The observed wavelength displacement in ether solution for the *C*-band has been attributed to hydrogen bonding between the amino group and the oxygen atom of the solvent (cf. refs. 10 and 11). This wavelength displacement between heptane and ether is observed for aniline, but a similar displacement is now not observed for N,N-dimethylaniline (10) where this type of hydrogen bonding is ruled out. Further, the dipole moment increases markedly for aniline in ether, compared with the dipole moment in heptane, whereas a similar increase in dipole moment is not observed for N,N-dimethylaniline (10). On the other hand, we have found that the addition of 3% by weight of ether to a solution of aniline in cyclohexane does *not* change the absorption spectrum to a spectrum similar to that of aniline in ether (see Table I and cf. also ref. 10 for the spectrum of aniline in heptane containing various amounts of dioxane). This latter observation therefore does not support the concept of a stoichiometric, permanent, hydrogen bond. Lastly, it may be noted that the wavelength displacements observed between cyclohexane and vapor phase spectra suggest that some interaction also occurs between aniline and cyclohexane molecules.

THE SPECTRA OF PARASUBSTITUTED ANILINES

The spectra of parasubstituted anilines are listed in Table II.

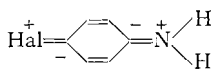
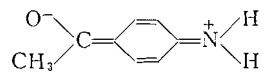
The early examples in Table II provide illustrations where both substituents are electron donating and the molecule absorbs essentially as aniline. It may be noted that for these examples the maximal extinction coefficient (ϵ_{max}) is frequently *reduced* relative to aniline, whereas in disubstituted benzene derivatives, when the substituents are electron withdrawing, the values of ϵ_{max} are usually *increased* relative to the monosubstituted parent compound (cf. 17, 18, 19).

Table II also shows that parasubstitution usually displaces the *B*-band of aniline towards longer wavelength. This is well illustrated by the spectra of the parahalogen-substituted anilines, and the magnitude of the displacements, compared with the wavelength displacements observed for meta- and ortho-isomers (see Tables III and IV), supports the postulate of dipolar forms, which may be associated with electron mobility acting along systems of conjugated bonds. However, resonance forms are evidently not entirely satisfactory in representing the relevant dipolar excited states (cf. ref. 13), although structures of type II may be used to provide a picture of the orbital delocalizations occurring in the electronic excited state.

Further, the bands are described as displaced aniline *B*-bands, but it should be noted that significant changes occur on parasubstitution. For example, whereas changing the solvent from cyclohexane to ethanol for aniline does not cause any appreciable wavelength displacement, precisely such a displacement is observed in parahalogen-substituted anilines; this displacement usually becomes increasingly pronounced with increased mesomeric interaction. Next, although normally the aniline band disappears in dilute acid media, for compounds such as *p*-nitroaniline where the mesomeric interaction is large, the band does not completely disappear, although the intensity is very greatly reduced (see Table II). Again, while for both *p*-aminoacetophenone and aniline the characteristic *hypsochromic* wavelength displacement is observed on changing the solvent from ethanol to water, in *p*-nitroaniline a *bathochromic* displacement is observed on changing the solvent from ethanol to water.



II



III

The absorptions at much longer wavelength for compounds like *p*-nitroaniline or *p*-aminoacetophenone may be associated with favorable resonance forms of type III contributing appreciably to the electronic excited state. The more appreciable contribution of resonance forms of type III, even in the ground state, presumably also accounts for the large dipole moments of these compounds (20) and the various effects noted by Wepster, who ascribed these effects, at least partly, to a decrease in the average angle of twist in the nitro group on substitution of an amino group in the para position (1, 21).

THE SPECTRA OF METASUBSTITUTED ANILINES

The spectra of metasubstituted anilines are listed in Table III.

For many of the spectra listed in Table III, the aniline B-band is readily discernible, as for example in *m*-methyl- or *m*-halogen-substituted anilines. It may be noted that the sensitiveness of the B-band to solvent changes is again different for metasubstituted anilines, such as *m*-aminoacetophenone, than for aniline.

As previously mentioned (18, 19), two B-bands can frequently be discerned in the spectra of metadisubstituted benzene derivatives, and these B-bands have been associated with transitions involving the two monosubstituted parent compounds. In this way, the

*This series of papers.
†B-band assignment doubtful.

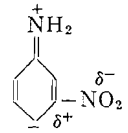
maximum at 226 mμ for *m*-aminoacetophenone in cyclohexane solution, the maximum for the same compound at 231 mμ in ethanol, the maximum at 233 mμ for *m*-nitroaniline in ethanol, and the maximum for the same compound at 224 mμ in *N* NaOH are all ascribed to aniline absorption. On the other hand, the inflections at 243 and 256 mμ for *m*-aminobenzaldehyde in cyclohexane are ascribed to the benzaldehyde chromophore, the inflection at 246 mμ for *m*-aminoacetophenone in cyclohexane is ascribed to the acetophenone chromophore, and the inflection at 241 mμ for *m*-aminobenzoic acid in ethanol is ascribed to the benzoic acid chromophore. Some typical features of the *B*-band assist in the assignments. For example, the characteristic doublet of the benzaldehyde *B*-band (cf. 19) appears in the spectrum of *m*-aminobenzaldehyde for the inflection near 250 mμ.

The meta-amino substituent, as expected, gives rise to a secondary interaction, which frequently causes an appreciable bathochromic wavelength displacement for the compounds listed in Table III (cf. 24). For example, in ethanol, the *B*-band of acetophenone at 240 mμ occurs as an inflection near 255 mμ in *m*-aminoacetophenone, and the *B*-band of benzoic acid at 227 mμ occurs as an inflection near 241 mμ in *m*-aminobenzoic acid. Similar displacements for other compounds, caused by the secondary effect of the meta-amino group, may be deduced from Table III. It is found that the wavelength displacement is reasonably constant, at least for similar compounds. Thus, whenever the non-amino substituent is electron withdrawing, the corresponding *B*-band appears to show an appreciable bathochromic wavelength displacement. An exception is provided in acid media, where the unshared electron pair of the amino substituent is presumably unable to contribute efficiently to the interaction with the benzene ring. Likewise, the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

non-amino substituent affects the aniline *B*-band in a manner which seems susceptible to generalization. For example, if the non-amino substituent is electron withdrawing, the effect on the aniline absorption appears to be quite generally a displacement to shorter wavelength accompanied by increased absorption intensity (see Table III).

This relatively greater intensity of the band associated with aniline absorption suggests that the amino group gives rise to greater mesomeric interaction in the electronic excited state. Structures, which may be crudely represented by resonance forms of of type IV, would again contribute to the electronic excited state, and these resonance



IV

forms, by analogy with the previously discussed resonance structures of that type (18), would be expected to be favored by an electron-withdrawing substituent in the meta position. On the other hand, if the meta substituent is electron donating, the band intensity of the aniline *B*-band is usually decreased (see Tables III and I). This decrease is qualitatively similar to the intensity decrease observed for the corresponding para isomers (see Table II). Both the changes may again be rationalized by resonance structures of type IV.

Since the amino group is relatively small, no appreciable buttressing interaction would be expected for metasubstituted anilines. In fact, buttressing effects are not readily discernible except possibly for the spectrum of *m*-iodoaniline (cf. 25). A buttressing interaction may also contribute to the spectral changes in the series aniline, *o*-toluidine, and 2,3-dimethylaniline. These compounds are reported to absorb in iso-octane solution at about 250 mμ with ϵ values of 9130, 8800, and 7550 respectively (1). Further, 2,3,5,6-tetramethylaniline, compared with 2,6-dimethylaniline, shows a reduced absorption intensity (1).

The *C*-band, as anticipated, is frequently more pronounced in metasubstituted anilines, compared with the *C*-band in aniline or parasubstituted anilines (26). Difficulties have arisen because of different assignments; for example, Morton and McGookin (23) note that wavelength displacements are observed in opposite senses for *m*- and *p*-nitro-N,N-dimethylaniline on changing the solvent from ethanol to water. An explanation for this apparent anomaly is provided if it is accepted that the relevant bands of the para isomer are *B*-bands, whereas the "similar" bands of the meta isomer are *C*-bands. In this way, we believe that the band of *p*-nitrodimethylaniline, which occurs in ethanol at 368.5 mμ, and the band of the same compound, which occurs in water at 422 mμ, are *B*-bands (cf. 18). On the other hand, we assume that the band of *m*-nitrodimethylaniline, which in ethanol occurs at 400.3 mμ, and which in aqueous solution is hypsochromically displaced to 385 mμ, is a *C*-band. A similar hypsochromic displacement on changing the solvent from ethanol to water is incidentally also observed for the *C*-band of *m*-nitroaniline (see Table III).

THE SPECTRA OF ORTHOSUBSTITUTED ANILINES

The spectra of orthosubstituted anilines are listed in Table IV.

The *B*-bands listed in Table IV can again be classified into the two types of *B*-bands

*This series of papers.
†B-band assignment doubtful.

as described in the previous section. Table IV then shows that both *B*-bands are frequently weakened in the ortho isomer compared with the corresponding *B*-bands in the meta isomer (see Table III). Examples of this are provided by the ortho and meta isomers of iodoaniline in cyclohexane, of aminoacetophenone in cyclohexane and ethanol, of aminobenzaldehyde in cyclohexane, and of aminobenzoic acid in ethanol and ether. In the absence of intermolecular hydrogen bonding (see below), one would expect steric effects to occur and the observed intensity decreases in the examples cited are in fact ascribed to steric interactions. Steric interactions may also occur in a number of other orthosubstituted anilines, such as *o*-toluidine and *o*-chloroaniline, for which, however, the data do not permit any definite conclusions. In this connection, it may be noted that, *compared with the B-band of the para isomer*, a hypsochromic wavelength displacement and a pronounced intensity decrease is almost invariably observed in the *B*-band of the ortho isomer. Since the resonance forms contributing to the ortho and para isomers may be regarded as similar to a first approximation, one might expect the *B*-bands of the ortho and para isomers to be similar *in the absence of steric* and other short-range *interactions*. A steric contribution to this "ortho effect" is also indicated by the fact that the decrease in absorption intensity becomes more pronounced for N,N-dimethylanilines (cf., for example, the ϵ_{max} values and integrated absorption intensities of N,N-dimethylaniline and of the corresponding *o*-methyl derivative (1)).

In the previous paragraph decreases in the absorption intensities have been used as indications of steric interactions, but unusual wavelength displacements may evidently

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12

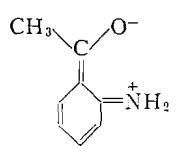
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

also indicate steric interactions. However, the wavelength displacements caused by steric interactions in this series of compounds appear to be small. For example, *o*-ethyl- and *o*-isopropyl-N,N-dimethylaniline, which presumably represent appreciably hindered compounds, still absorb maximally at 249 mμ (ϵ = 4950) and 248 mμ (ϵ = 4300) respectively, that is, at a similar maximal wavelength to N,N-dimethylaniline under identical conditions (λ_{max} 251 mμ, ϵ = 15,500) (1). This lack of an appreciable wavelength displacement, which has also recently been discussed from a theoretical viewpoint (4), may be related to the large mesomeric effect of the amino group. That is, it may be supposed that the appreciable double-bond character of the N-nuclear bond tends to keep the aniline chromophore planar and the second substituent does not contribute to the observed absorption. This mechanism has recently been described as a type III steric effect (27).

Generally, the amino group does not appear to be as sensitive to steric effects as, for example, the nitro group, which also causes appreciable mesomeric interaction. For example, an ortho-methyl group produces an appreciable intensity decrease in the *B*-band of nitrobenzene and similar compounds, whereas only a small intensity decrease is observed in the *B*-band of aniline, even compared with the *B*-band of the para isomer. Two, not mutually exclusive, explanations may account for the smaller steric effects in anilines. First, the amino group may not, because of its small size, cause appreciable steric interactions. One of the factors contributing to the relatively smaller size of the amino group may be the partial positive charge associated with excited states of the aniline chromophore. A second explanation may be that π–p electronic interaction, like π–π electronic interaction, gives rise to considerable double bond character in the N-nuclear bond, but that π–p interaction is less sensitive to steric interactions, compared with π–π electronic interaction.

Apart from steric interactions, which will tend to oppose the existence of coplanar resonance forms, other short-range interactions must also be considered. Intramolecular hydrogen bonding would be expected to be one of the most important of such interactions. For some examples, there is reasonably good evidence for an intramolecular hydrogen bond. For example, comparing the ortho and meta isomers of a number of compounds in which an intramolecular hydrogen bond would be anticipated, the following bathochromic wavelength displacements are obtained from the data listed in Tables III and IV: Aminoacetophenone in cyclohexane, *B*-band, 6 mμ; *C*-band, 27 mμ. Aminobenzoic acid in ether, *B*-band, 8 mμ; *C*-band, 13 mμ. Aminobenzoic acid in ethanol, *B*-band, 6 mμ; *C*-band, 13 mμ. Aminophenol in cyclohexane containing 2% ether, *B*-band, 1 mμ; *C*-band, 4.5 mμ. In all these compounds the ortho isomer absorbs at *longer* wavelength than the meta isomer, and the wavelength displacement may therefore be attributed, at least partly, to an intramolecular hydrogen bond.

Evidence for intramolecular hydrogen bonding may also be deduced from displaced and intensified *C*-bands in some ortho isomers, but this evidence is somewhat ambiguous (cf. ref. 26). Quite generally, and not unexpectedly, for a number of compounds the



V

evidence for intramolecular hydrogen bonding from ultraviolet spectroscopy is not convincing. A number of reasons suggest themselves for this observation. For example, apart from intramolecular hydrogen bonded forms, ortho-resonance forms of type V may contribute to the ground and excited states, and this may partly account for the observed bathochromic displacements of some of the *B*-bands listed in Table IV. Next, intramolecular hydrogen bond formation may be opposed by steric interactions; the two interactions, by giving rise to opposite spectral effects, may cause different displacements depending on which interaction predominates. Further, various forms of solute–solvent interaction, including intermolecular hydrogen bonding, may interfere with intramolecular hydrogen bonding. This, in fact, is suggested by the frequent absence of the spectral effects, associated with intramolecular hydrogen bond formation, in other than inert media (cf. Tables III and IV).

The *C*-band in orthosubstituted anilines gives rise to the expected changes (see ref. 26). It is generally more pronounced in orthosubstituted anilines.

EXPERIMENTAL

The ultraviolet absorption spectra were determined by standard methods using a Unicam SP500 or a Beckman Model DU spectrophotometer. For each compound at least two independent sets of observations were made. The spectrum in the vapor phase was determined at room temperature in a 2-cm cell against air. The spectral data obtained compare well with other data whenever these were previously recorded in the literature. Where comparisons are made involving the extinction coefficients at maximal absorption (ϵ_{max}) the change in ϵ_{max} may be qualitatively related to corresponding changes in the oscillator strengths f, as far as can be discerned from the shape of the absorption bands. The precision of λ_{max} values is estimated to be ± 0.5 mμ, and the precision of ϵ_{max} values $\pm 5\%$ or better. Values were normally reproducible to $\pm 2\%$.

The physical constants, after purification, of compounds, the spectra of which have not previously been reported in this series, are listed in Table V.

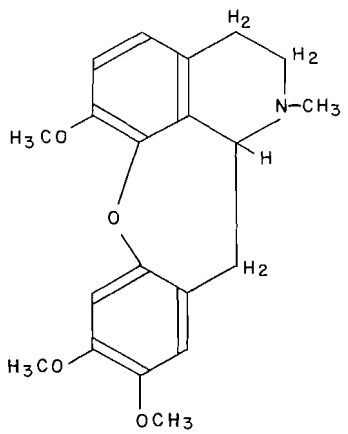
SUR LA SYNTHÈSE DE QUELQUES XANTHONES POLYSUBSTITUÉES[1]

R. Constantin et P. L'Écuyer

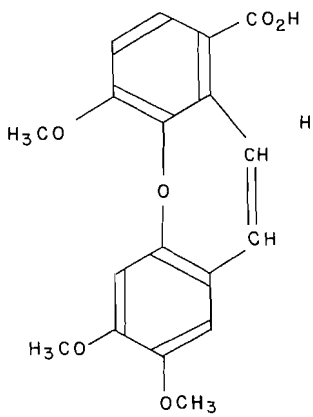
RÉSUMÉ

La synthèse de la 4,6,7-triméthoxy- et de la 1-méthyl-4,6,7-triméthoxy-9-xanthone a été réalisée en faisant agir un mélande d'anhydride acétique et d'acide sulfurique sur l'acide 6-(2′-méthoxy)- ou 6-(2′-méthoxy-5′-méthylphénoxy)-vératrique. La préparation de ces deux acides a été effectuée en condensant le 6-bromovératrate de méthyle avec le guaïacolate ou l'isocréosolate de potassium en présence de cuivre. La 1-carboxy-4,6,7-triméthoxy-9-xanthone, un produit de dégradation de la cularine, a été obtenue en oxydant la 1-méthyl-4,6,7-triméthoxy-9-xanthone par l'acide chromique en solution dans l'acide éthanoique.

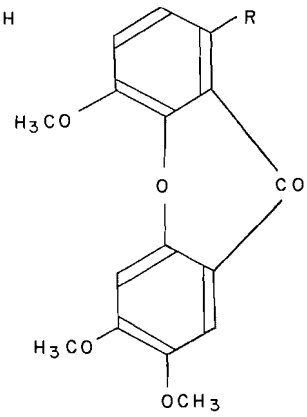
Manske (1, 2) a suggéré la formule I pour la cularine en se basant sur la structure des produits de dégradation qu'il en a obtenus et, en particulier, sur celle de la 2-styrolène-4,6,7-triméthoxy-dibenz[*b*,*f*]oxépine (II), provenant de la méthylation destructive de l'alcaloïde. L'oxydation de II lui a donné, en plus de l'acide dicarboxylique correspondant, une xanthone qui, selon toute probabilité, devait être la 1-carboxy-4,6,7-triméthoxy-9-xanthone (III, R = CO_2H). Manske n'a pas synthétisé cette xanthone, parce qu'il ne



(I)



(II)



(III)

R = H, $-CH_3$ ou CO_2H

connaissait aucune méthode facile de synthèse conduisant aux xanthones polysubstituées.

Manske et Kulka (3), en appliquant la réaction de Gattermann au 2,3′,4′-triméthoxydiphényl éther et au 2,3′,4′-triméthoxy-5-méthyldiphényl éther ont déjà synthétisé les aldéhydes 6-(2′-méthoxyphénoxy)- et 6-(2′-méthoxy-5′-méthylphénoxy)-vératriques qu'ils ont transformés par oxydation en acides 6-(2′-méthoxyphénoxy)- et 6-(2′-méthoxy-5′-méthylphénoxy)-vératriques avec des rendements respectifs de 12 et 10%. En condensant le 6-bromovératrate de méthyle avec le guaïcolate ou l'isocréosolate de

Contribution du Département de Chimie, Faculté des Sciences, Université Laval, Québec, P.Q. Ce mémoire est tiré de la thèse de doctorat de R. Constantin.

potassium en présence de poudre de cuivre et en saponifiant les esters qui se sont formés nous avons obtenu les mêmes acides 6-(2′-méthoxyphénoxy)- et 6-(2′-méthoxy-5′-méthylphénoxy)-vératriques avec des rendements respectifs de 45 et 30%.

L'action d'un agent déshydratant sur un acide arylsalicylique constitue une méthode pratique pour la préparation d'une xanthone simple (4, 5). En faisant agir un mélange d'anhydride acétique et d'acide sulfurique sur l'acide 6-(2′-méthoxy)- ou 6-(2′-méthoxy-5′-méthylphénoxy)-vératrique nous avons pu synthétiser la 2,3,5-triméthoxy-9-xanthone (III, R = H) et la 1-méthyl-4,6,7-triméthoxy-9-xanthone (III, R = CH_3).

L'oxydation de III (R = H) par l'acide chromique dans l'acide acétique glacial nous a permis de synthétiser la 1-carboxy-4,6,7-triméthoxy-9-xanthone (III, R = CO_2H). Le point de fusion de cette xanthone mélangée à un échantillon du produit que Manske a obtenu au cours de la dégradation de la cularine n'est pas déprimé et les spectres d'absorption dans l'ultraviolet (figures 1 et 2) des deux échantillons différents de la xanthone, sont identiques. Ceci confirme donc l'exactitude de la structure que Manske a suggérée pour la xanthone qu'il a obtenue à partir de la cularine et aussi de celle qu'il a proposée pour l'alcaloïde lui-même.

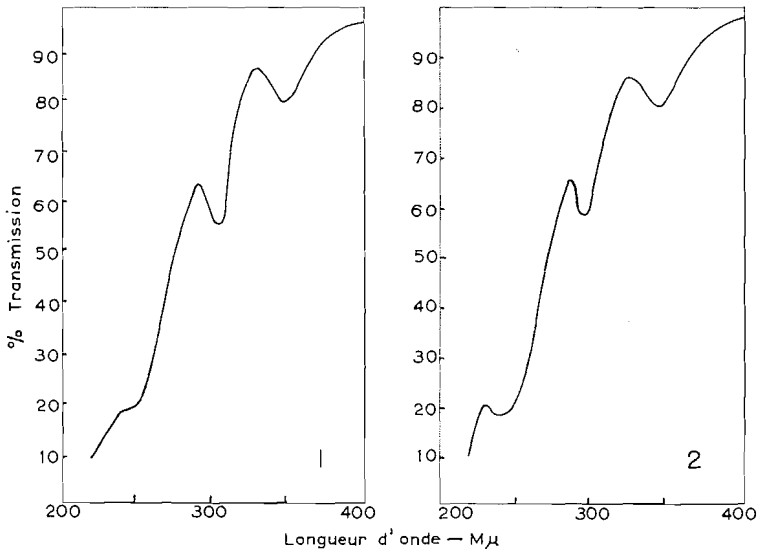

FIG. 1. Spectre d'absorption dans l'ultraviolet de la 1-carboxy-4,6,7-triméthoxy-9-xanthone synthétique.
FIG. 2. Spectre d'absorption dans l'ultraviolet de la xanthone obtenue par la dégradation de la cularine.

PARTIE EXPÉRIMENTALE*

Acides 6-(2′-méthoxyphénoxy)- et 6-(2′-méthoxy-5′-méthylphénoxy)-vératriques

On pulvérise dans un mortier un mélange de 6-bromovératrate de méthyle (0.01 mole), de guaïacolate ou d'isocréosolate de potassium (0.011 mole) et de la poudre de cuivre. On chauffe ensuite le mélange à 150° pendant 2 heures, puis à 180° pendant 15 minutes. Une fois la masse brune refroidie, on la pulvérise et on l'extrait à l'éther (3 fois avec 30 ml). Les extraits éthérés combinés sont lavés successivement à la soude 0.1 *N* et à l'eau, puis séchés et évaporés à siccité. Le résidu est saponifié en le chauffant à reflux en présence d'une solution à 3% d'hydroxyde de potassium dans le méthanol. On chasse la majeure partie du méthanol par ébullition, on dilue et on acidifie à l'acide

**Les points de fusion ont été pris à l'aide de l'appareil de Johns.*

sulfurique. Les acides 6-(2′-méthoxyphénoxy)- et 6-(2′-méthoxy-5′-méthylphénoxy)-vératriques sont essorés et cristallisés dans le benzène. Les p.f. sont respectivement 184 et 186°, et les rendements 1.37 g (45%) et 0.95 g (30% de la théorie).

4,6,7-Triméthoxy-9-xanthone (III, R = H)

A de l'acide 6-(2′-méthoxyphénoxy)-vératrique (1.6 g; 0.005 mole) dans le d'anhydride acétique (15 ml) on ajoute 2 ml d'acide sulfurique concentré. On porte la solution à 60° sur le bain-marie pendant 1 heure et on la verse ensuite sur de la glace. On essore le précipité et on le lave successivement à la soude 0.1 *N* et à l'eau. La 4,6,7-triméthoxy-9-xanthone cristallise dans le méthanol en fines aiguilles blanches de p.f. 238°. Rendement: 0.86 g (65% de la théorie). Calculé pour $C_{16}H_{14}O_5$: C, 67.11%; H, 4.92%. Trouvé: C, 66.4%; H, 5.0%.

1-Méthyl-4,6,7-triméthoxy-9-xanthone (III, R = CH_3)

On procède exactement de la même façon que pour la synthèse précédente, mais en utilisant l'acide 6-(2′-méthoxy-5′-méthylphénoxy)-vératrique comme matière première. La 1-méthyl-4,6,7-triméthoxy-9-xanthone s'obtient en fines aiguilles blanches en la cristallisant dans le méthanol ou l'éthanol. P.f. 211°. Rendement 0.26 g (40% de la théorie). Calculé pour $C_{17}H_{16}O_5$: C, 67.99%; H, 5.37%. Trouvé: C, 67.4%; H, 5.4%.

1-Carboxy-4,6,7-triméthoxy-9-xanthone (III, R = CO_2H)

On chauffe au bain-marie pendant 2 heures une solution de 1-méthyl-4,6,7-triméthoxy-9-xanthone (0.2 g) et d'oxyde chromique (0.3 g) dans l'acide acétique glacial (10 ml). On verse ensuite la solution sur de la glace et on essore le précipité qui s'est formé. La 1-carboxy-4,6,7-triméthoxy-9-xanthone cristallise dans l'acide éthanoique en fines aiguilles jaunâtres de p.f. 301°. Rendement: 0.15 g (70% de la théorie). Le p.f. mixte d'un échantillon de cette xanthone mélangée à un échantillon du produit que Manske a obtenu par la dégradation de la cularine est aussi 301°. Le spectre d'absorption dans l'ultraviolet des deux échantillons de provenance différente est aussi identique. Calculé pour $C_{17}H_{14}O_7$: C, 61.20%; H, 4.27%. Trouvé: C, 60.7%; H, 4.4%.

REMERCIEMENTS

Nous remercions le Dr. R. H. F. Manske pour nous avoir gracieusement fourni un échantillon du produit provenant de la dégradation de la cularine, puis le Conseil National de Recherches, l'office de Recherches de la Province de Québec et les Canadian Industries Limited, pour l'octroi de bourses d'études à l'un de nous (R. Constantin).

THE KINETICS OF MOLECULAR SIEVE ACTION. SORPTION OF NITROGEN–METHANE MIXTURES BY LINDE MOLECULAR SIEVE 4A[1,2]

H. W. HABGOOD

ABSTRACT

This system illustrates "partial molecular sieve action". Methane has a higher affinity for the sorbent and hence is preferentially sorbed at equilibrium, while nitrogen diffuses through the crystal more rapidly and thus is preferentially taken up during the early stages of sorption. Measurements were made with the pure gases and with mixtures at 0° and −79.4° C. The sorption isotherms fit Langmuir equations and the isosteric heats of sorption are essentially independent of concentration. The sorption rates for the pure gases may be characterized by diffusion coefficients, D, calculated in the usual manner assuming the flux of diffusion to be proportional to the concentration gradient. The resultant values for D increase with increasing sorbate concentration. Diffusion of a mixture may be formally characterized by D's for each component. While that for methane is approximately the same as for methane alone, D for nitrogen in mixtures is much larger than for the pure gas and also varies with composition. This, as well as the existence of a temporary maximum in the amount of nitrogen sorbed, may be explained by considering the driving force for diffusion to be the gradient in chemical potential rather than in concentration.

INTRODUCTION

"Molecular sieve" behavior during sorption by dehydrated crystalline zeolites results from the small and uniform size of the intracrystalline pores left by removal of the water of hydration. Molecules having a significantly larger cross section are totally excluded but somewhat smaller molecules may be sorbed slowly. Here the rate-determining step appears to be diffusion through the crystal channels with a significant energy of activation being required. With a mixture of two such sorbates, *partial* molecular sieve action may occur. The component having the lesser affinity for the solid may move faster through the lattice and, consequently, the sorbed phase would show an initial enrichment in this substance, followed by an equilibrium enrichment in the other, more strongly sorbed, component. Since there is often a rough correlation between molecular size and adsorptive affinity, such cases should be fairly common.

Most of our knowledge of this interesting class of sorbents is from the extensive work of R. M. Barrer and his students over the past fifteen years (1). Studies by Barrer and Robins on the sorption of binary gas mixtures (2) indicate that argon–krypton mixtures with dehydrated mordenite and ethane–propane mixtures with dehydrated chabazite show the behavior described above. These experiments in which sorption was carried out in a series of finite steps from a gas phase of constant volume and hence of varying composition were not, however, amenable to detailed analysis.

The present study was intended to examine a single system in some detail, primarily to investigate the relationship between the diffusion properties of the gases individually and in mixtures. The sorption of nitrogen, methane, and their mixtures by Linde Molecular Sieve 4A* (a dehydrated synthetic crystalline zeolite) was studied. This system proved to be a very satisfactory choice. The effective collision diameters of nitrogen and methane,

3.71 Å and 3.82 Å (3), are almost the same but nitrogen would be expected to have a significantly smaller minor diameter of around 3.0 Å. Since methane is, in general, more strongly adsorbed than nitrogen, the expected behavior, if the adsorbent pores are a suitable size, is initial preferential sorption of nitrogen changing to the preferential sorption of methane at equilibrium. The present work demonstrates that such behavior does indeed occur, although, as with many other diffusion phenomena, the simple Fick's Law approach is inadequate for a complete description.

EXPERIMENTAL

Apparatus and Method

Measurements were made of the progress of sorption with time and of the equilibrium sorption for the pure gases and for mixtures. For some of the work with the pure gases a conventional constant volume system was used in which the sorption was followed by change in pressure. For all of the measurements on gas mixtures a constant pressure flow system was used.

The constant pressure apparatus, as illustrated schematically in Fig. 1, permitted a continuous gas flow in order to maintain uniform composition and pressure in the gas phase. After the gas mixture had flowed over the sample for the desired length of time, the pressure and flow being maintained constant by adjustment of the appropriate valves, the contents of the cell were isolated by closing the outlet and inlet valves. The valve from the storage tank was closed one or two seconds before the inlet valve to the cell so that the manometer read the final pressure in the cell. The cell was then heated to 200° to bring about desorption, while the gas was expanded into a calibrated glass measuring system.

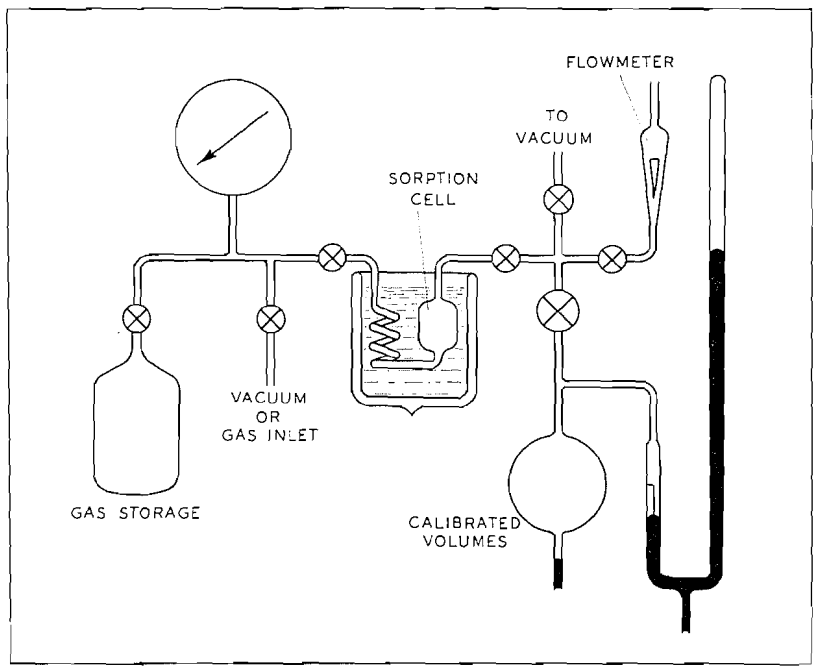

FIG. 1. Constant pressure flow system for sorption measurements.

Analysis of mixtures was by comparison of the thermal conductivity with that of a sample of the original mixture. It was necessary to mix the gas before analysis to ensure uniform composition and this was done by collection in a single bulb on charcoal at liquid air temperature followed by an hour's reheating. The thermal conductivity measurements were made with a Gow-Mac cell in a conventional bridge arrangement. It was found important to maintain the total cell current constant within 0.1% to obtain reproducible results.

A series of such measurements was carried out with different contact times. The dead space was measured both with helium and by extrapolation to zero time of the total gas volume. In calculating the amount of sorbed gas it is necessary to assume that the gas in the free space of the cell is of the same composition as the original gas mixture. A flow rate of about 10 times the average rate of sorption during the first minute appeared sufficient to ensure this, as shown by constancy of composition with varying flow rate. A higher rate would sometimes have been desirable for times less than one minute but it would then be uncertain that the gas had reached bath temperature. Measurements could be made to contact times as low as ten to fifteen seconds.

Two apparatuses of this type were used, one of glass with fritted disks at the inlet and outlet to retain the powdered zeolite and the other of metal for use at higher pressures with the zeolite in pellet form.

Gases

Purified grade nitrogen was passed through a charcoal trap cooled in dry ice – acetone. Some argon remained but this did not appear to collect on the zeolite. Phillips pure grade methane was passed through an ascarite column to remove carbon dioxide and through a charcoal trap cooled in dry ice – acetone to remove ethane.

Zeolite

The Molecular Sieve 4A was obtained as a fine crystalline powder and also in the form of extruded pellets $\frac{1}{16}$ inch diameter by about $\frac{1}{4}$ inch long. The pellets were more convenient for measurements at high pressures but the results cannot be compared with those from the powder because of differences in the total sorptive capacities and rates.

The external area of each form was determined from the B.E.T. adsorption isotherm at 0° for isobutane, which may be assumed not to penetrate the intracrystalline pores. Taking 47.4 Å^2 for the area of the isobutane molecule (4), surface areas of 10.5 and 6.9 m^2/g for pellets and powder respectively were obtained. This gives an average particle diameter for the powder of about 0.5 μ and an average intercrystalline pore diameter for the pellets of 0.1 to 0.5 μ.

The density of the dehydrated zeolite powder was determined with carbon tetrachloride (which is too large to penetrate the intracrystalline channels) to be 1.631 g/cc. The density of the hydrated crystals is given as 1.99 g/cc.

Some of the properties of this synthetic zeolite have been described by Breck *et al.* (5) and the crystal structure has been worked out by Reed and Breck (6).

Activation

The zeolite was received in essentially dehydrated form but all samples were further activated by heating under vacuum for 1 to 3 hours at 300° to 400°. The total water removed was around 1.6% and most of this came off below 300°. (The hydrated crystals contain 22.2% H_2O (5).) Activation to 400° appeared to be more reproducible than to 300°. Both the sorptive activity and the total sorptive capacity appeared to be very

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

sensitive to the precise degree of dehydration achieved; for example, the diffusion coefficients roughly quadrupled for activation at 400° compared to 300°. This behavior is similar to the findings of others (2, 5, 7, 8) and appears to result from the blocking action of a few residual water molecules which effectively seal off portions of the zeolite crystal. Dehydration at 400° was not sufficiently extreme to cause collapse of the crystal and decrease in adsorptive capacity, such as reported for chabazite at high temperatures (7).

Sudden sharp drops in activity often accompanying a large sorption were sometimes observed for samples with initially rather low diffusivities—e.g. those activated around 300°. A possible explanation is a non-uniform initial activation with a redistribution of the residual water, which was assisted by the local heat of sorption.

Because of this sensitivity of the zeolite and as a result of accidental exposures to air it was not possible to obtain all the information desired from a single sorbent sample. Only those results are included for which periodic repetition of some of the measurements showed the activity to be constant over the series of measurements.

RESULTS

Equilibrium Properties: Isotherms

Sorption isotherms, with one exception, gave good fits to the Langmuir equation. Some of the isotherms are shown in Fig. 2 and the Langmuir constants are given in Table I for measurements on two samples of powder at 0° and −79.4° C and on one

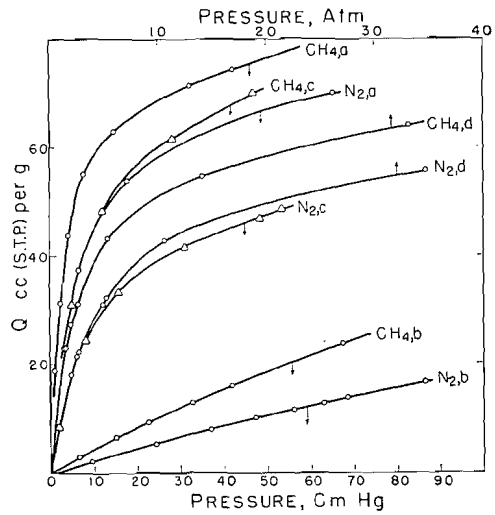

FIG. 2. Sorption isotherms. *a*—powder activated at 400° C, isotherms at 193.7° K; *b*—same sample as *a*, isotherms at 273.1° K; *c*—powder activated at 350° C, isotherms at 193.7° K; *d*—pellets activated at 400° C, isotherms at 273.1° K (upper scale).

sample of pellets at 0°. The nitrogen isotherm for the 350°-activated powder at −79.4° appears anomalous, as do the diffusion properties which were measured at the same time but there was no evident reason for this. The sorption of nitrogen at 700 mm and −78° reported by the Linde workers (5) agrees with the isotherm for the 400°-activated powder.*

**These authors also give a complete isotherm at this temperature which lies considerably above their single value and above our isotherm.*

Pellets (400°)	273.1	N_2	60.5	0.226		
		CH_4	65.5	0.355	0.64	0.60

[a]This isotherm did not fit the Langmuir equation.

[b]The separation factor was determined on a different sample, which gave the same sorption at 1 atm.

The monolayer values are one third to one half the total capacity of the crystal for tightly packed molecules of this size. Determination of such capacity cannot be made directly by sorption of nitrogen at liquid nitrogen temperatures because of the impracticably slow rates but sorption of oxygen, or of nitrogen by the calcium-exchanged form, at liquid nitrogen temperature is around 200 cc per g (5). Since the individual 11.4 Å diameter cavities would each then contain around fifteen molecules, the lower monolayer values at higher temperatures reflect a greater average mobility. The monolayer values decrease between 0° and −79.4°, which must mean that diffusion into parts of the crystal becomes vanishingly slow. In spite of the crystalline nature of this sorbent some inhomogeneities undoubtedly remain.

While complete isotherms for mixtures of nitrogen and methane were not obtained, several individual determinations were made. According to the Langmuir theory, the separation factor for a mixture should be the ratio of the "b" values for the pure gases. This comparison is made in Table I and the agreement is reasonably good. Barrer and Robins likewise found fairly good agreement with the Langmuir theory for pure gases and mixtures in chabazite (2).

Heats of Sorption

Isosteric heats of sorption were calculated from the isotherms at 193.7° and 273.1° K for the 400°-activated powder and these are shown in Fig. 3. For both gases, the heat of sorption appears to be essentially independent of concentration—a result similar to the general conclusions of Barrer and Sutherland (9) from much more extensive work on synthetic faujasite. There is a suggestion of a slight stepwise decrease at intervals of about 12 cc per g corresponding to integral numbers of molecules per cavity. Our value for nitrogen is somewhat lower and less concentration dependent than that given by Breck *et al.* (5).

Lattice Swelling during Sorption

An attempt was made to detect any expansion of the crystal lattice accompanying sorption. Using a Norelco X-ray diffractometer with a Geiger counter scanner the 832 and 910 reflections were examined relative to the 122 quartz line which fell between them. A dehydrated sample of the zeolite was allowed slowly to hydrate in the diffracto-

For personal use only.

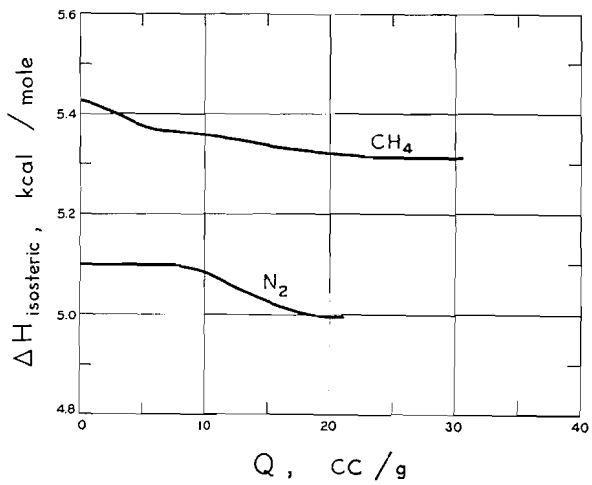

FIG. 3. Isosteric heats of sorption from isotherms at 193.7 and 273.1° K.

meter while the lines were scanned back and forth. The first measurements were taken about two minutes after the sample was opened to the air and from then until complete hydration there was no apparent change (±0.005 Å) in the unit cell spacing. (The value of 12.30 Å compares with 12.32 Å reported by Reed and Breck (6).) Observed expansions accompanying sorption of water on porous glass (10) and on carbon (11) are of the order of 0.2 to 0.3%. Other sorbates at higher pressures give similar expansion. With a maximum change of 0.05%, the crystalline zeolite appears to be more rigid than either of these amorphous materials.

Kinetic Properties—Pure Gases

As Barrer has shown (12), the slow step in these processes may be described as a process of diffusion. The amount of gas sorbed, Q, is found to be proportional to the square root of the time for as much as 50% of the total uptake. From this initial gradient, a diffusion coefficient may be calculated in the usual way according to the following equation:

$$D = \pi\left[\frac{V}{2A\,(C_0-Q_0)}\,\frac{\mathrm{d}Q}{\mathrm{d}(t^{\frac{1}{2}})}\right]^2. \qquad [1]$$

D, the diffusion coefficient, is defined by Fick's first law of diffusion

$$J = -D\,(\partial C/\partial x), \qquad [2]$$

where J is the flux of diffusing material and C is the concentration, expressed for the present work in cc (S.T.P.) per g of sorbent. C_0, the concentration at the outer surface, is taken as the equilibrium concentration from the sorption isotherm and Q_0 is the initial uniform concentration which may be zero. A and V are the external area and volume respectively of the sorbent particles. If D varies with concentration equation 1 gives an approximate average value over the concentration interval Q_0 to C_0. Crank (13) has discussed the evaluation of D as a function of C from a series of such measurements.

Obviously, for a given sample of sorbent, relative values of $D^{\frac{1}{2}}$ may be obtained from the ratio between $\mathrm{d}Q/\mathrm{d}(t^{\frac{1}{2}})$ and (C_0-Q_0).

The variation of D with concentration for each gas alone was examined for both

For personal use only.

powder and pellets.* Results for 350°-activated powder at 0° and −79° and for 400°-activated pellets at 0° are shown in Fig. 4. Measurements with the powder were made with constant C_0 and varying Q_0 and the individual measurements are shown as light horizontal lines over the range Q_0 to C_0 together with the fitted curve of D vs. C. Over the shorter concentration ranges at 0° no variation with concentration was found. Measurements with the powder were all made for $Q_0 = 0$ and the curve of D was obtained from the individual measurements according to the method described in Crank (13). Also shown in Fig. 4 are single values at each temperature for a powder sample activated at 400°, which was used for sorption from mixtures. Pellets activated at 300° gave D values about one quarter those for the 400° material and the isotherms were about 10% lower. A similar sensitivity appeared to exist for the powder.

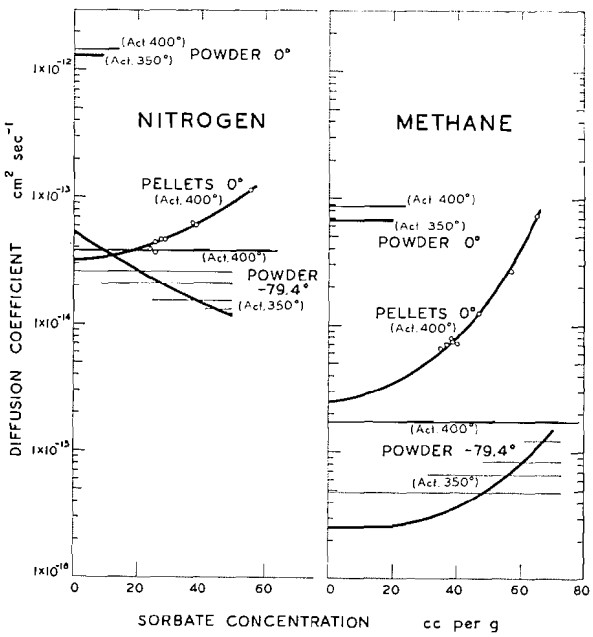

FIG. 4. Diffusion coefficients for pure nitrogen and pure methane. The light horizontal lines show individual measurements over the indicated concentration ranges. The measurements with the pellets were all made between 0 and the concentrations shown by the circles.

Diffusion coefficients for the pellets are seen to be considerably lower than for the powder. It is unlikely at these pressures (2 atmospheres and higher) that there is significant gas phase diffusional resistance in the intercrystalline pores of the pellets. All properties of the pellet form, the larger isobutane surface area, the slower rates of sorption, and the lower capacities, are consistent with the presence of some amorphous, non-sorbing binder, which, while adding to the total external surface, seals off part of the crystal surface through which sorption occurs.

**Most of the measurements with the pure gases were made under constant volume conditions where the pressure, and hence C_0, changes with time. As a result, the $Q-t^{\frac{1}{2}}$ plots begin to curve somewhat more quickly than with constant pressure sorption. The initial gradient is still given by equation 1, taking C_0 for zero time, and it can be shown (cf. ref. 13, pp. 31, 86) that the correction term to Q at time t near the beginning is approximately $(\pi t/4C_0)[dQ/d(t^{\frac{1}{2}})]_{t=0}[dC_0/d(t^{\frac{1}{2}})]$. By properly choosing the total volume of the system and the size of the sample, this correction at $t = 1$ minute can be kept within a few per cents.*

In general D increases with sorbate concentration. The one case of decreasing D was associated with an anomalous isotherm so that there is some uncertainty concerning its validity.

Relatively little has been reported previously for the concentration dependence of diffusion coefficients in dehydrated zeolites. Barrer and Brook (14) studying the sorption of several gases by chabazite found all the average diffusion coefficients to decrease with concentration—in some cases by a factor of 100. Barrer and Riley (15) for a synthetic chabazite-like zeolite found D to vary approximately as $(1-\theta)$, where θ is the fractional saturation. Tiselius (16) reported D for water in heulandite to increase rapidly with concentration and for ammonia in analcite (17) to be independent of concentration.

Activation energies for diffusion may be estimated from the diffusion coefficients for zero concentration. For the 350°-activated powder the following expressions are obtained:

$$\text{nitrogen: } D = 2.3\times10^{-9}\exp(-4070/RT),$$
$$\text{methane: } D = 5.8\times10^{-8}\exp(-7420/RT).$$

The D_0 values are of the same order as those reported for diffusion in chabazite (14).

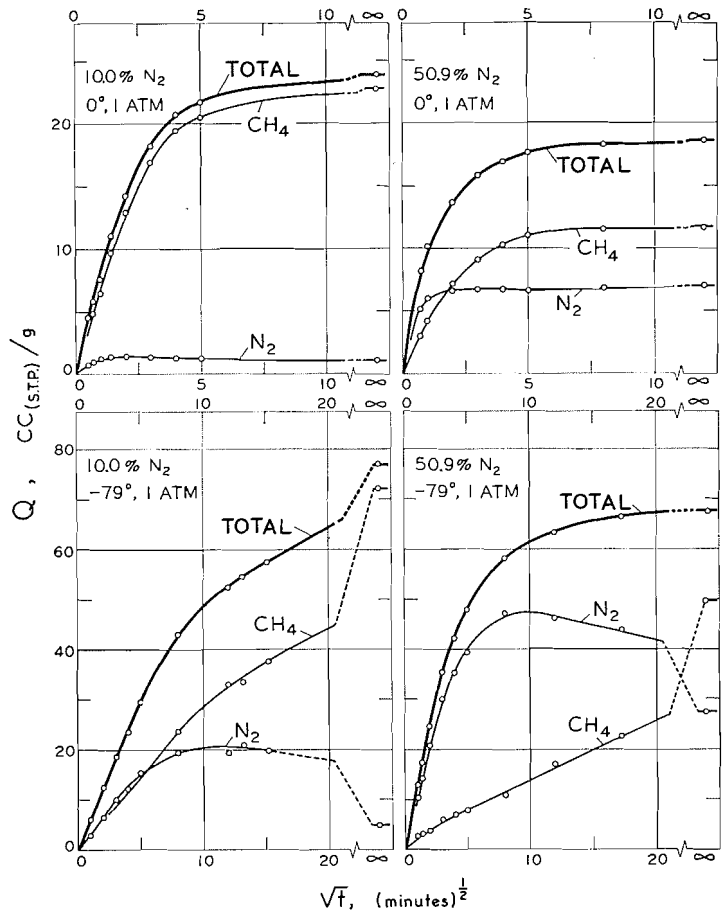

FIG. 5. Sorption from mixtures at 193.7° and 273.1° K. Zeolite powder activated at 400° C.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12

The activation energies are close to the 3.5 and 7.5 kcal that Kington and Laing (29) calculated as one set of possible values for diffusion in chabazite.

Mixtures

Sorption from mixtures containing 10.0% nitrogen and 50.9% nitrogen at 1 atmosphere and at 0° and −79.4° C is summarized in Figs. 5 and 6. The sample of powdered zeolite was activated at 400° C and gave equilibrium sorptions in agreement with the Langmuir isotherms in Table I. Relative diffusion coefficients for the pure gases were measured only at 1 atmosphere.

The most striking feature of these measurements is the maximum in the total nitrogen sorption, which occurs at a time prior to the establishment of complete equilibrium. This is seen in Fig. 5 only for the lower temperature, it may occur also at 0° but at a very short time where measurements are difficult to get. Measurements with samples of the pelleted zeolite (which had lower diffusion coefficients) did show a distinct maximum in the nitrogen sorption from a 10% mixture at 0°. As can be seen in Fig. 5, the initial sorption of each component is approximately linear in $t^{\frac{1}{2}}$, although less so than for the pure gases.

The degree of separation achieved by sorption from a mixture is often described by a separation factor, α, defined as follows:

$$\alpha_{N_2} = (X_{CH_4}/X_{N_2})\,(Y_{N_2}/Y_{CH_4}), \qquad [3]$$

where X and Y are the mole fractions in the gas and sorbed phases respectively. Y, of course, is an average value over the crystal, which will be uniform only at equilibrium. As shown in Fig. 6, α decreases from an initial value indicating nitrogen enrichment in the sorbed phase to an equilibrium value showing preferential sorption of methane. The value at low times is uncertain; gas diffusion resistances and depletion of the gas phase will tend to make it low; if the individual sorptions from a mixture are each truly initially linear with $t^{\frac{1}{2}}$, α should remain constant.

Fig. 7 shows plots of the variation of α with time for several experiments with the

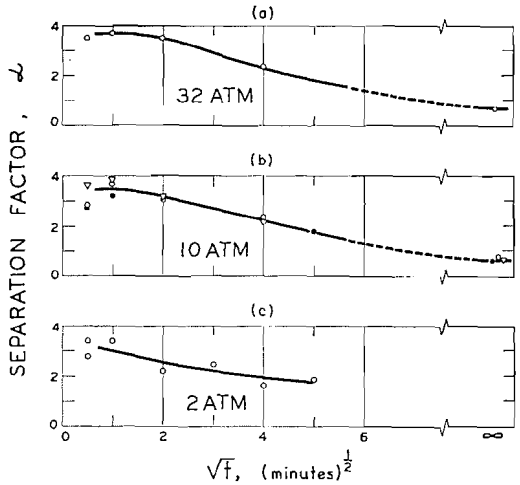

FIG. 7. Separation factors for sorption from 10.0% nitrogen mixture at 273.1° K with zeolite pellets. The different symbols for sorption at 10 atm refer to different sorbent activities.

zeolite pellets. These are very similar to those for the powder, although the actual sorption rates are much lower.

From the initial gradient of each component one may, formally at least, calculate a diffusion coefficient using equation 1 and taking for C_0 the equilibrium sorption for that component. The ratio of diffusion coefficients may also be expressed in terms of the separation factors as follows

$$\alpha_{\text{initial}} = \alpha_{\text{equilibrium}} (D_{N_2}/D_{CH_4})^{\frac{1}{2}}. \quad [4]$$

Diffusion coefficients thus determined in the mixture are compared with the values for the pure gases in Table II. It can be seen that while methane appears to have the same apparent D in the mixture as alone, nitrogen has a much enhanced value and thus the ratio is also higher. Since the increase in the apparent D for nitrogen is dependent also on the gas phase composition the simple approach of using the pure gas values for D in equation 4 is not satisfactory for predicting the behavior of mixtures.

DISCUSSION

Diffusion phenomena are usually approached from the point of view of Fick's Law (equation 2) even though in practice the resultant diffusion coefficient is markedly concentration-dependent. As a rule this is not too serious a drawback in view of the extensive experience and mathematical methods which have been accumulated to interpret measurements and to predict diffusion rates for different types of variation of D with concentration. However in the present system the Fick's Law approach is seriously inadequate. Not only are the diffusion coefficients in the mixture different from those for the pure gases but this approach can give no indication that the total sorption of the faster moving component (nitrogen) passes through a maximum before the final equilibrium is reached. The existence of such a maximum means that, in part, diffusion must be occurring under a negative Fick diffusion coefficient—a very uncommon, if not unique, situation.

It is therefore worth while to examine an alternative approach to diffusion. The chemical potential was suggested by Hartley in 1931 (18) as the fundamental driving force for electrolytic diffusion, and other sorts of diffusion have since been considered as flow under a gradient in chemical potential (19, 20, 21, 22). The chemical potential would appear also to be the driving force suggested by the methods of the thermodynamics of irreversible processes (23, 24), although this approach has not been carried through in detail for diffusion of adsorbed films. Babbitt (25, 26, 27) has approached diffusion from a hydrodynamical point of view and considers the surface diffusion of an adsorbed film as due to the gradient in spreading pressure.

The spreading pressure and the chemical potential of an adsorbed film are similar potential functions and are related as follows (28):

$$d\phi = \Gamma_A d\mu_A + \Gamma_B d\mu_B,$$

where ϕ is the spreading pressure, Γ is the concentration of adsorbate in moles per unit area, μ is the chemical potential, and A and B are two adsorbates. For a single adsorbate, the gradient in spreading pressure is therefore equal (apart from a constant factor) to the gradient in chemical potential multiplied by the adsorbate concentration. If, following other authors (18, 19, 20, 21, 22), we assume that the velocity of diffusion is proportional to the gradient in chemical potential, the two approaches are essentially equivalent in taking as the law of diffusion:

$$J = Cv = -CL\,(\partial\mu/\partial x), \qquad [5]$$

where J is the total flux of diffusing material in the x-direction in moles per unit time through unit cross-sectional area, C is the adsorbate concentration in moles per unit volume, v is the average diffusion velocity, and L is a proportionality constant.

For ideal gas diffusion or for diffusion in a mobile monolayer (27) this expression is equivalent to Fick's Law. For an adsorbed film obeying the Langmuir isotherm

$$\partial\mu/\partial x = (\partial\mu/\partial C)(dC/dx) = (RT/p)(dp/dC)(dC/dx),$$

where p is the partial pressure of the gas (assumed ideal) in equilibrium with sorbed phase of concentration C. This gives for the flux of diffusion

$$J = Cv = -[RTL/1-\theta](dC/dx), \qquad [6]$$

where $\theta = C/C_{\text{monolayer}}$. This result is identical with the one Babbitt obtained taking a constant resistive force per molecule. By comparison with equation 2 it is seen that

the Fick diffusion coefficient should accordingly vary as $1/(1-\theta)$, which is roughly what the present results show.

One might expect L to vary with concentration if, for example, there is any change in the openings in the crystal channels accompanying sorption. In view of the X-ray measurements reported above and the calculations of Kington and Laing (29) for chabazite, it is unlikely that the change in activation energy for diffusion would be more than 100 cal, or beyond experiment error. A difficulty remains of explaining the strong decrease in D which Barrer observed. He suggested, in effect, an additional entropy term (30) but this, presumably, is already included in the chemical potential function.

Mixtures

Let us now consider the sorption of a mixture of gases, A and B, as occurring under a gradient in chemical potential. The simplest approach is to assume that the flux of A is still given by equation 5, where the concentration and chemical potential are for A in the mixed sorbed phase. One could allow for an interaction with the other gas by assuming a more general expression:

$$J_A = C_A v = -C_A [L_{AA}(\partial\mu_A/\partial x)+L_{AB}(\partial\mu_B/\partial x)].$$

There is at present no evidence to justify such an extension so L_{AB} will be taken as zero. The presence of B will none the less affect the diffusion of A, since it is included in the mixed Langmuir isotherm

$$p_A = \theta_A/b_A(1-\theta_A-\theta_B).$$

Proceeding as before, using the chemical potential for the gas in equilibrium with C_A and C_B, we obtain

$$J_A = -[RTL_A/(1-\theta_A-\theta_B)] [(1-\theta_B)(dC_A/dx)+\theta_A(dC_B/dx)] \quad [7]$$

with an analogous expression for J_B, the flux of B.

This equation is adequate to explain the observed behavior in a qualitative way. Fig. 8 suggests the distribution of nitrogen and methane with distance from the external crystal surface at different times in the early stages of sorption. The relative amounts of the two substances are proportional to the actual values for a 10% nitrogen mixture at −79° C. Fig. 8 (*a*) is the hypothetical case of methane being unable to penetrate the lattice and θ_B being 0 everywhere but at the outer surface. Figs. (*b*) and (*c*) represent successive stages in the real situation. In region 1 a positive flux of A exists because although $-dC_A/dx$ is negative, $-dC_B/dx$ is strongly positive, and hence the sum of the two terms in equation 7 is positive. In the same region the flux of B will be less than that of pure B because of the negative value of $-dC_A/dx$. In region 2 $-dC_B/dx$ becomes smaller while $-dC_A/dx$ changes from negative to positive and hence a positive flux of A remains. In region 3 the situation is essentially diffusion of a single gas.

An alternative qualitative approach is to consider the equilibrium distribution of A corresponding to any given distribution of B (dashed lines in Fig. 8). The driving force for diffusion of A is a function of the gradient in the difference between this equilibrium concentration and the actual concentration. This gradient is always negative as in ordinary diffusion.

The uptake of A from a mixture is greater than from pure A at a pressure giving the same exterior surface concentration. Because of the high local concentrations the sorption of A may for a time exceed the equilibrium value at the surface, hence the observed

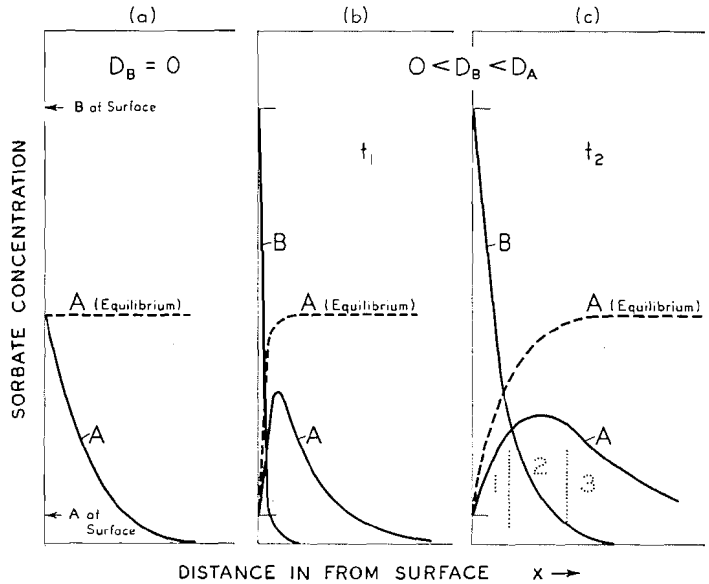

FIG. 8. Sorption from mixtures. Distribution of the sorbates within the crystal. Qualitative curves for 10% nitrogen mixture at 193.7° K. (*a*) Hypothetical case $D_{CH_4} = 0$; (*b*) and (*c*) successive distributions in the actual situation.

maximum. This maximum is more pronounced with the 10% than with the 50% nitrogen mixtures because the curvature of the isotherms gives a greater relative advantage to low partial pressures of nitrogen.

The slower gas, according to equation 7, should be somewhat retarded in the mixture. This appears to be so in the 50% mixture but the evidence is inconclusive.

In view of the complexity of the relationship between the Fick diffusion coefficient and concentration, it is somewhat surprising that the initial sorption-$t^{\frac{1}{2}}$ relationship holds as well as it does. The measurements suggest a somewhat S-shaped plot. An integration of equation 7 for the two species would be necessary to establish the precise shape and hence to quantitatively test this approach.

One may say, in general, that the distinctive feature of the diffusion of a mixture of gases into a porous solid is competition for the limited surface. Consequently, merely specifying the concentration of one sorbate is not a complete description and we may have the apparently anomalous flow of material from regions of low to high concentration. This paper has attempted to show that, qualitatively at least, these anomalies are removed by treating diffusion as flow under a gradient in chemical potential.

RADIATION CHEMISTRY OF SOLUTIONS

II. DOSE-RATE, ENERGY, AND TEMPERATURE DEPENDENCE OF A LEUCO TRIARYLMETHANE DOSIMETER SOLUTION[1]

W. A. Armstrong and G. A. Grant

ABSTRACT

The dose-rate, energy, and temperature dependence of the system 10^{-4} *M* 4,4′-(5-chloro-2-thenylidene)bis[N,N-dimethylaniline], 10^{-4} *M* ferrous ammonium sulphate, 0.1 *M* sodium chloride, and 7×10^{-3} *M* hydrochloric acid has been investigated. No energy dependence was observed in the range 0.16 to 2.0 Mev and no dose-rate dependence was observed in the range 4 to 230 rads/minute. However, with dose rates of 400 to 1200 rads/minute, postirradiation dye fading was observed. In the dosage range 0 to 1000 rads this fading is not extremely serious. The system is slightly temperature dependent at temperatures lower than 30° C and markedly dependent at higher temperatures. Dye yields of samples irradiated at 30° C were 10% higher than those of samples irradiated at 15° but 33% lower than those of samples irradiated at 45°.

INTRODUCTION

In a previous report (2), the effects of gamma radiation on acidic aqueous solutions of a number of 4,4′-thenylidene bis[N,N-dimethylaniline] compounds were described. Of the systems studied, the one best suited for dosimetric purposes consisted of 10^{-4} *M* 4,4′-(5-chloro-2-thenylidene)bis[N,N-dimethylaniline], 10^{-4} *M* ferrous ammonium sulphate, 0.1 *M* sodium chloride, and 7×10^{-3} *M* hydrochloric acid. With this system, the dye yield, as measured by the optical density at the main absorption peak of 633 mμ, increases linearly with increasing doses from zero to at least two thousand rads.

The common failing of most dosimeters developed for use in the low dosage range is their dose-rate and energy dependence. This is particularly true of systems based on acid formation from the decomposition of chlorinated hydrocarbons (4, 5, 6) where the mechanism involves a chain reaction. With this type of system it is necessary to shield out low-energy radiation and add some chain-breaking inhibitor.

Although the calculated *G* value of approximately one for the aqueous leuco system indicates the absence of chain reactions, the complicated mechanism is such that other factors might lead to dose-rate and energy effects. The present investigation was undertaken to determine the energy, dose-rate, and temperature dependence of the system.

EXPERIMENTAL

The radiation sources used to obtain the desired range of energies and dose rates are listed below:

1 curie of Cs^{137}	300 Kev Muller X-ray machine
150 curies of Co^{60}	2 Mev General Electric X-ray machine
300 curies of Co^{60}	2 curies of Cs^{137}

Procedure

The preparation of the system 10^{-4} *M* 4,4′-(5-chloro-2-thenylidene)bis[N,N-dimethylaniline], 10^{-4} *M* ferrous ammonium sulphate, 0.1 *M* sodium chloride, and 7×10^{-3} *M* hydrochloric acid has been described elsewhere (2). Solutions were found to be slightly

[1]*Manuscript received May 23, 1958.*
Contribution from Defence Research Board, Defence Research Chemical Laboratories, Ottawa, Ontario. Issued as D.R.C.L. Report No. 257.

light sensitive but blanks showed no change in color during the time required to complete an irradiation (as long as seven hours in a lighted room). Pyrex tubes of 9 mm inside diameter containing 3.3 ml of solution were used throughout. These tubes had a wall thickness of 2 mm, sufficient to ensure that electronic equilibrium was attained during the irradiations.

All dose rates were determined with Fricke ferrous sulphate, 0.8 N sulphuric acid dosimeter solution. The yield of ferric ion was measured spectrophotometrically by its own absorption at 304 mμ. Dose rates were calculated as shown below.

$$\text{Dose rate} = (\eta Fe^{+3}/t) \cdot (100/G) \cdot (1.602\times10^{-12}/100) \text{ rads/minute}$$

where t = irradiation time in minutes,
G = yield of Fe^{+3} = 15.5 molecules per 100 ev,
ηFe^{+3} = number of ferric ions per gram,
$= (6.023\times10^{23}/\epsilon\times1\times1000\times d) \cdot D_s - D_b$ ions/g,

where ϵ = molar extinction coefficient,
1 = path length of spectrophotometer cell,
D_s = optical density of irradiated sample,
D_b = optical density of blank,
d = density of solution.

Thus dose rate $= 9.649\times10^8 \cdot [(D_s-D_b)/G.\epsilon.1.d.t]$ rads/minute.

The energy absorbed in our system (E_S) can be related to the energy absorbed in the ferrous sulphate dosimeter (E_D) by the following equation:

$$E_S = E_D \cdot \mu_S/\mu_D$$

where μ_S = mass absorption coefficient of the system,
= mass absorption coefficient of 0.1 M sodium chloride.
μ_D = mass absorption coefficient of ferrous sulphate dosimeter,
= mass absorption coefficient of 0.8 N sulphuric acid.

For 160 Kev photons $\mu_S/\mu_D = 0.1479/0.1478 = 1.0007$ and for 1 Mev photons $\mu_S/\mu_D = 0.06336/0.06321 = 1.0024$. Hence for irradiations using the available sources previously mentioned $E_S = E_D$ to within 0.2%.

The housing and use of the 1-curie Cs^{137} source has been previously described (2). Eight sample tubes may be placed around this source and irradiated with gamma rays of 0.66 Mev effective energy at a dose rate of approximately five rads/minute.

The 150-curie Co^{60} source has been described by Aitken, Dyne, and Trapp (1). Three capsules, each containing about fifty curies, form a ring around the sample space. The capsules are attached to adjuster rods and the radiation flux is varied by moving the adjuster rods. Samples to be irradiated are placed on a lead piston and lowered into position. The introduction or removal of a sample requires less than one second. Samples can be irradiated at dose rates of 400 to 2000 rads/minute.

The 300-curie Co^{60} source is designed to give a narrow horizontal beam with a dose rate of 130 rads/minute at the collimator mouth. Because of the narrow field and the uncertain time required to swing the source into position, only one run was made with this source.

The Muller X-ray machine was operated at 300 kv and 10 ma. The beam was filtered to give radiation of 160 Kev effective energy, as measured in copper. With this arrangement samples can be irradiated at a maximum dose rate of 235 rads/minute.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

The General Electric machine was operated at 2 Mev and 1.5 ma and the unfiltered radiation used. The dose rate from this machine is very high, being 1000 rads/minute at a distance of 45 cm from the target. As it took approximately five seconds for the machine to reach operating conditions, doses of the desired magnitude (0 to 2000 rads) could not be measured as accurately as with the other radiation sources.

The temperature-dependence studies were performed using a 2-curie Cs^{137} source. The source is placed in the center post of a lucite box. Eight sample tubes may be placed in the box around the source each tube being $1\frac{3}{4}$ in. from it. Water from a constant-temperature bath is pumped through the box during irradiation. With this arrangement samples are irradiated at a rate of approximately 250 rads per hour.

RESULTS

1. Dose-Rate Dependence

Samples were irradiated with 160 Kev X-rays at dose rates of 6, 20, 90, and 235 rads per minute. The results plotted in Fig. 1 as dye yields recorded as optical densities measured at 633 mμ against dose in rads show no dose-rate dependence in this range.

Higher dose rates were obtained with the 150-curie Co^{60} source. Irradiations were made using dose rates of 400, 790, and 1200 rads/minute. Optical densities were measured 15 minutes after irradiation and again $\frac{3}{4}$ hour later. As illustrated in Fig. 2, there is a considerable postirradiation dye fading at these dose rates. However the degree of fading is the same, within the range of experimental error, for each of these dose rates. Results obtained with a dose rate of 4 rads/minute using the 300-curie Co^{60} source are also included in Fig. 2. No dye fading was observed at this dose rate. Optical densities measured 15 minutes after irradiation at dose rates of 400 rads/minute or greater are about 8% higher than those measured after irradiation at dose rates of 4 rads/minute, while optical densities measured 1 hour after irradiation at dose rates of 400 rads/minute or greater are about 8% lower than those measured after irradiation at dose rates of 4 rads/minute. The results of a further study of postirradiation dye fading are given in Table I.

TABLE I

These results indicate that the dye concentration reaches a maximum prior to 15 minutes after irradiation, decreases for the next one to two hours, after which it changes only slightly.

A number of changes in the system were made in an attempt to decrease the after reaction. Increasing the leuco concentration from 10^{-4} M to 5×10^{-3} M increased the

FIG. 2. Effect of dose rate with 1.25 Mev irradiation: ◒ 4 rads/minute, □ 400 rads/minute, △ 790 rads/minute, ○ 1200 rads/minute. Open symbols indicate measurements made 15 minutes after irradiation, darkened symbols 1 hour after irradiation.

amount of dye fading. With this system, the optical density of a sample which received a dose of 1000 rads at a dose rate of 1200 rads/minute decreased by 30% during the first hour following irradiation. Decreasing the sodium chloride concentration decreased greatly the sensitivity of the system and did not eliminate fading.

The effect of high dose rates on the corresponding trifluoroacetic acid system was also investigated. The system consisted of 10^{-4} *M* 4,4′-(5-chloro-2-thenylidene)bis[N,N-dimethylaniline], 10^{-4} *M* ferrous ammonium sulphate, 0.1 *M* sodium chloride, and 5×10^{-3} *M* trifluoroacetic acid. Dose-rate effects are shown in Fig. 3. As well as showing postirradiation fading, dye yields for doses received at 1200 rads/minute were about 18% lower than for doses received at 5 rads/minute.

For personal use only.

2. Energy Dependence

In Fig. 4, dye yields recorded as optical densities are plotted against dose in rads for primary energies of 0.160, 0.660, and 1.25 Mev. Dose rates were approximately five rads/minute in each case. There is no detectable energy dependence in the range 0.160 to 1.25 Mev.

Because of the machine design, irradiation with 2 Mev X-rays at this low dose rate was not possible and dye fading at high dose rates made it difficult to compare yields with those obtained using lower-energy radiations. However, as shown in Fig. 5, optical

densities of solutions irradiated in one case with 1.25-Mev γ-rays at 1200 rads/minute and in the other with 2-Mev X-rays at 920 rads/minute, when remeasured at corresponding times after irradiation, show no variation attributable to energy effects.

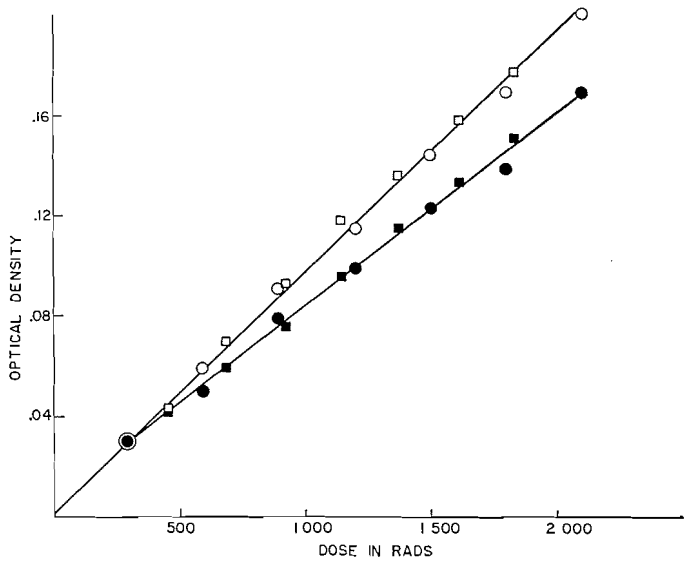

FIG. 5. Effect of energy at high dose rates (1000 rads/minute): ○ 1.25 Mev γ-rays (1200 rads/minute), □ 2 Mev X-rays (920 rads/minute). Open symbols indicate measurements made 15 minutes after irradiation, darkened symbols 1 hour after irradiation.

3. *Temperature Dependence*

Samples thermostated at temperatures from 15° to 45° C were irradiated with Cs^{137} γ-rays and optical densities measured after samples had been brought to room temperature. The optical densities of samples at various temperatures receiving given doses are listed in Table II. The slope of a plot of optical density vs. dose for each temperature is also given. The system is slightly temperature dependent at temperatures lower than 30° C and markedly dependent at higher temperatures. Raising the temperature from 20° to 30° C increases the dye yield per rad approximately 6%. However raising the temperature from 30° to 45° C increases the dye yield per rad approximately 22%.

TABLE II

DISCUSSION

As the mechanism of this system is not completely clear, the postirradiation fading at dose rates higher than 200 rads/minute cannot be wholly explained. Studies of the oxidation potential of the leuco compound (3) indicate that destructive oxidation of the dye occurs near the oxidation potential of the leuco compounds. Hence species formed during radiolysis which will oxidize the leuco compound may also be capable of destroying the dye. The dye fading at high dose rates is then probably due to the build-up in concentration of a dye-destroying species of relatively long life. The temperature dependence also supports the suggestion of the presence of a long-lived reactive species.

The postirradiation fading is not too serious in the range 0–1000 rads. Optical densities measured 15 minutes to 24 hours after irradiation at dose rates of 400–1200 rads/minute are within 8% of values obtained after irradiation at dose rates of 5–230 rads/minute. Optical densities measured at times greater than $1\frac{1}{2}$ hours after irradiation at high dose rates are within 2% of each other and are 6% to 8% lower than values obtained with low dose-rate exposures.

Although no temperature effects were observed when the dosimeter solution was being used at room temperature, thermostating the samples revealed a slight temperature dependence at temperatures lower than 30° and a considerable dependence at higher temperatures. A number of runs were carried out at 25° and 30° C. In all cases, dye yields for a given dose were the same. Hence only slight errors are introduced when working at room temperatures.

The system described in this report has been examined spectrophotometrically to determine the linearity of response, accuracy, reproducibility, dose-rate, energy, and temperature dependence. The results show that, in the energy range 160 kev to 2 Mev and with dose rates of 4 rads/minute to 1200 rads/minute, doses of 140 to 1000 rads absorbed at room temperature can be measured spectrophotometrically with 1-cm cells to within $\pm 8\%$. With dose rates of 4 rads/minute to 200 rads/minute, doses in this range can be measured more accurately as there are no postirradiation effects. At temperatures higher than 30° C there is a marked temperature dependence. The system should prove useful as a laboratory chemical dosimeter when employed within the limits outlined above.

ACKNOWLEDGMENTS

The authors wish to express their thanks to Dr. W. F. Baldwin and Dr. P. J. Dyne of Atomic Energy of Canada Limited for making available the 2 Mev X-ray machine and the 150-curie cobalt source as well as for valuable assistance and discussion. The authors would also like to thank Dr. J. A. Carruthers of these laboratories for the use of radiation sources.

SYNTHESIS OF N-SUBSTITUTED DIISOPROPANOLAMINES, THEIR SEBACATE POLYESTERS AND POLYURETHANE ELASTOMERS[1]

JEAN L. BOIVIN

ABSTRACT

Several N-substituted diisopropanolamines were prepared by reacting aqueous solutions of amines with excess propylene oxide at ordinary pressure but higher N-substituted diisopropanolamines had to be prepared in an autoclave at 200° C. The ionization constants of these bases were measured and recorded as pK_a values. Their infrared absorption spectra gave bands common to all diisopropanolamines mainly at 3.04, 7.14, 7.55, 7.85, 9.45, 10.6, and 11.95 microns. Their condensation with sebacic acid gave the corresponding polyesters, which were soluble in strong acids and had molecular weights of about 1500. The hydroxyl-terminated polyesters were cured with a slight excess of 2,4-tolylene diisocyanate at 100° C for 2 days to yield elastomers of brittle temperatures in the region of −50° C.

INTRODUCTION

During the course of a research project, there were indications that elastomers containing tertiary amino derivatives in the recurring unit of the chain would be valuable elastomers with respect to their low-temperature properties and toughness. Our attention was drawn to the N-substituted diisopropanolamines[2] as starting diols in the condensation with dibasic acids. It seemed that the N-substituted diisopropanolamines have not been described in the literature, but diisopropanolamine itself has been prepared by allowing aqueous ammonia to react with propylene oxide.

Preparation of N-Substituted Diisopropanolamines

The diisopropanolamines were prepared by adding propylene oxide in excess to aqueous solutions of various primary amines. The reaction is shown by the following equation:

$$RNH_2 + 2CH_3CH\!\!-\!\!\overset{\diagdown\,O\,\diagup}{}\!\!CH_2 \longrightarrow RN\left[CH_2CH(CH_3)OH\right]_2.$$

It is believed that secondary diols were formed, since their condensation with diacids was rather slow and the reaction of their polyesters with diisocyanate required 2 days for completion. The concentration of the aqueous amine solution varying from 25 to 95% as the molecular weight of the amine increased. Reactivity with propylene oxide was observed to decrease with increasing molecular weight. The condensation was usually carried out at 60–80° C by adding propylene oxide to the amine solution. The reaction was exothermic and cooling was necessary up to amylamine, but from amylamine to decylamine the mixture had to be heated and the addition of propylene oxide was slower. From dodecylamine to octadecylamine, the reaction had to be carried out in an autoclave at 200° C. Table I shows the diisopropanolamines prepared together with their physical properties and purity as based on their acid equivalent.

Tertiary butylamine yielded the monoisopropanolamine derivative only when the reaction was run at normal pressure. The yields ranged from 90 to 100% when the amine and propylene oxide were used in the respective molar ratios of 1:2.5. The water

solubility of the diisopropanolamines decreased in ascending the homologue series, reaching nearly complete insolubility with the N-octadecyl compound.

Condensation products were also obtained by reacting propylene oxide with various amines; details are recorded in Table II.

Basicity of the N-Substituted Diisopropanolamines

Since the diisopropanolamines contain a tertiary nitrogen atom, they should be quite basic and have a high ionization constant (K_b). It was noticed that the determination of the purity of the base by titration with standard acid using methyl red as indicator

was erratic with the high molecular weight N-alkylated diisopropanolamines. The ionization constant of the diisopropanolamines was therefore measured by dissolving the diisopropanolamines in standard acid and back-titrating with a standard base while recording the pH.

The pK_a was given by the middle of the flat portion of the titration curve and the ionization constants are recorded for these amines using the normal acidity scale (pK_a). The results given in Table II show that the first members of the series from C_3 to C_6 inclusive have strengths similar to that of ammonium hydroxide; the higher homologues are less basic until they reach a pK_a on the acid side. It is worth while to note that

*Determined graphically from the titration curves.
†Analysis by Micro-Tech Laboratories, Skokie, Illinois.

N-substituted monoisopropanolamines such as the N-methyl derivative are more basic than diisopropanolamine itself. Where two tertiary nitrogen atoms are present in the same molecule, two pK_a values were recorded indicating different degrees of ionization. Highly symmetrical molecules such as N,N′-bis-(2-hydroxypropyl)-piperazine exhibited only one ionization constant (pK_a of 7.1). In the case of N-morpholinoethyl diisopropanolamine the single pK_a obtained indicated that the two nitrogen atoms are equally electronegative.

Infrared Spectra

The infrared absorption spectra of all the N-substituted diisopropanolamines prepared were determined on a double beam Perkin–Elmer spectrophotometer between sodium chloride plates. They all exhibit similar absorption bands at 3.04, 7.14, 7.55, 8.85, 9.45, 10.6, and 11.95 microns excepting the CH bands.

The diisopropanolamines, which are probably associated hydroxylated compounds, exhibit an intense absorption band in the region of 3.0 to 3.04 microns which can be

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

attributed to the OH vibration. Most of the other bands are practically common to all the compounds studied and the N-substituents have no effect on the spectra at least for the N-alkyl derivatives. Substituents containing nitrogen or oxygen influenced the spectra in the region of 8.5 to 10 microns.

Polyesters from N-Substituted Diisopropanolamines and Sebacic Acid

The N-substituted diisopropanolamines were condensed with sebacic acid using a molar ratio of 1.1 to 1.0 at a temperature of 210–220° C for 20 hours, during which time water was eliminated. Nitrogen was passed through the melt to provide stirring and prevent oxidation. After heating for a further hour at 220° C under vacuum, the polyesters of sebacic acid were obtained and their molecular weight estimated by the hydroxyl end-group analysis after making a correction for the acidity number. Table IV shows the molecular weight, acidity number, and viscosity of the polyesters prepared. Determination of the pK_a values showed that they were weakly basic. The pK_a values range from 3 to 5.

Polyurethane Elastomers

The hydroxyl-terminated polyesters of N-substituted diisopropanolamines and sebacic acid were treated with various quantities of 2,4-tolylene diisocyanate, mixed thoroughly, and cured 48 hours at 100° C. The low-temperature brittleness of the elastomers was measured by determining the Gehman freeze point. Table IV shows the results. In most cases, the brittle point of the best specimen of elastomer was in the region of −50° C. The elastomers obtained from low molecular-weight-substituted diisopropanolamines were tough but the strength decreased in ascending the series. Owing to the high acid numbers of most polyesters prepared the elastomers were not free of bubbles.

CONCLUSION

There is an indication that N-substituted diisopropanolamine containing elastomers are slightly better at low temperature than those made from non-basic polyesters. However, these diols will be valuable intermediates to terminate any polymeric chain by secondary hydroxyl groups which are less reactive toward diisocyanates than the primary functions.

THE SPONTANEOUS PRECIPITATION OF HYDRATED ALUMINA FROM ALUMINATE SOLUTIONS[1]

T. VRBAŠKI,[2] H. IVEKOVIĆ,[3] AND D. PAVLOVIĆ[4]

ABSTRACT

The rates of spontaneous precipitation of hydrated alumina from unseeded and metastable sodium aluminate solutions of a molar relation for Na_2O/Al_2O_3 (α) ranging from 1.15 to 1.60 have been investigated. All precipitation curves showed autocatalytic characteristics with a pronounced induction period, during which no precipitation occurred, a steady state period, and a period of delayed precipitation. Empirical equations for calculating the maximum precipitation rate, for the time when this precipitation takes place, and for the amount of the precipitate at equilibrium for any of these aluminate solutions have been developed.

INTRODUCTION

The precipitation of hydrated alumina from metastable sodium aluminate solutions represents the basic reaction in the formation of alumina by the Bayer process.

This reaction has been the subject of extensive investigation using mainly hydrargillite as a seed substance (1, 2, 3, 4). Spontaneous process was also studied by Calvet *et al.* (5) and by Sato (6).

The experiments described below were carried out in order to obtain a closer insight into the kinetics of the spontaneous precipitation of hydrated alumina from unseeded aluminate solutions. The time after which first nuclei of hydrated alumina (hydrargillite) are formed in a clear solution is of greatest significance as the crystallites once formed act as seed substance (7). It is of great interest, therefore, to investigate the dependence of the induction period (6) on the molar relation (α), where $\alpha = Na_2O/Al_2O_3$, of the aluminate solution used.

As no crystallites are present in the clear solution at the beginning of the reaction, and since the precipitate formed will cause a considerable promotion of the precipitation rate, the precipitation would be expected to show autocatalytic characteristics (cf. 7). In the Bayer process such autocatalytic characteristics are masked by the action of the high concentration of seed material.

EXPERIMENTAL

Preparation of Sodium Aluminate Solutions

The solution of sodium aluminate was prepared in the way described in our previous paper (8). The aluminate solutions used were prepared by dilution of the stock solution with distilled water to a concentration of approximately one mole Al_2O_3 and 1.15 to 1.60 mole Na_2O.

The content of Al_2O_3 and Na_2O in the solution was determined by titration with 1 *N* HCl using tropeolin 00 and phenolphthalein respectively as indicators (9). The aluminate solutions were shaken continuously in stoppered Erlenmeyer flasks in a water bath at 30.0±0.1° C. When the agitation was discontinued the precipitate settled down quickly and the sample for analysis was taken from the supernatant liquid.

RESULTS

Each experiment was carried out using six different aluminate solutions. Their compositions are given in Table I.

TABLE I

THE COMPOSITION OF ALUMINATE SOLUTIONS

Solution	Al_2O_3, mole	Na_2O, mole	Initial molar relation for Na_2O/Al_2O_3 (α)	Molar relation for Na_2O/Al_2O_3 at equilibrium (α_e)
1	0.95	1.10	1.15	5.00
2	1.00	1.22	1.22	5.00
3	0.98	1.29	1.32	5.00
4	1.00	1.39	1.39	5.00
5	1.01	1.50	1.50	5.00
6	1.00	1.60	1.60	5.00

The solutions were prepared by diluting 100 ml samples of the freshly prepared stock solution to a volume of 150 ml. The molar percentage of the precipitated hydrated alumina was plotted against time. A family of curves was obtained as the molar relation for Na_2O/Al_2O_3 was varied. These are shown in Fig. 1. It was not found profitable to plot molar relation for Na_2O/Al_2O_3 against time because its values, depending on the initial molar relation, changed in a different way for each solution during the reaction.

All precipitation curves showed an autocatalytic trend with a characteristic induction period, during which no precipitation occurred, a steady state period, and a period of delayed precipitation.

(*a*) *The Induction Period*

It is evident from the Fig. 1 that the precipitation of hydrated alumina takes place

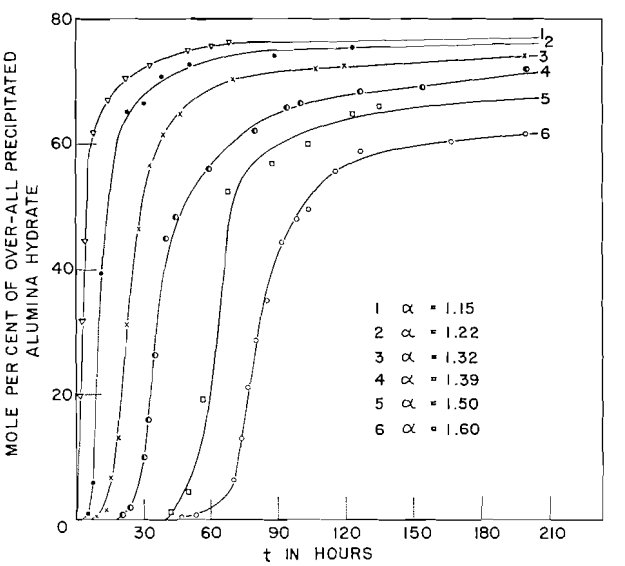

FIG. 1. Spontaneous precipitation of hydrated alumina from aluminate solutions of different molar relation for Na_2O/Al_2O_3. The volume of solutions was 150 ml, and the temperature 30.0±0.1° C.

only after an induction period, which becomes longer as the initial molar relation for Na_2O/Al_2O_3 is increased. This dependence of the induction period upon the initial molar relation is shown in Fig. 2.

The ratio of the induction period to the initial molar relation is not steady along the whole of the investigated region. The experimental curve (in Fig. 2) could be composed of two straight lines with an intersection point in S corresponding to a solution of a molar relation $\alpha = 1.385$ and an induction period of 685 minutes. Calvet *et al.* (10) found by thermochemical method of measuring the stability of solutions of sodium aluminate an instability ceiling at the same molar relation for Na_2O/Al_2O_3. This phenomenon might possibly be caused by a structural change of the aluminate solution (11) at this point. In the low molar relation region ($\alpha = 1.15$ to $\alpha = 1.40$) the increase of the induction period is slow, the slope being 62.0, i.e. only about a quarter of the succeeding slope over the region $\alpha = 1.40$ to $\alpha = 1.60$.

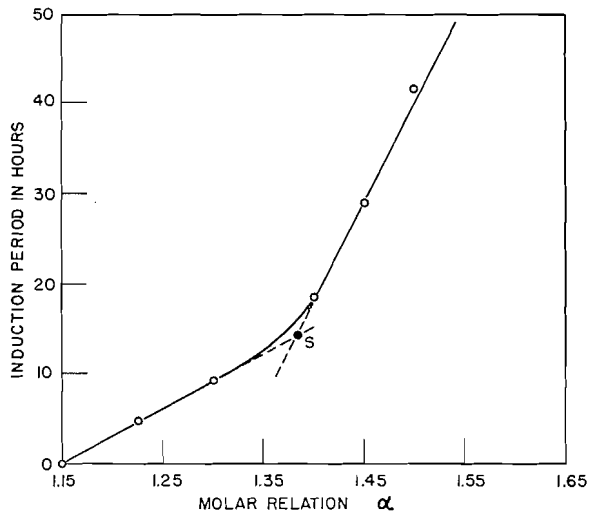

FIG. 2. The dependence of the induction period upon the initial molar relation for Na_2O/Al_2O_3.

(*b*) *The Equilibrium State*

In order to obtain data on the equilibrium state, the precipitation from solutions with higher molar relation had to be followed for up to sixty days. The amount of hydrated alumina precipitated at equilibrium was plotted against the initial molar relation. A straight line was obtained and could be expressed fairly well by the equation

$$C = 100 - 20\,\alpha, \qquad [1]$$

in which C is the molar percentage of over-all precipitated hydrated alumina and α the initial molar relation.

The molar relations established at equilibrium were found to be identical for all solutions and did not depend upon the initial molar relations used.

(*c*) *The Precipitation Rate*

The precipitation rate is higher if the initial molar relation of the aluminate solution is lower, as shown in Fig. 1. The amount of hydrated alumina precipitated in 100 minutes (ϕ) can be taken as a measure of the precipitation rate. Plotting the rates so obtained (ϕ) against time (t) we obtain a family of curves shown in Fig. 3.

For personal use only.

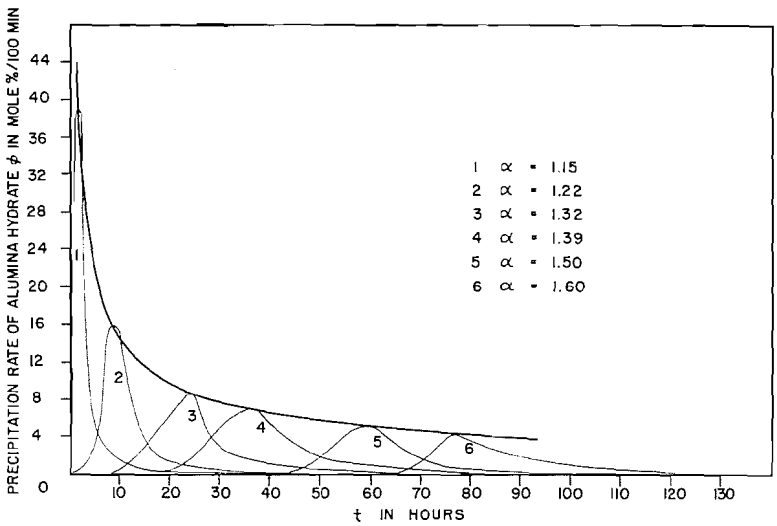

FIG. 3. Precipitation rates of hydrated alumina precipitated from aluminate solutions of various molar relations for Na_2O/Al_2O_3.

The maximum precipitation rate (ϕ_m) is higher if the initial molar relation (α) is lower. This relationship can be expressed by the equation

$$\log \phi_m = k(1/\log \alpha)^n, \quad [2]$$

where α is the initial molar relation, and n and k are constants. The average values of n and k are 0.761 ± 0.001 and 0.188 ± 0.001 respectively. They have been calculated from the equation [2] using pairs of corresponding values of α and ϕ_m. They could also be obtained graphically from a diagram in which log log ϕ_m versus log $1/(\log \alpha)$ was plotted. In the straight line so obtained n was the slope and log k the segment of the ordinate.

The maximum precipitation rate of any sodium aluminate solution of known initial molar relation can thus be readily calculated from the equation [2].

(*d*) *The Time of the Maximum Precipitation Rate*

Relationship between the maximum precipitation rate (ϕ_m) and the time of the maximum precipitation rate ($t_{\phi m}$) is obtained by connecting the peaks of the velocity curves in Fig. 3. This relationship can be expressed by the equation

$$\phi_m = k'(1/t_{\phi m})^{n'}, \quad [3]$$

where n' and k' are constants. The average n' and k' values calculated from the above equation or determined graphically, similarly as n and k values, are 0.610 ± 0.001 and 60.26 ± 0.15 respectively.

Combining [2] and [3] and eliminating ϕ_m the expression

$$t_{\phi m} = (\log k'/n') - (k/n')(1/\log \alpha)^n \quad [4]$$

is obtained.

Inserting numerical values of the constants into equation [4] we obtain

$$\log t_{\phi m} = 2.92 - 0.308(1/\log \alpha)^{0.761}. \quad [5]$$

The time of the maximum precipitation rate can thus be calculated directly from the initial molar relation for Na_2O/Al_2O_3.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

Comparison of the calculated and observed values of ϕ_m and $t_{\phi m}$ is given in Table II. The differences are within $\pm 1.15\%$.*

TABLE II

COMPARISON OF CALCULATED AND OBSERVED VALUES OF ϕ_m AND $t_{\phi m}$

Initial molar relation for Na_2O/Al_2O_3 (α)	ϕ_m		$t_{\phi m}$	
	Calculated by eq. 2	Observed	Calculated by eq. 4	Observed
1.15	38.9	39.0	2.0	2.0
1.22	16.2	16.1	8.6	8.8

On the Kinetics of Precipitation of the Hydrated Alumina

The family of curves in Fig. 1 indicates that the precipitation reaction behaves more like an autocatalytic reaction at higher molar relations and less so at lower molar relations when it seems to follow a simple logarithmic law.

This phenomenon can be readily explained on the basis of the expression for the autocatalytic reaction rate†

$$+dx/dt = (k_1+k_2x)(a-x), \qquad [6]$$

where k_1 is the first-order reaction rate constant, k_2 the constant of the autocatalysis, a the initial concentration of sodium aluminate, and x the concentration of hydrated alumina, i.e. of the catalyst produced at the time t. The use of this expression is only tentative. Attributing the discussed precipitation a reaction type of a definite order is not possible at present because of lack of information.

Since the precipitation does not start if crystallization nuclei are not present, k_1 is very probably small. As soon as the reaction initiates k_1 can be neglected compared to k_2x because x increases rapidly; x and thus (k_1+k_2x) tend to reach soon a final value and the precipitation reaction seems to behave like a first-order reaction. The same conclusion will be reached if we take into consideration similar expressions proposed by other authors (13).

In the solutions of low molar relation, crystallization nuclei are rapidly formed at the very beginning of the reaction and the entire course of precipitation seems to follow the first-order reaction law. In the solutions of higher molar relation similar behavior is observed after the initial autocatalytic period.

However, if an excess of seed material is added at the beginning of the reaction the precipitation reaction is expected to behave in the same way as that in the solutions of lower molar relation. This assumption has been confirmed by recent investigations of Herrmann *et al.* (7). The authors, however, pointed out that their empirically found expression should not be considered as a simple equation for a first-order reaction rate, although this expression showed some similarity with it.

**In conclusion it should be emphasized that for generalization of equations obtained the temperature dependence of the reaction should be determined. This will be the subject of a further study.*

†This expression can be deduced from the Ostwald's expression for the first-order reaction rate if the product formed acts as a negative catalyst (12).

AN INTERPRETATION OF THE MOISTURE DESORPTION ISOTHERM OF WHEAT[1]

H. A. Becker

ABSTRACT

It is shown that the moisture desorption isotherm of wheat can be interpreted in harmony with Cassie's theoretical assumptions regarding adsorption on localized sites by the equation

$$\frac{N}{S} = (1+K'f^n)\left(\frac{Kf}{1+Kf}\right),$$

where N is the number of adsorbed molecules per gram of wheat and S is the number of localized sites. $Kf/(1+Kf)$ is a Langmuir-type factor for adsorption of the low energy fraction of molecules, and $K'f^n$ is a factor for adsorption of the normally condensed fraction of molecules. In agreement with theory K', n, and S are independent of temperature. The dependence of K on temperature gives a value of -6.27 kcal/mole for the partial molal enthalpy of dilution of the low energy fraction of molecules, which is in the order of magnitude of a hydrogen bond. The analysis also illuminates the practice of the drying of wheat. An exact correspondence appears to exist between the calculated values of S and the apparent surface (or equilibrium) moistures observed in studying the diffusion of moisture out of wheat. The theoretical relation

$$m_s = 0.1157\ K/(1+K)$$

is therefore given for predicting apparent surface moisture contents in the vacuum drying of wheat, where

$$K = 3.05\times10^{-4}\exp(6270/RT).$$

Becker and Sallans (1) have made a comprehensive study of the moisture desorption isotherm of wheat. The isotherm was found to be sigmoid in shape and was described mathematically in three sections: at low relative vapor pressures, by the B.E.T. equation (2)

$$\frac{m}{m_L} = \frac{Kf}{1-f}\left(\frac{1}{1+(K-1)f}\right), \qquad [1]$$

where m is the moisture content, g/g dry basis, f is the relative vapor pressure, and m_L and K are constants; at intermediate relative vapor pressures, by the linear relation

$$m-m_0 = af, \qquad [2]$$

where m_0 and a are constants; and at high relative vapor pressures, by Smith's equation (3)

$$\frac{w-w_b}{w'} = \ln\frac{1}{1-f}, \qquad [3]$$

where w is the moisture content, g/g wet basis, and w_b and w' are constants. The use of the last two equations for accurate description of the isotherm was necessitated by the usual failure of the B.E.T. equation at intermediate and high relative vapor pressures. Even if put in the form for limited adsorption,

$$\frac{m}{m_L} = \frac{Kf}{1-f}\left(\frac{1-(n+1)f^n+f^{n+1}}{1+(K-1)f-Kf^{n+1}}\right), \qquad [4]$$

where n is the limiting number of layers of molecules, the B.E.T. equation will not accurately fit the data. However, the inexactness of the B.E.T. equation at all but

[1]*Manuscript received July 18, 1958.*
Contribution from the National Research Council, Prairie Regional Laboratory, Saskatoon, Saskatchewan. Issued as N.R.C. No. 4890.

low relative vapor pressures is of little consequence theoretically. The really irregular features of the data are (i) that the calculated moisture contents corresponding to a B.E.T. molecular monolayer, $m_L = 0.078$ g/g at 25° C and 0.060 g/g at 50° C, are markedly functions of temperature; and (ii) that there is no apparent relation between any of the constants in equations 1, 2, and 3 and the dynamic equilibrium moistures observed by the author (4) and by Becker and Sallans (5) in studying moisture diffusion out of the wheat kernel. It is the purpose of the present paper, therefore, to explain or eliminate these discrepancies.

THE ISOTHERM EQUATION

The B.E.T. equation was derived by Brunauer *et al.* (2) on the basis of a somewhat dubious evaporation–condensation mechanism. Cassie (6) has given the equation thermodynamic credence by derivation from statistical–thermodynamical arguments. In Cassie's view the equation is applicable to adsorption on localized sites, such as polar groups on a polymer molecule, rather than to adsorption on an unspecified surface. He postulated that the first molecule associated with each localized site is strongly adsorbed, while subsequently attached molecules are at the same energy level as in the normal liquid state. Adsorption of an essentially liquid fraction at vapor pressures below saturation is made possible by mixing with the low energy fraction. His version of the B.E.T. equation is written

$$\frac{N}{S} = \frac{Kf}{(1-f)}\left(\frac{1}{1+(K-1)f}\right), \qquad [5]$$

where N is the number of adsorbed molecules per gram of adsorbent and S is the number of localized sites. In the statistical–thermodynamical definition $K = (j_S/j_L)\exp(-\Delta\bar{H}_S/RT)$, which differs from Brunauer *et al.*'s definition by prefixing the ratio j_S/j_L where j_S and j_L are respectively the partition functions for molecules in the low energy state and in the normal liquid state; $\Delta\bar{H}_S$ is the partial molal enthalpy of dilution of the low energy (X) fraction of molecules; and R and T are respectively the gas constant and the absolute temperature. It appears that Cassie's arguments provide a reasonable and simple basis for interpretation of the moisture sorption isotherms of materials such as wheat. However, it can be expected that the course of multimolecular adsorption will rarely follow equations 1 or 4 exactly. If it is desired to obtain an accurate description of the adsorption isotherm with values of the B.E.T. constants which are consistent with their assumed behavior, then equation 4 should be written in a form which allows greater variation between the paths of adsorption of the "normally condensed" and the low energy fractions of molecules. A simple equation with flexible parameters for multimolecular adsorption, which still retains the theoretical skeleton of equation 5, can be formulated as follows.

Consider the adsorption of N molecules on X sites in a material which contains S localized sites. Following Cassie (6), we assume that X molecules are singly adsorbed, one to a site, with a constant, negative partial molal enthalpy of dilution, $\Delta\bar{H}_S$, in the order of several kilocalories. These X molecules provide the sites for adsorption of the remaining N–X molecules, which are assumed to be condensed with a zero partial molal enthalpy change. The adsorption of the X low energy molecules can reasonably be assumed, on the basis of Cassie's (6) and Enderby's (7) statistical–thermodynamical analyses, to be governed by the Langmuir form of equation 5

$$X/S = Kf/(1+Kf). \qquad [6]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

In Cassie's argument the adsorption of the N–X condensed molecules derives from random mixing with the X low energy molecules. It is obvious, however, that this process will be complicated by various influences resulting from the physical and chemical characteristics of both adsorbate and adsorbent. Even so, it appears that the state of the normally condensed molecules should be similar in some ways to a gaseous film in which the molecules are associated, on the average, in groups of n molecules each. The equation of state of such a film is (8)

$$\pi(n\sigma) = kT, \qquad [7]$$

where π is the film pressure, $\sigma = \Sigma/N$ is the area per molecule, Σ is the area of the film, and k is Boltzmann's constant. Conjunction with Gibb's equation

$$\pi = \frac{kT}{\Sigma}\int_0^f \frac{N}{f}\,df \qquad [8]$$

gives Freundlich's isotherm (1)

$$N = K'f^n. \qquad [9]$$

We shall therefore assume that the adsorption of the N–X normally condensed molecules on X available sites can be expressed by

$$(N-X)/X = K'f^n. \qquad [10]$$

Eliminating X between equations 6 and 10 we find for the adsorption isotherm

$$\frac{N}{S} = (1+K'f^n)\left(\frac{Kf}{1+Kf}\right). \qquad [11]$$

A definite physical significance can be attached to the parameters K and K' in this equation: at saturation the Langmuir part reduces to

$$X_1/S = K/(1-K) \qquad \text{or} \qquad K = X_1/(S-X_1), \qquad [12]$$

where X_1 is the number of occupied sites. Hence K is the numerical ratio of the occupied sites to the vacant ones at the saturation vapor pressure. Putting $S = X_1(1+K)/K$, equation 11 becomes

$$\frac{N}{X_1} = (1+K'f^n)\left(\frac{(1+K)f}{1+Kf}\right) \qquad [13]$$

and at $f = 1$, $N/X_1 = 1+K'$. Therefore K' can be thought of as the average number of normally condensed molecules per occupied site toward which adsorption tends at saturation.

THE EVALUATION OF THE ISOTHERM PARAMETERS

Before discussing the evaluation of the parameters S, K, K', and n, we shall summarize the assumptions to be made as to their behavior. The following assumptions are fundamental to equation 11:

(i) The number of localized sites, S, is a constant characteristic of the adsorbent.

(ii) The parameter K is independent of concentration but is dependent on temperature. The temperature dependency should be very nearly given by

$$\frac{\partial \ln K}{\partial\, 1/T} = -\frac{\Delta\bar{H}_s}{R}. \qquad [14]$$

(iii) The parameter K' and the exponent n are independent of temperature but may be dependent on concentration.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

The evaluation of the parameters may be carried out by trial and error treatment of data. A solution is obtained when the properties of the parameters are in accord with their assumed behavior. Eventually the exponent n will need to be considered as a function of the relative vapor pressure. The following cases may occur:

(i) $n = 0$. When n is equal to zero, K' will also be equal to zero, and the isotherm equation reduces to Langmuir's equation.

(ii) $n, K' =$ constants. The trial and error method should quickly yield a solution if n and K' can be treated as constants.

(iii) $K' f^n \ll 1$. In this case equation 11 reduces to Langmuir's equation.

(iv) K' and/or n are functions of relative vapor pressure. This most general case can be treated by writing equation 11 in the form

$$\frac{f(1+\phi(f))}{N} = \frac{1}{KS} + \frac{f}{S}, \qquad [15]$$

where $\phi(f) = K'f^n$. The problem then is to find a value of $\phi(f)$ which gives a linear relation between $f(1+\phi(f))/N$ and f, and a constant, temperature-independent value of S.

The general technique is illustrated by the following analyses of Bull's data (9) on the adsorption of water vapor by proteins or protein-like polymers. Figure 1 shows that a reasonably good correlation of the data on silk, wool, and gelatin is obtained by putting $1+K'f^n = 1+f+f^2$. (This substitution produces an approximation to the B.E.T. equation, since $1+f+f^2$ is an approximation to $1/1-f$.) The curves are linear in a wide region of relative vapor pressures, and the slopes of the linear regions are substantially independent of temperature. The moisture contents, m_L, corresponding to the number of localized sites, S, (m_L is given by the reciprocals of the slopes) are about 30% higher than predicted by the B.E.T. equation 1. A somewhat different relation is shown by nylon, Fig. 2, for which trial and error treatment of the data for 25° C gives

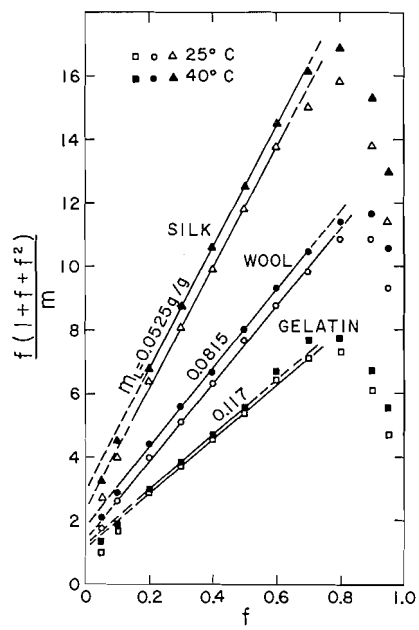

FIG. 1. Correlation of Bull's data on the adsorption of water vapor by silk, wool, and gelatin.

$K' = 5$ and $n = 2$. The data for 40° C show rather peculiar behavior at low relative vapor pressures. It may be noted that the B.E.T. equation does not fit the data on nylon at all.

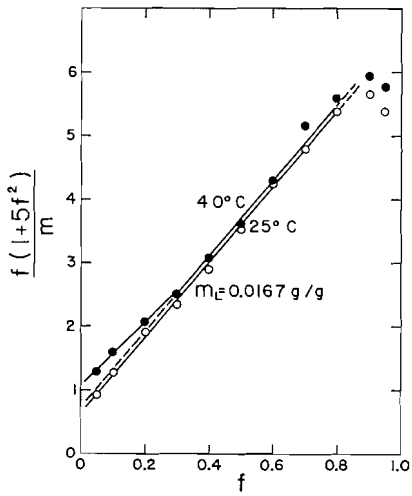

FIG. 2. Correlation of Bull's data on the adsorption of water vapor by nylon.

THE ANALYSIS OF THE MOISTURE DESORPTION ISOTHERM OF WHEAT

Becker and Sallans (1) determined the moisture desorption isotherm of wheat at temperatures of 25° and 50° C. As already noted in the introduction, the B.E.T. equation for $n = \infty$ was found to fit the data at low relative vapor pressures but gave values of the B.E.T. monolayer moisture content, m_L, which decreased markedly with increasing temperature. This discrepancy with Cassie's interpretation of m_L can be explained, most obviously, by hypothesizing an actual decrease in the number of localized sites available for adsorption. However, although the adsorptive capacity might diminish with rising temperature, owing to the exposure of non-polar areas, it is difficult to conceive of an over-all reaction which would cause a diminution of the number of polar groups exposed for water adsorption. We shall therefore accept the alternative explanation that the B.E.T. equation gives erroneous values of the parameters K and S, and assume that some form of equation 11 is applicable.

Trial and error examination of the data showed that the Langmuir form of the equation gives an excellent fit at low relative vapor pressures, Fig. 3. The values of the Langmuir parameters were thus found to be $K = 12.14$ and $m_L = 0.1157$ g/g at 25° C, and $K = 5.17$ and $m_L = 0.1178$ g/g at 50° C. As required, m_L so evaluated is constant within experimental error.

The data were subsequently analyzed to find empirical expressions for $K'f^n$. For this purpose the isotherm equation was arranged in the form

$$\frac{N}{S}\frac{1+Kf}{Kf} - 1 = K'f^n \qquad [16]$$

where $N/S = m/m_L$. Values of K' were calculated for integer values of n, and were found to have a minimum which moved toward higher vapor pressures with increasing value of n and reached the immediate neighborhood of $f = 1$ at $n = 4$. The minimum near $f = 1$, in value $K' = 2.2$, was then used to calculate values of n for a constant

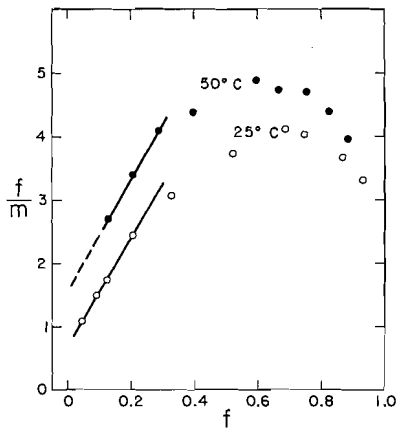

FIG. 3. Langmuir plot of moisture desorption equilibrium data on wheat.

K'. Figure 4 shows these values as a function of the relative vapor pressure. The relation is seen to be substantially independent of temperature, as it should be if the assumption of normal condensation of the multimolecularly adsorbed molecules has any truth. The calculations leading to Fig. 4 are summarized in Table I. It must be assumed that n becomes large at relative vapor pressures below 0.3 or, more likely, that K' becomes small, if the applicability of the Langmuir equation is to be retained.

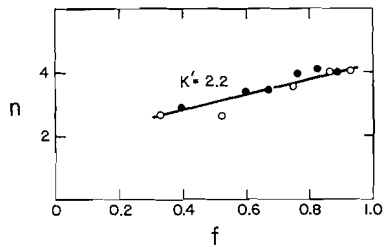

FIG. 4. Correlation of the exponent n with relative vapor pressure for $K' = 2.2$.

The rationale underlying the foregoing treatment of K' and n is as follows. The exponent n can be interpreted as being proportional to the number of normally condensed molecules on an average site. If so, it appears that n must increase with increasing relative vapor pressure and, for limited adsorption, approach constancy in the immediate neighborhood of $f = 1$. The parameter K' is in essence an equilibrium "constant", and if adsorption tends to a finite limit it is reasonable to assume that K' tends toward constancy at high relative vapor pressures. The analysis which has been given meets all of these conditions. K' is treated as a constant, and n increases with increasing relative vapor pressure and approaches constancy at $f = 1$. However, it may be seen from Table I that the assumption that K' and n are independent of temperature is fulfilled in any case, regardless of whether K' or n is treated as a constant, provided that reasonable values of K' or n are assumed.

The values found for the Langmuir constants K and S can be used directly to estimate some of the thermodynamic magnitudes involved in desorption. Equation 14 gives for K

$$K = 3.05 \times 10^{-4} \exp(6270/RT). \qquad [17]$$

Hence the partial molal enthalpy of dilution of the low energy fraction of the molecules is (for desorption equilibrium) $\Delta\bar{H}_S = -6.27$ kcal/mole. This is a reasonable value for one hydrogen bond. Multiplication by the number of moles of low energy molecules adsorbed at saturation then gives an estimate of the net heat of dehydration. Equation 12 gives for the pertinent moisture content

$$m_1 = m_L\{K/(1+K)\}, \qquad [18]$$

whence $m_1 = 0.1069$ g/g at 25° C, and 0.0989 g/g at 50° C. The corresponding net heats of dehydration ($-m_1\Delta\bar{H}_S/18$) are respectively 37.2 cal and 34.5 cal per gram of moisture-free wheat. A value of 43 cal/g was previously estimated (1) for 25° C.

The values of K' in Table I indicate that adsorption tends toward a limit of about 3.2 molecules per occupied site, or toward a moisture content of about 3.2 m_1. This gives a value of 0.34 g/g for 25° C, which is in good agreement with the previous estimate (3) of 0.37 g/g.

The results of the analysis of the desorption isotherm may now be compared with previous data (4, 5) on moisture equilibria in the diffusion of moisture out of the wheat kernel. The diffusion data were correlated by application of non-stationary state, integral diffusion equations with constant diffusion coefficients. The author in his recent study has shown that the form of the equation for vacuum drying in the range of initial moistures 0.13–0.25 g/g is

$$\bar{M} = 1-(2/\sqrt{\pi})X+0.326M^*X^2 \qquad [19]$$

where

$$\bar{M} = (\bar{m}-m_{s0})/(m_0-m_{s0}),$$
$$M^* = (m_0-m_{s\infty})/(m_0-m_{s0}),$$
$$X^2 = Dt/r^2,$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

$\bar{m}$ is the average moisture content of a drying wheat kernel at time t; m_0 is the initial, uniform moisture content at time zero; r is the volume to surface ratio of the wheat kernel; and D is the diffusion coefficient. m_{s0} and $m_{s\infty}$ are the dynamic, equilibrium moistures which we wish to explain; m_{s0} is the apparent value at time zero of the moisture content, m_s, at the surface of a drying wheat kernel, and $m_{s\infty}$ is the limiting value to which m_s tends with time.

