_{rs} \tag{1}$$

and

$$V=1/2\sum_{r,s} P_{rs}\,(F_{rs}-T_{rs})+\sum_{A<B} E_{AB}{}^{N}, \tag{2}$$

where $E_{AB}{}^{N}$ is the internuclear repulsion between atoms A and B, and where r and s run over all atomic orbitals. Details are shown elsewhere.[11]

Since the scaling factor to the wave function applies to the electronic coordinates as well as to the nuclear coordinates, the condition or threshold of geometry optimization is predicted to seriously affect components of the total energy. Therefore, the threshold of geometry optimization was set to be 0.000075 (maximum) and 0.00005 (rms) Hartree/Bohr or radian, which are less than one fifth of the standard geometry optimization.

As Eqs. 1 and 2 show, the convergence on the density matrix may be another important condition. The SCF criterion was set such that every element of the density matrix was to converge within 10^{-10}, 1000-times more severe than the standard SCF criterion. The effects of geometry optimization and the SCF convergence will be discussed in a later section.

Criteria of Energy Components. The first criterion of the adopted basis set is to compare the relative total energy (ΔE) with the experiment (criterion 1). However, this cannot apply to the components of the total energy.

The ratio V/T should be exactly -2 in any *equilibrium* geometry. Nelander has pointed out that the angular coordinates give no contribution to the ratio if all bond lengths are optimized with respect to the total energy.[12] The energy difference between any two sets of geometry-optimized conformations satisfies the relationship $\Delta V=-2\Delta T$, where ΔT and ΔV are the differences of the kinetic energy and the potential energy. Therefore, if the total energy increases when the geometry changes from one conformation to another, the potential energy must increase while the kinetic energy of electrons must decrease (criterion 2)

and the ratio $-\Delta V/\Delta T$ should be exactly 2, as to the appropriate Hartree-Fock wave function. Although the actual wave functions obtained by an SCF MO theory do not always give the required ratio exactly, it could be said that the closer the calculated ratio is to 2, the more the adopted basis set is appropriate for the considered system. This can be another criterion. However, it involves such a difficulty that when ΔT appears to be zero or very close to zero, the ratio becomes infinity or a very large number, overrating the error.

The $\Delta E+\Delta T$ value ($=\Delta V+2\Delta T$) should be zero; the closeness to zero shows exactly how energy components are calculated by the adopted basis set. We call the difference from zero the "virial error" for now. Since the virial error should be compared with respect to ΔE, we adopted the relative value $(\Delta E+\Delta T)/\Delta E$ as a quantitative measure for the error of the energy-component calculation (criterion 3).

Results and Discussion

We have chosen the following compounds: CH_3-CH_3, CH_3-NH_2, CH_2=CH-CH=CH_2, CH_2=CH-NH_2, and CH_2=CH-NO_2. The first and second compounds represent the aliphatic compounds and the others are interesting in that a change in the conformation of the functional group breaks up the conjugation between π systems or between a π system and its substituent.

Ethane. Ethane favors the staggered conformation **1** and the experimental rotational barrier was reported to be 12.3 kJ mol^{-1}.[13] Table 1 shows the results for ethane where the total energies, kinetic energies, and potential energies for the staggered conformation are listed. As for the eclipsed conformation **2**, only the differences from the staggered conformation are shown.

The calculated energy barrier (ΔE) ranges from 11 to 13 kJ mol^{-1}, a good agreement with the experiment,

regardless of the adopted basis set satisfying criterion 1. In the STO-*N*G methods, however, it is seen that both kinetic and potential energies increase as the geometry changes from the staggered conformation to the eclipsed one. This does not meet criterion 2. All other methods satisfy such a requirement.

Regarding criterion 3, as Fig. 1 shows, only STO-*N*G gave a relative virial error of more than 100% to the difference of the total energies. All other methods gave reasonably correct values where, interestingly, the inclusion of polarization functions did not improve the error. For example, the relative errors by 6-311G, 6-311G*, and 6-311G** were 0.08, 0.33, and 0.15, respectively, where the basis set without polarization functions gave the best result among them. Except for STO-*N*G, the difference of energy components, ΔT

a) In terms of au. b) kJ mol^{-1}.

and ΔV, were calculated to be 10 to 20 and 20 to 30 kJ mol^{-1}, respectively.

Methylamine. We have chosen two conformations: the staggered conformation **3** and the eclipsed conformation **4**. The rotational barrier of methylamine has been reported to be 8.3 kJ mol^{-1}.[14] The calculated rotational barriers shown in Table 2 were from 7 to 12 kJ mol^{-1}, in reasonable agreement with the experiment. However, the components by STO-*N*G appeared to be unsatisfactory, even qualitatively. The split-valence methods gave results which reasonably well satisfy criteria 1, 2, and 3. Very exceptionally, 6-311G gave a large relative virial error in addition to failure of criterion 2, although it was improved by the inclusion of polarization functions. As expected, the contraction number of the primitive Gaussian functions for the inner-shell atomic orbitals did not affect the ratio very much. It is also noted that the inclusion of polarization functions to the first-row atom and to the hydrogen atom seems not always to improve the relative virial error.

Butadiene. The rotational barrier from the trans to cis structures has been observed to be a value ranging between 24 and 32 kJ mol^{-1}.[15-17] We have chosen the planar trans structure with the lowest energy **5** and the orthogonal structure with the highest energy **6.**

As shown in Table 3, the calculated rotational barriers varied from 23 (STO-*N*G) to 51 kJ mol^{-1} (6-21G*), significantly larger than the observed values. This may stem from the difference of the electron-correlation energy between the orthogonal and planar structures: in the orthogonal structure the conjugation between two π systems are broken.

Vinylamine. We consider the orthogonal structure **7** (X=H) and the planar structure **8** (X=H). Vinylamine is the fundamental unit of enamines. The electronic effect of enamine has been explained as being a strong contribution of the structure CH_2^--CH=NH_2^+.[18]

Since vinylamine favors to take the imino form, the experimental rotational barrier may not be obtained, excluding the way to check the difference of total energies. However, the rotational barrier has been calculated to be between 26 and 32 kJ mol^{-1}.[19] Table 4 shows the energies for the planar structure and the differences for the orthogonal structure from the planar structure.

The total energy of the optimized orthogonal structure was calculated to be 25 to 35 kJ mol^{-1} higher than that of the planar structure by all MO methods, perhaps satisfying the first criterion. However, the components were divergent.

A comparison of the relative virial errors by *N*-21G*, *N*-21G**, *N*-31G*, and *N*-31G** leads to the fact that, contrary to the case of methylamine, the number of the primitive Gaussian functions for the inner-shell electrons is slightly concerned with the energy components: as a rule, the larger the number of functions, the better the results.

Nitroethene. Nitroethene has a planar structure with an electric dipole moment of 3.7 d,[20] indicating that a considerable number of electrons move to the nitro group. In an orthogonal structure **7** (X=O) such a conjugation is forced to cease. The conjugation energy is observed to be 20.2 kJ mol^{-1},[21] suggesting a strong contribution of the cannonical structure CH_2^+-CH=NO_2^-.

Table 5 shows that the calculated conjugation

energy ranges between 20 and 40 kJ mol^{-1}. The potential energies calculated by all methods increase in accordance with the corresponding total energies. However, the kinetic energy behaves differently according to the calculation method. This time, STO-*N*G gave the correct signs of ΔT, but ΔT's by *N*-21G, 6-21G**, 4-31G*, and 4-31G** failed to meet the second criterion. Criterion 3 is necessary for a quantitative discussion. Interestingly, such a requirement is satisfied by such rather smaller basis sets as 4-31G and 6-31G; the inclusion of polarization functions does not always improve the relative virial error.

Effect of the Conditions of Geometry Optimization and SCF Convergence. (a) Threshold of Geometry Optimization. It has been known that the kinetic and potential energies change in the first order of the error of the scaling factor to the wave function, while the total energy does only in the second order.[7,22] Since

a) Threshold at the density matrix, P_{rs}. b) In terms of au.

the scaling factor applies to the electronic coordinates as well as to the nuclear coordinates, the error of energy components can be grouped into two: the error due to electronic coordinates and that due to nuclear coordinates. The former may be improved by adopting a large basis set which allows a shrinking or expansion of the electronic distribution. The latter may be largely affected by the threshold of geometry optimization.

Table 6 shows how the energy-components are affected by the condition of geometry optimization. As an example, we investigated the case when the orthogonal structure of vinylamine is not properly optimized: namely, the energy difference between the optimized planar structure and the orthogonal structures in which the C-N bond is intentionally shifted from the equilibrium distance (r_0). A decrease of 0.0001A from r_0 makes no difference regarding the total energy. However, the differences of the kinetic or potential energy amount to 2.3 kJ mol^{-1} and the relative virial error increases from 0.11 to 0.18. The force at this point is 0.00014 Hartree/Bohr. Judging from this result, a threshold less than 0.0001 Hartree/Bohr may be absolutely necessary. However, a far more severe optimization than that consumes a large amount of computation time and is likely to go into oscillation. Therefore, a threshold of 0.000075 Hartree/Bohr, which is adopted in the present study, may be a practical compromise.

(b) Concerning the SCF Convergence. As already mentioned, an incomplete convergence of the density matrix, P_{rs}, may create errors in the energy components. Table 7 shows the relationship between the threshold of SCF convergence and the total energy and its components.

The total energy is not very sensitive until a threshold of 10^{-3} at the density matrix. However, the components are susceptible enough, even at 10^{-6} (The deviation from the threshold of 10^{-10} is 0.1 kJ mol^{-1}). Therefore, at least a threshold of 10^{-7} may be desirable.

Concluding Remarks

In the first paper of this series,[23)] we discussed the dependency of the electron density, the kinetic energy, and the potential energy of an atom on the adopted basis set. It was shown that the polarization functions must be added to atoms of the first row and the hydrogen atom in order to obtain well-balanced wave functions. The STO-*N*G method was also shown to give well-balanced wave functions. However, Fig. 1 shows that STO-*N*G gives a large amount of casual error, up to 500%. This error can be dramatically improved by using a split-valence method. This may be because in a split-valence method, the wave function has more spacial freedom for expansion or shrinking than that in the single zeta method, like STO-*N*G. The 4-31G and 6-31G methods resulted in a small amount of error, but the inclusion of polarization functions does not always improve the amount of error. This strongly suggests that the error in the split-valence method is caused by incomplete geometry optimization, rather than an incomplete basis set.

As we stated in the introduction, it may be worth investigating which energy, T or V, plays the major role in chemical phenomena. For such a purpose, we only need qualitative ΔT and ΔV, and any split-valence method seems to be eligible to be adopted. However, care must be taken regarding the calculated energy components, as always, in any kind of MO theoretical calculation.

The Electrocapillary Curves of the Phosphatidylcholine Monolayer at the Polarized Oil-Water Interface. I. Measurement of Interfacial Tension Using a Computer-Aided Pendant-Drop Method

Takashi KAKIUCHI, Masatoshi NAKANISHI, and Mitsugi SENDA*
Department of Agricultural Chemistry, Faculty of Agriculture, Kyoto University, Sakyo-ku, Kyoto 606
(Received October 19,1987)

The conditions for obtaining the electrocapillary curves of the dilauroylphosphatidylcholine (DLPC) monolayer formed at the polarized nitrobenzene-water interface have been studied using the pendant drop method. To facilitate the measurement, the system for the interfacial tension measurement, including the computer software for the data handling, has been developed based on digital image processing of the video image of a pendant drop. The 95% confidence interval of the measured interfacial tension value was ± 0.06 mN m^{-1}. The time required to measure an electrocapillary curve with 30 points was 30 min, while the time necessary to convert the image data to the interfacial tension was 1 min. The potential drop across the monolayer has been demonstrated to influence the stability of the monolayer strongly. The DLPC markedly lowered the interfacial tension by forming a stable monolayer when the interface was polarized so that the aqueous phase has a negative potential with respect to the nitrobenzene phase. On the other hand, when the aqueous phase became positively polarized, the adsorbed DLPC molecules started to desorb from the interface, giving rise to the disruption of the monolayer. The electrocapillary curves only in the former potential range were found to be thermodynamically meaningful.

The structure of the electrical double layer in the vicinity of the surface of lipid bilayers, monolayers, and biological membranes is important in understanding various surface phenomena associated with the biological as well as biomimetic membranes and, in general, with oil-water interfaces. The electrically polarizable oil-water interface is a useful means to study the electrical phenomena at the oil-water interface, in that the potential drop across the interface is accurately controlled externally.[1] This type of system has been used successfully to elucidate the double layer structure of ionic surfactant monolayers at oil-water interfaces,[2,3] aside from a wide range of applications to analytical chemistry and the electrochemistry of ion-transfer reactions.[4] If one introduces phospholipids to this type of interface, one may expect to be able to study in detail the interfacial and electrochemical properties of the phospholipid monolayer which are not readily accessible by other methods, e.g., the properties of the electrical double layer and the kinetics of ion-transfer reaction across the monolayer, by using the estahlished method of the analysis of the electrocapillary and electrochemical data.[4,5] Along this line, several groups have reported on the electrochemical characteristics of the phospholipid monolayers at the polarized oil-water interface: a retardation of the ion-transfer reaction from water to oil,[6,7] the differential capacitance of the phospholipid monolayers at the nitrobenzene-water interface[8] and at the dichloroethane-water interface,[9] and the electrocapillarity measurements at the dichloroethane-water interface in the presence of a phospholipid monolayer.[10] To analyse the double layer structure, the basic properties of the monolayer, e.g., the potential of zero charge and the excess charge density, must be evaluated. These quantities can be obtained by measuring the electrocapillary curve of the interface. Since phospholipids are highly surface active, the very dilute concentration of the μmol dm^{-3} order is enough to make up a saturated monolayer at the interface.[8] Such a low concentration of phospholipid requires a long time to reach the adsorption equilibrium. Accordingly, to obtain a thermodynamically meaningful electrocapillary curve, a method that is capable of measuring the equilibrium value of interfacial tension is desirable. For this purpose, the pendant-drop method and the sessil-drop method are the most suitable. Girault and Schiffrin have recently developed a new pendant-drop method by applying a video-image digitizer.[11] They later improved this method by introducing a video-image digitizer with a higher resolution specifically designed for the electrocapillary measurements.[10] In this study, we wish to report a similar apparatus also based on the video-image digitizing technique but with a higher accuracy and faster data handling using a commercially available video image digitizer in combination with computers. By using this new apparatus, the conditions for obtaining the equilibrium electrocapillary curve of the phosphatidylcholine monolayer at the polarized nitrobenzene-water interface have been studied.

Experimental

Reagents. Reagent-grade nitrobenzene was distilied and purified as has been described elsewhere.[1] The nitrobenzene and the nitrobenzene solution were equilibrated with water or an aqueous solution of lithium chloride at 25.0 °C overnight to ensure mutual saturation. Aqueous solutions of lithium chloride and tetrapentylammonium chloride (TPnACl), and a nitrobenzene solution of tetrapentylammonium tetraphenylborate (TPnATPB) were prepared as has been described elsewhere.[13] Reagent grade dichloro-

methane (DCM) and 1,2-dichloroethane (DCE) were purified as follows.[14] These solvents were washed three times with 10% $NaHCO_3$ to remove the HCl. The solvents were then washed with water. After they had then been dried with $CaCl_2$, the solvents were distilled. The fractions of bp 39 °C (DCM) and 83.5 °C (DCE) were collected and stored in the dark. These solvents were equilibrated with water at 25 °C overnight before use in the interfacial-tension measurements. The water used to prepare aqueous solutions for the interfacial tension measurements was first distilled and then redistilled in the presence of potassium permanganate after having been passed through ion-exchange resin and the Organic Removal Filter (Barnstead). The L-α-dilauroylphosphatidylcholine, DLPC, (Sigma) was dissolved in a 3 : 2 toluene-chloroform solution and then stored in a refrigerator until use. All the other chemicals were of a reagent grade.

Interfacial Tension Measurements. The block diagram

of the apparatus used for the interfacial tension measuremts is shown in Fig. 1. A glass cell and a video camera were set on an optical bench (Sigma Koki Co. Σ-06-(3)) 80 cm long and supported by two legs (Σ-02 and Σ-03) on rubber dampers. The cell (Fig. 2) had two windows consisting of optically flat borosilicate glass disks 3 cm in diameter (Fig. 2g), and it was installed in a cell holder mounted on a coarse-fine rotation stage (Σ-401-(2)). Two scale-etched Plexiglas plates mounted on a carrier beneath the rotation stage so that the two plates were parallel with the axis of the optical bench and sandwiched the glass cell were used to locate the position of an object in the cell. Two types of cell configurations were used in the measurement. In Configuration I, the cell (Fig. 2) was filled with an aqueous solution. In Fig. 2a, A is a platinum wire which served as an auxiliary electrode, while b is a reference electrode of a Luggin-capillary type in which an aqueous LiCl solution and an Ag/AgCl electrode were incorporated. A glass tube (Fig. 3) filled with a nitrobenzene solution was inserted into the solution in the cell. In Fig. 3, e and h are the platinum wire and the Luggin capillary used as the counter electrode and the reference electrode respectively in the nitrobenzene phase. The tip of this glass tube (i in Fig. 3) has an outer diameter of 2 mm and an inner diameter of 1 mm. This glass tube was mounted on a tip holder set on an assembly of a X,Y tilt stage (Σ-501), a X,Y precision translation stage (Σ-206), and a rack-pinion type X-block (Narisige, M-6). In Configuration II, a nitrobenzene solution was placed in the cell. In this case, a drop of the aqueous solution was formed in the nitrobenzene solution from the tip of the glass tube (Fig. 2b). The tip for this configuration was made of poly(tetrafluoroethylene) tubing 1 mm in outer diameter and 0.5 mm in inner diameter. Below, the interfacial tension was measured in Configuration I unless otherwise stated. The video camera, a CCD type with a picture element of 381(h)×492(v) (Tokyo Electronic Industry Co., CS3300), was secured with a lens holder (Σ-41-(3)) mounted on a set of a X,Y tilt stage (Σ-501) and a coarse-fine rotation stage (Σ-401-(2)). The television lens (Asahi Precision Co., Cosmicar 50 mm F1.4) was mounted on the CCD camera with an extension tube (Cosmicar, 40 mm). The standard tungsten bulb light source unit (Nikon) with a filter (GIF, Nikon) and a diffuse light mat was used to obtain the green diffuse light, which was shed into the flat window of the glass cell. The video signal from the camera was digitized by means of a video-image processor (Nippon Avionics Co., Image Mate) to 640(h)×482(v) pixels, each of which had 256 gray levels. The conversion can be made every 1/30 s. This image processor was controlled by a micro-computer (Fujitsu Co., FM-11AD2) through the GP-IB interface.

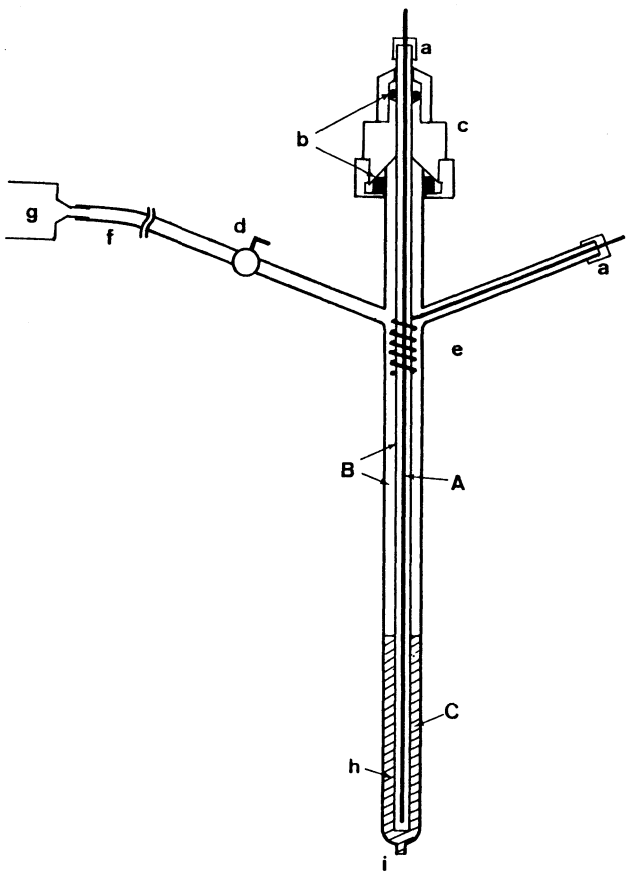

Fig. 3. Diagram of an upper part of the cell for Configuration I. (a) Silicone rubber cap, (b) O-ring, (c) connector, (d) stop cock, (e) Pt electrode, (f) silicone rubber tubing, (g) gas tight syringe, (h) luggin capillary, (i) tip to form a pendant drop, (A) Ag/AgCl electrode, (B) aqueous TPnACl solution, (C) nitrobenzene solution.

Alignment of the Video Camera: First, the rotation angle of the camera was adjusted so that the image of a vertically hanging string was seen horizontally on the screen of a monitor TV (Tokyo Eletronic Industry Co., 9M10A). Then, the position of the focal plane was found as follows. A micrometer with a mesh of 0.5 mm/div. (Kyoto Kogaku) was hung over from the glass tube holder into the position where the glass cell was otherwise located. The position and the angle of the micrometer were adjusted so that the plane of the micrometer was vertical to the axis of the optical bench, which the light beam was introduced in parallel with. The X,Y stage under the glass tube holder was adjusted to bring the micrometer to the focal plane. A high-precision steel ball 5.000±0.001 mm in diameter was hung from the glass tube holder into the focal plane. The number of pixels in the digitized image corresponding to the diameter of the ball in horizontal direction (a pixels) was recorded. The angle of the camera in the vertical direction was adjusted similarly using the micrometer. The number of pixels corresponding to the diameter of the steel ball was again recorded (b pixels). The angle of the camera was adjusted so that the plane of the CCD sensor in the camera was normal to the axis of the optical bench. The micrometer was hung into the position of the focal plane. The camera was turned, step by step, by rotating the rotation stage, and the number of pixels corresponding to the horizontal interval of the micrometer mesh was recorded. The position where the number of pixels was greatest, L_{max}, was found by plotting the number of bits against the rotation angle. The angle of the elevation of the camera was adjusted using the X,Y tilt stage, so that the $L_{max}a/b$ quantity was at its maximum.

Determination of the Conversion Factor and Correction of Distortion: To obtain the coordinates of the edge of the pendant drop from the digitized image, the relation between the true value of the coordinate and its corresponding value in the digitized image was determined by measuring an object having a known shape and dimensions. The possible distortion of the image was corrected by using the microme-

ter described above and a standard image processing technique. As was to be expected from the advantage of a CCD type video camera free from bulge distortion, the distortion of a video image was found to be negligibly small. The vertical and horizontal size factors of the measuring system were determined by measuring the size of a steel ball immersed in the cell (Fig. 2a) filled with 0.05 mol dm^{-3} LiCl.

Measurement of the Shape of a Pendant Drop: The drop was formed at the tip, after the glass tube had been brought to the position of the focal plane. To detect the edge of the drop, the change in the gray level was checked against the transverse distance across the drop image (Fig. 4). The gradient of this plot exhibited maxima at either two (Fig. 4) or four points. The gray level —at these two points in the former case and at the outer two points in the latter case— were used as the threshold level of the thresholding procedure.

Data-Processing: The thresholded data were transferred to the microcomputer through GP-IB and then compressed to generate run-length data before the data storage. The overall data acquisition and transfer required 30 s for 1 image data. The data were further processed by a computer (Fujitsu, FACOM M382) in the Kyoto University Data Processing Center. After the noises on the margin of a plane of the image and those due to dust stuck on the cell surfaces had been removed by a software technique, the coordinate for the circumference of the drop was extracted. The position of the apex was found, assuming that the drop had an axial symmetry.

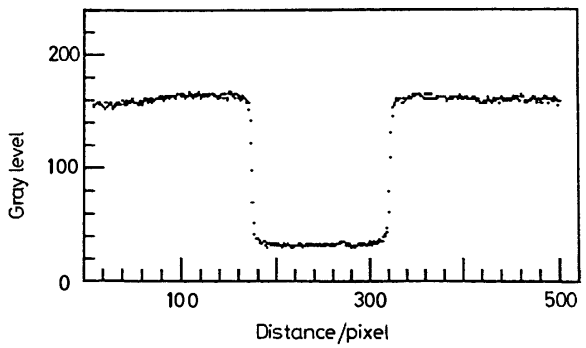

Fig. 4. Change of the gray level on the transverse distance across the drop.

Calculation of Interfacial Tension from the Drop Shape: The theoretical curve was obtained by solving numerically the Bashforth-Adams equation[15] in the following form:

$$\frac{d\theta}{ds} = 2 - \frac{\sin\theta}{x} + \beta y$$

$$\frac{dx}{ds} = \cos\theta$$

$$\frac{dy}{ds} = \sin\theta$$

for the initial conditions, $dx/ds=1$, $dy/ds=0$, and $d\theta/ds=1$ when $s=0$, where

$$\beta = -\frac{\Delta\rho g b^2}{\gamma}$$

In these equations, $x=X/b$, $y=Y/b$, and $s=S/b$. X and Y represent the Cartesian coordinate of a point P on the edge of the drop, S is the distance from the apex to P along the circumference of the drop, and b is the radius of the curvature at the apex. The origin of the coordinate was taken as the apex. θ is the angle between a tangent to the surface at P and the horizontal, $\Delta\rho$ is the density difference, g is the acceleration of gravity, and γ is the interfacial tension. An initial value for b was found from the curvature around the apex obtained by fitting the experimental points around the apex to a third-order polynomial. An initial value for β was set equal to -0.5. The calculated curve obtained using the Runge-Kutta method was fitted into the experimental curve based on the least square principle using the SALS (FORTRAN subroutine for regression analysis).[16] Since the drop shape had an axial symmetry, half of the experimental points were used for the regression

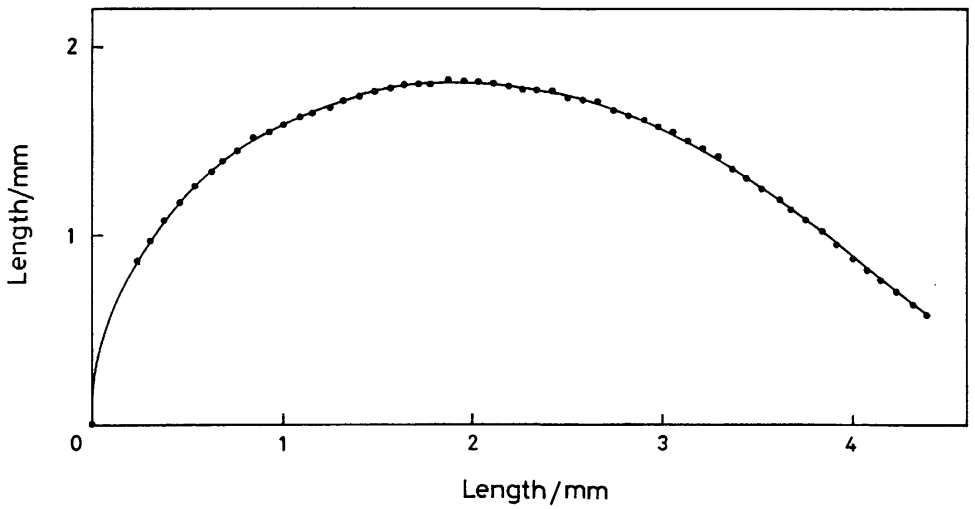

Fig. 5. An example of the result of the least square curve fitting of the numerical solution of the Bashforth-Adams equation to the experimental data; (—●—), experimental; (——), regression curve. The data is for the nitrobenzene-water interface at 25 °C.

Table 1. Values of Interfacial Tension for the 1,2-Dichloroethane-Water, Dichloromethane-Water, and Nitrobenzene-Water Interfaces at 25 °C

analysis. In the calculation with SALS, the Marquardt method and the biweight method were employed for the non-linear regression and the adjustment of the weight attached to each point respectively.[16] The cpu time required to evaluate an interfacial tension value from the run length data for each drop comprised of 250 points for half of the drop image was typically 2 s. Figure 5 shows an example of the curve fitting by the nonlinear regression analysis. The software for the control of the video-image processor and the data processing was written in Basic09 and the machine language on the operating system OS-9.[17] FORTRAN77 was used for data processing on FACOM M-382.

Control of the Pointial Differences. The potential drop across the interface was controlled with a laboratory-made four-electrode potentiostat similar to the type in Ref. 18. The solution resistance was compensated for by using a positive feedback method.[18]

All the measurements were made at 25.00±0.05 °C. The density of the solutions was measured as has been described elsewhere.[1]

Results and Discussion

The Interfacial Tension Measurement for the Pure Organic Solvent-Water Interface. First, the interfacial tensions between water and pure organic solvents were measured. The interfacial tensions for the DCE-water, DCM-water, and nitrobenzene-water interfaces at 25 °C are given in Table 1, with a 95% confidence interval. In general, the present results are in excellent agreement with the literature data given in the second column of Table 1. The 95% confidence interval of the present method is 0.06 on the average, and the precision is better than those obtained by Girault et al.[12] although their video image digitizer had a higher resolution, 1066(h)×575(v). The difference is probably to be ascribed to the method of calculating the interfacial tension from the drop image. They employed the inflection plane method[12] to minimize the computational time. The precision of this method[12] depends greatly on how accurately the point of inflection is determined. The curvature change is not always large enough to determine this point with a high accuracy, even when the curve-fitting technique with a higher polynomial is used. Moreover, the requirement that the inflection point be on the drop shape limits the applicability of this method. The advantage of the direct regression of the data to the Bashforth-Adams equation, which does not require the presence of the inflexion point, seems obvious. This method was first utilized by Girault et al.[11] for the pendant drop data with less resolution.

We have also compared the present method of data-analysis with the selected-plane method, which has been commonly used as a convenient method for calculating the interfacial tension from a drop shape.[19] A comparison of the two methods for the same data is given in Table 2. This table indicates that the selected-plane method gives a comparable interfacial tension value, but with a confidence interval 6 times wider. This result is expected, for the selected-plane method makes use of only a few out of the many experimentally obtained points in the calculation.

Electrocapillary Measurements. Electrocapillary curves in the absence of phospholipid adsorption were first recorded at intervals of 20 mV between 0.1 V and 0.5 V for the system represented by the cell:

I	II	III	IV	V	VI	VII
Ag	AgCl	0.02 M† TPnACl (W)	0.1 M TPnATPB (NB)	0.05M LiCl (W)	AgCl	Ag (I)

The interface between Phases IV and V is the polarized nitrobenzene-water interface. The potential of the right-hand-side of Cell(I) with respect to the left is denoted as E^{W-}_{O+}, where the super- and subscripts indicate that the reference electrodes in the aqueous and nitrobenzene phases are reversible to the anion (Cl^-) and the cation ($TPnA^+$) respectively. The nitrobenzene phase contained a 10% 3:2 toluene-chloroform mixture. The results for the triplicate measurements are shown in Fig. 6 (Curve A), with error bars for standard deviations. The average standard deviation of the interfacial tension was 0.25 mN m^{-1}, larger than the deviation for the pure solvents (Table 1) because of the fluctuation of the potential in the electrocapillarity measurements.

† 1 M=1 mol dm^{-3}.

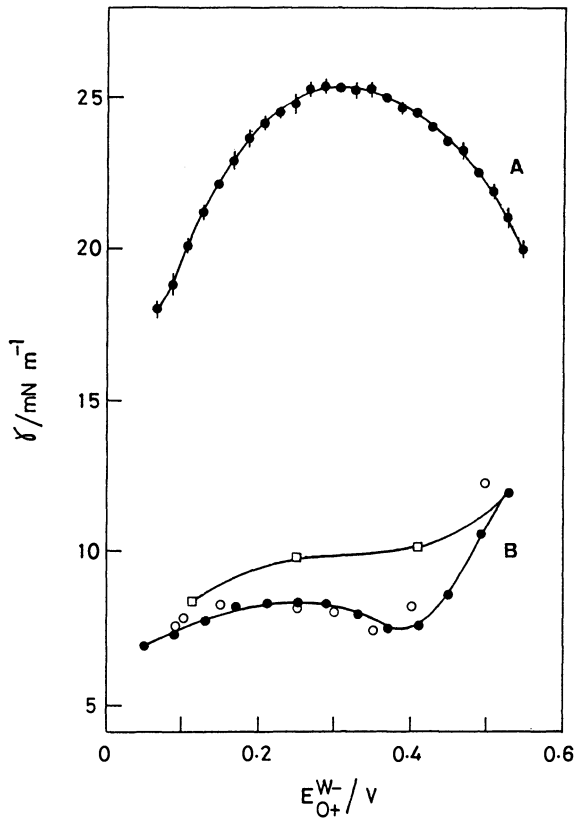

Fig. 6. (A) Electrocapillary curve for the interface between 0.1 mol dm^{-3} TPnATPB and 0.05 mol dm^{-3} LiCl at 25 °C. 20 μmol dm^{-3} DLPC and 0.05 mol dm^{-3} LiCl at 25 °C (—●—). (B) After the adsorption equilibrium was established under open circuit condition, the potential was first scanned from 0.05 to 0.5 V (—●—) and then reversed (—□—). These data are compared with the data obtained through the plot method (—○—).

The electrocapillary curves in the presence of the DLPC monolayer were measured in order to obtain the basic properties of the electrocapillarity of the phospholipid monolayers at the polarized nitrobenzene-water interface. For this measurement, Configuration II of the cell was used to ascertain that the amount of DLPC molecules in the bulk was enough to make up a monolayer at the interface. DLPC was dissolved in the nitrobenzene phase, which contained a 10% 3:2 toluene-chloroform mixture, to facilitate the dissolution of DLPC. The time variation in the interfacial tension was followed after the drop had been squeezed out of the tip at a constant potential. At least one hour was needed for the establishment of adsorption equilibrium, when the concentration of DLPC in the nitrobenzene phase, c_{DLPC}, was 1 μmol dm^{-3}. In the following measurements, the interfacial tension was measured 2 h after the formation of the interface.

The lower curve in Fig. 6 shows the electrocapillary curve recorded at c_{DLPC}=20 μmol dm^{-3} in Cell(I) after the DLPC had been allowed to adsorb 2 h in the open circuit. From the differential capacitance measurements of the same system, the saturated monolayer of DLPC, whose density at the interface was 0.75 nm^2 per DLPC molecule, was found to be formed at this concentration.[8] The measurement was first made at intervals of 40 mV by changing the potential from 0.05 V to 0.55 V (—●— in Curve B in Fig. 6). The interfacial tension was greatly suppressed by the strong adsorption of DLPC. The electrocapillary curve showed a convex shape between E^{W-}_{O+}=0.05 and 0.35 V. Beyond E^{W-}_{O+}=0.35 V, the interfacial tension abruptly increased with the increase in the potential. When the potential was reversed from the positive extreme of the potential to sweep in the negative direction, the interfacial tension gave a much higher value (—□— in Fig. 6) as compared with the value obtained initially at the same E^{W-}_{O+} value. This hysteresis probably reflects the slow diffusion process of DLPC and substantiates the desorption of the DLPC molecules from the interface in the positive extreme range of the potential. The concomitant increase in the differential capacitance in this potential region has also been observed.[8] When the potential was reversed at a potential less than 0.35 V, no such hysteresis was observed.

To check if the applied potential during the monolayer formation influences the properties of the monolayer after the adsorption equilibrium had been established, the monolayer was formed while the applied potential was kept at a constant value during the formation of the monolayer: the plot method. The open circles in Fig. 6 were recorded after the interface had been kept at a given value of E^{W-}_{O+} during the course of adsorption. The agreement of the results in Fig. 6 obtained from the two methods suggests that the electrical potential difference across the interface does not introduce any significant difference to the monolayer formed eventually at the interface, provided that the potential is less than 0.35 V, Region I. The discrepancy between the values obtained by the two methods in the potential range positive to E^{W-}_{O+}=0.35 V, Region II, indicates the slow processes associated with the desorption of DLPC molecules and possibly their reorientation within the monolayer. Correspondingly, the interfacial tension values obtained in Region I were reproducible, whereas the values in Region II were much less reproducible. At this positive extreme of the potential, fine, small, emulsion-like particles were sometimes observed coming spontaneously out of the tip. This is another piece of evidence of complicated non-equilibrium processes occurring in this potential range. Thus, only the data in Region I seem to be thermodynamically meaningful.

Figure 6 shows that the electrocapillary maximum, i.e., the potential of the zero charge was shifted by 100 mV to the negative direction accompanied by the formation of the saturated DLPC monolayer (Curve B). The reduced curvature of Curve B in Fig. 6 compared with the curve without the DLPC monolayer (Curve A in Fig. 6) suggests a decrease in the surface charge

density caused by the DLPC adsorption at a given value of the potential drop across the interface. The curvature, i.e., the second derivative of the interfacial tension with respect to E_{O+}^{W-} in Region I, gave the capacitance value of 11.5 $\mu F\ cm^{-2}$ for the DLPC monolayer. This is in accord with the value of 11 $\mu F\,cm^{-2}$ obtained from the differential capacitance measurements[8] for the same monolayer. This agreement confirms the thermodynamic consistency[1] of the two results in Region I. An electrocapillary curve similar to the curve in Fig. 6 has been obtained by Girault and Schiffrin[10] for an egg-yolk phosphatidylcholine monolayer at the DCE-water interface. They interpreted the positive slope in Region II (Region B in Ref. 10) as showing the positive excess charge density on the aqueous solution side, originating from the positively charged head group of adsorbed phosphatidylcholine molecules due to the protonation of the phosphate group of the phosphatidylcholine. However, the present results indicate that it is difficult to endow the electrocapillary curve in this region with any definite thermodynamic meaning. For the same reason, it is doubtful if we can estimate the surface charge density from the differential capacitance vs. the potential curve in the presence of phosphatidylcholine adsorption by the back-integration of the curve from the far positive potential in Region II, as was claimed by Wandlowski et. al.[9] for the dipalmitoylphosphatidylcholine adsorption at the DCE-water interface. The subsequent paper will treat the electrocapillary curves at different concentrations of DLPC in an attempt to analyze the double-layer structure of the adsorbed DLPC monolayer at the nitrobenzene-water interface.

The Entropy of Solution of Alkanes Measured by Gas-Liquid Chromatography and Interpreted by Means of Scaled Particle Theory†

Hideaki FUJIWARA,* Ikuji OHTAKU, Tatsuya TAKAGI, Saburo MURATA, and Yoshio SASAKI
Faculty of Pharmaceutical Sciences, Osaka University, 1-6 Yamadaoka, Suita, Osaka 565
(Received November 6, 1987)

The entropy of solution was measured by gas-liquid chromatography for the alkanes from pentane to decane in dibutyl phthalate solution. The results are discussed in relation to the Wertz-type equation, which correlates the entropy of solution with the thermodynamic third-law entropy of the solute, and to the scaled particle theory. A scaled particle treatment assuming non-spheres(spherocylinders) is shown to give improved results and to be promising in reproducing the experimental values of the entropy of solution, whereas the same treatment of spheres failed to explain the trend in the experimental values.

The entropy of reaction in gas phase can be predicted in principle by a molecular statistical theory for thermodynamic functions, since it is equal to the standard entropy of the products minus that of the reactants.[1] However, it is usually not easy to estimate the entropy of a reaction in solution, because each component is solvated more or less in solution and its entropy is considerably affected by the state of solvation. In this sense, the entropy of solution, which represents the difference in entropy between the two phases of gas and solution, becomes important for the understanding of the entropy of reaction in solution.

The authors have previously reported the entropy of reaction in solution in the case of a metal complex formation of organotin compounds[2] and of an inclusion complex formation of α-cyclodextrin with alcohols,[3] where an equation proposed by Wertz[4,5] was utilized to estimate the entropy of solution. In the Wertz-type equaion, molecules are assumed to lose a definite part of their gas phase entropy when transferred from the gas phase to solution. Hence the entropy of solution is expressed as a function of the thermodynamic third-law entropy in the gas phase. In an alternative more theoretical approach, scaled particle theory can give an estimate for the entropy of solution.[6,7] This approach is reported to give reasonable results for nonpolar solutes dissolved in water but not for those dissolved in nonaqueous solvents.[8]

In the present study, the entropy of solution of alkanes in an organic solvent is measured by means of gas-liquid chromatography, and the data are discussed in terms of the scaled particle theory, taking into account the effect of the molecular shape of solute and solvent. As an organic solvent, dibutyl phthalate is chosen. The solutes used are the normal alkanes from pentane to decane.

Experimental

Dibutyl phthalate for the chromatographic stationary phase (solvent) was distilled under reduced pressure, and coated on 60/80 mesh Chromosorb W AW-DMCS (25 wt%). The alkanes from commercial sources were used without further purification. The retention data were measured on a Yanagimoto G1880 gas chromatograph with a TCD cell using a carrier of He gas. The column temperature was measured with a copper-constantan thermocouple. The temperature range studied was from 58 °C to 103 °C. The retention time was measured 5 times at each temperature and averaged. The amount of solute injected was 2 μl. A correction for the vanishing amount of sample injected was not made because it was negligibly small in a preliminary experiment.

Calculations of the above retention data and the entropy of solution described below were all done by using programs written in Basic mode and compiled on personal computers of the NEC 9800 series.

Results

Determination of the Entropy of Solution by Means of Gas-Liquid Chromatography. The partition coefficient (k) is related to the specific retention volume V_g as in Eq. 1 when k, which is defined as the ratio of the concentrations in the gas and liquid phases, is represented as atm (in gas phase)/mol fraction (in liquid).[9] In Eq. 1, M_1 means the molar

$$k=\{M_1/(273.15\mathrm{R})\}V_g \quad (1)$$

weight of solvent and R is the gas constant. The temperature dependence of k affords the enthalpy (ΔH_s^0) and entropy (ΔS_s^0) of solution (Eq. 2).

$$\ln k=-\Delta H_s^0/(RT)+\Delta S_s^0/R \quad (2)$$

The measurement of retention times of solutes (t_s) and air (t_a) on the chromatograph provides the value of the specific retention volume:[10]

$$V_g=\{(t_s-t_a)jF/W\}(273.15/T) \quad (3)$$

where j, F, and W are the correction factor for the pressure, the flow rate of carrier gas, and the weight of solvent in the column, respectively.

A typical plot of $\ln k$ vs. $1/T$ in Eq. 2 is shown in Fig. 1. The values of ΔH_s^0 and ΔS_s^0 thus determined are summaried in Table 1. Errors in these values were

† The Solvation Effect on the Reactions in Solution. III.

Table 1. Enthalpies and Entropies of Solution for Alkanes in Dibutyl Phthalate Determined from Gas-Liquid Chromatography[a)]

Solute	ΔH_s^0/kJ mol^{-1}	ΔS_s^0/JK^{-1} mol^{-1}
Pentane	−22.3±3.0	−80.6±8.6
	(−20.2±3.0)	(−36.0±8.6)
Hexane	−28.2±0.8	−90.2±2.4
	(−26.1±0.9)	(−45.6±2.5)
Heptane	−32.1±0.9	−94.0±2.5
	(−30.1±0.9)	(−49.4±2.5)
Octane	−34.8±0.9	−94.7±2.5
	(−32.7±0.9)	(−50.2±2.6)
Nonane	−38.3±0.8	−97.9±2.2
	(−36.2±0.8)	(−53.4±2.3)
Decane	−41.9±12.7	−101.8±37.0
	(−39.8±12.8)	(−57.3±37.4)

a) The values are given for the standard states of 1 atm in gas phase and 1 mole fraction in liquid phase. Also listed in parentheses are the values for the standard state of 1 mol dm^{-3} in these two phases.

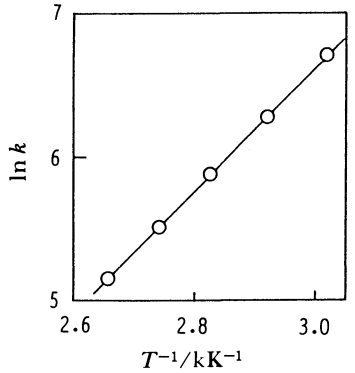

Fig. 1. The Plot of ln k measured by gas-liquid chromatography vs. $1/T$ for nonane in dibutyl phthalate.

estimated as equal to the 95% confidence range in the plot of ln k vs. $1/T$. The values thus determined corresponds to a reference state of 1 atm in the gas phase and 1 mole fraction in the liquid phase. These values are discussed below in terms of the scaled particle theory. Also the values of ΔH_s^0 and ΔS_s^0 can be defined for a reference state of 1 mol dm^{-3} for both the gas and liquid phases. In this case, the partition coefficient (K) is expressed as the ratio of the molar concentration in the gas and liquid phases, and Eq. 1 is replaced by Eq. 4,[9)]

$$K=(T\,\rho_1/273.15)\,V_g \tag{4}$$

where ρ_1 is the density of solvent. The plot of ln K vs. $1/T$ affords the ΔH_s^0 and ΔS_s^0 under a reference state of 1 mol dm^{-3} for both gas and liquid phases. The values thus determined are also listed in Table 1 in parentheses,[11)] where the density of the dibutyl phthalate (ρ_1) was approximated by an equation,

$$\rho_1=-0.000805T+1.0615 \tag{5}$$

from the data between 79.4 and 142.2 °C.[12)]

Discussion

The Wertz-type equation is derived as in Eq. 6 from the values of ΔS_s^0 given under the reference state of 1 mol dm^{-3} and from those of S_{298}^0 (g).[13)]

$$\Delta S_s^0=-0.095\,S_{298}^0\,(g)-6.0 \qquad r=0.952 \tag{6}$$
$$(0.043) \qquad (19.3)$$

In this equation r is the correlation coefficient between the observed and the recalculated values of ΔS_s^0. The standard errors are listed in parentheses. This equation resembles that given for alkylbenzenes dissolved in dimethyl or dioctyl phthalate.[2)] Although the Wertz-type equation can be predicted from the physical constants of the solvent, this was not possible in the present case because of the lack of S_{298}^0 of DBP in the gas and liquid phases. It is reported,[5)] and also observed by the present authors, that the coefficients of the Wertz-type equation vary depending on the series of compounds treated. Therefore, an alternative theoretical approach is attempted below on the basis of a scaled particle theory.

Calculation of the Entropy of Solution under a Sphere Model. According to the scaled particle theory, the entropy of solution is given as in Eq. 7 for the spherical molecules of solute as well as for the solvent, where the terms for cavity formation and for a correction for the different reference states in the gas and liquid phases are included.[5)]

$$\Delta S_s^0=S_{cav}+\alpha_p RT-R-R\ln\,(V_g/V_l) \tag{7}$$

In this equation, α_p is the thermal expansion coefficient of the solvent, and V_g/V_l is equal to RT/V_l under an ideal-gas assumption, V_l being the molar volume of solvent. S_{cav} in Eq. 7 is calculated as in Eq. 8 according to the definition of $S=-(\partial G/\partial T)_P$ and to the equation for G given in Refs. 6 and 7:

$$\begin{aligned}S_{cav}=R[&\{\ln(1-y)-3y/(1-y)\cdot(\sigma_2/\sigma_1)\\&-(3y/2)(2+y)/(1-y)^2\cdot(\sigma_2/\sigma_1)^2\}\\&+\alpha_p yT/(1-y)^3\cdot\{(1-y)^2+3(1-y)(\sigma_2/\sigma_1)\\&+3(1+2y)(\sigma_2/\sigma_1)^2\}]\end{aligned} \tag{8}$$

where σ_1 and σ_2 are the diameter of solvent and solute, respectively, and where y is called a "reduced number density"[7)] or a "compactness factor"[14)] of the solvent which is equal to $\pi\rho_1\sigma_1^3/6$, ρ_1 being the number density of solvent (N_A/V_l). The value of σ_2 is usually estimated by the Stearn-Eyring equation:[8)] $(\sigma_2)^3=V/N_A$ where V is the molar volume and N_A the Avogadro number. The best method of obtaining σ_1 is to utilize the Henry's law constants of rare gases in the relevant solvent. However, these constants are lacking, within the knowledge of the authors, and so σ_1 is also taken from the Stearn-Eyring equation. The values of ΔS_s^0 thus estimated lie between −55.1 J (K·mol)$^{-1}$ for pentane and −56.5 J (K·mol)$^{-1}$ for decane (Table 2): they only amount to around 60% of the experimental values, and the dependency on the carbon number of

the solute is small compared to the experimental results. These estimated values are not improved even if σ_1 is varied near the initial values of 7.74 Å (Fig. 2). Therefore, it is clear that the sphere model fails to explain the experimental values measured in dibutyl phthalate. Similar results are reported[8] for other non-aqueous solvents. In the present study an alternative model which assumes spherocylinderical shapes for the solute and solvent molecules is attempted below.

Calculation of the Entropy of Solution under a Spherocylinder Model. For nonspherical molecules of solute and solvent, a scaled particle treatment has been developed for the spherocylinders in isotropic as well as anisotropic solutions.[15] In this case S_{cav} turns out to be a function of a, l, α, λ, V_1, α_p, and T as in Eq. 9,

$$\begin{aligned} S_{cav} = R[&\ln X + (\alpha_p T/X)(1-X) \\ &+ (\alpha_p T/X - 1)\{\pi a(l+2a)\rho_1/X\}(2\alpha + \lambda/2) \\ &+ (\alpha_p T/X - 1)\{\pi(l+4a)\rho_1/X\}(\alpha\lambda/2 + \alpha^2) \\ &+ (2\alpha_p T/X - 1)\{\pi a(l+2a)\rho_1/X\}^2(\alpha\lambda + 2\alpha^2)] \end{aligned} \quad (9)$$

Table 2. The Entropy of Solution Calculated for the Sphere Model[a]

Solute	$\Delta S^0_{s,\,exptl}$[b]	σ_2[c]	$\Delta S^0_{s,\,calcd}$
Pentane	−80.6	5.78	−55.1

Decane	−101.8	7.08	−56.5

a) Given in a unit of J (K·mol)$^{-1}$. The molar volume and the thermal expansion coefficient are 279.19 ml mol^{-1} and 0.840/1000 K, respectively, for the solvent. b) Experimental values. c) The diameter of the solute in Å.

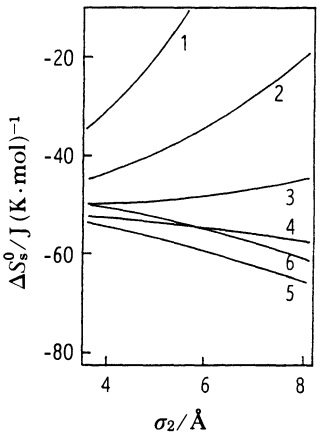

Fig. 2. The dependence of the calculated ΔS^0_s on the values of σ_1 and σ_2. Calculated under the sphere model by the use of Eq. 7. The values of σ_1 are 8.34, 8.14, 7.94, 7.74, 7.34, and 5.74 Å for curves 1 to 6, respectively. Note that the curve shifts upward in the figure on decreasing the values of σ_1 from 7.34 Å, whereas the experimental values ranges from −80 to −101 J (K·mol)$^{-1}$. The value of σ_1 estimated from the Stearn-Eyring equation is 7.74 Å.

where $X = 1 - \pi a^2 l\rho_1 - 4\pi a^2\rho_1/3$, and where α and λ are the radius and length of the solute molecule, respectively, and a and l those of the solvent, respectively (Fig. 3). Equation 9 is derived from Eq. 51 in Ref. 14, assuming that $\ln P_0$ in this reference is equal to $-G_{cav}/RT$ and $S_{cav} = -(\partial G_{cav}/\partial T)_P$. This model is equivalent to the above sphere model when l and λ are both taken as zero.

For the sake of model calculations, the size of the solute and solvent is estimated from the dimension of a single molecule. For solute molecules, a zigzag conformation is assumed and α is taken as the distance from the longer axis of symmetry to the CH_2 protons plus the van der Waals radius of hydrogen, λ being taken as a distance between the two end carbons (Fig. 4). The size of the solvent is not derived straightforwardly, a is set equal to 2.63 Å, a radius of the sphere for benzene derived from the Stearn-Eyring equation, and l is set equal to 7.77 Å to make the reduced number density equivalent to the sphere of radius 3.87 Å derived from the Stearn-Eyring equation for DBP. These values of a and l give the calculated values of ΔS^0_s/J (K·mol)$^{-1}$ amounting from −55.0 for pentane to −59.1 for decane. When the values of a and l are estimated from a molecular model, where the two butyl ester groups extend to the same direction in the same manner, a=2.70 Å and l=4.53 Å are obtained. These values give much improved results as is shown by "spherocylinders" in Fig. 5, i.e., ΔS^0_s/J (K·mol)$^{-1}$= −66.5 for heptane and −76.4 for decane. For these values of a and l, the reduced number density is equal to 0.41 and is well within a reasonable range. Therefore, a proper estimation of the size of the solvent

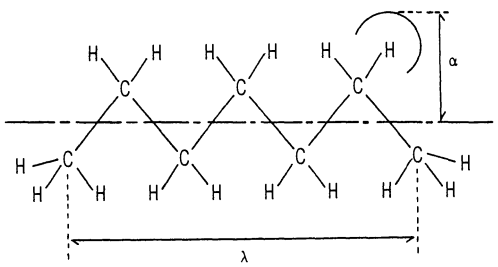

Fig. 4. The size of solute, α and λ, depicted typically for heptane. α is equal to 2.58 Å when the van der Waals radius of 1.2 Å is added. -·-·-: The longer axis of rotation.

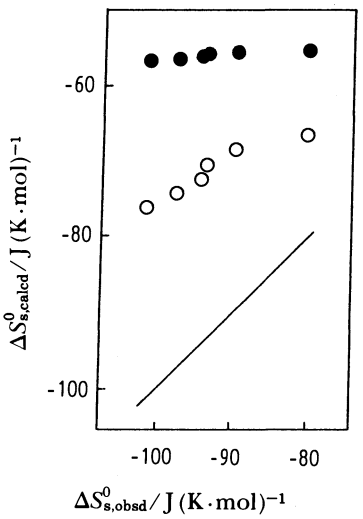

Fig. 5. The plot of ΔS^0_s calculated under the sphere and the spherocylinder models vs. $\Delta S^0_{s,obsd}$. ●: Calculated by means of the sphere model. ○: Calculated by means of the spherocylinder model. ——: The ideal interrelation of $\Delta S^0_{s,calcd}=\Delta S^0_{s,obsd}$.

molecule is expected to give much improved calculations of the entropy of solution. However, more elaborate calculations are not attempted here, because the solvent used in the present study is rather complicated in structure including polar groups. More elaborate calculations are now underway for a few solvents better approximated by simple rotamers such as disks, cylinders, and spherocylinders.

It has been reported,[8] and also confirmed by the authors that the entropy of solution of alkanes in water is well reproduced by calculations based on a sphere model. Contrary to this, the entropy of solution in an organic solvent treated here is better reproduced by a non-sphere model which assumes spherocylinders. Such a contrast may be interpreted as due to the difference in the shape of the solvent and also to the shape of the solute in each solvent. That is, the alkanes are considered to take on a rather spherical form in water as a result of the intramolecular hydrophobic interaction within a single molecule whereas they are considered to acquire a stretched form in organic solvents depending on the solute-solvent interactions in solution.

Stress Relaxation of Alginate Gels Crosslinked by Various Divalent Metal Ions

Masakatsu YONESE,* Kazuhiko BABA, and Hiroshi KISHIMOTO
Faculty of Pharmaceutical Sciences, Nagoya City University, Tanabe-dori, Mizuho-ku, Nagoya 467
(Received November 19, 1987)

Rheological properties of Alginate (Alg) gels were studied by measuring tensile stresses under small strains. The Alg gel rods were prepared in $CaCl_2$, $SrCl_2$, $BaCl_2$, and $Pb(NO_3)_2$ solutions in the range of 0.03—1.0 mol dm^{-3}. Their stresses showed long relaxation processes. By curve fitting method, equilibrium elastic moduli G_e, spontaneous elastic moduli G_e+G_r and relaxation times τ were obtained. The results G_e were independent of strains γ, and G_r and τ increased as increasing γ. The effects of Ca ion concentrations C_{Ca} on the elasticities were discussed by taking account of the ratio of Ca ion bindings obtained by dialysis equilibrium and that of junction formation obtained by circular dichroism. The values of G_e were analyzed by the theory of swollen gels. The number of the junctions was found to be constant in the region of $C_{Ca}>0.03$ mol dm^{-3}, and slight increases of G_e to be due to changes of the water content and the density of the Alg gels. The magnitudes of G_e and G_r depended on the kind of counterions, and decreased in the order, Ba-$\gg$Ca-$>$Sr-$>$PbAlg; this was almost the same as that of the ion selectivities.

Alginate (Alg) is a major structural polysaccharide found in intercelluar substances of brown algae. They are gelled by the addition of divalent metal ions except for Mg^{2+} ions. The gelations result from the stackings of alginate chains intermediated by the ions.[1] The interaction of Alg with them and the rheological properties of the gels such as rigidity and elasticity are dominated by the composition of the Alg, i.e., the ratio of β-D-mannulonate and α-L-guluronate, their block compositions and the kind of metal ions added.[2-4]

Alginate and its gels are used widely as food additives and pharmaceutically as hemostats. The gels are examined with respect to their application to matrices of drug delivery systems[5] and to the matrices of immobilized enzymes.[6] These applications of Alg gels take advantage of the characteristics of the lyotropic gels. However, from the basic point of view, the gel properties have not been elucidated sufficiently. In the previous paper,[7] effective charge densities of Alg were studied by a membrane potential method and the effects of sol-gel transition on them were reported. In this report, tensile stress relaxations of Alg gels were studied to elucidate their rheological characteristics, and the effects of the kind of metal ions present.

Experimental

Materials. Purified sodium alginate (NaAlg) was prepared from commercial NaAlg (Tokyo Kasei Kogyo Co., Ltd.) by dialyzing against distilled water for 3 d and by filtrating to remove insoluble substances, as described in the previous paper.[7] The purified NaAlg was stored in a refrigerator after freeze drying. The weight average molar mass of NaAlg was determined to be $\bar{M}_w=1.32\cdot10^5$ g mol^{-1} by using a light scattering photometer LS-8 (Toyo Soda Manufacturing Co., Ltd., Japan). The composition of the NaAlg was analyzed by circular dichroism (CD),[8] and ^{1}H NMR.[9] The guluronate fraction F_G and the consecutive guluronate fraction F_{GG} were determined to be 0.37 and 0.28. All other reagents were of special grade. Distilled and deionized water was used for preparation of aqueous solutions.

Dialysis Equilibrium. NaAlg solutions (0.75 w/v%) were put into dialysis tubes (Seamless Cellulose Tubing, Union Carbide Corp.), which were dipped in $CaCl_2$ and $MgCl_2$ solutions in the range of 0.001—0.1 mol dm^{-3} in dialysis cells. They were shaken in a thermostated bath (25 °C) for 48 h which was long enough to attain equilibrium. The concentrations of Ca, Mg, and Cl ions in the outer solutions were determined by chelate titrations and Mohr method, respectively. From these results, amounts of Ca and Mg ions bound to Alg were determined.

Preparation of Alginate Gel Rods for Measuring Stress Relaxations. NaAlg solutions (1.2 w/v%) in straight Teflon tubes (length: 6.0 cm, diameter: 0.4 cm) were gelled by dipping in $CaCl_2$, $SrCl_2$, $BaCl_2$, $Pb(NO_3)_2$, and HCl solutions in the concentration range of 0.03—1.0 mol dm^{-3}. The gels obtained are denoted as Ca-, Sr-, Ba-, Pb-, and HAlg, respectively. To attain an equilibrium swelling state, the gels had to be matured for 7 d in these solutions, renewed once daily. The Alg gel rods were then dipped for not less than 9 d in these solutions which were kept at 4 °C to prevent rotting. Before the measurements of their tensile stress, the Alg gel rods were reequilibrated for 48 h at the experimental temperature (25 °C).

Preparation of Alginate Gel Membranes for Measuring Circular Dichroism. To obtain Alg gel membranes with flat surfaces, a freezing method was developed. NaAlg solutions (1.2 w/v%) were put into Petri dishes with flat bases and were frozen for 20—30 min in a freezing chamber (−3—−5 °C). The frozen samples thus obtained had smooth surfaces. Then, $CaCl_2$ solutions in the concentration range of 0.001—1.0 mol dm^{-3} cooled to about 4—6 °C were poured gently and slowly down the wall of the petri dishes. To obtain equilibrated Alg gel membranes, the $CaCl_2$ solutions were renewed once daily and held at 25 °C for 7 d. By adding HCl solutions instead of $CaCl_2$ solutions, Alg gel (HAlg) membranes were also prepared.

Measurement of Tensile Stress of Alg Gel Rod. The schematic diagram of the apparatus for measuring the tensile stresses of the gels is shown in Fig. 1. The Alg gel rod G was fixed by clamps A and B made of plastic plates with rough surfaces to prevent them slipping. They were suspended in electrolyte solutions in which the gel was equilibrated. The strains were imposed on the gels in steps and the

tensile stresses σ were measured at 25 °C by strain gages SG (Shinkoh Communication Industry Co., Ltd.) connected to a constant direct current source CC (Model 691B, Metronix Corp. Tokyo) and a microvolt meter MV (Model AM-1001, Ohkura Electric Co.). The apparatus was set up in an air thermostated bath TB to eliminate temperature effects on the strain gages.

Measurement of Circular Dichroism. Measurements of circular dichroism CD were made on a CD spectropolarimeter (J-40S, NIHON BUNKOU) at 25 °C by using a 1 cm pathlength cell for NaAlg solutions. The CD of the Alg gel membranes were measured by putting them between perforated support film (PARAFILM, AMERICAN CAN COMPANY) and the thermostated 1 cm cell to prevent evaporation of water from the gels as much as possible and to maintain a constant temperature (25 °C).

Measurements of Densities and Water Contents of Alg Gels. The densities of the Alg gels were determined by a floating method, i.e., from the densities of mixed solvents composed of isooctane and carbon tetrachloride in which pieces of Alg gels were floated. The densities of the solvents were measured by densitometer (Anton Paar DMA602). The water content of the Alg gels were measured by the weight change after drying at 70 °C in vacuo for 10 h.

Theory and Method

Determinations of Elastic Modulus. An Alg gel rod elongated under a constant strain γ showes stress relaxation, which is expressed by the following equation as a function of time t,

$$\sigma=(G_e+G_r\exp(-t/\tau))\,\gamma \qquad (1)$$

where G_e and (G_e+G_r) are the equilibrium elastic modulus and the spontaneous elastic modulus respectively and τ is the relaxation time. The time courses of the stress of an Alg gel rod elongated under constant strains γ by steps are shown in Fig. 2 as one example. After a first stress of Alg gel σ_1 resulting from the first strain γ_1 attains an equilibrium value, a second strain γ_2 is imposed at time t_2, and the same process is continued consecutively. Imposing the nth strain, the stress σ_n can be expressed by the following equation according to the superimposal principle,

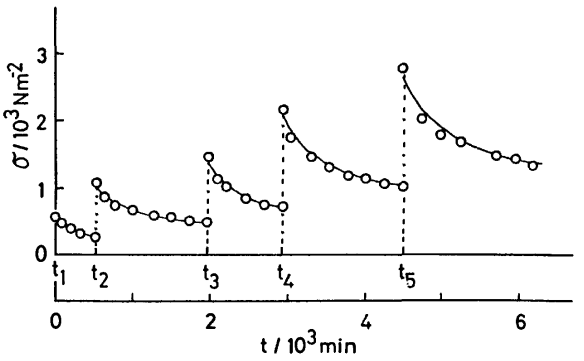

Fig. 2. Stress relaxation curve for CaAlg gel. Solid curves show the values calculated from Eq. 2 by curve fitting method. CaAlg was prepared in 0.3 mol dm^{-3} $CaCl_2$ solution. The value t_k shows time when kth strain is imposed.

$$\sigma_n=\sum_{k=1}^{n}\left\{G_{ek}+G_{rk}\exp\left(-\frac{t-t_k}{\tau_k}\right)\right\}(\gamma_k-\gamma_{k-1}) \qquad (2)$$

where a subscript k denote the values of the gel rod elongated by the kth strain γ_k. The t_1 and γ_0 values are 0. The kth strain γ_k is defined by

$$\gamma_k=(l_k-l_0)/l_0 \qquad (3)$$

where l_0 is the initial length of Alg gel rod and l_k is that of the elongated gel by kth strain.

Determination of Counterion Binding Parameters. Under equilibrium conditions, Donnan equilibrium is maintained between the free ions in an alginate phase in a dialysis tube (α phase) and ions in a bulk solution (β phase).[10] Two kinds of counterions occur in both phases, i.e., one was Na ions resulting from original sample NaAlg and the other was metal ions M from added electrolytes. In this report, bounding characteristics of the latter counterions M are discussed. Approximating the activity coefficients of the free counterions and co-ions are unity, the concentration of the free counterion in α phase $C^f_{M\alpha}$ is obtained by the following equation,

$$C^f_{M\alpha}=C_{M\beta}\,(C_{A\beta}/C_{A\alpha})^{z_M} \qquad (4)$$

where $C_{M\beta}$ is the concentration of the added counterion M in the β phase, $C_{A\alpha}$ and $C_{A\beta}$ are those of the co-ion (Cl^-) in the α and β phases, and z_M is the algebraic charge number of the counterion M. Bounding amounts of the counterions per unit weight of Alg b_M are obtained by

$$b_M=V_\alpha(C^T_{M\alpha}-C^f_{M\alpha})/w \qquad (5)$$

where $C^T_{M\alpha}$ is the total concentration of the counterion in the α phase, and w and V_α are the weight of Alg in the α phase and the volume of the α phase. When the bindings are Langmuir type isotherms, the relation between $1/b_M$ and $1/C^f_{M\alpha}$ is linear as expressed by the following equation

$$1/b_M=1/b^s_M+1/(b^s_M K C^f_{M\alpha}) \qquad (6)$$

and b^s_M and K are the saturated binding amounts and the binding constant.

Results

Counterion Binding Characteristics of Alginate. Binding amounts b_M mol g^{-1} of Ca and Mg ions to Alg at 25 °C were obtained from dialysis equilibria by using Eq. 5 and are shown in Fig. 3 as a function of the free counterion concentrations $C^f_{M\alpha}$. They showed Langmuir type isotherms and linear relations between $1/b_M$ and $1/C^f_{M\alpha}$ held. By Eq. 6, b^s_M/mmol g^{-1} and K/mol dm^{-3} were obtained; for Ca ion, b^s_M=2.25 and K=3.60, and for Mg ion, b^s_M=2.27 and K=0.584, respectively. The binding amounts of the Ca ions were saturated in the region of $C^f_{Ca\alpha}$>0.008 mol dm^{-3}. Since the values $C^f_{Ca\alpha}/C_{Ca\beta}$ were almost 1.0 in the region $C^f_{Ca\alpha}$>0.008 mol dm^{-3}, the saturated binding of Ca ions was attained in the region of the concentration of the bulk solutions $C_{Ca\beta}$>0.008 mol dm^{-3}. Hereinafter, the counterion concentrations in the β phase $C_{M\beta}$ are designated by C_M, as well as the concentrations of the bulk solutions used for the preparation of the Alg gels.

CD Spectrum of Alg Gels Different in Ca Ion Concentrations. The characteristic changes in CD accompanied by the gelation of Alg have been reported in the literature and the magnitudes of the changes have been attributed to the formation of junctions between the guluronate blocks (G block) induced by divalent metal ions such as Ca ion.[11,12] To investigate the effects of Ca ion concentrations on the junction formation by the CD method, attempts were made to prepare CaAlg gel membranes in various Ca ion concentrations (C_{Ca}=0.001—1.0 mol dm^{-3}). In the region of C_{Ca}<0.007 mol dm^{-3}, the gel membranes could not be formed or were too weak to set between the cell and the perforated support film for measuring CD spectrum. The CD spectra of CaAlg gel membranes prepared in the region C_{Ca}>0.007 mol dm^{-3} were measured at 25 °C. Figure 4 shows the ellipticities [θ] of NaAlg (0.6 w/v%) and those of a CaAlg (C_{Ca}=1.0 mol dm^{-3}) and a HAlg (C_H=1.0 mol dm^{-3}) gels. The CD spectrum of NaAlg showed a negative peak at 215 nm, but that of CaAlg gel showed the negative peak at about 219 nm and a positive one at 203 nm. The spectrum of HAlg gel was a negative broad peak and was found to be different from that of CaAlg.

On increasing the binding ratio of Ca ions to the carboxylic groups of Alg, the junctions, i.e., dimers between the G blocks and its aggregations, were reported to increase and the magnitudes of the peaks at 203 nm [θ]$_{203}$ to increase.[12] Morris et al. took the difference values between the values [θ] of NaAlg and Ca-NaAlg as a measures of the formation of the junctions. The relative values of the magnitudes of the peaks at 203 nm and at about 219 nm [θ]$_{203}$/[θ]$_{219}$ can also be taken as this measure. Since the Alg gel mem-

branes prepared in various Ca concentrations were different in water content and thickness, the relative values are more appropriate values. The values $[\theta]_{203}/[\theta]_{219}$ of CaAlg gel membranes prepared in the region of $0.007<C_{Ca}/\text{mol dm}^{-3}<1.0$ are shown in Fig. 5 as a function of C_{Ca}. They were found to be almost constant above the concentration at which the binding amounts of Ca ions were saturated. Under unsaturated conditions of Ca ion binding, the ratios of the junctions were reported to depend on the binding ratios of the Ca ions.[12] If CD of CaAlg gels prepared in the conditions of the unsaturated Ca ion bindings could be measured, the values $[\theta]_{203}/[\theta]_{219}$ should decrease with decreasing C_{Ca}.

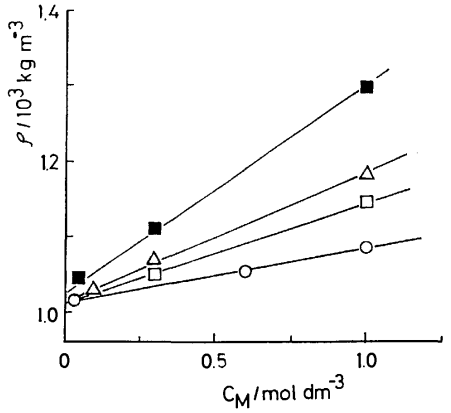

Fig. 7. Effects of counterion concentrations C_M on densities of Alginate gels ρ. Ca; ○, Sr; □, Ba; △, Pb; ■

Water Contents and Densities of Alg Gels. The water contents W_{H_2O} and densities ρ g cm^{-3} of various Alg gels prepared from NaAlg solutions (1.2 w/v%) are shown in Figs. 6 and 7 as a function of the concentration C_M of the solutions. W_{H_2O} decreased and ρ increased linearly with increasing C_M in the experimental range of $C_M<1.0$ mol dm^{-3}, and they depended on the kind of counterions. The order of magnitude of the former was H->Mg->Ca->Sr->Ba->PbAlg, and that of the latter was Pb->Ba->Sr->CaAlg. The smaller the water contents, the bigger became the densities.

Effects of Strains and Ca Ion Concentrations on Stress Relaxation of Alg Gel Rod. The time courses of stress of CaAlg gel rods were measured by imposing strains by steps. Figure 2 shows the results for CaAlg gel prepared in a $CaCl_2$ solution (0.3 mol dm^{-3}). The stress under each strain showed a long relaxation and attained an equilibrium state after above 20 h. From the time courses of the stress under strains, the elastic moduli G_{ek}, G_{rk} and the relaxation time τ_k can be obtained from Eq. 2 by using a curve fitting method. These values obtained by analyzing the time courses of stress measured for more than 20 h were independent of the measuring times. Accordingly we accepted these values as the true ones. The solid curves in Fig. 2 show the results calculated from Eq. 2 by using these elastic parameters. They are in good agreements with the experimental results. The values G_{ek}, G_{rk}, and τ_k obtained under the kth strain γ_k are

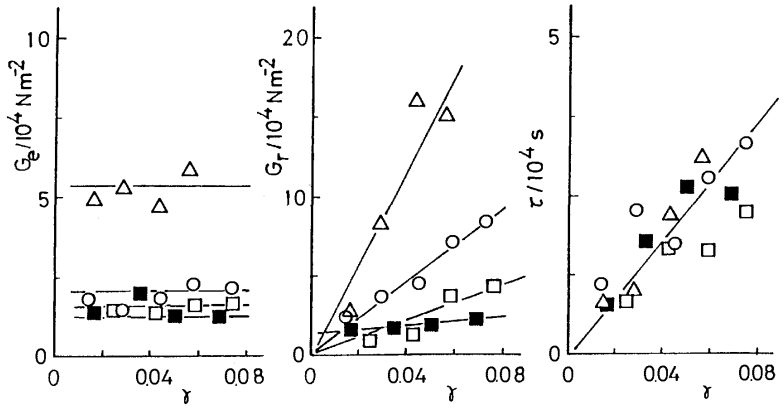

Fig. 8. Effects of strains on elastic moduli G_e, G_r, and relaxation time τ for Alg gels prepared by various divalent counterions. Ca; ○, Sr; □, Ba; △, Pb; ■. Alg gels were prepared in 0.3 mol dm^{-3} solutions.

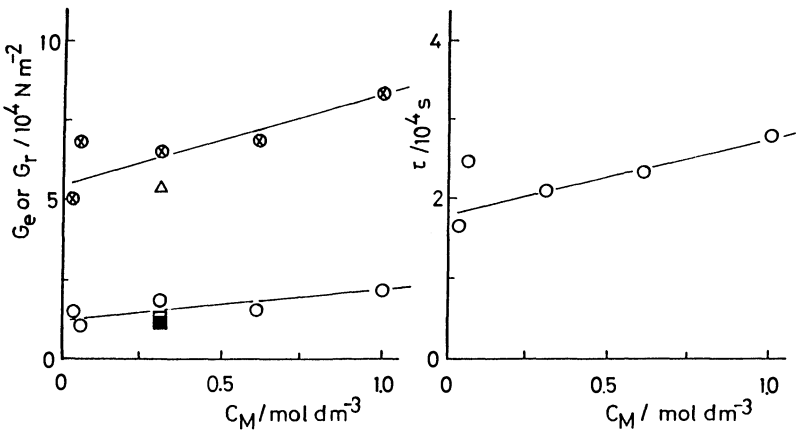

Fig. 9. Effects of counterion concentrations C_M on elastic moduli G_e, G_r, and relaxation time τ at constant strain (γ=0.05). CaAlg: G_e and τ; ○, G_r; ⊗. For Sr-, Ba-, and PbAlg, values G_e (C_M=0.3 mol dm^{-3}) are shown. Sr; □, Ba; △, Pb; ■.

hereinafter designated by G_e, G_r, and τ, i.e., the subscript k is deleted for simplicity. Figure 8 shows the results G_e, G_r, and τ of CaAlg prepared in 0.3 mol dm^{-3} $CaCl_2$ solutions, as a function of strain γ. The values G_e were almost constant in the small strains, but the values G_r and τ increased with increasing γ. The same tendencies were found in the results of CaAlg gels prepared from other $CaCl_2$ solutions at different in concentrations. The diameters and the lengths of the Alg gel rods were measured before and after the stress measurements, and the volume changes were found to be negligible in the experimental region of γ<0.08. Figure 9 shows the values G_e, G_r, and τ of CaAlg gels obtained at γ=0.05 as a function of the concentrations of $CaCl_2$ solutions in which CaAlg gels were prepared. These values were found to increase slightly as increasing C_{Ca} (>0.03 mol dm^{-3}). The increasing rates of G_r and τ were more than those of G_e.