The values found for m_{s0} and $m_{s\infty}$ in vacuum drying (4) are given in Table II, and are compared with the values found in this paper for the Langmuir parameters m_L and m_1. The similarities are clear: the apparent surface moisture content (m_{s0}) at time zero

TABLE II

COMPARISON OF THE ISOTHERM PARAMETERS m_L AND m_1 WITH THE DYNAMIC EQUILIBRIUM MOISTURES IN VACUUM DRYING m_{s0} AND $m_{s\infty}$

	m_L	$m_{s\infty}$	m_1	m_{s0}
25° C	0.1157	0.1159	0.1044	0.1069
50° C	0.1178	0.1153	0.0989	0.0989

appears to be identical with the moisture content (m_1) which corresponds to the number (X_1) of sites occupied at saturation, and the value ($m_{s\infty}$) toward which the surface moisture tends with time is evidently identical with the moisture content (m_L) which corresponds to the number (S) of localized sites. It can therefore be assumed that the apparent surface moisture content for the vacuum drying of wheat in the neighborhood of time zero is given by the relation (after equation 12)

$$m_s = 0.1157K/(1+K), \qquad [20]$$

where 0.1157 g/g is the average value found by the author (2) for $m_{s\infty}$. This interpretation also provides a qualitative explanation of the observed behavior (4, 5) of the diffusion coefficient. Clearly, molecules of the low energy fraction must be much less mobile than the normally condensed ones, and hence the diffusion coefficient should decrease markedly with decreasing concentration in the neighborhood of m_1 and m_L.

NEUTRON CAPTURE CROSS SECTION OF I^{129} AND I^{130} [1]

J. C. Roy and D. Wuschke

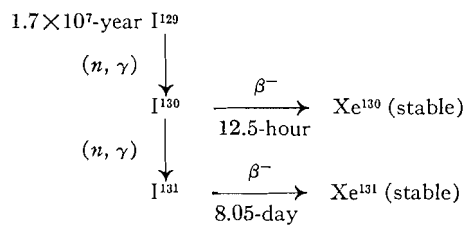
ABSTRACT

The capture cross section of I^{129} for 2200 m/sec neutrons and its resonance capture integral were determined by counting the beta rays emitted by the 12.5-hour I^{130} formed by an (n, γ) reaction on I^{129}. The σ_{2200} was found to be 26.7 ± 2.0 barns and the resonance capture integral 36 ± 4.0 barns. The effective capture cross section of I^{130} for reactor neutrons was measured to be 18.0 ± 3.0 barns by counting the beta rays emitted by the 8.1-day I^{131} produced by successive neutron capture in I^{129}. The neutron fluxes were measured with cobalt monitors; the thermal cross section and the resonance capture integral of Co^{59} were taken to be 36.5 and 48.6 barns.

INTRODUCTION

This paper describes measurements of the effective capture cross section of the 12.5-hour I^{130} for reactor neutrons. An activation method has been used which depends on successive neutron capture in the long-lived radionuclide I^{129} ($t_{\frac{1}{2}} = 1.7 \times 10^7$ years (1)). Obviously, the cross section for I^{130} obtained by this technique depends on that of I^{129} for which two different values have been reported in the literature. A value of 11 ± 4 barns, an unpublished measurement credited to Oak Ridge, is found in the compilation of neutron cross sections of Hughes and Harvey (2). Purkayastha and Martin (3), as an incidental experiment to their work on the yields of I^{129} in natural and neutron induced fission of uranium, found a value of 35 barns. They do not give the errors involved in the measurement. Since it is difficult to assess which of the two values is better and furthermore considering the large discrepancy between them, it seemed necessary to re-evaluate the thermal cross section of I^{129}. The resonance capture integral of I^{129} was also measured.

Both determinations were done by counting directly the beta rays emitted by the 12.5-hour I^{130} and 8.1-day I^{131} formed respectively by single and double neutron capture in I^{129} according to the following nuclear reactions:



EXPERIMENTAL

(a) *Irradiation*

The I^{129} used for the irradiations was obtained from the Oak Ridge National Laboratory. A mass spectrometer analysis supplied with the material gave the following composition: 51.3% I^{129} and 48.7% I^{127}.

The samples were prepared for irradiations by precipitating the iodide as palladous iodide by the addition of 0.05 molar solution of palladous chloride to a NaI solution (3). The precipitate was washed, dried at 60° C, and transferred to one arm of a U-tube in a vacuum line. The tube was evacuated and closed off from the rest of the line. The

[1]*Manuscript received June 13, 1958.*
Contribution from Research Chemistry Branch, Atomic Energy of Canada Limited, Chalk River, Ontario. Issued as A.E.C.L. No. 679.

palladous iodide was heated to liberate the iodine and distill it into the other arm of the tube, which was made of quartz. The tube was sealed off at a constriction to form a quartz ampoule containing the elementary iodine. It was irradiated in an aluminum capsule in the NRX reactor at Chalk River.

For the measurement of the resonance capture integral the quartz ampoules were wrapped with 0.028 in. thick cadmium sheet.

To obtain the neutron flux, a piece of cobalt wire was irradiated in each capsule; the details are described in section (*e*).

(*b*) *Chemical Purification*

After the irradiation, the quartz tube was crushed under a solution of sodium bisulphite. The solution was boiled to desorb the iodine on the quartz walls. No iodine carrier was added. The iodide was oxidized with nitrous acid (4) and the iodine extracted with carbon tetrachloride. The cycle of oxidation, reduction, and extraction was repeated several times. The final iodine extract in carbon tetrachloride was washed thoroughly with water and dried with magnesium sulphate. The concentration of iodine was then measured with a Beckman spectrophotometer. The details of the method used are given in section (*d*).

The iodine was then reduced and extracted from CCl_4 with water and the resulting solution made up to a known volume. Separate experiments showed that there is a loss of $7\pm3\%$ in the reduction and extraction step following the yield determination, and the yield was corrected accordingly. The preparation of the sample for counting depended on which radioactive species was to be counted.

(*c*) *Counting Techniques*

The activities of I^{130} and I^{131} were measured with a methane-flow proportional counter having a window thickness of 2.74 mg/cm^2.

Iodine-130 was measured by taking an aliquot from the standard solution and precipitating PdI_2 on an aluminum tray. The efficiency of the detector for I^{130} was determined in one experiment by measuring an aliquot from a standard solution (5) with a 4π counter. The estimated accuracy is $\pm3\%$.

In order to measure the I^{131}, the total iodide in the standard solution was precipitated as PdI_2, filtered on a "Millipore" paper, dried, and counted as such. The yield in the precipitation had to be determined because a fraction ($\sim20\%$) of the I^{131} activity was not carried with PdI_2. It was done by the addition of iodide carrier to the filtrate, reprecipitation, filtration, and counting. This procedure was repeated until no activity was left in the filtrate.

The efficiency of the detector for I^{131} was determined in an auxiliary experiment. A source of I^{131} was obtained from the Isotope Product Division, A.E.C.L.; aliquots were measured simultaneously in the 4π and proportional counter. The accuracy of the counting of I^{131} was estimated to be $\pm5\%$.

(*d*) *Yield Determination of* I^{129}

The amounts of iodine were of the order of 0.1 mg for the measurements of the I^{129} cross section and 0.5 mg for the measurements of I^{130} cross section. They were determined at the end of the chemical purification from the measurement of the optical density of iodine in carbon tetrachloride at 516 mμ with a Beckman spectrophotometer. The instrument was calibrated with carbon tetrachloride solutions of iodine standardized with arsenious acid. The solvent used for every optical measurement was passed through a silica gel column to remove traces of unsaturated compounds which could have reacted

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

with iodine. No change in concentration of iodine was observed in the solutions prepared in this way over a period of several weeks. The errors were considered to be ±2% and ±5% for amounts of 0.5 and 0.1 mg of iodine respectively.

(*e*) *Neutron Flux Monitoring*

The neutron fluxes were determined by the cobalt monitoring technique developed by Jervis (6). Weighed pieces of pure cobalt wire 0.005 in. in diameter and 0.4 in. in length, wrapped in aluminum foil, were placed in each capsule for all irradiations except for those done under cadmium. In these the wire was 4 in. in length and it was coiled around the quartz ampoule. The observed activity was corrected for self-shielding in the wire. The self-shielding correction for 0.005 in. Co wire is 2.1% and 5.5% for thermal and epicadmium neutrons, respectively (7). The accuracy of the flux determination is estimated to be ±2% (6).

A value of 36.5 barns (2) was used for the thermal neutron capture cross section of Co^{59} and 48.6 barns (8) for the resonance integral. The half-life of Co^{60} was taken to be 5.28 years (2).

The thermal neutron flux $(nv_0)_{th}$ was determined from the difference in activity of the monitors irradiated with and without cadmium covers. The resonance neutron flux $(nv)_{res}$ was obtained from the activity of the monitor irradiated with cadmium covers. Thus the fluxes are defined in the way described by Cabell *et al.* (9, 10).

(*f*) *Errors*

The errors involved in the operations and measurements just described are summarized in Table I. The total error resulting from the combination of each individual error is expressed as the square root of the sum of the squares of each error.

TABLE I

SUMMARY OF THE ERRORS INVOLVED IN THE MEASUREMENTS

Radionuclide	Loss in chemical purification (%)	Counting (%)	Yield determination (%)	Neutron flux (%)	Total (%)
I^{130}	±3	±3	±5	±2	±7
I^{131}	±3	±5	±2	±2	±6.5

RESULTS

(*a*) *Cross Section of* I^{129}

The counting of I^{130} was started about 30 hours after the end of the irradiation. This delay was necessary to allow for the decay of the 25-minute I^{128}, produced by the (n, γ) reaction in I^{127}. The average of six determinations of the half-life, each followed for 10 half-lives, was 12.5±0.1 hours, in agreement with the value of 12.6 hours given in the Table of Isotopes of Hollander *et al.* (11).

The effective cross section of I^{129}, σ_{eff}, for reactor neutrons is calculated from the equation

$$[1] \qquad A = N(nv_0)_{th}\sigma_{eff}(1-e^{-\lambda t}),$$

where A is the activity of I^{130} at the end of the irradiation of an unshielded sample,
N is the number of I^{129} atoms present during the irradiation,
$(nv_0)_{th}$ is the thermal neutron flux as defined in section (*e*) of Experimental,
λ is the disintegration constant of I^{130}, and
t is the time of irradiation.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

The details of the four irradiations without cadmium shielding are given in Table II.

An effective cross section under cadmium, $\sigma_{\text{eff, Cd}}$, is calculated from eq. [1] in a manner similar to σ_{eff}; A is now the I^{130} activity found under cadmium. The results of irradiations under cadmium are given in Table III.

Mean	—	—	—	—	27.7

TABLE III

EFFECTIVE CAPTURE CROSS SECTION UNDER CADMIUM FOR I^{129}

Experiment	I^{129} atoms	Time of irradiation, hours	$(nv_0)_{th}$	Activity, dis/sec	$\sigma_{\text{eff, Cd.}}$ barns
5	2.72×10^{15}	7.33	1.56×10^{13}	1.23×10^{4}	0.9
6	0.96×10^{15}	13.66	1.48×10^{13}	0.81×10^{4}	1.1
Mean	—	—	—	—	1.0

The σ_{2200} m/sec neutron cross section for I^{129} is obtained by the subtraction of the effective cross section under cadmium from the effective cross section for reactor neutrons and is found to be 26.7 ± 2.0 barns.

The resonance capture integral of I^{129} is related to its cadmium ratio, R_{Cd}, by the following relationship,

$$[2] \qquad \int_{0.5}^{\infty}\sigma_c\frac{dE}{E}=\frac{(nv_0)_{\text{th}}}{(nv)_{\text{res}}}\cdot\frac{\sigma_{2200}}{(R_{\text{Cd}}-1)}$$

where $(nv_0)_{\text{th}}/(nv)_{\text{res}}$ is the ratio of the thermal flux to the resonance flux per unit interval of ln E, calculated to be 36 ± 4 from the activities of cobalt monitors inside and outside cadmium. From a Cd ratio of 28 ± 3 for I^{129}, the resonance capture integral

$$\int_{0.5}^{\infty}\sigma_c\frac{dE}{E}$$

is found to be 36 ± 4. There is therefore very little resonance capture in I^{129}.

(*b*) *Cross Section of* I^{130}

The counting of I^{131} started about 15 days after the end of the irradiation in order to allow the 12.5-hour I^{130} to decay. Iodine-131 was identified by its half-life and gamma-ray spectrum. The average of two determinations of the decay period, each followed for five half-lives, was 8.1 ± 0.1 days after the subtraction of a long-lived residual activity of 1000 counts/minute. This background represents less than 1% of the initially observed I^{131} activity and most of it can be accounted for by the radiations of I^{129}. Values of 8.04 to 8.16 days are given for the half-life of I^{131} in Hollander *et al.* (11). A decay curve of one of the two samples is given in Fig. 1.

Some I^{126} (13.3 days) is produced by the reaction $I^{127}(n, 2n)I^{126}$ during the long

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

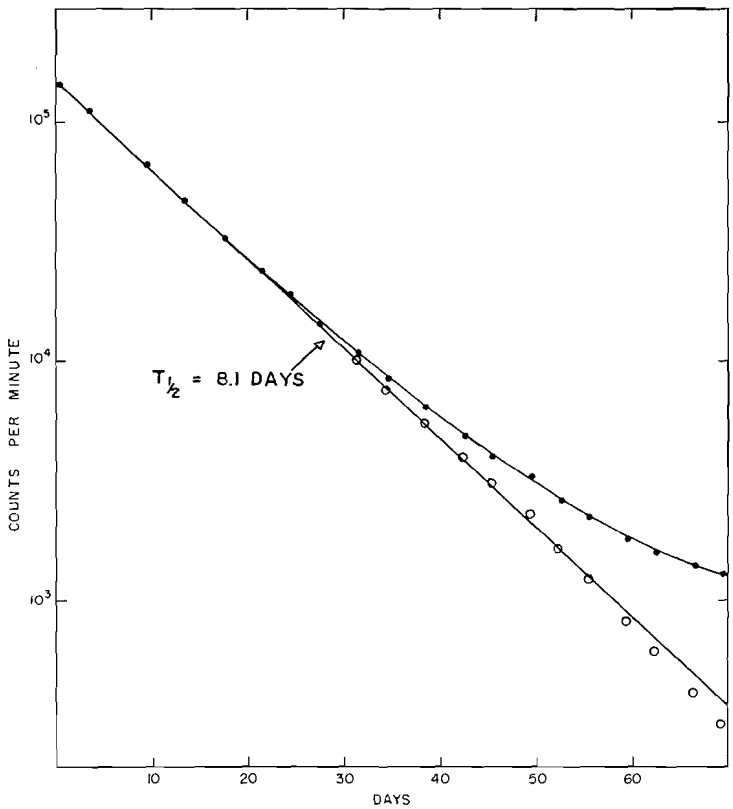

FIG. 1. Decay curve of I^{131}. A residual activity of 1000 counts/minute attributed to the radiations of I^{129} has been subtracted from the observed activity.

irradiation required to measure the I^{130} cross section. It does not interfere with the determination of the yield of I^{131}; its contribution was of the order of 2% when the counting of the samples was begun. This was shown by irradiating a known amount of natural iodine in a separate ampoule with the I^{129}. The I^{126} formed was counted under conditions identical with those used for I^{131}.

Since there were four shutdowns, each one of several hours, while the target material

TABLE IV

DETAILS OF THE IRRADIATION FOR THE FORMATION OF I^{131}

Segments x	Duration of a segment t_x (hours)	State of the reactor	Length of time from the end of segment to the end of the whole irradiation t'_x (hours)
1	26.33	On	536.3
2	7.67	Off	
3	54.75	On	473.9
4	22.65	Off	
5	248.1	On	203.2

For personal use only.

was in the reactor, the calculation of σ_{eff} for I^{130} from the observed I^{131} activity becomes involved. The effect of these shutdowns on the formation of I^{131} was taken into account by assuming that the whole irradiation consisted of nine segments, the details of which are given in Table IV. The five segments characterized by the operation of the reactor are considered as separate irradiations. Then the activity of I^{131}, B, at the end of the irradiation is the sum of the activities produced during each one of these segments, namely 1, 3, 5, 7, and 9. Each activity is multiplied by a factor $e^{-\lambda_B t'}$ to take into account the decay from the end of the segment to the end of the irradiation.

$$[3] \qquad B = B_9 + B_7 e^{-\lambda_B t'_7} + B_5 e^{-\lambda_B t'_5} + B_3 e^{-\lambda_B t'_3} + B_1 e^{-\lambda_B t'_1}.$$

The I^{131} activity, B_x, formed during each segment is

$$[4] \qquad B_x = \frac{N\sigma\sigma_A (nv_0)^2_{th} T_A}{0.693(T_A - T_B)} [T_A(1-e^{-\lambda_A t_x}) - T_B(1-e^{-\lambda_B t_x})] + P,$$

$$P = \frac{N_{A(x-1)} T_A \sigma_A (nv_0)_{th}}{(T_B - T_A)} (e^{-\lambda_A t_x} - e^{-\lambda_B t_x}).$$

The first term in eq. [4] represents the formation of I^{131} by successive neutron capture in I^{129}; the second term, P, represents the formation of I^{131} by neutron capture in I^{130} formed in the previous segments of the irradiation.

N is the number of I^{129} atoms present during the irradiation,

σ is the effective cross section of I^{129} for reactor neutrons, 27.7 barns,

σ_A is the effective cross section of I^{130} for reactor neutrons to be measured,

T_A is the half-life of I^{130}, taken to be 12.5 hours,

T_B is the half-life of I^{131}, taken to be 8.1 days,

λ_A and λ_B are the disintegration constants of I^{130} and I^{131} respectively,

t_x is the duration of a segment as given in Table IV,

t'_x is the time elapsed from the end of the final irradiation to the end of a segment, x,

N_{Ax} is the number of I^{130} atoms present at the end of the 2nd, 4th, 6th, and 8th segments and is equal to

$$[5] \qquad N_{Ax} = \left[\frac{N\sigma (nv_0)_{th}}{\lambda_A} (1 - e^{-\lambda_A t_{(x-1)}}) + N_{A(x-2)} e^{-\lambda_A t_{(x-1)}} \right] e^{-\lambda_A t_x}.$$

Initially $N_A = 0$.

The experimental details and the results are given in Table V.

TABLE V

EFFECTIVE CAPTURE CROSS SECTION OF I^{130} FOR REACTOR NEUTRONS

Experiment No.	I^{129} atoms	$(nv_0)_{th}$	Activity, dis/sec	σ_{eff} (I^{130}), barns
1	7.5×10^{17}	4.76×10^{13}	3.51×10^{4}	17.1
2	8.1×10^{17}	6.30×10^{13}	7.45×10^{4}	19.2
Mean	—	—	—	18.1

The value 18.0 ± 3.0 barns is for a typical reactor neutron spectrum in a vacant fuel rod position near the center of the NRX reactor. In the two positions used in these experiments, the epicadmium neutrons are 3.5% and 4% of the thermal flux. The assigned error includes the uncertainty in the value of the cross section of I^{129}.

ACKNOWLEDGMENTS

The authors wish to thank Dr. T. A. Eastwood for helpful discussions, Mrs. J. S. Merritt and Dr. P. J. Campion for doing the 4π β-counting.

STEREOCHEMISTRY OF REDUCTION OF KETONES BY COMPLEX METAL HYDRIDES[1]

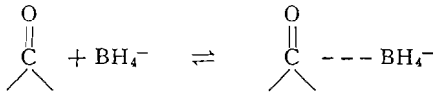
OWEN H. WHEELER[2] AND JOSÉ L. MATEOS[3]

ABSTRACT

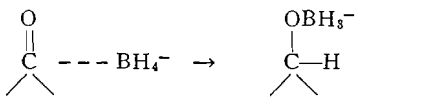
The stereochemistry of the reduction of a number of cyclic ketones with complex metal hydrides has been determined. In the absence of any large steric effect in the ketones, the reduction is essentially stereospecific, giving the more stable alcohol.

INTRODUCTION

The reduction of a carbonyl group by a simple metal hydride must proceed by four successive stages (1), utilizing each of the four available hydrogen atoms. Each stage probably involves two reaction steps, the initial reversible formation of a complex of the hydride ion and the carbon atom of the carbonyl group (I) and the irreversible transfer of hydrogen to this carbon atom (II).



(I)



(II)

In the case of a cyclic ketone there are two possible directions of attack, pseudo equatorial and pseudo axial, giving the axial or equatorial alcohol. Dauben and co-workers (2, 3) have discussed the stereochemistry of reduction of cyclic ketones in terms of "steric approach control" to the attack of the hydride upon the ketone (stage I), and "product development control", determined by the relative thermodynamic stabilities of the two alcohols formed (and governing the relative stabilities of the two possible transition states in stage II). For a complex metal hydride substituted with bulky substituents, approach to the carbon atom of the carbonyl group, in stage I, will take place from the less hindered side. In stage II the large steric size of the reagent will favor the formation of the transition state leading to the more stable of the two products, since a bulky group is more stable in this the equatorial position. Reduction of an unhindered ketone should thus give the equatorial alcohol, whereas a sterically hindered ketone could give either isomer depending on the direction of steric hindrance.

A number of complex metal hydrides have recently been prepared and the simplest is sodium trimethoxyborohydride. However, this undergoes disproportionation in solution (4) and the reduction of 2-methylcyclohexanone with this reagent gives the same ratio of isomers as does sodium borohydride (2). Recently H. C. Brown and McFarlin (5) have developed a simple preparation of lithium tri-*tert*-butoxyaluminum hydride and we have investigated the stereochemistry of the reduction of a number of cyclic ketones (Table I) with this reagent. In all cases this reagent is considerably more stereospecific than either lithium aluminum hydride or sodium borohydride.

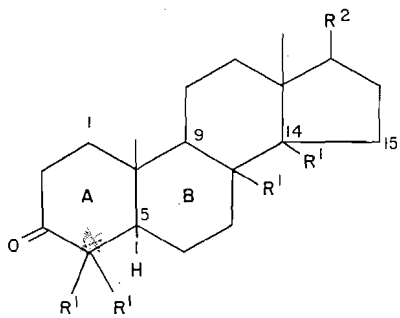
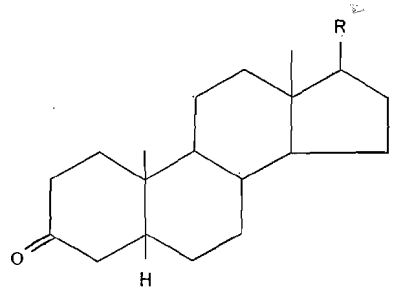
DISCUSSION

The keto group of cholestan-3-one (*IIIa*) is unhindered to attack from either an axial or equatorial direction (3, 6). In the transition state, however, the bulky alkoxide group could not occupy a pseudo-axial position, since it would be sterically hindered by the axial hydrogen atoms on carbon atoms 1 and 5. Moreover in such a position it is also sterically hindered to solvation (7), which would help to stabilize the ion. Thus the preferred transition state will be that with the alkoxy group in a pseudo-equatorial position, and the product observed is essentially that (β-cholestanol) which arises from this. Similarly coprostan-3-one (IV) is not subject to steric hindrance from either direction (6) and the equatorial (α) isomer is largely formed. A double bond at the union of rings A and B as in Δ^4- and Δ^5-cholesten-3-one will lead to a general flattening of the rings. The steric repulsion to a 3-α group will be less, since there is now no α-hydrogen at carbon-5 and the flattening of the rings moves the 3-position away from the 1-α hydrogen atom. However, electronic interaction (6) between the double bond and the pseudo-equatorial alkoxy group will greatly stabilize the transition state for formation of the equatorial alcohol, and this is formed exclusively in both cases.



III a R^1 = H
R^2 = Isohexyl

b R^1 = Me
R^2 = Isohexyl



IV R = Isohexyl

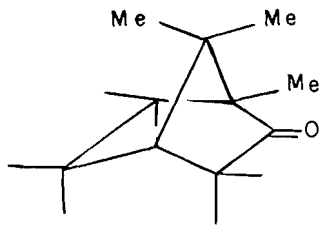
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

The attack on the ketone group of cholestan-7-one from an axial direction will be hindered by the axial hydrogen atoms at C-5, C-9, and C-14. However, approach to the keto group from a pseudo-equatorial direction is highly hindered by the axial methyl groups at C-10 and C-13 and by the eclipsing effect of the 15-α hydrogen atom (6), and cholestan-7α-ol is only formed in 6% yield. This same eclipsing effect will tend to expel the bulky alkoxy transition complex from the 7-β position, and 57% of cholestane is formed (cf. 6).

Approach to the 17-keto steroid group from the topside of the molecule is hindered by the axial methyl group on C-18. However, approach from the underside is free and the resulting pseudo-equatorial transition complex will not be hindered by the methyl group on C-18, since the *trans*-fusion of rings C and D bends the 17-position down away from this group. Thus, Δ^5-androsten-17-one-3β-acetate gives exclusively Δ^5-androsten-3β,17β-diol.

In the case of Δ^8-lanosten-3-one (III*b*) approach to the ketone group from the upper pseudo-equatorial direction is also hindered by the axial methyl group on C-4. However, again approach from the underside is unhindered and the pseudo-equatorial transition complex (stage II) is not very hindered by either methyl group. Accordingly the β-alcohol is the sole product.

The camphor molecule (V) presents an interesting case, since one of the *gem*-dimethyl groups on the bridgehead is placed nearly above the ketone group (8). Approach from the exo (equatorial) direction is hindered and, although there is little hindrance to approach from the *endo* (axial) direction, the resulting pseudo-exo transition complex will be highly hindered. The net result of these opposing factors is that only 25% of the exo product (isoborneol) is formed.



V

In the transition state of reduction of 4-methylcyclohexanone, the methyl group is free to take up either an axial or equatorial position (9), with the large alkoxy group remaining in the preferred equatorial position. Consequently lithium tri-*tert*-butoxy-aluminum hydride gives nearly the same isomer distribution as lithium aluminum hydride and sodium borohydride.

The complex of lithium aluminum hydride and excess aluminum chloride was first used for reduction by B. R. Brown (10). Aluminum hydride is formed as an intermediate (11), but the active reducing species may be AlH_2Cl (12). In the cases of the two saturated ketones, cholestan-3-one and coprostan-3-one, reduction was essentially stereospecific giving predominately the β-alcohols. Cholest-4-en-3-one, however, gave no alcohol. The product, previously reported as Δ^4-cholestene (13), was shown to be a mixture of cholestene with about 10% cholestane. Hydrogenolysis has been observed in the reduction of other compounds by this reagent (14, 15). Cholest-5-en-3-one gave a mixture which contained

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

cholest-4-en-3-one as well as alcohols. Because of these unfavorable observations and the uncertainty of the nature of the reducing reagent, no further work was carried out with this complex.

EXPERIMENTAL

Tetrahydrofuran and *t*-butanol were dried by refluxing with and distilling from lithium aluminum hydride and sodium, respectively. Lithium aluminum hydride and aluminum chloride were commercial samples which were finely ground. The ketones used were all analytically pure samples.

Reductions with lithium tri-tert-butoxy aluminum hydride.—In a typical experiment *t*-butanol (2 ml) was added slowly to a solution of lithium aluminum hydride (400 mg) in tetrahydrofuran (30 ml) at 0° (5). Cholestanone (1.0 g) in tetrahydrofuran (30 ml) was then added and the mixture allowed to stand at 0° for ½ hour and at room temperature for 1 hour. The mixture was then poured into excess dilute hydrochloric acid and the product extracted in the usual way. In this case the crude product was chromatographed on alumina and eluted with hexane–benzene giving α-cholestanol (14 mg), m.p. 182°–185°, and β-cholestanol (937 mg), m.p. 143°–146°. Both alcohols gave no depression on mixed melting-point determinations with authentic samples.

Coprostanone.—The product from coprostanone (200 mg) gave a precipitate with digitonin (50 mg) from which β-coprostanol (7 mg) was liberated with pyridine. α-Coprostanol (185 mg), m.p. 115°, was recovered by evaporation of the mother liquors (6).

Cholest-4-en-3-one.—Cholest-4-en-3-one (1.0 g) gave a crude product (1.0 g), m.p. 121°, which on chromatography using hexane–benzene as eluent (50 fractions) gave only cholest-4-en-3β-ol, m.p. 127°–131°, recrystallized from ether–methanol to m.p. 132°, $[\alpha]_D^{CHCl_3}$ +44°.

Cholest-5-en-3-one.—Cholest-5-en-3-one (500 mg) gave cholesterol, m.p. and mixed m.p. 148°, $[\alpha]_D^{CHCl_3}$ −42° (lit. $[\alpha]_D$ −39°, m.p. 149° (18)).

Cholestan-7-one.—Cholestan-7-one (500 mg) gave a product separated by chromatography into a fraction (243 mg) eluted with hexane, m.p. 65°–70°, recrystallized from hexane to m.p. 80°, $[\alpha]_D$ +30°. The infrared absorption showed no carbonyl or hydroxyl groups or double bond. Further elution with hexane–benzene gave 7α-cholestanol (27 mg), m.p. 92°–98° (lit. m.p. 94°–97° (19)), and 7β-cholestanol (168 mg), m.p. 103°–109° (lit. m.p. 108°–112° (19)).

Δ^5-*Androsten-17-one-3β-acetate.*—Reduction in like manner of Δ^5-androsten-17-one-3β-acetate gave a product, m.p. 183°–184°, $[\alpha]_D$ −54°. Reported for Δ^5-3β,17β-androstendiol, m.p. 182°–183°, $[\alpha]_D$ −55° (20).

Δ^8-*Lanosten-3-one.*—Δ^8-Lanosten-3-one (500 mg) gave a product, m.p. 142°–146°, recrystallized to m.p. 146°–148° and undepressed on admixture with lanostenol.

Camphor.—Two grams of this gave a product, m.p. 85°–110°, which could not be separated by chromatography on alumina (cf. 22). The mixture (500 mg) in pyridine (2 ml) was treated with *o*-nitrobenzoyl chloride and allowed to stand overnight. The pyridine was removed in vacuum and the isoborneol (106 mg), m.p. 210° from petroleum ether, separated by steam distillation (23). The residual borneol *o*-nitrobenzoate (618 mg) corresponded to borneol (322 mg).

4-Methylcyclohexanone.—Ten grams of 4-methylcyclohexanone gave a product n_D^{20} 1.4560, d_4^{30} 0.9061, which showed a small infrared ketone peak. After washing with sodium bisulphite solution the values were n_D^{20} 1.4569 and d_4^{30} 0.9063, and the compound showed no infrared carbonyl absorption. *Cis*- and *trans*-4-methylcyclohexanol have

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

respectively n_D^{20} 1.4614, 1.4561, and d_4^{30} 0.9173 and 0.9040 (24). The isolated product therefore contains 15% (from n_D^{20}) or 17% (from d_4^{30}) of the *cis*-isomer.

Reductions with lithium aluminum hydride – aluminum chloride.—In a typical experiment aluminum chloride (600 mg) was added to lithium aluminum hydride (135 mg) dissolved in ether (50 ml).

Cholestanone.—One gram of this ketone in ether (20 ml) was then added and the mixture allowed to stand at room temperature for at least four hours. The product (m.p. 141°–143°) was isolated by pouring the mixture into dilute hydrochloric acid. Recrystallization from ether–methanol gave β-cholestanol, m.p. 141°–142°, undepressed on admixture with an authentic sample.

Coprostanone.—Coprostanone (200 mg) gave a product from which β-coprostanol (12 mg) was isolated by digitonin separation. α-Coprostanol (180 mg) was isolated from the mother liquors, as before.

Cholest-4-en-3-one.—This gave a product, readily eluted from alumina with hexane, m.p. 65°, $[\alpha]_D^{CHCl_3}$ +56°. This rotation corresponds to Δ^4-cholestene ($[\alpha]_D$ +65°) 78% and cholestane ($[\alpha]_D$ +24°) 22%. Bromine titration showed the presence of about 85% olefin.

Cholest-5-en-3-one.—Five hundred milligrams gave a product (450 mg), which had λ_{max} 240 mμ, ε 15,700 corresponding to cholest-4-en-3-one 87%. Infrared spectra showed the presence of alcohols. No attempt was made to separate the mixture.

ACKNOWLEDGMENTS

SYNTHESES OF SUBSTITUTED GUANIDINES[1]

PAUL E. GAGNON, JEAN L. BOIVIN,[2] AND JOSEPH ZAUHAR[3]

ABSTRACT

Ethyl-, propyl-, and benzyl-guanidine nitrates were prepared from amine nitrates and calcium cyanamide or dicyandiamide. Carboxyalkylguanidines were made by condensing the corresponding amino acids with guanidine carbonate in aqueous medium. All the guanidine nitrates, except the benzyl derivative, were converted into the corresponding nitroguanidines by treatment with concentrated sulphuric acid. Esters and metal salts of 1-(α-carboxyalkyl)-2-nitroguanidines were also prepared.

INTRODUCTION

Guanidine nitrate is prepared by heating ammonium nitrate with calcium cyanamide in aqueous solution (1, 2) or in the presence of urea (3), or with dicyandiamide (4, 5). Carboxyalkylguanidines have been previously made from amino acids and cyanamide in aqueous solution (6, 7) and by the action of haloaliphatic acids on guanidine (8). A more recent method for the preparation of carboxyalkylguanidines involves the use of methylisothiourea in an ammoniacal medium (9, 10). Carboxymethylguanidine was synthesized by the direct condensation of guanidine carbonate and glycine in aqueous medium (11).

RESULTS

Alkylguanidines

The methods of preparation of guanidine nitrate were extended to the syntheses of substituted guanidine nitrates in view of their nitration into the corresponding 1-substituted 2-nitroguanidines. The reaction of aqueous solutions of amine nitrates with calcium cyanamide gave the corresponding guanidine nitrates in yields ranging from 35 to 41%, as recorded in Table I.

$$3RNH_2.HNO_3 + CaCN_2 \longrightarrow RHNC(=NH)NH_2.HNO_3 + 2RNH_2 + Ca(NO_3)_2$$

R = C_2H_5, C_3H_7, and $C_6H_5CH_2$

By heating the reactants in the solid state, instead of in aqueous solution, an increased yield was observed, namely, 86% for ethylguanidine nitrate, 67% for propylguanidine nitrate, and 51% for benzylguanidine nitrate. By adding urea to the dry reagents to depress the melting point of the mixtures, yields of about 40% were obtained. This behavior was unexpected because Wright obtained increased yields of guanidine nitrate from cyanamide (3) by using urea.

Ethyl-, propyl-, and benzyl-guanidine nitrates were also successfully synthesized by heating the amine nitrates with dicyandiamide. The over-all reaction can be expressed by the equation:

$$NCNHC(=NH)NH_2 + 2RNH_2.HNO_3 \longrightarrow 2RHNC(=NH)NH_2.HNO_3.$$

The latter method of preparation of ethyl-, propyl-, and benzyl-guanidine nitrates from amine nitrates and dicyandiamide gave yields up to 88% in some cases. In the preparation of guanidine hydrochloride from dicyandiamide and ammonium chloride (5), a biguanide hydrochloride is formed and ammonolyzed. A similar mechanism applies to the preparation of substituted guanidine nitrates from amine nitrates and dicyandiamide in which a substituted biguanide nitrate is the intermediate.

Carboxyalkylguanidines

Carboxyethylguanidine and carboxypropylguanidine were prepared from the corresponding amino acids and guanidine carbonate.

$$2H_2NCHRCOOH + [H_2NC(=NH)NH_2]_2.2H_2CO_3 \longrightarrow 2H_2NC(=NH)NHRCOOH + 2NH_3 + CO_2 + H_2O.$$

Cyclization of carboxyalkylguanidines can also take place (7, 12) in aqueous medium to form anhydro compounds.

$$2C_6H_5CH_2CH(NH_2)COOH + [H_2NC(=NH)NH_2]_2.H_2CO_3 \longrightarrow 2C_6H_5CH_2CH\text{(ring)}C{=}O + CO_2 + 3H_2O + 2NH_3$$

(ring: HN, C(=NH), NH)

Carboxyalkylguanidines when treated with a slight excess of dilute nitric acid gave the corresponding carboxyalkylguanidine nitrates. The nitrates slowly decomposed on heating in aqueous solution at temperatures above 100° C. Anhydrocarboxyphenylethylguanidine nitrate was obtained in the same manner.

Substituted Nitroguanidines

Ethyl- and propyl-nitroguanidines were obtained by a method similar to the production of nitroguanidine from guanidine nitrate using sulphuric acid (13, 14) but benzylnitroguanidine could not be obtained by this method, which confirms the results of other investigators (15). The results are shown in Table I.

Nitroguanidines substituted with an acid function were obtained by treating the corresponding carboxyalkylguanidine nitrates with concentrated sulphuric acid. The results are shown in Table II. To obtain 1-(α-carboxypropyl)-2-nitroguanidine, which was soluble in dilute sulphuric acid, the sulphate ions were eliminated and the compound was isolated as the dihydrate of the barium salt.

For personal use only.

$$HNO_3.H_2NC(=NH)NHRCOOH \longrightarrow H_2NC(=NNO_2)NHCHRCOOH + H_2O$$

1-(α-Carboxymethyl)-2-nitroguanidine was also identified by its lead salt; it was prepared by treating an aqueous solution of the nitroguanidine with lead oxide.

The esters of 1-(α-carboxyalkyl)-2-nitroguanidines were prepared by esterification with absolute ethanol in the presence of dry hydrogen chloride. The results are shown in Table II.

DISCUSSION

The present study has shown that the methods of syntheses of guanidine nitrate apply as well to the substituted guanidine nitrates with the difference that lower yields resulted with the use of amine nitrates. Guanidines substituted by a carboxylic group are monobasic in character and form the lead and barium salts. The solubilities of the nitro derivatives were greater than that of nitroguanidine itself or of the alkyl nitroguanidines. The esterification of 1-(α-carboxyalkyl)-2-nitroguanidines in the presence of hydrogen chloride did not yield the corresponding hydrochloride salts, which supports the view that acids combine with the free amino group to form salts.

EXPERIMENTAL PART

Alkylguanidine Nitrates

1. Syntheses from calcium cyanamide and amine nitrates in aqueous solution.—The amine nitrate (0.29 mole) was dissolved in water (100 ml) and the resulting solution was evaporated until it reached a boiling point of 100° C. Calcium cyanamide (55%, 0.05 mole) was added slowly while stirring and at that temperature the reaction occurred with frothing while some free amine was evolved. The guanidine nitrate salt crystallized from the solution on cooling. The results are shown in Table I.

2. Syntheses from amine nitrates and calcium cyanamide in the dry state.—Dry solid mixtures of amine nitrates (0.21 mole) and calcium cyanamide were heated at 110° C for 1 hour (55%, 0.05 mole), during which time free amine was liberated. The fluid

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

reaction products were diluted with hot water (40 ml) and the mixtures filtered while hot. On cooling, the guanidine nitrate salts crystallized and were separated by filtration. The experimental results obtained are given in Table I.

3. Syntheses from calcium cyanamide, amine nitrates, and urea.—Calcium cyanamide (55%, 0.05 mole), amine nitrates (0.21 mole), and urea (0.13 mole) were heated at 90° C for 1 hour, during which time some free amine was evolved. Hot distilled water (40 ml) was added and the mixtures were filtered while hot. The guanidine nitrate salts crystallized from the cooled filtrate and were isolated by filtration. The results are listed in Table I.

4. Syntheses from amine nitrates and dicyandiamide.—Mixtures of dicyandiamide (0.22 mole) and amine nitrates (0.44 mole) were heated in an oil bath. Fusion began at 70° C, was complete at 130–133° C, and the temperature was gradually raised to 170° C and kept there for 3 hours. Upon cooling, the crude guanidine nitrate salts crystallized from the solution and were recrystallized from water. The results obtained are given in Table I.

Alkylnitroguanidines

The substituted guanidine nitrate (0.46 mole) was slowly added to sulphuric acid (98%, 2.1 mole) and cooled to 5° C. After all the solid was added, the mixture was stirred at that temperature for 3 hours, and afterwards poured over cracked ice. A small amount of the product precipitated from the solution. The compound was separated by filtration, the filtrate neutralized with barium hydroxide, and the barium sulphate formed was filtered through charcoal. The resulting filtrate was evaporated under vacuum and a second crop of crystals was obtained. The compound was then recrystallized from ethanol. The results obtained are shown in Table I.

Carboxyalkylguanidines

An aqueous solution of guanidine carbonate (0.06 mole) was added to an aqueous solution of amino acid (0.12 mole) and the reaction vessel was heated on a sand bath for 24 hours, during which time ammonia was liberated. Upon cooling, the resulting liquid was filtered, and the filtrate evaporated under reduced pressure until a yellow viscous product remained. A mixture of absolute alcohol (50 ml) and acetone (50 ml) was added, with stirring, and the resulting solution was stored in a cool place for several hours. The carboxyalkylguanidine soon separated from the solution and after filtration and washing with ethanol, the crude product was recrystallized from water. The results are given in Table II.

Carboxyalkylguanidine Nitrates

Dilute nitric acid (0.06 mole) was added slowly to an aqueous solution of the carboxyalkylguanidine (0.05 mole) while it was being cooled and stirred, and the resulting solution was evaporated to dryness under vacuum. The product was recrystallized from water. The results are listed in Table II.

1-(α-Carboxyalkyl)-2-nitroguanidines

Concentrated sulphuric acid (98%, 0.06 mole) was cooled to 5° C and the carboxyalkylguanidine nitrate (0.01 mole) was added in small portions with continuous stirring and cooling whenever necessary. After all the nitrate salt was added, the mixture was further stirred for 15 minutes at the above temperature and then allowed to reach 20° C, where the mass was stirred for 3 hours. The sulphuric acid solution was then

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

poured over cracked ice, which effected precipitation, after 15 minutes, of the crude product, which separated by filtration and was recrystallized from water. The compounds prepared are shown in Table II.

Salts of 1-(α-Carboxyalkyl)-2-nitroguanidines

1-(α-Carboxymethyl)-2-nitroguanidine was also identified by its dihydrate lead salt obtained by treating 1-(α-carboxymethyl)-2-nitroguanidine with an excess of lead oxide (litharge). The compound had no melting point but decomposed above 300° C. Calc. for $C_6H_{14}O_{10}N_6Pb$: Pb, 38.50%. Found: 38.8%. 1-(α-Carboxypropyl)-2-nitroguanidine, which was soluble in sulphuric acid, was isolated by precipitating the sulphate with barium hydroxide, filtering off the barium sulphate, and evaporating the resulting filtrate under reduced pressure. The dihydrate barium salt of 1-(α-carboxypropyl)-2-nitroguanidine crystallized from the concentrated solution in colorless needles: m.p. 183–184° C. Yield, 27%. Calc. for $C_{10}H_{22}O_{10}N_8Ba$: C, 21.76; H, 4.00; N, 20.31%. Found: C, 22.2; H, 4.2; N, 19.9%.

Esters of 1-(α-Carboxyalkyl)-2-nitroguanidines

Pulverized samples of 1-(α-carboxyalkyl)-2-nitroguanidines (0.06 mole) were added to absolute ethanol (70 ml), and dry hydrogen chloride was added until the solution was saturated. The mixtures were then refluxed for 1 hour, filtered, and left to stand in a cool place. The crude esters which separated from the filtrates were recrystallized from ethanol. The compounds obtained were slightly soluble in water. The results are given in Table II.

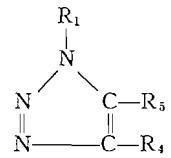
NOTES

THE ULTRAVIOLET AND INFRARED SPECTRA OF VICINAL-TRIAZOLE DERIVATIVES

E. LIEBER,[1] C. N. R. RAO,[2] T. S. CHAO,[3] AND H. RUBINSTEIN[4]

Unlike tetrazole (1, 2) vicinal-triazole absorbs in the ultraviolet region (3). Ramart-Lucas and Hoch (4) have observed that the ultraviolet spectra of the phenyltriazoles (I, $R_1 = C_6H_5$) vary according to the nature of the groups R_4 and R_5. However, they



I

found that phenyltriazoles do not exhibit any absorption in the near ultraviolet region, when R_5 is H, CH_3, C_6H_5, or COOH, and R_4 is H or COOH. This appeared rather unusual because alkyl and aryl groups in 4-position have been found (3) to produce bathochromic shifts. Also, the ultraviolet spectrum of 4-phenyltriazole (I, $R_1 = R_5 = H$ and $R_4 = C_6H_5$) has been compared to that of biphenyl (3). Lieber, Rao, and Chao (5) have studied the near-ultraviolet absorption spectra of substituted aminotriazoles and have discussed the results in terms of the resonance interaction of R_1, R_4, and R_5 with triazole nucleus. We have now studied the ultraviolet spectra of a few other derivatives of vicinal-triazole. The results are summarized in Table I.

TABLE I

ULTRAVIOLET ABSORPTION SPECTRA OF VICINAL-TRIAZOLE DERIVATIVES (I)

R_1	R_4	R_5	λ_{max} (mμ)	log ϵ_{max}
C_6H_5	H	OH	235	4.03
C_6H_5	H	Cl	228	4.03
C_6H_5	COOH	Cl	231	4.03
C_6H_5	$COOCH_3$	Cl	218	4.24

The infrared spectral data on the vicinal-triazoles derivatives are limited (3, 6). We have now studied the infrared spectra of several derivatives of vicinal-triazole. All the important absorption frequencies that are common to most of the derivatives in the region 900–1310 cm^{-1} are shown in Table II. The intensities are indicated by the symbols: (s) strong; (m) medium; (w) weak; and (vw) very weak.

The syntheses of the compounds used in this study have been reported (7). The ultraviolet absorption spectra were recorded in 95% ethanol using a Cary recording

			1181(w)			

spectrophotometer. The infrared spectra were recorded using a Perkin–Elmer spectrometer (Model 21). The samples were prepared in Nujol mulls or KBr pellets.

From the results in Table I and the earlier observations (3, 5), it is found that the triazole derivatives, I, absorb in the near-ultraviolet region immaterial of the substituents in 1-, 4-, and 5-positions. These results are in variance with the earlier work of Ramart-Lucas and Hoch (4). Further, it is hard to generalize that the influence of the substituents is greater in 5- than in the 4-position (4). From the spectra of 1-substituted 4-phenyl-1,2,3-triazoles (5) it appears that the 1-(4-phenyl-5-amino)-triazolyl group is not capable of strong resonance interaction, since the effect of the substituents on the 1-phenyl group on the spectra of these derivatives is of the same magnitude as that on benzene alone. It is interesting to see that 1-phenylaminotetrazole absorbs at 225 mμ (2) compared to 221 mμ of 1-phenyl-5-amino-1,2,3-triazole (5). This difference is explained on the basis of the difference in electronegativities of the triazole and the tetrazole ring systems. Tetrazole is more electronegative than triazole, because of the greater electronegativity of nitrogen compared to carbon.

Since all the triazole derivatives had phenyl groups attached to them, it was hard to assign infrared frequencies for the N=N and the C=C links of the triazole nucleus. Some of the weak intensity bands listed in Table II may be due to the substituted aromatic groups. It is interesting to see that all the vicinal-triazole derivatives, just like the thiatriazole and tetrazole derivatives (8), exhibit a medium or weak intensity band in the region 1277–1302 cm^{-1}. This band cannot be ascribed to C—N or C_6H_4—NH or $C_6H_5N<$ linkages. It may be due to the cyclic —N—N=N— configuration (8).

From Table II it can be seen that there are at least three bands in the regions 968–1003 cm^{-1}, 1101–1129 cm^{-1}, and 1045–1093 cm^{-1} which are characteristic of the vicinal-triazole ring system. However, the possibility of one of these bands in the region 1020–1220 cm^{-1} being the C—N vibration frequency is not completely eliminated. The

characteristic frequencies for vicinal-triazoles assigned by us agree with the observation of Hartzel and Benson (3), who assigned two bands between 1136–1087 cm^{-1} and 1020–971 cm^{-1} as characteristic of *v*-triazole.

ON THE PREPARATION AND SINTERING OF CLOUD PRECIPITATING AGENTS. LEAD DI-IODIDE MICROCRYSTALS

HENRY M. PAPÉE[1]

Lead iodide of relatively large and controlled specific surface areas had to be prepared in this laboratory in connection with a microcalorimetric study of heats of adsorption of water vapor on lead iodide surfaces (1).

EXPERIMENTAL

Attempts to prepare finely subdivided lead iodide by electrostatic precipitation of a smoke (2) failed because of considerable contamination of the product by elementary iodine, and because of low specific areas obtained. No significant improvement could be attained by varying the flow of the dry nitrogen carrying gas, the temperatures of the melt, and the potentials applied.

An entirely different method was therefore tried, and the pattern outlined by Marshall (3) was followed with some modifications. Twenty-five grams of ammonium iodide was dissolved in 700 cc of absolute ethanol, and cooled to −20° C. A boiling solution of 50 g of lead iodide in 50 cc of water was added with vigorous stirring. The resulting slurry was quickly centrifuged in a low-temperature centrifuge maintained at −15° C. The precipitate was decanted and repulped several times by means of an electromagnetic vibrator with water at 0° C and then with absolute ethanol which has been chilled to −20° C. This was followed by several repulpings with anhydrous ether at low temperatures.

The precipitate obtained was then placed in a desiccator and evacuated for 48 hours to a vacuum obtained by a 2-stage Edwards diffusion pump. The agglomerated product was ground in a mortar in an atmosphere of dry nitrogen and sieved through a 200-mesh screen. The compound was then placed again in a desiccator and again evacuated for 48

hours. Analysis of the product showed it to be 99.8% pure, and BET surface determinations led to values of 2.05 m^2/g. The stock was then stored in a desiccator at 25.0° C, and all further manipulations of samples were done under nitrogen of a humidity below 1%, in a dry box.

Sintering by Heating

Quantities of about 8 g of lead iodide were sintered under vacuum in a glass cell of the type represented in Fig. 1. The cell was fitted directly onto the BET apparatus, and a heating unit which could be controlled within 1° C was placed around it. It was seen that the same final results were obtained at a temperature of 100° C, whether the process of heating lasted for 6 or for 48 hours. The samples were heated therefore for 24-hour periods, BET measurements taken subsequently, and the relative change between

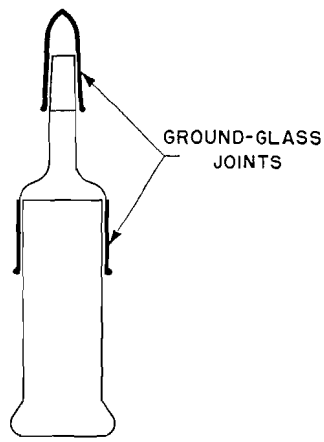

FIG. 1. Cell for storage, sintering, dispensing, and surface measurements of the product.

specific surface areas before (S_0) and after sintering (S) was plotted against the temperature of heating. Figure 2 gives the results obtained on samples originating from different batches of various initial specific areas. Each point represents a measurement taken on a different sample. It was noticed that, while salts whose area was reduced by sintering by exposure to saturated water vapor at 25° C follow the pattern of Fig. 2, samples which were presintered by heating give completely random results. The plot therefore represents measurements on crystals originating from one particular batch, and some others that were presintered by exposure to water vapor, and subsequently evacuated for long time periods.

The curve represented by Fig. 2 can be split in three parts:

(i) The ascending part, in which small variations of temperature seem to provoke considerable changes in the function and where, because of this, the error is considerable. This part has therefore been dotted.

(ii) The fairly rectilinear descending part of the curve.

(iii) The extrapolated part of the line, where there is a considerable scattering of the experimental values.

The parameters of the line in part (ii) are:

$$\text{Slope: } -0.003_2 \pm 0.0005\ (^\circ\text{C})^{-1}$$

$$\text{Intercept: } 0.50 \pm 0.06 \text{ units.}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12

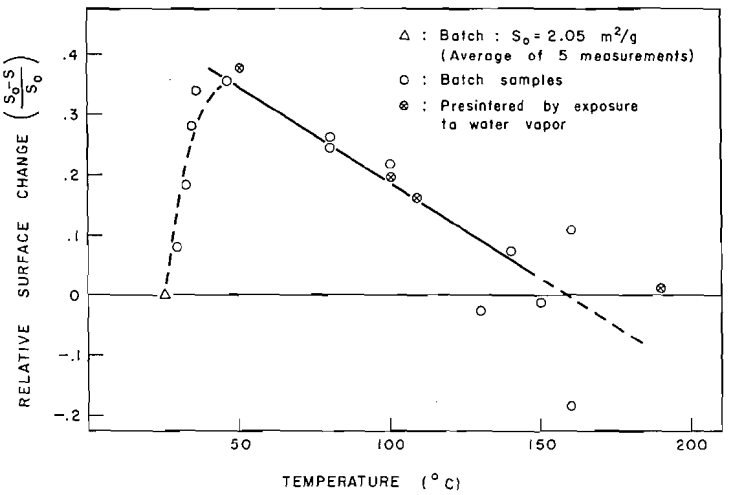

FIG. 2. Effect of sintering of lead iodide with temperature: plot of relative surface change against temperature of sintering, in degrees Centigrade.

The plot indicates a decrease of specific surface below 160° C and suggests a possible increase above that temperature of sintering.

Elementary iodine was observed in the traps during experiments which were performed in the higher temperature range. Since it was not expected that at these temperatures decomposition would set in, a separate experiment was performed at 240° C. Lead di-iodide of a specific surface of 1.5 m^2/g was placed in a long glass tube surrounded by a heating element, and was heated for 24 hours under an atmosphere of dry nitrogen at room pressure. During this time period, the salt underwent a process of stoichiometric decomposition into lead mono-iodide and elementary iodine, with the latter condensing on the colder part of the tube which protruded from the heater.

Sintering by Exposure to Water Vapor

Microcrystals of lead di-iodide, contained in the type of cell previously described, were evacuated for 12 hours by pumping with a diffusion pump. Water vapor was subsequently admitted from a cell containing distilled water at saturated vapor pressure. The cells were kept in communication for the required period of time. The cell containing the water was closed a few seconds before the end of the treatment, and, at the required time, the salt container was connected with the high-vacuum manifold. The latter was kept under vacuum by a 2-stage silicon oil diffusion pump, which was backed by a high-speed rotary mechanical pump and by a 24-liter flask branched in parallel. This was followed by 12 hours of evacuation. The whole operation was performed at 25.0° C. The surface area was then determined by BET nitrogen adsorption. Salt of an initial specific surface of 1.5_1 m^2/g was used for all of those experiments.

The results are given in Fig. 3. Two extra runs were performed with hydration times of 24 and 48 hours, and areas of 0.60_0 m^2/g were obtained in both cases. It was therefore assumed that the specific surface reached an asymptotic value of 0.60_0 m^2/g, and it was seen that under this condition the phenomenon follows first-order kinetics with respect to surface, as shown in Fig. 4. The parameters of the line are found to be:

$$\text{Slope: } -0.245 \pm 0.007 \text{ hours}^{-1}$$

$$\text{Intercept: } -0.04 \pm 0.03$$

DISCUSSION

The activity of lead iodide particles as condensation nuclei (4) and their properties toward ice nucleation (5, 6, 7) have recently resulted in investigations of the surface properties of these crystals (1, 8).

Sintering of the surface of lead di-iodide under exposure to water vapor is a slow process leading to asymptotic values. This can be visualized in terms of homogenization of initial imperfections on the surface and the absence of agglomeration between original particles. The curve of Fig. 3 follows a pattern similar to that of the curves obtained by Moffat and McIntosh (9), who studied the sintering of sodium chloride microcrystals under exposure to low partial pressures of water vapor. The pattern is, however, different from the one obtained recently by Papée (10), where sodium chloride microcrystals were sintered under exposure to water vapor at saturated vapor pressure at 25° C, and where no asymptotic values could be detected in the fast first-order process.

Experiments reported in this note indicate that the process of decrease of surface by heating under vacuum is accompanied by a contrary process of increase, and that the latter effect becomes prevalent at higher temperatures. Since no evidence indicating transition between phases, below 250°, could be found in the literature, it is assumed that the increase is due to thermal decomposition. This explains the controversial results obtained in measuring the melting point of the product (11, 12, 13). This controversy is not eliminated by data obtained by various workers who worked with purified products and knew that decomposition occurs (14), and by those who worked under inert atmospheres (15, 16) to eliminate the action of water vapor and oxygen. Similarly, measurements of vapor pressures of lead di-iodide at various temperatures seem to have led so far to controversial statements (17, 18) mainly because of misinterpretations of the experimental values and failure to analyze the final products.

The controversy noted above and the evidence of the present investigation points, however, to the conclusion that the crystals responsible for the condensation of water or for ice nucleation will have a strongly distorted lattice because of the nature of their preparation, and that this factor will possibly favor their action (19, 20). Since, furthermore, the compound can be decomposed by light (21, 22), and its over-all surface will sinter and homogenize only slowly under exposure to water vapor, as shown by experiments reported previously, a PbI_2 nucleus will probably remain active for long periods of time; even seasoned and originally inactive particles may eventually be activated photochemically.

Another surface-dependent factor that might favor condensation of water on lead iodide nuclei ought to be considered at the same time, since lead iodide gives rise to the photoelectric effect in the visible spectrum (23). It is to be expected that the nucleus will become electrically charged when illuminated, and will therefore bind water molecules by a sort of electrostriction, which, under suitable conditions, may promote coalescence (cf. ref. 24). The fact that freshly prepared lead iodide 'tires' with time towards its photoelectric properties, whether kept in moderate light or in darkness (25), may well be partly explained by the sintering of its surface when exposed to the water vapor in the atmosphere.

ACKNOWLEDGMENTS

Thanks are due to Messrs. T. W. Zawidzki and S. Tong for their help in preparing the lead iodide, and to Drs. G. C. Benson and K. J. Laidler and Mr. S. J. Birstein for many helpful discussions.

FUSED HETEROCYCLICS

PART II. SYNTHESIS OF QUINOLINO-(2 : 3 : 3′: 2′)-QUINOLINE: AN ISOMER OF CALYCANINE[1, 2]

RAGINI ANET[3]

ABSTRACT

The constitution of calycanine, a dehydrogenation product of the alkaloid calycanthine, is discussed. Calycanine dipicrate has been prepared, and, on the basis of its analysis and the infrared spectrum of calycanine, a quinolinoquinoline structure has been put forward for calycanine. The synthesis of quinolino-(2 : 3 : 3′: 2′)-quinoline is described.

Calycanine is an important degradation product of the alkaloid calycanthine (1). At the time that this work was carried out, the constitution of calycanine was not known,[4] and it was decided to investigate this base as a part of the studies on calycanthine (2).

Calycanine was first prepared by Marion and Manske (4) by the selenium dehydrogenation of the alkaloid, and later by Barger, Madaniveitia, and Streuli (5) by heating calycanthine with a variety of reagents. Calycanine, m.p. 310° C after sublimation, was found to be a very stable weak base, giving faintly fluorescent solutions. It did not give any coloration with *p*-dimethylaminobenzaldehyde (Ehrlich reaction). Elementary analysis led both groups of workers to put forward a $C_{16}H_{10}N_2$ formula for calycanine. One active hydrogen and no N-methyl group was found.

Barger *et al.* (5), on the basis of their formula for calycanthine, put forward structure (I) for calycanine. Manske and Marion (6) considered that Barger's structure was inconsistent with the properties of calycanine, viz., the negative Ehrlich reaction and its basicity. As a result of further analyses of the base they proposed a $C_{21}H_{15}N_3$ or $C_{21}H_{13}N_3$ formula for calycanine, and the structures (II) or (II*a*).

[4]*This work was recorded in a part of a D. Phil. Thesis, Oxford University, 1952. After the completion of this work, we became aware of the unpublished work of Clark and Woodward at Harvard University, who synthesized quinolino-(3 : 4 : 4′: 3′)-quinoline and found it to be identical with calycanine (3).*

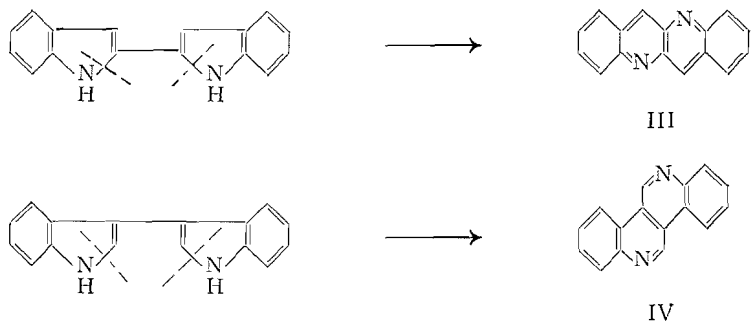
For personal use only.

At this stage, Hargreaves reported an X-ray investigation of calycanine (7). Although the results were not conclusive, he suggested that the size of the unit cell favored a C_{16} formula and that the molecule of calycanine was centrosymmetrical (8). Later, Manske, Marion, and Kulka (9) synthesized 2-(3-lepidyl)-3-carboline (II) and found it to be different from calycanine. They discarded the C_{21} expression and proposed a $C_{15}H_{10}N_2$ formula as being in agreement with their analytical figures and with the molecular weight according to Hargreaves's data.

In the present investigation, calycanine was prepared according to Barger *et al.* (5) by the zinc dust distillation of calycanthine. Analysis of the base did not distinguish between a C_{15} and a C_{16} formula, but calycanine formed a *dipicrate* whose analysis was in better agreement with the C_{16} than with the C_{15} formula. The infrared spectrum of calycanine showed no band attributable to an —NH group, thus ruling out both Barger's structure (I) and an indoloquinoline or indoloisoquinoline structure as suggested by the Canadian workers (9). The active hydrogen in calycanine must therefore be contained in a structural feature other than an —NH group. A quinolinoquinoline system in which the two pyridine rings are fused together, would, it was felt, fulfill such a requirement. Furthermore, such a system could easily arise from two indole nuclei as follows.



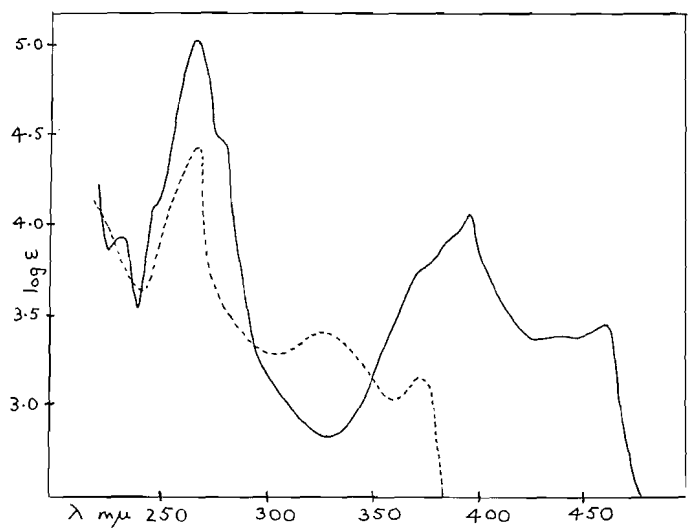


FIG. 1. Ultraviolet absorption spectra in methanol.
- - - Calycanine
—— Quinolino-(2 : 3 : 3′: 2 ′)-quinoline

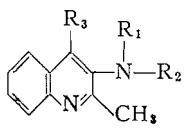
Of the six quinolinoquinoline structures formed by the fusion of the two pyridine nuclei, only two, quinolino-(2:3:3′:2′)-quinoline (III) and quinolino-(3:4:4′:3′)-quinoline, are centrosymmetrical. We have now synthesized the former, and found it to be different from calycanine. By exclusion of alternatives, structure (IV) was proposed for calycanine (cf. 2).

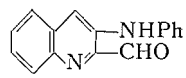
A possible explanation for the active hydrogen found in the Zerewitinoff determination on calycanine may be that one mole of the Grignard reagent adds to the C=N linkage of one quinoline ring, and as a result, the hydrogen atom on the carbon γ to the nitrogen of the other quinoline ring is activated.

The ultraviolet absorption spectrum of calycanine is recorded in Fig. 1.

Synthesis of Quinolino-(2:3:3′:2′)-quinoline: Epindoline

Although the base itself has not been prepared previously, two of its derivatives, viz., 4:4′-dihydroxy-6:6′-dimethyl- (10) and 4:4′-dihydroxyquinolino-(2:3:3′:2′)-quinoline (11), have been synthesized. The hydroxyl groups in the quinolinoquinoline or epindoline (10) system were found to be resistant to reduction (10) or acylation (11). The synthesis of the unsubstituted base was carried out as follows.





X

V. $R_1 = R_2 = H$; $R_3 = COOH$
VI. $R_1 = Ph$; $R_2 = H$; $R_3 = COOH$
VII. $R_1 = R_2 = Ph$; $R_3 = COOH$
VIII. $R_1 = Ph$; $R_2 = R_3 = H$
IX. $R_1 = R_2 = Ph$; $R_3 = H$

When 3-aminoquinaldine-4-carboxylic acid (V) (12) was heated with iodobenzene and copper catalyst under conditions described for the conversion of anthranilic acid to *o*-phenylaminobenzoic acid (13), a mixture of 3-phenylamino- and 3-diphenylamino-quinaldine-4-carboxylic acids (VI and VII respectively) was obtained. Attempts to prepare the monosubstituted acid exclusively were unsuccessful. It may be noted that 3-aminoquinaldine could not be arylated directly to give 3-arylaminoquinaldine (12, 14) and we have confirmed this difficulty in the reaction of 3-aminoquinaldine with iodobenzene. The mixture of carboxylic acids (VI and VII) could not be separated very satisfactorily, but the mixture of 3-phenylamino- and 3-diphenylamino-quinaldines (VIII and IX respectively) obtained on decarboxylation of the acids could be easily separated by chromatography over alumina.

Oxidation of 3-phenylaminoquinaldine with selenium dioxide, a reagent previously used for the oxidation of quinaldine to quinoline-2-aldehyde (15), gave 3-phenylamino-quinoline-2-aldehyde in 50% yield. It is interesting that this oxidation took place smoothly in spite of the presence of an easily oxidizable phenylamino group. Cyclization of the aldehyde to quinolino-(2:3:3′:2′)-quinoline was successful with concentrated sulphuric acid at 100° C, under the milder conditions described for the cyclization of *o*-phenylamino-benzaldehyde (13), the aldehyde (X) was recovered unchanged. The epindoline (III) was a bright yellow compound which charred but did not melt at 280° C. Its solutions in organic solvents were strongly fluorescent. The ultraviolet absorption spectrum of (III) is recorded in Fig. 1.

EXPERIMENTAL

All melting points are uncorrected. Analyses by Drs. Weiler and Strauss, Oxford.

Calycanine

This was prepared essentially according to Barger *et al.* (5) by the zinc dust distillation of calycanthine. At the same time, a neutral fraction smelling strongly of indole was obtained, but it failed to give any crystalline products. The basic portion gave calycanine, m.p. 302°–305° C, which was repeatedly sublimed to give needles from methanol, m.p. 306°–307° C. Its solution in methanol was faintly fluorescent in ultraviolet light, the fluorescence was unchanged on addition of alkali, but was slightly depressed with mineral acid. Found: C, 82.9; H, 4.4. Calc. for $C_{16}H_{10}N_2$: C, 83.5; H, 4.4%. Calc. for $C_{15}H_{10}N_2$: C, 82.5; H, 4.6%.

Calycanine Dipicrate

Chloroform solutions of calycanine and picric acid were heated together for a few minutes. On cooling, calycanine dipicrate separated as needles. It dissociated rapidly in alcohol and water but could be crystallized from chloroform containing picric acid in red needles, m.p. 238°–239° C. Found: C, 48.7; H, 2.39. Calc. for $C_{16}H_{10}N_2 \cdot 2C_6H_3N_3O_7$: C, 48.8; H, 2.32. Calc. for $C_{15}H_{10}N_2 \cdot 2C_6H_3N_3O_7$: C, 47.9; H, 2.36%.

3-Phenylaminoquinaldine-4-carboxylic Acid (VI)

Three grams of 3-aminoquinaldine-4-carboxylic acid (V) (12), 3.3 ml iodobenzene, 4.7 g freshly dried anhydrous potassium carbonate, and 0.15 g Ullmann's copper catalyst (Naturkupfer C) were refluxed in a mixture of 20 ml *cyclo*hexanol and 20 ml benzyl alcohol for 2 hours with strict exclusion of moisture. The reaction mixture was diluted with 50 ml water and steam-distilled to remove the alcohols. The solution was filtered hot and poured into dilute acetic acid. After 6–8 hours at room temperature, the flocculent precipitate was filtered (3.1 g, m.p. 250°–268° C) and extracted with a 1:1 mixture of chloroform–methanol to remove the disubstituted acid as well as some unchanged 3-amino acid. The residue (1.8 g) was crystallized from ethanol containing some pyridine in rhomboid needles, m.p. 298°–300° C with decomposition. Found: C, 73.0; H, 5.0. Calc. for $C_{17}H_{14}N_2O_2$: C, 73.4; H, 5.4%. The acid was sparingly soluble in alcohol, ether, benzene, and chloroform but easily soluble in pyridine. It did not dissolve readily in either dilute or concentrated hydrochloric acid, but gave a colorless potassium salt.

3-Phenylaminoquinaldine (VIII)

Two grams of the above acid (VI) was heated at 290°–300° C for 30 minutes. The acid melted with decomposition and some of the base sublimed into the condenser attached to the reaction flask. The melt was allowed to cool and extracted with methanolic hydrochloric acid. The acid extract was filtered, diluted with 50 ml water, and made strongly alkaline with potassium hydroxide. Ether extraction of the aqueous solution (charcoal) gave an oil which solidified on refrigeration (1.8 g, m.p. 90°–111° C). The base (VIII) was crystallized from very dilute alcohol in needles, m.p. 120°–121° C (lit. (16), m.p. 120°–121° C). Found: C, 82.1; H, 5.7. Calc. for $C_{16}H_{14}N_2$: C, 82.0; H, 6.0%. The base was very soluble in organic solvents to give non-fluorescent solutions.

The *picrate* formed in ethanol crystallized from the same solvent in golden yellow prisms, m.p. 230° C with decomposition. Found: C, 57.1; H, 3.8. Calc. for $C_{16}H_{14}N_2 \cdot 2C_6H_3N_3O_7$: C, 57.0; H, 3.7%.

3-Diphenylaminoquinaldine-4-carboxylic Acid (VII)

The chloroform–methanol extract from the preparation of the 3-phenylamino acid (VI) was evaporated to dryness and the residue repeatedly crystallized from the same solvents in stout needles, m.p. 270°–273° C with decomposition. Found: N, 7.6. Calc. for $C_{23}H_{18}N_2O_2$: N, 7.9%. The acid was soluble in chloroform and acetic acid, less so in acetone, and sparingly soluble in cold alcohol and benzene.

3-Diphenylaminoquinaldine (IX)

The diphenylamino acid (VII, 0.5 g) was decarboxylated by heating at 270°–275° C for 20 minutes. On working up the reaction mixture, as in the case of 3-phenylaminoquinaldine (VIII), the base was obtained as a yellow oil which solidified on trituration with alcohol. Crystallization from aqueous ethanol gave colorless prisms, m.p. 141°–142° C. Found: N, 9.2. Calc. for $C_{22}H_{18}N_2$: N, 9.0%. The base dissolved easily in organic solvents to give solutions with a vivid blue fluorescence.

The *picrate* prepared in ethanol formed yellow needles, m.p. 222°–223° C. Found: N, 12.8. Calc. for $C_{22}H_{18}N_2 \cdot C_6H_3N_3O_7$: N, 12.9%.

3-Phenylaminoquinoline-2-aldehyde (X)

3-Phenylaminoquinaldine (VIII, 0.9 g) and 0.45 g freshly prepared selenium dioxide were refluxed in 10 ml purified dioxan containing 1–2 drops of water. A vigorous reaction set in after 2 minutes and the solution turned dark, forming a red deposit of selenium. The heating was discontinued until the initial reaction was over, and the solution refluxed for a further 90 minutes. The dioxan was removed under reduced pressure and the black residue extracted with hot benzene (charcoal). Evaporation of the benzene extract gave an orange oil which solidified with a little cold ethanol (0.5 g, m.p. 98°–104° C). It was crystallized from dilute ethanol in needles, m.p. 109°–110° C. Found: C, 77.0; H, 4.8. Calc. for $C_{16}H_{12}N_2O$: C, 77.4; H, 4.8%. The aldehyde was very soluble in ether, benzene, and chloroform. An ethanolic solution of the aldehyde gave a deep red color with 2:4-dinitrophenylhydrazine hydrochloride in ethanol.

The *phenylhydrazone* was prepared by mixing an alcoholic solution of the aldehyde with a solution of phenylhydrazine in 50% acetic acid. On standing at room temperature for 1 hour, the phenylhydrazone separated as a red solid crystallizing from alcohol in yellow needles, m.p. 221–222° C. Found: C, 77.3; H, 5.4. Calc. for $C_{22}H_{18}N_4$: C, 77.9; H, 5.3%.

Quinolino-(2:3:3′:2′)-quinoline: Epindoline (III)

The aldehyde (X, 0.37 g) was heated with 1.4 ml concentrated sulphuric acid at 100° C under anhydrous conditions for 1 hour. The initial addition of sulphuric acid dissolved the aldehyde with evolution of heat. At the end of the reaction, the solution was poured into ice-cold water and made alkaline with ammonia. The precipitated solid (0.15 g) was extracted with 100 ml chloroform. Evaporation of chloroform gave bright yellow feathery needles, which were washed with ether to remove uncyclized aldehyde and crystallized from xylene to give stout yellow rods of epindoline which charred but did not melt at 280° C. Found: C, 83.2; H, 4.7. Calc. for $C_{16}H_{10}N_2$: C, 83.5; H, 4.4%. The base was sparingly soluble in ether, but moderately so in benzene, chloroform, and ethyl acetate. Its solutions in these solvents were bright yellow and gave a vivid green fluorescence on addition of a trace of ethanol. The solutions turned orangish and the fluorescence disappeared on addition of hydrochloric acid.

For personal use only.

The *picrate* formed in chloroform gave red needles from alcohol containing picric acid, and melted at 308°–310° C with decomposition. Found: C, 57.3; H, 2.8. Calc. for $C_{16}H_{10}N_2 \cdot C_6H_3N_3O_7$: C, 57.5; H, 3.0%.

ELECTROLYSIS OF LITHIUM HYDRIDE[1]

M. A. WEINBERGER, T. J. MOUSSEAU,[2] AND O. MAASS[3]

ABSTRACT

A method has been developed whereby current yields of as high as 70% of anodically discharged hydrogen can be maintained during continuous electrolysis of lithium hydride at or just below its melting point. Efforts to utilize this process for the separation of hydrogen and deuterium were unsuccessful.

INTRODUCTION

The electrolysis of heated lithium hydride was first investigated by Moers (1), who described a number of disturbing side effects which dogged his experiments. These showed up as wild fluctuations on the electrical meters monitoring the electrolysis and were ascribed by him to formation of lithium whiskers or metal fog which shorted the electrodes. This work was followed by that of Peters (2), who was able to demonstrate the validity of Faraday's laws for the separation of the electrolysis products. Optimum current efficiencies* for the electrolysis were found using solid lithium hydride at temperatures between 550 and 650° C, currents of 1–3 amp and electrolysis times of up to 3 minutes. In these experiments the hydrogen was pumped off as it was formed and corrections were made for hydrogen produced by thermal decomposition. Above the melting point, hydrogen evolution by electrolysis was found to be irregular and zero current yields were sometimes obtained. Other experiments showed that current yields dropped with increasing electrolysis times. Finally, Potter and Bockris (3) carried out electrolyses under hydrogen pressures of 1 atm to suppress thermal dissociation and showed that the electrolytically separated hydrogen was actually of anodic origin only. These workers also found that good current efficiencies (above 80%) were only obtained by electrolyzing for short times (up to $2\frac{1}{2}$ minutes) at temperatures below the melting point (570–610° C). One-half minute electrolysis at 680° C gave 27% yield, while a prolonged electrolysis (17.5 minutes) at 635° C gave only 2% of the amount of hydrogen calculated by Faraday's law. Recombination of the electrolysis products was believed to be the reason for the low efficiencies.

It appears that the liberated lithium metal is principally responsible for low electrolytic hydrogen yields and most of the apparent anomalies during the electrolyses. In the present work it was attempted to overcome this by depositing the lithium at a cathode with which it would form an alloy. Lithium alloys have been produced by electrolyzing fused lithium chloride – potassium chloride mixtures using the molten alloying metal as cathode (4). If lithium metal could in this way be prevented from spreading into or floating on the hydride and thus kept away from the hydrogen liberated at the anode, better yields should be obtainable. The choice of lithium scavenger cathode was limited to metals having a melting point below that of lithium hydride. Lead and aluminum were chosen. It was realized that because of their ability to form alloys with lithium these metals might decompose lithium hydride themselves, but it was hoped that some kind of equilibrium would be reached.

EXPERIMENTAL

The principal features of the electrolysis cell design were determined by the requirement that lithium deposition should occur only at the scavenger cathode. In addition, because of the corrosive nature of lithium hydride, possible cell materials were restricted to Armco iron or certain stainless steels (5), and no ceramic insulating materials could be used. The scavenger cathode then being in contact with the metallic cell walls, the latter had to be insulated from the active electrolyte to prevent lithium deposition there. This could be achieved by utilizing the poor electrical conductivity of solid lithium hydride at more than 150° below its melting point. Accordingly the cell was heated in such a way as to provide fused or nearly fused electrolyte between anode and scavenger cathode while at the same time maintaining an insulating layer of cooler solid lithium hydride on the walls of the cell not covered by the scavenger. The main heat input was therefore into the molten cathode and into the internally heated anode. By means of thermocouples, temperatures were measured in the cathode pool and at various points along the cell wall but could not be measured in the active electrolyte as the presence of metal there would have provided an auxiliary electrode.

The apparatus is shown in Fig. 1. The anode was supported by the cell lid from which it was electrically insulated and a means was provided to move it up or down in the cell. The lid and the upper part of the cell were water-cooled to protect the vacuum sealing gaskets and in addition a tube passing down the hollow anode shaft played cool nitrogen on the shaft wall opposite the teflon gasket. The temperatures of any of the gaskets never rose much above room temperature.

A conventional vacuum and gas handling system was attached to the cell.

The cell, lid, and anode were fabricated from 347 stainless steel, one of the materials recommended for use with lithium hydride (5). This material was chosen as it has a lower hydrogen permeability than pure iron. Welding was kept to a minimum and was done by the inert gas arc process. The cell after prolonged evacuation was first treated with hydrogen at 700° C. The first scavenger cathode material, reagent grade lead (7 lb), was then placed in the cell and hydrogen treatment at red heat continued. The cell was transferred to a dry box containing a helium atmosphere in which all subsequent dismantling, filling, and assembling procedures were carried out. About 280 g lithium hydride was placed in the cell, which was evacuated, filled with hydrogen, and heated. It was found that too much decomposition occurred and use of lead as cathode was abandoned, to be replaced by an aluminum–lithium mixture (15 mole % Li). The hydrogen treatment was repeated, some hydrogen being absorbed and the cell charged with 1 lb of lithium hydride (Maywood Chem. Co. 10-20 mesh). The cell was heated to 700° C, as measured by the thermocouple in the alloy. After this treatment, the cell was once again dismantled and all lithium hydride removed. A fresh 1-lb charge of hydride was placed in the cell (for later experiments the cell was almost filled with hydride to cut down dead space). When thermal decomposition had settled down to a low rate at 670–675° C, electrolysis was started using a stabilized current of 1 amp. This was obtained from storage batteries supplying 110 v d-c. by means of dropping resistors and a ballast tube. Cell voltage was not controlled but was measured. Cell temperatures were controlled manually and stability was enhanced by use of a constant voltage transformer.

Electrolyses were run for periods up to 27 minutes, during which time gas volumes of the order of 100 cc at the measured constant cell pressure (580–740 mm Hg) were collected

in a burette. The rate of thermal decomposition or absorption was determined before and after each electrolysis and used to calculate the corrected amount of hydrogen evolved during electrolysis.

RESULTS AND DISCUSSION

With Lead as Scavenger:

Decomposition of lithium hydride shown by hydrogen evolution set in at about 350° C. Hydrogen had to be removed to keep the pressure in the system below atmospheric pressure. During subsequent cooling and reheating the onset of decomposition occurred at higher temperatures (500–550° C). The rate of gas evolution decreased somewhat as decomposition proceeded but was still high after 70% of the lithium hydride initially present had been decomposed. This system therefore does not attain hydrogen dissociation pressures below 1 atm at reasonable concentrations of lithium in the scavenger.

For personal use only.

With Lithium–Aluminum as Scavenger:

Decomposition of lithium hydride occurred here too but after 1.2 moles had been decomposed the dissociation pressure settled down to somewhat less than an atmosphere at the operating temperatures. As the lithium content of the aluminum increased, higher temperatures were required for a given dissociation pressure. Working temperatures were chosen to give as low a rate of change of hydrogen evolution as possible, while maintaining a hydrogen pressure of 580–740 mm Hg. The other factor governing the choice of temperature was the electrical resistance of the electrolyte which with a cathode–anode separation of 1.5 cm was to be kept below 10 ohms. There was a rapid increase in resistance at temperatures below those shown in Table I. The rather large cell voltage fluctuations shown in the table for some of the runs were probably due to lack of homogeneity or local temperature instabilities in the melt. As mentioned previously the temperature measured was that of the alloy pool. In none of the experiments did the meter indications fluctuate wildly as found by Moers in the original electrolysis experiments.

From the results in Table I it appears to be rather difficult to prescribe optimum operating conditions for the electrolysis. The variables investigated were temperature, electrolysis time, and cell current. Temperature within the range studied, 670–689° C, does not seem to have too much effect. The other two variables are to some extent interrelated, since the electrolyses were run until a fixed amount of gas had been collected (100 or 127.5 cc at operating pressure), this gas, however, containing varying amounts of hydrogen produced by thermal decomposition. At first sight, the current efficiency seems to decrease with increasing duration of electrolysis, which would be in accord with the observations of Peters, and Potter and Bockris. Apparently electrolysis times of under 10 minutes correspond to yields of 60% and higher (Runs A1 to B9, E15 through F36) while electrolyses lasting for more than 20 minutes give yields of 40–50% (Runs B11 to D14). However, although the rate of electrolytic gas evolution was not usually measured, in two experiments (E16 and E17) where such measurements were made, the rate of volume increase was essentially constant for the whole period of the electrolysis. Hence the tentative supposition about a yield–time relation is not borne out in detail.

To the extent that the cell current is related to the electrolysis time, higher currents apparently correspond to better yields. This generalization does not fit experiments A1 to A8. The possibility that the higher yields in runs using 2 amp (E15 to F36) were artifacts due to thermal decomposition of the hydride by the heat liberated by the current is discounted (i) by experiments A7 and 8 where good yields were obtained with 0.29 amp, and (ii) by experiments B12 to B15 where the wattage dissipated was higher than in the 2-amp runs and much poorer yields resulted.

A possible explanation of the results discussed in the preceding paragraphs may be that the scavenger cathode is only partially effective: effective enough to make it possible to electrolyze lithium hydride near its melting point profitably for much longer periods than those used by Potter and Bockris but not quite able to prevent some lithium from getting into the melt. This would account for the apparent irregular yields and also for some of the cell voltage variations.

Hydrogen–Deuterium Separation:

Exchange of hydrogen with lithium hydride takes place slowly at room temperature (7) by means of a surface reaction and a diffusion process and would be expected to proceed much more rapidly at the working temperatures used here, where the additional mechanisms of dissociation and recombination are available. It was, however, of theoretical and practical interest to see whether one could detect any electrolytic separation

of the hydrogen isotopes. Mass spectrometric analyses of the hydrogen produced electrolytically (i.e. 59, 65, 76, 98, and 96% of the total gas collected in electrolysis series B, C, D, E, and F respectively) did not give significantly different deuterium–hydrogen ratios from those of the hydrogen produced by thermal decomposition. Thus if any separation occurred during the electrolysis it must have been masked by exchange.

The mass spectrometer analyses also showed that the gas contained only species of mass 2 and 3 and no significant amounts of species attributable to methane (from carbon in the steel), nitrogen, etc.

ACKNOWLEDGMENTS

The authors wish to express their gratitude to Mrs. K. O. Kutschke, National Research Council, Ottawa, and Mr. D. C. Austen, Atomic Energy of Canada Limited, Chalk River, for mass spectrometric analyses. They would also like to thank Dr. H. Sheffer, Dr. R. M. Heggie, and Dr. E. J. Casey for discussions.

DONOR ACCEPTOR REACTIONS OF TITANIUM TETRACHLORIDE WITH FORMAMIDE AND N,N-DIMETHYL FORMAMIDE[1]

JACQUES ARCHAMBAULT[2] AND ROLAND RIVEST

ABSTRACT

Co-ordination complexes of titanium tetrachloride with formamide and N,N-dimethyl formamide have been prepared. All the complexes found are explained through a co-ordination number of 6 for titanium (IV).

The infrared spectra of these compounds were measured; a negative shift observed for the carbonyl frequency and a positive shift observed for what is thought to be the C—N frequency are explained by a co-ordination through the oxygen of these molecules. Structural formulas are proposed for the compounds obtained.

INTRODUCTION

Titanium tetrachloride "A" is a very strong Lewis acid. Its reactions with donor molecules were very well summarized by Jackson (1) in 1939 and more recently by Archambault (2) in 1956. The only addition compound between "A" and an amide was prepared by Dermer and Fernelius (3). They reported the synthesis of an addition compound between "A" and N,N-diphenylacetamide, but the elementary analysis is the only evidence they have to support the proposed formula $TiCl_4.2CH_3CON(C_6H_5)_2$.

An amide, even with two donor atoms, oxygen and nitrogen, should not give a chelate with "A" because it would be a four-atom ring which is very seldom obtained (4). The bonding through both donors could lead to a polymeric species, but the molecular weight determination of one complex obtained indicated that this is not the case. So the remaining question to answer is the following: which atom in the donor molecule is complexed with "A"? Infrared spectra of some metal–urea complexes have been measured by Mizushima and Quagliano (5). They reveal that urea forms nitrogen-to-metal bonds with some transition metals and oxygen-to-metal bonds with others. Since the relative ability of the two donors is easily reversed by passing from one complex to another, it seemed to us that experimentation was the best way to get an answer to our question. N,N-dimethyl formamide was chosen for this purpose.

Furthermore, it is well known that substitution reactions occur very easily when the donor atom, oxygen or nitrogen, is combined with a more or less labile hydrogen. We had hoped that the use of formamide as a donor would give us additional information and lead to the answer of the previous question. It was also of interest to know if the strong molecular association of formamide would have any effect on the reaction.

EXPERIMENTAL

Materials and Manipulations

Reagent grade titanium tetrachloride was purified by the method of Gilchrist (6), redistilled, and used as such. The reagent grade of the amides and of the solvents used for infrared measurements was carefully dried over sodium sulphate and redistilled under completely dry atmosphere; the medium fraction was used for our experiments.

Titanium tetrachloride and its addition compounds are extremely sensitive to moisture, so all the experiments were performed under controlled atmosphere using dry nitrogen. Unless otherwise indicated, the addition of the titanium tetrachloride was made through

[2]*Fellow of l'Office Provincial des Recherches Scientifiques de la Province de Québec.*

a pressure-equalizing funnel and the reaction was allowed to take place in a closed system previously flushed with nitrogen. Agitation was provided with a Teflon-enclosed magnetic stirrer.

The System: $TiCl_4$–$HCON(CH_3)_2$

A solution of $TiCl_4$ in carbon tetrachloride was added dropwise to excess dimethyl formamide diluted in the same solvent. The reaction product, washed with carbon tetrachloride and dried under vacuum, is a yellow powder, much more stable to moisture than most adducts of $TiCl_4$ with organic molecules. The high melting point of this complex (220–225° C) is another evidence of its greater stability. The compound is soluble in polar solvents with or without decomposition, according to the donor ability of the solvent molecule. The analyses for titanium and chlorine were made gravimetrically on the same sample, the titanium being weighted as TiO_2 and the chlorine as AgCl. Carbon and hydrogen were determined by the conventional microcombustion technique and nitrogen by the Kjeldal method.

	% Ti	% Cl	% N	% C	% H	Ti/Cl
Calc. for $TiCl_4.2HCON(CH_3)_2$	14.26	42.22	8.34	21.42	4.20	1/4.00
Found	14.20	41.78	8.27	21.44	4.50	1/3.97

Ebullioscopic measurements were carried out on methylene chloride solutions of the adduct, using a Swietowslavski boiling-point apparatus. The molecular weight so found (340±15) is in good agreement with the formula weight (335.9) of the monomeric species. Then the idea of a polymeric chain through both donor atoms is to be rejected. Moreover, if we are to maintain the generally admitted co-ordination number of 6 for titanium (IV), we must exclude the possibility that both nitrogen and oxygen act as donors towards the same titanium atom. This will be confirmed by infrared spectrum investigations.

The System: $TiCl_4$–$HCONH_2$

A saturated solution of formamide in methylene chloride was added dropwise to a solution of $TiCl_4$ in the same solvent, so that the reaction medium was always in excess of "A". The reaction product is a yellow powder insoluble in methylene chloride from which it was separated by filtration. After being washed many times with fresh anhydrous CH_2Cl_2, it was dried under vacuum at room temperature. This product is much less stable to moisture than its dimethyl formamide congener. It has no definite melting point, but decomposes on heating with loss of HCl. An attempt to determine nitrogen by the micro Dumas method was unsatisfactory, but the Kjeldal method gave reliable results.

	% Ti	% Cl	% N	% C	% H	Ti/Cl
Calc. for $TiCl_4.2HCONH_2$	17.12	50.69	10.01	8.58	2.16	1/4.00
Found	17.42	49.43	9.88	9.44	2.39	1/3.78

The product is soluble only in highly polar solvents in which the possibility of decomposition due to interchange with the solvent molecules is not to be disregarded. Another restriction which should not be neglected is that ebullioscopic measurements on this adduct require a low-boiling solvent in order to avoid decomposition by heat. So molecular weight determinations could not be made because of the absence of a suitable solvent either for ebullioscopic or cryoscopic experiments.

Attempts to perform the reaction between pure reactants resulted in somewhat different compounds. In a first experiment, excess $TiCl_4$ has been slowly added to pure formamide at the temperature of 0° C. The reaction, which is highly exothermic, rapidly yields a yellow spongy solid. After being thoroughly washed with CCl_4 to remove excess $TiCl_4$, and dried under vacuum, this substance yielded a hygroscopic yellow product, the composition of which changed with varying drying temperature. We have found it pretty hard to repeat our results from one experiment to the other as shown in Table I. However, at room temperature, it appears that no substitution occurs, and one finds a compound of the following formula $TiCl_4.(HCONH_2)_2.nHCONH_2$ in which "n" varies from 3.5 to 4.5. This does not imply an exception to the normal co-ordination number of 6 for titanium (IV), but simply that we are dealing with the same hexa-co-ordinated compound more or less associated through hydrogen bridging, according to the following scheme.

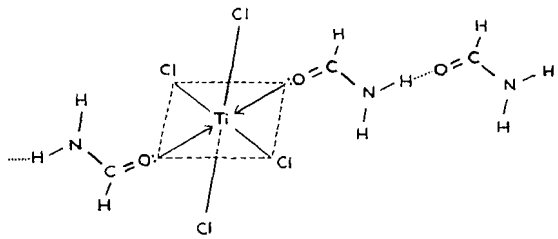

FIG. 1.

TABLE I

Drying temp.		% Ti theor.	% Ti found	% Cl theor.	% Cl found	Ti/Cl theor.	Ti/Cl found
20° C	$TiCl_4.4HCONH_2$	12.90	11.53 12.84	38.40	35.44 38.20	1/4	1/4.1 1/3.99
50° C	$TiCl_4.3HCONH_2$	14.75	14.24 14.28	43.73	40.01 40.69	1/4	1/3.79 1/3.84
100° C	$TiCl_3.HCONH.2HCONH_2$	16.28	16.22	38.90	37.81	1/3	1/3.15

If the drying temperature is increased, the composition changes gradually till one gets a ratio of Cl/Ti of 3.15 with approximately one mole of HCl and one mole of formamide pumped off.

Infrared Spectra and Structure Discussions

The infrared spectra were obtained by a Perkin–Elmer model 112 single beam spectrophotometer using NaCl prism. Characteristic absorption bands of $TiCl_4.2HCON(CH_3)_2$ are given in Table II, together with those of N,N-dimethyl formamide in different solvents.

From the spectra of $TiCl_4.2HCON(CH_3)_2$ and $HCON(CH_3)_2$ in methylene chloride and acetonitrile, the C=O stretching frequency of the complex is shown to be shifted by about 30 cm^{-1} to lower frequencies. A similar shift of the carbonyl band in complex compounds is an indication of co-ordination through the oxygen atom (5). Corresponding data for the adduct with formamide are recorded in Table III.

Once again, the carbonyl band is shifted by the amount of 28 cm^{-1} to lower frequencies. This is certainly a strong indication that co-ordination of either substituted or unsubstituted amides to titanium (IV) is made through oxygen rather than nitrogen.

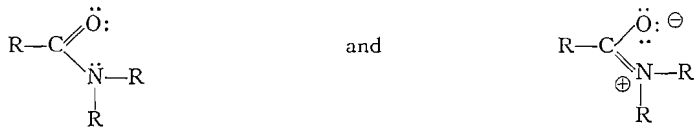
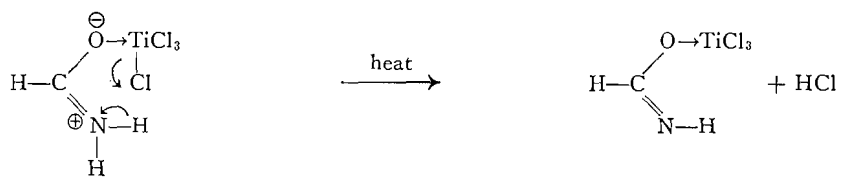
Nevertheless, since the contribution of the tautomeric form H—C(OH)=NH to formamide is negligible (7, 8) one could argue that the loss of HCl observed on heating the formamide adduct is an evidence of co-ordination by nitrogen. Indeed, this internal rearrangement generally implies that the donor atom is bonded to a more or less labile hydrogen, but in the case of formamide, it can be accounted for otherwise in terms of the resonance theory. As pointed out by Pauling (9) and Dewar (10), amides are in resonance between the two following forms:



The dipolar form contributes about 15% (8). The formation of a co-ordinated link through the free electron pair of nitrogen would result in the loss of the resonance energy of the parent base which amounts to 21 kcal/mole in formamide (9). However, the formation of O→Ti bonds is expected to increase the contribution of the dipolar structure (11, 12), so the positive formal charge on nitrogen eases the departure of a proton, according to the following mechanism:



On the other hand, if the effect of a Lewis acid on amides is to result in a greater double-bond character for the nitrogen-to-carbon bond and a greater single-bond character for the carbon-to-oxygen bond, one should be able to detect these effects by infrared spectra. As we have shown above, we observed a lowering of the C=O stretching frequency in both adducts, but unfortunately, the position of the C—N stretching band is not as well

For personal use only.

known. In fact, no data are available concerning the assignment of infrared absorption bands of N,N-dimethyl formamide.

Infrared spectrum of formamide has been more thoroughly investigated, and the position of the C—N stretching band is assumed to be at 1309 cm^{-1} in the liquid state, which is supported by the positive frequency shifts of this band accompanying the passage from vapor to liquid state and from formamide to formamide hydrochloride (13).

As shown in Table II, there is only one band of N,N-dimethyl formamide which suffers a positive shift when co-ordinating to titanium (IV), and this shift is of the same order, but opposite in direction, as the shift due to the lowering of the carbonyl frequency. This band is located at 1086 cm^{-1} in a non polar solvent like CS_2 and shifted to 1093 and 1095 cm^{-1} in CH_2Cl_2 and CH_3CN. Furthermore, its frequency increases by some 28–30 cm^{-1} when entering complexes. Such a behavior appears to be an argument in favor of its assignment to the C—N stretching vibration, although this tentative assignment needs to be checked by model compounds.

Moreover, the lack of a suitable solvent for the adduct $TiCl_4.2HCONH_2$ prevented us from finding out the exact position of its C—N band, which is well known for pure formamide. Emulsions were not too good in Nujol, and light diffusion occurred. Nevertheless, the C—N band appeared to be much broader and centered over higher frequencies, although it is difficult to estimate the value of the shift.

CONCLUSIONS

The results of elementary analysis, molecular weight determinations, and infrared measurements have led us to propose the following formulas for the compounds prepared:

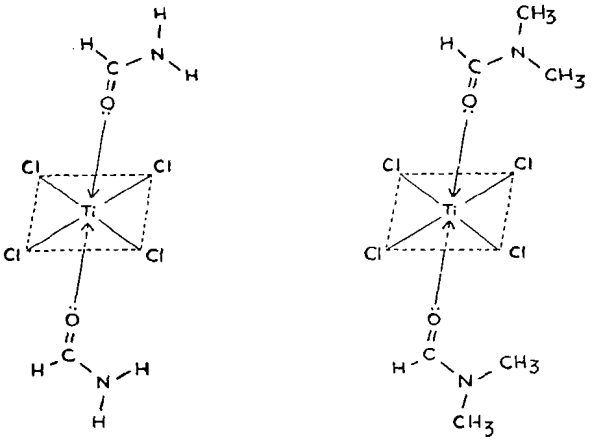

FIG. 2.

The corresponding *cis* forms are also a possibility.

ACKNOWLEDGMENTS

The authors are grateful to the following for their assistance: Prof. Camille Sandorfy for valuable discussions on the infrared spectra measured, the National Research Council of Ottawa for its financial assistance (R.R.), and l'Office Provincial des Recherches Scientifiques de la Province de Québec for a fellowship to one of us (J.A.).

RÉSUMÉ

On a préparé des complexes de coordination du tétrachlorure de titane avec la formamide et la N,N-diméthyl formamide. Tous les complexes isolés sont expliqués en attribuant au titane (IV) le nombre de coordination 6. Les spectres infrarouges de ces composés ont été mesurés. Une variation négative de la fréquence du carbonyle et une variation positive d'une bande attribuée à la vibration C—N sont expliquées en supposant que la coordination au titane se fait par l'oxygène des molécules d'amide. On propose des formules dans l'espace pour les composés préparés.

THE HEMICELLULOSE OF WHITE ELM (ULMUS AMERICANA) II. CONSTITUTION OF THE METHYL GLUCURONO-XYLAN[1]

J. K. GILLHAM AND T. E. TIMELL

ABSTRACT

The wood of white elm (*Ulmus americana*) has been found to contain less xylan than most other hardwoods. Partial hydrolysis of the hemicellulose component yielded an aldotriouronic acid, a glucuronosyl xylose, 2-*O*-(4-*O*-methyl-α-D-glucopyranosyluronic acid)-D-xylopyranose, 4-*O*-methyl-D-glucuronic acid, and galacturonic acid.

Hydrolysis of the fully methylated polysaccharide gave a mixture of 2-*O*- and 3-*O*-methyl-D-xylose, 2,3-di-*O*-methyl-D-xylose, 2,3,4-tri-*O*-methyl-D-xylose, and 2-*O*-(2,3,4-tri-*O*-methyl-α-D-glucopyranosyluronic acid)-3-*O*-methyl-D-xylopyranose in a molar ratio of 6:124:1:14. The number-average degree of polymerization of the methylated hemicellulose was 133 and that of the native polymer 185. On the basis of this and other evidence it is suggested that the xylan is linear and contains 185 1,4-linked β-D-xylopyranose residues, every seventh of which carries a single terminal side chain of 4-*O*-methyl-D-glucuronic acid attached by an α-glycosidic bond through C_2 of the xylose. The number of acid groups is larger than in other hardwood hemicelluloses so far studied.

In a previous investigation (1) it was shown that partial hydrolysis of a hemicellulose from white elm yielded a mixture of sugars containing xylose, 2-*O*-(4-*O*-methyl-α-D-glucopyranosyluronic acid)-D-xylopyranose, and several other uronic acids. The present paper is concerned with the nature of these sugar acids and with the structure and properties of the hemicellulose.

RESULTS AND DISCUSSION

Resolution of the mixture of sugar acids referred to previously (1) on a column of anion exchange resin yielded six fractions. The first acid to be eluted from the column (I) contained one methoxyl and one carboxyl group. Examination by paper chromatography after partial hydrolysis suggested the presence of xylose, a mono-*O*-methyl glucuronic acid, and the above aldobiouronic acid. Together with the equivalent weight (510) these facts indicated that I ($[\alpha]_D^{20}$ +75°) was a triouronic acid containing two xylose and one mono-*O*-methyl glucuronic acid residue. A similar triouronic acid has been isolated from trembling aspen (2), western hemlock (3), Monterey pine (4), loblolly pine (5), and milkweed floss (6).

The second acid obtained (II) was the aldobiouronic acid referred to above. The following fraction was further resolved by paper chromatography and elution from a cocoanut charcoal column (7). The first of the three acids thus obtained (III) was characterized as galacturonic acid after reduction to galactose. Acid IV contained no methoxyl group. Chromatographic examination indicated the presence in the hydrolyzate of glucuronic acid, glucuronolactone, and xylose. These results, together with the equivalent weight (354), suggested the presence of an aldobiouronic acid ($[\alpha]_D^{20}$ +85°) containing one glucuronic acid and one xylose residue. Such acids have frequently been isolated after partial hydrolysis of many non-woody plants, for example wheat straw (8). In wood, glucurone alone has so far been encountered in hydrolyzates from trembling aspen (9), black spruce (10), and white birch (11).

The next acid (V) was not further examined but the last (VI), which contained one methoxyl and one carboxyl group, was converted to the methyl ester, methyl glycoside,

[1]*Manuscript received July 14, 1958.*
Contribution from McGill University and Pulp and Paper Research Institute of Canada, Montreal, Quebec.

reduced with lithium aluminum hydride and hydrolyzed to yield 4-*O*-methyl-D-glucose, identified through its crystalline osazone. Acid VI was therefore 4-*O*-methyl-D-glucuronic acid, a common constituent of plant hemicelluloses (12). Its infrared spectrum was identical with that of an authentic specimen.

The elm wood was analyzed by standard methods (12) and found to contain cellulose (49.3), lignin (23.6), acetyl (3.9), ash (0.3), uronic anhydride (3.6), galactan (0.9), mannan (2.4), araban (0.6), and xylan (11.5%). The content of xylan was exceptionally low for a hardwood and, for example, less than half of that of white birch (13).

The hemicellulose was isolated by direct alkaline extraction of the wood as described previously (1). Earlier evidence suggested strongly that the polysaccharide possessed residues of 4-*O*-methyl-D-glucuronic acid linked to xylose. If this were so, the uronic anhydride content corresponded to 7.0 xylose residues per acid group and the methoxyl content to 7.2. The corresponding value obtained from the equivalent weight of the acidic polysaccharide was 6.8.

The fully methylated hemicellulose was subjected to methanolysis under conditions which were known to effect no cleavage of the aldobiouronic acid. The glycosides were resolved into an acidic and a neutral fraction on a column of ion exchange resin. The acidic fraction, which contained only one component, was converted to the ester glycoside, reduced, and hydrolyzed to give a mixture of reducing sugars which was resolved on a charcoal column, yielding 2,3,4-tri-*O*-methyl-D-glucose and 3-*O*-methyl-D-xylose, both of which were characterized through their aniline derivatives. The acid was accordingly 2-*O*-(2,3,4-tri-*O*-methyl-α-D-glucopyranosyluronic acid)-3-*O*-methyl-D-xylopyranose. The fact that the 4-position was unsubstituted in this acid but was substituted when the free acid itself was methylated (1) showed that its xylose moiety was linked to other sugar residues through C_4. This, in conjunction with the absence of any 3,4-di-*O*-substituted xylose, suggested that the acid side groups were attached directly to the framework of the hemicellulose.

The solution of the neutral glycosides was extracted with chloroform for removal of any highly substituted and therefore volatile xyloside (14). After concentration of the extract and the remaining aqueous solution, the glycosides were again combined and hydrolyzed and the resulting mixture of reducing sugars was resolved by fractional extraction of its aqueous solution with chloroform. The first compound to be extracted was identified as 2,3,4-tri-*O*-methyl-D-xylose through its aniline derivative. The major component, which was only sparingly soluble in chloroform, crystallized and was identified as 2,3-di-*O*-methyl-D-xylose. A mixture of two mono-*O*-methyl xyloses was recovered from the aqueous phase and resolved by paper ionophoresis to yield 2-*O*- and 3-*O*-methyl-D-xylose. The molar ratio among the mono-*O*-methyl xyloses, the 2,3-di-*O*-methyl-D-xylose, and the 2,3,4-tri-*O*-methyl-D-xylose was determined as 6 : 124 : 1 (15). The yield of the acid fragment, 14 moles per non-reducing end group, corresponded to 10 xylose residues per acid group, a value higher than expected. The reason for this was probably a loss of uronide material during the methylation. Similar observations have been made elsewhere (16, 17, 18).

The large amount of 2,3-di-*O*-methyl-D-xylose isolated indicated that the backbone of the polysaccharide was composed of xylopyranose residues linked through positions 1 and 4, while the high negative rotation (−70°) of the hemicellulose suggested that the anhydroxylose units were present in the β-configuration. The 2,3,4-tri-*O*-methyl-D-xylose evidently originated from the non-reducing end groups. The side chains consisted of 1,2-linked 4-*O*-methyl-D-glucuronic acid residues, all of which were recovered as the

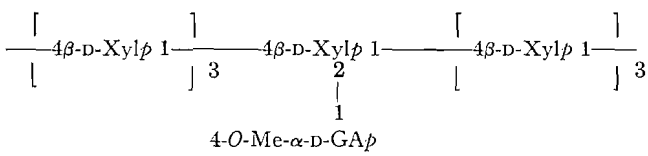
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

partly methylated aldobiouronic acid. The presence of the mono-*O*-methylated xyloses was therefore due to either incomplete methylation, demethylation, or branching.

When the number-average molecular weight of the methylated hemicellulose was determined by osmometry (19), a value of 24,000 was obtained. Assuming one 4-*O*-methyl-D-glucuronic acid group to be associated with 10 xylose residues, this corresponded to a degree of polymerization of 133. The number of non-reducing end groups indicated a number-average D.P. of 145, thus precluding the possibility of any branching. The presence of the mono-*O*-methyl xyloses was accordingly due to incomplete methylation or demethylation. Such phenomena have frequently been encountered elsewhere (16, 18, 20).

The hemicellulose was converted to the fully substituted acetate derivative without any apparent depolymerization (21). Osmotic pressure measurements indicated a number-average molecular weight of 45,900. Assuming the presence of seven anhydroxylose units for each acidic side group, this corresponded to a number-average degree of polymerization ($\bar{P}_n$) of 185. Intrinsic viscosities ($[\eta]$) were determined in cupriethylenediamine and in dimethyl sulphoxide. Application of a relationship developed for a similar hemicellulose (19) gave $\bar{P}_n$ values of 236 and 193, respectively. These somewhat higher values were probably due to the approximate nature of the constant relating $[\eta]$ and $\bar{P}_n$.

Summarizing the above evidence, a simplified structure can now be suggested for the main hemicellulose component in white elm wood. This methyl glucurono-xylan evidently contains an average of 185 β-D-xylopyranose residues linked together by 1,4-glycosidic bonds to linear macromolecules. Every seventh, on the average, anhydroxylose unit carries a single, terminal side chain of 4-*O*-methyl-D-glucuronic acid, attached by an α-glycosidic linkage to C_2 of the xylose. In the native state most of the hydroxyl groups of the polysaccharide are probably esterified with acetic acid (22).



The constitution of the hemicellulose of white elm is similar, albeit not identical, to that of other methyl glucurono-xylans isolated from deciduous woods. These polysaccharides are all, with one possible exception (23), linear, and contain side chains of α-1,2-linked 4-*O*-methyl-D-glucuronic acid residues. Of the species so far studied, European (24) and American (23) beech, white birch (16), yellow birch (25), sugar maple (25), and trembling aspen (26) all contain hemicelluloses with 10–11 xylose residues per acid side group. The present hemicellulose apparently possesses relatively more acid side chains. In this respect it is, actually, more similar to the methyl araboglucurono-xylans present in coniferous woods, which contain more acid groups than the hardwood xylans. Western hemlock, for example, has been reported (27) to contain 4.3 xylose residues for each 4-*O*-methyl-D-glucuronic acid, European larch (28) 5–6, loblolly pine (29) 6–7, and Norway spruce (30) 5 and (31) 5.4, respectively. A methyl glucurono-xylan which also possesses 7 xylose residues per each 4-*O*-methyl-D-glucuronic acid is present in kapok (32), whereas another seed hair, namely milkweed floss (6), contains only half as many of the same acid groups.

It is interesting to note in this connection that white elm is more similar to softwoods than to hardwoods also in its low content of xylan (11.3%). Judging from the limited

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

number of species so far studied, it appears as if a relatively low content of xylan in a wood is usually associated with a larger number of acid side groups in the latter. Inspection of some recently published analytical data (13) indicates that the uronic anhydride content is rather constant for most woods in spite of the fact that the content of xylan varies considerably and is generally much lower for the conifers than for the woody angiosperms. A strict comparison is not possible, however, since a portion of the uronic anhydride is always derived from pectic material in the wood (33).

The number-average degree of polymerization of the present hemicellulose is only slightly lower than that of a similar polysaccharide from white birch, namely 197 (19), and is approximately the same as that of the methyl glucurono-xylans present in sugar maple (25) and yellow birch (25). Unfortunately, no reliable data are presently available as to the weight-average molecular weight of any native wood xylan.

EXPERIMENTAL

General experimental conditions, analytical procedures, and solvents used for separating sugars were the same as described previously (1, 12, 16). All specific rotations are equilibrium values and melting points are corrected. Evaporations were carried out *in vacuo* at temperatures not exceeding 50° C.

Preliminary Characterization of Acid I

This was the first acid to be eluted from the column of ion exchange resin referred to in the previous paper (1). Partial hydrolysis of the partly crystalline material, followed by examination by paper chromatography (solvent A), indicated the presence of xylose, 4-*O*-methyl-D-glucuronic acid, aldobiouronic acid, and unhydrolyzed triouronic acid. Anal. Calc. for $C_{17}H_{28}O_{15}\cdot 3H_2O$: OCH_3, 5.9%; equiv. wt., 472. Found: OCH_3, 4.8%; equiv. wt., 510; $[\alpha]_D^{20}$ +75° (*c*, 1.0 in water).

Separation of Acids II–V

The eluate constituting the second main fraction from the ion exchange column was evaporated to dryness (250 mg) and resolved on three large sheets of Whatman No. 1 filter paper (solvent A). In this way acid II (110 mg) and acid V (3 mg) were separated from two other acids, which were combined and resolved (7) on a cocoanut charcoal (50–200 mesh, product of Fisher Scientific Company, Fair Lawn, N.J.) column (1.5×1.5 cm). Acid II (80 mg) was eluted with 5–7% and acid IV (20 mg) with 7–8% aqueous ethanol.

Chromatographic Identification of Acid III

The rate of movement on the paper chromatogram of this acid was the same as that of galacturonic acid. The methyl ester, methyl glycoside, formed by boiling with 4% methanolic hydrogen chloride under reflux for 6 hours, was reduced with lithium aluminum hydride (34, 35). After hydrolysis, paper chromatography (solvent B) suggested the presence of galactose.

Preliminary Characterization of Acid IV

Partial hydrolysis with 0.5 *N* sulphuric acid at 100° C for 20 hours, followed by paper chromatography (solvent A), indicated the presence of unchanged IV together with glucuronic acid, glucuronolactone, and xylose. Anal. Calc. for $C_{11}H_{18}O_{11}$: OCH_3, nil; equiv. wt., 326. Found: OCH_3, nil; equiv. wt., 354; $[\alpha]_D^{20}$ +85° (*c*, 1.8 in water).

Identification of Acid VI

Acid V was not further investigated because of the paucity of material available. Acid

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

VI (400 mg) was converted to the ester glycoside and reduced in dry tetrahydrofuran (25 ml) with a solution of lithium aluminum hydride (1 g) in the same solvent (30 ml). The neutral glycoside was hydrolyzed to give a sirup, chromatographically (solvent B) identical with 4-*O*-methyl-D-glucuronic acid. Anal. Calc. for $C_7H_{14}O_6$: OCH_3, 16.0%. Found: OCH_3, 15.9%; $[\alpha]_D^{20}$ +63° (*c*, 2.8 in water). The phenylosazone derivative (35, 36) had m.p. and mixed m.p. 157° and an infrared spectrum identical with that of an authentic specimen.

Characterization of the Hemicellulose

The hemicellulose was isolated as described before (1). Anal. Pentosan, 78.5%; uronic anhydride, 15.2% (potassium salt); OCH_3, 2.62% (free acid); $[\alpha]_D^{20}$ −70° (*c*, 1.1 in 2% potassium hydroxide).

Methylation of the Hemicellulose

The hemicellulose (18 g) was stirred with water (75 ml) and 40% (w/w) sodium hydroxide (150 ml) was added in an atmosphere of nitrogen, followed by dimethyl sulphate (135 ml) over a period of 20 hours at a temperature of 0° C. This treatment was repeated five times. The partly methylated material was recovered in the usual way and dissolved in tetrahydrofuran (37). Powdered sodium hydroxide (200 g) was added, followed by dropwise addition of dimethyl sulphate (200 ml) over a period of 10 hours. This treatment was repeated once. After neutralization with acetic acid, tetrahydrofuran was removed by distillation and the precipitated hemicellulose was dissolved in chloroform and reprecipitated into petroleum ether. Anal. OCH_3, 36.1%.

The product was dissolved in chloroform (100 ml) and to the solution dry dimethyl formamide (100 ml), silver oxide (5 g), and methyl iodide (10 ml) were added. The mixture was shaken in the dark for 36 hours after which silver oxide (5 g) and methyl iodide (10 ml) were added and shaking was continued for another 12 hours (38). Salts were removed by filtration, chloroform was added, and the solution was extracted with water for 4 days. It was then dried over calcium sulphate, filtered through Celite, and evaporated to 100 ml. Precipitation into petroleum ether yielded white fibers (9 g). Anal. OCH_3, 38.1%; $[\alpha]_D^{20}$ −62° (*c*, 0.82 in chloroform). The infrared spectrum indicated negligible absorption at the hydroxyl frequency of 3500 cm^{-1}.

Methanolysis of the Methylated Hemicellulose and Separation of the Acidic Component

The fully methylated polysaccharide (5.0 g) was boiled under reflux with 2% methanolic hydrogen chloride (100 ml) for 8 hours. Neutralization with silver carbonate, purification with hydrogen sulphide, and filtration through Celite yielded a sirup of glycosides (5.9 g). The ester groups were saponified with *N* sodium hydroxide at room temperature for 15 hours. Acidic sugars were adsorbed on a column of Dowex 1-X4 (acetate) exchange resin which was washed with water until free of neutral sugars. The acidic component was eluted with 2 *N* acetic acid and the solution was evaporated to a brown solid (1.08 g).

Preparation, Reduction, and Hydrolysis of the Ester Glycoside of the Partially Methylated Aldobiouronic Acid

The methyl glycoside of the partially methylated acid was reconverted to the methyl ester by boiling under reflux with 2% methanolic hydrogen chloride for 8 hours. It was then reduced with lithium aluminum hydride and subjected to methanolysis followed by hydrolysis with *N* hydrochloric acid. Removal of the acid and evaporation yielded a sirup which, when examined by paper chromatography (solvent C), appeared to contain equimolar amounts of a tri-*O*-methyl glucose and a mono-*O*-methyl xylose.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

Separation and Identification of 2,3,4-Tri-O-methyl-D-glucose and 3-O-Methyl-D-xylose

The above sirup was added to the top of a cocoanut charcoal column (1.5×5 cm). Elution with 10% aqueous ethanol gave a compound (263 mg) which corresponded by paper chromatography (solvent C) and paper electrophoresis in a borate buffer solution (39, 40) to 3-*O*-methyl-D-xylose. Anal. Calc. for $C_6H_{12}O_5$: OCH_3, 18.9%. Found: OCH_3, 17.9%. The 3-*O*-methyl-*N*-phenyl-D-xylosylamine, when recrystallized from ethyl acetate – petroleum ether, had m.p. 135–136° C; $[\alpha]_D^{20}$ +118° (*c*, 1.2 in ethyl acetate).

Elution with 20% aqueous ethanol gave a compound (206 mg) which was chromatographically identical with 2,3,4-tri-*O*-methyl-D-glucose. Anal. Calc. for $C_9H_{18}O_6$: OCH_3, 41.9%. Found: OCH_3, 41.0%; $[\alpha]_D^{20}$ +75° (*c*, 2.2 in water). The 2,3,4-tri-*O*-methyl-*N*-phenyl-D-glucosylamine had m.p. and mixed m.p. 146° C. Its infrared spectrum was identical with that of an authentic sample.

Separation of the Neutral Components of the Methylated Hemicellulose

The mixture of neutral glycosides (3.9 g) was extracted with chloroform and the aqueous and the chloroform solutions were concentrated separately, after which they were recombined and hydrolyzed with *N* sulphuric acid. After neutralization with barium carbonate and deionization (Amberlite IR-120 and Dowex 1-X4) the aqueous solution was exhaustively extracted with chloroform in a liquid–liquid extractor for 3 days, after which the extract was removed. Continued extraction of the aqueous solution with chloroform for 3 weeks, followed by concentration of the extract, gave a chromatographically pure di-*O*-methyl xylose. The remaining aqueous phase contained only mono-*O*-methyl xyloses. The first extract was dissolved in water and extracted with chloroform for 3 hours. Repetition of this process several times finally yielded a chromatographically pure tri-*O*-methyl xylose.

Preliminary Characterization of the Mono-O-methyl Xyloses

This fraction had a methoxyl content (18.0%) corresponding to that of a mono-*O*-methyl xylose. Ionophoresis in a borate buffer solution indicated the presence of 2-*O*- and 3-*O*-methyl-D-xylose, with the latter compound constituting the major part of the mixture.

Identification of 2,3-Di-O-methyl-D-xylose

Crystals, m.p. 78° C, formed slowly in the colorless sirup. Anal. Calc. for $C_7H_{14}O_5$: OCH_3, 34.8%. Found: OCH_3, 34.8%; $[\alpha]_D^{20}$ +23° (*c*, 2.0 in water). The 2,3-di-*O*-methyl-*N*-phenyl-D-xylosylamine, when recrystallized from ethyl acetate, had m.p. and mixed m.p. 141° C. Its infrared spectrum corresponded to that of an authentic specimen.

Partial Identification of 2,3,4-Tri-O-methyl-D-xylose

The sirup (20 mg) could not be induced to crystallize; $[\alpha]_D^{20}$ +20° (*c*, 1.3 in water). The aniline derivative, m.p. 98° C, had an infrared spectrum identical with that of an authentic sample.

Spectrophotometric Analysis of the Neutral Components of the Methylated Hemicellulose

A small portion of the mixture of methylated neutral sugars was applied to strips of filter paper which were irrigated with solvent C. The different sugars were located with guide strips, eluted with water, and adjusted to a convenient volume. Concentrations were determined by the *o*-aminodiphenyl method (15). The average value of three determinations was used. The relation between absorbance and concentrations of the three methyl sugars had been determined previously (16).

Determination of the Molecular Weight of the Methylated Hemicellulose

The osmometer used was a Zimm–Myerson (41) instrument as modified by Stabin and Immergut (42). Gel cellophane membranes, which had never been allowed to dry, were kindly supplied by American Viscose Corporation, Marcus Hook, Pa. The solvent was a 9:1 (v/v) mixture of chloroform–ethanol and the temperature was 30±0.01° C. The osmotic pressure was determined at four different concentrations by the static method and the values of the reduced osmotic pressure, h/w, as plotted against w, were extrapolated to zero concentration (Table I). The number-average molecular weight, $\bar{M}_n$, was calculated from the relationship $\bar{M}_n = 25{,}700/(h/w)_0$ and the corresponding degree of polymerization, $\bar{P}_n$, from the relationship $\bar{P}_n = \bar{M}_n \cdot n/M_R$, where n was the number of xylose residues present per acid side chain and M_R was the molecular weight of the repeating unit of the fully methylated polysaccharide.

TABLE I

*Concentration in g/kg solution.
†Osmotic height in cm solvent.

Preparation of the Acetyl Derivative of the Hemicellulose

Hemicellulose (5 g) and freshly distilled formamide (200 ml) were stirred for 5 hours, after which anhydrous pyridine (250 ml) was added followed by dropwise addition of acetic anhydride over a period of 5 hours. After being stirred over night, the gelatinous reaction mixture was poured into ice water with vigorous stirring and recovered as described by Carson and Maclay (21). A second esterification was carried out in the same way although without addition of formamide. The acetyl content of the fully acetylated product was 37.8% (43).

Determination of the Molecular Weight of the Acetylated Hemicellulose

The molecular weight of the acetylated, native hemicellulose was determined as described above for the methylated polysaccharide. The results are given in Table II.

Viscosity Measurements

Relative viscosities were determined with a Craig–Henderson viscometer (44) and

THE SYSTEM: NICOTINE – METHYLETHYL KETONE – WATER[1]

A. N. Campbell, E. M. Kartzmark, and W. E. Falconer[2]

ABSTRACT

The systems: nicotine–water and nicotine – methylethyl ketone were investigated by thermal analysis but the eutectic points were not obtained due to the extreme viscosity and consequent supercooling of solutions of high nicotine content.

The densities, viscosities, and refractive indices were determined for the nicotine – methylethyl ketone – water system at 25.0° C.

The mutual solubilities of nicotine, methylethyl ketone, and water were determined over the entire temperature range. A ternary critical point was found at 67.3° C, the critical composition being 27 weight per cent nicotine; 14 weight per cent methylethyl ketone.

The methylethyl ketone – water and nicotine–water solubility curves were redetermined. The existing data for the former system were confirmed but the data for the classical system nicotine–water were found to be seriously in error at the higher critical solution temperature. Thus the lower critical solution temperature was found to be 61.5° C, in good agreement with previous figures, but the upper critical solution temperature lies at 233.0° C, some twenty degrees higher than had been obtained by previous workers; the corresponding critical compositions are 36% and 40% nicotine respectively.

INTRODUCTION

The system nicotine–water presents the well-known egg-shaped diagram to be found in almost every textbook of physical chemistry. In other words this system is the classical example of a two-liquid system with both maximum and minimum critical solution temperatures. The system methylethyl ketone – water is similar in character, although the lower critical solution temperature is cut off by the occurrence of the solid phase, ice. It was thought that it would be of interest to investigate the three-component system: nicotine – methylethyl ketone – water, in order to determine the influence of one closed partial miscible region on another of the same type. There existed two main possibilities; either the third component would so increase mutual solubility that the volume of heterogeneity would shrink to a point before meeting the other volume of heterogeneity and thus two volumes of heterogeneity would exist in the solid model, or the two volumes would meet forming a tunnel. A further question was whether, in the latter case, the ternary critical solution temperatures would lie above or below those of the binary systems.

The system methylethyl ketone – water has been investigated by Rothmund (1) and by Marshall (2) but the most recent data are issued by the Shell Chemical Corporation (3). Rothmund found an upper critical solution temperature and he observed the tendency to a lower critical solution temperature but he could not realize it because of the occurrence of ice. Randall and McKenna (4) have determined the freezing curve of this system. The eutectic was found to lie at −88.88° C and the eutectic composition was 99.91 weight per cent methylethyl ketone.

Since our results differ radically (at the higher critical solution temperature) from the accepted data for the system: nicotine–water, it is necessary to deal in some detail with the literature of the subject. This system was first investigated by Hudson (5) in 1904. Neither he nor anyone else has been able to crystallize nicotine; it forms an amorphous solid on cooling. Hence the melting point is unknown.

[1]*Manuscript received May 10, 1958.*

Using the method of Alexejew, with solutions sealed in 1 mm diameter capillary tubing and heating in an air bath, Hudson determined the solubility curve for the nicotine–water system and found it to be completely closed. He found both critical compositions to be the same, viz., 32.2 weight per cent nicotine, and that the lower critical solution temperature was 61.0° C and the upper 210° C.

Tsakolotos (6) repeated the work of Hudson in 1909; he found the upper and lower critical temperatures to be 208° C and 60.8° C respectively, and both critical compositions to be 34 weight per cent nicotine. Tsakolotos claimed that the use of extremely pure nicotine did not greatly influence the form of the curve.

Leone (7), in 1926, re-examined the nicotine–water system and obtained results identical with those of Hudson, within one or two degrees. Leone used the method of Alexejew and placed his mixtures in Jena glass tubes which were heated in a double-jacketed paraffin oil bath. He found the upper critical temperature to be 213° C.

EXPERIMENTAL

All chemicals were of the highest purity. Since chemical analysis (of any degree of accuracy) was out of the question, physical analysis was used. Curves representing the behavior of any two physical properties, with respect to composition, make possible the analysis of any mixture, when plotted on a triangular diagram. In order, however, that the method may be accurate, it is necessary that the curves should intersect sharply. With this in mind, we surveyed the field by determining the viscosities, densities, refractive indices (for H_C = 6563 Å and for H_F = 4861 Å), and dispersions over the complete composition range of the ternary system. These results are given in Table I. As the result of this survey, we chose the refractive index for hydrogen red light (λ = 6563 Å) and the density.

Thermal analysis was carried out using a copper–constantan thermocouple and a Brown recording potentiometer. The two-junction thermocouple was calibrated from the freezing points of high purity materials. The available temperature range extended from 0° C to −130° C, with an accuracy of measurement of 0.5° C.

Numerous attempts were made to crystallize pure nicotine, using both slow and rapid cooling, but a glass-like mass was always obtained between −100° C and −120° C. The smooth cooling curve showed no irregularities or breaks. All solutions of water and nicotine containing more than 65 weight per cent nicotine failed to crystallize as did those solutions of methylethyl ketone – nicotine containing more than 50 weight per cent nicotine. Hence, no eutectic was observed in either system. No attempt was made to locate the ternary eutectic, since the binary eutectics were unobtainable. The freezing curve of the methylethyl ketone – water system had been determined previously (4). The freezing-point data are given in Tables II and III.

For the isothermal solubility determinations, three thermostats were used: one for the −11.4° C and 5.0° C isotherms, having a variation of ±0.3°; one operating at 25.0° C, for the analytical determinations of density and refractive index; and a third, used for all temperatures above 25° C, which had a variation of ±0.2° C. The mixtures were made up to approximately known over-all compositions, such that two equilibrium layers of more or less equal volumes would form at the temperature in question. Each layer was sampled, after 24 hours stirring, and analyzed by determining refractive index and density. A cell of heavy-walled glass was used for solutions whose vapor pressure was greater than one atmosphere and the pressure of the vapor was utilized to deliver samples of the top and bottom layers; it was possible to use this cell up to a pressure of twenty atmospheres.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

Isotherms of the ternary system were determined at −11.4° C, 5.0° C, 25.0° C, 50.0° C, 65.0° C, 67.5° C, 70.0° C, 85.0° C, 115.0° C, 140.0° C, and 143.0° C and of the nicotine–water conjugate pair at 150.0° C also. The ternary system could not be investigated at 150° C because the pressure was too high. The temperature was controlled to ±0.2° C and was measured by a calibrated mercury-in-glass thermometer reading in 1/10°.

The data for all the solubility measurements are listed in Table IV and the isothermal solubility diagrams are shown in Fig. 1 (*a* and *b*).

The Alexejew Method

The method of isothermal analysis was abandoned above 143.0° C because the pressure

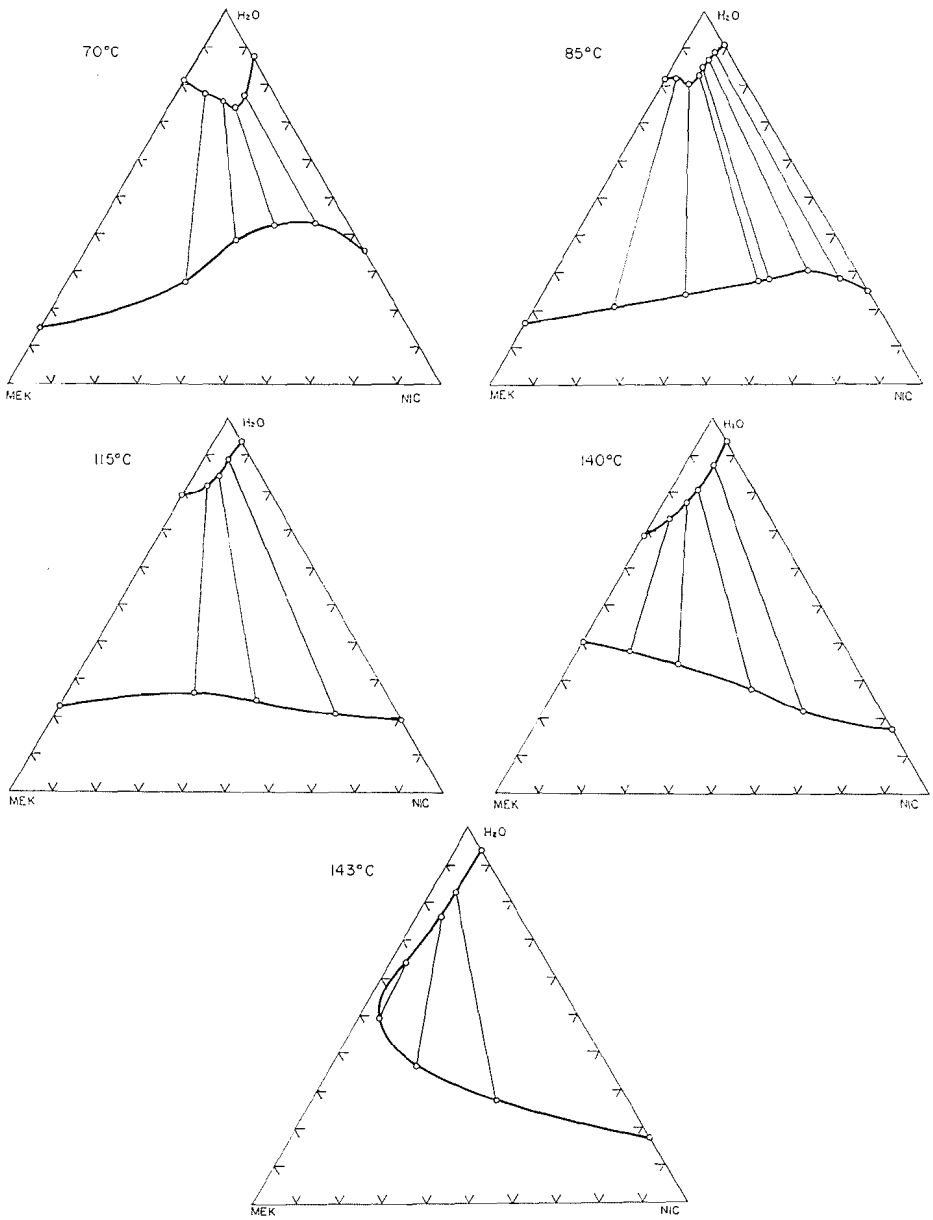

FIG. 1*b*.

developed made sampling impossible, and resort was made to the Alexejew method to complete the diagram. Our technique is described in complete detail because our results for this region differ so markedly from the accepted figures.

Mixtures of known composition by weight were placed in heavy-walled glass tubes, 8 mm in internal diameter and 12 cm in length. These tubes were filled to approximately two-thirds capacity and then sealed in the blowpipe; the liquid was kept cool to prevent evaporation and composition change during this operation. The tubes were investigated one by one, in a variable temperature bath filled with silicone oil. The temperatures at which homogeneity occurred on heating and that at which heterogeneity occurred on

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

cooling were noted and the mean temperature taken to be the solution temperature for the composition in question.

The bath was a glass vessel containing two gallons of silicone oil. In the neighborhood of the temperature of homogeneity it was heated at the rate of 1 degree in 5 minutes. The tubes were rotated in the bath by means of a motor and the rate of rotation was varied from 0 to 70 r.p.m. The rotation stirred the contents of the tubes thoroughly, but a speed of rotation greater than 70 r.p.m. developed sufficient centrifugal force to prevent the liquid in the tube flowing freely from end to end.

The temperatures of homogeneity or heterogeneity were measured by a single junction copper–constantan thermocouple. The couple was calibrated against the freezing points of indium (156.5° C), tin (231.9° C), and lead (327.3° C); all the metals were extremely pure. Temperature could be measured to ±0.5° C. The calibration was repeated after the series of observations was complete but no change in the calibration was observed. As a further check on the reliability of the temperature measurement a sample of pure tin was placed in a tube of the kind used for these measurements and the melting and freezing points determined by the same technique. The mean of these two temperatures agreed, within experimental error, with the literature value for the freezing point of tin.

The tubes were illuminated by a photo spotlight, mounted outside the bath. With this illumination, no difficulty was encountered in observing the condition of the mixture in the tube.

The data from these observations are listed in Table V. Fig. 2 shows temperature versus composition plots for fixed percentages of methylethyl ketone.

Finally, to check the upper critical solution temperature approximately, a few drops of nicotine–water of the upper critical composition were sealed in a piece of heavy-walled capillary tubing of 1 mm internal diameter and 25 mm in length. This was placed in an electrically heated melting-point apparatus and viewed through a magnifying lens. The thermocouple was placed in the opening along with the tube and the top of the opening plugged with asbestos wool. The total volume of the air space surrounding the tube was

between three and four milliliters. Using this apparatus the upper critical solution temperature of the nicotine–water system was found to be 234±2° C.

DISCUSSION OF RESULTS

The Binary System: Methylethyl Ketone – Water

At 25° C, methylethyl ketone and water are not completely miscible. Hence, the physical properties investigated, viz., density, viscosity, refractive index, and dispersion, were limited to the completely intersoluble region. The freezing-point curve of this system was not determined.

Our results for the mutual solubility of these two liquids above 0° C are in close agreement with the results of Marshall (2) and of the Shell Laboratories (3); they disagree with the earlier work of Rothmund (1). The upper critical solution temperature was found to be 142.6° C and the critical composition 45% by weight methylethyl ketone.

The lower critical solution temperature could not be obtained; at temperatures below −12° C crystallization of ice occurred though previous workers claim to have supercooled to −20° C. Our results for the solubility of water in methylethyl ketone are in exact agreement with those of Randall and McKenna (4) but our results for the solubility of methylethyl ketone in water appear to be slightly greater.

We estimate that the lower critical solution temperature, if it were realizable, would lie about −35° C and the critical composition would be about 75 weight per cent methylethyl ketone. The data for the mutual solubilities of the methylethyl ketone – water system are given in Table VI.

For personal use only.

The Binary System: Nicotine–Water

The physical properties, density, viscosity, and refractive indices, were investigated at 10% intervals, from 0 to 100% nicotine. A maximum density was observed at 70 weight per cent nicotine and a maximum viscosity at 77% nicotine. The graphs of refractive index against composition were straight lines. The density inversion at 90° C, observed by Hudson (5), was confirmed; the water-rich layer became heavier than the nicotine-rich layer about this temperature. We estimate that the eutectic composition, if the eutectic were realizable, would be about 75 to 80% nicotine, but the measurements could not be pushed beyond 65 weight per cent.

The results for mutual solubility by the isothermal analysis method varied slightly from previous measurements and tended to flatten the lower part of the solubility curve somewhat. The so-called "rectilinear diameter" was plotted (Fig. 3). The lower critical temperature was found to be 61.5±0.2° C and the lower critical composition 36 weight per cent nicotine.

The upper half of the solubility curve differs considerably from previous results. Identical solution temperatures were obtained, independently of whether the nicotine

used was old or new, freshly redistilled or not. The upper critical temperature was found to be 233.0±0.5° C, 20° higher than had previously been reported (5, 6, 7). The upper critical composition is 40% nicotine. The data for the mutual solubilities of the nicotine–water systems are given in Table VII and plotted in Fig. 3.

85.0	15.0	218.0
90.0	10.0	200.0

The Binary System: Methylethyl Ketone – Nicotine

Methylethyl ketone and nicotine are intersoluble at all temperatures. The densities, viscosities, and refractive indices were determined at intervals of 10% by weight. The graphs of these properties versus composition at 25° C are very nearly linear, with the exception of the viscosity curve whose slope begins to increase at a concentration of 50% nicotine, and continues to increase to a maximum at pure nicotine. The freezing curve shows no marked change of slope and therefore it is impossible to estimate the eutectic temperature and composition.

The Ternary System: Methylethyl Ketone – Nicotine – Water

At 25° C, these three substances are completely miscible except for a small region with a composition of less than 9% nicotine, and between 25 and 88% ketone. A picture of the solid model representing composition versus temperature can be visualized by imagining the isotherms of Fig. 1 to be placed vertically above one another at the appropriate distances. When this is done, a tunnel-shaped solid results. The upper part of this tunnel forms a smooth surface running from the upper critical solution temperature of the methylethyl ketone – water system to the upper critical solution temperature of the nicotine–water system, but, on the lower surface, a maximum occurs in the homogeneous volume, that is, a ternary critical solution point exists. The solubility surface rises from

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

the ice line of the methylethyl ketone – water system and meets a surface rising continuously from the lower critical solution temperature of the nicotine–water system. The maximum of this dent in the surface lies at a temperature of $67.3 \pm 0.2°$ C and at a composition of 27 weight per cent nicotine, and 14 weight per cent methylethyl ketone. If a corresponding critical point exists on the upper surface of the solubility model, the critical solution must contain so little nicotine, less than say one per cent, as to be non-detectable by our methods. The data for the ternary system (by the Alexejew method) are given in Table V.

Obviously, none of the systems was studied isobarically, but under the vapor pressure of the system which may be as great as twenty atmospheres. The question of what the data would be under a constant pressure of 1 atmosphere is meaningless, since the systems would cease to exist (they would vaporize completely) under this pressure.

THE DETERMINATION OF UO_3 AND U_3O_8 IN BROWN OXIDE[1]

L. G. STONHILL

ABSTRACT

Investigations leading to a method for the analysis of mixtures of the oxides UO_3, U_3O_8, and UO_2 are described.

Uranic oxide is extracted with hot ammonium citrate solution, uranic and uranous-uranic oxides are determined together by solution in phosphoric acid followed by titration of U(VI) with titanous sulphate, and uranous oxide found by difference.

INTRODUCTION

"Brown oxide" is a product consisting essentially of uranium dioxide, but with a molecular formula UO_{2+x}, where x is zero in the case of high purity brown oxide and will have larger values if oxygen is present in excess over the proportion required to form the dioxide.

It is important as an intermediate stage between refined UO_3 and uranium tetrafluoride ("green salt") in the production of uranium metal, and in addition, interest is developing in its use in reactor fuel elements without further processing.

In the Port Hope, Ontario, plant of Eldorado Mining and Refining Limited, "brown oxide" is produced by hydrogen reduction of UO_3 and then hydrofluorinated to "green salt" according to the reactions:

$$UO_3 + H_2 = UO_2 + H_2O,$$
$$UO_2 + 4HF = UF_4 + 2H_2O.$$

Owing to the difficulty of achieving complete reduction to UO_2 under plant conditions, a certain amount of U(VI) may remain in the "brown oxide" and will give uranyl fluoride by the reactions:

$$UO_3 + 2HF = UO_2F_2 + H_2O,$$
$$U_3O_8 + 8HF = 2UO_2F_2 + UF_4 + 4H_2O.$$

Therefore, as the uranyl fluoride content of "green salt" must be kept low, it is essential for control purposes to know the proportion of the higher oxides UO_3 and U_3O_8 in the "brown oxide" intended for its production; the research reported here was undertaken to provide such data.

It will be assumed in what follows that uranium is present in "brown oxide" only in the valencies IV and VI and the forms UO_2, U_3O_8, and UO_3. In the case of certain poorly reduced samples the author has made thermogravimetric observations which tend to support the latter assumption.

EXPERIMENTAL

1. *Determination of* UO_3

The loss in weight of a brown oxide sample after a 15-minute extraction with refluxing ammonium citrate solution is a method current in the industry for the estimation of UO_3 contents (1).

Under such conditions, however, U_3O_8 is markedly soluble and a source of error is thereby introduced. In the hope of overcoming this objection, qualitative tests were

[1]*Manuscript received May 20, 1958.*
Contribution from the Metallurgical Laboratories, Eldorado Mining and Refining Ltd., Ottawa, Canada.

made upon each of the three oxides with possible alternative complexants, listed in Table I. UO_3 dissolved fairly rapidly in cold solutions of some, but in other cases the application of heat was necessary; rapid dissolution then occurred.

UO_2, reduced at 500° in a mixture of hydrogen and nitrogen to simulate plant conditions, then ground to pass a 325-mesh screen, resisted the action of all the reagents under the conditions of the method described in section 4.1, and after 2 hours cold extraction (series A) or 15 minutes refluxing (series B) no dissolved uranium could be detected by the well-known peroxide test.

U_3O_8, prepared by igniting UO_2 in air at 500° followed by grinding to pass a 325-mesh screen, was detectably soluble in each reagent, and quantitative data on this solubility, obtained using the same conditions as for the UO_2 tests, are recorded in Table I. It should be noted that these are not equilibrium values but provide a comparative basis for selecting the reagent with least effect on U_3O_8.

TABLE I

SOLVENT ACTION OF VARIOUS REAGENTS ON U_3O_8

Reagent	Weight of U_3O_8 dissolved per 100 ml of reagent solution
Series A: Reaction with UO_3 fast in cold solution	
Hydrazine sulphate 5% w/v	10 mg
Oxalic acid 5% w/v	10
Sulphuric acid 2% v/v	6
Sulphosalicylic acid 5% w/v	4
Series B: Reaction with UO_3 fast in boiling solution (all solutions 5% w/v)	
Ammonium oxalate	18
Ammonium malonate	20
Ammonium succinate	19
EDTA	14
Ammonium tartrate	8.5
Ammonium citrate	8.3

Clearly, absolute specificity to UO_3 cannot be attained with the reagents so far suggested, but, of series A, sulphosalicylic and weak sulphuric acids might be of practical use, also ammonium citrate and tartrate of series B. All four are an improvement upon ammonium oxalate, and the latter's homologues, malonate and succinate, need not be further considered.

The reproducibility of results obtained using sulphosalicylic and weak sulphuric acids was found to be poor, apparently owing to their strong retention by UO_2, an effect noted elsewhere with potassium oxalate (2). On the other hand, ammonium citrate and tartrate both gave results which were reproducible and in agreement with each other within the limits of error associated with gravimetric procedures. Of this pair, ammonium citrate has been chosen for routine work but appears to have no special advantage over tartrate.

As the data in Table I imply, a 100%-pure U_3O_8 sample would be soluble to the extent of about 1.7% in both tartrate and citrate solutions under experimental conditions, but since brown oxide of good production quality contains only a few per cent U_3O_8, the latter's dissolution tendency may be expected to have no serious effect on the UO_3 values obtained in practice.

Regarding the preparation of samples for UO_3 determination, it has been found that

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

grinding beyond the stage at which the whole sample has been reduced below 325-mesh screen size does not significantly increase the proportion dissolved by ammonium citrate solution. Excessive grinding will in fact tend to increase the rate at which the contained U_3O_8 reacts, and should be avoided.

2. Determination of U_3O_8

For practical purposes, U_3O_8 is conveniently regarded as uranous–uranic oxide ($UO_2 \cdot 2UO_3$). Provided that it can be dissolved to give a mixture of U(VI) and U(IV) in the proportion of 2:1 expected from this formula, analysis of the resulting solution for either U(VI) or U(IV) would be a suitable method for its determination. In the present context, with both UO_3 and UO_2 also present, allowance must be made for a contribution to the quantity of both valency states arising from these other oxides because U_3O_8 cannot be specifically extracted from admixture. UO_3 present as such can be determined alone (as has been seen above) and therefore analysis of a solution of the mixed oxides for U(VI), with a correction for UO_3, would establish the amount of U_3O_8 present.

The experimental investigation was directed firstly towards a method for determining U(VI) in presence of U(IV), secondly to procedures for dissolving the mixed oxides without change in the proportions of each valency state, and finally to showing that U_3O_8 can in fact be determined in accordance with the foregoing discussion.

2.1 The Determination of U(VI)

It was quickly established that U(VI) cannot be determined spectrophotometrically in presence of U(IV). The main absorbance regions of equal concentrations of both valency states of uranium in sulphuric acid over the range of the Beckman DU instrument are such that U(VI) has no absorption wave-length unaffected by the presence of U(IV).

Attention was therefore transferred to volumetric methods. Consideration of the relevant oxidation–reduction potentials showed that either Ti(III) or Cr(III) should be suitable titrants for U(VI). Of the two, the more strongly reducing chromous ion has the operating disadvantage of instability in storage unless prepared in a highly purified state, and potentiometric titration with titanous sulphate was decided on.

The reduction of U(VI) by Ti(III) is slow at ordinary temperatures and low acidity, and in the titration of UO_3 dissolved in either hydrochloric, sulphuric, or phosphoric acids it was found necessary to increase both factors to speed up the reaction. At 80° C, and with an acid concentration of 50%, a satisfactorily sharp inflection of potential versus titrant volume was found to occur. As is usual in this type of titration (3) the addition of an ion with an intermediate redox potential to the solution being titrated speeded the attainment of a steady potential after each addition of titrant; ferrous sulphate was found satisfactory. Alternatively ammonium oxalate or citrate (4) may be used.

2.2 Dissolution of U_3O_8

While UO_3 dissolves rapidly in strong acids, U_3O_8 is rather more resistant and requires the application of heat. Phosphoric acid was found suitable as a solvent for all three oxides and is used in the recommended analytical procedure. At an early stage in these experiments it was obvious that air had to be completely excluded from hot solutions of U(IV) otherwise oxidation occurred, and special precautions were taken to ensure this. Air-free phosphoric acid was used for dissolution of the oxides, and both dissolution and titration stages were carried out in the same vessel, which was kept full of carbon dioxide throughout the analytical operations.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

2.3 Stoichiometry of U_3O_8

To demonstrate that U_3O_8 does in fact dissolve in phosphoric acid giving the ratio of U(VI) to U(IV) expected from the formula ($UO_2 \cdot 2UO_3$), weighed quantities of pure U_3O_8 were dissolved in phosphoric acid and titrated with a titanous sulphate solution previously standardized with pure UO_3. Within the usual limits of experimental error, the ratio of U(VI) to total uranium content was in each case found to be 2:3.

3. Determination of UO_2

It is not possible to extract UO_2 specifically from a mixture of oxides, and an approach via a U(IV) determination would, in the presence of U_3O_8, have little value. The UO_2 content of a mixture is for present purposes, therefore, taken as the difference from 100% of the sum of the UO_3 and U_3O_8 contents. An independent method involving thermogravimetric oxidation of the UO_2 will form the subject of a later communication.

In spite of the wide variation in composition between these samples, the concordance between total uranium values obtained by independent methods is satisfactory, and particularly so in the cases of samples A, H, and J (see Table II), where the directly assayed components constitute the major fraction of the whole, and where, consequently, analytical errors would have the largest effect on the total uranium value.

4. Analytical Procedures

1. Determination of UO_3

Reagent required: dibasic ammonium citrate.

The part of the sample used for the UO_3 determination should completely pass a 325-mesh sieve. Reflux an accurately weighed quantity, about 0.5 g, with 200 ml 5% ammonium citrate solution for 15 minutes. Recover the residue by filtration through a sintered-glass filter crucible under suction; wash with hot water, followed by acetone, and dry at 80° C for 1 hour. Determine the loss in weight of the original sample. This represents its UO_3 content.

2. Determination of U_3O_8

The apparatus required is depicted in Fig. 1. Reagents required:

(*a*) Phosphoric acid 50% v/v, air-free. This solution is freed from oxygen by passing in a stream of pure nitrogen or carbon dioxide.

(*b*) Pure U_3O_8. Ignite U_3O_8, UO_3, or UO_2 in air at 750° C for 1 hour. One gram of U_3O_8 is equivalent to 0.6793 g UO_3 when its solution is used for the standardization of titanous sulphate solution.

(*c*) Titanous sulphate solution. Dilute the commercial 15% titanous sulphate solution in the ratio 1:8 with 4 *N* sulphuric acid, and store in an aspirator bottle attached to a hydrogen generator. After the solution has been left standing for 2 days, standardize it with pure U_3O_8, following the titration procedure below.

(*d*) Ferrous ammonium sulphate, reagent grade.

The procedure is as follows: Weigh accurately a quantity of powdered brown oxide containing about 200 mg U(VI) as UO_3. Add this to 50 ml air-free 50% phosphoric acid in a 500-ml three-necked flask and swirl gently to mix. Pass CO_2 into the flask at this stage and throughout the subsequent procedure to prevent entry of oxygen. Heat to boiling, and allow the acid to concentrate until a clear solution is obtained. Cool somewhat, add 150 ml more air-free 50% phosphoric acid and a glass-covered magnetic stirring bar, heat to 80–85° C, add 0.25 g ferrous ammonium sulphate, and titrate potentiometrically with the standard titanous sulphate solution, stirring continuously. The result is the U(VI) content of the sample expressed as total equivalent UO_3; subtraction of the percentage of UO_3 found to be present as such by ammonium oxalate extraction

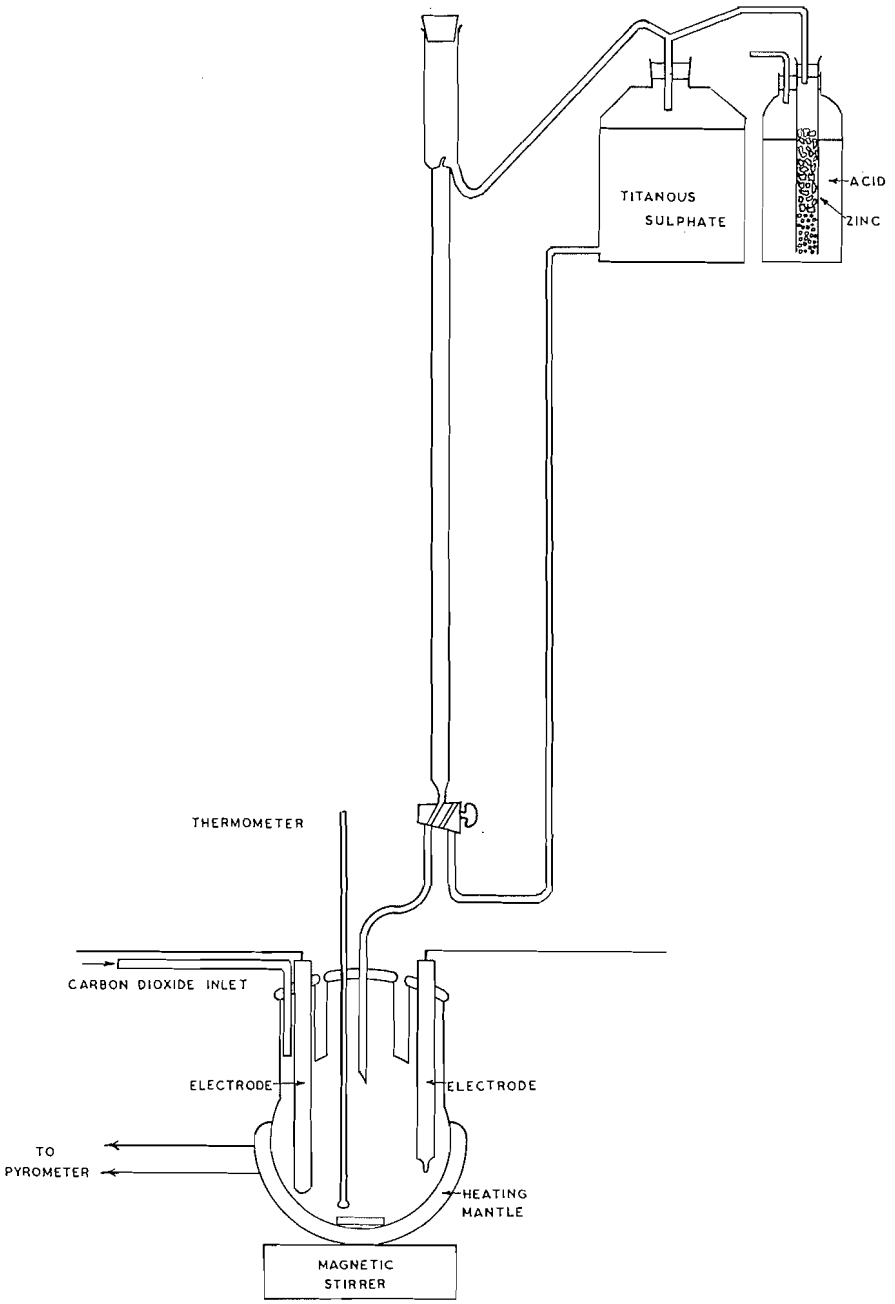

FIG. 1.

gives the percentage of the sample which is UO_3 present in U_3O_8; and the product of that figure and the factor 1.4717 is the percentage of actual U_3O_8 in the sample.

RESULTS

To test, over as wide a range of mixtures as possible, the performance of the analytical method resulting from the investigations described above, a series of brown oxide specimens of varying quality was assayed and a few of the results are shown in Table II.

TABLE II

RESULTS OF BROWN OXIDE ASSAYS

Sample	% UO_3	% U_3O_8	% UO_2 by difference
A	4.75	54.1	41.2
B	4.82	15.1	80.1
C	16.4	18.5	65.1
D	0.86	4.52	94.62
E	1.63	6.78	91.59
F	1.02	6.33	92.65
G	3.60	7.95	88.45
H	3.11	70.3	26.6
J	2.17	64.2	33.6

There is at present no alternative method for determining individual oxides in a mixture for comparison with the above results, but it is of interest to compare the total uranium content of each sample calculated from the results of the present method with that given by standard methods. The comparison is given in Table III.

TABLE III

COMPARISON OF TOTAL URANIUM VALUES

	% Uranium as given by:		
Sample	Present method	Conversion to U_3O_8	Differential colorimetry
A	86.10	85.89	86.04
B	87.41	87.21	87.25
C	86.73	86.46	86.32

THE GAS PHASE REACTIONS OF PERFLUORO-*n*-PROPYL RADICALS WITH METHANE AND ETHANE[1]

G. GIACOMETTI[2] AND E. W. R. STEACIE

ABSTRACT

The rate constants and activation energies for the reactions of C_3F_7 radicals with methane and ethane have been measured by photolyzing mixtures of $C_3F_7COC_3F_7$ and hydrocarbon with 3130 Å light. Photolysis of mixtures of the ketone, methane, and deuterium has been used to check previous measurements on the reaction of C_3F_7 and deuterium.

INTRODUCTION

The availability of completely fluorinated alkyl radicals obtained via a very simple mechanism from the photolysis of the corresponding ketones (1, 2) makes it worth while to study their reactions with simple hydrocarbons or other substrates, with the object of throwing further light on the effect of the structure of the reactants on the rate constants. The mechanism of production of n-C_3F_7 radicals from perfluoro di-*n*-propyl ketone has been investigated (2) and their reactions with hydrogen and deuterium have been subsequently studied (3).

While the mechanism of the photolysis is extremely simple in this case, especially compared with the non-fluorinated compound, there is one analytical feature of this system which complicates the situation. Owing to the very similar volatilities of the perfluoro di-*n*-propyl ketone and of the perfluoro-*n*-hexane, it is impossible to separate the latter from the bulk of the unreacted material by the usual low-temperature distillation technique.

This difficulty can be overcome, however, by taking advantage of the simplicity of the mechanism and estimating the hexane by a stoichiometric balance. This was done previously in the reaction of n-C_3F_7 with hydrogen and deuterium, although in this case some uncertainty affected the results because of ignorance of the fate of the hydrogen atoms produced in the system (3).

In this paper we present the analogous results obtained for the reactions of C_3F_7 radicals withm ethane and ethane, which are not affected by such a complication. This circumstance also permits an independent determination of the hydrogen reaction rate by performing experiments in the presence of both methane and deuterium.

EXPERIMENTAL

Apparatus

The apparatus was essentially the same as that used in the experiments on the hydrogen reaction. The light source was a B.T.H. high-pressure mercury lamp (ME/D, 250 watts) operated on stabilized 220 v d-c. The 3130 Å radiation was isolated by a standard set of filters. The quartz reaction cell was 10 cm long and had a capacity of 175 cc; it was fully illuminated by the parallel beam of light. The cell was maintained at the desired temperature by an aluminum block furnace and the temperature was constant to $\pm 1°$ C.

The filling system was of a conventional type as was the analytical line which consisted of two Ward–LeRoy stills, one solid nitrogen trap, a small mercury diffusion pump, a

gas burette, and a Toepler pump for sample collection. A small CuO furnace, operating at 250° C, could also be inserted in the line when necessary. All stopcocks were avoided by use of appropriate mercury cutoffs.

Materials

The ketone was supplied by Dr. L. C. Leitch of these laboratories and its purity checked by careful distillation in a Podbielniak column (b.p. 75° C) and by mass spectrometry. Deuterium was obtained from a Stuart Oxygen Company cylinder and was passed through hot palladium before storage in a 5-liter bulb connected to the line. Mass spectroscopic analysis gave a D content of 95.4% and all results have been corrected accordingly. Methane and ethane were research grade Philips products and were carefully checked for impurities in the mass spectrometer.

Procedure

After the ketone had been introduced into the cell, its pressure was measured with a constant-volume manometer. The ketone was then frozen out at liquid nitrogen temperature andm ethane or ethane was introduced at the desired pressure. The two reactants were then mixed by expanding them a few times by means of a Toepler pump. The total gas pressure was always measured as a further check. When deuterium was also present, the relative amount of the two gases was measured by reading their pressures in two separate sections of the apparatus whose volume ratio had been previously measured.

The photolysis was allowed to proceed up to 4 to 6% decomposition of the ketone. The analyses were carried out by the usual technique of low-temperature fractionation and mass spectrometry.

In the methane experiments the products of the photolysis were CO, C_3F_7H, $C_4F_7H_3$, C_2H_6, and C_6F_{14}. The first fraction was collected at −210° C and it contained all the CO together with large quantities of methane. The CO was then separated by oxidation in the CuO furnace and measured in the gas burette. Blank experiments showed that no methane was oxidized during the short time of the operation. After pumping off all the remaining methane and possible traces of ethane, a second fraction was collected at −105° C containing all the C_3F_7H and the $C_4F_7H_3$. The C_3F_7H content was estimated by the peak at mass 51 of its mass spectrum. The $C_4F_7H_3$ was estimated by difference and the main peaks of the mass spectrum of this compound are shown in Table I.

In the ethane experiments the products were CO, C_3F_7H, $C_5F_7H_5$, n-C_4H_{10}, and C_6F_{14}. CO was collected at −210° C and a few checks by oxidation in the CuO furnace showed that it did not contain ethane. Ethane was removed at −155° C. The fraction at

−105° C contained all the C_3F_7H, part of the $C_5F_7H_5$, and all the *n*-butane. A further fraction at −90° C contained only $C_5F_7H_5$. The mass spectrum of this compound is shown in Table II. The peak used for the analysis was the large 79 peak which does not occur with C_3F_7H, *n*-butane, or the ketone.

TABLE II

MASS SPECTRUM OF $C_3F_7C_2H_5$ (MAIN OR CHARACTERISTIC PEAKS)

Mass *n*	Relative height	Probable ion

77	12.9	$CF_2C_2H_3^+$
69	75.1	CF_3^+
59	32.1	$CFC_2H_4^+$

The experiments with methane and deuterium were carried out in a manner completely analogous to that used by Miller and Steacie (3) with mixtures of hydrogen and deuterium. The peaks at mass 51 and 52 were used to measure the ratio of C_3F_7H to C_3F_7D and blank runs were performed before each experiment to check the ratio in the absence of hydrogen.

RESULTS

The results for the three sets of experiments are summarized in Tables III, IV, and V. A few runs were performed at quite different light intensities and showed that the results were independent of such changes.

The mechanism postulated for the reaction with methane is the following:

$$C_3F_7COC_3F_7 \rightarrow 2\ C_3F_7 + CO, \quad [1]$$

$$2\ C_3F_7 \rightarrow C_6F_{14}, \quad [2]$$

$$C_3F_7 + CH_4 \rightarrow C_3F_7H + CH_3, \quad [3]$$

$$CH_3 + CH_3 \rightarrow C_2H_6, \quad [4]$$

$$CH_3 + C_3F_7 \rightarrow C_4H_3F_7. \quad [5]$$

TABLE V

THE REACTION OF n-C_3F_7 RADICAL WITH DEUTERIUM–METHANE MIXTURES*

Temp., °K	CH_4 pressure/D_2 pressure	51/52 ratio corrected	$k_3/k_{3''}$
370	1.52	3.38	2.22
421	1.56	1.95	1.25
396	1.92	2.87	1.50
358	1.49	3.71	2.49
397	1.38	2.00	1.45
382	1.22	2.26	1.85
455	1.36	1.23	0.905

*Total pressures were of the order of 50–60 mm Hg-$k_3/k_{3''}$ calculated from $R_{C_3F_7H}[D_2]/R_{C_3F_7D}[CH_4]$.

Fluorine abstraction reactions are ruled out by the absence of C_3F_8 in the products and no other reaction of importance in determining the amount of products seems to be possible. The rate of production of C_6F_{14} is thus very simply given by:

$$R_{C_6F_{14}} = R_{CO} - \tfrac{1}{2}(R_{C_3F_7H} + R_{C_4H_3F_7}). \quad [1]$$

The last column of Table III shows the values of

$$k_3/k_2^{\frac{1}{2}} = R_{C_3F_7H}/R_{C_6F_{14}}^{\frac{1}{2}}[CH_4]$$

calculated in this way,* and Fig. 1 shows the Arrhenius plot obtained. Least squares fitting of this plot give:
$k_3/k_2^{\frac{1}{2}} = 1.25\times10^{-8}e^{-9.5\times10^3/RT}$ molecule$^{-\frac{1}{2}}$ cc$^{\frac{1}{2}}$ sec$^{-\frac{1}{2}}$. The value for $E_3-\frac{1}{2}E_2$ is thus 9.5 $\pm$0.5 kcal/mole.

The mechanism for the ethane reaction is somewhat more complicated owing to the possibility of disproportionation in radical–radical reactions:

$$C_3F_7 + C_2H_6 \rightarrow C_3F_7H + C_2H_5, \quad [3']$$

**Under the conditions of the experiments the quantities of $C_4H_3F_7$ were so small that no accurate analysis was possible. Their exclusion from [1] cannot affect the value of $k_3/k_2^{\frac{1}{2}}$ by more than one per cent. They have therefore been omitted from the table.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

$$C_2H_5 + C_2H_5 \rightarrow C_2H_4 + C_2H_6, \quad [4'a]$$

$$C_2H_5 + C_2H_5 \rightarrow C_4H_{10}, \quad [4'b]$$

$$C_2H_5 + C_3F_7 \rightarrow C_3F_7H + C_2H_4, \quad [5'a]$$

$$C_2H_5 + C_3F_7 \rightarrow C_5F_7H_5. \quad [5'b]$$

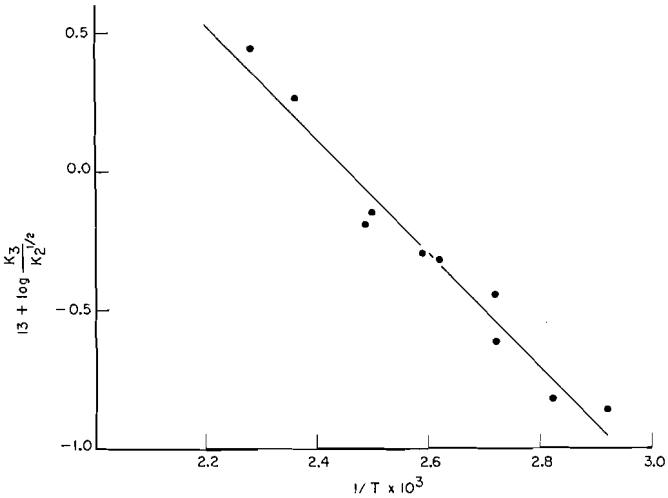

FIG. 1.

The stoichiometric balance can be carried out in this case by analyzing the products for CO, C_3F_7H, C_4H_{10}, and $C_5F_7H_5$ and assuming the ratio $k_{4'a}/k_{4'b}$ to be known. The best experimental value for the latter is 0.12, practically independent of temperature and pressure (4). The C_3F_7 radical balance will give the rate of formation of C_6F_{14} as in the former case:

$$R_{C_6F_{14}} = R_{CO} - \tfrac{1}{2}[R_{C_3F_7H} + R_{C_5F_7H_5}].$$

The balance for C_2H_5 radicals will give both the rate of formation of C_3F_7H from reaction [3'] and the ratio $k_{5'a}/k_{5'b}$:

$$(R_{C_3F_7H})_{3'} = \tfrac{1}{2}[R_{C_3F_7H} + R_{C_5F_7H_5} + 2.24\ R_{C_4H_{10}}]$$
$$k_{5'a}/k_{5'b} = [R_{C_3F_7H} - (R_{C_3F_7H})_{3'}]/R_{C_3H_5F_7}.$$

The justification of this procedure is indicated by the constancy of the value obtained for the latter expression over a range of temperatures as shown in Table IV. The table also gives the values of $k_{3'}/k_2^{\frac{1}{2}}$ obtained from

$$k_{3'}/k_2^{\frac{1}{2}} = (R_{C_3F_7H})_{3'}/R_{C_6F_{14}}^{\frac{1}{2}}\,[C_2H_6].$$

The Arrhenius plot of Fig. 2 gives for $E_{3'} - \frac{1}{2}E_2$ a value of 9.2 ± 0.5 kcal/mole and the expression for the rate is

$$k_{3'}/k_2^{\frac{1}{2}} = 2.24 \times 10^{-7}\, e^{-9.2\times 10^3/RT}\ \text{mole}^{-\frac{1}{2}}\ \text{cc}^{\frac{1}{2}}\ \text{sec}^{-\frac{1}{2}}.$$

The experiments in which methane and deuterium were put together into the reaction cell were devised to get a relative value of k_3 with respect to the rate constant of the reaction:

$$C_3F_7 + D_2 \rightarrow C_3F_7D + D. \quad [3'']$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

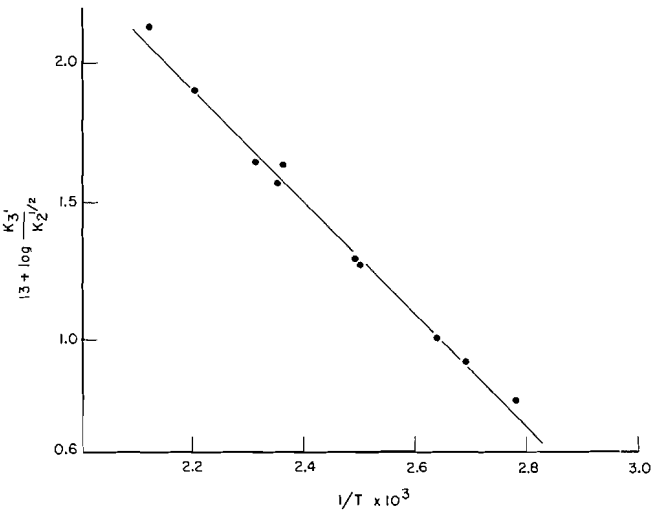

FIG. 2.

This method has already been used for the CF_3 radical by Pritchard and co-workers (5) and is simply based on the mass spectrographic estimation of the ratio RD/RH in the products. Some uncertainty arises from the fact that the fate of the D atoms produced in the abstraction is not known. In this case the possibilities are:

$$D + D + M \rightarrow D_2, \qquad [I]$$

$$D + CH_3 + M \rightarrow CH_3D, \qquad [II]$$

$$D + C_3F_7 \rightarrow C_3F_7D, \qquad [III]$$

$$D + CH_4 \rightarrow CH_3 + HD. \qquad [IV]$$

Table V gives the results of the runs performed at a total pressure of 60 to 70 mm of mercury. The Arrhenius plot is shown in Fig. 3 and the value for $E_3 - E_{3''}$ is found to be -3.4 ± 0.3 kcal/mole, the full expression for the ratio being:

$$k_3/k_{3''} = 1.99 \times 10^{-2}\, e^{3.42 \times 10^3/RT}.$$

DISCUSSION

An absolute result for reaction [3″] is obtained from our data quite independently of the one obtained by Miller and Steacie (3). The value of $E_{3''} - \frac{1}{2}E_2$ obtained in the present work is 12.9±0.8 kcal/mole, which checks with the former value of 13.8±0.5, within experimental error. A comparison of the frequency factors is probably of little significance, given the somewhat large error in the activation energies. On the other hand, a comparison of the rate values in the temperature range of the experiments may be useful. At 400° K the value of Miller and Steacie (calculated assuming only reaction III to occur) is 0.24×10^{-13} molecule$^{-\frac{1}{2}}$ cc$^{\frac{1}{2}}$ sec$^{-\frac{1}{2}}$ and in the present case a reasonable agreement with that value is obtained also neglecting reaction III: 0.27×10^{-13} molecule$^{-\frac{1}{2}}$ cc$^{\frac{1}{2}}$ sec$^{-\frac{1}{2}}$. Although the uncertainty in these values is only within a factor of 2, which may be of little or no significance for these experiments, the almost complete agreement between our rate value and the former one seems to show that the same mechanism is operative in both cases. Possible occurrence of reaction IV in our case might also give a reason for the discrepancy of almost one kilocalorie per mole in our activation energy.

It is of interest to compare data for the methane, ethane, and hydrogen reactions with C_3F_7 and other radicals such as CH_3 and CF_3 for which sufficiently reliable data are available. In Table VI the activation energies, frequency factors, and the rate constants at 400° K are listed for these reactions.

*The subscript R refers to the recombination reaction R + R → R_2. Units for k's and A's are molecules^{-1} cc sec^{-1}. E's in kcal/mole.

[a]From ref. 5.

[b]From Steacie, E. W. R. J. Chem. Soc. 3991 (1956).

[c]From ref. 3.

[d]Obtained in the present work.

It is very difficult to find some trend in the activation energies or in the frequency factors. The only general feature is that activation energies for the D_2 reactions are always 1.5 to 2.0 kcal/mole greater than those for H_2 and this seems to be due to the zero energy effect (3).

A striking feature can be noted in the behavior of the rate constants, however. It is apparent that great changes in reactivity (over 100-fold variation) are shown by the different radicals reacting with the hydrocarbons, while the hydrogen reaction is more or less insensitive to changes in the attacking radical.

It seems that there are two quite different types of reaction. It is interesting in this respect to point out that in the case of R + H_2 there is an almost linear relationship between log A and E for the three different radicals. Such a "compensation" behavior has been found already in other cases, and there has been a recent attempt to justify it on theoretical grounds (6), especially for the case of diatomic molecules. Such a relationship does not hold for R + R′H where, on the other hand, a different regularity is

apparent. The relative reactivity of each radical toward methane and ethane is approximately constant, as shown by the ratio of the rate values of Table VI. This behavior is analogous to the findings of Smid and Szwarc for radical abstractions and additions in solution (7). It will be of interest to see if the mentioned regularities still hold in reactions with other similar radicals.

The value of the disproportionation-to-recombination ratio for the reaction between C_3F_7 and C_2H_5 is the first one reported for a reaction between a completely fluorinated radical and a completely hydrogenated one. Since C_3F_7 is seemingly more reactive toward hydrocarbons than CH_3 the ratio was expected to be greater than the one reported for $CH_3 + C_2H_5$, which is of the order of 0.03 (8); this expectation is amply justified by the value found, 0.40.

ACKNOWLEDGMENT

The authors wish to thank Miss B. Thornton for the mass spectrometric analyses.

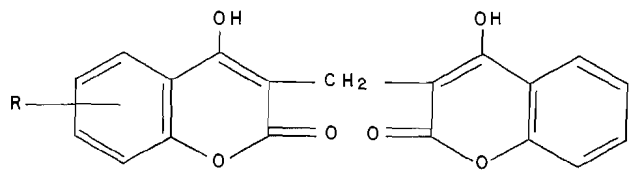
UNSYMMETRICALLY SUBSTITUTED 3,3′-METHYLENE BRIDGED 2,2′-DIHYDROXYCHROMONES[1,2]

R. A. Abramovitch and J. R. Gear

ABSTRACT

Unsymmetrically substituted dicoumarol derivatives* have been synthesized by taking advantage of the fact that 4-hydroxycoumarins will undergo the Mannich reaction at C_3 and also take part in Michael-type addition reactions. In the presence of methyl iodide, 4-hydroxy-3-*N*-piperidinomethylcoumarin and 4-hydroxycoumarin gave dicoumarol. By using monosubstituted 4-hydroxycoumarins a variety of unsymmetrically substituted dicoumarols have been prepared in good yield. The infrared spectra of some of the intermediates and products are reported and discussed.

A large variety of substituted derivatives of the anticoagulant dicoumarol have been prepared with a view to the production of a more active product having less side effects. These compounds fall into two main groups: (i) those bearing a substituent on the bridge methylene group are generally prepared by condensing an aldehyde or ketone with 4-hydroxycoumarin; (ii) symmetrically disubstituted dicoumarols, prepared by condensing a substituted 4-hydroxycoumarin derivative with formaldehyde, as well as combinations of (i) and (ii). Neither of these methods is amenable to the preparation of unsymmetrically substituted derivatives (I) of dicoumarol, which are of a twofold interest: (*a*) as possible physiologically active analogues of dicoumarol; (*b*) a monohydroxylated dicoumarol may be an active metabolic product of the anticoagulant but this hypothesis has never been tested owing to the unavailability of such hydroxydicoumarols. We have now developed a method which appears to be fairly general for the synthesis of this type of compound.



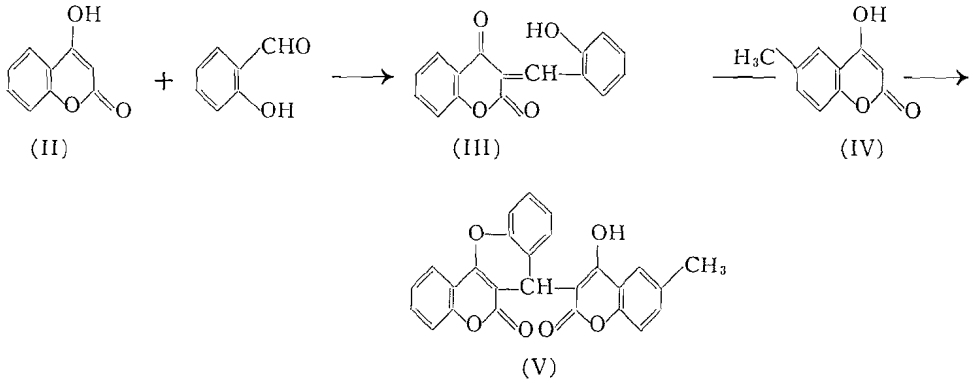
(I)

The methylene group at C_3 in 4-hydroxycoumarin is reactive and will undergo Michael addition with suitably activated double bonds. For instance, addition will take place across the double bond in ethylideneacetone (1). Sullivan *et al.* (2) suggest that formation of dicoumarol itself from formaldehyde and 4-hydroxycoumarin proceeds by this type of addition: the unstable 3-methylene-2,4-diketochroman is first formed; this is very reactive and cannot be isolated but reacts quickly with another molecule of 4-hydroxycoumarin to form dicoumarol, this last step involving a Michael addition.

[1]*Manuscript received May 15, 1958.*
Contribution from the Department of Chemistry, University of Saskatchewan, Saskatoon, Saskatchewan.
[2]*This article is based on a paper presented at the 41st Annual Conference and Exhibition of the Chemical Institute of Canada, Toronto, May 26–28, 1958.*

The chemical name for dicoumarol is 3,3′-methylenebis(2-hydroxychromone) (see p. 1506). On this basis the name of ring-monosubstituted derivatives becomes very clumsy, e.g., 2-hydroxy-7-methyl-3-chromonyl-2-hydroxy-3-chromonylmethane. We propose to use the name dicoumarol to represent the ring system of 3,3′-methylenebis(2-hydroxychromone) and this practice will be adhered to throughout this paper.

They obtained support for this suggestion by condensing 4-hydroxycoumarin (II) with an equimolar quantity of salicylaldehyde to give 3-(*o*-hydroxybenzylidene)-2,4-diketochroman (III), which could be isolated, and which reacted with 4-hydroxy-6-methylcoumarin (IV) to give (V), indicating the stepwise nature of the reaction. Incidentally, (V) was the only example of a derivative of an unsymmetrically substituted

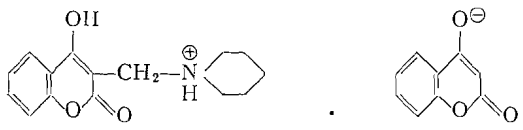


(II) (III) (IV)

(V)

dicoumarol we were able to find in the literature. If 3-methylene-2,4-diketochroman could be generated *in situ* in the presence of a substituted 4-hydroxycoumarin derivative, addition would take place to give the required type of compound. Condensation of 4-hydroxycoumarin with formaldehyde in the presence of a substituted 4-hydroxycoumarin was ruled out, since this would probably give rise to an inseparable mixture of dicoumarol derivatives. On the other hand, formation of the activated double bond *in situ* from a Mannich base was considered particularly suitable, since, by taking advantage of the active methylene at C_3, Robertson and Link (3) and also Prochazka (4) introduced a variety of aminomethyl groups in that position.

Heating together an equimolar mixture of 4-hydroxy-3-*N*-piperidinomethylcoumarin (VI) and 4-hydroxycoumarin (II) gave a highly insoluble 'addition complex' whose molecular composition corresponded to the sum of one mole of (VI) and one of (II). In view of the insolubility and instability of this complex its structure could be that of a salt of the type (VII*a*).



(VII*a*)

It was hoped that the infrared spectrum would shed some light onto its structure, so that it was first necessary to study the spectrum of 4-hydroxycoumarin and that of 4-hydroxy-3-*N*-piperidinomethylcoumarin, and then to see what changes took place when these two combined to form the complex.

Infrared Spectra of 4-Hydroxycoumarins

4-Hydroxycoumarin can exist in a number of tautomeric modifications, but, according to Arndt (5), because of resonance stabilization the two main forms are the 4-hydroxycoumarin (II) and the 2-hydroxychromone (VIII) structures (see also ref. 5*b*).

(II) (VIII)

As to which form predominates seems to depend on the experimental conditions and the nature of the substituents if present. From a study of the reactions of 4-hydroxycoumarin Klosa (6) concluded that the 4-hydroxycoumarin form (II) was favored but that under special conditions of solvent or acidity the chromone form could be favored. On the other hand, from a consideration of the ultraviolet spectra of 4-hydroxycoumarins in ethanol solution, Garden, Hayes, and Thomson (7) suggested that in this solvent 4-hydroxycoumarins could exist in the keto form (whether structures of types (VIII), or the diketonic structure, were meant is not clear).

It should be possible to distinguish between structures (II) and (VIII) by infrared spectroscopy: (II) should exhibit a band for an α,β-unsaturated six-membered ring lactone at *ca.* 1710 cm^{-1} (8), whereas (VIII) should have a band at *ca.* 1660 cm^{-1} corresponding to the $\alpha,\beta,\alpha',\beta'$-di-unsaturated ketone (9), and none at 1710 cm^{-1}. An elegant application of this principle is seen in the elucidation of the structures of novobiocin and its degradation products; novobiocin and 3-acetamido-7-acetoxy-4-hydroxy-8-methylcoumarin exist in the 4-hydroxycoumarin form (λ_{max} 5.92 μ) (10), whereas if a free —OH group is present at $C_{(7)}$ as in dihydronovobiocic acid (10) or in 4,7-dihydroxycoumarin (more correctly called 2,7-dihydroxychromone) (11) the chromone structure is the stable form (λ_{max} 6.0 μ). Similarly, the infrared spectra of 4-hydroxycoumarin, 4-methoxycoumarin, and 2-methoxychromone in the carbonyl region were studied by Knobloch and Prochazka (12). In dilute ethylene chloride solution 4-hydroxy- and 4-methoxycoumarin exhibited a single strong band at *ca.* 1710 cm^{-1} (with a medium intensity shoulder at 1700 cm^{-1}) corresponding to the α,β-unsaturated six-membered lactone structure, indicating that in that solvent 4-hydroxycoumarin probably exists exclusively in the 4-hydroxy form. On the other hand, 2-methoxychromone showed a single strong band at *ca.* 1650 cm^{-1} corresponding to the $\alpha,\beta,\alpha',\beta'$-di-unsaturated ketonic stretching motion. Again, Wildi (13) reports a single band at 5.90 μ for 4-hydroxy-3-phenylcoumarin in chloroform solution, together with a weak —OH stretching band at 2.87 μ.

Because of solubility and stability considerations it was only possible to measure the spectrum of the 'addition complex' obtained above as a Nujol mull so that it was desirable to study the spectrum of 4-hydroxycoumarin and 4-hydroxy-3-*N*-piperidinomethylcoumarin under such conditions. The spectrum of 4-hydroxycoumarin in the solid state is much more complex than the solution spectrum. There was no —OH band at *ca.* 2.9 μ but a medium shoulder was present at 3125 cm^{-1} together with two medium peaks at 2730 and 2560 cm^{-1}, indicating that the —OH group is strongly bonded. In the carbonyl region *two* bands were present: at 1700 (s) (with an ill-defined shoulder at 1709) and at 1673 cm^{-1}(s), the latter being the stronger of the two. The spectrum of 4-hydroxy-7-methoxycoumarin is rather similar* with bands at 3125 (sh)(m), 2760 (w), 2620 (w), 1707 (s) (medium shoulder at 1714 cm^{-1}), and 1672 cm^{-1} (ms). It seems rather unlikely

**This spectrum is very similar to that obtained by Dr. R. H. Thomson and co-workers using the* KBr *disk technique. We understand that they have made an infrared study of 4-hydroxycoumarins, which is due to be published soon, but as our limited study was necessary for an interpretation of our results we are including it here. We would like to thank Dr. Thomson for sending us a tracing of the spectrum of 4-hydroxy-7-methoxycoumarin in* KBr.

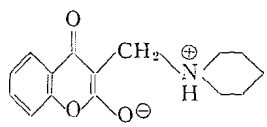
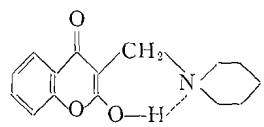
that the strong band at 1673 cm^{-1} should be due to the conjugated C=C in the 4-hydroxy form; the band for this group is probably merged with the strong broad band at 1618 cm^{-1}. There are two possible interpretations for the presence of the two carbonyl stretching bands at 1700 and 1673 cm^{-1}. One is that in the solid state the compound is a mixture of the two tautomeric modifications, (II) giving rise to the higher and (VIII) to the lower band. Alternatively, the 1673 cm^{-1} band could arise from partial intermolecular hydrogen bonding between the —OH group of one molecule and the lactone carbonyl group of another; the two bands would then be due to a mixture of chelated and unchelated lactone carbonyl groups in the solid state. In dilute ethylene chloride solution, such chelation would not take place and only the band at *ca.* 1710 cm^{-1} would be observed. This would also fit the fact that a chloroform solution of 4-hydroxy-3-phenylcoumarin has a single band at 5.90 μ and a weak —OH band at 2.87 μ (13) (though in this case the steric effect of the phenyl substituent might prevent effective intermolecular chelation). If the first interpretation is accepted one would have to assume that in ethylene chloride solution the 4-hydroxycoumarin form is stabilized with respect to the chromone structure. On the basis of the present evidence it does not seem possible as yet to decide between the two alternatives. The same remarks apply also to 4-hydroxy-7-methoxycoumarin, which again exhibits no peak at 3450 cm^{-1}; in this case the 1672 cm^{-1} peak is somewhat weaker than the 1701 cm^{-1} one and completely resolved from it.

4-Hydroxy-3-*N*-piperidinomethylcoumarin has no hydroxyl band in the 3 μ region (in Nujol mull). There are two bands at 2765 (m) and 2610 cm^{-1} (w), but only a single band is present at 1678 cm^{-1}. The Mannich base, therefore, either exists in the chromone form in the solid state, or is completely intermolecularly chelated, which is less likely. The absence of an —OH band could be due to such a chelation but could also be explained by internal salt formation (VI*a*) or internal hydrogen bonding (VI*b*).



(VI*a*)

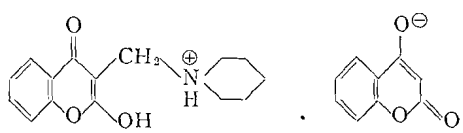


(VI*b*)

In the absence of a band at 2440–2350 cm^{-1} for an R_3NH^+ grouping (14) (VI*b*) seems the more probable structure.

The spectrum of the 'addition complex' in Nujol mull shows bands at 3170 (m) (broad) (bonded —OH), 2750 (m), 2730 (sh)(m), 2570 (m), 2470 (m) (R_3NH^+), 1719 (s) (α,β-unsaturated δ-lactone), and 1672 cm^{-1} (s) ($\alpha,\beta,\alpha',\beta'$-di-unsaturated $\rangle C{=}O$). These fit structure (VII*b*) rather well.*

The chemical evidence was also in accord with this ammonium salt structure for the



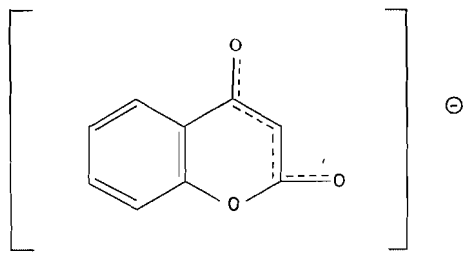
(VII*b*)

**For footnote see* NOTE *on p. 1505.*

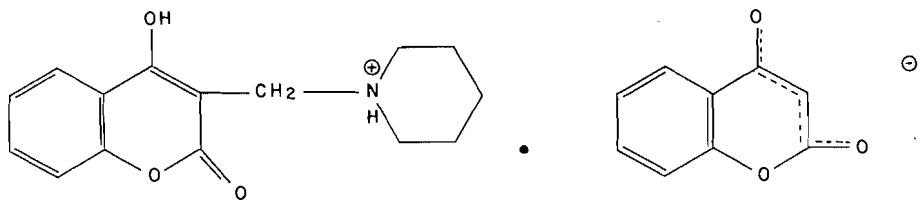
addition complex. Thus, it could not be recrystallized without decomposition; two recrystallizations from nitromethane transformed it completely into dicoumarol, which was also obtained by heating the complex with mineral acid. These properties are in accord with the known reactivity of Mannich bases quaternary salts (15). The structure postulated for the complex led us to the expectation that if 4-hydroxy-3-*N*-piperidinomethylcoumarin was quaternized with methyl iodide before treatment with 4-hydroxycoumarin (II), then the addition complex would not be formed and heating with (II) should lead to dicoumarol readily. This was fully confirmed by experiment, no complex being formed and dicoumarol (I, R = H) being obtained in good yield.

It was now necessary to prove that the reaction had taken place by the addition of the added 4-hydroxycoumarin to the 2,4-diketo-3-methylenechroman formed *in situ* from the Mannich base, and not by a partial reversal of the Mannich condensation followed by addition of the 4-hydroxycoumarin so formed to the chroman (the yield of dicoumarol obtained in the reaction already excludes this possibility). This was readily done by treating 4-hydroxy-3-*N*-piperidinomethylcoumarin methiodide with 4-hydroxy-7-methylcoumarin to give 7-methyldicoumarol (I; R = 7–CH_3–) which could also be obtained from 4-hydroxy-7-methyl-3-*N*-piperidinomethylcoumarin methiodide and 4-hydroxycoumarin. Because of possible ambiguity owing to the closeness of analytical figures

NOTE: *Drs. K. P. Link and S. Preiss have kindly informed us that they have observed a broad band at 1635 cm^{-1} in the spectrum of the sodium salt of 4-hydroxycoumarin, presumably corresponding to the anion*



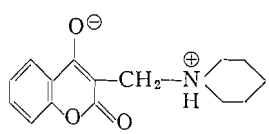
No band at 1719 cm^{-1} was observed. They suggest, therefore, that structure (VIIc) would fit the infrared data also.



(VIIc)

The fact that we observed a sharp band at 1672 cm^{-1} for this compound at a much higher frequency than the broad band for the anion seems to speak against this possibility though it does not rule it out by any means. We would like to thank Drs. Link and Preiss for pointing the possibility out to us.

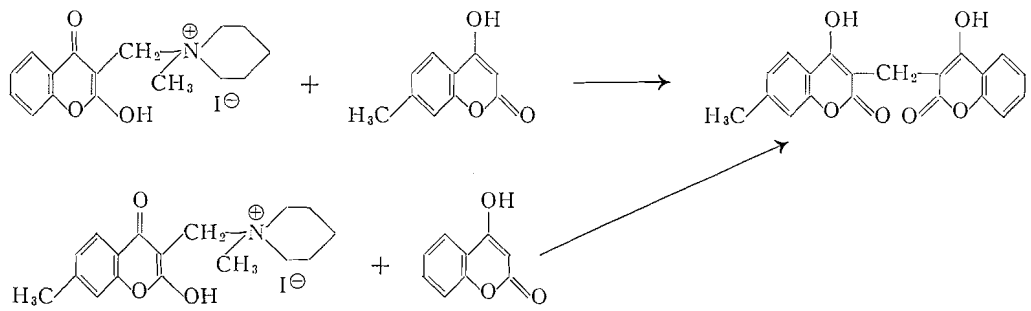
Structure



for the 3-piperidinomethyl derivative is ruled out by the absence of a band at 2440–2350 cm^{-1}.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

7,7′-dimethyldicoumarol was also prepared for comparison and shown to be different from the unsymmetrical dicoumarol obtained above.



Having established the nature of the reaction, a number of unsymmetrically substituted dicoumarols were prepared to examine its scope; 6-methyl-, 6-chloro-, and 7-hydroxydicoumarol were readily obtained in good yields from 4-hydroxy-3-*N*-piperidinomethylcoumarin methiodide and the corresponding substituted 4-hydroxycoumarin. With 4-hydroxy-7-methoxycoumarin a product was readily obtained which consisted mainly of the expected 7-methoxydicoumarol, m.p. 245–248°, as shown by analysis, ultraviolet and infrared spectra, and by demethylation to the 7-hydroxydicoumarol prepared above. A small proportion of the product, however, was a highly insoluble higher melting (290–292°) substance for which good carbon and hydrogen analytical values could not be obtained. That it was a dicoumarol derivative was shown by its infrared spectrum (dicoumarols have a very characteristic type of absorption bands in the 6 μ region) which, apart from the fact that it had one extra band at 1110 cm^{-1} (m), was practically identical with that of 7-methoxydicoumarol. Also its ultraviolet absorption spectrum in dioxan solution was very similar to that of 7-methoxydicoumarol, differing only slightly in the ratios of the intensities of the peaks, indicating that the chromophoric systems were probably the same. The starting 4-hydroxy-7-methoxycoumarin was a pure compound, as shown by a comparison of its melting point and infrared spectrum with that of a specimen kindly supplied by Dr. R. H. Thomson, and also by demethylating it to the known 2,7-dihydroxychromone. The higher melting by-product was not investigated further at this stage. The infrared spectra of the dicoumarols were measured and are reported in the experimental section. They are in accord with the results of Knobloch and Prochazka (12) and will not be discussed here (dicoumarol has been represented by the 4,4′-dihydroxydicoumarin formula throughout this paper for convenience, though the infrared data indicate that the correct structure is that of a 2,2′-dihydroxydichromone with strongly intramolecularly chelated —OH groups (see ref. 12)).

The method described here for the synthesis of unsymmetrically substituted dicoumarols seems to be of general application. It is probable that it can be extended to dicoumarols bearing a substituent at the bridge methylene group by using aldehydes other than formaldehyde in the Mannich reaction.

EXPERIMENTAL

The melting points are uncorrected. Infrared spectra were measured with a Perkin–Elmer Model 21 instrument using sodium chloride optics. Ultraviolet absorption spectra were measured with a Beckmann DK 2 recording spectrophotometer.

*Reaction between 4-Hydroxycoumarin and 4-Hydroxy-3-*N*-piperidinomethylcoumarin*

4-Hydroxy-3-*N*-piperidinomethylcoumarin was best prepared by the method of Robertson and Link (3).

(*i*) *Without Methyl Iodide*

Pure 4-hydroxycoumarin (0.164 g) and 4-hydroxy-3-*N*-piperidinomethylcoumarin (0.26 g) were dissolved in hot absolute ethanol (5 ml) and the solution boiled under reflux for 10 minutes. After 3 minutes a crystalline solid began to separate out. The cooled suspension was filtered, and the addition complex (A) (0.386 g) washed with a little hot alcohol. The product, m.p. 255–257°, could not be recrystallized without decomposition. It was insoluble in ethanol, benzene, chloroform, and carbon tetrachloride but soluble in dioxan, tetrahydrofuran, acetic acid, *cyclo*hexanone, and dimethyl formamide. One recrystallization from nitromethane gave impure product, m.p. 258–260°, and a second recrystallization from the same solvent converted the material into dicoumarol, m.p. 293–295°, undepressed on admixture with an authentic specimen. For analysis purposes, (A) was washed repeatedly with hot alcohol and dried, the melting point remaining unchanged at 255–257°. Found: C, 68.35; H, 5.5. Calc. for $C_{24}H_{23}O_6N$: C, 68.3; H, 5.5%.

Heating the addition complex (0.386 g) in ethanol with concentrated hydrochloric acid (2 drops) for $1\frac{3}{4}$ hours gave dicoumarol (0.129 g, 89.5%), m.p. 290–292°.

Infrared spectrum of the addition complex (Nujol mull) (main peaks only): 3170 (m) (broad), 2750 (m), 2730 (sh) (m), 2570 (m), 2470 (m), 1719 (s), 1672 (s), 1618 (s) (broad), 915 (m), 768 (s), 684 cm^{-1} (w).

(*ii*) *Using Methyl Iodide*

4-Hydroxy-3-*N*-piperidinomethylcoumarin (0.13 g) was dissolved in absolute ethanol (3 ml) and treated with an excess of methyl iodide (1 ml; if molar quantities are used only the addition complex (A) is obtained). 4-Hydroxycoumarin (0.082 g) in hot ethanol (3 ml) was added and the solution boiled under reflux for 4 hours, during which time dicoumarol gradually separated out. The product (0.151 g) was collected and recrystallized from *cyclo*hexanone giving pure dicoumarol, m.p. 289–292°. Found: C, 68.21; H, 3.36. $C_{19}H_{12}O_6$ requires C, 68.0; H, 3.6%.

Infrared spectrum (Nujol mull) (main peaks only): 2770 (w), 2650 (w), 1663 (s), 1640 (s), 1612 (s), 1575 (s), 1555 (m), 1112 (s), 913 (m), 772 (s), 751 (m), 742 cm^{-1} (s).

*4-Hydroxy-7-methyl-3-*N*-piperidinomethylcoumarin*

A solution of piperidine (0.73 ml) and formaldehyde (0.5 ml, 38%) in absolute ethanol (5 ml) was added to a boiling solution of 4-hydroxy-7-methylcoumarin (1.0 g) in absolute ethanol (10 ml) and the mixture kept at 5° in the refrigerator for 3 days. The solid which separated (1.42 g), m.p. 177–179°, was recrystallized by dissolving it in hot ethanol and adding anhydrous ether until a turbidity appeared and then allowing to stand. After three such recrystallizations the pure base, m.p. 173–174°, was obtained. Found: C, 70.27; H, 7.04. Calc. for $C_{16}H_{19}O_3N$: C, 70.31; H, 7.01%.

7-Methyldicoumarol

(*i*) *From 4-Hydroxy-7-methylcoumarin*

A solution of 4-hydroxy-3-*N*-piperidinomethylcoumarin (0.259 g) in ethanol was treated with methyl iodide (1 ml) and after heating for a few minutes a solution of 4-hydroxy-7-methylcoumarin (0.174 g) in hot ethanol was added and the mixture boiled under reflux for 3 hours. The solid which separated (0.31 g), m.p. 256–259°, was recrystallized from *cyclo*hexanone giving 7-methyldicoumarol, m.p. 261–262°. Found: C,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

68.80; H, 3.97. Calc. for $C_{20}H_{14}O_6$: C, 68.5; H, 4.03%. Infrared spectrum (Nujol mull) (main peaks only): 2755 (w), 2620 (w), 1658 (s), 1633 (s), 1613 (s), 1570 (m), 1555 (sh)(m), 1105 (s), 805 (m), 777 (m), 755 (m), 738 cm^{-1} (m).

The product was different from both dicoumarol and 7,7′-dimethyldicoumarol.

In the absence of methyl iodide the corresponding addition complex, m.p. 234–236°, was obtained in 70% yield. It, too, decomposed to give the dicoumarol on attempted recrystallization, and a specimen pure enough for analysis could not be obtained.

(*ii*) *From 4-hydroxy-7-methyl-3-N-piperidinomethylcoumarin*

Methyl iodide (1 ml) was added to a solution of 4-hydroxy-7-methyl-3-*N*-piperidinomethylcoumarin (0.273 g) in absolute ethanol, the solution heated for 5 minutes, and 4-hydroxycoumarin (0.162 g) in hot ethanol added. After boiling under reflux for 5 minutes the product began to separate. The mixture was refluxed for another $2\frac{1}{2}$ hours, cooled, filtered, and the solid (0.245 g), m.p. 255–258°, recrystallized from *cyclo*hexanone to give 7-methyldicoumarol, m.p. 255–257°, undepressed on admixture with the specimen obtained as under (i).

7,7′-Dimethyldicoumarol

Formaldehyde (2 ml, 38%) was added to a boiling solution of 4-hydroxy-7-methyldicoumarol (0.5 g) in 50% ethanol (50 ml) and the solution boiled for 5 minutes giving impure product (0.484 g), m.p. 273–293°. Recrystallization from glacial acetic acid gave 7,7′-dimethyldicoumarol, m.p. 292–294°, depressed to 260–270° on admixture with 7-methyldicoumarol. Found: C, 69.24; H, 4.47. Calc. for $C_{21}H_{16}O_6$: C, 69.2; H, 4.44%. Anschutz (16) gives m.p. 273–275° for this compound.

6-Methyldicoumarol

This was obtained in 89.4% yield from 4-hydroxy-6-methylcoumarin, 4-hydroxy-3-*N*-piperidinomethylcoumarin, and methyl iodide. It had m.p. 250–251° (from *cyclo*hexanone). Found: C, 68.57; H, 4.01. Calc. for $C_{20}H_{14}O_6$: C, 68.57; H, 4,03%.

6-Chlorodicoumarol

This was similarly obtained from 6-chloro-4-hydroxycoumarin, 4-hydroxy-3-*N*-piperidinomethylcoumarin, and methyl iodide. Yield 90.3%. Recrystallization from *cyclo*hexanone gave pure product, m.p. 266–268°. Found: C, 62.2; H, 2.93. Calc. for $C_{19}H_{11}O_6Cl$: C, 61.6; H, 3.00%. Infrared spectrum (Nujol mull) (main peaks only): 2720 (w), 2595 (w), 1657 (s), 1632 (s), 1607 (m), 1576 (m), 1500 (w), 1109 (m), 914 (w), 809 (w), 765 cm^{-1} (m).

7-Methoxydicoumarol

4-Hydroxy-7-methoxycoumarin was prepared from 2-hydroxy-4-methoxyacetophenone, diethyl carbonate, and pulverized sodium by the method of Desai and Sethna (17) and was identical in melting point (mixed melting point undepressed) and infrared spectrum with a specimen kindly supplied by Dr. R. H. Thomson (Aberdeen University, Scotland).

4-Hydroxy-3-*N*-piperidinomethylcoumarin (5.2 g) in absolute ethanol (50 ml) was treated with a large excess of methyl iodide (20 ml). 4-Hydroxy-7-methoxycoumarin (3.84 g) in ethanol (80 ml) was then added and the mixture boiled under reflux for 4 hours. The cooled suspension was filtered and the solid, m.p. 245–260°, extracted three times with boiling glacial acetic acid. On cooling, the combined extracts deposited slightly impure 7-methoxydicoumarol (5.0 g), which on recrystallization from glacial acetic acid gave product (4.9 g), m.p. 245–248°. Further recrystallizations from acetic acid did not raise the melting point. Found: C, 65.41; H, 4.05. Calc. for $C_{20}H_{14}O_7$: C, 65.57;

H, 3.85%. Infrared spectrum (Nujol mull) (main peaks): 1655 (s) (broad), 1620 (s), 1602 (s), 1565 (s), 1512 (m), 1098 (s), 835 (m), 805 (m), 775 (m), 752 (m), 740 cm^{-1} (sh)(m). Ultraviolet spectrum (in dioxan solution): λ_{max} 323 (infl.), 317, 307 (infl.), 289 $m\mu$ 10^{-3} ϵ: 35.99, 29.95, 37.52, 29.95.

The residue (0.5 g) from the acetic acid extraction was recrystallized from *cyclo*hexanone giving colorless crystals, m.p. 290–292°. Good analytical figures could not be obtained for this compound (found: C, 64.17; H, 4. 45%), which differed greatly in solubility from the 7-methoxydicoumarol, m.p. 245–248°, obtained above. The infrared spectrum was identical with that of 7-methoxydicoumarol except for a single weak peak at 1110 cm^{-1} which was absent in the spectrum of the lower melting product. The ultraviolet spectrum measured in dioxan is very similar to that of 7-methoxydicoumarol indicating that no change has occurred in the chromophoric system. λ_{max} 324 (infl.), 317, 307 (infl.), 289 $m\mu$ 10^{-3} ϵ (assuming the same molecular weight as 7-methoxydicoumarol): 35.44, 40.12, 33.70, 20.33.

4,7-Dihydroxycoumarin (2,7-Dihydroxychromone)

A mixture of 4-hydroxy-7-methoxycoumarin (0.8 g) and anhydrous aluminum chloride (4 g) in dry benzene (150 ml) was boiled under reflux for 6 hours. Crushed ice and dilute hydrochloric acid were then added to the cold mixture and the benzene evaporated off giving 4,7-dihydroxycoumarin (0.74 g), m.p. 265–268°, which could be recrystallized from dilute methanol. Bauer and Schoder (18) give m.p. 264° (decomp.) for this compound.

7-Hydroxydicoumarol

(i) 4-Hydroxy-3-*N*-piperidinomethylcoumarin (0.114 g) in absolute ethanol was treated with methyl iodide (2 ml) and then with 4,7-dihydroxycoumarin (0.75 g) and the mixture refluxed for 8 hours. Working up in the usual way gave 7-hydroxydicoumarol (0.115 g), m.p. 300–302°, which on recrystallization from glacial acetic acid had m.p. 300–302°. Found: C, 64.67; H, 3.79. Calc. for $C_{19}H_{12}O_7$: C, 64.77; H, 3.43%. Infrared spectrum (Nujol mull) (main peaks only): 3380 (m) (broad), 2740 (w), 2600 (w), 1655 (sh) (s), 1635 (s), 1608 (s), 1573 (s), 1315 (s), 1113 (s) (broad), 856 (m), 808 (m), 798 (m), 770 (s), 755 (s), 744 cm^{-1} (m).

(ii) 7-Methoxydicoumarol (0.5 g, m.p. 245–248°) and anhydrous aluminum chloride (2.5 g) in dry benzene (100 ml) were boiled under reflux for 8 hours. Cracked ice and dilute hydrochloric acid were added to the cold mixture, the benzene was removed, and the product recrystallized from glacial acetic acid giving 7-hydroxydicoumarol (0.321 g), m.p. 300–302° undepressed in admixture with material obtained as under (i) above. The infrared spectra of the two products were also identical.

ACKNOWLEDGMENTS

This work was carried out during the tenure (by J.R.G.) of a Thorvaldson Scholarship. We wish to thank Dr. R. H. Thomson (Aberdeen) for a specimen of 4-hydroxy-7-methoxycoumarin and Dr. L. Vining for the use of a Beckmann DK 2 recording spectrophotometer.

RECIPROCAL SALT PAIRS, INVOLVING THE CATIONS Li_2, Na_2, AND K_2, THE ANIONS SO_4 AND Cl_2, AND WATER, AT 25° C[1]

A. N. CAMPBELL, E. M. KARTZMARK, AND E. G. LOVERING[2]

ABSTRACT

In the reciprocal salt pair Li_2, K_2, Cl_2, SO_4, and water, at 25° C there are large areas in which potassium sulphate and potassium lithium sulphate ($KLiSO_4$) are separately in equilibrium with solution. Two incongruent invariant points exist. At one of these the composition of the solution is 0.917 mole fraction chloride,* 0.437 mole fraction lithium, and 19.4 moles of water per total mole of salt, the equilibrium solid phases being potassium chloride, potassium sulphate, and the double salt. At the second, the composition of the solution is 0.967 mole fraction chloride, 0.870 mole fraction lithium, and 13.8 moles of water per mole of salt, the solid phases being potassium chloride, double salt, and lithium sulphate monohydrate. One congruent invariant point exists, at which the composition of the solution is 1.00 mole fraction chloride, 0.960 mole fraction lithium, and 9.6 moles of water per mole of salt, the solid phases being lithium sulphate monohydrate, lithium chloride monohydrate, and potassium chloride.

In the reciprocal salt pair Li_2, Na_2, Cl_2, SO_4, and water, at 25° C there is an incongruent invariant point at which the composition of the solution is 0.873 mole fraction chloride, 0.668 mole fraction lithium, and 15.1 moles water per total mole of salt, the solid phases being sodium chloride, solid solution of sodium and lithium sulphates, and lithium sulphate monohydrate. A congruent invariant point exists, at which the composition of the solution is practically entirely lithium chloride, the solid phases present being lithium chloride monohydrate, lithium sulphate monohydrate, and sodium chloride.

INTRODUCTION

The two reciprocal salt pairs

$$Li_2Cl_2 + Na_2SO_4 \rightleftarrows Li_2SO_4 + Na_2Cl_2$$

and

$$Li_2Cl_2 + K_2SO_4 \rightleftarrows Li_2SO_4 + K_2Cl_2,$$

both at 25° C, which form the subject of this paper, are part of the five-component system: Li_2, Na_2, K_2, Cl_2, SO_4, water, at 25° C, which is being studied in this department. The component ternary systems are now all known, as well as the two four-component systems: Li_2, Na_2, K_2, Cl_2, H_2O and Li_2, Na_2, K_2, SO_4, H_2O. The reciprocal salt pair:

$$Na_2Cl_2 + K_2SO_4 \rightleftarrows K_2Cl_2 + Na_2SO_4$$

is also known. Nothing has been done on the remaining two reciprocal salt pairs. A bibliography is appended to this paper (1*a*–1*i*, 2).

Particular mention should be made, however, of a recent paper by Cavalca and Nardelli (3), who claim that the double salt $Na_3Li(SO_4)_2.6H_2O$ exists at 27° C. This is not in agreement with the work of Campbell and Kartzmark (4), who found no double salt but extensive solid solution at 25° C. As a final check on this point, two experiments were carried out. Appropriate mixtures of lithium sulphate, sodium sulphate, and water were stirred for 1 week in contact with excess of solid at 25° C. The solutions and wet residues were analyzed, both by determination of sulphate as barium sulphate and by viscosity. When these results were plotted on the triangular diagram of Campbell and Kartzmark, the tie lines found by the unsatisfactory barium sulphate method crossed, while those found by the viscosity method did not. This may constitute an explanation of the results of Cavalca and Nardelli.

EXPERIMENTAL

All chemicals used were of the highest purity and they were not further purified by us but the sulphates were dried by fusion. Solutions and solid phases were analyzed by evaporating to dryness, igniting, and weighing. Chloride radical was determined gravimetrically as silver chloride. The remaining solid was converted to sulphate by treatment with sulphuric acid, followed by ignition. A fixed weight (10 or 20 g) of sulphate mixture was dissolved in water, made up to fixed volume (100 ml), and the viscosity determined. The value of the viscosity gave the ratio of the two cations present. Sulphate radical was determined by difference, since the gravimetric determination of sulphate, in the presence of alkali metals, is notoriously unsatisfactory, although we have occasionally been forced to use the method. The method described above works very well. It is necessary to heat the sulphated solids at 600° C, for not less than six hours, to ensure that no trace of free sulphuric acid has been left. The dried sulphate mixture was tested for the presence of free acid and chloride radical, before it was used further. Viscosity curves for the systems potassium sulphate – lithium sulphate and sodium sulphate – lithium sulphate were obtained for mixtures of known composition.

The nature of the solid phases present was revealed to some extent by the chemical analysis taken in conjunction with a knowledge of the general trend of the solubility curve under investigation, but recourse was made to other methods whenever possible. Thus, sodium sulphate decahydrate was identified by removing a few of the characteristic crystals and warming them slightly when they underwent the transition to anhydrous salt. Solid solution (in sodium salt) was suspected when the lithium content began to rise above that which might reasonably be attributed to adhering mother liquor. Lithium sulphate monohydrate was identified by its prismatic habit and the fact that it does not dehydrate on a steam bath. We found it impossible to use the polarizing microscope because it was necessary to dry the solid phase and this could change the nature of the solid phases. Similarly, X-ray diffraction photography was found to be useless here. The wet solid phases gave indefinite pictures. In the course of the X-ray work, however, it was found that the X-ray powder diffraction data for lithium sulphate monohydrate, as given in the file of the American Society for Testing Materials, were not complete. Powder pictures of this material were therefore taken and will be offered for publication elsewhere by one of us (E.G.L.).

The Jänecke method of graphical representation (5) was used. In this system of representation, ternary invariant points appear as points on the sides; water is expressed by isohydrores or lines of equal water content. Experimentally, we started from each invariant point on the sides of the diagram in turn, making sure that a plentiful excess of the two solid phases was present, and progressively added small quantities of a cation or anion which did not participate in the original equilibrium. Equilibrium was attained by stirring for 24 hours after each addition when liquid and solid phases were analyzed. Invariance in quaternary systems showed itself by the composition of the liquid phase becoming constant with further additions; it was then a question of identifying the third solid phase which had appeared. If a new ion appeared (in appreciable quantity) for the first time in the solid phase, there was seldom any doubt as to the nature of the new solid phase. Moreover, since no solid phase occurs in the quaternary systems other than those occurring in the component ternary systems, it was usually obvious when two solubility curves intersected what the new phase would be.

DISCUSSION OF RESULTS

1. THE SYSTEM $K_2Cl_2 + Li_2SO_4 \rightleftarrows K_2SO_4 + Li_2Cl_2$, AT 25° C

The equilibrium diagram is shown as Fig. 1. The curves representing two solid phases in equilibrium with solution are shown as heavy lines, the lighter lines being isohydrores (lines of equal water content, expressed as moles of water per mole of total salts). The phase boundaries are usually drawn as straight lines because the experimental accuracy does not usually warrant indicating curvature. The isohydrores are very approximate, owing to lack of data, but they do indicate the course of isothermal evaporation. The stable pair of solid phases, that is, the pair of salts that can exist in contact with each other and with solution, consists of lithium sulphate monohydrate and potassium chloride. There are three invariant points. At the invariant point 8, in Fig. 1, the solid phases are potassium sulphate, potassium chloride, and double salt ($KLiSO_4$). Since the invariant point does not fall within the composition triangle, whose angular points represent the three solid phases, it is incongruent. The invariant point 17, where lithium sulphate

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

monohydrate, potassium chloride, and double salt are in equilibrium with solution, is also incongruent. Point 21, where the solid phases are lithium chloride monohydrate, lithium sulphate monohydrate, and potassium chloride, is congruent.

2. THE SYSTEM $Na_2Cl_2 + Li_2SO_4 \rightleftarrows Na_2SO_4 + Li_2Cl_2$, AT 25° C

The equilibrium diagram is shown in Fig. 2. The stable salt pair is similar to the previous system, i.e., the coexistent salts are sodium chloride and lithium sulphate monohydrate. Since no double salt occurs in this system, there are only two invariant points, one congruent and the other not. At the incongruent invariant point (point 7), the solid phases in equilibrium with solution are lithium sulphate monohydrate, sodium chloride, and a solid solution of sodium and lithium sulphates; the amount of lithium in the solid solution increases as the concentration of lithium in the liquid phase increases. At point H, the congruent invariant point, the solid phases are lithium chloride monohydrate, lithium sulphate monohydrate, and sodium chloride; the solution is very rich in lithium chloride. It has been shown by Campbell and Kartzmark (4) that the double salt $NaLiSO_4$ exists above 29.3° C. It is conceivable that this double salt could exist, at 25° C, in contact with the solution containing lithium and sodium chlorides. If it did exist, three invariant points would appear, in place of point 7, at which the solid phases would be double salt and (1) $Li_2SO_4 \cdot H_2O$ + NaCl; (2) NaCl + solid solution; (3) solid solution + $Li_2SO_4 \cdot H_2O$. All attempts to find such invariant points failed. It is known from the ternary system, Li_2Cl_2–Li_2SO_4–H_2O that the $LiCl \cdot H_2O$ field in the quaternary diagram must be extremely narrow; it cannot be investigated experimentally or expressed graphically to scale.

ACKNOWLEDGMENTS

We are indebted to Dr. R. B. Ferguson, of the Department of Geology, for advice and assistance with the X-ray photography and to the Consolidated Mining and Smelting Company of Canada for financial assistance in the form of a Cominco Fellowship.

THE KINETICS OF RADICAL REACTIONS IN THE TRACKS OF FAST ELECTRONS

A DETAILED STUDY OF THE SAMUEL–MAGEE MODEL FOR THE RADIATION CHEMISTRY OF WATER[1]

P. J. Dyne and J. M. Kennedy

ABSTRACT

The kinetic behavior of a γ-ray spur produced in water, having H and OH radicals distributed spatially in the manner suggested by Samuel and Magee, has been studied using an electronic computer. The variation in yield of the molecular products H_2, H_2O_2, and H_2O with rate constants, diffusion constants, and spur size has been obtained. The model gives agreement with experiment choosing spurs with a small "radius" of the order of 10 Å. On simple assumptions, however, the model predicts no difference in the molecular yields between heavy and light water and no isotopic separation in the formation of molecular hydrogen from isotopically enriched light water. Various special assumptions needed to give agreement with experiment for these isotope effects are discussed. The observed isotopic separation in the formation of molecular hydrogen is attributed to the preferential dissociation of an H atom from an excited HDO molecule. It is found that the yield of molecular hydrogen is less sensitive to the presence of scavengers than the yield of hydrogen peroxide.

1. INTRODUCTION

The products of the radiation decomposition of water are of two types, free radicals and molecules, and it is generally supposed that the molecular products (hydrogen and hydrogen peroxide) are formed by recombination of free radicals (H and OH) in regions of high radical concentration. In the model of this process proposed by Samuel and Magee (1) it was suggested that the radicals were formed by the dissociation of excited water molecules. Consequently, both species of radicals have initially a similar spatial distribution; some of these radicals recombine to give molecular products, others escape by diffusion into the bulk of the solution where they can be detected by their reactions as radicals. Several variations of this model are discussed by Dewhurst, Samuel, and Magee (2).

While this model has been widely accepted for the interpretation of the radiation chemistry of water no detailed study of its properties has been made in which the recombination of both reacting species (H and OH) is treated. As the kinetics of recombination and diffusion cannot be handled analytically the majority of calculations hitherto have been performed on a simplified version, a "one radical" model in which the one species has the "average" properties of H and OH. These calculations have shown that the model explains many of the features of the radiation decomposition of water and on this pragmatic basis the model has been accepted.

We have surmounted the main obstacle to the study of a two-radical model, the intractable nature of the equations, by programming the problem for numerical solution on the Chalk River Datatron Computer, and this paper presents the results of these calculations. A second, equally serious, obstacle remains and this is our lack of knowledge about the rate constants and diffusion constants and other parameters of the system. We have, accordingly, adopted an approach which is essentially the converse of that of experimental chemical kinetics; the "constants" (rate constants, etc.) of the systems are treated as parameters. We derive graphical relations between these parameters and

[1]*Manuscript received July 14, 1958.*
Contribution from the Research Chemistry and Theoretical Physics Branches, Atomic Energy of Canada Limited, Chalk River, Ontario.
Issued as A.E.C.L. No. 693.

the yields of radicals and molecular products. Our conclusions comprise a qualitative picture of the kinetic properties of the model, an estimate of the range of values of the parameters which will give agreement with experiment, and a discussion of the details of the isotope effects and scavenger effects.

2. THE SAMUEL-MAGEE MODEL

In their original paper Samuel and Magee (1) suggested that the passage of a high energy (1 Mev) β-particle through liquid water initiated the following sequence of events: the β-particle ionizes water molecules at widely spaced intervals along its track, each ionization forming a "spur". The ionized electron has, on the average, an energy of about 60 ev, which is rapidly lost as it ionizes and excites some of the surrounding water molecules forming, say, three H_2O^+ ions and three electrons. The ions recapture the ionized electrons after the electrons have been thermalized by collision with surrounding molecules and form excited water molecules. These in turn dissociate to give H atoms and OH radicals. The whole process from the initial ionization to the dissociation occurs in a time of the order of 10^{-13} seconds. The radicals are distributed inside a volume which is only a few molecular diameters across. For the purposes of calculation it was assumed that the initial distribution is given by a Gaussian with a modulus of 10 Å.

Samuel and Magee solved the kinetic equations for reaction and diffusion in a spur for the case of one species of radical where the spatial distribution was assumed *always* to be a Gaussian. This technique, known as the "Prescribed Diffusion Approximation", enabled them to calculate analytically the ratio of free radicals recombining to the total formed initially. They showed that for a "reasonable" choice of parameters, the calculated value agreed with experiment. These calculations were extended to the case of α-ray decomposition and tritium β-ray decomposition. With α-rays the primary ionizations lie very close together and the initial distribution consists of a column of radicals which expands in cylindrical symmetry; with tritium β-rays the spurs overlap quite shortly after their formation and recombination occurs partly in spherical and partly in cylindrical symmetry. Agreement with experiment for both these was obtained with the choice of parameters used for the calculation on high energy β-rays.*

3. THE TRACK EQUATION FOR THE TWO-RADICAL MODEL

The calculations on the "two-radical" model described in this paper deal only with the case of high energy β-rays, i.e. spurs which expand wholly in spherical symmetry with no overlapping. From these calculations we can predict differences in the behavior of H and OH and estimate the extent of recombination to reform H_2O which is not observable experimentally and which is not distinguished in a one-radical calculation from recombination to give H_2 and H_2O_2.

We adopt the convention that the hydrogen atom is species 1 with diffusion constant D_1 and recombination rate constant k_{11} and concentration C_1 which is a function of time and space. The OH radical is species 2 with constants D_2, k_2, C_2, etc. The rate constant for the recombination of H and OH radicals is k_{12}.

The track equations governing the kinetics reaction and diffusion are:

$$\partial C_1/\partial t = D_1\nabla^2 C_1 - [(N_1-1)/N_1]\, k_{11}C_1^2 - k_{12}C_1C_2 - k_{1S}C_1C_S, \qquad [1]$$

$$\partial C_2/\partial t = D_2\nabla^2 C_2 - [(N_2-1)/N_2]\, k_{22}C_2^2 - k_{12}C_1C_2 - k_{2S}C_2C_S, \qquad [2]$$

**Note added in proof: The results of some detailed computations on a one-radical model have recently been published by Flanders and Fricke, J. Chem. Phys. 28, 1126 (1958).*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

where N_1 and N_2 are the total number of radicals in the spur at time t, k_{1S} and k_{2S} are the rate constants for reaction with scavenger present in a small, uniform concentration C_S. The yields of hydrogen, hydrogen peroxide in one spur, are the values of

$$\int_0^\infty \int_0^\infty k_{11}C_1^2\, dv.dt, \int_0^\infty \int_0^\infty k_{22}C_2^2\, dv.dt, \text{ and } \int_0^\infty \int_0^\infty k_{12}C_1C_2\, dv.dt,$$

gives the amount of H_2O reformed in the spur. The quantities $(N_1-1)/N_1$ and $(N_2-1)/N_2$ are statistical factors which take into account the fact that, with a small number of radicals, the expression $k_{11}C_1^2$ must be reduced so that the bimolecular reaction of a radical with itself is not included, e.g. if there are six radicals in the spur, one particular radical can only react with five others and the rate is therefore 5/6 of the rate given by the standard kinetic expression.

The numerical method used is described in the Appendix.

4. THE INITIAL CHOICE OF CONSTANTS

Because none of the constants in the problem has been measured directly we have to estimate their order of magnitude a priori. As our object is to determine the sensitivity of the yields to variations in the constants, our initial choice is equivalent to defining the area to be explored. This is, of necessity, somewhat arbitrary.

First let $D_2 = 2\times10^{-5}$ cm^2/second (the same as the self-diffusion constant for water) (3). It seems entirely reasonable that OH and H_2O will diffuse at comparable rates. As the hydrogen atom is lighter, D_1 must necessarily be greater than D_2. Simple kinetic theory shows that the ratio $D_1/D_2 = \sqrt{(M_2/M_1)}$ where M_2 and M_1 are the masses of the two species. This gives $D_1 = 8\times10^{-5}$ cm^2/second. The use of this formula is equivalent to assuming identical scattering cross sections for the diffusion of H and OH in water. This study is confined to cases where $D_1/D_2 \approx 4$.

The initial choice of the rate constants has been made with the aid of the Smoluchowski relation

$$k_{12} = A(\sigma_1+\sigma_2)(D_1+D_2), \qquad [3]$$

where σ_1 and σ_2 are the collision diameters of the species 1 and 2. The value of A is discussed by Fricke (4) and following his arguments we have chosen a value of A so that k_{11} and k_{22} are both $\sim1\times10^{-11}$ and 1×10^{-11} cc/molecule second. With $\sigma_1 = 0.5$ Å and $\sigma_2 = 1.5$ Å we chose $k_{11} = 1.2\times10^{-11}$, $k_{12} = 3.0\times10^{-11}$, and $k_{22} = 0.9\times10^{-11}$. The larger value of k_{12} is mainly due to the statistical factor of two, which distinguishes between the collision numbers for like particles and unlike particles.

The constants k_{1S} and k_{2S} were taken as 1×10^{-11} and C_S were taken as 10^{-3} M. Two further constants which do not appear explicitly in the track equation must also be fixed. These are the initial size of spur and the number of radicals per spur. Following Samuel and Magee the *initial* concentration is taken to be a Gaussian.

$$C_1(r) = (N_1{}^0\,\beta^3/\pi^{3/2})\exp(-\beta^2r^2) \qquad [4]$$

where $1/\beta$ is the radius at which $C_1(r)$ has fallen to $1/e$ of its maximum value. No further assumption is made about the spatial distributions during the course of the reaction. We have taken $1/\beta = 10^{-7}$ cm $= 10$ Å which we denote by the symbol R. This value can be justified by noting that the spur is formed by the thermalization of a slow (50–70 ev) electron which excites, say, three to six water molecules during its lifetime. If the ex-

For personal use only.

citation cross section is of the order of the gas kinetic cross section, the mean distance between excitations in liquid water is found to be ∽10 Å. It follows that the value of 10 Å for the modulus of a Gaussian distribution is reasonable.

No experimental evidence on the size and structure of spurs is available for water. The most relevant measurements are statistics of the number of ion pairs in spurs generated in the gas phase obtained by Wilson (5) and Beekman (6) from cloud chamber photographs. The former finds an "average" spur size of between two and three ion pairs. This is not the most probable size; according to Wilson, 40% of the spurs contains only one ion pair. Beeckman finds 60% containing one ion pair. These measurements were made in air. Taking the energy per ion pair to be 32 volts, these data suggest an average energy deposition of 65±10 volts/spur. The only direct measurement of the number of water molecules dissociated initially is obtained from Firestone's (7) studies of the radiation decomposition of water vapor where the medium is so dilute that no recombination occurs. He finds $G(-H_2O) = 11\pm1$. Combining this value with the value of 65±10 volts per spur obtained above we obtain a value of 6±1 radical pairs per spur and we have taken $N = 6$ in our calculations. Monchick, Samuel, and Magee (8) chose $N = 5$ but they did not discuss the reasons for their choice.

In this argument we assume that the "average" spur, in terms of average *energy*, is the "average" spur for the value of yields, etc., which we are interested in calculating. It is conceivable that the yields vary very sharply as a function of N so that the two averages are different. However, using some of the values of the yields calculated as a function of N and weighting these according to a distribution in N given by the above arguments we find that the "average" spur does correspond to a six-radical pair spur.

5. THE CALCULATIONS

The detailed results of the calculations are presented in Table I. The numbers to the left of the double line are the constants which specify the individual case; those to the right are the values of the yields in one spur. The yields of H_2 and H_2O_2 are expressed as the number of atoms or radicals which have recombined to give these products. The number of molecules formed is half this number. $[H_2O^*]$ is the number of water molecules reformed, $[-H_2O]$ is the net decomposition. If the number of hydrogen atoms in the spur is N_1, we have

$$N_1 = N_2 = [H_2] + [H_2O^*] + [H] = [H_2O_2] + [H_2O^*] + [OH] = [H_2O^*] + [-H_2O], \qquad [5]$$

using square brackets to symbolize the yields defined above.

From the computation of each case a plot like Fig. 1 is constructed which shows the course of the reaction as a function of time. Several features of the process are shown in this figure. A significant fraction of the total amount of recombination occurs in times of the order of 10^{-11} seconds but the process is not complete until some 10^{-8} seconds have elapsed. The scavenging reaction is, at concentrations of $\sim10^{-3}$ molar, negligible until nearly 10^{-8} seconds have elapsed. The true yields of molecular products are given by the asymptotes to the curves in Fig. 1. These can be estimated, with sufficient accuracy, by a visual extrapolation at times of $\sim10^{-8}$ seconds.

6. EXPERIMENTAL VALUES OF THE RADICAL AND MOLECULAR YIELDS

These calculations related to the decomposition of pure water; experimental G-values for this system are given in Table II. We are indebted to A. O. Allen and H. A. Schwarz

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12

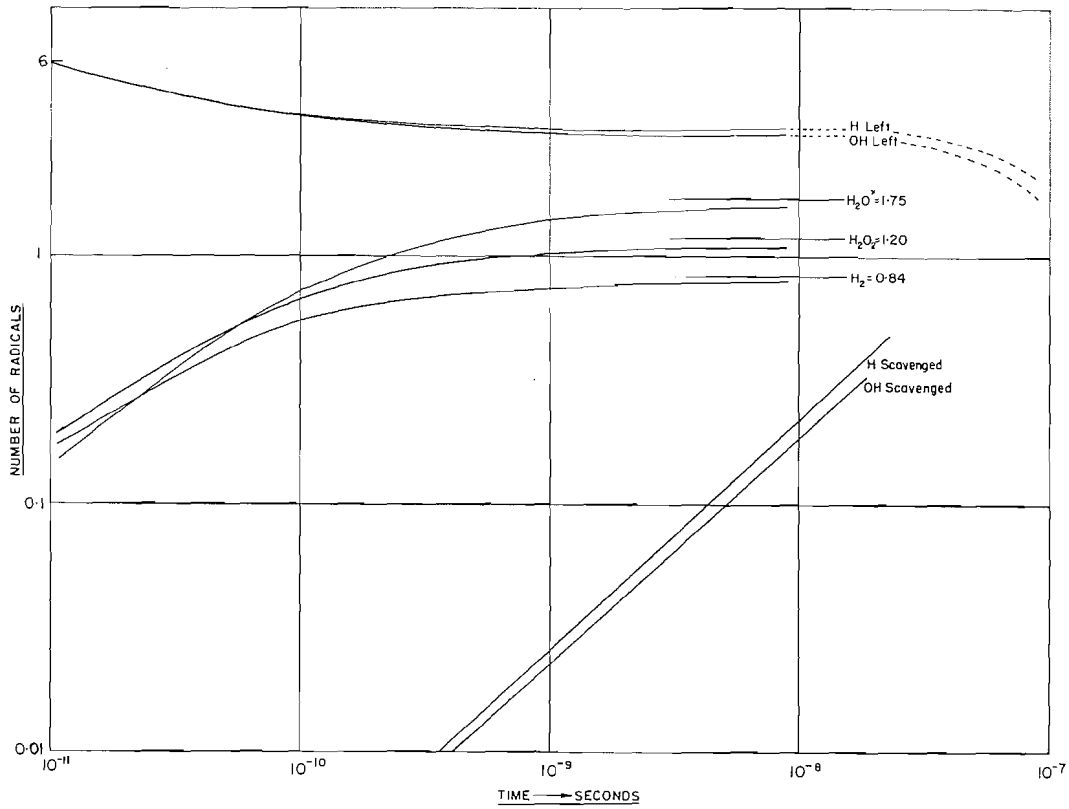

FIG. 1. Kinetics of recombination in a γ-ray spur for case I. The number of radicals which have recombined are plotted as a function of time together with the number which have not reacted. In times of the order of 10^{-7}–10^{-6} seconds the number of unreacted radicals falls sharply as they are scavenged.