Effects of the Kind of Counterions Used as Crosslinking Agents. The time courses of stress of various Alg gel rods prepared in $BaCl_2$, $SrCl_2$, and $Pb(NO_3)_2$ solutions (C_M=0.3 mol dm^{-3}) were measured. The values G_e, G_r and τ were obtained in the same manner as in the case of CaAlg gels and are shown in Figs. 8 and 9 together with the results for CaAlg. The results G_e of Ba-, Sr-, and PbAlg were independent of γ as well as CaAlg, and their values G_r and τ increased with increasing γ. The values G_e and G_r were found to depend significantly on the kind of counterions, and decreased in the order, Ba-≫Ca->Sr->PbAlg. However, their values for τ did not show significant differences. By adding H ions, Alg was gelled but the gels were too brittle to measure the stress.

Discussion

Estimation of Junction Densities. The stress relaxations of Alg gels are considered to be composed of two components, i.e., (1) a time independent component which is the stress resulting from the permanent junctions, and (2) the time dependent component which is associated with the reorientation of the network from unstable to stable and the rupture of weak junctions. The time independent component in small strains has been reported to be analyzed by the theory of rubber elasticity although the deviations from the ideal rubber elasticity were found at high strains.[13] It is used to give reasonable numbers of junctions per a molecule.[14,15]

Flory developed the theory for the stress of swollen gels by assuming an ideal rubber and a constant volume. The stress σ_e is expressed by the following equation,[16]

$$\sigma_e = RT\, v_p^{-2/3} w_p \left(\frac{1}{\bar{v}_g M_c}\right)\left(1-\frac{2M_c}{\bar{M}}\right)\left(\alpha-\frac{1}{\alpha^2}\right) \qquad (7)$$

where $\bar{M}$ and M_c are number averaged molar mass of polymer and that of the polymer chain interposed by adjacent crosslinks, α is the deformation of the network structure by an elongation ($\alpha=l/l_0=1+\gamma$), v_p and w_p are the volume fraction and the weight fraction of the network polymer in a gel, and $\bar{v}_g$ is a specific volume of the gel. Alg gels showed negligible volume changes due to elongations. The values M_c of Alg gels can be obtained by Eq. 7 from the results σ_e under small strains. The values v_p of Alg gels were obtained by the following equation

$$v_p = 1 - v_w(1-w_p)/\bar{v}_g \qquad (8)$$

where v_w is specific volume of water.

Figure 10 shows the values M_c and the numbers of the junction per alginate molecule $\bar{M}/M_c$ of CaAlg gels as a function of the concentration of Ca ions. They were obtained from the results σ_e of CaAlg gels elongated at γ=0.03 and 0.05, and were found to be independent of the strains (γ<0.05) and the concentrations of Ca ion in the experimental region (0.03<C_{Ca}/

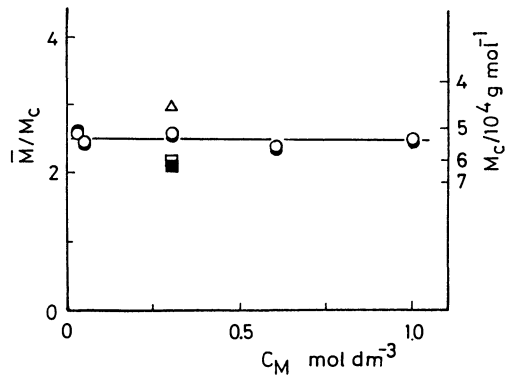

Fig. 10. Effects of counterion concentrations C_M on molar mass per cross-linked unite M_c and number of cross-linked unites per a molecule $\bar{M}/M_c$ under different strains γ=0.03 and 0.05. CaAlg: ●; γ=0.03, ○; γ=0.05. For Sr-, Ba-, and PbAlg, results under γ=0.05 and C_M=0.03 mol dm^{-3} are shown. Sr; □, Ba; △, Pb; ■.

mol dm^{-3}<1.0). In these calculations, the number averaged molar mass of Alg $\bar{M}$ was approximated to be equal to the weight average molar mass obtained by the light scattering method. The mean values M_c and $\bar{M}/M_c$ were $5.2\cdot10^4$ g mol^{-1} and 2.5. From these results, it can be concluded that during stress relaxation, Alg chains deform from unstable elongated network structures to stable ones without altering the numbers of the junctions in small strains. The slight increase of G_e shown in Fig. 9 is not attributable to the change of the numbers of the junction but to that of the water content and the density of the Alg gels shown in Figs. 6 and 7. Figure 11 shows the calculated values σ_e of CaAlg (C_{Ca}=0.3 mol dm^{-3}) from Eq. 7 as a function of α. They are in good agreement with the results in the small α region.

In the concentration region of C_{Ca} ($=C^f_{Ca\alpha}$)>0.008 mol dm^{-3}, the binding of Ca ions to Alg and the junction formation were saturated as shown in Figs. 3 and 5. However, in the region of C_{Ca}<0.03 mol dm^{-3}, the CaAlg gels were so weak that the elasticities could not be measured. From these results, free Ca ions in the region of 0.008<C_{Ca}/mol dm^{-3}<0.03 are considered to strengthen the junctions of the Alg gels, i.e., weaker junctions, such as dimers, aggregate further and grow into strong junctions. The contributions of the former to the elasticities of the gels should be much smaller than those of the latter. The aggregation of the dimers might result from the decrease of electrostatic repulsive force between Alg molecules due to the increase of shielding effects and the decrease of osmotic pressure with the increase of the free Ca ions. These effects also affect the water content W_{H_2O} and the density ρ of CaAlg gels. In the region of C_{Ca}>0.03 mol dm^{-3}, although the number of junctions formed by the aggregation is held constant, the values G_e, G_r, and τ are considered to increase with increasing C_{Ca} due to the effects of the changes of W_{H_2O} and ρ.

Segeren et al.[13] reported the value M_c of CaAlg gel to be $1.22\cdot10^4$ g mol^{-1} which is about 1/4 of our result. Comparing their Alg sample with ours, the molecular weight of theirs is almost equal to ouurs, but the fraction of guluronate in their sample is 0.714 which is more than twice as much as ours. The values M_c were found to depend significantly on the fraction of guluronate.

Effects of Counterion Species on the Stresses of Alg Gels. Figure 10 shows also the values M_c and M/M_c of Ba-, Sr- and PbAlg gels prepared in 0.3 mol dm^{-3} solutions. The results of M_c/g mol^{-1} and $\bar{M}/M_c$ were $4.5\cdot10^4$ and 2.9 for BaAlg, $6.0\cdot10^4$ and 2.2 for SrAlg, and $6.0\cdot10^4$ and 2.2 for PbAlg. The values $\bar{M}/M_c$ of Alg gels were found to vary slightly with the counterion species in the range of 2.2—2.9. As shown in Fig. 8, it is interesting that G_e and G_r of Alg gels are dependent on the kinds of counterions but their τ values are almost the same. The differences in these elastic properties of Alg gels formed by various divalent counterions can be explained by the following two reasons: (1) The junctions intermediated by these counterions differ in their strength, i.e., the contributions to the elastic moduli depend on the kind of divalent counterions. (2) All the guluronate blocks (G-blocks) can not be used for the formations of the crosslinks, and the ratios of the G-blocks used for the junctions differ by the kind of divalent counterions.

O. Smidrod et al. showed that on increasing the fraction of guluronate in Alg the selectivities for divalent ions became clear and decreased in the order, Ba^{2+}> Sr^{2+}>Ca^{2+}≫Mg^{2+}.[4] The magnitudes of G_e of Alg gels decreased in the order, Ba-≫Ca->Sr->PbAlg as shown in Fig. 8. BaAlg showed the maximum values in both properties. Although the orders of Ca and Sr are different between the elasticity and the selectivity, the difference in elasticities of Ca- and SrAlg was slight. MgAlg did not gell and the elasticity should be 0. Then, it can be summarized that the bigger are the selectivities, the bigger are the elasticities.

Guluronic units in the G-blocks take 1C conforma-

tions and form cavities with very hydrophilic inner surface in which the closest distance between the carboxylate groups is 4.7—5.7 A.[17] The junctions of Alg gels are formed by the stackings between the G-blocks intermediated by divalent counterions, which are efficiently coordinated by both carboxylate groups on the inner surface and oxygen atoms of saccharide rings. Taking the hydrophilicity of the cavities in considerations, the stackings between the G-blocks can be intermediated by hydrated counterions. The radii of hydrated ions r_i have been studied by various methods. We discuss qualitatively the relation between G_e of Alg gels and r_i of hydrated ions used for the gelation. The values r_i obtained by Stokes are r_{Mg}=4.4, r_{Ca}=4.2,r_{Sr}=4.2, r_{Ba}=4.1, and r_{Pb}=3.9 Å, respectively.[18] BaAlg possessed the maximum G_e. The size of hydrated Ba ions is considered to be the most suitable for intermediating the stackings of the G blocks and for forming stable junctions. As r_i of counterions are apart from r_{Ba}, weaker junctions are formed. Since r_{Mg} is too large to form stable junctions, Alg can not be gelled by Mg ions.

NMR Study of Dynamics of Carboxyl Proton in Crystals of Acetylenedicarboxylic Acid and *p*-Nitrobenzoic Acid

Nobuyoshi IMAOKA,† Sadamu TAKEDA,* and Hideaki CHIHARA
Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560
(Received November 30, 1987)

Two kinds of motions of proton in dimeric carboxyl group were distinguished by the temperature dependence of spin-lattice relaxation times of dipolar system (T_{1d}) and of Zeeman system (T_{1z}) on acethylenedicarboxylic acid (ADCA) and on *p*-nitrobenzoic acid (PNBA) in the *A2/a* form. High temperature motion of ADCA is 180° rotation of the eight-membered ring of dimeric carboxyl group about the axis nearly parallel to the hydrogen bonds. The activation energy of this motion of ADCA is 58 kJ mol^{-1}. The low temperature motion of ADCA and PNBA is the proton translation along the hydrogen bonds in a dimeric carboxyl group, which induces the minima of T_{1z} and T_{1d} at the same temperature. The activation energy derived from the high temperature slope of T_{1z} curve is 6.9 kJ mol^{-1} for ADCA and 2.5 kJ mol^{-1} for PNBA. The low temperature slope gives a small activation energy of 1.9 kJ mol^{-1} for ADCA and 1.0 kJ mol^{-1} for PNBA. The frequency dependence of T_{1z} in the low temperature limit was constant at low Larmor frequency. This result indicates that the translational motion of protons along the hydrogen bonds is not classical but quantum-mechanical.

Coupled motion of atoms, radicals, or molecules in solids is one of very interesting problems of molecular dynamics. We have been interested in the rotational tunneling of methyl groups in solids for some time.[1] In many cases, there are evidences of coupling of such motion between neighboring methyl groups. The strength of this coupling is considered to be determined primarily by the spacial proximity of neighboring methyl groups.

In the case of the eight-membered ring of carboxyl group dimer, two tautometric forms may exist by alternating the chemical bonds (single and double bonds) and the hydrogen bonds as shown in Fig. 1. Two hydrogen atoms in such an eight-membered ring must move in a concerted way along the hydrogen bonds during the alternation, i.e. the motion of the hydrogens must be a coupled transfer. The configurations, I and II, have the same energy in the isolated state (i.e. in gas phase) but in general have different energies in the solid state due to interaction with other molecules. Thus, the configurations can not be distinguished in the gas phase,[2] whereas different populations between I and II are seen in the solid state.[3]

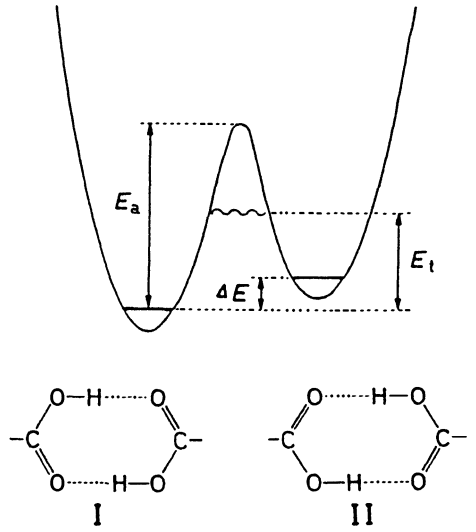

Fig. 1. Schematic view of double minimum potential of proton translation in a dimeric carboxyl groups and two corresponding configurations.

In recent years, the dynamics of protons in the carboxyl group dimers in solids has been investigated by nuclear magnetic resonance[4-6] and neutron scattering methods.[7-9] Meier et al.[4] and Nagaoka et al.[6] found a broad, shallow minimum in the temperature dependence of the proton spin-lattice relaxation time of the Zeeman system T_{1z} for several carboxylic acid dimers. This spin-lattice relaxation behavior can not be interpreted in terms of a classical, simultaneous hopping motion of the two protons between the unequal potential wells which correspond to the states I and II. For example, the activation energy derived from the low temperature side of the T_{1z} minimum is smaller than that from the high temperature side, contrary to the prediction that classical hopping motion of protons must result in a steeper slope of T_{1z} on the low temperature side of the minimum than on the high temperature side. Meier et al. and Nagaoka et al. assigned this T_{1z} minimum to the concerted translational motion of the protons along the hydrogen bonds in the eight-membered ring and also suggested that the quantum-mechanical tunneling effect played an important role in this motion. The temperature dependence of the correlation time of the translational motion of protons was explained by Meyer and Ernst[10] by the pocket state model of the tunneling motion. A preliminary model of the spin-lattice relaxation due to this tunneling mode was proposed by Nagaoka et al.[6] but the detailed nature of the spin relaxation due to tunneling is not known. We are much interested in the tunneling dynamics of the protons in this system and in particular what features will appear in the observables of the

† Present address: Central Laboratry, Asahi Chemical Industry Co., Ltd., 2-1, Samejima, Fuji, Shizuoka 416.

NMR as a result of such proton tunneling. Thus, we report in this paper several remarkable properties of observables of NMR, i.e. spin-lattice relaxation time of the Zeeman system (T_{1z}) and of the dipolar system (T_{1d}) and the shape of the absorption line for acetylenedicarboxylic acid and *p*-nitrobenzoic acid. Nagaoka et al.[6] also measured T_{1z} of *p*-nitrobenzoic acid but they dealt with a polymorphic phase different from the one of the present study.

The conversion between the states I and II in Fig. 1 is also possible by another mechanism, i.e. 180° rotation about the long axis, which is claimed by Furic.[11] There has been some controversy about the mechanism by which the conversion occurs. The initial and final states are the same in both mechanisms for some observables but the nature of the processes and the relevant energy level structure will be very different from each other.

Experimental

Materials. Acetylenedicarboxylic acid (hereafter called ADCA) was purchased from Tokyo Chemical Industry, Co., Ltd. and was further purified. Two kinds of samples were prepared. One was purified by recrystallization from dry diethyl ether solution in an evacuated closed system, keeping the specimen away from humidity. The other was purified by vacuum sublimation from 360 K onto a 273 K tip. Chemical analysis gave the relative masses, C 42.02%, H 1.83%; calculated for $C_4H_2O_4$: C 42.12%, H 1.78%. The differential thermal analysis of this specimen showed no peaks between 77 and 440 K. For the NMR measurements, these specimens were degassed in the glass ampules which were sealed off with helium gas of 2 kPa for heat exchange. Raman scattering experiment was performed on the recrystallized specimen which was sealed into a glass capillary with helium gas at 50 kPa.

p-Nitrobenzoic acid (PNBA) was purchased from Nakarai Chemicals and was recrystallized three times from methanol solution. Small single crystals were obtained. Analysis gave C 50.13%, H 2.97%, N 8.30%; calculated for $C_7H_5NO_4$ were C 50.31%, H 3.02%, N 8.38%.

Two polymorphic forms of PNBA have been known with the space groups, $P2_1/c$ (a=5.043, b=5.153, c=24.692 Å, β=96.89°, Z=4)[12] and $A2/a$ (a=12.918, b=5.042, c=21.298 Å, β=96.66°, Z=8).[13] The specimen we used for the NMR measurements was identified to be the $A2/a$ modification from the lattice parameters, a=12.9, b=5.04, c=21.2 Å and β=95°, from the X-ray Weissenberg photograph. It was confirmed by powder X-ray diffraction that the recrystallized PNBA was clearly different from sublimed PNBA in structure, the latter being used by Nagaoka et al. for their NMR measurements.[6] Here, we note that the differential thermal analysis of sublimed specimen showed a very small exothermic peak at about 100 K in the cooling direction, whereas the recrystallized specimen showed no anomaly between 80 and 510 K.

There was a suspicion that the sublimed specimen was in a metastable phase, which was transformed into a more stable form on cooling. An attempt to detect the thermal anomaly in the heating direction of DTA was not successful because it is the region of large drift in the DTA output. However, the diffraction pattern of a sublimed PNBA that had been anealed at 77 K was the same as that of the virgin sublimed sample. Therefore, the thermal anomaly as seen in the sublimed PNBA at about 100 K must be due to a reversible phase transition. The recrystallized specimen was pulverized and it was treated in the same way as for ADCA for NMR and Raman experiments.

Measurements. The proton spin-lattice relaxation time of the Zeeman system (T_{1z}) was measured by the 90° train-τ-90° pulse sequence; the relaxation times obtained by this method were confermed to be the same as those by the 180°-τ-90° method at several temperatures above 77 K. The length of 90° pulse was typically 1.3 μs. The dependence of T_{1z} on the intensity of external field was measured by the field cycling technique.[1] The spin-lattice relaxation time of the dipolar system (T_{1d}) was measured by the $90°_x$-t-$45°_y$-τ-$45°_y$ pulse sequence. The T_{1z}-process and T_{1d}-process of ADCA and PNBA could be expressed by a single exponential function except in the very low temperature region of ADCA. The absorption line shapes of ADCA and PNBA were recorded by the home-built Robinson type and Pound-Watkins type spectrometers. The width of field modulation was $2H_m$=0.85 G**. The temperature of the specimen was automatically kept constant within ±0.1 K during a measurement and was measured by a Chromel-P-Constantan thermocouple above 15 K and by Au/Fe-Chromel-P thermocouple and a germanium resistance thermometer below 15 K.

Results and Discussion

Identification of Two Types of Molecular Motions and 180° Rotation of Dimeric Carboxyl Group.

A. Acetylenedicarboxylic Acid. T_{1z}^{-1} and T_{1d}^{-1} curves of ADCA are shown in Fig. 2. Open circles and open squares are, respectively, T_{1z}^{-1} and T_{1d}^{-1} of the recrystallized specimen and closed circles are T_{1z}^{-1} of the sublimed specimen. It was found that the absolute values of T_{1z}^{-1} in the low temperature region ($T<25$ K) depended on the method of preparation. This result suggests that the relaxation process below 25 K is not an intrinsic property of ADCA crystal. We will shortly discuss the low temperature relaxation. The magnetization recovery was described by two exponential functions, i.e. fast relaxing component and slowly relaxing component, rather than by a single exponential function. We derived T_{1z}^{-1} (ex.) from the slowly relaxing component, because the magnetization of fast relaxing component was only about 20% of equilibrium value even at 4.2 K and disappeared at about 15 K. T_{1z}^{-1} (ex.) varied linearly with $H_0^{-1/2}$ (H_0: external magnetic field) and with T. We thus subtracted the extrapolated value of this extrinsic contribution from the observed relaxation rate (T_{1z}^{-1} (obs.)) to obtain the intrinsic relaxation rate (T_{1z}^{-1} (in.)) above 25 K,

$$T_{1z}^{-1}\,(\text{in.}) = T_{1z}^{-1}\,(\text{obs.}) - T_{1z}^{-1}\,(\text{ex.}). \qquad (1)$$

T_{1z}^{-1} (in.) and T_{1d} are shown in Fig. 3. There are two types of molecular motions which are effective on T_{1d} in different temperature regions. We will now consider three types of motions of protons in a dimeric carboxyl groups. These are (i) coupled translation of the two protons along the hydrogen bonds in a dimeric unit, (ii) 180° rotation of this eight-membered ring about the axis nearly parallel to the hydrogen bonds, and (iii) proton diffusion from a dimer to another.

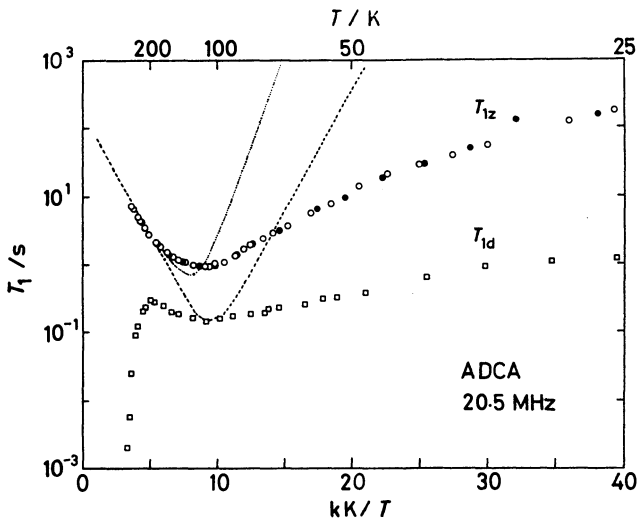

Fig. 3. Temperature dependence of the spin-lattice relaxation times of Zeeman system (O, ●) and of dipolar system (□). The extrinsic contribution to observed T_{1z}, which is seen in the low temperature region ($T<25$ K) in Fig. 2, are subtracted. The broken and dotted curves are the calculated T_{1z} for ΔE=0.2 kJ mol^{-1} and for ΔE=2.9 kJ mol^{-1}, respectively (see in the text).

Only the motion (i) of these three modes has a low enough potential barrier to induce "quantum-mechanical motion." It is noted that the minima of T_{1z} and T_{1d} occur at about the same temperature, 110 K in the case of ADCA (Fig. 3) and 70 K in the case of PNBA, as will be described below. This behavior cannot be expected from any classical random motion. Such a nonclassical behavior of the spin relaxation in the low temperature region will be discussed in detail in the following section (*Quantum mechanical behavior of*···). In contrast, the high temperature behavior of T_{1z} and T_{1d} must arise from slow classical motion because a much larger activation energy is involved. Therefore, it is reasonable to assess that the low temperature motion is of type (i) and high temperature motion is of either type (ii) or (iii); it may be possible to decide on the latter from the line shape measurement.

Typical differential absorption lines of ADCA at several temperatures are reproduced in Fig. 4. The width of the central line, which became observable at a higher temperature, was determined by the width of field modulation even if the modulation width was made as small as possible ($2H_m<0.1$ G). The intensity of this narrow component depended on the method of preparation of the sample, i.e. the intensity of recrystallized specimen was about 30 times larger than that of sublimed specimen. We ignore the contribution of this narrow component to the second moment for the moment and come back to this point in section C. The line shape below 150 K did not depended on the method of preparation.

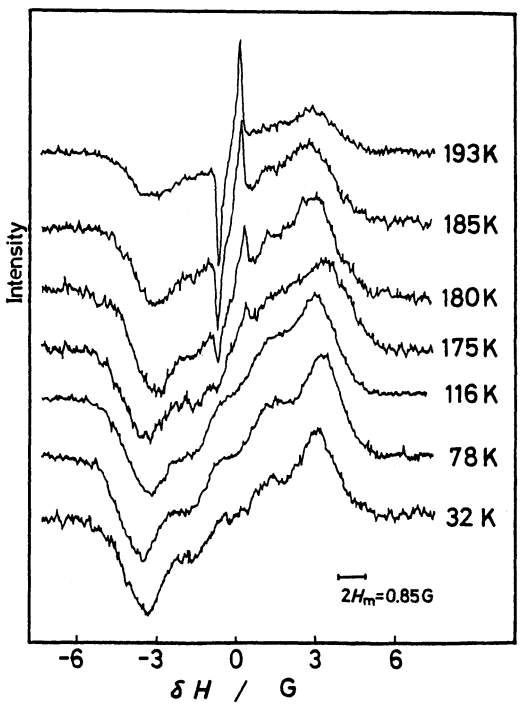

Fig. 4. The typical differential absorption line of recrystallized acetylenedicarboxylic acid at several temperatures.

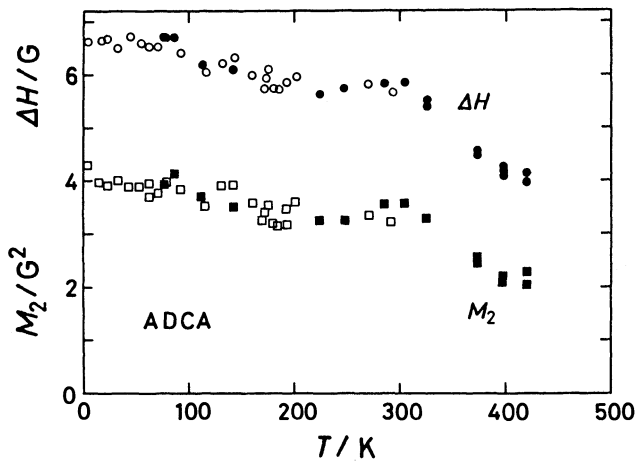

Fig. 5. The temperature dependence of maximum slope width (○, ●) and second moment (□, ■) of acetylenedicarboxylic acid; ○, □ are for the recrystallized sample and ●, ■, are for the sublimed sample.

The temperature dependences of the maximum slope width (ΔH) and the second moment (M_2) are shown in Fig. 5. The reduction of second moment (ΔM_2) due to 180° rotation of the eight-membered ring was estimated as follows. The rigid lattice value of the second moment of ADCA was calculated to be M_2 (rigid)=3.53 G^2 or 2.03 G^2 by using the formula,[14]

$$M_2\,(\text{rigid}) = (3/5)\,\gamma^4\hbar^2\,\mathrm{I}(\mathrm{I}+1)\sum_{j,k} 1/R_{jk}^6. \qquad (2)$$

taking into account only the intradimer contribution. The distance between the two protons within a dimeric unit is known to be R_I=2.37 Å in one configuration and R_II=2.16 Å in the other by the X-ray diffraction experiment[15] as shown in Fig. 6. It was also shown by X-ray diffraction that the configuration with a proton distance of 2.37 Å has somewhat larger population.[15] The angle θ between the two proton vectors (see Fig. 6) is 51.6°.[15] As temperature is increased, the dipolar interaction between the two protons becomes partially averaged by the low temperature motion, fast coupled translation of the two protons along the hydrogen bonds. Therefore, the averaged orientation of the proton-proton vector can be chosen as indicated by the broken line in Fig. 6. The angle ϕ depends on the temperature and on the energy difference ΔE indicated in Fig. 1. The value of ΔE will be discussed in the following section (*Classical picture*). The magnitude of intradimer contribution to ΔM_2 that arises from the 180° rotation was estimated to be less than 0.5 G^2 by assuming that the two potential minima of the rotation have the equal depth. The observed reduction, 1 G^2, which also includes the contribution from the interdimer interaction, is close to the estimate. The diffusion of protons from a dimeric acid unit to another in the crystal should cause a very large decrease in the second moment but there is no such indication in Fig. 5. Thus the high temperature motion of ADCA is the 180° rotation of dimeric carboxyl groups. The activation energy of this motion is 58 kJ mol^{-1} which was obtained from the slope of T_{1d}.

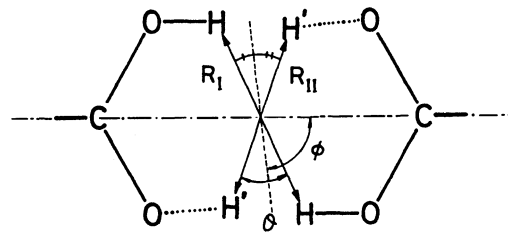

Fig. 6. The configuration of a dimeric carboxyl groups with two possible orientations of a proton-proton vector.

B. *p*-Nitrobenzoic Acid. The spin-lattice relaxation times, T_{1z} and T_{1d}, of PNBA are shown by closed circles and open squares, respectively, in Fig. 7. T_{1z} values measured at 59.53 MHz by Nagaoka et al.,[6] which are for the sublimed $P2_1/c$ modification, are also shown (○). The discrepancy between the T_{1z} values by us (●) and those by Nagaoka et al. (○) is clearly due to different polymorphic forms. It appears that the temperature variation of T_{1z} and $T_{1d}$of PNBA and that of ADCA are similar to each other (compare Figs. 3 and 7). There are also two types of molecular motions which are effective on T_{1d} in different temperature regions as in the case of ADCA and the minima of T_{1z} and T_{1d} at 70 K correspond to the translational motion of proton in a dimeric carboxyl group.

The differential line shape and maximum slope

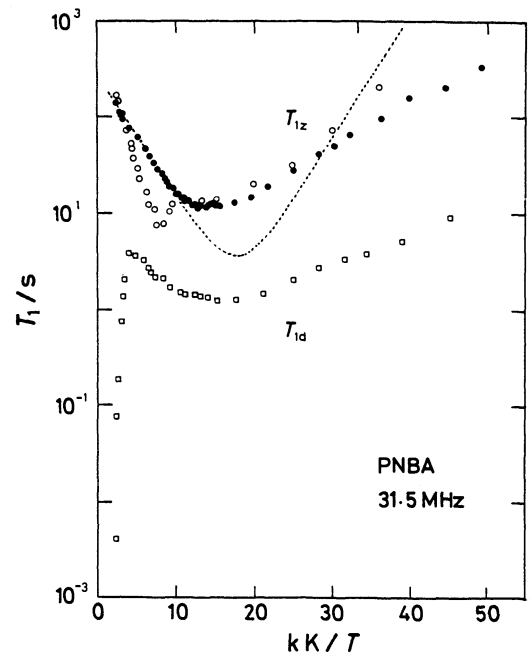

Fig. 7. Temperature dependence of spin-lattice relaxation times of Zeeman system (○, ●) and of dipolar system (□) of *p*-nitrobenzoic acid. ○ is observed at 59.53 MHz by Nagaoka et al.[6] The broken curve is the calculated T_{1z} from the classical formula (see in the text).

width of PNBA are shown in Figs. 8 and 9, respectively. The line shape of PNBA was very different from that reported by Gupta and Saxena.[16] Unlike the case of ADCA, the line width of PNBA stays constant up to 300 K. The apparent activation energy derived from the high temperature slope of T_{1d} of PNBA was 80 kJ mol^{-1}, larger than in the case of ADCA. The steep decrease of T_{1d} at high temperatures was observed for several carboxylic acid dimers and was attributed to the excitation of 180° flip motion of the dimer structure by Chiba for the first time.[17]

C. Narrow Component of Absorption Line of Acetylenedicarboxylic Acid. The narrow component of absorption line was observed at high temperature for sublimed and recrystallized ADCA as described above. It was also observed for α-oxalic acid at high temperature[18] but not for PNBA. The intensity of the narrow component of recrystallized and sublimed ADCA was reproducible during the several cycles of heating and cooling experiments. The narrow component was not due to any gaseous decomposition products because outgassing of the glass ampule did not change its intensity. The molecules of ADCA and oxalic acid have two carboxyl groups on both ends of a molecule (the head and the tail), which makes the exsistence of free carboxyl groups on certain crystal surface very plausible. In contrast, there will be no free carboxyl groups on the crystal surface of PNBA. Assuming that free carboxyl groups adsorb water strongly and, as a result, acid protons can migrate on the surface through hydrogen bonds, the narrow component of differential absorption line may be explained. From the temperature coefficient of the relative peak intensity (height) of this narrow component of the differential absorption line an energy difference of 20 kJ mol^{-1} was derived between the protons in the mobile state and in the static state for the recrystallized ADCA, which is close to the energy of an O-H···O hydrogen bond. The same value was obtained for the sublimed ADCA. Hence, the dependence of the intensity of narrow component on the method of preparation may be attributed to a difference in the water adsorbed area of the surface of the crystals.

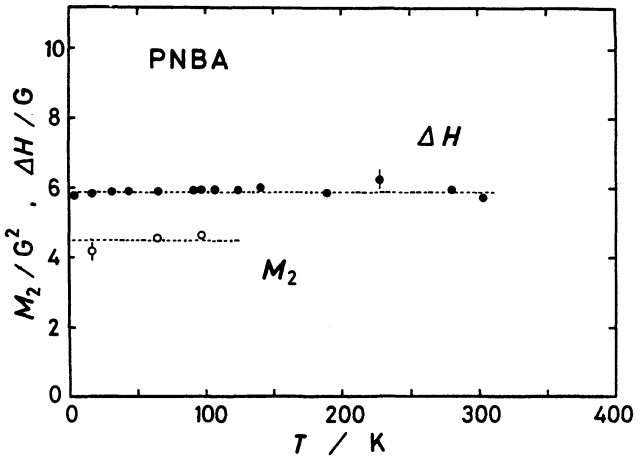

Fig. 9. Temperature dependence of the maximum slope width and second moment of *p*-nitrobenzoic acid.

Proton Translation Along the Hydrogen Bonds in a Dimer of Carboxyl Groups. A. Classical Picture. The translational motion of the two protons within a dimer of carboxyl group is probably the cause of the minimum of T_{1z} and T_{1d} as inferred in the preceding section. The temperature dependence of T_{1z} of PNBA and ADCA is very similar to that of other carboxylic acid dimers.[4-6] We will first attempt to calculate T_{1z} by a classical treatment of proton translation and compare the result of such calculation with the observed T_{1z}.

The spin-lattice relaxation formula due to classical hopping between unequal potential wells was derived[6]*** from a general expression of spin relaxation by Soda.[19] In general, T_{1z}^{-1} is given by

$$T_{1z}^{-1} = mC \sum_l A_l B(\tau_{cl}). \tag{3}$$

The sum is taken over the normal modes l of the molecular motion.[19] The coefficient, $C=(9/4)\gamma^4\hbar^2$, is the spin part of the dipolar interaction between the two protons and A_l is the structure-dependent coefficient for the normal mode l. The coefficient m denotes the fraction of the proton spins which relax directly due to motion among the total proton spins present in the crystal. In the present case of the dimeric carboxyl group, we take into account completely coupled translation of the two protons along the hydrogen bonds. T_{1z}^{-1} is then given by

$$T_{1z}^{-1} = mCAB(\tau_c) \tag{4}$$

where

$$B(\tau_c) = \tau_c/(1+\omega_0^2\tau_c^2) + 4\tau_c/(1+4\omega_0^2\tau_c^2)$$

$$A = (2/15)\,[a/(a+1)^2]\,[R_I^{-6} + R_{II}^{-6} + (1-3\cos^2\theta)R_I^{-3}R_{II}^{-3}]$$

$$a = \exp(\Delta E/RT)$$

$$\tau_c = [\tau_{c0}/(a+1)]\exp(E_a/RT).$$

R_i denotes the distance between the two protons in the i-th configuration and θ is the angle between the proton-proton vector of configurations I and II. Equa-

*** There is an error in the coefficient of Eq. 16 of Ref. 6.

tion 4 is of the same form as that given by Meier et al.[4] in the limit that $R_I=R_{II}$ and $\Delta E \ll E_a$ except for the coefficient A.

The values, ΔE, E_a, R_I, R_{II}, and θ which are necessary for the calculation of T_{1z}^{-1}, were obtained as follows. The energy difference (ΔE) between the two configurations of ADCA was derived from the temperature dependence of the integrated intensity of the Raman bands (O-H stretching vibrations; 2240 and 2280 cm^{-1}). Supposing that these two bands correspond to the different configurations, I and II, the energy difference, ΔE=0.2 kJ mol^{-1}, was derived from the temperature dependence of the relative intensity. The activation energy (E_a) was determined by assuming that on the high temperature side of the T_{1z} minimum the dominating motion is the classical jump over the top of the barrier. For such a classical jump motion, the slope of T_{1z} on the high temperature side of the T_{1z} minimum ($\omega_0\tau_c \ll 1$) is approximately described by $E_a-2\Delta E$ (when $a \gg 1$), and more generally it is described by the relation, ln $(T_{1z}^{-1}(a+1)^3) \propto (E_a+\Delta E)/RT$. The activation energy E_a=6.9 kJ mol^{-1} was thus derived. The values, R_I=2.37 Å, R_{II}=2.16 Å, and θ=51.6°, were calculated from the structural data.[15] T_{1z} calculated by use of these parameters is shown by the broken curve in Fig. 3. Stoeckli et al. recently determined the population difference between the two configurations (I and II) for ADCA from the quasi-elastic neutron scattering experiment.[9] The ratio of the populations was 0.2:0.8 at 250 K, from which energy difference ΔE was calculated to be 2.9 kJ mol^{-1}. T_{1z} was also calculated for ΔE=2.9 kJ mol^{-1} and is shown by the dotted curve in Fig. 3.

Similar calculation of T_{1z} was performed for PNBA (Fig. 7). Because of the absence of knowledge of the structure of configuration II, we assumed $R_I=R_{II}$=2.31 Å and θ=29.5° using the available structural data.[13] The energy difference between the two configurations, ΔE=0.2 kJ mol^{-1}, was obtained from the temperature dependence of the relative intensity of the Raman bands (3080 and 3090 cm^{-1}).

The parameters used in the calculations of T_{1z} of ADCA and PNBA are listed in Table 1.

B. Quantum Mechanical Behavior of Observables of NMR Due to Proton Tunneling. The observed temperature dependences of T_{1z} of ADCA and of PNBA are obviously not explained by the classical motion as shown in Figs. 3 and 7. Especially, the small temperature coefficients of T_{1z} at low temperatures are inexplicable (1.9 kJ mol^{-1} for ADCA and 1.0 kJ mol^{-1} for PNBA). The same behavior has already been pointed out by Nagaoka et al.[6] for several other carboxylic acid dimers.

The validity or failure of the classical model can be tested in another way. Thus, the ratio T_{1z}/T_{1d} is given by[20]

$$T_{1z}/T_{1d}=2+(1/3)\,\omega_0^2\tau_c^2 \qquad (5)$$

in the case that the dipolar field is modulated by random motion and therefore T_{1z}/T_{1d} should become progressively larger as the temperature is decreased ($\omega_0\tau_c \gg 1$). The experimental results, however, showed that T_{1z}/T_{1d} is almost constant even down to such low temperatures.

The frequency dependence of T_{1z} at low temperature limit also shows (Figs. 10 and 11) a large deviation

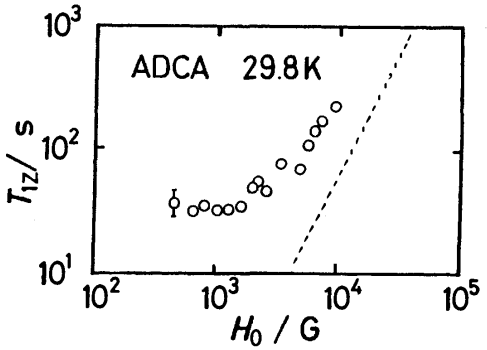

Fig. 10. Frequency (external field) dependence of spin-lattice relaxation time of Zeeman system of sublimed acetylenedicarboxylic acid.

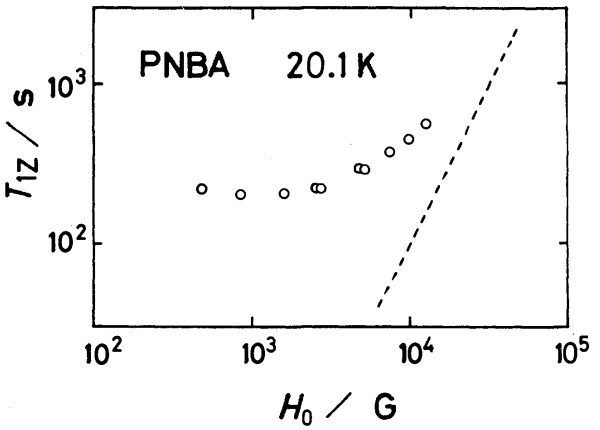

Fig. 11. Frequency (external field) dependence of spin-lattice relaxation time of Zeeman system of *p*-nitrobenzoic acid.

Table 1. Parameters of Proton Translation along the Hydrogen Bonds

	E_a/kJ mol^{-1}	ΔE/kJ mol^{-1}	τ_0/s	mCA'/s^{-2} [a]	R_I/Å	R_{II}/Å	θ/°	E_t/kJ mol^{-1}
ADCA	6.9	0.2	4.3×10^{-12}	2.45×10^{9}	2.16	2.37	51.6	1.9
	10.3	2.9[b]	3.0×10^{-12}	2.45×10^{9}	2.16	2.37	51.6	1.9
PNBA	2.5	0.2	3.7×10^{-12}	1.63×10^{8}	2.31	2.31	29.5	1.0

a) $A'=A/[a/(1+a)^2]$. b) Ref. 9.

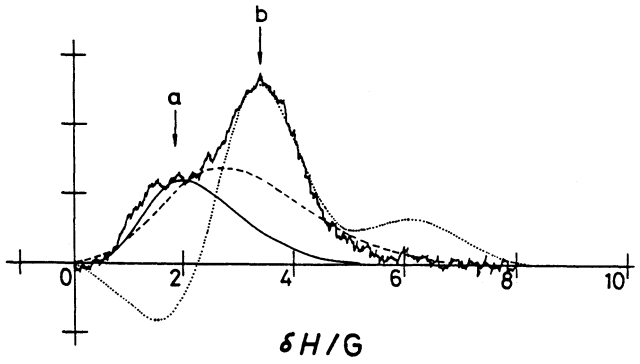

Fig. 12. A half of differential absorption line of ADCA at 4.2 K. Solid curve is the Pake doublet calculated using the parameters, proton distance r=2.37 Å and a Gaussian broadning factor β=0.8 G. Broken and dotted curves are the same calculations using the parameters r=2.16 Å (β=1.2 G) and r=1.9 Å (β=0.8 G), respectively.

from the classical prediction of H_0^2 dependence. It is obvious from this experimental result that some additional frequency terms other than the Larmor frequency must be involved in the spin relaxation formula. We can estimate that the additional frequency terms (ω') are of the order of $10^{7\pm1}$ Hz from Figs. 10 and 11. The value of H_0, at which T_{1z} begins to level off, is larger for PNBA than for ADCA. This means that ω' for PNBA is larger than for ADCA. The frequency, ω', must be connected to the tunneling rate (or tunneling frequency, ω_t) of proton translation along the hydrogen bonds.

Failure of the classical picture is also substantiated by the shape of absorption line at low temperatures (Fig. 12). It is not a simple Pake doublet[14] as one expects for an isolated proton pair like in the case of trichloroacetic acid[21] but there is another component in addition to a Pake doublet as demonstrated in Fig. 12. The peak **a** of Fig. 12 can be reproduced by the solid curve which is the Pake doublet calculated using the parameters, proton distance r=2.37 Å and a Gaussian broadning factor β=0.8 G.[14] The Pake doublet corresponding to the other configuration, r=2.16 Å (broken curve, β=1.2 G) can not explain the peak **b**. If we try to reproduce the peak **b** by a Pake doublet, we should take the parameters, r=1.9 Å and β=0.8 G (dotted curve). But there is no such a short distance between the protons. The shortest distance between the protons of different dimers of carboxyl group is 3.1 Å. Therefore the classical Pake treatment does not apply to ADCA at low temperature. The structure of the line shape disapeared, however, when the temperature was increased up to 190 K.

The more complete analysis of the line shape and its temperature dependence would require more detailed knowledge of the energy levels of the proton spin system.

Conclusion

There are two types of motions of protons in the crystals of ADCA and PNBA. The two motions are successively excited as temperature increases. At low temperatures, the protons jump between double minima along the hydrogen bond through tunneling mechanism. New evidences of proton tunneling were presented. The quantum effects are manifested not only in the temperature dependence of correlation time, τ_c, but also in the transition probability between the spin states, from which the detailed information about "tunneling" will be obtained. As the temperature is increased, the jump occurs also in the classical sense and at the same time the 180° rotation of the dimeric carboxyl group is gradually excited.

The authors would like to express their gratitude to Dr. Yasuhiro Takahashi of Department of Macromolecular Science of Osaka University for help provided in the X-ray diffraction experiment of PNBA. This work was partly supported by the Grant-in-Aid for Scientific Research No. 61430006 from the Ministry of Education, Science and Culture.

Excited-State Reactions of Coumarins. VII. The Solvent-Dependent Fluorescence of 7-Hydroxycoumarins

Tetsuo MORIYA
Electrotechnical Laboratory, Umezono, Tsukuba, Ibaraki 305
(Received December 2, 1987)

The excited-state reactions of 7-hydroxycoumarin (7HC) and 7-hydroxy-4-methylcoumarin (7H4MC) have been studied by measuring the absorption and fluorescence spectra in aqueous and organic solvents under acidic and basic conditions. Based on the solvent-dependent fluorescence of the fluorophores, the solvents could be classified into several groups: hydroxylic solvents, nonhydroxylic solvents with low dielectric constants, and those with high dielectric constants. In the hydroxylic solvent, protonation, deprotonation, and tautomerization were the main reactions, while in the nonhydroxylic solvent the formation of hydrogen bonding and ion pairs was essential. The fluorescence in water-ethanol mixtures and in aqueous sodium dodecyl sulfate solutions has also been examined in relation to the solvent-dependent spectra in pure hydroxylic and nonhydroxylic solvents.

The complicated behavior of the fluorescence from 7-hydroxycoumarins has been extensively studied in organic solvents and in neutral, acidic, and basic aqueous solutions.[1-4] Four fluorescent species have typically been observed in the photoexcited state, depending on the pH of the solution; they are identified as neutral, anionic, tautomeric, and protonated forms of the excited molecule. The reactions which generate these excited species are affected by the solvent so strongly that a careful examination of the fluorescence spectra, as well as the absorption spectra, is inevitable if we are to reach a correct conclusion. Basically, the solvents should be classified into two general groups in order to explain reasonably the fluorescent behavior of solvent-sensitive fluorophores; one group consists of "hydroxylic" solvents with hydroxyl substituents (-OH), and the other, of "nonhydroxylic" solvents without -OH. Such a classification is extremely meaningful, because the hydrogen-bonding ability and the ionizing power of the solvent determine in many ways the reaction process in excited states, such as the phototautomerization discussed in Ref. 4. As may readily be supposed, water, alcohols, water-organic mixtures, and aqueous solutions of surfactants belong to the hydroxylic-solvent group. Many of the aliphatic and aromatic solvents without -OH are nonhydroxylic solvents; the fluorescent behavior of the 7-hydroxycoumarins in these solvents is very different from that in the hydroxylic solvent. The purpose of the present study is to find a reasonable explanation of the solvent-dependent fluorescence by means of a unified model, one which includes the tautomerization, the acid-base reaction, and the ion pair formation with various additives.

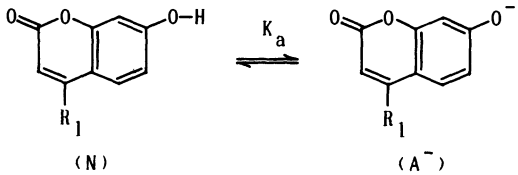
Experimental

Commercial-grade reagents of 7-hydroxycoumarin (7HC, Wako Pure Chemical) and 7-hydroxy-4-methylcoumarin (7H4MC, Tokyo Kasei) were purified by recrystallization from ethanol and then washed with diethyl ether; 7HC, mp 234 °C; 7H4MC, mp 186 °C. The organic solvents were of a spectroscopic grade from Dojindo Laboratories. The perchloric acid, hydrochloric acid, triethylamine (TEA), and butylamine (BA) were of a pure quality. The sodium dodecyl sulfate (SDS, Wako Pure Chemical) was of a biochemical grade. The water was permeated and distilled. The acidity and basicity of the solution were adjusted by the addition of $HClO_4$ and TEA (or BA) respectively.

The UV absorption spectra were obtained on a Hitachi 323 spectrophotometer, while the fluorescence spectra were measured on a Hitachi MPF 4 spectrofluorometer with an S-5-type photomultiplier. The concentration of fluorescent molecules in the solutions was ca. $4—5\times10^{-5}$ mol dm^{-3}. Spectral measurements were performed at 20 or 25 °C by controlling the temperature of the cell holder.

Results and Discussion

General Scheme for Excited-State Reactions. In a previous study,[4] the complex pH-dependence of the absorption and fluorescence spectra of 7HC and 7H4MC in aqueous solutions has been fully analyzed; the results may be summarized as follows. In the electronic ground state, there exist neutral molecular species (N) or anionic molecular species (A^-), depending on the pH of the solution. If the pH is changed from neutral to basic, the molecule is deprotonated at the 7-hydroxyl group:

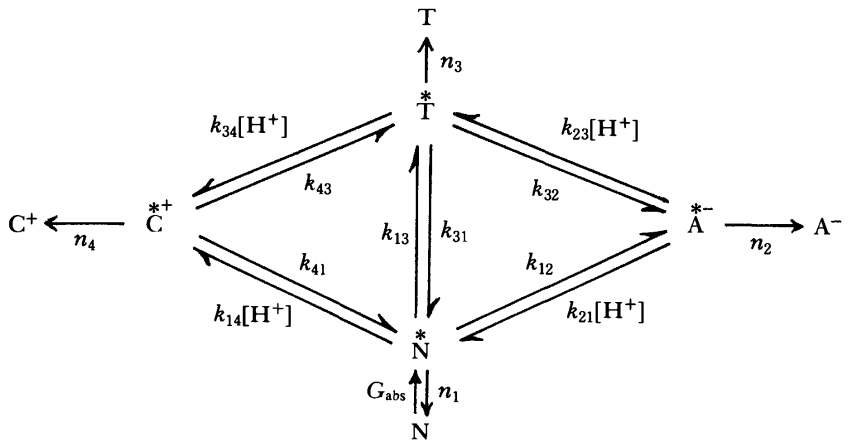


(1)

(N) (A⁻)

R_1=H, 7HC; R_1=CH_3, 7H4MC

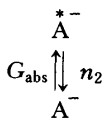
The absorption maxima of N and A^- in the aqueous solutions were at 324 and 366 nm (7HC), and at 321 and 361 nm (7H4MC), respectively; 7HC, pK_a=7.75; 7H4MC, pK_a=7.84.[5] Additionally, the absorption band corresponding to the cationic species (C^+), protonated at the 2-carbonyl group, was found at 353 nm (7HC) and 345 nm (7H4MC) in concentrated sulfuric acid ($H_0<-6$).[6] The absorption bands aligned in



Scheme 1.

wavelength as $N<C^+<A^-$.

When N was optically excited at around its absorption-peak wavelength, the fluorescence from four molecular species in the excited state were observed with the variation in the pH. One was a usual neutral molecule ($\overset{*}{N}$), and another was a tautomeric molecule ($\overset{*}{T}$), in which a hydrogen of the 7-hydroxyl group was transferred to the 2-carbonyl group; contrary to the case of N, A^-, and C^+, the ground state of $\overset{*}{T}$ could never be found by absorption measurements. Analogously to the ground states, an excited cation ($\overset{*+}{C}$) and an excited anion ($\overset{*-}{A}$) were formed in strongly acidic solutions and in basic solutions respectively. A unified scheme for the excited-state reactions may be depicted as Scheme 1.[4] Here, G_{abs} is the generation rate of $\overset{*}{N}$, while the n_j's are the transition rates of the excited species to their ground states. The k_{ij}'s and $k_{ji}[H^+]$'s are the protonation and deprotonation rates of the neutral, anionic, and cationic molecular forms in the excited state. k_{13} and k_{31} represent the reaction rates of the tautomerization that does not involve stepwise protonation or deprotonation processes, i.e., the "nondissociative" reaction rates.[4,7] In aqueous solutions, the fluorescence-peak wavelengths of $\overset{*}{N}$, $\overset{*+}{C}$, $\overset{*-}{A}$, and $\overset{*}{T}$ were 397, 431, 453, and 478 nm for 7HC, and 390, 419, 447, and 474 nm for 7H4MC, respectively. If A^- was selectively excited by choosing the wavelength in a neutral or basic solution, the situation became simple, because the fluorescent species was restricted to the anionic form ($\overset{*-}{A}$) alone; this comes from the fact that $\overset{*-}{A}$ is energetically most stable among the photoexcited states:[4]



Scheme 2.

Fluorescence Behavior in Hydroxylic Solvents. As hydroxylic solvents, isobutyl alcohol (*i*-BuOH, $D\cong$ 18.3), isopropyl alcohol (*i*-PrOH, 18.6), ethanol (EtOH, 25.0), methanol (MeOH, 32.4), and water (H_2O, 80.4) were employed, where D represents the static dielectric constant of the solvents at 20 °C.[8] The "acidic" and "basic" conditions have been realized by adding 0.29 mol dm^{-3} $HClO_4$ and 0.22 mol dm^{-3} TEA respectively to the solutions of 7HC and 7H4MC. The "strongly acidic" conditions have been attained by adding ca. 6 mol dm^{-3} $HClO_4$, and the "strongly basic" conditions, by adding TEA or BA up to ca. 4 mol dm^{-3}. In order to visualize the fundamental aspect

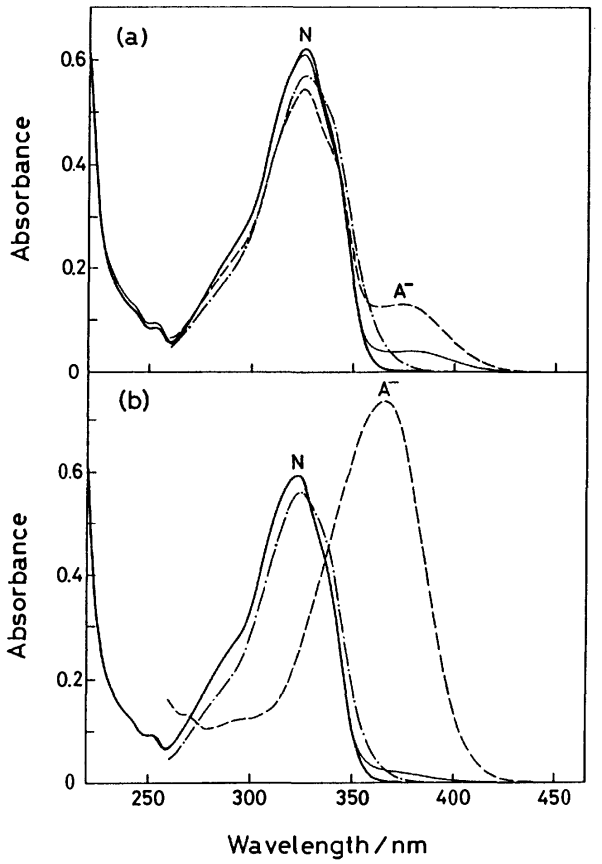


Fig. 1. UV absorption spectra of 7H4MC in *i*-BuOH (a) and in MeOH (b) for the neutral (——), acidic (——), strongly acidic (-·-·-), and basic (– – –) solutions at 20 °C.

of electronically ground states, the absorption spectra of 7H4MC in *i*-BuOH are compared to those in MeOH in Fig. 1. Only the N absorption band is observable in the acidic *i*-BuOH and MeOH solutions, while C^+ coexists with N in the strongly acidic solutions, as is shown by the shoulder on the long-wavelength side of the absorption spectra. The pure C^+ state was ultimately reached in concd. H_2SO_4 ($D \approx 101$ at 25 °C) and was observed at ca. 345 nm. The A^- band is found as a shoulder around 375 nm in the neutral and basic *i*-BuOH and in the neutral MeOH. In the basic MeOH, on the other hand, the pure A^- absorption peaking at 365 nm is observed as a result of the dissociation of 7-OH. When the strongly basic condition was attained by the addition of up to 4 mol dm^{-3} of BA, the 7-OH group was completely dissociated, even in solvents less polar than MeOH. Since the molar extinction coefficients (ε) at the pure A^- absorption peak are thus measurable for all the hydroxylic solvents, the dissociation ratio of the fluorophore, $[A^-]/([A^-]+[N])$, at a given basicity of the solution can be evaluated by $\varepsilon^A/\varepsilon_p^A$, where ε_p^A is the value for the pure A^- state, and ε^A, for the A^- contribution under the present experimental conditions. Figure 2 presents the dependence of $[A^-]/([A^-]+[N])$ on $1/D$ in solutions containing 0.22 mol dm^{-3} of TEA. Based on the dissociation process of 7H4MC, the ionizing power of the hydroxylic solvents can be qualitatively estimated as $H_2O \approx$ MeOH<EtOH<*i*-PrOH$\approx$*i*-BuOH. Irrespective of the drastic change in the ionizing power of the solvents, the spectral shape of each absorption band was similar in the solvents, whereas its peak was gradually blue-shifted with the increase in the D value (see Table 1).

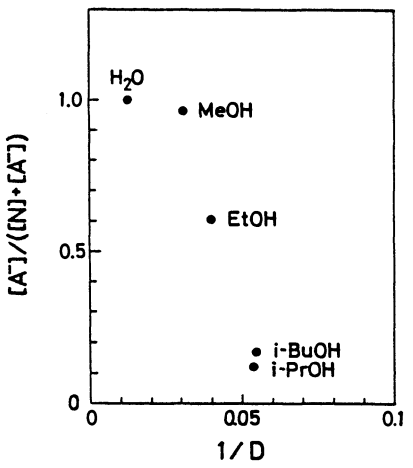

Fig. 2. Plots of the dissociation ratio, $[A^-]/([A^-]+[N])$, vs. $1/D$ in the basic hydroxylic solvents with 0.22 mol dm^{-3} TEA.

Bearing the ground-state behavior in mind, the fluorescence spectra of 7H4MC in the neutral, acidic, strongly acidic, and basic solutions have been studied in detail; some typical spectra in MeOH are shown in Fig. 3. In spite of the complex behavior, the phenomena were common throughout the hydroxylic solvents, and either Scheme 1 or Scheme 2 was again applicable. When the light illumination was actuated at ca. 320 nm in the neutral, acidic, and strongly acidic solutions, Scheme 1 could be applied, for only the neutral excited species $\overset{*}{N}$ was generated by the light absorption; in contrast, when excitation was done at ca. 360 nm in the basic solution, Scheme 2 was applied. The peak wavelengths of the fluorescence bands

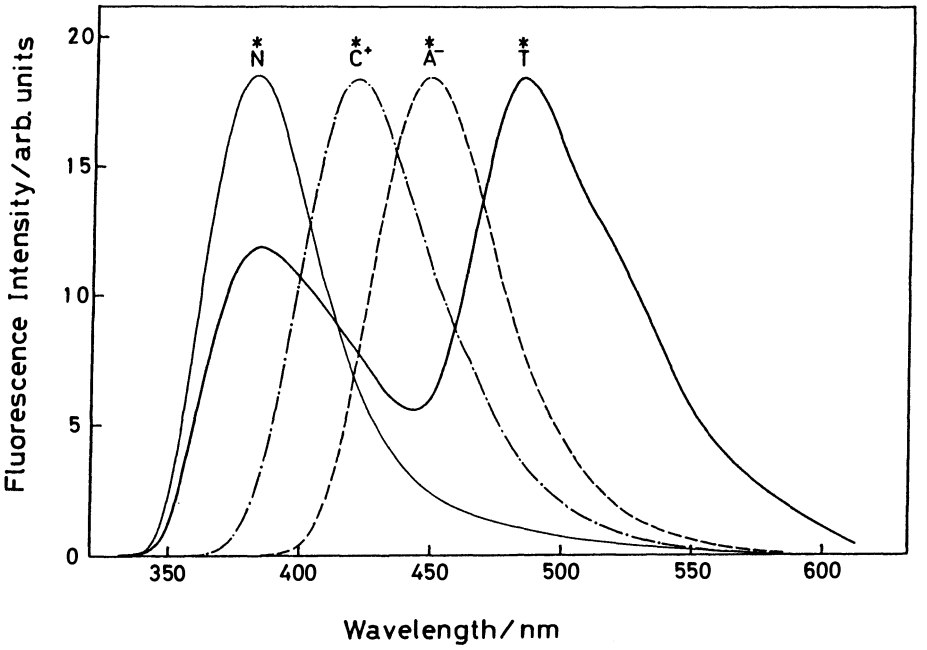

Fig. 3. Fluorescence spectra of 7H4MC in MeOH at 20°C. The excitation wavelength was 320 nm for the neutral (——), acidic (——), and strongly acidic (—·—·—) solutions, and was 380 nm for the basic (----) solution.

Table 1. Peak Positions of the Absorption and Fluorescence Spectra of 7H4MC in the Hydroxylic Solvents under Neutral, Acidic, and Basic Conditions at 20 °C

Solvent	D^{20}	Absorption			Fluorescence			
		N	C^{+} a)	A^{-}	$\overset{*}{N}$ b)	$\overset{*+}{C}$ b)	$\overset{*-}{A}$ c)	$\overset{*}{T}$ b)

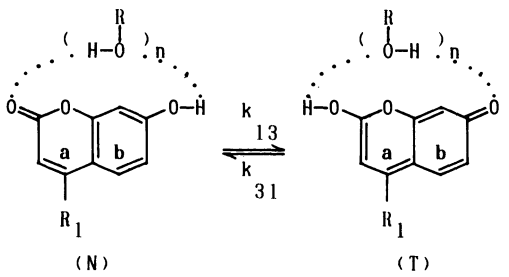
thus obtained were in this order: $\overset{*}{N}<\overset{*+}{C}<\overset{*-}{A}<\overset{*}{T}$; this order is parallel with that in the ground state except for $\overset{*}{T}$. Table 1 gives the peak position of each absorption and fluorescence band observed in the hydroxylic solvents. As D is increased from *i*-BuOH to H_2O, the $\overset{*}{T}$ band obviously bule-shifts, while the other three bands show small shifts without any systematic tendency. The optical transitions of coumarins originate from the π-π^* transition, which induces a very strong absorption ($\varepsilon>10^4$ $cm^{-1}mol^{-1}cm^3$).[9] If there is no other solvent-solute interaciton than the dielectric effect due to the molecular polarization, the dipole moment of the excited π-state (μ_e) is usually larger than that of the ground state (μ_g); then, the fluorescence band is red-shifted with the increase in the solvent polarity, whereas the polarity effect on the absorption band is small.[10] Adopting the qualitative parallelism of solvent polarity with D, the shifts of the absorption and fluorescence bands of the neutral and anionic species contradict the above-mentioned presumption ($\mu_e>\mu_g$) for the π-electron system. Probably, the hydrogen bond between the fluorophore and the solvent molecule as a result of the atomic-level interaction, which originates from the difference in the electronegativity of the heteroatoms, must be appropriately taken into account in the case of 7-hydroxycoumarins. The hydrogen-bonding interaction will stabilize the π-electron system by spreading its distribution towards nearby solvents. If the stabilization is more prominent in the ground state than in the excited state, the data for the neutral and anionic species, which suggest a more polar structure in the ground state ($\mu_e<\mu_g$), are consistently explained. It is hard to conjecture the electronic structures of the cationic and tautomeric species from the data in Table 1, for the pure absorption of the former is not found except in concd. H_2SO_4, while that of the latter cannot be found under any usual conditions. Nevertheless, based on the relative energy position and the small shift of the fluorescence band, $\overset{*+}{C}$ seems to belong in the same groups as $\overset{*}{N}$ and $\overset{*-}{A}$. The tautomeric species, on the other hand, must have a special π-electron distribution compared with the other three, because the increase in the hydrogen-bonding ability or the solvent polarity destabilized the excited state. Since the T absorption does not appear, the energy position of T may be highly pulled up from those of N and A^-. The chemical aspect of the tautomer can be partly presumed from its strained molecular structure, including a quinoid structure of the **b** ring of T in Scheme 3 as the main resonance component.

The $\overset{*+}{C}$ and $\overset{*-}{A}$ bands were singly observed in the strongly acidic and basic solutions respectively, while the $\overset{*}{N}$ and $\overset{*}{T}$ bands are always observed in pairs. An especially interesting situation occurs in the acidic solutions with 0.2—0.5 mol dm^{-3} $HClO_4$, where the rapid equilibration between $\overset{*}{N}$ and $\overset{*}{T}$ seems to be realized after the excitation of N; spectroscopically, the fluorescence of $\overset{*}{N}$ and tautomeric $\overset{*}{T}$ species is clearly measured, but neither that of $\overset{*+}{C}$ nor that of $\overset{*-}{A}$ is (see Fig. 3). It has been shown in Ref. 4 that the tautomerization of $\overset{*}{N}$ to $\overset{*}{T}$ is promoted by dissociative and nondissociative processes. The dissociative process has two possible pathways. The one generates the intermediate protonated species as $\overset{*}{N}\rightarrow\overset{*+}{C}\rightarrow\overset{*}{T}$; the other generates the intermediate deprotonated species as $\overset{*}{N}\rightarrow\overset{*-}{A}\rightarrow\overset{*}{T}$. The absence of $\overset{*+}{C}$ and $\overset{*-}{A}$ in the fluorescence spectra does not mean that $\overset{*+}{C}$ and $\overset{*-}{A}$ are not generated, but that the reactions rapidly proceed toward $\overset{*}{T}$ without enough time to fluoresce in the $\overset{*+}{C}$ or $\overset{*-}{A}$ state, as will be discussed further later. In hydroxylic solvents, there is another posibility: that $\overset{*}{N}$ is directly converted to $\overset{*}{T}$ by means of the concerted transfer of a hydrogen from the hydroxyl site to the carbonyl site with the aid of hydrogen bonds of solvent molecules described as:



R_1=H, 7HC; R_1=CH_3, 7H4MC

Scheme 3.

The same discussion holds for the three reversed reaction pathways from $\overset{*}{T}$ to $\overset{*}{N}$. Except for the conditions

of $[HClO_4]$=0.2—0.5 mol dm^{-3}, the fluorescence of $\overset{*-}{A}$ or $\overset{*+}{C}$ has been more or less observed in the wavelength region between the $\overset{*}{N}$ and $\overset{*}{T}$ bands. By chance, in the 7HC and 7H4MC solutions with $[HClO_4]$ of 0.29 mol dm^{-3} the fluorescence from $\overset{*-}{A}$ and $\overset{*+}{C}$ is simultaneously negligible; such peculiar conditions were helpful in the detailed study of tautomerization reactions in aqueous solutions.[4,11] Since the $\overset{*}{N}$ and $\overset{*}{T}$ bands are separated enough in wavelength, and since their spectral shapes are almost entirely maintained throughout the solvents, the fluorescent yields of $\overset{*}{N}$ and $\overset{*}{T}$ may be rigorously compared with each other. Although the D value is used as a convenient parameter to describe the macroscopic properties of solvents, it is not an appropriate measure of solvent-solute or solute-solute interactions. Therefore, the ratio of the fluorescence intensity of $\overset{*}{T}$ to that of $\overset{*}{N}$, I^T/I^N, is plotted in Fig. 4 against the polarity factor, $(D-1)/(2D+1)$; the factor was first derived by Kirkwood[12] to estimate the activity coefficient of reacting molecules in solvents and was then discussed extensively by Winstein et al.[13] in treating the linear free-energy relationship for the solvolysis rate of t-butyl chloride. As I^T/I^N is the value that reflects the tautomerization reaction rate in the solvents, the correlation between $\log(I^T/I^N)$ and $(D-1)/(2D+1)$ was examined first; however, the plots showed a marked curvature (Fig. 4). It is frequently seen that $(D-1)/(2D+1)$ does not fully correlate with the log of the reaction rate measured. Böhme et al.[14] plotted, though the theoretical basis was rather poor, the log of the hydrolysis rate of halogenated compounds against "log D"; they thus obtained a quite straight relationship. Therefore, this type of plot has been applied to the present problem, as is shown in Fig. 5; the plots are widely fitted with $I^T/I^N \propto D^{2.0\pm0.05}$ for 7H4MC and with $\propto D^{1.7\pm0.05}$ for 7HC at 20 °C. This empirical relation is exciting, because many reaction rates, either dependent on or independent of D, must be practically concerned in each fluorescence process.

In case that no fluorescence of $\overset{*-}{A}$ and $\overset{*+}{C}$ is detected, the following inequalities are satisfied:[11]

$$k_{12},\ k_{32} \ll k_{21}[H^+],\ k_{23}[H^+],$$

and

$$k_{14}[H^+],\ k_{34}[H^+] \ll k_{41},\ k_{43}. \tag{2}$$

Experimentally, all decay rates of the excited species, n_j's, are of the same order;[4,11] the integrated spectral intensity of each absorption band shows so little change with altering the solvents that the radiative-decay probabilities of the excited species (n_j^r) are nearly constant;[10] the decay rates n_j's are rather insensitive to D, judging from the fluorescence-yield and the lifetime measurements.[4,11] Based on these clues, we obtain the following theoretical prediction by analyzing the rate equations given in Ref. 4:[11]

$$\frac{I^T}{I^N} \propto \frac{n_3{}^r}{n_1{}^r} \cdot \frac{k_{13}+k_{13}^A+k_{13}^C}{n_3+k_{31}+k_{31}^A+k_{31}^C}, \tag{3}$$

where, corresponding to the forth- and back-reaction pathways of $\overset{*}{N} \rightleftarrows \overset{*-}{A} \rightleftarrows \overset{*}{T}$:

$$k_{13}^A = k_{12} \cdot \frac{k_{23}[H^+]}{n_2+k_{21}[H^+]+k_{23}[H^+]},$$

$$k_{31}^A = k_{32} \cdot \frac{k_{21}[H^+]}{n_2+k_{21}[H^+]+k_{23}[H^+]}, \tag{4}$$

and corresponding to the pathways of $\overset{*}{N} \rightleftarrows \overset{*+}{C} \rightleftarrows \overset{*}{T}$:

$$k_{13}^C = k_{14}[H^+] \cdot \frac{k_{43}}{n_4+k_{41}+k_{43}},$$

$$k_{31}^C = k_{34}[H^+] \cdot \frac{k_{41}}{n_4+k_{41}+k_{43}}. \tag{5}$$

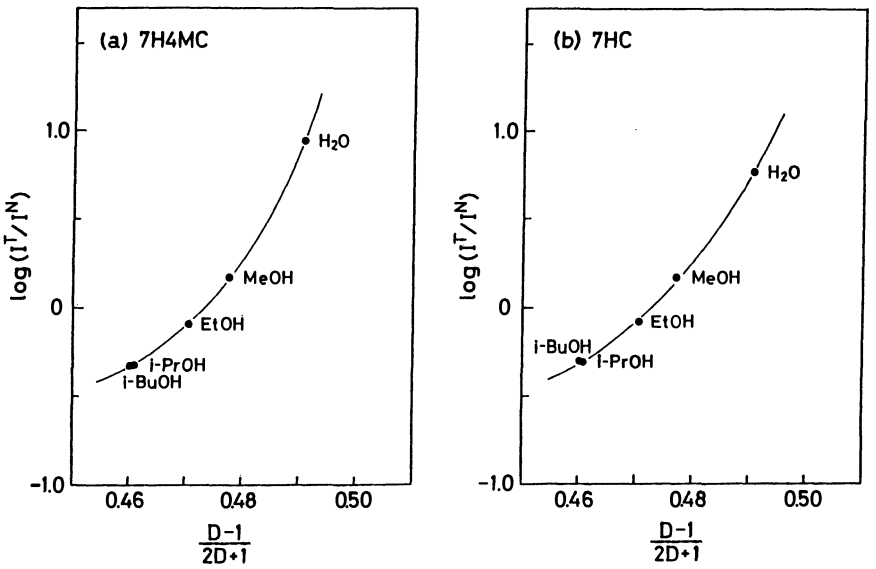


Fig. 4. Plots of $\log(I^T/I^N)$ vs. $(D-1)/(2D+1)$ in the acidic hydroxylic solutions of 7H4MC (a) and of 7HC (b) at 20 °C.

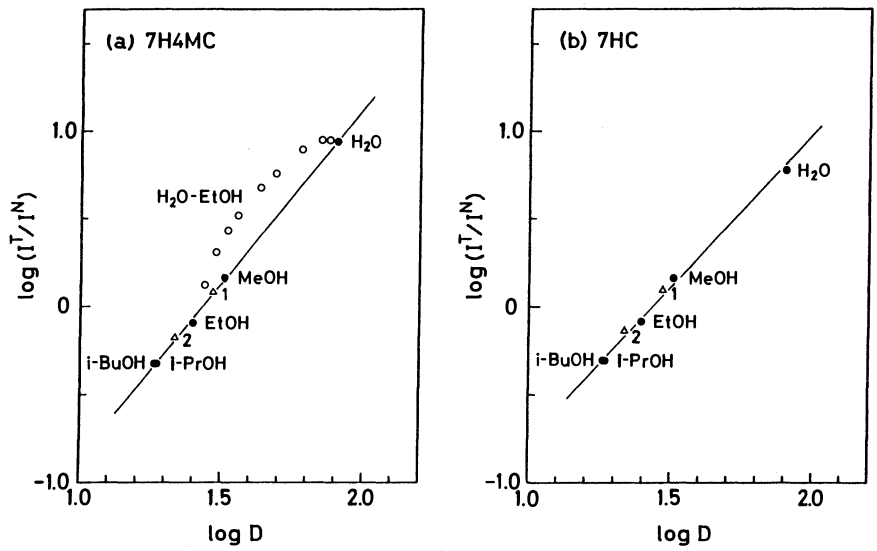

Fig. 5. Plots of $\log(I^T/I^N)$ vs. $\log D$ in the acidic hydroxylic solutions of 7H4MC (a) and of 7HC (b) at 20 °C. The plots for the MeOH–EtOH mixture (1), for the EtOH–*i*-PrOH mixture (2), and for the H_2O–EtOH mixture (○) are also shown.

Although the D dependency of the n_3, k_{13}'s, and k_{31}'s in Eq. 3 has not yet been exactly ascertained, it can be asserted that at least one of the tautomerization rates k_{13}, k_{13}^A, or k_{13}^C, would have a term superlinearly dependent on D if their power expansions of D could be carried out. The reaction pathway described by k_{13} in Scheme 3 is, of course, promoted by the increase in D, for the bridge of hydrogen bonds transferring a hydrogen between the two reactive sites is readily enhanced in polar hydroxylic solvents. This prediction will be confirmed later by an experiment in mixed solvents with various amounts of H_2O.

As for the dissociative tautomerization pathways in an acidic solution, the contribution from k_{13}^C is more important than that k_{13}^A. Equations 4 and 5 show that k_{13}^C linearly increases depending on $[H^+]$, but that k_{13}^A saturates at a large $[H^+]$ value. Furthermore, under the acidic conditions employed, the transiently generated C^{*+} is really evidenced by means of the fluorescence quenching measurement due to halide ions, as will be discussed in a later section. Therefore, $k_{13}^C \gg k_{13}^A$ is reasonable, and the dependence of I^T/I^N on D in Fig. 5 is mainly determined by the competition of k_{13} and k_{13}^C. The back-reaction rates, k_{31} and k_{31}^C, cannot dominate the D dependence of I^T/I^N, because these rates must compete with the large decaying probability, n_3 (ca. 2×10^8 s^{-1}),[4] in the denominator of Eq. 3, which is only slightly dependent on the D value.

Since, at any rate, the straight relationship in Fig. 5 holds very widely from *i*-BuOH to H_2O, log D for various hydroxylic solvents can be employed in order to estimate the chemical properties of microenvironments, such as the microscopic polarity and the hydrogen-bonding ability. It has been further revealed that the data in the mixed solvents of MeOH-EtOH and EtOH-*i*-PrOH follow well the predicted relation; the representative points are plotted in Fig. 5. Therefore, log D is the generally usable parameter that describes the microenvironment and the solvent-solute interaction, even in such mixed solvents.

Fluorescence Behavior in Nonhydroxylic Solvents. As compared with the hydroxylic solvents, nonhydroxylic solvents (also called "inert" or "aprotic" solvents) have so little hydrogen-bonding ability by themselves that the situation for excited-state reactions, as well as for ground-state equilibria, becomes extremely altered. Moreover, the formation of hydrogen bonds and ion pairs between acids and bases in the solution must be taken into account as important phenomena, for the dissociation process of proton liberation is highly suppressed in nonhydroxylic solvents due to the large or immeasurable "autoprotolysis" constant (for acetonitrile, $pK_{HS}\approx28.5$ at 25 °C, while it is immeasurable for the others).[15] As nonhydroxylic solvents, dioxane (D=2.2 at 20 °C), benzene (2.3), chloroform (4.8), ethyl acetate (6.2), dichloromethane (7.4), acetone (21.1), and acetonitrile (36.8) were examined; these solvents were afterwards classified into three groups (**1**, **2a**, and **2b**), as indicated in Table 2, in order to make the subsequent discussion systematic. The "acidic" and "basic" conditions have been realized, as before, by the addition of 0.29 mol dm^{-3} of $HClO_4$ and 0.22 mol dm^{-3} of TEA respectively. Since benzene, $CHCl_3$, and CH_2Cl_2 could not dissolve the indicated amount of $HClO_4$, the data in these solvents under the acidic conditions were taken into account as references.

The typical absorption spectra of 7H4MC in dioxane and in CH_3CN are shown in Fig. 6. In the acidic and basic dioxane, the absorption peak was red-shifted from that in the neutral solution (Fig. 6(a)). The same

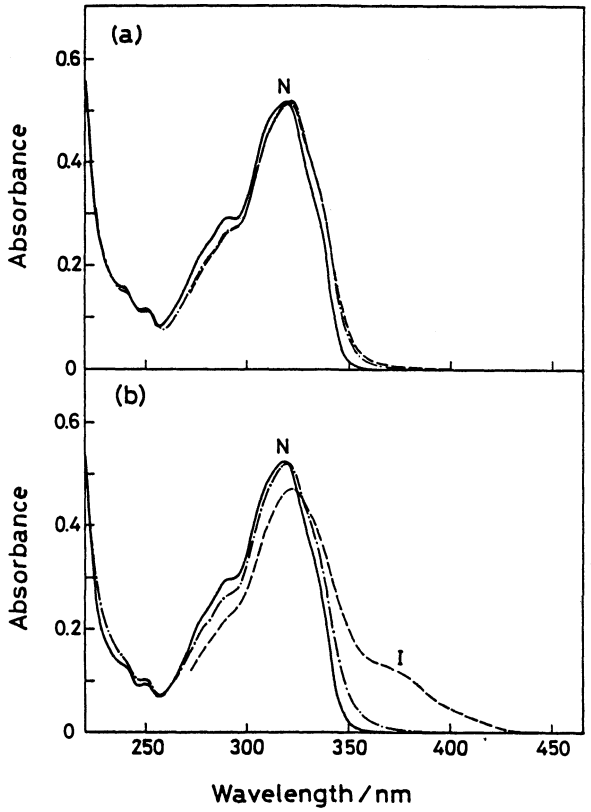

Fig. 6. UV absorption spectra of 7H4MC in dioxane (a) and in CH_3CN (b) for the neutral (——), acidic (–·–·–), and basic (----) solutions at 20°C.

red shift as in dioxane was observed in the acidic CH_3CN (Fig. 6(b)). Because of the very low D of dioxane, it is presumed that the acid-base complexes between the fluorophore and the additives, described as N(>CO)···$HClO_4$ and N(-OH)···NEt_3, are formed, where the substituents in the parentheses are concerned in the association and where the dots represent an attractive interaction such as the hydrogen bond; these ground-state complexes are indicated by NH and NB respectively. The absorption-peak wavelengths measured under various solvent conditions are given in Table 2. Evidently, 7-hydroxycoumarins can work as both acid and base, because they have a proton-donating hydroxyl group and a proton-accepting carbonyl group. Nagakura and Baba[16] found that the absorption spectra of 1 : 1 hydrogen bond complexes of phenols with suitable bases in nonhydroxylic solvents were shifted to longer wavelengths compared with the absorption spectra of the unbonded species; the shift was typically about 500 cm^{-1}, which corresponds to ca. 4 nm in the wavelength region of the present interest. Although a stoichiometric complex has not clearly been affirmed in the case of 7-hydroxycoumarins, it is probable that the hydrogen-bond interaction determines the absorption shift in the nonhydroxylic solvents dissolving $HClO_4$ and dissolving NEt_3 (TEA). The shifts of the NH and NB bands amount to 1—7 nm, as may be seen from Table 2.

In the basic CH_3CN, a long-wavelength side band (350—450 nm) appeared in addition to the main band NB at ca. 322 nm (Fig. 6(b)). This peakless side band, indicated by I, was always accompanied by the NB absorption, and the entire spectral profile was not changed by the further addition of TEA up to 2.4 mol dm^{-3}; this is in contrast with the result in MeOH, which has a D value similar to that of CH_3CN (the "iso-D-value" solvent), where the complete dissociation of 7-OH has been realized. Since the side band is commonly observed in **2a** and **2b**, but not in **1**, the most probable situation is that the ion pair between 7H4MC and TEA described as A^- $(-O^-)\cdots H\overset{+}{N}Et_3$ is generated as a result of the proton transfer in the acid-base complex due to the larger ionizing power of the solvents. If the ion pair is a stabilized molecular complex, and if it contributes to the long-wavelength absorption, the following ground-state equilibria must be taken into account:

$$\underset{(N)}{N}+NEt_3 \rightleftarrows \underset{(NB)}{N(-OH)\cdots NEt_3} \rightleftarrows \underset{(I)}{A^-(-O^-)\cdots H\overset{+}{N}Et_3} \quad (6)$$

Rigorously speaking, the ion pair I is a representative of variously coupled pairs, including such solvent-separated ones as $A^-(-O^-)\cdot\cdot(solvent)_n\cdot\cdot H\overset{+}{N}Et_3$; such a

Table 2. Peak Positions of the Absorption and Fluorescence Spectra of 7H4MC in the Nonhydroxylic Solvents under Neutral, Acidic, and Basic Conditions at 20 °C

	Solvent	D^{20}	Absorption				Fluorescence

a) Because of the absorption due to the solvent, the absorption peak, possibly < 325 nm, was not precisely decided. b) The absorption tail (360—400 nm) on the longer-wavelength side of the NB band. c) Found by excitation at 320 nm. d) Found by excitation at 360 nm. e) Found by excitation at 410 nm.

dispersed nature in the separation of ions may be reason why the I absorption is broad and peakless. It will be shown later that the ion pair I is intimately correlated with the excited-state ion pair, $\overset{*}{A}^{-}(-O^{-})\cdots H\overset{+}{N}Et_3$, i.e., $\overset{*}{I}$. Since $HClO_4$ usually forms an ion pair by itself, even in considerably inert solvents, it seems proper to state that the acid-base pairing between the fluorophore and $HClO_4$ has the structure described by $N(>CO)\cdots H^{+}\cdot ClO_4^{-}$. However, in contrast to the case of TEA, no distinct sign of the proton transfer from $HClO_4$ to fluorophore could be found by absorption measurements in the nonhydroxylic solvents with $[HClO_4]$ less than 0.3 mol dm^{-3}.

Now that the information on the ground states is fully known, the fluorescent behavior of 7H4MC is to be explored; the typical fluorescence spectra in dioxane and in CH_3CN under the neutral, basic, and acidic conditions are compared to each other in Fig. 7. The light illumination for the neutral solution was carried out at 320 nm, which excited the N state; this yielded the $\overset{*}{N}$ fluorescence. For the acidic and basic solutions, they were illuminated at 360 nm, thus exciting the long-wavelength side of the acid-base-complex absorption (NH and NB) and yielding the $\overset{*}{NH}$ and $\overset{*}{NB}$ fluorescences respectively. Figure 8 schematically depicts the peak positions in **1**, **2a**, and **2b** under various solvent conditions, while Table 2 gives the results. The behavior of these bands can be clearly classified into two types. The fluorescence bands for the one are ordered in wavelengths $\overset{*}{N}<\overset{*}{NB}<\overset{*}{NH}$ (Class 1); for the other, they are ordered $\overset{*}{N}<\overset{*}{NH}<\overset{*}{NB}$ (Class 2). The solutions of benzene, dioxane, and ethyl acetate belong to Class 1 (Solvents **1**), while those of $CHCl_3$, CH_2Cl_2, acetone, and CH_3CN belong to Class 2 (Solvents **2**), the latter being further divided into two groups (Solvents **2a** and **2b**). Here, judging from the energy position and the spectral shape, the $\overset{*}{T}$ band, which was accompanied by the $\overset{*}{N}$ band in the hydroxylic solvents, was not found in any nonhydroxylic solvent. The tautomerization of $\overset{*}{N}$ to $\overset{*}{T}$ may be supposed to be triggered only when the solvent has sufficient hydrogen-bonding ability and ionizing power, as in water and alcohols. This has been proved by the finding that the $\overset{*}{T}$ band appears distinctly in the nonhydroxylic solvents upon the addition of a small amount of H_2O.

From Fig. 8 and Table 2, the following tendencies can, at least, be deduced: 1) The peak shift of the $\overset{*}{N}$ band in each solvent class is small. 2) The $\overset{*}{NH}$ band in **1** and **2a** is blue-shifted with an increase in *D*. 3) The $\overset{*}{NB}$ band in **1** and **2a** is red-shifted with an increase in *D*. 4) By the selective excitation of I, new fluorescence bands ($\overset{*}{I}$) appear around 450 nm in the basic solutins of **2a** and **2b** (dashed curves). Because the peak shift of the $\overset{*}{N}$ fluorescence as well as the N absorption is small, the neutral species in the nonhydroxylic solvents has nonpolar structures in the excited and ground states. Considering that the deprotonation from acids and the protonation to bases in the nonhydroxylic solvents

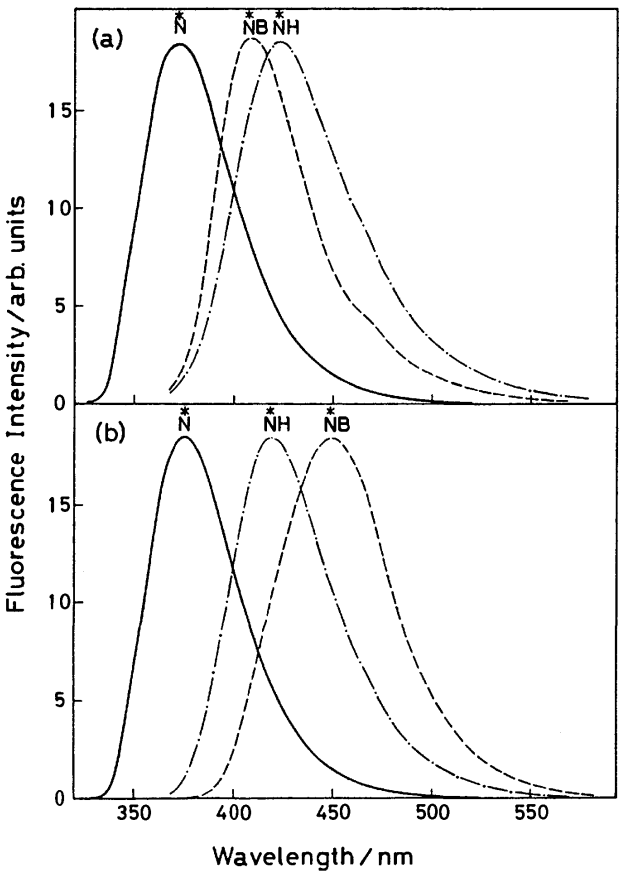

Fig. 7. Fluorescence spectra of 7H4MC in dioxane (a) and in CH_3CN (b) for the neutral (——), acidic (-·-·-), and basic (----) solutions at 20°C.

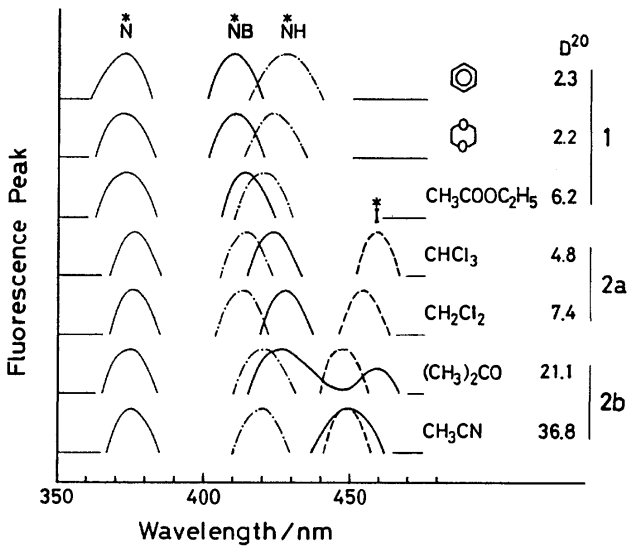

Fig. 8. Schematic drawings of the fluorescence peaks of 7H4MC in the nonhydroxylic solvents for the neutral (——), acidic (-·-·-), and basic (——) solutions excited at the main absorption band. The fluorescence peak shown by (----) was observed in the basic solutions of **2a** and **2b** excited at the long-wavelength absorption tail.

with lower D values are usually improbable, the $\overset{*}{NH}$ and $\overset{*}{NB}$ fluorescence in **1** and **2a** must originate from the excited-state acid-base complexes, analogous to the case in the ground state. Weller et al.[17] showed for several acid-base systems that a stronger hydrogen bond was possible in the excited state than in the ground state. Therefore, the larger red-shifts of the $\overset{*}{NH}$ and $\overset{*}{NB}$ bands from the $\overset{*}{N}$ band, compared with those of the NH and NB bands from the N band, are reasonable (Table 2). As D is increased, the $\overset{*}{NH}$ band systematically blue-shifts, but the $\overset{*}{NB}$ band red-shifts throughout the solutions of **1** and **2a**, in contrast to the small shifts of the NH and NB bands. Confining ourselves to the case in **1** and **2a**, which have D values less than 10, the fluorophore complexed with $HClO_4$ and with TEA is concluded to have a more polar structure in the excited state than in the ground state, although $\overset{*}{NB}$ is stabilized and $\overset{*}{NH}$ is destabilized by the increase in D. Such opposite tendencies result from the difference in the combining strengths of >CO ··· $HClO_4$ and -OH ··· NEt_3; the stabilization of the excited π-electron system due to the former is larger in **1**, while that due to the latter is larger in **2a**.

Several new features appear in the spectra when going from a low-D solvent to a high-D solvent. The most prominent feature is that the fluorescence spectra in the basic solutions of **2a** and **2b** depend complicatedly on the excitation wavelength; some typical examples for $CHCl_3$ and for acetone are shown in Fig. 9. Upon scanning the excitation towards longer wavelengths, the fluorescence spectra changed in shape and finally converged into a simple-shaped band at the excitation wavelength of 410 nm; this band is indicated by $\overset{*}{I}$ in Figs. 8 and 9. Since 410 nm corresponds to the pure I absorption, the $\overset{*}{I}$ fluorescence must result from the excited-state ion pair, $\overset{*-}{A}(-O^-)\cdots H\overset{+}{N}Et_3$. The ion-pair formation in the excited state has been confirmed by Weller et al. for a 2-naphthol-TEA system in methylcyclohexane.[17] Further, they have shown that the wavelength of the fluorescence increases with the promotion of ionization in the complex, in good accordance with the case of 7-hydroxycoumarins. In **2a**, the excitation of NB yields the pure $\overset{*}{NB}$ state, while the excitation of I yields the pure $\overset{*}{I}$ state; the critical transition of the excited state from $\overset{*}{NB}$ to $\overset{*}{I}$ upon a change in the excitation wavelength occurs at 400 nm, as may be seen from Fig. 9(a). This means that the potential barrier of the transformation between $\overset{*}{NB}$ and $\overset{*}{I}$ is large and that the proton transfer in the excited-state complex does not occur within its lifetime in the solutions of **2a**. In **2b**, on the other hand, the excitation of NB yields the long-wavelength component in addition to the $\overset{*}{NB}$ contribution, whereas the excitation of I yields only the pure $\overset{*}{I}$ state, as may be seen from Fig. 9(b). Such a feature comes from the large D values (more than 20) of **2b**. Probably, the potential barrier of the transformation between $\overset{*}{NB}$ and $\overset{*}{I}$ is small in **2b**, and so the following proton-transfer reaction becomes possible:

$$\underset{(\overset{*}{NB})}{\overset{*}{N}(-OH)\cdots NR_3} \rightarrow \underset{(\overset{*}{I})}{\overset{*-}{A}(-O^-)\cdots H\overset{+}{N}R_3} \qquad (7)$$

When $\overset{*}{NB}$ is generated from NB, a mixture of $\overset{*}{NB}$ and $\overset{*}{I}$ is observed by the fluorescence measurements, as may be understood from Eq. 7. The proton-transfer equilibrium in the excited state between species like $\overset{*}{NB}$ and $\overset{*}{I}$ has been extensively studied by Weller et al. for the 2-naphthol-TEA system;[17] the results are analogous to the present case. The stabilization of $\overset{*}{I}$ relative to $\overset{*}{NB}$ depends, of course, on the solvent employed. In this connection, the Class 2 solvents have been divided into two groups at the earlier stage of the analysis; one is comprised of $CHCl_3$ and CH_2Cl_2 (**2a**, halogenated aliphatic solvents), and the other, of acetone and CH_3CN (**2b**, solvents with polar groups such as >CO and -CN). From Table 2, the stabilization of the $\overset{*}{I}$ state from the $\overset{*}{NB}$ state in **2a** is pronounced, while that in **2b** is small or even absent. For the spectral change in **2b** with the excitation wavelength, the longer- and shorter-wavelength parts of the fluorescence band simultaneously decrease, while the center of the spec-

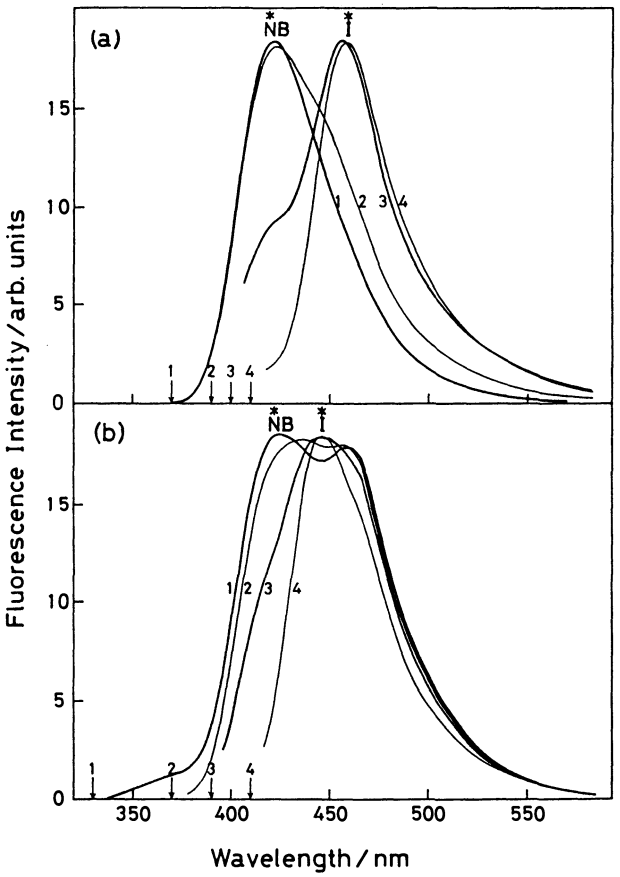

Fig. 9. Dependence of the fluorescence spectra of 7H4MC on the excitation wavelengths in the basic solutions of $CHCl_3$ (a) and of acetone (b). The arrows numbered show the excitation wavelengths for the corresponding fluorescence spectra.

tra is roughly maintained (see Fig. 9(b)). Possibly, the **2a** solvents are suitable for the stabilization of the ion pair, while various types of ion pairs[17] separated by such solvents as $\overset{*}{A}^{-}$ $(-O^{-})\cdots(\text{solvent})_n\cdots H\overset{+}{N}Et_3$ will take part in the fluorescence in **2b**, because **2b** has the hydrogen-bonding ability through the >CO and -CN groups, though it is very small. The hydrogen-bonding ability of the solvents affects the potential barrier for the ion-pair formation, thus making the excited-state reaction of Eq. 7 possible. The complicated behavior of the fluorescence in **2b** is a manifestation of the complex nature of the acid-base complex and the ion pair.

It becomes clear that the hydrogen bond between the fluorophore and TEA persists through the nonhydroxylic solvents. This can be understood from the fact that the only effective hydrogen donor in the basic solution is the 7-OH group of the fluorophore. On the other hand, $HClO_4$, is a rather unstable species as a hydrogen donor, especially in **2b**, due to the probabilities for self-ionization ($H^+ClO_4^-$), proton donation to solvents ($H^+\cdots ClO_4^-$), and protonation of the fluorophore ($\overset{*}{C}^{+}$ $(>COH^+)\cdots ClO_4^-$). Since the systematic blue shift of the $\overset{*}{N}H$ band is interrupted going from **2a** to **2b**, and since the peak position of $\overset{*}{N}H$ in **2b** is very close to that of $\overset{*}{C}^{+}$ in a hydroxylic solvent such as MeOH, a protonated fluorophore may be formed in the acidic solutions, i.e., $\overset{*}{N}H\approx\overset{*}{C}^{+}$ in **2b**. Similarly, the electronic state of $\overset{*}{I}$ in **2b** is thought to resemble that of $\overset{*}{A}^{-}$ of the hydroxylic solutions, judging from the good coincidence of their energy positions.

Fluorescence Behavior in Mixtures of Hydroxylic Solvents. The solvent polarity macroscopically represented by *D* is continuously changeable by using water-organic or organic-organic mixed solvents.[8] Since the excited-state reactions of 7-hydroxycoumarins have been sensitively influenced by the solvent polarity, it seemed fruitful to investigate further the fluorescence change in water-alcohol and alcohol-alcohol mixtures as typical examples. Figure 10 shows the fluorescence spectra of 7HC in a "weakly acidic" solution ($[HClO_4]=2\times10^{-5}$ mol dm^{-3}) and in an "acidic" solution ($[HClO_4]=0.2$—0.5 mol dm^{-3}) of H_2O-EtOH mixtures. Since the absorption was originated from N under these conditions, the optical excitation was fixed at 338 nm, near the absorption peak. In the weakly acidic solution the $\overset{*}{N}$ and $\overset{*}{A}^{-}$ bands, as well as the weak contribution of the $\overset{*}{T}$ band, are observable, while in the acidic solution the $\overset{*}{N}$ and $\overset{*}{T}$ bands, separated considerably in wavelength, are observable. As the ethanol content of the solutions (EtOH wt%) is increased, the polarity and the hydrogen-bond strength decrease continuously; they very much influence the stability of the excited states and the mobility of proton in the solutions.[18] From Fig. 10(a), the $\overset{*}{N}$ band in the wealky acidic solution enormously increases upon the increase in the EtOH wt%, while the $\overset{*}{A}^{-}$ band decreases. The weak $\overset{*}{T}$ contribution, noticed as a shoulder around 500 nm, seems to increase, though the quantitative separation of the overlapping $\overset{*}{A}^{-}$ and $\overset{*}{T}$ bands is difficult. The data can reasonably be explained if $\overset{*}{N}$ in the excited state

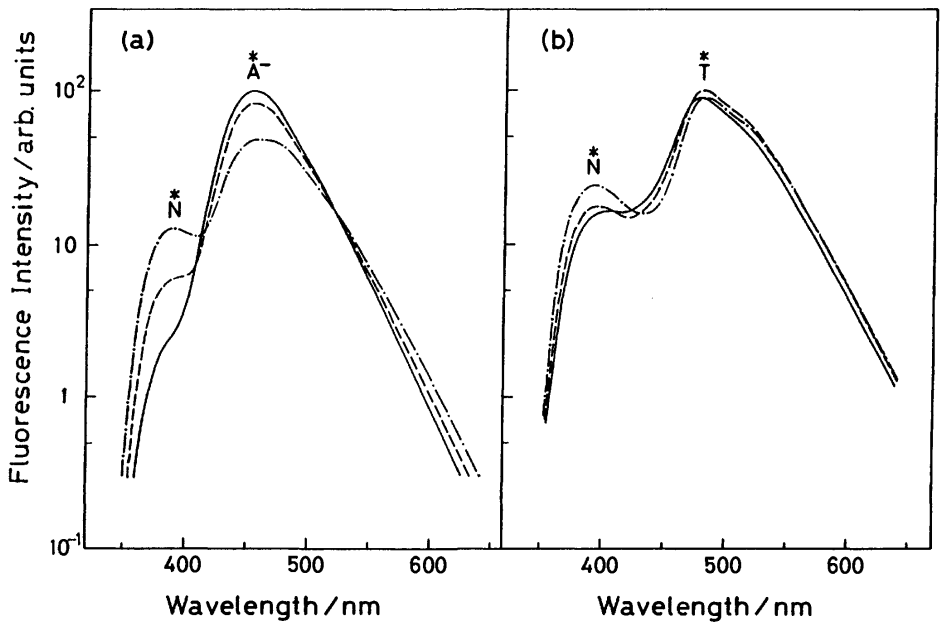

Fig. 10. Fluorescence spectra of 7HC in the H_2O-EtOH mixtures at 25 °C. (a), the weakly acidic solution ($[HClO_4]=2\times10^{-5}$ mol dm^{-3}) with the EtOH content: (——) 0 wt%, (----) 43 wt%, (-·-·-) 74 wt%. (b), the acidic solution ($[HClO_4]=0.5$ mol dm^{-3}) with the EtOH content: (——) 0 wt%, (----) 43 wt%, (-·-·-) 74 wt%.

becomes stabilized relative to $\overset{*}{A}^-$ under lower polarity conditions. It is instructive to note that the ionizing power of EtOH for the N state is much lower than that of H_2O, as has been shown in Fig. 2. Figure 11(a) shows the dependence of I^N/I_0^N on EtOH wt%, where I^N and I_0^N are the fluorescence intensities of the $\overset{*}{N}$ band in the water-ethanol mixtures and in pure water respectively.

As for the acidic solution with 0.5 mol dm^{-3} of $HClO_4$, the change is not straightforward (Fig. 10(b)). As the EtOH wt% is increased, the $\overset{*}{N}$ band increases and its peak position slightly blue-shifts, while the $\overset{*}{T}$ band increases at first and then decreases, with the peak position red-shifted. In Fig 11(b), the dependence of I^N/I_0^N and $(I^T/I_0^T)/(I^N/I_0^N)$ on EtOH wt% is plotted. Since the dependence of the fluorescence yield of each band on the solvent composition is not disregarded, it is difficult to know the precise reason for the curious behavior of the data at a low EtOH wt%. Nevertheless, becuase of the monotonic decrease in $(I^T/I_0{}^T)/(I^N/I_0{}^N)$ at higher EtOH wt% values, the generation rate of the tautomeric form, $\overset{*}{T}$, will be basically determined by the solvent polarity, which is intimately concerned with the promotion of the tautomerization processes from $\overset{*}{N}$ to $\overset{*}{T}$. In Fig. 5(a), log (I^T/I^N) vs. log D is plotted for the H_2O-EtOH system under acidic conditions. The same results for the MeOH-EtOH and EtOH-*i*-PrOH system are shown by the representative points (Δ) in Figs. 5(a) and 5(b). The plots for H_2O-EtOH deviate upwards from the straight dependence obtained earlier, while the plots for MeOH-EtOH and EtOH-*i*-PrOH follow the straight relationship. Obviously, H_2O is in a special position among hydroxylic solvents, because it can contribute a stronger hydrogen bond, even in a mixture, than can the alcoholic mixtures with similar D values. Since the participation of H_2O in the tautomerization of $\overset{*}{N}$ to $\overset{*}{T}$ has been shown to be most effective for the nondissociative pathway,[4] it can naturally be understood that the I^T/I^N of H_2O-EtOH system is larger than that of the alcoholic solvents (e.g., the value at MeOH in Fig. 5(a)). Further, H_2O may form an ordered aggregation of the "iceberg-like" structure around the fluorophore due to its manifold interactions, and the effective mobility of hydrogens may be raised compared with the value in the bulk solvent far from the fluorophore, where random structures of H_2O and EtOH prevail in the thermal equilibrium.

Solubilization into Micelles. It has recently been found that 7-hydroxycoumarins, as well as 7-ethoxycoumarins,[19] are solubilized into micelles formed in aqueous solutions of surfactants. When a surfactant with a concentration higher than the critical micelle concentration (cmc) is dissolved into the aqueous solutions of 7HC and 7H4MC, the fluorescent molecules are distributed between the micellar phase and the bulk-water phase. Such solubilization phenomena of fluorescers are detectable from the change in the fluorescence spectra as a function of the added concentration of surfactants (C_S).[19,20] Figure 12 shows the change in the fluorescence spectra of 7HC upon the addition of sodium dodecyl sulfate (SDS, cmc≈8×10^{-3} mol dm^{-3}); Fig. 12(a) shows the spectra measured under the "weakly acidic" conditions ([$HClO_4$]=3×10^{-4} mol dm^{-3}) at 25 °C, and Fig. 12(b), those measured under the "acidic" conditions ([$HClO_4$]=0.5 mol dm^{-3}).

As for the weakly acidic solution, the $\overset{*}{N}$ fluorescence increases and the $\overset{*}{A}^-$ fluorescence decreases upon the addition of SDS; the $\overset{*}{T}$ band seems to increase, though

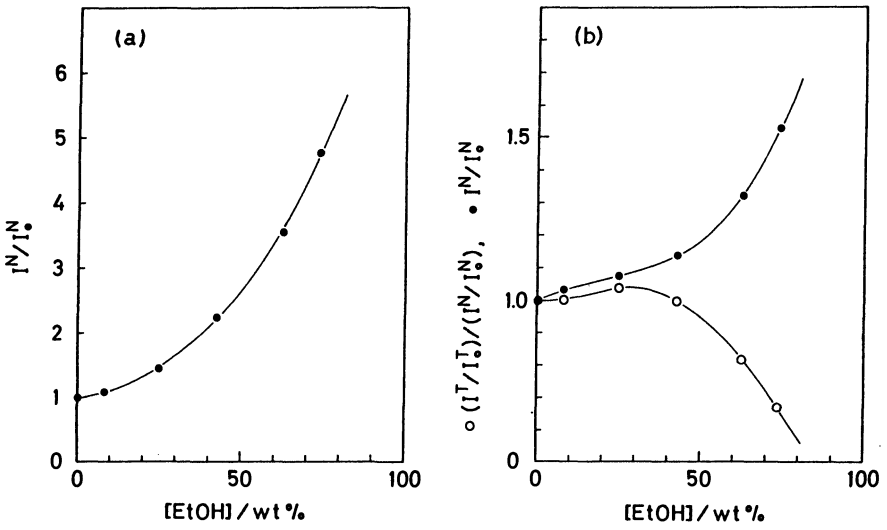

Fig. 11. Dependence of the relative fluorescence intensity of 7HC on the EtOH content of the H_2O-EtOH mixtures at 25 °C. (a), I^N/I_0^N (●) vs. EtOH wt% in the weakly acidic solution; (b), I^N/I_0^N (●) and $(I^T/I_0^T)/(I^N/I_0^N)$ (○) vs. EtOH wt% in the acidic solution.

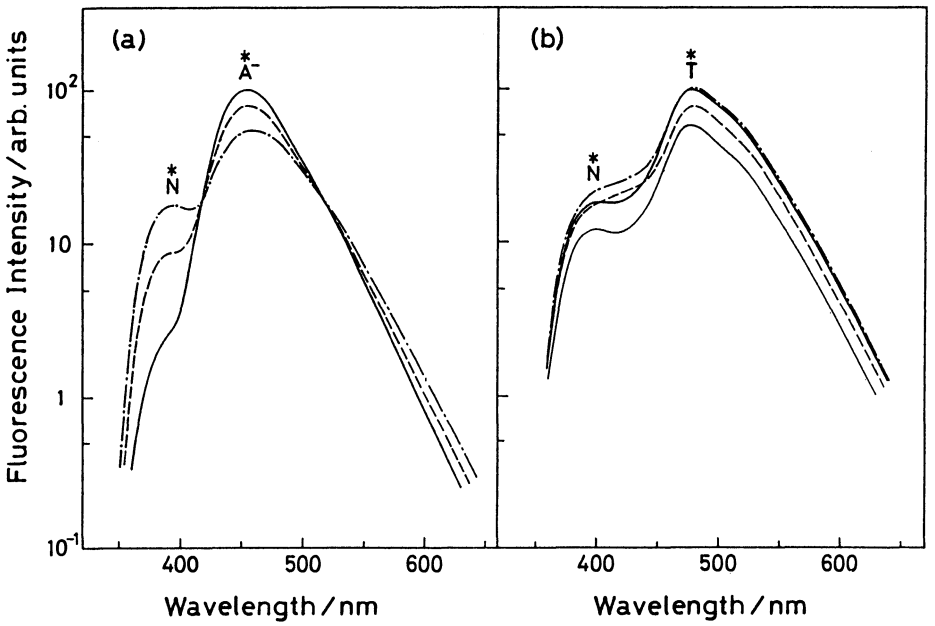

Fig. 12. Fluorescence spectra of 7HC in the aqueous micellar solutions of SDS at 25°C. (a), the weakly acidic solution ($[HClO_4]=3\times10^{-4}$) with the SDS concentration: (——) 0 mol dm^{-3}, (----) 15×10^{-3} mol dm^{-3}, (-·-·-) 50×10^{-3} mol dm^{-3}. (b), the acidic solution ($[HClO_4]=0.5$ mol dm^{-3}) with the SDS concentration: (——) 0 mol dm^{-3}, (-·-·-) 25×10^{-3} mol dm^{-3}, and the acidic solution ([HCl]=0.5 mol dm^{-3}) with the SDS concentration: (——) 0 mol dm^{-3}, (----) 25×10^{-3} mol dm^{-3}.

the quantitative separation of the overlapping $^*A^-$ and $^*T$ bands is difficult (Fig. 12(a)). Just as in the case of the H_2O-EtOH mixtures, the change is caused by the decrease in the microscopic polarity around the fluorophore solubilized into the micelle, for the interior of the micelle is hydrophobic and has a lower polarity than the bulk-water phase; the D value of the solubilized site within the micelle is between the values of aliphatic compounds (ca. 2) and of water (ca. 79).[19] Therefore, the overall spectral change upon the addition of the surfactant is, in effect, similar to that in the case of H_2O-EtOH (Fig. 10(a)). Figure 13 shows that the relative fluorescence intensity I^N/I_0^N begins to increase abruptly when the SDS concentration reaches a value near the cmc. Because the fluorescence change is extremely sensitive to the micelle formation in the solution, even a small-sized pre-micellar aggregation of SDS can be detected as a subtle upward deflection of the plots around 6×10^{-3} mol dm^{-3}. This value should be compared with the value of 8×10^{-3} mol dm^{-3} determined by such macroscopic properties of the solution as the ionic conductance.[21] The SDS concentrations from 6×10^{-3} to 8×10^{-3} mol dm^{-3} are considered to form the transition region from rather unstable pre-micellar formation to stable micellar formation in the equilibrium state. It should be mentioned here that the micellization proceeds as a result of the stepwise-association reaction, $D_{m-1}+S\rightleftarrows D_m$ (S is the surfactant monomer, D_m is the micelle with m surfactants, and $m\leqq n$, where n is the number of S in the stable micelle); strictly speaking, it is not a phase transition with a sharp variation in physical parameters. The change in the absorption spectra of several chromophores has usually been used as microscopic molecular probes for the micellization of surfactants.[21] The fluorescence change which reflects such excited-state reactions as

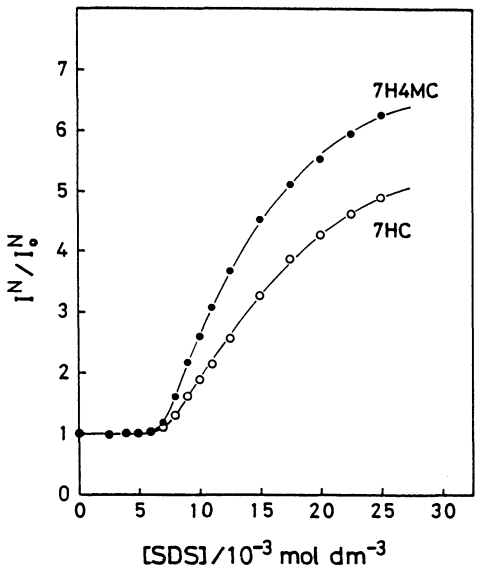

Fig. 13. Plots of the relative fluorescence intensity I^N/I_0^N vs. [SDS], for 7HC and 7H4MC in the weakly acidic solution at 25°C. The fluorescence intensity was monitored at 380 nm for 7HC (○), and at 370 nm for 7H4MC (●), respectively.

$\overset{*}{N} \rightleftarrows \overset{*-}{A}$ is another candidate for an optically sensitive probe of microenvironments being formed in the aqueous micellar system.

As for the acidic solution with 0.5 mol dm^{-3} of $HClO_4$, the fluorescence change is less pronounced than that of the weakly acidic solution. A weak contribution from $\overset{*+}{C}$ appears between the $\overset{*}{N}$ and $\overset{*}{T}$ bands upon the addition of SDS, as can be noticed by the disappearance of the dip between them; the apparent increase in the fluorescence around the $\overset{*}{N}$ band may be due to its contribution (Fig. 12 (b)). Since SDS is an anionic surfactant, cations are readily attached on the micelle surface and the [H^+] near the surface becomes higher than that in the bulk water. If the solubilization site of the fluorophore is not deep within the micelle,[19,20] the $\overset{*}{N}$ state generated from the solubilized N species by the light absorption will be protonated with H^+ concentrated near the surface; consequently, the $\overset{*+}{C}$ fluorescence will appear. It is well-established that halide ions are able to quench the fluorescence from the excited species of coumarins.[22-24] When the acid is altered from $HClO_4$ to HCl in the same concentration, the fluorescence intensity is decreased as a whole (Fig. 12(b)). Because the $\overset{*}{N}$, $\overset{*-}{A}$, and $\overset{*}{T}$ fluorescence were not quenched by Cl^- or ClO_4^- in the aqueous solution,[11] the fluorescence quenching by the addition of HCl instead of $HClO_4$ is attributable to the attractive interaction of $\overset{*+}{C}$ with Cl^-, which effectively induces the quenching. The $\overset{*+}{C}$ state generated by the excited-state reaction contributes, of course, to the tautomerization of $\overset{*}{N}$ to $\overset{*}{T}$ through the dissociative pathway and vice versa, although the $\overset{*+}{C}$ fluorescence is not detected to any extent in the solution without SDS. Therefore, both the $\overset{*}{N}$ and $\overset{*}{T}$ bands are decreased by the addition of Cl^- in the acidic solution. The total decay rate of $\overset{*+}{C}$ is composed of k_{41}, k_{43}, and the fluorescence quenching rate, k_q, corresponding to the $\overset{*+}{C} + Cl^- \rightarrow C^+ + Cl^-$ reaction; usually, their sum is larger than the generation rates of $\overset{*+}{C}$, $k_{14}[H^+]$ and $k_{34}[H^+]$, whereas these are somewhat enhanced for the fluorophore solubilized within the anionic micelle, resulting in the appearance of the $\overset{*+}{C}$ fluorescence. Since anions such as Cl^- are kept away from the surface of the anionic micelle, contrary to the case with H^+,[11] the quenching by Cl^- against the solubilized fluorophore must be weakened by the addition of SDS. The fluorescence intensity of the $\overset{*}{N}$ and $\overset{*}{T}$ bands has been recovered in the presence of the micelle relative to the value in the absence of the micelle, as may be seen from Fig. 12(b). Consequently, the $\overset{*}{N} \rightarrow \overset{*+}{C} \rightarrow \overset{*}{T}$ tautomerization pathway has been clearly confirmed by means of the fluorescence quenching and the solubilization phenomenon.

Conclusion

In order to explore systematically the complicated behavior of the fluorescence from the 7HC and 7H4MC solutions, solvents were divided into the two basic classes of hydroxylic and nonhydroxylic solvents, as popularly used in treating various chemical reactions in solutions. The fluorescence spectra in the hydroxylic solvents could be explained well by using the unified reaction model in the photo-excited states, which had been established by the study of the pH-dependent fluorescence in aqueous solutions. Especially, the fluorescence-intensity ratio between the neutral and tautomeric excited species in an acidic solution showed a remarkably straight relationship when log (I^T/I^N) was plotted against log D. This resulted from the competitive reactions of the tautomerization between the dissociative and nondissociative processes.

The fluorescence spectra in the nonhydroxylic solvents differed greatly from those in the hydroxylic solvents, for the ionizing power and the hydrogen-bonding ability were small. The low polarity of the solvents resulted in the stable formation of hydrogen bond complexes or ion pairs between various acids and bases. From the fluorescent behavior, the nonhydroxylic solvents could be further classified into these three groups; the extremely inert solvents such as dioxane (**1**), the halogenated aliphatic solvents (**2a**), and the solvents with polar groups, such as >CO and -CN (**2b**).

The fluorescence in the water-alcohol and alcohol-alcohol mixtures and that in the aqueous micellar solutions were measured under various conditions. The parameter of log D was well applicable to the alcoholic mixtures, although the aqueous alcohols behaved as stronger hydrogen-bonding solvents than had been expected. The solubilization of the fluorophore into the SDS micelle was detectable by the drastic change in the fluorescence spectra, and the possibility of the use of 7HC and 7H4MC as fluorescent probes of the microenvironment was pointed out.

Effect of Attractive Solvent-Solvent and Solvent-Solute Interactions on Partial Molal Quantities

Yosuke YOSHIMURA* and Masaru NAKAHARA
Department of Chemistry, Faculty of Science, Kyoto University, Oiwake-cho, Kitashirakawa, Sakyo-ku, Kyoto 606
(Received December 3, 1987)

The effect of the perturbation due to attractive solute-solvent and solvent-solvent interactions on the partial molal volume (PMV), entropy (PME), and enthalpy in infinitely dilute solution has been formulated on the basis of the first-order perturbation theory which comes from the van der Waals picture of liquid. PMV is found to be composed of the two compensating factors which arise from the solute-solvent and solvent-solvent attractive interactions treated as the perturbation; when the former is larger than the latter PMV becomes smaller. PME is influenced only indirectly by the attractive perturbation through the volume change due to the perturbation interactions. The limitations of the basic expressions derived are discussed in the case of large solute.

Although the perturbation theory of liquid has been developed to a large extent for the past two decades,[1-3] some fundamental problems still remain to be solved for its extensive application to the interpretation of the partial molal volume, entropy, and enthalpy in solution. In this paper we attempt to show how theoretical expressions for the partial molal quantities simply due to repulsive interactions are modified by the attractive interactions between solvent and solvent molecules and between solvent and solute molecules. This kind of study on the partial molal quantities is required for an advance in solution chemistry because it provides a theoretical framework for the molecular interpretation of the accurate experimental data accumulated for a variety of solution systems.

To understand the partial molal quantities, an interesting model was put forward by Sisskind and Kasarnowsky (SK) half a century ago.[4] This may be called "two-step dissolution theory" because a gaseous solute molecule is introduced into solvent in the following two steps: (i) the creation of a cavity in the solvent to accommodate the solute molecule and (ii) the introduction of the solute molecule into the cavity where the attractive interaction between the solute and solvent molecules is switched on. Pierotti used the SK model when he first transferred the fruit of the modern liquid theory to solution chemists.[5,6] He considered the first step in the reference system where no attractive interactions exist, and calculated changes in thermodynamic quantities accompanying the first step by applying the scaled particle theory. This SK picture is instructive but likely to make it ambiguous the role of the solvent-solvent interaction, as pointed out by Neff and McQuarrie (NM) on the basis of the mean field theory (a first-order perturbation theory).[7] Though a perturbation due to attractive interactions between solvent molecules is explicitly taken into account in the NM theory, the role of the solute-solvent and solvent-solvent interactions is not clearly explained. We shall present here simple and meaningful expressions for the partial molal quantities.

The standard form of the perturbation theory comes from the van der Waals (VDW) picture of liquid.[1-3] The VDW picture implies that the liquid structure is determined mainly by repulsive forces between molecules, and that attractive interactions can be regarded as the background mean field; the former forces are treated in the reference system and the latter as a perturbation. Although the VDW picture appears simple and intuitively perceptible, its implication is not so simple when it is applied to the partial molal quantities and their related properties. For example, the isothermal compressibility depends on the presence of attractive interactions as disclosed in this paper. On the other hand, however, the compressibility is directly related through the compressibility equation to the structure factor of liquid which is said to be dominated by repulsive interactions according to the VDW picture. Here we examine in detail how the two different views are related, and present a formulation of the partial molal volume, entropy, and enthalpy at infinite dilution on the basis of the first order perturbation theory. The present work is hoped to provide a perspective for understanding the molecular aspects of each partial molal quantity in solution.

Model of Solution

Our model system is composed of two species S and X; S is the solvent and X is the solute dissolved in S at infinite dilution. For simplicity, all the molecules are assumed to have the spherical symmetry. The molecules are characterized by the pair potentials

$$u_{YZ}(r) = u_{YZ}^{(0)}(r) + u_{YZ}^{(1)}(r), \quad (1)$$

where Y and Z denote S or X, and the superscripts (0) and (1) indicate the reference and the perturbed systems, respectively, and r is the separation. According to the VDW theory, the repulsive part of the intermolecular interaction is taken as the reference interaction and the attractive part as the perturbation. We take the number density of the reference system to be equal to that of the perturbed system.

In general, the repulsive interaction is very large and short-ranged. We assume that the reference potential is due to the hard-sphere interaction:

$$u_{YZ}^{(0)}(r) = +\infty \qquad 0 < r < \sigma_{YZ}$$
$$0 \qquad \sigma_{YZ} \leqq r, \qquad (2)$$

where the hard-core collision diameter σ_{YZ} is assumed to be independent of temperature and density. Since the reference system consists of the hard-sphere molecules, the radial distribution functions in the reference system are independent of temperature, and some restrictions are imposed on the thermodynamic behavior of the perturbed system as well as the reference system; see Appendix.

The attractive perturbation interactions $u_{YZ}^{(0)}(r)$ in Eq. 1 are assumed to vary slowly compared with σ_{SS} which characterizes the short range liquid structure determined by the hard-sphere molecules. This postulate is of great importance for making the mean field theory valid.

The van der Waals Picture for Solution Properties

Mean Field Theory of Solution. According to the present model of solution, the Hamiltonian of the system is described as

$$\mathcal{H} = \mathcal{H}^{(0)} + \mathcal{H}^{(1)}, \qquad (3)$$

where $\mathcal{H}^{(0)}$ is composed of the kinetic energy and the hard-core repulsive interactions between molecules and $\mathcal{H}^{(1)}$ is the perturbation due to the attractive interactions between molecules. According to the Bogoliubov variational theorem,[8] the following equation holds for the Helmholtz free energy A:

$$A \leqq A^{(0)} + \langle \mathcal{H}^{(1)} \rangle_0, \qquad (4)$$

where $A^{(0)}$ is the free energy of the reference system and $\langle \mathcal{H}^{(1)} \rangle_0$ is the ensemoble average of the perturbation in the reference system. In the mean field approximation (a primitive perturbation theory),[8] both sides of Eq. 4 are equal:

$$A = A^{(0)} + \langle \mathcal{H}^{(1)} \rangle_0. \qquad (5)$$

The pertubation term in Eq. 5 can be rewritten in terms of the radial distribution functions as follows:

$$\langle \mathcal{H}^{(1)} \rangle_0 = \frac{N_S^2}{2V} \int u_{SS}^{(1)}(r)\, g_{SS}^{(0)}(r)\, dr$$
$$+ \frac{N_S N_X}{V} \int u_{SX}^{(1)}(r)\, g_{SX}^{(0)}(r)\, dr, \qquad (6)$$

where $g_{YZ}^{(0)}(r)$ denotes the radial distribution function between Y and Z, which are X or S, in the reference system, N_S and N_X are the numbers of the solvent and solute molecules, respectively, and V is the volume of the solution. Though the second term in Eq. 6 disappears in the limit of infinite dilution of solute X, we need to retain it to derive expressions for the partial molal quantities of the solute as shown below.

In the reference system, the molecules occupy only one potential energy state, say 0, because they are hard. Since no changes in the population among the energy states and the probability density in the configurational space take place in the reference system, the entropy of the system is unaffected by the perturbation at the level of the mean field theory; this is easily demonstrated by differentiating Eq. 5 with respect to temperature.

First we examine the effect of the attractive interactions on the chemical potential of the solute because the chemical potential is the fundamental quantity which generates the partial molal quantities. The chemical potential of the solute X is directly obtained by differentiating Eq. 5 with respect to the number of molecules and taking the limit $n_X \to 0$,

$$\mu_X = \mu_X^{(0)} + n_S \int u_{SX}^{(1)}(r)\, g_{SX}^{(0)}(r)\, dr$$
$$+ \frac{n_S^2}{2} \int u_{SS}^{(1)}(r) \frac{\partial g_{SX}^{(0)}(r)}{\partial n_X} dr, \qquad (7)$$

where n_S and n_X are the number densities of the solvent and solute, respectively. Considering that the perturbation interactions $u_{SX}^{(1)}(r)$ and $u_{SS}^{(1)}(r)$ vary slowly compared with the short wavelength of the liquid structure, we can transform Eq. 7 into a more convienient form with a plausible approximation.

Figure 1 shows the solute-solvent radial distribution function $g_{SX}^{(1)}(r)$ and the solute-density derivative of the solvent-solvent radial distribution function, $n_S[\partial g_{SS}^{(1)}(r)/\partial n_X]$ in the hard-sphere system where $\sigma_{SS} = \sigma_{SX}$; the necessary information is available in the literature.[9]

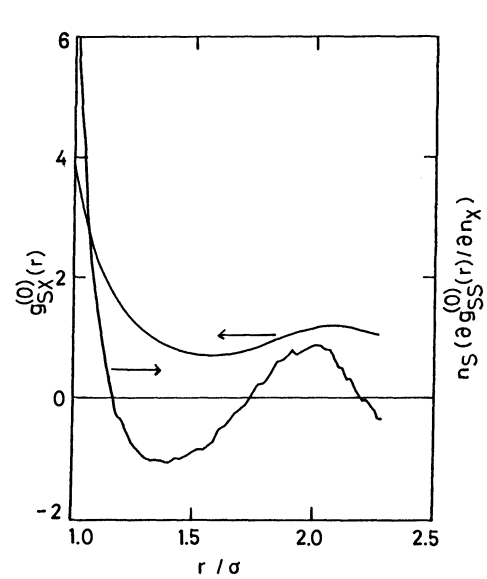

Fig. 1. The solvent(S)–solute(X) radial distribution function in the reference system, $g_{SX}^{(0)}(r)$ and the solute-density (n_X) derivative of the solvent–solvent radial distribution function, $n_S[\partial g_{SS}^{(0)}(r)/\partial n_X]$. $\sigma_{SX} = \sigma_{SS} = \sigma$; $n_S\sigma_{SS}^3 = 0.80$. The density derivative is obtained from the difference in the radial distribution function between $n_S\sigma_{SS}^3 = 0.75$ and 0.85.

The derivative of $g_{SS}^{(1)}(r)$ with respect to the solute density oscillates around zero with a wavelength of the order of σ_{SS}, and fades rapidly with increasing the distance. Since the perturbation pair potential $u_{SS}^{(1)}(r)$ varies slowly, the third term on the right-hand side of Eq. 7 may be ignored. On the other hand, the second term is insensitive to the number density but not negligible because $g_{SX}^{(1)}(r)$ oscillates around unity with a short wavelength. To this approximation, the chemical potential is composed of the following two terms as in the case of the Helmholtz free energy, Eq. 5:

$$\mu_X = \mu_X^{(0)} + n_S \int u_{SX}^{(1)}(r)\, g_{SX}^{(0)}(r)\, d\boldsymbol{r}, \tag{8}$$

$$= \mu_X^{(0)} + a_{SX} n_S , \tag{9}$$

where the integrand in the second term on the right-hand side of Eq. 7 or 8 is taken to be the constant a_{SX} because the integrand is independent of temperature and a dull function of the density as mentioned above. It is to be noted that when the third term on the right-hand side of Eq. 7 is neglected, the chemical potential of the solute becomes independent of the solvent-solvent perturbation interaction. Most of the following discussions are based on this assumption, and its limitations will be referred to later.

Equation of State of Pure Solvent. It is the equation of state of the pure solvent through that the solvent-solvent perturbation interactions affect the partial molal quantities of the solute. The equation of state is easily obtained from the Helmholtz free energy Eq. 5 by putting $N_X=0$. Differentiating the free energy with respect to the volume, we get the expression for pressure P as[1]

$$P = P^{(0)} + \frac{a_{SS}}{2} n_S^2 , \tag{10}$$

where $P^{(0)}$ is the pressure in the reference system. This is a generalized VDW equation of state, and a similar form of equation of state has been used for real system.[10]

Since the reference pressure $P^{(0)}$ is linearly dependent on temperature as shown by Eq. 38 in Appendix, and since a_{SS} is independent of temperature, we get the following equation for the reference pressure by differentiating Eq. 10 with respect to temperature T at constant density:

$$P^{(0)} = T\left(\frac{\partial P}{\partial T}\right)_V \tag{11}$$

It follows from Eqs. 10 and 11 that the "internal pressure" defined by $(\partial U/\partial V)_T$ is equal in magnitude to the attractive perturbation pressure with the sign opposite.

Long-Range Nature of Perturbation. The VDW theory of liquid is valid only for the short-range problem but not for the long-range one. We shall discuss this point according to Eq. 10.

The isothermal compressibility is related to the long-range part of the structure factor of liquid as follows:

$$\kappa kT = \frac{1}{n_S} + \int [g_{SS}(r) - 1] d\boldsymbol{r}. \tag{12}$$

where κ denotes the isothermal compressibility, $-(\partial V/\partial P)_T/V$. Note that the right-hand side of Eq. 12 indicates the Fourier component of the infinitely large wavelength of the total correlation function $g_{SS}(r)-1$. Thus the validity of the VDW picture for the long-range structure may be tested by comparing the isothermal compressibilities of the reference and the perturbed systems.

The VDW equation of state, Eq. 10, can be rewritten as

$$\frac{1}{\kappa} = \frac{1}{\kappa^{(0)}} + a_{SS} n_S^2 , \tag{13}$$

where α is the isobaric expansibility, $(1/V)(\partial V/\partial T)_P$. At 0.1 MPa, the pressure is negligible in comparison with the reciprocal of the compressibility (usually in the order of 1000 MPa). Thus the following equation holds at 0.1 MPa:

$$\frac{1}{\kappa} = \frac{1}{\kappa^{(0)}} + 2\left(-\frac{\alpha}{\kappa} T + P\right) , \tag{14}$$

where $\kappa^{(0)}=-(\partial V/\partial P^{(0)})_T)/V$. Let us show that the second term on the right-hand side of Eq. 13 is not negligible at 0.1 MPa. By inserting Eq. 11 into Eq. 10 and transforming the thermodynamic variables, we have

$$\frac{\kappa}{\kappa^{(0)}} = 1 + 2\alpha T. \tag{15}$$

Since the second term on the right-hand side is usually in the range of 0.6—0.8, it cannot be neglected; e.g., the value is 0.73 for carbon tetrachloride at 25 °C and 0.1 MPa.

The marked effect of the attractive perturbation on the isothermal compressibility tells us that the simple VDW picture is very useful for treating short-range problems but not accurate enough to describe the long-wavelength component of the liquid structure. This feature of the VDW picture has to be taken into account to calculate the thermodynamic quantities in the mean field approximation.

Partial Molal Volume

The partial molal volume is the quantity which reflects a response of the volume of the system to an increase in the number of the molecules of our interest. We can understand the way of the volume response using the following scheme: (i) The introduction of

the solute molecule into the solvent under isochoric conditions causes a pressure change, and (ii) the pressure change is transformed into the partial molal volume which is observed under isobaric conditions. These steps have quite different operational meanings; the second step depends on the compressibility of the whole system which is determined only by the solvent-solvent interaction, whereas the first step is characterized by the solute-solvent interaction. We show below how useful this picture is to understand the effect of perturbative interactions on the partial molal volume.

To make it easy to undestand how the partial molal volume is influenced by the attractive interactions through the pressure change, we may define a "partial molal pressure" P'_X[11] in the following way:

$$P'_X = (N_S+N_X)\left(\frac{\partial P}{\partial N_X}\right)_{T,V,N_S} \tag{16}$$

$$= -(N_S+N_X)\left(\frac{\partial \mu_X}{\partial V}\right)_{T,N_S,N_X}, \tag{17}$$

where the factor (N_S+N_X) is introduced in order to avoid the system size dependence of the "partial molal pressure." Inserting Eq. 9 into Eq. 17, we have

$$P'_X = P'^{(0)}_X + a_{SX}n_S^2, \tag{18}$$

where we take the limit $n_X \to 0$. Thus P'_X decreases with an increase in the perturbation between solute and solvent, without any influence of the solvent-solvent perturbative interaction. The exchange of the subscript S by X in Eq. 18 leads to the following expression for the "partial molal pressure" of solvent:

$$P'_S = P'^{(0)}_S + a_{SS}n_S^2. \tag{19}$$

This equation is consistent with Eq. 13 because the "partial molal pressure" of solvent is equal to the reciprocal of the isothermal compressibility of pure solvent.

The partial molal volume is directly related to the "partial molal pressure" as follows:

$$V_X = \frac{\kappa}{n_S+n_X}P'_X, \tag{20}$$

$$= \frac{\kappa}{\kappa^{(0)}}V_X^{(0)} + a_{SX}\kappa n_S, \tag{21}$$

where the limit of infinite dilution is taken. Using Eq. 13, we rewrite Eq. 21 as

$$V_X = V_X^{(0)} + \kappa n_S^2[a_{SX}V_S^{(0)} - a_{SS}V_X^{(0)}], \tag{22}$$

where we use the relation $V_S^{(0)}=n_S^{-1}$. This equation tells us that in contrast to P'_X, V_X is influenced by the solvent-solvent perturbative interaction through the compressibility. While P'_X decreases with increasing the solute-solvent perturbative interaction, κ increases with increasing the solvent-solvent perturbative interaction. The two factors compete in determining the partial molal volume.

One may expect that the perturbation effect on the partial molal volume will be small because of the presence of the competing factors in Eq. 22. This expectation is rationalized in the system where the solute molecule is identical in size with the solvent molecule in the reference system; $\sigma_{XS}=\sigma_{SS}$ and $g^{(0)}_{SX}(r)=g^{(0)}_{SS}(r)$. In this case the partial molal volume due to the attractive perturbation takes the simple form as

$$V_X^{(1)} = V_X - V_X^{(0)}$$

$$= \kappa n_S^2 V_X^{(0)}\int[u^{(1)}_{SX}(r)-u^{(1)}_{SS}(r)]g^{(0)}_{SX}(r)\,d\boldsymbol{r}. \tag{23}$$

The perturbation part of the partial molal volume arises from the difference in the attractive perturbation between solute-solvent and solvent-solvent pairs of molecules. When the solute-solvent attractive force is larger than the solvent-solvent attractive force, the partial molal volume of the solute is smaller than the reference value and vice versa. Especially when the solute-solvent interaction is identical with the solvent-solvent interaction, of course, the competing perturbations are canceled out.

Partial Molal Enthalpy and Entropy

We have shown in the preceding section that the "partial molal pressure" at constant volume has a simpler form than the partial molal volume at constant pressure. The same thing is said for the partial molal enthalpy and entropy. The partial molal energy $(U_X)_V$ and entropy $(S_X)_V$ at constant volume are given as

$$(U_X)_V = (U_X)_V^{(0)} + a_{SX}n_S, \tag{24}$$

$$(S_X)_V = (S_X)_V^{(0)} \tag{25}$$

The partial molal entropy at constant volume is unaffected by the perturbation interactions because no change in the molecular distribution over the energy states is brought about by the perturbation exerted on the reference system taken here.

As in the case of the partial molal volume discussed above, the conventional partial molal enthalpy and entropy can be derived from the corresponding partial molal quantities at constant volume as follows:

$$H_X = (U_X)_V + \frac{\alpha}{\kappa}TV_X, \tag{26}$$

$$S_X = (S_X)_V + \frac{\alpha}{\kappa}V_X. \tag{27}$$

The second term in Eq. 27 arises from the volume change due to the incorporation of the solute molecule into the solvent at constant pressure. The variation of the volume of the system actually causes a change in the probability density in the configurational phase space. This is the reason why the partial molal entropy is perturbed by the presence of the attractive forces.

Limiting Behavior of Large Solute

It is important to see the limitations of the basic assumptions used so far for deriving the expressions for the partial molal quantities. Only the partial molal volume is discussed below for this purpose.

Let us show that the expression for the partial molal volume, Eq. 21, fails to describe correctly the behavior of a large enough solute molecule. When the solute molecule is much larger than the solvent molecule, the second term in Eq. 21 may be estimated as

$$\kappa a_{SX} n_S = \kappa n_S \int u_{SX}^{(1)}(r) g_{SX}^{(0)}(r)\, dr,$$

$$= \kappa n_S u_{SX}^{(1)}(\sigma_{SX}) g_{SX}^{(0)}(\sigma_{SX}) \cdot \Delta \cdot 4\pi\sigma_{SX}^2, \tag{28}$$

where Δ is the length characteristic of the perturbation interaction; Δ may be as several times as large as σ_{SS}. This indicates that in Eq. 21, the second term of the order of σ_{SX}^2 becomes negligible compared with the first term of the order of σ_{SX}^3. As a result, the partial molal volume of the solute in the perturbed system becomes larger by the factor of $\kappa/\kappa^{(0)}$ than that in the reference system. In the limit of the large solute, on the other hand, the partial molal volume should become identical with the core volume of the solute, i.e., $(\pi/6)\,\sigma_{XX}^3 \simeq (4\pi/3)\sigma_{SX}^3$, both in the reference and the perturbed systems. Thus Eq. 21 cannot describe the true limiting behavior of the large solute.

The limitation of Eq. 21 disclosed above is ascribed to the neglect of the third term on the right-hand side of Eq. 7. The third term is negligible only when the size of the solute molecule is not very different from that of the solvent molecule. In other words, when the solute molecule is large enough, the effect of the solute molecule on the solvent-solvent radial distribution function is really long-ranged because of its large size.

It is difficult to obtain directly the derivative of the solvent-solvent radial distribution function involved in the third term in Eq. 7. However, its asymptotic behavior can be examined using the following relation which holds for the sufficiently large spherical solute:

$$-\frac{\pi}{6}\sigma_{XX}^3 (\delta N_X)_V = (\delta V)_{N_X}, \tag{29}$$

where $(\delta B)_Y$ denotes an infinitesimal change in quantity B at constant Y. Equation 29 shows the fact that the introduction of the macroscopic particle with volume v into the system at the constant volume has the same meaning as the shrinking of the system by the amount of v. Using Eq. 29, we evaluate the derivative involved in the third term in Eq. 7 as follows:

$$\frac{\partial}{\partial N_X}\left[\frac{N_S^2}{2V}\int u_{SS}^{(1)}(r) g_{SS}^{(0)}(r) dr\right] = \frac{\pi}{12}\sigma_{XX}^3 n_S^2$$

$$\times \left[\int u_{SS}^{(1)}(r) g_{SS}^{(0)}(r) dr - V\int u_{SS}^{(1)}(r)\frac{\partial g_{SS}^{(0)}(r)}{\partial V} dr\right], \tag{30}$$

$$= \frac{\pi}{12}\sigma_{XX}^3 n_S^2 a_{SS}, \tag{31}$$

where the second term on the right-hand side of Eq. 30 is neglected; note the relation

$$N_S[\partial g_{SS}^{(0)}(r)/\partial V] = -n_S^2[\partial g_{SS}^{(0)}(r)/\partial n_S]$$

and recall the reason for the neglect of the third term in Eq. 7. Following the abovementioned procedure for the partial molal volume, we have the relation

$$V_X = V_X^{(0)} + a_{SS}\kappa n_S^2\left[\frac{\pi}{6}\sigma_{XX}^3 - V_X^{(0)}\right], \tag{32}$$

where we neglect the term of the order of σ_{XX}^2, $a_{SX}\kappa n_S^2 V_S^{(0)}$. This equation correctly describes the limiting behavior of the large solute molecule; in fact, the second term disappears in the limit of large solute.

Probably because of the presence of the limitation of Eq. 21, Pierotti[5,6] gave a compromising expression for the partial molal volume as

$$V_X = \kappa kT(K_0 + K_1\sigma_{XX} + K_2\sigma_{XX}^2) + \frac{\pi}{6}\sigma_{XX}^3, \tag{33}$$

where K_0, K_1, and K_2 are the parameters which are given by the scaled particle theory as a function of the number density of the solvent, and k is the Boltzmann constant. Equation 33 gives the correct partial molal volume for the reference system where the solvent-solvent perturbation interaction does not exist, and has the correct partial molal volume in the limit of large solute. However, Eq. 33 is no longer valid for the system perturbed by the attractive solvent-solvent interaction, and the last term in Eq. 33 should read as $(\kappa/\kappa^{(0)})\,(\pi/6)\sigma_{XX}^3$ in the case of molecules of the common size, as pointed out by Neff and McQuarrie.[7]

Appendix

Thermodynamics of Hard-Body System. Some restrictions are imposed on the functional form of the thermodynamic quantities of the hard-body system. Such restrictions come simply from the fact that the internal energy of the hard-body system arises only from the kinetic energy of molecules and is independent of the configuration of the molecules. More explicitly, when the molecules have no internal freedom, the internal energy U is expressed by

$$U = \frac{3}{2}NkT, \tag{34}$$

where N and k are the total number of molecules and the Boltzmann constant, respectively. Thus the following equation holds for the hard-body system;

$$\left(\frac{\partial U}{\partial V}\right)_T = 0. \tag{35}$$

Using the thermodynamic relation, the following equations are derived from Eq. 35:

$$T\left(\frac{\partial P}{\partial T}\right)_V - P = 0, \tag{36}$$

$$\frac{P}{T} = \left(\frac{\partial P}{\partial T}\right)_V , \tag{37}$$

$$P = Tf(n), \tag{38}$$

where the $f(n)$ is the function of the number density n and independent of temperature and pressure. Using Eqs. 37 and 38 together with the Maxwell relation, we get the following equation:

$$\left(\frac{\partial S}{\partial V}\right)_T = f(n). \tag{39}$$

Thus the entropy is expressed as

$$S = S^* + \int_{V^*}^{V} f(n)\mathrm{d}V, \tag{40}$$

where the superscript * denotes the low density state of the system in which the system can be regarded as the ideal gas, and V the volume. The temperature dependence of the entropy in the hard-body system is identical with that in the ideal gas state. This equation denotes the fact that the configuration of the molecules are independent of the temperature in the hard-body system. The isothermal compressibility and the isobaric expansibility obey the following relations:

$$\frac{1}{\kappa} = Tn\frac{\mathrm{d}f(n)}{\mathrm{d}n}, \tag{41}$$

$$\frac{1}{\alpha} = \frac{1}{\kappa f(n)}, \tag{42}$$

$$= T\frac{\mathrm{d}\ln f(n)}{\mathrm{d}\ln n}, \tag{43}$$

where $f(n)$ is the function of n and independent of temperature. It can be shown that the behavior of the partial molal quantities in the hard-body system is also restricted; e.g., the partial molal volume is independent of temperature.

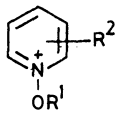
On the Reduction of *N*-Alkoxypyridinium Ions

Takashi SUMIYOSHI,* Meiseki KATAYAMA, and Wolfram SCHNABEL†
Department of Atomic Science and Nuclear Engineering, Faculty of Engineering, Hokkaido University, Sapporo 060
(Received December 4, 1987)

The reduction of 1-ethoxy-2-methylpyridinium (EMP^+) ions in aqueous solution at room temperature by e_{aq}^- and $\cdot CO_2^-$ was investigated in a pulse radiolysis study (irradiation with 10 ns pulses of 45 MeV electrons). For comparison, experiments with 1-methylpyridinium (MP^+) and unsubstituted pyridinium (PH^+) ions were carried out. With MP^+ and PH^+ the spectra of pyridinyl radicals were observed at the end of the pulse. In the case of EMP^+ the spectrum of the pyridinyl radical was not detectable. However, a new absorption band at 340 nm was formed with a significant delay after the reduction. Therefore, it was concluded that pyridinyl radicals formed by reduction of EMP^+ decompose very quickly into picoline and ethoxyl radicals. The latter add to EMP^+ with a rate constant $k=6\times10^7$ dm^3 mol^{-1} s^{-1}. The transient absorption band at 340 nm is ascribed to the adduct.

Recently, it was reported[1] that certain *N*-alkoxypyridinium salts of the general structure



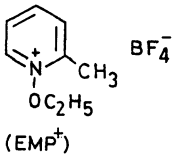
are quite appropriate to act as photoinitiators in free radical polymerizations of compounds possessing ethylenic double bonds. Since these pyridinium salts do not absorb light at $\lambda>300$ nm their utilization as photoinitiators in technical processes is possible only in conjunction with sensitizers. In Ref. 1 amino-substituted 3-ketocoumarins that absorb light at $\lambda>300$ nm were described as highly effective sensitizers. Although the mechanism of the interaction of excited sensitizers with pyridinium ions has not yet been disclosed, it appears probable that pyridinium ions are reduced by electron transfer according to the following mechanism:

$$S \longrightarrow S^* \quad (1)$$

$$S^* + Pyr^+ \longrightarrow S^+ + Pyr\cdot \quad (2)$$

Here, the following denotations are used:
S: sensitizer, S*: electronically excited sensitizer, S^+: sensitizer radical cation, Pyr^+: pyridinium ion, Pyr·: pyridinyl radical.

With respect to the initiation of free radical polymerization the question arises as to whether the pyridinyl radicals formed according to Reaction 2 are capable of reacting effectively with the monomer or Reaction 2 is followed by a rapid decomposition of the pyridinyl radicals yielding highly reactive species. In order to elucidate the reaction mechanism, the reduction of a typical *N*-alkoxypyridinium salt, namely 1-ethoxy-2-methylpyridinium tetrafluoroborate (EMP^+ BF_4^-) and of related compounds have been studied by means of pulse radiolysis. In this connection earlier work devoted to pyridinyl radicals is notable.[2-8] It was found, for instance, that the absorption spectra of pyridinyl radicals are characterized by rather strong maxima around 280 nm.



(EMP^+)

Experimental

Materials. 1-Ethoxy-2-methylpyridinium tetrafluoroborate (EMP^+ BF_4^-) was prepared according to a procedure described by Reichardt.[9] 1-Methylpyridinium tetrafluoroborate (MP^+ BF_4^-) was synthesized in the laboratory of Prof. H. Shirahama, Hokkaido University, and pyridinium chloride (PH^+ Cl^-) was a commercially available product (Wako Junyaku).

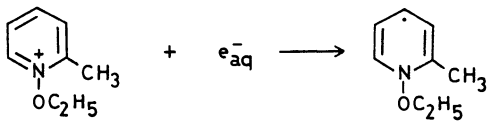
Irradiation of Sample Solutions. The pyridinium salts were dissolved in triply distilled water and irradiated in rectangular quartz cells with 10 ns pulses of 45 MeV electrons generated by a linear accelerator. As required samples were bubbled with argon or N_2O prior to irradiation. The absorbed dose was determined with the aid of the potassium thiocyanate dosimeter. Absorbed doses ranging from 20 to 130 Gy were applied to the solutions.

Results

(a) Experiments with 1-Ethoxy-2-methylpyridinium Tetrafluoroborate ($EMP^+BF_4^-$). (a-1) Reactions of Hydrated Electrons with EMP^+ Ions. The rate constant of the reaction of EMP^+ ions with hydrated electrons was measured by recording the decay of the optical absorption at 700 nm as a function of time after the pulse. Upon application of pseudo-first-order kinetic treatment $k(e_{aq}^- + EMP^+)=4.2\times10^{10}$ dm^3 mol^{-1} s^{-1} was obtained indicating that EMP^+ ions are reduced in a diffusion controlled reaction by hydrated electrons. In these experiments Ar-saturated aqueous solutions containing t-butyl alcohol (0.1 mol dm^{-3}) were used. The absorbed dose was 24 Gy. The decay of the absorption of the hydrated electrons was not accompanied by the formation of the absorption of the reduction product.