(private communication) for these numbers which in their opinion represent "the best values for γ-rays acting in neutral water containing vanishingly small amounts of active solutes" which suppress the reaction of H with H_2O_2 and of OH with H_2. The second line expresses these numbers as the number of atoms or radicals of one species which have combined to give the observed yield. This is the form used in Table I.

This table contains two different kinds of information. Firstly, adopting the Samuel–Magee interpretation, it follows that of the hydrogen atoms involved in the *net* decomposition (see equation [5]) a fraction, which we shall call $f(H_2)$, recombine to give molecular hydrogen. From Table II we see that $f(H_2) = 0.90/3.7 = 0.23$ and that the analogous quantity for OH radicals $f(H_2O_2) = 1.40/3.7 = 0.38$. The second kind of information is the value of the yields per unit of energy absorbed and this is summarized by saying that $G(-H_2O) = 3.7$.

7. YIELDS AS A FUNCTION OF THE OVER-ALL VALUES OF RATE CONSTANTS AND DIFFUSION CONSTANTS

One would expect the amount of recombination to depend critically on the *ratio* of the values of the rate constants to the values of the diffusion constants. It is obvious from an inspection of the track equation that if this ratio is fixed then the yield is determined; the absolute value of the constants determines the *time* in which the recombination

TABLE II

G-VALUES (YIELDS/100 EV) IN PURE WATER

	$G(H_2)$	$G(H_2O_2)$	$G(H)$	$G(OH)$	$G(-H_2O)$
(*a*)	0.45	0.70	2.8	2.3	3.7
(*b*)	0.90	1.40	2.8	2.3	3.7

(*a*) Yields expressed conventionally.
(*b*) Yields expressed as number of atoms or radicals which have combined to give these species.

occurs. This is demonstrated numerically by comparing case (A) with case (B). For brevity we shall refer to cases simply by letter, e.g. (A), (B), just as we are symbolizing the yields per spur by the use of square brackets, e.g. $[H_2]$, $[-H_2O]$. In (B) all the k's and all the D's have been divided by three but the yields are unchanged.

The variation of yields as the ratio of all the k's to the D's is changed is shown by (A), (C), and (D). In these cases the ratios $k_{11}:k_{12}:k_{22}$ are unchanged as are the values of D_1 and D_2. The yields, plotted as a function of k_{12}, are shown in Fig. 2: values of $f(H_2)$ and $f(H_2O_2)$ are plotted in Fig. 3. The values of $[H_2]$ and $[H_2O_2]$ are not very sensitive to the simultaneous variation of the constants as these recombination processes are working in competition with the recombination to form H_2O. The values of $f(H_2)$ and $f(H_2O_2)$ are however very sensitive to changes in the values of the rate constants.

An inspection of Fig. 3 shows that agreement with experimental values is obtained in a

fairly sharply defined region. The values of $f(H_2)$ and $f(H_2O_2)$ depend on the ratios k_{11}: k_{12}: k_{22} and we can only make the qualitative statement that the k's must be of the order of $2\text{–}6\times10^{-11}$ cc/molecule second to obtain agreement with experiment.

This simple point is worth re-emphasizing; for a spur of the size postulated the a

priori choice of diffusion constants and rate constants gives a strikingly sharp region of experimental agreement. The yields are, of course, a function of the initial size of the spur as discussed in Section 10.

Similar arguments apply to the over-all variation of the diffusion constants exemplified by (E), (A), and (F), whose yields are plotted in Fig. 4 as a function of D_1. This figure is a mirror image of Fig. 2—again exemplifying the fact that the yield depends only on the *ratio* of the rate constants to the diffusion constants.

Experimentally $G(H_2O_2)$ is about 80% greater than $G(H_2)$ and it is apparent from Table I that most of the cases give figures in this ratio. A similar comparison can be made for $G(H)$ and $G(OH)$. These inequalities are explained in this model by the large difference in diffusion constant between H and OH which outweighs the small difference between k_{11} and k_{22} which acts in the opposite direction ($k_{11} > k_{22}$).

8. YIELDS AS A FUNCTION OF THE INDIVIDUAL VALUES OF THE RATE CONSTANTS

Yields as a function of k_{11} are covered by (G) and (H) and plotted in Fig. 5, as a function of k_{12} are covered by (I) and (J) and plotted in Fig. 6, and as a function of k_{22} are covered by (K) and (L) and plotted in Fig. 7.

The curves show the expected form. $[H_2]$ is strongly dependent on k_{11} but not on k_{22} and $[H_2O_2]$ is similarly dependent on k_{22} but not on k_{11}.

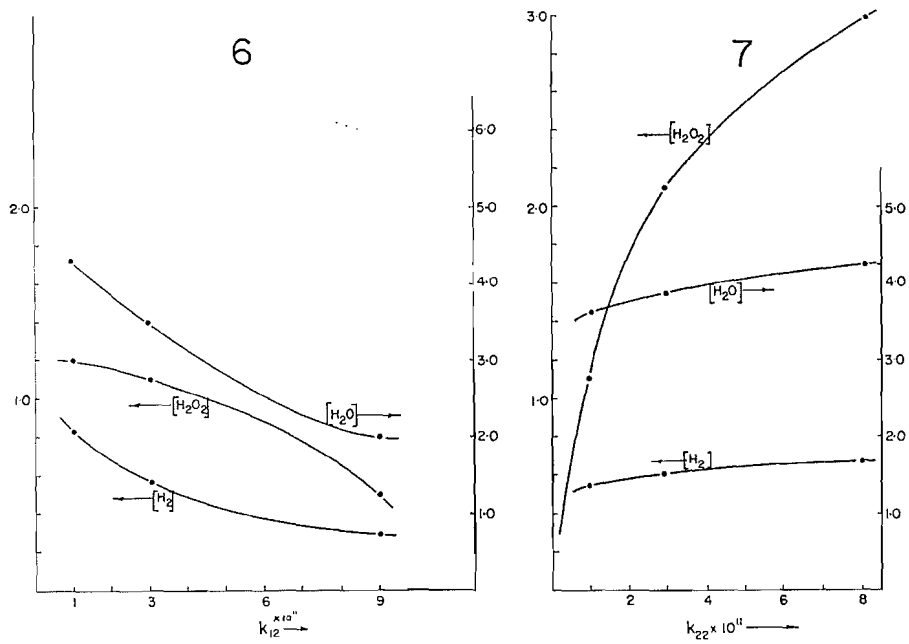

FIG. 6. Variation of yields with the values of k_{12}. Cases (A), (I), and (J).
FIG. 7. Variation in yields with a value of k_{22}. Cases (A), (K), and (L).

9. YIELDS AS A FUNCTION OF SPUR SIZE AND THE NUMBER OF RADICALS PER SPUR

There are two ways in which the variation of yield with the size of the spur can be examined. Either the relative size of the two distribution functions for the radicals or the size of both distributions may be changed. Owing to the "hot atom" effect the hydrogen atoms may be more widely dispersed than the hydroxyl radicals, i.e. $R_1 > R_2$,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

where R_1 and R_2 are the characteristic radii for H atoms and OH radicals respectively. Variation of R_1, keeping R_2 constant, is followed in (Y) and (Z) and the results are plotted in Fig. 8. As R_1 is increased $[H_2]$ decreases and both $[H_2O_2]$ and $[-H_2O]$ increase.

The yields as a function of both radical distributions are followed in (S) and (T). Values of $f(H_2)$ and $f(H_2O_2)$ derived from these cases are shown in Fig. 9; they are rapidly

For personal use only.

varying functions of size particularly for small values of the "radius". Yields as a function of the number of radicals per spur are shown in Fig. 10 for spurs of constant size (R = 10 Å) and for spurs of varying size determined by the relation $R\alpha(N)^{\frac{1}{3}}$, a radius of 10 Å being taken for the spur with N = 6. These latter values were obtained by interpolation from the changes in $f(H_2)$ and $f(H_2O_2)$ with R shown in Fig. 9. For example, the cube-root relation gives R = 11.5 Å when N = 9. From Fig. 9 we calculate the ratio of $f(H_2)$ at 10 Å to that at 11.5 Å and decrease the value of $f(H_2)$ for N = 9 by this ratio. This treatment assumes that these ratios (calculated for N = 6) are independent of N. This assumption was checked with a spot calculation for N = 15 with R = 20 Å. The calculation gave $f(H_2)$ = 0.22 and $f(H_2O_2)$ = 0.39. The interpolation technique gave $f(H_2)$ = 0.23, $f(H_2O_2)$ = 0.38.

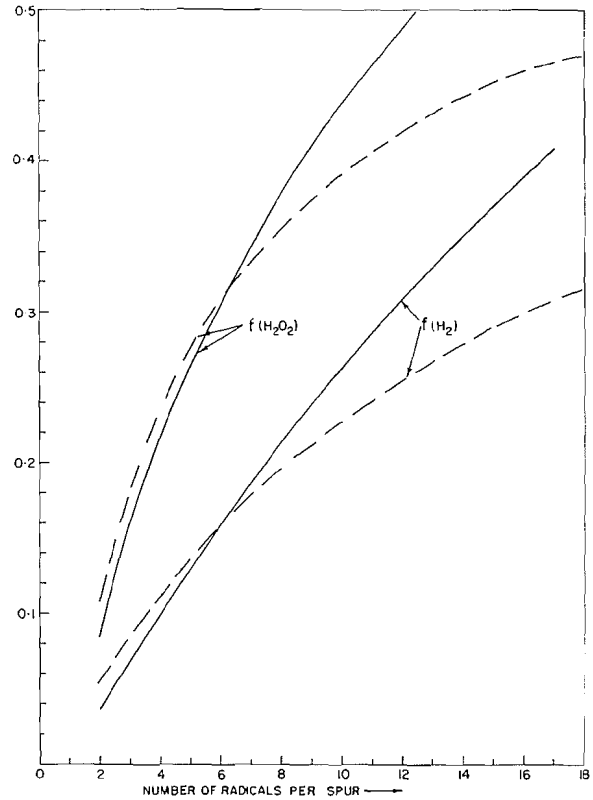

FIG. 10. Variation in $f(H_2)$ and $f(H_2O_2)$ with N, the number of radicals per spur. The full lines refer to spurs of constant size R = 10 Å. In the broken line values of $f(H_2)$ and $f(H_2O_2)$ are shown in which R varies as $\sqrt[3]{N}$ assuming that R = 10 Å when N = 6. Cases (A), (U), (V), (W), and (X).

The parameters N and R are, in a sense, complementary. If the k's and D's are fixed, we can always find values of R for any value of N which will give the experimental value of $f(H_2)$ or of $f(H_2O_2)$. This is illustrated in Fig. 11, where the solid line gives the values of N and R which give $f(H_2)$ = 0.24; the values were determined by interpolation as described in the last paragraph. The solid line corresponds to the choice of k's and D's made in (A). Another line would be generated by a different choice. For instance from Fig. 3 we find that N = 6, R = 10 Å, $k_{12} = 5.2\times10^{-10}$, $k_{11} = 2.1\times10^{-11}$, $k_{22} = 1.5\times10^{-11}$ would also give $f(H_2)$ = 0.24. This defines the circled point in Fig. 11. We can derive another line also defining $f(H_2)$ = 0.24 going through this point. This is indicated by the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

broken line and which is again obtained by interpolation. It does not matter for this argument whether or not this interpolation is exact. The point is that a whole family of lines exists describing spurs with $f(H_2)$ = a constant. By interpolation from Figs. 5 and 6 two other sets of k's can be found which would generate lines essentially coincident with the dotted line. These are: $k_{12} = 3.0\times10^{-11}$, $k_{11} = 1.7\times10^{-11}$, $k_{22} = 0.9\times10^{-11}$ and $k_{12} = 0.5\times10^{-11}$, $k_{11} = 1.2\times10^{-11}$, $k_{22} = 0.9\times10^{-11}$.

The plot in Fig. 11 illustrates the fact that we can, with our present information, make no unique choice of constants which will give agreement with experiment. Plots similar to Fig. 11 could be constructed for $f(H_2O_2)$ and $[-H_2O]$ which would restrict our choice from the larger number allowed by Fig. 11. Such a search would not be very useful. Instead we choose to pick out parameters which, if fixed, would give the most valuable information for the model. The two most important parameters from this point of view are the spur size or volume and the number of radical pairs per spur. It is quite clear from Fig. 11 that the model will only work for small spurs where the characteristic length R is less than 20 Å. The figure R = 10 Å was, in fact, originally chosen by Samuel and Magee to give agreement with experiment.

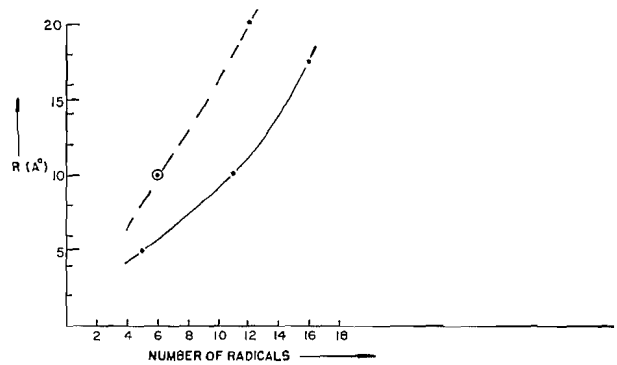

FIG. 11. Values of R, the radii, and N, number of radicals per spur, for which $f(H_2)$ = 0.24. The solid line refers to the choice of k's and D's made in (A). The dotted line refers to several choices of k's which for N = 6 and R = 10 Å also give $f(H_2)$ = 0.24.

10. ISOTOPE EFFECTS

Several workers have shown that (11, 12, and 13) the yield of deuterium gas from acidic solution in heavy water is about 25% less than the yield of hydrogen from the corresponding light water solutions. It is also known that the yield of the ferrous sulphate dosimeter is increased in heavy water solutions (14). If the stoichiometry for the oxidation of ferrous ion in light water is assumed to hold in heavy water these two observations show that, in 0.8 N H_2SO_4, $G(-D_2O)$ is greater than $G(-H_2O)$. Yields of hydrogen gas and hydrogen atoms and OH radicals and their deuterium analogues have been measured by Burton and Phung (13) in neutral solutions using benzene as a scavenger. They find that all the yields are lower than the corresponding yields in light water. The results are shown in Table III.

Burton and Phung point out that these results are not consistent with those of other workers, as may be seen by comparing Table III with Table II.

For this discussion the problem of isotope effects may be stated as follows, "Under what circumstances does the diffusion model predict a lower value of $G(D_2)$ coupled with (*a*) an increased value of $G(-D_2O)$ or (*b*) a decreased value of $G(-D_2O)$?" Following the arguments which are used in Section 4 to establish the initial choice of constants,

TABLE III

PRIMARY YIELDS IN THE RADIOLYSIS OF LIGHT AND HEAVY WATER

	$G(H_2)(D_2)$	$G(H_2O_2)(D_2O_2)$*	$G(OH)(OD)$	$G(H)(D)$	$G(-H_2O)(-D_2O)$
Light water	0.41	0.61	2.64	3.04	3.86
Heavy water	0.32	0.51	2.38	2.76	3.40

*The yield of peroxide is determined from stoichiometry.

the constants for heavy water are obtained by reducing D_1 to $1/\sqrt{2}$ of its value in (A) and adjusting k_{11} and k_{12} in accordance with the Smoluchowski relation (Section 4). This gives $k_{11} = 8.48\times10^{-12}$, $k_{12} = 2.296\times10^{-11}$, and $D_1 = 5.657\times10^{-5}$. These are the new constants for (M). It will be noted that the yields in (M) are identical with those of (A). The variation of constants required by "simple" theory produces no isotope effect. The qualitative explanation of this is that the change in k_{11} and k_{12} introduced in (M) compensates exactly for the slower diffusion of H atoms which would otherwise result in increased $[H_2]$ and $[H_2O^*]$ yields.

As the isotope effects are not explained by the "simple" choice of constants some special variation of one or more of them must be postulated. An obvious way of reducing the yield of molecular hydrogen would be to suppose that $k_{DD}/k_{HH} < 1/\sqrt{2}$. The effect of variation of k_{11} is shown in Fig. 5 and it is noted that a change in k_{11} required to reduce $[H_2]$ by $\frac{1}{4}$ leaves $[H_2O_2]$ virtually unchanged and decreases $[-H_2O]$ only slightly.

A decrease in $[-H_2O]$ could be explained by invoking the hot atom effect. As the displacement of the D atom on the dissociation of the excited D_2O molecule will be smaller than the corresponding displacement of an H atom it follows that the characteristic radii for these atoms will be different, i.e. $R_1(H) > R_1(D)$. An inspection of Fig. 8 shows that a relatively large change in R_1, of the order of 80%, is required to make the required decrease in $[H_2O_2]$ and $[-H_2O]$. This does not seem likely. It would also be necessary to postulate a further change in k_{11} large enough to affect the increase in the D_2 yield owing to the smaller characteristic radius for the deuterium atoms. A special variation in k_{11} does not therefore explain the results obtained in acidic heavy water solution and is not a very convincing explanation of the results obtained with benzene scavengers.

A choice of constants which would give a simultaneous decrease in all the molecular yields and radical yields is shown in (N). In this case both k_{11} and D_1 are smaller by a factor of two than they are in (A). k_{12} and all the other parameters are unaltered. The calculation shows that all the yields except $[H_2O^*]$ are smaller than they are in (A). When D_1 is reduced the H atoms are confined for a longer time to the region where the concentration of OH is high. $[H_2O^*]$ is therefore increased and $[-H_2O]$ is decreased. This removal of H atom and OH radicals from the central region in turn reduces $[H_2]$ and $[H_2O_2]$.

Now according to the Smoluchowski equation (Eq. [3]) k_{12} should be smaller if D_1 is smaller. By giving k_{12} the same value as in (A) we are in effect making it larger than it would be with a "simple" choice of constants. In other words a change in yields parallel to that found by Burton and Phung is obtained by increasing k_{12}. The variation of yields with k_{12} is shown in Fig. 6 and demonstrates graphically the reduction in $[H_2]$, $[H_2O_2]$, and $[-H_2O]$.

This explanation of the isotope effect in neutral solution is of interest because the arguments of Section 12 suggest that k_{12} is relatively greater in D_2O than in H_2O owing to differences in the initial spatial configuration of the radicals.

No simple variation in constants is apparent which will explain a decrease in $[H_2]$ coupled with an increase in $[-H_2O]$, as found in acid solutions. Speculations on this topic must be deferred until more detailed information on the yields in acid solutions is available. In any case the simple diffusion theory which neglects any effect of hydrogen ions and the intervention of such species as H_2^+ is not applicable to a discussion of acidic solutions.†

A second type of isotope effect is observed in the isotopic composition of molecular hydrogen evolved from dilute solution of heavy water. This has been studied by Kelly, Rigg, and Weiss (15), who measured the separation factor.

$$S = [H_2/HD]_{gas}/[H_2O/HDO]_{water} \simeq [HDO]\,[H_2]/[H_2O]\,[HD] \qquad [6]$$

for solution containing about 1 mole % deuterium and various scavengers. Deaerated ferrous sulphate solution gave $S \simeq 3.5$, close to the value of 3.8 for thermal equilibrium at room temperature. Solutions which contained efficient scavengers for hydrogen atoms, e.g. oxygen saturated ferrous sulphate and deaerated ceric sulphate, gave $S \simeq 2$. It was suggested that the hydrogen evolved from deaerated ferrous sulphate was thermally equilibrated but with solutions giving lower separation factors, exchange and equilibration were not taking place. Kelly, Rigg, and Weiss suggested that the hydrogen was produced by reactions involving excited molecules.

$$H_2O^* + H_2O^* \rightarrow H_2 + H_2O_2\ (k_1) \qquad [7]$$

$$H_2O^* + HDO^* \rightarrow HD + H_2O_2\ (k_2). \qquad [8]$$

The separation factor will be given by the ratio k_1/k_2. In their second publication (15*b*) Kelly, Rigg, and Weiss suggest that $k_1/k_2 \simeq 2$ owing to the difference in activation energy of the two reactions. A difference of 0.4 kcal, attributed to the different zero-point energies of H_2O, HDO, is postulated.

We have calculated the extent of recombination of H and D atoms in a spur to give H_2, HD, and D_2 and hence determined the separation factors predicted by the model. On "simple" assumptions the model gives $S = 1$, i.e. no separation.

Consider the statistics of the formation of HD from a spur containing $(n-1)$ H atoms and one D atom. Neglecting isotope effects in the rate constants the probability of forming an HD molecule is proportional to $(n-1)$, and the probability of forming an H_2 molecule is $(\frac{1}{2})(n-1)(n-2)$. The fraction of HD is $[HD]/([H_2] + [HD]) = 2/n$ of the total "hydrogen" produced in the spur. If the aqueous phase contains p% HDO (p is $\simeq 1$) then the percentage of spurs containing one HDO molecule is np. If the HDO dissociates statistically (this is discussed later) the percentage of spurs containing one D atom is $np/2$. The composition of all the evolved hydrogen is therefore $2/n \times np/2 = p$% HD and the separation factor is unity.

Isotope effects in the recombination and diffusion processes can be neglected because in the Samuel–Magee model, changes in rate constants and diffusion constants work in opposition to one another. We have used the "two radical" calculation to estimate the relative probabilities of recombination of H and D atoms in spurs containing six atoms in all. Putting $D_1 = 8\times10^{-5}$, $D_2 = 5.656\times10^{-5}$, $k_{11} = 1.2\times10^{-11}$, $k_{12} = 2.040\times10^{-11}$, and $k_{22} = 8.484\times10^{-12}$ and with spurs with $N_1 = 5$, $N_2 = 1$ and $N_1 = 1$, $N_2 = 5$ we find yields of $[H_2] = 0.68$ and $[HD] = 0.32$ and $[D_2] = 0.68$ and $[HD] = 0.32$, respectively. The numerical identity justifies the neglect of isotope effects and is in agree-

†*Note added in proof: A discussion of molecular and radical yields in* D_2O *which complements the present discussion has been given by Armstrong, Collinson, and Dainton, Proceedings of Second Conference on Peaceful Uses of Atomic Energy. P/1517.*

For personal use only.

ment with the statistical ratio of $2/n = \frac{1}{3}$ for the fraction of HD in a six-radical spur.

Two tacit assumptions have been made in this discussion, firstly that hydrogen and deuterium atoms are produced, "statistically", with equal probability from an HDO molecule and secondly that no exchange reactions of the type $H + HD \rightarrow H_2 + D$ occur in the track when scavengers are present. Calculation of these 'secondary' exchange reactions would require a more elaborate computation procedure. We note that rate constants for these exchange reactions are two to three orders of magnitude smaller than the rate constants for recombination and on this basis the amount exchange which would occur in the lifetime of the spur (10^{-8} seconds) would be small.

Mass spectral data on isotopically substituted molecules such as CH_3D show that the deuterium atom is 'more firmly' held than any one hydrogen atom by a factor of two or more (16). The theoretical interpretation of these results is general and predicts in principle the same effect for HDO, i.e. the dissociation.

$$HDO^* \rightarrow H + OD \qquad [9]$$

might be about twice as probable as

$$HDO^* \rightarrow D + OH. \qquad [10]$$

Such a difference would, in the present case, reduce the number of spurs containing a D atom below the value predicted statistically and would give a separation factor greater than unity as was found experimentally by Kelly, Rigg, and Weiss.

This difference would lead to a value of less than unity for the separation factor.

$$S' = [D_2/HD]_{gas}/[D_2O/HDO]_{liq} = [HDO]\,[D_2]/[D_2O]\,[HD]$$

describing the isotopic separation of gas evolved from dilute solution of HDO in D_2O containing scavengers. A value of 0.54 has been found experimentally in this laboratory for this system with the scavengers used by Kelly, Rigg, and Weiss.

The preferential dissociation of HDO to H + OD also explains the G-values found by Bardwell and Dyne (17) for the radiation-induced exchange of hydrogen atoms between liquid water and dissolved hydrogen. The exchange was followed by a tracer technique using H_2O containing about 1% HDO. The total amount of the exchange was calculated assuming that HDO dissociated statistically. This was between $\frac{1}{2}$ and $\frac{1}{3}$ of that found by Gordon and Hart (18), who studied the system D_2, H_2O and who were consequently able to detect directly every exchange.

11. THE EFFECT OF SCAVENGER CONCENTRATION

If the concentration of scavenger is increased the yields of molecular products decrease slowly. This effect (19, 20, 21), which has been extensively studied experimentally and theoretically, is due to competition between the scavenging process and the recombination process during the time in which the latter is proceeding at a significant rate.

The scavenger effect is calculated by varying the terms $k_{1S}C_S$ and $k_{2S}C_S$. A plot of the relative yields against C_S refers only to the particular choices of k_{1S}; if k_{1S} were larger than that chosen then the same decrease in yield would be observed at a correspondingly smaller value of C_S. The relative yields plotted in Fig. 12 were obtained with $k_{1S} = k_{2S} = 1\times10^{-11}$. It is found that the $[H_2]$ yield is less sensitive to scavenger than the $[H_2O_2]$ yield.

This arises because we have put $k_{1S} = k_{2S}$. Because of the greater diffusion constant of the H atom k_{1S} will be larger than k_{2S} with the practical result that the effects of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

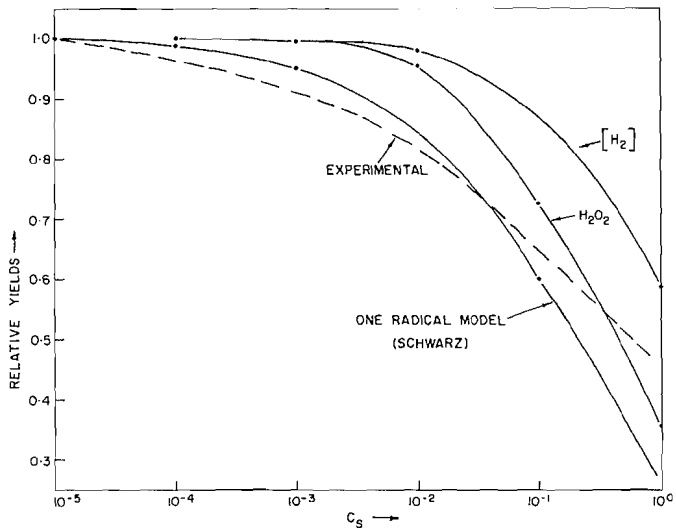

FIG. 12. Variation in relative yields with the scavenger concentration. The curves labelled H_2, H_2O_2 are from the present calculation. The calculated one radical model curve and the experimental curve are taken from Schwarz (19). Cases (A), (O), (P), (Q), and (R).

scavenger on $[H_2]$ and $[H_2O_2]$ will be more nearly equal.* Using the Smoluchowski equation to estimate the relative values of k_{1S} and k_{2S} we conclude that k_{1S} would be two or three times greater than k_{2S}. A calculation has shown that, at a concentration of 10^{-1} M with $k_{1S} = 3.0\times10^{-11}$ and $k_{2S} = 1.0\times10^{-11}$ the change in relative yields for $[H_2]$ and $[H_2O_2]$ are identical and fall on the curve for $[H_2O_2]$.

A theoretical curve calculated by Schwarz (19) is also shown in Fig. 12 together with an experimental curve. The theoretical curve was calculated analytically using a simplified one-radical model. The curve was adjusted by altering the scale on the concentration axis so that it coincided with the experimentally determined curve for the variation of $[H_2]$ with nitrite as scavenger. Schwarz showed that the data for both hydrogen and hydrogen peroxide yields for a variety of scavengers lay on similar curves. These curves could be brought into coincidence by multiplying the concentration by an empirical normalizing constant, which gives, in effect, the value of k_S relative to that for nitrite. These relative values were shown to be in agreement with experiment. The experimental curve in Fig. 12 is a curve which we have drawn from points plotted by Schwarz.

At large scavenger concentrations the experimental decrease in yield is less than that predicted. This is due to the assumption that C_S is a constant both in time and space. For $C_S = 1$ molar our numerical calculations show that three out of six radicals have reacted with scavenger in about 10^{-11} seconds. In this short time the spur has not expanded appreciably by diffusion and its effective volume is still $(10^{-7}\text{ cm})^3 = 10^{-21}\text{ cm}^3$. This volume contains less than one scavenger atom at a concentration of 1 M. It follows that there is a depletion of scavenger at high scavenger concentration inside the volume of the spur and the decrease in yield will be less than that predicted on the assumption that C_S is a constant.

At low scavenger concentrations the new theoretical curves and that given by Schwarz show a smaller decrease in yield than is observed experimentally. As this amounts to only 10%, this discrepancy may fairly be attributed to some of the simplifications

We are indebted to Dr. H. Schwarz for clarification on this point.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

inherent in our treatment of the model. The nature of one of these simplifications can be seen in calculations on the same effect by Ganguly and Magee (21). They used a one-radical model but took into account the effects of overlap of spurs. This becomes more significant as the energy of the primary β-particle is decreased; for β-particles of 0.01 Mev energy a curve is obtained which falls steadily as the concentration of scavenger is increased instead of having an initial flat portion for concentrations up to 10^{-3} M. The curves calculated by Ganguly and Magee are not, unfortunately, reproduced in sufficient detail to permit a detailed comparison. The present calculations and those of Schwarz apply to spurs generated by high energy β-particles; which are so far apart that they never overlap significantly.

The curve calculated by Schwarz was adjusted to give agreement with experiment; no a priori assumptions being made as to the value of k_S. From the figure it can be seen that k_S must be $\sim 10^{-10}$ rather than $\sim 10^{-11}$ for there to be agreement between theory and experiment. Rate constants of $\sim 10^{-10}$ are approaching the values given by the kinetic theory for gas-phase reactions. Most of the normalization constants given by Schwarz are of the order of unity or somewhat larger and values of k_S are correspondingly smaller, i.e. $3\text{–}5 \times 10^{-11}$.

The fact that the experimental yields for hydrogen and hydrogen peroxide lie on one curve (Fig. 12) is good evidence that they are formed by a similar process. The agreement between the experimental and theoretical curves is again evidence that this process is a bimolecular one, occurring in a diffusion-controlled scheme of the type proposed by Samuel and Magee and which is in competition with a scavenging reaction. This evidence does not however prove that the bimolecular processes are recombinations of hydrogen atoms and hydroxyl radicals; similar experimental curves would be obtained if, for instance, the products were formed by $2H_2O^* \rightarrow H_2 + H_2O_2$ and if the excited water molecule H_2O^* reacted with the scavenger to give other products.

12. A CRITICISM OF THE MATHEMATICAL CONSTRUCTION OF THE MODEL

The equations [1] and [2] used in these calculations apply the concepts of classical chemical kinetics to reactions occurring in small volumes containing only a few molecules and occurring in very short times which are of the order of magnitude of the time between molecular jumps in a liquid. The equations deal with spatial distributions of concentration which are expressed as a continuous analytic function of the co-ordinates—no account being taken of the movements of individual radicals. A treatment of the process as a form of "random walk" is clearly more appropriate and this could conceivably be handled with a large enough computer. Leaving aside the last practical difficulty, it is difficult to devise a molecular model for the diffusion and reaction of molecules in liquid water which is not open to objections as serious as those placed against the analytical treatment. In particular the results of a random walk treatment depend on the way in which, say, the spatial movements are defined; whether the directions are random or whether some directions are preferred, whether the distances in one jump are constant or variable, etc. It is as difficult to estimate the errors involved in making assumptions of this type as it is to estimate the errors in the use of the diffusion approximation.

The model, as used in this paper, does not take into account the possible correlations in the spatial distributions of the particles. As the excited water molecules, the parents of the reactive radicals are generated along the random path of a slow electron it is proper to describe the spatial distribution of these water molecules by a distribution function which is equivalent to a concentration. The spatial distribution of the H and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

OH radicals which originate from these excited water molecules will also be described by this or some similar concentration function and these functions are appropriate for calculating the probabilities of recombination $k_{11}C_1^2$, $k_{22}C_2^2$. They are not, however, necessarily applicable to the evaluation of the term $k_{12}C_1C_2$ because each hydrogen may be, on the average, much closer to the OH radical which was its original partner than it is to the nearest other hydrogen atom. In other words there is a correlation between the concentrations C_1 and C_2. In terms of the mathematical techniques used here this means that k_{12} is not a true rate constant as it will vary with time. In the case of extreme correlations between like particles k_{12} in equation [1] and [2] is initially much greater than the kinetic theory rate constant for the reaction $H + OH \rightarrow H_2O$. This is of interest in connection with the isotope effect where in section 10 we suggested that k_{12} was larger for the reaction $D + OD \rightarrow D_2O$ than it was for $H + OH \rightarrow H_2O$. The "constant" k_{12} depends initially on the separation between two radicals H, OH and D, OD. Because of the large relative difference in the masses of H and D atoms this may be significantly different. The isotope effect may be attributed to differences in the correlation functions, which are expressed in the term k_{12}.

If there is a very large correlation between H and OH, i.e. the initial separation between the dissociated atoms is small, then it follows that there is a high probability of these radicals recombining and they never really contribute to the initial number of radicals in the spur. For this reason the value of $G(-H_2O)$ given by Firestone for water vapor represents an upper limit for the initial amount of decomposition in the liquid water.

Monchick, Samuel, and Magee (8) have published a brief set of calculations on a two-radical model which includes a treatment of the correlation term. Their treatment is approximate and no significant differences are noticeable between their yield values and those obtained in these calculations which are approximate in the sense that k_{12} is taken as a constant.

In this paper we have examined the Samuel–Magee model pragmatically and have accepted its premises about primary processes in the spur without question. The model leads to reasonable interpretations of the experimental data but, with the exception of experiments on the isotope effects, it is not sufficiently well defined to allow any very critical tests. In the relatively restricted field of study we have not found any experimental data which the model cannot explain nor have we found any evidence for any "new" primary processes. Our numerical data have been presented so that they may suggest more decisive experiments and so that, when new data are available, the qualitative effect on the model can be readily estimated.

ACKNOWLEDGMENTS

We take pleasure in acknowledging the assistance of Mrs. Arden Okazaki in the writing of the detailed computer program and the benefit of many stimulating discussions with Dr. R. W. Attree, Dr. R. H. Betts, and Dr. Boris Davison.

APPENDIX

The Numerical Method

1. Analytical Transformations

The original equations for the concentrations C_1 and C_2 are

$$\partial C_i/\partial t = D_i\nabla^2 C_i - k_{ii}[(N_i-1)/N_i]C_i^2 - k_{12}C_1C_2 - k_{1S}C_iC_S \qquad [1]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

for $i = 1, 2$. The k_{ij} are rate constants, and N_i the total number of particles in the system

$$N_i(t) = \int C_i(r,t)\, dV. \qquad [2]$$

By convention, the particles are labelled so that D_1 is the larger of the two diffusion constants.

Three transformations are applied to the variables:

(*a*) A dimensionless space variable $\rho = r/\sqrt{(D_1 t)}$ is defined in order that a fixed range in ρ corresponds to an expanding range in r as time proceeds. This is to keep pace with the outward diffusion of the particles.

(*b*) A dimensionless time variable $x = \log(t/t_0)$ is used to take account of the fact that the phenomenon can be examined on an expanded time scale as time proceeds. The choice of the initial time t_0 is discussed below.

(*c*) New dependent variables are defined by

$$Y = \rho C_1; \qquad Z = \rho C_2. \qquad [3]$$

These effectively transform the spherical geometry to plane geometry and simplify the equations.

The final form becomes

$$\frac{\partial Y}{\partial x} = \left[\frac{\partial^2 Y}{\partial \rho^2} + \frac{\rho}{2}\frac{\partial Y}{\partial \rho} + \frac{Y}{2}\right] - \frac{k_{11}t_0 e^{-x/2}Y^2}{\rho} - \frac{k_{12}t_0 e^{-x/2}YZ}{\rho} - k_{1S}t_0 e^{x} C_S Y,$$

$$\frac{\partial Z}{\partial x} = \left[\Delta\frac{\partial^2 Z}{\partial \rho^2} + \frac{\rho}{2}\frac{\partial Z}{\partial \rho} + \frac{Z}{2}\right] - \frac{k_{22}t_0 e^{-x/2}Y^2}{\rho} - \frac{k_{12}t_0 e^{-x/2}YZ}{\rho} - k_{2S}t_0 e^{x} C_S Z, \qquad [4]$$

where $\Delta = D_2/D_1$.

2. Numerical Method

The problem is the integration of the pair of equations [3] from $x = 0$, given the initial spatial distributions

$$C_i(r,0) = [N_i(0)\beta^3/\pi^{3/2}]e^{-\beta^2 r^2}. \qquad [5]$$

The space dependence is handled by replacing the functions $Y(\rho)$ and $Z(\rho)$ at any time by 40-place tables Y_n, Z_n for $\rho = nh$ ($n = 0, 1, \ldots\ldots, 39$). The derivatives are then replaced by

$$\partial^2 Y_n/\partial\rho^2 = (Y_{n+1} - 2Y_n + Y_{n-1})/h^2,$$

$$\partial Y_n/\partial\rho = (Y_{n+1} - Y_{n-1})/2h, \qquad [6]$$

and the corresponding results for Z. Thus the system reduces to 80 simultaneous first-order ordinary differential equations for the Y_n and Z_n.

Because of the definitions [3], the conditions $Y_0 = Z_0 \equiv 0$ are imposed. At the outer boundary, we set $Y_{39} = Z_{39} \equiv 0$; this implies that h is sufficiently large that no appreciable error arises from confining the phenomenon to a finite volume.

The integration in time proceeds by a step-by-step process, correct to second order in Δx. A "mid-point" procedure is used to make the evaluation of the right-hand sides necessary only once per interval.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

3. The Input Data

The problem is defined by a choice of k_{11}, k_{22}, k_{12}, $k_{1S}C_S$, $k_{2S}C_S$, $N_1(0)$, $N_2(0)$, β_1, β_2, D_1, and Δ. In addition, t_0, h, and Δx must be chosen according to criteria imposed by the physics of the problem.

t_0 must be the time appropriate to the expansion of a δ-function distribution to the distribution given by $C_1(r, 0)$ when the diffusion constant is D_1; otherwise the expansion of the spatial co-ordinate will fail to keep pace with the phenomenon at subsequent times. In practice, $t_0 = \frac{1}{6}\beta_1^2 D_1$ has been used. The theoretical value, $t_0 = \frac{1}{4}\beta_1^2 D_1$ leads to an incipient instability in the mathematical treatment.

Once t_0 is chosen, the space interval h must be chosen to make the initial range of r contain all significant parts of the initial Gaussian distributions. If h is too small, the imposition of the outer boundary condition introduces errors that become magnified as time progresses; if it is too large, accuracy is lost through failure to make good use of the full 40-entry tables. With the given choice of t_0, a satisfactory value of h is 0.3.

Finally, Δx must be small enough to give reasonable accuracy in the time integrations. Experience has shown that $\Delta x = 0.22$ is reasonable for the cases run so far. An instability in the solution appears rather suddenly above $\Delta x = 0.25$.

4. Output

At the end of every step, the computer accumulates the losses of particles L_{ij} owing to each of the five recombination terms and recalculates N_1 and N_2. After every fifth or tenth step, the following information is printed:

Elapsed time:

L_{11}	L_{12}	L_{1S}	N_1	$(\text{sum})_1$
L_{22}	L_{12}	L_{2S}	N_2	$(\text{sum})_2$.

The elapsed time is $T = t_0(e^x - 1)$. The sums should remain equal to $N_1(0)$ and $N_2(0)$, within the accuracy of the calculation.

FATTY ACIDS OF THE SEED OIL OF CARDIOSPERMUM HALICACABUM[1]

MARY J. CHISHOLM AND C. Y. HOPKINS

ABSTRACT

The seed oil of *Cardiospermum halicacabum* L., family Sapindaceae, was found to have 11-eicosenoic acid as the major fatty acid in its glycerides. In this respect it is unique among the true natural fats. The amount of eicosenoic acid in the sample examined was 42% of the total long-chain fatty acids. The identity and amounts of the principal fatty acids of the oil were determined by gas chromatography and by distillation of the methyl esters. The estimated percentages were: palmitic 3, linolenic 8, linoleic 8, oleic 22, stearic 2, eicosenoic 42, arachidic 10. In addition, there was evidence of small proportions (1–2%) of a low-molecular-weight acid and of C_{22} acids.

In studying the occurrence of eicosenoic acid in seed oils, attention was directed to the family Sapindaceae. An unsaturated C_{20} acid has been reported as a minor component in the seed oil of three species of this family, although the acid was not completely identified in these instances (5, 6, 7).

Most of the Sapindaceae are found in tropical and subtropical regions but one genus, *Cardiospermum*, grows also in temperate climates. *Cardiospermum halicacabum* (balloon vine) was chosen for study. A previous analysis of its seed oil showed the presence of arachidic acid but not of unsaturated C_{20} acid (3). It was surprising, therefore, to find in the present work that the sample gave an oil in which 11-eicosenoic acid constituted 42% of the total fatty acids.

The other acids of the oil also differed in some respects from those of the more common seed oils.

EXPERIMENTAL

Properties of the Oil

Seed of *Cardiospermum halicacabum* L., originating in Holland, was obtained from a commercial seed house. The spherical seeds had an average weight of 0.074 g and were easily ground. The yield of oil, by extraction with petroleum ether, was 28.0% on a 10% moisture basis. Constants of the oil are shown in Table I.

TABLE I

PROPERTIES OF THE OIL

Iodine value	86.8	Acetyl value	0.9
Saponification value	206	Refractive index, 25°	1.4709
Unsaponifiable matter, %	0.4	Halphen test	Negative
Acid value	11.7		

Composition of the Fatty Acids

A sample of the oil was saponified, freed from unsaponifiable matter, and converted to methyl esters. During the removal of the solvent, after esterification, esters of any short-chain acids are volatilized. The analysis is therefore restricted to the longer-chain acids.

[1]*Manuscript received July 29, 1958.*
Contribution from the Division of Pure Chemistry, National Research Council, Ottawa, Canada.
Issued as N.R.C. No. 4767.

The esters were examined by gas chromatography, using a Perkin–Elmer fractometer, model 154-B. The detector was a thermistor type thermal conductivity cell. The column was 1 meter in length and was packed with Apiezon M stopcock grease on Celite. It was operated at 225° with a helium flow rate of 95 ml/minute at an inlet pressure of 15 p.s.i.

The proportions of the chief components were estimated from the chromatogram (Fig. 1) by chain length as follows: C_{16} 3, C_{18} 41, C_{20} 52. In addition there were minor peaks (not shown) indicating about 2% of a low-molecular weight acid and about 2% of C_{22} acid(s).

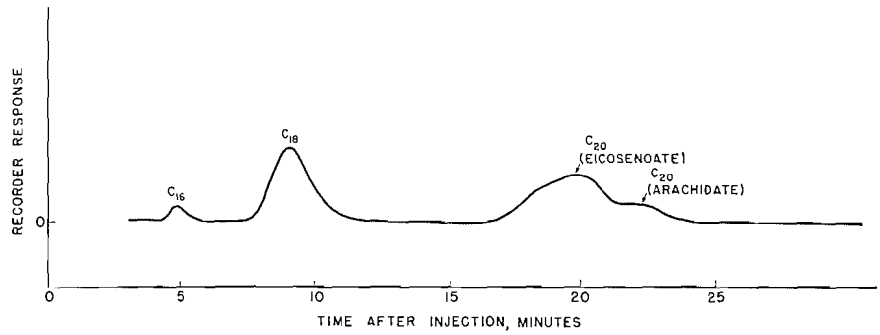

FIG. 1. Main portion of the gas chromatogram of the methyl esters. The peaks represent esters of C_{16}, C_{18}, and C_{20} acids.

A sample of the mixed esters was isomerized by alkali (45 minutes at 180° in glycerol) and examined by ultraviolet absorption. The results showed a content of 8.0% of dienoic acid and 7.6% of trienoic acid, calculated as octadecoic acids. A sample of the mixed fatty acids of the oil was brominated in ether. The insoluble bromo acid was recrystallized and identified as hexabromostearic acid (Table III).

The main portion of the oil was converted to methyl esters by methanolysis and the mixed esters (50 g) were distilled through a spinning band column at 0.5 mm pressure (Table II).

TABLE II

DISTILLATION OF METHYL ESTERS

Fraction	Temp., °C (0.5 mm)	Weight, g	Chain length	Iodine value	Refractive index, 25°
1	58–63	0.48		2.9	1.4260
2	63–114	1.16		8.0	1.4405
3	114–126	1.81		75.8	1.4490
4	126–136	1.57		119.1	1.4543
5	136–140	13.18	C_{18}	126.9	1.4558
6	140–147	2.04		95.2	1.4529
7	147–152	1.31		80.9	1.4529
8	152–156	1.36		79.2	1.4529
9	156	8.45	C_{20}	73.5	1.4524
10	156–159	13.08	C_{20}	57.1	Solid
R	Residue	4.50			

Fraction 2 was mainly palmitic ester. Fraction 5 was crystallized from acetone at −25°, giving a little methyl stearate, m.p. 38–38.5°. Oleic and linoleic acids were identified as components of the filtrate by hydroxylation with alkaline permanganate (Table III). Fraction 9 was almost pure methyl eicosenoate but yielded a little methyl arachidate, m.p. 45–45.5°. Fraction 10 gave arachidic acid in quantity. The identity of these acids was confirmed by mixed melting point in each case.

TABLE III

IDENTIFICATION OF ACIDS

Fraction	Acid	Identified as:	Melting point, °C
2	Palmitic	Palmitic acid	62–62.5
—	Linolenic	Hexabromostearic acid	180–181
5	Linoleic	*erythro,erythro*-9,10,12,13-Tetrahydroxystearic acid	171–172
5	Oleic	*erythro*-9,10–Dihydroxystearic acid	129–130
5	Stearic	Methyl stearate	38–38.5
9	11-Eicosenoic	*erythro*-11,12-Dihydroxyeicosanoic acid	129–130
		11-Eicosenoic N-hydroxyamide	69–70
10	Arachidic	Arachidic acid	74.5–75

Examination of the residue gave evidence of saturated and monounsaturated acids of chain length C_{22} (equivalent weights 343 and 342). Several of the intermediate fractions were examined further by gas chromatography.

Estimation of the fatty acid composition from all of the data gives the percentages shown in Table IV. The undetermined portion includes a low-molecular-weight acid and C_{22} acids.

TABLE IV

ESTIMATED FATTY ACID COMPOSITION (% OF TOTAL FATTY ACIDS)

Acid	%	Acid	%
Palmitic	3	Stearic	2
Linolenic	8	11-Eicosenoic	42
Linoleic	8	Arachidic	10
Oleic	22	Undetermined	5

DISCUSSION

The oil is unique in having eicosenoic acid as the chief component acid in its glycerides. The amount, 42% of the total fatty acids, is double that of the oils previously known to have a high eicosenoic acid content (18–20%) (1, 2).

As a source of this acid, the seed would compare favorably with jojoba seed (*Simmondsia californica* Nuttall), which contains a liquid wax having eicosenoic as its major fatty acid. The content of total fatty acids in jojoba wax is 50% (4) as compared to about 90% in *Cardiospermum* oil. The eicosenoic acid from all of the seed oils and jojoba wax has been identified as the Δ^{11}-isomer.

Isolation of 11-eicosenoic acid from *Cardiospermum* oil tends to confirm previous indications of a C_{20} unsaturated acid in the Sapindaceae family, viz., in species of *Nephelium* (5), *Dodonea* (6), and *Schleichera* (7). The amounts reported were 4.2, 3.1, and 8.9% of the fatty acids respectively, but the acid was not identified further in these instances. The present work shows that the family includes at least one species in which 11-eicosenoic acid is a major component of the seed oil.

The fatty acids of *C. halicacabum* include also arachidic, linolenic, and a low-molecular-weight acid, as found by Covello (3) and confirmed here.* Arachidic acid is in rather large amount (10%), and the quantity of palmitic acid is correspondingly small. This is

**Covello made a careful identification of linolenic acid by converting it to hexabromo- and hexahydroxystearic acids. However, he did not report identification of linoleic acid. His later mention of linoleic acid (ref. 3, p. 783) is manifestly a typographical error and should read "linolenic acid".*

characteristic of Sapindaceae oils. There is an appreciable content of linolenic acid. Its presence and amount, about 8%, are unusual for an oil of iodine value below 100.

GUANIDINE COMPOUNDS

II. PREPARATION OF MONO- AND N,N-DI-ALKYLGUANIDINES[1, 2]

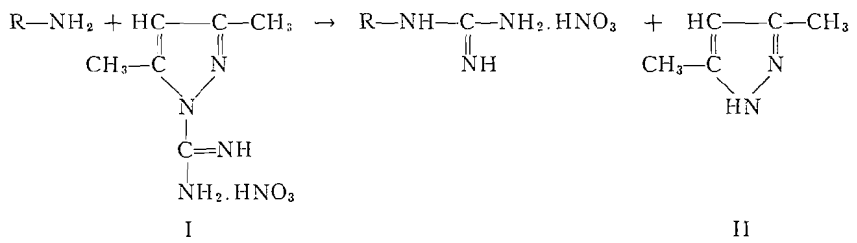
R. A. B. Bannard, A. A. Casselman, W. F. Cockburn, and G. M. Brown

ABSTRACT

1-Guanyl-3,5-dimethylpyrazole nitrate is superior to S-methylisothiouronium sulphate as a reagent for preparation of simple salts of mono- and N,N-di-alkylguanidines from cyclohexylamine, *trans*-2-aminocyclohexanol, pyrrolidine, and piperidine. S-Methylisothiouronium sulphate, however, gave a higher conversion in the case of dimethylamine. Cyanamide is not as useful a guanylating agent as those mentioned above. The paper chromatography of the mono- and N,N-di-alkylguanidines and the parent amines was studied using four solvent systems.

INTRODUCTION

Of the numerous methods reported in the literature for preparation of mono- and N,N-di-alkylguanidines, those which have been used most frequently are the Erlenmeyer synthesis (1), from amine salts and cyanamide (2, 3, 4, 5, 6), and the Rathke synthesis (7), from amines and an alkylisothiouronium or alkylisouronium salt (8, 9, 10, 11, 12). Both methods, however, frequently lead to poor yields of alkylguanidines, due principally to the formation of dicyandiamide by dimerization of cyanamide on the one hand (13) or hydrolysis of the alkylisouronium salt on the other (8, 14). In 1953, Scott, O'Donovan, and Reilly (15) described the preparation of a number of guanidine picrates in high yield by reaction of amines with 1-guanyl-3,5-dimethylpyrazole nitrate (I) as shown below.



I II

The sole by-product was 3,5-dimethylpyrazole (II) and the method thus seemed a suitable candidate to replace the older methods of synthesis, provided that salts other than the picrates used (15) to simplify recovery of the alkylguanidines proved isolable in high yields. Since we required a number of alkylguanidines in connection with other studies, it seemed of interest to evaluate the usefulness of the three methods of synthesis.

RESULTS AND DISCUSSION

Several procedures for guanylation of amine salts with cyanamide in aqueous or alcoholic solution (2, 4, 5, 6) were examined but all of these in our hands gave yields of alkylguanidines in the range 0–20%. The only method found to be effective was a fusion technique due to Sugino *et al.* (16, 17), by which procedure cyclohexylguanidine hydrochloride was obtained in 48% yield. Guanylation of *trans*-2-aminocyclohexanol

[1]*Manuscript received July 23, 1958.*
Contribution from Defence Research Chemical Laboratories, Ottawa, Canada.
Issued as D.R.C.L. Report No. 284.
[2]*For Part I see ref. 27.*

hydrochloride in the same manner, however, gave an intractable mixture and the method was not studied further when it became evident that the other two processes under examination are more reliable.

For guanylation of amines with S-methylisothiouronium sulphate, Phillips and Clarke's procedure (8) was modified by using 1.5 equivalents of amine per equivalent of guanylating agent, this being the ratio of reactants best suited to facile recovery of the alkylguanidine salt in a high state of purity. Results obtained using several primary and secondary aliphatic or heterocyclic amines are given in Table I.

TABLE I

GUANYLATION OF AMINES

Amine	Product isolated	% Yield	
		Isothiouronium method[a]	Guanylpyrazole method[b]
Dimethylamine	N,N-Dimethylguanidine	89.0[c]	66.8[c, e]
Piperidine	1-Guanylpiperidine	65.4[c]	80.5[c, f]
Pyrrolidine	1-Guanylpyrrolidine	59.0[g]	80.0[c, g]
Cyclohexylamine	Cyclohexylguanidine	54.5[b]	84.8[c, f]
trans-2-Aminocyclohexanol	*trans*-2-Guanidocyclohexanol	47.6[c]	75.8[d, g]

[a]Solvent—aqueous amine, 1.5 equivalents of amine per equivalent of isothiouronium salt.
[b]10 mole amine per mole guanylpyrazole salt.
[c]Solvent—amine.
[d]Solvent—ethanol.
[e]Isolated as sulphate.
[f]Isolated as hydrochloride.
[g]Isolated as nitrate.

In the case of pyrrolidine, cyclohexylamine and *trans*-2-aminocyclohexanol separation of the guanidine sulphates from the amine sulphates formed as by-products proved troublesome. However, 1-guanylpyrrolidine and cyclohexylguanidine were readily isolated as the nitrate and hydrochloride respectively after treatment of the crude product with a strong anion exchange resin. This simple expedient did not succeed for purification of *trans*-2-guanidocyclohexanol sulphate, but for this purpose three methods proved satisfactory. A three-column ion exchange process gave a 70% recovery of *trans*-2-guanidocyclohexanol sulphate. Paper chromatography on seed-test paper (18) gave a 78% recovery but was not suitable on a preparative scale. In the most satisfactory method, the large difference in water solubility of the picrates was utilized, and after purification, *trans*-2-guanidocyclohexanol picrate was converted to the sulphate by ion exchange with an over-all recovery of 66%. It is of interest to note in this connection that Angyal and Warburton (19) were unable to convert picrates of alkylguanidines to simple salts. This observation explains our reluctance to estimate yields in guanylation reactions by conversion to the readily isoluble picrates as other workers have done (15) because we wished to obtain simple salts. The use of a strong anion exchange resin, however, now apparently assures reconversion of alkylguanidine picrates to simple salts in high yields.

For guanylation with 1-guanyl-3,5-dimethylpyrazole nitrate, procedures used by Scott, O'Donovan, and Reilly (15) were followed, but in all cases the alkylguanidines were isolated as simple salts rather than picrates. The results given in Table I make it evident that the guanylpyrazole method is clearly superior to the isothiouronium method except for preparation of N,N-dimethylguanidine sulphate. It seemed desirable to determine whether the large excess of amine employed by Scott *et al.* (15) could be

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

reduced to a more reasonable level without seriously impairing the yield of alkylguanidine. Accordingly, several modifications in procedure were used in guanylation of *trans*-2-aminocyclohexanol. Using ethanol as solvent, an intractable mixture resulted when equimolar quantities of reactants were used but a twofold excess of amine led to a 65% yield of *trans*-2-guanidocyclohexanol. The same substance was obtained in 56% yield when an intimate mixture of equimolar quantities of reactants was fused for 1 hour at 100°. The latter modification should prove of value for guanylation of difficultly accessible amines.

The possibility of using the Sakaguchi (20) alkaline hypochlorite – α-naphthol reaction or the Fearon (21) alkaline hypochlorite – thymol reaction to follow the appearance of guanido compounds in reaction mixtures has been examined. The Sakaguchi reaction, which is specific for monosubstituted guanidines (22), has been used for quantitative estimation of certain compounds and optimum conditions for these methods are quoted in the literature. However, these procedures are too time consuming and rapid qualitative methods for the Sakaguchi and Fearon tests are described in the experimental section. S-Methylisothiouronium sulphate, cyanamide, and dicyandiamide interfere with the color reactions and the tests are thus unsatisfactory for following the appearance of guanido compounds in reaction mixtures containing such contaminants. The Sakaguchi test is more satisfactory than the Fearon test, since the latter is both less sensitive and more subject to interference.

The paper chromatographic behavior of the mono- and N,N-di-alkylguanidines was studied in four solvent systems in relation to the behavior of the parent amines (or salts) and certain other substances containing a guanido group. The results summarized in Table II make it clear that for separation of alkylguanidines from the corresponding amines the two solvent systems containing *n*-butanol are superior but that for separation of the guanido acids the two systems containing *tert*-butanol are preferable.

TABLE II

R_F VALUES OF AMINES AND ALKYLGUANIDINES

Compound	R_F in solvent system*			
	1	2	3	4
N,N-Dimethylguanidine sulphate	0.22[a, b]	0.19	0.70	0.44
Dimethylamine hydrochloride	0.36	0.12	0.69	0.36
1-Guanylpyrrolidine nitrate	0.57	0.42	0.73	0.56
Pyrrolidine	0.51	0.21	0.74	0.48
1-Guanylpiperidine hydrochloride	0.65	0.44	0.76	0.70
Piperidine	0.59	0.27	0.77	0.55
trans-2-Guanidocyclohexanol nitrate	0.68[c]	0.47	0.78	0.72
trans-2-Aminocyclohexanol hydrochloride	0.55	0.35	0.73	0.60
Cyclohexylguanidine hydrochloride	0.80	0.60	0.83	0.84
Cyclohexylamine hydrochloride	0.73	0.50	0.81	0.82
L-Canavanine sulphate	0.05	0.02	0.09	0.16
L-Arginine	0.19	0.03	0.46	0.19
Guanidoacetic acid	0.25	0.13	0.50	0.42
α-Guanidopropionic acid	0.39	0.29	0.63	0.59
β-Guanidopropionic acid	0.41	0.21	0.66	0.52

*1. *n*-Butanol, acetic acid, water (25:6:25 v/v).
2. *n*-Butanol, 1% hydrochloric acid (5:6 v/v).
3. *tert*-Butanol, acetic acid, water (2:1:1 v/v).
4. *tert*-Butanol, 1% hydrochloric acid (3:1 v/v).

[a]All substances except canavanine gave a blue spot with bromcresol green.

[b]Weber reagent gave pink or purple spots with the guanidine compounds and a white spot with amines.

[c]Sakaguchi reagent gave a red or pink spot with monoalkylguanidines and a greenish yellow spot with canavanine.

EXPERIMENTAL[1, 2]

1-Guanyl-3,5-dimethylpyrazole Nitrate

Aminoguanidine nitrate (68.0 g, 0.500 mole) was added portionwise over a period of $1\frac{3}{4}$ hours to a refluxing solution of 2,4-pentanedione (50.0 g, 0.500 mole) in 50% aqueous ethanol (140 ml) and the resultant solution heated under reflux for $2\frac{1}{4}$ hours. The crystals which separated when the solution was allowed to stand overnight were collected, washed with ether, and dried *in vacuo*. Further crops were obtained by dilution of the filtrate with ether. Recrystallization of the combined crude substances (78.3 g) from ethanol gave 64.6 g (64.6%) of 1-guanyl-3,5-dimethylpyrazole nitrate as colorless prisms, m.p. 166–168°. Thiele and Dralle (23) report m.p. 168°. A small sample was converted to the picrate, which had m.p. 206–208.5° after recrystallization from ethanol (cf. Scott and Reilly (24)).

Aminoguanidine Nitrate

Aminoguanidine bicarbonate was converted to the nitrate salt and the crude product recrystallized from ethanol–ether. Yield, 94% m.p. 142–144°. Theile (25) reports m.p. 144°.

Cyanamide

Cyanamide obtained from the Eastman Kodak Co. was treated with anhydrous ether. The insoluble dicyandiamide was removed by filtration, and the filtrate was evaporated to dryness *in vacuo*, yielding colorless hygroscopic cyanamide, m.p. 40–41° (26).

Cyclohexylguanidine Hydrochloride

(*a*) *Guanylpyrazole method.*—1-Guanyl-3,5-dimethylpyrazole nitrate (2.01 g, 0.01 mole) and cyclohexylamine (9.92 g, 0.100 mole) were heated under reflux with mechanical stirring for $2\frac{1}{2}$ hours in a carbon-dioxide-free apparatus. The resultant pale yellow solution was evaporated to dryness *in vacuo* and the oily residue triturated with anhydrous ether (8×15 ml) to remove by-product 3,5-dimethylpyrazole. Attempts to crystallize the crude cyclohexylguanidine nitrate proved fruitless and the oily material (2.16 g) was dissolved in water (50 ml) and passed through Amberlite IRA-400 (Cl^-) resin. The resin was washed with water until the effluent gave a negative Sakaguchi test. The combined effluents were evaporated to dryness *in vacuo* and the colorless crystalline residue was recrystallized from ethanol, yielding 1.51 g (84.8%) of cyclohexylguandine hydrochloride as stout colorless needles, m.p. 228–229°. Calc. for $C_7H_{16}N_3Cl$: C, 47.32; H, 9.08; N, 23.65; Cl, 19.96%. Found: C, 47.56; H, 8.85; N, 23.40; Cl, 19.80%.

(*b*) *Isothiouronium method.*—Cyclohexylamine (14.9 g, 0.150 mole), S-methylisothiouronium sulphate (13.9 g, 0.050 mole), and water (40 ml) were mixed at 25° in a carbon-dioxide-free apparatus. On warming the mixture to 40°, brisk evolution of methyl mercaptan began and continued while the temperature was raised to 95° over a period of 3 hours and the isothiouronium salt dissolved. The colorless solution was heated under reflux for $2\frac{1}{2}$ hours, then evaporated to dryness *in vacuo*, yielding 19.0 g of colorless crystalline material. Since earlier preparations had demonstrated the difficulty of separating the cyclohexylguanidine sulphate from by-product cyclohexylamine sulphate, the crude product was converted to the corresponding mixed hydrochlorides via Amberlite IRA-400 (Cl^-) resin. The eluate from the ion-exchange process was

[1] *All melting points are uncorrected.*
[2] *Microanalyses by Micro-Tech Laboratories, Skokie, Ill., and G. J. Helie of these Laboratories.*

evaporated to dryness *in vacuo* and the crystalline residue recrystallized from ethanol, yielding 9.70 g (54.5%) of cyclohexylguanidine hydrochloride, m.p. 228–229° alone, and in admixture with an authentic sample.

(*c*) *Cyanamide fusion method.*—Cyanamide (3.15 g, 0.075 mole) and cyclohexylamine hydrochloride (6.80 g, 0.050 mole) were intimately mixed, placed in a round-bottomed flask equipped with a reflux condenser and thermometer, and the reaction vessel immersed in a mechanically stirred oil bath at 100°. The temperature of the bath was raised slowly* to 140°, at which temperature fusion of the mixture occurred, accompanied by evolution of white fumes. The temperature of the bath was held at 140–150° for 1 hour, and on cooling, the product solidified, forming a pale yellow glass. The glass was dissolved in glacial acetic acid (150 ml) and the solution was diluted with acetone to precipitate the product as a colorless solid. The latter was collected and recrystallized from ethanol yielding 4.30 g (48.4%) of stout colorless needles, m.p. 228–229° alone, and in admixture with an authentic specimen.

Cyclohexylamine Sulphate

Cyclohexylamine sulphate was obtained as by-product during preparation of cyclohexylguanidine sulphate (27) by interaction of cyclohexylamine and S-methylisothiouronium sulphate. After recrystallization from 80% aqueous ethanol it was obtained as colorless platelets, m.p. 343–346° (decomp.). Calc. for $C_{12}H_{28}N_2SO_4$: C, 48.62; H, 9.52; N, 9.45%. Found: C, 48.73; H, 9.60; N, 9.26%.

dl-trans-2-Guanidocyclohexanol Nitrate

(*a*) *Fusion method.*—A mixture of 1-guanyl-3,5-dimethylpyrazole nitrate (2.01 g, 0.010 mole) and *dl-trans*-2-aminocyclohexanol (28) (11.5 g, 0.100 mole) was heated at 100° for 2 hours with frequent agitation and exclusion of carbon dioxide. After cooling, the melt was transferred to a Soxhlet extractor and extracted with anhydrous ether for removal of the by-product 3,5-dimethylpyrazole and unreacted amine. The residue was recrystallized from acetone (25 ml), yielding 1.54 g (70.0%) of *dl-trans*-2-guanidocyclohexanol nitrate as fine colorless platelets, m.p. 137–139°. Calc. for $C_7H_{16}N_4O_4$: C, 38.19; H, 7.32; N, 25.44%. Found: C, 38.11; H, 7.34; N, 25.68%. A 57.5% recovery of the unreacted amine was obtained via isolation of the hydrochloride (28). The experiment was repeated under conditions identical with those described above except that equimolar quantities of reactants were used. Yield, 1.23 g (55.8%).

(*b*) *In ethanol.*—1-Guanyl-3,5-dimethylpyrazole nitrate (2.01 g, 0.010 mole) and *dl-trans*-2-aminocyclohexanol (11.5 g, 0.100 mole) were dissolved in ethanol (50 ml) and the solution was heated under reflux for 2 hours in a carbon-dioxide-free atmosphere. The solution was evaporated to dryness *in vacuo*, and the residue was purified as described in (*a*) above, yielding 1.67 g (75.8%) of *dl-trans*-2-guanidocyclohexanol nitrate, m.p. 137–139°. A 75.5% recovery of the unreacted amine was effected via the hydrochloride The experiment was repeated using a twofold excess of amine under otherwise the conditions specified above. Yield, 1.43 g (65.0%).

dl-trans-2-Guanidocylclohexanol Sulphate

dl-trans-2-Aminocyclohexanol (17.3 g, 0.150 mole), S-methylisothiouronium sulphate (13.9 g, 0.05 mole), and water (45 ml) were caused to react under the same conditions

**If the rate of temperature rise exceeds approximately 1° per minute as the fusion point is reached, the reaction becomes very exothermic, causing the temperature of the melt to rise to approximately 200°.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

described for preparation of cyclohexylguanidine hydrochloride. The resultant crude mixture of *dl-trans*-2-guanidocyclohexanol sulphate and *dl-trans*-2-aminocyclohexanol sulphate (21.4 g) was treated with boiling methanol (75 ml) and the insoluble crystalline platelets collected and washed with methanol (2×10 ml). This substance (5.35 g) was identified as *dl-trans*-2-aminocyclohexanol sulphate by paper chromatography. The methanolic filtrate was evaporated to dryness *in vacuo* and the resultant colorless solid triturated with anhydrous ether to remove unreacted *trans*-2-aminocyclohexanol. The insoluble material was recrystallized from methanol, yielding 14.9 g of colorless crystalline substance, m.p. 210–220°, which was shown by paper chromatography to be *dl-trans*-2-guanidocyclohexanol sulphate contaminated with a small amount of the corresponding amine sulphate. Purification via the picrate, followed by reconversion to the sulphate (see below), gave 9.80 g (54.4%) of *dl-trans*-2-guanidocyclohexanol sulphate, m.p. 223–224°, as fine colorless needles. Calc. for $C_{14}H_{32}N_6SO_6$: C, 40.76; H, 7.82; N, 20.38; S, 7.77%. Found: C, 40.96; H, 7.91; N, 19.86; S, 7.55%.

dl-trans-2-Guanidocyclohexanol Picrate

dl-trans-2-Guanidocyclohexanol nitrate was converted to the picrate in 74.5% yield, m.p. 163–165°, after recrystallization from water. Solubility, *ca.* 1.6 g/100 ml water at 4°. Calc. for $C_{13}H_{18}N_6O_8$: C, 40.41; H, 4.70; N, 21.76%. Found: C, 40.76; H, 4.82; N, 21.94%.

dl-trans-2-Aminocyclohexanol Sulphate

dl-trans-2-Aminocyclohexanol (28) was converted to the sulphate in 91.5% yield. After recrystallization from 90% ethanol the substance was obtained as colorless platelets which sintered at 265° but did not melt. Calc. for $C_{12}H_{28}N_2SO_6$: C, 43.88; H, 8.59; N, 8.53; S, 9.76%. Found: C, 44.04; H, 8.74; N, 8.24; S, 9.67%.

dl-trans-2-Aminocyclohexanol Picrate

dl-trans-2-Aminocyclohexanol was converted to the picrate in 73.5% yield, m.p. 153–155°, after recrystallization from water. Solubility *ca.* 15 g/100 ml water at 4°. Calc. for $C_{12}H_{16}N_4O_8$: C, 41.86; H, 4.68; N, 16.28%. Found: C, 41.96; H, 4.69; N, 16.32%.

Purification of dl-trans-2-Guanidocyclohexanol Sulphate Contaminated with dl-trans-2-Aminocyclohexanol Sulphate

(*a*) *Picrate separation method.*—Crude *dl-trans*-2-guanidocyclohexanol sulphate (2.74 g), m.p. 210–220°, from the isothiouronium process was converted to the picrate, yielding 3.72 g (72.4%) of *dl-trans*-2-guanidocyclohexanol picrate, m.p. 163–165°, alone and in admixture with an authentic specimen. A portion of the picrate (1.93 g, 0.0050 mole) was dissolved in methanol and passed through a column of Amberlite IRA-400 ($SO_4^=$) resin (20 ml) which had been prepared in the usual manner and solvent-exchanged with methanol. The resin was washed with water until the effluent gave a negative Sakaguchi test. The combined eluates were evaporated to dryness *in vacuo* and the residue was recrystallized from methanol, yielding 0.94 g (91.2%) of *dl-trans*-2-guanidocyclohexanol sulphate, m.p. 222–224° (recovery 66%).

(*b*) *Ion exchange method.*—An Amberlite IRA-400 (OH^-) resin column (60 ml) was connected in series to an Amberlite IRC-50 (H^+) column (9.5 ml). Crude *dl-trans*-2-guanidocyclohexanol sulphate (5.60 g), m.p. 210–220°, was dissolved in water (130 ml) and the solution passed through the resin columns. Just sufficient guanido compound was used to ensure a slight "breakthrough" of alkylguanidine from the IRC-50 column as revealed by the Sakaguchi test. The IRC-50 column was disconnected, and eluted with

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

5% hydrochloric acid. The eluate was evaporated to dryness *in vacuo*, the residue dissolved in water (50 ml), and the solution passed through an Amberlite IRA-400 ($SO_4^=$) column (60 ml). The eluate was evaporated to dryness *in vacuo* and the residue recrystallized from methanol, yielding 3.90 g (69.6%) of *dl-trans*-2-guanidocyclohexanol sulphate, m.p. 222–224°.

(*c*) *Paper chromatographic method.*—An 18½ in. × 22 in. sheet of Whatman seed-test paper was washed chromatographically with 0.1 *N* hydrochloric acid (3 days), with water (4 days), with *n*-butanol, 1% hydrochloric acid (5:6) (1 day), and finally with water (2 days). Crude *dl-trans*-2-guanidocyclohexanol, m.p. 210–220° (200 mg), was applied in aqueous solution (2%) as a streak on the start-line and the chromatogram was developed for 66 hours by the descending technique in a "Chromatocab" using the above-mentioned solvent system. After drying at 40° reference strips were cut from the chromatogram and sprayed with Sakaguchi reagent. The band of alkylguanidine was marked, cut out, eluted with water (100 ml), and treated with Amberlite IRA-400 ($SO_4^=$) resin to reconvert to the sulphate. The solution was evaporated to dryness *in vacuo* and the residue was recrystallized from methanol, yielding 157 mg (78%) of *dl-trans*-2-guanidocyclohexanol sulphate, m.p. 223–224°.

1-Guanylpyrrolidine Nitrate

(*a*) *Guanylpyrazole method.*—1-Guanyl-3,5-dimethylpyrazole nitrate (10.0 g, 0.0497 mole) and pyrrolidine (35.5 g, 0.498 mole) were heated under reflux for 2½ hours in a carbon-dioxide-free atmosphere. The product was isolated as described for the preparation of cyclohexylguanidine hydrochloride, except that 1-guanylpyrrolidine nitrate proved readily crystallizable from ethanol and was obtained as stout colorless prisms, m.p. 157–157.5°. Yield, 7.00 g (80.0%). Calc. for $C_5H_{12}N_4O_3$: C, 34.09; H, 6.87; N, 31.80%. Found: C, 34.20; H, 6.95; N, 32.10%.

(*b*) *Isothiouronium method.*—Pyrrolidine (10.7 g, 0.150 mole), S-methylisothiouronium sulphate (13.9 g, 0.05 mole), and water (40 ml) were caused to react under the conditions described for preparation of cyclohexylguanidine hydrochloride. The colorless mixture of 1-guanylpyrrolidine sulphate and pyrrolidine sulphate resulting from the evaporation step was dissolved in water (650 ml), the solution passed through Amberlite IRA-400 (NO_3^-) resin, and the latter washed with water until the effluent gave a negative Weber test (29). The combined eluates were evaporated to dryness *in vacuo* and the colorless residue recrystallized from ethanol, yielding 10.4 g (59.0%) of 1-guanylpyrrolidine nitrate as stout colorless prisms, m.p. 157–157.5° alone and in admixture with an authentic specimen.

1-Guanylpiperidine Hydrochloride

1-Guanyl-3,5-dimethylpyrazole nitrate (2.01 g, 0.010 mole) and piperidine (8.52 g, 0.100 mole) were caused to react under the conditions described for preparation of cyclohexylguanidine hydrochloride and the product was isolated as described in the same preparation, since the nitrate salt of 1-guanylpiperidine did not prove to be readily crystallizable. Recrystallization from ethanol–acetone gave 1.32 g (80.5%) of 1-guanylpiperidine hydrochloride as fine colorless needles, m.p. 187–188.5°. Calc. for $C_6H_{14}N_3Cl$: C, 44.03; H, 8.62; N, 25.68; Cl, 21.67%. Found: C, 44.22; H, 8.74; N, 25.18; Cl, 21.63%.

1-Guanylpiperidine Sulphate

Piperidine (12.8 g, 0.150 mole), S-methylisothiouronium sulphate (13.9 g, 0.05 mole), and water (40 ml) were caused to react under the conditions specified for preparation of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

cyclohexylguanidine hydrochloride. Recrystallization of the crude product from 75% aqueous alcohol gave 11.5 g (65.4%) of 1-guanylpiperidine sulphate, as colorless stout prisms, m.p. 284–287° (decomp.). Calc. for $C_{12}H_{28}N_6SO_4$: C, 40.90; H, 8.01; N, 23.85%. Found: C, 40.80; H, 7.98; N, 24.15%. The mother liquor, on treatment with saturated aqueous picric acid gave 5.4 g of piperidine picrate, m.p. 152–153° alone and in admixture with an authentic sample.

N,N-Dimethylguanidine Sulphate

(*a*) *Guanylpyrazole method.*—1-Guanyl-3,5-dimethylpyrazole nitrate (2.01 g, 0.010 mole) and dimethylamine (18 g, 25% aqueous solution, 0.100 mole) were heated under reflux for 8 hours in a carbon-dioxide-free atmosphere, using a dry-ice condenser to prevent loss of dimethylamine. The sticky nitrate resulting from evaporation of the solution *in vacuo* was dissolved in water and converted to the sulphate via IRA-400 ($SO_4^=$) resin. Recrystallization of the crude sulphate from methanol gave 0.91 g (66.8%) of N,N-dimethylguanidine sulphate, as fine colorless crystals, m.p. 272–275°. Calc. for $C_6H_{20}N_6SO_4$: C, 26.46; H, 7.40; N, 30.86; S, 11.77%. Found: C, 26.17; H, 7.38; N, 30.67; S, 11.77%.

(*b*) *Isothiouronium method.*—To a suspension of S-methylisothiouronium sulphate (62.5 g, 0.225 mole) in water (75 ml) at 25° was added a solution of dimethylamine (122 g, 25% aqueous, 0.675 mole) in one portion. A mildly exothermic reaction occurred during which the isothiouronium salt dissolved, methyl mercaptan was evolved, the temperature rose to 35°, and loss of dimethylamine was prevented by use of a dry-ice condenser. The solution was heated under reflux for 30 minutes, then evaporated to dryness *in vacuo*, and the residue recrystallized from methanol, yielding 56.4 g, (89.0%) of N,N-dimethylguanidine sulphate, m.p. 272–275° alone, and in admixture with an authentic sample.

Sakaguchi Test for Monoalkylguanidines

For qualitative testing, the guanido compound in 1 ml of water was treated with the following reagents, in the order named, with thorough shaking between each addition. Sodium hydroxide (10% aqueous), 4 drops; α-naphthol solution (0.1% w/v in 95% ethanol), 6 drops; sodium hypochlorite (0.06 *N*, aqueous), 6 drops. The test is positive when the solution develops a pink, red-orange, or cherry-red color within 1 minute. The minimum quantity of cyclohexylguanidine detectable by the method was 5 γ. If more than 6 drops of α-naphthol or sodium hypochlorite solution are used, a yellow "blank" develops which does not interfere with the test.

Fearon Test for Monoalkylguanidines

The procedure was identical with that described for the Sakaguchi test except that it was necessary to use 12 drops of the thymol indicator (0.1% w/v in 95% ethanol). The test is positive when a golden yellow color develops within 1 minute. Three isomeric thymols were tested for usefulness as detectors. Thymol and *o*-thymol were capable of detecting 50 γ of cyclohexylguanidine hydrochloride but *p*-thymol (30) was capable of detecting only 0.5 mg or more of the same substance.

Inhibition of Sakaguchi and Fearon Tests

Cyanamide, dicyandiamide, and S-methylisothiouronium sulphate interfere with the Sakaguchi and Fearon tests. Cyanamide gives colored "blanks" (purple to Burgundy red) at concentrations greater than 0.3 mg/ml, and below this concentration 0.6 *N* hypochlorite must be used to obtain a positive reaction. S-Methylisothiouronium sulphate and dicyandiamide do not give colored blanks but their presence in concentrations

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

greater than 0.3 mg/ml necessitates the use of 0.6 *N* hypochlorite. Solutions containing more than 3 mg/ml of S-methylisothiouronium sulphate will not give a positive test if the concentration of guanido compound is less than 50 γ/ml.

Paper Chromatography of Amines and Guanidine Compounds

For paper chromatography, a 10 λ spot of a 2% aqueous solution of the amine or guanidine compound was applied to unwashed Whatman No. 1 paper. The chromatograms were developed for 18 hours in glass chromatographic tanks by the descending technique, using the solvent systems specified in Table II. The air-dried chromatograms were then sprayed with bromcresol green, Weber (29), or Sakaguchi reagent for detection of the substances.

THE CHEMISTRY OF THE "AMINOCHROMES"

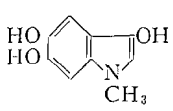
PART II. THE PREPARATION, PAPER CHROMATOGRAPHY, AND SPECTROSCOPIC PROPERTIES OF PURE ADRENOLUTIN; THE INFRARED SPECTRUM OF ADRENOCHROME[1,2]

R. A. Heacock and (in part) M. E. Mahon

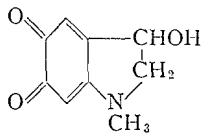
ABSTRACT

The preparation of adrenolutin monohydrate in pure crystalline form has been carried out by the alkaline rearrangement of aqueous solutions of adrenochrome, prepared from the silver oxide oxidation of adrenaline in aqueous solution. An anion-exchange resin (Dowex-1 (Cl^-)) was employed to remove inorganic contaminants from the reaction mixture prior to treatment with alkali. The pure anhydrous material has been prepared by the high vacuum sublimation of the monohydrate. The paper chromatographic, spectroscopic, and fluorimetric characteristics of adrenolutin have been investigated. On the basis of the infrared spectrum it is suggested that in the solid state, adrenolutin exists in the keto form, i.e. 2,3-dihydro-5,6-dihydroxy-*N*-methyl-3-ketoindole. The infrared spectrum of adrenochrome, in the solid state, agrees with the zwitterionic formulation suggested for this compound.

Adrenolutin (usually formulated as 3,5,6-trihydroxy-*N*-methylindole, I), the substance mainly responsible for the intense yellow-green fluorescence that develops in adrenaline solutions that have undergone oxidation in alkaline media, was first isolated in crystalline form and correctly identified by Lund in 1949 (1), from the alkaline rearrangement products of adrenochrome (II), although the correct structure had been assigned to the substance on theoretical grounds a year earlier (Ehrlen (2)).



I



II

The structure was subsequently confirmed by an unambiguous synthesis starting from 3,4-isopropylidenedioxyaniline (Balsiger *et al.* (3)).

The preparation of adrenolutin from adrenaline oxidized with potassium ferricyanide in aqueous bicarbonate buffer, followed by rearrangement with aqueous sodium hydroxide and acidification (4), gave, in our hands, somewhat variable results, and good yields of pure product could not be consistently obtained. It appeared that the product was contaminated with inorganic residues from the oxidation mixture which probably catalyzed its decomposition. It has recently been shown that adrenochrome prepared by the oxidation of adrenaline with silver oxide was often contaminated with traces of silver, and that this contamination could be minimized by passage of the reaction mixture through an ion-exchange resin (Dowex-1 (Cl^-)) prior to isolation of the products (5). The use of this procedure to remove contaminants from adrenochrome solutions has now been extended to the preparation of adrenolutin, and gave consistently good yields of adrenolutin monohydrate in a pure crystalline form. Although the water of crystallization could be removed by drying in a vacuum desiccator, the anhydrous material was always obtained as an

amorphous brownish-green powder. However high vacuum sublimation of the hydrate gave anhydrous adrenolutin in an analytically pure form as a bright yellow crystalline solid.

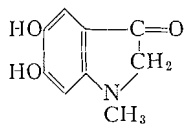
The paper chromatographic behavior of this substance has already been referred to in Part I of this series (5), and the present investigation has confirmed that the use of acid-washed chromatographic paper is essential when working with adrenolutin, since traces of heavy metals and other impurities present in unwashed papers catalyze the air oxidation of adrenolutin, and on unwashed paper only dark streaks of polymeric oxidation products were observed. The best solvents for paper chromatography appeared to be water ($R_f = 0.45$) or methanol ($R_f = 0.60$). These R_f values were obtained on prewashed Whatman No. 1 paper; a somewhat lower value was observed with water on Whatman No. 54 paper. Acidic solvents caused the characteristic yellow-green fluorescence of the compound to change to a pale pinkish-orange color; alkaline solvents were quite unsuitable and caused its rapid decomposition.

The ultraviolet and visible absorption spectra obtained from samples of adrenolutin prepared as described above corresponded well with those previously published (1). The fluorescence characteristics of this substance are of considerable importance, since they have been utilized for many years in empirical methods for the estimation of adrenaline (cf. Persky (6)). The current investigation has shown that there are slight variations in the maximum wavelengths of excitation and fluorescence depending on the solvent used. The highest intensity of fluorescence emission appeared to occur when acetone was used as solvent, with excitation at 405 mμ and the fluorescence measured at 490 mμ. In alkaline solution the molecule existed in the phenoxide ion form and in this case the maximum emission was observed at 515 mμ after excitation at 405 mμ (cf. 7).

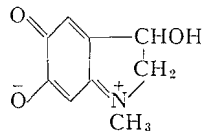
The infrared spectra of anhydrous and hydrated adrenolutin and 3,5,6-triacetoxy-*N*-methylindole ("triacetyladrenolutin") were measured in the solid state ("NUJOL" mulls). In the spectrum of the anhydrous compound, the peak at 3360 cm^{-1} was probably due to a hydrogen-bonded hydroxyl group (cf. 8, p. 84). The high-frequency region of the spectrum of the hydrate was more complicated; peaks were observed at 3480 and 2650 cm^{-1} and there were two shoulders on the "NUJOL" (C–H stretching) peak, at 3250 and 3100 cm^{-1}. These bands must presumably have arisen from the hydrogen-bonded phenolic O–H groups and the water of crystallization. It has recently been demonstrated spectroscopically that in the solid state, and in solution in chloroform and carbon disulphide certain indoxyl derivatives exist in the keto form (10). The sharp peak at 1647 cm^{-1} in the spectrum of the anhydrous compound was at a considerably lower frequency than those previously quoted for indoxyl carbonyls, both in chloroform solution and in the solid state (i.e. 1750–1710 cm^{-1}; 9, 10). However, the hydroxy groups at the 5- and 6-positions in the benzene ring would be expected to reduce the carbonyl frequency, e.g. the carbonyl stretching frequency of *p*-hydroxyacetophenone occurs at 1636 cm^{-1} in the solid state ("NUJOL" mull) and at 1653 cm^{-1} in chloroform (concentrated solution), whereas in acetophenone itself the carbonyl frequency occurs at 1686 cm^{-1} (pure liquid) (8, p. 120; 11), and this frequency is further reduced by the presence of a second hydroxy group in the benzene ring (12). Therefore, in the solid state, anhydrous adrenolutin probably exists in the keto form (III) (i.e. 2,3-dihydro-5,6-dihydroxy-*N*-methyl-3-ketoindole). In the case of the hydrate the spectrum in the "1700–1600 cm^{-1}" region was somewhat complicated, and the band at 1647 cm^{-1} was not observed, however, there were shoulders at 1632, 1610, and 1595 cm^{-1} on a main peak at 1575 cm^{-1}, but in this case no assignment of bands can be made with any degree of certainty. The triacetate exhibited well-defined bands at

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

1762 and 1740 cm^{-1}, the former being due to the 5,6-diacetoxy groups and the latter to the 3-acetoxy group (cf. Holt *et al.* (10)). Several attempts to measure the infrared



III



IV

spectrum of adrenochrome by the potassium bromide disk technique were unsuccessful, leading only to an ill-defined spectrum without very sharp peaks. It appeared that some decomposition and possibly some isomerization (to adrenolutin) had taken place during the preparation of the disk. However perfectly satisfactory spectra could be obtained from suspensions in "NUJOL". The results obtained can best be interpreted on the grounds of the zwitterionic structure (IV), suggested by Harley-Mason (13). There was an O–H stretching band at 3295 cm^{-1}, and in the "carbonyl region", the main band occurs at 1577 cm^{-1}; this was probably due to the $>C=\bar{O}$ group (cf. the strong band of the ionized carboxyl group occurs in this region (8); the bands at 1682, 1672, and 1622 cm^{-1} could be tentatively assigned to the $>C=\overset{+}{N}<$, $>C=O$ and the conjugated double bonds of the six-membered ring. The spectra of 2-iodoadrenochrome and six other "aminochromes" (14) were essentially the same as that of adrenochrome, indicating that all these compounds exist in the dipolar form.

EXPERIMENTAL

Preparation of Adrenolutin Monohydrate

L-Adrenaline (5.0 g) was suspended in water (150 ml) and concentrated hydrochloric acid added dropwise until a clear solution was obtained. Freshly prepared silver oxide (20.0 g) was added portionwise to the stirred solution and the stirring continued for 2 minutes. The reaction mixture was filtered through a Dowex-1 (Cl^-) (200/400 mesh) resin bed (diam. = 6.5 cm; height = 1.5 cm)* and the filtrate cooled in ice. A stream of nitrogen was passed through the filtrate, cooled in an ice bath, and 10% sodium hydroxide solution (50 ml) added. The brownish-yellow solution, which exhibited a brilliant green fluorescence, was stirred and acidified by the dropwise addition of glacial acetic acid; adrenolutin monohydrate was precipitated as a bright yellow crystalline solid (3.25 g), m.p. 232–235° with decomposition. (Found: C, 54.94; H, 5.56. Calc. for $C_9H_{11}O_4N$: C, 54.82; H, 5.62.) The product, which was dried at room temperature in a current of nitrogen, could be recrystallized from water (containing a small quantity of sodium hydrosulphite to prevent oxidation) and obtained in bright yellow prisms, m.p. 236° with decomposition.

Preparation of (Anhydrous) Adrenolutin

Adrenolutin monohydrate (0.1 g) was sublimed at 180–200°/3 mm and anhydrous adrenolutin was obtained in bright yellow prisms, m.p. 245° with decomposition. (Found: C, 60.59; H, 4.90. Calc. for $C_9H_9O_3N$: C, 60.33; H, 5.06.) Neither of these products showed any tendency to decolorize if stored at room temperature in the dry state.

**The resin was prepared by extensive washing with (1) 3 N hydrochloric acid and (2) water until neutral to litmus.*

Harley-Mason quotes melting points of 230–232° and 285°* for the monohydrate and anhydrous material respectively (4, 15). Lund states that the substance he isolated decomposes above 100° without melting (1); Balsiger *et al.*, quote melting point 195°* (anhydrous substance) (3), whilst Fischer obtained a melting point of 230–235° for the hydrate (16).

Paper Chromatography of Adrenolutin

Either Whatman No. 1 paper (washed with 2% acetic acid for 12 hours and dried prior to use) or Whatman No. 54 paper was used. Both the ascending and descending techniques were employed, each method gave approximately the same R_f values; *ca.* 20 to 30 μg of sample were applied to the paper in each case. The solvent was allowed to run a distance of *ca.* 35 cm. The solvents employed, namely water, 2% acetic acid, and methanol all ran very quickly and 2.5 to 3.5 hours were usually required for each run. The results obtained are given in Table I. Since adrenolutin is bright yellow in color its position on the developed chromatogram was usually self-indicating, however, the position of the spot could be confirmed as follows: (*a*) it showed a characteristic intense yellow-green fluorescence in ultraviolet light; (*b*) it gave a blue color with the ferric chloride – potassium ferricyanide reagent (cf. 5); (*c*) a violet color slowly developed after spraying with Ehrlich's reagent; (*d*) Gibb's reagent (*N*-2,6-trichloro-*p*-quinoneimine) gave a brown spot.

THE ELECTRICAL POLARIZATIONS OF *BIS*-MERCURIALS[1]

HENRY SAWATZKY AND GEORGE F WRIGHT

ABSTRACT

Very dilute solutions of diphenylmercury in carbon tetrachloride have been found not to have orientation polarization, but in not-so-dilute carbon tetrachloride or in dioxane and benzene at any concentration there is evidence of moment. Moreover, these moments vary negatively in carbon tetrachloride and dioxane and positively in benzene with respect to temperature. The angular C–Hg–C linkage responsible for orientation polarization is also demonstrated by appreciable moments for para methylmercuri-*bis*-benzene and the homologous durene. Magnitudes comparable with the aryl analogues are found for several alkyl *bis*-mercurials, but the similarity in the moments of trifluoromethyl and methyl-*bis*-mercury as well as a temperature coefficient for moment of the latter compound indicates that the C–Hg–C linkage may vary widely and easily. However, a lower limit may be set by the moments of mercuracyclohexane and mercuracycloheptane in which the mercury angle is fixed by the cyclic structure.

INTRODUCTION

For several decades the electrical polarization of diphenylmercury has seemed to be anomalous. Originally Bergmann and Schütz found the solute polarization in benzene to be 64 cc at 14.15° and concluded that it was due entirely to electronic polarization (1). Later Hampson (2) found the polarization to be 68.8 cc at 25° in benzene. Since this value exceeded the electronic polarization, and since greater deviations from electronic polarization were found for a number of *p*-disubstituted analogues of diphenylmercury, Hampson concluded that the C–Hg–C bond was angular in these substances. Others, and most recently Armstrong, LeFevre, and LeFevre (3), consider that the data may be better interpreted in terms of abnormal atom polarization. However, a direct measurement (4) has shown that diphenylmercury has a distortion polarization which actually

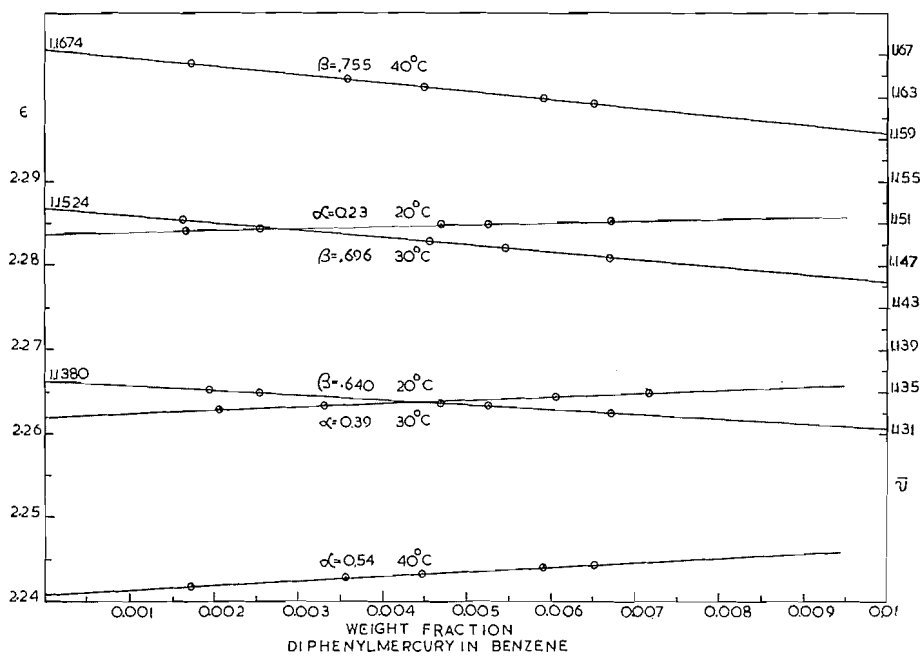

FIG. 1.

[1]*Manuscript received May 1, 1958.*
Contribution from the Department of Chemistry, University of Toronto, Toronto, Ontario, Canada.

is lower than that calculated from refractometric data. In view of this anomalous situation we have now examined a wider variety of *bis*-mercurials and of conditions under which the polarization is determined.

Diphenylmercury

The variation of electric polarization with respect to solvent, concentration, and temperature is shown in Table I. It may be seen in Fig. 1 that in benzene the relationship of both specific volume and dielectric constant is linear with respect to weight fraction even at concentrations less than 0.002, and extrapolation conforms closely with the values for the pure solvent. This seemingly normal behavior is belied by the augmentation of apparent moment as the temperature is increased from 20° to 40° (Table I). By contrast the apparent moment in dioxane (in which equally good linearity and extrapolation of $\delta\epsilon/\delta\omega$ and $\delta\bar{V}/\delta\omega$ have been observed) has shown a diminution as the temperature has been increased. Likewise with weight fractions (ω) of 0.005 to 0.01 it may be seen (Fig. 2) that the apparent moment in carbon tetrachloride decreases as the temperature rises from 20° to 40°. These variations have been plotted in Fig. 3. It is of interest that these curves (which might be straight lines within the ±0.01 D precision) intersect at about 25°.

*The P_{e-a} of 57.1 as obtained from solid dielectric data is used for the calculations of the dipole moments.
†Contrasted to Curran's 69.02 (6).

The observed polarization at 25° in carbon tetrachloride (71.6 cc) is not far from that reported (70.2 cc) by Armstrong, LeFevre, and LeFevre (3). However, it may also be seen in Fig. 2 that the latter agreement was attained only by using the concentration range specified by the three authors (3). In the concentration range of 0–0.005 weight fraction it is apparent that a sharply different $\delta\epsilon/\delta\omega$ (α) prevails at all temperatures, although no such inflection is observed in the $\delta\bar{V}/\delta\omega$ slope. The latter evidence for the constancy of β is confirmed by isopiestic measurements which show that diphenylmercury does not associate in carbon tetrachloride.

There have been doubts (3) about the significance of the value for distortion polarization (57.1 cc) determined from the dielectric constants of solid diphenylmercury pellets. The critics considered this value to be low, but the criticism is not entirely justified in view of the total polarizations (in cc, 58.2, 58.6, and 58.7) found at 20, 30, and 40° for diphenylmercury in very dilute tetrachloride solution. An assignment of orientation polarization which exceeds these values must be erroneous. Although our measured distortion polarization (57.1 cc) is 1.1 to 1.6 cc below the total polarizations mentioned above, we cannot safely assign the differences to orientation polarization. These differences are only slightly outside our experimental error. We cannot say whether the moment of diphenylmercury in dilute carbon tetrachloride solution is zero or whether it has a very low value which cannot be defined by the present experimental techniques. But we can say that the minimal polarizations which we have observed in very dilute carbon tetrachloride solutions are contradictory rather than confirmatory to recent claims (3) of zero dipole moment for diphenylmercury, because we have set a minimum which the distortion polarization cannot exceed.

In order to arrive at these conclusions it has been necessary to give careful attention to the purity of the carbon tetrachloride. For example the use of an old sample (ϵ_0 = 2.2303 and $\bar{V}$ = 0.6312) for the polarization study of diphenylmercury shows a decrease in $\delta\epsilon/\delta\omega$ at 25° (in the concentration range ω = 0.005 to 0.01) from 0.67 (in the pure solvent where ϵ_0 = 2.2268) to 0.50 in the old solvent, although the change in $\delta\bar{V}/\delta\omega$ does not exceed 0.01. Of course, this behavior is not unprecedented (p. 130, ref. 5) when the polarity of the solvent is increased. While we have been unable to characterize the impurity which raised the dielectric constant of the old carbon tetrachloride, we have found that deliberate addition of water to our purest solvent (resultant ϵ_0 = 2.2289 at 25°) lowers $\delta\epsilon/\delta\omega$ from 0.67 to 0.48, while $\delta\bar{V}/\delta\omega$ decreases from 0.174 to 0.163. Since these differences lower the apparent moment from 0.85 D to 0.63 D it is evident that rigorously purified solvent must be used for meaningful results.

The variation in polarization with respect to concentration may indeed provide an insight into the molecular behavior of diphenylmercury, especially since the medium, carbon tetrachloride, in which this variation occurs is tetrahedrally symmetrical, with little tendency toward co-ordination. We suggest that in this medium diphenylmercury is self-polarized at the higher concentrations. We presume that the effect of this self-polarization is a reduction in the tendency for diphenylmercury molecules to execute the 360° rotation which is ineffective toward the external field. We believe that this rotation, a consequence of the mass of the central atom, is indicated by the evident perturbation in the spectral absorption at 463 cm^{-1}.

It follows that in very dilute solution more molecules, freed from self-polarization, will completely rotate. The same circumstance ought to reduce the polarization at increased temperatures. This effect is observed (Fig. 3) in carbon tetrachloride.

In this connection it is of interest to compare the dielectric constants of pure carbon

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

tetrachloride at the several temperatures with the extrapolation to zero solute concentration. It is evident that the extrapolations for very dilute solutions must differ from those for not-so-dilute solutions. The extrapolation of $\delta\epsilon/\delta\omega$ for very dilute solutions is essentially indistinguishable from that of the pure solvent; ϵ_0 (solvent) minus ϵ_0 (solution) is less than 0.0002. On the other hand the extrapolation of $\delta\epsilon/\delta\omega$ for not-so-dilute solution shows at 20° C that ϵ_0 (solvent) minus ϵ_0 (solution) is 0.001, but at 40° it has decreased to 0.0005. This behavior would indicate that the solvent cavities differ in the two concentration ranges, and suggests that the effectively larger cavity due to self-polarization is decreased either by separation of diphenylmercury molecules, or by thermal agitation.

Benzene is not tetrahedrally symmetrical, so interaction of diphenylmercury with this medium is not unexpected. This interaction ought to minimize self-polarization and it should prevail over the entire concentration range. This expectation is realized in the linearity of the $\delta\epsilon/\delta\omega$ graph over a weight fraction range of 0.001 to 0.008 (Fig. 1) and more.

Table I shows that the apparent moment of diphenylmercury in benzene at 20° is lower than it appears to be in not-so-dilute carbon tetrachloride solution. Assuming that the behavior in the latter medium approaches that in the gas phase the solvent effect in benzene may be called negative. According to the opinions of several workers (5, p. 47), this effect is expected when the molecule contained in a cavity of polarizable solvent has its moment axis in the long dimension of the molecule. This description may apply to a bent molecule with mercury at one end of the dipole.

However, the situation at 20° is reversed at 40° where the moment in benzene is much higher than in carbon tetrachloride. In the absence of any prior opinions (5) about dependence of solvent effect on temperature we suggest that the change of molecular shape within the polarizable solvent cage may be due to C–Hg–C bond angle variation with respect to temperature. While this effect should not be profound, it must be remembered that throughout this argument we are considering moment variations which do not exceed 0.5 debye unit.

It would seem that dioxane is intermediate in behavior between the other two solvents. Indeed the concentration effect and the solvent polarizability effect may largely be compensated in dioxane. In this connection we point again to the intersections of Fig. 3. It is unfortunate that a vapor-phase moment value at this temperature (about 25°) is not available.

In any circumstance the data for diphenylmercury in the several solvents must be interpreted in terms of some type of induced polarization. This interpretation implies a definite dipole moment, even when it is very small (experimentally there are no negative moment values in very dilute carbon tetrachloride). The moments may be ascribed to C–Hg–C angularity and some of the differences may be due to variations in this angle. Evidence for differences in this angle will be presented in the remainder of this report.

Paradisubstituted Methylmercuribenzenes

If one assumes that benzene substituents are bonded coplanar with the ring then evidence of orientation polarization in a 1,4-dimercuribenzene ought to establish an angularity of bonding to mercury. To this end we have prepared 1,4-methylmercuri-*bis*-benzene (III*a* or *b*, R = H) by reaction of methyl chloride Grignard reagent with the 1,4-dibromomercuribenzene (II, R = H) derived from mercuric bromide and 1,4-bromomagnesium-*bis*-benzene (I, R = H).

Although the product III has a tendency toward disproportionation to dimethylmercury and a polymer it is sufficiently stable for determination of its electrical polarization at 20° in carbon disulphide. This polarization should have no orientation component if the methylmercuri group were included in the plane of the ring or if the conformation were entirely III*a* (R = H). On the other hand the substance ought to show evidence of moment if the conformation III*b* were contributory. When the additive electronic polarization (used because III will decompose partially during the time required for determination of the dielectric constant of the solid) is subtracted from the total polarization, the difference may be calculated as a moment of 0.91 debye unit.*

A further test of non-linearity has been accomplished with 1,4-methylmercuridurene (III*a* or *b*, R = Me). This substance has been synthesized by mercuration of durene (IV, R = Me), and treatment of the product II (R = Me) with methyl chloride Grignard reagent. The product III, R = Me, is only a little less prone toward disproportionation than the simpler homologue. From the total polarization in carbon disulphide at 20° is subtracted the electronic polarization, again calculated additively. The remainder represents an electric moment of 1.38 debye unit.

In order to compare the moments of the two 1,4-disubstituted phenylene mercurials it is necessary to assign a group moment to methylmercuri. Although we realize the limitation of group moment evaluations, we have used 1-bromo-4-methylmercuribenzene (VIII, R = H, X = Br) obtained by treatment of 1-bromo-4-bromomercuribenzene (VII, R = H) with methyl chloride Grignard reagent. Actually VII is a by-product in the preparation of II as a consequence of the partial Grignardization (VI) of 1,4-dibromobenzene (V, R = H).

The moment of VIII, calculated from additive electronic polarization, in carbon disulphide at 20° is 1.94 debye unit. If a value (m_1) of 1.5 debye is assumed (excluding mesomeric effects) for the 4-bromophenyl group then an equation in two unknowns, the methylmercuri moment (m_2) and its angular deviation from linearity (α), may be formulated

$$(1.94)^2 = (1.5)^2+(m_2)^2-2(1.5)(m_2)\cos\alpha.$$

**The disproportionation of the bis-mercurials described in this report is sufficiently slow that reliable polarization measurements can be made. This reliability has been demonstrated by recovery of the substance after the polarization measurement. However, the time required for analyses to be made elsewhere is detrimental. Additionally the high percentage of mercury in such compounds makes the results non-definitive. Consequently we have chosen to characterize the bis-mercurials analytically by quantitative conversion to the chloromercuri derivatives rather than by analysis of the elements.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

If one now combines this equation algebraically with the equation which defines the moment of 1,4-methylmercuri-*bis*-benzene (III, R = H)

$$(0.91)^2 = \sqrt{2} \cdot m_2 \cdot \sin \alpha,$$

then assuming that the methylmercuri group moment and the moment angle α are the same in both compounds, two sets of values may be calculated. One value ($m_2 = 0.72$ debye unit; $\alpha = 62°$) seems to be more probable than the other ($m_2 = 3.37$ debye unit, $\alpha = 10.9°$) because the methylmercuri moment ought to be much lower than the group moment (3.5 debye unit) assigned previously to the chloromercuri group (6). Actually the more probable moment value is in approximate agreement with that expected in consideration of the polarizations of diphenylmercury and dimethylmercury. Likewise the C–Hg–C angle (180° minus 62°) is comparable with that estimated for the aliphatic *bis*-mercurials described below.

It is of interest to compare the moments of methylmercuri-*bis*-benzene and the homologous durene. If the C–Hg–C linkage were linear then the moments of both compounds (III, R = H or Me) ought to be identically zero. Actually the moment of the durene (1.38 D) is found to be $\sqrt{2}$ times that (0.91 D) of the benzene. If the substituents in 1,4-methylmercuri-*bis*-benzene are simple-harmonically rotating then this ratio specifies that the substituents in the homologous durene (III, R = Me) are hindered from free rotation. Moreover, the ratio indicates that the hindrance retains the methylmercuri group on one side of the ring (III*b*, R = Me), since any contribution from III*a* (R = Me) would decrease the ratio.

This "on-side" conformation is not unexpected in view of recent observations in respect of the moment of 1,4-dinitrobenzene (7). On the other hand it must be realized that quantitative estimations of this sort are unjustified, despite their common use, and the $\sqrt{2}$ relationship may be fortuitous. For example the group moment and moment angle may differ among the compounds, the bond angle may differ from the moment angle, and the assumption of planarity of the aromatic rings with coplanarity of the substituent methyl groups is nowadays equivocal. However, the quantitative estimation does accentuate the qualitative fact that the observed moments establish the non-linearity of the C–Hg–C linkage.

Aliphatic bis-Mercurials

The electrical polarization data for a series of aliphatic *bis*-mercurials is shown in Table II. It may be seen by reference to the three solid substances with which the combined electronic-plus-atomic polarizations can be determined that the additive values for electronic polarization are not greatly in error. In no instance can a zero moment be designated. Even the polarization of hexafluorodimethylmercury in carbon tetrachloride is appreciable (*ca.* 0.3 D), although the range of concentrations ($\omega = 0.0008$ to 0.0025) is comparable with that of diphenylmercury in carbon tetrachloride where no orientation polarization can be detected.

The trend in moment among the homologous series (methyl > ethyl > propyl) is not very informative except for the unexpectedly low moment of hexafluorodimethylmercury.* In view of the high polarity of the C–F linkage a much higher polarization than has been observed, irrespective of the polarity (necessarily low) of the mercury–carbon

**We are indebted for this compound to Mr. D. Fishel, Ohio State University, who prepared it from trifluoromethyl iodide and cadmium amalgam by the procedure of Emeleus and Haszeldine (8).*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

linkage, would have been expected. In the absence of this difference one may assume that the C–Hg–C angular relationship is variable in respect of the polarity of the substituent groups.

TABLE II

POLARIZATION DATA, ALIPHATIC *bis*-MERCURIALS, R_2Hg

‡Density at 22°, 3.30.

The effect of temperature on the polarization of dimethylmercury in benzene has been examined briefly. The apparent augmentation of moment with increasing temperature is similar to that found for diphenylmercury in the same solvent, but is so slight (0.05 debye unit from 20 to 40°) that it might be ascribed to experimental error. However the difference is substantiated by comparison of the moment of diethylmercury (0.55 D at 20° in benzene) with that (0.39 D) reported in the same solvent at 14.5° (1).

In view of the evidence for a C–Hg–C angularity in these aliphatic *bis*-mercurials we have sought to examine analogues in which the angularity would be intrinsic in the structure. Of the last three items in Table II the first was once thought to be 1-oxa-4-mercuracyclohexane (9) but Grdenic proved by X-ray diffraction studies (10) that it is the dimer, 1,7-dioxa-4,10-mercuracyclododecane. Because of the flexibility of a 12-membered ring and also because of a possible tendency toward co-ordination of mercury with oxygen, the substance is not the ideal example we sought for examination of rigid angularity. Nevertheless a significant orientation polarization is observed which cannot be attributed alternatively to an abnormal atom polarization. At most the latter cannot exceed 3 cc, according to the value which we have obtained for the dielectric constant of the solid substance.

When 1,5-dichloromercuripentane is treated with sodium stannite the dimer of mercuracyclohexane is formed exclusively, and this dimer seems to be the stable form. However, by treatment of 1,5-dibromopentane with sodium amalgam in ethyl acetate (11) the monomer may be obtained in varying yield. Although this monomer, $C_5H_{10}Hg$, tends to transform easily to the dimer or polymer, it may be purified for immediate use by avoidance of elevated temperatures. The moment calculated from the electric polarization in benzene (0.86 D at 20°) is closely comparable with the moments of the non-cyclic *bis*-mercurials shown in Table II.

Application of Hilpert and Gruttner's method for the preparation of mercuracyclopentane (13, 12) yields only one product which seems to be the dimer, according to an isopiestic determination of molecular weight. Since the same product is obtained by

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

various reductions of 1,4-dichloromercuributane it would seem that monomeric mercuracyclopentane is too unstable for isolation in sufficient purity for electric polarization studies. The polarization of the dimer (probably 1,6-dimercuracyclodecane, since it can be reconverted to 1,4-dichloromercuributane by treatment with mercuric chloride) has not been measured.

The preparation of monomeric mercuracycloheptane has been more successful, and leads from either 1,6-dibromohexane or 1,6-dichloromercurihexane to a single product which is monomeric according to isopiestic molecular weight determinations (15, 14). The product can be reconverted to 1,6-dichloromercurihexane by means of mercuric chloride. Its moment is not strictly comparable with that of mercuracyclohexane because it has been necessary to use carbon disulphide as the solvent. However, the observed moment at 20° (0.9° D) is almost identical with that of mercuracyclohexane.

From these results it would seem that the C–Hg–C angle must be greater than 108–110°, but it may be as low as 120–130° in a stable configuration. Moreover, since the observed moments are less than twice as great as that of the comparable diethyl- and dipropyl-mercury the C–Hg–C angles in the latter substances need not exceed 150°.

But this estimate should not be construed to imply a fixed C–Hg–C angle for *bis*-mercurials. Indeed the apparent anomalies which have been observed by variation of temperature and solvent with diphenyl- and dimethyl-mercury, and also the lack of correlation of moment with polarity of substituents, is a strong indication that the C–Hg–C angle is widely variable. Perhaps this variability ought to be expected with a large atom-like mercury. Conversely one might say that mercurials are poor candidates for stereochemical studies. On the other hand the behavior of *bis*-mercurials may predict the day of better precision in measurement when no polyatomic substance is known that will not be oriented by an electrical field.

The authors are grateful for studentship aid and direct grants from the National Research Council of Canada which supported this research. They wish to thank Mrs. L. Westland and Mr. F. Lautenschlaeger for aid in the experimental work. Any experimental data not presented in the paper is available in the doctoral thesis of H. Sawatzky.

EXPERIMENTAL*

1,4-Chloromercuri-bis-durene

A mixture of 5.40 g (0.04 mole) of durene, 51.2 g (0.16 mole) of mercuric acetate, 40 ml of acetic acid, and 120 ml of methanol were refluxed for 4 days. The precipitated solid was removed by hot filtration and was washed with boiling ethanol, 11.7 g. This acetoxymercurial was then dissolved in 300 ml of hot acetic acid and the partially cooled system was treated with a solution of 10 g (0.17 mole) of sodium chloride in 50 ml of water. The solid product was filtered off and washed with boiling ethanol, 11.38 g (47%). It may be crystallized from pyridine but has no melting point. X-Ray diffraction pattern is [10] 7.59; [5] 4.45; [4] 3.97; [3] 2.85; [2] 3.52, 3.33, 2.96; [1] 4.63, 3.84, 3.21, 3.01, 2.63. Anal. Calc. for $C_{10}H_{12}Hg_2Cl_2$: C, 20.0; H, 2.01. Found: C, 20.3; H, 2.00.

1,4-Methylmercuri-bis-durene

Into 15 ml (0.0189 equiv.) of stirred methyl chloride or iodide Grignard reagent under nitrogen was added 2.00 g (0.0033 mole) of 1,4-chloromercuri-*bis*-durene. To the warm

Melting points have been corrected against standards according to Can. J. Technol.* **34, *89 (1956). X-Ray diffraction is reported at relative intensities I/I_1 at d spacings in angstroms using* CuKα (Ni *filtered*) *radiation.*

suspension was added 20 ml of dry diethyl ether. After 18 hours of stirring the system was poured on 50 g of crushed ice. Then 1% aqueous sulphuric acid was added until the system was slightly acidic. After evaporation of the ether the solid (1.47 g) was filtered off and almost dissolved in hot benzene. Evaporation of the filtered solution left 1.35 g (73%) of product which did not melt. Purification may be effected by crystallization from hot benzene (25 ml per g) but prolonged heating will cause disproportionation. X-Ray diffraction pattern is [10] 7.65; [9] 3.50; [6] 6.83; [5] 4.38; [4] 5.05; [3] 4.68, 4.03, 3.64, 2.26; [2] 2.92, 2.71; [1] 6.30, 3.35. In carbon disulphide α is 0.66 and β is 0.409, so $P_{2\infty}$ is 116.9 cc. With R_D = 76.4 cc, the moment is 1.38 D. Anal. Calc. for $C_{12}H_{18}Hg_2$: C, 25.6; H, 3.22. Found: C, 25.7; H, 3.25.

When a benzene solution of this material was treated with 2 mole equivalents of mercuric chloride in ether a white precipitate could be filtered off after 20 minutes. When this precipitate (88.7% after ether washing) was treated with bromine in aqueous potassium bromide it was converted to 1,4-dibromodurene, m.p. 200–203°. The benzene filtrate left methylmercuric chloride (83%, m.p. 164–168°) when it was evaporated.

1,4-Methylmercuri-bis-benzene

To a stirred suspension of 2.40 g (0.1 atom) of magnesium in 50 ml of dry ether was added 2 ml of ethyl bromide in 50 ml of ether during 30 minutes. Then a solution of 4.72 g (0.02 mole) of *p*-dibromobenzene and 3.85 ml (total 0.06 mole) of ethyl bromide in 100 ml of ether was added during 75 minutes. Strong reflux was maintained and continued during 12 hours, then 1.2 ml more of ethyl bromide was added. After 1 hour all the magnesium was consumed, so 27.2 g (0.1 mole) of mercuric chloride was introduced during 24 hours from a soxhlet extractor.

The solid product was filtered off and washed thoroughly with water, boiling ethanol, and boiling benzene. There remained 4.88 g (38%) of 1,4-bromomercuribenzene, identified by conversion in 93% yield to 1,4-diiodobenzene, m.p. 127–129°, by means of iodine in an alcoholic suspension of the mercurial.