† On leave from Hahn-Meitner-Institut Berlin, Germany.

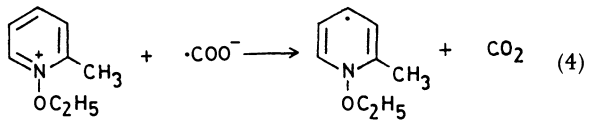
If pyridinyl radicals having a lifetime longer than the pulse length, were generated according to Reaction 3 a



(3)

transient absorption at $\lambda < 300$ nm should be formed simultaneously with the decay of the absorption of hydrated electrons. As can be seen from Fig. 1 a new absorption band was formed, however, with a formation lifetime definitely longer than that of the decay of hydrated electrons. Inset (a) in Fig. 1 shows the decay of the absorption of hydrated electrons at $[EMP^+BF_4^-]=1.12\times10^{-3}$ mol dm^{-3} and inset (b) shows the increase in the absorption at 340 nm at $[EMP^+ BF_4^-]=1.12\times10^{-3}$, 3.37×10^{-3} and 8.92×10^{-3} mol dm^{-3}. Obviously, the build-up rate increased with increasing concentration of pyridinium ions. Application of pseudo-first-order kinetic treatment yielded a bimolecular rate constant $k_2=6\times10^7$ dm^3 mol^{-1} s^{-1}.

(a-2) Reactions of $\cdot CO_2^-$ with EMP^+ Ions. The reduction of EMP^+ ions was also accomplished according to Reaction 4 by formate radical anions which were generated by reaction of hydroxyl radicals with formate ions according to Reaction 5.



(4)

$$\cdot OH + HCOO^- \longrightarrow H_2O + \cdot COO^- \quad (5)$$

Upon irradiation of N_2O-saturated $EMP^+BF_4^-$ solutions containig 0.05 mol dm^{-3} sodium formate the optical absorption spectrum (a) in Fig. 2 was formed during the pulse. It possesses a rather strong absorption band with a peak below 280 nm. The decay rate of this absorption band was found to be accelerated by increasing the pyridinium salt concentration. Actually, a similar rather strong absorption was also observed in the absence of pyridinium salt. Therefore, it is concluded that the absorption around 280 nm is due to $\cdot CO_2^-$ radical anions which are capable of reacting with pyridinium ions. The absorption peak of $\cdot CO_2^-$ radical anions has been reported to be located at about 250 nm, in aqueous solution.[10] In the present work, the ground state absorption of EMP^+ was very strong at wavelength below about 275 nm, making the solution almost opaque. Therefore, measurements of changes in the optical density below 280 nm were impossible. The decay of the absorption around 280 nm was followed up by the build-up of a new absorption band with a maximum at about 340 nm (spectrum (c) in Fig. 2). The rate of the reduction of EMP^+ ions by $\cdot CO_2^-$ ions was not correlated to the formation of the new absorption band as is demonstrated by typical kinetic traces shown in Fig. 3(a). Notably, the product of the reaction of $\cdot CO_2^-$ with EMP^+ could not be evidenced spectroscopically. Therefore, the reduction product must be very short-lived. In this respect, these findings correspond to results obtained with the reaction of hydrated electrons with EMP^+ (vide ante). In that case, quite similarly, the rate of decay of hydrated electrons did not correspond to the rate of formation of the new absorption band peaked at 340 nm. From the dependence of the lifetime of the absorption at 280 nm on the pyridinium salt concentration $k(\cdot CO_2^- + EMP^+)=2.1\times10^8$ dm^3 mol^{-1} s^{-1} was obtained. The rate of formation of the transient absorbing at 340 nm increased with increasing pyridinium salt concentra-

Optical absorption spectrum recorded 20 μs after the pulse. Insets: kinetic traces illustrating the decay of the absorption at 450 nm due to hydrated electrons (a) and the formation of the transient absorption at 340 nm at various concentrations of $EMP^+BF_4^-$ as indicated in the graph (b). D_{abs}=110 Gy.

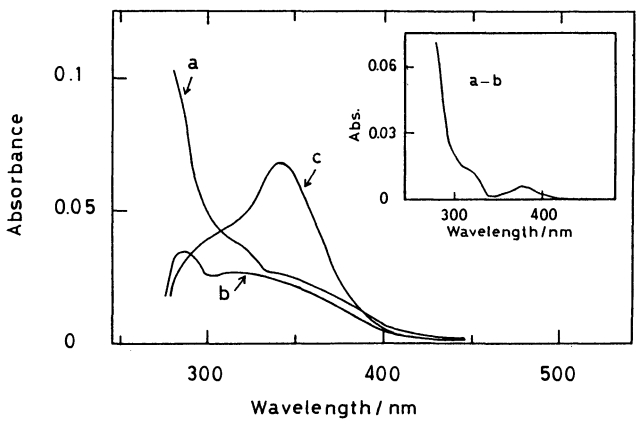


Fig. 2. Irradiation of $EMP^+BF_4^-$ (1.12×10^{-3} mol dm^{-3}) in N_2O-saturated aqueous solution containing 0.05 mol dm^{-3} sodium formate with a 10 ns pulse of 45 MeV electrons. D_{abs}=140 Gy. Optical absorption spectra recorded at the end of the pulse (a) and at 5 μs (b) and 80 μs (c) after the pulse. Inset: difference of spectra (a) and (b).

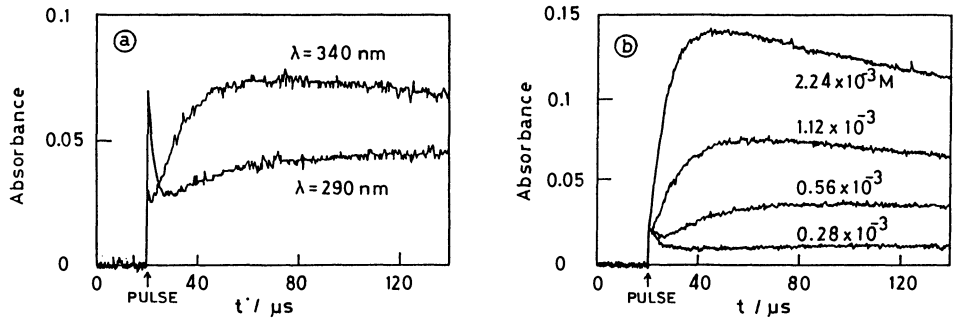

Fig. 3. Kinetic traces illustrating changes in the optical density after the pulse at λ=340 nm and 290 nm at [$EMP^+BF_4^-$]=1.12×10^{-3} mol dm^{-3} (a) and at 340 nm at various concentrations of $EMP^+BF_4^-$ as indicated in the graph (b). For other conditions refer to legend to Fig. 2.

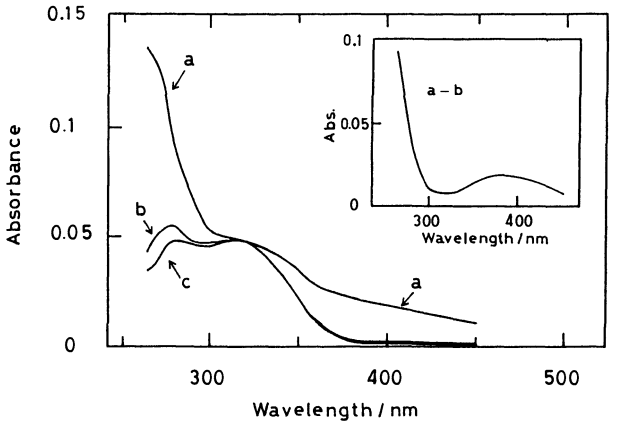

Fig. 4. Irradiation of $MP^+BF_4^-$ (1×10^{-3} mol dm^{-3}) in Ar-saturated aqueous solution containing *t*-butyl alcohol (0.1 mol dm^{-3}) with a 10 ns pulse of 45 MeV electrons. D_{abs}=140 Gy. Optical absorption spectra recorded at the end of the pulse (a) and 80 μs (b) and 160 μs (c) after the pulse. Inset: difference spectrum (a)—(b).

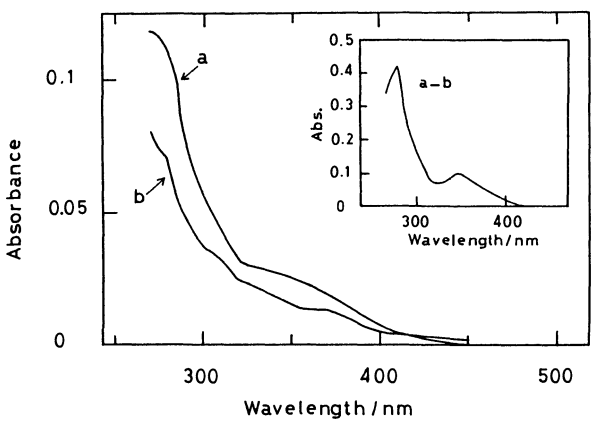

Fig. 5. Irradiation of PH^+Cl^- (6.1×10^{-4} mol dm^{-3}) in N_2O-saturated aqueous solution containing sodium formate (0.025 mol dm^{-3}) with a 10 ns pulse of 45 MeV electrons. D_{abs}=160 Gy. Optical absorption spectra recorded 500 ns (a) and 8 μs (b) after the pulse. Inset: difference spectrum (a)—(b).

tion yielding a bimolecular rate constant $k_2=8.2\times10^7$ dm^3 mol^{-1} s^{-1}.

(b) Experiments with 1-Methylpyridinium Tetrafluoroborate ($MP^+BF_4^-$). Upon reaction of hydrated electrons with MP^+ ions, i.e. upon irradiation of an Ar-saturated $MP^+BF_4^-$ solution containing *t*-butyl alcohol (0.1 mol dm^{-3}) the transient spectrum (a) in Fig. 4 was obtained. It possesses a strong absorption band with a maximum at $\lambda<280$ nm, which could not be disclosed due to the strong absorption of the 1-methylpyridinium salt in this wavelength range, and a weak band peaked at about 310 nm. The low wavelength portion of this spectrum decayed with a rate constant $k=4\times10^4$ s^{-1} leaving a long lasting spectrum with a broad maximum around 300 nm. Quite similar results were obtained with a N_2O-saturated solution containing sodium formate (0.05 mol dm^{-3}), i.e. in the case of the reaction of $\cdot CO_2^-$ with MP^+. Therefore, it is concluded that both hydrated electrons and $\cdot CO_2^-$ radical anions reduce MP^+ ions forming pyridinyl radicals. The rate of decay of hydrated electrons correlated with the rate of formation of the transient spectrum which is, therefore, assigned to the pyridinyl radical.

(c) Experiments with Pyridinium Chloride (PH^+Cl^-). Figure 5 shows a transient absorption spectrum (a) formed upon the reaction of $\cdot CO_2^-$ with PH^+, i.e. upon irradiation of a N_2O-saturated solution of PH^+Cl^- containing sodium formate (0.025 mol dm^{-3}). This spectrum possesses a maximum at about 270 nm. A quite similar spectrum was observed when hydrated electrons reacted with PH^+, i.e. when an Ar-saturated solution containing *t*-butyl alcohol (0.1 mol dm^{-3}) was irradiated. Also in this case, the rate of decay of hydrated electrons correlated with the rate of formation of the transient absorption spectrum as can be seen from Fig. 6, where the decay of the absorption at 450 nm (due to hydrated electrons) and the build-up of the absorption at 265 nm is shown. The latter absorption is, therefore, assigned to the pyridinyl radical. It should pointed out that the transient absorption spec-

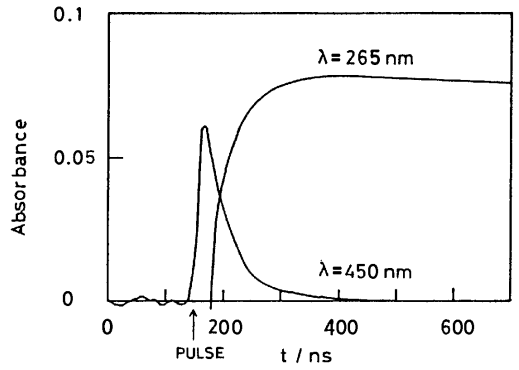

Fig. 6. Irradiation of PH^+Cl^- (8.15×10^{-4} mol dm^{-3}) in Ar-saturated aqueous solution containing *t*-butyl alcohol (0.1 mol dm^{-3}) with a 10 ns pulse of 45 MeV electrons. D_{abs}=140 Gy. Kinetic traces illustrating the decay of the optical absorption at 450 nm due to hydrated electrons and the formation of the optical absorption at 265 nm due to pyridinyl radicals.

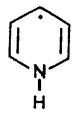
trum observed here is quite similar to the spectrum of the pyridinyl radical reported by Cercek and Ebert.[4]

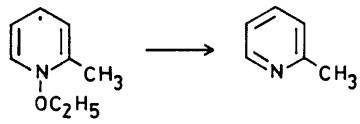
In conclusion, both $\cdot CO_2^-$ and e_{aq}^- were found to react with PH^+ forming the pyridinyl radical



which was detected by its characteristic absorption spectrum.

Discussion

The results show clearly, that, on reduction, the *N*-alkoxypyridinium ion EMP^+ exhibits a behavior quite different from that observed with *N*-methylpyridinium, MP^+, and pyridinium, PH^+. From the transient absorption spectra recorded after the pulse it is inferred that the latter two ions are converted to rather long-lived pyridinyl radicals upon reacting with hydrated electrons or $\cdot CO_2^-$ radical anions. In contrast, in the case of EMP^+ ions, the absorption of the corresponding pyridinyl radical was not observable, although EMP^+ reacts in a diffusion-controlled reaction with e_{aq}^-. From the fact that a new transient absorption band at 340 nm was formed a rather long time after the hydrated electron had reacted with EMP^+, it is concluded that the reduction product decomposes very rapidly, and that the resulting fragments are capable of reacting with EMP^+ ions. Upon studying the reduction of EMP^+ ions by $\cdot CO_2^-$ radical anions the same conclusion was arrived at. Also in this case pyridinyl radicals were not detectable spectroscopically, and the rate of decay of the radical anions did not correspond to the formation rate of a product absorbing at 340 nm. Consequently, it has to be assumed that the lifetime of the reduction product, the pyridinyl radical, is very short, probably shorter than one ns. The decomposition of the pyridinyl radicals leads to products which do not possess absorption bands in the wavelength range inspected (down to 260 nm) differing from that of EMP^+ or do not absorb at all at $\lambda>260$ nm. This conclusion is consistent with a decomposition mechanism according to Reaction 6, a process being comparable to dissociative electron capture processes occurring, e. g., with halogenated hydrocarbons:



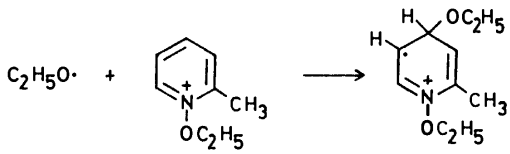
(6)

$$e^- + RCl \longrightarrow R\cdot + Cl^-$$

Ethoxyl radicals are not expected to absorb light markedly above 260 nm and the absorption spectrum of the other reaction product, 2-methylpyridine, is almost identical to that of EMP^+. According to this mechanism ethoxyl radicals are formed as reactive species capable of reacting, e.g., with olefinic compounds when *N*-alkoxypyridinium compounds are used as photoinitiators. In the present case, ethoxyl radicals are expected to undergo a self reaction according to Reaction 7, at sufficiently high $C_2H_5O\cdot$ concentration:

$$2\,C_2H_5O\cdot \longrightarrow \text{Products} \qquad (7)$$

Ethoxyl radicals can also react with EMP^+ ions. They can, for example, add to EMP^+ according to Reaction 8:



(8)

Reaction 8 is thought to give rise to the formation of the transient absorption peaked at 340 nm which is assigned to the adduct of ethoxyl radical to EMP^+. In accordance with this assignment, the formation rate of the transient absorption at 340 nm increased with inceasing EMP^+ concentration yielding the rate constant $k(C_2H_5O\cdot+EMP^+)=(6—8)\times10^7$ dm^3 mol^{-1} s^{-1}.

The authors are very grateful to Prof. Dr. Haruhisa Shirahama and his co-workers for synthesizing $MP^+BF_4^-$.

Hydrogen Formation from Water Adsorbed on Zeolite during Gamma-Irradiation

Masayoshi Aoki, Chiyoko Nakazato, and Takahiro Masuda*
Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Fukasawa 2-1-1, Setagaya-ku, Tokyo 158
(Received December 9, 1987)

The γ-radiolysis of water adsorbed on synthetic zeolite, MS 13X (Molecular Sieve 13X), has been investigated by the product analysis method using gas chromatography. One of the main products is molecular hydrogen, the G value of which increases with increasing amount of water adsorbed on MS 13X and reaches a first plateau (0.42) at ca. 4 mmol of water per g of MS 13X. At ca. 6 mmol g^{-1} of water, it resumes the increase and finally approaches a second plateau (1.2) at ca. 9 mmol g^{-1}. The formation of hydrogen is depressed by an electron scavenger, while ammonia, a scavenger of positive hole, enhances the hydrogen formation. The result indicates that hydrogen is produced through a reaction of water with electrons generated in MS 13X. The rate constant for the reaction of electrons with water adsorbed on MS 13X is estimated to be $(2.6\pm0.3)\times10^8$ dm^3 mol^{-1} s^{-1}, on the assumption that rate constants for reactions of electrons with some electron scavengers determined in liquid cyclohexane can be applied to this system.

Enhanced yield in the radiolysis of a substance adsorbed on solid has been explained in terms of the energy transfer from adsorbent to adsorbate. Exciton, electron, and positive hole have been proposed as energy carriers.[1-6] Recently we found that N_2O adsorbed on synthetic zeolite (Molecular Sieve 13X; abbreviated to MS) is radiolyzed to produce N_2 with a G value of 2.8, which is saturated against the adsorbed amount of N_2O.[7] In the presence of a second electron scavenger, $G(N_2)$ decreases with increasing amount of the second scavenger. Relative reactivities of electrons generated in MS toward several kinds of scavengers suggest that these electrons are similar to those produced in liquid 2,2-dimethylpropane with respect to reactivity.[8,9] This implies that electrons generated in MS are possibly in a "quasi-free" state. On the other hand, we found that adsorption of methanol alters relative reactivities to those observed in liquid cyclohexane or hexane.[5] In the system with methanol, molecular hydrogen is produced as a main product and the formation of hydrogen is explained by a mechanism including a reaction of electrons with adsorbed methanol. The estimated rate constant for the reaction of electrons with adsorbed methanol is much higher than that determined in liquid methanol. These suggest that electrons generated in MS adsorbing methanol is "slightly solvated" in a way similar to excess electrons in cyclohexane or hexane.[8-10]

The radiolysis of water adsorbed on MS is of interest in the reactivity and state of electrons generated in the system and their reaction with adsorbed water, because the reaction of "nearly dry" electrons with water can be approximated to a reaction occurring at the initial stage of radiolysis of liquid water.

In this study, an attempt was made to clarify the state of electrons generated in the MS-H_2O system by determining the relative reactivity of the electrons toward some electron scavengers. Molecular hydrogen was found to form from water adsorbed on MS and stepwise increase in $G(H_2)$ was observed with increasing amount of water. The relative reactivity determined by competition kinetics showed that electrons produced in this system are similar to those in the MS-CH_3OH system rather than those in MS-N_2O. The rate constant for the reaction of electrons with water adsorbed on MS was estimated by assuming that rate constants for reactions of electrons with some electron scavengers are the same with those obtained in liquid cyclohexane.

Experimental

Zeolite (Molecular Sieve 13X) was purchased from Nippon Kuromatokogyo K. K. The specific surface area is 1030 m^2 g^{-1}. Dinitrogen monoxide, ammonia, and sulfur hexafluoride were obtained from Takachiho Kagakukogyo K. K. and purified by distillation under vacuum before use. Carbon tetrachloride was obtained from E. Merck, Ltd.

The procedure of pretreatment of MS and introduction of adsorbates were described elsewhere in detail.[7] Molecular hydrogen and nitrogen were analyzed by gas chromatography according to the method employed in a previous work on silica gel.[4] Water was triply distilled after treatment with alkaline permanganate.

Results and Discussion

Molecular hydrogen is produced from water adsorbed on MS during γ-irradiation. The G value for hydrogen formation increases with increasing amount of water stepwise as shown in Fig. 1. G values are calculated on the basis of total energy absorbed by MS and water. At amounts below 6.6×10^{-4} mol g^{-1}, formation of hydrogen was hardly observed. This may be explained by consumption of water due to chemisorption of water by some active site of MS or reaction of hydrogen molecule or atom with the site, as has been discussed with the MS-CH_3OH system.[5] The formation of hydrogen is effectively depressed by electron scavenger. Figure 2 shows the dependence of $G(H_2)$ on the amount of several electron scavengers in the presence of 4 mmol g^{-1} of adsorbed water. At ca. 10^{-4}

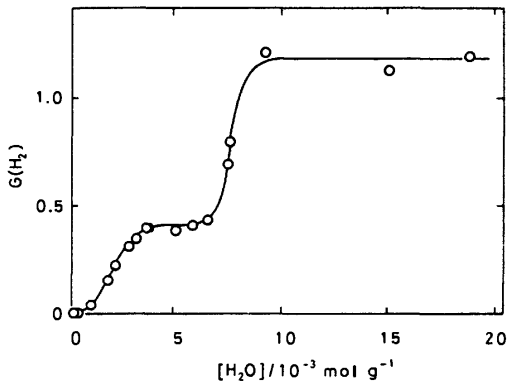

Fig. 1. Dependence of $G(H_2)$ on adsorbed amount of H_2O. Adsorbed amount is expressed as mol of H_2O per g of MS.

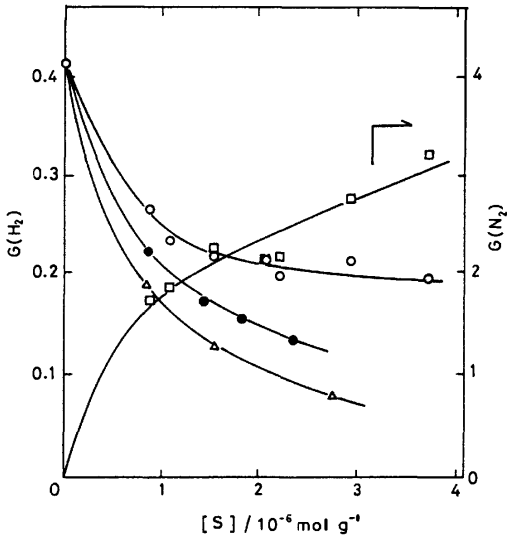

Fig. 2. Dependence of $G(H_2)$ and $G(N_2)$ on adsorbed amounts of scavengers. Adsorbed amount is expressed as mol of scavengers per g of MS. 4×10^{-3} mol g^{-1} of H_2O present. ○; N_2O, ●; CCl_4, △; SF_6, □; $G(N_2)$ produced from N_2O.

mol g^{-1} of scavengers, the formation of hydrogen is completely depressed in every case. Therefore, a precursor of hydrogen is thought to be eliminated by these electron scavengers. On the other hand, addition of ammonia, a positive hole scavenger, results in an enhancement of hydrogen formation. Since the formation of hydrogen from ammonia itself was hardly observed in the absence of water as shown in Fig. 3, the increase in $G(H_2)$ in the presence of water is caused by scavenging of positive hole. Therefore, molecular hydrogen is considered to be produced through a reaction of adsorbed water with electrons generated in MS. The formation of hydrogen is explained by the sequence of reactions

$$MS \longrightarrow MS^+ + e^-, \quad (1)$$

$$e^- + MS^+ \longrightarrow MS^*, \quad (2)$$

$$e^- + H_2O \longrightarrow H + OH^-, \quad (3)$$

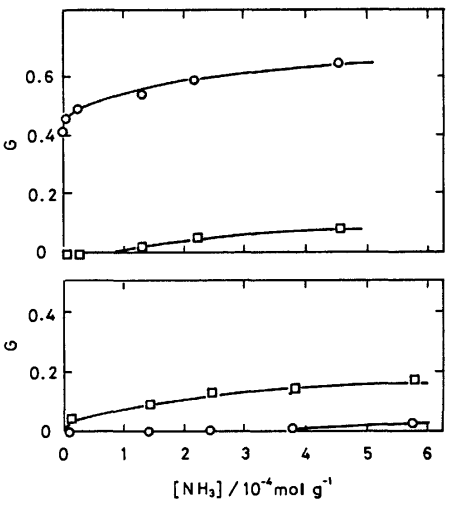

Fig. 3. $G(H_2)$ and $G(N_2)$ vs. $[NH_3]$. ○; $G(H_2)$, □; $G(N_2)$. Upper, 4×10^{-3} mol g^{-1} of H_2O present. Lower, H_2O absent.

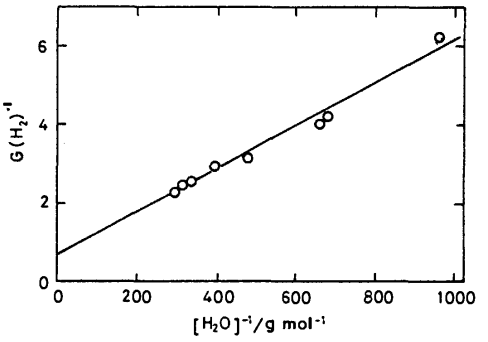

Fig. 4. $1/G(H_2)$ vs. $1/[H_2O_{ad}]$.

$$H + H \longrightarrow H_2. \quad (4)$$

In the presence of an electron scavenger or ammonia, Reaction 5 or 6 takes place:

$$e^- + S \longrightarrow \text{product(s)}, \quad (5)$$

$$MS^+ + NH_3 \longrightarrow \text{product(s)}. \quad (6)$$

From the above reactions, the following equation can be derived:

$$1/G(H_2) = 2(1 + k_2[MS^+]/k_3[H_2O_{ad}])/G_e \quad (I)$$

and

$$1/G(H_2) = 2\{1 + (k_2[MS^+] + k_5[S])/k_3[H_2O_{ad}]\}/G_e \quad (II)$$

where $[H_2O_{ad}]$ represents adsorbed amount of water. By plotting $1/G(H_2)$ against $1/[H_2O_{ad}]$ or $[S]$, G_e and the ratio of rate constants, k_5/k_3, can be estimated. Figures 4 and 5 are examples of the plots, which show a good linear relation. From the intercepts and slopes of these straight lines, G_e and the ratio of rate constants are calculated. In Table 1, the values estimated for various systems are summarized. G-values of electron agree fairly well with each other and the value (3.06 ± 0.07) is obtained as the average. From the ratio

of rate constants, k_5/k_3 relative rate constants based on k_{N_2O} can be calculated for CCl_4 and SF_6. In the last three columns, they are compared with those determined in liquid cyclohexane.[9,10] It is indicated that the electrons generated in water-adsorbing MS are similar to those in liquid cyclohexane with respect to the reactivity toward these scavengers. If the rate constants for these scavengers determined in cyclohexane are used as k_5, the rate constant for the reaction of the electrons with water adsorbed on MS is estimated to be $(2.6\pm0.3)\times10^8$ $dm^3\,mol^{-1}\,s^{-1}$ as an average (Table 2). This is quite different from the rate constant for the reaction of hydrated electrons with water in aqueous systems. As mentioned above, $G(H_2)$ increases with increasing amount of water stepwise and the experiments of scavengers were carried out at the amount of water which corresponds to the first plateau. Molecular Sieve 13X includes sodium ion of 6.4 $mmol\,g^{-1}$, which is known as a counterpart of the negative charge located on aluminium atom. Since the sodium ion in the hexagonal prism of MS cannot get into contact with water molecule, the content of the sodium ion effective for the adsorption of water will be less than 6.4 $mmol\,g^{-1}$. It can be considered, therefore, that the amount of the water at the first plateau is approximately equal to the effective amount of sodium ion. Furthermore, it is reported that water is adsorbed predominantly on the Na^+ sites of synthetic zeolite to form $(Na_4)^{3+}$-$(H_2O)_x$ by trapping an electron.[11,12] These suggest that hydrogen atom is formed from water through the reaction with sodium atom. Reaction 3 may be rewritten to

Table 2. Values of k_3 Calculated on the Basis of k_s Determined in Cyclohexane

Scavenger	$k_3/dm^3\,mol^{-1}\,s^{-1}$
N_2O	3.0×10^8
CCl_4	2.6×10^8
SF_6	2.3×10^8
Average	$(2.6\pm0.3)\times10^8$

$$e^- + Na^+ \longrightarrow Na, \quad (7)$$

$$Na + H_2O \longrightarrow Na^+ + OH^- + H. \quad (8)$$

This mechanism is consistent with the observed high reactivity of the electrons generated in the $MS-H_2O$ system toward water molecule.

One of the authors previously found that scavengers of positive hole with ionization potentials below 11.1 eV decolorize a color center of silica gel, which is assigned to a positive hole produced by γ-irradiation.[3] While the color center of silica gel is stable at room temperature, no absorption is observed in the case of irradiated MS. However, the electron affinity of MS^+ is at least above 10.85 eV, because methanol (I_p=10.85) reacts with MS^+ to produce formaldehyde and ethylene glycol.[5] Since the ionization potential of ammonia is 10.2 eV, the proposed mechanism including the scavenging of MS^+ by ammonia is reliable.

As seen in Fig. 2, the G value for nitrogen formation is apparently larger than the decrease in $G(H_2)$, even if $G(N_2)$ is equal to $2G(H_2)$. A similar disagreement in stoichiometry was observed in hexane and cyclohexane when N_2O was used as an electron scavenger.[13,14] As reported in a previous paper, the $G(N_2)$ from N_2O adsorbed on MS is 2.8 at adsorbed amounts of N_2O above 5×10^{-4} $mol\,g^{-1}$. In the presence of CH_3OH, values from 2.6 to 2.8 are estimated as G_e by plotting $1/G(H_2)$ vs. $1/[CH_3OH]$ or [S], whereas $G(N_2)$ is ca. 3.4 and differs from the G value of the electron scavenged by N_2O. Estimated G values for electrons generated in various systems of MS seem to converge in the neighborhood of 2.8. However, the $G(N_2)$ in the $MS-N_2O$ system differs from those in systems $MS-CH_3OH-N_2O$ and $MS-H_2O-N_2O$. The relative reactivity of the electrons produced in these systems toward some electron scavengers can be classified into two types, one observed in liquid 2,2-dimethylpropane and the other in liquid hexane or cyclohexane. These results suggest a resemblance in the energy state of excess electrons between liquid hydrocarbons and MS. The disagree-

ment of stoichiometry between $G(N_2)$ and G value of scavenged electron will, therefore, be related to the energy state of excess electrons generated in the irradiated systems.

Optical Absorption by Mn^{2+} Ions in $MnM(edta)\cdot 6H_2O$ (M=Zn, Cu, Ni, and Co)

Hisashi Togashi,*,† Norimichi Kojima, Toshiro Ban, and Ikuji Tsujikawa
Department of Chemistry, Faculty of Science, Kyoto University, Kyoto 606
(Received Decembder 9, 1987)

The optical absorption spectra of the Mn^{2+} ion in $MnM(edta)\cdot 6H_2O$ (M=Zn, Cu, Ni, and Co) were measured at low temperature. Fine structural bands corresponding to the $^6A_{1g}\rightarrow{}^4T_{2g}$ (D) and $^6A_{1g}\rightarrow{}^4A_{1g}$, ^4E_g (G) transitions were found. The fine structure corresponding to the $^6A_{1g}\rightarrow{}^4A_{1g}$, ^4E_g (G) transition in the Zn compound were analyzed with the ligand field theory and the assignment of the absorption peaks was performed. Although the spectra of the Zn, Cu, and Co compounds are similar, those of the Ni compounds show significant broadening, which is possibly due to the energy transfer caused by the overlapping of the absorption bands of the Ni^{2+} and Mn^{2+}ions.

Recently, bimetallic chelate complexes M′M″ (edta)·$6H_2O$ (M′,M″=metal elements in the 4th period, H_4edta= ethylenediaminetetraacetic acid) were synthesized[1,2] and their magnetic properties have been extensively studied.[3-6] It is because they are good models of one-dimensional ferrimagnets.

One can obtain large variety of isomorphous compounds with different magnetic interaction. In these crystals $[M'(H_2O)_4]^{2+}$ and $[M''(edta)]^{2-}$ are alternately bonded by the carboxyl group of the edta, hence bimetallic chains are formed.

The authors think that these compounds are suitable not only for the magnetic studies but also for the study on the interaction between the electronic states in different metal ions. Such studies have been practiced mainly on the crystals doped with foreign metal ions. However the spectra of the electronic transitions in such materials usually suffer inhomogeneous broadening, which is caused by the difference of the energy levels among the impurity sites. On the contrary, the spectra of M′M″ (edta)·$6H_2O$ will be free from inhomogeneous broadening because these compounds are pure crystals. Visible reflectance spectra of M′M″ (edta)·$6H_2O$ at room temperature were already measured by Escrivá et al.[7]

We prepared single crystals of $MnM(edta)\cdot 6H_2O$(M= Zn, Cu, Ni, and Co) and measured optical absorption spectra at low temperatures, for the purpose to observe the effects of the $[M(edta)]^{2-}$ on the electronic transitions in the $[Mn(H_2O)_4]^{2+}$.

First, preparation of the crystals and the measurement procedure are described. Secondly, the absorption spectra and the corresponding energy levels are discussed on the basis of the ligand field theory. Also we discuss the interaction between $[Mn(H_2O)_4]^{2+}$ and $[M(edta)]^{2-}$.

Experimental

$MnM(edta)\cdot 6H_2O$ (M=Zn, Cu, Ni, and Co) were obtained from the aqueous solution of $MnCl_2\cdot 4H_2O$ (1 mol), Na_2H_2 edta (1 mol), and nitrates or sulfates of M (1 mol) by heating on a water bath. The pH of the solution was adjusted between 5 and 6 by the use of Na_2CO_3 and HNO_3. The precipitated products were refined by recrystallization from water solution. The water solution of the recrystallized material was slowly evaporated at a temperature between 50 and 60 °C and yielded single crystals, of which typical dimension was 3×3×3 mm^3. The colors of the crystals were pale pink (M=Zn), blue (Cu), dark purple (Ni), and dark brown (Co).

It had been found[8] that the crystal structures of Cu and Co salts belong to an orthorhombic system C_{2v}^9-$Pn2_1a$ (Fig. 1). The X-ray diffraction pattern for the powder of our crystals of Cu and Co compounds agreed to these structures. From

the diffraction patterns of Ni and Zn compounds, they were found to belong also to the same space group. The lattice constants are shown in Table 1. From the similarity of the crystal parameters and of the spectra, which will be shown in the next section, it is confirmed that, in Ni and Zn compounds, a Mn ion is at the hydrate position and an M ion occupies the chelate position as well as Cu and Co compounds.

In order to measure the absorption spectra, the samples were immersed in liquid helium in a glass dewar. The temperature was lowered by pumping. A spectrometer Jobin-Yvon THR-1500 was used with an iodine lamp, and the electric signal were recorded on chart. When the temperature dependence of the spectra were measured, the samples were hinged to a copper block, with helium gas for heat exchange, sealed in a glass tube immersed in the liquid

helium. The copper block was heated by a manganin coil and its temperature was measured by a germanium and a platinum thermometer.

Results and Discussion

Preliminary measurement of absorption spectra was done at room temperature (Fig. 2). The absorption bands due to spin-allowed transitions in $[M(edta)]^{2-}$ (M=Cu, Ni, and Co) are so strong that most of them were saturated. Some absorption bands due to $[Mn(H_2O)_4]^{2+}$ were found. The assignment of the band peaks in Zn compound is shown in Table 2 (the peak energies agree with the results of Escrivá et al.[7]).

In the absorption spectra of Zn, Cu, Co, and Ni compounds at low temperatures, fine-structural bands were found in two energy regions, 27200—27400 cm^{-1} ($^6A_{1g}\rightarrow{}^4T_{2g}$(D)), and 24600—24900 cm^{-1} ($^6A_{1g}\rightarrow{}^4A_{1g}$, ^4E_g(G)), as shown in Figs. 3 and 4, respectively. Theoretically, the $^4T_{2g}$(D) term consists of 6 Kramers doublets, but we observed only two or three peaks which were separated by about 40 cm^{-1}.

As shown in Fig. 4, the absorption spectra of Zn, Cu,

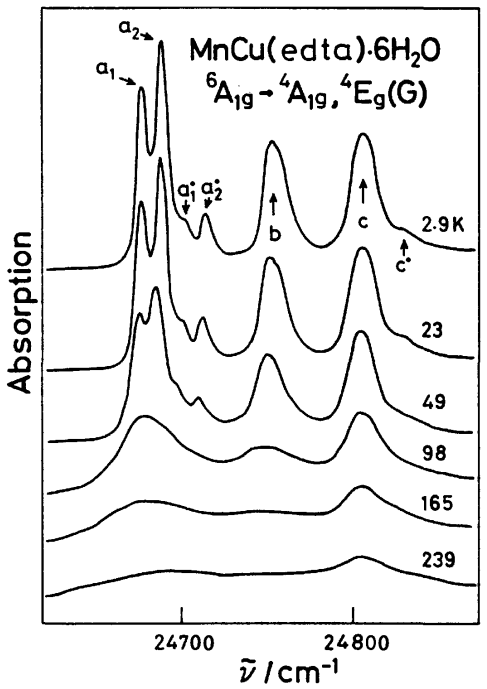

Fig. 5. Absorption spectra corresponding to $^6A_{1g}\rightarrow{}^4A_{1g}$, ^4E_g (G) transition in $MnCu(edta)\cdot 6H_2O$ at various temperatures. The spectra are intentionally shifted to the vertical direction.

and Co compounds in the $^4A_{1g}$, $^4E_g(G)$ region are similar in shape and peak energy. All absorption bands were characterized as due to electric dipole transitions. The absorption spectra can be grouped into three energy regions. We label the peaks and shoulders as shown in the left column of Table 3. The lowest energy region is composed of two peaks (a_1, a_2) associated with weaker peaks at higher energy side (a_1', a_2'); both the middle and the highest energy regions include a rather broad peak (b or c) with a weaker peak lying at higher energy side (b' or c'). For the Co compound the energy differences between a_1 and a_1', a_2 and a_2', b and b', and c and c' are all 25—26 cm^{-1}. Similar tendencies can be seen in the spectra of Zn and Cu compounds. Therefore it is considered that a_1', a_2', b' and c' are the sidebands which originate from a_1, a_2, b and c, respectively and that the elementary excitations corresponding to these sidebands are of the same energy.

In magnetic materials, elementary excitations usually appearing in the optical spectra are phonons and magnons. However, as the present compounds are concerned, the possibility of observing magnon sidebands can be excluded. As Zn^{2+} is not a magnetic ion, it inhibits the interaction between Mn^{2+} ions, then the magnon energy of Zn compound, if any, would be much smaller than the other compounds. Since the phonon energies are expected to be nearly the same because of the similarity in the crystal structure among these compounds, it can be concluded that these sidebands are phonon assisted ones.

The absorption spectra of $^6A_{1g}\rightarrow{}^4A_{1g}$, $^4E_g(G)$ transition in $MnNi(edta)\cdot 6H_2O$ are shown in Fig. 4(d), and the peak energies are listed in Table 3. This energy region is overlapping with the $^3A_{2g}\rightarrow{}^3T_{1g}(P)$ transition band in $[Ni(edta)]^{2-}$ (Ref. 9). In these spectra no splitting was observed for the a band, and the other peaks are also substantially broadened as compared with those in the other compounds. These broadening, of course, is not due to the inhomogeneity of the crystal. Nor does it seem to be due to the significant difference between Ni compound and the other ones in the way that the ligands coordinate to a Mn^{2+} ion, because the crystal parameters seem very similar among these materials (Table 1).

As will be shown later, the absorption hands a, b, and c are due to zero-phonon transitions. The width of a zero-phonon line can be explained[10] by the difference W in curvature between the potential curves for the ground and the excited states. We think that the shape of the potential curves of the $[Mn(H_2O)_4]^{2+}$ is changed, and then the W is increased, because of a resonant transfer of excitons between $^4A_{1g}$ and $^4E_g(G)$ band of $[Mn(H_2O)_4]^{2+}$ and $^3T_{1g}$ band of $[Ni(edta)]^{2-}$. However the elucidation of this phenomenon is the subject for future study.

In order to characterize the excitations corresponding to the absorption lines a_1, a_2, b, and c, we measured the temperature dependence of the absorption spectra of the Cu compound (Fig. 5). Since this compound

has the smallest sideband intensity among the three compounds, we thought that the overall intensity of the absorption in this region can be a good measure for the sum of the intensities of these peaks. The result shows the decrease of the intensity with increasing temperature (Fig. 6). This tendency is characteristic of pure electronic transitions. We analyzed the intensity change quantitatively, using an equation for the intensity of a zero-phonon transition line,[11] with the assumption that the excited state and the ground state have the potential curves of the same shape but the energies at their minima do not necessarily coincide. Also we assume that only one kind of phonon is involved in the temperature change of the zero-phonon transition. The equation is

$$\ln(I(T)/I_0) = -(E_0/\hbar\omega_0)[\coth(\hbar\omega_0/2kT)-1], \quad (1)$$

where $I(T)$ is the intensity at temperature T, I_0 the intensity at absolute zero, $\hbar\omega_0$ the energy of the phonon involved, and E_0 is the Stokes energy loss due to the mutual displacement of the curve minima. Parameters were obtained as E_0=65 cm^{-1}, $\hbar\omega_0$=123 cm^{-1} by the least squares method (Fig. 6).

The value of $\hbar\omega_0$ seems to be overestimated, because the temperature change of absorption intensity due to phonons is usually dominated by the phonon of lowest energy, and, as we already know, the 25 cm^{-1} phonon also exists in MnCu(edta)·6H_2O. This overestimation can be explained from the fact that the values of E_0 and $\hbar\omega_0$ are very sensitive to mixing of other bands (like phonon sidebands) with the intensity I. It is probable that phonon sidebands overlaps the bands of the zero-phonon transition, especially at higher temperatures. Nevertheless, the negative temperature dependence of the intensity of the origin peaks indicates that they are due to zero-phonon transitions.

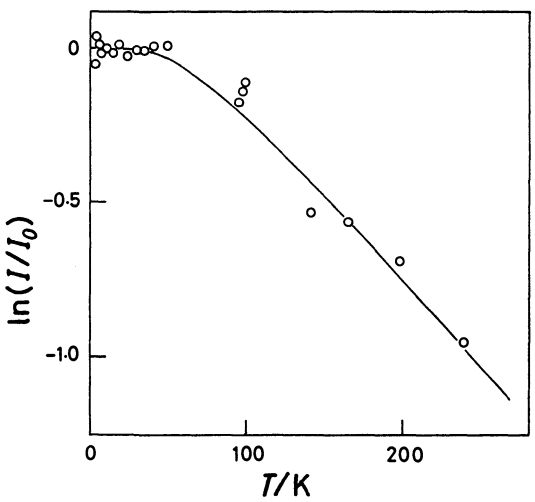

Fig. 6. Temperature dependence of the intensity of the absorption corresponding to the $^6A_{1g} \rightarrow {}^4A_{1g}, {}^4E_g$ (G) transition in MnCu(edta)·6H_2O. The solid line is the best fit one calculated from Eq. 1.

Next, we assign the a_1, a_2, b, and c peaks of MnZn (edta)·6H_2O to the 6 Kramers doublets of the $^4A_{1g}$, ^4E_g(G) terms. In the unit cell all sites of the Mn^{2+} ions are equivalent,[8] therefore all Mn^{2+} ions have the same energy levels.

In order to calculate the energy levels of the components in $^4A_{1g}$(G) and ^4E_g(G), it is necessary to obtain ligand field parameters[12] Dq, B, and C. As described previously a Mn^{2+} ion is coordinated by 4 water molecules and 2 carboxyl groups, forming a distorted octahedron. We calculated the ligand field parameters of this octahedron, using the room temperature data in Table 2, with the least squares method. The calculated energy levels are shown in the same table. These values, $10Dq$=8395, B=710, and C=3535 cm^{-1}, are very close to the parameters for $[Mn(H_2O)_6]^{2+}$, $10Dq$=8480, B=671, and C=3710 cm^{-1} (Ref. 13). This similarity seems to agree with the fact that $C_2O_4^{2-}$ is placed near H_2O in the spectrochemical series.

In coordination compounds of transition metal ions, in general, the most significant factor in lifting the degeneracy of the energy levels of a term ($^{2S+1}\Gamma$) is the ligand field of symmetry lower than cubic. As the site symmetry of Mn^{2+} ion in the MnM(edta)·6H_2O is 1, all kinds of lower symmetry fields, in some degree, contribute to the splitting. It seems that the largest contribution is from the ligand field of C_{2v} symmetry, because it is the highest symmetry a *cis*-MA_4B_2 cluster can have.

We approximate the cluster, $[Mn(H_2O)_4]^{2+}$ with two carboxyl groups, as *cis*-MA_4B_2 with C_{2v} symmetry. For the sake of calculation we define a cartesian coordinate system as follows: The direction of the linearly arranged A-M-A coincide with the z-axis and that the 2-fold axis of C_{2v} coincides with the $x+y$ axis. Also the one-particle wave functions of t_2 and e electrons are defined in the way that, under symmetry operations, wave functions ξ, η, and ζ of t_2 electrons are transformed like yz, zx, and xy, respectively, and u and v of e electrons behave like $3z^2-r^2$ and x^2-y^2, respectively.

When the potential V_0 of C_{2v} symmetry is expanded with r_i, which is the position vector of an i-th electron with its origin at the center of the metal ion, we obtain

$$V_0 = V_{cub} + V_{\alpha+\beta}^{(1)}(T_{1u}) + V_u^{(2)}(E_g) + V_\zeta^{(2)}(T_{2g}) + V_{\alpha+\beta}^{(3)}(T_{1u}) + V_u^{(4)}(E_g) + V_\zeta^{(4)}(T_{2g}) + (\text{higher order terms}), \quad (2)$$

where $V_{cub}=\sum v_{cub}(r_i)$ represents the cubic field potential, $V_\gamma^{(n)}(\Gamma_p)=\sum v_\gamma^{(n)}(\Gamma_p, r_i)$is a nth-order potential operator which is the γ component of an irreducible representation Γ of the cubic point group O_h, and p(=g, u) denotes the parity of the potential.

It is known that all the one-electron matrix elements among the $^4A_{1g}$, ^4E_g(G), and ^4E_g(D) levels are zero, Then, in order to lift the degeneracy of the $^4A_{1g}$ and ^4E_g(G), it is necessary to consider $^4T_{1g}$ and $^4T_{2g}$ terms.

Since the potential operators of odd parity are not important, we can assume that a perturbation Hamiltonian $V_L=V_\zeta^{(2)}$ (T_{2g}), neglecting the higher order terms than the second.

The wave functions of $^4A_{1g}$, $^4E_g(G)$, $^4T_{1g}$'s, and $^4T_{2g}$'s are described as

$$\psi(^4A_{1g}\, e_1\, 3/2)=(30)^{-1/2}\,(3|\xi\eta\zeta u\bar{v}|+3|\xi\eta\zeta\bar{u}v|-2|\bar{\xi}\eta\zeta uv|-2|\xi\bar{\eta}\zeta uv|-2|\xi\eta\bar{\zeta}uv|)$$

$$\psi(^4E_g(G)\, u3/2)=(42)^{-1/2}\,(4|\xi\eta\bar{\zeta}uv|-2|\xi\bar{\eta}\zeta uv|-2|\bar{\xi}\eta\zeta uv|-3|\xi\eta\zeta u\bar{v}|+3|\xi\eta\zeta\bar{u}v|)$$

$$\psi(^4E_g(G)\, v3/2)=(14)^{-1/2}\,(2|\bar{\xi}\eta\zeta uv|-2|\xi\bar{\eta}\zeta uv|-\sqrt{3}|\xi\eta\zeta u\bar{u}|+\sqrt{3}|\xi\eta\zeta v\bar{v}|)$$

$$\psi(^4T_{1g}{}^n\,\gamma\,3/2)=-\lambda_n|\xi\eta\bar{\zeta}\zeta u|-(\mu_n/\sqrt{2})\,(|\zeta\bar{\xi}\xi uv|+|\zeta\eta\bar{\eta}uv|)+\nu_n|\xi\eta uv\bar{v}|$$

$$\psi(^4T_{2g}{}^n\,\zeta\,3/2)=l_n|\xi\eta\bar{\zeta}\zeta v|+(m_n/\sqrt{2})\,(|\zeta\bar{\xi}\xi uv|-|\zeta\eta\bar{\eta}uv|)-n_n|\xi\eta vu\bar{u}|$$

(n=1, 2, and 3),

where superscripts n=1, 2, and 3 of $^4T_{1g}{}^n$ denote G, P, and F terms, respectively, and those of $^4T_{2g}{}^n$ correspond to G, D, and F, respectively, and the parameters λ_n, μ_n, ν_n, l_n, m_n, and n_n were obtained simultaneously with the determination of Dq, B, and C (Table 4).

The matrix elements of the $V_L=V_\zeta^{(2)}$ (T_{2g}) between ($^4A_{1g}$, $^4E_g(G)$) and ($^4T_{1g}$' s, $^4T_{2g}$'s) are expressed as

$$<^4T_{2g}{}^n\,\zeta|V_L|^4E_g(G)\,u>=(1/3\sqrt{14})\,(n_n-l_n)<e||v_\zeta^{(2)}(T_{2g})||t_2>$$

$$<^4T_{1g}{}^n\,\gamma|V_L|^4E_g(G)\,v>=(1/\sqrt{42})\,[\sqrt{3}(\nu_n-\lambda_n)<e||v_\zeta^{(2)}(T_{2g})||t_2>+4\mu_n<t_2||v_\zeta^{(2)}(T_{2g})||t_2>]$$

$$<^4T_{2g}{}^n\,\zeta|V_L|^4A_{1g}\,e_1>=(\sqrt{5/3}\sqrt{2})\,(l_n-n_n)<e||v_\zeta^{(2)}(T_{2g})||t_2>.$$

(n=1, 2, and 3)

The other matrix elements are zero.

The irreducible matrix elements $<t_2||v_\zeta^{(2)}(T_{2g})||t_2>$ and $<e||v_\zeta^{(2)}(T_{2g})||t_2>$ are equal to $\sqrt{6}<\zeta|v_\zeta^{(2)}(T_{2g})|\eta>$ and $\sqrt{3}<u|v_\zeta^{(2)}(T_{2g})|\zeta>$, respectively. For convenience, we approximate that

$$<t_2||v_\zeta^{(2)}(T_{2g})||t_2>=-(3/2)^{1/2}<e||v_\zeta^{(2)}(T_{2g})||t_2>,$$

which exactly holds when the field around the Mn^{2+} ion is spherically symmetric.

Table 4. The Coefficients λ_n,μ_n, and ν_n for $^4T_{1g}{}^n$ and l_n, m_n, and n_n for $^4T_{2g}{}^n$ in MnZn(edta)·6H_2O

	n=1	2	3
λ_n	0.977	−0.053	−0.207
μ_n	−0.125	0.643	−0.755
ν_n	0.173	0.764	0.622
l_n	0.843	−0.437	−0.312
m_n	0.441	0.895	−0.062
n_n	0.307	−0.085	0.948

By Koide and Pryce,[14] it has been shown that the difference in covalency between t_2 and e electrons can separate the $^4A_{1g}$ and $^4E_g(G)$ terms, even if the Mn^{2+} ion is in no lower symmetry field than cubic. Therefore we take into account the effect of the covalency by introducing a parameter Δ, which is defined as

$$\Delta\equiv E_0(^4E_g(G))-E_0(^4A_{1g}),$$

where $E_0(\Gamma)$ is the energy of a Γ term in the cubic field.

The covalency effect (Δ) and the low symmetry field (V_L) combine to separate the $^4A_{1g}$, $^4E_g(G)$ term into three states; $^4A_{1g}e_1$, $^4E_g(G)u$, and v. Furthermore each state is split into two Kramers doublets by spin-orbit interaction V_{so}, which will explain the energy difference between the a_1 and a_2 absorption lines. In the estimation of the magnitude of the spin-orbit interaction for the $^4A_{1g}$ and ^4E_g states, the effect of the α and the β components of the $^4T_{1g}{}^n$ and the ξ and the η components of the $^4T_{2g}{}^n$ can be neglected, because, they contribute, at the most, to the energies of $^4A_{1g}$, $^4E_g(G)$ through terms like

$$|<^4\Gamma e|V_{so}|^4T\delta>|^2/[E_0(^4\Gamma)-E_0(^4T)],$$

where $^4\Gamma e$ is the general expression of the components of the $^4A_{1g}$ and $^4E_g(G)$ terms and $^4T\delta$ represents $^4T_{1g}{}^n\alpha$, β and $^4T_{2g}{}^n\xi$, η. On the other hand, $^4T_{1g}{}^n\gamma$ and $^4T_{2g}{}^n\zeta$ contribute through terms like

$$<^4\Gamma e|V_L|^4T\psi><^4T\psi|V_{so}|^4\Gamma e>/[E_0(^4\Gamma)-E_0(^4T)],$$

where $^4T\psi$ denotes $^4T_{1g}{}^n\gamma$ or $^4T_{2g}{}^n\zeta$.

Therefore, the matrix elements which will significantly contribute to the splitting are calculated as

$$<^4T_{1g}{}^n\,\gamma\,M|V_{so}|^4A_{1g}\,M>=-(i/3\sqrt{15})\,[\sqrt{2}(\lambda_n-\nu_n)\,\zeta'+4\mu_n\zeta]M$$

$$<^4T_{1g}{}^n\,\gamma\,M|V_{so}|^4E_g(G)\,u\,M>=-(i/3\sqrt{21})\,[\sqrt{2}(\lambda_n-\nu_n)\,\zeta'+4\mu_n\zeta]M$$

$$<^4T_{2g}{}^n\,\zeta\,M|V_{so}|^4E_g(G)\,v\,M>=(i\sqrt{2}/\sqrt{21})\,(l_n-n_n)\,\zeta'M$$

(M=3/2, 1/2, −1/2, −3/2),

where $\zeta=(-i/3)<t_2||v_{so}||t_2>$ and $\zeta'=(i/3\sqrt{2})<t_2||v_{so}||e>$. We use the spherical-symmetry approximation also for the spin-orbit interaction parameters, in which $\zeta=\zeta'$.

With the use of the matrix elements obtained above, the energy levels of the $|^4A_{1g}\,e_1\,M>$, $|^4E_g(G)\,u\,M>$, and $|^4E_g(G)\,v\,M>$ ($M=\pm3/2,\ \pm1/2$) can be calculated. Neglecting the non-diagonal matrix elements between different spin states, we can reduce the secular equation of V_L+V_{so} between 36 components of $^4A_{1g}e_1$, ^4E_gu, and v, $^4T_{1g}{}^n\gamma$, $^4T_{2g}{}^n\zeta$ (n=1, 2, and 3) into 4 equations, each one corresponding to each spin state M. Because Kramers degeneracy still remains, we have to consider only two of them, e.g. those for M=3/2 and 1/2. We fixed the parameter ζ at 347 cm^{-1}, which is the value for a free Mn^{2+} ion, and adjusted the $<e||v_\zeta^{(2)}$

$(T_{2g})||t_2>$ and the Δ so as to fit the average energy of each state, $^4A_{1g}e_1$, $^4E_g u$, and v, to the corresponding one observed.

We obtained $<e||v_\zeta^{(2)}(T_{2g})||t_2>=1257$ and $\Delta=125$ cm^{-1}, and found that the (a_1, a_2), b and c bands correspond to the $^4A_{1g}$ e_1, ^4E_g v, and u states, respectively (Table 2). In the theory of Koide and Pryce, the effect of the covalency is taken into account by mixing the σ-orbitals of the ligands with those of the e-orbitals of the metal ion. The observed value of the Δ is a little larger than the theoretical upper limit, $\Delta=114.5$ cm^{-1}, which were estimated from the values of B and C. For the other compounds of Mn^{2+}, it was found[15] that a spin-doublet state situated near this energy region can influence the energy levels of the components of $^4A_{1g}e_1$, $^4E_g(G)u$, and v. Therefore it is possible that the calculated value of the Δ in MnZn (edta)·6H_2O is increased by the effect of a doublet state.

The calculated splittings of the $^4A_{1g}e_1$, $^4E_g(G)v$, and u due to the spin-orbit interaction are 4.6, 1.0, and 0.0 cm^{-1}, respectively. It is also found that the largest contribution to the eigenfunctions of these states is from the ζ components of $^4T_{2g}(G)$ or $^4T_{2g}(D)$ among the $^4T_{1g}$'s and $^4T_{2g}$'s. This result explains the fact that no splitting were observed in the b and c bands. However, for the splitting of the (a_1, a_2), the calculated value is smaller than the observed one. This descrepancy can be explained from the splitting of the $^4T_{2g}(G)$ or $^4T_{2g}(D)$ band due to the low symmetry field V_L; because the energy difference between each of these bands and the $^4A_{1g}$, $^4E_g(G)$ is only about 3000 cm^{-1}, it is possible that the energy shift of the ζ component of the either band toward the $^4A_{1g}$, $^4E_g(G)$ region increase the splitting of the $^4A_{1g}e_1$ state.

Figures 3 and 4 show that the absorption spectra of M=Zn, Cu, and Co compounds are very similar in shape, which implies that the interaction between $[Mn(H_2O)_4]^{2+}$ and $[M(edta)]^{2-}$ is not significant in these spectra.

Conclusion

The absorption spectra corresponding to the electronic transition in Mn^{2+} ion in MnM(edta)·6H_2O (M=Zn, Cu, Ni, and Co) were measured at low temperature.

It was found that the absorption spectra corresponding to the $^6A_{1g}\rightarrow{}^4A_{1g}$, $^4E_g(G)$ transition in Mn^{2+} ions in MnM(edta)·6H_2O (M=Zn, Cu, and Co) are similar to each other; the structure of their energy levels can be explained as caused by the covalency effect and by the interaction from the $^4T_{1g}$'s and $^4T_{2g}$'s through a low symmetry field $V_\zeta(T_{2g})$. The fine structure of the $^4A_{1g}$, $^4E_g(G)$ band in Zn compound was assigned, considering the splitting of the absorption peaks due to the spin-orbit interaction. In MnNi(edta)·6H_2O, although its spectra are similar to those of the other compounds in energy, its line widths are much broader than in the other materials. It seems that this broadening is related to the overlapping of the absorption bands of $[Mn(H_2O)_4]^{2+}$ and $[Ni(edta)]^{2-}$. However, further investigation is needed to solve this problem.

Calorimetric and Dielectric Studies of Phase Transitions in Rubidium Nitrite†

Keiichi MORIYA,†† Takasuke MATSUO, and Hiroshi SUGA*
Department of Chemistry and Chemical Thermodynamics Laboratory, Faculty of Science, Osaka University, Toyonaka, Osaka 560
(Received December 11, 1987)

The heat capacities of $RbNO_2$ crystal have been measured between 15 and 330 K. Two phase transitions were found at (264.04±0.06) K and (83.8±0.2) K. The enthalpy and entropy of transition are (9310±450) J mol^{-1} and (35.9±1.8) J K^{-1} mol^{-1} for the former and (48±5) J mol^{-1} and (0.58±0.05) J K^{-1} mol^{-1} for the latter. The entropy of the high temperature transition was interpreted in terms of the orientational disorder of the NO_2^- ion. The dielectric constant increased from 6 to 10 as the transition temperature 264.04 K was traversed from below, indicating the increased motional freedom of the polar anion in the high temperature phase.

A variety of phase transitions arising from orientational disordering of NO_2^- ions has been found in ANO_2 type compounds, where A represents an alkali metal or monovalent thallium.[1-7]

Rubidium nitrite crystallizes in the sodium chloride structure (space group O_h^5-Fm3m).[8] The NO_2^- ions having the C_{2v} symmetry must be orientationally disordered to be compatible with the octahedral symmetry of the anion site in the lattice. Occurrence of a phase transition is expected at a lower temperature because of the disorder. This offers a possibility of studying an order-disorder transition due to ionic orientations in a structurally simple crystal. In fact, Richter and Pistorius reported that $RbNO_2$ transformed to a low-temperature monoclinic phase at (261±2) K.[8] We studied the phase transition by calorimetric and dielectric methods.

Experimental

Sample Preparation. Rubidium nitrite was prepared from $Ba(NO_2)_2 \cdot H_2O$ and Rb_2SO_4(Merck Co., Ltd., suprapur reagent) in aqueous solution. The $Ba(NO_2)_2 \cdot H_2O$ crystal was prepared from extra-pure reagents of $NaNO_2$ and $BaCl_2 \cdot 2H_2O$ (both from Wako Pure Chemicals Co., Ltd.). Colorless crystals of $RbNO_2$ were obtained by slow evaporation of the filtered solution at 298 K. The crystals were purified by recrystallization from aqueous solution and washed with a small amount of ethanol. They were further purified by 30 passages of zone melting in a quartz tube. The crystals were carefully handled in nitrogen gas. Impurity ions found by atomic absorption spectra were Cs; 0.01%, Na; 0.02%, and K; 0.002%. The mass percent of the NO_2^- ion determined by the redox titration was 35% (calcd 35.0%). Nitrate ion impurity was less than 0.1% from the ratio of the Raman intensities of the internal vibrations of NO_3^- and NO_2^- ions.[9]

DTA and DSC. The enthalpy of fusion of $RbNO_2$ was determined by differential scanning calorimetry (Perkin Elmer Model DSC II). The DSC was run at the rate of 5 K min^{-1} from the room temperature to above the melting point. The temperature, enthalpy and the entropy of fusion were (693±3) K, (11.0±1.5) kJ mol^{-1} and (16±2) J K^{-1} mol^{-1}, respectively. The small entropy of fusion indicates that the ions are disordered in the solid phase.

Differential thermal analysis was made as a preliminary to the heat capacity measurement (Fig. 1). On the first cooling (Run 1), an exothermic peak appeared at 250 K. In the first heating run (Run 2), an endothermic and subsequent exothermic peaks appeared around 251 K. A second large endothermic anomaly occurred at 263 K. In the second heating run (Run 4), the two peaks around 251 K disappeared and only the endothermic peak at 263 K occurred. This result was interpreted as follows. In the pressure-temperature phase diagram of $RbNO_2$,[8] a triple point (300 bar, 261 K) was found, at which the high-temperature form I (Fm3m), the low-temperature monoclinic form II and the high-pressure form III (Pm3m) coexist. The temperature 250 K where the first endothermic peak occurred (Run 2) is close to the III-I phase boundary extrapolated to the atmospheric pressure. In the first cooling (Run 1), the sample transformed from the phase I to the metastable high-pressure phase III. It transformed exothermically to the stable monoclinic phase II on the subsequent heating and then endothermically to the stable high temperature phase I (Run 2). The hysteretic behavior thus deduced from DTA was

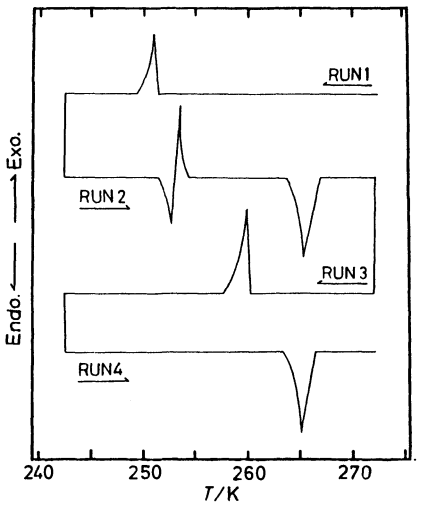

Fig. 1. DTA curves of $RbNO_2$ showing the stable–stable and metastable–stable transitions.

heeded in the following calorimetric experiment to prepare the sample in the stable form.

Heat Capacity Measurement. Heat capacities of $RbNO_2$ crystal were measured with an adiabatic calorimeter between 13 and 330 K. The calorimetric apparatus was described elsewhere.[10-13] The sample crystal was 36.947 g in mass corresponding to 0.28102 mol. The molar heat capacities are plotted in Fig. 2 and the numerical values are given in Table 1. Graphically smoothed heat capacities and derived thermodynamic functions are given in Table 2. A small heat-capacity anomaly occurred at (83.8±0.2) K. The anomaly at (264.04±0.06) K corresponds to the endothermic peak at (261±2) K found by DTA. The anomalous heat capacity appears to start to be significant far below the transition temperature. The disordering proceeded with increasing temperature until it completed discontinuously at the phase transition. No short range effect was found in the heat capacity of the high-temperature phase in contrast to the case of $NaNO_2$[1,14] where such an effect was very significant. The time required for the thermal equilibration in the calorimeter increased near the phase transition to about three days compared with fifteen minutes normally required. Such a behavior is often observed in the first-order phase transition.

Boak and Staveley measured the heat capacity of $RbNO_2$ between 83 and 483 K.[15] General temperature dependence of the present data agrees satisfactorily with theirs where the two sets of data overlap, although the absolute values are somewhat different. The small anomaly at 83.8 K has not been reported previously. However, the hysteretic behavior

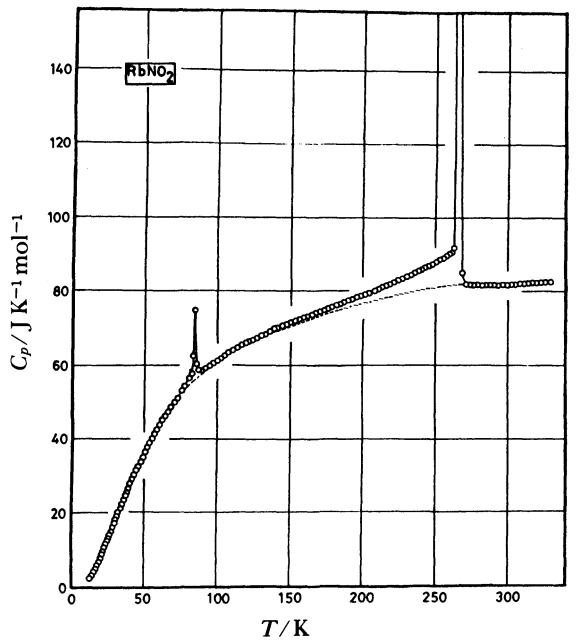

Fig. 2. Heat capacity of $RbNO_2$. The broken line represents the normal heat capacity calculated by the Debye and Einstein approximation optimized for $T \leq 65$ K.

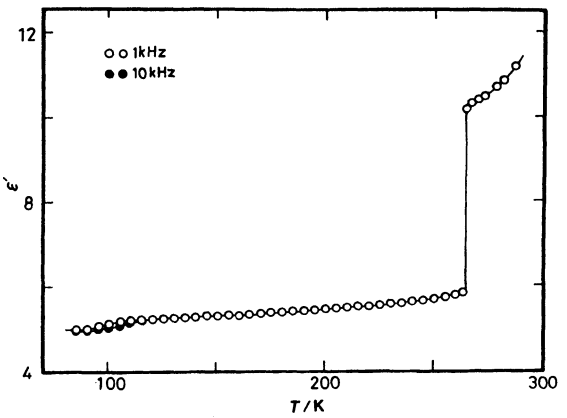

Fig. 3. Dielectric constant of $RbNO_2$ at 1 and 10 kHz.

found by the DTA has its counterpart in Boak and Staveley's calorimetric data that depended on the sample history in the corresponding temperature region. The two sets of data also agree with respect to the extended temperature range of the main anomaly below the transition temperature. The low temperature data ($T<80$ K) obtained in the present study are useful for the computation of the phonon heat capacity because the low frequency part of the entire lattice and molecular vibrational spectra is most significantly represented in the heat capacity of this temperature range.

Dielectric Constant. The dielectric constant was measured on a polycrystalline sample disc with a capacitance bridge, General Radio model 1615A, at 1 and 10 kHz. The sample was placed in a doubly thermostated environment. The temperature was regulated to 0.1 K between 80 and 290 K. As Fig. 3 shows the main transition (from phase II to I) is accompanied by a strong discontinuity of the dielectric constant characteristic of a first order phase transition. There is also a gradual increase of the dielectric constant below the transition point, corresponding to the similar gradual increase in the heat capacity.

A weak frequency dependence was found around 100 K. The magnitude of the dielectric dispersion is much smaller than those found in $TlNO_2$[2] and $CsNO_2$.[6] It is probably related to the residual disorder associated with the main transition. Because of the difference in the temperature, the dielectric dispersion and the subsidiary transition at 83 K cannot be connected with each other.

Results and Discussion

The Vibrational Heat Capacity. It is assumed that the observed heat capacity can be separated into the normal (vibrational) and the anomalous (configurational) parts. In order to evaluate the enthalpy and entropy of the phase transition, the normal heat capacity has to be estimated. $RbNO_2$ has $3 \times 4 = 12$ degrees of freedom, of which 6 degrees of freedom are the translational motion of Rb^+ and NO_2^- ions. The remaining 6 degrees of freedom are rotation (3) and internal vibrations (3) of the NO_2^- ion. The contributions from the acoustic and optical translational modes were calculated using the Debye and Einstein functions with the characteristic temperatures 108.0 and 188.3 K. The rotation vibration of the NO_2^- ion was approximated

with three independent one-dimensional vibrations of the characteristic temperature of 184.7 K. These characteristic temperatures were determined by fitting the Debye and Einstein functions to the heat capacity data between 15 and 65 K by the use of the nonlinear least squares method. There are three internal vibrations, symmetric stretching $\nu_1(A_1)$, antisymmetric stretching $\nu_2(B_2)$, and bending $\nu_3(A_1)$ modes, in the NO_2^- ion. Vibrational heat capacities of the three modes were calculated by the Einstein functions and taken into account in the least squares fitting as the known component of the total heat capacity. The vibrational frequencies, 1240 cm^{-1} (ν_1), 1320 cm^{-1} (ν_2), and 804 cm^{-1} (ν_3), were determined from the Raman and infrared spectra. The temperature dependence of the vibrational frequencies was neglected. The C_p-C_v correction becomes significant at higher temperatures. This term was calculated by the Nernst-Lindemann equation.[15]

$$C_p - C_v = A(T/T_p)C_p^2, \quad (1)$$

where $A=0.00112$ K mol J^{-1}. In this equation, T_p is the triple point temperature (approximated with the fusion temperature). The normal heat capacity was thus calculated as the sum of these five contributions.

$$C_p = C(\text{ac. translation}, 3D) + C(\text{opt. translation}, 3E) + C(\text{rotation}, 3E) + C(\text{internal}, 3E) + C_p - C_v. \quad (2)$$

Here, E and D stand for the Einstein and Debye functions, respectively. The numbers in the parentheses give the numbers of the degrees of freedom included in each term. The normal heat capacity thus calculated is given by the broken lines in Fig. 2.

The lengthy calculations involved in the optimization of the Debye and Einstein temperatures by the nonlinear least squares fitting described above were performed on a personal computer running on the BASIC. The Debye and Einstein parametrization of the vibrational heat capacity and the optimization procedure have been successfully applied to the simpler as well as more complex cases than the present one, including D_2O ice,[17] RbCN,[18] CH_3NH_3I,[19] $(CH_3NH_3)_2(TeBr_6)$,[20] $(CH_3NH_3)_2(TeI_6)$,[20] $NH_3NH_2H(CO_2)_2$,[21] and $(CD_3ND_3)_2(SnCl_6)$.[22]

No enthalpy relaxation was found in the entire temperature range. In $CsNO_2$[3,6] and $TlNO_2$[2,6] enthalpy relaxation related to the ionic reorientation occurred at low temperatures. Strong relaxational effects were also found in the dielectric measurement for these compounds. By contrast, the dielectric constant of $RbNO_2$ as a function of the temperature showed only a minor dispersion (Fig. 3). This agrees with the absence of the enthalpy relaxation in the calorimetric work.

The Enthalpy and Entropy of Transitions. The enthalpies of the transitions were determined by integrating the excess heat capacity and adding the latent heat of the transition to the integrated value. The entropies were determined in a similar way using the excess heat capacity divided by the temperature. They are collected in Table 3.

Table 3. Enthalpies and Entropies of the Phase Transitions of $RbNO_2$

T_t/K	ΔH_t/J mol^{-1}	ΔS_t/J K^{-1} mol^{-1}
83.8±0.2	48±5	0.58±0.05
264.04±0.06	9310±450	35.9±1.8

The entropy of transition determined from the high pressure phase equilibrium is 25.3 J K^{-1} mol^{-1}.[8] The previous calorimetric determination gave 32.3 J K^{-1} mol^{-1},[15] slightly smaller than the present value. The difference between the two calorimetric data may not be significant in view of the probable errors involved. The subsidiary transition at 83 K was found here for the first time and there are no other experimental data to compare with. The small entropy of transition suggests that the subsidiary transition is not an order-disorder change.

Configurational Entropy of the High-Temperature Phase. The phase equilibrium study[8] has shown that the volume change associated with the main transition is negligibly small. Therefore, it is reasonable to assume that the transition entropy is logarithmically related to the change of the number of the orientations available to the ions in the two phases.

$$\Delta S = R\ln(W_h/W_l). \quad (3)$$

Here R is the gas constant and W_h/W_l the ratio of the numbers of accessible ionic orientations in the high- and low-temperature phases, respectively. W_l may be equated to 1, because the NO_2^- ion is most probably ordered in the low-temperature phase in view of the absence of the large scale dielectric dispersion and the glass transition. The ionic disorder in the high-temperature phase is assumed to be orientational rather than positional in the sense that the positions of Rb^+ and NO_2^- ions are fixed on the fcc lattice points. We assumed further that the NO_2^- ions themselves are rigid so that they retain the C_{2v} symmetry in the crystal. Our problem is then to enumerate the allowed ionic orientations compatible with the average face-centered cubic symmetry. There is no configurational entropy for the spherically symmetric Rb^+ ion at the 4a position. The NO_2^- ion having the C_{2v} symmetry on the 4b position in the fcc Bravais lattice is obviously disordered. A nitrite group positioned about (1/2, 1/2, 1/2) is surrounded by the six nearest Rb^+ neighbours situated at the center of six faces of the cubic unit cell. The six cations form a regular octahedron. If we take the origin of the coordinate system at the center of the octahedron, the orientation of an NO_2^- ion can be specified by a set of nine position coordinates of the nitrogen and two oxygen atoms: N(a,b,c), O_I(d,e,f), and O_{II}(g,h,i). Different types of the disorder are generated by assigning one of the special or general positions to

each of the three atoms and then applying the symmetry operations to the first configuration thus specified to produce the rest.