The filtrate from which this product was obtained was evaporated and then steam-distilled to remove 11.9 g of ethylmercuric bromide. The residue yielded 1.96 g (23% as *p*-bromophenylmercuric bromide) which may be crystallized from benzene, m.p. 234–236°. It has been converted to *p*-bromophenylmercuric acetate, m.p. 198–201°, by means of silver acetate, and subsequently to *p*-bromophenylmercuric chloride, m.p. 251–253°, by means of sodium chloride (16). Also it was converted quantitatively to *p*-dibromobenzene by treatment with bromine in aqueous potassium bromide.

To a stirred suspension of 1,4-bromomercuri-*bis*-benzene (4.30 g, 0.0074 mole) in 25 ml of dry ethyl ether at 0° under nitrogen was gradually added 20 ml (0.02 equiv.) of Grignard reagent from methyl chloride or iodide. After subsequent stirring for 90 minutes the system was poured onto 200 g of crushed ice. The ether was evaporated and the remainder was extracted by 100 ml of pure carbon disulphide. Evaporation of the extract left 2.26 g (61% of the bromomercuri-*bis*-benzene) which was crystallized from 50 ml of 1:1 benzene – diethyl ether. The melting point of this methylmercuri-*bis*-benzene is 190–193° with decomposition at 185° indicating disproportionation. It does not contain halogen; X-ray diffraction pattern is [10] 4.56; [3] 3.75, 3.63, 3.34, 3.21; [2] 5.92, 5.23; [1] 5.62. In carbon disulphide α is 0.29 and β is 0.460 so $P_{2\infty}$ is 75.7 cc. If R_D is 57.9 cc the moment is 0.91 D.

Although a satisfactory elemental analysis was not obtained the methylmercuri-*bis*-benzene was analytically characterized when a suspension of 0.044 g (0.00087 mole) in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

1 ml of ethyl ether was shaken for 3 hours with a solution of 0.047 g (0.018 mole) of mercuric chloride in 5 ml of ether. The solid was filtered off and ether-washed, 0.047 g (98%) of 1,4-chloromercuri-*bis*-benzene which was converted quantitatively to 1,4-dibromobenzene. Anal. Calc. for $C_6H_4Hg_2Cl_2$: Cl, 12.93. Found: Cl, 12.97. The ether filtrate was evaporated to yield 0.0441 g (100%) of methylmercuric chloride, m.p. 168–170°, after crystallization from ethanol.

1-Bromo-4-methylmercuribenzene

A suspension of 0.87 g of *p*-bromophenylmercuric bromide (0.002 mole, obtained from the experiment reported above) in 25 ml of diethyl ether was stirred and ice-cooled under nitrogen, while 3.50 ml (0.0033 equiv.) of Grignard reagent from methyl chloride was added during 5 minutes. After 3 hours of subsequent stirring at ice-bath temperature the system was poured onto 75 g of crushed ice. The non-aqueous phase, dried by magnesium sulphate, was evaporated to leave an oil (0.63 g, 82%) which solidified when chilled to 4°. It was twice crystallized by solution (at 25°) in 1:1 ethanol–chloroform (32 ml per g) and subsequent chilling to −78°. The purified product, m.p. 52.1–52.7°, was characterized by cleavage with mercuric chloride, yielding methylmercuric chloride and *p*-bromophenylmercuric chloride, each in 100% yield. The Grignard reagent from methyl iodide cannot be used in this preparation because disproportionation occurs. In carbon disulphide this mercurial has $\alpha = 2.01$ and $\beta = 0.436$ so $P_{2\infty} = 122.9$ cc, and $\mu = 1.94$ D if $R_D = 49.9$ cc.

Mercuracycloheptane

A mixture of 450 g (0.195 atom Na) of 1% sodium amalgam, 16.5 g (0.07 mole) of 1,6-dibromohexane, 3 ml of ethyl acetate, and 25 ml of benzene was shaken at 70° (infrared lamp) for 1 day, after which time 25 ml each of benzene and water was added with agitation. After separation of the non-aqueous phase a subsequent extraction with 25 ml of benzene was accomplished. Evaporation of the benzene left 7.6 g of oily solid which was purified first by three crystallizations from chloroform (3 ml per g) from 25° to −78° and then by repeated crystallization from 4:1 ether–benzene and from 1:5 ethanol–benzene (3 ml per g) to melt at 58.5–60.2°. Anal. Calc. for $C_6H_{12}Hg$: Mol. wt., 285. Found (Willard and Blank (15)): Mol. wt., 273. Found (Barger-Rast (14)): Mol. wt., 286.

1,6-Dichloromercurihexane

A solution of 2.84 g (0.01 mole) of mercuracycloheptane in a minimum of benzene was treated with 2.72 g (0.01 mole) of mercuric chloride and then 10 ml of ethyl ether was added. The white suspension formed by stirring was filtered off and washed thoroughly with ether, 5.60 g (100%) of 1,6-dichloromercurihexane. Anal. Calc. for $C_6H_{12}Hg_2Cl_2$: Cl, 12.75. Found: Cl, 12.69. After crystallization from hot dimethylsulphoxide (15 ml per g) it melts questionably at 290° with decomposition. The X-ray powder diagram is [10] 11.72; [9] 3.31; [7] 2.65; [5] 2.38; [2] 2.99; [1] 2.25, 3.99, 4.44. Reduction of this high-melting mercurial by alkaline sodium stannite forms mercuracycloheptane, m.p. 58–60°, in 90% yield. Identity was established by mixture melting point.

Mercuracyclohexane

A mixture of 15 g (0.065 mole) of dibromopentane, 450 g (0.2 atom) of 1% sodium amalgam, 3 ml of ethyl acetate, and 50 ml of dry benzene was shaken in a stout sealed bottle at 75° for 24 hours. After treatment with 100 ml of cold water the spent amalgam

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

was separated and washed with 50 ml each of water and benzene. The benzene solutions, adequately dried, were vacuum evaporated leaving 8.20 g of oil. This oil was twice extracted by 5-minute reflux with 25 ml of absolute ethanol. The quickly cooled extract was filtered and further chilled to 40°. Slowly there appeared 0.53 g of crystals. Contrary to Hilpert and Gruttner the substance was found only in the extract. Three rapid crystallizations from a benzene–hexane mixture gave a product, m.p. 122.4–122.8°. The monomer seems to be very unstable thermally, and sometimes is not obtainable.

When this product was treated with mercuric chloride, a quantitative yield of 1,5-dichloromercuripentane was obtained. The X-ray diffraction pattern of this *bis*-chloromercurial is: [10] 4.33; [9] 3.34; [8] 3.18; [7] 3.56; [6] 1.97; [5] 2.71; [3] 2.11; [2] 2.45, 2.35, 2.30, 2.07; [1] 2.86, 2.17, 1.82, 1.78. Regeneration of the *bis*-mercurial by treatment with sodium stannite yielded only the dimer described by Hilpert and Gruttner (11). The monomeric *bis*-mercurial decomposed in boiling ethanol to yield an oil which seems to contain the dimer.

1,6-Dimercuracyclodecane

(*a*) *From dibromobutane.* –A mixture of 450 g (0.2 mole) of 1% sodium amalgam, 15.3 g (0.07 mole) of 1,4-dibromobutane, 3 ml of ethyl acetate, and 25 ml of benzene was shaken for 36 hours at 70°. The cooled system was then shaken with 25 ml of water and the benzene layer was separated and combined with a subsequent 25 ml benzene washing. Evaporation left an oil, 10.79 g, which was washed with cold ether leaving 3.79 g of sticky solid. Crystallization from an ether–benzene mixture gave a product, m.p. 44–45.2°.

(*b*) *From 1,4-dichloromercuributane.*—A sample of 0.50 g (10^{-4} mole) of 1,4-dichloromercuributane was treated with 40 ml of 10% aqueous sodium hydroxide and then with a solution of 1 g of stannous chloride dihydrate in 20 ml of 20% aqueous sodium hydroxide. The black suspension was filtered off when no more color change occurred. The black product was extracted with boiling xylene which was evaporated at low temperature leaving 0.17 g (66%) m.p. 37–40°. Crystallization from ether–benzene raised this melting point to 43–45°. Molecular weight determinations by the isopiestic method of Willard and Blank gave an average value of 499, while a freezing-point depression in diphenylmercury gave a value of 517. The calculated molecular weight is 513.

1,4-Dichloromercuributane

When 0.1294 g (253×10^{-6} mole) of dimercuracyclodecane in benzene is treated with 0.1390 g of mercuric chloride dissolved in a minimum of ethyl ether the resulting precipitate, washed with benzene and ether, weighs 0.253 g (93%). Its X-ray diffraction pattern is [10] 3.18; [9] 4.61; [7] 2.09; [5] 2.62; [4] 2.41; [3] 3.55, 1.78; [2] 2.53; [1] 4.00, 3.47, 2.49, 2.03 after crystallization from hot dimethylsulphoxide; m.p. 292–293° (with decomposition). Anal. Calc. for $C_4H_{10}Hg_2Cl_2$: Cl, 13.5. Found: Cl, 13.3.

Dialkylmercury Homologues

These mercurials were prepared from alkylmercuric halides according to the following general procedure. The alkylmercuric halide (0.026 mole) was dissolved and suspended in 150 ml of 10% aqueous sodium hydroxide. A solution of 8.33 g (0.035 mole) of stannous chloride dihydrate in 100 ml of aqueous sodium hydroxide was added. After 3 hours of agitation the system was steam-distilled (methyl and ethyl) or ether-extracted (propyl and butyl). All were dried with magnesium sulphate over an ether solution or (methyl)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

directly by potassium hydroxide pellets and then distilled. All except dimethylmercury (m.p. −42.8 to −41.9°) are unstable in light and dibutylmercury is unstable to heat.

PHYSICAL PROPERTIES OF DIALKYLMERCURY HOMOLOGUES

Alkyl	Boiling point, °C	mm	n_D^{20}
Methyl	90.7–91.1	755	1.54512
Ethyl	50–51	16	1.54541
n-Propyl	80.0–80.6	16.5	1.51755
n-Butyl	67	0.55	1.50812
	48	0.35	

Other bis-Mercurials

Diphenylmercury was dissolved in hot 93% ethanol (40 ml per g) and allowed to cool very slowly with stirring, m.p. 125–126°. The purification of 1,7-dimercura-4,10-dioxacyclododecane (10) was effected by crystallization from chloroform, m.p. 145–146°, and its dielectric constant at 22° was found to be 2.975. Hexafluorodimethylmercury as received from Mr. Fishel was sublimed at 85–95° and 750 mm until the melting point was constant at 166–166.5°.

Purification of Solvents

Benzene was purified according to a previous description (17) and was stored over sodium under nitrogen, $\epsilon = 2.284$ and $d = 0.8788$ at 20°. Dioxane, prepared as was described previously (17), was stored under nitrogen without sodium, $\epsilon = 2.224$ and $d = 1.0336$ at 20°. Carbon disulphide was thrice-stirred during 2 hours with 100 ml of 2.5% aqueous potassium permanganate per liter, then for 5 hours with metallic mercury (250 g per liter), and finally with 2.5% aqueous mercuric chloride (100 ml per liter). After drying with phosphorus pentoxide the solvent was distilled and stored under nitrogen in the dark, $\epsilon = 2.646$ and specific volume = 0.79135. Like dioxane it is unstable. The purification of 11 liters of carbon tetrachloride was accomplished by the method of Ingold and Powell (18) by digestion at 50–60° for 3 hours with 750 ml of Fehling's solution. The non-aqueous layer was then refluxed with 5% aqueous sodium hydroxide for 3 hours, then washed with water and stirred about 15 times with 100-ml lots of concentrated sulphuric acid until coloration ceased. After being washed with aqueous sodium carbonate the carbon tetrachloride was azeotropically distilled to remove most of the water. Then it was dried with phosphorus pentoxide, distilled, and stored under nitrogen in dark bottles, $\epsilon = 2.2415$ and $V = 0.62730$ at 20°.

Dielectric Constants of Solutions

All determinations were made at 500 kc in the apparatus described previously (19). Except for the studies with diphenylmercury in carbon tetrachloride no experiment was accepted if the individual determinations did not permit linear plots of $d\epsilon/d\omega$ (α) and $dV/d\omega$ (β). Moreover, no experiment was accepted in which the extrapolations of α and β to zero concentration differed more than ± 0.0002 in specific volume and ± 0.002 in dielectric constant from the values tabulated as follows.

Dielectric Constants of Solids

The method described previously (17, 20) has been followed. The pellet thickness was measured after the determination at 5 Mc by averaging the gauged value at 4

DIELECTRIC CONSTANTS AND SPECIFIC VOLUMES OF PURE SOLVENTS

Solvent	20°		25°		30°		40°	
	ϵ	V	ϵ	V	ϵ	V	ϵ	V
Benzene	2.2849	1.1381	–	–	2.2612	1.1524	2.2395	1.1670
Dioxane	2.2206	0.9675	–	–	–	–	2.1851	0.9900
Carbon disulphide	2.6470	0.7911	–	–	–	–	–	–
Carbon tetrachloride	2.2426	0.6273	2.2306	0.6313	–	–	2.1986	0.6436
	2.2380	0.6270	2.2272	0.6310*	–	–	2.1962	0.6435

*The final six values are the best obtained for CCl_4 to date.

quadrants of the cylinder; also oftentimes the pellet was broken into halves and the center measured as well. A redetermination of the dielectric constant of diphenylmercury pellets gave a value of 57.1 cc, thus confirming the previously reported value (19).

Infrared Spectrum of Diphenylmercury

Only three absorption bands were found in the 900–300 cm^{-1} spectral region for a 10% solution of diphenylmercury in benzene, although the strong absorption of the solvent at 680 cm^{-1} may have obscured the behavior of diphenylmercury in this frequency range. The bands at 732 cm^{-1} (80% absorption) and 706 cm^{-1} (40% absorption) were symmetrical and well resolved, but the band at 463 cm^{-1} (30% absorption) was unsymmetrical, showing evidence of perturbations on the low frequency side. This band also is of interest because of its possible relationship to the angle of swing postulated by deLazlo (21) for *bis*-bromophenylmercury.

Organomercuric Halides

With the exception of the first and fourth items of Table III these substances were prepared by cleavage of *bis*-mercurials by means of mercuric chloride in ether solution. The methylmercuric chloride was crystallized (13 ml per g) from 95% ethanol, m.p. 168.7–169.6°. The ethyl analogue from 1:1 benzene – carbon tetrachloride melted at 191.8–192.9°. The propyl homologue from 95% ethanol (15 ml per g) melted at 141–143° but after sublimation melted at 142.1° to 142.7°. The butyl homologue crystallized from benzene (5 ml per g) to melt at 125.5–126.2° and then from 95% ethanol (15 ml per g) to melt at 126.9–127.2°.

The preparation of chlormethylmercuric chloride was carried out according to Hellerman and Newman (22). The 97.5% yield was crystallized from ethanol, m.p. 128.5–130°. The X-ray diffraction is [10] 10.59, 3.22; [8] 4.05, 3.26; [6] 2.65, 2.62; [4] 1.90; [2] 2.35, 3.52; [1] 4.87, 2.93, 2.43, 2.00. It is of interest that the compound also may be obtained by the action of diazomethane on 2-hydroxyorganomercuric halides.

These chloromercurials were prepared to demonstrate that the R–Hg group becomes more electropositive with increasing size in the normal homologous series. This behavior is shown in Table III.

TABLE III

A study of the dielectric constants of these solid organomercurials is in progress with a view to clarify the discrepancy between the P_{e+a} values which we have measured versus the calculated values which appear in the literature (23).

THEORETICAL ASPECTS OF THE UNIMOLECULAR DECOMPOSITION OF NITROUS OXIDE[1]

E. Kerry Gill and Keith J. Laidler

ABSTRACT

The kinetic data for the unimolecular decomposition of nitrous oxide, recently analyzed by Johnston, have been considered from the standpoint of the theories of unimolecular decompositions. Particular attention is paid to the high-pressure first-order rates, the low-pressure second-order rates, and the pressure range over which the rates fall off. A normal-mode analysis is made for the molecular vibrations, and calculations are made on the basis of N. B. Slater's theory. It is found that when the change of multiplicity is taken into account the Slater theory gives a satisfactory interpretation of the high-pressure behavior, but gives rates that are much too small in the low-pressure region. The theories of Hinshelwood, Kassel, and Rice and Ramsperger account more satisfactorily for the rate of activation, and Kassel's theory accounts for the pressure fall-off. A modified theory of unimolecular reactions is proposed to explain the observed results.

INTRODUCTION

The thermal decomposition of nitrous oxide is of very special interest, since the molecule is one of the simplest capable of undergoing unimolecular breakdown. The reaction is therefore particularly suitable for testing the various theories of unimolecular reactions that have been proposed. Until recently the experimental results for the reaction have been somewhat confusing, owing to various complications such as the existence of surface effects. However Johnston (1) has recently carried out a detailed critical analysis of the various results and has shown that when the complications are eliminated the reaction represents an excellent example of a straightforward unimolecular decomposition. It is possible that Johnston slightly oversimplifies the situation (2), but it seems likely that the rate constants he deduces for the high- and low-pressure reaction are close to the true ones. They should certainly be sufficiently reliable to permit a careful test of the theories, and this is what has been done in the present paper. A similar analysis of the hydrogen peroxide decomposition has also been carried out and will be published elsewhere (3) together with a more detailed treatment of mechanisms (4).

As far as the high-pressure behavior is concerned, all modern theories of unimolecular reactions lead to approximately the same conclusions. Hinshelwood's expression (eq. [4] below) for the rate of energization together with Kassel's equation for the rate of breakdown of a critically energized molecule leads to the result that the high-pressure first-order rate constant is

$$k_\infty = k^{\ddagger} e^{-\epsilon^*/\mathbf{k}T}, \qquad [1]$$

where $k^{\ddagger}$ is of the order of magnitude of a vibrational frequency in the molecule ($\sim 10^{13}$ sec^{-1}) and ϵ^* is the energy of activation per molecule. Slater's theory (5, 6, 7, 8, 9, 10, 11) leads to the similar result that

$$k_\infty = \bar{\nu} e^{-\epsilon^*/\mathbf{k}T}, \qquad [2]$$

where $\bar{\nu}$ is a specially weighted average of the vibrational frequencies in the molecule. Eyring's absolute rate theory (12, 13) gives the relationship

$$k = \frac{\mathbf{k}T}{h} \frac{f^{\ddagger}}{f} e^{-\epsilon^*/\mathbf{k}T}, \qquad [3]$$

[1]*Manuscript received June 30, 1958.*
Contribution from the Department of Chemistry, the University of Ottawa, Ottawa 2, Canada.

where $\mathbf{k}T/h$ is close to a vibration frequency and the ratio of partition functions $f^{\ddagger}/f$ is usually close to unity. Frequency factors of 10^{13} sec^{-1} are therefore satisfactorily explained by all theories. Values significantly greater than this, of which there are a number of examples, are explained on the basis of eq. [3] in terms of a high value of $f^{\ddagger}/f$, which corresponds to a large positive entropy of activation. Modifications to equations [1], [2], and [3] are necessary when, as with nitrous oxide, the equation involves a change in multiplicity and therefore a small transmission coefficient.

As far as the low-pressure second-order behavior is concerned there are much wider divergences between the different theories of unimolecular reactions. This low-pressure rate is actually the rate of energization of the molecules, and there are two main expressions for this rate, corresponding to two fundamentally different definitions of energization. One of these expressions was first proposed by Hinshelwood (14) and has been employed in the subsequent theories of Kassel (15, 16) and of Rice and Ramsperger (17, 18). The definition of energization to which this expression applies is that the molecule contains, distributed amongst its s normal modes of vibration, at least the energy ϵ^* required for the reaction to occur. The rate of energization to this energy state is, to a good approximation,

$$k_1 = Z \frac{1}{(s-1)!} \left(\frac{\epsilon^*}{\mathbf{k}T}\right)^{s-1} e^{-\epsilon^*/\mathbf{k}T}, \qquad [4]$$

where Z is the collision number. Inherent in this treatment is the assumption that the energy can flow freely between the various modes so that provided the energy ϵ^* is in the molecule it may, after a sufficient number of vibrations, pass into one particular normal mode which is involved in the breakdown of the molecule.

In Slater's theory the contrary assumption is made that there can be no flow between the normal modes. Reaction occurs not when the energy gets into a particular mode but when the vibrations come suitably into phase, so that a critical co-ordinate becomes sufficiently extended. Not all molecules which are energized in the HKRR* sense are capable of undergoing reaction; only those which initially have the energy distributed in a particular way among the normal modes are capable of doing so. Slater's definition of energization is therefore a more stringent one than is HKRR's, and his expression for the rate of energization gives rise to much lower values. The expression is approximately

$$k_1 = Z\,(\epsilon^*/\mathbf{k}T)^{\frac{1}{2}(n-1)}(4\pi)^{\frac{1}{2}(n-1)} \prod \mu_k\, e^{-\epsilon^*/\mathbf{k}T}, \qquad [5]$$

where n is the number of normal modes concerned in the reaction and the μ's are quantities that are related to the "amplitude factors" for the various normal modes. A rigorous test of Slater's theory can only be made by carrying out a detailed vibrational analysis, a matter of considerable difficulty for all except very simple molecules. Slater's theory has been applied quantitatively to cyclopropane, which isomerizes thermally into propylene, and the results were very satisfactory (8). With hydrogen peroxide, on the other hand, the calculated low-pressure rates were much smaller than the experimental ones (3).

In the present paper both the HKRR and Slater theories are applied quantitatively to the nitrous oxide decomposition. It will be seen that Slater's expression gives much too low a rate of energization, but that the theory provides a satisfactory formulation

This abbreviation will be used to denote the point of view taken in the theories of Hinshelwood, Kassel, and Rice and Ramsperger.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

for the first-order behavior. A more general treatment of unimolecular processes is outlined at the end of this paper.

THE EXPERIMENTAL DATA

Only the bare results will be stated here; for a more detailed discussion of the experimental work reference should be made to Johnston's paper (1). The rate-controlling step is believed to be

$$N_2O = N_2 + O,$$

a reaction that is endothermic by 39.5 kcal. The high-pressure activation energy of the reaction is close to 60.0 kcal. At 888° K the high-pressure first-order rate constant is

$$k_\infty = 7.47 \times 10^{-4} \text{ sec}^{-1},$$

and this corresponds to a frequency factor of

$$8.134 \times 10^{11} \text{ sec}^{-1}.$$

By extrapolation of Johnston's second-order rate coefficients to zero pressure we estimate the rate of energization to be

$$k_1 = 14.0 \text{ cc mole}^{-1} \text{ sec}^{-1}.$$

The pressure at which the first-order rate coefficient falls to one-half of its limiting value is approximately

$$p_{\frac{1}{2}} = 1.3 \times 10^4 \text{ mm}.$$

THEORY OF THE HIGH-PRESSURE RATES

The experimental frequency factor at high pressures, 8.134×10^{11} sec^{-1}, is significantly below what would be expected on the basis of equations [1], [2], and [3] above. The frequencies of vibration of the molecule are of the order of 10^{13} sec^{-1}, so that $k^{\ddagger}$ in Kassel's theory is of this magnitude. Slater's average vibrational frequency, weighted using the μ values derived below, is

$$\bar{\nu} = 4.50 \times 10^{13} \text{ sec}^{-1}.$$

The value of $\mathbf{k}T/h$ at 888° K is equal to 1.85×10^{13} sec^{-1}. It is therefore seen that the experimental value is too low by between one and two powers of 10.

The reason for this lies in the fact that the rate-controlling step involves a change of multiplicity:

$$N_2O(^1\Sigma) \rightarrow N_2(^1\Sigma) + O(^3P).$$

Since a triplet and a singlet can only give a triplet it follows that the reaction must involve a transition from one potential-energy curve to another, as represented schematically in Fig. 1. The ground state of N_2O correlates with $N_2(^1\Sigma)$ and $O(^1D)$, and the curve for this crosses the repulsive curve for $N_2(^1\Sigma) + O(^3P)$. The forms of these curves have been discussed by Stearn and Eyring (19). At the time their paper was published, however, the experimental evidence pointed to an activation energy as low as 52 kcal and a transmission coefficient of about 10^{-4}. This suggested a resonance splitting of as little as 5 cal per mole, and difficulty was experienced in explaining such a small value. The value of 10^{-1} to 10^{-2} obtained above leads to a resonance separation of the order of 500 cal per mole and this is what might reasonably be expected on the basis of spin–orbit interactions (19).

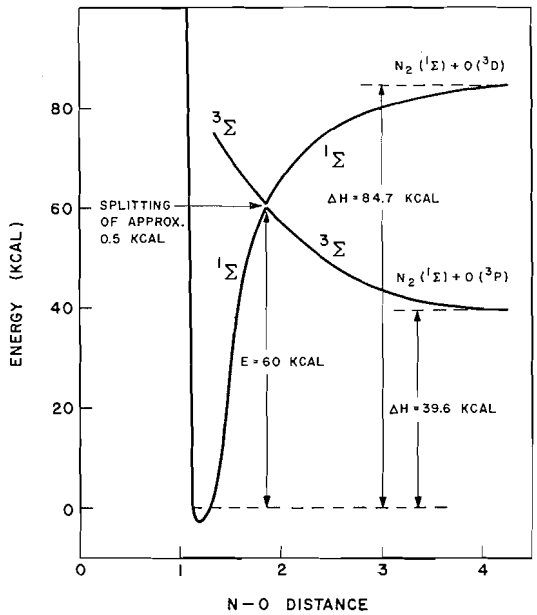

FIG. 1. Schematic potential-energy curves for the decomposition of nitrous oxide. The curves are based on those calculated by Stearn and Eyring, but are modified slightly to accommodate the latest thermochemical and kinetic values.

THEORY OF THE LOW-PRESSURE RATE

The low-pressure second-order rate constant, found experimentally to be about 14.0 cc $mole^{-1}$ sec^{-1}, is, according to all theories, the rate of energization of the molecule. This value must be explained in terms of the distribution of the energy of activation amongst the four normal modes of vibration, with or without flow of energy between the normal modes. In the calculations the collision diameter will be taken as 3.31×10^{-8} cm, as employed by Johnston (1). At 888° K this corresponds to a collision number Z of

$$3.182\times10^{-10} \text{ cc molecule}^{-1} \text{ sec}^{-1} = 1.916\times10^{14} \text{ cc mole}^{-1} \text{ sec}^{-1}.$$

The HKRR Theory

With s equal to 2 and ϵ^* equal to 60.0 kcal per mole the value of k_1 calculated using eq. [4] is 6.09 cc $mole^{-1}$ sec^{-1}, which is reasonably close to the experimental value of 14.0 cc $mole^{-1}$ sec^{-1}. This choice of s gives the best agreement; $s = 4$, for example, leads to 1.22×10^3 cc $mole^{-1}$ sec^{-1}. The reason that $s = 3$ and $s = 4$ leads to rates that are too high is presumably that there is little flow of energy between the two axial and the two bending modes (see below).

Slater's Theory

A vibrational analysis for the N_2O molecule has been carried out, and the details are given in the Appendix. The molecule is linear and the normal modes of vibration are shown in Fig. 2. Two of the frequencies, ν_1 and ν_3 in the conventional notation, correspond to axial vibrations, and one frequency, ν_2, corresponds to the doubly degenerate vibrations perpendicular to the axis. The motion of the molecule may be described in terms of three co-ordinates w, x, and y, of which w denotes the mutual displacement of the nitrogen atoms and x and y the components of the displacement of the oxygen atom relative to the center of the N–N distance; x is along the axis of the molecule and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

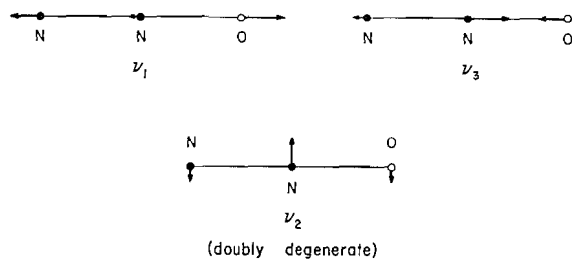

FIG. 2. The normal vibrations of nitrous oxide. The molecule is drawn to scale (equal N–N and N–O distances) and the vector lengths approximately represent the relative displacements.

y perpendicular to it. The analysis (cf. Appendix) leads to the result that the ratios of the displacements are:

$$\begin{aligned} &\text{for } \nu_1 \quad x{:}w{:}y = 1.00{:}0.429{:}0, \\ &\text{for } \nu_2 \quad x{:}w{:}y = 0{:}0{:}\text{constant}, \\ &\text{for } \nu_3 \quad x{:}w{:}y = -0.857{:}1.00{:}0. \end{aligned}$$

In applying Slater's theory we shall take as the critical co-ordinate for the dissociation into $N_2 + O$ the distance from the O to the center of mass of N–N. The variation in this co-ordinate, p, is equal simply to x; it does not involve w and y. Since the bending vibrations involve only y it follows that they do not contribute to the decomposition, so that we must take n equal to 2.* The amplitude factors, α, and the corresponding μ's, corresponding to the two axial vibrations are shown in Table I. The product of the μ's is given by

$$[6] \qquad \prod_k \mu_k = \mu_1\mu_3 = 0.3824.$$

Using eq. [5] the value of k_1 is then found to be, with $n = 2$,

$$k_1 = 1.40 \text{ cc mole}^{-1} \text{ sec}^{-1}.$$

This is below the experimental value by a factor of 10.

TABLE I

FREQUENCIES AND AMPLITUDE FACTORS (α AND μ) FOR THE TWO AXIAL MODES

i	ν_i/sec^{-1}	α_i	μ_i
1	3.864×10^{13}	1.300×10^{-3}	0.9066
3	6.709×10^{13}	-0.6048×10^{-3}	0.4218

THE FALLING-OFF OF THE HIGH-PRESSURE RATE COEFFICIENT

Figure 3 shows the experimental first-order rate coefficients as a function of pressure. The two lines to the left show the theoretical behavior based on Kassel's theory (15, 16), with s equal to 2 and to 4. These curves were constructed by numerical integration of Kassel's general rate equation

**It is readily shown using Slater's procedures that the bending vibrations do not make a contribution for any choice of axial co-ordinate.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

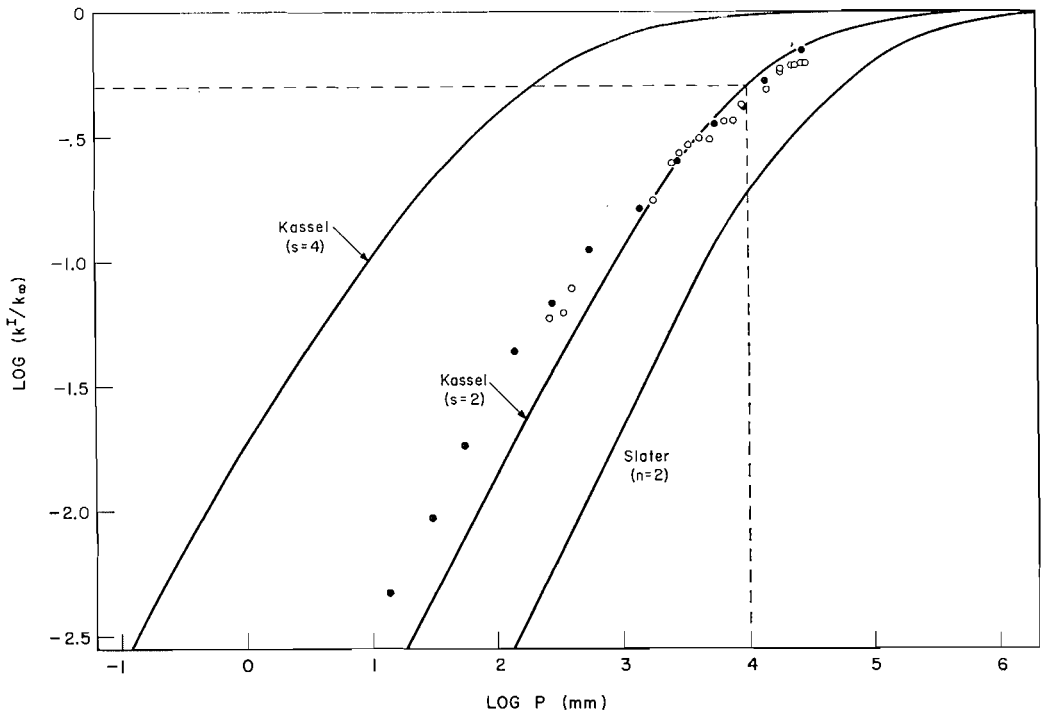

FIG. 3. Plot of the logarithm of the first-order rate coefficient against the logarithm of the pressure. The open circles represent the values given by Johnston (1), the closed circles values obtained by extrapolation. The calculated Kassel curve with $s = 2$ is seen to lie close to the experimental points, whereas Slater's curve gives rates that are too low except in the high-pressure region.

[7] $$\frac{k^I}{k_\infty} = \frac{1}{(s-1)!}\int_0^\infty \frac{x^{s-1}e^{-x}dx}{1+\dfrac{k^\ddagger}{k_{-1}[A]}\left(\dfrac{x}{b+x}\right)^{s-1}}$$

using the values

$$b = 34.63,$$
$$k^\ddagger = 7.47\times10^{-4}\ \text{sec}^{-1}\ \text{(experimental)},$$
$$k_{-1} = 3.182\times10^{10}\ \text{cc molecule}^{-1}\ \text{sec}^{-1}.$$

The curve for $s = 4$ is shown to lead to rates that are much higher than the experimental ones, but that for $s = 2$ falls very close to the experimental values. The pressure for $s = 2$ at which k^I reaches one-half the limiting rate is 1.3×10^4 mm, and this is essentially the same as the experimental value. It is of interest that the approximate relationship

[8] $$[A]_{\frac{1}{2}} = k_\infty/k_1$$

for the half pressure leads to a value of 6.78×10^3 mm.

Slater's curve is of the same shape as Kassel's, but is displaced to the right as shown in Fig. 3. The predicted half pressure is 6.3×10^4 mm, which is significantly larger than the observed value.

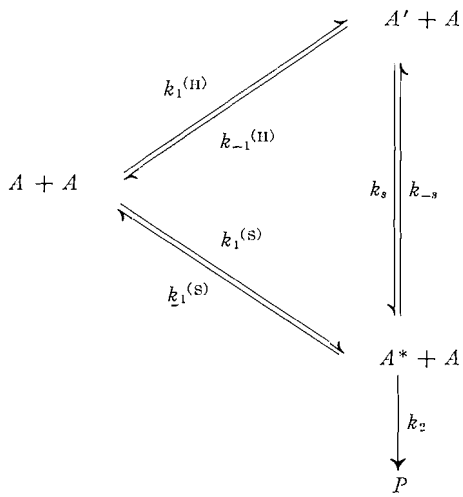
DISCUSSION

The main conclusion of the present work is that the Kassel treatment with s equal to 2 leads to satisfactory rates over the entire pressure range, and to a reliable estimate of the half pressure. The Slater expression, however, leads to rates that are significantly too low except in the high pressure region, and to too high a value for the half pressure.*

A similar conclusion has also been reached in the case of hydrogen peroxide (3) and other small molecules (4). Since a theoretical discussion of this problem is to be presented elsewhere (4) it will suffice at the present stage to note that in the case of small molecules there appears to be flow of energy between the normal modes, as envisaged by the HKRR theories but not by Slater's theory. Our view is that Slater is right in regarding reaction as occurring when a critical co-ordinate becomes sufficiently extended, but may be in error in prohibiting flow of energy between the modes.

A scheme of reactions that is consistent with this view is



Here a distinction has been made between the two types of energized molecules, represented by A' and A^*. The A^* molecules are those that are energized in the Slater sense; they contain ϵ^* or more of energy and have it distributed between the modes in such a way that, when the vibrations come suitably into phase, there can be a sufficient extension of the critical co-ordinate. The A' molecules are energized in the less stringent HKRR sense, the energy ϵ^* or more being simply distributed between the modes and *not* being suitably distributed for reaction to occur except by a flow of energy.

This scheme of reactions leads to Slater's expression for the high-pressure rate, and in general to the HKRR formula [4] at low pressures. If there is no flow, i.e. if $k_s = k_{-s} = 0$, Slater's theory will be correct at all pressures, but otherwise the HKRR formula will apply at least over a certain range.

Further implications of the mechanism, together with a discussion of other reactions, will be discussed elsewhere (4).

**It is worth mentioning that the treatment given involves the assumption that deactivation occurs on every collision. If this is not the case the Slater and Kassell rates of energization are correspondingly reduced. The conclusion that Slater's rate of energization is too low is then true a fortiori, Kassel's rates with $s = 2$ would then be too low, but agreement might be obtained with s equal to 3 or 4.*

APPENDIX

Vibrational Analysis

The theory of vibrations in asymmetric linear triatomic molecules, and of N_2O in particular, has been discussed by Rosenthal (20). The potential and kinetic energy functions and molecular parameters employed in that paper, along with the calculated force constants, have been used in the present investigation to compute the amplitude factors and other quantities required for Slater's treatment of unimolecular reactions.

The vibrational modes were shown above in Fig. 2. The mutual displacement of the nitrogen atoms is denoted by w, while x and y are the components of the displacement of the oxygen atom relative to the center of the two nitrogen atoms; x is the displacement along the axis and y that perpendicular to it.

The most general quadratic potential function consistent with geometrical symmetry may be written in terms of four force constants:

$$V = \tfrac{1}{2}(Ax^2+Bw^2+Cy^2+2Dxw). \quad [9]$$

If q_{NN} and q_{NO} denote the N–N and N–O distances we may define q and α by

$$q \equiv q_{NN}+q_{NO}, \quad [10]$$

$$\alpha \equiv q_{NN}/(2q_{NO}+q_{NN}), \quad [11]$$

and

$$\mu \equiv M/(M+2m), \quad [12]$$

where M and m are the masses of the oxygen and nitrogen atoms, respectively. The kinetic energy is then

$$T = \tfrac{1}{2}m\{2\mu\dot{x}^2+\tfrac{1}{2}\dot{w}^2+2\alpha^2\dot{y}^2[1+(\alpha^2/\mu)]^{-1}\}. \quad [13]$$

Using the definitions

$$E \equiv 2\mu, \quad [14]$$

[15] $$F \equiv \tfrac{1}{2},$$

[16] $$G \equiv 2\alpha^2[1+(\alpha^2/\mu)]^{-1},$$

the secular determinant is

[17] $$\begin{vmatrix} A-mE\lambda & D & 0 \\ D & B-mF\lambda & 0 \\ 0 & 0 & C-mG\lambda \end{vmatrix} = 0.$$

The observed frequencies are (21)

$$\nu_1 = 1288.7 \text{ cm}^{-1},$$
$$\nu_2 = 588.3 \text{ cm}^{-1},$$
$$\nu_3 = 2237.9 \text{ cm}^{-1},$$

and the values derived by Rosenthal (20) are:

$$\lambda_1 = 58.94\times10^{26} \qquad A = 14.72\times10^5 \text{ dynes cm}^{-1},$$
$$\lambda_3 = 1777.0\times10^{26} \qquad B = 17.20\times10^5 \text{ dynes cm}^{-1},$$
$$D = -7.08\times10^5 \text{ dynes cm}^{-1}.$$

By the use of the secular determinant [17] it is then found that

for ν_1, $x: w: y = (B-mF\lambda_1): -D: 0,$
$= 1.00: 0.429: 0;$

for ν_2, $x: w: y = 0: 0: (C-mG\lambda_2),$
$= 0: 0:$ constant;

for ν_3, $x: w: y = D: -(A-mE\lambda_3): 0,$
$= -0.857: 1.00: 0.$

In the application of Slater's method employed above, the critical co-ordinate was taken as the distance between the center of mass of the N–N system and the O atom. The variation p in this co-ordinate is equal to x, and the amplitude factor α_i is given by

[18] $$\alpha_i = \gamma_{xi} = x_i/\sqrt{V_{ii}}.$$

The calculated α's were shown in Table I above, which also gives the corresponding μ's.

The rest of the calculation is explained in the main body of the paper.

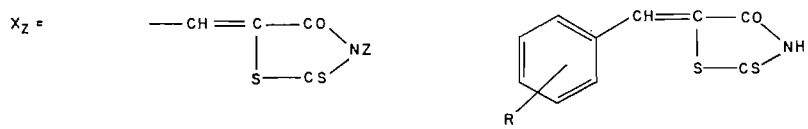
THE CONDENSATION OF RHODANINE WITH AROMATIC DIALDEHYDES AND SOME RELATED COMPOUNDS[1]

FREDERICK J. ALLAN,[2] G. GRAHAM ALLAN,[3] AND J. B. THOMSON

ABSTRACT

The condensation of rhodanine and its 3-ethyl and 3-phenyl derivatives with terephthaldehyde, pyridine-2,6-dicarboxaldehyde, and phthaldehyde has been investigated. Twenty-nine 5-arylidene-rhodanines containing an electrophilic substituent in the aromatic ring have been prepared.

Rhodanine condenses readily with a variety of aliphatic (1, 2, 3, 4), aromatic (5, 6), and heterocyclic (7, 8) aldehydes. The analogous reaction with ketones has been less extensively investigated (9, 10). Very few examples of rhodanine–diketone interaction have been described (11, 12, 13, 14, 15, 16) and we have been unable to find in the literature any reference to the condensation of rhodanine with dialdehydes. Our interest in rhodanine–dialdehyde adducts was actuated by the fungicidal and mildew-proofing properties of the 5-substituted rhodanines (I) in general, and the 5-arylidene-rhodanines (II) in particular (5, 6). In spite of the many variants of R in (II) only two compounds in which R is electrophilic have been evaluated as fungicides (5). The location of the substituent diminished or increased the fungitoxicity of (II), suggesting evaluation of electron distribution as a rationale for structure and activity. With a view to preparing further examples of this type of compound for testing we have examined the condensation of some aromatic dialdehydes with rhodanine derivatives.



(I) (II)

in X_H (Z = H), X_{Et} (Z = C_2H_5), X_{Ph} (Z = C_6H_5).

Termolecular reaction of rhodanine and the 3-ethyl and 3-phenyl derivatives (two molecular proportions) with terephthaldehyde (III*a*) or pyridine-2,6-dicarboxaldehyde (IV*a*) (one molecular proportion) proceeds with great facility to yield the diadducts (III*b*), (III*c*), (III*d*), (IV*b*), (IV*c*), and (IV*d*) respectively, which separated from the reaction mixture in an almost pure state. The aldehyde–rhodanine derivatives were prepared using ammonia – ammonium chloride (17), acetic acid – sodium acetate (19), or acetic acid – acetic anhydride – sodium acetate (7) as condensing agents. No crystalline adducts were obtained from the reaction of phthaldehyde with either rhodanine, 3-ethyl-, or 3-phenyl-rhodanine using these reagents or with 3-ethylrhodanine under the conditions used to condense phthaldehyde with malonic ester (18). Condensation of equimolecular proportions of 3-ethyl- or 3-phenyl-rhodanine (but not rhodanine itself) with the dialdehydes (III*a*) and (IV*a*) gave readily separable mixtures of the appropriate diadducts

described above and the related monoadducts (III*e*), (III*f*), (IV*e*), and (IV*f*). The retention of a free formyl group under the conditions of condensation is evidenced by analysis and the formation of an oxime (III*g*).

Concurrently with this study we have prepared for fungicidal and antibacterial evaluation* fifteen 5-arylidene-rhodanines (II) containing an electrophilic substituent in the benzenoid moiety and comprising two groups. The first group consists of the adducts (III*h*) to (III*p*) inclusive, containing the toxiphoric nitro group, which were synthesized by the condensation of rhodanine, its 3-ethyl and 3-phenyl homologues with 2-, 3-, and 4-nitrobenzaldehyde. The second group of adducts, (III*q*) to (III*v*) inclusive, was derived from the condensation of rhodanine and its congeners with phthaldehydic and terephthaldehydic acid; analogous derivatives of which have recently received attention as bactericidal agents (20, 21).

EXPERIMENTAL†

1,4-Phenylene-di-(5-methylenerhodanine) (III*b*)

A solution of terephthaldehyde (1.34 g, 0.01 mole) and rhodanine (2.66 g, 0.02 mole) in ethanol (20 ml) and concentrated ammonium hydroxide (7 ml, d., 0.88) was heated on the steam bath. A solution of ammonium chloride (7 g) in hot water (10 ml) was added and heating continued for 1 hour when orange needles had separated. Recrystallization from dimethylformamide gave the diadduct III*b* as fine orange needles (2.8 g, yield 77%) which did not melt below 360°. Calc. for $C_{14}H_8N_2O_2S_4$: C, 46.08; H, 2.2; N, 7.68; S, 35.25. Found: C, 45.81; H, 1.95; N, 7.31; S, 35.00%.

**Details of which we hope to publish later elsewhere.*

LIGHT-SCATTERING STUDIES ON ALUMINUM DISTEARATE[1]

A. E. Leger, J. C. Hyde, and H. Sheffer

ABSTRACT

A light-scattering study of aluminum distearate in dilute benzene solution suggests that it is a linear molecule of random coil shape. This is further substantiated by intrinsic viscosity – molecular weight data, the constancy of the ratio of the molecular weight to the square of the radius of gyration (Rg), the value of Φ in Flory's intrinsic viscosity – molecular weight relationship, and the close agreement between the theoretical and experimental results found for the unit length of the polymer chain. This average unit length has been calculated to be 4.46 Å.

INTRODUCTION

The fundamental structure of aluminum soaps remains rather obscure, although most authors (1, 2, 3, 4, 5, 6, 7, 8) agree that these substances dispersed in organic solvents are high polymers, the monomeric unit being the basic aluminum disoap, e.g. aluminum hydroxydistearate. Opinions differ, however, as to the nature of the chemical bonding between the monomeric units. McGee (6) and Gray and Alexander (5) have proposed an alternation of covalent and co-ordination bonds between the aluminum atom and oxygen atom of the hydroxyl radical to form the polymer chain. McBain (2) favors an association of the molecules into micelles, while McRoberts and Schulman (3) attribute the weak type of bonding exhibited by these molecules to hydrogen bonding. Recently the present authors (8) and Bauer *et al.* (7) gave evidence in favor of a structure similar to that proposed by Gray and Alexander, but with the carboxylate group also acting as a bridge between two aluminum atoms. These co-ordination bridge structures could easily be broken and could account for the changes in physical properties of solutions or gels on dilution, peptization, or on aging.

It has always been recognized that aluminum soap solutions are relatively unstable and deteriorate with time, with a gradual lowering of the molecular weight of the polymer. This instability has not as yet been fully explained but the breakdown is accelerated by moisture and in general by traces of acid or other polar compounds. The rate of change depends on the concentration, the more concentrated solutions being relatively more stable. A complete explanation of the physicochemical properties of aluminum soap solutions is impossible without a detailed knowledge of the structure of the soap molecule. It was considered important to obtain more data on molecular weight and viscosity characteristics of aluminum stearate solutions and deduce from these, if possible, the average size and shape of the molecules. It was recognized that interpretation of the results would be hampered by the instability of the polymer, so the experimental techniques employed were designed to diminish as much as possible its effect on the experimental data. Another limitation of the interpretation of the data lies in our lack of knowledge of molecular weight distribution characteristics and of any method of fractionation for this polymer.

Aluminum distearate swells in cold benzene and complete solution can be effected only by heating the mixture for some time. It would appear that the soap is a complex, probably cross-linked, polymer with relatively weak bonds. Prolonged heating causes the breakage of some of these bonds, resulting in a solution of polymer whose average molecular weight depends on the concentration.

If viscosity data are obtained for a series of solutions of differing concentration, made up by refluxing under standard conditions, a curve of the general shape OAB, as shown in Fig. 1, results. For a "starting" or refluxed solution of concentration 0.4%, point B is obtained. On dilution of this solution to 0.2% the reduced viscosity does not revert to point A but rather to point E (4), and by obtaining further points on the line BEC an intrinsic viscosity which is characteristic of the polymer in the 0.4% solution can be extrapolated. Similarly, dilution of the "starting" 0.2% solution gives the line AD and a lower intrinsic viscosity. Thus one can obtain characteristic intrinsic viscosities and corresponding average molecular weights for the polymers in the "starting" solutions. Viscosity and osmotic pressure data obtained in this manner were reported previously (4) and this paper extends the work to include light-scattering information.

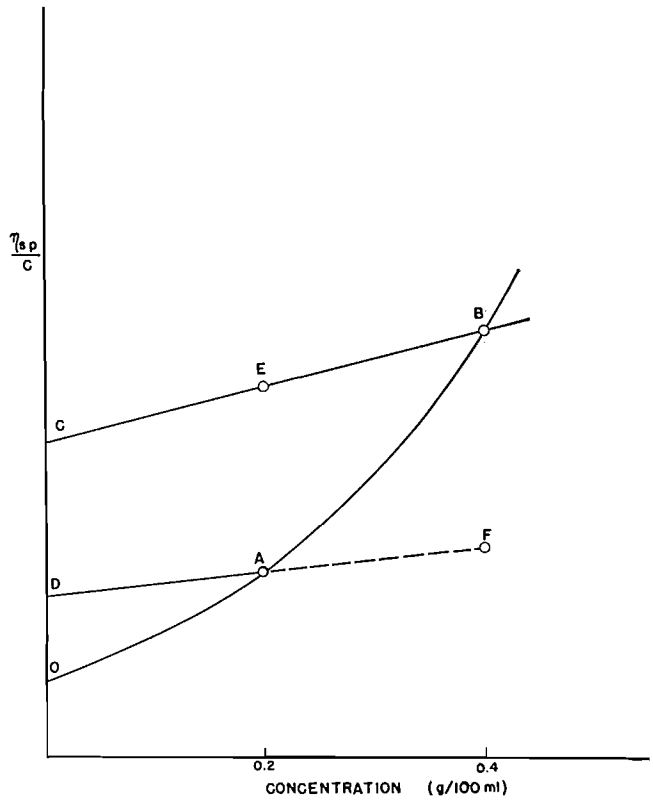

FIG. 1. A graphical representation of aluminum soap solution viscosity with changing concentration.

The fact that on dilution of solution *B* point E rather than A was obtained is an indication that the polymer is not merely an association colloid. Two other pieces of supporting evidence may be cited. One is that by melting and slowly resolidifying the soap under vacuum, material of much higher molecular weight is obtained (4) indicating that more polymer bonds are formed in the solid by this process than by association in solution. The other is concerned with the concentration of a dilute to a more concentrated one by evaporation of solution. On concentration of a 0.2% solution (point A) to 0.4%, point F on Fig. 1 is obtained rather than point B, which would be expected if the polymer were associating to larger micelles as the concentration is increased. This latter point was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

checked by light-scattering technique and it was found that solution F contained polymer of molecular weight within 10% of that of solution A, while solution B contained polymer of about five times the average molecular weight of polymer in solution A.

EXPERIMENTAL

Reagents

The aluminum distearate used in this investigation was prepared by the method described previously (4) and extracted with dry acetone in a Soxhlet to remove free fatty acid. Solutions were prepared by refluxing the soap in specially dried benzene for $1\frac{1}{2}$ hours under anhydrous conditions. A small portion of the benzene was distilled at the start of the refluxing period to remove any residual moisture from the soap, solvent, and glassware.

Viscosity

Viscosity measurements were made at $30° \pm 0.01°$ C using Ostwald viscometers with a benzene flowtime of about 100 seconds, and the data were corrected for kinetic energy.

Light-Scattering Measurements

The apparatus used for the light-scattering measurements has been described previously (9). The cell in cross section is half of a regular dodecagon so that it is possible to measure scattering at 90° and at two pairs of angles about 90° (33° and 147°, 60° and 120°). The appropriate correction for reflection at the exit face (10) was made. The wavelength used was 5461 Å, obtained from a mercury-vapor lamp (General Electric AH-4) with suitable filters. Reduced intensities were plotted by the Zimm method, extrapolating the data to zero angle and infinite dilution. A typical Zimm plot of the experimental data is given in Fig. 2.

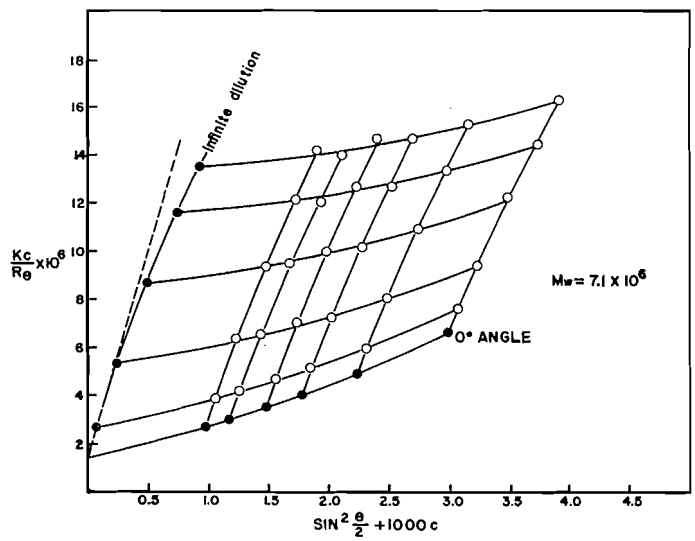

FIG. 2. A typical Zimm plot of experimental data obtained for aluminum distearate in benzene solution.

All measurements were made on aluminum distearate – benzene solutions previously cleared of dust particles by centrifuging at about 25,000 g for a few hours prior to use. A large number of "starting" solutions were prepared and the dilutions and measurements were made as fast as possible, the total time taken for each series being about 30 minutes.

RESULTS

A. Molecular Shape

The correlation of experimental data with theory is complicated by the lack of knowledge of the molecular weight distribution and by the possibility of branching of the polymer. However, it is possible to determine the radius of gyration (Rg) from the ratio of initial slope to the intercept in the Zimm plot, and the weight-average molecular weight from the reciprocal of the intercept of the infinite dilution curve. The use of the Zimm method obviates the necessity of making assumptions of the particle shape to obtain either value. The radius of gyration (Rg) and the weight-average molecular weight (Mw) are given in Table I for 21 different "starting" solutions of aluminum distearate. The ratio of the molecular weight Mw to the radius of gyration (M/Rg), to the square of the radius of gyration (M/Rg^2), and to the cube of the radius of gyration (M/Rg^3) are also given. It has previously been found (11, p. 211) that M/Rg is constant for spherical, $M/(Rg)^2$ for random-coiled, and $M/(Rg)^3$ for rod-shaped particles. As can be seen from Table I the ratio of M/Rg^2 has the greatest constancy. In making these calculations it is recognized that the absolute value of these ratios are in error as the molecular weight used is a weight average and Rg is a "Z" average length. Since, however, the "Z" and "W" average molecular weights will not have a widely varying ratio to one another, no great error is introduced in the constancy of the molecular weight radius of gyration ratio. This is especially true in the present case where the molecular weights considered are very high.

TABLE I

VALUES OF RADIUS OF GYRATION TO MOLECULAR WEIGHT RATIOS

Mw $\times 10^{-6}$	Rg Å	M/Rg $\times 10^{-2}$	$M/(Rg)^2 \times 10^{+2}$	$M/(Rg)^3 \times 10^{+5}$	$(\overline{r^2})^{\frac{1}{2}}$ Å
25.8	2790	8.95	3.20	1.13	6840

3.74	1150	3.25	2.82	2.46	2830
3.68	1190	3.09	2.60	2.38	2910
3.39	1220	2.78	2.28	1.87	2990
2.58	1020	2.52	2.47	2.42	2500
2.34	910	2.56	2.81	3.08	2220
1.32	750	1.76	2.35	3.14	1840
1.25	660	1.90	2.88	4.37	1660

The relative constancy of the M/Rg^2 ratio is an indication that the molecules are of the random coil type. It is known that for a random coil configuration the root-mean-square end-to-end length $(\overline{r^2})^{\frac{1}{2}}$ is equal to Rg $\sqrt{6}$. This relationship has been used to calculate the values of $(\overline{r^2})^{\frac{1}{2}}$ given in Table I.

It is also possible to correlate the light-scattering data with theoretically derived curves for spheres, coils, and rods and to determine which of these molecular shapes most closely satisfies the experimental data. The theoretical curves were calculated from the theoretical scattering functions for spheres, rods, and random coils and fitted to the experimental data to obtain the same 0° and 90° scattering. As can be seen in Fig. 3 the

experimental values are very close to the theoretical curves for random coils. Deviations of the curves could be explained by differences in polydispersity, branching, stiffness, or extension of the coils, and at the present time it would seem impossible to distinguish between these variables (12, 13).

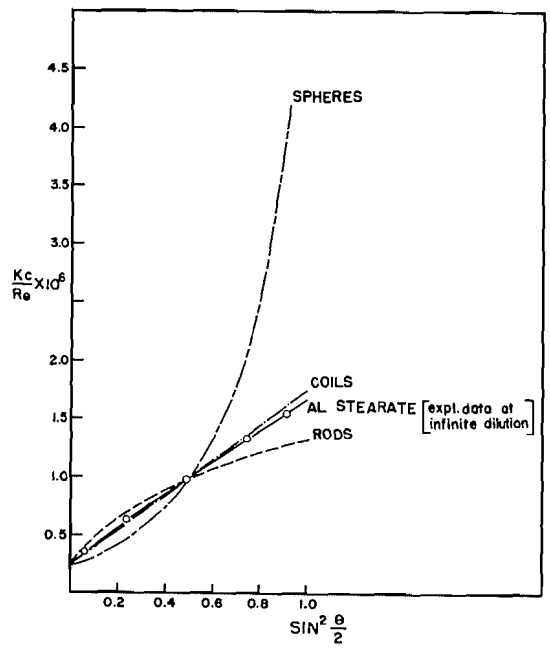

FIG. 3. A comparison of experimental data for aluminum distearate with theoretical curves for spheres, random coils, and rods.

Both the constancy of M/Rg^2 and the close agreement of the theoretical and experimental values lead to the conclusion that the molecules are indeed of the random coil type. This permits us to calculate the root-mean-square end-to-end distance as already noted and, as will be seen below, to derive some idea of the dimensions of the unit length of the molecule.

B. Viscosity – Molecular Weight Relationship

It is possible to derive some measure of the relationship between the intrinsic viscosity $[\eta]$ and the molecular weight of aluminum distearate (see Fig. 4). Although the data for extreme molecular weights introduce a curvature to the plot, for a large range of molecular weights this curve could be replaced by a straight line, within experimental error, which would correspond very closely to the theoretical value for linear molecules. This is shown by the dotted line in Fig. 4, its position having been determined by the least-squares method by neglecting the very high molecular weight and the very low viscosity values, which are less precise owing to experimental difficulties. The equation for this line is

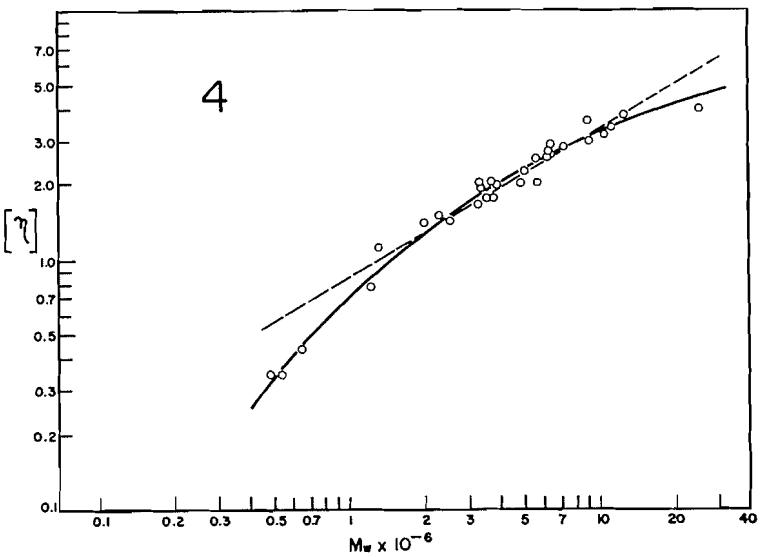
$$[\eta] = 2.93 \times 10^{-4} M^{0.58}$$

in which the value for α in $[\eta] = KM^{\alpha}$ corresponds rather closely to the expected value of 0.5, the theoretical value for linear molecules such as polybutadiene.

Huggins' "k'" values were calculated from the slope of the reduced viscosity–concentration curves. Its average value was 0.77, but the scatter of the experimental data

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

made it impossible to determine any possible molecular weight dependence. This value for k' is lower and more constant than those obtained previously (4) owing to a more precise method of measuring viscosity. In general, k' values greater than 0.5 have been accounted for by branching in well-fractionated polymer samples. Interpretation of the results in aluminum soap solutions is further complicated by the known polydispersity of the polymer and it would seem impossible at this time to separate one effect from the other.



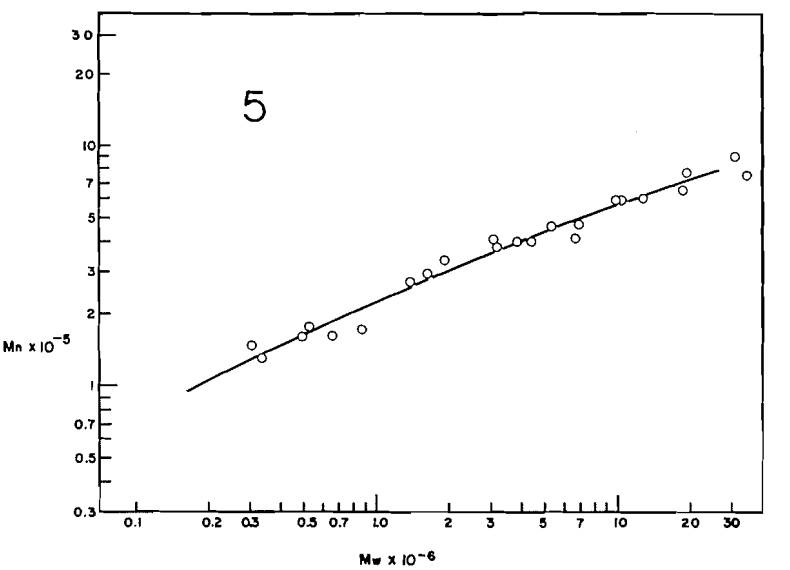


FIG. 4. Intrinsic viscosity [η] as a function of weight-average molecular weight (Mw) of aluminum distearate in benzene solution. The dotted line was obtained by neglecting three low molecular weight points and one high molecular weight point and drawing a straight line through the remainder by the method of least squares.

FIG. 5. Number-average molecular weight (Mn) as a function of weight-average molecular weight (Mw) for aluminum distearate in benzene solution.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

C. Number-Average and Weight-Average Molecular Weight Correlations

Previously published data (4) gave the relationship of number-average molecular weight (Mn) as measured by the osmotic pressure method to intrinsic viscosity.

The present study gives the weight-average molecular weight (Mw) also as a function of intrinsic viscosity. It is thus possible to correlate Mn to Mw and to indicate the polydispersity of the polymer. This relationship is shown in Fig. 5. Most of the data used in the $[\eta]$–Mn curve were obtained for aluminum dilaurate, but since there did not seem to be any significant change in this relationship for other aluminum soaps, the same values were used for aluminum stearate. The ratio of Mw/Mn varies from about 30 for an Mw of 10^7 to about 3 for an Mw of 10^6. This relationship emphasizes the very wide polydispersity of the aluminum soaps and will be used below to calculate unit lengths in aluminum soap polymers.

As the polymer chains are broken down to lower molecular weight units the polydispersity decreases. Evidence was obtained to show that bond breakage does not occur near the end of the chain to form monomers or other small units. For this a Fuoss–Mead osmometer was used with a "fast" membrane, and diffusion rates through the membrane were obtained for a series of polystyrene fractions of known molecular weight. Comparing the results with those obtained for aluminum stearate solutions it was ascertained that not more than traces of soap polymer were present with molecular weight below 80,000.

D. Unit Length in Aluminum Stearate Polymer

It should be possible to derive an estimate of the unit length of the polymer chain by making certain assumptions. A molecular model for aluminum disoap has been proposed by Bauer *et al.* (7) and modified by the present authors (8).

Fig. 6 gives details of this modified model. In the actual molecular configuration, it is of course impossible for the Al—O—Al backbone to be in a straight line as the distance between succeeding Al atoms is too great for bridge formation and a zigzag configuration must be adopted (Fig. 7).

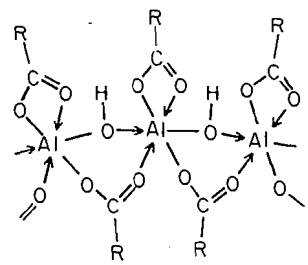

FIG. 6. Chemical formula of the aluminum soap molecule showing bridged and non-bridged carboxylate groups.

The evidence in favor of a bridge-type structure for the carboxylate group is mainly derived from experimental infrared absorption measurements. It has previously been shown (8) that in both aluminum tri- and di-soap two major absorption bands occur in the 6.1–6.4 μ region, and that these bands can be assigned to bridged and non-bridged carboxylate groups. This experimental evidence is corroborated by viscosity and molecular weight measurements. Bauer (7) has shown that peptization studies on aluminum disoaps can also be explained by a bridge-type structure.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

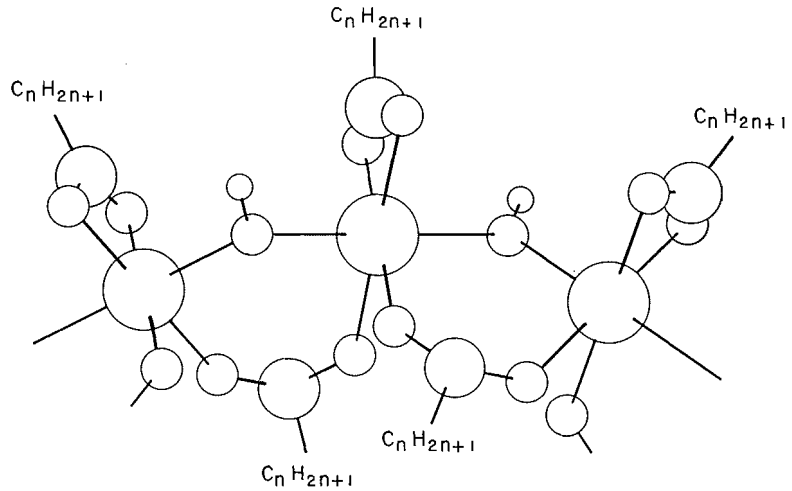

FIG. 7. Model of aluminum soap molecule showing bridged and non-bridged carboxylate groups.

The assumptions that are made in choosing this model are these:

1. The Al—O distances around the Al atoms are all equal. This assumption is probably not strictly accurate, and it is probable that the aluminum to hydroxyl bond length is greater than the aluminum–carboxylate distance, but this approximation is made to facilitate calculations in the absence of any definite value.

2. The O—O distance of a carboxylate group is taken as 2.28 Å, derived from an OCO angle of 125° and O—C bond length of 1.29 Å (14, p. 203).

3. The Al—O distance was taken as 1.92 Å, which is the sum of the covalent radii (14, p. 179). This gives a length of 2.71 Å for the O—O distance between the hydroxyl and carboxylate oxygen positions. This is higher than the 2.50 Å result found for most crystals in which aluminum–oxygen bonds are present.

The distances and angles involved in the calculation of the Al—O—Al bond angle are given in Fig. 8. The values of the Al—O—Al angle found by substituting plausible values of the O—O distance in the carboxylate group are given in Table II. These vary from a minimum of 130° to a maximum of 144°. The most probable value would probably be intermediate between all of these. For calculation purposes 135° was taken as the angle

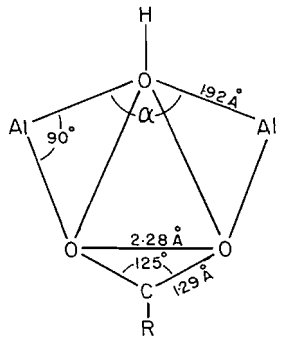

FIG. 8. Diagram of a portion of the aluminum soap molecule drawn through the Al—O—Al plane and showing its principal dimensions.

For personal use only.

Al—O—Al. This value could be compared to 130°–160° proposed for the Si—O—Si angle in polysiloxanes (15).

TABLE II

CALCULATIONS OF BOND ANGLE

Assumed distances, Å			
Atom distance		Carboxylate group	Calculated value, angle Al—O—Al
Al—O	O—O	O—O	
1.92	2.50	1.90*	134°
	2.71	1.83*	130°
	2.50	2.28	144°
	2.71	2.28	140°
			137°

*Minimum distance of the bridge carboxylate O—O distance projected on the Al—O—Al plane as it oscillates from its average position.

It has been shown by Kuhn and others (16, Chap. X) that for polymer coils not extended by solvent–polymer interaction, the root-mean-square end-to-end distance could be related to the number and structure of the unit comprising the chain by the following relation,

$$r^2 = nl^2\,[(1+\cos\alpha)\,(1+\cos\psi)/(1-\cos\alpha)\,(1-\cos\psi)], \qquad [1]$$

where l is the unit length, i.e. the O—Al—O length; n, the number of units, $n = M_z/M_o$; α is the supplement of the valence angle Al—O—Al, i.e. $180° - 135° = 45°$; and ψ the average value of the angle between the $(i+2)^{th}$ bond and the plane of the two preceding ones. All the units must be expressed in terms of the same average. The root-mean-square end-to-end distance $(\bar{r^2})^{\frac{1}{2}}$ is derived from Rg— the radius of gyration—which as measured by light-scattering is a "Z" average value. The average number of units in the chain must also be a Z average, which means that the M in the equation must also be a Z average molecular weight. To calculate values of Mz it was assumed that the molecular weight distribution could be expressed by an exponential distribution function, especially since the molecular weight will be large (17).

$$Mn:Mw:Mz:k:k+1:k+2 \qquad [2]$$

Since the relation of Mw to Mn is given in Fig. 5, it is possible to find k, and Mz/Mn will be $(k+2)/(k+1)$. This ratio is given in Table III, together with the Mw molecular weight as derived by light-scattering measurement and from which Mz is obtained. This in turn gives n in equation [1].

The evaluation of the end-to-end distance by the relation given above [1] involves two basic steps. The first calculation—equivalent to a kinetic theory random-walk problem—gives the unit length of the polymer chains if no restriction whatsoever is imposed on the orientation of each link to its predecessor. The second, expressed in [1] as a ratio of the cosine of various angles, restricts this orientation for certain conditions imposed by steric hindrance, valency angles, and bond position. The unit length of the polymer chain without any angle restriction is about 26.3 Å, as given in Table III.

					Average	4.46

The magnitude of the correction factor to be applied to this value for steric hindrance and valency angle will depend on the choice of the angles α and ψ. It has been shown that since α is the supplement of the Al—O—Al angle, it has a value of 45°. It is more difficult to choose a value for ψ. It is defined as the angle between the $(i+2)^{\text{th}}$ bond and the plane made by the preceding two bonds, and is equivalent to a restriction or rotation about the bond axis. In the case of aluminum disoap, free rotation is stopped at either 0° or 90° by the bridge structure. The average value of ψ is then 45°, which is the value used in [1].

These give an average unit length of 4.46 Å, as found in Table III. The lower values are probably more accurate as the number of units are greater and statistically more probable. This O—Al—O length is of course 2(Al—O), giving an Al—O bond length of 2.23 Å, compared with the calculated Al—O distance of 1.92 Å, as obtained from covalent radii.

Benoit (18) has shown that for polydisperse polymers made up of Gaussian chains, it is possible to obtain the number-average molecular weight and radius of gyration from the usual Zimm plot of the light-scattering data from the slope of the asymptote to the reciprocal scattering envelope at infinite dilution and at high-scattering angles. Unfortunately most of the data on aluminum stearate solutions were obtained with the dodecagonal cell, and extrapolation of this data is rather difficult with data available for only two backward angles. Several solutions were measured in a cylindrical cell with flat entrance and exit windows and the usual reflection and volume corrections made. Since the number-average molecular weight and root-mean-square end-to-end distance can both be calculated from the asymptote, no assumption need be made regarding the molecular weight distribution characteristics of the polymer. Three solutions examined in this way gave a number-average molecular weight of 2.48×10^5, 2.90×10^5, and 9.0×10^5, with an $(\overline{r_n^2})^{\frac{1}{2}}$ of 492 Å, 680 Å, and 835 Å, respectively. This leads to an

For personal use only.

O—Al—O distance of 4.19 Å, 3.78 Å, and 3.80 Å, with the same equations and angle assumptions used previously. These bond length values are very close to those obtained by assuming a molecular weight distribution for the polymer and are a further indication of the validity of the assumptions made in the calculations.

E. Flory's Relationship

Flory (16) has postulated that for linear random coil molecules

$$[\eta] = \Phi(\bar{r}^2)^{3/2}/M$$

where $(\bar{r}^2)^{\frac{1}{2}}$ is the root-mean-square end-to-end distance of the molecule and Φ is a constant usually taken as 2.1×10^{21}.

In Fig. 9 this relationship is given as a function of Mw as determined by light-scattering. This relation has been shown to hold for various polymer systems of linear molecules. In the present case, there is a slight molecular weight dependence in Φ, probably because of the increasing polydispersity at higher molecular weights. The intercept gives the Φ value found for other systems namely 2.1×10^{21}.

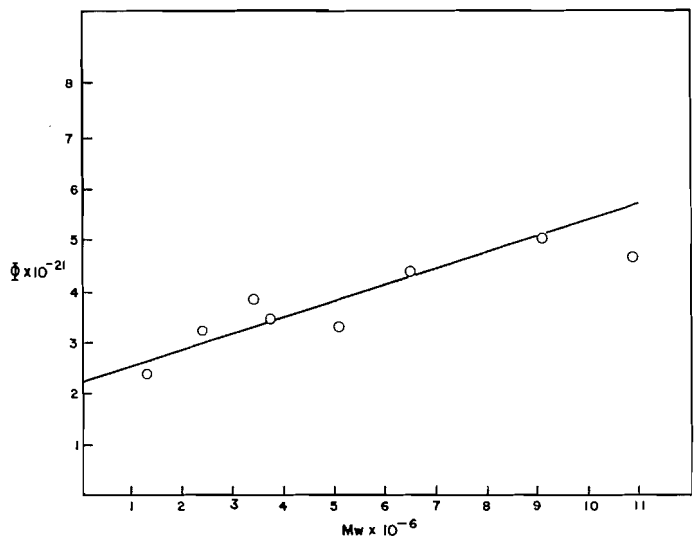

FIG. 9. Flory's Φ values as a function of weight-average molecular weight (Mn).

CONCLUSION

The results indicate that in dilute benzene solutions aluminum stearate is a linear molecule of random coil shape. In support of this conclusion, there is the expected intrinsic viscosity – molecular weight relationship, the experimental data satisfies the theoretical curves for random coils, the constancy of the ratio of the molecular weight to the square of the radius of gyration, the very close approximation of the Al—O bond length obtained by calculations based on this assumption, and expected value of Φ in the Flory intrinsic viscosity relationship.

It can also be concluded that for the aluminum distearate solutions, as prepared for our measurements, branching is not a predominant factor and the slight deviations from the usual linear molecules' behavior found above could be explained by the known very wide distribution of molecular weight.

NOTES

RESONANCE PARAMETERS FROM REACTIVITY CONSTANTS

C. N. RAMACHANDRA RAO* AND G. K. GOLDMAN

Recently, McDaniel and Brown (1) have compiled an extensive set of Hammett σ values based upon the ionization of benzoic acids. A number of electrophilic substituent constants, σ^+, have also been calculated based on the thermodynamic dissociation constants of benzoic acids by Brown and Okamoto (2). The σ^+ constants differ from the σ constants by an extra resonance factor resulting from the greater opportunity for resonance interaction by the substituents in electrophilic reactions. Such strong resonance interactions in electrophilic reactions occur between the electron-donating substituents and the electron-deficient centers of the reacting systems. Accordingly the σ_p^+ values differ greatly from the σ_p values for the ortho–para-directing groups. But the σ and σ^+ constants for the meta-directing substituents are very similar and the deviations fall within the limit of the estimated uncertainties of the constants (3). This is understandable, since the meta-directing groups exhibit no significant resonance interaction with the incipient carbonium ion. As one would expect, the σ_m and σ_m^+ values for groups are also similar, since the major contribution of a meta-substituent is by inductive interaction.

Although the resonance parameters of the substituents should vary with the electronic demands of the reaction, it has been possible to propose a single set of σ^+ values which would correlate the available data on electrophilic aromatic substitution and electrophilic side-chain reactions with good precision (2, 4). This suggests that the σ^+ constants can also be separated to independent inductive and resonance contributions similar to the quantitative separation of the Hammett σ constants by Taft (5),

$$\sigma^+ = \sigma_I + \sigma_R^+,$$

where σ_I and σ_R^+ are the inductive and resonance parameters respectively. The inductive

parameters in this equation are the same as those proposed by Taft (5, 6). This is reasonable, since the inductive effect should essentially be independent of the reaction.

We have now calculated the $\sigma_p - \sigma_I$, $\sigma_m - \sigma_I$, $\sigma_p^+ - \sigma_I$ and $\sigma_m^+ - \sigma_I$ for several substituents based on the recent compilations of the σ and σ^+ values (1, 2). The results are summarized in Table I. In Fig. 1 are plotted the $\sigma_p - \sigma_I$ versus the $\sigma_p^+ - \sigma_I$ for the electron-donating groups. With the exception of $\overset{+}{N}(Me)_3$, NCOMe, SMe, and F groups, all the other groups fall on a straight line. By least-square treatment the line can be represented by the equation:

$$\sigma_R^+ = 1.91\sigma_R - 0.03.$$

This linearity further confirms the suggestion that σ_R^+ of a group is essentially a constant to a first approximation and that σ_R^+ is not a very sensitive function of ρ (4).

indicated almost complete isomerization of the ethyl-β-C^{14} chloride by aluminum chloride. We have found substantially similar results for the alkylation of benzene with ethyl-β-C^{14} iodide, except that the aluminum chloride induced isomerization is much faster for the ethyl chloride (see Table I). Possibly, since chlorine is more electronegative than iodine, there may be a greater tendency for ethyl cation formation from ethyl chloride than from ethyl iodide under the influence of aluminum chloride.

TABLE I

		C_6H_5COOH	1448±19	1420±19	21	26

*The reactants used were 3.0 ml C_2H_5I, 1.5 g $AlCl_3$, and 60 ml C_6H_6.

†Corrected activities in c.p.m. on a molar basis were determined by converting all compounds to barium carbonate and counted as infinitely thick samples of constant geometry in a gas flow Geiger counter. Correction for the dilution by non-labelled carbon atoms was made by multiplying the observed activity with the number of carbon atoms per molecule in the compound assayed.

The ethyl-β-C^{14} iodide was purchased from Atomic Energy of Canada Limited. The Friedel–Crafts reaction was carried out using 3.0 ml of labelled ethyl iodide, 1.5 g of anhydrous aluminum chloride, and 60 ml of redistilled benzene. The ethylbenzene obtained was oxidized with potassium permanganate to give benzoic acid, the radioactivity in which was taken as a measure of the rearrangement of the C^{14}-labelled atoms from the β- to the α-positions of the ethyl group. In Expts. B and C (Table I), the labelled ethyl iodide was treated with the aluminum chloride for 1 hour at room and reflux temperatures, respectively, before the resulting mixture was used to alkylate benzene. Similar yields of ethylbenzene, within the range of 70–75% of theoretical, were obtained in Expts. A, B, and C.

The degree of isotope position rearrangement induced by aluminum chloride on ethyl-β-C^{14} iodide is dependent on temperature as indicated by the results of Expts. B and C. It is also dependent on the length of the contact time of aluminum chloride with ethyl iodide. Mixtures of ethyl-β-C^{14} iodide (3.0 ml) and anhydrous aluminum chloride (1.5 g) were heated at 40° C for various lengths of time and the resulting material, without any fractionation, was used to alkylate an excess of benzene (60 ml). Isotope position rearrangements in the ethyl side chain of the ethylbenzene obtained are shown graphically in Fig. 1. Under these conditions, the degree of rearrangement was found to increase with length of contact time until a maximum of 50% rearrangement, corresponding to a complete equilibration of the α- and β-carbons of the ethyl group, is reached after about 42 hours.

The finding that aluminum chloride is capable of inducing isomerization in the labelled ethyl halide, while the ethylation of benzene under the usual Friedel–Crafts conditions yielded unrearranged ethylbenzene, was interpreted by Roberts, Ropp, and Neville (1) as meaning that the alkylation either follows a displacement mechanism involving no free ethyl fragments, or if a carbonium ion mechanism were operative, the ions react with the aromatic reactants so rapidly as to exclude internal hydride shifts. More recently,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12

Jungk, Smoot, and Brown (2) suggested that the Friedel–Crafts alkylation is another example of substitution on saturated carbon, which may have a continuum of mechanisms ranging between the extremes of a direct displacement and one involving an alkyl cation that could give rise to rearrangement. Still another possibility that rearrangement in the Friedel–Crafts alkylation may arise from a separate process which occurs before the product-forming alkylation step has been pointed out (3). Applying any one of these explanations to the present results, one would expect that the rate of the Friedel–Crafts reaction between ethyl iodide and benzene should be faster than the rate of the aluminum chloride induced rearrangement on ethyl-β-C^{14} iodide. It is thus of interest to measure the rate of the ethylation under our experimental conditions. Instead of the usual titration of the liberated hydrogen halide, we have estimated the rate of ethylbenzene formation by an isotope dilution technique. Since 1 mole of ethylbenzene is

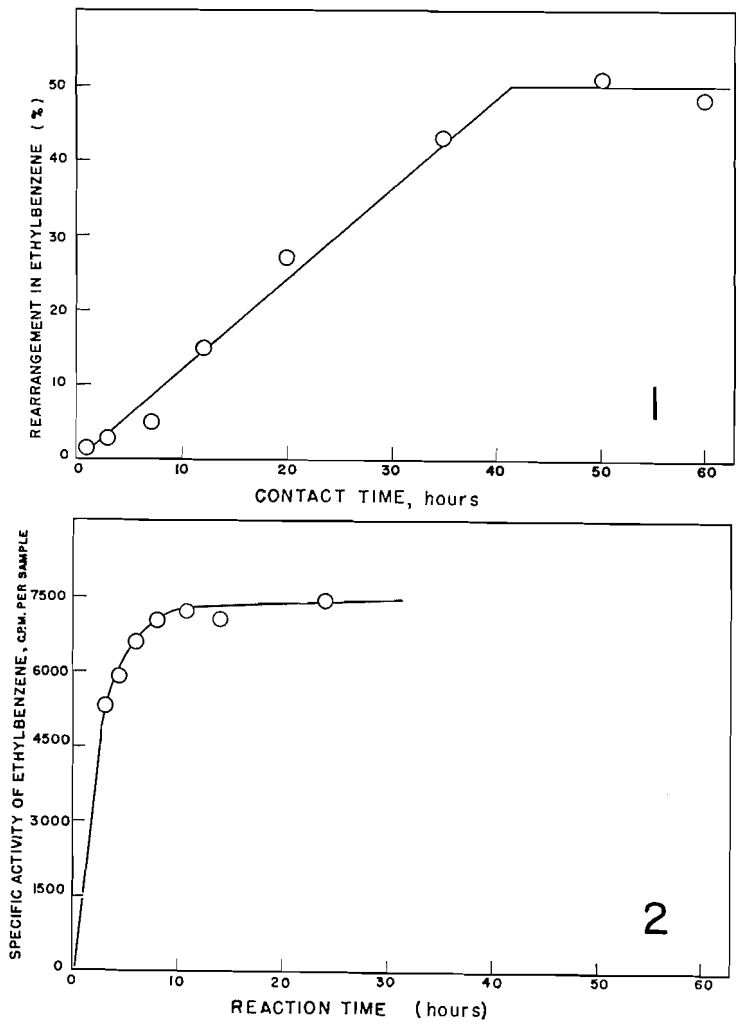

FIG. 1. Isotope position rearrangements in ethylbenzene from reaction of benzene with mixtures of labelled ethyl iodide and aluminum chloride that had been in contact at 40° for various lengths of time.

FIG. 2. Specific activities of ethylbenzene from aliquots of a Friedel–Crafts reaction at 40°, each aliquot having been diluted with a fixed amount of non-radioactive ethylbenzene.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

produced from 1 mole of ethyl iodide, the activity per mole of the ethylbenzene formed should be the same as the activity per mole of the ethyl-β-C^{14} iodide used, though the total quantity of ethylbenzene produced would increase with reaction time. If aliquots of the reaction mixture were withdrawn at various time intervals and a fixed amount of non-labelled ethylbenzene added to each aliquot, the specific activity of the ethylbenzene samples recovered from these aliquots should increase with reaction time and would reach a constant maximum value after the reaction is complete. As the specific activity of the diluted ethylbenzene is a measure of the quantity of labelled ethylbenzene actually produced by the Friedel–Crafts reaction it is not necessary to have quantitative isolation of all ethylbenzene from each aliquot. The radiochemical purity of the recovered ethylbenzene can be rigorously established by showing that the specific activity of the diluted ethylbenzene from various aliquots does not change significantly on repeated distillation. Such a kinetic study was carried out at 40° C, the reactants initially present being 120 ml of benzene, 6.0 ml of ethyl-β-C^{14} iodide, and 3.0 g of aluminum chloride. The results are given graphically in Fig. 2, the plateau of constant maximum specific activity being reached in about 12 hours. Assuming the specific activity at the plateau of Fig. 2 corresponds to 100% reaction, it is possible to calculate the percentage of ethyl iodide remaining unreacted at various times before the reaction was complete. This is shown in a semilogarithmic plot in Fig. 3, indicating that the reaction, as expected, is first order with respect to ethyl iodide. The first-order specific rate constant derived from Fig. 3 is 0.81×10^{-4} sec^{-1}.

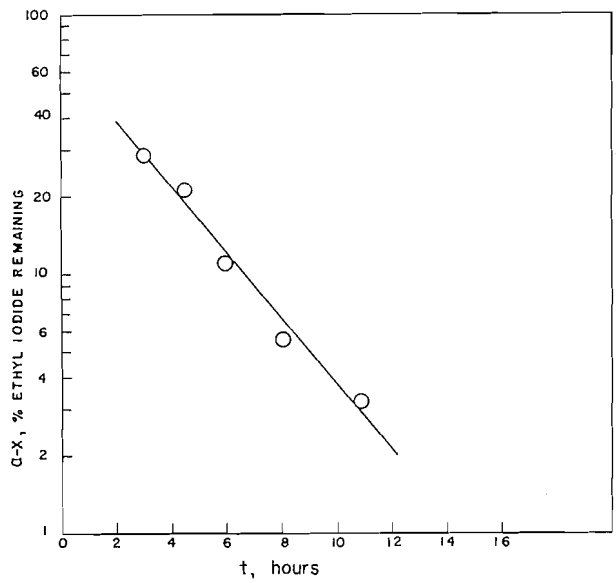

FIG. 3. First-order kinetic dependency on ethyl iodide in the formation of ethylbenzene. Calculated from Fig. 2.

Comparing Figs. 1 and 2, it is evident that at 40° C, the rate of the aluminum chloride induced rearrangement on pure ethyl iodide is slower than the rate of the Friedel–Crafts ethylation of benzene. Under the Friedel–Crafts reaction conditions, the ethyl iodide is diluted by the presence of an excess of benzene, thus the rate of the aluminum chloride induced rearrangement may be still slower. It is, therefore, reasonable to conclude that

in the Friedel–Crafts reaction between benzene and ethyl-β-C^{14} iodide, the rate of ethylbenzene formation is faster than the rate of a possible rearrangement of the ethyl iodide caused by the aluminum chloride.

POTATO X VIRUS

PART I. THE SIZE AND SIZE DISTRIBUTION OF POTATO X VIRUS IN TOBACCO SAP[1]

M. E. REICHMANN

ABSTRACT

Assuming an irreversible, random, end-to-end aggregation of a small percentage of potato X virus in tobacco sap, the flow birefringence parameters of such polydisperse systems have been calculated. The extinction angles χ were evaluated for different values of the ratio G/θ_1 (G gradient, θ_1 rotary diffusion constant of non-aggregated virus) for preparations containing between 0 and 15% by weight of aggregated material. A particle length of 6200 Å for the non-aggregated virus particle was derived and an amount of 13–15% aggregated material was estimated.

A partially purified and fractionated preparation of potato X virus was also investigated and an average particle length of 5400 Å was derived. Because of the possible contribution of small fragments, this length was taken as the lower limit.

The flow birefringence – gradient curve indicated that the potato X virus behaves like a rigid particle. No evidence of flexibility was obtained from extinction angle – gradient measurements in the range 0.1–0 M phosphate buffer concentrations at pH 7.2.

INTRODUCTION

The tendency of the elongated plant viruses to aggregate irreversibly in an end-to-end fashion, in the process of isolation and purification, has made it difficult to study the shape and size of these viruses in solution (1, 2, 3, 4). The potato X virus in particular presents a difficult problem, as even the mild treatment of ultracentrifugation renders much of the material insoluble (1, 3). The value of physicochemical studies on such preparations is, therefore, somewhat dubious (5, 6). The most reliable data on the size and size distribution of this virus come from electron microscope studies of untreated plant sap (7, 8), where a uniform particle length of 500 to 525 mμ and 10 mμ thickness is indicated with a small amount of the virus material present in the form of higher end-to-end aggregates of this elementary particle. However, since the information obtained from electron microscopy is pertinent only to the non-hydrated virus and, moreover, breakage or aggregation of particles can occur during the preparation of electron microscopic specimens (9, 10, 11), an investigation of the virus size and size distribution in the hydrated form is highly desirable. This paper deals with an analysis of flow birefringence measurements made on tobacco sap infected with potato X virus. In addition, a partial purification of the virus is described. In the process the aggregated fraction present in the sap was preferentially removed. Flow birefringence measurements on this preparation made it possible to determine the lower limit of the characteristic particle size. The flow birefringence technique is particularly suitable for such studies, because of its great sensitivity to the particle length (12) and because of the absence of flow birefringent material in the sap of healthy tobacco after freezing.

Theory

In the treatment that follows, three assumptions are made: 1. The elementary virus particle (here referred to as monomer) as well as the aggregates (polymers) is sufficiently rigid to be treated as rigid ellipsoids of revolution. 2. The end-to-end aggregation occurs at random. 3. The axial ratio is greater than five. Assumptions 1 and 2 are discussed further in the last section of this paper, while assumption 3 is certainly justified by electron microscopy data (4, 7).

The flow birefringence theory for polydisperse systems has been treated by Sadron (13). The flow birefringence parameters have been evaluated for Gaussian (14) and Montroll–Simha distribution functions (15, 16). In the case of random linear aggregation the distribution function will have a different form. The problem can be treated essentially as one of a bifunctional monomer undergoing condensation polymerization. Flory has treated the distribution of x-mers in such a system, and the weight fraction of x-mers W_x is given by the following expression (17):

$$W_x = xp^{(x-1)}(1-p)^2, \tag{1}$$

where p is the total fraction of material which has undergone polymerization. In the case of rigid particles the above expression also gives the size distribution WL_x:

$$WL_x = L_x/L_1\, p^{(L_x/L_1-1)}(1-p)^2. \tag{2}$$

Here L_x is the length of the x-mer and x has been replaced by L_x/L_1. By carrying out the summation over all x's from 1 to ∞ one can see that the function is normalized. This distribution function can thus be used for a derivation of the flow birefringence parameters: the extinction angle χ and the rotary diffusion constant θ. If the axial ratio of the monomer is greater than five, the rotary diffusion constant varies inversely as the cube of the particle length (16, 18) and the following relationship applies:

$$x = L_x/L_1 = (\theta_1/\theta_x)^{\frac{1}{3}} = (\alpha_x/\alpha_1)^{\frac{1}{3}} = \gamma. \tag{3}$$

Here the α's represent the ratio of the velocity gradient G to the respective rotary diffusion constant. The distribution function can now be expressed in terms of α and p only:

$$W_\gamma = \gamma p^{(\gamma-1)}\,(1-p)^2, \tag{4}$$

$\gamma = (\alpha_x/\alpha_1)^{\frac{1}{3}}$ can only assume integer values from 1 to ∞.

The extinction angle χ in a polydisperse system is given by the following expression (14, 16):

$$\tan 2\chi = A/B,$$

where

$$A = \sum_{x=1}^{\infty} W_x f(\alpha_x) \sin 2\phi_x,\quad B = \sum_{x=1}^{\infty} W_x f(\alpha_x) \cos 2\phi_x, \tag{5}$$

ϕ_x is the extinction angle of the x-mer, and $f(\alpha_x)$ is a form factor. Both quantities can be found in the tables of Scheraga, Edsall, and Gadd (19). Introducing W_x in terms of α from [4]:

$$A = (1-p)^2 \sum_{\gamma=1}^{\infty} \gamma p^{(\gamma-1)} f(\alpha_x) \sin 2\phi_x$$

$$B = (1-p)^2 \sum_{\gamma=1}^{\infty} \gamma p^{(\gamma-1)} f(\alpha_x) \cos 2\phi_x. \tag{6}$$

For values of p not exceeding 0.15 (less than 15% aggregated material) the series converge rapidly and the fifth term ($\gamma = 5$) does not contribute more than 2% to the sum. A and B and thus χ can be evaluated by neglecting higher terms in the series. Table I gives the values of χ for $\alpha_1 = 0$–4 and for $p = 0.02$–0.15. Figure 1 represents a plot of χ vs. α_1 for various degrees of aggregation p.

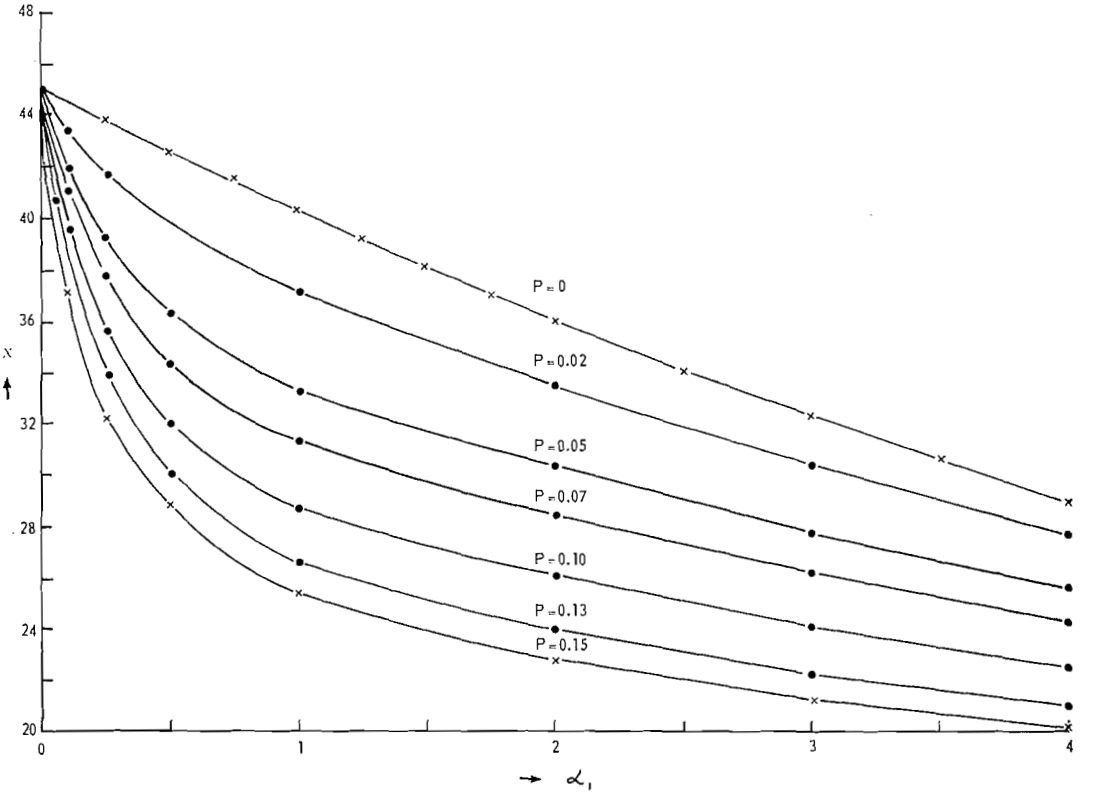

FIG. 1. Extinction angle – gradient curves for polydisperse systems with a Flory distribution function and various fractions p of aggregated material.

For values of α_1 greater than four, α_x becomes too large and the values of $f(\alpha_x)$ and ϕ_x in the tables of reference (19) are somewhat dubious. This, however, does not matter, as the largest deviations from the monodisperse curve $p = 0$ occur in the region of low α's. From the best fit of the theoretical and experimental curves in this region the amount of aggregated material p, as well as the rotary diffusion constant of the monomer, θ_1, can be determined. For prolate ellipsoids of revolution (16):

$$\theta = \frac{kT}{\pi\eta L^3}\frac{3}{2}(-1+2\ln 2\beta)$$

where k is Boltzman's constant, T is the absolute temperature, η is the solvent viscosity, and β is the axial ratio. The length of the monomeric virus particle has been calculated from this equation assuming $\beta = 60$ (4, 7). L_1 and θ_1, however, are not very sensitive to the axial ratio β, because of the logarithmic dependency.

MATERIAL AND METHODS

Preparation of Sap

One-month-old tobacco seedlings were infected with a severe potato X strain, isolated from a single lesion on *Gomphrena globosa*.* Two weeks after inoculation the young leaves were harvested and kept frozen overnight. They were then thawed at 5° C and squeezed in a mortar with a pestle. The sap was centrifuged for 45 minutes at 3500 r.p.m. All the operations were carried out in a cold room (0–5° C), and the brown color of the supernatant sap was not strong enough to interfere with the flow birefringence measurements. The extinction angles at various gradients were measured with a flow birefringence apparatus manufactured by the Rao Instrument Company, Brooklyn 5, New York (20, 22).

For more accurate measurements the sap was concentrated in a Petri dish in a desiccator to $\frac{1}{4}$ of its original volume. This did not change the values of the extinction angles. Dilutions were made with distilled water. The amount of birefringence was never less than 10° expressed in terms of the phase difference (which is twice the angular rotation of the Senarmont compensator). Under these conditions the isoclines were sharp enough to permit a reproducibility of at least 0.8° at gradients of 40 sec^{-1} or higher. The reproducibility on different preparations was also very good provided plants of approximately the same age were used. Sap from plants older than a month from the date of inoculation was deeper in color, and therefore no reliable data could be obtained. There was, however, some indication of the presence of more aggregated material than in younger plants.

Partial Purification and Fractionation

Fresh sap from tobacco plants infected with potato X virus was made 0.05 M in phosphate buffer pH 5.7, and centrifuged at 4000 r.p.m. for 40 minutes. Twenty-five

*The author is greatly indebted to Dr. N. S. Wright of the Plant Pathology Section of this laboratory for the supply of virus material.

grams of celite (Johns–Manville, Analytical Filter Aid) was mixed with 250 ml of supernatant sap and poured into a 45-mm diameter glass column with a fritted glass plate bottom. Mild suction was applied. The first 40 ml of sap that came through were recycled. No flow birefringence could be detected in the sap that passed through the column subsequently. The column was washed thoroughly with 0.05 *M* phosphate buffer pH 5.7. Distilled water was then used to elute the virus. Most of the virus came off the column in the first 20 ml of the eluent. About 70% of the virus was recovered. The solution was faintly yellow indicating the presence of impurities. In the Spinco ultracentrifuge a peak corresponding to the virus and a small shoulder near the meniscus were observed. This shoulder failed to separate after 45 minutes at 50,000 r.p.m. Electrophoretic patterns in 0.05 *M* phosphate buffer pH 7.0, taken with a model H Spinco Electrophoresis-Diffusion Apparatus, showed two components. In addition to a sharp, slow-moving peak corresponding to the virus, a faster-moving diffuse peak was present (Fig. 2).

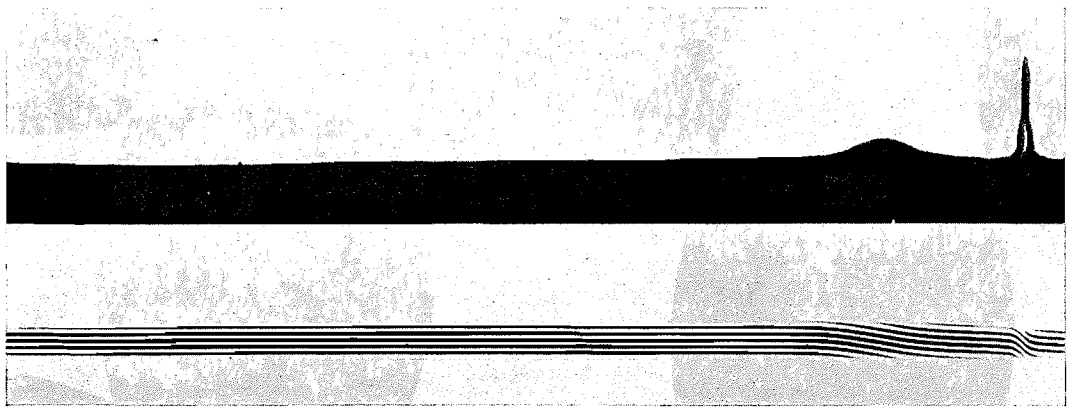

FIG. 2. Electrophoretic pattern of potato X virus after partial purification on celite column. Descending boundary, movement from right to left.

Subsequent purifications on a celite column were made by diluting the aqueous virus solution with 0.05 *M* phosphate buffer pH 5.7 to approximately the same virus concentration as in the sap, and repeating the procedure described above. The impurities present after the first purification could not be removed by additional treatment; also, the virus yields were much lower in the subsequent treatments than in the first one.

For flow birefringence measurements all solutions of the celite-treated virus were dialyzed against distilled water and centrifuged at 4000 r.p.m. for 40 minutes.

RESULTS AND DISCUSSION

Figure 3 represents a plot of the extinction angle χ as a function of gradient G for three different sap concentrations. Within experimental error the extinction angle is independent of concentration, indicating that the interactions of the virus particles with each other and with other sap constituents are negligible. Under these conditions the extinction angle is solely a function of particle length and velocity gradient. The solid lines in Fig. 3 are theoretical curves for a Flory distribution function with $\theta_1 = 70$ giving the best fit of the experimental points. The value $\theta_1 = 70$ corresponds to a length of 6200 Å for the monomer. The amount of aggregated material present in this sample can be estimated from Fig. 3 as 13 to 15%.

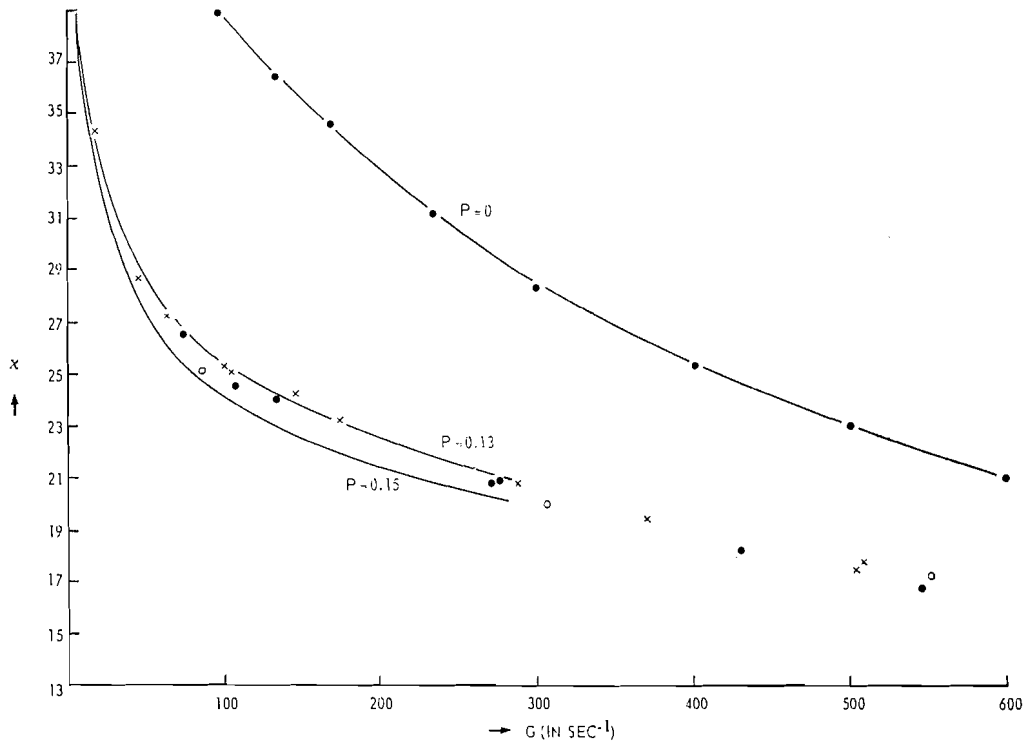

FIG. 3. Extinction angle – gradient curves of sap from potato X infected tobacco: X, four times concentrated sap; ●, one to one dilution of concentrated sap; O, one to three dilution of concentrated sap. Solid lines are theoretical curves from Fig. 1 assuming rotary diffusion constant 70.

In Fig. 4 the extinction angle as a function of gradient is plotted for partially purified potato X. Each treatment with celite caused a shift in these curves towards higher extinction angles, accompanied by a decrease in polydispersity features. After the fifth and subsequent absorptions on celite the shift became very minor.

The indication that the virus preparation was becoming less polydisperse excluded the possibility of a random breakage of virus particles. Also, the ultracentrifuge patterns remained unchanged, excluding the possibility of a splitting at specific sites. The most plausible explanation of the shift in the birefringence curves seems to be a preferential absorption of the aggregated materials by the celite column. The rotary diffusion constant of the five times celite-treated material at low gradients (100–200 sec^{-1}) is 60 to 70. Comparing this with the value of 70 derived above for the non-aggregated virus particles, it would seem that this preparation is virtually free of aggregated material. The slight polydispersity could therefore be attributed to shorter fragments present in the sap. Electron microscopy revealed the presence of short fragments in potato X preparations (4, 7, 8). The rotary diffusion constant of the five times celite-treated sample at 800 sec^{-1} is 105. This corresponds to a particle length of 5400 Å for a prolate ellipsoid of revolution. Because of the possibility of a contribution by shorter fragments, the latter value should be considered as the lower limit. Thus the characteristic hydrodynamic length of potato X virus in tobacco would be within the limits of 5400 to 6200 Å.

Curved and kinked potato X virus particles observed under the electron microscope suggested to some authors that a more flexible particle was involved than in the case

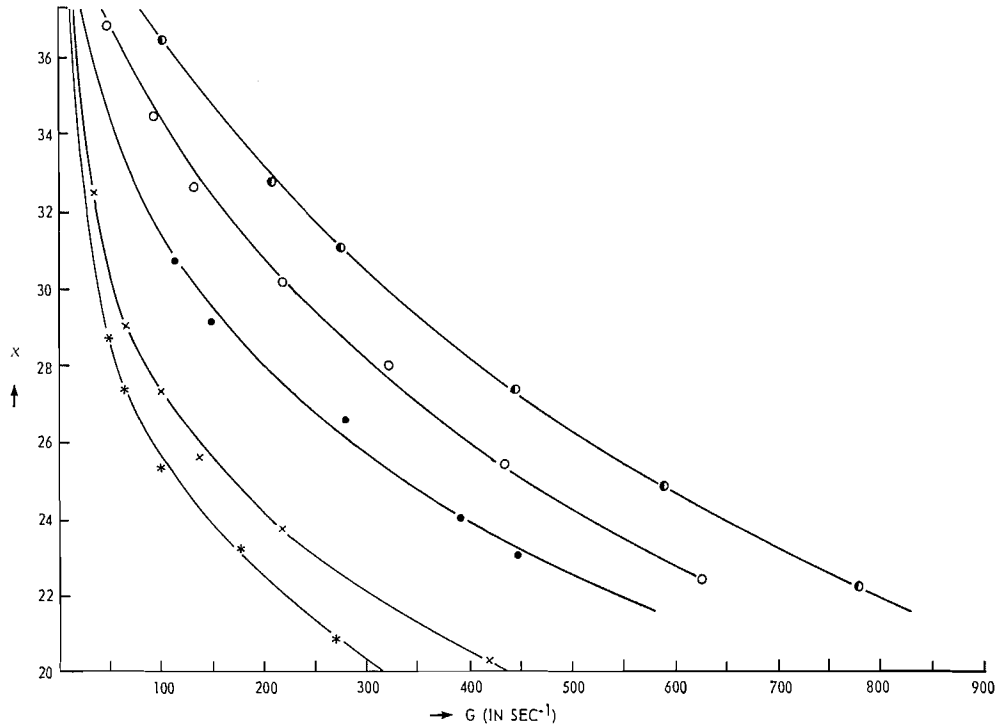

FIG. 4. Extinction angle – gradient curves of partially purified potato X virus on celite columns: *, virus in sap; X, once; ●, three times; ○, four times; and ◐, five times purified virus.

of the rigid tobacco mosaic virus (21). The difficulty encountered in an interpretation of flow birefringence data in the case of flexible particles (22) merits a closer examination of this problem. Valuable information regarding flexibility can be obtained from birefringence vs. gradient curves. In the case of rigid particles these curves have a downward curvature, the birefringence reaching a saturation value at high gradients (12). Figure 5 shows birefringence curves of potato X virus in sap, corresponding to the extinction angles in Fig. 3. The birefringence is expressed in degrees (twice the angular rotation of the Senarmont compensator), divided by relative concentrations, the most dilute sample being taken as having a concentration of one. The downward curvature is indicative of a rigid particle. Further evidence in support of inflexibility was obtained from extinction angle measurements of sap, dialyzed against distilled water and phosphate buffer pH 7.2, of varying ionic strength. The extinction angle – gradient curves remained unchanged in a range of phosphate concentrations of 0.1–0 M, indicating that no measurable stretching of the particles occurred with decreasing ionic strength.

The data on this paper confirm the conclusion from electron microscopy that a definite particle length is characteristic of the potato X virus in tobacco sap. In an earlier publication by Bode and co-workers (7) this characteristic length was given as 5600 to 5800 Å and 6000 to 6200 Å for two different strains of potato X respectively. In a later publication the first value was corrected to 5000 to 5250 Å, owing to previous errors in instrument calibration. A somewhat higher value from flow birefringence studies could be expected because of hydration and the error involved by substituting the cylindrical model with an ellipsoid of revolution (23), although a difference in the virus strains could also be a contributing factor (4, 7).

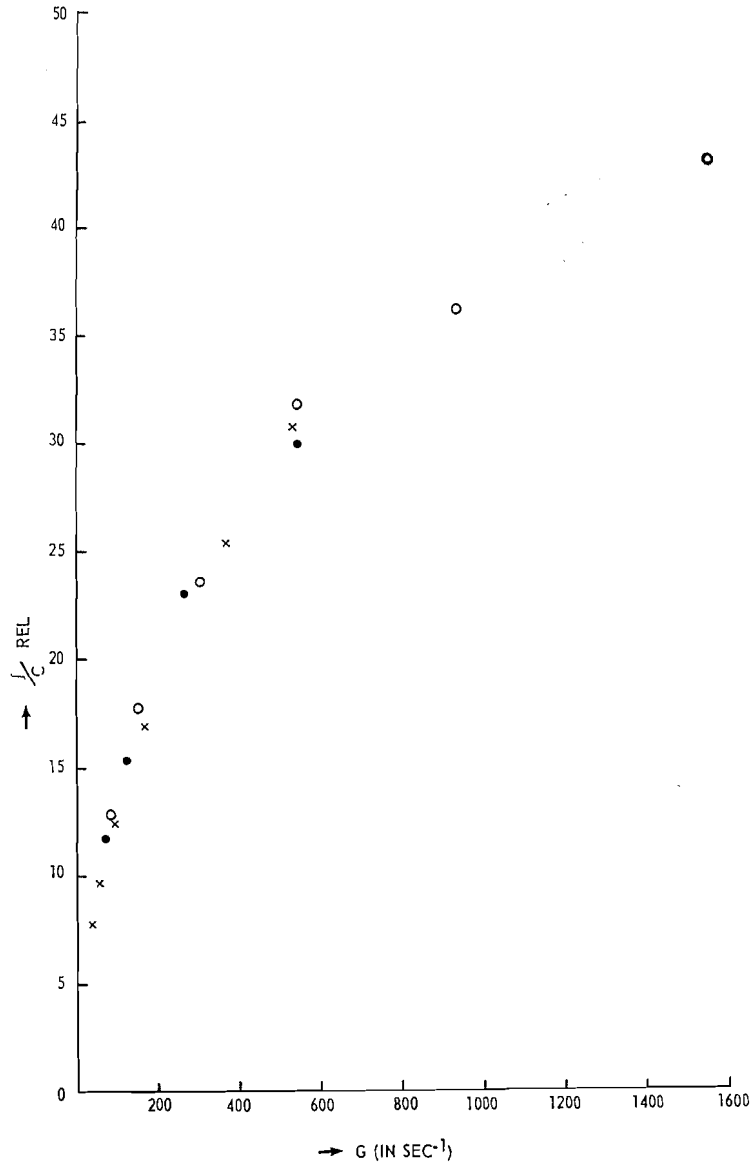

FIG. 5. Birefringence – gradient curves of potato X virus in sap. Points correspond to those given in Fig. 3.

It is difficult to make a comparison of the percentage of aggregated material reported here with that given in the literature. The wide fluctuation, from 23 particles in 651 (3.5%) (7) to 18% (8), is indicative either of great variability with growth conditions and virus strains or artefact formation during the drying processes. On the other hand, the flow birefringence value is open to criticism because of the inherent assumption of a random end-to-end aggregation. This is almost certainly an oversimplification of the mechanism involved. Furthermore the Flory distribution function does not account for fragments smaller than the monomeric unit which are present in all electron microscope mounts and for which there was evidence in the celite-fractionated material. A

close examination of the χ vs. G curves for other distribution functions will show that the curves are not very sensitive to the form of the distribution. Therefore the total amount of aggregated material determined in this way is probably a good estimate as long as the Flory distribution function is an approximate representation of the distribution.

OCCURRENCE OF β-DOLABRIN (4-ISOPROPENYLTROPOLONE) IN WESTERN RED CEDAR (THUJA PLICATA DONN.)[1]

J. A. F. GARDNER AND G. M. BARTON

ABSTRACT

The steam-volatile oil of western red cedar contains traces of a fifth tropolone, β-dolabrin (4-isopropenyltropolone), in addition to α-, β-, and γ-thujaplicin and 7-hydroxy-4-isopropyltropolone. The presence of β-dolabrin, previously obtained from Japanese "Hiba" wood by Nozoe, was detected by paper chromatography and proved by isolation of a sample from the steam-volatile oil by a combination of sodium salt precipitation, fractional crystallization, and preparative paper chromatography. The approximate composition of the steam-volatile oil from butt heartwood is given.

INTRODUCTION

The heartwood of western red cedar (*Thuja plicata* Donn.) has been shown to contain up to 1.2% by weight of the three isomeric isopropyltropolones, α-, β-, and γ-thujaplicin (1, 2, 3, 4). Recently, the presence also of a hydroxylated thujaplicin, 7-hydroxy-4-isopropyltropolone (2,7-dihydroxy-4-isopropyl-2,4,6-cycloheptatrien-1-one), was reported (5). This substance, for which the name β-thujaplicinol is now proposed, exhibits the same R_f and violet color reaction on paper chromatograms with ferric chloride as the "unknown enol" detected by Zavarin and Anderson (4) in the tropolone fractions of incense cedar (*Libocedrus decurrens* Torrey) and western red cedar. The occurrence in trace quantities in western red cedar of still another tropolone derivative, β-dolabrin (4-isopropenyltropolone), first detected by Nozoe *et al.* (6) in "Hiba" wood (*Thujopsis dolabrata* Sieb. et Zucc.), has now been proved.

During examination of the steam-volatile oil of western red cedar in this laboratory by the paper chromatographic technique of Zavarin and Anderson (4), the spot corresponding to β-thujaplicinol was observed to be usually elliptical, and sometimes, depending on temperature conditions, two barely separated spots were obtained. One of these gave the violet reaction with ferric chloride typical of β-thujaplicinol and the other of slightly greater R_f had a green-brown reaction similar to that of the thujaplicins. The R_f's and color reactions of this latter substance and its azo dye prepared by the method of Zavarin and Anderson (7) indicated it might be β-dolabrin.

In view of the importance of establishing the identity of trace components of wood extractives from the taxonomic viewpoint, proof of the presence of β-dolabrin in western red cedar was provided by isolating a sample. Because only trace quantities were involved according to the paper chromatograms, this presented considerable difficulty but was achieved by applying a combination of sodium salt precipitation and fractional crystallization to the tropolone fraction of the steam-volatile oil. This procedure provided, in addition to samples and approximate yields of the other components, residual solutions enriched in α-thujaplicin and β-dolabrin. From these, a sample of β-dolabrin was isolated by preparative paper chromatography. The material isolated had m.p. 55–56° C and showed no mixed melting point depression with an authentic sample, m.p. 56–57° C. The R_f's and ultraviolet absorption spectra of the two samples were identical. The infrared absorption spectra were also identical and showed strong bands at 1608, 1557,

[1]*Manuscript received August 1, 1958.*
Contribution from the Vancouver Laboratory, Forest Products Laboratories of Canada, a Division of the Forestry Branch, Department of Northern Affairs and National Resources. Presented at the 133rd National Meeting, American Chemical Society, San Francisco, U.S.A., April 14–18, 1958.

1470, and 1435 cm^{-1}, characteristic of the tropolone nucleus, and also two at 892 and 1407 cm^{-1}, typical of asymmetrically disubstituted ethylenes (8).

The above result shows that western red cedar as well as "Hiba" wood contains β-dolabrin. Since "Hiba" wood also contains α- and β-thujaplicin (9), there are at least three tropolones common to these species of the different genera *Thuja* and *Thujopsis* of the family Cupressaceae.

Previous analytical work (3) had shown that light-colored wood from the outer butt of mature trees had the highest content of tropolones. The composition of oil steam-distilled from freshly cut shavings of butt heartwood selected for its light straw color, estimated from yields and paper chromatographic analysis of fractions obtained, is recorded in Table I. It is, of course, to be expected that the yield and composition of the oil will vary considerably with the source of the wood (3). For optimum yields, it is necessary to distill the wood immediately after conversion to shavings because of the high volatility of the oil.

TABLE I

COMPOSITION OF STEAM-VOLATILE OIL OF WESTERN RED CEDAR BUTT HEARTWOOD (0.82% YIELD)

Components	Percentage of oil	Percentage of wood
Methyl thujate, other neutrals	21.1	0.17
Thujic acid	10.4	0.08
Tropolones	68.5	0.56
β-Thujaplicinol*	8	0.07
γ-Thujaplicin*	24	0.20
β-Thujaplicin*	35	0.30
α-Thujaplicin*	1	0.01
β-Dolabrin*	0.04	0.0003

*Figures for the individual tropolones are approximate, being derived from crude yields and quantitative paper chromatography of mother liquors.

EXPERIMENTAL

Melting points were determined on a Fisher–Johns melting point apparatus and are uncorrected. Infrared absorption spectra were determined on a Beckman Model IR-4 Infrared Spectrophotometer at the Fisheries Experimental Station, Vancouver, B.C. Ultraviolet absorption spectra were determined with a Beckman D.U. Spectrophotometer.

Steam Distillation of Light-colored Western Red Cedar Shavings

Butt-wood spalts selected for light straw color were reduced to shavings in a planer and steam-distilled immediately. Approximately 6 liters of aqueous distillate were collected per kilogram of shavings. The distillate was extracted five times with a sixth of its volume of chloroform and the extract concentrated under reduced pressure to leave a yellow oil. From 11.987 kg of shavings (moisture content 20.0%) 79 g or 0.82% based on the moisture-free wood were obtained.

Preparation of Tropolone Mixture

Steam-distilled oil (103 g) in chloroform (300 ml) was extracted with 1 *N* sodium hydroxide solution (6×50 ml) and back-extracted with chloroform. The chloroform solution was dried over anhydrous sodium sulphate and the solvent removed under reduced pressure to leave crude methyl thujate (21.8 g).

The alkaline solution was acidified and extracted with chloroform (3×100 ml). The

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

chloroform solution was than extracted with saturated aqueous sodium bicarbonate solution (5×50 ml). Acidification of the bicarbonate solution precipitated crude thujic acid (10.7 g). The chloroform solution, after extraction with bicarbonate, was washed with water and dried over anhydrous sodium sulphate, filtered, and the solvent removed. The residual oil was distilled under reduced pressure to yield the semicrystalline tropolones (66.0 g).

Fractionation of Tropolone Mixture

The tropolone mixture was dissolved in hot 3 *N* sodium hydroxide (350 ml) and the solution cooled. The deposited yellow sodium salts were filtered using a rubber dam to remove excess filtrate.

The caustic filtrate was acidified with 6 *N* sulphuric acid, extracted with chloroform, and the solvent removed to yield crude β-thujaplicinol.

The sodium salts were acidified with 6 *N* sulphuric acid in the presence of chloroform. Removal of the solvent from the chloroform layer left the mixed thujaplicins. The thujaplicin mixture (5.2 g approx. 40% γ-, 60% β-thujaplicin with traces of α-thujaplicin and β-dolabrin), and anhydrous sodium acetate (2.5 g) were refluxed in sodium-acetate-saturated ethanol (50 ml) for 1 hour. The solution was cooled to room temperature and the precipitated yellow sodium salt and excess sodium acetate removed by filtration. The precipitated salts were enriched with respect to γ-thujaplicin (approx. 75% γ-, 15% β-), while the filtrate was enriched with β-thujaplicin (approx. 70% β-, 30% γ-, traces of α-thujaplicin and β-dolabrin). Regeneration of the thujaplicins from the salts, and the filtrate and recrystallization from ligroin–chloroform and ligroin gave respectively γ- and β-thujaplicin. The mother liquors were combined to yield a solution, enriched with α-thujaplicin and β-dolabrin, on which the sodium acetate – sodium salt precipitation was repeated. This in turn yielded more γ- and β-thujaplicin and mother liquors which were combined for isolation of β-dolabrin.

Isolation of β-Dolabrin by Preparative Paper Chromatography

The qualitative technique of Zavarin and Anderson (4) was adapted. Sheets of Whatman No. 1 paper (6 in. × 22½ in.) were impregnated with 17% by volume of phosphoric acid, spotted with 0.2 ml of a chloroform solution (0.08 g/ml) of the residue from removal of solvent from the mother liquors above, and developed with iso-octane–toluene (3:1). The β-dolabrin zones were located by ultraviolet light, excised, and Soxhlet-extracted with petroleum ether (30–60° C) under a carbon dioxide atmosphere. Solvent removal left crystals (0.019 g from 45 sheets) which were triturated with a minimum of petroleum ether (30–60° C), filtered, and dissolved in petroleum ether (30–60° C). Slow evaporation of the solution yielded yellow crystals, m.p. 56–57° C, mixed melting point with authentic dolabrin 56–57° C. The ultraviolet and infrared absorption spectra of the isolated material and authentic β-dolabrin were identical. ν_{max}^{KBr} in cm^{-1}: 3240, 1628, 1608, 1557, 1494, 1470, 1435, 1406, 1313, 1274, 1257, 1230, 958, 911, 892, 823.

ACKNOWLEDGMENTS

The authors are indebted to MacMillan & Bloedel Ltd. and Canadian Forest Products Ltd. for samples of western red cedar, and to Professor Tetsuo Nozoe for a sample of β-dolabrin with its ultraviolet absorption spectrum. Miss Shirley McKelvey assisted with the experimental work.

LIGHT-SCATTERING STUDIES OF COPOLYMERS

I. EFFECT OF HETEROGENEITY OF CHAIN COMPOSITION ON THE MOLECULAR WEIGHT[1]

W. BUSHUK[2] AND H. BENOÎT

ABSTRACT

The classical light-scattering theory for polymer solutions is extended to solutions of copolymers which may be polydisperse in chain composition as well as in molecular weight. It is shown that much too high molecular weights will result from light-scattering data for copolymers owing to fluctuations in chain composition; the magnitude of this effect increases rapidly as the absolute value of the refractive index increment approaches zero. The methods for determining the usual weight-average molecular weight and polydispersity of composition are described.

The theory was tested with experimental results on: (1) a mixture of polystyrene and poly(methylmethacrylate), considered as a copolymer with the highest possible polydispersity of composition; (2) a high conversion, statistical copolymer of styrene and methylmethacrylate (copolymer I); and (3) a block copolymer of the same monomers (copolymer II). The apparent molecular weight for copolymer I ($M_w = 1.83 \times 10^5$) varied markedly with refractive index increment in much the same way as the total molecular weight for the mixture. The molecular weight of copolymer II ($M_w = 1.20 \times 10^6$) remained essentially constant in the same series of solvents. The polydispersities of composition obtained were 0.72 and 0.05 for copolymer I and II respectively compared with the maximum possible value equal to 1.0.

INTRODUCTION

Since the demonstration by Debye (1) that the amount of light scattered by solutions of high polymers is related to the mass of the solute molecules, light scattering has rapidly become one of the standard methods for the determination of molecular weights of macromolecules. The application of this technique to copolymers has not been equally successful. On one occasion (2) the molecular weight obtained for a sample of GR–S (butadiene–styrene copolymer) was found to vary with refractive index of the solvent and it was suggested that this might be due to heterogeneities in the composition of the particular sample. Similar anomalous molecular weights were obtained in this laboratory for other types of copolymers (3). Accordingly, it seemed desirable to study the problem of light scattering by copolymers and the use of this technique for the determination of molecular parameters both from theoretical and experimental viewpoints.

The theoretical treatment for the molecular weights of copolymers given in this paper is similar to that indicated by Stockmayer *et al.* (4) except that the final equations are arranged in somewhat more useful form. A preliminary report of the present study has already been published (5).

To test the theory, experimental data are presented for solutions of mixtures of polystyrene (PS) and poly(methylmethacrylate) (PMM) and two types of styrene–methylmethacrylate copolymers. These polymers were selected primarily because of the large difference between the refractive indices of the two homopolymers, polystyrene and poly(methylmethacrylate).

THEORETICAL

Introduction

In a homopolymer all the scattering elements scatter in the same manner; in a copolymer there may be two or more types of scattering elements depending on the number of monomer types that make up the copolymer. The treatment given here considers

[1]*Manuscript received August 5, 1958.*
Contribution from the Centre de Recherches sur les Macromolécules, Strasbourg, France, with financial assistance from the National Research Council of Canada.
[2]*Present address: Grain Research Laboratory, Winnipeg 2, Canada.*

only the binary copolymers, although it could be readily extended to include copolymers comprising more than two monomer types. The equations derived are completely general in that they are applicable to statistical, block, or graft copolymers, which may be polydisperse in mass as well as in composition.

Specific Refractive Index Increment

It is assumed that the refractivity of a copolymer is a simple sum of the refractivities of the two component homopolymers. As pointed out by Stockmayer *et al.* (4) this should be particularly true for block copolymers and probably does not introduce a very large error when applied to statistical copolymers. Accordingly, if c_A is the concentration of type A (polymer or monomer) and c_B is the concentration of type B, the refractive index of a solution of this copolymer (or mixture of homopolymers) will take on the value:

$$n = n_0+(dn/dc)_A c_A+(dn/dc)_B c_B, \quad [1]$$

where n_0 is the index of the pure solvent and the dn/dc are the specific refractive index increments for the components indicated. In this paper the two components A and B will be taken as polystyrene and poly(methylmethacrylate) respectively.

If the total concentration is $c = c_A+c_B$, then the increment for the solution will be

$$dn/dc = (n-n_0)/c = [(dn/dc)_A c_A+(dn/dc)_B c_B]/(c_A+c_B). \quad [2]$$

As has been verified on numerous occasions, equation [2] incorporates the fact that the specific refractive index increment of a solution of polymer depends only on the weight concentration and not on the molecular weight.

To simplify the notation set $(dn/dc)_A = \nu_A$; $(dn/dc)_B = \nu_B$; and $dn/dc = \nu$; and $x = c_A/(c_A+c_B)$ the weight fraction of component A. With this notation

$$\nu = x\nu_A+(1-x)\nu_B. \quad [3]$$

Accordingly the specific refractive index for a solution of copolymer in any solvent can be calculated if the composition of the copolymer and the increments for the corresponding homopolymers for the same solvent are known accurately.

Theory for Particles Small Compared with the Wavelength of Light

General

According to classical theory on light scattering, the excess scattering due to the solute particles of mass M, concentration c, and having ν for the specific refractive index increment (expressed in terms of the usual Rayleigh ratio R, extrapolated to zero concentration) can be put in the form

$$R = K'\nu^2 cM, \quad [4]$$

where $K' = (2\pi^2\eta_0^2)/(\lambda^4 N)$, in which η_0 is the refractive index of solvent, λ is the wavelength of the incident light in vacuum, and N is Avogadro's number. If the particles are polydisperse in molecular weight, M then becomes the weight-average molecular weight.

Now consider a solution of a copolymer which may show polydispersity of chain composition in addition to polydispersity of molecular weight. Assuming additivity of scattered intensities from the different scattering elements, equation [4] can be put in the form

$$R = K'\sum \nu_i^2 c_i M_i, \quad [5]$$

where c_i is the concentration of molecules of mass M_i and composition x_i. The refractive

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

index increment for this composition ν_i is defined by equation [3]. To separate the effects of heterogeneity of composition and molecular weight it would probably be clearer to use a double sum in equation [5]; that is, to characterize the species of molecular weight M_i by its compositions x_{ij}. However the writing can be simplified by using a single summation without affecting the rigorousness of the mathematical treatment. It is necessary only to keep in mind that it is possible to have different values of i for the same molecular weight.

The intensity of the scattered light that is actually measured is given by

$$R = K'\nu_0^2 c M_{ap}, \qquad [6]$$

where ν_0 is the average refractive index increment that is obtained by the usual methods of measurement and M_{ap} is the molecular weight that is obtained from the data by the standard method of extrapolation to zero concentration.

Equating the intensities given by equations [5] and [6] the molecular weight takes on the value

$$M_{ap} = \sum \nu_i^2 c_i M_i / \nu_0^2 c = (1/\nu_0^2) \sum \nu_i^2 \gamma_i M_i, \qquad [7]$$

where γ_i is defined as the relative concentration of molecules of composition x_i.

Equation [7] defines the molecular weight that is obtained experimentally for a polymer for which the component molecular species may exhibit different specific refractive index increments in a single solvent. This molecular weight will be referred to henceforth as the apparent molecular weight.

The significance of equation [7] can be best demonstrated by expanding the sum for specific cases to which it can be applied. The most important of these from the viewpoint of the present investigation is the copolymer of heterogeneous chain composition. This will be discussed first. The general equations obtained will then be applied to two special cases, the copolymer of homogeneous chain composition and a binary mixture of homopolymers.

Copolymer of Heterogeneous Composition

If $\nu_i \neq \nu_0$, which is the case when the composition of different molecules is different, equation [7] can be expanded to a more practical form by substituting for ν_i its value given by equation [3]. The new equation for the apparent molecular weight becomes

$$M_{ap} = (\nu_A\nu_B/\nu_0^2)\sum\gamma_i M_i + [\nu_A(\nu_A-\nu_B)/\nu_0^2]\sum\gamma_i M_i x_i^2 + [\nu_B(\nu_B-\nu_A)/\nu_0^2]/\sum\gamma_i M_i(1-x_i)^2. \qquad [8]$$

Equation [8] can be simplified further by introducing the equalities: $\sum\gamma_i M_i = M_w$; $\sum\gamma_i M_i x_i^2 = x_0 M_A$; and $\sum\gamma_i M_i(1-x_i)^2 = (1-x_0)M_B$. M_w is the weight-average molecular weight of the copolymer, M_A and M_B are defined as the weight-average molecular weights of the parts of the copolymer formed of monomer A and B respectively, and x_0 is the over-all average weight fraction of component A.

$$M_{ap} = (\nu_A\nu_B/\nu_0^2)M_w + [\nu_A(\nu_A-\nu_B)/\nu_0^2]\, x_0 M_A + [\nu_B(\nu_B-\nu_B)/\nu_0^2](1-x_0)M_B. \qquad [9]$$

Equations [8] and [9] show that if the copolymer is of heterogeneous chain composition, the molecular weight of the particular sample, obtained from light-scattering data, will depend on the refractive index of the solvent and, as will be seen later, this dependence is related to the degree of heterogeneity. It is therefore quite possible to obtain an infinitely high apparent molecular weight as the scattering may not necessarily be zero, when the average refractive index increment is zero, owing to heterogeneity of the sample.

From measurements in three solvents it should be possible, in principle, to solve for the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

three parameters M_A, M_B, and M_w from which the composition of the copolymer can be verified. From the same three sets of measurements it is also possible to obtain information on the degree of heterogeneity of composition.

The quantitative determination of the degree of polydispersity of chain composition becomes more feasible if equation [7] is expanded by a slightly different notation from that used to obtain equations [8] and [9]. In this case set

$$\delta x_i = x_i - x_0 \qquad [10]$$

where δx_i is the deviation in composition of molecules of type i from the average composition, x_0. According to this notation, equation [3] for the refractive index increment takes on the form

$$\nu_i = \nu_0 + \delta x_i(\nu_A - \nu_B) \qquad [11]$$

and the equation for the apparent molecular weight becomes

$$M_{ap} = M_w + 2(\nu_A - \nu_B)/(\nu_0)\sum\gamma_i M_i \delta x_i + (\nu_A - \nu_B)^2/(\nu_0^2)\sum\gamma_i M_i \delta x_i^2. \qquad [12]$$

It can be shown that equation [12] is equivalent to equation [9] by substituting in the former the following equalities,

$$2\sum\gamma_i M_i \delta x_i = (1-x_0)(M_w - M_B) - x_0(M_w - M_A) \qquad [13]$$

$$\sum\gamma_i M_i \delta x_i^2 = x_0(1-x_0)(M_A + M_B - M_w).$$

These relations are derived by substituting the value for δx_i given by equation [10] and expanding the sums indicated.

By introducing two new parameters P and Q, equation [12] becomes

$$M_{ap} = M_w + 2P[(\nu_A - \nu_B)/\nu_0] + Q[(\nu_A - \nu_B)/\nu_0]^2, \qquad [14]$$

in which P and Q are equal to $\sum\gamma_i M_i \delta x_i$ and $\sum\gamma_i M_i \delta x_i^2$ respectively. To plot equation [14] it is convenient to divide both sides of the equation by M_w.

According to equation [14], if M_{ap} is plotted against $(\nu_A - \nu_B)/\nu_0$, which varies with the refractive index of the solvent, the points should describe a parabola from which the values of the parameters M_w, P, and Q can be estimated. The value of M_w should agree with the value obtained from equation [9]. The other two parameters are related to the heterogeneity in composition of the sample by the definitions given above and should be constant for a particular copolymer. In general, the values of P and Q will vary between the following limits:

$$-x_0 M_w \leqslant P \leqslant (1-x_0)M_w,$$

$$0 \leqslant Q \leqslant M_w[1 - x_0(1-x_0)].$$

If the copolymer is monodisperse in mass or if the distribution of chain composition is independent of molecular weight, equation [14] simplifies further since under such conditions $P = 0$ and Q can only take on values between 0 and $x_0(1-x_0)M_w$. The maximum value of Q can only be realized with a mixture of two homopolymers.

The parameter Q/M_w for a specific copolymer may be defined as a quantitative measure of the polydispersity of chain composition. Accordingly the ratio of the value of Q/M_w, determined either graphically or by a direct calculation, to the maximum possible value, $x_0(1-x_0)$, seems to be a convenient index of the polydispersity in chain composition which can be used as an additional parameter for characterizing copolymers.

Copolymer of Homogeneous Composition

If the copolymer molecules are of uniform composition then $\nu_i = \nu_0$ for all values of i, $\delta x_i = 0$ and equation [12] gives

$$M_{ap} = M_w, \qquad [15]$$

where M_w is the usual weight-average molecular weight. That is, for a copolymer of homogeneous chain composition, the molecular weight obtained from light-scattering data will be independent of the refractive index of the solvent.

For this special case, equations [13] give $M_A = x_0 M_{ap}$ and $M_B = (1-x_0)M_{ap}$. These relations can then be used to determine the weight-average molecular weights of the two components of the copolymer.

Solution Containing Two Homopolymers

For a system comprising two homopolymers A and B, of molecular weights M_A and M_B and relative concentrations γ_A and γ_B, equations [7], [9], or [14] give

$$M_{ap} = (\nu_A^2 \gamma_A M_A + \nu_B^2 \gamma_B M_B)/\nu_0^2. \qquad [16]$$

Equation [16] shows that for a mixture of homopolymers the apparent molecular weight will depend on the refractive index of the solvent and in general will not be equal to the usual weight-average molecular weight. In a solvent with refractive index intermediate between those of the two polymers, concentrations can be selected so that the average refractive index increment will be zero. However the solution will still show positive scattering. The apparent molecular weight will then become infinite. For a solvent having the same refractive index as either component, equation [16] will give the weight-average molecular weight of the other component.

It is of interest to examine what happens to the parameters P and Q in this special case. The summations in the definitions of these parameters given above can be readily expanded to give

$$P = x_0(1-x_0)(M_A - M_B)$$
$$Q = x_0(1-x_0)[(1-x_0)M_A + x_0 M_B]. \qquad [17]$$

Equations [17] show that when the polymers are of the same mass, P will be zero as in the case of monodisperse (in mass) copolymers. If $M_A \neq M_B$, but are of the same order of magnitude, P will still be small compared with Q. This will not be true always and P can actually have values greater than those of Q when M_A and M_B are very different, that is, when the sample has a very broad distribution of molecular weight as well as of composition.

Theory for Particles of Size Comparable to the Wavelength of Light

If the dimensions of the solute molecules are greater than approximately 1/20 λ, the same type of destructive interference in the scattered light will result in the case of copolymers as with homopolymers. It is therefore necessary to make a correction for this interference in the usual manner by extrapolating to zero angle according to the method of Zimm (6). The value of the molecular weight so obtained will be the apparent molecular weight of the copolymer for the particular solvent used.

MATERIALS AND METHODS

Solvents

Solvents used for the light-scattering and the viscosity measurements were purified

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12

Polymers

The polystyrene used was a fraction of medium molecular weight obtained from a polydisperse polymer prepared at ordinary temperatures in the presence of an inhibitor. It was fractionated from benzene solution by precipitation by methanol. The polymer was dried in vacuum at 60° C. Its molecular weight and intrinsic viscosities in a number of solvents are listed in Table II which will be given in conjunction with a subsequent section.

The poly(methylmethacrylate) was of commercial origin (Plexiglass). It was purified by a single precipitation from a 2% solution in butanone by methanol followed by drying in vacuum at 60° C. Its molecular weight and intrinsic viscosities in a number of solvents are given in Table II.

TABLE II

SUMMARY OF RESULTS ON MIXTURES

†Measured on the Zeiss Interferometer.

Copolymer I was a statistical copolymer of styrene and methylmethacrylate prepared by using benzoyl peroxide as initiator. The copolymerization was allowed to proceed to about 95% conversion. It was then redissolved in benzene, precipitated by the addition of methanol, and dried in the usual manner. The composition of this copolymer was 68% PS and 32% PMM, as determined from the specific refractive index increments in five solvents. Combustion analysis gave its composition as 70% PS and 30% PMM.

Copolymer II was a block copolymer of styrene and methylmethacrylate. It was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

prepared by the method of Szwarc (7) in which the polystyrene was the living radical. Its composition from combustion analysis (and refractive index increments) was 70% PS and 30% PMM. It was used without further purification.

Methods

Solutions were prepared by weighing a predetermined quantity of polymer directly into a volumetric flask and making up to volume with dust-free solvent. Prior to the light-scattering measurements, portions of this solution of concentration c were diluted to $\frac{2}{3}c$, $\frac{1}{2}c$, and $\frac{1}{3}c$. Two samples of pure solvent (one to rinse the pipette used to transfer the dust-free solvent and the solutions) and the four solutions were centrifuged at 25,000g, for 1 hour to remove dust. With some of the higher density solvents it was necessary to filter the solutions through a fritted-glass filter prior to centrifugation.

Light-scattering measurements were made on a photometer described by Wippler and Scheibling (8) using the green mercury line (5460 Å) and pure benzene as the calibration standard. All experiments were made at 25±1° C. After the usual refractive index and volume corrections, the data were treated according to the extrapolation method of Zimm (6) using measurements ranging from 30 to 150° to the incident at the four concentrations shown above. Except where indicated otherwise, the refractive index increments were measured on a Pulfrich Refractometer with a divided cell using the green mercury line.

Molecular weights were calculated using the value of Carr and Zimm (9) for the Rayleigh ratio of benzene (16.3×10^{-6} for 5461 Å at 25° C). It was assumed that the correction factor owing to depolarization was negligible.

Viscosities were measured in a capillary viscometer described by Vallet (10). Viscometers with capillary diameters were selected so that the flow time for the pure solvent was at least 100 seconds.

RESULTS AND DISCUSSION

The most feasible way to test the theory developed above is to study the variation of the apparent molecular weight with refractive index of the solvent. The extent of this variation, in turn, depends on the degree of heterogeneity in chain composition of the copolymer. Accordingly, it should be possible in this manner to determine the effect of the variations in chain composition on the molecular weight determined by light scattering in any specific solvent.

The first series of light-scattering experiments were made on solutions of two homopolymers, comprising 65% PS and 35% PMM of the total polymer concentration. Two features of these solutions make these experiments significant. First, they are most suitable for testing the theory, since their compositions and refractive index increments are known accurately, and second, they can be regarded as solutions of copolymer having the greatest possible heterogeneity of chain composition.

Table II gives the results for the mixture in a series of solvents. The fourth column gives the ratio of the molecular weight obtained from the Zimm plot (M_{ap}) and the weight-average molecular weight calculated from the composition and the weight-average molecular weights of the homopolymers listed at the top of Table II. The viscosities are given as an additional characterization of the polymers used.

To illustrate the variation of the apparent molecular weight with refractive index of solvent, it is convenient to plot the ratio M_{ap}/M_w as a function of the index. Figure 1 shows such a plot of the data of Table II. Experimental data are shown as circles; the solid line represents a corresponding plot for which M_{ap} was calculated from equation

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

[16]. The agreement between theory and experiment is satisfactory considering the large experimental errors inherent in the measurements on solutions with very small refractive index increments.

The results for the copolymer I (statistical copolymer) are summarized in Table III. In this case the ratio M_{ap}/M_w was determined using the value of M_w (given later in Table V) calculated from equation [14] with the values of M_{ap} listed in Table III. The three unknowns of equation [14], M_w, P, and Q, were evaluated by solving three simultaneous equations. The value of M_w calculated in this manner is strongly dependent on the values for the refractive index increments for the two component polymers in the series of solvents used. Determination of the latter quantities involves a fairly large experimental error particularly in the cases where the increment is very small. Accordingly, it would probably be just as correct, and less laborious, to use for M_w the value of M_{ap} obtained with the solvent having the highest index increment (butanone).

*Calculated: $\nu_0 = 0.68(0.042)+0.32(-0.058)$.

Figure 2 gives the plots of M_{ap}/M_w as a function of the solvent refractive index. The circles represent data for copolymer I and the points those for copolymer II which will be discussed later. The lines represent points for which M_{ap}/M_w was calculated from equation [14] for the corresponding experimental conditions and the values of Q/M_w indicated. The second term of the right hand side of equation [14] was not included in the calculations for this plot, since it was found that when M_{ap} was plotted against $(\nu_A-\nu_B)/\nu_0$ the slope at $(\nu_A-\nu_B)/\nu_0 = 0$, which is equal to 2P, was essentially zero.

Figure 2 demonstrates clearly a marked variation in the apparent molecular weight of copolymer I with index of solvent. Even in the case of benzene, which is commonly used as solvent, the value of the apparent molecular weight is much higher than the true weight-average molecular weight.

Another method of plotting the data of Fig. 2 is demonstrated in Fig. 3. Here M_{ap}/M_w is plotted as a function of $(\nu_A-\nu_B)/\nu_0$. According to equation [14] the points in such a plot should fall on a parabola. One difficulty with using this plot is to find solvents that will give negative values of $(\nu_A-\nu_B)/\nu_0$. 1-Bromonaphthalene is one such solvent for styrene–methylmethacrylate copolymers; unfortunately measurements on copolymer I in this solvent could not be made owing to shortage of the copolymer. From Fig. 3 it is possible to estimate the value of Q/M_w that will best fit the experimental data. The value of this parameter for copolymer I is approximately 0.15. This result indicates an exceptionally high heterogeneity of chain composition, since the highest possible value that Q/M_w could have is 0.22.

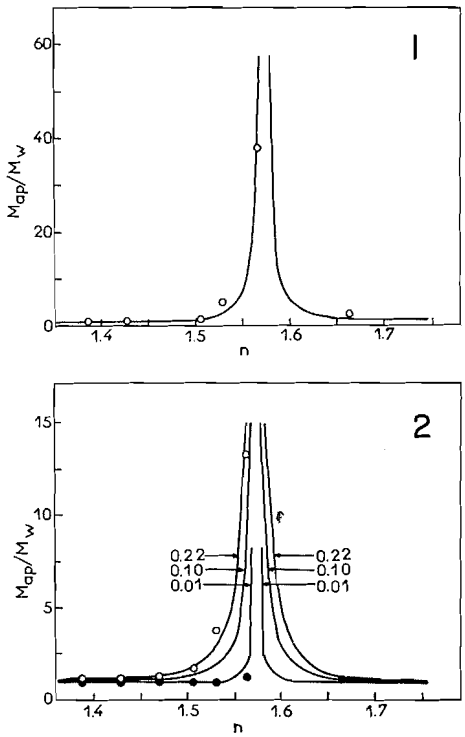

FIG. 1. Apparent (total) molecular weight of mixture comprising 65% PS and 35% PMM (expressed as M_{ap}/M_w) vs. refractive index of solvent. Circles, experimental data; lines, M_{ap} calculated from equation [16].

FIG. 2. Apparent molecular weight (M_{ap}/M_w) vs. refractive index of solvent. Experimental data: circles, copolymer I; points, copolymer II. Lines represent values of M_{ap} calculated from equation [14] with $P = 0$ and Q/M_w as indicated.

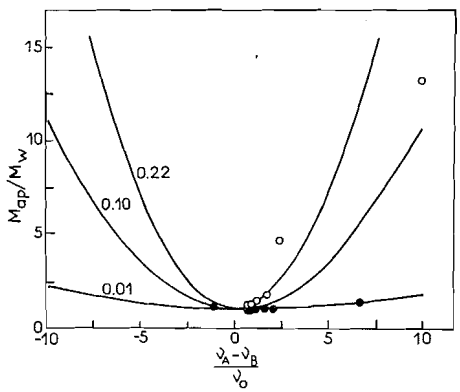

FIG. 3. Apparent molecular weight (M_{ap}/M_w) vs. $(\nu_A-\nu_B)/\nu_0$. Experimental data: circles, copolymer I; points, copolymer II. Lines represent data calculated from equation [14] with $P = 0$ and Q/M_w as indicated.

The high heterogeneity of composition found for copolymer I may seem somewhat contrary to the suggestion by Stockmayer (11) that the instantaneous distribution of chain composition of copolymers can be described by a very narrow Gaussian distribution curve. This is probably true in the case of low conversion copolymers (4); however, it

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

seems that high conversion copolymers may show considerable heterogeneity of chain composition. Indeed, the theory of copolymerization (12) does predict that high conversion copolymers will in general be of heterogeneous chain composition. It does not seem likely that copolymer I could be a mixture of copolymer and homopolymer of either type A or B.

A further remark is necessary regarding the merits of the two methods of plotting the experimental data shown by Figs. 2 and 3. Figure 2 gives a very striking demonstration of the extent of variation in the apparent molecular weight with the refractive index of the solvent. The deviation of M_{ap}/M_w from unity for the various solvents is related to the degree of heterogeneity of chain composition. To obtain a quantitative measure of this heterogeneity graphically, the plot of Fig. 3 is more useful than that of Fig. 2.

Table IV summarizes the light-scattering results on copolymer II (block copolymer). For this copolymer, the value of M_{ap}/M_w is equal to unity, within experimental error, for all the solvents used. Accordingly, it is concluded that copolymer II is of reasonably uniform chain composition. Whether this is generally true for copolymers prepared by the Szwarc method or whether the homogeneous composition can be attributed to the high degree of polymerization will have to be ascertained by further experiments. The results for copolymer II were plotted in Figs. 2 and 3 for the purpose of comparison.

TABLE IV

SUMMARY OF RESULTS ON COPOLYMER II

Composition: 70% PS+30% PMM

Solvent	ν_0 (cc g^{-1})	$M_{ap}\times10^{-6}$	M_{ap}/M_w
Butanone	0.195	1.42	1.18
Dioxane (p)	0.139	1.15	0.96
Carbon tetrachloride	0.116	1.39	1.16
Benzene	0.074	1.40	1.16
Chlorobenzene	0.051	1.30	1.08
Bromobenzene	0.015*	1.91	1.59
1-Bromonaphthalene	−0.096†	1.74	1.45

*Calculated: $\nu_0 = 0.70(0.042)+0.30(-0.058)$.
†Measured on the Zeiss Interferometer.

As indicated in the theoretical section, it should be possible to determine the weight-average molecular weights of the fractions comprising part A and B of the copolymer. The values obtained for the two copolymers used in this study are given in Table V. The values for M_A and M_B listed were calculated from equation [9] taking the values for M_{ap} from Fig. 2 for n equal to 1.49 where $\nu_B = 0$ and 1.61 where $\nu_A = 0$.

TABLE V

SUMMARY OF DERIVED DATA FOR COPOLYMERS I AND II

Copolymer	M_A	M_B	M_w	P/M_w	Q/M_w	Q/Q_{max}
I	1.74×10^5	0.82×10^5	1.83×10^5	0.01	0.16	0.72
II	0.84×10^6	0.36×10^6	1.20×10^6	0.00	0.01	0.05

Table V also gives the values of M_w, P/M_w, and Q/M_w. These were calculated from equation [14] using the values of M_{ap} for all the solvents used and listed in Tables III and IV.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

It may be seen that for copolymer II, which seems to be of reasonably homogeneous composition, the sum of the molecular weights of the components is equal to the molecular weight of the copolymer. This is not true for copolymer I in which case M_w is related to M_A and M_B by equation [16].

As found by graphical interpolation, the value of P (actually P/M_w) for copolymer I is considerably smaller than that of Q (Q/M_w). Accordingly, omission of the term containing P when using equation [14] seems to be justified. The calculated value of Q/M_w is in satisfactory agreement with that obtained by the graphical method.

The last column of Table V gives the ratio Q/Q_{max} where Q_{max} is calculated from the relation $x_0(1-x_0)$, which for both copolymers is approximately 0.22. This ratio may be taken as the quantitative measure of the heterogeneity of chain composition as compared with the maximum possible value equal to unity. Expressed in this manner, the heterogeneity of composition values are 0.72 and 0.05 for copolymer I and II respectively.

As an application of the findings presented in this paper, it should be possible to study the variation of chain composition of copolymers as a function of conversion during copolymerization by means of light scattering. Information of this type may be of considerable value in the interpretation of copolymerization kinetics.

ACKNOWLEDGMENTS

One of the authors (W.B.) wishes to make the following grateful acknowledgments. To Professor C. Sadron, Director, Centre de Recherches sur les Macromolécules, Strasbourg, for making available the facilities of the laboratory and for his kind interest throughout the project; to the professional members and the technicians of the same laboratory for their co-operation, assistance, and advice during the period the author spent at the laboratory; to the National Research Council of Canada for the financial assistance in form of an Overseas Postdoctorate Fellowship; to the Royal Society of Canada for the Rutherford Memorial Fellowship.

The authors wish to thank Drs. Banderet and Rempp of the Centre de Recherches sur les Macromolécules for providing copolymers I and II respectively.

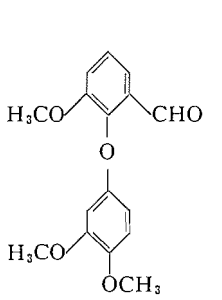
SUR LA SYNTHÈSE DE FORMYLDIPHÉNYL ÉTHERS POLYSUBSTITUÉS[1]

R. CONSTANTIN[2] ET P. L'ÉCUYER

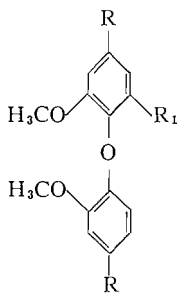
RÉSUMÉ

Bon nombre de formyldiphényl éthers ont été synthétisés en faisant réagir certains phénols avec la 2-chloro-5-nitrobenzaldéhyde ou la 3-nitro-4-chlorobenzaldéhyde. Plusieurs l'ont été en condensant le tosylate de la 5-nitrovanilline ou de la 4-hydroxy-3-nitrobenzaldéhyde avec divers phénols. Ces derniers ne donnent pas d'éthers avec la 2-chloro-5-nitrobenzaldéhyde; mais, cependant, les phénolates alcalins réagissent avec cette aldéhyde en solution alcoolique diluée. Par une série de réactions, les 2,2′-diméthoxy-4,4′-diformyl-6-nitro-, 2,2′-diméthoxy-4,4′-diformyl-, 2,2′-diméthoxy- 4,4′-bis-(β-carboxyvinyl)- et 2,2′-diméthoxy-4,4′-bis-(β-carboxyéthyl)-diphényl éthers ont été préparés.

Le travail de Purves (1) sur la synthèse de la papavérine et de la papavéraldine par la méthode de Pomeranz–Fritsch nous a fait imaginer que le 2,3′,4′-triméthoxy-6-formyldiphényl éther (I) pourrait servir de matière première à la préparation de la cularine. Le désir de préparer cette aldéhyde nous a conduits à l'étude des méthodes de synthèse des formyldiphényl éthers polysubstitués.



I



II

R = CHO, CH=CH$_2$–CO$_2$H ou CH$_2$—CH$_2$—CO$_2$H
R$_1$ = H ou NO$_2$

La préparation d'éthers diphényliques à partir d'un phénol et de chlorobenzènes convenablement activés a déjà été décrite par Grundon et Perry (2). Nous avons obtenu plusieurs formyldiphényl éthers en faisant réagir la 2-chloro-5-nitrobenzaldéhyde ou la 3-nitro-4-chlorobenzaldéhyde avec le phénol approprié en solution alcoolique diluée contenant 1 équivalent d'hydroxyde de sodium. Les rendements varient selon la nature et la position des groupes substituants (Tableau I).

Hems et quelques collaborateurs (3) avaient auparavant constaté que le tosylate du 2,4-dinitrophénol peut remplacer le 2,4-dinitrochlorobenzène dans les réactions de celui-ci avec un phénol pour donner aussi naissance à des diphényl éthers. Nous avons de cette façon préparé bon nombre de formyldiphényl éthers en condensant le tosylate de la 5-nitrovanilline ou de la 4-hydroxy-3-nitrobenzaldéhyde avec divers phénols dans la pyridine.

TABLEAU I

INFLUENCE DE LA NATURE ET DE LA POSITION DES GROUPES SUBSTITUANTS DANS LE PHÉNOLATE DE SODIUM SUR LE RENDEMENT DE SES RÉACTIONS (1 HEURE) AVEC LES FORMYLNITROCHLOROBENZALDÉHYDES EN SOLUTION AQUEUSE

	Rendement, %	
Phénolate	2-Nitro-4-formylchlorobenzène	2-Formyl-4-nitrochlorobenzène
2-Méthoxy	50.5	48
4-Méthoxy	52	53
3-Formyl	48	59
4-Formyl	25	30
2-Méthoxy-5-formyl	56.5	65
2-Méthoxy-4-formyl	15	5
2-Nitro	0	—
3-Nitro	49	—
4-Nitro	0	—
2-Méthoxy-3-nitro-5-formyl	22	—

Que l'on fasse réagir avec un phénol le tosylate d'un phénol ou un chlorobenzène convenablement activé, nous avons vérifié que le rendement de la réaction dépend de la durée de celle-ci. Il augmente graduellement jusqu'à un maximum qui s'obtient pour un temps de réaction allant de 60 à 90 minutes et décroît ensuite rapidement, lorsqu'on chauffe plus longtemps (Fig. 1).

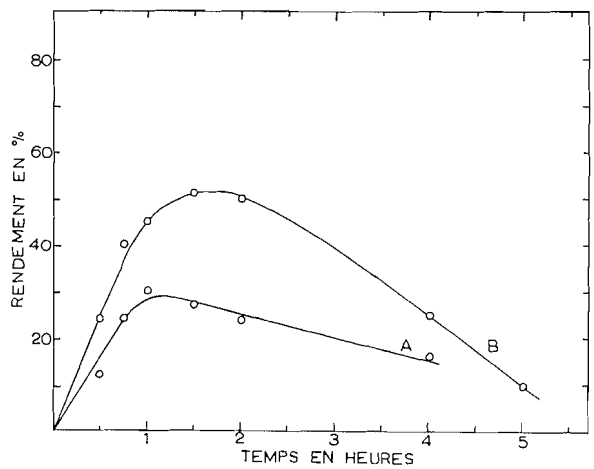

FIG. 1. Rendement de la réaction de 1 mole de guaïacol avec 3 moles de l'ester tosylique de la 5-nitrovanilline (A) ou de la 3-nitro-4-chlorobenzaldéhyde (B) en fonction du temps.

Quoique la réaction des formylchlorobenzènes ou des tosylates de phénols activés avec les phénols permette d'obtenir nombre de formyldiphényl éthers, il semble bien que la réaction de Hems ne va pas quand le groupement formyle est voisin du chlore ou du groupe oxytosyle, comme c'est le cas pour le 2-formyl-4-nitrochlorobenzène, par example. Il en est ainsi également pour la réaction d'Ullmann lorsque, en plus de la situation précédente, l'autre position voisine du chlore est occupée par un groupement méthoxyle. Par ailleurs, la réaction du tosylate de la 5-nitrovanilline ou de la 5-nitro-*o*-vanilline ne donne qu'une transestérification avec les phénolates alcalins. Nous avons cependant

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

réussi la condensation de la 2-chloro-5-nitrobenzaldéhyde avec les phénolates de sodium en milieu alcoolique dilué; mais nous n'avons pas réussi à obtenir la 2-chloro-3-méthoxy-5-nitrobenzaldéhyde pour préparer I.

Enfin, la condensation de la vanilline avec l'ester tosylique de la 5-nitrovanilline dans la pyridine a donné le 2,2′-diméthoxy-4,4′-diformyl-6-nitrophényl éther (II; R = CHO, $R_1 = NO_2$). Nous avons réduit celui-ci par le chlorure stanneux en 2,2′-diméthoxy-4,4′-diformyl-6-aminodiphényl éther et éliminé la fonction amine dans ce dernier en diazotant en présence d'acide hypophosphoreux pour isoler le 2,2′-diméthoxy-4,4′-diformyldiphényl éther (II; R = CHO, R_1 = H). En condensant celui-ci avec l'acide malonique dans la pyridine nous avons synthétisé le 2,2′-diméthoxy-4,4′-bis-(β-carboxy-vinyl)-diphényl éther (II; R = CH═CH—CO_2H, R_1 = H) dont la réduction par le nickel Raney a donné le 2,2′-diméthoxy-4,4′-bis-(β-carboxyéthyl)-diphényl éther (II; R = CH_2—CH_2—CO_2H, R_1 = H).

PARTIE EXPÉRIMENTALE*

Esters tosyliques de formylnitrophénols

Tout en agitant mécaniquement et en maintenant la température au-dessous de 5°, on ajoute du chlorure de *p*-toluènesulfonyle (0.11 mole) à une suspension du formyl-nitrophénol (0.1 mole) dans la pyridine (70 ml). Le tout se dissout et on abandonne la solution à la température ambiante jusqu'à ce qu'un précipité commence à se former. On verse alors le mélange dans environ 300 ml d'eau froide. On essore l'ester et on le lave à l'eau. Il cristallise dans le solvant approprié en lamelles blanches (Tableau II).

TABLEAU II

ESTERS TOSYLIQUES DE PHÉNOLS

Phénol	P.f., °C	Rdt, %	Solvant	Formule	N	
					% calculé	% trouvé
5-Nitrovanilline (2)	144–145	78	Acide acétique	$C_{15}H_{13}O_7NS$	3.98	3.9
5-Nitro-*o*-vanilline	72	74	Éthanol	$C_{15}H_{13}O_7NS$	3.98	4.1
2-Nitro-4-formylphénol	115	84	Éthanol	$C_{14}H_{16}NS$	4.36	4.5

Esters diphényliques dérivés de la 5-nitrovanilline

On bout à reflux pendant 1 heure une solution de tosylate de la 5-nitrovanilline (0.01 mole) et du phénol approprié (0.03 mole) dans de la pyridine (10 ml). On abandonne le mélange réactionnel à la température ambiante et, une fois refroidi, on le verse dans environ 100 ml d'eau froide. On extrait la suspension à l'éther, on lave l'extrait éthéré successivement à l'acide chlorhydrique et à la soude dilués, et enfin à l'eau, puis on l'évapore à siccité. On cristallise l'éther dans le solvant approprié (Tableau III).

Éthers diphényliques dérivés de la 3-nitro-4-hydroxybenzaldéhyde

On peut préparer ces éthers comme précédemment à partir du tosylate de la 3-nitro-4-hydroxybenzaldéhyde (0.01 mole) et du phénol requis (0.03 mole) dans la pyridine (10 ml) (façon de procéder (*a*)), ou bien en chauffant à reflux pendant 1 heure de la 3-nitro-4-chlorobenzaldéhyde (0.01 mole) avec le phénol approprié (0.03 mole) dans la pyridine (10 ml) (façon de procéder (*b*)), ou dans 5 ml d'eau contenant 0.4 g (1 équivalent)

**Les points de fusion ont été pris à l'aide de l'appareil de Johns.*

Éthers diphényliques dérivés de la 5-nitrosalicylaldéhyde

Dans une solution de 2-chloro-5-nitrobenzaldéhyde (0.01 mole) dans de l'éthanol (5 ml) on verse une solution du phénol approprié (0.01 mole) dans 5 ml d'eau contenant

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

0.4 g (1 équivalent) d'hydroxyde de sodium et on fait bouillir à reflux pendant 1 heure. Lorsque le mélange réactionnel est à la température ambiante on le dilue avec de l'eau, on essore l'éther précipité et on le cristallise dans l'éthanol sauf pour le 2′-méthoxy-2,5′-diformyl-4-nitrodiphényl éther qu'on cristallise dans l'acide éthanoique (Tableau V).

TABLEAU V

2-FORMYL-4-NITROPHÉNYL ARYL ÉTHERS

Groupe aryle	P.f., °C	Rdt, %	Forme cristalline	Formule	N % calculé	N % trouvé
2-Méthoxyphényle	113	48	Aiguilles blanches	$C_{14}H_{11}O_5N$	5.12	5.2
4-Méthoxyphényle	105	53	Aiguilles blanches	$C_{14}H_{11}O_5N$	5.12	4.9
3-Formylphényle	119–120	59	Prismes jaunâtres	$C_{14}H_9O_5N$	5.16	5.0
4-Formylphényle	131.5	30	Prismes blancs	$C_{14}H_9O_5N$	5.16	5.3
2-Méthoxy-4-formylphényle	71	47	Aiguilles blanches	$C_{15}H_{11}O_6N$	4.65	4.9
2-Méthoxy-5-formylphényle	210	65	Lamelles blanches	$C_{15}H_{11}O_6N$	4.65	4.6

2,2′-Diméthoxy-4,4′-diformyldiphényl éther (II; R = CHO, R_1 = H)

On ajoute 9.93 g (0.03 mole) de 2,2′-diméthoxy-4,4′-diformyl-6-nitrodiphényl éther à une solution de chlorure stanneux (23.0 g) dans 25 ml d'acide chlorhydrique concentré. On agite ce mélange pendant 2 heures à la température ambiante, puis 5 minutes à 80°. On refroidit et on décompose le composé complexe en le versant dans 150 ml d'eau. On essore l'amine, on la dissout dans 50 ml d'acide chlorhydrique dilué (1:1) et on la diazote à 0° par l'addition d'une solution de nitrite de sodium (2.1 g) dans 10 ml d'eau. Tout en agitant cette solution du sel de diazonium et en la maintenant à 0°, on verse lentement 100 ml d'acide hypophosphoreux à 30% préalablement refroidi à 0° et on laisse reposer le tout à cette température pendant 20 heures. On essore le précipité qui s'est formé et on le lave successivement à la soude diluée et à l'eau. Après avoir cristallisé dans un mélange de benzène et d'éther de pétrole, on obtient 6.5 g (76% de la théorie) de 2,2′-diméthoxy-4,4′-diformyldiphényl éther pur sous la forme de prismes blancs de p.f. 123°. Calculé pour $C_{16}H_{14}O_5$: C, 66.9%; H, 4.9%. Trouvé: C, 66.7%; H, 5.1%.

2,2′-Diméthoxy-4,4′-bis-(β-carboxyvinyl)-diphényl éther (R = CH=CH—CO_2H, R_1 = H)

On chauffe au bain-marie pendent 1 heure, puis à reflux durant 5 minutes, un mélange de 2,2′-diméthoxy-4,4′-diformyldiphényl éther (5.8 g, 0.02 mole), d'acide malonique (6.5 g, 0.08 mole), de pyridine (25 ml) et de pipéridine (0.5 ml). On verse ensuite la solution froide sur de la glace (100 g) additionnée de 25 ml d'acide chlorhydrique concentré et on filtre le précipité. On cristallise dans le benzène et on essore 5.9 g (80% de la théorie) de 2,2-diméthoxy-4,4′-bis-(β-carboxyvinyl)-diphényl éther pur sous la forme de cubes jaunâtres de p.f. 225–226°. Calculé pour $C_{20}H_{18}O_7$: C, 64.8%; H, 4.8%. Trouvé: C, 64.4%; H, 4.9%.

2,2′-Diméthoxy-4,4′-bis-(β-carboxyéthyl)-diphényl éther (R = CH_2—CH_2—CO_2H, R_1 = H)

À une solution vivement agitée de 2,2′-diméthoxy-4,4′-bis-(β-carboxyvinyl)-diphényl éther (7.41 g, 0.02 mole) dans 200 ml de soude à 10%, on ajoute, en petites portions et en l'espace de 1 heure, 20.0 g de l'alliage de nickel Raney. On filtre ensuite, on lave le précipité à l'eau et on verse le filtrat dans 10 ml d'acide chlorhydrique concentré. On essore le 2,2′-diméthoxy-4,4′-bis-(β-carboxyéthyl)-diphényl éther et on le cristallise dans

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

l'éthanol à 50%. L'éther cristallise en aiguilles blanches de p.f. 126°. Rendement: 6.0 g (80% de la théorie). Calculé pour $C_{20}H_{22}O_7$: C, 64.1%; H. 5.9%. Trouvé: C, 63.8%; H, 6.0%.

REMERCIEMENTS

ON THE SPECTRAL RESPONSE OF PHOTOCONDUCTION IN THIN SINGLE CRYSTALS OF ANTHRACENE[1]

J. FERGUSON[2] AND W. G. SCHNEIDER

ABSTRACT

The photoconduction of thin crystals of anthracene (sublimation flakes) has been studied as a function of the wavelength of the incident light as well as the geometry of the "surface cell" arrangement. With spot electrodes on one face of the crystal, the spectral response showed a very pronounced difference depending on whether the electrode face or the opposite face was illuminated. In the latter case the spectral response followed the absorption curve of the crystal, whereas when the electrode face was illuminated the photoconductivity was a minimum at wavelengths corresponding to maximum extinction coefficients of the crystal.

INTRODUCTION

Photoconduction of aromatic compounds has been the subject of a considerable number of recent publications (1–17). One important aspect of this work has been the study of the variation of the photocurrent with wavelength. Carswell (18) first noted that the spectral dependence of the photocurrent in anthracene crystals reproduced the absorption spectrum of the crystal, and Lyons and co-workers (3, 13, 14) have extended these measurements to other compounds. Lyons (4) has suggested a reason for the similarity between the absorption spectrum of the crystal and the spectral dependence of the photocurrent. During the course of an investigation of the absorption and fluorescence spectra of anthracene sublimation crystals (19, 20) we have remeasured the spectral dependence of the photocurrents in these crystals and we find that if particular care is taken to ensure that the electrode material is only on the surface on which the light falls, the spectral dependence does not reproduce the absorption spectrum. The present paper reports these measurements.

EXPERIMENTAL

The anthracene crystals were grown by sublimation in an atmosphere of carbon dioxide. Chromatographically pure anthracene which had been kept in the dark after purification was used. Crystals deliberately contaminated with tetracene were obtained by adding small amounts of tetracene to the anthracene before sublimation.

The sublimation crystals were usually transferred to a clean silica disk so that one of the developed *ab* crystal faces was in contact with the silica disk. The disk provided the necessary support for the very thin crystals. A few measurements were made on thicker crystals (about 3 μ) mounted over a slot cut in a silica disk so that only about one half of the crystal was supported by the disk. These measurements did not differ significantly from those made with the disk supporting all of the crystal.

Aquadag was initially used as the electrode material but it was found that at low light intensities the photocurrent showed an unusually long build-up time and this was eliminated by reverting to electrodes from alkadag. The electrodes were judged to be "good" if no back e.m.f. was found.

At first, electrodes were painted over each end of a crystal and also over part of the

silica disk. This produced an apparent variation of the spectral dependence of the photocurrent with crystal thickness. This variation was removed when care was taken to place the electrodes so that contact was made only with one *ab* face of the crystal. This was done by anchoring two flexible wires at diametrically opposite sides of a silica disk and making electrode contact to the exposed *ab* face with alkadag, taking particular care to prevent the electrode material from lapping over the edge of the crystal (see Fig. 1). Two arrangements were then possible, one with the light incident on the exposed *ab* face (electrode side), the other with the light incident on the opposite face.

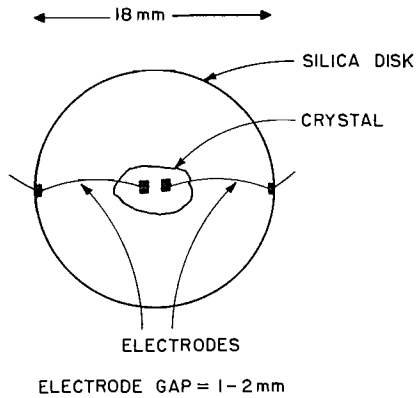

FIG. 1. Diagram of electrode arrangement. The incident light uniformly covered the electrodes and the area between the electrodes.

The silica disk was then mounted on a teflon block inside a brass cell fitted with a silica window. The cell, which could be evacuated, was clamped to a Keithley 200B micromicroammeter. Normally measurements were made in dry air but a few were made in an atmosphere of helium.

The spectral dependences were determined with a Beckman DU Spectrometer as a monochromator. The light source was a 500-watt projection lamp and the radiation was polarized by a sheet of polaroid between the exit slit and the cell. The wavelength knob of the monochromator was driven by a motor and the photocurrent was recorded by a Varian G10 recorder. The intensity dependence of the photocurrent was measured at different wavelengths by using filters of evaporated silver on silica. After the photoconduction measurements had been made the absorption spectrum in polarized light was determined in every case.

The photocurrents were usually in the range 10^{-13}–10^{-12} amp and slit widths varied from 0.05 to 0.4 mm, with 0.2 mm the usual value. No increased "resolution" was found at slit widths below this value.

RESULTS

A. Anthracene Crystals Containing Tetracene

There are two processes taking place after the absorption of light which could possibly complicate the interpretation of the spectral response of the photocurrent. These are the migration of excitation energy and reabsorption of fluorescence. It is important to demonstrate experimentally that migration of energy over a large number of lattice parameters (50–100) is not an essential factor in determining the spectral response. This

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

can be done simply by deliberately contaminating anthracene with small amounts of tetracene so as to quench the anthracene fluorescence and thereby reduce the mean free path of the exciton. This was done for a series of crystals with increasing tetracene concentration but no change in the polarized spectral response was observed, with either arrangement of electrodes and incident light, from that observed with pure anthracene crystals even when 90% of the emission was from the tetracene. These experiments also proved that reabsorption of fluorescence was not an important factor.

One observation, noted previously (15), is that the magnitude of the photocurrent is decreased markedly by the introduction of the tetracene. This suggests that the process leading to the production of charge carriers is one that does not take place in a time that is very short compared to the lifetime of the excited state, and the formation of charge carriers is thereby inhibited by any interaction which decreases, even slightly, the lifetime of this state.

B. Pure Anthracene Crystals

The spectral responses recorded here were all taken in dry air. Some measurements were made in which the cell was evacuated to 10^{-5} mm Hg and then dry helium introduced at atmospheric pressure. These showed that no significant changes occurred in the spectral response even after continued pumping resulting in appreciable sublimation of the crystals. As mentioned earlier, care was taken to ensure that the anthracene, after purification, was not exposed to light of high intensity so that photooxidation products on the surface of the crystals were kept to a minimum.

It was necessary to correct the spectral response in two ways. First, the intensity of the light incident on the crystal decreased with decreasing wavelengths so correction factors were calculated from the known energy distribution of the light source, the dispersion of the monochromator, and the transmission of the polaroid sheet. Measurements of the photocurrent at different wavelengths with polarized light of varying intensity showed that the photocurrent was directly proportional to the light intensity for both arrangements of light and electrodes. This result is needed to correct the response curves to equal energy input but is more important for an interpretation of the spectral response. Second, the spectral response has to be corrected in regions of the spectrum where the crystal transmits light. This occurs with very thin crystals for wavelengths within the absorption region and for all crystals at wavelengths on the absorption edge. In order to do this the absorption spectrum of each crystal was determined but no measurements of reflection losses were made. Although the latter will be small in regions where the absorption is strong (21) they are very important on the absorption edge when the optical density is less than about 0.2. As the correction factors convert the observed response to equal amounts of absorbed energy, they will be in serious error on the tail of the absorption band because the apparent absorption due to reflection is appreciable, and for this reason the corrected spectral dependences reported here cover only the wavelength region where reflection losses cause no appreciable error to the measured absorption spectrum.

As mentioned in the Experimental section, particular care is required in applying the electrode material to the crystals. If the electrodes are carefully placed only on the exposed *ab* face, then it is found that the spectral dependence depends critically on whether the incident light falls on this surface or on the opposite surface. Figs. 2 and 3 illustrate this behavior.

It was found that with light incident on the surface containing the electrodes the

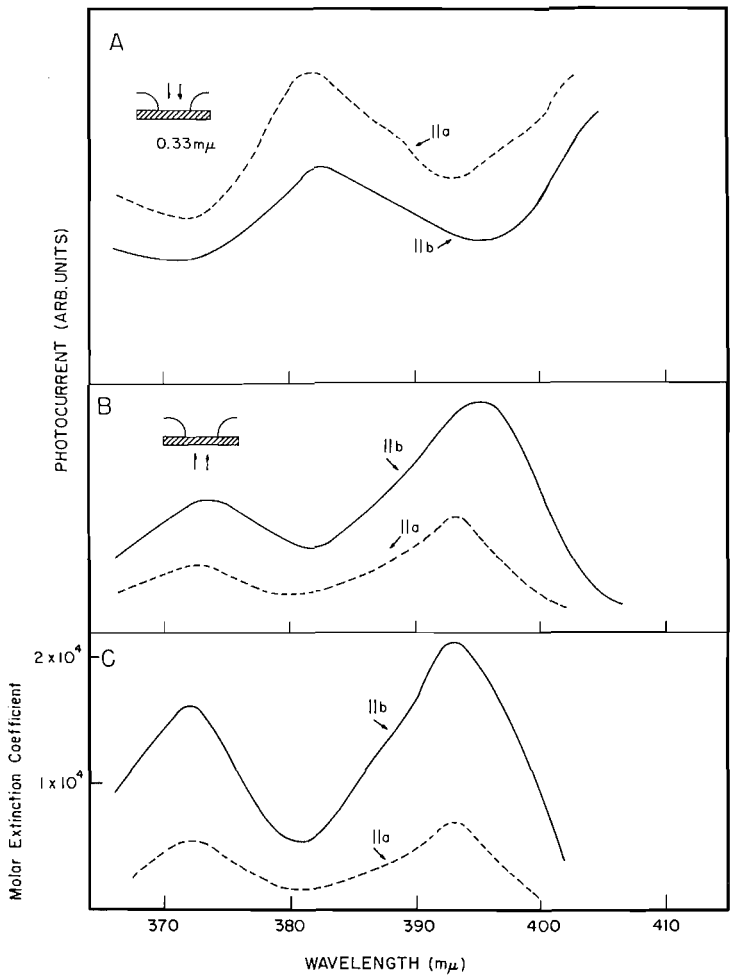

FIG. 2. The spectral dependence of the photocurrent (corrected to equal amounts of absorbed energy) in polarized light of a single anthracene crystal, thickness 0.33 μ; A, light incident on the surface containing the electrodes; B, light incident on the opposite face; C, the absorption spectrum of anthracene crystal (21).

wavelengths of maximum photocurrent correspond to wavelengths of minimum absorption coefficient, and this holds for both crystal polarizations. It is only when the light is incident on the other face that a resemblance is found between the spectral response of the photocurrent and the absorption spectrum of the crystal. In this case the wavelengths of maximum photocurrent correspond to wavelengths of maximum absorption coefficient and, although there is an apparent resemblance between the absorption spectrum and spectral response of the photocurrent, there is not a direct relation between the two. It must be assumed that in earlier reports of the spectral dependence of the surface cell the electrodes were not carefully confined to the surface on which the light was incident.

Measurements of the relative magnitudes of the photocurrents produced in the two arrangements were not made. However, with crystals of thickness about 4 μ mounted on silica and with electrodes not carefully confined to the top surface, i.e. electrode material painted over the crystal and onto the disk, the spectral response showed a resemblance to the absorption spectrum. This arrangement corresponds to electrodes simultaneously

on the front and back surfaces but with unequal distances between the electrodes. As the spectral response appeared similar to the absorption spectrum, we can assume that the arrangement with the electrodes on the back surface gives higher currents in the external circuit than the other arrangement.

A large number of measurements were made of the spectral response of a series of crystals of different thickness with the "true" surface cell arrangement, i.e. light incident

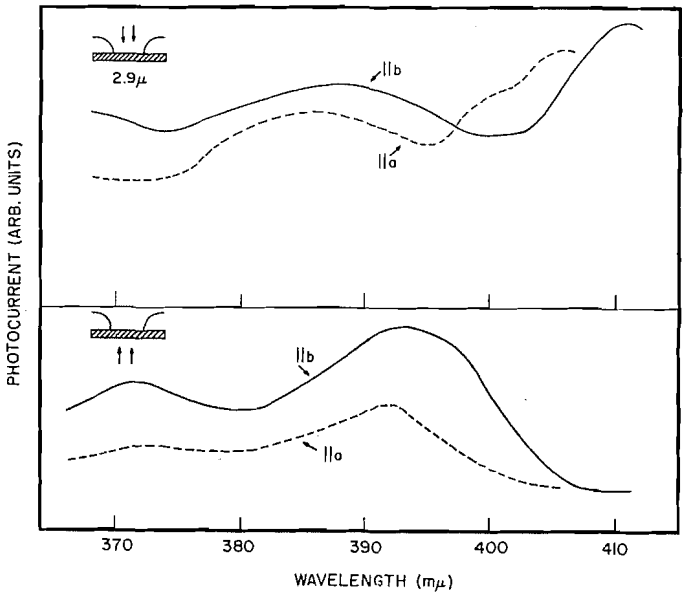

FIG. 3. The spectral dependence of the photocurrent (corrected to equal amounts of absorbed energy) in polarized light of a single anthracene crystal, thickness 2.9 μ. The top two curves were measured with the light incident on the surface containing the electrodes, the bottom two with the light incident on the opposite face.

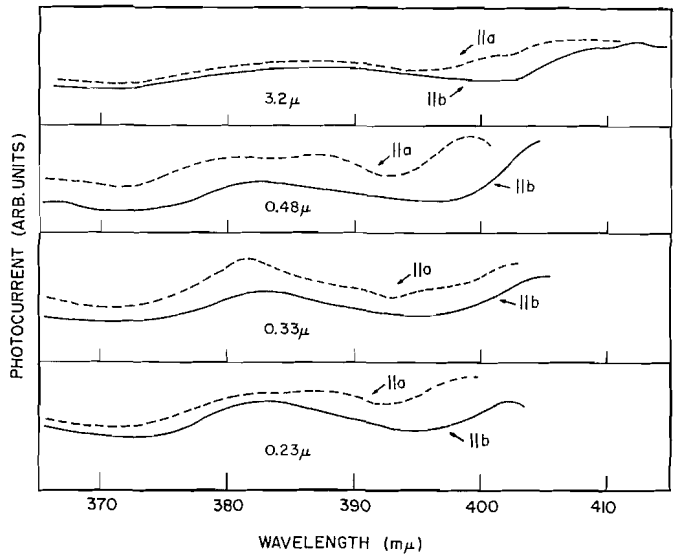

FIG. 4. The spectral dependence (corrected to equal amounts of absorbed energy) of the photocurrents in polarized light of four single anthracene crystals of different thickness, all measured with the light incident on the surface containing the electrodes.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12

on the face containing the electrodes. Fig. 4 shows some of the results. The crystal thickness ranges from 0.23 to 3.2 μ but there does not appear to be a dependence of the spectral response on crystal thickness. This is not strictly true for the *b* polarization, where there is seen to be a slight shift of the response to longer wavelengths for thicker crystals. This is interpreted as reflecting a modification of the surface energy levels in the thicker crystals (19), so that light absorbed near the surface is of slightly longer wavelength. The *a* polarization also shows variations in relative peak heights, as can be seen, but these show no correlation with crystal thickness.

DISCUSSION

It is apparent from Figs. 2, 3, and 4 that the wavelengths which are most strongly absorbed produce least photocurrent in the "true" surface cell arrangement. The result is striking and suggests immediately that carrier recombination limits the photocurrents in regions of high light absorption. However, the photocurrent is directly proportional to the light intensity and also, if recombination is limiting the photocurrent in these regions, then the spectral response in the arrangement where the light falls on the opposite *ab* face should be similar, whereas maximum photocurrent is found at wavelengths of high absorption coefficient.

Although the results are striking we are not able to interpret them at present. We do, however, make the suggestion that diffusion of charge carriers, hitherto neglected, should be seriously considered in any attempt at an explanation. The surface cell arrangement of electrodes must produce an inhomogeneous field within the crystal and this, coupled with diffusion of carriers, can possibly complicate the spectral dependence.

The parallelism between the spectral response within the absorption region and the absorption edge should be noted. Inside the absorption band we see that wavelengths of minimum light absorption (true surface cell arrangement) produce a higher photocurrent than wavelengths of maximum absorption. If we compare the absorption edge with the absorption band as a whole we see that the former produces a higher photocurrent than the latter, so the general rule appears to be that high photocurrents are obtained in regions of low light absorption. We must not therefore interpret the spectral response of the surface cell to mean that the absorption edge necessarily has a higher efficiency for charge carrier formation. This becomes clear when we compare the two regions in the other arrangement of the light and electrodes, the general rule here being that high photocurrents are obtained in regions of high light absorption.

We would like finally to suggest that considerable care be taken in the interpretation of spectral response curves of organic photoconductors as anthracene is not a unique case. It was shown earlier (22) that the spectral dependence of 9,10-dichloroanthracene is also critically dependent on incident light and electrode geometry. Also we note the attempt to assign the electronic states of the pyrene molecule from measurements of the polarized spectral dependence of single crystals of pyrene (14). The assignment of the lowest excited state is most likely correct but the sense of the polarization ratio as observed in the spectral dependence of the photocurrent is opposite to that found by direct absorption spectroscopy (23). This is then probably a result of some specific sensitivity of the electrode and incident light geometry.

KINETICS OF EXCITED MOLECULES

I. KETENE[1]

B. T. Connelly and Gerald B. Porter

ABSTRACT

The primary quantum yield of ketene decomposition was studied as a function of pressure, temperature, and wavelength. The results show that excited vibronic states are formed which may be degraded before dissociation can occur. The ratio of the rate of collisional degradation to the rate of dissociation decreases from 164 liters/mole at 3340 Å to 16.8 liters/mole at 3130 Å.

INTRODUCTION

Previous experiments have shown that the primary quantum yield of ketene decomposition is a function of the wavelength of the absorbed radiation. At 2700 Å Strachan and Noyes (1) found the primary quantum yield to be unity within experimental error, independent of pressure and temperature. At 3650 Å (1) the primary quantum yield, extrapolated to zero pressure of ketene, is much less than unity, decreases as pressure is increased, and increases with increase in temperature.

Following the absorption of 2700 Å radiation and the formation of an excited ketene molecule, dissociation occurs in less time than that required for collision with another molecule, to give a methylene radical and a molecule of carbon monoxide. The methylene radical then attacks another ketene molecule to form ethylene and another carbon monoxide, according to the following mechanism:

$$K + h\nu\ (2700\ Å) = K^m, \qquad [1m]$$

$$K^m = CH_2 + CO, \qquad [2m]$$

$$CH_2 + K = C_2H_4 + CO, \qquad [2m]$$

where K is a ketene molecule, and K^m is a ketene molecule excited by 2700 Å radiation. For each photon absorbed, one molecule of ketene is dissociated and two molecules of carbon monoxide are formed.

Strachan and Noyes (1) found the quantum yield of carbon monoxide formation to be 2.12 ± 0.15. They also found the ratio of the quantum yield of carbon monoxide formation to the quantum yield of ethylene to be 2.2 instead of 2.0 to be expected from reactions [1*m*] and [2*m*].

It is evident therefore that some methylene radicals are involved in another reaction, such as

$$CH_2 + y\,CH_2CO = \text{polymer} + CO.$$

At 3650 Å, the low quantum yields can be attributed to collisional deactivation and internal conversion of the excited ketene molecules (2), according to the following mechanism:

$$K + h\nu\ (3650\ Å) = K^q, \qquad [1q]$$

$$K^q = \text{products}, \qquad [2q]$$

$$K^q = K, \qquad [3q]$$

$$K^q + K = 2K. \qquad [4q]$$

The energy is dissipated in processes [3*q*] and [4*q*] as heat, since no fluorescence has ever been observed.

[1]*Manuscript received July 28, 1958.*
Contribution from the Department of Chemistry, University of British Columbia, Vancouver, B.C.

It is evident from the low quantum yield that reaction [3q] is more rapid than reaction [2q]. As the pressure is increased the rate of reaction [4q] increases from zero to become the dominant process. Extrapolation to zero pressure at 26° C gives a carbon monoxide quantum yield of approximately 0.07. At 3650 Å, therefore, dissociation occurs only after a finite time interval during which the excited ketene molecule may be deactivated.

Kistiakowsky and Mahan (3) found that the primary quantum yield at 3130 Å was independent of pressure and suggested a value of unity. However, they apparently investigated the photolysis over a narrow range of pressures and their results are therefore not conclusive. Investigation of the quantum yield at a number of wavelengths provides the means of determining the relation between the rate of dissociation and the energy of the dissociating molecule. It was therefore decided to investigate the photolysis of ketene at 3130 Å more carefully over a wide range of pressures using a technique whereby quantum yields could be determined accurately. This technique would reveal any small effect of pressure on the primary quantum yield that may have escaped detection in previous work (3).

It was felt that since another mercury-arc line, 3340 Å, occurs between 3130 Å and 3650 Å, precise quantum yield determinations at this wavelength would substantially increase our understanding of the process of deactivation.

EXPERIMENTAL

A medium pressure 100-watt Hanovia mercury-arc lamp was used as the light source for runs at 3130 Å. The lamp was encased in aluminum tubing with $\frac{1}{4}$-in. diameter hole opposite the arc. The lamp was run from a constant voltage regulator (115 volts). For runs at 3340 Å a B.T.H. medium pressure mercury-arc lamp was used. The divergent light beam passed through a combination of two quartz convex lenses.

A filter cell block consisting of two compartments each 2.5 cm long and with quartz windows, together with a 2-mm Corning 9863 filter to exclude visible radiation, was placed between the lenses and the cell. The quartz reaction cell of length 14.8 cm and diameter 3.6 cm was housed in a heated aluminum block in which the temperature could be controlled to within ±0.1° C. The emergent beam was passed through another convex lens and focused on the cathode of an RCA 935 photocell.

The filter solutions used are given in Table I and the respective transmissions at the various wavelengths are shown in Fig. 1. Filters A and B were similar to those of Hunt and Davis (4), although the nickel chloride was omitted. Filter C was similar to that suggested by Kasha (5).

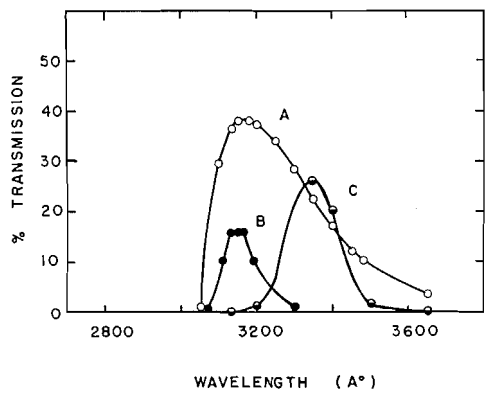

FIG. 1. Percentage transmission against wavelength for filters A, B, and C.

Gas Analyses

Gas analyses were carried out in an all-glass high-vacuum system evacuated by a standard-type oil pump and a single stage mercury diffusion pump. In this system mercury cutoffs were used in place of stopcocks.

The carbon monoxide analysis was performed by allowing the products to flow through successive baths cooled to −78° C, −196° C, −210° C (dry ice – acetone, liquid nitrogen, and solid nitrogen, respectively). The solid nitrogen trap was prepared by pumping on fresh liquid nitrogen for about fifteen minutes.

Ketene was condensed in the first two baths and the ethylene was collected in the solid nitrogen trap. Carbon monoxide was the only product not condensed at −210° C and was measured with a McLeod–Toepler gauge (1).

Diethyl Ketone

Diethyl ketone, used as the internal actinometer for runs at 3130 Å, was fractionally distilled (b.p. 101°). Once on the line, the diethyl ketone was distilled under vacuum and the middle third was retained.

Prior to each run, a quantity of diethyl ketone was transferred from a blackened storage bulb to a dry ice – acetone cooled trap and outgassed three times until all non-condensables and low-boiling gases were removed.

Ketene

Ketene was prepared in the vacuum system by pyrolyzing acetic anhydride (6). Trap-to-trap distillation was performed on the freshly prepared ketene and the middle third retained. Prior to each run, a quantity of ketene was thoroughly outgassed by three distillations similar to those for diethyl ketone. The ketene was stored in a trap immersed in liquid nitrogen to prevent polymerization.

Actinometry

3130 Å

Diethyl ketone was selected for experiments at 3130 Å where the quantum yield of carbon monoxide formation is 1.0 at 100° C (7). The use of an internal actinometer was found to be very convenient because it is devoid of the errors usually associated with external actinometers.

The measurement of the intensity absorbed during a run was performed by the conversion of the current from the photocell into a voltage which was continuously recorded on a 10-mv recorder. The following scale readings were taken:

R_i = cell empty,
R_t = photolyte in cell.

The recorder scale was calibrated using diethyl ketone as an internal actinometer.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

Scale readings were taken before and after each run to determine the average R_i. This was necessary because of the fluctuation and decay of the lamp, and polymer formation. R_t was measured continuously during each run.

The difference $R_i - R_t = R_a$ was calibrated in terms of absolute intensity by the measurement of carbon monoxide yields from the photolysis of diethyl ketone at 100° C. It was possible to measure R_a to within $\pm 0.5\%$ and, on averaging the results of a number of diethyl ketone runs, quantum yields of carbon monoxide formation from ketene were obtained within $\pm 3\%$.

At 3130 Å, an external actinometer was also used (8), but because of the large amount of reflection from the glass–air interfaces and because of the suspected polymer on the exit wall of the reaction cell, the values for the absolute intensity of the light were considerably lower than those obtained using diethyl ketone. Twelve runs were performed using potassium ferrioxalate actinometer; consistent results indicated the need for a conversion factor to be applied when the external liquid actinometer was used to estimate the energy absorbed during runs at 3130 Å.

The intensity found from a ferrioxalate run when multiplied by this conversion factor gave the intensity incident to the cell, reproducible to within $\pm 10\%$.

3340 Å

The potassium ferrioxalate actinometer was used for runs at 3340 Å, since no internal actinometer is available for this wavelength. The intensities obtained by this actinometry when multiplied by the conversion factor found previously were used to calibrate the recorder scale. Absorbed intensities were obtained from measurements of R_i, R_t, and R_a, as described previously.

RESULTS

3130 Å

Using filter solution combination A, at low pressures of ketene, a carbon monoxide quantum yield of 1.82 was obtained, whereas at high pressures around one atmosphere, the carbon monoxide quantum yield decreased to 1.08, as shown in Table II. A decrease in the carbon monoxide quantum yield at high pressures was expected.

The results of five diethyl ketone actinometer runs, at pressures ranging from 60 to 155 mm of diethyl ketone, and interspersed between the ketene runs, gave a light intensity of approximately 5.4×10^{14} quanta per second.

Using filter solution combination B, a new series of diethyl ketone actinometer runs gave intensities of approximately 1.6×10^{14} quanta per second. The carbon monoxide quantum yield at low pressures of ketene was 2.0 within experimental error, and at 1 atmosphere a value of 1.18 was obtained as shown in Table II.

Absorbed intensities varied from 0.442×10^{14} quanta per second at 17 mm to 1.911×10^{14} quanta per second at 751 mm. All ketene runs were conducted at 37° C.

It was found that the transmissions at 3130 Å of filters A and B were appreciably lower after 2 weeks' constant use.

3340 Å

The naphthalene in methyl alcohol solutions darkened after only a few hours' exposure to the lamp and its transmission at 3340 Å decreased noticeably. Even when a pyrex window, which absorbs 50% of the light at 3130 Å and 100% of light of shorter wavelengths, was placed in front of the naphthalene solution darkening continued. This effect may have been caused by the attack of methyl alcohol on the adhesive used to bond the quartz windows to the pyrex cell.

The intensity of the beam as measured using the ferrioxalate actinometer when multiplied by the conversion factor of 2.72 gave an incident intensity of approximately 2.1×10^{15} quanta per second. When related to the recorder, this became 0.87×10^{14} quanta per second per scale division. The carbon monoxide quantum yields were determined at both 37° C and 100° C and the results are summarized in Table II.

DISCUSSION

The photolysis of ketene at 2700, 3130, 3340, and 3650 Å can be explained by the following processes:

$$K + h\nu\ (2700\ Å) = K^m \qquad [1m]$$

$$K + h\nu\ (3130\ Å) = K^n \qquad [1n]$$

$$K + h\nu\ (3340\ Å) = K^p \qquad [1p]$$

$$K + h\nu\ (3650\ Å) = K^q \qquad [1q]$$

$$K^m = \text{products} \qquad [2m]$$

$$K^n = \text{products} \qquad [2n]$$

$$K^p = \text{products} \qquad [2p]$$

$$K^q = \text{products} \qquad [2q]$$

$$K^m = K \qquad [3m]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

$$K^n = K \quad [3n]$$
$$K^p = K \quad [3p]$$
$$K^q = K \quad [3q]$$
$$K^m + K = 2K \quad [4m]$$
$$K^n + K = 2K \quad [4n]$$
$$K^p + K = 2K \quad [4p]$$
$$K^q + K = 2K \quad [4q]$$

where K is a molecule of ketene, and K^m, K^n, K^p, and K^q are excited ketene molecules in order of decreasing vibrational energy. Reactions [1] represent activation; reactions [2] represent product formation; reactions [3] represent internal conversion; and reactions [4] represent collisional deactivation.

It is not implied that the above mechanism which represents the activation and deactivation of excited molecules K^m, K^n, K^p, and K^q formed at wavelengths 2700 Å, 3130 Å, 3340 Å, and 3650 Å is complete. It is obvious that a ketene molecule in vibronic state m can lose its excess energy by a series of vibrational cascades to states n, p, q, etc. until it eventually reaches the equilibrium vibrational state. The number of vibronic states may be 100 or more for a molecule initially in state m. The kinetics of such a process are very complicated and will be treated in a later paper (9).

For simplicity the present discussion will consider only reactions [1], [2], [3], and [4], with rate constants k_1, k_2, k_3, and k_4, to represent the activation, deactivation, and dissociation of excited ketene molecules in states m, n, p, and q.

In general,

$$1/\phi = 1+(k_3/k_2)+k_4[K]/k_2$$

represents the equation obtained by steady-state treatment; ϕ is the primary quantum yield, k_3/k_2 is the intercept in the plot $1/\phi$ against pressure, and k_4/k_2 is the slope in liters/mole.

2700 Å

Strachan and Noyes (1) found that the quantum yield of carbon monoxide formation was approximately two. According to the proposed mechanism the primary quantum yield is thus unity. It is evident, therefore, that over the range of pressures and temperatures used, internal conversion and collision deactivation of the excited ketene molecules is negligible. The only way in which these molecules can lose their excess energy is by dissociation. The observed quantum yields can be explained by the mechanism:

$$[1m], [2m].$$

That internal conversion and collisional deactivation are absent may be seen from the intercept of unity and the zero slope of the plot of $1/\phi$ against pressure.

3130 Å

The primary quantum yield of ketene decomposition at this wavelength appears as an isolated number in several papers devoted to ketene photolyses at other wavelengths (3, 9, 10, 11). However, only the recent work of Kistiakowsky and Mahan (3) gives experimental data. From the limited amount of information given it appears that photolyses were only performed at low pressures, in the region of 20 mm. It was found that the primary quantum yield was independent of pressure and possibly equal to unity.

This research has shown that when light which was not monochromatic but which contained quantities of both 3340 and 3650 Å radiation was used, primary quantum yields of 0.91 at 35.8 mm and 0.54 at 726.8 mm were obtained, as shown in Table II.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

The plot of $1/\phi$ against pressure intercepts the axis at approximately 1.1 and has a positive slope. It is likely, therefore, that internal conversion and collisional deactivation of the excited ketene molecule contribute slightly to the deactivation process.

Because of the known low quantum yields at 3650 Å and the suspected low yields at 3340 Å, a new series of experiments was performed using monochromatic 3130 Å radiation. The results of these experiments are shown also in Table II. The primary quantum yield is 1.0 at pressures between 17 and 60 mm, and 0.59 and 750.7 mm.

The plot of $1/\phi$ against pressure is shown in Fig. 2; although the extrapolation to zero pressure is unity, because of experimental error the presence of internal conversion is not entirely excluded from the mechanism. The positive slope of the plot in Fig. 2 indicates the presence of collisional deactivation, and hence the mechanism: [1n], [2n], [3n], [4n] may be postulated in which the extent of reaction [3n] is very small. k_3/k_2 is approximately zero while $k_4/k_2 = 16.8$ liters/mole.

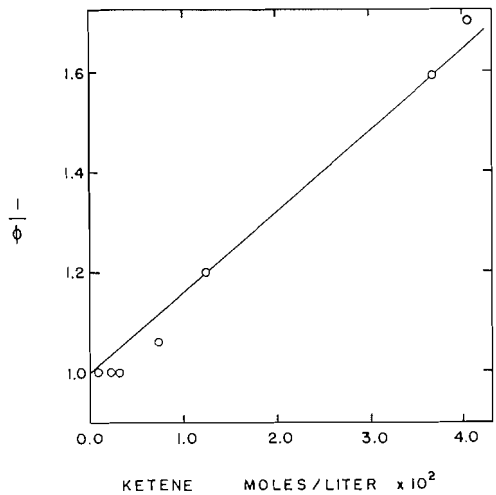

FIG. 2. Dependence of primary quantum yield on concentration at 3130 Å.

The mechanism of ketene decomposition at 3130 Å is intermediate between those postulated for 2700 Å and 3650 Å. From Table II it appears that at low pressures of ketene, every excited ketene molecule dissociates to form products, whereas, at pressures greater than approximately 60 mm, some of the excited molecules lose their energy by collision with unexcited molecules of ketene.

The photolysis at 3130 Å was not extended to higher temperatures because it was thought that little or no significant information would be obtained.

In three experiments the ethylene quantum yield was found to be 1/2.14 of the carbon monoxide quantum yield. This is approximately the same as that found at 2700 Å (1) and 3650 (1, 13).

3340 Å

This research has indicated that for photolyses at 37° C the primary quantum yield is 0.72 at 26 mm and 0.21 at 384 mm. The zero pressure intercept in Fig. 3 is 1.25. The slope of the plot is much steeper than for 3130 Å: 1.64×10^2 liters/mole. This indicates that considerable collisional deactivation of K^p occurs.

Four runs were performed at 100° C and as expected, both the slope and the intercept were smaller than for runs at 37° C. At 26.1 mm the primary quantum yield is 0.80 and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

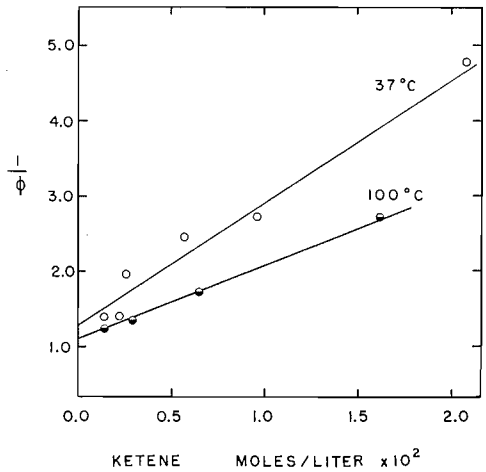

FIG. 3. Dependence of primary quantum yield on concentration at 3340 Å.

at 300 mm equals 0.37. The zero pressure intercept at 100° C is 1.1 and the slope of the straight line is 0.99×10^2 liters/mole, both obtained from Fig. 3. The ratio of the rates of internal conversion to product formation at 100° C is 0.1.

The mechanism for the activation and deactivation of K^p is: [1p], [2p], [3p], and [4p], at both 37° C and 100° C. From this information in Table II and Fig. 3, it was possible to estimate approximately the activation energy of reaction [2p] from the slope of the plot of $\log_e(k_4/k_2)$ against $1/T$. The slope is $(E_2-E_4)/R$. If E_4 is assumed to be zero, then E_2 is approximately 2 kcal/mole. This value is subject to a large uncertainty.

3650 Å

Strachan and Noyes (1) found a zero pressure intercept of 28 in the plot of reciprocal primary quantum yield against pressure. This corresponds to a primary quantum yield of approximately 0.036 at 26° C. The slope of the linear plot is 4.65×10^4 liters/mole.

Both the intercept and the slope decrease with increasing temperature. The activation energy of reaction [2q] is 4.5 kcal/mole.

k_3/k_4 as a Function of Wavelength

At 2700 Å, this ratio is indeterminant. Values of approximately 3×10^{-3}, 1.2×10^{-3}, and 6×10^{-4} all expressed in moles/liter are found for 3130 Å, 3340 Å, and 3650 Å, respectively. It must be emphasized that the values found for 3340 Å and particularly 3130 Å are subject to possible large errors.

k_2/k_4 as a Function of Wavelength

The slope of the plot of reciprocal quantum yield against pressure shows a marked dependence on wavelength, increasing from zero at 2700 Å to 4.65×10^4 liters/mole at 3650 Å. The intermediate values are 16.8 liters/mole at 3130 Å and 1.64×10^2 liters/mole at 3340 Å. It should again be pointed out that the result at 3650 Å was found at 26° C, whereas the other values were obtained at 37° C.

k_2/k_4 is thus 0.06, 0.61×10^{-2}, and 0.22×10^{-4} moles/liter at 3130, 3340, and 3650 Å respectively. In Fig. 4 these values are plotted against the energy of the exciting radiation. The slope increases rapidly as the energy of excitation increases.

If it is assumed that k_4, related to collisional deactivation, is virtually independent of the energy of the radiation, Fig. 4 represents the variation of k_2 with energy of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

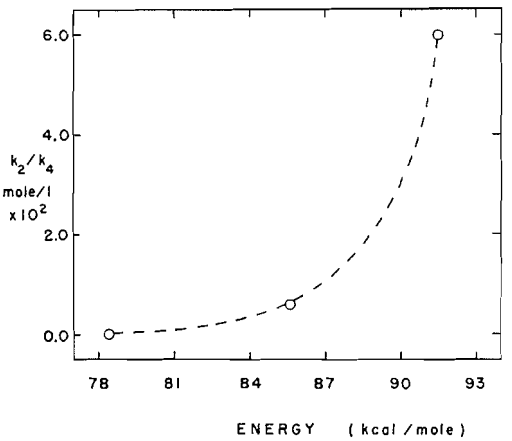

FIG. 4. Variation of k_2/k_4 with energy of excitation.

exciting radiation. It is evident, therefore, that the dissociation rate constant increases rapidly with increasing energy.

A further assumption that k_4 is the collision rate constant, 1.29×10^{11} moles^{-1} liters sec^{-1} calculated for a collision diameter of 3.5 Å, gives absolute values for k_2 of 7.74×10^{9}, 7.87×10^{8}, and 2.84×10^{6} sec^{-1} at 3130, 3340, and 3650 Å, respectively.

Energy of Activation of Reaction [2] as a Function of Wavelength

The apparent energy of activation for the dissociation reaction is 0, 2, and 4.6 (1) kcal/mole at 2700, 3340, and 3660 Å, respectively. The difference in activation energy at 3340 and 3660 Å does not correspond to the difference in energy of the absorbed quanta. The fact that the activation energy changes with wavelength implies the contribution of at least two different dissociation processes. These processes may arise from different electronic states, e.g., singlet and triplet states, whose ratio depends on wavelength. Since ketene neither fluoresces nor phosphoresces, the only evidence for the contribution of a second electronic state is the analogy with other ketones (12).

THE SOLUBILITY OF URANIUM PEROXIDE IN ACIDIC AND BASIC MEDIA AT 25° C[1]

KARL H. GAYER AND LANCELOT C. THOMPSON

ABSTRACT

The solubility of uranium peroxide $UO_4 \cdot 2H_2O$ was measured in NaOH and $HClO_4$ solutions. Possible reactions of $UO_4 \cdot XH_2O$ in dilute $HClO_4$ solutions and possible reaction of $UO_4 \cdot XH_2O$ in dilute NaOH solutions are indicated along with the calculated constants. As might be expected, the several oxygens associated with the uranium atom appear to make the hydroxide more acidic than basic.

The purpose of this investigation was to obtain information regarding the reactions of uranium peroxide in dilute sodium hydroxide and dilute perchloric acid. These data should give (1) partial evidence as to the ionic species.

Uranium peroxide has not been investigated in relation to its solubility in acid or base. The literature on this substance is concerned with its preparation and composition.

EXPERIMENTAL

Procedure

The general procedure is similar to that used by Garrett and Heiks (1).

Preparation of Conductivity Water

The preparation of conductivity water is that of Gayer and Woontner (2).

Colorimetric Reagents

A standard uranium solution was prepared by dissolving uranium trioxide $UO_3 \cdot H_2O$ (prepared by hydrolysis of the uranyl acetate) in perchloric acid. Aliquot portions of this solution were used to prepare the color standards. A 10% sodium hydroxide solution was prepared from Baker and Adamson reagent pellets and distilled water. A 20% sodium carbonate solution was prepared with Baker and Adamson anhydrous reagent and distilled water. Baker and Adamson 30% hydrogen peroxide was used in preparing colorimetric solutions.

Determination of pH

The flask necks were broken while enclosed in a rubber membrane and samples were taken using a Beckman 290–78 hypodermic-type glass electrode. Measurements were made with a Beckman Model G meter which was calibrated at pH 4 with 0.05 *M* potassium acid phthalate buffer, at pH 7 with Beckman 3581 buffer, and at pH 10 with boric acid – sodium hydroxide buffer.

Uranium Analysis

The uranium analysis was made with a Beckman Model B spectrophotometer using the $NaOH–Na_2CO_3–H_2O_2$ method to produce the color, as described in *Analytical Chemistry of the Manhattan Project* (3).

Uranium Peroxide $UO_4 \cdot XH_2O$

Pure $UO_4 \cdot XH_2O$ was prepared by adding 30% hydrogen peroxide to a solution of uranium nitrate until precipitation was complete. A small amount of $NaNO_3$ was added

[1]*Manuscript received June 18, 1958.*
Contribution from the Chemistry Department, Wayne State University, Detroit, Michigan. From a dissertation submitted by Mr. Lancelot C. Thompson in partial fulfillment of the requirements for the Doctor of Philosophy degree at Wayne State University.

For personal use only.

to the precipitate which was then washed with conductivity water until the washings gave a negative sodium flame test. This material was used in the equilibrium studies.

Uranium Peroxide $UO_4 \cdot 2H_2O$

The peroxide prepared as above was dried at 100°. Analyses of this material corresponded to the formula of the dihydrate. This material was used in the perchloric acid solubility studies and the X-ray analyses.

X-Ray Analyses

The X-ray data obtained on this material compares very favorably with that reported in the literature.

The *d* values given below were calculated from *a*, *b*, *c* values given in Katz and Rabinowitch (5).

TABLE I

Data of Watt *et al.* (4)		Gayer and Thompson				
d_{obs}	I/I^0	d_{obs}	I/I^0	d_{calc}	Index	% error
5.20	1.00	5.22	1.00	5.22	110	0.000
4.38	0.39	4.38	0.36	4.37	200	0.23
3.77	0.51	3.79	0.52	3.80	101	0.26
3.51	0.55	3.51	0.48	3.50	011	0.28
—	—	3.25	0.26	3.25	020	0.00
2.74	0.32	2.76	0.26	2.76	103	
2.65	0.31	2.66	0.26	2.66	013	
1.95	0.32	1.96	0.26	1.96	112	

Weighed samples of the peroxide prepared in the manner described above and dried at 100° were ignited to U_3O_8 and the percentages of uranium were calculated to be 70.0, 69.8, 69.8. Theoretical percentage of uranium in $UO_4 \cdot 2H_2O$ = 70.4.

From the percentage of uranium analyzed for and the X-ray data it can be seen that the compound prepared above is $UO_4 \cdot 2H_2O$.

THE DATA

The solubility data for uranium peroxide in acid and base solutions are collected in Tables II to IV. Conclusive results could not be obtained in regard to the reactions involved.

TABLE II

SOLUBILITY OF $UO_4 \cdot 2H_2O$ IN $HClO_4$ SOLUTIONS AT 25°*

TABLE III

EQUILIBRIA OF $UO_4 \cdot XH_2O$ IN $HClO_4$ SOLUTION AT 25°*

Activity of H^+ ion from pH measurements at equilibrium	Moles uranium/ 1000 g H_2O at equilibrium	K_1
1.4×10^{-2}	4.2×10^{-4}	3.1×10^{-2}
1.6×10^{-2}	5.2×10^{-4}	3.3
1.7×10^{-2}	5.7×10^{-4}	3.4
2.1×10^{-2}	7.4×10^{-4}	3.4
2.3×10^{-2}	8.4×10^{-4}	3.6
2.6×10^{-2}	1.0×10^{-3}	3.9
3.4×10^{-2}	1.5×10^{-3}	4.3
		Average $K_1 = 3.6\times10^{-2}$

*Each of the above values is actually the average of two experiments which agreed within 10% or less.

Equilibria in Acid Solutions

The fair amount of constancy of the equilibrium constant values and the relatively high hydrogen ion concentration at equilibrium suggests the possibility of reaction [1] taking place in solutions of perchloric acid concentration up to about 0.03 molal. The uranium dissolved, however, is proportional to the $[H^+].1.37$. This ratio cannot simply be explained by reaction

[1] $$UO_3(OH)_2 \cdot XH_2O(s) + H^+ \leftrightharpoons UO_4H^+ \cdot XH_2O + H_2O$$

$$K_1 = m_{UO_4H \cdot XH_2O} \cdot \gamma_{UO_4H^+ \cdot XH_2O} / m_{H^+} \cdot \gamma_{H^+} = 3.6\times10^{-2}.$$

One or more competing reactions is probably taking place in the studied acid region. Possibly a peptization of the polymerized solid is taking place.

$$\Delta F^\circ_1 = 1900 \text{ cal/mole}$$

assuming that

$$\gamma_{UO_4H^+ \cdot XH_2O} / \gamma_{H^+} = 1.$$

There is considerable difference of opinion as to the correct formula which should be used for uranium peroxide. We have chosen somewhat arbitrarily $UO_3(OH)_2 \cdot XH_2O$ for the equation in this work. Actually the reactions could be shown with other formulas, since the ratio of H^+ or OH^- to uranium would not be different.

TABLE IV

EQUILIBRIA OF $UO_4 \cdot XH_2O$ IN NaOH SOLUTION AT 25°*

Initial moles NaOH/1000 g H_2O	Activity of OH^- ion per 1000 g H_2O from pH values at equilibrium	Moles uranium per 1000 g H_2O at equilibrium	K_2
5.4×10^{-2}		1.0×10^{-4}	
1.1×10^{-1}	1.3×10^{-2}	1.7×10^{-4}	1.3×10^{-2}
1.8×10^{-1}	2.5×10^{-2}	2.3×10^{-4}	0.9×10^{-2}
2.2×10^{-1}	2.6×10^{-2}	2.5×10^{-4}	0.95×10^{-2}
2.7×10^{-1}	2.8×10^{-2}	3.1×10^{-4}	1.1×10^{-2}
3.2×10^{-1}	3.2×10^{-2}	3.6×10^{-4}	1.1×10^{-2}
3.6×10^{-1}	3.2×10^{-2}	3.8×10^{-4}	1.2×10^{-2}
7.2×10^{-1}		8.2×10^{-4}	
			Average $K_2 = 1.1\times10^{-2}$

*Each of the above set of values is actually the average of two experiments which agreed within 10% or less.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

Equilibria in Basic Solutions

The fair constancy of the equilibrium constant values suggests the possibility of reaction [2] in the concentration region of about 0.05 molal NaOH to 0.7 molal NaOH. The rather high equilibrium pH values would also support this contention. The excessive quantities of hydroxyl ion consumed per dissolved uranium however, precludes the possibility that reaction [2] is the only one taking place in this concentration region. Possibly a peptization of the polymerized solid is occurring. The solubility technique does not lend itself to distinguishing between competing reactions.

[2] $$UO_3(OH)_2XH_2O(s) + OH^- \leftrightharpoons HUO_5^- + XH_2O$$

$$K_2 = m_{HUO_5^-} \times \gamma_{HUO_5^-} / m_{OH^-} \times \gamma_{OH^-} = m_{HUO_5^-} / m_{OH^-} = 1.1 \times 10^{-2}$$

$$\Delta F_2 = 2700 \text{ cal/mole}$$

assuming that

$$\gamma_{HUO_5^-} / \gamma_{OH^-} = 1.$$

Water Solubility

The water solubility of $UO_4 \cdot XH_2O$ was determined from the average of three separate preparations of the oxide. (Each determination was done in duplicate so as to approach equilibrium from undersaturation and oversaturation.) Conductivity water was used as the solvent. The solubility was found to be 1.5×10^{-5} moles uranium peroxide/1000 g water.

ACKNOWLEDGMENTS

The authors gratefully wish to acknowledge the support of the U. S. Atomic Energy Commission Project No. At (11–1)–214 in sponsoring this work. They also wish to thank Mr. George McManus of the Physics Department of Wayne State University for the X-ray analyses.

PHYSICOCHEMICAL STUDIES OF LIGNINSULPHONATES

III. PROPERTIES OF FRACTIONS PREPARED BY SUCCESSIVE SULPHONATION OF PERIODATE LIGNIN[1]

D. A. I. Goring and A. Rezanowich

ABSTRACT

Periodate lignin was sulphonated in stages by a series of short bisulphite cooks. At each stage the soluble ligninsulphonate was removed and purified, and the residue was resulphonated. The 14 fractions thus obtained had constant methoxyl content and ultraviolet absorption coefficients. There was a gradual increase in the sulphur content as the integral reaction time increased, but 26% of the ligninsulphonate possessed a sulphur content of less than 3%. There was a marked increase in both the intrinsic viscosity and rate of solution with increase in reaction time. The mechanism of the sulphonation reaction is discussed in the light of these results.

INTRODUCTION

Many uses of spent sulphite liquor depend on the colloidal and polymeric properties of ligninsulphonate (1, 2, 3, 4, 5). However, information on the size, shape, and configuration of the molecule is scarce.

In an earlier paper in this series, Gardon and Mason (6) demonstrated that ligninsulphonates in spent liquor occurred in a wide range of molecular weights (from 4000 to 60,000). A similar conclusion was reached by McCarthy and co-workers (7), who obtained fractions of ligninsulphonate having molecular weights from 400 to 130,000. In the sulphite process it is possible that the lignin becomes soluble as a uniform monodisperse material. This may be either degraded or condensed during later stages of sulphonation to give the polydispersity observed. It is more likely, however, that lignins extracted at various times during the reaction will differ considerably in molecular weight. The present work is an attempt to study the properties of soluble ligninsulphonates produced at different stages of sulphonation.

The problem was simplified by use of periodate lignin prepared by a method similar to that of Purves and co-workers (8, 9). Periodate lignin, like protolignin, is insoluble in most solvents, and undergoes many of the same reactions (10). The phenyl propane chain is probably not broken during periodate oxidation, although some methoxyl is lost. As a starting material for physical studies it is probably as suitable as any other isolated lignin.

A kilogram of periodate lignin was prepared from white spruce. A large sample was cooked for successive short periods until most of the lignin was dissolved as sulphonate. After each stage of sulphonation the liquor and residue were separated. The residue was recooked and the soluble sulphonate was isolated from the liquor. The purified fractions were characterized by measurement of ultraviolet and visible absorption, methoxyl and sulphur content, and intrinsic viscosity.

A parallel investigation based on the sulphonation of wood was published by McCarthy and co-workers (11, 12) when this manuscript was in preparation. The results obtained are similar, although the present work is on an isolated lignin and is somewhat more detailed.

EXPERIMENTAL AND RESULTS

Periodate Lignin

A freshly cut, 35-year-old log of white spruce (*Picea glauca* (Moench) Voss) was reduced to a coarse sawdust with a dado circular saw. Six kilograms (dry weight) of the sawdust was subjected to cycles of periodate oxidation and alkaline hydrolysis in a 200-l stainless steel vessel at room temperature. The oxidation liquor was 2500 g of $Na_3H_2IO_6$ dissolved in 60 l of distilled water, the pH being kept at 4 with acetic acid. The hydrolysis liquor was 100 l of 0.1 *N* NaOH. There were usually two or three washings with distilled water after each oxidation and hydrolysis. After the final hydrolysis, it was necessary to neutralize the liquor before washing to reduce the high degree of swelling of the lignin.

Initially, removal of liquors and wash water was easily achieved with large bacterial filter candles. After the third hydrolysis, filtration was ineffective because the filters clogged immediately. At this stage the lignin was allowed to settle overnight when $\frac{4}{5}$ of the supernatant liquid could be removed with a siphon. The final washings were at pH 5–6. The cake of periodate lignin was frozen and the water removed by freeze-drying. The yield on a dry weight basis was 1 kg and represented 64% of the original lignin content of the wood. Some analytical data on this preparation of periodate lignin are given in Table I.

TABLE I

ANALYTICAL DATA ON PERIODATE LIGNIN

Moisture content	= 6%
Yield from wood (dry weight)	= 17.1%
Ash (dry weight)	= 2.4%
Klason lignin (dry weight; ash-free)	= 93.2%
Carbon (dry weight; ash-free)	= 60.8%
Hydrogen (dry weight; ash-free)	= 5.91%
Methoxyl (dry weight; ash-free)	= 12.8%
Sulphur	= Nil
Carbohydrate	= Nil

Sulphonation Procedure

Cooks were made in a stainless steel autoclave of 1200 cc capacity. The autoclave (Fig. 1) was designed to permit rapid heating and cooling as well as positive stirring of the reacting mixture. The vessel was heated to 130° C in 5 minutes by gas burners on the

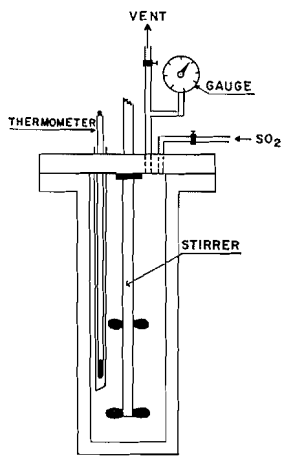

FIG. 1. Stainless steel autoclave used for sulphonation.

For personal use only.

bottom and sides. It was cooled to room temperature in 5 minutes by being lowered into a bucket of water. From the initial application of heat to the moment of lowering the vessel into the water, cooks were 30 minutes in duration except for the final two which were for 60 minutes each. Temperature was measured with a thermometer immersed in paraffin in a stainless steel well in the cover. Constant temperature was maintained manually at 130 (±1)° C with a gas burner.

The reaction mixture was stirred with a motor-driven, twin-screw stirrer. The gland on the stirrer was a carbon disk against which a steel disk rotated, the sealing pressure being supplied by the SO_2 in the liquor. At first it was impossible to retain a constant concentration of SO_2 because of slight leakage past the gland. Accordingly, an SO_2 cylinder at 55° C was connected to the autoclave and constant pressure of SO_2 was maintained manually at 115 (±5) p.s.i.g.

The initial sample of periodate lignin, ground to pass 150 mesh, weighed 43 g. The lignin was mixed with 500 cc of distilled water, de-aerated thoroughly by successive evacuation, and soaked overnight. For sulphonation, 500 cc of sodium base acid was added which produced a final concentration of 1% Na and 6% total SO_2. Accurate control of the initial concentration of SO_2 was unnecessary, since the pressure was adjusted in the autoclave at the start of the reaction.

After each sulphonation, the reaction mixture was centrifuged. The insoluble lignin residue was washed with distilled water and recentrifuged, the washings being added to the centrifuged liquor. The residue was then washed into the autoclave with 500 g of distilled water, the liquor was added, and the cook repeated.

Purification

The object of the purification procedure was to secure a neutral sodium ligninsulphonate free from both insoluble debris and excess inorganic ions. The method finally adopted was evolved by trial and error in preliminary experiments.

Cations and anions were removed with the ion-exchange resins Dowex 50-X12 (50–100 mesh) and Dowex 1-X10 (50–100 mesh) respectively.* The centrifuged liquor was stirred with 400 g of regenerated Dowex 50. This treatment removed 90% of the sodium present. The liquor was then evaporated from 1500 cc to 50–100 cc in a rotary vacuum evaporator at 45° C, deionized on columns, neutralized with NaOH to pH 7, and freeze-dried. With some of the later fractions it was necessary to centrifuge at 25,000 *g* after passage through the columns to remove finely dispersed debris.

Fourteen successive sulphonations were made over a period of 8 hours. Cooking time was 30 minutes for fractions S-1 to S-12 and 1 hour for the final two which are designated fractions S-14 and S-16. The residue after the final reaction was 2.7% of the original weight of the lignin. The total recovery on an ash and sulphur-free basis was 86%.

The rate of solution, R, for each fraction was computed from

[1] R = wt. of fraction (sulphur-free basis)/time of cooking interval.

**In preliminary tests with a purified commercial ligninsulphonate, the columns were found to absorb less than 2% of the lignin based on optical density in the ultraviolet. However, after many of the measurements described later were made, it was found that repassage through the columns removed about 10% by weight of the ligninsulphonate. The sulphur content of the re-ion-exchanged material was virtually unchanged, while the methoxyl content increased by 0.6%. Evidently, material low in methoxyl was being absorbed by the columns. Experiments showed that it was absorbed mostly by the anion-exchange column (Dowex 1-X10) and that it could not be removed by the customary regeneration with 4% of* NaOH. *It was unlikely that the absorbed material was an inorganic sulphur-containing anion because the sulphur content of the re-ion-exchanged fraction would then decrease. No other type of inorganic anion was introduced during the cooking and purification, and as shown in Table I the ash content of the periodate lignin was relatively low. No correction was made in the original data, except in the case of the second fraction in which 33% by weight was absorbed and the methoxyl content increased from 7.6% to 11.2%.*

As shown in Fig. 2, the rate of solution showed a maximum after 4 hours' cooking. Such a maximum is in fair agreement with other studies on sulphonation. The dotted line in Fig. 2 shows some previous data (13) obtained on a different batch of periodate lignin. For this series, reactions were done in sealed glass bombs at 130° C with a bisulphite solution containing 6% total SO_2 and 1% Mg^{++}. Here the SO_2 content decreased as the sulphonation proceeded, which is probably the cause of the slower rate of solubilization. In general, however, this curve shows the same trends as those obtained in the present study.

The fractional rate of solution, R_F, was calculated from

$$R_F = R/\text{wt. of material cooked.} \qquad [2]$$

In Fig. 3 the fractional rate of solution is plotted together with intrinsic viscosity against cooking time.

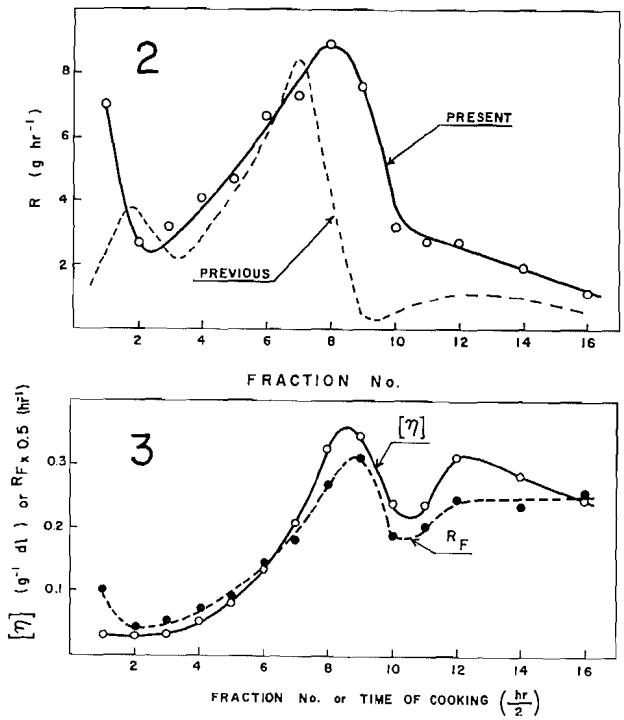

FIG. 2. Rate of solution at various stages of the sulphonation. The dotted line shows similar data from previous experiments. The abscissa units represent half-hourly and hourly intervals in the present and previous series respectively.

FIG. 3. Correlation of R_F and $[\eta]$ throughout the reaction.

Sulphur Content

Sulphur analyses were made with a Leco apparatus and the results are shown in Fig. 4. Mean error in triplicate determinations was ±2.6%. In previous experiments results with the Leco agreed within ±3% with gravimetric determinations as $BaSO_4$.

Apart from some irregularities in early fractions, there is a gradual rise in sulphur content as the cook proceeds. Some of the early fractions are soluble at a relatively low content of sulphur.

Sulphonation increases the weight of the lignin due to the replacement of —OH by —SO_3Na groups. Therefore values of yields, methoxyl content, and light absorption were adjusted to be based on the weight of unsulphonated lignin.

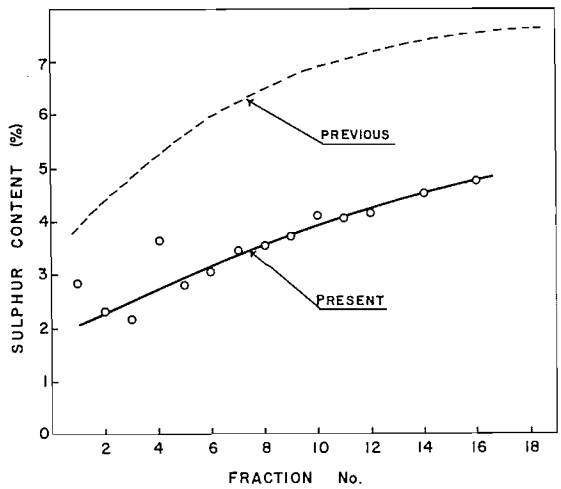

FIG. 4. Sulphur content of fractions at various stages. The dotted line shows similar data from previous experiments. The abscissa units represent half-hourly and hourly intervals in the present and previous series respectively.

Methoxyl Content

The methoxyl content was measured by TAPPI Standard Method 2M43. The mean error in duplicate determinations was ±1%. As shown in Table II the methoxyl content is fairly constant (±5%) and lies between 10 and 12%.