The smallest set of the equivalent orientations has twelve members represented by

$$\begin{matrix} \mathrm{N} & (a,0,0) \\ \mathrm{O_I} & (d,e,0) \\ \mathrm{O_{II}} & (d,\bar{e},0), \end{matrix} \quad (4)$$

and the eleven symmetry-related orientations. An NO_2^- ion in one of these orientations has the nitrogen atom on the 4-fold axis and the ionic plane coincident with the x-y plane or its equivalent. There are two others sets of twelve members each produced from

$$\begin{matrix} \mathrm{N} & (a,a,0) \\ \mathrm{O_I} & (d,e,0) \\ \mathrm{O_{II}} & (e,d,0), \end{matrix} \quad (5)$$

and

$$\begin{matrix} \mathrm{N} & (a,a,0) \\ \mathrm{O_I} & (d,d,f) \\ \mathrm{O_{II}} & (d,d,\bar{f}). \end{matrix} \quad (6)$$

In a similar way three 24-member sets of orientations are obtained from the configurations

$$\begin{matrix} \mathrm{N} & (a,b,0) \\ \mathrm{O_I} & (d,e,0) \\ \mathrm{O_{II}} & (g,h,0), \end{matrix} \quad (7)$$

$$\begin{matrix} \mathrm{N} & (a,a,c) \\ \mathrm{O_I} & (d,e,f) \\ \mathrm{O_{II}} & (e,d,f), \end{matrix} \quad (8)$$

and

$$\begin{matrix} \mathrm{N} & (a,0,c) \\ \mathrm{O_I} & (d,e,f) \\ \mathrm{O_{II}} & (d,\bar{e},f). \end{matrix} \quad (9)$$

The largest set has 48 members generated from the general positions,

$$\begin{matrix} \mathrm{N} & (a,b,c) \\ \mathrm{O_I} & (d,e,f) \\ \mathrm{O_{II}} & (g,h,i). \end{matrix} \quad (10)$$

The entropy of the orientational disorder is $R\ln 12=20.7\ \mathrm{J\,K^{-1}\,mol^{-1}}$ for (4), (5), and (6), $R\ln 24=26.4\ \mathrm{J\,K^{-1}\,mol^{-1}}$ for (7), (8), and (9), and $R\ln 48=32.2\ \mathrm{J\,K^{-1}\,mol^{-1}}$ for (10). The experimental value is close to the last one. Therefore, the nitrite ion is disordered in the most general way in the straightforward interpretation of the experimental data. However, an additional possibility exists that there are two (or more) nonequivalent sets of low-energy configurations being nearly degenerate. If the energy difference between such sets is negligible in comparison with $RT_c\simeq 2\ \mathrm{kJ\,mol^{-1}}$, the orientations belonging to the different sets will be equally occupied in the high-temperature phase. The high-temperature entropy should then be calculated by taking the mixed configurations into account. It is equal to $R\ln(12+24)=29.8\ \mathrm{J\,K^{-1}\,mol^{-1}}$ for the combination of the orientations generated from (4) and (7) as an example. Other combinations are also possible. Therefore, more specific prediction of the disordered structure will be overly speculative at present. The conclusion drawn from the enumeration of the number of configurations is that the orientational entropy as large as $32.2\ \mathrm{J\,K^{-1}\,mol^{-1}}$ can be associated with the single ion.

A set of thirty two orientations has been proposed for a nitrite ion in KNO_2.[23] However, we could not deduce this number by the symmetry argument described here.

The large entropy of transition and the small entropy of melting are complementary with each other as often found in highly disordered molecular crystals.[24] Importance of the orientational disorder was also pointed out by Hirotsu et al. in the ultrasonic study of the cubic phase of $RbNO_2$.[25] Structural determination that may reveal the nature of the ionic disorder at the molecular level will be informative, as it was with the disordered phase of KNO_2.[23]

(Received December 11, 1987)

Assignments of the normal vibrations of 2,6-dichloro-, 2,6-dibromo-, 3,5-dichloro-, and 3,5-dibromopyridines were made based on the polarization behavior of the Raman and infrared spectra in single crystals and the normal coordinate calculations. The effect of halo-substitution on the vibrational frequencies of the normal modes was discussed.

The Raman and infrared spectra of pyridine were studied by many workers.[1-4] Wong and Colson reviewed the previous works and reexamined the assignments of the normal vibrations of pyridine through the analysis of the high resolution FT-IR spectrum.[5] Very recently Ozono et al. reinvestigated the normal vibrations of pyridine based on the polarized Raman spectrum and gave new assignments for the out-of-plane vibrations.[6,7] Few investigations were made on the vibrational spectra of halo-substituted pyridines and reliable assignments of the normal vibrations, which are very important for the analyses of the fluorescence and phosphorescence spectra, have not been made yet.

In this paper, the assignments of the normal vibrations of 2,6- and 3,5-dihalopyridines will be discussed through the analyses of the polarized Raman and infrared spectra and normal coordinate calculations.

Experimental

Material. The samples, 2,6-dichloro- and 3,5-dichloropyridines (Nakarai Chemical Company), 2,6-dibromopyridine (Wako Chemical Company), and 3,5-dibromopyridine synthesized from pyridinium chloride were purified by repeated vacuum distillations.

Optical Measurements. The polarization measurements of the Raman spectrum were made in molten and single crystal phases with a Jeol 400 T Laser Raman Spectrophotometer. The sample was excited with the 514.5 nm line from an Ar^+ ion laser. A well grown single crystal of the sample was obtained by the Bridgman method and a cubic sample of about 5 mm^3 was cut off, where the cleavage plane was selected as one of the planes of the cube. Although the crystallographic analyses for these molecules were not reported yet, the crystal growth direction in the cleavage plane was found to be one of the extinction directions under the polarized light. The crystal growth direction was referred to as u axis and the direction perpendicular to this axis in the cleavage plane was to as v axis and the direction perpendicular to both the u and v axes to as w axis. The polarized Raman spectrum of the single crystal was denoted by two characters such as uv. The first letter refers to the direction of polarization of the excitation light and the latter to that of the scattering light. The method of measurement of the polarized Raman spectrum was exactly the same as that described previously.[8,9]

The infrared spectra were observed in vapor, CCl_4 and CS_2 solutions, and thin film obtained by sublimation, with a Hitachi Infrared Spectrophotometer Model 345. The polarized infrared spectra were observed in the thin film. The spectra measured with the incident lights polarized parallel and perpendicular to the crystal growth direction in the film plane are referred to as // and ⊥ spectra, respectively.

Normal Coordinate Calculation

The normal coordinate calculation was performed

through the standard GF matrix method with a FACOM M-380R computer at the Computer Center of Fukuoka University. The geometrical parameters of the molecules were assumed to be the same as those of pyridine except for the C-Cl and C-Br bonds, whose bond lengths were assumed to be 0.180 and 0.185 nm, respectively.

The F matrix elements for the in-plane and out-of-plane vibrations were evaluated with the potential fields of an improved modification of the Urey-Bradley and valence force fields, respectively, described previously.[9,10] The symbols given for the atoms and the molecular axes are illustrated in Fig. 1. The force constants used for the normal coordinate calculations of the in-plane and out-of-plane vibrations are listed in Tables 1 and 2, respectively, and the calculated results of the vibrational modes and frequencies are given in Tables 3 and 4.

Results and Discussion

The relative intensity of the Raman band in the polarized Raman spectra observed in the different orientations of the crystal is governed by the orientation of the molecule in the crystal in the oriented gas model approximation. If the crystal structure is known, the relative intensities of the Raman bands can be calculated from the direction cosines between the crystal and molecular axes and the assignments of the normal vibrations can be quantitatively made from the observed polarization behavior of the Raman bands. Even if the crystal structure is unknown, the polarization behavior of the Raman bands observed along and perpendicular to the crystal growth direction, which is one of the extinction directions, in the cleavage plane gives qualitative information on the classification of the Raman bands into certain symmetry species. This

is because the molecular vibrations belonging to the same symmetry species should show the same polarization behavior. We analyzed the polarized Raman spectra and reasonable assignments of the normal vibrations were made for dichloromaleic anhydride[10] and 2-halosubstituted pyrimidines[11] whose crystal structures were unknown.

The polarized Raman spectra of 2,6-dichloro-, 2,6-dibromo-, 3,5-dichloro-, and 3,5-dibromopyridines are shown in Figs. 2, 3, 4, and 5, respectively. As can be seen in the figures, the depolarized Raman bands observed in a molten phase could be classified into three types of polarization behavior in the polarized Raman spectra observed in the crystal. The intensities of the Raman bands belonging to the first type are the strongest in the uv spectrum and decrease in the uw, vv, and vw spectra in order. The second type bands are strongest in the uw spectrum and their intensities decrease in the ww and uu spectra in order, and the third type bands could be observed clearly only in the vw spectrum. The first, second, and third type polarization behavior will be referred to as the uv, uw, and vw polarization, and the bands showing these types of polarization are marked with ○, △, and ● in the figures, respectively.

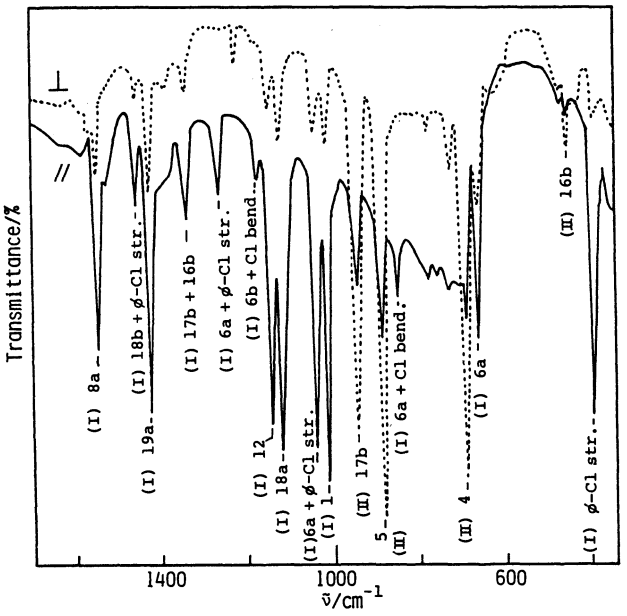

Fig. 8. Polarized infrared spectra of 3,5-dichloropyridine crystal.

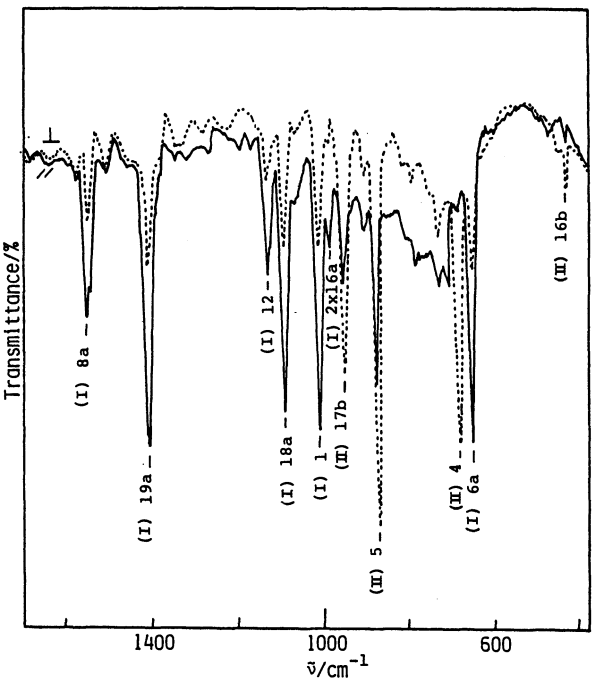

Fig. 9. Polarized infrared spectra of 3,5-dibromopyridine crystal.

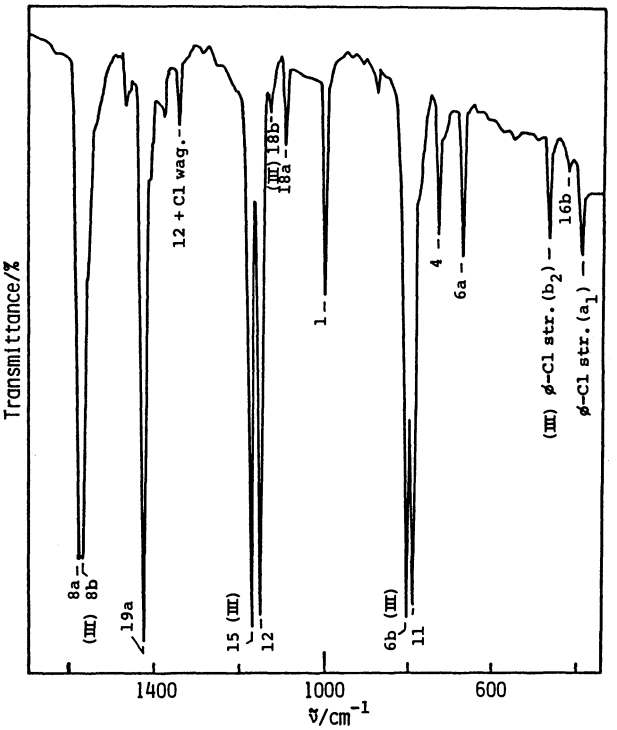

Fig. 10. Infrared spectrum of 2,6-dichloropyridine in solution.

The polarized infrared spectra of 2,6-dichloro-, 2,6-dibromo-, 3,5-dichloro-, and 3,5-dibromopyridines observed in the thin films are shown in Figs. 6, 7, 8, and 9, respectively, where the // and ⊥ spectra are drawn with the solid and dotted lines. The polarization behavior of the infrared bands could be classified into two types. The intensities of the bands belonging to the first type are stronger in the // spectrum than in the ⊥ spectrum while the intensities of the second type bands are weaker in the // spectrum than in the one. These two types of the bands will be referred to as types I and II, respectively as shown in the figures. Some infrared bands were observed strongly or clearly in the

CCl_4 and CS_2 solutions although observed very weakly or hardly in the thin film. This type of the bands will be referred to as type III. As an example, the infrared spectrum of 2,6-dichloropyridine observed in CCl_4 (1700—1000 cm^{-1}) and CS_2 (1000—350 cm^{-1}) is shown in Fig. 10, where these bands are marked with the symbol III. The very weak intensity of the type III bands in the thin film spectrum may be due to the polarization direction being nearly normal to the plane of the thin film.

Calculations of the principal moments of inertia of these molecules suggest that the infrared bands belonging to the a_1, b_2, and b_1 symmetry species show the B, A, and C rotational band contours, respectively. The vibrational modes were determined based on the normal coordinate calculation.

2,6-Dichloropyridine. a_1 Species: The strongly polarized Raman bands observed at 3078, 3030, 1400, 1133, 1072, 985, 664, and 409 cm^{-1} in molten phase could be straightforwardly assigned to the totally symmetric ν_2, ν_{7a}, ν_{19a}, ν_{12}, ν_{18a}, ν_1, ν_{6a}, and ϕ-Cl stretching vibrations, respectively, where ϕ refers to the pyridine ring. The corresponding infrared bands observed in vapor and the thin film showed the B band contour and the type I polarization, respectively. The infrared band observed at 1562 cm^{-1} was assigned to the ν_{8a} vibration because this band showed the type I polarization in the thin film, although the corresponding Raman band was depolarized in molten phase due to overlapping with the band assigned to the ν_{8b} vibration described later. The Raman band at 202 cm^{-1} was assigned to the Cl bending vibration of a_1 species because this band does not show any of the uv, uw, and vw polarization behavior.

b_2 Species: The infrared band observed at 1167 cm^{-1} showed the A band contour in vapor and therefore this band was assigned to the ν_{15} vibration of b_2 species. The corresponding infrared band in the thin film and the Raman bands in the crystal showed the type III and the uv polarization, respectively. The Raman bands observed at 1556, 1423, 1228, 452, and 374 cm^{-1} showed the uv polarization and thus were assigned to the ν_{8b}, ν_{19b}, ν_{14}, ϕ-Cl stretching, and Cl bending vibrations of b_2 species, respectively. The infrared bands observed at 1120 and 800 cm^{-1} showed the type III polarization and were assigned to the ν_{18b} and ν_{6b} vibrations, respectively.

b_1 Species: The infrared bands observed at 790 and

a) X refers to the Cl or Br atom. b) Observed in the infrared spectrum.

716 cm^{-1} showed the C band contour in vapor and the type II polarization in the thin film. Hence these bands were assigned to the ν_{11} and ν_4 vibrations of b_1 species, respectively. The corresponding Raman bands showed the uw polarization in crystal. The infrared band observed at 963 cm^{-1} showed the type II polarization and the Raman bands at 430 and 190 cm^{-1} showed the uw polarization. Therefore, these bands were assigned to the ν_{17b}, ν_{16b}, and Cl wagging vibrations of b_1 species, respectively.

a_2 Species: The Raman bands observed at 940, 577, and 185 cm^{-1} showed the vw polarization in crystal and were assigned to the ν_{17a}, ν_{16a}, and Cl wagging vibrations of a_2 species, respectively, because no corresponding bands could be observed in the infrared spectrum.

The polarization behavior of the Raman and the infrared bands of 2,6-dibromo-, 3,5-dichloro- and 3,5-dibromopyridines was exactly the same as that of 2,6-dichloropyridine except for the fact that the rotational band contours of the infrared bands were not resolved in the dibromopyridines. Assignments of the normal vibrations of these molecules were made based on the following polarization behavior.

a_1 Species: The polarized Raman bands in molten phase could be definitely assigned to the a_1 vibrations. The corresponding infrared bands showed the type I polarization in the thin films and some bands clearly showed the B band contour in vapor.

b_2 Species: The infrared bands showing the A band contour in vapor showed the type III polarization in the thin film and the corresponding Raman bands showed the uv polarization in crystal.

b_1 Species: The infrared bands showing the C band contour in vapor showed the type II polarization in the thin film and the corresponding Raman bands showed the uw polarization in crystal.

a_2 Species: The Raman bands showing the vw polarization were assigned to the a_2 vibration, because no corresponding infrared bands were observed.

The normal vibrations thus determined are given in Tables 3 and 4 and also shown in Figs. 2—10. The normal vibrations of the dihalopyridines show the following characteristic features. (1) The vibrational frequencies of the ν_{6a}, ν_{12}, ν_{6b}, ν_{18b}, ν_{16a}, and ν_{16b} vibrations increase markedly compared with those of pyridine. (2) The frequencies of the ϕ-Cl and ϕ-Br stretching vibrations decrease remarkably compared with the frequencies of the C-Cl and C-Br stretching vibrations of aliphatic compounds. These observations are well

explained in terms of the normal coordinate calculation.

The normal coordinate calculation gave the following results. (1) The ν_{6a} vibration mixes with the ϕ-X (X=Cl or Br) stretching vibration of a_1 species in the dihalopyridines and its frequency increases compared with the corresponding frequency of pyridine (602 cm^{-1}). The ν_{6a} vibration also interacts with the ν_{12} vibration and the frequency of the ν_{12} vibration increases compared with the corresponding frequency of pyridine (1030 cm^{-1}). The mixing of the ϕ-X stretching, ν_{6a}, and ν_{12} vibrations is larger in the dichloropyridines than in the dibromopyridines and thus the frequencies of the ν_{6a} and ν_{12} vibrations increase more largely in the dichloropyridines than in the dibromopyridines. The difference of the mixing may be due to the fact that the energy separation between the C-Cl stretching and ν_{6a} vibrations is smaller than that between the C-Br stretching and ν_{6a} ones. (2) The ν_{6b} vibration interacts with the ϕ-X stretching vibration of b_2 species and the frequency of the ν_{6b} vibration increases compared with the corresponding frequency of pyridine (650 cm^{-1}). The ν_{6b} vibration also interacts with the ν_{18b} vibration and the frequency of the ν_{18b} vibration increases compared with the corresponding frequency of pyridine (1045 cm^{-1}). The mixing of the ϕ-X stretching, ν_{6b}, and ν_{18b} vibration is larger in the dichloropyridines than in the dibromopyridines and thus the frequencies of the ν_{16b} and ν_{18b} vibrations increase more largely in the dichloropyridines than in the dibromopyridines. This may be due to the smaller energy separation between the ν_{6b} and C-Cl stretching vibrations compared with that between the ν_{6b} and C-Br stretching vibrations. (3) The ν_{16b} and ν_{16a} vibrations mix with the Cl or Br wagging vibrations. Thus the frequencies of the ν_{16b} and ν_{16a} vibrations of dihalopyridines increase compared with those of pyridine (408 and 377 cm^{-1}) but the frequency increase of the ν_{16a} vibration is larger than that of the ν_{16b} vibration. This may be due to the difference of the energy separation between the two interacting vibrations as described above.

Long-Lived Triplet Radical Ion Pair State of Porphyrin-Methylviologen Combined Systems as Revealed by a Large Magnetic Field Effect on Its Lifetime

Toshiro SAITO, Yoshinori HIRATA,* Hisashi SATO, Toshikatsu YOSHIDA,† and Noboru MATAGA*
Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560
(Received December 28, 1987)

The external magnetic field effect on the lifetime of the ion pair state has been examined for the porphyrin-methylviologen combined systems in polar solvents by using nanosecond laser flash photolysis techniques. Applying the external magnetic field, a drastic increase in the lifetime has been observed. For PIIMV^{2+} in DMSO under the magnetic field of 50 mT, the ion pair lifetime was almost three times longer than the zero field value, which can be deemed the ideal case of the external magnetic field effect due to the hyperfine interaction mechanism. The results clearly showed that the long-lived ion pair was formed by the intramolecular electron transfer from the triplet state of porphyrin.

Studies of external magnetic field effects upon photochemical reactions in solution provide important information concerning the microscopic reaction mechanisms. The external magnetic field effect on the behavior of radical ion pairs of electron acceptor/donor (A/D) systems such as pyrene/*N*,*N*-dimethylaniline (DMA) in polar solvents was observed already more than ten years ago.[1] The effect saturates at a rather low magnetic field (less than 20 mT) and, accordingly, is due to the hyperfine interaction (hfi) mechanism, by which singlet (S) and triplet (T) radical ion pairs can interconvert. Under the influence of an external magnetic field greater than the hyperfine coupling energy (ΔE_{hfc}), the triplet sublevels split due to the Zeeman effect into T_+, T_0, and T_- and the degeneracy of T_+, T_-, and S is lifted. Then such a strong external magnetic field inhibits the spin interconversion between singlet and triplet sublevels of the radical ion pair except for that between S and T_0. Although the effect is usually not large for the intermolecular (unlinked) systems, it can provide important informations about an interaction and separation distance between cation and anion radicals.

For the A/D systems linked by a polymethylene chain, both the mutual motion and distance of the individual radical ions are restricted compared with the unlinked systems. If the separation distance of the individual radical ions is so short that the spin exchange interaction, which splits the singlet and triplet levels of the radical ion pairs by the amount of twice of the exchange integral, 2J, is larger than the hyperfine interaction, the magnetic field effect of the hfi mechanism should not be observed. On the other hand, if the radical ions are kept at a proper distance where the hfi can play the dominant role, we can expect that the magnetic field effect is larger than that in the unlinked systems.

The external magnetic field effect of the pyrene-$(CH_2)_n$-DMA systems in acetonitrile solution was studied by Staerk et al.[2] They measured the exciplex fluorescence yield and lifetime for the molecules of n=8—16. The magnetic field effect increased with increasing chain length, while the larger influence of the exchange interaction, which appears as an effect inverse to the hfi, was observed for the shorter chain compounds. In their system the singlet radical ion pair, which is formed by photoinduced electron transfer from DMA to the excited pyrene and associates to form the fluorescent exciplex, changes its spin state by the hyperfine induced conversion to the triplet radical ion pair. For the longest chain molecule (n=16), the yield of the exciplex fluorescence at high magnetic field was 147% of the zero field value. Similar effect was observed for the fluorescence lifetimes (31 and 22 ns for 35 and 0 mT, respectively).

Tanimoto et al.[3] measured the external magnetic field effect on the fluorescence of phenanthrene-$(CH_2)_n$-DMA (n=3, 6, 8, 10). No magnetic field effect on the intramolecular exciplex fluorescence was observed for the molecules with n=3 and 6, while for the system of n=10 the fluorescence lifetime of the exciplex was 50 and 92 ns at the magnetic field of 0 and 810 mT, respectively. The dip, which seems to be an indication of the spin exchange effect, was clearly observed for the system of n=8.

In a previous paper we reported that the extremely long-lived radical ion pair was formed in the porphyrin (P)-methylviologen (MV^{2+}) system combined with flexible chains in highly polar solvents, such as dimethyl sulfoxide (DMSO) and methanol-acetone (1 : 1 by volume) mixture.[4] Such a long-lived intramolecular radical ion pair was not observed for the porphyrin (P)-quinone (Q) combined systems.[5] These results seemed to suggest that the coulomb interaction between the ionic species formed by the intramolecular photoinduced electron transfer may cause the quite different dynamic behavior between these two kinds of combined systems. Contrary to the latter case where the attraction force between P^+ and Q^- groups is expected, the repulsion between the P^+ and MV^+

† Present address: College of Integrated Arts and Science, University of Osaka Prefecture, Sakai, Osaka 591.

groups may prevent the ionic recombination and prolong the lifetime of the radical ion pair in the former case.

In order to elucidate the details of the dynamic behavior and structure of the radical ion pair, we have studied extensively the external magnetic field effect on the lifetime of the radical ion pair for P-MV^{2+} systems in DMSO and in a methanol-acetone (1 : 1) mixture. Applying an external magnetic field of less than 50 mT, the lifetime has increased extremely. The effect seems to saturate at about 30 mT, which suggests that the hfi mechanism is important for the observed effect. We propose here the mechanism that the long-lived radical ion pair of the P-MV^{2+} combined system observed in polar solvents is produced by the intramolecular electron transfer between triplet P and ground state MV^{2+}.

Experimental

A microcomputer-controlled excimer laser (XeF, 15 ns fwhm) photolysis system[6] was used for the transient absorption measurements in the nanosecond to microsecond time region. An excitation laser beam and a monitor light from a pulsed Xe lamp were crossed in a sample cell at the right angles. The monitor light was detected by a photomultiplier tube after passing through a monochromator. The signal, which was digitized by a digital storage scope (100 MHz, 8 bit), was accumulated and then the transient absorbance was calculated by a microcomputer. A Helmholtz coil with a gap width of 200 mm was used to apply an external magnetic field of up to 54 mT. The sample cell was placed at the center of the electro magnet and the field strength was monitored with a gaussmeter.

The porphyrin-methylviologen combined systems, P*n*MV^{2+} were synthesized by the method as given in the Appendix, and the synthesis of the reference compound PII by the similar method was described elsewhere.[9] Methylviologen was purified by repeated recrystallization from ethanol. All the solvents (Spectro Grade) were used without further purification.

Sample solutions were deaerated by several freeze-pump-thaw cycles and sealed in quartz cells with 1-cm optical path length. All the measurements were performed at room temperature.

Results and Discussion

Unlinked System. The fluorescence lifetime of the reference compound of porphyrin, PII, which has two long chains with an *N*-methylpyrolidine group instead of MV^{2+}, was 2 ns. Although we did not measure the triplet yield, it was reasonable to expect the high triplet yield, because the molecular structure and the fluorescence lifetime are similar to those of Zn etioporphyrin I (ϕ_T=0.94, τ_f=2.3 ns).[7] The triplet energy of etioporphyrin I is about 0.4 eV higher than that of the porphyrin cation-methylviologen monocation (MV^+) pair, which was estimated from the redox potential.[8] Therefore the electron transfer between the triplet state of PII and the ground state of MV^{2+} should

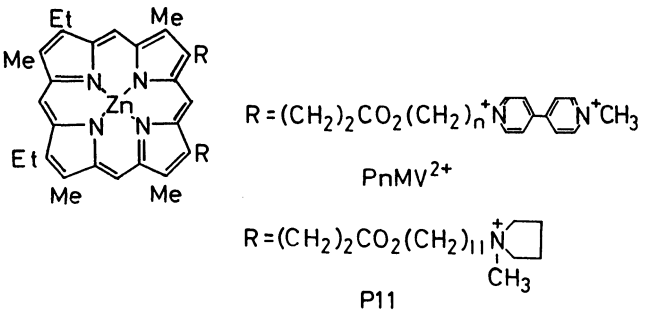

Fig. 1. Molecular structure of the samples.

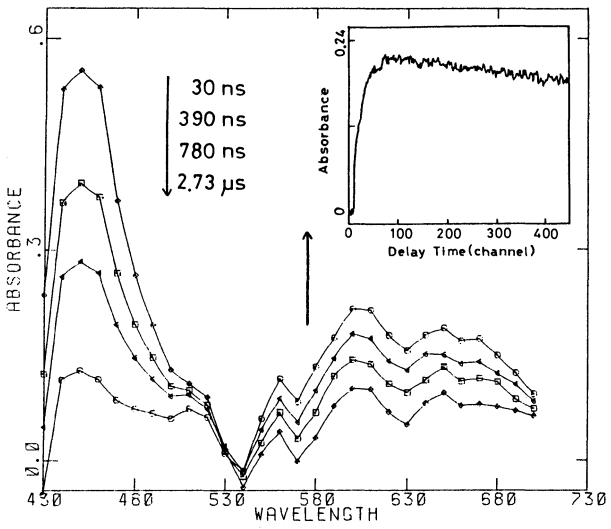

Fig. 2. Nanosecond time resolved absorption spectra of PII/MV^{2+} in DMSO. The decay time after the laser pulse excitation was indicated in the Figure. The rise and decay curve measured at 600 nm was also shown (insert, 39 ns/channel).

be a rapid process.

Figure 2 shows transient absorption spectra of PII/MV^{2+} in DMSO system. The absorption band in the short wavelength region (ca. 430 nm) can be ascribed to the triplet state of PII, the decay of which followed the exponential kinetics and the lifetime depended on the concentration of MV^{2+}. Increasing the delay time after the nanosecond laser pulse excitation, the $T_n \leftarrow T_1$ absorption of PII disappeared and a new absorption band in the 540—700 nm region built up. The latter should be assigned to the superposition of the absorption bands of PII cation and MV^+, the recombination of which seemed to be a quite slow process. The decay time of the PII triplet and the rise time of the ion radicals showed a quite good agreement. Therefore, it was concluded that the ion radicals were formed by the electron transfer from the triplet state of PII to MV^{2+}. Similar behavior was observed also in the methanol-acetone mixed solvent. Even at a high concentration of MV^{2+} (0.1 M), although the stable MV^+ formation disturbed the transient absorption measurements, the time dependence of the concentration of the ion radi-

cals could be explained by a homogeneous recombination kinetics, except at very short delay time (≦30 ns), where the porphyrin fluorescence was observed. We could not find any evidence for the presence of the long lived ion pair, which was observed for the linked system.[5] By the application of the external magnetic field less than 54 mT, no effect on the free ion yield was observed either in DMSO or methanol-acetone. In the case of the Py/DMA in acetonitrile system, the triplet yield decreased about 10% by the application of a magnetic field of 20 mT. little magnetic field effect on th Pll/MV^{2+} system may suggest that the lifetime of the geminate ion pair was too short because of the repulsive force between the radical cations.

Linked System. As described in Introduction, P6MV^{2+} and P11MV^{2+} in DMSO and methanol-acetone solutions form the long-lived ion pairs, of which the lifetimes are longer than 100 ns, through a photoinduced electron transfer reaction. The time dependence of the transient absorbance measured at 600 nm was shown in Fig. 3. The yield of the long lived

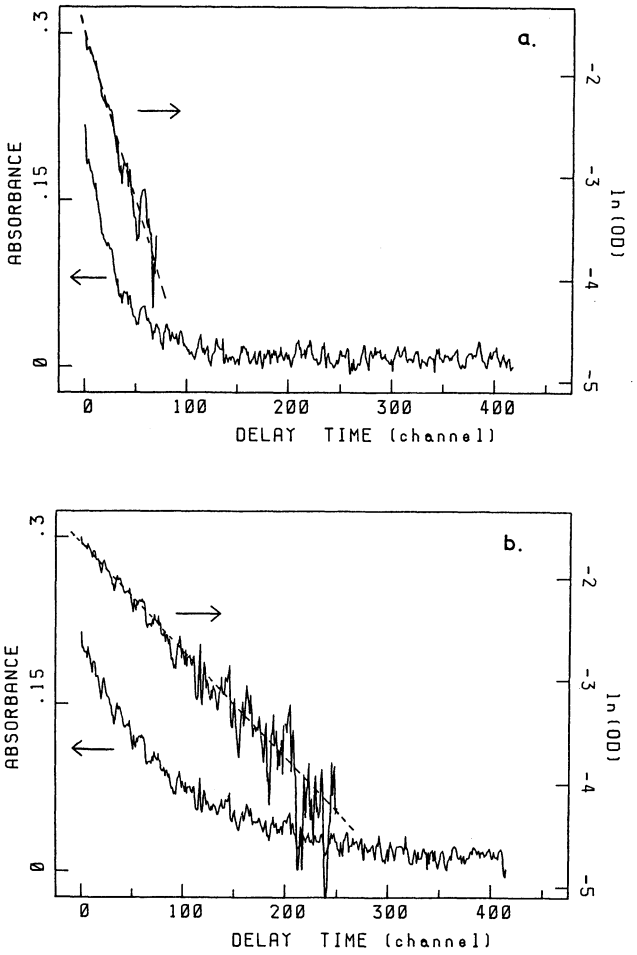

Fig. 3. Time dependence of the transient absorbance of P11MV^{2+} in DMSO (3.9 ns/channel): (a) in the absence of a magnetic field and (b) in the presence of maganetic field (50 mT). Semilogarithmic plot were also shown in the figure (right axis).

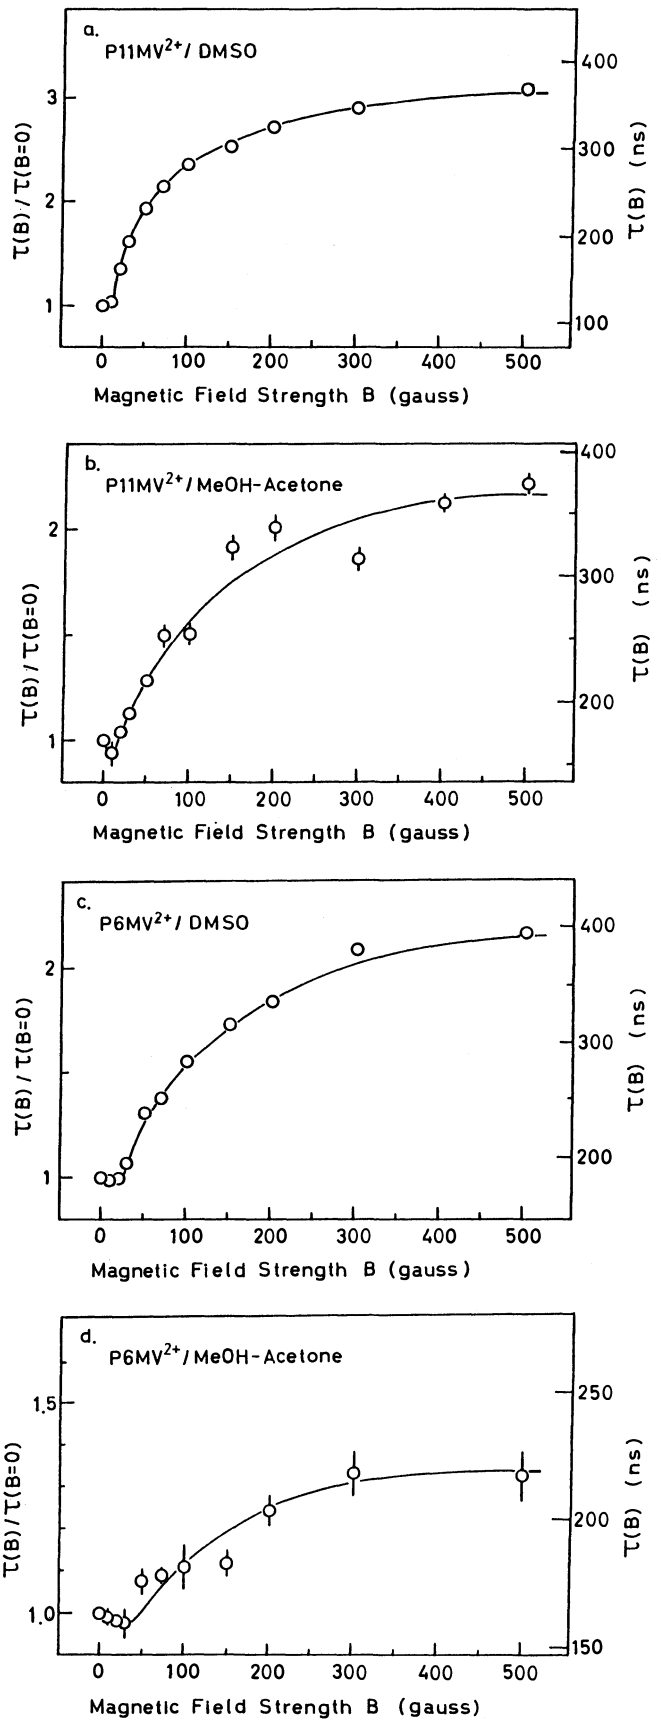

Fig. 4. Magnetic field dependence of the lifetime of $P^{+}nMV^{+}$: (a) n=11 in DMSO, (b) n=11 in methanol-acetone, (c) n=6 in DMSO, and (d) n=6 in methanol-acetone.

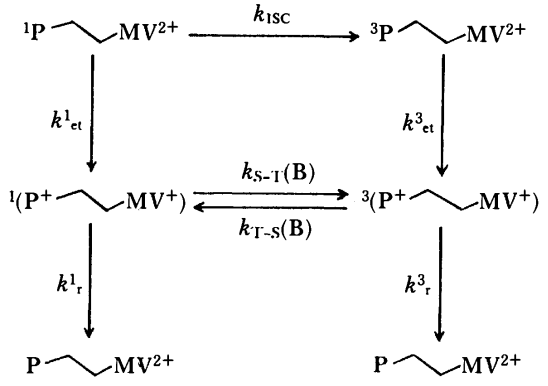
component depended on the excitation laser intensity, which should be due to the porphyrin radical cation produced via the two photon ionization. by subtracting this component decaying slowly via the homogeneous ionic recombination, the decay followed an exponential kinetics, as shown in the figure (semilogarithmic plot). In this way the lifetime of the short lived component of PllMV^{2+} in DMSO was determined to be 120 and 360 ns at 0 and 50 mT, respectively.

As shown in Fig. 4, by applying the external magnetic field, the lifetime of the ion pair increased drastically. The effect was prominent for the longer chain molecule and the larger effect was observed for the DMSO solution. For P6MV^{2+} the external magnetic field did not affect the ion pair lifetime up to 4 and 5 mT in DMSO and methanol-acetone solutions, respectively. Such threshold seemed to be lower for PllMV^{2+} in both solvents. The magnetic field effect was almost saturated at about 30 mT and under the influence of the external magnetic field of 50 mT, the lifetime of the ion pair of PllMV^{2+} in DMSO was three fold of that at zero field. This is a quite large effect compared with the results reported for other intramolecular exciplex systems.[2,3]

The magnetic field effect observed here should be due to the hfi mechanism since the effect saturates at a rather low external field of about 30 mT. Hyperfine interaction causes the interconversion between the almost degenerate singlet and triplet ion pair states and the degeneracy is lifted by the external magnetic field. The relaxation mechanism of this system can be shown as in Scheme 1. ^{1}P, ^{3}P, and P represent the first excited singlet, triplet, and ground states of the porphyrin moiety, respectively; k_{ISC} is the $S_1 \rightarrow T_1$ intersystem crossing rate constant of the porphyrin moiety; k^1_{et} and k^1_r are charge transfer and charge recombination rate constants in the singlet excited state, respectively, and k^3_{et} and k^3_r are those in the triplet state, respectively; $k_{T\text{-}S}(B)$ and $k_{S\text{-}T}(B)$ are the magnetic field dependent rate constants of interconversion between the triplet and singlet ion pairs. A singlet state and



Scheme 1.

three sublevels of a triplet state of the ion pairs are almost degenerate at zero-field. Under the influence of the external magnetic field only the degeneracy between S and T_0 remains. Therefore if the relaxation between the triplet sublevels are rapid compared with the S-T interconversion, it is quite reasonable to assume that $k_{T\text{-}S}(B)=k_{T\text{-}S}(0)/3$ and $k_{S\text{-}T}(B)=k_{S\text{-}T}(0)/3$ at the high external magnetic field limit.

In the previous paper,[4] by using the picosencond laser photolysis techniques we observed the formation of the singlet ion pair in the picosecond to nanosecond time regime. If we assume that the long-lived ion pair was originally formed in the singlet spin alignment, the magnetic field effect as observed in the present work requires that the rate constant of the recombination in the singlet phase is at most the same magnitude as the S-T interconversion rate, $k^1_r \leqq k_{S\text{-}T}$. Moreover, k^1_r should be much smaller than k^3_r. However, this is highly improbable. If k^1_r is larger than k^3_r, the observed magnetic field effect should be opposite to the actually observed, i.e. the ion pair lifetime should decrease with increase of the magnetic field strength. In the present system the energy level of the triplet state of porphyrin is higher than that of the triplet ion pair state estimated from the redox potentials ($E(A^-/A)=-0.216$ and -0.319 V NHE for $n=6$ and 11, and $E(D/D^+)=0.95$ V NHE).[9] Therefore the triplet ion pair should have a longer lifetime than that of the singlet ion pair, because the latter can recombine to form the ground state of the components, while the recombination process of the former is spin forbidden.

The above results strongly suggest that the long-lived ion pair is born in the triplet spin alignment. It is known that the rate constant of the $S_1 \rightarrow T_1$ intersystem crossing (k_{ISC}) of etioporphyrin I is about 4×10^8 s^{-1} [7] and a similar value can be expected for the present combined molecules. Although the $T_n \leftarrow T_1$ absorption was not observed clearly by our picosecond time resolved absorption measurements, the triplet yield of PllMV^{2+} in DMSO can be estimated to be about 0.4 (by using the value of τ_f=980 ps). This triplet yield seems to be high enough for the observed long-lived ion pair to be formed from the triplet porphyrin.

In tens of nanosecond regime, the yield of the long-lived ion pair for PllMV^{2+} in methanol-acetone was almost 30% of that in DMSO, which was consistent with the results of fluorescence lifetime measurements.[4] Namely the decay of the fluorescence in methanol-acetone did not follow the single exponential kinetics and the lifetime of the main component was shorter than that in DMSO, which seems to be consistent with the results of ion pair yield measurements. The conformation of PllMV^{2+} in methanol-acetone, which shows shorter fluorescence lifetime than in DMSO, seems to be more shrank. We could not observe the decay of the singlet ion pair in the previous work[4] because it was difficult to measure the time dependences of the transient absorption spectra of

the relevant species (triplet porphyrin, singlet ion pair, and triplet ion pair) in the 5—20 ns region; the singlet ion pair should decay in this time regime.

Assuming that k^3_r and k^1_r was 0 and in the order of 10^8—10^9 s^{-1}, respectively, the lifetime of the ion pair should be $1/k_{T\text{-}S}(B)$. The system of PllMV^{2+} in DMSO seems to be such an ideal case, because the rate of the T-S interconversion at the high magnetic field was one third of the zero-field value ($1/k_{T\text{-}S}(0)$=120 ns and $1/k_{T\text{-}S}(H_{sat})$=370 ns). This should be due to the large separation distance of the present radical ion pair linked by flexible chain, which makes the hyperfine interaction a dominant mechanism of the S-T interconversion. Similar large magnetic field effect was observed previously for k_{T-S} of the intermediate ion pair for the hydrogen abstraction of xanthone- xanthene in micellar solution.[1] In the case of the PllMV^{2+} in methanol-acetone mixed solvent, although the lifetime at high field limit was similar to that in DMSO, the magnetic field effect was about 250%. This result suggests that the spin-exchange effect is stronger in methanol-acetone than in DMSO, which should reduce $k_{T\text{-}S}$ even at zero-field. This reasoning is in accord with the possibility described above that PllMV^{2+} in methanol-acetone will have a more shrank conformation than in DMSO and also with the fact that the megnetic field effect starts at slightly higher field in methanol-acetone than in DMSO, although the difference is very small.

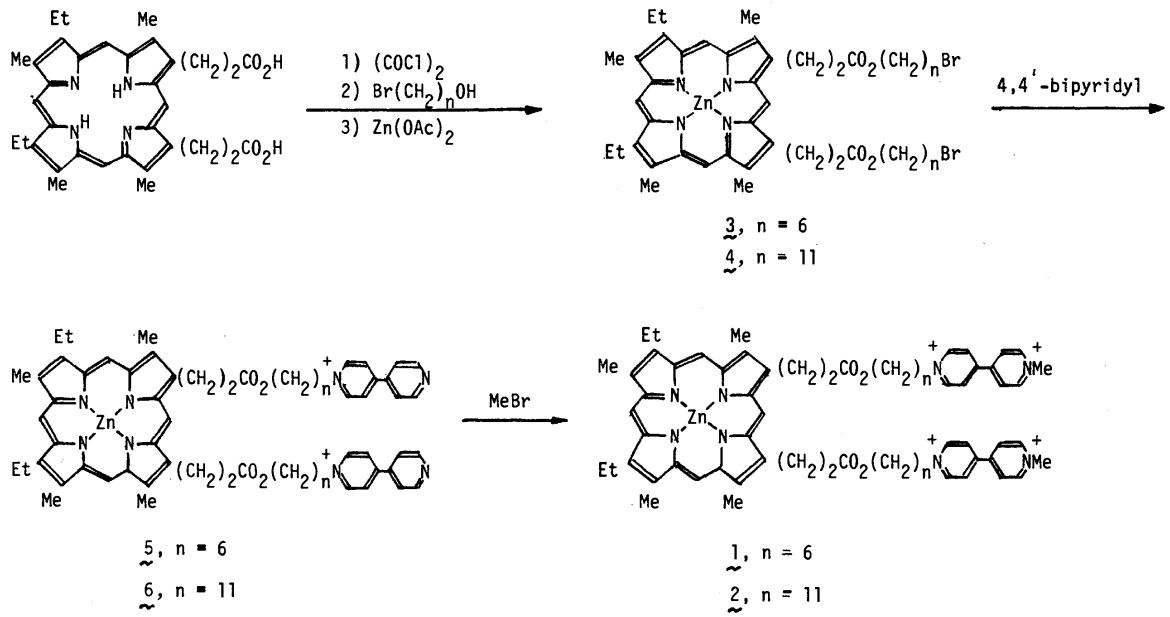
The threshold observed for the $\tau(B)/\tau(0)$ vs. B relation of P6MV^{2+} should be due to the spin exchange interaction. Even at zero-field, the singlet and triplet sublevels have slightly different energies bacause of the spin-exchange interaction. Since the exchange interaction decreases exponentially with increasing separation distance between radical ions, the effect is not significant for PllMV^{2+} in DMSO but seems to affect slightly the extent of the lifetime increase in methanol-acetone. Because of the shorter average distance between P$^+$ and MV$^+$ in P6MV^{2+} than in PllMV^{2+}, the exchange interaction will be stronger in the former. This stronger exchange interaction may bring about a smaller magnetic field effect on the lifetime of the radical ion pair of P6MV^{2+} in DMSO as well as methanol-acetone. It should be noted, however, that, in the case of P6MV^{2+} in methanol-acetone solution, the lifetime at the high field limit was much shorter than in the case of the other systems, which may suggest that k^3_r was not negligible compared with the T-S interconversion rate. This might be partially due to the chemical reaction from the triplet ion pair because we can recognize a slight degradation of P6MV^{2+} in the solvent after prolonged irradiation.

Although the threshold B value for the $\tau(B)/\tau(0)$ vs. B relation of P6MV^{2+} in methanol-acetone solution appears to be slightly greater than that in DMSO, the difference was not so large. It was confirmed[4] that P6MV^{2+} in methanol-acetone showed a large fraction of rapid decay component ($\tau \approx 330$ ps) of fluorescence, which could be ascribed to P6MV^{2+} with a little shrank conformation. Nevertheless, the singlet ion pair state produced by the rapid electron transfer corresponding to this fluorescence decay component will be rapidly deactivate to the ground state by back electron transfer and the long-lived triplet ion pair produced by electron transfer from triplet porphyrin which is formed by intersystem crossing competing with the slow fluorescence decay component ($\tau \approx 1$ ns) will be mainly responsible with the present study of the external magnetic field effect. On the other hand, the results of the previous study[4] on the fluorescence decay of P6MV^{2+} in DMSO indicate that the long-lived triplet ion pair in this solvent is produced also by electron transfer from the triplet porphyrin which is formed by intersystem crossing competing with electron transfer in the singlet state in the same time region (ca. 1 ns). Although the final configuration of the triplet ion pair state may be affected to some extent by a slight conformation change in the course of the electron transfer or immediately after the electron transfer from the triplet state, the above reasoning will interpret the fact that the exchange interaction in the long-lived ion pair of P6MV^{2+} in methanol-acetone is not much different from that in DMSO.

Appendix

Preparation of Covalently Linked Zn Mesoporphyrin IX-Viologen Complexes: Two Zn mesoporphyrins covalently linked with two viologen molecules through two long side chains of $-(CH_2)_2CO_2(CH_2)_n-$ (n=6 and 11), Zn mesoporphyrin IX bis[6-(1′-methyl-4,4′-bipyridinio)hexyl ester] tetrabromide (**1**) and bis[11-[4-(1-methyl-4-bipyridinio)-1-pyridino]undecyl ester] tetrabromide (**2**), were prepared by modification of the propionate groups in mesoporphyrin IX (Scheme 2). Thus, mesoporphyrin IX was converted into the 6-bromohexyl ester and 11-bromoundecyl ester by treating the corresponding bromohydrins with mesoporphyrin IX bis(acid chloride) in CH_2Cl_2 in the presence of Et_3N at room temperature. The acid chloride was prepared in situ from triethylammonium salt of mesoporphyrin IX with oxalyl dichloride. After removing an excess of bromohydrin by chromatography on Al_2O_3, the crude ω-bromoalkyl esters thus obtained were heated with $Zn(OAc)_2$ in $CHCl_3$ to give the Zn mesoporphyrin IX bromoalkyl esters **3** and **4** as reddish purple crystals. Treatment of **3** and **4** with a large excess of 4,4′-bripyridyl in DMF under reflux gave the respective monoalkylated 4,4′-bipyridinediim dibromides, **5** and **6**. On bubbling MeBr through a DMF solution of **5** and **6** at ambient temperature the expected Zn mesoporphyrin IX-methylviologen complexes **1** and **2** were precipitated as reddish brown crystals. The overall yield of **1** and **2** from mesoporphyrin IX was 23 and 25%, respectively. The formation of **1** and **2** as well as the intermediary compounds **3**—**6** were confirmed by elemental analyses, IR and ^{1}H NMR spectral data (see Experimental).

Experimental. ^{1}H NMR spectra were recorded on JEOL 4H-100 spectrometer. IR and UV-visible spectra were measured on a Hitachi Model 295 and Hitachi EPS-3T spec-



Scheme 2.

trometers, respectively. All reactions were carried out under N_2 atmosphere and all solvents used were dried by the conventional methods.

Zn Mesoporphyrin IX Bis(6-bromohexyl ester) (3) and Bis(11-bromoundecyl ester) (4): To a suspension of mesoporphyrin IX hydrochloride (0.25 g, 0.39 mmol) in CH_2Cl_2 (20 ml) was added Et_3N (0.9 ml, 6.5 mmol) and the mixture was stirred at room temperature for 1 h. The red solid residue obtained by concentration was treated with $(COCl)_2$, (0.25 ml, 3 mmol) in CH_2Cl_2 (30 ml) at ambient temperature for 1 h. Concentration of the reaction mixture in vacuo to dryness gave the diacid chloride as purple solids. A mixture of the bis(acid chloride) thus obtained, $Br(CH_2)_6OH$ (1.8 g, 10 mmol), and Et_3N (1 ml, 7.2 mmol) in CH_2Cl_2 (20 ml) was heated under reflux for 6 h. The concentrated residue was washed with H_2O and was chromatographed on Al_2O_3. Elution with $CHCl_3$ and subsequent evaporation gave mesoporphyrin IX bis(6-bromohexyl ester) as purple crystals (0.14 g, 40%). IR(nujol), ν (CO) 1730 cm^{-1}. A saturated solution of $Zn(OAc)_2$, (0.27 mmol) in MeOH (1.5 ml) was added to the bromo ester (0.14 g, 0.16 mmol) in $CHCl_3$ (15 ml) and the mixture was heated under reflux for 10 min. The concentrated mixture was purified by chromatography (Al_2O_3, benzene-$CHCl_3$ (1 : 1)). Recrystallization from $CHCl_3$-hexane gave **3** (0.13 g, 90%) as reddish purple crystals, mp 135—139 °C. Calcd for $C_{46}H_{58}N_4O_4Br_2Zn$: C, 58.16; H, 6.15; N, 5.90. Found: C, 58.52; H, 6.10; N, 5.92. IR (Nujol), ν (CO) 1730 cm^{-1}. ^1H NMR ($CDCl_3$); δ=9.00 (s, 1H, meso), 8.90 (s, 1H, meso), 8.72 (s, 2H, meso), 3.60 (s, 3H, ring CH_3), 3.56 (s, 3H, ring CH_3), 3.12 (s, 6H, ring CH_3), 1.66 (t, 3H, CH_3C), 1.58 (t, 3H, CH_3C), 0.5—1.5 (b, 16H, $C(CH_2)_4C$), 2.7—4.3 (m, 20H, other CH_2).

The compound **4** was also prepared as reddish-purple crystals by a similar procedure employed for the preparation of **3**, but using $Br(CH_2)_{11}OH$. The yield based on mesoporphyrin IX hydrochloride was 29%, mp 101—103.5 °C. Calcd for $C_{56}H_{78}N_4O_4Br_2Zn$: C, 61.37; H, 7.17; N, 5.11%. Found; C, 60.85; H, 7.34; N, 5.21%. IR (Nujol), ν (CO) 1730 cm^{-1}. ^1H NMR($CDCl_3$); δ=9.11 (s, 1H, meso), 8.95 (s, 1H, meso), 8.92 (s, 1H, meso), 8.84 (s, 1H, meso), 3.32 (s, 3H, ring CH_3), 3.26 (s, 3H, ring CH_3), 3.19 (s, 3H, ring CH_3), 3.11 (s, 3H, ring CH_3), 1.68 (t, 3H, CH_3C), 1.60 (t, 3H, CH_3C), 0.6—1.4 (b, 36H, $C(CH_2)_9C$), 3.0—4.2 (m, 20H, other CH_2).

Zn Mesoporphyrin IX Bis[6-(4,4'-bipyridinio)hexyl ester] Dibromide (5) and Bis[11-(4,4'-bipyridinio)undecyl ester] Dibromide (6): A mixture of **3** (0.086 g, 0.09 mmol) and 4,4'-bipyridyl (0.28 g, 1.8 mmol) in DMF (10 ml) was heated at 100 °C for 24 h. The concentrated reddish purple solids were washed with benzene (5×20 ml) to remove an excess of 4,4'-bipyridyl. On addition of benzene the solids became oil, which could be crystallized on treatment with hexane to give reddish-purple crystals (0.10 g, 90%), mp 177 °C. Calcd for $C_{66}H_{74}N_8O_4Br_2Zn \cdot 2H_2O$: C, 61.59; H, 6.11; N, 8.71%. Found: C, 61.25; H, 5.85; N, 8.45%. IR (Nujol); ν (CO) 1730, ν (C=C+C=N) 1540 and 1640 cm^{-1}. ^1H NMR (DMSO-d_6); δ=10.08 (s, 1H, meso), 10.05 (s, 2H, meso), 9.99 (s, 1H, meso), 8.40 (d, 4H, bpy), 8.10 (d, 2H, bpy), 8.02 (d, 2H, bpy), 7.88 (d, 2H, bpy), 7.72 (d, 4H, bpy), 7.40 (d, 2H, bpy), 3.62 (s, 6H, ring CH_3), 3.56 (s, 6H, ring CH_3), 1.80 (t, 6H, CH_3C), 1.28 (b, 8H, $C(CH_2)_4C$), 0.86 (b, 8H, $C(CH_2)_4C$), 3.10—4.38 (m, 20H, other CH_2).

The compounds **6** was prepared similarly from **4** as described above in 98% yield, mp 150—158 °C. Calcd for $C_{76}H_{94}N_8O_4Br_2Zn \cdot 2H_2O$: C, 63.17; H, 6.56; N, 7.75%. Found: C, 62.90; H, 6.72; N, 7.63%. IR (Nujol); ν (CO) 1730, ν (C=C+C=N) 1540 and 1640 cm^{-1}. ^1H NMR (DMSO-d_6); δ=10.04 (s, 1H, meso), 10.02 (s, 2H, meso), 9.98 (s, 1H, meso), 8.82 (d, 4H, bpy), 8.44 (d, 4H, bpy), 8.22 (d, 4H, bpy), 7.78 (d, 4H, bpy), 3.60 (s, ring CH_3), 3.58 (s, 6H, ring CH_3), 1.80 (t, 6H, CH_3C), 0.8—1.5 (b, 36H, $C(CH_2)_9C$), 3.2—4.6 (m, 20H, other CH_2).

Zn Mesoporphyrin IX Bis[6-(1'-methyl-4,4'-bipyridinio)-hexyl ester] Tetrabromide (1) and Bis[11-[4-(1-methyl-4-pyridinio))-1-pyridino]undecyl ester] Tetrabromide (2): A large excess of CH_3Br was bubbled through a solution of **5** (0.10 g, 0.08 mmol) at ambient conditions for 1 h. Reddish brown solids precipitated was filtered and washed with acetone. Recrystalization from MeOH-acetone gave **1** (0.08 g,

70%), mp 251 °C. Calcd for $C_{68}H_{80}N_8O_4Br_4Zn \cdot 2H_2O$: C, 54.65; H, 5.66; N, 7.49%. Found: C, 54.83; H, 5.86; N, 7.23%. IR (Nujol); ν (CO) 1730, ν (C=C+C=N) 1560 and 1640 cm^{-1}. ^1H NMR (MeOH-d_4); δ=9.96 (s, 1H, meso), 9.90 (s, 3H, meso), 8.49 (d, 2H, bpy), 8.35 (d, 2H, bpy), 8.03 (d, 2H, bpy), 7.89 (d, 2H, bpy), 7.56 (d, 4H, bpy), 7.43 (d, 2H, bpy), 7.24 (d, 2H, bpy), 4.11 (s, 6H, CH_3N^+), 3.61 (s, 6H, ring CH_3), 3.57 (s, 6H, ring CH_3), 1.85 (t, 6H, CH_3C), 0.97 (b, 8H, $C(CH_2)_4C$), 1.35 (b, 8H, $C(CH_2)_4C$), 3.3—4.5 (bm, 20H, other CH_2).

The compound **2** was prepared similarly from **6** as reddish brown crystals (87%), mp 269 °C. Calcd for $C_{78}H_{100}N_8O_4Zn \cdot 2H_2O$: C, 57.30; H, 6.41; N, 6.99. Found C, 57.08; H, 6.33; N, 6.99. IR (Nujol); (CO) 1730, ν (C=C+C=N) 1550 and 1640 cm^{-1}. ^1H NMR (MeOH-d_4); δ=9.96 (s, 1H,, meso), 9.94 (s, 2H, meso), 9.89 (s, 1H, meso), 8.70 (d, 2H, bpy), 8.41 (d, 2H, bpy), 8.10 (d, 2H, bpy), 7.90 (d, 2H, bpy), 7.42 (d, 4H, bpy), 7.26 (d, 4H, bpy), 4.29 (s, 3H, CH_3N^+), 4.12 (s, 3H, CH_3N^+), 3.56 (s, 6H, ring CH_3), 3.60 (s, 6H, ring CH_3), 1.85 (t, 6H, CH_3C), 1.0—1.7 (b, 36H, $C(CH_2)_9C$), 3.2—4.5 (bm, 20H, other CH_2).

The Micellar Properties of Dodecyltrimethylammonium Chloride as Studied by Ion-Selective Electrodes and Fluorescence Probe Technique

Tamaki MAEDA* and Iwao SATAKE
Department of Chemistry, Faculty of Science, Kagoshima University, Korimoto, Kagoshima 890
(Received January 9, 1988)

The activities of the surfactant ion, counter ion, and co-ion in micellar solutions of dodecyltrimethylammonium chloride (DTAC) in the presence of NaCl were determined by using ion-selective electrodes. An application of the charged phase separation model gave an apparent degree of counter ion association to the micelle of 0.68 regardless of the salt concentration. A tentative estimation of the intermicellar concentrations of surfactant ion and counter ion was made on the basis of an assumption that the activity coefficients of the monomeric surfactant ion and co-ion were identical with each other. In the concentration range above the critical micelle concentration (cmc), the intermicellar concentration of the surfactant ion decreased gradually with increasing surfactant concentration, whereas the reverse was found for that of counter ion. Similar behaviors were also found for the activity coefficients of these ions. However, an increase in salt concentration caused a successive decrease in the concentration dependences of intermicellar concentrations as well as activity coefficients. Measurements were also made with the fluorescence decay curves of micelle-solubilized pyrene. An analysis based on the knowledge of the intermicellar concentration of surfactant ion estimated above revealed that the micelle aggregation number of DTAC remained virtually constant over wide concentration range above the cmc.

The use of the ion-selective electrodes gives valuable informations about the micellar properties of ionic surfactant solutions such as an apparent degree (β) of counter ion association to the micelle and the intermicellar concentrations of surfactant ion (C_1) and counter ion (C_2). In the concentration range above the critical micelle concentration (cmc), an increase in surfactant concentration has been found to accompany always a monotonous decrease in surfactant ion activity (a_1)[1-11] while a linear increase in counter ion activity (a_2).[2-4,6,7,9-17] It has also been noted by Sasaki et al.[2] and Koshinuma[3] that $a_1a_2^{\beta}$ remains constant in accordance with a charged phase separation model. This fact provides a simple method for the determination of β. However the estimations of C_1 and C_2 require a knowledge of the activity coefficients of surfactant ion and counter ion in the presence of polyvalent micellar ions. In this connection, Sasaki et al.[2] and Cutler et al.[4] have ignored the effect of micellar ions on the activity coefficients of monomeric ions in their calculations of C_1 and C_2 in sodium dodecyl sulfate solution. The same procedure was also applied for the potentiometric study of 1-dodecylpyridinium chloride solution with and without added salt.[11]

In this paper is described an attempt to estimate C_1 and C_2 from activity data of surfactant ion, counter ion, and co-ion in solution of dodecyltrimethylammonium chloride with added salt. On the basis of a knowledge of C_1, we also determined the concentration dependence of the micelle aggregation number from the fluorescence decay curves of micelle-solubilized pyrene.

Experimental

Materials. Dodecyltrimethylammonium chloride (DTAC) was prepared by passing the aqueous solution of the corresponding bromide (purity>99%, Tokyo Kasei Kogyo Co., Ltd.) through an anion-exchange column (Organo, IRA-400) in the Cl^- state. The concentration of DTAC was determined by drying aliquots of the stock solution over phosphorus pentaoxide in vacuo at 110 °C. Pyrene (purity> 98%, Wako Pure Chemical Industries Co., Ltd.) was passed through silica gel in cyclohexane solution and recovered as white crystals. The purified pyrene gave the value of 1.8—1.9 for the ratio I_1/I_3 of the intensities of the first and the third vibronic peaks of the fluorescence spectrum in aqueous solution.

Electromotive Force Measurements. The counter ion and co-ion activities in DTAC solutions were measured potentiometrically by using a National chloride ion selective ceramic electrode IE-510103 and a HORIBA sodium ion selective glass electrode 1512A-06T, respectively. The following cell was constructed for the measurement of the surfactant ion activity.

> Reference electrode (Ag-AgCl)| Reference solution (DTAC, 1 mmol dm^{-3})|PVC membrane|Sample solution (DTAC; C, NaCl; C_S)| 1 mol dm^{-3} NH_4NO_3 agar bridge|Reference electrode (Ag-AgCl)

The preparation of the PVC membrane electrode is described elsewhere.[18] The electromotive forces (emf) of these cells were measured at 25 °C to a precision of ±0.1 mV with a Yokogawa Universal Digital Meter Model 2502 connected to a voltage follower amplifier (input impedance=10^{15} Ω). Prior to the measurements with DTAC solutions, the chloride ion and sodium ion electrodes were calibrated with a sodium chloride solution of known activity.[19] The semilogarithmic plot of emf vs. NaCl concentration gave a straight line down to ca. 5×10^{-4} mol dm^{-3} with a slope of 59.2 mV for the chloride ion electrode and 57.5 mV for the sodium ion electrode, respectively.

Fluorescence Decay Measurements. Fluorescence decay curves were measured by using the time-resolved fluorescence spectrophotometer (NAES-1100, HORIBA,Ltd.) at

25 °C. Pyrene was solubilized in DTAC stock solution (0.22 mol dm^{-3}) by sonicating the mixture for 30 min. All of the sample solutions were thoroughly deoxygenated before measurements by repeated freeze-pump-thaw cycles. Pyrene was excited at 337 nm and its emission was monitored through the filters (TOSHIBA, V-V40 monochrofilter and UV-35 cut-off filter). After fluorescence decay measurements, the concentration of pyrene was determined spectrophotometrically at 337 nm.

All measurements were conducted at constant salt concentrations (C_S).

Results and Discussion

The electromotive forces of the foregoing cells can be described as

$$E_i = E_i^{\ominus} + S_i \log a_i, \quad i = 1, 2, \text{ and } 3 \qquad (1)$$

where $E_i^{\ominus}$ refers to the standard electromotive force, a_i to the ion activity of component i, S_i to the observed slope of E_i vs. log a_i plot, and subscript 1, 2, and 3 to the surfactant ion, counter ion, and co-ion, respectively. If we denote the values at the cmc by superscript °, we immediately have

$$a_i/a_i^{\circ} = \exp\,[2.303(E_i - E_i^{\circ})/S_i]. \qquad (2)$$

In Figs. 1, 2, and 3 are shown the plots of E_1, E_2, and E_3 vs. the logarithm of DTAC concentration (C) at various NaCl concentrations (C_S), respectively. In consistent with previous results for 1-dodecylpyridinium chloride solutions,[11] an increase in DTAC concentration causes a monotonous decrease in a_1 but an increase in a_2 in the concentration range above the cmc. It should also be noted that the concentration dependences of a_1 and a_2 tend to decrease regularly with increasing salt concentrations. Similar salt effects are also noted for surfactant ion[5] and counter ion[16] activities in anionic surfactant solutions. The values of cmc (C_o) determined from the break points in Figs. 1 and 2 are summarized in Table 1. At higher surfactant concentrations, the value of E_3 is seen to decrease slightly but regularly with increasing concentrations, though the rate of decrease becomes progressively smaller as the salt concentration increases. The observed decrease in E_3 can reasonably be ascribed to the decrease in the activity coefficient (γ_3) of Na^+ ion, since the concentration of which is kept constant under our experimental conditions. These results allow us to estimate not only the degree (β) of counter ion association to the micelle but the activity coefficients and intermicellar concentrations of surfactant ion and counter ion respectively.

According to the charged phase separation model which has been confirmed to hold both in anionic[2-4,6,9,10] and cationic[9,11] surfactant solutions, $a_1 a_2^{\beta}$ should be constant in the concentration range above

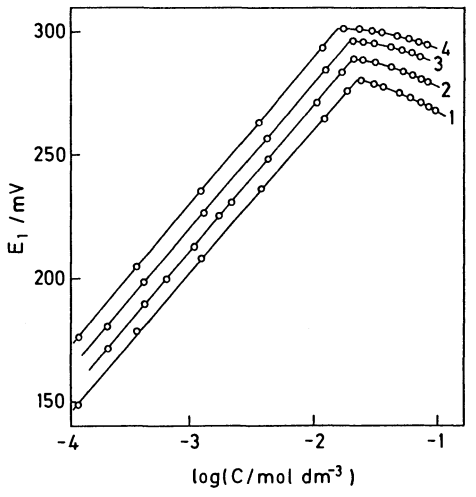

Fig. 1. The semilogarithmic plots of E_1 vs. C at 25 °C. The curves 2, 3, and 4 are displaced upward by 10, 20, and 30 mV, respectively. C_S/mmol dm^{-3}: 1; 0.5, 2; 5, 3; 10, 4; 20. The data for C_S=0 and 0.5 mmol dm^{-3} agree with each other within an experimental error.

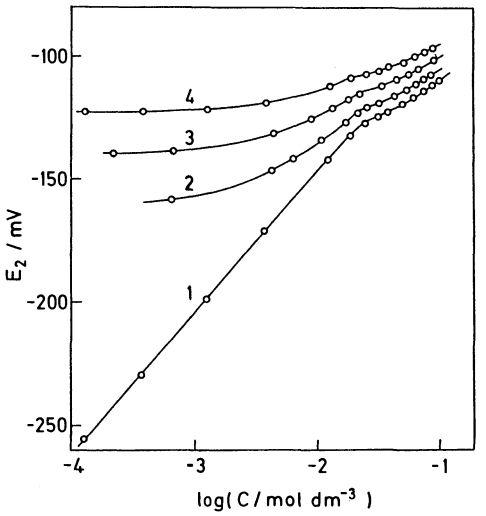

Fig. 2. The semilogarithmic plots of E_2 vs. C at 25 °C. C_S/mmol dm^{-3}: 1; 0, 2; 5, 3; 10, 4; 20.

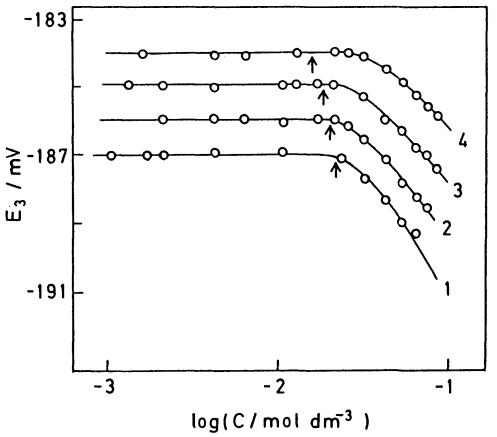

Fig. 3. The semilogarithmic plots of E_3 vs. C at 25 °C. The curves 2, 3, and 4 are displaced upward by 59, 72, and 92 mV, respectively. The arrow indicates the cmc determined from the break points in Figs. 1 and 2. C_S/mmol dm^{-3}: 1; 0.5, 2; 5, 3; 10, 4; 20.

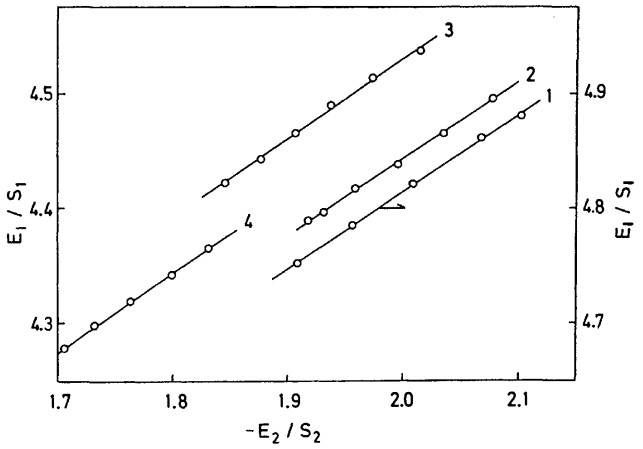

Fig. 4. Plots of E_1/S_1 vs. E_2/S_2 at varying salt concentrations. C_S/mmol dm^{-3}: 1; 0, 2; 5, 3; 10, 4; 20.

the cmc. It follows immediately from Eq. 1 that

$$E_1/S_1 = \text{const.} - \beta \cdot E_2/S_2. \quad (3)$$

As is shown in Fig. 4, a plot of E_1/S_1 against E_2/S_2 gives in fact a straight line regardless of the salt concentration. It should be noted that the value of β summarized in Table 1 is little affected by the salt concentration. A similar constancy in β was also found for 1-dodecylpyridinium chloride solutions with added salt.[11]

The estimation of the intermicellar concentration (C_1) of surfactant ion from a_1 data requires a knowledge of the activity coefficient (γ_1) which is experimentally rather difficult to determine. In this connection, it seems reasonable to assume that the activity coefficients of surfactant ion and co-ion in the bulk phase are nearly identical with each other, since the only difference between them lies in their ionic sizes. At a constant salt concentration, which is the case for the present experiment, this assumption leads immediately to

$$\gamma_1/\gamma_1^\circ \simeq \gamma_3/\gamma_3^\circ = a_3/a_3^\circ \quad (4)$$

$$C_1/C_1^\circ = C_1/C_o \simeq a_1 a_3^\circ/a_1^\circ a_3. \quad (5)$$

These equations enable us to estimate the concentration dependences of γ_1 and C_1 from the electromotive force data. The knowledge of the intermicellar concentration (C_2) and the activity coefficient (γ_2) of the counter ion can then be obtained by substituting the values of β and C_1 estimated above into the following relations.

$$C_2/C_2^\circ = C_2/(C_S + C_o) = [C_1 + C_S + (1-\beta)(C - C_1)]/(C_S + C_o) \quad (6)$$

$$\gamma_2/\gamma_2^\circ = a_2 C_2^\circ/a_2^\circ C_2 \quad (7)$$

The estimated values of γ_1, C_1, γ_2, and C_2 relative to those at the cmc are plotted in Figs. 5 and 6 as a function of $C-C_o$. At a given salt concentration, γ_1 and C_1 decrease monotonously with increasing surfactant concentrations, whereas the reverse change is found for γ_2 and C_2. An increase in salt concentration tends to depress the variations in γ_1, C_1, and γ_2 with surfactant concentration.

Table 1. The Values of C_o and β at Varying Salt Concentrations

C_S/mmol dm^{-3}	C_o/mmol dm^{-3}	β
0	22.4	0.68
5	20.4	0.67
10	18.8	0.69
20	16.2	0.68

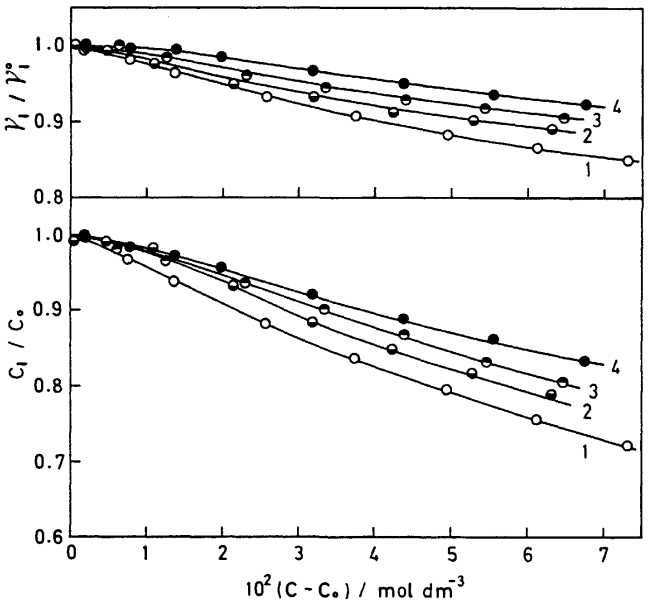

Fig. 5. The concentration dependences of γ_1/γ_1° and C_1/C_o estimated from Eqs.4 and 5. C_S/mmol dm^{-3}: 1; 0.5, 2; 5, 3; 10, 4; 20.

An attempt to estimate these parameters was made by Sasaki et al.,[2] Cutler et al.,[4] and Koshinuma[6,10] on the basis of the assumption that the mean ionic molarity of surfactant ion and counter ion in a micellar solution is identical with that in a hypothetical solution composing only of monomeric ions at a given mean activity. In solution of sodium dodecyl sulfate,[2,4] the value of C_1 thus calculated was found to have a tendency to decrease monotonously with surfactant concentration. According to the same assumption, we[11] also estimated the concentration dependences of γ_1, C_1, and γ_2 in solutions of 1-dodecylpyridinium chloride with and without added salt, and obtained the similar curves to those shown in Figs. 5 and 6. Unfortunately, however, an application of the above treatment to the present system leads to somewhat larger variations in these parameters with surfactant concentration. In their electrostatic approach based on the cell model, Gunnarsson et al.[20] made the numerical calculations of not only surfactant ion and counter ion activities but the intermicellar concentration of surfactant ion. It should be noted that their result for C_1 in sodium

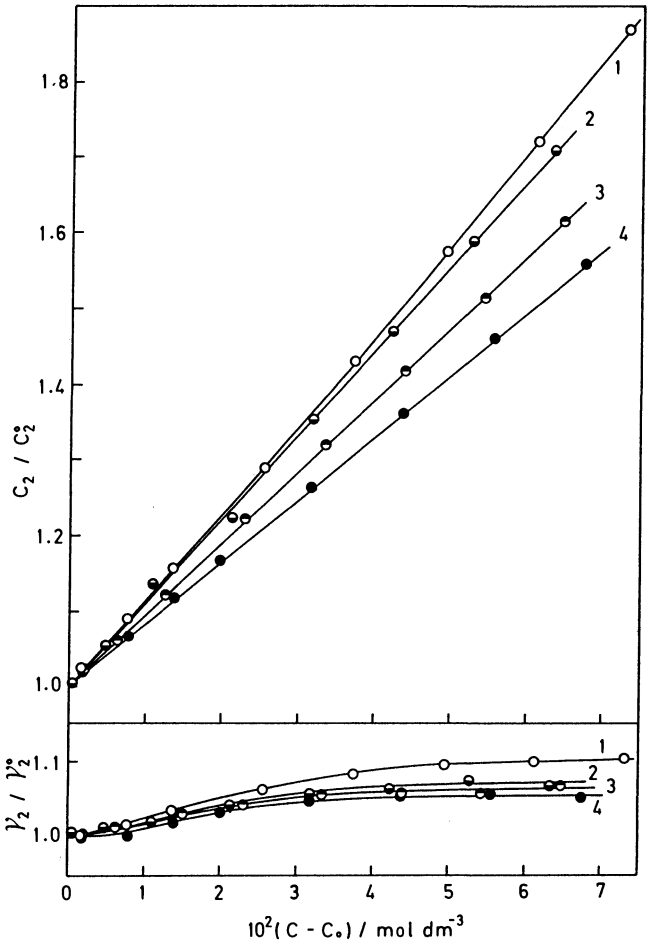

Fig. 6. The concentration dependences of C_2/C_2° and γ_2/γ_2° estimated from Eqs. 6 and 7. C_S/mmol dm^{-3}: 1; 0, 2; 5, 3; 10, 4; 20.

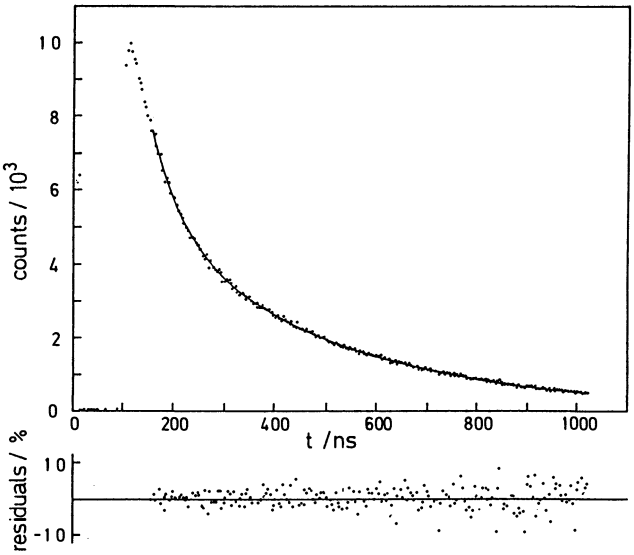

Fig. 7. The typical fluorescence decay curve and residuals at 25 °C. C=41.8 mmol dm^{-3}, C_S= 0.5 mmol dm^{-3}, [pyrene]=0.252 mmol dm^{-3}. Solid line: nonlinear least-squares fit.

Table 2. The Micelle Aggregation Number of DTAC at C_S=0.5 mmol dm^{-3}

C/mmol dm^{-3}	n	n'
35.2	62	56
41.8	61	55
48.4	63	57
52.8	61	55
59.4	62	56
72.6	63	57
220.0	—	63

dodecyl sulfate solution without added salt agree qualitatively well with the present results given in Fig. 5.

In order to demonstrate the utility of C_1 data, we determined the micelle aggregation number (n) of DTAC by fluorescence probe technique under the same experimental conditions as those for the activity measurements. Figure 7 shows the typical fluorescence decay curve of the micelle-solubilized pyrene at C_S=0.5 mmol dm^{-3} and C=41.8 mmol dm^{-3}. It has been well-known that this type of decay curve is described by the following equation based on the Poisson distribution of the pyrene molecules in micelles.[21]

$$I = I_0 \exp[R\{\exp(-k_E t) - 1\} - k_1 t] \quad (8)$$

where, I and I_0 are the fluorescence intensities at time t and zero, k_E and k_1 are the first-order rate constants for the intramicellar excimer formation and decay processes, and R is the number of fluorescence probe per micelle, i.e., R=[Pyrene]/[micelle], respectively. The values of I_0, R, k_E, and k_1 were evaluated from the observed decay curves by using the nonlinear least squares treatment based on modified Marquardt method.[22] According to the definition of R, we immediately have

$$n = R(C - C_1)/[\text{Pyrene}]. \quad (9)$$

The use of Eq. 9 together with C_1 data shown in Fig. 5 permits the precise determination of the micelle aggregation number. The values of n thus determined at C_S=0.5 mmol dm^{-3} are summarized in the second column of Table 2. It is worth noting that the value of n remains essentially constant over wide concentration range above the cmc. In conventional estimations of n based on the fluorescence probe technique,[23-28] C_1 in Eq. 9 has always been replaced by the cmc, C_o. Such a calculation is valid only at higher surfactant concentrations where C_1 can safely be ignored as compared to C. In the concentration range near the cmc, however, it must be kept in mind that the use of C_o instead of C_1 tends to underestimate the value of n. For the sake of comparison, the micelle aggregation number, n', calculated from Eq. 9 with C_1=C_o is also given in Table 2. As would be anticipated, an appreciable difference is found between n and n' in the concentration range up to ca. 7×10^{-2} mol dm^{-3}. At sufficiently high surfactant concentrations, however, the value of n' agrees

well with the constant value of n at lower concentrations. These observations seem not only to reveal the importance of the knowledge of C_1 in the determination of micelle aggregation number by fluorescence probe technique, but to support the validity of the potentiometric method for estimating C_1 in ionic surfactant solution.

The authors wish to express their thanks to Professor Yoshihumi Kusumoto and Dr. Junichi Kurawaki of Chemical Institute, College of Liberal Art, Kagoshima University, for fluorescence decay measurements on a HORIBA NAES-1100 time-resolved fluorescence spectrophotometer.

The Structure of the Cyclodextrin Complex. XXI. Crystal Structures of Heptakis(2,6-di-*O*-methyl)-β-cyclodextrin Complexes with *p*-Iodophenol and *p*-Nitrophenol

Kazuaki HARATA
Research Institute for Polymers and Textiles, 1-1-4 Higashi, Tsukuba, Ibaraki 305
(Received January 9, 1988)

Crystal structures of heptakis(2,6-di-*O*-methyl)-β-cyclodextrin complexes with *p*-iodophenol and *p*-nitrophenol were determined by the X-ray analysis. These two crystals were isomorphous with the space group $P2_12_12_1$ and cell dimensions: a=14.796(3), b=18.853(5), and c=28.989(6) Å for the *p*-iodophenol complex, and a=14.779(2), b=18.965(3), and c=28.741(4) Å for the *p*-nitrophenol complex. The structures were solved by the heavy atom method combined with the phase refinement by the tangent formula and refined by the block-diagonal least-squares method to the R-values of 0.12 (*p*-iodophenol complex) and 0.10 (*p*-nitrophenol complex). The host molecule has a round shape, which is maintained by the intramolecular hydrogen bonds between the O(3)H hydroxyl group and O(2)CH_3 methoxyl group of the adjacent residue. The guest molecules in the both complexes are not included within the host cavity but located in the intermolecular space between host molecules. The host cavity includes water molecules and a methoxyl group of the adjacent host. Hydrogen bonds are formed only within the host cavity.

Cyclodextrins form a number of host-guest complexes with a variety of guest molecules.[1] In the crystalline state, guest molecules are usually included within the cavity of the host macrocycle.[2] Methylated cyclodextrins also form inclusion complexes with many guests, although the geometry of the host-guest interaction differs from that of corresponding cyclodextrin complexes because of the change in size and shape of the host cavity.[3] Therefore, it has been believed that the guest molecule should be fit into the host cavity to form the complex, even if only partially. Recently we have found that some disubstituted benzenes form 1 : 1 crystalline complexes with heptakis(2,6-di-*O*-methyl)-β-cyclodextrin (DM-β-CDx) but are not included within the host cavity. The short communication on the structure of the DM-β-CDx complexes with *p*-iodophenol (*p*-IP) and *p*-nitrophenol (*p*-NP) has been published.[4] In this paper, we destribe details of these crystal structures and discuss the host-guest interaction in comparison with cyclodextrin and other methylated cyclodextrin complexes.

Experimental

The DM-β-CDx complex with *p*-IP was crystallized at 50 °C by standing an aqueous solution of DM-β-CDx saturated with *p*-IP. Crystals of the *p*-NP complex were obtained at room temperature by the slow evaporation of an aqueous solution containing DM-β-CDx and *p*-NP in ca. 1 : 1 molar ratio. Lattice parameters of the crystals and diffraction intensity data were measured at room temperature on a Nicolet P3/F diffractometer with graphite-monochromated Cu $K\alpha$ radiation. By using θ-2θ scan mode, 4045 (*p*-IP complex) and 4670 (*p*-NP complex) independent reflections with $|F_o| \geqq 3\sigma(F)$ were obtained up to 118° in 2θ.

The structure of the *p*-IP complex was solved by the combination of the heavy atom method and the phase-refinement by the tangent-formula. On the electron-density map calculated by using the iodine phases, light atoms could

The occupancy factor of W2A and W2B is 0.6 and 0.4, respectively.

not be located because of the low resolution. Then, phases of 803 reflections with $|E| \geqq 1.4$ were refined by the tangent-formula. Most of light atoms were found on the E-map. The structure was refined by the block-diagonal least-squares method to the R-value of 0.12. A set of the coordinates of DM-β-CDx of the p-IP complex was used to determine the isomorphous structure of the p-NP complex, which was refined to the R-value of 0.10. The quantity minimized was $\sum w(|F_o|-|F_c|)^2$ with $w=1.0$ for all the reflections used. Final atomic coordinates are given in Tables 1 and 2. Tables of observed and calculated structure factors and anisotropic temperature factors are deposited to the Chemical Society of Japan (Document No. 8798). The computations were carried out on a FACOM M380 computer at the Research Information Processing System (RIPS) Center, Agency of Industrial Science and Technology, Tsukuba.

Description of the Structure and Discussion

As shown in Figs. 1 and 2, DM-β-CDx molecule has a round and rather symmetrical structure. The radius of the heptagon composed of seven glycosidic oxygen atoms is 4.84—5.21 Å in the *p*-IP complex and 4.92—5.16 Å in the *p*-NP complex. The average values of 5.05 and 5.07 Å is in good agreement with the radius of parent β-CDx.[5,6] The side lengths of the heptagon are in the range 4.25—4.49 Å (*p*-IP complex) and 4.33—4.44 Å (*p*-NP complex). Each 2,6-di-*O*-methylglucose residue inclines with the O(6) side turning to the inside of the macrocycle. The tilt-angles are in the range 5.6—24.4° in the *p*-IP complex and 2.2—24.7° in

the *p*-NP complex. Among the seven residues, the G6 residue is most tilted in both complexes. The distances between O(2) and O(3) of the adjacent residue, 2.72—3.10 Å in the *p*-IP complex and 2.79—3.05 Å in the *p*-NP complex, indicate that the O(3)H hydroxyl group is hydrogen-bonded to the O(2) atom of the adjacent

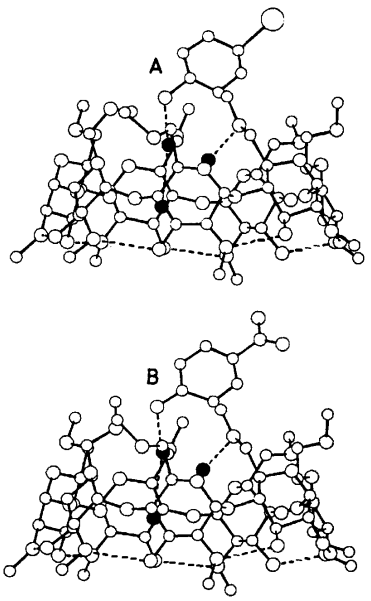

Fig. 2. Side-view of the DM-β-CDx complexes with *p*-IP (A) and *p*-NP (B). Water molecules are shown by full circles. Dashed lines indicate possible hydrogen-bonding contacts.

Table 3. Geometrical Data for Describing the Macrocyclic Conformation of DM-β-CDx

I. Distance from the center of gravity of seven O(4) atoms to each O(4) atom[a)]

Residue	Distance (*l*/Å)		Residue	Distance (*l*/Å)	
	p-IP	*p*-NP		*p*-IP	*p*-NP
G1	5.20	5.13	G5	5.11	5.08
G2	4.92	4.84	G6	4.98	4.92
G3	4.98	5.13	G7	5.13	5.14
G4	5.21	5.16	Average	5.05	5.07

a) Estimated standard deviations are 0.03 (*p*-IP complex) and 0.03 Å (*p*-NP complex).

II. Distance between O(4) and O(4′) of the adjacent residue[a)]

	Distance (*l*/Å)	
	p-IP	*p*-NP
O(4,G1)···O(4,G2)	4.38	4.41
O(4,G2)···O(4,G3)	4.41	4.41
O(4,G3)···O(4,G4)	4.49	4.44
O(4,G4)···O(4,G5)	4.25	4.33
O(4,G5)···O(4,G6)	4.43	4.44
O(4,G6)···O(4,G7)	4.48	4.41
O(4,G7)···O(4,G1)	4.29	4.34
Average	4.39	4.40

a) Estimated standaed deviations are 0.03 (*p*-IP complex) and 0.02 Å (*p*-NP complex).

III. Distance between O(2) and O(3′) of the adjacent residue[a)]

	Distance (*l*/Å)	
	p-IP	*p*-NP
O(2,G1)...O(3,G2)	2.81	2.79
O(2,G2)...O(3,G3)	2.88	2.88
O(2,G3)...O(3,G4)	2.73	2.79
O(2,G4)...O(3,G5)	3.04	2.97
O(2,G5)...O(3,G6)	2.85	2.87
O(2,G6)...O(3,G7)	3.10	3.05
O(2,G7)...O(3,G1)	2.94	2.90
Average	2.91	2.89

a) Estimated standard deviations are 0.03 (*p*-IP complex) and 0.02 Å (*p*-NP complex).

IV. Torsion-angle index[a)] and tilt-angle[b)] of each residue

Residue	Torsion-angle index (ϕ/°)		Tilt-angle (ϕ/°)	
	p-IP	*p*-NP	*p*-IP	*p*-NP
G1	112	124	5.8	5.5
G2	106	107	15.5	17.0
G3	138	122	16.1	14.2
G4	121	117	17.8	18.1
G5	107	112	5.6	2.2
G6	138	123	24.4	24.7
G7	106	113	19.7	17.6
Average	118	117	15.0	14.2

a) The torsion-angle index is defined as: $\phi=|\phi(C(1)-C(2))|+|\phi(C(2)-C(3))|+|\phi(C(5)-O(5))|+|\phi(O(5)-C(1))|-|\phi(C(3)-C(4))|-|\phi(C(4)-C(5))|$, where $\phi(C(1)-C(2))$ indicates the conformation angle of O(5)-C(1)-C(2)-C(3). b) The tilt-angle is defined as an angle made between the plane through seven O(4) atoms and the plane through C(1), C(4), O(4), and O(4′) of each residue.

V. Deviation of each O(4) atoms from the least-squares plane through seven O(4) atoms

Residue	Deviation (*d*/Å)		Residue	Deviation (*d*/Å)	
	p-IP	*p*-NP		*p*-IP	*p*-NP
G1	−0.01	−0.01	G5	0.17	0.13
G2	0.13	0.11	G6	0.01	0.03
G3	−0.04	−0.02	G7	−0.11	−0.10
G4	−0.16	−0.14	r.m.s. deviation	0.11	0.09

residue. All methyl groups point away from the center of the host macrocycle, thus the host cavity of DM-β-CDx is deeper than the cavity of parent β-CDx. The comparison of the O(4)···O(4′) distance (the side length of the O(4) heptagon) with the torsion-angle index gives no obvious correlation between them, although in parent β-CDx the strong correlation has been observed between the O(4)···O(4′) distance and the torsion-angle index. The methyl group may affect the conformation of the pyranose ring to break such linear correlation.

Except for methyl groups, the macrocyclic conformation of DM-β-CDx does not significantly differ from the conformation of parent β-CDx, as shown in

Table 4. Comparison of Geometrical parameters among β-Cyclodextrin and Methylated β-Cyclodextrins

Average values are given with standard deviations.

	β-CDx[a]	DM-β-CDx	TM-β-CDx[b]
Radius of the O(4) heptagon (l/Å)	5.0(0.2)	5.1(0.1)	5.0(0.3)
O(4)...O(4′) distance (l/Å)	4.3(0.1)	4.4(0.1)	4.3(0.1)
O(2)...O(3′) distance (l/Å)	2.9(0.1)	2.9(0.1)	3.5(0.2)
Glycosidic O(4) angle (ϕ/°)	118(1)	117(2)	117(3)
Planarity of the O(4) heptagon (d/Å)[c]	0.18	0.09	0.44
Torsion-angle index (ϕ/°)	120(7)	117(6)	123(13)
Tilt-angle (ϕ/°)	12(10)	14(8)	20(25)

a) See Ref. 5. b) Heptakis(2,3,6-tri-*O*-methyl)-β-cyclodextrin (Ref. 7). c) The root-mean-square deviation of the seven O(4) atoms.

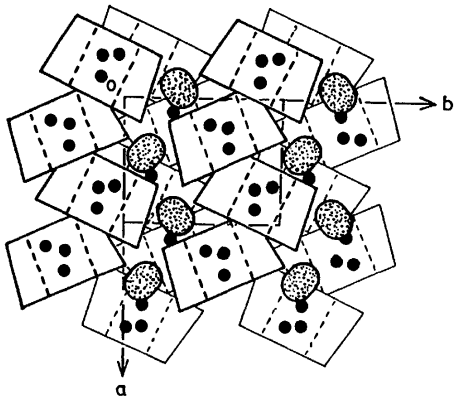

Fig. 3. A schematic drawing of the crystal structure. Water molecules are shown by full circles. Shaded ellipses indicate guest molecules.

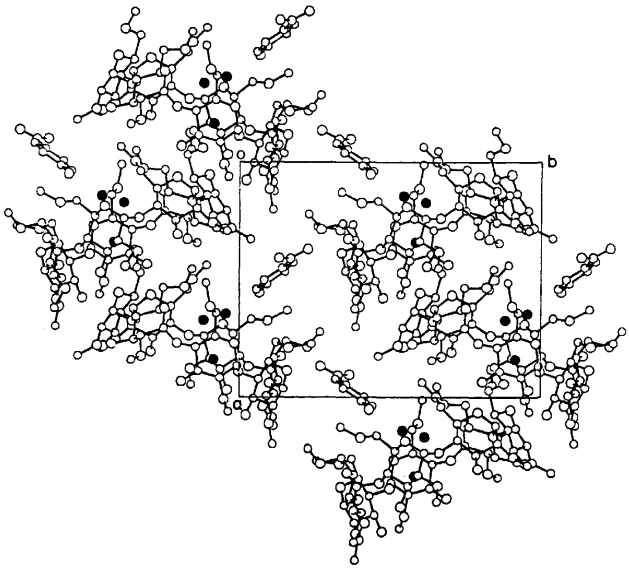

Fig. 4. The crystal structure of the DM-β-CDx complex with *p*-NP viewed along the c axis. Water molecules are shown by full circles. Symmetry-related molecules by the two-fold screw axis along the c axis are not shown because of the clarity of representation.

Table 4. By the methylation of O(3)H hydroxyl groups, the distance between O(2) and O(3) of the adjacent residue is increased from 2.9 Å to 3.5 Å. Moreover, each residue much more inclines with the tilt-angle in the range from −16.3° to 43.0°.[7] This indicates that the round shape of the macrocycle is maintained by the intramolecular O(2)···O(3′) hydrogen bonds in β-CDx and DM-β-CDx. The methylation of the O(2)H hydroxyl group does not affect the formation of intramolecular hydrogen bonds because the O(2)C(7)H_3 methoxyl group points away from the adjacent O(3)H hydroxyl group. The further methylation at the O(3) position blocks the formation of O(2)···O(3′) hydrogen bonds, and as the result, the macrocycle can no more retain the round structure.

Figure 3 shows the packing feature in the crystal. The DM-β-CDx molecules are stacked along the a axis. Since the DM-β-CDx molecule inclines by an angle of 25° against the a axis, the stacked molecules do not form a column structure but show a zigzag pattern. The O(2), O(3) side of the DM-β-CDx cavity is blocked by the O(6) side of the adjacent DM-β-CDx molecule which is related by the two-fold screw axis along the a axis. The O(6) side of the cavity is open to the intermolecular space, where the guest molecule is located. It is noteworthy that the guest *p*-IP and *p*-NP mole-

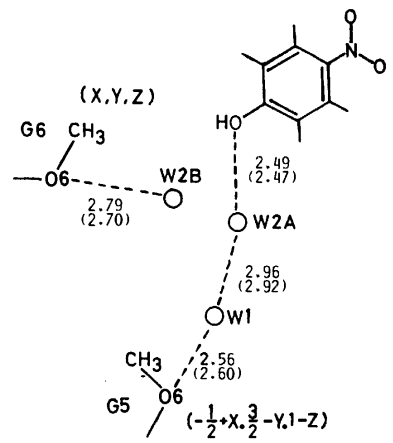

Fig. 5. A possible hydrogen bond scheme in the DM-β-CDx complex with *p*-NP. Corresponding hydrogen bond distances of the *p*-IP complex are given in parentheses.

cules are not included within the DM-β-CDx cavity but located in the crevice running zigzag along the a axis. Such geometrical relationship between host and guest is not observed in other cyclodextrin or methylated cyclodextrin complexes, except for the α-CDx-*m*-nitrophenol (1:2) complex, in which one guest is included within the host cavity and the other being located in the intermolecular space.[8] It is not easy to explain fully why the guest molecule is excluded from the host cavity, since the inclusion of the guest molecule by DM-β-CDx has been observed in the crystalline complex with 2-adamantanol.[9] One possible reason is that the intermolecular space has highly hydrophobic property because of many methyl groups. The guest molecule could be located in the intermolecular space rather than in the host cavity when the size and shape of the intermolecular space are more suitable for the guest molecule. On the other hand, in the crystal of native cyclodextrins, the intermolecular space is usually filled with water molecules which form a hydrogen bond network with many hydroxyl groups of the host molecule.

The DM-β-CDx cavity includes water molecules and one methoxyl group, O(6,G5)C(8,G5)H_3, which is inserted from the O(2), O(3) side. A possible hydrogen-bond scheme inside the host cavity is shown in Fig. 5. The W2 water molecule is disordered and occupies two sites, W2A and W2B. W2B is hydrogen-bonded to O(6,G6), while W2A forms hydrogen bonds with the hydroxyl group of the guest and W1 water molecule which is also hydrogen-bonded to O(6,G5) of the adjacent DM-β-CDx molecule related by the two-fold screw axis. Although the host cavity is extended and deepened by the methylation, the effective space of the cavity to include the guest molecule is reduced by the insertion of one methoxyl group of adjacent DM-β-CDx. Such close contact between host molecules may play an important role to exclude the guest molecule from the host cavity. It has been considered that the guest molecule should be included within the host cavity in the crystalline state. The present study, however, shows that the guest molecule is not necessarily included by the host molecule even if the complex has a 1:1 host-guest stoichiometry.

(Received May 29, 1987)

A relationship between acid amounts over TiO_2-ZrO_2 catalysts and their activities for nonoxidative dehydrogenation of ethyl benzene to styrene was examined. The catalysts were prepared by two different methods; one is simultaneous hydrolysis of Ti and Zr mixed alkoxides solution and the other is physical mixing of pure TiO_2 and ZrO_2. The former consists of fine TiO_2 and ZrO_2 particles and is expected a lot of Ti-O-Zr bonding between the fine particles, while the latter is composed of large particles and less amounts of Ti-O-Zr bonding might be expected. Although the Ti-O-Zr bonding has been considered to generate a new acid site and to enhance the rate of dehydrogenation of ethylbenzene, the acid amounts and the rates observed on unit surface areas of both catalysts were not significantly different. On the basis of these results, the role of Ti-O-Zr bondig in TiO_2-ZrO_2 catalyst for dehydrogenation of ethylbenzene is discussed.

Catalysis by metal oxides often depends upon their surface acidities originated from surface OH groups and structural deficiencies. It has been well-accepted that the surface acidity of a metal oxide can be improved by mixing it with another metal oxide to form a binary oxide.[1] The binary oxide should be prepared by coprecipitation method so as to be composed of fine respective oxide particles, resulting in a lot of metal(1)-O-metal(2) bonding at the fringe of particles. New and strong acid sites generated on the binary oxide have been believed due to the formation of this kind of bonding.[2]

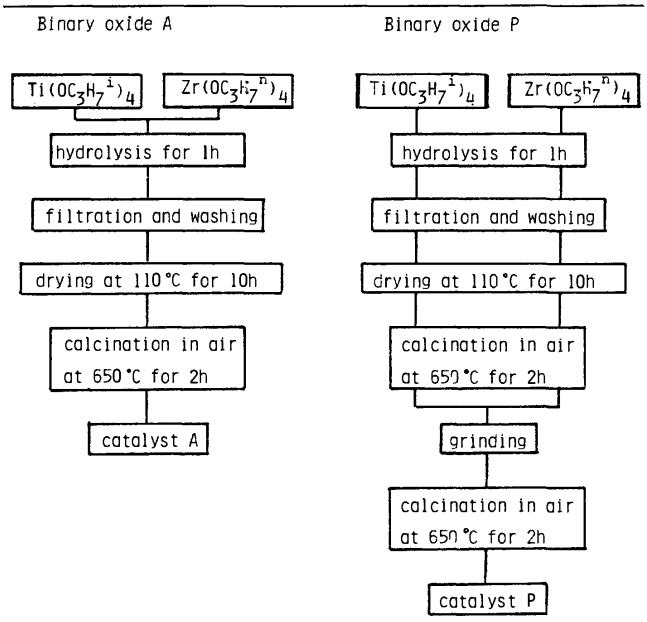
Recently, TiO_2-ZrO_2 binary oxide has been reported to exhibit a high potential for nonoxidative dehydrogenation of ethylbenzene to styrene and this high activity has been explained by a concerted two-center mechanism based on the generation of Ti-O-Zr bonding on the binary oxide catalyst, where Zr ions act as acid sites and Ti as basic sites.[3] Since the catalyst was prepared by coprecipitation of a mixed solution of Ti and Zr tetra chlorides in alcohol with aqueous ammonia, a small amount of chloride ions might remain in the powder as contamination. Considering that the surface acidity is too sensitive to contamination, the catalyst examined should be free from any impurities. In this experiment the TiO_2-ZrO_2 binary catalyst was prepared by simultaneous hydrolytic decomposition of a mixed solution of Ti tetraisopropoxide and Zr tetrapropoxides, which will be one of the best method to prepare oxide powders free from impurities.

The purpose of the present work is to examine the acidity and the rate of dehydrogenation of ethylbenzene on the catalyst thus prepared and to discuss the role of surface Ti-O-Zr bondings during the catalysis.

Experimental

Preparation of TiO_2-ZrO_2 Binary Oxide. The binary oxide composed of TiO_2 and ZrO_2 was prepared by two different methods described in Table 1. In one method, the binary oxide A was prepared by a simultaneous hydrolytic decomposition of titanium tetraisopropoxide (Kishida Chemical Co.) and zirconium tetrapropoxide (Alpha Products Co.) dissolved in benzene. The hydrolysis was carried out at room temperature using an excess amount of distilled water in flowing dry nitrogen. The precipitates thus obtained were dried at 110 °C in an oven, followed by calcination at 500—800 °C in air for 2 h. The weight ratio of TiO_2/ZrO_2 in the binary oxide was varied from 10/90 to 90/10 by changing the amounts of respective alkoxides in an appropriate ratio. In the other method, which will be designated as P, pure TiO_2 and ZrO_2 (total amount being ca. 2 g) were physically mixed and ground in an agate mortar for ca. 30 min, and subse-

Table 1. Preparation Procedures of the Binary Oxides A and P



Preparation procedures of TiO_2-ZrO_2 catalysts.

quently calcined at 650 °C in a similar manner as A. Pure TiO_2 and ZrO_2 were prepared by the hydrolysis of respective alkoxides, followed by drying at 110 °C in an oven and calcination at 650 °C in air. The specific surface areas of these oxides were measured by BET method using nitrogen at its liquid temperature. The structural differences in these binary oxides were studied by X-ray diffraction (Rigaku Denki Co., Geigerflex), operated at 30 kV with a filament current of 15 mA using Ni filter for Cu $K\alpha$ radiation. The distributions of metal ions in the TiO_2-ZrO_2 binary oxide powders were measured by means of EPMA (electron probe X-ray micro analyser, Hitachi Co., X-650), operated at an accelerating voltage of 20 kV. For EPMA measurements the sample powder was covered with thin Pt film to avoid a charge-up phenomenon.

Measurements of Acidity and Catalytic Activity. The surface acidity of the binary oxide was decided by butylamine titration using 1-phenylazo-2-naphthylamine (H_0=+4.0), *p*-dimethylaminoazobenzene (+3.3), benzeneazodiphenylamine (+1.5) and dicinnamal acetone (−3.0), dissolved in benzene, as indicators.[4] The sample powder was first calcined at 650 °C in air and prior to the acidity test the sample was recalcined at 300 °C in O_2 atmosphere, followed by evacuation at the same temperature. The sample thus treated was pored into benzene without exposure to air and a few drops of indicator were added to the sample. The sample was left for 24 h and then submitted to the titration test with butylamine. Several times of the titration tests were made for one sample to decide its surface acidity. The acid amount thus measured has an error larger than +0.1 mmol·g^{-1} because of the difficulty to find out the end point of titration.

The binary oxide powders were employed as catalysts for nonoxidative dehydrogenation of ethylbenzene to styrene. The catalyst powder was calcined at 650 °C for 4 h and the reaction was carried out at 620 °C with a continuous flow reaction system. A mixture of ethylbenzene and water was supplied into the reactor with N_2 stream. The flow rate of N_2 was 25 ml·min^{-1} and the feed rates of ethylbenzene and water were 25 and 43 ml·min^{-1}, respectively. This corresponds to the weight ratio of ethylbenzene/water being 2.

Table 2. Conversions of Ethylbenzene and Selectivities to Styrene, Toluene, and Benzene over the Binary Oxides A and P at 620 °C

Composition (Ti/Zr)	Surface area	EB conversion	Selectivity/%		
	$m^2 g^{-1}$	%	Sty	Tol	Ben
Binary oxide A					
10/90	56	6.7	93.2	2.0	4.8
25/75	92	9.0	94.6	1.7	3.7
50/50	141	11.6	95.5	1.4	3.1

Binary oxide P					
10/90	54	7.6	92.4	2.0	5.6
25/75	60	6.5	91.3	2.1	6.6
50/50	40	4.7	91.4	2.7	5.9
75/25	40	6.7	91.0	2.1	6.9
90/10	47	7.1	92.2	3.4	5.8
TiO	50	5.8	92.5	2.4	5.1
ZrO_2	56	3.7	89.0	3.4	7.6

The catalyst powder (2.5 g) was pelleted and placed over the catalyst bed located just below the preheater, containing rashig rings. A cooling trap was equipped at the outlet of the reactor to collect ethylbenzene, water and liquid products such as styrene, benzene and toluene. These liquids were analysed by gas chromatography using a column packed with SP-1200 and Bentone 34 coated Chromosorb W.

Results

BET Surface Area and X-Ray Diffraction. The BET surface areas of TiO_2, ZrO_2, and the binary oxide powders calcined at 650 °C are listed in Table 2 with other results. The surface area of the binary oxide A (TiO_2/ZrO_2=50/50) decreased with increasing the calcination temperature and reached constant above 750 °C (Fig. 1). The X-ray diffraction spectra of pure TiO_2 and ZrO_2 and the binary oxides are depicted in Figs. 2 and 3. The crystallographic structures of TiO_2 and ZrO_2 are determined to be rutile and monoclinic with a small amount of tetragonal, respectively, when calcined at 650 °C. The binary oxide P calcined at 650 °C showed sharp diffraction peaks assigned to TiO_2 (rutile) and ZrO_2 (monoclinic and tetragonal) with rational intensities according to the respective concentration. On the other hand the binary oxide A calcined at 650 °C showed rather broad diffraction peaks assigned to TiO_2 (anatase), ZrO_2 (monoclinic and tetragonal) and probably to the complex oxide, $TiZrO_4$, when the TiO_2/ZrO_2 ratio of the oxide A is in the range between 25/75 and 75/25. In Fig. 4 are shown the changes in X-ray diffraction pattern of the oxide A (TiO_2/ZrO_2=50/50) with the calcination temperature, indicating that a small amount of $TiZrO_4$ seems to be formed at 650 °C. In the case of binary oxide P, no formation of $TiZrO_4$ was observed even when the powder was calcined at 1100 °C in air for 12 h.

EPMA Measurements. The homogeneous distributions of Ti and Zr ions on the surface of the binary oxide A calcined at 650 °C are demonstrated by X-ray images with EPMA measurements (Fig. 5). While on the surface of the binary oxide P calcined at 650 °C, Ti and Zr ions were found to be localized, forming relatively large TiO_2 and ZrO_2 particles (also in Fig. 5).

Acidity and Catalytic Activity. The total acid amounts on TiO_2, ZrO_2 and the binary oxides calcined at 650 °C were measured by butylamine titration using 1-phenylazo-2-naphthylamine (H_0=+4.0) as an indicator and the results obtained are given in Figs. 6a and b. In Fig. 6a, the acid amount was expressed in terms of $mmol \cdot g^{-1}$, while in Fig. 6b in terms of $\mu mol \cdot m^{-2}$. The strong acid sites with $H_0 \leq +3.3$ were observed on the binary oxide A, while those strong acid sites were never observed on the binary oxide P. The acid amounts with various strengths measured on the binary oxide A are depicted in Fig. 7.

The catalytic activities of TiO_2, ZrO_2, and the binary oxide A and P for dehydrogenation of ethylbenzene at the stationary state are listed in Table 2 and depicted in Figs. 8a and b, where the activities were expressed in terms of $molecules \cdot g^{-1} \cdot s^{-1}$ and $molecules \cdot m^{-2} \cdot s^{-1}$, respectively, assuming first order reaction with respect to ethylbenzene.

Dscussion

The initial stage of the preparation of the binary

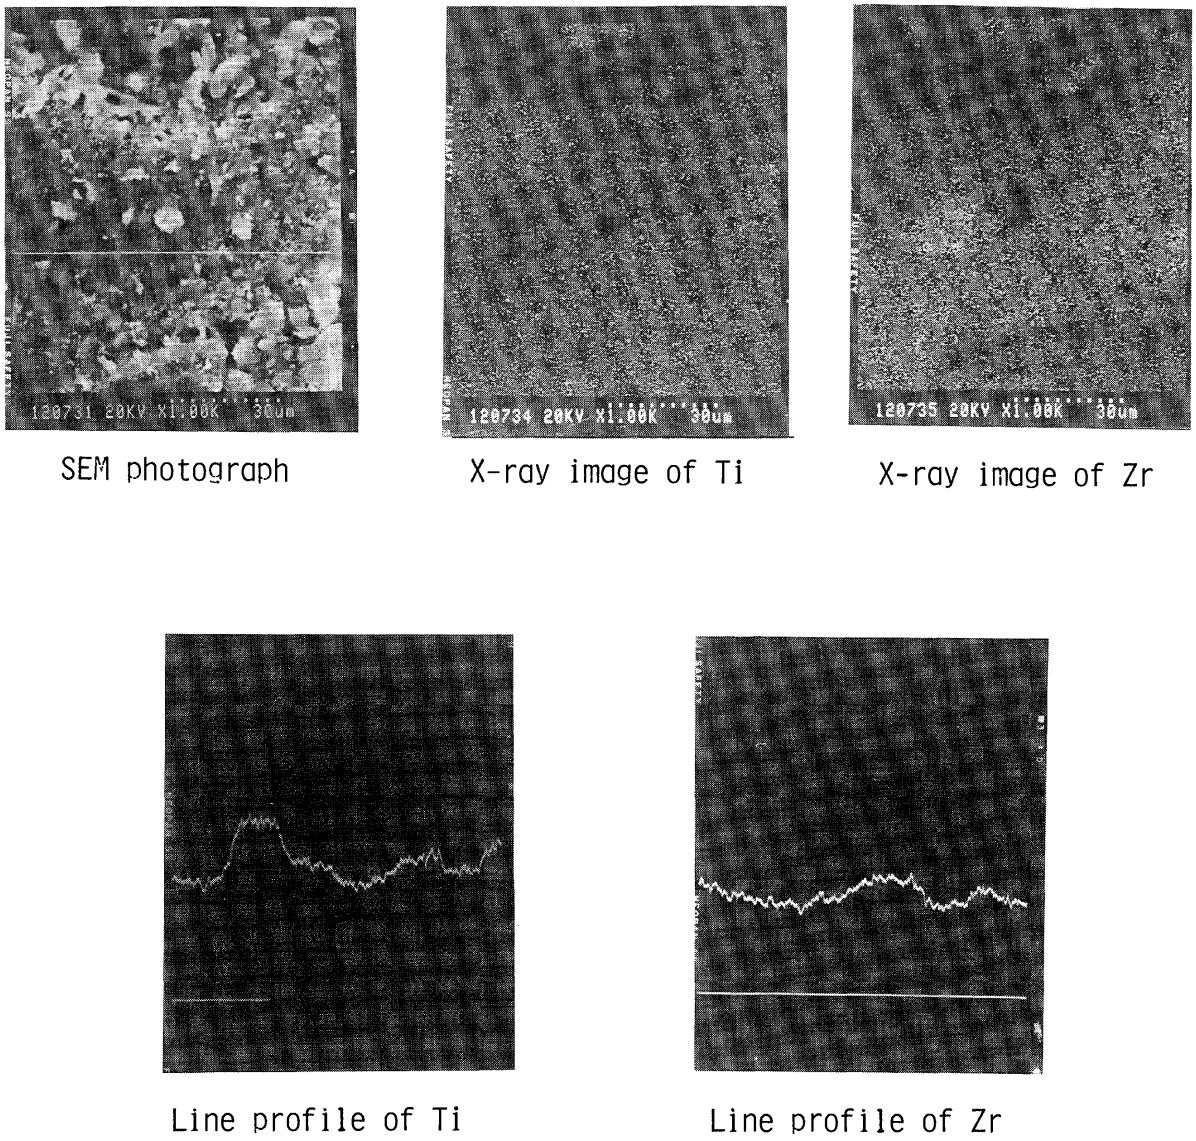

Fig. 5a. Distributions of Ti and Zr ions in the binary oxide A (TiO_2/ZrO_2=50/50) calcined at 650°C, measured by EPMA.

oxide A is the simultaneous hydrolytic decomposition of Ti and Zr alkoxides. Before the hydrolysis, the alkoxides solution was vigorously stirred at 60 °C for 2 h in flowing dry N_2, expecting that the rearrangements of metal ions will take place according to the following reaction;

$$n\ Ti(OC_3H_7)_4 + n\ Zr(OC_3H_7)_4 \longrightarrow [Ti(OC_3H_7)_m\text{-}O\text{-}Zr(OC_3H_7)_m] \quad (1)$$

By adding water the $(OC_3H_7)_m$ groups in the species above were substituted with $(OH)_m$ groups producing propyl alcohol, C_3H_7OH, due to the following reaction;

$$[Ti(OC_3H_7)_m\text{-}O\text{-}Zr(OC_3H_7)_m] + 2m\ H_2O \longrightarrow [Ti(OH)_m\text{-}O\text{-}Zr(OH)_m] + 2m\ C_3H_7OH \quad (2)$$

The hydrogen bonding between (OH) groups in the $[Ti(OH)_m\text{-}O\text{-}Zr(OH)_m]$ species might result in the formation of a gel-like precipitate, where Ti and Zr ions are highly dispersed forming a chemical bonding of Ti-O-Zr. This idea has been already adopted for the preparation of glassy materials such as SiO_2-ZrO_2[5] and SiO_2-TiO_2-ZrO_2[6] systems and of oxide powders such as $BaTiO_3$[7] and $SrTiO_3$.[8] Although the atomic dispersions of Ti and Zr ions are desired, considerable amounts of $[Ti(OC_3H_7)_m\text{-}O\text{-}Ti(OC_3H_7)_m]$ and $[Zr(OC_3H_7)_m\text{-}O\text{-}Zr(OC_3H_7)_m]$ species may be formed in spite of vigorous stirring of the alkoxides solution, and Ti-O-Ti and Zr-O-Zr bondings may also remain in the precipitate produced by hydrolysis. The Ti-O-Ti and Zr-O-Zr structures thus prepared may turn out to be fine TiO_2 and ZrO_2 crystallites, respectively, when the precipitate was dried and calcined in air.

In order to examine the structures of the products, X-ray diffraction patterns of the binary oxide A with various TiO_2/ZrO_2 ratios were obtained (see Figs. 2

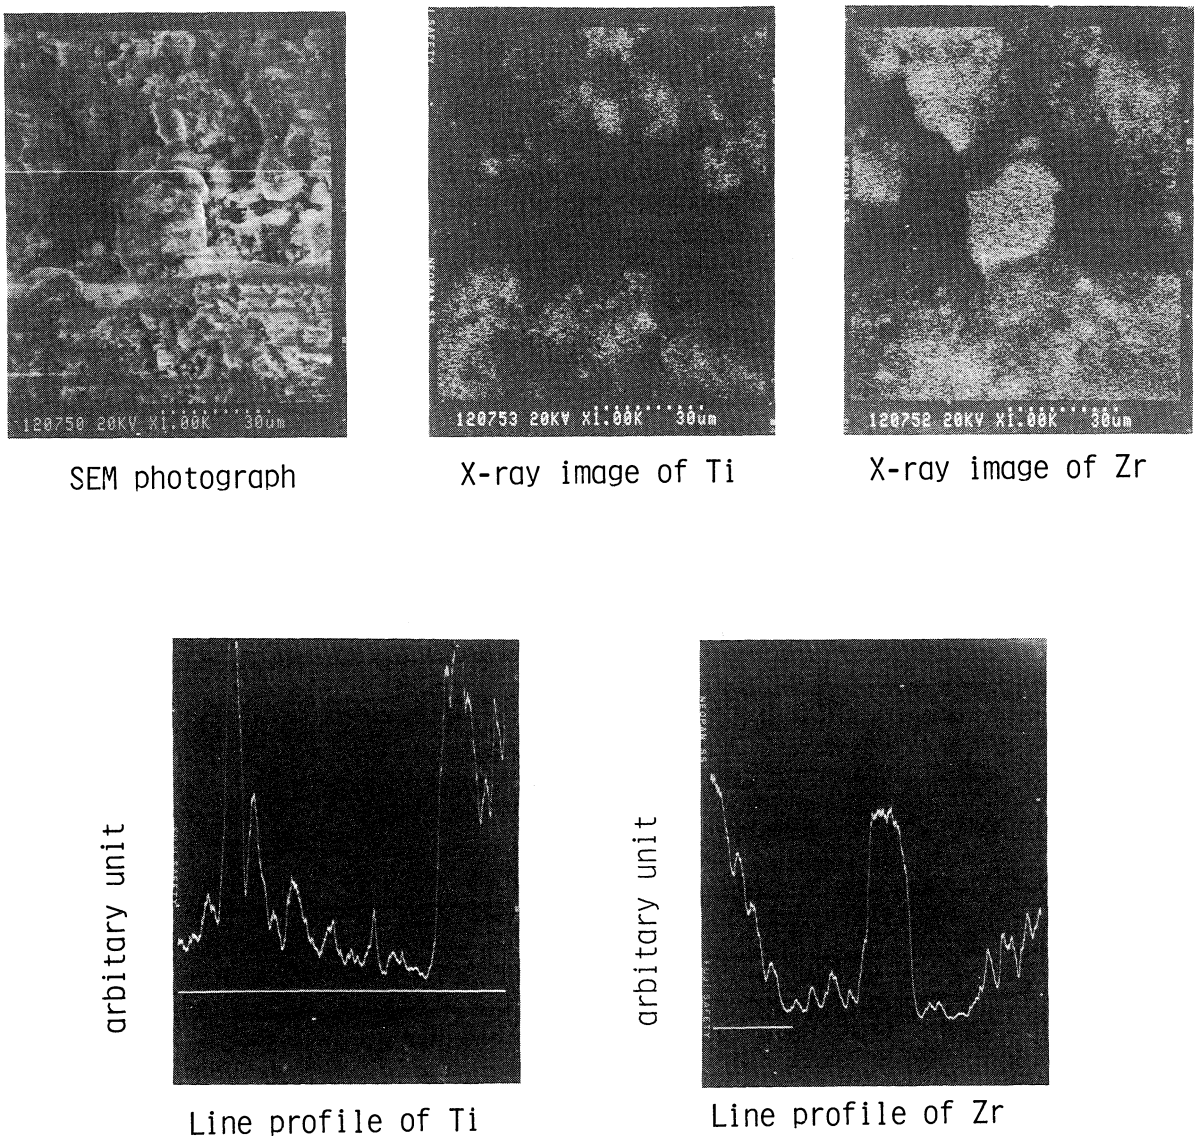

Fig. 5b. Distributions of Ti and Zr ions in the binary oxide P (TiO_2/ZrO_2=50/50) calcined at 650°C, measured by EPMA.

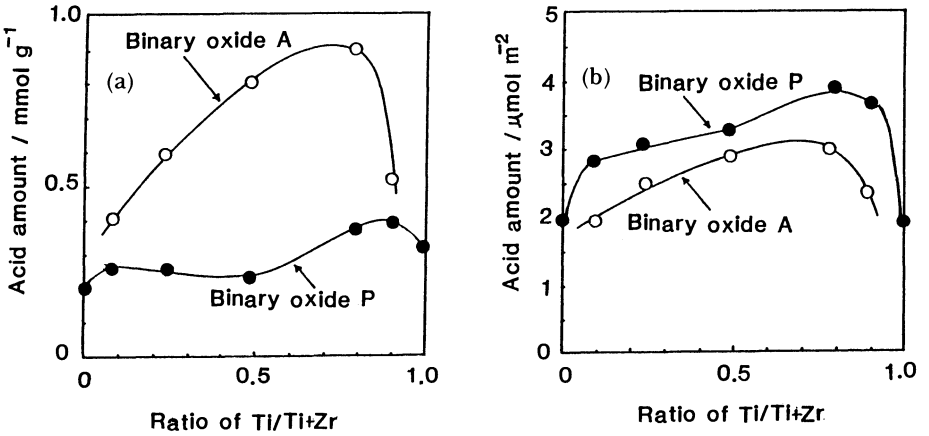

Fig. 6. a) Acid amounts on the binary oxides A and P with varaious TiO_2/ZrO_2 ratios expressed in terms of mmol·g^{-1}; the oxides were calcined at 650°C. b) Acid amounts on the binary oxides A and P with various TiO_2/ZrO_2 ratios expressed in terms of μmol·m^{-2}; the oxides were calcined at 650°C.

and 3). Several broad peaks were observed for the binary oxide A calcined at 650 °C with TiO_2/ZrO_2 ranging from 25/75, while for pure TiO_2 and ZrO_2 sharp diffraction peaks assigned to rutile and monoclinic with a small amount of tetragonal form, respectively, were observed. This indicates that the coexistence of Ti and Zr ions in the precipitate prevents the fine TiO_2 and ZrO_2 crystallites from their crystalline growth during calcination. It might be possible to say that the suppressions of the crystalline growth are attributed to formation of Ti-O-Zr network structure. As could be seen in Fig. 4, the formation of a small amount of $TiZrO_4$ was first observed when the binary oxide A was calcined at 650 °C for 4 h, which resulted in the reduction of the surface area of the oxide A (see Fig. 1). On the contrary, no peaks assigned to $TiZrO_4$ were observed in the binary oxide P even when calcined at the temperature as high as 1100 °C for 12 h. This means that the dispersions of Ti and Zr ions in the binary oxide A are extremely higher than those in the binary oxide P. The high dispersions of Ti and Zr ions in the binary oxide A were evidenced by EPMA measurements (see Fig. 5). It has been already proved by EXAFS (extended X-ray absorption fine structure) study[9] that the binary oxide A is predominantly composed of fine TiO_2 and ZrO_2 crystallites and that the binary oxide P mainly consists of large TiO_2 and ZrO_2 ones.

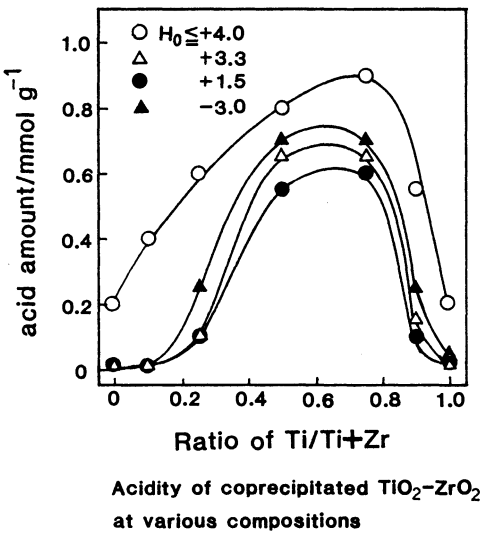

Fig. 7. Acid amounts with various acid strengths on the binary oxide A calcined at 650 °C.

Thus, a lot of Ti-O-Zr structures are expected at the interface between fine TiO_2 and ZrO_2 crystallites in the binary oxide A. It has been widely accepted that mixed oxide powders consisting of fine respective oxide crystallites often showed new acid sites originated from the generation of new bonding, M(1)-O-M(2), where M(1) and M(2) represent metal ions in the mixed oxide powders.[2] TiO_2-ZrO_2 system has been reported a typical case to generate new acid sites when the respective oxide crystallites are so small.[10] Indeed, the acid amount over 1 g of the binary oxide A was higher than that of the oxide P at any TiO_2/ZrO_2 ratios employed. (see Fig. 6a) While, as shown in Fig. 6b, the acid amounts over unit surface area of the binary oxide P is observed rather higher than those of the binary oxide A. Although the results might not be favorable for the opinion above, it is difficult to obtain rigid conclusions concerning the difference in the acid properties of the binary oxide A and P because of the ambiguity of the acid amounts measured in this work. No acid sites with $H_0 \leq +3.3$ were observed over the surface of binary oxide P, while considerable amounts of the acid sites with $H_0 \leq +3.3$ were generated on the surface of

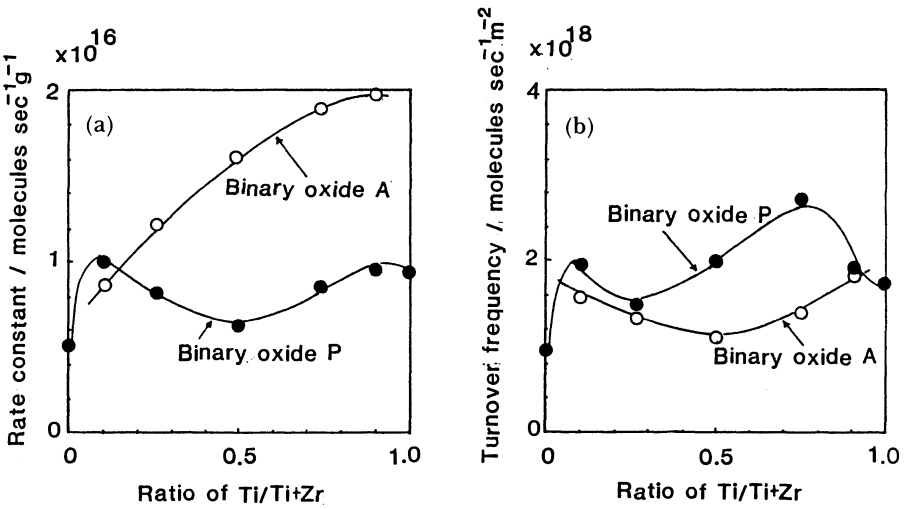

Fig. 8. a) Catalytic activities of binary oxides A and P expressed in terms of molecules·g^{-1}·s^{-1}; the catalysts were calcined at 650 °C before the reaction. b) Catalytic activities of binary oxidea A and P expressed in terms of molecules·m^{-2}·s^{-1}; the catalysts were calcined at 650 °C before the reaction.

binary oxide A, as shown in Fig. 7. Consequently, the total amounts of acid sites with $H_0 \leq +4.0$ over the binary oxide A might be the same as that on the binary oxide P, but the acid sites generated on the binary oxide A are much stronger than those on the binary oxide P. This probably due to the formation of Ti-O-Zr bonding over the binary oxide A[2] with a timid suspect whether the Ti-O-Zr bondings are merely required to generate a new and strong acid site. It must be mentioned that the acid amount, containing strong acid sites with $H_0 < +3.3$, on the binary oxide prepared by coprecipitation of a mixed solution of Ti and Zr tetrachlorides were observed almost the same as that on the binary oxide A. No significant effects of chlorine ions contaminated upon the acid property were recognized.

Recently, it has been reported that the binary oxide composed of fine TiO_2 and ZrO_2 particles is a potential catalyst for nonoxidative dehydrogenation of ethylbenzene to styrene.[3] It has been proposed that the reaction requires bifunctional sites, where one acts as an acid and the other acts as a basic site.[3] The high potential of the binary oxide for the dehydrogenation of ethylbenzene has been explained in terms of the generation of Ti-O-Zr bonding in the binary oxide, Ti ions being proposed to act as base and Zr ions as acid.

The nonoxidative dehydrogenation of ethylbenzene on the binary oxides A and P prepared in the present work was carried out at 620 °C to examine the role of Ti-O-Zr bonding during the reaction. The conversions of ethylbenzene and the selectivities to styrene over various catalysts are summarized in Table 2. From these results the rate constants and turnover frequencies were estimated assuming the first order with respect to ethylbenzene. As could be seen in Fig. 8a the rate constants over the binary oxide A expressed in terms of molecules $\cdot g^{-1} \cdot s^{-1}$ are observed to be higher than those over the binary oxide P. While the turnover frequency, given in Fig. 8b, showed the opposite results; turnover frequencies over the oxide A are rather smaller than those over the oxide P. If the dehydrogenation of ethylbenzene would take place on the bifunctional sites originated from Ti-O-Zr bonding over the catalyst surface, the results above means that almost the same or rather less amounts of Ti-O-Zr bonding are present over the unit surface area of the binary oxide A than on the binary oxide P. This is inconsistent with the idea that a lot of Ti-O-Zr bonding are on the surface of binary oxide A. In order to interpret this problem it might be favorable to deduce the conclusion that dehydrogenation of ethylbenzene would occur on the sites exposed on the surface of TiO_2 and ZrO_2 particles as well as on the sites composed of Ti-O-Zr bonding and that the reaction rate might not be so different in these active sites.

Thus, Ti-O-Zr bonding in TiO_2-ZrO_2 may not play an important role for nonoxidative dehydrogenation of ethylbenzene, being opposited to the previous opinion.[3]

Magnetic Behavior of Spin-Crossover Iron(III) Complexes Adsorbed on the Surface of Silicon Dioxide and Metal Dilution Effects on Magnetism

Yonezo MAEDA,* Masahiro TOMOKIYO, Kenji KITAZAKI, and Yoshimasa TAKASHIMA
Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812
(Received October 2, 1987)

The effects of metal dilution and adsorption on the surface of silicon dioxide on the spin-crossover behavior of $[Fe(acpa)_2]PF_6$, $[Fe(acpa)_2]BPh_4$, and $[Fe(bzpa)_2]PF_6$, which undergo fast spin-state interexchange on the ^{57}Fe Mössbauer timescale have been studied by using ^{57}Fe Mössbauer and EPR spectroscopies, powder X-ray diffraction and magnetic susceptibility, where Hacpa is *N*-(1-acetyl-2-propylidene)-2-pyridylmethylamine and Hbzpa *N*-(1-benzoyl-2-propylidene)-2-pyridylmethylamine. Solid solution compounds, $[Fe_xCo_{1-x}(acpa)_2]BPh_4$($x$=0.035 and 0.074) and $[Fe_{0.05}Co_{0.95}(bzpa)_2]PF_6$ exhibit spin-crossover phenomena. No difference in the spin-state interexchange rate is observed between the diluted compound and the corresponding undiluted one as far as the rates are evaluated by Mössbauer spectroscopy. Mössbauer spectra for $[Fe_{0.074}Co_{0.926}(acpa)_2]PF_6$ exhibit only a pair of quadrupole doublets assigned to the low-spin state in the temperature range from 78 to 298 K. The spin-state interexchange rates for $[Fe(acpa)_2]BPh_4$ and $[Fe(bzpa)_2]PF_6$ adsorbed on the surface of silicon dioxide become slow compared to those for the corresponding pure complexes and the narrowing of the spin-state transition temperature range is observed. On the contrary no detectable differences in the spin-state interexchange rates are observed between the Mössbauer spectra for $[Fe(acpa)_2]PF_6$ adsorbed on the surface of silicon dioxide and that for the pure complexes. These observations are interpreted in terms of a spin-state transition behavior in these complexes which is affected by the packing state in the solid state, which is dependent on the characteristic structure of the respective complex.

The study of thermally induced spin-state transition-(SST) phenomena has recently become an interesting research field.[1,2] Dynamical behavior in spin-state interexchange is caused by a cooperative solid state effect[3] and/or an intramolecular reorganization. It is important to gain some understanding about the mechanisms by which intermolecular interactions inhibit or enhance the rate of intramolecular spin-state interexchanges and to separate the intermolecular interaction from the intramolecular interaction. To solve the above problem, it is most effective to study the SST behavior in a system free from intermolecular interaction.

To study the nature of the interaction responsible for the spin-crossover behavior in "gradual transition type" complexes where SST takes place across a broad temperature range, the complexes $[Fe_xCo_{1-x}(acpa)_2]$-BPh_4(x=0.035 and 0.074), $[Fe_{0.074}Co_{0.926}(acpa)_2]PF_6$, $[Fe_{0.05}Co_{0.95}(bzpa)_2]PF_6$, and the complexes adsorbed on the surface of silicon dioxide(SD) were prepared.

Mössbauer spectroscopy is a useful tool for observing spin-state interexchange rates because the lifetime of the excited state of ^{57}Fe is critical. For a system of a very rapid interexchange rate ($>10^7$ s^{-1}) iron nuclei "see" an average of the properties of the low-spin and the high-spin states in the Mössbauer spectrum which depends on the proportion of each state. For a slow system ($<10^7$ s^{-1}) the Mössbauer spectrum shows a superposition of the two electronic states. The magnetic, ^{57}Fe Mössbauer and EPR spectroscopic properties of the complexes have been examined by Maeda et al.[4-6] The spin-state interexchange rates of $[Fe(acpa)_2]PF_6$ are comparable to the reciprocal of the ^{57}Fe Mössbauer timescale (0.98×10^{-7}s) and those of $[Fe(acpa)_2]BPh_4$ and $[Fe(bzpa)_2]PF_6$ are fast on the ^{57}Fe Mössbauer timescale.

Gütlich et al. and Seki and Sorai studied the spin-crossover propersies of diluted solid solutions $[Fe_xM_{1-x}$ $(phen)_2(NCS)_2]$ (x=0.01—1 and M=Mn, Co, Ni, and Zn),[7] $[Fe_xZn_{1-x}(2\text{-pic})_3]Cl_2\cdot C_2H_5OH$,[8,9] $[Fe_{0.01}Co_{0.99}(2$-$CH_3phen)_3](ClO_4)_2$[10] and $[Fe_xZn_{1-x}(ptz)_6](BF_4)_2$,[11] and suggested that for some systems the sizes of the low-spin domains decreased as the concentration of the host complexes increased.

Effects of counter ion sizes, solvation, grinding, and metal dilution on SST for $[Fe_xM_{1-x}(3\text{-}OCH_3\text{-}SalEen)_2]$-$PF_6$(M=Co, Cr)[12] and $[Fe_xCo_{1-x}(SalAPA)_2]ClO_4$[13] were studied by Hendrickson et al. They explained the various observations in terms of the nucleation and growth mechanism of phase.

All of these complexes except for $[Fe_xCo_{1-x}(Sal$-$APA)_2]ClO_4$ are spin-crossover complexes of "abrupt transition type" (SST which takes place in narrow temperature range, i.e., 2 K) with large cooperativity. The metal dilution sometimes influences the spin-state interexchange rate (R), transition temperature range (ΔT) and the transition temperature (T_c) defined as the temperature at which equal amounts of the high-spin and low-spin states coexist.

Experimental

Iron complexes were prepared using enriched ^{57}Fe by the same method as described elsewhere.[15]

$[Co(acpa)_2]BPh_4$: An ethanol solution of $Co(CH_3$-$COO)_2\cdot4H_2O$ is added to a solution containing a Schiff base prepared by mixing acetylacetone and 2-(aminomethyl)-pyridine in ethanol. Oxidation to give Co(III) complexes was carried out by adding 30% H_2O_2 solution. After the oxidant

was added, the solution was boiled for 5 min and an ethanol solution of $K[BPh_4]$ was added to the solution. The precipitation was separated, washed with ethanol and recrystallized twice from CH_2Cl_2-methanol.

Other cobalt complexes were prepared with the same procedure as described above except that the $[Co(bzpa)_2]BPh_4$ was recrystallized from acetone.

The ^{57}Fe-doped cobalt complexes were prepared by dissolving the corresponding cobalt complexes together with the appropriate weight of ^{57}Fe enriched iron(III) complexes in the solvent used for recrystallization and then by evaporation to dryness. X-Ray powder diffraction patterns for $[Fe(acpa)_2]BPh_4$ and $[Fe(bzpa)_2]PF_6$ were similar to that for the corresponding cobalt complexes, respectively. The diffraction positions for the solid solutions $[Fe_xCo_{1-x}(acpa)_2]BPh_4$ and $[Fe_{0.05}Co_{0.95}(bzpa)_2]PF_6$ were situated near those for the corresponding cobalt complexes, respectively. The diffraction pattern for $[Fe(acpa)_2]PF_6$ did not agree with that of the corresponding cobalt complex. The diffraction pattern for $[Fe_{0.074}Co_{0.926}(acpa)_2]PF_6$ was the same as that for the corresponding cobalt complex.

Two types of silicon dioxide(SD) were used; SD(A) and SD(AB)(Fuji Davison Co.). They are characterized by pores of average diameter 2.2 and 4 nm and of specific surface 650 and 590 $m^2 g^{-1}$, respectively. Finely powdered SD was dried in vacuo at 120 °C before use. The iron complexes were adsorbed on the surface of the SD at room temperature.

SD(A) of 200 mg was introduced into a CH_2Cl_2 solution containing $[Fe(acpa)_2]PF_6$ of 15 mg. The solution was shaken for a few minutes. It turned pale in color and the SD was separated by using a glass filter. The iron content adsorbed on the SD was determined by an atomic absorption technique. The SD adsorbing the complexes was coated with cellulose adhesive (alcohol-free collodion solution diluted with ether) to avoid decomposition of the complexes. The saturated amounts of the complexes adsorbed on the SD were $(10.9\pm3.3)\times10^{-4}$ mol g^{-1}.

$[Fe(acpa)_2]PF_6$ of 7.7 mg was adsorbed on the surface of SD of 200 mg. This volume corresponds to the area occupation of 1.6×10^{-13} cm^2 (a spuare of 4 nm) per one molecule. The size of the molecule is about 0.85 nm in diameter, which is calculated from the data of the crystal structure.[5]

$[Fe(acpa)_2]BPh_4$ and $[Fe(bzpa)_2]PF_6$ adsorbed on SD were prepared with the same procedure as that for $[Fe(acpa)_2]PF_6$, except that SD(AB) was used for the former complex because the former complexes were adsorbed much more on SD(AB) than on SD(A). The saturated amounts of the complexes adsorbed on SD were $(1.1\pm0.1)\times10^{-4}$ mol g^{-1} for the tetraphenylborate and $(3.0\pm0.4)\times10^{-4}$ mol g^{-1} for the hexafluorophosphate.

Mössbauer spectra and magnetic susceptibilities were measured by using an apparatus described elsewhere.[6] EPR spectra were obtained with a FES-FEX(JEOL, Ltd.) X-band spectrometer. The Mössbauer spectra were fitted to Lorentzian lines by using a least squares method. The isomer shift, δ was calibrated relative to the center of a spectrum of iron foil enriched with ^{57}Fe at 296 K, which was also used as a standard material for the velocity calibration.

Results and Discussion

The purities of the iron and cobalt complexes were checked by elemental analysis for C, H, and N, and the magnetic behavior vs. temperature for the enriched iron complexes was similar to that reported before.[4,5]

Spin-Crossover Properties of the Iron Complexes Diluted with Cobalt Complexes. Figure 1 illustrates the temperature dependence of the Mössbauer spectra for $[Fe_{0.074}Co_{0.926}(acpa)_2]BPh_4$. The temperature dependences of the isomer shift and quadrupole splitting QS for $[Fe_xCo_{1-x}(acpa)_2]BPh_4$ are shown in Fig. 2. The decrease of the quadrupole splitting and the increase in the isomer shift for the diluted complexes

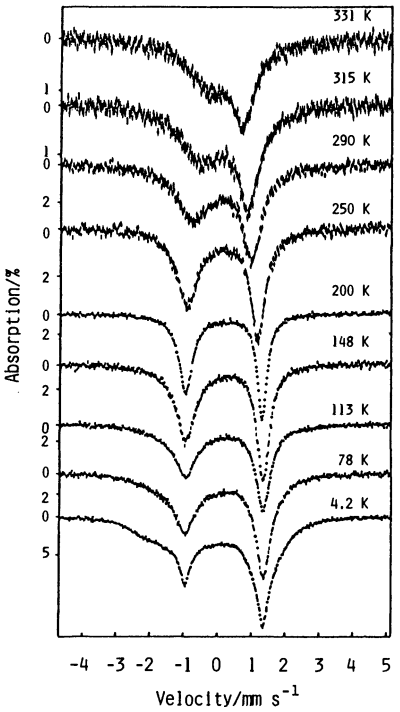

Fig. 1. Temperature dependence of Mössbauer spectra for $[Fe_{0.074}Co_{0.926}(acpa)_2]BPh_4$.

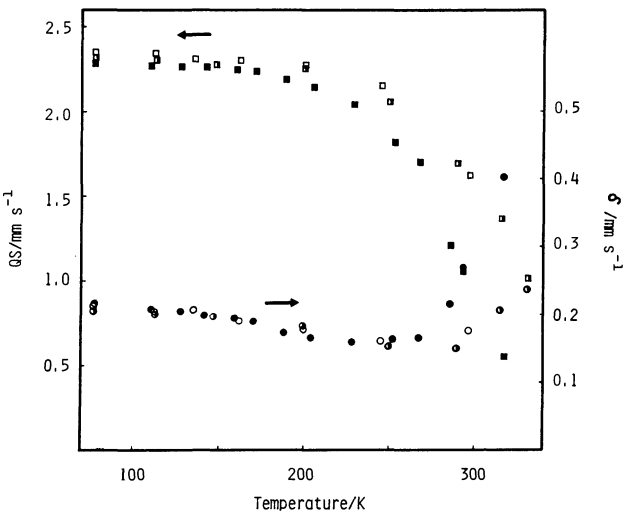

Fig. 2. Temperature dependences of the isomer shift and quadrupole splitting for $[Fe_xCo_{1-x}(acpa)_2]BPh_4$. QS; (■) for x=1, (◨) for x=0.074, (□) for x=0.035. δ; (●) for x=1, (◑) for x=0.074, (○) for x=0.035.

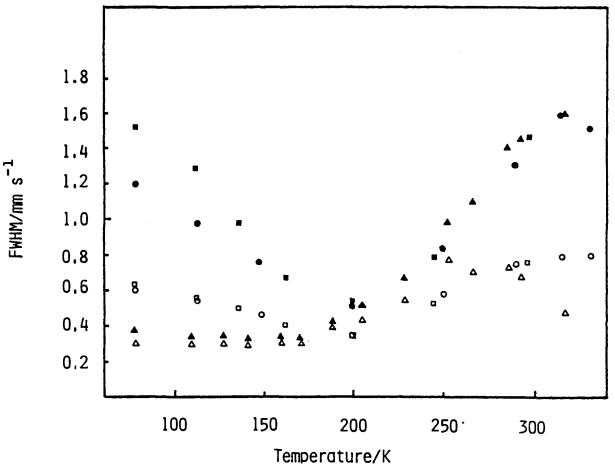

Fig. 3. Temperature dependences of fwhm for $[Fe_xCo_{1-x}(acpa)_2]BPh_4$. (△, ▲) for x=1, (○, ●) for x=0.074, (□, ■) for x=0.035. Open signs are for low energy line, closed ones for high energy line.

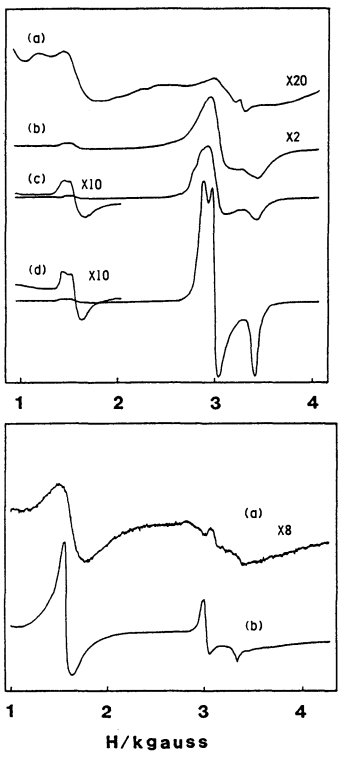

Fig. 4. Temperature dependences of EPR spectra for $[Fe_{0.035}Co_{0.965}(acpa)_2]BPh_4$ (in upper figure, a: 295 K, b: 193 K, c: 173 K, d: 130 K) and $[Fe_{0.05}Co_{0.95}(bzpa)_2]PF_6$ (in lower figure, a: 293 K, b: 78 K).

begin at higher temperature (about 20 K) than those for the undiluted complexes; the temperature range of SST for the diluted complexes shifts to higher temperature than that for the undiluted ones. Iron ions doped in cobalt complexes feel "positive pressure" by the lattice of the cobalt complexes because the radius of a cobalt(III) ion(0.075 nm in the high-spin state) is 0.004 nm smaller than that of an iron(III) ion(0.079 nm in the high-spin state). Therefore the ligand field at the position of an iron(III) ion becomes slightly stronger and thus the low-spin state is more stable. This "pressure effect/size effect" has been observed for some spin-crossover complexes.[7] The large shifts of T_c have been reported for $[(Fe_x, M_{1-x})(phen)_2(NCS)_2]$(M=Co, Cr, Zn) and $[Fe_xCo_{1-x}(3\text{-}OCH_3\text{-}SalEen)_2]PF_6$, which undergo "abrupt transition type" spin-crossover behavior. The complex $[Fe(acpa)_2]BPh_4$ belongs to the "gradual transition type" complexes, in which the coupling between SST and the lattice is supposed to be weak, and thus the small shift of T_c is reasonable. No difference in the spin-state interexchange rate between the diluted compound and the undiluted one is observed as far as the rates are evaluated by a Mössbauer spectroscopy.