TABLE II

METHOXYL CONTENT AND ULTRAVIOLET ABSORPTION OF FRACTIONS

Fraction	OCH_3 (%)	ϵ_{2800}	ϵ_{2050}
S–1	10.4	12.5	92.9
S–2	11.2	14.2	88.9
S–3	9.9	12.1	87.7
S–4	11.3	13.4	101.9
S–5	10.7	13.5	99.2
S–6	11.1	13.8	99.0
S–7	11.4	15.5	107.4
S–8	11.9	14.5	109.1
S–9	11.7	14.8	102.7
S–10	11.5	14.5	101.8
S–11	11.3	13.6	104.1
S–12	10.4	13.5	100.4
S–14	11.4	14.4	97.5
S–16	9.6	12.9	108.5

Light Absorption

Optical densities were measured in the visible and the ultraviolet with a Beckman DU spectrophotometer using 1-cm quartz cells. Measurements were made in duplicate at wavelengths of 5000 Å, 2800 Å, and 2050 Å with concentrations of 0.2, 0.002, and 0.001 g dl^{-1} respectively. The solvent was 0.1 *M* NaCl.

Absorption was expressed in terms of the coefficient ϵ given by

$$\epsilon = D/cL, \quad [3]$$

where

D = optical density,
c = concentration,
L = length of cell.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

As shown in Table II the ϵ values for wavelengths of 2050 Å and 2800 Å are fairly constant. Mean $\epsilon_{2050} = 100.1$ ($\pm 5\%$) cm^{-1} l g^{-1} and mean $\epsilon_{2800} = 13.8$ ($\pm 5\%$)cm^{-1} l g^{-1}. A similar constancy of ultraviolet absorption has been reported by McCarthy and co-workers (7). In the visible absorption at 5000 Å (Fig. 5) a pronounced maximum is noted after 3 hours' cooking, followed by a minimum and then a gradual increase in ϵ.

Intrinsic Viscosity

Viscosity was measured in Ubbelohde viscometers of the type described by Craig and Henderson (14). The dimensions were modified slightly to permit mounting in a Townson and Mercer water bath. Relative temperature changes were held to $\pm 0.005°$ C about the actual temperature of $25 \pm 0.05°$ C. The solvent was 0.1 *M* NaCl. Concentrations ranged from 1.5 to 0.2 g dl^{-1}.

The intrinsic viscosity, $[\eta]$, was obtained as usual by linear extrapolation of η_{sp}/c vs. c to zero concentration (Fig. 6).

The intrinsic viscosities of the fractions are shown in Fig. 3. There is a marked increase in $[\eta]$ with time of cooking up to about 4 hours, after which $[\eta]$ decreases but with another maximum at 6 hours. The correlation between $[\eta]$ and R_F will be discussed later.

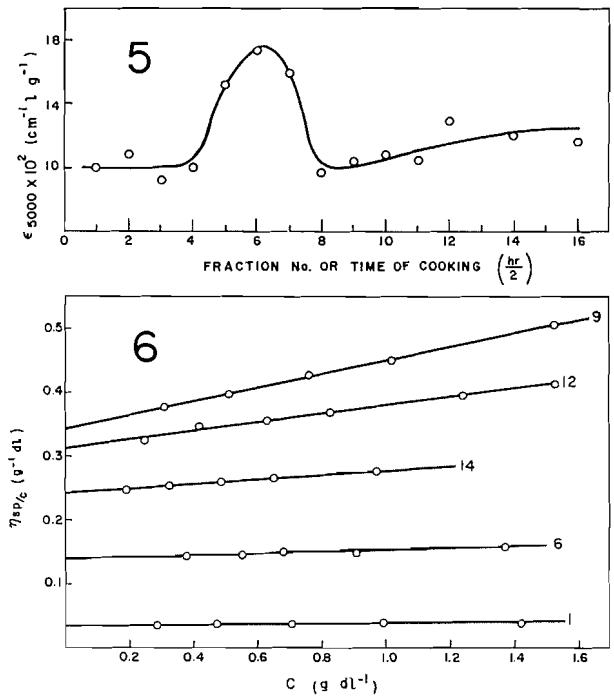

FIG. 5. Light absorption coefficient at 5000 Å at various stages.
FIG. 6. η_{sp}/c vs. c for some of the fractions: lines 1, 6, 9 etc., correspond to fractions S-1, S-6, S-9 etc.

DISCUSSION

As shown in Fig. 4 the sulphur content of the fractions increased with time of sulphonation. The curve suggests a lower rate of sulphonation in the later stages of the reaction in agreement with the results of others (15, 16). It is interesting to note that 26% of the ligninsulphonate possessed a sulphur content of less than 3%, which is generally regarded as the minimum required for solubility (17).

For comparison, the variation of sulphur content of soluble fractions with reaction time, obtained in a previous study (13), is given as the dotted line in Fig. 4. In this case the solubilized lignin was not separated from the reaction mixture but was reacted with the bisulphite solution for the full time of each cook. Both sets of data show an increase of sulphur content with time, but a higher degree of sulphonation of soluble fractions was obtained in the previous series. Rezanowich *et al.* (16) found that if the soluble and insoluble fractions from the same cook were recooked, the soluble portion was sulphonated to a higher degree than the insoluble portion. This is probably the reason why sulphur contents were higher in the previous results.

Comparison of the two series of data suggest that (*a*) some fractions are solubilized at fairly low sulphur contents ($< 3\%$) and (*b*) an appreciable portion of the sulphonation reaction occurs with the ligninsulphonate after it has been rendered soluble.

For all fractions, the ratio of ϵ_{2800} (cm^{-1} l g^{-1}) to methoxyl content (%) was 1.26 ($\pm 3\%$), which is in good agreement with the value 1.30 ($\pm 2\%$) derived for the first seven fractions of Gardon and Mason (6). These authors observed a marked increase of ultraviolet absorption and methoxyl content with molecular weight. In the present work, both ϵ_{2800} and methoxyl content remained constant to $\pm 5\%$ over a wide range of $[\eta]$ and therefore molecular weight. McCarthy and co-workers (11, 18, 19) have also found ϵ_{2800} constant for fractions prepared from non-dialyzable ligninsulphonate by precipitation with ethanol. This contradiction is probably due to a considerable portion of low methoxyl material in the low molecular weight samples of Gardon and Mason. On passing Gardon and Mason's fractions 7 and 8 through the ion-exchange columns, 42% and 70% respectively by weight was lost; methoxyl contents increased respectively from 3.3% and 2.1% to 6.9% and 6.7%. As mentioned earlier, considerably smaller increases in methoxyl content were noted after re-ion exchange of some of the fractions prepared for the present investigation.

From Table II, $\epsilon_{2050}/\epsilon_{2800}$ was 7.26 ($\pm 5\%$) for all fractions. This result supports ϵ_{2050} as a measure of lignin concentration as recommended by Kleinert and Joyce (20). In contrast to the constancy of ϵ_{2050} and ϵ_{2800}, absorption in the visible showed a pronounced maximum after 3 hours' cooking (Fig. 5). In a previous experiment (21) (not reported here in detail) it was found that prolonged cooking (24 hours) of an already sulphonated lignin increased ϵ_{5000} by a factor of 2 while ϵ_{2800} was essentially unchanged. Thus greater visible absorption would be expected in fractions isolated at the end of the reaction; the increase observed after 4 hours is probably due to this effect. However, the initial maximum in ϵ_{5000} suggests that greater visible absorption is characteristic of certain fractions of lignin. Fractions S-5, S-6, and S-7 which give rise to the maximum represented 28% of the material solubilized.

The initial increase in $[\eta]$ with fraction number (Fig. 3) indicates a marked increase in molecular weight as the lignin is made soluble. McCarthy and co-workers (11) have observed a similar increase in molecular weight for lignin sulphonates from spruce and hemlock. The maximum value of $[\eta]$ is 0.34 g^{-1} dl in fraction S-9 compared with the value of 0.075 g^{-1} dl for the highest molecular weight sample of Gardon and Mason (6). Based on the osmotic molecular weights of Gardon and Mason, the molecular weight of fraction S-9 is 250,000. On this basis, 57% of the material solubilized has a molecular weight of over 100,000. These values are somewhat higher than those found by other workers. McCarthy and co-workers (7) quote molecular weights up to 150,000 with about 2% of the lignin above 100,000. The highest value found by Gardon and Mason (6) was 58,000, although the integral distribution indicated values up to 100,000. A

possible reason for the higher molecular weights in the present series was that the lignin, once extracted, was not then subjected to further prolonged sulphonation. In an earlier experiment (21) it was noted that $[\eta]$ fell from 0.10 to 0.04 on resulphonating a lightly cooked ligninsulphonate. Felicetta and McCarthy (12) have demonstrated a similar degradation on prolonged cooking of non-dialyzable ligninsulphonates. Thus it is fairly certain that the soluble lignin is further degraded by the reaction as sulphonation proceeds. The present work indicates that relatively high molecular weights are obtained when the lignin is removed as soon as it is solubilized.

The correlation between the fractional rate of solution and $[\eta]$ (Fig. 3) lends support to the peptization theory of sulphonation proposed by Calhoun, Yorston, and Maass (22). The trends in Fig. 3 suggest that the rate at which lignin is made soluble depends on the molecular weight of the material solubilized. The initial increase in $[\eta]$ and R_F between fractions S-2 and S-9 is accompanied by an increase in the sulphur content (Fig. 4). If condensation reactions are neglected or assumed to occur rapidly, a sulphite cook may be regarded as a simultaneous sulphonation and hydrolysis of the insoluble lignin network. Fragments of lignin produced by the hydrolysis will become soluble as the sulphonation proceeds. The size of a solubilized fragment will be a function of its sulphur content because the lignin only becomes soluble when it acquires hydrophilic sulphonate groups. Thus, as the sulphur content increases, larger and larger fragments produced by the hydrolysis become soluble. The rate of solution thereby increases also.

The decrease in R_F and $[\eta]$ after fraction S-9, in spite of an increase in sulphur content, may be due to the presence of a more cross-linked lignin for which more extensive chain scission would be necessary to set fragments free. Also a more cross-linked molecule would have a lower viscosity for a given molecular weight and would be less soluble for a given sulphur content. If this explanation is correct, fractions of similar molecular weight from early and late in the cook should show clearly defined differences in molecular configuration. Light-scattering and viscometric experiments are now being carried out to investigate this possibility.

It is interesting to note that, in spite of the extremely fine subdivision of the lignin (150 mesh) and the vigorous stirring during the reaction, the rate of delignification is similar to that for the commercial cooking of wood chips. This suggests that diffusion processes have no gross effect on the rate of solution, although the rate at which the dissolved lignin diffuses out of the chip into the liquor is probably affected by the molecular weight of the ligninsulphonate.

ACKNOWLEDGMENTS

The authors wish to acknowledge the assistance of Mr. J. Jaworzyn in much of the experimental work.

VOLTAIC CELLS IN FUSED SALTS

PART V. THE SYSTEMS $Sn/SnCl_2$ (KCl–NaCl), $Fe/FeCl_2$ (KCl–NaCl), and $Mn/MnCl_2$ (KCl–NaCl)[1]

S. N. Flengas and T. R. Ingraham

ABSTRACT

Using a Ag/AgCl (KCl–NaCl) reference electrode, the standard electrode potentials of the systems $Sn/SnCl_2$ (KCl–NaCl), $Fe/FeCl_2$ (KCl–NaCl), and $Mn/MnCl_2$ (KCl–NaCl) were determined at 700° C and found to be 0.370 v, 0.520 v, and 1.205 v respectively. In each of the systems the Nernst equation was found to be applicable over the range of concentrations investigated.

The effect of temperature on the electromotive forces of the above cells was measured and the heats of the cell reactions were calculated from the data.

INTRODUCTION

In previous publications in this series (1, 2, 3, 4) standard potentials for several electrode systems in fused salts were reported. To determine the potentials, a silver – silver chloride electrode was used as a null point reference electrode, and an equimolar mixture of sodium and potassium chlorides was used as the solvent for the metallic salts.

In this investigation, the method was applied to the systems tin – stannous chloride, iron – ferrous chloride, and manganese – manganous chloride. These metal chlorides were found to give stable solutions in the alkali chloride – molten salt solvent.

PREPARATION OF MATERIALS

Because the anhydrous metallic salts required in this work were not commercially available, it was necessary to prepare them.

Anhydrous stannous (II) chloride was prepared from the corresponding hydrated salt of analytical grade by heating in a tubular electric furnace at 250° C under a continuous stream of dried gaseous HCl, produced by the action of concentrated H_2SO_4 on concentrated HCl.

Anhydrous ferrous (II) chloride was prepared from National Bureau of Standards certified iron filings by dissolution in concentrated HCl, and recovery of the hydrated ferrous salt by crystallization under an oxygen-free argon cover. The product was filtered under argon and washed with ether. Finally, the light-green hydrated ferrous chloride was dried by heating at 500° C in a stream of dry HCl. In the preparations of stannous chloride and of ferrous chloride, argon was used to flush the apparatus at the beginning and the end of the drying process. The dry divalent chlorides were stable in air and were pelletized without requiring any precautions against oxidation.

Anhydrous manganous (II) chloride was prepared from the corresponding hydrated salt of analytical grade, by heating at 600° C in the presence of a carbon tetrachloride vapor stream which was produced by flash distillation.

The anhydrous salts prepared by the foregoing methods were analyzed and found to be of a purity in excess of 99%. The impurity in each of the chlorides was the corresponding metal oxide.

Very pure (99.99%) tin was used as the liquid indicator electrode in the Sn–Ag voltaic cell. A $\frac{1}{2}$-in. diameter rod of very pure electrolytic iron (99.99%) was used as the indicator

[1]*Manuscript received July 28, 1958.*
Contribution from the Mineral Dressing and Process Metallurgy Division, Mines Branch, Department of Mines and Technical Surveys, Ottawa.

electrode in the Fe–Ag voltaic cell. The manganese metal indicator electrode for the Mn–Ag voltaic cell was prepared from pure electrolytic manganese metal (99.9%) which was remelted and cast into a cylindrical form. The casting was done in a water-cooled arc furnace, operated under reduced argon gas pressure. Platinum wire or tungsten wire was used as the indicator electrode connection to the potentiometer.

EXPERIMENTAL

The experimental technique and the apparatus used to study the tin, iron, and manganese systems were the same as in the previous experiments (3, 4) with solid and liquid metal indicator electrodes and cells under inert gas cover.

The experimental cells were of the type,

M	MCl_2 (x_2)		Asbestos	AgCl (x_1)	Ag
(−)	KCl–NaCl (1/1 mole)	‖	fiber	‖ KCl–NaCl (1/1 mole)	(+)
	(indicator electrode)			(reference electrode)	

where M was respectively tin (pool of liquid metal), iron, and manganese metal, and MCl_2 was respectively $SnCl_2$, $FeCl_2$, and $MnCl_2$ at a mole fraction x_2. The reaction in cells of this type is:

[1] $$M + 2Ag^+ = M^{2+} + 2Ag.$$

The relationship between the electromotive force and the metal ion concentration in the cell is given by the Nernst equation in the form:

[2] $$E_{cell} = (E^\circ_{M/M^{2+}} - E^\circ_{Ag/Ag^+}) - (2.303RT/2\mathcal{F})\log(x_2/x_1^2)$$

where $E^\circ_{M/M^{2+}}$ and E°_{Ag/Ag^+} are respectively the standard electrode potential of the half-cells $Sn/SnCl_2$, $Fe/FeCl_2$ or $Mn/MnCl_2$, and Ag/AgCl under the conditions of the experiments.

It will be observed that in equation [2] mole fractions are used instead of activities. The simplification is justified, as will be shown by the subsequent data, only when the activity coefficients or the complexity constants of the species involved in the cell reaction, or both, remain constant over the concentration range investigated. Thus, standard potentials calculated from equation [2] will include the effects due to both activities and complex formation.

From equation [2] it follows that when $\log(x_2/x_1^2)$ is equal to zero, the cell potential is the difference in the standard electrode potentials of the system.

RESULTS

The electromotive forces of the Sn–Ag, Fe–Ag, and Mn–Ag voltaic cells were measured first as a function of the metal ion concentration and then as a function of temperature.

The results of the experiments in which the concentration of the metal ion was varied at constant temperature are given in Table I. A 15 mv correction has been included for thermoelectric effects in the Sn–Ag cell and 9 mv in the Fe–Ag cell. No correction was required in the Mn–Ag cell.

When the electromotive forces of the cells were plotted against the term $\log(x_2/x_1^2)$, as calculated from the data given in Table I, the results were well represented by straight lines as shown in Figs. 1 and 2. The slopes of the experimental lines for Sn–Ag, Fe–Ag, and Mn–Ag systems agree well with the theoretical value for a two-electron electrode process as calculated from equation [2] (0.096, 0.095, and 0.097 as compared with

as a function of $\log(x_2/x_1^2)$, at constant temperature. M is (*a*) tin, (*b*) iron, and (*c*) manganese. MCl_2 is respectively $SnCl_2$, $FeCl_2$, and $MnCl_2$.

concentration. The potential was very steady and remained practically unchanged when the cells were left overnight.

The effect of temperature change on the electromotive forces of the tin, iron, and manganese cells was investigated next. The results of these experiments are given in Table III. The voltages have been corrected for thermoelectric effects. Also included in Table III are values for the standard potentials at different temperatures, calculated from the data, using equation [2].

From the standard potentials, using the procedure previously described (1, 2, 3, 4), it was possible to calculate for various temperatures the equilibrium constants (K) for the cell reactions given in Table II. The results of these calculations are given in Fig. 2, where $\log K$ was plotted against the reciprocal of absolute temperature. The curves are linear over the range of temperature investigated. The best straight lines were calculated by applying the least squares method.

The heat of reactions (ΔH_r) in cells of this type, as calculated according to the van't Hoff equation, is the difference between the heats of formation of the respective chlorides in the presence of the solvent.

The calculated values are:

$$\Delta H_{r(Sn/Sn^{++})} = -23.4 \pm 1.0 \text{ kcal/mole},$$
$$\Delta H_{r(Fe/Fe^{++})} = -27.8 \pm 1.4 \text{ kcal/mole},$$
$$\Delta H_{r(Mn/Mn^{++})} = -61.8 \pm 1.5 \text{ kcal/mole}.$$

PHOTOOXIDATION OF BUTENES BY NITROGEN DIOXIDE AT DIFFERENT WAVE LENGTHS[1]

S. SATO[2] AND R. J. CVETANOVIĆ

ABSTRACT

Photooxidation of butenes by nitrogen dioxide at room temperature has been studied at three different wave lengths: 2288, 2537, and 3261 Å. In the case of butene-1 an abrupt change in the ratios of reaction products is observed between 2537 and 2288 Å: about three times as much α-butene oxide as n-butyraldehyde is formed at 2288 Å, while the amounts of these two compounds are almost equal at the longer wave lengths. This discontinuity is ascribed to a difference in the mechanism of reaction with olefinic double bonds of the first excited state, $O(^1D)$, and the ground state, $O(^3P)$, of oxygen atoms. Experimental evidence indicates that there is collisional quenching of $O(^1D)$ to $O(^3P)$ atoms.

Reactions of *cis*- and *trans*-butene-2 and of isobutene are much less reproducible, particularly so that of isobutene, because of the much more readily occurring thermal reaction of the excess nitrogen dioxide present with the epoxides initially formed.

INTRODUCTION

The main features of the reactions between oxygen atoms and olefins have been recently established (1). Mercury-photosensitized decomposition of nitrous oxide was used as the source of oxygen atoms, which were believed to be produced in their ground electronic state. In connection with this work, a study was also made of the reactions of butene-1 and isobutene with oxygen atoms formed by photolysis of nitrogen dioxide at 3660 Å (2). At this wave length there is insufficient energy to produce electronically excited oxygen atoms and the general similarity of the two processes was taken as further evidence that ground state oxygen atoms were formed in the mercury-photosensitized decomposition of nitrous oxide.

It was thought of interest to attempt to study the behavior in similar reactions of the oxygen atoms in their first excited state, $O\ ^1D$, by photolyzing nitrogen dioxide at shorter wave lengths. It is believed (3) that at the wave lengths longer than 2450 Å, oxygen atoms are produced in this process in the ground state and at suitable wave lengths shorter than 2450 Å, in the first excited state. The long wave length threshold for this photolysis has been found to lie between 4047 and 4358 Å (4). The energy difference between 2450 and 4047 Å is 46.0 kcal/mole, which agrees with the energy difference between ^3P and ^1D states of oxygen atoms (45.2 kcal/mole).

In the present work a comparative study has been made of the photooxidation of butenes by nitrogen dioxide at 2288 and 3261 Å, obtained from a cadmium resonance lamp, and at 2537 Å, from a mercury resonance lamp. It would appear from the results obtained with butene-1 that the difference in multiplicity between ^3P and ^1D states of oxygen atoms leads to two distinct mechanisms of their interactions with olefinic double bonds. The usefulness of the reactions of the other butenes in this respect was, unfortunately, greatly reduced because of the considerably greater reactivity of the epoxide formed with excess nitrogen dioxide present and consequent poor reproducibility of the experimental results.

EXPERIMENTAL

Apparatus and experimental procedure used in the present work, as well as the method of purification of nitrogen dioxide, butene-1, isobutene, and *cis*- and *trans*-butene-2 (Phillips reagent grade products), were the same as described previously (2).

A chlorine filter was used to isolate the resonance line of 2288 Å from a cadmium lamp operated at 280±5° C. The emission spectrum, taken with medium quartz Hilger spectrograph, showed that the resonance line at 2288 Å was completely isolated from the stronger resonance line at 3261 Å. A very weak line at 2537 Å was observed, probably owing to a trace of mercury taken into the lamp along with cadmium. The intensity of this mercury resonance line, however, was negligible compared to the intensity of the line at 2288 Å. The light of 3261 Å was obtained from the same cadmium lamp by using a 7–54 Corning glass filter. The light of 2537 Å was obtained from a low pressure mercury resonance lamp and using again a 7–54 Corning glass filter.

Light intensities at the three wave lengths were adjusted by varying the distances of the light sources from the reaction cell and the diameters of the circular light apertures so that almost the same amounts of total reaction products were obtained. The amounts of products were estimated from the gas–liquid chromatography peak areas (2).

A few experiments were carried out in an attempt to measure directly the relative intensities of the light absorbed by nitrogen dioxide at the three wave lengths. The light intensities were so weak that the following technique had to be applied. A very small amount (1 μmole) of nitrogen dioxide and the same amount of butene-1 were taken into the reaction cell and the intensity of transmitted light was followed by means of a photoelectric circuit. Under these conditions the consumption of nitrogen dioxide after 2-hour irradiation was essentially the same at 2288 and 3261 Å (36 and 34%, respectively). The low pressure mercury lamp was not stable enough for this type of measurement.

RESULTS AND DISCUSSION

Photooxidation of Butene-1

Mixtures of 30 mm butene-1 and 3 mm nitrogen dioxide were photolyzed at different wave lengths for 2 hours. The absolute amounts of products formed were not too reproducible and for this reason their ratios are shown in Fig. 1, where the amount of

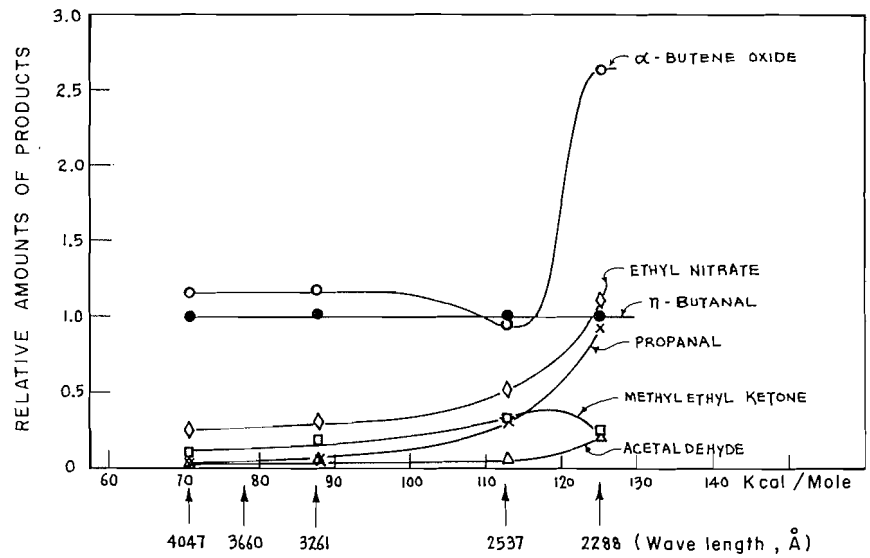

FIG. 1. Relative amounts of products (*n*-butyraldehyde taken as unity) in the photooxidation of butene-1 with nitrogen dioxide at various wave lengths (irradiation time, 2 hours; 30 mm of olefin, 3 mm NO_2; 25±2° C).

n-butyraldehyde is taken as unity.* The ratios were found to be well reproducible. The absolute amount of *n*-butyraldehyde decreased with decreasing wave length and at 2288 Å was approximately about half as great as at 3261 Å.

In Fig. 1, a discontinuity is observed between the wave lengths of 2537 Å and 2288 Å; at 2288 Å the amount of α-butene oxide is about three times as great as that of butanal, while these amounts are almost equal at longer wave lengths. The amount of methyl ethyl ketone gradually increases with decreasing wave length from 4047 Å to 2537 Å, but at 2288 Å it shows a marked decrease. The curves for ethyl nitrate, propanal, and acetaldehyde ascend monotonously with decreasing wave length. These last three compounds are secondary reaction products, while α-butene oxide, butanal, and methyl ethyl ketone are the primary addition products. These results, therefore, suggest that the mechanism of addition of oxygen atoms to butene-1 changes between 2288 Å and 2537 Å. In as much as this conclusion is correct, it can be explained by the difference in the electronic structure of oxygen atoms at the two wave lengths. The continuously increasing amounts of the secondary products, ethyl nitrate, propanal, and acetaldehyde, are, on the other hand, explainable in terms of the increasing amounts of energy with decreasing wave lengths.

The pressure dependence of photooxidation of 3 mm butene-1 by 3 mm nitrogen dioxide with various amounts of nitrogen added has been studied at 2288 Å and the results are shown in Fig. 2. Although there is a certain amount of scatter of the points, the pressure dependence in Fig. 2 is evidently quite different from that observed previously in the photooxidation of butene-1 at 3660 Å (Fig. 3*a* of ref. 2). With increasing total pressure, the amount of α-butene oxide decreases, the amounts of butanal and methyl ethyl ketone show a slight increase, and the secondary products, propanal, ethyl nitrate, and acetaldehyde, rapidly decrease. As the total pressure is increased, the ratios of all the products formed approach those observed at longer wave lengths. The rapid decrease in the

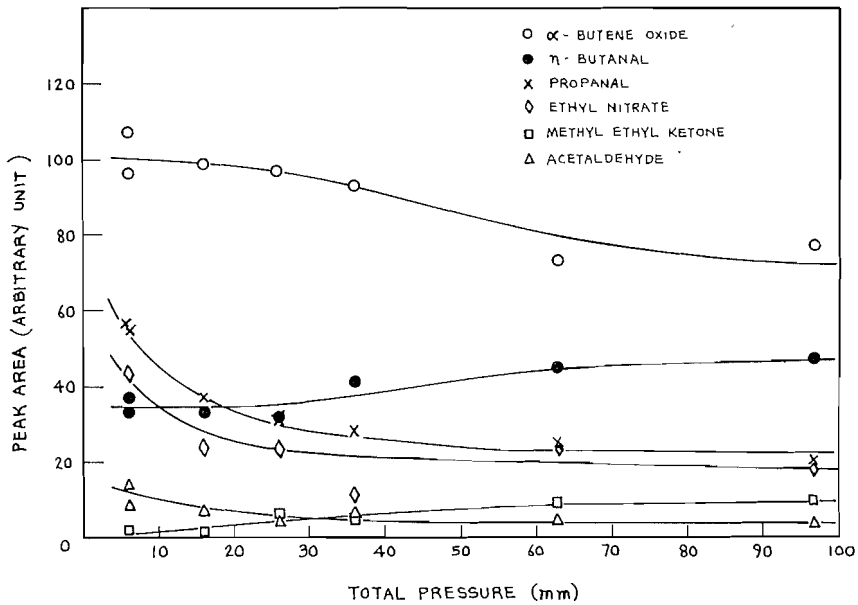

FIG. 2. Amounts of products in the photooxidation of butene-1 with nitrogen dioxide as a function of total pressure (3 mm butene-1, 3 mm NO_2, variable amounts of N_2; irradiation time, 2 hours; 25±2° C).

**The data at 4047 Å were taken from the previous work (4). The total amount of products was approximately equal to that obtained at the other three wave lengths.*

For personal use only.

amounts of secondary products is compatible with an increased dissipation of energy by collisions at higher pressures. The trends of the addition products, on the other hand, suggest the simultaneous occurrence of the quenching reaction

$$O(^1D) + M \rightarrow O(^3P) + M. \quad [1]$$

Photooxidation of Isobutene

Experiments similar to those described for butene-1 have been carried out also with isobutene. As already reported (2), isobutene oxide, which is one of the main products of addition of oxygen atoms to isobutene, was absent because of its rapid thermal reaction with nitrogen dioxide. Moreover, this reaction seemed to be the cause of poor reproducibility. In the case of isobutene, therefore, no significant results were obtained except that with decreasing wave length there was a very pronounced increase in the amount of acetone formed, which became equal to that of isobutyraldehyde at 2288 Å. The mechanism of formation of acetone in the case of isobutene is believed to be analogous to that of propanal in the case of butene-1.

Photooxidation of cis- and trans-Butene-2

The experimental results with *cis*- and *trans*-butene-2 are less reproducible than those with butene-1 but are better than those with isobutene. This is probably because β-butene oxide, one of the main products in the case of butene-2, reacts with nitrogen dioxide at a rate intermediate between those of α-butene oxide and isobutene oxide (5).

The results are summarized in Table I where relative amounts of products are given with methyl ethyl ketone taken as unity. The absolute amount of methyl ethyl ketone appears to increase on passing from longer to the shorter wave lengths, at least in the case of *trans*-butene-2. In these reactions four main addition products are known (1) to be formed: *cis*- and *trans*-β-butene oxide, methyl ethyl ketone, and isobutyraldehyde. The greater part of isobutyraldehyde is formed by combination of free radicals. For this reason this compound would be expected to be much reduced, with simultaneous formation of large amounts of nitro compounds, in the presence of excess nitrogen dioxide used in the present work. As shown in Table I, the four addition products are formed, although *cis*-β-butene oxide and isobutyraldehyde were not separated on the gas chromatographic column used and were not estimated separately. In addition large amounts of nitromethane and methyl nitrate and smaller amounts of acetaldehyde are also formed. The

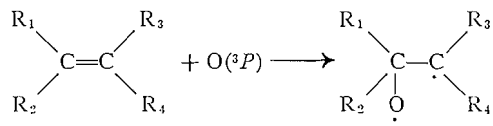
secondary products tend to increase at the lowest wave length used and are similar in that respect to the secondary products observed with butene-1.

It is not possible to say conclusively whether there is an increase in stereospecificity on passing from 2537 to 2288 Å. This uncertainty is due to the relatively poor reproducibility of the figures in Table I, the unknown extent of the thermal reaction with excess nitrogen dioxide of the two epoxides produced, and the fact that *cis*-β-butene oxide was not measured separately. The mean values do suggest an increase in stereospecificity; however, these values are, unfortunately, subject to large uncertainty.

Mechanisms of Addition of Oxygen Atoms (^3P and ^1D) to a Double Bond

According to the spin conservation rule, addition of an oxygen atom in the ground state, $O(^3P)$, to an olefin, which is in a singlet state, should give a triplet state of the activated complex, while the addition of the first excited oxygen atom, $O(^1D)$, should give a singlet state of the activated complex. In agreement with this, when oxygen atoms are produced by the mercury-photosensitized decomposition of nitrous oxide they are most likely in the ^3P state and the initial step of their addition to olefins was, therefore, formulated before (1) as follows:

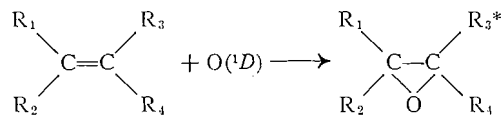


[2]

(A)

Here R stands for an alkyl radical or a hydrogen atom, and the first carbon atom of the double bond is assumed to be "less substituted". The transition complex is a stage in the formation of the biradical (A), which is presumably in the triplet state.

In the case of ^1D oxygen atoms, the activated complex is probably a stage in the following reaction,



[3]

(B)

where the intermediate (B) should be in the singlet state.

The two intermediates (A) and (B) may undergo internal rearrangements (1). However, both the *cis–trans* isomerization and the migration of R_1 or R_2 to the second carbon atom of the original double bond are likely to be much easier in (A) than in (B) and, therefore, the addition of the $O(^1D)$ atoms should be more stereospecific and should lead to predominant formation of the epoxides. Thus, in the case of butene-1 (where $R_1 = R_2 = R_3 = H$ and $R_4 = C_2H_5$), the relative amount of butanal formed from (A) should be larger than that from (B). This is in agreement with the experimental observation. At the same time, the extent of stereospecificity will depend also on the extent of the quenching reaction [1]. Even when large pressures of the olefin are used and the amount of any other kind of molecules present is negligible, a certain amount of quenching by the olefin itself is likely to occur and the reaction need not be completely stereospecific if the collision yield is smaller than unity. The extent of stereospecificity will then depend on

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

the average number of collisions of $O(^1D)$ atoms with the olefin before an effective collision takes place. Another factor which is likely to have an effect on the stereospecificity which can be observed under conditions of the present experiments is the high exothermicity of these reactions. As pointed out before (1) the addition products at the moment when they are formed are "hot" and, therefore, the observed stereospecificity will depend to a certain extent on the relative ease of isomerization under such conditions of the particular epoxides formed. Thus, although there is a large quantitative uncertainty in the results obtained with *cis*- and *trans*-butene-2, it is certain that at least in the case of *cis*-butene-2 the addition at 2288 Å is far from being completely stereospecific, i.e. some *trans*-epoxide is still formed. In view of the preceding discussion, however, this should not be taken as an argument against the mechanism proposed here for the addition of $O(^1D)$ atoms to olefins.

Fragmentation Products

Although the complexity of the studied processes precludes a complete explanation of the formation of the fragmentation products, it may be worth while to mention that the amounts of propanal, acetone, and acetaldehyde, in the case of butene-1, isobutene, and butene-2, respectively, increase rapidly with decreasing wave length of the light used for the reaction. It is very likely that these compounds are formed in all these reactions by a similar mechanism. Their formation might perhaps be due, directly or indirectly, to the excited oxygen molecules produced by the reaction of oxygen atoms with nitrogen dioxide (6). This matter, however, requires considerable further investigation.

ACKNOWLEDGMENTS

The authors are indebted to Dr. A. W. Tickner for mass spectrometer analyses, and to the Analytical Section of this Division for the infrared analyses.

SULPHINIC ACIDS AS ANALYTICAL REAGENTS[1]

T. P. FORREST[2] AND D. E. RYAN

ABSTRACT

The "specific" action of sulphinic acids with metal ions is not limited to compounds in which there is direct attachment of the $-SO_2H$ group to an aromatic ring. Since both aliphatic and aromatic sulphinic acids react similarly the assumption that an aromatic group is necessarily co-ordinated to the metal atom through its π system is not valid; the precipitated products are simple salts of the acids. Ferric iron yields at least two products with sulphinic acids. Ceric cerium is reduced in acid solution but an orange-yellow precipitate containing cerium is obtained from acetate-buffered solutions. Naphthalenesulphinic acid may be used to quantitatively precipitate Fe^{+++}, Th^{++++}, Zr^{++++}, U^{++++}, Ti^{++++}, Sn^{++++}, Bi^{+++}, Pd^{++}, Ag^{+}, Hg_2^{++}.

INTRODUCTION

Benzenesulphinic acid, $C_6H_5SO_2H$, and its alkali salts react with ferric salts in solutions of mineral acids to form the slightly soluble orange-yellow ferric benzenesulphinate $(C_6H_5SO_2)_3Fe$ (1). This compound has been stated (2) to be so insoluble that it is formed even in solutions containing fluoride and phosphate ions and that a distinct turbidity occurs in ferric salt solutions so dilute as to yield a scarcely perceptible pink color with thiocyanates. Although various sulphinic acids have been used for the determination and separation of ferric iron (3), Ackerman (4) and Dubsky (5) report that the determination of iron with sulphinic acids is not reproducible.

Tetravalent ions, such as cerium, thorium, uranium, tin, titanium, and zirconium, also react in acid solution to yield precipitates. Feigl (2) reported that, although the sulphinic acids are easily oxidized and ceric salts are powerful oxidizing agents, the compound $(C_6H_5SO_2)_4Ce$ is nevertheless formed in the reaction between these substances. A comparison of the reactivity of benzenesulphinic, benzylsulphinic, and cyclohexylsulphinic acids showed that only benzenesulphinic acid formed slightly soluble salts with the above-mentioned metal ions. These results led to the conclusion that direct attachment of the $-SO_2H$ group to an aromatic ring was necessary and that the phenyl group was co-ordinated to the metal atom through its system of conjugated double bonds. However, Krishna and Singh (3) precipitated ferric iron with *p*-anisylsulphinic acid in which the sulphinic acid group is separated from the aromatic ring by a methylene group.

The present work, therefore, was undertaken to determine the effect of the radical on the analytical behavior of sulphinic acids; this paper records the results of such an investigation.

COMPOUNDS INVESTIGATED

The following sulphinic acids were prepared: benzene, *p*-toluene, β-naphthalene, 2-thiophene, benzyl, cyclohexyl, *n*-hexyl, and *n*-butyl. The aromatic acids were prepared by reducing the corresponding sulphonyl chloride with sodium sulphite (3, 6). Part of the sulphinic acid was removed as a solid and the remainder was extracted with ether from the acidified reaction mixture. The aliphatic acids were prepared by the addition of sulphur dioxide to the Grignard reagent at $-50°$ C (7). The solid magnesium salt thus obtained was decomposed in acid solution and the sulphinic acid extracted with ether.

The ammonium salts, which are more stable than the acids, were prepared by bubbling

[1]*Manuscript received August 29, 1958.*

[2]*Holder, Canadian Industries Limited Fellowship, 1957–58.*

ammonia through an ethereal solution of the acid. The salts were purified by precipitating the ferric sulphinate, washing with water, and then treating with aqueous ammonia to remove iron as the hydrous ferric oxide; the filtrate was acidified, ether extracted, and the ammonium salt reprecipitated from the ether extract with ammonia.

Properties of Compounds

The aromatic acids were obtained as white solids, the melting points of which are listed in Table I. The aliphatic acids were all obtained as oils which could be solidified at $-10°$ C. Sulphinic acids decompose relatively easily (8); they may be oxidized by air to the sulphonic acid or may disproportionate according to the following equation

$$3RSO_2H \rightarrow RSO_3H + RSOSOR + H_2O.$$

The melting points varied, therefore, due to decomposition incurred in drying the acid and in heating while melting. Benzenesulphinic acid gave melting points varying from 72° to 81° C, although consistent results of 79° to 80° were obtained; literature references (3, 9) give melting points varying from 75° to 85° C.

TABLE I

MELTING POINTS OF SULPHINIC ACIDS

Sulphinic acid	M.p., ° C
Benzene	79–80
p-Toluene	81
2-Thiophene	67
Benzyl	65–68
β-Naphthalene	104–106

The ammonium salts of the aromatic acids were white solids. The butyl and cyclohexyl ammonium sulphinates were obtained as colorless oils, although the cyclohexyl compound solidified slightly below room temperature; the hexyl derivative was obtained as a white, waxy, solid that decomposed to give off ammonia at 35° C.

Ionization constants obtained from potentiometric titration data on the acids showed that they are all fairly strong organic acids. The results obtained for benzenesulphinic acid ranged from 0.96×10^{-2} to 1.28×10^{-2} and for *p*-toluenesulphinic acid from 1.48×10^{-2} to 2.10×10^{-2}. The constants of the aliphatic acids were of the order of 10^{-3}.

Reactions with Metal Ions

Similar reactions were shown by all the sulphinic acids. The reactions were carried out by adding a 2% aqueous solution of the ammonium salt of the sulphinic acid to 0.1 *M* solutions of the metal ions. In dilute acid solution voluminous precipitates were obtained with Ag^{+}, Hg_2^{++}, Hg^{++}, Pd^{++}, Fe^{+++}, U^{++++}, Zr^{++++}. Bi^{+++}, Ti^{++++}, and Sn^{++++} gave good precipitates under these conditions with naphthalene, benzene, and *p*-toluene sulphinic acids but a higher reagent concentration was required for precipitation with the other sulphinic acids. Slight precipitation was obtained with Cu^{++}, Pb^{++}, and Pt^{++++} at reagent concentration above two per cent. From 1 *N* sulphuric acid solution ceric cerium precipitated insoluble oxidation products of the sulphinic acids but an orange-yellow precipitate containing cerium was obtained from acetate-buffered solution. The rare earths were incompletely precipitated from solutions of their salts but were not obtained from solutions above 0.5 *N* in hydrochloric acid. No color or precipitate was noted with the following: Tl^{+}, Ba^{++}, Ca^{++}, Sr^{++}, Mg^{++}, Cd^{++}, Zn^{++}, Co^{++}, Ni^{++}, Fe^{++},

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

$Al^{\cdot\cdot\cdot}$, $As^{\cdot\cdot\cdot}$, $Sb^{\cdot\cdot\cdot}$, $Rh^{\cdot\cdot\cdot}$, $Ir^{\cdot\cdot\cdot\cdot}$, $As^{\cdot\cdot\cdot\cdot\cdot}$, WO_4'', MoO_4'', VO_4'''. In acid solutions the orange dichromate was reduced to the green chromic ion and the pink color of permanganate was discharged.

Since all the sulphinic acids investigated exhibit the same properties for precipitating metal ions, their selective action is not due to the co-ordination of an aromatic ring to the metal atom through its system of conjugated double bonds. The only significant difference in the products obtained is in their solubilities.

THE IRON REACTION

As previously stated ferric iron has been determined by precipitation of the reportedly very insoluble ferric benzenesulphinate. Use has been made of this reaction to determine iron volumetrically by titration with a standard sulphinic acid solution with dilute thiocyanate as an external indicator (3). However, in the preliminary experiments with ferric iron it was found that, in solutions containing less than 0.5 mg of iron per milliliter, only a yellow to red color developed when the theoretical amount of reagent was added. A red color was obtained on dropwise addition of reagent to more concentrated iron solutions but this color disappeared as the orange-yellow ferric sulphinate separated from solution on the addition of more sulphinic acid; the ferric sulphinate dissolved slowly in ferric chloride solution to regenerate the red color. These results show that, in addition to the insoluble 1:3 ferric benzenesulphinate, there is at least one other product of the reaction. The volumetric method for the determination of iron by sulphinic acids cannot be recommended; although the ferric sulphinate is precipitated from solutions containing more than two milligrams of iron per milliliter the end point is poor and in more dilute solutions a soluble colored complex only is formed.

Table II shows the effects of concentration and acidity on the precipitation of ferric iron by benzenesulphinic acid. The quantity of iron remaining in solution where precipitation occurred was determined colorimetrically with *o*-phenanthroline.

TABLE II

PRECIPITATION OF FERRIC IRON WITH BENZENESULPHINIC ACID

Iron present mg/ml	Acidity	Mole ratio of reagent to iron	Results
0.05	pH 3	10:1	Yellow solution; no precipitate
0.05	pH 3	40:1	Yellow solution; slight precipitation
0.25	pH 3	10:1	Good precipitation; 3.2 p.p.m. iron in filtrate
0.25	0.2 *N* HCl	10:1	Orange solution; slight precipitation
0.40	0.2 *N* HCl	10:1	Good precipitation; 7.4 p.p.m. iron in filtrate
0.60	0.2 *N* HCl	3:1	Red solution; no precipitate
0.60	0.2 *N* HCl	10:1	Good precipitation; 3.7 p.p.m. iron in filtrate

These results show that quantitative precipitation is markedly dependent upon concentration and that best precipitation occurs from slightly acid, relatively concentrated iron solutions. However, precipitates are obtained even in solutions containing as little as 0.05 mg of iron per milliliter provided an extremely large excess of reagent is added ($>40:1$).

In view of the above results an investigation into the statements regarding the extreme insolubility of ferric benzenesulphinate and its formation in the presence of fluoride and phosphate ions was carried out. The solubility was determined by preparing a saturated aqueous solution under nitrogen at 25° C; the iron content of the filtered solution, determined colorimetrically with *o*-phenanthroline, was 4.5×10^{-4} moles per liter after 7

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

hours and 10^{-3} moles per liter after 4 days. Since dibenzylsulphone was obtained from solutions of ferric benzylsulphinate similarly treated, the increase in solubility on standing is undoubtedly due to some decomposition of the sulphinate. The ferric benzenesulphinate dissolved completely in 1 *M* fluoride and phosphate solutions and no precipitation occurred from neutral solutions containing 20:1 ratio of fluoride or phosphate to iron; in 0.2 *N* acid solutions, however, in which the concentrations of fluoride and phosphate complexes are small, precipitation did take place.

Similar reactions with iron were obtained with the other sulphinic acids; the most insoluble ferric sulphinate was that of naphthalenesulphinic acid. The use of this compound as an analytical reagent is discussed below.

Nature of the Solid Ferric Benzenesulphinate

Analysis of the solid product of the reaction between ferric iron and benzenesulphinic acid, after drying at 110° C, gave 11.69% iron on ignition to the oxide; the theoretical value of $Fe(C_6H_5SO_2)_3$ is 11.65%. A sample, ether-washed and dried at room temperature, lost no weight on drying at 110° C for 2 hours; this result, together with the analysis given above for the dried compound, shows the absence of water of hydration in the precipitated product.

The orange solid was insoluble in ether, ethanol, dioxane, benzene, cyclohexane, chloroform, and carbon tetrachloride but dissolved in glacial acetic acid to give a red solution having a freezing-point depression that indicated complete dissociation. The absorption spectra of this solution, between 400–500 mμ, was identical with that of a solution of ferric nitrate in glacial acetic acid; the compound, therefore, dissociates completely to form the acetate complex.

The magnetic moment of the solid was determined by means of a Guoy balance and found to be 5.7 Bohr magnetons. This value is typical of ferric compounds having five unpaired electrons and shows that no inner orbital bonding has taken place.

The above results suggest that ferric benzenesulphinate is simply a salt of benzenesulphinic acid. Alimarin and Sotnikov (10) have recently concluded, on the basis of the reactivity of benzylsulphinic acid with metal ions, that the products are typical metallic salts of the acids.

THE CERIUM REACTION

Ceric cerium has been reported to react with benzenesulphinic acid to precipitate the ceric sulphinate $Ce(C_6H_5SO_2)_4$ (2); recently, however, the reaction has been stated to be a typical oxidation–reduction reaction yielding RSO_3H and R_2SO_2 with Ce^{+3} remaining quantitatively in solution (10). Our investigation has shown that insoluble white products are obtained on the addition of sulphinic acids to ceric solutions in 1 *N* sulphuric acid; the white product from benzenesulphinic acid addition contained no cerium and recrystallized from benzene as white needles melting, with decomposition, at 192° C; the melting point of diphenyldisulphone, $(C_6H_5SO_2)_2$, is 193° C. Titration of a standard benzenesulphinic acid solution with a 0.1 *M* ceric sulphate solution (1 *N* in H_2SO_4) using ferroin indicator gave a white precipitate; the ceric solution was decolorized and the end point occurred at a molar ratio of 1.8 cerium to 1 sulphinic acid. In acid solutions ceric cerium oxidizes sulphinic acids and is not precipitated, the cerium remaining quantitatively in solution; no precipitation occurred with cerous cerium in 1 *N* sulphuric acid solution.

From ceric solutions buffered at pH 4 with ammonium acetate, however, an orange-yellow precipitate containing cerium is obtained upon addition of sulphinic acids; cerous

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

cerium is precipitated at pH 4 as a white precipitate. The orange-yellow product obtained from ceric solutions with benzenesulphinic acid varied in composition, part of the product being extractable into ether to give an orange solution. The ether-soluble portion was reprecipitated as an orange solid on the addition of ligroin and gave on analysis, after drying *in vacuo* over boiling methanol, 30.9% Ce. The ether-insoluble portion, after drying in the same manner, gave on analysis 18.15% Ce; the theoretical value for $Ce(C_6H_5SO_2)_4$ is 19.88% Ce. It is evident that a mixture of products is obtained on the addition of sulphinic acids to nearly neutral solutions of ceric cerium.

The reaction of cerium with sulphinic acids depends markedly on the acidity of the solution which controls the oxidation potential of the system. At low acidity ceric cerium is precipitated but not purely as the simple metallic salt of the sulphinic acid whereas in strongly acid solution it is reduced and remains in solution as cerous cerium.

NAPHTHALENESULPHINIC ACID

Since naphthalenesulphinic acid gave the most insoluble precipitates in the preliminary experiments, its usefulness as a reagent for quantitative precipitation of a number of metal ions was briefly investigated. An excess of a 2% aqueous solution of ammonium naphthalenesulphinate was added to solutions of the metal ions, under varying conditions, and the filtrates tested by means of drop reactions for the metal; for the gravimetric results recorded the precipitates were washed with dilute solutions of the reagent and then ignited to the oxide. The results are given in Table III.

TABLE III

PRECIPITATION OF METAL IONS WITH NAPHTHALENESULPHINIC ACID

Metal ion	Conditions	Results
$Fe^{\cdot\cdot\cdot}$	0.05 mg/ml at pH 3	Good precipitation; 1 p.p.m. iron left in filtrate
	0.25 mg/ml in 0.2 *N* HCl	Good precipitation; 1.3 p.p.m. iron left in filtrate
		Benzenesulphinic acid gives no precipitation under the above conditions
$Zr^{\cdot\cdot\cdot\cdot}$	0.4 mg/ml in 0.4 *N* HCl	White precipitate; no zirconium detected in filtrate with alizarin
$Th^{\cdot\cdot\cdot\cdot}$	1 mg/ml	White precipitate; quantitative in acid solutions, < 5 p.p.m. thorium left in filtrate even in 0.5 *N* HCl
	0.1 mg/ml in 0.2 *N* HCl	Thorium oxide taken, 11.82 mg; recovered 11.87 mg
$Ti^{\cdot\cdot\cdot\cdot}$	0.1 mg/ml in 0.2 *N* H_2SO_4	Yellow precipitate; no titanium detected in filtrate with chromotropic acid
	0.05 mg/ml in 0.2 *N* H_2SO_4	Titanium dioxide taken, 7.94 mg; recovered, 7.95 mg
$Sn^{\cdot\cdot\cdot\cdot}$	0.3 mg/ml in 0.25 *N* HCl	White precipitate; no tin detected in filtrate by reduction to stannous tin and testing with ferric iron and *o*-phenanthroline
	1 mg/ml in 0.6 *N* HCl	Stannic oxide taken, 12.47 mg; recovered 12.50 mg
$U^{\cdot\cdot\cdot\cdot}$	0.1 mg/ml in 0.2 *N* HCl	White precipitate; no uranium detected in filtrate with ferrocyanide
$Bi^{\cdot\cdot\cdot}$	0.1 mg/ml in 0.2 *N* HNO_3	White precipitate; < 5 p.p.m. bismuth determined with stannite and lead solutions
$Pd^{\cdot\cdot}$	0.1 mg/ml in 0.03 *N* HCl	Brown precipitate turned slowly to canary yellow; no palladium detected in filtrate with mercuric iodide in dioxane
	0.1 mg/ml in 0.2 *N* HCl	No precipitate; yellow solution
$Hg_2^{\cdot\cdot}$	0.1 mg/ml in 0.2 *N* HNO_3	White precipitate; no mercury detected in filtrate with iodide
$Ag^{\cdot}$	1 mg/ml as solution of $AgNO_3$	White precipitate; no silver detected in filtrate with N,N-dimethylaminobenzalrhodanine
	1 mg/ml in 0.5 *N* HNO_3	Greyish precipitate, indicating reduction to metallic silver; silver ion detected in filtrate with N,N-dimethylaminobenzalrhodanine

Naphthalenesulphinic acid quantitatively precipitates a number of metal ions from acid solution and should, therefore, prove useful in the separation and determination of these metals.

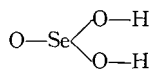
INFRARED SPECTRA AND STRUCTURE OF SELENIOUS ACID[1]

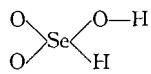
MICHAEL FALK[2] AND PAUL A. GIGUÈRE

ABSTRACT

The infrared spectra of selenious acid both crystalline and in solution in water and methanol were recorded from 2 to 30 μ. Assignment of the various frequencies is made on the basis of the crystal structure as determined from X-ray data. It is shown that the molecules have the symmetrical form (*a*), the asymmetrical one (*b*) proposed by Venkateswaran being



(*a*)



(*b*)

ruled out. The spectra of solutions in H_2O and D_2O confirm the existence of discrete H_2SeO_3 and D_2SeO_3 molecules with no indication of uncombined SeO_2 molecules even at high concentrations. This behavior is contrasted with that of SO_2 solutions.

INTRODUCTION

Recent spectroscopic investigations (1, 2) have confirmed the absence of measurable quantities of H_2SO_3 molecules in the various phases of the H_2O–SO_2 system. We have now completed a similar study of the H_2O–SeO_2 system prompted by the considerable differences between sulphurous and selenious acids. Unlike SO_2, SeO_2 combines with water to form a definite compound H_2SeO_3 stable both in solution and in the crystalline state. By X-ray diffraction Wells and Bailey (3) have shown that the crystal consists of nearly symmetrical SeO_3 pyramids linked together by strong O–H . . . O bonds. While the present work was in progress Detoni and Hadži (4) reported briefly on the infrared spectrum of the crystalline acid, interpreting their results in terms of molecules having the symmetrical form (*a*). The existence of stable H_2SeO_3 molecules in the solid phase is therefore well established.

The nature of aqueous solutions of selenious acid remained unsettled, however. By analogy with SO_2 persistence of free SeO_2 molecules in these solutions could be suspected. From a Raman study made over twenty years ago Venkateswaran (5, 6) had concluded that solutions of selenious acid present a complex system of two or three molecular species. His interpretation is now untenable as we shall see.

EXPERIMENTAL

Solid films of selenious acid were prepared by evaporating on a polished silver chloride plate solutions of selenium dioxide in chloroform or acetone and then allowing the films to hydrate in air. The latter reaction took place very readily at room temperature and at moderate humidity; once hydrated the films were indefinitely stable under these conditions, showing no tendency to effloresce. Aqueous solutions of selenious acid were prepared by adding weighed amounts of solid anhydrous SeO_2 to H_2O or D_2O. Absolute methanol was used to dissolve the pure crystalline acid. The high-purity sample of selenium dioxide was obtained through the courtesy of Dr. E. M. Elkin, Canadian Copper Refiners, Montreal East. The spectra were recorded by means of a Perkin–Elmer, Model 12-C infrared spectrometer using LiF, NaCl, and CsBr prisms.

RESULTS AND DISCUSSION

The molecular spectra of crystalline selenious acid must be considered first to help decipher those of the solutions.

Solid H_2SeO_3

A composite tracing of the spectrum of selenious acid in the solid state is reproduced in Fig. 1 and the average frequency of the various maxima found in some eighteen films are listed in Table I. Both the frequencies and the relative intensities agree closely

TABLE I

INFRARED BANDS OF CRYSTALLINE H_2SeO_3 AND SeO_2

(Frequencies in cm^{-1})

with the results of Detoni and Hadži (4). For comparison the infrared frequencies of anhydrous SeO_2 (7) are also given. Apart from a few very weak bands presumably due to traces of SeO_2 in the acid, there is no resemblance between the two spectra; nor is there any indication of the H_2O bands in the neighborhood of 1650 and 3300 cm^{-1} usually present in molecular hydrates. Generally speaking, the frequencies below 1000 cm^{-1} may be ascribed to the SeO_3 groups and those above, to the OH groups.

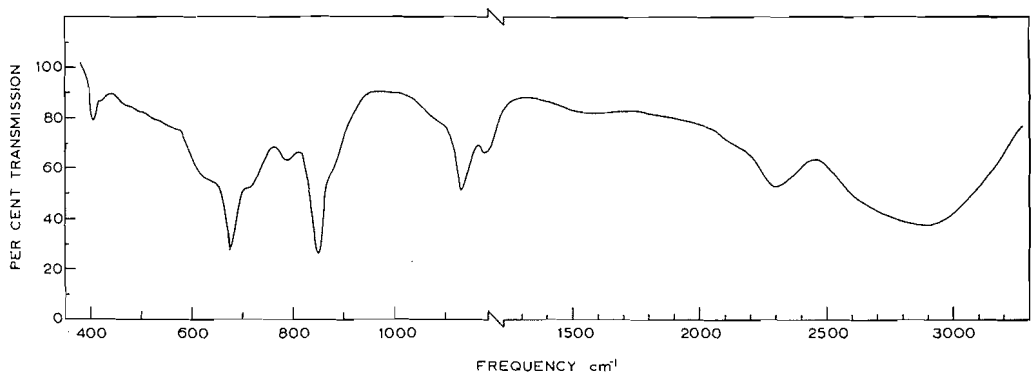

FIG. 1. Infrared absorption of crystalline selenious acid.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12

The two OH stretching frequencies at 2900 and 2320 cm^{-1} seem quite low compared with that of the free OH (about 3700 cm^{-1}). Such a large downward shift is indicative of strong hydrogen bonding in the crystalline acid and agrees with the short O–H · · · O distances found by X-ray diffraction, 2.56 and 2.60 Å (3). Correlations have been drawn by various authors between stretching frequencies and hydrogen bond lengths. One of the latest by Nakamoto, Margoshes, and Rundle (8) shows very good agreement for numerous compounds with O–H · · · O bonds. Taking the latter distance as 2.60 Å in H_2SeO_3, the OH stretching frequency should occur at 2500 cm^{-1}, nearly halfway between the observed values. A second relationship between frequency shift and hydrogen bond distance leads to the same approximate frequency: 3700–1200 = 2500 cm^{-1}. The large splitting between the two stretching frequencies (580 cm^{-1}) must result from the strong coupling of the two OH groups through the heavy selenium atom. In liquid H_2SO_4 the pair of corresponding bands occur at 3000 and 2430 cm^{-1} (9).

It is of interest to inquire where the hydrogen atoms are located in the H_2SeO_3 lattice. Judging from the rather low stretching frequencies one would expect an O–H bond somewhat longer than, for example, in ice: 1.01 Å (10). In fact a rough estimate based on Badgers's rule, using an average frequency of 2600 cm^{-1} leads to a distance of nearly 1.1 Å. On the other hand an empirical relationship between O–H · · · O distances and O–H bond lengths (8) yields about the same value as in ice. The discrepancy may come from the fact that the hydrogen bonds in the selenious acid crystal are not straight but bent. A neutron diffraction study of this and other mineral acids appears desirable.

The OH bending frequencies also are rather low (1178 and 1134 cm^{-1}) for such a strongly hydrogen-bonded system. Although the influence of hydrogen bonding on the deformation modes is much more complex and obscure than for the stretching modes it usually entails a slight shift toward *higher* frequencies. The situation here is somewhat reminiscent of that in tertiary alcohols (11) where a narrow association band arises near 1100 cm^{-1}. It would seem that even for a bonded hydrogen the bending frequency is strongly dependent on the "resultant mass" on the X atom in the group X–O–H · · · O.

In view of the small mass of the hydrogen atoms and the strong polarity of the O–H bonds the vibrations of the SeO_3 group can well be analyzed independently. Also for simplicity, a pyramidal configuration with C_{3v} symmetry is assumed since the three Se–O bonds are very nearly equivalent; 1.72, 1.75, and 1.76 Å (3) in the crystalline acid as a result of resonance. The normal Se–O single bond distance is about 1.81 Å (12) and the double bond, 1.68 Å (13). On the basis of that assumption one may expect a symmetrical stretching frequency and a doubly degenerate asymmetrical one. The pair of strong peaks at 849 and 675 cm^{-1} have been rightly assigned to these modes (4). The former has its equivalent at 890 cm^{-1} in the Raman spectra (5); there is, however, no trace in the infrared spectrum of the H_2SeO_3 crystal of any absorption near 600 cm^{-1} corresponding to the intense Raman shift at 597 cm^{-1}. Lastly, we assign the weak maximum at 403 cm^{-1} to a O–Se–O bending rather than a stretching mode as suggested by Detoni and Hadži (4). The other bending frequencies must lie beyond the range covered in this work.

Solutions of H_2SeO_3

The spectra of concentrated solutions of SeO_2 in H_2O and D_2O are shown in Fig. 2 and the frequency of the observed maxima are given in Table II. Progressive dilution of the solutions from 50 to 10% SeO_2 by weight resulted merely in a regular decrease of intensity for all the acid bands. The general resemblance of the spectra of H_2SeO_3 solutions and those of the crystalline acid leaves no doubt that the same species are

present in both cases. In particular the absence of any bands of uncombined SeO_2 in the solutions is conspicuous. In the deuterated system the OD bending frequency could not be observed as it falls in the region of strong absorption from SeO stretching near 900 cm^{-1}. Shifts of the hydrogen vibrations on passing from the crystal to solutions are not unexpected: it is, however, surprising that the deformation frequency should be shifted to the same extent (about 100 cm^{-1}) and in the same direction as the stretching frequencies.

The only peculiarity in the spectra of methanol solutions was the presence of a fairly strong absorption at 980 cm^{-1} which has no equivalent in either the aqueous solutions or in the crystalline acid. It resulted, no doubt, from oxidation of the alcohol by SeO_2, as shown by appearance, when it was left standing, of the characteristic red coloration of elemental selenium. For that reason these solutions were not studied further.

There is good agreement between our infrared frequencies and the Raman shifts reported by Venkateswaran (5, 6) for selenious acid solutions. For the crystal, however, his spectra have little in common with the present ones. Instead they resemble strangely

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12

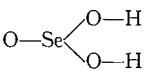
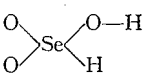
the Raman spectra of crystalline SeO_2 (14), which raises the suspicion that his samples were partly dehydrated by heating. From his results Venkateswaran concluded to the existence of two molecular species, a dihydroxyl, symmetrical form (*a*) and an asymmetrical one (*b*), the two being in a state of dynamic equilibrium in proportions varying



(*a*)



(*b*)

from phase to phase. This is obviously inconsistent with the observed permanence of all the infrared bands of selenious acid both in the solid state and in solutions over a wide range of concentration and temperature (25 to 90° C). In addition the asymmetrical form (*b*) is in contradiction with the X-ray data on the crystal (3) as well as the spectroscopic results of Detoni and Hadži (15) on a series of sulphinic and seleninic acids. Although the 2290 cm^{-1} frequency is of the right magnitude for a Se–H stretching mode (cf. 2260 and 2350 cm^{-1} in H_2Se) the fact that it is shifted to the same extent as the 2900 cm^{-1} frequency on going from crystal to solutions is sufficient proof that both vibrations involve OH groups. Selenium atoms do not normally participate in hydrogen bonding. Lastly, Venkateswaran's assignment of some of the solution bands, particularly that near 900 cm^{-1}, to the biselenite ion $HSeO_3^-$ cannot be correct in view of the very small dissociation constants of selenious acid ($k_1 = 2.4 \times 10^{-3}$ at 25° C).

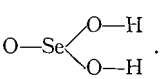
In conclusion the behavior of selenium dioxide towards water may be contrasted with that of the corresponding oxides of sulphur and tellurium. Whereas SeO_2 displays high affinity for water as exemplified by a great solubility (63% by weight at ordinary temperature) and formation of a well-defined compound stable in the free state and in solutions, SO_2 is only moderately soluble (8.3% by weight) and the solutions contain no detectable amount of H_2SO_3 molecules. The greater polarity of the Se–O bond in the dioxide compared with S–O bond may be partly responsible for the marked difference in properties. This is also apparent in the existence of polymer-like chains in crystalline selenium dioxide (16). As for tellurium dioxide it is quite insoluble in water, and it is doubtful if there exists a definite tellurous acid, H_2TeO_3.

ACKNOWLEDGMENTS

The authors are grateful to the National Research Council for financial help, to the Consolidated Mining and Smelting Co. for a fellowship (M.F.), and to Dr. E. M. Elkin, for a generous sample of very pure selenium dioxide.

RÉSUMÉ

On a étudié les spectres infrarouges de l'acide sélénieux à l'état cristallin et en solution dans l'eau et le méthanol. Les résultats s'accordent avec l'existence de molécules bien définies ayant la formule symétrique



.

Les spectres des solutions ne révèlent aucune trace de bioxyde de sélénium à l'état libre contrairement au cas du bioxyde de soufre.

THE STRUCTURE OF PYRROLE SALTS AND THE BASIC STRENGTHS OF SOME SIMPLE PYRROLES[1]

E. BULLOCK[2]

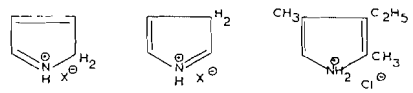
ABSTRACT

The infrared spectra of hydrohalide salts of some substituted pyrroles are typical of secondary amine salts. Unlike the free base, cryptopyrrole hydrochloride is easily hydrogenated. The basic strengths of cryptopyrrole and 2,4-dimethylpyrrole are calculated from ultraviolet spectroscopic data.

Contrary to statements in some textbooks and reviews, many substituted pyrroles show considerable basicity (1, 2, 3) and form salts with halogen acids (2, 4, 7, 8). It has been suggested that salt formation is an important step in the acid-catalyzed reactions of pyrroles (1, 2, 3, 5) and the basic property of the heterocyclic nitrogen atom may be a factor in the formation of III-type porphyrins from monopyrroles (6).

The action of dry hydrogen chloride on cryptopyrrole in ether was reported to give a dimer though the conditions were not specified exactly (9). The action of chlorine on a similar solution gave a low yield of a hydrochloride of the pyrrole (8). We obtained a good yield of this stable hydrochloride on treatment of cryptopyrrole in cold ether with dry hydrogen chloride. The salt regenerated the parent base on treatment with sodium acetate solution. The hydrochlorides of 2,4- and 2,5-dimethylpyrrole were isolated similarly but were less stable, especially in contact with the mother liquor. The parent bases could be regenerated from the salts, but after 1–2 hours standing, dimeric compounds were formed. In contact with picric acid solution the picrates of 2,4-dimethylpyrrole and cryptopyrrole behaved similarly; after 4 days the former yielded only the dimer picrate and the latter a mixture of dimer and monomer picrates.

The salts of pyrroles have been formulated as I or II (2, 3, 5) rather than as secondary amine salts, by direct reference to the resonance forms of pyrrole (10). The infrared spectrum of cryptopyrrole hydrochloride (Fig. 2) shows that it is most probably III.



I II III

The spectrum shows no normal >NH stretching frequency (cf. Fig. 1, cryptopyrrole band at 3370 cm^{-1}) but has a broad strong band centered at 2630 cm^{-1}. The absence of "immonium" bands (11) at 2100–1980 cm^{-1}, although not conclusive, supports III rather than I or II. Coupled with the disappearance of the >NH band, a strong peak appears at 1575 cm^{-1} in the hydrochloride spectrum. Ring vibrations complicate assignments in this region but it seems likely that cryptopyrrole bands at 1597 and 1695 cm^{-1} move to 1650 and 1745 cm^{-1} respectively in the salt and that the 1575 cm^{-1} band is new. This band is considered (12) to be characteristic of the secondary amine salts. The infrared

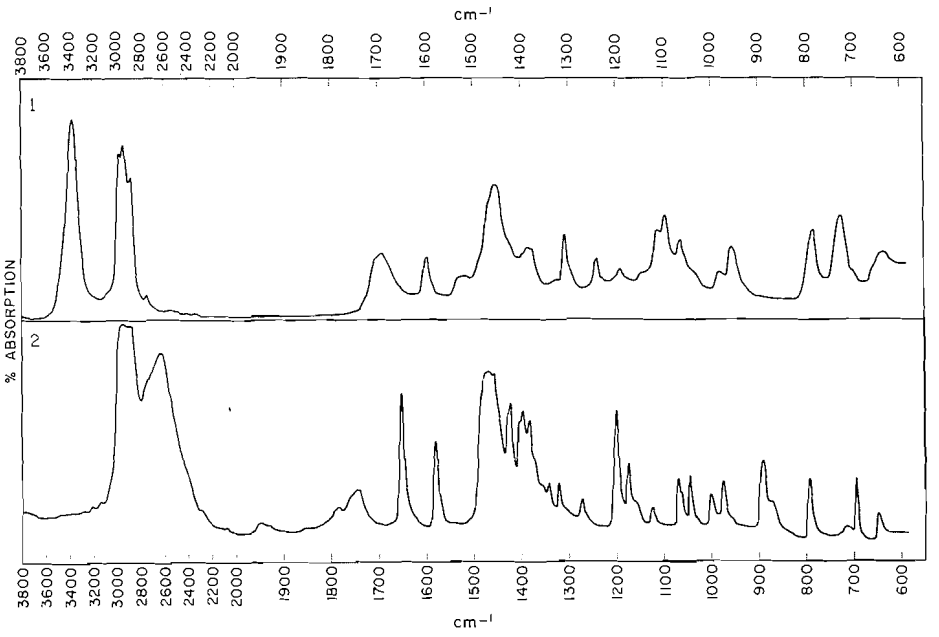

FIG. 1. Cryptopyrrole (thin film).
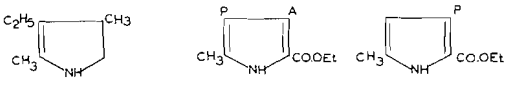
FIG. 2. Cryptopyrrole hydrochloride (nujol mull).

spectra of hemopyrrole- and cryptopyrrole-dicarboxylic acid hydrobromides show exactly analogous features. The picrates of 2,4-dimethylpyrrole and cryptopyrrole likewise show no normal $\rangle$NH absorption and are probably true salts.*

The ultraviolet spectra of cryptopyrrole and 2,4-dimethylpyrrole in normal hydrochloric acid are consistent with formulation of the salts as *cyclo*-pentadiene analogues (cf. 13). The additional alkyl group in cryptopyrrole causes a bathochromic shift of 11 mμ (λ_{max} 260 mμ compared with 249 mμ) in the main peak.

In neutral or alkaline solution at room temperature and atmospheric pressure, cryptopyrrole is not reduced by hydrogen over Adams' catalyst. In ethanolic hydrochloric acid under these conditions it rapidly takes up 1 mole of hydrogen, further reduction being very slow. The analysis of the product, its behavior with permanganate in acetone, and the infrared spectrum suggest that it is the Δ^3-pyrroline IV (15). As anticipated, the less basic pyrroles V and VI, whose ultraviolet spectra are unchanged by the addition of acid (cf. 14), were not reduced in similar conditions.

The pK_a's of cryptopyrrole and 2,4-dimethylpyrrole were determined by an ultraviolet spectroscopic technique (e.g. 16, 17). Solutions of the bases in various strengths of hydrochloric acid were used, rather than buffer solutions. The error introduced by



IV V VI

assuming that the pH of the solution is that of the acid is less than 2% for spectroscopic amounts of the base in 0.01 *N* acid.

The pK_a of the conjugate acid to cryptopyrrole is 2.84 and that of 2,4-dimethylpyrrole is 2.12. Allowing 0.7 units of p*K* per alkyl group and neglecting possible "positional" effects, the pK_a of pyrrole is estimated as 0.7. A previous estimate (18) gives the value 0.4. Attempts to measure the pK_a's of variously substituted alkyl pyrroles by other methods are in progress.

From these results it is concluded that: (*a*) In absence of acid, attack of electrophilic reagents may occur at the nitrogen atom of pyrroles. The known structure of the products of such reactions requires that the intermediate rearranges to give α-substituted derivatives. (*b*) In acid solution, the observed catalysis of some pyrrole reactions may be due to salt formation. The $\rangle NH_2^+$ group causes intense polarization of the diene system resulting in high electron density at the 2,5- (α-) positions.

EXPERIMENTAL

Melting points are uncorrected.

Cryptopyrrole Hydrochloride

A solution of the pyrrole (3 g) in dry ether (60 ml) was cooled in an ice bath and saturated with dry hydrogen chloride (3–5 minutes). The precipitated solid was filtered and washed with dry ether (5×20 ml) then dried in a vacuum desiccator over caustic soda. The product (3.2 g) was crystallized from alcohol–ether to large colorless needles, m.p. 109–117 (decomp.). Ehrlich reaction was positive cold. The product is stable *in vacuo* in the dark and is not deliquescent when free of cryptopyrrole (cf. 2, 7). Solutions in water and ethanol are acidic. Calc. for $C_8H_{14}NCl$ (monomer hydrochloride): Cl, 22.33. Calc. for $C_{16}H_{26}N_2Cl$ (dimer hydrochloride): Cl, 12.58. Found: Cl, 21.51. (Dried at room temperature *in vacuo*.) Infrared spectrum (nujol mull): Fig. 1. The spectroscopist reported that the sample became red during the determination. λ_{max} (1 *N* hydrochloric acid): 260 mμ; log ϵ: 3.56. The material sublimes slowly under water-pump vacuum (60–70° at 12 mm with some decomposition) to a white solid, m.p. 114–117° (decomp.), which slowly turns red on exposure to air.

Regeneration of the Parent Base

A solution of the salt in water was treated with sodium acetate and extracted with ether. The ether layer was washed with water and treated with picric acid. Yellow needles of cryptopyrrole picrate, m.p. 134° alone or mixed with an authentic sample (lit. 137° (20)), were obtained.

2,4-Dimethylpyrrole Hydrochloride

Freshly distilled 2,4-dimethylpyrrole (3.1 g) was dissolved in dry ether (60 ml) and cooled in an ice bath. A rapid stream of dry hydrogen chloride was bubbled through the solution (2–3 minutes) when a semisolid precipitate was formed. The ether was decanted and the product was washed with dry ether (3×50 ml) then taken up in water and neutralized with sodium acetate. The ethereal extract of this solution was washed with water and dried over potassium carbonate. Removal of the ether yielded an almost colorless oil (1.95 g) which distilled almost completely under reduced pressure (b.p. 56.5° at 11 mm).

A sample of the oil was converted to the picrate giving large yellow plates. The picrate is dimorphic showing signs of melting at 56°, accompanied by a collapse of the crystal structure to fine needles, m.p. 92–93° (lit. 91–92° from ethanol–ether (20)).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

A sample of the oil was treated with phenyl isothiocyanate and warmed on the steam bath. After 10 minutes the solid product was crystallized from heptane to large yellow needles, m.p. 111–113° (authentic sample 112–114° (19)). Ultraviolet absorption of the pyrrole in acid, λ_{max}: 249 mμ; log ϵ: 3.43.

2,5-Dimethylpyrrole Hydrochloride

The pyrrole (4.35 g) was treated as above, the colorless oil (1.43 g) liberated from the hydrochloride distilled at 60.0° at 11 mm.

Action of Hydrogen Chloride on α-Methylpyrrole

Under the conditions described above the only product recovered was a solid, probably the dimer.

Reduction of Cryptopyrrole

(*a*) *Acid solution.*—Cryptopyrrole (3.83 g) was dissolved in ethanol (40 ml) saturated with hydrogen chloride and Adams' catalyst (75 mg) was added. The material was hydrogenated at room temperature and atmospheric pressure for 2 hours, after which time 650 ml of hydrogen (almost 50% of theoretical amount for complete reduction) had been absorbed. (In a separate experiment, the uptake was approximately 65% after 6 hours.) The platinum was filtered off over "Celite" and the alcohol removed *in vacuo*. The residue was treated with sodium hydroxide solution (50 ml, 10% w/v) and extracted with ether (3×50 ml). The ethereal extract was washed with water and then re-extracted with a near-saturated solution of potassium dihydrogen phosphate in water (3×50 ml). The yellow phosphate extract was neutralized with sodium hydroxide and the liberated base was collected by further ether extraction (3×50 ml). This ether was well washed with water (5×50 ml), fresh ether being added to maintain the volume of the ethereal layer, and dried over sodium sulphate. Removal of the ether left a pale yellow oil (3.21 g) which gave no Ehrlich reaction. Distillation gave a main fraction, b.p. 152–155° (1.26 g). Calc. for $C_8H_{15}N$: C, 76.79; H, 12.09; N, 11.20. Found: C, 76.50; H, 12.07; N, 11.27. Infrared spectrum (thin film): 3280, 2960, 2890, 1680 (shoulder), 1650, 1550, 1462, 1383, 1305, 1250, 1045, 960 cm^{-1}. α-Naphthylurethane recrystallized from aqueous ethanol. Calc. for $C_{19}H_{22}ON_2$: C, 77.51; H, 7.53; N, 9.52. Found: C, 77.01; H, 7.94; N, 8.95. The picrate, m.p. 157–159°, crystallized in thick needles from ethanol–ether.

(*b*) *Neutral solution.*—In a similar experiment to that described in (*a*) but employing 95% ethanol, no hydrogen was absorbed beyond that required for the catalyst.

(*c*) *Alkaline solution.*—In ethanolic solution containing sodium ethoxide (approximately 2% w/v) the cryptopyrrole absorbed no hydrogen.

Attempted Reduction of Carboxylated Pyrroles

In conditions similar to those given in (*a*) above, cryptopyrrole tricarboxylic acid – triethyl ester (V) and 2-methyl-5-carbcthoxypyrrole-4-propionic acid ester (VI) were not reduced.

Determination of pK_a *Values*

Solutions containing spectroscopic amounts of the pyrroles in 1 *N*, 0.1 *N*, and 0.01 *N* hydrochloric acid (0.9–1.7 mg in 25 ml of acid) were prepared and the spectra were recorded from 300 mμ to 208 mμ on a Cary self-recording instrument. The operation of the instrument required approximately 4 minutes, the total time elapsing from completion of the weighing being about 10 minutes. It was found that the spectra were substantially unchanged after 30 minutes' standing, although the solutions became slightly

For personal use only.

colored. The spectra of the free bases were recorded in 95% ethanol and the pK_a values were calculated in the usual way (17).

Analyses are by Mr. H. Seguin and the infrared spectra were determined by Mr. R. Lauzon.

DISTRIBUTION OF NUCLEAR CHARGE IN THE PROTON-INDUCED FISSION OF Th^{232} [1]

B. D. Pate,[2] J. S. Foster, and L. Yaffe

ABSTRACT

The cross sections for the independent formation of I^{130}, I^{131}, Te^{131}, I^{132}, and I^{134} and for the cumulative formation of Te^{132}, I^{133}, and I^{135} in the proton-induced fission of Th^{232} have been measured at nine proton energies between 8 and 87 Mev. From these data and from published total chain yield data, charge distribution curves have been obtained. These are compared with published charge distribution curves for uranium fission at energies up to 480 Mev and together they show a shift of the most probable fission product charge toward stability and a widening of the distribution with increasing bombarding energy. These phenomena are interpreted in terms of current models for nuclear reactions.

INTRODUCTION

A voluminous literature exists on the distribution of nuclear mass in the fission process. In spontaneous fission (31) and in the fission of U^{233}, U^{235}, and Pu^{239} with neutrons of thermal energy, the familiar double-peaked distribution, corresponding to a preponderance of asymmetric fission modes, is observed (30). As the energy of bombarding particles is increased the mass distribution in the fission of these and other heavy nuclei becomes more and more symmetric (18, 33) and at sufficiently high energies a singly peaked distribution is observed (19).

About the nuclear charge distribution less is known. Data exist on the distribution from the fission of U^{235} with thermal neutrons (6, 7, 21) and with 14-Mev neutrons (34). Data also exist for the fission of uranium by 170-Mev protons (1), of bismuth by 190-Mev deuterons (10), and of uranium, thorium, and bismuth by 480-Mev protons (16), and there is fragmentary information from other systems. The present work was undertaken to investigate the changes that occur in the charge distribution from proton-induced fission of Th^{232} as the bombarding energy is raised from 8 to 90 Mev, the maximum proton energy of the McGill synchrocyclotron. This energy range is of interest in view of the substantial changes observed in the mass distribution (33). Also in this interval a change presumably begins in the nature of the initial step in nuclear reactions, from simple compound nucleus formation to a mechanism of direct interaction with individual nucleons (29). Thus at the lower energies studied, excitation of the nuclei at the end of the first step of the reaction will be essentially monochromatic whereas at the higher end of the bombarding energy range, a broad spectrum of excitation energies will be produced, with corresponding complexity of the reaction products observed. Ideally, in the determination of a charge distribution, one would wish to measure the independent yields of each of the nuclides in one or more fission chains. This, however, is precluded by the short half-lives of most of the members of any given mass chain. One substitutes a determination of independent yields of accessible nuclides in chains of different mass number, followed by correlation of these data. Correlation is customarily attempted by means of semiempirical or theoretical relationships (6, 7, 21, 27, 35) that

[2]*Present address: Department of Chemistry, Brookhaven National Laboratory, Upton, Long Island, N.Y.*

give the most probable nuclear charge, Z_p, for a given mass number A. Here Z_p is that charge value at which the peak of the charge distribution occurs, this not necessarily being an integral value. Distribution of yields around the most probable charge is usually assumed to be Gaussian and to be identical for all mass chains. These assumptions appear to be substantiated by much of the experimental evidence.

In the present experiment, yields of some iodine and tellurium nuclides in the mass region 130–135 were measured. The data have been correlated to give a charge distribution in this mass region under the assumptions that the distribution is symmetric about Z_p and that over the mass range investigated Z_p is displaced a constant amount from the Z_A value given by Pappas (21). (Z_A is that charge value, not necessarily integral, corresponding to stability for a given A.) A study over a mass range as small as six units does not provide sufficient data to test theories on the variation of Z_p with A.

EXPERIMENTAL TECHNIQUES AND RESULTS

1. Target and Irradiation

Thorium metal foil of about 190 mg/cm^2 superficial density was employed as the target material and was irradiated in the internal circulating proton beam of the McGill 82-in. synchrocyclotron. In all experiments, but the one at lowest energy, foils were irradiated in stacks of three, and the middle foil was used for the iodine yield determination. Loss of fission fragments by recoil from the target foil was thus compensated for by gain of recoils from the neighboring foils. In the lowest energy bombardment (8 Mev) energy loss considerations precluded the use of more than a single foil.

Upstream from the thorium was a monitor foil, again with a guard foil on both sides. For proton energies of 35 Mev and above, aluminum foils were used and beam intensities monitored via the $Al^{27}(p,3pn)Na^{24}$ reaction. The excitation function given by Hintz and Ramsey (13) was used with the cross-section scale reduced by a factor of 41/49, as indicated by the work of Crandall *et al.* (4). For lower energies copper monitor foils were used, the monitor reaction then being at 8 Mev, $Cu^{63}(p,n)Zn^{63}$ and at 26 Mev, $Cu^{65}(p,pn)Cu^{64}$. Here the cross-section data of Meadows (17) were used, with the appropriate scale correction. The leading edge and the top and bottom edges of the stack of six foils were aligned prior to bombardment by shearing with scissors after the foils had been clamped in the target holder.

The foils were mounted on a water-cooled probe and inserted into the cyclotron tank to a radius appropriate for the desired proton energy, using the data of Kirkaldy (15). Bombardments of 10–20 minutes and beam currents of the order of 10^{15} protons/cm^2 min were employed.

2. Chemical Processing and Measurement

After rapid removal of the target from the cyclotron probe and transfer to the radiochemistry laboratory, the thorium and monitor foils were sheared with scissors from the target clamp. This, together with the preliminary alignment described above, ensured that the monitor and target foils used in the experiment received the same flux. The middle target foil of the stack of three irradiated and likewise the middle monitor foil were selected for processing.

Three timed-separations of iodine activity from the irradiated target foil were accomplished by procedures previously described (8, 14, 34). The target foil was dissolved in concentrated hydrochloric acid, to which a known quantity of iodine (about 10 mg)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

in the form of iodide had been added, and the last traces of residue were dissolved by addition of ammonium silicofluoride. The solution was then made up to volume and an aliquot taken for the first iodine separation.

The aliquot was transferred to a separatory funnel and diluted with hydrochloric acid. An equal volume of carbon tetrachloride was then added, followed dropwise by 10% hydrogen peroxide to slight excess. The iodine produced was extracted into the carbon tetrachloride and the phases separated, the time from the end of the bombardment to the separation being noted. The iodine activity was purified by three cycles of extraction of iodine from the carbon tetrachloride layer by a saturated sulphur dioxide solution, followed by acidification of the aqueous extract with 6 *M* nitric acid, reoxidation of the iodine with 1 *M* sodium nitrite solution, and re-extraction into carbon tetrachloride. The iodine was finally extracted from the organic layer with slight excess of SO_2 water, and the aqueous solution made up to volume. Aliquots (1%) were taken and mounted for 4π-counting. The mounts used were 5–10 $\mu g/cm^2$ VYNS films coated with 2–5 $\mu g/cm^2$ of gold (22). A 100 λ aliquot of the separated iodide solution was pipetted, followed by pipette washings, on to the film, followed by 100% excess of 0.1 *M* silver nitrate solution. The resulting colloidal silver iodide solution was then rapidly evaporated to dryness, the time at which the last of the solution disappeared being taken as the time of separation from xenon-daughter activities. The sample was then placed in a 4π-counter and the disintegration rate measured as a function of time by techniques described elsewhere (23, 24, 25, 26). Measurements were made first at 15-minute intervals, later less frequently, and extended for 5 to 6 weeks from the end of bombardment.

Successive 1% aliquots from the separated iodine solution were mounted at intervals, 6-hourly at first, thereafter daily until all 20-hour I^{133} had decayed and no further xenon-daughter activities were being produced.

The time from the end of the bombardment to the first iodine separation was about 20 minutes. Further iodine separations were performed on additional aliquots of the dissolved thorium solution 2–3 hours and again 2–3 days after the end of bombardment. The procedure followed in each case was the same as that described above.

After the elapse of a time interval sufficient to allow substantial decay of iodine activity, semimicrogravimetric determination of iodine as AgI was performed on each of the three iodine solutions, to establish the chemical yields in the separations. The yields averaged about 70% so that the quantity of iodine carrier originally added resulted in less than 100 μg of AgI in the samples used for disintegration rate measurements.

As soon as convenient after the end of the bombardment, the middle monitor foil was dissolved in an appropriate acid, nitric for copper, hydrochloric for aluminum. The solution was made up to volume and a suitable aliquot (0.1–1%) mounted on a VYNS film for 4π-counting, as described above. Counting-rate measurements over several days followed by decay curve analysis allowed the counting rates of 38-minute Zn^{63}, 12.8-hour Cu^{64}, and 15.0-hour Na^{24} at the end of bombardment to be determined.

It is well known that active iodine produced in the fission of uranium and thorium in the form of oxides and oxysalts does not exchange readily with carrier iodide. The chemical separation of iodine activity from uranium metal targets by a procedure involving oxidation of carrier iodide to iodine and extraction into CCl_4 is reported (14) to be 100% complete. It was felt desirable to check this behavior with thorium metal for possible use in the present work. Accordingly, an irradiated thorium metal target was dissolved as above in the presence of iodide carrier. Two aliquots were then taken

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

and an iodine separation was performed on each. One was treated by the procedure outlined above, and the other by the usual procedure for the separation of iodine from uranium oxysalts (8). The latter involved the oxidation of the iodine to periodate by sodium hypochlorite in sodium hydroxide solution, followed by acidification of the solution with nitric acid and reduction of the iodine to the elementary form with hydroxylamine. Yields from the two separations (after correction for carrier recoveries) were identical within experimental error. Consequently the faster separation by peroxide oxidation of the iodide was adopted, as detailed earlier.

3. Results

The iodine and xenon activities which might be expected to appear in a sample separated from the products of a fission reaction are listed, together with their decay characteristics, see Table I. The list does not include isotopes which, because of their very long or short half-lives, would not be detectable in the present experiments.

The mixture of activities obtained from each separation was checked for radiochemical purity in two ways.

(*a*) *Gamma-radiation Measurements*

Gamma spectra were observed from suitable aliquots of the iodine activity stock solutions, by means of a $1\frac{1}{2}$ in. × 1 in. NaI (Tl) crystal with a Dumont 6292 photomultiplier, an Atomic Energy of Canada Limited amplifier (AEP 1448), and a single channel pulse-height analyzer. Figure 1 shows the spectra obtained at various times after the end of bombardment from a sample of iodine separated at 24 minutes after the end of bombardment from a thorium target irradiated with 26-Mev protons.

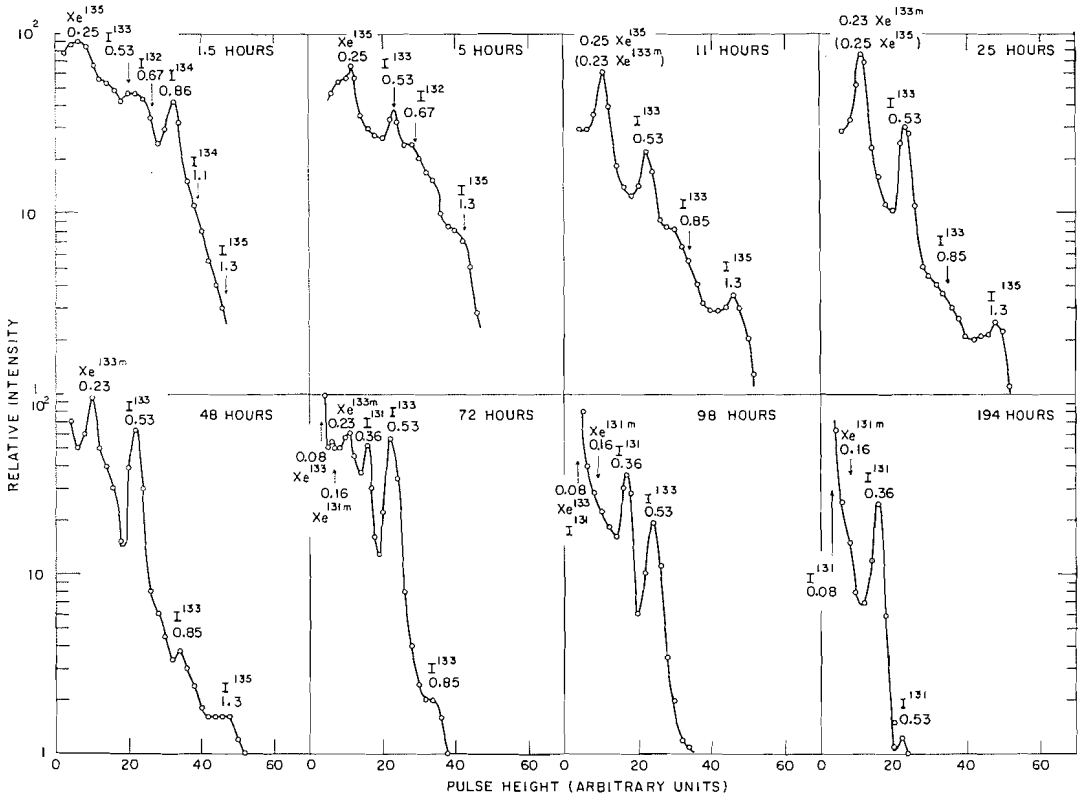

FIG. 1. Gamma spectra of iodine + xenon fission product mixture at various times after the end of bombardment.

The photopeaks are identified as to energy and isotope as indicated, and the positions at which other prominent γ lines in the decay schemes of the various iodine or xenon isotopes would be expected to appear are indicated by arrows.

It is seen that there are no features of the spectra which are inconsistent with the composition of the expected isotope mixture, either as to line energies or intensities. However, these measurements obviously do not constitute a very sensitive test for the presence or absence of activities other than those of iodine or xenon.

(*b*) *Beta-radiation Measurements*

The results of the analysis of beta-activity determinations, which are described below,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

constituted a more rigorous check on the effectiveness of the iodine purification procedure. The analysis of the decay curves in terms of the published half-life values in Table I was always successful, and in no case were decay periods observed other than those corresponding to iodine or xenon isotopes. The purification procedure was consequently considered to be satisfactory.

Figure 2 shows the analysis of a typical beta-decay curve obtained with a 4π-counter from iodine samples mounted as AgI as described earlier. The data are for the first sample separated from a target irradiated with 63-Mev protons. The open circles on the curve marked "iodine + xenon activity" represent observations made on a single sample mounted shortly after the end of the separation procedure. (The data presented extend over a 2-week period, but observations continued for a further month to assure positive identification of 8.05-day I^{131}.) The closed circles on the curve marked "iodine activity" represent observations made on a series of samples (one per plotted point) freshly mounted in succession from the stock iodine solution at intervals as described earlier. Since the data plotted were obtained promptly after mounting, they give closely the iodine disintegration rates alone at the times indicated, free of xenon-daughter contributions.

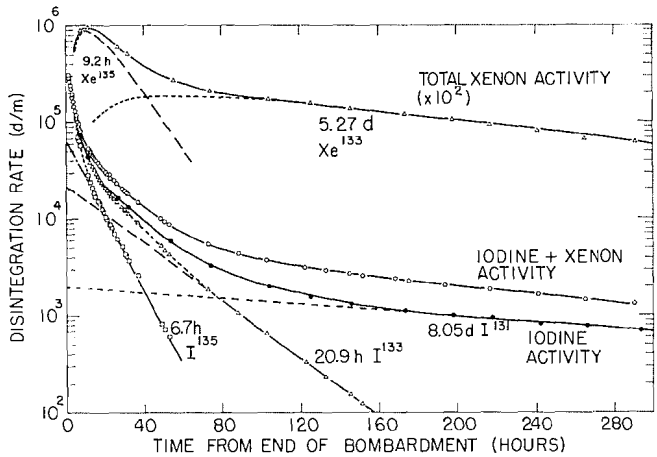

FIG. 2. Beta-decay curve of iodine + xenon fission product mixture.

The standard deviations on disintegration rate measurements were in general less than 1% and always less than the sizes of the plotted points.

The iodine + xenon data are more complete than the pure iodine data, since the mounting of successive samples was time-consuming, and more frequent preparations could not be fitted into the experimental schedule. However, the data can be combined to improve the definition of the pure iodine disintegration rate curve. The points plotted as open triangles on the curve marked "total xenon activity" are the result of the subtraction of one set of observations from the other, with the ordinate multiplied by 100 for reasons of clarity. From 120 hours after bombardment this curve exhibits an exponential decay with a half-period close to 5.27 days, corresponding to Xe^{133}. (The small scatter of the points, each representing a separate sample mounting, confirms the reproducibility of the procedure used.) From the intercept of the 5.27-day line with the ordinate, and from a knowledge of the time of separation and of parent half-life (20.9 hours), the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

growth and decay curve of Xe^{133} can be calculated. The early part of this curve is shown as a broken line. Subtraction of this curve from points at abscissa values less than 120 hours gives new points which are well fitted by 9.2-hour Xe^{135} growing from 6.7-hour I^{135}, as indicated by the dashed line. Summing of these two curves gives the smooth total xenon curve. Interpolation from this curve makes possible the determination of xenon-daughter contributions to the total disintegration rate at times other than those at which fresh mountings were made. (Contribution of 2.3-day Xe^{133m} formed in a rare decay mode of I^{133} to the observed xenon activity was apparently not large enough to disturb this method of treatment of the data.)

Subtraction of the interpolated xenon activities from the iodine + xenon data now allows the pure iodine curve to be drawn accurately between the observations made. By the usual method of successive subtractions the iodine decay curves can be analyzed clearly into 8.05-day, 20.9-hour, and 6.7-hour components corresponding to I^{131}, I^{133}, and I^{135} as shown in the figure. In experiments involving proton energies in excess of 74 Mev the data are well fitted by the addition of a 12.5-hour component, corresponding to I^{130}.

After subtraction of these periods, the data at times less than 12 hours from end of bombardment showed an exponential decay with a half-life which varies between 1 and 2 hours, presumably corresponding to a mixture of 52-minute I^{134} and 2.3-hour I^{132}, which the subtraction technique cannot resolve. The resolution is effected by a method originally due to Ford (5), in which the data are fitted to the sum of two exponential terms of the form:

$$A_t = A_1^{\circ} e^{-\lambda_1 t} + A_2^{\circ} e^{-\lambda_2 t},$$

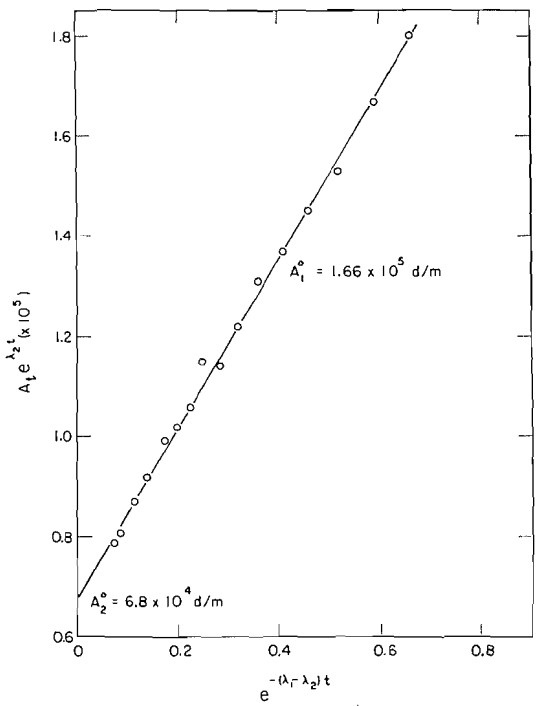

FIG. 3. Ford plot of beta-decay data for I^{132} and I^{134}.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

where A_t is the combined activity at time t, and $A_1°$ and $A_2°$ are the initial activities of components 1 and 2. Then.

$$A_t\, e^{\lambda_2 t} = A_2° + A_1°\, e^{-(\lambda_1-\lambda_2)t}.$$

Therefore in a plot of $A_t\, e^{\lambda_2 t}$ versus $e^{-(\lambda_1-\lambda_2)t}$ using the disintegration rate versus time data for A_t and the appropriate decay constants of I^{132} and I^{134} for λ_1 and λ_2, the initial activities of the two isotopes are obtained as the slope of the curve and as the intercept with the ordinate axis respectively.

Figure 3 shows a typical plot of this nature. The success of the fit was in all cases shown by the linear plot obtained, indicating the absence, over the time interval studied, of activities other than the two anticipated. In particular no deviation from linearity at small t values was observed, indicating the absence of 25-minute I^{128} in the samples studied in these experiments. It should be emphasized that the success of the analysis procedure described is probably due in no small degree to the precision of the disintegration rate measurements made by the 4π-counting technique, especially the relative precision of a series of measurements made on the same sample.

TREATMENT OF THE DATA

From the experimental observations described above, two types of cross-section data were obtained. First, from the disintegration rates of given iodine isotopes, measured in samples separated from the irradiated target at times long compared with precursor half-lives, cumulative formation cross sections could be calculated. Secondly, from similar measurements made on samples separated shortly after the end of bombardment, independent formation cross sections for some iodine isotopes and cumulative formation cross sections for some tellurium isotopes could be calculated.

Our method of treatment of the data is essentially similar to that of Wahl (34). It differs in detail, because, particularly at higher bombarding energies, formation cross sections of the observed iodine isotopes are comparable with those of the tellurium precursors. This fact invalidates some of the approximations which are useful at lower energies. Likewise, in the comparison of fractional chain yields for various mass numbers, it is no longer reasonable to assume that iodine cumulative yields represented total yields of the respective masses. With increasing bombarding energies, an increasing fraction of these yields appears at atomic numbers higher than that of iodine. We have used published mass yield curves for the fission of Th^{232}, U^{235}, and U^{238} by projectiles of various energies, together with suitable interpolations and extrapolations, to obtain the variation of total chain fission yield over the mass range studied.

The generalized relationship between the activity $A_n(T, t)$ of the nth member of a decay series, at a time t after the end of a bombardment of duration T, in which the first member is formed at a constant rate r has been given by Rubinson (28) in the form:

$$A_n(T, t) = r \sum_{i=1}^{n} b_i(1-e^{-\lambda_i T})\, e^{-\lambda_i t}$$

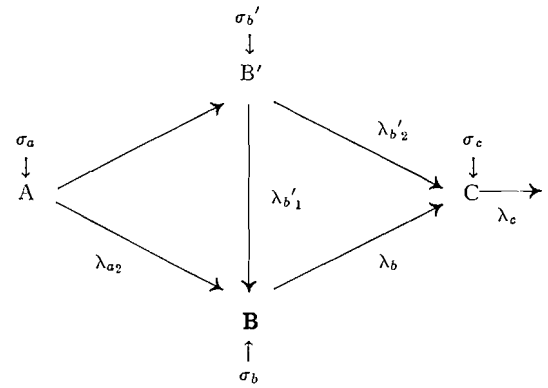
where

$$b_i = \prod_{j \neq i} \frac{\lambda_j}{\lambda_j - \lambda_i} (j = 1, 2, \ldots, n)$$

and the λ's are appropriate decay constants.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

This expression is useful in the construction of activity vs. time relationships for iodine nuclides, particularly where isomerism exists in the tellurium precursors. Thus in the generalized case of a decay scheme of the form



where σ's and λ's are formation cross sections and decay constants respectively (A, B, and C in the present work would be antimony, tellurium, and iodine isotopes), the appropriate expression for the activity of C after given irradiation and decay times may be obtained by summing contributions from the following decay routes:

$$\xrightarrow{\sigma_a} A \xrightarrow{\lambda_{a_1}} B' \xrightarrow{\lambda_{b'_2}} C$$

$$\xrightarrow{\sigma_a} A \xrightarrow{\lambda_{a_1}} B' \xrightarrow{\lambda_{b'_1}} B \xrightarrow{\lambda_b} C$$

$$\xrightarrow{\sigma_a} A \xrightarrow{\lambda_{a_2}} B \xrightarrow{\lambda_b} C$$

$$\xrightarrow{\sigma_{b'}} B' \xrightarrow{\lambda_{b'_2}} C$$

$$\xrightarrow{\sigma_{b'}} B' \xrightarrow{\lambda_{b'_1}} B \xrightarrow{\lambda_b} C$$

$$\xrightarrow{\sigma_b} B \xrightarrow{\lambda_b} C$$

$$\xrightarrow{\sigma_c} C$$

The assumption is implicit that the tin and earlier precursors of chains in the mass range 130–135 are too short-lived to have been observed in the present experiment. Their formation cross sections may be considered to add to those of the Sb precursors. In each case the rate of formation r in Rubinson's expression is given by

$$r_n = N\sigma_n f$$

where N and f are the number of target nuclei and bombarding particle flux respectively and σ_n is the appropriate cross section. Fortunately, however, it was possible to work with simpler expressions for reasons which will be discussed for each mass number.

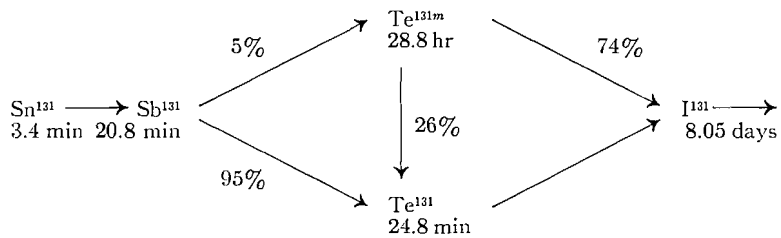
A = 130.—I^{130} is shielded by stable Te^{130} from formation by decay of precursors. The activity observed at bombarding energies of 74 Mev and above was therefore due to direct formation. The independent formation cross section was calculated via the simple expression

$$\lambda_a N_a = N\sigma_a f(1-e^{-\lambda_a T})\, e^{-\lambda_a t}.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

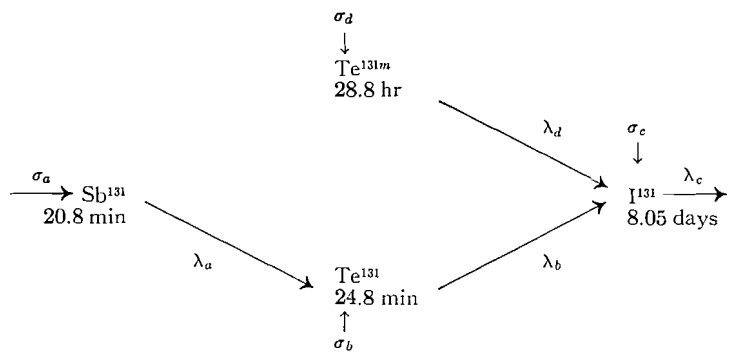
The failure to observe I^{130} at lower energies is assumed to have been due to the larger amounts of I^{135} formed which masked the activity.

A = 131.—The decay scheme (9, 11) of the 131 mass chain up to iodine is as follows:



For the purposes of the present work two simplifications were made. First, the 5% branch in the decay of Sb^{131} leading to the metastable state of Te^{131} was neglected in view of the comparatively long half-life of Te^{131m}. Second, the 26% isomeric transition of Te^{131m} was ignored, and all of the decay of this body was taken to proceed directly to I^{131}. This is expected to have little effect on the calculations (34), since, at short times after the end of bombardment, little of the Te^{131m} will have decayed by either path, and after long times the effect of the 24.8-minute half-life of Te^{131} will be negligible.

Thus the approximate decay scheme is now



and the corresponding expression for the activity of I^{131}, obtained as outlined above:

$$\lambda_c N_c(T,t) = N\sigma_a f\left[\frac{\lambda_b\lambda_c}{(\lambda_b-\lambda_a)(\lambda_c-\lambda_a)}(1-e^{-\lambda_a T})\,e^{-\lambda_a t}+\frac{\lambda_a\lambda_c}{(\lambda_a-\lambda_b)(\lambda_c-\lambda_b)}(1-e^{-\lambda_b T})\,e^{-\lambda_b t}\right.$$
$$\left.+\frac{\lambda_a\lambda_b}{(\lambda_a-\lambda_c)(\lambda_b-\lambda_c)}(1-e^{-\lambda_c T})\,e^{-\lambda_c t}\right]$$
$$+N\sigma_b f\left[\frac{\lambda_c}{\lambda_c-\lambda_b}(1-e^{-\lambda_b T})\,e^{-\lambda_b t}+\frac{\lambda_b}{\lambda_b-\lambda_c}(1-e^{-\lambda_c T})\,e^{-\lambda_c t}\right]$$
$$+N\sigma_d f\left[\frac{\lambda_c}{\lambda_c-\lambda_d}(1-e^{-\lambda_d T})\,e^{-\lambda_d t}+\frac{\lambda_d}{\lambda_d-\lambda_c}(1-e^{-\lambda_c T})\,e^{-\lambda_c t}\right]$$
$$+N\sigma_c f(1-e^{-\lambda_c T})\,e^{-\lambda_c t}.$$

For each bombarding energy, this expression was used to obtain three equations relating σ_a, σ_b, σ_c, and σ_d by insertion of the decay-constant values for the 131 chain the irradiation time T, the measured values of N and f, and also the three measured

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

iodine disintegration rates corresponding to the three separation times. A unique solution for the value of σ_c was not obtainable, but an approximate value was obtained by a further series of simplifications.

First, from the data from two samples separated several hours and 3 days respectively after end of bombardment, the values of $\sigma_a+\sigma_b+\sigma_c+\sigma_d$ and of σ_d alone were calculated under the assumptions:

$$\begin{aligned}&\text{(i)} \quad \sigma_d = \sigma_a+\sigma_b+\sigma_c;\\ &\text{(ii)} \quad \sigma_d = 4\sigma_b;\ \sigma_a = 0;\\ &\text{(iii)} \quad \sigma_d = 4\sigma_b;\ \sigma_a = \sigma_b;\\ &\text{(iv)} \quad \sigma_a = \sigma_b = 4\sigma_b.\end{aligned}$$

The value of σ_d was assumed to be about four times that of σ_b, as was found by Glendenin (9) in the thermal fission of U^{235}. The value of $\sigma_a+\sigma_b+\sigma_c+\sigma_d$ was found to be unchanged from one assumption to another to within 5% and the value of σ_d to within somewhat smaller limits.

By means of an average of the values calculated, an upper limit on σ_b was now calculated under the extreme assumption that $\sigma_a = \sigma_c = 0$, and an upper limit on σ_c, under the assumption that $\sigma_a = \sigma_b = 0$. Calculations were also made for σ_b and σ_c under the intermediate assumptions $\sigma_a = \sigma_b = \sigma_c$ and $\sigma_a = 0$, $\sigma_b = \sigma_c$. From these results mean values were obtained for σ_b and σ_c together with some indication of the magnitude of the associated uncertainty. The uncertainty in the I^{131} formation cross section (σ_c) and in that for Te^{131} ($\sigma_b+\sigma_d$) from this source was far greater than the uncertainties arising from other sources in the experimental technique.

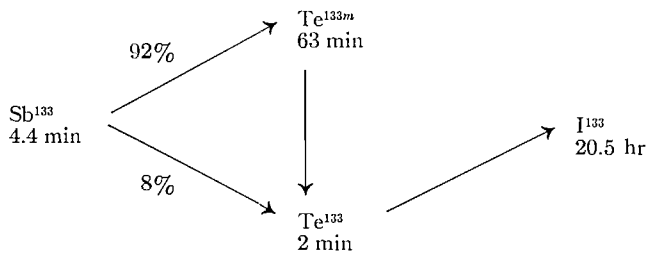
A = 132.—The decay scheme is as follows:

$$\underset{2\text{ min}}{Sb^{132}} \longrightarrow \underset{77.7\text{ hr}}{Te^{132}} \longrightarrow \underset{2.26\text{ hr}}{I^{132}}$$

In the present experiment, the time between the end of the irradiation and the first iodine separation was long compared with the Sb^{132} half-life. Consequently only a cumulative cross section for Te^{132} was obtained, together with an independent formation cross section for I^{132}. The appropriate activitity–time expression is

$$\begin{aligned}\lambda_b N_b(T,t) = N\sigma_a f\left[\frac{\lambda_b}{\lambda_b-\lambda_a}(1-e^{-\lambda_a T})\,e^{-\lambda_a t}+\frac{\lambda_a}{\lambda_a-\lambda_b}(1-e^{-\lambda_b T})\,e^{-\lambda_b t}\right]\\ +N\sigma_b f(1-e^{-\lambda_b T})\,e^{-\lambda_b t}.\end{aligned}$$

A = 133.—The 133 chain decay scheme is as follows (20):



Again, the time of 20 minutes between end of bombardment and the first iodine separation made it impossible to obtain independent yield information about I^{133} or about the Te^{133}

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

ground state. Consequently, only cumulative formation cross sections for I^{133} were calculated, using disintegration rate data from samples separated 3 days after the end of bombardment and the expression given above under $A = 130$.

A = 134.—From the decay scheme

$$Sb^{134} \longrightarrow Te^{134} \longrightarrow I^{134}$$
$$0.8 \text{ min} \qquad 44.5 \text{ min} \qquad 52.4 \text{ min}$$

it is clear that the 20-minute separation time was in this case too long compared with the Sb^{134} half-life and indeed rather long compared with the Te^{134} half-life for the purposes of obtaining accurate independent yield data. However, the data from the 20-minute and 2–3-hour separations were analyzed using the activity–time expression given for the 132 chain, and independent formation cross sections calculated for I^{134}.

A = 135.—The precursors of I^{135} are not known and are presumably of very short half-life. Therefore, only a cumulative cross section for this isotope was obtained in this work, by means of the activity–time expression given above under $A = 130$.

RESULTS

The results of the analysis outlined above are presented in Figs. 4, 5, and 6 in the form of excitation functions, independent or cumulative formation cross sections being designated σ_{ind} or σ_{cum} respectively. Also on these figures are included, for comparison, excitation function data of Tewes and James (33) for the total proton-induced fission, with an ordinate scale as indicated to the right of the figure. The initial rise with energy of all the cross sections measured in this work is clearly associated with the corresponding rise in the total fission cross section. The decreasing cross sections at higher energies reflect the broadening and shift of the charge distribution, which will be demonstrated below.

The uncertainties associated with the cross-section data presented are estimated to

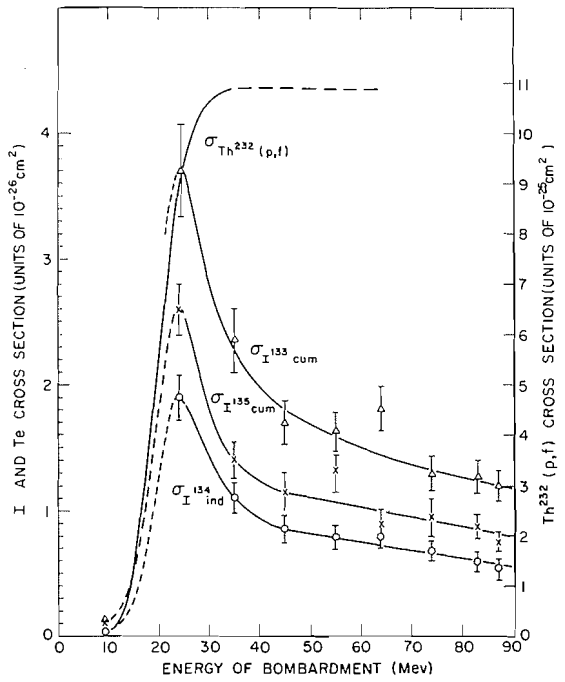

FIG. 6. Excitation functions for production of I^{133}, I^{134}, and I^{135} in Th^{232} (p,f) reaction.

be as follows: the exact proton energy at which the bombardment was made is uncertain due to energy spread in the cyclotron beam and to uncertainties in the calculated value of the energy loss in the target itself (2). Nevertheless, the beam energy was probably known to 2–5 Mev. The uncertainty in the cross-section values results from uncertainties in the original disintegration rate measurements (<1%), in the graphical decay curve analysis and associated extrapolations (5–10%), and from sources described earlier in the treatment of the activity data. The over-all uncertainty is thought to be 15–20%.

The cross-section data were converted into charge distribution curves for five bombarding energies by means of the mass yield data available in the literature and the total Th^{232} (p,f) cross-section data of Tewes and James (33) and of Steiner and Jungerman (32). The product of the fission yield for a given mass A and the total fission cross section gives the cumulative formation cross section for mass A. The division of the independent formation cross section for a given isobar of mass A by this cumulative formation cross section then gives that fraction of the mass chain formed directly as the particular isobar. These fractional values for the various iodine and tellurium nuclides were correlated in a plot versus the nuclide's displacement from stability along the isobaric chain. The assumptions implicit in such a correlation are that the distribution of yields along a chain is the same for chains of different mass, and that the displacement from stability of the charge value at which the highest yield occurs is independent of chain mass. Both assumptions are probably reasonable over the narrow region of mass (130–135) studied.