The iron complexes doped in the cobalt complexes show broad spectra above or below 200 K. Figure 3 shows the temperature variation of full width at half maximum (fwhm) for $[Fe_xCo_{1-x}(acpa)_2]BPh_4$. The observation that the line broadening increases with rising temperature above 200 K shows that the decrease in mixing of the ^2T state with increase in temperature weakens the spin-spin interaction, because the interaction is significant in the high-spin iron(III) complexes ($^6A_{1g}$). The fraction of the low-spin isomers to the total isomers is estimated to be 0.77 at 200 K on the basis of the magnetic susceptibility data. The line broadening at temperatures below 200 K may result from the spin-lattice relaxation dependent on temperature and spin-spin relaxation. The reasons for the line broadening below 200 K are complex due to the magnetic effects and the spectral shape at 4.2 K is not similar to that for $K_3[Fe(CN)_6]$ doping $K_3[Co(CN)_6]$[14] This problem was not examined further, but the observation of the line broadening supports the view that the iron complexes are isolated.

EPR spectra for the complexes were measured at various temperatures. The representative spectra are illustrated in Fig. 4 and the low-spin signals were observed at g=1.965, 2.219, and 2.291 for the diluted complexes. This observation suggests that an iron atom in the diluted complex is situated in a more distorted environment than that in the pure complex. The g=4 signal is characteristic of a high-spin ferric ion in a rhombically distorted environment.

The Mössbauer spectra for $[Fe_{0.05}Co_{0.95}(bzpa)_2]PF_6$ were measured at various temperatures and the temperature variations of the Mössbauer parameters are plotted in Figs. 5 and 6. In this case the effect of metal dilution on the magnetism is not clear except that slight line broadenings are observed. No observation of "pressure effect/size effect" for this complex shows that this effect does not have a dominant role in the stabilization of a low-spin state and that the effect of intermolecular interaction on spin-state transition may be weak for these complexes. SST properties T_c

and ΔT may be influenced by the lattice energy or elastic property of the complexes. The Mössbauer spectrum at 4.2 K is similar in the shape to that for $[Fe_{0.074}Co_{0.926}(acpa)_2]BPh_4$ except for the smaller quadrupole splitting observed. EPR signals for pure $[Fe(bzpa)_2]PF_6$ were very broad at 78 K,[4] but that for the diluted complexes are observed at $g_{//}=1.961$ and $g_{\perp}=2.166$ and the values are similar to that observed for pure $[Fe(acpa)_2]PF_6$. The observation of EPR spectra for the diluted complexes supports the view that the iron species are isolated satisfactorily in accordance with the results of the Mössbauer spectra measurements.

The Mössbauer spectra for $[Fe_{0.074}Co_{0.926}(acpa)_2]PF_6$ are shown in Fig. 7. From the Mössbauer spectrum for $[Fe_{0.074}Co_{0.926}(acpa)_2]PF_6$ at 298 K the ground state of the complexes is in a low-spin state. The iron complexes are not isomorphous with the cobalt complexes as seen from the powder X-ray diffraction patterns. The local geometric structure around an iron atom in $[Fe_{0.074}Co_{0.926}(acpa)_2]PF_6$ is assumed to be different from that in $[Fe(acpa)_2]PF_6$. This is reflected in the value of the quadrupole splitting; the diluted and pure complexes show QS=2.506 and QS=2.235 mm s^{-1} at 78 K, respectively. At 298 K the Mössbauer parameters for the former complex are QS=1.960 mm s^{-1} and δ=0.169 mm s^{-1}, and the decrease in the QS value for the diluted complexes is due to the increase in the population of the high-spin isomer or the temperature dependence of the quadrupole splitting. But the latter reason can be excluded because EPR analysis indicates that the first excited electronic state($^4T_2$) is at least 3000 cm^{-1} higher in energy than the ground state. The EPR signals for the low-spin isomer in the diluted com-

plexes are observed at g=1.948, 2.207, and 2.287 at 130 K.

Spin-Crossover Properties of the Complexes Adsorbed on the Surface of SD. Figure 8 shows the temperature dependence of the Mössbauer spectra for $[Fe(acpa)_2]PF_6$ adsorbed on SD(A). These spectra apparently exhibit two pairs of quadrupole doublets; the inner doublet is assigned to the high-spin isomer and the outer doublet to the low-spin isomer. However it is assumed from the spectral shapes that the spin-state interexchange rate is comparable to the inverse of the Mössbauer lifetime. The apparent SST behavior—R, ΔT, and T_c— is estimated to be similar to that for the undiluted complexes. From the Mössbauer parameters for the low-spin isomers at 78 K, QS=2.187 mm s^{-1} and δ=0.198 mm s^{-1}, the geometric structure of the molecule on SD(A) is estimated not to be influenced by physical adsorption on SD in contrast to that of the diluted complexes.

It is curious that no line broadening is observed for the Mössbauer spectra of the complexes supported on SD and as one of the reasons it may be that the complexes are not isolated satisfactorily but adsorbed linearly in the pores. The EPR spectra for the complexes supported on SD are in accord with that for the pure complexes except that the former material shows a signal at g=4.

The Mössbauer spectra for $[Fe(acpa)_2]BPh_4$ and

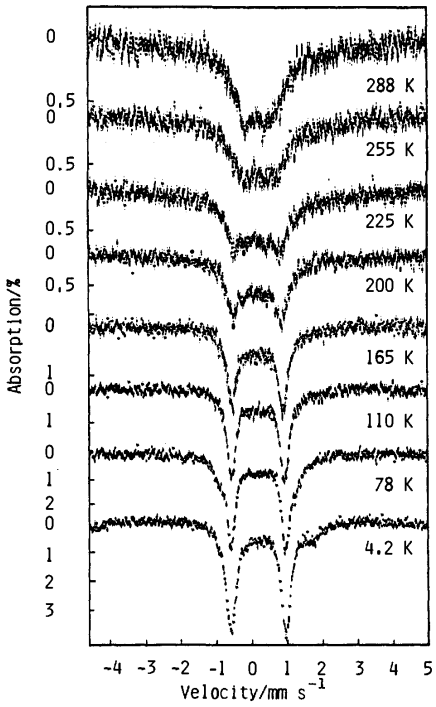

Fig. 10. Temperature dependence of the Mössbauer spectra for $[Fe(bzpa)_2]PF_6$ adsorbed on SD(A).

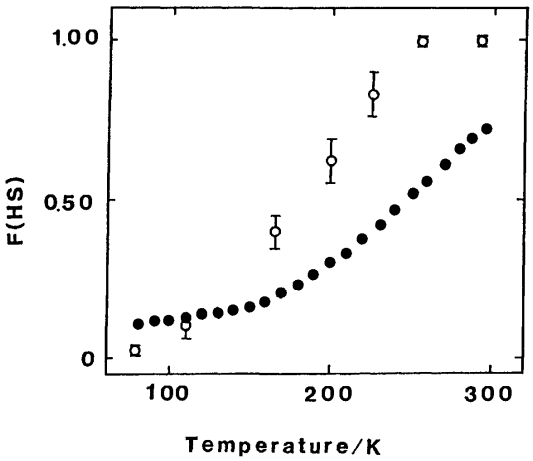

Fig. 11. Temperature dependences of the high-spin population F(HS) for $[Fe(bzpa)_2]PF_6$ adsorbed on SD(A) (○) and the pure complexes (●).

$[Fe(bzpa)_2]PF_6$ adsorbed on SD are illustrated in Figs. 9 and 10, respectively, in which the spectra show a superposition of the quadrupole doublets for the high-spin and low-spin isomers; The Mössbauer spectra at 78 K for both of the complexes show the existence of some impurity due to decomposed paramagnetic products and/or remaining high-spin species. In the spectra at 78 K (Fig. 9) the paramagnetic species and/or the high-spin isomers are observed in 0.4% absorption. They are observed in 0.7% absorption at 240 and 260 K. This illustrates that the absorptions in the center of the spectra are composed of that of the paramagnetic species and the high-spin isomers. That

is, the spectra have a superposition of the spectra for the high-spin isomers and that for the low-spin isomers. This supports a fact that the packing effect enhances the spin-state interexchange rate because it is likely that the complexes feel "free" in the adsorbed state than in the solid state.

At 78 K the quadrupole splitting for the outer doublet(QS=2.254 mm s^{-1}) of the adsorbed $[Fe(acpa)_2]BPh_4$ is almost equal to that(QS=2.288 mm s^{-1}) of the pure complexes, and the quadrupole splitting(QS=1.539 mm s^{-1}) for the adsorbed $[Fe(bzpa)_2]PF_6$ is equal to that (QS=1.542 mm s^{-1}) for the pure complexes. This supports the view that the geometric structures of the adsorbed complexes are consistent with that of the corresponding pure complexes, respectively.

As a representative example the temperature dependence of population of the high-spin isomers F(HS) for $[Fe(bzpa)_2]PF_6$ is plotted in Fig. 11, where the values for the adsorbed complexes were estimated from the Mössbauer spectra and that for the pure complexes from the effective magnetic moments. For the adsorbed complexes corrected values were used because the paramagnetic species are observed in the Mössbauer spectrum at 78 K. The T_c for the adsorbed complexes is estimated to be about 60 K lower than that for the pure complexes, but this large shift is unreliable because the temperature dependence of recoilless fraction of the paramagnetic species is not taken into account. It is unfortunate not to be able to prepare pure samples free from the paramagnetic species. However it is likely that T_c for the adsorbed complexes shifts to lower temperature and that the complexes are essentially in a high-spin state at 300 K. Similar transition behavior is observed for the adsorbed $[Fe(acpa)_2]$-BPh_4.

The EPR spectra of $[Fe(bzpa)_2]PF_6$ adsorbed on SD were measured at 293 and 78 K. The EPR signals for the low-spin isomer are observed at $g_{//}=1.960$ and $g_{\perp}=2.166$. These values are in accordance with that reported by Hendrickson et al. for the complexes dissolved in toluene and with that for the diluted complexes. This fact shows that the adsorbed complexes are satisfactorily isolated.

Finally the Mössbauer spectrum at 4.2 K for $[Fe(bzpa)_2]PF_6$ adsorbed on SD was measured. The high-spin species are not observed in the spectrum, but a shoulder which occurs at the Doppler velocity of 1.5 mm s^{-1} could have originated from decomposition products. The Mössbauer spectrum for $[Fe(bzpa)_2]PF_6$ decomposed by being kept in air on the surface of SD was measured. The relaxation spectrum of the magnetic hyperfine splitting observed will prove that the complexes are isolated from each other on the surface of SD.

The packing effects observed here are weaker than that for "spin transition type" complexes. The values of V and ΔV(V: volume per single molecule for the high-spin isomer, ΔV:volume difference between high-spin and low-spin isomers for single molecule) for $[Fe(acpa)_2]PF_6$ are $V=655.7$ Å^3, $\Delta V=23$ Å^3 and $\Delta V/V=3.5\%$. On the other hand for $[Fe(acpa)_2]BPh_4$ $V=1003.1$ Å^3. $\Delta V=34$ Å^3 and $\Delta V/V=3.4\%$ are observed.[15] Generally the ΔV values of from 23 to 98 Å^3, and $\Delta V/V$ values of from 3.4 to 6.2% are reported. These values for the complexes examined here seem to be in the same range as that reported for the abrupt transition type complexes. Hendrickson et al. have reported an example that the spin-state interexchange rate of diluted complexes is slower than that for the pure complexes.[13] Threfore, it is positive at the present time that spin-state interexchange rates are effected by crystal packing and that intramolecular SST takes place more or less under the co-oparativities with intermolecular interaction.

We wish to thank Dr. Hiroki Oshio of Institute for Molecular Science, Okazaki for the EPR measurement and Dr. Yoichi Sakai of Tokyo University for making available to us silicon dioxide.

Coordination Selectivity in Aluminum(III) Complex with 8-Hydroxy-7-[(2-hydroxy-5-carboxyphenyl)azo]-5-quinolinesulfonic Acid: Evidence for Linkage Isomerism

Zhi-Ping Bai, Hisahiko Einaga,*,† and Jinsai Hidaka
Department of Chemistry, University of Tsukuba, Ibaraki 305
†Institute of Materials Science, University of Tsukuba, Ibaraki 305
(Received October 12, 1987)

The coordination reaction of 8-hydroxy-7-[(2-hydroxy-5-carboxyphenyl)azo]-5-quinolinesulfonic acid (hcqs) to aluminum(III) has been investigated spectrophotometrically in a weakly acidic aqueous solution (pH 2—5) with 0.1 mol dm^{-3} NaCl at 22.0 °C; the thermodynamic stability, kinetics, and mechanism of the formation of the aluminum(III) complex were deduced. The ligand rapidly coordinates to aluminum(III), with its 8-quinolinol (*O-N*) moiety, to form a yellow complex (metal : ligand=1 : 1), and then the complex slowly changes, via an intramolecular rearrangement, to a red complex with its dihydroxyazo (*O-N-O*) moiety, thus showing a linkage isomerism. In the first coordination process, the complex is formed mainly via a pathway of the reaction of $AlOH^{2+}$ with $Hhcqs^{3-}$. The coordination reaction mechanism of aluminum(III) with related ligands, 4-hydroxy-3-[(2-hydroxy-5-carboxyphenyl)azo]-1-naphthalenesulfonic and 7-[(4-carboxyphenyl)azo]-8-hydroxy-5-quinolinesulfonic acid, is also discussed.

The selectivity of coordination modes[1] in metal complexes is one of the fundamental functions of multidentate ligands because of their steric restrictions. In our previous papers,[1-4] the reactions of aluminum(III) with such multidentate ligands as 8-hydroxy-7-[(6-sulfo-2-naphthyl)azo]-5-quinolinesulfonic acid (nqs),[1,2] 7-[(3,6-disulfo-8-hydroxy-1-naphthyl)azo]-8-hydroxy-5-quinolinesulfonic acid (hns),[3] and 7-[(2-carboxyphenyl)azo]-8-hydroxy-5-quinolinesulfonic acid (pqs),[4] have been investigated. The selective coordination sites of these ligands were found to be the 8-quinolinol moiety for nqs, the dihydroxyazo moiety for hns, and the carboxyhydroxyazo moiety for pqs. These findings mean that the coordination ability of the azo nitrogen atom is lower than that of the quinoline nitrogen atom, but that the fused chelate ring structure facilitates the coordination of the azo nitrogen atom in the aluminum(III) complex. Furthermore, it has been found that these ligands react with aluminum(III) with a single rate-determining step to form mono-ligand complexes, which involve a five-membered chelate ring with the *O-N* coordination mode for nqs[1,2] and two six-membered fused chelate rings with the *O-N-O* coordination mode for hns[3] and pqs.[4]

In this work, 8-hydroxy-7-[(2-hydroxy-5-carboxyphenyl)azo]-5-quinolinesulfonic acid (hcqs, **1**), which potentially coordinates to aluminum(III) either with the dihydroxyazo (*O-N-O*) moiety to form five- and six-membered fused chelate rings or with the 8-quinolinol (*O-N*) moiety to form a five-membered chelate ring, was synthesized for the first time in order to investigate its coordination behavior to aluminum(III). It was found that hcqs initially reacts with aluminum(III) to form a yellow complex with the *O-N* coordination mode, but finally forms a red complex with the *O-N-O* mode; the complex shows a linkage isomerism. This paper will be concerned with a detailed investigation of the equilibrium, kinetics, and mechanism of the aluminum(III) complex with hcqs.

Experimental

Reagents. The ligand, hcqs, was synthesized by the diazotization of 3-amino-4-hydroxybenzoic acid and by coupling to 8-hydroxy-5-quinolinesulfonic acid in a conventional way. The crude product was purified by a repeated salting-out of the aqueous solution with NaCl at pH 7—8. Found: C, 31.77; H, 3.18; N, 6.80%. Calcd for $C_{16}H_{10}N_3O_7SNa \cdot 2NaCl \cdot 4.5H_2O$: C,31.54; H, 3.14; N, 6.90%.

In order to compare them, the ligands, 4-hydroxy-3-[(2-hydroxy-5-carboxyphenyl)azo]-1-naphthalenesulfonic acid (hcns, **2**) and 7-[(4-carboxyphenyl)azo]-8-hydroxy-5-quinolinesulfonic acid (cqs, **3**), were synthesized by the diazotization of 3-amino-4-hydroxybenzoic acid and coupling to 1-naphthol-4-sulfonic acid, and by the diazotization of 4-aminobenzoic acid and coupling to 8-hydroxy-5-quinolinesulfonic acid, respectively. These ligands were then purified by repeated precipitations from an alkaline aqueous solution by means of acidification with HCl. Found: C, 38.44; H, 3.68; N, 5.34%. Calcd for $C_{17}H_{11}N_2O_7SNa \cdot NaCl \cdot 3.5H_2O$: C,38.38; H, 3.41; N, 5.27%. Found: C, 43.89; H, 3.43; N, 9.54%. Calcd for $C_{16}H_{10}N_3O_6SNa \cdot 2.5H_2O$: C,43.64; H, 3.43; N, 9.54%.

An aqueous aluminum(III) solution was prepared by precipitating $Al(OH)_3$ from an aqueous solution of $AlK(SO_4)_2 \cdot 12H_2O$ with alkali, after which the hydroxide was dissolved in water with a minimum amount of HCl. The solution was acidified slightly to prevent the hydrolysis of

aluminum(III) ions. It was then standardized by the EDTA titration method. All the other chemicals used were of an analytical or equivalent grade.

Measurements. Electronic absorption spectral measurements were made on JASCO spectrophotometers, models UVIDEC-505 and -601C. The rapid kinetic measurements were done on a JASCO spectrophotometer, model SS-25, to which a stopped flow apparatus, model SFC-5, a data processor, model DP-500, and a RIKADENKI X-Y recorder, model RW-11, were attached. The slow kinetic runs were monitored on a JASCO spectrophotometer, model UVIDEC-1. All the kinetic runs were carried out in an aqueous solution of 0.1 mol dm^{-3} NaCl at 22.0±0.1 °C under pseudo-first-order kinetic conditions with respect to the aluminum(III) concentration (ligand concentration: (1—7)×10^{-5} mol dm^{-3}). The absorbance changes with time were followed at 495 nm for the aluminum(III) complex with hcqs, at 375 nm for that with hcns, and at 490 nm for that with cqs. The complex formation can be clearly recognized at these wavelengths, which correspond to the maxima or shoulders in the spectra of the ligands. The observed rate constant, k_{obsd}, was calculated from the slope of the linear relation $-\ln(A_i-A_f)$ vs. t on the basis of Eq. 1:

$$\ln[(A_i-A_f)/(A_t-A_f)]=k_{obsd}\cdot t \quad (1)$$

where A_i, A_t, and A_f stand for the absorbances at the initial state, at time t, and at the equilibrium state of the kinetic process respectively. The $k_{obsd(1)}$ and $k_{obsd(2)}$ values for the first and second steps in the case of hcqs were calculated separately on the basis of Eq. 1, because the two steps take place according to different time scales. The A_t vs. t data were separately simulated on an NEC personal computer, model PC-9801E.

The pH value, pH_{meas}, was measured with a HORIBA pH meter, model F7-SS, equipped with glass and 3.33 mol dm^{-3} KCl calomel electrodes. The hydrogen ion concentration, $-\log[H^+]$, was calculated from pH_{meas} according to Eq. 2:

$$-\log[H^+]=pH_{meas}+\log f_{H^+} \quad (2)$$

The activity coefficient of the hydrogen ion, f_{H^+} (0.923), was estimated by defining a solution containing 0.0100 mol dm^{-3} HCl and 0.0900 mol dm^{-3} NaCl at 22 °C as $-\log[H^+]\equiv 2.00$. An acetic acid-sodium acetate buffer solution of less than 0.01 mol dm^{-3} was used to adjust the hydrogen ion concentration.

Results

Electronic Absorption Spectra. Figures 1 and 2 show the absorption spectra of hcqs and its aluminum-(III) complexes, together with those of aluminum(III) complexes of hcns and cqs for comparison. The fully deprotonated species, hcqs^{4-}, gives its dominant peaks corresponding to $\pi^*\leftarrow\pi$ transitions in the 20.0×10^3 cm^{-1} region due to the azo group and at 33.0×10^3 cm^{-1} due to the quinoline and benzene rings. The same spectral features were observed in cqs^{3-} and hcns^{4-}. Protonations at the coordination sites in hcqs^{4-} cause characteristic spectral shifts, which were used for the estimation of the protonation constants.

In the hcqs-aluminum(III) system, the absorbance at 495 nm, which corresponds to an absorption maximum wavelength of H_2hcqs^{2-} (at pH 4.5), decreased rapidly to attain a constant value within 10 s; afterwards, the absorbance began to increase slowly with the time to reach a limiting value after 10 min. The rate of the slow process was independent of the aluminum(III) concentration. Curve (1) in Fig. 2 shows the absorption spectrum when the absorbance at 495 nm is at its minimum. Upon standing, the absorption spectrum changes gradually with the time to Curve (2), but thereafter it does not change. Figure 3 depicts the absorption spectral change with the time in the slow process. The four isosbestic points at 457, 357, 323, and 292 nm indicate that the yellow complex corresponding to Curve (1) changes quantitatively to the red complex corresponding to Curve (2) in Fig. 2. Furthermore, Fig. 2 clearly demonstrates that Curve (1) conforms well to the absorption spectrum (Curve(3)) of the aluminum(III) complex with cqs, which coordi-

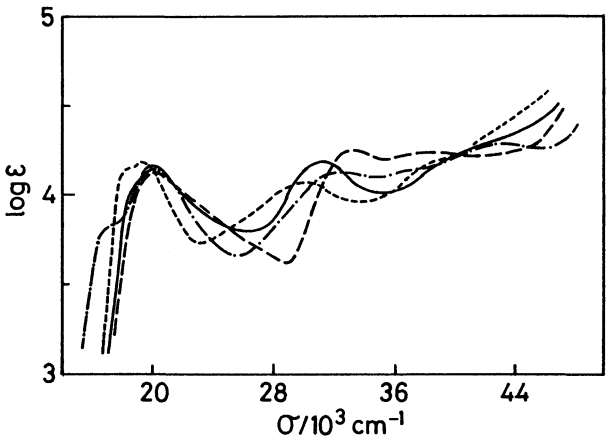

Fig. 1. Absorption spectra of hcqs: (----), H_3hcqs^- (pH 2.4); (——), H_2hcqs^{2-} (pH 5.0); (-·-·-), $Hhcqs^{3-}$ (pH 8.0); and (— — —), $hcqs^{4-}$ (pH 12.0). 0.1 mol dm^{-3} NaCl, 22 °C (cf. Table 1).

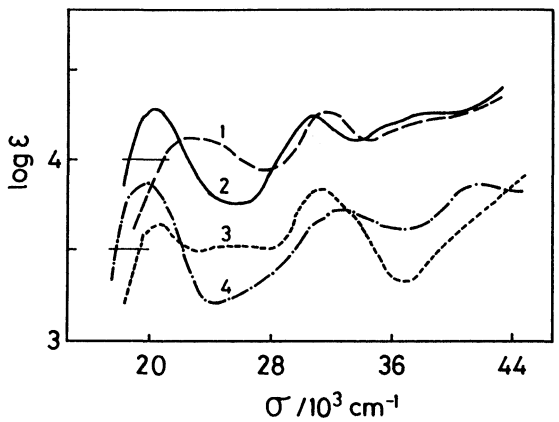

Fig. 2. Absorption spectra of aluminum(III) complexes with hcqs, hcns, and cqs at pH 4.5: 1, (— — —), Al(Hhcqs-*O*,*N*); 2, (——), Al(hcqs-*O*,*N*,*O*)$^-$; 3, (----), Al(cqs)$^-$; and 4, (-·-·-), Al(hcns)$^-$. Curves 3 and 4 are shifted 0.5 unit downward for clarity. 0.1 mol dm^{-3} NaCl, 22 °C.

nates solely with the 8-quinolinol moiety, and that Curve (2) conforms well to that (Curve(4)) of the aluminum(III) complex with hcns, which coordinates solely with the dihydroxyazo moiety.

Hence, it can be inferred that hcqs rapidly coordinates to aluminum(III) to give the yellow complex as a bidentate ligand with the *O-N* moiety and that it then rearranges to the red complex as a terdentate ligand with the *O-N-O* moiety:

$$\underset{\text{red}}{H_2hcqs^{2-}} + Al^{3+} \xrightarrow[\text{fast}]{k_{obsd(1)}} \underset{\text{yellow}}{Al(Hhcqs\text{-}O,N)} \xrightarrow[\text{slow}]{k_{obsd(2)}} \underset{\text{red}}{Al(hcqs\text{-}O,N,O)^-}$$

Protonations of Ligands and Stabilities of Complexes

Protonation. The protonation constants, K_{ai} (i= 1—4), of hcqs:

$$K_{ai}=[H_ihcqs^{(4-i)-}]/[H_{i-1}hcqs^{(5-i)-}][H^+] \quad (3)$$

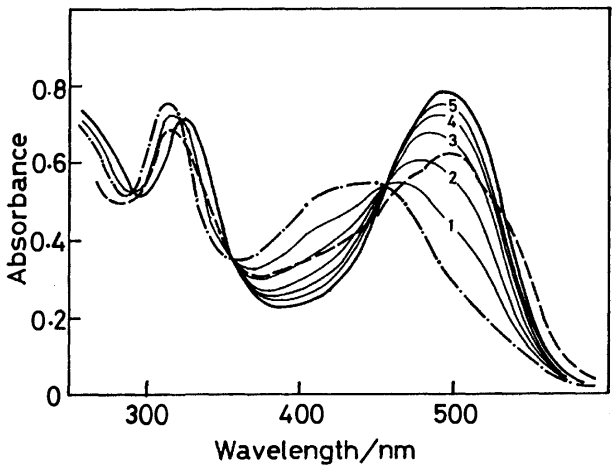

Fig. 3. Absorption spectral change with time of aluminum(III) complex with hcqs. (———), H_2hcqs^{2-}; (-·-·-), spectrum corresponding to yellow complex; (——), spectrum corresponding to red complex; (——), intermediate spectra from yellow to red complex recorded at 1, 1.5 min; 2, 3.5 min; 3, 6 min; 4, 9 min; and 5, 12 min. C_{Al}, 4.7×10^{-4} mol dm^{-3}; C_{hcqs}, 2.16×10^{-5} mol dm^{-3}, pH 4.5, 0.1 mol dm^{-3} NaCl, 22°C.

were determined spectrophotometrically[4] with the aid of Eq. 4:

$$\log\{(A_{(i-1)hcqs}-A_X)/(A_X-A_{(i)hcqs})\} = \log K_{ai}+\log[H^+] \quad (4)$$

where $A_{(i-1)hcqs}$, $A_{(i)hcqs}$, and A_X refer to the absorbances of solutions containing the ligand species $H_{i-1}hcqs^{(5-i)-}$ alone, $H_ihcqs^{(4-i)-}$ alone, and both of them respectively. Absorbance measurements were made at the following wavelengths: hcqs, 585, 345, and 295 nm (K_{a1}), 585 nm (K_{a2}), 550 and 360 nm (K_{a3}), and 360 nm (K_{a4}); hcns, 580 and 335 nm (K_{a1}), 508 and 265 nm (K_{a2}), and 527 nm (K_{a3}); cqs, 525 and 435 nm (K_{a1}), 530 nm (K_{a2}), and 510 nm (K_{a3}). The protonation constants of hcqs, together with those of hcns and cqs, are summarized in Table 1. A mutual comparison of these protonation constants and a comparison with those of the related ligands[1-4] indicate that, in the case of hcqs, K_{a1} corresponds to the protonation at the phenolate oxygen; K_{a2}, to that at the quinolinolate oxygen; K_{a3}, to that at the heterocyclic nitrogen; and K_{a4}, to that at the carboxylate oxygen atoms.

The compositions of the hcqs complexes were estimated by the method of continuous variation.[5] A sharp and single maximum at the ligand mole fraction of 0.5 was obtained for both the yellow and red complexes at 400, 497, and 270 nm, indicating that complexes with a 1 : 1 (Al : hcqs) composition are formed. The formation of the 1 : 1 complexes was also confirmed in the aluminum(III) complex with hcns (at 380 and 325 nm) and in that with cqs (at 519.5 and 320 nm).

Determination of Stability Constants. On the basis of the characteristic spectral features of the hcqs complexes, the protonation constants of hcqs, and the hydrolysis constant[6] of aluminum(III), K_{OH}(=$10^{-4.49}$ defined as $K_{OH}=[AlOH^{2+}][H^+]/[Al^{3+}]$), the 1 : 1 red complex formation equilibrium related to the H_2hcqs^{2-} species at pH 2.69 can be defined as follows:

$$Al^{3+}+H_2hcqs^{2-} \rightleftharpoons Al(hcqs)^-+2H^+ \quad (5)$$

The following materials balance relations hold for the present system:

$$C_{Al}=[Al^{3+}]+[AlOH^{2+}]+[Al(hcqs)^-] \quad (6)$$

Table 1. Protonations of Ligands and Stabilities of Complexes (0.10 mol dm^{-3} NaCl, 22°C)

Ligand	hcqs	hcns	cqs	Remark
I	10.26±0.04	10.84±0.06	—	Phenolate
II	6.36±0.05	6.74±0.05	7.40±0.08	Quinolinolate, naphtholate
III	2.98±0.05	—	2.43±0.05	Quinoline
IV	3.60±0.10	4.25±0.05	2.90±0.05	Carboxylate
Complex	$Al(hcqs\text{-}O,N,O)^-$	$Al(hcns)^-$	Al(cqs)	
$\log\beta_{11}$	14.15±0.10	15.27±0.10	7.49±0.10	

I) $\log(K_{a1}/\text{mol}^{-1}\text{ dm}^3)$ for hcqs, hcns; II) $\log(K_{a2}/\text{mol}^{-1}\text{ dm}^3)$ for hcqs, hcns, $\log(K_{a1}/\text{mol}^{-1}\text{ dm}^3)$ for cqs; III) $\log(K_{a3}/\text{mol}^{-1}\text{ dm}^3)$ for hcqs, $\log(K_{a2}/\text{mol}^{-1}\text{ dm}^3)$ for cqs; IV) $\log(K_{a4}/\text{mol}^{-1}\text{ dm}^3)$ for hcqs, $\log(K_{a3}/\text{mol}^{-1}\text{ dm}^3)$ for hcns, cqs.

$$C_{hcqs}=[H_2hcqs^{2-}]+[Hhcqs^{3-}]+[hcqs^{4-}]+[Al(hcqs)^{-}] \quad (7)$$

Equation 8 can be derived thus from Eqs. 5—7:

$$\log \alpha/r(1-\alpha)=\log \beta_{11}-\log K_{a1}K_{a2}-2\log[H^+]+\log[Al^{3+}] \quad (8)$$

$$\alpha \equiv [Al(hcqs)^-]/C_{hcqs}$$
$$r \equiv K_{a1}K_{a2}[H^+]^2/(1+K_{a1}[H^+]+K_{a1}K_{a2}[H^+]^2)$$
$$[Al^{3+}] \equiv (C_{Al}-\alpha C_{hcqs})/(1+K_{OH}/[H^+])$$

The experimental data are given in Fig. 4; the plot of $\log \alpha/r(1-\alpha)$ vs. $\log[Al^{3+}]$ is linear, with a unit slope. The $\log \beta_{11}$ ($\beta_{11}=[Al(hcqs)^-]/[Al^{3+}][hcqs^{4-}]$) value was determined to be 14.15±0.10 from the intercept; the stability constants are shown in Table 1.

Likewise, the 1 : 1 complex formation equilibrium related to $Hcqs^{2-}$ at pH 3.56 and to H_2hcns^{2-} at pH 2.83 can be defined as follows:

$$Al^{3+}+Hcqs^{2-} \rightleftharpoons Al(cqs)^-+H^+ \quad (9)$$

$$Al^{3+}+H_2hcns^{2-} \rightleftharpoons Al(hcns)^-+2H^+ \quad (10)$$

For cqs:

$$\log \alpha/r(1-\alpha)=\log \beta_{11}-\log K_{a1}-\log[H^+]+\log[Al^{3+}] \quad (11)$$
$$r \equiv K_{a1}[H^+]/(1+K_{a1}[H^+]+K_{a1}K_{a2}[H^+]^2)$$

For hcns:

$$\log \alpha/r(1-\alpha)=\log \beta_{11}-\log K_{a1}K_{a2}-2\log[H^+]+\log[Al^{3+}] \quad (12)$$
$$r \equiv K_{a1}K_{a2}[H^+]^2/(1+K_{a1}[H^+]+K_{a1}K_{a2}[H^+]^2)$$

The experimental data are plotted in Fig. 4 to obtain a $\log \beta_{11}$ value of 7.49±0.12 for the 1 : 1 cqs complex and a $\log \beta_{11}$ value of 15.27±0.10 for the 1 : 1 hcns complex; the stability constants are shown in Table 1.

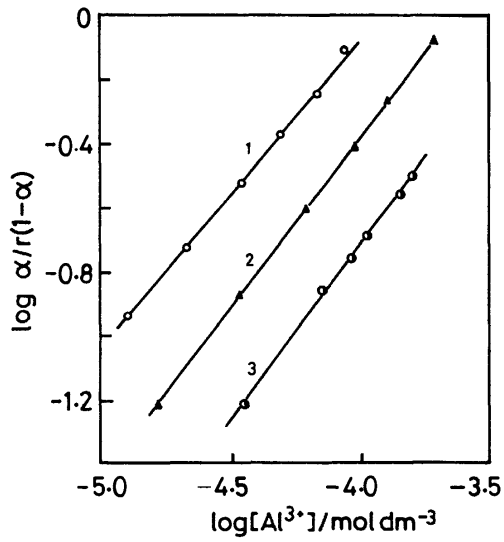

Fig. 4. Relations between $\log \alpha/r(1-\alpha)$ and $\log[Al^{3+}]$. 0.1 mol dm^{-3} NaCl, 22 °C. 1, for 1:1 hcqs complex(red), pH 2.69 (formate buffer), at 550 nm; 2, for 1:1 cqs complex, pH 3.56 (acetate buffer), at 405 nm; and 3, for 1:1 hcns complex, pH 2.83 (formate buffer), at 520 nm.

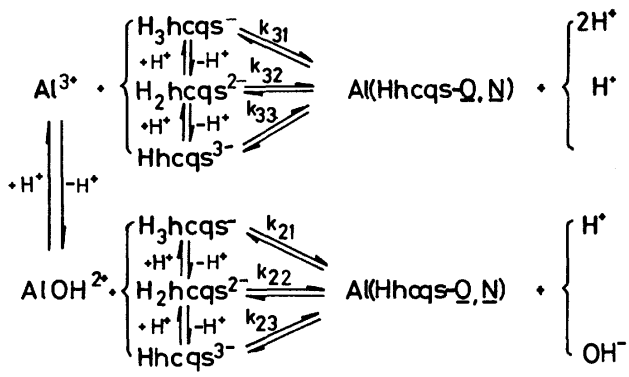
Kinetics and Mechanism. The formation of the hcqs complex can be treated in term of two consecutive reactions with different time scales: The rapid coordination of hcqs to aluminum(III) to form the yellow complex, Al(Hhcqs-*O*,*N*), followed by a slow intramolecular change to the red complex, $Al(hcqs\text{-}O,N,O)^-$. Each reaction step obeyed the first-order kinetics. A linear relation was obtained between the logarithmic absorbance change with time for more than 3.5 half-life periods for each step at 495 nm.

Rapid Process. By taking into consideration[7] the protonation constants of hcqs, the hydrolysis constant of aluminum(III), the stability constant of the 1 : 1 complexes, and the more rapid attainment of equilibria for the protolytic process[8] as compared with the complex formation process, which proceeds at pH 2—5, the rapid formation of Al(Hhcqs-*O*,*N*) can be considered to proceed as is shown in Scheme 1. Six possible



Scheme 1.

reaction pathways are proposed here, with their rate equations:

$$d[Al(Hhcqs\text{-}O,N)]/dt = \{k_{31}[H_3hcqs^-]+k_{32}[H_2hcqs^{2-}]+k_{33}[Hhcqs^{3-}]\}[Al^{3+}] + \{k_{21}[H_3hcqs^-]+k_{22}[H_2hcqs^{2-}]+k_{23}[Hhcqs^{3-}]\}[Al\,OH^{2+}] - \{k_{-31}[H^+]^2+(k_{-32}+k_{-21})[H^+]+(k_{-33}+k_{-22})+k_{-23}[OH^-]\}[Al(Hhcqs\text{-}O,N)] \quad (13)$$

Here, k_{ij} refers to the rate constant for the forward reaction pathway of $AlOH_{3-i}^{i+}$ (i=2 and 3) with $H_{4-j}hcqs^{j-}$, while k_{-ij} refers to the rate constant for the corresponding backward reaction pathway. Under the pseudo-first-order kinetic conditions with respect to the aluminum(III) concentration, the relation 14 between the modified rate constant, $k'_{obsd(1)}$, which can be defined by Eq. 15 from the $k_{obsd(1)}$ determined experimentally by using Eq. 1, while $[H^+]$ can be derived thus from Eq. 13:

$$k'_{obsd(1)}=k_{31}K_{a3}K_{a2}[H^+]^2+(k_{32}+k_{21}K_{a3}K_{OH})K_{a2}[H^+]+(k_{33}+k_{22}K_{a2}K_{OH})+k_{23}K_{OH}[H^+]^{-1} \quad (14)$$

Table 2. Kinetic Parameters (0.10 mol dm^{-3} NaCl, 22 °C)

Pathway	Rate constant/mol^{-1} dm^3 s^{-1}	Remark
$AlOH^{2+}+Hhcqs^{3-}$ (k_{23})	k_{23}: (1.37±0.35)×10^5	First step
Al(hcqs-*O*,*N*)(OH)→	k_{IV}: (3.43±0.45)×10^3	k_{IV}/s^{-1}, second step
$Al^{3+}+cqs^{3-}$(k_{33}) and $AlOH^{2+}+Hcqs^{2-}$(k_{22})	$k_{33}+k_{22}K_{a1}K_{OH}$: (1.34±0.40)×10^5	$K_{a1}=K_{a1(cqs)}$
$AlOH^{2+}+cqs^{3-}$(k_{23})	k_{23}: (7.20±0.30)×10^5	$K_{OH}=K_{OH(Al)}$
$Al^{3+}+Hhcns^{3-}$(k_{33}) and $AlOH^{2+}+H_2hcns^{2-}$(k_{22})	$k_{33}+k_{22}K_{a2}K_{OH}$: (4.44±0.46)×10^2	$K_{a2}=K_{a2(hcns)}$
$AlOH^{2+}+Hhcns^{3-}$(k_{23})	k_{23}: (3.91±0.35)×10^3	

$$k'_{obsd(1)} \equiv k_{obsd(1)}/\{1/\beta'_{11} + C_{Al}/[(K_{a3}K_{a2}[H^+]^2 + K_{a2}[H^+] + 1)(1 + K_{OH}/[H^+])]\} \quad (15)$$

where C_{Al} refers to the total concentration of aluminum(III) and β'_{11}, to the stability constant of Al(Hhcqs-*O*,*N*), which was tentatively estimated to be the same as that of Al(cqs). Figure 5 shows the experimental data plotted on the relation of $k'_{obsd(1)}$ vs. $[H^+]$; a linear relation with an intercept of zero, which indicates that Al(Hhcqs-*O*,*N*) is formed through the reaction pathway of $AlOH^{2+}$ with $Hhcqs^{3-}$. The rate constant, k_{23}, is given in Table 2.

Slow Process. In the slow process, the observed rate constant, $k_{obsd(2)}$, does not depend on C_{Al} at a constant hydrogen ion concentration; this is in contrast to the rapid process, in which $k_{obsd(1)}$ is linearly dependent on C_{Al}. This fact indicates that the slow process (the second reaction step) corresponds to an intramolecular rearrangement of the hcqs complex between two possible coordination modes of the ligand.

Scheme 2 shows the equilibria among possible complex species of Al(Hhcqs-*O*,*N*). Hence, the formation of the red complex, Al(hcqs-*O*,*N*,*O*)$^-$, can be expected via four possible reaction pathways, with the rate equations given as follows:

$$\begin{aligned} &d[Al(hcqs\text{-}O,N,O)]/dt \\ &\quad = -d[Al(Hhcqs\text{-}O,N)]/dt \\ &\quad = k_I[I] + k_{II}[II] + k_{III}[III] + k_{IV}[IV] \\ &\quad - \{k_{-I}[H^+] + (k_{-II} + k_{-III}) \\ &\quad + k_{-IV}[OH^-]\}[Al(hcqs\text{-}O,N,O)] \end{aligned} \quad (16)$$

By defining the modified rate constant, $k'_{obsd(2)}$, which can be defined by the use of Eq. 17 from the $k_{obsd(2)}$ value determined experimentally by using Eq. 1:

$$k'_{obsd(2)} \equiv k_{obsd(2)}/\{1/\beta''_{11} + 1/[(1 + K_{a1}[H^+])(1 + K_{OH}/[H^+])]\} \quad (17)$$

Eq. 18 can then be derived:

$$k'_{obsd(2)} = k_I K^{II}_{a1}[H^+] + (k_{II} + k_{III}K^{IV}_{a1}K^{I}_{OH}) + k_{IV}K^{I}_{OH}[H^+]^{-1} \quad (18)$$

Here, k_I, k_{II}, k_{III}, and k_{IV} are the rate constants for the forward pathways of the second reaction step related to the complex species of I, II, III, and IV; k_{-I}, k_{-II}, k_{-III}, and k_{-IV} are those for the reverse pathways corresponding to each species; β''_{11} is the stability constant of Al(hcqs-*O*,*N*,*O*)$^-$ with reference to Al(Hhcqs-*O*,*N*,); K^{II}_{a1} and K^{IV}_{a1} are the protonation constants of the complex species II and IV corresponding to the K_{a1} values of hcqs, and K^{I}_{OH} and K^{II}_{OH} are the hydrolysis constants of aluminum(III) in the complex species I and II respectively. In the following treatments, for convenience, K^{II}_{a1} and K^{IV}_{a1} were approximated to K_{a1}, and K^{I}_{OH} and K^{II}_{OH}, to K_{OH}. Figure 5 shows a linear relation with a zero intercept between $k'_{obsd(2)}$ and $[H^+]^{-1}$. That is, the intramolecular rearrangement

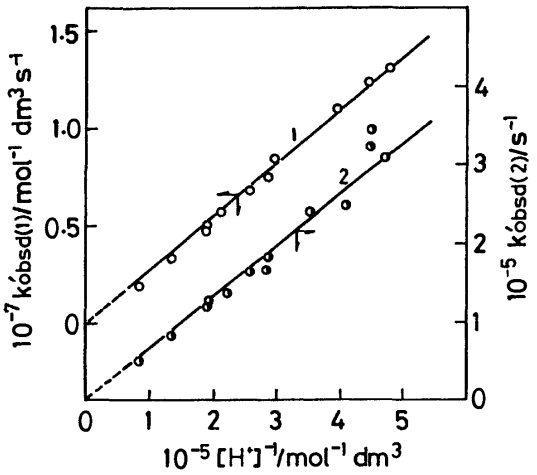


Fig. 5. Relation between $k'_{obsd(1)}$ and $1/[H^+]$ in the first step (1), and between $k'_{obsd(2)}$ and $1/[H^+]$ in the second step (2): C_{Al}, 4.7×10^{-4} mol dm^{-3}; C_{hcqs}, 2.16×10^{-5} mol dm^{-3}; 0.1 mol dm^{-3} NaCl, 22 °C; absorbance at 495 nm.

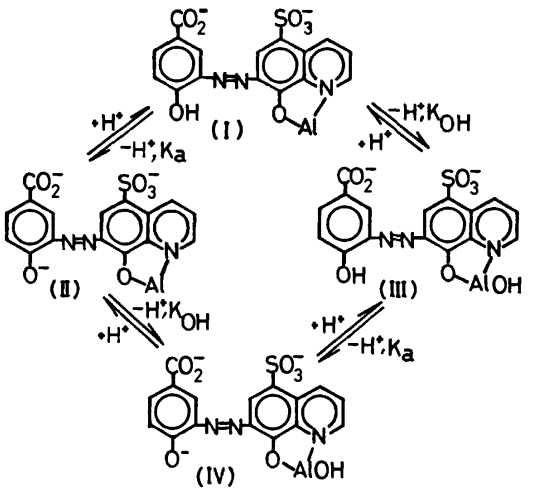

Scheme 2.

takes place through the pathway of the complex species IV. The rate constant, k_{IV}, is given in Table 2.

Formation of the cqs and the hcns Complexes. The kinetics of the formation of aluminum(III) complexes with cqs and hcns were also studied under pseudo-first-order kinetic conditions with respect to the aluminum(III) concentration. The coordination reaction of cqs to aluminum(III) was rapid, just as in the case of the first step of that of hcqs to aluminum(III); a linear relation was found between the logarithmic absorbance change with time for more than 3.5 half-life periods at 316, 400, and 495 nm. On the contrary, the coordination reaction of hcns to aluminum(III) was rather slow as compared with that of cqs, and the reaction rate was of the same order as that of the second step of the hcqs complex; a linear relation was obtained between the logarithmic absorbance change with time for more than 3.5 half-life periods at 495 nm.

The same mathematical treatments as in the case of the rapid process of the hcqs complex were carried out for the cqs and the hcns complexes in order to deduce the reaction pathways; similar relations between the modefied rate constant, k'_{obsd}, and $[H^+]$ were derived as follows:

For the cqs complex:

$$K'_{obsd} = k_{31}K_{a1}K_{a2}[H^+]^2 + (k_{32} + k_{21}K_{a2}K_{OH})K_{a1}[H^+] + (k_{33} + k_{22}K_{a1}K_{OH}) + k_{23}K_{OH}[H^+]^{-1} \quad (17)$$

For the hcns complex:

$$K'_{obsd} = k_{32}K_{a1}K_{a2}[H^+]^2 + (k_{33} + k_{22}K_{a2}K_{OH})K_{a1}[H^+] + (k_{34} + k_{23}K_{a1}K_{OH}) + k_{24}K_{OH}[H^+]^{-1} \quad (18)$$

Here, k_{ij} have the usual meanings. The plots of the experimental data in Fig. 6 indicate a linear relation between k'_{obsd} and $1/[H^+]$ for the cqs complex and a linear relation between k'_{obsd} and $[H^+]$ for the hcns complex. The kinetic parameters are summarized in Table 2.

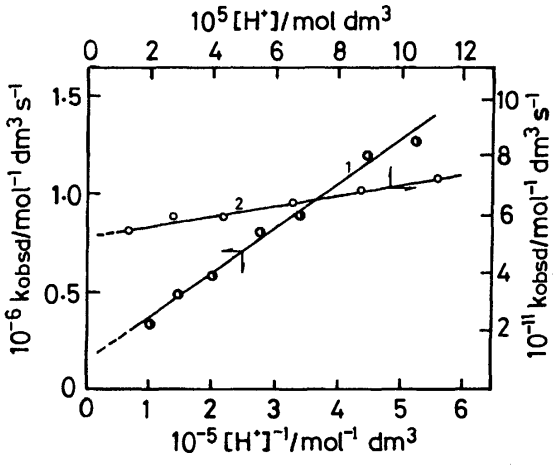

Fig. 6. Relation between k'_{obsd} and $1/[H^+]$ for 1:1 cqs complex at 490 nm (1); and between k'_{obsd} and $[H^+]$ for 1:1 hcns complex at 375, 330, and 265 nm (2). C_{Al}, 4.7×10^{-4} mol dm^{-3}; C_{cqs} or C_{hcns}, 2.4×10^{-5} mol dm^{-3}; 0.1 mol dm^{-3} NaCl, 22°C.

Discussion

The ligand hcqs shows coordination behavior unique to aluminum(III); namely, it forms two types of complexes, Al(Hhcqs-*O,N*) (yellow) and Al(hcqs-*O,N,O*)$^-$ (red),[9] which are in the linkage isomerism. This is unlike hns and pqs, which coordinate selectively to aluminum(III) only with one of the two coordination modes, although the linkage isomerism is possible for hns and pqs as well as for hcqs. The molecular models of the ligand species suggest that hcqs is stabilized more to a *trans-O,O* form (phenolate and quinolinolate oxygen atoms) with regard to the azo group by the intramolecular hydrogen bonds, whereas hns is less stabilized to the *trans-O,O* form with the intramolecular hydrogen bonds, while pqs has no such hydrogen bonds for the stabilization of the *trans-O,O* form. Hence, it can tentatively be inferred that the hydroxyl group ortho to the azo group on the aromatic ring opposite the 8-quinolinol moiety is prerequisite for the linkage isomerism.

The ligand hcqs first coordinates to aluminum(III) with the 8-quinolinol moiety to form the yellow complex. The absorption spectral and kinetic evidence indicates that the coordination behavior of hcqs to aluminum(III) was superposable on that of cqs, which functions as the *O-N* bidentate ligand, but was quite different from that of hcns, which functions as the *O-N-O* terdentate ligand. Taking the differences in molecular structure of these ligands into consideration,[10] Table 2 clearly indicates that the rate constants for each of the reaction pathways of hcqs and of cqs are of the same magnitude as those for the corresponding pathways of hns, nqs, pqs, and hqs.[1-4] Therefore, the rate-determining steps of hcqs and cqs for their coordination to aluminum(III) must be the same as those of hns, nqs, pqs, and hqs; donation via the 8-quinolinolate oxygen atom to aluminum(III). Chelate ring closure as the rate-determining step can probably be ruled out because the rate constants for cqs, hcqs, nqs, and hqs, all having the *O-N* bidentate ring, are intrinsically of the same magnitude, and they agree with those of hns and pqs. Incidentally, the considerably small rate constant for hcns compared with the rate constants for hns and pqs indicates that the chelate ring closure is the rate-determining step in the coordination of hcns to aluminum(III). Hence, it is inferred that the formation of Al(Hhcqs-*O,N*) proceeds through the coordination of the 8-quinolinolate oxygen atom to aluminum(III) as the rate-determining step,[1-4] followed by a rapid chelate ring closure to form a five-membered chelate ring.

The formation of the red hcqs complex shows a unique kinetic feature: The rate constant for the formation of the red complex is considerably smaller than

that of the cqs complex; rather, it is in line with that of the hcns complex. The molecular models of hcqs and hcns indicate that the coordination of these ligands with the *O-N-O* terdentate moieties requires transformation from the *trans-O,O* to the *cis-O,O* form with regard to the azo group by breaking the intramolecular hydrogen bond(s) after the coordination through the 8-quinolinolate oxygen atom as unidentate ligands. The small rate constants for the formation of the red hcqs complex and of the hcns complex reflect some contribution of this transformation; therefore, it may be concluded that the linkage isomerization of the yellow hcqs complex to the red one and the formation of the hcns complex proceed with the chelate ring closure as the rate-determining step.

Finally, it should be noted that hcqs and the related ligands can be classified into two groups with respect to the experimental relation of the modified rate constant, k'_{obsd} vs. $[H^+]$; linear relations between k'_{obsd} and $[H^+]$ hold for hcns, hns, pqs, and hqs, whereas linear relations between k'_{obsd} and $[H^+]^{-1}$ hold for hcqs, cqs, and nqs. The classification can be explained in terms of the basicity (protonation constant) of the oxygen donor atom on the quinoline ring; those ligands having a higher basicity conform to the former relation, while those having a lower basicity conform to the latter relation. This evidence also supports the important role of the oxygen atom in the 8-quinolinol moiety on the reaction kinetics with aluminum(III), especially the rate-determining step, of hcqs and the related multidentate ligands.

9) In this type, hcqs is able to form two kinds of chelate ring arrangements, depending upon which nitrogen atom in the azo group serves as a donor atom. They can be considered to be in equilibrium because of the high lability of the aluminum(III) complex and the lack of any difference in steric restrictions between these arrangements.

10) There are several pairs of reaction pathways proceeding in a parallel way and indistinguishable by a kinetic investigation because of proton ambiguity. The highest probable rate constant for each reaction pathway was tentatively estimated for the discussion.

(Received October 24, 1987)

Rates of racemization of the tris(1,10-phenanthroline)iron(II) cation, $[Fe(phen)_3]^{2+}$, have been measured at 7.5 °C to 17.5 °C in 1,2-dichloroethane, *o*-dichlorobenzene, nitrobenzene, and nitromethane, and in 1,2-dichloroethane solutions containing dimethyl sulfoxide (DMSO), *N*,*N*-dimethylformamide (DMF), methanol (MeOH), acetone (Ac), and acetonitrile (AN). In the four pure solvents, the observed racemization rates are markedly smaller than those calculated by the Van Meter and Neumann equation, which relates the racemization rate to the solvation energy of the phen ligands and viscous resistance. Addition of donor solvents to 1,2-dichloroethane solutions of the iron complex enhances the racemization rates. The degree of enhancement increases in the order AN < Ac < MeOH < DMF < DMSO and the activation energy decreases in the same order. This sequence lies in the order of increasing Gutmann donor number of the solvents, indicating a nucleophilic interaction of the solvents with the iron metal in the transition state. These obsevations may be interpreted in terms of Kepert's model for solvent-assisted racemization of tris-chelated complexes and the molecular structure of a solvate complex determined previously, and allow us to modify the Van Meter and Neumann equation.

The kinetics of racemization of the tris-chelated complexes of 1,10-phenanthroline (phen) with iron(II), nickel(II), and cobalt(III), $[Fe(phen)_3]^{2+}$, $[Ni(phen)_3]^{2+}$, and $[Co(phen)_3]^{3+}$, have been studied extensively,[1] and it was concluded that these three complexes racemize through different mechanisms: twist,[2] dissociative,[3,4] and electron exchange,[5] respectively. Solvent effects on the racemization reactions have been examined in organic solvents or in aqueous-organic solvent mixtures during recent decades.[6] In aqueous solutions, we have shown that a different solvent effect appears to reflect a difference between their racemization mechanisms.[7]

In our previous studies of racemization of the nickel complex in several solvents[8] and in 1,2-dichloroethane solutions containing various amounts of donor solvents,[9] the racemization rates were found to decrease with decreasing donicity of the solvents (Gutmann donor number[10]), indicating that attack of the donor on the central metal may be important for the racemization.[11] On the other hand, the racemization reaction of the iron complex has been thought to provide one of interesting examples of unimolecular reactions involving no formal separation of charge but the role of solvent in the racemization has not been obvious and is still a matter for discussion, especially with respect to the mechanism. In a study of the rates of dissociation and racemization of $[Fe(phen)_3]^{2+}$ in various solvents,[12] Van Meter and Neumann reported that solvent variation affects the rates of racemimization k_r, and derived empirically the equation,

$$\log k_r = c_i - (0.26\Delta G_L/2.303RT) - 0.48\log(\eta V_m), \quad (1)$$

where c_i, ΔG_L, η, and V_m are a constant, the free energy of solvation of the phen ligand, the solvent viscosity, and the molar volume of the solvent, respectively. Recently, the polarizability of solvents and added salts in aqueous solutions was suggested to be one of important factors which facilitate the racemization of the iron complex.[13] On the other hand, we noted that the racemization rates in aprotic solvents decrease with the solvent in the order, *N*,*N*-dimethylformamide > acetonitrile > nitrobenzene, despite the fact that the three solvents are very similar in ΔG_L; this sequence lies in the order of decreasing donicity of the solvents, implying that the donicity play a significant role on the racemization even in the case of the $[Fe(phen)_3]^{2+}$ complex,[14] as well as in the case of the $[Ni(phen)_3]^{2+}$ complex.[8,9]

In order to explore this possibility, first, we present further examples of solvents such as nitrobenzene in which the observed rate of the racemization is markedly smaller than that calculated by Eq. 1. Here, the contribution to the solvation energy, ΔG_L, for the $[Fe(phen)_3]^{2+}$ cations arising from ligand-solvent interactions was calculated from the solubility data for naphthalene by the method of Van Meter and Neumann.[15] Second, measurements of the racemization rates in 1,2-dichloroethane solutions with varying concentration of the donor solvents, dimethyl sulfoxide, *N*,*N*-dimethylformamide, methanol, acetone, and acetonitrile, were made over a temperature range. The results may be interpreted based on Kepert's model for solvent-assisted racemization of tris-chelated complexes.[16] Support for this is furnished by the X-ray structure of the nitrobenzene solvate, $[Fe(phen)_3]I_2 \cdot NB \cdot 2H_2O$, reported already.[17]

Experimental

Materials. The preparation of the optically active complex, (+)-$[Fe(phen)_3](ClO_4)_2 \cdot 3H_2O$, was performed according to the method of Dwyer and Gyarfas involving diastereoisomer resolution with antimonyl (+)-tartrate.[18]

Reagent-grade non-aqueous solvents were further purified before experimental use as follows. Nitrobenzene (NB), *o*-

dichlorobenzene (DCB), and 1,2-dichloroethane (DCE) were purified according to the procedures described in our previous papers[7,19,20] and nitromethane (NM) according to the method of Unni et al.[21]

Dimethyl sulfoxide (DMSO) was refluxed with potassium hydroxide for 3 h at 125 °C, and then fractionally distilled twice at 95 °C under reduced pressure with a nitrogen bleed. The middle fraction was collected each time. *N,N*-Dimethylformamide (DMF) was distilled fractionally under a pressure of a few millimeters. The middle cut was taken and, after being dried over 4-A Molecular Sieves for one week, distilled once more under vacuum at 65 °C with a nitrogen bleed. The middle fraction was collected. Methanol (MeOH), to which 6 M (1 M=1 mol dm^{-3}) sulfuric acid (25 cm^3 per liter) was added, was refluxed for several hours and distilled. The product was treated with 20 g of potassium hydroxide and 10 g of silver nitrate per liter, the mixture being refluxed and distilled. The distillate was dried over 3-A Molecular Sieves for 1 d, and then distilled fractionally from magnesium over nitrogen. Acetone (Ac) was dried over 4-A Molecular Sieves, filtered, and distilled. Acetonitrile (AN) was intermittently shaken or stirred (magnetic stirrer) with calcium hydride (10 g per liter) for 2 d, decanted, and then fractionally distilled from phosphorus pentaoxide (5 g per liter). The product was refluxed over calcium hydride (5 g per liter) for several hours, then fractionally distilled very slowly. The middle fraction was collected. All solvents have densities identical with or close to literature values: Observed densities for DCE, DCB, NB, and NM are given in Table 1; DMSO, 1.09525 (1.0958); DMF, 0.94401 (0.94397); MeOH, 0.78653 (0.78664); Ac, 0.78447 (0.78440); AN, 0.77662 (0.7766). Values in parentheses are from the literature.[22] Water contents in the solvents were measured coulometrically by using a Hiranuma AQ-3 aquacounter to be less than 0.01 M. Naphthalene was recrystallized three times from methanol. The melting point was 80.7 °C (lit,[23] 80.5 °C).

Rates of Racemization. The rates of racemization of (+)-$[Fe(phen)_3](ClO_4)_2$ in various solutions were determined over a temperature range by the method described in our previous work.[7] The optical rotations of the chelate were measured at 365 nm in DCE and DCB solutions and at 589 nm in NB and NM solutions by using a Perkin-Elmer Model 141 polarimeter with Hg and Na lamps, respectively. About 10^{-4} M solutions of the chelate were prepared by its dissolution in the appropriate solution. This solution was immediatedly poured into a 1-dm, water-jacketed, polarimeter tube and maintained at constant temperature (±0.1° C) by circulating water.

The values of the observed rotation, α, were plotted in the usual fashion, log α vs. time, and the slope of the straight line obtained is equal to $-k_r/2.303$ where k_r is the rate constant in s^{-1} for the racemization.

Solubility of Naphthalene. The procedure of solubility measurement was similar to that for $[Fe(phen)_3](ClO_4)_2$[24] except that the solubility of naphthalene, S_{naphth}, was determined from density measurements by using the equation,

$$S_{naphth} = 1000(d_0 - d)/(V_m d_0 - M_w), \quad (2)$$

where d_0 and d are the densities of a pure solvent and its solution containing naphthalene, respectively, and M_w is the molecular weight of naphthalene (M_w=128.175). The apparent molar volumes, V_m, of naphthalene, which are given in Table 1, were determined from density measurements by using the Eq. 2 for DCE, DCB, NB, and NM solutions with varying concentration of naphthalene prior to the solubility measurements. The densities of the sample solutions were measured by using a digital densimeter (Anton Paar Precision Density Meter, Model DMA 02D) with an internal measuring cell which is water jacketed with a water-circulating thermostat at 25.00±0.005 °C.

Results

Rates of Racemization. The rate constants in the various pure solvents are given in Tables 2 and 3. The errors are the standard derivations estimated from the residuals of the least-squares line for each run. The reproducibility of the measurements can be evaluated from the data obtained in duplicate under the same reaction conditions. There is no dependence of the racemization rate on the complex concentration in each solvent as given in Table 2. The activation parameters, E_a and log A for the rates were calculated from the Arrhenius plot of log k_r vs. $1/T$. The rate constants for DCE, DCB, NB, and NM at 25 °C were extrapolated from the Arrhenius plots. Table 4 gives the results and includes the data for AN, MeOH, Ac, and DMF[12] for comparison, indicating that the racem-

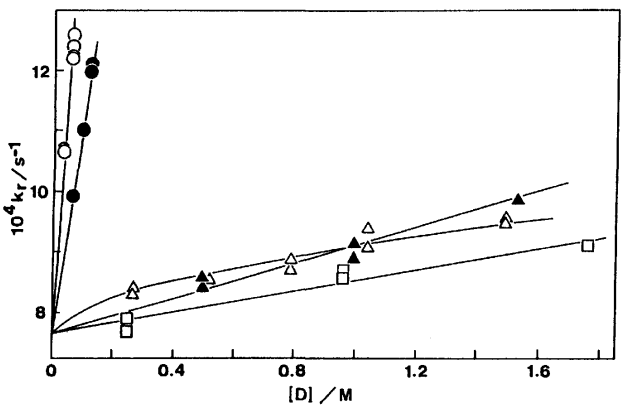

Fig. 1. Dependence of rate constant (k_r) for racemization of $[Fe(phen)_3]^{2+}$ on the concentration of donor solvent, [D], in DCE solution at 15.0 °C: (○), DMSO; (●), DMF; (△), MeOH; (▲), Ac; (□), AN.

ization occurs more slowly in DCE, DCB, NB, and NM.

Table 5 gives the rate constants in the DCE solutions with varying concentration of the various donor solvents and the typical results are illustrated in Fig. 1, where the data are plotted as k_r vs. donor solvent concentration, [D]. Figure 1 shows that the plots were good straight lines, except for MeOH. By a weighted least-squares procedure, the results were fitted to the equation,

$$k_r = k_0 + k_s[D], \quad (3)$$

where k_0 and k_s are the intercept and the slope of the plot, respectively. The values of k_0 were in agreement with the corresponding rate constants in the pure DCE solvent within error. Table 6 gives the k_s values with the activation parameters determined by the Arrhenius plots for k_s.

For MeOH, on the other hand, the plot shows a curve (Fig. 1). Similar rate behavior was observed for the racemization of $[Ni(phen)_3]^{2+}$ in the analogus solvent system.[9] The decrease of the accelerating effect is due to loss of MeOH activity[25] which is caused by self association of MeOH in DCE as reported for water and alcohols in relatively inert solvents.[26] Assuming dimerization of MeOH, we estimated an equilibrium constant of 0.49±0.20 M^{-1} for the formation of a dimer of MeOH and a k_s value of (2.28±0.43)×10^4 s^{-1} M^{-1} (Table 6).

In our previous study of the racemization of $[Ni(phen)_3]^{2+}$ in DCE solutions containing various amount of water,[8] it was found that the rate increases dramatically with increasing water content. However, the analogous increase in rate for $[Fe(phen)_3]^{2+}$ is very small: The k_r value at 15.0 °C is (8.19±0.06)×10^{-4} s^{-1}

in water-saturated DCE ($[H_2O]$=0.094 M) and is 7.65×10^{-4} s^{-1} in pure DCE (Table 2).

Solubility of Naphthalene. Table 1 gives the solubilities of naphthalene in the various solvents. Each value of the solubilities is the mean of data obtained in triplicate and the error is a mean deviation. Van Meter and Neumann showed that the solvation energy is related to the solubility or the free energy of solvation of naphthalene, ΔG_{naphth}, by the equation,[15]

$$\Delta G_L = 2.053\, \Delta G_{naphth}, \quad (4)$$

for which $\Delta G_{naphth} = -RT \ln S_{naphth} - \Delta G_{subl}$, where the free energy change, ΔG_{subl}, for the sublimation of naphthalene, is calculated, from the vaper pressure[27] of naphthalene at 25 °C, to be 30.57 kJ mol^{-1}. The Eq. 4 is valid especially for aprotic solvents, althouth some steric factors may become important in such a tris complex. The ΔG_L values calculated for DCE, DCB, NB, and NM are comparable to those for other aprotic solvents such as AN, Ac, DMF, etc. as given in Table 7.

Discussion

Since the racemization of $[Ni(phen)_3]^{2+}$ complex occurs mainly by a dissociative process,[4,28] measurements of the racemization rate, k_r, of the nickel complex allow us to estimate the dissociation rate, k_d, of the $[Fe(phen)_3]^{2+}$ complex as follows.[29] Figure 2 shows that a linear free-energy relationships[30] exists: A plot of log k_d for the iron complex against log k_r for the nickel complex in various solvents is linear, with slope 1.66±0.15 and intercept 4.21±0.77. The k_d values for DCE, DCB, NB, and NM can be extrapolated from this plot as the k_r values for the solvents are available from our data.[31] Table 4 gives the estimated k_d values with the values of k_r for the iron complex, indicating that racemization of the iron complex is extremely faster than dissociation in these solvents where the complex favors an intramolecular racemization process, as well as that in the other organic solvents, AN, Ac, DMF, etc. (more than 99.5% of the time).[1,12,32]

When the Van Meter and Neumann Eq. 1 is valid for a given solvent, the value of the constant, c_i, of an intrinsic part in the Eq. 1 should be -4.56.[33] Table 7 shows that this is the case for DMF and MeOH while the solvents, DCE, DCB, and NM, as well as NB,[14] have significantly lower c_i values: Despite similarities of ΔG_L and $\log(\eta V_m)$ between DMF and DCE, for example, the rate in DCE is smaller than that in DMF (Table 4). Furthermore, DCE or DCB is a solvent of lower dielectric constant compared to NM or NB and thus substantially all the complex cations are associated with the ClO_4^- ion into ion-pairs in the former solvent (about 10^{-4} M solutions of the complex used here)[34] while they are dissociated to a great extent in the latter.[35] However, the racemization rate or the c_i value in DCE or DCB is comparable to that in NM or NB. In addition, the racemization rates are independent of the complex concentrations in the solvents (Table 2). These results indicate that the ion pairing effect is negligibly small. DCE, DCB, NB, and NM have extremely low donicities[36] and so the c_i value appears to increase predominantly with increasing donor number of the solvents (Table 7). This implies that the c_i constant for the racemization should contain not only an intrinsic part but also a part due to a nucleophilic interaction with the iron metal.

In order to clarify the role of donor solvents in the racemization of the iron complex, the dependence of the rate on the concentration of added solvents was investigated in DCE solutions.[37] Figure 1 shows that addition of donor solvents to DCE solutions enhances the racemization rates and the correlation between them is linear. As presented for the $[Ni(phen)_3]^{2+}$ complex,[9] the rate behavior can be understood on the basis of the scheme,

$$(+)\text{-}[Fe(phen)_3]^{2+} + D \rightleftarrows (+)\text{-}[Fe(phen)_3]^{2+}\cdot D \rightarrow (-)\text{-}[Fe(phen)_3]^{2+} + D, \quad (13)$$

which, provided that an outer-sphere complex in a rapid preequilibrium is weak, leads to a second-order rate law.[38] Since the sizes of the added solvents do not greatly differ or the solvents are similar in ΔG_L, it is reasonable that equilibrium constants for the formation of the outer-sphere complexes for the solvents are approximately equal. Thus it is quite likely that the kinetics are controlled by the interaction of the complex cation with the added donor solvent molecule in the process concerned in the rate-determining step.

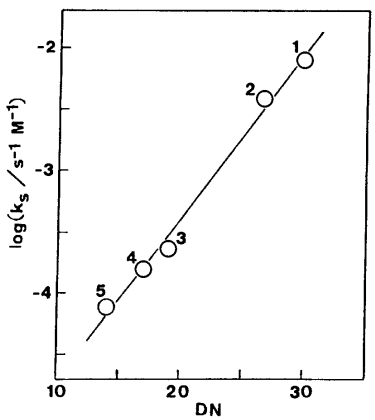

Fig. 3. Correlation of $\log k_s$ in DCE solutions containing donor solvents at 15 °C with Gutmann donor number DN of the solvents: (1), DMSO; (2), DMF; (3), MeOH; (4), Ac, (5), AN.

The k_s values derived by using Eq. 3 increase with added solvent in the order AN < Ac < MeOH < DMF < DMSO. This sequence lies in the order of increasing donicity of the solvents. A plot of $\log k_s$ against donor number shows a good linear correlation between them as shown in Fig. 3. Futher, Table 6 shows that a decrease in the activation energy, E_a, for the system, AN > Ac > DMF > DMSO, is consistent with the trend in $\log k_s$ as donor number of the solvent increases. This can be rationalized in terms of a mechanism involving expansion of a complex cation to a 7-coordinate transition state with one donor solvent as proposed for racemization of the $[Ni(phen)_3]^{2+}$ complex.[8,9,11] The trends in $\log k_s$ and E_a may be attributable to the ability of the solvents to stabilize the transition state by donation, which thus leads to a lower energy of activation for racemization.

Recently, we have reported the detailed structure of the nitrobenzene solvate, $[Fe(phen)_3]I_2 \cdot NB \cdot 2H_2O$, as a result of the X-ray structure determination.[17] In the structure, the nitrobenzene molecule occupies one of the three major V-shaped pockets between the phen ligands. Thus, the above solvent-assisted racemization of the tris-chelated complexes can be explained by a double-opposed-initiated twist proposed by Kepert[39] if it is assumed that a donor solvent molecule is placed instead of the nitrobenzene molecule in the solvate (Fig. 1 of Ref. 17), although differences in coordination to the metal center may be also involved, as well as differences in solvation energy in the transition state. Moreover, it has been reported that for ion-pair formation of the iron complex and arenesulfonate ions the above major pockets are also important.[40]

In summary, it is concluded that the donor number of the solvent is one of the important factors in solvent effects on the racemization of $[Fe(phen)_3]^{2+}$. From this point of view, we can relate the c_i constant to donor number (Table 7)[41] and derive the equation,

$$c_i = -5.66 + 0.057DN,$$

which may allow us to modify the Van Meter and Neumann Eq. 1. On the other hand, it is surprising that the racemization of the iron complex in Ac is extremely rapid (Table 4) while the accelerating effect of Ac on the racemization in DCE solutions is lower (Table 6). Langford and Tong have pointed out that changes in the bulk properties of the solvent beyond the contact solvation shell may influence reaction rates.[42] Further investigation is undertaken for clari-

fying bulk solvent effects on the racemization.

New Synthesis, Properties, and the Formation of the Hexamer of Nickel(II) Ethanethiolate, $[Ni(SEt)_2]_6$

Takeshi YAMAMURA
Department of Chemistry, Faculty of Science, Science University of Tokyo, Kagurazaka 1-3, Shinjuku-ku, Tokyo 162
(Received November 12, 1987)

$[Ni_3(SEt)_8]^{2-}$ reacted with water in acetone to give the known hexameric ring compound, $[Ni(SEt)_2]_6$, where SEt means $CH_3CH_2S^-$. The $[Ni(SEt)_2]_6$ was oxidized electrochemically in a quasi-reversible manner at +0.60 V (vs. SCE) in CH_2Cl_2. ^1H and ^{13}C NMR revealed that this compound has two types of -SEt (low- and high- field types; the chemical shift discrepancy is ca. 0.4 ppm for ^1H NMR), probably corresponding to the axial-equatorial configurations of the thiolate. The formation of the cyclic hexamer in CH_3CN and $CHCl_3$ in the presence of protic reagents was studied.

Metal complexes of simple thiolates (alkanethiolates or arenethiolates) are now substances that are of topochemical interest as potential sources of a variety of multi-nuclear compounds because of the bridging disposition of thiolate ligands.[1] The hexagonal molecular cycles, $[Ni(SEt)_2]_6$,[2] (Fig. 1),[3] $[Ni(SCH_2CH_2OH)_2]_6$,[4] $[Pd(SCH_2CH_2OH)_2]_6$,[5] the tetragonal analogue, tetrakis[bis-(*N*-methylpiperidine-4-thiolato) nickel],[6] and the octagonal analogue, $[Ni(SCH_2CH_2COOEt)_2]_8$,[7] form a novel topochemical group by their ring crown structure, with linked square planar units of M(II) (M=Ni and Pd) and bridging thiolates. The M-S frameworks of these compounds hold inside cylindrical vacancies surrounded by arrays of coplanar metal centers. This salient structural feature, the so called "tiara",[2] involves the possibility of developing new types of inclusion complexes. In practice, $[Ni(SCH_2CH_2COOEt)_2]_8$ takes one of the substituent pendant groups (-OEt) in a solid into its own hole by anchoring the ester oxygen to nickel atoms.[7]

In spite of its central situation in the tiara group, almost no efforts have been made to elucidate its basic character of the hexamer, $[Ni(SEt)_2]_6$, since the detouring[2a,c] synthesis and a structural short communication.[2b] In the course of our study of nickel-thiolate systems,[8] we have found a simple way to obtain the hexamer. This paper will present a description of the new synthetic method, aspects of the formation in aprotic media, and the result of the usual physicochemical measurements (NMR and electrochemistry).

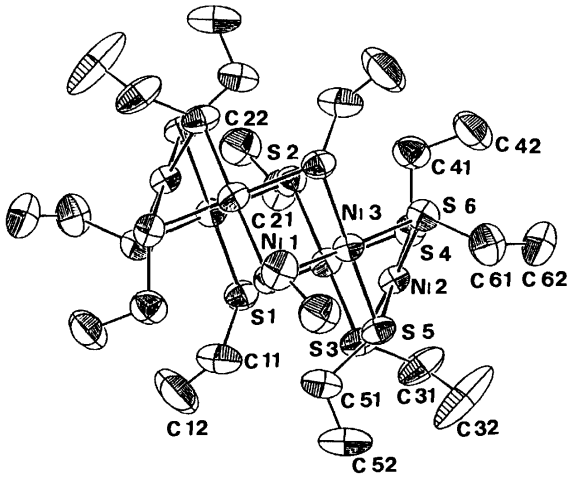

Fig. 1. ORTEP plot of the non-hydrogen atoms of $[Ni(SEt)_2]_6$ (triclinic) with 50% probability thermal elipsoids and the atom numberlings.[3]

Experimental

Every synthetic procedure was performed under a nitrogen or argon atmosphere. The solvents were refluxed over appropriate drying agents and distilled under argon. Sodium ethanethiolate was prepared from sodium and excess ethanethiol in methanol and dried completely (120 °C, in vacuo) before use.

Preparation of the Materials. $(NEt_4)_2[Ni_3(SEt)_8]$ was prepared according to A. D. Watson's method.[9]

$[Ni(SEt)_2]_6$: To a greenish brown solution of 0.50 g (0.37 mmol) of $(NEt_4)_2[Ni_3(SEt)_8]$ in 450 ml of acetone was added 0.2 g of commercial $[NMe_3Ph]^+Cl^- \cdot nH_2O$ (in acetone). The solution was then refluxed for 30 min, cooled to room temperature, and passed through a sintered glass to remove any insoluble impurities (red brown powder and an extra amount of $[NMe_3Ph]^+Cl^- \cdot nH_2O$). The filtrate, wine red in color, was placed in a refrigerator at −20 °C for 2 weeks. The black crystals which slowly grew in the flask were collected and dried in vacuo. Stable in air. Yield, 0.21 g (72%). Found: C, 26.65; H, 5.45; N, 0%. Calcd for $C_{24}H_{60}Ni_6S_{12}$: C, 26.55; H, 5.57; N, 0%. Absorption spectrum (in chloroform): 335 nm (ε=55600), 407 (20100), 515 (7030), 570 (sh, 5430). Soluble in benzene, toluene, xylene, chloroform, and dichloromethane. Slightly soluble in ethyl acetate. Insoluble in acetone, acetonitrile, dimethyl sulfoxide, ethanol, and water.

Physicochemical Measurements. The electronic spectra were recorded on a Hitachi Recording Spectrometer 340. The ^1H NMR spectra were obtained by the use of JEOL FX-90Q spectrometer. Electrochemical measurements were carried out by using a Yanaco Polarographic Analyzer, model P-1100, or a Hokuto Potentiostat/Galvanostat HA-201 in connection with a Fuso function generator, model 321. the molecular weight of the hexamer in solution was decided by the use of a Knauer Vapor Pressure Osmometer No. 01.00.

Results

The molecular weight of the "tiara" in benzene was

decided as 1100 (accuracy 10%) by means of vapor pressure osmometry with benzyl (molecular weight=210.3) as the standard. This result agrees with the theoretical value for $[Ni(SEt)_2]_6$, 1080. Therefore, the hexameric aggregation is maintained also in solution, at least in benzene.

Figure 2-a depicts the absorption spectrum of $[Ni(SEt)_2]_6$ in chloroform. This is composed of an intense LMCT band at 335 nm (ε=9270 $M^{-1}cm^{-1}$/Ni (1 M=1 mol dm^{-3})) and much weaker ones at 407 nm (ε=3350 $M^{-1}cm^{-1}$/Ni), 515 nm (ε=1170 $M^{-1}cm^{-1}$/Ni, deconvoluted), and 570 nm (ε=905 $M^{-1}cm^{-1}$/Ni, deconvoluted). No absorption was observed in NIR region. The spectrum differs in its intensity from that of $[Ni_3(SEt)_8]^{2-}$ [3d] (Fig. 2-b) at ca. 400 nm and in the 500—600 nm region.[10] According to Maki,[11] the bands at 407, 515, and 600 nm of the hexamer are to be assigned to the d-d transitions, $^1A_{1g} \rightarrow {}^1A_{2g}$, $^1B_{2g}$, and $^1A_{1g} \rightarrow {}^1E_g$ respectively, of a square planar Ni(II), judging from their wavelength regions and intensities.[12]

The ^1H NMR spectrum of the hexamer (in chloroform, at room temperature) is shown in Fig. 3-a. The spectrum reveals that two types of ethanethiolate, different in the strength of their diamagnetic shielding, exist in the solution. The correlation between the methylene and methyl protons of each EtS^- was decided by means of proton-proton decoupling technique (depicted in the figure). The observed chemical shifts of the methyl and methylene protons of the high-magnetic-field -SEt (CH_2; δ=1.76, CH_3; δ=1.08) agree well with those of $[Ni_2(SEt)_6]^{2-}$ (CH_2; δ=1.79—1.87, CH_3; δ=1.05 and 1.20) and $[Ni_3(SEt)_8]^{2-}$ (CH_2; δ=1.85—1.88, CH_3; δ=1.04—1.08).[13] Compared with these, the values of the low-magnetic-field -SEt are shifted ca. 0.4 ppm downward. The result of ^{13}C NMR indicates the same situation, showing that 4 kinds of carbon atoms exist in the solution (Fig. 3-b). The peaks were assigned by means of selective decoupling technique. (Low field -SEt: CH_2; δ=26.367, CH_3; δ=19.446. High field -SEt: CH_2; δ=20.177, CH_3; δ=16.229.)

The electrochemical behavior of $[Ni(SEt)_2]_6$ in dichloromethane (0.2 M $NBu^n_4PF_6$, vs. SCE, glassy carbon electrode) was studied over the potential range from −1.8 to +1.8 V by means of cyclic voltammetry (CV) at various scan rates (10—200 mV s^{-1}) and by means of differential pulse polarography (DPP) with a modulation amplitude 10 mV. No evidence for the reduction of the hexamer corresponding to the formation of the monoanion $[Ni(SEt)_2]_6^-$ was obtained in the region observed. The CV chart exhibited three oxidation peaks at +0.655, +1.05, and +1.61 V, within which the higher two were irreversible. Cyclic scans limited within 0.8 to 0 V revealed that the +0.655 V anodic peak was followed by a cathodic peak at +0.55 V (see Fig. 4). No scan rate dependence was observed for either anodic or cathodic peaks. That is, we obtained the relationship $(\partial E/\partial \log v)_T$=0,[17] which is applicable to reversible and quasireversible cases, while the cathodic anodic current ratio, i_{pc}/i_{pa},[18] calculated for the case of a 100 mV s^{-1} scan rate, was 0.92. Consequently, the oxidation process was quasireversible. This was also confirmed by DPP measurements. The

half height width, 100 mV, was slightly larger than the ideal reversible case (91 mV).[19]

The effects of ethanol, water, and H^+ itself on the hexamer generation were also examined. The absorption spectra of (a) $[Ni(SEt)_2]_6$ in $CHCl_3$ (b) $[Ni_3(SEt)_8]^{2-}$ in CH_3CN, and (c) $[Ni_3(SEt)_8]^-$ in commercial $CHCl_3$ including 1% EtOH are depicted in Fig. 2, with the extinction coefficient *per* Ni on the ordinate. As may be seen in Fig. 2, the major species in the $[Ni_3(SEt)_8]^{2-}/CHCl_3$ (commercial) solution was not $[Ni_3(SEt)_8]^{2-}$ itself, but $[Ni(SEt)_2]_6$, while the amount of the hexamer generated in commercial $CHCl_3$ was the same as in (b). Consequently, almost all of the $[Ni_3(SEt)_8]^{2-}$ was converted to the hexamer in commercial $CHCl_3$. On the other hand, in a purified $CHCl_3$ (dried with H_2SO_4, hence including almost no alcohol for stabilization) the original absorption spectrum of $[Ni_3(SEt)_8]^{2-}$, which was observed in dried acetonitrile, changed in a different way. In this case the spectrum changed inconspicuously in the 500—600 nm region both in spectral shift and in intensity. On the other hand, in the 300—400 nm region, the original peaks at 316 nm and 400 nm (sh) shifted to 330 nm and 416 nm respectively. Especially the latter peak grew remarkably. The reaction which accompanied this incomplete absorption change was also studied by ^1H NMR in dried $CDCl_3$. However, the results were not unequivocal except that the signals characteristic of the hexamer appeared only slightly. This means that the significant step generating the hexamer proceeds in the presence of EtOH. The addition of EtOH afforded the hexamer's spectrum also in acetonitrile. $[Ni(SEt)_2]_6$ was also generated in acetone by the addition of an almost equimolar amount of water to the trimer, as has been described above in discussing the synthesis.

The effect of water was more rigorous, and the use of excess water yielded an insoluble polymer, $[Ni(SEt)_2]_\infty$, in acetone or acetonitrile. For example, when 0.454 mM of $[Ni_3(SEt)_8]^{2-}$ in acetonitrile (dried 3 days over CaH_2; 1g/200 ml) was treated with water (5.0 equiv), the absorption pattern changed to one which resembled the hexamer's, but more gentle, and the intensity diminished to ca. 1/2 of the theoretical value within 4 h. However, 25 equiv of water led to a pseudo-exponential decomposition of $[Ni_3(SEt)_8]^{2-}$ with a decay constant of $k=1.29\times10^{-4}$ s^{-1} and yielded insoluble polymers. Eventually, the formation reaction of the hexamer from $[Ni_3(SEt)_8]^{2-}$ and water competed with polymerization processes. These results led us to the idea that the H^+ originating from EtOH or water play an important role in the hexamer formation or at least in the elongation of an open chain $[Ni(SEt)_2]_n(SEt)_2^{2-}$. The effect of H^+ was examined in a more direct manner by using $[NHEt_3]^+[BF_4]^-$ to $[Ni_3(SEt)_8]^{2-}$ in acetonitrile. The result was satisfactory. Immediately after mixing, the absorption spectrum changed from that of $[Ni_3(SEt)_8]^{2-}$ to one similar to the hexamer's spectrum, just as is observed in the $[Ni_3(SEt)_8]^{2-}/CHCl_3$(commercial) system.

Consequently, the reaction described as Eq. 1 proceeds in commercial $CHCl_3$, wet acetonitrile, or wet acetone:

$$2(NEt_4)_2[Ni_3(SEt)_8] \xrightarrow{(H^+)} [Ni(SEt)_2]_6 + 4(NEt_4)(EtS) \quad (1)$$

It should be added that the isolation of the crystalline hexamer from a chloroform solution was impossible, probably due to contamination by other oligomeric species.

Discussion

The synthesis of $[Ni(SEt)_2]_6$ was first achieved by the reaction of bis(alkylthio)dialkyltin with nickel chloride in cold ethanol.[2a] The hexamer was also synthesized from tetracarbonylnickel and dialkyldisulfides in benzene by the same authors.[2c] A simple synthesis of this compound from commercial nickel salts and ethanethiol in protic media has not yet been published. The condition of such synthesis in aprotic media (chloroform, acetonitrile) is, as has been studied in this work, not straightforward; it is suggestive of the necessity of mild protic conditions. The mixing of an excess amount of water promotes the formation of uncharacterizable polymer. However, as for the other thiols, the aspect is not so tedious. In practice, $[Ni(SCH_2CH_2OH)_2]_6$, and $[Ni(SCH_2CH_2COOEt)_2]_8$, are readily prepared from simple nickel salts and the corresponding thiols in an alkaline aqueous solution[4]

and 1-propanol[7] respectively. Dance and his coworkers referred briefly to an aqueous system in relation to the chain elongation of multinuclear Ni-SR.[7] According to them, in $Ni^{2+}/^{-}SCH(CH_3)CH_2OH$ in water, $[Ni(SR)_2]_6$ predominates at 25 °C, but a series of open chain complexes, $Ni[Ni(SR)_2]_n$ ($n<30$), appear at 75 °C in an appropriate pH region. This is a result which somewhat agrees with those of our study, suggesting the participation of H^+ in chain elongation. The cyclization process might be promoted by the presence of an oxygen atom. The structure of the upper tiara, $[Ni(SCH_2CH_2COOEt)_2]_8$, in the solid state would remain the actual field where the tiara is cyclized from its open-chain precursor by anchoring to an oxygen atom and is then stabilized.

To account for the appearance of geminal EtS- signals in ^1H and ^{13}C NMR experiments, two mechanisms can be proposed: 1) the ring-current mechanism and 2) the $d\pi(Ni)$-$d\pi(S)$ interaction mechanism. The most important orbitals in the ring-current mechanism are those composed of d_z2 orbitals on Ni atoms. If we assume ca. 2 Å as the radius and six electrons for this ring orbital, the shifts calculated for the equatorial and axial methylene protons are −0.27 and +0.26 ppm respectively at the position of the methylene protons.[20] This result agrees well with the experimental result obtained by ^1H NMR, but not with the ^{13}C measurement, which afforded about 10 times as large. Consequently, it is necessary to assume for any of axial or equatorial EtS^- a $d\pi(Ni)$-$d\pi(S)$ overlap, which promotes the magnetic shielding at the ethyl groups. However, it is impossible to decide which is the low field case, axial or equatorial.

The "tiara" structure is attractive from the point of view of developing a new type of inclusion catalyst. The quasireversible oxidation of the hexamer suggests the potentiality of "tiara" compounds for inclusive oxidation catalysts.

The present work was partially supported by a Grant-in-Aid for Scientific Research (No. 62540475) from the Ministry of Education, Science and Culture. The author gratefully acknowledges to the kind support of Professor Yukiyoshi Sasaki of Tokyo University, and wishes also to thank Dr. Toshio Kamata of the National Chemical Laboratory for Industry for the measurement of the molecular weight of $[Ni(SEt)_2]_6$.

12) Thiolate anions are intrinsically weak ligands ranked between chloride and azide, with an usual nephelausetic effect as is manifested for the Co^{2+} and Fe^{2+} complexes.[13,14] This fact, however, does not lead to the expectation that the local geometry of $Ni(SR)_4$ is limited to Td, because LMCT is also dominant in stabilizing the "tiara" framework as well as the ligand-field stabilization. The A_{2u} array of the Ni($3d_{xz}$, $3d_{yz}$)-S(2p) orbitals in the D_{3d} symmetry is the most plausible for such stabilization. Thus, the d-d transitions of $[Ni(SEt)_2]_6$ may be said to be characterized by a square planar local symmetry perturbed with the exchange interaction due to the thiolato bridging. At any rate, an assignment based on a simple crystal field calculation is not neccesarily reliable in a square planar case because it fails to estimate the π-bonding effect.[16]

(Received January 11, 1988)

Changes in electrical conductivity and the amount of adsorbed oxygen in porous ZnO were measured simultaneously in the temperature range of 200—600 °C. The saturated amount of adsorbed oxygen increased initially, went through a maximum at 500 °C, and then decreased with increasing temperature. The conductivity decreased exponentially with increase in the amount of adsorbed oxygen, which indicates that the energy barrier formed due to the chemisorbed oxygen controls the total conductivity. In a high temperature region, not only the chemisorbed oxygen, but also the oxygen diffused into the grain boundaries played important roles in changing the electrical conductivity. The diffused oxygen was examined by means of a depth profile of tracer ^{18}O measured by SIMS. The formation of the energy barrier at the grain boundary was confirmed by current-voltage characteristic measurements.

Zinc oxide is an n-type semiconductor with extrinsic defects, $V_O^{\cdot}$, $V_O^{\cdot\cdot}$, $Zn_i^{\cdot}$ and/or $Zn_i^{\cdot\cdot}$.[1-4] Based on the non-stoichiometry of ZnO, the logarithm of the electrical conductivity of pure ZnO is linear with respect to that of the oxygen partial pressure with a slope of $-1/4$ or $-1/6$ depending on the ionization state of donor defects. The rate of change in electrical conductivity is determined by slow diffusion of ionic species, and so the change is too slow to be observed at low temperatures in ZnO single crystal or polycrystals with high density.

On the other hand, the change in electrical conductivity of porous ZnO is rapid and large at low temperatures (<600 °C). It is well known that the electrical conductivity of the porous ZnO depends strongly on the amount and nature of the chemisorbed oxygen.[5-10] Negatively charged chemisorbed oxygen is attained by trapping conduction electrons from the bulk of ZnO. Then, the carrier concentration decreases and the electron depletion layer to compensate the negative charge on the surface is generated, simultaneously. This depletion layer acts as the conduction barrier. In a polycrystalline sample with high density or in a single crystal, the thickness of such a layer is thin enough and its effect as the barrier can be neglected. However, considering porous ZnO in which the average neck radius to connect the grains with each other is supposed to be very small, the thickness of a depletion layer could not be neglected as shown in Fig. 1.[6] Therefore, the electrical conductivity of a porous ZnO is affected not only by the additives but also by the microstructure associated with its processing. Various electrical conductivities for porous ZnO have been reported by many researchers.[7,11-14] The decrease in the electrical conductivity caused by chemisorbed oxygen has been explained either by carrier concentration decrease due to electron trapping by chemisorbed oxygen or by surface energy barrier formation.

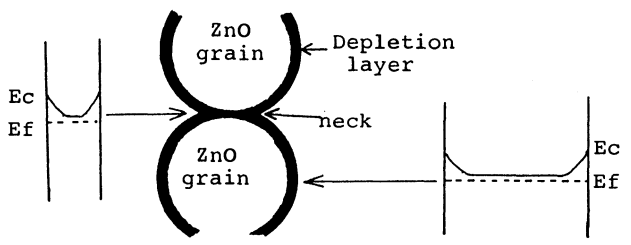

Fig. 1. Cross section of a connecting neck in a porous ZnO and energy band.

In this study, to determine the dominant mechanism for the electrical conductivity change of porous ZnO, the electrical conductivity of porous ZnO was measured as a function of the amount of adsorbed oxygen. The effect of oxygen diffused into grain boundaries was also examined by means of the depth profile of tracer (^{18}O) and the current-voltage characteristic measurements.

Experimental

(1) Sample Preparation. Nominally pure ZnO powder (99.99%, from Kojundo Chemical Lab. Co., Ltd.) was dispersed in an aqueous solution of $Al(NO_3)_3$ (99.9%, from Kanto Chemical Co., Ltd.) and dried. The resulting powder containing 0.5 mol% Al_2O_3 was calcined at 600 °C to decompose nitrate into oxide. The powder was shaped into a rectangular bar (5 by 5 by 15 mm) in a steel die (under 100 MPa pressure) and sintered at 900 °C for 1 min (S-1) or 800 °C for 1 h (S-2) in air. Aluminum oxide addition was to maintain the ZnO body porous. Of course, a trace amount of Al_2O_3 must have dissolved into the bulk ZnO promoting donor genera-

tion. To obtain a dense sample (S-3), the pressed powder was also sintered at 1300 °C for 4 h in air. The samples with the surface area of 2.1 $m^2 g^{-1}$ and 50% relative density (S-1), 3.2 $m^2 g^{-1}$ and 50% (S-2) and 95% (S-3), respectively, were obtained. SEM observation showed partial progress of sintering having occurred in the surface area of S-1 body.

(2) Electrical Conductivity and Adsorption of Oxygen. Surface area of the sample was determined by BET method at 77 K. The sample (S-1 or S-2) was enclosed in the holder illustrated in Fig. 2(b). The electrical conductivity was measured by a dc four probe method.

As the starting condition, the sample was heated at 600 °C in vacuum (10^{-4} Pa) until the conductivity reached 0.04 to 0.05 $S m^{-1}$ (about 20—25 h). At prescribed temperatures, oxygen was introduced into the holder, and the changes in the pressure and the electrical conductivity were measured simultaneously for 1 h. Change in the pressure by adsorption of oxygen was measured by using a fine vacuum gauge (BARATORON 222BA-0010 from MKS Co. Ltd.).

(3) The *I–V* Characteristic. After evacuation by the same method mentioned in (2), oxygen gas (400 Pa) was introduced into the sample holder at a fixed temperature, and after a prescribed oxidizing time the sample was quenched in liquid nitrogen. The relation between applied voltage and current was measured by a curve tracer (No. 5802 Kikusui Electronics Corp.) at room temperature.

(4) Depth Profile of Tracer ^{18}O. The enclosed sample (S-3) whose surface had been polished by diamond paste was heated at 600 °C in vacuum for 3 h, and ^{18}O (50 vol%) enriched oxygen was introduced into the sample holder at prescribed temperatures and annealed for 3 h. After annealing, the holder was quenched in liquid nitrogen.

The depth profile of tracer ^{18}O was measured by SIMS (Hitachi IMA-2A) under the so-called static SIMS condition; primary ion $^{40}Ar^+$, primary ion energy 1 keV, primary ion current 10^{-10} A, probe size 1 mm, secondary ion accelerating voltage 3 kV and residual gas pressure $<10^{-5}$ Pa.

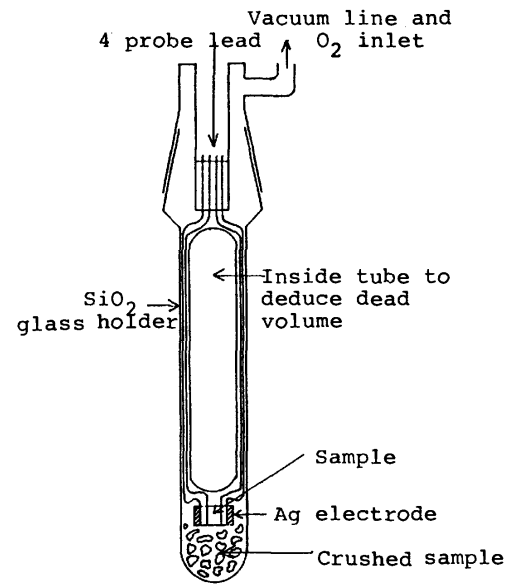

Fig. 2. Sample holder to measure the amount of adsorbed oxygen and the electrical conductivity, simultaneously.

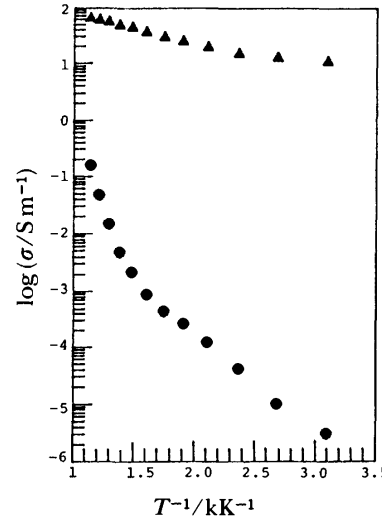

Fig. 3. Temperature dependences for a porous ZnO(S-2) in air (●) and under vacuum (▲). The electrical conductivity was measured on cooling process.

Results and Discussion

(1) Effect of Oxygen on the Electrical Conductivity of Porous ZnO. Figure 3 shows the temperature dependencies of electrical conductivity for S-2 in vacuum and in air. After annealing at 600 °C for 20 h in the respective atmosphere, the electrical conductivity was measured in the cooling process. Though the temperature dependence of electrical conductivity in vacuum was very small with an activation energy of 0.07 eV, that in air was large with an activation energy to be 2 to 3 eV.

The resulting adsorption isotherms coincided with the Langmuir type[15] in the whole temperature range from 200 to 600 °C in both samples. The saturated amount of adsorbed oxygen increased initially, went through a maximum at 500 °C and then decreased with increasing temperature in S-2. This pattern was similar to that measured by TDS (thermal desorption spectroscopy) in which the kind of chemisorbed oxygen was assumed as O^{2-},[8] while the saturated amount of adsorption decreased by repetition of the adsorption and desorption of oxygen and this effect was remarkable in S-1. This effect was explained in the following manner:[5] If high oxygen pressure causes some adsorption during sintering at high pretreatment temperature, the coulombic attraction between the adsorbed oxygen and the positively ionized defects§ may draw such defects toward the surface. Conversely, if the oxygen has been desorbed at high temperature, the adsorption centers, the defects, may diffuse away from the surface, and the number of sites for the low temperature adsorption would decrease slowly with

§ In this system, zinc atoms at interstitial sites, oxygen vacancies and substituted Al are the candidates for these defects.

time. Though the saturated amount of adsorption slightly depended on the order of measurement, the tendency of the temperature dependence of the saturated amount for S-1 with a low surface area corresponded to that measured by TDS.

Electrical conductivity decreased with increase in the amount of adsorbed oxygen in the whole temperature range as shown in Fig. 4. If the decrease in electrical conductivity resulted from the decrease in the total carrier concentration, the conductivity should have decreased linearly with increase in the amount of adsorbed oxygen which behaves as the electron trap. So, this model could not account for the change in the conductivity.

The effect of oxidation and reduction in the bulk should be also considered. The dependence of electrical conductivity on oxygen partial pressure was larger than expected from the change in nonstoichiometric composition by atmosphere. And the conductivity did not change above the pressure to attain saturation of adsorption which is approximately 1000 Pa at 600 °C. From these experimental results it is judged that oxidation and reduction in the bulk would have a the minor effect on changing the electrical conductivity in the present temperature and pressure regions.

The assumption that the energy barrier whose height increases with increase in the amount of adsorbed oxygen controls the total conductivity, could explain this result. Considering that the carrier mobility is constant throughout the sample, the electrical conductivity of a semiconductive material depends on the energy difference between the bottom of the conduction band (E_c) and the Fermi level (E_f) as $\sigma \propto \exp(-(E_c-E_f)/kT)$. The difference ($E_c-E_f$) is very small, about several hundredths of an electron volt as appeared in the temperature dependence measured in vacuum (Fig. 3). The presence of energy barrier makes this energy difference to be large as shown in Fig. 1. If

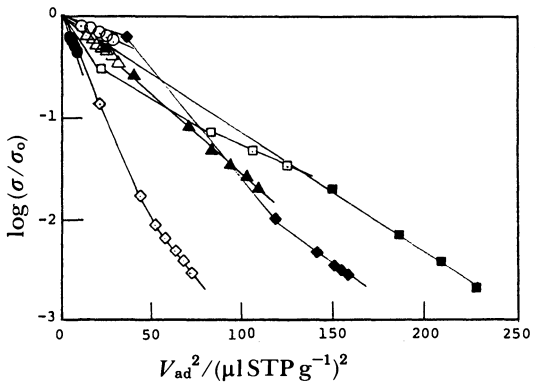

Fig. 4. The change of electrical conductivity against the amount of adsorbed oxygen: $\log(\sigma/\sigma_o)-V_{ad}^2$ where σ_o is the electrical conductivity in vacuum. Sample S-1; ●: 300°C, ▲: 400°C, ■: 500°C, ◆: 600°C. Sample S-2; ○: 300°C, △: 400°C, □: 500°C, ◇: 600°C.

the chemisorbed oxygen makes an acceptor type trap level on the surface of ZnO, the resulting energy barrier to compensate the excess charge is generated. The height of such a surface energy barrier (ϕ_s) is estimated as[5,16]

$$\phi_s = \frac{2eN_{ss}^2}{\varepsilon\varepsilon_o N_d} \quad (1)$$

where N_{ss} the trap state density which is proportional to the amount of adsorbed oxygen, N_d the donor density and the other symbols have their usual meanings. When N_{ss} is large, the change in the height, $\Delta\phi_s$, is approximated to be proportional to the change in N_{ss}. The effective thickness of such a barrier is so small that this effect is negligible in single crystal or polycrystal with high density. While this barrier plays an important role to decrease the conductivity in the case of porous body where a narrow neck connects the grains with each other. When this barrier is formed into an interior of the narrow neck region, the total conductivity should be controlled by such necks as $\sigma \propto \exp(-(E_{cv}-E_f+\phi)/kT)$ where E_{cv} is the bottom of the conduction band in vacuum and ϕ is the effective barrier height. Though the height of energy barrier at the surface is estimated by Eq. 1., the effective height is determined by the lowest energy barrier at the center of the cross section of the neck.

If the conductivity measured in this experiment was controlled by the mechanism discussed above, $\log(\sigma/\sigma_o)$ in Fig. 4 equals to ϕ/kT and the decrease in conductivity by two orders of magnitude corresponds to the generation of the energy barrier with an effective height to be 0.3 eV at 500 °C. The ϕ/kT increased linearly with increase in the amount of adsorbed oxygen at 600 °C or its square at 300—500 °C. This dependence agrees with the rule of generation of the surface energy barrier by the surface state of acceptor type. The effective height of the energy barrier might reflect the height of the surface energy barrier. The right end plot of each measurement almost agreed with the saturation of the change in the electrical conductivity and the adsorption of oxygen. Though the change in electrical conductivity depended on the amount of adsorbed oxygen in S-2 with a large surface area, that in S-1 with a smaller surface area showed a larger change in electrical conductivity at 600 °C where the amount of adsorption is smaller than at 500 °C. It is peculiar that a similar change in the electrical conductivity was observed in S-1 and S-2 at 600 °C. These results suggest that another mechanism is operative to change the electrical conductivity. When the surface energy barrier controls the total conductivity, the grains should be connected with each other by a small neck with the width to be comparable to the thickness of the depletion layer. The thickness of this layer is approximately by the Debye length.[7] The samples of this experiment contain Al_2O_3 as a promoter of donor

generation. Though the exact solubility limit of Al_2O_3 into ZnO has not been determined, the thickness is estimated to be below 10 nm by the assumption that 100 ppm of Al_2O_3 could dissolve into ZnO.

Because of the complicated microstructure, the precise neck radius could not be determined. Two kinds of samples, S-1 and S-2, have almost the same relative density of 50% and the average grain size of 0.5 μm. From the viewpoint of surface area, it is supposed that the neck radius of S-2 might be larger than that of S-1. Since the current flows through the wide neck which is difficult to form the barrier in its interior, the effective neck radius might have been enhanced by the partial progress of sintering in S-1. Considering that the neck radius of S-1 is larger than the thickness of the surface energy barrier, the smaller change in the electrical conductivity in S-1 by the oxygen chemisorption could be explained, i.e., the formation of the energy barrier is imperfect in S-1.

On the other hand, the anomalous change in the conductivity at 600 °C has not been clarified yet. Recognizing the neck as the grain boundary and assuming that the selective oxidation of the grain boundary by the rapid oxygen diffusion into such an area occurs, the energy barrier should be generated at the grain boundary and considerably change the electrical conductivity even in a sample with wide neck. Though the definite model to explain the formation of the barrier by the selective oxidation of the grain boundary could not be determined by this experiment, two models have been proposed for ZnO varistor: one is the formation of stoichiometric ZnO near the grain boundary regions,[17] and the other is the generation of acceptor states due to oxygen chemisorption along the grain boundaries.[18]

(2) The Energy Barrier along the Grain Boundary. If the energy barrier along the grain boundary is formed in ZnO, the non-ohmic behavior of resistivity should be observed like a varistor.[19,20] As reported in our previous paper, the non-ohmic property was observed in the porous ZnO.[21] From the proposed tunnel theory,[20] the non-ohmic coefficient, α, in the expression $I=(V/C)^{\alpha}$, where I is the current, V the applied voltage and C a constant, can be written as

$$\alpha = \frac{4}{3}(m\varepsilon_s)^{1/2}\frac{V}{hN_d^{1/2}(1+V/\phi)^{3/2}} \qquad (2)$$

where ϕ is the barrier height, N_d the donor density, V the applied voltage, and the other symbols have their usual meanings. Though it is not yet recognized which mechanism controls the non-ohmic characteristic in this experiment, the higher the barrier is, the larger α becomes in any model if the donor density is constant. As shown in Fig. 5,[18] the non-ohmic coefficient, α, increased with an increase in the oxidizing period, and α larger at 600 °C where the oxygen diffusion might be effective to generate the energy barrier than at 500 °C where the amount of adsorption was larger than that at 600 °C in S-1, while in the case of S-2 the maximum non-ohmic coefficient, α, was attained by the oxidation within several minutes. Therefore, the high energy barrier along the grain boundary is also formed by oxygen diffusion at 600 °C in even a wide neck. The deterioration of the characteristic for the sample oxidized for 24 h is explained by the diffusion into the bulk; i.e., the difference in chemical potential between the bulk and grain boundary might decrease.

(3) Oxygen on the Surface and in the Bulk. In the previous sections, the phenomena which could not be explained by the adsorption of oxygen were discussed on the assumption that the energy barrier along the grain boundary was formed by the rapid diffusion of oxygen into the grain boundary. To confirm the

The values were normalized under the condition as $V/V_{500°C}$. ●: from Langmuir's method ($V_a/V_{a500°C}$), ▲: Surface concentration ($V_s/V_{s500°C}$), ◇: Integrated concentration ($V_i/V_{i500°C}$).

validity of this assumption, the oxygen diffusion into the grain boundary should be examined.

The depth profiles of tracer ^{18}O in ZnO annealed at prescribed temperatures are shown in Fig. 6. In all measurements, the strengths of the primary beam of SIMS were weak and constant. Figure 6 shows the atomic fraction of ^{18}O against the measuring period. The measured fraction at the beginning might be strongly affected by the chemisorbed oxygen and that after long measuring period might indicate the effect of the penetration of oxygen into the interior of the sample. Though this time corresponds to the depth of etched crater, the depth was too small to be measured precisely. Hence, the correct diffusion coefficient could be not estimated.

In the temperature region 200—500 °C, the concentration of tracer increased with increasing temperature. At 600 °C, the concentration of tracer at the surface was smaller than that at 500 °C, but on the other hand, that in the interior was larger than that at 500 °C. The saturated amount of adsorption measured by Langmuir's method (V_a) for S-1, the tracer concentration at the surface (V_s) and the integrated concentration calculated from Fig. 6 in the time range 0 to 3 h (V_i) are shown in Fig. 7. Each plot was normalized to the values obtained at 500 °C as $V/V_{500°C}$. Though the temperature dependencies of V_a and V_s were similar in the whole temperature range, the V_i at 600 °C was larger than that at 500 °C. From Fig. 7, V_s reflects the amount of adsorbed oxygen. The integrated value (V_i) involved not only the enrichment of the tracer at the surface but also that in the interior.

The observation of the enrichment of the tracer in the interior of the sample indicated that the diffusion of oxygen effectively occurred at 600 °C. It is well known that the oxygen diffusion is accelerated along grain boundaries. The oxygen transport by diffusion is higher at higher temperatures and the difference in the diffusion rate between the grain and grain boundary is large at low temperatures due to the difference in its activation energy. The rapid diffusion along the grain boundary was observed even at 1000 °C.[22,23] Therefore, it would be reasonable to consider that the grain boundary is oxidized selectively at 600 °C by the rapid grain boundary diffusion, and this area might become the energy barrier for electron transport.

The authors wish to thank Dr.Shunichi Hishita of National Institute for Research in Inorganic Materials for analysis of the depth profile by using SIMS and helpful discussion. They also wish to thank Mr. Shigeru Ando of Ando Glass Blowing Technology Ltd. for his excellent technique for glass blowing. This work was partially supported by a Grant-in-Aid for Scientific Research from the Japanese Ministry of Education, Science and Culture (No. 60550543).

(Received July 30, 1987)

The cyanation of chlorobenzene catalyzed by $Ni(PPh_3)_n$, which was generated in situ from $NiBr_2(PPh_3)_2$-Zn-PPh_3(Ni : Zn : P=1 : 3 : 2 molar ratio), was at first examined with various MCN (M=K, Na)-solvent systems by three procedures in order to clarify the conditions under which the reaction occurs. The effects of the systems and the procedures on the reaction were remarkable. It was observed that the cyanide ion has an inhibitory action on both the reduction of Ni(II) and the oxidative addition of the halide to Ni(0). However, when such MCN-dipolar aprotic solvent systems as KCN-HMPA, KCN or NaCN-MeCN, which give low cyanide concentrations, were used, the reaction readily took place at 50—60 °C without reducing Ni(II) prior to the addition of MCN and adding MCN slowly. Various Y-substituted chlorobenzenes, except for those with Y=*o*-Cl, *o*-CN, and *m*-NO_2, were cyanated to give the corresponding nitriles in fair to good yields. $NiBr_2$-PPh_3 can be used in place of $NiBr_2(PPh_3)_2$ if MCN is added after reduction. In addition, less reactive halides, such as *o*-dichlorobenzene and *o*-chlorobenzonitrile, were fairly smoothly cyanated by the use of $NiBr_2$-1,1′-bis(diphenylphosphino)-ferrocene.

It was first reported by the present authors[1] and by Cassar[2] that non-activated aryl halides can react with the cyanide ion under moderate conditions in the presence of Pd and Ni catalysts to afford the corresponding nitriles. Pd(II) salts,[3,4] $Pd(PPh_3)_4$,[5] $Ni(PPh_3)_3$ (isolated or generated in situ from $NiCl_2(PPh_3)_2$-Mn·Fe alloy-PPh_3),[6,7] and $NiClAr(PPh_3)_2$[6] are known to be homogeneous transition metal catalysts for the cyanation. Recently, $K_3[Co(CN)_4]$, which is formed in situ from $CoCl_2$-KCN-KOH(aq)-H_2 has also been found to be effective.[8]

Previously, the present authors pointed out that the Pd(II)-catalyzed cyanation proceeds smoothly when KCN-HMPA is used as the MCN(M=K, Na)-solvent system, but fails to proceed in the NaCN-HMPA system, in which cyanide is more soluble.[3] This suggests that the cyanide ion itself has also an inhibitory action on the catalytic reaction. Hence, the selection of MCN-solvent systems is important for keeping the catalyst active. In the case of the nickel catalysts, however, little has been reported about the utility of dipolar aprotic solvents and the selection of MCN-solvent systems. Cassar et al. mainly used the NaCN-EtOH[2,6] and MCN-benzene-crown ether systems.[7] Concerning the use of dipolar aprotic solvents, it has been reported by them that, in DMF, the Ni(0)-catalyzed cyanation occurs only if NaCN is added slowly.[6]

In this paper, we investigate, under various conditions, the cyanation of aromatic halides catalyzed by Ni(0) phosphine complexes, which were generated in situ from the $NiBr_2(PPh_3)_2$-Zn-PPh_3 and $NiBr_2$-Zn-phosphorus ligand, and define the scope and limitations of the reaction more clearly.

Experimental

Materials. All the solvents were purified by the ordinary methods. The KCN (Merck), NaCN, zinc powder, triphenylphosphine, anhydrous $NiBr_2$ (Nakarai), 1,2-bis(diphenylphosphino)ethane, and 1,1′-bis(diphenylphosphino)ferrocene(Strem) were commercially available. All the aromatic halides were commercially available and were used without further purification. The tri-*o*-tolylphosphine,[9] dibromobis(triphenylphosphine)nickel,[10] and dicyanobis(triphenylphosphine)nickel[11] were prepared according to the literature methods.

Procedures. Four procedures were examined and compared. A typical example of each is described below.

Procedure A: A 30-ml flask was charged with $NiBr_2(PPh_3)_2$ (740 mg, 1.0 mmol), Zn powder (200 mg, 3.0 mmol), PPh_3 (520 mg, 2.0 mmol), and KCN (2.15 g, 33 mmol). This mixture was degassed by evacuation and flushed with nitrogen, and a solution of chlorobenzene (3.38 g, 30 mmol) and naphthalene (about 0.2 g, internal standard) in HMPA (8 ml) was added by the use of a syringe. The mixture was then heated at 60 °C for 6 h with vigorous stirring and, after cooling, shaken with aq NaCl-CH_2Cl_2. The organic layer was subjected to GC analysis.

Procedure B: The catalyst components, $NiBr_2(PPh_3)_2$, Zn, and PPh_3 (1 : 3 : 2 molar ratio), were placed in a flask whose side arm was connected, by means of a ground-glass joint, to a KCN container. After replcing the air with nitrogen, HMPA was added by the use of a syringe. The mixture was heated at 60 °C for 30 min with stirring, and then chlorobenzene was added. After continued heating for 30 min, KCN was added from the KCN container, and the reaction mixture was further heated at 60 °C for 6 h.

Procedure C: This procedure was the same as Procedure B except that the order of the addition of chlorobenzene and KCN was reversed.

Procedure D: Anhydrous $NiBr_2$, Zn powder, and phosphorus ligand (1 : 3 : 4 molar ratio; 1 : 3 : 2 for the bidentate ligand) were placed in a flask fitted with a KCN container. After replacing the air with nitrogen, HMPA was added by the use of a syringe. The mixture was heated at 60 °C for 1 h with stirring, and then KCN was added from the KCN container, followed by the addition of chlorobenzene without

delay. The reaction mixture was subsequently further heated at 60 °C for 6 h.

Analysis. The gas-chromatographic analyses were made by the use of a Shimadzu-GC-7A apparatus with He carrier gas, using a 3-m PEG-20M column for the analysis of the *p*-bromo-*N*,*N*-dimethylaniline, *m*-chlorofluorobenzene, methyl *p*-chlorobenzoate, *p*-chloroacetophenone, and 3-bromopyridine and a 3-m EGS column for the analysis of the other halides. The products were identified by comparison with authentic samples, and the yields were determined by using internal standards.

Preparation of Nitriles. Three isolated examples will be described here for illustration.

Benzonitrile: Chlorobenzene (3.38 g, 30 mmol) was cyanated by Procedure A described above. The resulting mixture was poured into water (20 ml), which was then extracted twice with ether (20 ml). The combined extracts were washed with water (10 ml), dried (Na_2SO_4), and concentrated. The residue was distilled to give 2.39 g (77%) of benzonitrile: bp 81—83 °C (20 mmHg (1 mmHg=133.322 Pa)); n_D^{20} 1.5279.

Methyl *p*-Cyanobenzoate: A mixture of methyl *p*-chlorobenzoate (5.12 g, 30 mmol), KCN (2.15 g, 33 mmol), $NiBr_2(PPh_3)_2$ (740 mg, 1.0 mmol), Zn powder (200 mg, 3.0 mmol), PPh_3 (520 mg, 2.0 mmol), and acetonitrile (12 ml) was kept at 50 °C for 6 h while being stirred under nitrogen (Procedure A). The resulting mixture was chromatographed on a silica-gel column, using hexane-ethyl acetate (29/1) as the eluent, to give 3.87 g (80%) of methyl *p*-cyanobenzoate: mp 66—67 °C; ^{1}H NMR ($CDCl_3$) δ=4.0 (3H, s), 7.7 (2H, d, J=8.8 Hz), and 8.1 (2H, d, J=8.8 Hz).

***p*-Acetylbenzonitrile:** *p*-Chloroacetophenone (4.64 g, 30 mmol) was cyanated in the same manner as methyl *p*-chlorobenzoate. The resulting mixture was chromatographed on a silica-gel column, using hexane-ethyl acetate (9/1) as the eluent, to give 3.58 g (82%) of *p*-acetylbenzonitrile: mp 57—58 °C; ^{1}H NMR ($CDCl_3$) δ=2.6 (3H, s), 7.7 (2H, d, J=8.7 Hz), and 8.1 (2H, d, J=8.7 Hz).

Solubilities of KCN and NaCN. Saturated solutions were generated by stirring the respective solvents (30 ml) with a large excess of cyanide at 60±1 °C under a nitrogen atmosphere. One-milliliter aliquots were withdrawn at intervals for analysis until it was evident that equilibrium had been attained. Samples were diluted to 100 ml with 0.1 mol l^{-1} NaOH and analyzed for the cyanide ion using a cyanide ion electrode-F-7 pH meter (Horiba).

Results and Discussion

In the Ni(0)-catalyzed cyanation of aromatic halides, the use of $Ni(PPh_3)_3$ generated in situ as a catalyst is convenient and practical because $Ni(PPh_3)_n$(n=3 or 4) and $NiXAr(PPh_3)_2$ are troublesome to prepare and handle. Thus, as the first attempt, the cyanation of bromobenzene with KCN-DMF as the MCN-solvent system was examined according to Procedure A, using four kinds of metals (powder) as reducing agents of Ni(II) (Table 1). The cyanation proceeded catalytically together with the coupling reaction. It is noteworthy that the catalytic cyanation occurred by only heating the reaction mixture, without reducing Ni(II) previously and adding KCN slowly. When NaCN-DMF was used instead of KCN-DMF, however, the reaction did not occur. Of the four metals, Zn was found to be most favorable. In what follows, $NiBr_2(PPh_3)_2$-Zn-PPh_3 (Ni : Zn : P=1 : 3 : 2 molar ratio) and $NiBr_2$-Zn-phosphorus ligand (Ni : Zn : P=1 : 3 : 4; 1 : 3 : 2 for bidentate ligand) will be used as the catalyst

Table 1. Catalytic Activity of $NiBr_2(PPh_3)_2$-Metal-PPh_3 for the Cyanation of Bromobenzene with KCN[a]

systems to generate Ni(0) phosphine complexes in situ.

Comparison of MCN-Solvent Systems and Reaction Procedures. The cyanation of chlorobenzene catalyzed by $Ni(PPh_3)_3$, which was generated in situ from $NiBr_2(PPh_3)_2$-Zn-PPh_3, was examined with various MCN(M=K, Na)-solvent systems by means of three procedures: A(catalyst-reactant mixing without pretreatment), B(catalyst reduction-halide addition-cyanide addition), and C(catalyst reduction-cyanide addition-halide addition) (see Experimental section for further details). The results are shown, together with the solubilities of MCN, in Table 2. The effect of MCN-solvent systems is remarkable and appears to be closely related to the solubilities of MCN.

With Procedure A, which is the most convenient of the three procedures, the cyanation proceeded smoothly by the use of certain MCN-dipolar aprotic solvent systems with lower cyanide solubilities than about 15 mmol l^{-1}. Of the systems tested, the KCN-HMPA and KCN-MeCN systems gave especially good results: benzonitrile was obtained in high selectivities (92—95%) at high conversions (99%), together with biphenyl in very low selectivities (2—6%). The KCN-TMU and NaCN-MeCN systems also gave good results. With the KCN-DMF and KCN-THF systems, biphenyl was produced in somewhat high selectivities compared with the above four systems. On the other hand, the KCN-EtOH system (solubility, 51.8 mmol l^{-1}) was not especially useful, though it caused the cyanation to

proceed, in contrast with the NaCN-EtOH system (solubility, 227 mmol l^{-1}).

With Procedure B, the catalytic cyanation proceeded even when the NaCN-EtOH (solubility, 227 mmol l^{-1}) and NaCN-HMPA (solubility, 461 mmol l^{-1}) systems were used, giving high cyanide concentrations. The KCN-HMPA and NaCN-HMPA systems gave particularly good results (95—100% conversions, 88% selectivity), near to those obtained using the KCN-HMPA and KCN-MeCN systems by Procedure A. However, the MeCN solvent gave less favorable results than did HMPA: in both KCN-MeCN and NaCN-MeCN systems, the reaction stopped at a conversion of about 20%, and the formation of biphenyl, accompanied by the oxidation of Ni(0) to Ni(II), was remarkable (35—37% selectivities). With the MCN-EtOH systems, the reproducibility of the results was fairly poor, especially with the NaCN-EtOH system, and good results were not obtained.[12]

With Procedure C, it was found that the inhibitory effect of the cyanide ion was remarkable and that the cyanation was accomplished by the use of MCN-dipolar aprotic solvent systems with cyanide solubilities lower than about 15 mmol l^{-1}. With the MCN-MeCN

systems, Procedure C gave better results than did Procedure B. In the NaCN-DMF system (solubility, 127 mmol l^{-1}), the cyanation was also attempted by adding chlorobenzene 5 min after the addition of NaCN, but the reaction was not initiated, such as when it was added 30 min later. This suggests that the cyanide ion coordinates to $Ni(PPh_3)_3$ rapidly under the conditions used (vide infra).

Distinct differences in the occurrence and progress of the cyanation between these three procedures, A—C, were thus observed. Here, the inhibition by the cyanide ion for the catalytic cyanation will be discussed mainly. With Procedure A, the reduction of $NiBr_2(PPh_3)_2$ by Zn powder appears to compete with the replacement of its bromine atom by a cyano group (Scheme 1). With good systems such as KCN-HMPA and KCN-MeCN, the solution turned reddish from green at an initial stage of the reaction to reveal the formation of $Ni(PPh_3)_3$ by reduction, while with poor systems, such as KCN-DMSO and NaCN-DMF, the solution turned pale yellow, suggesting that no reducible cyanonickel(II) complexes, $NiBr_{2-m}(CN)_m(PPh_3)_2$, were formed. In fact, the cyanation did not occur when $Ni(CN)_2(PPh_3)_2$(yellow) was used instead of $NiBr_2(PPh_3)_2$ in Procedure A. It was observed, however, that the dicyanonickel(II) complex served as a cyanation reagent instead of MCN in the Ni(0)-catalyzed cyanation.[13] Accordingly, even if $NiBr_{2-m}(CN)_m(PPh_3)_2$ is formed in part, it is advantageously converted into reducible $NiBr_{2-m}Cl_m(PPh_3)_2$ when the cyanation of chlorobenzene proceeds.

The results obtained by Procedure C, in which MCN is introduced prior to chlorobenzene, suggest that the cyanide ion also inhibits the oxidative addition of chlorobenzene to $Ni(PPh_3)_3$. Probably, a cyanide ion would coordinate to $Ni(PPh_3)_3$ to form $[Ni(CN)(PPh_3)_3]^-$,[14] for which it is difficult to undergo the oxidative addition of chlorobenzene. Therefore, the systems with low solubilities of MCN may be required also for the cyanation by Procedure C. On the other hand, Procedure B, in which chlorobenzene is introduced prior to MCN, made the cyanation possible even in the systems with relatively high solubilities of MCN, in contrast to Procedure C. This implies that the cyanation is smoothly initiated by a rapid reaction of CN^- with $NiClPh(PPh_3)_2$, which is formed prior to the addition of MCN, and that the concentration of the cyanide ion stays low, thus suppressing the formation of inactive $[Ni(CN)(PPh_3)_3]^-$ as a catalyst and permitting the catalytic cycle.

Biphenyl, the main by-product, is formed by the Ni(0)-catalyzed coupling of aryl halides: 2PhCl+Ni(0)→Ph-Ph+$NiCl_2$.[15] This reaction lowers the catalyst turnover of the cyanation because the Ni(0) is oxidized to ineffective Ni(II). This was remarkable in Procedure B in the MeCN solvent (vide supra).

Effect of Temperature and Time. The cyanation of PhCl by KCN was made by means of Procedure A at

a) Phosphorus ligand, DPPF=1,1′-bis(diphenylphosphino)ferrocene. b) $NiBr_2$: Zn : L=1 : 3 : 4 molar ratio for PPh_3 and 1 : 3 : 2 for DPPF; KCN/halide=1.1 molar ratio for monohalide and 2.2 for dihalide. Procedure D: Ni-Zn-L+HMPA, 60 °C-1 h, +KCN+halide, 60 °C-6 or 24 h (see Experimental section).

temperatures ranging from 40 to 80 °C in three solvents: HMPA, MeCN, and DMF. The results are shown in Table 3. In all cases, the best results were obtained at about 60 °C. It is noteworthy that the reaction always proceeded fairly smoothly, even at the low temperature of 40 °C (conversion: 81% at 6 h), in MeCN. Generally, at 80 °C the coupling reaction became much more rapid, thus deactivating the catalyst. In the case, for example, of HMPA at 80 °C, the reaction stopped at the low conversion of 35%; the solution turned from reddish brown to black (colloidal nickel), thus revealing the decomposition of the catalyst. Furthermore, the selectivity of biphenyl varied also with the reaction time(conversion), as exemplified by the results obtained with HMPA. The PhCN/Ph-Ph ratio increased with the increase in the conversion, ranging from 7.7 at 16% conversion to 48 at 99% conversion. This suggests that most of the biphenyl is fomed at an initial stage of the reaction.

Cyanation of Various Aromatic Halides. The cyanation of various aromatic halides was examined with the KCN-HMPA and KCN-MeCN systems by means of Procedure A, which is the most convenient of the three (Table 4). At first, the cyanation of chloroben-

zene and bromobenzene was attempted at a high halide/Ni ratio of 100 (KCN/Ni=110) in 20 ml of HMPA and MeCN. With the above two systems, good results were obtained even at such a high ratio, whereas with the KCN-DMF system, with a higher cyanide solubility, the cyanation was not initiated under similar conditions. Furthermore, with 20 ml of DMF, the halides were not cyanated even at a halide/Ni ratio of 30 (KCN/Ni=33), which is allowable with 8 ml of DMF.

All the Y-substituted chlorobenzenes were reactive for cyanation except those with Y=*o*-Cl, *o*-CN, and *m*-NO_2; they all gave fair to good yields, regardless of the Hammett σ values for the Y-substituents. In general, *o*-Y-substituted chlorobenzenes, especially those with Y=Cl and CN, were less reactive. However, *o*-chloroanisole and *o*-chlorotoluene were cyanated almost completely during a long reaction time. With *m*-chlorobenzylidyne trifluoride, the MeCN solvent gave a much higher selectivity than that obtained in HMPA. The former solvent was also a better one for *m*- and *p*-chlorobenzonitrile. *m*-Chlorofluorobenzene gave only *m*-fluorobenzonitrile selectively. Further, *p*-bromo-*N*,*N*-dimethylaniline and 3-bromopyridine also reacted to give fair yields of the nitriles.

Cyanation of Aromatic Halides with $NiBr_2$-Zn-Phosphorus Ligand Catalyst. The use of $NiBr_2$-PPh_3 in place of $NiBr_2(PPh_3)_2$, if it were allowable, would provide a more convenient procedure because it would then be unnecessary to prepare the nickel complex prior to the catalytic cyanation. Therefore, first the cyanation of chlorobenzene was attempted using $NiBr_2$-PPh_3 in place of $NiBr_2(PPh_3)_2$ in Procedure A (Table 5). As a result, the conversion was low (59%) compared with that with $NiBr_2(PPh_3)_2$. The good result of a 94% selectivity at a 95% conversion was, however, obtained by adopting Procedure D, in which a mixture of $NiBr_2$, Zn, and PPh_3 in HMPA was heated at 60 °C for 1 h prior to the addition of KCN and chlorobenzene.

Next, combinations of $NiBr_2$ and three phosphorus ligands (tri-*o*-tolylphosphine, 1,2-bis(diphenylphosphino)ethane, and 1,1′-bis(diphenylphosphino)ferrocene(DPPF)) were used for the cyanation of chlorobenzene and much less reactive halides, such as *o*-dichlorobenzene and *o*-chlorobenzonitrile. The former two ligands were ineffective for the cyanation of chlorobenzene. DPPF was effective, but not so good as PPh_3 (47% conversion, 72% selectivity). DPPF was, however, found to be a good ligand for *o*-dichlorobenzene and *o*-chlorobenzonitrile; the former halide gave *o*-chlorobenzonitrile and phthalonitrile in a total yield of 57% (68% conversion, 84% total selectivity), in contrast to a yield of 9% with PPh_3, while the latter halide gave phthalonitrile in the good yield of 82%. On the other hand, tri-*o*-tolylphosphine and 1,2-bis(diphenylphosphino)ethane were also ineffective for the cyanation of *o*-dichlorobenzene and *o*-chlorobenzonitrile.

The present work was partially supported by a Grant-in-Aid for Scientific Research (No. 254158) from the Ministry of Education, Science and Culture.

12) Cassar et al. have obtained good results by the use of the NaCN-EtOH system in the in-situ generated $Ni(PPh_3)_3$-catalyzed cyanation of aromatic halides (Ref. 6). However, the results we obtained following their procedure exactly were not so good as those reported by them and moreover, were poorly reproducible.

13) The reaction of PhCl (4.8 mmol) with $Ni(CN)_2(PPh_3)_2$ (2.4 mmol) for 6 h at 60 °C in HMPA (8 ml) in the presence of a nickel catalyst ($NiBr_2(PPh_3)_2$, 1 mmol; Ni : Zn : P=1 : 3 : 2) gave benzonitrile in a 78% yield.

14) The equilibrium between $Ni(PPh_3)_4$ and $Ni(PPh_3)_3$ in toluene is found to lie well to the latter side at room temperature (R. Mynott, A. Mollbach, and G. Wilke, *J. Organomet. Chem.*, **199**, 107 (1980)). Cyanonickel(0)-complex ions $[Ni(CN)_n(PPh_3)_{4-n}]^{n-}$ (n=1—4) are not obtained by the action of CN^- on $Ni(PPh_3)_4$, while it is known that $K_4[Ni(CN)_4]$ undergoes a complete triphenylphosphine displacement of cyanide to give $Ni(PPh_3)_4$ without any intermediate substitution products (H. Behrens and A. Müller, *Z. Anorg. Allg. Chem.*, **341**, 124 (1965); R. del Rosario and L. S. Stuhl, *J. Am. Chem. Soc.*, **106**, 1160 (1984)). Cassar et al. have, however, reported that the IR bands assigned to coordinate cyanide are observed when NaCN is added to a *N*,*N*-dimethylformamide solution of $Ni(PPh_3)_3$ (Ref. 6). Recently, it has been reported that a related nickel complex anion $[Ni(CN)(P(OMe)_3)_3]^-$ is formed by the reaction of (K · 18-crown-6)$_2$[$Ni(CN)_2\{\eta^2$-PhC≡CPh$\}$] with $P(OMe)_3$ (R. del Rosario and L. S. Stuhl, *Organometallics*, **5**, 1260 (1986)).

A Search for New Synthetic Routes toward Siccanin

Michiharu KATO, Yukio MATSUMURA, Kiyoshi HEIMA, and Akira YOSHIKOSHI*
Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, Sendai 980
(Received August 24, 1987)

11-Acetoxy-12bα-methoxymethyl-4,4,6aα,9-tetramethyl-1,2,3,4,4aα,5,6,6a,12aβ,12b-decahydro-12*H*-benzo[*a*]xanthene (**34**), which has been expected as a promising key intermediate for the synthesis of siccanin (**1**), was synthesized via acid-catalyzed cyclization of 1α-(2-hydroxy-6-methoxy-4-methylbenzyl)-8aα-methoxymethyl-2,5,5-trimethyl-1,4,4aα,5,6,7,8,8aα-octahydronaphthalene (**13**) and isomeric exo olefin **21**. The phenol acetate **34**, however, was so resistant to oxidation that no corresponding 12-oxo derivative, which was expected to provide 11-acetoxy-12bα-acetoxymethyl-12-oxo-4,4,6aα,9-tetramethyl-1,2,3,4,4aα,5,6,6a,12aα,12b-decahydro-12*H*-benzo[*a*]xanthene (**4**) on epimerization at its C(12a) position as well as hydrofuran ring formation at the C(12) position with its angular methoxymethyl substituent, was obtained.

Siccanin (**1**) is a mold metabolite produced by *Helminthosporium siccans*[1] and exhibits a remarkable antifungal activity against a variety of fungi. In particular, its high activity in low concentrations against *Trichophyton interdigitale* and *T. asteroids*, which cause fungal infection in skin, has been demonstrated to be clinically useful.[2]

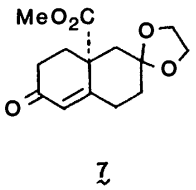
6

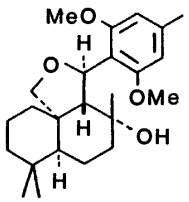
In the course of structural elucidation of **1**, Ishibashi et al.[2] have found that chromium trioxide oxidation of tetracyclic compound **2**, a derivative of **1**, gave dihydro-4*H*-1-benzopyran-4-one derivative **3** in moderate yield. They also demonstrated the cis, cisoid, cis ring system of **2** to be thermodynamically more stable than the corresponding 12aβ-H isomer as indicated by treatment of **3** with various bases giving unchanged material. Oida et al.[3] also reported that lithium aluminium hydride reduction converted tetracyclic ketone **4**, obtained on benzylic oxidation of diacetate **5**, to **1** as a result of concomitant tetrahydrofuran ring formation by internal nucleophilic displacement.

The above Sankyo group's work implies that a compound **6** epimeric with **5** at the C(12a) position would also serve as a synthetic intermediate for **1**, i.e. oxidation of **6** with chromium trioxide at its benzylic position followed by epimerization can be expected to produce **4**. Model syntheses of **1** based on the above presumption were thus reported by the Sankyo group.[3,4]

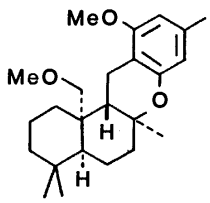
In preceding papers,[5] we reported the first total synthesis of racemic siccanin (*dl*-**1**), which was achieved from readily available octalone **7** via tetrahydrofuran derivative **8**. Our continuing effort for the synthesis of **1** was then directed to finding an alternative route based on the above presumption in combination with the olefin-phenol cyclization protocol, which seemed to be a more efficacious approach to the characteristic 1-benzopyran-4-one structure of **1** than that reported earlier.[5] We report here our findings in the investigation on this line.



7



8



9

We planned to synthesize tetracyclic compound **9**, a synthetic equivalent of the proposed compound **6**, from two olefinic phenols **13** and **21** by the olefin-phenol cyclization. For derivation to the former phenol, benzylic alcohol **10**,[5] epimeric mixture regarding the benzylic hydroxyl, was submitted to hydrogenolysis to give alcohol **11** smoothly (Scheme 1). Sub-

Scheme 2.

sequent dehydration of **11** with thionyl chloride in pyridine provided trisubstituted olefin **12** as the sole product in good yield. The phenol **13** was obtained from **12** by demethylation on heating with sodium ethanethiolate in *N,N*-dimethylformamide,[6] and its structure was confirmed by its physical data (IR and ^1H NMR) as well as regeneration of **12** on methylation with dimethyl sulfate under alkaline conditions.

Preparation of the latter phenol **21** was conducted from cis decalone **14**[5] on the application of the reported method.[4] According to our experience,[5] the C(3) position of **14** was protected to prevent preferential alkylation at this position under basic conditions (Scheme 2). Formylation of the sodium enolate of **14** with ethyl formate and subsequent thioacetalization of the resulting hydroxymethylene ketone **15** with 1,3-propanedithiol ditosylate afforded crystalline ketone **16** in 80% overall yield. The enolate anion of the product generated with methylsulfinylmethanide anion was then treated with formaldehyde at −10 °C to give exo-methylene ketone **17** in moderate yield. The ketone **17** was submitted to the Michael addition with the lithium salt of orcinol dimethyl ether[7] and gave oily diastereomeric mixture, from which single epimer **18**[8] was obtained by acid epimerization in high yield. After removal of the thioacetal group in **18** by desulfurization with Raney nickel, methylenation of the resulting ketone **19** by the Wittig reaction with methylenetriphenylphosphorane afforded exo olefin **20** in high overall yield. The desired phenol **21** was derived by demethylation of **20** with sodium ethanethiolate.[6]

Having the olefinic phenols **13** and **21** in hand, we focused our attention on their acid-catalyzed olefin-phenol cyclizations. The cyclization of **13** proceeded smoothly upon heating with *p*-toluenesulfonic acid in benzene to provide two isomeric tetracyclic compounds **9** and **22** in 51 and 16% yields, while **21** similarly produced the same products in 54 and 26% yields, respectively (Scheme 3).

As no informative data were obtained from their

^{1}H NMR spectra to distinguish between **9** and **22**, we attempted to define their structures by derivation of the authentic compound from natural siccanin (*l*-**1**).

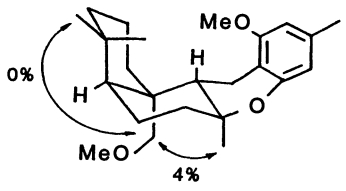
Nozoe et al. reported that siccanin (**1**), on treatment with boron trifluoride etherate in acetic anhydride, underwent cleavage of the C-O bond at the benzylic position to give triacetate **23** and siccanochromene E diacetate (**25**) as major and minor products, respectively.[9] With a view to obtaining siccanochromene E methyl ether (**26**), siccanin methyl ether (**28**)[9] was treated with the above Lewis acid under similar conditions, thus providing diacetoxy methyl ether **24** and acetoxy siccanochromene E methyl ether (**27**) in 80 and 19% yields, respectively. Subsequent reduction of the latter with lithium aluminium hydride afforded **26** quantitatively.

The methyl ether **26** was then submitted to catalytic hydrogenation over Pd-$SrCO_3$, affording two products, oily **29** and crystalline **33**, in a ratio of 81 : 19, and these products were presumed to be isomeric with respect to B/C ring juncture. Anticipation of the stereoselective hydrogenation at the convex face of molecule allowed us to assign the structure **29** to the major product. This surmise was chemically supported; dimethyl ether **30** obtained by methylation of **29** with methyl iodide was identical in all respects, except for optical rotations, with the exhaustive methylation product of the known diol **31**.[9]

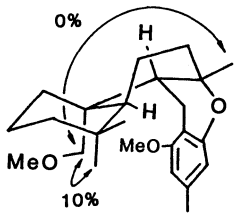
Consequently, the structure **33** could be assigned to the minor hydrogenation product, whose methyl ether was identical with the major cyclization product in comparison of their spectra.[1] This result also indicated that the structure **22** should be assigned to the minor cyclization product.

^{1}H NMR study of these cyclization products were highly suggestive of their conformations. Irradiation at methylene protons at δ 3.24 (CH_3OCH_2) in the spectrum of **9** in C_6D_6 resulted in a 4% NOE of the methyl protons (δ 1.39) on the carbon bearing an oxygen atom, whereas any ^{1}H NOE was not detectable between the methylene and gem. dimethyl protons. This finding seemed to indicate the steroid conformation **9a**[11]

with respect to the A/B rings for this compound. On the other hand, in the spectrum of **22** in $CDCl_3$, irradiation at one (δ 0.98) of methyl signals due to the gem. dimethyl grouping showed a 10% NOE in one of methylene proton signals at δ 2.63 (CH_3OCH_2), whereas no effect was observed between the methylene and the methyl protons (δ 1.20) on the carbon bearing an oxygen atom. In addition, the observed chemical shift (δ 2.63) of a methylene proton in methoxymethyl group of **22** is unusually high in comparison with other related compounds **9** (δ 3.27), **19** (δ 3.22), and **20** (δ 3.4), and this upfield shift would be ascribable to the shielding effect of aromatic ring. Such a stereochemical disposition seems to be allowed by a distorted conformation of its B ring by which one of methylene hydrogen atoms is disposed above the plane of aromatic ring. (cf. **22a**[11]), although we have no other evidence supporting this conformation.



9a



22a

The subsequent step in this synthesis was oxidation of the benzylic position of **9**. In expectation of preliminary information regarding this oxidation, we first submitted **30** to oxidation with chromium trioxide in aqueous acetic acid at 0 °C according to the literature.[1] The product, however, was *p*-quinone **36** formed in 40% yield.[12] Since this result indicated that methoxy was inadequate as a protective group in this oxidation, **9** was then transformed into acetylated phenol **34** by demethylation with sodium ethanethiolate[6] followed by acetylation of the resulting phenol **35**.

The acetylated phenol **34**, unfortunately, was extremely resistant to oxidation under similar conditions and gave rise to recovery of the unchanged substrate. On long duration of the oxidation at room temperature, some unidentified polar products[13] were formed, while no desired 1-benzopyran-4-one derivative was detectable despite of careful inspection of the reaction mixture. Attempted oxidation of **34** with other oxidants (cerium(IV) ammonium nitrate, lead(IV) acetate selenium dioxide, etc.) were also all fruitless. On the other hand, acetylated phenol **37** derived from **30** by demethylation with sodium ethanethiolate followed by acetylation of the resulting phenol **32** was submitted, for comparison, to chromium trioxide oxidation, yielding 1-benzopyran-4-one derivative **38**, albeit in low yield, in harmony with the previous observation.[3] Obviously **34** is suffered from a severe steric hindrance at the benzylic position.

In conclusion, the tetracyclic compound **34**, an equivalent of **6** that has been proposed as a promising synthetic intermediate[3,4] for *dl*-**1**, was synthesized via acid-catalyzed cyclization of the olefinic phenols **13** and **21**. This approach toward **1**, however, seems not to be feasible due to unsuccessful oxidation of **34** to the corresponding 12-oxo derivative.

Experimental

Melting points are uncorrected. IR spectra were obtained with a JASCO A-3 infrared spectrometer. ^{1}H NMR spectra were recorded on a JEOL FX90Q spectrometer using tetramethylsilane as an internal standard, and chemical shift values are given in δ and coupling constants (J) in hertz. Mass spectra were obtained on a Shimadzu LKB gas chromatograph-mass spectrometer equipped with a column (1 m) packed with OV-1 (1%). Ultraviolet spectra were recorded on a Cary model 14 spectrophotometer. Dry tetrahydrofuran (THF) and ethylene glycol dimethyl ether (DME) were obtained by distillation over lithium aluminium hydride. Other organic solvents, *N*,*N*-dimethylformamide (DMF), dimethyl sulfoxide (DMSO), and benzene were dried according to the standard procedure. All reactions, except for those in aqueous solutions, were carried out under dry N_2 or Ar atmosphere with use of standard procedures for the exclusion of moisture. Extracts obtained on workup of reaction mixtures were washed successively with water and brine, and then dried over $MgSO_4$, unless otherwise stated. Column chromatography was performed on silica gel (Merck, kieselgel 60, 70—230 mesh), and kieselgel GF_{254} was employed for preparative thin-layer chromatography (TLC) as absorbent. Solvents used for elution are shown in parentheses.

1α-(2,6-Dimethoxy-4-methylbenzyl)-8aα-methoxymethyl-2,5,5-trimethyl-1,4,4aα,5,6,7,8,8a-octahydronaphthalene (12). A mixture of **10**[5] (403 mg, 0.96 mmol), 10% Pd-C (80 mg) and ethanol (8 ml) was stirred at room temperature for 2 d under hydrogen. Filtration and subsequent concentration of the filtrate left an oil (395 mg), whose purification by TLC (1 : 1 ether-hexane) gave **11** (330 mg, 85%) as colorless crystals; mp 149—151 °C (from ether). IR (KBr) 3500, 1610, 1590, 1110, 970, 820 cm^{-1}. ^{1}H NMR ($CDCl_3$) δ=0.92 and 0.98 (3H, s each, $C(CH_3)_2$), 1.08 (3H, s, O-CCH_3), 1.1—2.1 (12H, m), 2.35 (3H, s, $ArCH_3$), 2.47 (1H, t, J=9 Hz, $CHCH_2Ar$), 2.85 (2H, d, J=9 Hz, $ArCH_2$), 3.15 and 4.05 (1H, d, J=10 Hz each, CH_2O), 3.39 (3H, s, OCH_3), 3.85 (6H, s, $ArOCH_3$), 6.40 (2H, s, ArH), and a small amount of **10**.

To a stirred solution of **11** (110 mg, 0.27 mmol) in pyridine (1 ml) was added thionyl chloride (36 μl, ca. 0.5 mmol) at 0 °C, and stirring was continued for 5 h at this temperature and then at room temperature for an additional 5 h. Ether was added and the solution was washed successively with water, aqueous $CuSO_4$, water, and brine, and then dried. The oily residue obtained by evaporation was purified by TLC (4 : 1 hexane-ether) to give **12** (69 mg, 66%) as colorless needles; mp 137—138 °C (from hexane-ether). IR (KBr) 1610, 1590, 1120, 975, 810 cm^{-1}. ^{1}H NMR ($CDCl_3$) δ=0.85 and 0.93 (3H, s each, $C(CH_3)_2$), 1.2—2.2 (10H, m), 1.48 (3H, br s, =C-CH_3), 2.35 (3H, s, $ArCH_3$), 2.67 (2H, d, J=7.2 Hz, CH_2Ar), 3.35 (3H, s, OCH_3), 3.24 and 3.52 (1H, d, J=9 Hz each, CH_2O), 3.81 (6H, s, $ArOCH_3$), 5.38 (1H, br s, =CH), 6.36 (2H, s, ArH).

Found: C, 77.40; H, 9.90%. Calcd for $C_{25}H_{38}O_3$: C, 77.67; H, 9.91%.

1α-(2-Hydroxy-6-methoxy-4-methylbenzyl)-8aα-methoxymethyl-2,5,5-trimethyl-1,4,4aα,5,6,7,8,8a-octahydronaphthalene (13). A mixture of **12** (176 mg, 0.46 mmol), sodium ethanethiolate (370 mg, 4.4 mmol) and DMF (5 ml) was heated at 110 °C for 4.5 h. After cooling to room temperature, water was added and the resultant solution was extracted with ether. Concentration of the extract and purification of the oily residue by TLC (1 : 1 hexane-ether) gave **13** (164 mg, quantitaive) as a viscous oil. IR ($CHCl_3$) 3300, 1620, 1580, 1110, 815 cm^{-1}. ^1H NMR ($CDCl_3$) δ=0.88 and 0.92 (3H, s each, $C(CH_3)_2$), 1.0—2.2 (9H, m), 1.55 (3H, s, $=CCH_3$), 2.24 (3H, s, $ArCH_3$), 2.4—3.05 (3H, m), 3.42 (3H, s, OCH_3), 3.56 and 3.70 (1H, d, J=10 Hz each, CH_2O), 3.77 (3H, s, $ArOCH_3$), 5.35 (1H, br s, =CH), 6.21 and 6.33 (1H, s each, ArH), 7.75 (1H, s, OH). MS (70 eV) m/z 372 (M^+).

Methylation of 13 with Dimethyl Sulfate. To a stirred solution of **13** (10 mg) in ethanol (0.5 ml) was added aqueous NaOH (38%, 0.1 ml) and then dimethyl sulfate (0.1 ml) at room temperature. After stirring for 1 h, the same amounts of dimethyl sulfate and the alkali solution were added and stirring was continued for an additional 1 h. The mixture was diluted with water and extracted with CH_2Cl_2. Concentration of the extract left crystals (10 mg, quantitative), whose IR and ^1H NMR were identical with those of **12**.

5,5-Dimethyl-3-hydroxymethylene-8aα-methoxymethyl-3,4,4aα,-5,6,7,8,8a-octahydro-2(1*H*)-naphthalenone (15). A 50% sodium hydride dispersion in mineral oil (1.453 g, 15.14 mmol) was washed with pentane, and benzene (20 ml) was added. A solution of **14**[5] (3.390 g, 15.14 mmol) in benzene (20 ml) was added to the above suspension, and the mixture was stirred at 0 °C for 30 min. A solution of ethyl formate (4.486 g, 60.5 mmol) in benzene (5 ml) was added, and stirring was continued at 0 °C for 1.5 h and then at room temperature for 10 h. The mixture was poured into ice water, and the benzene layer was extracted with aqueous NaOH. The extract was acidified with dilute HCl at 0 °C and extracted with CH_2Cl_2. Concentration of the extract left a semisolid, which was filtered through a short silica gel-column with the aid of hexane-ether (1 : 3) to give **15** (3.550 g, 93%) as colorless needles; mp 76—77 °C (from hexane-ether). IR (KBr) 3300—2500, 1650, 1600, 1120, 890 cm^{-1}. ^1H NMR ($CDCl_3$) δ=0.81 and 0.98 (3H, s each, $C(CH_3)_2$), 1.1—1.8 (8H, m), 2.05 (1H, m), 2.3—2.6 (2H, m), 3.00 and 3.10 (1H, d, J=10.0 Hz each, CH_2O), 3.30 (3H, s, OCH_3), 8.27 (1H, s, =CHOH), 13.9—14.4 (1H, br, =CHOH).

Found: C, 71.11; H, 9.19%. Calcd for $C_{15}H_{24}O_3$: C, 71.39; H, 9.59%