Tewes' and James' data (33) for the proton-induced fission of Th^{232} at energies of 8.0 and 21.1 Mev were used in conjunction with our data at 8 and 24 Mev, the mass yield data at 8 Mev being further checked by interpolation between the data of Wahl (34) on the 0-Mev (thermal) and 14-Mev neutron-induced fission of U^{235}. In the treatment of data in this paper at energies of 45 Mev and above, we have assumed that over the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

mass range 130–135 the total chain yield was independent of mass number and energy at a value close to that indicated by Newton (18). Consideration of his results and of mass yield data at much higher energy (19) indicates that this assumption is probably not in error over the present energy range by more than $\pm 10\%$.

The error introduced by using mass yield data from projectile target systems other than the Th^{232} + proton system is probably small. The mass range studied in this work includes nuclides on the heavy peak of the fission yield curve, the position and height of which changes little with changing target mass number and like parameters.

The charge distribution curves for 8-, 24-, 45-, 64-, and 87-Mev proton energies are shown in Fig. 7, in which the fraction of the chain yield is plotted as ordinate against $Z_A - Z$ as abscissa, where Z_A is the Z-value corresponding to the minimum potential energy (maximum beta stability) for a given A (21). In this plot neutron-excess nuclides lie to the right of the figure and neutron-deficient ones to the left. The location of the Gaussian distribution plotted in each case was determined so that the area under it summed to unit total chain yield, and also so that the independent yields of Te^{132}, I^{133}, and I^{135} and their precursors, as obtained from the curve, summed to a value for the corresponding cumulative yields close to that measured experimentally. This latter is a sensitive criterion for location of the curve, and renders it much more certain than is at first apparent.

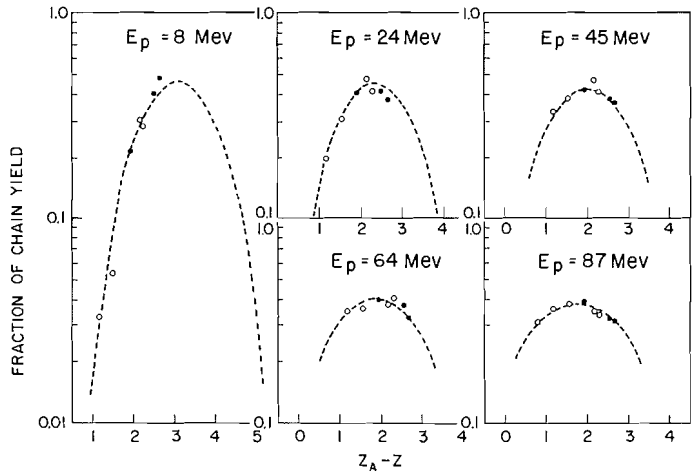

FIG. 7. Charge distribution curves in the Th^{232} (p,f) reaction at proton energies between 8 and 87 Mev.

The five charge distributions are shown assembled on Fig. 8, together with the curve of Glendenin (7) and Pappas (21) for thermal fission of U^{235}, of Wahl (34) for 14-Mev fission of U^{235}, of Aagaard *et al.* (1) for the 170-Mev proton-induced fission of uranium, and of Lavrukhina and Krasavina (16) for the 480-Mev proton-induced fission of uranium. The yield data of Aagaard *et al.* have been converted to a charge distribution in the manner outlined above, and those of Lavrukhina and Krasavina have been renormalized to give a distribution summing to unit chain yield. The position of the 170-Mev curve on the ordinate scale below the other curves is due to the fact that Aagaard *et al.* fitted their data to a wider distribution than those used by the other authors. The position of their curve on the abscissa scale in relation to the others presented, which is of more significance, is not affected by the normalization to unit chain yield.

In Table II the displacement of the maximum of the charge distribution from stability and the "half-width" of the distribution are tabulated with bombarding energy.

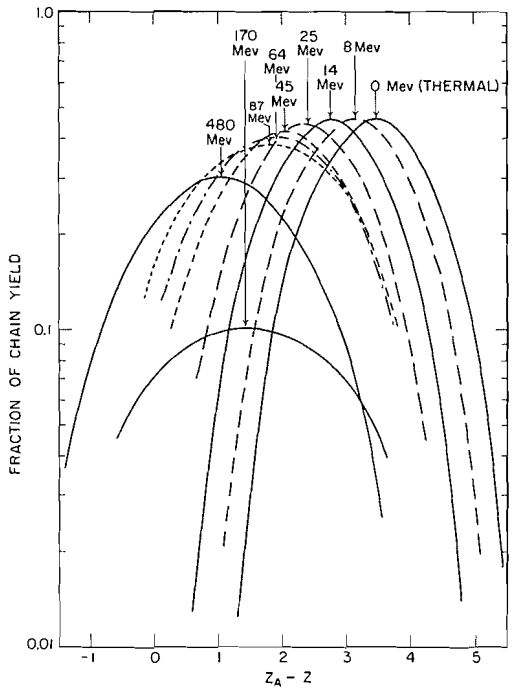

FIG. 8. Assembled charge distribution curves for thorium and uranium fission between 0 and 480 Mev bombarding energy.

DISCUSSION

The data in Table II show two effects. With increasing energy of bombarding particle, the charge distribution is observed to move towards stability, rapidly at first and then more slowly at higher energies. Secondly, while the width of the distribution remains approximately constant up to 25 Mev, at higher energies it shows evidence of increasing with increasing energies.

These effects may be rationalized in terms of a two-step model for nuclear reactions. In this model the projectile undergoes an initial rapid ($\sim 10^{-21}$ second) interaction with the target nucleus. The interaction will be predominantly the formation of a compound nucleus (3) for energies up to approximately 50 Mev. As the energy is raised above 50 Mev interaction with individual nucleons (12, 29) associated with prompt ejection of some nucleons becomes increasingly important. After this initial stage has terminated, the excitation energy deposited is dissipated in a second slower stage, largely by a particle-emission process described as nuclear evaporation, with which fission competes in heavy nuclei.

The shift of the charge distribution with increasing energy, which corresponds to a decrease in neutron/proton ratio of the fission products studied, is then interpreted as reflecting a decrease in the n/p ratio for the nuclide undergoing fission. This will be caused by increasing particle evaporation (predominantly neutron emission at moderate energies with heavy targets) prior to fission. Alternatively, the decrease in the n/p ratio of the fission products may, to some extent, be due to neutron evaporation after fission.

TABLE II

DISPLACEMENT OF CHARGE DISTRIBUTION MAXIMUM AND HALF-WIDTH OF DISTRIBUTION AS A FUNCTION OF BOMBARDING ENERGY

Bombarding energy (Mev)	Displacement of distribution maximum (units of Z)	Half-width of distribution (units of Z)
0	3.4	2.2
8	3.1	2.2
14	2.7	2.2
25	2.4	2.2
45	2.0	2.5
64	1.9	2.8
87	1.8	3.2
170	1.4	—
480	1.0	3.0

An increased width of charge distribution at higher energies is expected from the same picture, since a proliferation of both nuclear cascade and nucleon evaporation would lead to a wider distribution of fissioning nuclei and hence wider distribution of n/p values in the fission products.

Detailed interpretation in terms of calculations based on models of the nuclear cascade and nucleon evaporation processes will be presented in the succeeding paper.

FISSION OF EXCITED HEAVY NUCLEI[1,2]

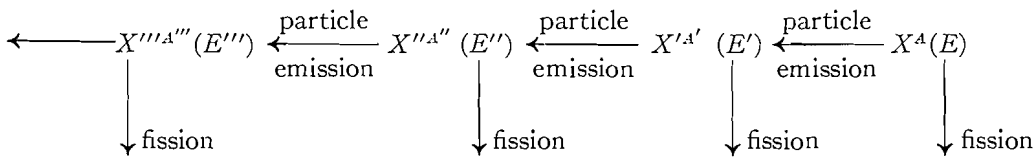
B. D. PATE

ABSTRACT

The results of published calculations on the prompt nuclear cascade and nuclear evaporation processes are combined with some assumptions regarding the nuclear fission process and fission widths to calculate the average neutron-to-proton ratios of fission products from Th + 8-Mev protons, Th + 87-Mev protons, and U + 450-Mev protons. Comparison of the results with experimental data indicates that the fission charge distribution mode characterized by the equal charge displacement hypothesis, hitherto considered a low energy phenomenon, persists in uranium and thorium up to the highest energy studied. There is also some evidence that fission occurs in excited heavy nuclei before complete de-excitation by particle emission, in agreement with other experimental work.

A. INTRODUCTION

Particle evaporation (30) and fission predominate during the de-excitation of heavy nuclei excited to energies above a few million electron volts. These two processes are expected to compete at each step during the de-excitation in the sense of the following scheme (25):



in which a nucleus of mass A excited to energy E evaporates particles to form successively nuclei of masses A', A'', etc. and energies E', E'' . . . with fission as an alternative to each particle evaporation step. The decrease in excitation energy per step, E–E', E'–E'', etc., equals the binding energy of the particle evaporated plus, in each case, the (variable) kinetic energy it carries off. The fragments from the fission of a nucleus of a given excitation energy E will themselves share in some way an excitation energy close to E, and may de-excite by further particle emission.

The relative probability that a nucleus in a given energy state de-excites via a specific reaction path is commonly described in terms of a partial "width" of the state for that reaction. Thus the competition between fission and particle emission from a given nucleus at a given energy may be expressed as a ratio Γ_f/Γ_{evap}, where Γ_f is the fission width and Γ_{evap} is a sum of particle emission widths

$$\Gamma_{evap} = \Gamma_n+\Gamma_p+\Gamma_d+\Gamma_t+\Gamma_\alpha+ \ldots \quad .$$

The ratio is expected to be a function of nuclear charge, mass, and excitation energy.

Fission-evaporation competition has been the subject of a number of previous studies, among the more recent being investigations with transuranium nuclei excited to energies up to 40 Mev (27, 28), and with thorium bombarded with protons of energies up to 100 Mev (3).

Interpretation of the experimental data is complicated by several factors aside from the complexity of a reaction scheme such as that illustrated above, for example, post-fission evaporation of nucleons from the fragments. Also a study of fission products gives only averaged information for the fission of the series of nuclei of different charge, mass, and excitation energy in the de-excitation chain.

Furthermore, as the bombarding energy is raised, the character of the initial nuclear interaction, which produces the excited nuclei whose de-excitation is to be studied, also changes. In addition to compound nucleus formation (2), characterized by the formation of a single nuclear type excited to a unique energy, reactions proceeding via direct interaction with individual nucleons (23) are observed. In some circumstances, the latter process occurs to a significant extent at energies as low as 14 Mev (14). It becomes more important with increasing energy and predominates above about 50 Mev.

Since such single nucleon reactions between target and projectile occur with the transfer of a variable amount of energy, generally less than the maximum available, and result in the prompt emission of a variable number of nucleons, de-excitation cascades such as that illustrated above begin from a range of nuclear charges, masses, and excitation energies.

Some previous attempts (1, 24) to interpret experimental data, making various assumptions regarding variation of Γ_f/Γ_{evap} with A, Z, and E, have suffered from lack of information regarding the nature of the prompt part of the nuclear interaction. The present work has the benefit of the results of detailed calculations which have been made both of the prompt initial nuclear interaction (17, 18) and of the evaporation process as it would occur in the absence of fission competition (5). It also differs from many previous studies in that it employs data on the nuclear charge distribution of fission products. The particular data used are those reported in the previous paper (20) for thorium irradiated with protons of 8- and 87-Mev energy, and those of Lavrukhina and Krasavina (15) for uranium with 480-Mev protons.

The following approach is used in the calculations. The distribution in nuclear charge, mass, and excitation energy at the end of the prompt interaction are obtained by assuming compound nucleus formation where appropriate, and elsewhere from the Monte Carlo calculations of Metropolis *et al.* (17, 18). These calculations, while being of the same general type and employing the same crude nuclear model (degenerate Fermi gas in a sharply defined nuclear potential) as previous calculations (10), nevertheless benefit from a three-dimensional relativistic treatment and good statistics. Their results are in reasonably good agreement with experiment (17, 18) and appear to be fairly reliable when used for the present purposes.

Next the Monte Carlo calculations of Dostrovsky *et al.* (5) are used to compute the course of evaporation cascades from each point in the A, Z, and E distribution at the end of the prompt cascade. These evaporation calculations have been made using the LeCouteur formalism (16) and do not take fission competition into account. The effect of the choice of input parameters for these calculations on the results obtained has not yet been completely investigated, and the results of the present analysis are uncertain to that extent. Parts (i) and (ii) of the calculations that follow (energies 8 and 87 Mev) are expected to be the least uncertain, since the nature of the evaporation reaction in heavy elements at excitation energies below 100 Mev (almost exclusively neutron emission) and the average de-excitation per particle emitted are not very sensitive to the choice of nuclear model and parameters that may reasonably be made. The same is not true for higher energies, and Part (iii) of the analysis, employing the results of

evaporation calculations for excitations of up to 480 Mev, has been made with those results obtained with a choice of parameters that seemed to lead to the best agreement with other experimental data. The parameters include a coulomb barrier independent of excitation energy with barrier penetration introduced in a manner similar to that used by LeCouteur (16), and a nuclear energy level density given by

$$w = C\, e^{2(0.1A\times E)^{\frac{1}{2}}},$$

where A is the mass number and C is a constant. The results of Part (iii) should be considered in the light of this uncertainty in the evaporation reaction calculations.

Fission competition has been introduced in the present analysis by means of three assumptions:

(1) $\Gamma_f/(\Gamma_f+\Gamma_{evap})$ increases sharply from zero to unity as the Z^2/A ratio is raised through some critical value. This step-functional behavior is illustrated in Fig. 1*a*, and it may be compared with the previously reported experimental results shown in Fig. 1*b* where the solid line is taken from the data of Seaborg (1) and the broken line from those of Huizenga (13).

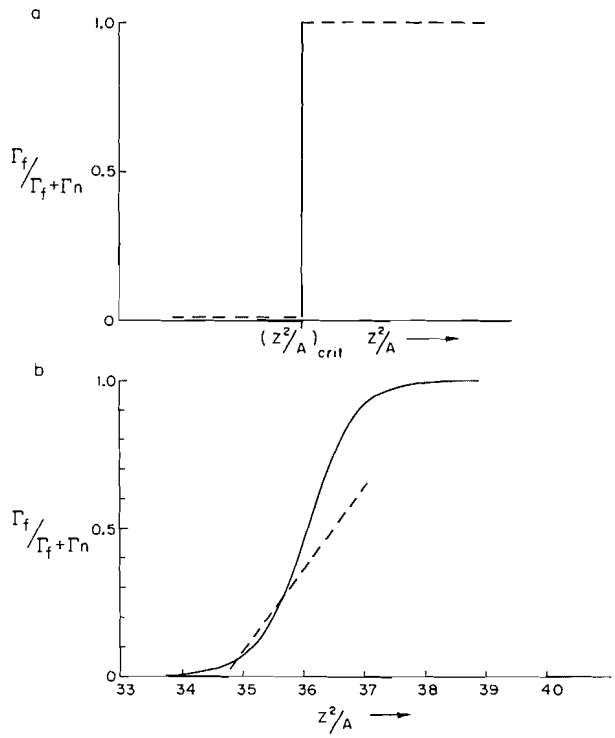

FIG. 1. Variation with Z^2/A of ratio of fission width to sum of fission and neutron widths for heavy elements. (*a*) Variation assumed in present calculations. (*b*) Experimental data (solid line from ref. (1), broken line from ref. (13)).

(2) Excitation energy of a fissioning nucleus is not (or is only to a small extent) transformed into kinetic energy of the fission fragments, or into electromagnetic radiation, but goes into excitation of the fragments (6) being divided between them in the ratio of their masses.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

(3) On the average, 2.5 "fission" neutrons are emitted regardless of energy or fission mode. There is no information regarding the variation of the average number of fission neutrons ($\bar{\nu}$) with excitation energies above a few million electron volts, other than that given by Harding and Farey (11), who interpreted their experimental data for uranium bombarded with 147-Mev protons in terms of a $\bar{\nu}$ value of 2.5 ± 1.0. Further there exist few data on the variation of $\bar{\nu}$ with nuclear type (and then only for thermal energy or spontaneous fission (4, 12)) and there is no information regarding the variation of $\bar{\nu}$ with charge division mode. Thus the assumption of the constancy of $\bar{\nu}$ under all conditions seems the most reasonable working assumption that can be made at present. It should be noted that a change in $\bar{\nu}$ of unity would produce a change in fission product neutron-to-proton ratio of about 0.01 (see later).

In the calculations that follow, the results of the variation of several parameters will be investigated. These parameters include the critical Z^2/A value at which the sharp increase in the $\Gamma_f/(\Gamma_f+\Gamma_n)$ function occurs, the energy dependence of $\Gamma_f/(\Gamma_f+\Gamma_n)$ (assumed to be one of two limiting forms) and the mode of distribution of nuclear charge in fission. Experimental evidence has been cited in the literature for two charge distribution processes, namely the equal charge displacement (ECD) process (7, 8, 19) and the unchanged charge distribution (UCD) process (9). The former, observed to account well for independent yield data for the products from the fission of U^{235} at thermal energies and at 14 Mev (29), is based on the postulate that the most probable nuclear charges of complementary fragments will be equally displaced from the charge value corresponding to stability for their respective masses. That is to say

$$Z_p = Z_A - \tfrac{1}{2}[Z_A + Z_{(A_f - \bar{\nu} - A)} - Z_f],$$

where Z_p is the most probable charge for a fragment of mass A, Z_A is the stable charge for mass A, A_f and Z_f are the mass and charge of the fissioning nucleus, and $\bar{\nu}$ as before is the average number of prompt fission neutrons. This process implies a rearrangement of nucleons prior to or during the fission act, and is commonly assumed to be a low-energy process. The unchanged-charge-distribution mode of fission (first postulated by Goeckermann and Perlman (9) to occur in the fission of bismuth with 190-Mev deuterons) produces fragments whose most probable neutron-to-proton ratio is the same as that of the fissioning nucleus. This implies that the nucleonic rearrangement indicated in ECD-type fission does not take place, and UCD is considered characteristic of "fast" or "high-energy" fission (9).

Comparison between the predicted and observed neutron-to-proton ratios of primary fission products will then be made in order to determine which of the various choices of parameters best fits the data.

B. CALCULATIONS AND RESULTS

The n/p ratios resulting from calculations based on the assumptions described above are compared with the observed most probable n/p ratio for fission products in the mass range 130–135 as reported (20) for the systems

(i) Th^{232} + 8.0-Mev protons,
(ii) Th^{232} + 87-Mev protons,

and for fission products of masses 90 and 130 as reported (15) for

(iii) U^{238} + 480-Mev protons.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

(*i*) Th^{232} + *8.0-Mev Protons*

The assumption of compound nucleus formation in this case is probably a good one. Consequently we must consider the de-excitation of Pa^{233} with an excitation energy

$$E^* = E_{\text{kinetic}} + E_{\text{proton binding}}$$
$$= 13.6 \text{ Mev},$$

since the proton-binding energy in Pa^{233} is 5.6 Mev (22). Thus we have the reaction scheme shown in Fig. 2; only neutron emission is considered for the evaporation reaction, since coulomb barrier effects render charged particle emission highly unlikely. The neutron-binding energies in Pa^{233} and Pa^{232} are 6.6 and 4.2 Mev (22) respectively so that formation of Pa^{231} is energetically possible. However, the evaporation calculations indicate that, in this region of charge, mass, and energy, the most probable de-excitation via neutron evaporation is greater than 9 Mev. Consequently the reaction would seldom proceed past Pa^{232}.

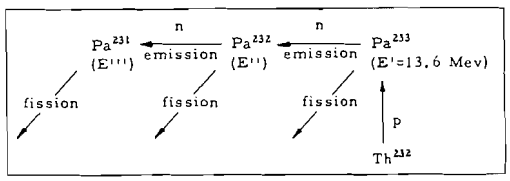

FIG. 2. De-excitation of Pa^{233} excited to 13.6 Mev.

Table I shows the n/p ratio calculated for both the ECD and the UCD mechanisms for the system of Fig. 2. The fission of Pa^{233} excited to 13.6 Mev is considered to lead to fission fragments sharing an excitation energy of about the same magnitude (see assumption (2)). Thus there is a significant probability for the evaporation of a neutron from each of the fission fragments, since the average neutron-binding energy in the iodine isotopes of mass 130–135 is about 7.4 Mev (22). This would reduce the n/p ratio calculated via ECD to 1.560 and via UCD to 1.514.

TABLE I

CALCULATED AND EXPERIMENTAL AVERAGE NEUTRON TO PROTON RATIOS FOR FRAGMENTS OF MASS 130–135 FROM THE FISSION OF Th^{232} WITH 8-MEV PROTONS

Fissioning nucleus	n/p Calculated via ECD	n/p Calculated via UCD	n/p observed
Pa^{233}	1.579	1.533	
Pa^{232}	1.570	1.522	1.566±0.004
Pa^{231}	1.560	1.511	

The experimental data in the preceding paper give a n/p ratio of 1.566±0.004. Thus they appear to be consistent with the fission of Pa^{232} via an ECD mechanism, perhaps with some contribution from ECD-type fission of Pa^{231} and Pa^{233}, and to be inconsistent with UCD-type fission.

(*ii*) Th^{232} + *87-Mev Protons*

The experimental data for this system will be compared with an analysis starting with the results of prompt cascade calculations for 83-Mev protons incident upon

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

U^{238}. (The difference in energy is neglected and the difference in target characteristics is taken into account by introduction of appropriate shifts in charges and masses of the reaction products.)

Figure 3 is a section of the chart of nuclides (Z plotted versus N) with the course of the reactions indicated on it. Immediately below the symbol and mass number for each nuclide are given its n/p and Z^2/A ratios. The Th^{232} target nucleus is enclosed by double lines, and the distribution of products from the prompt interaction (17) is given by the numbers (relative frequencies) in square boxes. The total number of cascades followed in the prompt interaction calculation was 1258 (in addition to those in which nuclear transparency was indicated). In addition to the number distribution given for each nuclide the excitation energy spectrum is available from the calculations (17). This is generally a continuous distribution except in the case of Pa^{233}, which is the compound nucleus product and is therefore excited to a unique energy.

The evaporation calculations (5) for heavy nuclei excited to 75 Mev indicate that 99.7% of the evaporated particles are neutrons. Consequently charged particle evaporation will be neglected. Also the average de-excitation per evaporated neutron is 9.2 Mev; the value shows no systematic trend with nuclear excitation in this energy region. Consequently a further simplification will be made, namely that all neutrons carry off exactly this energy. The evaporation reaction proceeds as indicated by the horizontal lines in Fig. 3, and leads to the final nuclide distribution shown by the unboxed numbers. (With the simplification used, the de-excitation of Pa^{233} leads to emission of $9\frac{1}{2}$ neutrons so that the 520 events are divided equally between Pa^{223} and Pa^{224}. Similar adjustments are made elsewhere as required.)

The incorporation of fission competition in the calculations must now be considered. The approximations made thus far would seem to make an analysis as sophisticated as that by Batzel (1) or Vandenbosch *et al.* (28) of doubtful value. Instead we shall examine two situations.

(1) The dependence of Γ_f/Γ_n on energy is greater than the dependence on nuclear type (specifically on the fissionability parameter Z^2/A). That is, increasing energy favors neutron emission sufficiently so that fission does not take place until the excitation energy is reduced below the neutron-binding energy at the end of the evaporation cascade.

(2) Γ_f/Γ_n is essentially independent of energy, but varies sharply with Z^2/A as described earlier and illustrated in Fig. 1*a*.

Again, both ECD- and UCD-type fission are to be considered, the n/p ratio resulting from the fission of each nuclide via the two mechanisms being calculated. The values are then weighted using the number distributions indicated for situations (1) and (2) above and averaged to give the mean n/p ratio expected for fission products of mass 130–135 in each case. The variation of total fission chain yield with mass number over the energy range and mass range considered is small enough to be neglected in the averaging.

The results of the calculation are compared with the experimental data in Table II. In Part 2 of Table II, the average n/p ratios calculated for fission fragments of mass 130–135 are listed both for the fragments initially formed by the fission act, still excited, and for these fragments after de-excitation by neutron emission. The average number of neutrons emitted was obtained by using average neutron-binding energy values appropriate to iodine nuclides in the indicated mass range (22) plus an estimated most probable

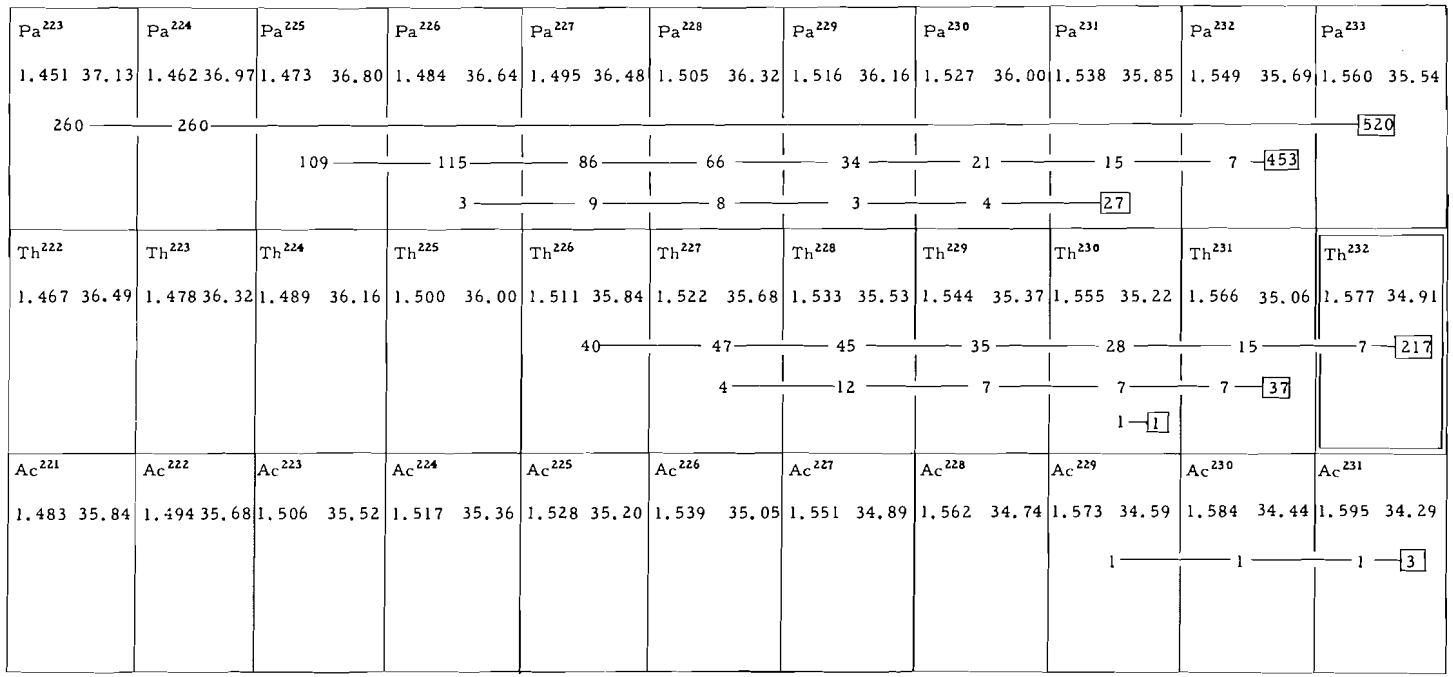

FIG. 3. Prompt cascade and evaporation reactions in thorium bombarded with 83-Mev protons.

neutron kinetic energy. In Part 1 fission is considered to take place in de-excited nuclei only, so that the fission fragments are considered to have excitation energies less than the neutron-binding energy.

TABLE II

CALCULATED AND EXPERIMENTAL AVERAGE n/p RATIOS FOR THE PRODUCTS OF THE FISSION OF Th^{232} WITH 87-MEV PROTONS—MASS NO. 130–135

1. Fission occurs after de-excitation by neutron emission in nuclides with greater than given Z^2/A value

Z^2/A greater than	ECD-type fission	UCD-type fission
37	1.478	1.423
36.6	1.491	1.435
36.3	1.497	1.441
36.0	1.499	1.445
35.5	1.506	1.450
35.0	1.511	1.458
34.5	1.512	1.459

Experimental value 1.502

2. Fission occurs at given Z^2/A value before complete de-excitation

	ECD-type fission		UCD-type fission	
Z^2/A	n/p ratio of initial fission fragments	n/p ratio of fragments after de-excitation	n/p ratio of initial fission fragments	n/p ratio of fragments after de-excitation
37.0	1.478	1.478	1.423	1.423
36.6	1.510	1.491	1.456	1.445
36.3	1.519	1.481	1.478	1.456
36.0	1.547	1.499	1.500	1.478
35.5	1.569	1.506	1.525	1.488
35.0	1.574	1.512	1.529	1.493
34.5	1.577	1.513	1.531	1.494

Experimental value 1.502

It is seen that the experimental n/p ratio is consistent with that calculated with the assumption that ECD-type fission occurs either during or at the end of de-excitation, in nuclides with Z^2/A values greater than 36.0. The n/p ratios calculated for UCD-type fission under various conditions are all inconsistent with the experimental value.

This conclusion is consistent with two other data. First, a Z^2/A value of 36.0 corresponds to a Γ_f/Γ_n value of nearly unity (1, 13), i.e. fission and neutron emission are roughly equally probable. Hence, that critical Z^2/A value of the step function assumed for $\Gamma_f/(\Gamma_f+\Gamma_n)$ which gives results most consistent with experiment, corresponds roughly to the mid-point of the $\Gamma_f/(\Gamma_f+\Gamma_n)$ functions reported previously which were based on other experimental evidence.

Second, we may calculate the cross section for the Th^{232} (p,f) reaction to be expected on the basis of the assumption that all nuclides of Z^2/A greater than 36.0 undergo fission. The total number of prompt interaction events followed in the Monte Carlo calculation (17) was 1336, of which 978 were found to give nuclides which were presumed to undergo fission. The geometric cross section for Th^{232} is 2.0×10^{-24} cm^2 for a nuclear radius parameter, $r_0 = 1.3\times10^{-13}$ cm. The fission cross section is then expected to equal

$$\sigma_f = \pi r^2 \times (978/1336)$$
$$= 1.4\times10^{-24} \text{ cm}^2$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

the value at 80 Mev is expected to be 1.1×10^{-24} cm^2 by extrapolation from published values at lower energies (26).

One further comparison with experiment may be made—namely the charge distribution for fragments of mass 130–135 may be calculated and compared with the charge distribution obtained from the mass distribution observed experimentally (20) for iodine isotopes. The calculation was made under the assumption that the charge distribution resulting from the fission of a single nuclide in this energy range is the same as that observed from the fission of U^{235} with thermal and with 14-Mev neutrons, with Z_p calculated via the ECD mechanism. The charge distribution resulting from the fission of a range of nuclides is then the sum of the separate distributions weighted by the number distribution for the fissioning nuclides (i.e. those of Z^2/A greater than 36.0) deduced from the above analysis. The calculated and observed distributions are shown in Fig. 4.

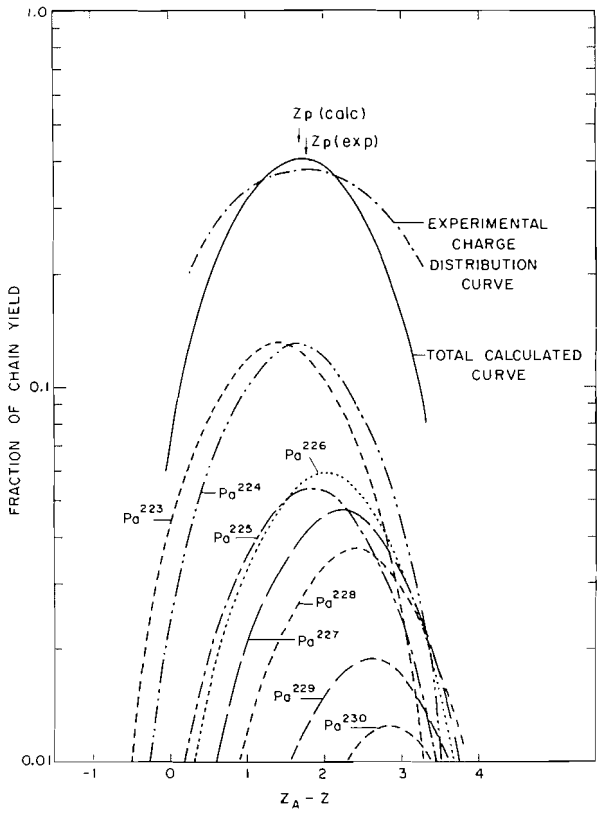

FIG. 4. Experimental and calculated fission product charge distributions in fission of Th^{232} induced by 83-Mev protons.

It is seen that the experimental distribution is wider than that calculated (although the Z_p values agree). This presumably reflects among other things the effect of one simplification made in this part of the analysis, namely that neutron-emission results in the loss of a constant amount of energy. Incorporation of a more realistic distribution of neutron-emission energies would presumably lead to a wider number distribution of fissioning nuclei, and hence a wider charge distribution.

(iii) U^{238} + *480-Mev Protons*

The experimental data for this system will be compared with the results of an analysis starting with the prompt cascade calculations for 450-Mev protons incident on U^{238} (18). Figure 5 shows again the Z versus N plot with the target nucleus enclosed in heavy lines. The frequency distribution from the prompt cascades is shown underlined in the top right-hand corner of each square.

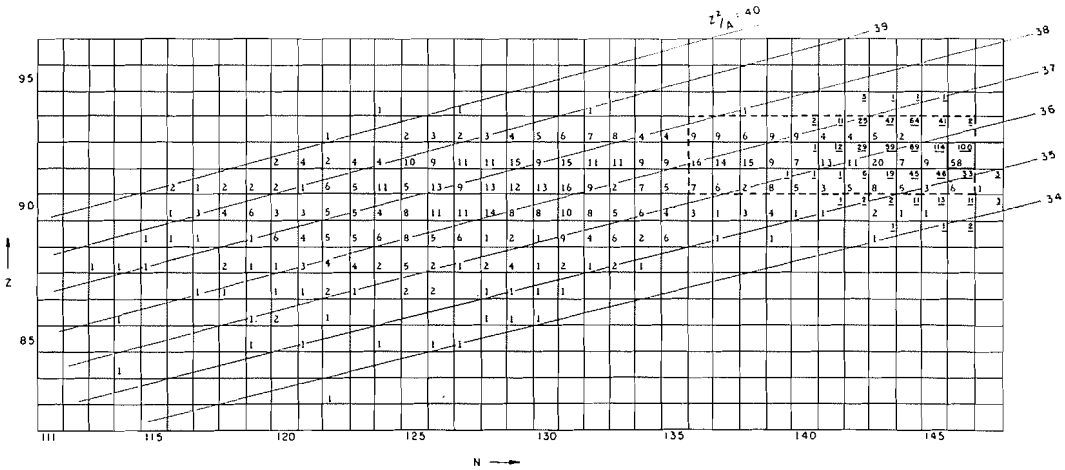

FIG. 5. Prompt cascade and evaporation reactions in uranium bombarded with 450-Mev protons.

At the excitation energies obtained in this system, charged particle emission from the product nuclei during the evaporation process is common, and no useful simplification in the treatment of that part of the reaction can be made. Consequently, from the evaporation–reaction calculations individual cascades have been chosen in which the initial A, Z, and E values match as closely as possible those for the products of individual prompt interaction cascades. These evaporation cascades have been used to specify the end product and intermediate products of the de-excitation process. The number of evaporation cascades that have been calculated is such that close matching is not difficult, and the sequence in which the data have been used is such as to ensure a random choice from among the prompt interaction and evaporation cascade data employed. The resulting number distribution of de-excited end products is shown in Fig. 5 in the bottom left-hand corner of each square. The region covered by Fig. 2 is shown enclosed in a dotted line to emphasize the much greater extent of particle emission induced at the higher bombarding energy. Also on Fig. 5 are shown lines connecting nuclides of equal Z^2/A value.

Additional information which may be obtained includes the number of de-excitation cascades which results in the transient formation of each nuclide and the spectrum of excitation energies with which it is formed.

Fission competition may now be introduced under the assumptions outlined earlier. The analysis is simplified by the general observation that the early part of a de-excitation cascade, when the excitation is highest, is characterized by emission of protons, neutrons, and alpha particles in such proportions that the evaporation "path" proceeds parallel to or towards the nuclear stability line. In the later, low-energy part of the cascade, however, coulomb effects predominate and neutron emission is favored. Consequently the Z^2/A value of nuclides successively formed in the de-excitation process generally decreases at first and then increases again, in a fairly smooth manner. Thus selection

For personal use only.

of events producing nuclides of a given Z^2/A (particularly at the higher Z^2/A values) does not introduce serious error owing to the fact that a given event may be counted more than once.

Owing to the wide range of mass numbers produced, the variation of yield of fission fragments of a given mass with mass number can no longer be neglected. As an approximation, during the averaging of the product n/p ratios, weighting for mass yield will be accomplished using the over-all mass-yield curve given by Lavrukhina and Krasavina (15) in addition to weighting by the number distribution. The error made by use of the over-all mass-yield distribution rather than the distribution appropriate to fission of a single nucleus is probably small, since the effect of weighting for mass yield is in any case quite small.

In Part 2 of the analysis, in which fission is considered to take place from excited nuclei, it is again assumed that the total excitation of the system is unchanged during the fission process, and that, on the average, it divides among the products in the ratio of their masses. This division reduces the excitation energy per fragment in general to below 150 Mev, in which region the calculations of Dostrovsky *et al.* (5) predict a predominance of neutron emission. The de-excitation of the fission fragments is then presumed to take place in this manner with an energy loss per neutron evaporation of about 11 Mev, an average figure for this energy and mass region.

The results of the analysis are shown in Table III, with n/p ratios given for fission fragments of mass about 90 and about 130, calculated under the various parameter choices.

TABLE III

CALCULATED AVERAGE n/p RATIOS FOR THE PRODUCTS OF THE FISSION OF U^{238} WITH 450-MEV PROTONS

1. Fission occurs after de-excitation by particle evaporation in nuclides with greater than a given Z^2/A value

Z^2/A greater than	ECD-type fission		UCD-type fission	
	$A = 90$	$A = 130$	$A = 90$	$A = 130$
40	1.200	1.330	1.261	1.262
39	1.233	1.361	1.301	1.302
38	1.253	1.385	1.333	1.336

Experimental values:	Mass 90 ~ 1.36							
	Mass 130 ~ 1.44–1.46							

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

The most probable n/p ratios observed by Lavrukhina and Krasavina (15) are as follows: for mass 90, about 1.36; and for mass 130, 1.44 to 1.46 depending on which of the presentations of the data one uses. The agreement of the calculations with these figures is good for ECD-type fission and poor for UCD-type fission, being the best for the assumption that fission occurs before complete de-excitation and when a Z^2/A value between 35 and 36 is reached. However, a decision between the assumptions of Parts (1) and (2) of the analysis cannot be made as definitely as one between the two fission modes.

The value of Z^2/A found for best fit with experiment is close to that found in Part (ii) and is satisfactory for the same reasons.

If one calculates the fission cross section expected from the above results, in the same way as described in Section (ii), one obtains the value of 1.32 barns compared with an experimental value of 1.12 barns (15).

C. DISCUSSION

Within its limitations, the analysis described above leads to the conclusion that fission of nuclides with Z in the range 87–93 with excitation energies up to a few hundred Mev proceeds predominantly via a process described by the equal-charge displacement mechanism. There is also some indication (from Part (iii)) that fission of these nuclides begins to compete effectively with particle emission when the Z^2/A value is greater than about 36, in a fashion independent of energy. This last conclusion is generally in agreement with conclusions drawn from lower energy studies (1, 28), and in disagreement with the results of an analysis by Shamov (24).

The indication of an equal charge displacement mechanism in the fission of uranium and thorium with protons of energy up to 480 Mev, which is in disagreement with some previously published conclusions (15, 28), is at first surprising, since ECD has hitherto been considered a low-energy process. However, it may well be that ECD-type fission is characteristic of nuclides of specific charge and mass, rather than of specific energy. This is consistent with the observation by Porile and Sugarman (21) that ECD-type fission occurs when bismuth is bombarded with 450-Mev protons but that UCD-type fission occurs in tantalum bombarded with protons of the same energy.

D. ACKNOWLEDGMENTS

It is a pleasure to acknowledge the generosity of N. Metropolis *et al.* in making available to the author the material of references (17) and (18) prior to publication, and of I. Dostrovsky and G. Friedlander in providing access to the data of reference (5) prior to publication. The author is also very grateful to his colleagues in the Brookhaven National Laboratory Chemistry Department and to L. Yaffe for a number of stimulating discussions and for criticisms of the manuscript. The technical assistance of Mrs. E. McIver and Mrs. P. Payne with much of the tedious analysis is also gratefully acknowledged.

THE PREPARATION OF SOME DERIVATIVES OF D-RIBONO-1→4-LACTONE AND D-RIBITOL[1]

L. HOUGH,[2] J. K. N. JONES, AND D. L. MITCHELL[2]

ABSTRACT

Reaction of D-ribono-1→4-lactone with acetone gave the 2,3-*O*-isopropylidene derivative from which 5-*O*-methyl-D-ribitol, 5-deoxy-D-ribitol, and 2,3-*O*-isopropylidene-D-ribitol were prepared.

INTRODUCTION

5-Deoxy and 5-*O*-substituted derivatives of D-ribitol were required and consequently attempts were made to prepare from D-ribono-1→4-lactone (I) the 2,3-*O*-isopropylidene intermediate (II) for specific substitution of the primary alcohol group (e.g. methylation, tosylation), followed by reduction of the lactone function and finally hydrolysis of the ketal. D-Ribono-1→4-lactone (I) readily condensed with acetone, the reaction being catalyzed by concentrated and dilute mineral acid or anhydrous copper sulphate, although it also underwent condensation with acetone, without any added catalyst, because of the favored *cis*-configuration of the hydroxyls at carbons 2 and 3. The formation of the *O*-isopropylidene derivative was accompanied by a significant change in optical rotation which fell from an initial value of $[\alpha]_D$ 43° to an approximate value of $[\alpha]_D$ −80°. The rate and extent of the condensation reaction was dependent upon the catalyst selected and in particular on the concentration of the mineral acid. Hydrolysis of the lactone derivative (II) in water proceeded slowly in a manner typical of a 1→4 lactone, but the presence of an *O*-isopropylidene ring superimposed on the lactone ring may make this evidence unreliable. The position of the ketal ring was located by reaction of the sodium *O*-isopropylidene-D-ribonate (III), obtained by mild alkaline hydrolysis of the lactone derivative (II), with sodium metaperiodate which resulted in the consumption of 1.03 moles of oxidant and the formation of 1.02 moles of formaldehyde. The *O*-isopropylidene group must therefore be situated at carbons 2 and 3. This was confirmed by methylation of the 2,3-*O*-isopropylidene-D-ribonolactone (II), followed by mild acid hydrolysis of the mono-*O*-methyl derivative (IV) to produce in good yield 5-*O*-methyl-D-ribono-1→4-lactone (V); this compound was identical with the lactone obtained by the alkaline-bromine oxidation of 5-*O*-methyl-D-ribose (1). The methylation evidence is thus compatible with the presence of a 1→4 lactone ring in the *O*-isopropylidene derivative (II). The possibility that the change in optical rotation prior to or during ketal formation was due to a ring shift from a 1→5- to the 1→4-lactone was considered. However, the original D-ribonolactone slowly hydrolyzed in water at room temperature [$[\alpha]_D$ 17.8° (initial) → $[\alpha]_D$ 8° (13 days)], a property characteristic of 1→4-lactones (2) and the magnitude of the values recorded by Rehorst for L-ribono-1→4-lactone is similar (3). 2,3-*O*-Isopropylidene-D-ribono-1→4-lactone and D-ribonolactone possessed an infrared absorption maximum at 1790 cm^{-1} and 1793 cm^{-1} respectively, which is consistent with the 1→4-lactone structure (cf. reference 3 (*a*)). The stabilizing effect of the exocyclic double bond, thus making carbon 1 trigonal, must be a considerable influence in this case because the *cis*-hydroxyls at carbons 2 and 3 would be expected to create steric pressure as a result of the close proximity of these groups on a five-membered ring.

Recent studies on the periodate oxidation of monosaccharides at pH 3.6 have revealed that they are oxidized almost completely in their ring forms with the formation of esters (formyl, glycollyl, and glyoxylyl) of glyceraldehyde and glycollaldehyde, further oxidation being dependent upon the rate of hydrolysis of the ester intermediates (4, 5). Similar oxidations of 1→4- and 1→5-pentonolactones would be expected to give rise to glyoxylic acid esters of glyceraldehyde (XI) and glycollaldehyde respectively. However, the former ester should be distinguished by a fairly rapid overoxidation reaction because the electrophilic hydroxyl group (from carbon 5) neighboring the ester linkage would facilitate its hydrolysis. In accord with this theory D-ribono-1→4-lactone and its 5-*O*-methyl derivative each consumed approximately one mole of periodate rapidly, which was followed by a slower but extensive oxidation, typical of 2-*O*-esters of glyceraldehyde to the approximate theoretical values (Fig. 1). Lactobiono-1→5-lactone behaved similarly after the initial rapid reaction with 3 moles of periodate (Fig. 1). The similarity between the oxidation curves of D-ribonolactone and 5-*O*-methyl-D-ribono-1→4-lactone would suggest that the former compound was indeed oxidized as a 1→4-lactone and it therefore seems likely that the change in optical rotation during acetonation cannot be ascribed to a ring shift (1→5- to 1→4-lactone), but must actually be related to the formation of the ketal ring.

1→4-Lactones are believed to be planar or nearly planar, but some degree of ring buckling might arise in the pentono- and hexono-lactones if the molecule possesses a bulky group at carbon 5 and substituents at carbons 2 and 3 in the true *cis*-configuration (XII) (cf. reference 5 (*a*)). Deviations from planarity have been observed in the D-ribofuranosyl ring system of crystalline adenosine (6) by X-ray analysis, but 1→4-lactol and 1→4-lactone ring systems are not precisely comparable. A shift in molecular rotation which should measure approximately the extent of ring buckling has been observed for 2,3-di-*O*-methyl-D-ribono-1→4-lactone and 2,3,5-tri-*O*-methyl-D-ribono-1→4-lactone (Table I). Such an effect is probably responsible for the large molecular rotational shift in the formation of 2,3-*O*-isopropylidene-D-ribono-1→4-lactone, although buckling of the lactone ring will result in a distortion of the *O*-isopropylidene ring which will then be asymmetric (cf. D-galactose and its 1,2-3,4-di-*O*-isopropylidene derivative). Asymmetrical *O*-isopropylidene rings have been suggested as being one of the factors responsible for molecular rotational shifts between methyl *O*-isopropylidene pyranosides and the corresponding methyl pyranosides (7). The substitution of a methoxyl group for the hydroxyl group at carbon 5 of various D-ribono-1→4-lactone derivatives results in a molecular rotational shift (in the positive direction) of approximately the same magnitude for each pair (Table I).

Tosylation of 2,3-*O*-isopropylidene-D-ribono-1→4-lactone (II) at a low temperature (*ca.* −20° C; 10 hours) produced the 5-*O*-tosyl derivative (VII) in quantitative yield.

TABLE I

ROTATIONS OF DERIVATIVES OF D-RIBONO-1→4-LACTONE IN WATER

	$[\alpha]_D$	M_D	Difference	Reference
D-Ribono-1→4-lactone	17.8	2636	+1809	(*)
5-*O*-Methyl-lactone	27.4	4445		(1)
2,3-Di-*O*-methyl-lactone	−31.5	−5538	+1754	(8)
2,3,5-Tri-*O*-methyl-lactone	−19	−3784		(9)
2,3-*O*-Isopropylidene-lactone	−57.5	−10820	+1900	(*)
2,3-*O*-Isopropylidene-5-*O*-methyl-lactone	−44.1	−8920		(*)

*Present paper.

When higher reaction temperatures and longer reaction periods were employed, lower yields and tarry products were often obtained. A simultaneous reduction of the lactone function to the primary alcohol and reductive cleavage of the tosyloxy group was effected in good yield by lithium aluminum hydride in tetrahydrofuran to give 2,3-*O*-isopropylidene-5-deoxy-D-ribitol (VIII). Hydrolysis of the product with cation exchange resin (H form) afforded 5-deoxy-D-ribitol (IX). Similarly, 5-*O*-methyl-D-ribono-1→4-lactone (V) and 2,3-*O*-isopropylidene-D-ribono-1→4-lactone (II) were reduced with lithium aluminum hydride to syrupy 5-*O*-methyl-D-ribitol (VI) and syrupy 2,3-*O*-isopropylidene-D-ribitol (X) respectively. The structures were verified by periodate oxidation experiments (Table III).

2,3-*O*-Isopropylidene-D-ribitol compounds are of interest because D-erythro hydroxyls are involved in the formation of a five-membered ketal ring of the αC-type (10, 11, 12) with bulky substituents in the *cis*-configuration at carbons 2 and 3. This unfavorable conformation (VIII′ and X′) would be expected to cause the ketal ring to be labile to acid, since deformation from the preferred zigzag conformation is considerable.

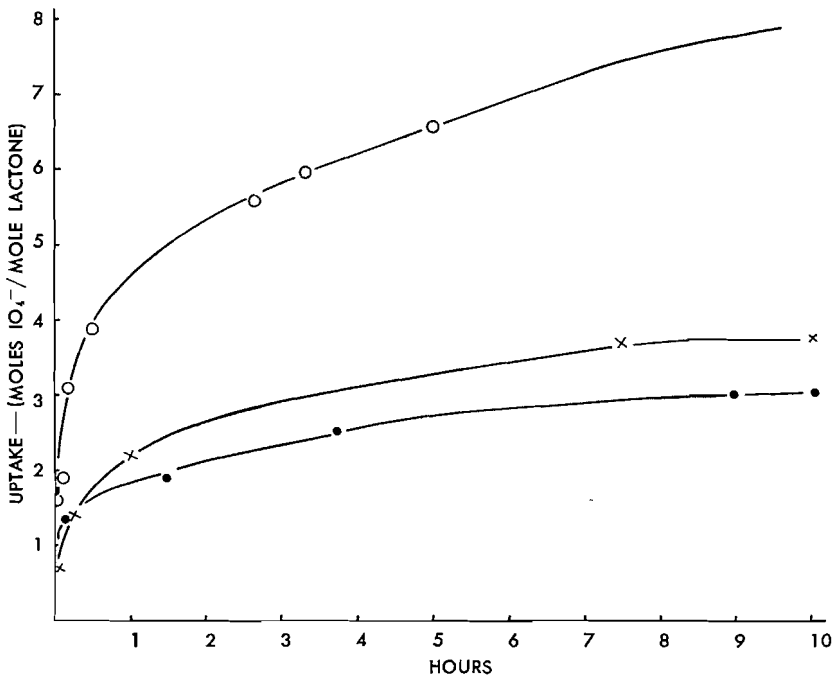

FIG. 1. Periodate oxidation of: —×— D-ribono-1→4-lactone (3.75–18.5 hours); —●— 5-*O*-methyl-D-ribono-1→4-lactone (3.05–21.0 hours); and —○— lactobiono-1→5-lactone (8.5–48 hours) (8.55–75 hours) at pH 3.7.

EXPERIMENTAL

Solutions were concentrated under reduced pressure (*ca.* 15 mm). Melting points were uncorrected and optical rotations were determined in water unless otherwise stated. Paper chromatography was carried out by the descending method (13) on Whatman No. 1 filter paper using the following solvent systems (v:v): (*a*) ethyl acetate – acetic acid – water (9:2:2); (*b*) ethyl acetate – acetic acid – formic acid – water (18:3:1:4); (*c*) butan-1-ol–ethanol–water (40:11:19); and (*d*) butan-1-ol–pyridine–water (10:3:3). Non-reducing compounds were detected on paper chromatograms with an alkaline

silver nitrate spray reagent (14). The rate of movement of the compound on paper chromatograms is quoted relative to that of the solvent front (R_f value). Wave numbers of infrared data are given to within ± 10 cm^{-1}.

*2,3-O-Isopropylidene-*D*-ribono-1→4-lactone*

(Assisted by R. J. Stoodley.) A solution of D-ribono-1→4-lactone (15 g) in acetone (600 ml) containing concentrated hydrochloric acid (6 ml) was shaken continuously for 18 hours at 25° C. The initial positive rotation decreased rapidly to reach a constant negative value (Table II). A control solution of D-ribono-1→4-lactone in dioxane and concentrated hydrochloric acid (2 drops) showed a relatively small change in optical rotation (Table II).

The solution was neutralized (silver or lead carbonate) and the inorganic salts were separated by filtration through a pad of cellulose. The combined filtrate and washings deposited crystals when concentrated. After trituration with cold acetone – light petroleum (b.p. 60–80° C), the crystals (14.0 g; 73.5%) were collected on a suction filter. They had a melting point of 138–139° C, $[\alpha]_D^{25°}$ −57.5° (initial value; *c*, 2.3) → −16.1° (20 days) and $[\alpha]_D^{24°}$ −65.7° (*c*, 2.13, pyridine; unchanged after 80 hours). ν_{max} 1790 cm^{-1} (chloroform; $C = 0$ for 1→4-lactone (15, 16)). D-Ribono-1→4-lactone gave an adsorption peak at 1793 cm^{-1} (nujol). Recrystallization from acetone–cyclohexane did not affect these constants. Anal. Calc. for $C_8H_{12}O_5$: C, 51.1; H, 6.4. Found: C, 51.4; H, 6.4.

When the condensation was catalyzed by 2 *N* hydrochloric acid (1% v:v), the rotation decreased less rapidly and reached a final rotation of $[\alpha]_D^{25°}$ −62.5° (30 hours).

A 5% solution of D-ribono-1→4-lactone in acetone revealed a polarimetric behavior similar to the acid-catalyzed reaction (Table II). After the optical rotation had reached a constant value, crystals of 2,3-*O*-isopropylidene-D-ribono-1→4-lactone were deposited, when the solution was concentrated.

TABLE II

OPTICAL ROTATION OF D-RIBONO-1→4-LACTONE IN VARIOUS SOLVENTS AT 25° C

Acidified acetone, c = 2.48	Hours:	0	0.33	0.5	2.8	3.8	15.8	18.3
	$[\alpha]_D$:	42.3°	−25°	−44.4°	−77.4°	−79°	−82.3°	−82.3°
Acidified dioxane, c = 2.5	Hours:	0	0.1	2.0	3.5	6.3	24.0	30.7
	$[\alpha]_D$:	52°	49.5°	48.5°	48°	46.8°	45°	43.6°
Water, c = 2.3	Hours:	0.25	23.0	42.5	66.2	90.5	138.5	322.8
	$[\alpha]_D$:	17.8°	17.4°	16.1°	14.8°	13.9°	11.7°	8.0°
Acetone, c = 5.0	Hours:	0.3	7	19	27	48	115	213
	$[\alpha]_D$ at 26° C:	39.8°	29.3°	7.4°	−3.9°	−24.2°	−48.7°	−65.2°

A solution of D-ribono-1→4-lactone (25 g) in acetone (500 ml) was heated under reflux in anhydrous conditions (calcium chloride tube). The optical rotation of the reaction mixture fell slowly, reaching a value of $[\alpha]_D^{25°}$ −8° after 92 hours. Anhydrous copper sulphate (5 g) was then added to the solution and the optical rotation fell to $[\alpha]_D^{25°}$ −77° (192.5 hours). The filtered solution was concentrated to a crystalline mass which was recrystallized from acetone – light petroleum (b.p. 60–80° C) to yield the *O*-isopropylidene derivative (21.5 g; 67%).

*2,3-O-Isopropylidene-5-O-methyl-*D*-ribono-1→4-lactone*

2,3-*O*-Isopropylidene-D-ribono-1→4-lactone (5.28 g) was treated three times with methyl iodide and active silver oxide (in the presence of anhydrous calcium sulphate), to aid solution chloroform was added to the first methylation. After filtration, the silver salts were thoroughly digested with chloroform. Concentration of the combined filtrates

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

yielded a pale yellow syrup (6.0 g) which was distilled at 90–100° C (bath temp.) and 10^{-5} mm to give the 5-*O*-methyl derivative [4.76 g; 84% with $n_D^{23°}$ 1.4490 at 90° C, $n_D^{23°}$ 1.4500 at 100° C, $[\alpha]_D^{27°}$ −56.8° (*c*, 3.0 ethanol), and $[\alpha]_D^{26°}$ −44.1° (*c*, 2.5)]. Anal. Calc. for $C_9H_{14}O_5$: C, 53.45; H, 7.0; OMe, 15.35. Found: C, 53.4; H, 7.5; OMe, 17.2.

5-O-Methyl-D-*ribono-1→4-lactone*

A mixture of a solution of 2,3-*O*-isopropylidene-5-*O*-methyl-D-ribono-1→4-lactone (4.5 g) in 40% aqueous acetone (100 ml) together with Amberlite resin IR-120 (H) (3 ml) was treated under reflux at 50° C. The initial specific rotation, $[\alpha]_D^{27°}$ −42.7°, rose to $[\alpha]_D^{27°}$ 9.5° (constant value; 60 hours). After it had been cooled, the solution was decanted from the resin, concentrated to a crystalline mass, and recrystallized from ethyl acetate to give 5-*O*-methyl-D-ribono-1→4-lactone (2.3 g; 63.5%) with m.p. 110–111° C, mixed m.p. 108.5–110° C, $[\alpha]_D^{25°}$ 26° (0.08 hours) → 19° (168 hours) (*c*, 0.94). R_f 0.71 (solvent *b*) and R_f 0.67 (solvent *d*). ν_{max} 1765 cm^{-1} (nujol) [lit. m.p. 109–110° C, $[\alpha]_D^{18°}$ 27.4° → 15.3° (7 hours; *c*, 9.0) (1)]. Anal.Calc. for $C_6H_{10}O_5$: C, 44.4; H, 6.2; OMe, 19.1. Found: C, 44.8; H, 6.2; OMe, 19.9.

5-O-Methyl-D-*ribitol*

A solution of 5-*O*-methyl-D-ribono-1→4-lactone (1.0 g) in anhydrous tetrahydrofuran (25 ml) was added dropwise to a suspension of lithium aluminum hydride (0.57 g) in tetrahydrofuran (25 ml). After the mixture had been heated under reflux for 4 hours, then cooled, ethyl acetate (2 ml) was added, followed by 70% aqueous alcohol (100 ml). The precipitate was separated by centrifugation and was washed twice with ethanol. The combined supernatants were percolated through Amberlite IR-120 (H) resin prior to concentration to a colorless syrup (0.78 g; 76%). Paper chromatographic examination of the compound revealed only a single spot with R_f 0.40 (solvent *b*), R_f 0.42 (solvent *d*), $[\alpha]_D^{25°}$ 10° (*c*, 1.0), and $n_D^{20°}$ 1.4802. Anal. Calc. for $C_6H_{14}O_5$: C, 43.4; H, 8.5; OMe, 18.7. Found: C, 43.5; H, 7.8; OMe, 20.6.

2,3-O-Isopropylidene-5-O-toluene-p-sulphonyl-D-*ribono-1→4-lactone*

2,3-*O*-Isopropylidene-D-ribono-1→4-lactone (1.13 g) was dissolved in cold (−20° C), anhydrous pyridine and toluene-*p*-sulphonyl chloride (2.38 g; 100% excess) was added in one portion. After the mixture had been kept for 10 hours at −20° C, with intermittent shaking, water (0.5 ml) was added and the solution was poured slowly into ice water (600 ml) with vigorous stirring. The crystals were collected by filtration and dried under reduced pressure at room temperature (2.07 g; 100%). Recrystallization from methanol gave prisms melting at 117.5–118° C and with $[\alpha]_D^{24°}$ −15.8° (*c*, 2.4 acetone). ν_{max} 1810 cm^{-1} (chloroform). Anal. Calc. for $C_{15}H_{18}O_7S$: C, 52.6; H, 5.3; S, 9.4. Found: C, 52.7; H, 5.3; S, 9.7.

2,3-O-Isopropylidene-5-deoxy-D-*ribitol*

To a suspension of lithium aluminum hydride (5.5 g) in anhydrous tetrahydrofuran (50 ml), a solution of 2,3-*O*-isopropylidene-5-*O*-toluene-*p*-sulphonyl-D-ribono-1→4-lactone (5.38 g) in tetrahydrofuran (50 ml) was added dropwise. The reaction mixture was heated under reflux for 5 hours, then ethyl acetate (20 ml) was slowly added dropwise, followed by 10% aqueous ethanol until the inorganic salts were precipitated. After filtration, the organic solvents were evaporated by repeated dilution with water and the product, obtained by continuous extraction with chloroform, was a syrup (2.38 g; 84%) with $n_D^{20°}$ 1.4510 and $[\alpha]_D^{27°}$ −15.5° (*c*, 2.7, ethanol). Anal. Calc. for $C_8H_{16}O_4$: C, 54.5; H, 9.15. Found: C, 52.9; H, 9.2.

5-Deoxy-D-ribitol

The above *O*-isopropylidene compound (2.09 g) was hydrolyzed with Amberlite IR-120 (H) resin under the conditions previously described for the preparation of 5-*O*-methyl-D-ribono-1→4-lactone. The product (1.51 g; 93%) crystallized spontaneously when the solution was concentrated to dryness. Recrystallization from ethyl acetate – methanol (5:1 v:v) gave 5-deoxy-D-ribitol with m.p. 77–80° C. The product contained solvent of crystallization which could be removed under reduced pressure to give a product melting at 65–69° C and $[\alpha]_D^{25°}$ −10.6° (*c*, 1.7). Anal. Calc. for $C_5H_{12}O_4$: C, 44.1; H, 8.9. Found: C, 44.1; H, 8.6.

2,3-O-Isopropylidene-D-ribitol

2,3-*O*-Isopropylidene-D-ribono-1→4-lactone (1.50 g) was treated with lithium aluminum hydride by the method described for the preparation of 5-*O*-methyl-D-ribitol, except the reaction period was extended to 8 hours and the ion exchange resin, Amberlite IR-120, was used in the ammonium form. The syrupy product (1.6 g) moved on paper chromatograms as a single spot (R_f 0.39; solvent *b*) and had $[\alpha]_D^{26°}$ −4.3° (*c*, 2.8, ethanol), $n_D^{20°}$ 1.4730. Anal. Calc. for $C_8H_{16}O_5$: C, 50.0; H, 8.4. Found: C, 49.2; H, 8.0.

D-*Ribitol* (*Adonitol*)

2,3-*O*-Isopropylidene-D-ribono-1→4-lactone (130 mg) was dissolved in ethanol (5 ml) and sodium borohydride (93 mg) was added in one portion. The solution was heated at 50° C for 5 hours and then kept at room temperature overnight. After acidification with acetic acid, the solution was passed down a column of Amberlite resin IR-120 (H) and the effluent was evaporated to dryness. After removal of acetic and boric acids by repeated co-distillations with methanol, the syrupy product was hydrolyzed with 0.01 *N* sulphuric acid (10 ml, 3 hours, 95° C). The cooled solution was neutralized (barium carbonate), then filtered, and the filtrate concentrated to a syrup. Examination of the product in solvent systems (*a*) and (*c*) revealed a single component which had a rate of movement identical with that of an authentic specimen of adonitol. The syrup readily crystallized on seeding with adonitol (ribitol).

When the reduction was carried out using water as the solvent under the conditions described above, the major product was an acid (paper chromatography) and only a small amount of adonitol was detected.

Periodate Oxidation Experiments

All reactions were carried out in the dark and at room temperature (*ca.* 18°).

(i) *Determination of the Reacted Periodate*

The lactone or pentitol derivative (10–15 mg; accurately weighed) was dissolved in water or the required buffer solution containing 0.3 *M* sodium metaperiodate solution (1 or 2 ml). The total volume was made up to 10 ml with additional buffer solution. A blank was run concurrently. Aliquot portions (2 ml) were withdrawn at intervals and pipetted into phosphate buffer (pH 7.0; 25 ml) containing 20% potassium iodide solution (1–3 ml), and the liberated iodine was titrated with 0.01 *N* sodium thiosulphate solution using starch solution as indicator (17).

In some cases the lactone was hydrolyzed to the aldonic acid (sodium salt) with a slight excess of 0.01 *N* sodium hydroxide solution prior to the addition of the sodium metaperiodate solution and sufficient water to bring the total volume to 20 ml. (Buffer solutions: pH 7.5, 0.05 *M* sodium bicarbonate solution; pH 3.7, 0.05 *M* acetic acid – sodium acetate solution.)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

(ii) *Estimation of the Formic Acid Produced*

Solutions containing *ca.* 5 mg of compound per milliliter of solution were oxidized with sodium metaperiodate solution under unbuffered conditions. At various intervals of time, ethylene glycol (1 ml) was added to aliquot portions (5 ml) and the acidic solution was titrated with 0.01 *N* sodium hydroxide solution using methyl red, screened with methylene blue as the indicator. A blank was run concurrently.

(iii) *Determination of the Formaldehyde Liberated*

Samples (2–4 mg; accurately weighed) were dissolved in water or buffer solution containing 0.3 *M* sodium metaperiodate solution (1 ml) and made up to 25 ml. At intervals, aliquot samples (1 ml) were withdrawn and the formaldehyde was estimated by the chromotropic acid method (18). A known weight of erythritol (periodate oxidized) was used as the source of formaldehyde for the preparation of the standard curve.

ACKNOWLEDGMENTS

The authors wish to thank Dr. G. R. Barker and Dr. D. C. C. Smith, of the University of Manchester, for a specimen of 5-*O*-methyl-D-ribono-1→4-lactone. They also wish to thank Mr. R. J. Stoodley for his assistance in the preparation of 2,3-*O*-isopropylidene-D-ribono-1→4-lactone, Messrs. B. S. Noyes and M. J. Graham for microanalyses, and Mr. M. C. B. Marshall for infrared absorption data. One of us (D.L.M.) thanks the Ontario Research Foundation for a grant which made this investigation possible.

THE REACTION OF 2,2-DIPHENYL-1-PICRYLHYDRAZYL WITH SECONDARY AMINES[1]

J. E. HAZELL[2] AND K. E. RUSSELL

ABSTRACT

The reaction of DPPH (2,2-diphenyl-1-picrylhydrazyl) with *N*-phenyl-1-naphthylamine, *N*-phenyl-2-naphthylamine, diphenylamine, and methylaniline has been studied and has been shown to be primarily a hydrogen abstraction process. Two moles DPPH react with 1–1.15 moles secondary amine to give 1.7–1.8 moles 2,2-diphenyl-1-picrylhydrazine and further products.

The reaction between DPPH and *N*-phenyl-1-naphthylamine is first order with respect to each reactant. The reaction of DPPH with the other amines is retarded by the major product 2,2-diphenyl-1-picrylhydrazine and the kinetics of the over-all reaction are complex. However second-order rate constants and activation energies have been obtained using initial rates of reaction. Possible reaction mechanisms are discussed.

This study of the reaction between 2,2-diphenyl-1-picrylhydrazyl (DPPH) and secondary amines forms part of a general investigation of the rates of hydrogen abstraction processes in solution using DPPH as the acceptor molecule. In spite of its existence as a stable free radical DPPH readily abstracts hydrogen atoms from mercaptans (1) and hydroaromatic compounds such as 1,4-dihydronaphthalene (2). A similar reactivity towards many secondary amines (3, 4), phenols, and hydrogen halides is observed. Rate studies on these reactions should give information concerning the influence of structure on the ease of hydrogen abstraction from the various donors.

As the acceptor molecule, DPPH has the advantage that it is a colored free radical which does not dimerize and its concentration can be estimated by its absorption in the visible region. However, it complexes with amines (3) and possibly with aromatic hydrocarbons (2) and such complexing may affect the kinetics of reaction. It may also be involved in steric effects which are not observed with small radicals.

In the present work the reactions between DPPH and certain secondary amines have been investigated with regard to stoichiometry and kinetics. It was hoped that the single hydrogen atom attached to nitrogen would be abstracted in the primary reaction. The secondary amines used were *N*-phenyl-1-naphthylamine, *N*-phenyl-2-naphthylamine, diphenylamine, and methylaniline. A few kinetic experiments were performed with di-*n*-propylamine.

EXPERIMENTAL

Materials

2,2-Diphenyl-1-picrylhydrazine and DPPH were prepared by the method of Goldschmidt and Renn (5). The hydrazyl crystals were heated to 75° *in vacuo* for 6 hours to break down a DPPH–chloroform complex.

Di-*n*-propylamine was distilled in a 20-plate column. Methylaniline was distilled under reduced pressure to give one sample. A second sample was obtained by conversion to the nitrosamine, followed by reduction with tin and hydrochloric acid and distillation. Diphenylamine was recrystallized from petroleum ether. The phenylnaphthylamines were recrystallized from 95% ethanol. The amines were stored in the dark.

[1]*Manuscript received in original form March 11, 1957, and, as revised, June 25, 1958.*
Contribution from the Department of Chemistry, Queen's University, Kingston, Ontario.
[2]*Milton Hersey Fellow 1955–56.*

Tetraphenylhydrazine was prepared by the oxidation of diphenylamine with lead dioxide (6). Diphenyldihydrophenazine was prepared by heating tetraphenylhydrazine in boiling toluene for 30 minutes (7); it was purified by dissolution in hot benzene and addition of 2 volumes of ethanol.

Alumina was deactivated by adding 500 g alumina to 20 cc water in a stoppered bottle.

Stoichiometry

Mixtures of DPPH and amine of varying ratio were made up in benzene, degassed, and heated to 55°. Reaction was virtually complete in less than an hour with the phenylnaphthylamines, but diphenylamine required some hours and methylaniline 2 days. If any significant amount of DPPH remained it gave a violet color to the solution. The results give an estimate of the number of moles DPPH reacting with 1 mole amine.

Benzene solutions of amine and DPPH, each at a known concentration (approximately 0.1 *M*), were heated to 55° until reaction was virtually complete, and were concentrated in an atmosphere of nitrogen. The products were separated on a column of deactivated alumina. Benzene was used as eluent.

The first fractions from the column contained the excess amine and part of the dehydrogenation products. The solvent was removed, and the amine was separated by careful treatment with small amounts of 95% ethanol in which the reaction products are almost insoluble; petroleum ether was used in the place of ethanol in the case of methylaniline. The phenylnaphthylamines and diphenylamine were identified by melting point and mixed melting point; methylaniline was identified by boiling point only. The excess amine was weighed in order to confirm the value of the DPPH to amine ratio determined colorimetrically.

The main fraction came down the column as a dark brown band. The solvent was removed from the eluate, the last traces of complexed benzene disappearing when the red solid was warmed *in vacuo*. The material was 1,1-diphenyl-2-picrylhydrazine, m.p. 170–171°, mixed m.p. 171–172°, and having an infrared spectrum identical with that of the pure hydrazine. It was weighed and the fraction of hydrazyl converted to hydrazine obtained. The infrared spectrum of the products in chloroform before separation on the column was compared with that of 1,1-diphenyl-2-picrylhydrazine at various concentrations. The results were consistent with the assumption that no hydrazine was produced or lost by reaction on the alumina column.

Further Products

In all cases a violet band of strongly adsorbed material appeared on the alumina column. It was removed by treating the alumina with ethanol. The yield was about 10% based on the amine reacting. The material was not identified, but a sample from the DPPH–diphenylamine reaction contained about 65% carbon suggesting that it was derived from the DPPH and was not simply a dehydrogenation product of the amine.

The first fractions from the column contained products derived from the dehydrogenated amine. The yields, based on the amine reacting, were 30%, 65%, 60%, and 40% respectively for methylaniline, diphenylamine, *N*-phenyl-1-naphthylamine, and *N*-phenyl-2-naphthylamine. In all cases some separation into bands occurred on the column, indicating the presence of more than one compound, but the separate fractions were impure judged by the wide temperature ranges over which they melted. A white solid, m.p. 128–132°, accounted for 40% of the amine reacting in the dehydrogenation of diphenylamine; the melting point was raised to 134–136° by admixture with tetra-

phenylhydrazine. Anal. Found: C, 86.37; H, 6.74. Calc. for $C_{24}H_{20}N_2$: C, 85.7; H, 6.00. Its infrared spectrum was almost identical with that of tetraphenylhydrazine; the absorption in the N–H stretching region was negligible, but weak bands below 1400 cm^{-1} indicate the possible presence of diphenyldihydrophenazine.

A yellow solid, m.p. 240–245°, accounted for 35% of the amine reacting in the dehydrogenation of *N*-phenyl-1-naphthylamine. Anal. Found: C, 87.4; H, 5.49. Calc. for $C_{32}H_{24}N_2$: C, 88.0; H, 5.54. Mol. wt. 480 (by Rast method). Oxidation of *N*-phenyl-1-naphthylamine with lead dioxide leads first to a red product and then to a yellow product, m.p. 266–268°, which gives the same analysis as the above solid. Infrared spectra of the two products are similar; a weak absorption at 3350 cm^{-1} is probably due to a minor impurity containing an N–H group. The yellow solid appears to be ultimately derived from two *N*-phenyl-1-naphthylamine molecules, but its structure is not known.

N-Phenyl-2-naphthylamine and methylaniline each gave a complex mixture of products. These were partially separated on the column but attempts to identify them were unsuccessful.

Kinetics

Reaction mixtures were prepared using measured amounts of benzene solutions of DPPH and amine. The reaction vessels were standard bore tubes of internal diameter 12 mm. The concentration of DPPH was followed by taking measurements of optical density with a Fisher electrophotometer. A 650 mμ filter was used because in this region the DPPH absorbs fairly strongly whereas the products of reaction absorb only weakly. The electrophotometer was adapted for constant temperature work by replacing the normal cell holder with a brass box with glass windows. Water from a Sargent thermostat was passed through the box by means of an Eastern Industries Circulating pump (Model B-1). Temperatures of 20°, 30°, 40°, and 50° were used and apart from the first 3 minutes of reaction the control was better than ±0.05°.

The experiments were normally performed in the presence of air. Experiments with degassed systems showed that oxygen had little or no effect on the initial rates of reaction. Degassing with the highly reactive phenylnaphthylamines was performed with the separate DPPH and amine solutions before they were mixed, so that the early stages of reaction could be observed.

For initial rate experiments, the amine concentrations used were in the range 1–5 $\times 10^{-4}$ *M* for the phenylnaphthylamines, 4–20$\times 10^{-4}$ *M* for diphenylamine, and 2–10$\times$ 10^{-3} *M* for methylaniline. The complete reactions were followed using concentrations some five times greater than these. The initial DPPH concentrations were in the range 6–30$\times 10^{-5}$ *M*.

No correction is required for the reaction of DPPH with the solvent, since experiments showed that the rate of this process is negligible at temperatures up to 50°.

RESULTS AND DISCUSSION

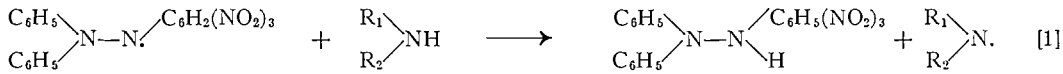
The results of the stoichiometric investigations are summarized in Table I.

The number of millimoles of amine reacting with 2 millimoles of DPPH was estimated (*a*) from experiments involving the disappearance of the violet color from reacting solutions, (*b*) from experiments involving the isolation of excess amine from solutions containing initially equimolar amounts of DPPH and amine. An uncertainty of up to 0.1 millimole arises in the first set of results because separate experiments have shown that some DPPH is removed by reaction with the products. The results of method (*b*) are maximum values, as the excess amine has probably not been completely isolated; 85–90% of the DPPH is recovered as 1,1-diphenyl-2-picrylhydrazine in each case.

The main process occurring is one of hydrogen abstraction by DPPH from the amine. In the case of diphenylamine the following evidence indicates that it is the amino hydrogen which is initially removed by the DPPH. Triphenylamine, a tertiary amine, does not react with DPPH at an appreciable rate. About 40% of the diphenylamine which reacts with DPPH is converted to tetraphenylhydrazine. Both lead dioxide and potassium permanganate oxidize diphenylamine to tetraphenylhydrazine showing that the amino hydrogen is most readily removed in related reactions. There is less definite evidence with the other amines. The yellow product from the *N*-phenyl-1-naphthylamine reaction shows only a weak N–H absorption in its infrared spectrum so that abstraction of the amino hydrogen certainly occurs in the reaction. Dimethylaniline reacts with DPPH at a very much lower rate than methylaniline. Whilst it is possible that attack by DPPH on a C–H bond does occur as a primary process in these reactions, attack on an N–H bond appears to be far more probable, and it is assumed here that it is the only important primary process.

The reactions are all retarded by the product 2,2-diphenyl-1-picrylhydrazine. Retardation is slight in the reaction of DPPH with *N*-phenyl-1-naphthylamine, but is quite considerable in other cases. For instance the addition of 2,2-diphenyl-1-picrylhydrazine at a concentration of 6×10^{-5} *M* to a solution containing *N*-phenyl-2-naphthylamine at a concentration of 5×10^{-4} *M* and DPPH at a concentration of 2×10^{-4} *M* reduces the initial rate of reaction by a factor of 3, and when the 2,2-diphenyl-1-picrylhydrazine concentration is increased to 15×10^{-5} *M* the rate is further reduced by a factor of 2. In order to obtain the rates of the unretarded reaction, the experimental results should be extrapolated back to zero reaction. However, the nature of the extrapolation is uncertain, and we have chosen to use as "initial rates" the rates of reaction after 3% reaction. These rates are close to the true values for *N*-phenyl-1-naphthylamine, but are less than the true values for the other amines.

The initial rate of reaction between DPPH and any of the amines is proportional to the concentration of DPPH and to the concentration of amine. This is readily understood if the primary process involves the attack of a molecule of DPPH on a molecule of amine, and this process is rate-determining in the initial stages of the reaction.



[1]

Rate constants (*k*) for this second-order reaction have been calculated from the rates of disappearance of DPPH, taking into account the stoichiometric results listed in Table I. The values of *k* at 20° have been recorded in Table II, together with activation energies (*E*) and frequency factors (*A*).

TABLE II

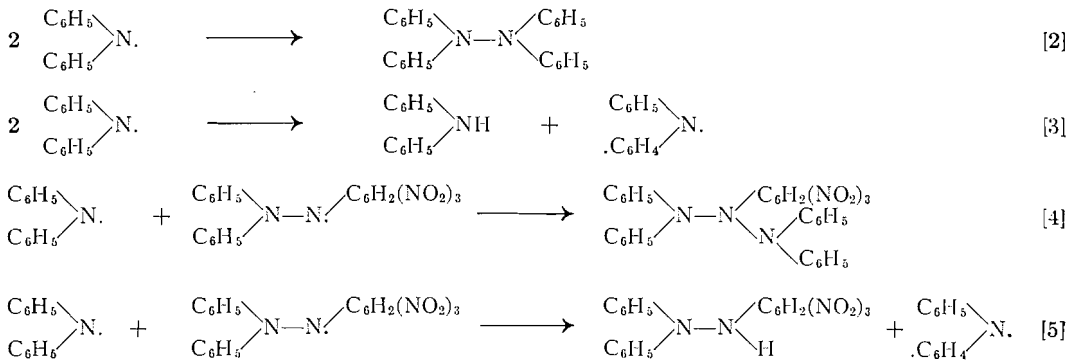
KINETIC RESULTS FOR THE REACTION OF DPPH WITH SECONDARY AMINES

Amine	k at 20° (cc/mole sec)	E (kcal/mole)	A (cc/mole sec)
N-Phenyl-1-naphthylamine	330	9.6	4.8×10^{9}
N-Phenyl-2-naphthylamine	580	11.0	1.1×10^{11}
Diphenylamine	53	12.8	2.3×10^{11}
Methylaniline	4.8	14.7	5.6×10^{11}

The value of E for the reaction with *N*-phenyl-1-naphthylamine is probably accurate to ±0.5 kcal/mole, but because of the difficulties associated with retardation by 2,2-diphenyl-1-picrylhydrazine, the other activation energies are not known to better than ±1 kcal/mole. The effect of structure on ease of abstraction of a hydrogen atom is clearly shown. The activation energies increase in going from the phenylnaphthylamines to methylaniline and this is associated with a considerable decrease in rate constant. Aliphatic amines are less reactive, the value of k at 20° for the reaction of DPPH with di-*n*-propylamine being approximately 0.2 cc/mole sec. The frequency factors are comparable to those obtained for reactions between DPPH and aliphatic mercaptans (1) and are of the same order as the frequency factors of hydrogen abstraction reactions involving methyl radicals (8). The relatively low value of the frequency factor for *N*-phenyl-1-naphthylamine is perhaps due to a steric effect.

The retardation of the reaction by the product 2,2-diphenyl-1-picrylhydrazine is explained by the reversal of reaction [1]; the concentration of amino radicals is reduced, and the over-all rate of reaction falls. The fall in rate can be adequately explained by the retarding effect of the diphenylpicrylhydrazine, and it is probable that complex formation between DPPH and amine, if it occurs, does not affect the kinetics of reaction.

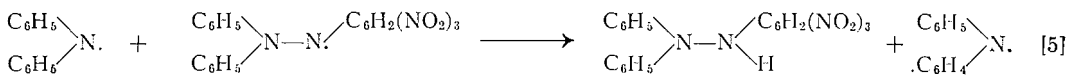
Little information has been obtained in this study concerning the further reactions of the amino radicals. In the DPPH–diphenylamine reaction the following processes may be considered, among others:



[2]

[3]

[4]



[5]

Reaction [2] occurs almost exclusively when diphenylamine is oxidized by lead dioxide at room temperature (6). It takes place to some extent in the dehydrogenation by DPPH as tetraphenylhydrazine accounts for about 40% of the products. It cannot occur exclusively, because this would require that 2 moles DPPH would react with 2 moles diphenylamine instead of the 1.2 moles diphenylamine observed experimentally. Reaction [3] involving the disproportionation of amino radicals probably occurs to some

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

extent at 55°, since tetraphenylhydrazine is slowly converted to diphenyldihydrophenazine in benzene solution at this temperature. Reaction [4] cannot be of great importance because 85–90% of the DPPH reacting is recovered as 2,2-diphenyl-1-picrylhydrazine. It is possible that the adduct is formed and then decomposes but infrared evidence indicates that such a decomposition does not take place on the alumina column. The disproportionation reaction [5] would help to explain the stoichiometric ratio of DPPH to diphenylamine observed experimentally. Attack at the ortho position may eventually lead to diphenyldihydrophenazine, but attack at the meta and para positions would give rise to more complex products. In the absence of a better knowledge of the dehydrogenation products further speculation on the secondary reactions does not appear to be warranted.

Two factors limit the accuracy of the kinetic results in Table II. In the first place, no allowance has been made for the possible primary attack of DPPH on C–H as well as on N–H bonds. Secondly, the retardation by 2,2-diphenyl-1-picrylhydrazine reduces the rate significantly with three of the amines even at 3% reaction, so that the rate constants quoted are less than the true values. Work in progress indicates that reactions involving phenols as donors are less subject to these limiting factors. It also shows that substituents in the aromatic ring may cause considerable changes in rates of dehydrogenation.

DISSOCIATION CONSTANTS OF THE CYANOHYDRINS OF SOME TRITERPENE KETONES[1]

OWEN H. WHEELER[2] AND V. S. GAIND[3]

ABSTRACT

The reactivity of a number of triterpene ketones towards cyanohydrin formation is influenced by groups present in rings remote from the keto group. The results are interpreted as evidence of "conformational transmission" of the effects of the substituents.

INTRODUCTION

Barton and co-workers (1) have recently shown that the rate of condensation of a number of triterpene ketones with benzaldehyde is influenced by substituents in other rings. The effect does not seem to be electronic and Barton has suggested (1, 2) that the substituents cause small changes in valency angles and in the co-ordinates of the atoms, producing small distortions throughout the whole molecule, and effecting the reactivity of some substituent in the rings. The term "conformational transmission" has been introduced (3) for this new effect produced by substituents.

Similar effects have recently been observed in the formation of cyanohydrins from ring A keto steroids (4), and in their rates of reduction with sodium borohydride (5).

In the present work we have measured the dissociation constants of the cyanohydrins (in 80% dioxane–water) of a number of triterpene ketones. Most of these ketones were also used in the study of benzylidene derivative formation (1). The compounds used fall into four groups: (*a*) lanostan-3-one (I), lanost-8-en-3-one (II) and α-onoceradienedione (III), which lack an 8-methyl substituent; (*b*) germanicone (IV) and allobetulone (V), which have different substituents in ring E; (*c*) β-amyrone (VI), oleanonic acid (VII) and dehydro-β-amyrone (VIII), which have differences in rings C and D; and (*d*) α-amyra-9,11(12)-dien-3-one (IX) and α-amyra-12-en-3,11-dione (X), which have another carbon skeleton. The differences in reactivity (Table II) vary over a range of 2.1, while the corresponding values for benzylidene formation (1) differ within a range of 2.2.

DISCUSSION

If the effect was electrostatic in origin, those substituents with a greater charge separation, such as an acid or ketone group, would be expected to show the largest differences. However, oleanonic acid (VII) and allobetulone (V) are only a little more reactive than lanostan-3-one (I), in which there can be no electrostatic interaction. Moreover, the α,β-unsaturated ketone system of α-amyra-12-en-3,11-dione (X) has a smaller effect than the diene system of α-amyra-9,11(12)-dien-3-one (IX). On the other hand if the effect is due to changes in the conformation of the rings then double bonds would have the largest effect, since a double bond placed in a cyclohexane ring changes all its valency angles (6). In support of this lanost-8-en-3-one (II), β-amyrone (V), and germanicone (IV) show large differences in reactivity as compared to lanostan-3-one (I), and the greatest differences are shown by the homoannular dienes dehydro-β-amyrone (VIII) and α-amyra-9,11(12)-dien-3-one (IX).

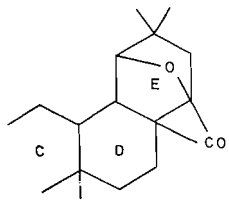
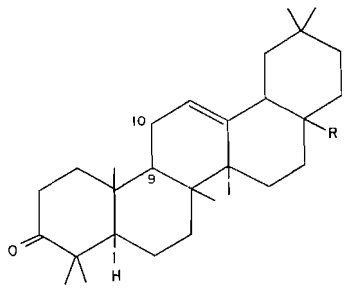
IV



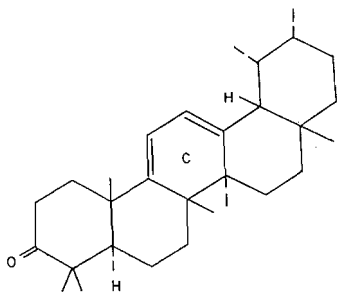
V



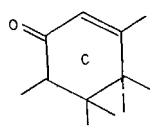
VI, R = Me

VII, R = CO_2H

VIII, $\Delta^{9(10)}$, R = Me



IX



X, ring C

In cyclohexanone the α and γ axial groups are 2.37 Å apart (6), whereas in cyclohexane they are 2.53 Å apart (6). Thus in the triterpene ketones any interaction between the 4 and 10 axial methyl groups is reduced on forming the cyanohydrin, and in agreement with this lanostan-3-one (I) cyanohydrin is more stable than that of cholestanone.

A double bond placed elsewhere within the rings would be expected to increase the distortion in ring A, by "conformational transmission", and to increase the 1–3 axial methyl interference in the ketones. Such an effect would favor cyanohydrin formation

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 190.90.36.8 on 09/04/12
For personal use only.

and the dissociation constants of the cyanohydrins of the unsaturated ketones are greater than those of the saturated ones. Moreover, those compounds having an axial methyl group at position 8, e.g. β-amyrone (VI), germanicone (IV), and dehydro-β-amyrone (VIII), form the more stable cyanohydrins. In these cases interaction between the 4, 10, and 8 axial methyl groups is possible.

The free-energy differences (calculated from $\Delta\Delta F = -RT \ln K_1/K$ at 25°) between the dissociation constant of the cyanohydrins of the various ketones are only small. Thus introducing a Δ^8 double bond (I and II) results in a difference of 0.11 kcal, in going from a double bond to a homoannular diene a difference of 0.17 kcal (VI and VIII), and changing a methyl group for a carboxylic acid grouping (VI and VII) a difference of 0.18 kcal. Changing the position of a double bond has little effect ($\Delta\Delta F = 0.05$ kcal for IV and VI).

The present results show a similar trend in the series of compounds studied as the results of Barton, Head, and May (1). However, the dissociation constant of the cyanohydrin of α-amyra-12-en-3,11-dione (X) shows a greater reactivity than expected. In this case the α,β-unsaturated ketone group may also have reacted with hydrogen cyanide (cf. cholest-4-en-3-one, ref. 4), and the measured dissociation constant may not be that of the 3-ketone cyanohydrin alone.

The experimental method was essentially that used in previous studies (4), but the equilibration time was increased to 20 to 25 hours. This will be more than sufficient, since Δ^8-lanosten-3-one reached equilibrium in some six hours (Table I).

*Initial concentrations, Δ^8-lanosten-3-one 0.00234 M, hydrogen cyanide, 0.00080 M, in 80% dioxane-water at 25.0°.

EXPERIMENTAL

Ketones

Many of the ketones were donated by Professor Barton.

Dehydro-β-amyrin was prepared by selenium dioxide oxidation of β-amyrin (7).

Lanost-8-en-3-one (II), β-amyrone (VI), and oleanonic acid (VII) were prepared by oxidation of the corresponding alcohols with chromium trioxide in pyridine (8).

Dissociation Constants

The triterpene ketones (25–30 mg) were dissolved in 80% aqueous dioxane (80 vol. purified dioxane + 20 vol. distilled water) (15 ml), and solutions of hydrogen cyanide (0.004 M, 5 ml) and 1% tri-*n*-propylamine (1 ml) in the 80% aqueous dioxane were added. The total volume was made up to 25 ml with the same solvent. The tightly stoppered flasks were allowed to equilibrate in a constant temperature bath, maintained at 25.0±0.1°, for 20–25 hours. Aliquots (5 ml) were then withdrawn and titrated with

NOTE ON THE INDUCTIVE AND MESOMERIC EFFECTS IN SUBSTITUTED BENZENE DERIVATIVES

C. SANDORFY

Inductive and mesomeric effects have become familiar terms with both organic and theoretical chemists since they were introduced by Ingold and others (1), and since the fundamental work of Wheland and Pauling (2). Among the numerous theoretical treatments we mention only those by Matsen (3, 4), who used an LCAO MO method combined with perturbation calculations, and by Murrell and Longuet-Higgins (5, 6), who used a simplified self-consistent field-molecular orbital method.

In 1949, the present author (7) published a series of diagrams of electronic charge distributions in monosubstituted benzene derivatives where, as in phenol or aniline, two electrons of the substituent can interact with the π-electrons of the benzene carbon atoms. The simple Hückel approximation of the LCAO MO method was used.

The extent of the mesomeric effect due to the addition of two more mobile electrons to the system depends in this approximation on the difference between the Coulombic integral, α_R, associated with the substituent, R, and α_C for a carbon atom. This difference is taken to be proportional to the corresponding difference in electronegativities or ionization potentials. The smaller these differences are, the easier it is for the electrons of the substituent to penetrate into the benzene ring orbitals.

The inductive effect is due to the fact that the presence of the substituent modifies the potential field in the benzene ring with the main result that the carbon linked to the substituent will have a somewhat increased electronegativity. This again may be represented by a supplement to its Coulombic integral, generally taken as a fraction of α_R.

It is interesting to see what would be the charge distribution if only the mesomeric or only the inductive effects are present. The purely mesomeric effect is obtained if we give an extra Coulombic integral to the substituent but none to the carbon linked to it. The purely inductive effect is obtained if we put the resonance integral between these two atoms, β, equal to zero and we give an extra Coulombic integral to the carbon atom linked to the substituent.

We have given $(\alpha_R - \alpha_C)$ the successive values of -2, -1, 0, 1, 2, and 3 in β units and to $(\alpha_{CR} - \alpha_C)$ one tenth of the respective values of the former difference. All the resonance integrals were taken to be the same, β (except of course the one necessary to compute the pure inductive effect).

In Fig. 1, the first row represents the pure mesomeric effect, the second row the pure inductive effect, and the third row the combined effect of the two. Electron charge densities (at the atoms) and bond orders (at the bonds) are as defined by Coulson and Longuet-Higgins (8). Overlap was neglected. The unit for the charges is the charge of an electron. Values greater than one represent partial negative charges, values smaller than one (or two for the substituent) partial positive charges. The second and third rows are taken from (7) and in the third row the last decimal is uncertain.

The diagrams in the third row having respectively $\alpha_R = 1$, 2, and 3 are probably fairly close to aniline, phenol, and fluorobenzene. $\alpha_R = -1$ would be close to phenylphosphine.

Figure 1 needs little comment. For positive values of α_R the mesomeric and inductive effects are opposed and practically additive. The positive charge on the substituent is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/04/12
For personal use only.

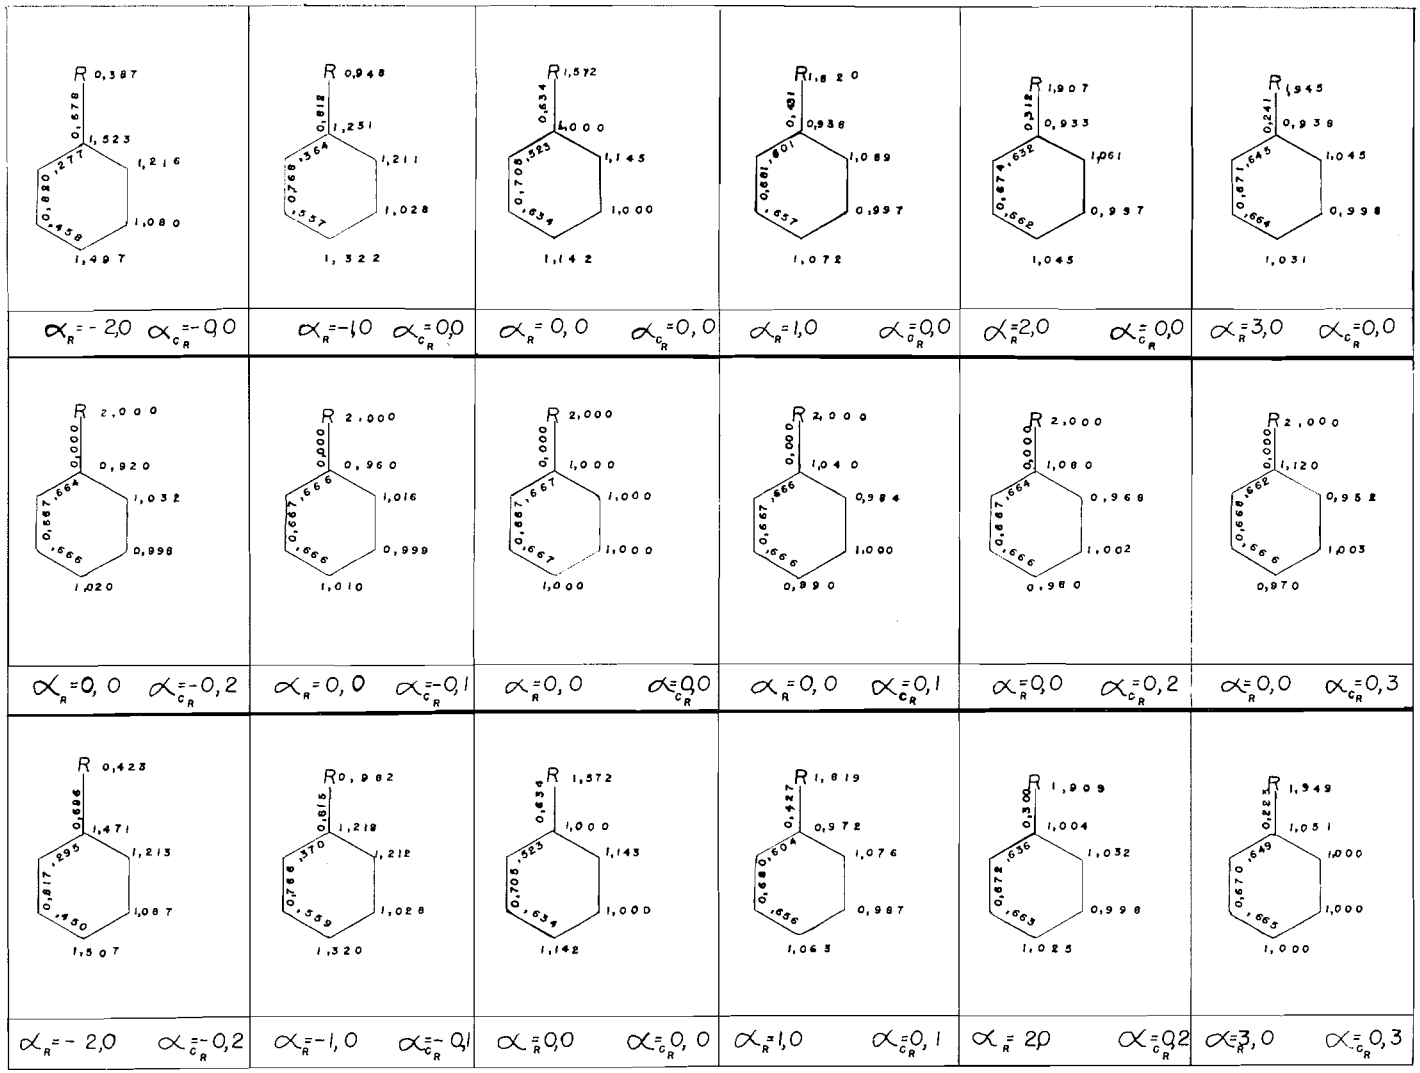

FIG. 1. First row: pure mesomeric effect. Second row: pure inductive effect. Third row: combined inductive and mesomeric effects. α_C is taken equal to zero.

determined only by the mesomeric effect, the negative charges in ortho and para by both effects. The ortho-para orienting character of the substituent is clearly brought out, as is the invariance of the meta position.

For negative values of α_R the situation is quite different. The very great positive charge appearing on the substituent because of the mesomeric effect is slightly diminished by the inductive effect, which from this point of view is again opposed to the mesomeric effect. The mesomeric effect sends a considerable negative charge into the para and ortho and even to the meta position, although much less to the last position. Curiously, the inductive effect leaves the ortho, meta, and para carbons practically unaffected.

Thus, while the inductive effect does not alter the charge on the substituent for positive values of $(\alpha_R - \alpha_C)$, it does influence the charges on the ring carbon atoms; the contrary is predicted for negative values of $(\alpha_R - \alpha_C)$ in this approximation.

The bond orders show that in the latter case, the benzene ring undergoes considerable deformation. The chemical behavior of the corresponding compounds should be interesting.

The inductive effect changes symmetrically if we change the sign of α_R but the mesomeric effect does not. The inductive effect affects not only the ortho position but also the para position.

As we know today, the simple approximation used to obtain these results is not very accurate. It has yielded, however, so many qualitatively correct results that our findings should have a relative interest even though the method does not correspond to the latest stage of development in theoretical chemistry.

The diagrams of the first row of Fig. 1 were obtained with the help of the Compution Centre of the University of Toronto. Free machine time was allotted by the National Research Council. The author wishes to express his thanks to these two institutions. Thanks are due to Professor D. Patterson for help in preparation of the manuscript.

RÉSUMÉ

Dans cet article on donne des diagrammes de répartition électronique représentant l'effet mésomère pur et l'effet inductif pur des substituants sur le noyau benzénique ainsi que leur effet simultané.

THE CONFIGURATION OF GLYCOSIDIC LINKAGES IN OLIGOSACCHARIDES VII. 4-*O*-β-D-GALACTOPYRANOSYL-D-GALACTOSE FROM WHITE BIRCH WOOD*

J. K. GILLHAM, A. S. PERLIN, AND T. E. TIMELL

Partial acid hydrolysis of an α-cellulose prepared from white birch (*Betula papyrifera*) wood has led to the isolation of a new disaccharide (1). The disaccharide is now shown to be 4-*O*-β-D-galactopyranosyl-D-galactose.

**Issued as N.R.C. No. 4963 and as Paper No. 256 on the Uses of Plant Products.*

determined only by the mesomeric effect, the negative charges in ortho and para by both effects. The ortho-para orienting character of the substituent is clearly brought out, as is the invariance of the meta position.

For negative values of α_R the situation is quite different. The very great positive charge appearing on the substituent because of the mesomeric effect is slightly diminished by the inductive effect, which from this point of view is again opposed to the mesomeric effect. The mesomeric effect sends a considerable negative charge into the para and ortho and even to the meta position, although much less to the last position. Curiously, the inductive effect leaves the ortho, meta, and para carbons practically unaffected.

Thus, while the inductive effect does not alter the charge on the substituent for positive values of $(\alpha_R - \alpha_C)$, it does influence the charges on the ring carbon atoms; the contrary is predicted for negative values of $(\alpha_R - \alpha_C)$ in this approximation.

The bond orders show that in the latter case, the benzene ring undergoes considerable deformation. The chemical behavior of the corresponding compounds should be interesting.

The inductive effect changes symmetrically if we change the sign of α_R but the mesomeric effect does not. The inductive effect affects not only the ortho position but also the para position.

As we know today, the simple approximation used to obtain these results is not very accurate. It has yielded, however, so many qualitatively correct results that our findings should have a relative interest even though the method does not correspond to the latest stage of development in theoretical chemistry.

The diagrams of the first row of Fig. 1 were obtained with the help of the Compution Centre of the University of Toronto. Free machine time was allotted by the National Research Council. The author wishes to express his thanks to these two institutions. Thanks are due to Professor D. Patterson for help in preparation of the manuscript.

THE CONFIGURATION OF GLYCOSIDIC LINKAGES IN OLIGOSACCHARIDES VII. 4-*O*-β-D-GALACTOPYRANOSYL-D-GALACTOSE FROM WHITE BIRCH WOOD*

J. K. GILLHAM, A. S. PERLIN, AND T. E. TIMELL

Partial acid hydrolysis of an α-cellulose prepared from white birch (*Betula papyrifera*) wood has led to the isolation of a new disaccharide (1). The disaccharide is now shown to be 4-*O*-β-D-galactopyranosyl-D-galactose.

**Issued as N.R.C. No. 4963 and as Paper No. 256 on the Uses of Plant Products.*

The compound, isolated by chromatography on paper, crystallized from methanol. It had melting point 204°, $[\alpha]_D$ +68°, and a degree of polymerization (2) of 2.0. Complete acid hydrolysis with hot 0.1 *N* sulphuric acid required about 8 hours, indicative of the presence of a pyranosidic non-reducing end unit in the compound. The only detectable component sugar produced by hydrolysis was D-galactose, identified by its chromatographic behavior, specific rotation, and by conversion to crystalline galactose 1-methyl-1-phenylhydrazone.

In acetic acid solution the disaccharide consumed lead tetraacetate relatively slowly, 1.8 moles being taken up in 30 minutes, which is consistent with the oxidation of a 4-substituted aldohexose unit (3). When treated with 1.5 moles of oxidant it afforded a product which on hydrolysis yielded (chromatographic evidence) the expected products, i.e., galactose, lyxose, and threose (3, 4). In 90% acetic acid and in the presence of potassium acetate 1 mole of carbon dioxide was liberated at a rate almost identical with that for methyl α-D-galactopyranoside (5), suggesting that formic acid was produced only from the galactopyranosidic non-reducing end unit. Further, the corresponding figure for lead tetraacetate uptake was 3.9 moles, which allows for the required consumption of 2 moles by the non-reducing end unit and for degradation of the reducing end unit to a di-*O*-formyl tetrose derivative by cleavage of carbon–carbon bonds 1,2- and 2,3- (4). These data are consistent only with the formulation of a 1,4-D-galactopyranosyl-D-galactose structure for the disaccharide.

The new galactobiose is distinct from 4-*O*-D-galactopyranosyl-D-galactose derived from okra mucilage by Whistler and Conrad (6) and from pectic acid by Jones and Reid (7), since the latter disaccharide* gave a different X-ray powder diagram and has $[\alpha]_D$ +173°, in contrast to the current value of $[\alpha]_D$ +68°. It is clear, therefore, that the glycosidic linkage of galactobiose from birch possesses the β-configuration which, at the same time, confirms the presence of an α-linkage in the disaccharide from okra mucilage and pectic acid.

EXPERIMENTAL

Isolation of the Disaccharide

Alpha cellulose (400 g), prepared from white birch (*Betula papyrifera*) as described earlier (1), was heated with *N* sulphuric acid (2000 ml) at 95° C for 40 minutes. After neutralization with barium carbonate the hydrolyzate was deionized and the mixture of products formed was partially resolved by chromatography on Whatman 3 MM paper using ethyl acetate:acetic acid:water (9:2:2) as solvent. A second chromatographic separation, using butanol:pyridine:water (10:3:3), afforded five disaccharide fractions (1). After several weeks in methanol, one of these fractions (98 mg) yielded crystals (25 mg) having m.p. 204° C (corr.) and $[\alpha]_D^{20}$ +68° (equilibrium value; *c*, 1.0, water); degree of polymerization found by the end-group method of Peat, Whelan, and Roberts (2), 2.06. The X-ray powder diagram of the compound was distinct from that of 4-*O*-α-D-galactopyranosyl-D-galactose; interplanar lattice spacings in Å were as follows (relative intensities are given in parentheses): 7.85 (56), 6.56 (49), 5.40 (53), 4.50 (100), 3.76 (71), 3.50 (47), 3.05 (44), 2.7 (diffuse) (51), 2.3 (diffuse) (44), 2.15 (23), 2.05 (30), 1.84 (14), 1.60 (8), 1.46 (9), 1.40 (4).

D-*Galactose 1-Methyl-1-phenylhydrazone*

The disaccharide (2.74 mg) was taken up in 0.5 ml of 0.1 *N* sulphuric acid (found, $[\alpha]_D^{25}$ +66°, equilibrium value) and heated on the steam bath to constant rotation (α_D^{25} +0.22°±0.01°, 0.5 dm tube), which required 7.5 hours. After neutralization with Dowex-1

*The authors are grateful to Prof. R. L. Whistler for providing a sample of this compound.

resin (bicarbonate form) the hydrolyzate was examined by paper chromatography using three solvent systems, each chromatogram suggesting that galactose was the only product formed and showing the presence of a trace of unhydrolyzed disaccharide. Accordingly, the specific rotation of the sugar produced on hydrolysis was $[\alpha]_D^{25}$ +77° (*c*, 0.576, 0.1 *N* sulphuric acid); (D-galactose has $[\alpha]_D^{20}$ +80°).

To the neutral hydrolyzate 0.5 ml of ethanolic 1-methyl-1-phenylhydrazine acetate (8) was added; the solution was stored in the dark at 35° C for 12 hours and then at 4° C for 9 hours. Crystals which formed were filtered off, washed with cold ethanol, and dried. Melting point 189–190° C (corr.), undepressed on admixture with authentic D-galactose 1-methyl-1-phenylhydrazone, m.p. 190–191° C. The known and unknown derivatives gave X-ray powder diagrams which were indistinguishable from each other.

Lead Tetraacetate Oxidation of the Disaccharide

(*a*) The galactobiose (1.0 mg), in 0.04 ml of water, was taken up in acetic acid (1.0 ml) and a solution of lead tetraacetate (5.0 mg) in acetic acid (1.0 ml) was added at room temperature. At 10, 20, and 30 minutes aliquots (0.5 ml) were withdrawn and the lead tetraacetate consumption measured by microtitration. Found: 1.0, 1.5, and 1.8 moles/mole, respectively. Under the same conditions maltose consumed 0.8, 1.3, and 1.5 moles/mole, respectively.

(*b*) In another experiment the galactobiose (1.1 mg) was treated with an aliquot of the lead tetraacetate solution equivalent to 1.5 moles of oxidant/mole. A negative starch–iodide test was obtained within two hours, water (2.0 ml) was added, divalent lead was removed with excess Amberlite IR-120, and the suspension was heated on the water bath for 2 hours. Examination of the hydrolyzate on a paper chromatogram, using two solvent systems and aniline oxalate spray (9), showed the presence of products corresponding to threose, lyxose, and galactose, in addition to unhydrolyzed material.

(*c*) On oxidation in the Warburg respirometer in 90% acetic acid and in the presence of potassium acetate (5), the galactobiose (1.1 mg) yielded carbon dioxide (formic acid) at the following rate (comparative data is given for methyl α-D-galactopyranoside oxidized simultaneously), in moles/mole:

Time (minutes)	15	20	40	60	80	140
Galactobiose	0.33	0.80	0.97	1.02	1.04	1.09
Methyl galactoside	0.32	0.73	0.89	0.98	1.01	1.01

At 140 minutes the total consumption of lead tetraacetate was 4.95 moles/mole which, corrected for the oxidant used in converting formic acid to carbon dioxide (1.09 moles/mole), corresponds to a lead tetraacetate uptake of 3.86 moles/mole by the disaccharide.

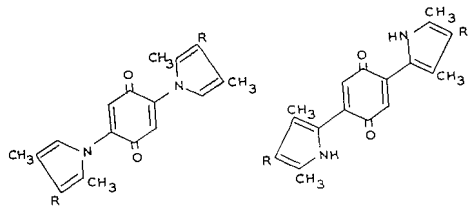
ADDITION OF PYRROLES TO 1,4-BENZOQUINONE*

E. BULLOCK†

Several workers have observed the formation of colored products from quinones and pyrroles (1, 2). In the reaction, four hydrogens are lost between two molecules of pyrrole and one of quinone, hydroquinone being a by-product. The structure I (2) is incompatible with the infrared spectra of the benzoquinone adducts of 2,4-dimethylpyrrole (I*a*) and cryptopyrrole (I*b*), since these show a "bonded" NH band at 3360 cm^{-1}.

The cryptopyrrole adduct must therefore possess structure II*b* and since the ultraviolet and visible spectra of the two adducts are almost identical, the product from 2,4-dimethylpyrrole is formulated as II*a*. Structure II gives a satisfactory explanation of the intense color of the compounds and their behavior with acid.



I

I*a*, R = H
I*b*, R = C_2H_5

II

II*a*, R = H
II*b*, R = C_2H_5

EXPERIMENTAL

The adducts were prepared according to Pratesi (2) and recrystallized from chloroform.

2,5-bis(2′,4′-Dimethyl-5′-pyrryl)p-benzoquinone (II*a*)

Calc. for $C_{18}H_{18}O_2N_2$: C, 73.41; H, 6.17; N, 9.97. Found: C, 73.26; H, 6.01; N, 9.55. λ_{max} (chloroform): 324, 545–552 mμ; log ϵ: 4.45, 4.37. Infrared spectrum: (saturated solution in chloroform, 1-mm cell) absorbed at 3360, 1618, 1385, 986, 965 cm^{-1}. Solution in *N,N*-dimethyl formamide was violet, turning yellow on addition of concentrated hydrochloric acid, the color being restored after neutralization.

2,5-bis(2′,4′-Dimethyl-3′-ethyl-5′-pyrryl)p-benzoquinone (II*b*)

Calc. for $C_{22}H_{26}O_2N_2$: C, 75.39; H, 7.49; N, 7.99. Found: C, 74.94; H, 7.36; N, 8.22. λ_{max} (chloroform): 327, 560–575 mμ; log ϵ: 4.49, 4.41. Infrared spectrum: (approximately 50% saturated solution in chloroform, 1-mm cell) absorbed at 3360, 1615, 1387, 1066, 993, 968 cm^{-1}.

Solution in *N,N*-dimethyl formamide was blue, turning very pale green on acidification; the solution became blue again on neutralization.

The analyses are by Mr. H. Seguin and the infrared determinations by Mr. R. Lauzon.

AN INFRARED CELL FOR SMALL GAS SAMPLES*

D. S. Russell

During the examination of some organic reaction products and the fractions from gas chromatographic separations, it was necessary to obtain the infrared spectra of very small gas samples. The conventional cylindrical gas cell usually provided for infrared work has a relatively large volume, most of which is not in the effective light path. A wedge-shaped metal cell has recently been available for small samples which provides much more efficient absorption of the light beam. Although the shape of this cell is quite satisfactory, there is no convenient method of transferring a gas sample to the cell completely from a vacuum system.

In order to overcome this problem, a glass cell was made whose volume conformed roughly to the shape of the converging light beam of a Perkin–Elmer model 21 spectrophotometer. In addition a small freeze-out tube was added to the bottom so that a small gas sample could be condensed from a vacuum system. Thus quantities of the order of 0.03 ml could be completely transferred to give satisfactory spectra in compounds which exhibited a normal absorption coefficient. Using a spectrophotometer equipped with scale expansion this limit could be extended considerably further.

The cell walls were constructed from flat pieces of pyrex glass fused together at the corners. A similar result could probably be obtained by flattening a slightly conical glass tube of appropriate dimensions. The ends were ground flat on abrasive paper on a plane surface. The sodium chloride windows were then sealed in place by a lead gasket which had been wetted with mercury. The cell assembly was clamped together in the usual way between two metal plates, and adjusted so that the light column fell on the slit when the cell was in place in the instrument.

The cell as illustrated has a light path of 5.0 cm and a total volume of 7.5 ml, which is approximately 1/10th the volume of the 5.0-cm conventional cell. Although some

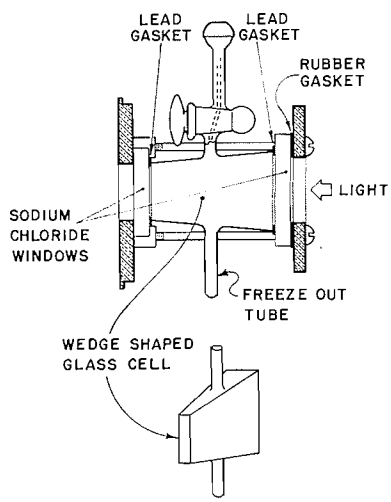

FIG. 1.

*Issued as N.R.C. No. 4940.

light was lost by the cell, it did extend the lower sample limit by at least a factor of five.

In use, packets of silica were fastened over the windows while the sample was being condensed into the cell by liquid nitrogen to prevent condensation of moisture on them.
